Drosophila is an ectothermic (cold-blooded) organism and thus the speed of development is dependent on temperature. As an example, measurements of the time required for completion of cellularization at different temperatures show that there is an increase in the speed of this process with increasing temperature (see Table 4.18.1). Cellularization in the embryo is severely affected at temperatures above 34°C. The permissive or physiological temperatures for various stages of development can be different and require experimental standardization. Lowering the temperature is a useful manipulation for slowing down development, especially in the study of fast processes such as calcium transients from the endoplasmic reticulum (Parry et al., 2005).

In addition, genetic and biochemical analysis of various biological processes has been greatly facilitated by the use of temperature-sensitive mutants, which have been isolated in various mutagenesis screens in *Drosophila* (Suzuki et al., 1967). These temperature-sensitive mutants have also proven useful for blocking processes by increasing the temperature at the desired time point during development. Thus, a combination of temperature control at desired time points during imaging may be useful for the study of various mutants and processes.

All microscopes may be equipped with a temperature controlled stage, maintained at the desired temperature with the help of circulating water from a water bath. Alternatively, microscopes may be equipped with a closed controlled environment chamber around the stage, which isolates the sample from the outside world, allowing for temperature control and perfusion of desired liquids.

GENERATION OF TRANSGENIC *DROSOPHILA* FOR LIVE FLUORESCENCE MICROSCOPY USING THE Gal4/UAS SYSTEM

BASIC PROTOCOL 1

This protocol describes how to generate transgenic *Drosophila* lines to enable single- or multifluorophore imaging in living tissue. To express fluorescently tagged proteins of interest in a spatially and temporally controlled manner, we specifically employ the Gal4/UAS system. This system has been extensively used for directed gene expression in *Drosophila* (Brand and Perrimon, 1993). Briefly, Gal4 is a yeast transcription factor that was shown to activate transcription in *Drosophila* (Fischer et al., 1988). *Drosophila* lines expressing the Gal4 protein are crossed to lines carrying the target gene of interest, which is genetically fused to a fluorescent protein (FP) variant and contains Gal4-binding sites (the UAS, or upstream activation sequence) within its promoter. The tagged gene of interest will be transcribed only in those cells and tissues where Gal4 is expressed. The effect of directed misexpression of any cloned gene on development can be then studied in living *Drosophila* tissue by fluorescence microscopy.

Materials

Gene of interest cDNA: e.g., from *Drosophila* Genomics Research Center (DGRC), *http://dgrc.cgb.indiana.edu*

Vector carrying genetically encoded fluorescent protein (FP) variant (e.g., mCherry, Clontech; EGFP and Cerulean, Addgene)

pUASP or pUAST vector for subcloning FP-tagged gene of interest and for transforming *Drosophila* (DGRC)

Drosophila Gal4 line for driving expression in tissue of interest (see FlyBase, *http://flystocks.bio.indiana.edu/Browse/misc-browse/gal4.htm*)

Drosophila balancer stock for generating flies for dual fluorescent imaging: Sp/SM6a; MKRS, Sb/TM6, Tb (see FlyBase, *http://flystocks.bio.indiana.edu/Browse/balancers/bala ncers.htm*)

Stereomicroscope with epifluorescence illumination (e.g., Zeiss Stemi SV11 or Leica MZ FLIII, with 1.0 or 1.6 objectives and 10 eyepiece)

Additional reagents and equipment for cloning genes (see *APPENDIX 3A*)

Generate fluorescently tagged construct of gene of interest

1. Fuse the gene of interest cDNA to the desired fluorescent tag.

   We suggest the use of the latest generation of FP spectral variants, which have been improved for folding, chromophore maturation, brightness, photostability, and minimal self-association (see UNIT 21.5). Cerulean (Rizzo et al., 2004), Venus (Nagai et al., 2002), and mCherry (Shaner et al., 2004) are optimized versions of previously used ECFP, EYFP, and DsRed, respectively. The monomerizing mutation A206K (Zacharias et al., 2002) can be applied to virtually any Aequorea victoria variant in order to generate a true monomer (m; e.g., mEGFP, mCerulean, mVenus). PA-GFP and mEosFP are currently the photoactivatable variants with the most potential for optical pulse-chase experiments in living Drosophila (see Basic Protocol 7). Choose the fluorescent variant or combination of variants based on the intended application requirements (see Basic Protocols 3 to 6).

   Most FPs have some acid sensitivity, and their fluorescence is quenched when targeted to acidic compartments such as the lumen of lysosomes or secretory granules. Avoid using acid-sensitive FPs (pK_a>6.0; e.g., mOrange, GFPs, and YFPs) when the proteins are targeted to compartments of low or unstable pH. Instead, use FPs with excellent pH resistance (pK_a<5.0; e.g., CopGFP, Cerulean, mKO, mRFP1, or mCherry) to avoid artifacts in quantitative measurements caused by acid quenching.

2. Subclone the FP-tagged gene into the pUASP or pUAST vector.

   The pUAST vector contains five Gal4/UAS sites and a minimal hsp70 promoter upstream of the cloning site for the gene of interest (Brand and Perrimon, 1993). The original pUAST vector was ineffective for expression of genes in the female germline during oogenesis. A modified vector (pUASP) was made (Rorth, 1998), which contains fourteen Gal4/UAS sites, a minimal transposase promoter upstream of the cloning site for the gene of interest, as well as the 3'UTR from a maternally expressed gene.

   If you are studying processes during oogenesis or very early embryogenesis (first 3 hr), clone the FP-tagged gene of interest into pUASP and not pUAST. Expression of the UASP-FP-tagged protein will occur in the female germline and the FP will be loaded into very early embryos when present in trans with the appropriate Gal4 driver.

   pUASP and pUAST are ampicillin-resistant vectors available at DGRC, together with information for cloning (http://dgrc.cgb.indiana.edu/vectors/store/vectors.html). Alternatively, genes of interest may be directly cloned in frame with fluorescent tags already encoded in the pUASP vector, also available at DGRC (http://dgrc.cgb.indiana.edu/vectors/store/vectors.html).

   We suggest that the expression of the FP-tagged proteins be verified either in mammalian cells or in Drosophila S2 cells. For S2 cells it will be necessary to cotransfect pActGal4 and pUASP-FP to drive the expression of the fluorescent protein.

Generate transgenic Drosophila carrying the UAS-FP-tagged transgene

3. Generate transgenic fly lines by injecting the UAS-FP-transgene vector into embryos and selecting transformed flies that carry the transgenes on different chromosomes.

   Detailed protocols for these steps are out of the scope of this chapter. Excellent protocols for these steps are available in other works (Santamaria and Gans, 1980; Rubin and Spradling, 1983; Kiehart et al., 2000).

   Alternatively, there are various academic institutions or companies (e.g., BestGene, Genetic Services) which perform embryo injections to generate transgenic fly lines. The fly lines obtained should be mapped to identify the chromosome in which the transgene is inserted.

   Both pUASP and pUAST contain a mini white gene. This is very useful for identifying the presence of the transgene in transformed progeny, if the plasmid is injected into embryos of white-eyed flies. Depending upon where the transgene is inserted into the fly genome, the eye color of the transgenic fly can range from light orange to red.

Carry out genetic crosses to express fluorescently tagged proteins of interest

4. Perform appropriate genetic crosses to bring the enhancer Gal4 and the pUASP constructs together for expression in the progeny (see Fig. 4.18.7).

   A scheme of genetic crosses is detailed in Figure 4.18.7 for the generation of embryos expressing a single (Fig. 4.18.7A) or multiple (Fig. 4.18.7B) FP-tagged proteins. Balancer chromosomes carry genetic markers that enable the selection of flies carrying both the nanos-Gal4 and pUASP-FP(s) in the F_1 generation. Alternatively, flies carrying both the nanos-Gal4 and pUASP-FP(s) may be selected by observing females under a stereomicroscope with epifluorescence illumination.

   Examples of adult females containing nanos-Gal4; pUASP-tubulin-GFP and maternal-α4-tubulin-Gal4; pUASP-mRFP are shown in Figure 4.18.7C.

   To express Gal4 in a tissue-specific manner, an enhancerless Gal4 was inserted randomly into the Drosophila genome (Brand and Perrimon, 1993). Depending on its site of integration, hundreds of lines were generated expressing Gal4 in distinct spatiotemporal patterns, each reflecting the native activity of the trapped enhancer. This has given the Drosophila community several enhancer-Gal4s that allow tissue-specific expression of Gal4. A

Figure 4.18.7 *(on next page)* Generation of flies expressing the fluorescent transgene of interest. (**A**) Example of genetic crosses showing the generation of flies expressing a single fluorescent transgene in early embryos. In the F_0 generation, flies carrying the Gal4 driver are crossed to those carrying the fluorescent transgene (pUASP-FP). F_1 females that carry both the nanos-Gal4 and the pUASP-FP are selected based on genetic markers or by observing females under a stereomicroscope with epifluorescence illumination. (These females express the protein of interest in the germline and thus will load the protein in early F_2 embryos.) pUASP-FP; nanos-Gal4 females may be crossed with sibling males of the same genotype or any other males of choice depending upon the genotype of the embryos that need to be imaged. (**B**) Example of genetic crosses showing the generation of flies expressing two fluorescent transgenes in early embryos. In the F_0 generation, flies carrying the fluorescent transgenes (pUASP-FP1 on the second chromosome and pUASP-FP2 on the third chromosome) are crossed to those carrying balancer chromosomes. Balancer chromosomes enable the selection of flies carrying both the pUASP-FP1 and pUASP-FP2 in the F_1 generation. F_2 generation flies containing the two transgenes are crossed to those carrying nanos-Gal4. In the F_3 generation, female flies carrying both pUASP transgenes and the Gal4 driver will express FP_1 and FP_2 during oogenesis, and the embryos produced by these flies are used for imaging. The females carrying the two transgenes and the Gal4 driver may be crossed with sibling males of the same genotype or any other males of choice depending upon the genotype of the embryos that need to be imaged. (**C**) Selection of adult flies expressing the fluorescent protein of interest in the female germline viewed using a stereomicroscope with epifluorescence illumination. Note the green fluorescent signal in the abdomen of flies expressing tubulin-GFP and the red fluorescent signal in flies expressing mRFP1. Control nanos-Gal4 flies show no fluorescent signal using the same green and red emission filters. The flies expressing the fluorescent transgenes may be selected and used for embryo collection. For the color version of this figure go to *http://www.currentprotocols.com*.

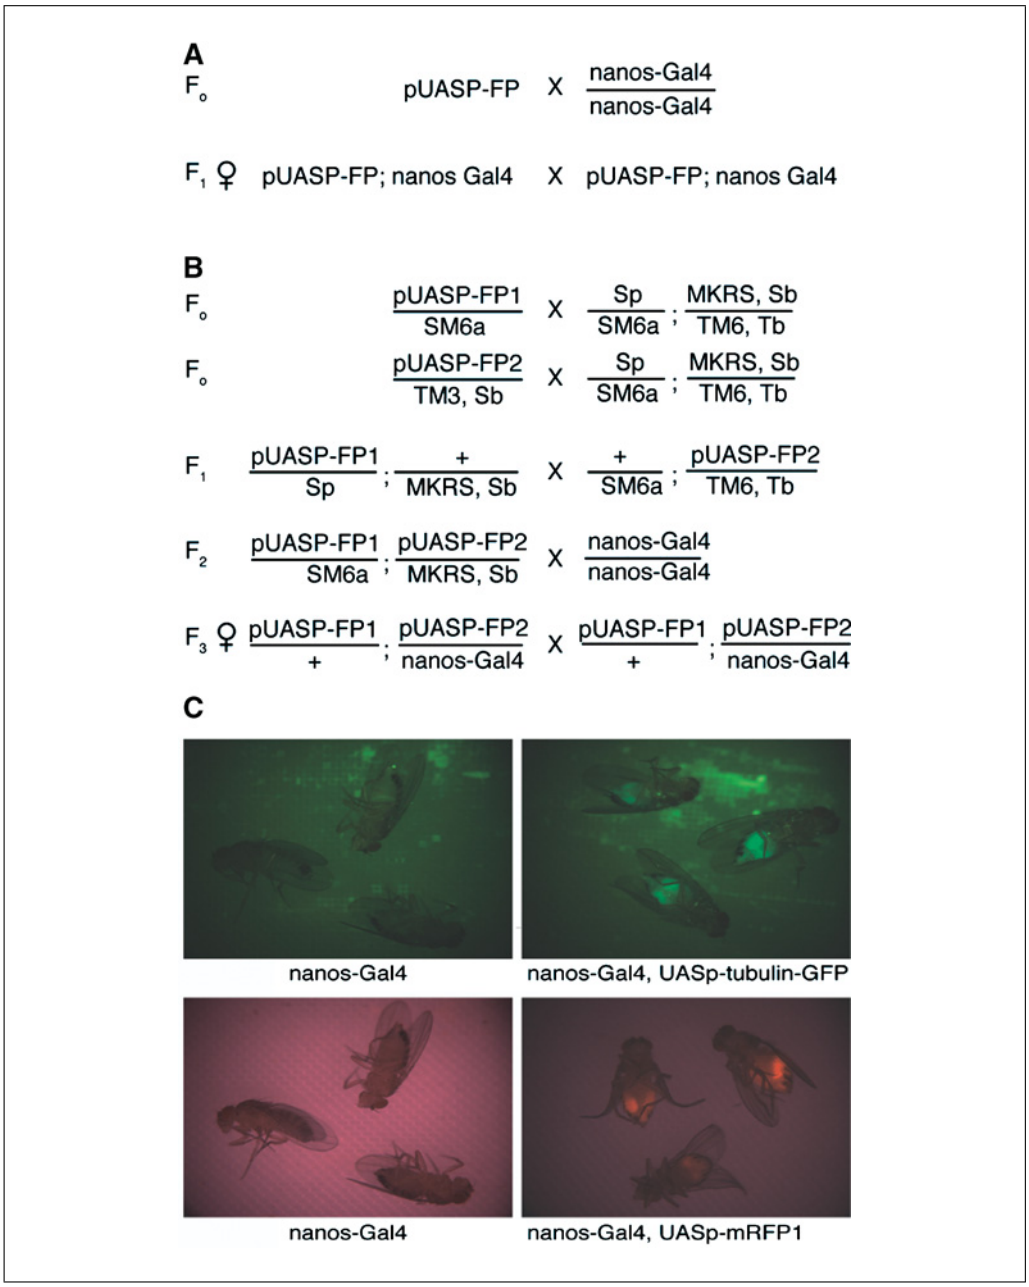

Figure 4.18.7 *(Legend on previous page)*

catalog of Gal4 lines is available from FlyBase at http://flystocks.bio.indiana.edu/Browse/misc-browse/gal4.htm.

Alternatively, when a heat-shock inducible hsp70-Gal4 is used, a temporal control of Gal4-driven expression during development is possible. In this case the target gene will be expressed in all tissues.

The enhancer Gal4 lines commonly used for expression of target genes during oogenesis are maternal-α4-tubulin-Gal4 and nanos-Gal4. If maternal-α4-tubulin-Gal4 or nanos-Gal4 females are crossed to males carrying UAST/UASP-transgenes, expression of fluorescently tagged proteins in F_1 embryos is not observed until early- to mid-gastrulation.

For imaging fluorescently tagged proteins in very early embryos, cross maternal-α4-tubulin-Gal4 or nanos-Gal4 lines to UASP-FP lines (Hacker and Perrimon, 1998; Van Doren et al., 1998). Emerging F_1 females will express the proteins of interest in the germline and thus will load these proteins in very early F_2 embryos.

It should be noted that nanos-Gal4 often appears to have variegated expression resulting in differential reporter/target transcript amounts in the ovaries and embryo.

PREPARATION OF *DROSOPHILA* EMBRYOS FOR FLUORESCENCE MICROSCOPY

Most protocols for preparing *Drosophila* embryos for live imaging involve dechorionation and mounting of embryos on a coverglass covered with halocarbon oil to prevent the embryos from drying out (Hazelrigg, 2000). Here, we present a protocol where embryos are mounted in phosphate-buffered saline or distilled water in a chambered coverglass. This protocol presents the following advantages: (1) embryos do not suffer from anoxia during long-term imaging (which is the case when embryos are covered with halocarbon oil), (2) it allows for quick mounting and screening of many embryos, and (3) water-immersion objectives can be used for imaging deeper into the embryo with minimal spherical aberrations (see Strategic Planning). Embryos mounted in this manner develop normally to first-instar larvae. Embryos may be mounted either on their posterior or on their dorsolateral/ventrolateral side depending upon the nature of the experiment.

Materials

Embryo collection cages that fit 60-mm petri dishes (Genesee Scientific)
Apple or grape juice agar plates (see recipe)
Yeast paste: prepared by mixing 1 g dry yeast with 1.8 ml distilled H_2O to make a thick paste
50% bleach: bleach (4% to 6% available chlorine) diluted 1:1 with distilled H_2O just prior to use
Phosphate-buffered saline (PBS; *APPENDIX 2A*)
Dichlorodimethylsilane (Fluka)
Egg basket (Fig. 4.18.3B): prepared by removing the stem of a plastic funnel (~60 mm top internal diameter) with a blade, slightly melting the small diameter opening, and attaching to a piece of 100-μm stainless steel wire or 100- or 120-μm nylon mesh (Genesee Scientific 57-102 *or* BD Falcon 352360)
Squirt bottle with distilled H_2O
Dissecting microscope (e.g., Zeiss Stemi SV6/11 or Stemi 2000)
Fine paintbrush (No. 1) for transferring and handling embryos
Imaging chamber: No. 1.0 Borosilicate LabTek Chambered Coverglass (Nunc) *or* No. 1.0 Borosilicate MatTek Glass-Bottom Dishes (MatTek)

Collect embryos

1. Take a freshly prepared apple juice agar plate and add a dab of thick yeast paste in the center of the plate.
2. Place 50 to 100, 2- to 3-day-old adult flies expressing the fluorescently tagged protein of interest in a cage and cover with a yeasted apple juice agar plate (Fig. 4.18.3A). Maintain flies in an incubator at 25°C.

   Collection plates must be at room temperature before use. Females will not lay eggs on cold plates!

3. Replace with a fresh apple juice agar plate at the same time every day for 2 to 3 days to synchronize egg laying.

   Change plates daily and monitor humidity. If agar plates are drying out, place a paper towel in a beaker containing water and put it close to the cage.

4. On the day of the imaging experiment, replace the fresh juice agar plate 1 hr before the actual egg collection. Incubate the cage at 25°C for 1 hr and discard this "prelay" plate.

   Females can retain fertilized eggs in the uterus for variable periods of time, so the prelay plate contains embryos at different stages.

5. Place a fresh apple juice agar plate and incubate for the appropriate time to obtain embryos at the desired stage of development prior to imaging.

   The same population of flies may be used for embryo collection in cages for ~10 days if apple juice agar plates are changed daily.

Dechorionate embryos

6. Add some distilled water in the apple juice agar plate and brush the embryos gently into suspension. Pour the water containing the embryos into the egg basket (Fig. 4.18.3B). Wash with copious amounts of distilled water, using a tap or squirt bottle, to get rid of the yeast paste.

7. Place the funnel containing the embryos in freshly prepared 50% bleach and agitate gently so the bleach solution disperses the embryos. Incubate 1 min with periodic gentle agitation.

   This treatment will remove the chorion, which makes the embryo opaque for imaging (Fig. 4.18.3B).

   Always prepare the 50% bleach solution fresh. Bleach loses its potency after dilution and with aging.

   When embryos are dechorionated, their hydrophobic vitelline membranes tend to stick to the sides of the funnel, and embryos also clump together. If dorsal appendages are still observed under the dissecting microscope just prior to mounting (see Fig. 4.18.3B), place embryos back in bleach solution for 5 to 10 sec, rinse thoroughly with distilled water, and check again. Do not overexpose embryos to bleach, or they will be damaged.

8. Immediately wash the embryos thoroughly with distilled water, using a tap or squirt bottle, to get rid of any residual bleach. Squirt distilled water on the inner sides of the funnel to bring embryos that stick to the sides onto the mesh.

Mount embryos on their dorsolateral/ventrolateral sides

9a. Blot the mesh containing the embryos on filter paper. Working rapidly under a dissection microscope, use a fine paintbrush to pick the dechorionated embryos from the mesh and mount them on a chambered coverglass on their dorsolateral/ventrolateral sides (Fig. 4.18.3C). Work rapidly to mount embryos so that they are not crowded and so that they do not touch each other, to avoid anoxia and defects in development.

10a. Slowly add PBS with a pipet from the side of the chamber in order to avoid air bubbles. Add enough PBS to cover the embryos and to compensate for evaporation during imaging (e.g., 2 ml for a two-chambered LabTek coverglass). If air bubbles form while mounting, use the paintbrush to gently move the embryo around to remove the air bubbles. Do not dislodge embryos from the coverglass, or they will float.

   Air bubbles will effectively block the light path and are deleterious for imaging—they appear as dark spheres or shadows. If the embryos are not dry enough, air bubbles will appear on the sides of the embryos upon addition of PBS.

   Distilled water may be used as an alternative to PBS. This is especially useful when imaging with an upright microscope and a water dipping objective (e.g., a Zeiss Plan-Apochromat 63×/1.0 VIS-IR water lens).

   Microscope objectives for high-resolution fluorescence microscopy have a correction collar to compensate for coverglass thicknesses between 0.14 and 0.18 mm. We recommend the use of No. 1.0 (0.13 to 0.16 mm) LabTek or MatTek chambered coverglasses. The use of thicker No. 1.5 (0.16 to 0.18 mm) coverglasses is not recommended because it will compromise working distance. The coverglass thickness can easily be measured on a laser scanning microscope, and the correction collar can be set to a high precision.

Mount embryos on their posterior sides

9b. To mount embryos on their posterior, coat the coverglass with dichlorodimethylsilane to render the glass surface hydrophobic. Add silane to cover the coverglass, let sit for 3 hr, then remove and wash thoroughly with distilled water.

Silane vapors are extremely volatile and toxic and therefore addition of silane to the chamber must be done in a fume hood. Silanized coverglasses are good to use for a week.

10b. Mount dechorionated embryos on the coverglass on their dorsolateral/ventrolateral sides as described in step 9a and add PBS. With the help of the paintbrush slowly move the embryos to an upright position so that they sit on their posterior side (Fig. 4.18.3C).

The hydrophobic vitelline membrane interacts with the hydrophobic silanized surface of the coverglass and prevents the embryo from floating during this manipulation.

The embryos must be mounted on the posterior side and not the anterior side because the micropyle (see arrow in Fig. 4.18.3C) present on the anterior side is very sensitive to manipulations.

TIME-LAPSE CONFOCAL IMAGING OF LIVING *DROSOPHILA* EMBRYOS

BASIC PROTOCOL 3

Time-lapse observation of developing embryos expressing fluorescent proteins (FPs) targeted to specific tissues and/or subcellular compartments can yield important information about the dynamics of cell rearrangements and/or changes in the spatial distribution of different proteins within single cells in the course of development. Moreover, it enables the investigator to simultaneously track multiple cellular events. This protocol focuses on noninvasive, time-lapse, confocal microscopic observation of fluorescently tagged proteins in living *Drosophila* embryos. It is assumed that the investigator is familiar with the basic operation of a confocal microscope. However, guidelines are given throughout the protocol to help in the determination of the optimal imaging conditions for living embryos expressing one or more FPs.

Materials

Drosophila embryos expressing fluorescent proteins (FPs) of interest (Basic Protocol 1), mounted in LabTek or MatTek imaging chamber (Basic Protocol 2)
Confocal laser scanning microscope (CLSM; e.g., Zeiss LSM 510 or Olympus FluoView FV1000) equipped with:
Laser lines and filter sets appropriate for the FPs of interest
High-numerical-aperture (NA), water-immersion objective (e.g., Zeiss C-Apochromat 40×/1.20 W Corr UV-VIS-IR water lens or Olympus UPLAPO 60×/1.2 NA water lens)

Set up the imaging system

1. Set up the confocal laser scanning microscope and its associated hardware. Use a high-NA objective for maximal signal collection and spatial resolution.

The brightness (fluorescence intensity) of the acquired image is proportional to NA^4/$magnification^2$. This means that a 40× objective is superior to higher-magnification objectives (60× or 100×) of identical NA values because it will yield the brightest images with the same resolving power. A 40× lens yields a field of view of 230 μm × 230 μm at zoom 1.0 on a Zeiss LSM 510, or 318 μm × 318 μm at zoom 1.0 on an Olympus FluoView FV1000.

We recommend the use of optical zoom during image acquisition with a 40× lens to yield images equivalent in size to using a 100× lens without compromising brightness or resolution. Higher magnification (60× or 100×) is required for imaging very small structures (e.g., transport intermediates and secretory granules).

If fluorescence is very weak (e.g., embryos with low expression levels of the FP), consider using less corrected high-NA oil lenses (e.g., a Fluar 40×/1.3 NA oil lens), which have fewer optical elements and higher light transmission. Use oil lenses only for imaging at the embryo surface closest to the coverslip to minimize spherical aberrations.

2. Turn on the appropriate excitation laser lines at least 15 min before starting image acquisition.

   This step will minimize power fluctuations that will compromise fluorescence intensity measurements during subsequent time-lapse imaging.

3. Configure the light path for optimal excitation and emission detection of the fluorophores expressed in the embryo.

   We recommend that the investigator closely examine the spectral profiles of the FPs of interest to ensure an optimal excitation and emission filter combination.

   Most software packages provide the user with a list of preset light path configurations for combinations of common fluorophores. However, the investigator should determine if the preset configuration is indeed optimal for the specific FP(s) of interest and modify the configuration, if needed. UNIT 21.5 provides an excellent overview of the latest generation of FPs and the optimal excitation and emission settings.

   The choice of filters is critical for achieving high signal-to-noise levels and minimizing spectral bleedthrough at the same time, and it should be based on the application. For example, if GFP is the only FP in the embryo, use a longpass filter (e.g., LP505) instead of a bandpass emission filter (e.g., BP505-530) to detect most of the GFP fluorescence.

Locate the embryos of interest

4. Place the imaging chamber containing the mounted embryos on the microscope stage.

5. Use bright-field (transmitted light) or/and epifluorescence illumination to locate the embryos of interest, and focus on the vitelline membrane, with the following considerations:

   Make sure the area of interest is within the working distance of the objective lens!

   If the area of interest is >60 μm deep in the embryo, consider using two-photon excitation with nondescanned detectors (see Fig. 4.18.2) in combination with a long-working-distance, high-NA water lens (e.g. a Zeiss C-Apochromat 40×/1.20 W Corr UV-VIS-IR water lens).

   Take care to avoid photobleaching the fluorescence in the embryo.

   If all embryos express the fluorophores of interest, do not use epifluorescence illumination to locate the embryos. Instead, use bright field illumination to locate the stages of development desired. If only a population of embryos is fluorescent or contains all fluorophores of interest, then use epifluorescence; minimize exposure to get the embryo in focus and centered in the field of view, and then quickly shutter the light. Use neutral density filters to attenuate illumination during focus and centering to preserve the fluorescence in the embryo.

6. Visually inspect the embryos to select normally developing embryos that have not been damaged during dechorionation. Avoid using embryos that have associated air bubbles or that are not completely dechorionated.

   Damaged embryos exude cytoplasm at the micropyle.

   Air bubbles effectively block light transmission and appear as dark areas in an otherwise fluorescent region, whereas pieces of chorion appear as bright autofluorescent structures. As a result, both air bubbles and pieces of chorion will compromise quantitative measurements of fluorescence if they are located in regions of interest.

7. Before starting the laser scanning, set the laser power down, the detector gain up, choose a fast scan time (typically 1 sec per scan), zoom 1.0, and adjust the pinhole to 1 to 2 Airy units.

   For imaging GFP-expressing embryos on a Zeiss LSM 510, start with 1.0% transmission of laser light (for the 488-nm line of a 25-mW argon laser with a tube current of 6A), PMT gain 800, 1 sec per scan, and a pinhole of 1.5 Airy units (1.3 μm optical slice for the Zeiss C-Apochromat 40×/1.20 W Corr UV-VIS-IR water lens).

8. Start fast laser scanning, bring the embryo to the desired focal plane, and move the region of interest (ROI) to the center of the field of view. Take a single scan.

   Most software packages have a low-resolution or/and rapid-scanning mode (Fast XY on Zeiss software or Focus×2 and Focus×4 on Olympus software) that makes preliminary scanning more efficient in rapidly selecting the focal plane and ROI with minimal exposure to laser light.

Set parameters and acquire images for single fluorophore imaging

9a. Determine the optimal instrument parameters for image acquisition in embryos expressing one FP. Optimize the parameters of percent transmission of excitation light, pinhole size, detector gain and offset, scan speed, averaging, zoom factor, and frame size based on the application requirements:

Use the lowest percent transmission of excitation light that will give a good signal-to-noise ratio but will also minimize photobleaching of the fluorophore and will not damage the embryo.

The optimal percent transmission of excitation light will depend on the laser output used (e.g., 40-mW and 25-mW lasers versus 1-mW or 5-mW lasers), the expression levels, brightness and photostability of the FPs, as well as the physical characteristics of the sample (e.g., imaging deeper in the embryo will require an increase in excitation light to compensate for loss of light due to scattering and out-of-focus absorption from surrounding tissue).

Adjust the pinhole size based on the experimental requirements.

Opening the pinhole to 1.5 to 2 Airy units (1.3-μm to 1.7-μm optical slice for the Zeiss C-Apochromat 40×/1.20 W Corr UV-VIS-IR water lens) will produce a thicker optical section compared to a pinhole of 1 Airy unit (0.9-μm optical slice for the same lens) and slightly reduce resolution, but it will significantly improve signal intensity and yield more specimen detail. This is particularly useful for dim samples.

Adjust the gain and black level (offset) of the PMT detector to take advantage of the full dynamic range of the detector. Scan the specimen, adjust the gain so that the brightest pixel in the image is slightly below white (gray level = 255), and adjust the black level so that the dimmest pixel is slightly above black (gray level = 0) in an 8-bit system.

This will ensure that all signals fall within the dynamic range of the PMT, and it is essential for quantitative measurements. All microscope software packages include a pseudocolor image display mode (also known as lookup tables, LUT) that facilitates adjustment of the dynamic range.

Take longer exposures to improve the signal-to-noise ratio, either by using longer scan times or/and averaging the signal from multiple scans (line by line or frame by frame).

We suggest the use of line averaging over frame averaging (which averages full frames), as it yields sharper images because there is less blurring due to movements in the embryo or slight changes in the focal plane. For dim specimens, summing the signal from multiple scans (line by line) will enable better signal detection.

Use a pixel size small enough to take advantage of the resolving capability of the lens but large enough to avoid oversampling.

The number of pixels and zoom control provide the capability to match the pixel size to the optical characteristics. A general guideline for selecting an appropriate zoom factor, based on the Nyquist Sampling Theorem, states that pixel size should be equal to the optical resolution divided by 2.3 (Webb and Dorey, 1995).

For example, for the Zeiss C-Apochromat 40×/1.20 W Corr UV-VIS-IR water lens, lateral resolution is 0.17 μm and the optimal pixel size would be 0.07 μm (which is met, e.g., with a 1024 × 1024 pixel frame and a zoom 3.0).

Making the pixel size too small will subject the embryo to more irradiation than necessary, with increased photobleaching. Because signal-to-noise is often more critical than optical resolution, in most cases sampling with a pixel size half the resolution is most useful without noticeable image degradation.

Determine the optimal zoom factor in order to visualize the structures of interest.

The rate of photobleaching is proportional to the square of the zoom factor. Thus, zooming in will increase the risk for photobleaching the fluorophores.

The best trade-off between signal intensity and resolution will depend on the characteristics of the sample and aims of the experiments.

10a. Once the appropriate instrument parameters have been determined, acquire time-lapse images:

Carefully monitor the first few images for correct detector gain and black level (offset) and adjust accordingly in order to work in the dynamic range of the detector.

If the image is saturated, try turning down the detector gain or lower the excitation light levels and restart the time-lapse sequence. To identify unwanted photobleaching of the fluorophore, measure the loss of fluorescence during acquisition of the time series. To minimize photobleaching the fluorophore(s), turn down the excitation levels, reduce light exposure by decreasing the scan speed and/or signal averaging, or zoom out (photobleaching is proportional to the square of the zoom factor).

Improve temporal resolution by reducing the number of pixels per frame, zooming in to image a smaller area, increasing scan speed, or reducing signal averaging.

You need to find a trade-off between the desired spatial resolution, the signal-to-noise ratio, and the speed of image acquisition based on the experimental requirements. Most commercial confocal microscopes enable the investigator to scan only a selected ROI or multiple ROIs without having to zoom in, thus preserving spatial resolution while minimizing exposure of the rest of the sample to illumination.

For acquiring >10 frames per sec, specialized systems with fast scanning capabilities and/or a very sensitive CCD camera for detection are necessary. Examples of such commercial systems are the Zeiss LSM 5 LIVE (up to 120 frames per sec at 512 × 512 pixels) and the spinning-disk confocal PerkinElmer UltraviewRS system (15 frames per sec at 672 × 512 pixels).

The Zeiss CLSM software offers an advanced time series macro called Multitime for imaging multiple samples in the same chamber. This enables the imaging of multiple embryos in tandem and at multiple stage locations defined by the user. It also includes an autofocus function, which compensates for the effects of mechanical and thermal focus drifts during long-term experiments. The user can define stage locations, focus, and time intervals for the individual acquisitions.

Set parameters and acquire images for multiple fluorophore imaging

9b. Determine the optimal instrument parameters for image acquisition in embryos expressing two or more FPs (multicolor imaging). Optimize the parameters of percent transmission of excitation light, pinhole size, detector gain and offset, scan speed,

averaging, zoom factor, and frame size based on the application requirements, with the following considerations:

Determine the capability of your microscope setup to minimize spectral bleedthrough (also referred to as cross-talk) resulting from excitation or/and emission spectral overlap exhibited by FP combinations, based on the spectral profiles of the FPs to be imaged, the excitation laser lines and emission filters available, as well as the potential use of software packages for spectral unmixing.

The primary concern when choosing fluorophores for simultaneous imaging is potential spectral bleedthrough. The most useful combinations that can be readily separated are cyan and either green or yellow (e.g., Cerulean and Venus, or Cerulean and mGFP), and red variants with either green or yellow FPs (e.g., EGFP and mCherry, or Venus and mRFP1). For triple imaging, the combination of cyan, yellow (or green), and red offers an excellent solution (e.g., Cerulean, Venus, and mCherry).

Spectral unmixing involves the collection of spectra during image acquisition in the FP-expressing embryo and a post-acquisition mathematical unmixing algorithm, and this is available in some setups (e.g., Zeiss LSM 510 META). The green and yellow combination (e.g., EGFP and Venus) is not often used together because of significant cross-talk, but spectral unmixing can be used to efficiently separate the signals.

Balance the desired parameters (fast image acquisition versus the optimal separation and signal-to-noise ratio for each fluorophore) by appropriately choosing the optimal parameters for each fluorophore (excitation levels, pinhole size, detector gain and offset, scan speed, and averaging).

The FPs vary in relative brightness and photostability (see UNIT 21.5) and may have different expression levels in the embryo, so that each color may require different image collection conditions. The rate of data acquisition slows with the addition of each color, due to the requirement for different image collection conditions.

Always use sequential line scanning (also referred to as multitrack line scanning) to rapidly switch between laser lines and collect the image for each channel one line at a time as the frame is being recorded.

This sequential scanning avoids exciting all fluorophores at the same time and is very effective in reducing or eliminating spectral bleedthrough. We do not recommend multitrack frame scanning because even small movements of subcellular structures or cells in the embryo will compromise the image and also decrease the accuracy of colocalization studies.

10b. Once the appropriate instrument parameters have been determined, acquire images of successive optical slices through the sample (*z*-sectioning) over time (*t*; 4D imaging):

Use an interfocal plane interval equal to half the optical slice thickness (which is determined by the NA of the lens and the pinhole size) to adequately sample the specimen in the *z*-axis.

For example, for the Zeiss C-Apochromat 40×/1.20 W Corr UV-VIS-IR water lens and a pinhole of 1 Airy unit (which corresponds to a 0.9-μm thick optical slice), use an interval of 0.45 μm for z-sectioning. Do not collect images at shorter intervals because this will result in oversampling with an increased risk of photobleaching.

Use image analysis software (e.g., ImageJ, free software from the National Institutes of Health, downloadable at http://rsb.info.nih.gov/ij; Volocity, Improvision; Imaris, Bitplane; or MetaMorph, Molecular Devices) to analyze the acquired 4D datasets (*xyzt*).

z-stacks (the whole stack or selected slices) can be projected or rendered in three dimensions for better visualization, and quantitative measurements of volume changes and fluorescence intensity changes, as well as particle tracking analysis, are possible.

11. After a series of images or *z*-stacks has been collected, immediately save them to disk.

Develop a strategy for labeling the image files before beginning to image. This will save time between successive imaging sessions in living, developing embryos. Always save raw unprocessed datasets and make sure they contain all the information that might be required later for image processing, measurements, and presentation purposes or for reusing the same parameters (e.g., pinhole size, excitation levels, lens magnification, and zoom factor, pixel dwell time) for imaging other samples.

BASIC PROTOCOL 4

TIME-LAPSE IMAGING OF LIVING *DROSOPHILA* EMBRYOS WITH TWO-PHOTON LASER SCANNING MICROSCOPY

Confocal laser-scanning microscopy (CLSM, Basic Protocol 3) is the method of choice for routine high-resolution 4D imaging up to ~40 μm deep in living *Drosophila* tissue. This protocol focuses on the use of two-photon excitation laser scanning microscopy (2PLSM) to image fluorescently tagged proteins up to ~100 μm deep in living *Drosophila* embryos (see Strategic Planning and Fig. 4.18.2). The larger penetration depth with two-photon excitation (*UNIT 4.11*) is due to (1) the lack of out-of-focus absorption of the excitation light, (2) significantly less scattering of the longer wavelengths used in two-photon excitation, and (3) a detection geometry that enables high-efficiency collection of multiply-scattered emission photons. The lack of out-of-focus excitation further reduces photodamage and thus increases tissue viability, which is crucial for long-term imaging. Finally, two-photon excitation allows imaging and photomanipulation (e.g., photobleaching) in a highly localized fashion. The major drawback of 2PLSM is local heating effects caused by the high concentrations of near infrared (NIR) photons required for two-photon excitation. Thus, the investigator needs to carefully optimize conditions for deep imaging in order to minimize such effects.

The major differences between a two-photon and a confocal microscope setup are the excitation laser and the detection pathway (*UNIT 4.11*). Two-photon excitation requires ultrafast pulsed lasers (now commercially available) and can be coupled with a laser scanning microscope setup (e.g., Zeiss LSM 5 META NLO). However, ultrafast pulsed lasers for 2PLSM are much more expensive than the visible light lasers commonly used for CLSM. Furthermore, a deeper understanding of the physics and more technical effort are required to optimize deep imaging with 2PLSM without damaging the living tissue. As a result, 2PLSM is not yet as widely applied as CLSM, but it is the method of choice for routine high-resolution imaging ~60 to 100 μm deep in living *Drosophila* embryos. Technical details on how to optimize the laser source for 2PLSM (beam size, pulse width, etc.) are beyond the scope of this protocol and are available in specialized reviews (Dickinson, 2005; Helmchen and Denk, 2005). The investigator needs to be familiar with time-lapse confocal imaging (Basic Protocol 3) before attempting 2PLSM.

Materials

Drosophila embryos expressing fluorescent proteins (FPs) of interest (Basic Protocol 1), mounted in LabTek or MatTek imaging chamber (Basic Protocol 2)
Zeiss LSM 510 META equipped with:
Coherent Chameleon titanium/sapphire laser, tunable from 720 nm to 930 nm
Filter sets appropriate for the FPs of interest
High-numerical-aperture (NA) water-immersion objective (e.g., Zeiss C-Apochromat 40×/1.20 W Corr UV-VIS-IR water lens)

Set up the imaging system

1. Set up the confocal laser scanning microscope and its associated hardware. Use long-working-distance, high-NA water-immersion objectives with high transmission to near infrared (NIR) and visible (VIS) wavelengths.

   The most widely used lasers for 2PLSM are titanium/sapphire (Ti:sapphire) lasers. Commercially available Ti:sapphire lasers provide computer-controlled wavelength tuning over a broad range (∼700 to 1000 nm) in an automated fashion. The average power (∼1 W over the central portion of the tuning range) provided by these commercial systems is sufficient for most applications.

   Most highly corrected high-NA objectives have >80% transmittance at visible wavelengths but low transmittance at NIR light. Long-working-distance lenses with a high NA are favored for deep imaging so that the beam can be focused deep into the tissue and the emission photons can be collected efficiently. Furthermore, high-NA lenses increase the two-photon excitation probability by increasing the density of the photon flux at the focal plane (the two-photon excitation probability is directly proportional to NA^4).

   For example, a Zeiss C-Apochromat 40×/1.20 W Corr UV-VIS-IR water lens is very effective for 2PLSM because it has a large working distance (280 μm at a 0.17-mm coverglass thickness) and enables deep imaging with minimal spherical aberrations; it has ∼85% transmittance at 500 nm and ∼75% transmittance at 820 nm, and a high collection efficiency.

2. Turn on the Ti:sapphire laser at least 30 min before starting to image. Mode-lock the laser at the desired wavelength.

3. Configure the light path for optimal excitation and emission detection of the fluorophores expressed in the embryo.

   Configure the dichroic mirrors in the light path so as to reflect the infrared excitation wavelengths to the sample. Two-photon excitation spectra of common FP variants have been recorded (Spiess et al., 2004): optimal excitation of ECFP occurs at ∼850 nm, EGFP at ∼950 to 970 nm, and EYFP at ∼960 to 970 nm. Suboptimal excitation wavelengths are routinely used and result in the same emission profiles and emission maxima (Spiess et al., 2004). Two-photon emission spectra are identical with one-photon emission spectra of the same FP variant. Choose appropriate emission filters with an IR block (e.g., a BP500-550 IR filter for two-photon excited EGFP).

4. Make the choice between descanned and nondescanned detection based on the imaging depth and the signal brightness.

   There are two major detection modes in 2PLSM. The first one uses exactly the same optical pathway as in CLSM, i.e., the emitted light is captured (descanned) using galvanometric scanning mirrors before passing through the pinhole to the detector. The pinhole in this case is set to its maximum aperture. This is called the descanned mode.

   The other detection mode is called the nondescanned mode. In nondescanned mode, the emitted light does not pass through the galvanometric scanning mirrors, and no pinhole is used. Instead, the emitted light is collected on an external detector outside the scanning module. Hence, a nondescanned detection light path allows collection of as many scattered fluorescence photons as possible and thus increases the signal-to- noise ratio when imaging deep in living tissue (see Fig. 4.18.2).

Locate the embryos of interest

5. Place the imaging chamber containing the mounted embryos on the microscope stage.

6. Use bright-field (transmitted light) or/and epifluorescence illumination to locate the embryos of interest, and focus on the vitelline membrane (see Basic Protocol 3, steps 5 and 6).

7. Before starting the laser scanning, set the laser power down, the detector gain up, choose a fast scan time (typically 1 sec per scan) and zoom 1.0.

   For imaging Venus-expressing embryos on a Zeiss LSM 510 META coupled with a Coherent Chameleon Ti:sapphire laser, start with 20% transmission of a 900-mW, 910-nm laser light, PMT gain 900, 1 sec per scan, and zoom 1.0 for a Zeiss C-Apochromat 40×/1.20 W Corr UV-VIS-IR water lens.

8. Start fast laser scanning, bring the embryo to the desired focal plane and move the region of interest (ROI) to the center of the field of view. Take a single scan.

   Most software has a rapid scanning mode ("Fast XY" W on Zeiss software) that makes preliminary scanning more efficient in rapidly selecting the focal plane and ROI with minimal exposure to laser light.

Establish conditions for maximal two-photon excitation and optimal image-acquisition

9. Determine the optimal instrument parameters for two-photon excitation and image acquisition. Optimize the following parameters based on the application requirements: percent transmission of excitation light, detector gain and offset, scan speed, averaging, zoom factor, and frame size. The guidelines provided for optimizing image acquisition in CLSM (Basic Protocol 3, steps 9a and 9b) also apply to 2PLSM.

   The probability of two-photon excitation is proportional to the incident photon flux density squared. Thus, the simplest way to increase two-photon excitation is by increasing the average power of the laser. However, this increases the heat produced and can dramatically affect viability and development or disrupt cellular structures.

   Use transmission images of the observed tissue and look for dramatic morphological changes due to photodamage during the experiment. Use any observations related to the question asked for assessing viability (cell cycle duration, cell cycle progression, etc.). For example, living embryos imaged with 20 mW of 910-nm laser light at the back aperture of a Zeiss C-Apochromat 40×/1.20 W Corr UV-VIS-IR water lens progress normally through syncytial nuclear cycles and cellularization.

   Poor alignment of the two-photon laser into the microscope will have a profound effect on excitation efficiency. Technical details regarding laser alignment and other parameters that affect two-photon excitation (e.g., beam size at the back aperture and pulse length) are available in specialized reviews (Dickinson, 2005; Helmchen and Denk, 2005).

Acquire time-lapse images: single focal plane or z-stack over time

10. Once the appropriate instrument parameters have been determined, acquire time-lapse images of one or more optical slices through the sample (*z*-sectioning) over time (see Basic Protocol 3, steps 10a and 10b).

11. After a series of images has been collected, immediately save them to disk.

    Develop a strategy for labeling the image files before beginning to image. This will save time between successive imaging sessions in living, developing embryos. Always save raw unprocessed datasets and make sure that they contain all the information that might be required later for image processing, measurements, and presentation purposes or for reusing the same parameters (e.g., excitation levels, lens magnification and zoom factor, pixel dwell time) for imaging other samples.

BASIC PROTOCOL 5

FLUORESCENCE RECOVERY AFTER PHOTOBLEACHING IN LIVING *DROSOPHILA* EMBRYOS USING A LASER SCANNING CONFOCAL MICROSCOPE CAPABLE OF SELECTIVE PHOTOBLEACHING

This protocol focuses on the application of the fluorescence recovery after photobleaching (FRAP) technique in living *Drosophila* embryos. Photobleaching is the photo-induced alteration of a fluorophore that extinguishes its fluorescence. In a typical FRAP experiment, fluorescence in a selected region of interest (ROI) within a cell is photobleached

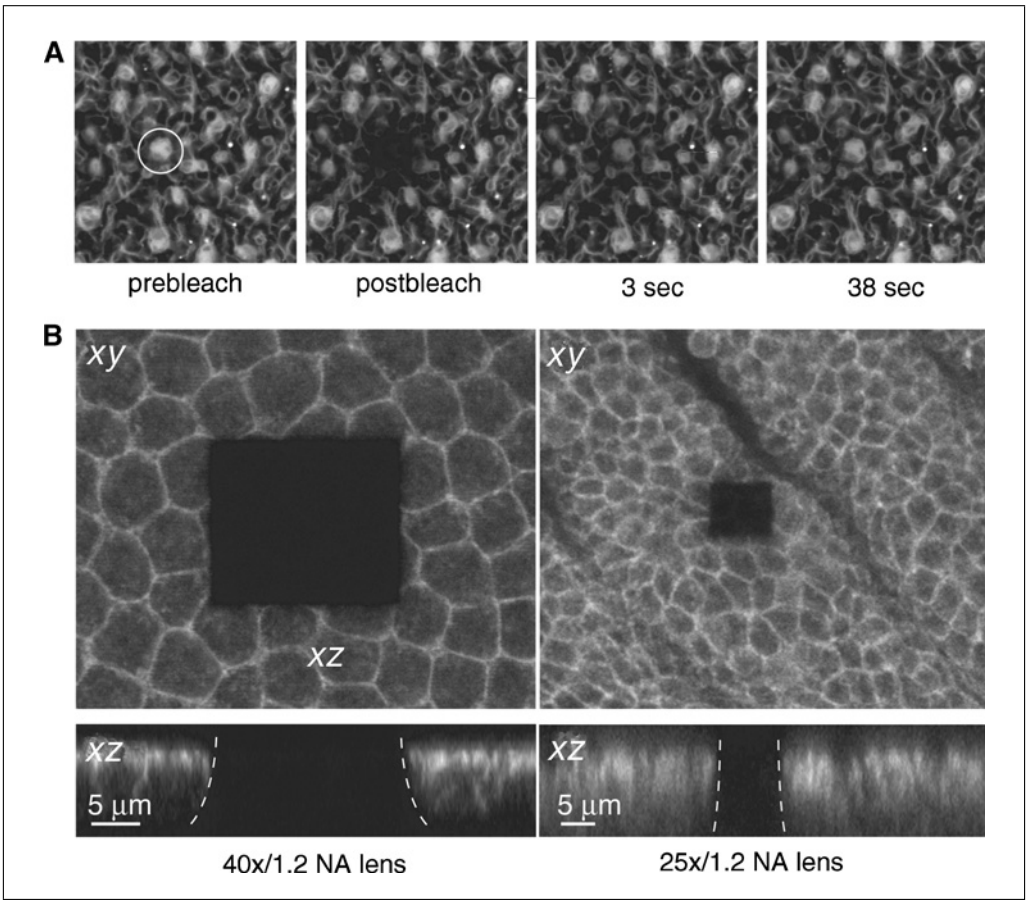

Figure 4.18.8 Example of FRAP and effects of lens magnification and NA in bleaching depth. (**A**) A region of interest (white outlined circle) is photobleached in a syncytial embryo expressing an ER lumenal protein. FRAP (see Basic Protocol 5) revealed that this protein is highly mobile in the ER lumen, and fluorescence recovery occurred in less than a minute. (**B**) A fluorescent embryo was fixed, and a region of interest was photobleached with lenses of different magnification and numerical aperture (NA). A high-resolution *z*-stack was then acquired to image the bleached volume. High-NA lenses (left panel) focus the laser beam best and bleach more efficiently in the focal plane, and the conical shape of the illumination pattern is obvious in *xz* sections. Conversely, low-NA lenses (right panel) bleach more uniformly along the optical axis, consistent with a more cylindrical shape of illumination.

once with a high-intensity laser beam, and fluorescence recovery in the bleached ROI is monitored over time with low-intensity laser light, as nonbleached molecules move into the bleached region (see Fig. 4.18.8). Quantitative measurements of the fluorescence recovery kinetics provide insights into protein and organelle mobility and dynamics, including (1) the estimation of the diffusion coefficient of molecules, (2) the fraction of mobile molecules under specific experimental conditions, and (3) the assessment of continuity or discontinuity in an organelle (for reviews, see Klonis et al., 2002; Carrero et al., 2003).

UNIT 21.1 describes in detail how to perform and analyze FRAP experiments in mammalian cells, and that unit should be consulted in addition to the protocol described here. Performing FRAP in living *Drosophila* embryos involves essentially the same principles as in a mammalian cell, but there are additional considerations specific to the thickness, geometry, and scattering properties of the tissue that should be taken into account when working with *Drosophila*. There is no universal protocol for FRAP experiments. Every photobleaching experiment is performed in a unique way, depending on the photobleaching characteristics of the fluorescent proteins (FPs) used, recovery kinetics of the process

under study, geometry of the ROI, and how the images will be analyzed. This protocol provides general guidelines that should be considered when performing photobleaching experiments in living embryos. The investigator needs to be familiar with time-lapse confocal imaging (Basic Protocol 3) before attempting photobleaching experiments.

Materials

Drosophila embryos expressing fluorescent proteins (FPs) of interest (Basic Protocol 1), mounted in LabTek or MatTek imaging chamber (Basic Protocol 2)

Confocal laser scanning microscope (CLSM) capable of selective photobleaching (e.g., Zeiss LSM 510 or Olympus FluoView FV1000), equipped with laser lines and filter sets appropriate for the FPs of interest

Set up the imaging system

1. Set up the microscope and prepare embryos for time-lapse confocal imaging as described in Basic Protocol 3 (steps 1 to 3) with the following considerations:

   Choose an FP that is bright and photostable under low-intensity illumination conditions, but photobleaches fast and irreversibly under high-intensity illumination.

   EGFP, Venus, or mCherry are examples of variants suitable for photobleaching experiments in embryos expressing a single FP.

   When designing photobleaching experiments in embryos expressing two FPs (e.g., Venus and mCherry), tag the protein of interest for photobleaching to the red-shifted variant (mCherry in this case) and not vice versa. This will eliminate cross-excitation of the blue-shifted variant (Venus) during photobleaching.

   Alternatively, suboptimal excitation of the blue-shifted variant can be used. For example, in embryos expressing EGFP and mCherry, use 458 nm to excite and photobleach EGFP (instead of the more optimal 488 nm) in order to minimize cross-exciting mCherry.

   Make sure that you have the appropriate laser power output needed for rapid and efficient photobleaching.

   Bleaching is achieved at the same wavelength as used for excitation, but with a typically 100- to 1000-fold higher intensity. For mGFP bleaching, a 25-mW or 30-mW, 488-nm Ar ion laser is sufficient for most applications. 100-mW 488-nm diode lasers are available for applications requiring rapid bleaching times. Most CLSMs use relatively weak HeNe lasers (1 mW) for green wavelengths. For routine photobleaching experiments with red variants, configure your system with stronger green lasers such as a 20- or 50-mW diode-pumped solid-state 532-nm laser or a 10-mW or 25-mW, 561-nm laser diode.

   Choose an appropriate objective lens.

   Water-immersion objectives used for high-resolution time-lapse confocal imaging of living Drosophila can also be used for photobleaching experiments (e.g., a Zeiss C-Apochromat 40×/1.20 W Corr UV-VIS-IR lens is sufficient for most applications). The NA of the objective is the property that most influences the depth and efficiency of photobleaching. High-NA lenses focus the laser beam best and bleach more efficiently in the focal plane, but they do not bleach out-of-focus regions as efficiently. Conversely, low-NA lenses do not focus the laser beam as well and bleach less efficiently, but they do so more uniformly along the optical axis in out-of-focus regions.

   The choice of the objective will depend on the thickness of the structure to be photobleached and the biological question asked. A 40×/1.20 NA water lens is sufficient for most applications while allowing for high spatial resolution, maximal signal collection, and minimal aberrations. If a larger depth of bleaching (i.e., bleach volume along the optical axis) is required (e.g., to bleach throughout the cytoplasm of epithelial cells) a 25×/ 0.8 NA is preferable (Fig. 4.18.8).

Establish FRAP conditions

2. Identify the embryo of interest, bring it to the desired focus, and move the ROI (cell or field of cells) to the center of the field of view (see Basic Protocol 3, steps 4 to 6).

3. Take a single scan and optimize the following parameters based on the application requirements: laser power and percent transmission of excitation light, pinhole size, detector gain and offset, scan speed, averaging, zoom factor, frame size, and acquisition frequency.

   Minimize bleaching during acquisition of the prebleach and postbleach series by using the minimum laser transmission to yield an acceptable image.

   Recommended conditions for a 25-mW, 488-nm argon laser are 0.1% to 1.0% transmission at a tube current of 6A.

   Adjust the pinhole size based on the experimental requirements.

   If photobleaching of the structure of interest in z is homogeneous, then an open pinhole is preferable in order to collect as much signal as possible for accurate fluorescence quantitation. However, when the ROI is thin or masked by a large diffuse pool of fluorescent molecules, a closed pinhole is preferable to image only the ROI.

   For example, when the protein of interest localizes both to the cytoplasm and to the plasma membrane, only a thin optical section will reveal the plasma membrane pool, and a closed pinhole should be used to measure plasma membrane–associated kinetics.

   Adjust the gain and black level (offset) of the PMT detector in order to acquire images using the full dynamic range of the detector (see Basic Protocol 3, step 9a).

   This is absolutely required for quantitative measurements of fluorescence intensity changes during the photobleaching experiment. Acquire 12-bit images rather than 8-bit images in order to increase the dynamic range of the measurements and enable detection of small changes in fluorescence intensity.

   Use zooms that include the whole cell containing the bleach ROI in order to correct the post-bleach series for the photobleached fraction.

   Zooms that include neighboring cells or other regions in the tissue in the same field as the bleach ROI are preferable in order to correct for acquisition photobleaching and laser fluctuations. Higher zooms are in general beneficial because they increase spatial and temporal resolution. Furthermore, the rate of photobleaching is proportional to the square of the zoom factor. Thus, zooming in will favor rapid photobleaching (but may also result in undesired bleaching during postbleach image acquisition).

   Adjust the time resolution (often more critical in photobleaching experiments than spatial resolution).

   To increase time resolution for the fluorescence recovery time series, minimize or avoid averaging and use a fast scan speed to yield an acceptable image. In cases of very fast recovery kinetics, reduce the number of pixels (frame size) to increase even more the acquisition frequency.

   For example, scanning a 512 × 512 frame at zoom 2.0 using the fastest scan speed on a Zeiss LSM 510 META yields a scan time of 786 msec and reducing the frame to 512 × 150 using the same zoom and scan speed yields a scan time of 230 msec. Most commercial confocal microscopes enable the investigator to scan only a selected ROI without having to zoom in, thus increasing time resolution, preserving spatial resolution, and minimizing exposure of the rest of the sample to illumination.

   For acquiring >10 frames per sec or simultaneously bleaching and acquiring images (required in the case of very rapid recovery kinetics), specialized systems are necessary. Examples of such commercial systems are the Zeiss 5 DUO system (which combines the ultrafast scanning and detection of a Zeiss LSM 5 LIVE with the photobleaching capability

of a Zeiss LSM 510 META), the Olympus FluoView FV1000 system with an SIM scanner (a synchronized laser scanning system that allows one to simultaneously image and bleach), and the PerkinElmer spinning disk UltraVIEW ERS with a PhotoKinesis unit (that enables bleaching selective targets as they are moving, after image acquisition has started).

These imaging parameters will be used for the prebleach series and for the fluorescence recovery time series.

4. Define an ROI for the photobleach.

   Most bleaching functions in commercial microscope operating software applications allow for the arbitrary selection of the bleach ROI shape and size. Using a larger ROI will result in longer bleaching times and longer fluorescence recovery times, but this may be preferable in the case of rapidly diffusing molecules.

5. Determine photobleaching conditions at the same scan speed and zoom used for image acquisition.

   The illuminating beam has a 3D profile (i.e., it bleaches and records fluorescence in a 3D volume). We recommend measuring the depth and efficiency of bleaching in the specific ROI in fixed tissue, and then using the same instrument parameters (objective, lasers, and imaging settings) for the actual experiment. Perform a bleach and then acquire a high-resolution z-stack of the bleached region to accurately calculate the dimensions of the bleached volume and the completeness of bleaching (Fig. 4.18.8). This information will be useful when assessing or generating models for fitting the FRAP data (see discussion in step 13).

   Photobleaching should be as rapid and as complete as possible (see discussion in step 13). To neglect the exchange of bleached and nonbleached molecules during bleaching, the total bleaching time should be at least 15 times smaller than the recovery half time (Meyvis et al., 1999).

   At a given scan speed and zoom, photobleaching efficiency will be determined by the laser power output, transmission of the laser used, number of bleach iterations, as well as abundance and diffusive properties of the FP under study. We recommend a series of pilot experiments in fixed tissue (if possible) to determine the minimum number of iterations needed for complete bleaching of the fluorophore under the same imaging settings used for image acquisition. If the bleach is not complete, increase the number of iterations, increase the laser output (useful for very dynamic processes), or zoom in.

   Alternatively, you can optimize photobleaching time and efficiency in living tissue in neighboring cells of the primary ROI.

   Recommended conditions for photobleaching with a 25-mW, 488-nm argon laser are 100% transmission at a tube current of 6 A.

Collect FRAP data

6. Once the appropriate instrument parameters for prebleach and postbleach image acquisition (step 3) and photobleaching (steps 4 and 5) have been determined, perform the actual photobleaching experiment by integrating steps 7, 8, and 9 in a time-lapse function.

   Most microscope operating software applications offer a bleaching function or a macro interface that enables the investigator to set up the parameters for the photobleaching experiment and integrate these in a time-lapse function: area to be bleached, number of prebleach images, laser transmission and iterations for bleaching, number of postbleach images, and interval between acquired images.

7. Acquire a series of five to 10 prebleach images to measure the total steady-state fluorescence intensity before photobleaching.

   This prebleach series will be used to correct the post-bleach series for the photobleached fraction, as well as the whole experiment for acquisition photobleaching and laser intensity fluctuations.

8. Selectively photobleach the ROI, using the conditions established in step 5.

9. Acquire a series of postbleach images until the fluorescence recovery process has reached a steady state.

   Adjust the image acquisition frequency to yield as many data points as possible during the recovery process, in particular during the recovery half time. Acquire postbleach images for 10 to 50 times longer than the recovery half time of the bleached protein of interest (Axelrod et al., 1976; Gordon et al., 1995).

10. After the end of the photobleaching experiment, immediately save the dataset to disk.

    If the bleach ROI is not automatically saved with the images, save a prebleach image with an overlay of the bleach ROI used. Knowledge of the precise position, size, and shape of the bleach ROI is absolutely required for quantitative measurements in this region. Do not rely on visually assessing the position of the bleach box based on the first postbleach images.

    Develop a strategy for labeling the image files before beginning to image. This will save time between successive imaging sessions in living, developing embryos. Always save raw unprocessed datasets and make sure that they contain all the information that might be required later for image processing, measurements, and presentation purposes or for reusing the same parameters e.g., (pinhole size, excitation levels, lens magnification and zoom factor, pixel dwell time) for imaging other samples.

11. Collect more than five FRAP datasets for statistical analysis for each condition using the exact same instrument parameters.

Process FRAP data

12. Perform basic FRAP data analysis in four steps:

    a. Determine raw fluorescence intensity measurements in ROIs of the cell.

    b. Subtract background and correct for the bleached fraction.

    c. Correct for laser fluctuations and photobleaching during acquisition.

    d. Normalize data to compare different experiments.

13. Use this initial image analysis to generate a plot displaying fluorescence changes in the bleached ROI over time.

    From this plot, a number of parameters can be extracted, including the half time for recovery ($t_{1/2}$) and the mobile and immobile fractions of the fluorescent molecules under study. For basic image analysis and kinetic modeling of FRAP data, consult UNIT 21.1 and Rabut and Ellenberg (2005).

    Despite the widespread use of photobleaching microscopy, few models exist for quantitative analysis of FRAP data acquired with CLSM. FRAP theory was initially developed for nonscanning microscopes, and many of the assumptions that were initially formulated are still widely used in quantitative FRAP models. However, bleaching and fluorescence recovery monitoring are fundamentally different in CLSM from FRAP with nonscanning microscopes (for a theoretical analysis of the bleaching process in CLSM, see Braeckmans et al., 2003).

    The validity of existing quantitative FRAP models or the need to generate a new model to analyze FRAP data obtained with CLSM depend ultimately on the process under study (e.g., 2D versus 3D diffusion), recovery kinetics, instrument parameters used for bleaching and acquisition of fluorescence recovery (which influence the depth and efficiency of bleaching), as well as the scanning and detection speed of the CLSM system used.

    An example of where the choice of the quantitative FRAP model is of great importance is the estimation of diffusion coefficients for rapidly diffusing molecules in the cytoplasm or nucleoplasm of the cell. To date, most FRAP models assume that both bleaching and image acquisition are sufficiently fast to neglect diffusion during those periods (Axelrod et al., 1976; Braeckmans et al., 2003). As a rule, the total bleaching time should be at least 15 times smaller than the recovery half time to neglect diffusion during bleaching (Meyvis

et al., 1999). However, in FRAP experiments with standard commercial CLSM systems, pixels are acquired sequentially, so the bleached region is imaged a few milliseconds after the start of image acquisition.

Furthermore, most applications require much longer bleaching times than theoretically required to neglect diffusion. Before the first postbleach image is acquired, significant diffusion takes place (demonstrated experimentally in Braga et al., 2004), and calculated diffusion coefficients with widely used FRAP models are significantly underestimated. Recently, a 3D FRAP model was developed that takes into account diffusion during the bleach period (Braga et al., 2004) and can be readily applied on most commercial CLSMs. Quantitative FRAP models have also been developed to address the interplay between diffusion and binding events (Sprague et al., 2004).

BASIC PROTOCOL 6

FLUORESCENCE LOSS IN PHOTOBLEACHING IN LIVING *DROSOPHILA* EMBRYOS USING A LASER SCANNING CONFOCAL MICROSCOPE CAPABLE OF SELECTIVE PHOTOBLEACHING

This protocol focuses on the application of the fluorescence loss in photobleaching (FLIP) technique in living *Drosophila* embryos. In a typical FLIP experiment, fluorescence in a selected region of interest (ROI) within a cell is repeatedly photobleached over time, and loss of fluorescence in nonbleached regions of the cell is monitored as nonbleached molecules move into the bleached region and get bleached. Measurements of the fluorescence loss kinetics provide insights into the exchange of components between compartments, including (1) the extent of continuity or discontinuity in an organelle and (2) exchange of fluorescent pools between different compartments under specific experimental conditions. The same guidelines we provide for FRAP experiments (Basic Protocol 5) should be considered when performing FLIP in living embryos. The investigator needs to be familiar with time-lapse confocal imaging (Basic Protocol 3) before attempting photobleaching experiments.

Materials

Drosophila embryos expressing fluorescent proteins (FPs) of interest (Basic Protocol 1), mounted in LabTek or MatTek imaging chamber (Basic Protocol 2)

Confocal laser scanning microscope capable of selective photobleaching (e.g., Zeiss LSM 510 or Olympus FluoView FV1000), equipped with laser lines and filter sets appropriate for the FPs of interest

Set up the imaging system

1. Set up the microscope and prepare embryos as described for FRAP in Basic Protocol 5, step 1).

Establish FLIP conditions

2. Identify the embryo of interest, bring it to the desired focus, and move the ROI (cell or field of cells) to the center of the field of view.

3. Take a single scan and optimize the following parameters based on the application requirements: laser power and percent transmission of excitation light, pinhole size, detector gain and offset, scan speed, averaging, zoom factor, frame size, and acquisition frequency (see Basic Protocol 5, step 3).

   These imaging parameters will be used for the prebleach series and for the images collected between successive bleaches.

   Include at least one neighboring unbleached cell (or group of cells) in the field in addition to the cell containing the bleach ROI. Fluorescence intensity changes in the control cells will be used to correct for acquisition photobleaching and laser fluctuations during the FLIP protocol.

4. Define an ROI for the photobleach (see Basic Protocol 5, step 4).

5. Determine photobleaching conditions at the same scan speed and zoom used for image acquisition (see Basic Protocol 5, step 5).

Collect FLIP data

6. Once the appropriate instrument parameters for image acquisition and photobleaching have been determined, perform the actual photobleaching experiment by integrating steps 7 to 9 in a time-lapse function.

   Most microscope operating software applications offer a bleaching function or a macro interface that enables the investigator to set up the parameters for the photobleaching experiment and integrate these in a time-lapse function: area to be bleached, number of prebleach images, laser transmission and iterations for bleaching, number of images between successive bleaches, and interval between acquired images.

7. Acquire a series of five to ten prebleach images to measure the total steady-state fluorescence intensity before photobleaching.

   This prebleach series can be used to correct the whole experiment for acquisition photobleaching and laser intensity fluctuations.

8. Selectively photobleach the ROI, using the conditions established in step 5.

9. Acquire one image of the whole cell and photobleach the ROI again. Repeat the process until the fluorescence intensity of the structure of interest is similar to background.

   If the proteins are mobile and the fluorescent structure of interest is continuous, the total fluorescence of the structure will be depleted over time. The time delay between successive bleaches should allow a significant fraction of molecules in unbleached regions to move into the bleach ROI. Collecting more than one image between successive bleaches is very useful for monitoring shifts in the focal plane. If the bleach ROI moves laterally during acquisition, the experiment should be aborted.

10. After the end of the photobleaching experiment, immediately save the dataset to disk.

    If the bleach ROI is not automatically saved with the images, also save a prebleach image with an overlay of the bleach ROI used. Knowledge of the precise position, size, and shape of the bleach ROI is absolutely required for quantitative measurements in regions outside the FLIP ROI. Do not rely on visually assessing the position of the bleach box based on the first postbleach images.

    Develop a strategy for labeling the image files before beginning to image. This will save time between successive imaging sessions in living, developing embryos. Always save raw unprocessed datasets and make sure that they contain all the information that might be required later for image processing, measurements, and presentation purposes or for reusing the same parameters (e.g., pinhole size, excitation levels, lens magnification and zoom factor, pixel dwell time) for imaging other samples.

11. Collect more than five FLIP datasets for statistical analysis for each condition, using the exact same instrument parameters.

Process FLIP data

12. Perform basic FLIP data analysis in four steps:

    a. Determine raw fluorescence intensity measurements in ROIs of the cell.

    b. Subtract background.

    c. Correct for laser fluctuations and photobleaching during acquisition.

    d. Normalize data to compare different experiments.

13. Use this initial image analysis to generate a plot displaying fluorescence changes in the bleached/unbleached ROIs over time.

From this plot, a number of parameters can be extracted, including the half time for equilibration and the mobile and immobile fractions of the fluorescent molecules under study. For basic image analysis and kinetic modeling using FLIP data, consult UNIT 21.1 *and Rabut and Ellenberg (2005).*

BASIC PROTOCOL 7

PHOTOACTIVATION IN LIVING *DROSOPHILA* EMBRYOS USING A LASER SCANNING CONFOCAL MICROSCOPE CAPABLE OF SELECTIVE PHOTOBLEACHING

Photoactivatable fluorescent proteins (PAFPs) present a powerful tool for the noninvasive optical labeling and tracking of proteins, organelles, and cells in living *Drosophila* tissues (Lippincott-Schwartz and Patterson, 2008). PAFPs undergo a change in their spectral properties upon irradiation with light of a specific wavelength and intensity. Some PAFPs (e.g., PA-GFP) convert from a dark to a bright fluorescent state upon photoactivation, whereas others (e.g., mEosFP) undergo photoconversion from a green to a red fluorescent form. PAFP-tagged proteins that undergo irreversible photoconversion can be used to monitor the movement of the tagged molecules within a steady-state population without interference from new protein synthesis, as newly synthesized molecules will not be fluorescent at the imaging wavelengths of the photoconverted species.

PA-GFP (Patterson and Lippincott-Schwartz, 2002) and mEos-FP (Wiedenmann et al., 2004) have the most potential among the available PAFPs for long-term protein tracking experiments, since they are both monomeric, undergo irreversible photoconversion, and exhibit high contrast between their pre- and post-activated states (i.e., from dark to green for PA-GFP or from green to red for mEosFP). Both PA-GFP and mEosFP have been successfully used in living *Xenopus* and chick embryos (Stark and Kulesa, 2005; Nienhaus et al., 2006). This protocol focuses on the photoactivation of PA-GFP- or mEos-FP-tagged proteins in living *Drosophila* embryos. While the protocol we describe may be adapted for other photoactivatable proteins, the various technical aspects of each protein must be considered. The investigator needs to be familiar with time-lapse confocal imaging and FRAP (Basic Protocols 3 and 5) before attempting photoactivation experiments. UNIT 21.6 describes in detail how to perform and optimize photoactivation experiments and should be also be consulted when using the protocol below.

Materials

Drosophila embryos expressing PA-GFP- or mEosFP-tagged proteins of interest (see Basic Protocol 1), mounted in LabTek or MatTek imaging chamber (see Basic Protocol 2)

Confocal laser scanning microscope capable of selective photobleaching (e.g., Zeiss LSM 510 or Olympus FluoView FV1000), equipped with a violet light laser line (e.g., a 405-nm diode laser or a 413-nm krypton laser), as well as visible light lasers appropriate for imaging PA-GFP or mEosFP

Set up the imaging system

1. Set up the microscope and prepare embryos for time-lapse confocal imaging as described in Basic Protocol 3, steps 1 to 4, with the following considerations:

   Configure the dichroic mirrors in the light path to accommodate both excitation sources: 405 or 413 nm for photoactivation, and 488 nm for imaging of photoconverted PA-GFP.

   Irradiation of PA-GFP with intense violet light (~400 nm) causes irreversible photoconversion of PA-GFP from a dark state (that does not fluoresce when excited at 488 nm)

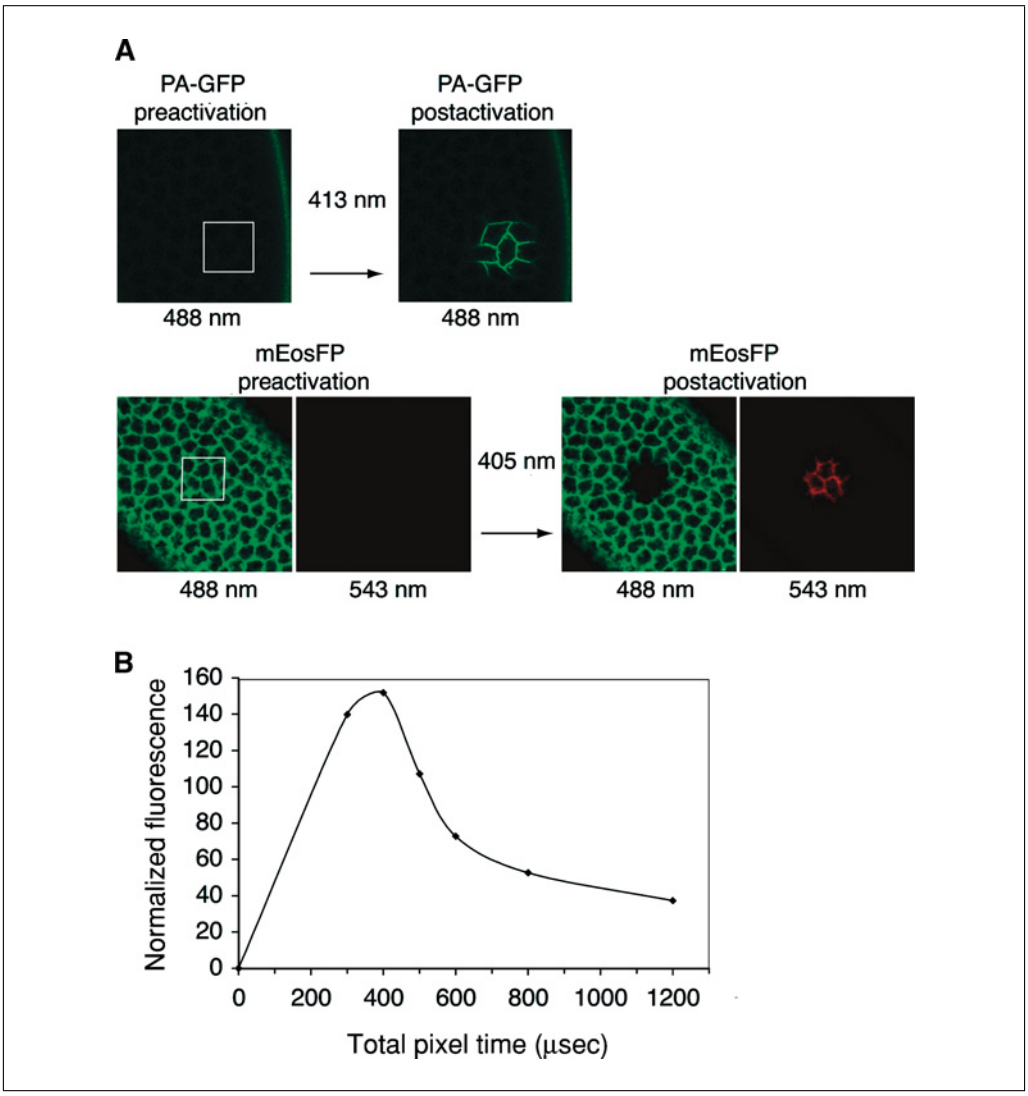

Figure 4.18.9 Example of photoactivation of PA-GFP and mEosFP in living embryos and optimization of total pixel time for maximal photoactivation (see Basic Protocol 7). (**A**) Irradiation of PA-GFP with 413 nm in a region of interest (white outlined square) in a living embryo causes photoconversion of PA-GFP from a dark state (that does not fluoresce when excited at 488 nm) to a bright green fluorescent state (that fluoresces at 488 nm). Bottom panel, Irradiation of mEos-FP with 405 nm in a region of interest (white outlined square) in a living embryo causes photoconversion of mEosFP from a green to a red fluorescent form. (**B**) Determination of the total pixel time required for optimal photoactivation, i.e., for the highest possible photoactivation with the least amount of bleaching. 0.68 mW of 405-nm laser power was used at the back aperture of an Olympus UPlanFl 40×/1.30 oil objective to photoactivate a region of interest in a living mEosFP-expressing embryo at zoom 3.0. Fluorescence was measured and plotted for different total pixel times. For 400 μsec total photoactivation pixel time (200 iterations at 2 μsec/pixel), full activation could be obtained. Fluorescence decreased over longer total pixel times due to photobleaching. For the color version of this figure go to *http://www.currentprotocols.com*.

to a bright green fluorescent state (that fluoresces at 488 nm; see Fig. 4.18.9). The excitation and emission spectra of photoactivated PA-GFP are slightly red-shifted compared with EGFP, so long-pass emission filters (LP505) or band-pass filters (BP505-530 or BP505-550) commonly used for EGFP imaging can be used for imaging PA-GFP.

Configure the dichroic mirrors in the light path to accommodate all excitation sources: 405 or 413 nm for photoactivation, 488 nm for imaging the green form before photoconversion and 543 nm (or 561 nm) for imaging the red form of mEosFP after photoconversion.

Irradiation of mEos-FP with violet light (~400 nm) causes irreversible photoconversion of mEosFP from a green to a red fluorescent form (see Fig. 4.18.9). Standard emission filters used for green/red imaging (see Basic Protocol 3, step 9b) can be used for imaging mEosFP.

Make sure that you have the appropriate violet light laser lines and laser power output needed for rapid and efficient photoactivation.

Both PA-GFP and mEosFP can be efficiently photoconverted with either a 25 to 50-mW, 405-nm diode laser or a 25-mW, 413-nm krypton laser.

Establish which lens available in your lab is most efficient in transmitting violet light, to optimize photoactivation.

Most highly corrected, high-NA objectives have the >80% transmittance to visible wavelengths but low transmittance to violet wavelengths (405 nm, 413 nm) required for photoactivation. For example, a Zeiss C-Apochromat 40×/1.20 W Corr UV-VIS-IR lens has 75% transmittance to 405 or 413 nm, compared to 80% to 85% transmittance for a Zeiss Fluar 40×/1.30 oil lens and 65% for a Zeiss C-Apochromat 63×/1.20 W Corr UV-VIS-IR for the same wavelengths. Also, high-NA lenses focus the laser beam best and photoactivate more efficiently in the focal plane compared to low-NA lenses. Lower-magnification lenses are recommended over higher-magnification lenses with an identical NA (e.g., a 40×/1.2 over a 63×/1.2 NA lens) because they often have a larger back aperture diameter and allow more light to reach the focal plane.

Establish photoactivation conditions

2. Identify the embryo of interest, bring it to the desired focus, and move the ROI (region of interest; cell or field of cells) to the center of the field of view (see Basic Protocol 3, steps 5 and 6).

3. Take a single scan and optimize the following parameters based on the application requirements: laser power and percent transmission of excitation light, pinhole size, detector gain and offset, scan speed, averaging, zoom factor, frame size, and acquisition frequency (see Basic Protocol 3, steps 9a and 9b, and Basic Protocol 5, step 3).

   PA-GFP fluoresces very little when excited at 488 nm (see Fig. 4.18.9). Unless a transgenic line has been generated, finding a embryo expressing PA-GFP can be problematic. Furthermore, finding the focal plane of interest before photoactivation can also be difficult in the absence of other fluorescent markers. Autofluorescence of the vitelline membrane and yolk can be used as a rough guide in pilot experiments to determine the focal plane in embryos that express PA-GFP (Fig. 4.18.9).

   Alternatively, co-expression of a cyan or red fluorescent marker in the same tissue that contains the ROI can be used as a guide to identify PA-GFP-positive cells.

   The level of PA-GFP or mEosFP fluorescence after photoactivation is not always easy to estimate. Some trial and error with various excitation power and detector gain settings will be required initially in order that fluorescence intensities in pre- and post-activation images are in the dynamic range of the detector.

   Slow scan speeds and/or high zooms are preferable because they increase the excitation power per unit area and thus result in shorter photoactivation times. However, they must be chosen so as not to cause undesired bleaching during pre- and post-activation image acquisition.

   These imaging parameters will be used for the pre- and post-activation time series.

4. Define an ROI for the photoactivation. Use the bleaching function available in commercial microscope operating software packages to arbitrarily select the photoactivation ROI shape and size.

   The size of the ROI will affect photoactivation time and depends on the biological process under study. For example, photoactivation time is not a critical factor when

photoactivation (typically in the range of msec to sec) is used to highlight a cell population that migrates in a period of tens of minutes. However, photoactivation time might be critical in the case of rapidly diffusing molecules.

5. Determine optimal photoactivation conditions at the same scan speed and zoom used for image acquisition, with the following considerations:

   Optimize the power and duration of the photoactivation so as to obtain the highest possible photoactivation with the least amount of bleaching.

   Photoactivation of PA-GFP and mEosFP is dependent on the duration of excitation power per unit area. This means that the level of photoactivation depends on the total time the photoactivation laser (405 or 413 nm) will spend per pixel. For longer than optimal total pixel times, the level of photoactivated fluorescence will decrease due to photobleaching by the repeated exposure to the 405-nm or 413-nm laser light.

   Conduct a series of pilot experiments (recommended) in fixed tissue (if possible) to determine the total pixel time required for optimal photoactivation (see Fig. 4.18.9).

   For a given objective, scan speed, zoom factor, and excitation power level (determined by the percent laser transmission used) measure the increase in fluorescence after photoactivation for different total pixel times. Increase the total pixel time by increasing the number of excitation scans (iterations) with the 405-nm or 413-nm laser.

   Fluorescence will increase to an apex (defined as the optimal total pixel time for photoactivation) and then decrease over longer total pixel times due to photobleaching. In the example in Figure 4.18.9, ~0.68 mW of 405-nm laser power was used at the back aperture of an Olympus UPlanFl 40×/1.30 oil objective. At zoom 3.0 and 400 μsec total photoactivation pixel time (200 iterations at 2 μsec/pixel), full activation could be obtained (Fig. 4.18.9B). At longer pixel times, photobleaching outbalances photoactivation and fluorescence decreases. In this case, photoactivated fluorescence appears depleted within the photoactivation ROI, which is surrounded by a fluorescent rim.

   Repeat the above measurements for a different excitation power and also for a different zoom factor.

   Decreasing the excitation power at the back aperture of the lens will require longer total pixel times. Higher zoom factors increase the excitation power per unit area and will shift the total pixel time and power required for optimal photoactivation to lower values. This optimization routine will be enough to determine the optimal parameters (objective, zoom factor, laser transmission, and total pixel time) for experiments on a daily basis, assuming minimal fluctuations in laser power and optical alignment.

   Use a handheld laser power meter to measure the excitation power at the back aperture of the objective. Simply remove the objective and measure the 405-nm or 413-nm laser power at the nosepiece at several transmission levels.

   This routine takes a few minutes, and knowledge of the power at the back aperture can be used to adjust photoactivation parameters in case of laser power or alignment fluctuations.

   Control for cytotoxicity when performing photoactivation experiments using short wavelengths (405-nm or 413-nm lasers).

   This step is imperative! Use any observations of photoactivation artifacts due to cytotoxicity related to the question asked (e.g., cell cycle duration, cell cycle progression).

Perform photoactivation experiment

6. Once the appropriate instrument parameters for pre- and post-activation image acquisition and photoactivation (steps 2 to 5) have been determined, perform the actual photoactivation experiment by integrating steps 7, 8, and 9 in a time-lapse function.

Most microscope operating software packages offer a bleaching function or a macro interface that enables the investigator to set up the parameters for the photoactivation experiment and integrate these in a time-lapse function: area to be photoactivated, number of preactivation images, laser transmission and iterations for activation, number of postactivation images and interval between acquired images.

7. Acquire a series of one to five pre-activation images. Use 488-nm excitation for PA-GFP or image simultaneously at 488 and 543 nm (or 561 nm) for mEosFP.
8. Selectively photoactivate the ROI, using the 405-nm or 413-nm laser and the conditions established in step 5.
9. Acquire a series of post-activation images using the excitation settings used for the pre-activation images in step 7.
10. After the end of the experiment, immediately save the dataset to disk. If the photoactivation ROI is not automatically saved with the images, also save a pre-activation image with an overlay of the ROI used.

Knowledge of the precise position, size, and shape of the bleach ROI might be required for quantitative measurements in this region, depending on the application.

Develop a strategy for labeling the image files before beginning to image. This will save time between successive imaging sessions in living, developing embryos. Always save raw unprocessed datasets and make sure that they contain all the information that might be required later for image processing, measurements, and presentation purpose or for reusing the same parameters (e.g., pinhole size, excitation levels, lens magnification and zoom factor, pixel dwell time) for imaging other samples.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Apple or grape juice agar plates

For 500 ml of apple or grape juice agar medium:
15 g agar
8 g sucrose
165 ml apple or grape juice
0.1 g methyl *p*-hydroxybenzoate (methyl paraben; Sigma)

Add water to the agar to a final volume of 335 ml and microwave 5 min to dissolve the agar. Dissolve the sucrose and methyl paraben in the juice by microwaving 5 min. Combine both microwaved mixtures and mix thoroughly. Pour ~8 ml per 60 × 15–mm petri dish (Genesee Scientific *or* BD). Once the juice agar plates have cooled and hardened, store up to ~1.5 month at 4°C in a sealed box (to prevent drying out).

COMMENTARY

Background Information

Advances in the development of user-friendly commercially available laser scanning microscopes and the generation of improved fluorescent protein (FP) variants that cover the entire visible spectrum have made fluorescence microscopy an enormously powerful tool in the biological community. The combination of these advances with *Drosophila* genetics, which enables the investigator to control the spatial and temporal expression of any protein of interest throughout development, has made it possible to gain insights into protein, organellar, and cellular dynamics in living tissues in a noninvasive way and with unprecedented resolution.

The generation of transgenic *Drosophila* has become a standard technique for the investigation of a wide variety of biological questions (Fujioka et al., 2000). Virtually any cloned gene can be inserted into the genome using the P transposable element system. A

large collection of *Drosophila* cDNAs is available at the *Drosophila* Genomics Research Center (DGRC; *http://dgrc.cgb.indiana.edu*). For a catalog of Gal4 transgenic lines that can be used to express the protein of interest in specific tissues or temporal patterns, the reader is referred to the FlyBase Web site at *http://flystocks.bio.indiana.edu/Browse/misc-browse/gal4.htm*. A catalog of vectors for subcloning fluorescently tagged genes of interest and for transforming *Drosophila* is available at DGRC (*http://dgrc.cgb.indiana.edu/vectors/store/vectors.html*).

Background information on microscopy and the use of FPs is available from several sources. For an excellent review on the latest generation of FP variants, the reader is referred to *UNIT 21.5*. The use of FPs to study protein dynamics has been reviewed (Lippincott-Schwartz et al., 2001; Lippincott-Schwartz and Patterson, 2003). The Molecular Expressions Web site (*http://micro.magnet.fsu.edu/primer*) is one of the best microscopy Web sites. It is an extremely resourceful and up-to-date Web site, covering topics from image formation and microscope basics to imaging parameters for FPs. It further features interactive tutorials that help the investigator understand in depth the different parameters involved in image acquisition (e.g., effect of pinhole size and lens NA on resolution, spectral bleedthrough in multicolor imaging). Basic confocal microscopy is reviewed in *UNIT 4.5*. For more detailed reviews of confocal laser scanning microscopy (CLSM), see Murray (2005) and *http://www.olympusconfocal.com/theory/LSCMIntro.pdf*. *UNIT 4.11* gives an introduction to two-photon excitation microscopy. For more detailed reviews of two-photon laser scanning microscopy (2PLSM) and deep-tissue imaging using 2PLSM, see Dickinson (2005) and Helmchen and Denk (2005).

The advantages and considerations of using CLSM and 2PLSM for live *Drosophila* tissue imaging are discussed at the beginning of this unit and in Basic Protocol 4. CLSM (Basic Protocol 3) is currently the method of choice for routine high-resolution imaging of living *Drosophila* tissue. The major drawback of CLSM is limited penetration depth due to scattering and out-of-focus absorption, which limit imaging to <40 μm deep in a living *Drosophila* embryo (see Fig. 4.18.2). For routine imaging at 40 to 100 μm deep in the embryo, 2PLSM (Basic Protocol 4) is the method of choice. The major drawback of 2PLSM is local heating effects caused by the high powers of near infrared (NIR) photons required for two-photon excitation. Furthermore, ultrafast pulsed lasers for 2PLSM are much more expensive than the visible light lasers commonly used for CLSM. Finally, more technical effort is required for the optimization of the laser source for two-photon excitation.

Photobleaching techniques applied to live cell imaging have transformed our understanding of cellular organization and protein dynamics. The mobility of virtually any molecule can be measured in any location in living cells, and the spatial and temporal dynamics of subcellular processes can be monitored with unprecedented resolution. For reviews of FRAP theory and applications, see Klonis et al. (2002), Carrero et al. (2003), and Lippincott-Schwartz et al. (2003). FRAP theory was initially developed for nonscanning microscopes, but many of the assumptions that were initially formulated are still widely used in quantitative FRAP models (Axelrod et al., 1976; Gordon et al., 1995). However, bleaching and fluorescence recovery monitoring are fundamentally different in CLSM and FRAP with nonscanning microscopes. Braeckmans et al. (2003) provides a thorough theoretical explanation of the bleaching process in CLSM. A 3D FRAP model was recently reported that can be easily applied to any commercial CLSM setup (Braeckmans et al., 2003). Braga et al. (2004) further developed a 3D FRAP model that takes into account diffusion during the bleach period. For basic image analysis and kinetic modeling of photobleaching data, see *UNIT 21.1*, Rabut and Ellenberg (2005), and Phair and Misteli (2001). Quantitative FRAP models have also been developed to address the interplay between diffusion and binding events (Sprague et al., 2004; Sprague and McNally, 2005).

Photoactivatable FPs enable the investigator to track individual cells or cell populations in developing tissues, probe organelle continuity, or monitor protein and organelle trafficking and turnover in living cells in a noninvasive way. For reviews of photoactivatable FPs and applications, refer to Lukyanov et al. (2005), Nienhaus et al. (2006), and Lippincott-Schwartz and Patterson (2008). Patterson and Lippincott-Schwartz (2004) and *UNIT 21.6* discuss the technical aspects of photoactivation using PA-GFP in a CLSM setup, PA-GFP in a CLSM setup. PA-GFP and mEos-FP have the most potential among the available PAFPs for long-term protein tracking experiments because they are both monomeric, undergo irreversible photoconversion, and

exhibit high contrast between their pre- and post-activated states. Both PA-GFP and mEosFP have been successfully used in living *Xenopus* and chick embryos (Stark and Kulesa, 2005; Nienhaus et al., 2006), and the use of PA-GFP has also been reported in the fly (Post et al., 2005).

Tvaruskó et al. (2005) provide an overview of image analysis tools for studying dynamic processes in living cells. ImageJ (previously known as NIH Image) is a free, powerful image analysis program developed at the National Institutes of Health, and it has many useful tools for analysis of confocal images. It can be downloaded from *http://rsb.info.nih.gov/ij*. Other widely used image analysis software packages are Volocity (Improvision), Imaris (Bitplane), or MetaMorph (Molecular Devices).

Critical Parameters and Troubleshooting

The critical parameters for setting up time-lapse imaging (Basic Protocol 3 and 4), photobleaching (Basic Protocols 5 and 6), or photoactivation (Basic Protocol 7) experiments in living *Drosophila* tissue and optimization of data collection are described in great detail in the respective protocols. We emphasize below some of the parameters that are critical for the success of imaging experiments in living tissue using CLSM and 2PLSM.

Choice of fluorescent protein

The investigator should use the latest generation of spectral variants, which have been improved for folding, chromophore maturation, brightness, photostability, and minimal self-association (see *UNIT 21.5*). However, the choice of a specific FP or combination of FPs depends exclusively on the application requirements. In all cases, the investigator needs to minimize undesired photobleaching of the FPs during image acquisition. For long-term protein tracking experiments, bright and photostable FPs are preferable. For multi-fluorophore imaging, the investigator should closely examine the spectral profiles of the FPs of interest, as well as the excitation and emission filters available in the CLSM setup, in order to optimize the light path and obtain maximal signal without spectral bleedthrough. Some effort is required to optimize signal collection for multiple fluorophores because FPs vary in relative brightness and photostability.

For photobleaching experiments, the FP should be bright and photostable under low-intensity illumination conditions, but photobleach fast and irreversibly under high-intensity illumination. The most desirable features for photoactivatable proteins are that they undergo irreversible photoconversion and that they exhibit high contrast between their pre- and post-activated states. PA-GFP and mEosFP fulfill these criteria and thus currently have the most potential.

Choice of objectives

Due to the thickness and geometry of the tissue, imaging subcellular processes during development often requires focal planes deep into the tissue. Because of the differences in refractive indices in the embryo interior and the immersion medium, severe spherical aberrations arise when focal planes are set >10 μm deep, and oil is used as an immersion medium. Unless optical sections are collected at the surface of the tissue closest to the coverglass, the investigator should always use water-immersion objectives to minimize spherical aberrations. Long-working-distance, high-NA water-immersion objectives corrected for coverglass thickness, field curvature, and chromatic aberrations (e.g., the Zeiss C-Apochromat 40×/1.20 W Corr UV-VIS-IR water lens or the Olympus UPLAPO 60×/1.2 NA water lens) are the best choice for high-resolution live 4D imaging of thick *Drosophila* tissue with CLSM.

Magnification, NA, and transmittance of the objective to specific wavelengths need to be carefully chosen based on the application. A high-NA objective for maximal signal collection and spatial resolution is generally preferable for high-resolution time-lapse imaging applications. Magnifications higher than 40× are not recommended because they yield less bright images and increase the risk for photobleaching. However, 60× or 100× lenses might be required for imaging very small structures (e.g., peroxisomes). Water-immersion objectives used for high-resolution time-lapse imaging can also be used for photobleaching experiments. The choice of the NA of the objective (which affects the depth of bleaching) will depend on the thickness of the structure to be photobleached. For photoactivation experiments, use high-NA objectives with high transmittance to violet wavelengths (405 nm, 413 nm). For two-photon excitation, use long-working-distance, high-NA water-immersion objectives with high transmission to near infrared (NIR) and visible (VIS) wavelengths.

Choice of microscope setup

Today, the investigator is confronted with the difficult task of choosing among a wide variety of user-friendly, commercially available laser scanning microscopes. The choice of the CLSM setup depends on the application requirements. High spatial resolution can be easily obtained with all modern commercial CLSM systems. Time resolution is often much more critical in photobleaching and photoactivation experiments than spatial resolution. If there is a need for fast image acquisition or simultaneous bleaching and image acquisition (required in the case of very rapid recovery kinetics), specialized systems are necessary. Examples of such commercial systems are the Zeiss 5 DUO system (which combines the ultrafast scanning and detection of a Zeiss LSM 5 LIVE with the photobleaching capability of a Zeiss LSM 510 META), the Olympus FluoView FV1000 system with a SIM scanner (a synchronized laser scanning system that allows to simultaneously image and bleach), and the PerkinElmer spinning disk UltraVIEW ERS with a PhotoKinesis unit (that enables bleaching selective targets as they are moving, after image acquisition has started).

Phototoxicity and photodamage

It is imperative to control for cytotoxicity when performing photoactivation experiments using short wavelengths (405-nm or 413-nm lasers) or two-photon excitation microscopy using high powers of near infrared (NIR) photons. Use transmission images of the observed tissue and look for morphological changes due to toxicity and photodamage during the experiment. Any observations related to the question asked (e.g., cell cycle duration, cell cycle progression) should be carefully examined for photoactivation or two-photon excitation artifacts.

Anticipated Results

The protocols described in this unit provide guidance to the investigator about various parameters that need to be considered while designing a live imaging experiment in the *Drosophila* embryo. The correct choice of objectives, choice of fluorophores, and choice of CLSM versus 2PLSM is imperative for a successful experiment. By following the suggestions given in every protocol, the investigator should be able to select embryos expressing the fluorescently tagged protein of interest and to perform time-lapse imaging in a desired tissue. The photobleaching protocols should enable the investigator to follow dynamics of protein molecules, organelles, or subsets of cells in the living *Drosophila* embryo. With the data obtained, the investigator can calculate the diffusion coefficient of a molecule and the mobile and immobile fractions of the molecules. Using the photoactivation protocol, the investigator should be able to perform optical pulse-chase experiments to study the spatiotemporal dynamics of proteins, organelles, and cells in the developmental context of choice.

Time Considerations

The generation of transgenic flies involves procurement of the cDNA of interest and cloning into the appropriate vector for injections. The injection of DNA into embryos, selection of the transformed flies, chromosome mapping, and checking for expression may take as long as 3 months. Genetic crosses performed to obtain flies that will express the fluorescent transgene will take ~15 days for one transgene and 30 days for two transgenes, at 25°C. Finally, the *Drosophila* embryos have to be aged to the desired stage of development prior to imaging. For example, imaging the early syncytial divisions (nuclear cycle 11 to 13) involves 1 hr for the prelay and an additional hour to age the embryo. The preparation and mounting of embryos in the LabTek/MatTek chamber take ~10 min.

The optimization of photobleaching and photoactivation may take a few hours, depending upon the prior experience of the investigator with CLSM. The actual time of the experiments depends on the application and the dynamics of the process under study. For example, the photobleaching experiment involving an endoplasmic reticulum lumenal protein (Figure 4.18.8A) has taken less than 1 min. This experiment was performed in early stages of the embryo before nuclear migration to the periphery. To perform multiple experiments of this type, the investigator will need to organize additional egg collections to obtain the same stage of development for further photobleaching experiments.

Quantitative Colocalization Analysis of Confocal Fluorescence Microscopy Images

Vadim Zinchuk[1] and Olga Zinchuk[2]

[1]Department of Anatomy and Cell Biology, Kochi University, Faculty of Medicine, Japan
[2]Institute of Anatomy, University of Berne, CH-3000, Berne, Switzerland

ABSTRACT

Colocalization is an important finding in many cell biological studies. This unit describes a protocol for quantitative evaluation of images with colocalization based on the calculation of a number of specialized coefficients. First, images of double-stained sections are subjected to background correction. Then, various coefficients are calculated. Meanings of the coefficients and a guide to interpretation of their results indicating either presence or absence of colocalization are given. Success in colocalization studies depends on the quality of analyzed images, proper preparation of them for coefficients calculations, and correct interpretation of obtained results. This protocol helps to ensure reliability of colocalization coefficients calculations. *Curr. Protoc. Cell Biol.* 39:4.19.1-4.19.16. © 2008 by John Wiley & Sons, Inc.

Keywords: quantitative colocalization • confocal fluorescence microscopy • image analysis

INTRODUCTION

Quantitative colocalization analysis (QCA) is a method to estimate the degree of colocalization of antigens in multicolor confocal immunofluorescence microscopy images. Colocalization is observed when staining of two or more antigens in the same section, labeled by corresponding antibodies with different excitation spectra and therefore visualized in different colors, overlaps. Although colocalization is a mere coexistence of molecules in a very close physical location, it can provide valuable clues clarifying their common characteristics. Scientific applicability of colocalization observed per se is, however, limited because it is perceived differently by the eye and thus can frequently be misleading. Thus, the method described here evaluates colocalization objectively by estimating its quantitative characteristics.

The method is applicable to dual-color confocal images of sections stained with antibodies with well-separated excitation spectra, acquired using proper set up of confocal microscopes, and stored in the image file format that preserves image data necessary for quantification. It relies on the use of specialized software that calculates a number of colocalization coefficients to understand the observed colocalization in greater detail. Prior to calculating the coefficients, the software performs background correction of the images. This important step is required to avoid obtaining false-positive results and is not available with other tools.

The protocol described in this unit demonstrates the use of QCA for studying functionally synergetic proteins. As an example, the use of the method is illustrated by quantifying colocalization of bile salt export pump (Bsep) and multidrug resistance protein 2 (Mrp2) in the liver. The background correction procedure is performed using different methods and is accompanied by the respective scatter grams. The meanings of coefficients and

DOI: 10.1002/0471143030.cb0419s39

their importance is explained. Finally, the interpretation of the results of coefficients calculations in terms of their biological significance is given.

STRATEGIC PLANNING

General

Successful QCA requires good knowledge and experience in basic immunohistochemical techniques (*UNIT 4.3*), confocal fluorescence microscopy (*UNIT 4.5*), and handling and processing of digital images. This unit provides practical information about quantitative colocalization and coefficients used to estimate it, gives tips for success in background correction procedure, and describes applicability of calculations results. Please refer to *UNITS 4.2* and *4.3* for basic information on basic fluorescence microscopy and immunofluorescence staining, respectively.

Steps of QCA

1. Ensure that image is properly prepared, acquired, and processed.

2. Open image in colocalization analysis software and perform background correction.

3. Calculate colocalization coefficients.

4. Save obtained results for further reference.

See also Table 4.19.1 for comments and tips.

Importance of Using Properly Prepared Images

Although QCA is the most important step in colocalization studies, it is just the final step. Its results are fully dependent on all previous steps of sample preparation, microscope set up, and image acquisition and handling. To emphasize the importance of image suitability to ensure reliable results of coefficients calculations, it is presented as a first step of QCA. The most important rules which should be followed to obtain confocal images useable for quantification are as follows:

Table 4.19.1 Steps of QCA

Step	Comments and tips
1. Ensure suitability of images	Make sure to use proper microscope set up and keep images unedited to prevent the loss of original information
2. Open image and correct background	Correct background in either Auto or Manual mode. Try several background correction settings to find out the best set up for your images. Once determined, keep them the same for all images in a study to ensure compatibility of calculations results.
3. Calculate coefficients	As a rule, calculate at least Pearson's correlation coefficient (R_r) and overlap coefficient according to Manders (R). Determine other coefficients as well if these two do not provide conclusive information and/or if you are interested in individual contribution of the antigens to the observed colocalization. Make sure that results of coefficients calculations fall within their values and pay attention to their dynamical changes. Use the opportunity provided by the software to view actually colocalized pixels in their image location.
4. Save obtained results for further reference	Save as much information about the analyzed image as is allowed by the software. You may find valuable information when examining image data in relation with coefficients calculations later on.

Sample preparation

1. Ensure that the antibodies you are using are specific and do not cross react.
2. Make the proper choice of fluorophores by selecting ones with well-separated excitation and emission spectra.
3. Use the same mounting medium for all of the samples that you will be performing calculations on.
4. As antifading reagents tend to increase background fluorescence, try to avoid using them.
5. Always use unstained control samples to check for autofluorescence.

Microscope set up

1. Reduce chromatic shift by using plan apochromatic lenses.
2. Maximize emission collection while avoiding bleed-through effect by using optimized emission filters.

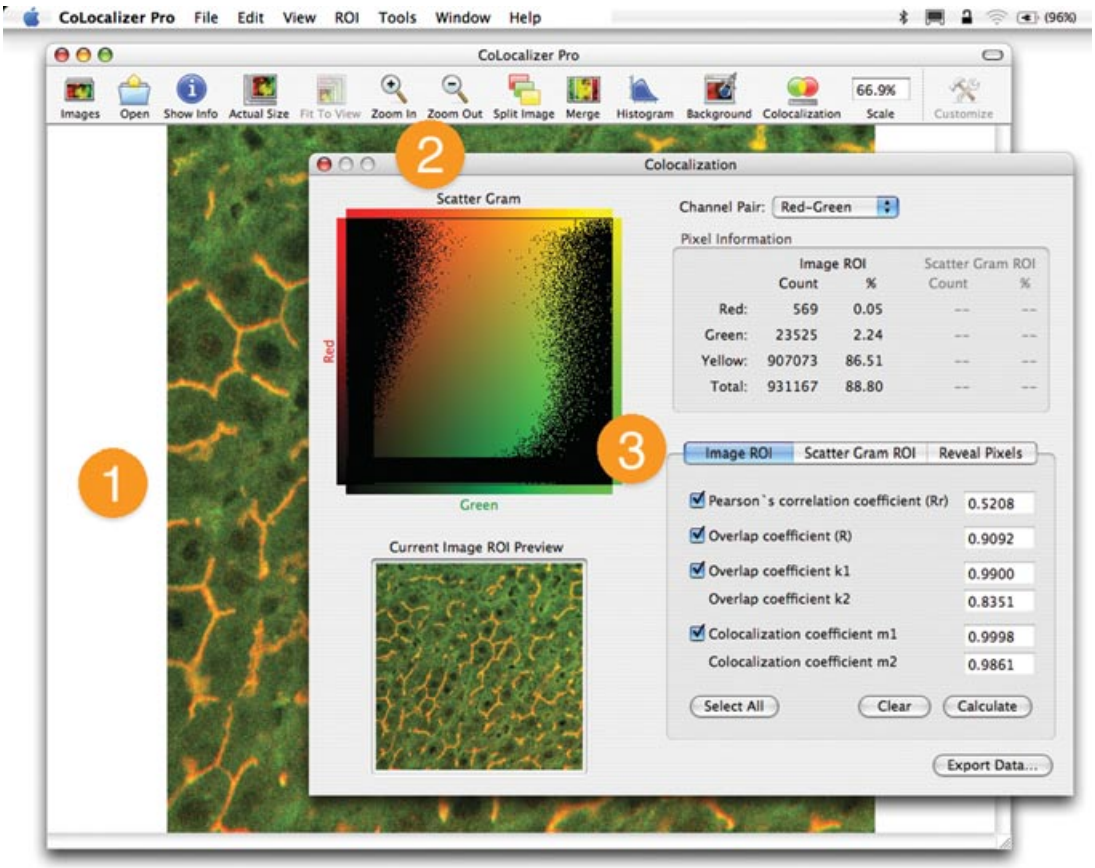

Figure 4.19.1 Main and Colocalization windows of CoLocalizer Pro software used for quantitative colocalization analysis. The image to be examined opens in the main window (1) and can be magnified to view areas with colocalization in greater detail (2). The ROI selection tool can be used for background correction in Manual mode and for selecting image area for coefficients calculations. After background correction procedure, image opens in a Colocalization window (3), where all the necessary calculations according to the selected pair of channels can be performed. For color version of this figure see *http://www.currentprotocols.com*.

3. Make sure you are using the same objective lens for obtaining all images you are planning to compare.

4. Ensure proper set up of the size of microscope pinhole.

Image acquisition and handling

1. Remember to acquire images sequentially to minimize bleed-through effect.

2. Avoid acquiring images that are too bright and images with too much contrast, as it may result in image saturation.

3. Never resave image files in any other graphic format than TIFF, as it may result in the loss of original data necessary for quantification.

4. Remember that any adjustments of brightness, contrast, etc. of your images using graphics-editing software may prevent further use of them for quantification purposes.

5. After making sure your images are suitable for colocalization studies, open them in QCA software (Fig. 4.19.1) and perform quantitative analysis according to the protocol below.

As an example of colocalized proteins, colocalization of bile salt export pump (Bsep) and multidrug resistance protein 2 (Mrp2) in the liver is shown (Fig. 4.19.2A). These proteins work in concert to regulate transport of bile salt and organic anions, respectively (Gerloff et al., 1998; Konig et al., 1999), but they are regulated differently and change their location and colocalization in response to various stimuli (Zinchuk et al., 2002, 2005b; Dombrowski et al., 2006). Bsep is stained in red, while Mrp2 is stained in green. The areas of location of both proteins are seen in yellow color. A respective scatter gram (Fig. 4.19.2B) reveals distribution of pixels according to the selected pair of channels.

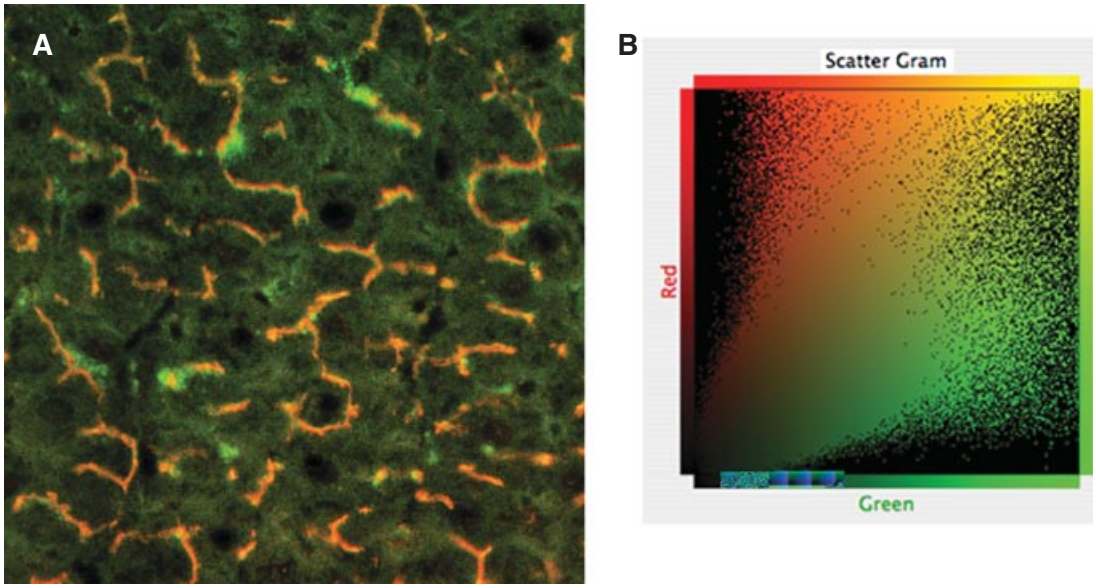

Figure 4.19.2 Confocal immunofluorescence micrograph of colocalized Bsep (red fluorescence) and Mrp2 (green fluorescence) proteins in the rat liver (**A**) alongside with its corresponding scatter gram (**B**). Note a significant number of pixels along the diagonal of Scatter Gram, a typical pixel representation of the image with colocalization. The scale bar indicates 10 μm. For color version of this figure see *http://www.currentprotocols.com*.

In the scatter gram, colocalized pixels are located along the diagonal, while those with no colocalization occupy left and bottom portions. As can be seen in the figure, the scatter gram represents unique information about an image file and is useful for viewing colocalized pixels in the image.

QUANTIATIVE COLOCALIZATION ANALYSIS

BASIC PROTOCOL

The present protocol is used to quantify colocalization in dual-color confocal microscopy images of sections stained with fluorescence-labeled antibodies with well-separated excitation spectra, obtained using correct microscope set up, and saved in the image file format that ensures preservation of image data required for quantification. It relies on the use of specialized software that enables determination of colocalization coefficients within a single session of image analysis, making calculation results not only highly relevant and comparable, but also easily reproducible. The validation of the results of quantitative colocalization experiments and their applicability are presented.

Materials

Cryostat-cut 6- to 8-μm thick sections of rat liver
Acetone for tissue fixation
Blocking solution: 10% (v/v) goat serum in 0.1 M Tris-buffered saline (TBS) containing 0.1% Triton X-100
Primary antibodies against Bsep and Mrp2 proteins [Santa Cruz Biotechnology; anti-Bsep antibody was donated by Dr. Bruno Stieger (Department of Medicine, University of Zurich, Switzerland)] or other proteins of interest (primary antibodies should be raised in different species)
Non-immune IgG to control the specificity of immunostaining
0.1 M Tris-buffered saline (TBS; *APPENDIX 2A*)
Corresponding secondary antibodies with different excitation spectra, e.g., Alexa 488 and Alexa 594 from Molecular Probes (antibodies should not be cross-reacting)
Glycerol

Poly-L-lysine-coated glass slides
Cover glass for mounting sections
Confocal microscope for image acquisition (any brand)
Argon-krypton laser (Siemens)
Software: either CoLocalizer Pro or CoLocalizer Express (CoLocalization Research Software; *http://homepage.mac.com/colocalizerpro/*) for QCA

Additional reagents and equipment for immunofluorescence staining (*UNIT 4.3*) and fluorescence microscopy (*UNIT 4.2*)

Perform immunostaining

1. Pick up a 6- to 8-μm thick section of liver on poly-L-lysine-coated glass slides, air dry for 1 hr, and fix in acetone for 30 min at −20°C.
2. Apply 500 μl blocking solution for 1 hr at room temperature to block nonspecific binding.
3. Incubate with 500 μl anti-Bsep antibody diluted 1:100 for 1 hr at room temperature.

   In parallel, perform the same procedure using non-immune IgG instead of primary antibodies to control specificity of immunostaining.
4. Rinse three times with 10 ml of 0.1 M TBS.
5. Incubate with 500 μl anti-Mrp2 antibody diluted 1:100 for another 1 hour at room temperature.

6. Rinse three times with 10 ml 0.1 M TBS.
7. Incubate with a mixture of corresponding secondary antibodies conjugated with Alexa 488 and Alexa 594, respectively, for 1 hr at room temperature. Dilute both antibodies 1:400.
8. Wash three times with 10 ml 0.1 M TBS.
9. Mount sections with glycerol and apply a coverglass.

Perform microscopy

10. Use immersion lens (e.g., Plan-Neofluar 40 /0.75 mm) of confocal microscope to examine sections.
11. Check samples for autofluorescence. If autofluorescence is detected, discard samples. If not, continue examining them.
12. Use an argon-krypton laser at the wavelength of 488 and 543 nm to visualize double fluorescence for green and red channels, respectively.
13. Keep the pinhole of the microscope at the same position when examining samples.
14. After finding satisfactory staining (not too bright and not too contrasty), perform sequential scanning for each channel to minimize the crosstalk of fluorophores.
15. Save images according to each channel (in this case you will need to merge them into one image for quantification purposes later on) or overlayed in TIFF format with maximum possible image resolution.

Transfer images from microscope and perform quantitative colocalization analysis

16. Transfer obtained images to a computer for analysis.

    We use a Mac Pro computer operated under Mac OS X 10.4.10, but even a less powerful computer is fully satisfactory. The minimum system requirement for the software is Mac OS X 10.2.8.

17. Import image to CoLocalizer Pro software for analysis and perform background correction on the imported image. Choose suitable background correction settings for your images by trying Auto mode first.

Correct background

Note the following: (1) The software will issue a warning if user attempts to perform coefficients calculations with no background corrected. (2) Low Contrast and Weak Fluorescence presets (Auto mode) may be too rough in some cases as the number of removed pixels can be excessive. (3) Successful background correction of the image with colocalization will show pixels concentrating along the diagonal of the scatter gram, while the majority of pixels at the right and bottom portions of it will be removed. The areas at right and bottom should however not be too wide. (4) For beginners, we recommend resetting the image to its original state every time when trying another background correction mode. With some experience, this may become unnecessary. (5) Once determined, background correction settings should be used consistently for all images you intend to compare. (6) Background correction will have an impact on coefficients calculations. Unsatisfactory corrected background can result in erroneous coefficients readings.

For automatic correction of background

18a. Correct background in Auto mode. After opening image (Fig. 4.19.3A) in the main window of the software, choose Background Correction under the Tools in the application menu bar or click Background icon.

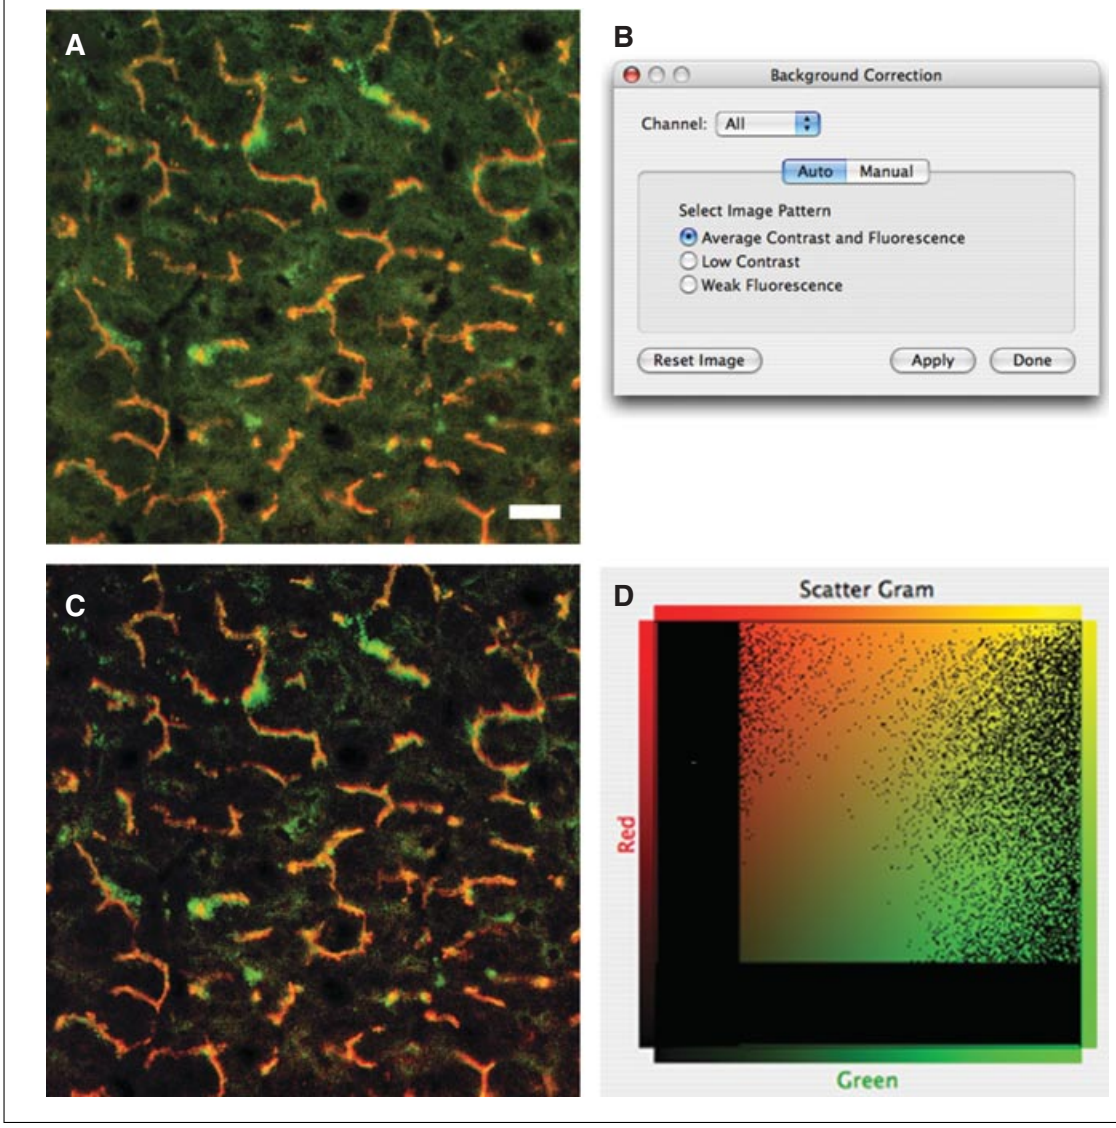

Figure 4.19.3 Background correction in Auto mode is straightforward and done by selecting one of the presets reflecting the most common image patterns. Image of colocalization of Bsep and Mrp2 proteins before (**A**) and after (**C**) correction. Background correction window (**B**) and the respective scatter gram following background correction using the Average Contrast and Fluorescence preset (**D**) are shown. Black areas at the right and the bottom of scatter gram indicate removed pixels (D). The areas are relatively narrow, which means that the number of removed pixels is acceptable. The scale bar indicates 10 μm. For color version of this figure see *http://www.currentprotocols.com*.

19a. Select Auto in the Background Correction window (Fig. 4.19.3B) and click Apply. Then, dismiss the Background Correction window by clicking Done.

Following background correction the image appears slightly changed due to the absence of the portion of pixels (Fig. 4.19.3C). The corresponding scatter gram reveals the extent of background correction (Fig. 4.19.3D).

20a. If the scatter gram shows a relatively small number of removed pixels (Fig. 4.19.3D), process the image for coefficients calculations.

If the background is more than shown, reset image and try correcting background in manual mode using Selected ROI.

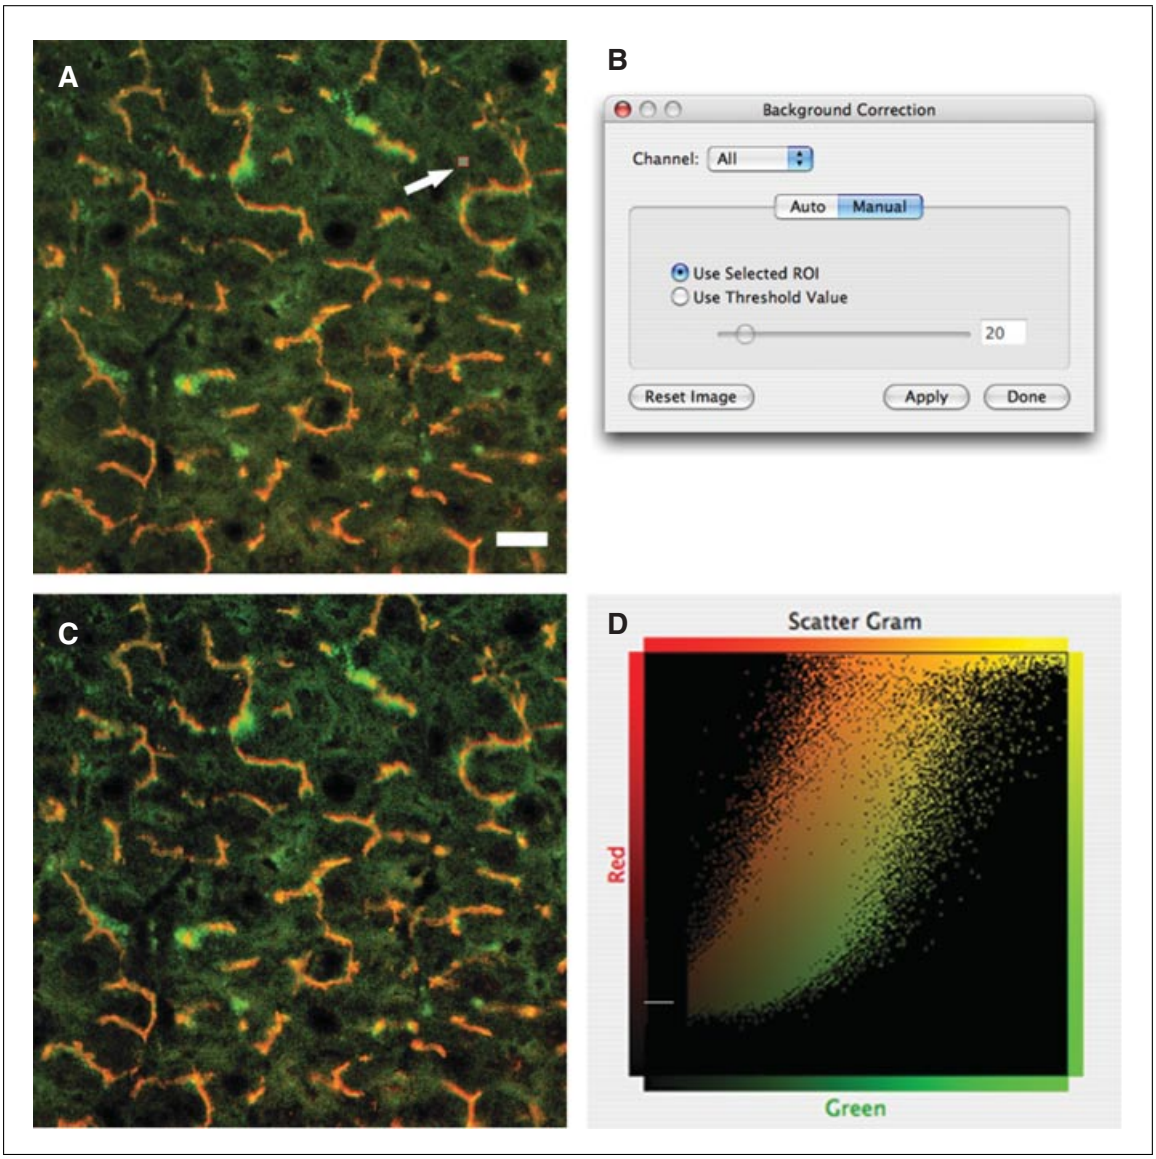

Figure 4.19.4 Background correction in Manual mode using selected ROI on the same test image before (**A**) and after (**C**) correction. Area at image background used for selecting pixel values for background correction is indicated by an arrow (A). Background correction window (**B**) and the respective scatter gram after background was corrected (**D**) are presented. Remaining pixels (yellow) tend to concentrate along the diagonal of the Scatter Gram, while the majority of pixels with Red (right portion) and Green (bottom portion) values are removed (D). The scale bar indicates 10 μm. For color version of this figure see *http://www.currentprotocols.com*.

For manual correction of background

18b. Correct background in manual mode (this is the mode we recommend to use) using Selected ROI. After opening image (Fig. 4.19.4A) in the main window of the software, choose Background Correction under the Tools in the application menu bar or click Background icon. Select Manual in the Background Correction window (Fig. 4.19.4B).

19b. Using rectangular or oval ROI selection tool, select a small area, e.g., 10 × 10 pixel size, in the image background.

If you are examining cells in culture, it is best to select any area outside of the cells. If you are examining tissue sections, select an area in the tissue background which is dark, but not completely black, i.e., that absorbed some fluorescence. Such areas can be considered as the areas containing only pixels of the background level.

20b. Then, click Apply and dismiss Background Correction window by clicking Done.

Following background correction the image will appear changed depending on the number of removed pixels (Fig. 4.19.4C). The corresponding scatter gram reveals the extent of background correction (Fig. 4.19.4D). Figure 4.19.4D shows what the scatter gram of a properly corrected image should look like: remaining pixels concentrate mainly along the diagonal of the scatter gram and the areas of removed red (at right) and green (at left) pixels are not too wide.

You may also try correcting background in Manual mode using Threshold Value. We find it useful for images that are more bright and contrasty than the average. It works similarly to Auto mode, with the exception that you are free to choose the exact number of pixels to be removed. It can provide good correction results, but, in comparison to the selected ROI option, does not give the important advantage of being able to tailor correction to the unique pixel profile of analyzed images.

21. After background correction step, perform coefficients calculations.

Calculate coefficients and view colocalized pixels

22. Using the whole image as a ROI, open Colocalization window, and proceed as described below.

23. Depending on the shape appearance of areas with colocalization, use a suitable ROI tool in the menu bar to select image areas containing predominantly colocalization.

In the test image used in this protocol, we used the Lasso tool.

24. Repeat calculations for at least three different areas with colocalization.

Thus, you will have at least four sets of data: one for the whole image and the other three for each of the selected ROIs. The resulting coefficients values will be the average of these four.

25. Select a pair of channels according to which coefficients will be calculated, for example red-green.

After selection is made, respective pixel information will be shown in the Pixel Information section of the Colocalization window (Fig. 4.19.5).

The total number of pixels shown in the Pixel Information section of the Colocalization window may not necessarily be 100% and this is correct, because pixels for colocalization analysis are counted according to channel pairs, taking into consideration color components. If, for example, a red-green pair of channels is selected, pixels with some levels of blue component may not be included to the count.

26. In the colocalization window, select coefficients you would like to calculate.

Pearson's coefficient is a default coefficient.

27. Calculate all coefficients paying particular attention to the results of Pearson's and Manders' coefficients.

28. After calculating coefficients for image ROI, perform calculations of coefficients for scatter gram ROI (M_1 and M_2 coefficients) by clicking Scatter Gram ROI tab in the Coefficients section of the Colocalization window.

29. Then, click Reveal Pixels tab in the same window section and view colocalized pixels in the image by clicking Colocalized button.

Under this tab, you may also select pixels of interest in the scatter gram and then view them in their image location by clicking Selected button. Highlight pixels by using any color you like using color picker.

30. Export calculations results as Text and Microsoft Excel files for further statistical analysis.

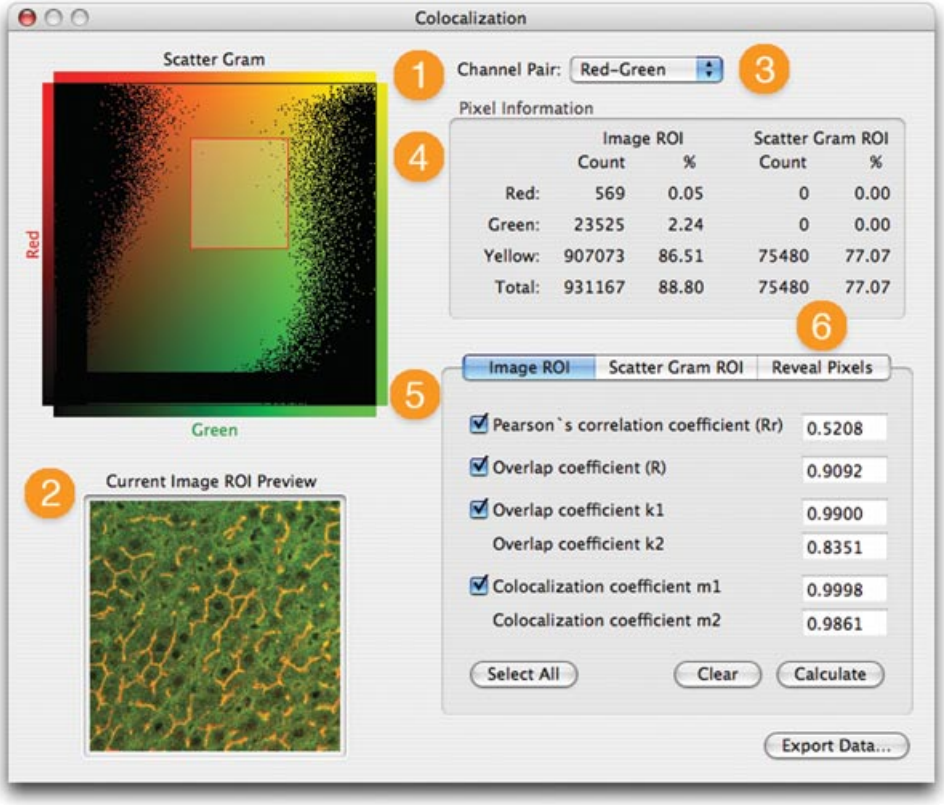

Figure 4.19.5 Colocalization window of the software shows scatter gram (1) of the selected ROI, the ROI itself (2), a pair of channels according to which the coefficients can be calculated (3), pixel information of the analyzed ROI (4), and the options to perform calculations of the coefficients (5). The important option to view exclusively colocalized pixels in the image is also given (6). All calculations results can be exported as Text and Microsoft Excel files. All data used for calculations can be saved in PDF and HTML formats and presented as session reports. For color version of this figure see *http://www.currentprotocols.com*.

Table 4.19.2 Comparison of Coefficients Obtained without Background Correction and with Background Corrected in Auto and Manual Modes[a]

Coefficients	Background not corrected	Background corrected in Auto mode	Background corrected using Selected ROI
Pearson's correlation coefficient (R_r)	0.91±0.1	0.86±0.1	0.74±0.08
Overlap coefficient according to Manders (R)	0.76±0.06	0.71±0.1	0.69±0.1
Overlap coefficients k_1 and k_2	0.99±0.1 and 0.83±0.1	0.97±0.08 and 0.73±0.07	0.91±0.07 and 0.70±0.1
Colocalization coefficients m_1 and m_2	1.0±0.1 and 1.0±0.1	0.99±0.1 and 0.98±0.09	0.99±0.09 and 0.94±0.08

[a]Calculation of coefficients with background intact results in obtaining ~20% of false-positive results. Results obtained after background corrected using Selected ROI appear to be the most applicable. An average of coefficients of five examined areas is shown. $p < 0.05$.

31. Make a report of the calculations session in either PDF or HTML format.

In addition to the analyzed image and calculations results, include in the report the image with scatter gram inserted in it. This is a very handy way to present the analyzed image together with its unique colocalization profile for publishing.

Results of coefficients calculations on the test image without and with background correction are presented in Table 4.19.2.

COMMENTARY

Background Information

The word "colocalization" is one of the most frequently used words in modern cell and molecular biological studies. It is used to describe the existence of two or more different molecules in a very close spatial position in the cell (Smallcombe, 2001). The molecules are visualized when examining images according to two or more fluorescence channels generated by corresponding fluorophores and observing the same specimen region. At the same time, the phenomenon behind it is perhaps one of the most misrepresented and misunderstood. The most common misconception is that colocalization of antigens equals sharing of their functional characteristics (North, 2006).

The theoretical basis of quantitative colocalization has been available for some time, but its adoption in practical studies has been slow. As a result, even in the current publications proteins continue to be described as "more" or "less" colocalized with no quantitative justification of any kind. Importantly, the lack of quantitative assessment does not allow researchers to extend their observations of colocalization to analyzing important changes of proteins in dynamics, as well as in association with other proteins (Lippincott-Schwartz et al., 2001).

In this protocol, we gathered in one unit all the necessary information required for performing reliable quantitative colocalization studies.

Background correction

Although confocal fluorescence microscopy allows demonstration of the precise location of fluorophores, confocal images are not usable for quantification right away because they have low signal-to-noise ratio. This means that they have high levels of background noise, which not only negatively affects image resolution by hiding structural details, but can also introduce false-positive results. It was estimated that these levels of noise can reach as high as 30% of maximum intensity of fluorescence (Landmann and Marbet, 2004). Thus, it can be approximately said that if QCA is performed on "raw" (with background intact) confocal images, the results will be 30% wrong. Therefore, prior to performing calculations of coefficients, background noise in confocal images must be removed, i.e., the background needs to be corrected. The background correction procedure, as well as all other steps, including coefficients calculations described in this protocol, are performed with the help of CoLocalizer Pro 2.0 software. The software is now widely used in various colocalization studies (Zinchuk et al., 2004, 2005a,b; Criscuoli et al., 2005; Kato et al., 2005; Cario et al., 2006; Head et al., 2006; Patel et al., 2006; Rey et al., 2006; Swaney et al., 2006; Tsutsumi et al., 2006; Berg et al., 2007; Clizbe et al., 2007; Desplanques et al., 2007; Mutch et al., 2007; Rocker et al., 2007; Van Acker et al., 2007; Watanabe et al., 2007). Although other software options to estimate colocalization exist as well, an important advantage of CoLocalizer Pro is that it is a stand-alone application not bundled with the microscopes and not tied to any proprietary image file format. The software has background correction functionality built-in, so that moving from the background correction step to calculation of colocalization coefficients is done in just a single button click. It should be mentioned that several image restoration techniques were recently introduced to improve the signal-to-noise ratio in confocal images by applying complex image restoration algorithms, but using them results in a significant image transformation. The approach based on the mentioned software, on the contrary, is quick, simple, and uses original image data. Importantly, background correction settings can be reused, thus ensuring that all images in a study are prepared in the same way, and thus the results of coefficients calculations are easily compatible and comparable. There are several options to perform the background correction procedure.

Background correction in Auto mode (option 1)

A simple and efficient way to correct background is by using presets options according to the most common image patterns. Software then uses special formulas to remove a predefined number of pixels according to these patterns, such as: (1) Average Contrast and Fluorescence, (2) Low Contrast, and (3) Weak Fluorescence.

According to their names, Average Contrast and Fluorescence, the default preset, should be used for images with average contrast and fluorescence intensity and should be suitable in the most cases. Low-contrast images should be corrected using the Low Contrast preset. If the image has weak fluorescence, the Weak Fluorescence preset should be chosen.

Background correction in Manual mode (option 2)

However, Auto mode may be too straightforward in some cases and remove too many pixels. Manual mode is much more sensitive and customizable. More importantly, it allows performance of background correction using the unique pixel profile of analyzed images. In this mode, background can be corrected using either: (1) Selected ROI or (2) Threshold Value.

Using these options, background can be corrected either for one or for all channels. Correcting for all channels is advantageous, because it is often difficult to predict what particular channel needs to be corrected. Selecting All channels guarantees that no "background noise" pixels will be left in the image. Viewing the corresponding scatter gram in the software colocalization window helps to determine the extent of pixel removal. If too many pixels are removed, the image can be reset and background correction repeated again by selecting a different area. Although this procedure requires some experience, you will become an expert in the background correction fairly quickly. When using Threshold Value, it is possible to select the exact extent of pixel removal.

Colocalization coefficients

Colocalization is determined by calculating a number of specialized values representing the proportion of colocalized pixels. These values are estimated according to colocalization coefficients (Fig. 4.19.5). The following coefficients are used.

Pearson's correlation coefficient (R_r)

$$R_r = \frac{\sum_i (S1_i - S1_{aver}) \cdot (S2_i - S2_{aver})}{\sqrt{\sum_i (S1_i - S1_{aver})^2 \cdot \sum_i (S2_i - S2_{aver})^2}}$$

where $S1$ represents signal intensity of pixels in channel 1 and $S2$ represents signal intensity of pixels in channel 2; $S1_{aver}$ and $S2_{aver}$ shows the average intensities of these respective channels. This coefficient, being one of standard measures in pattern recognition, was first employed to estimate colocalization and is used for describing the correlation of the intensity distributions between channels. It takes into consideration only similarity between shapes, while ignoring the intensities of signals. Its values range between -1.0 and 1.0, where 0 indicates no significant correlation and -1.0 indicates complete negative correlation.

Overlap coefficient according to Manders (R)

$$R = \frac{\sum_i S1_i \cdot S2_1}{\sqrt{\sum_i (S1_i)^2 \cdot \sum_i (S2_1)^2}}$$

where $S1$ represents signal intensity of pixels in channel 1 and $S2$ represents signal intensity of pixels in channel 2. This coefficient was developed specifically for estimating colocalization (Manders et al., 1993). Its advantage is that it is insensitive to the limitations of typical fluorescence imaging, such as efficiency of hybridization, sample photobleaching, and camera quantum efficiency. The values of this coefficient are in the range from 0 to 1.0. If the image has an overlap coefficient 0.5, it implies that 50% of both its objects, i.e., pixels, overlap. A value of zero means that there are no overlapping pixels.

Overlap coefficients k_1 and k_2

$$k_1 = \frac{\sum_i S1_i \cdot S2_i}{\sum_i (S1_i)^2}$$

and

$$k_2 = \frac{\sum_i S1_i \cdot S2_i}{\sum_i (S2_i)^2}$$

where $S1$ represents signal intensity of pixels in channel 1 and $S2$ represents signal intensity of pixels in channel 2. These coefficients

split the value of colocalization into a pair of separate parameters. They depend on the sum of the products of the intensities of two channels and are sensitive to the differences in the intensities of signals.

Colocalization coefficients m_1 and m_2

$$m_1 = \frac{\sum_i S1_{i,coloc}}{\sum_i S1_i}$$

Table 4.19.3 Coefficients Used to Estimate Colocalization with Their Meanings, Values, and Use

Coefficient	Meaning	Values	Usability
Pearson's correlation coefficient (R_r)	Describes the correlation of the intensity distribution between channels	From −1.0 to 1.0; 0 indicates no significant correlation and −1.0 indicates complete negative correlation	Useable in any colocalization experiment
Overlap coefficient according to Manders (R)	Indicates an actual overlap of the signals, is considered to represent the true degree of colocalization	From 0 to 1.0; 0.4 implies that 40% of both selected channels colocalize	Can be used in any colocalization experiment, especially applicable when the intensities of fluorescence of detected antigens differ
Overlap coefficients k_1 and k_2	Split the value of colocalization into the two separate parameters, allows determination of the contribution of each antigen to the areas with colocalization	Vary	Useable in any colocalization experiment
Colocalization coefficients m_1 and m_2	Describe the contribution of each one from two selected channels to the pixels of interest	From 0 to 1.0; m_1 and m_2 of 1.0 and 0.3 for red-green pair imply that all red pixels colocalize with green, but only 30% of green pixels colocalize with red	Useable in any colocalization experiment
Colocalization coefficients M_1 and M_2	Identical to m_1 and m_2, but applied to analyzing scatter gram ROI	From 0 to 1.0; M_1 and M_2 of 1.0 and 0.3 for red-green pair imply that all red pixels colocalize with green, but only 30% of green pixels	Useable in any colocalization experiment

Table 4.19.4 Troubleshooting Guide to QCA

Problem	Possible cause	Solution
Scatter gram shows too many pixels removed following background correction	Wrong choice of background correction method	If background was corrected in Auto mode, try using Manual mode. In Manual mode, use the Selected ROI preset and try selecting different image areas.
Scatter gram shows too few pixels removed following background correction	Background was not corrected enough	If background was corrected using Selected ROI, select different ROI. If Threshold Value was employed, use slider to increase the number of pixels to be removed.
Results of coefficients calculations do not fall within their standard values	Mistake(s) in image acquisition and handling	Obtain another image

Table 4.19.5 Summary of the Values of Coefficients Calculations Indicating Ranges When Antigens Can Be Interpreted as Colocalized and When Not[a]

Coefficient	Values indicating colocalization	Values indicating absence of colocalization
Pearson's correlation coefficient (R_r)	From 0.5 to 1.0	From −1.0 to 0.5
Overlap coefficient according to Manders (R)	From 0.6 to 1.0	From 0 to 0.6
Overlap coefficients k_1 and k_2	Any close values, like 0.5 and 0.6 or 0.8 and 0.9	Any distant values, like 0.5 and 0.9 or 0.2 and 0.7
Colocalization coefficients m_1 and m_2	More than 0.5	Less than 0.5
Colocalization coefficients M_1 and M_2	More than 0.5	Less than 0.5

[a]The table is based on a large pool of statistically significant coefficients results obtained when analyzing colocalization of various antigens in brain, heart, liver, kidney, muscle, and blood labeled by FITC, Texas Red, and various Alexa dyes.

and

$$m_2 = \frac{\sum_i S2_{i,coloc}}{\sum_i S2_i}$$

where $S1_{i,coloc} = S1_i$ if $S2_i > 0$ and $S2_{i,coloc} = S2_i$ if $S1_i > 0$. For example, if the red-green pair of channels is selected and m_1 and m_2 are 1.0 and 0.5, respectively, this means that all red pixels colocalize with green pixels, but only half of green pixels colocalize with red ones. The value of 1.0 for both channels indicates perfect colocalization.

Colocalization coefficients M_1 and M_2

$$m1 = \frac{\sum_i S1_{i,coloc}}{\sum_i S1_i}$$

and

$$m2 = \frac{\sum_i S2_{i,coloc}}{\sum_i S2_i}$$

These coefficients are identical to m_1 and m_2, but used for analyzing scatter gram ROI.

All coefficients are applied to examining selected ROI. ROI can represent the whole image or be just a small part.

For convenience, all described coefficients are also presented in Table 4.19.3.

Troubleshooting

See Table 4.19.4 for troubleshooting guide.

Anticipated Results

Table 4.19.5 gives interpretation of coefficients calculations results specifying when antigens can be considered as colocalized and when not.

Limitations

Reliable QCA is limited only by the suitability of images to be analyzed and their pixel resolution. Requirements for the suitability of images are described in the protocol in detail. Microscope-dependent suitability is constantly improving, as is the pixel resolution, together with the advancements of the quality of confocal microscopes.

Time Considerations

In comparison with performing immunohistochemical staining and confocal microscope observations, QCA requires very little time and is dependent solely on the results of immunofluorescence staining. The most time-consuming part can be the background correction step, but only until the proper setup is determined. Calculations of coefficients are usually done in a matter of minutes.

Visualizing Protease Activity in Living Cells: From Two Dimensions to Four Dimensions

Christopher Jedeszko,[1] Mansoureh Sameni,[1] Mary B. Olive,[1] Kamiar Moin,[1] and Bonnie F. Sloane[1]

[1]Department of Pharmacology and Karmanos Cancer Institute, Wayne State University School of Medicine, Detroit, Michigan

ABSTRACT

Proteolytic degradation of extracellular matrix (ECM) components by cells is an important metabolic activity as cells grow, remodel, and migrate through the ECM. The ability to analyze ECM degradation can be valuable in the study of developmental processes as well as pathologies, such as cancer. In this unit we describe an in vitro live cell–based method to image and quantitatively measure the degradation of ECM components by live cells. Cells are grown in the presence of fluorescent dye-quenched protein substrates (DQ-gelatin, DQ-collagen I, and DQ-collagen IV) that are mixed with protein matrices. Upon proteolytic cleavage, fluorescence is released that directly reflects the level of proteolysis by the cells. Using confocal microscopy and advanced imaging software, the fluorescence is detected and accurate measurements of proteolytic degradation in three and four dimensions can be assessed. *Curr. Protoc. Cell Biol.* 39:4.20.1-4.20.15. © 2008 by John Wiley & Sons, Inc.

Keywords: 3-D culture • recombinant basement membrane • DQ-substrates • proteases • live cell imaging • ECM

INTRODUCTION

In vivo, cellular microenvironments are constructed of complex combinations of extracellular matrix (ECM) proteins that are under constant turnover and modification. During most forms of cellular motility, cells remodel their immediate microenvironment via proteolytic degradation of ECM (Friedl and Wolf, 2003). Thus, the ability to examine the proteolytic degradation of ECM by living cells is crucial for understanding many aspects of cellular motility in normal processes and in pathologies, such as cancer. The assay described here allows one to quantitatively analyze extracellular and intracellular proteolysis associated with degradation of ECM surrounding the cells. This is a microscopy-based assay in which proteolysis of fluorogenic dye-quenched protein substrates (DQ-substrates) by live cells is imaged. The cells are grown as either two-dimensional (2-D) or three-dimensional (3-D) cultures on ECM or embedded in ECM, respectively. The DQ-substrates are mixed into the ECM and provide a protein substrate that can be cleaved by many proteases. This differs from the use of small molecule synthetic substrates that are cleaved selectively by a single protease or protease class.

Originally, the DQ-substrates were developed as nonselective, broad-spectrum substrates for in vitro applications, such as analysis of protease activity in solution (Menges et al., 1997). We have adapted their use for live-cell confocal imaging in order to investigate the contribution of multiple classes of proteases to ECM degradation by migrating or invading cells. Visualization and accurate quantitative analysis of ECM proteolysis relies on the fluorescent characteristics of the DQ-substrates. The native, undegraded DQ-substrates are heavily conjugated with the fluorogenic dye, fluorescein. The close

DOI: 10.1002/0471143030.cb0420s39

proximity of the dye molecules to each other renders native DQ-substrates fluorescently quenched due to a Fluorescence Resonance Energy Transfer (also known as Forster Resonance Energy Transfer or FRET) effect. Upon proteolytic hydrolysis of the DQ-substrate into smaller fragments, the fluorogenic dye molecules are separated, self-quenching is lost, and a strong fluorescence is emitted. The fluorescent signal is proportional to the proteolytic activity, and the pattern depends on the DQ-substrate itself. There is little background fluorescence in the absence of cells for either DQ-collagen I (Fig. 4.20.1A) or DQ-collagen IV (Fig. 4.20.1C). The cellular cleavage of DQ-collagen I (Fig. 4.20.1B) or DQ-collagen IV (Fig. 4.20.1D) differs, with the former appearing as fluorescent dots along the collagen I fibrils and the latter as diffuse fluorescence. Depending on the cell lines and ECM, cells will grow as either 2-D monolayers, e.g., on gelatin and collagen I, or as 3-D structures on complex matrices, such as reconstituted basement membrane (rBM; Fig. 4.20.2). The ECM can be mixed with any one of an assortment of DQ-substrates (e.g., DQ-albumin, DQ-gelatin, DQ-collagen I, or DQ-collagen IV) available through Invitrogen, thus creating customized combinations through which to analyze proteolysis in the context of a defined ECM. Recent studies from our laboratory and others employing this assay have shown that normal and tumor cells use several classes of proteases to actively degrade collagen IV and collagen I and, depending on the cell type, the degradation products are found intracellularly and/or extracellularly (Sameni et al., 2003; Cavallo-Medved et al., 2005; Podgorski et al., 2005; Tsai et al., 2005; Urbich et al., 2005; Sloane et al., 2006). We describe here the use of three combinations of matrices:

QUANTITATIVE MEASUREMENT OF PROTEOLYTIC DEGRADATION OF DQ-SUBSTRATES IN LIVE-CELL CULTURES USING A LASER SCANNING CONFOCAL MICROSCOPE

BASIC PROTOCOL 1

Cells are grown on ECM containing DQ-substrates as described in Support Protocol 1. Although either an inverted or an upright laser scanning confocal microscope can be used for imaging live cells, this assay is most readily performed using an upright microscope. An upright microscope is ideally suited due to the inherent thickness (1 to 3 mm) of the culture sample (DQ-substrate in ECM + cells). Regardless of the microscope, the sample thickness requires the use of objectives with long working distances. For live-cell imaging at high magnification on an upright microscope, we routinely use water-immersion dipping objectives (40× and 63× Achroplan) that can be immersed in the cell culture medium. Note that these are different than the normal high-power Apochromat water-immersion objectives. The latter have very-short working distances (10 to 15 µM) and cannot be used with thick specimens to obtain a sharp focus through the entire sample. For imaging with an inverted microscope, one will use either a lower magnification lens or a long-working-distance lens (see Commentary). In our laboratory, we routinely use a Zeiss upright microscope equipped with Zeiss LSM 510 META confocal optics and argon, HeNe, and two-photon lasers. Together with a microscope stage incubator, this setup allows a high level of flexibility in regard to sample dimensions, imaging timeframes, and fluorogenic dyes.

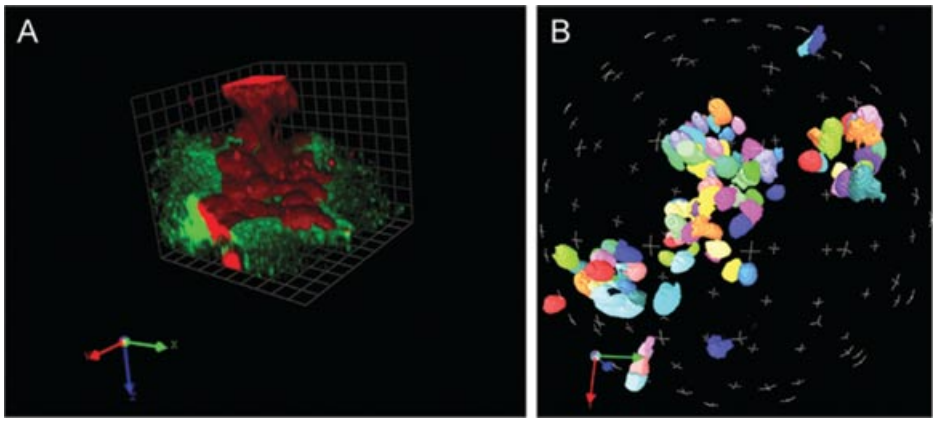

Figure 4.20.3 Frame captures of 3-D reconstructions of human breast cancer cells grown in rBM containing DQ-collagen IV. Image stacks containing the DQ-substrate channel (green), the nuclei channel (blue), and the CellTracker channel (red) were used to create graphical 3-D reconstructions/projections using the QVTR feature of the Volocity imaging software suite. The 3-D image can be rotated 360° in order to (**A**) view proteolysis of DQ-substrates (green) in relation to the cells (red) or (**B**) view only the nuclei for the purpose of counting cells. For color version of this figure see *http://www.currentprotocols.com*.

The key to quantitative imaging of proteolysis in three dimensions is the ability to acquire fluorescence without pixel saturation from single planes of focus encompassing the entire specimen. Confocal microscopy allows us to image sequentially above, through, and below the objects of interest. This optical *z*-sectioning and imaging of accumulated fluorescence gives a spatial 3-D output that represents proteolysis of DQ-substrates. Furthermore, the same field of view can be imaged repeatedly over a period of time to collect data in four dimensions (4-D), i.e., spatially and temporally. Regardless of whether data collection is over time or just a snapshot of one time point, accurate determination of proteolytic activity and localization of such activity requires the collection of data from all the cells and their surrounding 3-D volume (*x,y,z*-limits). As some cell types aggressively invade into the ECM, the optical sections may need to span several hundred micrometers in the *z*-direction. Therefore, prelabeling the cells (Support Protocol 1) and their nuclei (Basic Protocol 1) with fluorescent dyes will enable the user to not only define the entire relevant 3-D volume, but also to relate total DQ-substrate hydrolysis to cell number. In addition, prelabeling the cells with cell tracking dyes that occupy the entire cell enables differentiation of intracellular from extracellular proteolysis and their quantification (Basic Protocol 2). The additional data from nuclear and cytoplasmic staining allows normalization of proteolysis to cell number across samples. Visually, most advanced imaging applications are capable of transforming the collection of 2-D images from optical *z*-sections to graphical 3-D reconstructions of cells and areas of DQ-substrate degradation (Figure 4.20.3).

Materials

Cell-permeable DNA-binding dye [Hoechst 33342 (Invitrogen) or DRAQ5 (Biostatus Ltd)]

Cell culture medium

Prelabeled cell cultures established in ECM containing DQ-substrates (Support Protocol 1), grown on coverslips in 35-mm cell culture petri dishes

Upright laser scanning confocal microscope equipped with a water-immersion lens and appropriate filter sets and lasers

Microscope stage incubator with humidity, temperature, and CO_2 control

Prepare for imaging

1. Set up the microscope and stage incubator.

   In order to avoid power fluctuations during early imaging, turn on the microscope lasers for at least 5 min prior to imaging. When imaging over extended periods of time it is important to equilibrate the stage incubator to 37°C and 5% CO_2 and 40% to 50% noncondensing humidity.

2. To the 35-mm cell culture petri dishes containing prelabeled cell cultures, add DNA-binding fluorescent dye (Hoechst 33342) to a final concentration of 5 μg/ml in culture medium.

   The culture medium is unspecified as medium is user defined for the individual cell line(s) to be studied.

   When performing live-cell imaging over extended periods of time, the time to add the DNA dye is an important consideration. Some DNA binding agents like Hoechst 33342 and Draq5 are not toxic over short periods of time, yet may have adverse effects on the cells over longer times (hours). Therefore, it is recommended that these dyes be added to the culture medium 10 min before short-term imaging (<1 hr) or 1 hr before the end of long-term imaging. Alternatively, cells can be engineered to express a nuclear-targeted fluorescent protein.

3. Place the 35-mm cell culture dish on the microscope stage.

   Ensure that the coverslip is located in the center of the culture dish. This will allow ample room for the objective to navigate the entire surface of the coverslip.

4. Identify the structures of interest.

   Choose structures that are representative of the population being analyzed. The thickness of structures being imaged should not exceed the focal limit of the microscope.

Establish imaging parameters

5. Using a fast-scanning mode on the green channel (excitation 488 nm, emission 521 nm), bring structures into the focal plane with the brightest fluorescence.

6. Scan an image of the structure at the desired excitation light intensity, line averaging, zoom, etc.

7. Adjust the detector pinhole diameter to one airy unit.

8. Modify detector gain for maximal fluorescence signal without pixel saturation (pixel intensities that exceed the detector scale, i.e., >255 for an 8-bit image).

   Saturated pixels only register as the maximum detector value, 255, so the true pixel intensity cannot be calculated under these conditions. Detector gain and offset will vary depending on the DQ-substrate used (type/lot number) and the laser power. The imaging parameters should be held constant for all z-sections through the 3-D structures.

9. Repeat the same adjustments (steps 5 through 8) for the other channels used.

10. Define the *z* distance limits, including the first and last optical sections of a stack as well as the *z*-stack interval distance between optical sections.

    Use a fast-scan mode along with the manual focus adjustment to determine the focal plane in which the fluorescence signal from the DQ-substrate begins and ends. This is usually near the top and bottom of the cellular structures. These positions will be different for each structure imaged and will have to be determined for each structure. Larger structures and highly motile cells will require a greater number of sections to image the entire volume (x,y,z). Although the number of sections will change from structure to structure, the thickness of each section and distance between z-sections must be kept consistent in order to accurately compare structures.

Collect fluorescence data

11. Create a *z*-stack of images including scans for the DQ-substrate, DNA binding dye, and cell tracking dye.

    At each focal plane the fluorescence corresponding to all channels is collected. The green fluorescence represents cleaved DQ-substrate. The fluorescence from cytoplasmic cell tracking dyes, such as CellTracker, will be used to identify cellular boundaries. The fluorescence from DNA-binding dyes will define the nuclear area in all cells not in late mitosis and allow determination of cell number.

12. Collect at least two to four different *z*-stacks of representative cellular structures and surrounding matrix from each experimental condition and treatment.

BASIC PROTOCOL 2

QUANTITATIVE ANALYSIS OF CONFOCAL IMAGE *Z*-STACKS

Following the acquisition of data in the form of *z*-stacks, image analysis software is used for quantification. The fluorescence data acquired due to the proteolytic cleavage of DQ-substrates can be used to visualize DQ-substrate proteolysis and quantify proteolysis in particular areas or entire volumes (Fig. 4.20.4).

Materials

Z-stacks (Basic Protocol 1)

Computer system capable of processing large image files: 350 mHz or faster processor, large storage capacity, and at least 256 MB video RAM and minimum 1 GB system RAM

Advanced image processing/analysis software capable of applying thresholds and measuring pixel intensities [e.g., ImageJ (Open Source, Public Domain), MetaMorph (Molecular Devices), and Volocity (Improvision)]

Process the confocal image stacks for analysis

1. Export confocal *z*-stacks.

   This is performed only if the microscope software saves image stacks in a format that cannot be read by the available image analysis software. It is important to export in a format that retains all image information. We recommend that images be exported as uncompressed Tagged Image File Format (TIFF). This file format will be accepted by all image analysis software.

2. Open an image stack in its original file format or reassemble the exported TIFF files as an image stack.

   Almost all advanced image processing software packages can assemble a series of two-dimensional images into a three-dimensional image stack, provided the image names end in sequential numbers designating their positions in the stack.

3. Separate the DQ-substrate channel, the cell tracker channel, and the DNA-binding dye channel.

   The two-dimensional images containing data from DQ-substrate cleavage, cell tracking, and DNA-binding dyes are all captured on different channels. Fluorescence resulting from the cleavage of DQ-substrates is captured on the green channel due to the emission spectrum of the fluorochrome (FITC). In order to quantify the image information from this channel, it must first be separated from all other channels and processed for analysis. The result of separation will be three 8-bit gray-scale image stacks. The green channel stack will yield the total (extracellular and intracellular) degradation information. The red channel will be used to delineate the intracellular cytoplasmic area of cells and be used to separate intracellular from extracellular areas in the green channel (step 7). The blue channel will be used to determine the number of cells as long as each cell contains only one nucleus (step 10).

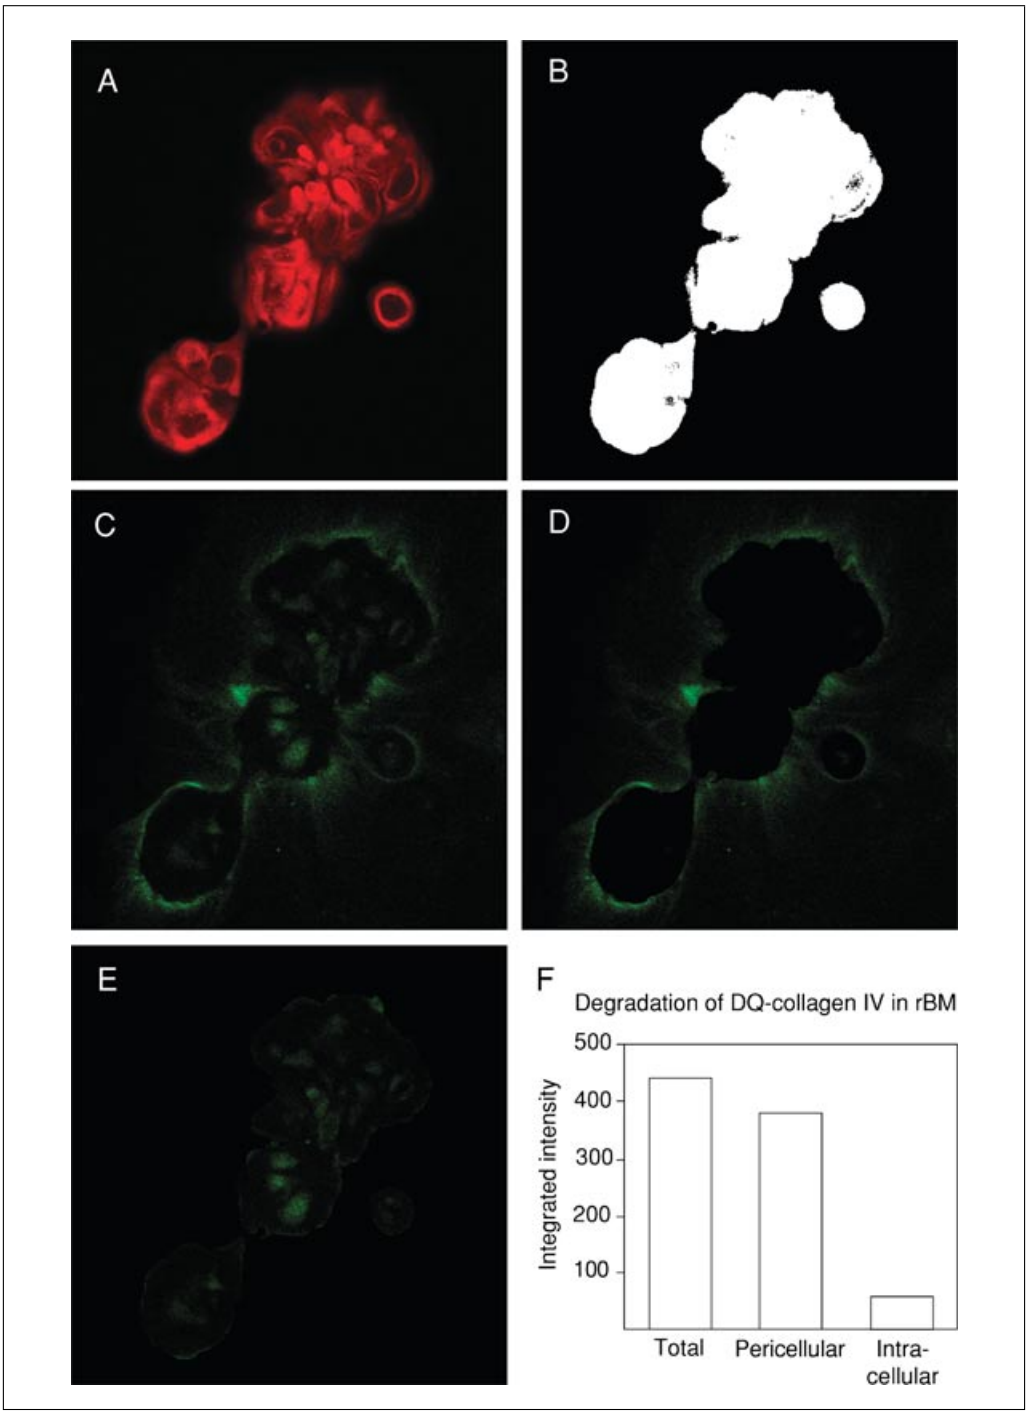

Figure 4.20.4 Quantification of proteolysis and discrimination of intracellular and extracellular localization of degradation fragments in human breast epithelial cells grown in rBM containing DQ-collagen IV. (**A**) Single optical section at equatorial plane showing fluorescence of the CellTracker Orange channel. (**B**) Same optical section but a binarized image of the CellTracker Orange and DNA dye channels. (**C**) Total (extracellular and intracellular) degradation fragments of DQ-collagen IV in same optical section. (**D**) Extracellular degradation fragments of DQ-collagen IV, obtained by masking image of panel C with the image from panel B to eliminate all signal from intracellular areas. (**E**) Intracellular degradation fragments of DQ-collagen IV. (**F**) Total degradation fragments of DQ-collagen IV in all optical sections were quantified as normalized integrated intensity per cell. Total fluorescence separated into intracellular and pericellular components using image arithmetic in MetaMorph software. For color version of this figure see *http://www.currentprotocols.com*.

4. Apply an inclusive intensity threshold to the DQ-substrate channel.

   Prior to measuring pixel intensities, most imaging programs require that the image data that constitutes signal be in some way distinguished from nonsignal, or background, image data. This is commonly referred to as thresholding or segmentation and is usually applied on the basis of gray-scale levels. Such a threshold defines the range of gray-scale values that describe the regions of interest. Subsequent measurements are applied only to pixels that fall within this range. Although the selection is arbitrary, it must be held constant for all image stacks used for comparison. It is a good idea to record these threshold ranges for later reference. Use image stacks that represent the most intense and least intense signals when determining threshold range

5. Measure the intensities of all pixels under the threshold and log data to a spreadsheet.

   Many advanced imaging software applications have several measures of intensity. It is best to measure integrated intensity rather than average intensity, as this will incorporate the threshold range applied earlier. Some software packages output one integrated intensity value for each x,y image plane in the stack. In this case, sum this value across image planes and export data to a spreadsheet. This value will represent total degradation and later be averaged by the number of cells.

Separate intracellular from extracellular degradation

6. Combine the cell tracking and DNA-binding dye channels using an arithmetic addition function.

   In order to completely mask all intracellular degradation, the fluorescence intensity data from the cell tracking and DNA-binding dye channels need to be combined to make a new stack.

7. Binarize the stack created in step 6.

   The fluorescence intensity data from the new stack need to be maximized or saturated at all pixels representing intracellular areas. This is done by converting the 8-bit image stack into a binary image stack. The result of the binerization is an image stack in which all pixels that contained cell tracking and DNA binding dye fluorescence are now at maximum intensity.

8. Determine pericellular degradation by applying an arithmetic subtraction of the binerized data obtained in step 7 from the DQ-substrate channel image stack.

   To calculate extracellular degradation (Degradation$_P$), the fluorescence information (gray value) from areas considered intracellular must be removed using an image arithmetic subtract function. The binarized stack (C) from step 7 provides the spatial information (x,y coordinates) needed for the imaging software to subtract the gray-value data from corresponding x,y coordinates in the total DQ-substrate channel stack (Degradation$_T$). The result of this function is the creation of a new stack (Degradation$_P$) containing only fluorescence data from extracellular regions. Measure and record the intensities of all pixels in the image stack.

$$\text{Degradation}_\text{P} = \text{Degradation}_\text{T} - \text{C}$$

9. Determine intracellular degradation by applying an arithmetic subtraction of the pericellular degradation stack created in step 8 from the total DQ-substrate channel stack (Degradation$_\text{T}$).

   To calculate intracellular degradation, the fluorescence information (gray value) from the extracellular degradation stack (Degradation$_P$) must be subtracted from the total DQ-substrate channel (Degradation$_T$). The result of this operation is the creation of a new stack (Degradation$_I$) containing only fluorescence data from intracellular regions. Measure and record the intensities of all pixels of the image stack.

$$\text{Degradation}_\text{I} = \text{Degradation}_\text{T} - \text{Degradation}_\text{P}$$

Determine the cell number in image stack

10. Create a 3-D reconstruction using the fluorescence from the DNA-binding-dye channel.

    Due to inherent differences in the sizes and shapes of cellular structures within an imaged area, degradation information (total, intracellular, pericellular) is normalized to the number of cells represented by the number of nuclei present. Accurate determination of nuclei requires the software to render nuclei in three dimensions and display a visual representation of the rendering that can be manipulated in three dimensions (x,y,z-directions) by the user.

11. Use a classifier to define all nuclei as objects and segment them from one another.

    Most advanced image analysis software allows classification of objects based on intensity thresholds and size constraints. Many also have functions like noise reduction and separation of touching objects via an edge detection algorithm and shape constraints. Some software packages even allow classification of objects based on morphometric parameters, such as X and Y centroid, radial dispersion, texture moment difference, etc. These additional parameters are not generally necessary for the discrimination of ovoid objects, such as nuclei from the background and from each other. Create a custom classifier combining as many classification criteria as needed to define nuclei as discrete objects in three dimensions. For the first image, it may be necessary to apply the classifier more than once, evaluating its ability to successfully describe the nuclei. When satisfied, save the classifier. It should apply to the other images as well, provided the same settings were used to acquire the images.

12. Count the objects.

    If a counting option does not exist in the software, manually count the objects classified. Each measurement represents one object. Advanced imaging software will generally apply a unique color overlay to each identified object to assist the user in visualization of the distinct objects.

13. Evaluate the classifier in 3-D rendered mode.

    Evaluate the classifier once again by rotating the 3-D structure and viewing the overlay resulting from the measurement. If satisfied that the classifier has correctly segregated individual nuclei, record the count in the spreadsheet. Because this is highly subjective, more than one observer should evaluate.

14. Divide the desired intensity measure from the DQ-substrate channel by the total number of nuclei to obtain degradation per cell.

PREPARE CELL CULTURES ON ECM CONTAINING DQ-SUBSTRATES

SUPPORT PROTOCOL 1

The cell cultures being imaged must be grown on or within ECM containing the desired DQ-substrate. The ECM can exert a dramatically different effect on cellular morphology and physiology. The formation of unique structures such as monolayers, spheroids, acini, tubes, and branching clusters may depend on the composition and stiffness of ECM, media supplements, densities of cell seeding, etc. We have found that on gelatin and collagen type I, cells primarily grow as 2-D monolayers like those seen on uncoated plastic and glass. In contrast, in complex matrices they form 3-D structures (e.g., see Fig. 4.20.2).

Prior to setting up cell cultures on ECM containing DQ-substrates, cells should first be prelabeled with a fluorescent cell tracking dye. Alternatively, cells can be transfected or transduced to drive expression of a fluorescent protein, such as monomeric Red Fluorescent Protein (mRFP), which we have found to remain cytosolic. There are two reasons to use fluorescently labeled cells: (1) to delineate the intracellular area taken up by cells in order to separate intracellular from extracellular degradation using imaging analysis software; and (2) to distinguish among the different cell types in cocultures. Invitrogen

provides several cell tracking fluorescent dyes with distinct excitation/emission spectra. This allows the user to label different cell types with unique colors, thus distinguishing each cell type in cocultures. The investigator must be aware of the limitation of the microscope for handling multiple colors and availability of excitation and emission bandwidths. After establishing cell cultures on ECM containing a DQ-substrate, the user can begin imaging immediately or at a later time. Cells will begin to degrade DQ-substrates shortly after seeding; however, sufficient hydrolysis for detection may require hours to accumulate. If long periods of culture time are required, as when the cells are slow to form 3-D structures or when degradation needs to be monitored in later stages of culture, the 3-D structures may need to be grown in the absence of DQ-substrates, harvested, and then reseeded onto coverslips coated with ECM containing DQ-substrate. Please see Support Protocol 2 for indications when reseeding should be considered.

Materials

DQ-substrates: DQ-collagen IV, DQ-collagen I, DQ-gelatin (Invitrogen)
Cell line of interest
CellTracker Orange CMTMR Dye (Invitrogen)
Powdered bovine skin gelatin (Sigma)
Sucrose (Sigma)
1× and 10× phosphate-buffered saline, sterile (PBS; *APPENDIX 2A*)
Collagen I (Cohesion Laboratories)
NaOH
Recombinant basement membrane (rBM): Matrigel (BD) or Cultrex (Trevigen)
Cell culture medium, phenol red–free

56°C water bath
0.22-μm filter
12-mm no.1 round glass coverslips, acid-washed and sterilized by baking
35-mm cell culture petri dishes
100-μl pipettor
37°C humidified incubator

Additional reagents and equipment for trypsinizing and counting cells (*UNIT 1.1*)

1. Reconstitute DQ-substrate in water.

   All DQ-substrates are shipped from the manufacturer as a lyophilized powder requiring reconstitution. This is accomplished at room temperature with sterile distilled water for at least 1 hr. We recommend making a stock solution of 1 mg/ml. Once reconstituted, 10- to 20-μl aliquots should be made and stored at 4°C.

2. Preload cells with membrane permeable cell tracking dye.

   Subconfluent cells should be prelabeled 2 to 3 hr before establishing cultures on ECM containing DQ-substrate. The chemistries of the individual dyes differ and their distribution within the cell can vary among cell types. Invitrogen has developed several thiol-reactive Cell Tracker probes that are nontoxic and yield fluorescent products that are retained inside live cells through several population doublings. These membrane permeable dyes undergo a GST-mediated reaction to produce membrane-impermeant glutathione–fluorescent dye adducts. We recommend that one test several dyes and determine concentrations and incubation times for each cell type to ensure dye distribution throughout cytoplasm. The duration of culture time before and during imaging must be considered since the dye is diluted as cells divide. We have found that Cell Tracker Orange CMTMR works well and will detail its use here (see below).

Dilute DQ-substrates in ECM

DQ-substrates need to be diluted in an appropriate ECM depending on your experimental requirements. There are several different commercially available ECM (e.g., gelatin,

collagen I, and rBM), which complement the different DQ-substrates. In our laboratory we dilute DQ-substrates with their constituent matched ECM (i.e., DQ-gelatin with gelatin, DQ-collagen I with collagen I, DQ-collagen IV with rBM). The rationale for diluting DQ-collagen IV in rBM is that collagen IV is a major component of basement membranes in vivo and in commercially available rBMs from EHS tumors. Each ECM requires slightly different handling techniques and therefore each will be discussed separately. Regardless of the DQ-substrate or the ECM used, we have found that the ideal final concentration of DQ-substrate is 25 μg/ml. Because there are lot-to-lot variations in both the DQ-substrates and the ECM, we recommend that all experiments be repeated with the same lot.

Prepare a gelatin + DQ-gelatin substrate

3a. Add 2% powered bovine skin gelatin and 2% sucrose to sterile PBS and heat to 56°C in a water bath until both gelatin and sucrose dissolve.

4a. Filter solution using a sterile 0.22-μm syringe filter.

5a. Allow to cool slightly before adding DQ-substrate at 25 μg/ml.

Avoid cooling to room temperature because gelatin will begin to solidify as it cools.

Prepare a collagen I + DQ-collagen I substrate

3b. Purchase collagen I and store at 4°C as a liquid.

4b. Prior to mixing with DQ-substrates, convert collagen I into a state in which it will solidify. To do this make a solution containing 80% (w/v) collagen I, 10% (v/v) 10× PBS, and 10% (v/v) 0.1 N NaOH (pH 7.4).

5b. At this point mix the collagen I solution with DQ-substrate to a final concentration of 25 μg/ml. Gently pipet to ensure thorough mixing.

Prepare recombinant basement membrane + DQ collagen IV substrate

3c. Thaw rBM on ice overnight at 4°C.

The rBM remains a liquid on ice but solidifies rapidly when warmed so it should be handled on ice at all times.

4c. Dilute the appropriate amount of DQ-substrate with an appropriate amount of rBM in a prechilled container to a final concentration of 25 μg/ml.

5c. Mix on ice using gentle pipetting to avoid creating bubbles. Keep on ice.

Take extra precautions during pipetting as errors may occur due to the viscosity of the rBM.

Prepare cultures

6. Coat glass coverslips with ECM containing DQ-substrate. Place two round coverslips in a 35-mm cell culture dish. Using a 100-μl micropipettor, carefully pipet and spread 50 μl of the solution made above over the entire surface of each coverslip.

Take care not generate air bubbles and stay within the dimensions of the coverslip.

7. Promptly place in either a humidified incubator at 37°C without CO_2 for 15 min (rBM) or 30 min (collagen I), or at 4°C for 10 min (gelatin).

The coated coverslips must be promptly placed in a humidified incubator to prevent dehydration/shrinking of the ECM. Include control coverslips that will be cultured without cells.

Alternatively, the investigator may choose to directly coat the bottom of a 35-mm dish.

8. Seed cells onto coated coverslips. While the rBM is solidifying, trypsinize and count the prelabeled cells (*UNIT 1.1*).

   Be sure that cells are in a single-cell suspension.

9. Centrifuge the cells 5 min at 80 to 100 × *g*, room temperature, and resuspend in culture medium so that the desired number of cells per coverslip is contained in a 50-μl volume.

   The culture medium is unspecified as medium is user defined for the individual cell line(s) to be studied.

   If doing a coculture experiment, a mixture of cell types should be made with the appropriate cell numbers mixed in a 50-μl volume of medium.

10. Place 50 μl suspension of cells onto each coated coverslips. Carefully place the 35-mm dish containing the cells on coverslips into a 37°C incubator. Allow 30 to 60 min for the cells to attach to the ECM.

    If performing coculture keep in mind that one cell line may require longer times to adhere to the ECM.

11. Fill the 35-mm culture dish with 2 ml of culture medium. If using assay supplements, these should be added at this time.

12. Incubate for desired time before imaging.

    The time period between seeding cells and imaging must be determined by the investigator and depends on the experimental design and cell types. Imaging can commence as soon as cells have attached to the ECM. We have imaged up to 3 weeks after seeding with negligible loss of fluorescence intensity.

SUPPORT PROTOCOL 2

HARVESTING 3-D SPHEROIDS OF CELLS GROWN IN rBM: AN ALTERNATIVE TO DIRECTLY GROWING ON ECM CONTAINING DQ-SUBSTRATES

When cells in rBM need to be grown over long periods of time before imaging, the cultures may first be grown without DQ-substrates and then transplanted into fresh ECM that has been mixed with the DQ-substrate. Harvesting the initial cultures from rBM requires gentle enzymatic digestion of the rBM so that the cellular structures can be removed with minimal disruption. Therefore, harvesting is only recommended for cell types that grow as tight spheroids or aggregates. Harvesting will significantly alter the 3-D morphology of structures composed of tubes, networks, and branches.

Materials

Cell culture grown on rBM within a 60-mm cell culture dish
1× phosphate-buffered saline (PBS; *APPENDIX 2A*), sterile
6 U/mg lyophilized dispase (Roche)
Cell culture medium, phenol red–free

37°C incubator
Microscope
5-ml pipet
15-ml conical tube
Centrifuge

Additional reagents and equipment for preparing cultures on freshly coated coverslips (Support Protocol 1)

1. Aspirate medium from the cell culture and wash cells twice, each time with 5 ml PBS.

2. Dilute the lyophilized dispase to 1.5 U/ml using sterile PBS. Add 2 ml dispase solution to completely cover the dish. Place culture dish into a 37°C incubator. After 15 min, begin to periodically monitor dish with a standard microscope for the release of cellular structures.

   Complete digestion should occur within 60 minutes.

3. Add 1 ml fresh PBS. Use gentle pipetting with 5-ml pipet to complete the release of cellular structures from the rBM and culture dish. Use additional PBS if needed. Collect cellular structures with pipet into a 15-ml conical tube.

4. Gently centrifuge structures 5 min at 80 × *g*, room temperature.

   Spinning cells at 80 × g for 5 min will be sufficient to pellet even the smallest clusters of cells. If structures are large (>200 cells), we recommend that structures be allowed to sediment to the bottom of a 15-ml conical tube instead of centrifuging.

5. Aspirate the PBS and resuspend structures in appropriate volume of fresh cell culture medium.

   The culture medium is unspecified as medium is user defined for the individual cell line(s) to be studied.

   The volume used for resuspension will depend on the initial number of structures in the original dish and the number of structures desired per coverslip. As in Support Protocol 1, ~50 μl of medium can be pipetted onto a coated coverslip

6. Gently pipet cellular structures onto freshly coated coverslips from Support Protocol 1 and incubate.

7. Image the cultures at the appropriate time.

COMMENTARY

Background Information

The ability of cells to degrade ECM was formerly imaged by growing cells on FITC-labeled ECM and looking for a loss in fluorescence as a result of ECM degradation. With this method it is often difficult to assess loss of fluorescence, in particular small losses, because the background fluorescence is so intense. As a result the areas of fluorescence loss may not be associated with cells. For example, we have found tracks in which there is loss of fluorescence when tumor cells are grown on FITC-labeled ECM (Sloane, 1996). These tracks suggest that the cells are migrating and degrading the ECM as they migrate. We developed the DQ-substrate assay described here so that proteolysis by live cells could be imaged in real-time.

The fluorescence of the DQ-substrates is quenched as a result of extensive labeling, the close association of FITC molecules, and a transfer of nonradiative energy, i.e., a FRET effect. Upon proteolytic cleavage, the distance between the FITC molecules increases, resulting in emission of fluorescence (see Fig. 4.20.1B and D). This increase in fluorescence occurs on a nonfluorescent background (see Fig. 4.29.1A and C) and thus is readily observed. Furthermore, the gain in fluorescence can be imaged without fixation. When we use DQ-substrates for imaging of proteolysis by live cells, we see fluorescent fragments of DQ-substrates both extracellularly and intracellularly. At least some of the intracellular fluorescence represents intracellular degradation as cell-permeable inhibitors of lysosomal cysteine cathepsins reduce the amount of intracellular fluorescence (Sameni et al., 2000, 2003). The presence intracellularly of fluorescent fragments of DQ-substrates requires endocytosis by live cells. This may be due to endocytosis of intact DQ-substrate and its degradation intracellularly or endocytosis of fluorescent fragments of DQ-substrate that had been degraded extracellularly. In either case, the intracellular fluorescence could not be visualized unless the cells were alive, a clear advantage of the DQ-substrate assay. A potential disadvantage is that the DQ-substrates are proteins, so they do not allow one to directly assess the activity of any individual protease or protease class. As some DQ-substrates are proteins that would be encountered in vivo by migrating or invading cells, e.g., collagen IV or I, analyzing their degradation could allow one to identify proteases that are involved

in normal developmental or pathological processes. Furthermore, more than one protease or protease class can degrade these protein substrates, and thus their use should allow one to identify multiple proteases and potentially proteolytic pathways that are involved in these processes.

Another advantage of DQ-collagen substrates is that they allow one to study proteolysis in cells growing in a 3-D context that mimics the in vivo environment. There are several excellent reviews on the value of 3-D in vitro models (Schmeichel and Bissell, 2003; Debnath and Brugge, 2005; Yamada and Cukierman, 2007).

Critical Parameters

These protocols describe methods to set up and image cell cultures using an upright microscope equipped with long-working-distance dipping objectives. Although an upright microscope is ideal for the sample thicknesses of 3-D cultures, inverted microscopes can be used. Several microscope companies manufacture long-working-distance (2 to 3 mm) high-power dry objectives, such as the Zeiss 40× LD and 63× LD Plan-neofluar, which can be used in inverted microscopes. Along with long-working-distance dry objectives, growing cells on glass-bottom culture dishes (coverslip thickness) will minimize the distance between the objective and the cells within the ECM. Furthermore, microscope-grade glass has optical characteristics that are optimal for high-quality imaging.

Troubleshooting

Fluorescence from DQ-substrates appears as large, amorphous deposits that are not associated with cells. The DQ-substrates may have been handled improperly following solubilization. Once in solution the DQ-substrates should not be frozen. Do not vortex any solution containing DQ-substrates and avoid excessive pipetting. Also, do not let either the substrate or the ECM dry out. Make sure that the lot number of DQ-substrate has not expired or been recalled.

Collagen I does not adhere well to glass. We recommend establishing cell cultures on collagen I polymerized within a 35-mm plastic culture dish or on plastic coverslips. Note that the increased surface area of a 35-mm dish will also mean that higher cell numbers must be seeded.

Anticipated Results

Specific results will depend on the cells analyzed, the use of monolayer or three-dimensional cultures, and the DQ-substrates and ECM used for the assay. Degradation of the DQ-substrates can be seen within hours after plating and can be imaged in real-time in cultures growing in an incubator on the microscope stage. If stability of the setup can be maintained, cultures can be imaged in real-time for long time periods; we have imaged for as long as 24 hr. This requires a stage incubator that can maintain temperature, humidity, oxygen tension, and CO_2. Degradation of the DQ-substrates is seen within hours after plating. Not surprisingly, the denatured substrate DQ-gelatin is degraded faster than is either DQ-collagen I or DQ-collagen IV. Whether the DQ-substrates are degraded extracellularly, intracellularly or both may depend on the ECM in which they are mixed. The ECM can affect the morphology of the cells and whether they grow as two-dimensional monolayers or three-dimensional structures (e.g., see Fig. 4.20.2) and in addition can influence the ability of the DQ-substrates to be endocytosized.

Time Considerations

3-D cellular structures and cocultures require long imaging times. The thicker a 3-D structure is, the more optical sections needed to image. It may take minutes to record an optical section into each fluorescent channel; this is particularly true for high-resolution images requiring long scan times. If one is imaging cocultures in which each cell type is labeled with a fluorescent dye/marker, then each color must be scanned into a separate fluorescent channel. Another consideration is that variability among structures requires imaging of a greater number of structures if the data are to be statistically significant.

Time at which one should perform fluorescent labeling. Since cytoplasmic dyes that can be used to prelabel cells will be diluted out with each cell division, these dyes can only be used to label short-term cultures, or need to be added shortly before imaging, e.g., 2 hr (Support Protocol 1). The timing of staining with DNA binding dyes, such as Hoechst 33342 may affect cell viability. Due to their interaction with DNA, these dyes will induce apoptosis of most cells within 12 hr.

Photoactivated Localization Microscopy (PALM) of Adhesion Complexes

Hari Shroff,[1] Helen White,[1] and Eric Betzig[1]

[1]Howard Hughes Medical Institute, Janelia Farm Research Campus, Ashburn, Virginia

ABSTRACT

Key to understanding a protein's biological function is the accurate determination of its spatial distribution inside a cell. Although fluorescent protein markers allow the targeting of specific proteins with molecular precision, much of this information is lost when the resultant fusion proteins are imaged with conventional, diffraction-limited optics. In response, several imaging modalities that are capable of resolution below the diffraction limit (~200 nm) have emerged. Here, both single- and dual-color superresolution imaging of biological structures using photoactivated localization microscopy (PALM) are described. The examples discussed focus on adhesion complexes: dense, protein-filled assemblies that form at the interface between cells and their substrata. A particular emphasis is placed on the instrumentation and photoactivatable fluorescent protein (PA-FP) tags necessary to achieve PALM images at ~20 nm resolution in 5 to 30 min in fixed cells. *Curr. INTRODUCTION

The accurate determination of a protein's spatial distribution inside a cell is often intimately related to its function. Fluorescence microscopy allows the imaging and subsequent analysis of protein distributions inside cellular specimens, and fluorescent proteins allow an investigator to genetically target a protein with molecular precision. Unfortunately, valuable information is lost when conventional fluorescence microscopy is used to image the resulting protein fusions, because diffraction limits the smallest features that can be resolved with an optical microscope to ~200 nm.

In response, a number of far-field superresolution imaging modalities that are capable of breaking the diffraction barrier have emerged (Gustafsson, 2000, 2005; Betzig et al., 2006; Hess et al., 2006; Rust et al., 2006; Willig et al., 2006). Photoactivated localization microscopy (PALM; Betzig et al., 2006) relies on the stochastic activation, localization, and bleaching of single photoswitchable molecules, and initially used photoactivatable fluorescent proteins (PA-FPs, reviewed in Wiedenmann and Nienhaus, 2006; also see *UNIT 21.6*) at the high density and localization precision necessary to provide images at $>10\times$ higher spatial resolution than corresponding diffraction-limited images (Fig. 4.21.1). Several other methods (Hess et al., 2006; Rust et al., 2006) have relied upon similar characteristics of photoswitchable molecules to provide superresolution, albeit at lower density and spatial resolution.

This unit describes the application of PALM to the imaging of adhesion complexes, transmembrane protein assemblies that form attachment points between the cytoskeleton and substratum and that are critical in cell migration (Zamir and Geiger, 2001). Adhesion complexes represent a particularly good test system for PALM: as many types of proteins (>90) are concentrated in structures as small as 0.5 μm (Zaidel-Bar et al., 2007), conventional fluorescence imaging is clearly inadequate to resolve internal adhesion complex structure (Fig. 4.21.1).

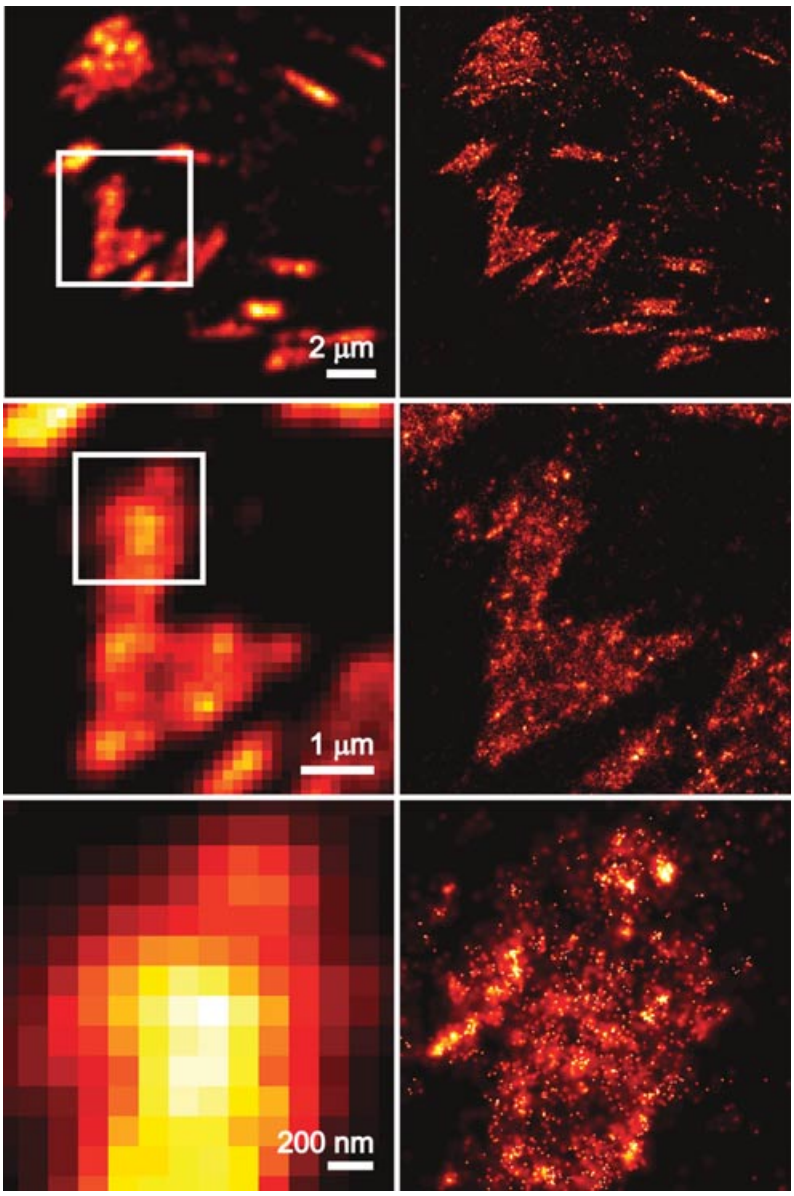

Figure 4.21.1 Comparison between diffraction-limited, summed TIRF (left) and PALM (right) images of tdEos/vinculin distributions in adhesion complexes present at the surface of a fixed HFF-1 fibroblast. Middle/bottom panels show higher magnification views of the boxed regions in top/middle panels. Note the greatly increased resolution and dynamic range evident with PALM. Displayed images were rendered from 40,000 single-molecule images; >100,000 molecules are plotted in each PALM image. For color version of this figure see *http://www.currentprotocols.com*.

Several considerations are important in achieving the best PALM images of adhesion complexes. First, the choice of photoactivatable tag dictates the maximum achievable resolution; this consideration is discussed in Strategic Planning. Second although PALM instrumentation is relatively straightforward, some additional knowledge in designing a PALM system is helpful and is covered in Basic Protocol 1. A method that uses PALM instrumentation in combination with appropriate sample preparation techniques to provide superresolution images of the adhesion protein paxillin is described in Basic Protocol 2. Finally, Basic Protocol 3 describes the additional steps necessary to undertake dual-color PALM-imaging of two adhesion complex proteins (vinculin and α-actinin).

STRATEGIC PLANNING

PALM is a single-molecule technique: the raw data consist of a stack of thousands of individual frames, each containing diffraction-limited fluorescence images of single photoswitchable molecules present in the sample. The fluorescence images of each molecule are analyzed to determine their centers with high precision, and the resultant information is used to generate a high-resolution PALM image of the positions of the molecules. The resolution of PALM is thus dependent on *localization precision*: how well the position of each single molecule can be determined from its diffraction-limited image. Perhaps more subtle but equally important in determining the ultimate PALM resolution is the *density* of molecules present in the sample (see Background Information for a detailed discussion of factors influencing PALM resolution). The localization precision depends on maximizing the signal-to-noise ratio in each image, a characteristic that in turn depends on maximizing the collected photons from each photoswitchable molecule and minimizing the background fluorescence. These instrumentation considerations are discussed in Basic Protocol 1. However, the localization precision also depends on the total number of photons emitted by each molecule before it bleaches, an intrinsic property of the molecule. Furthermore, taking full advantage of the molecular density in each sample is contingent on the *contrast ratio* of the molecule, another intrinsic property (see Background Information). It is the authors' belief that the correct choice of photoswitchable molecule is the single most important factor in obtaining high-quality PALM images—that choice is the subject of this section.

All PALM experiments currently conducted by the authors use PA-FPs as the photoswitchable molecules, instead of exogenously introduced caged dyes—such as caged fluorescein, resorufin, or rhodamine (Mitchison et al., 1998; Betzig et al., 2006)—that are conjugated to antibodies or proteins via small-molecule labeling strategies (Chen and Ting, 2005; Giepmans et al., 2006). PA-FPs have the tremendous advantage of being exquisitely specific; by genetically fusing a PA-FP to a target protein and transfecting the cellular sample, the investigator is assured that there is a 1:1 correspondence between a detected molecule and its target, and thus avoids the nonspecific binding that arises with dye-conjugated antibodies or proteins. PA-FPs also better approximate the size of a target protein, whereas antibodies can introduce considerable uncertainty due to their size (10 to 20 nm, depending on whether both primary and secondary antibodies are used). Due to their small size, PA-FPs can achieve higher densities in principle than antibodies, and thus offer increased PALM resolution. Finally, PA-FP genes are readily available as plasmid DNAs and are easily ligated to DNA coding for the protein target, whereas at the present time, caged dyes are not commercially available and must be custom synthesized. Some of the potential downsides of PA-FPs are mentioned in Critical Parameters and Troubleshooting.

Most PA-FPs can be broken up into two classes: those that switch from a green fluorescent state to an orange state (e.g., EosFP, Wiedenmann et al., 2004; KikGR, Tsutsui et al., 2005; and Kaede, Ando et al., 2002) upon photoactivation, and those that switch from a dark state to a green fluorescent state (e.g., PA-GFP, Patterson and Lippincott-Schwartz, 2002; or Dronpa, Ando et al., 2004) upon photoactivation. After testing candidates from both classes, the authors have concluded that EosFP is the best choice for PALM, due both to the high number of emitted photons before bleaching (>1000 photons, providing localization precision to $\sim$10 nm; Shroff et al., 2007) and the greatly increased contrast ratio ($>10^3$, providing both increased localization precision and enabling PALM-imaging of densely-labeled specimens) relative to other PA-FPs (see Fig. 4.21.2 and Background Information). Also, as the activated state of Eos has a fluorescence emission spectrum that peaks at 580 nm, emission filters can be chosen to minimize cellular autofluorescence (more prevalent in the 450 to 550 nm region, overlapping with the emission spectrum of

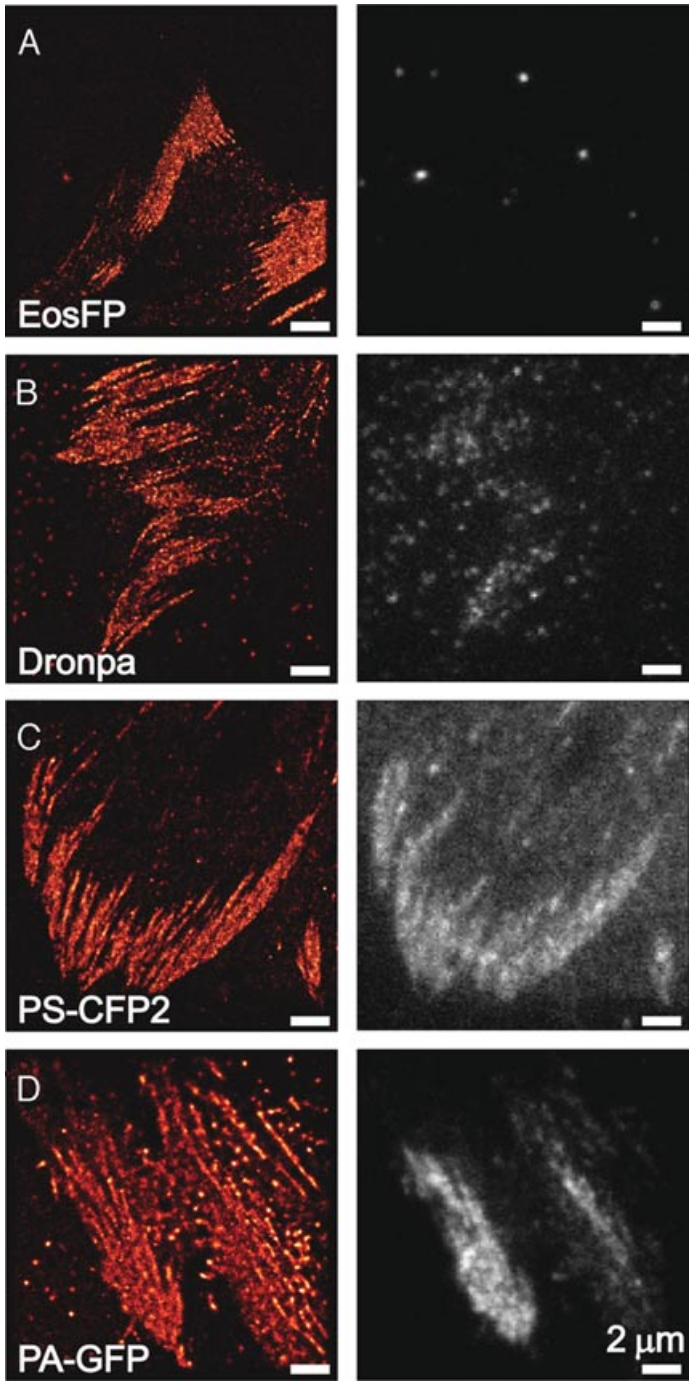

Figure 4.21.2 Comparison of contrast ratios for four different PA-FPs, each fused to the adhesion protein paxillin. Left column tabulates PALM images obtained in each case: (**A**) mEosFP; (**B**) Dronpa; (**C**) PS-CFP2; (**D**) PA-GFP. Right column contains, for each PA-FP, frame 1000 of the stack of single-molecule images used to generate the corresponding PALM image on the left. Background largely reflects emission from the large pool of inactive PA-FPs. Note the correlation between low background (i.e., high contrast ratio between the active and inactive states) and crispness of the PALM image (i.e., localization precision). Reproduced from Shroff et al., 2007. For color version of this figure see *http://www.currentprotocols.com*.

PA-GFP and Dronpa). Finally, unlike KikGR, EosFP can be completely photoconverted from its green state to the orange state, a characteristic that is essential for the serial dual-label PALM procedure described in Basic Protocol 3.

Despite these factors, there may be situations where it is advantageous to use other PA-FPs as the PALM label. For example, in dual-label PALM-imaging (Shroff et al., 2007), it is necessary to use EosFP in conjunction with another PA-FP (either Dronpa or PS-CFP2; Chudakov et al., 2004, 2007). If the investigator must use an FP or fluorophore as a conventional, diffraction-limited label, and the label has significant spectral overlap with EosFP, it may be necessary to use a different PA-FP as the PALM label (although it is better to first pick the PALM label and then the diffraction-limited label, as the choice of PA-FPs is considerably more limited). Finally, any FP-labeling strategy is prone to aggregation artifacts, and these problems can be exacerbated if the label is present in nonmonomeric form. EosFP is currently available in tetrameric, dimeric, tandem-dimeric (commonly used by the authors and available from Michael Davidson, Florida State University), and monomeric forms, but only the first three forms fold efficiently at 37°C. The development of a monomeric Eos that folds at 37°C is ongoing, but in the interim there may be some applications that demand the existing monomeric PA-FPs—Dronpa, PA-GFP, PS-CFP2, or Dendra2 (Chudakov et al., 2007).

PREPARING PALM INSTRUMENTATION

BASIC PROTOCOL 1

Instead of a conventional step-by-step protocol, this section describes the instrumentation necessary for PALM. As PALM is inherently a single-molecule technique, standard methods for suppressing background fluorescence and for detecting relatively faint single-molecule emissions apply (Weiss, 1999). In particular, total internal reflection (TIRF) microscopy (Axelrod, 2001; *UNIT 4.12*) is advantageous for PALM, because the evanescent excitation wave penetrates <200 nm into the sample, leading to extreme rejection of the background fluorescence common in cellular samples, thus facilitating the detection of single fluorescent molecules. TIRF is also a widefield technique, implying that many molecules per frame can be imaged simultaneously, thus vastly increasing the acquisition speed. TIRF is particularly appropriate for imaging adhesion complexes, as these structures are located close (within 100 nm) to the substrate and are thus within the TIRF excitation region. Note that TIRF is not an absolute requirement for PALM, as certain specimens (such as bacteria) are sufficiently thin that autofluorescence does not impede the localization of single molecules illuminated in epifluorescence. Also, other studies (Hess et al., 2006; Egner et al., 2007) have reported epifluorescence PALM imaging, albeit with lower resolution images than those reported here.

With some minor modifications and additions to the existing hardware, it is possible to adapt an existing commercial TIRF microscope for PALM (Shroff et al., 2007; Fig. 4.21.3). Free-space coupling (i.e., without an optical fiber) of appropriate excitation and activation lasers into the microscope ensures that enough power is delivered to the sample, and permits fast PALM imaging. Using a microscope objective with as high a numerical aperture (NA) as possible allows high photon collection efficiency and facilitates TIRF. Choosing an appropriate electron-multiplying charge-coupled device (EMCCD) camera is an important factor in imaging the faint emissions from single fluorescent molecules, as is choosing the best available excitation, emission, and dichroic filters. Finally, a computer with acquisition software, image acquisition board, and a large hard drive is important for acquiring and storing the large PALM acquisition stacks. The authors have tried to be as general as possible in describing the major components, but have given specific recommendations when relevant. Note that Carl Zeiss has recently licensed the PALM technology, with plans to develop commercial PALM microscopes.

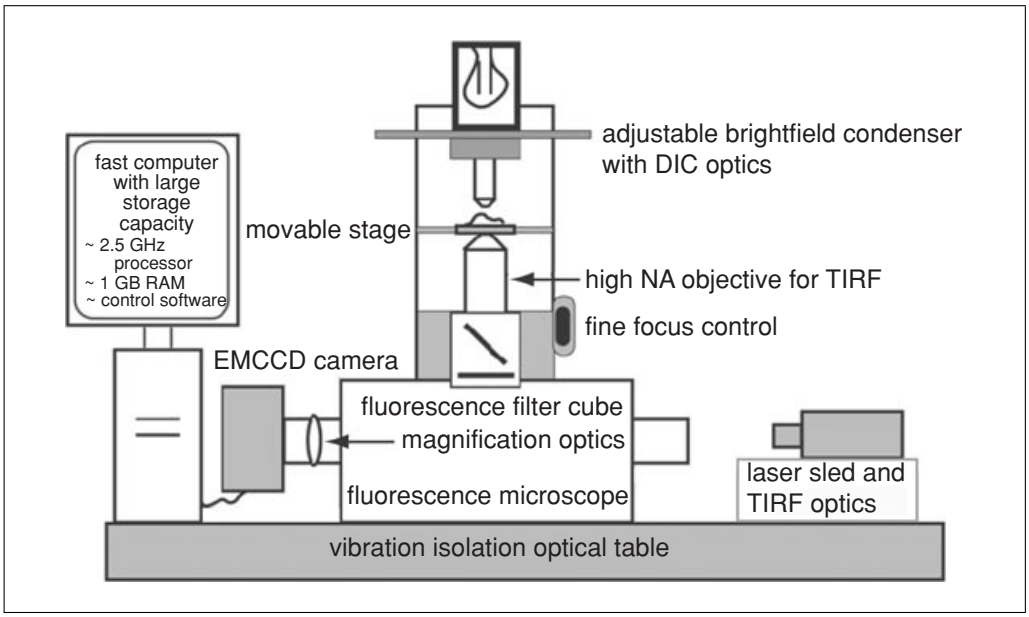

Figure 4.21.3 Cartoon view of the main instrumentation components necessary for PALM. See the text for a detailed discussion of various components, and note that Figure 4.21.6 and Figure 4.21.7 show a detailed view of the sled and TIRF optics for coupling the excitation and activation lasers into the microscope body, while Figure 4.21.4 and Figure 4.21.5 show the sample holder and sample chamber (not shown in cartoon) in detail. The figure is not drawn to scale.

Materials

Optical table (Technical Manufacturing Corporation)
Inverted fluorescence microscope (e.g., Olympus IX-81) assembly, including:
- Brightfield and DIC optics
- Capability for TIRF illumination
- High NA objective lenses (1.45 NA, 1.49 NA, or 1.65 NA) with matching coverslips, and immersion media
- Internal magnification lens (optional, depending on objective magnification)
- Additional magnification before camera (optional, depending on objective magnification)

Mercury *or* xenon lamp
Mechanically stable stage and sample mount
Appropriate excitation and activation lasers and optics (beam expanders, neutral density filters, half-wave plates, and dichroic beamsplitters) for coupling lasers into the TIRF microscope path
Appropriate excitation, emission, and dichroic filters
Acousto-optic tunable filter (AA Opto-Electronic, AA-AOTFnC-VIS)
EMCCD camera (see step 12 for details)
Computer with appropriate control software (see step 14 for details)
Computer with appropriate analysis software (see step 16 for details)

Set up inverted fluorescence microscope with associated optics and stage

1. Bolt a research-quality fluorescence microscope to an optical table in order to minimize unwanted vibrations and to prevent relative motion between the microscope and table. Use a microscope with ports for epi- and TIRF-illumination, and for mounting an EMCCD camera for detection. Use a brightfield condenser and differential interference contrast (DIC) optics for imaging samples conventionally before PALM-imaging, and a mercury or xenon lamp to aid in initial examination

of the specimen with diffraction-limited epifluorescence imaging prior to PALM-imaging.

Some of these components are illustrated in Fig.4.21.3.

The authors use an Olympus IX-81 as the base microscope for PALM. The microscope is bolted to a 4 × 8–ft optical table, large enough to comfortably fit both the microscope and the associated lasers and TIRF optics described below. The back-port of the microscope is fitted with the Olympus U-DP dual-port tube to switch between widefield epi-illumination (with a mercury or xenon lamp) and laser illumination (for TIRF). The microscope is also fitted with a polarizer, analyzer, and Nomarski DIC prisms for transmitted DIC imaging. Given the sample chamber design described below, a long working-distance condenser is necessary to prevent the condenser from physically colliding with the sample chamber. The authors use an NA 0.55, 27-mm working-distance condenser (Olympus, IX2-LWUCD). Finally, the authors recommend using an adjustable, focusable lamp housing (Olympus, IX-HLSH100), as they have obtained more uniform DIC illumination with this device than with the standard lamp housing (U-LH100L-3-5), which cannot be focused or adjusted.

2. Minimize sample drift by bolting a mechanically stable, rigid stage to the microscope frame.

   If a motorized stage with linear encoders is used, it is easy to repeatedly return to the same position on the sample, a feature that is useful for marking appropriately transfected cells.

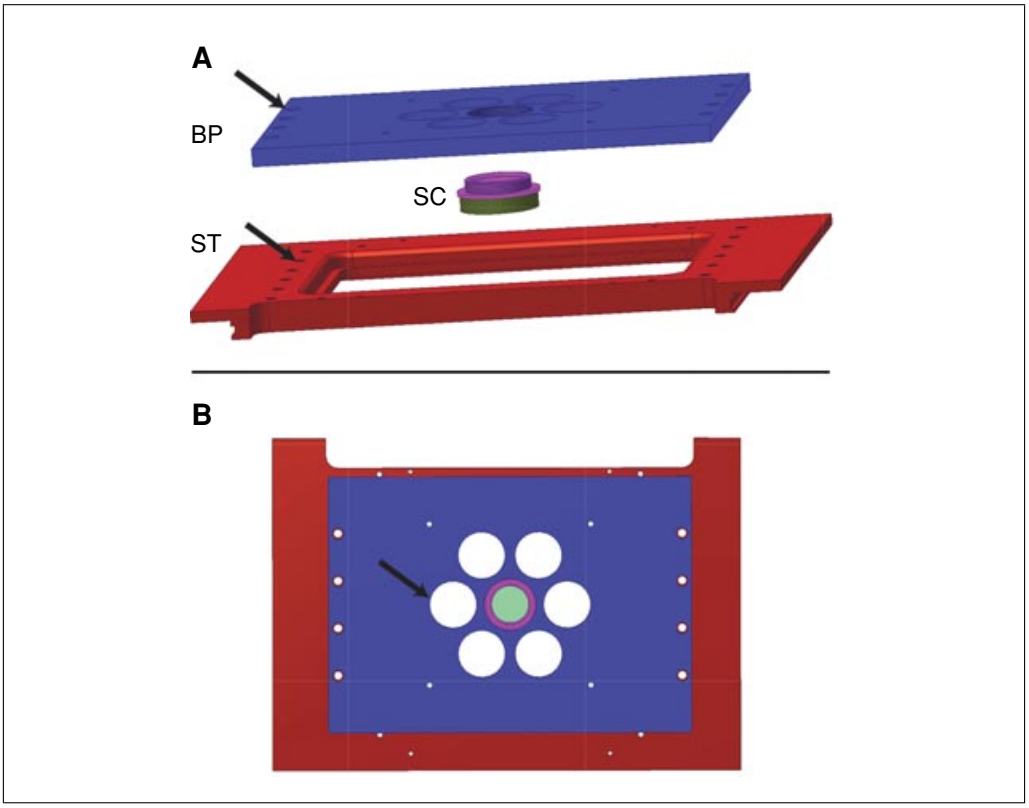

Figure 4.21.4 Sample holder assembly. (**A**) The sample holder in PALM consists of a sample chamber assembly (SC, shown in more detail in Figure 4.21.5), that is threaded and fits into a top, steel baseplate (BP). The BP contains holes that are sized appropriately so that it can be bolted into the threaded holes of the ASI stage (ST) with appropriately threaded screws. Holes for bolting BP to ST are shown with arrows. (**B**) Bird's eye view of the sample holder. Additional access holes in BP (arrows) are useful for cleaning out old immersion oil from the bottom surface of SC (as might accumulate with the high-index oil used with the 1.65 NA objective), while keeping the BP bolted to ST.

Although most stages come with a variety of inserts for convenient sample loading, use of clips to hold down the sample should be avoided. A more stable option is to design a baseplate that can be bolted to the stage (Fig. 4.21.4), and a threaded coverslip holder that contains the sample (Fig. 4.21.5) and that can be attached firmly to the baseplate.

The authors use an MS-2000 XY stage with linear encoders (ASI). The stage is bolted to the IX-81 frame directly above the objective, and a baseplate holding the sample chamber (that holds the sample-containing coverslip) is bolted to the stage.

TIRF excitation scheme

3. Select appropriate laser wavelengths for activating and exciting the PA-FP chosen as the PALM-label. Use solid-state diode lasers to provide ample power at a reasonable cost.

   Almost all available PA-FPs are activated efficiently at 405 nm; thus a laser with this wavelength is required. For PALM-imaging EosFP, a 561-nm laser is also advised, as it can be used for excitation of the activated (orange) state (an Argon/Krypton mixed gas laser has a 568-nm laser line, which is closer to the 580-nm absorption peak of EosFP, but this laser is also considerably more expensive than a 561-nm diode laser).

   A 488-nm laser is also very useful for imaging the inactive state of EosFP (i.e., for imaging the distribution of EosFP at the diffraction limit before PALM-imaging and determining which cells are expressing the fusion protein at the desired levels), and is essential for exciting the activated (green) state of Dronpa or PA-GFP.

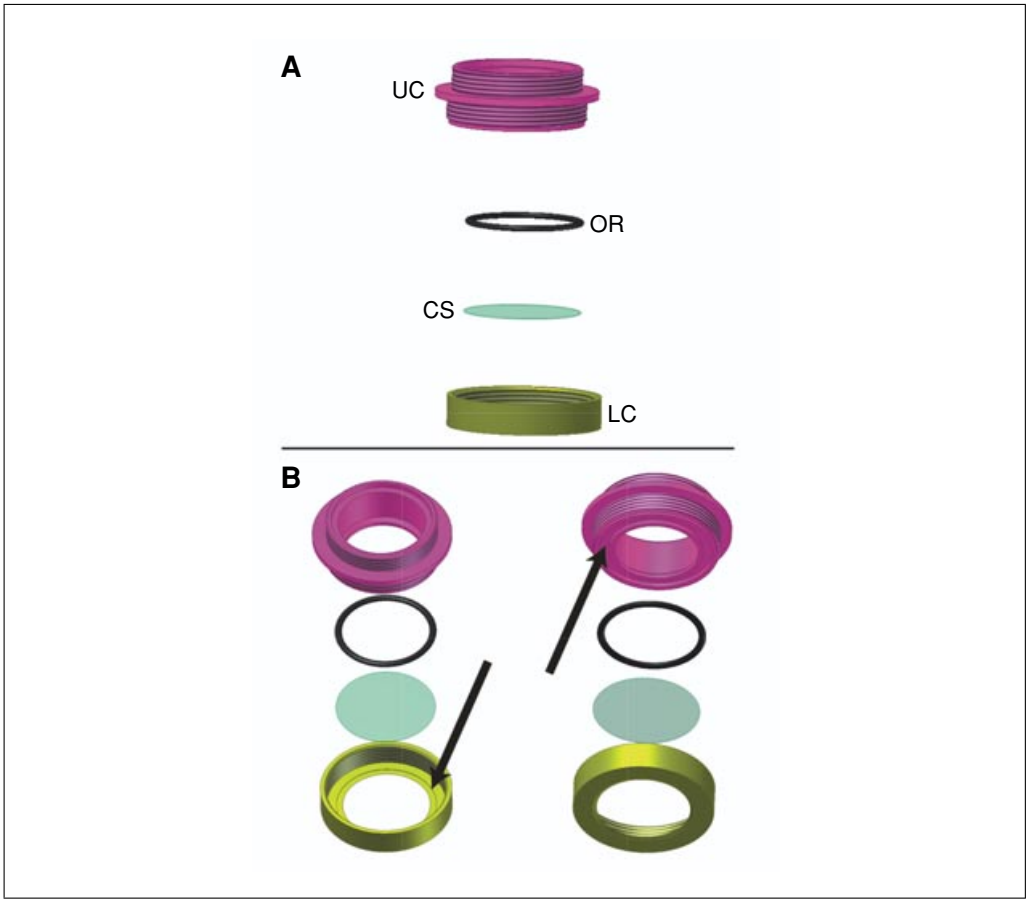

Figure 4.21.5 Sample chamber assembly. (**A**) The sample chamber used in PALM consists of upper (UC) and lower (LC) steel assemblies that thread together. Between these two components are sandwiched the coverslip (CS) containing the sample, and an O-Ring (OR). OR prevents leaks when CS is immersed in buffer. (**B**) Different perspective view of the sample chamber assembly, with grooves in UC and LC for OR and CS indicated with arrows.

The authors use a 50-mW 405-nm laser (Coherent, 405-50C) for activation, a 150-mW 561-nm laser (Crystalaser, GCL-150-561) to excite the active state of EosFP, and a 50-mW 488-nm laser (Newport Spectra-Physics Cyan Scientific Laser) for imaging the inactive state of EosFP or the activated state of Dronpa. The characteristics from these diode lasers are not always as advertised: the mode quality may be poor and the intensity may drift slightly. For PALM, these characteristics are not critical, as long as enough power is available to excite or activate molecules in the desired region at the sample. However, a particularly poor beam profile may be difficult to focus at the back focal plane (BFP) of the objective without clipping, may be hard to co-align with the other laser beams, and may thus impede successful TIRF illumination of the specimen. The authors have noticed that the beam quality from the 405-nm laser is somewhat poor; utilizing a spatial filter (a telescope system consisting of 12-mm and 50-mm focal length lenses separated by the sum of their focal lengths, and a 10-μm pinhole positioned at the intermediate image plane between the two lenses) immediately after the laser output cleans up the beam profile considerably and improves the ease with which the sample is TIRF-activated.

4. Free-space couple all lasers into a TIRF-capable illumination microscope port. Use neutral density filters and half-wave plates (FIL) to control the intensity and polarization [important for maximum transmission through the acousto-optic tunable filter (AOTF) element discussed below] of each beam. In addition, use a narrow bandpass excitation filter (Semrock LL01-488-25) with the 488-nm laser to reduce emission noise. Use beam expanders (BE) after each laser to yield a common beam diameter (important for establishing an excitation/activation region of common size at the sample).

   One possible coupling scheme is shown in Figure 4.21.6 (reproduced from the supporting information in Shroff et al., 2007). Activation and excitation lasers are indicated by their respective wavelengths. Beam expanders are made from achromatic lenses (Edmund Scientific) mounted in $^1/_2$-in. diameter lens tubes (Thorlabs).

5. Combine the 488-nm and 561-nm excitation beams with a dichroic beamsplitter (DC) prior to passage through an acousto-optic tunable filter (AOTF), then combine excitation beams with the 405-nm activation beam with a second dichroic beamsplitter (DC).

   An FF-506-Di02-25 × 36 (Semrock) dichroic beamsplitter is used to combine 488-nm and 561-nm beams before the AOTF.

   The AOTF serves as a rapid switch to select between wavelengths, and can also be synchronized to the frame acquisition cycle of the detection EMCCD (discussed further below) in order to minimize photobleaching during the read-out period between frames.

   Synchronization can be easily achieved by connecting the Fire output signal from the EMCCD detector to the AOTF input. The AOTF output beam in turn is combined with the 405-nm activation beam using a second dichroic beamsplitter (Semrock, FF458-Di02-25×36). The reason for combining the activation beam with the excitation beams in a position downstream of the AOTF is that the AOTF used does not transmit wavelengths <450 nm efficiently. Goniometer (Thorlabs, cat. no. GN05)–mounted glass windows (CVI Inc.; 2 windows/goniometer, each 12.5-mm diameter, 5-mm thick) are used to fine-adjust the position of each beam (TX, TY), thereby facilitating their mutual overlap, and the assorted dichroic beamsplitters and mirrors in the system provide further adjustment of the position and direction of propagation.

   Although it is also possible to couple all three lasers into a commercial TIRF illumination unit using an appropriate multi-wavelength fiber (e.g., the PointSource kineFlex fiber), these fibers transmit at best 50% to 60% of the incident laser light, and typically <50% due to the poor mode quality of the beams from the diode lasers. This results in excitation intensities that are too low for the fastest PALM acquisitions.

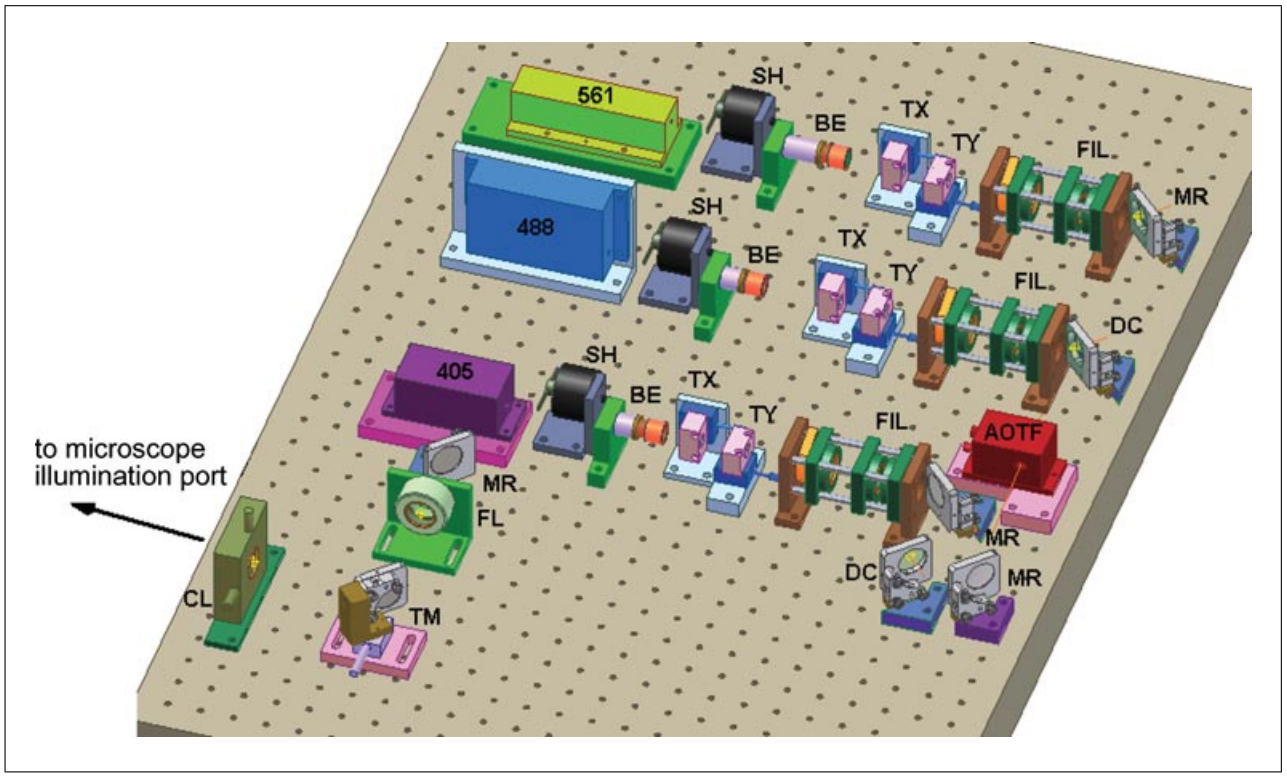

Figure 4.21.6 Scheme for coupling excitation and activation light into the microscope for PALM. Lasers 488 and 561 excite the active forms of Dronpa and EosFP, respectively, and laser 405 converts each of these PA-FPs to the active form. The remaining elements are used to overlap the three lasers beams, adjust their diameters, and ensure their mutual propagation in a common direction (see text for a more detailed discussion). Symbol key: SH = shutter; BE = beam expander; TX = x direction beam translator; TY = y direction beam translator; FIL = filter group (wavelength, intensity, and polarization); MR = mirror; DC = dichroic beamsplitter; AOTF = acousto-optic tunable filter; FL = focusing lens; TM = translating mirror; CL = collimating lens. See the text in Basic Protocol 1 for discussion. Reproduced from Shroff et al., 2007.

6. Once excitation and activation beams are co-aligned, bring them to a focus at the back focal plane (BFP) of the objective used for TIRF excitation and activation.

   This can be done with the aid of two lenses, FL (focusing lens) and CL (collimating lens; Fig. 4.21.6 and Fig. 4.21.7).

7. Position the entire laser illumination system relative to the imaging microscope such that the BFP of lens CL is coincident with the front focal plane of a 200-mm relay lens internal to the microscope (Fig. 4.21.7). By doing so, the focus created by lens FL is imaged at the BFP of the microscope objective.

   With this geometry, the image of the focus can be moved within the objective BFP using the translating mirror (TM), thereby switching between epi and TIRF modes of laser excitation without affecting the position of the spot at the sample. Lastly, by switching between lenses CL of differing focal length, and by changing the magnification of the BEs, the diameter of the beam launched into the microscope can be changed, resulting in a change in the excitation/activation spot size, and thus the laser intensity, at the sample. Small spots can be used to achieve fast single-molecule frame rates (~10 to 20 msec), or large spots can be used to image at slower rates but over larger fields of view.

   The commercial Olympus IX-81 TIRF Illuminator can be conveniently modified and stripped down to conform with the guidelines presented above. This system is usually attached to the rear port of the IX-81. The authors use the U-DP attachment (Olympus) to switch between arc lamp and TIRF illumination (Fig. 4.21.7), but only the 200 mm relay lens in the TIRF illuminator is necessary—the entire fiber-coupling assembly can be removed.

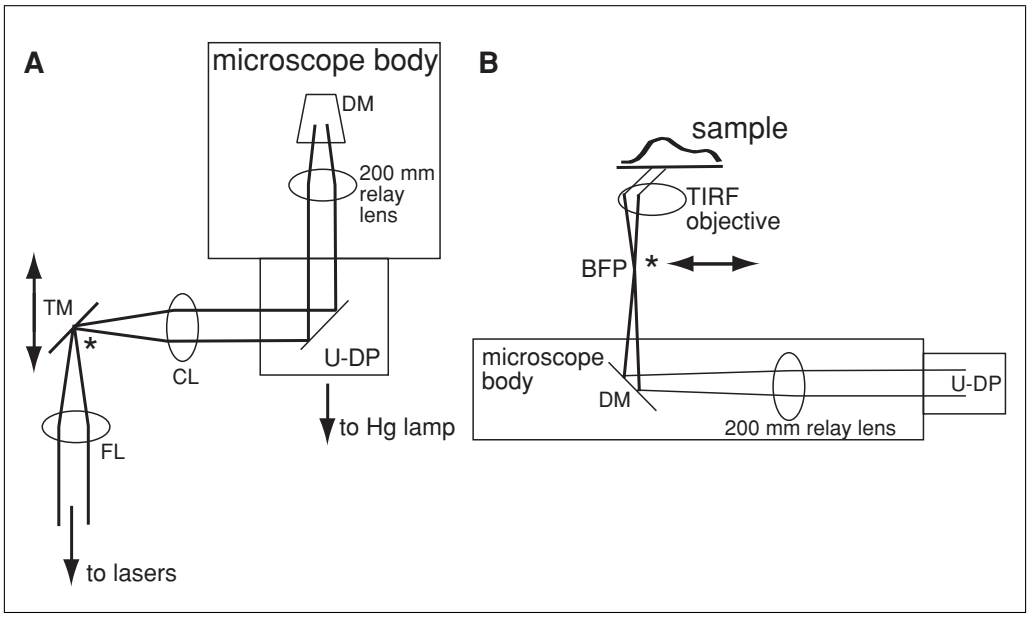

Figure 4.21.7 Cartoon view of the optical path used for TIRF illumination. (**A**) Bird's eye view. Laser light is focused by lens FL, reflected from mirror TM, and recollimated by lens CL (note that these 3 optical elements are shown also in Figure 4.21.6). It enters the microscope back port via the Olympus U-DP attachment (used for switching between TIRF and mercury or xenon lamp illumination), whereby a single 200-mm relay lens (internal to the microscope body) focuses the light onto the back focal plane (BFP) of the objective, via the dichroic mirror (DM) in the filter cube assembly (not shown for clarity). (**B**) Side view of the light path after the U-DP. Light focused at the objective BFP emerges from the objective (shown as a single lens for clarity) as parallel rays, illuminating the sample at a critical angle in TIRF. Note that the focus at the BFP of the objective and the focus created between CL and FL are located in conjugate planes (indicated by the asterisks in the cartoon); translating TM thus serves to translate the focus at the BFP, allowing easy switching between epi- and TIRF configurations without changing the location of the illumination spot at the sample. See the text in Basic Protocol 1 for discussion.

Excitation, dichroic, and emission filters

8. Carefully choose excitation, dichroic, and emission filters to maximize the fluorescence signal while rejecting excitation light.

   The use of lasers can sometimes preclude the use of excitation filters, as the excitation light is already quasi-monochromatic. However, occasionally, broadband emission noise generated in the laser cavity or autofluorescence generated elsewhere in the optical path necessitates the use of narrowband excitation filters.

9. Select the dichroic filter to simultaneously reflect both activation and excitation wavelengths (so that time is not wasted in switching dichroics between activation and excitation steps during the PALM-imaging), while transmitting the much weaker fluorescent emissions with high efficiency.

10. Finally, select the emission filter to provide >6 OD suppression of excitation light and activation light, while maximally transmitting the fluorescence emission.

    Bandpass emission filters have been found to better suppress the excitation light than longpass filters, such as Raman edge filters. Dichroic and emission filters can be conveniently combined in a fluorescence filter cube holder and placed within the microscope in a standard filter cube turret, but excitation filters must be placed upstream of the dichroic.

    For PALM-imaging the activated state of EosFP, the authors use the dichroic FF562-Di02-25×36 (Semrock) and the bandpass emission filter FF01-617/73-25 (Semrock). For imaging the inactive state of EosFP or the activated state of Dronpa, the dichroic T495lp (Chroma) and the bandpass emission filter ET525/50 (Chroma) are used; equivalent results can be obtained with a standard GFP filter cube set.

High NA objectives

11. To achieve TIRF, the NA of the objective lens must be greater than the index of refraction *n* of the sample (typically 1.38 for cellular components). The number of objectives that satisfy this criterion are limited, and practically the investigator is limited to objectives of NA 1.45, 1.49, and 1.65 (the last manufactured exclusively by Olympus).

    Higher NAs imply both better photon collection efficiency and an increased range of angles over which TIRF is achieved (wider TIRF annulus). Better photon collection efficiency results in a greater signal-to-noise ratio and thus higher localization precision of individual molecules. A wider TIRF annulus leads to a greater range of adjustment of the evanescent wave decay length, and makes achieving TIRF easier than with a more limited annulus, as it is easier to focus a spot at the BFP of the objective without clipping the beam. The investigator is thus urged to purchase the objective with the highest possible NA, subject to the constraints discussed below.

    It is important to note that the 1.65 NA objective, while providing substantially better TIRF than other objectives, requires expensive high-index ($n = 1.78$) coverslips (APO100X-CG, Olympus), and high-index ($n = 1.78$) immersion oil (Series M, Cargille). The oil is toxic to work with, requiring gloves and added safety precautions, and the coverslips are expensive and difficult to reclean. The oil also absorbs in the visible spectrum, particularly at the 405-nm activation wavelength. It thus degrades over time and may need to be replaced during an experiment. Degradation is exacerbated at higher laser powers and elevated temperatures, making this objective unsuitable for experiments on living cells and for the fastest PALM imaging (where increased power is necessary to bleach activated molecules as fast as possible). Obtaining high-quality DIC images with this objective is problematic, as it is not strain-free. Furthermore, it is not a plan objective, so care must be taken to image the specimen near the center of the field-of-view; otherwise aberrations degrade the quality of the point spread function (PSF) and thus limit the localization precision. Despite these caveats, the authors have observed >1.5× photon collection efficiency of the 1.65 NA objective compared to a 1.49 NA objective and significantly lower autofluorescence of the high-index coverslips compared to the more conventional glass coverslips used with the lower NA objective. The authors thus recommend the 1.65 NA objective for PALM-imaging fixed samples when the PALM image quality is of paramount importance and when acquisition time is not critical. For applications when high-quality DIC is important, on living cells that require 37°C, or when speed is critical, the 1.49 NA objective is the better choice.

    When using 1.45 or 1.49 NA objectives, it is important to use the correct immersion oil and coverslip thickness in order to minimize image aberrations (especially spherical aberration). Most high NA oil objectives are designed to work with no. 1.5 thickness glass coverslips; the authors use 25-mm no. 1.5 coverslips from Warner Instruments (cat. no. 64-0715). Index-matched immersion oils can be obtained from Cargille Laboratories—the authors recommend using type DF immersion oil, as it has very low autofluorescence and minimizes aberrations (type FF oil is marginally less autofluorescent, but introduces slight aberrations in the PSF).

EMCCD camera

12. To take full advantage of the wide-field TIRF geometry in PALM and to amplify the single-molecule fluorescence emissions from PA-FPs, use an electron-multiplying cooled CCD (EMCCD) camera as the detector.

    These cameras are capable of single-photon detection, as they employ an on-chip multiplication gain that boosts weak signals above the readout noise of the camera. Furthermore, fast (up to 10 MHz/pixel) readout and the ability to operate the camera in frame-transfer mode (spooling acquired data to disk while simultaneously acquiring new data) allow rapid PALM-imaging. The ability to cool the chip to −50°C or less ensures that dark noise (thermal motion of charges in the sensor that can be spuriously counted as photons) is negligible. Most chips can also be purchased with a back-illuminated option (light impinges on the back side of a thinned CCD instead of the front side), leading to a quantum efficiency (the ratio of incident to detected photons) of ∼90% across the visible spectrum.

Many single-molecule fluorescence laboratories use EMCCD cameras from Andor Technology. Several options exist, with different pixel sizes, chip sizes, and readout speeds. The investigator should consider the total system magnification (important in optimizing localization accuracy, discussed below) and desired imaging area before deciding what chip to purchase.

The authors use a DV887ECS-BV (Andor Technology) as the EMCCD, operating in frame-transfer mode and with 10 MHz A/D readout speed. A 512 × 512 pixel chip with 16-μm pixels and a system magnification of 120 offers a total field-of-view of ~70 μm. In practice, a smaller region of the chip is used for imaging (typically 128 × 128 or 256 × 256 pixels) for decreased acquisition time and decreased file sizes.

Optimizing system magnification

13. When localizing single molecules, it is important to match the pixel size of the EMCCD camera to the size of the point spread function (PSF, the diffraction-limited image of a point emitter). If the pixel size is too large, the molecule's PSF will be concentrated within too few pixels (undersampled), and there will not be sufficient spatial resolution to determine the center of the PSF precisely. Conversely, if the pixel size is too small, the PSF will be spread out across too many pixels, and the signal/noise per pixel will be too low to precisely determine the PSF center. The best choice is a pixel size that is approximately equal to the standard deviation in the PSF—see Thompson et al. (2002) for a more complete discussion.

    Given the different magnifications of the high NA objectives mentioned above (typically 60× or 100×), it is thus often necessary to increase the total magnification of the imaging system to meet the above criterion. This is accomplished either by the use of internal magnification lenses in the microscope system (usually either a 1.6× or 2× system), or a magnification system placed immediately between the camera and microscope port.

    When imaging with the 100×, 1.65 NA objective, the authors employ a 1.2× C-mount adaptor (Diagnostic Instruments, DD12NLC) before the EMCCD for a total system magnification of 120×. When using the 60×, 1.49 NA objective, the authors employ a 2× internal magnification lens and a 1.2× C-mount adaptor for a total magnification of 144×. The effective pixel size when using the camera mentioned above is thus 133 or 111 nm depending on the objective used.

Computer hardware and software requirements

14. A computer with sufficient RAM, processor power, and hard drive space to process and store the stack of single-molecule frames that make up an eventual PALM image is essential. Additionally, the computer must have a slot for a digital acquisition card—the Andor EMCCD cameras typically come with their own card (PCI format). Minimum requirements for running the Andor EMCCD are a 2.4 GHz Pentium processor, 1 GB of RAM, and Microsoft Windows 2000 or XP. An analog output board and/or USB interface may be useful for controlling the power of activation and excitation lasers.

    The authors use an industrial computer (Advantech) with 2 GB RAM, a dual-core 3 GHz processor, and a 320 GB hard drive. As PALM images are typically composed of tens of thousands of single-molecule frames (corresponding file sizes can easily be >5 GB, especially if large fields of view are imaged), large hard drives are necessary for initial storage of data—the authors thus recommend purchasing as large a hard drive as possible. For long-term storage of PALM data, a server with larger storage capacity is recommended. A fast connection to archival storage is also helpful, to prevent long delays while transferring data.

15. As PALM imaging is expedited by simultaneously activating the PA-FPs and exciting them, in principle no sophisticated software is needed to independently control or shutter the lasers. The Andor EMCCD cameras come with software [Andor Solis (i)] that is sufficient for acquiring PALM single-molecule image stacks, but in practice it may be desirable to develop integrated software that allows the user to control

the laser power (via analog or TTL control), camera acquisition parameters (EM gain, exposure time, and total number of recorded frames), and shuttering for the lasers.

16. As recording a long series of single-molecule frames can be relatively taxing on a computer, the authors perform the localization analysis and image rendering post acquisition using a different computer and appropriate analysis software. With efficient coding, it may be possible to perform the analysis in real-time, or close to real-time, thus eliminating the need for transporting large data files to a different analysis computer. The basic strategy in rendering PALM images is to replot each molecule *m* as a Gaussian centered at coordinates $\mathbf{x}_m$, $\mathbf{y}_m$ and of width $\boldsymbol{\sigma}_m$ (the latter represents the positional uncertainty, or standard error on the mean position of the molecule), where $\boldsymbol{\sigma}_m$ is typically much less than the positional standard deviation in the original diffraction-limited PSF, $\mathbf{s}_m$. The relevant analysis can be broken down into several steps. First, intensity peaks in the raw data that correspond to individual molecules (or fiducial markers, see Basic Protocol 2 below) are identified. This identification allows image data corresponding to a molecule to be summed across all frames and pixels in which the molecule appears. Second, $\mathbf{x}_m$, $\mathbf{y}_m$ and $\boldsymbol{\sigma}_m$ are determined by fitting the summed intensity data to a Gaussian mask, according to the theory described in Thompson et al. (2002). If fiducial markers are used in the experiment, these parameters can be corrected for sample drift during the acquisition. Finally, the molecules are rendered as Gaussians whose brightness indicates the probability that the molecule can be found at a given location. A more complete description of the analysis software is beyond the scope of this unit, but the reader is directed to the supplementary information in Betzig et al. (2006) for more detailed information.

BASIC PROTOCOL 2

PALM-IMAGING tdEos/PAXILLIN DISTRIBUTIONS IN FIXED CELLS

This protocol describes the PALM imaging of tdEos/paxillin distributions in fixed fibroblast cells. The protocol can be broken up into several steps. First, the cells must be transiently transfected with the tdEos/paxillin plasmid and plated onto appropriately cleaned coverslips. Although the cells can be transfected with common chemical reagents—e.g., Lipofectamine (Invitrogen), Effectene (Qiagen), FuGENE (Roche)—the authors have had far better success with the Nucleofection kit from Amaxa Biosystems, routinely achieving transfection efficiencies of >70% with high cell viability. Cleaning coverslips, plating cells, and subsequent transfection are covered in Support Protocols 1 and 2. Second, the transfected cells must be chemically fixed under conditions that preserve as much of the native cellular structure and EosFP fluorescence as possible. The fixation procedure described below is a modification of the protocol described in Galbraith et al. (1998). Finally, the fixed, transfected cells are PALM-imaged with a microscope similar to that described in Basic Protocol 1.

Although the example described here is the imaging of tdEos/paxillin in HFF-1 cells, the protocol is general: the authors have successfully adapted it for PALM-imaging vinculin, actin, α-actinin, and zyxin in CHO and NIH 3T3 cells.

Materials

EM grade paraformaldehyde
Clean water (filtered through a Millipore system)
10 N NaOH solution
2× PHEM buffer (see recipe)
Cleaned coverslips (Support Protocol 1) plated with HFF-1 cells transfected with tdEos/paxillin, in 35-mm plastic dishes (Support Protocol 2)

Immersion oil
100-nm and 40-nm Au particles (Microspheres-Nanospheres, cat. nos. 790114-010 and 790122-010)

Chemical hood
1-liter glass beaker
Hotplate with magnetic stirring capability
Magnetic stir bar
0.2-μm filter
37°C warm room or equivalent heating system
Fine steel forceps
Microscope set up (as described in Basic Protocol 1)
Lens paper
EMCCD camera (see Basic Protocol 1)
Benchtop vortexer/sonicator

Fix transfected cells

1. Prepare 4% paraformaldehyde (PF) solution by adding 4 g PF to 100 ml clean water in a glass beaker. Place the beaker (with a magnetic stir bar) on a hotplate, and heat the solution to ~80°C while stirring. Carefully add 80 μl of 10 N NaOH (this is necessary to fully dissolve the PF) to the mixture. When the PF appears dissolved, filter the solution using a 0.2-μm filter to remove any residual solid particulates.

   The investigator should wear gloves, and this procedure should be conducted in a fume hood, as paraformaldehyde is quite toxic. Monitor the solution carefully, as it should be kept from boiling.

2. Prepare 2% (v/v) PF/1× PHEM buffer (fixative) by combining the 4% PF and 2× PHEM solutions in equal volumes. Also prepare 1× PHEM by combining 2× PHEM and clean water in equal volumes. Heat the fixative and 1× PHEM to 37°C.

   Fresh fixative should be prepared daily for best morphological preservation of the cells.

3. Transfer the 35-mm dish containing the transfected sample (Support Protocol 2) from the incubator to the warm room. Gently pipet the growth medium off the cells and replace it with 1 ml prewarmed fixative. Incubate for 15 min at 37°C, then wash the coverslips three times, each time with 1 ml 1× PHEM.

   Pipetting/removing solutions should be done gently to ensure that cells are not ripped from the coverslip. Care should be also taken to ensure that the coverslip is completely immersed in liquid, so that it does not dry out.

Identify transfected cells that are suitable for PALM

4. With forceps, carefully lift and transfer the fixed sample from the 35-mm plastic dish to the sample holder and microscope stage. Immerse the sample in 1× PHEM once the sample is placed in its holder (to prevent it from drying out) and wipe off the bottom surface of the coverslip (the side that will face the objective) with lens paper (it is essential that water and immersion oil do not mix during the imaging).

5. Apply the appropriate immersion oil to the chosen TIRF objective.

6. Focus on the cells with the microscope eyepiece, using either brightfield or DIC optics.

7. Start the acquisition software and cool the EMCCD camera to −50°C or lower.

   The authors have not noticed a significant decrease in dark noise below −50°C.

8. At the maximum gain of the EMCCD, use the 488-nm laser at low power in combination with the GFP filter cube to scan the sample in TIRF and identify cells that express tdEos/paxillin fusion proteins. If a stage with linear encoders is used, note the positions of suitable cells so that they can be easily found later.

   As paxillin forms distinctive finger-like structures at the cell surface, identification of transfected cells should be straightforward.

   Note that because EosFP switches its fluorescence from green to orange upon photoactivation, the green fluorescence (excited by 488-nm light) provides a convenient monitor of protein expression at the diffraction-limited level, and can be used to screen cells to decide if they are suitably transfected for PALM.

   The determination of the 488-nm power to use in this step is empirical and depends on the particular experimental configuration. Generally, the authors use as low a power as possible in illuminating the sample (10 to 30 μW over an excitation region $\sim$30 μm in diameter, for intensities of $\sim$1 W/cm^2 at the sample) so as not to bleach the inactive EosFP molecules before PALM-imaging. A power meter is useful for measuring the laser power; the authors use a FieldMaxII-TO digital power meter (Coherent).

   With experience, the investigator can use the real-time intensities displayed by the camera acquisition software to determine what an acceptable level of transfection is, how much power to apply, and what exposure time should be used for minimal bleaching of the sample. Finally, note that there is often an inverse correlation between the cell health and the level of transfection; brightly fluorescent cells may not necessarily have the best morphology and vice versa. The investigator should find a cell that is sufficiently transfected but also appears to have good morphology in DIC.

9. If a suitable cell is found, prepare a 10× dilution of Au particles in 1× PHEM. Vortex the suspension until it is well-mixed (it may be necessary to also vortex the stock solution of fiducials if they have settled to the bottom of the container).

   Sonicating the mixture can also aid in breaking up Au aggregates.

   Because the Au particles are fluorescent but do not bleach during the acquisition period, they function as fiducial markers, and are important in correcting for mechanical drift during the acquisition period (Betzig et al., 2006). The basic strategy is to determine the position of the fiducials over the entire image acquisition, and to subtract these positions from the coordinates of the localized molecules when reconstructing a PALM image.

   The authors have found that 100-nm Au particles are best when imaging the orange, activated state of EosFP, whereas 40-nm Au particles are better when imaging the green, activated state of Dronpa.

   The concentration of Au fiducials (and incubation time) should be determined empirically. Generally it is best to have 2 to 5 fiducials visible in the imaging field of view when PALM-imaging—their positions can be averaged and used to remove drift more accurately than if only one fiducial is found. Conversely, too many fiducials impede the isolation of single molecules, as it is difficult to identify molecules located near a fiducial.

10. Carefully pipet off the 1× PHEM solution covering the coverslip, and replace it with 1 ml of the Au suspension. Incubate 5 to 10 min, or long enough for the Au particles to settle and stick to the coverslip surface, at 25°C.

11. Once a suitable density of Au fiducials is achieved, rinse the sample once with 1 ml 1× PHEM.

PALM-image a suitable cell

12. Switch to the appropriate filter cube for imaging the activated state of EosFP, and illuminate the sample with the 561-nm laser. Adjust the laser power until it is sufficient for achieving good signal-to-noise (S/N) images of single activated molecules and fiducials at the desired exposure time.

The laser power should be increased until single molecules can be visualized at high S/N at a minimal exposure time. The intensity of fiducials should be comparable to single-molecule fluorescence; occasionally, it is possible that fiducials will be too dim or too bright (the latter will saturate the EMCCD, and are usually indicative of Au aggregates), in which case the investigator is advised to add more fiducials. Also, in the case of the 1.65 NA objective, a practical limit on the maximum laser power is set by the absorption in the immersion oil. The final power and exposure time are dependent on the details of the investigator's setup, and are again best determined empirically. The authors typically use ~10 mW of 561-nm power (over an excitation region 30 μm in diameter, for intensities of ~ 1 kW/cm^2) and 20 to 50 msec exposure times.

13. With the laser power and exposure time adjusted, start the PALM acquisition. Illuminate the sample initially only with the 561-nm laser beam, to bleach the small population of EosFP molecules that appears fluorescent at the start of the acquisition.

    There is a population of EosFP that is spontaneously activated (and is thus excited) at the start of any PALM acquisition. These molecules must be bleached before activating further molecules, otherwise too many molecules will be activated at once, impeding the isolation of individual molecules and degrading the localization precision (Fig. 4.21.8A).

14. Illuminate the sample with the 405-nm activation laser at low power (it may be necessary to insert neutral density filters into the beam path to reduce the laser power). As the acquisition proceeds and the pool of unactivated molecules is depleted, increase the activation power in order to keep the number of activated molecules roughly constant per frame.

    Care must be taken to ensure that the optimal number of molecules is activated per frame. If too few molecules are activated at a given time, the data acquisition is slowed down and it will take longer to acquire the complete PALM dataset (Fig. 4.21.8B). The 405-nm laser power should be increased until the molecular density per frame increases. If too many molecules are activated, the image will appear diffraction-limited, retarding localization accuracy (Fig. 4.21.8A). The 405-nm laser power should be decreased until single molecules are easily discerned. From a speed perspective, the optimal activation power occurs when molecules appear "bumper to bumper," separated just enough to be spatially resolved (Fig. 4.21.8C).

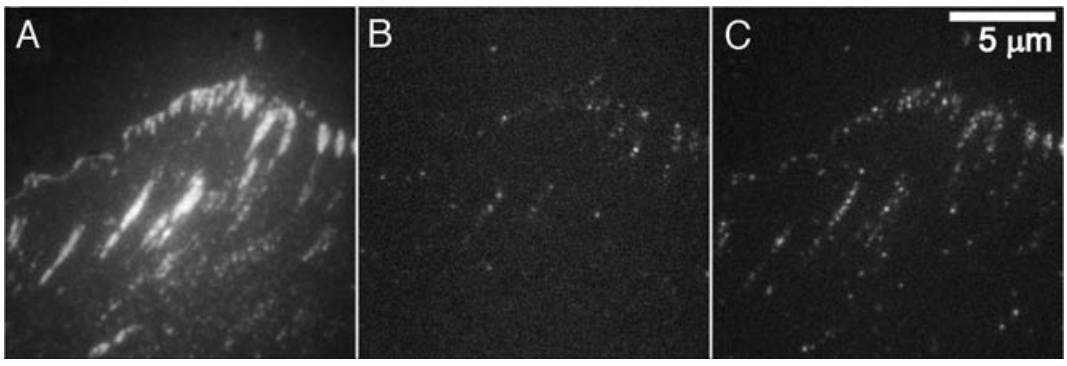

Figure 4.21.8 The effect of different levels of activation power on single-molecule frames in a PALM acquisition. Images are of tdEos/paxillin molecules in adhesion complexes, and were taken with identical excitation power and exposure time, but differing levels of activation power. In (**A**), the activation power was too high: too many molecules were activated and thus it is difficult to discern individual molecules. The image appears diffraction limited, impeding the localization of single-molecules. In contrast, (**B**) displays a frame where the activation power was too low; consequently few molecules are excited and it will take longer than necessary to excite and bleach all tdEos molecules. The optimal activation power is illustrated in (**C**), where single-molecules are in close proximity but still resolvable. For color version of this figure see *http://www.currentprotocols.com*.

15. Proceed with data acquisition, collecting frames until the population of single activated molecules becomes insignificant even at high activation laser power.

For long acquisitions, and depending on the mechanical stability of the instrument, it may be necessary to manually adjust the focus of the objective during PALM-imaging. Although several commercial auto-focus systems exist for correcting objective focus drift during data acquisition, there is always a slight time lag between when the auto-focus system is engaged and when the focus is reset to the original position. A simpler (and less expensive) alternative is to manually adjust the focus of the microscope during the PALM acquisition. A microscope system with an ultra-fine focus is useful for this purpose.

BASIC PROTOCOL 3

DUAL-COLOR PALM-IMAGING OF tdEos/VINCULIN AND DRONPA α-ACTININ IN FIXED CELLS

Single-color PALM can reveal the spatial distribution of a target protein at >10× resolution than with conventional fluorescence microscopy. While informative, cellular function is often driven by the interaction of two or more proteins. It would thus be valuable to accurately determine the spatial distribution of several interacting proteins using a multicolor superresolution technique. As described in Shroff et al. (2007), it is possible to serially PALM-image two adhesion complex proteins by tagging the first with EosFP and the second with Dronpa. This protocol shows that, with relatively few modifications, it is possible to adapt Basic Protocol 2 for the PALM-imaging of vinculin (Ziegler et al., 2006) and α-actinin (Otey and Carpen, 2004; Fig. 4.21.9).

Materials

HFF-1 cells cotransfected with tdEos/vinculin and Dronpa/α-actinin plasmid constructs (these plasmids are made in-house by the authors, but can also be obtained from Mike Davidson, Florida State University)

100-nm and 40-nm Au particles (Microspheres-Nanospheres, cat. nos. 790114-010 and 790122-010)

Additional reagents and equipment for cleaning coverslips (Support Protocol 1), transfecting cells (Support Protocol 2), and PALM-imaging both Eos (Basic Protocol 2) and Dronpa

Prepare sample

1. Follow Support Protocols 1 and 2 for cleaning coverslips and transfecting cells. Instead of using the amaxa system to nucleofect cells with only a single plasmid, cotransfect cells with both plasmid constructs.

As transiently transfecting cells with more than one expression plasmid stresses the cellular machinery more than if a single plasmid is transfected, some optimization of DNA concentration may be necessary to obtain optimal cell viability and expression level. The investigator is recommended to start with equal concentrations of both plasmid DNAs, and increase/decrease the concentration of either or both until a high percentage of cells survive the nucleofection and express enough of both proteins for good dual-color PALM-imaging.

2. Follow steps 4 to 8 in Basic Protocol 2 to identify transfected cells suitable for PALM.

As α-actinin cross-links actin stress fibers, and vinculin localizes to adhesion complexes at the termini of stress fibers, cells that are doubly-transfected should exhibit both morphologies (compare Fig. 4.21.9A and Fig. 4.21.9B). It should thus be possible to identify appropriately transfected cells by scanning the sample in TIRF, using the 488-nm laser.

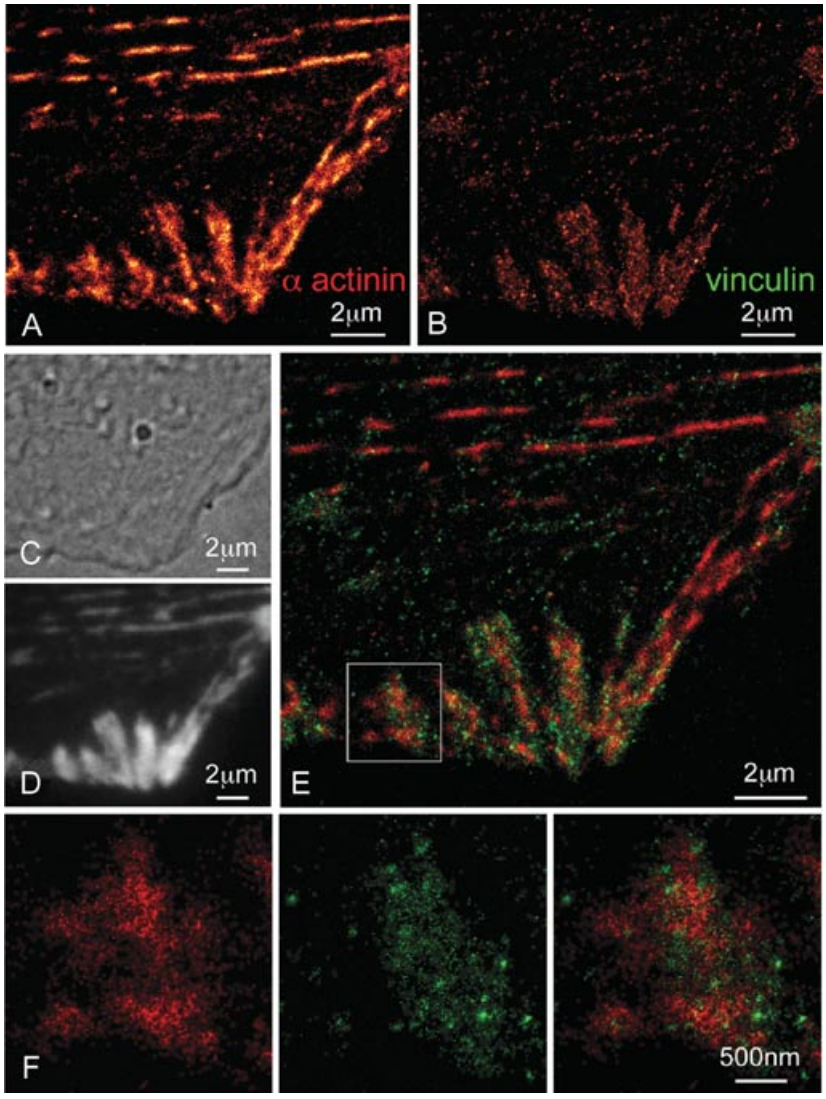

Figure 4.21.9 Dual-color PALM image of tdEos/vinculin and Dronpa/α-actinin in a fixed HFF-1 cell: (**A**) PALM image of Dronpa-tagged α-actinin; (**B**) PALM image of tdEos-tagged vinculin; (**C**) DIC image revealing morphology; (**D**) TIRF image of combined tdEos and Dronpa emission (note the distinct morphologies of α-actinin and vinculin); (**E**) dual-color PALM overlay of α-actinin (red) and vinculin (green); (**F**) α-actinin, vinculin, and overlaid PALM images within the single adhesion shown in the box in (E). Panels (E) and (F) reveal that α-actinin and vinculin only partially co-localize within each adhesion complex, with α-actinin existing in large patches emanating from stress fibers and vinculin coalescing in small, dense clusters scattered across each adhesion. Reproduced from Shroff et al., 2007. For color version of this figure see *http://www.currentprotocols.com*.

3. Prepare a 1:1 mixture of 40 nm Au particles and 100 nm Au particles, and incubate the sample with a 10× dilution as described in steps 9 to 11 of Basic Protocol 2.

   As both Eos and Dronpa are to be imaged, it is useful to include both kinds of fiducials. For registering both Eos and Dronpa images post-acquisition, it is essential that some fiducials show up in both Eos and Dronpa channels.

PALM-image the Eos channel

4. Follow steps 12 to 15 in Basic Protocol 2 to PALM-image the Eos channel. Ensure that all Eos molecules are bleached before proceeding.

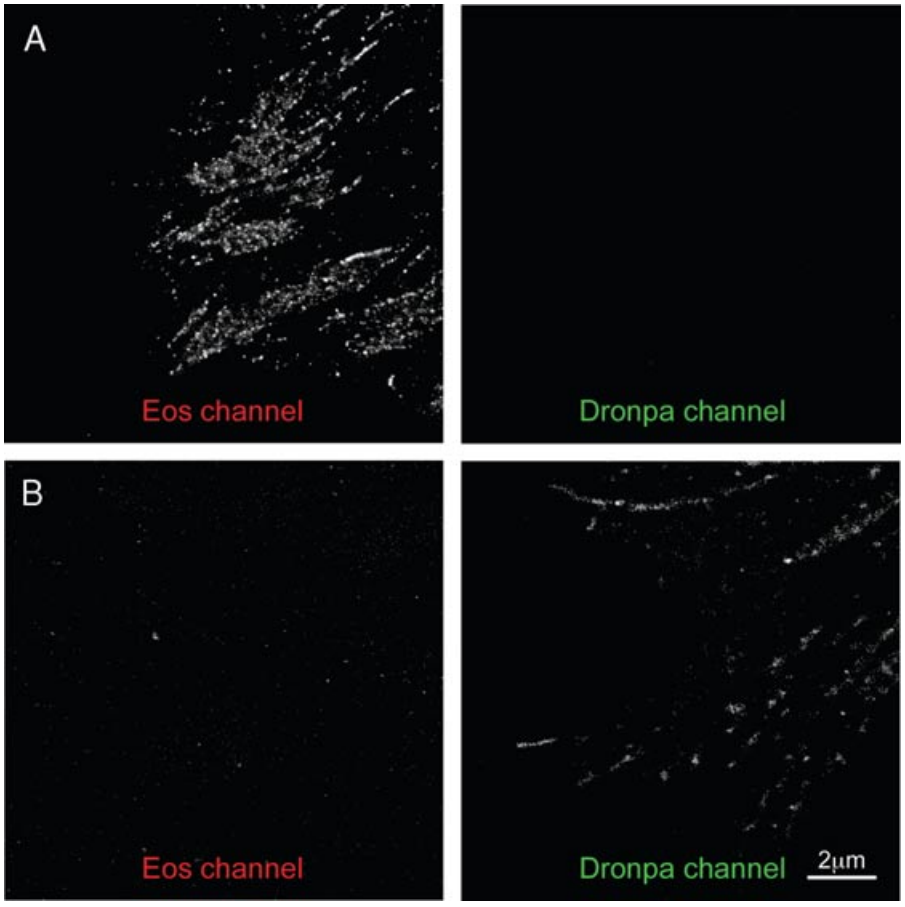

Figure 4.21.10 Crosstalk control experiments. (**A**) Left: Eos channel PALM image of tdEos-tagged paxillin in an HFF-1 cell. Over 221,000 molecules were localized over 100,000 frames. Right: Dronpa channel PALM image of the same cell. 8900 molecules were localized over 50,000 frames. Note the negligible misidentification of Eos as Dronpa. (**B**) Left: Eos channel PALM image of Dronpa-tagged paxillin in an HFF-1 cell. 7800 molecules were localized over 50,000 frames. Right: Dronpa channel PALM image of the same cell. Over 22,000 molecules were localized over 8200 frames. The number of detected molecules in the Eos channel in (B) is comparable to that found in untransfected control cells. In all cases, the Dronpa channel image was obtained after the EosFP channel image, and the images from both channels are plotted at identical brightness and contrast. Reproduced from Shroff et al., 2007.

As the technique described in Shroff et al. (2007) is serial, it is important to thoroughly activate and bleach the tdEos/vinculin molecules before attempting to PALM-image the Dronpa/α-actinin. Otherwise, residual Eos molecules that fluoresce in the green channel will be incorrectly identified as Dronpa molecules. The authors recommend doing control experiments akin to those described in Figure 4.21.10, to gain an intuition for what the background should look like in the Eos channel after all Eos molecules are bleached, and before PALM-imaging the Dronpa channel. Such crosstalk control experiments are also a good check to ensure that fluorescence emission filters are optimized and that bleed-through of one fluorescent tag onto the other channel is negligible.

PALM-image the Dronpa channel

5. Turn off the 405-nm and 561-nm lasers. Switch to the GFP filter cube for imaging Dronpa. Start the acquisition software and illuminate the sample with the 488-nm laser.

Initially, the pool of Dronpa molecules that were activated during the course of PALM-imaging Eos will fluoresce, contributing a bright green background and making it difficult

to discern single Dronpa molecules. Within several hundred frames (depending on the exposure time and laser power used), this background should die down, as Dronpa molecules are driven into a dark state with prolonged exposure to 488 nm. Ensure that the imaging area appears mostly dark (there are always some Dronpa molecules that are spontaneously active and appear to blink during the acquisition) before proceeding to the next step.

The high-index immersion oil used with the 1.65 NA objective is considerably less tolerant to 488 nm than 561 nm, as the absorption is greater in the bluer portion of the spectrum. Consequently, it is recommended to use a lower laser power with 488 nm than with 561 nm. The choice of how much power to use is best determined by the investigator. The authors use 3 to 5 mW (measured prior to the entrance of the objective) and 50 to 100 msec exposure time.

6. After the bright background of activated Dronpa molecules dies down, turn on the 405-nm laser at lower power. Follow steps 14 and 15 of Basic Protocol 2, gradually ramping the 405-nm laser power until all Dronpa molecules have been activated and bleached.

PREPARING CLEAN COVERSLIPS

SUPPORT PROTOCOL 1

For PALM experiments, the coverslips upon which the cells are grown should be cleaned as thoroughly as possible. This is because debris deposited on the coverslips is often excited by the activation and excitation lasers, and will contribute either to elevated background counts in each frame or as spurious single-molecule fluorescence. This protocol describes a chemical cleaning method based on the industry standard for removing contaminants from semiconductor wafers. It is considerably less reactive (and hazardous) than other cleaning methods, but still adequate for PALM-imaging. Although 1% hydrofluoric acid (HF) is suitable for cleaning conventional glass coverslips in ~5 min (see supporting information in Betzig et al., 2006), it reacts with the high-index coverslips used with the 1.65 NA objective, rendering them opaque and unsuitable for imaging.

Materials

Ammonium hydroxide
Hydrogen peroxide
Clean water (filtered through a Millipore system)
Methanol (spectroscopic grade)
Clean air supply (preferably filtered through a 0.2-μm pore-size filter)
RBS-35 liquid detergent concentrate (Pierce, cat. no. 27950)
Acetone (spectroscopic grade)

Chemical fume hood
100-ml graduated cylinder
250-ml glass beaker
25-mm diameter glass coverslips, no. 1.5 (Warner Instruments, cat. no. 64-0715; for use with 1.45 NA or 1.49 NA objectives)
High-index 20-mm diameter coverslips (Olympus, cat. no. APO100X-CG; for use with 1.65 NA objective)
Hotplate with magnetic stirring capability
Magnetic stir bar
Corrosion-resistant staining rack for holding coverslips (Thomas Scientific, cat. no. 8542E40)
Metal tongs for holding staining rack
Fine steel forceps
Compressed butane/natural gas, burner, and lighter

1. In a chemical fume hood, use a 100-ml graduated cylinder to prepare the etch solution by combining 125 ml clean water, 25 ml ammonium hydroxide, and 25 ml hydrogen peroxide in a 250-ml beaker. Heat the mixture to 80°C, and add a bar for stirring.

   The investigator should wear gloves, and take care to avoid exposing the skin to the corrosive solvents used in the cleaning solution.

2. Load the staining rack with coverslips and place it into the etch solution with the metal tongs. Let the coverslips incubate at least 3 hr (overnight is preferred for high-index coverslips) while stirring.

3. Fill another 250-ml beaker with clean water and carefully transfer the rack into the new beaker. Rinse the rack with copious amounts of clean water (at least 10 beaker volumes). Dispose of the cleaning solution appropriately.

4. Carefully remove a cleaned coverslip from the rack with the steel forceps (holding the coverslip near the edge) and rinse both sides with methanol.

   The methanol can be conveniently stored in a squeeze bottle and squirted onto the coverslip.

5. Rapidly remove excess methanol from the coverslip by blowing it away with the filtered air.

   A pipet tip can be connected with tubing to the air supply and used as an aid in blowing away the methanol.

6. Connect the burner to the butane (or natural gas), and light. Pass the coverslip quickly through the topmost portion of the flame, and repeat this process three times.

   The coverslip should be dry (or almost).

   Care must be taken not to hold the coverslip too long (more than a second) in the flame, otherwise it may crack due to thermal shock.

7. Store the cleaned coverslip dry in a clean staining rack. Repeat steps 4 to 6 with the rest of the coverslips. Cover the filled staining rack to prevent dust from settling on the coverslips, and store dry until the coverslips are ready for use.

8. The high-index coverslips are expensive, but can be recleaned and reused several times. Store used coverslips in a 2% solution of RBS detergent solution, and rinse with copious amounts of clean water before repeating steps 1 to 4. Before repeating steps 5 to 7, sonicate the coverslip for 5 min in acetone and rinse well with clean water.

SUPPORT PROTOCOL 2

TRANSFECTION OF tdEos/PAXILLIN INTO HFF-1 CELLS

Using the Nucleofector 96-well shuttle system (amaxa biosystems), HFF-1 cells are nucleofected with plasmid DNA in accordance to the manufacturer's guidelines for optimal viability and transfection efficiency. Nucleofection of lower passage cells harvested while in log growth, with highly purified DNA, results in transfection efficiencies >70%.

NOTE: All solutions and materials coming into direct contact with live cells must be sterile and proper aseptic technique should be used accordingly.

NOTE: All incubations are performed in a humidified 37°C, 5% CO_2 tissue culture incubator unless otherwise specified.

Materials

70% ethanol
Human plasma fibronectin diluted in 1× PBS (without divalent cations)
1% (w/v) BSA/DMEM HG, heat-inactivated (see recipe)

HFF-1 growth medium (see recipe)
0.05% (w/v) trypsin-0.53mM EDTA
Cell Line 96-well Nucleofector Kit SE (amaxa, VHCA-1001) containing:
SE solution
Supplement
Plasmid: tdEos/paxillin (~0.5 to 1 μg/μl)
Normal human foreskin fibroblast (HFF-1) cells (ATCC cat. no. SCRC-1041) grown in 75-cm^2 cell culture flasks with 0.2-μm vent caps for 2 to 3 days before transfection

Compressed butane/natural gas, burner, and lighter
Fine steel forceps
Cleaned coverslips (see Support Protocol 1)
35 × 10–mm cell culture dishes
37°C water bath
1.5-ml microcentrifuge tube *or* 15-ml conical centrifuge tubes
Centrifuge capable of 90 × *g* (Eppendorf 5810 or equivalent)
Centrifuge rotor (Eppendorf 5810 A-4-62 or equivalent)
Rainin LTS pipets (0.1 to 200 μl)
Rainin LTS tips (RT-L10F and RT-L200F)
Nucleofector 96-well shuttle system (amaxa biosystems)

Additional reagents and equipment for performing a viable cell count (*UNIT 1.1*)

Pre-coat coverslips with 10 μg/ml fibronectin (day 1)

1. Spray forceps with 70% ethanol and pass through flame of ignited butane gas to sterilize. Use forceps to transfer each cover slip to a 35 × 10–mm dish. Add ~200 μl of 10 μg/ml fibronectin-1× PBS solution to coverslip surface and store overnight at 4°C.

Transfect cells (day 2)

2. Remove fibronectin solution and block coverslips with 200 μl heat-inactivated 1% BSA-DMEM. Store 1 to 2 hr at room temperature.

3. Remove BSA solution and add 1.5 to 2.0 ml HFF-1 growth medium per dish; incubate 30 to 60 min at 37°C in humidified 5% CO_2 to equilibrate dishes to culture conditions prior to plating cells.

4. Prewarm the HFF-1 growth medium and trypsin-EDTA in a 37°C water bath.

5. Acclimate the amaxa Nucleofector Kit SE and plasmid to room temperature.

6. Mix the volume of Nucleofector SE solution required by experiment. Use a mix ratio of 162.5 μl SE solution to 36 μl 96-well supplement. A total of 20 μl is required per shuttle well.

7. Use 5.0 ml trypsin-EDTA to detach HFF-1 cells per 75-cm^2 tissue culture flask. Neutralize cell suspension with an equal volume of HFF-1 growth medium.

   Before harvest, cells should be ~70% confluent.

8. Count an aliquot of the cells (*UNIT 1.1*) and calculate the volume sufficient to nucleofect 4 to 5 × 10^5 live cells per shuttle well. Transfer cell suspension to microcentrifuge tube(s) and centrifuge 7 min at 90 × *g*, room temperature.

   If a larger volume of cell suspension is required, a larger 15- ml conical centrifuge tube may be used to centrifuge cells.

   Per manufacturer's recommendation, one spin-down is preferred.

9. Carefully, remove all fluid from the pellet and gently resuspend the cells in 20 µl Nucleofector SE solution (prepared in step 6) per 4 to 5×10^5 live cells. Add ~1 µg plasmid DNA per 20 µl of Nucleofector SE solution. Gently mix cells, plasmid, and nucleofector solution. Load 20 µl per shuttle well.

   Per manufacturer recommendation, the volume of plasmid solution should not exceed 2 µl per shuttle well.

   Rainin RT-L10F tips are recommended by manufacturer for loading shuttle wells. Avoid creating air bubbles.

10. Load plate in amaxa apparatus, select program DS 137, and initiate nucleofection.

11. Upon completion of nucleofection, remove shuttle plate and add 80 µl HFF-1 growth medium (from dishes prepared in step 3) per shuttle well. Place shuttle plate inside incubator. After 10 min, transfer contents of each shuttle well to a pre-equilibrated 35-mm dish (prepared in step 3) and gently dispense cell suspension on top of coverslip surface.

12. Incubate plates at 37°C in 5% humidified CO_2.

    Cells are imaged ~24 to 36 hr post-nucleofection.

REAGENTS AND SOLUTIONS

Use ultrapure water purified by reverse osmosis and Millipore Milli-Q system in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

BSA, 1% (w/v)/DMEM HG (heat-inactivated)

Prepare 1% (w/v) BSA fraction V (EMD OmniPur 2930) in high glucose DMEM (DMEM HG) without phenol red (Cellgro, 17-205-CV) supplemented with 4 mM L-glutamine. Heat for 30 min at 56°C and filter with a 0.2-µm cellulose acetate filter. Store up to 1 month at 4°C.

HFF-1 growth medium

High glucose DMEM without phenol red (Cellgro, 17-205-CV)
15% (v/v) FBS
4 mM L-glutamine
Store up to 1 month at 4°C

PHEM buffer, 1×

60 mM PIPES
25 mM HEPES
10 mM EGTA
2 mM $MgCl_2$
Adjust pH to 6.9 using NaOH
Store up to 1 year at 4°C

COMMENTARY

Background Information

Resolution considerations in PALM

The ultimate resolution achievable in PALM (Betzig et al., 2006), stochastic optical reconstruction microscopy (STORM; Rust et al., 2006), and fPALM (Hess et al., 2006) is dependent on two criteria: the localization precision (how well the center of each PSF can be determined) and the density of available photoactivatable molecules.

In the case of negligible background, it can be shown (Thompson et al., 2002) that the error in the PSF center determination is inversely proportional to the square root of the number of collected photons. Thus, a photoactivatable tag that emits 100-fold more photons

than another would give a 10-fold increase in localization precision. Indeed, synthetic fluorophores such as Cy3 yield $>10^6$ collected photons and enable localization down to ~1.5 nm (Yildiz et al., 2003) in ideal conditions. Maximizing the collection efficiency of the instrument (with high NA objectives and appropriate filters and camera) while rejecting background (with TIRF) is thus critical for high localization precision.

Although a high number of collected photons are desirable from a localization standpoint, in practice other factors (errors in the PSF fit, drift correction, background due to other fluorescent tags present at high density, or autofluorescence of the sample) limit the localization precision to ~10 nm for the majority of photoactivatable molecules. Furthermore, from the perspective of PALM-imaging as fast as possible, it is undesirable to use a tag that emits too many photons, as it takes a longer time to bleach the tag. Molecular bleaching is in fact the rate-limiting step in acquiring more data, as a given tag should be bleached before another can be activated and imaged in the same diffraction-limited region (DLR).

EosFP is well-matched to PALM needs: using the 1.65 NA objective and TIRF, >1000 photons are collected on average per molecule. This is enough photons to localize most molecules to within 20 nm (>85% of the molecules in Figure 4.21.1 are localized to within this precision), but not so many photons that molecules persist over too many frames. In contrast, Dronpa emits too few photons per switching cycle, and the localization precision and thus resolution are compromised as a result [compare Dronpa and Eos images in Shroff et al. (2007)].

Besides localization precision, the other key determinant of resolution is the density of molecules. According to the Nyquist-Shannon sampling theorem (Shannon, 1949), the sampling interval (mean distance between neighboring localized molecules) must be at least twice as fine as the desired resolution; otherwise, the feature of interest will be undersampled and unresolved. For example, in two dimensions (applicable for PALM-imaging adhesion complex systems), to achieve 10-nm resolution, molecules must be spaced 5 nm apart in each dimension, for a minimum density of 4×10^4 molecules/μm^2 or ~2000 molecules in a DLR of 250-nm in diameter.

As mentioned in the introduction, PA-FPs are better suited to achieving these densities than caged dye conjugated antibodies, as although caged dyes are often smaller than PA-FPs, the large size of antibodies still limits the densities that can be practically achieved. This situation may change if small-molecule labeling strategies (Chen and Ting, 2005; Giepmans et al., 2006) improve to the point where caged dyes can be routinely attached to a target protein with very high specificity.

Regardless of the labeling strategy (endogenous PA-FPs, exogenous caged dyes, or the cyanine dyes used in STORM), another factor that influences both the maximum achievable density and the localization precision is the contrast ratio, which is the ratio in fluorescence intensity between the inactive and activated states of the photoswitchable molecule. If the contrast ratio is less than the density of the probe in a given diffraction-limited region, the weak intensity from the inactive molecules will overwhelm the intensity from a single activated molecule, confounding both localization and the measurement of densely labeled samples. Figure 4.21.2 illustrates the contrast ratio for four common PA-FPs, showing that the large contrast ratio of Eos, which has been shown to be capable of measuring densities as high as 10^5 molecules/μm^2 (Betzig et al., 2006), or sufficient for 10-nm resolution, results in superior images, both at the single-molecule and PALM levels. The contrast ratio has not been measured for most photoswitchable molecules, but based on the reports so far, EosFP is the only PA-FP able to achieve imaging resolutions <20 nm. Note that the synthetic caged dye Q-rhodamine has a very high contrast ratio (see supporting material in Betzig et al., 2006), and that a new rhodamine-amide with very high contrast ratio has been recently reported (Fölling et al., 2007).

Critical Parameters and Troubleshooting

Although increasing the density of expressed PA-FPs is desirable from the standpoint of the Nyquist criterion and to increase spatial resolution, the investigator should be wary of overexpression artifacts. In some cases, the size of the PA-FP tag may affect the function of the target protein deleteriously. Controls should be done to ensure that the morphological and kinetic characteristics (shape, growth, and motility) of the transfected cells used for PALM-imaging are as close as possible to their untransfected neighbors. As mentioned in Strategic Planning, expressing non-monomeric PA-FPs at high density may also lead to increased aggregation, so the investigator is urged to interpret all PALM results with care.

Transfected cells should be imaged as soon as possible after fixation. The authors have noticed a pronounced decrease in sample fluorescence several hours post-fixation, presumably due to degradation of the PA-FPs. As a decreased number of detected molecules leads to a decrease in the final resolution, the authors fix samples immediately prior to imaging. Also, morphology of the cells is better preserved if fresh fixative is made daily.

During the acquisition period, the most critical parameter to control is the degree of photoactivation at the sample. If too many molecules are photoactivated simultaneously (Fig. 4.21.8A), it will be difficult to localize each one precisely, leading to decreased resolution in the final PALM image. This problem is easy to diagnose by carefully monitoring the acquisition as it proceeds: if the sample is diffraction-limited in appearance, and the investigator cannot make out the blinking and bleaching that is characteristic of single-molecule fluorescence, the activation power is likely too high and needs to be reduced until single-molecule fluorescence is visible (Fig. 4.21.8C). The authors avoid this problem by starting each PALM acquisition with the activation laser off; only after most molecules are bleached is the activation laser turned on, and at a very low power.

Another important consideration that has been neglected in several recent reports is the importance of the drift correction procedure. Uncorrected drift manifests itself as a blur in the final PALM image. Especially for longer acquisitions, and depending on the mechanical stability of the system, mechanical drift can be >100 nm. It is thus critical to measure and then correct the drift if the desired spatial resolution is to be better than this.

Both the degree of photoactivation and drift correction are important when performing dual-color PALM, but now the investigator must also ensure that the population of Eos-tagged molecules are completely bleached before PALM-imaging the Dronpa channel, or else the Eos molecules will be spuriously identified as Dronpa molecules. As illustrated in Figure 4.21.10, after bleaching out the Eos channel, the level of background counts in the Dronpa channel should be comparable to the background measured in an untransfected cell.

Anticipated Results

When a TIRF microscope is adapted for PALM as described in Basic Protocol 1, EosFP is used as the photoactivatable tag, and the guidelines in Basic Protocol 2 followed, the investigator can expect PALM images similar to Figure 4.21.1, with high (~20 nm) spatial resolution. Following Basic Protocol 3 leads to dual-color superresolution imaging of adhesion complexes, and images akin to Figure 4.21.9. If laser power is not limiting, single-color PALM experiments on living systems are feasible, because molecules can be activated and bleached fast enough to track slowly evolving processes (e.g., adhesion complex dynamics that evolve on the timescale of tens of seconds) at superresolution. Dual-color, superresolution imaging of live cells awaits the development of new, spectrally distinct PA-FPs; because the approach outlined in Basic Protocol 3 is serial, it cannot be used in simultaneous two-color imaging. The authors expect that, in time, PALM will yield new biological insights, especially for those systems that can be densely labeled and are easily amenable to TIRF. For thicker specimens such as tissues, methods will need to be developed for sectioning (either optical or physical) of the sample, PALM-imaging the individual sections, and reassembling the three-dimensional PALM image.

Time Considerations

Clean coverslips are prepared in ~12 hr (Support Protocol 1). It takes an additional 12 hr to coat the cleaned coverslips with fibronectin. Once cells are ready for transfection (see Support Protocol 2), it takes ~1 hr to perform the amaxa transfection and then a further 24 to 48 hr before expression levels are suitable for PALM. Imaging takes between 5 to 30 min if high laser powers are used to bleach the activated molecules, although this time depends on the size of the desired field of view, and the density and number of expressed PA-FPs. Sample preparation thus constitutes the bulk of the preparation time in PALM.

Culturing MDCK Cells in Three Dimensions for Analyzing Intracellular Dynamics

Natalie Elia[1] and Jennifer Lippincott-Schwartz[1]

[1]Cell Biology and Metabolism Branch, National Institute of Child Health and Human Development, National Institutes of Health, Bethesda, Maryland

ABSTRACT

Epithelial cells grown in three-dimensional (3-D) cultures of extracellular matrix differentiate into a multicellular structure of polarized cells. This process shares many characteristics with the physiological development of an epithelial tissue and the formation of polarity in epithelial cells. Imaging 3-D cultures of polarized epithelial cells is therefore a powerful tool to study epithelial architecture and morphogenesis under close-to-physiological conditions. The new generation of confocal microscopes allows live-cell imaging of fluorescently tagged molecules in these cultures. This opens up new opportunities for studying how molecules behave and are distinguished asymmetrically within a 3-D setting. This unit discusses technical aspects for culturing and imaging MDCK 3-D culture for both fixed 3-D cultures and live-cell imaging. *Curr. Protoc. Cell Biol.* 43:4.22.1-4.22.18. © 2009 by John Wiley & Sons, Inc.

INTRODUCTION

Madin-Darby canine kidney (MDCK) cells embedded in extracellular matrix (ECM) form three-dimensional (3-D) cultures. These cultures are spherical cysts characterized by a hollow lumen surrounded by one layer of polarized cells (Fig. 4.22.2C). 3-D MDCK cultures recapitulate numerous features of epithelial tissues in vivo (O'Brien et al., 2002; Debanath and Brugge, 2005) and therefore provide an ideal model system to study epithelial morphogenesis and polarity under physiological conditions in a tissue culture dish.

Live-cell imaging of 3-D MDCK cultures using fluorescently tagged proteins provides a unique opportunity to study the intracellular dynamics of proteins in these cells.

This unit describes fluorescence-based techniques to image intracellular proteins in fixed and live 3-D cultures using confocal fluorescent microscopy. It begins by describing the general requirements for fluorescent imaging of these cultures. Then, a protocol for plating and growing MDCK 3-D cultures for both fixed and live-cell imaging is provided. Next, an indirect immunostaining protocol is described. A live-cell imaging protocol is then discussed, including the optimal settings for imaging different fluorescently tagged proteins and the more advanced live-cell imaging techniques of fluorescence recovery after photobleaching (FRAP) and fluorescence loss in photobleaching (FLIP).

STRATEGIC PLANNING

Culture Conditions

Conditions for growing MDCKII cells (herein referred to as MDCK) in 3-D cultures are described in this unit. Other MDCK clones may require different conditions for 3-D culture formation.

Current Protocols in Cell Biology 4.22.1-4.22.18, June 2009
Published online June 2009 in Wiley Interscience (www.interscience.wiley.com).
DOI: 10.1002/0471143030.cb0422s43

Because MDCK cells may lose their ability to form a 3-D culture when they are subjected to repeated trypsinization cycles, it is important to use low-passage cells and to have a large number of frozen aliquots for each cell type.

Fluorescent Tags

Imaging a fluorescently tagged protein in live 3-D cultures usually requires that the protein already be stably expressed in the MDCK cells. This is because it is very difficult to transfect 3-D cultures with the conventional transfection reagents (i.e., Lipofectamine, Fugen6) after the cultures are formed. In addition, transiently transfecting the cells before plating them in collagen is very inefficient because the level of the over-expressed protein usually drops by the time the 3-D cultures are formed and ready to be imaged (4 to 9 days later). To obtain the best high-quality images, the protein of interest should be tagged with a bright fluorescent protein that is not sensitive for photobleaching, such as EGFP. Moreover, it is best to use a clonal line strongly expressing the fluorescent protein of interest. If this is impossible, FACS sorting of the cells after transfection to enrich the population of expressing cells is recommended.

BASIC PROTOCOL 1

GROWING MDCK THREE-DIMENSIONAL CULTURES

To induce 3-D culture formation of MDCK cells, extracellular matrix components need to be provided. This protocol will describe plating of MDCK cells in a collagen I matrix, which is a major component of the extracellular matrix. Plated in collagen I, MDCK cells form 3-D cultures that further differentiate into tubes in the presence of the hepatocyte growth factor, HGF (O'Brien, 2002). This protocol describes plating of MDCK 3-D cultures in membrane filter inserts (Fig. 4.22.1B), which is best suited for immunofluorescence, or in chamber slides (Fig. 4.22.1A), which are required for live-cell imaging. For immunofluorescence, MDCK 3-D cultures may also be plated in chamber slides; however, the quality of the images will be best when the cells are plated in membrane filters due to the smaller distance of the cultures from the coverslip.

Since both protocols are very similar, they will be described as one with specific instructions for each method indicated at the necessary steps.

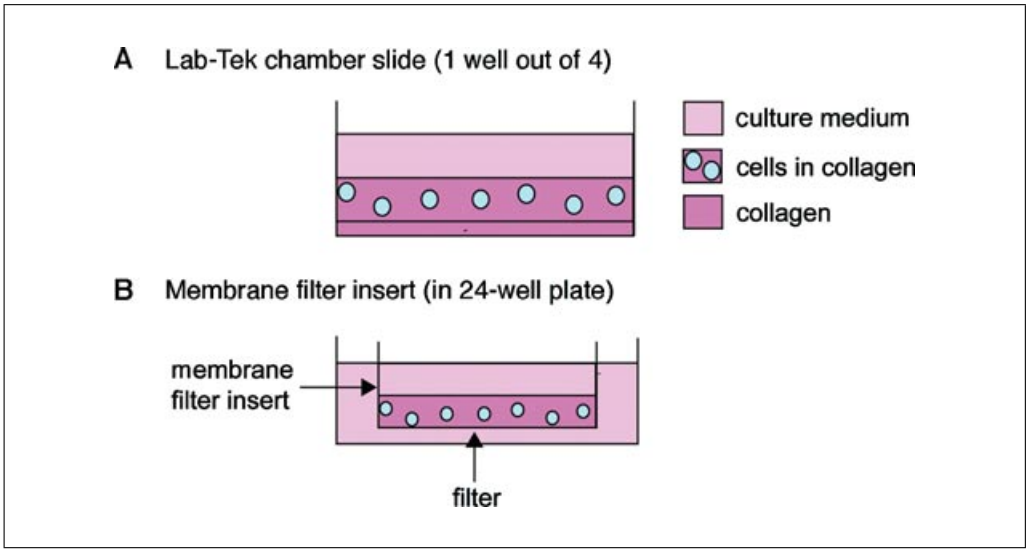

Figure 4.22.1 Schematic representations of 3-D culturing of MDCK cells plated in a chamber slide (**A**) or in a membrane filter insert (**B**).

NOTE: All solutions and equipment coming into contact with cells must be sterile, and proper sterile technique should be used accordingly.

NOTE: All culture incubations should be performed in a humidified 37°C, 5% CO_2 incubator unless otherwise specified.

Materials

MDCK II cells
MEM supplemented with 10% FBS, 2 mM glutamine, 100 IU/ml penicillin, and 100 mg/ml streptomycin
1 mg/ml of G418, optional
0.25% (w/v) trypsin/1 mM EDTA
200 mM GlutaMAX (GIBCO, Invitrogen) stock (or 200 mM glutamine)
280 mM $NaHCO_3$ in water (store at 4°C)
10× MEM without glutamine (store at 4°C)
1 M HEPES, pH 7.6
3 mg/ml PureCol purified collagen I (INAMED Biomaterials) or any highly purified bovine collagen I (store at 4°C)

Sterile tissue culture hood
10-cm tissue culture dishes
15-ml conical tube
pH indicator strips
4-well Lab-Tek chamber slide (Nalge Nunc cat. no. 155383)
37°C oven
Nunc Anapore membrane inserts (0.2-μm pore, 10-mm; Nalge Nunc cat. no. 13935)
Hemacytometer

Prepare cells

1. Grow MDCK II cells in MEM supplemented with 10% FBS, 2 mM glutamine, 100 IU/ml penicillin, and 100 mg/ml streptomycin. When using a stable cell line, add the selection antibiotic (e.g., G418 1 mg/ml).

   For stable cell lines the medium should contain 1 mg/ml of G418 or any other antibiotic that was used to generate the cell line.

2. Maintain cells by splitting every 3 to 4 days with 0.25% trypsin/EDTA (*UNIT 1.1*).

   MDCK cells should be split 1 day post-confluency (100%), after they have formed a tightly packed layer of hexagonal cells.

3. Split a post-confluent dish of MDCK II cells 1:10 to a 10-cm dish 1 day prior to plating day.

   This step is required to make sure that the cells are in their growing and proliferating stage, which is crucial for 3-D culture formation.

4. Prepare collagen I solution by combining the following in a 15-ml conical tube:

   750 μl 200 mM GlutaMAX (final 24 mM)
   625 μl 280 mM $NaHCO_3$ (final 2.8 mM)
   625 μl 10× MEM (final 1×)
   125 μl 1 M HEPES, pH 7.6 (final 20 mM)
   4.13 ml collagen I (final 2 mg/ml)
   Total volume 6.255 ml

   Mix by pipetting up and down. Verify that the pH is neutral by applying 100 μl of the collagen I solution onto a pH indicator strip. If the pH is not neutral, make a fresh

solution. Use a fresh HEPES stock. Do not try to neutralize pH because this will change the concentration of collagen in solution. Store the solution at 4°C during plating procedure to avoid premature polymerization of the collagen. Do not keep for more than a few hours.

Make a fresh collagen I solution for every experiment.

Prepare plates

5a. *For live-cell imaging.* Precoat the chamber slide with 75 to 100 µl of collagen I solution for each well of a 4-well chamber slide. Make sure the collagen solution completely covers the bottom of the chamber by tapping on the chamber. If tapping does not help, use a pipet tip to spread the solution throughout the well surface. Incubate chamber for 30 min in a 37°C oven (without CO_2). Gently tilt the dish to make sure the collagen has polymerized. If not, incubate for a longer period of time.

Precoating is a critical step for live-cell imaging because it reduces the number of cells that adhere to the coverslips and thus do not form a 3-D culture. However, precoating with too much collagen solution will increase the distance of the 3-D cultures from the coverslip, which will dramatically reduce imaging quality due to the thickness of the sample.

5b. *For immunostaining*. Place Nunc membrane filter inserts into each well of a 24-well plate.

Precoating is not necessary for this procedure.

Prepare cells

6. Trypsinize cells with 1 ml of 0.25% trypsin/EDTA for ~10 min in a cell incubator. After cells fully detached from the dish, add ~10 ml MEM growth medium.

7. Pipet cells up and down to obtain a single-cell suspension.

MDCK cells tend to form cell clumps and therefore it is often necessary to pipet them vigorously to obtain a single-cell suspension.

8. Pellet cells by centrifuging 4 min at 400 × *g*, room temperature.

9. Remove supernatant and wash cell pellet with ~5 ml medium. Repeat centrifugation in step 8.

10. Remove supernatant and resuspend cells in 2 ml medium. Pipet up and down to avoid cell clumps. Avoid bubbles.

This step is critical for obtaining uniform cultures with a single central lumen.

11. Determine cell concentration (cells/ml) using a hemacytometer (*UNIT 1.1*).

12. Add cells to the collagen solution to a final concentration of 3×10^4 cells/ml.

For live cell imaging, cells can be plated at higher concentrations (up to 6×10^4 cells/ml).

When adding the cells, make sure that the volume of cells does not exceed 10% of the collagen solution volume because the diluted collagen solution will not polymerize properly into a matrix.

Plate cells

13a. *For live-cell imaging.* Add 300 µl of collagen/cell mixture to a precoated single well of a 4-well chamber slide. Make sure that that the collagen/cell solution is evenly distributed by gently shaking the dish and avoiding bubble formation.

13b. *For immunostaining*. Apply 150 µl of collagen/cell mixture to the center of a membrane filter insert. Make sure that the collagen/cell solution is evenly distributed by gently shaking the dish and avoiding bubble formation.

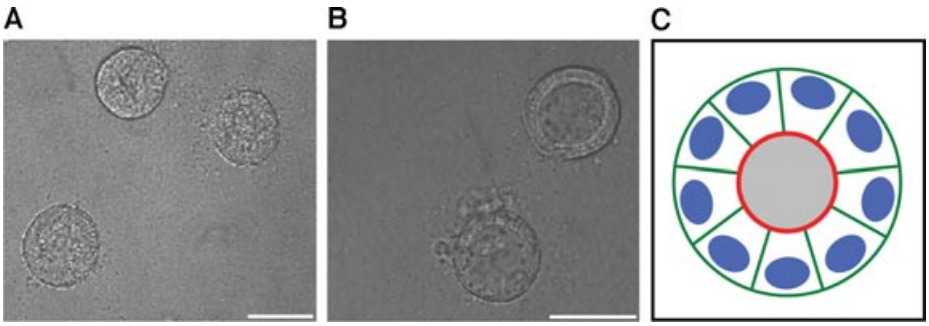

Figure 4.22.2 A bright field image of 3-D cultures of MDCK cells plated in a Lab-tek chamber slide at day 4 (**A**) and day 7 (**B**). Scale bar = 50 μm. (**C**) A schematic representation of a 3-D culture. Red, apical membrane; green, basolateral membrane; blue, nucleus; gray, lumen. For color version of this figure go to *http://www.currentprotocols.com.*

14. Incubate 30 to 45 min in a 37°C oven without CO_2.

    Collagen I polymerizes best under these conditions. Different temperatures or CO_2 levels may cause uneven polymerization that can cause variability in 3-D culture morphology in the same dish. It is therefore recommended to place the dish in the 37°C oven as soon as possible and to avoid CO_2.

    The time required for polymerization may differ between different batches of purified collagen I.

15. Gently tap the dish to make sure that the collagen has solidified and formed a gel texture.

16. After the collagen has polymerized, add culture medium to the wells and place in a 37°C, 5% CO_2 incubator.

    For chamber slides, add 500 μl to each well of a 4-well slide.

    For membrane filter inserts, add 500 μl to the inside of the insert and 1 ml to the outside (between the insert and the 24-well plate well; see Fig 4.22.1).

Maintain 3-D cultures

17. For chamber slides, change the medium every 1 to 2 days. For membrane filter inserts, change the medium every 2 to 3 days.

18. Observe the cultures for formation and development of the lumen.

    A lumen is already observed at day 4 (Fig 4.22.2) and cultures continue to develop until day 12. For a more extensive description of culture morphology, see Anticipated Results.

INDIRECT IMMUNOFLUORESCENCE OF MDCK 3-D CULTURES

BASIC PROTOCOL 2

The intracellular localization of proteins in 3-D culture may be different than that found in other systems due to differences in environmental cues and morphogenetic responses. It is therefore crucial to study the localization of endogenous proteins via indirect immunofluorescence (*UNIT 4.3*). Indirect immunofluorescence also allows for the assessment of correct cell polarity and other morphological features of the 3-D cultures prior to performing live-cell imaging experiments. Common polarity markers that specifically label certain domains in polarized cells (apical membrane, basolateral membrane, tight-junctions) should be used in indirect immunofluorescence analysis (Figs. 4.22.3 and 4.22.4). This permits detection of morphological phenotypes that may have been induced by overexpression of the protein of interest and evaluation of the quality of the

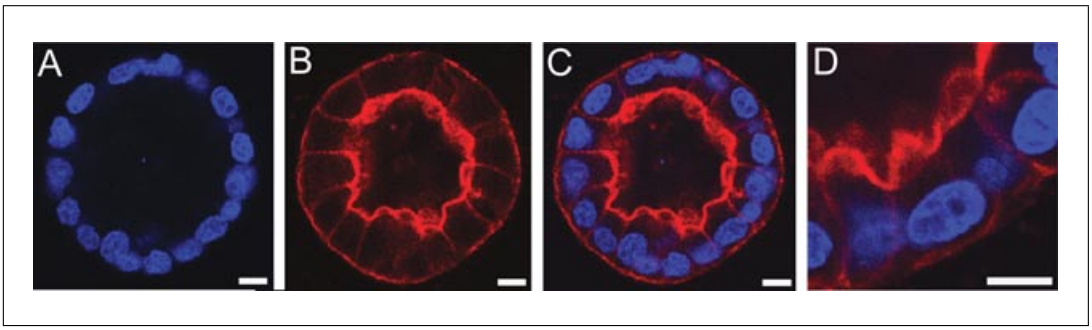

Figure 4.22.3 An immunofluorescent image of a fixed MDCK cyst in a 3-D culture at day 5. Nuclei were stained with Hoechst 33258 (blue) (**A**) and actin was stained with Texas-red phalloidin (red) (**B**). Images were taken using a 60× oil objective NA 1.4. (**C**) Merged image. (**D**) A zoomed-in image of polarized cells in the culture. Scale bar = 10 μm. For color version of this figure go to *http://www.currentprotocols.com.*

cultures. Importantly, it permits determination of whether the 3-D culture is fully polarized. Live-cell imaging of 3-D cultures that are not fully polarized may lead to misleading results.

The most commonly used method for indirect immunofluorescence of 3-D cultures involves whole-culture fixation. This approach is less time consuming and avoids extensive culture extraction that may affect culture morphology. This method is described in detail and includes recommended staining for culture evaluation.

Materials

3-D MDCK cultures on membrane inserts (see Basic Protocol 1)
1000 U/ml collagenase-1 (type CVII, Sigma cat. no. C-2799) in PBS+ stock (store in aliquots at −80°C)
PBS+: 1× PBS supplemented with 0.9 mM Ca^{2+} and 0.5 mM Mg^{2+} (store at room temperature)
4% (w/v) paraformaldehyde (PFA)
Permeabilization solution: 10% FBS, 0.5% Triton X-100 in PBS (make fresh for every experiment, store at 4°C during the experiment)
Primary antibody against protein of interest
Secondary antibody tagged with fluorophore (e.g., Alexa and Cy dyes)
Hoechst 33258 nuclear dye (Molecular Probes cat. no. H-3569)
Fluorescently tagged phalloidin (Molecular Probes; Invitrogen)
Fluoromount-G mounting solution (SouthernBiotech cat. no. 0100-01)
Clear nail polish

37°C incubator
Platform shaker
Microscope slides
Carbon steel blades
Fine forceps
Circular coverslips (18 to 25 mm)

Treat cultures with collagenase

1. To improve the permeability of the antibody through the collagen matrix, treat 3-D cultures with collagenase. Dilute a 1000-U/ml aliquot of collagenase-1 stock solution 1:10 with PBS+.
2. Wash cultures quickly three times with PBS+ (250 μl to the inside of the membrane insert and 500 μl to the outside).

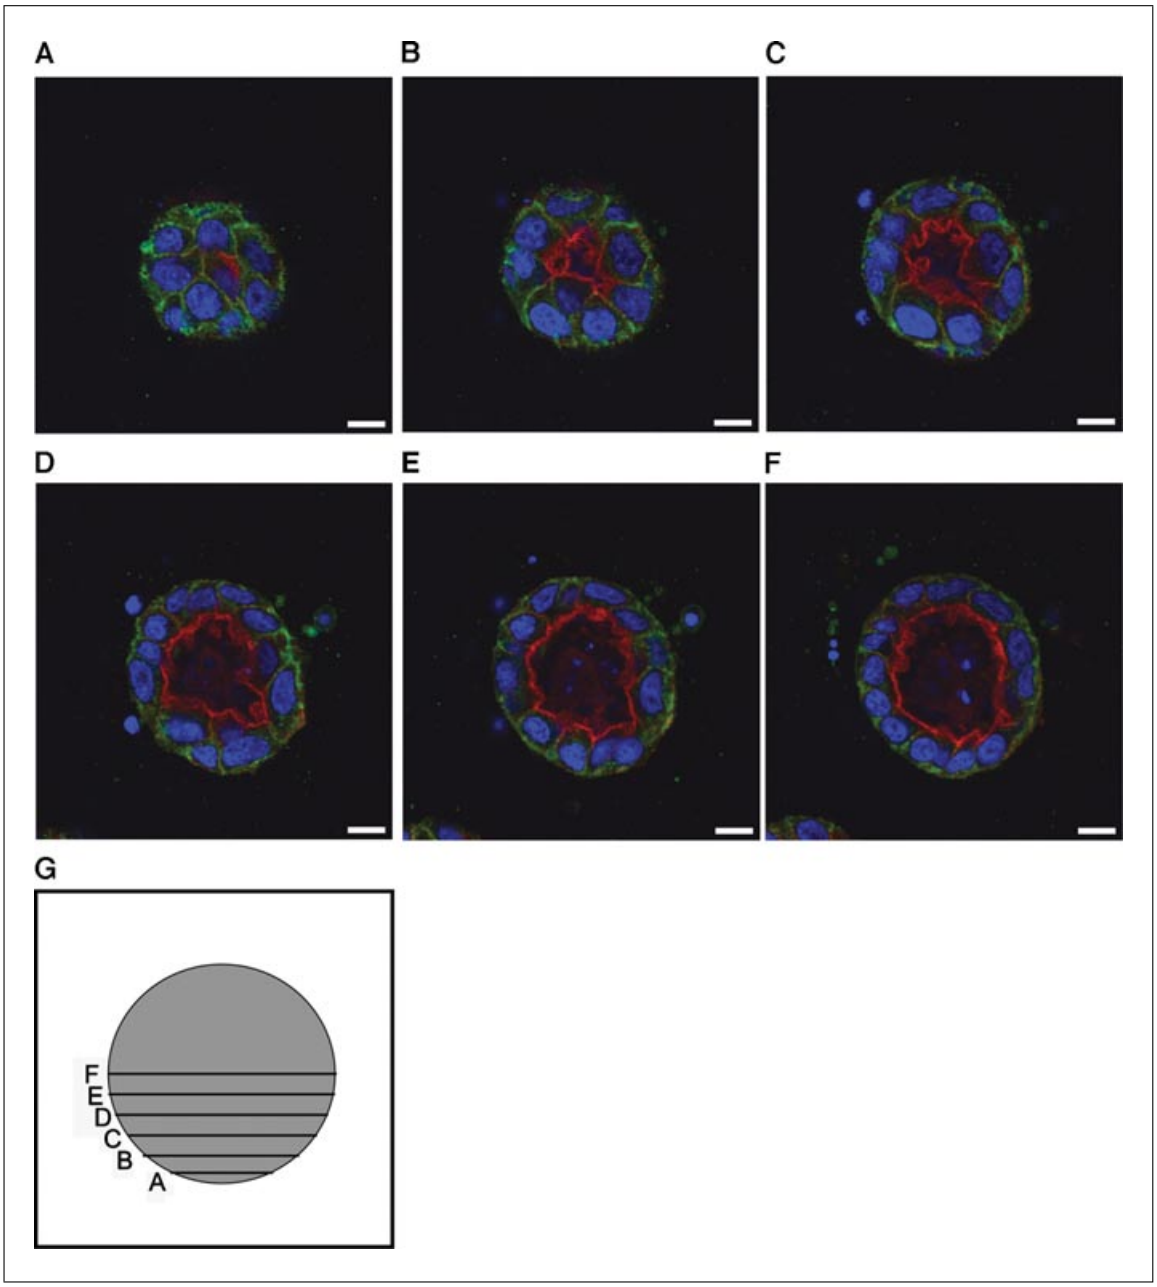

Figure 4.22.4 (**A-F**) Different optical *z* sections of an MDCK cyst in a 3-D culture from the bottom (A) to the middle (F) of the culture. Culture was fixed at day 5 and stained with Hoechst 33258 (blue), Phalloidin (red), and E-cadherin (green). (**G**) A schematic view of the different optical *z* sections shown in (A-F). Scale bar = 10 μm. For color version of this figure go to *http://www.currentprotocols.com.*

3. Apply 250 μl of collagenase-1 solution to the inside of the membrane insert and 500 μl to the outside. Incubate 10 min in a 37°C incubator. Do not incubate for longer times.

   Extensive collagenase treatment will solubilize the collagen matrix, which will make the sample difficult to work with and may affect culture morphology.

4. Wash cultures quickly three times with PBS+ (250 μl to the inside and 500 μl to the outside).

Fix cultures

5. Add 4% PFA (250 μl to the inside and 500 μl to the outside). Shake slowly for 30 min at room temperature.

6. Wash quickly three times with PBS+ followed by three 10-min washes (apply 250 µl to the inside and 500 µl to the outside).

Fixed cultures can be stored for up to 2 weeks at 4°C in 0.1% PFA.

Permeabilize and block

7. Add permeabilization solution (250 µl to the inside and 500 µl to the outside) and shake slowly for 30 min at room temperature.

Stain with antibody

8. Dilute primary antibody to the desired working dilution in permeabilization solution.

Use at least two times the concentration as that for adherent cells on a coverslip or according to manufacturer's instructions.

9. Add 200 µl diluted primary antibody to the inside of a membrane insert and 250 µl to the outside. Incubate overnight at 4°C.

Overnight incubation is usually recommended to maximize antibody permeability. Shorter incubation times (shaking for 3 to 4 hr at room temperature) may be possible in some cases.

Antibody permeability is a potential problem in whole-mount immunofluorescence of 3-D cultures since the antibody needs to penetrate the collagen polymers, the cell membrane, and the lumen in some cases. It is therefore important to use high antibody concentrations and long incubation times to increase the probability for maximal antibody staining.

10. Wash six times—three quick washes followed by three 10-min washes—with permeabilization solution (apply 250 µl to the inside of the membrane filter and 500 µl to the outside).

11. Dilute secondary antibody tagged with fluorophore to the desired working dilution in permeabilization solution.

For the Alexa and Cy dyes, a 1:400 dilution usually gives a strong fluorescence signal that is easily detectible through the collagen layer.

12. For nuclear staining, add Hoechst 33258 at a 1:1000 dilution to the secondary antibody mix.

Nuclear staining is recommended as an indicator for culture morphology.

13. For actin staining, add a fluorescently tagged phalloidin (Molecular Probes; Invitrogen) at a 1:300 dilution to the secondary antibody mixture.

Cytoskeleton staining is also recommended as a routine staining at this stage.

14. Add 200 µl secondary antibody solution to the inside of a membrane insert and 250 µl to the outside of the insert. Incubate 2 to 3 hr with shaking at room temperature.

15. Wash six times with permeabilization solution—three quick washes followed by three 15-min washes (250 µl to the inside and 500 µl to the outside).

Mount samples

16. Apply a large drop of Fluoromount-G mounting solution onto a microscope slide.

17. Cut the bottom of the membrane insert with a carbon steel blade and lift the gel carefully with fine forceps.

The membrane filters are rigid and therefore cutting them without breaking them can be difficult. Even if the filter breaks, the gel can still be lifted off the filter. It is important not to damage the collagen gel.

18. Place the gel (with or without the glass filter) onto the Fluoromount-G mounting solution drop on the microscope slide. Make sure that the top of the gel is facing up.
19. Cover the gel with a circular coverslip (18 to 25 mm). Make sure the culture is completely covered with mounting solution. If not, apply extra mounting solution to the edge of the coverslip. Avoid bubbles at all times. Avoid pressing the coverslip toward the gel.
20. Wait a few minutes to allow the mounting solution to spread and remove excess mounting solution, but be careful not to remove too much.

    If unsure, it is preferable to have some excess left.
21. Place the sample in a dark place overnight at room temperature to allow the mounting solution to dry.
22. Seal the sample with clear nail polish.

    Store samples for up to 6 months at 4°C in the dark.

IMAGING IMMUNOSTAINED 3-D CULTURES

BASIC PROTOCOL 3

MDCK 3-D cultures form a three-dimensional hollow sphere composed of a single cell layer. The average diameter of the sphere is 50 to 60 μm and, therefore, images from different focal planes should be taken and combined together to image the entire structure. This can be done by taking a series of optical sections using confocal microscopy. *Z* sectioning through a 3-D culture also allows examination of the intracellular localization of proteins in single cells. For this purpose, it is best to take an optical *z* section from the middle of the cyst (where the lumen is the largest). This optical section provides a nice cross section of the polarized cells surrounding the lumen (Fig. 4.22.4F). In this view it easy to determine whether a protein is localized to the apical, basal, or lateral membrane.

One of the difficulties in imaging whole-mount 3-D cultures is the thickness of the sample and the distance of the cells from the coverslip. This means that the imaging parameters should be adjusted very carefully to acquire the best possible images. However, even when the imaging parameters are optimized, the image quality will still be lower than imaging adherent cells on a coverslip.

Materials

Immunostained 3-D culture sample
High-resolution confocal microscope (e.g., either the Olympus F1000 or the Zeiss 510)
Oil-immersion objective: 40× NA 1.3 Plan Neofluar or UPlanFI or 60×/63× NA 1.4 Plan Apochromat oil objective
Three-dimensional rendering software for image analysis of 3-D culture cysts (e.g., Volocity software from Improvision)

Set up microscope

1. Use a high-resolution confocal microscope for imaging immunostained 3-D cultures.
2. Image immunostained 3-D cultures using an oil objective.

   A 40× NA 1.3 objective allows imaging deeper into the collagen and is therefore recommended for imaging cysts that are buried deep in the collagen.
3. To improve image quality, use a 1 airy unit pinhole size, image at low speed, average each pixel at least two times, and increase pixel resolution when necessary (>512 × 512).

4. When detailed intracellular localization is required, zoom in and focus on three to four cells of the culture and acquire thinner *z* sections (up to 50% overlap between two *z* sections).

   Imaging using these parameters can be time consuming. To save time, it is usually enough to image only one half of the cyst. If imaging half the cyst, make sure to image the half that is closer to the coverslip.

5. (Optional) Use a spinning disk confocal microscope, which enables high-speed image acquisition.

   A spinning disk confocal microscope is also recommended for imaging fine intracellular structures such as microtubules, which can be resolved better in this system.

Analyze data

6. Use a three-dimensional reconstruction of a 3-D culture cyst to provide detailed information that is not readily detectible from looking at the *z* sections separately. It is therefore recommended to use a three-dimensional rendering software for image analysis of 3-D culture cysts (e.g., Volocity software from Improvision).

ALTERNATE PROTOCOL

LIVE-CELL IMAGING OF MDCK 3-D CULTURES

Live-cell imaging of 3-D cultures is a powerful tool to study both the dynamics of cells in a culture during culture morphogenesis and the dynamics of intracellular proteins in a single cell in real time. Live-cell imaging can also be used as a more direct way to study protein localization because it gets around the need to use antibodies, which sometimes have permeability and specificity issues. This protocol details the culture conditions and the microscopy setups that are best suited for live-cell imaging of 3-D cultures.

Materials

Fluorescently labeled 3-D MDCK cultures (see Basic Protocol 1)
Collagen-coated 4-well chamber slides (Nunc; see Basic Protocol 1)
FM4-64 membrane dye (Invitrogen)

37°C incubator
37°C, 5% CO_2 incubator
Confocal microscope (for high-speed acquisition, spinning disc confocal or the Zeiss LSM live duo system)
Water objective (40× or 60× NA1.2)

Prepare cultures

1. Plate 300 µl collagen solution of fluorescently labeled MDCK cells in a precoated 4-well chamber slide as described in Basic Protocol 1. Incubate 30 to 45 min at 37°C without CO_2.

   Cultures can be imaged from day 1 to day 12 depending on the desired experiment.

2. To fluorescently label the plasma membrane of live cells in 3-D culture, apply 4 µM of FM4-64 dye to the culture medium and incubate 1 hr in a 37°C 5% CO_2 tissue culture incubator.

   Imaging 3-D cultures in bright field gives poor images (Fig. 4.22.5). It is therefore difficult to determine the cell boundaries in a 3-D culture and the subcellular localization of the protein of interest in a single cell. Fluorescence labeling of the plasma membrane outlines the boundaries of all cells in the sample and makes it easy to detect 3-D culture cysts, to distinguish between different cells in a cyst and to outline the different membranes of a single cell (apical, basolateral).

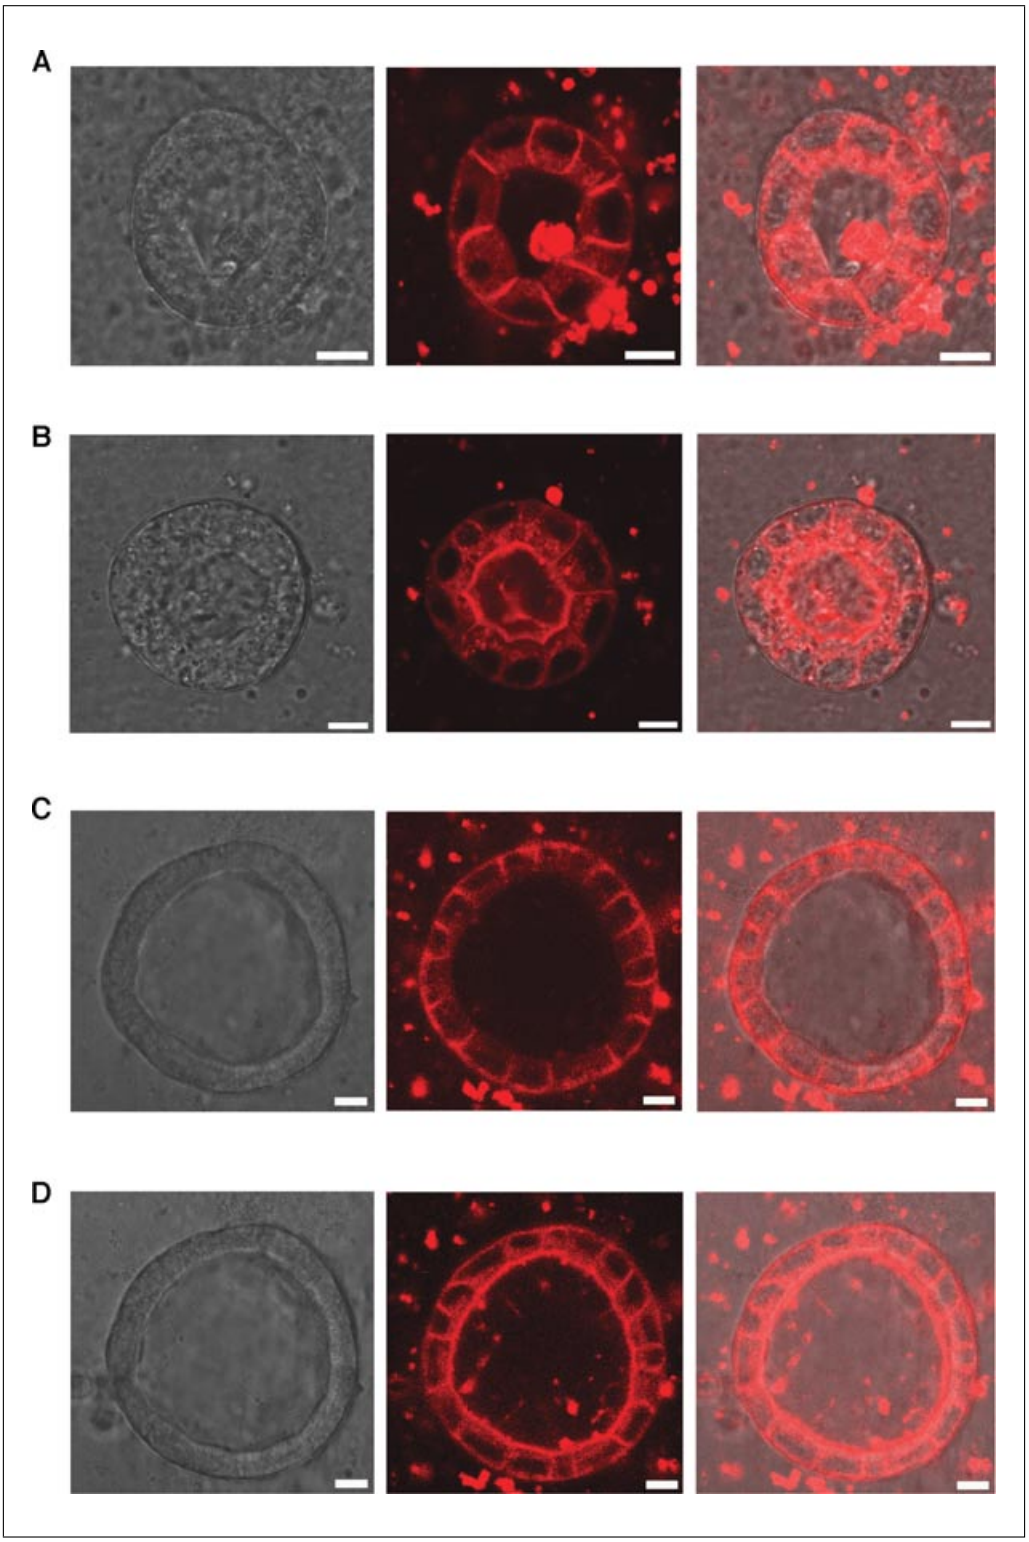

Figure 4.22.5 Live-cell imaging of MDCK cysts in 3-D cultures using the membrane dye FM4-64. (**A,B**) cultures at day 4. (**C,D**) cultures at day 6. (**A,C**) 30 min after addition of the dye the basolateral membrane is labeled. (**B,D**) 2 hr post-dye addition the apical membrane is labeled as well as intracellular endocytic structures. Scale bar = 10 μm. For color version of this figure go to *http://www.currentprotocols.com.*

The dye will initially label the basolateral membrane and than the apical membrane (60 min later; Fig. 4.22.4). During this time, the FM4-64 dye will also endocytose. The intracellular staining of the dye is stable for days and therefore this dye can be used for extensive live imaging experiments (up to several days).

Set up microscope

Live-cell imaging of collagen-embedded 3-D cultures is somewhat challenging. Both the thickness of the sample and the collagen itself lead to fluorescence light scattering and therefore high laser intensity is required to acquire an image. Imaging under these conditions makes the specimen sensitive to photobleaching of the fluorescence signal and to culture photodamage. It is therefore very important to optimize the fluorescence parameters prior to performing a live-cell imaging experiment. These parameters should be adjusted for every experiment depending on the intensity of the fluorescence signal and the condition of the cultures. There are, however, a few general guidelines that can be followed.

3. Use a confocal microscope to image live 3-D cultures. For high-speed image acquisition it is best to use either a spinning disc confocal or the Zeiss LSM live duo system.
4. Select the culture. Image only the cysts that are closest to the coverslip and have the brightest fluorescence.

   Increasing the imaging distance will greatly reduce image quality and will require higher laser intensities, which will lead to extensive photobleaching and photodamage.

   Using the cultures with the brightest fluorescence will reduce the laser intensity required for imaging and will therefore minimize photobleaching and culture photodamage.
5. Use a water objective (40× or 60× NA1.2) to maximize depth of field and minimize photobleaching.

   However, in some cases, a 63× NA 1.4 or a 40× NA 1.3 are also applicable.
6. Use line scanning, scan at low speed, average each pixel at least twice, and increase pixel resolution when necessary (>512 × 512).
7. Set up the pinhole between 1 and 1.5 airy units to give the best *z*-sectioning results. When taking a series of *z* sections, make sure the sections overlap.
8. For extended imaging (more than a few hours), use an auto-focus or a perfect-focus module to avoid focus shift in time.

   This will prevent focus drift in time and will allow detection of whole culture movement along the z axis in time.

BASIC PROTOCOL 4

FRAP AND FLIP IN MDCK 3-D CULTURES

Photobleaching techniques are highly useful to study the intracellular dynamics of proteins. In fluorescence recovery after photobleaching (FRAP), a specific region of interest (ROI) is bleached once with a high-laser intensity and the diffusion rate of the protein of interest to this region can be determined. In fluorescence loss in photobleaching (FLIP), the depicted region of interest is repeatedly bleached and the kinetics of fluorescence signal decay from different domains throughout the cell can be measured. The rate of recovery in FRAP and the fluorescence decay pattern in FLIP reflect the subcellular dynamics of the protein of interest, therefore providing a direct tool to study protein dynamics in real time (for more information, see *UNIT 21.1*). There are two critical points that should be taken under consideration when applying these techniques to 3-D cultures. First, these techniques require exposure of the sample to high laser power for long durations, which can cause extensive photodamage to the cells in the culture and extensive photobleaching of the sample. Second, the 3-D culture is a thick specimen and the time it takes to image throughout the *z* axis greatly reduces time resolution.

To get around these difficulties, it is best to use the Zeiss live duo line scanner, which is capable of taking hyperfast z sections, or a spinning disk confocal. The scanning and photobleaching parameters should also be adjusted to enable efficient photobleaching of the ROI with minimal photobleaching of the overall sample. Extensive photobleaching of the specimen will greatly affect the results of both FRAP and FLIP experiments. It is therefore very important to measure the change in fluorescence in different parts of the photobleached cells as well as in neighboring cells in every photobleaching experiment (see Figs. 4.22.6 and 4.22.7).

In general, all of the suggestions regarding culture condition, culture preparation, and imaging setups listed for live-cell imaging holds here but with some modifications.

Suitable scanning and bleaching parameters for EGFP using the Zeiss live duo line scanner are listed below:

1. Objective: The C-Apochromat 63× water objective NA 1.2 is recommended.
2. Scanning parameters: Frame size 1024 × 1024, scan speed between 1 to 2 frames/sec, frame mean 1, pinhole size up to 2 μm.
3. Bleaching parameters: Scan speed 6 μsec/pixel, iteration 3×. Low iteration number is crucial to avoid culture photodamage.

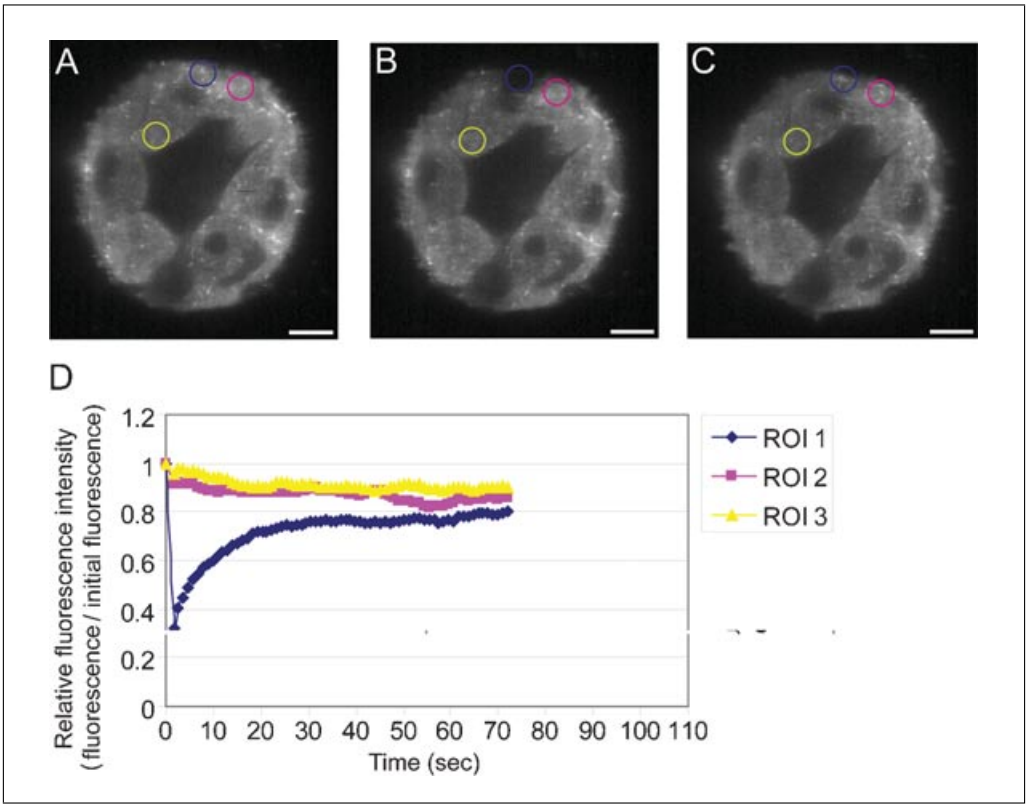

Figure 4.22.6 FRAP analysis of MDCK cells stably expressing the plus end binding protein clip170-GFP in 3-D cultures. (**A**) Before bleaching, (**B**) the first image post bleaching. (**C**) 25 sec post bleaching the bleached area has recovered. (**D**) The change in fluorescence intensities over time. ROI 1: the bleached zone; ROI 2: a different region of the same cell; ROI 3: a region from a neighboring cell. The ROIs are depicted in (A-C) and are color coded according to the graph (**D**). Cultures are in day 4. Scale bar = 10 μm. For color version of this figure go to *http://www.currentprotocols.com.*

COMMENTARY

Background Information

Epithelial cells serve as a barrier between the interior of the body and the outside world. To accomplish this barrier function, epithelial tissues have developed special characteristics such as polarized morphology, unique cell-cell contacts, and intimate interactions with the extracellular matrix (ECM). MDCK cells have been extensively studied as a model system for epithelial polarity mainly due to their ability to form apical-basolateral polarity in a tissue culture dish. When plated on a permeable filter, MDCK cells form a monolayer of polarized cells in which the basal membrane is attached to the filter and the apical membrane faces the culture medium (Simons and Fuller, 1985) Although much of the knowledge regarding cell polarity came from these studies, this system is somewhat artificial since it provides a strong cue for polarization, which also determines directionality. Plated in collagen, or any other extracellular matrix, MDCK cells form a three-dimensional cyst composed of polarized cells. In this system, MDCK cells embedded in extracellular matrix organize in a multicellular structure that creates its own lumen. This process recapitulates many of the physiological characteristics of lumen formation during epithelial development and share many morphological similarities to epithelial tissue (McAteer et al., 1987; O'Brien et al., 2002; Martin-Belmonte and Mostov, 2008). This system therefore provides a unique opportunity to study epithelial morphogenesis in a tissue culture dish. Moreover, MDCK 3-D cultures also provide a more physiological model system for cell polarity, its regulation, and its relationships with the extracellular matrix. Using this system, it was shown that Rac1 determines apical membrane orientation

through an effect on the basolateral membrane (O'Brien et al., 2001) and that CDC42 and aPKC (atypical protein kinase c) are essential for the formation of both the apical membrane and the inner lumen (Martin-Belmonte et al., 2007)

Plated in 3-D cultures, epithelial cells form cysts that are characterized by a spherical epithelial monolayer with a central single hollow lumen (Fig. 4.22.2C). The epithelial cells surrounding the lumen are polarized with the apical membrane facing the inner lumen. The apical membrane is separated from the basolateral membrane by the tight junction complex (TJ), which also creates a diffusion barrier to the inner lumen (Martin-Belmonte and Mostov, 2008).

3-D cultures are also used in cancer research as a tissue culture tool for tumor progression and reversion and many of the current knowledge on 3-D cultures came from these studies (Schmeichel and Bissell, 2003; Debnath and Brugge, 2005). 3-D culture development and lumen formation was of focus in these studies and several distinctive stages in culture formation were specified. First, apicobasal polarization is observed and the lumen is filled with unpolarized cells. Second, the nonpolarized cells trapped inside the layer of polarized cells undergo apoptosis. This leads to the formation of a hollow lumen, which is maintained throughout the lifetime of the culture. Apoptosis has also been shown to occur during lumen formation in MDCK cultures plated on collagen (Kim et al., 2007; Martin-Belmonte et al., 2008). However, the preliminary steps of 3-D culture formation and the role of apoptosis in 3-D culture development are not fully understood.

The protocols described in this unit are optimized for growing MDCK cells in a collagen I matrix. Other extracellular matrixes (such as Matrigel) and other cell lines (such as mammary epithelial cells) can also be used as a 3-D culture model system. The advantage of using a collagen matrix is the simplicity of the matrix components. However, for some applications, using a more complex extracellular matrix is required. A protocol for growing 3-D cultures of breast cancer cell lines in Matrigel was recently published by Mina Bissell's group (Lee, 2007). This protocol is highly recommended when these parameters are desired.

3-D cultures can also be used for biochemical analysis. Those protocols are however outside the scope of this unit. An extensively detailed protocol for biochemical analysis of MDCK cells in 3-D cultures is described by Keith Mostov's group (O'Brien et al., 2006); Mostov is one of the pioneers in studying MDCK cells in 3-D cultures. It also includes plating and immunostaining protocols for MDCK cells in collagen and is recommended as another source of information for issues that might not be covered in this unit.

Live-cell imaging is a powerful technique to study cellular morphogenesis in real time. These techniques, however, have not been applied for 3-D culture formation in the past, mainly due to technical difficulties. 3-D cultures are a relatively challenging specimen for live-cell imaging for several reasons. First, the cultures are embedded in matrix and therefore the distance between the cells and the objective is substantially larger than in adherent cells. Second, the matrix that surrounds the cells scatters the fluorescent light. Third, the culture is a complex and thick organization of cells in all directions (x, y, z) and imaging it in all dimensions is time consuming and therefore gives poor resolution in time. The new generation of high-speed confocal microscopes provides new possibilities for live-cell imaging that can be optimized for 3-D culture imaging. Imaging those cultures live can shed light on epithelial morphogenesis, the involvement of different proteins in these stages, and the intracellular dynamics of proteins during this process.

Critical Parameters

There are a few parameters that need to be considered before starting a 3-D culture experiment.

Before plating cells for 3-D culturing, the type of desired experiment should be determined. For an immunostaining experiment, it is better to plate the cultures on membrane filter inserts, and for live-cell imaging, the culture should be plated on a chamber slide.

For live-cell imaging, the cells should stably express a fluorescent-tagged version of the protein of interest. Moreover, the fluorescent signal should be as strong as possible to overcome the difficulties of imaging these samples.

The general morphology of the cultures should be estimated before any live-cell imaging experiment. This could be done using the FM4-64 membrane dye or by fixing and immunostaining the culture after the imaging experiment. It is critical to determine if the culture has normal morphology (a single hollow lumen surrounded by a monolayer of polarized cells) because altered morphology may affect intracellular dynamics.

Table 4.22.1 Troubleshooting Guide for Growing and Imaging 3-D Cultures

Protocol	Problem	Possible cause	Solution
Growing MDCK 3-D cultures (see Basic Protocol 1)	Collagen I does not polymerize	pH is not neutral	Check the pH of the collagen I solution before adding the cells. pH should be neutral. Lower pH inhibits polymerization.
		Insufficient incubation time	Increase incubation time in 37°C oven. Different batches of purified collagen I often require different polymerization time.
	No 3-D culture cyst formation or altered 3-D culture cyst morphology (see Anticipated Results)	Cell concentration	Plate cells again and make sure to use the recommended cell concentration. A very low concentration will decrease the probability for 3-D culture formation. A too high concentration will lead to cell aggregation and to defects in lumen formation.
		Cells are not in their proliferative state	Make sure the cells being used for plating 3-D cultures do not exceed 70% confluency
			Thaw a new aliquot of MDCK cells with a low passage number
		Cells were not in a single-cell suspension when plated	MDCK cells tend to form cell clumps. Pipet the cells up and down throughout all cell preparation stages. When counting the cells, make sure that they are not in clumps.
		Cells were over trypsinized	Trypsinize cells for the minimum required time. Add an extra wash with culture medium before plating the cells to efficiently remove trypsin.
		For cells plated in chamber slides: chamber slide was not coated properly	Increase the volume of collagen I solution used for pre-coating
			Make sure the collagen solution covers the entire surface of the chamber slide
			Make sure the collagen solution used for precoating has completely polymerized before adding the collgen/cell mixture
Immunofluorescence (see Basic Protocol 2)	No antibody staining	Permeability of the antibody	Antibody permeabiliztion problems can be caused by insufficient breakdown of the collagen matrix by the collagenase that is used to permeabilize the collagen matrix. Make sure to use a fresh aliquot of collagenase solution at the specified concentration. Try increasing the incubation time by 1 to 2 min.
			Incubate with primary antibody overnight
			Increase secondary antibody incubation time
	High background	Insufficient blocking	Increase incubation time with permeabilization solution
			Make sure the antibodies are diluted in permeabilization solution
			Replace 10% FBS with fish skin gelatin (7 mg/ml) in permeabilization solution

continued

Table 4.22.1 Troubleshooting Guide for Growing and Imaging 3-D Cultures, *continued*

Protocol	Problem	Possible cause	Solution
	Antibody staining is not as expected	Detergent in permeabilization solution distorts protein localization	Use saponin (0.025%) instead of Triton X-100 in permeabilization solution
Live-cell imaging (see Basic Protocol 3)	Unable to focus on cultures in bright field	Cells are too far from coverslip	Change to a water objective or to an objective with slightly lower NA
			Reduce the volume used for precoating of the chamber slide
	No or very little fluorescence signal	Cells are too far from slide/coverslip	Try finding a 3-D culture cyst that is closer to the slide/cover slip. Change to a 40× NA 1.3 objective. When using a point scanner, zoom in to achieve the same magnification.
		Fluorescence signal is quickly bleached	Switch to a water objective
			Minimize exposure to light before image acquisition
		Fluorescent signal is masked	Clean both the objective and the slide/coverslip thoroughly before imaging. Make sure to use the immersion oil recommended by the manufacturer.
		Expression level of the fluorescently tagged protein is too low	FACS sort the cells to enrich the population of high fluorescent cells

The overall condition of the cells in the chamber slide well should also be taken under consideration before starting an experiment. Extensive death of neighboring cells, for example, can affect the physiology of a culture with normal morphology in ways yet to be evaluated. This is especially critical in 3-D cultures because diffusion inside the collagen polymer is limited and therefore the different cellular factors that are released during cell death will remain in the surrounding area for a long time and will not be washed out easily. It is therefore recommended to image only 3-D cultures that are part of a chamber slide culture that is in good condition.

Troubleshooting

See Table 4.22.1 for troubleshooting imaging of 3-D cultures.

Anticipated Results

3-D culture morphology

The overall morphology of 3-D culture cysts can be observed by bright field. In the authors' experience, at day 4 a small lumen surrounded by few cells is observed (Fig. 4.22.2A). At day 7, cultures continue to develop and the lumen grows bigger (Fig. 4.22.2B).

Immunostaining

The following are recommended immunostainings for evaluating culture morphology and polarization.

Nuclear staining. If cultures develop normally, expect a single circular layer of nuclei (Fig. 4.22.3A). Looking for these unique circles is very useful when screening for cultures with normal morphology.

Phalloidin staining. Actin is highly accumulated on the apical surface of the polarized cells surrounding the lumen (Fig. 4.22.3B). In addition, a weaker actin staining can also be observed throughout the outline of the cells. Therefore, phalloidin staining is recommended to evaluate cell polarity and to determine the boundaries of the cells surrounding the lumen.

A 3-D culture is a three-dimensional sample that is composed of many cells. Therefore, different optical slices through the z axis will

show different populations of cells in the 3-D culture and different areas of the lumen. A series of different optical sections of a single 3-D culture cyst is presented in Figure 4.22.4 to demonstrate the different appearances of the cyst in the *z* dimension.

Live-cell imaging

The membrane dye FM4-64 can be used to label the membranes of individual cells in live 3-D cultures. This dye can be used at any time point between 30 min and several days depending on the desired experiment. The dye changes its staining over time and it is therefore important to distinguish between the different labeling patterns. At the first stage, the basolateral membrane is stained (~30 min after adding the dye; Fig. 4.22.5A,C). Later on, this staining is accompanied by an apical membrane staining and an intracellular pool of endocytosed dye (~1.5 hr after adding the dye; Fig. 4.22.5B,D). At steady state, the apical membrane staining usually remains, the endocytosed pool increases, and the basolateral staining disappears.

FRAP of intracellular proteins

After photobleaching, a specific ROI, the specified area should be completely dark while the rest of the fluorescence in the culture should not be affected. During recovery (if any) the bleached box should be gradually filled with fluorescence. Figure 4.22.6 demonstrates a FRAP experiment of the microtubule plus end binding protein Clip170.

FLIP of intracellular proteins

In FLIP experiments, the area of the ROI is continuously bleached and the total decay of fluorescence in the cell is monitored. In these experiments, the overall fluorescence signal of a protein that has a cytosolic pool should be decreased in time. However, the fluorescence in neighboring cells should remain the same and this should be used as a control. Figure 4.22.7 represents a FLIP experiment of Clip170.

Time Considerations

Plating 3-D cultures require 2 to 4 hr. Growing cultures and developing them take 4 to 12 days. Immunostaining requires 2 days.

Interference Reflection Microscopy

Valarie A. Barr[1] and Stephen C. Bunnell[2]

[1]National Cancer Institute, National Institutes of Health, Bethesda, Maryland
[2]Sackler School of Graduate Biomedical Science, Tufts University, Boston, Massachusetts

ABSTRACT

Interference reflection microscopy (IRM) is an optical technique used to study cell adhesion or cell mobility on a glass coverslip. The interference of reflected light waves generates images with high contrast and definition. IRM can be used to examine almost any cell that will rest upon a glass surface, although it is most useful in examining sites of close contact between a cell and substratum. This unit presents methods for obtaining IRM images of cells with particular emphasis on IRM imaging with a laser scanning confocal microscope (LSCM), as most LSCM are already capable of recording these images without any modification of the instrument. Techniques are presented for imaging fixed and live cells, as well as simultaneous multi-channel capture of fluorescence and reflection images. *Curr. Protoc. Cell Biol.* 45:4.23.1-4.23.19. © 2009 by John Wiley & Sons, Inc.

Keywords: reflection contrast microscopy • confocal microscopy • contrast enhancement • refractive index • cell adhesion

INTRODUCTION

This unit describes a microscopic technique that uses reflected light to visualize structures at or near a glass coverslip. Interference reflection microscopy (IRM), also known as interference contrast, interference reflection contrast, and surface contrast microscopy, has been used to study a wide range of cellular behaviors including cell adhesion, motility, exocytosis, and endocytosis. This technique relies on reflections from an incident beam of light as it passes through materials of different refractive indices. In the case of a cell on a glass coverslip, reflected beams are generated as light passes from the coverslip to aqueous medium, and again as light goes from the aqueous medium to the cell membrane. These reflected beams interfere, producing either constructive or destructive interference depending on the thickness of the layer of aqueous medium between the cell membrane and the glass surface. For monochromatic light, intensity in the IRM image is a function of the distance between the cell and coverslip and can indicate the strength of adhesion to the surface.

This unit includes protocols for fixed and live-cell imaging IRM, as well as protocols for coating coverslips for use with this technique. A very wide variety of samples can be imaged by IRM, including embedded material. In fact, the technique was originally used to image mineral samples. However, in this unit, we are concerned with IRM of cells and in particular IRM using a laser scanning confocal microscope. Moreover, a detailed description of IRM of fixed embedded samples using epi-illumination is available (Prins et al., 2005). Specific examples are included with each protocol, but the techniques can be applied very broadly.

STRATEGIC PLANNING

Obtaining images with the IRM technique requires using a microscope with a suitable light path for collecting reflected light, samples with a different refractive index than the embedding medium, and an interface between the objective and sample made of material

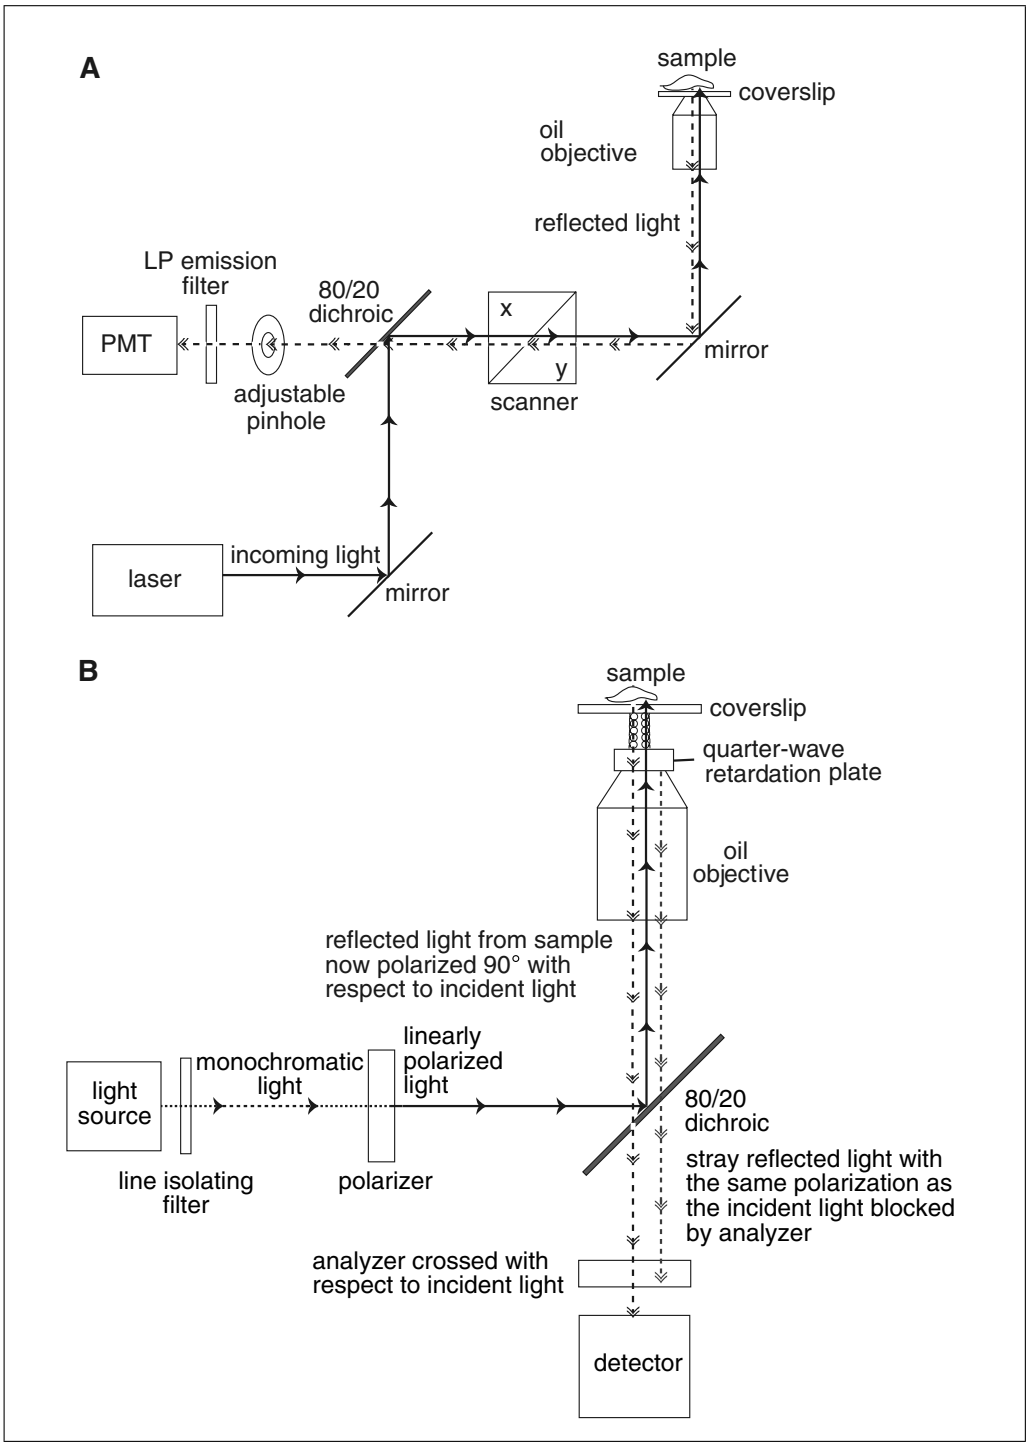

Figure 4.23.1 *(legend appears on following next page)*

with yet another refractive index, usually glass. Oil immersion objectives must be used and the mounting medium should have a lower refractive index than the immersion oil so that the first reflected beam is generated at the coverslip/medium or coverslip/cell interface. Polychromatic light will produce colored interference fringes while monochromatic light produces quantifiable gray-scale interference images.

Laser scanning microscopes already possess a suitable light path (Fig. 4.23.1A) and require only a configuration where the reflected laser light is able to reach a detector through an emission filter that allows the incident light to pass through. Since reflected

light is abundant compared to the amount of light emitted by most fluorescent molecules, the laser intensity and detector gain can be reduced for IRM imaging. Simply focusing at the coverslip with a sample containing cells that have adhered to the slide should generate an IRM image. With a slightly different configuration, IRM images can also be collected simultaneously with fluorescent images in systems with multiple detectors. Most spinning disk confocal microscopes do not have a light path that is easily adapted to IRM imaging.

Nonconfocal epi-illumination microscopes can also be used to collect IRM images, but some modification of the light path is usually needed to enhance contrast and reduce stray reflections that might otherwise overwhelm the IRM image (Fig. 4.23.1B). Stray reflections are removed by ensuring that the reflected light coming from the sample is polarized 90° relative to the incident light and then allowing only light reflected from the sample to pass through an appropriately oriented polarizer in front of the detector. The first optical element needed for this transition is a polarizer that converts the incoming beam to linearly polarized light. This polarized light then passes through a quarter-wave retardation plate placed on the objective lens with the fast axis set at 45° relative to the axis of the polarizer. This converts the linearly polarized light into circularly polarized light. When the circularly polarized light is reflected from the sample it changes handedness, that is right-handed circularly polarized light becomes left-handed circularly polarized light. As it passes back through the lambda quarter plate again, the circularly polarized light is converted back to linearly polarized light now polarized at 90° relative to the incident beam. Finally, another polarizer, the analyzer, is set in front of the detector at an orientation 90° relative to the first polarizer. Thus, only the rotated beam reflected from the sample reaches the detector (Ploem, 1975; Dorogi and Keller, 1993).

Other devices can be added to further improve the image. The contrast of the image can be enhanced by adding a central stop and field diaphragm before the first polarizer. In addition, an aperture that allows variation of the illuminating numerical aperture (NA) can also be useful for some studies (Izzard and Lochner, 1976). To obtain quantifiable gray-scale images, a line-isolating filter is needed to produce monochromatic light. Although this sounds complicated, most microscope manufacturers can supply and install all the optical elements needed for IRM imaging on an epi-illumination microscope.

It is often necessary to add a layer of material to the coverslip for adhesion or activation of the cell being imaged. This does not usually present a problem in obtaining good IRM images. IRM images have been taken with coverslips coated with antibodies, integrin

Figure 4.23.1 *(appears on previous page)* Suitable light paths for IRM imaging (**A**) Light path in a laser scanning confocal microscope. The laser, usually 543 nm or 633 nm, is reflected by the main beamsplitter into the microscope, through the objective where it reflects from the sample. The galvanometric mirrors in the scanner deflect the laser, scanning across the entire field to produce a full image. The reflected beams pass back through the neutral dichroic, 80/20 in this diagram, and are sent to the detector. The emission filter is chosen to allow the incident light to reach the detector. The pinhole can be either completely open or closed down to one Airy unit. (**B**) Light path in an epi-illumination microscope. White light from a high-pressure mercury or xenon lamp passes through a line-isolating filter and a polarizer to produce monochromatic, linearly polarized incident light. The main beamsplitter reflects this light into the microscope, through the objective and then through a quarter-wave retardation plate. The emerging light is now circularly polarized. The reflected light is circularly polarized but with the opposite handedness from the incoming beam. After passing back through the quarter-wave plate, the reflected light is now linearly polarized with an orientation 90° with respect to the incident light. The reflected light passes through the neutral dichroic, 80/20 in this diagram, and through the analyzer, a second polarizing filter oriented 90° relative to the first polarizer, to reach the detector. Stray light from internal reflections in the microscope will be linearly polarized with the original orientation and will not pass through the analyzer to the detector.

ligands, or other thin layers of protein. IRM can even be performed on cells migrating on polymer films (Csaderova et al., 2002).

If long-term imaging is desired, precautions must be taken to ensure the viability of the samples as is necessary for all live-cell imaging techniques. This usually means using an incubation system on the microscope stage to control heat, humidity, and CO_2 needed to maintain the pH of the culture medium. A complete discussion of stage incubators is beyond the scope of this unit but a page is listed under Internet Resources containing links to many manufacturers of these devices.

IRM is quite sensitive to the plane of focus, so refocusing will usually be needed during longer experiments. Most microscope manufacturers now produce microscopes with built-in autofocusing modules. When the module is activated, it maintains a defined focal plane throughout the experiment. Almost all confocal systems, even those without a built-in focusing module, also have software that either allows scripting of a time series to include an autofocus step or have subroutines that allow the user to assemble a series of microscope commands so that an autofocus routine can be run at discrete intervals during a time series. However, some autofocus routines are very slow and add considerable time between images. It is often possible to manually refocus during image acquisition, although this can be quite tedious. This method is often the fastest and may be required if the cells themselves are moving. Another approach is to collect a short *z*-stack around the plane of focus and select the best focal plane after the time series ends.

BASIC PROTOCOL

INTERFERENCE REFLECTION IMAGING OF PARAFORMALDEHYDE-FIXED NIH 3T3 CELLS WITH A LASER SCANNING CONFOCAL MICROSCOPE

This protocol consists simply of placing a sample with cells either resting on or attached to a glass coverslip onto a microscope equipped with a suitable light path, and then focusing on the coverslip through an oil immersion objective. Either live or fixed samples can be used. In contrast to fluorescent imaging of fixed samples, the refractive index of the mounting medium should be different from that of the immersion oil and coverslip in order to generate reflected beams.

Materials

Samples (e.g., fixed NIH 3T3 cells)
DMEM cell culture medium (see recipe) or other suitable cell culture medium (with refraction index different from immersion oil)
Phosphate-buffered saline (PBS; see recipe)
2.5% (w/v) paraformaldehyde (see recipe)

Culture flasks for maintaining cell cultures before imaging
Lab-Tek II Chambered Cover Glasses, two-well (Nalge Nunc, cat. no. 155379) or other no. 1 or no. 1.5 coverslips (glass-bottom 96- or 384-well plates may be used)
37°C, 5% CO_2, humidified incubator
Laser Scanning Confocal Microscope equipped with oil immersion objective

Prepare the cells

1. Prepare samples (e.g., fixed NIH 3T3 cells). Plate cells in DMEM culture medium directly into the Lab-Tek II chambered coverslip 10^4 cells/cm^2; for fibroblasts, the 2-well size is usually best. For a 2-well chamber, use 4×10^4 cells in 2 ml of culture medium.

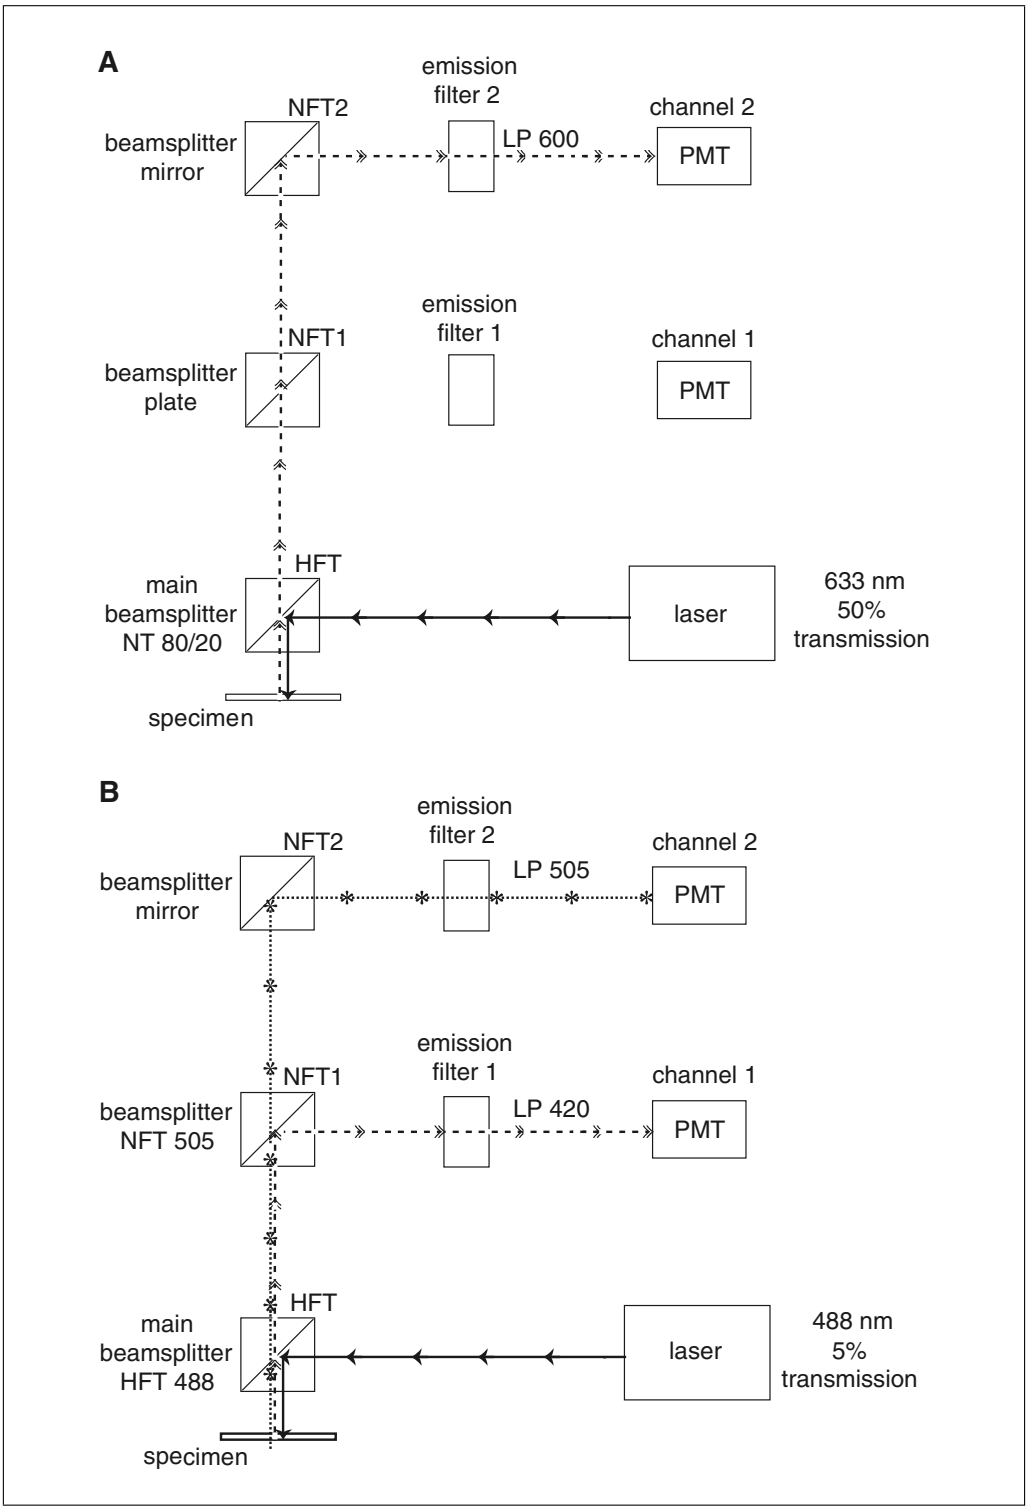

Figure 4.23.2 *(legend appears on following next page)*

2. After growing the cells overnight in a standard incubator (37°C, 5% CO_2, and 95% humidity), rinse them twice in 1.5 ml PBS and fix them in 1.5 ml 2.5% paraformaldehyde for 15 min at room temperature (~21°C).
3. Rinse the fixed cells three times, each time in 1.5 ml PBS.
4. Image the cells in PBS.

For other kinds of cells, different culture media could be used, other coverslips could be used for cell adhesion, and the fixation conditions could be varied to suit the experiment.

Set up a configuration

5. For the most commonly used configuration for a laser scanning microscope, use either a red (543 or 568 nm) or far red (633 or 647 nm) laser line, although any laser line can be used to generate a reflection image.
6. As the main beamsplitter, usually use a neutral dichroic (80/20 or 70/30).
7. Select the secondary beamsplitters to direct the reflected light to an emission filter that allows the incident laser light to pass to the detector (Fig. 4.23.2A).
8. An example of a standard IRM configuration is the one used for focusing on a slide prior to running an automated pinhole adjustment routine; it usually provides a suitable IRM configuration.

DIC images can also be obtained using a transmitted light detector, but the focal plane for IRM and DIC images is usually different.

9. An easy way to obtain both a DIC and an IRM image is to use the same software that is used for obtaining *z*-stacks during fluorescence imaging. Then set the two parameters to obtain an IRM image near the coverslip followed by a DIC image at a higher focal plane.

Figure 4.23.2 *(appears on previous page)* Suitable configurations for obtaining IRM images with a laser scanning confocal microscope. (**A**) Detection of an IRM image alone. Any laser line can be used but usually a red or far-red line is used. This example shows a configuration using a 633-nm laser. The main beamsplitter is a neutral 80/20 or 70/30 dichroic depending on which is available in the microscope. This will direct the incoming laser to the sample but will still allow the reflected light to reach the detector. The reflected light could be sent to either of the two detectors in this diagram, as long as the emission filter will allow the light to pass. Here, the LP 600-nm filter will pass the 633-nm reflected light, but almost any LP filter would be suitable. Therefore, any detector in the system can usually be used to capture an IRM image. (**B**) Simultaneous detection of fluorescent and IRM images. In this case, the configuration settings will be based primarily on those needed to detect the emitted fluorescence and the IRM image will be captured with whatever detector is free and has a suitable emission filter. This example shows simultaneous imaging of green fluorescence (505 to 530 nm) and reflected light. The laser line, 488 nm, and the main beamsplitter, NFT 488, are chosen to fit the characteristics of the fluorophore. The IRM image will be formed with the reflected light that passes through the main dichroic because it is not a perfect optical device. If the main dichroic is so efficient that no incident light is allowed through, it will be necessary to use a neutral dichroic for the IRM image. The emission side beamsplitters are chosen to send the emitted fluorescence to one detector and the incident wavelength to another. In this diagram, all light longer than 505 nm is gathered for the fluorescence image and all shorter wavelengths, including 488 nm, are used for the IRM image. If the fluorescence is very weak, this beamsplitter can even be set at 470 nm, to collect as much light as possible for the fluorescent image. The remaining reflected light will be sufficient to produce an IRM image. While the emission filter for the fluorescence image should match the emitted fluorescence, almost any long-pass filter will allow the reflected light to reach the detector.

Focus on the sample

10. Use DIC or other transmitted light mode to find and focus on cells.
11. Turn on the laser, adjust focus while in scanning mode to find the bright reflection image, which will only appear over a very narrow range of focal planes.
12. Determine if open or narrow pinhole is optimal for the desired IRM images.

    Decreasing the size of the pinhole increases the sharpness of the IRM image; however, small variations in focus will produce an IRM image containing interference fringes. Taking an IRM image with an open pinhole will produce an image that is less sensitive to focus drift (see Anticipated Results for illustrations). Therefore, the experimenter needs to decide which parameter is more important, the sharpness of the image or insensitivity to focus drift.

13. Adjust detector gains for high-contrast image.
14. Readjust focus to obtain a zero-order interference image and then readjust the detectors for best contrast.

TIME-LAPSE IRM IMAGING OF LIVE MIGRATING *DICYTOSTELIUM DISCOIDEUM* AMOEBA

ALTERNATE PROTOCOL 1

Most confocal systems contain software that allows repeated image acquisition. Activating the appropriate imaging subroutine while using an IRM configuration allows the acquisition of IRM images over time. This allows imaging of many kinds of motile cells ranging from migrating *Dicytostelium discoideum* amoeba to activated T cells spreading on a stimulatory surface. If mammalian cells are being used, a microscope stage incubator may be needed. The exact kind of stage incubator will depend on the kind of microscope being used, the kind of cells being imaged, and the length of the experiment. A Web site is given at the end of this unit with links to numerous manufacturers of these devices. In addition, the microscope manufacturers themselves also produce stage incubators.

***Additional Materials** (also see the Basic Protocol)*

PB buffer for *Dicytostelium discoideum* (see recipe) or culture medium without phenol red for other cells
Dicytostelium discoideum amoeba developed according to standard protocols (Parent, 2001) or other live cells
Lab-Tek II one-well chambers (Nalge Nunc, cat. no. 155360)

1. Plate living *D. discoideum* cells into Lab-Tek II chambered coverslips.

   Developed cells should be diluted in PB buffer to 2×10^6 cells/ml and 5 μl drops should be placed in the chamber. Several drops can be placed in a single well.

   For Dicytostelium discoideum, either the one- or two-chamber size is usually best.

2. Allow amoebas to adhere for 5 min and then cover with 3 ml PB buffer for a one-well chamber.

   Other cells should be plated and covered with an appropriate culture medium.

3. Set up an incubation system if needed and allow the system to come to equilibrium. Put the chambers with cells onto the microscope stage.

   For Dicytostelium discoideum, no environmental controls are needed.

4. Proceed according to the Basic Protocol (steps 5 to 8 and 10 to 14) to obtain an IRM image of a live cell. If desired, add a transmitted light detector to the configuration and set a *z*-stack that will capture an IRM image in focus near the bottom of the

z-stack and a transmitted light image at the top of the z-stack (see Basic Protocol step 9).

5. Run a test series with time-lapse acquisition software to determine if refocusing will be needed. If so, add an autofocusing subroutine.

   The exact nature of the autofocusing will depend on the microscope being used and the desired interval between images.

6. Run full time-lapse image acquisition.

7. Select the best images from the z-stack if capturing multiple focal planes.

ALTERNATE PROTOCOL 2

MULTI-CHANNEL FLUORESCENCE AND IRM IMAGING

This protocol describes collecting both IRM and fluorescence images simultaneously using two photomultiplier detectors. If live cells are to be imaged over time, the same considerations for refocusing and incubation from Alternate Protocol 1 will apply.

Additional Materials *(also see the Basic Protocol and Alternate Protocol 1)*

Live sample cells expressing a fluorescent marker [e.g., transfected Jurkat T cells, clone E6.1 (ATCC # TIB-152) expressing a ZAP70 tagged with YFP and spreading on a stimulatory surface]
Imaging buffer (see recipe)

Stage incubator
Hot air blower (Nevtek) and objective heater (Bioptechs) for temperature control on the microscope stage for the Jurkat T cells
Lab-Tek II four-well chambered coverslips (Nalge Nunc, cat. No. 155382) coated with murine IgG1 to CDε clone Hit3a (BD Pharmingen) to activate the Jurkat T cells (see Support Protocol)
Laser Scanning Confocal Microscope equipped with at least two photomultipliers

1. Prepare cells. For Jurkat T cells, centrifuge the suspended cells from an actively growing culture for 5 min at 200 × g, 23°C. Resuspend the cells in imaging buffer at a density of 2×10^6 cells/ml.

   Fixed cells can also be used.

2. Set up the stage incubator.

3. For Jurkat T cells, turn on the objective heater and hot air blower, then place an antibody-coated coverslip on the microscope stage. Remove the PBS that has been stored in the chamber and fill the chamber about half full with warm imaging buffer. Then allow the system to come to thermal equilibrium.

4. Set up configuration to collect two channels simultaneously.

5. Select the laser to be used based on the excitation of the fluorescent probe being monitored.

6. In most cases, the main beamsplitter can be the optimal dichroic for fluorescence imaging because enough reflected light will pass through to generate an image. Since the IRM image will be collected at a shorter wavelength than the emitted fluorescence, select the secondary beamsplitters to send the reflected light through an emission filter that allows the incident light to reach the detector.

   As much emitted light as possible is sent to a detector through an emission filter suitable for the emitted fluorescence. Figure 4.23.2B shows a configuration suitable for collection of FITC, GFP, or YFP while simultaneously collecting IRM images.

7. Add the 3 to 5 μl resuspended Jurkat T cells (6000 to 10,000 cells) to the equilibrated chamber on the microscope stage.

   Alternatively, cells could be added to a chamber before placing it on the stage. For some adhesion assays, it may be necessary to add the cells several hours before imaging begins.

8. Proceed according to the Basic Protocol (steps 5 to 8 and 10 to 14). In this case, it is possible to use fluorescence for the initial focusing step.

   For Jurkat T cells, focusing is done quickly so that cells can be visualized soon after first contact with the coverslip.

   For time-lapse and live cell imaging, use the conditions in Alternate Protocol 1.

PREPARING COATED COVERSLIPS FOR IRM IMAGING

SUPPORT PROTOCOL

Coverslips may be coated with a large number of different substances to promote adhesion or activation of the cells being imaged. This protocol gives basic instructions for cleaning and coating coverslips.

Materials

Coverslip cleaning solution (see recipe)
Poly-L-lysine solution (Sigma-Aldrich, cat. No. P8920)
Distilled water
Fibronectin coating solution (see recipe)
Antibody coating solution (see recipe)
Phosphate-buffered saline (PBS; see recipe)

Coverslips [e.g., Lab-Tek II 4-well chambered coverslips; Nalge Nunc, cat. no. 155382 (but any chamber with a no. 1 or no. 1.5 coverslip bottom can be used)]
Drying oven

Prepare the coverslips

1. Clean the coverslips with cleaning solution by filling the chambered coverslip halfway and incubating 15 min at room temperature.
2. Completely remove cleaning solution by aspiration.
3. Dry the chambers in a drying oven set at 45°C for at least 30 min.
4. Dilute a commercially available poly-L-lysine solution to 0.01% in distilled H_2O.

   Poly-L-lysine solution can be stored up to 6 months at room temperature.

5. Fill the clean chambers halfway with the 0.01% poly-L-lysine and incubate 15 min at room temperature.

   In many cases, the desired coating will not adhere directly to a glass surface, so a preliminary coating of poly-L-lysine is applied first.

6. Completely remove the solution by aspiration.
7. Dry the chambers at 45°C for at least 30 min.

   These chambers can be stored for several weeks.

8. Add the appropriate coating solution either to cleaned or cleaned and poly-L-lysine–coated chambered coverslips.

For fibronectin coating

9a. Dilute 10 to 25 μg/ml fibronectin in PBS and add to a cleaned coverslip so that the coverslip is barely covered (e.g., 400 μl in one well of a four-well chambered coverslip).

10a. Incubate the coverslip for 1 to 2 hr at 37°C.

11a. Aspirate the solution.

12a. Plate the cells on the coated coverslip.

For antibody coatings

9b. Dilute 10 μg/ml antibody in PBS.

10b. Add antibody solution to the poly-L-lysine–coated coverslips so that the coverslip is barely covered (400 μl in one well of a four-well chambered coverslip).

11b. Incubate the coverslips overnight at 4°C.

12b. Rinse three times, each time with 1 ml PBS.

13b. Store filled with PBS.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Antibody coating solution (10 μg/ml in PBS)

20 μl anti-human CD3ε antibody clone Hit 3a 200 μg/ml (BD Pharmingen, cat. no. P555336)
380 μl phosphate-buffered saline (PBS; see recipe)
Use immediately, store coated chamber <1 week at 4°C

Cleaning solution

70 ml of 100% (v/v) ethanol (Sigma-Aldrich, cat. no. E7023)
20 ml distilled water
10 ml of 10 M HCl (Sigma-Aldrich, cat. no. H7020)
Store <1 year at room temperature

DMEM culture medium

50 ml fetal bovine serum (FBS; Invitrogen, cat. no. 10437-028)
5 ml glutamine (from a 100× stock from Invitrogen, cat. no. 25030-081)
5 ml penicillin/streptomycin (from a 100× from Invitrogen, cat. no. 15140-122)
DMEM medium (Invitrogen, cat. no. 11995) to 500 ml
Filter sterilize using a 0.22-μm filter
Store <1 month at 4°C

Fibronectin coating solution (10 to 25 μg/ml in PBS)

25 μl fibronectin (1 mg/ml solution; Sigma-Aldrich, cat. no. F1141)
975 μl phosphate-buffered saline (PBS; see recipe)
Use immediately

Imaging buffer

5 ml fetal bovine serum (FBS; Invitrogen, cat. no. 10437-028)
0.125 ml of 1 M HEPES, pH 7.0 (Invitrogen, cat. no. 15630-130)
RPMI medium, without phenol red (Invitrogen, cat. no. 11835) to 50 ml
Filter sterilize using a 0.22-μm filter
Store <1 month at 4°C

Paraformaldehyde, 2.5% (w/v)

2.5 g paraformaldehyde (Ted Pella, cat. no. 18501)
100 ml phosphate-buffered saline (PBS; see recipe)
Prewarm PBS to 65°C and dissolve paraformaldehyde while heating to 80°
Store <6 months at −20°C

PB buffer (5 mM potassium phosphate pH 6.2)

0.68 g KH_2PO_4 (JT Baker, cat. no. 3246-01)
1.34 g $Na_2HPO_4 \cdot 7H_2O$ (Mallinckrodt Chemicals, cat. no. 7914-04)
Distilled H_2O to 1 liter
Store <6 months at room temperature

Phosphate-buffered saline (PBS)

1× phosphate-buffered saline without calcium or magnesium (Invitrogen, cat. no. 10010-031)
Store <6 months at room temperature

COMMENTARY

Background Information

Most of the analytical work on IRM comes from epi-illumination microscopes, not from IRM performed with a confocal microscope; however, the physical interactions are the same. In 1964, Curtis first applied the optical methods previously used to examine reflections from thin films to cells grown on glass coverslips (Curtis, 1964). Curtis analyzed his images in terms of reflections from the glass/medium and the medium/cell interface (Fig. 4.23.3A). The first reflection, r_1, is generated as light travels from the glass coverslip (η_1=1.515) to the culture medium ($\eta_2 \sim 1.34$) and another reflection, r_2, is generated as the light crosses from the medium into the cell ($\eta_3 \sim 1.37$). When the two reflected beams meet at a detector, they can interfere, producing an interference image.

The strength of a reflected beam at a single interface is proportional to the difference in refractive indices. In this system, these differences are relatively small (Izzard and Lochner, 1976), so only the primary reflections contribute to the IRM image. The greatest difference in refractive indices occurs at the glass/medium interface (1.515 − 1.34). Thus, in the absence of interference, the brightest reflection will come from the cell-free areas of the coverslip. Any areas in the IRM image that are brighter than the cell-free background must be due to positive interference, while darker areas are due to negative interference.

While light is a complex quantum phenomenon that can be viewed in several different ways, to understand the generation of the interference image it is easiest to think of the reflected light as two waves, r_1 and r_2. The superposition of the two reflected light waves at the detector generates the interference image. Because the two reflected waves have gone different distances through different materials, the two reflected waves may reach the detector with different phases. Constructive interference occurs if the waves arrive at the detector in phase, that is aligned so the amplitudes of the peaks add together and the superimposed wave is larger than the two incoming waves. Alternatively, destructive interference occurs if the waves are aligned peak to trough, so the superimposed wave is smaller than either incoming wave.

The alignment of the two reflected waves can be predicted by calculating the optical path difference (OPD), that is, the difference between the optical paths traveled by the two waves. The length of an optical path is defined as the product of physical path length and refractive index of the material through which the light wave travels. Two major factors affect the OPD; the difference in the physical paths traveled by the reflected beams and a phase reversal that affects beams reflected from light passing from material with lower refractive index into material with a higher refractive index. In our example (Fig. 4.34.3A), reflected wave r_2 has traveled farther than wave r_1 by going through the thin film of medium with a thickness of d twice. Considering only light that arrives at normal incidence (when θ; the refraction angle = 0), this gives a physical path difference of $2d$ and an OPD of $2d\eta_2$. In addition, there is the phase shift at the medium/cell interface and the sign of the electric field of the

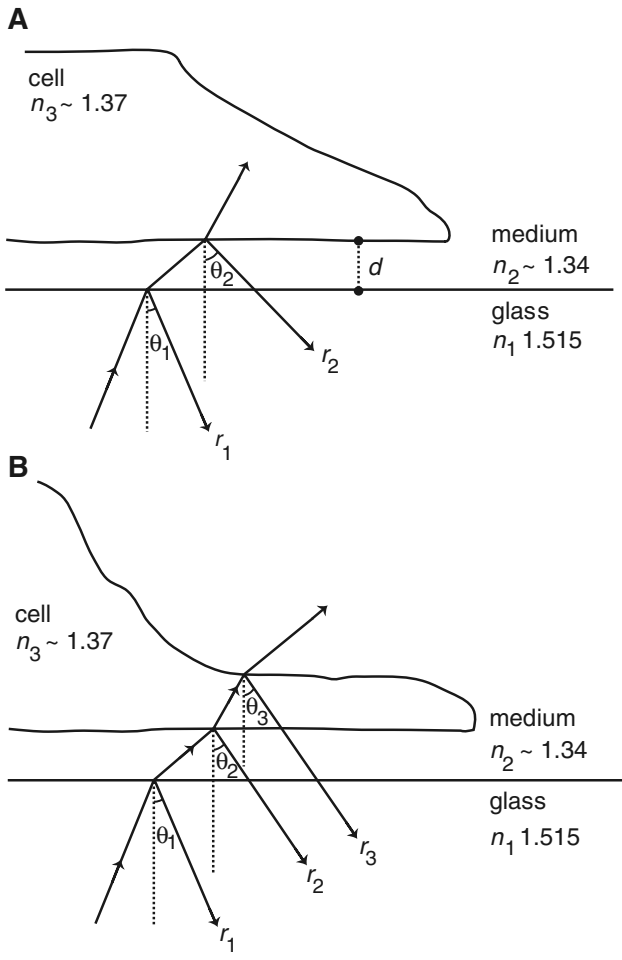

Figure 4.23.3 Diagrams representing the reflections generated by a cell on a coverslip. (**A**) Cell separated from the coverslip by a thin layer of thickness (*d*). The first reflection, r_1, is generated at the glass/medium interface with incident angle θ_1. The refracted beam continues through the medium and generates another reflection, r_2, with reflection angle θ_2 at the medium/cell interface. r_2 will undergo a phase reversal because it occurs at a transition from lower to higher refractive index. The light that continues through the cell can be used to form a transmitted light image if an appropriate detector is available. (**B**) An additional reflection from the top of the cell may also contribute to the IRM image. When higher-order interference fringes contribute to the image, the top of the cell will also contribute a third reflection, r_3.

reflected light is inverted. This can be represented in the OPD calculation as an additional path length of $\lambda/2$, so the OPD between r_1 and r_2 is $2d\eta_2 + \lambda/2$. If the light approaches the surface obliquely with a refraction angle θ, the OPD is $2d\eta_2\cos\theta + \lambda/2$.

It is possible to understand how an IRM image is produced by a cell on a coverslip by examining the OPD between the reflected waves as the distance between the cell and the coverslip varies. If the OPD is an integer multiple of the wavelength of the light, $m\lambda$, the waves align exactly peak-to-peak, generating maxima in the inference image. The integer m is called as the order of interference. Given that the OPD between r_1 and r_2 is $2d\eta_2 + \lambda/2$, the first maximum occurs in the image when $d = \lambda/4\eta_2$. As the cell gets closer to the coverslip and d gets smaller, the superimposed waves become more out of phase and the reflected intensity diminishes. When the OPD is $(m + {}^1/_2)\,\lambda$, the waves align exactly peak to trough, generating minima in the image. The first minimum is generated as d approaches 0, giving an OPD near $\lambda/2$, where there is maximum destructive interference. So in a zero-order image ($m = 0$), the OPD is smaller than λ and the darkest areas correspond to places where the cell touches the coverslip while the brightest areas correspond to places where the

distance between the cell and coverslip is $\sim^1/_4$ of the wavelength of the incident light (Beck and Bereiter-Hahn, 1981; Verschueren, 1985).

However, it is clear that a full quantitative analysis of the interference pattern that would allow calculation of d or η from reflection images is much more complicated. In 1976, Izzard and Lochner determined that reflections from further away also contribute to the interference image, producing images with interference fringes inside the cell (Izzard and Lochner, 1976). In this case, the cell acts as a second thin film (Fig. 4.23.3B) and reflections from the top membrane are seen in the IRM images. These higher-order patterns can be eliminated by increasing the illuminating numerical aperture of the system, which allows light entering at more oblique angles to contribute to the image. When the illuminating numerical aperture was >1, their IRM image only contained reflections from areas where the layer of medium was thin, generally <100 to 150 nm. This effect was attributed to a decrease in contrast in the interference fringes produced at greater distances from the coverslip because in the higher order fringes light reflecting at more oblique angles produce maxima in the interference pattern that overlap with minima from light entering at sharper angles. Gringell and Todd challenged this conclusion by showing that the loss of contrast could occur because increasing the illuminating numerical aperture strongly damped the maxima and minima of the higher-ordered fringes (Gingell and Todd, 1979). However, they agreed that at higher illuminating numerical aperture, it is not necessary to consider the reflections from the top of the cell if thickness of the cytoplasm is >1 μm and the distance between the cell and coverslip <250 nm. Their calculations also showed that IRM images from areas of very thin cytoplasm, such as spreading edges, would be affected by reflections from the top of the cell even at high illuminating numerical aperture (Gingell, 1981).

Later, Thorell and his colleagues suggested that the darkest areas of IRM images were due to weak reflections from areas of direct contact between the cell and coverslip (Bereiter-Hahn et al., 1979). They argued that if the darkest areas were interference minima where d is near to but not yet zero, the intensity seen in the image should be affected by changes in the incident wavelength or refractive index of the medium. Since neither perturbation had any effect, they concluded that these areas were not interference minima. However, as interference images from small gaps ($d < 5$ nm) are also relatively insensitive to changes in wavelength and refractive index, the exact nature of the darkest area remains controversial (Gingell and Vince, 1982).

Overall, there is general agreement that if the distance between the cell and coverslip is between 0 and about 100 nm, the intensity in the reflected light pattern increases with distance (Abercrombie and Dunn, 1975; Verschueren, 1985; Opas, 1990). In the IRM image, whites occur where the thickness of the layer of medium is ~100 nm, grays are generated at intermediate distances, while blacks occur at distances <15 nm and are an indication of strong adhesion (Fig. 4.23.4). If the IRM image contains areas where the thickness of the cell is <1 μm, reflections from the top of the cell will contribute significantly to the image and even semi-quantitative interpretation will be difficult unless the thickness of the cytoplasm is known.

It should be clear from this discussion, that reflection interference contrast is quite different from differential interference contrast (DIC) despite the similarities in the two names. DIC employs polarized light and special Wollaston prisms to convert differences in refractive indices into gray level differences, producing pseudo-three-dimensional images (Keller, 1997). Moreover, IRM is also different from total internal reflection fluorescence or TIRF microscopy. The latter uses a laser turned to a very oblique angle to generate an evanescent wave that is used to excite fluorophores near the coverslip (Toomre and Manstein, 2001).

Critical Parameters and Troubleshooting

The most critical parameter is to use a microscope with a suitable light path. It should be possible to see a very bright reflection from the coverslip when the focus is moved slightly below the focal plane of cells adhering to the coverslip. The exact z position is also critical; it is very easy for the focus to shift to a position where no image is visible.

The refractive index of the mounting medium is important, as a larger difference in refractive index generates brighter reflections. It is best to avoid alcohol- and acetone-based fixatives, as these will induce shrinkage in the samples that can affect contacts with the coverslip.

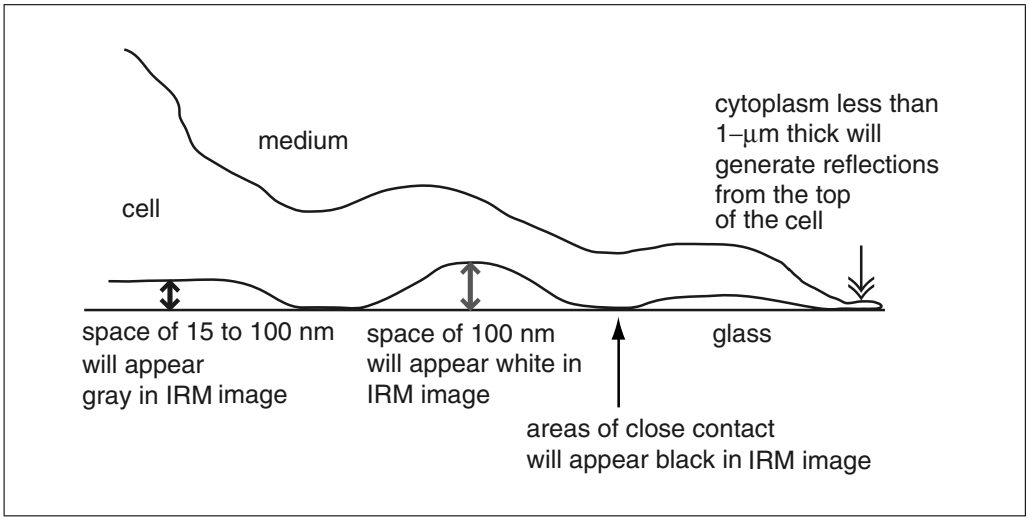

Figure 4.23.4 Gray-level intensities observed in a zero-order IRM images. The size of the gaps between the cell and coverslip have been exaggerated. A cell adhering to the coverslip will generate black areas on an IRM image in areas of close contact where the gap between the cell and coverslip is <15 nm (black arrow). If the gap is between 15 and 100 nm, the IRM image will show shades of gray (double-headed arrow). The brightest areas on the IRM image will come from areas where the cell is ~100 nm from the coverslip (gray double-headed arrow). If the cytoplasm is <1-μm thick (feathered arrow), reflections from the top of the cell will affect the intensity of the IRM image, so it will not be possible to approximate the distance between the cell and the coverslip unless the thickness of the layer of cytoplasm is known.

Anticipated Results

This technique should produce a gray-scale image of approximately the same shape as the cell being viewed. Figure 4.23.5A shows a DIC image of a NIH 3T3 fibroblast in the left panel and an IRM image of the same cell taken with a Zeiss 510 LSCM with the pinhole completely open in the middle panel. The right panel shows another IRM image taken with a 1.0-μm optical slice to reduce the field of focus. Because these are very flat cells, the DIC image has very low contrast, particularly when compared to the dramatic IRM image. As explained in the Commentary, in this zero-order IRM image, the darkest areas come from the regions of closest contact, where the cell is either adhered to the coverslip or is no more than 15 nm from the coverslip. The intensity of the reflected light increases with distance from the coverslip and the brightest areas in the image come from regions that are ~100 nm ($\lambda/4d\eta_{medium}$) from

Figure 4.23.5 *(appears on following next page)* IRM images of fixed NIH 3T3 cells. Images were obtained with a Zeiss LSCM 510 using a 63× oil objective NA 1.4. The configuration shown in Figure 4.23.2A was used for (A) and (B). A similar configuration using a 543-nm laser line was used for the last part of (C). (**A**) Comparison of DIC and IRM images of the same cell. Left panel: low-contrast DIC image showing intracellular organelles and details of the cell shape, but containing little information about the adherent surface. Bar = 10 μm. Middle panel: High-contrast IRM image taken with an open pinhole. Right panel: IRM image taken with the pinhole set a 1 Airy unit (1 AU). This is similar to the other IRM image, but the smaller pinhole gives a sharper image. (**B**) Effects of focal plane in images taken with narrow or open pinhole. Top panels: Images of the same field taken at successively higher focal planes with the pinhole set to 1 AU. The higher-order interference fringes are evident with little change in focus. Bottom panels: A similar series of images taken at successively higher focal planes with the pinhole completely open. These images are primarily formed from the zero-order interference fringe. Bar = 5 μm. (**C**) The zero-order interference image is similar when taken with light of different wavelengths. Top panels: The zero-order (left side) and higher-order (right side) images taken with a 633-nm laser. Bottom panels: The zero-order (left side) and higher-order (right side) images taken with a 543-nm laser. Bar = 20 μm. The dark areas of close contact indicated with black arrowheads outlined in white remain fairly constant through this set of images. While there is some variation in the remaining gray level intensities in the two zero-order images, the overall appearance of the images is very similar. In contrast, the higher-order interference images are shifted substantially by changes in incident wavelength.

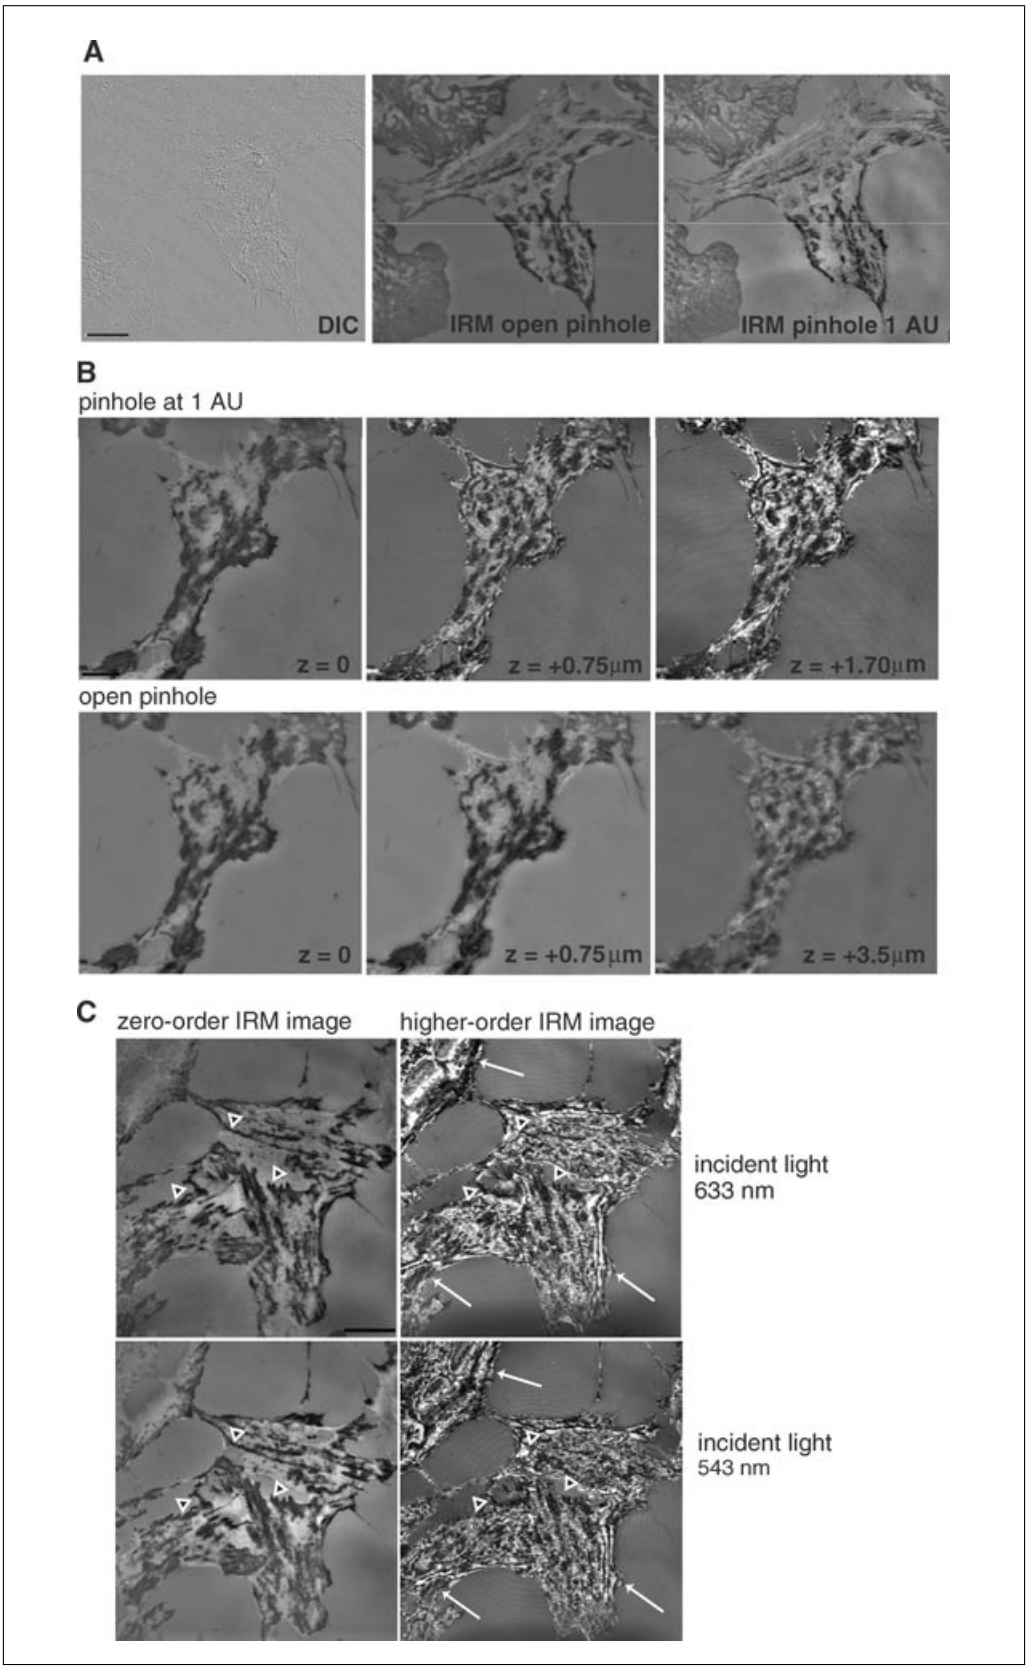

Figure 4.23.5 *(legend appears on previous page)*

the coverslip. The information in the DIC image is quite different, showing finer details at the edge of the cell, as well as showing structures inside the cell itself. The two IRM images look very similar but reducing the pinhole often produces sharper images. However, using a reduced pinhole can introduce other problems, as shown in the next set of images (Fig. 4.23.5B). The first panel shows an IRM image with a 1.0-μm optical slice as before, while the middle panel shows an image taken at a slightly higher focal plane. In the second image, more interference fringes are beginning to show up and complicate the zero-order image. The right panel shows an IRM image from a still higher focal plane that is completely dominated by the interference fringe pattern. Since the smaller pinhole restricts the focal plane, more light is gathered from higher in the cell as the focal plane is moved up. This allows imaging of the reflections from either the top of the cell or the nuclear membrane generating higher-order reflection fringes. The lower panels show equivalent images taken with the pinhole open. In these images, the higher-order fringe pattern is less visible and the image is out of focus before the interference fringes contribute significantly to the image. Information about the OPD at the different areas can be obtained from the fringe pattern; however, for most applications the zero-order image is more useful. The last set of images demonstrates the effects of changing the laser wavelength (Fig. 4.23.5C). The zero-order images shown in the left panels are similar in images whether 633-nm light or 543-nm light is used. In particular, the dark areas of close contact are virtually unchanged, although the gray levels in areas of intermediate distance show some variation. In contrast, the right panels contain images showing the higher-order interference fringes, where the pattern itself is a function of wavelength. In these images, fringe patterns change substantially as the wavelength changes.

Figure 4.23.6 shows a time series of IRM images from migrating *Dicytostelium discoideum* and DIC images captured in the same

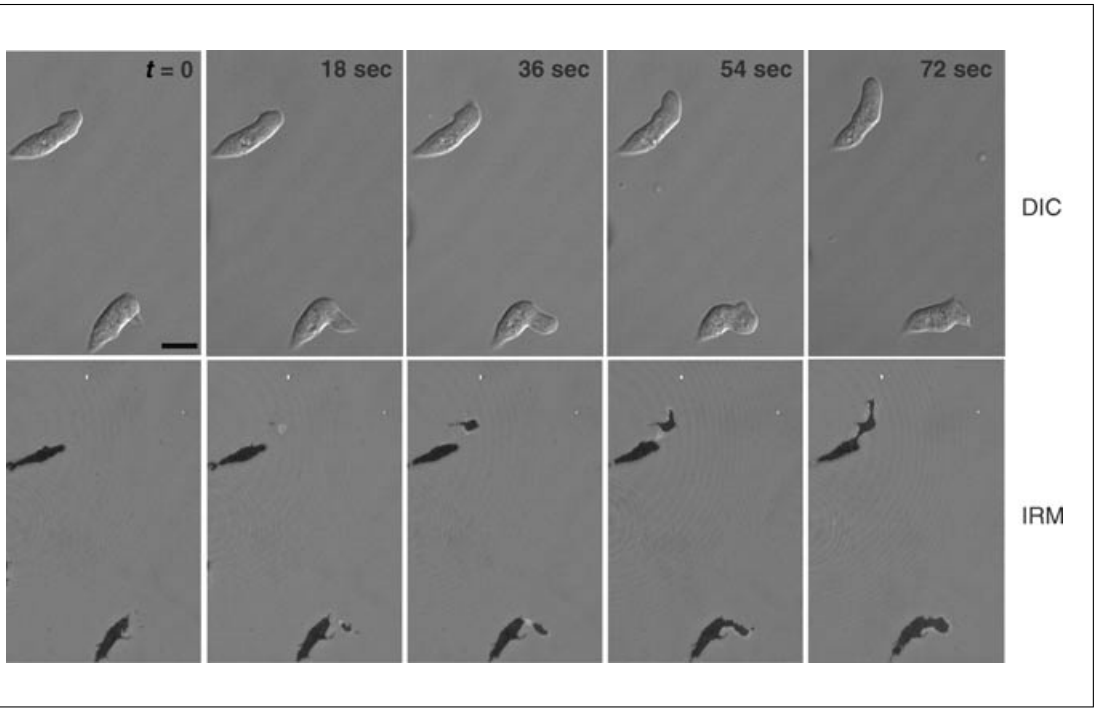

Figure 4.23.6 Application of IRM to migrating *Dicytostelium discoideum* cells. *Dicytostelium discoideum* amoeba were developed according to standard protocols to produce mobile cells. The images were taken using the same settings as Figure 4.23.5 with the addition of a transmitted light detector to the track. DIC optics installed on the microscope were used for the transmitted light image. Instead of single images, *z* stacks were collected at each time point and different focal planes were chosen to show the DIC or IRM images. Top panels: Time series of DIC image from the top of the *z* stack. The cells appear to glide over the coverslip. Bottom panels: IRM images from the bottom of the *z* stack in the same time series. Bar = 10 μm. These images clearly show that the amoeba move by extending a pseudopod that is not in contact with the coverslip and then forming a new contact site some distance from the cell body.

z-stack. The DIC images appear to show an amoeba gliding continuously over the coverslip, while the IRM image clearly shows a new contact site forming at a discrete distance from the current adhesion site. The IRM image also shows streaks of material left behind as the amoeba moves along. Thus, the IRM image contains information about cell adhesion during migration that cannot be obtained from the DIC image.

Figure 4.23.7 shows a time series of a spreading T cell along with simultaneous fluorescent imaging of an YFP-tagged protein. The YFP-tagged protein is a proximal kinase, ZAP-70, that is required for signal transduction downstream of the T cell receptor. These images show the immediate recruitment of the kinase to areas where the cell touches a stimulatory coverslip that is coated with anti-T cell receptor antibodies.

The high-contrast IRM images are useful for quantifying the extent and area of cell-surface contact. For example, to find the areas of activated T cells, an IRM image of a field of spread T cells was taken (Fig. 4.23.8; left panel). This image is easy to threshold using automated routines (middle panel). In this case, the built-in thresholding algorithm from

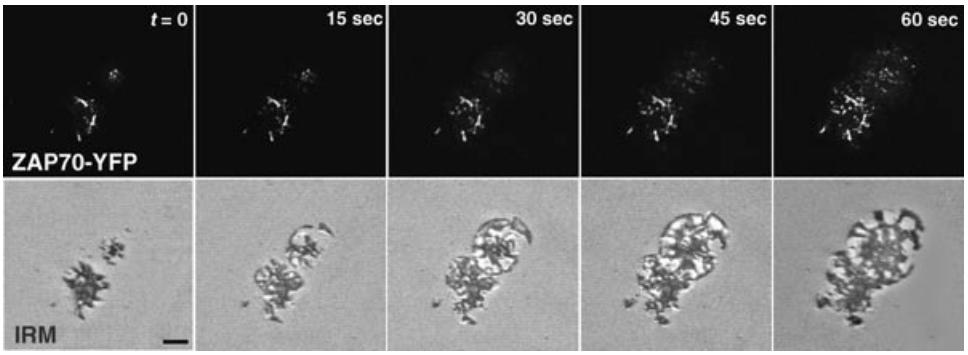

Figure 4.23.7 Simultaneous capture of fluorescence and interference reflection images of transfected Jurkat T cells expressing ZAP70-YFP. The configuration shown in Figure 4.23.2B was used to obtain these images. Top panels: Time series of YFP fluorescent images. The ZAP70-YFP clusters as the T cell spreads on the stimulatory coverslip. Bottom images: IRM images captured in the same track clearly show the T cell spreading across the coverslip. Bar = 5 μm. A comparison of the two images shows that ZAP70 clusters at the contact sites.

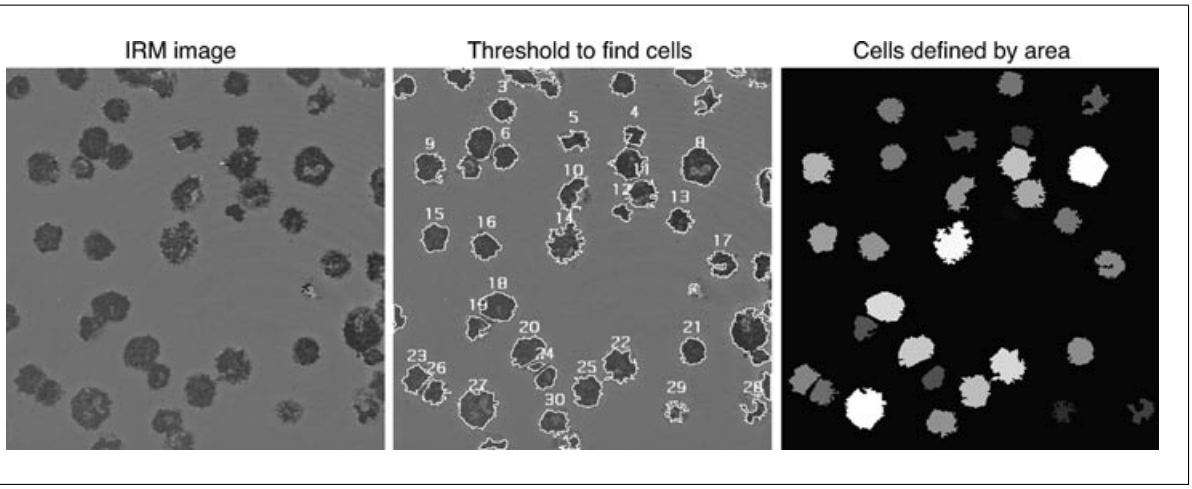

Figure 4.23.8 Quantification of an IRM image. Left panel: IRM image of fixed mouse T cells obtained using the same conditions as the cells in Figure 4.23.5. The T cells were allowed to spread on a stimulatory coverslip and were then fixed in 2.5% (w/v) paraformaldehyde. Middle panel: An auto-thresholding algorithm was used to outline the T cells based on the gray-level contrast and object shape. Some touching cells were improperly outlined together and were then separated by hand, for example no. 23 and no. 26. Right panels: The same field of cells visualized with an LUT where the gray level of each cell is proportional to its area. Lighter colors indicate cells with larger areas.

the software package iVision (BioVision) was used to outline the individual cells and identify each outlined cell with a number. The left panel shows an image where the gray level of each cell is proportional to the area outlined in the IRM image.

Time Considerations

The time frame for completing the protocols will vary tremendously depending on the kind of experiments to be performed and the samples being imaged. At one end of the spectrum, T cells could be resuspended in sample buffer, followed by live imaging of <3 min so the entire protocol could be completed in <15 min. Alternatively, if the experiments require precoating coverslips, culturing cells for days before beginning imaging, and conclude with days of imaging, the entire protocol may encompass an entire week.

Fluorescence Correlation Spectroscopy in Living Cells: A Practical Approach

Nihal Altan-Bonnet[1] and Grégoire Altan-Bonnet[2]

[1]Department of Biology, Rutgers University, Newark, New Jersey
[2]Program in Computational Biology and Immunology, Memorial Sloan Kettering Cancer Center, New York, New York

ABSTRACT

Fluorescence correlation spectroscopy (FCS) is a single-molecule fluorescence technique used to monitor molecular dynamics. It can be applied to living cells expressing fluorescently labeled proteins and lipids to determine the diffusion timescales and the total number of diffusing fluorescent molecules in the cell. A practical step-by-step approach to performing FCS with a commercial spectroscopy/microscopy system, the Zeiss Confocor 3, how to set up live-cell FCS experiments, acquire reliable data, and finally how to analyze the data acquired, are all described in this unit. *Curr. Protoc. Cell Biol.* 45:4.24.1-4.24.14. © 2009 by John Wiley & Sons, Inc.

Keywords: fluorescence correlation spectroscopy • FCS • live-cell imaging • green fluorescent protein • GFP • diffusion

INTRODUCTION

Fluorescence correlation spectroscopy (FCS) is a single-molecule fluorescence technique used to monitor molecular dynamics. When applied to living cells, FCS has been used to decipher the diffusion times of protein and lipid molecules, to determine the concentrations of a particular molecule at a specific cellular location, and to determine kinetic parameters such as on/off rates, constants, and binding coefficients for protein/protein interactions (Schwille, 2001).

The basic principle of FCS is that a fluorescent molecule emits photons while moving through a confocal volume illuminated by a laser (Fig. 4.24.1). The number of photons that can be collected from the confocal volume depends on the diffusion time of the fluorescent molecules (which is a function of the mass of the molecule), the concentration of molecules, the quantum yield of the fluorophore attached to the molecule, and finally the size of the illuminated volume, which is dependent on the instrument (Krichevsky and Bonnet, 2002). Typically, a small diffraction-limited confocal volume of $(0.3)^2 \times 1\text{–}\mu m^3$ (about the size of an *E. coli*) is excited with a laser beam, and then the emitted photons are collected and counted on a photodiode detector. These measurements are then used to calculate and display autocorrelation and cross-correlation functions, coincidence diagrams, photon count histograms, count rate diagrams, and pulse density histograms, from which diffusion times, on/off rates, etc., can be extracted using data-fitting and -modeling software (Bacia and Schwille, 2003).

In this protocol, the basic design of an FCS measurement in living cells is presented, and critical issues in experimental design (from the choice of dyes or cells to data analysis) are addressed. The user must be aware that FCS requires subsequent adjustments in the experimental design (e.g., choice of fluorophore, derivation of analytical fitting equations, etc.) to successfully address specific biological questions.

STRATEGIC PLANNING

Equipment and Materials

The ConfoCor 3/LSM 510 system is a commercially available system from Carl Zeiss Microimaging, which combines an LSM 510 META laser scanning microscope with an FCS module to acquire high-resolution images and sensitive fluctuation analysis. The ConfoCor 3 detection allows one to quantitatively analyze the concentration, position, interaction, and mobility of molecules. The new experimental capabilities provided by the ConfoCor 3 take effect in the investigation of molecule distribution in cells, of diffusion processes by fluorescence correlation spectroscopy, and of protein complex formation in the detection of common movements and the quantification of receptor/ligand interactions.

The software controls the detection module and allows convenient analysis of single measurements or software-controlled multi-measurements. Autocorrelations are calculated in real time, i.e., at the same time as the current measurement. And there is always the choice of using the raw data for individual analysis.

Other options include advanced software modules that incorporate the most common methods, free diffusion, anomalous diffusion (Wachsmuth et al., 2000), and flow (Gosch et al., 2000), provide for user-defined models, allow for global and interactive fitting with the possibility of defining start values and boundaries, and make photon counting histograms possible (Chen et al., 1999, 2000).

Nunc Lab-Tek (*http://www.nuncbrand.com/en/page.aspx?id=2298*), Mat-tek chambers (*http://www.glass-bottom-dishes.com*) are deep-welled chambers with cover-glass bottoms onto which cells are plated. Many cells stick directly onto glass but the surfaces can also be coated with poly-lysine to facilitate sticking. The cover-glass bottoms of the chambers allow high-magnification, high-resolution microscopy with water-immersion objectives. Cells should be plated sufficiently in advance such that they have adhered and acclimated to culture conditions. For FCS experiments, the cell medium should be one without phenol red dye, to limit background fluorescence noise. Additionally, if carbon

dioxide levels on the microscope stage cannot be controlled, supplement the medium with HEPES buffer, pH 7.2, to 25 to 50 mM final concentration.

High numerical aperture (NA) water-immersion objectives are critical components of an FCS system. The signal-to-noise ratio for an FCS measurement is proportional to the square of the collected fluorescence per fluorescent object, hence the need to maximize NA (Krichevsky and Bonnet, 2002). Living cells are imaged in water-based media; therefore it is best to use water-immersion objectives whose limited spherical aberrations ensure a more accurate definition of the confocal volume from which FCS measurements are made. Typically, a 40×/1.2-NA water-immersion objective with collar adjustment for the thickness of the coverslip is used; this minimizes aberrations in the *z*-axis and provides a tight diffraction-limited confocal volume of illumination inside the primarily aqueous cytoplasm of a living cell.

Fluorescent dyes are used for calibrating an FCS instrument. Fluorescent dyes (e.g., Oregon Green or FITC), fluorescently labeled dextran, or Fluospheres (Invitrogen) can all be used for instrument calibration prior to acquisition from cells. Typically, a single concentration of Oregon Green (100 nM dilution) in phosphate-buffered saline (PBS) is placed into an 8-well LabTek chamber with no. 1.5 coverslip bottom. Calibration should be done daily for every experiment to align pinhole and the detectors and maximize the number of collected photons.

Choice of labeling for molecule of study must be determined, e.g., GFP, YFP, CFP, and mRFP are used for FCS measurements. XFP-tagged proteins can be exogenously expressed in cells by transfecting a plasmid encoding the chimera ≥8 hr prior to FCS. Alternatively, the fluorophores Oregon Green, FITC, Rhodamine 6G, etc. can be covalently linked to the protein or lipid molecule under study and microinjected into the cells. Special care in the choice of organic fluorophores should be taken to maximize the signal-to-noise ratio for FCS analysis. Practically, this implies maximizing the number of photons that are collectable from one individual fluorophore (Koppel, 1974). In particular, when studying internal conformational changes, e.g., rotation, intramolecular quenching (Bonnet et al., 1998; Haupts et al., 1998), one should avoid fluorophores with large singlet-triplet rate of conversion (e.g., use Oregon Green over triplet-prone FITC). Furthermore, one should always prefer dyes that minimize photobleaching. This is especially relevant when performing FCS on slow-diffusing molecules such as membrane proteins.

Any cell type (flat cells like fibroblasts or rounded cells like lymphocytes) can be used for FCS measurements as long as cells are adherent to or can be tethered on the glass coverslip (e.g., by cross-linking onto poly-L-lysine-coated coverslips or by adsorption onto antibody-coated coverslips) to minimize movement during fluorescence acquisition (in the latter case, proper control experiments must be performed to validate that the tethering does not perturb biological functions).

For transfection, any nucleic acid transfection agent can be used. Fugene (Roche Diagnostics) or Lipofectamine (Invitrogen) is usually used. The protocols for transfection can be obtained from the manufacturers' Web sites.

The level of fluorescent protein expression is an important parameter because too high levels of expression force the experimenter to decrease laser excitation to avoid detector saturation with the fluorescence collected from fluorescent objects. This decreased laser excitation in turn would substantially decrease the number of emitted photons that can be collected per fluorescent object and, therefore, the FCS measurements. One solution is to photobleach a large fraction of the fluorescence from the cell before making FCS measurements. In the ConfoCor 3 Acquisition menu, one can set the FCS protocol to bleach for a user-defined amount of time at a high laser intensity setting before switching to a lower laser power for the actual FCS acquisition.

SETTING UP FLUORESCENCE CORRELATION SPECTROSCOPY FOR LIVING-CELL MEASUREMENTS

This protocol describes the steps for setting up the Zeiss LSM 510 ConfoCor 3 FCS system, one of the more popular turnkey FCS systems commercially available. For other setups, the step-by-step instructions may vary.

Materials

Cells growing on a glass-bottomed culture dish (Mat-Tek) or chambered slide (Lab-Tek, Nunc) with lid at 50% confluency
Medium for incubation on microscope stage (culture medium with serum but without phenol red, supplemented with 25 to 50 mM HEPES)
Petroleum jelly (e.g., Vaseline, Cheeseborough)
100 mM Oregon Green in PBS or other fluorescently labeled molecule for calibration

FCS machine, e.g., Zeiss LSM 510 ConfoCor 3 FCS system
8-well Nunc-Lab Tek chambers

Prepare cells

1. One hour prior to FCS measurements, change the medium of the cells at 50% confluency into a medium that is optimal for keeping cells on the microscope stage.

   This medium is typically the tissue culture medium that the cells are normally maintained in (containing serum), buffered with 20 to 50 mM HEPES, pH 7.3, but without phenol red.

   The absence of phenol red pH indicator (commonly used in tissue culture media) helps to minimize the levels of background fluorescence during FCS.

2. Fill the Nunc Lab-Tek chambers as high as possible with the medium to ensure a large volume above the cells that will not evaporate over the course of the measurement time. Moreover, to minimize evaporation, smear the inside of the chamber lid with a coat of petroleum jelly and fit the lid onto the chamber.

   Sealing the lid with petroleum jelly allows the user to open the lid for adding various agents to the cell medium and will limit evaporation, which can cause changes in the salt concentrations and pH of the medium. Alternatively, if cells are left alone for long periods of time or if no additions are necessary, the outside edges of the lid can be glued to the chamber.

   There are several options for temperature control of the microscope stage. An airstream incubator ASI 400 (Nevtek) in combination with a digital thermometer with a thermocoupler (Omega Instruments) whose temperature sensor is attached to the head of the condenser or to a site on the stage adjacent to the cell chamber is a convenient set-up for holding steady temperatures (±0.5°C) in most applications requiring imaging up to 12 hr (Rabut and Ellenberg 2004; Altan-Bonnet et al., 2006). It also allows easy access to the cell chamber for adding reagents to the cells during the course of the experiment while on the stage without shaking the cell chamber or stage, both of which could result in the loss of the position of the cell being imaged. The drawbacks are exposure to ambient CO_2 and humidity, the usual degradation of the buffer, and the fact that over time the medium will gradually evaporate and become basic in pH. If long-term maintenance of cells is necessary, then it is recommended to invest in a closed chamber set-up that encloses the microscope stage and optics.

Set up for microscopy

3. Turn on the FCS machine following the manufacturer's instructions. Turn on the stage temperature control and set it to the desired temperature. Wait at least 30 min before FCS acquisition.

4. Turn on all needed lasers. Wait at least 30 min before starting measurements to allow stabilization and to minimize fluctuations in laser output.

   Typically, the argon laser should be run at 50% of maximum output. This setting maximizes the stability of laser emission.

5. Go to ConfoCor mode, and set up the optical path—this includes choosing the laser line for excitation, choosing the laser line intensity, selecting the dichroic mirrors that will allow both the 488-nm excitation and emission >500 nm, and selecting the emission band-pass filters and the detector.

   For example, for Oregon Green or GFP, excitation is 488 nm at ~1% intensity, a 488-nm dichroic mirror, and a band-pass filter of 500 to 550 nm.

6. First, place the 8-well Nunc-Lab Tek chamber containing 100 nM Oregon Green (or another fluorescently labeled molecule) in PBS onto the stage.

7. Go to the Sample Carrier menu and select the correct sample carrier, i.e., chamber type (in this case, a Nunc 8-well chamber).

8. Select the exact chamber position from which the Oregon Green dye acquisition will be made. Focus 200 μm above the glass coverslip into the solution.

   One easy way to determine if you are above the glass coverslip is to run a line scan from the confocal imaging mode. Start out the line scan with the pinhole completely open and the objective far away from the bottom of the glass coverslip. As you are running the line scans, move the focus wheel of the microscope such that the objective will move closer to the glass coverslip. While moving up the objective, pay attention to the line scan window, which will output a line with a hill, which is the reflected excitation light not yet focused on a glass coverslip surface. As the objective hits the bottom glass coverslip surface, the line will increase in amplitude, then decrease, and finally hit a maximum again when the objective reaches the top surface of the glass coverslip. At this point, one can use the objective control stepper (present on most confocal systems) to go 200 μm above the top glass coverslip.

Align and optimize system

9. Set the Pinhole, from the ConfoCor 3 Adjust menu item, to 70 μm and run Pinhole Alignment. Adjust the pinhole using the Oregon Green dye solution. During pinhole alignment, move the pinhole along the *x* and *y* axis until the maximum intensity of emission is found.

10. Once the pinhole is aligned, take a Count Rate of the solution (this is, the number of photons emitted by individual molecules per second).

    At a concentration of 100 nM Oregon Green, the minimal count per molecule should be at least ~5000 counts/sec. If lower than this, realign pinholes either through the software for a minimal alignment or manually for more significant alignment issues (this procedure usually requires service by a professional contractor).

Optimize image

11. Switch to the chamber with cells once the system is aligned and optimized with the Oregon Green sample. Switch to confocal imaging mode (i.e., go out of FCS menu). Perform a single *x-y* scan of the cells (in confocal imaging mode; Fig. 4.24.2A). When appropriate cells have been identified for imaging, acquire quick scans while adjusting the focus, the pinhole, laser intensity, detector gain, and amplifier gain, to determine the optimal image.

    The quality of this image will effect where you spot the beam for collecting FCS data.

    The x-y scan pinhole should be adjusted to give a high-resolution image, typically ~1 Airy unit. To be <1 Airy unit is usually not recommended since there is very little resolution gained to compensate for the significant loss in light collection from the sample.

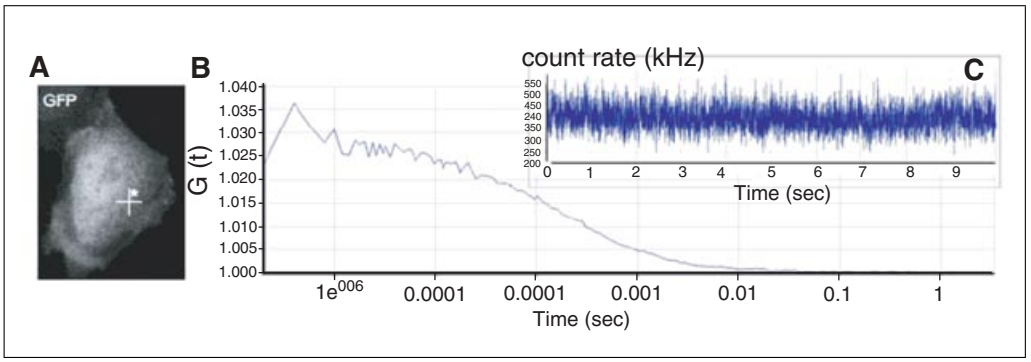

Figure 4.24.2 Autocorrelation on cytosolic GFP. Autocorrelation function is collected from a confocal volume chosen in the cell cytoplasm where soluble GFP is being expressed (**A**). Note how the baseline for the autocorrelation function is flat (between 100 msec and 1 sec) yielding a good fit and diffusion estimate (**B**). The count rate is stable indicating the necessary lack of photobleaching (Inset **C**).

12. When the object is to collect correlation spectra from the plasma membrane or any other membrane, acquire a z-stack of 1 μm and determine the z-position where the fluorescence intensity is at its peak. It is best to limit the laser excitation intensity and keep the number of z slices to a minimum to minimize bleaching the sample.

13. Save the image in a database and keep a copy of it on the screen.

14. Switch back to the FCS (or ConfoCor) mode.

Select the method

15. Go to the Methods menu item. Select from either of the preexisting methods or set up a new method.

16. To set up a new method, go to Acquisition Setup under the Measure menu, and then change the laser excitation, dichroic, and band-pass filter settings to the appropriate settings for the fluorophore inside the cells.

    For GFP-expressing cells, these settings will be similar to those used to obtain count rates for Oregon Green dye.

17. Save these settings under a new method name.

18. Keep laser excitation intensity low such that the Triplet Fraction is <10% of the molecules.

    The triplet state of the molecule is when it is in an excited but dark state—where it has given off only a portion of the absorbed energy as photons. To determine the triplet fraction at a particular laser intensity, pay attention to the Triplet Fraction column of the data table generated during FCS acquisition.

19. Go to the Measure menu option. Switch carrier from 8-well Nunc to LSM Image. Then mark positions in the cell where data collection is desired (Fig. 4.24.2A). Pick several positions within the cell and one position outside the cell for background measurement. Do not forget to hit the Mark positions button for this will number each position.

20. Go to Acquisition under the Measure menu, and set the acquisition time from each site in the cell.

    Typically, this time should be ~10 to 15 sec or 1000-fold the diffusion time of the molecule being investigated.

21. Set the Repeat count (this is the number of readings taken from each site).

    For good data fitting, take at least ten measurements from each site.

Acquire data

22. Start acquisition.

    During acquisition, fluorescence read out will be taken from each site for a pre-defined amount of time (~10 sec). A typical read out for GFP expressed in the cytoplasm is presented in Fig. 4.24.2 including the Correlation function G(t) versus lagtime (B) and the count rate over time (C).

    Longer acquisitions from a single marked site will allow for more statistical information for long lagtimes (t >1 sec). This will benefit curve fitting but it may also result in increased bleaching of the sample. Typical acquisition times are 10 sec. In the acquisition menu, one can also introduce a pre-bleach time prior to FCS acquisition. Here the sample will be photobleached for a discrete amount of time before recording correlation. This is useful if the sample fluorescence is too high. Always perform measurements a second time with five times higher power to check consistency with power amplitude.

23. Save the correlation graphs generated by the Zeiss LSM software. Additionally, save the raw acquired data and export as a .txt file to an analysis software (e.g., Prism, Kaleidagraph, or Matlab) for further custom modeling and fitting.

CHECKING THE CONFOCAL AND FCS ALIGNMENT

SUPPORT PROTOCOL

This is a simple way to check the ConfoCor and FCS *x-y* alignment.

Materials

1 μmol FITC solution in DMSO
No. 1 coverslips
ConfoCor FCS system (Zeiss LSM 510)

1. Place a drop of FITC solution onto a no.1 coverslip.
2. Dry in the dark 30 min in ambient air.
3. Set up the ConfoCor FCS system for confocal imaging (see Basic Protocol 1).
4. Using LSM mode, image the surface of the coverslip in the confocal setup. Leave the LSM image window and control screen on the computer screen.
5. Go back to the ConfoCor Measurement menu and mark positions on the recorded LSM image.
6. Set up a long-time exposure (10 min) for FCS measurement with maximal laser power (100% of 488-nm line) to bleach the marked sites.
7. Re-image the surface of the coverslip using LSM mode and measure by drawing a line using the overlay option in the ConfoCor image display menu, the shift between the targeted FCS site (under the arrow), and the actual measurement site (bleach spot).
8. Adjust the *x* and *y* registries under the Settings in the LSM+ConfoCor menu item.
9. Repeat steps 4 to 6 to ensure the accurate registry of confocal and FCS volumes.

ANALYZING FCS DATA

BASIC PROTOCOL 2

The most difficult task in a successful FCS measurement is the fitting and interpretation of the collected data. Although these are common tasks of any experimental measurement, there are a few issues that are specific for FCS and these will be addressed in this section.

FCS monitors any fluctuation of fluorescence within the confocal volume. Typically, any variation of fluorescence on time-scales from 1 μsec to 1 sec will generate a relaxation in

the autocorrelation curve that must be fitted and interpreted. To successfully process the data, the experimenter must derive an analytical formula accounting for all fluctuations. For FCS in living cells, these analytical fits may be hard to derive, which leaves the experimenter with hard-to-interpret phenomenological time-scales that are still sufficient for an analytical assay in perturbation experiment (comparison of wild-type and drug-treated or gene-perturbed cells).

Simple two-dimensional diffusion model for a single species

$$G(\tau)=\left[1+\frac{1}{N}\right]\left[\frac{1}{1+\frac{\tau}{\tau_D}}\right]$$

Equation 4.24.1

Where N is the average number of fluorescent objects within the confocal volume, τ_D the correlation time $\tau_D = \omega^2/4/D$, where D is the diffusion coefficient of the fluorescent object and ω is the radial diameter of the confocal volume. The LSR510-ConfoCor software has the capacity to use a theoretically more accurate diffusion fit including the longitudinal diffusion. But, a three-dimensional formula does not improve the statistical accuracy of the fit, and it requires careful calibration of the longitudinal dimension of the confocal volume to be valuable. A typical curve for soluble GFP diffusing with a cell cytoplasm is presented in Fig. 4.24.2.

Simple two-dimensional diffusion model for multi-species

$$G(\tau)=\left[1+\sum_i \frac{1}{N_i}\right]\left[\frac{1}{1+\frac{\tau}{\tau_i}}\right]$$

Equation 4.24.2

Where N_i is the average number of fluorescent objects labeled i within the confocal volume, $\tau_0 = \omega^2/4/D_i$, where D_i is the diffusion coefficient of the fluorescent object labeled i and ω is the radial diameter of the confocal volume. Note that the more difference there is between the diffusion of the fluorescent objects, the better the fit of the data.

Abnormal diffusion

In many living cell settings, the diffusion of fluorescent objects encompasses multi-scale, multi-time-scale moves. An explicit description of such a convoluted process is formally impossible, and experimenters routinely use a phenomenological "stretched diffusion" formula to fit the FCS data. An example of such a fit was used by Weiss et al. (2003):

$$G(\tau)=\left[1+\frac{1}{N}\right]\left[\frac{1}{1+\left(\frac{\tau}{\tau_D}\right)^{\alpha}}\right]$$

Equation 4.24.3

where N is the average number of fluorescent objects within the confocal volume, τ_D is a characteristic diffusion time-scale, and α is the stretching parameter (with $0<\alpha<1$). The smaller the value of α, the more convoluted the diffusion is.

Relaxation model with two-dimensional diffusion

When the fluorescent object under study fluctuates between quenched and fluorescent states, FCS can monitor the chemical relaxation of this process (Haupts et al., 1998; Altan-Bonnet et al., 2003):

$$G(\tau)=1+\left[\frac{1}{N}\right]\left[\frac{1}{1+\frac{\tau}{\tau_0}}\right]\left(1+\beta e^{-\frac{\tau}{\tau_R}}\right)$$

Equation 4.24.4

where N is the average number of fluorescent objects within the confocal volume, τ_0 is the characteristic diffusion time-scale, and τ_R is the characteristic chemical-relaxation time-scale. For a simple on-off with characteristic chemical rates k_{on} and k_{off}:

$$\tau_R=(k_{on}+k_{off})^{-1} \text{ and } \beta=K_{equilibrium}=\frac{k_{on}}{k_{off}}$$

Equation 4.24.5

In practice, the dynamic range for the FCS autocorrelation amplitude β is too small to yield an accurate estimate of K—a separate measurement is then required.

More generally, the analytical fits used to analyze FCS measurements can become complicated by the rich dynamics of a system (e.g., Altan-Bonnet et al., 2003). There are reviews documenting different applications with different fitting functions for FCS measurements in living cells (Krichevsky and Bonnet, 2002; Carl Zeiss Microimaging, 2006).

FCS output parameters

A typical FCS curve for diffusing fluorescently tagged molecules within the cytoplasm of a living cell and the associated fit to help FCS users understand what each parameter means (see Fig. 4.24.3) is described on a mixture of two species (component no. 1 and 2):

$$G(\tau)=1+\left(\left[\frac{1}{N_1}\right]\left[\frac{1}{1+\frac{\tau}{\tau_1}}\right]+\left[\frac{1}{N_2}\right]\left[\frac{1}{1+\frac{\tau}{\tau_2}}\right]\right)\left(1+\left[\frac{p}{1-p}\right]e^{\frac{-\tau}{\tau_T}}\right)$$

Equation 4.24.6

Diffusion times are $\tau_1 = 100$ μsec and $\tau_2 = 10$ msec, with $N_1 = 2$ and $N_2 = 2$ particles/confocal volume. The dye has a triplet time τ_T of 1 μsec and a triplet fraction at 10% ($p = 0.1$). Note how the two diffusion times yield two relaxations that can hardly be separated.

Typically, the fit is:

$$G(\tau) = 1 + \left(\sum_i \frac{1}{N_i} \frac{1}{1 + \frac{\tau}{\tau_i}} \right) \left(1 + \left[\frac{p}{1-p} \right] e^{\frac{-\tau}{\tau_T}} \right) = 1 + \left(\sum_i \beta_i \frac{1}{1 + \frac{\tau}{\tau_i}} \right) \left(1 + \beta_{\text{triplet}} e \frac{-\tau}{\tau_T} \right)$$

Equation 4.24.7

ConfoCor fitting software generates a table with the following parameters:

a. Count rate [kHz] is the total number of photons collected by a detector per second.
b. Correlation is the amplitude of the correlation function $G(0)$.
c. Counts per molecule [kHz] is computed as (Count rate)$(G(0) - 1)$. This parameter can be very useful to estimate the state of aggregation of a fluorescent protein.
d. Amplitude Number particles $= N_i$ (note that

$$G(0) - 1 = \sum_i \frac{1}{N_i}$$

Equation 4.24.7A

when the triplet fraction p is negligible).
e. Triplet state fraction [%] is $p(100)$.
f. Triplet state relaxation time [μsec] is τ_T.
g. Component i fraction [%] is

$$\text{Component } i \text{ Fraction } [\%] = 100 \left[\frac{N_i}{\sum_i N_i} \right]$$

Equation 4.24.7B

h. Component i diffusion time [μsec]: τ_i,
i. Translation structural parameter should be fixed upon calibration of the optical setup. To calibrate the size of the confocal volume, perform an FCS measurement on a solution of fluorescent dye (e.g., Oregon Green) at a known concentration c. Measure the amplitude number of particles (N) in the FCS measurement. Then,

$$V_{\text{confocal}} = \frac{N}{cN_a}$$

Equation 4.24.8

where $N_a = 6.02 \times 10^{23}$ is the Avogadro number.

In particular, this will enable you to calibrate the translational structure parameter (TSM) as:

$$\text{TSM} = \frac{V_{\text{confocal}}}{\pi \omega^2}, \text{where } \omega = \sqrt{4D\tau_D}$$

Equation 4.24.9

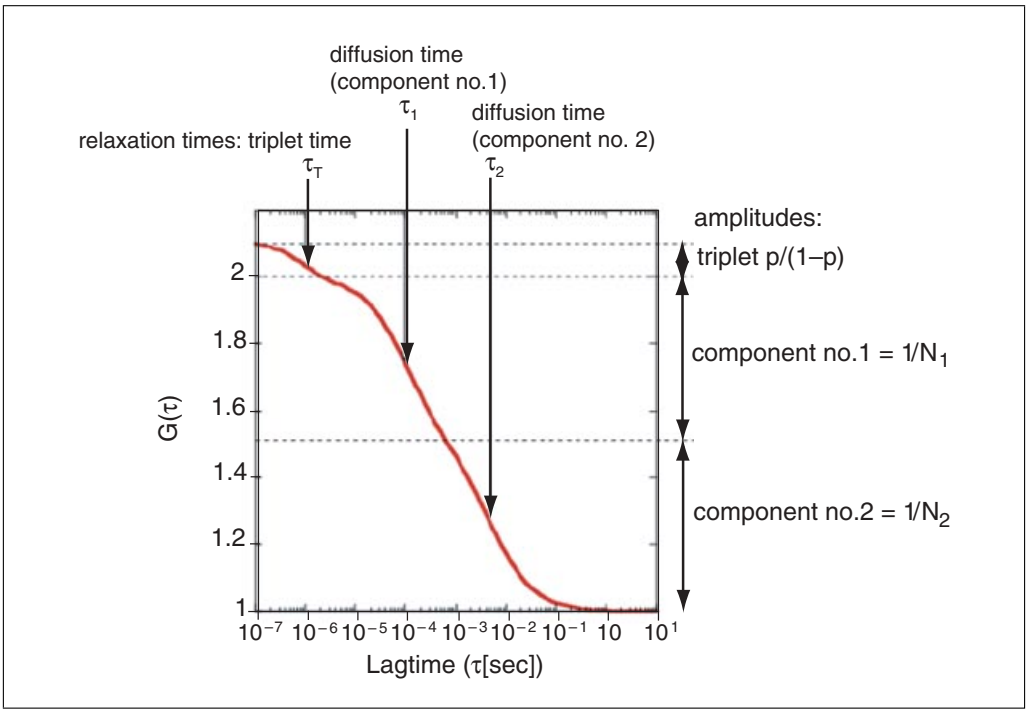

Figure 4.24.3 Typical FCS curve and relevant parameters.

It corresponds to the aspect ratio of the confocal volume, defined as the ratio of its longitudinal direction with the transversal dimension. Typically, this parameter should be set ~10.

COMMENTARY

Background Information

Fluorescence correlation spectroscopy (FCS) is a technique to monitor the relaxation dynamics of a biomolecular system. It relies on fluctuation in the rate of photon emission for fluorescent objects; these fluctuations classically arise from diffusion in and out of a collection volume or via quenching/dequenching of fluorophores upon conformational changes. FCS was originally designed as a spectroscopy technique to monitor kinetic relaxation in bulk solution, e.g., the kinetics of reversible binding of ethidium bromide onto double-stranded DNA (Magde et al., 1972). Since the 1990s and the reliance on confocal microscopy setup to optimize fluorescence collection (Rigler et al., 1993), FCS has become more practical and moved towards more applications in living cells—for a review, see Schwille (2001). The introduction of FCS capabilities onto commercial confocal microscopes was a key step towards making this technique accessible to the cell biology community.

FCS offers many advantages compared to other techniques that have been used to monitor biomolecular events by fluorescence, e.g., fluorescence recovery after photobleaching (FRAP) or fluorescence resonance energy transfer (FRET). FCS in living cells achieves single molecule resolution by minimizing the background fluorescence (confocal setup typically limits the collection volume to a 0.3 × 0.3 × 1–μm^3 volume) and optimizing the photon collection efficiency (the introduction of reliable single-photon avalanche photodiodes was critical to make FCS accessible beyond Optics). FCS is particularly useful for application in living cells, as it yields complex measurements to match molecular complexity: using FRET, one may estimate the complexity of a mixture of fluorophores (e.g., aggregation, stoichiometry, etc.); using FRAP, one could monitor biomolecular dynamics (e.g., estimation of diffusion coefficients, estimation of mobile versus immobile fractions); FCS can achieve all these measurements at once (Hess et al., 2002), and yield additional information (in particular, an absolute estimate of concentrations of fluorescent molecules).

Critical Parameters and Troubleshooting

Optimizing the signal-to-noise ratio of FCS measurements

Optimizing an FCS measurement implies optimizing the actual number of photons collected from individual fluorescent objects. This parameter can be obtained from the count rate/molecule in the LSM 510-ConfoCor software.

Typically, for GFP in living cells, with 1% of the 488-nm lane of a 40-Watt argon laser, and a 70-μm collection pinhole, one should obtain typically 15,000 photons per sec (15 kHz/molecule). Once the experimental system (with a chosen fluorophore) has been configured, only three parameters—the optical alignment, the laser excitation, and the acquisition time—need to be optimized by the experimenter. LSM 510 ConfoCor 3 allows the experimenter to automatically align the acquisition pinhole (in *x* and *y* directions) based on maximization of collected fluorescence. The *z*-alignment is more difficult to optimize but factory settings are usually sufficient. The experimenter should then increase the laser intensity until fluorescence photobleaching becomes prevalent (this can be detected by seeing a non-flat baseline at long lag times, Fig. 4.24.4). Finally, the experimenter should then increase the percentage of laser power to P_b when fluorescence photobleaching becomes prevalent (this can be detected by seeing a non-flat baseline at long lag times, Fig. 4.24.4). The authors usually set back the laser power to $P_b/10$ to minimize photobleaching during actual data acquisition. Finally, the experimenter should optimize the acquisition time to allow sufficient photon collection and achieve statistical significance for the autocorrelation function while minimizing photobleaching in the spot of interest.

Note that the number of photons collected from individual fluorophores may be limited by the saturation of the photoreceptors (theoretically 5 million counts/sec, practically 1 million photons/sec). Thus, there are intrinsic limitations on the concentration of fluorescent objects per confocal volume that is compatible with sufficient photon collection for FCS. Typically, if one would like to collect at a count rate of 5000/sec/molecule, there will be at most 200 molecules in a confocal volume of typically 1fl, and the maximum concentration of fluorescent objects in this experiment would be 0.4 μM. Hence the need to select lower-expressing cells or pre-bleach the samples.

Photobleaching

Photobleaching of the fluorophore under consideration should not be a concern in FCS experiments when relaxation time-scales <50 msec are under consideration (typical for proteins diffusing in the cytoplasm). However, for membrane proteins or for proteins bound to large biological objects (vesicles, mitochondria, etc.), residency time within every confocal volume gets larger than 50 msec, and one should pay special attention to the issue of photobleaching.

In a typical FCS application in living cells, photobleaching appears as a large decay in the autocorrelation function with typical time-scales between 100 msec and 10 sec (Fig. 4.24.4). To maintain the statistical relevance of data fitting, one must make sure that the autocorrelation baseline at long lag times is flat. The rule of thumb is then to obtain at least half a decade of flat baseline at

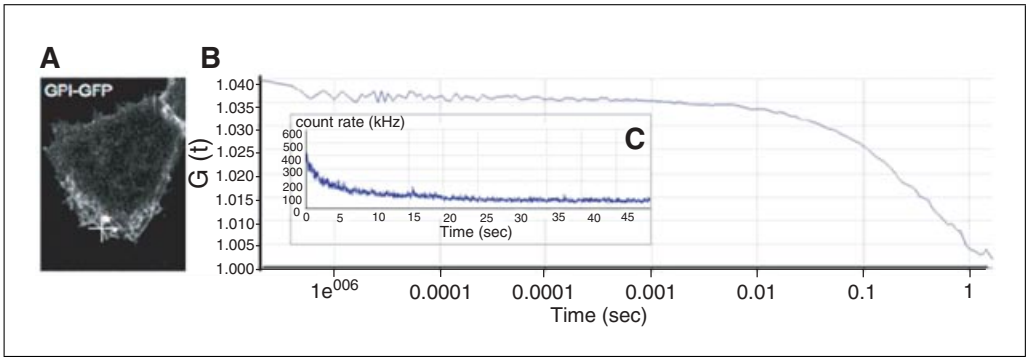

Figure 4.24.4 Autocorrelation on plasma membrane–associated GPI-GFP. Autocorrelation function is collected from in a confocal volume chosen on the plasma membrane, where GFP is anchored via a GPI domain (**A**). Note how the baseline for the autocorrelation function is not flat (between 100 msec and 1 sec) because of photobleaching of the plasma membrane–anchored GFP (**B**). Photobleaching is apparent as an exponential decay in the countrate (Inset **C**).

1.0 to be secure that photobleaching will not be an issue in the analysis of the autocorrelation function. A second rule to experimentally control for photobleaching consists in repeating every FCS measurement with increased laser excitation; if photobleaching is irrelevant, the overall shape of the autocorrelation function should not be affected by the change in laser intensity.

Triplet formation and environmental variation of fluorescence

In some experiments, one would like to gain information about faster fluorescence fluctuations (with time-scales <100 μsec compared to typical diffusion events >100 μsec), in particular, to study GFP dynamics and gain information on pH environment in living cells, or to study small fluorophore diffusion. In that range of time-scales, one must pay attention to potential artifacts due to the fluorophore internal dynamics or detector limitations.

Fluorophore internal dynamics in the 10- to 100-μsec range as measured by FCS can be informative of the biological environment (e.g., monitoring GFP quenching at low pH). On the other hand, triplet formation (a situation where the fluorophore goes from a singlet-excitable state to a triplet-quenched state) occurs with time-scales between 1 μsec and 10 μsec (Fig. 4.24.5). An easy solution to control for potential excitation-induced dynamics is to check the consistency of the FCS measurements for different laser intensities. Note that diffusion time-scales will increase slightly as laser intensity is increased because of an increase of excitation volume.

Triplet formation is a problem encountered mostly with inorganic dyes (e.g., FITC) at high laser intensity. GFP and other naturally fluorescent proteins have very low triplet conversion probability (Widengren and Rigler, 1998). It is not recommended to use the LSM 510-ConfoCor to decipher sub-microsecond fluctuation dynamics as detector after pulsing, because it introduces a highly correlated signal in the autocorrelation curve in that time-range (Krichevsky and Bonnet, 2002).

Aligning confocal and FCS volumes

In the Zeiss ConfoCor 3 as well as the Leica FCS2, scanner mirrors of the confocal microscope are used for precise positioning, ensuring that the correlation spectra are recorded from the exact locations marked on the images scanned. However, it is still good practice to check for any offset between the scanners and the FCS stage positioning, especially if precision is needed <100 nm in x and y. To determine the offset, one can use a macro (available on the Zeiss or Leica instruments) or do it manually with an 'ad hoc' procedure to ensure that the two confocal volumes from which fluorescence is collected are exactly aligned, such that confocal imaging and FCS measurements are in registry. Note that misregistry along the z axis is unlikely as this optical alignment does not vary much from the factory-settings; only x and y alignments need to be performed before every FCS session (see Support Protocol).

To perform offset compensation with a macro, follow instrument manufacturer's instructions.

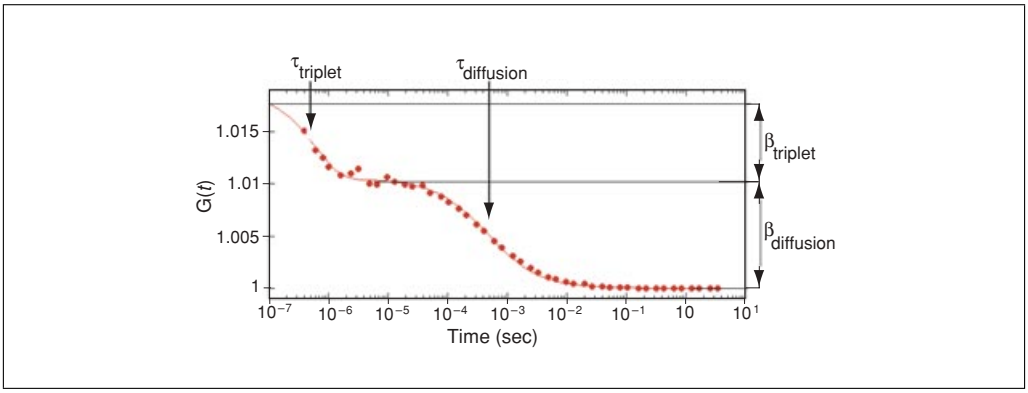

Figure 4.24.5 Autocorrelation function (circle) and associated fit (continuous line) for a solution of FITC-labeled IgG. The fit corresponds to a single component two-dimensional diffusion with a triplet relaxation equation (Equation 4.24.5). The two relaxations can easily be distinguished: the slow one is associated with diffusion ($\tau_{diffusion} = 500$ μsec) and the fast one with triplet relaxation ($\tau_{triplet} = 0.6$ μsec). Their respective amplitudes are $\beta_{diffusion} = 0.01$ (hence there are $1/\beta_{diffusion} = 100$ fluorescent objects per confocal volume) and $\beta_{triplet} = 0.82$ (hence, $p_{triplet} = 0.45$ as $\beta_{triplet} = p_{triplet}/(1 - p_{triplet})$.

Anticipated Results

From millisecond-resolution FCS measurements of fluorescently labeled objects, one can determine how many species of molecules may be diffusing through the confocal volume; measure the diffusion coefficient of the molecules; measure the actual number of molecules diffusing within the confocal volume; and from there calculate the total number of molecules within the cell. One can also determine the fraction of triplet state molecules within the fluorescing population. The measurements of the fluorescence per object can yield an estimate of the number of aggregated molecules, if the fluorescence per molecule has been properly calibrated. For cytosolic soluble GFP, a typical diffusion time scale is ~100 to 250 μsec, triplet state fraction is ~10% to 20%, counts per molecule is ~10 kHz.

Time Considerations

From turning on the instrument to aligning and calibrating the instrument with dye molecules until it is ready for recording correlation spectra from experimental samples takes 30 min up to 2 hr. Once the instrument is aligned, actual recordings from sites within a cell can take from a few seconds to a few minutes, depending on the number of sites and the number of recordings obtained from each site. Data analysis can take several hours or more depending on the experimenter's knowledge of statistics.

Analysis of Mitochondrial Dynamics and Functions Using Imaging Approaches

Kasturi Mitra[1] and Jennifer Lippincott-Schwartz[1]

[1]Cell Biology and Metabolism Program (CBMP), National Institute of Child Health and Human Development (NICHD), NIH, Bethesda, Maryland

ABSTRACT

Mitochondria are organelles that have been primarily known as the powerhouse of the cell. However, recent advances in the field have revealed that mitochondria are also involved in many other cellular activities like lipid modifications, redox balance, calcium balance, and even controlled cell death. These multifunctional organelles are motile and highly dynamic in shapes and forms; the dynamism is brought about by the mitochondria's ability to undergo fission and fusion with each other. Therefore, it is very important to be able to image mitochondrial shape changes to relate to the variety of cellular functions these organelles have to accomplish. The protocols described here will enable researchers to perform steady-state and time-lapse imaging of mitochondria in live cells by using confocal microscopy. High-resolution three-dimensional imaging of mitochondria will not only be helpful in understanding mitochondrial structure in detail but it also could be used to analyze their structural relationships with other organelles in the cell. FRAP (fluorescence recovery after photobleaching) studies can be performed to understand mitochondrial dynamics or dynamics of any mitochondrial molecule within the organelle. The microirradiation assay can be performed to study functional continuity between mitochondria. A protocol for measuring mitochondrial potential has also been included in this unit. In conclusion, the protocols described here will aid the understanding of mitochondrial structure-function relationship. *Curr. Protoc. Cell Biol.* 46:4.25.1-4.25.21.

Keywords: mitochondria • imaging • live cell

INTRODUCTION

Mitochondria are double membrane-bound organelles harboring their own DNA; they have been classically thought to be the powerhouse of the cell. Recent studies of mitochondria in the cellular context have revealed several other functional contributions of the organelles, including redox homeostasis, lipid modification, calcium homeostasis, and cell death processes (Scheffler, 2001). The inner membrane of mitochondria maintains a transmembrane gradient of ions that is known as mitochondrial potential. Measuring mitochondrial potential, which drives mitochondrial ATP synthesis (Nicholls and Budd, 2000), can assess mitochondrial function and integrity. Although early studies with isolated mitochondria have elaborately described mitochondrial properties, today's challenge is to understand the widespread roles of mitochondria and their interplay with other intracellular organelles. Live cell imaging of mitochondria, more than a decade ago, revealed these organelles are highly dynamic. Since then many researchers have focused on understanding the dynamism of these organelles (Detmer and Chan, 2007), as this property might be coupled to how mitochondria perform their many functions inside the cells. Therefore, techniques for imaging mitochondria are continually being improved to help further understand the structure/function relationship of these dynamic organelles.

Mitochondria are distributed throughout the cell and they exist in different sizes and forms that range from small granular to highly filamentous shapes. Although lack of

DOI: 10.1002/0471143030.cb0425s46

mitochondrial dynamism is deleterious to cells, it is not understood how changes in mitochondrial morphology bring about change in mitochondrial function (reviewed in Detmer and Chan, 2007). The dynamics of mitochondrial forms within cells is controlled by specific molecules involved in mitochondrial fission and fusion, as well as those controlling the cytoskeletal structure, most importantly microtubules (De Vos et al., 2005). The steady-state fission-fusion events of mitochondria together with the motility of individual mitochondria pose serious challenges for high-resolution live cell imaging of mitochondria; this challenge has only been recently met with the advent of confocal microscopes with high-speed acquisition. This unit describes fluorescence-based confocal imaging approaches to study mitochondrial dynamics and function in live mammalian cells.

STRATEGIC PLANNING

Live cell imaging of mitochondria can be performed by tagging resident mitochondrial proteins with fluorescent proteins or by adding specific mitochondrial targeting sequences to fluorescent proteins (Okamoto et al., 2001). Commercially available dyes can also be used, although with limitations (Chen, 1988). Depending on the researcher's interest, there are various approaches for imaging mitochondria. For example, high-resolution three-dimensional imaging can provide details about mitochondrial structures and their association with organelles like the endoplasmic reticulum. Time-lapse imaging techniques allow aspects of mitochondrial dynamics to be studied quantitatively and qualitatively. It can also be used to visualize exchange of molecules, like mitochondrial DNA, between mitochondria undergoing fission and fusion events (Detmer and Chan, 2007). The physical and electrical continuity between mitochondria undergoing fission and fusion can also be studied using live cell imaging approaches employing FRAP and microirradiation protocols. Finally, mitochondrial potential can be quantified on a single cell or single mitochondrion based on incorporation of specific fluorescent dyes.

As mitochondria are an integral part of the cell death signaling machinery, their morphology is highly sensitive to the status of cellular health. A great deal of caution, therefore, is required to avoid causing any perturbations to this organelle during imaging. The points discussed below should always be considered when preparing samples for imaging mitochondria in order to optimize imaging conditions and to avoid artifacts. The protocols described here are optimized for adherent cells with 75% confluency. However, they can be modified as per the requirements for suspended cells.

Sample Preparation

1. When working with mitochondrial markers tagged to fluorescent proteins (FP), it is recommended to first make a stable cell line expressing the molecule of interest. This is because transient expression itself is a stress to cells, which might affect mitochondrial morphology. For example, we have found that the DsRed molecule targeted to the mitochondrial matrix causes mitochondrial fragmentation after 48 hr of transient transfection. For primary cultures where markers cannot be stably expressed, transient expression systems can be used to express molecules at low levels for short period of time. One can also choose to use fluorescent dyes to stain mitochondria for short-term experiments.

In the case of overexpression systems, transient or stable, precautions have to be taken to ensure that expression of the fluorescent molecule of interest is not altering mitochondrial morphology. This can be done by comparing mitochondrial morphology in the stable line and its parental line. The steps include: (1) staining the parental line (that is not expressing the mitochondrial FP) with a fluorescent mitochondrial dye (Mitotracker green etc.); (2) counting cells according to mitochondrial morphology as fragmented/intermediate/tubular (Karbowski et al., 2006); (3) counting cells according to

mitochondrial morphology as fragmented/ intermediate/tubular in the stable line expressing mitochondrial fluorescent protein; (4) comparing the distribution of mitochondrial morphology of the parental line to that of the cell population expressing the fluorescent mitochondrial molecule.

2. The medium used for imaging should always be pre-incubated in a 37°C incubator with 5% CO_2 for 30 to 60 min.

3. The pre-incubated medium should be used to replace the medium in which cells were grown in the imaging chambers. This has to be done immediately after the plated cells have been brought out of the incubator. Next, the medium in the imaging chamber has to be carefully overlayed with mineral oil that would form a meniscus on the medium. The level of the medium has to be high enough so that the oil meniscus is not close to the bottom of the chamber where cells are plated, which might kill the cells. The actual purpose of the mineral oil is to prevent CO_2 from escaping the medium, which would change the pH of the medium. CO_2-independent medium can be used to avoid use of mineral oil. However, this is not recommended for experiments demanding more than 1 hr. In this time, evaporation of water from the medium would concentrate the components of the medium, which in turn might affect mitochondrial morphology and function.

4. The stage warmer should be preset 30 to 45 min before commencement of the experiment. A properly calibrated temperature probe is mandatory. The calibration of the temperature probe should be checked by dipping the probe in two water baths maintained at different temperatures. This ensures that the monitored temperature at the stage is correct. To monitor the stage temperature, the temperature probe should be put at the top of the objective (but not touching it), exactly at the point where the specimen in the stage holder to be imaged will be held during imaging.

Choice of Mitochondrial Marker

As mitochondria are double membrane-bounded organelles, one needs to have knowledge about the localization of the molecule/dye of interest in the mitochondria for proper interpretation of imaging results. At the resolution of light microscopy, one cannot distinguish between the outer and inner membranes but can distinguish between the (outer/inner) membranes and the matrix. Therefore, the final outcome of experiments might differ with different choices of molecules to image mitochondria.

Although high-resolution *z* stacks can be acquired by using fluorescent dyes, time-lapse imaging for assessment of mitochondrial dynamics could be erroneous when performed with fluorescent dyes. This is because dye addition has the possibility of affecting mitochondrial behavior. The best and reproducible result is obtained by using fluorescent mitochondrial markers like mitoRFP/mitoGFP/mitoYFP. Use fluorescent molecules with the excitation peak at longer wavelengths to avoid the possibility of mitochondrial damage from more energetic shorter wavelengths. Only the stable lines expressing mitochondrial markers can be imaged for very long time periods, even more than 24 hr. By contrast, experiments using fluorescent dyes need to be performed within 30 to 45 min, after which the mitochondria usually fragment in response to the foreign chemical.

For photobleaching experiments, the mitochondrial fluorescent tag should be chosen such that it is bright and photostable under low illumination but photobleaches fast and almost irreversibly. The irreversibility of photo bleaching is very important because if the bleached molecule reverts to its fluorescent state it will contribute to the recovery. This would lead to erroneous conclusion about the physical mitochondrial process under investigation. This can be checked by performing the experiment, with the exact same configuration as chosen, but in a fixed sample. If the reversion of the bleached molecule is minimal there should be no recovery in the fixed sample.

BASIC PROTOCOL 1

HIGH-RESOLUTION *z*-STACK AND TIME-LAPSE IMAGING OF MITOCHONDRIA

Analyzing a *z*-stack across the depth of the cell provides steady-state three-dimensional information about mitochondrial morphology while time-lapse imaging allows changes in mitochondrial morphology (dynamics) to be studied over time. Figure 4.25.1 depicts a representation of a projection of *z*-stacks of mitochondria in a single cell.

Materials

Stably transfected cells expressing fluorescent-tagged molecule of interest *or* mitochondrial fluorescent dyes of interest
Chosen dye (see the Support Protocol)
Immersion oil

Labtek or Matek chambers
CO_2 incubator at 37°C
Microscope stage heater and temperature probe (e.g., Oka-lab)
Confocal laser scanning microscope, like Zeiss LSM510 or similar, with appropriate laser and filter sets required for imaging
63× Plan-Neofluar oil objective with high NA (1.4)

1. Plate stably transfected cells in Labtek/Matek chambers at least 10 to 16 hr before imaging.
2. Stain the cells with the chosen dye, if required (see the Support Protocol).
3. Prepare the sample (see Sample Preparation in Strategic Planning).
4. Preheat the microscope stage to 37°C. Turn on the appropriate laser at least 15 min prior to the experiment to give it time to stabilize.
5. Put a drop of immersion oil on the objective and fix the chamber to be used to the stage holder properly.

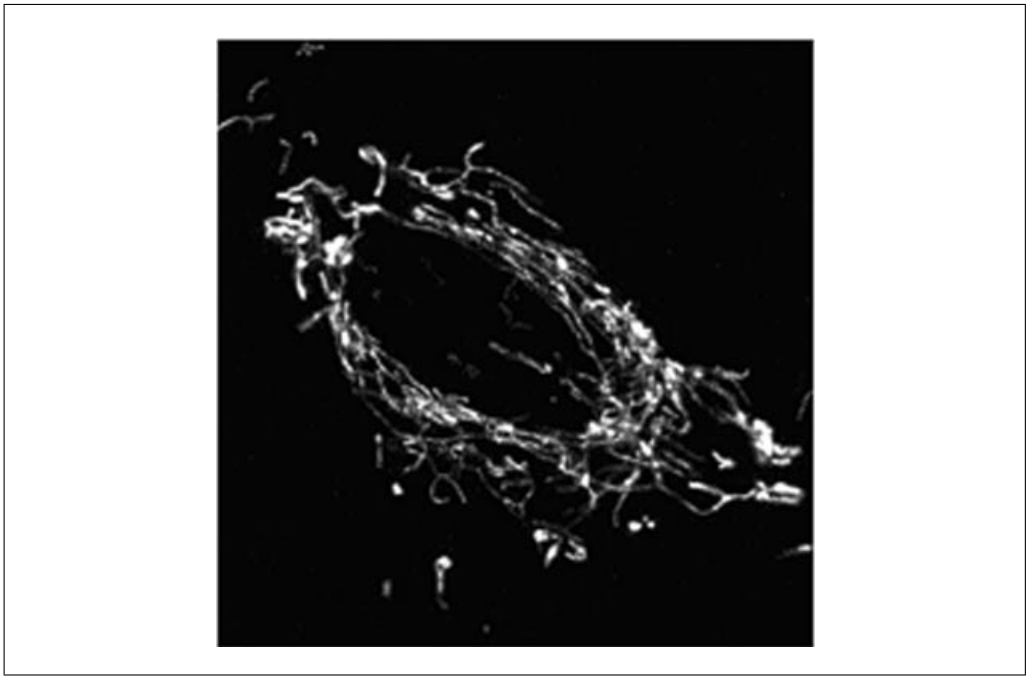

Figure 4.25.1 High-resolution image of mitochondria in a stable fibroblast cell line expressing mitoRFP. The image is a projection of *z*-stacks of mitochondria. A 543-nm HeNe laser was used for imaging and *z*-stacks were acquired following Basic Protocol 1. Imaging settings are listed in Table 4.25.1. The raw image has been converted into gray scale.

Table 4.25.1 Scanning Parameters for Acquiring High-Resolution *z*-Stacks of Mitochondria

Parameter	Value
Zoom[a]	2.5-3
Pixel size	1024 × 1024
Scan speed	7
Scan number for averaging	2
Pinhole	1 airy unit
Laser intensity	1%-20%
Detector gain	600

[a]High-resolution imaging of mitochondria would limit the investigator to scan one cell at a time, or part of a cell or even individual mitochondria. To image a whole cell the zoom factor (digital magnification) will have to be decided based on the size of the cell. A zoom factor of more than 5 is not recommended as this would cause the image to be pixilated, but this value can be used, if absolutely necessary, by adjusting other parameters.

6. Choose the appropriate configuration for the fluorophore to be imaged.

   To be able to do so one needs prior knowledge of the excitation and emission properties of the fluorophore (UNIT 21.5)

7. Choose a cell to be imaged by using the FAST scan button in minimum zoom.

   One can also quickly select a cell by looking through the eyepiece of the microscope with the proper filter. Selecting a cell, if not accomplished within few seconds, might cause bleaching of the fluorophore or photodamage to the mitochondria.

8. Adjust the laser intensity and detector gain according to the brightness of the sample in such a way that the signal from any pixel is not saturated (as checked in the palette in the LSM 510 systems).

   For quantitative imaging, this is essential, but for qualitative purposes some pixels may be allowed to cross the threshold to be able to detect other very faint pixels. This is because the fluorescent signal might not be distributed to all the mitochondria homogeneously, especially in certain conditions where normal mitochondrial morphology is perturbed.

9. Set the scanning parameters including zoom, pixel size, scan speed, scan number for averaging, pinhole, laser intensity, detector gain, etc. and scan a single section.

   Table 4.25.1 provides values for these parameters for proper imaging of mitochondria of a whole cell. If necessary, the parameters can be changed to yield better results.

10. If satisfied with the image, check for minimal bleaching.

    This is very important for time-lapse imaging. With laser power and scanning parameters being fixed, bleaching would depend on:

    (1) Scanning frequency: As mitochondrial movement per second is below the resolution limit of light microscope (as measured in neurons; De Vos et al., 2003), an imaging speed of 1 frame per second serves the purpose. One can further reduce the speed to 0.2 frames per second or 1 frame every 5 sec.

    (2) Number of scans: The total number of scans in a time series would depend on the duration of the experiment. For minimal bleaching, it is recommended to give more time between scans when intended to perform a longer time series experiment.

    The scanning parameters can be altered to reduce bleaching by enhancing scan speed and reducing averaging. Doing so will compromise the resolution. Therefore, a degree of trade

off between resolution and dynamics of mitochondrial structure has to be considered; the choice will be dependent on the goal of the experiment being performed.

Bleaching could arise during acquisition of z-stacks. This can be assessed by performing a time series where the time interval will be the same as the scan time of a single z-section. If there is no reduction in signal in this time, the parameters are suitable for z-sectioning. If not, the laser intensity and detector gain have to be adjusted according to the brightness of the sample.

11. Acquire the time series or *z*-stacks and save images.

    For acquiring overlapping z-stacks, the size of the optical slice should be twice than that of the z-interval, while for non-overlapping z-stacks, the optical slice should be close to that of the z-interval. For example, if pinhole size allows light from a 1-μm optical slice, the z-interval should be 0.5 μm for overlapping z-stacks and 1 μm for non-overlapping z-stacks. Oversampling might scan the same portion of the image more than once while undersampling might miss scanning portions. This could introduce errors in quantitative measurements like mitochondrial size, especially in case of tubular mitochondria.

    For long-term time series experiments, one should be aware of the drift in focus (due to thermal or other fluctuations) in the imaging setup and include autofocusing modules, like Multitime (Zeiss) for correcting the drift.

ALTERNATE PROTOCOL

IMAGING MITOCHONDRIAL MORPHOLOGY ALTERATIONS

The morphology of the mitochondria is influenced directly and indirectly by many factors. For example, nearly all the agents causing mitochondria-dependent cell death have been found to cause mitochondrial fragmentation (Karbowski and Youle, 2003). Recent studies are also being focused on identifying drugs that would directly impact the mitochondrial fission-fusion machinery and alter mitochondrial morphology (Cassidy-Stone et al., 2008). To image the effect of drugs or other chemicals on mitochondrial morphology/function, include the following steps for modifying acquisition of time series as mentioned in Basic Protocol 1. An example is illustrated in Figure 4.25.2, where time-lapse images have been acquired immediately after addition of microtubule depolarizing drug, nocodazole (5 μg/ml) to investigate the change in mitochondrial morphology after disrupting microtubules. Note the alteration in mitochondrial morphology from time 0 (before addition) to 30 min after addition.

Additional Materials *(also see Basic Protocol 1)*

Drug of choice (e.g., 5 μg/ml nocodazole)

1. Prepare the sample as in Basic Protocol 1 (or as in the Sample Preparation section of Strategic Planning), but do not overlay the sample medium with mineral oil.
2. Acquire 2 to 5 images of the chosen field.
3. Stop scanning and carefully remove the lid of the chamber.
4. Carefully aspirate 50% of the medium from the chamber using a pipet.
5. Add a volume equal to the volume removed of a 2× concentration of the drug to the chamber.

   The drug is added at twice the working concentration for the drug.

6. Carefully overlay with mineral oil.
7. Put the lid of the chamber back and quickly resume imaging.

   Care should be taken not to alter the plane of focus during the procedure of addition of drug. If the focus appears to be shifted, one has to quickly reset the focus keeping the last scanned image of the field as standard. The time period between stopping and resuming scanning has to be taken into account during the final analysis of the time series.

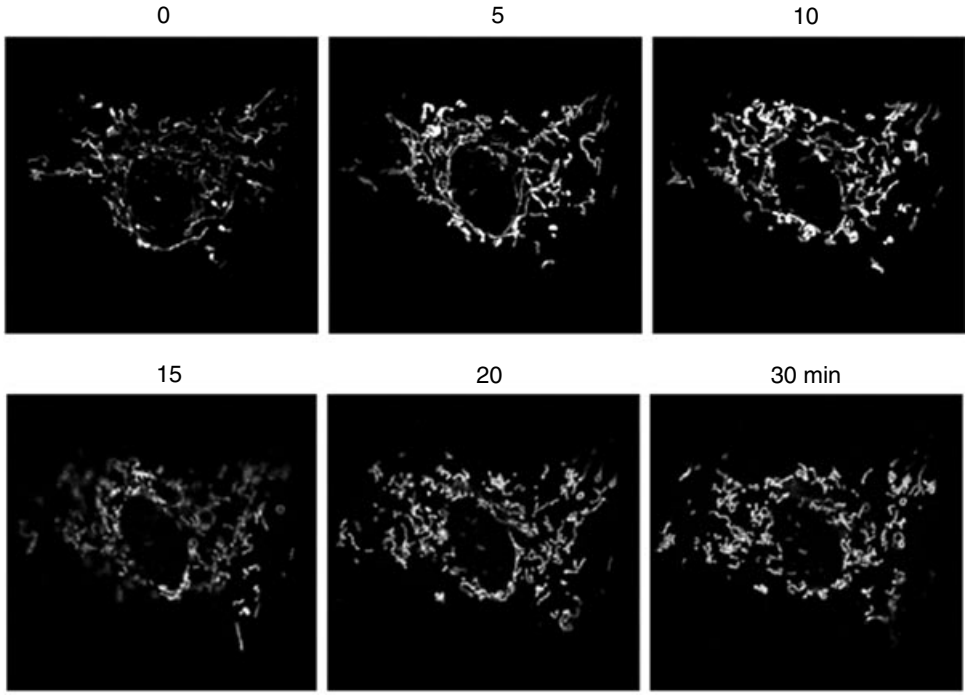

Figure 4.25.2 Time series of mitochondria after addition of nocodazole to depolymerize microtubules. Experiment was performed in a fibroblast line stably expressing mitoRFP. Time-lapse images were acquired following Basic Protocol 1 and the Alternate Protocol. The numbers represent time (in min) after addition of nocodazole. A 543-nm HeNe laser was used. The raw image has been converted into gray scale. Images were acquired using a 63× objective in zoom 2. Pinhole size was 2.5 airy units.

FLUORESCENCE RECOVERY AFTER PHOTOBLEACHING ON MITOCHONDRIA

BASIC PROTOCOL 2

Fluorescence recovery after photobleaching (FRAP) is a powerful biophysical method that is used to understand the dynamics of molecules or structures in live cells. This method involves photobleaching of fluorescent molecules within a certain area of a cell and then monitoring recovery of fluorescence in the bleached zone by movement of molecules/organellar structures from the surrounding unbleached zone. For more detailed discussion of the theory of FRAP, please see *UNIT 21.1*. This experiment involves time-lapse imaging as it depends on the kinetics of mitochondria per se or that of a mitochondrial protein. Three types of information related to mitochondrial dynamics can be obtained from FRAP experiments depending on the time scale of recovery: (1) mobility of the fluorescent molecule—the time scale of recovery is in milliseconds and the recovery kinetics is a measure of diffusion of the fluorescent molecule of interest; (2) mitochondrial continuity: the time scale of recovery is from few seconds to 2 to 3 min depending on the area of bleach; this gives a measure of continuity of the mitochondrial compartment where the fluorescent molecule resides (please refer to Mitra et. al., 2009 for a specific example); (3) mitochondrial movement/dynamics (fission-fusion): the time scale is between 2 to 3 min to ∼1 hr; this recovery is due to the combination of mitochondrial motility and fission-fusion dynamics. The time scale of the FRAP experiment has to be chosen depending on the investigator's goal. The protocol here uses a microscope with faster scanning speed for measuring molecular mobility. Since the protocols are the same for all three options, they are mentioned under the same heading.

Materials

Confocal laser scanning microscope, like Zeiss LSM510 or similar, with appropriate laser and filter sets
63× Plan-Neofluar oil objective with high NA (1.4) is best for imaging mitochondria in tissue culture cells
Microscope stage heater and temperature probe

1. Repeat steps 1 to 7 from Basic Protocol 1.
2. Set the scanning parameters including mode, zoom, pixel size, scan speed, scan number for averaging, pinhole, laser intensity, detector gain, etc. Verify the set of parameters by doing a single scan each time after adjusting a parameter. Table 4.25.2 provides FRAP parameters for all the three options.

   Settings may be altered to improve imaging depending on the system.

3. *Define region of interest (ROI):* Bleaching will be performed and recovery will be followed in the specified ROI.

   Two important criteria about selection of an ROI should be considered.

   Size: One should have an expectation regarding the source of recovery of fluorescence (for all options) in the ROI before setting this parameter. The size of the ROI should not be more than 30% to 50% of the total signal area, so that the recovery of fluorescence in a given time from the unbleached zone (70% to 50%) can be appreciably detected. The time to reach maximal recovery by movement of molecule inside mitochondria (molecular mobility, mitochondrial continuity) or that of mitochondria themselves (mitochondrial mobility/dynamics) would depend on the available unbleached fluorescence that would contribute to the recovery. The ROI size would be dependent on which option of the FRAP one chooses to do. For molecular mobility, the ROI should be only around 0.5 × 0.5 μm; just enough to cover a small zone on an individual mitochondria (Table 4.25.2,

Table 4.25.2 Scanning Parameters for Performing FRAP Analysis on Mitochondria

Parameter	Molecular mobility	Mitochondrial continuity	Mitochondrial mobility/dynamics
Objective	63×	63×	63×
Zoom	1	2	2-3
Pixel size	512 × 80	512 × 512	512 × 512
Scan speed	9	8	7-8
Scan number for averaging	1	1	1
Pinhole[a]	Open	Open	Open
Laser intensity	0.5%-10%	0.5%-10%	0.5%-10%
Detector gain	600	600	600
Size of ROI	0.5 × 0.5 μm	Variable[b]	Variable[b]
Time interval	5 msec	1 sec	5 min
Bleaching time	7 μsec	>1 msec <1 sec	>1 msec <1 sec
Bleach iterations	2	5	5
Time-lapse imaging duration	500 msec	1-5 min	30 min to 1 hr

[a]The pinhole should be kept open to be able to collect light from the whole depth of the cell. If the pinhole were narrow, then movement of mitochondria in and out of the optical plane would introduce fluctuations in the reading. However, an open pinhole would compromise the resolution to a certain extent. Reduction of laser intensity can sometimes help to avoid out-of-focus signal, which, however, would depend on organization of mitochondria in the cell of interest.
[b]Refer to the text on ROIs.

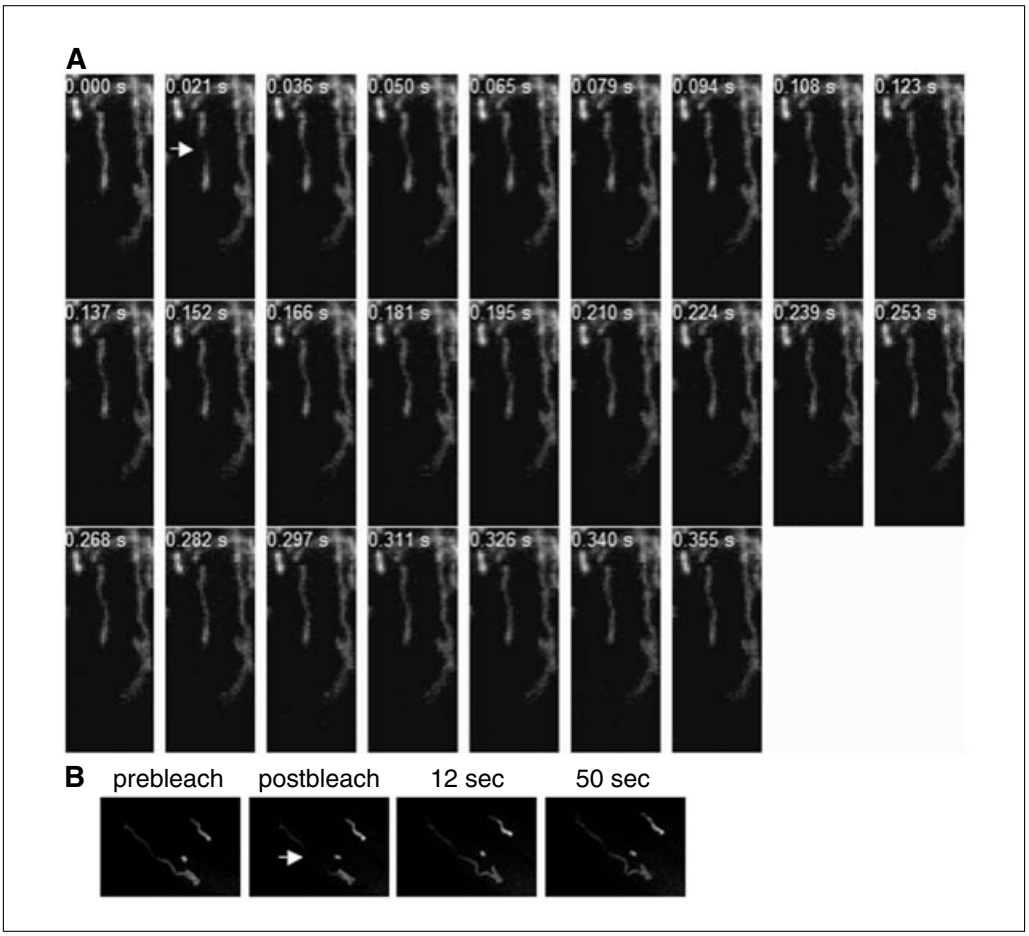

Figure 4.25.3 Fluorescence recovery after photobleaching on single mitochondria. Experiment was performed in a fibroblast line stably expressing mitoRFP following Basic Protocol 2. The time scale of recovery is in milliseconds. The arrow points to the bleached zone. Another mitochondrion in the field of view gives an assessment of overall bleaching during the recovery period. High-speed laser scanning confocal microscope (Zeiss LSM5 Duo) was used in **A** while a similar but slower microscope (Zeiss 510) was used in **B**. Prebleach and postbleach images depict mitochondria before and after the single bleaching pulse, respectively. A 543-nm HeNe laser line was used for imaging and other imaging settings used are mentioned in Table 4.25.2.

Fig. 4.25.4). For mitochondrial continuity and mobility/dynamics, one can decide to have the ROI spanning 5% to 2% of the cell either across the cell or locally (Fig. 4.25.3).

Placement: For continuity and mobility/dynamics measurements, the ROI should be placed in a region where the mitochondrial population is roughly uniformly distributed. In all the options, the ROI should be placed close to the center of the area of the total distributed signal. This means close to the center of the cell for continuity and dynamic measurements (Fig. 4.25.4) and the center of the mitochondrion of interest for molecular mobility studies (Fig. 4.25.3). This allows for movement of the fluorescence from all directions of the surrounding unbleached zone into the bleached zone. Wrong placement of the ROI, for example ROI placed to one side, might introduce errors in analyses and interpretation of the results.

4. *Standardize bleaching conditions:* Photobleaching is achieved by using maximum power of the of the same laser that is used for scanning. If the fluorescent molecule of choice is RFP, then it is recommended to use 458-, 488-, and 514-nm Argon lasers in addition to the less powerful 543-nm HeNe laser. As the RFP excitation spectrum with the peak at 543 nm also includes these wavelengths, the other lasers will enhance bleaching. For powerful 543-nm lasers, this might not be necessary.

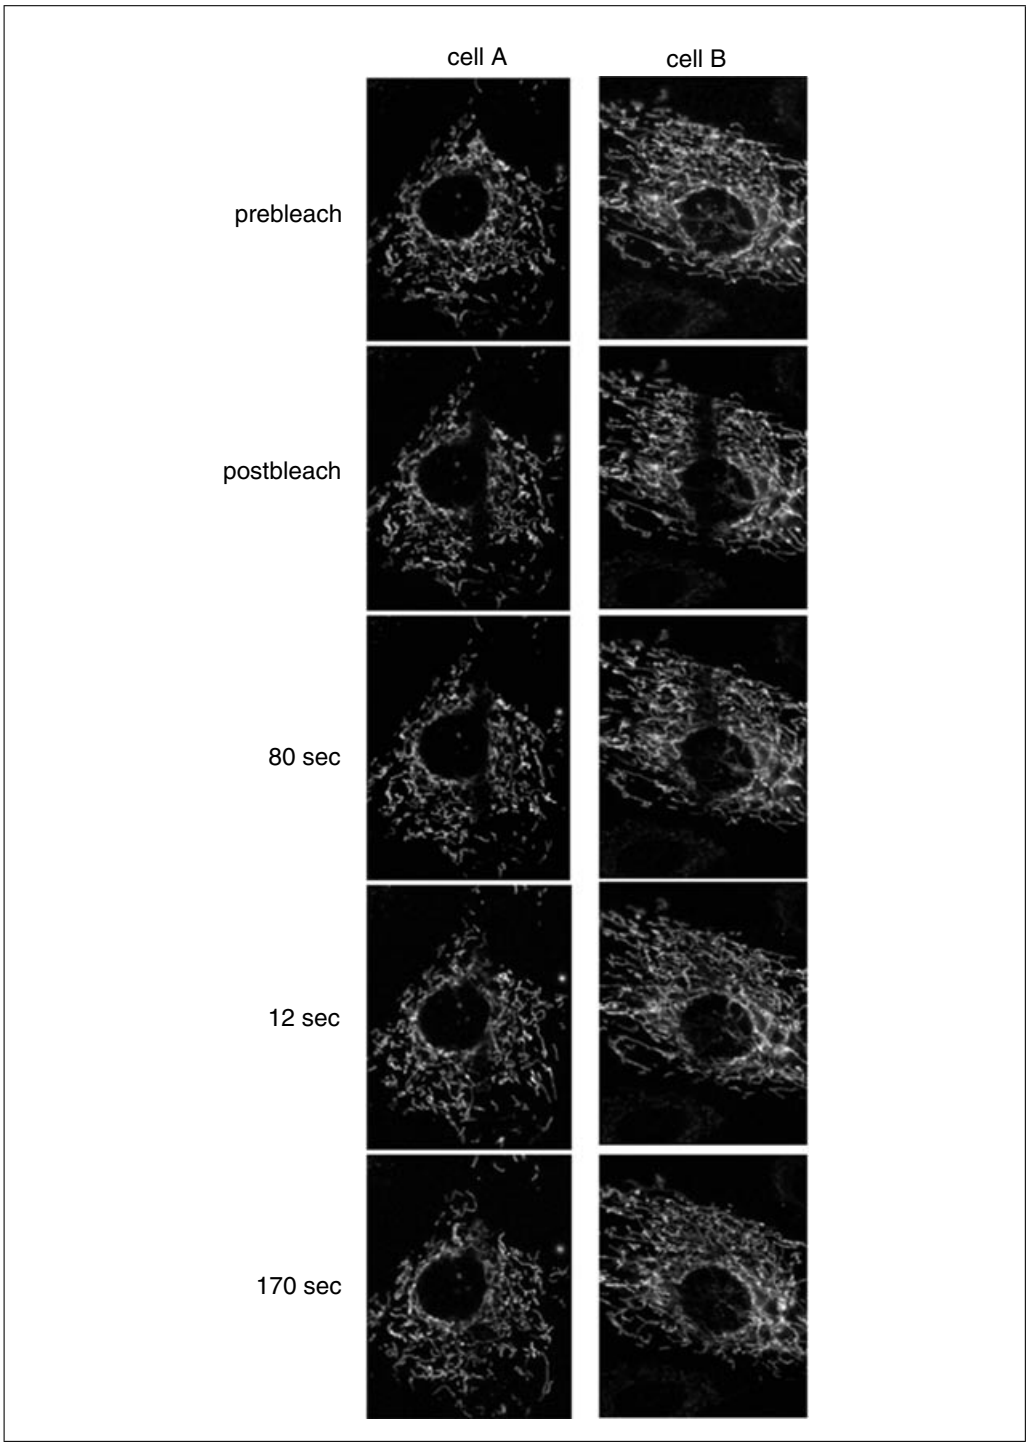

Figure 4.25.4 Fluorescence recovery after photobleaching on a mitochondrial population. Experiment was performed in a fibroblast line stably expressing mitoRFP following Basic Protocol 2. Prebleach and postbleach images depict mitochondria before and after the single bleaching pulse, respectively. The numbers represent time after post bleach in seconds. Two cells, A and B, have been shown to compare different recovery kinetics. A 543-nm HeNe laser line was used for imaging and other imaging settings used is mentioned in Table 4.25.2.

In continuity and mobility/dynamics measurements, bleaching should be as fast and as complete as possible; this can be increased by increasing the number of bleaching iterations; for molecular mobility measurements where the recovery kinetics is in milliseconds, bleaching should be faster and restricted to 20% to 40% of the initial fluorescence intensity. However, one should consider a trade off between the number of bleaching iterations and bleaching time. Bleaching for longer than necessary could damage mitochondria.

5. *Set the time interval and total imaging time:* These parameters depend on the option chosen.

   Scanning in short intervals would necessitate faster scanning. This may be achieved by restricting the scanning area to the zone of interest (Fig. 4.25.3A).

6. Acquire and save the time series to be analyzed when required.

   The quantitative analysis can be performed according to Goodwin and Kenworthy (2005). The number of recovery curves required for statistically significant analyses should be between 10 to 20. The data may be used to calculate half-time of recovery (t1/2), mobile and immobile fractions of the fluorescent molecule (see UNIT 21.1), diffusion coefficients (Partikian et al., 1998), and continuity parameters (Karbowski et al., 2006). An example of analysis of FRAP data has been provided in Figures 4.25.4 and 4.25.5. The figures depict analyses of mitochondrial connectivity in each of the two cells; bleaching was performed in the long ROI and the recovery in the small ROIs in each cell is compared to the recovery in the long ROI of the same cell. In cell A, individual ROIs appear to have different recovery kinetics while in cell B, individual ROIs have similar kinetics.

   The analysis will include correction for overall photobleaching that might have occurred during acquisition of the time series and total fluorescence that could contribute to the recovery. As mitochondria usually form small or large networks sharing their contents and continuously rearrange the branching points of the networks, it is very difficult to

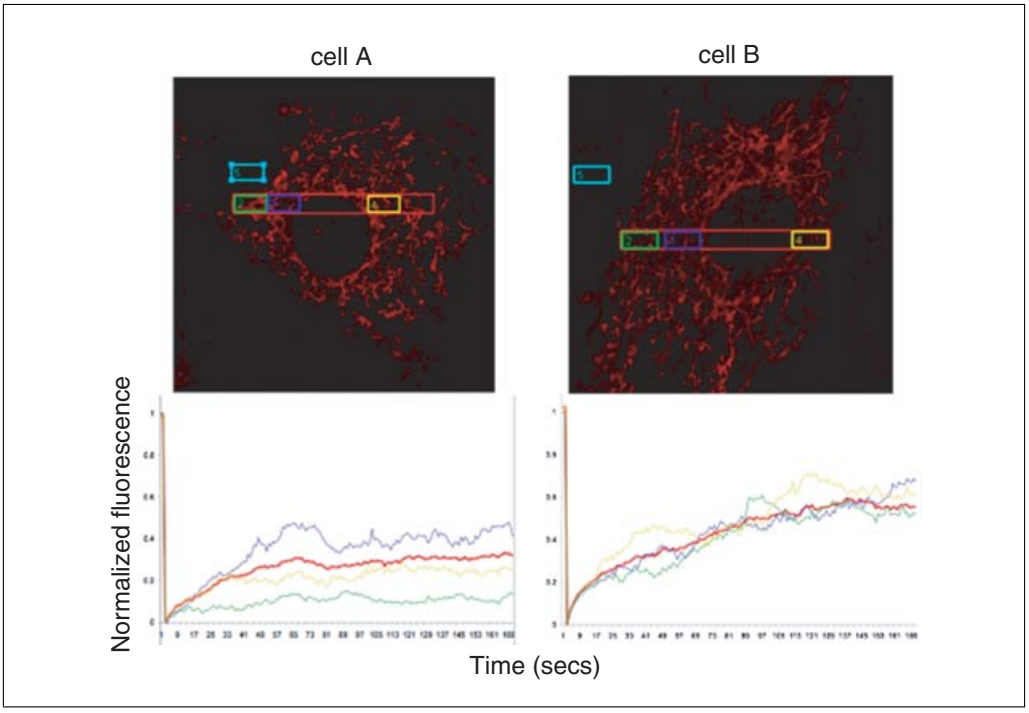

Figure 4.25.5 Analysis of connectivity by FRAP on a mitochondrial population. Images of cell A/B of Figure 4.25.4 were analyzed according to Goodwin and Kenworthy (2005). Different ROIs are color-coded corresponding to the associated graph showing recovery kinetics. The signal in the blue ROI was used to subtract the background signal. Signal was bleached in the red ROIs and recovery was monitored in all the ROIs. The analyses here do not include correction for bleaching and are normalized by the initial fluorescence. For the color version of this figure go to *http://www.currentprotocols.com/protocol/cb0425*.

have a knowledge of the total source of unbleached fluorescence that could contribute to the recovery. Depending on the analysis performed, the total source of unbleached fluorescence factor might be considered constant or ignored. For example in molecular mobility, if the individual mitochondrion appears to form a part of the network, then it is recommended not to consider the factor. However, it is recommended that this kind of an analysis be performed on mitochondria near the edge of the cell where there will very few separated mitochondrial elements (Fig. 4.25.3B). In the example of connectivity analysis provided in Figure 4.25.5, the normalization by the total fluorescence has been ignored. In this case, the alternative is to consider the total mitochondrial fluorescence as the source of recovery (which may not be the case in reality).

FRAP on mitochondria to analyze mitochondrial connectivity or diffusion of mitochondrial molecule is complicated by the motility of the organelles. This problem cannot be avoided, but some verification has to be done before proceeding for image analyses. Careful examination of the time series images is required for any of the three possible errors that could have been introduced during image acquisition: (1) sudden appearance of one or more motile mitochondria in the ROI considered; (2) mitochondria shifting or moving away, thus making the signal in the ROI unrepresentative of the experimental result for molecular mobility measurement; (3) the whole cell of interest moving during acquiring the time series for continuity and mobility/dynamics measurements. Any time series having one or more of these errors have to be discarded from the analyses.

BASIC PROTOCOL 3

MICROIRRADIATION ASSAY TO ASSESS ELECTRICAL CONTINUITY IN MITOCHONDRIA

Knowledge of mitochondrial biochemistry and energetic properties has been used to design fluorescent dyes (commercially available from Molecular Probes) to stain mitochondria in live cells (*UNIT 4.4* and Support Protocol 1 covers staining of mitochondria with these dyes). The fluorescent derivatives of certain cationic lipophilic compounds (i.e., TMRE) concentrate inside the mitochondria that maintain inner membrane potential. Therefore, uptake of TMRE can be used to quantitatively determine mitochondrial transmembrane potential. TMRE-loaded mitochondria are highly sensitive to laser scanning, which is reflected in the spontaneous depolarization that can happen when imaging TMRE loaded mitochondria in cells (Bunting, 1992). This phenomenon can be manipulated in a controlled fashion using a high-intensity laser to irradiate and thus depolarize TMRE-loaded mitochondria, resulting in immediate loss of TMRE from the irradiated mitochondria (Amchenkova et al., 1988). Directed irradiation in an ROI can cause controlled depolarization very locally in an individual mitochondrion in a cell. This local depolarization will rapidly spread from the irradiated point to mitochondrial elements in electrical continuity to the irradiated point (Fig. 4.25.6). Therefore, one can assess the extent of electrical continuity of mitochondria in an individual by micro-irradiating one point in a mitochondrion and monitoring, by time-lapse imaging, the spread of depolarization to other electrically continuous mitochondria.

Materials

Microscope stage heater and temperature probe
Laser scanning confocal microscope with (1) a 543-nm laser line and appropriate filter sets for imaging rhodamine and (2) a 2-photon chameleon laser
63× plan neofluar objective
Power meter (from Coherent)

Additional reagents and equipment for staining with TMRE (Support Protocol)

1. Preheat the microscope stage to 37°C and turn on the 543-nm HeNe laser and the 2-photon chameleon laser.
2. Stain with TMRE as in the Support Protocol.

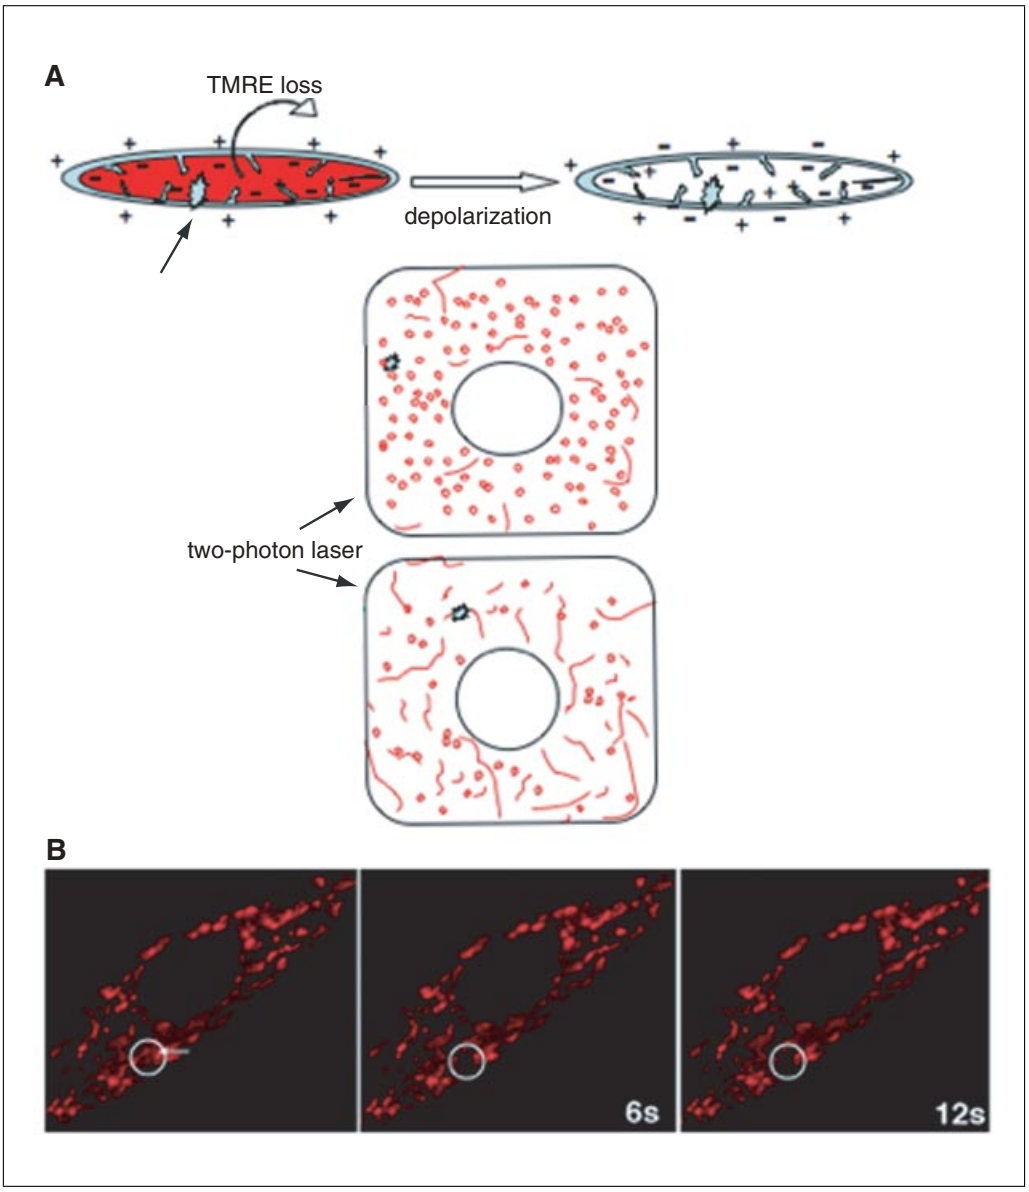

Figure 4.25.6 Microirradiation of TMRE-loaded mitochondria. (**A**) Depicts schematic representation of the microirradiation protocol. Mitochondria maintaining transmembrane potential (of charge) incorporate TMRE in the matrix. After being irradiated (green arrows) by the 2-photon laser locally, loss of TMRE occurs from the whole mitochondria due to depolarization triggered by the laser (as depicted for a single mitochondria in the upper panel and inside a cell in the lower panels). When this experiment is performed in cells, only single mitochondria are targeted for irradiation. (**B**) Shows images of a microirradiation experiment in a fibroblast where the arrow points to the site of irradiation. Images were acquired following Basic Protocol 3. Loss of TMRE signal is seen in the circled area in the time mentioned in seconds. For the color version of this figure go to *http://www.currentprotocols.com/protocol/cb0425*.

3. Repeat steps 1 to 7 from Basic Protocol 1.
4. *Set up imaging settings:* Use the 543-nm laser line for imaging. To image TMRE, use settings for Rhodamine. An open pinhole is used to collect signal from the whole cell. Choose zoom factor 4 for high-resolution imaging. Scanning speed and averaging can be decided by the investigator to obtain best possible resolution.
5. *Define ROI:* To be able to cause microirradiation for assessing electrical continuity one should choose an ROI covering only a small area of the mitochondrial population. The ROI should not exceed an area of 1 × 1–μm.

6. *Set up microirradiation settings*: Chose the 2-photon chameleon laser as the bleaching laser for causing microirradiation. Tune the laser to 800 nm. Use 10% to 20% of the laser power and appropriate filters to cut off longer wavelengths. Set number of iterations to 5. Set optimum imaging speed to one frame per second to be able to monitor spread of depolarization.

   All parameters, including the objective, should be kept constant for reproducible microirradiation, as each will affect the net power delivered to unit area of the sample. The choice of the microirradiating laser depends on the power of the laser. As the physics behind 2-photon excitement requires the laser to be highly powerful (Piston, 1999), this type of laser has been used in this protocol. Proper alignment of the 2-photon laser is critical to achieve the required power for microirradiation (see Dickinson, 2005 for details about 2-photon microscopy). The power at the rear end of the objective should be optimally ~60 mW, as measured with the power meter. Any other laser achieving the power requirement can also be used to microirradiate.

7. *Assess damage to the cell and mitochondria:* The optimal microirradiation settings should aim at causing mitochondrial depolarization and loss of TMRE within the ROI but not damage the cell or fragment the irradiated mitochondrion.

   The damage to the cell can be assessed by performing time-lapse imaging with the transmitted light/DIC, with the microirradiation setup. This time series has to be examined carefully to confirm that no unwanted formation has occurred at the point of irradiation and the cell has not swelled in the time scale of the experiment, both of which would indicate cell damage.

   Mitochondrial damage can be assessed by performing the microirradiation time-lapse experiment on cells expressing a mitochondrial fluorescent protein marker. Observing the mitochondria at the irradiated zone carefully, in the microirradiation time series, one should confirm that the microirradiation does not fragment the mitochondrion in the time scale of the experiment, which could be an indication of damage.

   If there is any indication of cellular or mitochondrial damage, the power of microirradiation has to be minimized by reducing the bleaching iterations or the power of the laser.

8. Acquire the microirradiation time series and save images to be analyzed when required.

SUPPORT PROTOCOL

STAINING MITOCHONDRIA IN LIVE CELLS TO ASSESS MITOCHONDRIAL FUNCTION BY IMAGING

Knowledge of the mitochondrial lipid environment has been used to synthesize fluorescent compounds that stain mitochondria in live cells. This protocol describes staining and imaging of live tissue culture cells using the mitochondrial labels TMRE, JC-1, mitotracker green, or Picogreen. Mitotracker Green and Non Acridyl Orange are such compounds that can be used to measure mitochondrial mass. Therefore, from the same cells stained with both Mitotracker green and TMRE (for mitochondrial potential, see Basic Protocol 3), one can assess mitochondrial potential per unit of mitochondrial mass on a single-cell basis or in single mitochondria. Compounds like JC-1 are also taken up by the mitochondria by the virtue of their transmembrane potential. This dye, which gets enriched in the high potential zones of mitochondria, can form aggregates that have altered emission spectra (Smiley et al., 1991). Moreover, mitochondrial DNA can be visualized with the DNA binding dye PicoGreen (Ashley et al., 2005; Fig. 4.25.7).

Additional Materials *(also see Basic Protocol 1)*

Appropriate growth medium
Respective dye: e.g., TMRE/Mitotracker Green/JC-1/Picogreen (Molecular Probes)
DMSO
Mineral oil

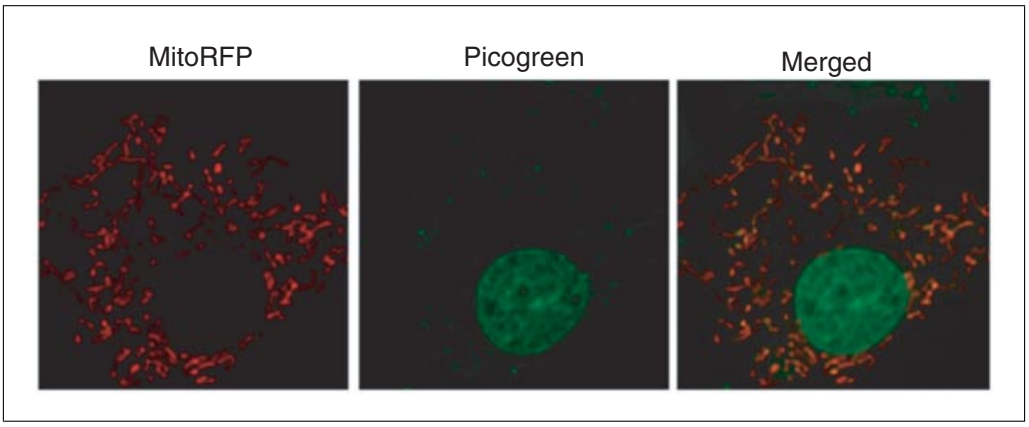

Figure 4.25.7 Picogreen staining of mitochondrial DNA. For the color version of this figure go to *http://www.currentprotocols.com/protocol/cb0425*.

37°C CO_2 incubator
Fluorescence microscope with proper filters for Rhodamine and Fluorescein

1. Plate cells in Labtek or Matek chambers with 75% confluency and perform the experimental procedure as required on the cells at least 16 hr after plating.
2. Incubate required volume of growth medium in the CO_2 incubator 1 hr at 37°C.
3. Thaw an aliquot of the respective dye and make the staining solution by diluting in the pre-incubated medium. Follow Table 4.25.3 for working concentrations.

   Each dye solution should be made in DMSO and maintained as small aliquots at −20°C. Freezing and thawing more than 5 to 6 times is not recommended.
4. Add a generous volume of the staining solution to the cells and incubate for 15 min in 37°C incubator.
5. Wash the cells three times, each time with pre-incubated medium in the same volume as that of the added staining solution (from step 4).
6. For double staining of Mitotracker Green and TMRE (to assess mitochondrial potential per unit mass), add diluted TMRE solution to cells already stained with Mitotracker green at this point and incubate for 15 min more.

   The following criteria have to be confirmed:

   (1) TMRE loading is below the quenching limits: When mitochondria are overloaded with TMRE a phenomenon of self-quenching occurs between TMRE molecules (Ward et al., 2000). This reduces the net TMRE signal obtained from mitochondria and thus will produce erroneous results. The concentration of TMRE mentioned here is below quenching limits but one should check this for every experimental set up as mentioned below.

   (2) No FRET occurs between Mitotracker Green and TMRE: fluorescence resonance energy transfer is a process by which energy is transferred from a donor molecule to an acceptor molecule with an overlapping excitation spectrum with the donor emission spectrum (UNIT 17.1). It has been reported that at certain concentrations FRET occurs from Mitotracker Green to TMRE molecules inside the mitochondria (Elmore et al., 2004). This will reduce the green signal in the presence of TMRE. Although the protocol involves much lower concentrations of both the dyes than necessary to undergo FRET, it is recommended this be verified in every experimental set up.

   Both of these caveats can be easily verified by performing time-lapse imaging of a double-stained sample after adding FCCP as mentioned in the Alternate Protocol. Addition of

Table 4.25.3 Working Concentration for Various Mitochondrial Fluorescent Dyes

Fluorescent dye	Working concentrations
TMRE	25-50 nM
Mitotracker Green	50-100 mM
Mitotracker red 633i[a,b]	250 nM
JC-1[c]	5 nM
PicoGreen[d]	1:500 dilution

[a]Overstaining results in the incorporation even in the endoplasmic reticulum.
[b]This dye and some others not mentioned here, are dependent on the mitochondrial potential to variable extents. Please refer to the relevant literature for the correct choice of dyes.
[c]Although the dye JC-1 can be used for qualitative purposes to assess heterogeneity in mitochondrial potential, it does not yield quantitative results and also often causes distortion in mitochondrial morphology. The dye forms particulate structures in solution; therefore, it is recommended to do a serial dilution after spinning down the solution each time. Otherwise, the particulate structure will deposit down on the bottom of the chamber during staining and the cells close to the particulate matter will incorporate more of the dye, yielding very erroneous results.
[d]Dilution is from a stock bought from Molecular Probes (P7581). Mitochondrial DNA would appear as cytoplasmic dots if optimally stained with this stain as seen in Figure 4.25.5. It is always recommended to perform dual staining with another mitochondrial marker or dye as cytoplasmic dots could also be due to mycoplasma infections.

FCCP would cause mitochondrial depolarization and loss of TMRE from the mitochondria. Therefore, if depolarization by FCCP reduces the mitochondrial red signal, the TMRE used is below the quenching level. On the other hand, if depolarization by FCCP increases the intensity of TMRE signal from mitochondria, it is an indication that TMRE loading is beyond the quenching levels. In this case, the working TMRE concentration has to be lowered and the test has to be repeated further. If the loss of TMRE signal by FCCP does not enhance the green signal from Mitotracker Green, then it is an indication of lack of energy transfer between the two fluorescent dyes. If addition of FCCP increases the signal from Mitotracker Green (indicative of FRET), then the working concentrations of the dyes have to be reduced and the test has to be repeated further.

In immortalized cells, an alternative for normalizing the mitochondrial mass could be replacing Mitotracker Green with stably expressing mitoGFP. This fluorescent molecule has a similar spectrum to that of Mitotracker Green and resides in the mitochondrial matrix. For this purpose, one needs to transfect mitoGFP into the cell line and select a stable clone that will be expressing mitoGFP equally in all the cells derived from the clone.

It is recommended to always include a control for hyperpolarization and depolarization in this analysis. Oligomycin would cause hyperpolarization by reducing mitochondrial ATP synthase activity and the ionophore FCCP would cause depolarization (Nicholls and Ward, 2000). As the assessment of mitochondrial potential by this kind of an analysis is done on a comparative scale, the samples treated with oligomycin and FCCP would serve to define the uppermost and lowermost limits in the scale of detection.

7. Repeat step 5.

8. Add pre-incubated medium and layer with mineral oil on top of the medium.

Add enough medium to ensure that the mineral oil meniscus does not touch the bottom of the chamber where cells are coated.

Table 4.25.4 Imaging Parameters for Measuring Mitochondrial Potential per Unit Mass

Parameter	Individual cell	Individual mitochondria
Objective	40×	63×
Zoom	0.7	2-3
Scan speed	8	8
Averaging	2	2
Optical slice	Open	1 μm
z-section	———	0.5 μm
Laser power[a]	1%-10%	1%-10%

[a]The TMRE imaging of mitochondria at zoom 2 or 3 should be done very cautiously, as high laser power could quickly photodamage TMRE-loaded mitochondria (Bunting, 1992). Therefore, for optimum results, scanning laser intensity of the both the lasers should be kept as low as possible.

9. Choose the appropriate parameters for imaging, as is listed in Table 4.25.4.

   For assessing mitochondrial potential per unit mass, the configuration of filters for imaging should be chosen so that they restrict bleed through from one channel to the other in cells stained with both Mitotracker Green and TMRE. Adjust the laser intensity and detector gain according to the brightness of the sample in such a way so that the signal from any pixel is not saturated. Follow Table 4.25.4 for setting imaging parameters depending on whether the aim is to detect total mitochondrial potential per cell or that of individual mitochondria in single cells. Parameters can be altered for better imaging depending on the system.

10. Perform imaging as soon as possible according to the relevant set of imaging parameters.

    Beyond a period of 30 to 45 min, the mitochondria might start fragmenting leading to erroneous results.

    There could be variations in the sensitivity level according to the cell type and one should make a note of that. Generally, more sensitive cells would allow less time before mitochondria fragment and alter potential as an indication of a death trigger. Therefore, everything should be ready before the experiment and one should be quick in finishing all the scans.

11. Save the images and analyze the images at your convenience.

    The ratio of TMRE/Mitotracker Green is an assessment of mitochondrial potential in arbitrary units.

COMMENTARY

Background Information

The name mitochondria is a fusion of the Greek words "mito" meaning filaments and "chondro" meaning grains. The length of each mitochondrion can extend from 500 nm to 1 mm or more, the average diameter being 500 nm (Detmer and Chan, 2007). Contributions of electron microscopists aided in the detailed understanding of mitochondrial structure while biochemical analyses of isolated mitochondria identified the organelle as a seat of intermediate metabolism. In this era of live cell imaging, mitochondrial biologists are motivated to understand the structure-function relationship of mitochondria in live cells.

Imaging of mitochondria in live yeast and mammalial cells has been made possible by designing vectors expressing fluorescent proteins that are tagged to either a resident mitochondrial protein or any particular mitochondrial targeting sequence, targeting the fluorescent protein into any of the three mitochondrial compartments. Detailed strategy to that end in

yeast can be found in Okamoto et al. (2001) and mammals in Rizzuto et al. (1996). The latest generation of fluorescent protein variants is discussed in *UNIT 21.5*. The targeted fluorescent protein essentially enables the researchers to visualize the behavior of mitochondria within cells and/or study the behavior of the particular fluorescently tagged mitochondrial protein.

High-resolution live cell imaging of mitochondria aided in understanding the correlation of mitochondrial fragmentation and physiological properties of apoptotic cytochrome *c* release (Frank et al., 2001) or ROS production (You et al., 2006). The varied mitochondrial morphology in a population of cells can be quantitated from static images as fragmented, intermediate, or tubular according to the predominant mitochondrial morphology in an individual cell. However, in some extreme instances when mitochondria could also appear as clumps, it is erroneous to include them in any of the above three categories of mitochondrial morphology. These clumps could arise from clumping of fragmented mitochondria or collapse of a fused form of mitochondria. Therefore, in these situations, it is critical to perform FRAP analysis of any mitochondrial matrix molecule. This assay provides important measurements for mitochondrial continuity that would arise in fused mitochondrial structures. The assay could also be modified in a variety of aspects to understand mitochondrial dynamism. The interpretation of the recovery after photobleaching has to be carefully performed where the time scale of recovery is crucial for highly mobile organelles like mitochondria; failing to appreciate this property might yield confusing results. Furthermore, the alteration of recovery kinetics in a FRAP study for mitochondrial connectivity or motility might be contributed to by altered diffusing properties of the matrix molecule of interest. This has to be verified by performing FRAPs in individual mitochondria and any statistically significant change has to be included in the analysis of matrix continuity. To capture the complete kinetics of the recovery of the matrix molecule special microscopes are required with super fast scanning modules, like LSM5 Duo or Nikon epifluorescence microscope with super-fast integration time of the camera and photomultipliers attached to the microscope (Partikian et al., 1998). This will allow very fast photobleaching on the order of microseconds (Fig. 4.25.4A) that is required for molecules with diffusion coefficient in the order of 2–3 $\times$ $10^{(-7)}$ cm^2/sec, as in mitochondrial matrix. Slower microscopes, with longer bleaching time, will spread the bleaching beyond the bleach box, therefore increasing the recovery time (Fig. 4.25.4B). This kind of analysis might be used in a comparative scale but the data should not be used to determine diffusion coefficient.

The microirradiation protocol of TMRE-loaded mitochondria was first designed by Amchenkova et al (1988), and a similar technique has been also used to study various other organelles (Berns, 2007). High laser power has been shown to introduce holes in mitochondria (Khodjakov et al., 2004), thus disrupting mitochondrial potential across the inner membrane. Laser-induced depolarization of TMRE-loaded mitochondria has also been shown to increase localized ROS production (O'Reilly et al., 2003). This experiment has to be performed with caution about the cellular damage during the experimentation (as discussed before) and controls have to be included each day of experimentation. When dealing with more than one cell type, proper controls have to be included for each cell type under examination. It has to be very well appreciated that in a controlled setup the irradiated cell, behaving normally within the small time span of the experiment, might eventually die. Therefore, long-term experimentation may not be performed on such a cell. The microirradiation experiment is important from the mitochondrial bioenergetics point of view, as this qualitatively addresses the electrical continuity of the mitochondria at any given time point that might have impact on the total ATP output from the mitochondrial system (Skulachev, 2001).

The staining of mitochondria with different commercially available dyes is routinely practiced and the background information may be obtained from *UNIT 4.4*.

Post-processing of image analysis is a critical step for proper interpretation of imaging data. Although this unit does not cover image analysis in detail, mention may be made of some software that will be helpful for the purpose. Among the proprietary software, Zeiss' own Image Examiner can be used to analyze laser scanning confocal images. A free downloadable version that can be used as a viewer is available on Zeiss' Web site (*http://www.zeiss.de/C12567BE0045ACF1/Contents-Frame/CAA2EF638EC5F0D3C1256ADF0050E2F1*). Volocity and Metamorph can also be used. An open source software called Image J (*http://rsbweb.nih.gov/ij/download.html*) is very helpful for all basic purposes. Relevant plugins can be included for advanced purposes.

Table 4.25.5 Troubleshooting Guide to Live Cell Mitochondrial Imaging

Problems	Possible causes[a]
z-stacks and time lapse	
Fragmented/clumped mitochondria	Cells are not healthy pH or temperature shock Mineral oil touching the cells High amount of lipid-based transfecting agents used Transient transfection of the mitochondrial marker Effects of over-expression of the protein Immensely high scanning laser power Use of high-energy/low-wavelength laser (413/405-nm etc) or any other UV laser
Immotile mitochondria	Cells are not healthy for any of the reasons mentioned above High speed of imaging
Projection of *z*-stacks is blurry	Oversampling along *z*-axis Wide pinhole High scanning speed Saturated signals Low power objective
FRAP	
No recovery	Dead cells Fragmented mitochondria Immotile mitochondria Bleach box covers more than 30% of the total signal Inappropriately low pinhole size Bleaching caused by high laser power
Bleached zone is more than the bleach box	Misalignment of the laser head and bleach box Slow bleaching
Not enough bleaching	Low laser power chosen for bleaching For RFP, 488-, 458-, and 514-nm lasers not chosen
Poor recovery curve	Very long time intervals set for monitoring recovery phase Signal saturated in the beginning Scanning laser causing bleaching Not enough bleaching by the bleaching laser(s) Bleached molecule reverting to the fluorescent stage Movement of mitochondria interfering with recovery
Microirradiation	
No loss of TMRE after microirradiation	No irradiation due to application of lower laser power Misalignment of the 2-photon laser Low iterations chosen for irradiation Low zoom factor chosen
Mitochondria shifting away during imaging *or* mitochondria fragmenting	Cell is swelling due to more than optimum irradiation
Increase in TMRE signal after microirradiation	TMRE loading is beyond quenching levels

continued

Table 4.25.5 Troubleshooting Guide to Live Cell Mitochondrial Imaging

Problems	Possible causes[a]
Staining for potential	
No staining	Mitochondria are absolutely depolarized because cells are not healthy (as mentioned above)
Poor resolution	Overstaining Inappropriate pinhole size Lack of proper washing after staining
The oligomycin/FCCP-treated samples not producing expected results as controls	Overload of TMRE beyond the quenching levels FRET between Mitotracker Green and TMRE Bleed through from detector channel for Mitotracker Green to that of TMRE
Loss of TMRE while scanning	Power of the scanning laser power is more than optimum
Fragmented mitochondria	Stained sample left for more than 30 to 45 min

[a]For solutions please refer to the corresponding sections.

One could also include self-written macros in the list of Image J plugins.

Troubleshooting

This section discusses the problems that might arise while or before imaging mitochondria in particular. The general troubleshooting for imaging per se will not be discussed here. The possible causes to any problem are very crisply mentioned here and are discussed in more detail in the relevant protocol. See Table 4.25.5 for a troubleshooting guide.

Anticipated Results

The protocols described in this unit will help the researcher to understand mitochondrial function by imaging. The precautions mentioned here for imaging mitochondria are very critical to be able to achieve the goal of establishing structure/function relationships of mitochondria. By the correct use of imaging parameters and choice of fluorophore, the investigator can not only acquire static mitochondrial images but also perform time-lapse imaging on mitochondria. Live cell imaging of mitochondria including the FRAP and microirradiation protocols can be used by investigators to study the dynamics of mitochondria in quantitative terms and can also be used to understand dynamics of individual proteins in mitochondria. For example, study of the fluorescently tagged intermembrane space protein cytochrome *c* by live cell imaging has uncovered many important aspects of apoptotic release of this protein into the cytosol (Goldstein et al., 2000). Live cell imaging studies of mitochondria imply that imaging of fluorescent-tagged versions of mitochondrial proteins have tremendous potential of unraveling many unexplored aspects of mitochondrial physiology and its crosstalk with other cellular compartments.

Time Considerations

Generation of a stably expressing cell line takes 1 to 2 months depending on the cell type. Staining with fluorescent dyes and sample preparation takes from 30 min to 2 hr. Stained samples should be imaged within 45 min. Acquiring each *z*-stack will take <1 min; it takes a little longer for very slow scan speeds. The total time for a time-lapse experiment would depend on the kinetics of the phenomenon to be observed. To observe mitochondrial dynamism, a time lapse of 2 to 3 min should be sufficient. Each FRAP assay will take from less than half a minute to an hour, depending on the goal of the experiment. Extent of electrical continuity can be captured within 15 sec or less.

CHAPTER 5
Characterization of Cellular Proteins

INTRODUCTION

Proteins are the most diverse, versatile components of living organisms. They are widely variable in size, shape, charge, stability, solubility, and other physical-chemical properties. This diversity derives from their being composed of combinations of about 20 distinct amino acids arranged in any number and sequence. The polypeptide chain folds into a particular conformation which is largely determined by the sequence of amino acids. The virtually limitless number of possible conformations allows proteins to perform a variety of cellular functions. Proteins can act as catalysts, receptors, hormones, carriers, membrane channels, molecular motors, cytoskeletal elements, protective shells, regulators of gene expression, components of the translation and trafficking machineries, and so on. They are found in every subcellular compartment and some are secreted into the extracellular space, where they modify the surroundings of the cell or exert effects on other cells.

The structural and functional plasticity of proteins, and their critical roles in most cellular processes, make them prime subjects of interest to cell biologists. There are many excellent methodologies to characterize the structural features of purified proteins. These methodologies have been covered in several books. Most often, however, cell biologists are confronted with the task of characterizing specific proteins in mixtures with other proteins, as is the case for whole cells, subcellular fractions, cell extracts, and partially purified proteins. In many cases, the protein of interest is a minor component of these mixtures. Over the years, scientists have learned how to take advantage of the structural and functional diversity of proteins to devise methods that allow the characterization of specific proteins in complex mixtures. These methods consist of separating proteins according to their physical-chemical properties using techniques such as ultracentrifugal sedimentation on sucrose gradients or gel filtration, followed by detection of the proteins by some specific enzymatic activity or, more often, by their reactivity with specific antibody reagents. This type of approach is the focus of the protocols presented in this chapter.

The chapter begins with an overview of the physical state of proteins within cells (*UNIT 5.1*). The overview discusses the classification of proteins into globular, fibrous, and transmembrane proteins. This is followed by a description of the modes of association of proteins with membranes and the determinants of topology of transmembrane proteins. *UNIT 5.1* then discusses the factors that determine the physical heterogeneity of proteins, including size, charge, chemical modifications, and oligomeric or multimeric assembly. This leads to a description of some of the methods that are used to characterize the properties of proteins in complex mixtures.

Transmembrane proteins can assume a number of different topologies. For example, the amino and carboxy termini of the polypeptide chains can be exposed to either the lumenal/extracellular or cytosolic aspects of intracellular organelles. The simplest integral membrane proteins have only one membrane-spanning segment. However, many polypeptide chains span the membrane two or more times. Although the topology of transmembrane proteins can, in many instances, be inferred from amino acid sequence

Contributed by Juan S. Bonifacino
Current Protocols in Cell Biology (2000) 5.0.1-5.0.2

information, experimental verification is always required. *UNIT 5.2* includes a set of protocols designed to assess the topologies of proteins within membranes. The first is based on the accessibility of proteins within intact cells or membrane-bound organelles to externally added proteases. The effects of proteolysis are then generally evaluated by one-dimensional polyacrylamide gel electrophoresis (*UNIT 6.1*), often in combination with immunoblotting (*UNIT 6.2*) or immunoprecipitation (*UNIT 7.2*). Another protocol in *UNIT 5.2* is based on the accessibility of protein epitopes to antibody reagents, using immunofluorescence microscopy as a means of detecting the antibody (also see *UNIT 4.3*). Methods for marking proteins with epitope tags are presented as a complement to the accessibility-based protocols. *UNIT 5.2* ends with a method to assess topology using reporter fusions in yeast cells.

Sizing of a protein in its native state can be accomplished by determining its hydrodynamic parameters, such as the sedimentation coefficient and Stokes' radius. Knowledge of these parameters in many cases allows calculation of the molecular masses of the native protein or protein complexes. *UNIT 5.3* contains a detailed description of one of the most commonly used methods for estimating the size of cellular proteins: sedimentation-velocity analysis on sucrose gradients. This method consists of analyzing the migration of proteins on a continuous gradient of sucrose upon application of a centrifugal field. After fractionation of the gradient, proteins are detected by measurement of an intrinsic activity or by polyacrylamide gel electrophoresis (*UNIT 6.1*) in combination with immunoblotting (*UNIT 6.2*) or immunoprecipitation (*UNIT 7.2*). *UNIT 5.3* also describes the use of equations to calculate the hydrodynamic parameters of proteins from sedimentation experiments.

UNIT 5.4 presents several methods for determining the nature of protein-membrane associations (i.e., distinguishing peripheral versus integral membrane proteins). Although most integral membrane proteins are associated with membranes via hydrophobic polypeptide segments, a subset are tethered to the membranes by glycosyl phosphatidylinositol (GPI) groups. This unit presents a method for examining membrane association through GPI groups, based on hydrolysis with phosphatidylinositol-specific phospholipase C (PI-PLC). GPI-anchored proteins and some transmembrane proteins are resistant to solubilization by certain nonionic detergents such as Triton X-100. For some, this is due to their association with plasma membrane domains enriched in glycosphingolipids and cholesterol. These domains are sometimes contained within invaginations of the plasma membrane known as caveolae. This unit provides a protocol for solubilization of Triton-insoluble plasma membrane proteins using detergents such as octylglucoside or CHAPS. Also included are procedures for isolation of caveolar membrane domains.

In addition to sedimentation-velocity analysis (*UNIT 5.3*), another commonly used method for estimating the size of cellular proteins in their native state is size exclusion chromatography (also known as gel filtration; *UNIT 5.5*). In this method, a solution of proteins (the "mobile phase") is passed over a column containing a matrix of porous particles (the "stationary phase"). Proteins partition according to their ability to penetrate the interior of the particles, such that larger proteins elute earlier than smaller ones. The size of the proteins can be estimated by comparison with the behavior of protein standards of known molecular size. The parameter that best characterizes the behavior of proteins on size exclusion chromatography is the Stokes radius, R_s. Knowledge of this parameter, and of parameters derived from sedimentation-velocity analysis (*UNIT 5.3*), allows calculation of the molecular weights of proteins.

Juan S. Bonifacino

Overview of the Physical State of Proteins Within Cells

The word protein comes from the Greek word *proteios*, meaning primary. And, indeed, proteins are of primary importance in the study of cell function. It is difficult to imagine a cellular function not linked with proteins. Almost all biochemical catalysis is carried out by protein enzymes. Proteins participate in gene regulation, transcription, and translation. Intracellular filaments give shape to a cell while extracellular proteins hold cells together to form organs. Proteins transport other molecules, such as oxygen, to tissues. Antibody molecules contribute to host defense against infections. Protein hormones relay information between cells. Moreover, protein machines, such as actin-myosin complexes, can perform useful work including cell movement. Thus, studying proteins is a prerequisite in understanding cell structure and function.

The physical characterization of proteins began well over 150 years ago with Mulder's characterization of the atomic composition of proteins. In the latter half of the nineteenth century Hoppe-Seyler (1864) crystallized hemoglobin and Kühn (1876) purified trypsin. A variety of physical methods have been developed over the years to increase convenience and precision in the characterization and isolation of proteins. These include ultracentrifugation, chromatography, electrophoresis, and others. In many instances our understanding of cell proteins parallels the introduction and use of new techniques to examine their structure and function.

PROTEIN CLASSIFICATIONS

All proteins are constructed as a linear sequence(s) of various numbers and combinations of ~20 α-amino acids joined by peptide bonds to form structures from thousands to millions of daltons in size. Proteins are the most complex and heterogeneous molecules found in cells, where they account for >50% of the dry weight of cells and ~75% of tissues.

Proteins can be classified into three broad groups: globular, fibrous, and transmembrane (Fig. 5.1.1; Table 5.1.1). Globular proteins are, by definition, globe-shaped, although in prac-

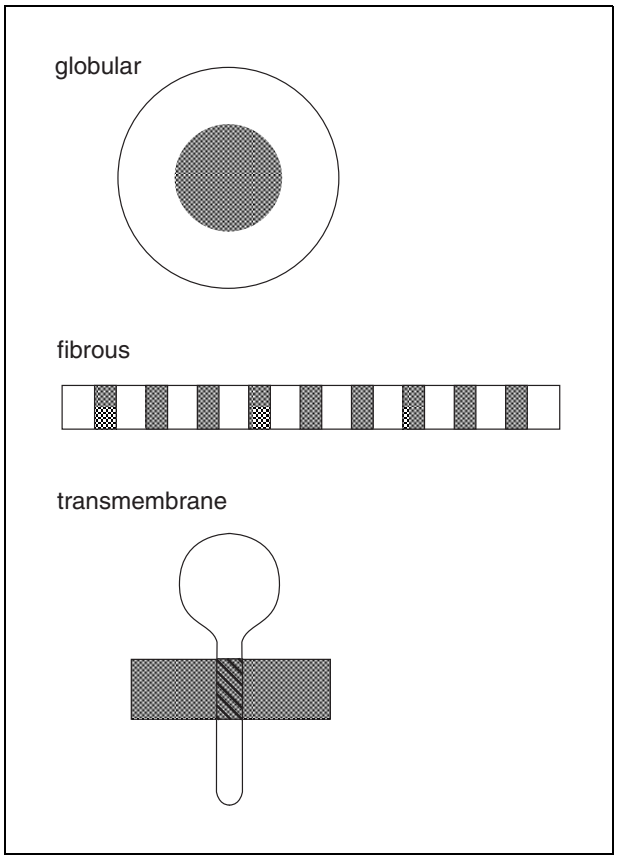

Figure 5.1.1 General classifications of proteins. In these schematic representations of globular, fibrous, and transmembrane proteins, hydrophobic regions are shaded. Note that the disposition of hydrophobic residues often reflects the protein class.

Contributed by Howard R. Petty
Current Protocols in Cell Biology (1998) 5.1.1-5.1.10

Table 5.1.1 Broad Classifications for Proteins[a]

Type	Location/type	Examples
Globular	Intracellular	Hemoglobin, lactate dehydrogenase, cytochrome *c*
	Extracellular	Serum albumin, immunoglobulins, lysozyme
Fibrous	Intracellular	Intermediate filaments, tropomyosin, lamins
	Extracellular	Collagen, keratin, elastins
Transmembrane	Single pass	Insulin receptor, glycophorin, HLAs[b]
	Multipass	Glucose transporter, rhodopsin, acetylcholine receptor

[a]Additional information regarding fibrous and transmembrane proteins can be found in Squire and Vibert (1987) and Petty (1993). Information concerning globular proteins can be found in numerous books on proteins and enzymes such as Schultz and Schirmer (1979).

[b]Human histocompatibility leukocyte antigens.

tice they can be spherical or ellipsoidal. Globular proteins are generally soluble in aqueous environments. Examples of globular proteins are hemoglobin, serum albumin, and most enzymes. Fibrous proteins are elongated linear molecules that are generally insoluble in water and resist applied stresses and strains. Collagen is a physically tough molecule of connective tissue. Just as collagen gives strength to connective tissues, intermediate filaments linked to desmosomes give strength to cells in tissues. The third general class of proteins, transmembrane proteins, contain a hydrophobic sequence buried within the membrane; these proteins are discussed more fully below (see Membrane Proteins).

These protein categories are not mutually exclusive. For example, the nominally fibrous intermediate filament proteins also have globular domains. Similarly, transmembrane proteins almost always possess globular domains. Thus, these definitions serve as a useful guide but should not be rigidly applied.

HYDROPATHY PATTERNS OFTEN REFLECT A PROTEIN'S CLASSIFICATION

A key physical feature of proteins is their hydropathy pattern (i.e., the distribution of hydrophobic and hydrophilic amino acid residues). Indeed, hydrophobic interactions provide the primary net free energy required for protein folding. Figure 5.1.1 illustrates the disposition of hydrophobic amino acids in proteins. In an intact globular protein, hydrophobic amino acids are generally shielded from the aqueous environment by coalescing at the center of the molecule, with the more hydrophilic residues exposed at its surface. However, the linear arrangement of hydrophobic residues fluctuates in an apparently random fashion. The α helices within globular proteins may express a hydrophobic face oriented toward the center of the protein. (Within these helices hydrophobic residues are nonrandomly positioned every three or four amino acids to yield a hydrophobic face.) For coiled-coil α helix–containing fibrous proteins, such as tropomyosin and α-keratin, hydrophobic residues at periodic intervals allow close van der Waals contact of the chains and potentiate assembly as hydrophobic residues are removed from the aqueous environment (Schulz and Schirmer, 1979; Parry, 1987). Secondarily, regularly spaced charged groups can also contribute to the shape of fibrous proteins (Schulz and Schirmer, 1979; Parry, 1987). Transmembrane proteins provide a rather different physical arrangement of hydrophobic residues in which hydrophobic residues are collected primarily into a series of amino acids that is embedded within a cell membrane.

One important means of analyzing the hydropathy of a sequenced protein is a hydropathy plot (Kyte and Doolittle, 1982). In this method, each amino acid residue is assigned a hydropathy value, an ad hoc measure that largely reflects its relative aqueous solubility; these values are plotted after being averaged. The successful interpretation of hydropathy plots

depends on the parameters chosen for averaging. The parameters are the number of residues averaged (amino acid interval or "window") and how many amino acids are skipped when calculating the next average (step size). Using this approach with a window of ~10 residues, it is often possible to find the positions of hydrophobic residues coalescing near the interior of globular proteins. The method is particularly useful in predicting transmembrane domains of proteins, generally with a window of ~20 amino acids. To detect the repetitious pattern of coiled-coil fibrous proteins, however, windows smaller than the repeat length would be required.

MEMBRANE PROTEINS

In addition to their presence in the extracellular and intracellular milieus, proteins are also found in association with biological membranes. Proteins constitute one-half to three-quarters of the dry weight of membranes. Membrane proteins perform a broad variety of functions including intermembrane and intercellular recognition, transmembrane signaling, most energy-harvesting processes, and biosynthesis in the endoplasmic reticulum (ER) and Golgi complex.

Membrane proteins have been traditionally characterized as integral (or intrinsic) or peripheral (or extrinsic) on the basis of operational criteria. Peripheral membrane proteins are associated with membrane surfaces and can be dislodged from membranes using hypotonic or hypertonic solutions, pH changes, or chelation of divalent cations. Components of the erythrocyte membrane skeleton, for example, are peripheral membrane proteins. Although most peripheral proteins are removed by washing a sample with buffers, integral proteins cannot be removed by such treatments. To isolate integral membrane proteins, which are embedded within the lipid bilayer, one must use detergents that disrupt the bilayer and bind to the proteins, thus solubilizing them. In general, integral membrane proteins have a portion of their peptide sequence buried in the lipid bilayer whereas peripheral proteins do not. However, the discovery of glycosylphosphatidylinositol (GPI)-linked membrane proteins added to the ambiguity of the situation. GPI-linked proteins are globular proteins with no membrane-associated peptide sequence, yet they require harsh conditions for solubilization.

As the technology for studying membrane proteins improved, it became necessary to develop a more precise vocabulary to describe membrane proteins. Transmembrane integral membrane proteins have at least one stretch of amino acids spanning a membrane. Membrane proteins are classified as type I, II, III, or IV depending on the nature of their biosynthesis and topology in membranes (Spiess, 1995; Table 5.1.2 and Fig. 5.1.2). The biosynthetic insertion of these proteins in membranes is, in turn, dependent on the presence or absence of a cleavable signal peptide, the relative positions of the hydrophobic transmembrane domain and positively charged topogenic signals, and/or

Table 5.1.2 Definitions of Integral Transmembrane Proteins

Type	Definition	Examples
I	An N-terminal–cleavable signal peptide is removed at the luminal face yielding a luminal N terminal during biosynthesis. (Positive charges are found on C-terminal side of first long hydrophobic sequence after the signal peptide.)	LDL receptor, insulin receptor, glycophorin A, thrombin receptor
II	An N-terminal–uncleaved signal peptide leads to a cytoplasmic N terminus. (Positive charges are generally found on N-terminal side of first long hydrophobic sequence.)	Transferrin receptor, sucrase/isomaltase, band 3
III	A long N-terminal hydrophobic sequence is followed by a sequence of positive charges. This leads to a luminal N terminus in the absence of a cleavable signal peptide.	β-Adrenergic receptor, cytochrome P450
IV	A short C terminus is present at the luminal side of membrane. A large N terminus is exposed at the cytoplasmic face.	Synaptobrevin, UBC6

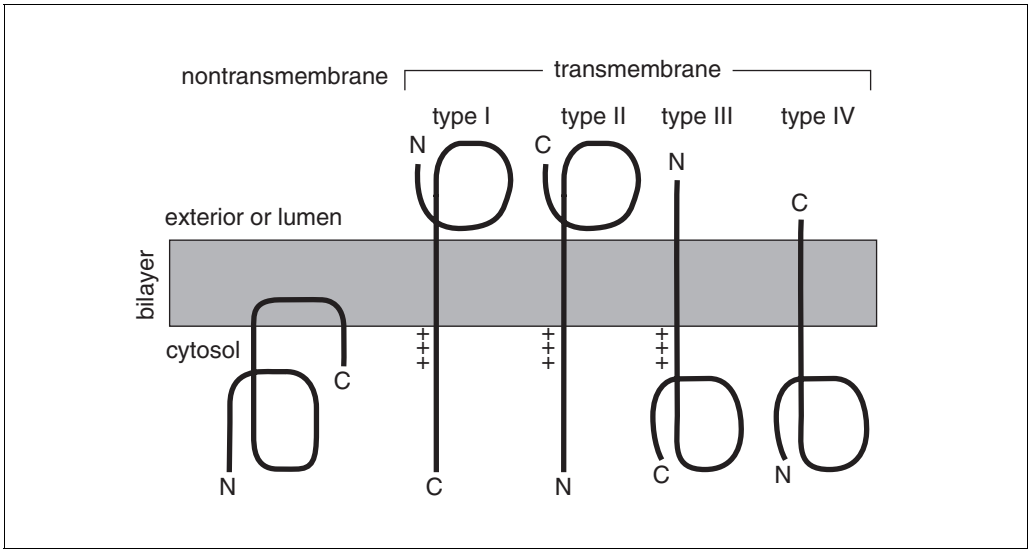

Figure 5.1.2 Membrane proteins containing hydrophobic anchors. A nontransmembrane or monotopic membrane protein is anchored to the membrane via a hydrophobic amino acid sequence. Transmembrane proteins are classified as types I, II, III, and IV (Table 5.1.2). The first transmembrane segment of a multispanning membrane protein can be inserted as in type I, II, or III proteins. This segment functions as a start-transfer peptide. Subsequent transmembrane segments will function as stop-transfer and start-transfer sequences, resulting in a multispanning membrane topology (see Fig. 5.2.1).

the mechanism of nascent protein delivery to the ER.

Type I membrane proteins are synthesized with an amino-terminal signal sequence that is inserted into the ER membrane. When the signal sequence is proteolytically removed in the ER lumen, a new luminal amino terminus is exposed. A series of positively charged residues at the C-terminal side of the first hydrophobic transmembrane domain following the signal sequence generally denotes the end of the first transmembrane domain (von Heijne and Gavel, 1988). Although a hydrophobic transmembrane domain followed by a positive sequence of amino acids is sufficient to act as a stop-transfer signal, this motif is not required for stop-transfer events and other, less well-understood regulatory mechanisms are also involved (Andrews and Johnson, 1996).

Membrane proteins types I, II, and III are delivered to the ER membrane via a signal recognition particle (SRP)-dependent mechanism. In contrast to type I proteins, type II and III membrane proteins do not have a cleavable N-terminal signal sequence. Instead, they have an internal hydrophobic signal that acts as both a signal sequence for ER delivery and a transmembrane domain in the mature protein. Type II proteins have a cytoplasmic amino terminus and a luminal (or extracellular) carboxyl terminus. In this case a positively charged sequence of amino acids at the N-terminal side of the first hydrophobic sequence causes the amino terminus to be retained at the cytoplasmic face of the ER membrane. Thus the internal uncleaved signal peptide becomes the transmembrane domain of the mature protein.

Type III membrane proteins have the same overall topology as type I proteins, but they are inserted into membranes by a different mechanism. In type III proteins the first hydrophobic sequence of amino acids is immediately followed by a series of positively charged amino acids. Thus, the first hydrophobic sequence becomes the transmembrane domain of the protein, with the amino terminus at the luminal face of the membrane.

Type IV membrane proteins are characterized by a large, cytoplasmically exposed amino-terminal domain and a short carboxyl-terminal domain facing the lumen. Importantly, these proteins are delivered to the ER by an unknown SRP-independent mechanism.

In addition to the single-pass membrane proteins just described, integral membrane proteins can display zero, two, three, or more transmembrane domains. Some membrane proteins, such as cytochrome b_5, have protein segments buried in the hydrophobic core of membranes but do not cross the membrane. Membrane proteins with multiple membrane-spanning domains are classified as type I, II, or

III depending on the topogenic signals in the first transmembrane domain. For example, a multispan membrane protein with a cleavable signal sequence, luminal amino terminal, and a positively charged sequence following the first transmembrane domain from the amino terminal, such as the thrombin receptor, is a type I membrane protein. The remaining transmembrane domains are inserted into the bilayer depending on the orientation of the first transmembrane domain. Multispanning type II and III proteins are similarly defined according to the properties of their single-spanning counterparts.

In addition to hydrophobic protein sequences acting as membrane anchors, membrane proteins may also carry bilayer-associated hydrophobic lipid components. These hydrophobic lipid anchors define three broad groups of lipid-modified proteins: fatty acylated, isoprenoid-linked, and GPI-linked (Fig. 5.1.3). Several cytosolic transmembrane proteins have been identified that contain a covalently attached hydrophobic fatty acyl residue. For example, fatty acids, including palmitic, palmitoleic, *cis*-vaccenic, and cyclopropylene-hexadecanoic, are covalently linked to the amino terminus and the amino-terminal glycerylcysteine of *E. coli* lipoprotein. Moreover, palmitate- and myristate-labeled transmembrane proteins have been observed in eukaryotic cells (e.g., Schlesinger et al., 1980).

In both isoprenoid-linked and GPI-linked proteins, globular proteins become membrane-bound due to the addition of a hydrophobic lipid moiety. Certain proteins containing conserved cysteine residues at or near the C-terminus are modified by prenylation, in which a farnesyl or geranylgeranyl isoprenoid tail is added (Zhang and Casey, 1996). This hydrophobic moiety promotes protein association with the cytoplasmic face of cell membranes. Notably, cytosolic G proteins and protein kinases that participate in signal transduction are prenylated.

GPI-linked proteins are a major class of membrane proteins (Cardoso de Almeida, 1992; Englund, 1993). In contrast to isoprenoid-modified proteins, GPI-linked proteins are attached to the luminal or extracellular face of membranes via a glycosylphosphatidylinositol anchor of variable structure (e.g.,

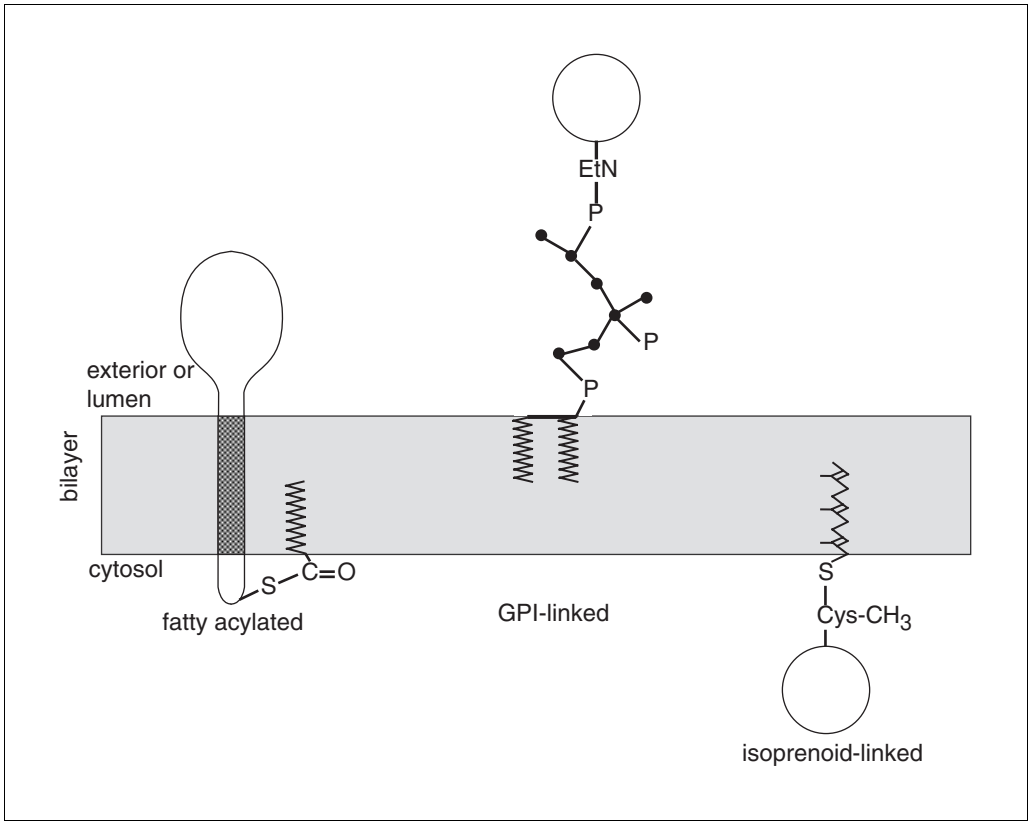

Figure 5.1.3 Membrane proteins containing lipid moieties. In the simplest case, fatty acids can be covalently attached to transmembrane proteins. Hydrophobic tails are also attached to proteins to form isoprenoid-linked proteins. A third class of lipid-attached proteins are the GPI-linked proteins. Hydrophobic regions are shaded.

Fig. 5.1.3). Well over 100 GPI-linked proteins have been identified in cells, where they perform numerous functions including acting as enzymes and receptors. The ability of GPI-linked proteins, which possess no transmembrane or cytosolic sequences, to elicit transmembrane signals seems paradoxical. However, studies have suggested that interactions with other proteins, including transmembrane integrins (Petty and Todd, 1996), contribute to transmembrane signaling of these proteins. Although GPI-linked proteins must collaborate with other membrane proteins to elicit signals, they do possess certain functional advantages. First, GPI-linked proteins (and isoprenoid-linked proteins as well) diffuse in membranes much faster than transmembrane proteins and thus relay information faster. Second, certain cells, such as leukocytes, can rapidly shed their GPI-linked proteins, thus altering their functional properties in seconds. Although the importance of lipid-linked membrane proteins has only recently been appreciated, the impact of these structures on our understanding of cell properties is growing rapidly.

ADDITIONAL FACTORS AFFECTING THE PHYSICAL HETEROGENEITY OF PROTEINS

Additional factors contributing to the physical-chemical heterogeneity of proteins are size, charge, chemical modifications, and assembly. A typical amino acid has a molecular mass of ~110 Da, and a small protein has a molecular mass of a few thousand daltons (e.g., for insulin, M_r = 5733). Large proteins have molecular masses of several hundred thousand daltons. When proteins are assembled to form large multiprotein complexes such as ribosomes, molecular masses are well into the millions. The diameters of these structures range from 4 Å for an individual amino acid to ~30 nm for a ribosome.

Electrostatic charge is of major importance in protein structure and function. Charged proteins are more soluble than uncharged proteins. The large number of positive charges on histones allow them to bind DNA. The spatial arrangement of charges on cytochrome *c* allows it to bind the complementary charges of its oxidase and reductase, thereby orienting the proteins prior to electron transfer. Similarly, the arrangement of charges on the apoprotein and receptor for low-density lipoprotein (LDL) allows for lock-and-key–like interactions (Petty, 1993). In addition to structural and binding considerations, electrostatic interactions play a regulatory role. For example, the phosphorylation and dephosphorylation of insulin receptors alter electrostatic interations between the active site and a regulatory loop of the kinase domain, thereby changing its three-dimensional shape (Hubbard et al., 1994). This changes the V_{max} of the kinase, thus triggering intracellular signals.

In addition to the types of physical heterogeneity listed above, >100 distinct chemical modifications of proteins have been observed. These include, for example, glycosylation, ubiquitin attachment, phosphorylation, acetylation, and hydroxylation (Table 5.1.3). Thus, proteins undergo extensive physical-chemical modification.

PROTEIN ASSEMBLIES

Proteins can be assembled in a variety of states in both aqueous media and within membranes. Protein assembly into complex supramolecular structures plays vital roles in enzyme regulation, cell skeleton formation, and transmembrane signaling. Both covalent bonds and noncovalent bonds participate in protein assembly. One frequently encountered covalent mechanism of protein assembly is the formation of disulfide bonds. These covalent linkages often form during protein maturation. They can link two separate proteins together or two portions of the same protein. For example, the two chains of insulin molecules are held together by disulfides, as are the two chains of its membrane receptor. However, disulfide bond formation is mostly limited to oxidative environments such as the ER lumen and the exterior face of the cell surface.

One of the best-known examples of noncovalent assembly is the formation of hemoglobin tetramers. Polymerization is another frequently encountered mechanism for protein assembly in cells. The globular protein actin polymerizes to form microfilaments in the absence of covalent bond formation. Intermediate filaments are formed by the polymerization of fibrous proteins. Under certain circumstances transmembrane proteins polymerize as well; bacteriorhodopsin, for example, forms two-dimensional pseudocrystals called purple membranes. Protein assemblies formed from various numbers of similar units are homodimers, homooligomers, and homopolymers.

Assembly of protein structures from dissimilar subunits is more common than assembly from identical subunits. For example, heterodimers are formed from the α and β chains of integrins within cell membranes. Complex

Table 5.1.3 Common Physical-Chemical Modifications of Proteins[a]

Modification	Example
Homodimerization	Transferrin receptor
Homooligomerization	*S. typhimurium* glutamine synthetase
Homopolymerization	Actin
Heterodimerization	Integrins
Heterooligomerization	Histones, proteasomes
Heteropolymerization	Ribosomes
Proteolytic cleavage	Signal peptide cleavage in ER
Prosthetic group addition	Heme addition to cytochromes and hemoglobin
Oxidation-reduction	Disulfide bond formation in ER
Glycosylation	Glycoprotein maturation
Phosphorylation	Regulation of protein function, such as the tyrosine kinase activity of insulin receptors
Acetylation	Blockage of N-termini of certain membrane proteins
Ubiquitination	Ubiquitin-dependent proteolysis via proteasomes, histones
Hydroxylation	Proline hydroxylation on collagen
Fatty acylation	Insulin receptors, *E. coli* lipoprotein
Isoprenylation	G proteins
GPI addition	Alkaline phosphatase, urokinase receptors

[a]For details, see Freedman and Hawkins (1980, 1985), Schlesinger et al. (1980), Englund (1993), and Zhang and Casey (1996).

heterooligomeric and heteropolymeric structures vary from relatively small structures such as histone octamers, which bind to DNA in the nucleus, to large particles such as ribosomes, found both in the cytosol and attached to nuclear and ER membranes. The signal recognition particle is a relatively small heterooligomeric structure, composed of one RNA subunit and six proteins, that potentiates the delivery of secretory and most membrane proteins to the ER membrane. Membrane-associated heterooligomeric structures have also been observed. One of the best examples of such structures is the components of the electron transport systems in chloroplasts and mitochondria (Petty, 1993). For example, the ubiquinone-cytochrome *c* reductase is composed of eleven different subunits. Thus, proteins can be assembled in a variety of manners within cells.

Although some protein assemblies, such as intermediate filaments, are static structures, many are dynamic structures which provide functional flexibility. For example, microfilaments can rapidly assemble and disassemble. In addition to the physical changes in assembly state, compositional dynamics is also observed. For example, interferon γ treatment alters the composition of proteasomes. Developmental changes in protein composition are also observed. As an example, fetal and newborn forms of a component of cytochrome *c* reductase are expressed in humans. Thus, protein assemblies can be characterized by both physical and compositional dynamics.

ALTERING THE SOLUBILITY OF PROTEINS: PROTEIN EXTRACTION

The in vitro characterization of cellular proteins begins with their extraction from tissues or cells into a buffer. With the exception of globular secretory proteins, such as those found in plasma, proteins are generally not easily accessible for experimental manipulation. For example, many fibrous proteins are not soluble in aqueous buffers. Cellular proteins are entrapped within or on a cell and therefore must be extracted from the cell in a soluble form.

A variety of methods including osmotic lysis, enzyme digestion, homogenization using a blender or mortar and pestle, and disruption by French press and sonication have been employed to disrupt cells. For a cytosolic protein such as hemoglobin, no further extraction from the sample is necessary. However, many important cellular proteins, such as those associated with membranes, cytoskeletal components, and DNA, remain insoluble. To further solubilize cell proteins, both nonionic (e.g., Triton

X-100) and ionic (e.g., sodium dodecyl sulfate) detergents are often employed. Detergents are small amphipathic molecules that interact with both nonpolar and polar environments. Detergents disrupt membranes. They also bind to hydrophobic regions of proteins, such as their transmembrane domains, thereby replacing the unfavorable contacts between hydrophobic protein regions and water with the more favorable hydrophilic domains of the detergent. Thus, instead of the hydrophobic regions of the insoluble protein forming an aggregate in the bottom of a test tube, the protein becomes soluble and can be employed in most in vitro analyses.

In addition to detergents, several other solubilization strategies are useful for the extraction and in vitro characterization of proteins (Table 5.1.4). Chaotropic agents enhance the transfer of nonpolar molecules to aqueous environments by their disrupting influence on water structure. Chaotropic agents are generally large molecular ions such as thiocyanate (SCN^-), perchlorate (ClO_4^-), and trichloroacetate (CCl_3COO^-). Hydrophobic interactions are also reduced by exposure to organic solvents and low salt concentrations. Electrostatic interactions are reduced by high salt conditions; this decreases the Debye-Hückel screening length and coulombic attraction. To disrupt hydrogen bonds, high concentrations of urea or guanidine are often employed. More vigorous methods of sample denaturation using very low pH or harsh detergents such as sodium dodecyl sulfate are also used to diminish intermolecular contacts.

Once proteins are extracted, their size can be characterized by ultracentrifugation on sucrose gradients (*UNIT 5.3*), gel filtration chromatography, SDS-PAGE (*UNIT 6.1*), and other methods (Table 5.1.5). The charge characteristics of proteins can be assessed using isoelectric focusing and ion-exchange chromatography. Specific interactions, such as antigen-antibody and biotin-avidin interactions, can also be employed in the characterization and isolation of proteins. These are useful in immunoblotting (*UNIT 6.2*) and affinity chromatography methods.

LIMITATIONS OF THE IN VITRO MANIPULATION OF PROTEINS

The very act of isolating proteins perturbs their physical environment. Although this is not

	Reversed-phase HPLC	*CPMB 10.12*

[a]For references in CPMB see Ausubel et al. (eds.) 1998.

often a major problem, a few cautionary notes should be made. The most primitive compartment of a cell, the cytosol, is a chemically reducing environment. Consequently, free sulfhydryl groups are observed in the cytosol; in fact, multiple cytosolic pathways help in preserving the proper redox conditions. On the other hand, the extracellular milieu and the luminal side of the ER are oxidative environments. The oxidizing condition within the ER is presumably due to the unidirectional transport of glutathione and cystine. Consequently, disulfides are frequently observed in the ER and extracellular environments. Thus, to prevent disulfide formation during manipulation, sulfhydryl blocking reagents such as iodoacetamide are included in extraction buffers (see *UNIT 7.2*). The cytosol is also a K^+-rich and Ca^{2+}-poor solution. These parameters should be considered in designing physiologically relevant experiments.

The experimental manipulation of membrane proteins is decidedly more difficult. The exterior face exists in a high Na^+ and Ca^{2+} solution that is oxidative; just the opposite is true for the cytoplasmic face. Since no appropriate solvent exists for such isolated proteins, experimental questions can be directed at properties associated with just one face of the molecule. A second limitation common to all in vitro studies of transmembrane proteins is that they must be solubilized using detergents. In addition to solubilizing a transmembrane protein, detergents can also bind to hydrophobic regions in the globular domain(s) of the protein, thus affecting the properties under study. One means of countering this problem is to test several detergents in the hope of finding one that retains the full biological activity of the purified protein.

Protein solubilization can also lead to loss of physiologically relevant protein-protein interactions. This can occur by simple dilution or by disruption of noncovalent interactions among proteins. For example, hemoglobin exists as a supersaturated solution in vivo which cannot be duplicated in vitro. Furthermore, protein-protein associations are generally stronger in the restricted confines of membranes than alter solubilization into a buffer. Thus, protein assemblies found in cells may disappear during solubilization. One means of countering these potential difficulties is to covalently cross-link protein assemblies prior to disruption and to solubilize proteins using mild detergents (e.g., Brij-58).

CONCLUSIONS

Structural motifs, especially stretches of hydrophobic amino acids, contribute to the shape of a protein and its classification as globular, fibrous, or transmembrane. Proteins are heterogeneous at many different levels including physical attributes, covalent modifications, and supramolecular assembly. The physical properties of proteins are used to characterize and isolate these molecules. For example, the size of a protein is examined by sedimentation on sucrose gradients (*UNIT 5.3*), gel filtration, and polyacrylamide gel electrophoresis (*UNIT 6.1*). Its charge is the key physical parameter in isoelectric focusing and ion-exchange chromatography. The units that follow contain detailed protocols describing the characterization of cellular proteins.

Determining the Topology of an Integral Membrane Protein

A variety of approaches have been developed for assigning the aqueous domains of integral membrane proteins to either side of a biological membrane. This unit describes three general methods that can be used to solve the topologies of eukaryotic membrane proteins whose primary sequences have been deduced from their corresponding DNA sequences: (1) testing of water-soluble domains for their accessibility to a reagent added to membranes exhibiting a defined orientation (see Basic Protocols 1 and 2), (2) epitope tagging (see Support Protocol), and (3) a genetic approach in which a reporter enzyme fused to various truncated fragments of a membrane protein acts as a sensor of sequences disposed intra- or extracytoplasmically (see Basic Protocol 3).

STRATEGIC PLANNING

Before initiating an experimental analysis, it is helpful to build a conceptual model of a protein's topology (see Fig. 5.1.2 for a representation of different types of integral membrane proteins). Inspection of the primary sequences of integral membrane proteins usually reveals a pattern of alternating stretches of hydrophilic (water-soluble) and hydrophobic (water-insoluble) amino acids. Very good computer-based approaches are used to illuminate these patterns (Kyte and Doolittle, 1982; Engelman et al., 1986). The results are presented as a graph, in which each amino acid is compared to the hydrophobicity of the amino acids immediately surrounding it in the linear sequence. When visual inspection of the graph reveals a hydrophobic stretch containing at least 18 to 20 amino acids, a segment is identified that is long enough to potentially span the membrane in an α-helical configuration (Deisenhofer et al., 1985). To build this conceptual model, the authors use MacVector software available form Oxford Molecular.

A representative hydropathy analysis of signal peptidase subunit SPC12 (Kalies and Hartmann, 1996) is shown in Figure 5.2.1A. Since this graph reveals an even number of putative transmembrane segments (two) for SPC12, the resulting model predicts that the N and C termini localize to the same side of the membrane. It should be noted that intra- and extracytoplasmic domains are not distinguishable using this analysis; thus, two opposing models for SPC12 topology are compatible with the analysis performed (see Fig. 5.2.1B). A hydropathy plot alone is, therefore, not a predictor of transmembrane orientation, nor is it assured that such a plot will identify all membrane-spanning segments. Experimental evidence is necessary to establish the orientations of integral membrane proteins within the lipid bilayer.

Protease Digestion

In this experimental approach (see Basic Protocol 1), a protease exhibiting a broad substrate specificity is used as a probe of membrane protein topology. When the enzyme is added to only one side of the target membrane or membrane vesicle, the size of the proteolytic fragment(s) generated reveals the accessible site(s) and hence the orientation across the membrane of the protein segment(s) containing this site or sites. A proteolytic fragment is detected using a specific antibody. Usually, a series of antipeptide antibodies are prepared, such that each hydrophilic domain is recognized by a specific antibody. The number of hydrophilic domains is usually greater than the number of hydrophobic domains by one. For example, SPC12 has two hydrophobic domains and three hydrophilic domains. Thus, a minimum of three antipeptide antibody preparations are needed to probe the hydrophilic domains of SPC12. Sometimes, however, an antipeptide antibody does

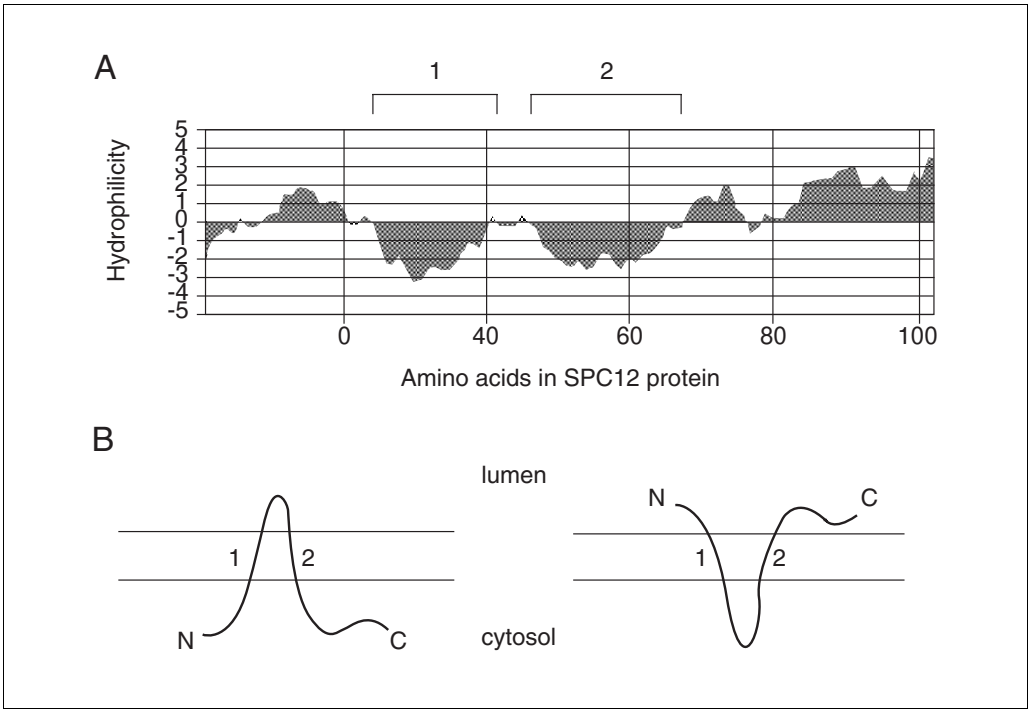

Figure 5.2.1 (**A**) Hydropathy analysis of SPC12 protein (Kalies and Hartmann, 1996). The data were obtained using the method of Kyte and Doolittle (1982). Hydrophilicity was examined using a window of seven amino acids. The positions of two potential transmembrane segments are shown. (**B**) Conceptualized topologies of SPC12. The data from (A) were used to construct two possible topologies. Hydrophobic segments 1 and 2 are shown spanning the membrane.

not recognize the corresponding peptide sequence in the intact protein; consequently, two or more antipeptide antibody preparations directed against a single hydrophilic domain may be needed.

In addition to this series of antipeptide antibodies, a control antibody is needed that recognizes a luminal protein of the closed membrane system to be analyzed. The orientation of a hydrophilic domain proteolyzed on addition of a protease can then be determined with confidence, providing the luminal protein control is resistant under this condition. A second control uses a mild detergent to solubilize the membranes. Protein sequences localized to both membrane surfaces and to the luminal space are exposed to the protease after detergent addition (Fig. 5.2.2 illustrates these points).

Unusually small hydrophilic domains may be resistant to proteolysis, even if they are exposed to the protease in the absence of detergent. Since addition of detergent often renders the entire protein susceptible, it is not always clear whether a domain that is resistant to proteolytic attack in the absence of detergent is localized to the lumen of the vesicle or just naturally resistant. As discussed below, the accessibility of such domains may be enhanced by using a foreign epitope (or multiple epitopes) inserted into the sequence of a small hydrophilic domain, thereby increasing its size (see Epitope Tagging and Reporter Gene Fusions).

The major advantage of using protease digestion to determine membrane protein topology is that proteins can be examined in their native form without any alterations to their primary sequences, such as those resulting from epitope additions and gene fusions (see Epitope Tagging and Reporter Gene Fusions). The picture derived from protease digestion should therefore reflect the true state of the protein in the cell, especially when the protein is examined in an in vivo expressed form (such as in whole cells or a specific cellular

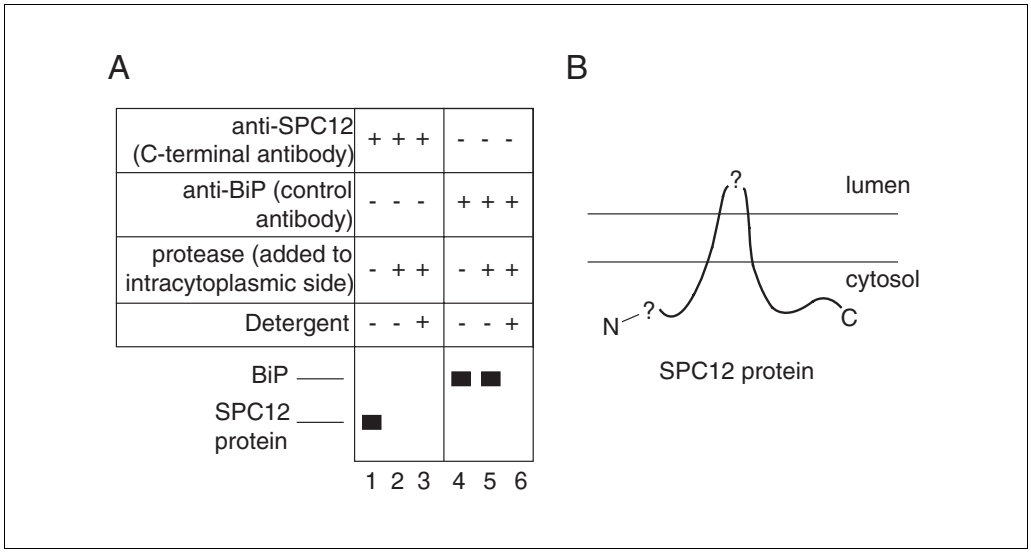

Figure 5.2.2 (**A**) Idealized immunoblot. The cartoon depicts an immunoblot of proteolyzed microsomes probed with an antibody directed against a C-terminal peptide of SPC12 or control antibodies directed against BiP, a luminal binding protein present in microsomal vesicles (Haas and Wabl, 1984; Bole et al., 1986). Addition or omission of a reagent from the mixture is indicated by + and –, respectively. The positions of BiP and SPC12 are indicated. For further discussion of (A), see Anticipated Results. (**B**) Deduced topology of SPC12's C terminus. The C terminus of SPC12 is presumed to localize to the cytosolic side of the membrane on the basis of the idealized results depicted in (A). The locations of the N terminus and presumed luminal domain of SPC12 cannot be assigned from these data and are therefore indicated with question marks.

organelle). Since membrane proteins are present both at the cell surface and at the surface of intracellular organelles, the literature should be reviewed to pick a procedure for enrichment of the desired membrane from a particular cell type. Examples of protease-digestion studies of membrane proteins residing within isolated organelles and organelle-derived vesicles are described by Graham et al. (1994), Kalies and Hartmann (1996), Kalish et al. (1995), and Li and Shore (1992). Regardless of the procedure chosen, it should produce membranes having a defined orientation, such that polypeptide domains exposed to the lumen, which corresponds to the extracytoplasmic side of the membrane for enriched organelle preparations and microsomal vesicles, are insensitive to the added protease in the absence of detergents.

A disadvantage of the protease digestion approach is that protein fragments must sometimes be identified to assess the topology of a particular region within a membrane protein. Since protein fragments are usually observed by SDS-PAGE (see Fig. 5.2.2) using the protease digestion protocol, small fragments (<2 kDa) may be difficult to detect.

While it is preferable to examine a protein in the membrane in which it resides normally, a procedure may not be available for enrichment of the desired membrane. As an alternative, an in vitro system of enriched microsomal membranes incubated cotranslationally with a membrane protein can be used (Walter and Blobel, 1983; Mize et al., 1986; see *UNIT 11.4*). This in vitro system is useful for examining proteins residing within the endoplasmic reticulum (ER) membrane and proteins transported from the ER to either the lysosome or another compartment of the secretory pathway (such as the cell surface).

Immunofluorescence Staining

An immunofluorescence staining technique is presented in this unit (see Basic Protocol 2) as a second experimental approach for determining membrane protein topology. In principle, this technique is similar to protease digestion, except that a fluorophore-con-

jugated secondary antibody is employed, instead of a protease, as a probe. A series of antipeptide antibodies is prepared, each recognizing a specific hydrophilic domain of the membrane protein under study. The antipeptide antibodies used for the protease digestion approach may be useful in the immunofluorescence staining approach provided that the antibodies recognize their corresponding epitopes in the membrane protein embedded within the lipid bilayer.

For the immunofluorescence staining protocol, the antibodies are added individually to the surface of an appropriate membrane, which must be closed and exhibit a defined orientation. When the antibody binds to an exposed hydrophilic domain, the antibody can be visualized using a fluorophore-conjugated secondary antibody that emits light detectable by confocal laser scanning microscopy or epifluorescence (see *UNIT 4.3* for a description of these microscopic techniques). Light detected from a bound antibody is evidence that the corresponding hydrophilic domain localizes to the exterior surface of the membrane examined. Protein domains exposed to the inside surface of the plasma membrane can also be probed after membrane permeabilization (Canfield and Levenson, 1993).

As with protease digestion, a major advantage of using the immunofluorescence staining approach is that a protein can be examined in its native form. A further advantage not available using protease digestion is that the orientation of a domain is determined using a microscope instead of detections of proteolytic fragments that may be very small. On the other hand, both immunofluorescence staining and protease digestion approaches suffer from the problem that particularly small hydrophilic domains may be inaccessible to the antibody or protease added. Thus, it may be possible to assign only a subset of the hydrophilic domains to a particular side of the membrane using either approach. Another potential problem with the immunofluorescence staining procedure is that the detergent used to permeabilize the membrane may expose an extracellular domain that is buried within a protein or protein complex. An extracellular domain inaccessible to the antibody in the absence of detergent could therefore be interpreted falsely to localize to the intracellular surface of the membrane.

Epitope Tagging

In determining membrane protein topology using epitope tagging (see Support Protocol), a foreign epitope is placed within the sequence of a membrane protein. The topology of the domain containing the inserted epitope can then be determined using protease digestion or immunofluorescence staining. The advantage of using a foreign epitope to assess topology is that a single antibody preparation available commercially is employed in lieu of a series of antipeptide antibodies, which can be expensive, time-consuming to prepare, and may not always recognize the intact membrane protein. Furthermore, a small epitope is inserted into a protein's sequence as opposed to fusion of a longer reporter domain, such as in construction of gene fusions (see Reporter Gene Fusion). This small epitope is less likely to alter the native orientation of the protein under study. In addition, multiple epitopes can be inserted into a single hydrophilic domain. The addition of multiple epitopes increases the likelihood that small hydrophilic domains will be accessible to the protease or antibody added. A foreign epitope may, however, inhibit the function of the protein into which it is placed. Since it may be unclear whether epitope insertion disrupts amino acids critical for activity or alters a protein's topology, the results obtained are more reliable when the epitope-tagged protein is shown to be functional in cells or in an in vitro assay.

A general guideline for minimizing interference with the topology of the target protein is to place the epitope ≥15 amino acids from the nearby transmembrane segment(s). This avoids interfering with charged residues that may be important for determining the

orientation of a transmembrane segment (Hartmann et al., 1989). In addition, tagging the N- and C-terminal ends of some membrane proteins should be avoided, since their termini often contain compartment-localization signals (for example, see von Heijne, 1984; Nilsson et al., 1989; Swinkels et al., 1991). However, if it is determined that such signals do not exist at the termini of the target protein, the N and/or C termini are often good sites for epitope tagging, because placement of the epitope at either end does not interrupt the linear sequence of the target protein internally. If the hydrophilic domain to be probed is very small, it may be impossible to place a foreign epitope >15 amino acids from the upstream and/or downstream transmembrane segment. In such instances, one can still place the epitope within the hydrophilic domain; however, caution should be used when interpreting the topological picture derived from study of a very small domain tagged with a foreign epitope.

A variety of epitope tags are available (see Background Information); however, the HA epitope derived from the influenza hemagglutinin protein (Wilson et al., 1984) is recommended because it contains only two nonclustered charges and has been used previously in topological studies (e.g., Canfield and Levenson, 1993). Clusters of negatively charged amino acids have been shown to interfere with the integration of membrane proteins into the ER membrane, especially when the charge cluster is located near the luminal side of a transmembrane segment (Green and Walter, 1992).

Representative DNA fragments used to tag membrane proteins internally and at the N- and C-terminal ends are shown in Figure 5.2.3. These fragments can be synthesized (complementary strands must be prepared) and then inserted into naturally occurring restriction sites or into sites constructed by site-directed mutagenesis. The restriction sites used should be located in sequences corresponding to the protein's hydrophilic domains. To insert these DNA fragments, blunt-end restriction sites should be used when possible, or sites producing sticky ends can be made blunt-ended by standard molecular biological techniques. In addition, the DNA fragments shown in Figure 5.2.3 contain a blunt-end restriction site (*Pvu*II). This restriction site provides a means to introduce a second fragment encoding the HA epitope. Such double-tagged proteins may allow the target protein to be better recognized by anti-HA antibodies than their corresponding single-tagged versions (Canfield et al., 1996). Repetitive insertion of DNA fragments encoding the HA epitope into each new *Pvu*II site makes it possible to create proteins tagged multiple times within a single hydrophilic domain. It should be noted, however, that increasing the size of a particular domain significantly may render the protein nonfunctional.

Reporter Gene Fusions

A genetic approach for determining membrane protein topology is also available (see Basic Protocol 3). A series of gene fusions are constructed in which an enzyme (reporter moiety) is joined to various truncated fragments of an integral membrane protein (Fig. 5.2.4). The enzyme used for a reporter moiety is chosen because it exhibits activity only when placed on one side of the membrane. On expression of the fusions in vivo, measurements of enzyme activity indicate the orientation of the domains that contain the fusion joints (Fig. 5.2.5). This approach has been developed to examine proteins inserted into the membrane of the ER in the yeast *Saccharomyces cerevisiae* (Sengstag et al., 1990). However, numerous membrane proteins located throughout the secretory pathway and on the surfaces of cells contain signals for targeting to the ER membrane. These proteins are therefore amenable to topological analysis on integration within the ER membrane prior to trafficking to their ultimate destinations.

To avoid interfering with integration of the target protein, the joint connecting the membrane protein fragment and the reporter moiety should be placed ≥15 amino acids

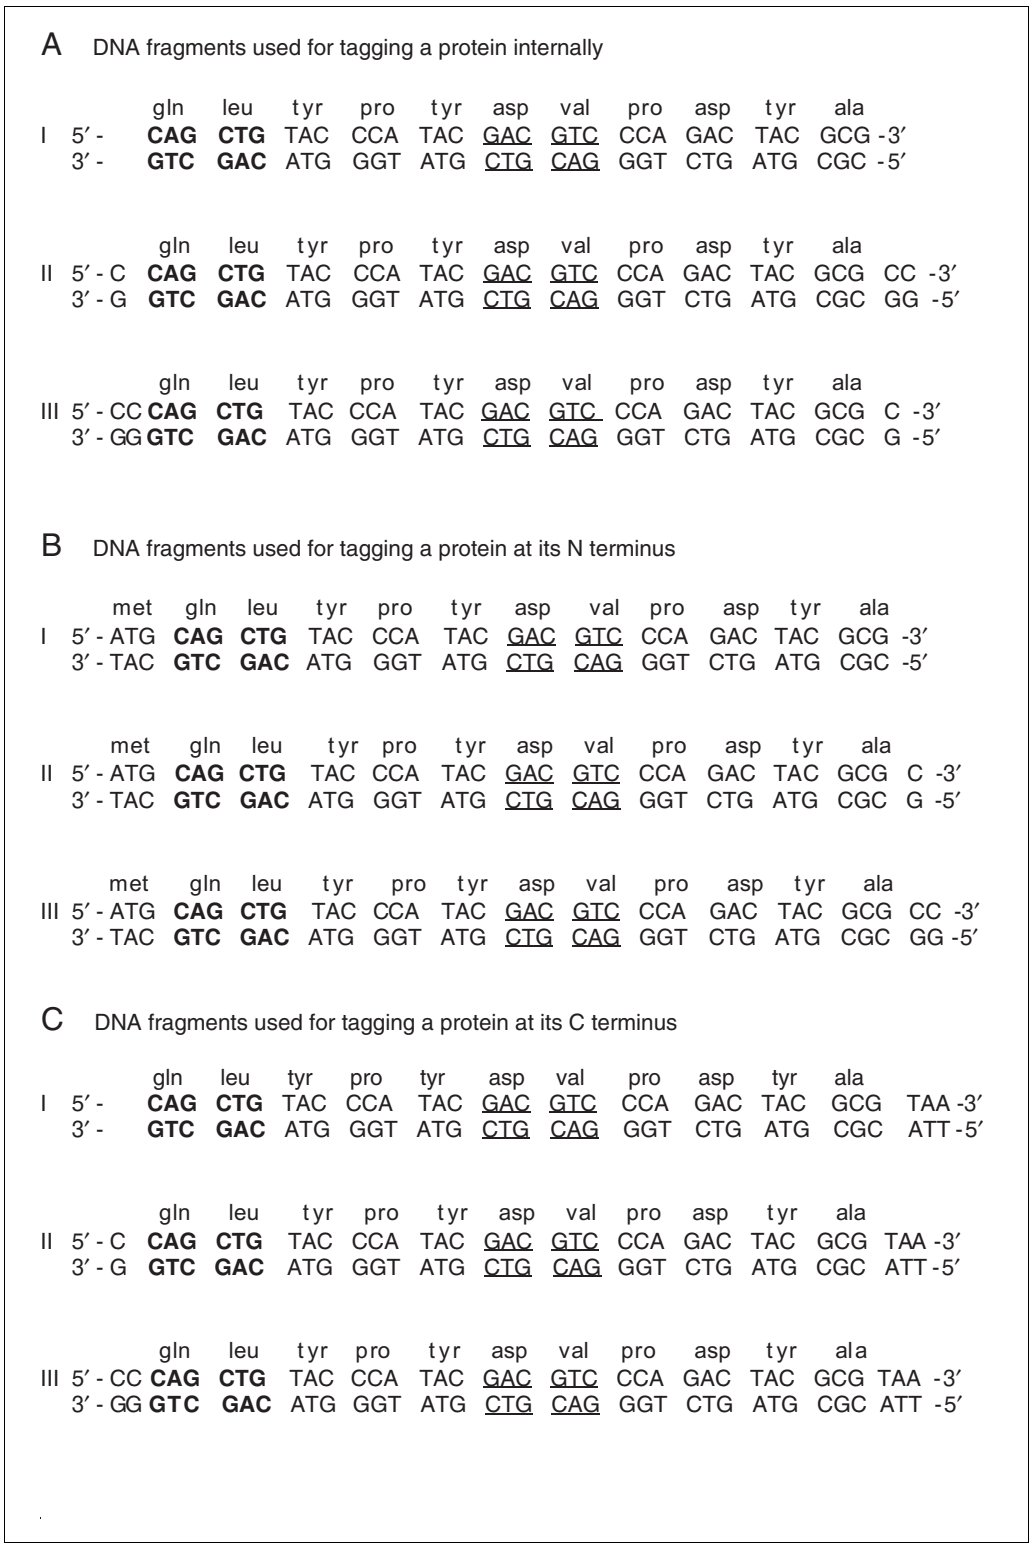

Figure 5.2.3 Examples of DNA fragments used for tagging proteins with the HA epitope. Use of fragments I, II, and III allow in-frame fusions to any reading frame internally (**A**), at the N terminus (**B**), or at the C terminus (**C**). If the translation initiation and termination codons endogenous to the gene of interest are used, the ATG codons shown in (B) and TAA codons shown in (C) can be eliminated from the fragments depicted here. *Pvu*II (bold) and *Aat*II (underlined) restriction sites are indicated.

from the upstream transmembrane segment. When probing a hydrophilic domain containing <15 amino acids, it is acceptable to place the fusion joint after the first 3 to 5 amino acids of the following hydrophobic stretch, if one exists, in order to avoid disrupting charged residues that may be critical for orienting the upstream transmembrane segment (an example of this placement within a downstream transmembrane segment is shown in Figure 5.2.6). If, on the other hand, the small domain being probed lies at the protein's C terminus, the fusion joint should be placed at the C-terminal end of the protein.

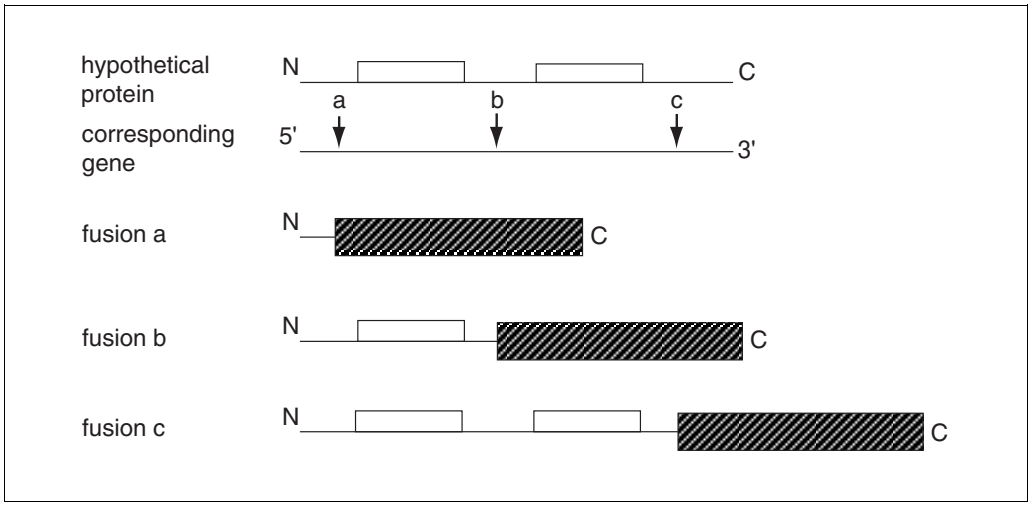

Figure 5.2.4 Placement of fusion joints in an integral membrane protein. Putative transmembrane segments are indicated by open boxes. The positions of the fusion joints to be constructed in the corresponding gene are indicated by arrows and denoted a, b, and c. A series of fusions of the invertase fragment-histidinol dehydrogenase (inv-HD) sequence (striped box) to N-terminal fragments of the hypothetical protein are indicated as fusions a, b, and c.

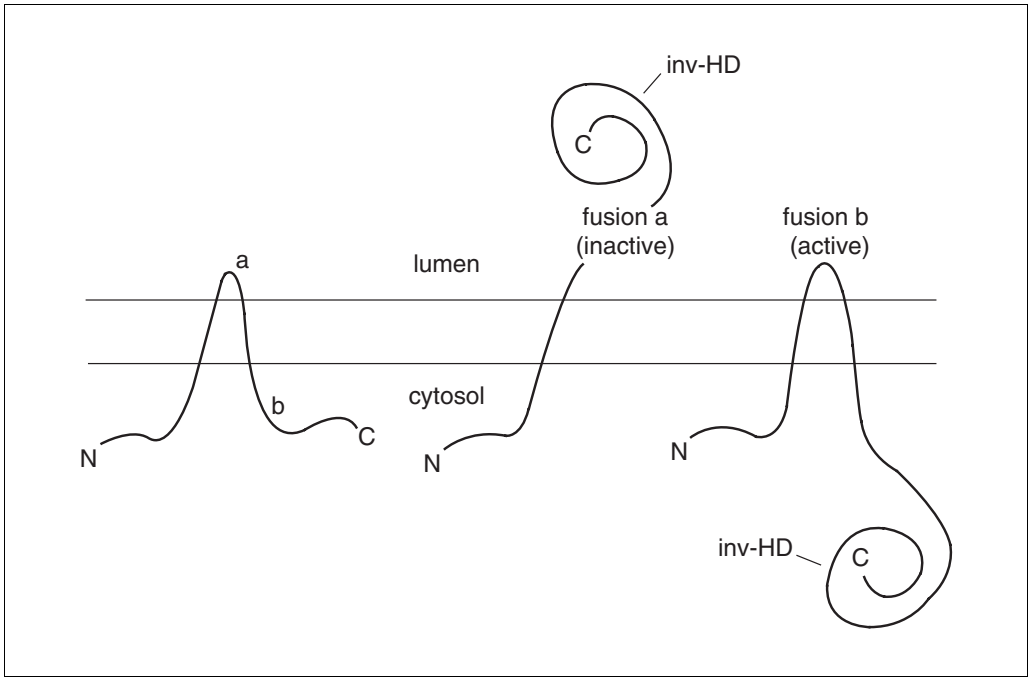

Figure 5.2.5 Fusion approach to determining membrane protein topology. The fusion of inv-HD at positions a and b in a hypothetical protein are indicated. Fusion a lacks HD activity due to the translocation of HD to the luminal side of the membrane. Fusion b exhibits HD activity due to the presence of HD in the cytosol.

Selecting a Method

A number of factors govern the selection of a protocol best suited for assessing the topology of a particular protein. Since protease digestion and immunofluorescence staining are used to probe a full-length protein, as opposed to truncated fragments, results obtained from these approaches may be more reliable, although problems associated with accessibility to the protease or antibody used can occur. Use of a foreign epitope to assess membrane protein topology can also yield very reliable results, provided the inserted epitope does not inhibit function of the target protein. Because of its simplicity, however, the reporter fusion approach is often employed as a way to get a general picture. As this approach involves fusion of a large foreign domain to N-terminal fragments, the topological assignments should be augmented with measurements of at least a few hydrophilic regions in the intact functional protein to determine whether different approaches yield the same topological picture. By complementing the reporter fusion analysis with one of the first two approaches, the derived map should provide a reasonably accurate assessment of the protein's topology. An example of this complementary approach is described by Lai et al. (1996).

BASIC PROTOCOL 1

PROTEASE DIGESTION

This protocol uses ER-derived vesicles from canine pancreas. These microsomes are purified according to the method of Walter and Blobel (1983) and exhibit a cytoplasmic-side-out orientation. Digestion of a hydrophilic domain present on the surface of microsomal vesicles therefore indicates that the exposed region is disposed to the cytosolic side of the membrane. This protocol uses immunoblotting to examine unlabeled proteins present in these membranes, although radiolabeled proteins integrated in vitro can also

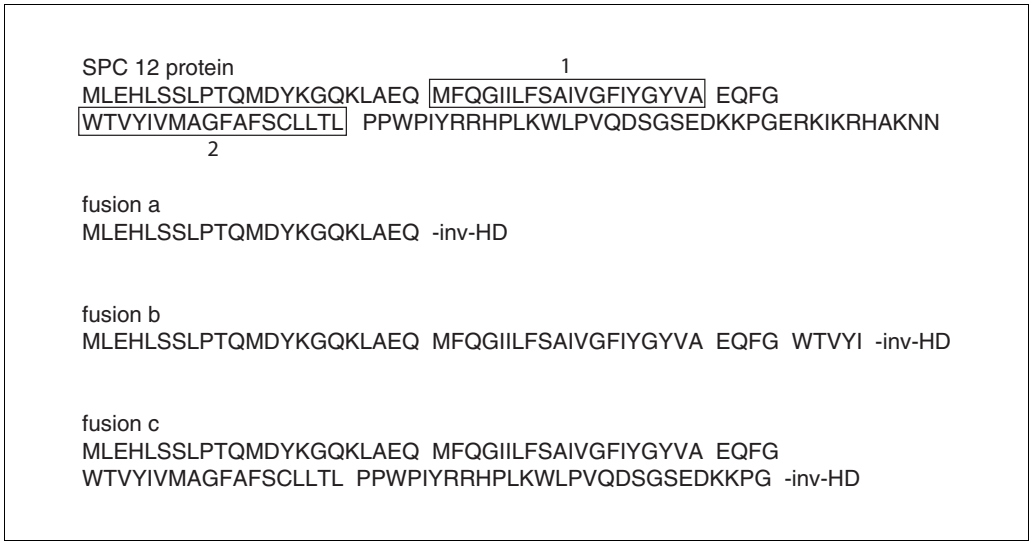

Figure 5.2.6 Positioning of fusion joints in SPC12 protein. The inv-HD reporter was placed at three positions in the SPC12 protein to discern the orientation of the three hydrophilic domains flanking hydrophobic segments 1 and 2 (open boxes). Note that the fusion joint of fusion c is placed >15 amino acids from the upstream hydrophobic segment. However, since the hydrophilic domain located between hydrophobic segments 1 and 2 consists of only 4 amino acids (EQFG), it is not possible to place the fusion joint more than 15 amino acids from hydrophobic segment 1 without capturing most of hydrophobic segment 2 in fusion b. Therefore, the fusion joint is positioned such that only 5 amino acids of hydrophobic segment 2 are present in fusion b. In placing the fusion joint at this position, the charged residues immediately following hydrophobic segment 1 are left undisturbed. Fusion a lacks a putative transmembrane segment and will remain cytosolic regardless of the topology of the N terminus of intact SPC12 protein. One exception to this is that, if the polypeptide chain contains an N-terminal signal sequence (von Heijne, 1984), fusion a would probably be transported to the ER lumen.

be studied (Walter and Blobel, 1983; Mize et al., 1986; see *UNIT 11.4* for analysis of protein translocation into canine microsomes). The protocol can also be adapted to microsomes prepared from metabolically labeled cells (*UNIT 7.1*; Bonnerot et al., 1994). As a control to determine whether the target protein is inherently sensitive to the protease used, proteolyzed membranes are compared to membranes solubilized in a mild detergent, such as Triton X-100, prior to protease addition.

In this protocol, proteinase K is employed as a representative protease due to its broad substrate specificity. In addition, proteinase K is active under the buffer conditions described (as are many other proteases), and proteinase K retains activity in the presence of Triton X-100. The buffer also contains sucrose to help maintain the integrity of membrane vesicles. Another control, which tests for the presence of intact membranes, examines a luminal protein native to the membrane vesicles used. Provided the membranes are intact, the luminal protein control should be resistant to proteinase K in the absence of detergent. Examples of ER proteins used for control purposes are TRAPβ (Kalies and Hartmann, 1996) and BiP (Mullins et al., 1995).

Materials

Canine pancreatic microsomal membranes (see *UNIT 11.4*)
Magnesium/sucrose/BSA (MSB) buffer (see recipe)
20% (w/v) Triton X-100
10 mg/ml proteinase K (see recipe)
100% (w/v) trichloroacetic acid (TCA) (see recipe)
2× SDS sample buffer (*APPENDIX 2A*)
Antibodies directed against a series of peptides corresponding to specific hydrophilic regions of the target protein
Control antibodies directed against a luminal protein or a luminal domain of a membrane protein in the membrane system to be analyzed

Additional reagents and equipment for preparing canine pancreatic microsomes (*UNIT 11.4*), separating proteins by SDS-PAGE (*UNIT 6.1*), and detecting proteins by immunoblotting (*UNIT 6.2*)

Prepare microsomal membranes

1. Purify microsomal membranes according to the method described in *UNIT 11.4*.

   Microsomes are stored at −80°C at a final concentration of 50 A_{280} units per ml. One equivalent is defined as 1 μl of this mixture. When stored under these conditions, microsomes are stable ≥1 year.

   Be sure that inhibitors of the protease to be used are omitted from the original membrane preparation (such as PMSF in the case of proteinase K; see APPENDIX 1B). If protease inhibitor is present, wash the membranes by centrifuging 20 min at ~100,000 × g, 4°C. Suspend the pellet in MSB buffer at the same concentration by pipetting up and down in a plastic tip.

2. Slowly thaw ~50 μl of microsomes by placing a tube containing the microsomes in ice.

   This amount of membranes is needed for examinations that use one antipeptide antibody and a control antibody. An additional 50-μl aliquot is needed for each additional examination.

3. Prepare ten samples, each containing 5 μl (5 equivalents) rough microsomes diluted with MSB buffer to a final volume of 20 μl in microcentrifuge tubes.

   Steps 3 to 8 should be performed using tubes kept in ice. Polypropylene microcentrifuge tubes have been found to work satisfactorily.

4. Add 1 µl of 20% (w/v) Triton X-100 to five of the tubes and mix by pipetting the solution up and down.

   These detergent-treated aliquots serve as controls to demonstrate that the target protein is inherently sensitive to the protease used. The five tubes lacking Triton X-100 are sample tubes and the five tubes containing Triton X-100 are control tubes.

Perform protease digestion

5. Add 10 mg/ml proteinase K to four of the sample tubes and four of the control tubes to yield final concentrations of 1, 20, 100, and 500 µg/ml.

   The amount of protease is varied to find the concentration which allows good digestion of the target protein yet is low enough that the protease does not destroy the membrane structure (thus making the membrane permeable to the protease added). Protease should be omitted from the fifth tube in the sample and control sets.

6. Mix samples by pipetting the solutions up and down a few times and incubate 30 min.

7. Stop proteolysis by adding 100% (w/v) TCA to a final concentration of 15%.

Analyze protein digests

8. Incubate all ten tubes 15 min on ice and collect TCA pellets by microcentrifuging 5 min at ~10,000 rpm (8,000 × *g*), room temperature.

9. Remove supernatant and suspend the pellets in 10 µl of 2× SDS sample buffer and 10 µl H_2O by vortex mixing at room temperature.

   Be sure that all of the pellet has been suspended. The mixtures should be blue because of bromphenol blue, which is present in the sample buffer. If the tubes are yellow (because of high acidity), 1-µl aliquots of 1 M Tris base can be added successively and then mixed until the mixture turns blue.

10. Load 10 µl from each tube into sample wells of a SDS-PAGE gel.

    The lanes should be organized as follows. The first five lanes contain one-half of the mixture from the five sample tubes, and the next five lanes contain one-half of the mixture from the five control tubes. The next five lanes contain one-half of the mixture from the five sample tubes, and the final five lanes contain one-half of the mixture from the five control tubes.

    A 12.5% polyacrylamide gel can be used to identify protein fragments of ~2 to 30 kDa, whereas a 7% acrylamide gel can be used to identify protein fragments of 30 to 100 kDa.

11. Analyze samples using SDS-PAGE (*UNIT 6.1*).

12. Examine the separated protein fragments by immunoblotting (*UNIT 6.2*), using one of the antipeptide antibodies and the control antibody directed against a luminal protein or a luminal domain of a membrane protein in the membrane system to be analyzed.

    The blot should be cut in half. The gel portion containing the first ten lanes is to be immunoblotted with an antibody directed against the target protein. The gel portion containing the second group of ten lanes should be subjected to immunoblotting using an antibody directed against the luminal protein control. The data should be interpreted by following examples described in Figure 5.2.2A and Anticipated Results.

13. Repeat steps 3 to 12 using each of the antipeptide antibodies and the control antibody.

IMMUNOFLUORESCENCE STAINING

This protocol illustrates use of an immunofluorescence technique to probe the topology of membrane proteins. The protocol is designed specifically to examine proteins confined to the plasma membranes of cells lacking an outer cell wall, such as cultured mammalian cells. This protocol has been optimized for using human embryonic kidney (HEK) 293 cells, although other cultured cell lines can be used with only minor modifications (noted below). These cells can be grown on glass coverslips and permeabilized with low concentrations of a mild detergent (Nonidet P-40 is used here), which allows antibodies access to the cytoplasmic compartment. The permeabilized cells and a second nonpermeabilized cell preparation are incubated with an antipeptide antibody followed by incubation with a fluorophore-conjugated secondary antibody. Cells are then examined by fluorescence microscopy (*UNIT 4.2*). As a control, cells expressing a plasma membrane protein of known topology should be examined using antibodies directed to a cytosolic domain and an extracytoplasmic domain.

This approach can employ primary antibodies directed against peptides corresponding to the membrane protein under study, such as the antipeptide antibodies described in Basic Protocol 1. However, antipeptide antibodies are found often not to recognize their corresponding epitopes within a native membrane protein (Carrasco et al., 1986). The procedure described here therefore uses a membrane protein that has been tagged with the HA epitope (see Support Protocol for methods regarding epitope tagging). Use of the HA epitope can minimize cost and time associated with the preparation of antipeptide antibodies. The primary and secondary antibodies used in this protocol are the anti-HA epitope mouse monoclonal antibody 12CA5 and a rhodamine-conjugated rabbit anti-mouse IgG, respectively, but other combinations of antibodies can be used as well (Canfield and Levenson, 1993).

Materials

HEK 293 cells (ATCC #CRL 1573)
4% (w/v) paraformaldehyde (see recipe)
Nonidet P-40/goat serum/BSA (NGB) solution (see recipe)
Anti-HA mouse monoclonal antibody 12CA5 (Boehringer Mannheim)
Rhodamine-conjugated rabbit anti-mouse immunoglobulin G (IgG)
DMEM/FBS/HEPES (DFH) solution (see recipe)
Fluoromount G mounting medium (Fisher)

6-well tissue culture plates
Glass coverslips, 22-mm diameter

Additional reagents and equipment for immunofluorescence staining of fixed mammalian cells (*UNIT 4.3*), epifluorescence (*UNIT 4.2*) or confocal laser microscopy, and growing cultured mammalian cells (*UNIT 1.1*)

1. Seed HEK 293 cells stably expressing the polypeptide of interest on glass coverslips and grow 2 to 3 days at 37°C in 6-well plates before processing for immunofluorescence.

   Alternatively, transient transfections can be performed on cells grown on glass coverslips in 6-well plates (UNIT 1.1). Cells should be handled using typical aseptic technique required for growing cells in culture (UNIT 1.3).

   The glass coverslips should be cleaned thoroughly using a strong detergent and washed extensively with distilled water.

   Duplicate cultures are needed in order to provide sets to be examined in the absence and presence of permeabilizing agents and in the absence or presence of the polypeptide of

interest. A single 6-well plate thus provides a triplicate analysis of cells to be treated with permeabilizing agents and containing the polypeptide of interest and a triplicate analysis of cells treated with permeabilizing agents and lacking the polypeptide of interest. A distinct plate provides a triplicate analysis for the set not treated with permeabilizing agents and either containing or not containing the polypeptide of interest (see below).

All steps except the antibody incubations can easily be carried out in 6-well tissue culture plates, using volumes of 2 to 3 ml per well for incubations and washes.

Methods for HA tagging, and testing for function of tagged proteins in transiently transfected HEK 293 cells are described in the Support Protocol.

2. For the permeabilized set, aspirate culture medium and wash coverslips once in PBS. Replace PBS with 4% paraformaldehyde (2 to 3 ml) and fix 10 min at room temperature.
3. Aspirate fixing reagent and rinse cells three times with PBS. Permeabilize and block cells in NGB solution (2 to 3 ml) for 15 min at room temperature.
4. Dilute monoclonal antibody 12CA5 to 1 µg/ml in NGB. Centrifuge antibody dilution 2 min at 8000 × *g* to remove aggregates.

   Although this antibody is supplied at a specified concentration, different batches appear to have different characteristics, and it may be necessary for individual users to optimize their antibody dilutions.

5. Place coverslips cell-side-up on Parafilm and immediately add primary antibody (100 µl per coverslip). Incubate 1 hr at room temperature in a covered, humidified chamber.

   A small petri dish or any small covered container will serve as a humidified chamber.

   For more tightly adherent cells, the volume of antibody used can be reduced further as follows. Pipet antibody (50 µl) directly onto Parafilm. Place coverslips on droplet, cell-side-down.

6. Return coverslips to NGB (2 to 3 ml) in the 6-well plate. Wash three times with PBS (10 min each wash) and once with NGB.
7. Incubate cells 1 hr at room temperature in NGB solution (2 to 3 ml) containing a rhodamine-conjugated rabbit anti-mouse IgG.

   The secondary antibody should be diluted according to the supplier's recommendations. Optimization of antibody dilution may be necessary.

8. Return coverslips to NGB solution and wash three times with PBS.
9. Dip coverslips in distilled water and mount on slides using Fluoromount-G (15 µl per slide).
10. For the nonpermeabilized set, replace growth medium with DFH solution and chill 15 min to 4°C.

    These cells provide the set that is nonpermeable in the presence of primary antibody. These steps can most conveniently be performed concurrently with processing of permeabilized cells.

11. Incubate with monoclonal antibody 12CA5 (2 µg/ml) for 1 hr in a humidified chamber at 4°C as described in step 5.

    Note that a higher concentration of antibody is used for this low-temperature incubation.

12. Wash three times with cold DFH and once with cold PBS.

13. Fix, permeabilize, and incubate "nonpermeabilized" cells with secondary antibody, as described in steps 2 to 3 and 7 to 9.

    The nonpermeabilized set is permeabilized immediately before addition of secondary antibody. This step serves not only to bind the secondary antibody to the primary antibody but also to determine whether the secondary antibody binds nonspecifically to either surface of the plasma membrane.

14. Examine permeabilized and nonpermeabilized cells using epifluorescence or confocal laser scanning microscopy.

    Fluorescence staining of only the permeabilized set is suggestive of an antibody bound to a cytosolic domain, whereas fluorescence appearing in both the permeabilized and nonpermeabilized sets reveals a domain placed at the extracytoplasmic side of the plasma membrane. A range from 5% to 25% of the cells on a particular coverslip may be stained well.

    The control cells lacking the polypeptide of interest are needed because one difficulty associated with the use of 12CA5 is that it is not absolutely specific for the HA epitope. Cross-reactivity is seen both on immunoblots and by immunofluorescence in nontransfected or nontagged cells.The resulting background may decrease the sensitivity with which the transfected, tagged polypeptide can be visualized. If the background signal is too high to detect the protein of interest, even after diluting the primary and secondary antibodies further than that described above, try other anti-HA antibody preparations such as those available from BAbCO. Note, however, that some of these antibodies may not recognize HA tags placed internally within the protein sequence.

EPITOPE TAGGING

SUPPORT PROTOCOL

In this protocol, a series of molecular biological manipulations are used to place a foreign epitope into a hydrophilic region of a membrane protein. Integration of the expressed protein leads to placement of the epitope on one side of the membrane. The orientation of the tagged domain can be assessed by monitoring the accessibility of the epitope to a protease (see Basic Protocol 1) or to its cognate antibody (see Basic Protocol 2).

The HA epitope, YPYDVPDYA, is recommended for use in this protocol because it contains only two charged amino acids. As shown in Figure 5.2.3, a set of three DNA fragments (differing by addition of 0, 1, or 2 base pairs at one or both ends) can be used to place the HA epitope internally within the sequence of a protein, N-terminally, or C-terminally. The fragments are inserted into a blunt-end restriction site occurring naturally within the protein's gene or into a restriction site constructed by site-directed mutagenesis (see *APPENDIX 3*). Depending on the reading frame of the site into which the epitope is inserted, only one of the three DNA fragments is needed to permit in-frame fusion between the membrane protein sequence and the epitope at its N and/or C termini. These fragments also contain the blunt-end *Pvu*II restriction site. This site provides a convenient place to insert a second fragment encoding the HA epitope, which is used if the single tag is found not to present the membrane protein adequately to the added antibody. Alternatively, DNA fragments containing a blunt-end restriction site other than *Pvu*II, such as *Eco*RV, can be synthesized if this *Pvu*II site is not unique on the plasmid containing the gene of interest. The DNA sequence encoding the HA epitope depicted in Figure 5.2.3 also contains an *Aat*II restriction site that can be used to verify insertion of the fragment into the plasmid used. It is usually necessary to verify orientation of the inserted fragment by DNA sequencing. This is not the only way to introduce an epitope into a membrane protein. A DNA sequence encoding the epitope can be introduced by site-directed mutagenesis.

Having introduced a DNA fragment encoding the HA epitope into a cloned gene, the tagged protein should be tested for function. If the tagged protein exhibits normal functional properties, then it is likely that the epitope introduced has not altered the overall

structure of the protein. To test for function, many types of assays can be performed. The type of assay used is dependent on the particular protein under study. For example, the HA-tagged rodent Na,K-ATPase α subunit can be tested for its ability to confer ouabain resistance to HEK 293 cells transfected with the tagged DNA construct (see Basic Protocol 2; Canfield et al., 1996). A tagged protein can be introduced into yeast cells, testing for complementation of a mutant lacking that protein or an evolutionarily conserved protein (Kurihara and Silver, 1993). Alternatively, a tagged protein may be expressed to high levels, enriched, then tested for activity using an in vitro assay.

Materials

TE buffer (*APPENDIX 2A*)
Plasmid DNA encoding the protein of interest
E. coli cells to be transformed

Additional reagents and equipment for synthesizing oligonucleotides (*APPENDIX 3*), ligating DNA (*APPENDIX 3*), transforming *E. coli* (*APPENDIX 3*), isolating plasmid DNA from *E. coli* (*APPENDIX 3*), identifying plasmids by restriction endonuclease digestion (*APPENDIX 3*), and sequencing oligonucleotides (*APPENDIX 3*)

1. Determine whether fragment I, II, or III (Fig. 5.2.3) is needed to produce an in-frame fusion between the N- and/or C-terminal ends of the HA epitope and the target protein.

2. Synthesize the appropriate DNA fragment(s) identified from step 1.

   Complementary oligonucleotides should be synthesized.

3. Mix two complementary DNA strands together, each to a final concentration of 1 A_{260} unit per 50 µl in TE buffer.

   Oligonucleotides are usually synthesized with their 5′ ends unphosphorylated. The oligonucleotides used should be left unphosphorylated to prevent insertion of multiple oligonucleotides into the linearized plasmid.

4. Anneal the strands by heating the solution 5 min at 70°C and then letting the solution cool in air at room temperature.

5. Mix 5 µl of the oligonucleotide solution with 0.1 µg of linearized plasmid DNA encoding the protein of interest, ligate the mixture in 10 µl of ligation buffer, and transform *E. coli* with the ligation mixture (*APPENDIX 3*).

   The DNA should be linearized at a restriction site contained within a sequence corresponding to the hydrophilic domain to be probed. If such a restriction site does not exist, one can be introduced by site-directed mutagenesis (as illustrated below, blunt-end sites are preferable). If possible, the epitope should be placed ≥15 amino acids from the nearby transmembrane segment(s). If the restriction site used produces sticky ends, the site should be made blunt-ended using standard molecular biological manipulations. To minimize religation of the plasmid without the DNA fragment to be inserted, the ligation mixture should be treated with the restriction enzyme used to produce the blunt end, provided a restriction enzyme producing blunt ends was used.

   The above-described ratio of fragment and linear plasmid is acceptable in many instances. However, sometimes this ratio may need to be varied in order to achieve efficient ligation of the fragment to the plasmid. Try increasing the concentration of oligonucleotides from 1 A_{260} unit to 2, 5, and 10 A_{260} units per 50 µl in TE buffer (step 3).

   Any of the E. coli strains commonly used for plasmid transformations is suitable, such as HB101 and MC1061.

6. Isolate plasmids from individual *E. coli* transformants and identify plasmids containing the insert using restriction analysis (*APPENDIX 3*).

If a fragment shown in Figure 5.2.3 is synthesized, restriction enzymes AatII and PvuII are useful for identifying the desired construct.

7. Determine the DNA sequence of the fragment inserted and residues surrounding this fragment to ensure correct orientation and in-frame fusion.

8. Express the epitope-tagged protein in an appropriate cell and test for its function. Examine its topology using Basic Protocols 1 or 2.

   If the tagged protein is not recognized by antibodies directed against the HA epitope, double-HA-tagged proteins can be constructed by inserting the appropriate DNA fragment (Fig. 5.2.3) into the PvuII site of the construct tagged with only one HA epitope. Successive insertions into each new PvuII site will produce proteins tagged with increasing numbers of HA epitopes.

   Plasmid DNA can be stored indefinitely in TE buffer at −20°C and should be introduced into the cell examined prior to use.

REPORTER GENE FUSIONS

BASIC PROTOCOL 3

In this protocol, a series of gene fusions is constructed in which a reporter moiety is fused to various truncated fragments of a target membrane protein. To construct these fusions, DNA fragments encoding a series of N-terminal fragments of a membrane protein should be synthesized by the polymerase chain reaction (PCR; see *APPENDIX 3*). For each PCR amplification, two primers are required: one corresponding to a sequence upstream of the promoter of the relevant gene and one corresponding to sequences at the desired fusion joint. Only one upstream primer is required, whereas a downstream primer corresponding to each of the fusion joints is usually needed. For construction of PCR fragments, the upstream primer contains a *Bam*HI site or a site compatible with the *Bam*HI sticky end, such as *Bgl*II or *Bcl*I. The downstream primer contains a *Xho*I site or a site compatible with *Xho*I, such as *Sal*I. Compatible sites are needed when the DNA fragment to be inserted contains an internal *Bam*HI or *Xho*I site. To ensure that the reading frame is maintained across the fusion joint, the *Xho*I site in the downstream primer is placed in the following reading frame: C TCG AG (where TCG encodes an in-frame serine).

A vector that can be used for expression of fusions in yeast is pA189invHD (Green and Walter, 1992; Fig. 5.2.7). pA189invHD is used for construction of gene fusions encoding the C-terminal moiety histidinol dehydrogenase (HD). HD is a cytoplasmic enzyme that is enzymatically inactive when fused to a luminal domain of a membrane protein inserted into the ER membrane. This shuttle vector contains the 2μm DNA fragment for replication in yeast and the ColE1 replication origin for replication in *E. coli*. pA189invHD can be selected in yeast cells containing a mutation in the *URA3* gene due to the presence of plasmid-borne *URA3*. The vector can also be maintained in *E. coli*, as it confers ampicillin resistance. pA189invHD contains a single *Bam*HI site and a single *Xho*I site. Restriction of pA189invHD with *Bam*HI and *Xho*I generates two DNA fragments (13 kb and 0.8 kb). The larger of these fragments contains the selectable markers and origins of replication described above. The smaller fragment encodes a portion of arginine permease, whose topology was analyzed previously using this vector system (Green and Walter, 1992). The fragment encoding arginine permease is therefore replaced with PCR-amplified fragments encoding N-terminal truncations of the membrane protein to be examined. For examining the topology of a protein without its native promoter, the yeast *ADH1* promoter (Bennetzen and Hall, 1982) is included on pA189invHD. When using the *ADH1* promoter, the upstream primer should contain a *Bam*HI site in front of the initiation codon for the membrane protein. For efficient expression from the *ADH1* promoter in pA189invHD, it is important that no ATG codon is present between the *Bam*HI site and the initiation codon.

Materials

Reporter plasmid (Fig. 5.2.7): pA189invHD (available from Neil Green, Vanderbilt University)

S. cerevisiae strain FC2-12B (*MATα trp1-1 leu2-1 ura3-52 his4-401 HOL1-1 can1-1*; available from Neil Green, Vanderbilt University)

SD +HIS agar plates (see recipe)

SD +HOL agar plates (see recipe)

Thermocycler

Additional reagents and equipment for the polymerase chain reaction (PCR; *APPENDIX 3*), agarose gel electrophoresis (*APPENDIX 3*), restriction endonuclease digestion (*APPENDIX 3*), and transformation of *E. coli* and *S. cerevisiae* (*APPENDIX 3*)

Construct gene fusions

1. Amplify by PCR a series of DNA fragments encoding truncations of a membrane protein, using appropriate primers.

   The DNA primers used in the PCR amplification can be synthesized by one of a number of companies offering services in oligonucleotide synthesis. The upstream primer should

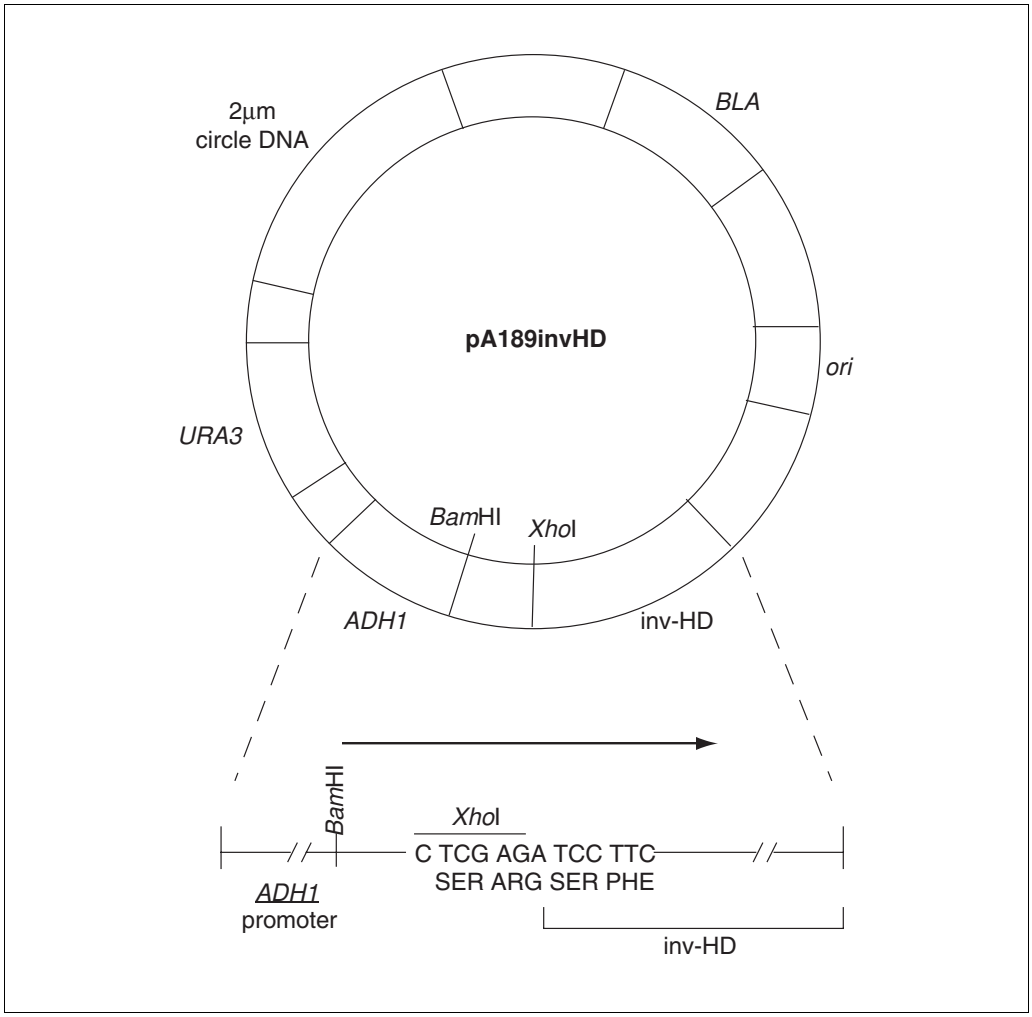

Figure 5.2.7 Gene fusion vector pA189invHD. The direction of transcription is indicated by an arrow. Abbreviations: *BLA*, β-lactamase gene; *ADH1*, alcohol dehydrogenase gene promoter; *URA3*, orotidine-5′-phosphate decarboxylase gene; ori, ColE1 replication origin; inv-HD, fusion of invertase fragment-histidinol dehydrogenase genes.

contain a 5′ BamHI site (or compatible site) followed by at least 20 nucleotides complementary to the DNA sequence to be amplified. The downstream primer should contain a 5′ XhoI site (or compatible site) followed by at least 20 nucleotides from the reverse strand of the DNA sequence to be amplified. The BamHI site should be placed immediately before the initiation codon if the ADH1 promoter of pA189invHD is to be used or before the promoter of the gene to be studied. The XhoI site should correspond to a site in a hydrophilic domain of the membrane protein studied. It is also recommended that the primers contain 2 to 3 nucleotides at the 5′ end of the restriction site for efficient cutting by the restriction enzyme after PCR amplification.

2. Purify the amplified fragments by agarose gel electrophoresis and digest with *Bam*HI and *Xho*I.

   Overnight restrictions are sometimes needed for efficient cutting of XhoI sites located near the ends of DNA fragments.

3. Digest the reporter plasmid pA189invHD with *Bam*HI and *Xho*I.

4. Purify the larger, 13-kb DNA fragment produced from the restriction digestion by agarose gel electrophoresis (see *APPENDIX 3*). Ligate the 13-kb fragment to each of the fragments produced in step 2.

   The smaller fragment (0.8 kb) encodes a part of arginine permease and should be discarded.

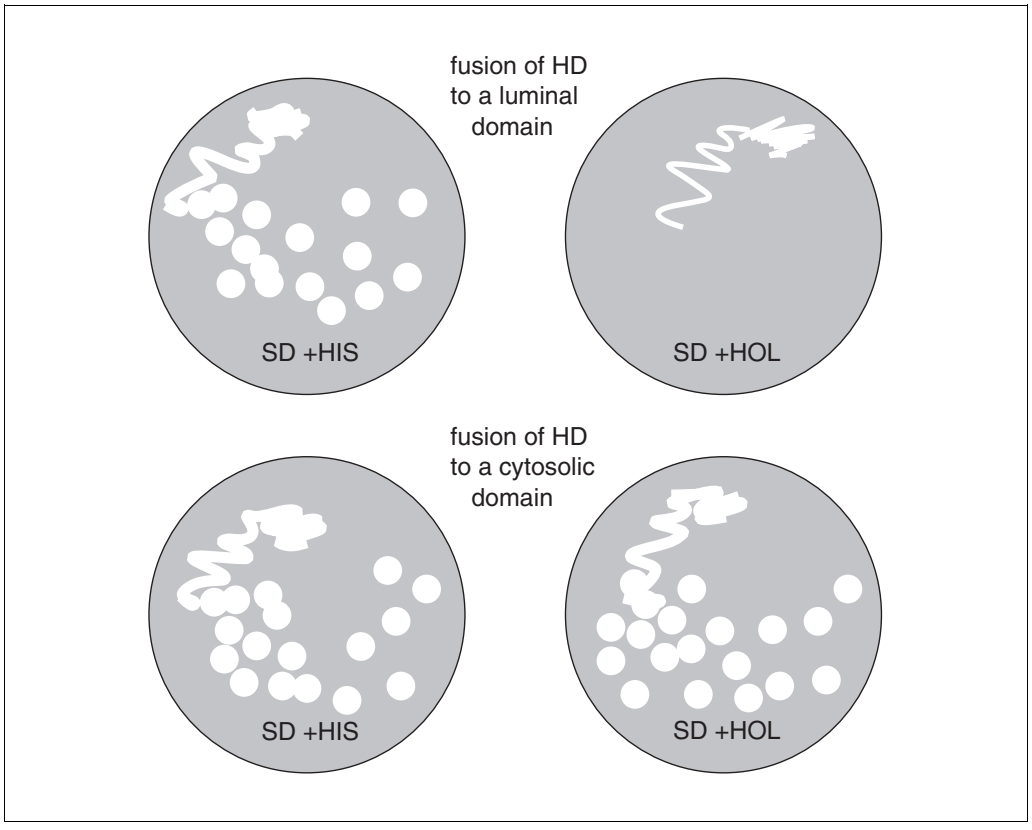

Figure 5.2.8 Cell growth assay for determining membrane protein topology. Cells of yeast strain FC2-12B bearing a fusion protein that fuses the HD moiety to a luminal domain of an integral membrane protein or bearing a fusion protein that fuses the HD moiety to a cytosolic domain of an integral membrane protein are streaked for single colonies on SD +HIS agar plates and SD +HOL agar plates, then incubated 4 to 5 days at 30°C. When large colonies appear on SD +HIS agar plates and little growth is detected on SD +HOL agar plates, the reporter is interpreted to be fused to a luminal domain of the membrane protein under study. On the other hand, when large colonies appear on both the SD +HIS and SD +HOL agar plates, the reporter is interpreted to be fused to a cytosolic domain.

5. Transform a standard Amp^s *E. coli* strain and isolate the desired plasmid construct.

   A variety of E. coli strains can be used, such as strains HB101 and MC1061.

Perform genetic assay

6. Transform the construct isolated from *E. coli* into *S. cerevisiae* strain FC2-12B and select transformants on SD +HIS agar plates.

   Yeast cells should be handled using aseptic technique.

   Strain FC2-12B contains a ura3 mutation that permits selection for pA189invHD-derived plasmids. Transformants should appear as individual colonies after 4 days on agar plates incubated at 30°C.

7. Test transformed yeast cells for growth by streaking cells on SD +HOL agar plates and SD +HIS agar plates.

   Individual colonies should appear after 4 to 5 days at 30°C. An example of the results expected is shown in Figure 5.2.8. As shown in this figure, fusion of HD to a luminal or cytosolic domain does not affect cell growth on SD +HIS agar plates. However, fusion of HD to a luminal domain inhibits growth on SD +HOL agar plates. Fusion of HD to a cytosolic domain does not inhibit cell growth on either type of agar plate.

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

DMEM/FBS/HEPES (DFH) solution

10% (v/v) fetal bovine serum
20 mM *N*-2-hydroxyethylpiperazine-*N*′-2-ethanesulfonic acid (HEPES), pH 7.4
Prepare in supplemented Dulbecco's modified Eagle medium (DMEM; *APPENDIX 2A*)
Prepare fresh

The fetal bovine serum should not be heat-inactivated.

Magnesium/sucrose/BSA (MSB) buffer

150 mM potassium acetate
5 mM magnesium acetate
50 mM *N*-2-hydroxyethylpiperazine-*N*′-2-ethanesulfonic acid (HEPES), pH 7.6
200 mM sucrose
1 mM dithiothreitol (*APPENDIX 2A*)
Prepare fresh

Nonidet P-40/goat serum/BSA (NGB) solution

0.05% (v/v) Nonidet P-40 (Igepal AC-630)
5% (v/v) goat serum
1% (w/v) BSA
Prepare in PBS (*APPENDIX 2A*), pH 7.4
Prepare fresh

Paraformaldehyde, 4%

Heat 900 ml water to 55° to 60°C on a stirring hot plate in a fume hood. Add 40 g paraformaldehyde powder and stir 30 min. If powder has not dissolved, add a few NaOH pellets one at a time (waiting a few minutes between pellets) until the paraformaldehyde dissolves. Add 100 ml of 10× PBS (*APPENDIX 2A*), filter, cool to room temperature, and adjust to pH 7.4 with HCl. Store up to 1 week at 4°C.

CAUTION: *The fume hood is used because paraformaldehyde fumes are toxic. The "Prill" form of paraformaldehyde from EM Sciences is safest to use, as it pours without creating a cloud.*

Proteinase K, 10 mg/ml

10 mg proteinase K (lyophilized powder, ~80% protein, 10 to 20 U/mg protein; Sigma)
1 ml 50 mM HEPES, pH 7.6
Prepare fresh on ice

No activation of the proteinase K is necessary; the purchased enzyme is ready to use.

SD +HIS agar plates

0.7 g/liter yeast extract (without amino acids; Difco)
20 g/liter glucose
20 g/liter agar
0.1 mg/ml L-tryptophan
0.1 mg/ml L-leucine
0.1 mg/ml L-histidine

Mix the ingredients together before autoclaving. Pour the autoclaved solution into 100 × 15–mm petri dishes. Store plates <1 month at 4°C.

SD +HOL agar plates

0.7 g/liter yeast extract (without amino acids; Difco)
20 g/liter glucose
20 g/liter agar
0.1 mg/ml L-tryptophan
0.1 mg/ml L-leucine
0.1 mg/ml L-histidinol dihydrochloride (Sigma)

Filter-sterilize the histidinol solution and add to the remainder after autoclaving. Store plates <1 month at 4°C.

TCA, 100%

250 g solid trichloroacetic acid (TCA)
141 ml water
Store <6 months at 4°C

COMMENTARY

Background Information

Integral membrane proteins can often be distinguished from peripherally bound proteins in that the latter are extractable from the membrane under conditions of high pH (Steck and Yu, 1973; Fujiki et al., 1982; Russel and Model, 1982). Resistance of integral membrane proteins to extraction is attributed to the presence of transmembrane segments which help anchor proteins to the lipid bilayer. Visual and computer-based inspections of the primary sequences of integral membrane proteins usually reveal one or more hydrophobic amino acid stretches interspersed among hydrophilic stretches in an alternating pattern. This pattern suggests a topology in which neighboring hydrophilic domains are positioned on opposite sides of a membrane through integration of hydrophobic transmembrane regions. These topological predictions have been generally confirmed through an emerging number of crystal structures of integral membrane proteins (Deisenhofer et al., 1985; Xia et al., 1997). Despite the availability of methods for X-ray diffraction analyses of membrane proteins, topological studies still occupy an important place in protein structural studies. This is due to the fact that structures of membrane proteins are much less easily obtained than those of water-soluble proteins because of difficulties in obtaining crystals. As most integral membrane proteins require a specific topology for function, determining the orientations of hydrophilic domains may provide significant insight into the proteins' roles in vivo.

Protease digestion

Protease digestion is one of the oldest methods for determining membrane protein topology. This approach relies on the principle that the lipid bilayer is generally impermeable to proteases. Therefore, addition of a protease to the outside surface of a membrane vesicle results in degradation of protein sequences lo-

cated on the exterior surface, thereby revealing the luminal content (Gerber et al., 1977). It is best to examine a protein in its native membrane environment. The protease digestion protocol described in this unit (see Basic Protocol 1) is useful for examining proteins residing within isolated ER membrane vesicles by immunoblotting, although this procedure can be adapted easily to the study of proteins present in the plasma membrane and in other membrane-bound organelles. The primary difference is in the enrichment procedure used to isolate the desired membrane preparation (Li and Shore, 1992; Graham et al., 1994; Kalish et al., 1995).

Alternatively, one may examine the topologies of proteins integrated into microsomal vesicles in vitro. Such proteins are found to assume a specific topology that can be probed by the addition of a protease (Mize et al., 1986). In vitro–expressed proteins can, however, suffer the problem of being integrated inefficiently (Skach et al., 1994), and in vitro systems may not offer a functional assay assuring that the membrane protein has achieved its native structure. However, the membrane integration machinery in the ER is believed to perform accurately in vitro, at least with native membrane proteins (see *UNIT 11.4*).

In order to gain a complete picture of a protein's topology using the protease digestion method, each hydrophilic domain must be inherently sensitive to the protease used. That is, accurate pictures are obtained only when each domain is digestible either at the surface of the vesicle or in detergent-solubilized solutions. To ensure that the hydrophilic domain being probed can be proteolytically cleaved, it should contain a site recognized by the protease used. Proteases exhibiting a broad substrate specificity, such as proteinase K and trypsin, should therefore be used.

For particularly small domains, accessibility to a protease may be a problem. Furthermore, since digested regions are probed with antibodies directed against a series of peptides corresponding to various hydrophilic regions within the membrane protein, there is no guarantee that all of the antibody preparations will recognize the intact protein (Seckler et al., 1986). Despite these potential problems, the protease digestion approach is a proven method, particularly as it has been used to probe large hydrophilic domains.

Immunofluorescence staining

Immunofluorescence staining has been used widely to analyze the topology of proteins localized to the plasma membrane (Canfield and Levenson, 1993; Canfield et al., 1996). This method (see Basic Protocol 2) has the advantage that domains present on either side of the membrane can be visualized with a microscope, as opposed to detection of proteolytic fragments which may be small and difficult to find by SDS-PAGE. Compared to the protease digestion approach, immunofluorescence staining has not been used generally to study membrane protein topology in organelle-based systems. It should be possible, however, to identify hydrophilic domains located at the surface of peroxisomes in mammalian cells by taking advantage of the fact that the plasma membrane, but not the peroxisomal membrane, is permeabilized with the detergent digitonin (Swinkels et al., 1991). Since both plasma and peroxisomal membranes are permeabilized after addition of Triton X-100, use of these detergent combinations should permit a topological analysis of peroxisomal proteins.

Epitope tagging

Preparation of antipeptide antibodies needed for Basic Protocols 1 and 2 is costly and time-consuming. These problems are exacerbated by the fact that many antipeptide antibodies fail to recognize their corresponding epitope within the intact membrane protein. An alternative approach, epitope tagging, is therefore presented in this unit (see Support Protocol). A DNA fragment encoding a foreign epitope recognized by a commercially available antibody is introduced into the gene encoding a membrane protein. A tagged domain can then be identified using protease digestion (see Basic Protocol 1) or immunofluorescence staining (see Basic Protocol 2; Canfield and Levenson, 1993; Skach et al., 1994; Canfield et al., 1996).

There are, however, disadvantages that may result from the addition of an epitope. The epitope may render the membrane protein into which it has been inserted nonfunctional (Canfield et al., 1996). In such cases, it is not always clear whether the topology has been disrupted or whether the epitope has been inserted into a site critical for activity. In either event, results derived from studies of a nonfunctional protein are unreliable in the absence of supportive topological data. Even if the tagged protein is functional, the possibility remains that the foreign

epitope has disrupted the topology of a region unimportant to the protein's activity under the conditions measured.

Although the HA epitope has been used successfully for determining membrane protein topology (Canfield and Levenson, 1993), it contains two charged amino acids (YPYDVPDYA; Wilson et al., 1984). A number of studies have shown that charged residues located near membrane-spanning sequences play a role in determining transmembrane orientation in eukaryotic cells. Indeed, introduction of clusters of negatively charged amino acids proximal to transmembrane segments can inhibit their integration (Green and Walter, 1992). However, the HA epitope contains fewer charged amino acids than FLAG (DYKDDDDK; Hopp et al., 1988), c-myc (EQKLISEEDL; Evan et al., 1985), and VSV-G (YTDIEMNRLGK; Kreis, 1986) epitopes and is therefore recommended for use. The AU1 epitope (DTYRYI) derived from the papillomavirus major capsid protein also contains only two charged amino acids (Lim et al., 1990); however, it has not yet been utilized for topological analysis to the extent that the HA epitope has.

To avoid interfering further with integration of the target protein, the foreign epitope should be placed ≥15 amino acids from the neighboring transmembrane segment(s) without disrupting membrane targeting signals which are commonly present at the N- and/or C-terminal ends of the polypeptide chain. Another concern is that addition of artificial sequences into a membrane protein may affect its stability or localization to a compartment within the cell. Indeed, retention of mutant proteins in the secretory pathway is well documented (Gething et al., 1986; Kreis and Lodish, 1986). Loss of stability or missorting may be evidenced through failure to find the tagged protein in its normal cellular location.

Reporter gene fusions

Since the mid-1980s, a genetic approach has been used to solve membrane protein topologies (see Basic Protocol 3). The reporter gene fusion method was developed originally to study the topology of plasma membrane proteins in bacterial systems (Manoil and Beckwith, 1986; Froshauer et al., 1988) and then adapted for the study of proteins integrated into the ER membrane in the yeast *Saccharomyces cerevisiae* (Sengstag et al., 1990). More recently, the reporter enzyme β-galactosidase has been used for topological studies in *Caenorhabditis elegans* (Doan et al., 1996; Lai et al., 1996). Reporter fusion approaches developed for analyses in yeast and *C. elegans* examine membrane proteins integrated into the ER and either residing within the ER or transported to a compartment of the secretory pathway or to the lysosome. Due to conservation of the ER membrane integration machinery in diverse eukaryotic organisms (Hartmann et al., 1994), cross-species analyses of eukaryotic proteins using the simple yeast system are probably valid. Recently, a gene fusion system has been used to study the topology of a protein localized to the peroxisomal membrane (Elgersma et al., 1997), and it is likely that over the next few years the reporter gene fusion method will be extended to other organelles and eukaryotic cell types.

The cytoplasmic enzyme histidinol dehydrogenase (HD) is well suited for use as a reporter of membrane protein topology in yeast cells (Sengstag et al., 1990). HD is encoded by the *HIS4* gene in *Saccharomyces cerevisiae* (Donahue et al., 1982). When expressed on the cytosolic side of the membrane, HD converts histidinol to histidine, an activity that permits yeast that are *his4*$^{-}$ to grow on agar plates supplemented with histidinol instead of histidine. On the extracytoplasmic side, however, HD is enzymatically inactive in vivo, presumably due to its sequestration from the histidinol substrate, glycosylation of the HD moiety, and/or degradation of HD within the ER lumen (Green and Walter, 1992; Mullins et al., 1995).

To construct gene fusions in pA189invHD, the 800-bp *Bam*HI-*Xho*I fragment can be replaced with a DNA fragment encoding an N-terminal truncation of the target membrane protein. This leads to the production of fusions between the upstream membrane protein fragment and the C-terminal inv-HD sequence. In pA189invHD, the inv sequence (an internal fragment of the yeast invertase protein; Taussig and Carlson, 1983) serves as a spacer that separates HD from the membrane-spanning segments of the upstream membrane protein (Green and Walter, 1992).

The main advantage of the reporter gene fusion approach described here is its simplicity. The cell growth assay provides a quick and reliable means of assessing the location of a hydrophilic domain within a membrane protein examined in yeast. Furthermore, a fusion joint can be constructed anywhere along the primary sequence using standard molecular biological protocols. This means that all hydrophilic domains within a multispanning protein, includ-

ing small domains, can, in principle, be examined by constructing a series of gene fusions. However, such fusions eliminate from the construct all sequences in the membrane protein located downstream of the fusion joint. This approach therefore makes the assumption that membrane proteins integrate into the bilayer in a linear fashion, from the N to the C terminus. This idea is in accord with the model that membrane proteins contain alternating signal and stop transfer signals positioned linearly along the primary sequence (Friedlander and Blobel, 1985). While this assumption may be accurate in some instances, the fusion approach cannot identify transmembrane domains that insert into the membrane with the help of C-terminal sequences (Finer-Moore and Stroud, 1984).

In light of current models suggesting that multiple transmembrane domains accumulate within the translocation channel before their entry into the lipid bilayer (Hegde and Lingappa, 1997), caution should be used when interpreting results obtained using only the reporter fusion approach. For this reason, combining the gene fusion approach with one of the other approaches described in this unit will not only yield a more reliable topological picture but may also provide information about the mechanism of integration of the protein examined.

Critical Parameters

Protease digestion

Several factors are important for interpreting membrane protein topology using the protease digestion method. Determining the location of a hydrophilic domain that is at the side of the membrane to which the protease has not been added can be difficult, if the domain in question is small. This is due to the fact that digestion of those portions exposed to the protease may leave a fragment too small to detect using SDS-PAGE. Thus, the failure to detect a protein fragment may be due to a detection problem, not to the susceptibility of the domain to the protease added (see Anticipated Results). On the other hand, a domain exposed to the protease may be resistant or inaccessible if the domain is small. Therefore, it is critical to interpret carefully results regarding the disposition of a small domain. To assign a small hydrophilic domain to the correct side of the membrane, it is best to examine the topology over the entire protein, then determine whether the results obtained are consistent with the deduced assignment of the domain(s) in question. One way to enhance the chance that a small domain is susceptible is to use a protease that has a broad substrate specificity, such as proteinase K or trypsin. The use of a control protein or protein domain that faces the luminal side of the membrane system to be probed is essential to the analysis, since the membranes examined must be closed and impermeable to the protease added in the absence of detergent.

Immunofluorescence staining

There are several technical features of the immunofluorescence staining protocol that are critical to a successful outcome. The use of very clean coverslips is necessary. Coverslips should be washed in a strong detergent and rinsed thoroughly to remove all traces of the detergent. The adherence of tissue culture cells to the coverslips can be a problem sometimes. The protocol described here works well for HEK 293 cells, but when other cells are used, different types of coverslips can be tried. For example, Lab-Tek Chamber Slides (Nunc) provide a surface to which many cell types attach well. When using HEK 293 cells, it is observed that cells which are about 70% confluent yield the best staining results. Using the procedures outlined here, it takes about 3 days following seeding on coverslips to achieve this confluency; however, different times may be necessary in different experiments. In addition, these conditions may need to be varied for cell types other than HEK 293 cells.

The most important control is to examine cells lacking the protein of interest. This control detects the background staining that may appear in the cells under study. If the cells containing the protein of interest give a much more intense staining than cells lacking the protein, then the results should be reasonably reliable. The protocol listed here calls for a membrane protein control to be analyzed. This control is very useful, provided that antibodies directed against this control protein are available. If not, then it is essential that at least one hydrophilic domain located on the intracytoplasmic side of the membrane be probed, as such a domain controls for the possible disruption of the membrane prior to addition of the primary antibody.

Epitope tagging

Epitope tagging offers an inexpensive shortcut to analyzing membrane protein topology using either the protease digestion or the immunofluorescence staining protocol. However, there is one issue that is important in achieving the reliability necessary. The results are more

certain to be valid if the epitope does not inhibit function of the target protein. It is therefore important to examine the function of the epitope-tagged protein using an in vivo or in vitro assay. To improve the chance that the epitope does not alter the topology of a protein (and thus its function), an epitope lacking clusters of charged amino acids, such as the HA epitope, should be used. Furthermore, the epitope should be placed >15 amino acids away from the upstream and/or downstream transmembrane segments, in order to avoid disrupting the content of charged amino acids already existing near the transmembrane segments. If it is not possible to obey this 15 amino acid restriction (because the domain probed is small) then place the epitope as far away as possible from the transmembrane segment(s).

Reporter gene fusions

When membrane protein topology is assessed using an in vivo assay (such as the one described here), the reporter gene fusion approach is the quickest way to determine membrane protein topology. However, the fusions constructed usually render the target protein nonfunctional. Topological assignments are therefore best served by using this method to gain only a general picture of a protein's topology and then complementing the data with at least a partial analysis using one of the above-listed approaches. Since a functional assay is not always practical, there are some issues to consider when constructing the fusions in order to minimize the chance that the reporter affects the topology of the protein being probed. The fusion joint should be constructed >15 amino acids away from the upstream transmembrane segment. For small hydrophilic domains, the fusion joint can be placed after the first few amino acids of the downstream transmembrane segment if one exists (see Fig. 5.2.6). Another factor that is important is the amino-terminal sequence of the reporter itself. When the reporter contains clusters of charged amino acids at its amino terminus, the reporter may inhibit the integration of the upstream transmembrane segments. Indeed, the His4p reporter appears to suffer this problem (Green and Walter, 1992). For this reason, the reporter construct described in this protocol contains a spacer sequence consisting of a fragment of invertase (Fig. 5.2.7).

Troubleshooting

Refer to Table 5.2.1 for a troubleshooting guide.

Anticipated Results

A typical result expected from the protease digestion method (see Basic Protocol 1) is shown in Figure 5.2.2A. Note that no apparent fragment is detected from proteolysis of the representative protein SPC12 in the absence of detergent (lane 2). If a fragment had been detected, the result would have suggested that the C terminus localizes to the luminal side of the membrane. However, such a fragment could have been quite small (as few as 20 to 30 amino acids) if the C-terminal hydrophilic domain contained only a few amino acids. A clue as to the expected size of a particular fragment can be obtained by examining a hydropathy plot of the protein. Data similar to those shown in Figure 5.2.2A are expected from the analysis of epitope-tagged proteins (see Support Protocol), except that instead of antipeptide antibodies, antibodies directed against the epitope employed should be used. Results expected from immunofluorescence analyses (see Basic Protocol 2) of epitope-tagged proteins have been reported (Canfield and Levenson, 1993; Canfield et al., 1996). Results expected from reporter fusion analyses (see Basic Protocol 3) in yeast (Sengstag et al., 1990) and *C. elegans* (Doan et al., 1996; Lai et al., 1996) have also been reported.

Time Considerations

The time frames given below are for procedures that work well in the first few attempts. Longer times will, of course, be needed when significant troubleshooting is required.

Protease digestion

Antipeptide antibodies directed against each hydrophilic domain of the target protein can take 3 months or longer to prepare. This time can be spent working out the conditions for preparing enriched membranes containing the protein of interest. If control antibodies are available, they can be used to verify the integrity of the membranes being prepared. It usually takes no more than 2 to 3 days to obtain most membrane preparations. The protease treatments and SDS-PAGE analyses also take 2 to 3 days (see Basic Protocol 1).

Immunofluorescence staining

As with the protease digestion technique, most of the time is spent preparing a series of antipeptide antibodies. This time is lessened if commercially available epitope tags are used (see Support Protocol). When examining cells grown in tissue culture medium (see Basic

Table 5.2.1 Troubleshooting Guide for Problems Encountered in Determining Membrane Protein Topology

Problem	Possible cause	Solution
Protease digestion		
Target protein is not degraded in detergent.	Protein is resistant to protease used.	Try another protease.
	Protein is shielded by other proteins.	Treat membrane with buffer containing 500 mM potassium acetate and add 500 mM potassium acetate to the detergent control. To release ribosomes from ER microsomes, treat with MSB containing 500 mM potassium acetate, 0.2 mM GTP, 1 mM puromycin.
	Protein is part of a protease-resistant complex.	Preincubate membranes 10 min at 40°-60°C. Monitor membrane integrity using a control membrane protein.
The target protein is digested in the detergent but not in intact vesicles.	The protein may lack a cytoplasmic domain or is shielded.	Treat membranes with 500 mM potassium acetate as described above before adding the protease.
Poor proteolysis of target and control proteins is found.	Protease inhibitors or nonfunctional protease is present.	Ensure inhibitors are absent from membrane preparation by washing membranes by high-speed centrifugation (see Basic Protocol 1, step 1). Be sure protease is active by examining proteolyzed and unproteolyzed membranes using SDS-PAGE (*UNIT 6.1*).
Degradation of a luminal protein control occurs even without addition of detergent.	Too much protease is used.	Titrate protease to lower concentrations than those indicated in Basic Protocol 1.
	The membrane is leaky.	Change the cell fractionation protocol (Chapter 3).
Immunofluorescence staining		
The antibody used does not recognize the target protein in the permeabilized and nonpermeabilized sets.	The antibody used binds the target protein inefficiently in the context of the membrane.	Test whether antibody binds the protein by immunoblotting (*UNIT 6.2*) or immunoprecipitation (*UNIT 7.2*) from detergent-solubilized membranes.
		If the hydrophilic domain being probed is small, try inserting one or more epitopes into the domain (see Support Protocol) and repeat analysis.
Hydrophilic domains presumed to be located on opposite sides of the membrane are detected in both the permeabilized and nonpermeabilized sets.	The nonpermeabilized cells were leaky at the time primary antibody was added.	Be sure that detergent was not added to DFH solution. Examine a control protein with known topology.
Control cells lacking the polypeptide of interest are stained strongly by the secondary antibody.	The concentrations of primary and/or secondary antibodies are tood high.	Test whether dilution of the antibodies decreases the background signal. Try using a different primary antibody preparation.
Epitope tagging		
The tagged protein is not functional.	The protein is degraded, mislocalized, or out of frame.	Test whether protein is present in its native membrane by immunoblotting (*UNIT 6.2*) or immunoprecipitation (*UNIT 7.2*). Sequence the gene segment encoding the epitope and flanking amino acids.

continued

Table 5.2.1 Troubleshooting Guide for Problems Encountered in Determining Membrane Protein Topology, continued

Problem	Possible cause	Solution
	The epitope inhibits the active site or topology of the protein.	Place the epitope at a different site in the protein domain, including sites further away from the transmembrane stretches. Alternatively, proceed with topology assays, but corroborate results using a different method.
The antibody does not recognize an epitope-tagged protein even though the protein is functional.	The epitope is inaccessible.	Introduce multiple epitopes into the site.
Reporter gene fusions		
Fusions to hydrophilic domains on both sides of a putative transmembrane segment possess HD enzymatic activity.	The L-histidinol reagent is contaminated with histidine.	Test whether strain FC2-12B grows on SC +HOL agar plates. If it does, try a different batch of histidinol or a different supplier.
	The hydrophobic segment identified does not actually span the membrane, or the transmembrane segment inserts into the bilayer aided by downstream sequences not contained in the fusion protein.	Reassess whether the hydrophobic segment is a transmembrane segment. Monitor topology of the region in question using a different approach.
None of the fusions possess enzymatic activity.	The fusions are not made.	Sequence fusion joints to ensure reading frame is maintained. Ensure that no ATG codons are present between the promoter and the initiation codon. Use the strong *ADH1* promoter on pA189invHD.
Fusions expected to be inactive are active.	The fusion joint interferes with integration of the upstream sequences.	Position the joint further away from the upstream transmembrane segment. Corroborate results using a different method.

Protocol 2), it takes about 3 days to grow cells on coverslips before the immunofluorescence analysis. The analysis takes about 1 day, which includes fixing the cells, incubating with primary and secondary antibodies, and examining the cells by microscopy.

Epitope tagging

The time required to perform the molecular biological manipulations required to introduce a foreign epitope into each hydrophilic domain of a membrane protein (see Support Protocol) depends on the number of distinct hydrophilic domains present in the protein and whether single, double, or multiple tags are introduced into each domain. A person skilled in the use of molecular biological techniques could introduce a set of single and double tags into a type I integral membrane protein (Fig. 5.1.2) in <1 month, test the function of the various tagged proteins in vivo or in vitro in a few weeks, and localize the epitopes with respect to the membrane using protease digestion (see Basic Protocol 1) or immunofluorescence staining (see Basic Protocol 2) in ~1 week using either technique. Thus, in ~2 months, one could tag such a protein and examine its topology. Longer periods (up to 6 months) may be required to examine proteins containing several transmembrane segments.

Reporter gene fusions

Using the described systematic approach for constructing gene fusions (see Basic Protocol 3), a series of constructs can be made in <1 month by a person experienced in using molecular biological techniques. Analyses of the fusions require ~1 week using the yeast system or a few weeks using a higher eukaryotic system.

Determination of Molecular Size by Zonal Sedimentation Analysis on Sucrose Density Gradients

This unit describes one of best methods for estimating molecular size of proteins or protein complexes under nondenaturing conditions, namely, zonal sedimentation analysis on sucrose gradients. This method separates macromolecules on the basis of sedimentation in a centrifugal field. In simplest terms, larger molecules will be subjected to a greater force in a given time of centrifugation at a constant speed, and will therefore migrate farther into a gradient than smaller molecules. Migration is a property of the sedimentation coefficient of a given macromolecule and reflects its mass, shape, density, and hydration state. Thus, given appropriate controls and the value of the partial specific volume (a measure of the density of a macromolecule), mass can be either approximated or, given the value of the Stokes radius, calculated.

Because separations are performed under nondenaturing conditions, sedimentation analysis is suitable for determination of the molecular size of multisubunit protein complexes or of the oligomerization state of a homooligomer. The method, first developed by Martin and Ames (1961), is particularly suitable for globular proteins and can be used with some limitations for mass approximation of integral membrane proteins in detergent solutions. Most importantly, proteins or protein complexes in heterogeneous mixtures, such as cell lysates and homogenates, cell supernatants, and sera, can be analyzed by this assay if an appropriate activity (enzyme activity, antibody binding, or spectrophotometric property) can be measured. During separation, a sucrose gradient provides stability for sedimentation of macromolecules against diffusion and mechanical disturbance while permitting sedimentation at constant velocity.

Traditional methods of sedimentation analysis have provided relatively broad fractionation of protein complexes, particularly integral membrane proteins in detergent solutions, permitting only rough estimations of molecular mass. Nevertheless, these determinations have consistently approximated the actual molecular mass of globular soluble proteins. Furthermore, recent advances in gradient formation and fractionation may provide for more precise analyses. Although the protocols in this unit focus on proteins, zonal centrifugation is also suitable for size determination of nucleoprotein complexes, including viruses, and small nucleic acid species.

Protocols are provided for the preparation of sucrose gradients, the separation of cell lysates on the gradients (see Basic Protocol 1 and Alternate Protocol 1), and fractionation of the sucrose gradients themselves to provide molecular size determinations over narrow or broad ranges (see Basic Protocol 2 and Alternate Protocols 2 and 3). Support protocols are provided for choosing molecular size markers to use in estimating sedimentation coefficients and molecular weights (see Support Protocol 1), for calculating sedimentation coefficients (see Support Protocol 2), and for calculating molecular mass based on sedimentation coefficient and other parameters (see Support Protocols 3, 4, and 5). An additional protocol is provided for differential sedimentation in sucrose gradients made with either water or deuterium oxide (heavy water; D_2O), which allows for the direct determination of partial specific volumes and thus circumvents some of the assumptions implicit in molecular weight estimations based on migration relative to marker proteins (see Basic Protocol 3).

STRATEGIC PLANNING

In zonal centrifugation an initial preparation, for example, a cell lysate, is subjected to centrifugation through a sucrose gradient in an ultracentrifuge, and then the gradient is eluted into distinct fractions. Analysis is therefore limited by (1) the method for detection of the protein of interest within the fractions and (2) the method for calculating the sedimentation coefficient itself and the corresponding molecular weight. These accompanying methods must be thought out and prepared in advance if a meaningful analysis is to be obtained. Furthermore, consideration needs to be given to the range of separation and to the resolution needed in order to determine (1) the slope of the gradient, (2) the size of tube for ultracentrifugation, and (3) the length of ultracentrifugation. Finally, one must consider the variety of available methods for formation and fractionation of the gradients and choose those most appropriate for the anticipated needs and/or equipment availability.

Detection of Proteins within Fractions

The primary assays for detecting a given protein during the development of the zonal centrifugation technique were spectrophotometric identification and enzymatic activity measurement. Spectrophotometric detection is limited either to analysis of purified proteins or relatively simple mixtures of a few proteins by detection at 280 nm, or to analysis of proteins with unique spectral properties within a mixture (such as heme-containing or chromogenically tagged proteins). Conventional protein detection at 280 nm requires at least microgram quantities for any reasonable analysis. Similar nonspecific protein detection methods can make use of protein assays such as the Lowry and Bradford assays; while perhaps more sensitive, these assays are also limited to analysis of only purified or partially purified proteins. Simple gel electrophoresis (*UNIT 6.1*) and staining with Coomassie blue or silver may provide useful analyses of somewhat more complex mixtures and more limiting (submicrogram) quantities. This method requires knowledge of the molecular mass of at least one subunit of a protein complex.

Enzymatic activity is still a useful parameter for assaying either purified proteins or proteins within a mixture; however, it is useful within a mixture only if a unique activity can be ascribed to a single protein. Furthermore, activity assays are variably sensitive to the concentration of the enzyme, and any assay must take into account the buffer components of the gradient fractions and any effect of sucrose concentration.

Today, most methods of detection rely on antibodies specific for the protein in question. Since antibodies can be exquisitely specific, immunodetection can be performed on fractions of the most crude samples, including cell and tissue homogenates and lysates. Furthermore, most immunodetection methods are unaffected by common components in the gradients themselves, and they are extremely sensitive, requiring only minute quantities of protein that would be undetectable by other means. Applicable immunodetection methods include enzyme-linked immunosorbent assays (ELISAs), SDS gel electrophoresis and immunoblotting (*UNITS 6.1 & 6.2*), and immunoprecipitation of metabolically labeled or surface radioiodinated proteins within a cell lysate (*UNIT 7.2*). When using radiolabeled source material, one must take particular care to follow typical precautions to avoid contamination of the experimenter and surroundings during the fractionation of the sucrose gradients (see *APPENDIX 1D*).

Methods for Formation of Gradients

One of the most critical points for the success of the zonal centrifugation experiment is preparation of the sucrose gradients. For accurate analyses, all gradients within a given experiment must be prepared to be as nearly identical as possible. Furthermore, the

gradient should be as linear as possible in order for macromolecules to migrate consistently. Therefore, the choice of method for formation of gradients is a critical one. This unit describes two of the most frequently used methods for formation of sucrose density gradients. The first method, using the Gradient Master (Biocomp), is clearly superior in that multiple gradients can be prepared identically, consistently, and simultaneously with minimal time and effort. However, the Gradient Master is not inexpensive and may not be available to all laboratories; furthermore, it requires extra accessories for each different sized centrifuge tube in which gradients are required to be made. Alternate Protocol 1 describes how to make gradients using a mixing chamber, a more common, versatile, and inexpensive device available in many laboratories and from many vendors. This method is more time-consuming and has the potential to provide less consistent and nonlinear gradients. However, if proper care is taken, mixing chamber devices can provide gradients of sufficient quality for most experimental needs. Other instruments not described here may be available from other manufacturers.

Sedimentation Conditions

Variables in the sedimentation conditions include length of time of centrifugation, size of the tube, and slope of the sucrose density gradient. All of these variables affect the migration and resolution of proteins and should be considered prior to the experiment. The appropriate length of time of centrifugation is dependent on the range of fractionation desired. Shorter runs will provide a greater range of fractionation, but the resolution will be small. Longer runs may result in precipitation of high-molecular-weight material, but they will provide greater resolution in lower-molecular-weight ranges. In general, maximal resolution is obtained if the protein(s) of interest migrates near the middle of the gradient after the run. If the approximate molecular weight and corresponding expected sedimentation coefficient are known, then the time required for the protein to migrate halfway through the gradient can be estimated from the equation $T = k'/2S$, where T is the time in hours, k' is a constant for any given rotor at a given speed (335 for the SW41 Ti rotor at 39,000 rpm used in the examples in this protocol), and S is the sedimentation coefficient of the protein. Obviously, changing the rotor used and the corresponding size of the tube will affect the length of the centrifuge run required for sedimentation of a given protein complex; it should take roughly half as long for a protein of a given size to migrate to the middle of a 60-mm tube than it would for the same protein to migrate to the middle of a 120-mm tube under the same centrifugal force. The concentration of sucrose in the gradient can also affect sedimentation. An increased concentration of sucrose in the gradient can allow for greater resolution in higher-molecular-weight ranges. A 5% to 20% sucrose gradient permits a relatively constant velocity of particle movement and so is a good starting point for samples of unknown characteristics.

Methods for Fractionation of Gradients

Fractionation of the gradient is the most important step in determining the resolution of the sedimentation experiment. Care must be taken to minimize the amount of turbulence during elution to avoid disturbing the gradient and causing band spreading. Although microbore tubing may be used during elution, for example, to elute material through a peristaltic pump and/or to a fraction collector, be aware that the tubing introduces mixing caused by laminar capillary flow; fluid contacting the wall of the tubing moves at a slower rate than fluid in the middle of the tubing. Traditional methods of elution introduce a significant degree of mixing due to turbulence and/or laminar capillary flow. These methods have therefore provided relatively low resolution for the sedimentation experiment. In most cases, however, this low resolution has been sufficient to provide information on the relative mass of a protein or protein complex.

There are many methods of gradient elution, and numerous commercial devices are available to perform them. Generally speaking, there are two ways of eluting the gradient: from the bottom and from the top. Elution from the top requires suction, either mechanically from a pump or manually from a pipettor. Among the most popular instruments for this type of elution is the Büchler Auto Densi-Flow system (Labconco) which uses a stepper motor to continually lower a suction head; the suction head contains an electronic eye that detects the top of the gradient and controls the stepper motor. Another popular instrument, available from ISCO, uses a syringe pump to dispense a dense solution through the bottom of the tube, pushing up on the gradient and into a suction head at the top of the gradient. The suction process with both instruments can result in significant turbulence and band spreading due to the nature of hydrodynamic forces and capillary action. A recent theoretical advance involves use of a stepper motor and a trumpet-shaped tip to elute the gradient from the top. The trumpet tip is designed to minimize the effects of capillary flow and turbulence in the suction. The manufacturers (Biocomp) claim that this allows for high resolution of bands separated by as little as 1.5 mm. All of these instruments are quite costly and are variably available in different laboratories that routinely perform sedimentation analyses. To use them, the reader is referred to the manufacturer's instructions.

Elution from the bottom eliminates the requirement for suction during the elution, but it is limited in that any pellet that forms at the bottom of the tube during centrifugation may interfere with elution, causing turbulence and mixing of material from the pellet with material contacting the pellet. This problem can be largely avoided by first clearing the sample prior to fractionation by centrifugation at 100,000 × *g*. Nevertheless, given the length of centrifugation and the constant subjection to high *g* forces, it is likely that some pellet will form in most samples during an experiment.

This unit describes low-cost, simple protocols of gradient elution that use common equipment available in most laboratories. All of these protocols are more cumbersome and less efficient than the automated elution methods using the instruments described above. Nevertheless, they can provide fractionation with sufficient resolution for most needs.

Calculation of Sedimentation Coefficient and Molecular Weight

Once the samples have been sedimented through gradients, fractionated, and analyzed for the presence of the protein of interest and standard proteins, sedimentation coefficients can be estimated or calculated. The sedimentation coefficient, *S*, is expressed in units called the Svedberg (S); one Svedberg is equivalent to 10^{-13} sec. The value of *S* can be calculated directly from the results of the experiment: the time of centrifugation, the angular velocity of the rotor, and the position of migration of the sample. However, this value is not in itself particularly meaningful. Reported values of sedimentation coefficients are under the "standard state" of water at 20°C ($S_{20,w}$). Therefore, calculated *S* values must be converted to $S_{20,w}$ values for any meaningful analysis. Methods for determination of these parameters are discussed in detail in Support Protocols 2, 3, 4, and 5. However, consideration of *S* values must be given in the planning stages of the experiment, as these values can be used to estimate the molecular weight or the oligomerization state of macromolecules.

In most cases, experiments will include a sample in which protein standards of known sedimentation coefficient are fractionated in parallel or in the same tube as experimental samples. The choice of standard proteins and the method chosen to detect them must be considered in planning the experiment, including determining the number of centrifuge tubes used. In some cases, such as analyses of integral membrane proteins, it may be

desirable to use intrinsic standards with characteristics that are as similar as possible to the sample in question. In other cases, such as analyses of soluble globular protein complexes, purified proteins available from commercial sources may suffice as size standards. A list of some typical standard proteins along with their sedimentation coefficients, partial specific volumes, and molecular weights is provided in Table 5.3.2 in Support Protocol 1.

Additional pieces of information and some assumptions will be required. In some cases, it is possible to estimate molecular mass by assuming a globular conformation with typical hydration and density, similar to standard proteins used in the analysis. If it is comfortable to assume that the properties of the standard proteins and the unknown sample are similar, then relative sedimentation coefficients can be estimated directly by comparing the migration of standard proteins to that of the sample. This is described in Support Protocol 2. However, for samples with unknown properties, and particularly for integral membrane protein complexes in detergent solutions, these assumptions and estimations may not be appropriate. The difficulties are amplified for integral membrane protein complexes by the typically high partial specific volumes of some common detergents, such as Triton X-100 and NP-40, relative to that of spherical proteins.

For more precise analyses, as described in Support Protocols 3, 4, and 5, other parameters will be needed. The concentration of sucrose in each fraction must be determined by refractometry (described in Basic Protocol 1) in order to extrapolate the values of density and viscosity of the medium, which in turn are parameters necessary to convert values of S to $S_{20,w}$. A value for partial specific volume (υ) must be included as well and can be attained in one of three ways. If the sample is known to be globular and water soluble, then one can use a "typical" value of υ as listed in Table 5.3.2 in Support Protocol 1. If the contents of the sample are known or can be estimated (such as in analysis of the oligomeric state of a purified complex), including the amino acid, sugar, and detergent composition of each component, then one can calculate a value for υ by summing the individual υ values of each component as described in Support Protocol 4. Finally, υ and $S_{20,w}$ can be measured directly by monitoring the sedimentation through two different solutions of distinct densities; in practice, this can be done by performing two parallel sedimentation experiments in which one gradient solution is made with water and the other with D_2O, as described in Basic Protocol 3. The methods used should be considered carefully based on the degree of precision required in the analysis and on the available information regarding the sample under analysis.

ZONAL SEDIMENTATION USING SUCROSE GRADIENTS FORMED BY A GRADIENT MASTER

BASIC PROTOCOL 1

This protocol first describes one of the best methods for preparing sucrose density gradients, and then describes the use of these gradients for sedimenting protein mixtures in a preparative ultracentrifuge. The proteins are recovered by fractionation (for hole puncture and elution, see Basic Protocol 2; for peristaltic elution, see Alternate Protocol 2; for manual fractionation from the top of the gradient, see Alternate Protocol 3) and detected by an appropriate method (see Strategic Planning). An alternative way of making sucrose gradients using a mixing chamber is given in Alternate Protocol 1.

Multiple gradients can be reliably and reproducibly prepared in a single step using the Gradient Master, an instrument designed by Coombs and Watts (1985) and marketed by Biocomp Instruments (see *SUPPLIERS APPENDIX*). The basis of the protocol is to create each gradient in a single tube, using solutions corresponding to the beginning and endpoint concentrations of sucrose. The more dense solution is placed at the bottom, and the less dense solution is placed at the top. The tube is then capped, tilted at a sharp angle, and

rotated about its longitudinal axis at a predetermined speed. If the angle and speed of rotation are appropriate, this procedure mixes the contents in a reproducible and precise fashion to form a linear gradient from the most to the least dense sucrose concentration. The manufacturer provides explicit protocols for the formation of gradients of various concentrations of sucrose and other media in tubes of various sizes. The protocol below describes preparation of a typical gradient of 5% to 20% sucrose in 14 × 89–mm tubes, which are used in the Beckman SW41 Ti swinging-bucket rotor or equivalent for the preparative ultracentrifuge. The protocol can be adapted for sucrose gradients of different concentrations or for different sized tubes according to the manufacturer's instructions.

Once the gradients are formed and cooled to 4°C, samples are loaded onto the gradients and subjected to ultracentrifugation. For analysis of results, standard proteins are also sedimented under the same conditions (for use of molecular size markers, see Support Protocol 1). Centrifugation is typically performed at the maximum safe speed for a particular rotor (in this example, 39,000 rpm in the SW41 Ti rotor, with an average force of 188,000 × *g*). As discussed in Strategic Planning, the length of time of centrifugation and the size of the ultracentrifuge tube and corresponding rotor can be varied and depend on the range of fractionation desired. The concentration of sucrose in the gradient can also be varied; it has been clearly demonstrated that particles move at constant velocity through a 5% to 20% sucrose gradient, and thus this is a good starting point. The example here uses a 5% to 20% gradient in centrifuge tubes designed for the SW41 Ti swinging-bucket rotor.

Materials

Buffer ingredients for stock solutions (e.g., HEPES, NaCl, Triton X-100, protease inhibitors, sodium azide)
Sucrose, ultrapure
Sample in 100 to 250 µl volume (e.g., cell lysate)

Whatman no. 1 filter paper or 0.22-µm filter
Refractometer
14 × 89–mm centrifuge tubes for SW41 Ti rotor
Gradient Master (Biocomp), base unit, marker block, and holder for six 14 × 89–mm tubes
10-ml syringe fitted with a 6-inch wide-bore cannula
SW41 Ti rotor (Beckman) or equivalent
Ultracentrifuge (Beckman LS-70M or equivalent)

Prepare sucrose stock solutions

1. Prepare stocks for the buffers to be used for the sucrose gradients.

   All stocks should be filter sterilized, using a 0.22- or 0.45-µm filter for long-term storage, except for detergent stocks. A typical buffer for fractionation of cell lysates and analysis of integral membrane proteins by immunodetection methods would contain:

   0.02 M HEPES, pH 7.4 (from a 1 M stock)
   0.15 M sodium chloride (from a 5 M stock)
   0.05% (w/v) Triton X-100 (from a 20% stock)
   Protease inhibitors (from individual stocks as needed)
   0.02% (w/v) sodium azide (from a 2% stock).

   In this example, the buffer is at physiological ionic strength and pH. Triton X-100 is included as a nonionic detergent to maintain solubility of integral membrane proteins; it could be omitted for analysis of soluble proteins in membrane-depleted cell homogenates, or substituted by another detergent as appropriate. Optimally, several runs in different detergents with distinct properties would be performed to ensure that physiological

complexes are observed. Other detergents of choice might include the zwitterionic detergent CHAPS or the neutral detergent n-octylglucoside, either of which may be removed from samples later by dialysis. Sodium azide is included as a preservative and may be omitted without serious consequences if the gradients are poured and used in a timely fashion. In most cases, protease inhibitors are not necessary at this stage if they were included in cell lysates; however, maintenance of some labile proteins may require the continued presence of inhibitors that block proteases by noncovalent interactions.

Different applications will require different buffers. For example, nucleotides, calcium, magnesium, or other ions may be required to maintain the integrity of some protein complexes. Finally, buffers of different pH or ionic strength may be required for some applications, which may complicate analysis of the sedimentation coefficient.

2. Prepare a 60% (w/v) stock solution of ultrapure sucrose in doubly deionized or distilled water with 0.02% (w/v) sodium azide. Filter the stocks at least through Whatman no. 1 filter paper, and preferably through a 0.22-µm filter, to remove any particulates.

   Use only Ultrapure sources of sucrose; contaminants present in reagent grade sucrose may disrupt protein complexes and interfere with preparation of stocks. When preparing the sucrose stock solution, assume that the sucrose is not 100% pure. Even ultrapure sources may not be 100% sucrose on a per weight basis. Do not bring the solution to final volume until you have checked the concentration of an initial solution by refractometry.

3. Check the concentration of the sucrose stock solution using a refractometer. Place a drop of the solution on the refractometer window and read the refractive index. Calculate the true sucrose concentration based on the refractive index and adjust the concentration such that the refractive index reads 1.4418.

   The refractive index, a measure of the viscosity of the solution, provides the most accurate way to determine sucrose concentration. The refractive indices for given concentrations of sucrose at 20°C have been predetermined and are listed in Table 5.3.1. A 60% sucrose solution at 20°C should have a refractive index of 1.4418. Temperature affects the refractive index, so readings of solutions at other temperatures must take into account a correction factor. Correction factors and additional data are available in the CRC Handbook of Chemistry and Physics (Lide, 1997).

Table 5.3.1 Refractive Index of Standard Aqueous Sucrose Solutions[a]

Sucrose concentration (%)	Refractive index
0	1.3330
3	1.3374
5	1.3403
7	1.3433
10	1.3479
12	1.3510
15	1.3557
20	1.3639
25	1.3723
30	1.3811
35	1.3902
40	1.3997
50	1.4200
60	1.4418

[a]Data from Lide (1997).

4. Using the buffer and sucrose stock solutions and doubly deionized or distilled water, prepare working solutions of 5% (w/v) sucrose and 20% (w/v) sucrose in the appropriate buffer.

   When sodium azide is used as a preservative, large quantities of stock solutions can be prepared and stored at 4°C. Otherwise, enough should be prepared for all of the samples in the experiment.

   In this example, there will be six tubes for the SW41 Ti rotor. Each tube has a capacity of 12.6 ml and will receive 6.3 ml of each solution. Thus, ≥38 ml of each working solution is required, and more should be prepared to be safe. Working solutions should be checked for sucrose concentration by refractometry.

Prepare gradients

5. Prepare centrifuge tubes by marking the half-full line. Place each tube into the appropriate marker block of the Gradient Master and draw a line on the tube just above the level of the block. Label each tube for sample identification.

6. Using a pipet, fill each tube to ~2 mm above the half-full line with the less dense endpoint solution—in this example, the 5% sucrose working solution. Be careful not to make any bubbles while filling the tube.

   For the SW41 Ti rotor, this should take ~6.3 ml per tube.

7. Using a 10-ml syringe fitted with a 6-inch wide-bore cannula, underlay each tube with the heavier endpoint solution—in this example, the 20% sucrose working solution. To do this, carefully lower the cannula to the bottom of the tube, and slowly push the plunger of the syringe to release the contents. Keep the end of the cannula close to but below the interface and slowly fill the tube. Continue filling until the interface lies exactly at the half-full line. Carefully remove the cannula, and cap the tube with the short caps provided with the Gradient Master. Remove any air bubbles. Repeat this procedure for all tubes to be used in the experiment (at least two to provide a balance tube for a single run).

   The interface between the light and dense solutions will be visible as a sharp line. Be careful not to disturb the upper layer by pushing too fast or by shaking the cannula while dispensing the heavy solution. Placement of the cap should remove any air space in the tube; be sure that there are no bubbles.

8. Prepare the Gradient Master for forming the gradients. First, level the Gradient Master base unit according to the manufacturer's instructions. Then, set the time, angle, and rpm of rotation appropriate for the gradient being prepared.

   The manufacturer provides a table with optimal parameters for common gradients, and provides a protocol to determine the optimal parameters for less common gradients.

   In this case, a 5% to 20% gradient in 14 × 89–mm tubes requires 2 min 25 sec of rotation at an angle of 81.5° from the vertical at 15 rpm.

9. Finally, place tubes into the tube holder and start the rotation by pressing run.

   The Gradient Master will tilt the tubes at the appropriate angle, rotate at the desired speed for the desired amount of time, and then return the tubes to the vertical position.

10. Uncap the tubes, balance the tubes by weighing them on a laboratory balance and removing any excess from the very top, and store the tubes at 4°C until ready for the samples.

    The gradients are cooled to 4°C before samples are loaded. It is convenient to store the gradients, covered with plastic wrap, in a cold room. Gradients are stable for several days, but it is usually best to prepare them a few hours before use. Preparation of samples may

proceed or conclude during cooling of the gradients. Be sure that your colleagues are aware not to bang into the tubes—this will obviously disturb the gradients!

Load and centrifuge samples

11. Before loading the samples, be sure that the ultracentrifuge has been turned on and is cooled to the appropriate temperature.

    Most often, it is convenient to perform the ultracentrifugation at 4°C. The ultracentrifuge should be turned on with the vacuum running if it is cooling or cooled to prevent condensation within the chamber.

12. Carefully remove and discard material from the top of the gradient equivalent to the volume of sample that you wish to load.

    After separation, the width of the ultimate bands will be at least the same as the width of the sample loaded. Therefore, the sample volume should be minimal compared to the volume of the tube. For the 14 × 89–mm tubes of the SW41 Ti rotor, the volume loaded should be ≤250 µl for efficient resolution, and a smaller volume (~100 µl) is preferable. The sample must be in a solution that is less dense than the lower endpoint sucrose solution (e.g., 5% sucrose) such that it remains at the top of the gradient. It is a good idea to prefilter the sample or clear it by ultracentrifugation at high g forces. Be sure to include enough tubes to balance the SW41 Ti rotor; if an odd number of samples is required, prepare a balance tube with an equivalent gradient and an equivalent volume of sample.

13. Carefully and very slowly load the sample onto the gradient, taking care to avoid disturbing the top of the gradient.

14. Place all gradients into the buckets of the rotor and carefully transport them to the ultracentrifuge. Place the buckets into the rotor head. Turn off the vacuum to the ultracentrifuge, and open the ultracentrifuge door. Carefully lower the rotor into the ultracentrifuge chamber. Close the door and start the vacuum. Set the speed, time of centrifugation, acceleration rate (as slow as possible), and deceleration rate (brake off). Begin centrifugation by pressing start.

    Speed and time should be determined for each experiment. Generally, each rotor is run at maximum speed, but slower speeds may permit resolution of lower-molecular-weight material in a convenient time frame. Time of centrifugation will depend on the resolution and fractionation range desired. Generally, times start at ~16 hr and go up to 48 hr. To achieve equivalent separations in shorter times, use a smaller tube and sample size.

End the run

15. Be sure that the ultracentrifuge has stopped rotating. Turn off the vacuum, open the chamber door, and remove the rotor from the ultracentrifuge. Close the door to the ultracentrifuge and restart the vacuum. If another run is not planned, allow the ultracentrifuge to return to room temperature before turning off the vacuum; ensure that the vacuum is released (open the chamber door and reclose it), and turn off the power.

16. Remove sample buckets from the rotor and place them in the carrying tray. Carefully store the buckets briefly at 4°C until elution.

    Samples should be eluted as soon as possible (within a few hours) to avoid band spreading and loss of resolution. Following elution (for details on fractionation of gradients, see Basic Protocol 2 and Alternate Protocols 2 and 3), the fractions are analyzed using the appropriate, predetermined method (see Detection of Proteins).

ALTERNATE PROTOCOL 1

ZONAL SEDIMENTATION USING SUCROSE GRADIENTS FORMED BY A GRADIENT MAKER

The Biocomp Gradient Master used in Basic Protocol 1 is a relatively expensive instrument and may not be universally available. However, it is possible to create individual sucrose gradients with significant reproducibility using a standard polycarbonate mixing chamber, which is a much less expensive item. The basic device, available from numerous sources, contains two separate cylindrical chambers connected by a small tube at the bottom of each chamber. It is critical that the dimensions of the two chambers are identical. Typically, a stopcock is placed within the connecting tube to prevent contact between the chambers until desired. An outlet tube emanates from the bottom of one of the chambers (chamber 1) and is usually also connected with a stopcock to prevent flow until desired. A stir bar is placed in chamber 1, and the device is placed on a stir plate. A typical design is outlined in Figure 5.3.1.

The operation of the mixing device is theoretically simple. Equal volumes of the endpoint sucrose solutions are placed in each chamber, and the connection between the two chambers is opened. If the heights of the liquids in the two chambers are the same, then there should be no flow from one chamber to the other. If the outlet tube is now opened, however, fluid will flow out of chamber 1. This will create an imbalance in the hydrostatic pressure in the two chambers; as a result, fluid from chamber 2 will flow into chamber 1 such that the height of the liquids in the two chambers remains the same. If the less dense sucrose solution is placed in chamber 1, this means that the more dense sucrose solution will flow into chamber 1 as fluid exits the device. If the outflow is slow, and the solution in chamber 1 at any given time is kept well mixed by the action of the stir bar, then the result will be a linear gradient of sucrose concentration, from the least dense to the most

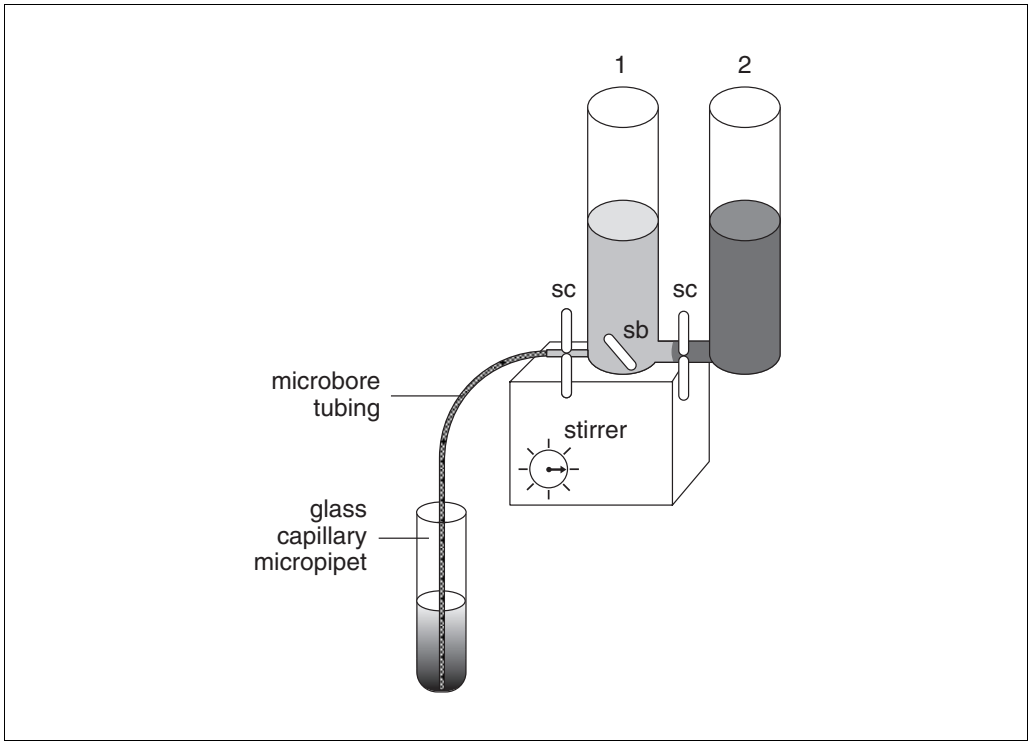

Figure 5.3.1 Formation of sucrose gradients with manual gradient maker. A typical apparatus is diagrammed. The dense (darker) material is in chamber 2 (2), and the less dense material is in chamber 1 (1). Material is kept constantly stirred by adding a stir bar (sb) in chamber 1 and placing chamber 1 over an electric stirrer as indicated. Stopcocks (sc) regulate the flow between the chambers and out of chamber 1. Microbore tubing and a glass capillary micropipet carry the material into the gradient tube.

dense, exiting the device. For preparation of sucrose gradients, the outflow will enter the bottom of a centrifuge tube, such that the increasingly dense solution will continually underlie the fluid already present in the tube.

The mixing chamber device can be connected through any of a variety of apparatuses to increase the efficiency and speed with which gradients are formed, including a peristaltic pump, a specialized flow sensor/delivery system (such as the Auto Densi-Flow system from Labconco), or a system to deliver the gradient solution to multiple tubes at once (such as the Büchler Density Gradient Forming System from Labconco). All of these require specialized equipment that may be quite costly but which may be available in laboratories that routinely perform these procedures.

The protocol below describes the basic procedure for gradient formation using gravity flow and the 5% to 20% sucrose gradient and 14 × 89–mm ultracentrifuge tubes as an example. As with the Gradient Master, different endpoint sucrose solutions and different sized tubes can be easily accommodated.

Additional Materials *(also see Basic Protocol 1)*

Gradient maker, small volume (e.g., 15 ml)
Microbore tubing
Glass capillary micropipet
Peristaltic pump or other pumping device (optional)

Prepare sucrose solutions and set up gradient maker

1. Prepare 5% and 20% sucrose working solutions (see Basic Protocol 1, steps 1 to 4), allowing a slight excess (perhaps 1 ml extra per sample) of each final sucrose solution to ensure sufficient filling of each tube by this method. Be sure to prepare enough.

2. Place the gradient maker on a stir plate on a shelf or attach to a ring stand to provide a sufficient flow rate to the tube on the bench. Level the gradient maker using a bubble level. Attach a sufficient length of microbore tubing to the outflow connector of the gradient maker so as to reach the tubes in a rack on the bench. Finally, attach a glass capillary micropipet to the end of the tubing.

   The glass capillary micropipet should fit snugly into the microbore tubing. The inner diameter of the microbore tubing and capillary micropipet should be as similar as possible to that of the outflow connector of the gradient maker in order to minimize turbulence during the preparation of the gradient.

3. Place the glass capillary pipet into a centrifuge tube in a rack on the bench such that the open end of the capillary pipet is at the bottom of the tube. Test flow rates from the gradient maker using water and ensure that the rate is ≤0.5 to 1 ml/min. Adjust the rate by moving the gradient maker up or down relative to the bench or alternatively by adjusting a peristaltic pump.

   It is easiest to use gravity to elute the gradient from the gradient maker. Alternatively, the outflow tubing can be connected through a peristaltic pump to provide even flow at a slow rate. However, care should be taken to minimize the length of tubing through which the sucrose solution will flow. Passage through the tubing creates turbulence, which may disrupt the linearity and reproducibility of the gradient. The use of a peristaltic pump may provide additional turbulence. In addition, care should be taken to minimize the speed at which the gradient is formed, because too great a speed of flow will create additional turbulence. A flow rate of ≤0.5 to 1 ml/min allows for sufficient mixing and ensures a linear gradient. The capillary micropipet can be held in place over the centrifuge tube using a cap with a small hole pierced through it, through which the tubing and capillary micropipet are passed. Care should be taken such that the cap does not contact the contents of the tube.

Load sucrose solutions in the gradient maker

4. Make sure that all stopcocks are in the vertical (closed) position. Place 6.4 ml of 5% sucrose solution in chamber 1 (from which the outflow connector emanates). Open the stopcock between the two chambers briefly to allow for the tube connecting them to fill with the solution (this ensures that there are no air bubbles blocking flow between the two chambers). Transfer any solution that accumulated in chamber 2 back to chamber 1, but make sure that the connecting tube between the chambers stays full of solution.

   Entrapment of air bubbles is the biggest problem with this technique; any air bubbles in the connecting tube or the outflow tubing will slow the movement of the solutions, cause turbulence, and prevent efficient formation of linear gradients. Care must be taken to avoid trapping air bubbles. It may be necessary to carefully tap on the chamber device to get full flow between the two chambers.

5. Place 6.4 ml of 20% sucrose solution in chamber 2. Place a small flea stir bar in chamber 1. Engage the stir plate at a speed sufficient to mix the entire contents of chamber 1 without creating bubbles or a large vortex in the solution.

6. Check the height of the solutions in the two chambers. If necessary, carefully add enough sucrose solution to the appropriate chamber to bring the solutions in the two chambers to exactly the same height.

7. Open the stopcock between the two solutions.

   If the height of the solutions in the two chambers was the same, there should be no flow between them at this point.

Form the gradients

8. Carefully open the stopcock to the outflow tubing to begin emptying the contents of chamber 1.

   As the contents empty, the gradient should be eluted into the centrifuge tube, and the height of the solution in both chambers 1 and 2 should fall evenly. If necessary, adjust the height of the device and the stir plate to ensure a slow, even flow rate.

   If necessary, carefully tap the outflow tube to begin the flow.

9. When both chambers and the outflow tubing are empty, and the gradient is completely formed, carefully and slowly remove the glass micropipet from the tube. If the volume of liquid in the tube is too high (overflowed the centrifuge tube) or too low (did not fill the centrifuge tube completely), then adjust the volume for each solution for the next tube. Rinse and dry the gradient maker and repeat steps 3 to 8 for each tube in the experiment. Store the gradients in a rack at 4°C until the experiment is performed.

Perform ultracentrifugation

10. Load and centrifuge samples (see Basic Protocol 1, steps 10 to 16).

SUPPORT PROTOCOL 1

USE AND PREPARATION OF COMMON MOLECULAR SIZE MARKERS

For most purposes, standard size markers should be included either in a separate tube or mixed with the sample for determination of sedimentation coefficient and molecular size of the sample of interest. It is critical to understand the limitations of the use of these markers. Sedimentation coefficients are affected by molecular mass, density, shape, and hydration; density and hydration are considered in the value of the partial specific volume (υ). Soluble globular proteins are roughly spherical in shape, tightly packed, and have similar degrees of hydration. They therefore have similar partial specific volumes. Thus, by comparing the sedimentation rates of soluble globular proteins, it is possible to infer molecular mass using the following formula, as described by Martin and Ames (1961):

$S_1/S_2 = (M_{r1}/M_{r2})^{2/3}$, in which S_1 and S_2 are the sedimentation coefficients of two proteins, and M_{r1} and M_{r2} are the apparent molecular weights of these proteins.

Table 5.3.2 provides a list of some common soluble proteins, their sedimentation coefficients, and molecular weights. It is apparent from the data that the equation above holds rather well for this set of proteins, primarily because the υ values are similar. For a given sedimentation experiment, it is best to choose two or three different proteins as standards covering a range of sedimentation coefficients. Try to choose standards that will be in the range of molecular weight expected for the particular sample. Then the equation above can be used with values determined from the standard migrating closest to the sample, or an average of M_r values calculated from the migration of each of several standards can be chosen as the final value.

These standards are not appropriate for calculation of the sedimentation coefficients of proteins with dissimilar υ values. Examples are proteins with extended rather than globular conformations, denatured proteins, and integral membrane proteins in detergent solutions. Nevertheless, the soluble standards are useful for comparing different runs and ensuring reproducibility of gradients. Furthermore, relative sedimentation coefficients can be determined, and these may be useful in determining the oligomeric state of a given protein subunit, regardless of its conformation. Finally, molecular mass can be estimated by comparison to a more relevant standard protein. For example, the size of an integral membrane protein with immunoglobulin-like domains can be compared with the known size of an immunoglobulin superfamily member, such as surface IgG (155 kDa), in the same detergent solution. Similarly, extended soluble molecules, like myosins, could be compared with the migration of different myosins of known sedimentation behavior and aggregation number. So long as antibodies to similar molecules as well as sources of these molecules are available, these analyses are possible and may yield more relevant information concerning relative molecular mass. It should be made clear, however, that this type of analysis is subject to limitations based on the assumption that the partial specific volume and/or detergent binding of the test sample is similar to that of the standard.

Table 5.3.2 Sedimentation Coefficient, Partial Specific Volume, and Corresponding Molecular Weight of Typical Protein Standards[a]

Protein	$S_{20,w}$ (S)	Molecular weight	υ (ml/g)
Bovine heart cytochrome *c*	1.7	12,300	0.728
Lysozyme	1.9	14,400	0.726
Sperm whale myoglobin	2.0	17,200	0.741
Chicken ovalbumin	3.6	42,881	0.748
Bovine serum albumin	4.6	66,000	0.734
Human transferrin	4.9	77,049	0.765
Human serum IgG	7.1	155,000	0.735
Rabbit aldolase	7.3	158,000	0.742
Bovine catalase	11.3	247,000	0.730
Rat β-glucuronidase	12.5	288,000	0.731
Horse heart ferritin	16.5	460,000	0.738
E. coli β-galactosidase	15.9	540,000	0.730
Thyroglobulin	19.3	667,000	0.720
Human serum α-macroglobulin	19.6	720,000	0.731

Additional Materials *(also see Basic Protocol 1 and Alternate Protocol 1)*

Protein standards (e.g., Sigma)

1. Weigh out relevant standard proteins and suspend in a buffer identical to that in which samples are prepared.

   The amount used will depend on the method of analysis. Initially, it may be best to identify standards by SDS polyacrylamide gel electrophoresis (UNIT 6.1) and staining with Coomassie blue (APPENDIX 3). In this case, it would be optimal to use ~100 μg of each standard protein in the mix. Subsequent studies can be done with more limited numbers of standards, and analysis may be by absorbance at 280 nm or protein assay with less protein once the general elution position is known.

2. Remove insoluble material by microcentrifugation for 15 min at maximum speed, 4°C. Discard the pellet.

3. Load the standards on a separate gradient from the sample and fractionate by ultracentrifugation in the same manner as the sample (see Basic Protocol 1, steps 11 to 16).

   Following elution (see Basic Protocol 2 or Alternate Protocol 2 or 3), the fractions can be analyzed by a convenient assay, such as SDS-PAGE (UNIT 6.1) and staining with Coomassie blue (APPENDIX 3). If space is limited, it may be possible to analyze the standards in the same tube as the sample either by mixing with a concentrated stock solution or by dissolving standards in the sample tube. While this may minimize the number of tubes used, it has disadvantages in that unknown potential interactions between the standards and the sample may affect sedimentation properties, and different analyses may be required to assay for standards and sample.

BASIC PROTOCOL 2

FRACTIONATION BY PUNCTURE AND ELUTION FROM THE BOTTOM OF THE GRADIENT

As described in Strategic Planning, fractionation of the gradient is the most critical step in determining the resolution of the sedimentation experiment. Numerous commercial instruments are available to remove fractions from either the top or the bottom of the gradient tube, and each has its advantages and disadvantages. Because these instruments are costly and not uniformly available, this unit provides protocols for simple methods of gradient elution that use common and/or inexpensive equipment (this protocol covers hole puncture and elution; for peristaltic elution, see Alternate Protocol 2, and for manual elution from the top of the gradient, see Alternate Protocol 3). While these methods are more cumbersome and less efficient than the automated elution methods, they nonetheless provide sufficient resolution to allow for reproducible sedimentation analyses under most conditions at low cost and without specialized equipment.

Hole puncture and elution from the bottom of the gradient is a simple and useful technique and was the first used for gradient fractionation. A hole is introduced in the bottom of the ultracentrifuge tube, and the gradient is then eluted from the bottom in drops, collecting drops counted manually or with a fraction collector. Although the hole may be created by hand with a needle, this creates the risk of skewing the placement of the hole (if it is not directly at the bottom, the gradient will not be eluted linearly), of inserting the needle too far into the gradient (eliminating the most dense fractions), and of disturbing the gradient by placement of the needle. A number of inexpensive devices are commercially available for holding the centrifuge tube and creating a hole at the bottom in a standardized way. One of the most popular units is made by Büchler. Nevertheless, puncturing with a common needle is sufficient for most purposes.

Materials

Gradients to be eluted (see Basic Protocol 1 or Alternate Protocol 1)
Sample tubes for fraction collector (e.g., 12 × 75–mm or microcentrifuge tubes)
Ring stand and clamp for tubes
27-G needle or commercial puncture device (e.g., Büchler)
Microbore tubing
Fraction collector (optional)

1. Perform a test elution using a gradient prepared in the same type of tube as the sample(s). Prepare sample tubes to collect the material eluted from the gradient. Pierce the bottom of the centrifuge tube with a 27-G needle. Leaving the needle in place, collect drops such that fractions of the desired volume are collected, and determine the number of fractions of the same drop number required to completely elute the gradient.

   Piercing the centrifuge tube with a 27-G needle should make a hole small enough such that the gradient elutes slowly by dripping from the bottom. The number of fractions desired will vary depending on the needs of the experiment. Higher resolution will obviously require analysis of more fractions. Fraction size should be no less than the volume of sample initially loaded onto the gradient; the final band of separated material cannot occupy less volume than it did when it started. It should also be recognized that the volume of a drop will increase as the gradient is eluted and the sucrose concentration in the fractions decreases. Thus, fractions collected by drops will not be of consistent volume. Although the changes in volume are relatively minor and will be consistent across different samples if the hole size is consistent, they may affect the results in the analyses that follow.

2. Place the first gradient to be eluted in a clamp attached to a ring stand. Be sure that the centrifuge tube is firmly held in place.

3. Prepare the required number of sample tubes for collection of fractions and number them.

   In this procedure, the most dense fractions are eluted first and the least dense fractions are eluted last. For the purposes of the calculations described in the support protocols, fractions should be numbered backwards—that is, the least dense (last collected) fraction should be numbered 1, and the most dense fraction (first collected) should be given the last number.

4. Place the collection tubes directly under the centrifuge tube, leaving enough room for the needle and for some manipulation.

5. Pierce the bottom of the centrifuge tube with the needle. Leaving the needle in place, collect fractions as drops from the needle.

   The Büchler apparatus uses a screw pin to pierce the tube under controlled conditions, and then remains in place for the gradient material to pass through. This makes the hole size more consistent, allows for a more controlled formation of drops, and permits attachment of microbore tubing to a fraction collector.

6. Store sample tubes at 4°C until ready to assay fractions for the presence of the sample of interest and/or for marker proteins.

   Detection of proteins within fractions can be done by any of a variety of methods (see Strategic Planning).

ALTERNATE PROTOCOL 2

FRACTIONATION BY PERISTALTIC ELUTION FROM THE BOTTOM OF THE GRADIENT

Despite the spreading of bands due to extensive laminar capillary flow, the technique of peristaltic elution is popular because of its full automation, its use of simple, common equipment, its speed, and its relative ease to set up. A capillary micropipet is attached to a peristaltic pump and then placed in the gradient tube. The gradient is then eluted from the bottom through the capillary micropipet and into a fraction collector by the action of the peristaltic pump. This can be done in the cold room to avoid thermal inactivation of the sample.

Additional Materials *(also see Basic Protocol 2)*

Gradients to be eluted (see Basic Protocol 1 or Alternate Protocol 1)
Mock gradient (same gradient as used for samples)

Peristaltic pump
Fraction collector with appropriate tubes (12 × 75–mm tubes or 1.5-ml microcentrifuge tubes)
Glass microbore capillary pipet
Microbore tubing
Cap for centrifuge tubes with hole in the middle for microbore tubing
Rack for centrifuge tubes

1. Set up a peristaltic pump in line with a fraction collector. Using a mock gradient of identical composition to that used in the experiments, determine the pump speed to provide a slow, even flow of material in the direction out of the sample side (0.5 to 1 ml/min). Determine the fraction volume required to elute the entire gradient into the designated number of fractions. Adjust the fraction collector to collect fractions of the appropriate size. Prepare the fraction collector with the appropriate number of tubes and include extra tubes in case there are problems with the fraction collector.

   In this case, the fraction collector must be integrated with the peristaltic pump to determine the time required for the appropriate collection volume. Try to minimize the amount of tubing used to make the connection between sample, peristaltic pump, and fraction collector.

   It is best to collect on the basis of time rather than drop size, because the drop size will change as the sucrose concentration changes through the gradient. To determine the speed of the peristaltic pump and the time or drop number required to collect fractions of a certain size, perform a "dry run," first with water and then with a mock sucrose gradient. A collection rate of ~0.5 to 1 ml/min is sufficient for adequate resolution under most circumstances using the 14 × 89–mm tubes. Choose the number of tubes and the fraction size relevant for the level of resolution required. The fraction size should not be smaller than the volume of the initial sample applied to the sucrose gradient.

2. Place a glass microbore capillary pipet on the end of the microbore tubing from the peristaltic pump that is to come from the sample.

3. Prepare a cap for the gradient centrifuge tube with a small hole in the center so the cap sits outside of the lip of the tube, and the capillary pipet fits through the hole.

   An old bottle cap, the cap from a 17 × 100–mm tissue culture tube, or even a thick layer of Parafilm will be sufficient.

4. Place the first gradient sample in a rack close to the peristaltic pump and make sure the sample is held firmly in place. Place the cap over the tube. Slowly place the microbore capillary pipet through the hole in the cap and into the sample tube, being careful not to disturb the gradient. Be sure that the capillary pipet is resting directly at the bottom of the tube and is supported by the cap.

   The hole should have been placed such that the capillary pipet sits in the center of the tube.

5. Turn on the peristaltic pump and the fraction collector simultaneously.

   The gradient should be eluted into fractions of a constant volume. In this procedure, the most dense fractions are eluted first and the least dense fractions are eluted last. For the purposes of the calculations described in the support protocols, fractions should be numbered backwards—that is, the least dense (last collected) fraction should be numbered 1, and the most dense fraction (first collected) should be given the last number.

6. Store sample tubes at 4°C until ready to assay fractions for the presence of the sample of interest and/or for marker proteins.

   Detection of proteins within fractions can be done by any of a variety of methods, as outlined under Strategic Planning.

MANUAL FRACTIONATION BY REMOVAL OF MATERIAL FROM THE TOP OF THE GRADIENT

ALTERNATE PROTOCOL 3

Manual fractionation provides relatively low resolution and may be cumbersome or tiresome for the operator. Nevertheless, it requires no special equipment and can provide reproducible results.

Additional Materials *(also see Basic Protocol 2)*

Manual pipettor and tips

1. Prepare the required number of sample tubes for each gradient and number them. Determine the fraction volume required to elute the entire gradient into the designated number of fractions.

   For the 14 × 89–mm tubes of the SW41 Ti rotor, separation into twelve fractions requires a fraction size of ~1 ml, whereas separation into fifteen fractions requires a fraction size of ~0.8 ml.

2. Place each gradient tube in a tightly fitted rack so that movement is minimized.

3. Set a pipettor to the appropriate volume. Steadying your arm against a firm support, carefully place the tip of the pipettor just below the top of the gradient. Slowly take up the appropriate volume from the top of the gradient, continually lowering the pipet tip such that it stays in the same position relative to the top of the gradient. Dispense into the first sample tube. Repeat this process until the gradient is completely eluted.

   In this procedure, the least dense fractions are eluted first and the most dense fractions are eluted last. For the purposes of the calculations described in the support protocols, fractions should be numbered starting with number 1.

   If desired, suspend any pellet that has formed at the bottom of the gradient using an appropriate buffer and transfer to a new sample tube. For some purposes it may be of interest to analyze the pelleted material, for example, to determine whether any of the protein of interest has aggregated, resulting in an insoluble mass. In this case, it may be necessary to use denaturing conditions, such as 0.1% SDS, 6 M guanidine·HCl, or 8 M urea, to solubilize the pellet.

4. Store sample tubes at 4°C until ready to assay fractions for the presence of the sample of interest and/or for marker proteins.

   Detection of proteins within fractions can be done by any of a variety of methods as outlined under Strategic Planning.

SUPPORT PROTOCOL 2

DETERMINATION OF SEDIMENTATION COEFFICIENTS BY EXTRAPOLATION FROM MIGRATION OF STANDARD PROTEINS

As described in Strategic Planning, the sedimentation coefficient, *S*, of an unknown sample can be calculated directly from the parameters of the fractionation and the migration of the sample. However, *S* values will vary depending on the temperature and composition of the medium through which the sample is sedimenting, and they must be converted to a sedimentation coefficient under the standard state of water at 20°C ($S_{20,w}$) for there to be any meaningful relationship to molecular weight. If the properties of the standard proteins and the sample are similar, then relative sedimentation coefficients can be easily estimated directly by comparing the migration of standard proteins to that of the sample, as described in this support protocol. A more precise analysis is based on other measurable or calculable parameters (see Support Protocols 3, 4, and 5).

This protocol can be used if the experiment included standard proteins with known $S_{20,w}$ values and aqueous soluble, globular test samples. If the migration of the standards is determined, then the sedimentation coefficient can be calculated by assuming that the sample and the standard have similar partial specific volumes.

Materials

Results from analysis of fractions for presence of sample of interest
Results from analysis of fractions for presence of standards
Calculator

1. Calculate a ratio, *R*, based on the distance traveled by the standard and the experimental sample from the meniscus. According to the equation from Martin and Ames (1961),

$$R = \frac{\text{distance traveled from meniscus by sample}}{\text{distance traveled from meniscus by standard}}$$

   Assuming that fractions of equal size were taken, substitute the distance traveled by the quantity [peak fraction # − 1].

   The value of [peak fraction # − 1] is taken because elution with fraction 1 is equivalent to no migration (this should be approximately the volume loaded onto the gradient).

2. Using the value of *R* and the known $S_{20,w}$ value of the standard, compute the $S_{20,w}$ value of the sample.

   Since macromolecules move linearly through the gradient over time, the ratio R also represents the ratio of sedimentation values, such that

$$R = \frac{S_{20,w} \text{ of sample}}{S_{20,w} \text{ of standard}}$$

   Therefore, $S_{20,w}$ of sample = $R \times S_{20,w}$ of standard.

   These calculations assume that the S value observed is proportional to that under standard conditions of water at 20°C. If the sedimentation buffer has physiological levels of salt and is near neutral pH, this assumption is a reasonable one.

DETERMINATION OF SEDIMENTATION COEFFICIENTS BY CONVERSION OF $S_{T,m}$ TO $S_{20,K}$ VALUES

A more accurate assessment of sedimentation coefficient can be made if one eliminates assumptions regarding any similarity between sample and standard regarding shape and the value of the partial specific volume. This method uses first a calculation of a

sedimentation coefficient $S_{T,m}$ for the conditions of the experiment (see Support Protocol 3), and then conversion to a standard sedimentation coefficient $S_{20,w}$ (see Support Protocol 5). These calculations require knowledge of a number of measured and extrapolated parameters. The measured parameters are (1) the distance migrated by the sample in the experiment (described below), (2) the sucrose concentration of the medium at the sample elution position (by refractometry of fractions), and (3) the time (t) of centrifugation. Using these measurements, one can extrapolate the values of other parameters, such as (1) density (ρ) and (2) viscosity (η) of the medium (from standard tables for sucrose solutions of various concentrations and at various temperatures) and (3) the distance from the center of rotation to the sample after centrifugation (manufacturer's information + distance migrated). Standard tables of density and viscosity of sucrose solutions are available (Lide, 1997), and these values are quite valid for aqueous solutions in the absence of detergent. For analyses of integral membrane proteins in detergent solutions, these values will be altered by the detergent, making the calculations less reliable. However, for most purposes, it will be sufficient to use these published values in estimating $S_{20,w}$ values. The final parameter is the partial specific volume (υ) of the sample protein or protein complex. This value can be either roughly estimated for a water soluble structure of presumably spherical shape, more closely approximated by summing the partial specific volumes of known components (see Support Protocol 4), or measured directly (see Basic Protocol 3).

Determination of the Value of $S_{T,m}$

SUPPORT PROTOCOL 3

As described by Martin and Ames (1961), the sedimentation coefficient S at a given temperature T in a solvent m is defined as $S_{T,m} = (dr/dt)/\omega^2 r$, in which dr/dt is the distance traveled over time or velocity in mm/sec (constant in sucrose gradients), r is the distance from the axis of rotation in mm, and ω is the angular velocity of the rotor in radians/second. These parameters can be determined relatively easily from the measurements of the experiment.

Materials

Results from analysis of fractions for presence of sample of interest
Results from analysis of fractions for presence of standard
Metric ruler
Calculator

1. Calculate the value of dr/dt, as described in Clarke (1975), by measuring the distance traveled by the molecule in the gradient during the centrifugation: $dr/dt = (R - r_0)/t$, in which r_0 is the position of the sample when applied at the top of the gradient, R is the position of the sample at the end of the run, and t is the time of centrifugation in seconds.

   The value of $(R - r_0)$ is the distance that the band has migrated in the tube. To calculate this, measure the length of the tube and multiply by the relative position of the sample after centrifugation. For example, if a 14 × 89–mm tube is used and the sample elutes in the middle fraction of the gradient, then the distance traveled would be 89 mm × 1/2 or ~45 mm.

2. Calculate the angular velocity, expressed in radians/second, as $\omega = 2\pi$ rpm/60, in which rpm is the speed of rotation of the rotor during the experiment.

   Using the SW41 Ti rotor at 39,000 rpm, $\omega = (2\pi)(39{,}000)/60 = 4082$ radians/sec.

3. Calculate the average distance r_{avg}, taken as $r_{avg} = r_{min} + (R - r_0)/2$, in which r_{min} is the distance from the center of the rotor to the top of the tube (which should be provided by the manufacturer of the rotor).

The distance traveled by the macromolecule will have constantly changed during the course of the experiment. However, one can calculate the average S value by using the average value of r during the course of the experiment, r_{avg}, which is defined as the position halfway between the starting point (r_0) and ending point (R) of travel for the sample. The value of r_{min} for the SW41 Ti rotor is 67.4 mm. Thus, for a band migrating in the center of the tube, r_{avg} = 67.4 mm + (45 mm/2) = 89.9 mm.

4. Using these values, calculate $S_{T,m}$ as

$$S_{T,m} = \frac{dr/dt}{\omega^2 r_{\text{avg}}} = \frac{(R - r_0)/t}{(2\pi \text{ rpm}/60)^2 [r_{\text{min}} + (R - r_0/2)]}$$

Using the figures above for a band migrating in the center of the tube in a SW41 Ti rotor centrifuged 16 hr at 39,000 rpm, the corresponding $S_{T,m}$ value is 5.2×10^{-13} sec or 5.2 S.

The difficulties in this calculation lie in the measurement of R. Typically, the zonal sedimentation experiment results in broad bands of protein, and so the measurement of R is approximated as the center of migration. Both the calculation and the measurements, and therefore the value for S at the end, are inexact. Finally, for determination of a typical sedimentation coefficient under standard conditions ($S_{20,w}$), this calculation is only the beginning. To use the value of $S_{T,m}$ to calculate $S_{20,w}$, see Support Protocols 4 and 5.

SUPPORT PROTOCOL 4

Determination of the Value of Partial Specific Volume (υ)

The partial specific volume is the most thorny value in determining the sedimentation coefficient of a protein or protein complex. Partial specific volume υ is defined as the increase in volume of an infinite volume of solvent by dissolving 1 g of solute, and it is expressed in liter/g or ml/mg. It is essentially a measure of the packing or density of the protein. Standard pycnometric methods for measuring partial specific volumes are impractical for all but the most readily available purified proteins and are impossible for proteins in complex mixtures, such as cell lysates, or for integral membrane protein complexes. One tenable method for determining partial specific volume of a protein in a mixture is parallel sedimentation in media with different densities (see Basic Protocol 3). However, information regarding the sedimentation coefficient of some proteins can be inferred by making certain assumptions even if partial specific volumes are not measured.

First, most soluble globular proteins or protein complexes have partial specific volumes that fit within the range of 0.72 to 0.75 ml/mg. If a protein or protein complex can be expected to fit this description, then start by assuming a similar value for its υ and enter it into the equation given below for $S_{20,w}$ values. This is only valid for proteins that lack glycosylation and associated lipids/detergents.

Alternatively, if the composition of the protein or protein complex is known (e.g., for determining the oligomerization state of a protein with one known subunit), the value of υ can be estimated by summing the υ values of each component using the following equation from Cohn and Edsall (1943): $\upsilon = \Sigma\, \upsilon_i w_i$, in which υ_i is the partial specific volume of each component and w_i is the percent mass of each component in the final complex. If the amino acid sequence of the protein component is known, this equation can be used to compute the value of υ for the protein component by summing the known partial specific volumes (υ_i) of individual amino acids on a weighted basis (w_i). If the sample is a glycoprotein with a known number of N- and O-linked glycans, the contribution of these glycans to the total value of υ can be included by summing the υ_i values of each individual sugar residue within the glycan (based on the composition of a standard N- or O-linked glycan; see below) and then factoring in the relative mass contribution of the glycan to the molecular weight of the glycoprotein.

Table 5.3.3 Partial Specific Volume of Amino Acids[a]

Amino acid	υ (ml/mg)	Amino acid	υ (ml/mg)	Amino acid	υ (ml/mg)
Alanine	0.74	Glycine	0.64	Proline	0.76
Arginine	0.70	Histidine	0.67	Serine	0.63
Asparagine	0.62	Isoleucine	0.90	Threonine	0.70
Aspartic acid	0.60	Leucine	0.90	Tryptophan	0.74
Cysteine	0.61	Lysine	0.82	Tyrosine	0.71
Glutamic acid	0.66	Methionine	0.75	Valine	0.86
Glutamine	0.67	Phenylalanine	0.77		

[a]Values from Cohn and Edsall (1943).

Table 5.3.4 Partial Specific Volume of Sugar Residues[a]

Residue	υ (ml/mg)
Hexoses (mannose, glucose, galactose, fucose)	0.613
N-Acetylhexosamines (e.g., GlcNAc, GalNAc)	0.666
N-Acetylneuraminic acid (sialic acid)	0.584
N-Glycolylneuraminic acid (sialic acid)	0.557

[a]Values from Gibbons (1972). A typical high mannose N-linked oligosaccharide would consist of 2 *N*-acetylglucosamine residues (GlcNAc) and 5 to 8 mannose residues. A typical complex N-linked oligosaccharide would consist of 3 to 5 GlcNAc residues, 3 to 5 mannose residues, a fucose residue, 1 to 3 galactose residues, and 1 to 3 sialic acid residues (primarily *N*-acetylneuraminic acid in humans). The composition of O-linked glycans in glycoproteins within the secretory pathway and nucleus varies, and usually begins with addition of *N*-acetylgalactosamine (GalNAc).

Table 5.3.5 Partial Specific Volume, Aggregation Number, Monomer Molecular Weight, and Critical Micelle Concentration of Typical Detergents in Biological Buffers[a]

Detergent	υ (ml/mg)	Aggregation number[b]	Molecular weight (g/mol)[c]	Critical micelle concentration (mM)[d]
Ionic				
Sodium deoxycholate	0.76	12	415	4
Nonionic				
$C_{12}E_8$	0.97	120	540	0.09
NP-40	0.94	140	603	0.3
Octyl-β-D-glucoside	0.85	84	292	25
Triton X-100	0.94	100-155	625	0.29
Tween 80	0.896	58	1310	0.012
Zwitterionic				
CHAPS	0.81	10	615	6.5
Surfactant-like				
Digitonin	0.74	60	1229	—

[a]Values from Clarke (1975), Watts et al. (1982), Horne et al. (1986), and Neugebauer (1994).

[b]Aggregation number is the number of monomers included in a typical micelle.

[c]Molecular weight of the monomer. Micelle molecular weight is computed as the product of the aggregation number and the monomer molecular weight.

[d]Critical micelle concentration (CMC) is the concentration above which the detergent monomers are primarily incorporated into micelles. Below the CMC, the detergent behaves primarily as monomers. Values are for detergent in aqueous solution with >0.05 M salt at 20°C.

Finally, if the sample is an integral membrane protein or protein complex dissolved in a detergent solution, one must factor in the relative mass contribution and the υ value of the detergent. It is possible to directly measure detergent binding using radiolabeled detergent and a quantitative assay for the protein in question (e.g., see Clarke, 1975). Otherwise, assumptions concerning the amount of detergent bound must be made. For proteins with single membrane-spanning regions, assume that the protein is bound by its transmembrane domain to a single detergent micelle. In this case, mass contributions by the detergent must consider the aggregation number for each detergent (the number of monomers included within a typical micelle) and the monomer molecular weight. Proteins with multiple membrane-spanning regions or additional hydrophobic domains may bind more detergent per complex, however, and so this assumption may not be valid. It should be clear that calculation of the partial specific volumes in this manner is considered an estimate and is based on numerous assumptions (composition of the complex, composition of oligosaccharides, binding of detergent) that may not be accurate.

Tables 5.3.3, 5.3.4, and 5.3.5 provide relevant data for partial specific volumes of amino acids, sugar residues, and common detergents, along with relevant properties of some of the detergents necessary for calculating percent mass contributions. Note that addition of glycans will decrease the value of υ, whereas incorporation into typical nonionic detergents will tend to increase the value of υ. The opposite effect will be apparent for the sedimentation coefficient.

SUPPORT PROTOCOL 5

Determination of the Value of $S_{20,w}$

Once the value of $S_{T,m}$ has been calculated (see Support Protocol 3) and the value of υ has been either determined experimentally or estimated (see Support Protocol 4), the value of $S_{T,m}$ must be corrected to the value of $S_{20,w}$ at the "standard state" of 20°C in water. This correction, as described by Martin and Ames (1961), relies not only on the partial specific volume (υ) of the protein but also on the viscosity (η) and density (ρ) of the medium used in the experiment. The correction is applied as

$$S_{20,w} = S_{T,m} \frac{\eta_{T,m}}{\eta_{20,w}} \frac{(1/\upsilon - \rho_{20,w})}{(1/\upsilon - \rho_{T,m})}$$

in which $\eta_{T,m}$ and $\rho_{T,m}$ are the viscosity and density, respectively, of the medium m at the temperature T of the experiment, and $\eta_{20,w}$ and $\rho_{20,w}$ are the viscosity and density of water at 20°C. For a sample at the position r_{avg}, halfway between the starting point and endpoint of migration, one can determine the values of $\eta_{T,m}/\eta_{20,w}$ and $\rho_{T,m}$ from published tables on the basis of the experimentally determined densities of sucrose (measured by refractometry) at each eluted fraction.

Materials

Fractions eluted from sucrose gradients (see Basic Protocol 2 or Alternate Protocol 2 or 3)
Refractometer

1. Using a refractometer, determine the refractive index of each fraction from the origin to the peak position in which the sample eluted. From the refractive index, calculate the concentration of sucrose in each fraction using the values in Table 5.3.1 (or the more comprehensive published values in Lide, 1997).

   If the experiment was successful, the sucrose concentration should increase linearly from the origin to the last sample when plotted on a graph.

2. Determine the fraction corresponding to the average distance traveled by the sample, r_{avg}, which is the fraction halfway between the origin (fraction 1) and the endpoint of migration for the sample, keeping in mind that fraction 1 should be considered equivalent to no migration.

   For example, if the sample migrated to the halfway point in the 5% to 20% sucrose gradient and the gradient was eluted into fifteen tubes of equal volume, then the sample would have eluted with a peak at fraction 8, and r_{avg} would have been obtained in fractions [(8 − 1)/2 + 1] or fraction 4.5—this is halfway between fractions 4 and 5.

3. Using the sucrose concentrations determined in step 1 and the value of r_{avg} determined in step 2, calculate the concentration of sucrose at r_{avg}.

   In this example, a linear gradient would predict that fractions 4 and 5 would have sucrose concentrations of ~6.7% and ~7.8%, respectively; therefore, at r_{avg} the sucrose concentration would be 7.25%.

4. From published tables, determine the values of $\eta_{T,m}/\eta_{20,w}$ and $\rho_{T,m}$ corresponding to the sucrose concentration at r_{avg}.

   For the example described, $\eta_{T,m}/\eta_{20,w}$ at r_{avg} would be 1.222 and $\rho_{T,m}$ at r_{avg} would be 1.0269.

   Note that the use of these values assumes that other components of the sample buffer, such as salts and detergent, have no effect on viscosity or density. This may not be valid when using detergents in the analysis of integral membrane proteins.

5. Use the values of $\eta_{T,m}/\eta_{20,w}$, $\rho_{T,m}$, and $S_{T,m}$ at r_{avg} and the value of υ to calculate $S_{20,w}$ according to the equation above.

   In this example, assuming a "typical" υ of 0.74 liter/g, the value of $S_{20,w}$ is computed as

$$S_{20,w} = (5.2S)(1.222)\frac{(1/0.74 - 1.00)}{(1/0.74 - 1.0269)} = 6.9S$$

   From this sample calculation, it is clear how critically the values of the viscosity and density of the medium and the partial specific volume impact on the final value of the sedimentation coefficient.

DETERMINATION OF PARTIAL SPECIFIC VOLUME AND SEDIMENTATION COEFFICIENT BY PARALLEL SEDIMENTATION IN MEDIA WITH DIFFERENT DENSITIES

BASIC PROTOCOL 3

As discussed above, one of the major limitations to interpreting the data from a sedimentation experiment is the inaccessibility of the value of the partial specific volume (υ) for the sample in question. It would therefore be desirable to have a means to measure both partial specific volume and sedimentation coefficient in a single experiment without any assumptions regarding the structure of the sample under study. This protocol describes a rather simple technique based on a method described by Edelstein and Schachman (1967) for sedimentation equilibrium experiments and later adapted for zonal sedimentation through sucrose gradients by Meunier et al. (1972) and Clarke (1975). In this protocol, sedimentation is performed simultaneously in two tubes with media of different density. All other components being equal, the density of the media is altered by using either water (H_2O) or deuterium oxide (D_2O) as the solvent. Because these two solvents are chemically similar, it can be assumed that the values of both $S_{20,w}$ and υ will be the same in the two gradients. Therefore, using sedimentation data from both gradients and solving two equations with two variables, one at a time, it is possible to determine both $S_{20,w}$ and υ. The method is based on the correction formulas described above (see Support Protocol

5), in which $S_{20,w}$ is dependent on the density of the medium. The use of D_2O raises the basal density from 1.0 g/liter to 1.11 g/liter. The technique is enhanced through the use of $D_2{}^{18}O$, if available, which changes the density even more and allows for more reliable calculations.

Materials

Deuterium oxide (heavy water, D_2O)
Additional reagents and equipment for zonal sedimentation using sucrose gradients (see Basic Protocol 1 or Alternate Protocol 1), fractionation of gradients by elution (see Basic Protocol 2 or Alternate Protocols 2 or 3), and detection of proteins within fractions (see Strategic Planning)

Perform zonal sedimentation analysis

1. Prepare sucrose stock solutions and sedimentation buffers in 90% D_2O. Prepare a fresh stock solution of 60% sucrose using 90% D_2O as the solvent, and measure sucrose concentration by refractometry. Prepare final working solutions using this sucrose stock and the regular buffer and salt stock solutions made in H_2O, bringing the final working solution to a total of 90% (v/v) D_2O.

   All of the solutions should be made with 90% D_2O replacing H_2O. D_2O can be purchased from typical chemical vendors (e.g., Sigma, Fisher, Aldrich) at 99% purity, which is sufficient for these experiments. Using 90% D_2O rather than 100% simplifies making the gradient solutions such that stock salt solutions in H_2O can still be used.

2. Using Basic Protocol 1 or Alternate Protocol 1, prepare parallel gradients using the working solutions made in H_2O and in D_2O.

   There should be enough gradients to fractionate both the experimental sample and the standards (see Support Protocol 1) in both H_2O and D_2O.

3. Apply the samples to the gradients and subject them to ultracentrifugation.

4. Using Basic Protocol 2 or Alternate Protocol 2 or 3, elute fractions for each gradient.

5. Test for the presence of the sample and the standard proteins using the appropriate assays, and determine the distribution in each gradient. Measure the refractive index of each fraction from each gradient, and determine the corresponding sucrose concentration.

Determine partial specific volume and sedimentation coefficient

6. Determine the values for R (distance traveled from the meniscus) and r_{avg} for the sample and for standards in each gradient as described for a single gradient (see Support Protocols 2 and 3). Using the value of r_{avg} and the measurements from refractometry of the fractions, determine the sucrose concentration and the corresponding medium density (ρ_i) at r_{avg} from standard tables.

   A given protein would be expected to migrate a shorter distance in the gradient prepared in 90% D_2O than in the gradient prepared in H_2O.

7. Choose a standard σ that migrates similarly to the unknown sample U in each gradient for further analysis. Use the migration of the standard to solve for K_i in the equation $R_{i\sigma} = K_i S_{20,w\sigma}(1 - \upsilon_\sigma \rho_i)$, in which $R_{i\sigma}$ is the distance traveled from the meniscus for the standard, $S_{20,w\sigma}$ is the sedimentation coefficient for the standard, υ_σ is the partial specific volume of the standard, and ρ_i is the density of the medium at r_{avg}. Determine K_i for both media, resulting in a K_1 and a K_2 value (where $i = 1$ is H_2O and $i = 2$ is D_2O).

   These values will be constant for a given medium and a given range of migration, and they will allow determination of the sedimentation coefficient and partial specific volume of the

unknown sample. The value of K_i includes the parameters of viscosity, density of water under standard conditions, angular velocity, and speed of migration.

8. Using the values of R_i, ρ_i, and K_i determined above, solve for the partial specific volume υ_U of the unknown sample:

$$\upsilon_U = \frac{R_1K_2 - R_2K_1}{R_1K_2\rho_2 - R_2K_1\rho_1}$$

Since the value of $S_{20,w}$ does not change in different media, then the equation for migration in two different media is expressed as

$$\frac{R_{1U}}{R_{2U}} = \frac{K_1(1-\upsilon\rho_1)}{K_2(1-\upsilon\rho_2)}$$

Thus, knowing the values of R_i, ρ_i, and K_i in H_2O and D_2O allows for calculation of υ_U by rearrangement to the equation above.

9. Finally, use the value of υ_U to determine the value of $S_{20,wU}$ using the original formula: $R_{iU} = K_iS_{20,wU}(1 - \upsilon_U\rho_i)$, or any of the formulas described for single gradients (see Support Protocol 5).

It should be noted that for integral membrane proteins in detergent solutions, the values of υ and $S_{20,w}$ calculated here include the contributions from the detergent. Determination of the contribution of the detergent to these parameters requires knowledge of the mass of detergent bound relative to the mass of the protein complex (see Support Protocol 4). Clarke (1975) includes formulas to calculate these values for the protein alone using this information.

COMMENTARY

Background Information

Molecular mass of individual polypeptide chains is easily estimated by gel electrophoresis techniques using charged denaturing reagents, such as sodium dodecyl sulfate, to maintain the polypeptides in an extended conformation and neutralize charge effects (*UNIT 6.1*). However, determining the molecular mass of a multisubunit protein complex is a more difficult undertaking. Denaturation nearly always results in disruption of the complex, making size analysis under denaturing conditions impossible. Fortunately, there are a variety of techniques available to determine characteristics that correspond to the size of protein complexes under nondenaturing conditions. The two most widely used and applicable techniques are gel-filtration (size exclusion) chromatography and sedimentation analysis on sucrose density gradients. Both techniques are advantageous in that they are applicable to analysis of individual complexes within heterogeneous mixtures of proteins, such as cell lysates, given an appropriate specific analytical assay for the particular protein complex of interest. Both can also be used to estimate the size of integral membrane protein complexes that are solubilized in detergents, albeit with a number of limitations. Neither technique allows direct measurement of molecular weight, but rather provides parameters that correlate with molecular weight for particles with a given shape. However, each is useful for determining relative molecular size or oligomerization state. Furthermore, given several other parameters, molecular weight can be directly calculated from combined data obtained from both sedimentation and gel-filtration analyses.

Gel-filtration chromatography permits determination of the Stokes radius of a given molecule, which is roughly proportional to molecular mass for a globular protein or protein complex. It can be a very high resolution technique for determining the molecular mass of soluble proteins, particularly when coupled to a high-performance liquid chromatography system. However, it has a number of drawbacks for analysis of integral membrane protein complexes due to the contribution of molecular mass of detergent micelles used to solubilize these complexes, although the use of detergents with small micelle sizes can minimize this difficulty. Furthermore, one is limited to analysis of a single sample at a time unless multiple chromatographic columns are set up simultaneously. Altering the size discrimination of the

column is difficult in that it requires changing the gel matrix.

Sedimentation analysis circumvents some of these difficulties and provides a different measure of molecular size—a sedimentation coefficient. Multiple samples can be analyzed in a single experiment, limited only by the number of sample positions in an ultracentrifuge rotor. Size discrimination can be altered by simply changing the sucrose concentration within the gradient or the time of ultracentrifugation. Although detergents do affect the sedimentation rate, the inclusion of proper controls or knowledge of the physical characteristics of the detergent can permit accurate analyses of integral membrane protein complexes. One drawback of this type of analysis is that there are a number of assumptions implicit in interpreting most simple sedimentation experiments; although protocols provided in this unit permit the elimination of some of these assumptions, others must be made in most cases. Another drawback is the limited resolution of the technique using traditional methods. Even this drawback, however, has been addressed in recent advances.

Theory

The theoretical basis for the zonal sedimentation experiment is in the definition of the sedimentation coefficient, *S*. The sedimentation coefficient in a given medium is defined by the equation $S = (dr/dt)/\omega^2 r$, in which r is the distance traveled by a macromolecule, ω is the angular velocity of the rotor, and dr/dt is the distance traveled over time (for complete discussion of theory, see Tanford, 1961; Williams, 1972). Classical experiments by Svedberg and others established the techniques of sedimentation equilibrium and sedimentation velocity to analyze the properties of purified macromolecules in solution under standard conditions (water at 20°C). These techniques begin with a uniform distribution of macromolecules in solution, and then follow either the shape of the curve of a distribution of macromolecules throughout the gradient after equilibrium has been reached between sedimentation and flotation (sedimentation equilibrium) or the velocity of movement of the leading edge of sedimenting material (sedimentation velocity). These classical techniques require a specialized analytical ultracentrifuge and relatively large quantities of purified material for analysis (for complete discussion, see Van Holde, 1975). They are thus limited in applicability, particularly for unpurified proteins.

Martin and Ames (1961) modified the velocity sedimentation technique by following the movement of a band or zone of macromolecules through a sucrose gradient. The beauty of the sucrose gradient is that dr/dt is nearly constant—that is, there is little variability in the speed with which the molecule moves as it passes through the gradient. Thus, at a given angular velocity and time, S is inversely proportional to r, allowing for direct determination of sedimentation coefficients from migration at a single time point. This avoided the difficulties of the sedimentation velocity experiment, which required measurement of position at various times during the experiment to establish a rate of movement through the medium. Furthermore, it permitted identification of proteins within a complex mixture by analysis subsequent to centrifugation.

Classical sedimentation coefficients, as described in published tables, are corrected to the standard state of water at 20°C. Therefore, observed sedimentation coefficients must be corrected for the properties of the medium to determine the standard sedimentation coefficient, $S_{20,w}$. The sedimentation coefficient is a property of the size and density of a macromolecule. Therefore, the $S_{20,w}$ value is affected by the density and viscosity of the medium relative to that of the macromolecule in question. Higher density will provide a greater buoyancy, and higher viscosity will deter the movement of the macromolecule through the gradient.

The value of $S_{20,w}$ can be expressed as

$$S_{20,w} = \frac{dr}{dt}\frac{\eta_{T,m}}{\eta_{20,w}}\frac{(1/\upsilon - \rho_{20,w})}{(1/\upsilon - \rho_{T,m})}\frac{1}{\omega^2 r}$$

in which $\rho_{T,m}$ and $\rho_{20,w}$ are the density of the medium m at temperature T and of water at 20°C, respectively, and $\eta_{T,m}$ and $\eta_{20,w}$ are the viscosity of the medium m at temperature T and water at 20°C, respectively. The value υ is the partial specific volume, which is defined as the inverse of the density of the macromolecule and is expressed as volume per mass. For most globular proteins with a spherical shape, partial specific volumes fall within the range of 0.72 to 0.75 ml/mg, and there is therefore a roughly linear relationship between sedimentation coefficient and molecular weight. Thus, for most globular proteins in neutral aqueous solutions, the value of the sedimentation coefficient can be extrapolated directly to molecular weight.

Other variables, however, may influence the sedimentation coefficient such that it may not be an accurate measure of molecular weight. For example, a protein that is less densely

packed than the typical globular protein, such as those with a toroid shape or a high proportion of polar, solute-exposed amino acids, will have a higher partial specific volume and higher sedimentation coefficient for a given molecular mass than a densely packed, globular protein. Similarly, asymmetry will have a dramatic effect on the sedimentation coefficient; thus, proteins with elongated structures, such as myosins and integral membrane proteins in detergents, will have a reduced sedimentation coefficient for a given molecular mass. Thus, sedimentation coefficient alone cannot be used as a direct measure of molecular weight unless the properties of the macromolecule are known.

A protocol is provided to determine the partial specific volume of a protein complex using sedimentation in media with different densities (see Basic Protocol 3). This protocol uses two parallel gradients in which the solute is either water or deuterium oxide. Since each of these solvents has a distinct density but otherwise are chemically similar, migration in each gradient will differ solely by virtue of the density of the medium. However, the values of $S_{20,w}$ and υ are constant, regardless of the density of the media. Therefore, if one first calculates a constant for each medium [which includes the parameters $(dr/dt)/\omega^2 r$, $\rho_{T,m}$, and $\eta_{T,m}$] by using values for a standard protein with similar migration to the unknown sample, then one can solve for υ of the sample and use this value to calculate $S_{20,w}$. For a protein complex soluble in aqueous medium, such as a nuclear or cytosolic protein complex, these values represent the final goal of the experiment. For integral membrane proteins or protein complexes solubilized in detergents, however, it is necessary to subtract from these values the contribution from the detergent.

Assuming that the sedimentation coefficient $S_{20,w}$ and partial specific volume υ are accurately determined, the molecular weight M of a macromolecular complex can be calculated by providing the value of the Stokes radius, a, determined by gel-filtration analysis under similar buffer conditions:

$$M = \frac{6\pi N a S_{20,w} \eta_{20,w}}{1 - \upsilon \rho_{20,w}}$$

in which N is Avogadro's number, $\eta_{20,w}$ is the viscosity of water at 20°C, and $\rho_{20,w}$ is the density of water at 20°C. This is the only valid way to accurately determine molecular weight from either sedimentation or gel-filtration experiments without making a number of assumptions regarding the nature of the protein complex.

Practical considerations

The sedimentation of a macromolecule is affected by the medium in which the experiment is done. The density and viscosity of the medium will affect the rate of sedimentation and are included in standard equations for determining the sedimentation coefficient. For accurate determinations, most experiments should be done at near neutral pH and physiological ionic strength, because interactions with buffer components may affect the degree of hydration or intermolecular interactions and thereby alter the partial specific volume of the macromolecule under study.

One of the most important buffer components for integral membrane proteins are detergents. Detergents are required to solubilize most integral membrane proteins (Helenius and Simons, 1975; Tanford and Reynolds, 1976), but the properties of the detergent, particularly its partial specific volume and aggregation number for association with micelles, will affect the migration of the protein-detergent complex during fractionation (Doms, 1990). In addition, some detergents may disrupt particularly labile protein complexes. Detergents tend to have high partial specific volume values and therefore will drastically alter the sedimentation of a bound protein complex.

Detergents with high aggregation numbers, such as the common nonionic detergents Triton X-100 and NP-40, will have high detergent:protein mass ratios in a complex and will thus contribute largely to the sedimentation properties and partial specific volumes of the complex. The zwitterionic detergent CHAPS and the nonionic detergent *n*-octylglucoside tend to be favorable for both sedimentation and gel-filtration experiments because of their small micelle size. The surfactant-like detergent digitonin is also useful to solubilize labile protein complexes. To extract the maximal amount of information from a sedimentation experiment, it is necessary to know the amount of detergent bound to a protein complex. This value is often difficult to determine, particularly for proteins within a complex mixture, and usually requires the use of radioactive detergent and quantitation of the protein sample (Clarke, 1975). It should be mentioned that many water-soluble and peripheral membrane proteins will bind detergent as well, often in a less predictable manner (Helenius and Simons, 1975).

Regardless of the caveats, there are several ways of extracting information from sedimentation experiments even in the absence of an exact molecular weight determination. For ex-

ample, the oligomerization or aggregation state of a single subunit can be inferred by comparing the migration of samples known to exist in monomeric versus oligomeric conformation. This may be useful, for example, in following the changes in oligomeric state over time by pulse-chase metabolic labeling experiments. Even without knowledge of different conformations, some assumptions can be made. For example, regardless of the caveats described here, a 50-kDa subunit that migrates with a sedimentation coefficient of ~15 S is unlikely to exist in solution as a monomer. Furthermore, for proteins that do not interact with detergents, one can determine both sedimentation coefficients and partial specific volumes by differential sedimentation in H_2O and D_2O (see Basic Protocol 3). By making a number of assumptions regarding composition of a complex, amount of detergent bound (number of detergent micelles bound), and values provided in this unit for partial specific volumes of detergents, glycan moieties, and amino acids, these experiments can allow one to estimate molecular size even for an integral membrane glycoprotein.

There are numerous ways of performing the sedimentation experiment, mostly based on the different means of creating and eluting the gradient. To form the gradient, the method of choice employs the Biocomp Gradient Master (see Basic Protocol 1). The Gradient Master produces reliable, consistent gradients with minimal effort. Other protocols, including Alternate Protocol 1 using a manual gradient maker, are trickier to master, more time-consuming, and offer less reproducibility because each gradient is made separately. Nevertheless, the manual method may be more attractive to a laboratory with a limited budget. Other commercial devices are available for making gradients, but for the money, the design of the Gradient Master is superior.

For elution of the gradients, there are many more methods, and each laboratory has its favorite. The three presented in this unit all use inexpensive and/or common equipment that is likely to be available in most laboratories. Elution from the bottom through hole puncture (see Basic Protocol 2) is probably the best choice for optimal resolution. However, unless one of the commercial piercing devices is available (such as the Büchler apparatus), it may be difficult to master optimal placement of the hole and to control the rate of flow. Furthermore, the method is cumbersome because the drops are usually collected manually. Finally, since all of the material passes through the bottom, any precipitated material that accumulated at the bottom will contact the remaining contents of the tube and may interact with this material, block the flow, or cause turbulence, all of which will affect the resolution of the experiment.

The technique of elution from the bottom by action of a peristaltic pump (see Alternate Protocol 2), which is one of the most widely used methods, has the advantage that it can be set up to work automatically in a cold room without constant supervision. However, it suffers the greatest amount of laminar capillary flow turbulence of any of the methods and has the same difficulties with a pellet as the hole puncture method. The final method, pipetting from the top (see Alternate Protocol 3), is cumbersome, suffers from variable suction-induced turbulence, and may frustrate the technologically inclined investigator. However, it is the least expensive, offers the least disturbance of the pellet, and can provide reproducible results. All of the commercial devices mentioned, particularly the trumpet-tip eluter from Biocomp, are likely to provide superior resolution to these more simple methods. However, the devices are all quite costly and may limit the adaptability of the technique to different sized ultracentrifuge tubes and rotors.

For computational analysis, the choice of protocols is dependent on the needs of the experiment. If relative migration is the only concern—for example, if the experiment is to follow the oligomerization state of a polypeptide over a time course or series of different treatments or to merely separate known complexes for analysis—then assignment of an absolute value for $S_{20,w}$ may not be necessary, and the experiment can be done using markers simply as a reference point (for preparation and analysis of molecular size markers, see Support Protocols 1 and 2). For more accurate determinations of $S_{20,w}$ values, clearly the superior method would eliminate any assumptions regarding partial specific volume. Thus, it would be optimal to use Basic Protocol 3 in which sedimentation is done in parallel gradients with H_2O and D_2O. On the other hand, if the composition of the complex is known definitively, then either an assumed average υ value of 0.74 ml/mg or υ values estimated from summation of the weighted contribution of υ_i values may be sufficient (see Support Protocols 3 through 5).

Critical Parameters and Troubleshooting

The critical parameters of the zonal sedimentation experiment fall into two categories: those that affect the experimental outcome and those that affect the interpretation. These are discussed separately.

Experimental factors

The critical parameters for the success of the fractionation of a protein sample are (1) the method of detection of the protein sample, (2) the preparation of the sample for sedimentation, (3) the linearity and reproducibility of the sucrose gradients, (4) care in ultracentrifugation, and (5) the ability to elute the gradients with the least amount of turbulence and disturbance.

1. The method of detection must be sufficiently worked out beforehand to ensure that the sedimentation experiment can be analyzed properly. The detection method must be sensitive enough to detect a sample after fractionation, assuming distribution and dilution over several fractions. On the other hand, the method should also provide linear (or at least nearly linear) detection of sample over the range of concentrations used in order to be able to detect a peak of migration among several fractions. Furthermore, the method must not be sensitive to components of the sucrose gradient itself; otherwise, these components must be removed by a dialysis or precipitation step prior to analysis. For these reasons, immunologic detection techniques, such as immunoblotting (*UNIT 6.2*), immunoprecipitation of radiolabeled material (*UNIT 7.2*), and ELISAs, are typically the methods of choice. Even in these cases, however, the sucrose gradient solution may interfere. For example, large amounts of sucrose may affect the integrity of a lane in a polyacrylamide gel. The volume of the fraction needs to be considered for application to the well of a gel or a 96-well plate; if the fraction size is 0.8 ml but the well only holds 40 µl, only 5% of the fraction can be assayed without a concentration step. Be certain that the details of the analysis and compatibility with the fractionation are worked out well before starting the density gradient experiment. Failure to do so may mean that a fractionation is done with no ability to detect the desired component.

2. Sample preparation should also be resolved before attempting the sedimentation experiment. The volume of the sample should be minimized in order to maximize the resolution of the sucrose gradient fractionation. Bands are not concentrated during centrifugation, and therefore the volume of the sample will be the smallest volume in which the desired component will ultimately elute after fractionation. If particulates are not removed, they may disrupt the gradient during the run, resulting in band spreading and loss of resolution. Furthermore, they will contribute to a pellet during the centrifugation, which may interfere with the elution method and cause additional band spreading. The sample as prepared must be less dense than the least dense endpoint sucrose solution (5% in the example given). The concentration of the sample and the buffer in which it is prepared must be considered; a highly concentrated cell lysate, for example, may be dense due to the contents of the lysate rather than the buffer, and may sink in 5% sucrose. This will be apparent on loading of the sample. It is important that the buffer of the sucrose gradient closely approximates that of the lysate. Otherwise, material from the sample may precipitate on contact with the sucrose gradient solution during loading. Lastly, the stability of the sample should be considered prior to the experiment for timing of preparation of the sample and the gradients. If the protein or enzyme under analysis is unstable in solution, it may not survive the long centrifugation required in the sedimentation experiment or a prolonged period between sample preparation and loading.

3. The linearity and reproducibility of gradient formation are necessary for two reasons. First and most important, changes in the slope of the gradient will result in changes in the velocity of the sample components as they migrate through the tube during centrifugation. Since the basis of the use of the sucrose gradient is to maintain a constant velocity (allowing for computation of rate of movement by measuring distance traveled at one time point), any alterations in velocity completely invalidate subsequent computation of sedimentation coefficient. Thus, unless the sample has a sedimentation coefficient and partial specific volume identical to that of one of the standards, it will not be possible to determine even a relative sedimentation coefficient if the gradient is not linear. The other critical aspect of gradient linearity is the physical stability of the sample maintained by the gradient during handling of the ultracentrifuge tube. If the sucrose concentration is uniform or nearly uniform for any length of the tube, the sample is more likely to

be disrupted during loading, eluting, or other handling. This will result in an erratic and heterogeneous distribution.

If using the Gradient Master (see Basic Protocol 1), a lack of linearity of the gradient may result if the angle, speed, or time of rotation is not optimal for the particular gradient being made. Check the manufacturer's recommendations and recheck the procedure for programming the Gradient Master for the desired parameters. If using a manual gradient maker (see Alternate Protocol 1), there may be numerous causes for a lack of linearity. Turbulence and inappropriate mixing of samples may occur if any bubbles are present in any of the connections between chambers or to the sample, if there is too rapid a flow from the gradient maker, if the microbore tubing is too long, or if the glass micropipet is not sturdily held in place or is not resting firmly at the bottom of the tube. Too much or too little volume will also disrupt the experiment, particularly if volume is not reproducible from tube to tube. It may be helpful to prepare some mock gradients with a dye in one of the solutions to test for linearity using either method. Linearity can be determined after elution by refractometry of each fraction. Finally, any inconsistency in preparation of the sucrose stock solutions may cause loss of reproducibility of migration from one experiment to the next; samples will move faster in a 4% to 16% gradient than in a 5% to 20% gradient because of lower density and viscosity. Inconsistencies will result in altered migration in different experiments. Thus, it is important to check the sucrose concentrations of the stock solutions by refractometry.

4. Care must be taken during the beginning and end stages of centrifugation such that the tubes are not disrupted by mishandling or by too rapid acceleration or braking in the ultracentrifuge. Each of these mishaps may disrupt the gradients, causing mixing and eventual loss of resolution. The simplest way to avoid this is to take appropriate care in loading the centrifuge rotor in the ultracentrifuge and then program the ultracentrifuge with the slowest possible acceleration rate and no brake at the end of the run; although it will take a long time for the rotor to reach full speed (typically ~15 min for the SW41 Ti rotor) and to come to a stop (usually ~30 min for the SW41 Ti rotor), it is worth it to ensure the proper outcome of the experiment.

5. The final and perhaps most critical feature of the experimental manipulation is the elution. All of the described methods provide some degree of turbulence or laminar capillary flow during the elution, which will affect the resolution of the experiment. Too much turbulence will disrupt the gradient and result in broad bands after analysis or in irregular, nonsymmetrical elution profiles. Most of the automated methods also introduce some turbulence, albeit less than the manual methods. The best way to reduce turbulence is to elute as slowly as possible. If using the hole puncture method (see Basic Protocol 2), be sure that the hole is at the very bottom and that the hole is not clogged by any precipitate (this can be avoided by preclearing the sample of particulates). Try to use a needle that produces the smallest possible drop volume. It may be helpful to attach the needle to some tubing or a drop former to standardize the size of the drop for a given viscosity. If using the peristaltic pump (see Alternate Protocol 2), be sure that the capillary micropipet is firmly placed within the tube, that the pump flow is constant (some pumps introduce a certain degree of backflow and should be avoided), and that the amount of microbore tubing between sample and fraction collector is minimal. If an overly large backflow is observed, check to make sure that the pump is set up appropriately. If using the manual pipetting method (see Alternate Protocol 3), be sure that the pipettor remains as close to the top of the tube as possible as material is withdrawn from the gradient. If using the automated instruments, be sure to follow the manufacturer's instructions carefully!

Interpretation of data

Interpreting the data from the sedimentation experiment is also subject to a number of critical parameters (see Support Protocols 1 through 5). It is most important to choose as standards molecules that resemble the test sample as closely as possible. If partial specific volumes of the test sample and standards are similar, then it is likely that sedimentation coefficients will be accurately measured and molecular weights accurately estimated based on migration of the standards. The use of standards with dissimilar partial specific volumes will reduce the accuracy of these determinations. Even when using the parallel D_2O/H_2O system (see Basic Protocol 3), standards chosen for determination of the K_i values must have similar values for sedimentation coefficient and partial specific volume. Otherwise, there will be a significant degree of error in the calculations, because the K_i constants include partial specific volume. Most importantly, it is critical not to

make the mistake that the sedimentation properties correspond precisely to molecular weight; these properties may reflect molecular weight but cannot be extrapolated directly without information concerning the Stokes radius or frictional coefficient.

The use of detergents to solubilize integral membrane proteins introduces a major hindrance to interpretation of sedimentation experiments. Calculated values will always include contributions from the detergent, and it is difficult to accurately assess experimentally what these contributions are. Perhaps the best way to derive meaningful information is to perform the sedimentation analysis in several different detergents with distinct properties. Combined data from these different analyses, interpreted with the known properties of the detergents (aggregation number, molecular weight, and partial specific volume), may permit determination of the contribution of the detergent to the size of the protein complex. Such an analysis may also reveal any differences in stability of protein complexes in different detergents by dramatic changes in size of the complex. Be careful in this interpretation, however; large increases in sedimentation coefficient, partial specific volume, and molecular weight may also reflect a high degree of binding to detergents, such as Triton X-100, with high values of micelle molecular weight and partial specific volume. It is always wise to perform the analysis in different detergents to strengthen interpretation of the size of the protein complex.

Anticipated Results

The expected results will obviously vary depending on the nature of the sample tested, the number of fractions collected, and the particular method used. If one of the traditional methods, as outlined here, is used for eluting the gradient and fractions are collected that are equal in volume to the preparation loaded onto the gradient, then one might expect a single, discrete molecular species to elute in a symmetrical distribution over fractions corresponding to three to five volumes of loaded sample. The center of the peak would correspond to R for the purposes of calculation. Calculations of $S_{20,w}$ (and υ, if the double gradient system is used) would be expected to have an intrinsic error of ~5% due to the turbulence and mixing of most of these methods and the imprecision of the measurements. The more fractions that are collected (within reason), the higher the precision will be. If one of the automated elution methods is used, resolution may be greatly improved, with distribution over one to two low-volume fractions and a lower intrinsic error under the best circumstances.

On the other hand, many macromolecules may not elute as a single, discrete species. For example, many proteins that are misfolded, unassembled, or in the process of folding or assembly tend to form heterogeneous aggregates and/or associate with varying numbers of chaperone proteins (Gething and Sambrook, 1992; Hartl, 1996). This heterogeneity will be apparent as a broad distribution over many fractions of the gradient. In these cases, the material with the lowest sedimentation coefficient (earliest fraction) may contain monomers. A protein would also have a heterogeneous distribution if it exists in the cell in multiple oligomeric forms. An example would be major histocompatibility complex (MHC) class II molecules, which are incorporated into a nine-subunit complex during assembly and early biosynthetic transport, but which are eventually incorporated into the plasma membrane as heterodimers associated with a small peptide. The steady-state distribution of one of the subunits of a MHC class II molecule would therefore appear as two peaks in a sedimentation experiment, one corresponding to the nonamer and the other to the dimer (Roche et al., 1991). A protein that exists with multiple partners in the cell, such as many well-described transcription factors and cytoskeletal elements, may also have a heterogeneous distribution due to the formation of such multiple complexes.

Lastly, other biophysical features, such as instability of a protein complex or heterogeneity in detergent binding, may result in the lack of a discrete peak of elution. In many of these examples, the use of specific antibodies that recognize only a single conformation of a protein complex, and/or the use of pulse-chase metabolic labeling combined with immunoprecipitation from individual fractions, may reduce or eliminate heterogeneity by limiting analysis to individual complexes or particular stages of biosynthetic assembly and molecular lifetime. Migration of standard proteins in a discrete peak would serve to distinguish between a biologically relevant heterogeneous distribution and a poor experiment.

Time Considerations

The time required to complete the technical aspects of the sedimentation experiment will vary depending on the preparation time for the sample to be analyzed, the method of gradient

preparation, the time required for centrifugation, and the method of assaying for the sample. Typically, the gradients can be prepared, loaded, and started in the ultracentrifuge in a single day. This is particularly true when using the Gradient Master to prepare the gradients—gradient preparation can take <1 hr, and sample loading takes only a few minutes per gradient. The manual method, on the other hand, requires at least 35 to 45 min to make each gradient including preparation time; if the sample needs to be freshly prepared before loading, it may be a long day. A typical gradient run would be 16 hr (overnight if the sample is loaded into the ultracentrifuge in the evening). Elution can take anywhere from 15 to 45 min per sample, depending on the protocol used; the automated methods are faster than the manual methods. If the assay is rapid, the sample preparation is not complicated, and the sedimentation is performed for 16 to 20 hr, the entire experiment can be finished in 2 days. A typical experiment using cell lysates and assay by immunoblotting is more realistically completed in 3 to 4 days.

Analysis of the Association of Proteins with Membranes

This unit contains several protocols for analyzing the association of proteins with membranes. These include complementary protocols for determining if a given protein is an integral or peripheral membrane protein–i.e., alkaline carbonate extraction (see Basic Protocol 1), urea extraction (see Alternate Protocol 1), high-salt extraction (see Alternate Protocol 2), and Triton X-114 phase separation (see Alternate Protocol 3).

In addition, protocols are included for assessing whether a protein is associated with membranes via a C-terminal glycophospholipid anchor, termed glycosyl phosphatidylinositol (GPI). Here, a phosphoinositol (PI)–specific phospholipase is used to enzymatically release the hydrophobic "greasy foot" from this class of membrane proteins (see Basic Protocol 2). Some membrane components are selectively resistant to solubilization by Triton X-100 at 4°C; these proteins can be solubilized using other detergents (see Basic Protocol 3).

Finally, there are two protocols for purifying caveolae-derived plasma membrane domains from cultured cells (see Basic Protocol 4). One uses Triton X-100; the other is a detergent-free method (see Alternate Protocol 4).

The unit also contains protocols for Triton X-114 precondensation (see Support Protocol 1) and preparation of a protease inhibitor stock solution (see Support Protocol 2) to be used in the corresponding basic protocols.

ALKALINE CARBONATE EXTRACTION

BASIC PROTOCOL 1

This method developed by Fujiki et al. (1982a) uses alkaline pH to disrupt membranes. Under these conditions, membrane vesicles are converted to open membrane sheets that can be recovered with an ultracentrifugation step. The soluble contents of the vesicles are released into the supernatant fraction. Proteins peripherally associated with the membrane are also found in the supernatant. Only integral membrane proteins remain associated with the membrane under those conditions. This method can be used on membrane proteins from all intracellular membranes. Examples include but are not limited to membranes isolated from the endoplasmic reticulum (Fujiki et al., 1982a,b), peroxisomes (Fujiki et al., 1982a,b), mitochondria (Fujiki et al., 1982a,b; Scherer et al., 1992), Golgi (Scherer et al., 1996) and plasma membrane (James et al., 1989).

The identical procedure can be performed with cells radiolabeled as described in *UNIT 7.1*. If an immunoprecipitation of the respective fraction is desired rather than a direct application to SDS-PAGE, the samples should be treated as described in steps 1 to 4; however, instead of adding an equal volume of 2× SDS-PAGE sample buffer in step 5a, the samples should be treated with nonionic detergents as in steps 5b and 6b (also see *UNIT 7.2*)

Materials

Cells of interest
Phosphate-buffered saline (PBS; *APPENDIX 2A*), ice-cold
100 mM NaCl
100 mM sodium carbonate, pH 11.5, ice cold
2× SDS-PAGE sample buffer (*APPENDIX 2A*)
Triton X-100

Contributed by R.B. Schwab, T. Okamoto, P.E. Scherer, and M.P. Lisanti
Current Protocols in Cell Biology (2000) 5.4.1-5.4.17

N-octyl glucoside
Tris·Cl, pH 7.5 (*APPENDIX 2A*)
NaCl

2-ml Dounce homogenizer
Beckman TL-100 centrifuge with TLA 100.2 rotor
26-G needles and 1-ml syringes
95°C water bath

Additional reagents and equipment for SDS-PAGE (*UNIT 6.1*), immunoblotting (*UNIT 6.2*), and immunoprecipitation (*UNIT 7.2*)

1a. *For adherent cells:* Wash ~1×10^7 cells three times with ice-cold 20 ml PBS, then once with 100 mM NaCl.

1b. *For nonadherent cells:* Wash ~1×10^7 cells as in step 1a, but isolate cells between washes by gentle microcentrifugation (2 min at a maximum of $1000 \times g$, 4°C).

2. Scrape (adherent) or resuspend (nonadherent) cells into 1 ml of ice-cold 100 mM sodium carbonate, pH 11.5, and homogenize with five strokes in a 2-ml Dounce homogenizer.

3. Incubate homogenate 30 min at 4°C, then centrifuge 60 min at 150,000 to 200,000 × *g* (100,000 rpm in a TLA 100.2 rotor), 4°C.

4. Transfer the supernatant to a fresh tube and resuspend pellet in 1.0 ml of 100 mM sodium carbonate, pH 11.5.

To facilitate the resuspension of the pellet, the pellet fraction can be homogenized in the Dounce homogenizer.

For SDS-PAGE and/or immunoblotting

5a. Immediately mix pellet and supernatant fractions with an equal volume of 2× SDS-PAGE sample buffer. Shear genomic DNA in pellet sample by passing through a 26-G needle several times.

If necessary, samples can be neutralized by adding 5 to 10 µl of 1 M Tris·Cl, pH 7.0. The shearing will decrease the sample's viscosity.

6a. Heat samples at 95°C for 5 min.

The samples can now be used directly for SDS-PAGE (UNIT 6.1) and immunoblot analysis (UNIT 6.2). Load equal volumes of both supernatant and pellet fraction. Alternatively, samples can be stored frozen at –20° or –80°C for weeks.

For immunoprecipitation

5b. Add Triton X-100 to a final concentration of 1% (w/v), *N*-octyl glucoside to a final concentration of 60 mM, Tris·Cl, pH 7.5, to a final concentration of 50 mM, and NaCl to a final concentration of 300 mM.

The pH of the final solution should not exceed 8.0. If necessary, add more Tris·Cl, pH 7.5, to lower the pH.

6b. Incubate sample on ice for 5 min, then microcentrifuge 10 min at $15,000 \times g$, 4°C, to remove insoluble debris. Immunoprecipitate using a standard reaction (*UNIT 7.2*).

UREA EXTRACTION

ALTERNATE PROTOCOL 1

This procedure is identical to the alkaline carbonate extraction (see Basic Protocol 1), except that 100 mM sodium carbonate, pH 11.5, is replaced with a solution containing 2 M urea and 20 mM 2-(*N*-morpholino)ethanesulfonic acid (MES), pH 6.5. Moderately high concentrations of urea (2 M) are commonly used to extract peripheral and soluble proteins from vesicles (Schook et al., 1979). Urea diminishes the hydrophobic interactions and thereby removes these proteins from the membrane. It is important to note that cyanate is formed spontaneously from urea. The cyanate ion can react with both amino and sulfhydryl groups of amino acids causing such problems as irreversible inactivation of enzymes and altered retention times on reversed-phase HPLC after Edman degradation of proteins. Therefore, solutions should be prepared fresh from high-quality urea, or the solution should be deionized prior to use. Store urea-containing solutions up to 1 week at 4°C.

HIGH-SALT EXTRACTION

ALTERNATE PROTOCOL 2

At high concentrations, salt exerts effects on proteins that depend both on the concentration and the nature of the salt. In this context, NaCl and KCl are primarily used to disrupt polar interactions between peripheral membrane proteins and integral membrane proteins. Once again this procedure is identical to the alkaline carbonate extraction (see Basic Protocol 1), except in this case 100 mM sodium carbonate is replaced with a solution containing 10 mM Tris·Cl, pH 8.0 (*APPENDIX 2A*)/0.5 M NaCl. KCl may be used as an alternative to NaCl. Salt solutions can be stored at room temperature, but must be chilled well prior to use.

TRITON X-114 PHASE SEPARATION

ALTERNATE PROTOCOL 3

A solution of the nonionic detergent Triton X-114 is homogeneous at 0°C but separates into an aqueous phase and a detergent phase above 20°C. The extent of this detergent-phase separation increases with temperature. When membrane fractions are solubilized with a Triton X-114 solution on ice and then placed at 37°C, hydrophilic proteins are found in the aqueous phase, whereas integral membrane proteins are recovered in the detergent phase. Integral membrane proteins can thus be separated from soluble and peripheral proteins.

Tris/NaCl/EDTA buffer (see recipe)
TNET-OG buffer (see recipe)
2× SDS-PAGE sample buffer (*APPENDIX 2A*)

Additional reagents and equipment for immunoprecipitation (*UNIT 7.2*), SDS-PAGE (*UNIT 6.1*), and immunoblotting (*UNIT 6.2*)

1. Add 1 ml ice-cold cell lysis buffer to 2–5 × 10^6 cells and lyse cells by incubating 45 to 60 min at 4°C.
2. Transfer solution to a microcentrifuge tube and microcentrifuge 15 min at 10,000 × *g*, 4°C.
3. Transfer supernatant to a fresh microcentrifuge tube and incubate at 37°C for 3 min.
4. Centrifuge solution 1 min at 10,000 × *g*, room temperature. Transfer the upper (aqueous) phase, which should represent ~95% of the total volume, to a fresh microcentrifuge tube. Retain the detergent phase for step 6.

5. Re-extract the aqueous phase from step 4 by adding 100 µl cell lysis buffer and repeating steps 3 and 4. Discard the lower detergent phase from this step.

6. Re-extract the detergent phase from step 4 by adding 10 vol Tris/NaCl/EDTA buffer. Repeat steps 3 and 4 then discard the upper, aqueous phase.

7a. *For aqueous phase*: Use the aqueous phase (from step 5) directly for immunoprecipitation reactions (*UNIT 7.2*).

7b. *For detergent phase*: Dilute the detergent phase (from step 6) to 1 ml with TNET-OG buffer and use for immunoprecipitation (*UNIT 7.2*).

7c. *For direct analysis of the extracted samples by SDS-PAGE:* Mix 5% of both aqueous (approx. 50 µl) and detergent phases (2.5 µl) with 50 µl 2× SDS-PAGE sample buffer.

If not to be analyzed immediately, samples can be stored at −20° or −80°C for 1 to 2 weeks.

SUPPORT PROTOCOL 1

TRITON X-114 PRECONDENSATION

The purpose of this support protocol is to prepare a precondensed stock solution of Triton X-114 (Bordier, 1981). Precondensation is required to remove certain impurities that may interfere with the phase separation properties of Triton X-114.

Materials

Triton X-114
Tris-buffered saline (TBS): 10 mM Tris·Cl, pH 7.4 (*APPENDIX 2A*)/150 mM NaCl
Sodium dodecyl sulfate (SDS)
Triton X-100

1. Add 20 g Triton X-114 to 980 ml Tris-buffered saline.

2. Allow to dissolve at 4°C for ~1 hr with stirring or until solution is clear, then incubate at 30°C overnight with stirring.

3. Discard the large aqueous phase (upper phase) and replace with fresh Tris-buffered saline. Once again dissolve at 4°C and incubate overnight at 30°C.

4. Repeat step 3 two more times.

The last detergent phase (lower phase) is the stock solution to use for experiments.

5. *Optional:* Determine the concentration of the last detergent phase by measuring the absorbance of a 1:1000 dilution in the presence of 1% SDS at 275 nm and compare to the absorbance of a set of standard solutions of Triton X-100 at 275 nm to determine the final concentration.

The extinction coefficient of Triton X-100 is virtually identical to that of Triton X-114.

There is actually no real need to determine the exact concentration of the final stock as it varies between 9.5% and 10.5% Triton X-114 and can simply be used at a dilution of 1:10. See recipe for cell lysis buffer in Reagents and Solutions.

6. Store the final stock solution up to 1 week at 4°C.

PREPARATION OF 100× PROTEASE INHIBITORS STOCK SOLUTION

SUPPORT PROTOCOL 2

Protease inhibitors are used to prevent proteolysis during extraction. This stock mixture inhibits most common proteases (also see *APPENDIX 1B*).

Materials

Antipain
Pepstatin A
Leupeptin
Dimethylsulfoxide (DMSO)

1. Make separate 1000× solutions of antipain, pepstatin A, and leupeptin by dissolving 5 mg of each in 500 µl DMSO.
2. Combine 50 µl of each 1000× solution and add 350 µl DMSO.
3. Divide this combined 100× stock solution into small aliquots (i.e., 100 µl) and store at –20°C.
4. Use 10 µl/ml for a final concentration of 10 µg/ml of each protease inhibitor. Do not exceed 10 µl/ml (final DMSO concentration should be <1%).

PI-PLC CLEAVAGE OF GPI-LINKED PROTEINS

BASIC PROTOCOL 2

This procedure is used to detect glycosyl phosphatidylinositol (GPI)-linked proteins by converting them from a hydrophobic to a hydrophilic state. The procedure consists of the enzymatic removal of the GPI anchor using phosphatidylinositol-specific phospholipase C (PI-PLC). The removal of the GPI anchor causes the protein to shift from the detergent-rich phase to the detergent-poor phase of Triton X-114 extracts.

Materials

Cells of interest
Tris/NaCl/EDTA buffer (see recipe)
PI-PLC incubation buffer (see recipe)
1000 U/ml PI-PLC (phosphatidylinositol-specific phospholipase C; Boehringer Mannheim)
Phenyl-Sepharose 4B (Pharmacia Biotech)
Tris-buffered saline (TBS): 20 mM Tris·Cl, pH 8.0 (*APPENDIX 2A*)/150 mM NaCl
12.5 mg/ml (100×) sodium deoxycholate
Trichloracetic acid
2× SDS-PAGE sample buffer (*APPENDIX 2A*)
1 M Tris·Cl, pH 8.0 (*APPENDIX 2A*)
1% (w/v) SDS/200 mM Tris·Cl, pH 8.0 (see *APPENDIX 2A* for Tris·Cl)
TNET buffer (see recipe)

Eppendorf vortex mixer
Boiling water bath

Additional reagents and equipment for Triton X-114 phase separation (see Alternate Protocol 3), SDS-PAGE (*UNIT 6.1*), and immunoprecipitation (*UNIT 7.2*).

1. Using ~1×10^7 cells, follow the Triton X-114 phase separation protocol (see Alternate Protocol 3) with the following variations:
   a. In step 3 of Alternate Protocol 3, incubate samples at 37°C for 20 min instead of 3 min.
   b. In step 6 of Alternate Protocol 3, re-extract samples twice against fresh Tris/NaCl/EDTA buffer, keeping the detergent phases.

2. Dilute the detergent-rich phases 10-fold with PI-PLC incubation buffer and add PI-PLC to a concentration of 4 to 8 U/ml.
3. Mix continuously on a vortex mixer at 37°C for 1 hr.
4. Repartition samples by microcentrifuging 1 min at 10,000 × *g*, room temperature. Collect the upper (aqueous) phases.
5. Prepare a 50% slurry of phenyl-Sepharose 4B in Tris-buffered saline. Add 200 µl of the slurry per ml aqueous phase and incubate samples overnight at 4°C to remove trace amounts of hydrophobic membrane proteins.
6. Microcentrifuge samples 10 sec at ≤2000 × *g*, 4°C, and transfer supernatants to fresh microcentrifuge tubes. Repeat to clear all beads.
7. Precipitate by adding sodium deoxycholate (as 100× stock) to 125 µg/ml and trichloracetic acid to 6% (w/v). Incubate on ice for 10 min.
8. Microcentrifuge samples 4 min at 10,000 × *g*, 4°C, and remove supernatant.

9a. *For SDS-PAGE*: Resuspend each pellet in an equal volume of of 2× SDS-PAGE sample buffer and neutralize by adding small amounts (~5 µl) of 1 M Tris·Cl, pH 8.0, and use for SDS-PAGE (*UNIT 6.1*).

9b. *For immunoprecipitation*: Resuspend each pellet in 100 µl of 1% (w/v) SDS/200 mM Tris·Cl pH 8.0. Boil 5 min, then dilute samples in 10 vol TNET buffer. Proceed with immunoprecipitation (*UNIT 7.2*).

BASIC PROTOCOL 3

DETERGENT SOLUBILIZATION OF TRITON X-100 INSOLUBLE INTEGRAL MEMBRANE AND GPI-LINKED PROTEINS

Several caveolar membrane components are selectively resistant to solubilization by Triton X-100 at 4°C, which is the most commonly used protocol for the solubilization of integral membrane proteins. The unusual Triton insolubility of these caveolar domains has been attributed to their high glycosphingolipid content, as glycosphingolipids are intrinsically Triton-insoluble. They can, however, be solubilized in other detergents, such as octylglucoside or CHAPS. Solubilization can also be performed using SDS under experimental conditions that permit denaturation of protein or protein complexes.

Materials

Cells of interest
Phosphate-buffered saline (PBS; *APPENDIX 2A*)
Detergent solution—one of the following:
60 mM *N*-octylglucoside in either TBS (20mM Tris·Cl, pH 8.0/150 mM NaCl) or MES-buffered saline (25 mM MES, pH 6.5/150 mM NaCl)
30 mM CHAPS in either TBS (20mM Tris·Cl, pH 8.0/150 mM NaCl) or MES-buffered saline (25 mM MES, pH 6.5/150 mM NaCl)
Wash buffer containing Triton X-100 (*UNIT 7.2*)

Additional reagents and equipment for immunoprecipitation (*UNIT 7.2*)

1. Wash 1×10^6 to 1×10^7 cells twice in PBS (see Basic Protocol 1, steps 1a and 1b).
2. Add 1 ml of 60 mM *N*-octylglucoside or 30 mM CHAPS in TBS or MES-buffered saline. Vortex, then incubate at 4°C for 30 min to 1 hr.

   60 mM N-octylglucoside is most frequently used for solubilizing caveolae because it is the most efficient detergent for this purpose.

3. Centrifuge 10 min at 15,000 × *g*, 4°C, to remove insoluble debris.
4. Use the supernatant for a standard immunoprecipitation reaction (*UNIT 7.2*).

5. Wash immunoprecipitates with Triton X-100–containing wash buffer as described in *UNIT 7.2*.

   This alternative wash buffer is used to minimize the amount of N-octylglucoside needed, as that detergent is rather expensive. After washing, the packed beads can be stored frozen for weeks.

TRITON-BASED PURIFICATION OF CAVEOLAE-DERIVED MEMBRANES

BASIC PROTOCOL 4

Caveolae are vesicular organelles attached to the plasma membrane that have a characteristic lipid and protein composition (Sargiacomo et al., 1993; Lisanti et al., 1994). Caveolae membranes are highly enriched in glycosphingolipids and cholesterol, making them extremely light and therefore buoyant in sucrose density gradients. This unique lipid composition also confers resistance to solubilization by nonionic detergents such as Triton X-100 and NP-40 at low temperatures. For example, when intact cells were fixed in paraformaldehyde, extracted with Triton X-100, and then examined by electron microscopy, the insoluble membranes that remained were found to be caveolae (Moldovan et al., 1995). These special properties allow the isolation of caveolae from other cell organelles as described below and in Alternate Protocol 4.

Materials

MDCK (Madin-Darby canine kidney) cells (or virtually any other nontransformed cell line)
DMEM medium containing 5% FBS (*UNIT 1.2*) with 100 IU/ml penicillin and 50 µg/ml streptomycin
Phosphate-buffered saline (PBS; *APPENDIX 2A*), ice-cold
Lysis buffer for caveolae (see recipe)
5%, 30%, and 80% sucrose solutions (see recipe)
MES-buffered saline: 25 mM 2-(*N*-morpholino)ethanesulfonic acid (MES)/150 mM NaCl

75-cm^3 tissue culture flasks
150-mm tissue culture dishes
Cell scrapers
15-ml tubes
Dounce homogenizer
Beckman L8 ultracentrifuge with SW 41 rotor and corresponding ultraclear centrifuge tubes

Additional reagents and equipment for cell culture and trypsinization of cells (*UNIT 1.1*), preparation of serum-containing tissue culture medium (*UNIT 1.2*), and preparation of sucrose gradients (*UNIT 5.3*)

1. Split MDCK cells by trypsinization (*UNIT 1.1*) from one 75-cm^2 flask into three 75-cm^2 flasks, and grow to confluence in DMEM/5% FBS . Split cells from the flasks into six 150-mm dishes. Let cells grow for at least 2 days (to confluence) before harvesting.

   Omit any antifungal agents such as Nystatin or Fungizone, as these are cholesterol-binding antibiotics that will disrupt caveolae architecture.

2. Rinse the cells in each 150-mm dish three times, each time with 20 ml ice-cold PBS. Thoroughly remove PBS and add 1 ml of ice-cold lysis buffer for caveolae. Collect cells with a cell scraper and place in a 15-ml tube on ice. Rinse dish with an additional 1 ml of lysis buffer for caveolae to collect remaining cells and pool with the first 1 ml in the tube.

   Use each plate for a separate gradient.

3. Homogenize with 8 to 10 strokes of a Dounce homogenizer. Adjust to 40% (w/v) sucrose by adding an equal volume (2 ml) of ice-cold 80% sucrose. Vortex briefly until homogeneous.
4. Place homogenate at the bottom of an ultraclear Beckman ultracentrifuge tube and form a linear gradient atop it, using 4 ml each of 5% sucrose and 30% sucrose, at a flow rate of not more than 0.5 ml per min (*UNIT 5.3*). Adjust the weight of each gradient to within 0.1 g.
5. Centrifuge 12 to 16 hr (overnight) at 200,000 × *g* (39,000 rpm in an SW 41 rotor), 4°C.
6. Collect twelve 1-ml fractions from the top (*UNIT 5.3*). Snap freeze in liquid nitrogen and store frozen at −80°C.

   Fraction 13 is the insoluble pellet.

   Subsequent analysis of the total fractions can be done without pelleting the membranes.
7. *Alternatively:* Harvest the opaque band (migrating at ~10% to 20% w/v sucrose), dilute with MES-buffered saline, and microcentrifuge 60 min at 15,000 × *g*, 4°C. Snap freeze the pellet in liquid nitrogen and store at −80°C.

   A 150-mm dish of MDCK cells representing 9 to 11 mg protein yields ~4 to 6 μg of caveolae-enriched membrane domains—i.e., ~0.05 % of the initial homogenate. Triton X-100 extraction solubilizes ~85% of the protein (8.5 mg), the majority of which remains in the 40% (w/v) sucrose layer, while ~1.5 mg forms an insoluble pellet below the 40% sucrose.

   Organelle-specific membrane marker assays can be performed (Sargiacomo et al., 1993; Lisanti et al., 1994). These assay systems are not affected by the presence or absence of 1% Triton X-100 in the initial homogenate.

   The purified caveolar fractions can be combined.
8. Store frozen at −80°C for months, until further use in immunoblotting or immunoprecipitation.

ALTERNATE PROTOCOL 4

DETERGENT-FREE PURIFICATION OF CAVEOLAE-DERIVED MEMBRANES

Recently, it has been suggested that the inclusion of detergent in the initial homogenization step results in the loss of resident prenylated caveolin-associated proteins, such as $G_{\beta\gamma}$ subunits. To preserve these interactions, a detergent-free method for the purification of caveolin-rich membrane domains has been developed. This slightly modified scheme replaces the detergent Triton X-100 with sodium carbonate. Sodium carbonate extraction is routinely used to determine if proteins are firmly attached to membranes and caveolin is not solubilized by sodium carbonate. Using this modified scheme, endogenous caveolin and recombinant caveolin have been shown to be recovered almost quantitatively in fractions 5 and 6 while excluding most cellular proteins. In addition, caveolin has been shown to be separated from the GPI-linked plasma membrane marker, carbonic anhydrase IV. This is consistent with recent observations that GPI-linked proteins are not concentrated directly within caveolae but may reside in close proximity to the ''neck regions'' of caveolae within intact cells. This method is adapted from Song et al. (1996).

Materials

MDCK (Madin-Darby canine kidney) cells or any other cell
Phosphate-buffered saline (PBS; *APPENDIX 2A*), ice cold
500 mM sodium carbonate, pH 11, ice cold

MES-buffered saline: 25 mM MES, pH 6.5/0.15 M NaCl
MES-buffered saline plus 1% (w/v) Triton X-100 and PMSF
5%, 35%, and 90% (w/v) sucrose (see recipe)
3× SDS-PAGE sample buffer (see recipe)

Cell scrapers
Polytron tissue grinder (Kinematica GmbH, Brinkmann Instruments)
Branson Sonifier 250 (Branson Ultrasonic)
Beckman ultracentrifuge with SW 41 rotor and corresponding (14 × 89–mm) ultraclear tubes

Additional reagents and equipment for immunoprecipitation (*UNIT 7.2*) and SDS-PAGE (*UNIT 6.1*)

1. Culture cells to produce six 150-mm plates at confluence (see Basic Protocol 4, step 1). Wash cells three times with ice-cold PBS (see Basic Protocol 4, step 2).
2. Add 1 ml ice-cold 500 mM sodium carbonate, pH 11.0 to one plate of cells, scrape the cells into the liquid and transfer to the second plate. Continue in this manner for all six plates. Repeat with a second 1-ml aliquot of sodium carbonate and combine.
3. Place cells on ice. Disrupt the cells using a Polytron tissue grinder at maximum setting for 30 sec.
4. Sonicate cells constantly for 30 sec at setting 2 on the Branson Sonifier 250. Next, sonicate cells with 30-sec bursts at a setting of 4 or 5. Look at the lysate. If it is relatively clear and free of clumps, then it is ready to use. If not, sonicate an additional 30 sec at setting 2.
5. Add the 2 ml of cell lysate to 2 ml of 90% (w/v) sucrose in a 14 × 89–mm Beckman centrifuge ultraclear tube. Vortex until homogeneous.

   The volume of tube is a little more than 12 ml.

   After mixing with the cell lysate the final concentration of sucrose is 45% (w/v).
6. Atop the 45% layer, add 4 ml of 35% sucrose, then 4 ml of 5% sucrose, to generate a discontinuous sucrose gradient.

   Be careful when adding successive layers so as to not disrupt the layer beneath.
7. Centrifuge 12 to 16 hr (overnight) at 200,000 × *g* (39,000 rpm in an SW 41 rotor), 4°C.
8. Collect twelve 1-ml fractions from the top (*UNIT 5.3*). Snap freeze all fractions in liquid nitrogen and store frozen at −80°C.

   Fraction 13 is the insoluble pellet.

   A light-scattering band confined to the 5%/35% sucrose interface contains caveolin, a protein concentrated in caveolae, but excludes most other cellular proteins. Analyze total fractions (do not pellet).

   The purified caveolar fractions can be stored frozen at −80°C for months until further use in immunoblotting (UNIT 6.2) or immunoprecipitation (UNIT 7.2).
9. Mix with an equal volume of 3× SDS-PAGE sample buffer that contains 100 mM NaOH to disrupt SDS-resistant caveolin complexes. Analyze by SDS-PAGE (*UNIT 6.1*).

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Cell lysis buffer

1% (w/v) Triton X-114 (from precondensed stock; see Support Protocol 1)
10 mM Tris·Cl, pH 7.4 (*APPENDIX 2A*)
150 mM NaCl
1 mM EDTA
Store up to 1 month at 4°C
10 µl/ml 100× protease inhibitor stock solution (see Support Protocol 2; final concentration 10 µg/ml each of antipain, pepstatin, and leupeptin), added immediately before use

Lysis buffer for caveolae

1% (w/v) Triton X-100
25 mM 2-(*N*-morpholino)ethanesulfonic acid (MES)
150 mM NaCl
Store up to 1 month at 4°C
Add 100 µl of saturated ice-cold ethanol solution of PMSF per 10 ml of buffer immediately before use.

PI-PLC incubation buffer

100 mM Tris·Cl, pH 7.4 (*APPENDIX 2A*)
50 mM NaCl
1 mM EDTA
0.5 M methyl-α-D-mannopyranoside
Prepare fresh

SDS sample buffer with NaOH, 3×

150 mM Tris·Cl, pH 6.8
300 mM dithiothreitol
6% (w/v) SDS
0.3% (w/v) bromophenol blue
30% (w/v) glycerol
30 mM NaOH
Add 1 M NaOH to a final concentration of 100 mM just before use
Store up to several months at −20°C

Sucrose solutions for Basic Protocol 4 (80%, 30%, and 5% w/v)

80% (w/v): Prepare an 80% (w/v) solution of sucrose in MES-buffered saline [25 mM 2-(*N*-morpholino)ethanesulfonic acid (MES), pH 6.5/150 mM NaCl, without PMSF or Triton X-100].

30% (w/v): Dilute 37.5 ml of 80% (w/v) sucrose to 100 ml with MES-buffered saline.

5% (w/v): Dilute 6.25 ml of 80% (w/v) sucrose to 100 ml with MES-buffered saline.

Prepare fresh each time

Sucrose solutions for Alternate Protocol 4 (90%, 35%, and 5% w/v)

90% (w/v): Prepare 90% (w/v) sucrose in MES-buffered saline (final concentration of MES is 10 mM, pH 6.5, and that of NaCl is 150 mM; the rest of the volume is water). Since 90% (w/v) sucrose is hard to dissolve, it is generally heated. First, heat a beaker of water until it boils. Next, place the 90% sucrose mixture, contained in a smaller uncapped beaker/bottle, in the boiling water. Stir the sucrose until it completely dissolves. Store 90% (w/v) sucrose at room temperature for up to one

year (it crystallizes at colder temperatures). Prechill only the amount to be used, just before use.

35% (w/v): Dilute 90% (w/v) sucrose to 35% (w/v) in MES-buffered saline containing 250 mM sodium carbonate, pH 11.0.

5% (w/v): Dilute 90% (w/v) sucrose to 5% (w/v) in MES-buffered saline containing 250 mM sodium carbonate, pH 11.0.

Store the diluted sucrose solutions up to 6 months at 4°C.

A stock solution of 500 mM sodium carbonate is made by simply dissolving sodium carbonate in water. The pH of the solution is about 11. The pH does not need to be adjusted. This solution can be stored at 4°C up to one year.

TNET buffer

1% (w/v) Triton X-100
150 mM NaCl
5 mM EDTA
25 mM Tris·Cl, pH 8.0 (*APPENDIX 2A*)
Store up to 1 month at 4°C
10 µl/ml 100× protease inhibitor stock solution (see Support Protocol 2), added immediately before use

TNET-OG buffer

1% (w/v) Triton X-100
150 mM NaCl
5 mM EDTA
25 mM Tris·Cl, pH 8.0 (*APPENDIX 2A*)
60 mM *N*-octylglucoside
Store up to 1 month at 4°C
10 µl/ml 100× protease inhibitor stock solution (see Support Protocol 2), added immediately before use

Tris/NaCl/EDTA buffer

10 mM Tris·Cl, pH 7.4 (*APPENDIX 2A*)
150 mM NaCl
1 mM EDTA
Store up to 1 month at 4°C
10 µl/ml 100× protease inhibitor stock solution (see Support Protocol 2), added immediately before use

COMMENTARY

Background information

From a practical point of view, it is essential to isolate membranes that preserve their in vivo physical properties in order to identify proteins associated with specific membrane domains. The membrane isolation method that uses high pH sodium carbonate buffer efficiently removes peripherally associated proteins (>90%), releases <10% of the integral membrane proteins in caveolae, and preserves the original membrane properties. Thus this method is useful for preparing membranes for further isolation of specific domains. Integral proteins are also not removed using high salt buffer (1 M or 3 M NaCl or 0.6 M KCl) or urea, treatments which efficiently remove peripheral proteins. Extraction with urea and high salt are alternative methods for isolating membranes to identify integral membrane components.

Caveolae

Caveolae are vesicular organelles attached to the plasma membrane, with a diameter of ~50 to 100 nm. The principal protein components of caveolae are members of the caveolin family of proteins, termed caveolins 1, 2, and 3. Caveolins 1 and 2 are most abundantly expressed in adipocytes, endothelial cells, and fibroblastic cell types, while the expression of

caveolin 3 is muscle-specific. Caveolins interact directly with a number of caveolae-associated signaling molecules, such as H-Ras, heterotrimeric G-proteins, epidermal growth factor receptor, protein kinase C, Src-family tyrosine kinases, and nitric oxide synthase (NOS) isoforms.

In addition to specific proteins, caveolae are enriched in certain lipids such as glycosphingolipids and cholesterol. Using liposomal systems, it has been well established that lipid microdomains consisting of glycosphingolipids and cholesterol can be formed when a certain ratio of glycosphingolipids, cholesterol, and phospholipids are mixed, even in the absence of protein components. It has been proposed that glycosphingolipids can be tightly packed with cholesterol because of their saturated fatty acid composition. These lipids are exclusively localized in the outer leaflet of the lipid bilayer. Phospholipids with saturated fatty acids and cholesterol constitute the inner leaflet of the microdomains. Caveolin associates with these microdomains by direct interaction with cholesterol and glycosphingolipids.

Caveolae purification

Several methods have been developed for purifying caveolae (Chang et al., 1994; Lisanti et al., 1994; Sargiacomo et al., 1993; Schnitzer et al., 1995a,b; Smart et al., 1995; Song et al., 1996). Initially, these methods took advantage of the natural detergent-insolubility of caveolae membranes. More recently, detergent-free methods have become available that are dependent on the intrinsic light buoyant density of caveolae membranes (Smart et al., 1995; Song et al., 1996). Purification of caveolae by all of these methods reveals the dramatic enrichment of caveolins and signaling molecules relative to plasma membrane. Signaling molecules appear to form a tight complex with caveolin 1.

Caveolae have also been shown to be detergent-resistant structures in vivo. For example, when intact cells were fixed with paraformaldehyde, extracted with cold Triton X-100, and then examined by electron microscopy, the insoluble membranes that remained were found to be caveolae (Moldovan et al., 1995). In support of these morphological findings, caveolins are Triton X-100–insoluble in caveolae (Sargiacomo et al., 1993; Lisanti et al., 1994), but Triton X-100 soluble in the Golgi (Smart et al., 1994). This compartment-specific Triton X-100 insolubility is most likely due to the association of caveolin with cholesterol and sphingolipids, which form a Triton X-100–insoluble microenvironment, termed a liquid-ordered phase.

Biochemical isolation of caveolae membrane domains takes advantage of the unique temperature dependence of solubilization with Triton X-100. Caveolae microdomains are solubilized by Triton X-100 at temperatures >8°C, but not at 4°C. Therefore, caveolae microdomains can be isolated biochemically from cultured cells or tissues as insoluble material after solubilizing the cells with Triton X-100 at 4°C. Since caveolae membrane domains are light because of their lipid composition, caveolae microdomains are purified more than 2000-fold with a single sucrose gradient ultracentrifugation. Caveolae microdomains are recovered as a fine dense band at the border of 5% (w/v) and 35% (w/v) sucrose after ultracentrifugation at 200,000 × *g* overnight. Caveolin-1 is used as a marker protein for caveolae organelles. The amount of caveolae protein isolated by this procedure is typically 5 μg out of 10 mg starting material (equivalent to six 150-mm culture dishes). Caveolae structure is still preserved in caveolae isolated by this procedure. As octylglucoside possesses a similar structure to glycosphingolipids, this nonionic detergent is used for solubilization of caveolae microdomains. Although urea, as well as high salt, is frequently used for solubilization of membrane-bound proteins, these methodologies do not solubilize caveolae microdomains.

Although the use of Triton X-100 for caveolae isolation is straightforward and well established, not all caveolae protein components are recovered in the caveolae fraction by this procedure. For example, the H-Ras protein was initially proposed not to be a caveolar component. Triton X-100 is able to dissociate H-Ras and other prenylated proteins from caveolae microdomains. The same is true for Gβγ subunits. The sodium carbonate method has been developed to alleviate this problem. Because of its high pH, sodium carbonate solubilizes proteins peripherally associated with the membrane. In contrast, integral membrane proteins are not solubilized by this method. This method also allows purification of caveolae microdomains by more than 2000-fold. Caveolin-1 is again recovered within caveolae microdomains. The purity of caveolae microdomains obtained with this methodology is therefore comparable to that with the Triton X-100 method. The caveolae purification approach with sodium carbonate is termed the "detergent-free caveolae purification method." With this method, the H-Ras protein has been reproduc-

ibly recovered in caveolae microdomains. As caveolae residents are more broadly purified with detergent-free approaches, the authors recommend the detergent-free method as the first methodology to be employed for caveolae purification. Another potential problem in using Triton X-100 for caveolae isolation is a possible contamination of artificial lipid membrane domains for which lipid composition is similar to that of caveolae. Solubilized lipids released from membranes treated with Triton X-100 may form artificial lipid domains like caveolae, since glycosphingolipids have a high affinity for association with cholesterol. The detergent-free method has an advantage over the Triton X-100 method in this regard. The authors recommend using both of these methodologies to localize the protein of one's interest in caveolae.

Caveolae-related domains or pre-caveolae or both?

A number of investigators have purified "caveolae" from cells and tissues that lack apparent expression of caveolin (Kubler et al., 1996; Parolini et al., 1996; Brown and London, 1997; Simons and Ikonen, 1997). These domains have been termed detergent-insoluble glycolipid membrane complexes (DIGs), Triton-insoluble complexes (TICs), detergent-resistant membranes (DRMs), and low-density membranes (LDMs). The authors suggest that the term caveolae-related domains (CRDs) be used to describe these structures. Like caveolae, these microdomains are dramatically enriched in cholesterol, sphingolipids, and lipid-modified signaling molecules (Brown and London, 1997; Simons and Ikonen, 1997). The existence of "caveolae-related domains" or CRDs that do not contain caveolin has caused considerable confusion (Simons and Ikonen, 1997). However, this was at a time when only one caveolin gene was known to exist, i.e., caveolin (now termed caveolin-1). It is now known that there are other caveolin genes, such as caveolin-2 and -3. In addition, it has been shown that caveolin-1 and caveolae are down-regulated in response to cell transformation, while caveolin-2 levels remain constant (Scherer et al., 1997). As a consequence, many commonly used cell lines lack caveolin-1 protein expression and visible caveolae, because they are immortalized or transformed. Also, other detergent-insoluble membrane proteins have recently been cloned, and one or more of them may represent functional homologs of the caveolins (Bickel et al., 1997; Puertollano et al., 1997; Simons and Ikonen, 1997).

CRDs can also be produced in vitro simply by mixing cholesterol, sphingolipids, and phospholipids in the appropriate ratio (Brown and London, 1997). Their Triton insolubility is a physical property of their molecular organization that produces a liquid-ordered membrane domain (rather than fluid or liquid-crystalline). Caveolin-1 is found associated with glycosphingolipids in vivo as shown using chemical cross-linking with a radiolabeled glycosphingolipid GM1 (Fra et al., 1995a). It binds cholesterol directly (Murata et al., 1995) and requires a high local concentration of cholesterol (>30%) to insert into model lipid membranes (Murata et al., 1995; Li et al., 1996a). These findings suggest that a true functional relationship exists between CRDs and mature caveolae. For example, during the biogenesis of mature caveolae, CRDs would need to exist as precursors for proper insertion of caveolins into membranes. Thus, in cells that express caveolins, these CRDs may represent "pre-caveolae" that simply lack caveolins. In support of this reductionist model, recombinant expression of caveolin-1 in cells that lack morphologically detectable caveolae is sufficient to drive the formation of mature invaginated caveolae (Fra et al., 1995b; Li et al., 1996b; Engelman et al., 1997). This indicates that cells normally make the ingredients that are necessary for the formation of mature caveolae, and insertion of caveolin proteins may only be a late phase in this process.

GPI-anchored proteins and their association with caveolae

The GPI anchor contains two fatty acyl groups and several sugars, including glucosamine, mannose, and inositol (Fig. 5.4.1). Various experiments have shown that the phospholipid anchor is both necessary and sufficient for binding these cell-surface proteins to the plasma membrane. The enzyme PI-specific phospholipase C cleaves the phosphate-glycerol bond in phospholipids as well as in glycosyl phosphatidylinositol anchors. Treatment of cells with phospholipase C releases glycosyl phosphatidylinositol-anchored proteins such as the Thy-1 protein and alkaline phosphatase from the cell surface. Experimentally, the PI-PLC mediated cleavage can be performed in intact cells, extracted membranes, and purified proteins reconstituted in liposomes.

GPI-linked proteins can be associated with CRDs and caveolae in the outer leaflets of lipid bilayers by using their saturated fatty acid moiety directly inserted into the unique lipid environment.

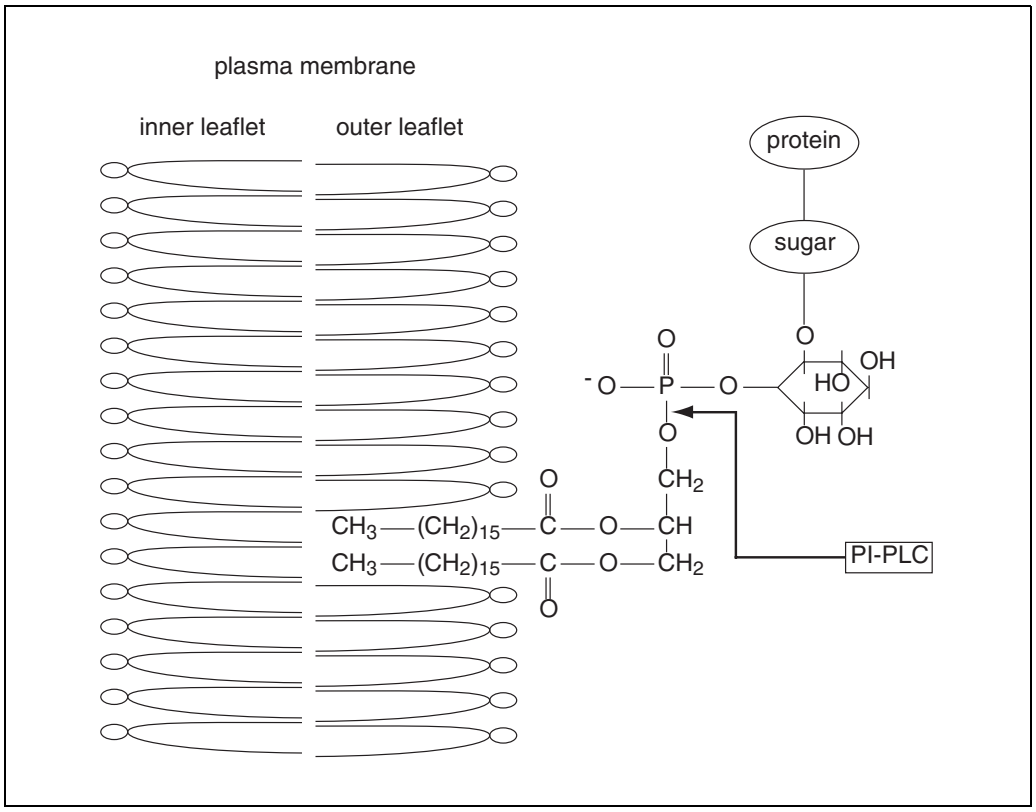

Figure 5.4.1 The glycosyl phosphoinositol (GPI) anchor. PI-PLC, phosphatidylinositol-specific phospholipase C.

It has been debated whether GPI-anchored proteins are constitutively associated with caveolae or are only associated with caveolae upon cross-linking with antibody probes. In the case of the tissue factor (TF) receptor system, this GPI-anchored protein is only associated with caveolae upon binding its natural ligand (Sevinsky et al., 1996). Thus, antibody probes may mimic natural endogenous ligands and target clustered GPI-anchored proteins to caveolae.

GPI-anchored molecules are recovered associated with membrane fractions that are resistant to solubilization to 1% Triton X-100 or 1% Triton X-114 at 4°C. It is, therefore, reasonable to speculate that GPI molecules are also associated with membrane domains with basic biochemical characteristics similar to those of caveolae, irrespective of the argument whether GPI molecules are in fact localized in caveolae. This assumption is further strengthened by the fact that the membrane fraction which contains GPI molecules is solubilized by 60 mM *N*-octylglucoside in a highly efficient manner. Of note, 20 mM CHAPS is less effective in its solubilization. At 37°C, however, 1% Triton X-100 solubilizes GPI-containing membrane with a similar efficiency to that of *N*-octylglucoside. At this temperature, 1% Triton X 114 solubilizes the membrane with 60% efficiency compared to Triton X-100. Since Triton X-114 partitions GPI molecules to the aqueous phase with PI-PLC treatment, Triton X 114 phase separation is used for the detection of GPI molecules in membranes. This method also makes it possible to identify membranes which have a similar biochemical property to that of caveolae.

Critical Parameters

Whether a given protein is an integral or peripheral membrane protein can be determined by alkaline carbonate extraction, urea extraction, high-salt extraction, and Triton X-114 phase separation protocols. The following parameters should be kept in mind while performing experiments.

In order to avoid protein degradation, experiments should be performed at 4°C. Solutions should also be chilled before use. For Triton X-114 phase separation, samples should be incubated at 37°C after solubilization, then centrifuged at room temperature.

In order to achieve optimal solubilization, the authors recommend that solubilization be performed from 30 min to 1 hr. For Triton

X-114 phase separation, samples should be kept at 37°C for 3 min after solubilization. This 3-min incubation should be strictly observed for achieving optimal phase separation and avoiding protein degradation.

Membrane proteins have ionic as well as hydrophobic interactions, and for this reason 150 mM NaCl is included in solubilization solutions for Triton X-114 phase separation protocol. As the salt concentration is already high, 100 mM NaCl is sufficient for the alkaline carbonate protocol. In urea and high-salt protocols, no additional NaCl is necessary.

The efficiency of solubilization is directly influenced by protein-salt extraction methods, and 1 ml of the Triton X-114-containing lysis buffer per 2–5 × 10^7 cells should be strictly observed for Triton X-114 phase separation protocols (see Basic Protocol 4, step 1).

In Basic Protocols 1 and 3, the criterion for solubilization is retention in the supernatant after centrifugation of solutions for 1 hr at 105,000 × *g*. The authors recommend centrifugation at 150,000 to 200,000 × *g* for 1 hr in order to recover completely solubilized proteins.

In order to avoid cyanate formation from urea, it is important to prepare urea solution just before use. For Triton X-114 stock solution, precondensation is required to remove impurities. Protease inhibitors can be kept as 100× condensed solutions in freezer.

PI-PLC cleavage releases GPI-linked proteins from membranes. In the method described here (Basic Protocol 2), PI-PLC cleavage should be performed at 37°C in Triton X-114-containing solution for at least 1 hr.

Proteins in caveolae or CRD, including GPI-anchored proteins, are solubilized in 60 mM *N*-octylglucoside or 30 mM CHAPS at 4°C. The following parameters should be kept in mind while performing these experiments.

Detergent solubility is strictly dependent upon the temperature. Temperature should be kept below 4°C in order to assess the Triton X-100 insolubility of the protein in CRD. All the experiments should be performed on ice. At 8°C, most of the proteins in CRD can be solubilized even by buffers containing 1% Triton X-100 as the detergent. This should be kept in mind especially when purifying caveolae using sucrose density gradient centrifugation. Cell extraction with Triton X-100 should also be performed at 4°C. It is recommended that the experiment be performed in the cold room, with the temperature kept below 4°C. Solutions should also be kept at 4°C before use.

Perform solubilization for 30 min to 1 hr in order to avoid protein degradation by proteases and insufficient solubilization.

The authors recommend detergent solubilization of proteins in CRD at concentrations of 60 mM *N*-octylglucoside or 30 mM CHAPS. These concentrations were determined by the critical micellar concentration (CMC) of these detergents. In order to achieve complete solubilization of proteins localized in CRDs, it is important to use detergents at twice the concentration of CMC value.

Add protease inhibitors to the solubilization buffer to a final 1× concentration in order to prevent protease-mediated degradation of proteins during solubilization. This is especially important when whole animal tissues are used as a source of protein for extraction. The protease inhibitors (Support Protocol 2) should be used in TNET-OG buffer, TNET buffer, and cell lysis buffer. 1 mM PMSF alone is sufficient for lysis for caveolae.

NaCl at 150 mM should be added to the solubilization buffer in order to maintain proteins under physiological conditions.

Caveolins are the principal protein component of caveolae. It is therefore of essence to probe the blot of fractionated samples with anti-caveolin antibodies, which are available commercially from Transduction Laboratories (see *SUPPLIERS APPENDIX*) to track the position of caveolae-derived membranes in these sucrose density gradients.

Anticipated Results

Integral membrane proteins can be separated from soluble and peripherally associated membrane proteins using alkaline carbonate extraction, urea extraction, or high-salt extraction protocols. In the Triton X-114 phase separation protocol, the aqueous phase contains peripherally associated membrane proteins and the detergent phase contains integral membrane proteins.

Proteins within CRDs can be separated from non-CRD proteins, as long as 1% Triton-X 100 is used at temperatures below 4°C. More than 99.95% of the CRD protein can be separated from non-CRD proteins following ultracentrifugation on a sucrose gradient.

Time Considerations

For alkaline carbonate extraction, urea extraction, and high-salt extraction protocols, it takes 1 hr for cell preparation and solubilization, 1 hr for centrifugation, 1 hr for SDS-PAGE, and 24 hr for immunoblotting. For Tri-

ton X-114 phase separation, it takes 3 hr for cell preparation and solubilization, 1 hr for SDS-PAGE, and 24 hr for immunoblotting.

For purification of caveolae, detergent solubilization takes 1 hr and ultracentrifugation requires 24 hr. SDS-PAGE takes one hr and immunoblotting takes another 24 hr. Results will be available within 2 days.

Determination of Molecular Size by Size-Exclusion Chromatography (Gel Filtration)

One of the most popular methods for measuring the size of proteins is size-exclusion chromatography (SEC). Gel filtration is a synonymous term for SEC, except that the former indicates an aqueous mobile phase whereas the latter is more general. The principle underlying separation is as follows: the chromatographic support, or gel, consists of particles containing pores that can be penetrated by solute molecules to a degree dependent on their molecular size. Hence solute molecules partition, as a function of size, between mobile phase contained inside and outside the support particles. When a column is packed with such a support and a mobile phase is passed through it, larger molecules emerge earlier than smaller ones because the latter have more mobile phase available to them through increased access to the interior of the beads.

SEC is widely used for separation and characterization of polymers, including biological macromolecules, especially proteins. In addition to giving information on protein size, SEC can also be used for purification, analysis of purity, and for study of protein interactions, either self-association or with other molecules. This unit is concerned with the application of SEC for investigating molecular size of cellular proteins in their native (non-denatured) state. Sample, such as tissue extract, is applied to the column and mobile phase (aqueous buffer) is pumped through the column. Protein peaks in the eluate are visualized by on-line spectrophotometric detection, and fractions are collected for further analysis by specific assays to identify the elution volume, V_e, of each protein. Using this value and two additional parameters, V_o, the void volume, and V_t, the total volume, a distribution coefficient, K_d, for each protein can be calculated. The size of each protein can be then determined provided that the SEC column has been previously calibrated with suitable protein standards. Size is most commonly expressed as Stokes radius, R_S, a parameter that is known for many proteins. Some proteins that are recommended for use as calibration standards are listed in Table 5.5.3. If additional parameters gained from sedimentation analysis are available, the molecular weight may also be calculated (see *UNIT 5.3*).

Gel filtration is the term originally applied during development of the technique in the 1950s, and continues to be widely used by biochemists, and indeed by manufacturers, for SEC in an aqueous mobile phase. Conventional gel filtration is carried out on soft gels, such as Sephacryl, in glass or plastic columns with flow controlled by peristaltic pumps or gravity, and run times on the order of several hours. Improvements in technology have led to the introduction of new supports with decreased particle size and increased efficiencies, though requiring higher operating pressures. These size-exclusion high-performance liquid chromatography (SE-HPLC) systems have enabled purification and analysis of proteins to be carried out ten to a hundred times faster than by conventional gel filtration. A medium-pressure high-performance system called fast protein liquid chromatography (FPLC) that avoids the use of stainless steel components has been developed by one major supplier (Amersham Pharmacia Biotech). Columns developed for this system can also be operated on ordinary HPLC systems. In this unit protocols are provided for SE-HPLC (Basic Protocol 1) and for conventional gel filtration (Basic Protocol 2) including calibration of columns in terms of Stokes radius, R_S, using protein standards.

STRATEGIC PLANNING

Conventional SEC or SE-HPLC

This initial decision on whether to use a conventional or high-performance system is largely dictated by availability of equipment. Workers in laboratories with easy access to an HPLC or FPLC system and prepacked high-performance columns will benefit from much faster run times. However, if such equipment is unavailable then an empty column can be packed with gel and operated on a conventional chromatography system. This latter option clearly requires more time, not only for actual runs but also for conditioning the gel, packing the column, and checking its performance (see Basic Protocol 2). Its major advantage is that much larger volumes of sample can be processed.

Fractionation Range and Selectivity

Selection of the most appropriate prepacked column or packing material is crucial for success, since the support pore size controls the solute size range in which fractionation occurs. Different supports contain beads whose pores range in size from ~3 nm to 100 nm. Manufacturers usually specify pore size and indicate the fractionation range in terms of molecular weights of polymer types, with polypeptides and dextrans often being listed as examples. For example, Zorbax GF-250 prepacked columns, with 15-nm pore size, are stated as having a fractionation range for proteins from 4,000 to 400,000 daltons (Da). Fractionation ranges, pore size, particle size, and suppliers are listed in Table 5.5.1 for a selection of prepacked columns, and in Table 5.5.2 for a selection of packing materials. More detailed information is available on products from a wide variety of manufacturers listed in Wu (1999). Manufacturers' catalogues often show plots Kd against log molecular weight. For most globular proteins, this plot is a sigmoidal curve that is approximately linear in the middle section, where

$$K_d = a - b \log M$$

Table 5.5.1 Prepacked Columns for HPLC or FPLC[a]

Column	Pore size (nm)	Fractionation range for globular proteins (Da)	Particle size (μm)	Dimensions (diameter × length, mm)	Company[b]
Superdex 75 HR 10/30	6	3000-70,000	13	10 × 300	APB

where a is the intercept on the ordinal axis and b is the slope.

From such plots one can estimate fractionation range (the working range lies in the linear portion, between $\sim 0.9 > K_d > 0.1$) and the selectivity. This latter parameter depends on the slope of the plot and is a function of the pore size distribution. A support with average pore size distribution in a narrow band gives high selectivity (large value of b) but a restricted separation range (the larger the value of b, the lower the range of values for M). If no estimate is available for the size of the protein under investigation, it is better to use a support with a broad fractionation range. A support of higher selectivity in a more restricted fractionation range can then be used later to give a more precise value for solute size.

Selecting a Column for Conventional SEC

For conventional SEC a suitable empty column must be chosen for packing. Dimensions are typically 1 to 1.6 cm internal diameter and 50 to 100 cm long. Suitable columns include the C and XK series from Amersham Pharmacia Biotech, available in lengths up to 100 cm. These columns can be equipped with adaptors that enable the eluant to be applied directly to the bed surface. Other accessories include packing reservoirs so that the total gel bed can be poured in a single operation. For the highest degree of reproducibility, a thermostatic jacketed column may be used to allow precise temperature control. Alternatively, the column may be operated in a cold room. This may be particularly important for samples that must be kept at low temperatures. For many purposes, however, operation at room temperature, often in the presence of antimicrobial agents is adequate. In the case of SE-HPLC the short run times (10 to 15 min) generally mean that low temperatures are not necessary.

Identifying Peaks

Identifying the elution volume of each protein peak during calibration of a column with protein standards is carried out by on-line detection, usually with a UV monitor measuring absorbance at 210 to 220 or at 280 nm. However, when a sample of cell extract is subjected to chromatography there will be many proteins present and baseline resolution between them is unlikely to occur, so that peak identification is impossible. Identification of the elution volume of the protein of interest is then dependent on collecting the eluate using a fraction collector and assaying each fraction. Possible assays include electrophoresis and immunoblotting (Chapter 6), measurement of enzyme activity, and ligand-binding.

It is important that sufficient material is present in each fraction to facilitate the assay, but otherwise fraction volume should be minimized to reduce error in estimating elution volume. For example, fraction volume of 0.05 to 0.2 ml would be appropriate for SE-HPLC columns that have V_i values of 5 to 10 ml, whereas fraction volume of 1 ml would be sufficient to reduce error in estimating V_e to ~1% for conventional columns with V_i values of ~100 ml.

BASIC PROTOCOL 1

SE-HPLC

This protocol describes separation on a prepacked column using an HPLC system. It is the protocol of choice unless large sample volumes or lack of equipment require the use of a conventional chromatography system. A prepacked column is connected to an HPLC system and is equilibrated with mobile phase. Elution volumes are then determined for standards and sample. FPLC gives similar results (see Table 5.5.1 for FPLC-compatible columns).

Materials

Mobile phase (see recipe)
Total volume (V_t) marker (see recipe)
Void volume (V_o) marker (see recipe)
Protein calibration standards (see recipe)
Solution in mobile phase of protein whose size is to be determined

0.22-µm filters (protein-compatible type for solutions containing protein)
HPLC system, comprising injector, one pump, UV-detector, and chart recorder or integrator
Prepacked SE-HPLC column (Table 5.5.1) with appropriate fractionation range (see Strategic Planning)
Guard column
10- to 100-µl syringe compatible with injector used
Filtration apparatus
Vacuum pump
Fraction collector

Chromatographic procedure

1. Prepare mobile phase and filter through a 0.22-µm filter under vacuum.

   This removes dust particles and so improves column life. It also degasses the mobile phase, which helps prevent air bubbles forming in the detector; air bubbles can give rise to spurious peaks. However, it is less crucial to degas mobile phase for SE-HPLC than for reversed phase HPLC because, unlike the latter mode, there is no mixing of aqueous and organic solvents, a process that produces bubbles.

2. Prime HPLC pump and injector with mobile phase.

3. Connect the outlet of the injector to the inlet of the guard column. Connect the outlet of the guard column to the inlet of the main column. Connect the outlet of the main column to the inlet of the detector.

   Most manufacturers sell guard columns appropriate for use with their size-exclusion columns. In order to protect the expensive size-exclusion column it is strongly recommended that a guard column be used to remove particle contaminants and protein aggregates.

4. Allow the guard column and column to equilibrate in the mobile phase at the flow rate to be used for chromatography until the absorbance at the chosen wavelength for detection is constant.

   Columns are usually stored in 0.02% sodium azide or ethanol/water mixtures to prevent bacterial growth. When changing to the mobile phase required, some manufacturers

recommend that the flow rate should not exceed half the normal maximum flow rate. The flow rate to be used depends on the column/packing combination, and manufacturers' recommendations should be consulted so that maximum pressures are not exceeded. Typical flow rates are 1 ml/min, but sharper peaks may be obtained at lower flow rates of 0.5 or even 0.1 ml/min. Run times will, of course, be correspondingly longer, and for size estimation there is little advantage to be gained in very low flow rates (see Commentary, Resolution).

Proteins can be detected at various wavelengths in the UV range. Detection at 214 nm is more sensitive than at 280 nm (Shaw, 1997).

5. Using the syringe compatible with the injector, inject 20 µl of void volume marker to determine V_o.

   Because of the high reproducibility of flow rate given by HPLC pumps, time rather than volume is measured and volumes are calculated using the flow rate.

6. Inject 20 µl of total volume marker to determine V_t.

7. Inject a solution (20 µl) of one of the protein calibration standards and determine its elution volume, V_e, from the time at which the absorbance peak is at a maximum. Repeat this procedure until all the standards have been injected.

   A chromatogram showing the separation of seven solutes during a single run on a Zorbax Bio-series GF-250 column is shown in Fig. 5.5.1. One would not normally attempt to run

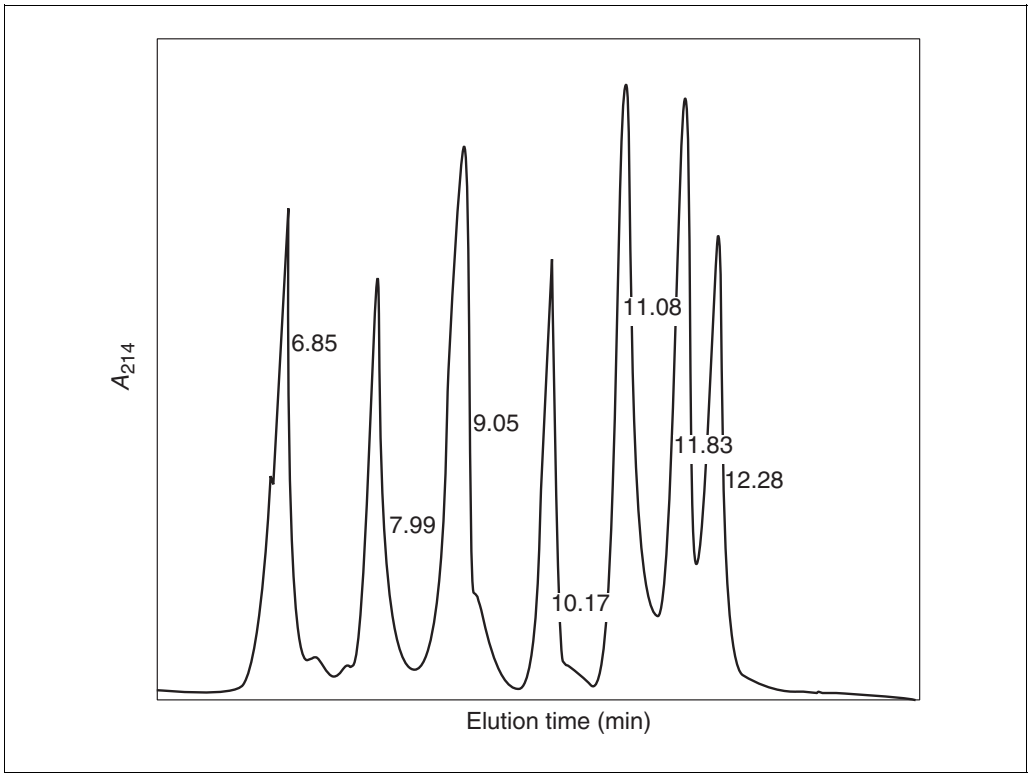

Figure 5.5.1 Separation of a mixture of seven solutes on a Zorbax Bio-series GF-250 column. 20 µl of a mixture containing ~1.5 µg of each protein was injected. The solutes were, in order of elution, thyroglobulin, alcohol dehydrogenase, ovalbumin, myoglobin, insulin, glucagon and sodium azide. The number beside each peak is the elution time in minutes. The absorbance of the highest peak, insulin, was 0.105. The equipment was a model 501 pump, a 441 absorbance detector operating at 214 nm, a 746 data module, all from Waters and a Rheodyne model 7125 injector with 20-µl loop. The column was a Zorbax Bio-Series GF-250 with guard column (Dupont). The mobile phase was 0.2 M sodium phosphate buffer, pH 7.0, and the flow rate was 1 ml/min. This figure is reproduced from Irvine (1996) with permission from Humana Press, Totowa, N.J.

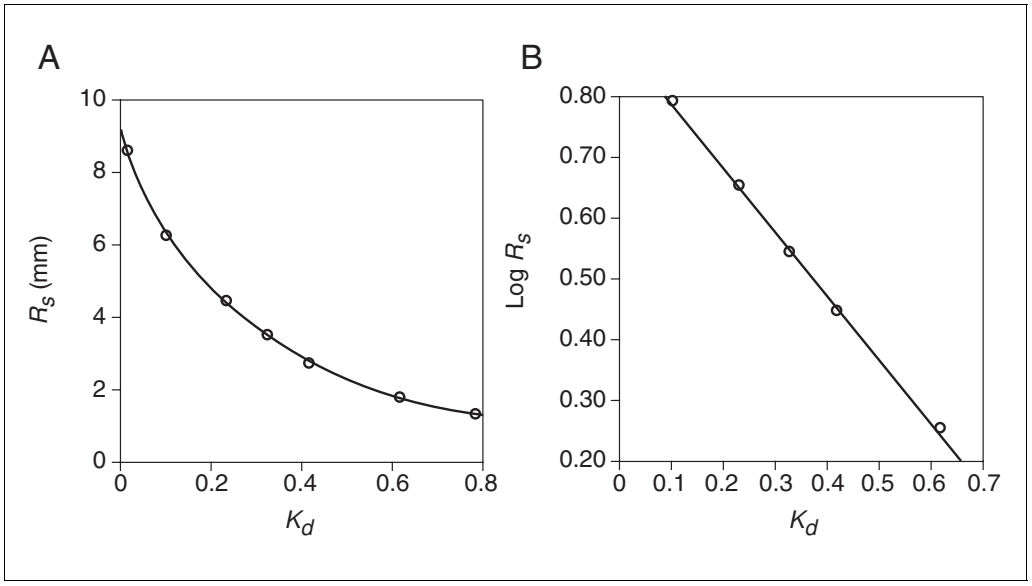

Figure 5.5.2 Plots of calibration curves for standard proteins. The data were obtained on the column and under the conditions described in Figure 5.5.1. The protein standards were thyroglobulin, apoferritin, yeast alcohol dehydrogenase, serum albumin, ovalbumin, myoglobin, and insulin. Stokes radii for these proteins are listed in Table 5.5.3 (except for alcohol dehydrogenase, with R_S = 4.55 nm). (**A**) A plot of R_S versus K_d in which all the data were used. (**B**) A plot of log R_S versus K_d. In the latter plot the top and bottom values of K_d (thyroglobulin and insulin) were omitted. V_o was determined to be 6.67 ml from the elution peak of blue dextran. V_t was determined to be 12.28 ml from the elution peak of sodium azide.

this number of standards at one time. The example does, however, show the resolution possible with SE-HPLC.

8. Inject a solution (20 µl) of the protein of unknown size and determine its elution volume, V_e, from the absorbance profile. If the sample contains more than one protein, and the peaks cannot be assigned with certainty, collect fractions and assay each fraction for the relevant activity.

   If a volume greater than 20 µl is required to facilitate assay, use this injection volume when measuring V_o and V_t and calibration standards. However, do not exceed 100 µl for a 7.5 × 300–mm column (see Commentary, Resolution).

9. If it is not to be used for several days, store the column in an appropriate antimicrobial solvent at room temperature.

Construction of calibration plots

10. Plot R_S versus K_d, and log R_S versus K_d.

    If the log plot is linear for the column used, it may be preferable to use this graph for estimating the size of the unknown protein.

    Once V_t, V_o, and the V_e values for a range of calibration standards are known for a column, it is possible to calculate K_d for each standard and construct a plot relating K_d and RS (see Background Information).

    Examples of such plots for protein standards on a Zorbax GF-250 column are shown in Figure 5.5.2.

    The R_S values for a number of proteins that have been shown to be suitable for column calibration are given in Table 5.5.3.

Table 5.5.3 Stokes Radii and Molecular Weights for Recommended Protein Standards[a]

Protein	Source	Molecular weight (Da)	Stokes radius (nm)
Cytochrome *c*	Horse heart	11,700	1.7
Ribonuclease A	Bovine pancreas	13,700	1.75
Myoglobin	Horse muscle	16,950	1.9
Trypsin inhibitor	Soybean	22,100	2.2
β-lactoglobulin	Bovine milk	35,000	2.75
Ovalbumin	Chicken egg	43,000	2.8
Alkaline phosphatase	*E. coli*	86,000	3.3
Serum albumin	Bovine serum	66,000	3.5
Transferrin	Human	81,000	3.6
Aldolase	Rabbit muscle	158,000	4.6
Catalase	Bovine liver	220,000	5.2
Aspartate transcarbamylase	*E.coli*	306,000	6.0
Apoferritin	Horse spleen	475,000	6.3
β-Galactosidase	*E.coli*	465,000	6.9
Thyroglobulin	Bovine thyroid	669,000	8.6

[a]Proteins found to be suitable for use as calibration standards as reported by Le Maire et al. (1986, 1987).

CONVENTIONAL SEC

BASIC PROTOCOL 2

This protocol describes how to pack a column and use it to carry out chromatography of proteins (see Table 5.5.2). Although acceptable results are obtained, the method is much more time consuming than using a prepacked column. However, larger sample volumes can be accommodated.

Materials

Mobile phase for conventional SEC (see recipe)
Gel filtration support (Table 5.5.2) with appropriate fractionation range (see Strategic Planning)
Colored marker (see recipe)
Total volume (V_t) marker (see recipe)
Protein calibration standards (see recipe)
Solution in mobile phase of protein whose size is to be determined

0.22-μm filters (protein-compatible type for solutions containing protein)
Buchner funnel and flask
Vacuum pump
Empty column (see Strategic Planning) with column fittings and packing reservoir
10-ml syringe
Peristaltic pump
UV-detector
Chart recorder or integrator
Filtration apparatus
Fraction collector
Sample applicator

Prepare the gel

1. Prepare mobile phase solution and filter through a 0.22-µm filter under vacuum.

   This removes dust particles and so improves column life. It also degasses the mobile phase, which helps prevent air bubbles forming in the column after it has been packed.

2a. *If the gel is supplied in dry form:* Weigh out the quantity of dry gel that will be required for the desired bed volume as calculated from the swelling factor given by the manufacturer. Add a volume of mobile phase equal to twice the final bed volume. Stir the slurry gently with a glass rod and allow the gel to swell for 24 hr.

   Stirring with a magnetic stir bar is not recommended as this can break the gel particles causing the formation of fines.

2b. *If the gel is supplied in pre-swollen form:* Wash the required quantity of swollen gel on a Buchner funnel to remove the storage buffer. Replace the storage buffer with a volume of mobile phase equal to twice the final bed volume.

3. Stir the slurry and then allow it to settle. Decant the liquid above the gel to remove fines. Replace the lost liquid with fresh mobile phase.

   Fines are damaged or smaller than average gel particles that can clog the gel bed or the nets at the column end. They can be detected as cloudiness in the top layer of liquid formed when the slurry is stirred and then allowed to stand. Since they settle more slowly than normal particles, they can be largely eliminated by repeatedly decanting.

4. Repeat step 3 until the liquid phase is clear. Adjust the volume of liquid so that the settled gel bed accounts for about half of the total volume.

Pour the column

5. Mount the column vertically (use a plumb line) on a laboratory stand.

   If the column has been used previously, make sure that it, and all fittings and nets, have been thoroughly cleaned. The column should be kept at a constant temperature and not placed in direct sunlight.

6. If the gel bed will occupy more than half the column volume, add a packing reservoir so that packing can be carried out in one operation.

   The packing reservoir is an extension that fits onto the top of the column and allows the whole gel slurry to be poured in one operation. It is required if the bed volume will be greater than half the volume of the empty column.

7. Add, via a syringe, a few milliliters of mobile phase through the outlet to flush back any air trapped in the outlet net. Close the outlet tubing.

   Ensure that the nets at the column ends are clean and have not been clogged by fines.

8. Repeat step 7 for the inlet adaptor and place it in a beaker of mobile phase to prevent air from entering.

   The adaptor is an adjustable column end piece. Columns are usually set up with one adaptor at the top and a fixed end piece at the bottom. The adaptor that will form the upper seal to the gel bed is slowly pushed down the inside of the column until it makes contact with the bed. Sample application is then much easier than to an unprotected layer of gel, where it is very easy to disturb the surface.

9. Prime the peristaltic pump with mobile phase and adjust the flow rate to the required value. Attach to the inlet of the column or packing reservoir. Stop the pump.

   Use a flow rate recommended by the manufacturer for the gel/column size combination (see, for example, Pharmacia Biotech, 1996). If the flow exceeds the recommended rate, the column bed may be compressed and flow rates will decrease.

10. Gently mix the gel slurry by swirling. In a single operation, pour the gel along a tilted glass rod into the column or reservoir.

Pack the column

11. Close the column using either reservoir lid or top adaptor, open the outlet and turn on the pump to start pumping mobile phase through the column. Check the flow rate because the back pressure from the column may alter the initial value.

12. Continue flow until the bed height is constant.

13. Stop the pump, remove packing reservoir if attached, and gently move the top adaptor flush onto the bed surface.

    Care must be exercised to keep the top of the bed layer even.

14. Resume flow for 1 hr to stabilize the gel bed height. Recheck the flow rate and readjust the adaptor flush onto the bed surface if necessary.

    For some gels the manufacturer recommends a higher flow rate at this stage than was used for packing the column. Otherwise use the same flow rate. After packing is complete there must be no space between the adaptor and gel bed as this would allow mixing to occur, especially during sample application, and this would adversely affect resolution.

Check the column

15. Inspect the column to ensure there are no cracks or air bubbles in the gel bed.

16. Inject an aliquot (~1% to 2% of the bed volume) of the colored marker using the sample applicator. Carry out chromatographic separation and determine the void volume from the blue dextran peak.

    Sample may be applied from a syringe via a valve system onto the column or into a loading loop. Sample may also be pumped directly onto the column. Sample loops have the advantage of giving reproducible sample volumes. For a well-packed column the colored marker should separate into sharp bands of color.

    V_o, or indeed the elution volume of any peak, requires accurate measurement of the volume of fractions collected. This can be done by weighing, although using a graduated cylinder may be acceptable. The elution volume will be the sum of the volumes of fractions prior to the fraction containing the peak apex, plus half the volume of that fraction.

17. Inject an aliquot of total volume marker and measure V_t.

    If it is desired to check the efficiency of the column, it is possible to calculate the number of theoretical plates from the equation

    $N = 5.54(V_e/W_h)^2$

    where N is the number of theoretical plates, V_e is the elution volume of peak, and W_h is the peak width at half the peak height.

    If efficiency is to be estimated from this step, the volume of sample loaded should not exceed 0.5% to 1% of V_t, otherwise peak width may be affected. For supports of small particle size (10-µm) use 0.5% V_t, whereas for 1000-µm particle size, 1% V_t is acceptable (Hagel, 1989). For most supports, V_t is between 80% and 95% of the bed volume.

18. Inject a solution (~1% to 2% of the bed volume) of one of the protein calibration standards and determine its elution volume, V_e, from the absorbance profile. Repeat this procedure until all the standards have been injected.

19. Inject a solution of the protein of unknown size and determine its elution volume, V_e, from the absorbance profile. If the sample contains more than one protein, and the peaks cannot be assigned with certainty, collect fractions and assay each fraction for the relevant activity (see Strategic Planning).

20. If it is not to be used for several days, store the column in an appropriate antimicrobial solvent at room temperature.

Construction of calibration plots

21. Plot R_S versus K_d, and log R_S versus K_d.

If the log plot is linear for the column used it may be preferable to use this graph for estimating the size of the unknown protein.

Once V_t, V_o, and the V_e values for a range of calibration standards are known for a column it is possible to calculate K_d for each standard and construct a plot relating K_d and R_S (see Background Information).

Examples of such plots for protein standards on a Zorbax GF-250 column are shown in Figure 5.5.2.

The R_S values for a number of proteins that have been shown to be suitable for column calibration are given in Table 5.5.3.

REAGENTS AND SOLUTIONS

Use Milli-Q purified water or equivalent for preparation of recipes. Filter all solutions through a 0.22-µm filter. Use a protein-compatible filter for sample solutions. Antimicrobial agents are often added to mobile phases, especially those in which columns are to be stored. 20% (v/v) ethanol is suitable for addition to columns and many gels for storage, but not during chromatography. Chlorhexidine (0.002% w/v) and sodium azide (0.02% w/v) are often used for the latter purpose. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

CAUTION: *Sodium azide is believed to be a mutagen. It should be handled with care (see suppliers' safety advice) and measures should be taken to avoid contact with solutions. It can also lead to explosions when disposed of via lead pipes. Solutions should be collected in waste bottles.*

Colored marker

Sequentially dissolve blue dextran (average molecular weight 2,000,000 Da) at 1 mg/ml, cytochrome *c* (molecular weight of 11,900 Da) at 4 mg/ml, and potassium dichromate (formula weight of 294 Da) at 1 mg/ml in 0.1 M sodium phosphate buffer, pH 7.0 (*APPENDIX 2A*) containing 0.1 M NaCl. Filter through a 0.22-µm filter. Store for 1 week at 4°C.

For a gel of large pore size (fractionation range lower limit 10,000 Da or more) omit the cytochrome c.

Mobile phase for conventional SEC

0.1 M sodium phosphate buffer, pH 7.0 (*APPENDIX 2A*) containing 0.1 M NaCl. Filter through a 0.22-µm filter. Store filtered buffer for 1 week at 4°C.

If antimicrobial agent, such as azide, has been added it can be stored for several months at 4°C.

The use of high ionic strength buffer is required to prevent ionic interactions, especially with silica-based columns (see Critical Parameters, Nonideal SEC). Sodoim chloride at 0.1 to 0.2 M is often added to SEC buffers for this purpose. It is advisable to consult the manufacturer's technical literature for advice on each individual packing material.

If antimicrobial agent is added it must be compatible with the assay or detection system used. For example, solutions of 0.02% (w/v) sodium azide have a high absorbance at low UV wavelengths, making detection at 214 nm impossible.

Mobile phase for SE-HPLC

0.2 M sodium phosphate buffer, pH 7.0. Filter through a 0.22-µm filter. Store filtered buffer for 1 week at 4°C.

If antimicrobial agent, such as azide, has been added it can be stored for several months at 4°C.

The use of high ionic strength buffer is required to prevent ionic interactions, especially with silica-based columns (see Critical Parameters, Nonideal SEC). Sodium chloride at 0.1 to 0.2 M is often added to SEC buffers for this purpose. However, if stainless steel systems are being used, it is better to avoid the use of chloride to prevent corrosion. It is advisable to consult the manufacturer's technical literature for advice on each individual column.

If antimicrobial agent is added it must be compatible with the assay or detection system used. For example, solutions of 0.02% w/v sodium azide have a high absorbance at low UV wavelengths, making detection at 214 nm impossible.

Protein calibration standards

Proteins suitable for use as standards are listed in Table 5.5.3. Dissolve each protein in the appropriate mobile phase at a concentration of ~0.5 mg/ml. Filter through a 0.22-µm filter.

Some proteins in solution can be stored for several months at −20°C, but others are unstable and must be freshly prepared. This must be determined by trial and error.

To save time, it is possible to mix two or more standards in the same run, provided the peaks are well separated and the proteins are homogeneous.

Total volume (V_t) marker

Dissolve acetone at a concentration of 5 mg/ml or sodium azide at a concentration of 10 mg/ml in the appropriate mobile phase. Filter through a 0.22-µm filter.

Water or deuterium oxide can also be used.

Detection of both acetone and azide is possible at 214 nm. Acetone can also be detected at 280 nm. Water gives a negative peak on spectrophotometric detectors. Deuterium oxide requires a refractive index detector.

Void volume (V_o) marker

Dissolve blue dextran (average molecular weight 2,000,000) at a concentration of 1 mg/ml in the appropriate mobile phase. Filter through a 0.22-µm filter. Store for 1 week at 4°C.

Blue dextran is adsorbed by some supports, for example, TSK G3000SW (Himmel and Squire, 1981). Calf thymus DNA has been reported to be a suitable alternative for supports with very large pore size (Pfannkoch et al., 1980).

COMMENTARY

Background Information

The chromatographic separation of proteins from small molecules on the basis of size was first described by Porath and Flodin (1959) who called the process "gel filtration." The column packing, or gel, was dextran cross-linked with epichlorohydrin and sold by Pharmacia under the trade name Sephadex. Moore (1964) applied a similar principle to the separation of polymers on cross-linked polystyrene gels in organic solvents, but named this "gel permeation chromatography." Although the terms gel filtration and gel permeation chromatography originally connoted aqueous and organic eluants respectively, both terms came to be used by manufacturers of such supports for the separation of peptides and proteins. Additional names, such as molecular sieve chromatography, steric exclusion, and gel chromatography have also been used, leading to some confusion. The term size exclusion chromatography (SEC) is more descriptive of the principle on which separation is based and is slowly replacing the older names. The molecular size of a solute molecule determines the degree to which it can penetrate the pores of the support. Molecules that are wholly excluded emerge from the column first, at the void volume, V_o. This represents the volume in the interstitial space (outside the support particles) and is measured by chromatography of very large molecules. Molecules that can enter the pores freely have full access to an additional space, the internal pore volume, V_i. Such molecules emerge at the total volume, V_t, which corresponds to the elution volume of molecules that are small enough to be distributed freely both inside and outside the pores and so have access to the total volume available to the mobile phase. Hence

$$V_t = V_o + V_i.$$

A solute molecule that is partially restricted from the pores will emerge with elution volume, V_e, between the two extremes, V_o and V_t. The distribution coefficient, K_d, for such a molecule represents the fraction of V_i available to it for diffusion. Hence

$$V_e = V_o + K_d V_i$$

and so

$$K_d = (V_e - V_o)/V_i$$

V_i is experimentally determined from the equation

$$V_i = V_t - V_o$$

Hence

$$K_d = (V_e - V_o)/(V_t - V_o)$$

Measurement of V_t is not trivial because many small molecules may experience ionic or hydrophobic interactions with the support (see Critical Parameters, Nonideal SEC). In addition, for supports with very small pore size, size exclusion effects may still operate even in the very-low-molecular-weight range (near a few hundred Da), restricting the possibilities for suitable markers. Deuterium oxide has been shown to be a reliable marker for V_t, but it requires a refractive index detector. In some cases it may be simpler to measure the geometric volume of the packed column bed, or bed volume, V_c. This is the sum of V_t and the solid support volume, V_s, which is not accessible to solvent. V_c (in ml) can be calculated from the equation for the volume of a cylinder, $\pi r^2 h$, where r is the radius of the column and h is the column length, both expressed in cm. The parameter K_{av} can then be used instead of K_d, where

$$K_{av} = (V_e - V_o)/(V_c - V_o)$$

Since

$$K_{av} = K_d V_i/(V_i + V_s)$$

K_{av} is directly proportional to K_d, as indeed is V_e. For comparison of results between different columns packed with the same support, K_d or K_{av} have obvious advantages since they are independent of column length.

Parameters descriptive of molecular size

Since the physical basis for discrimination in SEC is size, one would expect that there would be some parameter related to the dimensions and shape of the solute molecule that would determine its K_d value. All molecules with the same value for this parameter should have identical K_d values on a SEC column. Dimensional parameters that have been suggested for such a "universal calibration" include two terms related to the hydrodynamic properties of proteins, namely Stokes radius (R_S) and viscosity radius (R_η). In order to explain these terms it is necessary to consider briefly the hydrodynamic properties of proteins, particularly their diffusion coefficients and intrinsic viscosities. More detailed treatment can be found in Tanford (1961).

Stokes radius. Stokes law defines the frictional coefficient, f_0, for a spherical particle of radius, r_o, moving through a liquid of viscosity, η, by the following equation:

$$f_0 = 6\pi\eta r_o$$

If the frictional coefficient, f, were to be experimentally determined for a protein, using diffusion experiments or dynamic light scattering, one could make the assumption that the protein was a spherical particle and so calculate a value for its radius from Stokes equation. This is called the Stokes radius, R_S, and is the radius of the sphere that would have the frictional coefficient of the protein under consideration.

Now the radius, R, of a spherical particle is related to its volume, V, by the equation

$$V = (4/3)\pi R^3$$

and molecular volume is given by the equation

$$V = M\nu/N$$

where M is molecular weight, ν is partial specific volume and N is Avogadro's number. Hence

$$4/3\pi R^3 = M\nu/N$$

Partial specific volume can be calculated for a protein of known amino acid composition by summation of amino acid residue volumes (see *UNIT 5.3*). Hence, if the molecular weight and amino acid composition of any protein is known (say, from mass spectrometry) this enables values for M and ν, and hence its theoretical radius, R, to be calculated. Invariably we find that $R_S > R$. In other words, proteins behave like larger spheres than would be predicted from their mass and molecular volume. This is the consequence of proteins having shapes that are not perfect spheres and/or of hydration by solvent molecules, so the Stokes radius has no exact physical meaning for most proteins.

Combining the terms representing theoretical radius, R, with the Stokes equation gives a theoretical frictional coefficient, f_0, where:

$$f_0 = 6\pi\eta(3M\nu/4\pi N)^{1/3}$$

Since $R_S > R$, the ratio f/f_0 is >1; it is not possible for f/f_0 to have a value <1 since, for a given particle volume, a perfect sphere has the lowest possible diffusion coefficient. Most globular proteins are found to have f/f_0 values between 1 and 1.4, indicating neither a high degree of solvation nor asymmetry. If the f/f_0 ratio is much larger than unity this indicates that the hydrodynamic behavior of the protein is very different from that of an unsolvated sphere. For example, myosin, a protein consisting of two globular heads connected to a long coiled tail, has a value of 3.65 for f/f_0.

Viscosity radius. An alternative to the Stokes radius comes from employing hydrodynamic volumes derived from the Einstein viscosity law for spherical solute molecules

$$[\eta] = 2.5(NV_h/M)$$

where $[\eta]$ is the intrinsic viscosity of the solute molecule and V_h is its hydrodynamic volume (Nave et al., 1993).

The radius, R_η relating to this hydrodynamic volume can be calculated using the equation:

$$R_\eta = (3[\eta]M/10\pi N)^{1/3}$$

R_η is usually referred to as the viscosity radius, but is sometimes called the viscosity-based Stokes radius. This can lead to considerable confusion in the literature because many authors do not distinguish between Stokes radius derived using diffusion data from that derived using viscosity data. For nearly spherical globular proteins the two are virtually identical. However, for elongated shapes $R_\eta > R_S$, for example by ~15% for random coil polymers, and by even greater values for long fibrous molecules (Tanford et al., 1974).

Current evidence appears to indicate that R_η is more closely correlated to SEC behavior than is R_S (Horiike et al., 1983; Potschka, 1987). However, even this parameter is not suitable for a universal calibration that includes globular proteins, random coils, and rods (Dubin and Principi, 1989).

Several mathematical models that relate SEC to the geometries of protein solutes and support pores have been proposed. These models give rise to various plots that should result in a linear relationship between a function of solute radius, usually R_S, and some SEC parameter, usually K_d (Ackers, 1970). However, none has proven totally satisfactory. A more general treatment based on a Gaussian distribution of pore size was used to develop a statistical model that gave rise to the widely quoted equation:

$$R_S = a + b\ \mathrm{erfc}^{-1}K_d$$

where a and b are constants and erfc^{-1} is the inverse error function complement (available from statistical tables; Ackers, 1970).

This equation continues to be used by many workers, but it has been criticized on theoretical and experimental grounds (Nozaki et al., 1976; Le Maire et al., 1987). Le Maire et al. (1987) advocate plotting K_d directly against R_S. Such a plot is non-linear and sufficient data points must be included to adequately cover the separation range. However, for some supports, though not for others, a plot of ln R_S versus K_d gives a straight line (Le Maire et al., 1989). Examples of both a direct plot and a log plot are shown in Figure 5.5.2.

For random coiled polymers, molecular weight varies in a predictable manner with Stokes radius. For reduced proteins in a denaturing solvent, such as guanidinium hydrochloride, it is thus possible to relate SEC behavior directly to molecular weight (Fish et al., 1970). Usually K_d versus log molecular weight is plotted, giving a sigmoidal calibration curve with an approximately linear portion between K_d = 0.1 and K_d = 0.8. Since the K_d is proportional to K_{av} or V_e, plots of these parameters against log molecular weight are also used. For native proteins, however, since there is no direct relationship between molecular weight and R_S, calculation of molecular weight from SEC data requires knowledge of the sedimentation coefficient. Stokes radii of standard proteins and their K_d values are used to produce a calibration curve (see above) from which the Stokes radius of the unknown can be determined. Since the product of sedimentation coefficient and Stokes radius is related to molecular weight, as described in *UNIT 5.3*, the equation on page 5.3.27 can be used to calculate accurate molecular weights for proteins of known sedimentation coefficient.

Critical Parameters

Nonideal SEC

Ideal SEC separates solutes only on the basis of size. This will only occur when the support is neutral and of similar polarity to the mobile phase. If the support is more hydrophobic than

the mobile phase, then hydrophobic interactions with solute molecules will delay their elution. If there are charges present on the support, then ion-exchange can occur with oppositely charged solute molecules, delaying their elution. In extreme cases, solute molecules can emerge well after V_t. Solute molecules with the same charge as that of the support will experience electrostatic repulsion from the pores, referred to as "ion exclusion," and emerge earlier than expected on the basis of size. Silica to which a hydrophilic phase such as a diol has been bonded still contains underivatized silanol groups. Above pH 3 these are largely anionic and will interact with ionic solutes. Depending on the value of its isoelectric point, a protein can be cationic or anionic at pH 7. Proteins that are positively charged will undergo ion exchange, causing them to be retarded. Conversely, anionic proteins will experience ion exclusion, and will be eluted earlier than expected on the basis of size alone (Pfannkoch et al., 1980; Irvine and Shaw, 1986). Silica-based packings give rise to a greater or lesser degree to nonideal SEC. The nonsilica based supports, such as Superose, with a lower surface density of ionizable groups and low hydrophobicity, might be expected to produce more nearly ideal SEC (Dubin and Principi, 1989). In order to reduce ionic interactions with either type of support, it is necessary to use a mobile phase of high ionic strength. On the other hand, an increase in ionic strength promotes the formation of hydrophobic interactions. To minimize both ionic and hydrophobic interactions, the mobile phase should have an ionic strength between 0.2 and 0.5 M (Regnier, 1983).

Detection

By far the most common technique applied for the detection of polypeptides is spectrophotometry. Peptide bonds absorb UV light with a maximum ~187 nm, but wavelengths below 200 nm are seldom used because of interference from buffer components; in practice 210, 214, or 220 nm are the most frequently reported wavelengths. In mobile phases that absorb strongly in the far UV range, monitoring the absorbance in the most sensitive region for proteins (200 to 220 nm) is no longer possible, and a longer wavelength, such as 280 nm, must be used. Only proteins that contain tyrosine or tryptophan will absorb light at 280 nm. With a 280-nm detector set at ten times the sensitivity of a 214-nm detector, a single tyrosyl residue produces a similar deflection at 280 nm to five peptide bonds at 214 nm; a single tryptophanyl residue produces a similar deflection to fifteen peptide bonds (Shaw, 1997).

Solubilization of membrane proteins is often carried out in nonionic detergent. However, some of the commonly used detergents, such as Triton X-100, contain aromatic groups that absorb in the UV range and so interfere with detection at 280 nm. This difficulty can be avoided by using detergents such as octylglucoside or the alkyl polyethers for solubilization.

On-line light scattering detectors give direct information on molecular weight that is independent of elution position and have been applied to detection of proteins and their aggregates (Wen et al., 1996). Electrospray ionization mass spectrometry (EI-MS) requires the use of volatile solvents, and so its application to SEC of native proteins has been restricted due to prevalence of mobile phases of high ionic strength.

Resolution

Chromatographic modes such as ion exchange or reversed phase require a change in mobile phase composition during the run. In such gradient-based modes, volumes that greatly exceed the geometric column volume, V_c, are often used. SEC operates by isocratic elution, i.e., with a mobile phase of fixed composition. This has the advantage that there is no need to re-equilibrate the column between runs, so that the next sample can be injected immediately after a volume of eluant equal to V_t has passed, assuming that ideal SEC is operating. However, from consideration of the equation $V_e = V_o + K_d V_i$, it is clear that in SEC all separations must occur within a relatively small volume equal to the pore volume, V_i. For the most frequently used HPLC column sizes, this value ranges from ~5 ml (for columns of dimensions 7.5×300 mm) to 12 ml (for columns of dimensions 10×300–mm). All the components of the mixture to be separated must be resolved within this volume. The practical peak capacity, n (the maximum number of peaks that can be separated on a given column), may be estimated from the equation

$$n \approx 1 + (V_i / V_t) N^{1/2} / 4 R_{es}$$

in terms of pore fraction, V_i/V_t, plate number, N, and resolution, R_{es} (Hagel, 1992). From this equation it can be estimated that practical peak capacities for SEC columns will be ~13 completely resolved peaks on well-packed columns. Hagel (1989) has discussed several parameters than can be altered in order to increase

resolution. These include maximizing pore volume, number of theoretical plates, column length, permeability (V_i/V_o), and decreasing particle size and flow rate. Although lower flow rates generally lead to an increase in resolution, this is not usually a critical factor in determining protein size, so that in practice relatively high flow rates can be used. Typical flow rates are 0.5 to 1.0 ml/min for a 7.5 × 300–mm prepacked SE-HPLC column to 5 to 40 cm/hr, depending on the support, for a conventional SEC column.

Loading is a function of volume and concentration of sample applied, and both of these will affect resolution (Regnier, 1983). Solutions containing high sample concentrations can lead to increased viscosity and hence decreased diffusion coefficient of solutes, leading to decrease in resolution. This is more of a problem for preparative than analytical SEC, where protein concentrations are usually <1 mg/ml. For maximum resolution the volume in which sample is dissolved should be <0.5% of the column volume (~50 µl for a 7.5 × 300–mm column with 10-µm particles; Hagel, 1989). In general, however, achieving baseline resolution in SEC is less critical for estimating protein size than for other applications, such as purification.

Troubleshooting

In SE-HPLC especially, but also in conventional SEC, it is most important to filter solutions to prevent clogging of the column with insoluble material. The use of a guard column is very beneficial in this respect. It needs to be replaced periodically, as soon as any increase in the usual operating pressure is observed.

In conventional SEC, decreased flow rates can result from clogging of column ends with fines. Reversing the flow may help, but otherwise the column will need repacking. Decreased flow can also arise because the column bed may have become compressed, usually due to flow rates that are too high. When repacking a column, nets need cleaning and the gel should be treated to remove fines (see Basic Protocol 2, step 3).

Spurious peaks in the UV detector are often due to air bubbles forming as eluate emerges at the low pressure end of the column. Degassing the mobile phase will overcome this problem.

Anticipated Results

Running standard proteins gives a very good indication that the technique is working normally, since the calibration curve should be smooth if R_S is plotted against K_d (see Fig 5.5.2A) or approximately linear if log R_S is plotted against K_d (Fig. 5.5.2B). If a standard runs abnormally, nonideal SEC may be operating (see Critical Parameters). In such a case, changes in the ionic strength or pH of the mobile phase should markedly affect the K_d value obtained.

Time Considerations

For SE-HPLC equilibrating the column may take ~30 to 6 min. Each run takes ~15 min. For conventional SEC packing, swelling the gel takes a day and packing the column takes several hours. Each run takes 5 to 10 hr, depending on flow rate used.

Identification of Proteins in Complex Mixtures Using Liquid Chromatography and Mass Spectrometry

Most cellular processes are executed and regulated by multiple proteins that act as part of a complex mixture. The identification of protein interactions in complex mixtures can provide fundamental information about the cellular processes being studied. Attempts to study protein interactions have traditionally focused on the isolation and identification of individual proteins. Understanding the role of a protein in a complex mixture, however, may depend not only on identifying an individual protein but also on identifying other proteins in the mixture and the effect of their association on the cellular system. Protein mixtures can be composed of proteins acting as tightly bound complexes, or they may include loosely bound proteins whose activity depends on self-assembly into a larger protein structure. Additionally, protein mixtures may include proteins that interact in a transient association, including protein-modifying enzymes such as proteases and kinases. This unit describes the current state of technologies available for directly identifying proteins in complex mixtures using liquid chromatography (LC) and mass spectrometry (MS). Two basic approaches are typically used. In one, proteins are separated by polyacrylamide gel electrophoresis (PAGE), isolated, digested, and analyzed by MS. In the second, LC and MS are directly coupled, allowing identification of proteins in complex mixtures without prior separation. For a detailed discussion of these approaches, see Background Information.

This unit focuses on the direct LC-MS methods. Samples are prepared from mixtures of proteins by proteolytic digestion without separation (see Basic Protocol 1). The sample is loaded onto a microcapillary column (see Basic Protocol 2) and analyzed on-line using a combined method of LC and electrospray–ionization tandem mass spectrometry (ESI-MS/MS; see Basic Protocol 3). Additional protocols are given for data analysis (see Basic Protocol 4) and pulling and packing the microcapillary column (see Support Protocol). Finally, to allow MS analysis of proteins separated by PAGE, a protocol is given for preparing digested proteins in slices from one- or two-dimensional polyacrylamide gels (see Alternate Protocol).

NOTE: To avoid contamination of the proteins, wear gloves while working with the protein sample and avoid exposing the sample to dust.

SAMPLE PREPARATION FOR DIRECT ANALYSIS OF PEPTIDES IN MIXTURES

BASIC PROTOCOL 1

This protocol describes the preparation of samples to be analyzed directly in a one- or two-dimensional liquid chromatography–tandem mass spectrometry (LC-MS/MS) experiment, and it is based on the method described by Link et al. (1999). The protocol is described for a sample containing 1 mg of protein, although samples with as little as 100 µg can be routinely analyzed. The insoluble fraction is treated with cyanogen bromide to digest proteins into long peptides which can be further digested by Lys-C and trypsin. Formic acid is used to increase solubility.

Contributed by Claire Delahunty and John R. Yates III
Current Protocols in Cell Biology (2003) 5.6.1-5.6.17

Materials

Total cell lysates, insoluble fractions or membrane proteins, soluble fractions, or unknown sample
Cyanogen bromide (e.g., Aldrich), for insoluble fractions or membrane proteins only
96% (v/v) formic acid (e.g., Aldrich), for insoluble fractions or membrane proteins only
Ammonium bicarbonate (e.g., J.T. Baker), for insoluble fractions only
100 mM Tris, pH 8.5/8 M urea (e.g., Sigma)
1 M Tris (2-carboxyethyl)phosphine hydrochloride (TCEP; e.g., Pierce)/100 mM ammonium bicarbonate
500 mM iodoacetamide
Endoproteinase Lys-C (Roche Diagnostics)
100 mM $CaCl_2$ (e.g., Mallinckrodt Baker; *APPENDIX 2A*)
Porozyme bulk immobilized trypsin beads (Applied Biosystems)
88% (v/v) formic acid (e.g., Aldrich)

Additional reagents and equipment for trichloroacetic acid (TCA) precipitation (*UNIT 7.1*)

CAUTION: Cyanogen bromide is highly toxic and volatile; carry out all work with this compound in a well-ventilated fume hood. TCA is extremely caustic. Protect eyes and avoid contact with skin when preparing and handling TCA solutions

Prepare sample fractions (total cell lysates or unknown samples only)

1. Place a total cell lysate or unknown sample containing ~1 to 5 mg protein in a 1.5-ml microcentrifuge tube and separate the soluble and insoluble fractions by microcentrifuging 30 min at 4000 rpm. Transfer the soluble fraction to a clean 1.5-ml microcentrifuge tube and proceed to step 2. Keep the insoluble fraction in the original microcentrifuge tube and pretreat with cyanogen bromide (steps 3 to 5).
2. Precipitate a volume of the soluble fraction equivalent to 500 µg protein using TCA (*UNIT 7.1*). Proceed to step 6.

   Starting amounts can be 100 µg to 2 mg. Adjust reagents accordingly.

Pretreat with cyanogen bromide (insoluble fractions or membrane proteins only)

3. Prepare a solution of 500 mg/ml cyanogen bromide in 96% formic acid in a chemical fume hood.
4. Add 100 µl of the cyanogen bromide solution to the insoluble pellet and incubate overnight at room temperature in the dark.
5. Add 100 µl water and carefully adjust the pH to 8 to 8.5 using solid ammonium bicarbonate. Reduce volume almost to dryness in a Speedvac evaporator. Proceed to step 6.

Reduce and carboxyamidate proteins

6. Resuspend sample (step 2 or step 5) in 30 µl of 100 mM Tris·Cl, pH 8.5/8 M urea.
7. Add 0.15 µl of 1 M TCEP (5 mM final concentration) and incubate 10 min at room temperature.
8. Add 1.2 µl of 500 mM iodoacetamide (20 mM final concentration) and incubate 20 min in the dark.

Perform enzyme digestion

9. Add 5 µl of 1.0 µg/µl endoproteinase Lys-C and incubate 4 to 8 hr at 37°C in the dark.

   A 1:100 ratio of enzyme to sample concentration is used.

10. Add 82.5 µl water to dilute solution to 2 M.

11. Add 2.4 µl of 100 mM $CaCl_2$ (2 mM final concentration) and 10 µl Porozyme bulk immobilized trypsin beads. Incubate with shaking 12 hr at 37°C in the dark.

12. Quench by adding 5.8 µl of 88% formic acid and microcentrifuge the samples 10 min at 14,000 rpm (maximum speed). Transfer supernatant to a clean 1.5-ml microcentrifuge tube and discard the pellet.

    The sample is now ready to be loaded onto the LC column (see Basic Protocol 2). It should be loaded within a few hours, or can be stored indefinitely at –80°C.

SAMPLE PREPARATION BY IN-GEL DIGESTION OF SILVER- OR COOMASSIE-STAINED SPOTS FOLLOWING PAGE

ALTERNATE PROTOCOL

This protocol describes the technique used to isolate peptides from a protein purified by one- or two-dimensional PAGE, and is based on the method by Jensen et al. (1999). Gel slices of widely varying acrylamide content (≤18%) and size can be processed in this way. A gel spot of interest is excised from the polyacrylamide gel and subjected to destaining. The gel piece is then dried and rehydrated with a reducing and alkylating procedure. The alkylated proteins are digested to peptides in-gel, extracted, lyophilized, and resuspended in 5% formic acid. Samples are then ready for analysis.

Materials

Coomassie- or silver-stained (*UNIT 6.6*) one- or two-dimensional acrylamide gel (*UNITS 6.1 & 6.4*) containing proteins of interest
30 mM potassium ferricyanide
100 mM sodium thiosulfate
Acetonitrile (e.g., Fisher), HPLC grade
25 and 100 mM ammonium bicarbonate (J.T. Baker)
10 mM Tris(2-carboxyethyl)phosphine (TCEP; e.g., Pierce)/100 mM ammonium bicarbonate
Iodoacetamide/ammonium bicarbonate solution (see recipe)
Trypsin digestion solution (see recipe), 4°C
50 mM ammonium bicarbonate/5 mM $CaCl_2$ (e.g., Mallinckrodt Baker)
5% (v/v) formic acid (e.g., Aldrich)

Glass plate, cleaned with methanol or ethanol
Scalpel or razor blades, cleaned with methanol or ethanol
Gel-loading pipet tips

Excise protein band

1. Wash a Coomassie- or silver-stained polyacrylamide gel containing proteins of interest two times with water for 10 min each.

2. Transfer gel to a glass plate and use a scalpel or razor blade cleaned with methanol or ethanol to excise the band of interest. Cut as close to the protein as possible to reduce the amount of background gel. Excise a second gel piece of approximately the same size from a nonprotein region to use as a control.

   The gel should be kept moist with water while the bands are excised.

3. Cut the gel piece into 1 × 1–mm squares (gel thickness will vary). If the gel stain is dark, place two to three 1 × 1–mm squares into a 1.5-ml microcentrifuge tube. If it is faint, use up to ten pieces.

   Volumes in subsequent steps are based on a starting gel volume of ~100 µl and should be scaled as appropriate.

4. Microcentrifuge 10 sec at 14,000 rpm (maximum speed) so that the gel pieces settle to the bottom of the tube.

Destain gel

5. *For silver stain only:* Prepare a fresh 1:1 (v/v) mixture of 30 mM potassium ferricyanide/100 mM sodium thiosulfate. Cover silver-stained gel cubes with 100 µl of this solution and incubate 5 min at room temperature. Discard liquid and wash gel pieces three times with 100 µl water to quench the reaction. Discard water and proceed to step 6.
6. Wash gel pieces (silver-stained from step 5 or Coomassie-stained from step 4) with 2 vol (200 µl) water for 15 min. Shake well or vortex lightly.
7. Remove water with a gel-loading pipet tip, being very careful not to remove any portion of the gel.
8. Add 100 µl water followed by 100 µl acetonitrile and wash gel pieces 15 min.
9. Remove liquid and add 100 µl acetonitrile to cover the gel pieces. Tap tube with fingers to mix.
10. Allow the pieces to shrink (they will turn sticky white) and then remove the acetonitrile.
11. Rehydrate with 100 µl of 100 mM ammonium bicarbonate for 5 min.
12. Add 100 µl acetonitrile and incubate 15 min. If a strong blue color persists, incubate again for 15 min with constant vortexing.
13. Remove liquid and dry ~15 min in a Speedvac evaporator. If blue color persists, repeat wash starting with step 9.

Reduce and alkylate proteins

14. Rehydrate gel pieces with 100 µl of 10 mM TCEP/100 mM ammonium bicarbonate to cover the gel. Tap tube with fingers to mix and incubate 20 to 30 min at room temperature.
15. Remove liquid and quickly add 100 µl freshly prepared iodoacetamide/ammonium bicarbonate solution. Incubate 30 min at room temperature in the dark.
16. Remove liquid and add 100 µl acetonitrile to cover gel pieces.
17. Allow the pieces to shrink (again, they will turn sticky white) and remove acetonitrile.
18. Add 100 µl of 100 mM ammonium bicarbonate and rehydrate 5 min.
19. Add 100 µl acetonitrile and incubate 15 min.

    All the Coomassie stain should be removed at this point. If a blue color still persists, steps 9 to 19 should be repeated.

20. Remove liquid and dry down completely in the Speedvac evaporator (≥30 min).

    The actual drying time will depend on the original volume of gel.

Perform in-gel digestion

21. Add 50 µl prechilled (4°C) trypsin digestion solution to just cover the gel pieces and incubate 45 min on ice. Check gel pieces every 15 min and add more digestion solution if they are not covered.
22. Remove supernatant and add 50 µl of 50 mM ammonium bicarbonate/5 mM $CaCl_2$. Incubate overnight at 37°C.

Extract peptides

23. Microcentrifuge tubes for ~30 sec at maximum speed, transfer buffer to a 1.5-ml microcentrifuge tube, and keep gel pieces.
24. Add 100 µl of 25 mM ammonium bicarbonate to cover the gel pieces and incubate 15 min at room temperature.

    The volume should not exceed 100 µl.

25. Add 100 µl acetonitrile and incubate 15 min at room temperature while vortexing. Transfer supernatant to the 1.5-ml tube in step 23 and keep gel pieces.
26. Add 100 µl of 5% formic acid to the gel pieces and incubate 15 min at room temperature.
27. Add 100 µl acetonitrile and incubate 15 min at room temperature while vortexing. Transfer supernatant to the 1.5-ml tube in step 23 and keep gel pieces.
28. Repeat steps 26 to 27, but discard gel pieces.
29. Dry sample in the Speedvac evaporator for ~2 hr.
30. Resuspend peptides in 10 to 30 µl of 5% formic acid.

    The peptides can be stored indefinitely at −80°C before being analyzed (see Basic Protocol 3).

LOADING A PROTEIN SAMPLE FOR MICROCAPILLARY COLUMN LIQUID CHROMATOGRAPHY

BASIC PROTOCOL 2

The digested protein sample is loaded onto the column in a method similar to column packing (see Support Protocol).

Materials

Digested protein sample (see Basic Protocol 1 or Alternate Protocol)
Pre-equilibrated microcapillary column (see Support Protocol)
High-pressure bomb designed for pneumatically loading microcapillaries (see Dongré et al., 1997) connected to helium gas tank

1. Place microcentrifuge tube containing acidified peptides in the center of a high-pressure bomb connected to a helium gas tank.
2. Close the bomb lid and tighten the screws.
3. Insert a pre-equilibrated microcapillary column into the bomb (point up) until the flat end of the column is immersed in the sample and is touching the bottom of the tube. Tighten the screw that holds the microcapillary.
4. Turn the helium gas tank on at 300 to 700 psi to pressurize the bomb and thus load the sample.

Loading progress can be monitored by measuring the solvent displaced from the column. The volume of the eluent solvent should be equal to the volume of the sample being loaded.

CAUTION: *The bomb is under high pressure. Make sure a safe and pressure-tested device is used.*

5. After loading is complete, slowly depressurize the bomb to avoid disrupting the packing material, and securely grasp the column while opening the bomb.

Sample is now loaded onto the strong cation exchange portion of the column and is ready for analysis (see Basic Protocol 3). The loaded column should be used immediately. If not, the column should be stored tip down in buffer A (see Basic Protocol 3) and used as soon as possible. Column tips are very fragile.

SUPPORT PROTOCOL

PREPARING MICROCAPILLARY COLUMNS FOR LIQUID CHROMATOGRAPHY

Microcapillary columns (Kennedy and Jorgenson, 1989) for one- or two-dimensional LC-MS/MS are created from fused-silica microcapillaries by using a laser puller. The laser puller is critical for creating capillary columns, and attempts to manually pull the capillaries can give unsatisfactory and irreproducible results. The pulled capillary (column) is then packed using a protocol that is similar for single and biphasic columns.

Additional materials *(also see Basic Protocol 2)*

Methanol (e.g., Fisher), HPLC grade
C_{18} packing material
Partisphere strong cation exchange (SCX; Whatman; for biphasic columns only)
Buffer A: 5% (v/v) acetonitrile/0.1% (v/v) formic acid

Laser puller (model P-2000; Sutter Instruments)
Ceramic scribe
100 × 365–µm (i.d. × o.d.) fused-silica capillary (J&W Scientific)
Alcohol burner
PEEK microcross splitter (Upchurch)
Quaternary high-performance liquid chromatography (HPLC) pump

Pull microcapillary column

1. Set the program of a laser puller for three cycles as follows:

Heat	270°C
Filament	0
Velocity	30
Delay	128 msec
Pull	0.

These values are specifically for a 100 × 365–µm microcapillary in the Sutter Instruments laser puller. They are unitless (except the delay) and are preset in this instrument. If another puller is used, the values will have to be determined empirically.

2. Use a ceramic scribe to cut a 50- to 54-cm length of 100 × 365–µm fused-silica capillary from the bulk. Use an alcohol burner to burn off the coating covering ~3 cm in the center part of the microcapillary. Clean the capillary using a methanol-soaked lint-free tissue.

3. Place the microcapillary in the puller, run the program and form two pulled columns. Store the pulled columns at room temperature, free of dust, with special care to protect tip.

The column tip will have an internal diameter of ~2 to 5 μm and each column will be ~25 to 27 cm long.

Pack column

4. Measure ~500 μg C_{18} packing material into a 1.5-ml microcentrifuge tube and suspend it in 1 ml methanol.
5. Place the microcentrifuge tube in the center of a high-pressure bomb connected to a helium gas tank. Position the lid and make sure all screws are secure.
6. Insert the column (step 3) into the bomb (point up) until the flat end of the column is immersed in the packing material. Gently tap the end of the column against the bottom of the tube and then raise it ~0.5 cm from the bottom. Tighten the screw that holds the microcapillary.
7. Turn the helium on at 300 to 700 psi and fill column to a length of 7 to 10 cm.

   Packing material should be seen moving up the microcapillary. As loading progresses, methanol accumulating at the tip of the column can be removed with a lint-free tissue. If the packing material slows too much before the desired packing length is achieved, the capillary can be loosened and tapped gently on the bottom of the tube to reactivate the process.

   CAUTION: *The bomb is under high pressure. Make sure a safe and pressure-tested device is used.*

8. Slowly depressurize the bomb to avoid disrupting the packing material and securely grasp the column while opening the bomb.

9a. *For a one-dimensional reversed-phase column:* Remove the column from the bomb and store in methanol up to 1 week at 4°C until pre-equilibration.

9b. *For a two-dimensional (biphasic) reversed-phase column:* Remove the column from the bomb and replace the microcentrifuge tube with a second tube containing 500 μg Partisphere SCX in 1 ml methanol. Repeat column packing as described (steps 6 to 8). Store packed column in methanol up to 1 week at 4°C until pre-equilibration.

   Because the SCX resin remains suspended in the methanol slurry, tapping the column on the bottom of the tube is not always necessary.

Pre-equilibrate column

10. Place the column in a PEEK microcross splitter.

    The splitter is used to interface the microcapillary column with the mass spectrometer.

11. Place a quaternary HPLC pump in-line with the splitter and equilibrate the microcapillary column for 30 min using buffer A at a flow rate of 100 μl/min.
12. Store equilibrated column up to 24 hr at 4°C or room temperature.

MULTIDIMENSIONAL PROTEIN IDENTIFICATION TECHNOLOGY FOR ANALYZING COMPLEX MIXTURES

BASIC PROTOCOL 3

Combining liquid chromatography (LC) with electrospray ionization–tandem mass spectrometry (ESI-MS/MS) allows on-line analysis of complex protein mixtures. This protocol describes separation by multidimensional protein identification technology (MudPIT). In this technique, a pulled microcapillary column is packed with two independent chromatography phases. In the first dimension, peptides are separated by strong cation exchange and are eluted into the second phase by a step gradient of increasing salt concentration. The second phase consists of reversed-phase material, which separates the

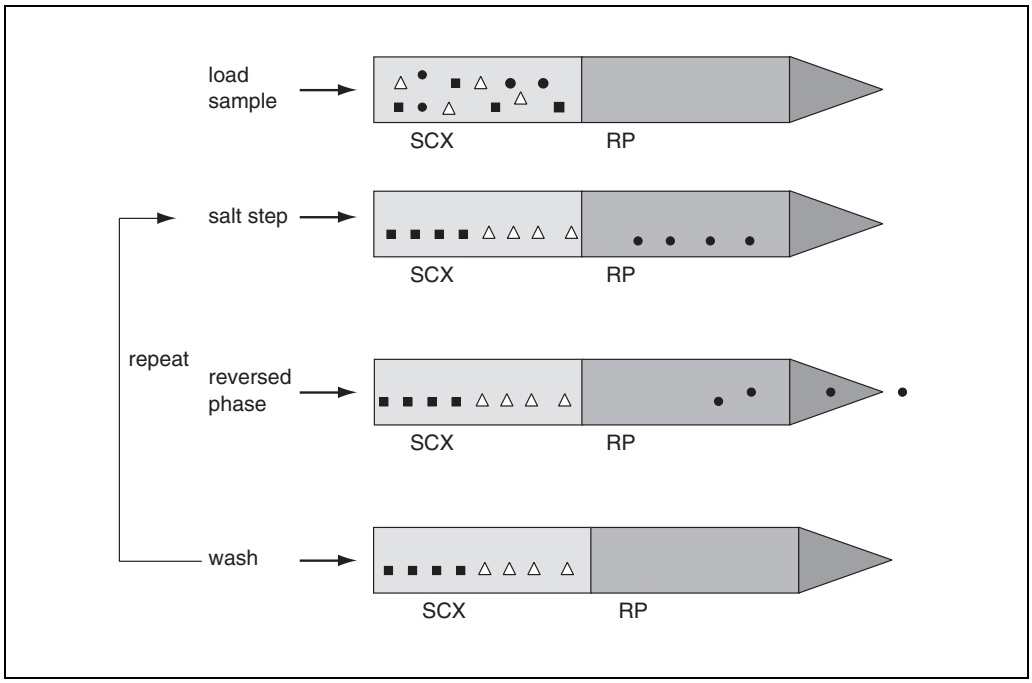

Figure 5.6.1 Integrated two-dimensional liquid chromatography. Peptides are separated in the first dimension by strong cation exchange (SCX) followed by reversed-phase (RP) separation and elution into the mass spectrometer. Triangles, circles, and squares represent different peptides.

peptides on the basis of hydrophobicity before they are eluted directly into the mass spectrometer (Fig. 5.6.1). The method described is for a six-step multidimensional separation. For highly complex or concentrated samples, twelve-step programs are frequently used and simply require smaller increments in the proportion of buffer C used in step 5. If one-dimensional separation is used, the salt steps in the chromatography are eliminated. For two-dimensional LC, a quaternary HPLC pump is required to deliver the three different buffers necessary for two-dimensional separations.

Materials

Microcapillary column loaded with protein sample (see Basic Protocol 2)
Buffer A: 5% (v/v) acetonitrile/0.1% (v/v) formic acid
Buffer B: 80% (v/v) acetonitrile/0.1% (v/v) formic acid
Buffer C: 500 mM ammonium acetate (e.g., Sigma)/5% (v/v) acetonitrile/0.1% (v/v) formic acid

PEEK microcross splitter (Upchurch)
LCQ ion trap mass spectrometer (ThermoFinnigan) including custom platform for nanoelectrospray, or equivalent tandem mass spectrometer
XYZ translational positioner (Newport)
HPLC system, including quaternary HPLC pump (e.g., Agilent, ThermoFinnigan, Waters; for two-dimensional LC only) and nitrogen gas source

Set up HPLC and MS system

1. Place a microcapillary column loaded with a protein sample in a PEEK microcross splitter and mount it on the custom platform of an LCQ ion trap mass spectrometer.

   The platform replaces the original electrospray source and is described in Yates et al. (2000). Plans for the platform may be available from the author by a material transfer agreement.

2. Align the column with the mass spectrometer orifice using an XYZ translational positioner.

The column should be directly in line with the mass spectrometer at a distance of 2 to 3 mm.

3. Set up an HPLC system, including a quaternary HPLC pump for two-dimensional LC. Split the flow from the HPLC with the PEEK microcross splitter so that effective flow rate from the HPLC is 0.15 to 0.25 µl/min and spray voltage is 2.4 kV. Set the nitrogen gas (sheath gas) flow rate to 0.2 liter/min.

   For one-dimensional LC, a binary HPLC pump can be used.

Perform chromatography

4. Run a 100-min gradient of 0% to 100% buffer B in buffer A. Hold 10 min at 100% buffer B.

5. Run the following 110-min program.

   a. 3 min with 100% buffer A
   b. 2 min with 10% buffer C in buffer A
   c. 5 min with 100% buffer A
   d. 10-min gradient from 0% to 15% buffer B in buffer A
   e. 90-min gradient from 15% to 55% buffer B in buffer A.

   Repeat this program four more times, but increase the concentration of buffer C (substep b) in each repetition until 80% is obtained (e.g., 10%, 25%, 50%, and 80%).

6. Run the following 130-min program.

   a. 5 min with 100% buffer A
   b. 20 min with 80% buffer C
   c. 5 min with 100% buffer A
   d. 10-min gradient from 0% to 10% buffer B in buffer A
   e. 90-min gradient from 10% to 45% buffer B in buffer A.

Set up and run mass spectrometer

7. Set the LCQ ion trap mass spectrometer to acquire a full MS scan over the *m/z* range of 400 to 1400, with an electron multiplier voltage of 1000 V.

   The LCQ is operated via an Instrument Methods file in the Sequence Setup window of Xcalibur.

8. Select for the top three ions from the MS scan to be analyzed automatically in a tandem MS/MS experiment.

   Dynamic exclusion is enabled with a repeat count of 1, a duration of 0.5 min, and a 30- to 45-sec exclusion duration window.

9. Set relative collision energy to 35% with a 30-msec activation time.

10. Run sample and collect data.

    As the peptide mixture elutes into the mass spectrometer, data are acquired in a data-dependent manner.

BASIC PROTOCOL 4

ANALYSIS OF LIQUID CHROMATOGRAPHY–TANDEM MASS SPECTROMETRY DATA

The great quantity of data generated in a two-dimensional LC-MS/MS experiment is most efficiently analyzed by algorithms that search the experimental data against known sequences in DNA or protein databases (see Internet Resources). The most effective algorithms for searching databases with MS/MS data require no interpretation of the raw data. In these algorithms, the data are directly correlated with protein or DNA data contained in the database. Several algorithms exist to analyze MS/MS data. The SEQUEST algorithm (Thermo Finnigan) can run directly on the LCQ ion trap mass spectrometer. Alternatively, Web-based search tools are available (see Internet Resources).

SEQUEST matches a peptide sequence in the database with MS/MS spectra by first identifying those peptides with matching molecular weight. The specificity of the enzyme used to digest the mixture significantly reduces the number of possible match candidates. From this list of candidates, predicted fragment ions for each of the peptides are generated and the similarity of the reconstructed spectra to the experimental data is determined. The cross-correlation value is a measure of the quality of the match between the sequence and the spectrum. The difference between the correlation score for the top-scoring match candidate and the candidate ranked second is a measure of the quality of the match versus other possible sequences.

In general, spectra of modified peptides can be searched through available databases. The mass increment of the modification is added to the mass of the unmodified amino acid and this new mass is used in the database search. For example, to search for phosphorylated residues, the program is told to look for mass changes of 80 to Ser, Thr, and Tyr residues. This search is usually done in a differential manner by checking to see if each occurrence of Ser, Thr, or Tyr is modified. To search different types of modifications, the increase in molecular weight expected for the residue is input into the program. Some types of modifications (e.g., methionine oxidation, phosphorylation) may not occur at all possible locations, and thus the possibility of modification must be considered separately for each occurrence of the amino acid.

Database searching can be performed with peptides obtained from organisms without completed genome sequences if a genome sequence is available for a related organism. For example, to analyze peptides from a rat protein, one would create a database of all mammalian protein sequences for the search. Databases are large text files of sequences; consequently the sequences available for related organisms (e.g., human, mouse, and rat) are combined into a single file for the search.

REAGENTS AND SOLUTIONS

Use HPLC-grade water and solvents in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Iodoacetamide/ammonium bicarbonate solution

100 µl 1 M ammonium bicarbonate (J.T. Baker; 100 mM final)
900 µl H_2O
10 mg iodoacetamide (Sigma; 55 mM final)
Always make fresh

Trypsin digestion solution

5 µl 1 M $CaCl_2$ (e.g., Mallinckrodt Baker; *APPENDIX 2A*; 5 mM final)
50 µl 1 M ammonium bicarbonate (50 mM final)
945 µl H_2O
Store up to 1 week at 4°C
Just before use, add 2.5 µl of 0.5 µg/µl trypsin (Promega) per 100 µl total volume (12.5 ng/µl final)

COMMENTARY

Background Information

The development of methods to separate complex mixtures of proteins using two-dimensional gel electrophoresis led to large-scale studies of global protein expression, which is now referred to as proteomics. Using two-dimensional electrophoresis, hundreds of proteins could be separated and visualized, but identification of the individual proteins using Edman sequencing methods was very difficult and time consuming (Aebersold, 1986; Matsudaira, 1987). Advances in techniques to sequence proteins using mass spectrometry (MS; Hunt, 1986) soon replaced the slower and less-sensitive chemical degradation methods.

MS techniques have been most frequently coupled with two-dimensional polyacrylamide gel electrophoresis (PAGE; Jensen et al., 1999b). Proteins separated by two-dimensional PAGE are identified by MS after a sequential analysis of tryptic digests of the individual gel spots. As powerful as this integrated method is, it is limited in its sensitivity and its ability to analyze specific classes of proteins (Gygi et al., 2000; Santoni et al., 2000), and it does not have a broad dynamic range. Two-dimensional PAGE is also a time-consuming and labor-intensive technique that is inherently limited for high-throughput analysis because it requires individual proteins to be excised and extracted from the gel prior to mass analysis.

As an alternative to gel-based methods, liquid chromatographic techniques have now been coupled directly with the mass spectrometer, enabling identification of proteins in complex mixtures through chromatographic separation based on chemical properties followed by separation based on mass-to-charge ratios (m/z) and subsequent structural characterization (Eng et al., 1994; McCormack et al., 1997; Gatlin et al., 1998; Link et al., 1999; Washburn et al., 2001; Wolters et al., 2001; MacCoss et al., 2002).

Mass spectrometry

MS has proven to be a valuable technique for protein mixture analysis (Yates, 1998a; Washburn and Yates, 2000; Yates et al., 2000; Peng and Gygi, 2001). The design of a mass spectrometer makes it particularly well suited for this purpose. All mass spectrometers are composed of three fundamental parts (Fig. 5.6.2). The first segment is the ionization source where the sample molecules are converted into gas phase ions and are introduced into the mass spectrometer. The ions enter the second segment, the mass analyzer, where they are separated on the basis of their m/z values before passing into the third segment, the ion detector. Until the mid-1980s, MS was most commonly used for the characterization of small molecules because there was no way to convert larger biological molecules to gas phase ions. The advent of MS as a technique for the analysis of biological molecules was greatly expedited by the development of important ionization techniques that allowed the transfer of large, biologically important molecules into the gas phase with little or no fragmentation (Fenn et al., 1989). For protein analysis, the two most common ionization techniques are matrix-assisted laser desorption/ionization (MALDI) and electrospray ionization (ESI).

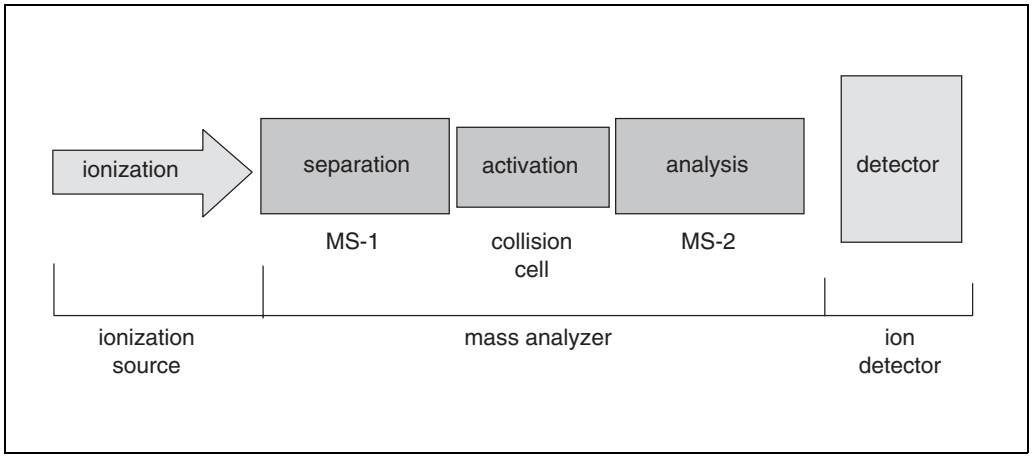

Figure 5.6.2 All mass spectrometers are composed of three basic parts: an ionization source, a mass analyzer, and an ion detector. The mass analyzer depicted in this figure is from a tandem mass spectrometer. MS-1 and MS-2 indicate the tandem mass spectrometers.

Matrix-assisted laser desorption/ionization

In the MALDI technique, analyte is co-crystallized with an acidified matrix and deposited on a polished stainless steel plate. The matrix is a small molecule that absorbs energy from a pulsed laser of specific wavelength. The energy absorbed from the laser is thermally dissipated, resulting in rapid dissociation of the matrix and analyte from the plate surface. The matrix and analyte are both transferred to the gas phase as ions. MALDI is typically coupled with a time-of-flight (TOF) mass analyzer. TOF analyzers separate ions based on the time it takes them to travel the length of the flight tube. Analytes are introduced into the TOF tube when the MALDI plate containing the co-crystallized analyte and matrix is placed in the vacuum chamber of the TOF instrument. High voltage is applied to the MALDI plate, generating a strong electric field between the plate and the entrance to the TOF analyzer. Ions of smaller mass are accelerated toward the flight tube entrance faster than those of larger mass and, once inside the TOF tube, smaller ions traverse the flight path and reach the detector more quickly. The detector records the time and intensity of ions and, once flight time is correlated with mass, generates a spectrum of observed *m*/*z* values. Because the charge of most ions generated in MALDI is 1, the spectrum is usually a straightforward account of ion masses.

Electrospray ionization

In the ESI technique, ionization is achieved when an electric field is applied to a flowing analyte solution. The applied potential imparts a charge to the liquid, creating small droplets of analyte-containing solvent that move toward the entrance to the mass spectrometer. As the solvent particles move into the mass spectrometer, they are repeatedly desolvated and fragmented into smaller particles in a process that results in multiply charged ions.

Unlike MALDI, ESI is performed at atmospheric pressure and can easily be coupled to separation methods such high-performance liquid chromatography (HPLC) or capillary electrophoresis (CE) to allow continuous infusion of samples. By utilizing microbore capillaries and extremely low flow rates for introduction of the sample, detection limits at the femtomole level are possible with excellent signal-to-noise ratios (Gatlin et al., 1998). ESI is most frequently coupled with a triple quadrupole, quadrupole-time-of-flight (QTOF), or ion trap mass spectrometer. Triple quadrupole mass analyzers are comprised of three sets of four parallel metal rods. When direct current and radio frequency voltage is applied to these rods, an electric field is created, which directs the trajectory of ions as they progress down the axis between the rods. If an ion meets the *m*/z requirements determined by the voltage to the quadrupole, it will pass through the quadrupole; all other ions will be rejected. In the triple quadrupole instrument, electric fields are generated in the first and third set of quadrupoles, whereas radio frequency voltages are applied to the second quadrupole. The second quadrupole serves as a collision cell where ions collide with atoms of neutral gases to form peptide fragments (Hunt et al., 1986). In the QTOF instrument, the third quadrupole is replaced by a TOF mass analyzer, resulting in a hybrid instrument that has the high mass accuracy of a TOF instrument coupled with the resolution of a quadrupole instrument.

An ion trap instrument operates by collecting and storing ions coming from the source in a trap, scanning the collection of ions for their *m*/*z* values, and sequentially ejecting ions from the trap for MS/MS analysis. Ions are maintained in the trap by the application of direct current and radio frequency voltages; they are ejected from the trap by stepping the radio frequency. For the analysis of proteins and peptides, as well as other biological molecules, the mass analyzer portion of the mass spectrometer typically includes two mass analyzers separated by an ion-activation device (Fig. 5.6.2). In this tandem arrangement of mass analyzers (MS/MS), a mixture of tryptic peptides is introduced into the first mass analyzer where they are separated by their *m*/*z* values. After separation, selected ions are advanced to the ion-activation device. While numerous ion-activation techniques are available, the one most commonly used is collision-induced dissociation (CID). In CID, slow-moving peptide ions collide with inert gas molecules with sufficient kinetic energy to cause peptide bonds to break. The charged fragments from this dissociation are advanced to the second mass spectrometer where they are separated on the basis of their *m*/*z* values before progressing to the ion detector (Fig. 5.6.3). These low-energy collisions result in fragmentation primarily at the amide bond of the peptide, creating a ladder of sequencing ions that differ by one amino acid. By assembling the collection of ions and determining the mass difference between fragments, the amino acid sequence of the peptide can be determined (Hunt et al., 1986).

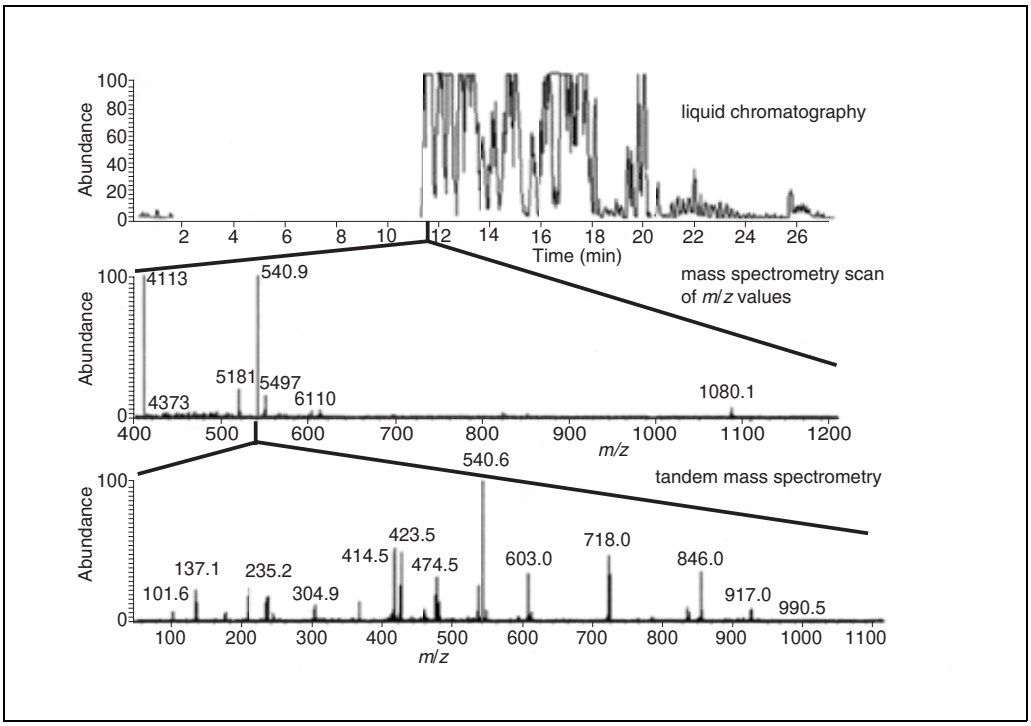

Figure 5.6.3 In the LC-MS/MS technique, peptides are first separated in a liquid chromatographic step. Fractions from the chromatography are subjected to MS and selected ions from the MS experiment are further fragmented in an MS/MS experiment.

Protein mixture analysis: MALDI versus ESI

Even using MS techniques, high-throughput analysis of protein mixtures was not feasible until large databases of protein and DNA sequence information became available and search algorithms were developed that could correlate MS data to the information in the databases (Eng et al., 1994; Yates, 1998b). The information generated by both MALDI-TOF-MS and ESI-MS/MS experiments has been used to identify proteins in complex mixtures.

The high accuracy of peptide mass measurement using a MALDI-TOF instrument allows elucidation of the amino acid composition of the peptide, and computerized search algorithms allow matching of the observed data with proteins in a database. In this method, a collection of peptides generated from tryptic digestion of a mixture of proteins is analyzed with the MALDI-TOF-MS. The masses of the individual peptides can be used to search against databases of known proteins to identify theoretical peptides of matching masses and their respective protein sources. Because mass alone is not always unique for peptide identification, it is typical that a number of peptides from a protein would be needed for identification.

Unlike MALDI, the peptide fragmentation data collected from the ESI-MS/MS experiment are specific for a unique amino acid sequence. Because fragmentation patterns of peptides in a CID experiment are predictable, theoretical fragmentation patterns can be generated from sequences in a database, and the observed spectra can be searched against these (see Basic Protocol 4). Because the spectral data are sequence specific, only a single peptide spectrum is needed for protein identification. The ESI-MS/MS method requires no pre-interpretation of spectra prior to a database search. Algorithms automatically search uninterpreted MS/MS spectra against protein and DNA databases (Fig. 5.6.4). Sensitivity for peptide detection using either MALDI or ESI is 0.5 to 10 fmol.

Sample preparation: PAGE versus LC

When analyzing samples of highly complex mixtures, sample complexity must usually be reduced before the sample is introduced into the mass spectrometer. As discussed above, one method of achieving this is through separation of the proteins by gel electrophoresis. For protein mixtures of low complexity, one-dimensional SDS-PAGE (*UNIT 6.1*) has been used. Using this technique, proteins can be separated on the basis of molecular weight, but the degree of resolution is modest. For more complex mixtures, a two-dimensional SDS-PAGE sepa-

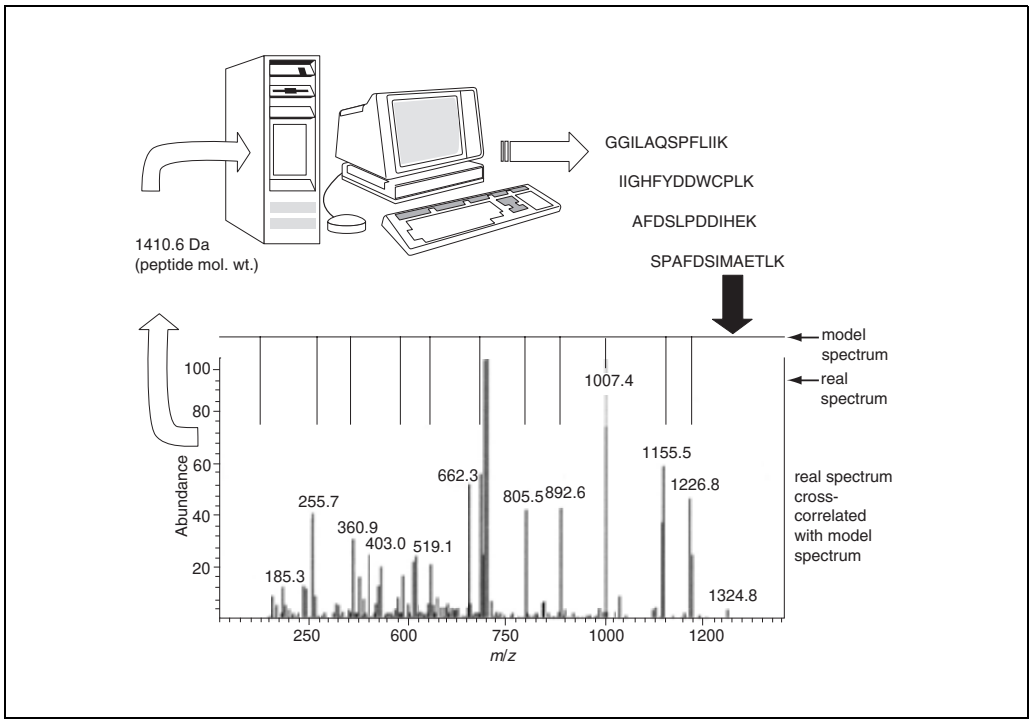

Figure 5.6.4 Search algorithms employed for LC-MS/MS data interpretation search uninterpreted MS/MS spectra against protein and DNA databases. Results are scored on the cross-correlation fit between a theoretical (or model) spectrum and the tandem mass spectra obtained from the experiment (real spectrum).

ration method (*UNIT 6.4*) has been widely adopted. In this technique, proteins are separated on the basis of isoelectric point in the first dimension and by molecular weight in the second. The resolution capability of two-dimensional SDS-PAGE is excellent, and it is theoretically capable of detecting up to 10,000 protein spots. Nevertheless, the method lacks sufficient dynamic range to identify low-abundance proteins in complex mixtures and has been shown to be incompatible with certain classes of proteins (Gygi et al., 2000; Santoni et al., 2000). To mitigate some of the problems of identifying minor protein constituents from a two-dimensional gel, an enrichment step is possible prior to electrophoresis. However, enrichment techniques require some knowledge of biological or chemical activity and are thus often not possible when working with unknown proteins.

Alternatively, mixtures of proteins can be proteolytically digested without separation and directly analyzed by microcolumn-LC-MS/MS. By combining liquid chromatography with ESI-MS/MS, on-line analysis of complex mixtures is possible. In this method, a pulled microcapillary column is packed with a reversed-phase packing material and molecules are separated on the basis of their molecular weight in the reversed-phase chromatography step and then separated according to their *m/z* value in the mass spectrometer. After the mixture is loaded on the chromatography column, no further sample handling is necessary. When even greater peptide separation is desired, multidimensional protein identification technology (MudPIT) can be employed (Link et al., 1999; Washburn and Yates, 2000; Washburn et al., 2001; Wolters et al., 2001). In this technique, peptides are first separated by strong cation exchange, and are eluted onto a second phase by a step gradient of increasing salt concentration. The second phase consists of reversed-phase material that separates on the basis of hydrophobicity. Peptides are then eluted directly onto the MS. Methods for direct analysis of protein mixtures have been applied to a number of systems and have been proven useful over a large dynamic range and for all classes of proteins, including membrane proteins.

Critical Parameters

The success of protein mixture analysis by MS is largely dependent on the success of the methods used to isolate and purify the proteins to be analyzed. For gel-based methods, analysis is usually performed on peptides obtained by enzymatic digestion after separation of the proteins on a gel. Ideally, each band excised from the gel represents a single protein. Prefractiona-

tion of complex samples prior to gel electrophoresis might be required to obtain clean separation. Sample handling steps should be minimized to avoid unnecessary sample loss and to reduce the risk of contamination of the sample with keratin, which can easily obscure the sample protein in the mass spectrum. It is therefore critical to wear gloves when working with the proteins and to avoid exposure to dust. Care must also be taken to eliminate contaminants from glassware and plasticware. Proteins purified on a two-dimensional gel can be extracted from the gel and digested with trypsin prior to analysis on the mass spectrometer, or they can be digested in the gel prior to extraction. The protocol for in-gel digestion of proteins described here (Basic Protocol 1) is a widely used and very effective method. The authors have been able to reduce the time required for this protocol, however, by reducing or eliminating some of the wash steps.

For direct analysis of proteins using LC-MS/MS, low–flow rate LC (200 to 300 nl/min) is necessary to achieve sensitivity at the femtomole scale. Flow rates should not, however, drop below 100 nl/min, or the flow may stop completely. Optimal flow rates can be achieved using a standard LC setup equipped with a precolumn splitting device. Successful chromatography is also dependent on producing, packing, and loading a high-quality microcapillary column. Microcapillaries are most reproducibly constructed using a commercial laser puller, but in some labs they are produced manually by weighting the end of the capillary while heating the center. Microcapillary columns should have an internal diameter of 50 to 100 μm, with a tip internal diameter of ~5 μm. Microcapillaries with smaller diameters can clog easily; larger diameters result in less-efficient electrospray. Frequently, spray problems that arise from larger column diameters can be offset by increasing the voltage.

Columns should be packed with packing material that is 3 to 10 μm in size. A number of different packing materials are suitable for proteomics applications including Aqua (Phenomex), Betabasic (Thermo Hypersil-Keystone), Targa (Bodman Industries), and Polaris (Metachem). Zorbax (Hewlett-Packard) has also been used but requires the use of an ion-pairing solvent (i.e., 0.02% heptaflourobutryic acid added to HPLC solvents), which may cause signal suppression in the mass spectrometer.

Troubleshooting

For two-dimensional LC-MS/MS analysis, the production of the microcapillary column is critical for success. If the column is not properly pulled, then packing material will not load smoothly and chromatography will be poor. If no solvent flow is seen at the tip of the column during column loading, attempts can be made to slightly open the tip by gently scoring it with a ceramic scribe. If the solvent flow does not improve after a few attempts to score the column tip, it should be abandoned, as it usually proves problematic throughout the rest of the experiment. If the column becomes plugged during loading of the sample, it is frequently a sign that the sample has not been properly centrifuged prior to loading to ensure that particulate in the sample does not enter the column. Often, clogged tips can be opened by immersing the column in hot water. If the column tip breaks after the sample has been loaded, it is possible to pack another microcapillary column with 4 cm of the reversed-phase material and attach the original column with a PEEK connector.

It is important to use clean, fresh solvents for chromatography on the microcapillary column because impure HPLC solvents can result in high background noise. Finally, the mass spectrometer needs to be cleaned and tuned approximately every 10 to 15 days, depending on use. The loss of calibration can usually be detected by a blank MS/MS spectrum or a marked decrease in the size of the raw file in the data output after acquisition. If this happens, the instrument needs to be recalibrated using commercial standards.

Anticipated Results

Identification of proteins by LC-MS/MS or two-dimensional electrophoresis followed by MS/MS is made by the identification of peptides generated by enzymatic digestion of the protein. The fraction of the intact protein sequence represented by the identified peptides is referred to as sequence coverage. Reliable identification of a protein is possible with as little as 5% to 10% coverage. Experimental results depend on the complexity of the sample, the enzyme used to digest the sample, and the source of the sample. In a recent publication, MacCoss et al. (2002) showed sequence coverage for five proteins (Cdc2, Cdc13, Cig 1, Crystallin α A chain, and Crystallin α B chain). Trypsin digestion resulted in sequence coverage ranging from 28.9% to 74.5%. Combined results from digestion with three separate en-

zymes increased the sequence coverage to 57.8% to 94.9%.

Using these methods, all post-translational modifications—including phosphorylation, methylation, and acylation—can be identified. Attachment of carbohydrates and lipids is possible but more complex as these modifications are more labile.

Time Considerations

The time required for LC-MS/MS analysis is dependent on the complexity of the sample and the method used to analyze it. For trypsin-digested, gel-purified proteins, a one-dimensional column with a 20- to 50-min gradient is sufficient, whereas a one-dimensional separation of simple mixtures will usually require a 2- to 3-hr gradient. The time required for a multidimensional protein identification technology (MuDPIT) run is determined by the number of salt bumps incorporated in the experiment. A six-step run lasts ~12 hr and a twelve-step run lasts ~24 hr. Additionally, pulling columns will take less than 5 min and column packing will take 15 to 90 min depending on how many phases are being loaded. Sample loading will take anywhere from 15 min to 5 hr depending on the volume and viscosity of the sample and on the size of the column being loaded.

ABSTRACT

Correct localization and topology are crucial for a protein's cellular function. To determine topologies of membrane proteins, a new technique, called fluorescence protease protection (FPP) assay, has recently been established. The sole requirements for FPP are the expression of fluorescent-protein fusion proteins and the selective permeabilization of the plasma membrane, permitting a wide range of cell types and organelles to be investigated. Proteins topologies in organelles like endoplasmic reticulum, Golgi apparatus, mitochondria, peroxisomes, and autophagosomes have already been determined by FPP. Here, two different step-by-step protocols of the FPP assay are provided. First, we describe the FPP assay using fluorescence microscopy for single adherent cells, and second, we outline the FPP assay for high-throughput screening applications. *Curr. Protoc. Cell Biol.* 49:5.7.1-5.7.12. © 2010 by John Wiley & Sons, Inc.

Keywords: protein topology • fluorescence microscopy • high-throughput screening

INTRODUCTION

This unit describes a fluorescence-based imaging technology, which combines live-cell microscopy with a biochemical approach to assess transmembrane protein topology (Lorenz et al., 2006). The technique uses fluorescent protein (FP) fusion proteins. Our approach provides information about the position of a FP tag relative to a lipid membrane. The FPP assay requires no additional design beyond the construction of a FP fusion protein expressed in either tissue culture or primary cells. The assay is based upon the inaccessibility of proteases to protected intracellular regions of permeabilized cells. To permeabilize cells, we take advantage of the sharp gradient of cholesterol in the lipid bilayers of cells. Relative to other intracellular membranes, the lipid bilayer of the plasma membrane contains by far the most cholesterol, with ~65% to 80% of the free cellular cholesterol (Liscum and Munn, 1999). In this assay, we use the cholesterol-binding drug digitonin to selectively permeabilize the plasma membrane.

Permeabilization allows the protease trypsin to enter the cell from the extracellular environment. As a consequence, not only proteins facing the environment, but also intracellular membrane protein domains facing the cytosol are degraded by the protease. Trypsin-mediated destruction of FP fusions with proteins-of-interest (e.g., N- or C-terminal tags) will thus shed light on the orientations of the target proteins (Fig. 5.7.1).

In this unit, two FPP protocols are described to visualize and quantitate protein topology: FPP for fluorescence microscopes (see Basic Protocol 1) and FPP for high-throughput screening using a fluorescence microplate reader (see Basic Protocol 2). This unit also

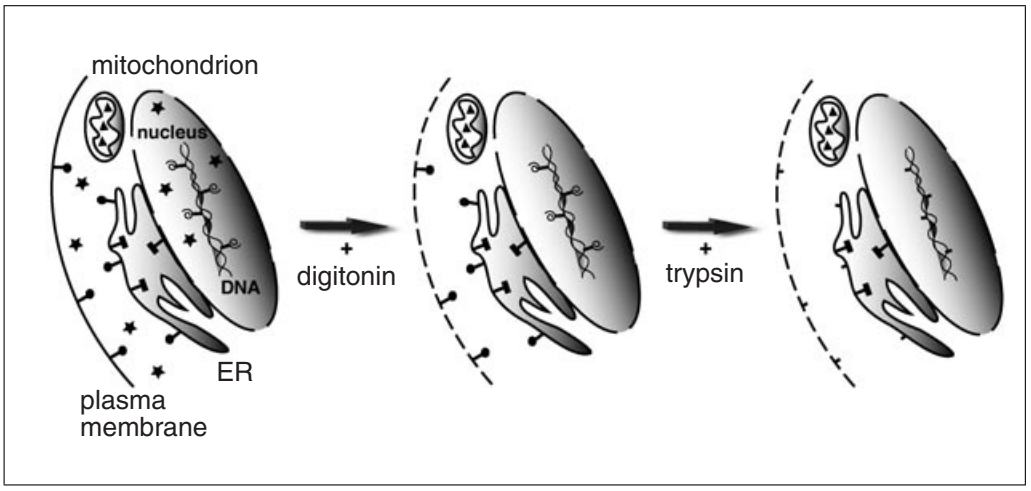

Figure 5.7.1 Mechanism and possible applications of the FPP assay. Cartoon of the FPP assay illustrates localization of different fluorescent protein–tagged proteins, soluble or membrane bound. Addition of digitonin permeabilizes the plasma membrane and causes release of unbound cytosolic and nuclear molecules (star). Membrane- (disc) or DNA-bound (spiral) molecules will stay. Incubation with the protease trypsin digests all fluorescent proteins that are not protected by a lipid membrane. Luminal proteins of the ER (rectangle) or mitochondrion (triangle) are protected from proteases by a lipid membrane. These shielded fluorescence signals will remain.

describes a support protocol for optimizing permeabilization and trypsin treatment of cells.

STRATEGIC PLANNING

Fluorescent Protein Tag

The method requires the construction of a fusion between the coding sequence of a FP and the gene-of-interest. We recommend creating different sets of expression plasmids encoding FP-fusion proteins. For single-spanning membrane proteins, at least two versions of the protein should be created, an amino- and a carboxy-terminal fusion with a FP. For multi-spanning membrane proteins, in addition to N- and C-terminal fusions, either a fusion with an FP inserted within the protein-of-interest or a truncated fusion should be made. Special care must be taken when genes of transmembrane proteins with a targeting sequence or signal sequences are fused to a FP at the amino-terminus. The targeting sequence or signal sequence is often removed by proteolytic cleavage following protein translocation. In such cases, the FP must be inserted after the cleavage site of the signal sequence to generate a mature fusion protein-of-interest harboring an amino-terminal FP tag.

BASIC PROTOCOL 1

FPP ASSAY FOR FLUORESCENCE MICROSCOPES

This protocol describes, first, the plating and transfection of cells in chamber slides, which is required for live-cell imaging, and second, the use of digitonin and trypsin to determine membrane topology of the protein-of-interest. To optimize the FPP assay with untested proteins-of-interest, please pay special attention to the Support Protocol.

NOTE: All solutions and equipment coming into contact with cells must be sterile, and proper sterile techniques should be applied accordingly.

NOTE: All culture incubations should be performed in a humidified 37°C, 5% CO_2 incubator, unless otherwise specified.

CAUTION: Digitonin is toxic by inhalation, by skin contact, and if swallowed. Wear suitable protective clothing and gloves.

Materials

Adherent cells (e.g., HeLa, COS-7, NRK, HEK293) to be transfected with a soluble FP and/or a FP fusion plasmid
Cell culture medium for cells of interest (e.g., RPMI 1640 or DMEM, supplemented with 10% FBS, 2 mM glutamine, 100 U/ml penicillin, and 100 μg/ml streptomycin)
FP expression plasmid (e.g., Clontech) encoding the fluorescent protein-of-interest
Transfection reagent (e.g., FuGENE 6; Roche)
FP (soluble) expression plasmid, e.g., mCFP, EGFP (Clontech)
KHM buffer (see recipe) or cell culture medium without FBS and without phenol red
Protease solution (see recipe)
Digitonin (see recipe)

Sterile tissue culture hood
8-well Lab-Tek chamber slide (Nalge Nunc, cat. no. 155411)
Inverted fluorescence microscope (either widefield or confocal), capable of time lapse recording

Additional reagents and equipment for transfection of cells (*UNIT 20.6*)

Set up the imaging chamber

1. To image adherent cells on chambered slides, seed cells on Lab-Tek chambered coverglass in 0.2 ml cell culture medium.

   The cell density for imaging depends on cell type, cell size, and experimental design. Confluency of cells should be 60% to 90% at the time of the FPP assay.

   These chambers consist of wells with a cover glass bottom, which permits the use of high-numerical-aperture oil objectives for viewing.

Transfect the cells

2. To enhance the probability of having multiple cells to choose from, transfect the cells with a FP chimeric protein vector using a high-efficiency transfection method, such as a lipid transfection reagent with low toxicity (e.g., FuGENE6; *UNIT 20.6*). To control for plasma membrane permeabilization, use double-transfected cells: cells co-expressing the FP-tagged protein-of-interest together with a spectral different soluble FP with non-overlapping spectral properties, e.g., mCFP, EGFP (Clontech).

   Before performing an FPP assay protocol, the investigator must ensure that there is sufficient FP fluorescence in the expressing cells to maintain a significant fluorescent signal relative to background noise during image acquisition. Most standard transfection protocols are sufficient to provide bright specimens. Stable transfectants express lower levels of protein. Transient transfectants usually express higher levels of proteins; this sometimes results in overexpression artifacts, such as protein aggregation or saturation of protein targeting machinery, which lead to inappropriate localization. Immunofluorescence staining of the endogenous protein with specific antibodies should always confirm proper localization of the overexpressed FP-tagged protein.

   Adherent cells should be transiently transfected 6 to 24 hr prior to the experiment. Most commercially available FP expression vectors are under the control of a very strong promoter, e.g., CMV promoter.

Set up the imaging system

3. Set up the fluorescence microscope and its associated hardware.

   It is assumed that the investigator is familiar with the basic operation of the microscope.

   Use a high-NA objective for maximal signal collection and spatial resolution.

Configure the light path for optimal excitation and emission detection of the fluorophores expressed in the transfected cells.

We recommend that the investigator closely examine the spectral profiles of the FPs of interest to ensure an optimal excitation and emission filter combination.

Most software packages provide the user with a list of preset light path configurations for combinations of common fluorophores. However, the investigator should determine if the preset configuration is indeed optimal for the specific FP of interest and modify the configuration, if needed.

The choice of filters is critical for achieving high signal-to-noise levels and minimizing spectral bleed-through at the same time.

Optional: Pretrypsinization for plasma membrane localized FP

If you are investigating the topology of a plasma membrane protein, these steps are required, otherwise, continue with step 11.

4. Remove the cell culture medium from the cells co-expressing the FP-tagged protein-of-interest and a soluble FP.
5. Wash the cells three times, for 1 min each time in 0.2 ml KHM buffer (or alternatively with serum-free medium), at a temperature that is appropriate for the experiment.

   In our hands, temperatures of 20° to 37°C were suitable for the protocol.

6. Place the chamber containing the cells in KHM buffer on the fluorescence microscope stage.
7. Record the images, which represent the pretrypsinization and prepermeabilization situation.
8. Add 0.2 ml 4 to 8 mM of the protease solution (in KHM buffer) directly onto the cells.

   Use the effective trypsin concentration determined according to the Support Protocol.

9. Immediately, start taking images on the fluorescence microscope to record how fast fluorescent signals of the protein-of-interest tagged with a FP disappear.
10. Wash the cells three times, for 1 min each time in 0.2 ml cell culture medium containing serum, at a temperature that is appropriate for the experiment.

    This step is required to inhibit the protease activity of trypsin before permeabilizing the plasma membrane.

Permeabilize the plasma membrane

11. Remove the cell culture medium from the cells co-expressing the FP-tagged protein-of-interest and a soluble FP. Wash the cells three times, for 1 min each time in 0.2 ml KHM buffer (or alternatively with serum-free medium), at a temperature that is appropriate for the experiment.
12. Place the chamber containing the cells in KHM buffer on the fluorescence microscope stage.
13. Record the first images, which represent the prepermeabilization situation.
14. To permeabilize the plasma membrane, add the same volume of KHM buffer containing the (previously determined) effective digitonin concentration to the cells (see the Support Protocol).

    The overexpressed soluble FP diffuses freely in the cytosol and nucleoplasm. Effective permeabilization of the plasma membrane by digitonin results in the disappearance of the FP signal within 10 to 60 sec.

15. Take images of the cells after the digitonin application to capture the post-permeabilization situation.

    The fluorescence signal of the membrane-anchored FP will remain and data acquisition should be reduced to few frames to prevent bleaching of the FP.

Disrupt fluorescence signal

16. Wash the cells in 0.2 ml KHM buffer (optional) and then add 0.2 ml 4 to 8 mM of the protease solution (in KHM buffer) directly onto the cells.

    Use the effective trypsin concentration determined according to the Support Protocol.

17. Immediately, start taking images on the fluorescence microscope to record how fast fluorescent signals of the protein-of-interest tagged with a FP disappear or persist.

    Duration of imaging should be adapted according to the Support Protocol.

Quantify fluorescence signal-intensities

18. Assess recorded images and quantify signal intensities to determine the subcellular localization and topology of the protein.

    As the FPP assay provides a visual screen for determining protein orientations within membranes, an unaffected FP signal will indicate a protected protein domain (i.e., not exposed to the cytosol), while the disappearance of the FP signal will clearly indicate the exposure of the FP-containing protein domain to the cytosolic side. Hence, the persistence or disappearance of the fluorescence signal upon the FPP assay will give information about the protein's localization and topology.

    Freely available image analysis software (e.g., ImageJ, NIH) or software on existing microscope platforms (e.g., Zeiss LSM Image Examiner, Zeiss) can be used to measure fluorescence intensities.

ESTABLISH CONDITIONS FOR OPTIMAL PLASMA MEMBRANE PERMEABILIZATION AND DESTRUCTION OF FPs

SUPPORT PROTOCOL

This protocol describes how to optimize plasma-membrane permeabilization using digitonin, followed by the determination of effective trypsin concentration, to analyze FP localization.

Additional Materials *(also see Basic Protocol 1)*

FP (soluble) expression plasmid, e.g., mCFP, EGFP (Clontech)
Membrane-anchored, but cytosol-facing FP, e.g., Caveolin 1-YFP (Tagawa et al., 2005) *or* VSVG-YFP (Presley et al., 1997)

NOTE: Soluble- and membrane-anchored FPs must have non-overlapping spectral properties.

Set up the imaging chamber

1. To visualize adherent cells on chambered slides, seed cells on Lab-Tek chambered coverglass.

Transfect the cells

2. To enhance the probability of having multiple cells to choose from, transfect the cells with soluble- and membrane-anchored FP vectors using a high-efficiency transfection method, such as a lipid transfection reagent with low toxicity (e.g., FuGENE6; *UNIT 20.6*).

3. Determine the optimal expression level of the FPs and the time requirements for imaging empirically for each sample and condition.

Set up the imaging system

4. Set up the fluorescence microscope and its associated hardware.

Permeabilize the plasma membrane

5. Remove the cell culture medium from the cells expressing a soluble FP only. Wash the cells three times, each time for 1 min in 0.2 ml KHM buffer (or alternatively with serum-free medium), at a temperature that is appropriate for the experiment.
6. Place the chamber-containing cells in KHM buffer on the fluorescence microscope stage.
7. Record the first images, which represent the prepermeabilization situation.
8. To permeabilize the plasma membrane, add the same volume of KHM buffer containing digitonin to the cells. Determine the effective digitonin concentration by applying increasing concentrations of digitonin.

   Effective permeabilization of the plasma membrane using digitonin results in the complete disappearance of the fluorescence signal within 10 to 60 sec.

   A good starting concentration for most cell lines tested (COS-7, NRK, HeLa, BHK, N2a) is 20 μM digitonin. If 20 μM digitonin is not sufficient to permeabilize the cells, increase the digitonin concentration in 20 μM increments. Use the lowest possible digitonin concentration that provides efficient plasma membrane permeabilization.

Permeabilize the plasma membrane and disrupt FP

9. To permeabilize the plasma membrane of cells that express a soluble FP and a membrane-anchored FP, wash cells in 0.2 ml KHM buffer.
10. Record the first images, which represent the prepermeabilization situation.
11. Incubate the cells with KHM buffer containing the (previously determined) effective digitonin concentration.
12. Take images of the cells after the digitonin application to capture the post-permeabilization situation.
13. Wash cells in 0.2 ml KHM buffer (optional) and add 0.2 ml 4 to 8 mM of the protease solution (in KHM buffer) directly onto the cells.
14. Immediately, start taking images on the fluorescence microscope to record how fast fluorescent signals disappear or persist.

    The effective protease concentration results in the disappearance of the FP signal within 30 to 90 sec.

    Under special circumstances in which the sensitivity of the protein-of-interest to trypsin or its accessibility is under question, the use of an alternative protease (e.g., 50 μg/ml proteinase K), or a combination of proteases, is recommended.

BASIC PROTOCOL 2

FPP ASSAY FOR HIGH-THROUGHPUT SCREENING (HTS)

This protocol describes, first, the preparation of cells for the HTS FPP assay, and second, a step-by-step guide to determine the membrane localization of the protein-of-choice under a variety of conditions. It is recommended to determine the required concentrations of digitonin and trypsin, timing of the permeabilization step, and FP destruction according to Basic Protocol 1 and the Support Protocol prior to performing the following high-throughput protocol.

Materials

Adherent cells to be transfected with a soluble FP and/or a FP fusion plasmid
Transfection reagent (e.g., FuGENE 6; Roche)
Cell culture medium for cells of interest (e.g., RPMI 1640 or DMEM, supplemented with 10% FBS, 2 mM glutamine, 100 U/ml penicillin, and 100 μg/ml streptomycin)
FP (soluble) expression plasmid, e.g., mCherry (Clontech)
FP expression plasmid containing DNA encoding the protein-of-interest
0.05% (w/v) trypsin/0.53 mM EDTA (Invitrogen)
Phosphate-buffered saline, calcium- and magnesium-free (CMF-PBS)
KHM buffer (see recipe) *or* cell culture medium without FBS and without phenol red
Digitonin (see recipe)
Protease solution (see recipe)

Sterile tissue culture hood
10-cm cell culture dish
Hemacytometer
96-well tissue culture plates (Special Optics Low Fluorescence Assay Plates; Sigma-Aldrich: Corning CLS3720)
Microplate fluorescence reader [e.g., from Varian (Cary Eclipse), BioTek, Tecan)]
Microplate washer and dispenser (e.g., EL406, BioTek; multichannel pipets may be used for initial trial experiments)

Transfect the cells

1. To facilitate robust expression levels of the FPs in cells, transfect cells in a large tissue culture dish (e.g., 10-cm tissue culture dish) using a high-efficiency, nontoxic transfection method, such as a lipid transfection reagent with low toxicity (e.g., FuGENE6; *UNIT 20.6*).

   Adherent cells should be transiently transfected 18 to 24 hr prior to the FPP assay.

   To control each step of the experiment, it is advised to use four different cells. First, cells transfected with a soluble FP only; second, cells transfected with the protein-of-interest tagged with a FP; third, cells transfected with both plasmids; and fourth, nontransfected cells. The two FPs should have non-overlapping spectral properties.

Set up the imaging chamber

2. Trypsinize the transfected cells as follows:
   a. At a time point 5 to 6 hr post-transfection, wash the cells with 10 ml CMF-PBS and remove the PBS.
   b. Add 2 ml trypsin/EDTA and wait for 3 to 5 min or until the cells are easily detached by slightly knocking on the tissue culture dish (time depends on the cell line used).
   c. Stop the trypsinization by adding 8 ml of cell culture medium containing 10% FBS.
   d. To break up the cell clumps, in order to obtain a single-cell suspension, pipet the cell sample up and down several times.
3. Count the cells with a hemacytometer and transfer them into 96-well tissue culture plates equipped with transparent bottoms.

   These chambers consist of white or black wells with a cover glass bottom, which permits the use of a fluorescence reader.

   The cell density for fluorescence scanning depends on cell type, cell size, and experimental design. Confluency of cells should be 70% to 80% at the time of the FPP assay.
4. Leave the cells for at least 12 hr in a tissue culture incubator.

Modulate cell culture conditions

5. Add certain drugs or inhibitors, infect with viruses or bacteria, etc. according to the experimental design.

Set up the fluorescence reader

6. Set up the fluorescence reader and the acquisition software.

   Fluorescence readers with a bottom-reading mode are preferred.

   We recommend that the investigator closely examine the spectral profiles of the FPs of interest to ensure an optimal excitation and emission filter combination.

   Most software packages provide the user with a list of preset light path configurations for combinations of common fluorophores. However, the investigator should determine if the preset configuration is indeed optimal for the specific FP of interest and modify the configuration, if needed.

   The choice of filters (bandwidth of fluorescence detection) and time of acquisition is critical for achieving high signal-to-noise levels and minimizing spectral bleed-through at the same time.

   The bottom-reading mode should be preferred over top reading, as it provides better signal-to-noise ratios for adherent cells.

Permeabilize the plasma membrane

7. Place the 96-well plate with the transfected cells in a microplate washer and dispenser.

8. Remove the cell culture medium from the cells and wash the cells three times, each time for 1 min in 0.15 ml KHM buffer (or alternatively with serum-free and phenol-red free medium), at a temperature that is appropriate for the experiment.

   In our hands, temperatures of 20° to 37°C were suitable for the protocol.

9. Place the 96-well plates with cells in KHM buffer on the fluorescence reader.

10. Record the first dataset, which represents the prepermeabilization situation.

11. Place the 96-well plate in a microplate washer and dispenser.

12. Add the same volume of KHM buffer containing the (previously determined) effective digitonin concentration to the cells (see the Support Protocol).

    The soluble FP diffuses freely in the cytosol and nucleoplasm. Effective permeabilization of the plasma membrane by digitonin results in the diffusion of soluble FPs outside the cell and consequently the disappearance of the FP-signal within 10 to 60 sec.

13. Place the 96-well plates in digitonin/KHM buffer on the fluorescence reader.

14. Measure the fluorescence of the cells after the digitonin application to capture the post-permeabilization state. Use the end-point or single-point acquisition mode to prevent bleaching of the fluorescence signal.

Destroy fluorescence signal

15. Place the 96-well plate with the permeabilized cells in the microplate washer and dispenser.

16. Wash cells in 0.15 ml KHM buffer (optional) and then add 4 to 8 mM of the protease solution (in KHM buffer) directly onto the cells.

17. Place the 96-well plate with the cells in trypsin/KHM buffer on the fluorescence reader.

18. Use the kinetic-fluorescence acquisition mode to record how fast fluorescent signals of the protein-of-interest tagged with a FP disappear or persist. Measure the signals

in intervals to prevent bleaching of the fluorescence signal [e.g., every 1 min, depending on the previously determined timing of trypsin-mediated disruption of the fluorescence signal (see the Support Protocol)].

Quantify fluorescence signal intensities

19. Assess acquired fluorescence data. Normalize the data using the fluorescence signal of non-transfected cells (blank). Use signal intensities of replicates to calculate the median and standard deviation of the samples, and determine loss of fluorescence signal dependent on different treatments or concentrations.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Digitonin stock solution

Dissolve digitonin (Calbiochem, cat. no. 300410) in water (24.58 mg/ml, 20 mM) by shaking in a thermomixer at 100°C until a clear solution is obtained.

Commercial digitonin sometimes has very low solubility because of purity problems. Always choose the highest-purity or purify digitonin according to a protocol by Janski and Cornell (1980).

Solubilized digitonin remains stable in solution for at least 1 week at room temperature. The capability of digitonin to permeabilize membranes may differ from batch to batch from all suppliers because of differences in purity.

KHM buffer

110 mM potassium acetate
20 mM HEPES, pH 7.4
2 mM $MgCl_2$
Store up to 6 months at 4°C

Protease solution

Dissolve trypsin in KHM buffer to get an 8 mM solution. Make aliquots and store up to 12 months at −20°C.

Alternatively, 50 μg/ml proteinase K can be used for the FPP assay.

COMMENTARY

Background Information

The FPP assay utilizes specific permeabilization of the cholesterol-rich plasma membrane using digitonin and the resulting accessibility of intracellular compartments to nonspecific proteases. Cholesterol is the prevalent sterol in vertebrates, and the intercalation of digitonin into cholesterol-rich membranes leads to their leakiness. Digitonin forms a complex with unesterified 3-β-hydroxysterols (Takagi et al., 1982). The extent of permeabilization is sufficient to allow cytosolic contents to diffuse across the plasma membrane. However, intracellular organelles and the cytoskeletal system are retained in cells permeabilized with digitonin (Plutner et al., 1992; Wilson et al., 1995). In addition to movement of cytosolic contents out of the cell, permeabilization allows relatively small molecules, like the protease trypsin, to enter the cell from the extracellular environment. Digitonin is unable to permeabilize lipid membranes with low cholesterol content efficiently (e.g., endoplasmic reticulum, Golgi, peroxisomes, mitochondria, and autophagosomes). Hence, lipid membrane–enclosed organelles are not accessible to trypsin. Trypsin will exclusively destroy the FP if it is facing the cytosol or exoplasmic environment. Therefore, the FPP assay provides information about the localization and membrane orientation of a fluorescence-tagged protein.

Critical Parameters

The critical parameters for setting up time-lapse imaging (Basic Protocol 1) and

high-throughput screening (Basic Protocol 2) experiments are described in great detail in the respective protocols. There are several considerations for microscopy imaging and high-throughput screening experiments in living cells that require additional emphasis.

Choice of fluorescent protein

The investigator should use the latest generation of spectral variants, which have been improved for folding, chromophore maturation, brightness, and photostability. In all cases, the investigator needs to minimize undesired

Table 5.7.1 Troubleshooting Guide for Fluorescence Protease Protection (FPP) Assay

Problem	Possible cause	Solution
Fluorescence signal of soluble FP does not disappear after digitonin application.	Inefficient digitonin concentration for plasma membrane permeabilization.	Increase digitonin concentration.
The effective digitonin concentration for cell permeabilization does not work in every cell culture well.	Difference in cell confluencies lead to altered plasma membrane permeabilization.	Keep cell confluencies constant in different cell chambers.
	Remaining medium with FBS (contains cholesterol) in the cell culture chamber captures digitonin.	Be sure to wash the samples three times with KHM buffer before the application of digitonin.
Digitonin permeabilizes intracellular membranes.	Digitonin concentration that is too high may permeabilize membranes with low cholesterol content.	Reduce and optimize digitonin concentration.
Fluorophore signal on either side of an organelle membrane is gone after addition of trypsin.	Both fluorophores were bleached.	Decrease excitation light intensity or reduce acquisition time per frame.
	Digitonin concentration is too high.	Reduce and optimize digitonin concentration.
Intracellular organelle morphology changes dramatically upon prolonged digitonin incubation.	Organelle morphology of different cell types is variably affected by digitonin.	Keep digitonin incubation time as short as possible and wash cells in KHM buffer immediately after permeabilization.
	Change of milieu for very sensitive organelles, like mitochondria.	Replace KHM buffer with a more complex, cytosol-like buffer (Kuznetsov et al., 2008).
Digitonin permeabilization and protease digestion vary significantly between cells in the same chamber.	The distribution of digitonin and protease is restricted in the cell chamber.	Ensure efficient blending of digitonin and protease by adding sufficient volumes to the chamber.
Cells are mostly on the edge of the tissue culture well.	Convex meniscus of culture medium. Plates were swirled for seeding.	Use a small volume for cell seeding and add more medium later.
Cells do not adhere to the tissue culture well with the glass bottom for imaging or HTS.	Cells adhere better to plastic than to glass.	Try fibronectin (5 $\mu g/cm^2$), laminin (2 $\mu g/cm^2$), or collagen (5 $\mu g/cm^2$) coating before seeding.
There is no difference in the fluorescence signal before and after digitonin treatment with a soluble FP in the HTS-protocol.	Bottom reader detects FP, which was released from cells into the supernatant.	Add one additional wash step between the digitonin treatment and scanning with fluorescence reader.
High standard deviation of the HTS-data.	Nonuniform expression of FP.	Generation of stable cell lines.
Very low signal with fluorescence reader.	You are using a top reader.	Use the bottom reader mode. Use a well-established FP-tagged protein to verify sensitivity of the fluorescence reader.
	FP expression is very low.	Choose a higher expressing clone of the stable transfected cell line.

photobleaching of the FPs during data acquisition. Bright and photostable FPs are preferable. For multifluorophore imaging, the investigator should closely examine the spectral profiles of the FPs of interest, as well as the excitation and emission filters available in the microscope and fluorescence reader setup, in order to optimize the light path and obtain maximal signal without spectral bleedthrough. A further problem is the potential aggregation of some fluorescent proteins, which impedes any cellular application and the FPP assay especially.

Choice of objectives

High numerical aperture (NA) oil-immersion objectives corrected for coverglass thickness, field curvature, and chromatic aberrations (e.g., Zeiss Plan-Apochromat 63×/ 1.4 NA oil lens or the Olympus PLAN APO 60×/1.4 NA oil lens) are good choices for high-resolution imaging. However, high magnification and high numerical aperture objectives may increase the risk of photobleaching.

Troubleshooting

Table 5.7.1 lists some problems that may be encountered in fluorescence imaging and HTS of the FPP assay along with some possible causes and solutions.

Anticipated Results

By following the suggestions given in every protocol, the investigator should be able to select cells expressing the fluorescent-tagged protein-of-interest. Plasma membrane permeabilization upon digitonin treatment immediately provides data on whether the protein-of-interest is stably bound to any cellular structure or is freely diffusing in the cytosol or nucleoplasm (the fluorescence signal disappears). Such a complete disappearance of signal from the cells is also observed for soluble FP alone. As outlined in the Support Protocol, a soluble FP alone can be used as the control molecule to determine the appropriate digitonin concentration to permeabilize the plasma membrane.

Addition of trypsin to digitonin-permeabilized cells will provide further information about the subcellular localization and topology of the protein-of-interest. The exact position of the FP tag within the fusion protein sequence is important for topology determination using the FPP assay. If the FP tag is fused to the terminus of a protein, which is enclosed within a protected subcellular environment like the lumen of intracellular organelles, the FP signal will be resistant to protease addition. In contrast, if the protein-of-interest spans the membrane of an intracellular organelle and the FP-tagged domain is exposed to the cytosol, the FP tag will be affected by the addition of protease.

Time Considerations

Basic Protocol 1

Steps 1 and 2 require 30 min each for cell plating and transfection, plus 6 to 24 hr to detect fluorescent protein expression in transfected cells. Steps 3 to 17 require ~20 to 30 min for sample preparation and data acquisition to carry out the FPP assay on one sample. Analyzing the images and quantifying the signal intensities (step 18) requires an additional 10 to 20 min per sample.

Basic Protocol 2

Steps 1, 2, and 3 require 30 min each for cell plating and transfection, plus 12 to 24 hr to detect fluorescent protein expression in transfected cells (step 4). Steps 5 to 18 require about 30 to 40 min for sample preparation and data acquisition to carry out the FPP assay on one 96-well plate. Analyzing the images and quantifying the signal intensities (step 19) require an additional 10 to 20 min per plate.

CHAPTER 6
Electrophoresis and Immunoblotting

INTRODUCTION

The development of powerful new technologies is a major driving force of scientific progress. A good example of this is the role that electrophoretic techniques have played in the evolution of modern cell biology. Electrophoresis and related applications have contributed greatly to the understanding of the molecular bases of cell structure and function. The combination of high resolution, ease of use, speed, low cost, and versatility of electrophoretic techniques is unmatched by any other method used to separate proteins. It is for this reason that electrophoresis is an indispensable tool in any cell biology laboratory and that papers describing basic techniques of protein electrophoresis (e.g., Laemmli, 1970, and O'Farrell, 1975, to name just a couple) are among the most cited articles in this field. Laemmli's technique of discontinuous gel electrophoresis in the presence of SDS, for example, continues to be widely used and referenced almost 30 years after publication. Thus, no book of techniques in cell biology would be complete without a detailed description of electrophoretic techniques.

Chapter 6 begins with *UNIT 6.1*, which is a collection of state-of-the-art protocols for analyzing proteins by one-dimensional electrophoresis under denaturing conditions on polyacrylamide gels. Sodium dodecyl sulfate (SDS), in combination with a reducing agent and heat, is most often used as a denaturant. This type of electrophoresis is thus referred to as SDS-polyacylamide gel electrophoresis (SDS-PAGE). Denaturation of the proteins prior to electrophoresis allows for enhanced resolution and discrimination of proteins on the basis of molecular size rather than charge or shape. Utilization of a discontinuous system (i.e., the apposition of "stacking" and "separating" gels) results in concentration of dilute samples and enhanced band sharpness. *UNIT 6.1* presents an overview of electricity and electrophoresis, followed by detailed protocols for SDS-PAGE using either Laemmli's buffers and gel system or modifications of this system (i.e., use of Tris-tricine buffers, higher concentrations of buffers, gradient gels, single-concentration gels, and minigels). The unit also explains how to calculate the apparent molecular weights of proteins from SDS-PAGE data.

The next unit in the chapter, *UNIT 6.2*, describes protocols for immunoblotting (also referred to as western blotting). In this technique, proteins separated by any of the electrophoretic techniques described in *UNIT 6.1* are electrophoretically transferred ("electroblotted") onto a membrane. The membrane, which thus becomes a replica of the polyacrylamide gel, is subsequently probed with antibodies to specific proteins. The primary antibodies can be revealed by an additional incubation with ^{125}I-labeled secondary antibodies or protein A, followed by autoradiography (*UNIT 6.3*). In recent years, however, the use of radioiodinated antibodies has been progressively replaced by nonradioactive detection with antibodies coupled to enzymes such as alkaline phosphatase or horseradish peroxidase (see *UNIT 16.5*). The enzymes act on substrates which are converted to colored, luminescent, or fluorescent products. Nonradioactive methods are just as sensitive as radioactive methods, with the added advantage that they do not require the special precautions associated with the use of radioactivity. Nonradioactive detection is nowadays the method of choice for visualizing immunoblotted proteins. A disadvantage of nonradioactive methods is that they have a narrower linear range of detection, which can be a problem in experiments that require accurate quantitation of protein levels.

Contributed by Juan S. Bonifacino
Current Protocols in Cell Biology (2002) 6.0.1-6.0.3

Radiolabeled proteins separated by electrophoresis or proteins detected by immunoblotting with radioiodinated antibodies or protein A can be visualized by autoradiography, as described in *UNIT 6.3*. In this technique, ionizing radiation emanating from the radionuclides impresses a photographic film. The technique can be made more sensitive by the use of intensifying screens or scintillating compounds, which emit light upon radiation absorption, which then impresses the film. The unit contains several protocols for autoradiographic detection of various radionuclides, including methods for enhancing the signal with intensifying screens or by fluorography. Also included in *UNIT 6.3* are discussions of the quantification of film images by densitometry and the direct detection and quantification of radioactive samples in gels by phosphor imaging.

The resolution of electrophoretic techniques can be enormously enhanced by combining two different electrophoretic procedures performed successively in perpendicular directions (i.e., two-dimensional gel electrophoresis). The most common type of two-dimensional gel electrophoresis is based on separation of proteins by isoelectric focusing on a tube gel (first dimension) followed by SDS-PAGE on a slab gel (second dimension). The two processes separate proteins on the basis of charge and size, respectively, allowing resolution of up to several thousand proteins on a single two-dimensional gel. *UNIT 6.4* describes several methods for separating proteins by two-dimensional isoelectric focusing/SDS-PAGE. In addition, this unit presents a protocol for two-dimensional nonreducing/reducing electrophoresis in which proteins are separated by SDS-PAGE under nonreducing conditions in the first dimension and under reducing conditions in the second dimension. This type of two-dimensional gel electrophoresis allows analysis of intersubunit disulfide bonds in multiprotein complexes and, in some cases, of intrasubunit disulfide bonds. Both types of two-dimensional gel electrophoresis can be used for either analytical or preparative purposes.

Another useful method for electrophoretic separation of cellular proteins is one-dimensional electrophoresis under nondenaturing conditions. Two protocols describing variations of this method are included in *UNIT 6.5*. What distinguishes this method from those described in *UNIT 6.1* and *UNIT 6.4* is that protein samples are not exposed to denaturing agents (i.e., SDS or urea) either prior to or during electrophoresis. Thus, proteins migrate according to their native properties, such as size, shape, and charge. This allows analysis of the oligomeric state of proteins, conformational changes, charge heterogeneity, and post-translational modifications that affect conformation or charge while having minimal effects on the molecular weights of the proteins. In many cases, this method preserves the intrinsic function of the proteins, which allows their detection with specific activity or binding assays. The first protocol describes continuous electrophoresis on nondenaturing polyacrylamide gels. This system involves electrophoresis on a single separating gel and uses the same buffer in the chambers and the gel. The second protocol, discontinuous electrophoresis on nondenaturing polyacrylamide gels, is a variation of SDS-PAGE in which SDS and reducing agents are omitted from all the solutions. Determination of the migration of proteins on parallel gels made up of different concentrations of acrylamide and bisacrylamide allows calculation of their molecular weights using Ferguson plots.

Proteins separated by electrophoresis can be visualized by direct staining of the gels. Four procedures for staining proteins in gels based on different principles are presented in *UNIT 6.6*. These procedures involve staining with Coomassie blue, silver, SYPRO ruby or zinc ions. The unit describes the basic protocols and provides guidelines for the selection of a specific protocol.

The separation of proteins by polyacrylamide gel electrophoresis is limited to proteins with molecular weights less than ~300,000. The electrophoretic separation of larger proteins or multiprotein complexes requires the use of other matrix materials. A suitable material is agarose, which is most commonly used for the separation of DNA. *UNIT 6.7* presents protocols for the electrophoretic separation of proteins on agarose gels. In

addition to permitting the separation of very large proteins, these protocols allow the analysis of multimerization or aggregation. Although these processes can also be analyzed by sedimentation on sucrose gradients (*UNIT 6.3*) or gel filtration (*UNIT 6.4*), agarose gel electrophoresis is more convenient for analysis of large numbers of samples.

One-Dimensional SDS Gel Electrophoresis of Proteins

Sean R. Gallagher[1]

[1]UVP, Inc., Upland, California

ABSTRACT

Electrophoresis is used to separate complex mixtures of proteins (e.g., from cells, subcellular fractions, column fractions, or immunoprecipitates), to investigate subunit compositions, and to verify homogeneity of protein samples. It can also serve to purify proteins for use in further applications. In polyacrylamide gel electrophoresis, proteins migrate in response to an electrical field through pores in a polyacrylamide gel matrix; pore size decreases with increasing acrylamide concentration. The combination of pore size and protein charge, size, and shape determines the migration rate of the protein. In this unit, the standard Laemmli method is described for discontinuous gel electrophoresis under denaturing conditions, that is, in the presence of sodium dodecyl sulfate (SDS). Both full-size and minigel formats are detailed. Several modifications are provided for specific applications. For separation of peptides and small proteins, the standard buffers are replaced with either a Tris-tricine buffer system or a modified Tris buffer in the absence of urea. Continuous SDS-PAGE is a simplified method in which the same buffer is used for both the gel and the electrode solutions and the stacking gel is omitted. Other protocols cover the preparation and use of ultrathin gels and gradient gels, and the simultaneous preparation of multiple gels. *Curr. Protoc. Cell Biol.* 37:6.1.1-6.1.38. © 2007 by John Wiley & Sons, Inc.

INTRODUCTION

Electrophoresis is used to separate complex mixtures of proteins (e.g., from cells, subcellular fractions, column fractions, or immunoprecipitates), to investigate subunit compositions, and to verify homogeneity of protein samples. It can also serve to purify proteins for use in further applications. In polyacrylamide gel electrophoresis (PAGE), proteins migrate in response to an electrical field through pores in the gel matrix; pore size decreases with higher acrylamide concentrations. The combination of gel pore size and protein charge, size, and shape determines the migration rate of the protein.

The standard Laemmli method (see Basic Protocol 1) is used for discontinuous gel electrophoresis under denaturing conditions, that is, in the presence of sodium dodecyl sulfate (SDS). The standard method for full-size gels (e.g., 14 × 14 cm) can be adapted for the minigel format (e.g., 7.3 × 8.3 cm; see Basic Protocol 2). Minigels provide rapid separation but give lower resolution.

Several alternate protocols are provided for specific applications. The first two alternate protocols cover electrophoresis of peptides and small proteins, separations that require modification of standard buffers: either a Tris-tricine buffer system (see Alternate Protocol 1) or a modified Tris buffer in the absence of urea (see Alternate Protocol 2). Continuous SDS-PAGE is a simplified method in which the same buffer is used for both gel and electrode solutions and the stacking gel is omitted (see Alternate Protocol 3). Other protocols cover the preparation and electrophoresis of various types of gels:

DOI: 10.1002/0471143030.cb0601s37

ultrathin gels (see Alternate Protocol 4), multiple single-concentration gels (see Support Protocol 1), gradient gels (see Alternate Protocol 5), multiple gradient gels (see Support Protocol 2), and multiple gradient minigels (see Support Protocol 3). Proteins separated on gels can be subsequently analyzed by immunoblotting (*UNIT 6.2*), autoradiography or phosphor imaging (*UNIT 6.3*), or staining with protein dyes (*UNIT 6.6*). Protein size is determined by comparing the mobility of the protein band to the mobility of the dye front (see Support Protocol 4).

CAUTION: Before any protocols are used, it is extremely important to read the following section about electricity and electrophoresis.

ELECTRICITY AND ELECTROPHORESIS

Many researchers are poorly informed concerning the electrical parameters of running a gel. It is important to note that the voltages and currents used during electrophoresis are dangerous and potentially lethal. Thus, safety should be an overriding concern. A working knowledge of electricity is an asset in determining what conditions to use and in troubleshooting the electrophoretic separation, if necessary. For example, an unusually high or low voltage for a given current (milliampere) might indicate an improperly made buffer or an electrical leak in the chamber.

Safety Considerations

1. Never remove or insert high-voltage leads unless the power supply voltage is turned down to zero and the power supply is turned off. Always grasp high-voltage leads one at a time with one hand only. Never insert or remove high-voltage leads with both hands. This can shunt potentially lethal electricity through the chest and heart should electrical contact be made between a hand and a bare wire. On older or homemade instruments, the banana plugs may not be shielded and can still be connected to the power supply at the same time they make contact with a hand. With commercial modern power supplies, this is less of an issue. However, with age and use, wires may become exposed through cracks in the insulation or poor connections. Carefully inspect all cables and connections and replace frayed or exposed wires immediately.

2. Always start with the power supply turned off. Have the power supply controls turned all the way down to zero. Then hook up the gel apparatus: generally, connect the red high-voltage lead to the red outlet and the black high-voltage lead to the black outlet. Turn the power supply on with the controls set at zero and the high-voltage leads connected. Then turn up the voltage, current, or power to the desired level. Reverse the process when the power supply is turned off: i.e., to disconnect the gel, turn the power supply down to zero, wait for the meters to read zero, turn off the power supply, and then disconnect the gel apparatus one lead at a time.

   CAUTION: *If the gel is first disconnected and then the power supply turned off, a considerable amount of electrical charge is stored internally. The charge will stay in the power supply over a long time. This will discharge through the outlets even though the power supply is turned off and can deliver an electrical shock.*

Ohm's Law and Electrophoresis

Understanding how a gel apparatus is connected to the power supply requires a basic understanding of Ohm's law: voltage = current × resistance, or $V = IR$. A gel can be viewed as a resistor and the power supply as the voltage and current source. Most power supplies deliver constant current or constant voltage. Some will also deliver constant power: power = voltage × current, or $VI = I^2R$. The discussion below focuses on constant current because this is the most common mode in vertical SDS-PAGE.

Most modern commercial equipment is color-coded so that the red or positive terminal of the power supply can simply be connected to the red lead of the gel apparatus, which goes to the lower buffer chamber. The black lead is connected to the black or negative terminal and goes to the upper buffer chamber. This configuration is designed to work with vertical slab gel electrophoreses in which negatively charged proteins or nucleic acids move to the positive electrode in the lower buffer chamber (an anionic system).

When a single gel is attached to a power supply, the negative charges flow from the negative cathode (black) terminal into the upper buffer chamber, through the gel, and into the lower buffer chamber. The lower buffer chamber is connected to the positive anode (red) terminal to complete the circuit. Thus, negatively charged molecules, such as SDS-coated proteins and nucleic acids, move from the negative cathode attached to the upper buffer chamber toward the positive anode attached to the lower chamber. SDS-PAGE is an anionic system because of the negatively charged SDS.

Occasionally, proteins are separated in cationic systems. In these gels, the proteins are positively charged because of the very low pH of the gel buffers (e.g., acetic acid/urea gels for histone separations) or the presence of a cationic detergent (e.g., cetyltrimethyl-ammonium bromide, CTAB). Proteins move toward the negative electrode (cathode) in cationic gel systems, and the polarity is reversed compared to SDS-PAGE: the red lead from the lower buffer chamber is attached to the black outlet of the power supply, and the black lead from the upper buffer chamber is attached to the red outlet of the power supply.

Most SDS-PAGE separations are performed under constant current (consult instructions from the manufacturer to set the power supply for constant current operation). The resistance of the gel will increase during SDS-PAGE in the standard Laemmli system. If the current is constant, then the voltage will increase during the run as the resistance goes up.

Power supplies usually have more than one pair of outlets. The pairs are connected in parallel with one another internally. If more than one gel is connected directly to the outlets of a power supply, then these gels are connected in parallel (Fig. 6.1.1). In a parallel circuit, the voltage is the same across each gel. In other words, if the power supply reads 100 V, then each gel has 100 V across its electrodes. The total current, however, is the sum of the individual currents going through each gel. Therefore, under constant current it is necessary to increase the current for each additional gel that is connected to the power supply. Two identical gels require double the current to achieve the same starting voltages and electrophoresis separation times.

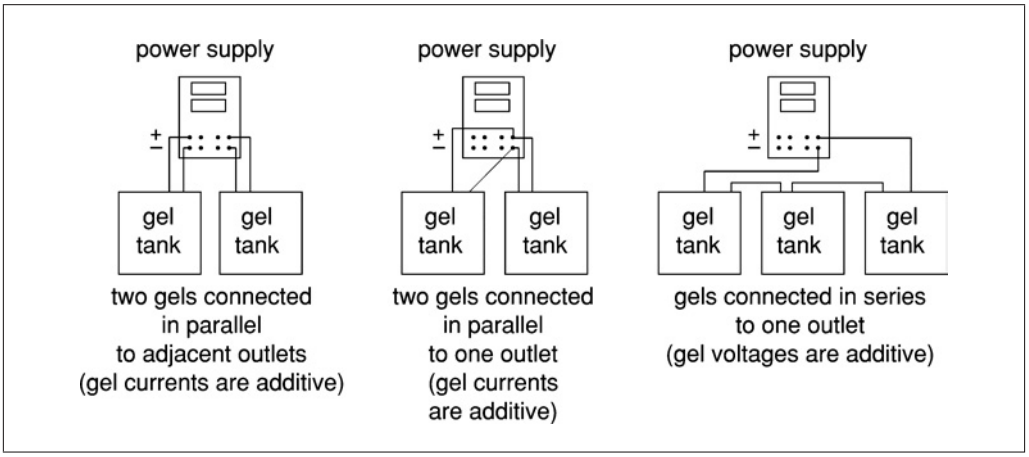

Figure 6.1.1 Series and parallel connections of gel tanks to power supply.

Multiple gel apparatuses can also be connected to one pair of outlets on a power supply. This is useful with older power supplies that have a limited number of outlets. When connecting several gel units to one outlet, make certain the connections between the units are shielded and protected from moisture. The gels can be connected in parallel or in series (Fig. 6.1.1). When gels are connected through the same outlet in parallel, the principle of additive currents is the same as for gels connected through different outlets in parallel. In the case of two or more gels running off the same outlet in series, the current is the same for every gel. If 10 mA is displayed by the power supply meter, for example, each gel in series will experience 10 mA. The voltage, however, is additive for each gel. If one gel at a constant 10 mA produces 100 V, then two identical gels in series will produce 200 V (100 V each) and so on. Thus, the voltage can limit the number of units connected in series on low-voltage power supplies.

Gel thickness affects the above relationships. A 1.5-mm gel can be thought of as two 0.75-mm-thick gels run in parallel. Because currents are additive in parallel circuits, a 0.75-mm gel will require half the current of the 1.5-mm gel to achieve the same starting voltage and separation time. If gel thickness is doubled, then the current must also be doubled. There are limits to the amount of current that can be applied. Thicker gels require more current, generating more heat that must be dissipated. Unless temperature control is available in the gel unit, a thick gel should be run more slowly than a thin gel.

NOTE: Milli-Q-purified water or equivalent should be used throughout the protocols.

BASIC PROTOCOL 1

DENATURING (SDS) DISCONTINUOUS GEL ELECTROPHORESIS: LAEMMLI GEL METHOD

One-dimensional gel electrophoresis under denaturing conditions (i.e., in the presence of 0.1% SDS) separates proteins based on molecular size as they move through a polyacrylamide gel matrix toward the anode. The polyacrylamide gel is cast as a separating gel (sometimes called resolving or running gel) topped by a stacking gel and secured in an electrophoresis apparatus. After sample proteins are solubilized by boiling in the presence of SDS, an aliquot of the protein solution is applied to a gel lane, and the individual proteins are separated electrophoretically. The stacking gel, through a combination of low porosity and a lower buffer concentration and pH, concentrates proteins into a thin stack before they enter the resolving gel. 2-Mercaptoethanol (2-ME) or dithiothreitol (DTT) is added during solubilization to reduce disulfide bonds.

This protocol is designed for a vertical slab gel with a maximum size of 0.75 mm × 14 cm × 14 cm. For thicker gels or minigels (see Basic Protocol 2 and Support Protocol 3), the volumes of stacking and separating gels and the operating current must be adjusted. Additional protocols describe the preparation of ultrathin gels (see Alternate Protocol 4) and gradient gels (see Alternate Protocol 5), as well as the use of gel casters to make multiple gels, both single-concentration gels (see Support Protocol 1) and gradient gels (see Support Protocol 2).

Materials

Separating and stacking gel solutions (Table 6.1.1)
H_2O-saturated isobutyl alcohol
1× Tris·Cl/SDS, pH 8.8 (dilute 4× Tris·Cl/SDS, pH 8.8; Table 6.1.1)
Protein sample, on ice
2× and 1× SDS sample buffer (see recipe)
Protein molecular weight standards (Tables 6.1.2 and 6.1.3)
6× SDS sample buffer (see recipe; optional)
1× SDS electrophoresis buffer (see recipe)

Electrophoresis apparatus: e.g., Protean II 16-cm cell (Bio-Rad) or SE 600/400 16-cm unit (Hoefer) with clamps, glass plates, casting stand, and buffer chambers
0.75-mm spacers
0.45-μm filters (used in stock solution preparation)
25-ml Erlenmeyer side-arm flasks
Vacuum pump with cold trap
0.75-mm Teflon comb with 1, 3, 5, 10, 15, or 20 teeth
Screw-top microcentrifuge tubes (recommended)
25- or 100-μl syringe with flat-tipped needle
Constant-current power supply (see Electricity and Electrophoresis above)

Pour the separating gel

1. Assemble the glass-plate sandwich of the electrophoresis apparatus according to manufacturer's instructions using two clean glass plates and two 0.75-mm spacers.

   If needed, clean the glass plates in liquid Alconox or RBS-35 (Pierce). These aqueous-based solutions are compatible with silver and Coomassie blue staining procedures.

2. Lock the sandwich to the casting stand.

3. Prepare the separating gel solution as directed in Table 6.1.1, degassing using a rubber-stoppered 25-ml Erlenmeyer side-arm flask connected with vacuum tubing to a vacuum pump with a cold trap. After adding the specified amount of 10% ammonium persulfate and TEMED to the degassed solution, stir gently to mix.

   The desired percentage of acrylamide in the separating gel depends on the molecular size of the protein being separated. Generally, use 5% gels for SDS-denatured proteins of 60 to 200 kDa, 10% gels for SDS-denatured proteins of 16 to 70 kDa, and 15% gels for SDS-denatured proteins of 12 to 45 kDa (Table 6.1.1).

   The stacking gel is the same regardless of the separating gel used.

4. Using a Pasteur pipet, apply the separating gel solution to the sandwich along an edge of one of the spacers until the height of the solution between the glass plates is ~11 cm.

   Use the solution immediately; otherwise it will polymerize in the flask.

   Sample volumes <10 μl do not require a stacking gel. In this case, cast the resolving gel as usual, but extend the resolving gel into the comb (step 10) to form the wells. The proteins are then separated under the same conditions as used when a stacking gel is present. Although this protocol works well with single-concentration gels, a gradient gel is recommended for maximum resolution (see Alternate Protocol 5).

5. Using another Pasteur pipet, slowly cover the top of the gel with a layer (~1 cm thick) of H_2O-saturated isobutyl alcohol, by gently layering the isobutyl alcohol against the edge of one and then the other of the spacers.

   Be careful not to disturb the gel surface. The overlay provides a barrier to oxygen, which inhibits polymerization, and allows a flat interface to form during gel formation.

   The H_2O-saturated isobutyl alcohol is prepared by shaking isobutyl alcohol and H_2O in a separatory funnel. The aqueous (lower) phase is removed. This procedure is repeated several times. The final upper phase is H_2O-saturated isobutyl alcohol.

6. Allow the gel to polymerize 30 to 60 min at room temperature.

   A sharp optical discontinuity at the overlay/gel interface will be visible on polymerization. Failure to form a firm gel usually indicates a problem with the ammonium persulfate, TEMED, or both. Ammonium persulfate solution should be made fresh before use. Ammonium persulfate should "crackle" when added to the water. If not, fresh ammonium persulfate should be purchased. Purchase TEMED in small bottles so, if necessary, a new previously unopened source can be tried.

Table 6.1.1 Recipes for Polyacrylamide Separating and Stacking Gels[a]

SEPARATING GEL

Stock solution[b]	Final acrylamide concentration in separating gel (%)[c]									
	5	6	7	7.5	8	9	10	12	13	15
30% (w/v) acrylamide/ 0.8% (w/v) bisacrylamide	2.50	3.00	3.50	3.75	4.00	4.50	5.00	6.00	6.50	7.50
4× Tris·Cl/SDS, pH 8.8	3.75	3.75	3.75	3.75	3.75	3.75	3.75	3.75	3.75	3.75
H_2O	8.75	8.25	7.75	7.50	7.25	6.75	6.25	5.25	4.75	3.75
10% (w/v) ammonium persulfate[d]	0.05	0.05	0.05	0.05	0.05	0.05	0.05	0.05	0.05	0.05
TEMED[e]	0.01	0.01	0.01	0.01	0.01	0.01	0.01	0.01	0.01	0.01

Preparation of separating gel

In a 25-ml side-arm flask, mix 30% acrylamide/0.8% bisacrylamide solution, 4× Tris·Cl/SDS, pH 8.8 (see reagents, below), and H_2O. Degas under vacuum ~5 min. Add 10% ammonium persulfate and TEMED. Swirl gently to mix. Use immediately.

STACKING GEL (*3.9% w/v acrylamide*)

In a 25-ml side-arm flask, mix 0.65 ml of 30% acrylamide/0.8% bisacrylamide, 1.25 ml of 4× Tris·Cl/SDS, pH 6.8 (see reagents, below), and 3.05 ml H_2O. Degas under vacuum 10 to 15 min. Add 25 µl of 10% ammonium persulfate and 5 µl TEMED. Swirl gently to mix. Use immediately.

REAGENTS USED IN GELS

30% (w/v) acrylamide/0.8% (w/v) bisacrylamide

Mix 30.0 g acrylamide and 0.8 g *N,N′*-methylenebisacrylamide with H_2O in a total volume of 100 ml. Filter the solution through a 0.45-µm filter and store at 4°C in the dark. The 2× crystallized grades of acrylamide and bisacrylamide are recommended. Discard after 30 days, as acrylamide gradually hydrolyzes to acrylic acid and ammonia.

CAUTION: Acrylamide monomer is neurotoxic. A mask should be worn when weighing acrylamide powder. Gloves should be worn while handling the solution, and the solution should not be pipetted by mouth.

4× Tris·Cl/SDS, pH 6.8 *(0.5 M Tris·Cl containing 0.4% w/v SDS)*

Dissolve 6.05 g Tris base in 40 ml H_2O. Adjust to pH 6.8 with 1 N HCl. Add H_2O to 100 ml total volume. Filter the solution through a 0.45-µm filter, add 0.4 g SDS, and store at 4°C up to 1 month.

4× Tris·Cl/SDS, pH 8.8 *(1.5 M Tris·Cl containing 0.4% w/v SDS)*

Dissolve 91 g Tris base in 300 ml H_2O. Adjust to pH 8.8 with 1 N HCl. Add H_2O to 500 ml total volume. Filter the solution through a 0.45-µm filter, add 2 g SDS, and store at 4°C up to 1 month.

[a]The recipes produce 15 ml of separating gel and 5 ml of stacking gel, which are adequate for a gel of dimensions 0.75 mm × 14 cm × 14 cm. The recipes are based on the SDS (denaturing) discontinuous buffer system of Laemmli (1970).

[b]All reagents and solutions used in the protocol must be prepared with Milli-Q-purified water or equivalent.

[c]Volumes are in milliliters. The desired percentage of acrylamide in the separating gel depends on the molecular size of the protein being separated. See annotation to step 3, Basic Protocol 1.

[d]Best to prepare fresh. Failure to form a firm gel usually indicates a problem with the ammonium persulfate, TEMED, or both.

[e]TEMED, *N,N,N,N*-tetramethylethylenediamine.

Table 6.1.2 Molecular Weights of Protein Standards for Polyacrylamide Gel Electrophoresis[a]

Protein	Molecular weight (Da)
Cytochrome *c*	11,700
α-Lactalbumin	14,200
Lysozyme (hen egg white)	14,300
Myoglobin (sperm whale)	16,800
β-Lactoglobulin	18,400
Trypsin inhibitor (soybean)	20,100
Trypsinogen, PMSF treated	24,000
Carbonic anhydrase (bovine erythrocytes)	29,000
Glyceraldehyde-3-phosphate dehydrogenase (rabbit muscle)	36,000
Lactate dehydrogenase (porcine heart)	36,000
Aldolase	40,000
Ovalbumin	45,000
Catalase	57,000
Bovine serum albumin	66,000
Phosphorylase *b* (rabbit muscle)	97,400
β-Galactosidase	116,000
RNA polymerase, *E. coli*	160,000
Myosin, heavy chain (rabbit muscle)	205,000

[a]Protein standards are commercially available as prepared mixtures (see Table 6.1.3).

Pour the stacking gel

7. Pour off the layer of H_2O-saturated isobutyl alcohol and rinse with 1× Tris·Cl/SDS, pH 8.8.

   Residual isobutyl alcohol can reduce resolution of the protein bands; therefore, it must be completely removed. The isobutyl alcohol overlay should not be left on the gel longer than 2 hr.

8. Prepare the stacking gel solution as directed in Table 6.1.1.

   Use the solution immediately to keep it from polymerizing in the flask.

9. Using a Pasteur pipet, allow the stacking gel solution to trickle slowly into the center of the sandwich along an edge of one of the spacers until the height of the solution in the sandwich is ~1 cm from the top of the plates.

   Be careful not to introduce air bubbles into the stacking gel.

10. Insert a 0.75-mm Teflon comb into the layer of stacking gel solution. If necessary, add additional stacking gel to fill the spaces in the comb completely.

    Again, be careful not to trap air bubbles in the tooth edges of the comb; they will cause small circular depressions in the well after polymerization that will lead to distortion in the protein bands during separation.

11. Allow the stacking gel solution to polymerize 30 to 45 min at room temperature.

    A sharp optical discontinuity will be visible around the wells on polymerization. Again, failure to form a firm gel usually indicates a problem with the ammonium persulfate, TEMED, or both.

[a]Abbreviations: 1-D, one-dimensional gels; 2-D, two-dimensional gels; Im, immunoblotting; Pre, prestained; Fluor, fluorescent; Gly, glycoprotein; Phos, phosphoprotein; Bio, biotinylated; Tag, tagged; IEF, isoelectic focusing; Nat, native.

[b]2-D standards are useful as independently characterized internal controls or reference standards for 2-D SDS-PAGE. Many investigators simply use an internally characterized test sample as a reference set.

[c]Prestained standards, while not as sharply delineated as unstained standards, can be used to monitor progress of the separation since the bands are visible through the gel cassette during electrophoresis. They are also useful for marking the position of a band after electroblotting to a nitrocellulose or PVDF membrane prior to immunoassay or analysis by mass spectrometry.

Prepare the sample and load the gel

12. Dilute a portion of the protein sample to be analyzed 1:1 (v/v) with 2× SDS sample buffer and heat 3 to 5 min at 100°C in a sealed screw-cap microcentrifuge tube. If the sample is a precipitated protein pellet, dissolve the protein in 50 to 100 µl of 1× SDS sample buffer and boil 3 to 5 min at 100°C. Dissolve protein molecular weight standards in 1× SDS sample buffer according to supplier's instructions; use these standards as a control (Tables 6.1.2 and 6.1.3).

    For dilute protein solutions, consider using 5:1 protein solution/6× SDS sample buffer to increase the amount of protein loaded. Proteins can also be concentrated by precipitation in acetone, ethanol, or trichloroacetic acid (TCA), but losses will occur.

    For a 0.8-cm-wide well, 25 to 50 µg total protein in <20 µl is recommended for a complex mixture when staining with Coomassie blue, and 1 to 10 µg total protein is needed for samples containing one or a few proteins. If silver staining is used, 10- to 100-fold less protein can be applied (0.01 to 5 µg in <20 µl depending on sample complexity).

    To achieve the highest resolution possible, the following precautions are recommended. Prior to adding the sample buffer, keep samples at 0°C. Add the SDS sample buffer (room temperature) directly to the 0°C sample (still on ice) in a screw-top microcentrifuge tube.

Cap the tube to prevent evaporation, vortex, and transfer directly to a 100°C water bath for 3 to 5 min. Let immunoprecipitates dissolve for 1 hr at 56°C in 1× SDS sample buffer prior to boiling. DO NOT leave the sample in SDS sample buffer at room temperature without first heating to 100°C to inactivate proteases (see Critical Parameters and Troubleshooting). Endogenous proteases are very active in SDS sample buffer and will cause severe degradation of the sample proteins after even a few minutes at room temperature. To test for possible proteases, mix the sample with SDS sample buffer without heating and leave at room temperature for 1 to 3 hr. A loss of high-molecular-weight bands and a general smearing of the banding pattern indicate a protease problem. Once heated, the samples can sit at room temperature for the time it takes to load samples.

13. Carefully remove the Teflon comb without tearing the edges of the polyacrylamide wells. After the comb is removed, rinse wells with 1× SDS electrophoresis buffer.

    The rinse removes unpolymerized monomer; otherwise, the monomer will continue to polymerize after the comb is removed, creating uneven wells that will interfere with sample loading and subsequent separation.

14. Using a Pasteur pipet, fill the wells with 1× SDS electrophoresis buffer.

    If well walls are not upright, they can be manipulated with a flat-tipped needle attached to a syringe.

15. Attach gel sandwich to upper buffer chamber following manufacturer's instructions.

16. Fill lower buffer chamber with the recommended amount of 1× SDS electrophoresis buffer.

17. Place sandwich attached to upper buffer chamber into lower buffer chamber.

18. Partially fill the upper buffer chamber with 1× SDS electrophoresis buffer so that the sample wells of the stacking gel are filled with buffer.

    Monitor the upper buffer chamber for leaks and, if necessary, reassemble the unit. A slow leak in the upper buffer chamber may cause arcing around the upper electrode and damage the upper buffer chamber.

19. Using a 25- or 100-µl syringe with a flat-tipped needle, load the protein sample(s) into one or more wells by carefully applying the sample as a thin layer at the bottom of the wells. Load control wells with molecular weight standards. Add an equal volume of 1× SDS sample buffer to any empty wells to prevent spreading of adjoining lanes.

    Disposable loading tips can be used with automatic pipettors to simplify loading.

    Preparing the samples at approximately the same concentration and loading an equal volume to each well will ensure that all lanes are the same width and that the proteins run evenly. If unequal volumes of sample buffer are added to wells, the lane with the larger volume will spread during electrophoresis and constrict the adjacent lanes, causing distortions.

    The samples will layer on the bottom of the wells because the glycerol added to the sample buffer gives the solution a greater density than the electrophoresis buffer. To keep bands tight, hold the tip of the needle near the bottom of the well and load the samples slowly. The bromphenol blue in the sample buffer makes sample application easy to follow visually.

20. Fill the remainder of the upper buffer chamber with additional 1× SDS electrophoresis buffer so that the upper platinum electrode is completely covered. Do this slowly so that samples are not swept into adjacent wells.

Run the gel

21. Connect the power supply to the cell and run at 10 mA of constant current for a slab gel 0.75 mm thick, until the bromphenol blue tracking dye enters the separating gel. Then increase the current to 15 mA.

    For a standard 16-cm gel sandwich, 4 mA per 0.75-mm-thick gel will run ~15 hr (i.e., overnight); 15 mA per 0.75-mm gel will take 4 to 5 hr. To run two gels or a 1.5-mm-thick gel, simply double the current. When running a 1.5-mm gel at 30 mA, the temperature must be controlled (10° to 20°C) with a circulating constant-temperature water bath to prevent "smiling" (curvature in the migratory band). Temperatures <5°C should not be used because SDS in the running buffer will precipitate.

    If the level of buffer in the upper chamber decreases, a leak has occurred.

22. After the bromphenol blue tracking dye has reached the bottom of the separating gel, disconnect the power supply.

    Refer to Safety Considerations under Electricity and Electrophoresis.

Disassemble the gel

23. Discard electrophoresis buffer and remove the upper buffer chamber with the attached gel sandwich.

24. Orient the gel so that the order of the sample wells is known, remove the sandwich from the upper buffer chamber, and lay the sandwich on a sheet of absorbent paper or paper towels.

25. Carefully slide one of the spacers halfway from the edge of the sandwich along its entire length. Use the exposed spacer as a lever to pry open the glass plate, exposing the gel.

26. Carefully remove the gel from the lower plate. Cut a small triangle off one corner of the gel so the lane orientation is not lost during staining and drying. Proceed with protein detection.

    Gradient gels are most easily picked up without tearing from the high-concentration end of the gel using gloved fingers. Single-concentration gels <10% can be picked up and placed in fixative, but are more easily removed if first immersed in fixative while left on the plate, allowing the gel to float off.

    The gel can be stained with Coomassie blue or silver (UNIT 6.6), or proteins can be electroeluted, electroblotted onto a polyvinylidene difluoride (PVDF) membrane for subsequent staining or sequence analysis, or transferred to a membrane for immunoblotting (UNIT 6.2). If the proteins are radiolabeled, they can be detected by autoradiography (UNIT 6.3).

ALTERNATE PROTOCOL 1

ELECTROPHORESIS IN TRIS-TRICINE BUFFER SYSTEMS

Separation of peptides and proteins under 10 to 15 kDa is not possible in the traditional Laemmli discontinuous gel system (see Basic Protocol 1). This is due to the comigration of SDS and smaller proteins, obscuring the resolution. Two approaches to obtain the separation of small proteins and peptides in the range of 5 to 20 kDa are presented: the following Tris-tricine method and a system using increased buffer concentrations (see Alternate Protocol 2). The Tris-tricine system uses a modified buffer to separate the SDS and peptides, thus improving resolution. Several precast gels are available for use with the tricine formulations (Table 6.1.4).

Table 6.1.4 Precast Gels Available from Selected Suppliers

	Format		Application				Instrument Compatibility			
	Large	Mini	2-D[a]	Native	Peptide	SDS	Bio-Rad	Cambrex	Hoefer	Invitrogen
Bio-Rad	X	X	X	X	X	X	X			
Cambrex		X	X	X	X	X	X	X	X	X
Jule	X	X	X	X	X	X	X	X	X	X
Invitrogen		X	X	X	X	X	X	X	X	X

[a]Two-dimensional analysis.

Table 6.1.5 Recipes for Tricine Peptide Separating and Stacking Gels[a]

SEPARATING AND STACKING GELS

Stock solution[b]	Separating gel	Stacking gel
30% (w/v) acrylamide/0.8% (w/v) bisacrylamide	9.80 ml	1.62 ml
Tris·Cl/SDS, pH 8.45	10.00 ml	3.10 ml
H_2O	7.03 ml	7.78 ml
Glycerol	4.00 g (3.17 ml)	—
10% (w/v) ammonium persulfate[c]	50 µl	25 µl
TEMED	10 µl	5 µl

Prepare separating and stacking gel solutions separately.

In a 50-ml side-arm flask, mix 30% acrylamide/0.8% bisacrylamide solution (Table 6.1.1), Tris·Cl/SDS, pH 8.45 (see reagents, below), and H_2O. Add glycerol to separating gel only. Degas under vacuum 10 to 15 min. Add 10% ammonium persulfate and TEMED. Swirl gently to mix; use immediately.

ADDITIONAL REAGENTS USED IN GELS

Tris·Cl/SDS, pH 8.45 *(3.0 M Tris·Cl containing 0.3% w/v SDS)*

Dissolve 182 g Tris base in 300 ml H_2O. Adjust to pH 8.45 with 1 N HCl. Add H_2O to 500 ml total volume. Filter the solution through a 0.45-µm filter, add 1.5 g SDS, and store at 4°C up to 1 month.

[a]The recipes produce 30 ml of separating gel and 12.5 ml of stacking gel, which are adequate for two gels of dimensions 0.75 mm × 14 cm × 14 cm. The recipes are based on the Tris-tricine buffer system of Schagger and von Jagow (1987).
[b]All reagents and solutions used in the protocol must be prepared with Milli-Q-purified water or equivalent.
[c]Best to prepare fresh. Failure to form a firm gel usually indicates a problem with the persulfate, TEMED, or both.

Additional Materials *(also see Basic Protocol 1)*

Separating and stacking gel solutions (Table 6.1.5)
2× tricine sample buffer (see recipe)
Peptide molecular weight standards (Table 6.1.6)
Cathode buffer (see recipe)
Anode buffer (see recipe)
Coomassie blue G-250 staining solution (see recipe)
10% (v/v) acetic acid
50-ml Erlenmeyer side-arm flasks

Table 6.1.6 Molecular Weights of Peptide Standards for Polyacrylamide Gel Electrophoresis[a]

Peptide	Molecular weight (Da)
Myoglobin (polypeptide backbone)	16,950
Myoglobin 1-131	14,440
Myoglobin 56-153	10,600
Myoglobin 56-131	8,160
Myoglobin 1-55	6,210
Glucagon	3,480
Myoglobin 132-153	2,510

[a]Peptide standards are commercially available from Sigma-Aldrich. See Sigma-Aldrich Technical Bulletin MWSDS70-L for molecular weight markers for proteins.

1. Prepare and pour the separating and stacking gels (see Basic Protocol 1, steps 1 to 11) using the recipes in Table 6.1.5.
2. Prepare the sample (see Basic Protocol 1, step 12), but substitute 2× tricine sample buffer for the 2× SDS sample buffer, and heat the sample at 40°C for 30 to 60 min to improve solubilization prior to loading. Use peptide molecular weight standards (Table 6.1.6).

   If proteolytic activity is a problem (see Basic Protocol 1, step 12), heating samples to 100°C for 3 to 5 min may be required.
3. Set up the electrophoresis apparatus and load the gel (see Basic Protocol 1, steps 13 to 20), but use cathode buffer or water to rinse the wells, use cathode buffer in the upper buffer chamber, and use anode buffer in the lower buffer chamber.

   The cathode buffer contains the tricine.
4. Connect the power supply to the cell and run 1 hr at 30 V (constant voltage) followed by 4 to 5 hr at 150 V (constant voltage). Use a heat exchanger to keep the electrophoresis chamber at room temperature.
5. After the tracking dye has reached the bottom of the separating gel, disconnect the power supply.

   Refer to Safety Considerations under Electricity and Electrophoresis.

   Coomassie blue G-250 is used as a tracking dye instead of bromphenol blue because it moves ahead of the smallest peptides.
6. Disassemble the gel (see Basic Protocol 1, steps 23 to 26). Stain proteins in the gel for 1 to 2 hr in Coomassie blue G-250 staining solution. Follow by destaining with 10% acetic acid, changing the solution every 30 min until background is clear (3 to 5 changes). For higher sensitivity, use silver staining as a recommended alternative.

   Prolonged staining and destaining will result in the loss of resolution of the smaller proteins (<10 kDa). Proteins diffuse within the gel and out of the gel, resulting in a loss of staining intensity and resolution.

ALTERNATE PROTOCOL 2

NONUREA PEPTIDE SEPARATIONS WITH TRIS BUFFERS

A simple modification of the traditional Laemmli buffer system presented in Basic Protocol 1, in which the increased concentration of buffers provides better separation between the stacked peptides and the SDS micelles, permits reasonable separation of peptides as small as 5 kDa.

Additional Materials *(also see Basic Protocol 1)*

Separating and stacking gel solutions (Table 6.1.7)
2× Tris·Cl/SDS, pH 8.8 (dilute 4× Tris·Cl/SDS, pH 8.8; Table 6.1.1)
2× SDS electrophoresis buffer (see recipe)

1. Prepare and pour the separating and stacking gels (see Basic Protocol 1, steps 1 to 11), using the modified recipes in Table 6.1.7. After removing the isobutyl alcohol overlay from the separating gel, rinse with 2× Tris·Cl/SDS, pH 8.8, rather than 1× Tris·Cl/SDS.

2. Prepare the sample and load the gel (see Basic Protocol 1, steps 12 to 20), but substitute 2× SDS electrophoresis buffer for the 1× SDS electrophoresis buffer.

Table 6.1.6 lists the standards for small protein separations.

Table 6.1.7 Recipes for Modified Laemmli Peptide Separating and Stacking Gels[a]

SEPARATING AND STACKING GELS

Stock solution[b]	Separating gel	Stacking gel
30% (w/v) acrylamide/0.8% (w/v) bisacrylamide	10.00 ml	0.65 ml
8× Tris·Cl, pH 8.8	3.75 ml	—
4× Tris·Cl, pH 6.8	—	1.25 ml
10% (w/v) SDS[c]	0.15 ml	50 µl
H_2O	1.00 ml	3.00 ml
10% (w/v) ammonium persulfate[c]	50 µl	25 µl
TEMED	10 µl	5 µl

Prepare separating and stacking gel solutions separately.

In a 25-ml side-arm flask, mix 30% acrylamide/0.8% bisacrylamide solution (see Table 6.1.1), 8× Tris·Cl, pH 8.8, or 4× Tris·Cl, pH 6.8 (see reagents below), 10% SDS, and H_2O. Degas under vacuum 10 to 15 min. Add 10% ammonium persulfate and TEMED. Swirl gently to mix. Use immediately.

ADDITIONAL REAGENTS USED IN GELS

4× Tris·Cl, pH 6.8 *(0.5 M Tris·Cl)*

Dissolve 6.05 g Tris base in 40 ml H_2O. Adjust to pH 6.8 with 1 N HCl. Add H_2O to 100 ml total volume. Filter the solution through a 0.45-µm filter and store up to 1 month at 4°C.

8× Tris·Cl, pH 8.8 *(3.0 M Tris·Cl)*

Dissolve 182 g Tris base in 300 ml H_2O. Adjust to pH 8.8 with 1 N HCl. Add H_2O to 500 ml total volume. Filter the solution through a 0.45-µm filter and store up to 1 month at 4°C.

[a]The recipes produce 15 ml of separating gel and 5 ml of stacking gel, which are adequate for one gel of dimensions 0.75 mm × 14 cm × 14 cm. The recipes are based on the modified Laemmli peptide separation system of Okajima et al. (1993).
[b]All reagents and solutions used in the protocol must be prepared with Milli-Q-purified water or equivalent.
[c]Best to prepare fresh. Failure to form a firm gel usually indicates a problem with the ammonium persulfate, TEMED, or both.

3. Run the gel (see Basic Protocol 1, steps 21 and 22).

   Note that the separations will take ~25% longer than those using Basic Protocol 1. The increased buffer concentrations lead to faster transit through the stacking gel but lower mobility in the resolving gel.

4. Disassemble the gel (see Basic Protocol 1, steps 23 to 26).

   Proteins in the gel may now be stained.

ALTERNATE PROTOCOL 3

CONTINUOUS SDS-PAGE

With continuous SDS-PAGE, the same buffer is used for both the gel and electrode solutions. Although continuous gels lack the resolution of the discontinuous systems, they are extremely versatile, less prone to mobility artifacts, and much easier to prepare. The stacking gel is omitted.

Additional Materials *(also see Basic Protocol 1)*

Separating gel solution (Table 6.1.8)
2× and 1× phosphate/SDS sample buffer (see recipe)
1× phosphate/SDS electrophoresis buffer (see recipe)

Table 6.1.8 Recipes for Separating Gels for Continuous SDS-PAGE[a]

SEPARATING GEL

	Final acrylamide concentration in the separating gel (%)[c]										
Stock solution[b]	5	6	7	8	9	10	11	12	13	14	15
30% (w/v) acrylamide/0.8% (w/v) bisacrylamide	2.5	3.00	3.50	4.00	4.50	5.00	5.50	6.00	6.50	7.00	7.50
4× phosphate/SDS, pH 7.2	3.75	3.75	3.75	3.75	3.75	3.75	3.75	3.75	3.75	3.75	3.75
H_2O	8.75	8.25	7.75	7.25	6.75	6.25	5.75	5.25	4.75	4.25	3.75
10% (w/v) ammonium persulfate[d]	0.05	0.05	0.05	0.05	0.05	0.05	0.05	0.05	0.05	0.05	0.05
TEMED	0.01	0.01	0.01	0.01	0.01	0.01	0.01	0.01	0.01	0.01	0.01

Preparation of separating gel

In a 25-ml side-arm flask, mix 30% acrylamide/0.8% bisacrylamide solution (see Table 6.1.1), 4× phosphate/SDS, pH 7.2, and H_2O. Degas under vacuum about 5 min. Add 10% ammonium persulfate and TEMED. Swirl gently to mix. Use immediately.

ADDITIONAL REAGENTS USED IN GELS

4× phosphate/SDS, pH 7.2 *(0.4 M sodium phosphate/0.4% w/v SDS)*

Mix 46.8 g $NaH_2PO_4 \cdot H_2O$, 231.6 g $Na_2HPO_4 \cdot 7H_2O$, and 12 g SDS in 3 liters H_2O. Store at 4°C for up to 3 months.

[a] The recipes produce 15 ml of separating gel, which is adequate for one gel of dimensions 0.75 mm × 14 cm × 14 cm. The recipes are based on the original continuous phosphate buffer system of Weber et al. (1972).
[b] All reagents and solutions used in the protocol must be prepared with Milli-Q-purified water or equivalent.
[c] Volumes are in milliliters. The desired percentage of acrylamide in the separating gel depends on the molecular size of the protein being separated. See Basic Protocol 1, annotation to step 3.
[d] Best to prepare fresh. Failure to form a firm gel usually indicates a problem with the ammonium persulfate, TEMED, or both.

1. Prepare and pour a single separating gel (see Basic Protocol 1, steps 1 to 4), except use the recipe in Table 6.1.8 and fill the gel sandwich to the top. Omit the stacking gel. Insert the comb (see Basic Protocol 1, step 10) and allow the gel to polymerize 30 to 60 min at room temperature.

2. Mix the protein sample 1:1 with 2× phosphate/SDS sample buffer and heat to 100°C for 2 min.

   For large sample volumes or samples suspended in high-ionic-strength buffers (>50 mM), dialyze against 1× sample buffer prior to electrophoresis. Note that the precautions about proteases (see Basic Protocol 1, step 12) apply here.

3. Assemble the electrophoresis apparatus and load the sample (see Basic Protocol 1, steps 13 to 20) using the phosphate/SDS electrophoresis buffer. Load empty wells with 1× phosphate/SDS sample buffer.

4. Connect the power supply and start the run with 15 mA per 0.75-mm-thick gel until the tracking dye has entered the gel. Continue electrophoresis at 30 mA for 3 hr (5% gel), 5 hr (10% gel), 8 hr (15% gel), or until the dye reaches the bottom of the gel.

   Use temperature control if available to maintain the gel at 15° to 20°C. SDS will precipitate below 15°C in this system.

5. Disassemble the gel (see Basic Protocol 1, steps 23 to 26).

   See Safety Considerations in introduction. Proteins in the gel may now be stained.

CASTING AND RUNNING ULTRATHIN GELS

ALTERNATE PROTOCOL 4

Ultrathin gels provide superb resolution but are difficult to handle. In this application, gels are cast on GelBond, a Mylar support material. Silver staining is recommended for the best resolution. Combs and spacers for gels <0.5 mm thick are not readily available for most protein electrophoresis units. However, by adapting combs and spacers used for DNA sequencing, casting gels from 0.2 to 0.5 mm thick is straightforward.

Additional Materials *(also see Basic Protocol 1)*

95% (v/v) ethanol
GelBond (Lonza) cut to a size slightly smaller than the gel plate dimensions
Glue stick
Ink roller (available from art supply stores)
Combs and spacers (0.19 to 0.5 mm; sequencing gel spacers and combs can be cut to fit)

1. Wash gel plates with water-based laboratory detergent followed by successive rinses with hot tap water, deionized water, and finally 95% ethanol. Allow to air dry.

   Gel plates must be extremely clean for casting thin gels. Gloves are needed throughout these procedures to prevent contamination by proteins on the surface of skin.

2. Apply a streak of adhesive from a glue stick to the bottom edge of the glass plate. Quickly position the GelBond with the hydrophobic side down (a drop of water will bead up on the hydrophobic surface). Apply pressure with Kimwipe tissue to attach the GelBond firmly to the plate. Finally, pull the top portion of the GelBond back, place a few drops of water underneath, and roll flat with an ink roller.

   Make sure the GelBond does not extend beyond the edges of the upper and lower sealing surface of the plate. This will cause it to buckle on sealing. Reposition the GelBond if needed to prevent it from extending beyond the glass plate. Material may also be trimmed to fit flush with the plate edge.

3. Assemble the gel cassette according to the manufacturer's instructions (also see Basic Protocol 1, steps 1 and 2). Just prior to assembly, blow air over the surface of both the GelBond and the opposing glass surface to remove any particulate material (e.g., dust).

   Sequencing gel spacers can be easily adapted. First, cut the spacers slightly longer than the length of the gel plate. Position a spacer along each edge of the glass plate and assemble the gel sandwich, clamping in place. With a razor blade, trim the excess spacer at top and bottom to get a reusable spacer exactly the size of the plate.

4. Prepare and pour the separating and stacking gels (see Basic Protocol 1, steps 3 to 9). In place of the Teflon comb, insert a square well sequencing comb cut to fit within the gel sandwich. Allow the stacking gel to polymerize 30 to 45 min at room temperature.

   Less solution is needed for ultrathin gels. For example, a 0.5-mm-thick gel requires 33% less gel solution than a 0.75-mm gel.

5. Prepare the sample and load the gel (see Basic Protocol 1, steps 12 to 20).

   When preparing protein samples for ultrathin gels, 3 to 4 μl at 5 μg protein/μl is required for Coomassie blue R-250 staining, whereas 10-fold less is needed for silver staining.

6. Run the gel (see Basic Protocol 1, steps 21 and 22), except conduct the electrophoresis at 7 mA/gel (0.25-mm-thick gels) or 14 mA/gel (0.5-mm-thick gels) for 4 to 5 hr.

7. When the separation is complete, disassemble the unit and remove the gel (see Basic Protocol 1, steps 23 to 26) with the GelBond still attached. With a gloved hand, wash away the adhesive material from the back of the GelBond under a stream of water before proceeding to protein detection.

   Either Coomassie blue or silver staining may be used, but silver staining produces particularly fine resolution with thin GelBond-backed gels. Compared to staining thicker (>0.75 mm) gels, thin (<0.75 mm) gels stain and destain more quickly. Although the optimum staining times must be empirically determined, all steps in Coomassie blue and silver staining procedures are generally reduced by half.

SUPPORT PROTOCOL 1

CASTING MULTIPLE SINGLE-CONCENTRATION GELS

Casting multiple gels at one time has several advantages. All the gels are identical, so sample separation is not affected by gel-to-gel variation. Furthermore, casting ten gels is only slightly more difficult than casting two gels. Once cast, gels can be stored for several days in a refrigerator.

Additional Materials *(also see Basic Protocol 1)*

Separating and stacking gels for single-concentration gels (Table 6.1.9)
Multiple gel caster (Bio-Rad, Hoefer)
100-ml disposable syringe and flat-tipped needle
Extra plates and spacers
14 × 14–cm acrylic blocks or polycarbonate sheets
250- and 500-ml side-arm flasks (used in gel preparation)
Long razor blade *or* plastic wedge (Wonder Wedge, Hoefer)
Resealable plastic bags

Pour the separating gel

1. Assemble the multiple gel caster according to the manufacturer's instructions.

   With the Hoefer unit, make sure to insert the large triangular space filler plug in the base of the caster. The plug is removed when casting gradient gels (see Support Protocol 2).

Table 6.1.9 Recipes for Multiple Single-Concentration Polyacrylamide Gels[a]

SEPARATING GEL

Stock solution[b]	Final acrylamide concentration in the separating gel (%)[c]										
	5	6	7	8	9	10	11	12	13	14	15
30% (w/v) acrylamide/ 0.8% (w/v) bisacrylamide	52	62	72	83	93	103	114	124	134	145	155
4× Tris·Cl/SDS, pH 8.8	78	78	78	78	78	78	78	78	78	78	78
H_2O	181	171	160	150	140	129	119	109	98	88	78
10% (w/v) ammonium persulfate[d]	1.0	1.0	1.0	1.0	1.0	1.0	1.0	1.0	1.0	1.0	1.0
TEMED	0.21	0.21	0.21	0.21	0.21	0.21	0.21	0.21	0.21	0.21	0.21

Preparation of separating gel

In a 500-ml side-arm flask, mix 30% acrylamide/0.8% bisacrylamide solution (see Table 6.1.1), 4× Tris·Cl/SDS, pH 8.8 (Table 6.1.1), and H_2O. Degas under vacuum ~5 min. Add 10% ammonium persulfate and TEMED. Swirl gently to mix. Use immediately.

STACKING GEL

In a 250-ml side-arm flask, mix 13.0 ml 30% acrylamide/0.8% bisacrylamide solution, 25 ml 4× Tris·Cl/SDS, pH 6.8 (Table 6.1.1), and 61 ml H_2O. Degas under vacuum ~5 min. Add 0.25 ml 10% ammonium persulfate and 50 µl TEMED. Swirl gently to mix. Use immediately.

[a]The recipes produce about 300 ml of separating gel and 100 ml of stacking gel, which are adequate for ten gels of dimensions 1.5 mm × 14 cm × 14 cm, with extra solution should there be a leak or spill while casting the gels. For thinner spacers or fewer gels, calculate volumes using the equation in the annotation to step 4. The recipes are based on the SDS (denaturing) discontinuous buffer system of Laemmli (1970).
[b]All reagents and solutions used in the protocol must be prepared with Milli-Q-purified water or equivalent.
[c]Volumes in table body are in milliliters. The desired percentage of acrylamide in separating gel depends on the molecular size of the protein being separated. See Basic Protocol 1, annotation to step 3.
[d]Best to prepare fresh. Failure to form a firm gel usually indicates a problem with the persulfate, TEMED, or both.

2. Assemble glass sandwiches and stack them in the casting chamber. Stack up to ten 1.5-mm gels and fill in extra space with acrylic blocks or polycarbonate sheets to hold the sandwiches tightly in place. Make sure the spacers are straight along the top, right, and left edges of the glass plates and that all edges of the stack are flush.

   The presence of loosely fitting sandwiches in the caster will lead to unevenly cast gels, creating distortions during electrophoresis. Polycarbonate inhibits gel polymerization. Therefore, if polycarbonate sheets are placed in the caster before and after the set of glass sandwiches, the entire set will slide out as one block after polymerization. Placing polycarbonate sheets between each gel sandwich makes them easier to separate from one another after polymerization.

3. Place the front sealing plate on the casting chamber, making sure the stack fits snugly. Secure the plate with four spring clamps and tighten the bottom thumb screws.

4. Prepare the separating (resolving) gel solution (Table 6.1.9).

   A 12-cm separating gel with a 4-cm stacking gel is recommended.

   If fewer than ten gels are prepared (Table 6.1.9), use the following formula to estimate the amount of separating gel volume needed:

   volume = gel no. × height (cm) × width (cm) × thickness (cm) + 4 × gel no. + 10 ml.

5. Using a 100-ml disposable syringe with flat-tipped needle, inject the resolving gel solution down the side of one spacer into the multiple caster. A channel in the silicone plug distributes the solution throughout the whole caster. Avoid introducing bubbles by giving the caster a quick tap on the benchtop once the caster is filled.
6. Overlay the center of each gel with 100 μl H_2O-saturated isobutyl alcohol and let polymerize for 1 to 2 hr.
7. Drain off the overlay and rinse the surface with 1× Tris·Cl/SDS, pH 8.8. If the gels will not be used immediately, skip to step 12.

Pour the stacking gel

8. Prepare the stacking gel solution either singly (see Basic Protocol 1, step 8) or for all the gels at once (Table 6.1.9).

   The stacking gel solution should be prepared just before it is poured.

9. Fill each sandwich in the caster with stacking gel solution.
10. Insert a comb into each sandwich and let the gel polymerize for 2 hr.

    Insert the combs at a 45° angle to avoid trapping air underneath the comb teeth. Air bubbles will inhibit polymerization and cause dents in the wells and a distorted pattern of protein bands.

11. Remove the combs and rinse wells with 1× SDS electrophoresis buffer.

Remove the gels from the caster

12. Remove the gels from the caster and separate by carefully inserting a long razor blade or knife between the gel sandwiches.

    A plastic wedge (Hoefer's Wonder Wedge) also works well.

13. Clean the outside of each gel plate with running water to remove the residual polymerized and unpolymerized acrylamide.
14. Overlay gels to be stored with 1× Tris·Cl/SDS, pH 8.8, place in a resealable plastic bag, and store at 4°C until needed (up to 1 week).

ALTERNATE PROTOCOL 5

SEPARATION OF PROTEINS ON GRADIENT GELS

Gels that consist of a gradient of increasing polyacrylamide concentration resolve a much wider size range of proteins than standard single-concentration gels (see Critical Parameters and Troubleshooting). The protein bands are also much sharper, particularly in the low-molecular-weight range. Unlike single-concentration gels, gradient gels separate proteins in a way that can be represented easily to give a linear plot from 10 to 200 kDa. This facilitates molecular weight estimations.

The quantities given below provide separating gel solution sufficient for two 0.75-mm gels (~7 ml of each concentration) or one 1.5-mm gel (~14 ml of each concentration). Volumes can be adjusted to accommodate gel sandwiches of different dimensions.

Additional Materials *(also see Basic Protocol 1)*

Light and heavy acrylamide gel solutions (Table 6.1.10)
Bromphenol blue (optional; for checking practice gradient)
10% ammonium persulfate (prepare fresh)
TEMED

Gradient maker (30 to 50 ml, Hoefer SG30 or SG50; *or* 30 to 100 ml, Bio-Rad 385)
Tygon tubing with micropipet tip
Peristaltic pump (optional; e.g., Markson A-13002, A-34040, or A-34105 minipump)
Whatman 3MM filter paper

Set up the gradient maker and prepare the gel solutions

1. Assemble the magnetic stirrer and gradient maker on a ring stand as shown in Figure 6.1.2. Connect the outlet valve of the gradient maker to Tygon tubing attached to a micropipet tip that is placed over the vertical gel sandwich. If desired, place a peristaltic pump in line between the gradient maker and the gel sandwich.

   A peristaltic pump will simplify casting by providing a smooth flow rate.

2. Place a small stir-bar into the mixing chamber of the gradient maker (i.e., the chamber connected to the outlet).

Table 6.1.10 Light and Heavy Acrylamide Gel Solutions for Gradient Gels

	Acrylamide concentration in light gel solution (%)[a,b]									
Stock solution	5	6	7	8	9	10	11	12	13	14
30% acrylamide/0.8% bisacrylamide[c]	2.5	3.0	3.5	4.0	4.5	5.0	5.5	6.0	6.5	7.0
4× Tris·Cl/SDS, pH 8.8[c]	3.75	3.75	3.75	3.75	3.75	3.75	3.75	3.75	3.75	3.75

TEMED[d]	0.005	0.005	0.005	0.005	0.005	0.005	0.005	0.005	0.005	0.005

	Acrylamide concentration in heavy gel solution (%)[a,b]										
Stock solution	10	11	12	13	14	15	16	17	18	19	20
30% acrylamide/0.8% bisacrylamide[c]	5.0	5.5	6.0	6.5	7.0	7.5	8.0	8.5	9.0	9.5	10.0
4× Tris·Cl/SDS, pH 8.8[c]	3.75	3.75	3.75	3.75	3.75	3.75	3.75	3.75	3.75	3.75	3.75
H_2O	5.0	4.5	4.0	3.5	3.0	2.5	2.0	1.5	1.0	0.5	0
Sucrose (g)	2.25	2.25	2.25	2.25	2.25	2.25	2.25	2.25	2.25	2.25	2.25
10% ammonium persulfate[d]	0.05	0.05	0.05	0.05	0.05	0.05	0.05	0.05	0.05	0.05	0.05
TEMED[d]	0.005	0.005	0.005	0.005	0.005	0.005	0.005	0.005	0.005	0.005	0.005

[a] To survey proteins ≥10 kDa, 5% to 20% gradient gels are recommended. To expand the range between 10 and 200 kDa, a 10% to 20% gradient gel is recommended.
[b] Volumes are in milliliters (sucrose is in grams). Keep light gel solution at room temperature prior to use (no longer than 1 hr). Keep heavy solution on ice.
[c] See Table 6.1.1 for preparation.
[d] Ammonium persulfate and TEMED are added directly to the gradient chambers immediately before the gel is poured. It is best to prepare ammonium persulfate fresh. Failure to form a firm gel usually indicates a problem with the ammonium persulfate, TEMED, or both.

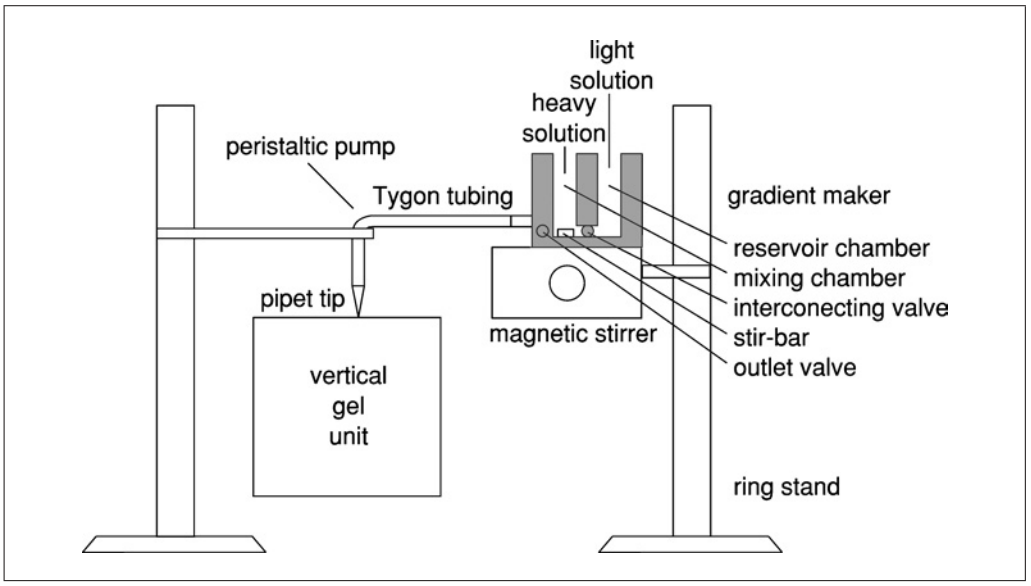

Figure 6.1.2 Gradient gel setup. A peristaltic pump, though not required, will provide better control.

3. Using the recipes in Table 6.1.10, prepare light and heavy acrylamide gel solutions *without* ammonium persulfate or TEMED.

   Recommended gradient ranges are 5% to 20% for most applications (to separate proteins of 10 to several hundred kilodaltons).

   Deaeration is not recommended for either the light or heavy solution. Omitting the deaeration will allow polymerization to proceed more slowly, letting the gradient establish itself in the gel sandwich before polymerization takes place.

   Keep the heavy solution on ice until use. Once the ammonium persulfate is added to the heavy solution, it will polymerize without TEMED, albeit more slowly; keeping the solution on ice prevents this. The gel solution will come to room temperature during casting. The higher the percentage of acrylamide, the more severe the problem of premature polymerization.

4. With the outlet port and interconnecting valve between the two chambers closed, pipet 7 ml of light (low-concentration) acrylamide gel solution into the reservoir chamber for one 0.75-mm-thick gradient gel.

   A practice run with heavy and light solutions is recommended. Bromphenol blue should be added to the heavy solution to demonstrate linearity of the practice gradient.

5. Open the interconnecting valve briefly to allow a small amount (~200 µl) of light solution to flow through the valve and into the mixing chamber.

   The presence of air bubbles in the interconnecting valve may obstruct the flow between chambers during casting.

6. Add 7 ml of heavy (high-concentration) acrylamide gel solution to the mixing chamber.

7. Add 23 µl of 10% ammonium persulfate and ~2.3 µl TEMED per 7 ml acrylamide solution to each chamber. Mix the solutions in each chamber with a disposable pipet.

Form the gradient and cast the gel

8. Open the interconnecting valve completely.

   Some of the heavy solution will flow back into the reservoir chamber containing light solution as the two chambers equilibrate. This will not affect the formation of the gradient.

9. Turn on the magnetic stirrer and adjust the rate to produce a slight vortex in the mixing chamber.

10. Open the outlet of the gradient maker slowly. Adjust the outlet valve to a flow rate of 2 ml/min. If using a peristaltic pump, calibrate the flow rate with a graduated cylinder prior to casting the gel.

    Some adjustment of the flow rate may be necessary during casting. If the light solution is not flowing into the mixing chamber, a bubble may be caught in the interconnecting valve. Quickly close the outlet and cover the top of the reservoir chamber with a gloved thumb. Push down with the thumb to increase the pressure in the chamber and force the air bubble out of the center valve.

11. Fill the gel sandwich from the top. Place the pipet tip against one side of the sandwich so the solution flows down one plate only. The heavy solution will flow into the sandwich first, followed by progressively lighter solution.

12. Watch as the last of the light solution drains into the outlet tube and adjust the flow rate to ensure that the last few milliliters of solution do not flow quickly into the gel sandwich and disturb the gradient.

13. Overlay the gradient gel with H_2O-saturated isobutyl alcohol. Allow the gel to polymerize ~1 hr.

    In this gel system, the gel will polymerize from the bottom (i.e., heavy solution) up. Because polymerization is an exothermic reaction, heat can be felt evolving from the bottom of the gel sandwich during polymerization. A sharp optical discontinuity at the gel-overlay interface indicates that polymerization has occurred. In general, 1 hr is adequate for polymerization.

14. Remove the H_2O-saturated isobutyl alcohol and rinse with 1× Tris·Cl/SDS, pH 8.8. Cast the stacking gel (see Basic Protocol 1, steps 8 to 11).

    The gel can be covered with 1× Tris·Cl/SDS, pH 8.8, sealed in a plastic bag, and stored for up to 1 week.

Load and run the gel

15. Prepare the protein sample and protein molecular-weight-standards mixture. Load and run the gel (see Basic Protocol 1, steps 13 to 26).

    The gel can be stained with Coomassie blue or silver (UNIT 6.6).

16. After staining, dry the gels onto Whatman 3MM or equivalent filter paper.

    Gradient gels >0.75 mm thick require special handling during drying to prevent cracking. The simplest approach to drying gradient gels is to use thin gels; ≤0.75-mm gradient gels with ≤20% acrylamide solutions will dry without cracking as long as the vacuum pump is working properly and the cold trap is dry at the onset of drying. For gradient gels >0.75 mm thick, add 3% (w/v) glycerol to the final destaining solution to help prevent cracking. Another method is to dehydrate and shrink the gel in 30% methanol for up to 3 hr prior to drying. Then place the gel in distilled water for 5 min before drying.

CASTING MULTIPLE GRADIENT GELS

SUPPORT PROTOCOL 2

Casting gradient gels in a multiple gel caster has several advantages. In addition to the time savings, batch casting produces gels that are essentially identical. This is particularly important for gradient gels, where slight variations in casting technique can cause variations in protein mobility. The gels may be stored for up to 1 week after casting to ensure internal consistency from run to run during the week. Furthermore, gels with several ranges of concentrations (e.g., 5% to 20% and 10% to 20% acrylamide) can be cast and stored, giving much more flexibility to optimize separations.

Additional Materials *(also see Alternate Protocol 5)*

Plug solution (see recipe)
Light and heavy acrylamide gel solutions for multiple gradient gels (Table 6.1.11)
TEMED
H_2O-saturated isobutyl alcohol

Multiple gel caster (Bio-Rad, Hoefer)
Peristaltic pump (25 ml/min)
500- or 1000-ml gradient maker (Bio-Rad, Hoefer)
Tygon tubing

Set up system and pour separating gel

1. Assemble the multiple caster as in casting multiple single-concentration gels (see Support Protocol 1, steps 1 to 3), making sure to remove the triangular space filler plugs in the bottom of the caster.

   The plug is used only when casting single-concentration gels.

Table 6.1.11 Light and Heavy Acrylamide Gel Solutions for Casting Multiple Gradient Gels

	Acrylamide concentration in light gel solution (%)[a,b]									
Stock solution	5	6	7	8	9	10	11	12	13	14
30% acrylamide/0.8% bisacrylamide[c]	28	33	39	44	50	55	61	66	72	77
4× Tris·Cl/SDS, pH 8.8[c]	41	41	41	41	41	41	41	41	41	41
H_2O	96	91	85	80	74	69	63	58	52	47
10% ammonium persulfate[d]	0.55	0.55	0.55	0.55	0.55	0.55	0.55	0.55	0.55	0.55
TEMED	0.054	0.054	0.054	0.054	0.054	0.054	0.054	0.054	0.054	0.054

	Acrylamide concentration in heavy gel solution (%)[a,b]										
Stock solution	10	11	12	13	14	15	16	17	18	19	20
30% acrylamide/0.8% bisacrylamide[c]	55	61	66	72	77	83	88	94	99	105	110
4× Tris·Cl/SDS, pH 8.8[c]	41	41	41	41	41	41	41	41	41	41	41
H_2O	55	50	44	39	33	28	22	17	11	5.5	0
Sucrose (g)	25	25	25	25	25	25	25	25	25	25	25
10% ammonium persulfate[d]	0.55	0.55	0.55	0.55	0.55	0.55	0.55	0.55	0.55	0.55	0.55
TEMED	0.054	0.054	0.054	0.054	0.054	0.054	0.054	0.054	0.054	0.054	0.054

[a]To survey proteins ≥10 kDa, 5% to 20% gradient gels are recommended. To expand the range between 10 and 200 kDa, a 10% to 20% gradient gel is recommended.
[b]Volumes are in milliliters (sucrose is in grams). Recipes produce ten 1.5-mm-thick gradient gels with 10 ml extra solution to account for losses in tubing. Keep light gel solution at room temperature prior to use (no longer than 1 hr). Keep heavy solution on ice.
[c]See Table 6.1.1 for preparation.
[d]Best to prepare fresh. Failure to form a firm gel usually indicates a problem with the ammonium persulfate, TEMED, or both.

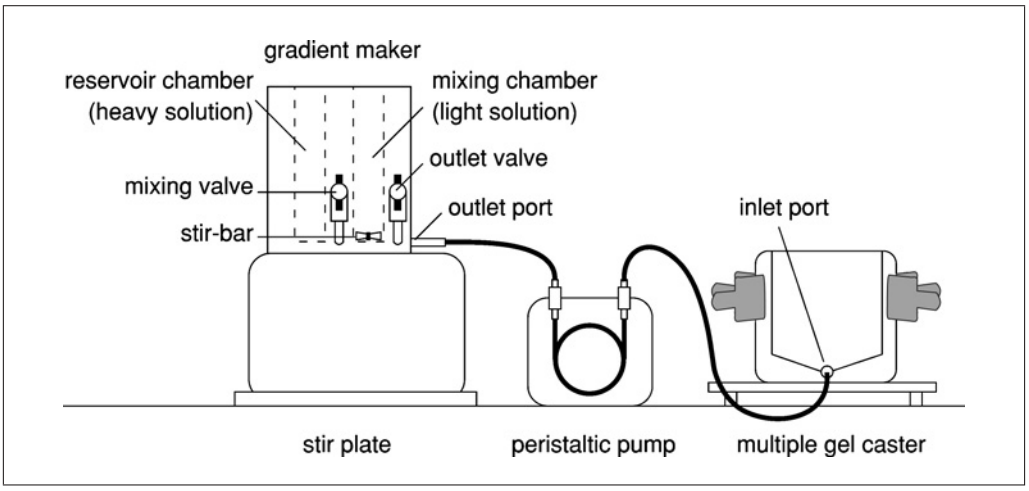

Figure 6.1.3 Setup for casting multiple gradient gels. Casting multiple gradient gels requires a peristaltic pump and a multiple gel caster. Gel solution is introduced through the bottom of the multiple caster.

2. Set up the peristaltic pump (Fig. 6.1.3). Using a graduated cylinder and water, adjust the flow rate so that the volume of the gradient solution plus volume of plug solution is poured in ~15 to 18 min (~25 ml/min).

3. Set up the gradient maker. Close all valves and place a stir-bar in the mixing chamber, which is the one with the outlet port. Attach one end of a piece of Tygon tubing to the outlet of the gradient maker. Run the other end of the tubing through the peristaltic pump and attach it to the red inlet port at the bottom of the caster.

   Choose a gradient maker that holds no more than four times the total volume of the gradient solution to be poured (i.e., a 1000- or 500-ml gradient maker).

4. Prepare solutions for the gradient maker (Table 6.1.11).

   Deaeration is not recommended for gradient gels.

5. *Immediately* after adding TEMED to the gel solutions, pour the light (low-concentration) solution into the mixing chamber (the one with the port). Open the mixing valve slightly to allow the tunnel to fill and to avoid air bubbles. Close the valve again and pour the heavy (high-concentration) acrylamide solution into the reservoir chamber.

6. Start the magnetic stirrer and open the outlet valve; then start the pump and open the mixing valve.

   In units for casting multiple gels, acrylamide solution flows in from the bottom. To use a multiple casting unit, the light solution is placed in the mixing chamber and the heavy solution in the reservoir. This is the reverse of casting a single gel (see Alternate Protocol 5). Thus, light solution enters the multiple caster first, followed by progressively heavier solution. Finally, the acrylamide solution is stabilized in the multiple caster with a heavy plug solution and allowed to polymerize (see step 8 and manufacturer's instructions).

7. When almost all the acrylamide solution is gone from the gradient maker, stop the pump and close the mixing valve. Tilt the gradient maker toward the outlet side and remove the last milliliters of the mix. Do not allow air bubbles to enter the tubing.

8. Add the plug solution to the mixing chamber and start the pump. Make sure that no bubbles are introduced. Continue pumping until the bottom of the caster is filled with plug solution to just below the glass plates; then turn off the pump. Clamp the tubing close to the red port of the casting chamber.

9. Quickly overlay each separate gel sandwich with 100 µl H_2O-saturated isobutyl alcohol. Use the same amount on each sandwich. Allow the gels to polymerize for ~1 hr.

   Failure to use the same amount of overlay solution will cause the gel sandwiches to polymerize at different heights.

10. Drain off the overlay and rinse the surface of the gels with 1× Tris·Cl/SDS, pH 8.8.

Pour stacking gel and remove gels from caster

11. Prepare and cast the stacking gel as in casting multiple single-concentration gels (see Support Protocol 1, steps 8 to 11).

12. Remove gels from the caster and clean the gel sandwiches (see Support Protocol 1, steps 12 and 13). Store gels, if necessary, according to the instructions for multiple single-concentration gels (see Support Protocol 1, step 14).

BASIC PROTOCOL 2

ELECTROPHORESIS IN SINGLE-CONCENTRATION MINIGELS

Separation of proteins in a small-gel format is becoming increasingly popular for applications that range from isolating material for peptide sequencing to performing routine protein separations. The unique combination of speed and high resolution is the foremost advantage of small gels. Additionally, small gels are easily adapted to single-concentration, gradient, and two-dimensional SDS-PAGE procedures. The minigel procedures described are adaptations of larger gel systems.

This protocol describes the use of a multiple gel caster. The caster is simple to use, and up to five gels can be prepared at one time with this procedure. Single gels can be prepared using adaptations in the manufacturer's instructions. A multiple gel caster is the only practical way to produce small linear polyacrylamide gradient gels (see Support Protocol 3).

Materials

Minigel vertical gel unit (Hoefer Mighty Small SE 250/280 *or* Bio-Rad Mini-Protean II) with glass plates, clamps, and buffer chambers
0.75-mm spacers
Multiple gel caster (Hoefer SE-275/295 *or* Bio-Rad Mini-Protean II multicasting chamber)
Acrylic plate (Hoefer SE-217 *or* Bio-Rad 165-1957) or polycarbonate separation sheet (Hoefer SE-213 *or* Bio-Rad 165-1958)
10- and 50-ml syringes
Combs (Teflon, Hoefer SE-211A series or Bio-Rad Mini-Protean II)
Long razor blade
Micropipet
Additional reagents and equipment for standard denaturing SDS-PAGE (see Basic Protocol 1)

Pour the separating gel

1. Assemble each gel sandwich by stacking, in order, the notched (Hoefer) or small rectangular (Bio-Rad) plate, 0.75-mm spacers, and the larger rectangular plate. Be sure to align the spacers properly, with the ends flush with the top and bottom edge of the two plates, when positioning the sandwiches in the multiple gel caster (Fig. 6.1.4).

   The protocol described is basically for the Hoefer system. For other systems, make adjustments according to the manufacturer's instructions. Alternatively, precast minigels can be purchased from a number of suppliers (see Table 6.1.4).

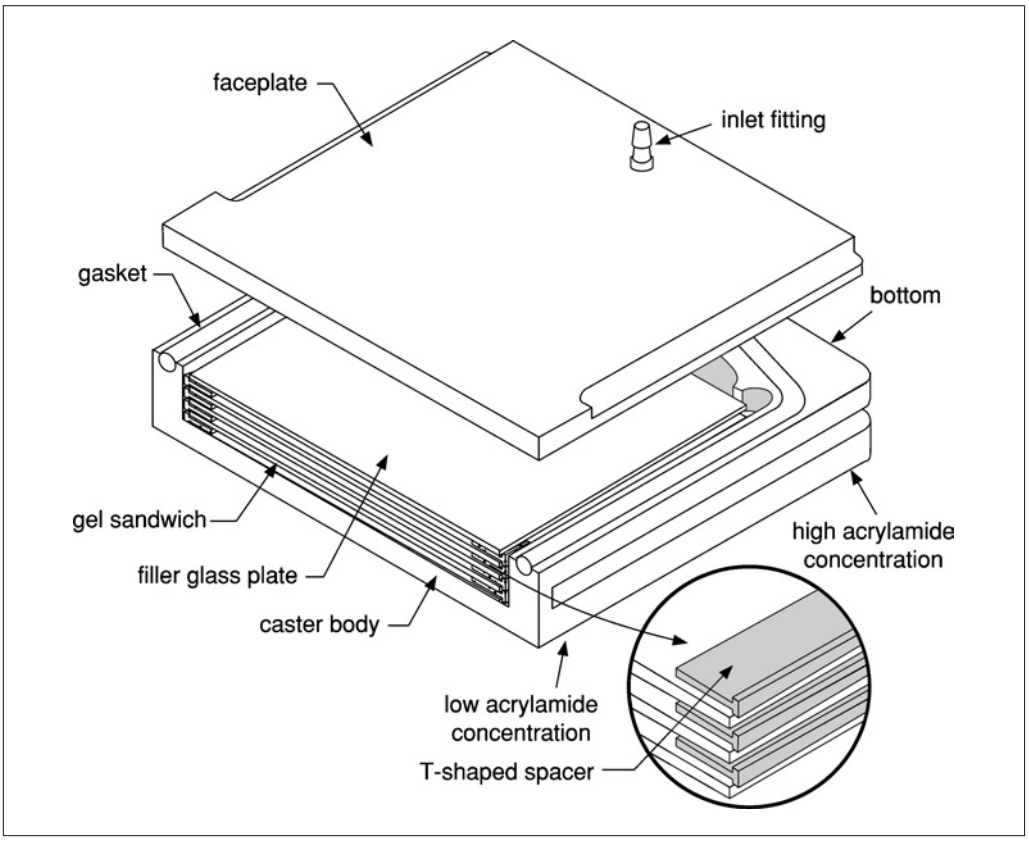

Figure 6.1.4 Minigel sandwiches positioned in the multiple gel caster. Extra glass or acrylic plates or polycarbonate sheets are used to fill any free space in the caster and to ensure that the gel sandwiches are held firmly in place.

The multiple casters from Hoefer have a notch in the base designed for casting gradient gels. A silicone rubber insert fills up this space when casting single-concentration gels. The Hoefer spacers are T-shaped to prevent slipping. The flanged edge of the spacer must be positioned against the outside edge of the glass plate. Placing a sheet of wax paper between the gel sandwiches will help separate the sandwiches after polymerization.

2. Fit the gel sandwiches tightly in the multiple gel caster. Use an acrylic plate or polycarbonate separation sheet to eliminate any slack in the chamber.

   Loosely fitting sandwiches in the caster will lead to unevenly cast gels, creating distortions during electrophoresis.

3. Place the front faceplate on the caster, clamp it in place against the silicone gasket, and verify alignment of the glass plates and spacers.

4. Prepare the separating gel solution as directed in Table 6.1.1. For five 0.75-mm-thick gels, prepare ~30 ml solution (i.e., double the volumes listed).

   To compute the total gel volume needed, multiply the area of the gel (e.g., 7.3 × 8.3 cm) by the thickness of the gel (e.g., 0.75 mm) and then by the number of gels in the caster. If needed, add ~4 to 5 ml of extra gel solution to account for the space around the outside of the gel sandwiches.

   Do not add TEMED and ammonium persulfate until just before use.

5. Fill a 50-ml syringe with the separating gel solution and slowly inject it into the caster until the gels are 6 cm high, allowing 1.5 cm for the stacking gel.

6. Overlay each gel with 100 µl H_2O-saturated isobutyl alcohol. Allow the gels to polymerize for ~1 hr.

Pour the stacking gel

7. Remove the isobutyl alcohol and rinse with 1× Tris·Cl/SDS, pH 8.8.

   Stacking gels can be cast one at a time with the gel mounted on the electrophoresis unit, or all at once in the multiple caster.

8. Practice placing a comb in the gel sandwiches before preparing the stacking gel solution. Press the comb against the rectangular or taller plate so that all teeth of the comb are aligned with the opening in the gel sandwich, then insert into the sandwich. Remove combs after practicing.

9. Prepare the stacking gel solution (2 ml per gel) as directed in Table 6.1.1. Fill a 10-ml syringe with stacking gel solution and inject the solution into each gel sandwich.

10. Insert combs, taking care not to trap bubbles. Allow the gels to polymerize 1 hr.

11. Remove the front faceplate. Carefully pull the gels out of the caster, using a long razor blade to separate the sandwiches.

    If the gels are left to polymerize for prolonged periods, they will be difficult to remove from the caster.

    The gels can be stored tightly wrapped in plastic wrap with the combs left in place inside a sealable bag to prevent drying for ∼1 week. Without the stacking gel, the separating gel can be stored for 2 to 3 weeks. Keep gels moist with 1× Tris·Cl/SDS, pH 8.8, at 4°C. Do not store gels in the multiple caster.

Prepare the sample, load the gel, and conduct electrophoresis

12. Remove the combs and rinse the sample wells with 1× SDS electrophoresis buffer. Place a line indicating the bottom of each well on the front glass plate with a marker.

13. Fill the upper and lower buffer chambers with 1× SDS electrophoresis buffer. The upper chamber should be filled to 1 to 2 cm over the notched plate.

14. Prepare the protein sample and protein standards mixture (see Basic Protocol 1, step 12).

15. Load the sample using a micropipet. Insert the pipet tip through the upper buffer and into the well. The mark on the glass plate will act as a guide. Dispense the sample into the well.

    For a complex mixture, 20 to 25 μg protein in 10 μl SDS sample buffer will give a strongly stained Coomassie blue pattern. Much smaller amounts (1 to 5 μg) are required for highly purified proteins, and a 10- to 100-fold smaller amount of protein in the same volume (e.g., 10 μl) is required for silver staining.

16. Electrophorese samples at 10 to 15 mA per 0.75-mm gel until the dye front reaches the bottom of the gel (∼1 to 1.5 hr).

17. Disassemble the gel (see Basic Protocol 1, steps 23 to 26). Proceed with detection of proteins.

SUPPORT PROTOCOL 3

PREPARING MULTIPLE GRADIENT MINIGELS

Polyacrylamide gradients not only enhance the resolution of larger-format gels but also greatly improve protein separation in the small format. Casting gradient minigels one at a time is not generally feasible because of the small volumes used, but multiple gel casters make it easy to cast several small gradient gels at one time. The gels are cast from the bottom in multiple casters, with the light acrylamide solution entering first. This is the opposite of casting one gel at a time, in which the heavy solution enters from the top of the gel sandwich and flows down to the bottom.

Additional Materials *(also see Basic Protocol 2)*

Plug solution (see recipe)

Additional reagents and equipment for preparing gradient gels (see Alternate Protocol 5)

Set up the system and prepare the gel solutions

1. Assemble minigel sandwiches in the multiple gel caster as described for single-concentration minigels (see Basic Protocol 2, steps 1 to 3).

2. Set up the 30-ml gradient maker, magnetic stirrer, peristaltic pump (optional), and Tygon tubing as in Figure 6.1.3. Connect the outlet of the 30-ml gradient maker to the inlet at the base of the front faceplate of the caster.

   The monomer solution will be introduced through the inlet at the bottom of the front faceplate of the caster first, followed by progressively heavier solution.

3. Prepare light and heavy acrylamide gel solutions (Table 6.1.10). Use ~12 ml of each solution for five 0.75-mm-thick minigels.

   Adjust volumes if a different thickness or number of gels is needed. Do not add ammonium persulfate until just before use. Deaeration is not recommended for gradient gels.

4. With the outlet and interconnecting valve closed, add the heavy solution to the reservoir chamber. Briefly open the interconnecting valve to let a small amount of heavy solution through to the mixing chamber, clearing the valve of air.

5. Fill the mixing chamber with light solution. Add 4 µl TEMED per 12 ml acrylamide solution to each chamber and mix with a disposable pipet.

Form the gradient and cast the gels

6. Turn on the magnetic stirrer. Open the interconnecting valve and allow the chambers to equilibrate. Then slowly open the outlet port to allow the solution to flow from the gradient maker to the multiple caster by gravity (a peristaltic pump may be used for better control). Adjust the flow rate to 3 to 4 ml/min.

   Faster flow rates are possible and will also produce good gradients. However, a fast flow increases the potential for introduction of bubbles into the caster.

7. Close the outlet port as the last of the gradient solution leaves the mixing chamber, just before air enters the outlet tube. Fill the two chambers with plug solution and slowly open the outlet once again.

8. Allow the plug solution to push the acrylamide in the caster up into the plates. Close the outlet when the plug solution reaches the bottom of the plates.

   A discontinuity between the bottom of the gels and the plug solution will be obvious.

9. Quickly add 100 µl H_2O-saturated isobutyl alcohol to each gel sandwich. Let the gels polymerize undisturbed for ~1 hr.

10. Prepare and pour the stacking gel (see Basic Protocol 2, steps 9 and 10).

Disassemble the system

11. Disconnect the gradient maker, place the caster in a sink, and remove the front faceplate. The plug solution will drain out from the bottom of the caster.

12. Remove the gels (see Basic Protocol 2, step 11).

    Gradient minigels can be stored as described for single-concentration minigels (see Basic Protocol 2, step 11 annotation). For instructions on preparing, loading, and running the gels, see Basic Protocol 2, steps 12 to 17.

SUPPORT PROTOCOL 4

CALCULATING MOLECULAR MASS

Determining the molecular mass of an unknown protein or nucleic acid fragment is straightforward given the use of calibration size standards in the same gel. Typically, a tracking dye such as bromphenol blue is added to the sample prior to loading on the gel (e.g., see recipe for SDS sample buffer). The tracking dye moves ahead of the proteins and serves as a relative mobility marker. A set of protein standards is separated in the same gel as the protein sample containing the unknown. The standards are used to create a standard curve of relative mobility versus size or molecular mass. Although digital image analysis has greatly simplified calculating the mass of an unknown protein separated by electrophoresis, manual assessments of molecular mass are useful and use the same basic calculations.

1. Calculate the relative mobility (R_f) using following formula:

   R_f = distance migrated by protein/distance migrated by marker.

   Placing a molecular mass/R_f mobility acetate overlay calculator (Fig. 6.1.5) on the gel is a quick way to determine R_f. Simply align the top and bottom of the overlay with the top of the gel and the dye front, respectively, to get a read out of R_f.

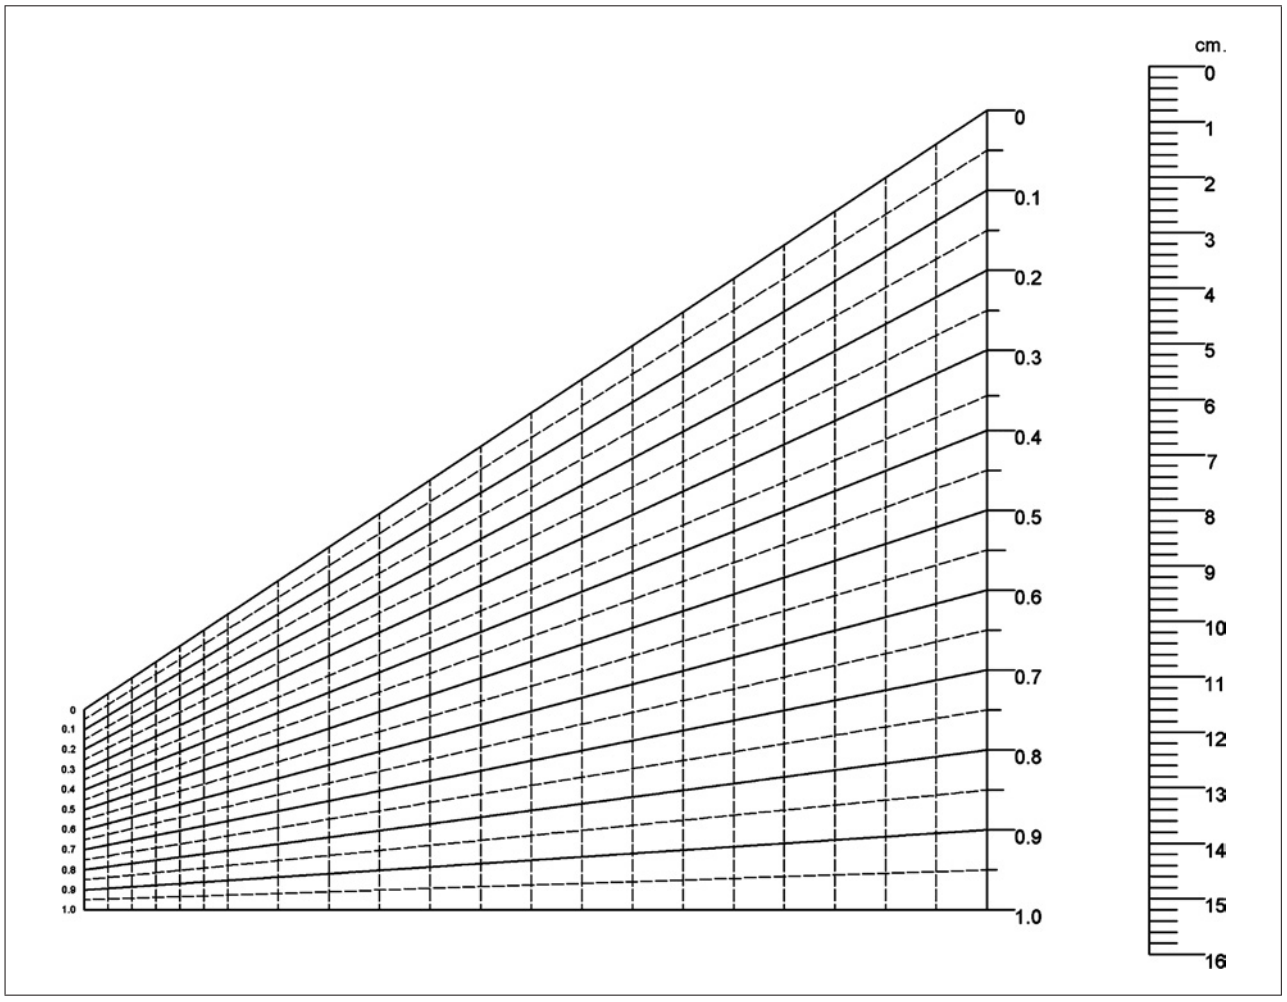

Figure 6.1.5 Example of an R_f calculator. This sheet is copied to transparency film using a paper copier and used as an overlay on the gel. When the transparency is placed on top of the gel, so that the top of the gel aligns with the top of the calculator and the dye front aligns with the bottom of the calculator, the R_f can be read directly off the overlay. Note that the calculator accommodates a range of gel lengths. The overlay should be copied at a 1:1 ratio so that the centimeter scale remains accurate. However, as long as the overlay can fit the top and bottom of the gel, the R_f numbers will be accurate.

2. Plot log protein mass on the *y* axis versus relative mobility of the standards on the *x* axis (Fig. 6.1.6).
3. Perform linear regression using a calculator or analysis program.
4. Use the linear regression equation ($y = mx + b$) to estimate the mass of the unknown:

   Log molecular weight = (slope)(mobility of unknown) + *y* intercept.

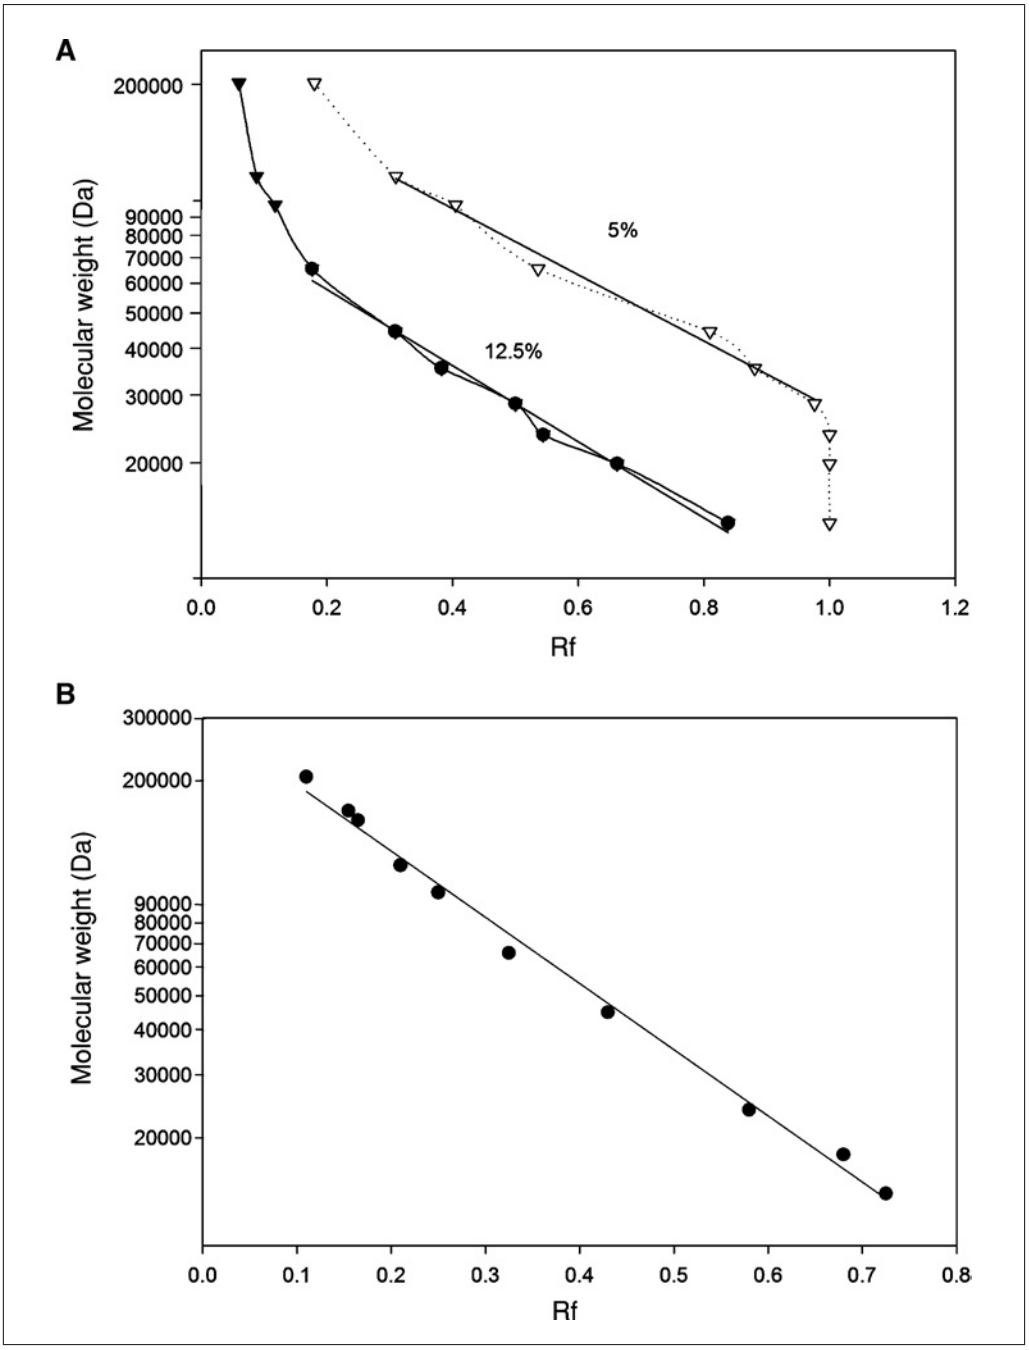

Figure 6.1.6 Standard protein molecular weight curves for **(A)** single concentration (5% and 12.5%) and **(B)** gradient (5% to 20%) gels. Protein standards are separated via SDS-PAGE, visualized by staining with Coomassie blue (*UNIT 6.6*), and measured relative to the dye front to give the relative mobility (R_f). Note the single-concentration gel has a more limited range of linearity than the gradient gel. The standard curve permits the calculation of the molecular weight of an unknown by using the R_f of the unknown to predict the molecular weight.

REAGENTS AND SOLUTIONS

Use Milli-Q water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Anode buffer

121.1 g Tris base (0.2 M final)
500 ml H_2O
Adjust to pH 8.9 with concentrated HCl
Dilute to 5 liters with H_2O
Store at 4°C up to 1 month

Final concentration is 0.2 M Tris·Cl, pH 8.9.

Cathode buffer

12.11 g Tris base (0.1 M final)
17.92 g tricine (0.1 M final)
1 g SDS [0.1% w/v final; recrystallization (see recipe) optional]
Dilute to 1 liter with H_2O
Do not adjust pH
Store at 4°C up to 1 month

Coomassie blue G-250 staining solution

200 ml acetic acid (20% v/v final)
1800 ml H_2O
0.5 g Coomassie blue G-250 (0.025% w/v final)
Mix 1 hr and filter (Whatman no. 1 paper)
Store at room temperature indefinitely

Phosphate/SDS electrophoresis buffer

Dilute 500 ml of 4× phosphate/SDS, pH 7.2 (Table 6.1.8) with H_2O to 2 liters. Store at 4°C up to 1 month.

Final concentrations are 0.1 M sodium phosphate (pH 7.2)/0.1% (w/v) SDS.

Phosphate/SDS sample buffer, 2× (for continuous systems)

0.5 ml 4× phosphate/SDS, pH 7.2 (Table 6.1.8; 20 mM sodium phosphate final)
0.2 g SDS [2% w/v final; recrystallization (see recipe) optional]
0.1 mg bromphenol blue (0.001% w/v final)
0.31 g DTT (0.2 M final)
2.0 ml glycerol (20% v/v final)
Add H_2O to 10 ml and mix

Plug solution

0.125 M Tris·Cl, pH 8.8 (*APPENDIX 2A*)
50% (w/v) sucrose
0.001% (w/v) bromphenol blue
Store at 4°C up to 1 month

Recrystallized SDS (optional)

High-purity SDS is available from several suppliers, but for some sensitive applications (e.g., protein sequencing) recrystallization is useful. Commercially available electrophoresis-grade SDS is usually of sufficient purity for most applications.

continued

Add 100 g SDS to 450 ml ethanol and heat to 55°C. While stirring, gradually add 50 to 75 ml hot H_2O until all SDS dissolves. Add 10 g activated charcoal (Norit 1, Sigma) to solution. After 10 min, filter solution through Whatman no. 5 paper on a Buchner funnel to remove charcoal. Chill filtrate 24 hr at 4°C and 24 hr at −20°C. Collect crystalline SDS on a coarse-frit (porosity A) sintered-glass funnel and wash with 800 ml −20°C ethanol (reagent grade). Repeat crystallization without adding activated charcoal. Dry recrystallized SDS under vacuum overnight at room temperature. Store in a desiccator over phosphorous pentoxide (P_2O_5) in a dark bottle.

If proteins will be electroeluted or electroblotted for protein sequence analysis, it may be desirable to crystallize the SDS twice from ethanol/H_2O (Hunkapiller et al., 1983).

SDS electrophoresis buffer, 5×

15.1 g Tris base (0.125 M final)
72.0 g glycine (0.96 M final)
5.0 g SDS [0.5% w/v final; recrystallization (see recipe) optional]
H_2O to 1000 ml
Dilute to 1× or 2× for working solution, as appropriate

Do not adjust the pH of the stock solution, as the solution is pH 8.3 when diluted. Store at 0° to 4°C until use (up to 1 month).

SDS sample buffer, 2× (for discontinuous systems)

25 ml 4× Tris·Cl/SDS, pH 6.8 (Table 6.1.1)
20 ml glycerol (20% final)
4 g SDS [4% w/v final; recrystallization (see recipe) optional]
2 ml 2-ME *or* 3.1 g DTT (0.2% v/v 2-ME or 0.2 M DTT final)
1 mg bromphenol blue (0.001% w/v final)
Add H_2O to 100 ml and mix
Store in 1-ml aliquots at −70°C

To avoid reducing proteins to subunits (if desired), omit 2-ME or DTT (reducing agent) and add 10 mM iodoacetamide to prevent disulfide interchange.

SDS sample buffer, 6× (for discontinuous systems)

7 ml 4× Tris·Cl/SDS, pH 6.8 (Table 6.1.1)
3.0 ml glycerol (30% v/v final)
1 g SDS [10% w/v final; recrystallization (see recipe) optional]
0.93 g DTT (0.6 M final)
1.2 mg bromphenol blue (0.012% w/v final)
Add H_2O to 10 ml (if needed)
Store in 0.5-ml aliquots at −70°C

Tricine sample buffer, 2×

2 ml 4× Tris·Cl/SDS, pH 6.8 (Table 6.1.1; 0.1 M)
2.4 ml (3.0 g) glycerol (24% v/v final)
0.8 g SDS [8% w/v final; recrystallization (see recipe) optional]
0.31 g DTT (0.2 M final)
2 mg Coomassie blue G-250 (0.02% w/v final)
Add H_2O to 10 ml and mix

COMMENTARY

Background Information

Although electrophoresis has been studied for over two centuries, Arne Tiselius (University of Uppsala, Sweden) put the technique on the map with his Ph.D. thesis in 1930, which demonstrated moving zones of serum proteins in a special square-shaped, free-solution electrophoresis cell. His original work showed for the first time that protein components in serum could be separated, giving the now familiar designations for α, β, and γ globulin. Arne Tiselius was awarded the Nobel Prize in Chemistry in 1948 (*http://nobelprize.org/chemistry/laureates/1948/index.html*) "... for his research on electrophoresis and adsorption analysis, especially for his discoveries concerning the complex nature of the serum proteins."

Electrophoresis is the movement of a charged particle, including large molecules such as DNA and proteins, in a liquid medium under the influence of an electric field. The driving force (QE) on the charged molecule is a product of the charge (Q) and the electric field (E) across the separation gel. Larger proteins move more slowly, as do proteins with a lower net charge. Furthermore, if a protein is in native (compact) form it will migrate more quickly than the same protein fully denatured and extended, where it experiences more frictional resistance with the surrounding medium. Resistance in electrophoresis is defined as $f = 6\pi rv\eta$, where f is the resistance of the medium to electrophoretic movement, r the radius of the protein (assumed to be a sphere), v the electrophoretic velocity, and η the viscosity of the fluid. The elements contributing to driving force and resistance together indicate that protein charge, size, shape, solution viscosity, and applied voltage are key factors influencing electrophoretic separation.

Electrophoresis is used to separate complex mixtures of proteins (e.g., from cells, subcellular fractions, column fractions, or immunoprecipitates), investigate subunit compositions, and verify homogeneity of protein samples (Table 6.1.12). It can also serve to purify proteins for use in further applications. In polyacrylamide gel electrophoresis (PAGE), proteins migrate in response to an electrical field through pores in a gel matrix consisting of polymers of cross-linked acrylamide. The pore size is determined by acrylamide concentration. The combination of gel pore size and protein charge, size, and shape determines the migration rate of the protein.

Polyacrylamide gels form after polymerization of monomeric acrylamide into polymeric polyacrylamide chains and cross-linking of the chains by *N,N′*-methylenebisacrylamide (Fig. 6.1.7). The polymerization reaction is initiated by the addition of ammonium persulfate, and the reaction is accelerated by TEMED, which catalyzes the formation of free radicals from ammonium persulfate. Because oxygen inhibits the polymerization process, deaerating the gel solution before the polymerization catalysts are added will speed up polymerization; deaeration is not recommended for the gradient gel protocols because slower polymerization facilitates casting of gradient gels.

Precast gels for commonly used vertical minigel and standard-sized SDS-PAGE apparatuses are available from several manufacturers (Table 6.1.4). Flatbed (horizontal) isoelectric focusing (IEF) and SDS-PAGE gels are not listed. Hoefer supplies a range of horizontal gels for a variety of applications and should be consulted for further information. When using precast gels, pay strict attention to shelf life. In general, manufacturers overrate the shelf life, and the sooner the gels are used, the better. When reasonably fresh, precast gels provide excellent resolution that is as good or better than a typical gel cast in the laboratory.

The most widely used method for discontinuous gel electrophoresis is the system described by Laemmli (1970). This is the denaturing (SDS) discontinuous method used in Basic Protocol 1. A discontinuous buffer system uses buffers of different pH and composition to generate a discontinuous pH and voltage gradient in the gel. Because the discontinuous gel system concentrates the proteins in each sample into narrow bands, the applied sample may be more dilute than that used for continuous electrophoresis.

In the discontinuous system the sample first passes through a stacking gel, which has large pores. The stacking gel buffer contains chloride ions (called the leading ions) whose electrophoretic mobility is greater than the mobility of the proteins in the sample. The electrophoresis buffer contains glycine ions (called the trailing ions) whose electrophoretic mobility is less than the mobility of the proteins in the sample. The net result is that the faster migrating ions leave a zone of lower conductivity between themselves and the migrating protein. The higher voltage gradient in this zone allows the proteins to move faster and to "stack" in the zone between the leading

Table 6.1.12 Key Applications of Protein Electrophoresis[a]

Technique	Separation principle	Application	For more information
Native PAGE	Native charge, size, and shape	Purification, determination of native protein size, and identification of protein complexes	*UNIT 6.5*
1-D SDS-PAGE	Size dependent: SDS imparts a negative charge to proteins, giving a constant charge to mass ratio	Size estimation, purity check, purification, subunit composition, protein expression	*UNIT 6.1*
IEF	Intrinsic charge with both native and denatured proteins	Purification, purity check, isoenzyme analysis	Ploegh (1995)
2-D SDS-PAGE	Isoelectric point in the first dimension, size in the second	Protein expression, purification, posttranslational analysis, proteomics	*UNIT 6.4*

[a]Abbreviations: 1-D, one-dimensional; 2-D, two-dimensional; IEF, isoelectric focusing.

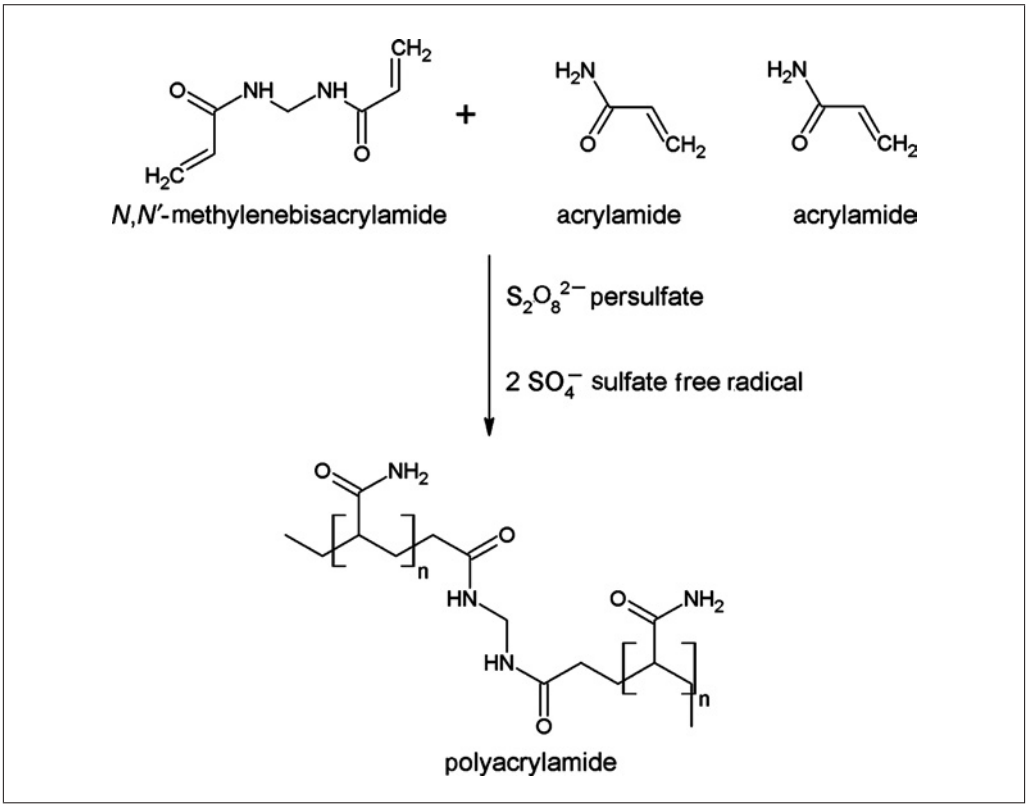

Figure 6.1.7 Structures of acrylamide and bisacrylamide and the associated reaction producing the polyacrylamide matrix used for protein separation.

and trailing ions. After leaving the stacking gel, the protein enters the separating gel. The separating gel has a smaller pore size, a higher salt concentration, and higher pH compared to the stacking gel. In the separating gel, the glycine ions migrate past the proteins, and the proteins are separated according to either molecular size in a denaturing gel (containing SDS) or molecular shape, size, and charge in a nondenaturing gel.

Proteins are denatured by heating in the presence of a low-molecular-weight thiol

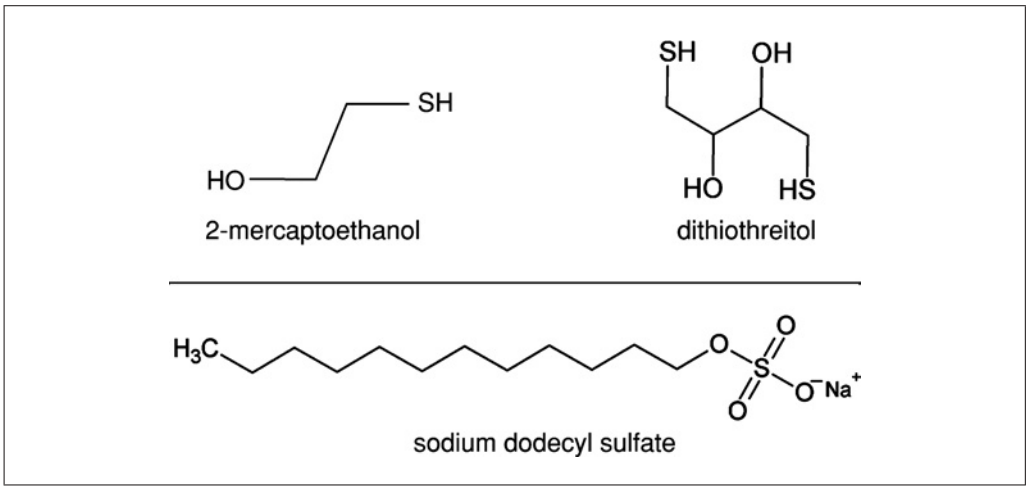

Figure 6.1.8 Structures of sodium dodecyl sulfate, dithiothreitol, and 2-mercaptoethanol: used to break disulfide bonds in proteins so they are fully denatured.

(2-ME or DTT) and SDS (Fig. 6.1.8). Most proteins bind SDS in a constant-weight ratio, leading to identical charge densities for the denatured proteins. Thus, the SDS-protein complexes migrate in the polyacrylamide gel according to size, not charge. Most proteins are resolved on polyacrylamide gels containing from 5% to 15% acrylamide and 0.2% to 0.5% bisacrylamide (see Table 6.1.1). The relationship between the relative mobility and log molecular weight is linear over these ranges (Fig. 6.1.6). With the use of plots like those shown in Figure 6.1.6, the molecular weight of an unknown protein (or its subunits) may be determined by comparison with known protein standards (Table 6.1.2). In general, all of the procedures in this unit are suitable for radiolabeled and biotinylated proteins without modification.

Basic Protocol 1 relies on denaturing proteins in the presence of SDS and 2-ME or DTT. Under these conditions, the subunits of proteins are dissociated and their biological activities are lost. A true estimate of a protein's molecular size can be made by comparing the relative mobility of the unknown protein to proteins in a calibration mixture (Support Protocol 4). Gradient gels (Alternate Protocol 5) simplify molecular-weight determinations by producing a linear relationship between log molecular weight of the protein and log % T over a much wider size range than single-concentration gels. Although percent acrylamide monomer is a more common measure of gel concentration, % T, the percentage of total monomer (acrylamide plus bisacrylamide) in the solution or gel, is used for molecular weight calculations in gradient gels. The % T of a stained protein is estimated assuming the acrylamide gradient is linear. For example, proteins in the gel shown in Figure 6.1.9 were separated in a 5.1% to 20.5% T acrylamide gradient. The % T of the point halfway through the resolving gel is 12.5% T. Simply plotting log molecular mass versus distance moved into the gel (or R_f) also produces a relatively linear standard curve over a fairly wide size range.

If two proteins have identical molecular sizes, they more than likely will not be resolved with one-dimensional SDS-PAGE, and two-dimensional SDS-PAGE should be considered. Unusual protein compositions can cause anomalous mobilities during electrophoresis (see Critical Parameters and Troubleshooting), but similar-sized proteins of widely different amino acid composition or structure may still be resolved from one another using one-dimensional SDS-PAGE. Purified protein complexes or multimeric proteins consisting of subunits of different molecular size will be resolved into constituent polypeptides. Comparison of the protein bands obtained under nonreducing and reducing conditions provides information about the molecular size of disulfide cross-linked component subunits. The individual polypeptides can be isolated by electroelution or electroblotting, and the amino acid sequences can be determined.

Both the tricine (Schagger and von Jagow, 1987) and the modified Laemmli (Okajima et al., 1993) peptide separation procedures presented here (Alternate Protocols 1 and 2) are simple to set up and provide resolution down to 5 kDa. To separate peptides below 5 kDa, the tricine procedure must be modified by preparing a 16.5% T, 2.7% C resolving gel that uses a 10% T spacer gel between the stacking

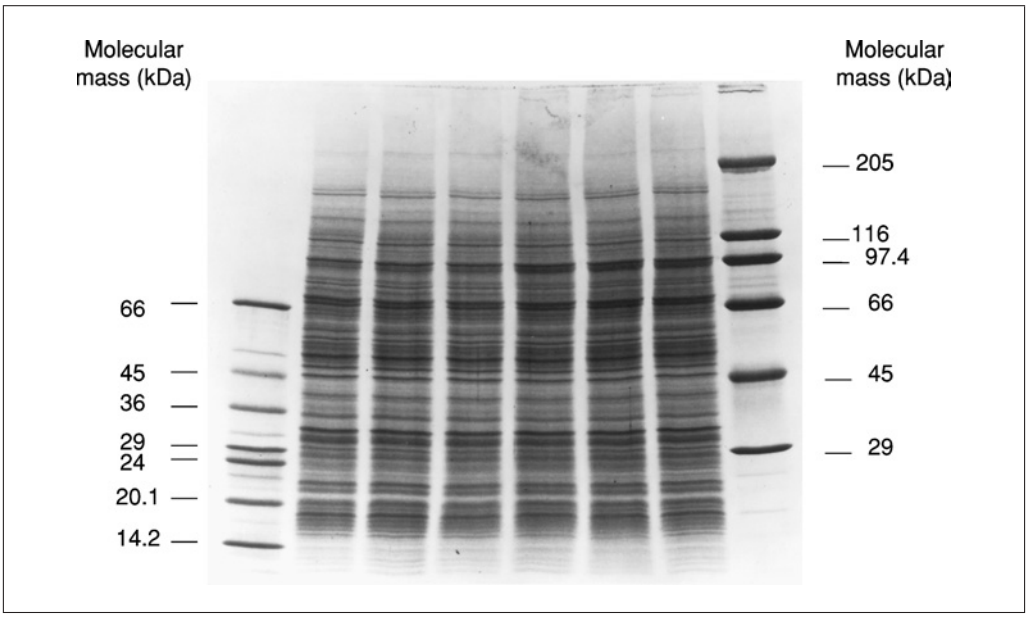

Figure 6.1.9 Separation of membrane proteins by 5.1% to 20.5% T polyacrylamide gradient SDS-PAGE. Approximately 30 μl of 1× SDS sample buffer containing 30 μg of Alaskan pea (*Pisum sativum*) membrane proteins was loaded in wells of a 14 × 14–cm, 0.75-mm-thick gel. Standard proteins were included in the outside lanes. The gel was run at 4 mA for ≈15 hr.

and resolving gel (Schagger and von Jagow, 1987). The % C is the percentage of cross-linker (bisacrylamide) in the total monomer (acrylamide plus bisacrylamide).

Continuous electrophoresis, where the same buffer is used throughout the tank and gel, is popular because of its versatility and simplicity. The phosphate system described in Alternate Protocol 3 is based on that of Weber et al. (1972). Although unable to produce the high-resolution separations of the discontinuous SDS-PAGE procedures, continuous SDS-PAGE uses fewer solutions with one basic buffer and no stacking gel. Artifacts are also less likely to occur in continuous systems. Pepsin, for example, migrates anomalously on Laemmli-based discontinuous SDS-PAGE but has the expected mobility after electrophoresis in the phosphate-based continuous system described here. This is also true of cross-linked proteins.

Multiple gel casting (Support Protocols 1 to 3) is appropriate when gel-to-gel consistency is paramount or when the number of gels processed exceeds five a week. The variety of multiple gel casters, gradient makers, and inexpensive pumps available from major suppliers simplifies the process of casting gels in the laboratory. Alternatively, precast gradient gels are available for most major brands of gel apparatuses (Table 6.1.4).

Minigels (Basic Protocol 2) are generally considered to be in the 8 × 10–cm size range, although there is considerable variation in exact size. Every technique that is used on larger systems can be translated with little difficulty into the minigel format. This includes standard and gradient SDS-PAGE and separations for immunoblotting and peptide sequencing. Two-dimensional SDS-PAGE electrophoresis also adapts well, but here the limitation of separation area becomes apparent; for high-resolution separations, large-format gels are required. Gradient minigels (Support Protocol 3) are popular due to the combination of separation range and resolution (Matsudaira and Burgess, 1978). They are particularly useful for separation of proteins prior to peptide sequencing.

Mylar support (GelBond) provides a practical way of casting, running, and, staining extremely thin gels. When gels <0.75 mm thick are used, reagents have much better access both into and out of the gel, reducing staining time in both Coomassie blue and silver staining. Double and broadened images caused by differential migration of the protein across the thickness of the gel are minimized, improving resolution.

Critical Parameters and Troubleshooting

If an electrophoretically separated protein will be electroeluted or electroblotted for sequence analysis, the highest-purity reagents available should be used. If necessary, SDS

can be purified by recrystallization following the procedure given in Reagents and Solutions.

If the gels polymerize too fast, the amount of ammonium persulfate should be reduced by one-third to one-half. If the gels polymerize too slowly or fail to polymerize all the way to the top, use fresh ammonium persulfate or increase the amount of ammonium persulfate by one-third to one-half. The overlay should be added slowly down the spacer edge to prevent the overlay solution from crashing down and disturbing the gel interface.

After a separating gel is poured, it may be stored with an overlay of the same buffer used in the gel. Immediately prior to use, the stacking gel should be poured; otherwise, there will be a gradual diffusion-driven mixing of buffers between the two gels, which will cause a loss of resolution.

The protein of interest should be present in 0.2- to 1-μg amounts in a complex mixture of proteins if the gel will be stained by Coomassie blue (*UNIT 6.6*). Typically, 30 to 50 μg of a complex protein mixture in a total volume of <20 μl is loaded on a 0.75-mm-thick slab gel (16 cm, 10 wells).

When casting multiple gradient gels, eliminate all bubbles in the outlet tubing of the gradient maker. If air bubbles get into the outlet tube, they may flow into the caster and then up through the gradient being poured, causing an area of distortion in the polymerized gel. Air bubbles are not so great a problem when casting single gradient gels from the top. As the gels are cast, the stirrer must be slowed so that the vortex in the mixing chamber does not allow air to enter the outlet.

Uneven heating of the gel causes differential migration of proteins, with the outer lanes moving more slowly than the center lanes (called smiling). Increased heat transfer eliminates smiling and can be achieved by filling the lower buffer chamber with buffer all the way to the level of the sample wells, by maintaining a constant temperature between 10° to 20°C, and by stirring the lower buffer with a magnetic stirrer. Alternatively, decrease the heat load by running at a lower current.

If the tracking dye band is diffuse, prepare fresh buffer and acrylamide monomer stocks. If the protein bands are diffuse, increase the current by 25% to 50% to complete the run more quickly and minimize band diffusion, use a higher percentage of acrylamide, or try a gradient gel. Lengthy separations using gradient gels generally produce good results (Fig. 6.1.9). Check for possible proteolytic degradation that may cause loss of high-molecular-weight bands and create a smeared banding pattern.

If there is vertical streaking of protein bands, decrease the amount of sample loaded on the gel, further purify the protein of interest to reduce the amount of contaminating protein applied to the gel, or reduce the current by 25%. Another cause of vertical streaking of protein bands is precipitation, which can sometimes be eliminated by centrifuging the sample or by reducing the percentage of acrylamide in the gel.

Proteins can migrate faster or slower than their actual molecular weight would indicate. Abnormal migration is usually associated with a high proportion of basic or charged amino acids (Takano et al., 1988). Other problems can occur during isolation and preparation of the protein sample for electrophoresis. Proteolysis of proteins during cell fractionation by endogenous proteases can cause subtle band splitting and smearing in the resulting electrophoretogram (electrophoresis pattern). Many endogenous proteases are very active in SDS sample buffers and will rapidly degrade the sample; thus, first heating the samples to 70° to 100°C for 3 min is recommended.

In some cases, heating to 100°C in sample buffer will cause selective aggregation of proteins, creating a smeared layer of Coomassie blue–stained material at the top of the gel (Gallagher and Leonard, 1987). To avoid heating artifacts and also prevent proteolysis, the use of specific protease inhibitors during protein isolation and/or lower heating temperatures (70° to 80°C) have been effective (Dhugga et al., 1988).

Although continuous gels suffer from poor band sharpness, they are less prone to artifacts caused by aggregation and protein cross-linking. If streaking or aggregation appear to be a problem with the Laemmli system, then the same sample should be subjected to continuous SDS-PAGE to see if the problem is intrinsic to the Laemmli gel or the sample.

If the protein bands spread laterally from gel lanes, the time between applying the sample and running the gel should be reduced in order to decrease the diffusion of sample out of the wells. Alternatively, the acrylamide percentage should be increased in the stacking gels from 4% to 4.5% or 5% acrylamide, or the operating current should be increased by 25% to decrease diffusion in the stacking gel. Use caution when adding 1× SDS electrophoresis buffer to the upper buffer chamber. Samples

can get swept into adjacent wells and onto the top of the well arm.

If the protein bands are uneven, the stacking gel may not have been adequately polymerized. This can be corrected by deaerating the stacking gel solution thoroughly or by increasing the ammonium persulfate and TEMED concentrations by one-third to one-half. Another cause of distorted bands is salt in the protein sample, which can be removed by dialysis, gel filtration, or precipitation. Skewed protein bands can be caused by an uneven interface between the stacking and separating gels, which can be corrected by starting over and being careful not to disturb the separating gel while overlaying with isobutyl alcohol.

If a run takes too long, the buffers may be too concentrated or the operating current too low. If the run is too short, the buffers may be too dilute or the operating current too high.

If double bands are observed, the protein may be partially oxidized or partially degraded. Oxidation can be minimized by increasing the 2-ME concentration in the sample buffer or by preparing a fresh protein sample. If fewer bands than expected are observed and there is a heavy protein band at the dye front, increase the acrylamide percentage in the gel.

Anticipated Results

Polyacrylamide gel electrophoresis done under denaturing and reducing conditions should resolve any two proteins, except two of identical size. Resolution of proteins in the presence of SDS is a function of gel concentration and the size of the proteins being separated. Under nondenaturing conditions, the biological activity of a protein will be maintained.

Comparison of reducing and nonreducing denaturing gels can also provide valuable information about the number of disulfide cross-linked subunits in a protein complex. If the subunits are held together by disulfide linkages, the protein will separate in denaturing gels as a complex or as smaller-sized subunits under nonreducing or reducing conditions, respectively. However, proteins separated on nonreducing denaturing gels appear more diffuse and exhibit less overall resolution than those separated on reducing gels.

Gradient gels provide superior protein-band sharpness and resolve a larger size range of proteins, making them ideal for most types of experiments in spite of being more difficult to prepare. Molecular-weight calculations are simplified because of the extended linear relationship between size and protein position in the gel. Increased band sharpness of both high- and low-molecular-weight proteins on the same gel greatly simplifies survey experiments, such as gene expression studies where the characteristics of the responsive protein are not known. Furthermore, the increased resolution dramatically improves autoradiographic analysis. Preparation of gradient gels is straightforward, although practice with gradient solutions containing dye is recommended. The gradient gels can be stored for several days at 0° to 4°C before casting the stacking gel.

Time Considerations

Preparation of separating and stacking gels requires 2 to 3 hr. Gradient gels generally take 5 min to cast singly. Casting multiple single-concentration gels requires an additional 10 min for assembly. Casting multiple gradient gels takes 15 to 20 min plus assembly time. It takes 4 to 5 hr to run a 14 × 14–cm, 0.75-mm gel at 15 mA (70 to 150 V), and 3 to 4 hr to run a 0.75-mm gel at 20 mA (80 to 200 V). Overnight separations of ~12 hr require 4 mA per 0.75-mm gel. It takes 4 to 5 hr to run a 1.5-mm gel at 30 mA. Electrophoresis is normally performed at 15° to 20°C, with the temperature held constant using a circulating water bath. For air-cooled electrophoresis units, lower currents and thus longer run times are recommended.

It takes ~1 hr to run a 0.75-mm minigel at 20 mA (100 to 120 V). Separation times are not significantly different for gradient minigels.

An excellent book describing gel electrophoresis of proteins.

Immunoblotting and Immunodetection

Immunoblotting (often referred to as western blotting) is used to identify specific antigens recognized by polyclonal or monoclonal antibodies. Protein samples are solubilized, usually with sodium dodecyl sulfate (SDS) and reducing agents such as dithiothreitol (DTT) or 2-mercaptoethanol (2-ME). Following solubilization, the material is separated by SDS-PAGE (*UNIT 6.1*). The antigens are then electrophoretically transferred in a tank (see Basic Protocol 1) or a semidry transfer apparatus (see Alternate Protocol 1) to a nitrocellulose, PVDF, or nylon membrane, a process that can be monitored by reversible staining (see Support Protocol 1) or by Ponceau S staining (see Support Protocol 2). Previously stained gels may also be blotted (see Alternate Protocol 2).

The transferred proteins are bound to the surface of the membrane, providing access for reaction with immunodetection reagents. All remaining binding sites are blocked by immersing the membrane in a solution containing either a protein or detergent blocking agent. After probing with the primary antibody, the membrane is washed and the antibody-antigen complexes are identified with horseradish peroxidase (HRPO) or alkaline phosphatase enzymes coupled to the secondary anti-IgG antibody (e.g., goat anti–rabbit IgG). The enzymes are attached directly (see Basic Protocol 2) or via an avidin-biotin bridge (see Alternate Protocol 3) to the secondary antibody. Chromogenic or luminescent substrates (see Basic Protocol 3 and Alternate Protocol 4) are then used to visualize the activity. Finally, membranes may be stripped and reprobed (see Support Protocol 3).

NOTE: When handling gels and membranes wear powder-free gloves.

PROTEIN BLOTTING WITH TANK TRANSFER SYSTEMS

BASIC PROTOCOL 1

In this procedure, blotting is performed in a tank of buffer with the gel in a vertical orientation, completely submerged between two large electrode panels. In some systems up to four gels can be transferred at one time. For difficult-to-transfer proteins (>100 kDa or hydrophobic; e.g., myosin), tank blotting is preferable to semidry systems (see Basic Protocol 2) because prolonged transfers are possible without buffer depletion. However, transfers >1 hr at high power require cooling using a heat exchanger and a circulating water bath that can maintain a constant transfer temperature of 10° to 20°C.

Materials

Samples for analysis
Protein molecular weight standards (*UNIT 6.1*), prestained (Sigma or Bio-Rad) or biotinylated (Vector Labs or Sigma)
Transfer buffer (see recipe)

Powder-free gloves
Scotch-Brite pads (3M) or equivalent sponge
Whatman 3MM filter paper or equivalent
Transfer membrane: 0.45-µm nitrocellulose (Millipore or Schleicher & Schuell), PVDF (Millipore Immobilon P), neutral nylon (Pall Biodyne A), *or* positively charged nylon (Pall Biodyne B; Bio-Rad Zetabind) membrane
Electroblotting apparatus (EC Apparatus, Bio-Rad, or Amersham Pharmacia Biotech)
Indelible pen (e.g., Paper-Mate ballpoint) or soft lead pencil

Additional reagents and equipment for gel electrophoresis (*UNIT 6.1*) and staining proteins in gels and on membranes (see Support Protocol 1)

NOTE: Deionized, distilled water should be used throughout this protocol.

Current Protocols in Cell Biology (1998) 6.2.1-6.2.20

Electrophorese the protein sample

1. Prepare antigenic samples and separate proteins using small or standard-sized one- or two-dimensional gels (*UNIT 6.1*). Include prestained or biotinylated protein molecular weight standards in one or more gel lanes.

   The protein markers will transfer to the membrane and conveniently indicate membrane orientation and sizes of proteins after immunostaining.

   A variety of gel sizes and percentages of acrylamide can be used (UNIT 6.1). Most routinely used are either 14 cm × 14 cm × 0.75–mm gels or 8 cm × 10 cm × 0.75–mm minigels. Acrylamide concentrations vary from 5% to 20%, but are usually in the 10% to 15% range.

Assemble the immunoblot sandwich

2. When electrophoresis is complete, disassemble gel sandwich and remove stacking gel. Equilibrate gel 30 min at room temperature in transfer buffer.

   Oil from hands blocks the transfer.

   Match the appropriate transfer buffer to the membrane (see Reagents and Solutions).

   Gel equilibration is required to prevent a change in the size of the gel during transfer. Any shift in gel dimension will result in a blurred transfer pattern.

3. Assemble transfer sandwich in a tray large enough to hold the plastic transfer cassette. Fill with transfer buffer so that cassette is covered.

   The transfer cassette should be assembled under buffer to minimize trapping of air bubbles. Use Figure 6.2.1 as a guide to assembly.

4. On bottom half of plastic transfer cassette, place Scotch-Brite pad or sponge, followed by a sheet of filter paper cut to same size as gel and prewet with transfer buffer.

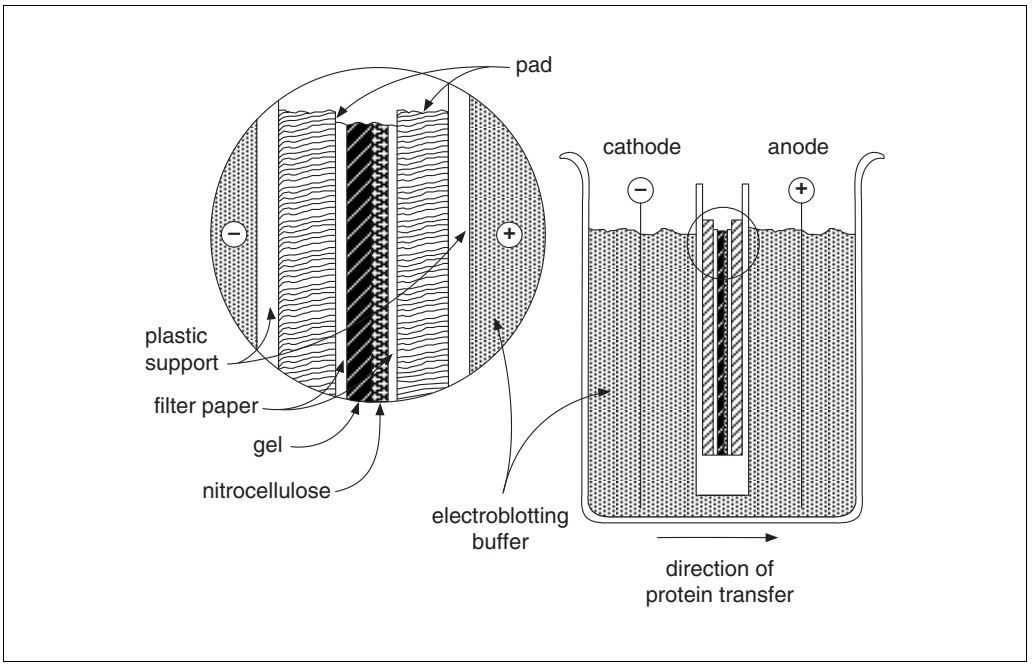

Figure 6.2.1 Immunoblotting with a tank blotting unit. The polyacrylamide gel containing the protein is laid on a sheet of filter paper. The uncovered side of the gel is overlaid with a sheet of membrane precut to the size of the gel plus 1 to 2 mm on each edge, then this membrane is overlaid with another sheet of filter paper. The filter paper containing the gel and membrane is sandwiched between Scotch-Brite pads. This sandwich is placed in a plastic support, and the entire assembly is placed in a tank containing transfer buffer. For transfer of negatively charged protein, the membrane is positioned on the anode side of the gel. For transfer of positively charged protein, the membrane is placed on the cathode side of the gel. Charged proteins are transferred electrophoretically from the gel onto the membrane. Transfer is achieved by applying a voltage of 100 V for 1 to 2 hr (with cooling) or 14 V overnight.

5. Place gel on top of filter paper. The side of the gel touching the paper arbitrarily becomes the cathode side of the gel (i.e., ultimately toward the negative electrode when positioned in the tank). Remove any air bubbles between gel and filter paper by gently rolling a test tube or glass rod over surface of gel.

   Any bubbles between the filter paper, gel, and membrane will block current flow and prevent protein transfer. This problem is indicated on the membrane by sharply defined white areas devoid of transferred protein.

   Proteins are usually negatively charged in transfer buffer and move toward the positive anode. However, some proteins may be positively charged. An additional membrane placed on the cathode side of the gel will bind these proteins.

6. Prepare transfer membrane. Cut membrane to same size as gel plus 1 to 2 mm on each edge. Place into distilled water slowly, with one edge at a 45° angle. Equilibrate 10 to 15 min in transfer buffer.

   The water will wick up into the membrane, wetting the entire surface. If it is inserted too quickly into the water, air gets trapped and will appear as white blotches in the membrane. Protein will not transfer onto these areas.

   This wetting procedure works for nitrocellulose and nylon membranes only. PVDF membranes are hydrophobic and will not wet simply from being placed into distilled water or transfer buffer. For these membranes, first immerse 1 to 2 sec in 100% methanol, then equilibrate 10 to 15 min with transfer buffer. Do not let membrane dry out at any time. If this occurs, wet once again with methanol and transfer buffer as described above.

7. Moisten surface of gel with transfer buffer. Place prewetted membrane directly on top side of gel (i.e., anode side) and remove all air bubbles as in step 5.

   Poor contact between the gel and membrane will cause a swirled pattern of transferred proteins on the membrane. Some proteins will transfer as soon as the gel is placed on the membrane; repositioning the gel or membrane can result in a smeared or double image on the developed blot.

   The use of 0.2-μm membranes may improve retention of smaller-molecular-weight proteins.

8. Wet another piece of Whatman 3MM filter paper, place on anode side of membrane, and remove all air bubbles. Place another Scotch-Brite pad or sponge on top of this filter paper.

9. Complete assembly by locking top half of the transfer cassette into place (Fig. 6.2.1).

   It is important to orient the sandwich so that the membrane faces the anode (positively charged) side of the tank.

Transfer proteins from gel to membrane

10. Fill tank with transfer buffer and place transfer cassette containing sandwich into electroblotting apparatus in correct orientation. Connect leads of power supply to corresponding anode and cathode sides of electroblotting apparatus.

    Transfer buffer should cover the electrode panels but should not touch the base of the banana plug.

11. Electrophoretically transfer proteins from gel to membrane for 30 min to 1 hr at 100 V with cooling or overnight at 14 V (constant voltage), in a cold room.

    Transfer time is dependent on the thickness and the percent acrylamide of the gel, as well as the size of the protein being transferred. In general, proteins are transferred within 1 to 6 hr, but high-molecular-weight molecules may take longer. Overnight transfer at low voltage is reliable and convenient. Cooling (at 10° to 20°C) is required for transfers >1 hr at high power. Heat exchanger cooling cores using a circulating water bath are placed into the transfer unit for cooling.

12. Turn off the power supply and disassemble the apparatus. Remove membrane from blotting apparatus and note orientation by cutting a corner or marking with a soft lead pencil or Paper-Mate ballpoint pen.

    Many ballpoint inks come off, but Paper-Mate stays on the membrane.

    Membranes can be dried and stored in resealable plastic bags at 4°C for 1 year or longer at this point. Prior to further processing, dried PVDF membranes must be placed into a small amount of 100% methanol to wet the membrane, then in distilled water to remove the methanol.

13. Stain gel for total protein with Coomassie blue to verify transfer efficiency. If desired, stain membrane reversibly to visualize transferred proteins (see Support Protocol 1), or irreversibly with Coomassie blue, India ink, naphthol blue, or colloidal gold.

    These staining procedures are incompatible with nylon membranes.

    If membrane shows significant staining on the backside, either the gel was heavily overloaded or the membrane has poor protein-binding capacity (see Troubleshooting). In either case, protein-binding sites on the side facing the gel are saturated, allowing protein to migrate to the other side of the membrane. Nitrocellulose in particular will show diminished binding capacity with age or poor storage conditions (e.g., high temperature and humidity). In addition, some proteins simply do not bind well to a particular matrix. By using several membrane sheets in place of one, the protein can be detected as it passes through each consecutive sheet. This will give an indication of how efficiently the membrane binds to a particular protein.

14. Proceed with immunoprobing and visual detection of proteins (see Basic Protocols 2 and 3 and Alternate Protocols 3 and 4).

ALTERNATE PROTOCOL 1

PROTEIN BLOTTING WITH SEMIDRY SYSTEMS

Even and efficient transfer of most proteins is also possible with semidry blotting, a convenient alternative to tank transfer systems. Instead of being placed vertically into a tank filled with transfer buffer, the gel is held horizontally between buffer-saturated blotting paper that is in contact with the electrodes (Fig. 6.2.2), greatly reducing the amount of buffer required. The electrodes are close together, giving high field strengths and rapid transfer with a standard electrophoresis power supply. Prolonged transfers (>1 hr) are not recommended; tank blotting (see Basic Protocol 1) should be used for proteins that require long blotting times for efficient transfer.

Additional Materials *(also see Basic Protocol 1)*

Six sheets of Whatman 3MM filter paper or equivalent, cut to size of gel and saturated with transfer buffer
Semidry transfer unit (Amersham Pharmacia Biotech, Bio-Rad, or Sartorius)

1. Prepare samples and separate proteins using small or standard-sized one- or two-dimensional gels (*UNIT 6.1*).

   Because transfer efficiency depends on many factors (e.g., gel concentration and thickness, protein size, shape, and net charge) results may vary. Below is a guideline for 0.75–mm–thick SDS-PAGE gels transferred by semidry blotting.

Percent acrylamide (resolving gel)	Size range transferred (~100% efficiency)
5–7	29–150 kDa
8–10	14–66 kDa
13–15	<36 kDa
18–20	<20 kDa

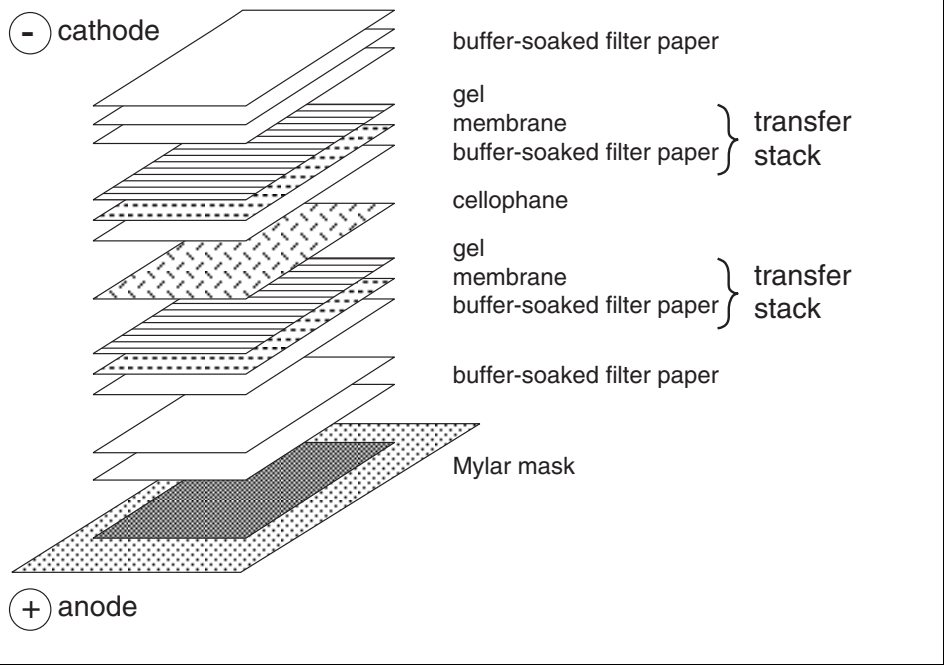

Figure 6.2.2 Immunoblotting with a semidry transfer unit. Generally, the lower electrode is the anode, and one gel is transferred at a time. A Mylar mask (optional in some units) is put in place on the anode. This is followed by three sheets of transfer buffer–soaked filter paper, the membrane, the gel, and finally, three more sheets of buffer-soaked filter paper. To transfer multiple gels, construct transfer stacks as illustrated, and separate each with a sheet of porous cellophane. For transfer of negatively charged protein, the membrane is positioned on the anode side of the gel. For transfer of positively charged protein, the membrane is placed on the cathode side of the gel. Transfer is achieved by applying a maximum current of 0.8 mA/cm^2 of gel area. For a typical minigel (8 × 10 cm) and standard-sized gel (14 × 14 cm), this means 60 and 200 mA, respectively.

2. Prepare transfer membrane (see Basic Protocol 1, step 6).
3. Disassemble gel sandwich. Remove and discard stacking gel.

   Equilibration of the separating gel with transfer buffer is not normally required for semidry blotting, but it may improve transfer in some cases.

4. Place three sheets of filter paper saturated with transfer buffer on the anode (Fig. 6.2.2).

   Most transfer units are designed so that negatively charged proteins move downward toward either a platinum or graphite positive electrode (anode).

   CAPS transfer buffer, pH 10.5 (see recipe for transfer buffer) can be used in place of the Tris/glycine/methanol transfer buffer of Basic Protocol 1. CAPS buffer should be used if the protein is to be sequenced right on the membrane (Moos, 1992), as glycine will interfere with this procedure.

   The filter paper should be cut to the exact size of the gel. This forces the current to flow only through the gel and not through overlapping filter paper. Some manufacturers (e.g., Amersham Pharmacia Biotech) recommend placing a Mylar mask on the lower platinum anode. With an opening that is slightly less than the size of the gel, the mask forces the current to flow through the gel and not the surrounding electrode area during transfer.

5. Place equilibrated transfer membrane on top of filter paper stack. Remove all bubbles between membrane and filter paper by rolling a test tube over surface of membrane.

   Any bubbles in the filter paper stack or between the filter paper, membrane, and gel will block current flow and prevent protein transfer. This problem is indicated on the membrane by sharply defined white areas devoid of transferred protein.

6. Place gel on top of membrane. Gently roll a test tube over surface of gel to ensure intimate contact between gel and membrane and to remove any interfering bubbles.

   Poor contact between the gel and membrane will cause a swirled pattern of transferred proteins on the membrane. Some proteins will transfer as soon as the gel is placed on the membrane; repositioning the gel or membrane can result in a smeared or double image on the developed blot.

7. Complete the transfer stack by putting the three remaining sheets of filter paper on top of gel. Roll out bubbles as described above.

   Multiple gels can be transferred using semidry blotting. Simply put a sheet of porous cellophane (Amersham Pharmacia Biotech) or dialysis membrane (Bio-Rad or Sartorius) equilibrated with transfer buffer between each transfer stack (Fig. 6.2.2). Transfer efficiency is dependent on the position of the transfer stack in the blotting unit and for critical applications transferring one gel at a time is recommended. The gel next to the anode tends to be more efficiently transferred when blotting more than one gel at a time.

Transfer proteins from gel to membrane

8. Place top electrode onto transfer stack.

   Most units have safety-interlock features and can only be assembled one way. Consult manufacturer's instructions for details.

   Once assembled, do not move the top electrode. This can shift the transfer stack and move the gel relative to the membrane. Some transfer will occur as soon as the gel contacts the membrane, and any shifting of the transfer stack after assembly will distort the transfer pattern.

9. Carefully connect high-voltage leads to the power supply (see *UNIT 6.1* for safety precautions). Apply constant current to initiate protein transfer. Transfers of 1 hr are generally sufficient.

   In general, do not exceed 0.8 mA/cm^2 of gel area. For a typical minigel (8 × 10 cm) and standard-sized gel (14 × 14 cm) this means ~60 and 200 mA, respectively.

   Monitor the temperature of the transfer unit directly above the gel by touch. The unit should not exceed 45°C. If the outside of the unit is warm, too much current is being applied. Note that units with graphite electrodes are more prone to heating, because graphite has much more resistance to current flow than platinum or steel electrodes.

10. After transfer, turn off power supply and disassemble unit. Remove membrane from transfer stack, marking orientation as in step 12 of Basic Protocol 1. Proceed with staining and immunoprobing (see Basic Protocol 1, steps 13 and 14).

ALTERNATE PROTOCOL 2

BLOTTING OF STAINED GELS

Gels stained with Coomassie blue R250 can be effectively immunoblotted by the following procedure, based on Perides et al. (1986) and Dionisi et al. (1995). Briefly, the stained gel is soaked in a series of solutions designed to increase the solubility of the proteins after staining and fixation. After transfer, the membranes are treated with 45% or 100% methanol to decrease the Coomassie blue bound to the membrane prior to processing for chromogenic development. For chemiluminescent development, removal of the Coomassie blue is generally not needed.

Materials

Destained gel containing proteins of interest
25 mM Tris base/192 mM glycine/1% SDS
25 mM Tris base/192 mM glycine/0.1% SDS

1. Soak destained gel containing proteins of interest in distilled water for 15 min.
2. Equilibrate gel with 25 mM Tris base/192 mM glycine/1% SDS for 1 hr with gentle agitation.
3. Transfer gel to 25 mM Tris base/192 mM glycine/0.1% SDS and equilibrate 30 min with gentle agitation.

   To increase transfer efficiency of larger proteins, the gel should be transferred to the above solution with 6 M urea for an additional 30 min.

4. Proceed with transfer (see Basic Protocol 1, steps 2 to 12).

   For the most efficient transfer and binding to the membrane, the transfer buffer should contain SDS.

5. After transfer, soak membranes for 10 to 30 min in 45% methanol (nitrocellulose) or 100% methanol (nylon or PVDF) to remove the bound Coomassie blue.

   This step is not needed if using chemiluminescent reactions or radiolabeled protein A for immunodevelopment. Destaining of the nitrocellulose membrane is enhanced by adding a small ball of laboratory tissue to the methanol to absorb the Coomassie blue.

6. Proceed with immunoprobing and visual detection of proteins (see Basic Protocols 2 and 3 and Alternate Protocols 3 and 4).

REVERSIBLE STAINING OF TRANSFERRED PROTEINS

SUPPORT PROTOCOL 1

To verify transfer efficiency, nitrocellulose and PVDF membranes can be reversibly stained. This method will not work on nylon membranes.

Additional Materials *(also see Basic Protocol 1)*

Ponceau S solution (see recipe)

Additional reagents and equipment for photographing membranes

1. Following protein transfer to nitrocellulose or PVDF (see Basic Protocol 1 or Alternate Protocol 1), place membrane in Ponceau S solution 5 min at room temperature.
2. Destain 2 min in water. Photograph membrane if required and mark the molecular-weight-standard band locations with indelible ink.
3. Completely destain membrane by soaking an additional 10 min in water.

QUANTITATION OF PROTEIN WITH PONCEAU S

SUPPORT PROTOCOL 2

In addition to qualitatively visualizing proteins on membranes after blotting, Ponceau S provides a convenient method for quantifying the amount of protein in a given lane. By eluting the dye off the strip and reading in a spectrophotometer (A_{525}), an internal control value of protein on a lane is obtained. This value is used to correct for any differences in protein loading from lane to lane. Comparison of the Ponceau S value to the chemiluminescent or chromogenic immunodetection value determined by densitometry provides a straightforward correction for lane-to-lane variation. This method works best for complex mixtures where the immunodetected protein represents a small proportion of the total protein (Klein et al., 1995).

Additional Materials *(also see Basic Protocol 1)*

Spectrophotometer and 2-ml cuvette

1. Following protein transfer to nitrocellulose, PVDF, or nylon (see Basic Protocol 1 or Alternate Protocol 1), stain membrane, photograph, and destain (see Support Protocol 1).

   Membranes should be destained until the background becomes white.

2. Mark lanes with a soft pencil and cut lanes into strips.
3. Place each strip into 7 ml of distilled water for 7 min and remove the resulting solution. If any particulates are visible, centrifuge 30 min at 2000 rpm to remove them.
4. Read A_{525} in a 2-ml cuvette.

   Any variation in gel-to-gel sample loading and blotting efficiency will be reflected in a change in A_{525} of the sample lanes when compared to the control. The change in A_{525} can be calibrated to a known amount of protein loaded on the control lane. This will be a relative value, however, since the transfer out of the gel and binding to the membrane is rarely 100%.

BASIC PROTOCOL 2

IMMUNOPROBING WITH DIRECTLY CONJUGATED SECONDARY ANTIBODY

Immobilized proteins are probed with specific antibodies to identify and quantitate any antigens present. The membrane is immersed in blocking buffer to fill all protein-binding sites with a nonreactive protein or detergent. Next, it is placed in a solution containing the antibody directed against the antigen (primary antibody). The blot is washed and exposed to an enzyme-antibody conjugate directed against the primary antibody (secondary antibody; e.g., goat anti-rabbit IgG). Antigens are identified by chromogenic or luminescent visualization (see Basic Protocol 3 and Alternate Protocol 4) of the antigen/primary antibody/secondary antibody/enzyme complex bound to the membrane. Tween 20 is a common alternative to protein-blocking agents when using nitrocellulose or PVDF filters.

Materials

Membrane with transferred proteins (see Basic Protocol 1 or Alternate Protocol 1)
Blocking buffer appropriate for membrane and detection protocol (see recipe)
Primary antibody specific for protein of interest
TTBS (nitrocellulose or PVDF) or TBS (nylon; see *APPENDIX 2A* for recipes)
Secondary antibody conjugate: horseradish peroxidase (HRPO)–or alkaline phosphatase (AP)–anti-Ig conjugate (Cappel, Vector Labs, Kirkegaard & Perry, or Sigma; dilute as indicated by manufacturer and store frozen in 25-µl aliquots until use)
Heat-sealable plastic bag
Powder-free gloves
Plastic box

1. Place membrane in heat-sealable plastic bag with 5 ml blocking buffer and seal bag. Incubate 30 min to 1 hr at room temperature with agitation on an orbital shaker or rocking platform.

   Usually 5 ml buffer is sufficient for two to three membranes (14 × 14–cm size). If membrane is to be stripped and reprobed (see Support Protocol 3), blocking buffer must contain casein (for AP systems) or nonfat dry milk.

   Plastic incubation trays are often used in place of heat-sealable bags, and can be especially useful when processing large numbers of strips in different primary antibody solutions.

2. Dilute primary antibody in blocking buffer.

   Primary antibody dilution is determined empirically but is typically 1/100 to 1/1000 for a polyclonal antibody (Fig. 6.2.3), 1/10 to 1/100 for hybridoma supernatants, and ≥1/1000

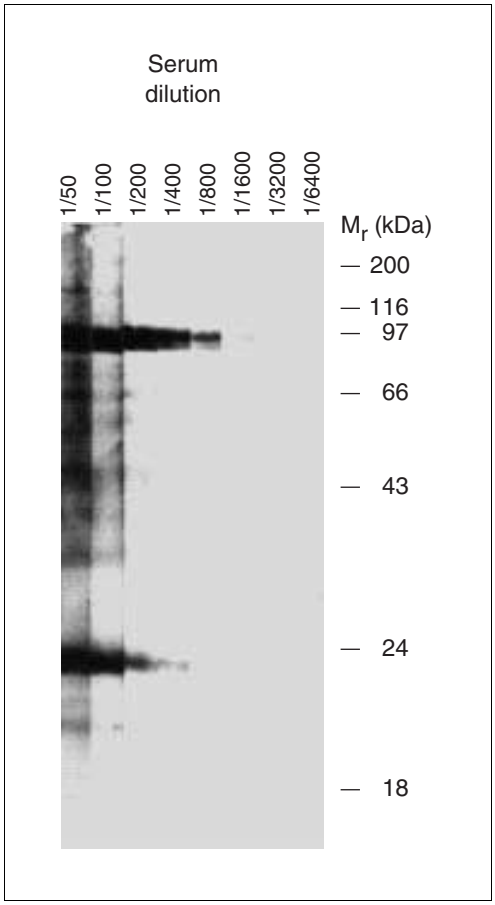

Figure 6.2.3 Serial dilution of primary antibody directed against the 97-kDa catalytic subunit of the plant plasma membrane ATPase. Blot was developed with HRPO-coupled avidin-biotin reagents according to the second alternate protocol and visualized with 4-chloro-1-naphthol (4CN). Note how background improves with dilution.

for murine ascites fluid containing monoclonal antibodies. Ten- to one-hundred-fold higher dilutions can be used with alkaline phosphatase– or luminescence–based detection systems. Both primary and secondary antibody solutions can be used at least twice, but long-term storage (i.e., >2 days at 4°C) is not recommended.

3. Open bag and pour out blocking buffer. Replace with diluted primary antibody and incubate 30 min to 1 hr at room temperature with constant agitation.

   Usually 5 ml diluted primary antibody solution is sufficient for two to three membranes (14 × 14–cm size). Incubation time may vary depending on conjugate used.

   When using plastic trays, the primary and secondary antibody solution volume should be increased to 25 to 50 ml. For membrane strips, incubation trays with individual slots are recommended. Typically, 0.5 to 1 ml solution/slot is needed.

4. Remove membrane from plastic bag with gloved hand. Place in plastic box and wash four times by agitating with 200 ml TTBS (nitrocellulose or PVDF) or TBS (nylon), 10 to 15 min each time.

5. Dilute secondary antibody HRPO- or AP-anti-Ig conjugate in blocking buffer.

   Commercially available enzyme–conjugated secondary antibody is usually diluted 1/200 to 1/2000 prior to use (Harlow and Lane, 1988).

6. Place membrane in new heat-sealable plastic bag, add diluted HRPO- or AP-anti-Ig conjugate, and incubate 30 min to 1 hr at room temperature with constant agitation.

   When using plastic incubation trays, see step 3 annotation for proper antibody solution volumes.

7. Remove membrane from bag and wash as in step 4. Develop according to appropriate visualization protocol (see Basic Protocol 3 or Alternate Protocol 4).

ALTERNATE PROTOCOL 3

IMMUNOPROBING WITH AVIDIN-BIOTIN COUPLING TO SECONDARY ANTIBODY

The following procedure is based on the Vectastain ABC kit from Vector Labs (see *SUPPLIERS APPENDIX*). It uses an avidin-biotin complex to attach horseradish peroxidase (HRPO) or alkaline phosphatase (AP) to the biotinylated secondary antibody. Avidin-biotin systems are capable of extremely high sensitivity due to the multiple reporter enzymes bound to each secondary antibody. In addition, the detergent Tween 20 is a popular alternative to protein-blocking agents when using nitrocellulose or PVDF filters.

Additional Materials *(also see Basic Protocol 2)*

Blocking buffer appropriate for membrane and detection protocol (see recipe)
TTBS (nitrocellulose or PVDF) *or* TBS (neutral or positively charged nylon; see *APPENDIX 2A* for recipes)
Vectastain ABC (HRPO) or ABC-AP (AP) kit (Vector Labs) containing the following: reagent A (avidin), reagent B (biotinylated HRPO or AP), and biotinylated secondary antibody (request membrane immunodetection protocols when ordering)

1. Equilibrate membrane in appropriate blocking buffer in heat-sealed plastic bag with constant agitation using an orbital shaker or rocking platform. For nitrocellulose and PVDF, incubate 30 to 60 min at room temperature. For nylon, incubate ≥2 hr at 37°C.

   TTBS is well suited for avidin-biotin systems. For nylon, protein-binding agents are recommended. Because nonfat dry milk contains residual biotin, which will interfere with the immunoassay, it must be used in the blocking step only. If membrane is to be stripped and reprobed (see Support Protocol 3), blocking buffer must contain casein (for AP systems) or nonfat dry milk.

   Plastic incubation trays are often used in place of heat-sealable bags, and can be especially useful when processing large numbers of strips in different primary antibody solutions.

2. Prepare primary antibody solution in TTBS (nitrocellulose or PVDF) or TBS (nylon).

   Dilutions of sera containing primary antibody generally range from 1/100 to 1/100,000. This depends in large part on the sensitivity of the detection system. With high-sensitivity avidin-biotin systems, dilutions from 1/1000 to 1/100,000 are common. Higher dilutions can be used with AP- or luminescence-based detection systems. To determine the appropriate concentration of the primary antibody, a dilution series is easily performed with membrane strips. Separate antigens on a preparative gel (i.e., a single large sample well) and immunoblot the entire gel. Cut 2- to 4-mm strips by hand or with a membrane cutter (Schleicher and Schuell; Inotech) and incubate individual strips in a set of serial dilutions of primary antibody. The correct dilution should give low background and high specificity (Fig. 6.2.3).

3. Open bag, remove blocking buffer, and add enough primary antibody solution to cover membrane. Incubate 30 min at room temperature with gentle rocking.

   Usually 5 ml diluted primary antibody solution is sufficient for two to three membranes (14 × 14–cm size). Incubation time may vary depending on conjugate used.

   When using plastic trays, the primary and secondary antibody solution volume should be increased to 25 to 50 ml. For membrane strips, incubation trays with individual slots are recommended. Typically, 0.5 to 1 ml solution/slot is needed.

4. Remove membrane from bag and place in plastic box. Wash membrane three times over a 15-min span in TTBS (nitrocellulose or PVDF) or TBS (nylon). Add enough TTBS or TBS to fully cover the membrane (e.g., 5 to 10 ml/strip or 25 to 50 ml/whole membrane).

5. Prepare biotinylated secondary antibody solution by diluting two drops biotinylated antibody with 50 to 100 ml TTBS (nitrocellulose or PVDF) or TBS (nylon).

   This dilution gives both high sensitivity and enough volume to easily cover a large 14 × 14–cm membrane.

6. Transfer membrane to fresh plastic bag containing secondary antibody solution. Incubate 30 min at room temperature with slow rocking, then wash as in step 4.

   When using plastic incubation trays, see step 3 annotations for proper antibody solution volumes.

7. While membrane is being incubated with secondary antibody, prepare avidin-biotin-HRPO or -AP complex. Mix two drops Vectastain reagent A and two drops reagent B into 10 ml TTBS (nitrocellulose or PVDF) or TBS (nylon). Incubate 30 min at room temperature, then further dilute to 50 ml with TTBS or TBS.

   Diluting the A and B reagents to 50 ml expands the amount of membrane that can be probed without greatly affecting sensitivity. Sodium azide is a peroxidase inhibitor and should not be used as a preservative. Casein, nonfat dry milk, serum, and some grades of BSA may interfere with the formation of the avidin-biotin complex and should not be used in the presence of avidin or biotin reagents (Gillespie and Hudspeth, 1991; Vector Labs).

8. Transfer membrane to avidin-biotin-enzyme solution. Incubate 30 min at room temperature with slow rocking, then wash over a 30-min span as in step 4.

9. Develop membrane according to the appropriate visualization protocol (see Basic Protocol 3 or Alternate Protocol 4).

VISUALIZATION WITH CHROMOGENIC SUBSTRATES

BASIC PROTOCOL 3

Bound antigens are typically visualized with chromogenic substrates. The substrates 4CN, DAB/$NiCl_2$, and TMB are commonly used with horseradish peroxidase (HRPO)–based immunodetection procedures, while BCIP/NBT is recommended for alkaline phosphatase (AP)–based procedures (see Table 6.2.1). After incubation with primary and secondary antibodies, the membrane is placed in the appropriate substrate solution. Protein bands usually appear within a few minutes.

Materials

Membrane with transferred proteins and probed with antibody-enzyme complex (see Basic Protocol 2 or Alternate Protocol 3)
TBS (*APPENDIX 2A*)
Chromogenic visualization solution (Table 6.2.1)

Additional reagents and equipment for gel photography

1. If final membrane wash (see Basic Protocol 2, step 7, or see Alternate Protocol 3, step 8) was performed in TTBS, wash membrane 15 min at room temperature in 50 ml TBS.

   The Tween 20 in TTBS interferes with 4CN development (Bjerrum et al., 1988).

2. Place membrane into chromogenic visualization solution. Bands should appear in 10 to 30 min.

3. Terminate reaction by washing membrane in distilled water. Air dry and photograph for a permanent record.

Table 6.2.1 Chromogenic and Luminescent Visualization Systems[a]

System	Reagent[b]	Reaction/Detection	Comments[c]
Chromogenic			
HRPO-based	4CN	Oxidized products form purple precipitate	Not very sensitive (Tween 20 inhibits reaction); fades rapidly upon exposure to light
	DAB/$NiCl_2$[d]	Forms dark brown precipitate	More sensitive than 4CN but potentially carcinogenic; resulting membrane easily scanned
	TMB[e]	Forms dark purple stain	More stable, less toxic than DAB/$NiCl_2$; may be somewhat more sensitive[e]; can be used with all membrane types; kits available from Kirkegaard & Perry, TSI, Moss, and Vector Labs
AP-based	BCIP/NBT	BCIP hydrolysis produces indigo precipitate after oxidation with NBT; reduced NBT precipitates; dark blue-gray stain results	More sensitive and reliable than other AP-precipitating substrates; note that phosphate inhibits AP activity
Luminescent			
HRPO-based	Luminol/H_2O_2/ *p*-iodophenol	Oxidized luminol substrate gives off blue light; *p*-iodophenol increases light output	Very convenient, sensitive system; reaction detected within a few seconds to 1 hr
AP-based	Substituted 1,2-dioxetane-phosphates (e.g., AMPPD, CSPD, Lumigen-PPD, Lumi-Phos 530[f])	Dephosphorylated substrate gives off light	Protocol described gives reasonable sensitivity on all membrane types; consult instructions of reagent manufacturer for maximum sensitivity and minimum background (see Troubleshooting)

[a]Abbreviations: AMPPD or Lumigen-PPD, disodium 3-(4-methoxyspiro{1,2-dioxetane-3,2′-tricyclo[3.3.1.1^{3,7}] decan}-4-yl)phenyl phosphate; AP, alkaline phosphatase; BCIP, 5-bromo-4-chloro-3-indolyl phosphate; 4CN, 4-chloro-1-napthol; CSPD, AMPPD with substituted chlorine moiety on adamantine ring; DAB, 3,3′-diaminobenzidine; HRPO, horseradish peroxidase; NBT, nitroblue tetrazolium; TMB, 3,3′,5,5′-tetramethylbenzidine.

[b]Recipes and suppliers are listed in Reagents and Solutions except for TMP, for which use of a kit is recommended.

[c]See Commentary for further details.

[d]DAB/$NiCl_2$ can be used without the nickel enhancement, but it is much less sensitive.

[e]McKimm-Breschkin (1990) reported that if nitrocellulose filters are first treated with 1% dextran sulfate for 10 min in 10 mM citrate-EDTA (pH 5.0), TMB precipitates onto the membrane with a sensitivity much greater than 4CN or DAB, and equal to or better than that of BCIP/NBT.

[f]Lumi-Phos 530 contains dioxetane phosphate, $MgCl_2$, CTAB (cetyltrimethylammonium bromide), and fluorescent enhancer in a pH 9.6 buffer.

ALTERNATE PROTOCOL 4

VISUALIZATION WITH LUMINESCENT SUBSTRATES

Antigens can also be visualized with luminescent substrates. Detection with light offers both speed and enhanced sensitivity over chromogenic and radioisotopic procedures. After the final wash, the blot is immersed in a substrate solution containing luminol for horseradish peroxidase (HRPO) systems or dioxetane phosphate for alkaline phosphatase (AP) systems, sealed in thin plastic wrap, and placed firmly against film. Exposures range from a few seconds to several hours, although typically strong signals appear within a few seconds or minutes.

Additional Materials *(also see Basic Protocol 3)*

Luminescent substrate buffer: 50 mM Tris·Cl, pH 7.5 (HRPO; *APPENDIX 2A*) *or* dioxetane phosphate substrate buffer (alkaline phosphatase; see recipe)
Nitro-Block solution (AP reactions only): 5% (v/v) Nitro-Block (Tropix) in dioxetane phosphate substrate buffer, prepared just before use
Luminescent visualization solution (Table 6.2.1)
Clear plastic wrap

Additional reagents and equipment for autoradiography (*UNIT 6.3*)

NOTE: See Troubleshooting section for suggestions concerning optimization of this protocol, particularly when employing AP-based systems.

1. Equilibrate membrane in two 15-min washes with 50 ml substrate buffer.

   For blots of whole gels, use 50 ml substrate buffer; for strips, use 5 to 10 ml/strip.

2. *For AP reactions using nitrocellulose or PVDF membranes:* Incubate 5 min in Nitro-Block solution, followed by 5 min in substrate buffer (volumes as in step 1).

   Nitro-Block enhances light output from the dioxetane substrate in reactions using AMPPD, CSPD, or Lumigen-PPD concentrate. It is required for nitrocellulose and recommended for PVDF membranes. It is not needed for Lumi-Phos 530, AP reactions on nylon membranes, or HRPO-based reactions on any type of membrane. Lumi-Phos 530 is not recommended for nitrocellulose membranes.

3. Transfer membrane to visualization solution. Soak 30 sec (HRPO reactions) to 5 min (AP reactions; volumes as in step 1).

   Alternatively, lay out a square of plastic wrap and pipet 1 to 2 ml visualization solution into the middle. Place membrane on the plastic so that the visualization solution spreads out evenly from edge to edge. Fold wrap back onto membrane, seal, and proceed to step 5.

4. Remove membrane, drain, and place face down on a sheet of clear plastic wrap. Fold wrap back onto membrane to form a liquid-tight enclosure.

   To ensure an optimal image, only one layer of plastic should be between the membrane and film. Sealable bags are an effective alternative. Moisture must not come in contact with the X-ray film.

5. In a darkroom, place membrane face down onto film.

   Do this quickly and do not reposition; a double image will be formed if the membrane is moved while in contact with the film. A blurred image is usually caused by poor contact between membrane and film; use a film cassette that ensures a tight fit.

6. Expose film for a few seconds to several hours.

   Typically, immunoblots produce very strong signals within a few seconds or minutes. However, weak signals may require several hours to an overnight exposure. If no image is detected, expose film 30 min to 1 hr, and if needed, overnight (see Troubleshooting).

7. If desired, wash membrane in two 15-min washes of 50 ml TBS and process for chromogenic development (see Basic Protocol 3).

   Chemiluminescent and chromogenic immunoblotting can be easily combined on a single blot to provide a permanent visual marker of a known protein. First probe membrane with the chemiluminescent reactions to record on film. If stripping and reprobing is needed, then process by wetting and NaOH treatment (see Support Protocol 3). For the last reaction, use chromogenic development to produce a permanent visual record of the blot. Alternatively, once the film record of the chemiluminescent blot is recorded, the blot can be rinsed briefly with distilled water and placed in the appropriate chromogenic solution for chromogenic development of the blot. This results in a permanent reference stain on the blot for comparison to the more easily scanned and quantitated film record.

SUPPORT PROTOCOL 3

STRIPPING AND REUSING MEMBRANES

This stripping procedure works with blotted membranes from one- and two-dimensional gels as well as with proteins blotted from previously stained gels (Suck and Krupinska, 1996). Reprobing PVDF membranes that have been developed with chemiluminescent reagents is simple and straightforward. All residual antibodies are removed from the membrane by first rewetting it in water and then briefly treating it with NaOH. Although repeated reprobing can lead to loss of signal, up to five reprobings generally are feasible. The blot should have been previously blocked with 5% nonfat dry milk prior to treatment.

Materials

0.2 M NaOH

1. Wash blot 5 min in distilled water.

   In order to effectively reprobe the membranes, casein (for AP systems) or nonfat dry milk must be used as the blocking agent. Chromogenic development leaves a permanent stain on the membrane that is difficult to remove, and should not be used when reprobing. The stain can interfere with subsequent analysis if reactive bands from sequential immunostainings are close together.

2. Transfer to 0.2 M NaOH and wash 5 min.
3. Wash blot 5 min in distilled water.
4. Proceed with immunoprobing procedure (see Basic Protocol 2 and Alternate Protocol 3).

   Casein or nonfat dry milk is recommended as blocking agent when reprobing membranes.

REAGENTS AND SOLUTIONS

*Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see **APPENDIX 2A**; for suppliers, see **SUPPLIERS APPENDIX**. For selection of appropriate chromogenic or luminescent solutions, and for definition of abbreviations, see Table 6.2.1.*

Alkaline phosphate substrate buffer

100 mM Tris·Cl, pH 9.5
100 mM NaCl
5 mM $MgCl_2$

BCIP/NBT visualization solution

Mix 33 µl NBT stock (100 mg NBT in 2 ml at 70% DMF, stored <1 year at 4°C) and 5 ml alkaline phosphate substrate buffer (see recipe). Add 17 µl BCIP stock (100 mg BCIP in 2 ml of 100% DMF, stored <1 year at 4°C) and mix. Stable 1 hr at room temperature.

Recipe is from Harlow and Lane (1988). Alternatively, BCIP/NBT substrates may be purchased from Sigma, Kirkegaard & Perry, Moss, and Vector Labs.

Blocking buffer

Colorimetric detection:

For nitrocellulose and PVDF: 0.1% (v/v) Tween 20 in TBS (TTBS; *APPENDIX 2A*).

For neutral and positively charged nylon: Tris-buffered saline (TBS; *APPENDIX 2A*) containing 10% (w/v) nonfat dry milk. Prepare just before use.

TTBS can be stored ≤1 week at 4°C.

Luminescence detection:

For nitrocellulose, PVDF, and neutral nylon (e.g., Pall Biodyne A): 0.2% casein (e.g., Hammarsten grade or I-Block; Tropix) in TTBS (*APPENDIX 2A*). Prepare just before use.

continued

For positively charged nylon: 6% (w/v) casein/1% (v/v) polyvinyl pyrrolidone (PVP) in TTBS (*APPENDIX 2A*). With constant mixing, add casein and PVP to warm (65°C) TTBS. Stir for 5 min. Cool before use. Prepare just before use.

4CN visualization solution

Mix 20 ml ice-cold methanol with 60 mg 4CN. Separately mix 60 µl of 30% H_2O_2 with 100 ml TBS (*APPENDIX 2A*) at room temperature. Rapidly mix the two solutions and use immediately.

DAB/$NiCl_2$ visualization solution

5 ml 100 mM Tris·Cl, pH 7.5 (*APPENDIX 2A*)
100 µl DAB stock (40 mg/ml in H_2O, stored in 100-µl aliquots at −20°C)
25 µl $NiCl_2$ stock (80 mg/ml in H_2O, stored in 100-µl aliquots at −20°C)
15 µl 3% H_2O_2
Mix just before use

CAUTION: *Handle DAB carefully, wearing gloves and mask; it is a carcinogen.*

Suppliers of peroxidase substrates are Sigma, Kirkegaard & Perry, Moss, and Vector Labs.

Dioxetane phosphate substrate buffer

1 mM $MgCl_2$
0.1 M diethanolamine
0.02% sodium azide (optional)
Adjust to pH 10 with HCl and use fresh

Traditionally, the AMPPD substrate buffer has been a solution containing 1 mM $MgCl_2$ and 50 mM sodium carbonate/bicarbonate, pH 9.6 (Gillespie and Hudspeth, 1991). The use of diethanolamine results in better light output (Tropix Western Light instructions).

Alternatively, 100 mM Tris·Cl (pH 9.5)/100 mM NaCl/5 mM $MgCl_2$ can be used (Sandhu et al., 1991).

Dioxetane phosphate visualization solution

Prepare 0.1 mg/ml AMPPD or CSPD (Tropix) *or* Lumigen-PPD (Lumigen; see Table 6.2.1) substrate in dioxetane phosphate substrate buffer (see recipe). Prepare just before use. Lumi-Phos 530 (Boehringer Mannheim or Lumigen) is a ready-to-use solution and can be applied directly to the membrane.

This concentration of AMPPD substrate (240 µM) is the minimum recommended by Tropix Western Light. Ten-fold lower concentrations can be used but require longer exposures.

Luminol visualization solution

0.5 ml 10× luminol stock [40 mg luminol (Sigma) in 10 ml DMSO]
0.5 ml 10× *p*-iodophenol stock [optional; 10 mg (Aldrich) in 10 ml DMSO]
2.5 ml 100 mM Tris·Cl, pH 7.5 (*APPENDIX 2A*)
25 µl 3% H_2O_2
H_2O to 5 ml
Prepare just before use

Recipe is from Schneppenheim et al. (1991). Premixed luminol substrate mix (Mast Immunosystems; Amersham ECL; Du Pont NEN Renaissance; Kirkegaard & Perry LumiGLO) may also be used. p-iodophenol is an optional enhancing agent that increases light output. Luminol and p-iodophenol stocks can be stored for ≤6 months at −20°C.

Ponceau S solution

Dissolve 0.5 g Ponceau S in 1 ml glacial acetic acid. Bring to 100 ml with water. Prepare just before use.

Transfer buffer

Add 18.2 g Tris base and 86.5 g glycine to 4 liters of water. Add 1200 ml methanol and bring to 6 liters with water. The pH of the solution is ~8.3 to 8.4. For use with PVDF filters, decrease methanol concentration to 15%; for nylon filters, omit methanol altogether.

CAPS transfer buffer can also be used. Add 2.21 g cyclohexylaminopropane sulfonic acid (CAPS; free acid), 0.5 g DTT, 150 ml methanol, and water to 1 liter. Adjust to pH 10.5 with NaOH and chill to 4°C. For proteins >60 kDa, reduce methanol content to 1% (Moos, 1992).

COMMENTARY

Background Information

Immunoprecipitation has been widely used to visualize the antigens recognized by various antibodies, both polyclonal and monoclonal (*UNIT 7.2*). However, there are several problems inherent with this method, including the requirement for radiolabeling of antigen, co-precipitation of tightly associated macromolecules, occasional difficulty in obtaining precipitating antibodies, and insolubility of various antigens (Talbot et al., 1984).

To circumvent these problems, electroblotting (Towbin et al., 1979)—subsequently popularized as western blotting or immunoblotting (Burnette, 1981)—was conceived. Immunoblotting is a rapid and sensitive assay for the detection and characterization of proteins that works by exploiting the specificity inherent in antigen-antibody recognition. It involves the solubilization and electrophoretic separation of proteins, glycoproteins, or lipopolysaccharides by SDS-PAGE (*UNIT 6.1*) or urea-PAGE, followed by quantitative transfer and irreversible binding to nitrocellulose, PVDF, or nylon. This technique has been useful in identifying specific antigens recognized by polyclonal or monoclonal antibodies and is highly sensitive (1 ng of antigen can be detected).

Electroblotting of previously stained gels is a convenient way to visualize and document the gel prior to immunoblotting. Transfer efficiencies at all molecular weights will be lower with fixed and stained gels. This is particularly true of proteins >50 kDa (Perides et al., 1986). The additional incubation in 6 M urea will significantly increase transfer efficiency of all proteins and is required for proteins >50 kDa.

Ponceau S staining provides an easy method for calibrating and quantitating the amount of material on a nitrocellulose or PVDF blot. An alternative to this method is to use an internal protein control with a separate antibody probe, but these tend to be expensive and time-consuming to use. Other applications for Ponceau S calibration include monitoring transfer efficiency under varied conditions for optimization of tank and semidry blotting.

Immunoblotted proteins can be detected by chromogenic or luminescent assays (see Table 6.2.1 for a description of the reagents available for each system, their reactions, and a comparison of their advantages and disadvantages). Luminescent detection methods offer several advantages over traditional chromogenic procedures. In general, luminescent substrates increase the sensitivity of both HRPO and phosphatase systems without the need for radioisotopes. Substrates for the latter have only recently been applied to protein blotting (see Gillespie and Hudspeth, 1991; Sandhu et al., 1991; Bronstein et al., 1992). Luminescent detection can be completed in as little as a few seconds; exposures rarely go more than 1 hr. Depending on the system, the luminescence can last for 3 days, permitting multiple exposures of the same blot. Furthermore, the signal is detected by film, and varying the exposure can result in more or less sensitivity. Luminescent blots can be easily erased and reprobed because the reaction products are soluble and do not deposit on the membrane (see below). Compared to chromogenic development, the luminescent image recorded on film is easier to photograph and to quantitate by densitometry.

Alkaline phosphatase–based luminescent protocols that achieve maximum sensitivity with minimum background can be complex, and the manufacturer's instructions should be consulted (see Reagents and Solutions). The procedure described in Alternate Protocol 4 gives reasonable sensitivity on nitrocellulose, PVDF, and nylon membranes with a minimum of steps.

Critical Parameters

First and foremost, the antibody being used should recognize denatured antigen. Nonspecific binding of antibodies can occur, so control antigens and antibodies should always be run in parallel. Time of transfer and primary anti-

body and conjugate dilutions should always be optimized.

A variety of agents are currently used to block binding sites on the membrane after blotting (Harlow and Lane, 1988). These include Tween 20, PVP, nonfat dry milk, casein, BSA, and serum. A 0.1% (v/v) solution of Tween 20 in TBS (TTBS), a convenient alternative to protein-based blocking agents, is recommended for chromogenic development of nitrocellulose and PVDF membranes (Blake et al., 1984). In contrast to dry milk/TBS blocking solution (BLOTTO), TTBS is stable and has a long shelf life at 4°C. Furthermore, TTBS generally produces a clean background and permits subsequent staining with India ink. However, even with the application of such standard blocking procedures as 5% to 10% milk protein or 0.05% to 0.1% Tween 20, background can still be a significant problem. If this happens, using a blocking protein (e.g., goat, horse, or rabbit normal serum) from the same species as the primary antibody can reduce the background, presumably by reducing cross-reactivity between the primary antibodies and the blocking agent. Combinations of blocking agents can also be effective. Thus, 0.1% human serum albumin (HSA) and 0.05% Tween 20 in TBS is recommended when probing Immobilon-P membranes with human serum (Craig et al., 1993). However, this can also lead to overall loss of antigen signal, requiring a ten-fold increase in the primary antibody (serum) concentration to achieve an adequate background free antigen signal.

When using chemiluminescent detection for immunoblotting, high background frequently occurs, particularly for strong signals (Pampori et al., 1995). Several methods are available for reducing the background from chemiluminescent reactions. These include changing the type and concentration of blocking agents (see above), optimizing antibody concentrations, letting the reaction proceed for several minutes before exposing to film, or simply limiting the exposure time of the film on the blot. These procedures are not always successful, however, and can lead to inconsistent results. An alternative approach is to reduce the concentration of reagents ten-fold. This effectively removes the background and has a number of advantages which include lower cost, increased signal-to-noise ratio, and reduced detection of cross-reacting species.

Two types of nylon membrane are used for western transfer—neutral (e.g., Pall Biodyne A) and positively charged (e.g., Pall Biodyne B). Although the positively charged membranes have very good protein-binding characteristics, they tend to give a higher background. These membranes remain positively charged from pH 3 to pH 10. Neutral nylon membranes are also charged, having a mix of amino and carboxyl groups that give an isoelectric point of 6.5. Because of their high binding capacity, positively charged membranes are popular for protein applications using luminescence.

Nylon membranes require more stringent blocking steps. Here 10% nonfat dry milk in TBS is recommended for chromogenic development. During luminescence development, however, background is a more significant problem. Compared to dry milk, purified casein has minimal endogenous alkaline phosphatase activity (AP activity leads to high background) and is therefore recommended as a blocking agent for nitrocellulose, PVDF, and nylon membranes. Positively charged nylon requires much more stringent blocking with 6% (w/v) casein and 1% (v/v) polyvinylpyrrolidone (PVP). Because nonfat dry milk and casein may contain biotin that will interfere with avidin-biotin reactions, subsequent steps are done without protein-blocking agents when using these systems. If background is a problem, highly purified casein (0.2% to 6%) added to the antibody incubation buffers may help.

If reprobing is desired, blots can be air dried and stored at 4°C for 3 months after chemiluminescence detection. After drying, store in a sealed freezer bag until use. Repeated probing will lead to a gradual loss of signal and increased background. However, this will depend in part on the properties of the sample.

If the primary procedure is problematic due to loss of sensitivity or an increase in the background, then two possible alternative procedures for stripping membranes are recommended. The first uses 2-mercaptoethanol and SDS (Kaufmann et al., 1987; Tesfaigzi et al., 1994). Briefly, the membranes are incubated in 2% SDS/100 mM Tris·Cl, pH 7.4/100 mM 2-mercaptoethanol for 30 min at 70°C, effectively removing primary and secondary antibodies. As with the primary procedure recommended above, the repeated probing should be done with caution due to the potential loss of detection signal, and 5% nonfat dry milk is required as a blocking agent. The milk blocking agent facilitates antibody removal from the blot (Kaufmann et al., 1987). The second uses guanidine·HCl. For nylon and PVDF membranes (do *not* use with nitrocellulose), incubate the immunoblot in 7 M guanidine·HCl for

10 min at room temperature. (The short wash time is critical, as guanidine·HCl is a very strong denaturant, so do not leave the filter in this solution >15 min.) Pour off excess guanidine·HCl and then rinse the membrane several times in 1× TTBS. Reblock the membrane and proceed with the standard immunoblotting procedure. Membranes stripped using this procedure can generally be reused three or four times.

Troubleshooting

There are several problems associated with immunoblotting. The antigen is solubilized and electrophoresed in the presence of denaturing agents (e.g., SDS or urea), and some antibodies may not recognize the denatured form of the antigen transferred to the membrane. The results observed may be entirely dependent on the denaturation and transfer system used. For example, zwitterionic detergents have been shown to restore the antigenicity of outer membrane proteins in immunoblotting (Mandrell and Zollinger, 1984). Gel electrophoresis under nondenaturing conditions can also be performed.

Other potential problems include high background, nonspecific or weak cross-reactivity of antibodies, poor protein transfer or membrane binding efficiency, and insufficient sensitivity. For an extensive survey and discussion of immunoblotting problems and artifacts, see Bjerrum et al. (1988).

If no transfer of protein has occurred, check the power supply and electroblot apparatus to make sure that the proper electrical connections were made and that power was delivered during transfer. In addition, check that the correct orientation of filter and gel relative to the anode and cathode electrodes was used.

If the transfer efficiency using the tank system appears to be low, increase the transfer time or power. Cooling (using the unit's built-in cooling cores) is generally required for transfers >1 hr. At no time should the buffer temperature go above 45°C. Prolonged transfers (>1 hr) are not possible in semidry transfer units due to rapid buffer depletion.

Alternatively, the transfer buffer can be modified to increase efficiency. Adding SDS at a concentration of 0.1% to the transfer buffer improves the transfer of all proteins out of the gel, particularly those above 60 to 90 kD in size. Lowering the concentration of methanol will also improve the recovery of proteins from the gel. These procedures are tradeoffs. Methanol improves the binding of proteins to PVDF and nitrocellulose, but at the same time hinders transfer. With SDS present, transfer efficiency is improved, but the SDS can interfere with protein binding to the membrane. Nylon and PVDF membranes are particularly sensitive to SDS interference. If needed, 0.01% to 0.02% SDS may be used in PVDF membrane transfer buffers (Millipore, 1990). SDS and methanol should not be used in the transfer buffer for nylon (Peluso and Rosenberg, 1987).

Gel cross-linking and thickness also have a profound effect on the transfer efficiency. In general, 0.5- to 0.75-mm-thick gels will transfer much more efficiently than thicker gels (e.g., 1.5 mm thick). Gels with a higher acrylamide percentage will also transfer less efficiently. Proteins can be particularly difficult to transfer from gradient gels, and a combination of longer transfer times, thin gels, and the addition of SDS to the transfer buffer may be needed.

If the protein bands are diffuse, check the transfer cassette. The gel must be held firmly against the membrane during transfer. If the transfer sandwich is loose in the cassette, add another thin sponge or more blotter paper to both sides.

Occasionally, a grid pattern will be apparent on the membrane after tank transfer. This is caused by having either the gel or the membrane too close to the sides of the cassette. Correct this by adding more layers of filter paper to diffuse the current flowing through the gel and membrane. Use a thinner sponge and more filter paper if necessary.

If air bubbles are trapped between the filter and the gel, they will appear as clear white areas on the filter after blotting and staining. Take extra care to make sure that all bubbles are removed.

Insufficient blocking or nonspecific binding of the primary or secondary antibody will cause a high background stain. A control using preimmune serum or only the secondary antibody will determine if these problems are due to the primary antibody. Try switching to another blocking agent; protein blocking agents may weakly cross-react. Lowering the concentration of primary antibody should decrease background and improve specificity (Fig. 6.2.3).

Due to the nature of light and the method of detection, certain precautions are warranted when using luminescent visualization (e.g., Harper and Murphy, 1991). Very strong signals can overshadow nearby weaker signals on the membrane. Because light will pipe through the membrane and the surrounding plastic wrap, overexposure will produce a broad diffuse im-

age on the film. The signal can also saturate the film, exposing the film to a point whereby increased exposure will not cause a linear increase in the density of the image on the film.

With the alkaline phosphatase substrate AMPPD, nitrocellulose, PVDF, and nylon membranes require 2, 4, and 8 to 12 hr, respectively, to reach maximum light emission. In addition, PVDF is reported to give a stronger signal than nitrocellulose (Tropix Western Light instructions). Positively charged nylon requires special blocking procedures to minimize background (Gillespie and Hudspeth, 1991). These procedures include using a blocking and primary antibody solution containing 6% casein, 1% polyvinylpyrrolidone-40 (PVP-40), 3 mM NaN_3, 10 mM EDTA, and PBS, pH 6.8. Prior to use, the casein must be heated to 65°C to reduce alkaline phosphatase activity in the casein itself. In addition, maximum sensitivity has been observed when free biotin or biotinylated proteins are removed by pretreating the casein with avidin-agarose (Sigma).

Anticipated Results

Immunoblotting should result in the detection of one or more bands. Although antibodies directed against a single protein should produce a single band, degradation of the sample (e.g., via endogenous proteolytic activity) may cause visualization of multiple bands of slightly different size. Multimers will also form spontaneously, causing higher-molecular-weight bands on the blot. If simultaneously testing multiple antibodies directed against a complex protein mixture (e.g., using patient sera against SDS-PAGE-separated viral proteins in AIDS western blot test), multiple bands will be visualized. Typically, picogram to nanogram sensitivities are common in protein blotting and immunodetection procedures.

Time Considerations

The entire immunoblotting procedure can be completed in 1 to 2 days, depending on transfer time and type of gel. Gel electrophoresis requires 4 to 6 hr on a regular gel and 1 hr on a minigel. Transfer time can be 1 hr (high-power transfer) to overnight. Blocking, conjugate incubation, and washing each take 30 min to 1 hr. Finally, substrate incubation requires 10 to 30 min (chromogen) and a few seconds to several hours (luminescence).

Detection and Quantitation of Radiolabeled Proteins in Gels and Blots

This unit presents procedures for visualizing and quantitating radiolabeled proteins separated by sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS-PAGE; *UNIT 6.1*) or affixed to filter membranes. Autoradiography (see Basic Protocol) is the most common method by which this is accomplished, and X-ray film is the traditional recording medium. The use of autoradiography with gels requires that the gel be dried prior to being placed in contact with the film (see Support Protocol 1). The decay of radioactive materials within the dried gel or filter leaves an image on the film that reflects its distribution in the sample. Film images can be quantified by densitometry (see Support Protocol 4) to obtain a relative measure of the amount of radioactivity in the sample.

The use of X-ray films for autoradiography, however, suffers from two drawbacks: lack of sensitivity and a limited linear range over which the image density reflects the amount of radioactivity. Lack of sensitivity can be overcome by fluorography (see Alternate Protocol 1) or by the use of intensifying screens (see Support Protocol 2), both of which enhance the radioactive signal. Ensuring that the exposure is within a linear range requires careful controls; film is often preflashed (see Support Protocol 3) to increase the linear measurement range for weakly radioactive samples, and it is important to ensure that the film not be saturated to attain strong radioactive signals. Sensitivity and linear ranges of measurement can be greatly extended by using a phosphor imaging system (see Alternate Protocol 2). Phosphor imaging also makes it much faster and easier to quantify radioactive samples.

To enhance radioactive signals, solid-state scintillation is frequently employed to convert the energy released by radioactive molecules to visible light. This is accomplished in several different ways. In fluorography (see Alternate Protocol 1) organic scintillants are incorporated into the sample to increase the proportion of emitted energy detected from low-energy β particles (e.g., from ^{3}H, ^{14}C, and ^{35}S). Another method uses high-density, fluorescent "intensifying screens" (see Support Protocol 2), which are placed next to the sample and used to capture the excess energy of γ rays (e.g., those produced by ^{125}I) and high-energy β particles (e.g., from ^{32}P).

CAUTION: When working with radioactivity, take appropriate precautions to avoid contamination of the experimenter and the surroundings. Carry out the experiment and dispose of wastes in appropriately designated areas, following the guidelines provided by your local radiation safety officer (also see *APPENDIX 1D*).

AUTORADIOGRAPHY

BASIC PROTOCOL

Autoradiography uses X-ray film to visualize and quantitate radioactive molecules that have been electrophoresed through agarose or polyacrylamide gels (*UNIT 6.1*), hybridized to filters (e.g., immunoblots; *UNIT 6.2*), or chromatographed through paper or thin-layer plates. A photon of light or the β particles and γ rays released from radioactive molecules "activate" silver bromide crystals on the film emulsion. This renders them capable of being reduced through the developing process to form silver metal (a "grain"). The silver grains on the film form the image.

The choice of film is critical for autoradiography. Double-coated films (e.g., Kodak X-Omat AR and Fuji RX) contain two emulsion layers on either side of a polyester support and are most commonly used for autoradiography (Laskey and Mills, 1977). Double-coated films are ideal for detecting the high-energy β particles emitted by ^{32}P and ^{125}I,

Contributed by Daniel Voytas and Ning Ke
Current Protocols in Cell Biology (1998) 6.3.1-6.3.10

since they can penetrate the polyester support and expose both emulsion layers. These films are normally used with calcium tungstate ($CaWO_4$) intensifying screens at reduced temperature (−70°C); they are highly sensitive to the blue light emitted by these screens. The green-light-sensitive BioMax MS film (Kodak) is a double-coated film spectrally matched to the blue- and green-light-emitting BioMax MS intensifying screen. The BioMax MS film/BioMax MS intensifying screen system normally gives greatest sensitivity to ^{32}P (four times greater than that of X-Omat AR film with $CaWO_4$ screens).

Single-coated films, containing one emulsion layer (e.g., Kodak BioMax MR), are optimized for direct-exposure techniques with medium-energy radioisotopes (e.g., ^{14}C, ^{35}S, and ^{33}P, but not ^{3}H). The majority of the β particles emitted by these isotopes cannot pass through the polyester support of double-coated films, and therefore the emulsion layer on the other side of the film is useless. Even though direct exposure with single-coated films gives better clarity for medium-energy isotopes, single-coated films often require longer exposure times. Fluorography, therefore, is often used to enhance sensitivity. The blue-light-sensitive double-coated X-Omat AR film is generally used for fluorography with 2,5-diphenyloxazole (PPO; which emits at 388 nm), sodium salicylate (which emits at 420 nm), and commercial fluorographic solutions and sprays (e.g., from Amersham and DuPont NEN; which emit light in the blue end of the spectrum).

Materials

Fixed and dried gel (see Support Protocol 1) or filter (e.g., from immunoblotting; *UNIT 6.2*)
Developer: Kodak developer and replenisher, prepared according to the manufacturer's instructions, 18° to 20°C
Fixer: Kodak fixer and replenisher, prepared according to the manufacturer's instructions, 18° to 20°C
Metal film cassette or paper film cassette with particle-board supports and metal binder clips
Plastic wrap (e.g., Saran Wrap)
X-ray film
Trays to hold film processing solutions
Clips for hanging film

1. In a darkroom illuminated with a safelight, place the sample (e.g., dried gel or filter) in the film cassette. Cover the sample with plastic wrap to prevent it from sticking to the film and contaminating the cassette with radioactivity.

   The safelight should be a bulb of <15 W that is equipped with a Kodak GBX-2 red filter (or equivalent).

   Fluorescent glow-in-the-dark ink (available at craft stores) is a convenient way to mark samples exposed to film. The ink can be spread on adhesive labels, which in turn are placed on the plastic wrap around the edge of the sample. If exposed to light prior to autoradiography, the ink will fluoresce and expose the film, making it possible to orient the film image on the dried gel after developing.

2. Place a sheet of X-ray film on top of the sample, then close and secure the film cassette (see Fig. 6.3.1).

   If preflashed film is used for direct exposure (see Support Protocol 3), the exposed side should face the sample. Preflashed film should be used if sample is weakly radioactive or if quantitation of the radioactivity is desired. For single-coated film, the emulsion layer should face the sample.

   If a paper cassette is used, particle-board supports the same size as the cassette should be placed on either side and secured with the metal binder clips. This will ensure that the sample and film are held in contact and do not shift during exposure.

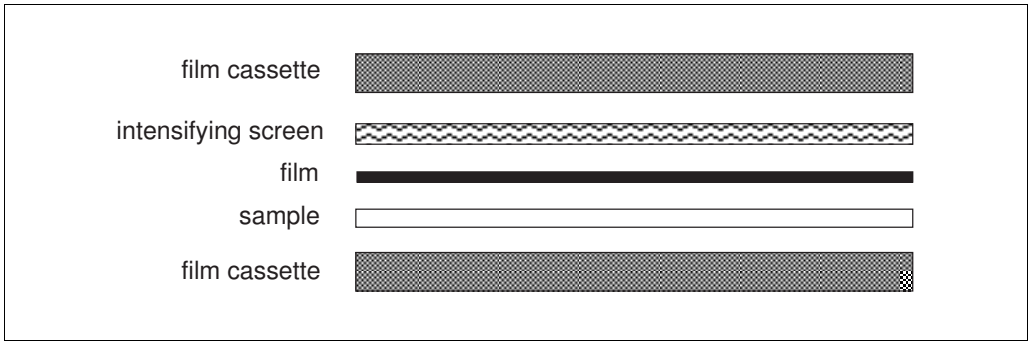

Figure 6.3.1 Autoradiography setup: intensifying screen, film, and sample in film cassette.

3. Expose the film for the desired length of time and at the appropriate temperature.

   Time of exposure will depend on the strength of the radioactivity in the sample and, in most cases, will have to be determined empirically by making multiple exposures for different lengths of time. To help estimate exposure time, a Geiger counter can often be used to detect the relative amount of radioactivity in the sample. With experience, this can help alleviate the trial and error often associated with obtaining the optimum exposure. Time of exposure and use of internal controls are particularly important if quantitative comparisons between experiments are desired.

4. After exposure, return cassette to the darkroom and remove film for developing.

   If the film was exposed at −70°C, allow the cassette to come to room temperature before developing. This will avoid static discharge, which can cause black dots or stripes on the autoradiogram.

   Automated film developers are also available and can be used to develop the film.

5. Immerse the film for 5 min in 18° to 20°C developer, then wash 1 min in running water at room temperature.

   Shorter periods of time in developer will yield a lighter image. The amount of time in developer, therefore, can be used to roughly control intensity of the image.

6. Immerse the film for 5 min in 18° to 20°C fixer, then wash for 15 min in running water.

7. Hang the film to dry.

   The orientation of the film with respect to the gel can be determined by the images of the fluorescent markers.

FIXING AND DRYING GELS FOR AUTORADIOGRAPHY

SUPPORT PROTOCOL 1

SDS-PAGE gels containing radiolabeled proteins should be fixed and dried before exposure to film. This will prevent the gel from sticking to the film, improve the sharpness of the image, and increase sensitivity slightly. However, if the specific activity of the sample is high or the detection method is sensitive (e.g., where a phosphor imager is used; see Alternate Protocol 2), then fixing and drying the gel may not be necessary. Gel dryers are available from a number of manufacturers (e.g., Bio-Rad), most of which use heat and a vacuum to accelerate the drying process.

Materials

Gel from SDS-PAGE (*UNIT 6.1*)
Fixing solution: 10% (v/v) glacial acetic acid/20% (v/v) methanol in H_2O
Alternative fixing solution (for gels with ≥15% acrylamide or thicker than 1.5 mm): 3% (v/v) glycerol/10% (v/v) glacial acetic acid/20% (v/v) methanol in H_2O

Glass dish
Rotary shaker
Filter paper (Whatman 3MM) in sheets at least 1 to 2 cm larger than gel
Plastic wrap (e.g., Saran Wrap)
Gel dryer with vacuum pump

1. After electrophoresis, remove the gel and the supporting glass plates from the electrophoresis apparatus and place in a glass dish. Carefully remove the upper glass plate by gently prying apart the corners with a metal spatula. Make a notch in the upper right hand corner of the gel for orientation.

   Since the gel contains radiolabeled proteins, be sure to follow the necessary guidelines for handling radioactivity. Everything that comes in contact with the gel is potentially radioactive.

2a. *For gels with <15% acrylamide and <1.5 mm thick:* Place the glass dish in a fume hood and pour enough fixing solution into the dish to cover the gel. Place the dish on a rotary shaker and gently rotate until 5 min after all of the blue color from the bromphenol blue in the sample buffer (if used) has disappeared (~30 min total).

   The bromphenol blue typically used in SDS-PAGE sample buffer will turn yellow as the acidic fixing solution diffuses into the gel.

   During fixing, the gel will typically slide off the lower glass plate, which can be removed.

2b. *For gels with ≥15% acrylamide or >1.5 mm thick:* Fix gel as in step 2a, but soak 1 hr in alternative fixing solution.

   The glycerol in the alternative fixing solution should help prevent cracking during drying.

3. Pour off the fixing solution and rinse the gel for a few minutes with deionized water.

   CAUTION: *Remember that solutions that come in contact with the gel are potentially radioactive.*

4. Carefully pour off the water and position the gel in the center of the glass dish. Be sure that any excess water is drained. Place a sheet of Whatman 3MM filter paper, at least 1 to 2 cm larger than the gel, over the gel.

   The gel will stick to the filter paper, which will allow it to be lifted and turned over with the gel side facing up.

5. Cover gel with plastic wrap. Smooth the wrap with a piece of tissue paper to remove any air bubbles or wrinkles.

6. Place a piece of filter paper on the gel support of the gel dryer to prevent contamination of the dryer by radioactivity.

7. Place the filter paper/gel/plastic wrap sandwich on the filter paper in the gel dryer with the plastic sheet facing up.

8. Position the rubber sealing gasket of the gel dryer over the gel. Set the appropriate heat setting on the gel dryer (normally 80°C; 60°C if the gel contains a fluor). Apply the vacuum and allow the gel to dry (typically 2 hr for a gel of 1 mm thickness).

Removing the gel before it is completely dry can lead to cracking; it is therefore not a good idea to rush the drying process. A rough indication of whether the gel is dry can be obtained by feeling the gel under the sealing gasket. If the gel is dry, it should be warm over the entire surface.

9. Remove gel from dryer and proceed with autoradiography (see Basic Protocol).

USE OF INTENSIFYING SCREENS

SUPPORT PROTOCOL 2

Intensifying screens are used to enhance the film image generated by radioactive molecules (Laskey and Mills, 1977; Laskey, 1980). They are used strictly in conjunction with strong β-emitting isotopes such as ^{32}P or γ-emitting isotopes such as ^{125}I. Emissions from these forms of radiation will frequently pass completely through a film, but they can be absorbed by an intensifying screen which fluoresces and exposes the film with multiple photons of light. While an intensifying screen will substantially enhance the film image as compared with direct exposure (Table 6.3.1), some loss of image resolution will occur due to light scatter. Intensifying screens are distributed by most laboratory supply companies (e.g., Fisher, Sigma, and Kodak).

As shown in Figure 6.3.1, the film should be placed between the sample and the intensifying screen. Preflashed film (see Support Protocol 3) should be used if the sample is weakly radioactive or if quantitation of the radioactivity is desired. The preflashed side of the film should be placed adjacent to the intensifying screen. For very weakly radioactive samples, a second screen can be placed on the other side of the radioactive sample (i.e., screen, then sample, then film, then screen), but this causes further loss in resolution due to light scatter. Also, the sample and sample support must be sufficiently transparent to allow light from the second screen to reach the film. The film should be exposed at −70°C to stabilize the silver bromide crystals activated by the radioactivity or the light emitted from the screen.

Table 6.3.1 Different Methods for Isotope Detection and Their Sensitivities[a]

Isotope	Method[b]	Sensitivity[c]	Enhancement over direct autoradiography[d]
^{125}I	S	100	16
^{32}P	S	50	10.5
^{14}C	F	400	15
^{35}S	F	400	15
^{3}H	F	8000	>100

[a]Exposures conducted at −70°C using preexposed film.

[b]S, intensifying screen; F, fluorography using PPO.

[c]Defined as dpm/cm^2 required for detectable image (A_{540} = 0.02) in 24 hr.

[d]Direct autoradiography for comparison was performed on Kodirex film (Laskey, 1980).

PREFLASHING (PREEXPOSING) FILM

Silver bromide crystals that are activated by light, β particles, or γ rays are highly unstable and quickly revert back to their stable form. The absorption of several photons increases their stability but does not ensure development; approximately five photons of light are required to obtain a 50% probability that any single silver bromide crystal will be developed during film processing. This inefficiency means that film images produced by very low levels of exposure will be disproportionately faint. However, two measures can be taken to maximize efficiency and linearity of exposure at the low levels commonly encountered in ordinary use. First, the film should be preexposed to a hypersensitizing flash of light, which provides several photons per silver bromide crystal and stably activates them without providing enough exposure to cause them to become developed. This allows a linear relationship to be drawn between the film image and the amount of radioactivity in the sample. Second, film exposure should be conducted at low temperatures (−70°C) to slow the reversal of activated silver bromide crystals to their stable form (Laskey and Mills, 1975).

Film can be hypersensitized by exposure to a flash of light (<1 msec) provided by a photographic flash unit or a stroboscope before being placed onto the radioactive sample for exposure of the autoradiogram (Laskey and Mills, 1975, 1977). As the optimal light intensity required for preexposure varies with the type of film and the flash unit being used, the ideal exposure is best determined empirically as described below.

Materials

Stroboscope or flash unit (e.g., Auto 22 Electronic Flash from Vivitar or Sensitize Pre-Flash from Amersham Pharmacia Biotech)
Neutral-density filter (Kodak)
Orange filter (Wratten 22; Kodak)
X-ray film
Spectrophotometer

1. Cover the stroboscope or flash unit with the neutral-density and orange filter.

   This serves to decrease the intensity of emitted light, particularly the blue wavelengths to which X-ray films are most sensitive. Filters are not required for the Amersham flash unit.

2. Place the film perpendicular to the light source at a distance of ≥50 cm to ensure uniform illumination.

3. Expose a series of test films for different flash lengths, then develop them (see Basic Protocol).

   An uneven fog level on film can be remedied by placing a porous paper diffuser, such as Whatman no. 1 filter paper, between the film and the light source.

4. Cut the films into pieces that fit into a cuvette holder of a spectrophotometer and measure the absorbance at 540 nm.

   Choose an exposure time that causes the absorbance of the preexposed film to increase by 0.15 with respect to film that was not preexposed.

FLUOROGRAPHY

ALTERNATE PROTOCOL 1

Organic scintillants can be included in radioactive samples to obtain autoradiograms of weak β-emitting isotopes such as ^{3}H, ^{14}C, and ^{35}S. The scintillant fluoresces upon absorption of β particles from these isotopes, facilitating film exposure. Fluorographs of radioactive molecules in polyacrylamide gels have traditionally used the scintillant PPO (2,5-diphenyloxazole; Laskey and Mills, 1975). PPO, however, has largely been replaced with commercial scintillation formulations that reduce the amount of preparation time and are considerably safer to use. These scintillants (e.g., Enhance from NEN Life Science) come with complete instructions for their use. In addition, spray applicators are also available that can be used on filters or thin-layer plates. The expected levels of image enhancement obtained through fluorography are listed in Table 6.3.1. Sodium salicylate can also be used for fluorography as described below (Chamberlain, 1979). It yields levels of image enhancement comparable to organic scintillants, although it sometimes causes a more diffuse film image. The conditions should work for most standard sizes and thicknesses of gels.

CAUTION: Gloves should be worn at all times; sodium salicylate can elicit allergic reactions and is readily absorbed through the skin.

Materials

Polyacrylamide gel
1 M sodium salicylate, pH 5 to 7, freshly prepared

Additional reagents and equipment for fixing and drying gels (see Support Protocol 1)

1. If gel is acid-fixed, soak for 1 to 5 hr in ~20 vol water to prevent precipitation of salicylic acid from the sodium salicylate.
2. Soak gel 30 min in 10 vol of 1 M sodium salicylate, pH 5 to 7.

   To prevent cracking of gels with >15% acrylamide or thicker than 1.5 mm, 2% (v/v) glycerol can be added to the 1 M sodium salicylate.
3. Dry the gel (see Support Protocol 1) and proceed with autoradiography (see Basic Protocol).

DENSITOMETRY

SUPPORT PROTOCOL 4

Film images obtained by autoradiographic methods can be quantified by densitometry. Densitometers work by comparing the intensity of light transmitted through a sample with the intensity of the incident light. The amount of light transmitted will be proportional to the amount of radioactivity in the gel, provided that the film has been properly preexposed (see Support Protocol 3). The linear range of correctly preexposed film is 0.1 to 1.0 absorbance units. However, if the preexposure is excessive—i.e., an increase of >0.2 absorbance units (A_{540}) treated film/untreated film—smaller amounts of radioactivity will produce disproportionately dense images. Autoradiograms that exceed an absorbance of 1.4 absorbance units (A_{540}) have saturated all available silver bromide crystals and also cannot be evaluated quantitatively.

Densitometers are available from several manufacturers (e.g., Molecular Dynamics, Bio-Rad, and UVP). Most models come with software that facilitates calculations and allows the user to define the region of the film to be measured. Procedures for the use of these machines vary and instructions are provided by the manufacturer. Densitometers are also available that measure light reflected from a sample. Reflectance densitometers are useful in instances where the sample medium is completely opaque—e.g., filters that have been probed using nonradioactive colorimetric detection assays.

ALTERNATE PROTOCOL 2

PHOSPHOR IMAGING

Phosphor imaging screens can be used as an alternative to film for recording and quantifying autoradiographic images (Johnston et al., 1990). They can detect radioisotopes such as ^{32}P, ^{125}I, ^{14}C, ^{35}S, and ^{3}H. There are several advantages of phosphor imaging over film: (1) linear dynamic ranges are 5 orders of magnitude, compared to ~1.5 orders of magnitude for film (Fig. 6.3.2); (2) exposure times are 10 to 250 times faster than with film; (3) quantification is much easier and faster, and most imagers come with software to directly analyze data; (4) fluorography and gel drying are often unnecessary because of the sensitivity of phosphor imaging; and (5) phosphor screens can be reused indefinitely if handled carefully.

Phosphor imaging screens are composed of crystals of $BaFBr:Eu^{+2}$. When the screen is exposed to ionizing radiation such as α, β, or γ radiation, or wavelengths of light shorter than 380 nm, the electrons from Eu^{+2} are excited and then trapped in an "F-center" of the $BaFBr^{-}$ complex; this results in the oxidation of Eu^{+2} to Eu^{+3}, which forms the latent image on the screen. After exposure, the latent image is released by scanning the screen with a laser (633 nm). During scanning, Eu^{3+} reverts back to Eu^{+2}, releasing a photon at 390 nm. The luminescence can then be collected and measured in relation to the position of the scanning laser beam. The result is a representation of the latent image on the storage phosphor imaging plates. The image can then be viewed on a video monitor and analyzed with the aid of appropriate software.

Some companies (e.g., Bio-Rad) offer different screens for use with different isotopes. They vary principally in the protective coating on the screen, which is optimized for low- or high-energy β particles or γ rays. No coating is typically used for weak β emitters such as tritium. More recently, screens have also been developed that measure chemiluminescence. Such screens are particularly valuable for use with many nonradioactive labeling protocols.

The protocol below is for the PhosphorImager system from Molecular Dynamics; other phosphor imaging systems are available from Bio-Rad, Imaging Research, and National Diagnostics.

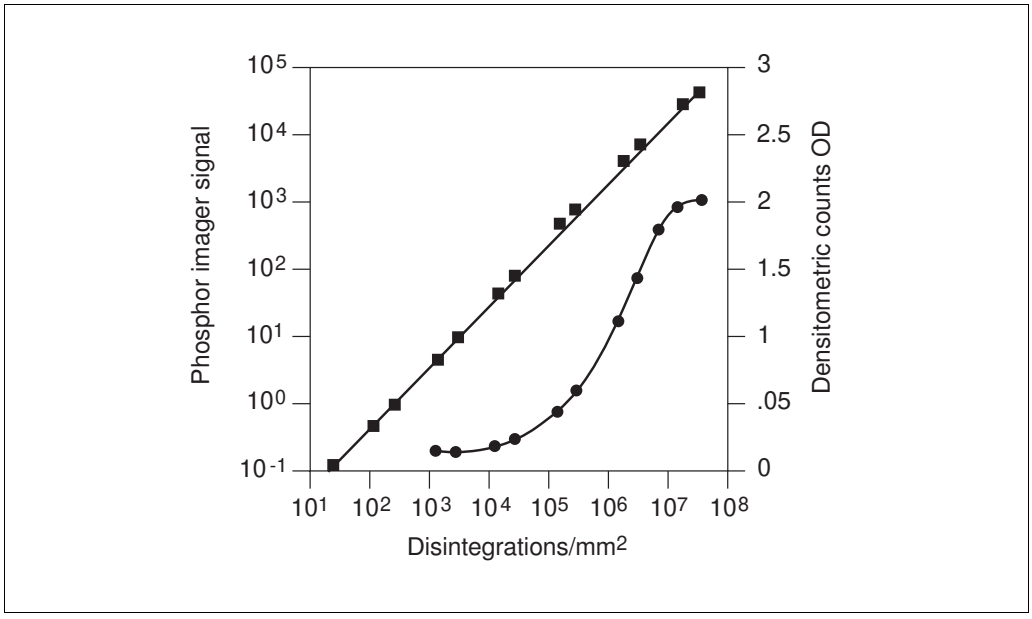

Figure 6.3.2 ^{32}P dilution series quantified on Model GS-525 phosphor imager (squares), compared to film (circles). Image courtesy of Bio-Rad, Hercules, Calif.

Materials

Gel or filter (e.g., from immunoblotting; *UNIT 6.2*)
PhosphorImager system (Molecular Dynamics) including:
ImageEraser light box
Exposure cassette with phosphor screen
Scanning software

1. Erase any latent image on the phosphor screen left by a previous user, or caused by background radiation, by exposure to visible light.

   The PhosphorImager system comes with an extra-bright light box (ImageEraser) for this purpose. Standard laboratory light boxes may also be used.

2. Cover gel or filter with plastic wrap to protect the exposure cassette. Place wrapped gel or filter in the PhosphorImager cassette and close to begin exposure.

   The gel does not have to be dried for this procedure. The phosphor screen is affixed to the lid of the cassette. Exposure times are typically one-tenth of the time required for film exposure.

3. After exposure, slide the screen face down into the PhosphorImager system.

4. Select the scanning area using the software supplied with the PhosphorImager and start scanning.

   The blue light emitted during scanning is collected to produce the latent image.

5. Analyze and quantitate the image using the software provided.

6. Erase the phosphor screen by exposing it to visible light as in step 1.

COMMENTARY

Background Information

The ability to detect radiolabeled proteins is critical to many studies in cell biology. A variety of labeling methods are described throughout this manual, many of which are used to follow protein purification, protein processing, or the movement of proteins within the cell. More often than not, detection of radiolabeled proteins is coupled with the resolving power of SDS polyacrylamide gel electrophoresis (SDS-PAGE; *UNIT 6.1*). Radiolabeled proteins separated on gels can be used directly to obtain an autoradiographic image. Alternatively, proteins separated by SDS-PAGE are frequently transferred to membranes (*UNIT 6.2*) and detected using radiolabeled probes such as antibodies and ^{125}I-labeled protein A. The autoradiographic image, whether generated on film or a phosphor screen, reflects the distribution of the radioactive proteins on the two-dimensional surface of the gel or filter. Molecular sizes of radiolabeled proteins, therefore, can be determined by correlating their positions with molecular markers. Also, the density of the band images can be used to determine the relative quantities of the radiolabeled proteins in the sample.

Critical Parameters

The sensitivity of the detection device and the strength of the radioactive signal are the two most important parameters for autoradiography. Sensitivity can be enhanced by treating samples with fluors or by using intensifying screens (Table 6.3.2). Because phosphor imaging is 10 to 250 times more sensitive than film (Johnston et al., 1990), this technology makes it possible to monitor radioactive samples that would previously have gone undetected with film.

A second important parameter is the range over which the measurement device is linear. Film requires preflashing in order for the intensity of the image to be linear with respect to the amount of radioactivity, particularly for weakly radioactive samples (Laskey and Mills, 1975, 1977). Phosphor imaging offers a much wider linear range of measurement (5 orders of magnitude compared to 1.5 for film; Johnston et al., 1990). This makes it possible to accurately

Table 6.3.2 Film Choice and Exposure Temperature for Autoradiography

Isotope	Enhancement method	Film	Exposure temperature
^{3}H	Fluorography	Double-coated	−70°C
^{35}S, ^{14}C, ^{32}P	None	Single-coated	Room temperature
^{35}S, ^{14}C, ^{32}P	Fluorography	Double-coated	−70°C
^{32}P, ^{125}I	$CaWO_4$ intensifying screens	Double-coated	−70°C

quantitate very weak or very strong radioactive samples.

Troubleshooting

Cracking is one of the most common problems encountered when drying gels. This often occurs if the gel is removed from the dryer before it has adequately dried or if drying temperatures are too high. To overcome this problem, drying times should be extended and the performance of the vacuum pump and heater unit should be checked. For many gels, particularly for those with high percentages of polyacrylamide or >1.5 mm thick, cracking can be reduced by using an alternative fixing solution containing glycerol (3% glycerol/10% glacial acetic acid/20% methanol; see Support Protocol 1).

Among the biggest problems encountered in autoradiography are images that are either too weak or too intense. Such problems can be solved by varying the exposure time. Estimating initial exposure time is difficult, since the amount of radioactivity in the sample is often unknown. A Geiger counter can offer some guidance with certain isotopes. For highly exposed film, the length of time in developer can be reduced to produce a lighter image. It is particularly important to remember that if accurate quantification of the film image is desired, film must be preflashed so that there is a linear relationship between the amount of radioactivity in the sample and the image intensity.

Artifacts, such as black spots and stripes, can be avoided during developing by making sure that no moisture comes in contact with the film and that films exposed at −70°C are brought to room temperature before developing. Also, it must be noted that β particles from weak isotopes such as ^{3}H cannot penetrate plastic wrap, and plastic wraps can attenuate signals from ^{35}S and ^{14}C up to two-fold.

Anticipated Results

The protocols described here should yield a film image of a gel that can be quantified, stored, and photographed for publication.

Time Considerations

Fixing a gel will require ~45 min. Drying will take an additional 2 hr for a gel 1 mm in thickness. Incorporation of a fluor will add ~45 min to the processing time.

For gels >1.5 mm thick or with >15% acrylamide, an additional 30 min will be required for fixing and ~30 additional minutes will be required for drying.

The length of exposure for films in autoradiography can range from a few minutes to a few weeks, depending on the strength of the radioactivity in the sample. Most exposures last from several hours to a few days. Exposure time can be reduced more than 10-fold with a phosphor imager.

Two-Dimensional Gel Electrophoresis

Two-dimensional gel electrophoresis combines two different electrophoretic separating techniques in perpendicular directions to provide a much greater separation of complex protein mixtures than either of the individual procedures. The most common two-dimensional technique uses isoelectric focusing (IEF) (see Basic Protocols 1 and 2) followed by sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS-PAGE) in a perpendicular direction (see Basic Protocol 3). This combination of isoelectric point (pI) and size separation is the most powerful tool for protein separations currently available. After staining, proteins appear on the final two-dimensional gel as round or elliptical spots instead of the rectangular bands observed on one-dimensional gels. Although the total separating power of large-format two-dimensional gels is estimated to be >5000 spots per gel, in practice a single two-dimensional separation of a complex mixture such as a whole-cell or tissue extract may produce 1000 to 2000 well-resolved spots when a sensitive detection method is used.

Until recently, the most common IEF procedures were based on the use of soluble ampholytes, relatively small organic molecules with various isoelectric points and buffering capacities. The pH gradient for IEF gels is produced when the soluble ampholytes migrate in the gel matrix until they reach their isoelectric point. Because stable pH gradients outside the pH 4.0 to 8.0 range are difficult to create with soluble ampholytes, alternative protocols using nonequilibrium conditions are required to resolve proteins with pI values below 4.0 (see Alternate Protocol 1 for acidic proteins) or above 8.0 (see Alternate Protocol 2 for basic proteins). One of the more important limitations of soluble ampholytes is the difficulty in obtaining highly reproducible pH profiles, especially when very narrow pH ranges are needed.

An increasingly attractive alternative to soluble ampholytes is the use of immobilized pH gradient (IPG) gels (see Basic Protocol 2). In this system, the buffering side chains are covalently incorporated into the acrylamide matrix, and any pH range and curve shape can be generated by pouring a gradient gel using two solutions that differ in ampholyte composition rather than acrylamide concentration. As with tube gels, the initial electrophoresis is followed by a second separation using SDS-PAGE in a perpendicular direction (see Basic Protocol 4). The use of IPG gels has recently increased, for at least three major reasons: many of the technical problems associated with their use have been solved or substantially minimized, reproducible premade IPG gels are now commercially available, and lately strong interest has arisen in using two-dimensional gels for proteome analysis studies (analyzing and comparing the complete protein profiles of cell lines, tissue samples, or single-celled organisms).

Another common two-dimensional electrophoresis format is a nonreducing/reducing electrophoretic separation (see Alternate Protocol 3), which provides useful information about intersubunit disulfides or protein-protein complexes that have been cross-linked using a bifunctional chemical cross-linker containing a disulfide bond within the linker region.

This unit also includes support protocols describing pI standards and pH profile measurements (see Support Protocol 1), electrophoresis of immobilized pH gradient gels (see Support Protocol 2), casting Immobiline gels (see Support Protocol 3), preparation of tissue culture cells and solid tissues for isoelectric focusing (see Support Protocols 4 and 5), preparation of molecular weight standards for two-dimensional gels (see Support Protocol 6), and two-dimensional protein databases (see Support Protocol 7).

Current Protocols in Cell Biology (1999) 6.4.1-6.4.36

NOTE: High-purity water (e.g., Milli-Q water or equivalent) is essential for all solutions. For cautions relating to electricity and electrophoresis, see Safety Considerations in the introduction to *UNIT 6.1*.

BASIC PROTOCOL 1

HIGH-RESOLUTION EQUILIBRIUM ISOELECTRIC FOCUSING IN TUBE GELS

This protocol describes the preparation of broad-range first-dimension gels using soluble ampholytes that resolve proteins with pI values between approximately 4.0 and 8.0, and is based on the original procedure described by O'Farrell (1975). The procedure presented here refers specifically to 3-mm IEF tube gels (first-dimension) combined with 1.5-mm-thick 16 × 16–cm (size of separating gel) second-dimension gels (see Basic Protocol 3) and may be easily adapted to a variety of different gel sizes (see Table 6.4.1). A 3-mm IEF gel has a total protein capacity of ~500 µg for complex protein mixtures such as whole-cell extracts. The maximum capacity of any single protein spot is ~0.5 to 5 µg, depending on the solubility of the protein near its isoelectric point and the separation distance from any near neighbors.

In this protocol, gels are cast and prefocused before the sample is loaded. The proteins are then separated according to isoelectric point, and the gels are extruded from the tubes and stored. Measuring pH profiles in IEF gels is a convenient and accurate method for determining pI (see Support Protocol 1). To provide optimal reproducibility, multiple gels should be cast and run simultaneously. This is especially important for comparative studies involving complex mixtures of proteins.

The IEF gels may be cast either by pouring the gel solution into the gel tubes (steps 3a to 7a) or by using hydrostatic pressure (steps 3b to 7b). Pouring the gel solution into the gel tubes is convenient for 3-mm-diameter IEF gels and requires only a minimal excess of reagents. Because the gels are cast using a long needle and syringe, for narrower gels, where the needle does not fit inside the gel tube, casting using hydrostatic pressure is more appropriate. This method requires a larger excess of reagents and special casting cylinders. Many types of ampholytes are readily available from different suppliers to form the desired pH profiles. As ampholytes may vary significantly in their performance, careful selection of the appropriate ampholytes is usually necessary (see Commentary).

Materials

Chromic acid, in acid-resistant container
Urea (ultrapure)
30% acrylamide/0.8% bisacrylamide (see recipe)
20% (w/v) Triton X-100 (see recipe)
Ampholytes (e.g., pH 3-10/2D; ESA)
TEMED (*N*,*N*,*N*′,*N*′-tetramethylethylenediamine)
2.5% (w/v) ammonium persulfate (see recipe; prepare immediately before use)
8 M urea (see recipe; prepare immediately before use)
0.1 M orthophosphoric acid (H_3PO_4; see recipe)
0.1 M NaOH (make fresh daily)
Lysis buffer (see recipe)
Protein samples to be analyzed
Equilibration buffer (see recipe)
2-Mercaptoethanol

Isoelectric focusing apparatus (e.g., Protean II xi 2D from Bio-Rad or equivalent) with glass tubes, casting stand, buffer chambers, rubber grommets, and plugs
37°C water bath

continued

110°C oven
10-ml syringe equipped with filter capsule (0.22 or 0.45 µm, e.g., Costar µStar LB)
10-ml syringe equipped with blunt needle [e.g., 20-G × 6 in. (15 cm) or 18-G × 6 in. (15 cm)]
Large glass cylinder sealed at bottom with Parafilm (optional, for hydrostatic pressure casting method only)
2000-V power supply
60-ml syringe
Metal or plastic scoop
Dry ice pellets

Wash tubes and prepare the gel mixture

1. Remove the glass tubes from a chromic acid–filled container. Extensively wash the tubes with water, using high-purity water for the last wash. Dry the tubes at least 1 hr in an oven at 110°C and store them at room temperature, covered with aluminum foil.

   To prevent gels from sticking to the glass tubes, gel tubes have to be very clean. Satisfactory results are obtained by storing the tubes in chromic acid between uses and washing them shortly before use. Because drying the tubes requires at least 1 hr, cleaning steps should be performed the day before gels will be cast.

   CAUTION: *Chromic acid is highly corrosive; follow supplier's precautions carefully.*

2. Prepare the gel solution by mixing:

   16.9 g urea
   4.0 ml of 30% acrylamide/0.8% bisacrylamide
   3.0 ml of 20% (w/v) Triton X-100
   7.5 ml water
   3.0 ml ampholytes.

   Briefly warm the mixture in a 37°C water bath to solubilize urea if needed.

   To minimize decomposition of urea, never warm any solutions containing urea above 37°C, use ultrapure urea, and prepare solutions immediately before use.

   Choice of ampholyte composition is one of the key factors determining the quality of isoelectric focusing separations. Substantial differences in performance, resolution, and shape of the pH gradient formed may be observed with different combinations of ampholytes and with ampholytes from different suppliers. ESA's ampholytes (pH 3-10/2D) are suited for most applications and give reproducible results.

   Although purity of all reagents is important, the purity of urea and choice of ampholytes are among the most critical factors for the quality and performance of isoelectric focusing. Most commercially available reagents marketed specifically for two-dimensional gel electrophoresis should be suitable, although individual lots of reagents from any supplier may provide variability and/or unacceptable results.

Cast gels by pouring

3a. Wrap one end of each glass tube with Parafilm and mount the tube in a casting stand. Mark all the tubes to indicate the desired gel height.

   For reproducible results, all gels should be the same height.

4a. Filter the gel solution using a 10-ml syringe equipped with a syringe-tip filter capsule. Briefly degas the gel solution (~5 min) either by sonication or under vacuum. Then add 42.5 µl TEMED and 187.5 µl of 2.5% (w/v) ammonium persulfate solution to the filtered gel mixture and swirl gently to mix.

5a. Using a 10-ml syringe with a blunt needle, fill each glass tube with gel solution to the desired height. Make sure there are no air bubbles trapped in the gel.

A needle is the best choice for casting gels if tubes of 3-mm inner diameter are used. For narrower tubes, the use of hydrostatic pressure is more appropriate (see steps 3b to 7b, below). For long gels the needle can be extended by inserting a piece of capillary polyethylene tubing over the needle tip. The amount of gel solution described in step 2 is sufficient for sixteen 3-mm tube gels that are 16 cm long.

6a. Immediately overlay each gel with ~50 µl of 8 M urea.

A pipettor with a capillary pipet tip is a convenient tool for overlaying with urea. Avoid mixing the overlay and gel solutions. Polymerization starts to occur ~15 min after the addition of TEMED and ammonium persulfate. It is essential that the gels be poured and overlaid before significant polymerization has occurred.

7a. Let the gels polymerize at least 3 hr prior to use.

Urea decomposes at a substantial rate at room temperature; therefore, the gels should be used the same day they are cast.

Cast gels using hydrostatic pressure

3b. Place a rubber band around the gel tubes so they form a tight bundle. Place the bundle inside a larger glass cylinder that is sealed at the bottom with several layers of Parafilm. All tubes must be precisely vertical.

The dimensions of the larger cylinder depend on the dimensions and number of gel tubes. Excessive space will require more gel solution to cast the gels.

4b. Filter the gel solution using a 10-ml syringe and filter capsule. Degas the gel solution briefly (~5 min) either with sonication or under vacuum. Add 42.5 µl TEMED and 187.5 µl of 2.5% ammonium persulfate solution and swirl.

5b. Pipet the gel solution into the bottom of the glass cylinder. Gently run water down the outside of the tube bundle using a wash bottle. Keep adding water until the gel mix reaches the desired height.

Hydrostatic pressure will force the gel solution into the tubes. Sufficient gel solution must be used to obtain the desired gel height while avoiding forcing any water into the tubes. The volume of gel solution required can be estimated as follows: number of gels × 3.14 × (tube internal radius in cm)^2 × height in cm + ~10 ml to keep a safe level of gel mix at the bottom of the casting cylinder. As water is less dense than the gel solution, the water level will be slightly higher than the level of gel solution inside the tubes.

6b. Overlay the gels with 8 M urea.

Urea decomposes at a substantial rate at room temperature; therefore, the gels should be used the same day they are cast.

7b. Let the gels polymerize at least 3 hr prior to use.

Mount the gels in the electrophoresis unit

8. Prepare the lower electrode solution by degassing the proper amount of 0.1 M H_3PO_4 under vacuum with stirring for at least 5 min. Fill the bottom electrophoresis chamber.

The amount of phosphoric acid depends on the length of the gel tubes and the type of electrophoresis unit. The solution should cover the entire gel for good heat dissipation. Approximately 3 liters are required for Protean II xi 2D electrophoresis units.

9. Remove the gel tubes from the casting stand, remove the Parafilm from the tube bottoms, and inspect gels for irregularities or trapped air bubbles. Discard imperfect gels. If using gels cast with hydrostatic pressure, remove the bundle of tubes en bloc, cut off excess acrylamide with a razor blade, and then rinse away remaining acrylamide particles from the outside of each tube.

10. Place a rubber grommet on the top of the tube. Approximately 5 mm of the tube should be visible above the upper edge of the grommet.

11. Mount the tube with the grommet in the upper reservoir and plug any unused holes.

    After the tube is seated, its lower end must be submerged in the lower electrode solution. Be sure to remove any air bubbles trapped at the bottom of the tube by shaking or tapping the tube gently. Alternatively, with some units bubbles can be dislodged by raising and lowering the tubes or by using a long curved needle and syringe.

Prefocus the gels

12. Prepare the 0.1 M NaOH upper electrode solution by degassing under vacuum with stirring for at least 5 min.

    The amount of upper electrode solution necessary depends on the type of electrophoresis chamber. If a Bio-Rad Protean II xi 2D apparatus is used, 1 liter of 0.1 M NaOH is sufficient for both prefocusing and the separation.

13. Remove the 8 M urea overlay from the top of the gels using a Pasteur pipet and place ~50 µl lysis buffer on the top of each gel.

14. Overlay lysis buffer with the degassed 0.1 M NaOH to fill the gel tubes. Avoid mixing of NaOH with the lysis buffer.

15. Pour the degassed 0.1 M NaOH into the upper chamber, making sure that all the gel tubes are covered with the electrode solution. Check carefully for leaks and air bubbles, then place lid on apparatus.

16. Connect the electrodes to a power supply by the red (+) lead to the lower chamber and the black (–) lead to the upper chamber.

    The voltages and currents used during electrophoresis are dangerous and potentially lethal. Safety considerations are given in the Electricity and Electrophoresis section of UNIT 6.1.

17. Prefocus for 30 min using 500 V constant voltage.

Load the samples

18. Turn off power supply (see Safety Considerations in *UNIT 6.1*), disconnect leads, and remove lid. Using a 60-ml syringe, remove the electrode solution (0.1 M NaOH) from the upper chamber.

19. Remove the electrode solution and the overlay solution from each tube. Be careful not to damage the gel surface.

20. Place ~50 µl lysis buffer on the top of each gel. Wait at least 2 min.

21. Remove the lysis buffer from the tubes.

    Rinsing the gels with lysis buffer removes any residual NaOH and protects the samples against exposure to high pH.

22. Load protein samples to be analyzed and carefully overlay each sample with ~50 µl lysis buffer diluted with water 8:2 (v/v). Avoid mixing the buffer with the sample.

    The overlay solution protects samples from direct contact with the strong base used as an upper electrode solution. Dilution of the lysis buffer with water is necessary to decrease the density so the overlay does not mix with the sample.

    A 3-mm-i.d. × 16-cm-long IEF gel has a total protein capacity of ~500 µg for whole-cell extracts and other complex protein mixtures. The maximum capacity for any single protein spot is ~0.5 to 5 µg, depending on its solubility near its isoelectric point and the separation distance from any near neighbors. Preparation of relatively pure protein samples for

isoelectric focusing is generally straightforward. The sample usually may be prepared in one of the following ways: dialyze into any compatible low-ionic-strength buffer, lyophilize in a volatile or compatible low-ionic-strength buffer and dissolve in lysis buffer, or precipitate the protein using trichloroacetic acid (TCA) and redissolve in lysis buffer. For preparing extracts from cultured cells and from tissue samples, see Support Protocol 4 and Support Protocol 5, respectively.

The minimum sample concentration of protein or radioactivity has to be sufficient for the desired detection method. For complex protein mixtures such as tissue or cell extracts, a 500-µg total load is recommended for Coomassie blue staining or electroblotting (UNIT 6.2) for subsequent structural analysis, a 50-µg total protein load should be sufficient for silver staining or immunoblotting, and no less than 100,000 counts/gel is recommended for proteins labeled with ^{3}H, ^{14}C, or ^{35}S for autoradiography purposes. Sample volumes should be <150 µl for 3-mm gels and <40 µl for 1.5-mm gels. This implies at least a 5 µg/µl protein concentration in the sample for gels to be stained with Coomassie blue.

23. Carefully fill all tubes with 0.1 M NaOH. Avoid mixing the NaOH solution with the overlay solution and the sample.

24. Fill the upper reservoir with 0.1 M NaOH. Be sure that all gel tubes are covered with the solution.

Run the gels

25. Connect the electrodes to a power supply with red (+) to the lower chamber and black (−) to the upper chamber.

26. Focus for a total of 12,000 Vhr.

Unlike other electrophoretic techniques, in IEF the volt-hour is the most common unit describing the "time" of isoelectric focusing. The initial voltage is usually set according to the desired number of volt-hours in a way that is convenient for the operator (i.e., so that the separation will run overnight), but it should not be <400 V. The upper voltage limit is restricted by heat released in the gels during isoelectric focusing. At constant voltage the current will be the highest during the first hour of separation. The initial current will be strongly influenced by the ionic strength of the samples loaded onto the gels. An initial voltage of <800 V is recommended for 3-mm gels loaded with samples containing less than 100 mM salts/buffers; the voltage could be increased to 1200 V after ~1 hr, if cooling is used. The current is a derivative of voltage and is never preset for isoelectric focusing purposes. Some power supplies allow preprogramming the desired number of volt-hours and continuously adjust voltage and current during the isoelectric focusing procedure (constant power). The total number of volt-hours is a major factor that affects separation in the first dimension. Optimal focusing time will vary for different ampholyte combinations, but 12,000 Vhr is a reasonable value for most systems. To achieve a total of 12,000 Vhr set the power supply to 667 V for 18 hr. These conditions are convenient for an overnight separation and do not require use of a cooling unit. Higher voltages can be used but may cause overheating of gels unless a highly efficient cooling system is employed. The maximum practical voltage decreases with increased gel tube inner diameter. Focusing for too long may cause cathodic drift and result in a shifted pH profile in the gel, whereas focusing for a short time will decrease resolution.

Extrude and store gels

27. Turn off power supply and carefully disconnect leads. Detach the lid and remove the NaOH solution from the upper reservoir of the electrophoresis chamber using a 60-ml disposable plastic syringe.

28. Remove one gel tube at a time from the chamber.

29. Using a 10-ml syringe equipped with a blunt needle, slowly and carefully inject water between the gel and glass tube. Start from the bottom of the tube, then repeat the procedure from the top. The gel should slide out of the glass tube.

It is convenient to let the gel slide from the glass tube onto a metal or plastic scoop, which facilitates transfer of the gel into a storage vial. It is relatively easy to break the gel during extrusion, and practicing on several unused gels is recommended. To extrude smaller-diameter gels, use water pressure generated by a syringe connected to the gel tube with Tygon tubing. If clean, unscratched glass tubes are used, extrusion should be easy.

30. Using the scoop, slide the gel into a 4.5-ml cryovial containing 3 ml equilibration buffer and 50 µl 2-mercaptoethanol. Close the vial, incubate exactly 5 min at room temperature, then freeze by placing the tube horizontally on top of dry ice pellets. Do not move or agitate the tube while the sample is freezing.

    The IEF gels may be run on a second-dimension gel immediately (see Basic Protocol 3), or can be stored at −80°C for many weeks. Even when the second-dimension is to be run immediately, extruded gels should be frozen after a carefully controlled incubation time at room temperature, such as the 5 min cited above for 3-mm-i.d. gels, to minimize diffusion of proteins out of the IEF gel. This short incubation before freezing will allow glycerol to diffuse into the gel. Too short an incubation or agitation during freezing can result in gel breakage. The total incubation time in equilibration buffer (sum of the time prior to freezing and after thawing) is critical and should be carefully controlled. Insufficient incubation time in equilibration buffer will not allow sufficient time for SDS to diffuse into the gel and saturate sites on the proteins. Excessive incubation times can result in appreciable protein losses due to diffusion out of the highly porous IEF gel.

CONDUCTING pH PROFILE MEASUREMENTS

SUPPORT PROTOCOL 1

Standards with different isoelectric points can help in evaluating the performance of a specific system and determining the effective pH range in the isoelectric focusing gel. Many pI standards are commercially available from different suppliers. It is most useful to separate a mixture of standard proteins that is prepared from several individual proteins or purchased as a preformulated kit. This mixture should be run in parallel with experimental samples on a separate reference gel. It is generally not recommended to run pI standards together in the same gel with samples because of possible interference with migration and identification of proteins of interest. Instead of analyzing standard proteins, a more precise evaluation of the pH profile can be made by directly measuring the pH throughout the gel using either a surface pH electrode or the following procedure.

1. Prepare and focus one or two gels (see Basic Protocol 1, steps 1 to 26) without any sample in parallel with experimental samples.
2. Prepare 20 to 40 glass test tubes each containing 1 ml high-purity, degassed water for each gel that will be used to measure the pH gradient (measurements on duplicate gels are recommended).

    The number of tubes required per gel equals twice the gel length (in cm).

3. After electric focusing is completed, extrude the blank gels (see Basic Protocol 1, steps 27 to 29). Briefly rinse the gels with water.

    After extrusion, gel surfaces may be contaminated with electrode solutions. Rinsing with water is essential for obtaining reliable pH profiles.

4. Place the gel on a glass plate with a plastic ruler below the plate. Cut the gel into 0.5-cm pieces using a sharp razor blade.
5. Place each gel piece in a test tube containing 1 ml water.

    Do not mix the order of samples because each gel piece represents a single pH profile data point.

6. Place all test tubes on a shaker and shake gently for 1 hr at room temperature.

7. Read the pH of each solution and plot the pH profile as a function of the distance from the top of the gel.

ALTERNATE PROTOCOL 1

NONEQUILIBRIUM ISOELECTRIC FOCUSING OF VERY ACIDIC PROTEINS

Basic Protocol 1 is sufficient for separating proteins with isoelectric points greater than ~3.5 to 4.0. For very acidic proteins, however, a nonequilibrium system is needed. The major features of this method are utilization of a shorter focusing time (without reaching equilibrium), a modified ampholyte mixture, and different electrode solutions.

Additional Materials *(also see Basic Protocol 1)*

10% (w/v) ammonium persulfate (prepare immediately before use)
Concentrated sulfuric acid (used in lower chamber electrode solution)
Ampholytes, pH 2-11 (used in upper chamber electrode solution)

To analyze very acidic proteins, follow Basic Protocol 1 with these exceptions in the indicated steps:

2. When preparing the gel solution, use the following mixture of ampholytes: 2.4 ml ampholytes pH 2.5-4 and 0.6 ml ampholytes pH 2-11.

4. Following the procedure for casting gels by pouring, add 100 µl of 10% ammonium persulfate solution, swirl, add 42.5 µl TEMED, and swirl again.

   Gel mixtures containing entirely or predominantly very acidic or very basic ampholytes are generally difficult to polymerize. Use of an increased ammonium persulfate concentration and adherence to the proper order of adding the reagents should ensure polymerization.

8. Prepare the bottom chamber electrode solution by adding 4.5 ml concentrated sulfuric acid to 3 liters water. Degas at least 5 min.

Omit steps 12 to 19 (do not prefocus the gels).

20. Remove the 8 M urea (polymerization overlay solution) and place ~50 µl lysis buffer on top of each gel. Wait at least 2 min, then remove the lysis buffer.

23. Carefully fill all tubes with the upper chamber electrode (anode) solution prepared by mixing pH 2-11 ampholytes with water in a 1:40 ratio.

24. Fill the upper buffer chamber (anode) with the solution described in step 23.

    Iminodiacetic acid (10 mM) may be a more economical alternative anode solution.

26. Focus for a total of 4000 Vhr.

ALTERNATE PROTOCOL 2

NONEQUILIBRIUM ISOELECTRIC FOCUSING OF BASIC PROTEINS

In general, most equilibrium IEF gel systems using soluble ampholytes produce pH gradients that do not exceed pH 8.0 on the basic end, yet many proteins have higher pI values. For this reason samples containing very basic proteins are usually focused using a nonequilibrium system. In an equilibrium system, proteins are loaded on the basic end of the gel and migrate toward the acidic end until they reach a pH equal to their pI. In nonequilibrium systems, the sample is loaded on the acidic end of the gel, and focusing is terminated after a relatively short time (fewer volt-hours).

To run nonequilibrium IEF gels, follow the procedure previously described (see Basic Protocol 1) with these alterations in the indicated steps:

8. Use 0.1 M NaOH as the lower electrode solution.

   Electrode solutions and electrodes are reversed in this procedure relative to equilibrium isoelectric focusing.

Omit steps 12 to 19 (do not prefocus the gels).

20. Remove the 8 M urea (polymerization overlay solution) and place 50 µl lysis buffer on top of each gel. Wait at least 2 min, then remove the lysis buffer.

23. After loading the samples and overlaying with lysis buffer diluted with water 8:2 (v/v) as in Basic Protocol 1, use 0.1 M H_3PO_4 instead of NaOH to fill all gel tubes.

24. Use 0.1 M H_3PO_4 as the upper electrode solution.

25. Reverse the connection of electrodes—i.e., connect the red (+) lead to the upper chamber and the black (−) lead to the lower chamber.

26. Focus for a total of 3000 to 5000 Vhr.

    The optimal number of volt-hours depends on the nature of the sample and the ampholytes used. The values recommended above may need to be adjusted empirically.

ISOELECTRIC FOCUSING USING IMMOBILIZED pH GRADIENT GEL STRIPS

BASIC PROTOCOL 2

In immobilized pH gradient (IPG) gels, the ampholytes are covalently linked to the acrylamide matrix, which facilitates production of highly reproducible gradients as well as very narrow pH gradients for optimal resolution of minor charge differences. A variety of precast gels and all the necessary equipment are commercially available from either Amersham Pharmacia Biotech or Bio-Rad. Equipment and chemicals are also available for the user to cast gels in the laboratory (see Support Protocol 3), although precast gels are likely to suffice for the majority of applications. Narrow strips of precast IEF gels (Immobiline DryStrips or Ready Strip IPG strips) may be used to achieve a first-dimension separation for two-dimensional gel electrophoresis, and broader precast slab gels (Immobiline DryPlates) can be used to compare multiple samples after IEF separation only (see Support Protocol 2 and Table 6.4.3). In this protocol, precast Immobiline DryStrips from Amersham Pharmacia Biotech are rehydrated overnight using the reswelling cassette (one to twelve sample strips may be handled at a time); samples are applied using sample cup holders and gel strips are isoelectric focused overnight. This procedure has been adapted from instruction booklets provided by Amersham Pharmacia Biotech with Immobiline Dry Strip Kits and with the Immobiline DryStrip reswelling tray. Recently, both Amersham Pharmacia Biotech and Bio-Rad have developed newer IEF systems, the IPGphor Isoelectric Focusing System and the Protean IEF Cell, respectively. These systems simplify IPG strip handling and the overall isoelectric focusing procedure. The IPGphor system also integrates IPG strip reswelling and electrophoresis steps in a single strip holder. These systems include very high-voltage power supplies integrated with efficient cooling units to permit more rapid isoelectric focusing. In general, premade commercial IPG strips from any supplier can be used with any isoelectric focusing device that can physically accommodate the strip. The appropriate user manuals should be consulted for specific details.

Since there is a greater selection of pH ranges for premade Immobiline DryPlates than DryStrips, it is sometimes convenient to cut DryPlates into strips prior to rehydrating the gel to obtain narrower pH ranges where needed. See Basic Protocol 4 for details concerning preparing and running the second-dimension gel.

Wear gloves throughout the procedure and handle the Immobiline DryStrips with forceps where feasible to prevent extraneous protein contamination of the gels and gel solutions.

Table 6.4.1 Rehydration Solutions for Immobiline DryStrips[a]

Component	Final conc.	DryStrip type		
		3-10L	3-10NL	4-7L
Ultrapure urea[b]	7 M	2.1 g	2.1 g	2.1 g
Thiourea[b]	2 M	0.76 g	0.76 g	0.76 g
CHAPS[c]	2%	0.1 g	0.1 g	0.1 g
Pharmalyte pH 3-10	1:50[d]	100 µl		
Pharmalyte pH 4-6.5			50 µl	100 µl
Pharmalyte pH 8-10.5			25 µl	
Ampholine pH 6-8			25 µl	
DTT	0.3%	75 mg	75 mg	75 mg
Bromphenol blue	Trace	A few grains	A few grains	A few grains
Milli-Q water		To 5 ml	To 5 ml	To 5 ml

[a]Rehydration solutions should be prepared fresh immediately before use or stored as frozen aliquots and should be filtered using a 0.2-µm filter. Minimize total time the solution is at room temperature prior to use to minimize decomposition of urea. If the reswelling tray is used, ~250 or 400 µl rehydration solution is required per 11- or 18-cm DryStrip, respectively.

[b]A "total urea" concentration of 9 M is typically used. Thiourea is more effective than urea for minimizing protein precipitation during isoelectric focusing, but its solubility is lower. The combination of 7 M urea/2 M thiourea usually results in superior sample solubilization and isoelectric focusing as compared with 9 M urea alone.

[c]The optimal detergent and detergent concentration should be empirically determined. Other common alternatives are Triton X-100 and octyl-glucoside. The detergent used must be nonionic or zwitterionic to avoid high current and consequent overheating during isoelectrofocusing.

[d]Alternatively, soluble ampholytes are available as preformulated "IPC buffer" concentrates for each type of IPG strip.

Thoroughly clean all equipment with a mild laboratory detergent solution, rinse well with Milli-Q water, and allow to dry before using. Solutions containing 10 M urea may be heated *briefly* to 30° to 40°C to aid in solubilization.

Materials

Urea (ultrapure)
CHAPS or Triton X-100
Pharmalyte 3-10, 4-6.5, and/or 8-10.5 soluble ampholytes (see Table 6.4.1; Amersham Pharmacia Biotech)
Ampholine pH 6-8 (Amersham Pharmacia Biotech)
DTT (dithiothreitol)
Bromphenol blue
Precast Immobiline DryStrips (Amersham Pharmacia Biotech)
DryStrip cover fluid (Amersham Pharmacia Biotech)
Immobiline DryStrip kit (Amersham Pharmacia Biotech) including:
  Cathode electrode
  Anode electrode
  Sample cup bar
  Tray
  Sample cups
  Immobiline strip aligner
  IEF electrode strips
  Sample application pieces
  Instruction manual

continued

Protein sample to be analyzed
Lysis buffer (see recipe)

Immobiline DryStrip reswelling tray (Amersham Pharmacia Biotech)
Forceps
Filter paper
Glass plate
Flatbed electrophoresis unit (Amersham Pharmacia Biotech Multiphor II or equivalent)
Recirculating cooling water bath
Power supply (minimum capacity of 3000 to 3500 V)
Petri dishes

Additional reagents and equipment for protein detection by staining (*APPENDIX 3*) and/or for electroblotting (*UNIT 6.2*, optional)

Rehydrate the Immobiline DryStrip(s)

1. Prepare an appropriate rehydration solution for the type of DryStrips to be used as described in Table 6.4.1 (~400 µl rehydration solution per 18-cm DryStrip).

   The rehydration solution should contain 7 M urea/2 M thiourea, and 2% CHAPS or another appropriate detergent (zwitterionic or nonionic) such as Triton X-100, NP-40, or n-octyl-glucoside should be included in the rehydration solution to aid in sample solubility. The optimal detergent and detergent concentration may vary with type of sample and should be determined empirically.

   One possible method of loading large sample volumes onto IPG gels is to add the sample directly to the rehydration solution. Sample loading during rehydration is preferred when using the IPGphor system with its single strip holder for both rehydration and isoelectric focusing.

   Solutions containing urea should be filtered using a 0.2-µm filter before use.

2. Slide the protective lid off the reswelling tray and level the tray by adjusting the leveling feet until the leveling bubble is centered.

3. For an 18-cm gel, pipet 350 to 400 µl of rehydration solution into a slot of the reswelling tray. Move the pipet along the length of the well while adding the solution to spread it evenly throughout the length of the slot. Avoid excessive air bubble formation while pipetting this solution.

   If the IPGphor system is used, pipet the rehydration solution containing the protein sample into each cleaned ceramic holder.

4. Remove the protective cover from the Immobiline DryStrips and gently place them, gel side down, into the prepared slot.

   To facilitate their removal after rehydration, the strips should be oriented with their pointed ends at the sloped end of the slots in the rehydration tray. Be careful not to trap any air bubbles under the gel strips.

5. Overlay each strip with 2 to 3 ml of DryStrip cover fluid to prevent evaporation and urea crystallization. Slide the protective lid into place and allow gels to rehydrate overnight (~16 hours) at room temperature.

   Shorter rehydration times can be used, although a minimum of 6 to 8 hr is usually needed to completely and reproducibly rehydrate the gels. Do not substantially exceed 16 hr as extensive incubation, especially rehydrating gels over a weekend, increases potential problems due to evaporation and subsequent urea crystallization. In addition, long incubation times increase the extent of urea decomposition, which will increase the risk of amino group modification on proteins by the cyanate produced from urea decomposition.

   If the IPGphor system is used, a low voltage (30 to 40 V) can be applied during rehydration, which improves isoelectric focusing and protein yields of some samples. With this device,

protocols can be preprogrammed so as to allow isoelectric focusing to immediately follow rehydration. Hence, both rehydration with low voltage and isoelectric focusing can be completed overnight, since ~8 hr is sufficient for rehydration, and up to 8000 V can be used in later stages of isoelectric focusing to shorten the total focusing time.

6. After the overnight rehydration, slide the lid off the reswelling tray. Place a forceps tip into the slight depression under each strip and remove the strip. Gently blot any excess oil or moisture from the plastic backing of the rehydrated strips with filter paper. A damp piece of filter paper may also be used to blot the surface of the gel. Some of the paper may adhere to the gel and should be gently peeled away. The gel is now ready to be placed in the strip aligner on the cooling plate of the electrophoresis unit.

   Do not allow the gel to dehydrate prior to placing it on the cooling plate in step 11. (Steps 7 to 10 should be completed prior to removing the strips from the reswelling tray.)

Run the first dimension

7. Level the Multiphor II electrophoresis unit, then connect it to a circulating cooling water bath. Allow it to cool to 15°C for 1 to 2 hr to ensure even cooling. Do not cool below 15°C to prevent precipitation of urea in the gels.
8. Pipet ~5 ml DryStrip cover fluid onto the surface of the Multiphor II cooling plate. Position the Immobiline DryStrip tray on the cooling plate oriented with the red (+, anodic) electrode at the top, near the cooling tubes.

   Avoid large air bubbles between the cooling plate and the tray (small bubbles should not cause a problem).

9. Connect the red and black electrode leads on the tray to their respective positions on the Multiphor II unit. Pour 10 ml of DryStrip cover fluid into the tray. Place the Immobiline DryStrip aligner on top of the oil, groove side up.

   Avoid getting oil on top of the strip aligner. The possible presence of small air bubbles under the strip aligner is not important.

10. Cut two electrode strips to a length of 11 cm (regardless of the number of DryStrips used). Place the electrode strips onto a clean glass plate and soak each one with 0.5 ml Milli-Q water. Blot with a Kimwipe or tissue paper to remove excess water.

    The electrode strips should be evenly soaked and just damp after blotting. Excessive water could cause sample streaking.

11. Transfer the strips from step 6 to adjacent grooves in the aligner tray. Position the rounded (acidic) end of each strip near the top of the tray at the red electrode (anode) near the cooling tubes, and the square end at the bottom of the tray near the black electrode (cathode). Be sure that the edges of all gel strips at the anode end are lined up evenly.
12. Place the blotted electrode strips from step 9 on top of the gel surface of the DryStrips near the anode and cathode ends of the gel. Position the red (anode) and black (cathode) electrodes on top of the electrode strips at their respective ends.

    After the electrodes have been pressed down on top of the electrode strips, check that the gel strips have not shifted position.

13. Push the sample cups onto the sample cup bar. Place the sample cup bar near the anode end of the gel so that the small spacer arm just touches the electrode and the sample cups are nearest to the electrode, but do not allow the cups to touch the gel.

    The sample cups should face the nearest electrode. The acidic end of the gel can usually be used for sample application; however, the optimal loading position may need to be determined empirically for different types of samples. At high protein concentrations and/or at non-optimal pH, samples may precipitate in the gel at the loading position.

14. Position one sample cup above each gel strip and push down to ensure good contact between the bottom of the sample cup and the gel strip. Make sure the gel strips have not shifted position.

15. Pour 70 to 80 ml of DryStrip cover fluid into the tray (it will cover the gels). If oil leaks into the sample cups, adjust the cups to stop leakage. When there is no leakage into the sample cups, add enough cover fluid to the tray to completely cover the sample cups (~150 ml).

16. Pipet protein samples (in lysis buffer) into the sample cups by underlaying. The sample should sink to the bottom of the cup. Check for leakage of the sample out of the sample cup.

    Samples should either be lyophilized and then solubilized in lysis buffer, or diluted 9 parts lysis buffer to 1 part sample. The maximum volume each sample cup holds is 100 µl. The complexity of the sample, the sample solubility at the loading concentration and pH used, the thickness of the second-dimension gel, and the detection method to be employed should be considered when deciding how much protein to load. As a starting reference, typical loading ranges for 1.0- to 1.5-mm-thick 18-cm × 18-cm gels would be ~5 to 20 ng per major spot for silver staining and ~1 to 5 µg per major spot for Coomassie blue staining. When very complex samples are used such as whole cell extracts, total protein loads are likely to be ~20 to 100 µg for silver staining and ~200 to 1000 µg for Coomassie blue staining. The salt concentration in samples should be kept <50 mM and, if the sample contains SDS, the final SDS concentration should be <0.25%.

17. Place the lid on the Multiphor II unit and connect the leads to a power supply. Focus the gels with constant voltage for 2 to 3 hr at 500 V followed by 12 to 16 hr at 3500 V for a total of 40 to 60 kVhr. Refer to the user manual for exact recommended voltage conditions for each type of Immobiline DryStrip.

    The optimal number of Vhr will depend upon the pH range of the Immobiline Strip used, the type of sample, and the sample load and volume; therefore, the optimal Vhr should be empirically determined for different applications.

18. When isoelectric focusing is complete, disconnect the power supply and remove the cover from the Multiphor II unit. Remove the electrodes, electrode strips, and sample cup bar from the tray.

    If gels are to be run in the second dimension immediately after isofocusing, steps 1 to 3 of Basic Protocol 4 should be completed prior to terminating isofocusing.

19. Using forceps, remove the DryStrips from the tray. If the gels are to be run in the second dimension immediately, place in a petri dish with the support film along the wall of the dish and proceed directly to equilibration of the gel (see Basic Protocol 4, step 4). Alternatively, gels may be stored sealed in a plastic bag at −80°C until ready to run the second-dimension gel.

    Gels may be stored at least 2 to 3 months at −80°C. Do not place in the equilibration buffers required for the second dimension prior to storage.

ELECTROPHORESIS ON IMMOBILIZED pH GRADIENT GELS

SUPPORT PROTOCOL 2

In this protocol, after precast IEF gels (Immobiline DryPlates) from Amersham Pharmacia Biotech are rehydrated, samples are loaded and subjected to isoelectric focusing. Gels are typically run at 2500 to 3500 V and require focusing times of 2 to 7 hr. Protein samples may be detected by conventional methods such as Coomassie blue or silver staining. Isoelectric points can be determined with the use of pI calibration proteins; alternatively, because the gradient is linear, one can measure the migration distance across the gel and estimate the pI at each location. As noted in Basic Protocol 2, Immobiline DryPlates can be cut into 3-mm-wide strips to use as the first dimension of two-dimensional gels, since

DryPlates are available in narrower pH ranges than DryStrips. DryPlates can also be used as described in this protocol to simultaneously separate multiple samples in a single dimension. Applications of this method include initial screening of samples to determine the optimal pH gradient prior to running more time-consuming two-dimensional gels, prescreening fractions from a chromatographic purification step prior to running two-dimensional gels, and evaluation of charge heterogeneity of purified proteins.

Additional Materials *(also see Basic Protocol 2)*

Precast DryPlate gel (Amersham Pharmacia Biotech)
Repel-Silane (Amersham Pharmacia Biotech)
Paraffin oil
Protein samples to be analyzed
Reswelling Cassette kit (Amersham Pharmacia Biotech) including:
  125 × 260 × 3–mm glass plate with 0.5-mm U frame
  125 × 260 × 3–mm glass plate
  Silicone tubing
  Pinchcock
  Clamps
  20-ml syringe
Roller (Amersham Pharmacia Biotech)
Whatman no. 1 filter paper

Flatbed electrophoresis unit (Amersham Pharmacia Biotech Multiphor II)
10° *or* 15°C cooling water bath
Electrode strips
Sample applicator strip or sample application pieces
Power supply (minimum capacity 3000 to 3500 V)

Additional reagents and equipment for protein detection by staining (*APPENDIX 3*) and for electroblotting (*UNIT 6.2*; optional)

Rehydrate the gel

1. Remove precast gel from packaging. If the entire gel is not needed, cut off the required number of lanes and reseal the unused gel. Mark the polarity of the gel section to be used by cutting a small triangle off the anode corner. Handle the gel by the support film only.

   It is critical that the lanes are cut from the gel in the proper orientation to preserve the pH gradient (see Fig. 6.4.1), and polarity must be indicated for proper orientation of electrodes later in the procedure.

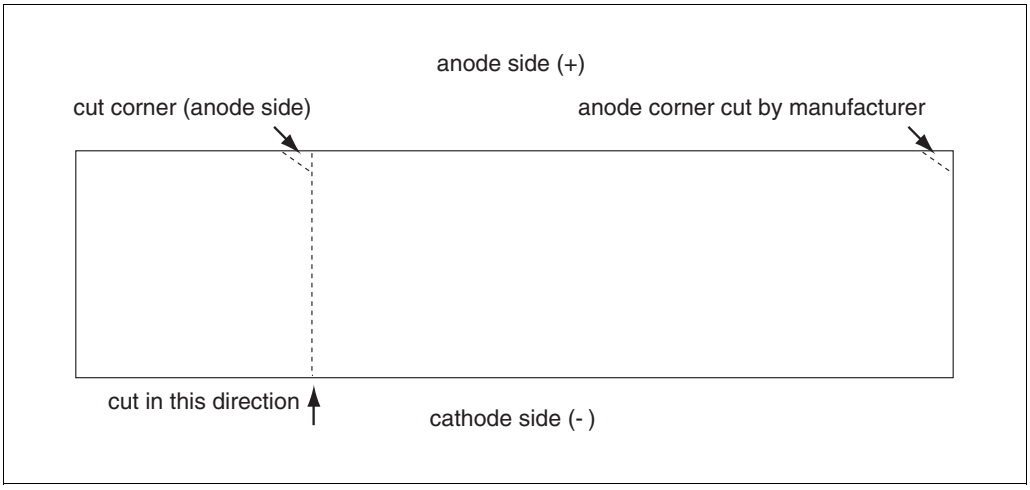

Figure 6.4.1 Marking orientation of a precast IPG gel when only a portion of the gel is used.

2. Use the Reswelling Cassette to rehydrate the gel. Connect silicone tubing through hole in the bottom corner of the U-frame plate, seal with silicone glue, and connect the pinchcock to the other end of the tubing. Place a glass plate on a clean flat surface and wet with a few drops of water. Place the gel on the plate, gel side up. Gently roll with a clean rubber roller to remove any air bubbles.

3. Cover the plate and gel with the plate fitted with the U frame.

   The U-frame plate should be coated with a thin layer of Repel-Silane to prevent the gel from sticking to the plate.

4. Place clamps around the edges of the plates, making sure the seal is tight.

5. Slowly fill the cassette with the desired rehydration solution using a 20-ml syringe connected to the silicone tubing and let stand for the recommended amount of time. Precool electrophoresis unit 1 to 2 hr prior to electrophoresis (see step 9).

   Reswelling with water for 2 to 3 hr is normally sufficient. If using additives such as urea, Triton, glycerol, or reducing agents, allow the gel to rehydrate overnight. Additives can be used to improve solubility of proteins near their isoelectric point. Reducing reagents such as DTT are used to reduce disulfide bonds.

6. When gel has been allowed to rehydrate completely, remove the clamps and gently pry the plates apart.

7. Moisten a piece of filter paper with water and place on top of the gel, then layer with a piece of dry filter paper.

8. Gently blot the gel by rolling over the dry filter paper with the rubber roller to remove excess water. The gel is now ready to be placed on the cooling plate.

   Do not let the gel dehydrate prior to placing it on the cooling plate in step 11.

Run the gel

9. Connect the flatbed electrophoresis unit to a recirculating cooling water bath. Allow to cool to 10°C for 1 to 2 hr to ensure even cooling. If the gel has been rehydrated in the presence of urea, do not cool below 15°C so that urea does not precipitate.

10. Pipet 2 to 3 ml paraffin oil onto the surface of the cooling plate.

11. Position the gel on the cooling plate, being careful not to trap air bubbles between the gel and the plate. Orient the gel so that the polarity of the gel matches the polarity of the cooling plate.

12. Soak two electrode strips with ~3 ml water, then blot to remove excess water.

13. Lay a blotted electrode strip along each long edge of the gel. Cut off the ends of the electrode strip so that it does not extend beyond the edge of the gel.

14. Load protein samples to be analyzed onto the gel. Use an applicator strip for sample volumes between 5 and 20 µl (make sure contact between the strip and the gel is uniform). Use sample application pieces for sample volumes >20 µl. Remove the application pieces halfway through focusing. For sample volumes of 2 to 10 µl, samples may be spotted directly on the gel without using applicator strips. See manufacturer's instructions for further details.

    An important experimental consideration is the position in the pH gradient where the sample is applied. The acidic end of the gel can usually be used for sample application; however, the optimal loading position may need to be determined empirically for different types of samples. At high protein concentrations and/or at nonoptimal pHs, samples may precipitate in the gel at the loading position.

Samples should contain <50 mM salt or buffer components; greater concentrations will cause local overheating of the gel. If possible, salt-free samples should be solubilized or dialyzed in the rehydration buffer.

15. Align the electrodes with the electrode strips, put the safety lid in place, and connect the apparatus to the power supply. Conduct electrophoresis at 3000 V.

    Broad-range IPG gels, such as Immobiline DryPlate, pH 3-10, should be run at ~3000 V for 2 to 4 hr. Narrower-range gels are also run at 3000 V but may require a focusing time of 4 to 7 hr.

16. After removing gels from the electrophoresis apparatus, detect proteins using any conventional staining technique such as Coomassie blue or silver staining.

17. Preserve the gels by sealing in a plastic bag or by drying for a permanent record. Alternatively, electrotransfer the proteins on the gel to a membrane.

    To dry a gel, presoak it first in a preservation solution. For silver-stained gels, use a solution of 5% to 10% (w/v) glycerol/30% (v/v) ethanol; for Coomassie blue–stained gels, use a solution of 5% to 10% (w/v) glycerol/16% (v/v) ethanol/8% (w/v) acetic acid. After soaking the gel, place it on a glass plate gel side up, cover with a cellophane sheet soaked in preservation solution, and allow to dry at room temperature.

    For electrotransfer (UNIT 6.2), use film remover to remove the plastic support film from the gel. Electrotransfer of proteins to a polyvinylidene difluoride (PVDF) membrane using a Multiphor II NovaBlot transfer kit (Amersham Pharmacia Biotech) is recommended. Transferring IPG gels requires special procedures; see the transfer kit manual for instructions.

SUPPORT PROTOCOL 3

CASTING AN IMMOBILINE GEL

An alternative to precast IPG gels is the use of Amersham Pharmacia Biotech Immobilines to cast immobilized pH gradient gels with customized pH gradients and ranges, including very narrow pH ranges, to improve separation of proteins with small charge differences. This protocol describes the general procedure of casting custom-made Immobiline gels. The Reswelling Cassette used in Basic Protocol 2 for rehydrating gels is employed for casting the gels, which are polyacrylamide gels poured with a gradient of Immobilines following instructions provided by Amersham Pharmacia Biotech application note 324.

Additional Materials *(also see Support Protocol 2)*

GelBond PAG film (Amersham Pharmacia Biotech)
Immobiline solutions (Amersham Pharmacia Biotech)
2.5% (v/v) glycerol

Gradient maker
Orbital shaker

Additional materials and equipment for rehydrating immobilized pH gradient gels (see Basic Protocol 2)

Cast the gel

1. Coat the plate with the U frame with Repel-Silane to prevent the gel from sticking to the glass plate.

2. Place a glass plate on a clean, flat surface and wet with several drops of water. Cover with a sheet of GelBond PAG film, hydrophilic side up. Use the roller to remove any air bubbles trapped between the film and the glass plate.

3. Place the plate with the U frame on top of the GelBond PAG film. Clamp the plates together on three sides.

4. Mix the Immobiline solutions following the instructions provided by Amersham Pharmacia Biotech application note 324 to prepare the desired pH range. Cast the pH gradient gel using a gradient maker.

   Once the catalysts have been added to the gel solution, it is important to work quickly to ensure that the gradient is poured before polymerization occurs. See UNIT 6.1 for instructions for using gradient makers.

5. Do not disturb the gel during the first 10 min to allow the gradient to stabilize. Allow the gel to polymerize 1 hr in a 50°C oven.

Dry and store the gel

6. Allow the gel to cool to room temperature, then disassemble the cassette. Cut off a small corner to label the anode end of the gel.

7. Wash the gel 2 to 3 hr with 200 to 300 ml water. Use an orbital shaker and change the water two or three times.

   At this stage the gel may be used immediately (if no additives are needed) or dried as described in steps 8 to 10.

8. Wash the gel 30 min to 1 hr with 200 to 300 ml of 2.5% (v/v) glycerol.

9. Place the gel on a glass plate (gel side up) in a dust-free environment and allow to dry at room temperature overnight.

10. Store the dried gel in a sealed plastic bag at −20°C for up to 2 months.

    The gels may be rehydrated when needed (see Support Protocol 2).

PREPARING TISSUE CULTURE CELL EXTRACTS FOR ISOELECTRIC FOCUSING

SUPPORT PROTOCOL 4

Preparation of samples containing relatively pure proteins for isoelectric focusing is generally straightforward (see Basic Protocol 1, step 22). In contrast, complex samples such as whole-cell extracts, tissue extracts, or subcellular fractions are more difficult to prepare for successful isoelectric focusing. Solubility limitations both prior to isoelectrofocusing and during focusing restrict analysis of these complex samples to protocols that include nonionic detergents and urea (see Basic Protocol 1). In addition, the presence of DNA and RNA in crude cell extracts further complicates isoelectric focusing. The protocol presented below is suitable for preparing samples from cell cultures and is based on quantities compatible with silver staining or Coomassie blue staining. If smaller cell numbers and high-sensitivity detection methods such as autoradiography are used, volumes and quantities should be adjusted as needed.

In this protocol the cells are harvested and washed in phosphate-buffered saline (PBS) with proteolysis inhibitors, then lysed in Tris/SDS buffer using sonication, after which the total protein concentration is determined in the lysate. The lysate is further treated with a mixture of DNase and RNase, and additional SDS and reducing agent are added. At this stage, the samples can be stored at −80°C for an extended time or, after addition of urea and lysis buffer, may be loaded directly onto prefocused IEF gels. Filtration of the final sample prior to loading onto the IEF gel is essential for quality of isoelectric focusing.

Materials

Cell culture flasks containing cells of interest
PBS with proteolysis inhibitors (PBS/I buffer; see recipe)
Dry ice/ethanol (optional, for freezing samples)
Tris/SDS buffer (see recipe)
BCA protein assay kit (Pierce)
DNase and RNase solution (see recipe)
20% (w/v) SDS (*APPENDIX 2E*)
2-Mercaptoethanol
Urea (ultrapure)
Lysis buffer (see recipe)

50-ml centrifuge tube
Centrifuge with rotor (e.g., Beckman JS-4.2), 4°C
1- to 2-ml cryovials
Microcentrifuge, 4°C
Sonicator with microtip
0.2-µm microcentrifuge filter units (e.g., Millipore Ultrafree-MC filter units)

Harvest and wash the cells

1. Place cell culture flasks containing cells of interest on ice.
2. Rapidly wash cells three times with 2 to 6 ml PBS/I buffer. Keep the flasks on ice.

   The required volume of PBS/I buffer depends on the flask size. For example, use 2 ml for a 25-cm^2 tissue culture flask and 6 ml for a 75-cm^2 tissue culture flask.

3. Add 2 to 6 ml PBS/I buffer to the flask, scrape the cells using a cell scraper, and transfer the suspension to a 50-ml centrifuge tube. Repeat this step with another 2 to 6 ml buffer to ensure complete transfer of the cells.

   Cells grown in suspension are washed in an analogous manner using repetitive centrifugation.

4. Collect the cells by centrifuging 15 min at 2600 × *g* (3000 rpm in Beckman JS-4.2 rotor), 4°C.
5. Discard the supernatant and resuspend the cells in a small volume of PBS/I buffer.
6. Transfer the cell suspension to a labeled cryovial.

   The weight of the empty cryovial can be determined prior to use if the wet weight of the cell pellet is desired as a reference value rather than cell number, radioactivity, or another criterion.

7. Microcentrifuge the cells 15 min at maximum speed, 4°C.
8. Remove and discard the supernatant using a pipettor or Pasteur pipet. Weigh the vial containing the cell pellet. Record the wet weight of the cell pellet (in mg).
9. Freeze the cell pellet in a dry ice/ethanol mixture (optional).

   Frozen cells can be stored at −80°C for at least several months.

Prepare the cell pellets for isoelectric focusing

10. Retrieve cell pellets from −80°C storage if samples were frozen.
11. Add 400 µl Tris/SDS buffer per 50 to 100 mg cell pellet wet weight. Keep the cells on ice at all times.

    The total amount of protein in the pellet is roughly 5% of the wet pellet weight.

12. Sonicate the sample three times for 3 sec using a sonicator with a microtip at medium power. Keep the samples on ice during sonication.

    Use pulse sonication or wait at least 5 min between sonications. Minimizing heat generation is essential because substantial proteolysis can occur if the sample warms appreciably. If additional sonication is necessary (i.e., if the sample is not homogeneous), let the sample cool down on ice before the next series of sonications.

13. Run a BCA protein assay to determine the protein concentration if sample will be loaded on that basis. For maximum accuracy use the same amount of Tris/SDS buffer in standards as in experimental samples.

14. Prepare labeled cryovials to store aliquots of the sample, if desired. Precool vials on ice prior to making aliquots.

    The amount of protein per aliquot depends on the anticipated future uses of the sample, as repeated freezing and thawing should be avoided. About 500 µg/gel whole-cell extract is a maximum load for preparative purposes using 3-mm gels (i.e., isolation of proteins for sequencing or other structural work). Approximately 50 µg/gel is an appropriate load for silver staining. The final protein concentration after completion of the protocol (steps 15 to 20) will equal the concentration found by protein assay divided by 1.1, owing to the addition of reagents after the protein assay step.

15. Add 20 µl DNase and RNase solution per 400 µl Tris/SDS buffer used for sonication (step 11). Incubate 10 min on ice.

16. Add 20 µl of 20% SDS solution and 5 µl of 2-mercaptoethanol per 400 µl Tris/SDS buffer used in step 11. Incubate 5 min at 37°C.

17. Quickly divide samples into previously prepared cryovials and immediately freeze aliquots using a dry ice/ethanol bath. Store at −80°C. Samples stored at −80°C are stable ≥1 year.

    Work quickly to minimize potential proteolysis.

    This step may be omitted if the samples are to be loaded on IEF gels immediately. Generally, the total amount of sample greatly exceeds the amount required for an IEF gel, and freezing aliquots is beneficial. To avoid potential reproducibility problems, all samples should be processed identically.

Prepare the samples for isoelectric focusing

18. If cell extracts were frozen, thaw samples and immediately add dry urea to 9 M final concentration.

    The amount of urea (in mg) equals 0.83 times the sample volume (in µl). For example, use 83 mg urea per 100 µl sample. The final volume of the sample (with urea added) equals 1.6 times the initial volume (160 µl in the same example).

19. Add an equal volume of lysis buffer (160 µl in the above example) and warm briefly if necessary to dissolve urea.

20. Filter samples using a 0.2-µm microcentrifuge filter unit by microcentrifuging at maximum speed, room temperature, until the entire sample has passed through the filter. Load the desired volume onto the IEF gel.

    If a 500-µg total protein load per 3-mm gel is desired (a practical maximum load for most whole-cell extracts), the protein concentration determined during the protein assay has to be ≥5 µg/µl. If the sample is less concentrated, the sample volume required will be too large for a 3-mm IEF gel. Alternatively, sample loads can be based on cell numbers, radioactivity, or any other appropriate reference (see Basic Protocol 1, step 22).

SUPPORT PROTOCOL 5

PREPARING PROTEINS IN TISSUE SAMPLES

Tissue samples are usually solubilized in lysis buffer using homogenization. After centrifugation, the protein sample can be loaded onto the first-dimension gel. In general, much higher sample-to-sample variability is expected when tissue samples are analyzed.

Materials

Tissue samples
Lysis buffer (see recipe)

Dounce homogenizer or equivalent
Ultracentrifuge and rotor (e.g., Beckman Ti70), 2°C

1. Place tissue sample in a Dounce homogenizer, add ~2 ml lysis buffer per 100 mg tissue, and homogenize the sample on ice (e.g., 3 to 5 strokes).
2. Let the mixture stand a few minutes, then transfer to an appropriately sized ultracentrifuge tube depending on total sample volume.
3. Centrifuge 2 hr at 100,000 × *g* (e.g., 33,000 rpm in a Beckman Ti70 rotor for 100,000 × *g*), or 1 hr at 200,000 × *g*, 2°C.
4. Divide the supernatant into aliquots and freeze at −80°C or immediately load an appropriate volume onto the IEF gel.

BASIC PROTOCOL 3

SECOND-DIMENSION ELECTROPHORESIS OF IEF TUBE GELS

Second-dimension gels are identical to those described in *UNIT 6.1* except for sample loading, which requires a broad, flat well. A broad well can be cast using an appropriate two-dimensional comb if the second-dimension gel thickness is slightly larger than that of the first-dimension gel. Alternatively, when the second-dimension gel is being cast, water can be layered over the entire surface of the gel to produce a flat surface that will accommodate the first-dimension gel.

Narrow analytical isoelectric focusing gels (≤1.5 mm) that fit between the glass plates of the second-dimension gel do not generally require a stacking gel, although a stacking gel may improve resolution under some circumstances. Stacking gels are essential when first-dimension gels >1.5 mm are loaded on reduced-thickness second-dimension gels, for example, when 3-mm first-dimension gels are loaded on 1.5-mm second-dimension gels. To ensure the best reproducibility, casting multiple second-dimension gels in a multigel casting stand is strongly recommended. This is especially important when gradient gels are used for the second-dimension and/or critical comparisons of multiple samples are planned.

This protocol describes all the specific steps required for successfully casting and running the second-dimension gel. The use of beveled plates and an agarose overlay is especially important when 3-mm IEF gels are loaded onto 1.5-mm second-dimension gels.

Materials

2% (w/v) agarose (see recipe)
Equilibration buffer (see recipe)
Isoelectric focusing gels containing protein samples to be analyzed (see Basic Protocol 1)
Piece of agarose containing molecular weight standards (see Support Protocol 6)

Beveled glass plates
Boiling water bath
Metal or plastic scoop

Additional reagents and equipment for linear and gradient Laemmli gels (*UNIT 6.1*)

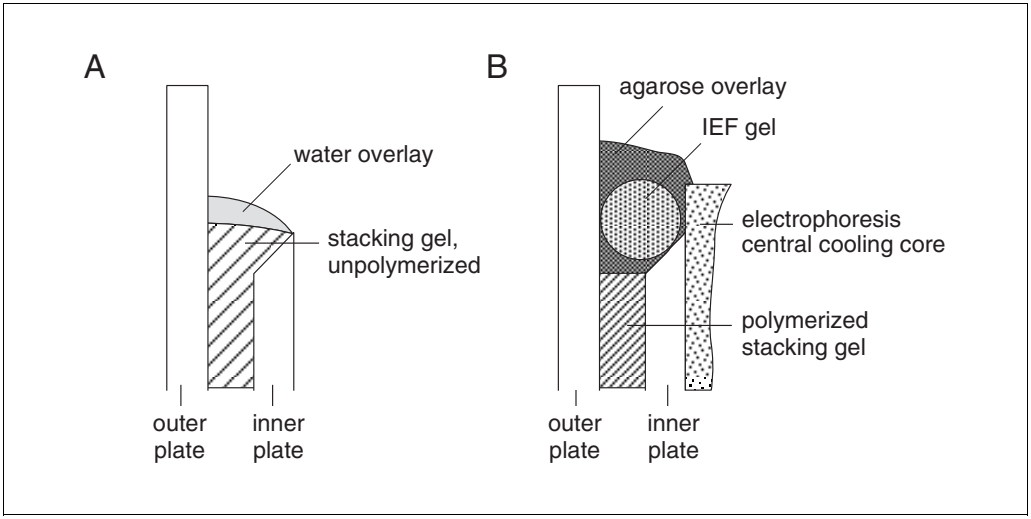

Figure 6.4.2 Casting the second-dimension gel and loading the IEF gel. (**A**) The stacking gel solution should reach to the upper edge of the beveled plate, and then the gel solution has to be overlaid with a minimum volume of water. The water will stay on the surface because of surface tension. (**B**) After polymerization, the gel is mounted on the central cooling core of the electrophoresis unit, and the equilibrated IEF gel is placed on top of the polymerized stacking gel. Excess buffer is removed, and the IEF gel is overlaid with hot agarose/equilibration buffer mixture. After the agarose solidifies, the upper electrophoresis chamber is filled with buffer.

Cast the second-dimension gels

1. Assemble the glass-plate sandwich of an electrophoresis apparatus, using a beveled plate for the shorter side of the gel sandwich.

   A beveled plate provides more space for a thicker IEF gel and will accommodate a first-dimension gel that is at least 1 to 2 mm larger than the thickness of the second-dimension gel.

2. If the thickness of the first-dimension gel exceeds that of the second-dimension gel, pour a separating gel of the desired acrylamide concentration and immediately overlay with water to produce a smooth surface. The separating gel height should be a minimum of 2 cm below the top of the beveled plate to accommodate the stacking gel.

3. After the separating gel has polymerized (a sharp interface between the polymerized gel and the water overlay will reappear), remove the overlay, rinse the gel surface with water, and pour the stacking gel. The stacking gel solution should reach to the top of the bevel. Immediately overlay the stacking gel solution with a minimum amount of water, which will adhere owing to the surface tension (see Fig. 6.4.2A).

   A water overlay of the stacking gel provides a smooth surface and better contact between the IEF gel and second-dimension gel. A small volume of water has to be used to avoid lowering the upper edge of the stacking gel below the edge of the beveled plate. The stacking gel height must be between 1.5 and 2 cm. The solution is filled to the top of the bevel so that after the slight shrinkage that occurs during polymerization the top of the polymerized gel will be near the bottom of the bevel (see Fig. 6.4.2B).

Load the isoelectric focusing gels onto the second-dimension gels

4. Assemble second-dimension gels in an electrophoresis chamber. Do not pour electrophoresis buffer into the upper chamber.

5. Melt 2% (w/v) agarose in a boiling water bath and add an equal volume of equilibration buffer for use in step 11. Keep agarose/equilibration buffer in the boiling water bath until step 11 is completed.

6. Retrieve isoelectric focusing gels containing protein samples to be analyzed from storage. Incubate cryotubes containing frozen IEF gels in a 37°C water bath for 15 min for a 3-mm tube gel. A 5- to 7-min incubation is sufficient for 1.5-mm or thinner IEF gels. Do not agitate during thawing, as vigorous agitation of a partially thawed gel can break the gel.

   During this thawing/equilibration step, SDS in the equilibration solution in which the gels were frozen diffuses into the gel matrix and binds to proteins in the IEF gel. The length of incubation in the equilibration buffer is critical because insufficient saturation of proteins with SDS will contribute to vertical streaks on staining. On the other hand, extended incubation in equilibration buffer will result in excessive loss of proteins owing to diffusion of protein out of the gel, which is especially critical for thin IEF gels. For this reason, it is recommended that after extrusion from the IEF tube IEF gels be initially incubated for 5 min to allow adequate diffusion of glycerol into the gel to minimize gel breakage, followed by freezing on dry ice (see Basic Protocol 1, step 30). This is desirable even if the second-dimension gel will be run directly after isoelectric focusing, as it is the most feasible way of precisely controlling the equilibration time while the remaining gels in the IEF run are extruded.

7. Pour the gel and equilibration solution out of the cryovial onto a metal or plastic scoop. Carefully remove excess equilibration buffer with a pipet.
8. Place a few milliliters of electrophoresis buffer on the top of the second-dimension gel.
9. Slowly slide the IEF gel off the scoop and onto the top of the second-dimension gel. Remove all air bubbles trapped between the gels. Remove excess electrophoresis buffer from the top of the second-dimension gel.

   The basic end of the gel may be placed on either the left or right side of the second-dimension gel. However, once a convention is established, all gels should be oriented the same way. The acidic end of the IEF gel can be recognized in two ways: the bromphenol blue will usually be yellow, and a bulge (increased gel diameter) will be present.

10. Place a piece of agarose containing molecular weight standards (see Support Protocol 6) beside the basic side of the IEF gel (optional).

    Note that when molecular weight standards are used, the isoelectric focusing gel has to be shorter than the width of the second-dimension gel.

11. Carefully overlay the IEF gel (and the gel piece with standard proteins) with the hot agarose/equilibration buffer mixture (~2 ml/gel) prepared in step 5. Let the agarose solidify.

    The agarose prevents the IEF gel from shifting position and ensures good contact between the IEF and second-dimension gels.

12. Carefully pour electrophoresis buffer into the upper reservoir, taking care to avoid disturbing the agarose-covered IEF gel.
13. Connect electrodes and run the gels.

    See UNIT 6.1 for electrophoresis conditions.

BASIC PROTOCOL 4

SECOND-DIMENSION ELECTROPHORESIS OF IPG GELS

In this protocol, vertical gel electrophoresis is used as the second dimension for IPG gels in an analogous manner to the protocol described for the second dimension of IEF tube gels (see Basic Protocol 3). One difference is the use of second-dimension gel spacers or gel apparatus that will accommodate an 18-cm-long Immobiline DryStrip; Bio-Rad offers a conversion kit to increase the gel width from 16 cm to 18 cm, and Amersham Pharmacia Biotech offers the Iso-Dalt gel system. The use of beveled plates is not necessary as the 0.5-mm strips are narrower than the second-dimension gel (1.0 or 1.5 mm thick). Another change involves a two-step equilibration of the strips prior to electrophoresis.

Additional Materials *(also see Basic Protocol 3)*

DryStrip equilibration solutions 1 and 2 (see recipes; prepare fresh in step 4)
Immobiline IPG DryStrip with focused protein (see Basic Protocol 2)
Platform shaker

Cast the second-dimension gel

1. Assemble the glass-plate sandwich of an electrophoresis apparatus, using gel plates wide enough to accommodate an 18-cm-long DryStrip gel.

   Beveled plates are not necessary. If the spacers are not wide enough to accommodate an 18 cm gel, the ends of the gel strip may be trimmed away from the IPG gel so that it will fit on top of the second dimension; however, some very basic or acidic proteins may be lost.

2. Pour a separating gel of the desired acrylamide concentration and immediately overlay with water to produce a smooth surface.

   The separating gel should be a minimum of ~2.5 cm below the top of the inner plate to accommodate a 2-cm stacking gel.

3. After the separating gel has polymerized, remove the water overlay, rinse the gel surface with water to remove any unpolymerized acrylamide, and pour the stacking gel to a height of 0.5 cm from the top of the plate. Overlay with water to produce a smooth surface.

   A water overlay provides a smooth surface for better contact between the Immobiline DryStrip and the second dimension gel. The stacking gel height should be ~2 cm.

Load the Immobiline IPG DryStrip gel onto the second-dimension gel

4. Prepare Immobiline DryStrip equilibration solutions 1 and 2 (see recipe).

5. Assemble the second-dimension gels in a electrophoresis chamber. Do not pour electrophoresis buffer into the upper chamber.

6. Melt 2% (w/v) agarose in a boiling water bath. Mix a solution of 1 part 2% agarose to 2 parts equilibration solution 2.

   Keep agarose/equilibration buffer mixture in boiling water bath until step 11 is completed.

   The agarose prevents the IPG DryStrip from shifting position and ensures good contact between the IEF and second-dimension gels.

7. Using forceps, remove the IPG gels from the electrophoresis tray after isoelectric focusing is complete or from the −80°C freezer (see Basic Protocol 2, step 19) and place each strip in a separate petri dish with the support film side of the strip facing the petri dish wall. Add 15 ml of DryStrip equilibration buffer 1. Cover and place on a platform shaker for 10 min.

   Strips may be run in the second dimension immediately after isofocusing or after storage at −80°C. If the strips have been stored at −80°C, remove them from the freezer, then place in petri dish as stated and continue with the equilibration procedure.

8. Discard equilibration buffer 1 and add 15 ml of equilibration buffer 2. Cover and place on a platform shaker for 10 min.

9. Dampen a piece of filter paper and place on a glass plate. Remove the DryStrips from equilibration buffer 2. Place each strip on its edge on the filter paper to remove any excess buffer.

   Strips should not be left in this position for >10 min, or spot sharpness may be affected.

10. Add a small amount of SDS electrode buffer along the glass plate above the second-dimension gel. Place the DryStrip gel in the well with the gel facing out and the basic side to the left. Push the DryStrip down so that it is firmly in contact with the stacking gel of the second-dimension gel. Remove excess running buffer.
11. Overlay the IPG gel strip with the agarose/equilibration buffer (from step 6) and allow agarose to solidify.
12. Carefully pour electrophoresis buffer into the upper reservoir, taking care to avoid disturbing the agarose-embedded IPG DryStrip.
13. Connect electrodes and run the gels.

    See UNIT 6.1 for electrophoresis conditions.

SUPPORT PROTOCOL 6

PREPARING MOLECULAR WEIGHT STANDARDS FOR TWO-DIMENSIONAL GELS

Molecular weight markers are usually necessary for the identification of proteins or as references to describe experimental proteins on two-dimensional gels. In many cases, molecular weight markers are required only at the beginning of a project. Once the system is established, common proteins in the sample (e.g., actin or tubulin) provide sufficient references for molecular weight identification on subsequent gels. To minimize any differences in migration of the molecular weight standards and isoelectric focused proteins, the standard proteins should be loaded on the second-dimension gel in the same manner as the IEF gel. This protocol describes the preparation of standards in solidified agarose. The agarose pieces may be stored at −80°C for at least a year and provide a convenient source of standards for the second-dimension gel. The procedure described is recommended for 3-mm IEF gels. Narrow standards in solidified agarose (made in tubes ≤1.5 mm in diameter) can be prepared by the same method, but extrusion of the thinner agarose gel without breaking is more difficult. The protocol supplies molecular weight markers containing ~2.5 µg of each standard suitable for Coomassie blue staining or 0.25 µg of each standard for silver staining.

Materials

Molecular weight standards (Table 6.1.2)
1× SDS sample buffer (*UNIT 6.1*)
2% (w/v) agarose (see recipe)

Boiling water bath
Glass tubes (3-mm inner diameter)
Plastic or metal tray

1. Prepare 3 ml molecular weight standards in 1× SDS sample buffer using 250 µg of each standard.

   The stated amount is appropriate for Coomassie blue staining of gels. If silver staining is planned, use 25 µg of each standard.
2. Mix the standards with 2 ml of 2% (w/v) agarose melted in a boiling water bath.
3. Prepare clean glass tubes by wrapping one end with Parafilm. Pour the hot mixture into the tubes and let the agarose solidify.
4. Carefully extrude the agarose from the tubes.
5. Cut agarose rods into 5-mm pieces using a razor blade.
6. Freeze all pieces separately on a plastic or metal tray using dry ice.
7. Collect frozen pieces in a plastic bottle and store at −80°C. The standards may be stored ≥1 year.

DIAGONAL GEL ELECTROPHORESIS (NONREDUCING/ REDUCING GELS)

ALTERNATE PROTOCOL 3

Protein subunit compositions and cross-linked protein complexes can be analyzed by two-dimensional gel electrophoresis using separation under nonreducing conditions in the first dimension followed by reduction of disulfide bonds and separation under reducing conditions in the second dimension. Most proteins will migrate equal distances in both dimensions, forming a diagonal pattern. Proteins containing interchain disulfide bonds will be dissociated into individual subunits and can be resolved in the second-dimension gel.

The approach is similar to that described for two-dimensional gel electrophoresis (see Basic Protocol 3) except, in this protocol, the first-dimension gels are nonreducing (i.e., 2-mercaptoethanol or dithiothreitol is omitted from sample buffer) SDS-denaturing gels instead of isoelectric focusing gels. Use of 1.2-mm tube gels for the first-dimension separation and 1.5-mm slab gels for the second-dimension run is recommended.

Additional Materials *(also see Basic Protocol 3)*

Separating and stacking gel solutions (see Table 6.1.1)
1× SDS sample buffer *without* reducing agents (*UNIT 6.1*)
Reducing buffer (see recipe)
1.5% (w/v) agarose in reducing buffer (see recipe; optional, for securing first-dimension gel on second-dimension gel)
Two-dimensional comb (optional)

Additional reagents and equipment for casting tube gels (see Basic Protocol 1), SDS-PAGE (*UNIT 6.1*), and protein staining (*APPENDIX 3*)

Pour and run the first-dimension gel

1. Clean and dry 1.2-mm glass gel tubes for the first-dimension gel (see Basic Protocol 1, step 1).

2. Prepare a separating gel solution with the desired percentage acrylamide (Table 6.1.1); omit the stacking gel for the first dimension.

   Stacking gels can usually be avoided in the first dimension by keeping sample volumes small (i.e., ≤10 µl).

   Less than 200 µl of gel solution is required to cast a single 1.2-mm tube gel 12 cm in length. Adjust the amounts from Table 6.1.1 accordingly.

3. Cast the first-dimension polyacrylamide gels in 1.2-mm tubes using a syringe with a long needle (see Basic Protocol 1, step 5a). Overlay with water and allow the gels to polymerize.

4. Prepare samples in 1× SDS sample buffer without any reducing reagents (i.e., no 2-mercaptoethanol or DTT). Load the samples and electrophorese until the tracking dye is ~1 cm from the bottom of the tube.

Reduce sample and run the second-dimension gel

5. Extrude the gel from the tube (see Basic Protocol 1, steps 27 to 29).

6. Place the extruded gel in a test tube containing 5 ml reducing buffer. Equilibrate 15 min at 37°C with gentle agitation.

7. Cast the second-dimension separating and stacking gels (see Basic Protocol 3, steps 1 to 3), making sure that the top of the stacking gel is at least 5 mm below the top of

the short glass plate. Layer water across the entire stacking gel or use a two-dimensional comb.

Most two-dimensional gel combs have a separate small well for a standard or reference sample.

The use of beveled plates (see Basic Protocol 3, steps 1 to 3) is not essential but is still preferred because it will facilitate loading of the first-dimension gel. In this procedure, the first-dimension gel will fit between the glass plates if 1.2-mm tubes are used for the first dimension and 1.5-mm gels are used for the second dimension.

8. Load the first-dimension gel onto the second-dimension gel. Remove any air bubbles trapped between the gels.

   If the first-dimension gel does not remain securely in place, it can be embedded using 1.5% (w/v) agarose in reducing buffer.

9. Carefully pour electrophoresis buffer into the upper electrophoresis chamber and electrophorese using voltages and times appropriate for the gel type selected.

   Parameters for electrophoresis are given in UNIT 6.1.

SUPPORT PROTOCOL 7

USING TWO-DIMENSIONAL PROTEIN DATABASES

Computerized image acquisition and manipulation constitute the only practical method for systematic qualitative and quantitative evaluation of complex protein patterns from different samples that are to be compared by high-resolution two-dimensional gel analysis. Examples of experimental applications include comparisons of tumor cells or tissues with appropriate normal controls and comparisons of a single cell line under different experimental conditions.

There are currently a number of commercially available image acquisition/computer systems specifically designed for comparing two-dimensional gels and storing associated information in a database. The systems include both hardware and the necessary software for comparing different gels and producing databases containing the two-dimensional protein patterns, with options for annotating specific spots and producing quantitative comparisons among large numbers of different samples. With most systems, images can be acquired from either stained gels or autoradiographs. The equipment used to obtain two-dimensional gel images includes laser scanners, video cameras, and phosphoimagers. After image acquisition, software running on a microcomputer or workstation is used to refine the image, detect spots, and match spots between different gels.

It is essential that very high-quality, reproducible gels be used for computerized comparisons. The greatest dynamic range in protein abundance for a single two-dimensional gel can be obtained using autoradiography or phosphoimaging (*UNIT 6.3*). With these methods, up to several thousand spots can be compared and tracked. A representative reference gel or a composite image can be stored and used as a reference for future experiments.

Information related to each spot on the two-dimensional pattern, including the quantity of protein in the indicated spot on different gels used in the comparison, can be archived and updated. Other known information related to a specific spot can also be added to the investigator-built database, including the pI, molecular weight, amino acid composition, sequence, and/or identity of the protein and any other important attributes correlated with the indicated spot. A number of research groups, including those of Garrels and Celis (Garrels, 1989; Garrels and Franza, 1989; Celis et al., 1991), have extensively characterized hundreds of spots from specific cell lines and have used multiple methods to characterize proteins of interest. The most definitive methods for establishing the identi-

ties for proteins of interest detected by computer-assisted comparisons are protein sequence analysis and, more recently, mass spectrometry of tryptic fragments. Both methods are compatible with the quantities of protein that can be recovered from two-dimensional gels.

REAGENTS AND SOLUTIONS

*Use Milli-Q-purified water or equivalent in all recipes and protocol steps. For common stock solutions, see **APPENDIX 2A**; for suppliers, see **SUPPLIERS APPENDIX**.*

30% acrylamide/0.8% bisacrylamide

30 g acrylamide
0.8 g bisacrylamide
H_2O to 100 ml

Filter solution through 0.2- to 0.45-µm filter (e.g., Micro Filtration Systems, cellulose nitrate, 0.2 µm). Store at 4°C (stable at least 3 months).

CAUTION: *Acrylamide is a neurotoxin. Wear gloves and a dust mask when handling solid acrylamide. Wear gloves when working with acrylamide solution. Never pipet acrylamide solutions by mouth.*

Agarose in reducing buffer, 1.5% (w/v)

Mix 0.15 g agarose and 10 ml reducing buffer (see recipe). Heat in boiling water bath until dissolved. Prepare immediately before use.

Agarose, 2% (w/v)

Mix 2 g agarose and 100 ml water. Stir on a hot plate until dissolved. Keeping the solution near 100°C, divide by placing 5-ml aliquots in 25-ml glass screw-cap tubes. Let the aliquots solidify. Store at 4°C (stable at least 3 months).

Ammonium persulfate, 2.5% (w/v)

0.25 g ammonium persulfate
H_2O to 10 ml
Prepare immediately before use

DNase and RNase solution

Mix 2.50 ml of 1 M Tris·Cl, pH 7.0 (*APPENDIX 2A*), 250 µl of 1 M $MgCl_2$, (*APPENDIX 2A*), and 2.2 ml water. Add to 5 mg DNase (Worthington) and dissolve DNase. Add 2.5 mg RNase (in solution; Worthington). Mix well, divide into 50- or 100-µl aliquots, and store at −80°C (stable at least 1 year).

The volume of RNase solution needed is variable and depends on the protein concentration, which is reported on the vial label (in mg/ml). The volume of RNase added should be <200 µl; if a larger volume is used, the amount of H_2O should be decreased proportionally.

Final concentrations are 0.5 M Tris·Cl, pH 7.0, 0.1 M $MgCl_2$, 0.1% (w/v) DNase, and 0.05% RNase.

DryStrip equilibration solutions

20 ml 1 M Tris·Cl, pH 6.8 (*APPENDIX 2A*)
72 g ultrapure urea
60 ml glycerol
2 g sodium dodecyl sulfate (SDS)
67 ml Milli-Q-purified water
For solution 1: Add 50 mg DTT per 10 ml of equilibration buffer
For solution 2: Add 0.45 g iodoacetamide and a few grains bromphenol blue per 10 ml of equilibration buffer

Make fresh immediately before use

Final concentrations are 50 mM Tris·Cl, pH 6.8; 6 M urea; 30% glycerol; and 1% SDS in a final volume of 200 ml.

EDTA, 2% (w/v)

2 g Na_2EDTA
H_2O to 100 ml
Adjust to pH 7.0 with NaOH
Store at room temperature (stable several months)

Titrate while dissolving. EDTA is difficult to dissolve without addition of NaOH even when the disodium salt is used.

Equilibration buffer

3 g SDS
7.4 ml 2% (w/v) EDTA, pH 7.0 (see recipe)
10 ml glycerol
2 ml 1.0 M Tris·Cl, pH 8.65 (*APPENDIX 2A*)
0.3 ml bromphenol blue (saturated solution in H_2O)
H_2O to 100 ml
Store at room temperature (stable for several weeks)

Final concentrations are 3% (w/v) SDS, 0.4 mM EDTA, 10% (v/v) glycerol, and 20 mM Tris·Cl, pH 8.65.

Leupeptin, 2 mg/ml

20 mg leupeptin
10 ml water
Divide into convenient volumes
Store at −20°C (stable at least 1 year)

Lysis buffer

2.59 g urea (ultrapure)
1.6 ml H_2O
0.25 ml 2-mercaptoethanol
0.3 ml ampholytes
1.0 ml 20% (w/v) Triton X-100 solution (see recipe)
Prepare immediately before use

Use same ampholytes as for the IEF gel formulation. To dissolve urea, warm the mixture in a 30°C water bath if necessary.

Orthophosphoric acid (H_3PO_4), 0.1 M

13.7 ml 85% phosphoric acid
Water to 2 liters
Make fresh daily

Must be degassed prior to use.

PBS, 10×

152 g NaCl
24 g monobasic sodium phosphate, anhydrous
1600 ml H_2O
Adjust pH to ~6.7 with NaOH
Add H_2O to 2 liters
Store at room temperature (stable at least 1 month)

The 1× solution should be pH 7.3 to 7.5. Final concentrations are 130 mM NaCl and 10 mM sodium phosphate.

PBS with proteolysis inhibitors (PBS/I buffer)

20 ml 10× PBS (see recipe)
20 ml 2% (w/v) EDTA, pH 7.0 (see recipe)

continued

200 µl 0.15 M phenylmethylsulfonyl fluoride (PMSF) in 2-propanol
100 µl 2 mg/ml leupeptin (see recipe)
200 µl 1 mg/ml pepstatin (see recipe)
Adjust to pH 7.2 with HCl
Add H_2O to 200 ml
Prepare immediately before use

Diisopropyl fluorophosphate (DFP) is a better serine protease inhibitor than PMSF at lower temperatures (0° to 4°C); however, although both compounds are toxic, exceptional caution must be exercised with DFP owing to its volatility. If DFP is used, work in a chemical fume hood and carefully follow the supplier's precautions. DFP and PMSF have half-lives on the order of hours in aqueous neutral solutions, and the degradation rate increases rapidly as the pH is increased above neutral. Make aqueous solutions immediately before use. Use of 1 M NaOH is convenient to inactivate residual DFP or PMSF.

Final concentrations are 10 mM sodium phosphate, 130 mM NaCl, 0.2% EDTA, 0.15 mM PMSF, 1µg/ml leupeptin, and 1 µg/ml pepstatin.

Pepstatin, 1 mg/ml

10 mg pepstatin
10 ml anhydrous ethanol
Divide into convenient volumes
Store at −20°C (stable at least 1 year)

Thaw aliquots and mix well immediately before use.

Reducing buffer

0.5 g dithiothreitol (DTT)
0.1 g SDS
1.51 g Tris base
Adjust to pH 6.8 with HCl
Add H_2O to 100 ml
Prepare fresh every time

Final concentrations are 0.5% (w/v) DTT, 0.1% (w/v) SDS, and 125 mM Tris·Cl, pH 6.8.

Tris/SDS buffer

0.3 g SDS
0.6 g Tris base
Adjust to pH 8.0 with HCl
Add H_2O to 100 ml
Divide into 5-ml aliquots
Store at −80°C (stable at least 1 year)

Final concentrations are 0.3% (w/v) SDS and 50 mM Tris·Cl, pH 8.0.

Triton X-100 solution, 20% (w/v)

3 g Triton X-100
12 ml H_2O
Warm in 37°C water bath to dissolve Triton X-100
Store at 4°C (stable ~2 weeks)

Urea, 8 M

0.75 g ultrapure urea
1.0 ml H_2O
Prepare immediately before use

Avoid heating above room temperature.

COMMENTARY

Background Information

Two-dimensional gel electrophoresis, using isoelectric focusing followed by SDS-PAGE, is the single most powerful analytical method currently available for separating complex protein mixtures such as whole-cell or tissue extracts. It is therefore a valuable method for following disease-related changes or for detecting changes in protein expression under diverse experimental conditions. To achieve maximum reproducibility between samples to be compared, multiple gels should be cast and run simultaneously (Anderson and Anderson, 1978a,b).

Despite the exceptionally high resolving power of the method, the total number of proteins that can be resolved in a single two-dimensional gel is only ~1000 to 2000, whereas the total number of proteins in a single mammalian cell type is likely to be at least 10 to 20 times higher. Therefore, the old guideline that a single spot on a two-dimensional gel is a single protein needs to be revised as analytical detection methods improve. Conversely, a single protein (single gene product) can produce multiple, usually adjacent spots in the isoelectric focusing dimension owing to variable degrees of chemical or posttranslational modification. Common examples of variable posttranslational modifications that can usually be detected on two-dimensional gels include phosphorylation, glycosylation, and acetylation. Examples of chemical modifications that cause charge heterogeneity include deamidation of side-chain amines (usually asparagines), oxidation of sensitive side chains, and modification of lysines. Potential modification of lysines by urea is particularly important because urea rapidly decomposes to form cyanate, which readily reacts with amino groups, especially above pH 7. Despite potential side reactions, urea is the most useful IEF additive for maintaining solubility of proteins near their isoelectric points.

Two-dimensional PAGE has become a valuable preparative tool for protein isolation in addition to its historical role as an analytical method. The sensitivity of many protein analysis methods has improved to the point where one or several spots from two-dimensional gels are sufficient for protein identification using mass spectrometry methods.

Commercially available equipment for running two-dimensional gels can be divided into four groups based on size: microgels (Amersham Pharmacia Biotech Phast system), minigels (e.g., Bio-Rad or Amersham Pharmacia Biotech), standard or full-sized gels (e.g., Bio-Rad or Amersham Pharmacia Biotech), and large or "giant" gels (ESA Investigator 2D gel system or Amersham Pharmacia Biotech Iso-Dalt gel system). In general, the larger the gel, the better the final resolution, but as gel size increases so do costs, difficulty of gel handling, and time requirements.

Standard-size gels provide adequate resolution for most applications and are relatively easy to handle. A 3-mm soluble ampholyte tube IEF gel or a 0.5 mm × 3 mm × 18-cm Immobiline gel has a total protein capacity of ~500 µg for complex protein mixtures such as whole-cell extracts. The maximum capacity for any single protein spot is ~0.5 to 5 µg, depending on the solubility of the protein near its isoelectric point and the separation distance from any near neighbors. A variety of alternative gel sizes, their limits, and their advantages are summarized in Table 6.4.2. The lower protein limit for any of the systems is determined strictly by the available detection methods.

Proteins can be detected in two-dimensional gels by the same wide range of techniques used for one-dimensional gels. Autoradiography (*UNIT 6.3*), silver staining, and electroblotting to PVDF membranes (*UNIT 6.2*) followed by colloidal gold or colloidal silver staining or immunodetection (*UNIT 6.2*) are among the most sensitive techniques available. If a larger amount of protein is available, Coomassie blue staining of the gel or amido black staining of a PVDF membrane after electrotransfer (*UNIT 6.2*) would be the detection methods of choice.

The major technical limitation in two-dimensional gel electrophoresis is gel-to-gel variation. Even when extreme care is exercised to produce highly reproducible first- and second-dimension gels, some gel-related variability among gels cast at the same time is likely to persist. Another source of variability includes differences in extraction or recovery of proteins during sample solubilization and handling. Maximizing resolution and reproducibility is especially important if computerized comparisons of two-dimensional gels of complex protein mixtures such as cell or tissue extracts are being attempted.

Isoelectric focusing using soluble ampholytes

Soluble ampholytes are mixtures of low-molecular-weight organic compounds with differing side-chain pK_a values that provide buffering capacity. In an IEF gel, the ampholytes migrate to their isoelectric point, where they provide buffer-

Table 6.4.2 Size Options for Two-Dimensional Gel Electrophoresis

Gel type	First-dimension gel		Second-dimension gel[a]		Purpose	Comments[b]
	Diameter *D* (mm)	Length *L* (cm)	Thickness *T* (mm)	Height *H* (cm)		
Microgels/minigels[c]	<1.5	<10	<*D*	<10	Analytical	1-4
	<1.5	<10	>*D*	<10	Analytical	3-6
	>1.5	<10	<*D*[d]	<10	Analytical/preparative	1,2,7,8
Full-size gels[e]	<1.5	12-18	<*D*	12-18	Analytical	1-4
	<1.5	12-18	>*D*	12-18	Analytical	3-6
	>1.5	12-18	<*D*[d]	12-18	Analytical/preparative	1,2,7,8
Giant gels[f]	<1.5	>20	>*D*	>20	Analytical	4-6,9
	>1.5	>20	<*D*[d]	>20	Analytical/preparative	1-3,7

[a]The second-dimension gel width has to be at least equal to the IEF tube gel height.

[b]Key to comments: (1) tube gel cannot be placed directly on top of second-dimension gel, and use of agarose is recommended; (2) use of stacking gel is recommended; (3) extrusion and handling are relatively difficult; (4) total protein load is limited to usually ≤50 µg for whole-cell or tissue extracts; (5) tube gel can be placed directly on top of second-dimension gel, and use of agarose is not necessary; (6) use of a stacking gel is not necessary; (7) total protein load capacity is relatively large; (8) extrusion and handling are relatively simple; (9) extrusion and handling are very difficult.

[c]Minigel systems provide rapid separations with moderate resolution. Microgels (Phastgels) are precast gels that are slightly smaller than most minigels.

[d]Use of second-dimension gels thicker than 1.5 mm is generally not recommended owing to difficulty with either efficient staining or efficient electroblotting.

[e]Full-size gels provide resolution satisfactory for most applications.

[f]Giant gels provide very good resolution. Specialized equipment is required, such as Investigator 2D (ESA), Iso-Dalt (Hoeffer Pharmacia), or homemade giant-size gel systems.

ing capacity and hence produce stable pH gradients. In theory, any desired pH gradient could be produced by blending ampholytes with appropriate pK_a values. In practice, it is relatively easy to produce pH gradients from ~pH 3.5 or 4.0 to pH 8.0, but stable soluble gradients outside this range are usually not technically feasible. Within these pH limits, some manipulation of the gradient shape and pH range is possible by blending different amounts of specific pH range ampholytes. For example, 0.50 ml of pH 5-7 ampholytes plus 0.25 ml of pH 4-8 ampholytes can be used instead of 0.75 ml of pH 4-8 ampholytes alone to increase the separation distance of proteins in the pH 5.0 to 7.0 range.

Basic Protocol 1 is based on use of 3-mm first-dimension isoelectric focusing gels and 1.5-mm second-dimension gels using the Bio-Rad two-dimensional gel apparatus (Protean II xi 2D). The method can be easily adapted to equipment from other suppliers or to different-sized gels by adjusting the quantities of reagents used. The protocol uses 8 M urea and Triton X-100 as solubilizing agents. Solubilization of the protein sample applied to the gel as well as maintenance of solubility during electric focusing are the most critical factors influencing the quality of separation in the first dimension. The most common modification to Triton X-100–based procedures is addition of 3-[(3-cholamidopropyl)dimethylammonio]-1-propanesulfonate (CHAPS) to the gel and solubilizing buffer mixtures. Addition of SDS to complex samples such as tissue or cell extracts can also enhance reproducible solubilization of the largest possible subset of proteins. Although SDS is charged, in the presence of Triton X-100 it is separated from proteins during focusing and migrates to the acidic end of the gel. Regardless of the method used to maintain solubility, some proteins (especially those >100 kDa) tend to precipitate at pH values approaching their isoelectric point and thus produce horizontal smears on the final second-dimension gel.

Basic Protocol 1 requires several modifications for successful separation of very acidic (Alternate Protocol 1) or very basic (Alternate Protocol 2) proteins. In both cases, prefocusing of the gels must be avoided, and the isoelectrofocusing time has to be reduced. A short separation time does not allow the system to reach equilibrium and is used to establish the desired

Table 6.4.3 Commercially Available Precast IPG Gels and Immobiline Chemicals

Name	Use	Available pH range
Immobiline DryPlate[a]	Running one-dimensional immobilized pH gradient gels	pH 4.0-7.0, pH 4.2-4.9, pH 4.5-5.4, pH 5.0-6.0, pH 5.6-6.6
Immobiline DryStrip[a]	Running first dimension in two-dimensional gels	
110 mm		pH 4-7L, pH 3-10L

[d]A nonlinear gradient with best resolution at pH 5.0-7.0.

pH gradient. Separation of very acidic proteins requires modifications of gel and electrode solutions. Separation of very basic proteins has to be performed with the positions of electrodes and electrode solutions reversed in the electrophoresis chamber.

The total protein load per gel depends on the complexity of the sample, the solubility of proteins in the sample, and the diameter of the first-dimension gel. Approximately 4 times as much total sample can be applied to a 3-mm gel compared with a 1.5-mm gel. Another advantage of a larger-diameter isoelectric focusing gel is that extrusion and gel handling are easier owing to improved strength of the gel. If care is exercised in loading the first-dimension gel onto the 1.5-mm second-dimension gel, the final resolution will be similar to that obtained using smaller-diameter IEF gels. The separating or resolving power of a system is dependent on the quality of ampholytes used, the slope of the pH gradient, and the lengths of both first- and second-dimension gels.

Immobilized pH gradient gels

In immobilized pH gradient (IPG) gels (Basic Protocol 2), the pH gradient is an integral part of the polyacrylamide matrix (Strahler and Hanash, 1991). Because the pH gradient is covalently associated with the polyacrylamide gel matrix, precise, reproducible, and very high-resolution separations can be achieved. A variety of precast gels and all the necessary equipment are commercially available from either Amersham Pharmacia Biotech or Bio-Rad. Reproducible two-dimensional gels can be obtained by running a sample on a narrow strip of immobilized pH gradient gel and then running it in a vertical SDS second-dimension gel. Isoelectrofocusing is performed in a horizontal electrophoresis unit in which multiple gel strips may be run simultaneously. Equipment and reagents are also available for the user to cast custom Immobiline gels in the laboratory.

Some of the major advantages of using precast IPG gels are their ease of use and high reproducibility, the time savings realized, and the fact that precision narrow-range gradients can be used to resolve small charge differences. Because the pH gradient is covalently coupled to the polyacrylamide gel matrix, the pH gradient remains stable and linear during prolonged electrophoresis, thus ensuring reproducibility. This is in contrast to conventional IEF gels, where gradient drift occurs during prolonged electrophoresis. Additionally, the precast gels can be rehydrated in water or in solutions with one or more additives such as urea, CHAPS or Triton X-100, carrier ampholytes, glycerol, and reducing agents, which may help to increase protein solubility. Precast gel strips are available with pH ranges such as pH 3.0 to 10.0 or pH 4.0 to 7.0 as well as narrower ranges (as DryPlates). In addition, a variety of Immobilines permits the user to cast IPG gels with customized pH gradients of any gradient range and shape between pH 3.0 and pH 10.0.

Table 6.4.3 lists types of commercially available gels and Immobilines. With the Immobiline

system, the apparent pI of a given protein may be slightly different from that determined by other methods. Therefore, it is recommended that a broad-range gradient be tried initially, followed by a narrower-range gradient, if needed.

Diagonal gel electrophoresis

Diagonal gel electrophoresis is a form of two-dimensional analysis useful for investigating the subunit composition of multisubunit proteins containing interchain disulfide bonds (Goverman and Lewis, 1991). Proteins are electrophoresed in the first-dimension in a tube gel (or a slab gel) under nonreducing conditions. The proteins are then reduced in situ, and the first gel (or a strip thereof) is layered onto a second gel and electrophoresed. In the second gel, the proteins migrate at right angles to the original, first-dimension migration. Most cellular proteins are not disulfide-linked and will fall on the "diagonal" in this system; that is, they migrate approximately equal distances in both directions during electrophoresis and lie approximately on the diagonal line connecting opposite corners of the gel. On reduction, component subunits of proteins connected by interchain disulfide bonds will resolve below the diagonal because the individual subunits migrate faster than the disulfide-linked complex during the second electrophoresis. Some proteins with internal disulfide bonds, but no interchain disulfides, may migrate slightly above the diagonal because internal disulfides can produce a more compact molecular shape (causing faster migration in the first dimension).

Investigator 2D gel system

The Investigator 2D gel system was introduced in 1990 by Millipore as the first commercial "large" or "giant" format two-dimensional gel system designed for analytical purposes, although analogous homemade units had been reported earlier (Garrels, 1979; Young et al., 1983). This product line, including precast first- and second-dimension gels, can now be purchased from ESA. The Investigator 2D gel system uses larger gel sizes than the gels described in this unit as well as a number of novel approaches and reagents designed to enhance resolution and gel-to-gel reproducibility. The major features of this system include the following: an increased length of the first-dimension gel (20 cm), an increased length and width of the second-dimension gel (20 $\times$ 22 cm), a thread reinforcement of the isoelectric focusing gel, temperature control during electrophoresis of the second-dimension gel, and use of a special high-tensile-strength acrylamide to facilitate handling of the large, thin second-dimension gel. Narrow gel tubes (1.2 mm) for the first-dimension are standard, but 3-mm-inner-diameter tubes are available to accommodate larger protein loads. The 3-mm IEF gels do not have the thread reinforcement. One modification related to the above protocol includes addition of 0.3% (w/v) CHAPS in the gel solution, which is intended to improve the solubility of proteins and their migration and separation in the gel. The system is supplied with a manual that adequately describes the method.

Critical Parameters and Troubleshooting

Although no individual steps in two-dimensional gel analysis are exceptionally difficult, the large number of steps involved increase the likelihood and possible severity of errors or problems. Several steps are especially critical and may require optimization. The first is sample preparation. Proteins applied to IEF gels have to be completely solubilized. Residual precipitate or even soluble aggregates are likely to cause artifacts on the end of the tube gel or position on the IPG strip where the sample is loaded. Precipitated or aggregated proteins may also interact with soluble proteins, causing components with normally good solubility to coprecipitate or migrate anomalously.

Two general rules of thumb apply to sample solubility: (1) the more complex the sample or the more crude the extract, the more likely problems will be encountered with sample solubility, and (2) the higher the protein load applied to the gel, the more likely solubility problems will arise. Care must also be taken to avoid proteolysis during sample preparation, especially when complex, impure samples are used. If samples are frozen either before or after solubilization, they should be stored at −80°C and should not be subjected to repeated freeze-thawing. Addition of SDS to the solubilization solution increases the solubilization of some proteins; however, SDS should only be used when the IEF gels contain urea and Triton X-100, as the solubilizing agents are required for effective separation of the strongly anionic SDS molecules from the proteins during isoelectric focusing. Heating of samples in urea-containing solutions must be avoided because urea readily decomposes to cyanate, which reacts with amino groups and causes charge heterogeneity. High concentrations of salts and buffers in the sample should be avoided. Ionic compounds increase the conductivity of the sample and can result in localized overheating, especially for Immobiline gels.

Samples analyzed on immobilized pH gradient gels should not contain precipitates. The concentration of salts and buffer ions in the sample should be kept to a minimum (<50 mM) to avoid local overheating of the gel during electrophoresis. If the sample forms aggregates or precipitates at the point of application, apply the sample to a different location (different pH) on the gel, or load the sample during the rehydration step.

Early decisions that must be made include the size of the gels required and whether a soluble ampholyte system or an Immobiline gel will be used. The major consideration affecting appropriate gel size is the degree of resolution needed. In general, the smallest gel format should be selected that will provide the needed degree of resolution, because smaller gels are easier, less expensive, and faster to run. Therefore, quick screening of samples or analysis of relatively simple samples can easily be accomplished with microgels or minigels. In contrast, if detailed qualitative or quantitative comparisons of cell or tissue extracts are planned, standard-size or large gels are indicated. Similarly, 3-mm or larger first-dimension tube gels followed by 1.5-mm second-dimension gels in the standard or large format are indicated if the two-dimensional gels will be used for preparative isolation of a protein for applications such as raising antibodies or conducting structural analysis. Immobilized pH gradient gels should very seriously be considered as an alternative to soluble ampholyte gels for most separations owing to their stable and reproducible pH profiles. The IPG gels are particularly appropriate when a narrow pH range is required.

Immobilized pH gradient gels are typically run at 2500 to 3500 V and typically require a focusing time of 16 to 18 hr. Use of high voltage (8,000 to 10,000 V) integrated power supplies/cooling units can shorten focusing times to <4 hr. Optimal focusing conditions may be experimentally determined by applying the sample to different positions on the gel and estimating the time for the migration patterns to coincide. Some proteins may require longer run times to reach their pI. Because there is no gradient drift, the potential problems with longer run times are limited to sample modifications or drying out of the gel. These problems usually can be minimized by including a reducing agent in the rehydration solution and coating the top surface of the gel with paraffin oil.

The quality of the first-dimensional separation is strongly dependent on the purity of the reagents used, especially the urea and ampholytes. One fairly commonly encountered frustration, when soluble ampholyte gels are used, is that different batches of ampholytes from the same supplier will sometimes produce markedly different two-dimensional gel patterns. Therefore, it is advisable to purchase an adequate supply of a single lot of ampholytes to meet anticipated needs for an entire study where such an approach is feasible. However, whereas ampholytes usually have a reasonably long shelf life at 4°C (usually up to a year), shelf life as well as total ampholyte requirements often cannot be predicted with much certainty.

When any doubt arises about the purity or quality of ampholytes or any other reagent, the reagent should be replaced immediately. Constant monitoring of the system performance, especially when changing lots of ampholytes, urea, or acrylamide, can help minimize potential reagent-associated problems. In most cases, the best standard for a given two-dimensional gel system is an experimental sample or control that is available in sufficient quantity so that many replicate aliquots can be frozen and stored for an extended time at −80°C; alternatively, a sample that can be reproducibly prepared over a long time frame would make an acceptable standard. Such an experimental standard or reference is more likely to detect subtle, but experimentally important, changes in the two-dimensional gel system than commercially available IEF or SDS gel standard mixes.

Another critical factor is equilibration of the first-dimension gel in the second-dimension equilibration buffer. During this step, urea diffuses out of the IEF gel while SDS and reducing reagent diffuse into the gel. If the gel is inadequately saturated with SDS, vertical streaking will result. However, if the gel is incubated in the equilibration buffer for an extended time, a substantial amount of the protein can rapidly diffuse out of the large-pore IEF gel. Losses arising from diffusion can be critical for any experiment because different proteins will diffuse at different rates, but rigorous control of the incubation step is especially important if quantitative comparisons among gels are planned. The simplest method of controlling the incubation time is to freeze the extruded IEF gel after a carefully controlled 5-min incubation in the equilibration buffer; any additional equilibration incubation time required can then be incorporated and carefully controlled when the sample is thawed for loading onto the second-dimension gel.

Another crucial step is loading of the equilibrated IEF gel onto the top of the second-dimension gel. Any irregularity or obstruction between the two gels, including particles of dirt or air bubbles, will affect the flow of current and disrupt

the resolution of proteins in the final gel. Similarly, poor contact or any movement of the IEF gel during electrophoresis of the proteins out of the IEF gel into the second-dimension gel will lead to artifacts. Therefore, it is advisable to embed the IEF gel in a buffered agarose matrix to ensure good electrical contact between the gels and to prevent gel movement after electrophoresis is initiated.

Finally, the choice of second-dimension gel composition and separation conditions can influence the quality of results. A proper percentage of acrylamide should be selected to optimize resolution within the desired molecular mass range. If gradient gels are needed, use of a multiple gel casting stand is the best way to ensure reproducibility among samples within a single experiment. Further details on optimization of two-dimensional gel systems are presented by Hochstrasser et al. (1988).

When no technical, sample-related, or reagent-related problems are encountered, the final stained two-dimensional gels should contain numerous rounded or slightly elliptical spots. Typically, more than 1000 spots can be detected on a standard 16 × 14–cm gel when using a sensitive staining protocol such as silver staining or autoradiography and a whole-cell extract as a sample. Some horizontal streaks for most high-molecular-mass proteins (proteins exceeding ~100 kDa) are common owing to the decreased solubility of larger proteins near their isoelectric points, even in the presence of urea and nonionic detergent. However, excessive horizontal smearing of proteins smaller than 100 kDa indicates poor isoelectric focusing, which could be related to one or more of the following factors: sample improperly solubilized or contaminated with interfering substances such as large nucleic acid molecules, poor purity of reagents (check the urea first), poor-quality ampholytes, or insufficient isoelectric focusing (total volt-hours too low). It is important to note that in general the solubility of any protein is the lowest near its isoelectric point, but there are vast differences among proteins in terms of both the minimum concentration where precipitation becomes a problem and the degree to which precipitation can be prevented by adding different solubilization agents. The best conditions for maintaining solubility during isoelectric focusing for a given sample type must be determined empirically, although the most universal conditions are those described in the protocols in this unit. In contrast, IEF systems that do not use any detergents or denaturants are limited to that fairly small percentage of proteins which maintain good solubility near their isoelectric point.

If high-molecular-weight proteins are expected but are not present in the final two-dimensional gel, check the sample preparation protocol as well as the sample storage conditions. The most likely problem is proteolysis during sample preparation. Multiple freeze-thawing cycles could contribute to this problem. Vertical smears on the two-dimensional gel suggest (1) insufficient equilibration of the IEF gel (not enough SDS bound to the proteins), (2) poor contact between the IEF and second-dimension gels, or (3) problems related to the stacking gel (too short or wrong buffer). Use of a stacking gel is especially important when large-diameter IEF gels are loaded onto smaller second-dimension gels.

Omission of Triton X-100 or other nonionic or zwitterionic detergent from the final sample loaded on the gel can yield poor results, especially for samples containing SDS, because the amount of detergent in the IEF gels alone may be insufficient to remove bound SDS from proteins. The presence of Triton X-100 in the sample is especially important when SDS sample buffer is used to solubilize protein samples (i.e., after immunoprecipitation). The amount of Triton X-100 in the lysis buffer is normally sufficient for effective dissociation of SDS from proteins. If poor results are encountered with SDS-containing samples, try decreasing the final SDS concentration and/or increasing the final Triton X-100 concentration in the sample.

If no proteins are detected on the gel, check whether (1) the total protein load is appropriate for the detection method used, (2) the orientation of electrical connections is wrong or electrical connection during isoelectric focusing is poor (all gels from that run will be blank), (3) an air bubble obstructs current in a single IEF tube, or (4) the electrical connection is incorrect or is poor during the second-dimension gel separation. Careful monitoring of current and voltage at the beginning, during, and at the end of electrophoretic separations is strongly recommended. Recording the initial and final current and voltage will also facilitate troubleshooting. Additional guidelines for troubleshooting and evaluating artifacts in two-dimensional gel electrophoresis are described by Dunbar (1987).

Anticipated Results

A two-dimensional electrophoretic separation of proteins should produce a pattern of round or elliptical spots separated from one another. The pI range of the separated proteins as well as the observed molecular weight range depend on the first-dimension isoelectric focusing protocol and the percentage of acrylamide used for the second-

dimension gel. A complex protein mixture such as a whole-cell extract should produce more than 1000 silver-stained spots distributed over most of the gel area. Fewer spots will be detected with less sensitive detection techniques such as Coomassie blue staining. On the other hand, separation of radiolabeled proteins and use of multiple exposures permit detection of many low-abundance proteins.

Time Considerations

Time requirements are very dependent on gel size and whether an external cooling unit is used to permit faster separations. Isoelectric focusing using the standard-size gel format described in Basic Protocol 1 with 3-mm tubes is most conveniently done in an overnight run of ~16 to 18 hr. This separation time can be decreased to ~5 to 6 hr using higher voltages and an external cooling device. Isoelectric focusing of 18-cm-long IPG gels requires ~16 to 18 hr. Extruding a set of sixteen IEF tube gels and freezing them in equilibration buffer takes 1 to 2 hr, including setup time. Preparing and running SDS gels is described in UNIT 6.1. It takes ~30 min to thaw, equilibrate, and load two second-dimension gels.

Overall, if standard-size gels are used without external cooling, it will take ~3 working days before the results of two-dimensional electrophoresis are obtained. A single person can conveniently run about 16 two-dimensional gels in one week, depending on the amount of electrophoresis equipment available. The rate-limiting step in most laboratories is running the second-dimension gels because 16 soluble ampholyte IEF gels or 12 IPG gels can be focused in one run, but loading, running, and detecting results from 12 to 16 second-dimension gels requires substantial operator time and electrophoresis equipment.

One-Dimensional Electrophoresis Using Nondenaturing Conditions

Nondenaturing or "native" electrophoresis—i.e., electrophoresis in the absence of denaturants such as detergents and urea—is an often-overlooked technique for determining the native size, subunit structure, and optimal separation of a protein. Because mobility depends on the size, shape, and intrinsic charge of the protein, nondenaturing electrophoresis provides a set of separation parameters distinctly different from mainly size-dependent denaturing sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS-PAGE; *UNITS 6.1*) and charge-dependent isoelectric focusing (IEF; *UNIT 6.4*). Two protocols are presented below. Continuous PAGE (see Basic Protocol) is highly flexible, permitting cationic and anionic electrophoresis over a full range of pH. The discontinuous procedure (see Alternate Protocol) is limited to proteins negatively charged at neutral pH but provides high resolution for accurate size calibration.

CONTINUOUS ELECTROPHORESIS IN NONDENATURING POLYACRYLAMIDE GELS

BASIC PROTOCOL

Separation of proteins by nondenaturing electrophoresis requires the same type of equipment used for denaturing slab gels (*UNIT 6.1*) and is adaptable to a range of gel sizes (e.g., from 7.3 × 8.3–cm minigels to 14 × 16–cm full-size gels) and matrix types (e.g., single-concentration and gradient gels). This protocol outlines straightforward procedures for making acrylamide solutions, casting separating gels (stacking gels are omitted), loading samples, and conducting electrophoresis. Continuous systems, although flexible, do not give the high-resolution separation found in discontinuous systems (see Alternate Protocol).

Separation in a continuous system (i.e., in which the same buffer is used for preparing acrylamide solutions and filling electrophoresis chambers) is governed by pH, and this protocol describes four types of buffers useful over discrete ranges from pH 3.7 to pH 10.6. Use of unadjusted acetic acid gel buffer can extend the range to pH 2.0. The choice of pH and thus the buffer system depends on the protein being studied (i.e., its isoelectric point) and often must be determined empirically. In general, the system should be between pH 5.0 and 8.0 for optimal results. Extremes of pH can lead to precipitation or denaturation of the protein. Acrylamide concentrations are empirically determined, but the higher the percent acrylamide, the sharper the protein bands.

It is important to include native protein standards in the electrophoresis runs. Several manufacturers supply standards for isoelectric focusing that are also suitable for native electrophoresis. The standards have a range of isoelectric points and will carry a net positive, negative, or zero charge depending on the pH of the gel system. Alternatively, Sigma supplies a standard kit that is useful for calculating molecular weights under neutral pH, nondenaturing conditions. The samples and standard proteins, should be used at concentrations of ~1 to 2 μg/μl.

Materials

4× acetic acid gel buffer (200 mM acetic acid, pH 3.7 to 5.6; see recipe)
4× phosphate gel buffer (400 mM sodium phosphate, pH 5.8 to 8.0; see recipe)
4× Tris gel buffer (200 mM Tris·Cl, pH 7.1 to 8.9; see recipe)
4× glycine gel buffer (200 mM glycine, pH 8.6 to 10.6; see recipe)
300 mM sodium sulfite (0.38 g in 10 ml H_2O; used in acetic acid gel preparation)
Protein samples to be analyzed

Native protein standards
Electrophoresis buffer: appropriate 4× gel buffer diluted to 1× with H_2O
75-ml side-arm flask (used in gel preparation)

Additional reagents and equipment for gel electrophoresis (*UNIT 6.1*) and staining proteins in gels (*APPENDIX 3*)

Prepare the gel

1. Assemble the glass-plate sandwich of the gel electrophoresis unit and secure it to the casting stand.

   Either single-concentration or gradient gels can be used in the minigel or standard-size format. Gradient gels will enhance the band sharpness of the separated proteins.

2. Prepare acrylamide solutions according to the recipes in Table 6.5.1, Table 6.5.2, Table 6.5.3, or Table 6.5.4, adding the ammonium persulfate and TEMED just before use.

   Deaeration of the solution before the polymerization catalysts are added will speed polymerization by removing inhibitory oxygen, but this is not generally required. The pH used depends on many factors. The most important are the pI values of both the protein of interest and any contaminants, as well as protein mobility and protein solubility. Determining which pH and thus which buffer system to use is largely empirical. However, extremes of pH (<4.0 and >9.0) can lead to denaturation and should be avoided. Prior knowledge of the pI of a protein (UNITS 6.4) allows determination of the net charge under

Table 6.5.1 Recipes for Acetic Acid Nondenaturing Polyacrylamide Gels[a]: pH Range 3.7 to 5.6[b]

Stock solution[c]	Final acrylamide concentration in gel (%)[d]						
	5	7.5	10	12.5	15	17.5	20
30% acrylamide/0.8% bisacrylamide	6.7	10	13.3	16.8	20	23.32	26.6
300 mM sodium sulfite[e]	0.4	0.4	0.4	0.4	0.4	0.4	0.4
4× acetic acid gel buffer	10	10	10	10	10	10	10
H_2O	22.58	19.28	15.98	12.48	9.28	5.96	2.68
10% (w/v) ammonium persulfate[e,f]	0.3	0.3	0.3	0.3	0.3	0.3	0.3
TEMED[f]	0.02	0.02	0.02	0.02	0.02	0.02	0.02

Preparation of gel

In a 75-ml side-arm flask, mix 30% acrylamide/0.8% bisacrylamide solution (see Table 6.1.1), 300 mM sodium sulfite, 4× acetic acid gel buffer (see Reagents and Solutions), and H_2O. If desired to speed polymerization, degas under vacuum ~5 min. Add 10% ammonium persulfate and TEMED. Swirl gently to mix. Use immediately.

[a]The recipes produce 40 ml gel solution, which is adequate for one gel of dimensions 1.5 mm × 14 cm × 16 cm or two gels of dimensions 0.75 mm × 14 cm × 16 cm.

[b]The pH range can be extended to ~2.0 (the pH of acetic acid) by using unadjusted acetic acid in place of 4× acetic acid gel buffer, although there is little buffering capacity at this pH.

[c]All reagents and solutions used in the protocol must be prepared with Milli-Q-purified water or equivalent.

[d]Units of numbers in table body are milliliters. The desired percentage of acrylamide in the gel solution depends on the molecular size of the protein being separated.

[e]Must be freshly made. Sodium sulfite is needed for efficient polymerization at acid pH.

[f]Added just before polymerization.

Stock solution[b]	Final acrylamide concentration in gel (%)[c]						
	5	7.5	10	12.5	15	17.5	20
30% acrylamide/0.8% bisacrylamide	6.7	10	13.3	16.8	20	23.32	26.6
4× phosphate gel buffer	10	10	10	10	10	10	10
H_2O	23.08	19.78	16.48	12.98	9.78	6.46	3.18
10% (w/v) ammonium persulfate[d,e]	0.2	0.2	0.2	0.2	0.2	0.2	0.2
TEMED[e]	0.02	0.02	0.02	0.02	0.02	0.02	0.02

Preparation of gel

In a 75-ml side-arm flask, mix 30% acrylamide/0.8% bisacrylamide solution (see Table 6.1.1), 4× phosphate gel buffer (see Reagents and Solutions), and H_2O. If desired, degas under vacuum ~5 min to speed polymerization. Add 10% ammonium persulfate and TEMED. Swirl gently to mix. Use immediately.

[a]The recipes produce 40 ml gel solution, which is adequate for one gel of dimensions 1.5 mm × 14 cm × 16 cm or two gels of dimensions 0.75 mm × 14 cm × 16 cm.
[b]All reagents and solutions used in the protocol must be prepared with Milli-Q-purified water or equivalent.
[c]Units of numbers in table body are milliliters. The desired percentage of acrylamide in the gel solution depends on the molecular size of the protein being separated.
[d]Must be freshly made.
[e]Added just before polymerization.

the separation conditions (i.e., if gel pH < protein pI, the protein will have a net positive charge; if gel pH > protein pI, the protein will be negatively charged).

3. Pour gel to 2 cm from the top of the gel mold and insert the comb. Avoid trapping air bubbles under the comb teeth.

   Air bubbles will cause small semicircular depressions in the well and lead to distortions in the protein banding pattern.

4. Allow gel solution to polymerize 1 to 2 hr.

   Polymerization is indicated by a sharp optical discontinuity around the wells.

Prepare samples and load the wells

5. Solubilize the protein sample to be analyzed using 5% (w/v) sucrose in water or dilute (1 to 5 mM) gel buffer if possible. Also prepare native protein standards.

   The concentration of protein will vary depending on the sample complexity and detection method. For Coomassie blue staining of highly enriched samples such as the standards, use 1 to 2 mg/ml (1 to 2 μg/μl). For more complex mixtures, use 5 to 10 mg/ml (5 to 10 μg/μl). Load 10- to 100-fold less for silver staining. In general, samples should be loaded in a minimum volume, preferably 10 to 20 μl for 0.75- and 1.5-mm-thick gels, respectively. With thin gels, this means using a more concentrated protein sample.

6. Remove comb carefully and rinse wells with electrophoresis buffer (appropriate 4× gel buffer diluted to 1×).

   Rinsing with electrophoresis buffer is needed to remove residual unpolymerized acrylamide monomer, which will continue to polymerize after comb removal, creating uneven wells that may interfere with sample loading.

Table 6.5.3 Recipes for Tris Nondenaturing Polyacrylamide Gels[a]: pH Range 7.1 to 8.9

Stock solution[b]	Final acrylamide concentration in gel (%)[c]						
	5	7.5	10	12.5	15	17.5	20
30% acrylamide/0.8% bisacrylamide	6.7	10	13.3	16.8	20	23.32	26.6
4× Tris gel buffer	10	10	10	10	10	10	10
H_2O	23.08	19.78	16.48	12.98	9.78	6.46	3.18
10% (w/v) ammonium persulfate[d,e]	0.2	0.2	0.2	0.2	0.2	0.2	0.2
TEMED[e]	0.02	0.02	0.02	0.02	0.02	0.02	0.02

Preparation of gel

In a 75-ml side-arm flask, mix 30% acrylamide/0.8% bisacrylamide solution (see Table 6.1.1), 4× Tris gel buffer (see Reagents and Solutions), and H_2O. If desired, degas under vacuum ~5 min to speed polymerization. Add 10% ammonium persulfate and TEMED. Swirl gently to mix. Use immediately.

[a]The recipes produce 40 ml gel solution, which is adequate for one gel of dimensions 1.5 mm × 14 cm × 16 cm or two gels of dimensions 0.75 mm × 14 cm × 16 cm.

[b]All reagents and solutions used in the protocol must be prepared with Milli-Q-purified water or equivalent.

[c]Units of numbers in table body are milliliters. The desired percentage of acrylamide in the gel solution depends on the molecular size of the protein being separated.

[d]Must be freshly made.

[e]Added just before polymerization.

7. Fill wells with electrophoresis buffer. If desired, prerun gel.

The gel can be prerun at this point to remove any charged material such as ammonium persulfate from the gel prior to loading the sample. Assemble the electrophoresis unit and fill the buffer chambers with electrophoresis buffer. Run the gel at 300 V until the current no longer drops. This should take ~30 min. Disassemble the unit, discard the buffer, and proceed to the next step.

8. Carefully load up to 10 µl (0.75-mm gels) or 20 µl (1.5-mm gels) sample per lane as a thin layer at the bottom of the wells. Load control wells with native protein standards. Add an equal volume of electrophoresis buffer to any empty wells to prevent spreading of adjoining lanes.

Mobility (R_f) markers require special consideration in nondenaturing gel systems. For cationic systems, cytochrome c (pI ~9 to 10, 5 to 10 µg/lane) works well as an R_f marker. Bromphenol blue (10 µg/ml) is a suitable marker for anionic systems. The marker should be included in the solubilization buffer with the sample.

Perform the separation

9. Assemble the gel unit, fill the upper and lower buffer chambers with electrophoresis buffer, and connect the unit to the power supply. Set current to 30 mA for a 1.5-mm-thick gel (15 mA for a 0.75-mm-thick gel).

If the protein is negatively charged under the separation conditions, then the standard SDS-PAGE electrode polarity should be used (proteins will migrate to the anode or positive electrode; see UNIT 6.1). If the protein is positively charged, then the electrodes should be reversed at the power supply (i.e., red high-voltage cable to the black output and black high-voltage lead to the red output) so the positively charged protein migrates to the negative cathode.

Table 6.5.4 Recipes for Glycine Nondenaturing Polyacrylamide Gels[a]: pH Range 8.6 to 10.6

Stock solution[b]	Final acrylamide concentration in gel (%)[c]						
	5	7.5	10	12.5	15	17.5	20
30% acrylamide/0.8% bisacrylamide	6.7	10	13.3	16.8	20	23.32	26.6

H_2O	23.08	19.78	16.48	12.98	9.78	6.46	3.18
10% (w/v) ammonium persulfate[d,e]	0.2	0.2	0.2	0.2	0.2	0.2	0.2
TEMED[e]	0.02	0.02	0.02	0.02	0.02	0.02	0.02

Preparation of gel

In a 75-ml side-arm flask, mix 30% acrylamide/0.8% bisacrylamide solution (see Table 6.1.1), 4× glycine gel buffer (see Reagents and Solutions), and H_2O. If desired, degas under vacuum ~5 min to speed polymerization. Add 10% ammonium persulfate and TEMED. Swirl gently to mix. Use immediately.

[a]The recipes produce 40 ml gel solution, which is adequate for one gel of dimensions 1.5 mm × 14 cm × 16 cm or two gels of dimensions 0.75 mm × 14 cm × 16 cm.

[b]All reagents and solutions used in the protocol must be prepared with Milli-Q-purified water or equivalent.

[c]Units of numbers in table body are milliliters. The desired percentage of acrylamide in the gel solution depends on the molecular size of the protein being separated.

[d]Must be freshly made.

[e]Added just before polymerization.

10. Continue electrophoresis until the R_f marker reaches the bottom of the gel.

    For minigels, electrophoresis will take 1 to 2 hr. Standard gels require 4 to 6 hr runs.

11. Turn off power supply, disassemble the unit, and remove gel from sandwich.

12. Stain the gel according to *APPENDIX 3*.

NATIVE DISCONTINUOUS ELECTROPHORESIS AND GENERATION OF MOLECULAR WEIGHT STANDARD CURVES (FERGUSON PLOTS)

ALTERNATE PROTOCOL

One straightforward approach to discontinuous native electrophoresis is to leave out the SDS and reducing agent (DTT) from the standard Laemmli SDS-PAGE protocol (*UNIT 6.1*). The gels are prepared as described in *UNIT 6.5* except that the sample buffer contains no SDS or DTT (samples are not heated), and the gel and electrophoresis solutions are prepared without SDS. This protocol illustrates the separation of standard proteins at four different concentrations of acrylamide and how the results are used to construct a molecular weight standard curve (Ferguson plot) without the need for SDS. By plotting relative mobility against %T (percentage weight per volume of acrylamide plus bisacrylamide in the gel), the presence of isoforms and multimeric proteins can also be detected.

Materials

4× Tris·Cl, pH 8.8 (1.5 M Tris·Cl; *APPENDIX 2A*)
4× Tris·Cl, pH 6.8 (0.5 M Tris·Cl)
Protein sample of interest
2× Tris/glycerol sample buffer (see recipe)

Native protein standards (e.g., Sigma nondenatured protein molecular weight kit)
Tris/glycine electrophoresis buffer (see recipe)

1. Assemble the glass-plate sandwich of the gel electrophoresis unit and place it in the casting stand.
2. Prepare and cast the gels, using 4× Tris·Cl, pH 8.8, for the separating gel and 4× Tris·Cl, pH 6.8, for the stacking gel instead of the SDS-containing counterparts (Table 6.1.1). Prepare a minimum of four separate gels at different acrylamide concentrations.

   A typical range of concentrations is from 5% to 12.5% (e.g., 5%, 7.5%, 10%, 12.5% acrylamide). As with SDS-PAGE, typical gel thickness ranges from 0.75 to 1.5 mm. The 0.75-mm-thick gels are recommended because they offer a combination of fast staining and high resolution.

3. Mix protein sample of interest 1:1 with 2× Tris/glycerol sample buffer to attain a 1 to 2 µg/µl final concentration. Also prepare native protein standards. Remove comb, rinse wells, and load 10 to 20 µl per well for Coomassie brilliant blue staining, and 1 to 2 µl for silver staining.

   Some proteins must be dissolved in 50 mM NaCl or water to become fully solubilized prior to mixing with the sample buffer (Sigma, 1986).

4. Assemble gel electrophoresis unit, using Tris/glycine electrophoresis buffer to fill both lower and upper buffer chambers. Connect power supply and conduct electrophoresis.

   Conditions for separation are the same as for discontinuous SDS-PAGE (i.e., 30 mA for 1.5-mm-thick gels, 15 mA for 0.75-mm-thick gels). For standard-size gels the separation takes 4 to 5 hr; for minigels, 1 to 2 hr is required. Alternatively, standard gels can be run at 4 to 6 mA/gel overnight.

5. After the bromphenol blue R_f marker has reached the bottom of the gel, fix and stain the proteins in the gels according to *APPENDIX 3*. Estimate relative mobilities of the proteins.

   An example of a stained gel is shown in Figure 6.5.1. A minimum of four gel concentrations is recommended. In Figure 6.5.1, Sigma native molecular weight standards were separated on 5%, 7.5%, 10%, and 12.5% acrylamide gels (5.1%, 7.7%, 10.3%, and 12.8% T, respectively).

6. Plot log R_f against gel concentration (% T) (Fig. 6.5.2). Determine the slope of K_r using linear regression.
7. Plot $-\log K_r$ of the curves from step 6 against log molecular weight of the standards (Fig. 6.5.3). Determine the slope using linear regression.
8. Estimate the size of the standards and unknowns from the generated curve (Ferguson plot).

   Use the curve generated by linear regression to estimate the predicted size of the standard for comparison to the actual size stated by the supplier. This indicates the accuracy of the curve. The $-\log K<D_r$ value (y) of the unknown is then used to predict the molecular weight (x).

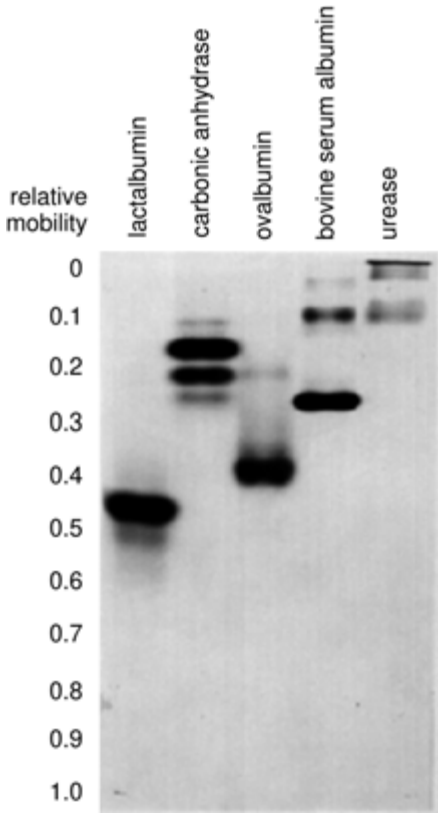

Figure 6.5.1 Separation of native protein standards under nondenaturing conditions by discontinuous polyacrylamide gel electrophoresis at 12.8% T. Approximately 20 μg protein was loaded per lane on a 1.5-mm-thick, 16-cm-long gel. The gel and samples were prepared according to the Alternate Protocol and were electrophoresed 16 hr at 6 mA. Proteins were stained with Coomassie blue.

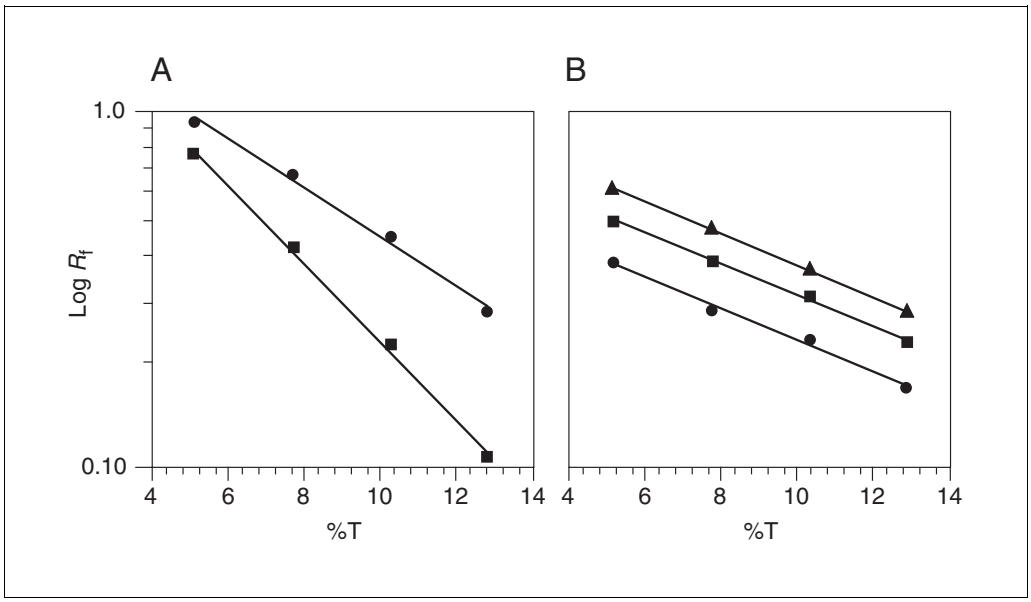

Figure 6.5.2 Effect of %T on the relative mobility of several native proteins. The relative mobility (R_f) of the standard proteins shown in Figure 6.5.1 was determined at four different gel concentrations and plotted as log R_f against %T. See text for details. (**A**) BSA monomer (squares) and dimer (circles); (**B**) carbonic anhydrase isoforms.

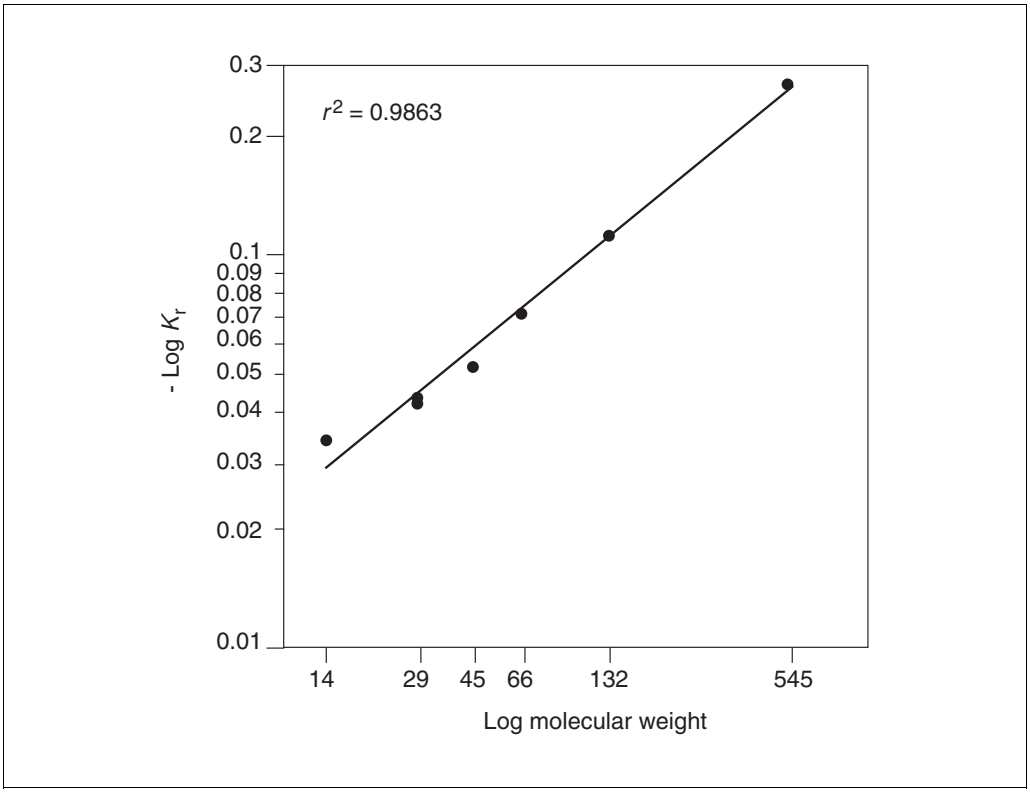

Figure 6.5.3 Native molecular weight standard curve. The –log slope of the line (K_r) from Figure 6.5.2 is plotted against log molecular weight of the standards.

REAGENTS AND SOLUTIONS

*Use Milli-Q-purified water or equivalent for the preparation of all buffers. For common stock solutions, see **APPENDIX 2A**; for suppliers, see **SUPPLIERS APPENDIX**.*

Acetic acid gel buffer, 4× (200 mM acetic acid, pH 3.7 to 5.6)

11.49 ml glacial acetic acid
Add to 500 ml H_2O
Adjust to pH 3.7 to 5.6 with 1 M NaOH
Add H_2O to 1000 ml
Store up to 1 month at 4°C

Glycine gel buffer, 4× (200 mM glycine, pH 8.6 to 10.6)

15.01 g glycine
Add to 500 ml H_2O
Adjust to pH 8.6 to 10.6 with 1 M NaOH
Add H_2O to 1000 ml
Store up to 1 month at 4°C

Phosphate gel buffer, 4× (400 mM sodium phosphate, pH 5.8 to 8.0)

55.2 g $NaH_2PO_4 \cdot H_2O$
Add to 500 ml H_2O
Adjust to pH 5.8 to 8.0 with 1 M NaOH
Add H_2O to 1000 ml
Store up to 1 month at 4°C

Tris gel buffer, 4× (200 mM Tris·Cl, pH 7.1 to 8.9)

24.23 g Tris base
Add to 500 ml H_2O
Adjust to pH 7.1 to 8.9 with 1 M HCl
Add H_2O to 1000 ml
Store up to 1 month at 4°C

Tris/glycerol sample buffer, 2×

25 ml 0.5 M Tris·Cl, pH 6.8 (*APPENDIX 2A*)
20 ml glycerol
1 mg bromphenol blue
Add H_2O to 100 ml and mix
Store in 1-ml aliquots up to 6 months at −70°C

Tris/glycine electrophoresis buffer

15.1 g Tris base
72.0 g glycine
H_2O to 5000 ml
Store up to 1 month at 4°C

COMMENTARY

Background Information

Under nondenaturing conditions, in which protein activity, native charge, and conformation are sustained, electrophoretic separation depends on many factors, including size, shape, and charge. Characteristics such as intrinsic molecular weight (i.e., in the absence of denaturation), the number of isoforms, and the presence of multimeric proteins can be determined with nondenaturing electrophoresis (often called native electrophoresis).

The most important application of nondenaturing electrophoresis is in the determination of native protein size (see Alternate Protocol). Ferguson plots (reviewed by Andrews, 1986) were first described for starch gels (Ferguson, 1964) and then for polyacrylamide gels (Hedrick and Smith, 1968). Ferguson plots are prepared by separating proteins under nondenaturing conditions at several different gel concentrations. As the acrylamide concentration (%T) is increased, the relative mobility (R_f) of the protein decreases. This is plotted as log relative mobility (on the *y* axis) versus %T (on the *x* axis) to produce a straight line. The slope of this line is referred to as the retardation coefficient (K_r) and measures how effectively a protein is slowed by the increase in %T. Large proteins will be retarded much more significantly than small proteins with increasing gel concentration, with the size of the protein being proportional to the slope of the curve. Once the K_r plots for several size standards are generated (Fig. 6.5.2), the K_r values are plotted against the molecular weight of the standard proteins using a log-log graph (Fig. 6.5.3). The retardation coefficient also depends on a large number of other variables including temperature, pH, buffer type, ionic strength, and %C (percent bisacrylamide cross-linker). All these factors should be kept constant for a given experiment.

In addition to estimated size, other types of information are available from the Ferguson plots (Rodbard and Chrambach, 1971; Andrews, 1986). For example, if two components differ in size but have the same charge per unit size (e.g., for a multimeric protein with identical subunits), curves similar to those illustrated by BSA monomer and dimer (Fig. 6.5.2A) will result. Note that when the curve is extrapolated back to 0% T, it is evident that the monomer and the dimer have similar free solution mobilities. Furthermore, as the acrylamide concentration is increased, the separation between the two also increases. However, if two proteins have similar sizes but different amounts of charge, the curves will be parallel on the log plot. This is illustrated by the carbonic anhydrase isoforms (Fig. 6.5.2B). In this example, optimal separation of the isoforms occurs at the lower concentrations of acrylamide as this is a log plot.

Further applications of nondenaturing electrophoresis include preparative purification. The pH of the gel determines the net charge on the protein. Below its isoelectric point (pI) a protein will have a net positive charge, whereas above its pI it will have a net negative charge.

In general, most proteins will be positively charged at pH 2.0 to 4.0; above pH 8.0, most proteins will be negatively charged. As these general guidelines imply, the majority of proteins have isoelectric points between pH 4.0 and 8.0. There are, however, many exceptions. A protein with a highly acidic isoelectric point (e.g., pepsin, with a pI of 2.2) will remain negatively charged at a pH down to its pI. Although a full range of pH options are given, extremes of pH (<4.0 and >9.0) should be avoided, if possible, to minimize denaturation or inactivation. By picking an appropriate electrophoresis pH, it is possible to ensure that the protein of interest will be either positively or negatively charged so that it can be selectively run into the gel, excluding a large proportion of contaminants that have the opposite or no charge. Furthermore, the pH conditions determine the mobility and can be adjusted to ensure a difference in mobility between the protein of interest and contaminants.

Continuous gel systems (see Basic Protocol) offer the most flexibility in terms of separation design. The pH can be tailored so that a given protein has a net positive, neutral, or negative charge. Depending on the polarity of the gel, the protein can then be excluded from or electrophoresed into the gel. Discontinuous gels have a fixed pH and gel polarity. For the nondenaturing Laemmli gel presented in the Alternate Protocol, the proteins of interest should have an isoelectric point of ≤7.0 in order to be negatively charged so that they move into the gel. Other more basic and more acidic discontinuous gel systems can be found in Hames (1990) and Schägger (1994).

Critical Parameters

The success of a gel separation under nondenaturing conditions depends on many factors, and two of the most important are protein solubility and isoelectric point. The protein must be soluble at the pH and the ionic strength of the gel, and it must be charged at that pH in order to move into the gel. If the protein experiences a pH below its isoelectric point, then it will have a net positive charge and will move to the negative electrode. Note that this is the reverse of typical SDS-PAGE. If the protein experiences a pH above its isoelectric point, it will have a net negative charge and will migrate to the positive electrode.

Solubility is a complex issue. Membrane-associated and other hydrophobic proteins are difficult to separate by nondenaturing electrophoresis (Schägger, 1994). Nonionic detergents at concentrations up to 1% and solubilizing reagents such as urea (4 to 8 M) can be used, but these reagents, especially urea, are likely to alter the protein's conformation and most likely the isoelectric point by exposing previously hidden charged groups. If detergent or urea must be included for solubilization, the minimum required to solubilize the protein should be used. Schägger (1994) lists several nonionic detergents suitable for solubilization. Among the more popular are octylglucoside and CHAPS. In general, detergents should be used near the critical micelle concentration (CMC; 0.001% to 1%, depending on the detergent).

The gel concentration has a dramatic effect on resolution and should be optimized in order to achieve the best separation and band sharpness. In general, increasing the %T will improve band sharpness.

Troubleshooting

Gel polymerization at acid pH can be problematic, and sodium sulfite is needed for efficient polymerization (Andrews, 1986). Both the ammonium persulfate and the sodium sulfite must be freshly made, and the highest quality reagents available should be used. Furthermore, the gel solutions should be at room temperature for effective polymerization.

If the protein does not enter the gel and no stained material is present at the well surface, try reversing the polarity of the electrode. If material concentrates at the top of the gel, try lowering the acrylamide concentration. Stained material at the top of the gel may also indicate poor solubilization, and increasing the ionic strength of the solubilization buffer or adding a small amount of urea and/or nonionic detergent may be required.

Anticipated Results

Proteins will resolve depending on their solubility and native charge at the chosen pH. Ideally, a distinct band representing the protein of interest will be visible. If the band is diffuse, then increasing the gel concentration or using a gradient gel will improve resolution. If the band is not visible, then the protein may be at its isoelectric point or may have moved out of the gel because it had the wrong charge. Continuous gel systems, although more versatile, will give lower resolution than discontinuous gels. Detergents or other solubilizing agents such as urea may be needed to fully solubilize and resolve the protein. Once the conditions that resolve the protein are determined, Ferguson plots will give indications of multiple

subunit structure, native size, and potential isoform relationships.

Time Considerations

Separations will be complete when the tracking dye or protein reaches the bottom of the gel. For minigels, this generally takes 1 to 2 hr, using 15 or 30 mA for 0.75- or 1.5-mm-thick gels, respectively. Standard-format gels require 4 to 5 hr at 15 or 30 mA for 0.75- or 1.5-mm-thick gels, respectively. Standard-format gels can also run overnight at 4 to 6 or 8 to 12 mA for 0.75- or 1.5-mm-thick gels, respectively.

Staining Proteins in Gels

Polyacrylamide gel electrophoresis (PAGE) is a powerful method for the resolution of protein mixtures according to the proteins' charge-to-mass ratio (nondenaturing-PAGE; *UNIT 6.5*), mass (SDS-PAGE; *UNIT 6.1*), isoelectric point (isoelectric focusing) or combinations of these properties (two-dimensional PAGE; *UNIT 6.4*). A number of protocols have been developed to visualize the separated protein bands following electrophoresis. In this unit, four different methods, which are widely used in cell biology laboratories, are described. These are: staining with the dye Coomassie blue (Basic Protocol 1 and Alternate Protocol 1), silver staining (Basic Protocol 2), fluorescent staining with SYPRO Ruby (Basic Protocol 3), and negative staining with zinc (Basic Protocol 4).

Staining with Coomassie blue (Basic Protocol 1) is a relatively simple and very popular method, albeit less sensitive than other procedures. A variation of this protocol, suitable for staining proteins in isoelectric focusing gels, is described under Alternate Protocol 1. Staining with silver (Basic Protocol 2) is probably the most sensitive method, although it is time-consuming and incompatible with some downstream applications (see Commentary). The remaining two methods (Basic Protocols 3 and 4) are more sensitive that Coomassie blue staining and recommended for downstream applications where protein fixation needs to be avoided (e.g., analysis of biological activity). Some of the protocols can be combined. For instance, some researchers prefer to stain gels first with Coomassie blue (Basic Protocol 1) or zinc (Basic Protocol 4) and, if higher sensitivity is necessary, subsequently with silver (Basic Protocol 2). Further details on the differences between the methods, as well as guidelines for their selection according to specific applications, are discussed in the Commentary.

In the following protocols, the volumes of solutions are indicated in "gel volumes." When staining slab mini-gels, 10 gel vol correspond to ~50 to 80 ml.

STAINING PROTEIN GELS WITH COOMASSIE BLUE

BASIC PROTOCOL 1

Coomassie brilliant blue R-250, a triphenylmethane anionic dye, binds avidly to almost all proteins in either native or denatured states and is widely used for detection of proteins in polyacrylamide gels. In this protocol, proteins separated by either nondenaturing- or SDS-PAGE (one- or two-dimensional) are fixed and stained by soaking the gel in a Coomassie blue staining solution; the unbound dye is subsequently removed by washing with destaining solution to yield blue protein bands on a clear background.

Materials

Polyacrylamide gel containing protein(s) of interest (see *UNIT 6.1*)
Coomassie blue staining solution (see recipe)
Destaining solution: 30% (v/v) methanol/10% (v/v) acetic acid in distilled water (store up to 4 months at room temperature)
Storage solution: 7% (v/v) acetic acid/5% (v/v) methanol in distilled water (store up to 4 months at room temperature)
Plastic container with lid (pipet tip containers are appropriate for staining mini-gels)
Platform shaker (optional)

CAUTION: Glacial acetic acid and methanol are volatile and toxic. The destaining and storage solutions should be prepared in a chemical fume hood, and gloves should be worn throughout the staining procedure.

Contributed by Esteban C. Dell'Angelica and Juan S. Bonifacino
Current Protocols in Cell Biology (2000) 6.6.1-6.6.14

NOTE: All steps should be performed at room temperature.

1. Remove polyacrylamide gel from electrophoresis assembly and place it in a plastic container with lid containing a large excess (~10 gel vol) of Coomassie blue staining solution.
2. Incubate with gentle agitation for ≥20 min for a gel ≤1 mm thick or ≥1 hr for a gel >1 mm thick.

   The use of a platform shaker is recommended. Most proteins are fixed due to the presence of methanol in the staining solution; gels can therefore be left in staining solution for many hours (i.e., overnight) without any adverse effect, unless the protein(s) of interest is very small (<5 kDa) and can be lost by diffusion due to incomplete fixation.
3. Remove the Coomassie blue staining solution and rinse the gel briefly with distilled water.

   The Coomassie blue staining solution can be reused several times.
4. Add ~10 gel vol of destaining solution and incubate with gentle agitation until the solution becomes as dark as the gel matrix.
5. Discard the destaining solution.
6. Repeat steps 4 and 5 several times until a clear background is obtained.

   Both the total amount of destaining solution and the destaining time can be reduced by placing a piece of adsorbent material with affinity for the Coomassie dye (e.g., Whatman 3MM filter paper) inside the container having the gel in destaining solution.

   NOTE: *Avoid excessive incubation of the gel with destaining solution as it can result in decreased sensitivity due to dissociation of protein-dye complexes.*
7. Add ~10 gel vol storage solution and incubate for 10 to 15 min with gentle agitation.

   At this point, the gel can be stored at 4°C for several months in a plastic container or sealed plastic bag containing storage solution. Alternatively, it can be soaked in 2% (v/v) glycerol for 15 to 30 min, placed onto Whatman 3MM filter paper, and subsequently dried on a vacuum system.

ALTERNATE PROTOCOL 1

STAINING PROTEIN GELS WITH COOMASSIE BLUE AFTER ISOELECTRIC FOCUSING

In polyacrylamide gel isoelectric focusing, proteins are resolved based on their isoelectric points on a pH gradient generated by a mixture of ampholytes. Many commercially available ampholytes bind Coomassie blue and, therefore, interfere with protein detection. To overcome this problem, the following procedure involves treatment with trichloroacetic acid (TCA) to fix proteins while removing ampholytes and uses $CuSO_4$ in the staining solution to help reduce the background (Righetti and Drysdale, 1974).

Additional Materials *(see also Basic Protocol 1)*

Polyacrylamide isoelectric focusing gel with protein(s) of interest (e.g., *UNITS 6.4 & 15.4*)
20% (w/v) TCA solution in water
IEF Coomassie blue stock solution (see recipe)
10% (w/v) $CuSO_4$ in distilled water (store for up to 4 months at room temperature)

CAUTION: TCA is extremely caustic. Protect eyes and wear gloves when preparing and handling TCA solutions.

1. Make fresh staining solution by mixing 90 ml of destaining solution, 10 ml of IEF Coomassie blue stock solution and 1 ml of 10% (w/v) $CuSO_4$ in distilled water.
2. Remove polyacrylamide gel from isoelectric focusing assembly and place it in a plastic container with lid containing 5 to 10 gel vol of 20% (w/v) TCA solution in water.
3. Incubate for 30 to 60 min with gentle agitation.

   The use of a platform shaker is recommended. In this step, proteins are selectively fixed while ampholytes are removed from the gel.
4. Remove the TCA solution and add ~10 gel vol destaining solution.

   Do not reuse the TCA solution; dispose of it following applicable safety regulations for chemical waste. In this step, the TCA is removed from the gel.
5. Incubate 15 min with gentle agitation.
6. Discard the destaining solution and add freshly prepared staining solution (from step 1).
7. Incubate with gentle agitation for ≥20 min for a gel ≤1 mm thick or ≥1 hr for a gel >1 mm thick.
8. Remove the staining solution and rinse the gel briefly with distilled water.

   Do not reuse the staining solution.
9. Destain the gel (see Basic Protocol 1, steps 4 to 7).

STAINING PROTEIN GELS WITH SILVER

BASIC PROTOCOL 2

Silver staining is based on the selective reduction of silver ions at sites of the gel that contain proteins and other macromolecules. The following protocol is adapted from that of Blum et al. (1987), and involves pretreatment of a fixed polyacrylamide gel with thiosulfate (step 6) followed by impregnation with silver nitrate (step 9) and color development with formaldehyde at a high pH (steps 12 and 13). Pretreatment with thiosulfate significantly increases the sensitivity and improves the contrast of protein staining. In addition, the presence of low concentrations of thiosulfate during color development reduces nonspecific staining of the gel surface. The procedure is applicable for both nondenaturing- (*UNIT 6.5*) and SDS-PAGE (one- or two-dimensional; *UNIT 6.1* and *UNIT 6.4*) and yields dark (brown to black) protein bands on a clear background.

Materials

Polyacrylamide gel containing protein(s) of interest (see *UNITS 6.1, 6.4 & 6.5*), either unfixed or fixed and stained with Coomassie blue (see Basic Protocol 1 and Alternate Protocol 1)
Deionized water (HPLC grade or Milli-Q)
50% (v/v) ethanol in deionized water
Fixative solution (see recipe)
Thiosulfate solution (see recipe)
Silver nitrate solution (see recipe)
Developer solution (see recipe)
50% (v/v) methanol/12% (v/v) acetic acid in deionized water
50% (v/v) methanol in water

continued

Plastic container with lid (pipet tip containers are appropriate for staining mini-gels)
Clean plastic containers (at least six; lids of pipet tip containers are appropriate for staining mini-gels)
Aluminum foil
Platform shaker (optional)

CAUTION: Glacial acetic acid and methanol are volatile and toxic; solutions containing these solvents should be prepared in a chemical fume hood and handled with care.

NOTE: All solutions should be prepared in deionized water (Milli-Q or HPLC grade). At all times wear gloves that have been rinsed extensively with distilled water. Handle the gel by using clean forceps having blunt tips or by touching the corners with clean, powder-free gloves. All steps should be performed at room temperature.

Fix the gel

1. Remove polyacrylamide gel from electrophoresis assembly and place it in a plastic container with lid containing a large excess (~10 gel vol) of fixative solution.

   Steps 1 and 2 are for unfixed gels only. If the polyacrylamide gel was previously fixed and/or stained with Coomassie blue (Basic Protocol 1 or Alternative Protocol 1), proceed directly to step 3.

2. Incubate for ≥30 min with gentle agitation.

   The use of a platform shaker is recommended.

Pretreat the gel

3. Transfer the gel to a clean plastic container having ~10 gel vol of 50% ethanol in deionized water. Incubate 20 min with gentle agitation.
4. Replace the solution with another ~10 gel vol of 50% (v/v) ethanol in deionized water. Incubate 20 min with gentle agitation. Repeat this step once (total of three pretreatment steps).

   The plastic container used in steps 3 and 4 can be reused in step 16. Discard the ethanol solution and rinse the container briefly with deionized water.

5. Transfer the gel to a clean plastic container having ~10 gel vol deionized water and incubate 5 to 10 min with gentle agitation.
6. Discard the water and add ~10 gel vol thiosulfate solution. Incubate for exactly 1 min with gentle agitation.

   Incubations longer than 1 min will result in increased background staining.

7. Tranfer the gel to a clean plastic container having ~10 gel vol deionized water and incubate exactly 20 sec.
8. Change the water in the container and incubate exactly 20 sec. Perform this step twice (for a total of three).

   The plastic container used in steps 7 and 8 can be reused in steps 10 and 11 but should first be rinsed thoroughly with deionized water.

Stain the gel

9. Transfer the gel to a clean plastic container containing 5 to 10 gel vol silver nitrate solution. Cover the container with aluminum foil and incubate 20 min with gentle agitation.

   Light exposure causes the reduction of silver ions and may therefore result in increased background staining.

10. Transfer the gel to a clean plastic container having ~10 gel vol deionized water and incubate exactly 20 sec.

11. Change the water in the container and incubate again exactly 20 sec.

The plastic container used in steps 10 and 11 can be reused in steps 14 and 15 but should first be rinsed with deionized water.

Develop the gel stain

12. Transfer the gel to a clean plastic container having ~10 gel vol developer solution.

13. Incubate with gentle agitation until the protein band(s) of interest becomes visible (or until the gel matrix begins to get too dark).

This step lasts a few minutes (≤10 min) and requires continuous visual inspection as the protein bands may develop rapidly, and long incubations may result in high background staining. Since some developing will still occur during steps 14 and 15, it is advisable to proceed to the next step as soon as the staining is judged to be optimal.

14. Transfer the gel to a clean plastic container having ~10 gel vol deionized water. Incubate 30 sec.

15. Change the water in the container and incubate an additional 30 sec.

16. Transfer the gel to a clean plastic container having ~10 gel vol 50% methanol/12% acetic acid in deionized water. Incubate 10 min with gentle agitation.

17. Remove the solution from the container and add ~10 gel vol of 50% methanol.

The gel can be stored in this solution for several months at 4°C. Alternatively, the gel can be rehydrated by soaking in water for 5 to 10 min, soaked in 2% (v/v) glycerol for another 15 to 30 min, placed onto Whatman 3MM filter paper, and then dried on a vacuum system.

FLUORESCENCE DETECTION OF PROTEINS IN GELS

BASIC PROTOCOL 3

In this method, proteins separated on polyacrylamide gels [either nondenaturing- (*UNIT 6.5*) or SDS-PAGE, one- or two-dimensional (*UNIT 6.1* or *UNIT 6.4*)] are incubated with SYPRO Ruby, a commercially available fluorescent compound that interacts specifically with proteins. Following incubation, protein bands can be readily visualized using standard 300-nm transillumination.

Materials

Polyacrylamide gel containing protein(s) of interest (see *UNIT 6.1*, *UNIT 6.4*, or *UNIT 6.5*)
SYPRO Ruby protein gel stain (Molecular Probes)
Distilled water

Plastic container with lid (pipet tip containers are appropriate for staining mini-gels)
Platform shaker (optional)
300-nm UV transilluminator
Photographic camera or CCD camera (optional)

CAUTION: The potential toxicity of the SYPRO Ruby dye, which comprises an organic component and ruthenium, has not been fully evaluated. Gloves should be worn throughout the staining procedure. For disposal, the stain solution should be poured through activated charcoal, and the dye adsorbed to activated charcoal destroyed in a chemical incinerator following local environmental regulations.

NOTE: Protect SYPRO Ruby protein gel stain from light. If the plastic container with lid used for staining is transparent, cover it completely with aluminum foil.

NOTE: All steps should be performed at room temperature.

1. Remove polyacrylamide gel from electrophoresis assembly and place it in a plastic container with lid containing a large excess (~10 gel vol) of SYPRO Ruby protein gel stain.
2. Incubate 3 hr with gentle agitation.

   The use of a platform shaker is recommended.
3. Remove the SYPRO Ruby protein gel stain and rinse the gel briefly with distilled water.

   Do not reuse the stain solution. Follow local recommendations for the disposal of potentially toxic organic compounds.
4. Add ~10 gel vol distilled water and incubate 10 min with gentle agitation.
5. Change the distilled water in the container and incubate another 10 min with gentle agitation.
6. Visualize protein bands by fluorescence on a 300-nm UV transillumination unit.

   Images can be acquired using a photographic camera with appropriate film (e.g., Polaroid 667 black-and-white print film) or a CCD camera.

   CAUTION: *Use UV-rated eye protection to avoid direct exposure of the eyes to the UV light.*

   At this point, the gel is ready for downstream applications (e.g., electroelution and immunoblotting).

BASIC PROTOCOL 4

REVERSIBLE PROTEIN STAINING WITH ZINC

In this method, protein bands separated on SDS-PAGE gels [one- or two-dimensional (*UNIT 6.1* or *UNIT 6.4*)] are visualized as clear spots on an opaque white background, the latter being generated by precipitation of SDS with zinc ions. This negative staining procedure is sensitive, fast, and completely reversible upon removal of zinc with a chelating agent.

Materials

Polyacrylamide gel containing protein(s) of interest (see *UNIT 6.1*)
GelCode E-Zinc Reversible Stain Kit (Pierce), containing:
  E-Zinc Stain
  E-Zinc Developer
  E-Zinc Eraser
Distilled water
Plastic container with lid (pipet tip containers are appropriate for staining mini-gels)
Platform shaker (optional)

NOTE: All steps should be performed at room temperature.

Stain the gel

1. Remove polyacrylamide gel from electrophoresis assembly and place it in a plastic container with lid containing ~10 gel vol E-Zinc Stain solution.
2. Incubate 10 min with gentle agitation.

   The use of a platform shaker is recommended.

3. Remove the E-Zinc Stain solution from the container and replace it with ~10 gel vol E-Zinc Developer solution.

   Do not reuse the stain solution.

4. Incubate 1 to 2 min with gentle agitation. Proceed to the next step as soon as the staining is judged to be optimal.

5. Remove the E-Zinc Developer solution from the container and replace it with ~10 gel vol distilled water.

   Do not reuse the developer solution.

Wash the gel

6. Incubate 1 min with gentle agitation.

7. Change the water in the container.

8. Visualize the protein bands by placing the polyacrylamide gel on a dark (black or blue) surface.

   The stained gel can be kept in water for several weeks at 4°C.

Solubilize the SDS/zinc precipitate (optional)

9. Incubate the gel with ~10 gel vol E-Zinc Eraser with gentle agitation until the gel matrix is completely clear (~5 to 10 min).

   These two steps involve solubilization of the SDS/zinc precipitate to completely destain the gel, thus allowing further analysis of the protein band(s) of interest.

10. Rinse the gel with distilled water.

    At this point, the gel is ready for downstream applications (e.g., electroelution, immunoblotting, etc.).

REAGENTS AND SOLUTIONS

*Use HPLC-grade or Milli-Q-purified water or equivalent in all recipes and protocol steps. For common stock solutions, see **APPENDIX 2A**; for suppliers, see **SUPPLIERS APPENDIX**.*

Coomassie blue staining solution

For 100 ml: Dissolve 0.1 g Coomassie brilliant blue R-250 in a mixture of 30 ml methanol and 20 ml water. Subsequently, add 40 ml of water and 10 ml of glacial acetic acid. Store for up to 4 months at room temperature.

CAUTION: *Glacial acetic acid and methanol are volatile and toxic and should be handled in a chemical fume hood.*

This solution is 0.1% (w/v) Coomassie brilliant blue R-250 in methanol/acetic acid/water (3:1:6 v/v/v).

Developer solution

Dissolve 6 g Na_2CO_3 in 98 ml water. Add 50 µl of 37% formaldehyde and 2 ml of thiosulfate solution (see recipe). Prepare fresh before use.

CAUTION: *Formaldehyde is toxic and carcinogenic. Wear gloves and handle the concentrated (37%) solution in a chemical hood.*

Fixative solution

Mix 50 ml of methanol with 12 ml glacial acetic acid and add water to 100 ml. Add 50 µl of 37% formaldehyde. Prepare fresh before use.

CAUTION: *Glacial acetic acid and methanol are volatile and toxic. Formaldehyde is toxic and carcinogenic. Wear gloves and prepare the solution in a chemical fume hood.*

IEF Coomassie blue stock solution

Dissolve 0.2% (w/v) Coomassie brilliant blue R-250 and 60% (v/v) methanol in water. Store for up to 4 months at room temperature.

Silver nitrate solution

Dissolve 0.2 g $AgNO_3$ in 100 ml water. Add 75 µl of 37% formaldehyde. Protect the solution from light. Prepare fresh before use.

CAUTION: *Formaldehyde is toxic and carcinogenic. Wear gloves and handle the concentrated (37%) solution in a chemical fume hood.*

Discard the solution if it becomes cloudy.

Thiosulfate solution

Dissolve 20 mg $Na_2SO_4 \cdot 5H_2O$ in 100 ml water. Prepare fresh before use.

COMMENTARY

Background Information

The first protocols developed for the visualization of proteins bands after electrophoresis in polyacrylamide or other gel matrices relied on the use of dyes with selective avidity for polypeptides. Among these dyes, which included amido black 10B and fast green FCF, the Coomassie blue dyes gave higher sensitivity (Wilson, 1979) and became routinely used. A large number of staining protocols using Coomassie brilliant blue R-250 as a dye have been published (see Neuhoff et al., 1985, and references therein). The protocol described in this unit (Basic Protocol 1) involves simultaneous protein fixation and staining in a solution containing the dye in methanol/acetic acid/water, followed by removal of the unbound dye by washing with methanol/acetic acid/water. This is the most commonly used protocol for protein staining in gels. Proposed variations to this procedure include using no methanol to retain small polypeptides (Schägger and von Jagow, 1987), decreasing the concentrations of both methanol and acetic acid to limit protein fixation (Rosenfeld et al., 1992), and using ion-pairing agents to reduce background (Choi et al., 1996). Protocols using a colloidal form of Coomassie brilliant blue G-250, which rival in sensitivity those using Coomassie brilliant blue R-250, have also been described (see for example: Neuhoff et al., 1985; DeSilva, 1995).

A dramatic increase in sensitivity was achieved with the introduction of protein staining methods based on the selective reduction of silver ions to form metallic silver images (Switzer et al., 1979). The method relies on the autocatalytic reduction of silver, a key phenomenon of the photographic process, and differences in reduction potential of silver at the sites occupied by macromolecules relative to that at the rest of the gel matrix. The differences in reduction potentials can be manipulated to obtain either a positive or negative image of protein bands. Positive silver staining protocols comprise the following stages: (1) fixation of proteins and elimination of interfering substances (e.g., amino acids, Tris, SDS), (2) sensitization with an agent to increase sensitivity and/or contrast, (3) impregnation with silver solution (silver nitrate, basic silver ammonia or silver-diamine complex), (4) controlled rinse to remove silver ions not associated with proteins, (5) image development, and (6) image development stopping (reviewed by Rabilloud et al., 1994). The procedure described in Basic Protocol 2 (Blum et al., 1987) involves sensitization with thiosulfate, impregnation with silver nitrate, and image development using a dilute formaldehyde solution at high pH. Small amounts of thiosulfate included in the developer solution help to keep the background low by complexing silver ions that otherwise could form spurious silver deposits in the gel matrix. This procedure is highly sensitive and compatible with virtually all types of PAGE systems. Unlike other silver staining protocols, which yield a mixture of positive and negative bands or different band colors, the images of the protein bands are rather uniform. A drawback of this and other silver staining methods is that they can also stain other macromolecules, namely DNA, RNA and bacterial lipopolysaccharides.

Procedures for the fluorescent staining of proteins in polyacrylamide gels include covalent modification with fluorescamine or fluorescein isothiocyanate, and noncovalent staining with the hydrophobic probes 1-anilinonaphthalene-8-sulfonic acid or nile red (see

Steinberg et al., 1996, and references therein). A family of fluorescent protein stain reagents, including SYPRO Orange, SYPRO Red, and SYPRO Ruby, has recently been introduced and reported to be highly sensitive and protein specific (Steinberg et al., 1996). These reagents detect protein-SDS complexes, rather than protein functional groups, and are compatible with most downstream applications. Known interferences are colored stains or prosthetic groups, Triton X-100, and the excess of SDS at the migration front. A simple protocol for protein staining with SYPRO Ruby, which is commercially available and said to be the most sensitive dye within the SYPRO family, is described in Basic Protocol 3.

A different group of protein staining methods for SDS-PAGE are based on the reversible formation of SDS precipitates, thus allowing visualization of protein bands as clear areas on an opaque background. Although SDS precipitation can be simply achieved by lowering the temperature of the gel to 0° to 4°C for a few hours, faster and more sensitive methods involve the formation of insoluble complexes with heavy metal salts such as copper (Garfin, 1990) or zinc (Fernández-Patron et al., 1995a). A protocol for rapid, reversible staining with zinc is described in Basic Protocol 4. The protocol uses a kit that is commercially available at a reasonable price. If cost is a major issue, however, the reader is referred to the protocol described by Fernández-Patron et al. (1995a).

Additional staining methods not discussed in this unit include radiolabeling with [^{35}S]thiourea and silver bromide (Wallace and Saluz, 1992), combined Coomassie blue/zinc staining (Fernández-Patron et al., 1995b) and mixed Evans blue/rhodamine-B staining (Na et al., 1994).

Critical Parameters

Comparison of staining procedures

None of the staining methods is optimal for all types of applications. The choice of the most appropriate method for a particular experiment will depend on a number of considerations, including: sensitivity, simplicity, duration, long-term documentation, quantitation, and downstream applications. The following guidelines are restricted to the procedures described in this unit, namely staining with Coomassie blue (Basic Protocol 1 and Alternate Protocol 1), silver (Basic Protocol 2), SYPRO Ruby (Basic Protocol 3) and zinc (Basic Protocol 4).

Sensitivity

Figure 6.6.1 shows a comparative experiment in which serial dilutions of protein standards were run on SDS-PAGE (*UNIT 6.1*) and subsequently stained following the four Basic Protocols described in this unit. Among the four methods, silver (Fig. 6.6.1B) and Coomassie blue staining (Fig. 6.6.1A) gave the highest and lowest sensitivity, respectively. The detection limit of fluorescent staining with SYPRO Ruby could be greatly enhanced by the integration effect of a CCD or photographic camera. Thus, while by direct observation (on a UV transillumination unit) SYPRO Ruby staining was significantly less sensitive than negative zinc staining, both methods gave comparable sensitivities upon the use of a CCD camera to integrate the signal of SYPRO Ruby-stained bands (Fig. 6.6.1C and D).

Simplicity

While staining with Coomassie blue, SYPRO Ruby, or zinc are relatively simple methods, silver staining involves a number of steps that need to be carefully controlled, most notably sensitization with thiosulfate (Basic Protocol 2, step 6), rinsing with water before and after silver impregnation (Basic Protocol 2, steps 7 to 8 and 10 to 11, respectively) and image development (Basic Protocol 2, step 13). In fact, the duration of the image development step critically influences the sensitivity of silver staining, thus resulting in experiment-to-experiment variations in band color intensity. Staining with SYPRO Ruby requires a UV transilluminator to visualize the protein bands and the careful disposal of this potentially toxic dye (see Basic Protocol 3).

Documentation

Gels stained with Coomassie blue, silver, or zinc can be stored at 4°C for several weeks without significant decrease in sensitivity. For long-term storage, gels stained with Coomassie blue, silver, or SYPRO Ruby can be equilibrated in 2% (w/v) glycerol and dried on a gel dryer, although in the case of SYPRO Ruby–stained gels this can result in decreased sensitivity. For photography or digital image acquisition, the blue bands of Coomassie blue-stained gels have less contrast than the dark brown/black bands of silver-stained gels, and SYPRO Ruby–stained gels require the use of an appropriate photographic film (e.g., Polaroid 667 black and white film) or a sensitive CCD camera. Negatively zinc-stained gels can

be problematic for photography or imaging on a CCD camera.

Quantitative analysis

Scanning densitometric analyses of protein bands from stained polyacrylamide gels have been used to determine the relative abundance of proteins in complex mixtures, the purity of protein samples, and even the stoichiometry of multisubunit protein complexes. These quantitative analyses are performed assuming identical staining properties of the different proteins in the sample (i.e., that their staining results in the same band intensity per protein mass unit). This assumption is not necessarily correct, especially for Coomassie blue or silver staining where band intensities are known to be influenced by the proteins' amino acid compositions. Another limitation is that measurements should be made only within a linear range. Staining with SYPRO dyes, which interact with the protein-SDS complex rather than protein functional groups, has been reported to give relatively less protein-to-protein variability and

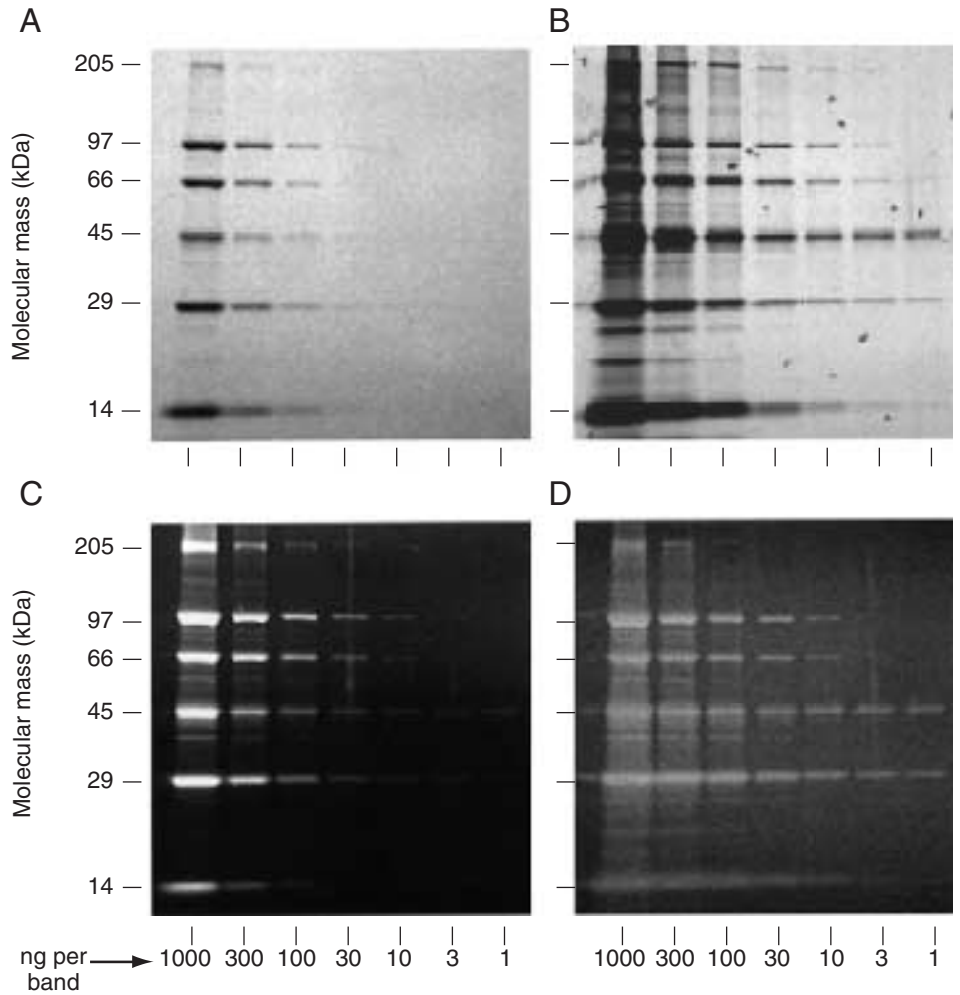

Figure 6.6.1 Comparison of the protein staining methods described in this unit. Serial dilutions of a mixture of rabbit muscle myosin (~205 kDa), rabbit muscle phosphorylase b (~97 kDa), bovine serum albumin (~66 kDa), chicken ovalbumin (~45 kDa), bovine erythrocyte carbonic anhydrase (~29 kDa) and chicken egg lysozyme (~14 kDa) were resolved by SDS-PAGE on a 4% to 20% T gradient gel and stained with: (**A**) Coomassie blue (Basic Protocol 1), (**B**) silver (Basic Protocol 2), (**C**) SYPRO Ruby (Basic Protocol 3), or (**D**) zinc (Basic Protocol 4). The amounts (in nanograms) per band loaded on each lane are indicated at the bottom of the figure. Images of stained gels were acquired on a Bio-Rad Gel Doc 1000 gel documentation system, using a standard UV (300 nm) transilluminator with (**A**, **B**, **D**) or without (**C**) a UV/white light conversion screen (Bio-Rad). The image shown in (**C**) was acquired using an integration time of 0.6 sec in order to optimize sensitivity.

Table 6.6.1 Troubleshooting Guide for Staining with Coomassie Blue (Basic Protocol 1)

Problem	Cause	Solution
No bands are detected		
Background is completely clear	Amount of protein(s) below detection limit	Check protein concentration in original sample. Stain the gel with silver (Basic Protocol 2).
Background is dark blue	Insufficient destaining	Continue to destain the gel until the background is clear (steps 4 to 6).
Protein bands are too faint		
	Staining solution is too old (i.e., methanol has evaporated)	Prepare new Coomassie blue staining solution.
	Insufficient staining time	Re-stain the gel using a longer staining time (step 2)
	Excessive destaining	Re-stain the gel monitoring band and background color during destaining (steps 4 to 6)
High background areas		
High background restricted to lanes with samples	Interfering compounds in the samples	Fix proteins with TCA before staining (see Alternate Protocol 1, steps 2 to 5).
Blue spots at the gel surface	Powder or dirt deposited on the surface during handling of the gel	Use clean, powder-free gloves. Remove powder or dirt by gently touching the surface with a powder-free glove.

Table 6.6.2 Troubleshooting Guide for Staining with Silver (Basic Protocol 2)

Problem	Cause	Solution
Protein bands are absent or too faint		
Background is clear	Amount of protein(s) below detection limit	Check protein concentration in original sample.
	Insufficient image development	Re-stain the gel extending the image development step (step 13) until background begins to get too dark.
	Formaldehyde is too old (white polymers in concentrated solution)	Use formaldehyde from a fresh concentrated solution.
	Silver nitrate solution is not fresh	Prepare fresh silver nitrate solution just before use. Discard the solution if it becomes cloudy.
Background is too dark	Gel has been overdeveloped	Monitor image development (step 13) continuously. Proceed to the next step as soon as the staining is considered satisfactory.
	Poor quality of reagents	Use reagents of the highest purity available. Prepare the solutions using HPLC-grade water.
Band images and background color develop too fast	Concentration of sodium thiosulfate ($Na_2S_2O_3$) in developer and thiosulfate solutions is not optimal	Increase sodium thiosulfate concentration in both solutions (e.g., 2- to 3-fold). Do not reuse the solutions.
Metallic silver is deposited on the gel surface	Powder or dirt deposited on the surface during gel handling	Handle the gels with clean forceps or gloves that have been rinsed with water.
	Metallic silver present in the silver nitrate solution	Protect the solution from light. Discard the solution if it gets cloudly.

Table 6.6.3 Troubleshooting Guide for Fluorescent Staining (Basic Protocol 3)

Problem	Cause	Solution
Protein bands are absent or too faint		
Clear background	Amount of protein(s) below detection limit	Check protein concentration in original sample. Stain the gel with silver (Basic Protocol 2).
	Direct eye visualization is not sensitive enough	Visualize the bands by using a CCD camera or by photography.
	Photographic or imaging conditions are not appropiate	Use sensitive photographic films (Polaroid 667 black-and-white or similar film) or appropiate CCD camera. Increase exposure (integration) time.
	Stain solution too old or inactivated by light	Use fresh stain solution. Protect it from the light. Do not reuse it.
	Protein(s) of interest pre-stained or containing colored prosthetic groups	If possible, remove prosthetic group(s) from proteins and avoid using pre-stained proteins. Otherwise, use an alternative staining method (e.g., Basic Protocol 2 or Basic Protocol 4).
Highly fluorescent background	Too much unbound dye remains in the gel matrix	Rinse the gel further with water (i.e., repeat steps 4 and 5).
	Gel is placed for visualization on an autofluorescent plastic surface (e.g., Saran Wrap)	Place the gel directly onto the surface of the UV transillumination unit.
	Gel is attached to a polyester surface with affinity for the dye (e.g., backing material of PhastGels)	Remove the gel from the polyester surface before visualization.
Heavy stain at the SDS-PAGE migration front	SYPRO dyes bind micellar SDS at the migration front	Allow the SDS front to migrate out of the gel.
Odd marks at the gel surface	Portions of the gel squeezed or have powder deposits due to handling	Handle the gel gently, wearing gloves that have been rinsed with water.

Table 6.6.4 Troubleshooting Guide for Staining with Zinc (Basic Protocol 4)

Problem	Cause	Solution
Protein bands are absent or too faint	Insufficient contrast due to the use of clear surfaces for visualization	Visualize the bands by placing the gel against a dark surface.
	Gel is overdeveloped	Destain the gel (steps 9 and 10) and stain again monitoring the appearance of bands against a dark surface.
	Amount of protein(s) below detection limit	Check protein concentration in original sample. Stain the gel with silver (Basic Protocol 2).
Blackground does not turn opaque	Stain solution or developer are too old	Use fresh stain and developer solutions (do not reuse them).

longer linear ranges than the other staining methods (Steinberg et al., 1996). Nevertheless, in order to check the validity of the measurements it is always advisable to load in the gel, together with the sample(s) to be quantitated, internal controls or a calibration curve with standard protein(s).

Downstream applications

Although PAGE was initially used only for analytical purposes, a large variety of microtechniques have been developed that use PAGE as a preparative step. Proteins separated by one- or two-dimensional PAGE can be treated in-gel with proteases (Rosenfeld et al., 1992) or cyanogen bromide (Córdoba et al., 1997) to obtain peptide fragments for microsequencing, electroeluted, or transferred to nitrocellulose or poly(vinylidene difluoride) (PVDF) membranes (*UNIT 6.2*) for further analysis such as immunodetection or Edman degradation. Proteins separated by nondenaturing PAGE (*UNIT 6.5*), or sometimes even by SDS-PAGE, can be analyzed in-gel for enzymatic or ligand-binding activity. Both the SYPRO Ruby and negative zinc staining methods are compatible with virtually all of these applications. A notable exception is activity analysis of proteins separated by nondenaturing PAGE which are sensitive to SDS, as both staining procedures require the presence of SDS for band visualization. On the other hand, Coomassie blue and silver gel staining involve protein fixation and, therefore, are compatible with fewer downstream applications. It is worth mentioning, however, that Coomassie-stained proteins can be efficiently electrotransferred to PVDF membranes for Edman degradation sequencing (U. Hellman, pers. commun.), although for immunoblot analysis the Coomassie blue dye is a known interference. Coomassie blue staining has been widely used to visualize protein bands destined for in-gel generation of peptides for microsequencing, mainly because these downstream applications have not been sensitive enough to allow analysis of protein bands below the detection limit of the dye. Recent methodological improvements, however, have made it possible to obtain sequence information from as little as 5 ng of protein from polyacrylamide gels stained with silver (Wilm et al., 1996).

Troubleshooting

Tables 6.6.1 to 6.6.4 summarize common problems that may arise during staining of proteins in polyacrylamide gels. Before using any of the methods to analyze a "real" sample, it is advisable to test the method first on a gel containing known amounts of standard proteins (e.g., see Fig. 6.6.1).

Anticipated Results

The protocols described in this unit should allow detection of submicrogram amounts of protein separated by PAGE as exemplified by Figure 6.6.1.

Time Considerations

By far, negative staining with zinc is the fastest method among the ones described in this unit. Images can be obtained within 20 min after the polyacrylamide gel is removed from the electrophoresis unit. Silver staining requires 30 min for fixation and another ~2.5 hr to complete the procedure. Both the Coomassie blue and SYPRO Ruby procedures require ~3.5 hr for obtaining optimal protein-to-background staining ratio. Suboptimal staining with SYPRO Ruby can be obtained by incubating the gel with stain solution for 60 to 90 min and skipping the subsequent washing steps (Basic Protocol 3, steps 4 and 5). In the case of Coomassie blue staining, binding of the dye to proteins is a fast process that depends mainly on its rate of diffusion into the gel matrix (Hitchman and Ekstrom, 1994). Removal of the unbound Coomassie dye from the gel, which also relies on diffusion, can be accelerated by placing an adsorbent material with affinity for the dye (e.g., Whatman 3MM filter paper) into the destaining solution with the gel or by increasing the temperature of destaining (e.g., to 37°C). In both cases, however, caution should be taken to avoid excessive destaining that could decrease sensitivity.

Agarose Gel Electrophoresis of Proteins

This unit describes the use of agarose gel as a matrix for the electrophoresis of proteins. Although agarose is widely used as a material for molecular sieving, it is not often used for the electrophoresis of proteins. When it is used for this purpose, it is generally employed for the electrophoresis of very large proteins. In other electrophoresis procedures it is part of a composite polyacrylamide/agarose system. The system described below utilizes agarose alone as the gel matrix. As with acrylamide gels, the proteins thus separated may be transferred to a membrane (immunoblotting) for further analysis, or the proteins may be identified directly in the gel using stains or labeled antibodies. A particular advantage of the method described in the Basic Protocol is the preparation of the gel in a horizontal electrophoresis bed which saves time and eliminates many of the difficulties commonly encountered in the preparation of acrylamide or composite gels in a vertical preparation apparatus.

These protocols describe methods for the separation and identification of von Willebrand factor (vWF), an extremely large plasma protein that is comprised of multimers ranging from 850,000 to 20,000,000 Da. The methods can be applied to other mixtures containing large proteins, multimeric proteins, and other large protein complexes such as fibrinogen and fibrin complexes (Shainoff, 1991). While the use of an SDS buffer system allows separation of proteins on the basis of size, nondenatured proteins can be separated in "native" agarose gels if their charge and configuration allow for satisfactory partitioning. Von Willebrand factor multimers are stable in SDS due to their disulfide linkages, and the protocols below utilize SDS. The agarose gel electrophoresis and blotting with immunodetection procedure (see Basic Protocol) utilizes identification of protein by a specific antibody followed by chemiluminescent detection methods. Major advantages of this method include the technical ease of preparing the gel, increased sensitivity, and a much shorter turn-around time than in-gel antibody analysis (see Alternate Protocol). It also eliminates the use of radioactive isotopes**.** In addition, the primary and secondary antibodies can be easily removed and the membrane (PVDF) probed again with a different detection antibody. This allows the laboratory the opportunity to detect a second protein or antigenic site on the same protein and also a "second chance" to correct an omission in the procedure, especially for samples in limited supply (*UNIT 6.2*); however, the immunoblotting step of such large proteins must be done with care in order to assure the adequate transfer of the largest proteins. The Alternate Protocol uses direct identification of the protein in the gel by a specific radiolabeled antibody, eliminating the immunoblotting step, but sacrificing sensitivity.

AGAROSE GEL ELECTROPHORESIS AND BLOTTING WITH IMMUNODETECTION

BASIC PROTOCOL

The following is a method for separating a complex mixture of human plasma proteins by continuous SDS horizontal (submerged) agarose gel electrophoresis. The very large multimers of circulating plasma von Willebrand factor (or more highly purified preparations of this protein) are identified using a specific antibody and visualized using a chemiluminescent reagent. This protocol utilizes a 20×25–cm horizontal gel apparatus. Dry agarose is weighed, mixed with electrophoresis buffer, and melted in a hot water bath. The agarose is allowed to partially cool, then is poured into a horizontal casting frame with a Teflon comb in place, and allowed to solidify. The gel is covered with 1 to 2 mm cold electrophoresis buffer and the comb is carefully removed. Prepared samples containing the proteins of interest are diluted with sample buffer and loaded into wells. Electrophoresis is carried out for 3 to 6 hours at 4°C. The gel is placed into a vertical tank transfer

Current Protocols in Cell Biology (2002) 6.7.1-6.7.13

apparatus (*UNIT 6.2*), and the proteins are transferred overnight onto an immobilization matrix (PVDF membrane). The membrane is blocked and probed with a polyclonal primary antibody specific for the antigen of interest and, after washing, a conjugated secondary antibody is introduced. After incubation the membrane is washed again, and the protein bands of interest are illuminated with a chemiluminescent detection system.

Materials

SeaKem HGT(P) agarose (Bio Whittaker or equivalent)
1× electrophoresis buffer, 4°C (see recipe)
Protein samples
2× sample buffer (see recipe)
0.25× transfer buffer without methanol (see recipe)
Blocking buffer (*UNIT 6.2*) containing 5% (w/v) nonfat dry milk, fresh
Antibodies:
  Primary: rabbit anti-vWF (Dako)
  Secondary: donkey horseradish peroxidase–linked anti-rabbit Ig (Amersham Pharmacia)
ECL Western Blotting Analysis system (Amersham Pharmacia)

Aluminum foil
Boiling waterbath (optional)
Horizon 20-25 horizontal electrophoresis apparatus (Life Technologies) or equivalent
Teflon comb (e.g., 1 × 9–mm, 20-well)
Pipet with fine tip or equivalent
0.45-µm Immobilon-P polyvinylidene fluoride (PVDF) membrane (Millipore)
Additional reagents and equipment for protein transfer to membranes and immunoblotting (*UNIT 6.2*)

Cast agarose gels

1. Weigh 1.2 g SeaKem HGT(P) agarose and transfer to a 250-ml flask containing 200 ml of 1× electrophoresis buffer. Add a Teflon-coated magnetic stir bar and tightly cover the flask with aluminum foil.

2. Heat in a boiling water bath, with slow mixing to avoid bubbles, until clear. Alternatively, microwave until boiling

   CAUTION: *Whenever a solution is heated in a microwave the chance of superheating ("boil up") is always present. Protective gloves, gown, and eyewear should be worn at all times.*

3. Assemble Horizon 20-25 horizontal electrophoresis apparatus or equivalent according to manufacturer's recommendations.

   The wedge shaped casting dams of the Horizon (Life Technologies) horizontal apparatus are easily placed in backwards, resulting in leaking of liquid agarose. Care should be exercised so that the dams form a perpendicular angle with the UVT tray.

4. Cool agarose to 55° to 60°C and pour the molten agarose into the electrophoresis apparatus to a depth of 4 mm.

   It is often helpful to prewarm the electrophoresis apparatus with warm water or in an oven to avoid cooling the agarose and causing the agarose to solidify unevenly.

5. Carefully insert the desired (e.g., 1 × 9–mm, 20-well) Teflon comb with care to avoid bubbles.

Removing the comb while the agarose is still in a molten state and then reinserting often eliminates the formation of bubbles under the teeth of the comb.

6. After the agarose has solidified, place the apparatus at 4°C and allow the agarose to age 20 to 30 minutes.

   The electrophoresis is to be carried out at 4°C. The apparatus may either be placed in a cold room, the electrophoresis buffer can be circulated through a refrigeration unit, or the apparatus can be packed in wet ice.

7. Overlay the solidified gel with 2 to 3 mm electrophoresis buffer, 4° C.

8. Remove the sample comb by lifting vertically in one smooth motion.

   It is helpful to hold the gel down with the gloved fingers of the other hand to keep the gel from being pulled up when the comb is removed.

Prepare and load sample

9. Dilute the protein samples to twice the desired concentration using distilled water. Immediately add the diluted sample to an equal volume of 2× sample buffer.

10. Load a sample volume of 10 to 15 µl into the bottom of each sample well using a pipet with a fine tip or equivalent.

    Prior to sample loading examine each sample well to ascertain that air bubbles are not trapped in the well.

Electrophorese gel (also see UNIT 6.1)

11. Run samples into the gel matrix at a constant current of 25 mA for ~30 min or until the sample dye has completely entered the gel.

12. Pause the electrophoresis and decrease the level of the electrophoresis buffer to ~1 mm above the upper surface of the gel. Increase the constant current to 50 mA and run for an additional 3 to 4 hr, or until the marker dye has migrated at least 6 to 7 cm.

Blotting the gel

13. Perform immunoblotting to a 0.45-µm Immobilon-P polyvinylidene fluoride (PVDF) membrane in a tank transfer system as described (*UNIT 6.2*), with the exception of the following conditions:

    a. Electrophoretically transfer at a constant current of 100 mA at 4°C overnight.
    b. Use 0.25× transfer buffer without methanol.
    c. Use blocking buffer containing 5% (w/v) nonfat dry milk.

Immunodetect protein

14. Perform immunoprobing with directly conjugated secondary antibody as described (*UNIT 6.2*), except with the following variations which are specific for immunodetection of von Willebrand Factor protein:

    a. Dilute primary antibody, rabbit anti-vWF, to a concentration of 1:4000.
    b. Dilute secondary antibody, donkey horseradish peroxidase–linked anti-rabbit Ig, to a concentration of 1:2000.

Visualization

15. Visualize von Willebrand factor protein on the PVDF membrane by meticulously following the recommendations enclosed in the ECL Western Blotting Analysis system.

Visualization with Luminescent Substrates is discussed in UNIT 6.2. To determine the optimal concentration of antibody, run a preliminary gel followed by immunoblotting. Cut the blot into several vertical test strips, each containing 1 to 2 lanes. Use the supplier's recommended concentration of antibody as a starting point and process the test strips with 3- to 10- to 30-fold increased and decreased antibody concentrations in separate containers.

ALTERNATE PROTOCOL

AGARAOSE GEL ELECTROPHORESIS WITH IN-GEL ANTIBODY ANALYSIS

This alternative protocol describes a method for separating large plasma proteins using SDS agarose electrophoresis and visualizing the protein of interest directly in the gel with a ^{125}I-radiolabeled rabbit antibody, in this case, to human von Willebrand factor protein, and autoradiography (see also *UNIT 6.3*). The methodology applied to agarose electrophoresis of von Willebrand factor is outlined below. The gel preparation consists of mating two glass plates on a horizontal surface separated by a 0.5-mm spacer. A sheet of GelBond support film is fixed to the glass plate to provide support for the agarose. Agarose at a concentration of 1.35% (w/v) is poured between the glass plate and the spacer plate. After the gel is solidified, the apparatus is disassembled and 1.0 × 0.1–cm wells are punched into the gel. The gel is placed into a horizontal electrophoresis chamber, presoaked wicks are attached to the gel, and sample volumes of 8 µl are loaded. The prepared samples are electrophoresed until the sample dye has migrated 8 to 10 cm. The gel is immediately fixed with isopropanol/glacial acetic acid fixing solution. After the gel is washed, it is blocked with ethanolamine/BSA. The gel, after a second series of washes, is incubated with ^{125}I-labeled anti-vWF antibody for 10 to 24 hours at room temperature. After extensive washing and drying the gel is placed in a cassette with film and exposed 1 to 5 days.

Materials

In-gel sample buffer, fresh (see recipe)
Borate saline buffer (BSB; see recipe)
Sample
0.5% (w/v) bromphenol blue in H_2O
Isopropanol
Agarose gel buffer (see recipe)
SeaKem HGT(P) agarose (FMC/BioWhittaker Molecular)
Agarose running buffer (see recipe)
Fixing buffer (see recipe)
Blocking buffer, in-gel (see recipe)
^{125}I-labeled rabbit anti-human vWF polyclonal antibody (Dako #A0082): radiolabel using protocol of choice and immunopurify (Hoyer and Shainoff, 1980; also see *UNIT 7.10*)
2% (w/v) human IgG (see recipe)
High-salt wash buffer (see recipe)

12 × 75–mm polypropylene tube
12.5 × 26.0 × 0.3–cm glass plate (Amersham Pharamacia Biotech)
12.5 × 24.0–cm spacer plate with adherent 0.5-mm spacers (Amersham Pharmacia Biotech)
12.4 × 25.8–cm GelBond film (Amersham Pharmacia Biotech)
Flexiclamps (Amersham Pharmacia Biotech)
20-ml syringe
60°C oven
Aluminum foil
Gelman Delux electrophoresis chamber (Gelman Sciences) or equivalent

104 × 253–mm paper electrophoresis electrode wicks (Amersham Pharmacia Biotech)
Flattened no. 2 cork borer
Forceps, fine
Horizontal rotary mixer
Forced hot-air dryer (optional)
Kodak X-Omatic film cassette with Lanex screens and film

CAUTION: When working with radioactivity, take apptopriate precautions to avoid contamination of the experimenter and the surroundings. Carry out the experiment and dispose of wastes in an appropriately designated area, following the guidelines provided by your local radiations safety officer (also see *APPENDIX 1D*).

Prepare sample

1. Prepare 3 ml fresh in-gel sample buffer.
2. Label a 12 × 75–mm polypropylene tube for each sample to be assayed. Add 20 µl borate saline buffer (BSB), 120 µl sample buffer, and 10 µl sample into each tube.
3. Cover each tube, vortex gently, and incubate 2 hr at 37°C.
4. Add 8 µl of 0.5% bromphenol blue to each sample and mix gently.

Prepare agarose gel

5. Prepare a boiling water bath by placing approximately 50 ml distilled water in a 250-ml beaker and incubating on a hot plate with magnetic stirring capabilities.
6. Use isopropanol to clean the 12.5 × 26.0 × 0.3–cm glass plate and 12.5 × 24.0–cm spacer plate with its adherent 0.5–mm spacers. Dry with a lint-free tissue (e.g., Kimwipe).

   It is advisable, because of the fragile nature of this gel, to prepare sufficient materials to pour a gel in reserve in the eventuality that one is rendered unusable.

7. Place a few milliliters of distilled water on the glass plate and adhere the hydrophilic side of a 12.4 × 25.8–cm GelBond film. Express any trapped air or excess water with a lint-free tissue.
8. Mate the glass plate with the adherent GelBond film and the spacer plate. Clamp with two flexiclamps.

   The gel-forming sandwich should consist of the glass plate (the larger of the two plates) with an adherent piece of GelBond film (hydrophilic side to the glass plate) and the spacer plate with its adherent spacer bars placed on top of the GelBond (Fig. 6.7.1).

9. Place the clamped plates and a 20-ml syringe in a 60°C oven for ~10 minutes to equilibrate.
10. Measure 40 ml agarose gel buffer into a 50-ml Erlenmeyer flask and add a Teflon-coated magnetic stir bar. Pour 0.54 g SeaKem HGT(P) agarose into the flask, tightly cover with aluminum foil, and place the flask into the boiling water bath (step 5). Dissolve the agarose with constant stirring. After the solution becomes clear, continue boiling an additional 10 min.
11. Remove the heated glass plate assembly (gel-forming sandwich) and the 20-ml syringe from the oven. Quickly fill the heated syringe with 20 ml hot agarose, and holding the plate assembly at an ~75° angle, fill the narrow space in the plate assembly using a back and forth motion to prevent bubbles from being trapped in the gel.

   Use of a needle with the syringe is optional.

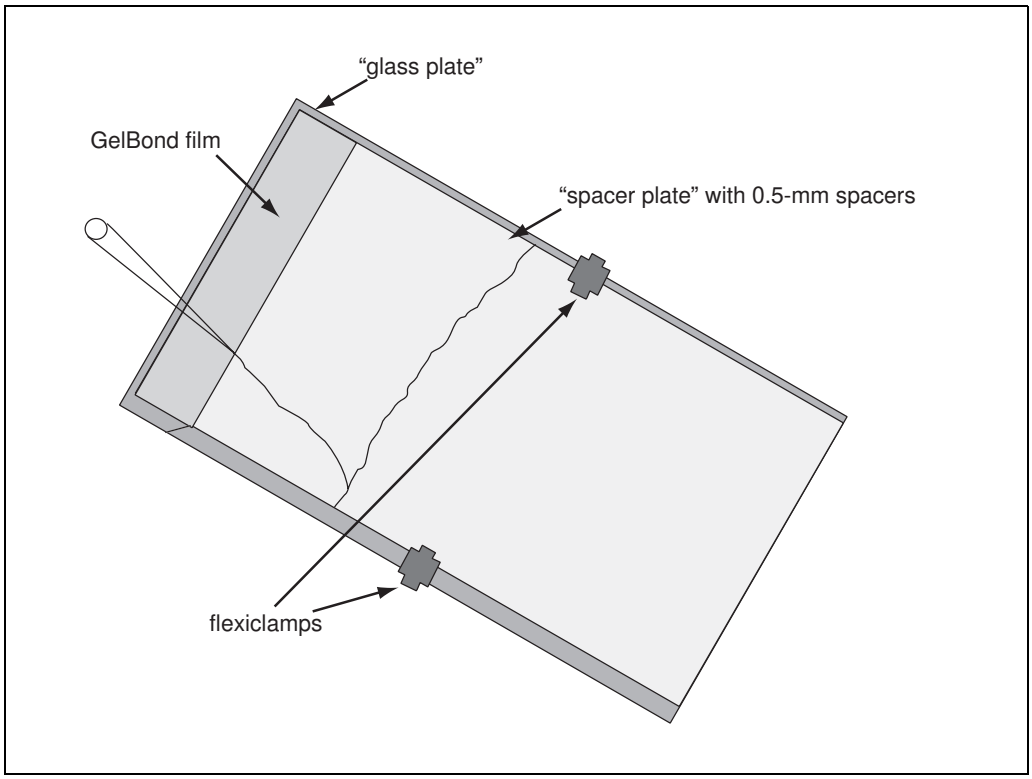

Figure 6.7.1 Diagram of casting gel in the Alternate Protocol. The layers include (back to front): the "glass plate" (the larger of the two plates), GelBond film (hydrophilic side adherent to the glass plate), and the "spacer plate" with attached 0.5-mm spacer bars. The agarose fills the narrow space between the GelBond and the "spacer plate."

12. After filling, lay the plate assembly flat and allow to cool and solidify ~45 min.

Electrophorese gel

13. Position the Gelman Delux electrophoresis chamber or equivalent electrophoresis apparatus on a flat surface and fill each electrode chamber with 400 to 450 ml agarose running buffer. Place 104 × 253–mm paper electrophoresis electrode wicks in each chamber to equilibrate in running buffer.

14. Remove the flexiclamps. Insert a thin spatula blade between the spacer plate and the gel attached to the glass plate. Carefully pry upward to separate the spacer plate. Examine the gel against a bright light for bubbles, thin areas, or areas of separation from the GelBond film.

    The agarose gel should now be attached to the GelBond support backing and be easily handled.

15. Punch the required number of 0.1 × 10-mm wells using a flattened no. 2 cork borer. Use a fine set of forceps to remove the agarose from the interior of each well.

    It is helpful to construct a template to place under the gel to facilitate punching the wells in an evenly spaced straight line. Also, it is necessary to work quickly because these gels are very thin and dry out rapidly.

16. Place a glass plate across the bridge on the electrophoresis chamber and place the gel attached to the GelBond on top of the plate. Affix the presoaked wicks (step 13) on each side of the gel so that there is continuity between the agarose running buffer in the electrode chambers and the gel.

17. Load 8 µl of sample into each well. Place the cover over the electrophoresis apparatus and connect the power supply.

18. Electrophorese at 25 V for ~30 min at room temperature to allow the samples to enter the gel matrix. Increase the power supply to 50 V and continue electrophoresis until the dye marker has migrated 8 to 10 cm from the wells (~3 to 5 hr).

Fix gel

21. Add 200 ml fixing buffer to a container appropriate to the size of the gel. Carefully remove the paper wicks and place the gel in fixing buffer 1 hr without agitation.

    The gel can also fix overnight in fixing buffer for a convenient stopping point.

22. Wash the gel 1 hr with 200 to 300 ml BSB with gentle mixing on a horizontal rotary mixer.

    A prerinse ~1 to 2 min before the wash with ~100 ml BSB is recommended

23. Prepare 250 ml fresh in-gel blocking buffer. Block gel 1 hr with gentle mixing.

24. Prerinse gel with ~100 ml BSB. Wash 1 hr with 200 to 300 ml BSB.

Immunodetect protein

25. Prepare a solution of dilute ^{125}I-labeled rabbit anti-human vWF polyclonal antibody in BSB to a concentration of ~2×10^6 cpm in a volume sufficient to cover the gel. Add 0.5 ml of 2% human IgG to the antibody solution.

    The majority of the gels can be covered with 50 to 70 ml.

    In an effort to minimize the volume of radioactive solutions, the authors' laboratory keeps a supply of dedicated plasticware to accommodate a wide variety of gel sizes. Strict laboratory precaution should be exercised in the preparation, handling, and disposal of radioactive materials.

26. Incubate the gel in the antibody solution at least 16 to 24 hr with gentle mixing.

27. Discard the antibody solution, adhering to standard radiation safety waste disposal protocols.

28. Wash the gel 1 hr in 200 ml high-salt wash buffer with gentle mixing using a horizontal rotary mixer.

29. Repeat the wash an additional three to four times.

    The washes should be monitored and continued until all excess ^{125}I is removed.

30. Wash 1 hr in 200 ml distilled water. Repeat once.

31. Dry the gel with a forced hot-air dryer directed on the gel, or air dry the gel.

Autoradiograph the gel

32. Place the gel in a Kodak X-Omatic film cassette with a Lanex screen. Under dark room conditions, place a piece of Kodak X-Omat film on the gel and then incubate the cassette at −70°C. Expose for an appropriate amount of time.

    Times vary from 1 to 5 days. It is helpful to secure the gel to the cassette with tape to keep it from changing position.

REAGENTS AND SOLUTIONS

*Use deionized or distilled water in all recipes and protocol steps. For common solutions, see **APPENDIX 2A**; for suppliers, see **SUPPLIERS APPENDIX**.*

Agarose gel buffer

0.05 M Na_2HP0_4
0.1% (w/v) SDS
Adjust pH to 7.0 with concentrated HCl
Filter and store up to 3 months at room temperature

Agarose running buffer

0.1 M Na_2HP0_4
0.1% (w/v) SDS
Adjust pH to 7.0 with concentrated HCl
Store up to 3 months at room temperature

Blocking buffer, in-gel

15 ml 16.6 M ethanolamine (1.0 M)
250 mg fatty-acid-free Fraction V BSA
Add H_2O to ~200 ml
Adjust pH to 8.0 with concentrated HCl
Add H_2O to 250 ml
Prepare fresh on the day of use

Borate saline buffer (BSB)

15.4 g boric acid (36 mM)
65.06 g NaCl (143 mM)
1.40 g NaOH (0.005 N)
Add 1.56 ml concentrated HCl to adjust pH to 7.83
Adjust volume to 7 liters with H_2O
Store up to 3 months at room temperature

Electrophoresis buffer, 1×

Dilute 10× TAE (see recipe) 1/10 in water. Add 10 ml of 20% (w/v) SDS (*APPENDIX 2A*) per 2 liters. Final concentrations are 40 mM Tris-acetate, 1 mM EDTA, and 0.1% (w/v) SDS. Final pH is 7.8 to 8.3. Store up to 1 week at room temperature.

The solution is also referred to as 1× TAE-SDS. Two liters are required for the application.

Fixing buffer

50 ml isopropanol (25%)
20 ml glacial acetic acid (10%)
130 ml H_2O
Prepare fresh on the day of use

High-salt wash buffer

56.78 g Na_2HPO_4 (0.1 M final)
233.6 g NaCl (1 M final)
Adjust pH to 7.0 with concentrated HCl
Add H_2O to 4 liters
Store up to 3 months at room temperature

Human IgG, 2%

2.0 g human IgG in 100 ml BSB (see recipe)
Store in aliquots up to 1 year at −20°C

In-gel sample buffer

Stock solution
0.01M Na_2HP0_4
Adjust pH to 7.0 with HCl
Filter and store up to 3 months at room temperature
Working solution
To 3 ml stock solution add:
20.64 mg iodoacetamide
37.5 mg SDS
Prepare fresh

Sample buffer, 2×

20 ml 10× TAE (see recipe)
1 ml 20% (w/v) SDS (*APPENDIX 2A*)
20 ml glycerol
0.2 g bromphenol blue
Add H_2O to 200 ml
Store up to 1 year at room temperature

TAE, 10×

48.4 g Tris base (400 mM)
20 ml 0.5M EDTA (10 mM; *APPENDIX 2A*)
Adjust pH to 7.8 with glacial acetic acid
Adjust volume to 1 liter
Store up to 1 year at room temperature

Transfer buffer without methanol, 0.25× and 10×

For a 10× solution
250 mM Tris·Cl, pH 8.3 (*APPENDIX 2A*)
1.92 M glycine
1.0% (w/v) SDS
Store up to 1 year at room temperature
This is the stock solution for transfer buffer and is also known as Tris/glycine/SDS (TG/SDS).

For a 0.25× solution
Dilute 10× transfer buffer 1/40 in distilled water. Final concentrations are 6.25 mM Tris·Cl, 48 mM glycine, and 0.025% (w/v) SDS. Final pH is 8.3. Store up to 1 week at room temperature.
Four liters are required for the application.

Table 6.7.1 Troubleshooting Guide for Agarose Electrophoresis and Immunoblotting

Problem	Possible cause	Solution
Agarose electrophoresis		
Run time too long or too short	Buffer concentration too high or too low	Verify buffer preparation
	Voltage too high or too low	Review and increase or decrease voltage or current settings
Band spreads into other lanes	Sample diffusing out of well or into surrounding gel	Minimize time for sample loading and start electrophoresis promptly
Samples leak underneath gel	Bottom of well torn when removing comb	Remove comb slowly
Bands migrate at different rates (visualized as "smiles," "frowns," and "sneers")	Gel cast unevenly	Use level to verify that the apparatus is level
	Uneven heat distribution	Decrease power settings. Cool buffer to 4°C. Circulate buffer.
Bands not in straight lines (visualized as a "wiggle")	Artifacts in wells	Flush wells with electrophoresis buffer
		Inspect wells for trapped air bubbles
Bromphenol turns yellow	pH change during electrophoresis	Verify pH of buffer
		Circulate buffer during run
Immunoblotting		
High background	Insufficient blocking	Increase concentration and/or time of blocking step
	Overdevelopment	Remove membrane from substrate after 1 min
	Protein contamination	Wash or replace fiber pads and clean apparatus
	Incomplete washing	Increase wash time and volume
		Review recipe, especially Tween 20
	Primary or secondary antibody too concentrated	Review supplier's recommendations
		Run test strips to optimize reactions
Weak signal or no reaction	Sample load insufficient	Increase amount of sample
	Low antibody specificity	Increase antibody concentration
	Antigen not transferred	Increase transfer time. Stain membrane for protein transfer.
	Conjugate not active	Mix more thoroughly

COMMENTARY

Background Information

The major use of agarose in protein analysis is its application as a matrix for molecular sieving; however, it is also widely used as a material that can be modified to form an affinity matrix for affinity chromatography. Because of its ability to separate proteins of very large size, it is also utilized for electrophoresis and preparation of very large proteins, ranging from several million to approximately fifty-thousand daltons. Agarose has the advantage of being nontoxic. In addition, it may be melted to allow recovery and further studies of the separated protein, and an excised band may be directly injected into an animal for immunization. Also, the use of native gels allows separation and recovery of nondenatured proteins for functional studies.

The electrophoresis procedure outlined above illustrates the ability of agarose to separate proteins of molecular weights that exceed

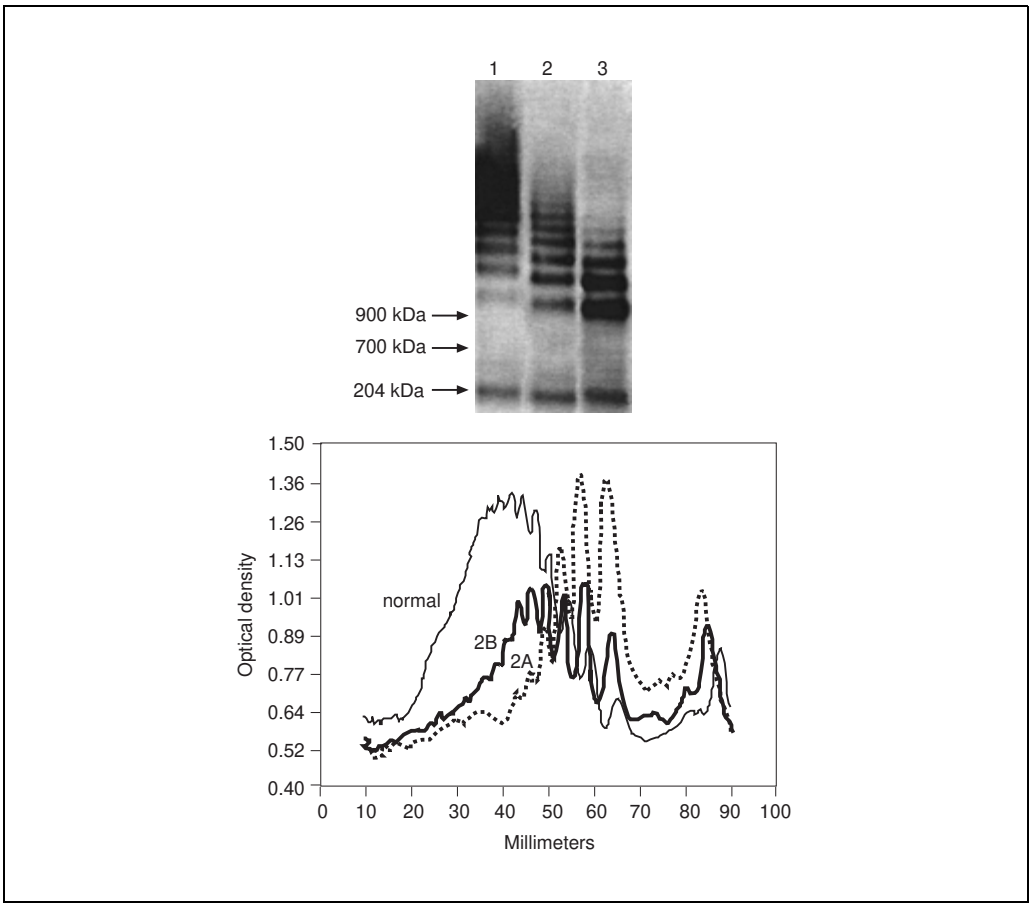

Figure 6.7.2 Luminograph of vWF multimers from normal plasma (lane 1), von Willebrand disease Type 2B plasma (lane 2), and von Willebrand disease Type 2A plasma (lane 3). A densitometric tracing is seen below. Reproduced with permission from Krizek and Rick (2000).

1×10^6 Da. For smaller proteins, higher concentrations of agarose (e.g., 3%) and shorter blotting times may be used. In instances where electroblotting cannot be carried out because of precipitation of the proteins during transfer due to separation from detergent, the proteins can be immobilized in the gel to prevent diffusion before immuno-identification. Immobilization of the proteins also allows for the use of sequential antibodies for identification of protein bands. Additionally, in-gel identification may also be important if there is uneven transfer of proteins due to dissimilar transfer characteristics. Immobilization of the proteins in the gel is accomplished with the use of an agarose gel that is modified by the addition of glycidol to yield a glyceryl agarose that contains aldehyde groups after oxidation by periodate. Proteins are covalently bound in the gel after electrophoresis by reaction of their amino groups with the aldehydes in the presence of the reducing agent, sodium cyanoborohydride. Further direct probing with antibodies can be carried out without the need for transfer to another support (Shainoff, 1993). Composite gels of agarose or glyoxal agarose have also been prepared to provide differing degrees of sieving (Peacock and Dingman, 1968; Shainoff, 1993).

Although few proteins are as large as vWF, the evaluation of von Willebrand factor multimers illustrates an important clinical application of the use of agarose as a medium for electrophoresis. Assessment for the presence of the largest multimers is physiologically important for the diagnosis of von Willebrand disease and for selection of the most appropriate treatment (Rick, 2001). The original procedure for this analysis (see Alternate Protocol, with minor modifications) included glycidol in the agarose which served to aid in the fixation of the protein bands while the further washing and antibody identification steps were accomplished (Hoyer and Shainoff, 1980). It was subsequently found that diffusion of protein bands was not a limiting factor with vWF, and this immobilization step was eliminated from the method.

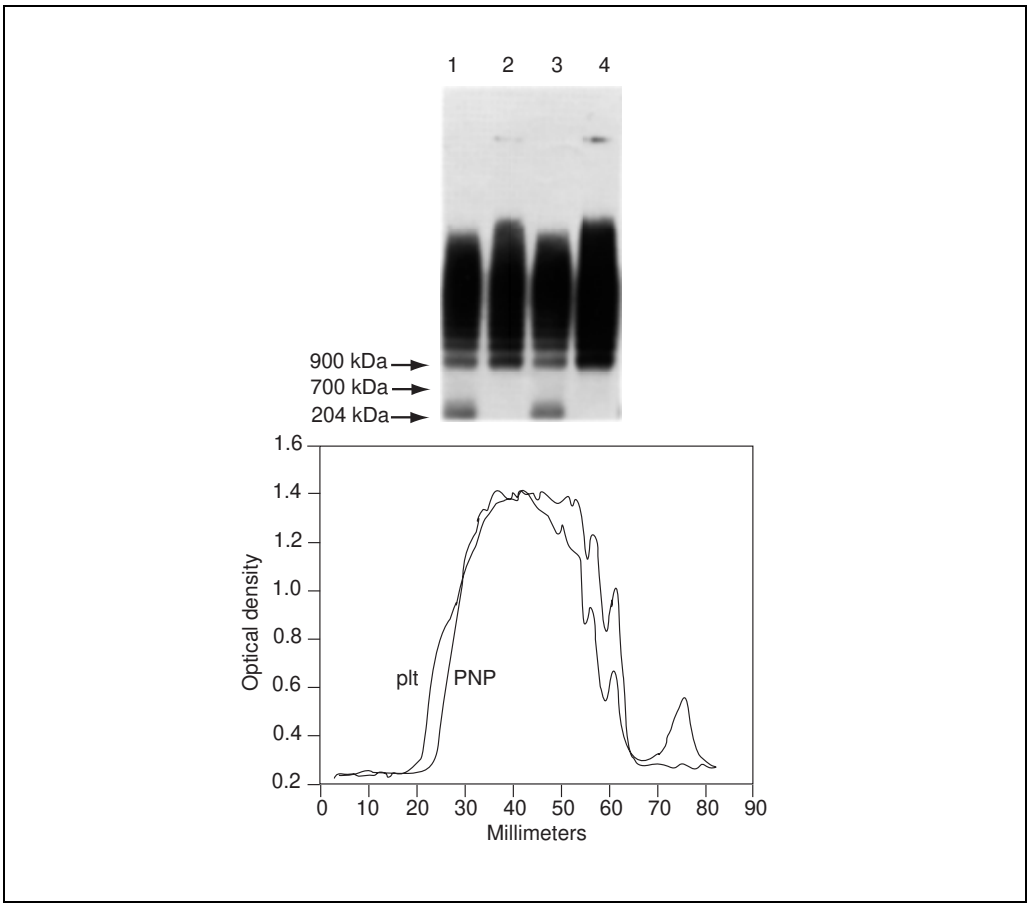

Figure 6.7.3 Luminograph of vWF multimers in pooled normal plasma (PNP; lanes 1 and 3) and vWF multimers extracted from platelets (plt; newly synthesized vWF; lanes 2 and 4). The densitometric tracing below shows the earlier "take-off" of the platelet vWF, indicating larger multimers. Adapted with permission from Krizek and Rick (2000).

Analysis of the distribution of von Willebrand factor multimers is also used to assess the function of an important protease that cleaves von Willebrand factor and decreases the prothrombotic "unusually high-molecular-weight" multimers of von Willebrand factor; these multimers are initially synthesized and secreted into the circulation, but are cleaved by the vWF protease (Krizek and Rick, 2001; Aronson, Krizek, and Rick, 2001).

Critical Parameters and Troubleshooting

It is important to maintain the temperature at 4°C during electrophoresis using the horizontal bed (see Basic Protocol). The blotting step must be carried out for a sufficient time to allow transfer of very high-molecular-weight proteins. Thorough washing after blocking buffer and antibody additions is important in both protocols. See Table 6.7.1 for troubleshooting agarose gel electrophoresis and immunoblotting.

Anticipated Results

The radiographs that result from the chemiluminescent and radioactive detection procedures show a wide distribution of multimer sizes of normal von Willebrand factor. In certain subtypes of von Willebrand disease (i.e., Type 2) there is a marked or modest decrease in the higher-molecular-weight multimers (Fig. 6.7.2). If newly synthesized von Willebrand factor is extracted from platelets, the unusually high-molecular-weight multimers are seen (Fig. 6.7.3). In samples that are incubated under conditions that activate the von Willebrand factor protease, a decrease in the high and intermediate sized multimers is seen (Fig. 6.7.4; Rick and Krizek, unpub. observ.).

Time Considerations

Both protocols should be started in the morning to allow sufficient time for electrophoresis. Horizontal electrophoresis and blotting can be completed within 48 hours: blotting is conveniently completed overnight and detec-

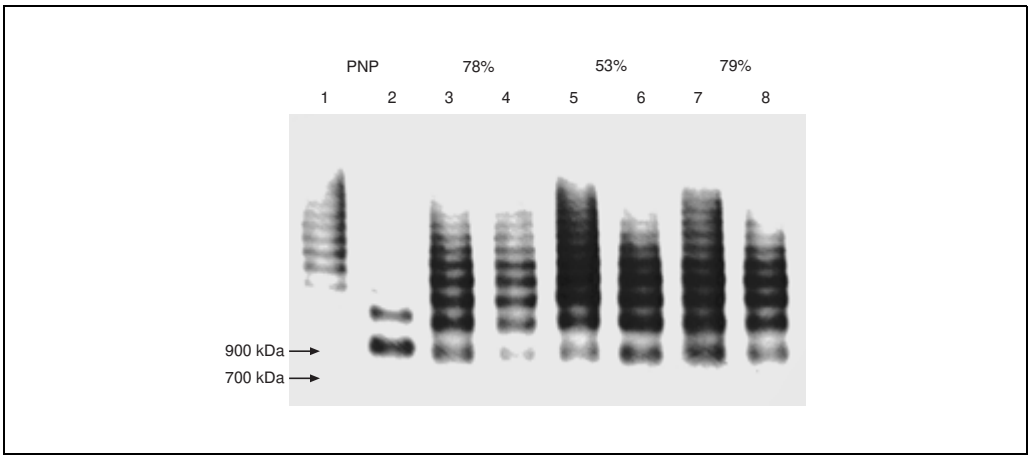

Figure 6.7.4 Luminograph of pooled normal plasma (PNP) showing normal vWF multimers (lane 1) and proteolysed multimers of normal vWF from PNP after exposure to conditions that activate the vWF protease (lane 2). Paired samples from patients with thrombotic thrombocytopenic purpura who have an inhibitor to the vWF protease are seen in lanes 3 to 8. Odd lanes contain plasma samples using conditions that do not activate the vWF protease, and even lanes contain the paired sample that was exposed to conditions that activate the protease. Very little proteolysis is observed in these patients' plasmas due to the presence of an inhibitor (even lanes). The numbers above the patient lanes indicate the retention of the high-molecular-weight multimers.

tion procedures can be completed the next day. The Alternate Protocol takes up to 5 or more days to obtain results, largely due to the time required for the incubation with antibody and development of the autoradiogram. Also, a radiolabeled antibody specific for the protein to be identified must be available.

Fluorescence Detection of Glycoproteins in Gels and on Electroblots

The co-translational and post-translational covalent attachment of oligosaccharides to proteins is a common cellular event in eukaryotes, regulated by a variety of glycosidases and glycosyltransferases (Beeley, 1985; Reuter and Gabius, 1999; *UNIT 15.2*). Glycosylation profiles are dynamic, changing during development, differentiation, and disease. Glycosylation of proteins is critical to the adhesiveness of microorganisms and cells, cellular growth control, cell migration, tissue differentiation, and inflammatory reactions. Differences in glycosylation profiles are often used as a "barometer" to assess disease states. With the advent of proteomics, genome-wide protein analysis, there is renewed interest in the rapid and sensitive identification of glycoproteins by methods that do not require degradation of the protein component of the macromolecule (Packer et al., 1999; Hirabayashi et al., 2001). Until recently, there have been relatively few methods available for the direct analysis of glycans on proteins transferred to membranes and most especially of glycans on proteins within polyacrylamide gels (Packer et al., 1999; Koketsu and Linhardt, 2000; Raju, 2000) . Such methods could readily be incorporated into integrated proteomics platforms that utilize automated gel stainers, image analysis workstations, robotic spot excision instruments, protein digestion work stations, and mass spectrometers (Patton, 2000a,b).

There are two principal approaches to the detection of glycoproteins in gels and on blots; reacting carbohydrate groups by periodate/Schiff's base (PAS) chemistry and noncovalent binding of specific carbohydrate epitopes using lectin-based detection systems. The PAS method involves oxidation of carbohydrate groups, followed by conjugation with a chromogenic substrate (acid fuchsin, Alcian Blue), a fluorescent substrate (dansyl hydrazine, 8-aminonaphthalene-1, 3,6-trisulfonate, Pro-Q Emerald dye), biotin hydrazide, or digoxigenin hydrazide. Signal is detected directly in the case of the chromogenic or fluorescent conjugates and indirectly using enzyme conjugates of antibodies for bound digoxigenin or enzyme conjugates of streptavidin for bound biotin. Lectins permit detection of certain structural subclasses of glycoproteins by similar methods to those used in standard immunoblotting applications. Typically, lectin conjugates of biotin along with enzyme conjugates of streptavidin or direct conjugates of lectin and enzyme are utilized along with chromogenic, fluorogenic, or chemiluminescent substrates. Just as in immunoblotting, the most popular enzymes used to detect lectin or streptavidin are alkaline phosphatase and horseradish peroxidase.

This unit describes periodate/Schiff's base and lectin methods for the detection of glycoproteins. The Pro-Q Emerald 300 glycoprotein detection method permits fluorescent direct detection of glycoproteins in gels (see Basic Protocol 1) or on blots (see Alternate Protocol) without the use of enzyme amplification systems. The method may also be used to detect lipopolysaccharides, constituents of the outer membrane surrounding gram-negative bacteria. The Pro-Q glycoprotein blot stain protocol for concanavalin A (see Basic Protocol 2) is suitable for the detection of glycoproteins containing α-mannopyranosyl and α-glucopyranosyl residues on blots using an alkaline phosphatase–based signal amplification system. Using different enzyme-lectin conjugates, such as alkaline phosphatase conjugates of wheat germ agglutinin or *Griffonia simpliifolia* lectin II (GS-II), the method can be adapted to the detection of other glycan structures present in glycoproteins.

BASIC PROTOCOL 1

FLUORESCENT DETECTION OF GLYCOPROTEINS IN POLYACRYLAMIDE GELS

Pro-Q Emerald 300 Glycoprotein Gel Stain Kit provides a robust method for differentially staining glycosylated and non-glycosylated proteins in the same gel. The technique combines the green fluorescent Pro-Q Emerald 300 glycoprotein stain with the orange-red fluorescent SYPRO Ruby total protein gel stain.

Pro-Q Emerald 300 glycoprotein stain reacts with periodate-oxidized carbohydrate groups, creating a bright green-fluorescent signal on glycoproteins. Using this stain allows detection of <1 ng glycoprotein/band, depending upon the nature and the degree of glycosylation, making it 100-fold more sensitive than the standard periodic acid–Schiff base method using acidic fuchsin dye (rosaniline). The green-fluorescent signal from the Pro-Q Emerald 300 stain can be visualized using a standard 300-nm UV (UV-B) illumination source. The Pro-Q Emerald 488 Glycoprotein Gel Stain Kit is quite similar to the Pro-Q Emerald 300 Glycoprotein Gel Stain Kit, but it is optimized for use with gel scanners equipped with 470- to 488-nm lasers. The Pro-Q Emerald dye staining method is more reliable than mobility-shift assays using glycosidases since even glycoproteins that are not susceptible to deglycosylation with specific enzymes may readily be identified as glycoproteins.

After detecting glycoproteins with Pro-Q Emerald 300 dye, total protein profiles may be detected using SYPRO Ruby protein gel stain. SYPRO Ruby protein gel stain interacts noncovalently with basic amino acid residues in proteins. The stain is capable of detecting <1 ng of protein/band, making it at least as sensitive as the best silver staining procedures available. The orange-red fluorescent signal from SYPRO Ruby protein gel stain can be visualized using a standard 300-nm UV (UV-B) illumination source, or alternatively may be excited using 470- to 488-nm laser, gas discharge, or xenon arc sources.

Materials

Protein sample of interest
Fix solution (see recipe)
Wash solution (see recipe)
Pro-Q Emerald 300 Glycoprotein Gel Stain Kit (Molecular Probes) containing:
- 50× Pro-Q Emerald 300 reagent, concentrate in DMF
- Pro-Q Emerald 300 dilution buffer
- Periodic acid (oxidizing reagent; see recipe)
- CandyCane glycoprotein molecular weight standards (see recipe), sufficient volume for approximately 20 gel lanes
- SYPRO Ruby protein gel stain

Deionized, high quality water
10% (v/v) methanol or ethanol, spectroscopy grade (optional)
7% (v/v) glacial acetic acid (optional)

Polystyrene staining dishes (e.g., a weighing boat for minigels or larger container for larger gels)
Orbital shaker
UV transilluminator
Photographic camera or CCD camera and appropriate filters

Additional reagents and equipment for SDS-polyacrylamide gel electrophoresis (*UNIT 6.1*)

Run gel

1. Prepare the protein samples of interest (e.g., crude protein isolates, cell lysates, serum, partially purified plasma membranes) for SDS-polyacrylamide gel electrophoresis.

   Typically, the protein sample is diluted to ~10 to 100 µg/ml with 2× sample buffer, heated for 4 to 5 min to 95°C, and 5 to 10 µl of diluted sample is then applied per gel lane for 8 × 10–cm gels. Larger gels require proportionally more material.

   For convenience, CandyCane glycoprotein molecular weight standards may also be applied to a lane or two. Typically, 2 µl of this standard is diluted in 6 µl of sample buffer and heated in the same manner as the samples to be characterized. These standards contain a mixture of glycosylated and non-glycosylated proteins ranging from 14 to 180 kDa in molecular weight. The standards serve as molecular weight markers and provide alternating bands as positive and negative controls for glycoprotein and total protein detection. Each protein is present at 0.5 mg/ml.

2. Separate proteins by SDS-polyacrylamide gel electrophoresis using standard methods (*UNIT 6.1*).

   The staining procedure is optimized for gels that are 0.5- to 1- mm thick.

Fix gel

3. After electrophoresis, fix the gel by immersing it in 75 to 100 ml of fix solution in a polystyrene staining dish and incubating with gentle agitation (e.g., on an orbital shaker at 50 rpm) for 45 min at room temperature.
4. Wash the gel by incubating it in 50 ml wash solution with gentle agitation for 10 min at room temperature. Repeat wash one additional time.
5. Oxidize the gel in 25 ml periodic acid solution with gentle agitation for 30 min at room temperature.
6. Wash the gel in 50 ml wash solution with gentle agitation for 5 to 10 min at room temperature. Repeat this washing step two additional times.

Stain gel for glycoproteins

7. Prepare fresh Pro-Q Emerald 300 staining solution by diluting the 50× Pro-Q Emerald 300 concentrate reagent 50-fold into Pro-Q Emerald 300 dilution buffer.

   For example, dilute 500 µl of 50× Pro-Q Emerald 300 reagent into 25 ml dilution buffer to make enough staining solution for one 8 × 10–cm gel.

8. Incubate the gel in subdued light in 25 ml of Pro-Q Emerald 300 staining solution (step 7) while gently agitating for 90 to 120 min.

   The signal can be seen after ~20 min and maximum sensitivity is reached at ~120 min. Staining overnight is not recommended.

9. Wash the gel with 50 ml wash solution for 15 min at room temperature. Repeat this wash one additional time. Do not leave the gel in wash solution for >2 hr, as the staining signal will start to decrease.
10. Visualize the stain using a standard UV transilluminator.

    The Pro-Q Emerald 300 stain has an excitation maximum at ~280 nm and an emission maximum near 530 nm. Stained glycoproteins can be visualized using a 300 nm UV-B transilluminator.

11. Document results before proceeding to the next step. Use a photographic camera or CCD camera and the appropriate filters to obtain the greatest sensitivity (see Fig. 6.8.1).

    Pro-Q Emerald dye signal will fade after SYPRO Ruby dye staining.

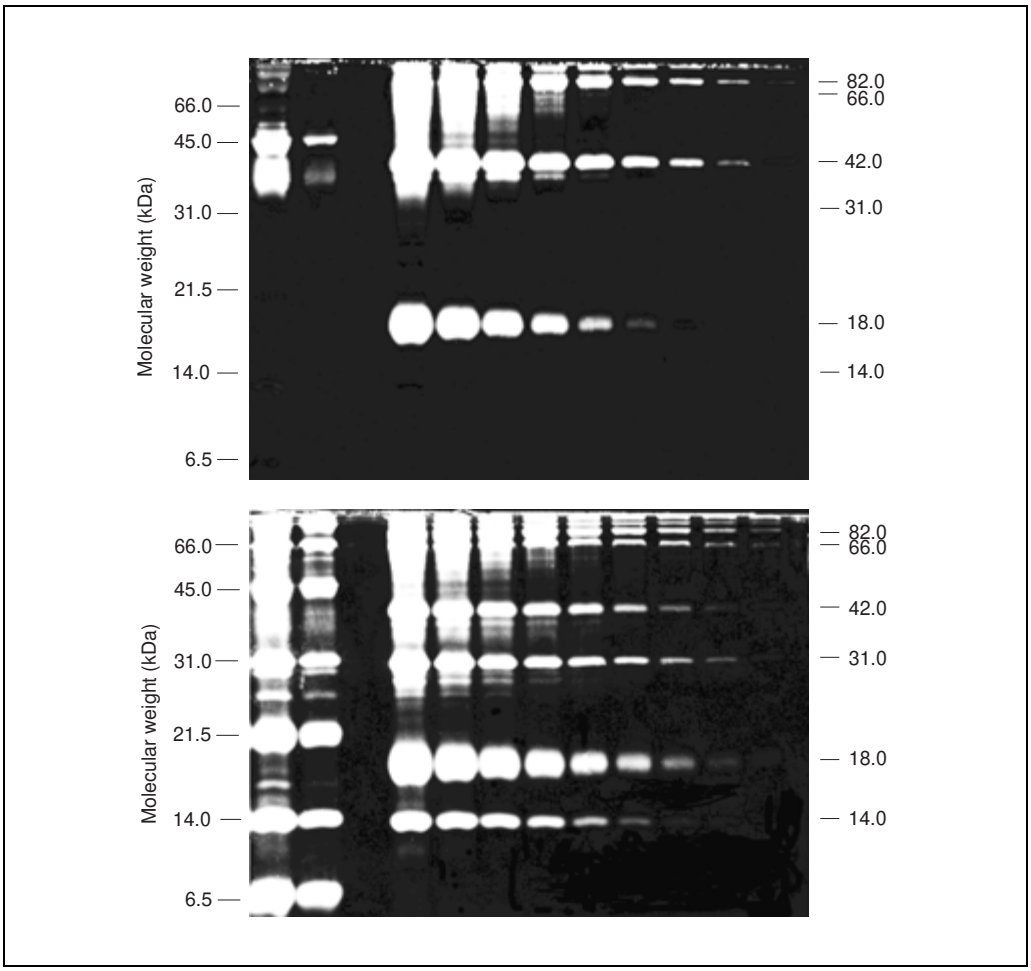

Figure 6.8.1 Sensitivity and specificity of glycoprotein detection in 13% SDS-polyacrylamide gels using Pro-Q Emerald 300 glycoprotein gel stain. (**A**) Detection of glycoproteins using Pro-Q Emerald 300 glycoprotein gel stain. (**B**) Detection of the total protein profile using SYPRO Ruby protein gel stain. Lanes 1 and 2, broad range molecular weight markers containing the 45-kDa glycoprotein ovalbumin, 1000 and 250 ng, respectively. Lane 3, blank. Lanes 4 to 12, CandyCane molecular-weight markers, a mixture of glycosylated and unglycosylated proteins (1000 to 3.9 ng, as two-fold serial dilutions). Gels were imaged using a Lumi-Imager F1 instrument (Roche Molecular Biochemicals). Both dyes were excited using the instrument's 300-nm UV-B transilluminator and images were captured using the instrument's cooled CCD camera. Pro-Q Emerald 300 dye signal was collected using the standard 520-nm band-pass emission filter. Gels were then stained with SYPRO Ruby protein gel stain and SYPRO Ruby dye signal was collected using the 600-nm band-pass emission filter provided with the instrument. Figure courtesy of Courtenay Hart, Molecular Probes.

Stain the gel for total protein

12. In order to counter-stain non-glycosylated proteins in the sample, pour the SYPRO Ruby protein gel staining solution into a small, clean plastic dish.

    For one or two standard-size mini-gels, use ~50 ml to 100 ml of staining solution; for larger gels, use 500 to 750 ml.

13. Place the gel into the staining solution and gently agitate (e.g., on an orbital shaker at 50 rpm) at room temperature.

    The staining time ranges from 90 min to 3 hr, depending upon the thickness and percentage of polyacrylamide in the gel. Specific staining can be seen in as little as 30 min. However, a minimum of 3 hr of staining is required for the maximum sensitivity and linearity. For convenience, gels may be left in the dye solution overnight or longer without over staining.

14. After staining, rinse the gel in water for 30 to 60 min to decrease background fluorescence.

    Alternatively, to further decrease background fluorescence, the gel can be washed in a mixture of 10% methanol (or ethanol) and 7% acetic acid for 30 min instead of water. The gel may be monitored periodically using UV illumination to determine the level of background fluorescence.

15. Visualize the stain using an appropriate method (see Fig. 6.8.1).

    The stained gel is best viewed on a standard 300-nm UV-B transilluminator, though stain will be visible using a 254-nm UV-C or 365-nm UV-A transilluminator. Gels may also be visualized using various laser scanners: 473-nm (SHG) laser, 488-nm argon-ion laser, or 532-nm (YAG) laser. Alternatively, use a xenon arc lamp, blue fluorescent light, or blue light–emitting diode (LED) source. Gels may be photographed by Polaroid or CCD camera. Use Polaroid 667 black-and-white print film and the SYPRO protein gel stain photographic filter (Molecular Probes).

FLUORESCENT DETECTION OF GLYCOPROTEINS ON ELECTROBLOT MEMBRANES

ALTERNATE PROTOCOL

Pro-Q Emerald 300 Glycoprotein Blot Stain Kit provides a robust method for differentially staining glycosylated and non-glycosylated proteins on the same electroblot. The technique combines the green fluorescent Pro-Q Emerald 300 glycoprotein stain with the orange-red fluorescent SYPRO Ruby total protein gel stain.

The Pro-Q Emerald 300 glycoprotein stain reacts with periodate-oxidized carbohydrate groups, creating a bright green-fluorescent signal on glycoproteins. Using this stain, allows detection of <1 ng glycoprotein/band, depending upon the nature and the degree of glycosylation, making it 100-fold more sensitive than the standard periodic acid–Schiff base method using acidic fuchsin dye (rosaniline). The green-fluorescent signal from Pro-Q Emerald 300 stain can be visualized using a standard 300-nm UV (UV-B) illumination source. The Pro-Q Emerald 488 Glycoprotein Blot Stain Kit is quite similar to the Pro-Q Emerald 300 Glycoprotein Gel Stain Kit, but is optimized for use with gel scanners equipped with 470- to 488-nm lasers. The staining method is more reliable than mobility-shift assays using glycosidases since even glycoproteins that are not susceptible to deglycosylation with specific enzymes may readily be identified as glycoproteins.

After detecting glycoproteins with Pro-Q Emerald 300 dye, total protein profiles may be detected using SYPRO Ruby protein blot stain. SYPRO Ruby protein blot stain interacts noncovalently with basic amino acid residues in proteins. The stain is capable of detecting <4 ng of protein/band, making it at least as sensitive as the best colloidal gold staining procedures available. The orange-red fluorescent signal from SYPRO Ruby protein blot stain can be visualized using a standard 300 nm UV (UV-B) illumination source or alternatively may be excited using 470- to 488-nm laser, gas discharge, or xenon arc sources.

Materials

Protein sample of interest
PVDF membrane
Fix solution (see recipe)
Wash solution (see recipe)
Pro-Q Emerald 300 Glycoprotein Blot Stain Kit (Molecular Probes) containing:
  50× Pro-Q Emerald 300 reagent, concentrate in DMF
  Pro-Q Emerald 300 dilution buffer
  Periodic acid (oxidizing solution; see recipe)

CandyCane glycoprotein molecular weight standards (see recipe), sufficient volume for ~20 gel lanes
SYPRO Ruby protein blot stain
Methanol, spectroscopy grade (optional)
Glacial acetic acid (optional)

95°C heat block
Polystyrene staining dishes (e.g., weighing boat for minigels or larger containers for larger gels)
Orbital shaker
UV epi-illuminator
Photographic camera or CCD camera and appropriate filters

Additional reagents and equipment for SDS-polyacrylamide gel electrophoresis (*UNIT 6.1*) and electroblotting (*UNIT 6.2*)

Run gel

1. Prepare the protein samples of interest (e.g., crude protein isolates, cell lysates, serum, partially purified plasma membranes) for SDS-polyacrylamide gel electrophoresis.

   Typically, the protein sample is diluted to ~10 to100 µg/ml with 2× sample buffer, heated for 4 to 5 min at 95°C, and then 5 to 10 µl of diluted sample is applied per gel lane for 8 × 10–cm gels. Larger gels require proportionally more material.

   For convenience, CandyCane glycoprotein molecular weight standards may also be applied to a lane or two. Typically, 2 µl of this standard is diluted in 6 µl of sample buffer and heated in the same manner as the samples to be characterized. These standards contain a mixture of glycosylated and non-glycosylated proteins ranging from 14 to 180 kDa in molecular weight. The standards serve as molecular weight markers and as alternate bands of positive and negative controls for glycoprotein and total protein detection. Each protein is present at 0.5 mg/ml.

2. Separate proteins by SDS-polyacrylamide gel electrophoresis using standard methods (*UNIT 6.1*).

   The procedure is optimized for gels that are 0.5- to 1-mm thick.

Prepare blot

3. After electrophoresis, transfer the proteins to PVDF membrane using standard electroblotting procedures (*UNIT 6.2*).

   The use of nitrocellulose membranes is not recommended.

4. After transfer, fix the blot by immersing in 25 ml fix solution and incubate with gentle agitation (e.g., on an orbital shaker at 50 rpm) for 45 min at room temperature.

5. Wash the blot by incubating in 25 ml wash solution with gentle agitation for 10 min, room temperature. Repeat this wash step one additional time.

6. Oxidize the blot in 25 ml periodic acid solution with gentle agitation for 30 min.

7. Wash the blot in 25 ml wash solution with gentle agitation for 5 to 10 min. Repeat this washing step two additional times.

Visualize glycoproteins

8. Prepare fresh Pro-Q Emerald 300 staining solution by diluting the 50× Pro-Q Emerald 300 concentrate reagent 50-fold into Pro-Q Emerald 300 dilution buffer.

   For example, dilute 500 µl of 50× Pro-Q Emerald 300 concentrate reagent into 25 ml of dilution buffer to make enough staining solution for one 8 × 10–cm gel.

9. Incubate the blot in the dark in 25 ml Pro-Q Emerald 300 staining solution (step 8) while gently agitating for 90 to 120 min, room temperature.

   The signal can be seen after ~20 min and maximum sensitivity is reached at ~120 min. Staining overnight is not recommended.

10. Wash the blot with 25 ml wash solution for 15 min at room temperature. Repeat this wash one additional time. Do not leave the blot in wash solution for >2 hr, as the staining signal will start to decrease.

11. Allow the membrane to air dry.

12. Visualize the stain using a standard 300-nm UV epi-illuminator.

    The Pro-Q Emerald 300 stain has an excitation maximum at ~280 nm and an emission maximum near 530 nm.

    A UV transilluminator may also be used to visualize the glycoproteins, but this results in poorer detection sensitivity.

13. Document results before proceeding to the next step using a photographic camera or CCD camera with the appropriate filters to obtain the greatest sensitivity.

    Pro-Q Emerald dye signal will fade after SYPRO Ruby dye staining.

Visualize total protein

14. In order to counter-stain non-glycosylated proteins in the sample, pour the SYPRO Ruby protein blot stain solution into a small, clean plastic dish.

    For one or two standard-size mini-blots, use ~50 ml to 100 ml of staining solution; for larger blots, use 500 to 750 ml.

15. Place the air-dried blot face down onto the surface of the staining solution and gently agitate (e.g., on an orbital shaker at 50 rpm) for 15 min at room temperature.

16. After staining, rinse the blot in four changes of water for 1 min each to decrease background fluorescence.

17. Allow blots to air dry and visualize the stain using an appropriate method.

    The stained blot is best viewed on a standard 300-nm UV epi-illuminator, though stain will be visible using a 254-nm UV-C or 365-nm UV-A epi-illuminator. Blots may also be visualized using various laser scanners: 473-nm (SHG) laser, 488-nm argon-ion laser, or 532-nm (YAG) laser. Alternatively, use a xenon arc lamp, blue fluorescent light, or blue light–emitting diode (LED) source.

    Blots may be photographed by Polaroid or CCD camera. Use Polaroid 667 black-and-white print film and the SYPRO protein gel stain photographic filter (Molecular Probes). Exposure times vary with the intensity of the illumination source; for an f-stop of 4.5, ~1 to 3 sec should be required.

FLUORESCENT DETECTION OF GLYCOPROTEINS CONTAINING TERMINAL α-MANNOPYRANOSYL AND α-GLUCOPYRANOSYL RESIDUES ON ELECTROBLOT MEMBRANES

BASIC PROTOCOL 2

Lectins are sugar-binding proteins of nonimmune origin capable of agglutinating cells or precipitating glycoconjugates (Beeley, 1985). The specific interactions between labeled lectins and oligosaccharides form the basis of glycoprotein detection after separation by gel electrophoresis and transfer to membranes by electroblotting. Concanavalin A is a tetrameric protein, with each subunit containing a carbohydrate-binding site, a calcium ion–binding site, and a manganese–ion binding site. Concanavalin A binds specifically

to α-D-mannopyranosyl and α-D-glucopyranosyl residues, with substitutions or modifications at the C-3, C-4, or C-6 positions of the ring structure leading to greatly diminished binding (Beeley, 1985).

The Pro-Q Glycoprotein Blot Stain Kit with concanavalin A utilizes alkaline phosphatase-conjugated concanavalin A along with the fluorogenic substrate DDAO phosphate [9H-(1,3-dichloro-9,9-dimethylacridin-2-one-7-yl) phosphate] to detect glycoproteins on nitrocellulose and poly(vinylidene difluoride) (PVDF) membranes. The detection procedure is similar to that of standard western (immuno)blotting. DDAO phosphate is rapidly converted to the long wavelength, red-fluorescent product, DDAO. DDAO absorbs maximally at either 275 nm or 646 nm and emits maximally at 659 nm. Consequently, the blots may be imaged using standard UV epi-illumination or with a laser-based gel scanner equipped with appropriate excitation source. The enzymatic amplification step greatly enhances the signal, allowing low nanogram detection of glycoproteins, a sensitivity on par with chemiluminescence detection methods. Pro-Q Glycoprotein Blot Stain kits with wheat germ agglutinin or with *Griffonia simpliifolia* lectin II (GS-II) allow detection of *N*-acetylglucosamine and sialic acid residues or terminal *N*-acetylglucosamine residues, respectively. The detection procedures for these lectins are quite similar to the concanavalin A method, and the same fluorogenic substrate, DDAO-phosphate is used in the kits.

Materials

Protein samples of interest
PVDF membrane
50% methanol
Wash solution II (see recipe)
Blocking solution (see recipe)
Pro-Q Glycoprotein Blot Stain Kit with Concanavalin A (Molecular Probes) containing:
  Concanavalin A, alkaline phosphatase conjugate (Con A-AP) stock solution (see recipe)
  DDAO phosphate stock solution (see recipe)
  Dimethylformamide (DMF)
  CandyCane glycoprotein molecular weight standards (see recipe), sufficient volume for ~20 gel lanes
Incubation buffer (see recipe)
10 mM Tris/1 mM $MgCl_2$, pH 9.5

Polystyrene staining dishes (e.g., weigh boat for minigel or larger container for larger gels)
Plastic wrap
UV epi-illumination and a digital or film camera, or a laser equipped with a 633-nm helium-neon laser or 635-nm diode laser source

Additional reagents and equipment for SDS-polyacrylamide gel electrophoresis (*UNIT 6.1*), electroblotting procedures (*UNIT 6.2*), and SYPRO Ruby protein blot staining (see Alternate Protocol)

Run gel

1. Prepare the protein samples of interest (e.g., crude protein isolates, cell lysates, serum, partially purified plasma membranes) for SDS-polyacrylamide gel electrophoresis (*UNIT 6.1*).

   Typically, the protein sample is diluted to ~10 to 100 μg/ml with 2× sample buffer, heated for 4 to 5 min at 95°C, and 5 to 10 μl of diluted sample is then applied per gel lane for 8× 10–cm gels. Larger gels require proportionally more material.

For convenience, CandyCane glycoprotein molecular weight standards may also be applied to a lane or two. Typically, 2 µl of this standard is diluted in 6 µl of sample buffer and heated in the same manner as the samples to be characterized. These standards contain a mixture of glycosylated and non-glycosylated proteins ranging from 14 to 180 kDa in molecular weight. The standards serve as molecular weight markers and as alternating bands of positive and negative controls for glycoprotein and total protein detection. Each protein is present at 0.5 mg/ml.

2. Separate proteins by SDS-polyacrylamide gel electrophoresis using standard methods (*UNIT 6.1*).

   The procedure is optimized for gels that are 0.5- to 1-mm thick.

Blot proteins

3. After electrophoresis, transfer the proteins to PVDF membrane using standard electroblotting procedures (*UNIT 6.2*).

   The use of nitrocellulose membranes is not recommended.

4. *Optional*: Stain blots with SYPRO Ruby protein blot stain at this point to visualize the total protein pattern and to verify that the blotting procedure was successful. Follow the staining procedure described in Alternate Protocol, steps 14 to 17.

   Total protein staining must be performed prior to lectin blotting as the blocking mixture will produce very high background on the blot. Since SYPRO Ruby protein blot stain is washed off during the subsequent lectin blotting process, it is important to document staining results before continuing with the procedure.

5. If the PVDF blot is dry, briefly hydrate in 50% methanol and incubate in wash solution II for 10 min at room temperature. Repeat the wash step for a total of three washes.

Visualize glycoproteins

6. Incubate the blot in blocking solution for 1 to 2 hr at room temperature.
7. Briefly pellet any potential protein aggregates in the Con A-AP stock solution by microcentrifugation. Using the supernatant only, dilute the Con A-AP stock solution 2000-fold by adding 5 µl to 10 ml of incubation buffer for a final concentration of 1 µg/ml. Remove the blocking solution that the blot is immersed in and incubate the blot with Con A-AP solution for 1 hr at room temperature.
8. Remove the diluted Con A-AP solution and wash the blot in blocking solution four times for 10 min each at room temperature.
9. Perform two final washes in wash solution II for 5 min each at room temperature.
10. Dilute the DDAO phosphate stock solution 1000-fold into 10 mM Tris/1 mM $MgCl_2$, pH 9.5, for a final concentration of 1.25 µM.

    Approximately 1 ml of the DDAO phosphate staining solution will be needed for an 8× 10–cm blot. Note that DDAO phosphate is unstable when stored at room temperature as an aqueous solution. Always make up the DDAO phosphate staining solution just prior to use.

11. Incubate the blot in freshly prepared DDAO phosphate staining solution.

    The staining step may be performed either face up or face down, depending on the configuration of the imaging instrumentation being used. If using UV epi-illumination or a laser scanner with a light source that illuminates from above the imaging bed, stain the blot face up. For laser scanners with light sources that illuminate the blot from below the imaging bed, stain the blot face down.

12. Using powder-free gloves, cut a piece of plastic wrap to the size of the blot. For face-up staining, place the blot on the plastic wrap and pipet 1 ml of DDAO phosphate staining solution onto the blot. For face-down staining, pipet 1 ml of the DDAO

phosphate staining solution onto the plastic wrap and lay the blot face down onto the solution, being careful not to trap air bubbles.

The time required for optimal staining must be determined empirically because the substrate turnover rate depends on the amount of glycoprotein on the blot. Generally, a 5- to 20-min incubation is sufficient, but overnight incubation is permissible. Do not wash the blot after staining as this will cause extensive loss of signal. The blot may be air-dried, however.

13. Visualize the fluorescent DDAO product using either UV epi-illumination and a digital or film camera, or using a laser equipped with a 633-nm helium-neon laser or 635-nm diode laser source. For UV epi-illumination, place the blot, signal side up, on a flat surface. For highest sensitivity and lowest background, use a UV-blocking filter, such as the SYPRO gel stain photographic filter. Long-pass filters with a cutoff at ~630 nm are ideal for CCD-cameras. For laser scanners, place the blot, signal side down, on the scanner bed. For highest sensitivity, match the light sources and filters of the instrument as closely as possible to the absorbance maximum (646 nm) and emission maximum (659 nm) of DDAO.

14. If desired, the Con A-AP complex can be stripped off of the blot and the blot reprobed with another lectin-AP complex or an antibody-AP complex. To strip, incubate the blot in stripping buffer for 40 min at 50°C with gentle agitation. Then, wash the blot in wash buffer two times for 5 min each at room temperature.

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Blocking solution

50 mM Tris·Cl, pH 7.5 (*APPENDIX 2A*)
150 mM NaCl
0.2% (v/v) Tween 20
0.25% (w/v) Mowiol 4-88 (Calbiochem or VWR)
Store up to 6 months at room temperature

The use of Mowiol 4-88 in the Blocking buffer is not essential, but does decrease background staining and improves detection sensitivity. As an alternative to Mowiol 4-88, 0.5% (w/v) bovine serum albumin or 4% (w/v) gelatin (high purity, e.g., TopBlock from Juro Supply) may be used.

CandyCane molecular weight standards

For a standard lane on an 8 × 10–cm gel, dilute 0.5 µl of the standards with 7.5 µl of 2× sample buffer (see recipe) and vortex. This will result in ~250 ng of each protein per lane, a sufficient amount for detection of the glycoproteins by the Pro-Q Emerald 300 stain. For large 16 × 18–cm gels, double the amount of standard and buffer used. Store up to 6 months at room temperature.

Con A-AP stock solution

Prepare a 2 mg/ml stock solution of Con A-AP by dissolving the vial contents in 250 µl deionized water and add 2 mM sodium azide. The stock solution is stable for at least 6 months when stored undiluted at 4°C. Do not freeze.

DDAO phosphate stock solution

Add 200 µl DMF to the vial containing 250 µg DDAO phosphate {[9H-(1,3-dichloro-9, 9-dimethylacridin-2-one-7-yl] phosphate, diammonium salt} to make 1.25 mg/ml stock solution. Store the stock solution at –20°C, desiccated and protected from light. When properly stored, the stock solution should be stable for at least 6 months. When the solution turns a blue color, the substrate has broken down and is no longer usable. Prepare the working solution fresh.

Fix solution

Prepare a solution of 50% methanol and 50% deionized water. Store up to 6 months at room temperature.

One 8 × 10–cm gel will require ~100 ml of fix solution.

Incubation buffer

Prepare blocking solution (see recipe) with 1 mM $CaCl_2$ and 0.5 mM $MgCl_2$. Store up to 6 months at room temperature.

Periodic acid solution

Add 250 ml of 3% (v/v) acetic acid to the bottle containing the periodic acid (oxidizing solution) and mix until completely dissolved. Store up to 6 months at room temperature.

Sample buffer, 2×

100 mM Tris·Cl, pH 6.8 (*APPENDIX 2A*)
20% (v/v) glycerol
4% (w/v) sodium dodecyl sulfate
0.1% (w/v) bromophenol blue
Store up to 6 months at room temperature

Wash solution

Prepare a solution of 3% (v/v) glacial acetic acid in water. Store up to 6 months at room temperature.

One 8 × 10–cm gel will require ~400 ml of wash solution.

Wash solution II

Prepare a solution of 50 mM Tris·Cl, pH 7.5/150 mM NaCl. Store up to 6 months at room temperature.

COMMENTARY

Background Information

The analysis of protein glycosylation is readily accomplished by polyacrylamide gel electrophoresis (Koch and Smith, 1990; Packer et al., 1997; Taverna et al., 1998; Koketsu and Linhardt, 2000). However, relatively few high-sensitivity methods have been developed to reliably detect oligosaccharide residues covalently attached to proteins for visualization in polyacrylamide gels or on electroblot membranes (Packer et al., 1997; Packer et al., 1999; Koketsu and Lindhardt, 2000). Perhaps the most common procedure to visualize glycoproteins reported in the literature entails detection by periodic acid/Schiff (PAS) staining using the colorimetric acid fuchsin dye. A major limitation of this method is that detection sensitivity is poorer than Coomassie Blue staining, rendering the technique obsolete for modern high-sensitivity proteomics investigations. Other methods in use include PAS-labeling with digoxigenin hydrazide followed by immunodetection with anti-digoxigenin antibody conjugated to alkaline phosphatase, or PAS-labeling with biotin hydrazide, followed by detection with horseradish peroxidase or alkaline phosphatase conjugated to streptavidin (Packer et al., 1995). Lectins are commonly employed to detect certain structural subclasses of glycoproteins by methods similar to those employed in immunoblotting (Koketsu and Lindhardt, 2000). All of these methods require that pro-

teins be electroblotted to membranes first and many glycoproteins transfer relatively poorly. In addition, detection of glycoproteins after electroblotting is very time consuming compared with direct detection in gels. A recently developed approach to the detection of glycoproteins relies upon the utilization of a new fluorescent hydrazide, Pro-Q Emerald 300 dye, that is affixed to glycoproteins using a standard PAS conjugation mechanism (Steinberg et al., 2001). The glycols present in glycoproteins are initially oxidized to aldehydes using periodic acid. The dye then reacts with the aldehydes on the glycoproteins to generate the fluorescent conjugate. A reduction step with sodium metabisulfite or sodium borohydride is not required to stabilize the resulting conjugate.

Critical Parameters

All stock solutions should be prepared using deionized water (dH_2O) having a resistance of at least 18 MΩ. All stock solutions may be stored for up to 6 months at room temperature, except when specifically indicated. Dilution of the DDAO phosphate stock solution or the Pro-Q Emerald 300 dye solution should be performed immediately prior to their use in the staining protocols. Both reagents are unstable when stored at room temperature as aqueous solutions. The staining methods outlined in this unit are highly sensitive and it is critical that all glassware and staining dishes be scrupulously clean. Gels and blots should never be touched or otherwise manipulated using bare hands. Always wear powder-free latex gloves when handling gels and blots during all staining procedures for the fluorescence detection of glycoproteins.

Troubleshooting

Should the detection sensitivity obtained using the cited fluorescence methods be suboptimal, there are two potential sources for the problem, either instrumental or chemical. With respect to the imaging instrument, it is important to clean the surface of the transilluminator after each use with deionized water and a soft cloth (e.g., cheesecloth). Otherwise, fluorescent dyes can accumulate on the glass surface and cause a high background fluorescence. The polyester backing on some pre-cast gels is highly fluorescent. For maximum sensitivity using a UV transilluminator, the gel should be placed polyacrylamide side down and an emission filter used to screen out the blue fluorescence of the plastic. For UV detection of fluorophores, a 300-nm UV-B transilluminator with six 15-watt bulbs is recommended. Excitation with different UV light sources, such as a simple hand held UV lamp will not provide the same level of detection sensitivity as a full-fledged transilluminator. For all three procedures described in this unit, using a Polaroid camera and Polaroid 667 black-and-white print film, the highest sensitivity is achieved with a 490-nm long-pass filter, such as the SYPRO protein gel stain photographic filter (S-6656; Molecular Probes). Gels are typically photographed using an f-stop of 4.5 for 2 to 4 sec, using multiple 1-sec exposures. Using a CCD camera, images are best obtained by digitizing at ~1024 × 1024–pixels resolution with 12-, 14-, or 16-bit gray-scale levels per pixel. A 520-nm long-pass filter is suitable for visualizing Pro-Q Emerald dye, while a 580-nm long-pass filter is appropriate for detection of DDAO. A CCD camera-based image analysis system can gather quantitative information that will allow comparison of fluorescence intensities between different bands or spots. Using such a system, the Pro-Q Emerald dye and the DDAO dye have a linear dynamic range of three orders of magnitude.

A potential problem associated with the Pro-Q Emerald 300 glycoprotein gel stain is nonspecific labeling of non-glycosylated proteins. The most common source of this problem is the presence of residual SDS in the polyacrylamide gel. Adding an extra fixation step to the procedure should prevent its occurrence. The author finds that an overnight fixation step for two-dimensional gels is advisable. When detecting glycans using Pro-Q Emerald 300 glycoprotein gel stain, it is prudent to run control gels in which the periodate oxidation step has been omitted. Similar precautions are advisable when evaluating results using other glycoprotein detection methods. This avoids erroneous interpretation of results arising from low levels of noncovalent binding of dye molecules or confusion arising from the inherent fluorescence of certain high-abundance proteins in the gel profile.

The most common problem encountered using the Pro-Q glycoprotein detection kit with concanavalin A is poor signal intensity. This is usually due to decomposition of the DDAO phosphate stock solution. When the stock solution appears by eye to be a blue color, the substrate has broken down and is no longer usable.

Table 6.8.1 Comparison of Commonly Used Glycoprotein Detection Methods for Polyacrylamide Gels and Electroblot Membranes

Detection method	Time required (hr)	Number of steps	Detection sensitivity (1) α1-acid glycoprotein (40% CHO)[a] (2) glucose oxidase (12% CHO)[a] (3) avidin (7% CHO)[a]		Assets (+) or liabilities (–)

[a]Abbreviations: CHO, carbohydrate; na, not applicable.

Anticipated Results

The performance characteristics of the Pro-Q Emerald 300 Glycoprotein Gel Stain Kit, Pro-Q Emerald 300 Glycoprotein Blot Stain Kit, and Pro-Q Glycoprotein Detection Kit with Concanavalin A are summarized in Table 6.8.1 and contrasted with alternative glycoprotein detection technologies. The fluorescence-based methods permit detection of low-nanogram amounts of glycoprotein with a dynamic range of quantitation that encompasses three orders of magnitude of glycoprotein abundance. Pro-Q Emerald 300 dye may be used to detect a variety of glycoconjugates in addition to glycoproteins, such as bacterial lipopolysaccharides (LPS) and glycogen. Detection sensitivity for chondroitin 4-sulfate, however, is ~3000-fold poorer than glycogen or LPS, with limits of detection in the vicinity of 16 μg of applied material. This is not unexpected as glycosaminoglycans such as chondroitin sulfate, hyaluronic acid, and keratan sulfate are known to stain poorly by conventional PAS procedures. Concanavalin A specifically binds to nonsubstituted and 2-*O*-substituted α-mannosyl residues and thus detects fewer glycoproteins than the Pro-Q Emerald 300 dye. For example, α1-acid glycoprotein is not detected by concanavalin A. Similarly, glycoproteins such as ovomucoid (28 kDa) and ovotransferrin (76 kDa) are not effectively detected by concanavalin A. The differences in staining specificity between the Pro-Q glycoprotein detection kit with concanavalin A, the Pro-Q glycoprotein detection kit with wheat germ agglutinin and the Pro-Q Emerald 300 glycoprotein stain kits can be exploited in defining structural features of glycans on glycoproteins.

Time Considerations

The time considerations and number of steps required to detect glycoproteins using the Pro-Q Emerald 300 Glycoprotein Gel Stain Kit, Pro-Q Emerald 300 Glycoprotein Blot Stain Kit, and Pro-Q Glycoprotein Detection Kit with Concanavalin A are summarized in Table 6.8.1 and contrasted with alternative glycoprotein detection technologies. The methods can be completed in ~2 to 4 hr and require 5 to 7 steps to complete. This compares favorably with other methods that may require as much as 6 hr and 11 steps to complete.

Digital Electrophoresis Analysis

Gel electrophoresis has become a ubiquitous method in molecular biology for separating biomolecules. This prominence is the result of several factors, including the robustness, speed, and potentially high throughput of the technique. The results of this method are traditionally documented using silver halide–based photography followed by manual interpretation. While this remains an excellent method for qualitative documentation of single-gel results, digital capture offers a number of significant advantages when documentation requires quantitation and sophisticated analysis. Digital images of gel electropherograms can be obtained rapidly using an image-capture device, and the images can be easily manipulated using image analysis software.

REASONS FOR DIGITAL DOCUMENTATION AND ANALYSIS

There are several reasons to consider digital documentation and analysis of electrophoresis results. These justifications can usually be categorized into issues of ease of handling, accuracy, reproducibility, and cost.

Ease of Handling

A major advantage of the digital revolution has been in storage and retrieval of information. Storage in notebooks and filing cabinets previously meant that searching for specific data or experiments was a tedious manual process. With digital information, modern search engines can quickly find specific information in a fraction of the time usually required for a manual search. Making backup copies of nondigital data can be difficult, expensive, and time-consuming since it requires copying, retyping, or photographic reproduction. Copies of digital data can be generated more easily and at reduced costs.

Manipulation of information is also easier when it is in a digital format. While the cut-and-paste analogy comes from physical documentation, it takes on a new perspective when applied digitally. Electrophoresis images can be resized, cropped, and inserted into reports. Data can be passed to spreadsheets and statistical packages for analysis and later insertion into notebooks and reports. These reports can be passed out via the Internet to colleagues throughout the world. A single individual can do all this in a few hours.

Digital analysis also provides an easier method for handling the data when comparing large numbers of results or large numbers of separate experiments. Research that requires comparing the banding patterns on 1000 gels containing 50 lanes each can be an undertaking of heroic proportions if the analysis is performed manually. Database software can dramatically speed the analysis and handle the more mundane tasks, leaving the researcher free to interpret the data.

Accuracy

The human eye is an extremely versatile measuring instrument. It can handle light intensities covering a range of nearly nine orders of magnitude and is sensitive to a fairly wide spectrum of light (Russ, 1995). Yet the eye cannot accurately and reproducibly quantitate density and patterns, nor can it deal with large numbers of bands or spots. Accuracy of measurement is a primary reason for using digital analysis on electrophoretically separated proteins and nucleic acids. Two categories of accuracy are key to digital analysis: positional accuracy, which is important for mobility determinations such as molecular weight, and quantitative accuracy.

Positional accuracy is based on both resolution of the recording medium and measuring accuracy. Silver halide–based recording has a theoretical resolution based on ~2000 imaging elements (silver grains) per inch. Measurement traditionally occurs using a ruler, with an accuracy of ~20 to 40 elements (50 to 100 elements per inch). In comparison, typical digital systems have 200 to 600 picture elements (pixels) per inch. The advantage that digital systems have is in measuring accuracy, which can occur at the level of a single imaging element.

Quantitative accuracy is also an issue. The amount of material represented by a band or spot is difficult to determine accurately from an image of a gel unless it is a digital image. On a digital image, the amount present is directly correlated with the derived volume of the band or spot—the volume is calculated using the intensity values of the pixels within the object.

Reproducibility

Any technique or measurement is only as good as its ability to be faithfully replicated. With software-defined routines, measurements

Contributed by Scott Medberry and Sean Gallagher
Current Protocols in Cell Biology (2002) 6.19.1-6.19.14

are performed in the same manner every time. Allowing the computer to do repetitive tasks and complicated calculations minimizes the chance for individual errors. This does not imply that such measurements are correct, just that they are reproducible. An incorrect routine or algorithm can also invalidate data.

Cost

A consideration when evaluating any laboratory method is cost. Digital electrophoresis analysis equipment can be expensive. In many cases, however, it offers the only method for achieving acceptable analysis performance. In other cases, equal performance can be achieved using silver halide technology. However, traditional photography can also be expensive when the costs of consumable supplies such as film and developers, as well as other expensive requirements such as developing tanks and dark rooms, are included. Often, digital methods can be a good choice when all costs are considered.

KEY TERMS FOR IMAGING

There are several specialized terms encountered during digital image analysis. The most commonly encountered are contrast, brightness, gamma, saturation, resolution, and dynamic range. They describe controls on how the light detectors report a range of light intensities. Below is a brief description of each.

Contrast

Contrast describes the slope of the light intensity response curve. An increase in the contrast increases the slope of the curve. The result is a more detailed display over a narrowed range of intensities with less detail in the remaining portions of the intensity range. This is depicted in Figure 6.9.1A and 6.9.1B, where a normal, unadjusted image and a contrast-adjusted image are displayed, respectively. The contrast was increased on midrange intensity values in Figure 6.9.1B to highlight band intensity differences at the expense of background information. Images with a narrow range of informative intensities can benefit from increasing the contrast, since that effectively increases the scale and improves detection of minor differences in intensity. Contrast settings should be lowered if information is being lost outside of the contrast range. For example, in Figure 6.9.1B, loss of background information between peaks indicates that this image should not be used for quantitation.

Brightness

While brightness can have many different definitions, only one will be considered here. Brightness shifts the light intensity response curve without changing its slope as is shown in Figure 6.9.1C. Another name for brightness is black level, since it is commonly used to control the number of black picture elements (pixels) in an image. Incorrect brightness levels can lead either to high background and potential image saturation or, as is illustrated in Figure 6.9.1C, to a total loss of background information and partial loss of band information.

Gamma

Nonlinear corrections are often applied to images to compensate for how the eye perceives changes in intensity, how display devices reproduce images, or both. The most common correction is an exponential one, with the exponent in the equation termed the gamma. A typical gamma value for camera-based systems is 0.45 to 0.50, and is illustrated in Figure 6.9.1D. This is a compromise value that compensates for the 2.2 to 2.5 gamma present in most video monitors and the print dynamics of most printers. Since it is a nonlinear correction, special care must be taken if quantitation is desired. Unless directed to by the manufacturer, gamma values other than 1.0 should be avoided when quantitating. More information on gamma correction can be found on Poynton's Gamma FAQ (*www.inforamp.net/~poynton/Poynton-color.html*).

Dynamic Range

Dynamic range describes the breadth of intensity values detectable by a system and is usually expressed in logarithmic terms such as orders of magnitude, decades, or optical density (OD) units. A large dynamic range is important when trying to quantitate over a wide range of concentrations. The most accurate quantitation occurs in the linear part of the dynamic range, which is usually not the complete dynamic range of the system. An additional consideration is the dynamic range of the visualization method. Many popular visualization methods have linear dynamic ranges of 1 to 2.5 orders of magnitude. An imaging system with greater dynamic range analyzing the results of such a visualization method will not improve the dynamic range.

Saturation

Saturation occurs when a detector or visualization method receives input levels beyond

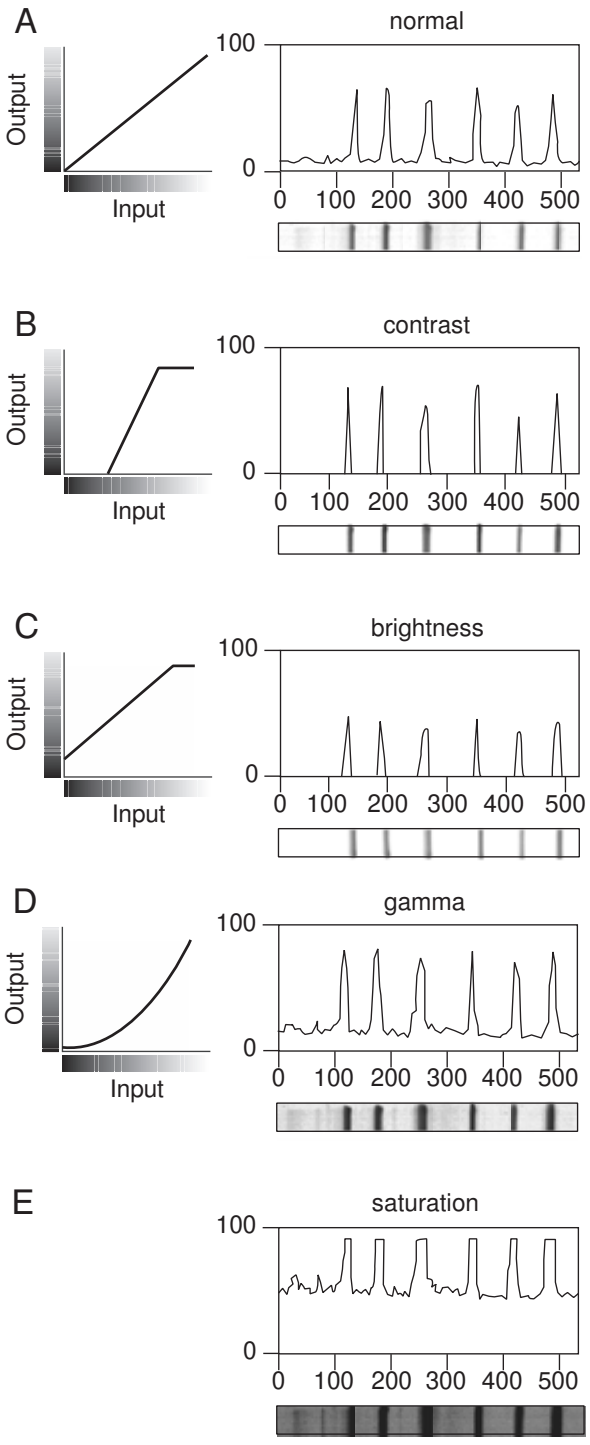

Figure 6.9.1 Examples of how altering image capture settings affects the image and the analysis. The graph on the left displays the light intensity response curve used for image capture while the image and resulting lane profile on the right display how the setting affects the image. The lane profile displays pixel position versus normalized pixel intensity (**A**). In this case, the output has not been altered, giving a straight line with a slope of 1 on the response curve. (**B**) The image acquisition was adjusted to increase the contrast of the displayed image. Although useful for images with a narrow range of informative intensity values, increasing the contrast can lead to a loss of low and high values. (**C**) Decreasing the brightness reduces peak values but also leads to a loss of the weak bands and original background. (**D**) Gamma adjusts raw data to appear more visually accurate. Note that this leads to a loss of fidelity between the adjusted image and the original. (**E**) Saturation indicates that the detector is reporting its maximum value or that the dynamic range for the visualization method has been exceeded.

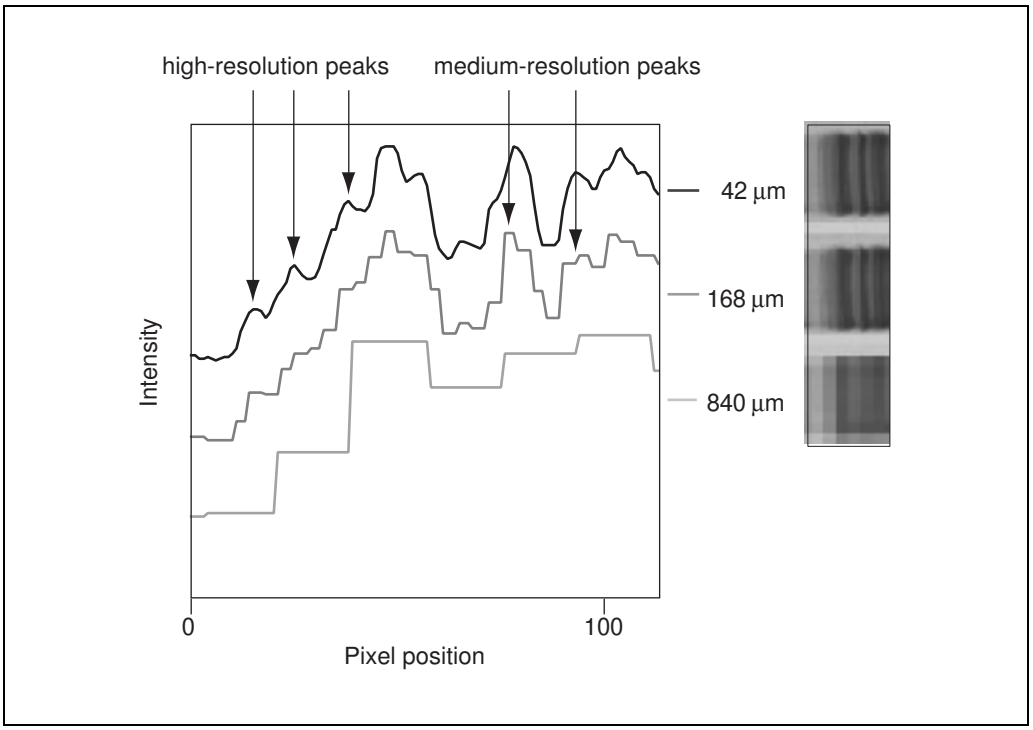

Figure 6.9.2 The effect of spatial resolution on the ability to detect closely spaced objects. Whole-cell protein lysates from *E. coli* were separated using SDS-PAGE and visualized with Coomassie blue staining. An image was captured at 42 μm (600 dpi), 168 μm (150 dpi), and 840 μm (30 dpi) from a segment of the lane, and a lane profile was generated for each image. The lane profiles have offset intensities to allow for comparison. Only major bands can be detected with the low-resolution image (840 μm); at higher resolutions more bands are detectable.

the maximum end of the dynamic range. This results in a loss of detail and quantitative information from those data points that are saturated. For fluorescent and luminescent samples, reduction in the sampling time can sometimes correct saturation problems. Optical density-based visualization techniques can also generate saturated images, as is illustrated in Figure 6.9.1E; this can sometimes be avoided with longer sampling times or increased detection source intensities. More often, it will be necessary to perform another electrophoresis with more dilute samples or to alter the visualization process to generate a less optically dense material.

Resolution

Resolution is the ability of a system to distinguish between two closely placed or similar objects. Three types of resolution are important for analysis—spatial resolution, intensity resolution, and technique-dependent resolution.

Spatial resolution is the ability to detect two closely placed objects in one-, two-, or three-dimensional space. It is most accurately described as the closest distance two objects can be placed and still be detected as separate objects. In practice, it is often defined nominally in terms of the number of detectors per unit area such as dots per inch (dpi) or the number of detectors present in total or in each dimension such as 512 × 512 (262,144 total detectors). Actual resolution is less than half the nominal resolution due to the need for two detectors for every resolvable object (one for the object and one for the separation space) and the effects of optical resolution. Figure 6.9.2 demonstrates how spatial resolution can affect detection of objects. The 42-μm resolution image allows detection of closely spaced bands, the 168-μm resolution image detects fewer bands, and the 840-μm resolution image detects only major bands. For instruments with on-line detection systems, a pseudo spatial resolution is often reported in units of time from the start of the separation or the time interval between two objects crossing the detection path.

Intensity resolution is the ability to identify small changes in intensity. It is a function of both the dynamic range of a detector and the number of potential values that detector can report. Greater dynamic range decreases the intensity resolution of a given detector. The number of potential values a detector reports is

described by its bit depth. An 8-bit detector can report 256 (2^8) different possible values, while a 12-bit detector can report 4,096 (2^{12}) values, and a 16-bit detector can report 65,536 (2^{16}) values. The higher the bit depth, the greater the intensity resolution.

Technique-dependent resolution directly affects the spatial and intensity resolution. Electrophoretic separation techniques that generate overlapping objects or that have object separation distances shorter than the spatial resolution will fail to provide reliable data. Many factors, including the amount of sample loaded, gel pore size, buffer constituents, and electrophoresis field strengths, can dramatically affect separation and resolution of biomolecules. Likewise, detection methods that can only generate a small range of discrete intensity values will not benefit from systems with improved intensity resolution.

IMAGE CAPTURE

Devices

Capturing digital images involves a detection beam or source, a sensor for that beam or source, and some method of assembling a two-dimensional image from the data generated. Most systems use a light source for detection. The light wavelengths used range from ultraviolet (UV) to infrared (IR) and can be broad spectrum or narrow wavelength. Broad-spectrum detection is more versatile since it can often be used for more than one detection wavelength. However, when compared to narrow-wavelength sources such as lasers, broad-spectrum detection suffers from reduced sensitivity and reduced dynamic range. While many types of light sensors have been used, including charge-coupled devices (CCDs), charge-injection devices (CIDs), and photon multiplier tubes (PMTs), technology advances in CCDs have led to their dominance. CCDs are semiconductor imaging devices that convert photons into charge. This charge is then read and converted into a digital format via an analog-to-digital converter (ADC).

The method of image assembly depends on the light source and detector geometry. One method is to capture the image all at once using a two-dimensionally arrayed CCD detector similar to the detectors found in digital and video cameras. Typically a camera-type sensor is paired with a light source that evenly illuminates the sample. This same sensor is often used with fluorescent and chemiluminescent detection methods, as its ability to detect light continuously over the entire sample reduces image capture times. Another method of image assembly is to capture the image a line at a time. This typically involves a linearly arrayed CCD scanning slowly across the sample in conjunction with the detection beam of light. The data from each line is then compiled into a composite image. Spatial resolution in this method can be significantly better on large-format samples than the resolution of a camera-based system. This method is also advantageous when OD-based detection is used, since the more focused light beam is usually of higher intensity and can penetrate denser material. A third method of image assembly is to use a point light source and single-element detector on each point on a sample. The image is then compiled from each point sampled. This method is slower than the others but can offer extremely high resolution and sensitivity. A fourth commonly encountered method is that of generating a pseudoimage of electrophoresis results through the use of a finish line type of detection system. This is comprised of a light source positioned at the bottom of the gel (i.e., the end opposite of the site of sample loading) and light detectors positioned next to each lane to detect the transmitted light or emitted fluorescence. A lane trace is generated using time on the *x* axis and light intensity on the *y* axis. The pseudoimage is then generated from this data (Sutherland et al., 1987).

Capture Process

Prior to image capture, electrophoretic separation and any visualization steps are performed. To calibrate the separation process, standards are usually run at the edges of the gel and often at internal positions. If quantitation of specific proteins or nucleic acids is to be performed, a dilution series of standards with similar properties to the experimental samples should also be included. After separation, the protein or nucleic acid is visualized if necessary. Visualization can include binding of a fluorochrome or chromophore such as Coomassie blue, precipitation of metal ions such as copper, silver, or gold, enzymatic reactions, and exposure of film or phosphor screens to radiant sources. These methods can be grouped based on the type of detection into optical density, fluorescence, chemiluminescence, and radioactivity. The suitability of popular detection devices with these methods is described in Table 6.9.1. Once visualization has occurred, image capture consists of the following steps: previewing the image while

Table 6.9.1 Compatability of Popular Image-Capture Devices with Common Visualization Methods[a]

Visualization method	Image-capture device				
	Silver halide photography	CCD camera	Desktop scanner	Storage phosphor	Fluorescent scanner
Optical density[b]	+	+	++	−	−
Fluorescence	+	+	−	−	++
Chemiluminescence	+	++	−	±	−
Radioactivity	+	−	−	++	−

[a]The device with the highest sensitivity and greatest dynamic range for a visualization method is marked with a ++, other devices that can detect this visualization method are indicated with a +, and devices that are not suitable for a visualization method are indicated with a −. A ± indicates that only some devices of this type can be used with this visualization method.

[b]Optical density methods include Coomassie blue staining.

adjusting capture parameters, capturing the image, and saving the image for later analysis.

During the preview process, capture parameters are optimized for data content and for ease and rapidity of later processing steps. Typically, the first step is to place the sample so that when the image is captured, the rectangular edges of the gel are horizontal and vertical on the monitor and any lanes are either horizontal or vertical. Since band and spot detection will be much easier if the image is properly oriented, this eliminates the need to later rotate the image digitally. Image rotation is time-consuming and can result in spatial linearity errors (a change in the size and shape of objects in image) caused by rectangular image-capture device geometries. The next step for camera-based systems is to adjust magnification and to focus the sample image. For thicker samples, it might be necessary to reduce the aperture on camera-based systems to get a sufficient depth of field to focus the entire sample. Often at this point image imperfections—e.g., dust, liquid, or other foreign objects that will detract from later analysis—are detected, and they need to be removed. Next, image intensity is set. Within the area of interest on the image, band or spot peaks should have values less than the maximum saturated value, and the background should have nonzero values. This is usually accomplished through adjustment of the light-source intensity or the sensor signal integration. If the device allows precapture optimization of other parameters such as spatial resolution, contrast, brightness, gain, or gamma, they are adjusted next. Note that this only applies to controls that affect the response of the sensor or processing of the image prior to a data reduction step and not to controls that affect the image at later stages. The latter process can enhance visualization of specific features but is best left to adjustments in look-up tables (LUTs) in later analysis steps rather than during image capture, since there is a risk of data loss during postacquisition image processing. LUTs are indexed palettes or tables where each index value corresponds to color or gray-scale intensity values present in an image. Many image analysis programs alter LUTs instead of image values directly, since it both is faster and does not change the original image data.

Once all the capture parameters are optimized, the image capture process is initiated. This might take less than a second for images captured with camera-based detectors and up to hours for scanning single-point detectors. When the image has been captured, it should be carefully examined for content. It should fully capture the area of interest and the parameters should have been set so that all necessary information is detectable. Furthermore, it should be in a form that will allow for easy analysis. Extra time spent optimizing the capture parameters will often result in a reduction in total image analysis time and in an increase in data quality. When the best possible image has been captured, it often contains information outside the area of interest. While this is unlikely to cause problems with later analysis, it is often advantageous to crop the image so that the only portion that is saved contains the area of interest. This reduces the amount of disk space necessary to store the image, and the image usually will load and analyze faster with the analysis software.

The last step in image capture is to save the image. Several options are available at this point, including choosing which location to

save the image at, what file type or format to use, and whether to use some form of compression.

The location where the image is saved is not as trivial a question as it might seem if the image will need to be transferred to another computer at some point. File sizes can easily exceed 15 megabytes on high-resolution images. This is a manageable size for hard drives but exceeds current floppy drive sizes by an order of magnitude. There are software utilities available that will subdivide files into disk-size chunks and then reassemble them at the next computer, but this is an inconvenient and slow method. If the computer used to help capture the image is connected to a network, the image files can easily be transferred this way or potentially saved on a central server. Alternatively, several types of high-capacity removable media are available (e.g., Zip or Jazz). This usually requires the installation of additional hardware onto two or more computers but does make backing up data easier.

Since image files can be very large, compression techniques are sometimes used to reduce disk space requirements. Compression algorithms use several methods, typically by replacing frequent or repetitive values or patterns with smaller reference values and by replacing pixel values with the smaller difference values describing the change in adjacent pixels. When the file is later decompressed, the compressed values are then replaced with the original information. Not all images compress equally, with simple images containing mostly repetitive motifs compressible by ≥90%, while complex images will benefit much less from compression. Because compression is a much slower method of saving files and will not benefit every file, compression is not used to save all files. Several different forms of compression are available but are separable into two main classes, lossless and lossy. Lossless methods faithfully and completely restore the image when it is decompressed (no loss of data) but offer only moderate file compression; compression values range from ~10% to 90%, depending on the image. Examples of lossless compression include Huffman coding (Huffman, 1952), RLE (Run Length Encoding), and LZW (Lempel, Ziv, and Welch; Welch, 1984). In comparison, lossy methods such as JPEG (Joint Photographic Experts Group), MPEG (Moving Picture Experts Group), or fractal compression schemes can reach compression values of ≥98% (Russ, 1995). The trade-off is that not all information from the original file is recovered during decompression. Lossy compression is sometimes necessary for applications with extremely large image files such as real time video capture, but it usually represents an unacceptable loss of data if used with electrophoresis image capture.

Many different file types have been developed to store digital images. Some of these file types are proprietary or hardware specific. For example, PICT is a Macintosh format and BMP is a PC-compatible format. Each file type has its own structure. Some types do not allow compression, for others it is optional, and for some it is mandatory. File types vary in the types of images they support, particularly in the number of colors or gray levels. Below is a brief description of a few of the more prevalent file types.

TIFF (Tagged-Image File Format) is one of the most commonly used formats. It is particularly versatile since it is an open format that can be modified for specific applications. One reason for its versatility is the ability to attach or tag data to the image. The tags can include information such as optical density calibration, resolution, experimenter, date of capture, and any other data that the application software supports. TIFF images can be monochrome, 4-, 8-, or 16-bit gray-scale, or one of many color-image formats. Compression is optional, with LZW, RLE, and JPEG often supported (Russ, 1995). Since TIFF is supported by both Macintosh and PC computers, it is a good choice for multiple-platform environments. The versatility of TIFF can also be a weakness. Since there are many different tagging schemes and since not all programs support all possible compression and color schemes, it is sometimes not possible for one program to access the information in a TIFF file generated by a different program.

GIF (Graphics Interchange Format) is a file format that is widely encountered on the Internet due to its compactness and standardization. Its compactness is attributable to a mandatory modified LZW compression. Another feature of GIF is the use of a LUT to index the values in the image. One interesting ability of GIF is that it supports storing multiple images within a single file. This can offer some advantages for applications such as time-lapse image capture. A GIF image can contain no more than 256 individual color or gray levels and does not support intensity resolutions higher than 8 bit. In addition, since the image

is implemented as a LUT, it also is not a true gray-scale image. Due to these limitations and others, alternative formats such as PNG have been developed to replace GIF.

PICT is a file format and graphics metafile language (it contains commands that can be played back to recreate an image) designed for the Apple Macintosh. It can contain both bitmap images and vector-based objects such as polygons and fonts. It supports a ≤256-gray-level LUT, and monochrome images can be RLE compressed. Because it only offers a 256-gray-level LUT, it has the same weaknesses that GIF does with true gray-scale and high-intensity-resolution images. In addition, any vector objects in the image are difficult to translate on a PC since they are designed to be interpreted by Macintosh QuickDraw routines.

BMP is the native bitmap file format present on Windows-based PCs. It supports 2-, 16-, 256-, or 16-million-level images. With images of ≤256 gray levels, it implements a LUT, while the highest-resolution image is implemented directly. RLE compression is optional for 16- and 256-gray-level images. Since compression is prohibited on 16 million-gray-level images and there is no intermediate level supported beyond 256 levels, BMP is not a good choice for images with high-intensity resolution requirements.

ANALYSIS

Once the image has been captured, the data needs to be analyzed and distilled into information about the results of the electrophoresis experiment. Through the use of standards and experimenter input, this software-driven process can estimate mass and quantity of objects in an image and detect relationships between objects within one image and between similar images. The type of software used depends on the analysis to be performed. Images from single electrophonetic separations are examined by one-dimensional analysis software optimized for lane-based band detection. Images from two-dimensional electrophoresis are best handled by specific programs designed to detect spots and to assign two mobility values and a quantity value to the spot. After the initial characterization of bands and spots, comparisons are often made between bands or spots from different experiments through the use of database programs and matching algorithms.

Software for One-Dimensional Analysis

Lane positioning

For one-dimensional analysis, the first activity is to detect the lanes on the image. One of three different methods is commonly employed for this. For images with straight, well-defined lanes with a large number of bands, automatic lane-detection algorithms can quickly and accurately place the lanes. On images with very well-defined lanes, such as pseudoimages from finish-line type electrophoresis equipment, automated lane calling based on image position is possible. For images with "smiling," bent, or irregular lanes, manual positioning of the lanes is often the fastest and most accurate method of lane definition. Regardless of the method of identifying the lanes, the lane boundaries need to be carefully set for accurate quantitation and mass determinations. Lane widths should be wide enough so that the entire area of all bands in that lane are included, but they should not be so wide as to include bands from adjacent lanes. To accomplish this, curved or bent lanes might need to be used in order to follow the electrophoresis lane pattern. Lane length and position also must be adjusted as necessary so that all bands of interest are included. If mass determinations are necessary, the sample loading point should probably also be included in the lane or be the start of the lane. At this point, lines of equal mobility (often called R_f or iso-molecular-weight lines) are added to the image as necessary. These lines allow for correction of lane-to-lane deviations in the mobility of reference bands and generate more accurate measurements of mass. A similar form of correction is also possible for within-lane correction of mobilities. This correction is important for accurate detection and quantitation of closely spaced bands.

Band detection

Once the lanes have been defined, the bands present in each lane need to be detected. There are many methods for detecting bands. One method is to systematically scan the lane profile from one end to the other, identifying regions of local maxima as bands. Another common method is to use first- and second-order derivatives of the lane image or lane profile in order to find inflection points in the change of slope in pixel intensity values (Patton, 1995). Regardless of the method used, it is often necessary to alter the search parameters so that they perform reliably under a given experimental condition.

Typical search parameters include ones for detection sensitivity, smoothing, minimum interband gaps, and minimum or maximum band peak size. Smoothing reduces the number of bands detected due to noise in the image. A minimum interband gap is often used to avoid detection of false secondary bands on the shoulders of primary bands. Limitations on peak sizes, especially for within-lane comparison to the largest band's peak, can be a useful way to allow sensitive detection of bands in underloaded lanes without detecting false bands in overloaded lanes.

Band edges are often detected in addition to band peaks in order to further define bands or to quantitate band amounts. This can be accomplished by using local minima, derivatives of the lane profile, or fixed parameters such as image distances or a percentage of band peak height. The band edges can be applied as edges perpendicular to the long axis of the lane or as a contour of equal intensity circling the band. The perpendicular method is advantageous for bands with uneven distribution of material across the face of the band, while the latter method is better for "smiling" or misshapen bands.

Background subtraction

With nearly all electrophoresis procedures, the most informative images have a low level of signal intensity at each pixel that does not result from protein or nucleic acid. Instead, this background intensity is attributable to the gel medium, the visualization method, electronic noise, and other factors. Since this background tends to be nonuniformly distributed throughout the image, failure to subtract it can make band detection and quantitation less accurate. Many methods of background subtraction are possible. Sometimes it is possible to generate a second image under conditions that do not detect the protein or nucleic acid. The second image is then digitally subtracted from the data-containing image to remove the background. More often, background information must be obtained from a single image. If the background varies uniformly across the image, a line that crosses the variation can be defined at a point where no bands are present. The intensity values at each point on the line can be used as the background value for the pixels perpendicular to the line at that point. Commonly, background is also present as variations in intensity along the long axis within each lane. One simple method is to take the lowest point in the lane profile as the background. Another method is to use an average value of the edge of each band as the background for that band. More complicated methods such as valley-to-valley and rolling-disk use local minima points in the lane profile to define a variable background along the length of the lane. Because there can be many different causes and distributions of background, no single method of background determination can be recommended for all experiments.

Characterization

Once lanes and bands have been detected, it is possible to interpret the mobility of the nucleic acid or protein bands. Depending on the method of electrophoretic separation, information on mass (length or size), pI, or relative mobility (R_f) can be inferred from mobility information. The mobility is characterized using a standard curve with internal standards of known properties. The type of curve depends on several parameters. By definition, with R_f-based separation, a linear first-order curve is used since it represents the linear relationship between mobility and R_f. Similarly, pI and mobility are generally linear in isoelectric focusing separations. For separations based on size, a curve generated from mobility versus the log of the molecular weight provides a relatively good fit as measured by the correlation coefficient (R^2). Several other curves have been suggested for size-based separations, including modified hyperbolic curves and curves of mobility versus (molecular weight)$^{2/3}$ that have good correlation coefficients (Plikaytis et al., 1986). In some cases, no single curve equation can adequately represent the data, and methods of fitting smooth contiguous curves using only neighboring points, such as a Lagrange or spline fit (described in Hamming, 1973), are necessary. This is most common for size separations with a very large range of separation sizes and with nonlinear gradient gels. Care must be taken with multiple-curve techniques since they rely on only a few data points for any one part of the composite curve, and outlying data points can drastically affect the outcome.

For size and R_f determination, a uniform position must be found in each lane as a point from which to measure the mobility of each band. Many software analysis packages use the end of the lane as the measuring start point, so for them it is important to position each lane start point at an iso-molecular-weight or iso-R_f point. A convenient point is the well or sample-loading position since it is usually easily de-

tectable and at an equal mobility position in each lane. A consistent point on each band must also be chosen to measure mobility. A band's peak is easily defined in digital image analysis and is commonly used. Since peak positions are harder to detect visually than edges on silver halide images, the leading band edge is sometimes used when comparing digital results with silver halide–based results.

Once lanes and bands have been detected, it is also possible to quantify the amount or at least relative amount of nucleic acid or protein present in each band. The amount in a band is related to the sum total of the intensity values of each pixel subtracted by the background value for each pixel in a band. For absorptively detected bands, intensity values are converted to OD values. The total value that is calculated is equivalent to the volume of the band and can be directly compared to other bands that are within the linear range for the visualization method. If standards of known amounts are loaded onto the same gel, they can be used to generate a standard curve that converts band volume into standard units such as micrograms. For greatest accuracy, it is important to be able to generate multiple standard curves when using visualization methods, such as Coomassie blue staining, that are affected by band or spot composition.

Quantitation becomes more complicated when bands are not fully resolved. In this case, material from one band is contributing to the volume measurement of an adjacent band and vice versa. The simplest method for handling this is to partition into each band only the volume within its edges. Alternatively, a Gaussian curve can be fitted to each band and the volume contained within the curve used to estimate the amount of the band. Since most electrophoresis bands have a pronounced skew towards the leading edge of the band, modified Gaussian curves have also been used (Smith and Thomas, 1990). In either case, the curve-fitting process is calculation intensive and can significantly increase analysis times for images with many bands.

Software for Two-Dimensional Analysis

In two-dimensional analysis, the first-dimension separation is performed in a single column or lane and then a second separation is performed perpendicular to the first. The result after visualization is a rectangular image of up to 10,000 spots. The most common two-dimensional gel type is one in which protein is separated first by apparent pI and second by molecular weight, although two-dimensional separation of nucleic acids is also possible. While many of the concepts and analysis techniques used with one-dimensional gels are applicable to two-dimensional gels, the complex nature of most two-dimensional gels requires somewhat different methodology. For example, spots are more difficult to detect since they are not conveniently arranged in lanes and can vary more in shape and overlap than bands. In addition, two-dimensional experiments usually require some method of comparing between two images, whereas one-dimensional images usually contain all of the information from an experiment.

Spot detection

Probably the most difficult aspect of two-dimensional analysis is efficient and accurate spot detection. If it is incorrectly done, it can lead to hours of manual editing. Due to the complexity and computational intensity of some algorithms, the detection process itself can last hours on relatively fast desktop computers. One theoretically effective but computationally intense method is to treat the image as essentially a three-dimensional image with spots treated as hills and background as valleys. A large number of Gaussian curves are then combined to describe the topology of the image. Many other methods make use of a digital-imaging technique known as filtering. In essence, filtering is a way to weight the value of a pixel and its neighbors in order to generate a new value for a pixel. By passing a filter across an image pixel by pixel, a secondary image is generated. Filters can be designed for many tasks, including sharpening an image or removing high-frequency noise. Filters can also be generated to help detect spots by making images that are first and second derivatives of the original image. The derivative images indicate inflection points in the intensity pattern and can be used to detect spot centers and edges. In a different method, called thresholding, filters can be used to detect the edges of objects. Instead of looking for inflection points, threshold filters identify intensities above a set level or at ratios between central and edge pixels above a set value. Since the edges on two-dimensional spots tend to be diffuse, sharpening filters are sometimes used prior to the thresholding filter. In some cases, multiple techniques are used to detect spots (Glasbey and Horgan, 1994).

Unlike one-dimensional detection, detection on images of two-dimensional experiments usually requires secondary processing to get acceptable performance. One example of a secondary process is to discard spots with sizes below a set minimum or above a set maximum. Another is to analyze spots that are oval for possible splitting into two spots. Even after secondary processing, it is likely that a small amount of manual editing will be necessary. When manually editing an image, care must be taken to use as objective criteria as possible, especially if two or more images are to be matched and spot volumes compared.

Characterization

In a two-dimensional system, determination of protein or nucleic acid mobility is complicated by the fact that there are two mobilities to account for and that the second-dimension separation tends to make estimation of the separation which occurred in the first dimension more difficult. One method for dealing with this is to have a series of markers in the sample that, after both separations are completed, are evenly distributed within the gel and image. It is also possible to estimate separation characteristics from calibration points located at the periphery of the gel. For example, distance measurements can be used to pass calibration data from the first dimension separation, and standards can be separated at the ends of the gel to calibrate for mobility in the second dimension. Regardless of the method used, in many instances, a series of related images will be examined and similar spots in each image will be matched. When this occurs, it is possible to calibrate one image and then pass the calibration information via the matches to the related images.

Quantity determination is similar in many regards to that which occurs in one-dimensional analysis, but there are some differences. If spot edges are detected, a simple method of determining spot volume is to take the sum of the intensity value of each pixel in the spot reduced by a background intensity value. Multiple Gaussian curves can also be fitted to the spot to approximate the volume (Garrels, 1989). More difficult is attempting to compensate for a skewed distribution in a size-separating dimension while trying to use a regular Gaussian fit for a pI separation, such as is encountered with the most common form of two-dimensional protein separations. The distribution of background makes quantitation more difficult in two-dimensional gels. There is no lane-dependent component, so it is necessary to use other methods such as image stripes, finding local minimum values or using values derived from the spot edges to determine background values.

Matching

Matching is the process in which proteins or nucleic acids with similar separation properties are linked or clustered together. Matching can occur within one image or between multiple images as long as a frame of reference is established. Matching allows for comparisons between samples. It also makes annotation and data entry easier, since if one spot or band is matched to others and is characterized or annotated, this information is easily passed to all the other matches. An underlying assumption of matching is that objects with similar separation properties are actually similar. Care must be taken to confirm the identity of matched spots or bands by other methods on critical experiments.

A simple form of matching is to link bands or spots at similar positions on the gel images. This works well when separation and imaging conditions are uniform. This is very seldom the case, since slight differences in the electrophoresis, visualization, and imaging conditions across a gel and between gels generates incorrect matching with this method. Since bands on one-dimensional gels are relatively easy to calibrate for mobility, matching can occur along contours of equal mobility. This dramatically decreases but does not eliminate the variability in detecting similar bands. Much of the remaining variability can be attributed to calibration errors. This error can often be compensated for by allowing a small tolerance in mobility values in determining whether a band is matched or not. Because of the difficulties in calibrating mobility in two-dimensional gels, it is often more practical to use matched spots for calibrating mobility than vice versa. Spot matching between two two-dimensional images starts with finding a small number of landmark spots that are used as seeds for subsequent matches (Appel et al., 1991; Monardo et al., 1994). There are many methods for finding the landmarks in both images, including finding the highest-intensity spots, finding spots in unique clusters, and manual positioning. The most common procedure from this point is to derive a vector that describes the direction and extent of the path from one matched spot to the other when the two images are superimposed. The vector is used as the basis for finding more matches near the landmark matches. To allow

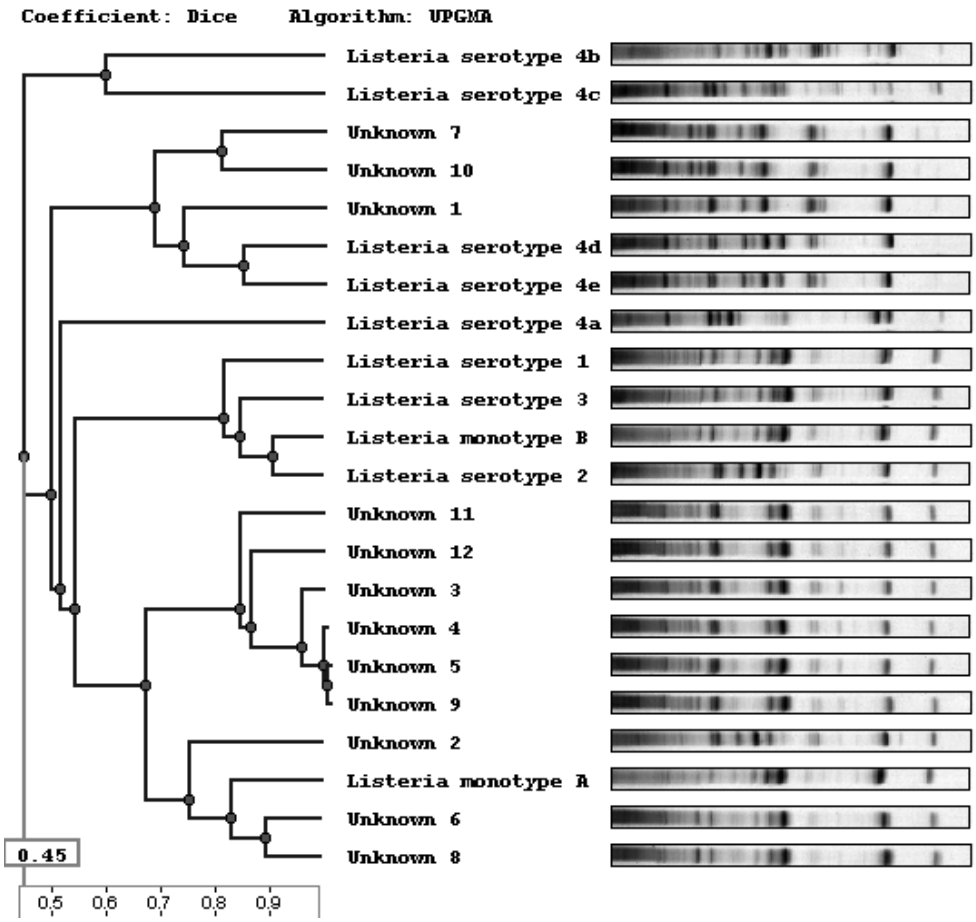

Figure 6.9.3 Example of a dendrogram generated from similarity data on band matching between lanes. DNA samples from 22 isolates of *Listeria* were subjected to Random Amplification of Polymorphic DNA (RAPD) analysis and the resulting electrophoresis image was analyzed with ImageMaster software (Amersham Pharmacia Biotech). Clustering was performed using the Dice coefficient with a tree structure based on the Unweighted Pair-Group Method using Arithmetic Averages (UPGMA). Similarity values between isolates can be determined by locating the node that connects the isolates and reading the value from the scale on the lower left edge of the dendrogram.

for error, the area within a small radius is searched extending from the end of the vector. Once another match is found, its vector is computed and used as the starting point for finding neighboring matches. From this progression, the entire gel is matched. If all vectors are displayed graphically when matching is complete, questionable matches can often be identified as vectors that are significantly different from neighboring vectors.

One specialized use of matching is as an estimator of the similarity and potential genetic relatedness of organisms. For example, on a one-dimensional gel image, a ratio of the matched to unmatched bands for each pairwise combination of lanes can be calculated. This ratio can be used as an indicator of similarity, with values near 1 indicating a pair of highly similar lanes, and values near zero indicating very dissimilar lanes. Assuming that the contents of the lanes are valid samples of the originating organism's genetic makeup, the information on lane similarity can be converted to estimates of genetic similarity. A convenient way to display this similarity data graphically is to generate a dendrogram with similar objects close to each other and less similar objects more distantly placed. An example of such a dendrogram is presented in Figure 6.9.3, where samples from *Listeria* isolates are arranged based on banding pattern.

Databases

In many cases, image analysis is not the last step in the process. The image and analysis data need to be archived in a searchable format. There may be a need to analyze the data from multiple experiments conducted at different sites or in laboratories around the world. Bioinformatic links to diverse data sources might be desired to help develop a unified understanding of the biology behind particular phenomena. When these situations arise, database programs can be utilized to store, link, and search image analysis results.

As the number of images that are captured and analyzed grows, it becomes increasingly more difficult to find particular information from the large number of files that are stored. Relatively simple databases can be used if the major requirement is to find previously analyzed images and associated data. Such databases often display a miniaturized version of each image to aid in visual scanning for the file as well as simple searching for image-specific information such as date of analysis, file name, or other information that was entered at the time of image capture. More powerful database products are also available that can perform complex searches on data generated during the analysis. For an example, a search on a two-dimensional database might include finding proteins exhibiting a specific expression profile and having a molecular weight >20 kDa with a pI between 3 and 5 or 8 and 10 with an amount <50 ng in a series of experiments conducted <1 year ago. Such searches can quickly target potentially interesting molecules for further analysis.

With the increasing ease of transferring data through the Internet as well as local- and wide-area networks, it has become practical to quickly find and examine data from distant locations. Of course, great care must be taken to ensure that similar experimental conditions are employed, as otherwise the results will be difficult to compare. In this manner it is sometimes possible to dramatically increase the sample size and statistical accuracy as well as the probability of detecting rare events. In addition, if one data set is more completely characterized, this extra information can be extracted and applied to the other data set. For example if there is a band in common in two databases and there is sequence information for it in one database, that sequence information can be added to the other database. Currently most public electrophoresis database sites are two-dimensional protein databases. A list with links to many of these Internet database sites can be found at *http://www-lmmb.ncifcrf.gov/EP/table2Ddatabases.html*.

With biological questions becoming more complicated and the answers to the questions often requiring information from a variety of sources, it is becoming increasingly important to be able to move easily between information sources. A relational type of database can help achieve this. Unlike a conventional database with a fixed arrangement of data, relational databases have links between related files that allow for easy movement from one file to another. Another approach to interconnecting electrophoresis data with data from other sources is to generate a series of hypertext links between data sets, similar to what occurs on the Internet. Selecting a specific link moves the search to the related network site and the related information. Regardless of the method, the end goal is similar. An example of what is possible: a researcher selects a protein spot on a two-dimensional gel image, which triggers accessing of related information on this protein. The protein sequence is accessed from mass spectroscopy analysis of the spot on a separate gel. The sequence of the gene and the cDNA that generated the protein is retrieved. The expression pattern of the gene in various tissues and conditions, as well as information on similar genes in other organisms, is incorporated. Citations and annotations to this are retrieved as well. All of this information is compiled automatically into an interactive report about the protein. From this report, the researcher can formulate a more refined hypothesis and plan the most appropriate experiments to test it.

Two-Dimensional Blue Native Polyacrylamide Gel Electrophoresis

Wolfgang W.A. Schamel[1]

[1]Max Planck-Institut für Immunbiologie und Universität Freiburg, Biologie III, Freiburg, Germany

ABSTRACT

Multiprotein complexes play crucial roles in nearly all cell biological processes. Blue Native Polyacrylamide Gel Electrophoresis (BN-PAGE) is a powerful method to study these complexes. It is a native protein separation method that relies on the dye Coomassie blue to confer negative charge for separation. It has a higher resolution than gel filtration or sucrose density ultracentrifugation and can be used for protein complexes from 10 kDa to 10 MDa. If a second-dimension SDS-PAGE is applied (two-dimensional BN/SDS-PAGE), the size, subunit composition, and relative abundance of the different multiprotein complexes can be studied. In recent years, there has been a large increase in the number of publications where BN-PAGE was used to study protein-protein interactions. Here, we give detailed protocols for the separation of multiprotein complexes by two-dimensional BN/SDS-PAGE and for a related technique to determine the stoichiometry of these complexes. *Curr. Protoc. Cell Biol.* 38:6.10.1-6.10.21. © 2008 by John Wiley & Sons, Inc.

Keywords: multiprotein complex • native • gel electrophoresis • two-dimensional • Coomassie blue • protein-protein interaction

INTRODUCTION

Blue Native Polyacrylamide Gel Electrophoresis (BN-PAGE; Basic Protocol 1) separates native proteins and protein complexes independently of their individual isoelectric points, with high-resolution capacity. This is done by conferring a negative charge on all proteins via the dye Coomassie blue. The separation depends mainly on the size of the protein complex. In combination with a second-dimension sodium dodecyl sulfate–PAGE (SDS-PAGE) in a perpendicular direction (Basic Protocol 2), it is an excellent choice to identify and characterize multiprotein complexes. It allows the determination of the size, subunit composition, and relative abundance of different multiprotein complexes from total cell and tissue homogenates, as well as from purified material. In addition, it is used for a one-step preparative purification of protein complexes.

One critical step in performing high-quality BN-PAGE is the preparation of the sample, which has to be devoid of potassium and divalent cations. The most useful source for protein complexes is a cellular lysate or tissue extract. Preparation of a cellular lysate suitable for separation by BN gels is done by dialysis to remove any cations and metabolites (see Support Protocol). A detailed protocol for pouring and running of the BN gradient gels (see Basic Protocol 1) and denaturation of the separated proteins followed by separation using a second dimension SDS-PAGE (see Basic Protocol 2) is given. Visualization of the resulting two-dimensional gel can be done according to standard protocols, including general protein stains (*UNIT 6.6*) and immunoblotting, often referred to as western blotting (*UNIT 6.2*).

A second dimension is not always required. Proteins can be detected after BN-PAGE by such standard procedures as general protein stains or transfer of the proteins to a

membrane under denaturing (see Alternate Protocol 1) or native (see Alternate Protocol 2) conditions followed by immunodetection. Using these protocols, there is a special requirement for the antibodies used to detect the proteins of interest, because Coomassie blue interferes with fluorescence-based visualization methods and because native proteins are often detected by different antibodies than those that detect denatured proteins.

A powerful method to determine the stoichiometry of multiprotein complexes is the Native Antibody-based MObility Shift (NAMOS) assay (see Basic Protocol 3). It is based on one-dimensional BN-PAGE and uses the fact that proteins migrate more slowly during the electrophoresis when an anti-subunit antibody is bound.

NOTE: High-purity water (e.g., Milli-Q or distilled water) should be used for all solutions. For cautions relating to electricity and electrophoresis, see Safety Considerations in the introduction to *UNIT 6.1*.

NOTE: Wear powder-free gloves throughout the procedure and work on ice or at 4°C whenever native proteins/protein complexes are present.

CAUTION: Acrylamide is hazardous; see *APPENDIX 2A* for guidelines on handling, storage, and disposal.

BASIC PROTOCOL 1

FIRST-DIMENSION BLUE NATIVE ELECTROPHORESIS

In this protocol, the pouring and running of vertical slab blue native (BN) gels is described. BN gels are gradient gels of low acrylamide percentage and strength. Thus, pouring and handling of the gels is not trivial. The gradient has to be even, in order to prevent any step that would result in the erroneous accumulation of proteins at a particular height of the gel. The BN gel solution with the higher acrylamide/bisacrylamide concentration is heavier than the low-percentage gel because of its high glycerol content. This density difference aids in establishment of a uniform gradient inside the glass plates. The same gel equipment that is used for normal SDS-PAGE can be used, but one has to be certain that no traces of SDS are present. To ensure absence of any detergent, the BN equipment should not be used for SDS-PAGE. BN gels are poured at room temperature and are cooled to 4°C before samples are loaded in the cold room. Alternatively, gel apparatuses that allow cooling can be used. Precast BN gels have recently been made commercially available, but in the author's experience, these are not as good as self-made gels.

It is strongly recommended to use multicasting equipment to pour several gels at once. This avoids steps of the gradient, saves time, and ensures best reproducibility for critical comparisons of multiple samples. Casting of multiple gradient gels is described in *UNIT 6.1*, Support Protocols 2 and 3, and Figures 6.1.3 and 6.1.4. Using these protocols, BN gels can be prepared using BN-specific solutions.

Materials

Low-percentage BN separating gel solution (see recipe)
High-percentage BN separating gel solution (see recipe)
Isobutyl alcohol
3× BN gel buffer (see recipe)
BN stacking gel solution (see recipe)
100× pervanadate solution (optional, if phosphorylation must be preserved; see recipe)
Sample: dialyzed cell lysate (Support Protocol), tissue homogenate, purified protein complex
Marker mixes 1 and 2 (see recipe)
BN anode buffer (see recipe)

BN cathode buffer (with 0.02% w/v Coomassie blue; see recipe)
BN cathode buffer (with low, 0.002% w/v Coomassie; see recipe)

Gel electrophoresis apparatus (see *UNIT 6.1*)
Gradient mixer (self-made or, e.g., from BioRad; Fig. 6.1.2)
Peristaltic pump (Fig. 6.1.2)
Power supply

Additional reagents and equipment for polyacrylamide gel electrophoresis (*UNIT 6.1*) and protein staining in gels (*UNIT 6.6*)

Set up the apparatus

1. Wash glass plates and pouring devices extensively with water.

   Do not use equipment that has been previously used for SDS-PAGE. No traces of detergent should be present on the glass plates

2. Assemble the glass plate sandwich of an electrophoresis apparatus.

   UNIT 6.1 describes these procedures in detail.

Prepare the gradient

3. Set up the equipment to pour gradient gels as shown in Figure 6.1.2 (*UNIT 6.1*).

   Gels will be poured at room temperature. For reproducibility, and to make the pouring more effective, it is recommended to pour at least 10 gels at once using multicasting equipment (e.g., BioRad).

4. Close the valves and place a magnetic stir bar into the mixing chamber of the gradient maker. Prepare low- and high-percentage BN separating gel solutions (see Reagents and Solution). Adjust the acrylamide/bisacrylamide concentration of the high-percentage BN separating gel solution according to your needs (Table 6.10.1). Add APS and TEMED only immediately before use.

   The volumes of the two solutions combined should be exactly equal to the volume required to fill the glass plate sandwich to the required height.

   When using multicasting equipment, the dead volume of the apparatus has to be determined empirically and added to the required volume of the gel solutions.

5. Pour the low-percentage (light) BN separating gel solution into the reservoir chambers and the high-percentage (heavy) BN separating gel solution into the mixing chamber of the gradient mixer (Fig. 6.1.2).

6. Open the interconnecting valve and force out the air bubble inside the connecting channel by pressing over the right cylinder with your thumb.

   CAUTION: *Make sure to wear gloves, in order to avoid contact with acrylamide.*

Cast the Blue Native separating gels

7. Switch on the peristaltic pump, open the outlet valve, and allow the gel to slowly enter between the glass plates. Ensure that the needle at the end of the Tygon tubing is always above the height of the liquid, so that the gradient is not disturbed.

   When using multicasting equipment, the gel solutions enter between the glass plates from the bottom. In this case, the low-percentage BN separating gel solution has to be placed into the mixing chamber and the high-percentage one into the reservoir chamber (Fig. 6.1.3). Figure 6.1.2 shows a pipet tip at the end of the Tygon tubing, but a needle may be more appropriate since a pipet tip might be too wide to fit between the glass plates.

8. Prepare water-saturated isobutyl alcohol by shaking isobutyl alcohol and water in a glass bottle. Using a Pasteur pipet, overlay the separating gel with water-saturated isobutyl alcohol (upper alcoholic phase from the mix) by gently layering the alcohol

Table 6.10.1 Gel Solutions for BN-PAGE[a]

	Low% BN separating gel solution	High% BN separating gel solution					Stacking gel solution
	4%	7%	10%	12%	16%	18%	3.2%
40% acrylamide/ bisacrylamide mix[b] (ml)	3.00	5.25	7.50	9.00	12.00	13.50	1.00
3× BN gel buffer[b] (ml)	10.00	10.00	10.00	10.00	10.00	10.00	4.17
dH_2O (ml)	17.00	—	—	—	—	—	7.33
70% (v/v) glycerol (ml)	—	14.75	12.50	11.00	8.00	6.50	—
10% ammonium persulfate (µl)	108	84	84	84	84	84	167
TEMED (µl)	11	8	8	8	8	8	17

[a]Numbers in the body of the table are milliliters of stock solution, except 10% APS and TEMED which are microliters and should be added only when the low- and high percentage BN gel solutions are already in the chambers of the mixing apparatus.
[b]See recipe in Reagents and Solutions.

against the edge of one and then the other of the spacers to produce a smooth surface.

In the multicasting equipment, all gels must be overlaid with the same volume of water-saturated isobutyl alcohol.

9. Clean pouring apparatus with water (do not use detergent).

10. Allow the gel to polymerize for at least 30 min at room temperature. Remove the isobutyl alcohol, wash twice with water, and overlay with 1× BN gel buffer. Store at 4°C (stable at least 1 year).

Pour the stacking gel

11. Just before use, pour the stacking gel using an appropriate comb and the BN stacking gel solution (see Reagents and Solutions).

Due to the low percentage of acrylamide/bisacrylamide, the comb might be difficult to remove without damaging the gel. Try to move the comb perpendicular to the plane of the glass plates while removing it to allow air to enter. Alternatively, the percentage of acrylamide/bisacrylamide can be increased to 3.5%.

Load the samples and run the Blue Native gels

All steps should be performed at 4°C (e.g., in a cold room).

12. Add 100× pervanadate solution to the dialysed lysate to a concentration of 1×, if phosphorylation needs to be preserved.

13. Mount the gel in the electrophoresis apparatus and load 5 to 30 µl dialysed cell lysate (prepared as in Support Protocol) in the dry wells of the mounted gel.

As control, an aliquot of the sample can be boiled with 1% SDS to destroy all multiprotein complexes. Leave one lane free between this control and the non-SDS samples.

14. Load 10 µl marker mix 1 and 10 µl marker mix 2 in two adjacent wells.

Only ferritin is seen during the electrophoresis, due to its brown color.

Alternatively, commercially available high-molecular-weight markers can be used (e.g., from Invitrogen or GE Healthcare).

15. Carefully overlay the samples in each well with the BN cathode buffer. Fill the upper/inner chamber with BN cathode buffer (containing 0.02% w/v Coomassie blue as described in Reagents and Solutions) and the lower/outer chamber with BN anode buffer.

16. Connect electrodes. If a small gel has been prepared (e.g., using BioRad Protean II or III), run at 100 V; if a large gel has been prepared (e.g., using BioRad Protean II xi), run at 150 V. Continue electrophoresis at the appropriate abovementioned voltage until the sample has entered the separating gel. At that point, increase voltage to 180 V for small gel or 400 V for large gel.

    Coomassie blue comes into contact with the samples inside the wells during the electrophoresis.

17. Remove the BN cathode buffer (especially from within the wells) after two-thirds of the gel run. Fill the upper/inner chamber with BN cathode buffer (low Coomassie blue) that contains only 0.002% (w/v) Coomassie blue. Continue electrophoresis at 180 V for small gel or 400 V for large gel.

    This procedure ensures that the individual lanes can be identified after the gel is run and can be omitted if a second-dimension gel is not to be applied (see, e.g., Alternate Protocols 1 and 2), or if precipitated material is visible between the stacking and separating gel.

18. Turn off power supply and remove the electrodes once the dye front has reached the bottom of the gel.

Extrude and store Blue Native gels

19. Remove the glass plates, with the gel in-between, from the electrophoresis apparatus.

20. Open the glass plates by lifting the smaller one and keeping the gel attached to the bigger, bottom plate. Remove the stacking gel with the smaller glass plate.

21. Cut away the lanes where the marker mixes were loaded from the rest of the gel using the smaller glass plate. Visualize the marker proteins by standard Coomassie blue or silver staining (*UNIT 6.6*).

    For some purposes, the ferritin marker (440 and 880 kDa), which is visible without staining, is sufficient. When assigning the positions of the marker, take into consideration that the gel might shrink upon staining.

    Alternatively, after the first-dimension BN-PAGE, proteins can be stained directly with silver or Coomassie brilliant blue (UNIT 6.6), or detected by immunoblotting (western blotting; Alternate Protocols 1 and 2). Optionally, stained spots can be cut out and the proteins identified by mass spectroscopy.

22. Stamp out each individual lane with the smaller glass plate. Either immediately run the second dimension SDS-PAGE (Basic Protocol 2), or freeze each lane wrapped in aluminum foil at −20°C (stable at least 1 year).

    Do not bend a frozen gel piece, since it breaks easily. Alternatively, the first-dimension BN gel can be transferred to a membrane followed by immunoblotting to visualize the proteins of interest (Alternate Protocols 1 and 2).

PREPARATION OF CELL LYSATES FOR BLUE NATIVE GEL ELECTROPHORESIS

SUPPORT PROTOCOL

Blue Native (BN) gel electrophoresis is suitable for the separation of pure proteins as well as complex protein mixtures such as subcellular fractions or cell lysates. Sample preparation is one of the critical steps in performing high-quality BN gels. First, the proteins have to be present in soluble and native form. Thus, the choice of detergent is important and one should start BN experiments by testing several nonionic detergents

for the protein/protein complex of interest (see Commentary). The detergent should be effective enough to extract the proteins from cellular membranes, but at the same time mild enough to keep multiprotein complexes intact. The most commonly used detergents are given in Reagents and Solutions. The proteins must be eluted in native form, if the purification procedure includes binding to a matrix, as e.g., in immuno- or affinity purifications (often referred to as immunoprecipitation; see *UNIT 7.2*). Second, the sample has to be prepared without potassium or divalent cations, since Coomassie blue and Coomassie blue–bound proteins precipitate with those ions and consequently do not enter the gel. Hence, cations that interact with Coomassie blue have to be removed and substituted by 6-aminohexanoic acid, in order to maintain a certain ionic strength of the solution, which is necessary for the solubility and stabilization of many protein complexes. Sodium ions are tolerated to a maximum concentration of 50 mM. Third, samples have to be loaded with detergent on BN gels. Otherwise, proteins aggregate during the stacking step of the electrophoresis.

Membrane and organelle fractions lysed in BN lysis buffer can be directly applied to BN gels. Cellular lysates have to be dialysed against BN dialysis buffer, in order to remove small cations and metabolites. Proteins bound to a matrix are washed and eluted in BN dialysis buffer.

This protocol describes the preparation of cell lysates. Cells are washed and lysed in any lysis buffer, although we recommend using the BN lysis buffer. After removal of insoluble material, the lysate is dialysed against BN dialysis buffer. In this protocol, a self-made dialysis setup utilizing dialysis membranes is described. Alternative desalting methods can be applied as well.

Materials

Cell culture dish (10 to 15 cm) containing cells of interest (80% confluent)
Phosphate-buffered saline (PBS; see recipe), ice cold
BN lysis buffer (see recipe)
BN dialysis buffer (see recipe)

Cell scrapers
10- to 50-ml centrifuge tubes
Refrigerated cell culture centrifuge (with adaptor cavities for microcentrifuge tubes in rotor accommodating 50-ml tube)
Dialysis membranes, MWCO 10 to 50 kDa (boiled and kept at 4°C in 0.001 M EDTA)
1-ml reaction tubes (e.g., microcentrifuge tubes)
Beaker (100-ml to 1-liter, depending on sample size)

Harvest and wash the cells

1. Place cell culture dish containing cells on ice.
2. For adherent cells, wash cells three times, each time with 2 to 10 ml ice-cold 1× PBS.

   Cells grown in suspension are washed three times with ice-cold 1× PBS by repeatedly pelleting the cells by centrifugation for 5 min at 350 × g, 4°C.

   The volume of PBS used for one washing step should be equal to the volume of medium in which the cells were cultivated.
3. Add 2 to 10 ml (i.e., volume in which cells were cultivated) of ice-cold 1× PBS to the dish, remove the cells using a cell scraper, and transfer the cell suspension to a 10- to 50-ml centrifuge tube.

   This step is omitted for cells grown in suspension.

4. Collect cells by centrifugation for 5 min at 350 × *g*, 4°C, and remove supernatant.
5. Resuspend cells in 1 ml cold 1× PBS, transfer cell suspension into a small reaction tube (e.g., microcentrifuge tube), and pellet cells by centrifugation for 5 min at 350 × *g*, 4°C.
6. Remove and discard the supernatant using a pipet.
7. Either move on to step 8 or freeze the cell pellet at −20°C.

   Frozen cells can be stored at −20°C for at least 6 months.

Prepare the cell lysates

8. Resuspend the cell pellet in ice-cold BN lysis buffer (or other lysis buffer that has been used successfully to extract your multiprotein complex of interest).

   The concentration of cells per volume lysis buffer depends on the amount of protein that should be loaded on the BN gel. As an approximation, use 10^6 cells per 250 to 500 µl lysis buffer.

9. Incubate on ice for 15 min to allow cell lysis.

   The lysis time can be prolonged, if it is convenient—e.g., in the case where many different samples are processed and some of them have to wait for the last ones.

10. Microcentrifuge 15 min at 13,000 × *g*, 4°C, to remove insoluble material.

Prepare to dialyze the lysate

11. Melt a hole in the cap of a microcentrifuge tube using the large-diameter end of a hot Pasteur pipet. Chill the tube on ice.
12. Transfer the supernatant from step 10 into the chilled tube from step 11.
13. Place a dialysis membrane over the opened tube and close the cap.

    Make sure that there are no folds or tears in the dialysis membrane.

14. Seal the cap at the edges with Parafilm.

    Make sure that the hole in the tube is not covered by the Parafilm.

15. Invert the tube and centrifuge upside-down at the lowest speed possible in the adaptor cavity for 50-ml tubes in a cell culture centrifuge for 10 sec at 4°C.
16. Prepare a 100-ml beaker with ice-cold BN dialysis buffer and a magnetic stirrer. Use at least 10 ml dialysis buffer per 100 µl sample.
17. Fix the tube upside down inside the beaker and remove air bubbles from the hole beneath the cap.

    Make sure that the dialysis membrane is not damaged.

Dialyze lysate

18. Switch on the magnetic stirrer and dialyze for 6 hr or overnight in a cold room.

    Make sure that stirring is not creating air bubbles at the dialysis membrane.

19. Collect the dialysed cell lysate in a new chilled microcentrifuge tube and analyze by BN-PAGE (Basic Protocol 1).

    If the sample will be subjected to two-dimensional analysis, reserve one-third of the sample to serve as a control in the second-dimension analysis.

    Freezing and thawing of cell lysates might lead to the aggregation of proteins. Therefore, the cell lysate should be separated immediately by BN-PAGE. For some proteins, freezing might be possible and has to be determined empirically.

BASIC PROTOCOL 2

SECOND-DIMENSION DENATURING ELECTROPHORESIS

A denaturing second-dimension gel is suitable to identify and characterize multiprotein complexes. It is recommended to use vertical denaturing (SDS) discontinuous gel electrophoresis (Laemlli method of SDS-PAGE; described in detail in *UNIT 6.1*, Basic Protocol 1). These gels can be linear or gradient slab gels run under reducing or nonreducing conditions. The only exception is that loading of the first-dimension BN gel strip requires a broad, flat well. The BN gel strip has to be fit between the glass plates of the second gel. The easiest way is to slightly increase the thickness of the second dimension compared to the first dimension. If this is done by putting cellophane tape on the spacers of the second dimension gel, the BN gel strip can be inserted without breaking and still sit firmly enough to prevent any movement during the electrophoresis. Alternatively, procedures as described in *UNIT 6.4* can be employed.

This protocol describes all the specific steps required for successfully casting and running the second-dimension SDS-PAGE, with extensive reference to *UNIT 6.1*. Typical expected results are depicted in Figure 6.10.1.

Materials

2× SDS sample buffer (*UNIT 6.1*)
1× SDS electrophoresis buffer (*UNIT 6.1*)
Lane from a BN-PAGE gel (Basic Protocol 1)

Thin adhesive tape (e.g., tesa tape; *http://www.tesatape.com*)
Platform shaker

Additional reagents and equipment for SDS-PAGE (*UNIT 6.1*) and two-dimensional gel electrophoresis (*UNIT 6.4*)

Cast the second-dimension SDS gels

1. Take spacers of the same thickness as the ones that were used for the first dimension (see Basic Protocol 1). Wrap thin adhesive tape once around them, in order to increase their thickness slightly.

2. Assemble the glass-plate sandwich using these spacers.

   A second-dimension gel that is slightly thicker than the first-dimension gel allows fitting in the first-dimension gel slice without problems, but still fixing it between the glass plates so that it cannot move.

3. Pour the separating SDS-PAGE gel as described in *UNIT 6.1*.

   For everyday purposes, degassing of the gel solution is not necessary. It is recommended to use multicasting equipment to pour several SDS gels at once. It saves time and ensures best reproducibility for comparisons of multiple samples. Casting of multiple gradient gels is described in UNIT 6.1.

4. Pour the stacking gel (*UNIT 6.1*) using combs that contain one large pocket that is wide enough to accommodate the first-dimension gel slice and one or two additional wells for marker and control samples (*UNIT 6.4*).

   After removing the comb, clean the large pocket of polymerized gel remnants using a spacer that has not been enlarged with a layer of tape.

Load the Blue Native gel strips onto the second-dimension SDS gels

5. Retrieve the first-dimension BN gel strips from storage. Incubate them for 10 min at room temperature in 2× SDS sample buffer by shaking in a small tray on a platform shaker.

   Make sure to work under a hood if working with a reducing sample buffer containing 2-mercaptoethanol.

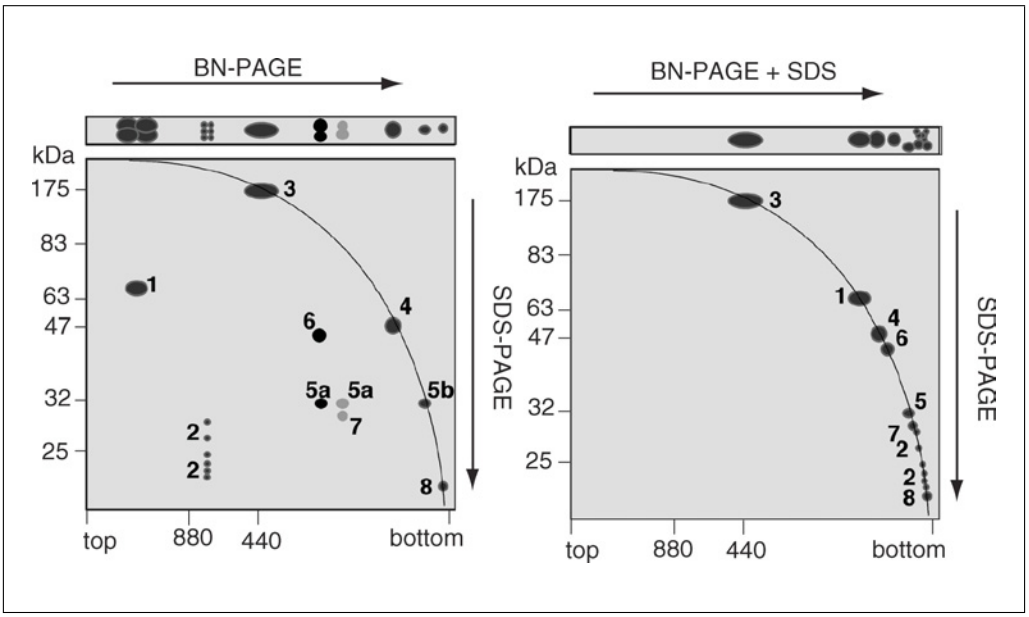

Figure 6.10.1 Two-dimensional BN/SDS-PAGE of cellular lysates. In this hypothetical experiment, total cellular lysates were prepared and dialyzed (Support Protocol). In (**A**), proteins were separated by BN-PAGE (Basic Protocol 1) and a subsequent second-dimensional SDS-PAGE (Basic Protocol 2). Visualization of the protein was done with silver staining. Monomeric proteins (#3, #4, and #5b) were localized to a hyperbolic-shaped diagonal, indicating that they had the same size in the first and in the second dimension. In contrast, proteins that were present in the same multiprotein complex were found as individual spots aligned in vertical columns. Complex #1 was a homotetrameric protein complex. Complex #2 was composed of six proteins of small individual sizes. Proteins #6 and #5 as well as #7 and #5 formed dimeric complexes. In addition, protein #5 was found as a monomer (#5b). Thus, protein #5 existed in three different forms. From the intensity of the spots, one could deduce that complex #6:#5 was more abundant than complex #7:#5. In (**B**), the dialysed lysate was boiled with 1% SDS before separation by BN-PAGE and SDS-PAGE. SDS destroys all multiprotein complexes; thus, the hyperbolic-shaped diagonal can identified. A similar wet experiment is described in Camacho-Carvajal et al. (2004).

6. Heat the strips with the sample buffer in a microwave oven at medium power until the solution boils. Let the gel strips shake for another 10 min at room temperature while cooling down.

   Heating the proteins in the presence of SDS leads to their unfolding and to the disruption of multiprotein complexes.

7. Fill the large pocket of the second-dimension gel with 1× SDS electrophoresis buffer, removing all air bubbles. Incline the gel with the large glass plate at the bottom. Let the first-dimension gel slice enter between the glass plates. Avoid any air bubbles and push carefully with a spacer without added tape.

8. Place the gel into the electrophoresis apparatus and load the markers and control samples into the small wells.

   It is recommended to keep one-third of the sample to be separated by the first dimension BN-PAGE (Support Protocol, step 19), boil it in 1× SDS electrophoresis buffer, and use it as a control sample in the second dimension.

9. Overlay the first-dimension gel strip with a 3-mm layer of 2× SDS sample buffer.

Run and analyze the second-dimension SDS gel

10. Run and disassemble the gel as described in *UNIT 6.1* (Basic Protocol 1).

    The dye front contains not only the bromphenol blue of the SDS sample buffer but also the Coomassie blue from the first dimension. The dye front of the first dimension will be visible as a dark blue spot at the bottom of the second dimension.

11. Visualize proteins using any method available.

The most commonly used methods are transfer to a membrane followed by immunodetection (western blotting; UNIT 6.2) or staining with silver or Coomassie brilliant blue (UNIT 6.6). Optionally, stained spots can be cut out and the protein identified by mass spectroscopy.

ALTERNATE PROTOCOL 1

DENATURING TRANSFER OF THE PROTEINS FROM THE FIRST-DIMENSION BN-PAGE GEL TO A MEMBRANE FOR IMMUNOBLOTTING

Protein complexes separated by BN gels can be visualized by immunoblotting (also referred to as western blotting) without a second-dimension separation. If a cell lysate is analyzed, a very specific antibody is necessary that does not cross-react with other proteins. It is recommended to first test the quality of the antibody by second-dimension BN/SDS-PAGE (see Commentary). In general, the same antibodies that are used for immunodetection after SDS-PAGE are potentially suitable.

In this protocol, the proteins/multiprotein complexes are first denatured within the BN gel by boiling in SDS. Subsequent steps, including the transfer to a membrane and the immunoblotting procedure, are similar to the standard protocol used after SDS-PAGE (*UNIT 6.2*). If PVDF membranes are used, the bound Coomassie blue can partially be removed. This is not the case for nitrocellulose membranes that can be used to immobilize the proteins after BN-PAGE as well.

Materials

First-dimension BN-PAGE gel (Basic Protocol 1)
Phosphate buffered saline (PBS; see recipe for 10×) containing 1% (w/v) SDS
Denaturing BN transfer buffer (see recipe)
Destaining solution (see recipe)

Platform shaker
PVDF (polyvinylidene fluoride) membrane (see *UNIT 6.2*)

Additional reagents and equipment for immunoblotting (*UNIT 6.2*)

1. Soak the first-dimension BN gel in 1× PBS with 1% SDS for 15 min by shaking in a small tray on a platform shaker.
2. Heat in a microwave at medium power until the solution boils. Let the gel shake for another 10 min at room temperature.
3. Transfer the denatured proteins to a PVDF membrane by wet or semi-dry blotting (*UNIT 6.2*). Use the denaturing BN transfer buffer, since it includes SDS.

   A protocol for wet transfer is described in UNIT 6.2 (Basic Protocol 1, including Fig. 6.2.1). Semi-dry transfer is described in UNIT 6.2 (Alternate Protocol 1, including Fig. 6.2.2).

   Before transfer, mark the ferritin marker with a pen on the membrane, since it is difficult to see afterwards.

4. *Optional:* Partially remove the transferred Coomassie blue from the PVDF membranes by incubation in destaining solution for 30 min.

   Immunodetection can also be performed without the destaining step. Coomassie blue cannot be removed completely and shows strong fluorescence at several wavelengths. Therefore, detection with fluorescently labeled antibodies cannot be done. In this case a second-dimension SDS-PAGE has to be used for immunoanalysis (Basic Protocol 2).

5. Block the membrane and immunodetect under standard conditions (*UNIT 6.2*).

NATIVE TRANSFER OF THE PROTEINS FROM THE FIRST-DIMENSION BN-PAGE GEL TO A MEMBRANE FOR IMMUNOBLOTTING

ALTERNATE PROTOCOL 2

Proteins are separated by BN-PAGE under native conditions. Transfer to a membrane and visualization by immunoblotting can also be performed under native conditions. If a cell lysate is analyzed, a very specific antibody that does not cross-react with other proteins is necessary. The antibodies that are used for immunodetection after SDS-PAGE might not be suitable, since they recognize unfolded proteins. Antibodies that recognize folded proteins and protein complexes, as used for immunoisolation (e.g., immunoprecipitation), flow cytometry, or immunofluorescence methods, should be tested for the application in this protocol.

In this protocol, the proteins/multiprotein complexes are transferred to a membrane in their native form. The following immunoblotting procedure is similar to the standard protocol used after SDS-PAGE (*UNIT 6.2*).

Materials

First-dimension BN-PAGE gel (Basic Protocol 1)
Native BN transfer buffer (see recipe)
Destaining solution (see recipe)
PVDF membrane (see *UNIT 6.2*)

Additional reagents and equipment for immunoblotting (*UNIT 6.2*)

1. Briefly rinse the first-dimension BN gel in native BN transfer buffer.
2. Transfer the native proteins to a PVDF membrane by semi-dry or wet blotting (*UNIT 6.2*). Use the native BN transfer buffer, since it does not contain SDS.

   Conditions for transfer are the same as those used for SDS-PAGE gels (UNIT 6.2).

   Before transfer, mark the ferritin marker with a pen on the membrane, since it is difficult to see afterwards.

3. *Optional:* Partially remove the transferred Coomassie blue from the PVDF membranes by incubation in destaining solution for 30 min.

   Immunodetection can also be performed without the destaining step. Coomassie blue cannot be removed completely and shows strong fluorescence at several wavelengths. Therefore, detection with fluorescently labeled antibodies cannot be accomplished. In this case a second-dimension SDS-PAGE has to be done (Basic Protocol 2).

4. Block the membrane and immunodetect under standard conditions (*UNIT 6.2*).

NATIVE ANTIBODY-BASED MOBILITY SHIFT (NAMOS) ASSAY

BASIC PROTOCOL 3

This protocol is a variant of Basic Protocol 1 and describes a method to determine the stoichiometry of multiprotein complexes based on BN-PAGE. It makes use of the fact that the proteins and protein complexes are separated in their native state. Antibodies that recognize a certain subunit of a protein complex are added to the sample before separation by BN-PAGE. This allows the formation of super-complexes comprising the protein complex and the antibody. Since the migration distance in BN-PAGE depends on the size of a protein complex, it directly reflects the number of bound antibodies and thus the copy number of the subunit they bind to. This method is called the Native Antibody-based MObility Shift (NAMOS) assay. With the NAMOS assay, it is even possible to determine the stoichiometry of a protein complex that is present in low amounts within a total cell lysate. Due to the large amount of added antibody, detection of the protein complex of interest has to be done by immunoblotting as described in Alternate Protocols 1 and 2, and *UNIT 6.2*.

Before performing the NAMOS assay, one has to set up the sample preparation (Support Protocol 1) and immunodetection (Alternate Protocols 1 and 2) conditions. It is required that the multiprotein complex of interest be separated as a single, clearly visible complex after BN-PAGE.

Typical expected results are displayed in Figure 6.10.2.

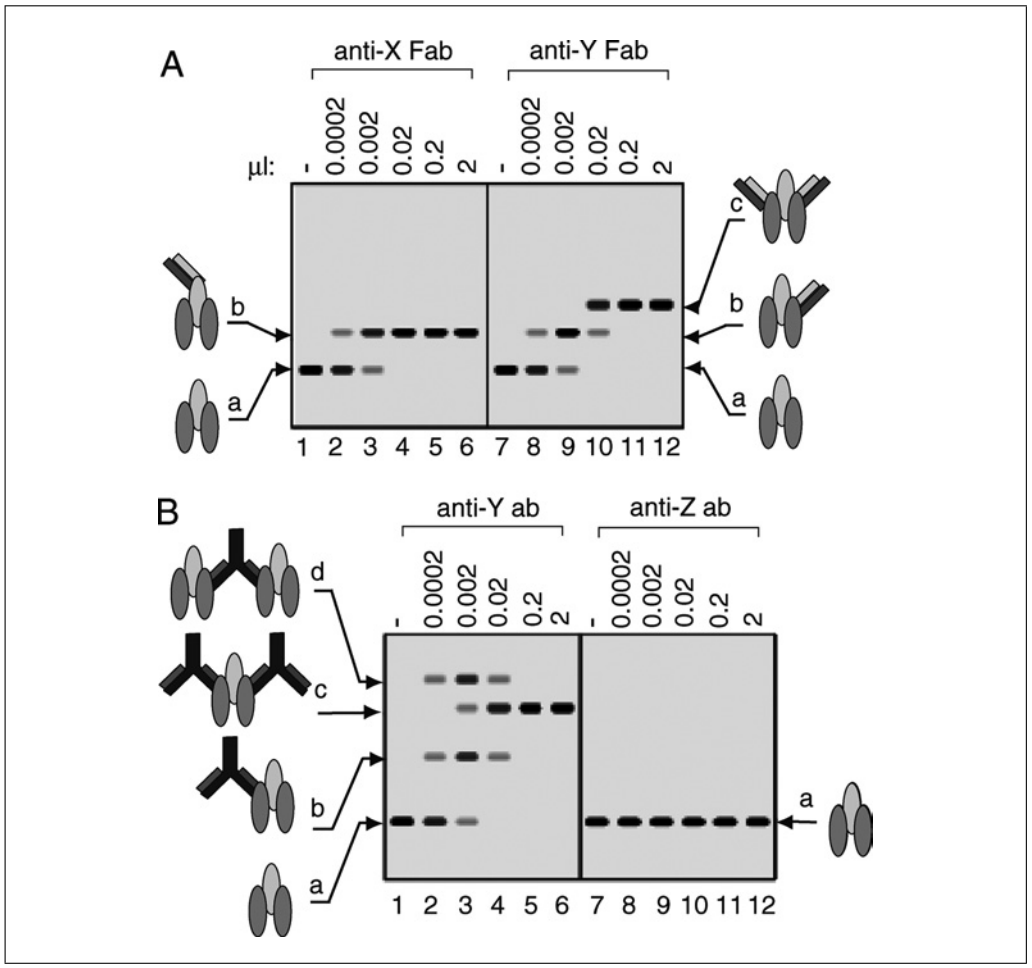

Figure 6.10.2 The Native Antibody-Based Mobility Shift (NAMOS) Assay. In this hypothetical experiment, the protein complex of interest comprises one X and two Y subunits (XY_2). Its stoichiometry is to be determined by the NAMOS assay (Basic Protocol 3). Cellular lysates containing complex XY_2 were separated by BN-PAGE and visualized by anti-XY_2 immunoblotting. Indeed, XY_2 was one defined complex (lanes 1 and 7, band a). In (**A**), increasing amounts of an anti-X Fab fragment were incubated with the lysate before separation. Consequently, a new band (band b) appeared with a concomitant loss of band a (lanes 2 to 6). Band b corresponded to a Fab-XY_2 complex, indicating that XY_2 contained one binding site for the anti-X Fab fragment and, thus, one copy of protein X. An anti-Y Fab fragment produced two bands (lanes 8 to 12, bands b and c), demonstrating that XY_2 had two copies of protein Y. In (**B**) complete antibodies were used for the NAMOS assay. In contrast to the Fab fragment, an antibody is able to simultaneously bind to two XY_2 complexes. Using anti-Y, one can see that these "super"-complexes (band d) disappeared with increasing concentrations of the antibody (lanes 2 to 5). At saturating concentrations, all XY_2 complexes bound to two antibodies (lanes 5 and 6, band c), indicative of two copies of protein Y in the complex. Thus, complete antibodies also allow the determination of stoichiometry. As a control, an irrelevant anti-Z antibody did not produce any shift of complex XY_2 (lanes 7 to 12). A similar wet experiment and possible difficulties in performing the NAMOS assay are described in Swamy et al. (2007).

Materials

Monoclonal antibodies that react with the proteins of interest
BN dialysis buffer (see recipe)
Sample for BN-PAGE
1-ml reaction tubes (e.g., microcentrifuge tubes)

Additional reagents and equipment for casting and running BN-PAGE gels (see Basic Protocol 1) and analysis of Blue Native gels by immunoblotting (Alternate Protocol 1 or 2)

Prepare the samples and load the Blue Native gel

1. Prepare a dilution series of the monoclonal antibodies of interest using the BN dialysis buffer containing the same detergent as the sample. Start with ~1 μg of antibody in 2 μl in the first reaction tube, then dilute 1:10, 1:100, 1:1,000, and 1:10,000 in another four tubes. Place the tubes on ice.

   Antibodies are mostly dissolved in PBS and, thus, the nondiluted antibody will be present with sodium chloride. If only 2 μl are used, the resulting salt concentration is tolerated by BN-PAGE. If, however, more than 2 μl have to be used, it is recommended to dialyze the antibody against BN dialysis buffer without any detergent (Support Protocol). Use fresh antibodies that have not been frozen and thawed too often, in order to avoid the presence of antibody aggregates. If possible, use Fab fragments of the antibodies.

2. Use any sample as described in the Support Protocol, e.g., a dialysed lysate or purified proteins. Add 10 to 20 μl of sample to each antibody-containing tube, mix, and incubate 20 min on ice.

3. Cast and pour the BN gel as in Basic Protocol 1. Use an acrylamide concentration (Table 6.10.1) in which the multiprotein complex of interest is located on the lower third of the gel after the electrophoresis.

   The reason for this is that all "antibody shifts" will be above the protein complex.

4. Load the BN gel at 4°C as in Basic Protocol 1. Load the samples in the order of the dilution (see Fig. 6.10.2). At the end, also load the solution containing the multiprotein complex (with no antibody) as reference.

   Do not load any sample in the well next to the sample with the highest concentration of antibody. In this well, the marker mix can be loaded. If a second series of antibody-added samples is loaded, use the reverse order (see Fig. 6.10.2).

Run and analyze the Blue Native gel

5. Run NAMOS BN gels as described in the Basic Protocol 1, except reduce the voltage at the beginning of the separation; if a small gel has been prepared (e.g., using BioRad Protean II or III), run at 50 V; if a large gel has been prepared (e.g., using BioRad Protean II xi), run at 75. Continue electrophoresis at the appropriate abovementioned voltage until the sample has entered the separating gel. At that point, increase voltage to 180 V for small gel or 400 V for large gel.

6. Analyze the gels by immunoblotting (Alternate Protocol 1 or 2) using only antibodies that recognize the protein/protein complex of interest.

   The detection method should not stain the monoclonal antibodies used at steps 1 and 2. For example, for detection, use directly labeled antibodies or polyclonal rabbit antiserum in combination with labeled anti–rabbit IgG antibodies that do not cross-react with the antibodies that were used for the shift. In order to control for the cross-reactivity, also load the highest concentration of the monoclonal antibody alone, i.e., without adding the protein/protein mixture of interest.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Acrylamide/bisacrylamide mix

50 ml of 19:1 acrylamide/bisacrylamide solution
239 ml of 37.5:1 acrylamide/bisacrylamide solution
Store at room temperature (stable at least 1 year)

This will result in a ratio of 32:1 with 40% acrylamide.

BN anode buffer

Dilute 50 ml of 1 M bis-Tris stock solution (pH adjusted to 7.0 with HCl; store up to 1 year at room temperature) to 50 mM final by adding water to 1 liter.

BN cathode buffer

15 ml 1 M bis-Tris stock solution (pH adjusted to 7.0 with HCl) (15 mM final)
50 ml 1 M tricine (50 mM final)
0.2 g Coomassie blue G250 (not other Coomassie blues) (0.02% w/v final)
H_2O to 1 liter
Store at room temperature (stable at least 1 year)

BN cathode buffer (low Coomassie)

15 ml 1 M bis-Tris stock solution (pH adjusted to 7.0 with HCl) (15 mM final)
50 ml 1 M tricine (50 mM final)
0.02 g Coomassie blue G250 (not other Coomassie blues) (0.002% w/v final)
H_2O to 1 liter
Store at room temperature (stable at least 1 year)

BN dialysis buffer

Mix 2× BN lysis buffer stock solution (see recipe) and the detergent stock solution (see recipe) of choice so that the BN lysis buffer has a final concentration of 1× and the detergent solution has a final concentration of 0.1× (but for digitonin, use 0.3×, due to its low critical micelle concentration). Add PMSF and sodium orthovanadate (see recipe for protease and phosphatase inhibitor stock solutions) to a final concentration of 1×. Prepare fresh just before use and cool to 4°C.

Upon addition of orthovanadate, the buffer will assume a yellow color.

BN gel buffer, 3×

150 ml 1 M bis-Tris stock solution (pH adjusted to 7.0 with HCl) (150 mM final)
200 ml 1 M 6-aminohexanoic acid (Sigma-Aldrich) stock solution (200 mM final)
H_2O to 1 liter
Store at room temperature (stable at least 1 year)

BN lysis buffer

Mix 2× BN lysis buffer stock solution (see recipe) and the detergent stock solution (see recipe) of choice so that both have a final concentration of 1×. Add protease and phosphatase inhibitors (see recipe) to a final concentration of 1×. Prepare fresh just before use and cool to 4°C.

Upon addition of orthovanadate, the buffer will assume a yellow color.

BN lysis buffer stock solution (without detergent and inhibitors), 2×

40 ml 1 M bis-Tris stock solution (pH adjusted to 7.0 with HCl) (20 mM final)
500 ml 1 M 6-aminohexanoic acid (Sigma-Aldrich) stock solution (500 mM final)
40 ml 1 M NaCl (20 mM final)
4 ml 0.5 M EDTA, pH 8.0 (*APPENDIX 2A*; 2 mM final)
200 ml glycerol (10% v/v final)
H_2O to 1 liter
Store at room temperature (stable at least 1 year)

Preparation of an EDTA stock solution is described in UNIT 6.4.

BN stacking gel solution

3 ml 3× BN gel buffer (see recipe)
0.72 ml acrylamide/bisacrylamide mix (see recipe)
5.28 ml H_2O
120 µl 10% (w/v aqueous) ammonium persulfate (add immediately before pouring gel)
12 µl TEMED (add immediately before pouring gel)

This will result in a 3.2% solution. Adjust volumes as necessary.

Denaturing BN transfer buffer

5.81 g Tris base (48 mM final)
2.93 g glycine (39 mM final)
200 ml methanol (20% final)
1 g SDS (0.1% final)
H_2O to 1 liter
Store at 4°C (stable at least 1 year)

Destaining solution

450 ml methanol (45% v/v final)
100 ml acetic acid (10% v/v final)
H_2O to 1 liter
Store at room temperature (stable at least 1 year)

Detergent stock solutions

2× digitonin:

Prepare a 2% (w/v) solution of digitonin (Sigma-Aldrich) in water by heating to 95°C. Store in 1- to 10-ml aliquots up to 5 years (possibly longer) at −20°C.

Thawed solutions are stable at room temperature for up to 1 week. If a precipitate forms, reheat the solution to 95°C until the digitonin redissolves.

10× Brij 96:

Prepare a 10% (w/v) solution of Brij 96 (e.g., Brij 96V) in water. Store up to 1 year (possibly longer) at room temperature.

10× Triton X-100:

Prepare a 10% (w/v) solution of Triton X-100 in water. Store up to 1 year (possibly longer) at room temperature.

10× NP-40:

Prepare a 10% (w/v) solution of Nonidet P-40 (NP-40) in water. Store up to 1 year (possibly longer) at room temperature.

10× dodecylmaltoside:

Prepare a 10% (w/v) solution of dodecylmaltoside (Sigma-Aldrich) in water. Store up to 1 year (possibly longer) at 4°C.

Any nonionic detergent that has been proven to be useful for the cells and proteins of interest can be used as well.

High-percentage BN separating gel solution

5 ml 3× BN gel buffer (see recipe)
5.63 ml acrylamide/bisacrylamide mix (see recipe)
4.38 ml 70% (v/v) glycerol
42 µl 10% (w/v aqueous) ammonium persulfate (add immediately before pouring gel)
4.2 µl TEMED (add immediately before pouring gel)

This will result in a 15% solution. Adjust volumes and acrylamide/bisacrylamide concentration as necessary. Useful concentrations range from 6% to 18%.

Low-percentage BN separating gel solution

5 ml 3× BN gel buffer (see recipe)
1.5 ml acrylamide/bisacrylamide mix (see recipe)
8.5 ml H_2O
54 µl 10% (w/v aqueous) ammonium persulfate (add immediately before pouring gel)
5.4 µl TEMED (add immediately before pouring gel)

This will result in a 4% solution. Adjust volumes as necessary.

Marker mix 1

20 µl 1 M bis-Tris stock solution (pH adjusted to 7.0 with HCl)
20 µl 1 M NaCl
143 µl 70% (v/v) glycerol
5 mg ferritin (440 kDa and 880 kDa)
5 mg catalase (232 kDa)
5 mg bovine serum albumin (66 kDa and 132 kDa)
H_2O to 1 ml
Store at 4°C (stable at least 1 year)

Marker mix 2

20 µl 1 M bis-Tris stock solution (pH adjusted to 7.0 with HCl)
20 µl 1 M NaCl
143 µl 70% (v/v) glycerol
5 mg thyroglobulin (670 kDa)
5 mg aldolase (158 kDa)
H_2O to 1 ml
Store at 4°C (stable at least 1 year)

Native BN transfer buffer

5.81 g Tris base (48 mM final)
2.93 g glycine (39 mM final)
200 ml methanol (20% final)
H_2O to 1 liter
Store at 4°C (stable at least 1 year)

Pervanadate, 100×

Mix, in the following order:
50 µl 50 mM sodium orthovanadate
57 µl H_2O
15 µl 30% H_2O_2
Incubate 5 to 30 min at room temperature (becomes brownish)
Prepare fresh

Phosphate-buffered saline (PBS), 10×

152 g NaCl (130 mM final)
24 g monobasic sodium phosphate, anhydrous (10 mM final)
1600 ml H_2O
Adjust pH to 7.4 with NaOH.
Add H_2O to 2 liters
Store at room temperature (stable at least 1 year)

PBS with 1% (w/v) SDS

100 ml of 10× PBS (see recipe; 1× final)
100 ml 10% (w/v) SDS stock solution (*APPENDIX 2A*; 1% final)
Add H_2O to 1 liter
Store at room temperature (stable at least 1 year)

Protease and phosphatase inhibitor stock solutions

1000× leupeptin:
Prepare a 10 mg/ml solution of leupeptin in water. Store in 1-ml aliquots up to 5 years (possibly longer) at −20°C.
1000× aprotinin:
Prepare a 10 mg/ml solution of aprotinin in water. Store in 1-ml aliquots up to 5 years (possibly longer) at −20°C.
100× PMSF:
Prepare a 100 mM solution of phenylmethylsulfonyl fluoride (PMSF) in ethanol. Store in 1-ml aliquots up to 5 years (possibly longer) at −20°C.
100× sodium orthovanadate:
Prepare a 50 mM solution of sodium orthovanadate in water. Store up to 1 year (possibly longer) at room temperature.
100× sodium fluoride:
Prepare 1 M solution of sodium fluoride in water. Store up to 5 years (possibly longer) at room temperature.

COMMENTARY

Background Information

Most if not all proteins require binding to other proteins in order to fulfill their function. Thus, they form multiprotein complexes (MPCs). Most proteins are part of several distinct complexes, as well as being present as monomers. The abundance of distinct complexes of which a certain protein is a subunit can vary enormously. Furthermore, complexes might have different stabilities and these can change over time and space. Therefore, identifying and analyzing complexes is a difficult task.

Common techniques to study complexes such as immuno-precipitation (*UNIT 7.2*) or two-hybrid (*UNIT 17.3*) methods allow the identification of binding partners of the protein of interest; they, however, do not yield any information about the size, number, composition, and relative abundance of MPCs. A high-resolution method that resolves these problems is Blue Native polyacrylamide gel electrophoresis (BN-PAGE; Schägger and von Jagow, 1991; Schägger et al., 1994). Originally it was developed by Hermann Schägger to separate mitochondrial membrane complexes in the mass range from 10 to 10,000 kDa (Schägger and von Jagow, 1991; Schägger et al., 1994). Later, the protocol was modified for general applicability (Camacho-Carvajal et al., 2004). Since the first description of BN-PAGE, descriptions of its use in publications has increased exponentially. It has been applied successfully in nearly every area of multiprotein research—e.g., purification of complexes, determination of their size (Schägger et al., 1994; Schägger, 1995; Model et al., 2001; Dudkina et al., 2005) and stoichiometry (Schamel et al., 2005; Swamy et al., 2007), protein complex assembly (Model et al., 2001), structure determination by two-dimensional crystallization and electron microscopy (Poetsch et al., 2000), identification of multiprotein complexes with mass spectroscopy (Rexroth et al., 2003; Camacho-Carvajal et al., 2004; Millar et al.,

2005), or clinical diagnostics of human disorders (Schägger, 1995; Schägger et al., 1996).

In principle, BN-PAGE can be used to identify protein complexes in a given biological sample or to further characterize known protein complexes (or protein-protein interactions). For the second application, it is recommended to first test a series of different nonionic detergents for their effects on the extractability and stability of the protein-protein interaction of interest by co-immunoprecipitation (*UNIT 7.2*) followed by SDS-PAGE (*UNIT 6.1*). Only a successful co-purification indicates that the complex of interest is stable and abundant enough to be detected by BN-PAGE.

In BN-PAGE, the dye Coomassie blue, which binds nonspecifically to proteins and is itself negatively charged, is used. Therefore, the electrophoretic mobility of a multiprotein complex is determined by the negative charge of the bound Coomassie blue dye and the size and shape of the complex. Coomassie blue does not act as a detergent and preserves the structure of protein complexes. In contrast to other native gel electrophoresis systems, protein complexes are separated independently of isoelectric point and, therefore, the size of a complex can be estimated. In addition, the binding of Coomassie blue to proteins reduces their tendency to aggregate during the stacking step of the electrophoresis.

Following the first-dimension BN-PAGE, a number of subsequent biochemical techniques can be applied. Although proteins are already visible as blue bands after BN-PAGE, it can be useful to stain again with Coomassie blue to reach a higher detection sensitivity. Alternatively, silver staining (*UNIT 6.6*) or immunoblotting (*UNIT 6.2*) are commonly used. The individual subunits of a complex can be identified by SDS-PAGE or the Native Antibody-Based Mobility Shift (NAMOS) assay (see Basic Protocol 3). The NAMOS assay is a variant of BN-PAGE in which the stoichiometry of multiprotein complexes can be determined without purification of the complex of interest (Swamy et al., 2007).

Critical Parameters and Troubleshooting

Potential problems in pouring and running acrylamide gels in general are described in *UNIT 6.1*. These include problems in the polymerization of the gel and critical factors when using multicasting equipment.

Removing the comb of the BN stacking gel might destroy the wells of the stacking gel, due to the low percentage of acrylamide. Try to remove the comb slowly, pulling it out slightly perpendicular to the plane of the gel. This allows air to enter the wells. If this does not help, increase the acrylamide/bisacrylamide concentration of the BN stacking gel by 0.3%. If the gel pieces that form the wells are not broken, but just displaced, try to fix them with a syringe needle. Unwanted air bubbles in the stacking gel can be aspirated using a syringe. Test for leakiness with the BN cathode buffer before loading your sample.

A proper acrylamide concentration for the BN gel and the subsequent second-dimension SDS gel should be selected to optimize resolution within the desired molecular weight range. Use 4% to 7% BN gels for protein complexes of more than 1000 kDa, 4% to 10% for 500 kDa, 4% to 12% for 250 kDa, and 4% to 18% for proteins smaller than 100 kDa.

The first critical step in BN-PAGE is the preparation of the sample, since potassium and divalent cations that interact with Coomassie blue have to be removed. They are substituted by 6-aminohexanoic acid in order to maintain a certain ionic strength of the solution, which increases the solubility of many proteins. Therefore, the lysate has to be dialysed against BN dialysis buffer.

One frequent problem is that Coomassie blue and Coomassie blue–bound proteins precipitate in the gel wells, and subsequently the sample does not enter the gel. In this case, either reduce the amount of sample or improve dialysis of the sample. Use a larger dialysis reservoir volume, remove all air bubbles at the dialysis membrane, or prolong dialysis time.

Depending on the detergent, the dye front might contain peaks of detergent that prevent proteins from entering below these areas. This is pronounced when using polyoxyethylene detergents such as Brij 96 and Triton X-100. If your multiprotein complex of interest runs at a higher position than these precipitates, then this might not be a problem. Otherwise reduce the amount of detergent in the BN dialysis buffer.

To detect the protein of interest by Coomassie brilliant blue staining, it should be present in 0.5 to 2 μg amounts. If silver staining is used, this amount can be reduced to 0.1 μg. 20 to 40 μg of a protein mixture is typically loaded into a well of 50-μl volume on a 1-mm slab BN gel (16 cm, 15 wells). For immunoblotting, much less protein is required, depending on the quality of the antibody used for detection.

Instead of giving a defined band in the first dimension or a circular spot in two-dimensional BN/SDS-PAGE, a smear that was generated in the first dimension may be seen. This could have several reasons. First, the electrophoresis might not have been optimal. Try to improve dialysis of the sample (see above). If the protein migrates much higher than the dye front, a shorter electrophoresis might help. Second, the protein might have aggregated. Decrease the amount of sample loaded. Do not freeze and thaw the sample. Try to further purify the protein of interest under native conditions. Third, the protein might be present in several overlapping complexes. A two-dimensional BN/BN-PAGE could prove whether several overlapping complexes coexist that contain the protein of interest. For details and other techniques to explore this possibility, see Schamel et al. (2005).

Sometimes the protein is detected in a defined complex, but not in a reproducible manner. In this case the complex might have been an artifact generated during the electrophoresis step. This could be due to a step in the gel gradient—i.e., the gradient was not continuous. When pouring the gradient, make sure that there is a continuous flow of liquid and also that the flow is continuous between the two cylinders of the gradient maker. While loading the first-dimension gel slice onto the second-dimension SDS-PAGE, there could have been a small air bubble under the slice. This prevents entry of protein along that vertical line, giving the impression that two MPCs exist, rather than one.

If a certain interaction between two proteins is not seen by co-immunopurifications, do not expect to detect it by BN-PAGE. If the protein of interest is only found as a monomer, although it should be present in a complex, the complex could have been disrupted by detergent or be of low abundance. Thus, the choice of detergent is important in extracting but not disrupting multiprotein complexes. Without detergent, proteins tend to aggregate during the stacking step of the electrophoresis and do not enter the separating gel properly. Thus, a certain concentration of detergent has to be present in the sample. Unfortunately, general rules for the choice of detergent do not exist. Compare several detergents of different classes and three different concentrations of each in preliminary experiments, including detergents that allow successful co-immunopurifications of the proteins expected to be present in a common complex.

In the BN lysis buffer, orthovanadate is included to inhibit phosphatases. Since orthovanadate is a small molecule, it is rapidly separated from the sample during the BN-PAGE run. Since it is a reversible inhibitor, phosphatases become active once orthovanadate is removed. Thus, phosphorylation of the proteins might be lost during the native electrophoresis, where active phosphatases might be present. Since pervanadate irreversibly inhibits phosphatases, it should not be omitted from the BN dialysis buffer when phosphorylation of proteins needs to be preserved.

One common surprise that is encountered in performing BN-PAGE is that the size of the protein complex of interest does not match the expected value. First, the detergent micelle around transmembrane regions adds to the size of the corresponding protein. Hence, the size of the protein or protein complex might be larger than that obtained by simply adding the molecular weights of the individual subunits. Thus, to estimate the size of transmembrane proteins (complexes), the mass calibration markers should also be transmembrane proteins solubilized with the same detergent. Some water-soluble proteins match the calibration curve of dodecylmaltoside-solubilized transmembrane proteins, and therefore might be used as standards (Schägger et al., 1994). Second, protein glycosylation and phosphorylation might alter the running behavior of proteins in BN-PAGE. Note that the marker proteins are usually non-transmembrane, non-glycosylated, and non-phosphorylated proteins. Especially if you work with transmembrane proteins, you cannot deduce the molecular weight of the proteins from BN-PAGE. Third, in addition to their molecular weight, proteins are also separated according to their shape and number of bound Coomassie blue molecules. Thus, proteins that deviate significantly from a ball-like shape and very basic proteins show reduced mobility. Lastly, it might be that the expected molecular weight value of the protein complex is wrong.

Many antibodies that work well for the immunodetection (western blotting) of your protein of interest after SDS-PAGE do not recognize the protein after the first-dimension BN-PAGE. In the author's experience, the removal of Coomassie blue from the blotting membrane does not help. Try both conditions for the transfer to the blotting membrane (Alternate Protocols 1 and 2). If this does

not help, then a two-dimensional BN/SDS-PAGE must be performed. In any case, one should verify immunoblotting results of a first-dimension BN-PAGE by two-dimensional BN/SDS-PAGE, in order to prove that the detected protein indeed is the protein of interest and not a cross-reactivity of the antibody.

Performing a successful NAMOS assay critically depends on the quality of the antibodies used to shift the protein complex of interest (Swamy et al., 2007). Several problems could arise. First, protein complexes clustered by antibodies can be very large; thus, use Alternate Protocol 1 to disassemble these aggregates to efficiently transfer them to the blotting membrane. Second, some antibodies aggregate with themselves, thus producing a ladder-like shift pattern (Swamy et al., 2007). With these antibodies, a continuous increase in antibody concentration leads to a constant generation of new larger bands while smaller ones disappear. Thus, the stoichiometry of a multiprotein complex cannot be determined with this type of antibody; however, it is possible to determine whether all complexes contain the subunit in question. Use a fresh preparation of antibody, prepare Fab fragments, or remove antibody aggregates by ultracentrifugation. Third, it is possible that a given antibody cannot bind to all identical subunits of a multiprotein complex, probably because the complex is not symmetric, rendering the epitope accessible in one copy of the subunit but not in its neighboring copy. Likewise, if the two epitopes are very close within the complex, two antibody molecules might not be able to bind simultaneously due to steric hindrance. This type of antibody gives an underestimate of the actual stoichiometry (Swamy et al., 2007). In conclusion, not all antibodies result in the number of shifts that correspond to the number of subunit copies present in the protein complex. Thus, it is recommended to use several independent antibodies per subunit, and the Fab fragments of those antibodies.

Anticipated Results

In BN-PAGE, native protein and multiprotein complexes are separated according to their size. Thus, using two-dimensional BN/SDS-PAGE, protein complexes can be identified and characterized in terms of their relative abundance, subunit composition, and size. Since BN-PAGE is only the separation technique, the sensitivity of detection depends on the detection method used. Furthermore, the NAMOS assay allows the determination of the stoichiometries even from nonpurified complexes. Typical results are illustrated in Figures 6.10.1 and 6.10.2. Comparison of two or more samples is possible if the pouring and running of the gels was done in similar way. In combination with modern mass spectroscopy, BN-PAGE, with its high-resolution properties, is an excellent choice to identify novel protein complexes from any biological source.

Time Considerations

Preparation of the sample as described in the Support Protocol takes 6 hr or overnight. If purified proteins or organelle fractions are used, the required time can be substantially longer. However, if utilizing desalting columns to obtain samples with low cation concentrations, the time can be shorter. Since the sample should be separated immediately by BN-PAGE (and cannot be frozen and stored), one should reserve some time for gel loading, which usually takes another 0.5 to 1 hr. Depending on the gel size, running of the BN-PAGE takes from 6 hr to overnight. Loading of two second-dimension SDS-PAGE gels takes ~1 to 1.5 hr. Running the SDS-PAGE takes between 1.5 hr and overnight, again depending on the size of the gels. Thus, two-dimensional BN/SDS-PAGE takes at least 1.5 days—not counting the visualization process of the proteins of interest.

One rate-limiting step is the running of the second-dimension gels. 30 to 40 lanes can easily be separated in parallel on two BN gels, but loading, running, and detection from 30 to 40 second-dimension gels requires substantial operator time and electrophoresis equipment. Therefore, whenever possible, one should try to use only first-dimension BN gels without the need for the second dimension.

Pouring gradient gels is another time-consuming process. To minimize the time requirement, it is strongly recommended to use multicasting equipment to pour several gels at once. This also ensures best reproducibility for critical comparisons of multiple samples.

Acknowledgements

I thank Michael Reth and Klaus Pfanner for initially introducing me to BN-PAGE and Hermann Schägger for his invaluable help in setting up the technique. I further thank Balbino Alarcón for his advice on establishing the NAMOS assay and members of my laboratory for constantly improving the various BN techniques: Margarita Camacho-Carvajal, Mahima Swamy, Thomas Bock, Eszter Molnar, Susana Minguet, Elaine Pashupati Dopfer, and Gabrielle Siegers.

ABSTRACT

The two basic groups of complex DNA damage are double-strand breaks (DSBs) and non-DSB oxidatively-induced clustered DNA lesions (OCDLs). The single-cell gel electrophoresis (SCGE) or comet assay has been widely used for the detection of low levels of various types of DNA lesions including single-strand breaks (SSBs), DSBs, and oxidized bases per individual cell. There are limited data on the use of the comet assay for the detection of non-DSB clustered DNA lesions using different repair enzymes as enzymatic probes. This unit discusses a novel adaptation of the comet assay used to measure these unique types of lesions. Until now OCDL yields have been measured using primarily pulsed-field agarose gel electrophoresis. The advantages offered by the current approach are: (1) measurement of OCDL levels per individual cell; (2) use of a small number of cells (∼10,000) and relatively low doses of ionizing radiation (1 to 2 Gy) or low levels of oxidative stress, which are not compatible with standard agarose gel electrophoresis; and finally, (3) the assay is fast and allows direct comparison with pulsed-field gel electrophoresis results. *Curr. Protoc. Cell Biol.* 49:6.11.1-6.11.17.

INTRODUCTION

This unit describes the analytical execution of a novel adaptation of the single-cell gel electrophoresis (SCGE) method using DNA agarose plugs. The standard comet assay uses a constant electric field, similar to any electrophoresis, to force migration of protein-free fragmented DNA embedded in a DNA/low-melting-point agarose mixture. During electrophoresis the fragmented DNA migrates out of the cell nucleus and into the gel matrix according to its length, forming a tail that resembles a comet tail, hence the name. The adaptation presented here allows measurement of bi-stranded non-double strand break (DSB) oxidatively-induced clustered DNA lesions (OCDLs) per individual cell. The novelty of this assay lies in the fact that DNA/agarose plug technology is used for measuring clusters per individual cell in the comet assay. This adaptation allows direct quantitative comparison with the most widely used independent method of pulsed-field gel electrophoresis (PFGE; Sutherland et al., 2003). The comet assay differs from PFGE in that it is a simpler and faster method already utilized in biomonitoring and genotoxicity assessment. Although both techniques involve the embedding of cells in a low-melting-point agarose suspension, lysis, and electrophoresis, comet assays offer a unique advantage since DNA fragmentation can be visualized under the

DOI: 10.1002/0471143030.cb0611s49

microscope per individual cell using fluorescent DNA staining. The major experimental principles/methodology reside in the principle that supercoiled duplex DNA can be fragmented by DNA endonucleases, hydrogen peroxide, ionizing radiations, etc. The resulting DNA migration is directly related to the extent of DNA damage as evidenced by the formation of the comet tail. Therefore, DNA migration is a function of both size and amount of broken DNA fragments. The measurement of DNA damage is based on the percentage of fluorescence of the DNA in the tail rather than in the analysis of DNA fragment distribution. On the other hand, PFGE through the application of a pulsed and rotating electric field can be used for the analysis of DNA fragment distribution for lengths ranging from ~6 Mbp up to a few kilobasepairs.

This unit focuses on the utilization of SCGE for measurement of closely spaced (clustered) DNA lesions on opposing strands (bi-stranded; OCDLs) and on the same strand (uni-stranded or tandem; total sites) in human cells exposed to relatively low doses of ionizing radiation (1 to 10 Gy) or any other oxidizing agent capable of inducing equivalent levels of oxidative injury in the cell. This novel adaptation of SCGE uses DNA agarose plugs as in PFGE and has the following advantages compared with previous versions of SCGE: (1) the results are directly comparable with PFGE and other techniques measuring yields of clustered DNA damage; (2) the assay is practical, simple, and reproducible; and (3) the use of plugs allows for the production and extended storage of multiple samples whereas traditional SCGE methods did not. Earlier studies by Visvardis et al. (2000) have shown that the use of DNA agarose plugs can also be used in the comet assay for detection of strand breaks induced by the restriction enzyme *Not*I in human DNA. No studies exist on the use of this methodology in the detection of clustered DNA damage.

Successful SCGE requires basic knowledge of DNA agarose gel electrophoresis and fluorescence microscopy. Since it involves cell processing and enzymatic processing of DNA, knowledge and abilities in cell culture and basic enzymology are also required. This unit provides detailed methods for preparing cells for treatment with an oxidizing agent, creation of DNA agarose plugs, and repair enzyme treatment (see Basic Protocol 1), running an SCGE assay (see Basic Protocol 2), and proper quantitative analysis of the level of OCDLs and total sites per cell (see Support Protocol).

STRATEGIC PLANNING

Choice of Proper Repair Enzymes

The standard comet assay can be used for detection of frank single-strand breaks (SSBs) and double-strand breaks (DSBs) (denaturing and non-denaturing conditions, respectively) directly induced by any oxidizing agent. For the additional detection of OCDLs, the use of cellular repair enzymes is necessary. This unique approach for quantifying these types of bi-stranded oxidative DNA damage in human cells using DNA repair enzymes isolated from *E. coli* was initially developed by Sutherland et al. (2000a). Human or bacterial repair enzymes like formamidopyrimidine [fapy]-DNA glycosylase (Fpg), endonuclease III (*Endo*III), and endonuclease IV (*Endo*IV), with their appropriate buffers, can be used as enzymatic damage probes to cleave specific DNA lesions (Sutherland et al., 2003). The choice of enzyme is dependent on the type of oxidized base damage one aims to detect. For example, for the detection of abasic (AP) sites (DNA sites with a missing base), the human APE1 or bacterial *Nfo* can be used; in the detection of oxidized purines, the human OGG1 or bacterial Fpg can be used. The cleavage sites of different enzymes used for the detection of clusters are listed in Table 6.11.1. Although these enzymes are commercially available, the user must always check the specificity (Holt and Georgakilas, 2007) and, if possible, compare commercial enzymes with the same enzymes produced in the laboratory using bacterial cells (Georgakilas et al., 2004). Once a lesion is detected, as shown in Figure 6.11.1, in each cluster, repair enzymes will excise

Table 6.11.1 Bacterial or Human Repair Enzymes Used as Enzymatic Probes for the Detection of Oxidatively Clustered DNA Lesions (OCDLs) and their Expected Substrates

Repair enzyme used as damage probe[a]	Substrates
Human hAPE1 or *E. coli* Nfo protein (endonuclease IV)	Abasic: Several types of abasic sites including oxidized abasic sites, abasic sites modified with alkoxyamines and DNA containing urea residues; no activity is expected towards oxidized bases
Human OGG1 or *E.coli* Fpg protein (DNA glycosylase) Associated AP lyase activity	Oxidized purines (oxypurines): Majority of oxidized purines like FapyGua, FapyAde, C8-oxoGuanine, C8-oxoAdenine, and to a lesser extent, other modified purines and some abasic sites
Human NTH1 protein or *E.coli Endo*III (endonuclease III) Associated AP lyase activity	Oxidized pyrimidines (oxypyrimidines): Thymine residues damaged by ring saturation, fragmentation, or ring contraction including thymine glycol (Tg) and uracil residues (5-fo-Ura), FapyAde, 5-OH-Cyt and to a lesser extent FapyGua; some abasic sites

[a] All enzymes are commercially available from New England Biolabs or can be isolated using an approach similar to the one described by Georgakilas et al. (2004).

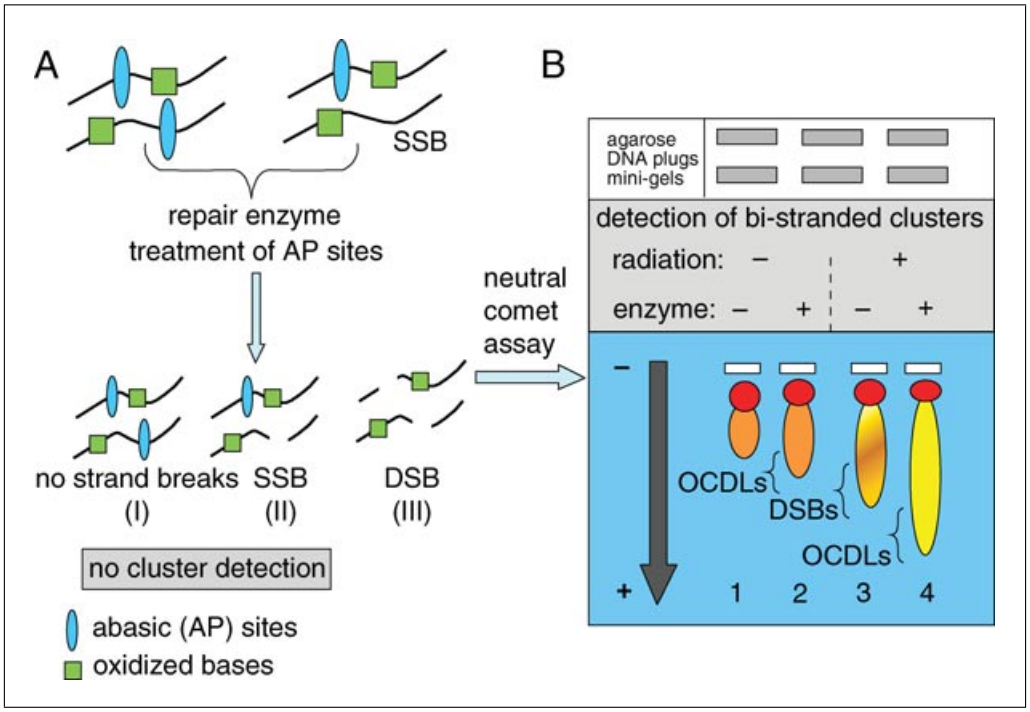

Figure 6.11.1 Detection of bi-stranded oxidatively induced clustered DNA lesions (OCDLs) using a modified neutral comet assay and agarose-DNA plugs as mini gels. (**A**) Principles of detection using a repair enzyme for a representative ideal type of a cluster consisting of a set of four bi-stranded base lesions (abasic-AP- sites and oxidized bases). Alternatively, one of the lesions can be a single-strand break, SSB. As shown in pathways I and II, no or incomplete cleavage of AP lesions by the repair enzyme AP endonuclease will lead to no detection of the cluster. In the case of cleavage of both lesions by the enzyme and induction of a DSB, detection of the cluster occurs (III). (**B**) Detection of clusters using neutral (non-denaturing) comet assay. Microscope slides containing human cells embedded in agarose plugs can be subjected to constant field electrophoresis and the double-strand breaks (DSBs) and OCDLs can be measured in the same run as the ones being induced by radiation. For lanes 1 and 2 (non-irradiated) low levels of endogenous OCDLs are expected. For lanes 3 and 4 (irradiated) higher levels of OCDLs are expected. Comparison of lane 3 and 1 will provide the yield of prompt DSBs induced by radiation. The measurement is based in the increase of comet tail moment (TM = %DNA in tail × tail length) and equations described in the Support Protocol.

the lesion and cleave the DNA strand by their intrinsic lyase activity (DNA glycosylases) or in the case of an AP endonuclease, it will cleave the DNA strand directly. In either case, an SSB is created in each strand or a DSB in the case of a cluster (Fig. 6.11.1). These de novo DSBs are equal to the clusters detected by the enzymatic probe (Sutherland et al., 2000b).

Choice of Neutral or Alkaline Running Conditions for the SCGE

The alternative uses of neutral or alkaline gel electrophoresis can provide the user the option of calculating bi-stranded or total lesions. Neutral (non-denaturing) conditions, described in this unit, can be used to detect and measure DSBs and OCDLs (non-DSB clusters) with the use of repair enzymes. With alkaline electrophoresis, one can detect all induced SSBs and alkali-labile or other enzyme-sensitive sites that are converted to breaks during alkaline electrophoresis (total sites). The term total sites refers to all the lesions existing in each DNA strand (Fig. 6.11.1). OCDLs only refer to the bi-stranded lesions located in opposing strands. In addition to normal and oxidized abasic sites, several oxidized bases including 5,6-dihydroxy-5,6-dihydrothymine, 5-formyluracil, and oxazolone may be converted into strand breaks under the alkaline conditions of single-cell gel electrophoresis analysis (Pouget et al., 2002; Douki et al., 2006). Although the novel adaptation of SCGE presented here is considered highly efficient and acceptable for the calculation of OCDL levels per cell, it does not directly calculate the exact number of sites per individual cell as does PFGE.

BASIC PROTOCOL 1

TREATMENT OF CELLS WITH AN OXIDIZING AGENT AND PREPARATION OF AGAROSE PLUGS

The concepts of DNA cluster quantification are simple, but execution is technically and analytically demanding. The major experimental principles and methodology underlying these measurements are discussed. In every experiment to calculate levels of bi-stranded clusters using neutral SCGE, the use of ionizing radiation (X- or γ-rays) as a standardization control is recommended. Even low doses of these types of radiations ($\sim$1 Gy) have been found to induce detectable levels of clusters in human cells (Sutherland et al., 2000a; Holt and Georgakilas, 2007). In addition, a linear response of cluster yields in response to increasing dose is expected for a wide range of doses (1 to 20 Gy). Separate samples can be prepared as a positive control using hydrogen peroxide, since it has been found that low-to-moderate concentrations of hydrogen peroxide ($\leq$100 μM) do not induce detectable levels of bi-stranded clusters (Holt and Georgakilas, 2007). In the case of tandem (total) lesions, both agents are expected to give detectable yields.

For treatment with the oxidizing agent, $\sim$10,000 cells in complete medium are exposed to this agent (similar to ionizing radiation) on ice. Cells must be kept on ice before and during the treatment period to inhibit any repair processes. Immediately following treatment and if no repair measurements are intended, EDTA is added to a final concentration of 50 mM and the cells are maintained in this solution until further processed. In the case of repair experiments for measuring processing efficiency, the cells are exposed to the agent at room temperature and are incubated at 37°C until the desired time-point and processed into sample plugs as described below. The non-treated (negative controls) must be processed in exactly the same manner as the the oxidizing agent–treated samples. To minimize oxidation artifacts during DNA isolation, all buffers must be freshly prepared, autoclaved, purged with argon or nitrogen for 15 min, and supplemented with 50 μM phenyl-tert-butyl nitrone in DMSO (PBN; Sigma), a non-toxic, free radical spin trap and scavenger (Lu et al., 2004; Tsao et al., 2007).

Materials

1% (w/v) molecular biology grade, normal-melting-point agarose in 1× PBS
Cells
Complete medium
Trypsin, optional
Phosphate buffered saline (PBS; *APPENDIX 2A*)
Trypan blue
Hydrogen peroxide (H_2O_2)
1 M Na_2EDTA
Low-melting-point agarose prepared in TE (molecular biology grade; Bio-Rad)
Plug lysis solution (see recipe)
1× TBE electrophoresis buffer (see recipe)
Appropriate repair enzymes and autoclaved and filtered buffers for enzymes (Fpg, *Endo*III, *Endo*IV; New England Biolabs)
1 M KCl, pH 7.8 (*APPENDIX 2A*), ice cold
Alkaline denaturation buffer (see recipe), ice cold

Autoclaved-sterile microscope slides (3 × 5–in.) and 18-mm^2 coverslips (Corning)
25-cm^2 cell culture flasks
Hemacytometer
^{137}Cs source
Refrigerated centrifuge
PFGE plug molds (BioRad)
37°C incubation oven or thermal cycler

Prepare slides

1. Prepare 3 × 5–in. microscope slides fully covered with 1 ml of 1% (w/v) molecular biology grade, normal-melting-point agarose in 1× PBS. Allow slides to dry overnight at room temperature.

   Make sure the agarose is maintained at 37°C to ensure solution consistency while applying. Using a Pasteur pipet, ensure that the agarose is uniformly applied on the surface of the slide and allow to dry at room temperature, then store the slides in a slide box in a dry environment.

   This should be done 24 hr prior to plug preparation to ensure complete drying of slides.

Prepare agarose/DNA plug

2. Grow cells in a 25-cm^2 cell culture flask in 5 ml complete medium at optimum conditions recommended by supplier.

   Cells can be grown in larger flasks if more sample plugs are desired.

   Cell concentration should not exceed 1 × 10^6 cells/ml. If cells are adherent, grow to ~95% confluence.

   Any type of cell line or even primary cells can be used.

3. Once cells reach appropriate confluence, trypsinize (if adherent; Francisco et al., 2008), resuspend in 1 to 2 ml PBS, and place on ice for 10 min.

4. Count cells after trypsinization.

   The expected yield of a 25-cm^2 flask if seeded at 50,000 cell/ml should be at least 25,000 cell/ml.

   The count will indicate how many sample plugs can be made from the contents of each flask. About 10,000 cells must be used per plug. Since preparation of a total number of ~10 to 20 plugs is recommended, a minimum of 100,000 to 200,000 cells is required for each treatment. Assuming one radiation dose, negative (untreated) control, and positive

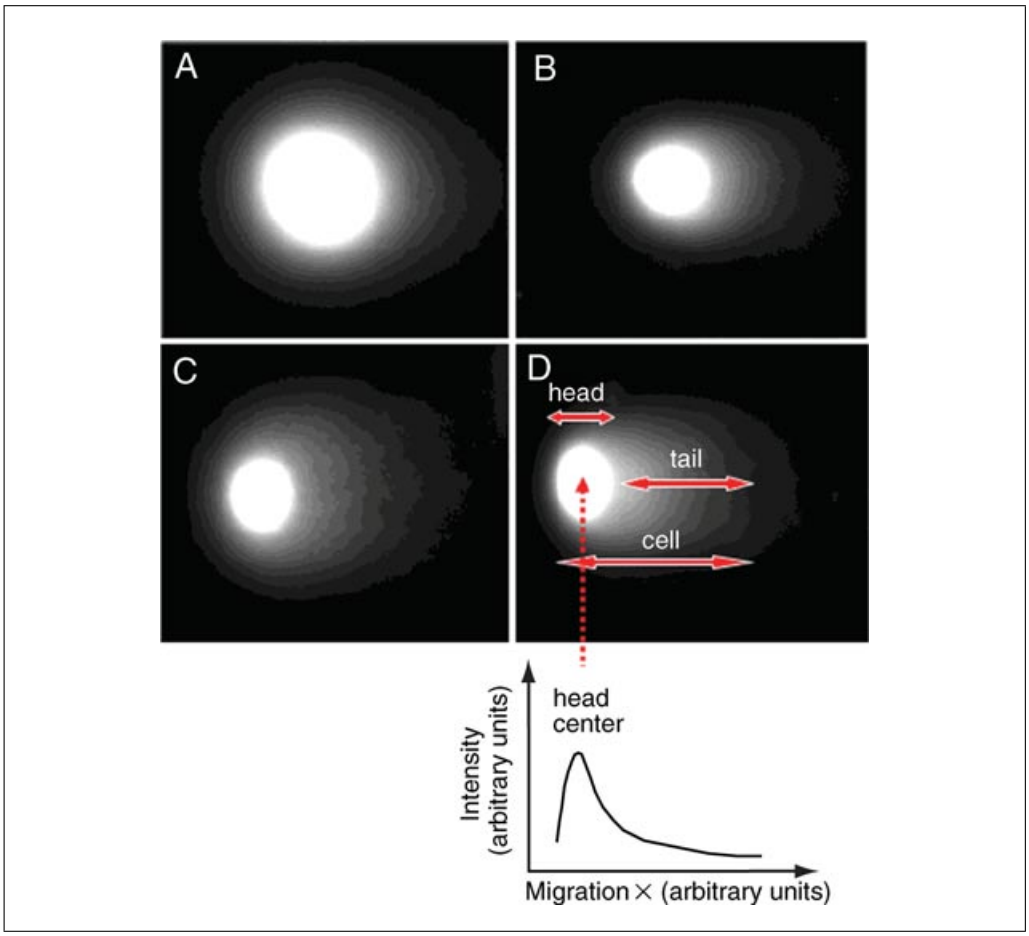

Figure 6.11.2 Detection of bi-stranded oxidatively induced clustered DNA lesions (OCDLs) induced by γ-irradiation in human pre-B acute lymphoblastic leukemia NALM-6 cells using single-cell gel electrophoresis (comet assay), non-denaturing conditions, and Fpg repair enzyme as a damage probe. (**A**) Upper left panel shows an unirradiated single cell (used as control) with a tail moment (TM) = ~6 μm. (**B**) Upper right panel shows an unirradiated cell treated with *E.coli* repair enzyme Fpg for the detection of oxypurine clusters with a TM = ~10 μm. Lower left panel (**C**) shows a single cell exposed to exposed to 5 Gy of γ-rays without repair enzyme treatment and with TM = ~ 20 μm. (**D**) Lower right panel shows cells a single exposed to 5 Gy of γ-rays treated with Fpg with a TM = ~ 35 μm. Tail moment = tail length (μm) × % tail DNA (intensity of stained DNA). An example of the suggested intensity profile (densitogram) is also shown in the specific comet (D). The increase in the tail moment for the enzyme-treated samples is attributed to the additional DNA fragmentation induced by recognition and cleavage of bi-stranded clustered lesions by the repair enzyme.

control (H_2O_2), a total minimum number of ~300,000 to 600,000 cells is suggested per experiment.

5. Determine the percent of viable cells using Trypan blue (Georgakilas et al., 2004) or other exclusion assay, e.g., erythrosin B(EB, Sigma).

6. Expose cells to low level γ-rays, for example, 3 to 5 Gy using a ^{137}Cs source. Use hydrogen peroxide (H_2O_2) as a positive control (50 to 100 μM, 15 min on ice).

   Exposure time will vary depending on the extent of DNA damage (oxidation) desired. At 5 Gy of γ-rays and under non-denaturating conditions, a tail moment (TM) of ~15 to 20 μm is expected (DSBs; Fig. 6.11.2).

7. Immediately after irradiation, add 1M Na_2EDTA to the medium to a final concentration of 50 mM. Maintain the cells in this medium on ice until further processed.

8. Perform a second Trypan blue exclusion assay after γ-ray exposure to assess cell viability and extent of cell death induced by γ-ray exposure.

   Viability directly after irradiation should be the same as prior to irradiation (≥90%). It should be measured immediately following irradiation; therefore, cell death should not be an issue if the procedure has not somehow compromised cell viability and initiated apoptosis or necrosis.

9. After irradiation and addition of Na_2EDTA, wash cells three times in 3 ml PBS each wash, centrifuging 5 min at 450–1000 × *g*, 4°C, each time.

10. Resuspend the cells in 1 to 2 ml PBS and count cells.

    The number of cells must be ~10,000 cells per plug. The cell count will establish the total number of cells available, which will determine the number of plugs that can be produced. If the percentage of dead cells does not exceed 5% to 10%, the presence of dead cells should not have a significant impact on the levels of DNA damage detected.

11. After centrifugation, embed the cells in an equal volume of low-melting-point agarose plugs at a final agarose concentration of 0.85% using plug molds similar to PFGE molds.

    PFGE plug molds can be purchased from various companies such as BioRad. Slight volume differences may exist between brands or type of plug molds. Typically, plug mold volume ranges from 80 to 100 μl. For example, if ten plugs are to be created, then 100,000 cells (500 μl in PBS) must be mixed with an equal volume of low-melting-point agarose and distributed equally to the ten molds.

    The formation of these DNA plugs allows direct comparison with PFGE.

12. Incubate the plugs (10 to 20 plugs) in 50 ml plug lysis solution for 1 hr on ice at 4°C in the dark.

13. After completion of lysis, wash plugs in 50 ml of 1× TBE electrophoresis buffer for 1 hr at 4°C in the dark with two buffer changes.

14. Mount up to six plugs per agarose-coated microscope (from step 1) slide using 0.85% low-melting-point agarose (Fig. 6.11.1).

15. Apply one to two 18-mm^2 coverslips over the plugs and allow the agarose to solidify 10 min at 4°C.

16a. *For neutral SCGE running conditions (detection of DSBs).* Wash the slides in 50 ml of 1× TBE electrophoresis buffer for 1 hr at 4°C in the dark with three buffer changes (Fig. 6.11.3).

16b. *For alkaline SCGE running conditions (detection of SSBs).* Wash plugs extensively in ice-cold alkaline denaturation buffer, and incubate in the same buffer for 45 min at 4°C in the dark (Fig. 6.11.3).

    For the detection of DSBs (neutral conditions) or SSBs (alkaline conditions), no further enzyme or other treatment is required, and therefore the slides with mounted plugs are subjected to electrophoresis.

17. For detection of DSB or SSB, proceed to Basic Protocol 2, step 1a or 1b (also see Fig. 6.11.3).

Repair enzyme treatment (detection of OCDLs and total enzyme sites)

Continuation from step 13 to detect OCDLs and total sites. At this point, neutral or alkaline conditions are being used; enzyme treatment for the detection of clustered sites is identical as shown in the flow chart of Figure 6.11.3. Differential handling occurs only after step 19 below. The steps of the following repair enzyme treatment are additional steps for OCDL detection. These steps are performed following lysing of plugs and prior to mounting on the slides.

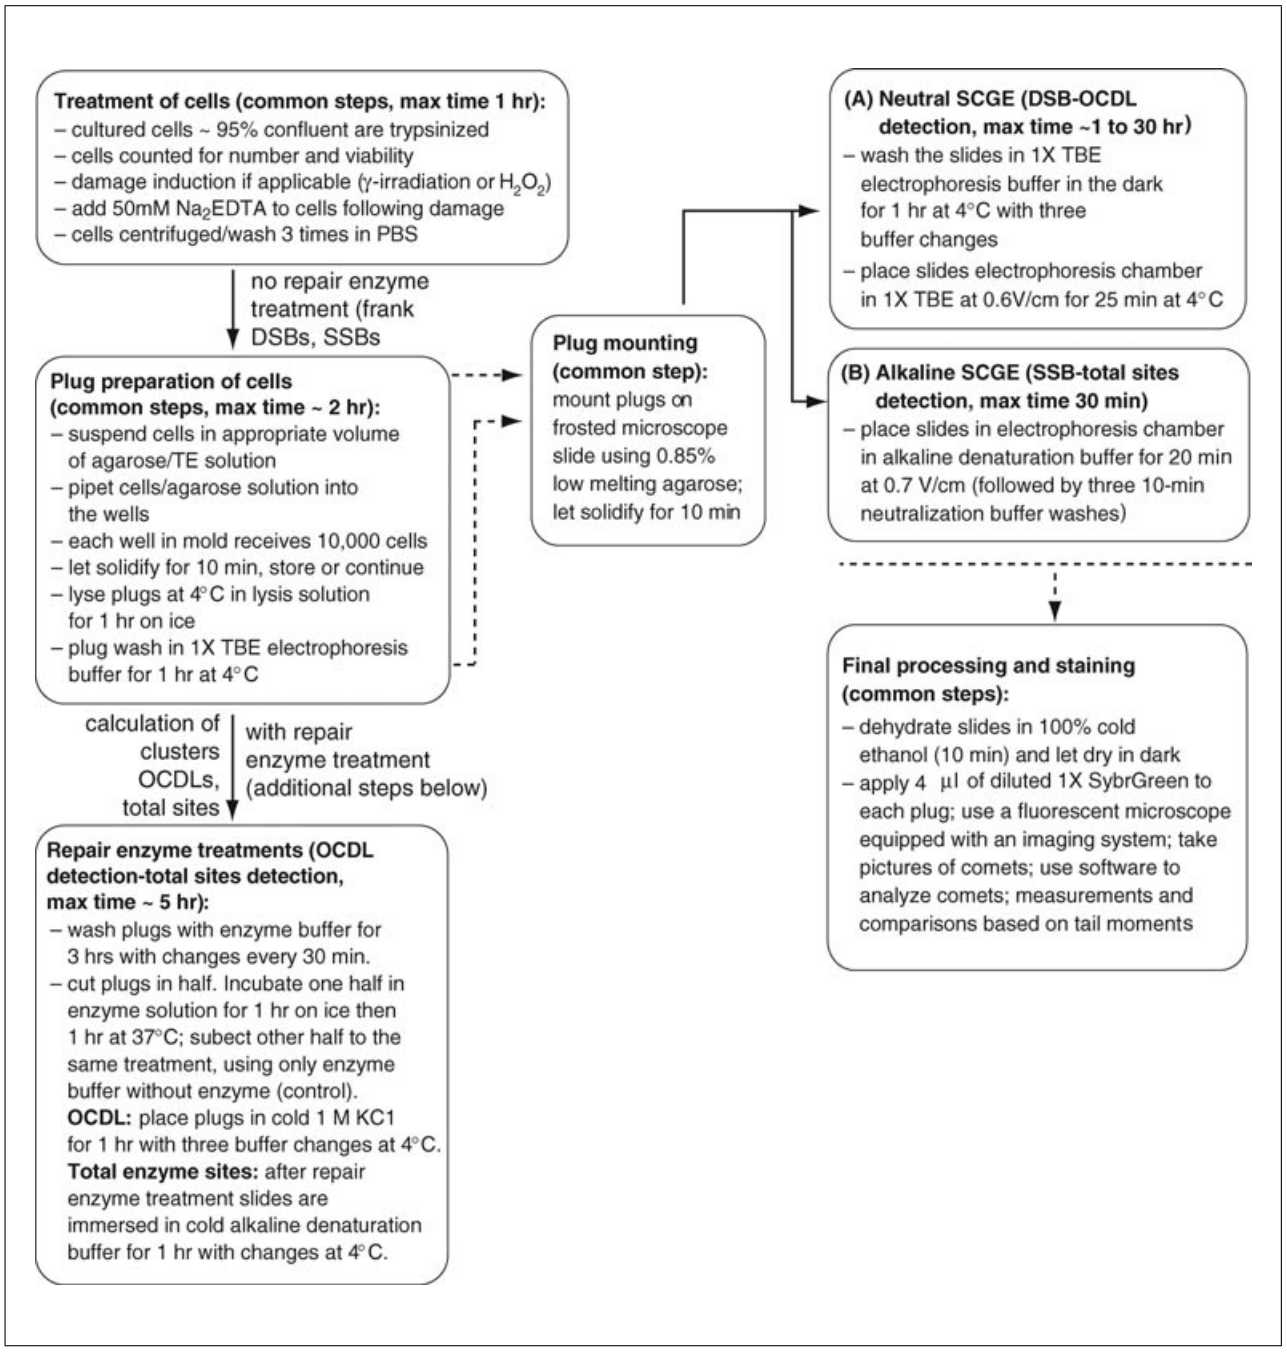

Figure 6.11.3 Overview (flow chart) of this adaptation of the single-cell gel electrophoresis (comet assay) used for the detection of bi-stranded oxidatively induced clustered DNA lesions (OCDLs) using low-melting-point agarose DNA plugs similar to pulsed-field gel electrophoresis (PFGE). In each step (box) the maximum recommended time is indicated along with the key steps followed.

18. To determine the ideal repair enzyme quantity, perform titration studies with the enzyme and the sample(s) with the highest expected level of DNA damage.

    For example in the case of radiation, the highest radiation dose, e.g., 5 Gy, should be used and titration curves should be calculated using increasing enzyme amounts (0 to 1 enzyme units/plug) in the appropriate enzyme buffer and incubated for 1 hr at 37°C. The optimum enzyme amount is calculated at the point when the titration curve reaches a plateau (Holt and Georgakilas, 2007).

    At the same time, the ideal enzyme amount must offer the minimum non-specific cleavage detected using a control sample (e.g., non-irradiated; Holt and Georgakilas, 2007).

19. To equilibrate the plug in enzyme buffer, after lysis, wash plugs with 1 ml/plug appropriate repair enzyme buffer as indicated by the manufacturer for 3 hr with six changes of buffer, 30 min each change.

    For example, for Fpg, use 10 mM Tris·Cl/10 mM $MgCl_2$, pH 7.0.

20. Cut each plug in half. Incubate one half of the plug (+) in 0.3 ml/plug enzyme solution (enzyme buffer plus enzyme amount), for 1 hr on ice followed by 1 hr in a 37°C incubation oven or thermal cycler. Subject the other half of the plug (−) to the same treatment, using just the enzyme buffer, i.e., without the enzyme.

    For example, the enzyme solution can consist of 0.5 U Fpg and 1 mM DTT in 300 μl of Fpg buffer.

For neutral conditions (OCDL detection)

21a. Following repair enzyme treatment, place plugs in 1 ml/plug ice-cold 1 M KCl (pH 7.8) for 1 hr with three buffer changes at 4°C to stop the enzyme reaction (KCl-treatment).

22a. Place slides in 1× TBE electrophoresis buffer for 1 hr with three buffer changes. Mount plugs on an agarose-coated microscope slide using 0.85% low-melting agarose and leave 10 min at 4°C. Once the agarose has cooled and the plug is affixed to the slide, proceed onto the electrophoresis portion of the experiment (see Basic Protocol 2, step 1b). Proceed to Basic Protocol 2, step 1a.

    As an additional test for the efficiency of KCl treatment to disrupt the DNA-protein complexes, a proteinase K treatment can be used. Following repair enzyme treatment, slides can be placed in a proteinase K solution (2 mg/ml proteinase K in plug lysis buffer, pH 7.8) for 1 hr at 37°C and then washed three times with TE buffer on ice (1 hr each wash).

For alkaline conditions (total sites detection)

21b. In the case of alkaline SCGE and after repair enzyme treatment, immerse plugs in 3 ml ice-cold alkaline denaturation buffer for 1 hr with three buffer changes at 4°C.

22b. Mount plugs on an agarose-coated microscope slide using 0.85% low melting agarose and left 10 min at 4°C. Once the agarose has cooled and the plug is affixed to the slide proceed onto the electrophoresis portion of the experiment (see Basic Protocol 2, step 1b).

RUNNING SINGLE-CELL GEL ELECTROPHORESIS (SCGE)

BASIC PROTOCOL 2

The SCGE in general is a rapid and sensitive technique for assessing low levels of DNA damage in human or plant cells. The use of repair enzymes significantly increases the sensitivity of the assay by a factor of 2 to 3 (Holt and Georgakilas, 2007). The actual electrophoresis part of the assay is considered very critical since slight changes in the electrophoretic conditions can induce a wide variability in results. In all cases, special attention should be given to three major parameters: the ionic strength of the electrophoretic buffer, the electric field strength, and the number of slides submerged in the electrophoretic tank. A higher ionic strength buffer will lead to an overestimation of real damage values appearing as longer comet tails. A conductivity meter can be used to ensure the same conductivity between experiments. At the same time, lower than needed ionic strength will result in low conductivity and underestimation of damage values. For this reason different slide numbers in the electrophoretic tank should be avoided since a high number can result in lower conductivity. Finally, all electrophoretic conditions including voltage and electric field strength (V/cm) should be standardized to controls, i.e., not to give significant yields of damage of non-damaged controls. The comet assay is in general a very versatile technique for detecting damage, and alterations to the electrophoresis running conditions can be used to quantify the level of a wide variety of DNA lesions.

Materials

Agarose-coated slides with treated DNA plugs (see Basic Protocol 1)
Neutral electrophoresis buffer (see recipe), ice cold
Alkaline (denaturation) electrophoresis running buffer (see recipe), ice cold
Neutralization buffer: 0.4 M Tris·Cl, pH 7.5 (store at 4°C)
100% ethanol, ice cold

30-cm horizontal constant-field gel electrophoresis chamber
Constant-field agarose gel electrophoresis apparatus with power supply
Storage box for slides under dark condition

1a. *Running SCGE under neutral conditions (DSB or OCDL detection)*. Place up to six slides (use always the same number) with mounted plugs into a 30-cm horizontal constant-field gel electrophoresis chamber containing 1× TBE and run for 25 min at 0.6 V/cm at 4°C. Proceed to step 3.

1b. *Running SCGE under alkaline conditions (SSBs or total enzyme sites detection).* Place up to six slides (use always the same number) with mounted plugs into a 30-cm horizontal constant-field gel electrophoresis chamber in ice-cold alkaline denaturation buffer for 20 min at 0.7 V/cm and at 4°C.

2b. To remove excess alkali, wash the slides three times for 10 min each wash with neutralization buffer. Proceed to step 3.

3. Dehydrate the slides in 100% ice-cold ethanol (10 min) and allow slides to dry in dark. Allow slides to dry at room temperature in the dark until plugs dehydrate and lay flush with the microscope slide, then cover box and store slides in a dry room until analysis.

The slides can be stored indefinitely in the dark after dehydration.

SUPPORT PROTOCOL

QUANTITATIVE ANALYSIS OF SCGE SLIDES

Quantitative analysis of SCGE slides assumes that undamaged DNA strands are too large and do not leave the nucleus, whereas the smaller the DNA fragments, the farther they are able to migrate within the gel matrix after the application of a constant electric field. Therefore, the amount of DNA that leaves the nucleus (head) is a measure of the amount of DNA damage in the cell (comet tail; Fig. 6.11.2). Image analysis measures the overall fluorescence intensity for the whole nucleus and the overall fluorescence intensity of tails, and compares the two signals. The stronger (brighter) the signal from the migrated tail DNA, the more damage has been induced by the oxidizing agent (Fig. 6.11.2).

Materials

SYBR Green DNA staining dye (Cambrex BioScience) diluted 1:10,000 (1×) in TE buffer (10,000× SybrGreen)
Fluorescence microscope (20×, 40×, or 60× objective lens) equipped with a monochrome CCD camera
Comet analysis software (e.g., CometScore, Tritek)

Stain slide and analyze

1. Rehydrate the slides 10 min in 5 ml deionized water at room temperature. Apply 40 µl of diluted SYBR Green (1×) to each plug on the slides.

To visualize and analyze the DNA damage, the slides should be stained with a DNA staining dye that efficiently stains both double- and single-stranded DNA like SYBR Green.

2. View individual (non-overlapping) cells, or comets, using a fluorescence microscope equipped with (at least) a monochrome charge-coupled device (CCD) imaging system.

   The type and objective is selected by the user.

   Each damaged cell within the plug will be seen as possessing a comet-like tail.

   The authors' laboratory uses a 20× objective to capture more comet cells per picture. Usually, in an asynchronous cell population, i.e., cells of different cell cycle phases, a relatively varying tail length (5% to 20% variation in length) will be observed. In synchronized cell populations, this phenomenon is expected to be minimized. If the exposure to the oxidizing agent (for example, ionizing radiation) induces random hits in the DNA, then a uniform distribution of damage (tail length) is to be expected in every cell (Fig. 6.11.2).

3. Conduct analysis with any appropriate comet software package measuring the Tail Moment (Olive et al., 1990). Measure 100 cells per plug with three replicates.

   The authors' laboratory uses CometScore (Tritek) as an effective, easy, and free package to score 100 cells per plug with three replicates (semi-automated).

   Tail moment (TM) is defined as the product of the tail length and the fraction of total DNA in the tail and it is calculated by multiplying the percent (%) DNA in the tail (which the software quantifies by dividing tail to total-head and tail-cell intensity) by the tail length (distance from the nucleus to the end of the tail). Thus, calculating the tail moment not only factors in the amount of DNA that migrates into the comet tail, but also the distance it migrates:

   tail moment (μm) = tail length × tail %DNA

   The tail moment can be explained as a true physical tail moment about the center of a comet head. Longer tails will differentiate cells with high damage compared to controls (very small tail; Fig. 6.11.2). The center of the comet head and the full extension of tail length are calculated by the user as shown in Figure 6.11.2 or automatically by the software. The software usually provides several scoring options like additional calculation of olive tail moment, tail length etc. Read software instructions carefully.

4. In all cases, calculate frank DSBs (directly induced by the oxidizing agent) as the tail moment increase (TMI) after irradiation:

$$\text{TMI (DSBs or SSBs)} = \text{TM}_{\text{IRR}} - \text{TM}_{\text{UNIRR}}$$

   where TM_{IRR} is the absolute TM value for the irradiated sample while TM_{UNIRR} is the corresponding TM for the unirradiated (control).

5. In the case of OCDLs (neutral conditions) or total sites (alkaline conditions), use the following equation:

$$\text{TMI (OCDLs or total enzyme sites)} = \text{TM}_{(+\text{enzyme})} - \text{TM}_{(-\text{enzyme})}$$

   where the $\text{TM}_{(+\text{enzyme})}$ is the absolute TM value after enzyme treatment while $\text{TM}_{(-\text{enzyme})}$ is the TM value for the non-enzyme treated sample (control).

   The extent of DNA liberated from the head of the comet is directly proportional to the amount of DNA damage. In all cases, the increase in tail moment is attributed to additional DNA fragmentation induced by recognition of clustered lesions by repair enzyme (Fig. 6.11.1).

   Percent DNA in tail is directly related to amount of stain fluorescence in the tail. Special emphasis must be given to the minimization of light-exposure of cells during the duration of processing post-irradiation.

6. To correlate the TMI values with the values obtained from PFGE, which are usually expressed as number of lesions/Gbp/Gy in the case of radiation, assume an average number of 1000 SSBs/cell and 40 DSBs/cell at 1 Gy for X- or γ- rays (Pouget et al., 1999; Hada and Georgakilas, 2008). Based on the calculated rate of TMI/Gy plot, the SSB or DSB induction yield expressed as lesions/Gbp (assuming an average genome size of 6.4 Gbp for a diploid cell) as analytically described in Francisco et al., (2008). Apply the same calculations and plots for OCDLs using average yields obtained from the literature.

   For example, for Fpg-clusters, an average yield of 60 Fpg-clusters/cell at 1 Gy of γ-rays can be used for human cells (Hada and Georgakilas, 2008).

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****. 50μM phenyl-t-butyl nitrone (PBN) should be used in all buffers except enzyme buffers used during plug treatment (see Critical Parameters).*

Alkaline denaturation/electrophoresis buffer

12 g NaOH (300 mM final)
0.29 g EDTA (1 mM final)
pH to 13 using 0.5 M NaOH
Bring to 1 liter with double-distilled H_2O
Store up to 2 weeks at 4°C

EndoIII buffer

3.15 g Tris·Cl (20 mM final)
0.29 g EDTA (1 mM final)
pH to 8.00 using 1 N NaOH or 1N HCl
Bring to 1 liter with double-distilled H_2O
Store up to 2 weeks at 4°C

Endo IV buffer

7.87 g Tris·Cl (50 mM final)
5.84 g/liter (100 mM NaCl final)
2.0331 g/liter $MgCl_2$ (10 mM final)
pH to 7.9 using 1 N NaOH or 1 N HCl
Store up to 2 weeks at 4°C

Fpg buffer

1.576 g Tris·Cl (10 mM final)
2.0331 g $MgCl_2$ (10 mM final)
pH to 7.00
Bring to 1 liter with double-distilled H_2O
Store up to 2 weeks at 4°C

KCl stop mix solution (for neutral assay)

16.681 g HEPES KOH (70 mM final)
7.456 g KCl (100 mM final)
29.225 g EDTA (100 mM final)
pH to 7.60
Bring to 1 liter with double-distilled H_2O
Store up to 8 weeks at 4°C

Neutral electrophoresis buffer, 1× TBE

89 mM Tris·Cl
89 mM boric acid
1 mM EDTA
pH to 8.5
Store up to 6 weeks at 4°C

Plug lysis solution

1.2114 g Tris·Cl (100 mM final)
29.225 g EDTA (100 mM final)
146.1 g NaCl (2.5 M final)
pH to 10.00
Bring to 1 liter with double-distilled H_2O
Store up to 6 weeks at room temperature
Immediately prior to use, add:
1% (v/v) Triton X100
10% (v/v) DMSO

TE buffer

1.576 g Tris·Cl (10 mM final)
29.25 g EDTA (1 mM final)
pH to 9
Bring to 1 liter with double-distilled H_2O
Store up to 6 weeks at room temperature

Tris-Borate-EDTA (TBE) buffer, 10×

108 g Tris base
55 g boric acid
9.3 g EDTA
pH to 8.30
Add double-distilled H_2O to bring to 1 liter
Store up to 6 weeks at room temperature
Dilute to 1× using double-distilled H_2O

COMMENTARY

Background Information

Principles of OCDL detection

There is an abundance of research dedicated to understanding the types and significance of DNA lesions induced in the cell endogenously or exogenously. Endogenous or exogenous oxidative stress is a major generator of protein and DNA damage (Franco et al., 2008). Examples of endogenous stress are various metabolic byproducts including hydroxyl radicals and hydrogen peroxide. Examples of exogenous oxidative stress are very low doses of ionizing radiation (X-rays, γ-rays, and α-particles) or various chemicals inducing a generation of free radicals (Hada and Georgakilas, 2008). In contrast to single isolated lesions, complex DNA damage, the signature of ionizing radiation and high levels of oxidative stress in cells and tissues, is comprised of closely spaced uni-stranded (tandem) or bi-stranded lesions forming a cluster of DNA damage (Fig. 6.11.1; Georgakilas, 2008). Numerous studies suggest the important role of oxidative DNA damage and its repair in cancer and aging (Hussain et al., 2003; Kastan and Bartek, 2004). This pool of oxidative DNA damage can contain a wide variety of single or clustered DNA lesions, including single-strand breaks (SSBs), oxidized bases and/or apurinic-apyrimidinic (abasic, AP) sites (Ward, 1994) in the form of isolated lesions as well as in the form of clustered ones (1 to 10 bp apart; Goodhead, 1994; Sutherland et al., 2000a). Bi-stranded or tandem DNA clusters can be resistant to processing by glycosylases or endonucleases, as shown in

in vitro studies (Chaudhry and Weinfeld, 1997; Harrison et al., 1999; McKenzie and Strauss, 2001; David-Cordonnier et al., 2002; Georgakilas et al., 2002; Eot-Houllier et al., 2005; Cunniffe et al., 2007). Such repair-resistant clusters can persist in cells or tissues for a substantial time after irradiation (up to several days or weeks; Georgakilas et al., 2004; Gollapalle et al., 2007).

One of the best known methods for the detection and measurement of clusters is a modified version of PFGE. As a second independent method, a few groups have developed a modified version of the neutral SCGE or comet assay again using repair enzymes as damage probes (Blaisdell and Wallace, 2001; Holt and Georgakilas, 2007). Since 1984 (Ostling and Johanson, 1984) and later in its alkaline version in 1988 (Singh et al., 1998), the SCGE, a modified version of microgel electrophoresis, has been widely used for the detection of low levels of various types of DNA lesions including SSBs, DSBs, and oxidized bases as reviewed in Collins (2004) and Olive and Banath (2006). The comet assay or microgel assay under neutral running conditions has been used for the detection of DSBs in a variety of cells including lymphocytes (Olive and Banath, 1993; Angelis et al., 1999; Yang et al., 2004; Trenz et al., 2005). There is very limited data on the use of the neutral comet assay (Angelis et al., 1999; Holt and Georgakilas, 2007) or microgel assay (Blaisdell and Wallace, 2001; Yang et al., 2006) for the detection of non-DSB clustered DNA lesions using different repair enzymes as enzymatic probes. In all cases, incomplete cleavage of lesions by the repair enzymes can lead to a detection of only a fraction of the clusters (Fig. 6.11.1; Hada and Georgakilas, 2008). This issue becomes very important especially in the case of high linear energy transfer (high-LET) radiations (damaging to DNA) where the density of the lesions is expected to be very high (Nikjoo et al., 2001). The clusters described in Figure 6.11.1 are in general an idealized form of a simple cluster. In reality and particularly in the case of high-LET, a complex DNA lesion would be expected, for example, an SSB or DSB with five to ten additional surrounding lesions (Georgakilas, 2008). Therefore, each cluster detected by the enzyme is only a fraction of the lesions participating in the cluster. The correction can be performed by using the alkaline version of the technique measuring the total number of lesions in the DNA (Francisco et al., 2008).

Critical Parameters

Buffers and solutions

All solutions and buffers should always be prepared with deionized, double-distilled, sterile water using sterile containers, and should be sterilized by appropriate means before use (e.g., autoclave). They should also be purged with argon or nitrogen and 50 μM phenyl-*tert*-butyl nitrone in DMSO (PBN; Sigma) should be added to minimize artifactual DNA oxidation that can give rise to increased background DNA damage. PBN should not be used for enzyme treatment buffers since it may inhibit enzyme activity. In addition, sterile reaction containers and measuring instruments should be used; gloves should always be worn to prevent any nuclease contamination. The use of a timed and thermoregulated instrument (i.e., PCR thermal cycler) for all enzyme assays rather than a water bath increases precision and reproducibility of reactions and minimizes introduction of nucleases or other contaminants resulting from immersion in a water bath. Fresh, filtered, and autoclaved solutions should be used, and solutions remaining after reactions are completed should be discarded (Sutherland et al., 2003).

Enzymes

Enzyme purification should always be performed using absolutely sterile solutions, equipment, and conditions. General purification procedures should be followed, modified, and updated as appropriate. The specific activity, specific cleavage, and non-specific cleavage are assessed by enzyme assays, and progress to protein purity is assessed by polyacrylamide gel electrophoresis at each step of the purification. The enzyme reactions must be terminated by use of a proper "stop mix" solution that halts enzyme action, disrupts DNA-protein interactions, but neither denatures the DNA nor interferes with subsequent gel electrophoresis (Sutherland et al., 2003). Enzyme–DNA complexes may interfere with DNA migration on the electrophoretic gel by inducing an artifactual decrease of the TM. Additional digestion with proteinase K removes residual enzymes and generally dissociates such resistant and strongly associated complexes, minimizes interference artifacts, and increases reproducibility.

Troubleshooting

Cloudy or white appearance of plugs

A cloudy or white appearance of the plugs can be caused by not properly dissolving the agarose or not removing/neutralizing all alkaline solution on the slides. Ensure that agarose is completely dissolved before using it. For incomplete removal of alkaline solution, longer and/or slightly more aggressive washes can be used.

Agarose plugs continually come off slide

Ensure that the agarose used to affix the plug to the slide has solidified before placing the slide in the electrophoresis chamber. Excessively aggressive washes can remove plugs as well. Decrease humidity by using low humidity conditions; for example, use a humidity-controlled chamber.

Tail moments differ despite same experimental conditions

Ensure all buffers are at correct pH and always apply the same duration and electric field (V/cm) for electrophoresis. Ensure cell viability of no less than 90%.

Comets are hard to score due to overlapping tails

Use a lower number of cells per plug.

Comets appear too bright

This can be due to overuse of dye or dye that is too concentrated. It may take a few minutes before the comets fluoresce under the microscope. Allow time for this to happen before adding additional dye.

Anticipated Results

When cells are exposed to an oxidizing agent like ionizing radiation and treated with a repair enzyme for the detection of clustered DNA lesions, an obvious difference in the comet tail should be detected between the enzyme-treated and non-treated samples as, in Figure 6.11.2. Increase in tail moment (TM) must be linear with dose at least up to ~10 Gy for the detection of non-DSB clusters and up to ~20 Gy for detection of DSBs. In many cases of exposing exponentially growing cells to an oxidizing agent, a great variation of TMs can be detected. This is due to cells with different DNA content and therefore users must try to score cells with similar DNA content (total intensity).

Time Considerations

Cell treatment, processing, DNA agarose plug creation, and electrophoresis can be completed in 4 to 5 hr. All steps must be performed within the exact time limits to avoid experimental variations and inconsistencies (see boxes of with maximum times allowed in Fig. 6.11.3). Special attention should be given to the time frame allowed for repair enzyme treatment since this can induce a great variability in the results. Therefore, use the same set time (1 hr at 37°C) for each experiment. Longer incubation times can result in increased comet tails and non-specific cleavage. In addition, special emphasis should be given to the time period from the moment slides with plugs are taken out of the electrophoresis, neutralized, and stained with a fluorescence dye. The most accurate and reliable results are obtained when scoring is performed immediately. Increased camera sensitivity will provide maximization of the acquisition of fluorescence from a cell and this will improve confidence in the metrics. To preserve fluorophore performance, illumination should be removed automatically when cells are not being imaged to prevent light-induced fluorescence quenching. If storage of plugs is needed, plugs can be stored in autoclaved TE solution purged with argon or nitrogen and added 50 μM phenyl-*tert*-butyl nitrone in DMSO (PBN; Sigma). For longer periods of storage (storage over 6 weeks), expect higher background damage. Storage up to 6 weeks under the described conditions is not expected to increase the background levels of DNA clusters significantly.

CHAPTER 7
Protein Labeling and Immunoprecipitation

INTRODUCTION

The characterization of cellular proteins in complex mixtures, as well as analysis of their biosynthesis, processing, intracellular trafficking and degradation, generally requires that the proteins be labeled either intrinsically (*UNIT 7.1*) or extrinsically. The labeled proteins are then isolated by immunoprecipitation (*UNIT 7.2*) and analyzed using electrophoretic techniques (Chapter 6).

Intrinsic labeling refers to the incorporation of a labeled precursor into the protein during synthesis. The most common form of intrinsic labeling consists of supplying the labeled precursor to live cells so that it becomes incorporated into proteins by the cell's own biosynthetic machinery. This form of intrinsic labeling is referred to as metabolic or biosynthetic labeling. The complexity and fidelity of the cell's biosynthetic pathways does not allow much flexibility in the design of precursors suitable for metabolic labeling. For instance, chemical derivatization of amino acid precursors renders them extraneous to plasma membrane transporters and aminoacyl-tRNA synthetases. Incorporation of unnatural amino acids can also affect the folding and stability of the polypeptide chains. Thus, the choice of precursors is limited to those labeled with an uncommon isotope of one of its constituent atoms. Although stable heavy isotopes have been used to label precursors, by far the most common means of labeling amino acids entails substituting radionuclides such as ^{35}S, ^{3}H, or ^{14}C in place of their nonradioactive counterparts. Because isotopes have identical biochemical properties, these substitutions do not affect protein synthesis.

The first unit in this chapter (*UNIT 7.1*) presents a compilation of protocols for metabolic labeling of proteins in mammalian cells using radiolabeled amino acids. The preferred radiolabeled amino acid for this purpose is [^{35}S]methionine, although [^{35}S]cysteine or ^{3}H-labeled amino acids can also be used. One of the methods described in *UNIT 7.1* is referred to as pulse labeling, and consists of incubating the cells with the radiolabeled amino acid for short periods (10 to 30 min). Pulse labeling is used to label newly synthesized proteins. In many cases, the pulse is followed by a chase in which cells are further incubated with the unlabeled counterpart of the precursor used for labeling. Pulse-chase protocols allow study of the fate of proteins after synthesis. Another method described in this unit is referred to as long-term labeling, and consists of labeling cells for periods of 6 to 32 hr. Long-term labeling is generally used to study the properties of mature proteins or protein complexes, rather than their biogenesis.

Metabolically labeled proteins can be directly analyzed using electrophoretic techniques (*UNIT 6.1*). Most often, however, specific metabolically labeled proteins are isolated from other cellular proteins by immunoprecipitation. Even when metabolically labeled proteins are first separated by the physical methods described in Chapter 5, specific proteins ultimately have to be isolated by immunoprecipitation. Immunoprecipitation techniques exploit the ability of the immune system to produce specific antibodies to virtually any protein (see Chapter 16). In the most widely used immunoprecipitation protocols, antibodies are bound to protein A–agarose beads, after which the immobilized antibodies are incubated with a detergent extract of the cells. Specific proteins can then be rapidly separated from other proteins in the mixture by repeated washing of the beads. *UNIT 7.2*

Contributed by Juan S. Bonifacino
Current Protocols in Cell Biology (2002) 7.0.1-7.0.3

describes a series of simple protocols for immunoprecipitation of proteins from cell extracts. Included in this unit are protocols for extracting both adherent and suspended animal cells under either nondenaturing or denaturing conditions. There is also a protocol for lysing yeast cells, which requires mechanical breakage of the cell wall. *UNIT 7.2* also includes procedures for binding antibodies to protein-agarose beads, incubating the antibody-bound beads with cell extracts, and washing the beads. Finally, the unit describes an immunoprecipitation-recapture protocol in which proteins are immunoprecipitated twice sequentially with either the same antibody or different antibodies. This type of protocol can be used to reduce the nonspecific background of the first immunoprecipitation or to analyze the composition and assembly of multiprotein complexes.

Proteins can be metabolically labeled using precursors other than amino acids—e.g., sulfate, lipids, carbohydrates, and phosphate, provided that the proteins are modified by the addition of these groups. *UNIT 7.3* describes protocols for both long-term and pulse-chase metabolic labeling using [^{35}S]sulfate. Use of these protocols allows radiolabeling of proteins that are sulfated on either tyrosine residues or carbohydrate moieties. *UNIT 7.4* describes protocols for metabolic labeling fatty-acylated proteins with [^{3}H]palmitic acid or [^{3}H]myristic acid. This unit also includes protocols for determining the type of linkage in which the fatty acid is attached and the identity of the fatty acid. *UNIT 7.5* deals with another type of lipid modification of proteins, namely prenylation by addition of farnesyl or geranylgeranyl groups. Metabolic labeling of prenylated proteins can be achieved by incubation with [^{3}H]mevalonic acid, which is a precursor of prenyl groups. Prenylated proteins are often also carboxyl-methylated. This modification can be studied by metabolic labeling with [^{3}H-methyl]methionine, a protocol for which is also included in this unit.

The yeast, *Saccharomyces cerevisiae*, is widely used as a model organism for the study of cellular processes that are common to all eukaryotic cells. Critical to these studies is the ability to label yeast proteins metabolically. Metabolic labeling and immunoprecipitation of yeast proteins can be achieved by modification of methods described for mammalian proteins (*UNITS 7.1 & 7.2*). *UNIT 7.6* describes protocols for metabolic labeling yeast proteins with ^{35}S-labeled amino acid mixtures and for mechanical disruption of the labeled yeast cells with glass beads (a variation of this method of yeast cell lysis is described in *UNIT 7.2*). In addition, *UNIT 7.6* includes protocols for preparation of spheroplasts from the radiolabeled yeast cells by enzymatic lysis of the cell wall, and for treatment of immunoprecipitated yeast proteins with endoglycosidase H. This unit also discusses criteria for metabolic labeling of yeast cells with precursors other than ^{35}S-labeled amino acid mixtures.

Another organism that is commonly used in biological research is the fruit fly, *Drosophila melanogaster*. Unlike *Saccharomyces cerevisiae, Drosophila* is a multicellular organism and possesses a body organization and function that is in many ways similar to that of higher eukaryotes. Powerful genetic methodologies have been developed that allow detailed analyses of embryonic development and function of organ systems. Studies at the cellular level in *Drosophila*, however, have lagged behind. Methods for metabolically labeling *Drosophila* cells in culture, in particular, are hard to find. In *UNIT 7.7* we present a protocol for metabolic labeling and immunoprecipitation using *Drosophila* S2M3 cells. The unit also contains a protocol for the growth and maintenance of S2M3 cells. Finally the Commentary provides references for preparation of primary cultures of *Drosophila* cells. The ability to culture *Drosophila* cells from wild-type and mutant flies allows analysis of the cellular roles of specific gene products.

The protocols described thus far describe labeling of proteins and protein conjugates by incubation of cells with radiolabeled precursors (i.e., intrinsic labeling). However, proteins can also be labeled, either in purified form or in mixtures, after extraction from the cells (i.e., extrinsic labeling). *UNIT 7.9* presents the first set of protocols in this chapter

dealing with extrinsic labeling of proteins. In our aerobic world, cellular proteins are constantly suffering oxidative damage by reactive oxygen species. Amino acid residues, such as histidine, lysine, arginine, proline, threonine, cytosine, tyrosine and aspartate, can all undergo oxidative modification within cells. Upon protein extraction from cells, modified amino acid residues can be detected and quantified by reaction with specific chemical reagents. The products of these reactions can then be analyzed by gel electrophoresis, mass spectrometry, or ELISA, either directly (as described in this unit) or following isolation of specific proteins by immunoprecipitation (*UNIT 7.2*).

Most of the protocols discussed to this point are based on intrinsic labeling of cellular proteins or protein conjugates. However, proteins can also be labeled extrinsically by chemical modification of specific amino acid residues. A commonly used method is the chemical modification of tyrosine resides with ^{125}iodine. Radioiodination can be used to label proteins on the cell surface and in isolated organelles, detergent extract, or soluble fractions as described in *UNIT 7.9*. Proteins can be labeled to high specific activities, generally with little or no loss of function. The risk of contamination by inhalation of volatile radioiodine, however, has led to the replacement of radioiodination by safer extrinsic labeling techniques such as biotinylation.

Juan S. Bonifacino

Metabolic Labeling with Amino Acids

Metabolic labeling techniques are used to study biosynthesis, processing, intracellular transport, secretion, degradation and physical-chemical properties of proteins. In this unit, protocols are described for metabolically labeling mammalian cells with radiolabeled amino acids (Table 7.1.1). Cells labeled using these procedures are suitable for analysis by immunoprecipitation (*UNIT 7.2*), characterization of cellular proteins (see Chapter 5), analysis of protein trafficking, and one- and two-dimensional gel electrophoresis (see Chapter 6). The first protocols describe pulse-labeling (10 to 30 min) of mammalian cells in suspension with [^{35}S]methionine (see Basic Protocol), and necessary modifications for adherent mammalian cells (see Alternate Protocol 1). Alternate protocols are also presented for pulse-chase analysis (see Alternate Protocol 2) and long-term labeling ("steady state," 6 to 32 hr; see Alternate Protocol 3). This is followed by conditions for metabolic labeling of cells with radiolabeled amino acids other than [^{35}S]methionine (see Alternate Protocol 4). The degree of label incorporation can be determined by precipitation with trichloroacetic acid (TCA; see Support Protocol).

NOTE: All solutions and equipment coming into contact with living cells must be sterile, and aseptic technique should be used accordingly.

NOTE: All culture incubations should be performed in a humidified, 37°C, 5% CO_2 incubator unless otherwise specified. Some media (e.g., DMEM) may require altered levels of CO_2 to maintain pH 7.4.

Table 7.1.1 Radiolabeled Amino Acids Used in Metabolic Labeling of Proteins

Amino acid[a]	Frequency (%)[b]	Radioisotope	Specific activity (Ci/mmol)	Comments[c]
Leucine	10.4	^{3}H	5-190	E
Serine	8.1	^{3}H	5-40	T, I
Glutamic acid	7.3	^{3}H	15-80	T, I
Lysine	7.0	^{3}H	40-110	E
Alanine	7.0	^{3}H	10-85	T
Valine	6.2	^{3}H	10-65	E
Glycine	5.7	^{3}H	10-60	T, I
Threonine	5.6	^{3}H	5-25	E
Arginine	5.0	^{3}H	30-70	E
Aspartic acid	4.9	^{3}H	10-50	T, I
Proline	4.9	^{3}H	15-130	—
Glutamine	4.5	^{3}H	20-60	T, I
Phenylalanine	4.5	^{3}H	15-140	E
Tyrosine	3.6	^{3}H	15-60	—
Asparagine[d]	3.5	—	—	—
Cysteine	3.4	^{35}S	>800	—
Isoleucine	2.9	^{3}H	30-140	E
Histidine	2.5	^{3}H	30-70	E
Methionine	1.8	^{35}S	>800	E
Tryptophan	1.3	^{3}H	20-30	E

[a]All amino acids in this table are in the L configuration.
[b]Frequency of amino acid residues in proteins, taken from Lathe (1985).
[c]E, essential amino acids; T, amino acids that are modified by transamination (Coligan et al., 1983); I, amino acids that are converted by cells to other amino acids.
[d]Asparagine is difficult to label (Coligan et al., 1983).

SAFETY PRECAUTIONS FOR WORKING WITH ^{35}S-LABELED COMPOUNDS

When working with radioactive materials, take appropriate precautions to avoid contamination of the experimenter and the surroundings. Carry out the experiment and dispose of wastes in an appropriately designated area, following guidelines provided by the local radiation safety officer (also see *APPENDIX 1D*).

Solutions containing ^{35}S-labeled compounds have been found to release volatile radioactive substances (Meisenhelder and Hunter, 1988). In addition to the usual safety practices followed when handling radioactive materials (see *APPENDIX 1D*), some extra precautions should be taken when using ^{35}S-labeled amino acids:

1. Vials containing ^{35}S-labeled compounds should always be handled in a designated fume hood equipped with an activated charcoal filter. This includes thawing the solution, opening the vial, and adding the radiolabeled amino acid to the labeling medium. Before opening, vials should be vented with a needle attached to a syringe packed with activated charcoal. Avoid using tissue culture hoods for this purpose as they are likely to become contaminated.
2. Minimize exposure of ^{35}S-containing solutions to the air.
3. Use baths, incubators, and centrifuges designated for work with radioactive materials. Place a tray containing a layer of activated charcoal in the CO_2 incubator to reduce the amount of ^{35}S-labeled compounds released to the air during cell labeling. Alternatively, filters impregnated with activated carbon (β-Safe, Schleicher & Schuell) can be attached to the covers of tissue culture dishes.
4. Monitor areas used during labeling by conducting wipe tests.
5. Dispose of solid and liquid ^{35}S waste quickly and with appropriate precautions.

BASIC PROTOCOL

PULSE-LABELING OF CELLS IN SUSPENSION WITH [^{35}S]METHIONINE

Pulse-labeling of proteins is performed by incubating cells for short periods (≤30 min) in culture medium containing a radiolabeled amino acid. The conditions described below are optimized for labeling times of 10 to 30 min. The same protocol is used for labeling cells for up to 6 hr, although a smaller number of cells and/or a larger amount of labeling medium should be used for optimal results. Very short pulses (<10 min) may require special conditions that are discussed elsewhere (see Critical Parameters). For labeling times >6 hr, see Alternate Protocol 3. [^{35}S]methionine is the radiolabeled amino acid of choice for metabolic labeling of proteins because of its high specific activity (>800 Ci/mmol) and ease of detection. A potential disadvantage of [^{35}S]methionine is its low abundance in proteins (~1.8% of the average amino acid composition; see Table 7.1.1). For proteins that contain little (e.g., only one) or no methionine, other radiolabeled amino acids should be used (see Alternate Protocol 4).

Materials

[^{35}S]L-Methionine (>800 Ci/mmol) or [^{35}S]-labeled protein hydrolyzate (>1000 Ci/mmol)
Pulse-labeling medium (see recipe), warmed to 37°C
Cell suspension (e.g., Jurkat, RBL, K562, BW5147, T and B cell hybridomas), grown in a humidified, 37°C, 5% CO_2 incubator or prepared from tissues (e.g., lymphocytes, *UNIT 2.2*)
PBS (*APPENDIX 2A*), ice cold
Vacuum aspirator with trap for liquid radioactive waste

Additional reagents and equipment for TCA precipitation (optional; see Support Protocol)

1. Thaw [^{35}S]methionine at room temperature and prepare a 0.1 to 0.2 mCi/ml working solution in prewarmed (37°C) pulse-labeling medium.

   CAUTION: *Volatile ^{35}S-containing compounds can be released during the labeling procedure (refer to Safety Precautions and APPENDIX 1D). Keep [^{35}S]methionine-containing medium in a tightly capped tube in a 37°C water bath until use. Do not let it sit >60 min at 37°C.*

2. Harvest 0.5–2 × 10^7 cells in suspension by centrifuging 5 min at 300 × *g*, room temperature.

3. Wash cells with ~10 ml prewarmed pulse-labeling medium. Centrifuge 5 min at 300 × *g*, room temperature, and aspirate supernatant. Resuspend cells by gently tapping the bottom of the tubes and repeat wash.

4. Resuspend cells at 5 × 10^6 cells/ml in prewarmed pulse-labeling medium and incubate 15 min in a 37°C water bath to deplete intracellular pools of methionine. Invert tubes periodically to resuspend cells.

5. Centrifuge cells 5 min at 300 × *g*, room temperature, and aspirate supernatant.

6. Resuspend cells in a fresh 15-ml centrifuge tube, using 2 ml [^{35}S]methionine working solution (step 1). Cap tubes tightly. Incubate cells 10 to 30 min (see Critical Parameters) in a 37°C water bath, resuspending frequently by gentle inversion of the tubes.

   Alternatively, use a rotator placed in a 37°C incubator.

7. Centrifuge cells 5 min at 300 × *g*, 4°C, and aspirate supernatant. Resuspend with gentle swirling in 10 ml ice-cold PBS and repeat centrifugation.

   CAUTION: *The medium and wash are radioactive—follow applicable safety regulations for disposal.*

   Because of the short times and high concentrations of radiolabeled amino acids employed, pulse-labeling may not result in complete depletion of label from the medium. If this is the case, the labeling mixture can be reused. Collect the labeling medium containing [^{35}S]methionine or ^{35}S-labeled protein hydrolyzate and filter carefully through a 0.45-µm filter unit. Estimate the percentage of unincorporated radioactivity by scintillation counting aliquots of the labeling mixture before and after labeling the cells. Store the labeling mixture up to 2 months frozen at −20°C.

8. *Optional:* Determine amount of label incorporation by trichloroacetic acid (TCA) precipitation (see Support Protocol 1).

   Labeled cells are now ready for the desired processing and analysis. If cell pellets cannot be processed immediately, they can be kept on ice for a few hours or frozen at −80°C for several days. Thaw frozen cell pellets on ice before analysis. In most cases, freezing cells will not affect the biochemical properties of the proteins, but freezing and thawing cell extracts after solubilization with detergents (UNIT 7.2) can cause dissociation of multisubunit complexes or proteolysis of labeled proteins.

ALTERNATE PROTOCOL 1

PULSE-LABELING OF ADHERENT CELLS WITH [^{35}S]METHIONINE

Labeling adherent cells is essentially the same as described for cells in suspension except that cells are labeled while attached to a dish. As with suspended cells, adherent cells are pulse-labeled 10 to 30 min (see Basic Protocol introduction). Alternatively, some adherent cells can be detached from plates by incubation for 10 min at 37°C with 10 mM EDTA in PBS (*APPENDIX 2A*) and labeled as a suspension (see Basic Protocol). This is particularly advantageous when labeling cells for pulse-chase experiments, because it simplifies handling of multiple samples and allows more uniform labeling of the cells.

Additional Materials *(also see Basic Protocol)*

Adherent cells (e.g., HeLa, NRK, M1, COS-1, CV-1, or fibroblasts or endothelial cells in primary culture; *UNITS 2.1 & 2.3*)
100-mm tissue culture dishes

1. Grow adherent cells to 80% to 90% confluency in 100-mm tissue culture dishes.

   Depending on the cell type, a confluent 100-mm dish will contain 0.5–2 × 10^7 cells.

2. Prepare [^{35}S]methionine working solution as described (see Basic Protocol, step 1).

3. Aspirate culture medium from the dishes and wash twice by gently swirling with 10 ml prewarmed (37°C) pulse-labeling medium, aspirating medium after each wash.

4. Add 5 ml prewarmed pulse-labeling medium and incubate 15 min in a humidified, 37°C, 5% CO_2 incubator to deplete intracellular pools of methionine.

5. Remove medium from cells, add 2 ml [^{35}S]methionine working solution (from step 2), and incubate 10 to 30 min in a CO_2 incubator.

   If necessary, as little as 1 ml of labeling medium per plate can be used. It is critical, however, that the plates sit on a perfectly horizontal surface during incubation to avoid drying of the cell monolayer.

6. Remove medium from cells. Wash once with 10 ml ice-cold PBS and remove PBS.

   CAUTION: *The medium and wash are radioactive—follow applicable safety regulations for disposal.*

   If significant detachment of cells occurs during labeling, it may be necessary to scrape the cells carefully in the [^{35}S]methionine-containing medium and transfer the suspension to a 15-ml centrifuge tube before centrifuging and washing with PBS.

7. Add 10 ml ice-cold PBS and scrape cells carefully with either a disposable plastic scraper or a rubber policeman.

8. Transfer the suspension to a 15-ml centrifuge tube, centrifuge 5 min at 300 × *g*, 4°C, and discard supernatant.

9. *Optional:* Determine amount of label incorporation by trichloroacetic acid (TCA) precipitation (see Support Protocol 1).

   Labeled cells are now ready for the desired processing and analysis (see Basic Protocol, step 8 annotation, if cells are not to be used immediately).

PULSE-CHASE LABELING OF CELLS WITH [^{35}S]METHIONINE

ALTERNATE PROTOCOL 2

Pulse-chase protocols are used to analyze time-dependent processes, such as posttranslational modification, transport, secretion, or degradation of newly synthesized proteins. Cells in suspension or adherent cells are pulse-labeled with [^{35}S]methionine (see Basic Protocol and Alternate Protocol 1), after which they are incubated (chased) in complete medium containing excess unlabeled methionine, as described below.

Additional Materials *(also see Basic Protocol and Alternate Protocol 1)*

Chase medium (see recipe), 37°C

1. Prepare 0.5–2 × 10^7 cells per sample per time point, and pulse-label 10 to 30 min with 2 ml of 0.1 to 0.2 mCi/ml [^{35}S]methionine per 0.5–2 × 10^7 cells (see Basic Protocol, steps 1 to 6, or see Alternate Protocol 1, steps 1 to 5).
2. Remove the [^{35}S]methionine working solution, wash once with 10 ml 37°C chase medium, and add 10 ml 37°C chase medium.

   Rapid termination of the labeling reaction can be achieved by adding two times the volume of chase medium containing excess unlabeled methionine (15 mg/liter) directly to the labeling mixture.

   Final concentration of cells in suspension should be 2 × 10^6 cells/ml for chases ≤2 hr, or 0.5 × 10^6 cells/ml for chases >2 hr. For adherent cells, add 10 ml/100-mm dish.
3. Incubate for the desired time at 37°C. Incubate cell suspensions with rotation in tightly capped tubes. Incubate adherent cells in a CO_2 incubator.

4a. *For cells in suspension:* Collect cells by centrifuging 5 min at 300 × *g*, 4°C.

   The supernatant can be discarded or can be collected for analysis of proteins that are secreted or shed into the medium.

4b. *For adherent cells:* Scrape off adherent cells and transfer to 15-ml centrifuge tubes. Centrifuge 5 min at 300 × *g*, 4°C, and either save or discard the supernatant as in step 4a.

5. *Optional:* Determine amount of label incorporation by trichloroacetic acid (TCA) precipitation (see Support Protocol 1).

   Labeled cells are now ready for the desired processing and analysis (see Basic Protocol, step 8 annotation, if cells are not to be used immediately).

LONG-TERM LABELING OF CELLS WITH [^{35}S]METHIONINE

ALTERNATE PROTOCOL 3

Long-term labeling refers to continuous metabolic labeling of cells for periods of 6 to 32 hr. Long-term labeling is particularly advantageous when studying proteins that are synthesized at low rates. It is also used to accumulate mature labeled proteins, rather than biosynthetic precursors, for characterization of their properties. Steady-state labeling is a form of long-term labeling in which cells are incubated with the radiolabeled amino acid until the rates of synthesis and degradation of the radiolabeled proteins are equal. Steady-state labeling allows calculation of the stoichiometry of subunits within a protein complex, provided that the primary structure of the subunits is known. In these procedures, unlabeled methionine is added to the medium to maintain cell viability and to sustain incorporation of label for the duration of the experiment. The amount of unlabeled methionine added depends on factors such as the length of the labeling period and the cell density. Media containing between 5% and 20% the normal amount of unlabeled methionine are generally used. The conditions described below are suitable for overnight (~16 hr) labeling of cells in suspension or adherent cells.

Additional Materials *(also see Basic Protocol and Alternate Protocol 1)*

Long-term labeling medium (see recipe), warmed to 37°C
75-cm^2 tissue culture flask

1. Prepare a 0.02 to 0.1 mCi/ml [^{35}S]methionine working solution in prewarmed (37°C) long-term labeling medium (see Basic Protocol, step 1).

For cell suspensions

2a. Prepare and wash cells once with prewarmed long-term labeling medium (see Basic Protocol, steps 2 and 3).

3a. Resuspend 0.5–2 × 10^7 cells in 25 ml of 0.02 to 0.1 mCi/ml [^{35}S]methionine working solution and transfer to a 75-cm^2 tissue culture flask.

For adherent cells

2b. Grow 0.5–2 × 10^7 adherent cells in a 75-cm^2 tissue culture flask (80% to 90% confluency) in a CO_2 incubator. Wash once with prewarmed long-term labeling medium (see Alternate Protocol 1, step 3).

3b. Add 25 ml of 0.02 to 0.1 mCi/ml [^{35}S]methionine working solution to each 75-cm^2 flask.

4. Tighten caps to prevent release of volatile ^{35}S-labeled compounds. Incubate 16 hr in a CO_2 incubator.

5. Wash cells and determine incorporation (see Basic Protocol, steps 7 and 8, or Alternate Protocol 1, steps 6 to 9).

Labeled cells are now ready for the desired processing and analysis (see Basic Protocol, step 8 annotation, if cells are not to be used immediately).

ALTERNATE PROTOCOL 4

METABOLIC LABELING WITH OTHER RADIOLABELED AMINO ACIDS

In some instances, it may be necessary to label proteins with radiolabeled amino acids other than [^{35}S]methionine—e.g., when the proteins have a low methionine content or have no methionine residues at all. In these cases, the best choices are [^{35}S]cysteine or [^{3}H]leucine.

Cysteine residues are more abundant in proteins than are methionine residues (3.4% versus 1.8%; Table 7.1.1), although cysteine is less stable. Formulations of [^{35}S]cysteine that have high specific activity (>800 Ci/mmol) can be obtained from several companies. Leucine has the advantage of being the most frequent amino acid in proteins (10.4%; Table 7.1.1) and specific activities of [^{3}H]leucine are the highest among ^{3}H-labeled amino acids (up to 190 Ci/mmol). If proteins are known to be rich in a particular amino acid or if special methods are to be performed (e.g., radiochemical sequencing or multiple labeling), ^{3}H-labeled amino acids other than [^{3}H]leucine can be used.

Label cells with these amino acids as described for [^{35}S]methionine in the previous protocols. Substitute [^{35}S]cysteine or ^{3}H-labeled amino acids in the labeling medium. Use labeling media lacking cysteine or any other respective amino acid.

CAUTION: Solutions containing [^{35}S]cysteine release volatile ^{35}S-labeled compounds (refer to Safety Precautions).

TCA PRECIPITATION TO DETERMINE LABEL INCORPORATION

SUPPORT PROTOCOL

In metabolic labeling experiments, it is often useful to monitor the incorporation of radioactivity into total cellular proteins. This can easily be achieved by precipitation with trichloroacetic acid (TCA) using BSA as a carrier protein. This protocol can be used at the end of the labeling procedures in each protocol.

Materials

Labeled cell suspension (see Basic Protocol or Alternate Protocols 1 to 4)
BSA/NaN_3: 1 mg/ml BSA containing 0.02% (w/v) sodium azide (NaN_3)
10% (w/v) TCA solution (see recipe), ice cold
Ethanol

Filtration apparatus attached to a vacuum line
2.5-cm glass microfiber filter disks (Whatman GF/C)

CAUTION: TCA is extremely caustic. Protect eyes and avoid contact with skin when preparing and handling TCA solutions.

1. Add 10 to 20 µl of a labeled cell suspension to 0.1 ml BSA/NaN_3. Place on ice.
2. Add 1 ml ice-cold 10% (w/v) TCA solution. Vortex vigorously and incubate 30 min on ice.
3. Filter the suspension onto 2.5-cm glass microfiber filter disks in a filtration apparatus under vacuum.
4. Wash the disks twice with 5 ml ice-cold 10% (w/v) TCA solution and twice with ethanol. Air dry 30 min.

   CAUTION: *The wash fluids should be handled as mixed chemical/radioactive waste—follow applicable safety regulations for disposal (see APPENDIX 1D).*

5. Spot the same volume of the radiolabeled cell suspension used in step 1 (10 to 20 µl) on a glass microfiber disk. Air dry.

   This disk will be used to measure the total amount of radiolabeled amino acid in the cell suspension.

6. Transfer disks from steps 4 and 5 to 20-ml scintillation vials, add 5 ml scintillation fluid, and measure the radioactivity in a scintillation counter.
7. Calculate the ratio of TCA-precipitable label to total radioactivity (i.e., the ratio of sample radioactivity in step 4 to the total radioactivity in step 5).

REAGENTS AND SOLUTIONS

*Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see **APPENDIX 2A**; for suppliers, see **SUPPLIERS APPENDIX**.*

NOTE: Use sterile tissue culture technique to prepare these reagents.

Chase medium

Pulse-labeling medium (see recipe) containing 15 mg/liter unlabeled methionine or equivalent excess amount of other amino acid used for radiolabeling. Store up to 2 weeks at 4°C.

Long-term labeling medium (90% methionine-free medium)

Mix 9 vol pulse-labeling medium (see recipe), lacking methionine or other appropriate amino acid, with 1 vol chase medium (see recipe) containing the same amino acid. Store up to 2 weeks at 4°C.

Pulse-labeling medium

Use supplemented Dulbecco's modified Eagle medium (DMEM; see *APPENDIX 2A* but omit nonessential amino acids) or RPMI 1640, each lacking methionine or other specific amino acid, but containing 10% (v/v) FBS (dialyzed overnight against saline solution to remove unlabeled amino acids). Add 25 mM HEPES buffer (with pH adjusted to 7.4 with NaOH). Store up to 2 weeks at 4°C.

The amino acid used to label cells is omitted from this medium (e.g., if [^{35}S]methionine is employed, methionine-free DMEM or RPMI 1640 must be used). Specific amino acid–free media can be obtained from several tissue culture media suppliers, or can be prepared (see APPENDIX 2B) from amino acid–free medium by adding individual amino acid components, omitting the one that will be used to label. A kit for the preparation of such media is available (Select-Amine from Life Technologies).

Trichloroacetic acid (TCA) solution, 10% (w/v)

Prepare a 100% (w/v) TCA stock solution by dissolving the entire contents of a newly opened TCA bottle in water (e.g., dissolve the contents of a 500-g bottle of TCA in sufficient water to yield a final volume of 500 ml). Store up to 1 year at 4°C. Prepare 10% (w/v) TCA by dilution and store up to 3 months at 4°C.

CAUTION: *TCA is extremely caustic. Protect eyes and avoid contact with skin when preparing and handling TCA solutions.*

COMMENTARY

Background Information

Metabolic labeling of cellular proteins is achieved by placing cells in a nutritional medium containing all components necessary for growth of cells in culture, except for one amino acid that is substituted by its radiolabeled form. The radiolabeled amino acids are transported across the plasma membrane by carrier-mediated systems and, once in the cytosol, are loaded onto tRNA molecules before being incorporated into newly synthesized proteins.

Because metabolic labeling techniques use the metabolic machinery of the cell to incorporate radiolabeled amino acids, there are limitations on the type of radiolabeled amino acids that can be employed. The list of potential precursors is restricted to L-amino acids normally found in proteins, in which one or more atoms are substituted by a radioisotope (Table 7.1.1). Sulfuric amino acids, such as methionine and cysteine, are conveniently labeled with ^{35}S. Most other amino acids can be obtained labeled with ^{3}H.

Critical Parameters

The protocols in this unit should be considered as models from which more specific methods can be designed. The conditions described here have been optimized for radiolabeling proteins that are expressed at low to moderate levels (10^4 to 10^5 copies per cell) and assume that the labeled cells will be used for immunoprecipitation (*UNIT 7.2*). This level of expression is characteristic of most endogenous membrane proteins, luminal organellar proteins, signal transduction proteins, and transcription factors. More abundant proteins, such as cytoskeletal proteins or proteins expressed by infection or transfection, can be labeled with less radiolabeled amino acid and/or fewer cells. The choice of a particular labeling protocol and its modification will be aided by careful consideration of a number of parameters that influence the incorporation of radiolabeled amino acids into proteins, as discussed below.

Selection of amino acid label

Purified [^{35}S]methionine of high specific activity (>800 Ci/mmol) can be obtained from several suppliers of radiolabeled amino acids. Protein hydrolyzates of *Escherichia coli* grown in the presence of $[^{35}SO_4]^{2-}$ (e.g., Tran^{35}S-label from ICN Biomedicals or Expre^{35}S^{35}S from NEN Life Sciences) can be used as substitutes for [^{35}S]methionine in metabolic labeling techniques. These preparations contain ^{35}S distributed among several different compounds. In a typical batch, ~70% of the radioactivity will be present as [^{35}S]methionine and ~15% as [^{35}S]cysteine; the remainder are other ^{35}S-labeled compounds. Labeling with these radioactive protein hydrolyzates in methionine-free medium will result in incorporation of label only in methionine residues; use of methionine- and cysteine-free medium will result in labeling of both methionine and cysteine residues.

Purified [^{35}S]methionine should be used whenever certainty of labeling with only [^{35}S]methionine is required. Another reason for using purified [^{35}S]methionine is that it tends to be more stable and emit less volatile decomposition products than ^{35}S-labeled protein hydrolyzates. In most cases, however, the relatively inexpensive radioactive protein hydrolyzates (~1/3 the cost of [^{35}S]methionine) can be used instead of purified [^{35}S]methionine. [^{35}S]methionine preparations should be stored frozen at −80°C. Under these conditions, they are stable for at least 1 month; the half-life of ^{35}S is 88 days.

For proteins with one or no methionine residues but several cysteine residues, labeling with [^{35}S]cysteine (available with specific activities >800 Ci/mmol) is a good option. ^{35}S-labeled protein hydrolyzates are not good sources of [^{35}S]cysteine for radiolabeling because only ~15% of the ^{35}S-labeled compounds are [^{35}S]cysteine.

Purified [^{3}H]leucine (available with specific activities of up to 190 Ci/mmol) is a good alternative to ^{35}S-labeled amino acids. The half-life of ^{3}H is ~12 years. The specific activities of other ^{3}H-labeled amino acids range between 5 and 140 Ci/mmol (Table 7.1.1). Several problems can arise when using certain ^{3}H-labeled amino acids due to their participation in metabolic pathways. The following problems must be considered when using tritiated amino acids for metabolic labeling of proteins.

Nonessential versus essential amino acids. Cells are able to synthesize nonessential amino acids from other compounds. If the radiolabeled amino acids used are nonessential, their specific activity will be reduced by dilution with the endogenously synthesized amino acids. Therefore, essential amino acids (E in Table 7.1.1) should be favored for metabolic labeling.

Transamination. The α-amino groups of many amino acids can be removed in reactions catalyzed by transaminases (T in Table 7.1.1). Deamination of the radiolabeled amino acids can be prevented by addition of the transaminase inhibitor (aminooxy)acetic acid during starvation and labeling of the cells (Coligan et al., 1983).

Interconversion. Certain radiolabeled amino acids can be converted by cells into other amino acids (I in Table 7.1.1). This problem is of particular importance in methods used to determine the amino acid composition or sequence of radiolabeled proteins.

Labeling time

The experimental purpose, the turnover rate of the protein of interest, and the viability of the cells should all be considered when determining the length of time for labeling. If the purpose of the experiment is to identify or characterize a protein precursor, pulse-labeling (10 to 30 min) must be used (see Basic Protocol and Alternate Protocol 1). If the protein of interest has a low turnover rate or if it is necessary to accumulate a labeled mature product, a protocol for long-term labeling (6 to 32 hr) is more appropriate (see Alternate Protocol 3). If the biosynthesis, posttranslational modification, intracellular transport, or fate of newly synthesized proteins is being analyzed, a pulse-chase protocol should be used (see Alternate Protocol 2).

The turnover rate of the protein of interest is an important parameter to be considered when determining the labeling time. Proteins with a high turnover rate are optimally labeled for short times. Longer times will result in increased labeling of other cellular proteins, causing a decrease in the relative abundance of the labeled protein of interest in the cell lysate. This could result in increased detection of nonspecific proteins in immunoprecipitates (see *UNIT 7.2*). Conversely, proteins that turn over slowly should be labeled for longer times.

Incorporation of radiolabeled amino acids into proteins is directly proportional to their length of labeling time for a certain period, after which it tends to plateau. When all the limiting amino acid is consumed, protein synthesis ceases. The length of the initial phase of linear incorporation will vary with the concentration of the labeling amino acid and the density and metabolic activity of the cells.

Concentration and specific activity of the radiolabeled amino acid

Because radiolabeled amino acids are used in limiting amounts, their incorporation into proteins is directly proportional to their concentration in the labeling medium. If very short pulses are required, the concentration of labeled amino acid can be increased to compensate for the shorter labeling time. The incorporation of radiolabeled amino acids is also directly proportional to their specific activity. Addition of unlabeled amino acids, as is required in long-term labeling protocols, will result in reduced incorporation over short periods.

Cell density

At low cell densities, the amount of labeled protein synthesized is directly proportional to the cell concentration. At high densities, however, incorporation will increase nonlinearly. Very concentrated cell samples (>5×10^7 cells/ml) can only be labeled for short periods (≤5 min) as rapid loss of metabolic activity and cell viability will occur due to acidification of the medium and accumulation of toxic metabolites.

Conditions for very short pulses

Very short pulses (2 to 10 min) are required to study posttranslational modifications that occur shortly after synthesis. This includes folding, disulfide bond formation, and early carbohydrate modifications of newly synthesized proteins. Proteins that are rapidly degraded after synthesis are also best studied with very short pulses. The protocol for very short pulses is similar to the Basic Protocol for pulse-labeling, with the following modifications: (1) the pulse-labeling medium contains higher concentration of radiolabeled amino acid (up to 1 mCi/ml), (2) labeling is stopped by addition of ice-cold PBS containing 20 mM freshly prepared *N*-ethylmaleimide (NEM) to prevent oxidation of free sulfhydryls, and (3) if a chase is necessary, 1 mM cycloheximide is added to the chase medium to quickly stop the elongation of nascent polypeptide chains. For additional details on very short pulses, see Braakman et al. (1991).

Temperature and pH

Unless otherwise required for special conditions (e.g., heat shock, temperature-sensitive mutants), metabolic labeling should be performed at 37°C. For this reason, it is important that the labeling medium be warmed to 37°C before adding it to the cells. A dramatic reduction in incorporation occurs at room temperature. It is also important that the pH of the labeling medium be ~7.4.

Anticipated Results

A typical incorporation of labeled amino acid precursor after a 30-min pulse under the conditions described in this unit (see Basic Protocol and Alternate Protocols 1 and 2) is 5% to 20%. In the case of long-term labeling, the incorporation typically reaches 30% to 60%. If the labeled cells are used for immunoprecipitation (*UNIT 7.2*), followed by SDS-PAGE (*UNIT 6.1*) and autoradiography (*UNIT 6.3*), specific bands should be visible within two hours to two months of exposure.

Time Considerations

It takes 1 to 2 hr to prepare cells and materials for labeling. The actual labeling time depends upon the protocol chosen—pulse-labeling takes 10 to 30 min and long-term labeling takes 6 to 32 hr. Washing and processing cells may take an additional 1.5 hr.

Immunoprecipitation

Immunoprecipitation is a technique in which an antigen is isolated by binding to a specific antibody attached to a sedimentable matrix. The source of antigen for immunoprecipitation can be unlabeled cells or tissues, metabolically or extrinsically labeled cells (*UNIT 7.1*), subcellular fractions from either unlabeled or labeled cells (see Chapter 3), or in vitro–translated proteins (*UNIT 11.2*). Immunoprecipitation is also used to analyze protein fractions separated by other biochemical techniques such as gel filtration or sedimentation on density gradients (*UNIT 5.3*). Either polyclonal or monoclonal antibodies from various animal species can be used in immunoprecipitation protocols. Antibodies can be bound noncovalently to immunoadsorbents such as protein A– or protein G–agarose, or can be coupled covalently to a solid-phase matrix.

Immunoprecipitation protocols consist of several stages (Fig. 7.2.1; see Basic Protocol 1). In stage 1, the antigen is solubilized by one of several techniques for lysing cells. Soluble and membrane-associated antigens can be released from cells grown either in suspension culture (see Basic Protocol 1) or as a monolayer on tissue culture dishes (see Alternate Protocol 1) with nondenaturing detergents. Cells can also be lysed under denaturing conditions (see Alternate Protocol 2). Soluble antigens can also be extracted by mechanical disruption of cells in the absence of detergents (see Alternate Protocol 3). All of these lysis procedures are suitable for extracting antigens from animal cells. Yeast cells require disruption of their cell wall in order to allow extraction of the antigens (see Alternate Protocol 4). In stage 2, a specific antibody is attached, either noncovalently or covalently, to a sedimentable, solid-phase matrix to allow separation by low-speed centrifugation. This unit presents the noncovalent attachment of antibody to protein A– or protein G–agarose beads (see Basic Protocol 1). Stage 3 consists of incubating the solubilized antigen from stage 1 with the immobilized antibody from stage 2, followed by extensive washing to remove unbound proteins (see Basic Protocol 1). Immunoprecipitated antigens can be dissociated from antibodies and reprecipitated by a protocol referred to as "immunoprecipitation-recapture" (see Basic Protocol 2). This protocol can be used with the same antibody for further purification of the antigen, or with a second antibody to identify components of multisubunit complexes or to study protein-protein interactions (Fig. 7.2.2). Immunoprecipitated antigens can be analyzed by one-dimensional electrophoresis (*UNIT 6.1*), two-dimensional electrophoresis, or immunoblotting (*UNIT 6.2*). In some cases, immunoprecipitates can be used for structural or functional analyses of the isolated antigens. Immunoprecipitates can also be used as sources of immunogens for production of monoclonal or polyclonal antibodies.

IMMUNOPRECIPITATION USING CELLS IN SUSPENSION LYSED WITH A NONDENATURING DETERGENT SOLUTION

BASIC PROTOCOL 1

In this protocol, unlabeled or labeled cells in suspension are extracted by incubation in nondenaturing lysis buffer containing the nonionic detergent Triton X-100 (steps 1 to 7). This procedure results in the release of both soluble and membrane proteins; however, many cytoskeletal and nuclear proteins, as well as a fraction of membrane proteins, are not efficiently extracted under these conditions (see *UNIT 5.1*). The procedure allows immunoprecipitation with antibodies to epitopes that are exposed in native proteins.

For immunoprecipitation, a specific antibody is immobilized on a sedimentable, solid-phase matrix (steps 8 to 14). Although there are many ways to attach antibodies to matrices (see Commentary), the most commonly used methods rely on the property of immunoglobulins to bind *Staphylococcus aureus* protein A, or protein G from group G *Streptococcus* (Table 7.2.1). The best results are obtained by binding antibodies to protein A or

Contributed by Juan S. Bonifacino and Esteban C. Dell'Angelica
Current Protocols in Cell Biology (1998) 7.2.1-7.2.21

protein G that is covalently coupled to agarose beads. In this protocol, Sepharose beads are used (Sepharose is a more stable, cross-linked form of agarose). Immunoprecipitation is most often carried out using rabbit polyclonal or mouse monoclonal antibodies, which, with some exceptions (e.g., mouse IgG1), bind well to protein A (Table 7.2.1). Antibodies that do not bind to protein A–agarose can be adsorbed to protein G–agarose (Table 7.2.1) using exactly the same protocol. For optimal time management, incubation of antibodies with protein A–agarose can be carried out either before or during lysis of the cells.

The final stage in immunoprecipitation is combining the cell lysate with the antibody-conjugated beads and isolating the antigen (steps 18 to 26). This can be preceded by an optional preclearing step in which the lysate is absorbed with either "empty" protein A–agarose beads or with an irrelevant antibody bound to protein A–agarose (steps 15 to

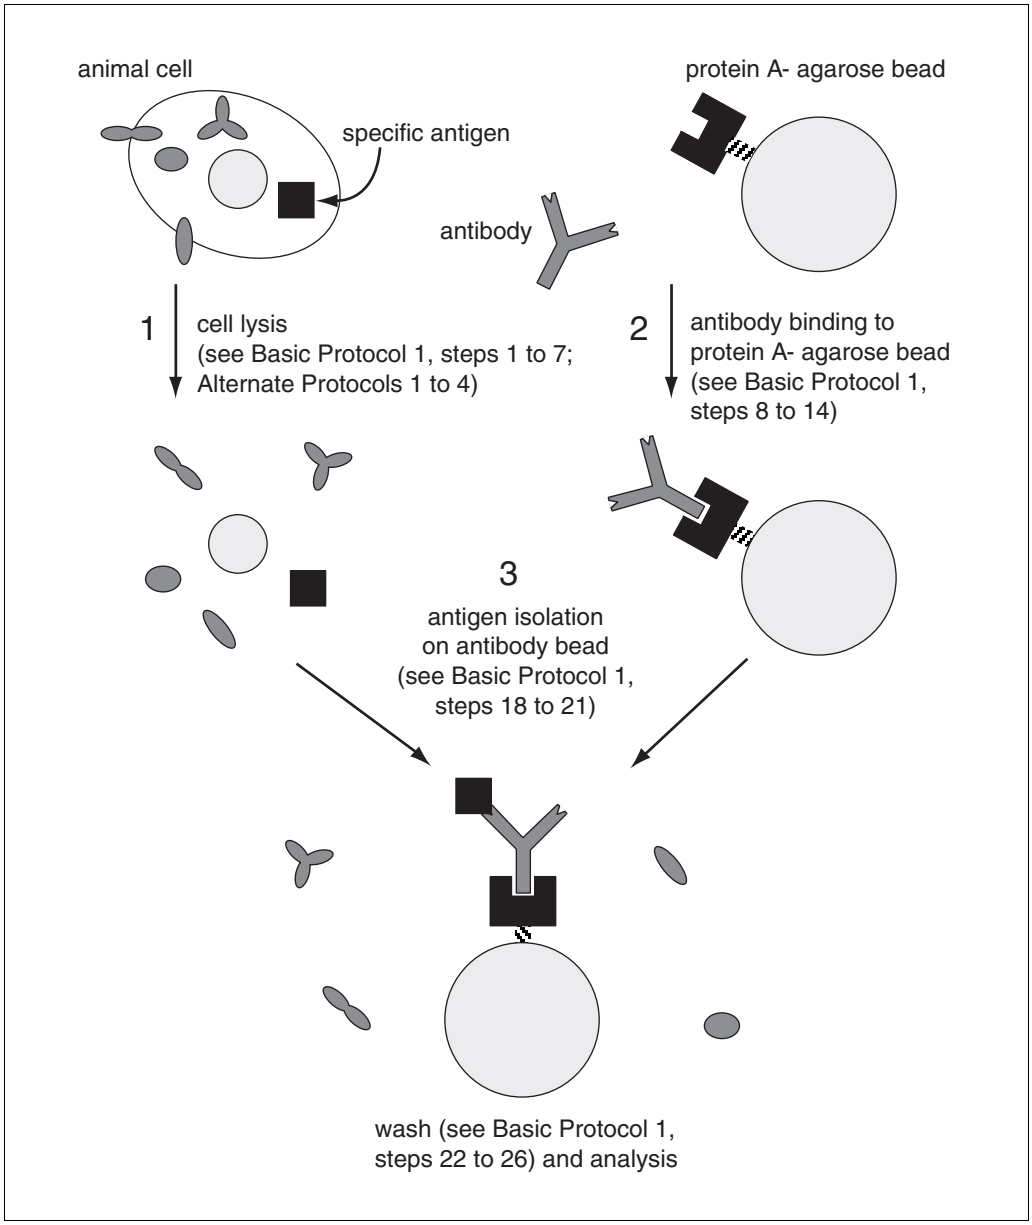

Figure 7.2.1 Schematic representation of the stages of a typical immunoprecipitation protocol. (**1**) Cell lysis: antigens are solubilized by extraction of the cells in the presence or absence of detergents. To increase specificity, the cell lysate can be precleared with protein A–agarose beads (steps 15 to 17, not shown). (**2**) Antibody immobilization: a specific antibody is bound to protein A–agarose beads. (**3**) Antigen capture: the solubilized antigen is isolated on antibody-conjugated beads.

17). The need for preclearing depends on the specific experimental system being studied and the quality of the antibody reagents. The protocol described below incorporates a preclearing step using protein A–agarose. Protein fractions separated by techniques such as gel filtration or sedimentation on sucrose gradients (*UNIT 5.3*) can be used in place of the cell lysate at this stage. After binding the antigen to the antibody-conjugated beads, the unbound proteins are removed by successive washing and sedimentation steps.

Materials

Unlabeled or labeled cells in suspension (*UNIT 7.1*)
PBS (*APPENDIX 2A*), ice cold
Nondenaturing lysis buffer (see recipe), ice cold
50% (v/v) protein A–Sepharose bead (Sigma, Pharmacia Biotech) slurry in PBS containing 0.1% (w/v) BSA and 0.01% (w/v) sodium azide (NaN_3)

Table 7.2.1 Binding of Antibodies to Protein A and Protein G[a,b,c]

Antibody	Protein A binding	Protein G binding[d]
Monoclonal antibodies[e]		
Human IgG1	++	++
Human IgG2	++	++
Human IgG3	–	++
Human IgG4	++	++
Mouse IgG1	+	++
Mouse IgG2a	++	++
Mouse IgG2b	++	++

Sheep	+	++

[a] ++, moderate to strong binding; +, weak binding; –, no binding.

[b] A hybrid protein A/G molecule that combines the features of protein A and protein G, coupled to a solid-phase matrix, is available from Pierce.

[c] Information from Harlow and Lane (1988), and from Pharmacia Biotech, Pierce, and Jackson Immunoresearch.

[d] Native protein G binds albumin from several animal species. Recombinant variants of protein G have been engineered for better binding to rat, mouse, and guinea pig IgG, as well as for avoiding binding to serum albumin.

[e] Protein A binds some IgM, IgA, and IgE antibodies in addition to IgG, whereas protein G binds only IgG.

Specific polyclonal antibody (antiserum or affinity-purified immunoglobulin) or monoclonal antibody (ascites, culture supernatant, or purified immunoglobulin)
Control antibody of same type as specific antibody (e.g., preimmune serum or purified irrelevant immunoglobulin for specific polyclonal antibody; irrelevant ascites, culture supernatant, or purified immunoglobulin for specific monoclonal antibody; see Critical Parameters)
10% (w/v) BSA (*APPENDIX 2A*)
Wash buffer (see recipe), ice cold

Microcentrifuge with fixed-angle rotor (Eppendorf 5415C or equivalent)
Tube rotator (capable of end-over-end inversion)

CAUTION: When working with radioactivity, take appropriate precautions to avoid contamination of the experimenter and the surroundings. Carry out the experiment and dispose of wastes in an appropriately designated area, following the guidelines provided by the local radiation safety officer (also see *APPENDIX 1D*).

NOTE: All solutions should be ice cold and procedures should be carried out at 4°C or on ice.

Prepare cell lysate

1. Collect cells in suspension by centrifuging 5 min at 400 × *g*, 4°C, in a 15- or 50-ml capped conical tube. Place tube on ice.

   Approximately 0.5–2 × 10^7 cells are required to yield 1 ml lysate, which is generally used for each immunoprecipitation.

   Labeled cells are likely to have been pelleted earlier as part of the labeling procedure. If the cells are frozen, they should be thawed on ice before solubilization.

2. Aspirate supernatant with a Pasteur pipet attached to a vacuum trap.

   CAUTION: *Dispose of radioactive materials following applicable safety regulations (APPENDIX 1D).*

3. Resuspend cells gently by tapping the bottom of the tube. Rinse cells twice with ice-cold PBS as in steps 1 and 2, using the same volume of PBS as in the initial culture.

4. Add 1 ml ice-cold nondenaturing lysis buffer per ~0.5–2 × 10^7 cells and resuspend pellet by gentle agitation for 3 sec with a vortex mixer set at medium speed.

   Do not shake vigorously as this could result in loss of material or protein denaturation due to foaming.

5. Keep suspension on ice 15 to 30 min and transfer to a 1.5-ml conical microcentrifuge tube.

   Tubes can have flip-top or screw caps. Screw-capped tubes are preferred because they are less likely to open accidentally during subsequent procedures. They are also recommended for work with radioactivity.

6. Clear the lysate by microcentrifuging 15 min at 16,000 × *g* (maximum speed), 4°C.

   Centrifugation can be carried out in a microcentrifuge placed in a cold room or in a refrigerated microcentrifuge. Take precautions to ensure that the 4°C temperature is maintained during the spin (e.g., use a fixed-angle rotor with a lid, as the aerodynamics of this type of rotor reduces generation of heat by friction). If it is necessary to reduce background, the lysate can be spun for 1 hr at 100,000 × g in an ultracentrifuge.

7. Transfer the supernatant to a fresh microcentrifuge tube using an adjustable pipet fitted with a disposable tip. Do not disturb the pellet, and leave the last 20 to 40 µl of supernatant in the centrifuge tube. Keep the cleared lysate on ice until preclearing (step 15) or addition of antibody beads (step 18).

NOTE: *Resuspension of even a small amount of sedimented material will result in high nonspecific background due to carryover into the immunoprecipitation steps. A cloudy layer of lipids floating on top of the supernatant will not adversely affect the results of the immunoprecipitation.*

When the lysate is highly radioactive—as is the case for metabolically labeled cells—the use of tips with aerosol barriers is recommended to reduce the risk of contaminating internal components of the pipet.

Cell extracts can be frozen at −70°C until used for immunoprecipitation. However, it is preferable to lyse the cells immediately before immunoprecipitation in order to avoid protein degradation or dissociation of protein complexes. If possible, freeze the cell pellet from step 3 rather than the supernatant from step 7.

Prepare antibody-conjugated beads

8. In a 1.5-ml conical microcentrifuge tube, combine 30 µl of 50% protein A–Sepharose bead slurry, 0.5 ml ice-cold PBS, and the following quantity of specific antibody (select one):

   1 to 5 µl polyclonal antiserum

   1 µg affinity-purified polyclonal antibody

   0.2 to 1 µl ascitic fluid containing monoclonal antibody

   1 µg purified monoclonal antibody

   20 to 100 µl hybridoma culture supernatant containing monoclonal antibody.

The quantities of antibody suggested are rough estimates based on the expected amount of specific antibodies in each preparation. Quantities can be increased or decreased, depending on the quality of the antibody preparation (see Commentary).

Substitute protein G for protein A if antibodies are of a species or subclass that does not bind to protein A (see Table 7.2.1).

If the same antibody will be used to immunoprecipitate multiple samples (e.g., samples from a pulse-chase experiment; UNIT 7.1), the quantities indicated above can be increased proportionally to the number of samples and incubated in a 15-ml capped conical tube. In this case, the beads should be divided into aliquots just prior to the addition of the cleared cell lysate (step 18).

Antibody-conjugated beads can be prepared prior to preparation of the cell lysate (steps 1 to 7), in order to minimize the time that the cell extract is kept on ice.

9. Set up a nonspecific immunoprecipitation control in a 1.5-ml conical microcentrifuge tube by incubating 30 µl of 50% protein A–Sepharose bead slurry, 0.5 ml ice-cold PBS, and the appropiate control antibody (select one):

   1 to 5 µl preimmune serum as a control for a polyclonal antiserum

   1 µg purified irrelevant polyclonal antibody (an antibody to an epitope that is not present in the cell lysate) as a control for a purified polyclonal antibody

   0.2 to 1 µl ascitic fluid containing irrelevant monoclonal antibody (an antibody to an epitope that is not present in the cell lysate and of the same species and immunoglobulin subclass as the specific antibody) as a control for an ascitic fluid containing specific monoclonal antibody

1 µg purified irrelevant monoclonal antibody as a control for a purified monoclonal antibody

20 to 100 µl hybridoma culture supernatant containing irrelevant monoclonal antibody as a control for a hybridoma culture supernatant containing specific monoclonal antibody

The amount of irrelevant antibody should match that of the specific antibody and the antibody should be from the same species as the specific antibody.

10. Mix suspensions thoroughly. Tumble incubation mixtures end over end ≥1 hr at 4°C in a tube rotator.

    Addition of 0.01% (w/v) Triton X-100 may facilitate mixing of the suspension during tumbling. Incubations can be carried out for as long as 24 hr. This allows preparation of the antibody-conjugated beads prior to immunoprecipitation.

11. Microcentrifuge 2 sec at 16,000 × *g* (maximum speed), 4°C.

12. Aspirate the supernatant (containing unbound antibodies) using a fine-tipped Pasteur pipet connected to a vacuum aspirator.

13. Add 1 ml nondenaturing lysis buffer and resuspend the beads by inverting the tube 3 or 4 times.

    For lysates prepared with detergents (this protocol and see Alternate Protocols 1 and 2), use 1 ml nondenaturing lysis buffer; for lysates prepared by mechanical disruption (see Alternate Protocol 3), use detergent-free lysis buffer (see recipe).

    Use of a repeat pipettor is recommended when processing multiple samples.

14. Wash by repeating steps 11 to 13, and then steps 11 and 12 once more.

    At this point the beads have been washed twice with lysis buffer and are ready to be used for immunoprecipitation. Antibody-bound beads can be stored up to 6 hr at 4°C until used.

Preclear lysate (optional)

15. In a microcentrifuge tube, combine 1 ml cell lysate (from step 7) and 30 µl of 50% protein A–Sepharose bead slurry.

    The purpose of this step is to remove from the lysate proteins that bind to protein A–Sepharose, as well as pieces of insoluble material that may have been carried over from previous steps. If the lysate was prepared from cells expressing immunoglobulins—such as spleen cells or cultured B cells—the preclearing step should be repeated at least 3 times to ensure complete removal of endogenous immunoglobulins.

    If cell lysates were frozen and thawed, they should be microcentrifuged 15 min at 16,000 × g (maximum speed), 4°C, before the preclearing step.

16. Tumble end over end 30 min at 4°C in a tube rotator.

17. Microcentrifuge 5 min at 16,000 × *g* (maximum speed), 4°C.

Immunoprecipitate

18. Add 10 µl of 10% BSA to the tube containing specific antibody bound to protein A–Sepharose beads (step 14), and transfer to this tube the entire volume of cleared lysate (from step 7 or 17). If a nonspecific immunoprecipitation control is performed, divide lysate in two ~0.4-ml aliquots, one for the specific antibody and the other for the nonspecific control.

    In order to avoid carryover of beads with precleared material, leave 20 to 40 µl of supernatant on top of the pellets in the preclearing tubes. Discard beads and remaining supernatant. The BSA quenches nonspecific binding to the antibody-conjugated beads during incubation with the cell lysate.

19. Incubate 1 to 2 hr at 4°C while mixing end over end in a tube rotator.

    Samples can be incubated overnight, although there is an increased risk of protein degradation, dissociation of multiprotein complexes, or formation of protein aggregates.

20. Microcentrifuge 5 sec at 16,000 × *g* (maximum speed), 4°C.

21. Aspirate the supernatant (containing unbound proteins) using a fine-tipped Pasteur pipet connected to a vacuum aspirator.

    The supernatant can be kept up to 8 hr at 4°C or up to 1 month at −70°C for sequential immunoprecipitation of other antigens or for analysis of total proteins. To reutilize lysate, remove the supernatant carefully with an adjustable pipet fitted with a disposable tip. Before reprecipitation, preabsorb the lysate with protein A–Sepharose (as in steps 15 to 17) to remove antibodies that may have dissociated during the first immunoprecipitation.

    CAUTION: *Dispose of radioactive materials following applicable safety regulations.*

22. Add 1 ml ice-cold wash buffer, cap the tubes, and resuspend the beads by inverting the tube 3 or 4 times.

    Use of a repeat pipettor is recommended when processing multiple samples.

23. Microcentrifuge 2 sec at 16,000 × *g* (maximum speed), 4°C.

24. Aspirate the supernatant, leaving ~20 µl supernatant on top of the beads.

25. Wash beads three more times (steps 22 to 24).

    Total wash time (steps 22 to 26) should be ~30 min, keeping the samples on ice for 3 to 5 min between washes if necessary (see Critical Parameters).

26. Wash beads once more using 1 ml ice-cold PBS and aspirate supernatant completely with a drawn-out Pasteur pipet.

    The final product should be 15 µl of settled beads containing bound antigen.

    Immunoprecipitates can either be processed immediately or frozen at −20°C for later analysis. For subsequent analysis of the isolated proteins prior to electrophoresis (e.g., comparison of the electrophoretic mobility of the antigen with or without treatment with glycosidases), samples can be divided into two or more aliquots after addition of PBS. Transfer aliquots of the bead suspension to fresh tubes, centrifuge and aspirate as in the previous steps. Immunoprecipitates can be analyzed by one-dimensional electrophoresis (UNIT 6.1), two-dimensional electrophoresis, or immunoblotting (UNIT 6.2).

IMMUNOPRECIPITATION USING ADHERENT CELLS LYSED WITH A NONDENATURING DETERGENT SOLUTION

ALTERNATE PROTOCOL 1

Immunoprecipitation using adherent cells can be performed in the same manner as with nonadherent cells (see Basic Protocol 1). This protocol is essentially similar to steps 1 to 5 of Basic Protocol 1, but describes modifications necessary for using the same nondenaturing detergent solution to lyse cells attached to tissue culture plates. It is preferable to use cells grown on plates rather than in flasks, because the cell monolayer is more easily accessible.

Additional Materials *(also see Basic Protocol 1)*

Unlabeled or labeled cells grown as a monolayer on a tissue culture plate (*UNIT 7.1*)

NOTE: All solutions should be ice cold and procedures should be carried out at 4°C or on ice.

1. Rinse cells attached to a tissue culture plate twice with ice-cold PBS. Remove the PBS by aspiration with a Pasteur pipet attached to a vacuum trap.

   CAUTION: *Dispose of radioactive materials following applicable safety regulations.*

2. Place the tissue culture plate on ice.

3. Add ice-cold nondenaturing lysis buffer to the tissue culture plate.

   Use 1 ml lysis buffer for an 80% to 90% confluent 100-mm-diameter tissue culture plate. Depending on the cell type, a confluent 100-mm dish will contain 0.5–2 × 10^7 cells. For other plate sizes, adjust volume of lysis buffer according to the surface area of the plate.

4. Scrape the cells off the plate with a rubber policeman, and transfer the suspension to a 1.5-ml conical microcentrifuge tube using an adjustable pipettor fitted with a disposable tip. Vortex gently for 3 sec and keep tubes on ice for 15 to 30 min.

   Tubes can have flip-top or screw caps. Screw-capped tubes are preferred because they are less likely to open accidentally during subsequent procedures. They are also recommended for work with radioactivity.

5. Clear the lysate and perform immunoprecipitation (see Basic Protocol 1, steps 6 to 26).

ALTERNATE PROTOCOL 2

IMMUNOPRECIPITATION USING CELLS LYSED WITH DETERGENT UNDER DENATURING CONDITIONS

If epitopes of native proteins are not accessible to antibodies, or if the antigen cannot be extracted from the cell with nonionic detergents, cells should be solubilized under denaturing conditions. This protocol is based on that for nondenaturing conditions (see Basic Protocol 1, steps 1 to 7), with the following modifications. Denaturation is achieved by heating the cells in a denaturing lysis buffer that contains an ionic detergent such as SDS or Sarkosyl (*N*-lauroylsarcosine). The denaturing lysis buffer also contains DNase I to digest DNA released from the nucleus. Prior to immunoprecipitation, the denatured protein extract is diluted 10-fold with nondenaturing lysis buffer, which contains Triton X-100; this step protects the antigen-antibody interaction from interference by the ionic detergent. Immunoprecipitation is performed as described (see Basic Protocol 1).

The following protocol is described for cells in suspension culture, although it can be adapted for adherent cells (see Alternate Protocol 1). Only antibodies that react with denatured proteins can be used to immunoprecipitate proteins solubilized by this protocol.

Additional Materials *(also see Basic Protocol 1)*

Denaturing lysis buffer (see recipe)
Heating block set at 95°C (Eppendorf Thermomixer 5436 or equivalent)
25-G needle attached to 1-ml syringe

1. Collect cells in suspension culture (see Basic Protocol 1, steps 1 to 3). Place tubes on ice.

2. Add 100 µl denaturing lysis buffer per ~0.5–2 × 10^7 cells in the pellet.

3. Resuspend the cells by vortexing vigorously 2 to 3 sec at maximum speed. Transfer suspension to a 1.5-ml conical microcentrifuge tube.

   The suspension may be very viscous due to release of nuclear DNA.

   Tubes can have flip-top or screw caps. Screw-capped tubes are preferred because they are less likely to open accidentally during subsequent procedures. They are also recommended for work with radioactivity.

4. Heat samples 5 min at 95°C in a heating block.
5. Dilute the suspension with 0.9 ml nondenaturing lysis buffer. Mix gently.

   The excess 1% Triton X-100 in the nondenaturing lysis buffer sequesters SDS into Triton X-100 micelles.

6. Shear DNA by passing the suspension five to ten times through a 25-G needle attached to a 1-ml syringe.

   If the DNA is not digested by DNase I in the denaturing lysis buffer or thoroughly sheared mechanically, it will interfere with the separation of pellet and supernatant after centrifugation. Repeat mechanical disruption until the viscosity is reduced to manageable levels.

7. Incubate 5 min on ice.
8. Clear the lysate and perform immunoprecipitation (see Basic Protocol 1, steps 6 to 26).

IMMUNOPRECIPITATION USING CELLS LYSED WITHOUT DETERGENT

ALTERNATE PROTOCOL 3

Immunoprecipitation of proteins that are already soluble within cells (e.g., cytosolic or luminal organellar proteins) may not require the use of detergents. Instead, cells can be mechanically disrupted by repeated passage through a needle, and soluble proteins can be separated from insoluble material by centrifugation. The following protocol describes lysis of cells in a PBS-based detergent-free lysis buffer. Other buffer formulations may be used for specific proteins.

Additional Materials *(also see Basic Protocol 1)*

Detergent-free lysis buffer (see recipe)
25-G needle attached to 3-ml syringe

NOTE: All solutions should be ice-cold and procedures should be carried out at 4°C or on ice.

1. Collect and wash cells in suspension (see Basic Protocol 1, steps 1 to 3).
2. Add 1 ml of ice-cold detergent-free lysis buffer per ~0.5–2 × 10^7 cells in a pellet.
3. Resuspend the cells by gentle agitation for 3 sec with a vortex mixer set at medium speed.
4. Break cells by passing the suspension 15 to 20 times through a 25-G needle attached to a 3-ml syringe.

   Extrusion of the cell suspension from the syringe should be rapid, although care should be exercised to prevent splashing and excessive foaming. Cell breakage can be checked under a bright-field or phase-contrast microscope. Repeat procedure until >90% cells are broken.

   It is helpful to check ahead of time whether the cells can be broken in this way. If the cells are particularly resistant to mechanical breakage, they can be swollen for 10 min at 4°C with a hypotonic solution containing 10 mM Tris·Cl, pH 7.4 (APPENDIX 2A) before mechanical disruption.

5. Clear the lysate and perform immunoprecipitation (Basic Protocol 1, steps 6 to 26).

ALTERNATE PROTOCOL 4

IMMUNOPRECIPITATION USING YEAST CELLS DISRUPTED WITH GLASS BEADS

Unlike animal cells, yeast cells have an extremely resistant, detergent-insoluble cell wall. To allow extraction of cellular antigens, the cell wall needs to be broken by mechanical, enzymatic, or chemical means. The most commonly used procedure consists of vigorous vortexing of the yeast suspension with glass beads. The breakage can be done in the presence or absence of detergent, as previously described for animal cells (see Basic Protocol 1, Alternate Protocol 2, and Alternate Protocol 3). The protocol described below is suitable for mechanical disruption of most yeast species, including *Saccharomyces cerevisiae* and *Schizosaccharomyces pombe*. A protocol for metabolic labeling for yeast has been described by Franzusoff et al. (1991).

Additional Materials *(also see Basic Protocol 1)*

Unlabeled or radiolabeled yeast cells
Lysis buffer, ice cold: nondenaturing, denaturing, or detergent-free lysis buffer (see recipes)
Glass beads (acid-washed, 425- to 600-μm diameter; Sigma)

NOTE: All solutions should be ice-cold and procedures should be carried out at 4°C or on ice.

1. Collect 10 ml of yeast culture at 1 OD_{600} per immunoprecipitation sample, and centrifuge 5 min at 4000 × *g*, 4°C. Place tube on ice.
2. Remove supernatant by aspiration with a Pasteur pipet attached to a vacuum trap.

   CAUTION: *Dispose of radioactive materials following applicable safety regulations.*
3. Loosen pellet by vortexing vigorously for 10 sec. Rinse cells twice with ice-cold distilled water as in steps 1 and 2.

   Radiolabeled yeast cells are likely to have been pelleted earlier as part of the labeling procedure. If the pellets are frozen, they should be thawed on ice prior to cell disruption.
4. Add 3 vol ice-cold lysis buffer and 3 vol at 1 OD_{600} glass beads per volume of pelleted yeast cells.

   Use nondenaturing lysis buffer or detergent-free lysis buffer as required for the antigen under study. If the experiment requires denaturation of the antigen, the procedure can be adapted (see Alternate Protocol 2 for higher eukaryotic cells); however, the yeast cells must be broken with glass beads before heating the sample at 95°C.
5. Shake cells by vortexing vigorously at maximum speed for four 30-sec periods, keeping the cells on ice for 30 sec between the periods.

   Check cell breakage under a bright-field or phase-contrast microscope. It is helpful to check ahead of time if the cells can be broken in this way.
6. Remove the yeast cell lysate from the beads using a pipettor with a disposable tip. Transfer to a fresh tube.
7. Add 4 vol (see step 4) lysis buffer to the glass beads, vortex for 2 sec, and combine this supernatant with the lysate from step 6.
8. Clear the lysate and perform immunoprecipitation (see Basic Protocol 1, steps 6 to 26).

IMMUNOPRECIPITATION-RECAPTURE

Once an antigen has been isolated by immunoprecipitation, it can be dissociated from the beads and reimmunoprecipitated ("recaptured") with either the same antibody used in the first immunoprecipitation or with a different antibody (Fig. 7.2.2). Immunoprecipitation-recapture with the same antibody allows identification of a specific antigen in cases where the first immunoprecipitation contains too many bands to allow unambiguous identifica-

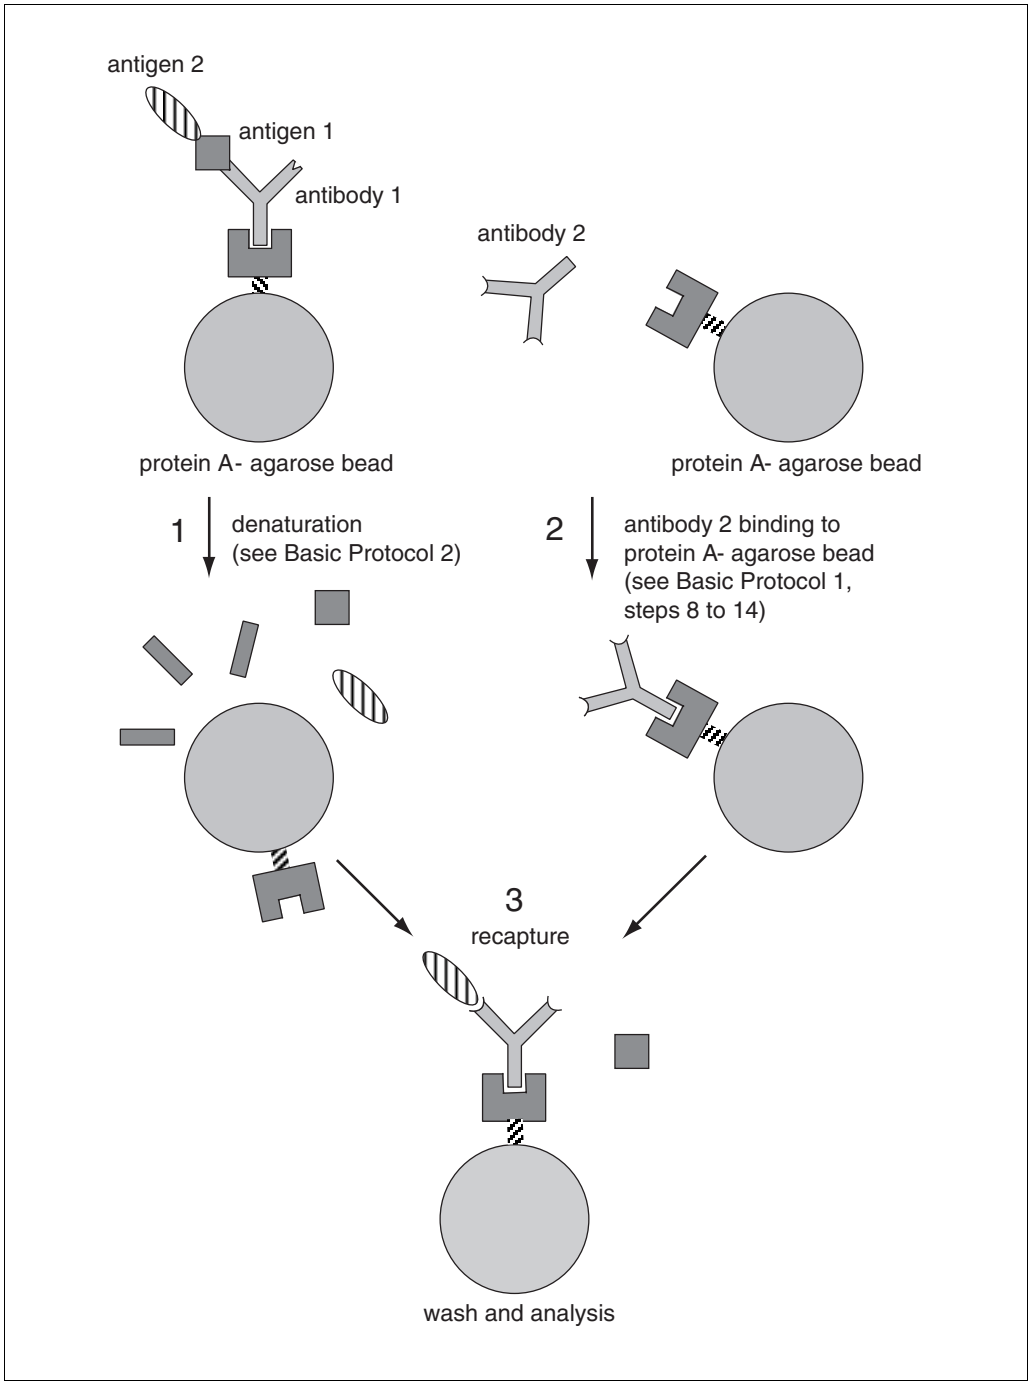

Figure 7.2.2 Scheme showing the stages of immunoprecipitation-recapture. (**1**) Dissociation and denaturation of the antigen: an antigen immunoprecipitated with antibody 1 bound to protein A–agarose beads is dissociated and denatured by heating in the presence of SDS and DTT. (**2**) Immobilization of the second antibody: antibody 2 is bound to protein A–agarose beads. (**3**) Recapture: the denatured antigen (striped oval) is recaptured on antibody 2 bound to protein A–agarose beads. Alternatively, antibody 1 can be used again for further purification of the original antigen (square).

tion. By using a different antibody in the second immunoprecipitation, immunoprecipitation-recapture can be used to analyze the subunit composition of multi-protein complexes (Fig. 7.2.3). The feasibility of this approach depends on the ability of the second antibody to recognize denatured antigens.

Dissociation of the antigen from the beads is achieved by denaturation of antigen-antibody-bead complexes at high temperature in the presence of SDS and DTT. Prior to recapture, the SDS is diluted in a solution containing Triton X-100, and the DTT is neutralized with excess iodoacetamide. Recapture is then performed as in the first immunoprecipitation (see Basic Protocol 1, step 26).

Materials

Elution buffer (see recipe)
Beads containing bound antigen (see Basic Protocol 1, step 26)
10% (w/v) BSA (*APPENDIX 2A*)
Nondenaturing lysis buffer (see recipe)
Heating block set at 95°C (Eppendorf Thermomixer 5436 or equivalent)

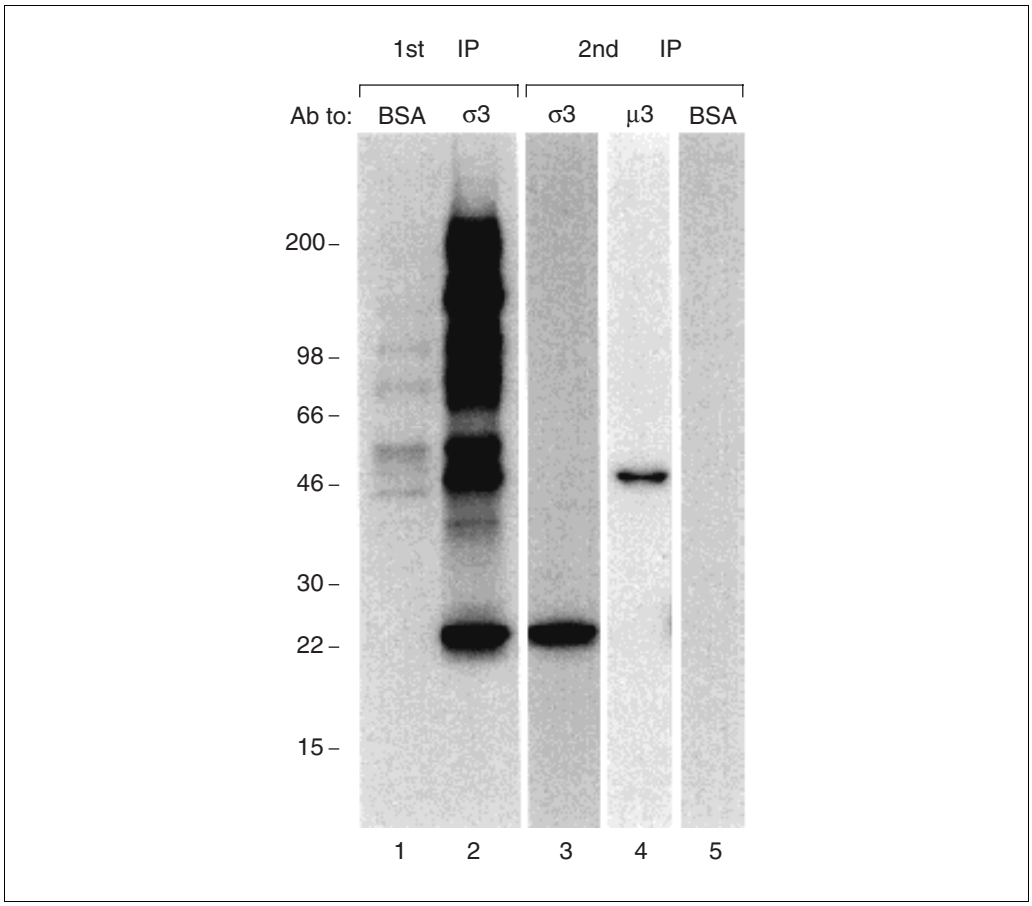

Figure 7.2.3 Example of an immunoprecipitation-recapture experiment. Human M1 fibroblasts were labeled overnight with [^{35}S]methionine (*UNIT 7.1*) and extracted with nondenaturing lysis buffer (see Basic Protocol 1). The cell extract was then subjected to immunoprecipitation with antibodies to BSA (irrelevant antibody control; lane 1) and to the AP-3 adaptor (σ3; lane 2), a protein complex involved in protein sorting. Notice the presence of several specific bands in lane 2. The AP-3 immunoprecipitate was denatured as described in Basic Protocol 2 and individual components of the AP-3 complex were recaptured with antibodies to two of its subunits: σ3 (M_r ~22,000; lane 3) and μ3 (M_r ~47,000; lane 4). An immunoprecipitation with an antibody to BSA was also performed as a nonspecific control (lane 5). The amount of immunoprecipitate loaded on lanes 1 and 2 is ~1/10 the amount loaded on lanes 3 to 5. Notice the presence of single bands in lanes 3 and 4. The positions of M_r standards (expressed as $10^{-3} \times M_r$) are shown at left. IP, immunoprecipitation.

1. Add 50 µl elution buffer to 15 µl beads containing bound antigen. Mix by vortexing.

   The DTT in the elution buffer reduces disulfide bonds in the antigen and the antibody, and the SDS contributes to the unfolding of polypeptide chains.

2. Incubate 5 min at room temperature and 5 min at 95°C in a heating block. Cool tubes to room temperature.

3. Add 10 µl of 10% BSA. Mix by gentle vortexing.

   BSA is added to prevent adsorption of antigen to the tube, and to quench nonspecific binding to antibody-conjugated beads.

4. Add 1 ml nondenaturing lysis buffer.

   The iodoacetamide in the nondenaturing lysis buffer reacts with the DTT and prevents it from reducing the antibody used in the recapture steps. The presence of PMSF and leupeptin in the buffer is not necessary at this step.

5. Incubate 10 min at room temperature.

6. Clear the lysate and perform second immunoprecipitation (see Basic Protocol 1, steps 6 to 26).

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Denaturing lysis buffer

1% (w/v) SDS
50 mM Tris·Cl, pH 7.4 (*APPENDIX 2A*)
5 mM EDTA (*APPENDIX 2A*)
Store up to 1 week at room temperature (SDS precipitates at 4°C)
Add the following fresh before use:
10 mM dithiothreitol (DTT, from powder)
1 mM PMSF (*APPENDIX 2A*)
2 µg/ml leupeptin (store 10 mg/ml stock in H_2O up to 6 months at −20°C)
15 U/ml DNase I (store 15,000 U/ml stock solution up to 2 years at −20°C)

1 mM 4-(2-aminoethyl)benzenesulfonyl fluoride (AEBSF), added fresh from a 0.1 M stock solution in H_2O, can be used in place of PMSF. AEBSF stock can be stored up to 1 year at −20°C.

Detergent-free lysis buffer

PBS (APPENDIX 2A) containing:
5 mM EDTA (*APPENDIX 2A*)
0.02% (w/v) sodium azide
Store up to 6 months at 4°C
Immediately before use add:
10 mM iodoacetamide (from powder)
1 mM PMSF (*APPENDIX 2A*)
2 µg/ml leupeptin (store 10 mg/ml stock in H_2O up to 6 months at −20°C)

1 mM 4-(2-aminoethyl)benzenesulfonyl fluoride (AEBSF), added fresh from a 0.1 M stock solution in H_2O, can be used in place of PMSF. AEBSF stock can be stored up to 1 year at −20°C.

Elution buffer

1% (w/v) SDS
100 mM Tris·Cl, pH 7.4 (*APPENDIX 2A*)
Store up to 1 week at room temperature
10 mM dithiothreitol (DTT, add fresh from powder before use)

Nondenaturing lysis buffer

1% (w/v) Triton X-100
50 mM Tris·Cl, pH 7.4 (*APPENDIX 2A*)
300 mM NaCl
5 mM EDTA (*APPENDIX 2A*)
0.02% (w/v) sodium azide
Store up to 6 months at 4°C
Immediately before use add:
10 mM iodoacetamide (from powder)
1 mM PMSF (*APPENDIX 2A*)
2 μg/ml leupeptin (store 10 mg/ml stock in H_2O up to 6 months at –20°C)

1 mM 4-(2-aminoethyl)-benzenesulfonyl fluoride (AEBSF), added fresh from a 0.1 M stock solution in H_2O, can be used in place of PMSF. AEBSF stock can be stored up to 1 year at –20°C.

Wash buffer

0.1% (w/v) Triton X-100
50 mM Tris·Cl, pH 7.4 (*APPENDIX 2A*)
300 mM NaCl
5 mM EDTA (*APPENDIX 2A*)
0.02% (w/v) sodium azide
Store up to 6 months at 4°C

COMMENTARY

Background Information

The use of antibodies for immunoprecipitation has its origin in the *precipitin* reaction (Nisonoff, 1984). The term precipitin refers to the spontaneous precipitation of antigen-antibody complexes formed by interaction of certain polyclonal antibodies with their antigens. The precipitation arises from formation of large networks of antigen-antibody complexes, due to the bivalent or polyvalent nature of immunoglobulins and to the presence of two or more epitopes in some antigens. This phenomenon was quickly exploited to isolate antigens from protein mixtures; however, its use remained limited to antibodies and antigens that were capable of multivalent interaction. In addition, the efficiency of precipitate formation was highly dependent on the concentrations of antibody and antigen. Thus, the precipitin reaction was not generally applicable as a method for immunoprecipitation.

A significant improvement was the use of secondary anti-immunoglobulin reagents (generally anti-immunoglobulin serum) to cross-link the primary antibodies, thus promoting the formation of a precipitating network. Protocols based on the use of cross-linking secondary antibodies are still used in immunoprecipitation and are reputed to give very low backgrounds (Springer, 1996).

In the 1970s, immunoprecipitation became widely applicable to the study of cellular antigens as a result of several technological advances. A critical development was the introduction of methods for the production of monoclonal antibodies (Köhler and Milstein, 1975). The ability to produce unlimited amounts of antibodies with specificity against virtually any cellular antigen had a profound impact in many areas of biology and medicine. The fact that preparation of monoclonal antibodies did not require prior purification of the antigens accelerated the characterization of cellular proteins and organelles, a process in which immunoprecipitation protocols played a major role. To this day, monoclonal antibodies produced in mice or rats continue to be among the most useful tools in cell biology.

Another important development was the discovery of bacterial Fc receptors, proteins found

on the surface of bacteria that have the property of binding a wide range of immunoglobulins. Two of the most widely used bacterial Fc receptors are protein A from *Staphylococcus aureus* and protein G from group G streptococci. Protein A and protein G bind both polyclonal and monoclonal antibodies belonging to different subclasses and from different animal species (Table 7.2.1). Protein A was initially used to adsorb immunoglobulins as part of fixed, killed *Staphylococcus aureus* particles. Both protein A and protein G are now produced in large quantities by recombinant DNA procedures and are available coupled to solid-phase matrices such as agarose. In most cases, the binding of polyclonal or monoclonal antibodies to immobilized protein A (or G) avoids the need to use a secondary antibody to precipitate antigen-antibody complexes. Because of their broad specificity and ease of use, protein A–agarose and protein G–agarose (and related products) are the state-of-the-art reagents for the isolation of soluble antigen-antibody complexes in immunoprecipitation protocols.

Recent progress in the field of antibody engineering (reviewed by Rapley, 1995; Irving et al., 1996) promises to make antibody production a less time-consuming and haphazard process. Antibody fragments with high affinity for specific antigens can now be selected from phage display antibody libraries. Selected recombinant antibodies can then be produced in large quantities in *Escherichia coli*. Techniques have been developed for producing antibodies in soluble, secreted form. Affinity tags are added to the recombinant antibody molecules to facilitate purification, detection, and use in procedures such as immunoprecipitation. While attractive in principle, the production of recombinant antibodies has been plagued by technical difficulties that so far have limited their widespread use in cell biology. However, as technical problems are overcome, recombinant techniques will progressively replace immunization of animals as a way of producing antibodies for immunoprecipitation and for other applications.

Critical Parameters

Extraction of antigens

Isolation of cellular antigens by immunoprecipitation requires extraction of the cells so that the antigens are available for binding to specific antibodies, and are in a physical form that allows separation from other cellular components. Extraction with nondenaturing detergents such as Triton X-100 (see Basic Protocol 1 and Alternate Protocol 1) or in the absence of detergent (see Alternate Protocol 3) allows immunoprecipitation with antibodies to epitopes that are exposed on native proteins. Other nondenaturing detergents such as Nonidet P-40, CHAPS, digitonin, or octyl glucoside are also appropriate for extraction of native proteins (*UNIT 5.1*). Some of these detergents (e.g., digitonin) preserve weak protein-protein interactions better than Triton X-100. If the antigen is part of a complex that is insoluble in nondenaturing detergents (e.g., cytoskeletal structures, chromatin, membrane "rafts") or if the epitope is hidden within the folded structure of the protein, extraction under denaturing conditions is indicated (see Alternate Protocol 2).

The number of cells necessary to detect an immunoprecipitated antigen depends on the cellular abundance of the antigen and on the efficiency of radiolabeling. The protocols for radiolabeling (*UNIT 7.1*) and immunoprecipitation described in this book are appropriate for detection of antigens that are present at low to moderate levels (10,000 to 100,000 copies per cell), as is the case for most endogenous integral membrane proteins, signal transduction proteins, and transcription factors. For more abundant antigens, such as cytoskeletal and secretory proteins or proteins that are expressed by viral infection or transfection, the quantity of radiolabeled cells used in the immunoprecipitation can be reduced accordingly.

Production of antibodies

Immunoprecipitation can be carried out using either polyclonal or monoclonal antibodies (see discussion of selection below). Polyclonal antibodies are most often prepared by immunizing rabbits, although polyclonal antibodies produced in mice, guinea pigs, goats, sheep, and other animals, are also suitable for immunoprecipitation. Antigens used for polyclonal antibody production can be whole proteins purified from cells or tissues, or can be whole or partial proteins produced in bacteria or insect cells by recombinant DNA procedures. Another useful procedure is to immunize animals with peptides conjugated to a carrier protein. Production of polyclonal antibodies to recombinant proteins and peptides has become the most commonly used approach to obtain specific probes for immunoprecipitation and other immunochemical techniques, because it does not require purification of protein antigens from their native sources. The only requirement for making these antibodies is knowledge of the

sequence of a protein, information which is now relatively easy to obtain as a result of cDNA and genomic DNA sequencing projects. Polyclonal antibodies can be used for immunoprecipitation as whole serum, ammonium sulfate–precipitated immunoglobulin fractions, or affinity-purified immunoglobulins. Although all of these forms are suitable for immunoprecipitation, affinity-purified antibodies often give lower backgrounds and are more specific.

Most monoclonal antibodies are produced in mice or rats. The sources of antigen for monoclonal antibody production are the same as those for production of polyclonal antibodies, namely, proteins isolated from cells or tissues, recombinant proteins or protein fragments, and peptides. A significant advantage of monoclonal antibodies is that antigens do not need to be purified to serve as immunogens, as long as the screening method is specific for the antigen. Another advantage is the unlimited supply of monoclonal antibodies afforded by the ability to grow hybridomas in culture or in ascitic fluid. Many monoclonal antibodies can now be produced from hybridomas deposited in cell banks or are directly available from companies. Ascitic fluid, cell culture supernatant, and purified antibodies are all suitable sources of monoclonal antibodies for immunoprecipitation. Ascitic fluid and purified antibodies should be used when a high antibody titer is important. Cell culture supernatants have lower antibody titers, but tend to give cleaner immunoprecipitations than ascitic fluids due to the lack of contaminating antibodies.

Selection of antibodies: Polyclonal versus monoclonal

What type of antibody is best for immunoprecipitation? There is no simple answer to this question, as the outcome of both polyclonal and monoclonal antibody production protocols is still difficult to predict. Polyclonal antibodies to whole proteins (native or recombinant) have the advantage that they frequently recognize multiple epitopes on the target antigen, enabling them to generate large, multivalent immune complexes. Formation of these antigen-antibody networks enhances the avidity of the interactions and increases the efficiency of immunoprecipitation. Because these antibodies recognize several epitopes, there is a better chance that at least one epitope will be exposed on the surface of a solubilized protein and thus be available for interaction with antibodies. Thus, the likelihood of success is higher. These properties can be a disadvantage, though, as some polyvalent antibodies can cross-react with epitopes on other proteins, resulting in higher backgrounds and possible misidentification of antigens. By being directed to a short peptide sequence, anti-peptide polyclonal antibodies are less likely to cross-react with other proteins. However, their usefulness is dependent on whether the chosen sequence turns out to be a good immunogen in practice, as well as on whether this particular epitope is available for interaction with the antibody under the conditions used for immunoprecipitation.

Unfractionated antisera are often suitable for immunoprecipitation. However, there is a risk that serum proteins other than the antibody will bind nonspecifically to the immunoadsorbent, and in turn bind proteins in the lysate that are unrelated to the antigen. For instance, transferrin can bind nonspecifically to immunoadsorbents, potentially leading to the isolation of the transferrin receptor as a contaminant (Harford, 1984). Polyclonal antisera can also contain antibodies to other antigens (e.g., viruses, bacteria) to which the animal may have been exposed, and these antibodies can also cross-react with cellular proteins during immunoprecipitation. Affinity-purified antibodies are a better alternative when antisera do not yield clean immunoprecipitations. Affinity-purification can lead to loss of high-affinity or low-affinity antibodies; however, the higher specificity of affinity-purified antibodies generally makes them "cleaner" reagents for immunoprecipitation.

The specificity, high titer, and limitless supply of the best immunoprecipitating monoclonal antibodies are unmatched by those of polyclonal antibodies. However, not all monoclonal antibodies are useful for immunoprecipitation. Low-affinity monoclonal antibodies can perform acceptably in immunofluorescence microscopy protocols (*UNIT 4.3*) but may not be capable of holding on to the antigen during the repeated washes required in immunoprecipitation protocols. The use of ascitic fluid has the same potential pitfalls as the use of polyclonal antisera, as ascites may also contain endogenous antibodies to other antigens and proteins such as transferrin that can bind to other proteins in the lysate.

In conclusion, an informed empirical approach is recommended in order to select the best antibody for immunoprecipitation. In general, it is advisable to generate and/or test several antibodies to a particular antigen in order to find at least one that will perform well in immunoprecipitation protocols.

Antibody titer

The importance of using the right amount of antibody for immunoprecipitation cannot be overemphasized. This is especially the case for quantitative immunoprecipitation studies, in which the antibody should be in excess of the specific antigen. For instance, in pulse-chase analyses of protein degradation or secretion (*UNIT 7.1*), it is critical to use sufficient antibody to deplete the antigen from the cell lysate. This is particularly important for antigens that are expressed at high levels, a common occurrence with the growing use of high-yield protein expression systems such as vaccinia virus or replicating plasmids in COS cells. Consider for example a protein that is expressed at high levels inside the cell, and of which only a small fraction is secreted into the medium. If limiting amounts of antibody are used in a pulse-chase analysis of this protein, the proportion of protein secreted into the medium will be grossly overestimated, because the limiting antibody will bind only a small proportion of the cell-associated protein and a much higher proportion of the secreted protein. The same considerations apply to degradation studies. Thus, it is extremely important in quantitative studies to ensure that the antibody is in excess of the antigen in the cell samples. This can be ascertained by performing sequential immunoprecipitations of the samples (see Basic Protocol 1, annotation to step 21). If the second immunoprecipitation yields only a small amount of the antigen relative to that isolated in the first immunoprecipitation (<10%), then the antibody titer is appropriate. If, on the other hand, the amount of antigen isolated in the second immunoprecipitation is >10%, either more antibody or less antigen should be used.

Too much antibody can also be a problem, as nonspecific immunoprecipitation tends to increase with increasing amounts of immunoglobulins bound to the beads. Thus, titration of the antibody used for immunoprecipitation is strongly advised.

Immunoadsorbent

If cost is not an overriding issue, the use of protein A– or protein G–agarose is recommended for routine immunoprecipitation. Protein A– or protein G–agarose beads (or equivalent products) have a very high capacity for antibody binding (up to 10 to 20 mg of antibody per milliliter of gel). Both protein A and protein G bind a wide range of immunoglobulins (Table 7.2.1). Backgrounds from nonspecifically bound proteins are generally low. Protein A– and protein G–agarose beads are also stable and easy to sediment by low-speed centrifugation. A potential disadvantage, in addition to their cost, is that some polyclonal or monoclonal antibodies bind weakly or not at all to protein A or protein G (Table 7.2.1). This problem can be solved by using an intermediate rabbit antibody to the immunoglobulin of interest. For example, a goat polyclonal antibody can be indirectly bound to protein A–agarose by first incubating the protein A–agarose beads with a rabbit anti-goat immunoglobulin, and then incubating the beads with the goat polyclonal antibody. Anti-immunoglobulin antibodies (e.g., rabbit anti–goat immunoglobulins) coupled covalently to agarose can also be used for indirect immunoprecipitation in place of protein A– or protein G–agarose.

Fixed *Staphylococcus aureus* particles (Pansorbin) can be used as a less expensive alternative to protein A–agarose. They have a lower capacity, can give higher backgrounds, and take longer to sediment. However, they work quite well in many cases. In order to establish if they are appropriate for a particular experimental setup, conduct a preliminary comparison of the efficiency of protein A–agarose with *Staphylococcus aureus* particles as immunoadsorbent.

Specific antibodies coupled covalently to various affinity matrices can also be used for direct immunoprecipitation of antigens. After binding to protein A–agarose, antibodies can be cross-linked with dimethylpimelimidate (Gersten and Marchalonis, 1978). Purified antibodies can also be coupled directly to derivatized matrices such as CNBr-activated Sepharose (Springer, 1996). This latter approach avoids having to bind the antibody to protein A–agarose. Covalently bound antibodies should be used when elution of immunoglobulins from the beads complicates further analyses of the complexes. This is the case when proteins in immunoprecipitates are analyzed by one- or two-dimensional gel electrophoresis (*UNIT 6.1*) followed by Coomassie blue or silver staining, or are used for microsequencing. Also, the released immunoglobulins could interfere with detection of some antigens by immunoblotting (*UNIT 6.2*) following immunoprecipitation.

Nonspecific controls

For correct interpretation of immunoprecipitation results, it is critical to include appropriate nonspecific controls along with the specific samples. One type of control consists of setting up an incubation with an irrelevant antibody in the same biochemical form as the

experimental antibody (e.g., serum, ascites, affinity-purified immunoglobulin, antibody bound to protein A–agarose or directly conjugated to agarose), and belonging to the same species and immunoglobulin subclass as the experimental antibody (e.g., rabbit antiserum, mouse IgG2a). For an antiserum, the best control is preimmune serum (serum from the same animal obtained before immunization). Nonimmune serum from the same species is an acceptable substitute for preimmune serum in some cases. "No-antibody" controls are not appropriate because they do not account for nonspecific binding of proteins to immunoglobulins. In immunoprecipitation-recapture experiments, control immunoprecipitations with irrelevant antibodies should be performed for both the first and second immunoprecipitation steps (Fig. 7.2.3). Another type of control is to perform an immunoprecipitation from cells that do not express a specific antigen in parallel with immunoprecipitation of the antigen-expressing cells. For instance, untransfected cells are a perfect control for transfected cells. In yeast cells, null mutants that do not express a specific antigen are an ideal control for wild-type cells.

Order of stages

In the immunoprecipitation protocols described in this unit, the antibody is prebound to protein A–agarose before addition to the cell lysate containing the antigen. This differs from other protocols in which the free antibody is first added to the lysate and the antigen-antibody complexes are then collected by addition of the immunoadsorbent. Although both procedures can give good results, the authors prefer the protocols described here because this method allows better control of the amount of antibody bound to the immunoadsorbent. Prebinding antibodies to the immunoadsorbent beads allows removal of unbound antibodies. The presence of unbound antibodies in the incubation mixture could otherwise result in decreased recovery of the antigen on the immunoadsorbent beads. Another advantage of the prebinding procedure is that most proteins other than the immunoglobulin in the antibody sample (e.g., serum proteins) are removed from the beads and do not come in contact with the cell lysate. This eliminates potential adverse effects of these proteins on isolation of the antigen.

Washing

The five washes described (see Basic Protocol 1; four with wash buffer and one with PBS) are sufficient for maximal removal of unbound proteins; additional washes are unlikely to decrease the background any further. The last wash with PBS removes the Triton X-100 that can lead to decreased resolution on SDS-PAGE. It also removes other components of the wash buffer that could interfere with enzymatic treatment of immunoprecipitates. It is not advisable to complete all the washes quickly (e.g., in 5 min), because this may not allow enough time for included proteins to diffuse out of the gel matrix. Instead, beads should be washed over ~30 min, which may require keeping the samples on ice for periods of 3 to 5 min between washes. In order to reduce nonspecific bands, samples can be subjected to an additional wash with wash buffer containing 0.1% (w/v) SDS, or with a mixture of 0.1% (w/v) SDS and 0.1% (w/v) sodium deoxycholate (Fig. 7.2.4). This wash should be done between the fourth wash and the wash with PBS.

Troubleshooting

Two of the most common problems encountered in immunoprecipitation of metabolically labeled proteins are failure to detect specific antigens in the immunoprecipitates, and high background of nonspecifically bound proteins for antigens that were radiolabeled in vivo and analyzed by SDS-PAGE (*UNIT 6.1*) followed by autoradiography or fluorography (*UNIT 6.3*). When immunoprecipitates are analyzed by immunoblotting (*UNIT 6.2*), an additional problem may be the detection of immunoprecipitating antibody bands in the blots (Table 7.2.2).

Anticipated Results

For antigens that are present at >10,000 copies per cell, the radiolabeling and immunoprecipitation protocols described in this book would be expected to result in the detection of one or more bands corresponding to the specific antigen and associated proteins in the electrophoretograms. Specific bands should not be present in control immunoprecipitations done with irrelevant antibodies. If antigens are labeled with [^{35}S]methionine (*UNIT 7.1*), specific bands should be visible within 2 hr to 2 months of exposure. Due to the relatively low yield of the immunoprecipitation-recapture procedure (<10% of that of a single immunoprecipitation step), detection of specific bands is likely to require longer exposure times. This may turn out to be problematic due to the radioactive decay of ^{35}S (half-life = 88 days). In immunoprecipitation-recapture experiments in which the antibodies used for the first and second

immunoprecipitation steps recognize different antigens (e.g., for the study of protein-protein interactions; Fig. 7.2.2), it is advisable to include in the second immunoprecipitation step a positive control with either the antibody used for the first immunoprecipitation (if the antibody recognizes both the native and denatured forms of the antigen) or a different antibody with specificity for the same antigen (Fig. 7.2.3, lane 3).

Time Considerations

Preparation of cell extracts (Basic Protocol 1 and Alternate Protocols 1 to 4) takes 1 to 3 hr to complete, and isolation of the antigen on antibody-conjugated beads takes 2 to 3 hr. Binding antibodies to immunoadsorbent beads can be done prior to or simultaneously with preparation of the cell extracts and also takes 1 to 3 hr. Therefore, the whole immunoprecipitation procedure can be completed in 1 day. Immunoprecipitates can be analyzed immediately (e.g., resolved by SDS-PAGE) or frozen and analyzed another day. Immunoprecipitation-recapture experiments (Basic Protocol 2) require an additional 1 to 2 hr to denature and prepare the antigen for immunoprecipitation, and 2 to 3 hr to isolate the antigen. Completion

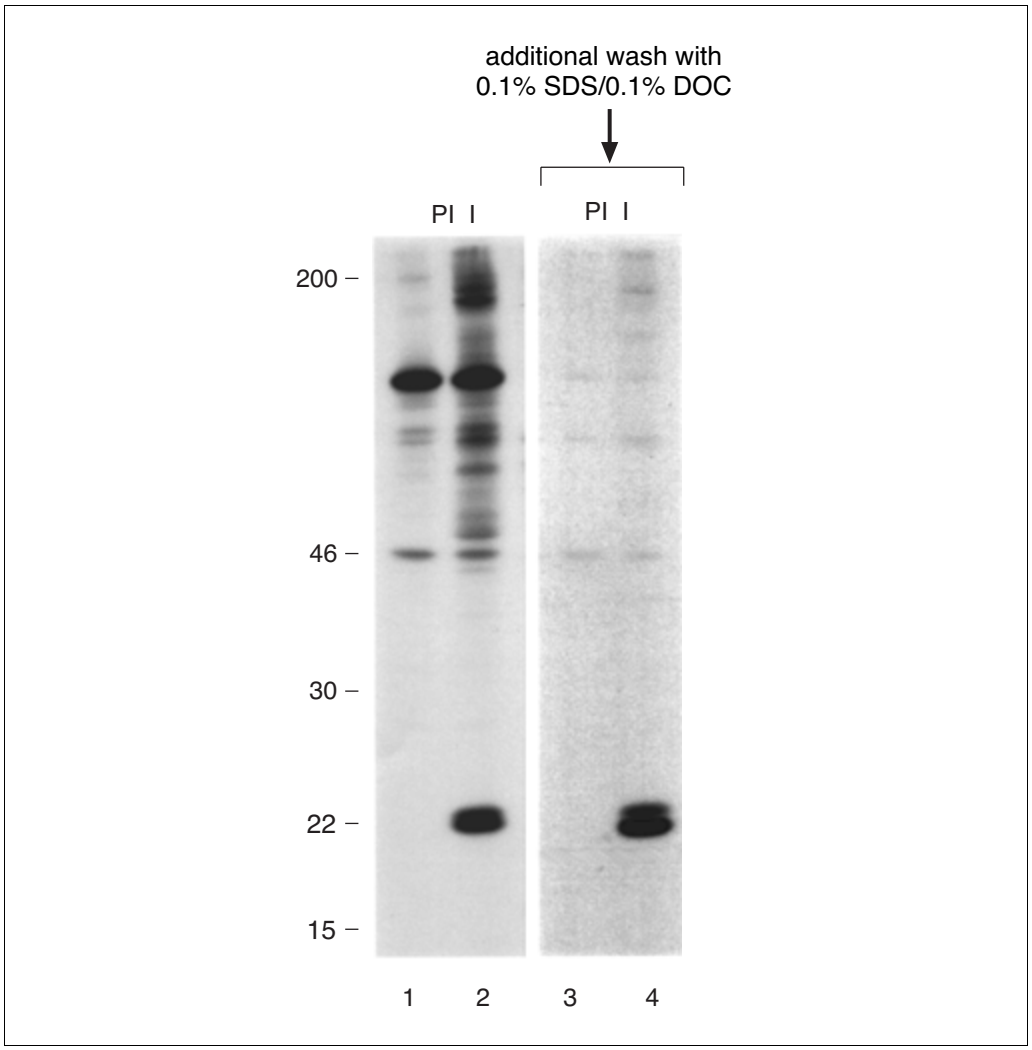

Figure 7.2.4 Lowering background by washing with SDS and sodium deoxycholate (DOC). In this experiment, BW5147 cells (mouse thymoma) labeled with [^{35}S]methionine for 1 hr were extracted with nondenaturing lysis buffer (see Basic Protocol 1). The extracts were subjected to immunoprecipitation with protein A–agarose beads incubated with either preimmune (PI) or immune (I) serum from a rabbit immunized with the ribosomal protein L17 (doublet at M_r ~22,000). Lanes 1 and 2 correspond to immunoprecipitates obtained using the protocols described in this unit. Notice the presence of nonspecific bands and/or associated proteins in lane 2. Lanes 3 and 4 correspond to beads that were washed an additional time with 0.1% (w/v) SDS and 0.1% (w/v) DOC. Notice the disappearance of most of the nonspecific bands and/or associated proteins. The positions of M_r standards (expressed as $10^{-3} \times M_r$) are shown at left.

Table 7.2.2 Troubleshooting Guide for Immunoprecipitation

Problem	Cause	Solution
No specific radiolabeled antigen band		
Gel is completely blank after prolonged autoradiographic exposure	Poorly labeled cells: too little radiolabeled precursor, too few cells labeled, lysis/loss of cells during labeling, too much cold amino acid in labeling mix, wrong labeling temperature	Check incorporation of label by TCA precipitation (*UNIT 7.1*); troubleshoot the labeling procedure
Only nonspecific bands present	Antigen does not contain the amino acid used for labeling	Label cells with another radiolabeled amino acid, or for glycoproteins, with tritiated sugar
	Antigen expressed at very low levels	Substitute cells known to express higher levels of antigens as detected by other methods; transfect cells for higher expression
	Protein has high turnover rate and is not well labeled by long-term labeling	Use pulse labeling
	Protein has a low turnover rate and is not well labeled by short-term labeling	Use long-term labeling
	Protein is not extracted by lysis buffer used to solubilize cells	Solublize with a different nondenaturing detergent or under denaturing conditions
	Antigen is not extracted with Triton X-100 at 4°C	Extract with Triton X-100 at 37°C or use another detergent
	Antibody is nonprecipitating	Identify and use antibody that precipitates antigen
	Epitope is not exposed in native antigen	Extract cells under denaturing conditions
	Antibody does not recognize denatured antigen	Extract cells under nondenaturing conditions
	Antibody does not bind to immunoadsorbent	Use a different immunoadsorbent (Table 7.2.1); use intermediate antibody
	Antigen is degraded during immunoprecipitation	Ensure that fresh protease inhibitors are present
High background of nonspecific bands		
Isolated lanes on gel with high background	Random carryover of detergent-insoluble proteins	Remove supernatant immediately after centrifugation, leaving a small amount with pellet; if resuspension occurs, recentrifuge
High background in all lanes	Incomplete washing	Cap tubes and invert several times during washes
	Poorly radiolabeled protein	Optimize duration of labeling to maximize signal-to-noise
	Incomplete removal of detergent-insoluble proteins	Centrifuge lysate 1 hr at 100,000 × *g*
	Insufficient unlabeled protein to quench nonspecific binding	Increase concentration of BSA

continued

Table 7.2.2 Troubleshooting Guide for Immunoprecipitation, continued

Problem	Cause	Solution
	Antibody contains aggregates	Microcentrifuge antibody 15 min at maximum speed before binding to beads
	Antibody solution contains nonspecific antibodies	Use affinity-purified antibodies; absorb antibody with acetone extract of cultured cells that do not express antigen; for yeast cells, absorb antibody with null mutant cells
	Too much antibody	Use less antibody
	Incomplete preclearing	Preclear with irrelevant antibody of same species of origin and immunoglobulin subclass bound to immunoadsorbent
	Nonspecifically immunoprecipitated proteins	Fractionate cell lysate (e.g, ammonium sulfate precipitation, lectin absorption, or gel filtration) prior to immunoprecipitation; after washes in wash buffer, wash beads once with 0.1% SDS in wash buffer or 0.1% SDS/0.1% sodium deoxycholate
Immunoprecipitating antibody detected in immunoblots		
Complete immunoglobulin or heavy and/or light chains visible in immunoblot	Protein A conjugate or secondary antibody recognizes immunoprecipitating antibody	Use antibody coupled covalently to solid-phase matrix for immunoprecipitation; probe blots with primary antibody from a different species and the appropriate secondary antibody specific for immunoblotting primary antibody

of an entire immunoprecipitation-recapture experiment requires a very long workday. Alternatively, samples can be frozen after the first immunoprecipitation, and the elution and recapture can be carried out another day.

Metabolic Labeling with Sulfate

Many newly synthesized secretory or transmembrane proteins are posttranslationally modified as they traverse the secretory pathway (*UNIT 15.1*). Posttranslational modifications can be exploited to determine where a protein normally resides in a cell or to follow its transport through the cell. One of these modifications is the addition of sulfate either to the protein backbone on tyrosine residues or to carbohydrate side chains. Sulfation of proteins on tyrosine occurs in the lumen of the *trans*-Golgi network (TGN; Niehrs and Huttner, 1990) through the action of the enzyme tyrosylprotein sulfotransferase (TPST). Sulfation of carbohydrate side chains on proteins also occurs in the later compartments of the Golgi complex, mediated by a variety of sulfotransferases (for recent review see Bowman and Bertozzi, 1999). The xylose side chains of proteoglycans can also be sulfated. Thus, sulfation can potentially be used to study the transport of a variety of molecules as long as they (1) are substrates for the sulfotransferases and (2) are resident in or pass through the compartment(s) that contains the sulfotransferases.

Incorporation of radioactive sulfate into sulfated proteins and proteoglycans is a useful tool to study protein/proteoglycan transport from the Golgi complex. It provides greater resolution of the kinetics of transport than does metabolic labeling in the endoplasmic reticulum using radiolabeled amino acids (see *UNIT 7.1*). This unit describes how to label mammalian cells in culture with radioactive sulfate to determine whether the protein or proteoglycan of interest is a substrate for sulfotransferases and can be labeled with [^{35}S]sulfate.

This unit describes a long-term labeling protocol for adherent monolayer cells in culture (see Basic Protocol 1), which ensures that a high specific activity is achieved for subsequent analysis. Modification of this protocol to provide a pulse-chase protocol (see Basic Protocol 2) is achieved by shorter labeling times (the pulse), followed by a quenching of the label with excess cold sulfate (the chase).

CAUTION: When working with radioactive materials, take appropriate precautions to avoid contamination of the experimenter and the surroundings. Carry out the experiment and dispose of wastes in an appropriately designated area, following guidelines provided by the local radiation safety officer (also see *UNIT 7.1* and *APPENDIX 1D*)

NOTE: All solutions used for the labeling protocols are tissue culture–grade reagents. Sterility of the media, label, and cultures is important for long-term labeling procedures.

NOTE: All culture incubations should be performed in a humidified, 37°C, 5% CO_2 incubator unless otherwise specified. Some media (e.g., DMEM) may require altered levels of CO_2 to maintain pH 7.4.

LONG-TERM [^{35}S]SULFATE LABELING OF MONOLAYER CELLS IN CULTURE

BASIC PROTOCOL 1

The most useful way to initially determine if the molecule of interest is sulfated is to label the cells to steady state using a lengthy labeling period—e.g., a time equivalent to at least one cell cycle period. This ensures that all the proteins within the cell that can be labeled with sulfate are labeled and provides the highest signal for starting the analysis. Cell cultures ~70% to 80% confluent are required along with the appropriate labeling medium and CO_2 incubators. All washing steps are performed at room temperature in a sterile cabinet.

Contributed by Sharon A. Tooze
Current Protocols in Cell Biology (1999) 7.3.1-7.3.7

Materials

Dialyzed serum (see recipe)
200 mM L-glutamine in H_2O
Sulfate-free DMEM (see recipe)
Sodium [^{35}S]sulfate (>1000 Ci/mmol)
Cells of interest, cultured to 70% to 80% confluence
DPBS (*APPENDIX 2A*), 4°C

Additional reagents and equipment for immunoprecipitation of proteins (*UNIT 7.2*) or for SDS-PAGE (*UNIT 6.1*) and fluorography (*UNIT 6.3*)

NOTE: The labeling medium is a modified formula for DMEM, which the author has found works best. Other media, such as RPMI, have not been used as successfully.

NOTE: All solutions for overnight labeling should be prepared and used under aseptic conditions.

NOTE: The size of the cultures used depends on the amount of the protein of interest present in the cells and the techniques used for subsequent analysis.

1. Prepare depletion medium by adding one-tenth the normal concentration of dialyzed serum and 4 mM glutamine to sulfate-free DMEM.

   Prepare enough medium to wash cultures once and for the addition of label. The amount of wash and labeling medium required depends on the size of the culture. Typically a 35-mm-diameter dish requires 2.0 ml and a 90-mm-diameter dish requires 10 ml.

   The addition of glutamine before each experiment allows the sulfate-free DMEM to be stored up to 6 months.

2. Prepare labeling medium by removing the appropriate amount of depletion medium to a plastic tube and adding sodium [^{35}S]sulfate to 0.2 to 0.5 mCi/ml.
3. Warm both media to 37°C in a water bath.
4. Gently wash cells once with depletion medium. Remove wash thoroughly and add labeling medium.
5. Ensure that cells are well covered, return them to the CO_2 incubator, and incubate overnight (≥16 hr).
6. Remove dishes from incubator and place on ice. Remove labeling medium and save.
7. Wash cells three times with ice-cold DPBS
8. Lyse in an appropriate solution and analyze by immunoprecipitation (*UNIT 7.2*) followed by SDS-PAGE (*UNIT 6.1*) and fluorography (*UNIT 6.3*). Use a lysis buffer that is optimal for solubilizing the cells and protein of interest.

   If the protein or proteoglycan of interest is secreted it maybe possible to detect it in the labeling medium. Adjust the medium with salts, buffer, and detergent to that present in the lysis conditions used for immunoprecipitation and proceed as in UNIT 7.2.

   After such a labeling experiment, it is worthwhile analyzing the total lysate and an aliquot of the medium by SDS-PAGE (UNIT 6.1). The molecule of interest may be highly sulfated and readily detectable without prior enrichment, even if it is a relatively minor fraction of the total protein.

PULSE-CHASE [^{35}S]SULFATE LABELING OF MONOLAYER CELLS IN CULTURE

Once the relative abundance of a protein is known and it can be easily detected after an overnight labeling with [^{35}S]sulfate, it is possible to use the radioactive sulfate in a pulse-chase protocol. This is done by labeling the protein for a short period of time (e.g., a 4- to 5-min pulse). The short time period is required to ensure that the labeled protein is still in the TGN. Further incubation (the chase) is done at 37°C after the addition of excess unlabeled sulfate to stop the incorporation of radioactive sulfate. The chase can be carried out for any length of time; the position of the radiolabeled proteins in the cell will be a function of the chase time. This procedure is invaluable if the protein or proteoglycan is thought to be secreted. If the protein or proteoglycan is thought to localize to a post-Golgi compartment, the protocol can be combined with cell fractionation to identify the intracellular compartment. The very short pulse provides a very accurate starting point for the analysis, and the kinetics of transport or secretion of the protein can be easily obtained.

Depending on the experiment it will be necessary to prepare several identical cultures: a dish of cells is required for each time point, including a zero time point, which is defined as the end of the pulse. A typical time course may have five or six chase time points (for example, 5, 10, 20, 40, and 80 min).

Materials

Cultured cells of interest, ~70% to 80% confluent
Dialyzed serum (see recipe)
200 mM L-glutamine in H_2O
Sulfate-free DMEM (see recipe)
Sodium [^{35}S]sulfate (>1000 Ci/mmol)
DPBS (*APPENDIX 2A*), 4°C
Chase medium (see recipe)
Platform rocker

Additional reagents and equipment for immunoprecipitation of proteins (*UNIT 7.2*), SDS-PAGE (*UNIT 6.1*), and fluorography (*UNIT 6.3*)

1. Label dishes of cultured cells on bottom with appropriate time or sample number and organize them on an easily movable tray. Return to incubator.

   It is important to be organized before the experiment begins as the manipulations must be carried out as quickly as possible during the time course.

2. Prepare ~4 vol depletion medium for each culture dish by adding dialyzed serum to 1/100th the normal concentration and 4 mM glutamine to sulfate-free DMEM.

   For each time point, enough depletion medium will be needed to make the labeling medium, wash each culture twice, and incubate once for the depletion step. For washes and depletion, use 2.0 ml for a 35-mm-diameter dish and 10 ml for a 90-mm-diameter dish. For labeling medium, use 1.0 ml for a 35-mm dish and 2.5 ml for a 90-mm dish. A reduced volume of labeling medium is used to save on the cost of the label.

   The addition of glutamine before each experiment allows the sulfate-free DMEM to be stored up to 6 months.

3. Prepare the labeling medium required for all dishes as one batch. Transfer the amount required for each dish, multiplied by the number of dishes, to a plastic tube and add [^{35}S]sulfate to give 5 mCi/ml.

4. Warm both media to 37°C in a water bath.

5. Gently wash all dishes twice with depletion medium. Thoroughly remove second wash and add another aliquot of depletion medium. Incubate 20 min in the incubator.

   The depletion step reduces the intracellular pool of sulfate to allow the highest specific activity of incorporated radioactive sulfate to be achieved.

6. Remove depletion medium from all dishes and quickly add equal aliquots of labeling medium to each culture. Start timer. Ensure that cells are well covered, place on a platform rocker in the 37°C CO_2 incubator, and incubate for 4 min.

   The culture dishes should be rocked gently during the labeling period as the volume of medium used is not sufficient to cover cells.

   This 4-min incubation is effectively a 2-min pulse because 2 min is required for the [^{35}S]sulfate to be converted to the activated sulfate donor (PAPS, see Commentary).

7. Remove all dishes from incubator and quickly place the time-zero dish on ice. Remove labeling medium from the time-zero dish and save. Add ice-cold DPBS to that dish and keep on ice. Remove label from remaining dishes at room temperature, discard, add chase medium at twice the volume of the labeling medium, and return to the incubator but do not rock.

8. At predetermined time points, remove the appropriate dish from the incubator, place immediately on ice, remove and save medium, and add ice-cold DPBS. Keep dishes on ice. Repeat until all the dishes are on ice and the chase protocol is complete.

9. Wash all dishes three times with ice-cold DPBS.

10. Lyse in an appropriate solution and immunoprecipitate (*UNIT 7.2*). Use a lysis buffer that is optimal for solubilizing the cells and protein of interest.

11. If the protein/proteoglycan of interest is secreted, adjust the medium saved from the zero time point and each chase time point by adding salts, buffer, and detergent to the conditions required for immunoprecipitation, and proceed as in *UNIT 7.2*.

    CAUTION: *Remember that the time-zero medium contains the radioactive-sulfate solution and should be treated with appropriate precautions.*

12. Analyze immunoprecipitates by SDS-PAGE (*UNIT 6.1*) and fluorography (*UNIT 6.3*).

REAGENTS AND SOLUTIONS

*Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see **APPENDIX 2A**; for suppliers, see **SUPPLIERS APPENDIX**.*

Chase medium

Use Dulbecco's minimal essential medium (DMEM; as purchased from supplier) or another growth medium. Use $^1/_{100}$th the normal serum concentrations to avoid problems with serum proteins during the analysis. Add 160 mM Na_2SO_4 (filter sterilized through a 0.2-µm filter) to a final concentration of 1.6 mM. Prepare fresh for each experiment.

Dialyzed serum

Dialyze serum overnight against DPBS (*APPENDIX 2A*) at 4°C. Use 100 times the serum volume for the dialysis, and change the solution once during dialysis. Sterile filter after dialysis and store in 1- or 2-ml aliquots in sterile tubes for up to 1 year at −20°C. After thawing, store dialyzed serum up to 1 month at 4°C.

Low–Met/Cys amino acid mixture, 10×

For 1 liter:

0.84 g L-arginine·HCl
0.063 g L-cystine
0.30 g glycine
0.42 g L-histidine·HCl
1.05 g L-isoleucine
1.05 g L-leucine
1.46 g L-lysine·HCl
0.03 g L-methionine
0.66 g L-phenylalanine
0.42 g L-serine
0.95 g L-threonine
0.16 g L-tryptophan
0.94 g L-valine
Mix into sterile Milli-Q-purified water and adjust volume to 1 liter
Store up to 6 months at −20°C

Having low methionine and cystine improves the sulfate incorporation by reducing the amount of sulfated essential amino acids that can be broken down, thereby diluting the radioactive pool of sulfate. Methionine and cystine at one-tenth the normal amount is usually sufficient to maintain protein synthesis and keep the cells healthy.

Tyrosine is added to the dilute sulfate-free DMEM because it is insoluble at 10× the normal concentration.

Do not add antibiotics as some (e.g., streptomycin) are sulfate salts.

Sulfate-free Dulbecco's minimal essential medium (DMEM)

For one liter:

265.00 mg $CaCl_2 \cdot 2H_2O$
0.10 mg $Fe(NO_3)_3 \cdot 9H_2O$
400.00 mg KCl
168.75 mg $MgCl_2 \cdot 6H_2O$
6400.00 mg NaCl
125.00 mg $NaH_2PO_4 \cdot H_2O$
5 ml 20% (w/v) glucose
10 ml 11.0 mg/ml sodium pyruvate, added dropwise
3 ml 0.5% (w/v) phenol red
49.3 ml 7.5% (w/v) $NaHCO_3$
72.0 mg tyrosine
40 ml 100× MEM vitamins (Sigma)
100 ml 10× low–Met/Cys amino acid mixture (see recipe)

Combine all ingredients except phenol red in 900 ml Milli-Q-purified water, cover, and stir to dissolve for several hours at room temperature or overnight at 4°C. Add phenol red and adjust pH to 7.2 with 1 M NaOH. Adjust volume to 1 liter. Sterile filter with 0.2-µm filter. Store up to 6 months at 4°C in the dark.

Use plastic containers or glassware that have not been washed with detergent to prepare media.

Sodium pyruvate is added dropwise to avoid precipitation.

COMMENTARY

Background Information

Posttranslational modifications of proteins and proteoglycans can be exploited to follow the route of the modified molecules through the secretory pathway. Sulfation on both carbohydrates and tyrosine residues is particularly useful for studying events in the later compartments of the secretory pathway—i.e., those after the *trans*-Golgi—and to study secretion. A short pulse of sulfate (5 min or less) can be used to label the proteins or proteoglycans in the compartment where the sulfotransferase is resident. Incubation with excess sulfate starts the chase of the sulfated molecules out of the Golgi complex to their final destination. Thus, the major advantage of using sulfation to follow proteins through the cell is the ability to label the molecules late in the secretory pathway, providing a sharply defined cohort of labeled molecules as the starting point for subsequent analysis.

Sulfation of carbohydrate chains on proteins and proteoglycans in the lumen of the Golgi complex is catalyzed by a variety of different sulfotransferases, some of which are only known as activities, while others have been extensively characterized, cloned, and sequenced. A co-substrate for the sulfotransferases is 3′-phosphoadenosine-5′-phosphosulfate (PAPS), which is synthesized in the cytosol and translocated across the Golgi membrane (for a comprehensive explanation see Huttner and Baeuerle, 1988). Sulfation of carbohydrates on proteins can occur on the N- or O-glycan chains (see *UNIT 15.2*), while sulfation of proteoglycans occurs on the glycosaminoglycan moiety. It is possible to determine the nature of the sulfated N- or O-glycan by using a variety of endoglycosidases that cleave the N- or O-linked oligosaccharide chains, such as endoglycosidase H (endo H; see *UNIT15.2*). There are several classes of sulfated proteoglycans, the most common being keratan sulfate, heparan sulfate, heparin, chrondroitin sulfate, and dermatan sulfate. Determining whether a sulfated molecule is a proteoglycan is more complex, as there is a limited range of available endoglycosidases, heparinase being the most commonly used. For the best methods to approach the analysis of more complex sulfated molecules, see Linhardt (1994).

The analysis of sulfated tyrosine residues in the protein backbone is more tractable. Posttranslational modification by sulfation on tyrosine residues is catalyzed by the enzyme tyrosylprotein sulfotransferase (Beisswanger et al., 1998) and occurs by transfer of the activated donor PAPS to the tyrosine residue. Sulfation of tyrosine residues, although widespread, is highly selective. The consensus features of the substrate recognition sequence in the protein backbone have been defined (Huttner and Baeuerle, 1988), allowing one to predict whether the protein of interest may be sulfated. If it is likely that the protein is sulfated on tyrosine residues, this can be confirmed by first demonstrating that the sulfated protein is resistant to endoglycosidases, and then chemically treating the protein with $Ba(OH)_2$, which allows the identification of Tyr-SO_4 by thin-layer chromatography (Huttner, 1984). A recent paper elegantly demonstrated just this approach (Farzan et al., 1999). This paper also demonstrated the usefulness of the drug chlorate, which inhibits the first enzyme (ATP-sulfurylase) in the biosynthesis of PAPS, and thereby inhibits the sulfation of both proteins and proteoglycans (Baeuerle and Huttner, 1986).

An interesting application of these approaches is to use the tyrosine sulfation consensus sequence to insert a sulfation site as a method of tagging secretory proteins to follow their movement out of the Golgi complex. This is particularly useful if the protein is not posttranslationally modified by N- or O-linked glycosylation. An example of this approach was pioneered by Niehrs et al. (1992).

Critical Parameters and Troubleshooting

The most important consideration is optimization of sulfate incorporation into the molecule to be analyzed. The efficiency of sulfation is the most variable parameter and relies on maintaining the cells in a medium that is compatible with continued protein synthesis and with sulfate labeling conditions. During the incubation with [^{35}S]sulfate, a series of reactions in the cytosol converts the [^{35}S]sulfate into [^{35}S]PAPS. Thus, it is important to reduce the concentration of endogenous PAPS to increase the specific activity of the radiolabeled PAPS. In some cell types this can be done easily by preincubation with sulfate-free medium, and is enhanced by reducing the methionine and cystine (Yanigashita et al., 1989).

If the suggested medium (DMEM) is not compatible with the cell types being used, it is possible to substitute other media prepared without sulfate, or even to substitute DPBS for

the labeling medium. However, if the suggested labeling medium is not suitable, pilot experiments should be done on total extracts to test the efficiency of [^{35}S]sulfate incorporation. It has been observed that some media (such as RPMI) do not allow efficient sulfate incorporation. Suitable media can be easily tested by incubating the cells for long-term labeling (see Basic Protocol 1) in the test medium, then measuring the incorporation of ^{35}S into proteins. One simple method to do this is to precipitate the proteins with trichloroacetic acid and then count the insoluble precipitate (see *UNIT 7.1*). The goal is to optimize the ^{35}S incorporation per microgram of protein.

Anticipated Results

The result of labeling with [^{35}S]sulfate should be a protein or proteoglycan that is radioactively labeled to allow easy detection.

Time Considerations

Four elements affect the time required to complete this type of experiment. These include the length of time required to (1) seed and culture cells to 70% to 80% confluence, (2) label overnight and prepare the sample (2 days total), (3) immunoprecipitate, and (4) expose the radioactive sample for detection. Parameters 1 through 3 should be known by the investigator before starting the experiment. Parameter 4 will depend on the specific activity of the [^{35}S]PAPS in the cell and the resulting incorporation of sulfate. Low levels of incorporation may result in exposure times exceeding a week.

Metabolic Labeling with Fatty Acids

Protein acylation is the covalent attachment of fatty acids to a protein; the most commonly added fatty acids are myristate (14:0) and palmitate (16:0). First, radiolabeled fatty acids are used to label eukaryotic cells (see Basic Protocol 1). The radiolabeled material produced can then be analyzed by various methods: the type of fatty acid linkage can be determined (see Basic Protocol 2), the nature of the protein-bound label can be determined to check for interconversion (see Basic Protocol 3), and the protein-bound fatty acid can be identified (see Basic Protocol 4).

CAUTION: When working with radioactivity, take appropriate precautions to avoid contamination of the experimenter and the surroundings. Carry out the experiment and dispose of wastes in appropriately designated area, following the guidelines provided by your local radiation safety officer (also see *APPENDIX 1D*).

BIOSYNTHETIC LABELING WITH FATTY ACIDS

BASIC PROTOCOL 1

To identify proteins that are modified with fatty acid groups, cultured cells are incubated first in medium containing sodium pyruvate, which acts as a source of acetyl-CoA and minimizes interconversion of the fatty acid to other metabolites, and then with [^{3}H]fatty acids. Fatty acids tritiated at positions 9 and 10 provide the best combination of high specific activity and detectability for in vitro labeling, and because the tritium label is far removed from the carboxyl end where β-oxidation occurs, reincorporation of label is minimized.

Materials

Cells for culture
Complete tissue culture medium appropriate for cells
Labeling medium: complete tissue culture medium containing the relevant dialyzed serum and 5 mM sodium pyruvate, 37°C
5 to 10 μCi/μl [9,10(*n*)-^{3}H]fatty acid, e.g., [9,10(*n*)-^{3}H]palmitic acid or [9,10(*n*)-^{3}H]myristic acid (30 to 60 Ci/mmol; Amersham International, American Radiolabeled Chemicals, or NEN Research Products) in ethanol
PBS, pH 7.2 (*APPENDIX 2A*), ice-cold
1% (w/v) SDS or SDS sample buffer (for SDS-PAGE, when using adherent or nonadherent cells respectively; *UNIT 6.1*) *or* RIPA lysis buffer (for immunoprecipitation; see recipe)
5× SDS sample buffer (see recipe)

Cell scrapers
Nitrogen gas

Additional reagents and equipment for culturing cells (*UNIT 1.1*), immunoprecipitation (*UNIT 7.2*), SDS-PAGE (*UNIT 6.1*), treating a gel with sodium salicylate (*UNIT 6.3*), and fluorography (*UNIT 6.3*)

NOTE: All reagents and equipment coming into contact with live cells must be sterile, and proper sterile technique should be used accordingly.

NOTE: All culture incubations are performed in a humidified 37°C, 5% CO_2 incubator unless otherwise specified. Some media (e.g., DMEM) may require altered levels of CO_2 to maintain pH 7.4.

Contributed by Caroline S. Jackson and Anthony I. Magee
Current Protocols in Cell Biology (2000) 7.4.1-7.4.10

1. On the day before the labeling experiment, split the cells into fresh complete tissue culture medium.

   Set up the cells at two split ratios; then choose the culture closest to 70% to 80% confluency for labeling.

2. The next day, replace the medium with a minimum volume of 37°C labeling medium. Incubate 1 hr.

   Cells in suspension should be used at a cell density of 10^6 to 10^7 cells/ml. For adherent cells that are 70% to 80% confluent, the minimum amount of medium necessary to cover the dish—e.g., 1.5 ml for 60-mm dishes and 3 ml for 100-mm dishes—should be used.

3. Add 5 to 10 µCi/µl [9,10(*n*)-^{3}H]fatty acid to a concentration of 50 to 500 µCi/ml. Incubate up to 24 hr.

   Cells vary in the rate and extent of incorporation (see Critical Parameters), so both the amount of label and the duration of incubation need to be optimized. Labeling cells overnight in the presence of 200 µCi/ml [^{3}H]fatty acid will maximize the chances of detecting labeled proteins. The amount of label and/or time of incubation can then be reduced if good incorporation of label is achieved, or increased if poor incorporation is attained.

   Short labeling times (e.g., pulses on the order of minutes up to 2 hr) require amounts of label at the higher end of the indicated range. In this case, uptake is relatively low and the medium plus label can be reused one or more times. The level of label in the medium can be monitored by scintillation counting. For longer incubations the interconversion of fatty acids becomes a greater problem, and the protein-bound fatty acid label should be analyzed (see Basic Protocols 3 and 4).

   If the [^{3}H]fatty acid is not supplied in ethanol or if the concentration is too low, remove the solvent by blowing nitrogen over the solution in its original container until dry and redissolve the label in ethanol at a concentration of 5 to 10 µCi/µl. Do not transfer into another container or evaporate the solvent in a plastic container, as this will cause a significant loss of label that will adhere to the side of the container.

For adherent cells:

4a. Place the dish on ice and aspirate the medium. Wash the cells twice with ice-cold PBS and lyse the cells by adding 1% SDS for SDS-PAGE (*UNIT 6.1*) *or* RIPA lysis buffer for immunoprecipitation (*UNIT 7.2*), using 100 µl of 1% SDS for a 60-mm dish or 300 µl for a 100-mm dish, or 1 ml RIPA lysis buffer.

   CAUTION: *Radioactive medium and washes must be disposed of appropriately.*

5a. Using a cell scraper, remove the lysed cells from the dish and transfer them to a 1.5-ml microcentrifuge tube. Add 20 µl lysate to 5 µl of 5× SDS-PAGE sample buffer. Use all of lysate for immunoprecipitation. Resuspend immunoprecipitate in 20 µl SDS sample buffer.

   For SDS-PAGE, use DTT at a final concentration ≤20 mM, and do not boil the samples, but incubate them only 3 min at 80°C; this is necessary because the thioester linkage of the fatty acid is susceptible to cleavage.

For nonadherent cells:

4b. Microcentrifuge the cell suspension 1 min at 6000 rpm, 4°C, to pellet the cells. Decant the supernatant and wash the cell pellet once by resuspending it in 1 ml ice-cold PBS and centrifuging again.

5b. Lyse the cells by resuspending the cell pellet in 100 µl SDS-PAGE sample buffer for discontinuous SDS-PAGE (*UNIT 6.1*) *or* 1 ml RIPA lysis buffer for immunoprecipitation (*UNIT 7.2*) for 10^6 to 10^7 cells. Resuspend immunoprecipitate in 20 µl SDS sample buffer.

CAUTION: *Radioactive medium and washes must be disposed of appropriately.*

For analysis of total protein-bound fatty acid label, lyse the cells in 100 µl 1% SDS.

For SDS-PAGE, use DTT at a final concentration ≤20 mM, and do not boil the samples, but incubate them only 3 min at 80°C; this is necessary because the thioester linkage of the fatty acid is susceptible to cleavage.

6. Analyze whole-cell lysate or immunoprecipitate on an SDS-PAGE minigel, using 20 µl lysate per lane. Store remaining lysate at −20°C.

7. Treat the gel with sodium salicylate (*UNIT 6.3*). Using preflashed film, fluorograph the gel (*UNIT 6.3*) at −70°C.

   Typical exposure times are overnight to 1 month.

   Alternatively, the gel may be treated with DMSO/2,5-diphenyloxazole (DMSO/PPO) instead of sodium salicylate (see Magee et al., 1995).

ANALYSIS OF FATTY ACID LINKAGE TO PROTEIN

BASIC PROTOCOL 2

To determine the type of linkage by which the [^{3}H]fatty acid is attached to the protein (i.e., thioester, oxyester, or amide linkage), the fatty acid is selectively cleaved from the protein. The most convenient method is to run replicate lanes on an SDS-PAGE gel, cut the lanes apart, and analyze each lane separately. Thioesters and amides are by far the most common types of linkage; oxyesters ar extremely rare.

Materials

Lysate or immunoprecipitate from [^{3}H]fatty acid–labeled cells (see Basic Protocol 1, step 6)
0.2 M potassium hydroxide (KOH) in methanol
Methanol
1 M hydroxylamine·HCl, titrated to pH 7.5 with NaOH
1 M Tris·Cl, pH 7.5 (*APPENDIX 2A*)

Additional reagents and equipment for SDS-PAGE (*UNIT 6.1*), treating a gel with sodium salicylate (*UNIT 6.3*), and fluorography (*UNIT 7.2*)

1. Run an SDS-PAGE gel (*UNIT 6.1*) using 20 µl lysate or immunoprecipitate from [^{3}H]fatty acid–labeled cells in each of four lanes.

2. Cut the four lanes apart and transfer each lane to a 15-ml tube containing one of the following solutions:

   0.2 M KOH in methanol
   Methanol
   1 M hydroxylamine·HCl
   1 M Tris·Cl, pH 7.5.

   Incubate 1 hr at room temperature with shaking.

   The 0.2 M KOH in methanol will cleave thio- and oxyesters, but not amides; 1 M hydroxylamine·HCl will rapidly cleave thioesters but will cleave oxyesters only poorly, and will not cleave amides. Methanol and 1 M Tris·Cl serve as controls.

3. Wash each gel strip three times, 5 min each time, with water. Treat the strips with sodium salicylate and fluorograph using preflashed film at −70°C (*UNIT 6.3*).

   Typical exposure times are overnight to 1 month.

Alternatively, the gel may be treated with DMSO/PPO instead of sodium salicylate (see Magee et al., 1995).

Cleavage is measured as a reduction in the fluorographic signal compared to those for controls, and can be quantitated by densitometric scanning of the lane or scintillation counting of excised bands. Bands with fatty acids linked to the protein by thioesters will be missing or greatly reduced in lanes treated with 0.2 M KOH in methanol and 1 M hydroxylamine·HCl; oxyesters will be greatly reduced or missing in the lane treated with 0.2 M KOH in methanol and may be slightly reduced in the lane treated with 1 M hydoxylamine·HCl; and amide linkages will not be affected by any of these treatments, so that proteins with amide-linked fatty acids will appear in all four lanes.

BASIC PROTOCOL 3

ANALYSIS OF TOTAL PROTEIN-BOUND FATTY ACID LABEL IN CELL EXTRACT

Due to problems of interconversion of fatty acids by β-oxidation and chain elongation and of reincorporation of label into other metabolic precursors, the protein-bound label derived from [^{3}H]fatty acids should be analyzed, especially for experiments with long labeling incubations. This protocol is used to determine how much of the label has been converted into other fatty acids or metabolites during the incubation; a different procedure must be used to determine whether the fatty acid on the protein of interest is different from that added during labeling (see Basic Protocol 4).

Materials

0.1 M HCl/acetone, −20°C
Lysate from [^{3}H]fatty acid–labeled cells in 1% SDS (see Basic Protocol 1, step 4a or 5b)
1% (w/v) SDS
2:1 (v/v) chloroform/methanol
Diethyl ether
6 M HCl (concentrated HCl diluted 1:1 with H_2O)
Hexane
5 to 10 µCi/µl [9,10(*n*)-^{3}H]fatty acid standards (30 to 60 Ci/mmol; Amersham International, American Radiolabeled Chemicals, or NEN Research Products) in ethanol
90:10 (v/v) acetonitrile/acetic acid
EN^{3}HANCE spray (NEN Research Products)

15-ml polypropylene centrifuge tubes
Mistral 3000i benchtop centrifuge with swing-out four-bucket rotor or equivalent
Nitrogen gas
30-ml thick-walled Teflon container with an air-tight screw top
110°C oven
Thin-layer chromatography tank
RP18 thin-layer chromatography plate (e.g., Merck)
Kodak XAR-5 film, preflashed

Precipitate protein

1. Add 5 vol of 0.1 M HCl/acetone to 100 µl lysate from [^{3}H]fatty acid–labeled cells in 1% SDS in a 15-ml polypropylene tube. Incubate ≥1 hr at −20°C.

   This will precipitate the protein.

2. Centrifuge 10 min at 1500 × *g* (1000 rpm in Mistral 3000i swing-out rotor), 4°C, to pellet the precipitate. Remove the supernatant and allow the pellet to air dry gently.

Remove free label

3. Dissolve the pellet in a minimum volume of 1% SDS and transfer to a 1.5-ml microcentrifuge tube. Add 5 vol of 0.1 M HCl/acetone. Incubate ≥1 hr at −20°C.

4. Repeat steps 2 and 3.

   These precipitation steps concentrate the protein and remove much of the SDS and free label.

5. Add 500 µl of 2:1 chloroform/methanol and vortex. Centrifuge 10 min at 1000 rpm, 4°C, and remove the supernatant. Repeat this step at least three times until no more free label is extracted into the organic solvent, as determined by scintillation counting of the supernatant.

6. Add 100 µl diethyl ether to the pellet and vortex. Centrifuge 10 min at 1000 rpm, 4°C, and decant the supernatant. Dry the pellet by placing the microcentrifuge tube under a gentle stream of nitrogen.

7. Place the tube into a 30-ml thick-walled Teflon container with an air-tight screw top containing 1 ml of 6 M HCl. Flush the tube and container with nitrogen. Close the lid tightly and incubate in an oven 16 hr at 110°C.

   This hydrolyzes the fatty acids from the protein.

Extract hydrolyzed fatty acids

8. Extract the contents of the tube twice with 0.5 ml hexane and pool the extracts. Dissolve the residue in 0.5 ml of 1% SDS. Determine the radioactivity in the hexane extracts and in the residue.

   Fatty acids will be extracted into hexane, while label incorporated into sugars and amino acids will be mainly in the hexane-insoluble residue.

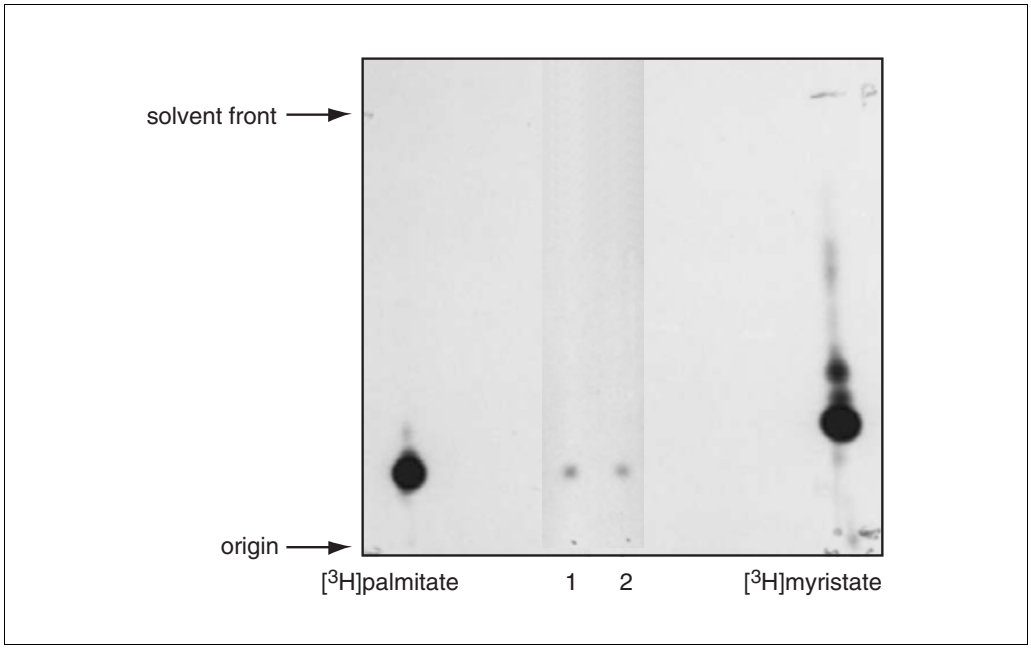

Figure 7.4.1 Fluorogram of thin-layer chromatography plate showing analysis of acylated nerve growth factor (NGF) receptor. Outside lanes, migration of 0.5 µCi [^{3}H]palmitate and [^{3}H]myristate standards. Lane 1, NGF receptor immunoprecipitated from cells labeled with [^{3}H]palmitic acid. Lane 2, NGF receptor immunoprecipitated from cells labeled with [^{3}H]myristic acid. Although the cells were labeled with different fatty acids, the protein was labeled with palmitic acid due to chain elongation of [^{3}H]myristic acid to [^{3}H]palmitic acid by the cells. Exposure for standards, 1 week; exposure for lanes 1 and 2, 1 month.

9. Evaporate the hexane extracts just to dryness with a gentle stream of nitrogen. Dissolve in 2 to 5 µl of 2:1 chloroform/methanol.

It is important not to overdry the sample because it may then be difficult to dissolve.

Identify fatty acids

10. Preequilibrate a thin-layer chromatography tank with 90:10 acetonitrile/acetic acid for 15 min.

11. Spot resuspended hexane extract onto an RP18 thin-layer chromatography plate. Dilute 1 µl [9,10(*n*)-^{3}H]fatty acid standards in ethanol to give 1 µCi/µl and spot 0.5 µl in parallel lanes. Develop the plate in 90:10 acetonitrile/acetic acid. Air dry the plate.

12. Detect the radioactivity by spraying the plate with EN^{3}HANCE spray and exposing it to preflashed Kodak XAR-5 film overnight at −70°C. Identify the fatty acids.

See Figure 7.4.1 for an example of a typical fluorogram.

BASIC PROTOCOL 4

ANALYSIS OF FATTY ACID LABEL IDENTITY

This protocol is used to identify the labeled fatty acid(s) associated with a specific protein band on an SDS-PAGE gel. Following electrophoresis, the band of interest is located either by comparison with molecular weight standards or more accurately by fluorography of a sodium salicylate–treated gel (see *UNIT 6.3*). DMSO/PPO–treated gels cannot be used. The labeled material is analyzed by thin-layer chromatography.

Materials

SDS-PAGE gel of lysate from [^{3}H]fatty acid–labeled cells
Additional reagents and equipment for analysis of protein-bound label (see Basic Protocol 3)

1. Excise the band(s) of interest from a wet or dried (fluorographed) SDS-PAGE gel. Wash three times with shaking, 5 min each, with 0.5 ml water.

If the gel is fluorographed it should be treated with sodium salicylate (UNIT 6.3), not DMSO/PPO solution. The dried gel piece will rehydrate and the salicylate will be washed out during the washes.

2. Place the gel piece in a 1.5-ml microcentrifuge tube and lyophilize.

3. Hydrolyze the fatty acids in the band and identify them by thin-layer chromatography (see Basic Protocol 3, steps 7 to 12).

REAGENTS AND SOLUTIONS

*Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see **APPENDIX 2A**; for suppliers, see **SUPPLIERS APPENDIX**.*

RIPA (RadioImmunoPrecipitation Assay) lysis buffer

1% (w/w) Nonidet P-40 (NP-40)
1% (w/v) sodium deoxycholate
0.1% (w/v) SDS
0.15 M NaCl
0.01 M sodium phosphate, pH 7.2 (*APPENDIX 2A*)
2 mM EDTA (*APPENDIX 2A*)
10 mM sodium fluoride

continued

0.2 mM sodium vanadate added fresh from 0.2 M stock solution
100 U/ml aprotinin (Trasylol, Pentex/Miles)
Store buffer without vanadate at 4°C up to 1 year

Sodium vanadate stock solution can be stored in plastic at room temperature.

SDS sample buffer (for discontinuous systems), 5×

3.125 ml 1 M Tris·Cl, pH 6.8 (0.313 M final)
1 g SDS (10% final)
5 mg bromphenol blue (0.05% final)
5 ml glycerol (50% final)
H_2O to 10 ml
Store at room temperature
Add DTT to appropriate concentration (see Basic Protocol 1, annotations under steps 5a and 5b) just before use

Warm the solution before use because it tends to solidify.

COMMENTARY

Background Information

The two most common acyl groups that modify proteins are 14-carbon myristic acid and 16-carbon palmitic acid (Fig. 7.4.2), and they occur both on different and on overlapping sets of proteins. By increasing the hydrophobicity of the protein, these fatty acid moieties can play a role in localization of the protein to the membrane and sometimes to specific types of membrane structures—e.g., glycolipid-enriched domains (lipid rafts) or caveolae (Rodgers et al., 1994). Identifying the type of acylation of a protein and determining whether the level of modification can be affected by stimuli can provide more information on the mechanisms of action of proteins involved in signaling pathways.

Fatty acids are used in labeling cells in vitro because they will diffuse across the plasma membrane and then be converted to acyl-CoA by the action of the enzyme acyl-CoA synthetase. This activated form of the fatty acid is the substrate for protein-acyl transferase activities that transfer the acyl group to the protein. Tritiated fatty acids are most commonly used in biosynthetic labeling of proteins, but fluorescent analogs of fatty acids have been used to study palmitoylation of rhodopsin (Moench et al., 1994a,b), and [ω-^{125}I]iodo–fatty acids have been used to study myristoylation of v-src (Peseckis et al., 1993).

A wide variety of proteins are myristoylated, including viral structural proteins and many proteins involved in cell signaling, such as the α subunits of trimeric G proteins and the Src family of tyrosine kinases (Resh, 1994; Wedegaertner et al., 1995). Myristoylation most commonly occurs cotranslationally via an amide linkage to an NH_2-terminal glycine residue, and is an irreversible modification. Myristoylation is dependent on the removal of the initiator methionine and has been shown to occur by the time the nascent polypeptide is 100 amino acids long. Inhibitors of protein synthesis will

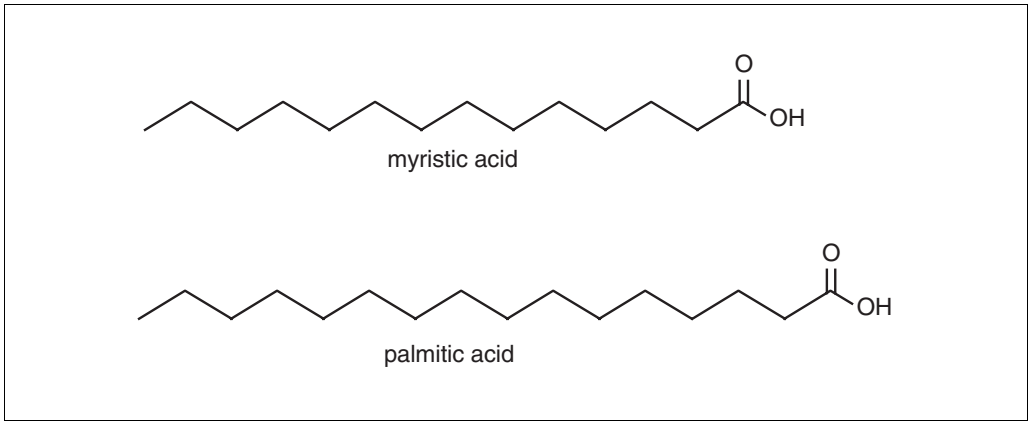

Figure 7.4.2 Structures of myristic and palmitic acids.

therefore block myristoylation. The enzyme responsible for NH_2-terminal myristoylation, *N*-myristoyl transferase (NMT), was first isolated from *Saccharomyces cerevisiae*; both the yeast and human homologs have been well characterized and show different protein substrate specificities (Gordon et al., 1991). Substrate specificity of yeast NMT is determined by recognition of a sterically unhindered NH_2-terminal glycine followed by an amino acid sequence that conforms to the following criteria: an uncharged residue or proline at position 2; any amino acid at positions 3 and 4; serine (more common), alanine, or threonine at position 5; no proline at position 6; and, preferably, basic residues at positions 7 and 8. Residues C-terminal to this region appear to be important in recognition of the α subunits of trimeric G proteins and the Src family of tyrosine kinases (Glover et al., 1988; Gordon et al., 1991).

The NMT enzymatic reaction proceeds by formation of a myristoyl-CoA-enzyme complex, subsequent binding of the peptide, transfer of the myristate moiety to the peptide, release of CoA, and release of the myristoylated peptide (Rudnick et al., 1991). Several assays have been developed for this enzyme (e.g., King and Sharma, 1991; Rudnick et al., 1992; French et al., 1994). Inhibitors of myristoylation include 2-hydroxymyristic acid, which is converted in vivo to 2-hydroxymyristoyl-CoA, a potent inhibitor of NMT. Other inhibitors of acylation are fatty acid analogs and other compounds that inhibit acyl CoA synthetase and therefore block the conversion of fatty acids to acyl CoA; the latter include α-bromopalmitate (DeGrella and Light, 1980) and the triacsin family of antibiotics (Tomoda et al., 1987). The endogenous pool of fatty acid can be depleted by incubation with cerulenin, an antibiotic that inhibits de novo fatty acid biosynthesis.

Myristoylation of a protein can be necessary for its activity, e.g., the transforming activity of Src (Kamps et al., 1986). Myristoylation alone may not be sufficient for a protein to be localized to the membrane; for this, further lipid modification, such as palmitoylation or cooperative interaction with protein sequences, is required (Resh, 1994).

Palmitoylation more accurately referred to as *S*-acylation, (with and without myristoylation) occurs on many signaling molecules, including rhodopsin, α-subunits of G proteins, and Src-family tyrosine kinases. *S*-acylation is a post-translational event occurring via a thioester linkage to a cysteine residue, and where it occurs with NH_2-terminal myristoylation, the myristoylation is usually a prerequisite for *S*-acylation. This may be because the enzyme responsible for *S*-acylation recognizes the myristoylated protein or, more likely, because myristoylation brings the protein to the correct cell location for *S*-acylation to occur. *S*-acylation is also found in conjunction with isoprenoid modification at the C-terminus of proteins belonging to the Ras superfamily; it is responsible for the localization of these proteins to the membrane (Newman and Magee, 1993). This *S*-acylation is dependent on prior modification of the protein by isoprenoid. G protein subunits such as the α_1 subfamily and members of the Src family of tyrosine kinases have an NH_2-terminal amino acid sequence of Met-Gly-Cys, where the initiator methionine is removed and replaced by myristate and the cysteine is *S*-acylated (Resh, 1994). *S*-acylation is a reversible modification and has been shown to be dynamic in vivo, with the level of *S*-acylation changing in response to various stimuli such as receptor activation, insulin, and growth factors (James and Olsen, 1989; Jochen et al., 1991; Wedegaertner et al., 1995). This phenomenon is thought to play a role in switching on or off signaling molecules by altering either the localization of the molecules or their presentation to other signaling molecules with which they interact. Deacylation of proteins is catalyzed by the activity of protein-*S*-acyl thioesterase (Camp and Hoffman, 1993). Protein-*S*-acyltransferase activities have been reported by several groups, but attempts to purify these to homogeneity have so far been unsuccessful. In fact, the possibility that *S*-acylation is nonenzymatic has recently been raised (Dunphy and Linder, 1998).

Analysis of the type of fatty acid linkage present should always be performed. Post-translational myristoylation via a thioester linkage has been found in platelets (Muszbek and Laposata, 1993). The term "palmitoylation" is not strictly accurate because other long-chain fatty acids, such as stearate (18:0) and oleate (18:1), can also be thioesterified to proteins; "*S*-acylation" is now becoming more commonly used to describe this modification. The acylating activity seems to be relatively unspecific for chain length and degree of unsaturation, and utilizes acyl-CoAs partly in proportion to their abundance in the cell—hence the predominance of palmitate. This and the potential for interconversion of labeled fatty acids necessitate analysis of the chain length of the attached label. Other methods can be used to identify the type of fatty acid attached to the

protein, depending on the availability of appropriate equipment; these include gas chromatography, reversed-phase HPLC, and mass spectroscopy (Aitken, 1992). Structural and sequence analysis of the acylated protein can be performed using mass spectrometry (Aitken, 1992).

Further information about the cellular localization of acylated proteins can be found by extraction of the cell lysate in the presence of either Triton X-114 or X-100. Extraction with Triton X-114, which has the property of phase separation at 30°C, can distinguish between hydrophobic and hydrophilic proteins (Aitken, 1992). Extraction of membranes with Triton X-100 at 4° and 37°C can identify proteins that are associated with glycolipid cholesterol–enriched lipid rafts (Rodgers et al., 1994).

Critical Parameters and Troubleshooting

Cells should be subconfluent; it is recommended that the cells be plated at two split ratios so the culture closest to 70% to 80% confluency can be selected to be used for labeling.

The pH of all solutions should be ≤7.5 in order to avoid hydrolysis of labile thioesters; the high pH of SDS-PAGE buffers does not seem to be a problem when using minigels, where the running times are relatively short. Dithiothreitol (DTT) or 2-mercaptoethanol should be used with care, as these can also cleave thioester bonds; for SDS-PAGE a maximum concentration of 20 mM DTT should be used and samples should not be boiled but incubated only 3 min at 80°C.

The use of short labeling times (especially for palmitate labeling) will reduce reincorporation of the label.

The ability to detect myristoylation and/or *S*-acylation of a protein using these methods will depend on the ability of the cells to take up radiolabeled compounds and incorporate them into metabolic precursors; the pool sizes of endogenous fatty acids and fatty acyl–CoA esters; the expression level of the protein-myristoyl transferase and supposed protein-*S*-acyl transferase; the abundance, rate of synthesis, and turnover of the protein(s) and modification(s) of interest; and the efficiency of antibodies for immunoprecipitation.

Anticipated Results

Typically, it is possible to detect myristoylated proteins using fluorographic exposure times ranging from <1 week for high-level expression of protein in transformed cells (e.g., Lck in LSTRA cells) to 1 to 4 weeks for a well-expressed endogenous protein.

Time Considerations

In vitro labeling experiments require 2 to 3 days for growing and labeling the cells. Harvesting the cells, preparing the lysate for SDS-PAGE (with or without prior immunoprecipitation) and SDS-PAGE require 1 to 2 days plus time for fluorography.

Linkage analysis of the labeled proteins takes 1 to 2 hr after the gel has been run. Analysis of the label in cell lysates requires 1 day to precipitate the protein, remove free label, and hydrolyze the sample. A second day is required to extract the label and perform thin-layer chromatography, and fluorography requires an overnight exposure. Analysis of the protein-bound label in gel bands takes ~3 days after fluorography (dried gel) and a similar amount of time from a wet gel, except the analysis begins after the gel has been run.

Metabolic Labeling of Prenyl and Carboxyl-Methyl Groups

In the last fifteen years or so, several post-translational modifications of proteins with lipid moieties have been discovered. Analysis of fatty acylation is covered in *UNIT 7.4*. This unit describes methods for analysis of prenylation and the carboxyl-methylation that often accompanies it. The two prenoid groups that have been found attached to proteins—farnesyl (C15) and geranylgeranyl (C20)—are both derived from intermediates in the isoprenoid biosynthetic pathway that utilizes mevalonic acid. In the protocols described here, radiolabeled mevalonate is used to label these intermediates in intact cells (see Basic Protocol 1); the labeled intermediates then become incorporated into proteins. Carboxyl-methylation of C-terminal prenylated cysteine residues often occurs subsequent to prenylation. Methods are given for radiolabeling of the methyl group with [^{3}H-methyl]-methionine, that is converted intracellularly into *S*-adenosylmethionine (see Basic Protocol 2). Three recent publications (Casey, 1990; Hooper and Turner, 1992; Casey and Buss, 1995) contain a number of methods related to analysis of lipid modification of proteins.

CAUTION: When working with radioactivity, take appropriate precautions to avoid contamination of the experimenter and the surroundings. Carry out the experiment and dispose of wastes in appropriately designated area, following the guidelines provided by your local radiation safety officer (also see *APPENDIX 1D*).

NOTE: All reagents and equipment coming into contact with live cells must be sterile, and proper sterile technique should be used accordingly.

NOTE: All culture incubations are performed in a humidified 37°C, 5% CO_2 incubator unless otherwise specified. Some media (e.g., DMEM) may require altered levels of CO_2 to maintain pH 7.4.

PRENYLATION OF PROTEINS IN CULTURED CELLS

BASIC PROTOCOL 1

To radiolabel intermediates in the isoprenoid biosynthetic pathway, cultured cells are incubated with [^{3}H]mevalonic acid, which is the 6-carbon precursor to isopentenyl diphosphate. Isopentenyl diphosphate (5-carbon) is polymerized in a stepwise fashion to yield farnesyl (15-carbon) and geranylgeranyl (20-carbon) diphosphates, which are the known precursors of protein-bound prenyl groups. To maximize incorporation of exogenous [^{3}H]mevalonate, the endogenous pool of unlabeled mevalonate is usually depleted by preincubation with an inhibitor of hydroxymethyl glutaryl–coenzyme A (HMG-CoA) reductase, the enzyme responsible for production of mevalonate from hydroxymethyl glutarate. Medium containing dialyzed serum is also used to reduce the endogenous pool.

Materials

Cells
Complete tissue culture medium appropriate for the cells, 37°C
Complete tissue culture medium containing dialyzed serum, 37°C
10 mM mevinolin (see recipe)
1 μCi/μl *R*-[5-^{3}H]mevalonic acid (10 to 40 Ci/mmol; DuPont NEN or American Radiolabeled Chemicals)
PBS, pH 7.2 (*APPENDIX 2A*) ice-cold
1× SDS-PAGE sample buffer (*UNIT 6.1*) or RIPA lysis buffer for immunprecipitation (*UNIT 7.4*)
Nitrogen gas

Contributed by Anthony I. Magee
Current Protocols in Cell Biology (2000) 7.5.1-7.5.8

Additional reagents and equipment for immunoprecipitation (*UNIT 7.2*), SDS-PAGE (*UNIT 6.1*), treating a gel with sodium salicylate (*UNIT 6.3*), and fluorography (*UNIT 6.3*)

1. On the day before the labeling experiment, split the cells into complete tissue culture medium.

   Set up cells at two split ratios and choose the culture closest to 70% to 80% confluency for labeling. The cultures should contain 10^6 to 10^7 cells.

2. On the day of the experiment, replace the culture medium with a minimum volume of prewarmed complete tissue culture medium containing dialyzed serum. Add 10 mM mevinolin to a final concentration of 50 µM. Preincubate the cells in this medium ≥60 min.

   Mevinolin is an inhibitor of HMG-CoA reductase. Alternative HMG-CoA reductase inhibitors are compactin/mevastatin (Sigma) and pravastatin (Pravachol, Bristol-Meyers Squibb).

3. Transfer enough 1 µCi/µl *R*-[5-^{3}H]mevalonic acid to label all samples at a concentration of 50 to 200 µCi/ml into a microcentrifuge tube. If necessary, remove organic solvent by exposing the tube to a gentle stream of nitrogen, but do not dry the mevalonic acid completely.

   The volume of the [^{3}H]mevalonic acid can be made up with sterile water to facilitate accurate pipetting.

   Alternatively, the organic solvent may be removed in a Speedvac evaporator.

   The mevalonic acid must not be heated above room temperature because it is unstable.

4. Add the partially dried [^{3}H]mevalonic acid at the desired concentration to the culture medium. Incubate up to 24 hr.

   The most appropriate concentration of label and duration of incubation should be experimentally determined for each cell type. Mevalonic acid and mevinolin tend to cyclize to form the acetone (see Troubleshooting). If this is suspected, the lactone can be hydrolyzed (see recipe for mevalonic acid in Reagents and Solutions).

5. Place the cells on ice and aspirate the medium. Wash the cells twice with ice-cold PBS.

   CAUTION*: Radioactive medium and washes must be disposed of appropriately.*

6. Lyse cells in the appropriate solution for further processing—e.g., for a 50-mm dish containing 4×10^6 cells, add 0.2 ml of 1× SDS-PAGE sample buffer (*UNIT 6.1*) or 1 ml RIPA lysis buffer for immunoprecipitation (*UNIT 7.2*).

   Use the entire lysate for immunoprecipitation.

7. Analyze the lysate or immunoprecipitate by SDS-PAGE (*UNIT 6.1*).

   Use 25 µl of the whole cell lysate for a minigel or 50 µl for a standard gel; load all of the immunoprecipitate after solubilizing it in 25 or 50 µl of 1× SDS-PAGE sample buffer.

8. Treat the gel with sodium salicylate and fluorograph the gels at −70°C using preflashed film (*UNIT 6.3*).

   Typical exposure times are 1 week to 1 month, although exposures up to 3 months may sometimes be required (see Time Considerations).

   Alternatively, the gel may be treated with DMSO/2,5-diphenyloxazole (DMSO/PPO) instead of sodium salicylate (see Magee et al., 1995), or with other commercially available water-soluble fluors such as Enlightening (DuPont NEN) or Amplify (Amersham).

CARBOXYL-METHYLATION OF PROTEINS IN CULTURED CELLS

BASIC PROTOCOL 2

Prenylation at C-terminal CXXX and CXC motifs is followed by carboxyl-methylation of the α-carboxyl group directly or after removal if XXX residues. This is performed by a membrane-associated methyl transferase that uses the universal methyl group donor *S*-adenosylmethionine (SAM). The methyl group of SAM can be radiolabeled in vitro by [^{3}H-methyl]methionine, and it is then transferred onto the α-carboxyl group as an alkali-labile ester. This can be distinguished from alkali-stable methylations such as lysyl N-methylation by treating the sample with sodium hydroxide, which releases [^{3}H]methanol. The released volatile [^{3}H]methanol is collected by distillation into scintillation fluid and counted (Chelsky et al., 1985; Gutierrez et al., 1989). Labeled methionine will also be incorporated into the peptide backbone and is alkali-stable, thus providing an internal standard that can be used to calculate the stoichiometry of carboxyl-methylation. The length of the labeling incubation required to get an acceptable signal depends inversely on the expression level of the protein under study.

Materials

Cells
Complete tissue culture medium (CM) appropriate for the cells
Methionine-free tissue culture medium containing dialyzed serum (MFM)
95:5 (v/v) MFM/complete culture medium with dialyzed serum (95:5 MFM/CM)
1 μCi/μl L-[^{3}H-methyl]methionine (~80 Ci/mmol, Amersham)
PBS, pH 7.2 (*APPENDIX 2A*), ice-cold
1× SDS-PAGE sample buffer (*UNIT 6.1*) or RIPA lysis buffer (*UNIT 7.4*)
1 M NaOH
1 M HCl

Warm room or incubator at 37°C
Preflashed film (*UNIT 6.3*)

Additional reagents and equipment for immunoprecipitation (*UNIT 7.2*), treating a gel with sodium solicylate (*UNIT 6.3*), SDS-PAGE (*UNIT 6.1*), and fluorography (*UNIT 6.3*)

Label the cells

1. On the day before the labeling experiment, split the cells into fresh complete tissue culture medium.

   Set up cells at two split ratios and choose the culture closest to 70% to 80% confluency for labeling. The cultures should contain 10^6 to 10^7 cells.

For labeling times ≤8 hr

2a. On the day of the experiment, replace the culture medium with the minimum volume MFM, e.g., 3 ml for a 100-mm tissue culture dish. Incubate 1 hr.

3a. Add 200 μCi [^{3}H-methyl]methionine per milliliter MFM. Incubate up to 8 hr.

For labeling times of 8 to 24 hr

2b. On the day of the experiment, replace the culture medium with the minimum volume 95:5 MFM/CM, e.g., 3 ml for a 100-mm tissue culture dish. Incubate 1 hr.

3b. Add 50 µCi [^{3}H-methyl]methionine per milliliter 95:5 MFM/CM. Incubate 8 to 24 hr.

4. After labeling is complete, aspirate the medium and wash the cells twice with ice-cold PBS.

   CAUTION*: Labeling and wash media are radioactive.*

5. Lyse in the appropriate solution for further processing—e.g., for a 50-mm dish containing 4×10^6 cells, add 0.2 ml 1× SDS-PAGE sample buffer (*UNIT 6.1*) or 1 ml RIPA lysis buffer for immunoprecipitation (*UNIT 7.2*).

Separate and fluorograph the samples

6. Analyze the immunoprecipitate or lysate by SDS-PAGE (*UNIT 6.1*).

   Use 25 µl whole-cell lysate for a minigel or 50 µl for a standard gel. Use the whole immunoprecipitate solubilized in 25 or 50 µl of 1× SDS-PAGE sample buffer.

   The α-carboxyl-methyl esters are stable at the moderately alkaline pH of the standard Laemmli gel system, whereas methyl esters of the side-chain carboxyls of aspartate and glutamate are quite labile.

7. Treat the gel 20 min with sodium salicylate (*UNIT 6.3*) and immediately dry gel at 60°C on a backing of filter paper.

   The gel must not be dried at too high a temperature.

   Alternatively, the gel may be treated with DMSO/PPO instead of sodium salicylate (see Magee et al., 1995) or with other commercially available water-soluble fluors, such as Enlightening (Dupont NEN) or Amplify (Amersham).

8. Using radioactive ink, mark the filter paper to note the alignment of the gel. Fluorograph the gel at −70°C, using preflashed film. Expose the film for 1 week to 1 month.

   An inexpensive radioactive ink can made by washing out old radiolabel vials with a small volume (e.g., 0.1 ml) of an aqueous solution containing 0.01% (w/v) bromphenol blue.

9. Using the alignment marks, align the film exactly with the gel. Excise the radioactive band(s) of interest with a scalpel.

Release the alkali-labile label

10. Place each gel piece into a separate 1.5-ml microcentrifuge tube. Carefully lower the open tube into a scintillation vial that contains enough scintillation fluid to come about half way up the side of the tube.

11. Add enough 1 M NaOH into the tube to cover the gel piece (usually 100 to 200 µl). Immediately cap the scintillation vial, leaving the tube open inside. Incubate overnight in a 37°C warm room or 37°C incubator.

    During this incubation, radioactive methanol is hydrolytically released and distilled into the scintillation fluid.

12. The next day, uncap the vial and carefully remove the microcentrifuge tube, taking care not to spill any of the contents into the vial. Recap the vial.

    This scintillation vial contains the alkali-labile [^{3}H]methanol.

Analyze the sample for alkali-stable label

13. Neutralize the NaOH in the microcentrifuge tube by adding an equal volume of 1 M HCl. Transfer the contents of the tube to a new scintillation vial.

This scintillation vial contains the alkali-stable [^{3}H]label which represents [^{3}H]methionine incorporated into the peptide backbone. However, alkali-stable methyl groups cannot be distinguished from backbone methionine in this way, so it is essential to have good reason to believe that other methyl groups are not present before alkali-stable counts can be used to calculate stoichiometry of carboxyl-methylation.

14. Add a volume of scintillation fluid to this vial equal to that used for the alkali-labile sample (step 12).
15. Count both samples in a scintillation counter using the tritium channel.

Calculate the methylation stoichiometry

16. Calculate the methylation stoichiometry as:

$$\text{stoichiometry} = \frac{\text{alkali} - \text{labile cpm} \times \text{number of methionine residues in protein}}{\text{alkali} - \text{stable cpm.}}$$

This calculation can only be made if the methionine content of the protein is known. Also the possibility that the initiator methionine might be removed must be taken into account. This can be predicted from the primary sequence (Aitken, 1992).

REAGENTS AND SOLUTIONS

Use deionized or distilled in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Mevalonic acid, 100 mM

Hydrolyze mevalonic acid lactone (Sigma) to the free acid (Kita et al., 1980) by dissolving 30 mg mevalonic acid lactone in 1.8 ml ethanol at 55°C. Add 0.9 ml of 0.6 M NaOH and 18 ml water. Incubate 30 min at room temperature. Adjust to pH 8 with HCl and dilute to 100 mM. Store indefinitely at −20°C.

Mevinolin, 10 mM

Dissolve 90 mg mevinolin in 1.8 ml ethanol at 55°C. Add 0.9 ml of 0.6 M NaOH and 18 ml distilled water. Incubate 30 min at room temperature. Adjust to pH 8 with HCl and dilute to 10 mM. Store indefinitely at −20°C in 500-µl aliquots.

Mevinolin, also called Lovastatin and Mevacore, is available from Merck or Biomol Research Labs (see SUPPLIERS APPENDIX; Alberts, 1988). It is supplied as the lactone and must be hydrolyzed to the free acid as described in the recipe for mevalonic acid above (Kita et al., 1980).

COMMENTARY

Background Information

Prenylation of proteins is a widespread post-translational modification that occurs at C-terminal motifs of the type CXXX, CXC, or CC (where C is cysteine and X is any amino acid). Recent reviews give a thorough description of this field (Clarke, 1992; Giannakouros et al., 1993). Either the 15-carbon isoprenoid farnesol or the 20-carbon isoprenoid geranylgeraniol (see Fig. 7.5.1) can be added, depending on the exact sequence at the C-terminus. $CX_1X_2X_3$ motifs where X_3 is a small residue (e.g., methionine, serine, or alanine), are farnesylated; whereas if X_3 is large and hydrophobic (e.g., leucine or phenylalanine), they are geranylgeranylated. The nature of the X_1 and X_2 residues also influences the ability of the motif to become prenylated such that some apparent CXXX sequences are not modified. The CXC and CC motifs are also geranylgeranylated on both cysteines. The prenoid moiety is attached by a thioether linkage to the sulphydryl group of cysteine; this is an extremely stable linkage that is irreversible in vivo, but it can be chemically cleaved in vitro to allow analysis of the chain length of the attached isoprenoid (Farnsworth et al., 1990).

Prenylation occurs on otherwise cytosolic soluble proteins and is catalyzed by a ubiquitous family of at least three soluble heterodi-

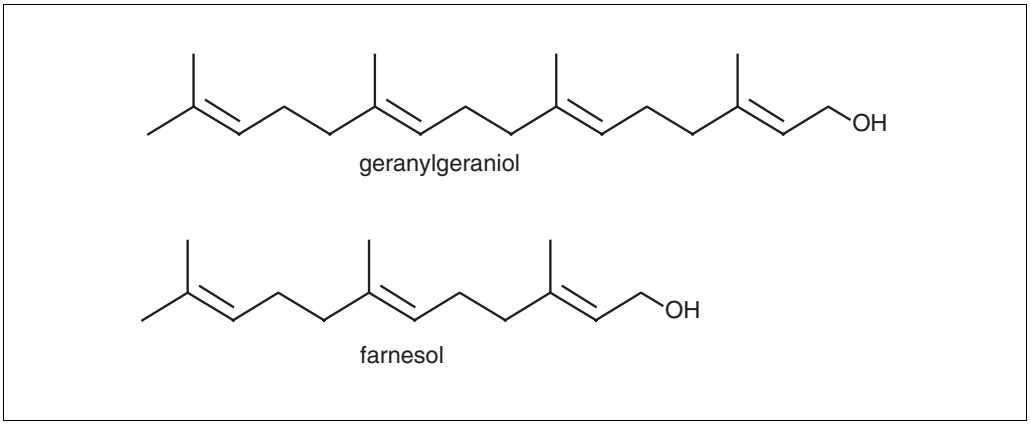

Figure 7.5.1 Structures of isoprenoid groups used in post-translational modification.

meric enzymes: farnesyl transferase, geranylgeranyl transferase I (active on CXXX motifs) and geranylgeranyl transferase II (active on CXC and CC motifs). In addition, geranylgeranyl transferase II has a third associated subunit called Rab escort protein that is required for activity. These enzymes utilize the activated diphosphates of farnesol and geranylgeraniol that are normal intermediates in the isoprenoid biosynthetic pathway, that leads to many important end products such as steroids, ubiquinone, and dolichols (Goldstein and Brown, 1990). Mevalonic acid is the precursor of these polyisoprenyl diphosphates and is readily taken up by most cells in culture. Hence radioactive mevalonate can be used to radiolabel prenyl chains biosynthetically. To maximize incorporation, endogenous mevalonate is usually depleted by preincubation of cells with an inhibitor of hydroxymethylglutaryl coenzyme A (HMG-CoA) reductase, the enzyme responsible for mevalonate synthesis. Both the ability of cells to take up exogenous mevalonate and the sensitivity to HMG-CoA reductase inhibitors can vary enormously and needs to be experimentally tested (e.g., the yeasts *Saccharomyces cerevisiae* and *Schizosaccharomyces pombe*; Giannakouros et al., 1992).

Subsequent to and dependent on prenylation, other modifications can take place. CXXX motifs are proteolyzed to remove the XXX residues by a membrane-associated endoprotease; then they are carboxyl-methylated on the free C-terminal α-carboxyl by a membrane-bound carboxyl-methyl transferase. This methyl ester group is chemically relatively labile; it is sensitive to mild alkali, although it is not as labile as the side-chain methyl esters of aspartate and glutamate, which can hydrolyze even during electrophoresis in mildly alkaline buffers such as are used in the standard Laemmli SDS-PAGE system (Laemmli, 1970). This lability is used experimentally as a test for the C-terminal α-carboxyl-methyl ester (Chelsky et al., 1985; Gutierrez et al., 1989). CXC motifs become doubly geranylgeranylated and are therefore also carboxyl-methylated because the methyl transferase recognizes a C-terminal prenylated cysteine. CC motifs, on the other hand, are not carboxyl-methylated. Many prenylated proteins also become palmitoylated (*S*-acylated) on nearby upstream cysteines. *S*-acylation is discussed in *UNIT 7.4*.

The primary function of prenylation is in membrane localization of substrate proteins that would otherwise be cytosolic because they are usually lacking in hydrophobic peptide sequences (Parenti and Magee, 1995). To perform this localization function, prenyl groups generally act in cooperation with themselves (e.g., for the doubly geranylgeranylated CXC proteins), with other modifications such palmitate moieties, or with peptide sequences. For example, the prenylated CXXX sequences of Ras proteins must cooperate with palmitoylation sites (in the case of H-ras, N-ras and K[A]-ras) or a polybasic region (as in K[B]-ras), which probably interacts with acidic membrane phospholipids (Hancock et al., 1991; Newman and Magee, 1993). These cooperating signals specify not only general membrane binding, as might be expected for a hydrophobic lipid moiety, but also targeting to specific subcellular destinations. The mechanism of this intracellular targeting is at present obscure.

Membrane association of prenylated proteins is frequently reversible in vivo. This is achieved in several ways (Newman et al., 1992). Both *S*-acylation and carboxyl-methylation can be dynamic in vivo, thus allowing modulation of the hydrophobicity and/or charge of the C-terminus. Phosphorylation of residues near the C-terminus will change the charge, reducing the interaction with acidic

phospholipid head groups. Thirdly, many prenylated proteins are removed from membranes by sequestration of their prenylated domains by binding proteins that mask the hydrophobic group and form soluble 1:1 complexes. These mechanisms allow prenylated proteins to move between subcellular sites, which is often an essential part of their function.

Critical Parameters and Troubleshooting

All of the labeling protocols in this unit that use cultured cells perform optimally when subconfluent cells are used. Certainly cells that are fully confluent should not be used. To ensure that cells at an appropriate density are available, it is helpful set up cultures at two different split ratios and use the ones that are most suitable. Occasionally a cell line is encountered that labels very poorly. Increasing the amount of radiolabel and/or the duration of labeling may lead to a satisfactory result. In the case of [^{3}H]mevalonic acid labeling, the amount of mevinolin used and the duration of pretreatment can be increased. [^{14}C]mevalonic acid has been used by some workers for radiolabeling prenyl moieties. Although tritium has a lower intrinsic detectability than ^{14}C due to its weaker emission, the author nevertheless finds ^{3}H is more sensitive because tritiated compounds can generally be obtained at much higher specific activities than ^{14}C derivatives, and that more than compensates for the weaker emission. For [^{3}H-methyl]methionine labeling, it may help to reduce the concentration of unlabeled methionine in the medium to zero and to increase the duration of pretreatment.

It is always useful to include an aliquot of the total cell lysate on the SDS-PAGE gel to assess the efficiency of labeling. Low levels of tritium require the highest sensitivity of fluorography for most rapid detection. The author has found that treating the gel with 2,5-diphenyloxazole in dimethylsulfoxide is the most sensitive method (Laskey, 1980; Magee et al., 1995). However, this method cannot be used if further processing of the gel for prenyl group analysis or alkaline release of carboxyl-methyl groups is to be performed. In these cases, fluorography is best performed after treating the gel with the water-soluble fluor salicylic acid (Chamberlain, 1979) or a commercial equivalent; this method is approximately half as sensitive.

Mevalonic acid and mevinolin tend to cyclize to form the lactone. If this is suspected (e.g., as indicated by a fall-off in labeling efficiency), the lactone can be hydrolyzed by the method of Kita et al. (1980) as described in the recipes (see Reagents and Solutions). Lipid substrates should never be dried to completion in plastic tubes because they are often irreversibly adsorbed to the surface.

The ability to detect prenylation and/or carboxyl-methylation of any given protein using these methods will depend on a number of factors: the ability of the cells to take up radiolabeled compounds and incorporate them into metabolic precursors; the sensitivity of the cells to hydroxymethylglutaryl coenzyme A (HMG-CoA) reductase inhibitors; the pool sizes of endogenous mevalonate, prenyl diphosphates, and *S*-adenosylmethionine (SAM); the expression level of the protein prenyl transferases and carboxyl-methyl transferase; the abundance, rate of synthesis, and turnover of the protein(s) and modification(s) of interest; and for immunoprecipitation, the efficiency of the antibodies.

Anticipated Results

Typically it is possible to detect prenylated proteins using fluorographic exposure times of one to a few days for transfected cDNAs expressed at high levels, e.g., in COS cells, or in vitro translated mRNAs, 2 or 3 weeks for well-expressed endogenous proteins, or up to 3 months for endogenous proteins expressed at low levels or in cells that incorporate mevalonate poorly.

Similar exposure times are required for carboxyl-methylated proteins. However, because much of the radiolabel incorporated into these proteins is in the form of backbone methionine, the exposure time to detect the protein by fluorography may not be a good guide to the sensitivity of detection for alkali-labile methyl groups. This can be predicted if the primary sequence of the protein and therefore, its methionine content is known; it clearly becomes more of a problem with larger proteins and those with many methionines.

Time Considerations

Labeling experiments using cultured cells typically require ~3 days to grow and label the cells. Harvesting and analyzing the cells by SDS-PAGE (with or without immunoprecipitation) take an additional 2 days, plus the time required for fluorography. After the fluorogram is developed, it takes 2 to 4 hr plus an overnight incubation to perform the analysis for alkali-labile and alkali-stable label, and the samples can be counted the next day.

Metabolic Labeling and Immunoprecipitation of Yeast Proteins

Saccharomyces cerevisiae, hereafter referred to as yeast, has long been an important model system for studying basic cellular processes. An essential component of many of these studies has been the ability to pulse-label newly synthesized proteins and to follow the fate of a specific protein during a chase period by immunoprecipitation (*UNIT 7.2*) and SDS-PAGE (*UNIT 6.1*). Because yeast can assimilate inorganic sulfate into methionine and cysteine (Marzluf, 1997), it is possible to label yeast cells with $^{35}SO_4^{2-}$. However, for this purpose most researchers use a mixture of [^{35}S]methionine and [^{35}S]cysteine, which equilibrates more directly into the intracellular pools of charged aminoacyl-tRNAs. A cellular hydrolysate from *E. coli* labeled with $^{35}SO_4^{2-}$, marketed as TRAN^{35}S-LABEL (ICN) or EXPRE^{35}S^{35}S (NEN), works well as a source of [^{35}S] amino acids for metabolically labeling yeast proteins (see Basic Protocol).

Because yeast have a rigid cell wall, lysing the labeled cells in order to immunoprecipitate a specific protein poses an additional challenge. Mechanical shearing is the simplest and least expensive method for lysing yeast. This is done by vigorously vortexing samples in the presence of glass beads. Alternatively, one can remove the cell wall enzymatically using a β-glucanase preparation marketed as Zymolyase 100T (Seikagako Kogyo), Oxalyticase (Enzogenetics), or yeast lytic enzyme (ICN). The resulting spheroplasts can then be lysed by reducing the osmotic support (see Alternate Protocol). Both procedures are described below.

CAUTION: When working with radioactivity, take appropriate precautions to avoid contamination of the experimenter and the surroundings. Carry out the experiment and dispose of wastes in appropriately designated areas, following the guidelines provided by the local radiation safety officer (see also *APPENDIX 1D*).

LABELING AND IMMUNOPRECIPITATING YEAST PROTEINS

BASIC PROTOCOL

The proteins of yeast are metabolically labeled using an *E. coli* hydrolysate as the source of [^{35}S]amino acids. After labeling, the cells are lysed using glass beads, and the protein(s) of interest are immunoprecipitated using specific antibody and protein A-Sepharose. Then the immunoprecipitates are analyzed by SDS-PAGE (*UNIT 6.1*) and fluorography (*UNIT 6.3*).

Materials

Yeast
Minimal medium containing 2% (w/v) glucose (SD medium), without agar (*UNIT 1.6*)
Methionine-free SD medium (*UNIT 1.6*)
[^{35}S]-protein hydrolyzate labeling mix (>1000 Ci/mmol)
50× chase solution (see recipe)
50% (w/v) trichloroacetic acid (TCA)
Acetone, ice cold
SDS/urea buffer (see recipe)
Detergent IP buffer (see recipe)
Antibody specific for protein of interest
Preimmune serum for a negative control
Protein A–Sepharose (see recipe)
Detergent/urea buffer (see recipe)

Contributed by Todd R. Graham
Current Protocols in Cell Biology (2000) 7.6.1-7.6.9

50 mM Tris·Cl, pH 7.5/1% (w/v) SDS
1× (w/v) SDS sample buffer (*APPENDIX 2A*)

125-ml culture flask
Disposable 1.7-ml centrifuge tubes
0.1- to 0.25-mm glass beads (Glen Mills)
Ready-Caps and vials (Beckman)
SpeedVac evaporator
Additional reagents and equipment for SDS-PAGE (*UNIT 6.1*)

Grow cells

1. Innoculate a single yeast colony from a plate into 25 ml of SD medium contained in a 125-ml culture flask. Use the appropriate medium supplements necessary to support growth of strains carrying auxotrophic mutations and to maintain selection for any plasmids. Shake vigorously (250 rpm) in a 30°C incubator overnight.

   It is usually best to innoculate the culture in the morning to ensure that there will be an adequate number of cells for the next day.

2. Use a spectrophotometer to measure the OD_{600} of a 1:4 or 1:10 dilution (in water) of the overnight culture.

   Since turbidity or light scattering is being measured in the spectrophotometer rather than absorbance, it is best to read in the 0.05 to 0.5 range to achieve a linear response to cell density. A culture with an OD_{600} reading of 1.0 (corrected for dilution) is considered to have a cell concentration of 1 OD_{600}/ml, which is equivalent to ~1×10^7 cells/ml for most strains.

3. Proceed to step 5 if the overnight culture is still in log phase (has not exceeded an OD_{600} of 1.0) and a sufficient number of cells are available for labeling.

   The number of cells required for a pulse-chase experiment depends on the expression level of the protein of interest and has to be determined empirically. However, a total of 8 OD_{600} are required for a typical pulse-chase experiment in which 2 OD_{600} of cells are harvested at each of four time points.

4. For overnight cultures exceeding an OD_{600}/ml of 1.0, dilute to 0.25 OD_{600} in the same medium (25 to 50 ml) and grow for 4 to 5 hr as described above.

   The cells will usually double only once in this time period when cultured in minimal medium.

5. Measure and record the OD_{600} of the culture and pellet the yeast by centrifuging 5 min at 5000 × *g*. Discard the spent medium and resuspend the cells in SD medium (methionine-free) to a concentration of 5 OD_{600}/ml.

6. Determine the number of cells required for the experiment and transfer an appropriate culture volume to a disposable centrifuge tube (i.e., Falcon 2059 or 2070).

   The culture should occupy <10% the total volume of the tube.

Label cells

7. Preincubate the cells at the desired temperature (typically 30°C) for 15 min with vigorous shaking (250 rpm). To initiate the labeling period, add [^{35}S]methionine and cysteine to a final concentration of 125 µCi/ml (or use 25 µCi/OD_{600} if a different concentration of cells is used). Incubate 5 to 15 min.

8. To initiate the chase, add 50× chase solution to a 1× final concentration. At the desired chase times (e.g., 0, 5, 15 and 45 min), transfer equal aliquots (100 to 400 µl) from

the culture to properly labeled microcentrifuge tubes sitting on ice containing 0.25 vol 50% (w/v) TCA (final TCA concentration equals 10%) to terminate the chase.

CAUTION: *TCA is extremely caustic. Protect eyes and avoid contact with skin when preparing and handling TCA solutions.*

The cells can be stored in 10% TCA in a refrigerator for several days or processed immediately for immunoprecipitation.

Lyse cells

9. After at least 15 min in TCA, pellet the cells 10 min in a microcentrifuge at full speed. Aspirate the supernatant into a radioactive waste trap and wash the pellet with ~1.0 ml of ice-cold acetone. Microcentrifuge for 4 min at full speed and aspirate the acetone into the radioactive waste trap. Repeat the acetone wash.

   CAUTION: *The supernatants and washes should be handled as mixed chemical/radioactive wastes; follow applicable safety regulations for disposal (also see APPENDIX 1D).*

   Individually immersing the bottom of the tubes in a bath sonicator and then vortexing will help disperse the pellets.

10. Dry the acetone-washed TCA pellets in a SpeedVac evaporator, then add 100 µl of SDS/urea buffer and let sit for at least 15 min at room temperature.

11. Add glass beads (0.1- to 0.25-mm) to 80% to 90% (v/v) of the sample volume and vortex 1 min.

    Care should be taken here because glass beads adhering around the lip of the tube will prevent the cap from closing tightly. Use a razor blade to cut the bottom off of a microcentrifuge tube and use this as a "funnel" for adding the glass beads. A 0.1-ml capacity Coors porcelain spatula (Fisher, VWR) works well to deliver the appropriate volume of glass beads.

12. Heat the samples 4 min at 95°C, then vortex again for 15 to 30 sec.

13. Add 900 µl of detergent IP buffer, vortex and put the samples on ice for ≥10 min.

14. Microcentrifuge the samples 15 min at full speed and transfer 0.85 ml of the supernatants (lysate) to fresh tubes being careful not to disturb the glass beads or any insoluble material pelleted on top of the glass beads.

15. To determine the incorporation of ^{35}S into protein, spot 5 µl of each supernatant into a Beckman Ready-Cap, transfer the caps to vials and measure the radioactivity in a scintillation counter.

    Alternatively, measure incorporation of radioactivity by TCA precipitation (UNIT 7.1).

Immunoprecipitate protein

16. Add antiserum (usually 1 to 2 µl per OD of labeled cells) and 75 to 100 µl protein A–Sepharose suspension to the supernatants. Put the tubes in a rack and lay the rack on its side and rock the samples for 4 hr to overnight in a cold room. Agitate sufficiently to keep the protein A–Sepharose in suspension.

    Alternatively, use antibody pre-bound to protein A–Sepharose (see UNIT 7.2).

17. Pellet the immune complexes by microcentrifuging 30 sec at 3000 × g and transfer the supernatants to fresh tubes.

    Do not discard these supernatants as it is often desirable to immunoprecipitate a second protein from these lysates.

18. Wash the pellets twice with 1 ml of detergent/urea buffer, then once with detergent IP buffer. Aspirate each supernatant from the washes into the radioactive waste trap.
19. (*Optional*) To immunoprecipitate the lysates with a second antibody, clear any remaining antigen-antibody complexes by adding 75 µl of protein A–Sepharose and rocking the samples for 2 hr in the cold as above. Microcentrifuge 10 min at full speed and transfer the supernatants to fresh tubes. Use the cleared lysate to immunoprecipitate with a second antibody.
20. Resuspend the pellets in 100 µl of 50 mM Tris·Cl, pH 7.5/1% SDS and heat at 95°C for 4 min. Repeat steps 13 to 18, omitting step 15. Dry the final pellet for 5 to 10 min under vacuum.

    A second immunoprecipitation ("recapture") step is usually required to achieve a "clean" immunoprecipitation.
21. Resuspend the pellets in 50 µl of 1× SDS sample buffer and heat at 95°C for 4 min. Subject half of the sample to SDS-PAGE (*UNIT 6.1*). Save the remainder of the samples (at 4°C) in case the electrophoresis has to be done again. Process gels for fluorography or phosphor imaging (*UNIT 6.3*).

ALTERNATE PROTOCOL

MAKING YEAST SPHEROPLASTS

Proteins secreted from yeast are usually retained in the periplasmic space, which lies between the plasma membrane and the cell wall. The contents of the periplasmic space can be separated from the cells by enzymatically removing the cell wall and pelleting the resulting spheroplasts. Secreted proteins will remain in the supernatant. In addition, if one wishes to perform native immunoprecipitations or fractionate labeled yeast cells, it is necessary to remove the cell wall in order to gently lyse the cells by reducing the osmotic support.

Additional Materials *(also see Basic Protocol)*

Radiolabeled yeast cells
2× spheroplast/stop solution (see recipe)
Bovine serum albumin (BSA), fatty acid–free Fraction V
10 mg/ml Zymolyase 100T (Seikagako Kogyo)

1. Grow and label yeast cells (see Basic Protocol, steps 1 to 7).
2. Chase the cells, substituting 1 vol 2× spheroplast/stop solution for the 50% (w/v) TCA (see Basic Protocol, step 8). Add BSA to 1 mg/ml to act as a carrier if secreted proteins are going to be TCA precipitated from the periplasmic space fraction.
3. Keep samples on ice until all the chase points are collected.
4. Add 2 µl of 10 mg/ml Zymolyase 100T (ICN) per OD_{600} of cells in each sample and incubate 30 min at 30°C with gentle agitation.
5. Pellet cells by microcentrifuging 5 min at 5000 × *g* and transfer the supernatants to fresh tubes.
6. To monitor the spheroplasting reaction, take 200 µl of a 10 OD_{600}/ml suspension of unlabeled cells in 1× spheroplast/stop buffer, split the sample equally and add Zymolyase to one of the tubes. After incubating 30 min at 30°C, remove 25 µl from each tube and dilute to 1 ml with water. Read the OD_{600}.

    The untreated sample should give an OD_{600} reading of ~0.25, but the treated sample should lyse when diluted in water and give an OD_{600} reading that is 5% to 10% that of the untreated sample (~0.01 to 0.025). If the OD_{600} reading of the treated sample is ≥10% of the untreated sample, add more Zymolyase to the samples and continue the incubation.

Process yeast spheroplasts for immunoprecipitation or subcellular fractionation

7a. *For TCA precipitation followed by immunoprecipitation:* Add 0.25 vol of 50% TCA to the supernatants and 0.5 ml of 10% (w/v) TCA to the cell pellets to precipitate proteins. Proceed from this point to step 9 of the Basic Protocol.

7b. *For immunoprecipitation without TCA precipitation:* Dissolve cell pellets in 100 µl SDS-urea buffer, then heat at 95°C for 4 min to lyse cells and avoid TCA precipitation and glass-bead lysis steps. Proceed from this point to step 13 of the Basic Protocol.

7c. *For native immunoprecipitation:* Resuspend the cell pellets in 1 ml nondenaturing lysis buffer (*UNIT 7.2*). Perform native immunoprecipitation from the lysates as described in *UNIT 7.2*.

7d. *For subcellular frationation:* Lyse the spheroplasts by resuspending the cell pellet in low-osmotic-strength buffer (e.g., 25 mM Tris·Cl, pH 7.2/0.1 M sorbitol) and fractionate to enrich specific organelles (Graham et al., 1994).

ENDO H TREATMENT OF IMMUNOPRECIPITATES

SUPPORT PROTOCOL

N-linked oligosaccharides on yeast glycoproteins are sensitive to endoglycosidase H (endo H) regardless of the extent of Golgi modification. Thus, endo H treatment can be used to determine if an immunoprecipitated protein is modified with N-linked oligosaccharides (also see *UNIT 15.2*). Add 64 µl of freshly prepared SDS-2ME solution (0.2% w/v SDS/1% w/v 2-mercaptoethanol) to dried immunoprecipitates (Basic Protocol, step 17) and heat 4 min at 95°C. Add 16 µl of 250 mM sodium citrate pH 5.5 buffer to each sample. Mix and centrifuge briefly. Transfer 40 µl of each sample to a fresh tube, then add 0.5 mU of Endo H (0.5 µl) to one portion and incubate each pair of samples (+ and − endo H) overnight in a 37°C air incubator. Then add 13.3 µl of 4× SDS sample buffer (*APPENDIX 2A*) to each tube, heat 4 min at 95°C and electrophorese the samples in an SDS-polyacrylamide gel (*UNIT 6.1*).

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Chase solution, 50×

50 mM methionine
5 mM cysteine
Filter sterilize and store up to 1 year at −20°C in small aliquots

Detergent IP buffer

50 mM Tris·Cl, pH 7.5
0.1 mM EDTA
150 mM NaCl
0.5% (w/v) polyoxyethylenesorbitan monolaurate (Tween 20)
Store up to 3 months at 4°C

Detergent/urea buffer

100 mM Tris·Cl, pH 7.5
200 mM NaCl
0.5% (w/v) polyoxyethylenesorbitan monolaurate (Tween 20)
2 M urea
Store up to 3 months at 4°C

Protein A–Sepharose

Swell 0.4 g protein A–Sepharose CL-4B (Pharmacia) in 11.2 ml of 10 mM Tris·Cl (pH 7.5)/1 mM NaN_3/1 mg/ml bovine serum albumin for 2 hr to overnight at 4°C. Aspirate the supernatant from the settled beads and add fresh buffer to the original volume. Store up to 3 months at 4°C.

SDS/urea buffer

50 mM Tris·Cl, pH 7.5 (*APPENDIX 2A*)
1 mM EDTA
1% (w/v) SDS
6 M urea
Store up to 1 month at room temperature

Spheroplast/stop solution, 2×

2 M sorbitol
50 mM Tris·Cl, pH 7.5 (*APPENDIX 2A*)
40 mM NaN_3
40 mM NaF
Store up to 6 months at room temperature
Add 20 mM DTT from 1 M stock solution just before use

COMMENTARY

Background Information

Radiolabeling of proteins, lipids, and carbohydrates

Incorporation of ^{35}S into newly synthesized yeast protein can be achieved by labeling cells with either $^{35}SO_4^{2-}$ or a mixture of [^{35}S]methionine and [^{35}S]cysteine. While $^{35}SO_4^{2-}$ is less expensive and is primarily incorporated into protein in yeast (and not other macromolecules such as polysaccharides), there are drawbacks to its use. For example, standard minimal medium contains a high concentration of cold sulfate, which obviously competes with the isotope for incorporation into protein and also represses the synthesis of the high-affinity sulfate permeases (Cherest et al., 1997). Thus, efficient uptake of $^{35}SO_4^{2-}$ requires growing the cells in a specially prepared low-sulfate medium (LSM) to induce expression of the permeases. LSM is SD medium where chloride salts are used in place of sulfate salts. LSM is supplemented with 100 µM $(NH_4)_2SO_4$ for growing cells and 25 µM $(NH_4)_2SO_4$ for labeling. Even with these precautions, a relatively high concentration of $^{35}SO_4^{2-}$ (250 to 500 µCi/ml) is needed to achieve an adequate incorporation of radiolabels into protein. Therefore, labeling cells with [^{35}S]amino acids has become the method of choice because standard minimal media (SD, methionine-free) can be used, and it is not necessary to starve the cells for sulfate prior to labeling. Care should be taken when working with small proteins or peptides to check if methionine or cysteine residues are present in the sequence. If not, it is possible to label cells with [^{3}H]leucine (or other amino acid) in minimal medium (SD, leucine-free).

The methods described in this unit can also be used to study the phosphorylation of proteins in vivo. Cells can be labeled with $^{32}PO_4^{3-}$ in a low-phosphate medium in which the phosphate salts in LSM are replaced with the appropriate chloride salts and then supplemented with 50 µM potassium phosphate. Cells are typically labeled 20 to 60 min at 100 µCi/OD_{600} (Reneke et al., 1988).

A substantial amount of $^{32}PO_4^{3-}$ is incorporated into phospholipid to the extent that cells can be labeled in standard minimal medium if one wishes to examine the bulk cellular phospholipid content. Cells are grown for six generations in minimal medium (supplemented with 0.1 mM inositol and 1 mM choline) containing 10 µCi/ml $^{32}PO_4^{3-}$ for steady-state determinations, or pulse-labeled 10 to 60 min at 50 µCi/ml (Klig et al., 1985). After labeling, the lipids are extracted in a polar extraction solvent and separated by two-dimensional paper chromatography (Steiner and Lester, 1972).

Yeast glycoproteins can also be radiolabeled with [2-^{3}H]mannose, which is specifically incorporated into O- and N-linked oli-

gosaccharides as well as a small percentage of lipid-linked products. The label is not incorporated into other compounds because catabolism of mannose, specifically the conversion of mannose-6-phosphate to fructose-6-phosphate, results in the removal of the label as tritiated water (Huffaker and Robbins, 1982). It is also helpful to grow and label the cells in minimal medium containing 1% galactose as the carbon source rather than glucose. Galactose will not compete with mannose for entry into the cell. Cells can be labeled continuously during growth at 0.1 to 10 μCi/ml or pulse-labeled at 100 to 500 μCi/ml with the cells at 20 OD_{600}/ml (Byrd et al., 1982).

Labeling conditions

The medium that yeast are grown in, as well as other conditions such as temperature and the stage of growth, can have a dramatic influence on the expression of specific genes. For example, if one wishes to examine the protein encoded by a galactose-regulated gene in a pulse-chase experiment, it is essential to culture the cells in galactose rather than glucose as the carbon source. In addition, many genes involved in fermenting carbon sources other than glucose are repressed when cells are grown in glucose. To derepress these genes, shift cells to medium containing 0.1% glucose for 1 hr prior to labeling or simply culture the cells using a different carbon source. However, labeling is typically done in synthetic minimal medium containing glucose, and it is preferable to grow the cells in the same medium used during the labeling period to avoid inducing changes in cellular metabolism. Another important consideration is that cells in the logarithmic stage of growth incorporate substantially more ^{35}S into protein than stationary phase cells.

One of the advantages of working with yeast is the availability of a large number of mutants that exhibit a defect in some cellular process. For temperature-sensitive mutants, it is often desirable to incubate cells at the nonpermissive temperature prior to labeling in order to establish the mutant phenotype. The length of this incubation period depends on the nature of the mutation carried by the strain and usually has to be determined empirically. In the case of the *sec18-1* mutant, for example, protein transport is blocked almost immediately upon shifting to the nonpermissive temperature and the cells remain viable for ≥2 hr (Graham and Emr, 1991). As a control, it is important to label wild-type cells that have been subjected to the same temperature shifts to be certain that the mutation and not the change in temperature is the cause of any effects being observed.

Critical Parameters and Troubleshooting

Yeast colonies used to innoculate the overnight culture should be <2 weeks old, particularly if they were grown on a minimal plate in order to select for a plasmid carried by the strain. It is preferable that the overnight culture does not grow to stationary phase because many strains can take several hours to start doubling again when diluted in minimal medium. However, 4 to 5 hr of incubation after diluting in fresh medium is usually sufficient for stationary phase cells to start growing. Poor growth of some strains in minimal medium can result in low incorporation of ^{35}S amino acids into protein ($<5 \times 10^6$ cpm/OD_{600}). In this case, add 0.2% (w/v) Difco yeast extract to the growth (steps 1 to 3) and chase (step 8) media. If yeast extract is used, it is essential to wash the yeast twice with sterile water (~30 ml) before resuspending the cells in labeling medium lacking yeast extract (steps 4 to 7). It is also very important to use clean glassware and centrifuge tubes that are free of detergent at all steps. Poor incorporation of ^{35}S in labeling experiments is usually solved by carefully remaking the medium. Old (>1 month) or improperly stored [^{35}S] amino acids can also contribute to labeling problems.

In some cases, a biological process may not go to completion during the chase period. For example, some fraction of a protein that is normally completely secreted in 15 min may remain inside the cell even after a 60-min chase. This may indicate that the cells are being depleted of energy or some other critical nutrient. To remedy this problem, add yeast extract and additional glucose to a final concentration of 0.2% and 2% (w/v), respectively, to the chase (step 8).

Some integral membrane proteins will aggregate when the cell lysates are heated to 95°C in SDS-urea buffer. In this case, the protein will migrate near the top of the resolving gel or even remain in the stacking gel during electrophoresis. To help prevent this from occurring, heat the samples at 50°C for 5 min or 37°C for 10 min (steps 12, 20, and 21). These conditions do not inactivate cellu-

lar proteases as efficiently as the 95°C incubation, so addition of protease inhibitors may be necessary if degradation products are apparent on the autoradiograms.

The quality of the data produced by the procedures described here is primarily dependent on the quality of the antiserum and the expression level of the proteins being examined. Perhaps the most critical parameter is at step 14 of the Basic Protocol, to carefully transfer the supernatant from the clearing centrifugation step without carrying over any insoluble material. In addition, the "double" immunoprecipitation protocol (step 20), while not essential, usually provides immunoprecipitated proteins that are free of background bands. However, there are additional steps that can be taken to "clean up" immunoprecipitations (*UNIT 7.2*).

1. After step 15, add 75 µl of protein A–Sepharose to the supernatants, rock the samples for 1 hr in the cold room and microcentrifuge 10 min at full speed. Then transfer the supernatants to fresh tubes and proceed to step 16.

2. If a strain is available that does not express the protein of interest (e.g., a strain carrying a complete disruption of the gene encoding the protein of interest), it is possible to prepare a cold-competing cell lysate to add to the immunoprecipitations. To do this, pellet the unlabeled cells and resuspend them at 250 OD_{600}/ml in SDS/urea buffer. Add glass beads until they occupy ~80% of the sample volume, vortex for 1 min and then heat 4 min at 95°C. Add 9 vol of detergent IP buffer, mix well by vortexing, and centrifuge 10 min at 10,000 × *g*. The cold-competing cell lysate can then be added in place of the detergent IP buffer at steps 13 and 20 of the Basic Protocol.

3. Several pathogenic fungi have cell wall carbohydrate structures that are antigenic and are similar to those of *Saccharomyces cerevisiae*. Thus, animal serum can carry antibodies that cross-react with yeast glycoproteins causing background problems in immunoprecipitates. This problem is usually apparent in pre-immune control immunoprecipitations. Yeast mannan (Sigma) can be added at 0.5 mg/ml at steps 13 and 20 to help reduce this background. Using affinity purified antibodies may also help to ameliorate this potential problem.

4. Some investigators wash the immunoprecipitates an additional time (step 17) in 1% (v/v) 2-mercaptoethanol to reduce background. Likewise, the concentration of detergent, SDS, or urea can be increased in the wash buffers to provide greater stringency. However, depending on the antibodies being used, these steps can cause significant loss of the protein of interest from the immunoprecipitates.

Anticipated Results

The basic labeling procedure should result in the incorporation of 0.5 to 4 × 10^7 cpm/OD_{600}. Specific bands should be visible anywhere from 2 hr to 2 weeks after exposure of dried gels to X-ray film. At this level of incorporation, a protein that constitutes ~0.1% of cellular protein should be visible in 5 to 40 hr on the autoradiogram.

Time Considerations

Typically, 15 to 30 min are required on day 1 for innoculation of cultures. Cell labeling and preparation of cell lysates for immunoprecipitation requires ~4 hr on day 2, and the initial antibody incubations are usually performed overnight (step 16). The first wash steps require 30 to 90 min on the morning of the third day (step 17), and the second antibody incubations are for 4 to 7 hr (step 20). The second wash steps and gel loading requires 30 to 90 min. With this regimen, samples are electrophoresed overnight and the gel is processed the morning of the fourth day. Depending on the extent of labeling and the expression of the target protein(s), fluorography can take hours or weeks.

Metabolic Labeling and Immunoprecipitation of *Drosophila* Proteins

Cultured cells derived from the fruit fly, *Drosophila melanogaster*, provide a powerful experimental system for the biochemical and cell biological study of protein function. Given the great availability of mutant flies, the ability to culture cells from such mutants permits large amounts of cellular material of homogeneous genotype to be obtained for investigation. This unit describes a method for metabolic labeling and immunoprecipitation of proteins from cultured *Drosophila* cells (see Basic Protocol). The specific methods presented here work well for the wild-type S2M3 cell line, which was adapted from Schneider S2 cells to grow in Shields and Sang M3 medium. The Support Protocol describes the procedure for growth and maintenance of these cells. When combined with pulse-chase approaches and subcellular fractionation, this method permits the investigation of such questions as the turnover and cellular localization of specific proteins.

NOTE: All solutions and equipment coming into contact with living cells must be sterile, and aseptic technique should be used accordingly.

LABELING AND IMMUNOPRECIPITATION OF PROTEINS FROM *DROSOPHILA* S2M3 CELLS

BASIC PROTOCOL

Wild-type S2M3 cells can be labeled using either purified [^{35}S]methionine or an ^{35}S-labeled *E. coli* hydrolysate as a source for radioactive amino acids. Following metabolic labeling, the cells are gently solubilized with detergent and the protein of interest is immunoprecipitated using specific antibodies and protein A–Sepharose (*UNIT 7.2*). The precipitated proteins can then be analyzed by SDS-PAGE (*UNIT 6.1*) and autoradiography (*UNIT 6.3*).

Materials

Wild-type *Drosophila* S2M3 cells (ATCC CRL 1963) growing in culture in M3 medium (see Support Protocol)
M3 growth medium (see recipe)
M3 labeling medium (see recipe)
[^{35}S]L-Methionine (>800 Ci/mmol) or ^{35}S-labeled *E. coli* protein hydrolysate (e.g., TRAN^{35}S-LABEL, EXPRE^{35}S^{35}S; ICN Biomedicals; >1000 Ci/mmol)
Activated charcoal
PBS (*APPENDIX 2A*), ice-cold
Cell lysis buffer (see recipe)
1:1 (v/v) protein A–Sepharose bead slurry in PBS (store up to 24 hr at 4°C)
Specific antibody against protein of interest
IP wash buffer: 0.1% (v/v) Triton X-100 in PBS (*APPENDIX 2A*) 1× SDS sample buffer (*APPENDIX 2A*)
35-mm tissue culture dishes
Large sealed container (e.g., Tupperware)
Cell scrapers
End-over-end rotator
Additional reagents and equipment for culturing *Drosophila* cells (see Support Protocol)

CAUTION: When working with radioactive materials, take appropriate precautions to avoid contamination of the experimenter and the surroundings. Carry out the experiment and dispose of wastes in an appropriately designated area, following guidelines provided by the local radiation safety officer (also see *UNIT 7.1* and *APPENDIX 1D*).

Current Protocols in Cell Biology (2001) 7.7.1-7.7.6

Metabolically label cells

1. Grow cells to ~60% to 70% confluence in 35-mm tissue culture dishes at 25°C in *Drosophila* M3 growth medium (see Support Protocol).

   The doubling time for these cells is ~24 to 26 hr.

   These cells do not require a humidified CO_2 atmosphere for growth and can be cultured in a cool enclosed space such as a bench cabinet or drawer.

   If cells are to be transfected, adjust plating such that they are at the proper confluence at the time of labeling.

2. Rinse cells briefly with two changes of 1 ml each of M3 labeling medium. Then incubate cells with 1 ml fresh M3 labeling medium for 30 min to 1 hr to deplete intracellular methionine pools.

3. Thaw [^{35}S]methionine or ^{35}S-labeled *E. coli* hydrolysate and prepare a 100 to 200 µCi/ml labeling solution in M3 labeling medium.

   CAUTION: Open stock vials of ^{35}S-labeled amino acids in a fume hood, since volatile ^{35}S-containing compounds can be released.

4. Remove M3 labeling medium from cells and replace with 0.5 ml of [^{35}S]methionine labeling solution. Incubate cells 30 min to 2 hr at 25°C in a large sealed container containing a moistened paper towel. Place a 35-mm petri dish that contains a small amount of activated charcoal into the sealed container to absorb any released ^{35}S-containing compounds.

   Alternatively, a filter that is impregnated with activated charcoal can be used.

   The time of labeling can be shortened to 5 to 10 min to accommodate pulse-chase protocols. However, the concentration of radioactive amino acids should be increased to 0.5 to 1 mCi/ml and the chase medium should contain 1 g/liter yeast hydrolysate, a 10-fold excess of unlabeled methionine, and 10% undialyzed FBS.

5. Remove [^{35}S]methionine labeling solution and rinse cells three to four times with 1 ml of ice-cold PBS. Combine the labeling solution and the washes in a 10-ml screw-cap centrifuge tube and centrifuge 5 min at 300 × *g*, 4°C, to collect any cells that may have detached during the labeling period. Remove the supernatant.

   CAUTION: Discard the used labeling solution, all of the wash solutions, and all contaminated disposable material as radioactive waste following the established guidelines set by the local radiation safety officer.

6. Add 2 to 3 ml of ice-cold PBS and scrape cells with a disposable cell scraper. Transfer cell suspension to a 10-ml screw-cap conical centrifuge tube. Combine with the cells collected from the labeling solution.

7. Centrifuge pooled cells for 5 min at 300 × *g*, 4°C, and discard supernatant.

Lyse cells and perform immunoprecipitation

8. Add 0.5 ml of ice-cold cell lysis buffer to each tube and incubate in ice/water slurry for 20 min.

9. Microcentrifuge 1 min at maximum speed, 4°C, to bring down insoluble material.

10. Transfer supernatant to a fresh tube and add 0.5 ml of additional cell lysis buffer.

11. Add 50 µl of a 1:1 protein A–Sepharose/PBS slurry and place tubes at 4°C on an end-over-end rotator for 0.5 to 1 hr to help "preclear" the supernatant and minimize nonspecific binding of cellular proteins to the protein A–Sepharose beads.

The protein A–Sepharose should be washed prior to use by resuspending 50 µl, the beads should then be resuspended in PBS at 1:1, in 1 ml of PBS and centrifuging 1 min at maximum speed, 4°C.

12. Microcentrifuge 1 min at maximum speed, 4°C, to bring down the beads, and transfer the supernatant to a fresh tube.
13. Add 50 µl of fresh 1:1 protein A–Sepharose suspension and add the appropriate amount of specific antibody against the protein of interest.

    The amount of antibody used will vary for each specific antibody preparation, but a good rule of thumb is to use a small excess of antibody to ensure a more quantitative recovery of the desired protein.
14. Incubate the tube at 4°C on an end-over-end rotator for 1 to 2 hr and pellet the immune complexes by microcentrifuging 1 min at maximum speed, 4°C.
15. Discard supernatant and wash the immune complexes by resuspending the beads in 1 ml of IP wash buffer and microcentrifuging again at maximum speed, 4°C. Repeat two more times.
16. Resuspend the immune complexes in 50 µl of 1× SDS-PAGE sample buffer and process for SDS-PAGE (*UNIT 6.1*) and autoradiography (*UNIT 6.3*).

GROWTH AND MAINTENANCE OF CULTURED *DROSOPHILA* S2M3 CELLS

SUPPPORT PROTOCOL

Most *Drosophila* cells, including S2M3 cells, are conveniently cultured at 22°C to 25°C in tightly capped 25-cm^2 culture flasks and do not require a regulated CO_2 atmosphere. Thus, these cells can be cultured in a dry, cool place (e.g., a bench cabinet), provided that the temperature remains stable. Subculturing is accomplished by dislodging the cells from the flask by passing a gentle stream of medium over the cells with a pipet and transferring the cells to a new flask at the desired split ratio.

Materials

Drosophila S2M3 cells (ATCC CRL 1963)
M3 growth medium (see recipe)
25-cm^2 (T-25) tissue culture flasks with plug-seal caps

1. Aspirate off the old medium from a culture grown in a 25-cm^2 flask in a sterile tissue culture hood.
2. Tilt the flask and pass a gentle stream of medium (~2 to 3 ml) over the cells using a sterile cotton-plugged 5¼-in. Pasteur pipet fitted with a rubber bulb.

   Most Drosophila cell lines adhere loosely to the growth substrate and thus do not require treatment with trypsin to dislodge them from the substrate. Indeed, the use of trypsin should be avoided since many lines are sensitive to trypsin.

   Cotton-plugged pipets can be sterilized by autoclaving them in square metal canisters and are an inexpensive alternative to using disposable plastic pipets.
3. Pipet the cells up and down, gently, to disperse them into a homogeneous suspension.
4. Transfer cells at a split ratio of 1:3 to 1:10 into a new 25-cm^2 flask that contains 3 ml of fresh M3 growth medium warmed to room temperature.

   S2M3 cells, like most Drosophila cells, should not be subcultured at high split ratios since they do not grow well when sparsely plated.
5. Tightly seal the flasks and place in a dry, cool place (e.g., a bench cabinet) where the temperature is fairly constant at 22° to 25°C.

Cells can also be plated into 35-mm-diameter dishes containing 1.5 to 2 ml of M3 medium for individual experiments; however, the outsides of these dishes should be sealed with Parafilm.

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX.***

Cell lysis buffer

1% (v/v) Triton X-100
50 mM Tris·Cl, pH 7.4 (*APPENDIX 2A*)
300 mM NaCl
5 mM EDTA
20 mM iodoacetamide
Store up to 6 months at 4°C
Just before use, add the following protease inhibitors:
100 µg/ml PMSF
1 µg/ml aprotinin

M3 growth medium

Shields and Sang M3 insect medium (Sigma-Aldrich) without *L*-glutamine and with potassium bicarbonate
10% (v/v) fetal bovine serum (FBS)
100 U/ml penicillin
100 µg/ml streptomycin
Store up to 2 to 3 months at 4°C

M3 labeling medium

Prepare Shields and Sang M3 insect medium without *L*-glutamine, with potassium bicarbonate lacking methionine, cysteine, and yeast hydrolysate (Sigma-Aldrich). Supplement the medium with 100 U/ml penicillin and 100 mg/ml streptomycin. This medium can be supplemented with 10% FBS that has been dialyzed overnight against saline to remove unlabeled amino acids. Store up to 6 months to 1 year at –20°C

COMMENTARY

Background Information

Since the late 1960s, roughly 100 continuous cell lines have been established from both wild-type and mutant *Drosophila* flies. Refer to Echalier (1997) for an excellent and comprehensive treatise on *Drosophila* cell culture and for specific methods to establish cell lines from *Drosophila* flies. Of the many wild-type cell lines described, the most commonly used lines are Echalier and Ohanessian's Kc cell line (Echalier and Ohanessian, 1970) and Schneider's S1, S2, and S3 cell lines (Schneider, 1972). Both the Kc line and the S2 line are available from ATCC. Both of these continuous cell lines were established from early *Drosophila* embryos, as were most continuous *Drosophila* cell lines described thus far. Both wild-type and mutant *Drosophila* cells have been used to investigate such processes as insect hormone responses, cell adhesion, and EGF signaling.

Metabolic labeling and immunoprecipitation methods have been used to study protein function in a variety of cultured *Drosophila* cell lines, often in conjunction with transfection studies. As an example, Zak and Shilo (1990) utilized pulse-chase labeling and immunoprecipitation to study biosynthesis of the *Drosophila* EGF receptor homolog, DER. Buzin and Petersen (1982) profiled the pattern of protein expression induced during heat shock using metabolic labeling with [^{35}S]methionine and two-dimensional electrophoresis in Kc cells.

Critical Parameters and Troubleshooting

Three important factors must be considered when designing metabolic labeling experi-

ments for cultured *Drosophila* cells: composition of culture medium, growth properties of the cells, and methods of transfection.

The three most commonly used media for culturing *Drosophila* cells are Echalier-Ohanessian's D22 medium (Kc cells), Schneider's medium (S1, S2, and S3 cells), and Shields and Sang M3 medium (S2M3 cells, Shields' G1 line, Sang's *shibire* S4 line). Both Schneider's medium and Shields and Sang M3 medium are commercially available from Sigma-Aldrich; Schneider's medium is also available from Life Technologies. A methionine-, leucine-, and yeast extract–free formulation of M3 medium is also available from Sigma-Aldrich, which is useful for metabolic labeling. Most *Drosophila* media are supplemented with 5% to 20% fetal bovine serum. Since most formulations of *Drosophila* culture media contain either yeast extract or lactalbumin hydrolysate, it is important to omit these during metabolic labeling since they provide a source of unlabeled amino acids that could reduce labeling efficiency. All of these media formulations can be conveniently made in the laboratory (see Echalier, 1997), and thus can be prepared with these supplements omitted in addition to the particular amino acid to be labeled.

Another important consideration is the growth conditions of *Drosophila* cells. Almost none of the established cell lines require a regulated CO_2 atmosphere, and almost all grow optimally at 22°C to 25°C. Thus, most *Drosophila* cells can be conveniently cultured literally on the bench top. However, caution must be exercised to ensure that the temperature does not rise much above 27°C, since the *Drosophila* heat-shock response is induced at temperatures of 30° to 37°C (see Echalier, 1997). During the heat-shock response, the synthesis of most proteins is repressed in favor of heat-shock proteins (Buzin and Petersen, 1982). Also, many *Drosophila* cells adhere loosely to the growth substrate and often detach and grow in suspension. Thus, any floating cells should also be collected from the labeling medium during metabolic labeling experiments. Finally, one should avoid sparse plating (e.g., >1:20 split ratio), since *Drosophila* cells do not grow well at low cell densities.

Drosophila cells can be transfected using a modified calcium phosphate coprecipitation method (*UNIT 15.5*), lipid-based transfection reagents, and electroporation. The most widely used method of transfection is a modified calcium phosphate method where *N,N-bis*(2-hydroxyethyl)-2-aminoethanesulfonic acid (BES) is substituted for HEPES as a buffering agent (Chen and Okayama, 1987). 2× BES-buffered saline (2× BBS) contains 50 mM BES, pH 6.95, 280 mM NaCl, and 1.5 mM Na_2HPO_4. It is filter-sterilized and stored at −20°C).This change gives an ~10-fold higher transfection efficiency (Cherbas et al., 1994). Lipofectin-mediated transfection has also been shown to work well for cultured Kc and S2 cells (Echalier, 1997). Finally, electroporation works well for Kc167 cells (Cherbas et al., 1994). With regard to expression vectors, two commonly used promoters for efficient expression of proteins in *Drosophila* cells are the actin5C promoter (Jaynes and O'Farrell, 1988) and the metallothionein promoter (Bunch et al., 1988). Proteins are efficiently expressed in many cells when their transcripts are driven by the activity of these promoters. Three expression vectors, which utilize these promoters, are commercially available from Invitrogen. They are useful for expressing proteins in *Drosophila* cells; pMT/V5-His A,B,C (Metallothionein promoter); pMT/BiP/V5-His A,B,C (metallothionein promoter); pAc5.1/V5-His A,B,C (actin5C promoter).

Finally, proper controls should always be utilized to assess the specificity of each antibody used for immunoprecipitation. If using polyclonal antiserum, preimmune serum should be used on a duplicate sample to assess the specificity of immunoprecipitation. If using monoclonal antibodies, an irrelevant antibody should be used from the same species as the specific antibody, to assess nonspecific binding. Also, a mock immunoprecipitation, where the primary antibody is omitted, should be included to control for nonspecific binding to the protein A–Sepharose beads. The primary antibody should be titrated to optimize the amount used for immunoprecipitation such that it is present only in slight excess, to minimize nonspecific binding.

Anticipated Results

In a typical experiment, using a 30-min to 1-hr labeling period as described (see Basic Protocol), clearly visible bands result on X-ray film after 16 hr to 24 hr exposure following SDS-PAGE (*UNIT 6.1*) and autoradiography (*UNIT 6.3*). The relative transient transfection efficiency using the modified calcium phosphate method ranges from 10% to 20%. Thus, immunoprecipitation of transiently transfected proteins is variable and should be optimized for each specific case. This protocol should also

work equally well for labeling and immunoprecipitation of endogenous proteins.

Time Considerations

It usually requires 1.5 to 3 hr to prepare cells and perform the labeling, depending on the time used for labeling. Approximately 30 min is required to prepare cell extracts and 2 to 4 hr is required for immunoprecipitation. Washing and processing may require an additional 1 hr.

Metabolic Labeling of Glycoproteins with Radioactive Sugars

Most proteins synthesized in the secretory apparatus of mammalian cells are glycosylated. These glycoproteins are components of secretory and endocytic organelles, including the endoplasmic reticulum, Golgi complex, plasma membrane, endosomes, and lysosomes. These glycoproteins are also important constituents of the extracellular space. The glycans of these molecules include *N*-linked chains, which are linked to asparagine residues, and *O*-linked chains, which are linked to serine and threonine residues. The latter group includes short mucin-type chains and large glycosaminoglycan chains.

For glycoproteins from cultured cells, structural studies of glycoprotein glycans are best carried out on radioactive molecules prepared by metabolic labeling. This unit describes two methods for the preparation of metabolically labeled glycoconjugates from cultured cells. The first describes pulse-chase labeling (see Basic Protocol). Typically, cells are labeled in a pulse incubation of 5 to 30 min, followed by a chase incubation of up to several hours. Molecules labeled in this way are suitable for initial studies to characterize the types of glycans on a glycoprotein and to gather information about their biosynthesis. As an alternative, a method for long-term labeling is also described (see Alternate Protocol). Because the cells are labeled over one or more generations, uniform labeling of all the sugar residues in a molecule can be achieved, with each residue of a particular type being labeled to the same specific activity. This uniform labeling is important for detailed structural studies; however, only glycoproteins with mature glycans can be prepared using this protocol, so it provides little information about biosynthesis.

The unit also contains support protocols for the liberation of *N*- (see Support Protocol 1) and *O*-linked (see Support Protocol 2) glycans from glycoproteins. These protocols can be used to prepare labeled glycans for characterization and detailed structural analysis.

CAUTION: When working with radioactive materials, take appropriate precautions to avoid contamination of the experimenter and the surroundings. Carry out the experiment and dispose of wastes in an appropriately designated area, following guidelines provided by your institution's Radiation Safety Officer (also see *UNIT 7.1* and *APPENDIX 1D*).

PULSE-CHASE LABELING WITH RADIOACTIVE PRECURSORS

BASIC PROTOCOL

It is important to optimize labeling conditions to obtain maximum incorporation of the radioactive precursor. The radioactive precursor must be chosen with care. First, only some sugars—e.g., galactose (Gal), glucose (Glc), glucosamine ($GlcNH_2$), and mannose (Man)—are incorporated with high efficiency. Others are incorporated poorly because cells do not have pathways for their efficient uptake and utilization. Second, many sugar precursors undergo extensive metabolism within cells. This metabolism may result in the loss of radioactivity from the precursor or conversion to molecules that cannot be incorporated into glycans. The precursor may also be converted into other sugars that are incorporated, resulting in glycans with several different types of radioactive residues. Consequently, choosing an appropriate radioactive precursor will help to ensure that glycans with the label in the desired sugar residues are obtained. In addition, the labeling conditions should be chosen to optimize precursor incorporation into the glycoproteins of interest. For sugars, this is usually achieved by labeling in medium with reduced glucose concentration. Similarly, for sulfate and phosphate labeling, medium deficient in these compounds is used. Finally, it is necessary to make sure that the precursor is

Contributed by Martin D. Snider
Current Protocols in Cell Biology (2002) 7.8.1-7.8.11

incorporated throughout the labeling period and to ensure that the cells remain healthy. These issues are discussed in detail elsewhere in the unit (see Commentary).

Metabolic labeling may be carried out either in a tissue culture incubator with a CO_2/air atmosphere or in an air atmosphere. In the former case, bicarbonate-buffered medium is used. In the latter, HEPES-buffered medium is employed, which is usually more convenient for short labelings. In addition, because incubations of radioactive samples do not need to be carried out in a tissue culture facility, use of HEPES-buffered medium limits the amount of lab space that must be certified for use with radioactive materials.

Materials

Growth medium: tissue culture medium supplemented with dialyzed serum (see recipe; use the serum concentration required for growth of the cultured cells being studied)

Tissue culture cells

Labeling medium (see recipe)

Radioactive precursor: [^{35}S]sulfate, [^{32}P]orthophosphate, or sugar labeled with either ^{3}H or ^{14}C

Phosphate-buffered saline (PBS; *APPENDIX 2A*), ice cold

Additional reagents and equipment for experiments optimizing label incorporation (see Critical Parameters)

1. Perform small-scale preliminary experiments to determine incubation conditions that give optimal incorporation of label as described (see Critical Parameters). Based on these experiments, choose the appropriate: (1) radioactive precursor, (2) number of cells, (3) labeling medium, (4) volume of labeling medium, (5) concentration of radioactive precursor, and (6) labeling time.
2. Prepare tissue culture cells in either subconfluent monolayers by plating cells in growth medium at high density 1 to 2 days prior to the experiment, or suspensions.

   Suggested plating densities are given in Table 7.8.1.
3. Prepare labeling medium from sterile stocks and warm to 37°C.

   For most experiments with radioactive sugars, this will be Glc-free MEM with nonessential amino acids supplemented with ~0.1 mg/ml Glc and 2% to 5% (v/v) dialyzed serum. For labeling with sulfate and phosphate, use medium deficient in unlabeled precursor. Prepare enough medium for washing and labeling the cells with radioactive precursor (Table 7.8.1).

Table 7.8.1 Parameters for Plating and Labeling Cultured Cells

Culture	Cell number[a]	Wash	Label[b]	Chase[c]
Cell monolayers				
16 mm (24-well plate)	1.4×10^5	0.2 ml	0.1 ml	0.2 to 0.4 ml
35 mm	6×10^5	0.5 ml	0.3 ml	0.5 to 1.5 ml
60 mm	1.5×10^6	1 ml	0.7	1 to 3 ml
100 mm	4×10^6	3 ml	2 ml	3 to 10 ml
Cell suspensions[d]	Not applicable	5×10^6/ml	1.3×10^7/ml	0.5 to 2×10^6/ml

[a]For the Basic Protocol, cell monolayers are plated at the indicated densities 1 to 2 days prior to labeling. The density may have to be adjusted for individual cell lines. When long chases are used the cell density should be reduced. For the long labeling periods required for the Alternate Protocol, lower cell numbers should also be used.

[b]These volumes are suggested for experiments with labeling times of 1 hr or less, such as those of the Basic Protocol. Larger volumes must be used for longer pulse labelings and for the long incubations required in the Alternate Protocol.

[c]For chase incubations, the smaller volumes can be used for short chases. For longer incubations, larger volumes will be required to furnish enough nutrients for the cells.

[d]For cell suspensions, use the indicated cell densities to calculate the appropriate volumes.

4. Prepare a stock of radioactive precursor in warm labeling medium.

   Many sugars are supplied in ethanol solution. If this is the case, remove the appropriate volume of solution from the source vial and transfer to a test tube. Place the tube in a beaker of warm water (30° to 40°C) and dry the ethanol under a stream of nitrogen. Dissolve the radioactive sugar in the appropriate volume of labeling medium (Table 7.8.1) and warm to 37°C. For short labeling incubations, this solution need not be sterile. For longer incubations, filter sterilize using a disposable plastic syringe and filter.

   Best results are usually obtained with precursor of the highest available specific activity. For ^{3}H-labeled sugars, this is usually 30 to 60 Ci/mmol (1.1 to 2.2 TBq/mmol).

   See Critical Parameters, Optimizing labeling conditions, for a discussion of the rationale behind the choice of medium.

5a. *For cell monolayers:* Aspirate the medium and rinse the plate twice with labeling medium.

   Suggested volumes are provided in Table 7.8.1.

5b. *For suspension cells:* Centrifuge the cells 5 min at 200 × *g*, room temperature. Aspirate the supernatant and suspend in warm labeling medium (Table 7.8.1). Repeat once and centrifuge.

6. Add the labeling medium containing the radioactive precursor. For cell suspensions, suspend the cells in the medium. Incubate at the appropriate temperature in a CO_2/air or air atmosphere, depending whether the medium is buffered with bicarbonate or HEPES, respectively.

   The incubation time should have been determined previously from pilot experiments (see Commentary and step 1).

7. Remove the labeling medium, saving an aliquot for analysis of precursor utilization, if desired.

   It may be possible to reuse this solution to label another cell sample if the supply of nutrients and radioactive precursor are not exhausted during the incubation. In this case, the solution may be used immediately or stored frozen.

8. (*Optional*) If a chase incubation is to be performed, wash the cells once in warm growth medium containing normal levels of Glc. Add warm growth medium and incubate at 37°C for the desired time. Remove the medium, saving it for sample isolation if the glycoprotein of interest is secreted. Chill the cells on ice, wash them several times with ice-cold phosphate-buffered saline (PBS), and harvest.

   This growth medium can contain either HEPES or bicarbonate as a buffer, depending on whether or not the chase incubations will be done in a CO_2/air atmosphere. Table 7.8.1 lists suggested volumes.

   For studies of glycan biosynthesis samples will usually be collected at several chase times.

   In most cases, the glycoprotein of interest is isolated by immunoprecipitation (UNIT 7.2).

LONG-TERM LABELING WITH RADIOACTIVE PRECURSOR

ALTERNATE PROTOCOL

This protocol is useful for obtaining molecules with uniformly-labeled glycans, where all the sugar residues of a particular type are labeled to the same specific activity. This uniform labeling is crucial if the glycans are to be used for detailed structural studies. An additional advantage of this technique is that cells can be labeled with precursors that are taken up poorly by cultured cells, namely fucose (Fuc), mannosamine (ManN), xylose (Xyl), N-acetylglucosamine (GlcNAc), N-acetylmannosamine (ManNAc), and sialic acids. As described above (see Basic Protocol), it is important to optimize the labeling

conditions to obtain maximum incorporation and to ensure that the cells are healthy (see Commentary). The labeling may be carried out in either bicarbonate-buffered medium in a CO_2-containing atmosphere or in HEPES-buffered medium in air.

Additional Materials *(also see Basic Protocol)*

Disposable plastic syringe and 0.2-µm syringe filter

1. Carry out small-scale preliminary experiments to optimize the incorporation of label (see Critical Parameters; also see Basic Protocol, step 1).
2. In growth medium, prepare cell suspensions, or prepare subconfluent monolayers by plating cells 1 to 2 days prior to the experiment.

   The cells must be sparse enough that they will survive the entire labeling period. Suggested plating densities are given in Table 7.8.1.

3. Prepare a stock of radioactive precursor in warm growth medium as described (see Basic Protocol, step 4). Sterilize using a disposable plastic syringe and 0.2-µm syringe filter.

4a. *For monolayer cells:* Aspirate the growth medium and replace with medium containing radioactive precursor.

4b. *For suspension cells:* Centrifuge cells 5 min at 200 × *g*, room temperature. Aspirate the supernatant and suspend in labeling medium containing radioactive precursor.

   Suggested volumes are given in Table 7.8.1.

5. Incubate 12 to 48 hr at the appropriate temperature in a CO_2/air or air atmosphere, depending whether HEPES or bicarbonate is the buffer in the labeling medium.

   The incubation time should have been determined previously from pilot experiments (see Commentary and step 1).

6. Remove the labeling medium and save if the glycoprotein of interest is secreted. Otherwise, if required, save an aliquot for further analysis.
7. For isolation of cellular glycoproteins, chill the cells by placing on ice. Wash the cells several times with ice-cold PBS and harvest.

   In most cases the glycoprotein of interest will be isolated by immunoprecipitation (UNIT 7.2).

SUPPORT PROTOCOL 1

ENZYMATIC RELEASE OF *N*-LINKED GLYCANS FROM GLYCOPROTEINS

This protocol can be used to prepare *N*-linked glycans from labeled glycoproteins using peptide *N*-glycosidase F, an enzyme that cleaves intact *N*-linked glycans from polypeptides. All mammalian *N*-linked glycans are substrates for this enzyme (Tarentino et al., 1985; Chu, 1986). Since the enzyme will not use native glycoproteins as substrates, the glycoprotein substrates are first denatured with SDS. Excess nonionic detergent (e.g., NP-40) is added prior to digestion with the enzyme to prevent denaturation of the glycosidase.

Materials

Sample (e.g., see Basic Protocol or Alternate Protocol)
1% (w/v) SDS/0.1 M EDTA/0.5 M 2-mercaptoethanol
200 mM sodium phosphate, pH 8.6 (*APPENDIX 2A*)
10% (w/v) NP-40

Peptide *N*-glycosidase F (PNGase F, *N*-glycanase) from *F. meningosepticumi* or recombinant enzyme expressed in *E. coli* (Glyko or Roche Diagnostics)

Additional reagents and equipment for immunoprecipitation (*UNIT 7.2*)

1. Immunoprecipitate the protein of interest from the sample (*UNIT 7.2*).

   The protein of interest may be collected on a solid support, such as agarose beads. Alternatively, proteins can be precipitated from medium or cell lysates as described below (see Support Protocol 2, steps 1 to 3).

   Lysate from 1×10^7 cells can be processed using this protocol.

2. Add 20 µl of 1% (w/v) SDS/0.1 M EDTA/0.5 M 2-mercaptoethanol to the immunoprecipitate, or to the pellet of precipitated protein, in microcentrifuge tubes. Mix well and heat 5 min at 95°C. Cool to room temperature and microcentrifuge briefly at maximum speed to collect the liquid at the bottom of the tube.

3. Add 20 µl of 200 mM sodium phosphate, pH 8.6, 15 µl of 10% (w/v) NP-40, and 25 µl water. Mix.

4. Add 2 U of peptide *N*-glycosidase F. Incubate 18 hr at 37°C.

5. Mix and microcentrifuge briefly at maximum speed to collect the liquid at the bottom of the tube.

   This solution contains free glycans. These can be characterized by chromatography or subjected to detailed structural analyses. The glycans may be frozen at −20°C and stored indefinitely; their lifetime is limited only by the decay of the radioisotope.

RELEASE OF *O*-LINKED GLYCANS FROM GLYCOPROTEINS

SUPPORT PROTOCOL 2

Incubation of glycoproteins with alkaline sodium borohydride cleaves *O*-linked glycans from glycoproteins and reduces them to the corresponding oligosaccharide alcohols (Carlson, 1968). These released glycans are suitable for structural analysis. The protocol can be performed on culture medium, cell lysates, or immunoprecipitated proteins attached to a solid support (e.g., agarose beads).

Materials

Sample (e.g., see Basic Protocol or Alternate Protocol)
20% (w/v) trichloroacetic acid (i.e., 20 g TCA in 89.4 ml H_2O), ice cold
80% (v/v) aqueous acetone, ice cold
1 M $NaBH_4$/50 mM NaOH
4 M acetic acid
Cation exchange resin: AG 50-X8 (Bio-Rad), H^+ form
Methanol
Nitrogen gas

Disposable chromatography column (e.g., Bio-Rad Poly-Prep columns)
Glass test tubes
Lyophilizer or SpeedVac evaporator

NOTE: Steps 1 to 3 apply only for whole cells or cell extracts. For immunoprecipitates on a solid support, begin at step 4.

1. Precipitate proteins from the sample in microcentrifuge tubes by adding an equal volume of ice-cold 20% (w/v) trichloroacetic acid and incubating 1 hr on ice. Microcentrifuge 10 min at 14,000 × *g*, 4°C. Discard the supernatant.

   If the sample contains a nonionic detergent such as NP-40, it will precipitate at this step.

2. Add 200 µl ice-cold 80% (v/v) aqueous acetone. Vortex, microcentrifuge, and discard the supernatant. Repeat.

   This step will extract the trichloroacetic acid and nonionic detergent from the sample.

   CAUTION: *The wastes from immunoprecipitation are mixed chemical wastes and should be handled appropriately (see Radiation Safety Officer and APPENDIX 1D).*

3. Let the tubes air dry at room temperature to remove most of the acetone. Take care not to let the sample dry completely.

4. Add 200 µl of 1 M $NaBH_4$/50 mM NaOH. Incubate 16 hr at 45°C. Vortex several times during the incubation.

   For immunoprecipitates, the $NaBH_4$ solution is added to the pellet of immunoprecipitated glycoprotein on a solid support.

5. Add 16.6 µl of 4 M acetic acid to destroy excess $NaBH_4$.

   The sample may foam as hydrogen gas is released from decomposition of the $NaBH_4$.

6. Prepare 0.9 ml cation exchange resin in disposable columns. Rinse with 3 ml water.

7. Load each sample onto a column and collect the flowthrough in glass test tubes. Rinse the column with 0.9 ml water, pooling this with the flowthrough.

8. Dry the samples using a lyophilizer or Speed-Vac evaporator.

9. Dissolve each residue in 50 µl methanol. Place the tubes in warm water and evaporate the methanol under a stream of nitrogen. Repeat this step 3 more times.

   This treatment converts the boric acid derived from the $NaBH_4$ to methyl borate, which is removed by evaporation.

10. Dissolve the glycans in water and transfer the liquid to a microcentrifuge tube.

    This solution contains free glycans. These can be characterized by chromatography or subjected to detailed structural analyses. The glycans may be frozen at −20°C and stored indefinitely. Their lifetime is limited by the decay of the radioisotope.

REAGENTS AND SOLUTIONS

*Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see **APPENDIX 2A**; for suppliers, see **SUPPLIERS APPENDIX**.*

Dialyzed serum

Place serum in dialysis tubing and dialyze fetal bovine serum against a 20-fold excess of 0.15 M NaCl at 4°C with stirring (*APPENDIX 3D*). Change the dialysis buffer after 12 and 24 hr. Remove the serum from the dialysis bag and filter sterilize into sterile containers. Store up to 1 month at 4°C or up to 1 year at −80°C.

Labeling medium

Formulas for media deficient in glucose, sulfate, or phosphate are given in Table 7.8.2. These are used for labeling with radioactive sugars, sulfate, or phosphate, respectively. To prepare these media, add the liquid components to water (80% of the final volume). Add the dry components and stir until dissolved. Use either 25 mM sodium bicarbonate or 20 mM HEPES as a buffer, depending on whether or not the medium will be used in the presence of CO_2. Because the calcium and magnesium salts can form insoluble precipitates, add them last after the other salts have dissolved. Antibiotic and antimycotic agents (e.g., penicillin and streptomycin) can be added from liquid concentrates if desired. Adjust the pH to 7.1 to 7.2

Table 7.8.2 Deficient MEM with Nonessential Amino Acids for Incorporation of Sugar, Phosphate, or Sulfate Precursors

Ingredient	Glucose free	Phosphate free	Sulfate free
NaCl	3.4 g	3.4 g	3.4 g
KCl	0.2 g	0.2 g	0.2 g
$NaH_2PO_4 \cdot 2\ H_2O$	79 mg	—	79 mg
$CaCl_2 \cdot 2\ H_2O$	0.13 g	0.13 g	0.13 g
$MgSO_4 \cdot 7\ H_2O$	0.1 g	0.1 g	—
$MgCl_2 \cdot 6\ H_2O$	—	—	0.1 g
Phenol Red	5 mg	5 mg	5 mg
MEM 100× vitamins	5 ml	5 ml	5 ml
MEM 100 × nonessential amino acids	5 ml	5 ml	5 ml
MEM 50× amino acids (with L-glutamine)	10 ml	10 ml	10 ml
D-glucose	—	0.5 g	0.5 g
Buffer[a]			
$NaHCO_3$	1.1 g	1.1 g	1.1 g
HEPES	2.38 g	2.38 g	2.38 g

[a]Use sodium bicarbonate if incubations will be performed in the presence of CO_2; otherwise, use HEPES.

with 1 M HCl or 1 M NaOH and add water to bring the volume to 500 ml. Because this medium is prepared from separate components, the initial pH may be farther from the desired value than for most powdered media. Sterilize by filtration into sterile 100-ml bottles using a 0.2-μm bottletop filter. Store up to 3 months at 4°C.

Labeling with radioactive precursor is usually carried out in medium with a reduced concentration of the precursor and related compounds. Some deficient media can be purchased from suppliers. These media are also readily prepared from standard chemicals and liquid concentrates of MEM components, which are available from most suppliers of tissue culture media (e.g., Life Technologies, Sigma-Aldrich). Other reagents should be tissue-culture grade.

COMMENTARY

Background Information

The glycans are important constituents of glycoproteins and proteoglycans. They provide important functional groups of mature molecules. The glycans are also important in glycoprotein folding and in glycoprotein transport along the secretory and endocytic paths. Glycoprotein glycans are synthesized in a complex process that begins in the endoplasmic reticulum and ends in the Golgi complex (Kornfeld and Kornfeld, 1985; Lidholt, 1997; Perez-Vilar and Hill, 1999). The biosynthesis of these glycans is not only interesting in its own right, it has also been instrumental in understanding the compartmentation and function of the secretory pathway (see *UNITS 15.1 & 15.2*).

Initial studies of the glycans on a glycoprotein of interest are usually performed by studying molecules metabolically labeled in the protein backbone with radioactive amino acids (e.g., [^{35}S]methionine; *UNIT 7.1*). Typically a protein is labeled in a pulse-chase protocol. The protein is then immunoprecipitated (*UNIT 7.2*) and the size of the protein is monitored by SDS gel electrophoresis (*UNITS 6.1 & 15.2*). As the glycans are assembled during transport through the ER and Golgi, the apparent size of the glycoprotein increases on the gel. Additional information may be obtained using several modifications of this experiment.

First, treatment of cells with inhibitors of glycosylation provides information about the nature of the glycans. For example, tunicamycin, which inhibits the synthesis of *N*-linked glycans, has been widely used to test whether these glycans are added to proteins (Elbein, 1987).

Second, glycoproteins may be treated with specific endo- and exoglycosidases after they are isolated from the cells (*UNIT 15.2*). For example, the endoglycosidase peptide *N*-glycanase, which cleaves *N*-linked glycans from the peptide backbone can be used to test for the presence of these structures. Endoglycosidase H is also used widely because it cleaves immature N-glycans but not mature complex-type structures. Similarly, exoglycosidases, including neuraminidases, galactosidases, and mannosidases can be used both separately and in combination to test for the presence of sialic acid, Gal, and Man residues at the nonreducing ends of glycans. In all these cases, the effects of the treatments are assessed by comparing the mobility of treated and untreated samples by gel electrophoresis (*UNIT 15.2*). Some of these procedures can also be carried out on unlabeled proteins detected by immunoblotting with a specific antibody (*UNIT 6.2*).

Although much can be learned about protein glycosylation by this approach, these methods cannot provide information about the details of glycan structure. This analysis requires molecules with radioactively-labeled glycans.

Critical Parameters

Choosing a radioactive precursor

The choice of a radioactive label is determined by many issues. Obviously, the label must be a precursor of one of the sugar residues in the glycan of interest. The complex pathways of sugar uptake and metabolism and their relation to glycoprotein synthesis must also be considered (Fig. 7.8.1).

First, the position of the sugar in the glycan should be considered. If the goal is to study the maturation of a glycan during biosynthesis, sugars close to the reducing end of the structure are the desirable label, because these will be added first. All subsequent glycans in the pathway will be labeled. Conversely sugars that are added late in the pathway will only be found in mature structures.

Second, the ability of cells to take up and incorporate radioactive precursors must be considered. Some precursors are taken up rather poorly. These include fucose, ManN, Xyl, GlcNAc, ManNAc and sialic acids. Other sugars are taken up efficiently. This group includes Gal, Man, and GlcN; however, their uptake and incorporation is competitive with unlabeled Glc in the medium. Consequently, the incorporation of sugars in this group can be significantly improved by labeling in medium with reduced Glc. On the other hand, labeling in Glc-free medium must be avoided because Glc starvation can affect the synthesis of sugar precursors by the cells, which results in the synthesis of glycoproteins with altered glycans (Rearick et al., 1981).

Third, the conversion of intermediates within the cells must be considered carefully. This problem can be a serious one for sugar labeling because many precursors undergo extensive metabolism within mammalian cells. The metabolic pathways are summarized in Figure 7.8.1. For example, labeled GlcN is incorporated into glycoproteins as labeled GlcNAc, GalNAc, and sialic acids. This situation is different from the one encountered when cells are labeled with amino acids. In the latter case, the essential amino acids are effective precursors (e.g., ^{35}S-methionine) because these compounds cannot be synthesized and cells carry out only limited conversions. In some cases the problem of sugar metabolism can be overcome by choosing precursors whose radioactivity is lost upon conversion to other sugars. For example [2-^{3}H]Man is incorporated into glycans primarily as Man, with a small fraction as Fuc. The other pathway for metabolism of this sugar produces unlabeled fructose 6-phosphate, with loss of the radioactivity as $^{3}H_2O$. Specific labeling has also been obtained using cultured cell lines mutated in sugar metabolism. For example, the Chinese hamster ovary (CHO) cell mutant ldlD is defective in UDP-Gal epimerase (Kingsley et al., 1986), which interconverts both the UDP-Glc/UDP-Gal and UDP-GlcNAc/UDP-GalNAc pairs. As a consequence, radioactive Gal and GalN are specific labels in these cells because they are not converted to other sugars and because de novo synthesis is blocked. They are incorporated with high specific activity as Gal and GalNAc, respectively.

Optimizing labeling conditions

Obtaining the maximum incorporation into the glycoprotein of interest requires optimizing the conditions used for metabolic labeling. The optimal conditions will vary depending on which protocol is used (see Basic Protocol and Alternate Protocol). The conditions used will depend on the abundance of the glycoprotein that is being studied. Labeled glycans from abundant glycoproteins can be prepared in adequate amounts from small cultures. Conversely, glycoproteins of low abundance will require larger cultures, larger amounts of label, and

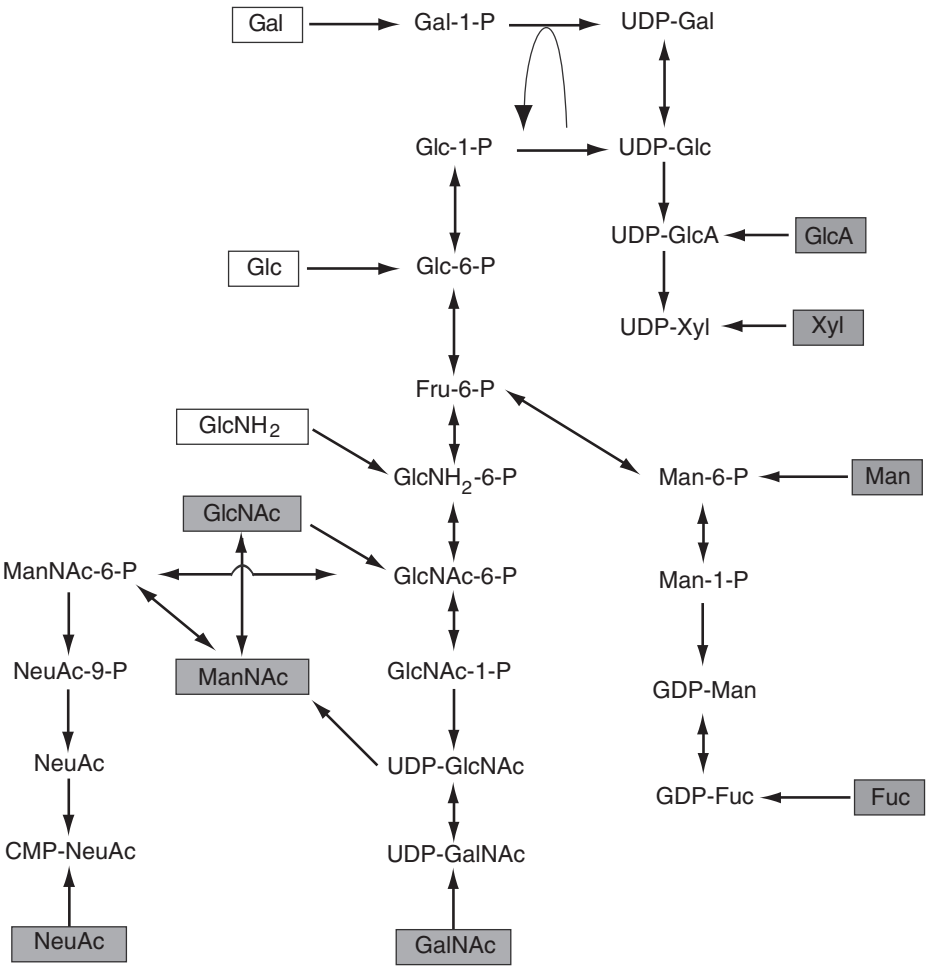

Figure 7.8.1 Pathways of sugar metabolism in mammalian cells. Compounds in boxes are precursors that can be taken up and incorporated into glycoconjugates. Pathways for conversion into the nucleotide sugar donors for biosynthesis are shown. Sugars in open boxes compete with Glc for uptake and incorporation. These are incorporated efficiently and can be used in the labeling procedures (see Basic Protocol and Alternate Protocol). Sugars in shaded boxes do not compete with Glc. They are incorporated less efficiently and should be used only in long-term labeling experiments (see Alternate Protocol). Abbreviations used: Fru, fructose; Fuc, fucose; Gal, galactose; GalNAc, N-acetylgalactosamine; Glc, glucose; GlcA, glucuronic acid; GlcNAc, N-acetylglucosamine; $GlcNH_2$, glucosamine; Man, mannose; ManNAc, N-acetylmannosamine; NeuAc, N-acetylneuraminic acid (a sialic acid); P, phosphate; UDP, uracil diphosphate; Xyl, xylose.

longer labeling periods. The following issues must be considered.

1. *Cell number*. It is advisable to label the largest number of cells possible. For cell monolayers, this is usually achieved with subconfluent cultures grown by plating cells at high density 1 to 2 days before use. For the Alternate Protocol, the cells must not become overgrown during the long labeling incubation. Suggested cell numbers are given in Table 7.8.1.

2. *Labeling volume*. Maximum incorporation is usually achieved when cells are incubated in the smallest volume possible. For pulse labeling (see Basic Protocol), the author usually labels cell suspensions at concentrations up to 1.3×10^7 cell/ml. For monolayer cells, the author uses minimum volumes of 0.3, 0.7, and 2 ml for 35-, 60-, and 100-mm dishes, respectively (Table 7.8.1). These volumes are appropriate for incubations of 1 hr or less. Larger volumes must be used for longer labelings.

3. *Medium*. As discussed above, Glc in the medium competes with the uptake and incorporation of many sugars. Consequently, for the

Basic Protocol, it is advisable to use these precursors in medium with reduced Glc (0.1 mg/ml). Lowering the Glc concentration further is not advisable because Glc starvation can affect glycan synthesis (Rearick et al., 1981). Serum that has been dialyzed to remove low-molecular-weight constituents should also be used. Preparation of dialyzed serum and medium with reduced Glc is described in Reagents and Solutions. The long-term labeling in the Alternate Protocol is usually carried out in complete medium to provide sufficient nutrients.

The cells must not exhaust the supply of Glc or other nutrients in the medium. As a rule of thumb for determining the nutrient supply in the medium, the author estimates that a confluent culture (~1×10^6 cells/ml) in normal medium (1 g/liter Glc) will exhaust its Glc in ~24 hr. This can be used to estimate the length of time available for cells under labeling conditions taking into account the increased cell concentration and reduced Glc concentration in the medium.

4. *Concentration of radioactive precursor*. Small-scale labeling can be carried out to determine the optimal concentration and specific activity (Diaz and Varki, 1995). Radioactive precursor is added to all cultures. In addition, cultures are supplemented with increasing concentrations of unlabeled precursor. The incorporation of radioactivity is determined and plotted against the total concentration of precursor. At low concentrations, incorporation will not depend strongly on concentration. At higher concentrations, incorporation will decrease linearly with concentration. The break point on the curve is the concentration that is saturating for uptake and incorporation. Choose a concentration 1.5- to 2-fold higher than this for incorporation.

5. *Labeling time*. Labeling time is determined by several factors. For pulse labeling (see Basic Protocol) the labeling time must be short enough to generate a homogeneous cohort of labeled molecules at the end of the pulse; however, longer labelings will yield greater incorporation. Consequently, the goal is to select the longest labeling time that still yields a set of molecules with similar glycans in a single cellular location. Most glycoproteins leave the ER within 10 to 40 min of synthesis and traverse the Golgi within a few minutes. The overall time required to traverse the secretory pathway is 30 to 90 min. These times can be used as a guide for choosing pulse labeling times. For long-term labeling (see Alternate Protocol), the turnover rate of the glycoprotein under study is a key factor. Since most cellular proteins have lifetimes of 12 to 24 hr, this limits the yield in long labelings, when the degradation of labeled protein approaches the synthesis of new molecules.

Small-scale pilot experiments should be performed to find optimal labeling conditions. The incorporation should increase with time, demonstrating an adequate supply of nutrients and radioactive precursor. For the Basic Protocol, glycan structure should be monitored to demonstrate that a homogeneous cohort of molecules is generated at the end of the pulse. Finally, the survival of the cells should be monitored by microscopy, trypan blue exclusion, and growth (*UNIT 1.1*) after returning to normal medium to ensure that the cells survive under the labeling conditions. Once optimal conditions have been defined, the amount of labeled glycoprotein recovered should be used to determine how to scale up conditions for preparative experiments.

Anticipated Results

The amount of labeled protein depends on the planned experiments. If the protein will be analyzed by electrophoresis, then only 200 to 1000 cpm/sample is required. If structural studies will be carried out, larger amounts (1×10^3 to 1×10^4 cpm) are required. The amount of labeled protein recovered will depend on the issues discussed in the preceding section. In addition to these factors, the choice of radioisotope is important. Because of their longer half lives, ^{3}H- and ^{14}C-labeled compounds have lower specific activity than ^{35}S and ^{32}P that are used to label proteins and nucleic acids. As an example, ~1×10^4 cpm were recovered in labeled transferrin receptor when 5×10^6 K562 human leukemia cells were labeled with 150 µCi [2-^{3}H]mannose for 45 min in 375 µl (Snider and Rogers, 1986).

As in all pulse-labeling experiments, the incorporation of radioactivity into products occurs with a lag time, while the radioactive label enters intracellular precursor pools. The turnover time of these pools determines the lag time that precedes incorporation into the product of interest. This turnover will also determine the continued incorporation at the beginning of the chase as radioactivity in the precursor pools is incorporated into product. This issue can be an important one for labeling glycans. For example, during the incorporation of [^{3}H]Man into *N*-linked glycans, the mannose is transferred via GDP-Man and dolichol-linked intermedi-

ates. Because the turnover time of these pools is 5 to 10 min in mammalian cells, there is a significant lag time before incorporation begins. In addition, incorporation continues to increase for 5 to 10 min after the beginning of a chase.

Time Considerations

Pulse-chase experiments take up to 24 hr, depending on the length of the chase. In a typical experiment, the pulse-chase labeling can be completed, cells can be lysed, and immunoprecipitation of the desired protein can be begun in a single day. Ten to twenty samples can be labeled and processed at once by one person. If very short pulses and chases are performed, it may not be possible to perform the required manipulation on large numbers of samples. In this case, it may be necessary to do the labeling on two smaller sets of samples. Long-term labeling experiments require 12 to 48 hr. Release of N- and O-linked glycans each requires ~24 hr. Groups of 10 to 20 samples can be handled easily by one person.

Analysis of Oxidative Modification of Proteins

Reactions between protein molecules and reactive oxygen species (ROS) often lead to the modification of certain amino acid residues such as histidine, lysine, arginine, proline, and threonine, forming carbonyl derivatives. Carbonylation of proteins has thus often been employed for the quantification of generalized protein oxidation. Besides carbonylation, other types of oxidative damage that have been investigated in depth are the modifications of cysteine, tyrosine, and aspartate, or asparagine residues. Except for cysteine residues, whose oxidation is often determined by the loss of protein thiol groups, quantification of oxidative damage to tyrosine, and aspartate residues is usually carried out by the measurement of specific oxidation products such as dityrosine, nitrotyrosine (when nitrogen species are the oxidants), and isoaspartate.

This unit provides a variety of protocols for the determination of the protein oxidation products indicated above. A method for the quantification of protein carbonyls using spectrophotometric determination with a carbonyl specific reagent, 2,4-dinitrophenylhydrazine (DNPH), is described (see Basic Protocol 1), as are the details of immunoblot detection using anti-DNP antibodies to detect the carbonylation of specific proteins (see Support Protocol 1). Radiolabeling detection of total and specific proteins using tritiated sodium borohydride, another quantification method, is also included (see Basic Protocol 2 and Support Protocol 2) in this unit. Procedures are outlined for the selective determination of protein thiol groups radiolabeled with [^{14}C] iodoacetamide followed by gel electrophoresis (see Basic Protocol 3). Procedures for dityrosine measurement by GC/MS are described (see Basic Protocol 4), as are preparation of dityrosine standards and nitrotyrosine detection by competitive ELISA (see Support Protocols 3 and 4). Methods for the detection of isoaspartate formation in proteins/peptides, analyzed by a methyl transfer reaction catalyzed by protein-L-isoaspartyl methyltransferase (PIMT), using [^{3}H]methyl-*S*-adenosyl-L-methionine (SAM) as the methyl donor are given (see Basic Protocol 5), and the details of the different buffers needed for the electrophoretic separation of proteins containing isoaspartate residues are described (see Support Protocol 5).

NOTE: Tissue collection and preparation must be carried out in buffers supplemented with antioxidants, such as 100 μM diethylenetriaminepentaacetic acid (DTPA) and 1 mM butylated hydroxytoluene (BHT). The use of antioxidant buffers may be especially critical for the detection of trace amounts of oxidized products formed during aging or under oxidative stress. In addition, all buffers should be bubbled with nitrogen before use.

SPECTROPHOTOMETRIC QUANTITATION OF PROTEIN CARBONYLS USING 2,4-DINITROPHENYLHYDRAZINE

BASIC PROTOCOL 1

Protein carbonyl groups can specifically react with 2,4 dinitrophenylhydrazine (DNPH) to generate protein conjugated hydrazones (protein-DNP) which have a peak absorbance around 360 nm. The use of DNPH thus provides an index for the quantification of protein carbonyl content in protein mixtures or purified proteins.

Contributed by Liang-Jun Yan and Rajindar S. Sohal

Current Protocols in Cell Biology (2002) 7.9.1-7.9.25

Materials

DNPH solution (see recipe)
Protein solution
2 M HCl
20% (v/v) trichloroacetic acid solution, ice-cold (TCA; see recipe)
1:1 (v/v) ethanol/ethyl acetate
0.2% (w/v) SDS/20 mM Tris·Cl, pH 6.8 (*APPENDIX 2A*)
Bicinchoninic acid protein assay kit (BCA; Pierce Co.)
Bovine serum albumin (BSA)

Benchtop centrifuge
Branson 2200 sonicator

1. Add 200 µl of DNPH solution to 1 ml of protein solution. Incubate the mixture at room temperature for 60 min. Prepare a blank by adding 200 µl of 2 M HCl without DNPH to one sample. Incubate under the same conditions.

   For tissue samples, start with 0.5 to 1.0 mg/ml protein. If higher protein concentrations are used for DNPH treatment, it will be very hard to dissolve the pellet after washing off the free DNPH (see Critical Parameters and Troubleshooting).

2. Add 1.2 ml of 20% trichloroacetic acid (TCA) solution to the DNPH-treated protein solution and blank, then incubate on ice 10 min. Centrifuge the sample in a benchtop centrifuge for 10 min at 750 to 1000 × *g*, room temperature.

3. Wash the pellet by adding 3 ml 1:1 (v/v) ethanol/ethyl acetate, followed by centrifugation in a benchtop centrifuge for 10 min at 750 to 1000 × *g* at room temperature. Sonicate at full power, room temperature, in a Branson 2200 sonicator until the pellet is completely broken up.

4. Repeat step 3 twice. Solubilize the final pellet in 1 ml 0.2% (w/v) SDS/20 mM Tris·Cl, pH 6.8.

   If the carbonyl content of lipoproteins is to be determined, use a denaturing buffer of 3% (w/v) SDS/150 mM sodium phosphate buffer, pH 6.8, to dissolve the final pellet (see Critical Parameters and Troubleshooting).

5. After the pellet is completely dissolved, pipet 100 µl of the protein solution for protein assay using the BCA kit. Use bovine serum albumin (BSA) as the protein standard.

   Initially, 6 M guanidine·HCl was used to dissolve the protein pellet, but samples dissolved in such a high concentration of guanidine·HCl are not suitable for further analysis by other techniques such as polyacrylamide gel electrophoresis (SDS-PAGE, UNIT 6.1).

6. Scan the sample in a spectrophotometer from 320 nm to 450 nm. Use the peak absorbency around 360 nm to calculate the carbonyl content. Use the protein samples treated with HCl, but not with DNPH, as blanks.

   The extinction coefficient (ε) for DNPH is 22,000 $M^{-1}cm^{-1}$. Protein carbonyl content (nmol/mg protein) = (absorbance × 10^6/22,000)/mg protein = absorbance × 45.45/mg protein.

7. Identify specific carbonylated proteins by SDS-PAGE (*UNIT 6.1*) and immunoblotting (see Support Protocol 1, also see *UNIT 6.2*).

IMMUNOBLOT DETECTION OF PROTEIN CARBONYLS

SUPPORT PROTOCOL 1

To identify specific proteins that are carbonylated, DNPH-treated proteins can be further separated by gel electrophoresis according to standard techniques. Once the proteins are electrotransferred from the gel to a PVDF membrane, protein-bound DNP in individual proteins can be probed by the use of anti-DNP antibodies (also see *UNIT 6.2*).

Materials

DNPH-treated proteins (Basic Protocol 1)
5% (w/v) nonfat dry milk in Tris-buffed saline with Tween-20 (TBST; see recipe)
Primary antibody (anti-DNP antibody; Sigma)
Secondary antibody: may be horseradish peroxidase–conjugated; select on the basis of nature of primary antibody
Tris-buffered saline with and without Tween-20 (TBS and TBST; see recipe)
ECL detection solution (Amersham)

Minigel electrophoresis unit and transfer unit (Bio-Rad; also see recipe for minigel recipes in *UNIT 6.1*)
Immobilon-P membranes (Millipore)
UV-transparent plastic wrap
X-ray film

Additional reagents and equipment for SDS-PAGE (*UNIT 6.1*), staining gels with Coomassie blue (*UNIT 6.6*), and electroblotting proteins onto membranes (*UNIT 6.2*)

1. Separate DNPH-treated proteins by SDS-PAGE in a minigel electrophoresis unit (*UNIT 6.1*).

   DNPH-treated protein samples dissolved in 0.2% SDS/20 mM Tris buffer, pH 6.8 can be directly mixed with SDS-PAGE loading buffer and analyzed by SDS-PAGE.

   Two gels are usually run simultaneously, one for protein staining by Coomassie blue (UNIT 6.6), and the other for immunoblot detection.

2. Electroblot proteins from polyacrylamide gel to Immobilon-P membrane using a transfer unit per manufacturer's instructions.

   For an efficient transfer, perform tank transfer rather than semidry transfer (see UNIT 6.2 for additional details).

3. Block the membrane by immersing it in 5% (w/v) nonfat dry milk TBST for at least 1 hr at room temperature.

4. Wash the membrane with at least 50 ml TBST for 10 min. Repeat twice.

5. Immerse the membrane in primary antibody solution for at least 1 hr.

   Primary antibody solution is prepared by diluting the primary antibody in TBST solution containing 0.2% (w/v) BSA. Dilution of anti-DNP antibody is highly variable. A range of 1:1,000 to 1:10,000 is recommended (see Critical Parameters and Troubleshooting). Overnight incubation at 4°C usually gives better results. Do not reuse the antibody.

6. Wash the membrane with at least 50 ml TBST three times, each time for 10 min.

7. Incubate the membrane with secondary antibody at room temperature for at least 3 hr.

   Antibody is diluted in TBST solution containing 0.2% (w/v) BSA. Secondary antibody dilution usually ranges between 1:10,000 and 1:25,000 (see Critical Parameters and Troubleshooting). Do not reuse the antibody.

8. Wash the membrane three times with at least 50 ml TBST, each time for 10 min.

9. Wash the membrane twice with at least 50 ml TBS (no Tween 20), each time for 5 min.

10. Immerse the membrane with ECL detection solution for 1 min at room temperature.

    ECL detection solution comes with the enhanced chemiluminescence (ECL) detection kit from Amersham.

11. Drain off excess detection solution and wrap membrane in plastic wrap. Gently smooth out any air bubbles. Immediately expose the membrane to X-ray film.

    Film is usually exposed to the membrane for 0.5 to 2 min.

    During immunoblot detection of protein carbonyls, it is preferable to include both a positive and a negative control on the SDS-PAGE. A positive control can be BSA oxidized by an oxidant such as hypochlorite followed by DNPH treatment as described (see Basic Protocol 1). A negative control is usually the sample not treated with DNPH. The inclusion of a positive control will indicate whether the anti-DNP antibody reacts properly, while the inclusion of a negative control will identify any proteins that cross-react with anti-DNP antibody. Occurrence of a cross-reaction between a protein and the antibody indicates that immunoblotting is not DNP-dependent for this particular protein. In such a case, anti-DNP antibodies from a different source may have to be tried.

BASIC PROTOCOL 2

QUANTITATION OF PROTEIN CARBONYLS DERIVATIZED WITH TRITIATED SODIUM BOROHYDRIDE

When protein concentration is a limiting factor, or when the studied proteins, such as heme-containing proteins, have absorption maxima around 360 nm, protein carbonyls cannot be determined by the use of DNPH. In such cases, tritiated sodium borohydride, which is able to convert protein carbonyl groups into protein-bound ethanol groups, can be used. Because of the introduction of tritium onto oxidized proteins, the method provides a quantitative measurement of protein carbonyl content.

Materials

Protein solution
3 M Tris·Cl, pH 8.6 (*APPENDIX 2A*)
0.5 M EDTA, pH 8.0 (*APPENDIX 2A*)
[^{3}H]$NaBH_4$ working solution (see recipe)
2 M HCl
20% (v/v) trichloroacetic acid solution, ice-cold (TCA; see recipe)
1:1 (v/v) ethanol/ethyl acetate
0.2% (w/v) SDS/20 mM Tris·Cl , pH 6.8 (*APPENDIX 2A)*
0.5% (w/v) SDS/0.1 M NaOH
BCA protein assay kit (Pierce)
Scintisafe Plus 50% cocktail (Fisher Scientific.)

Benchtop centrifuge
Scintillation vials

CAUTION: Perform all incubations in a hood as tritium gas may be released during the reaction. When working with radioactive materials, take appropriate precautions to avoid contamination of the experimenter and the surroundings. Carry out the experiment and dispose of wastes in an appropriately designated area, following guidelines provided by the local radiation safety officer (also see *UNIT 7.1* and *APPENDIX 1D*).

1. Prepare a 1-ml reaction mixture containing 86 mM Tris·Cl, pH 8.6 (add from 3 M stock), 0.86 mM EDTA (add from 5 M stock), 50 mM tritiated sodium borohydride (add from working solution described in Reagents and Solutions), and 0.5 to 1.0 mg of protein.

    86 mM Tris buffer, pH 8.6 is used as the incubation buffer, as the authors have found that if phosphate buffer is used, proteins can be degraded during incubation.

EDTA is included in the reaction mixture so that any potential carbonyl-independent labeling can be prevented.

2. Incubate 30 min at 37°C. Add 200 µl of 2 M HCl to stop the reaction. Add an equal volume of 20% TCA (final concentration 10%) to precipitate the proteins.

   HCl also serves to render the alkaline reaction mixture acidic; otherwise, 10% TCA (final concentration) would not be sufficient to precipitate all proteins.

3. Keep the solution on ice for 10 min and then centrifuge 10 min at 750 to 1000 × *g*, 4°C, in a benchtop centrifuge.

4. Wash the protein pellet with 1:1 ethanol/ethyl acetate at least three times.

5. Dissolve the final pellet in 1 ml 0.5% SDS/0.1 M NaOH. Determine protein concentration for each sample using a BCA protein kit.

   Determination of protein concentration is necessary because the recovery after washing with ethanol/ethyl acetate is rarely 100% (see Critical Parameters and Troubleshooting).

6. Count the radioactivity of each sample by adding 4 ml Scintisafe Plus 50% cocktail to the sample and counting on a scintillation counter, or quantitate by electrophoretic separation and excision of a specific protein band (see Support Protocol 2).

   For the determination of the carbonyl content in a protein mixture, the sample can be counted right after the addition of scintillation cocktail. For the quantitation of the carbonyl content of a specific individual protein, the protein has to be separated from other proteins by means of SDS-PAGE, then processed as described in Support Protocol 2.

GEL ELECTROPHORETIC QUANTITATION OF PROTEIN CARBONYLS DERIVATIZED WITH TRITIATED SODIUM BOROHYDRIDE

SUPPORT PROTOCOL 2

To quantitate the carbonyl content of a specific protein in a protein mixture, as identified by immunoblot technique, protein samples derivatized with tritiated sodium borohydride can be separated by SDS-polyacrylamide gel electrophoresis (*UNIT 6.4*). The target protein band on the gel can then be excised and dissolved in 30% hydrogen peroxide, and incorporated radioactivity measured by the use of a scintillation counter.

Additional Materials *(also see Basic Protocol 2)*

Tritiated protein sample (see Basic Protocol 2)
30% (v/v) hydrogen peroxide

Additional reagents and equipment for SDS-PAGE (*UNIT 6.1*) and staining gels with Coomassie blue R-250 (*UNIT 6.6*).

CAUTION: When working with radioactive materials, take appropriate precautions to avoid contamination of the experimenter and the surroundings. Carry out the experiment and dispose of wastes in an appropriately designated area, following guidelines provided by the local radiation safety officer (also see *UNIT 7.1* and *APPENDIX 1D*).

1. Label protein samples with [^{3}H]$NaBH_4$ (see Basic Protocol 2). Mix the labeled protein sample with SDS-PAGE loading buffer.

   TCA precipitation and washing with organic solvent is not needed.

2. Heat the sample 5 min at 95°C. Separate the tritiated protein sample by SDS-PAGE.

3. Stain the gel with Coomassie blue R-250 (*UNIT 6.6*) and destain until the bands can be clearly visualized.

4. Excise each band with a razor blade.

5. Put the excised gel bands in scintillation vials; incubate for 2 hr at 60°C to dry the gel slices.
6. Add 1 ml of 30% hydrogen peroxide to each vial and incubate for 24 hr at 60°C.
7. Add 4 ml Scintisafe Plus 50% cocktail and keep the vials at 4°C for at least 12 hr.

   Use Scintisafe Plus 50% cocktail because it is specifically designed for gel slices with solubilizers such as hydrogen peroxide. Other cocktails, such as Scintiverse BD, become emulsive after mixing with the solubilized gels, which can decrease counting efficiency.
8. Count radioactivity with a scintillation counter.

BASIC PROTOCOL 3

GEL ELECTROPHORETIC ANALYSIS OF PROTEIN THIOL GROUPS LABELED WITH [^{14}C] IODOACETAMIDE

To identify specific proteins in a tissue sample or a protein mixture exhibiting loss of thiol groups due to oxidative damage, the thiols can be labeled with [^{14}C] iodoacetamide and analyzed by gel electrophoresis. The gels, after being dried onto filter papers, can be autoradiographed. Loss of thiol groups is inversely correlated with radioactive intensity shown by autoradiography (*UNIT 6.3*). Oxidized proteins thus identified can be further quantitated by the use of liquid scintillation counting technique, exactly as described in Support Protocol 2 of this unit.

Materials

Protein sample
1% (w/v) SDS/0.6 mM Tris·Cl buffer, pH 8.6 (*APPENDIX 2A*)
2-mercaptoethanol, neat
Nitrogen gas
500 mM [^{14}C] iodoacetamide, 1 μCi/ml (Amersham)
500 mM nonradiolabeled iodoacetamide
SDS-PAGE gels for Bio-Rad Mini gel system (see recipe):
  10% resolving gel
  4% stacking gel
10% (v/v) trichloroacetic acid (see recipe)

Whatman 3MM filter paper
X-ray film

Additional reagents and equipment for SDS-PAGE (*UNIT 6.1*) and staining gels with Coomassie blue R-250 (*UNIT 6.1*).

CAUTION: When working with radioactive materials, take appropriate precautions to avoid contamination of the experimenter and the surroundings. Carry out the experiment and dispose of wastes in an appropriately designated area, following guidelines provided by the local radiation safety officer (also see *UNIT 7.1* and *APPENDIX 1D*).

1. Dissolve protein sample (up to 1 mg) in 1 ml of 1% SDS/0.6 M Tris·Cl, pH 8.6.

   The inclusion of 1% SDS is meant to completely denature the protein and expose buried thiol groups.
2. Add 10 μl of 2-mercaptoethanol and incubate under nitrogen gas for 3 hr at room temperature.
3. Add 100 μl colorless 500 mM [^{14}C]iodoacetamide solution to a final concentration of 1 μCi/ml, using 500 mM freshly prepared, nonradiolabeled iodoacetamide, in distilled water, to dilute the [^{14}C]iodoacetamide to the proper level of radioactivity. Incubate at 37°C for 30 min with constant gentle agitation.

   CAUTION: *Iodoacetamide is intrinsically unstable in light, especially in solution; reactions should therefore be carried out in the dark.*

Iodoacetamide solutions must be colorless. A yellow color indicates the presence of iodine, which will quickly oxidize protein thiol groups and prevent labeling. Free iodine can also modify tyrosine residues.

The use of nonradiolabeled iodoacetamide will ensure an excess of the reagent over total thiol groups and a complete labeling.

4. Resolve proteins by SDS-PAGE with a 10% separating gel and 4% stacking gel using the Laemmli gel system (*UNIT 6.1*). After proteins are adequately separated, fix the gel in 10% TCA for 60 min. Stain with Coomassie blue R-250 and destain (*UNIT 6.6*).

   The sample incubation prior to loading should be done at 95°C for 5 min.

   With method described in this protocol, actual radioactivity counts can be obtained for any given samples, which can be used for statistical data analysis. A phosphor imager may not be appropriate in terms of quantitation, as it only gives the relative band intensity and thus may not be able to detect slight differences between samples.

5a. *For unknown protein samples:* Dry gels onto Whatman 3MM filter paper and expose to X-ray film for up to two weeks at −70°C.

   To identify target proteins, purify the protein using two-dimensional gel electrophoresis (UNIT 6.4) and perform N-terminal microsequencing, followed by a computer database search.

5b. *Given target proteins:* Proceed to Support Protocol 2, step 4.

QUANTIFICATION OF PROTEIN DITYROSINE RESIDUES BY MASS SPECTROMETRY

BASIC PROTOCOL 4

In this protocol, trace amounts of dityrosine residues formed in proteins due to oxidative damage are first released by acid hydrolysis. The released dityrosine residues are then analyzed by mass spectrometry following derivatization with heptaflurorbutyric anhydride/ethyl acetate. The assay entails the use of radiolabeled dityrosine as the internal standard in order to be quantitative.

Materials

Tissue sample
o,*o*′-dityrosine internal standards, labeled and unlabeled (see Support Protocol 3)
Nitrogen gas
6 M HCl/1% (v/v) benzoic acid/1% (v/v) phenol
Argon
10% and 0.1% (v/v) TCA solution (see recipe)
50 mM $NaHPO_4$/100 μM diethylenetriamine pentaacetic acid (DTPA), pH 7.4
25% methanol
1:3 (v/v) HCl/*n*-propyl alcohol
1:4 (v/v) pentafluoropropionic anhydride/ethyl acetate
Ethyl acetate
n-propanol
0.1% (w/v) trifluoroacetic acid (TFA)

Supelclean SPE reversed-phase C-18 column (Supelco)
Hewlett Packard 5890 gas chromatography equipped with a 12-m DB-1 capillary column interfaced with Hewlett-Packard 5988A mass spectrometer

CAUTION: When working with radioactive materials, take appropriate precautions to avoid contamination of the experimenter and the surroundings. Carry out the experiment and dispose of wastes in an appropriately designated area, following guidelines provided by the local radiation safety officer (also see *UNIT 7.1* and *APPENDIX 1D*).

1. Dry tissue sample under nitrogen and add 50 pmol ^{13}C-labeled *o,o′*-dityrosine as an internal standard.
2. Hydrolyze the sample in a tube flushed with an inert gas (i.e., argon) at 110°C for 24 hr in 0.5 ml of 6 M HCl/1% benzoic acid/1% phenol.
3. Supplement the sample with 50 µl 10% (v/v) TCA solution and pass over a reversed-phase C-18 column that has been previously washed with 12 ml of 50 mM $NaHPO_4$/100 µM diethylenetriamine pentaacetic acid (DTPA), pH 7.4, followed by 12 ml of 0.1% TFA.
4. Elute amino acids with 25% methanol and dry under vacuum for derivatization.

   Dityrosine is stable to acid hydrolysis and ~80% of the internal standard should be recovered from the C-18 column using this procedure.
5. Convert amino acids to carboxylic acid esters by the addition of 200 µl of 1:3 (v/v) concentrated HCl/*n*-propyl alcohol. Heat for 10 min at 65°C.
6. Add 50 µl of 1:4 (v/v) pentafluoropropionic anhydride/ethyl acetate to prepare pentafluoropropionyl derivatives of the amino acids. Heat at 65°C for 30 min.
7. Dry the derivatized samples under nitrogen and redissolve in 50 µl of ethyl acetate.
8. Analyze 1 µl of the sample using a gas chromatograph interfaced with a mass spectrometer with extended mass range. Set the injector and ion source temperature at 250°C and 150°C, respectively. Obtain full scan mass spectra and selected ion monitoring with the *n*-propyl heptafluorobutryl and the *n*-propyl pentafluoropropionyl derivatives of both authentic and isotopically labeled dityrosine in the negative-ion chemical ionization mode with methane as the reagent gas.

   The mass spectrum of the n-propyl heptafluorobutyryl derivative of dityrosine includes a small molecular ion at mass-to-charge (m/z) 1228 (M^-) and prominent ions at m/z 1208 (M^--HF) and 1030 (M^--$CF_3(CF_2)CHO$). Use m/z 1208 to quantify dityrosine.
9. For the analysis of tyrosine, dilute one aliquot of the derivatized amino acid (from step 7) 1:100 (v/v) with ethyl acetate. Inject 1 µl of the sample into the gas chromatograph with a 1:100 split prior to mass analysis. Maintain the initial column temperature of 120°C for 1 min and then increase to 220°C at 10°C/min.

   The mass spectrum of the n-propyl heptafluorobutyryl derivative of tyrosine reveals prominent ions at m/z 595 (M^--HF) and 417 [M^--$CF_3(CF_2)_2CHO$]. Use m/z 417 to quantify tyrosine.

   To ensure that interfering ions are not coeluting with the analyte, monitor the ratio of ion currents of the two most abundant ions of tyrosine and dityrosine in all analyses. Baseline-separate authentic and radiolabeled standards to exhibit retention times identical to those of analytes derived from tissue samples.

SUPPORT PROTOCOL 3

PREPARATION OF *o,o′*-DITYROSINE STANDARD

Dityrosine can be formed by horseradish peroxidase–catalyzed oxidation of tyrosine in the presence of hydrogen peroxide. Dityrosine produced in the mixture can then be purified by chromatographic methods. If radiolabeled dityrosine is to be made, radiolabeled tyrosine should be used as a starting material.

Materials

Horseradish peroxidase (grade I; Boehringer Mannheim)
0.1 M borate buffer, pH 9.1 (see recipe)
5 mM L-tyrosine (Sigma) or [$^{13}C_6$] L-tyrosine (Cambridge Isotope Laboratories) in 0.1 M borate buffer, pH 9.1
30% (v/v) H_2O_2
2-mercaptoethanol
0.01 M NaOH (*APPENDIX 2A*)
200 µM borate buffer, pH 8.8: diluted from 0.2 M borate buffer (see recipe) with H_2O
2.75 × 19.5–cm DEAE cellulose chromatography column (Bio-Rad)
20 µM $NaHCO_3$, pH 8.8 (see recipe)
Concentrated and 100 mM formic acid
100 mM NH_4HCO_3

Benchtop centrifuge
4 × 34.5–cm BioGel P-2 column (200-4-mesh; Bio-Rad)

CAUTION: When working with radioactive materials, take appropriate precautions to avoid contamination of the experimenter and the surroundings. Carry out the experiment and dispose of wastes in an appropriately designated area, following guidelines provided by the local radiation safety officer (also see *UNIT 7.1* and *APPENDIX 1D*).

1. Mix 10 mg horseradish peroxidase with 500 ml of 5 mM tyrosine solution prepared in 0.1 M borate buffer, pH 9.1.

   Use [$^{13}C_6$]tyrosine to prepare o,o′-[$^{13}C_{12}$]dityrosine if radiolabeled dityrosine is needed. Follow guidelines on the use and disposal of radioactive materials.

2. Add 142 µl of 30% H_2O_2 and swirl the solution briefly. After incubation at room temperature for 30 min, add 175 µl of 2-mercaptoethanol to the reaction mixture. Immediately freeze the solution in liquid nitrogen and lyophilize to dryness.

3. Dissolve the lyophilized substance in 250 ml of distilled water and adjust the pH to 8.8 with a few drops of 0.01 M NaOH. Load the solution onto a 2.75 × 19.75-cm DEAE column that has been pre-equilibrated with 20 µM $NaHCO_3$, pH 8.8. Elute the column with 200 µM borate buffer, pH 8.8.

   Under these conditions, tyrosine and dityrosine will elute in the breakthrough fractions.

4. Pool and lyophilize the dityrosine-containing solutions. Resuspend the lyophilized material in 20 ml of cold water and centrifuge for 15 min at 1000 × *g* in a benchtop centrifuge. Extract the pellet with 15 ml of water and combine the two supernatants. Adjust the pH to 7.0 with formic acid and incubate at 0°C overnight.

5. Remove any precipitate by centrifuging for 10 min at 1000 × *g* in a benchtop centrifuge, 4°C. Load the supernatant on a BioGel P-2 column equilibrated with 100 mM NH_4HCO_3. Elute the column with 100 mM NH_4HCO_3 with a flow rate 40 ml/hr. Monitor the elution of dityrosine at 370 nm.

   Under these conditions, dityrosine elutes earlier than tyrosine. Therefore, fractions constituting the first peak should be collected. Dityrosine elution can also be monitored by the use of a fluorometer (λ_{ex} = 280 nm; λ_{em} = 300 nm); however, the collected fractions need to be diluted before measurement.

6. Collect dityrosine fractions and lyophilize. Dissolve the lyophilized dityrosine in 20 ml of 100 mM formic acid. Adjust the pH to 2.5 by adding concentrated formic acid. Remove any precipitate that is formed during the pH adjustment by microcentrifuging

for 10 min at 1000 × *g*, room temperature, in a benchtop centrifuge. Load the solution to a BioGel P-2 column (same as above) equilibrated with 100 mM formic acid. Elute the column with 100 mM formic acid, lyophilize the dityrosine-containing solution, and store at −20°C.

The yield of dityrosine should be around 20%.

SUPPORT PROTOCOL 4

ANALYSIS OF PROTEIN-BOUND NITROTYROSINE BY A COMPETITIVE ELISA METHOD

The availability of anti-nitrotyrosine antibodies provides a very sensitive method for the detection of protein-bound nitrotyrosine in tissue samples, namely enzyme-linked immunosorbant assay (ELISA). In this protocol, nitro-BSA is coated onto ELISA plates, and nitrotyrosines are quantitated by the use of anti-nitrotyrosine antibodies. Competition is accomplished by adding either a potentially nitrated protein sample or a known amount of nitrotyrosine (in the form of nitro-BSA) as a standard. Each competes with the coated nitrated proteins for antibody binding. The amount of antibody that binds to the coated nitro-BSA is inversely proportional to the amount of nitrated protein (sample or standard) present in the solution added to the well of the plate.

Materials

10 µg/ml nitro-bovine serum albumin (nitro-BSA; Alexis Biochemicals) in plate coating buffer
Nitro-BSA standard (see recipe)
ELISA buffers (see recipe):
  Plate coating buffer
  1× phosphate-buffered saline/Tween 20 (PBST)
  Blocking buffer
  1× diethanolamine (DEA) buffer
Protein sample
Primary antibody: mouse anti-nitrotyrosine antibodies (Upstate Biotechnology)
Secondary antibody: rabbit anti-mouse IgG conjugated with alkaline phosphatase
Tris-buffered saline/Tween-20 (TBST; see recipe)
1 mg/ml *p*-nitrophenyl phosphate (5-mg tablets; Sigma) in DEA buffer (see recipe for ELISA buffer)
96-well ELISA plates
Plastic wrap
Plate reader

Prepare the ELISA plate

1. The day before the assay, coat each of the wells of a 96-well ELISA plate that are to be used to assay protein samples with 100 µl of 10 µg/ml nitro-BSA in plate coating buffer (1 µg nitro-BSA/well). Leave the wells to be used for blanks empty.

   Plate coating may have to be optimized (see Critical Parameters and Troubleshooting).

2. Wrap the plate with plastic wrap and incubate at 4°C overnight.

3. Add 100 µl of each protein sample (1 to 10 µg/ml) to be assayed to 100 µl primary antibody diluted 1:500 with blocking buffer, and incubate at 4°C overnight. Add 100 µl of this solution to the designated well. Prepare nitro-BSA competitor the same way for a standard curve.

   The nitrotyrosine in BSA and the protein sample will compete with the coating antigen (nitro-BSA in this case) for antibody binding.

The standard curve range is determined with serial dilutions of nitro-BSA between 10 µg/ml to 1 µg/ml. This will give a curve whose middle part is linear and flanked by a plateau curve on either side. The points that signal the start and the end of the linear part should be taken as the range for the standard curve.

A series of dilutions of the protein sample may need to be tried in order to have readings that will fall within the linear range of nitro-BSA competition curve (see Critical Parameters and Troubleshooting).

Perform ELISA

4. The day of the assay, rinse the plate three times with 1× PBST, add 300 µl blocking buffer to each well, including blanks, and incubate for 60 min at room temperature.
5. Remove the blocking buffer from the plate and discard. Add 100 µl of a serial dilution of each of the protein samples prepared in primary antibody solution (step 3) to each sample well. Add 100 µl of a serial dilution of nitro-BSA prepared with primary antibody to the designated wells on the same plate to generate a standard curve. Add 100 µl 1× PBST, without antibody, to blank wells.
6. Incubate at room temperature for 2 hr.
7. Rinse three times with TBST. Add 100 µl of secondary antibody diluted 1:1000 with blocking buffer to each sample and standard well. Add 100 µl PBST to blank wells.
8. Incubate at room temperature for 2 hr.

Detect nitrotyrosine

9. Discard reaction solutions from the wells and wash three times with PBST. Add 100 µl of 1 mg/ml *p*-nitrophenyl phosphate to all wells including the blanks.

   Remove any air bubbles with a clean needle.

   p-Nitrophenyl phosphate is a substrate for alkaline phosphatase and will provide a colorimetric group upon cleavage.

10. After 30 min, clean the bottom of the plate with a Kimwipe and read at 450 nm on a microtiter plate reader. Estimate nitrotyrosine concentration using the nitro-BSA standard curve. Express nitrotyrosine concentration in the protein sample as an equivalent of nitrotyrosine in nitro-BSA.

ENZYMATIC ANALYSIS OF ISOASPARTATE FORMATION

BASIC PROTOCOL 5

A novel technique for the determination of isoaspartate formation involves the use of protein-L-isoaspartyl methyltransferase (PIMT). PIMT catalyzes methyl transfer reactions using methyl-*S*-adenosyl-L-methionine (SAM) as the methyl donor. Because PIMT is highly specific for protein isoaspartate residues, the use of tritiated SAM, where the methyl group is radiolabeled, provides a quantitative method for the determination of isoaspartate residues formed in proteins/peptides.

Materials

0.2 M Bis-Tris buffer, pH 6.0 (see recipe)
10 µM [^{3}H]methyl-S-adenosyl-L-methionine (5 to 15 Ci/mmol; [^{3}H] SAM; NEN)
Protein-L-isoaspartyl methyltransferase (PIMT; Promega Corporation or purified from a known source)
0.2 M NaOH (*APPENDIX 2A*)
Safety-Solve II counting fluor (Research Products International)

Sponge plugs (Jaece Industries): cut into small pieces
Scintillation vials with extra caps

CAUTION: [^{3}H]methanol is volatile at room temperature. Perform all reactions under a hood. When working with radioactive materials, take appropriate precautions to avoid contamination of the experimenter and the surroundings. Carry out the experiment and dispose of wastes in an appropriately designated area, following guidelines provided by the local radiation safety officer (also see *UNIT 7.1* and *APPENDIX 1D*).

1. Add [^{3}H]SAM to a final concentration of 10 µM to a protein sample solution in 0.2 M Bis-Tris buffer, pH 6.0, containing 40 U of PIMT in a microcentrifuge tube.

   The sample protein amount is usually between 0.5 and 1 mg and the total reaction volume is 50 µl.

   Blanks that do not have the protein to be analyzed and standards that have known concentrations of isoaspartate should be carried out under the same conditions at the same time.

   The Promega version of the enzyme comes included in the ISOQUANT Isoaspartate Detection kit.

2. Incubate the reactions for 30 min at 30°C.
3. Place the tubes on ice for 15 min to stop the PIMT-catalyzed methyl transfer reaction.
4. Microcentrifuge the tubes at 4°C for 2 min to bring all of the liquid to the bottom of the tube. Place on ice.
5. Add 50 µl of 0.2 M NaOH to hydrolyze the methyl esters so that [^{3}H] methanol can be released from the assayed proteins.

   Tubes may be vortexed briefly to collect liquid.

6. Immediately transfer 50 µl of each reaction solution to a sponge insert in a scintillation vial cap and place the cap on a vial containing 4 ml Safety-Solve scintillation cocktail.
7. Incubate the capped vials at 37°C for 60 min.

   Diffusion of methanol into the scintillation liquid is time-dependent. To obtain reproducible results, it is critical to incubate all reactions for the same length of time.

8. Remove the caps and replace with new caps that do not contain sponge inserts.
9. Count the samples in a scintillation counter.

SUPPORT PROTOCOL 5

GEL ELECTROPHORETIC ANALYSIS OF ISOASPARTATE FORMATION

To identify which proteins in a tissue sample or a protein mixture contain isoaspartate residues, the protein sample, incubated with [^{3}H]SAM and PIMT (see Basic Protocol 5), can be further analyzed by SDS-PAGE (*UNIT 6.1*) after mixing with acid SDS-PAGE sample buffer (see recipes for acid SDS-PAGE buffers). Protein bands can then be excised from the gel and solubilized in 30% hydrogen peroxide, exactly as described in Support Protocol 2 of this unit; however, for the measurement of isoaspartate formation, acid SDS-PAGE (pH 2.4), rather than the Laemmli gel system (pH 8.3), should be performed (see recipes for acid SDS-PAGE). This is necessary, as high pH running buffer will hydrolyze the base-labile isoaspartate methyl esters, leading to the release of [^{3}H]methanol into the running buffer. Do not use sodium hydroxide to stop the PIMT-catalyzed reaction when the samples are to be analyzed by acid SDS-PAGE.

REAGENTS AND SOLUTIONS

*Use deionized distilled water for the preparation of all buffers. For common stock solutions, see **APPENDIX 2A**; for suppliers, see **SUPPLIERS APPENDIX**.*

Acid SDS-PAGE buffers (pH 2.4)

2× resolving gel buffer:
0.1 M H_2NaPO_4
2% (w/v) SDS
6 M urea
Adjust pH to 2.4 with HCl
Store up to several months at 4°C

1× running buffer:
0.03 M NaH_2PO_4
0.1% (w/v) SDS
0.2 M acetate
Adjust pH to 2.4 with HCl
Store up to 1 year at room temperature

2× sample buffer:
2% (w/v) SDS
6 M urea
10% (v/v) glycerol
0.01% (w/v) pyronin Y dye
16.5 mM NaCl
Adjust pH to 1.4 with HCl
Store up to 1 year at −20°C

2× stacking gel buffer:
2% (w/v) SDS
6 M urea
0.033 M NaCl
Adjust pH to 1.4 with HCl
Store up to 2 months at 4°C

Bis-Tris buffer, 0.2 M, pH 6.0

41.84 g bis-Tris (Sigma)
Adjust volume to 1 liter with H_2O
Adjust pH with concentrated HCl
Store up to 6 months at 4°C

Borate buffer, 0.1 M, pH 9.1

6.184 g boric acid
Adjust volume to 1 liter with H_2O
Adjust pH with 1 M NaOH
Store up to 2 months at room temperature

Borate buffer, 0.2 M, pH 8.8

12.37 g boric acid
Adjust volume to 1 liter with H_2O
Adjust pH with 1 M NaOH
Store up to 2 months at room temperature

DNPH solution

Dissolve 198 mg 2,4-dinitrophenylhydrazine (DNPH; mol. wt. 198.1) in 100 ml 2 M HCl (10 mM DNPH final). Store up to 1 year at room temperature in the dark since DNPH can be destroyed by light.

DNPH may require 1 to 2 hrs of constant stirring for complete solubilization.

ELISA buffers

Blocking buffer: Prepare 0.2% (w/v) gamma globulin (Sigma) in PBST (see below). Filter this buffer through 0.45 µm filter and store up to 1 week at 4°C.

1× diethanolamine (DEA) buffer:
24.25 ml 98% diethanolamine
200 ml H_2O
0.25 ml 20% NaN_3
25 mg $MgCl_2 \cdot 6H_2O$
Adjust pH to 9.8 with concentrated HCl
Bring to 250 ml with H_2O

Use Milli-Q purified water or equivalent.

10× phosphate-buffered saline/Tween 20 (PBST):
80 g NaC1
2 g KH_2PO_4
11.5 g Na_2HPO_4
2 g KC1
5 ml Tween 20
10 ml 20% (w/v) NaN_3
Dilute to a total volume of 2 liters with with H_2O
Store up to 2 months at room temperature

Plate coating buffer:
0.795 g Na_2CO_3
1.465 g $NaHCO_3$
0.5 ml 20% (w/v) NaN_3
Bring to 500 ml with H_2O
If necessary, adjust the pH with 1 M NaOH to ensure it is ~9.6

Use Milli-Q purified water or equivalent.

[^{3}H]Sodium borohydride ([^{3}H]$NaBH_4$) working solution

Add 5 ml 1 M nonradiolabeled sodium borohydride dissolved in 0.1 M NaOH to the original bottle in which tritiated sodium borohydride (activity 222.3 mCi/mmol; NEN Life Science Products) was received. Divide the solution into 100-µl aliquots in microcentrifuge tubes (0.5 ml/tube) and store up to 2 years at −80°C.

$NaHCO_3$, 20 µM, pH 8.8

16.8 mg $NaHCO_3$
Adjust volume to 1 liter with H_2O
Adjust pH with 1 M NaOH
Dilute 1:10 just before use
Store up to 2 months at room temperature

Nitro-BSA standard

Adjust the pH of a 5 mg/ml BSA solution (in water) to 3.5 with acetic acid. Add concentrated sodium nitrite (200 mM) to the BSA solution to obtain a final concentration of 1 mM. Incubate the reaction on a rotator at 37°C for 24 hr. The color change of the solution from colorless to yellow after the incubation usually indicates the presence of nitrotyrosine. Dialyze the nitrated BSA solution overnight against ELISA coating buffer. Determine nitrotyrosine concentration at 430 nm using a spectrophotometer ($\varepsilon = 4100\ M^{-1}cm^{-1}$, pH > 8.5). Store up to 2 months at 4°C.

SDS-PAGE gels (for Bio-Rad Mini gel system)

10% resolving gel:

6.1 ml 2× resolving buffer (Bio-Rad)
2.5 ml 40% 29:1 acrylamide/bisacrylamide
0.1 ml 0.06%, w/v $FeSO_4$
0.1 ml 1% (w/v) ascorbic acid
1.1 ml distilled water
0.1 ml 0.3% H_2O_2
Store up to 6 months at 4°C

4% stacking gel:

4.0 ml 2× stacking gel buffer (Bio-Rad)
0.5 ml 40% 29:1 acrylamide/bisacrylamide
0.065 ml 0.06%, w/v $FeSO_4$
0.065 ml 1%, w/v ascorbic acid
0.305 ml distilled water
0.065 ml 0.3% H_2O_2
Store up to 6 months at 4°C

IMPORTANT NOTE: *$FeSO_4$, ascorbic acid, and H_2O_2 are used as gel polymerization catalysts; prepare fresh.*

Trichloroacetic acid (TCA) solution, 20%, 10%, and 0.1% (v/v)

Prepare TCA stock solution by adding 227 ml water to a 500-g bottle of TCA. Add 10 ml of TCA stock solution to 40 ml of water to prepare 20% (v/v) TCA. Dilute to appropriate percentage with water. Store up to 1 year at room temperature.

Tris-buffered saline with and without Tween-20 (TBST and TBS)

100 mM Tris·Cl, pH 7.5 (*APPENDIX 2A*)
0.9% (w/v) NaCl
0.1% (v/v) Tween-20 (omit for TBS)
Store up to 2 months at 4°C

COMMENTARY

Background Information

Proteins are acknowledged to be one of the major targets of endogenously generated reactive oxygen species (ROS; Stadtman, 1992). The study of protein oxidative modifications not only contributes to the elucidation of the mechanisms of ROS-mediated damage, but may also aid in understanding how protein oxidation is linked to losses in physiological functions under pathological processes or during aging. Furthermore, the identification of the protein targets of oxidative damage may potentially lead to the development of strategies that may ameliorate oxidative stress.

Several factors seem to be involved in intracellular accumulation of oxidized proteins. One major factor is the cellular level of oxidative stress, determined by the balance between the rate of ROS generation and the efficiency of antioxidative defenses (Stadtman and Berlett, 1997). The other factor determining the steady-state amount of oxidized proteins is the activity of proteolytic enzymes (Stadtman and Berlett, 1997). It is now firmly established that mild oxidation of proteins

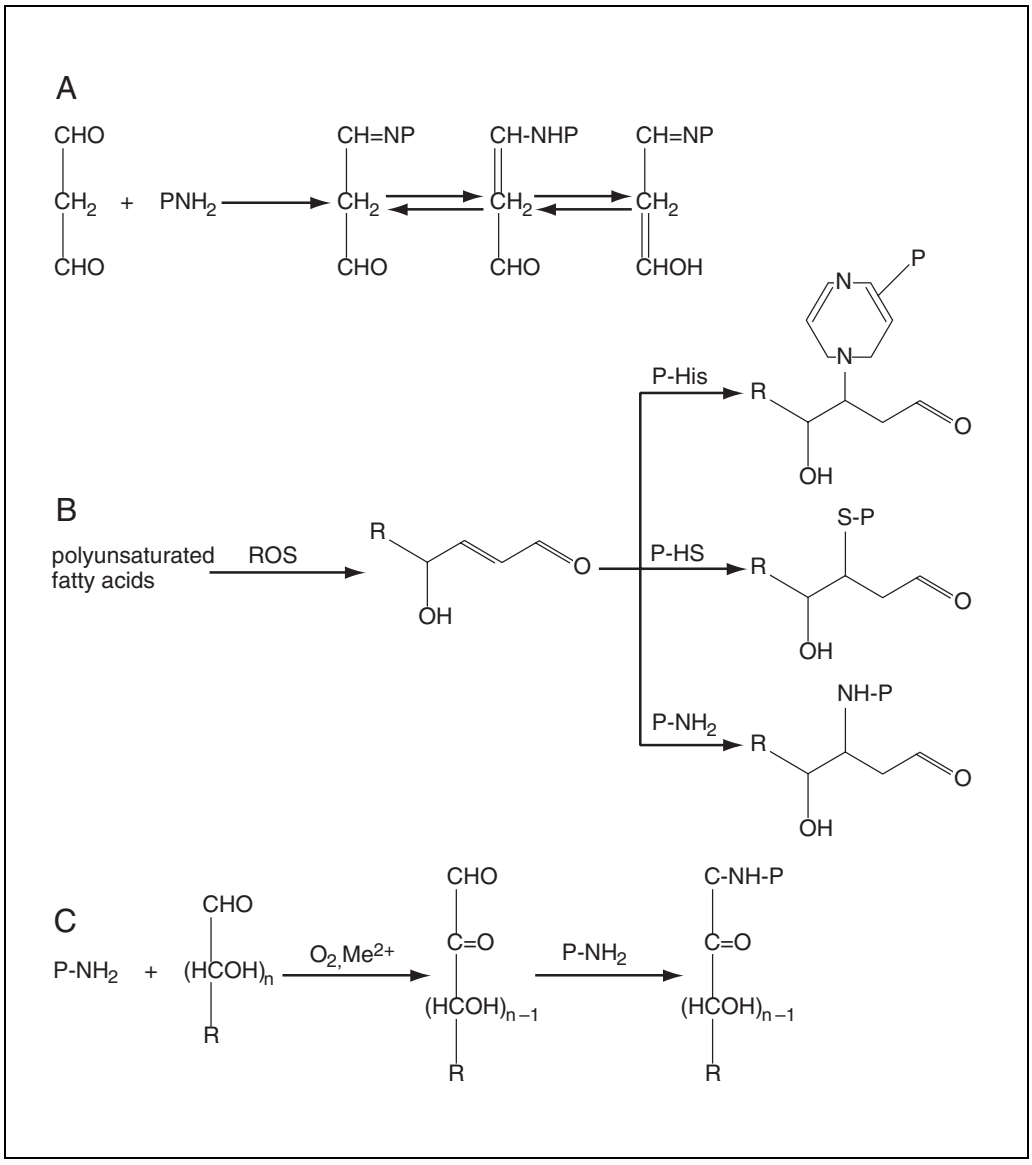

Figure 7.9.1 Generation of protein carbonyls by glycation and glycoxidation and by reactions with lipid peroxidation products of polyunsaturated fatty acids. (**A**) Reactions of protein amino groups (PNH_2) with the lipid peroxidation product, malondialdehyde. (**B**) Michael addition of 4-hydroxy-2-nonenal to protein lysine (P-NH_2), histidine (P-His), or cysteine (PSH) residues. (**C**) Reactions of sugars with protein lysyl amino groups (P-NH_2). "Me" represents "metal ions." Abbreviation: ROS, reactive oxygen species.

facilitates their eventual degradation by proteases, while heavily oxidized proteins in which cross-links usually occur are resistant to proteolysis (Davies et al., 1987). Oxidative damage to proteases themselves can further attenuate cellular ability to degrade oxidized proteins (Agarwal and Sohal, 1994).

Analysis of protein carbonylation

Some known mechanisms by which protein carbonylation occurs are shown in Figure 7.9.1. The reaction between DNPH and protein carbonyls, shown in Figure 7.9.2, was initially used for the measurement of metal catalyzed oxidative damage to glutamine synthase (Levine, 1983). The procedure, although very useful for the determination of protein carbonyl content in tissue samples, is not selective and is subject to interference by proteins containing chromophores that have absorbance near 360 nm. In contrast, immunoblotting is highly selective and can detect carbonylation of individual proteins, but the method is not meant to provide quantitative information. The borohydride reduction method, when used in conjunction with gel electrophoresis, is both selective and quantitative (Yan and Sohal, 1998a). Using protein carbonyls as an index, oxidative dam-

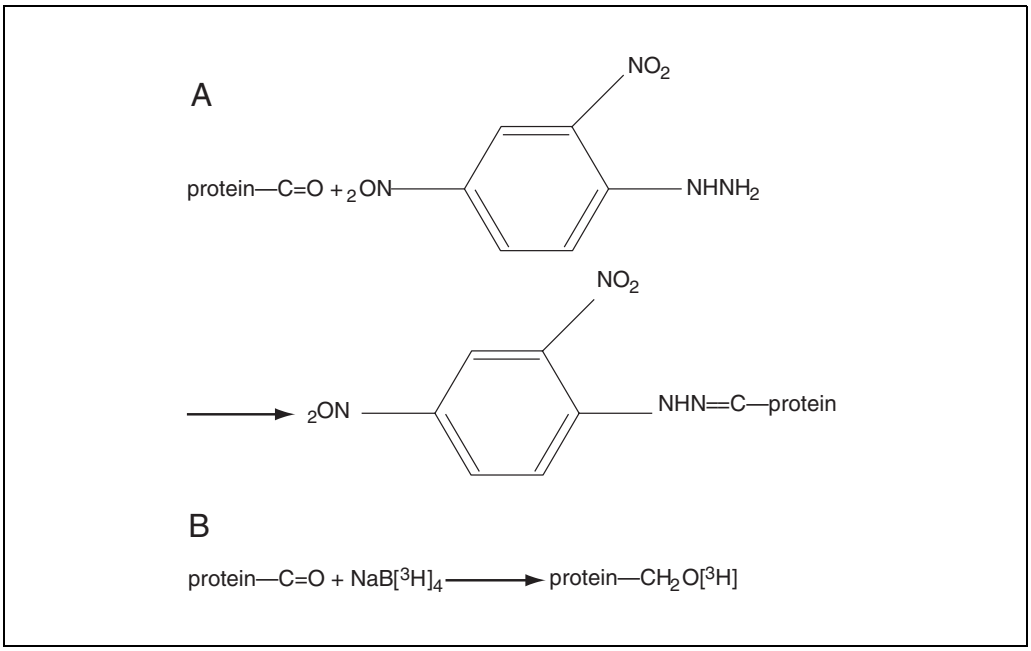

Figure 7.9.2 Methods for labeling protein carbonyls: (1) Derivatization of protein carbonyls with 2,4- dinitrophenylhydrozine (DNPH), forming protein conjugated dinitrophenylhydrozones. (2) Derivatization of protein carbonyls with tritiated sodium borohydride.

age to proteins has been found to be associated with aging and oxidative stress as well as a number of pathologies (Stadtman, 1992). Moreover, protein oxidation during aging has been recently established to be a highly selective phenomenon. Using the housefly as a model system, the authors' laboratory has demonstrated that in flight-muscle mitochondria, only aconitase and adenine nucleotide translocase exhibited a discernible age-dependent increase in protein carbonylation and a corresponding loss in their activities (Yan et al., 1997; Yan and Sohal, 1998b).

The four protocols for the measurement of protein carbonyls described in this unit are relatively simple and easy to perform, without the requirement of elaborate instrumentation. Analysis of protein carbonylation by methods other than those described here may also be used, should the relevant equipment be readily accessible. One such procedure requires HPLC separation, which has the advantage that the removal of free DNPH is unnecessary because the HPLC column can separate proteins from small molecules (Levine et al., 1994). HPLC requires a very small amount of proteins and can monitor both protein and protein-bound DNP absorption at two wavelengths simultaneously. The derivatization of protein carbonyls by DNPH, however, needs to be carried out in solutions that are compatible with HPLC columns. Another method, which also involves the use of anti-DNP antibodies, is the ELISA measurement of protein carbonyls (Buss et al., 1997). This method is quite sensitive and may be used for determination of whole tissue carbonyls, but it is only semiquantitative and lacks selectivity.

Recently, a fairly new method, the MALDI-MS technique, has been applied for the determination of protein carbonyls. The method works very well for small peptides or proteins such as cytochrome c, but for large peptides, the proteins need to be digested with proteases. The resulting small peptides are then separated by HPLC. A potential problem for large proteins with this method is that if a large number of small peptides are generated after protease digestion, HPLC separation of these peptides can become very tedious.

Analysis of protein thiol groups

Protein thiol groups (mainly cysteine residues) not only stabilize and maintain the three-dimensional conformation of many proteins but are also involved in biological redox couplings. Due to their high reactivity, protein thiol groups are very sensitive to oxidative damage induced by a variety of oxidation systems. Loss of protein thiol groups has been demonstrated during aging and in disease (Hughes et al., 1980; McKenzie et al., 1996).

Most of the currently available methods for quantitative analysis of protein thiol groups depend upon the formation of chemical derivatives. Due to the nucleophilic property of the –SH group, alkylation of cysteine thiol groups by

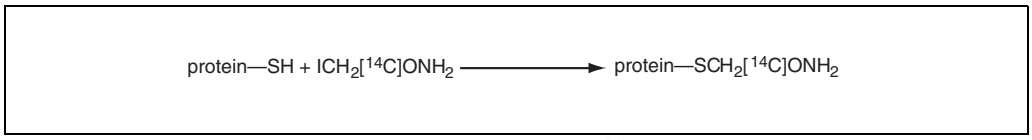

Figure 7.9.3 Radiolabeling of protein thiol groups with [^{14}C]iodoacetamide.

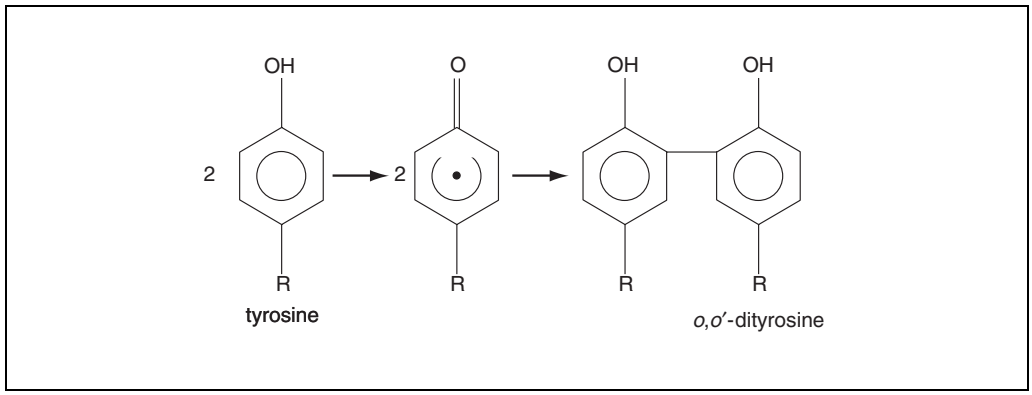

Figure 7.9.4 Formation of one molecule of *o,o′*-dityrosine from two molecules of tyrosine via tyrosyl radical intermediates.

alkylators such as iodoacetamide is widely used for either blocking or quantification of protein-bound thiols. There are two advantages when iodoacetamide is used. First, iodoacetamide does not create a carboxylate functional group; therefore, no new negative charges are introduced into the protein (Fig. 7.9.3). This may be necessary when the alkylated protein is to be analyzed by isoelectric focusing gel electrophoresis. Second, the bond formed from the reaction of iodoacetamide and a thiol group is a stable thioether linkage that is irreversible under normal gel electrophoretic conditions. Furthermore, when radiolabeled iodoacetamide is used, the reaction provides a highly quantitative method for the measurement of protein thiol groups. The use of iodoacetamide, together with gel electrophoresis, has led to a successful identification of glyceraldehyde-3-phosphate dehydrogenase as the enzyme that exhibits the most loss of protein thiol groups during inflammatory bowel disease (McKenzie et al., 1996).

Another classical method for the determination of protein thiol groups involves the use of 5,5′-dithiobis (2-nitrobenzoic acid) also known as DTNB or Ellman's reagent (Ellman, 1959). DTNB undergoes disulfide interchange with the release of 5-thio-2-nitrobenzoic anion (TNB), which has an absorption maximum at 412 nm and can be quantitated spectrophotometrically. The disadvantage of the DTNB method is that TNB is highly subject to reoxidation in an alkaline solution in the presence of oxygen and metal ions and its molar extinction coefficient changes slightly as a function of the solvent system used. In addition, DTNB itself can undergo hydrolysis of its disulfide bond at a pH higher than 9. Moreover, without prior protein purification, DTNB cannot be used for the quantification of individual proteins that exist in tissue homogenates and may have undergone the most loss of thiol groups caused by oxidative damage during aging or in diseases.

Analysis of tyrosine modification

Dityrosine formation. o,o′-Dityrosine is formed either when a hydroxyl radical cross-links tyrosines or by the reaction between protein bound tyrosine and a tyrosyl radical (Fig. 7.9.4). Dityrosine exhibits intense fluorescence at ~400 nm and thus can be measured with an excitation wavelength of ~315 nm in alkaline solutions or ~284 nm in acidic solutions. Based on this property, dityrosine, formed in proteins oxidized in vitro, have been frequently measured by HPLC equipped with a fluorometer as the detection device (Giulivi and Davies, 1993). A disadvantage is that molecules that co-elute, but structurally differ from dityrosine may confound the procedure. Moreover, the HPLC fluorometric method has not yet been successfully used for the detection of dityrosine formation during natural aging, suggesting that the amount of dityrosine in proteins, without challenge by severe oxidative stress, is below HPLC detection limit.

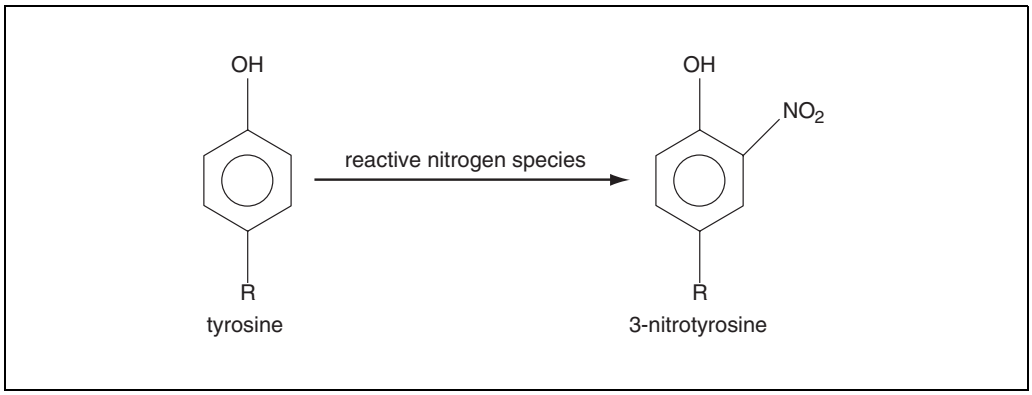

Figure 7.9.5 Formation of nitrotyrosine via reactive nitrogen species-mediated nitration of tyrosine.

In contrast, the GC/MS method described in this unit for dityrosine detection is highly sensitive and can structurally distinguish dityrosine from other tyrosine-modified derivatives, thereby reducing potential confusions caused by compounds that coelute with dityrosine during chromatography. GC/MS analysis also permits the use of a stable, isotopically labeled internal standard which, other than its heavy isotope, is structurally identical to dityrosine, and therefore behaves identically during sample preparation and analysis. Inclusion of such a standard also corrects for the dityrosine loss during processing and thus increases the precision of quantitative measurements. Using the GC/MS method, dityrosine concentrations in various mouse tissues have been found to be elevated during aging and are significantly decreased by caloric restriction (Leeuwenburgh et al., 1997). However, this method lacks selectivity when tissue samples are used as experimental materials, since no distinction can be made in the degree of dityrosine content among different protein species.

Nitrotyrosine formation. Nitrotyrosine is formed by reactions between tyrosine and reactive nitrogen intermediates (Fig. 7.9.5). Its level is elevated, especially during inflammation. Peroxynitrite, produced by the reaction between the nitrogen monoxide radical and superoxide, has been proposed to be the major oxidant that causes nitrotyrosine formation in living systems (Ischiropoulos et al., 1992). Nitrotyrosine can be easily determined spectrophotometrically as its maximum absorbance ranges from 350 nm to 450 nm, shifting from 365 nm (colorless) at pH < 3 to 428 nm (yellow) at pH > 9. However, the amount contained in tissue samples without oxidative challenge is far below the detection limit of a spectrophotometer. The ELISA method described in this unit, although only semiquantitative, is very sensitive for the measurement of nitrotyrosine in tissue samples. This method is especially useful when individual proteins in tissue samples need not be analyzed. For identification of specific proteins that might exhibit selective nitration during aging or under oxidative stress, immunoblot detection using anti-nitrotyrosine antibodies may be preferred.

Analysis of isoaspartate formation

Isoaspartate residues are usually formed from the deamidation of asparaginyl residues or isomerization of aspartyl residues (Fig. 7.9.6). Formation of isoaspartate residues in a protein not only alters the protein's structure, but may also cause the loss of the protein's activity. Although isoaspartate formation was initially found in in vitro aging of proteins stored at neutral pH (Graf et al., 1971), the discovery of the enzyme protein-L-isoaspartyl methyltransferase (PIMT) suggests that isoaspartate formation in proteins is physiologically relevant (Clark, 1985). Indeed, it has been found that a variety of tissue samples are able to be tritiated when incubated in the presence of PIMT and [^{3}H]*S*-adenosyl methionine (SAM; Aswad, 1995), demonstrating the occurrence of isoaspartate formation in vivo. Therefore, methods for the detection and quantification of isoaspartate formation in proteins/peptides are of interest to investigators studying post-translational modification of proteins.

The discovery of PIMT also provides a useful tool for the quantification of isoaspartate formation in proteins (Fig. 7.9.7), as described in this unit. The only limitation of the method, however, is that PIMT, as a single enzyme, is not commercially available. Isoaspartate formation can also be measured by isoelectric focusing gel analysis or proteolytic digestion of the protein followed by mass spectral analysis of the peptides resolved by reversed-phase HPLC. The isoelectric focus-

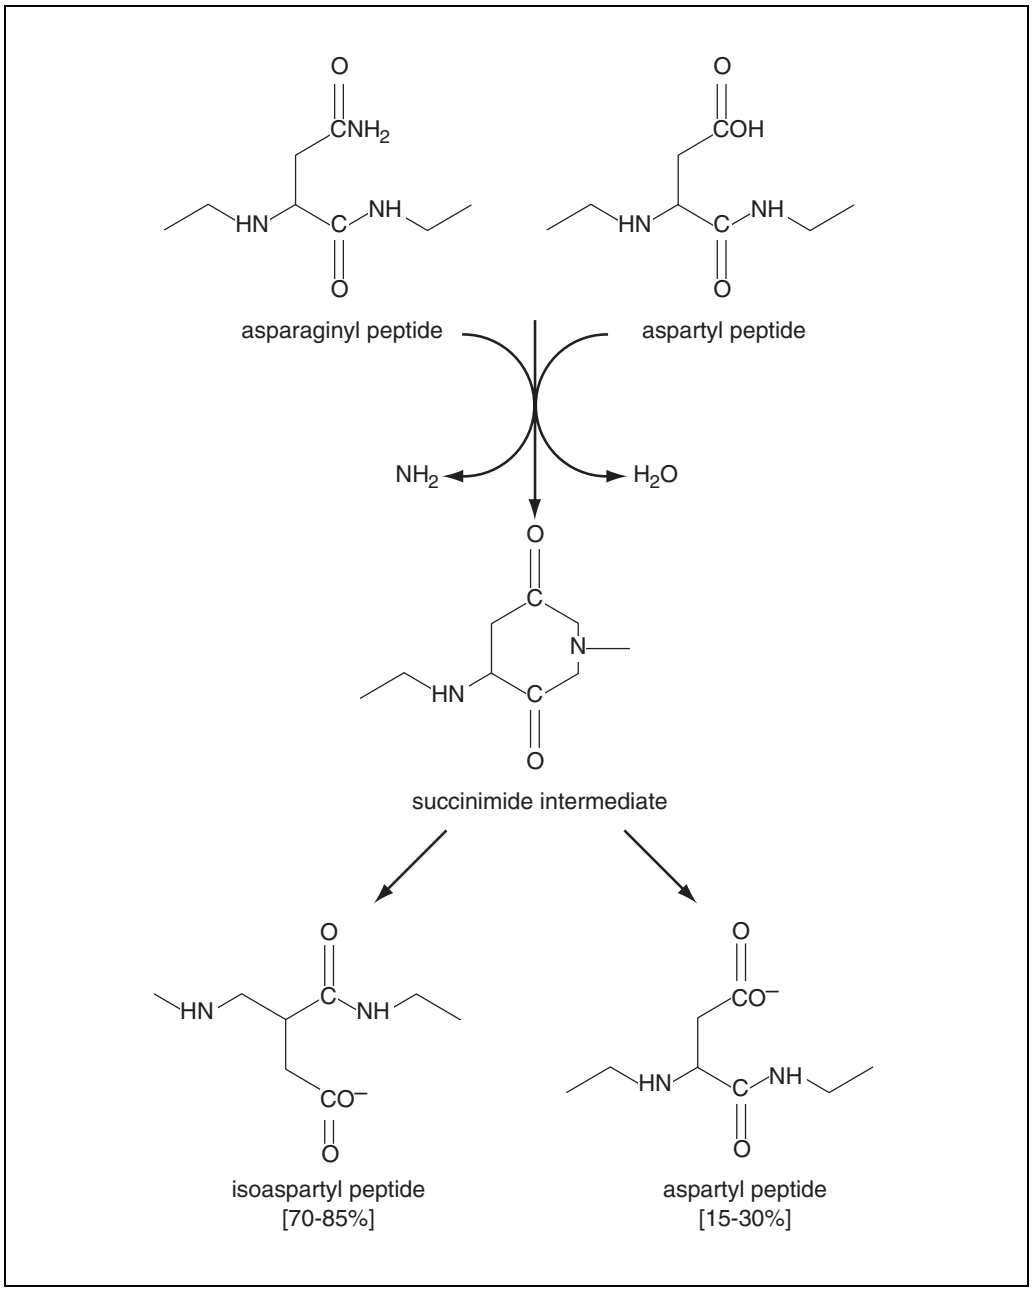

Figure 7.9.6 Formation of isoaspartate by the deamidation of asparagine or the isomerization of aspartate.

ing method is based on the fact that isoaspartate formation in a protein results in a net change of the protein's charge. However, the method cannot detect the formation of isoaspartate residues derived from aspartic acid which do not alter the net charge of the protein (i.e., aspartyl isomerization). In addition, changes in the isoelectric focusing pattern of a protein may also result from the modification of other amino acid residues, such as methionine or lysine oxidation; therefore, the isoelectric focusing method is not specific. Proteolytic digestion of a protein followed by HPLC and mass spectral analysis is capable of detecting the presence of isoaspartate residues in the protein; however, the HPLC method, based on the retention time of the digested peptides, may not be able to resolve subtle changes in the peptide that arise from the deamidation of a particular peptide. Moreover, many changes may affect the retention time of a particular peptide, which could coelute with the isoaspartate-containing peptide and therefore does not necessarily indicate the presence of isoaspartate residues.

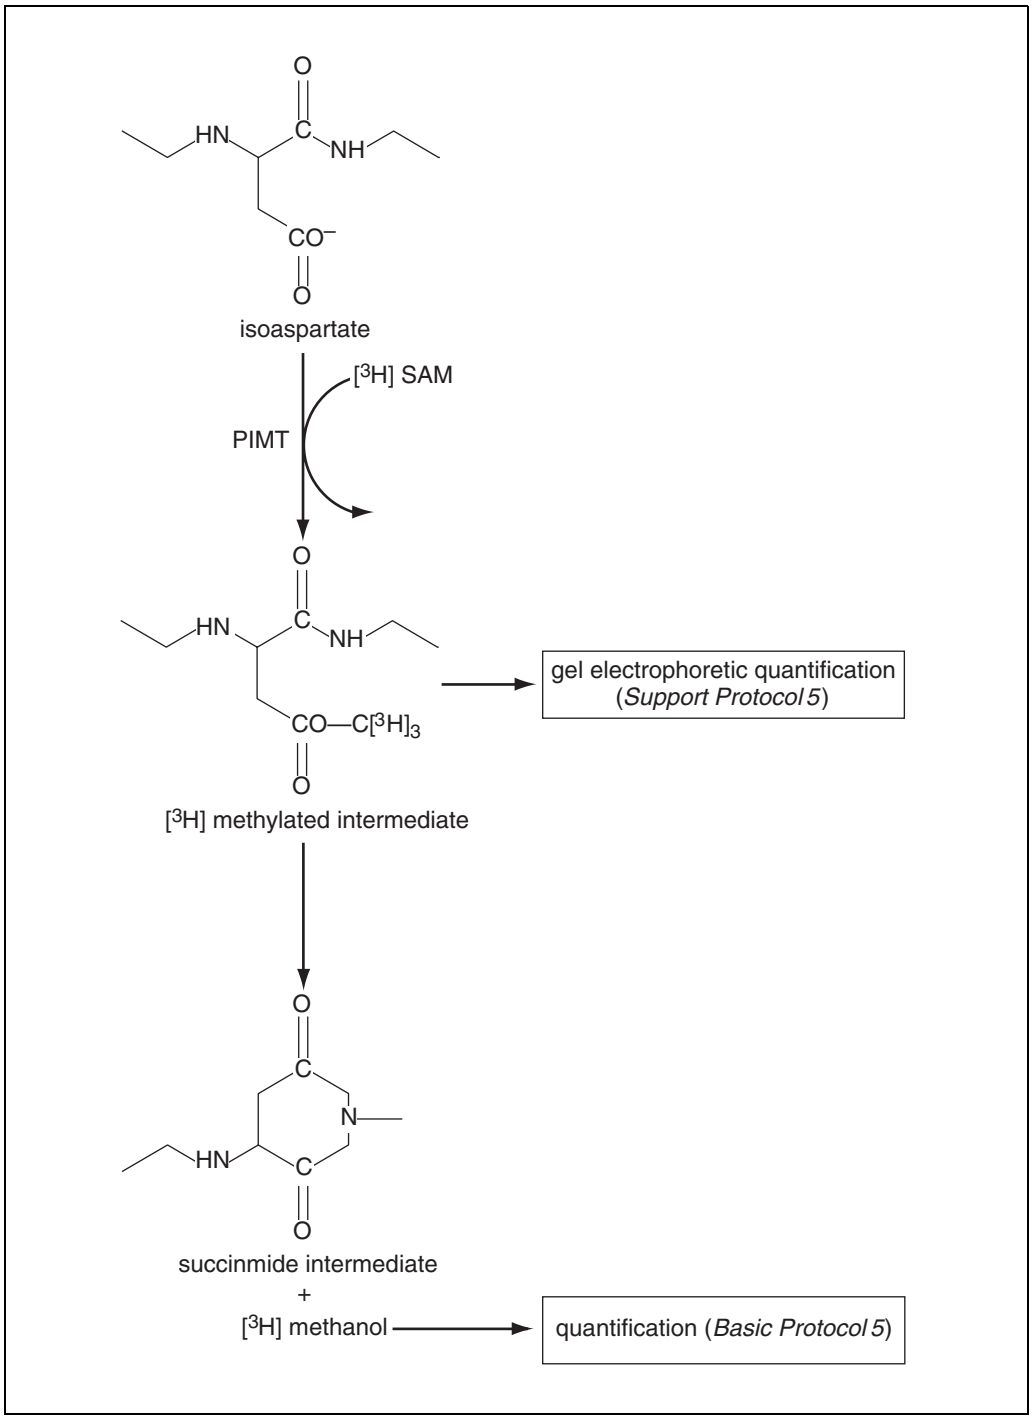

Figure 7.9.7 Pathway for the PIMT-catalyzed methylation of isoaspartate used for quantitation.

Critical Parameters and Troubleshooting

In all studies concerning oxidative damage to proteins, auto-oxidation of the tissues by ambient oxygen, following tissue isolation, should be minimized. Accordingly, tissue collection and preparation must be carried out in buffers supplemented with antioxidants, such as diethylenetriaminepentaacetic acid (DTPA) and butylated hydroxytoluene (BHT). The use of antioxidant buffers may be especially critical for the detection of trace amounts of oxidized products formed during aging or under oxidative stress. In addition, all buffers should be bubbled with nitrogen before use.

Analysis of protein carbonylation

Depending upon the method used, protein carbonyl content can be expressed as either nmol/mg protein or cpm/mg protein for the

DNPH (see Basic Protocol 1) and $NaBH_4$ (see Basic Protocol 2) method respectively. Therefore, the only critical parameter for protein carbonyl quantification is the protein concentration. As a rule, protein concentration after washing with ethanol/ethyl acetate, should always be determined. In addition, it should be noted that a high concentration of protein-conjugated DNP interferes with the BCA protein assay; therefore, for heavily oxidized proteins that have extremely high carbonyl content determined by DNPH, protein concentration should be assayed by UV absorption at 280 nm using BSA as a standard .

Two potential problems may arise when protein carbonyl content is measured spectrophotometrically using DNPH. First, absorption of protein-bound DNP in some experiments may be lower than that of a blank, which is the same protein sample treated with HCl (2 M) rather than DNPH. This problem may be caused by chromophores of certain proteins in the sample. If this is indeed the case, protein carbonyl content may have to be determined by other methods, such as the use of tritiated sodium borohydride (see Basic Protocol 2). The problem can also be caused by the difference in protein concentrations between a blank and a sample due to loss of proteins during washing. Therefore, care should be taken to minimize protein loss during washing steps, and protein concentration should always be determined after the removal of free DNPH (see Basic Protocol 2, step 4). Second, for tissue samples, it may be very difficult to dissolve the final protein pellet after washing. This problem is most likely caused by the use of high concentration of proteins in the initial step where protein samples are treated with DNPH. The authors have found that starting with 1 mg/ml protein will render the final pellet readily soluble. The solubility of a protein pellet will also depend on the nature of the protein; for example, lipoproteins and collagen are always quite difficult to dissolve after treatment with DNPH. In such a case, a denaturing buffer containing 150 mM phosphate and 3% SDS, pH 6.8 should be used.

For immunoblot detection of protein carbonyls, a major concern is the dilution of antibodies. If overdiluted, the immunostaining signal may be very weak; if underdiluted, the background may be too dark. Therefore, it is critical to optimize each antibody's dilution so that the immunostain signal is maximized while background staining is minimized. In addition, the amount of protein loaded onto SDS-PAGE should not be too high. Otherwise, nonspecific immune reactions may occur. Generally, 5 μg of a protein mixture is enough and less may be used for a purified protein.

When protein carbonyl content is determined by tritiated sodium borohydride (see Basic Protocol 2), protein concentrations should always be determined after the removal of free tritium because protein recovery after washing is rarely 100%. An 80% to 90% recovery for mitochondrial proteins has been routinely obtained in the authors' laboratory. When tritiated proteins are analyzed by SDS-PAGE, solubilization of more than one band of the same protein in one vial may be necessary to obtain enough radioactivity counts.

Analysis of protein thiol oxidation

When protein thiol groups are determined by radiolabeling with [^{14}C] iodoacetamide in conjunction with gel electrophoresis, it is necessary to include a final concentration of 1% SDS in the reaction mixture so that complete labeling can be ensured. For some proteins, the nucleophilicity of the thiolate (S^-) anion may be lower than potentially competing alcohol and amino groups in the same proteins; therefore, the iodoacetamide reaction may not be absolutely specific. In such cases, experimental conditions may need to be optimized by varying temperature, pH, and duration of the reactions so that the labeling for cysteine residues will be specific.

It should be noted that iodoacetamide is intrinsically unstable in light, especially in solution; reactions should therefore be carried out in the dark. Adding cysteine, glutathione, or mercaptosuccinic acid to the reaction mixture will quench thiol-reactive species, forming highly water-soluble adducts that are easily separated from proteins during gel electrophoresis.

Analysis of tyrosine oxidative modification

For GC/MS measurement of protein dityrosine residues, dityrosine always needs to be released by acid hydrolysis. Although it has been demonstrated by other investigators that the procedure of acid hydrolysis does not induce more oxidation of tyrosine, which can lead to additional dityrosine formation, care should be taken to ensure no further oxidation indeed takes place for a given sample under given experimental conditions by adding antioxidants to buffers. For such purposes, pure tyrosine should be used as a control during the acid hydrolysis process. In addition, for tissue samples (protein mixtures), the dityrosine level is usually above the detection limit of GC/MS method; however, this may not be the case for an individual protein. Therefore, it may be advisable to determine whether the

protein of interest has a dityrosine level that is above the limit of detection. To achieve this, analyze the protein at two widely different concentrations, 50- to 100-fold. If no dityrosine is detectable in the concentrated sample, it is most likely that the protein does not contain a significant amount of dityrosine residues.
