The localization of the lipid-binding domains listed in Table 24.4.1 is well documented. However, from time to time, one will encounter a problem when making a new probe or introducing mutations or deletions in any of these probes. This is a "localization" that is not related to interactions with phospholipids but is due to technical problems. High concentrations or more often folding problems of the expressed fusion proteins are usually responsible for this phenomenon, which results in the formation of large fluorescent aggregates that are found in various parts of the cell but mostly associated with the perinuclear area and could overlap with the Golgi. Very often this localization corresponds to the ER-associated protein degradation and represents the proteosome (Hitchcock et al., 2003). The authors experienced such problems with the EBFP-fused PLCδ1PH and with some chimeric constructs. In such cases, a fraction of the expressed protein still could fold properly and function as expected, and there are also cells that express less of the protein or, for a shorter time, do not display this problem. It is important to recognize this aggregation artifact and not to interpret it as a true localization. Sometimes it helps to reduce expression by using a less active promoter or to lower the temperature by 5° to 7°C during transfection and culture. However, the authors were not successful with these manipulations once the construct showed this aggregation behavior.

No localization is observed on the membrane where the lipid is expected to be

If GFP fluorescence is observed, but it is not associated with the membrane, it should be confirmed that the expression construct contains the sequence for the lipid-binding domain. Plasmid preparations of pEGFP-based plasmids often contain a ~600-bp DNA piece that is present without digestion by restriction enzymes. This band is usually faint but can be mistaken for an insert when confirming the DNA construct by restriction enzyme digestion analysis. This is especially problematic because many PH domains are encoded by DNA sequences of ~500 bp.

It also has to be realized that the amount of lipid produced and available for binding by a fluorescent probe is limited. Therefore, the membrane-bound fraction may not be distinguishable from the high cytosolic background of the unlocalized fusion protein when a cell expresses high amounts of the fusion protein. This is another reason to study cells that express low concentrations of the fusion protein. When PtdIns(4,5)P_2 is monitored with PLCδ_1PH-GFP, saturation within a wide range of expression level was not observed. We assume that there is a compensatory increase in the amount of PtdIns(4,5)P_2 in the cells expressing larger amounts of the lipid-binding protein. Compensatory increases are less likely to occur with lipids that are only formed in response to acute stimulation, such as PtdIns(3,4,5)P_3.

Nuclear localization

All of the domains listed in Table 24.4.1 can penetrate the nuclear pore and enter the nucleus, although their movement in and out is clearly limited. Many of the PH domains (Grp1-PH, ARNO-PH, Btk-PH, OSBP-PH, OSH2-PH) show very prominent nuclear localization. With the increased interest in nuclear phosphoinositides (Irvine, 2006) and the clear presence of these lipids in the nuclear matrix (in a still poorly understood physical form), localization of PH domains sparks the interest of many researchers. However, nuclear localization of these domains is also observed with mutants that do not bind the inositol lipids. This does not rule out that the wild-type constructs do have some nuclear binding components, but it shows that the major force of nuclear enrichment is not a reflection of lipid binding. It is very likely that the numerous basic residues characteristic of these domains are responsible for their nuclear localization; this is supported by the fact that algorithms based on the primary sequences of these proteins accurately predict their nuclear localization. However, if the protein binds to a lipid that is already present and abundant during expression, such as PtdIns(4,5)P_2, it will keep the domain out of the nucleus, provided that the amount of the expressed protein does not saturate the lipid available for binding. Again, choosing cells in which the expression levels are low also ensures less localization in the nucleus.

Plasma membrane localization—true or false?

The authors believe that many investigators have wrong ideas about how plasma membrane localization can be recognized especially under a confocal microscope. They expect a strong fluorescence signal outline of cells and no signal over the cytoplasm. This is true for cells that are round in shape or arranged as cobblestones such as MDCK cells. However, plasma membrane localization can

be more difficult to recognize in cells that are solitary and very flat such as COS cells. In such flat cells, one could see even fluorescence when imaging the glass-attached membrane surface giving the impression that the probe is also present in the cytoplasm. Moving upwards on the cell can change the view to a very fuzzy ring with some worm-like intensity (representing ruffles and microfilopodia) as the membrane covering the nucleus appears in the z-plane (Fig. 24.4.1B). It requires a trained eye to differentiate between plasma membrane and cytosolic constructs in such cells. A good guide is to see if the fluorescence clearly outlines the nucleus and its intensity is diminishing toward the periphery of the cells, both being signs of cytosolic localization.

In an opposing way, cytosolic proteins can show a phenomenon that the authors call "pseudo membrane localization," which gives the impression that the protein is in the membrane. In very flat cells, the edge of the cell and the membrane ruffles often appear as high-intensity lines or wrinkles because of the way the membrane appears in the imaged plane. Since membrane ruffling is a common response of cells to stimuli that activate PI 3-kinases and can be reversed with PI3K inhibitors, this "apparent" localization will show the same PI 3-kinase dependence as the real plasma membrane recruitment of PtdIns(3,4,5)P_3 recognizing domains. Therefore, it can give the impression that the construct localizes to the membrane ruffles in stimulated cells even when it does not actually bind to PtdIns(3,4,5)P_3. Comparing the fusion protein–expressing cells with control cells expressing only GFP is essential to resolving true versus false membrane localization. A useful measure of true plasma membrane recruitment is to monitor the decrease in intensity of the probe in the cytoplasm. The authors find that often this decrease can be best judged by the increased contrast between the cytoplasm and the nucleus, which appears sharper as the cytoplasmic fluorescence decreases. True membrane localization also has to fulfill several criteria. The localization of the fusion protein should follow the lipid changes that are evoked by physiological or pharmacological means. For example, PI 3 kinase inhibitors, such as wortmannin or LY294002 prevent the formation of 3-phosphorylated lipid products, so treatment of the transfected cells with these inhibitors should eliminate localization of fluorescent probes that recognize 3-phosphorylated lipids. Also, robust activation of PLC should cause a decrease in the localization of probes detecting PtdIns(4,5)P_2. However, the extent of change often is smaller than what can be detected by the eye or even with more sensitive quantification. For example, many G protein–coupled receptors evoke a Ca^{2+} signal (indicating PLC activation), yet no detectable change in PLCδ_1PH-GFP distribution. This does not mean that the probe does not work. It only means that the PLC activation is not robust enough, or the PIP 5 kinase activity is so active that there is little change in the concentration of the PtdIns(4,5)P_2 in the membrane.

A further observation of practical importance is that live cells lose localization of the PLCδ1PH-GFP (and some other domains) when they are kept at room temperature for >15 to 20 min. The reason for this has not been explored in detail, but it may be that lipid synthesis is slowed because of either ATP depletion or the physicochemical properties of the membrane change. Warming the cells to 37°C does not correct the situation within 30 min. Thus, live-cell imaging should be performed using a temperature-controlled microscope system within a short period of time after placing the cells in the observation medium.

Anticipated Results

Expression of GFP-fused inositol lipid binding domains should yield a fluorescent signal that is easy to recognize and distinguishable from background autofluorescence. In fact, the larger problem often is too high of expression, especially in COS-7 cells. In these cells, the biology is greatly distorted; therefore, these cells should not be used for analysis (see Fig. 24.4.1 for an example). HEK293 or HeLa cells will express more moderate levels of the same constructs since they do not express the large T antigen that generates many copies of the plasmid in COS cells. The distribution of the individual domains will reflect the localization of the lipid to which it binds except additional interactions of the domain with other membrane components or proteins may significantly alter the localization of the probe. Lastly, the lipid changes are not always large enough to be observed by the eye or even by quantification of the data. Many cells generate clearly detectable Ca^{2+} signals by PLC activation without a noticeable change in PLCδ1PH-GFP localization. These negative data do not necessarily mean that the probe is not working. A positive control is always a useful way to check a newly studied construct.

Time Considerations

Performing a live-cell imaging experiment is not particularly time consuming. A typical experiment starts out by preparing the coverslips (~2 hr with drying) and seeding cells for the experiment. Cells are transfected on the following day with plasmid DNA (~1 hr depending on the number of coverslips). For most phosphoinositide-binding domains, the transfection begins at ~1400 hr and the transfection medium is changed to one with serum ~1900 hr for experiments that are planned for the following day. It is not recommended to use cells after >24 to 30 hr after transfection with these domains. The actual experiment requires setting up the microscope and the heated stage (~30 min) and waiting for equilibration (~30 min). Depending on the type of experiment, a sample is rarely on the stage >30 min. Data analysis is done off-line and can be more time consuming than the actual experiment depending on the application. Design and generation of a new construct is a more time-consuming process that can take from 1 week (optimal) to several weeks.

It is important to remember that the time-consuming part of live-cell imaging is the many times an experiment must be repeated. Many recordings cannot be used because of technical problems such as moving cells or focus-drift occurring during time-lapse imaging. Also, one must repeat experiments many times before being confident that the chosen pictures actually represent a reproducible biological process. Due to individual variations among cells, this is often not appreciated by users who are used to methods that give averaged cell responses.

Acknowledgments

The authors would like to thank Dr. Mark Lemmon (Univ. Pennsylvania, Philadelphia) for the OSH1-PH-GFP and OSH2-PH-GFP constructs. The confocal imaging was performed at the Microscopy & Imaging Core of the National Institute of Child Health and Human Development, NIH with the kind assistance of Drs. Vincent Schram and James T. Russell. This research was supported in part by the Intramural Research Program of the National Institute of Child Health and Human Development of the National Institutes of Health. Péter Várnai is also a Bolyai Fellow of the Hungarian Academy of Science and was also supported by the Hungarian Scientific Research fund (OTKA NF-68563) and the Medical Research Council (ETT 440/2006).

CHAPTER 25
Nanotechnology

INTRODUCTION

Hard-earned insights from molecular and cell biology over the last 20 years have ushered in a new era of experiments on single molecules rather than on populations of molecules. Termed nanotechnology, this field of biological research focuses on the control of cellular structure and dynamics on the atomic and molecular scale (1 to 100 nm) and on the fabrication of devices for measuring within that size range. Many of the new tools used in nanotechnology come from colloidal science, including quantum dots and nanotubes. By combining these tools with live cell fluorescent imaging techniques and other analytical methods such as atomic force microscopy, nanotechnology has opened up many new experimental avenues for understanding how molecules move and assemble into complex structures within cells and tissues.

UNIT 25.1 discusses the use of quantum dots (QDs) for live cell imaging and flow cytometry. QDs have many advantages over conventional fluorophores, including increased brightness and photostability, which make them exceptional tools for live cell imaging. The unit focuses on the use of streptavidin-coupled QDs, as they have universal applicability due to their ability to recognize biotin coupled to a ligand or antibody that has been bound to a receptor or protein.

ABSTRACT

This unit describes the use of quantum dots (QDs) for live-cell imaging and the use of QDs in flow cytometry for quantitative analysis of ligand binding constants and receptor density. Conventional fluorophores and visible fluorescent protein (VFP) constructs have allowed visualization of many cellular processes. However, organic and biomolecular fluorophores have limitations in their applications, due to their small Stokes' shift and tendency to photobleach during prolonged imaging. QDs have many advantages over conventional fluorophores, including high brightness and photostability, which make them an exceptional tool for live-cell imaging. There are a large variety of commercially available QDs with different surface reactivities and characteristics. The authors have limited the laboratory protocols presented here to the use of streptavidin-coupled QDs because this gives almost universal applicability to any cell surface receptor by coupling the ligand or antibody that recognizes the receptor to biotin and visualizing the complex by use of QDs. *Curr. Protoc. Cell Biol.* 36:25.1.1-25.1.18. © 2007 by John Wiley & Sons, Inc.

Keywords: quantum dots • live-cell imaging • binding constants • receptor number • biotinylated ligands

INTRODUCTION

The responses of a cell to its surrounding environment result largely from the transduction of signals from the outer cell surface to the cytoplasm and nucleus. These signals are initiated when a ligand binds to a membrane receptor, initiating signaling cascades that control numerous cellular processes such as gene expression, cell migration, and cell division. Macromolecular protein dynamics and localization, as well as signaling cascades, can be directly visualized in the living cell using fluorescence microscopy [see other units on FRAP (*UNIT 21.1*), ion imaging, and fluorescent imaging (Chapters 4 and 21)].

In this unit, the authors describe protocols for forming biotin-ligand (or biotinylated-'protein of interest') and streptavidin-QD (SAvQD) complexes for use in live-cell microscopy (see Support Protocol 1). In the case when the precoupling of the QD to the ligand inhibits function, an alternative two-step labeling protocol is provided. Support Protocol 2 discusses ways to avoid cross-linking of QD-ligand complexes if the ligand is labeled with multiple biotins. Basic Protocol 1 gives details for in vivo cell labeling with QD-ligand complexes and image acquisition, with special emphasis on temporal acquisition of image series to visualize cellular processes. Experiments to determine QD-ligand binding constants (Basic Protocol 2) and absolute number of receptors per cell (Basic Protocol 3) by complementary flow cytometry measurements are also described.

STRATEGIC PLANNING

What are quantum dots and how are they useful for live-cell imaging?

Water-soluble, bio-functionalized semiconductor quantum dots (QDs) are fluorescent nanoparticles that provide advantages of much greater photostability compared to conventional fluorescent dyes, and as a consequence, single QDs can be easily detected in living cells and their localization monitored for minutes to hours to days. The core of the QD consists of a semiconductor nanocrystal, typically CdSe surrounded by a passivation shell of ZnS, as well as an outer shell to make them biocompatible (Alivisatos et al., 2005; Smith et al., 2006). Absorption of a photon anywhere in a continuum rising toward the UV generates an electron-hole pair, which upon recombination (in ~10 to 20 nsec) results in the emission of a less energetic photon. The emission wavelength is dependent on the size of the core (smaller core size = lower emission wavelength), which can be varied by controlled synthesis conditions (Fig. 25.1.1). These characteristics and the fact that QDs have a large absorption cross-section, particularly in low visible to UV wavelengths, allows for the simultaneous excitation of many spectrally distinct QD emitters with a single wavelength. (See later section on multispectral fluorescence imaging and analysis).

Many types of QDs are commercially available from Invitrogen (*http://probes.invitrogen.com/products/qdot*) and Evident Technologies (*http://www.evidenttech.com*). These include surface-accessible moieties such as amino, carboxyl, peptides, biotin, streptavidin, protein A, and IgGs. The manufacturers provide kits for coupling your favorite molecule to QDs with extensive protocols and the reader is referred to these sites for details. In addition, membrane-permeable QDs (having nona-arginine on the surface) and other methods of intracellular delivery are available so that QDs may be used to label cells for reintroduction into animals and long-term cell tracking. The larger CdSe QDs, emitting at >600 nm, have extended geometries with dimensions of ~40 nm. These large sizes make accessibility a problem in tight junctions between cells or in permeabilized tissues (Arndt-Jovin et al., 2006). Emission wavelengths of QDs have been extended into the near NIR using CdTe as cores (Kim et al., 2004; Gao et al., 2005; Smith et al., 2006), thus enhancing their use in live-animal studies. An exciting in vivo quantum dot

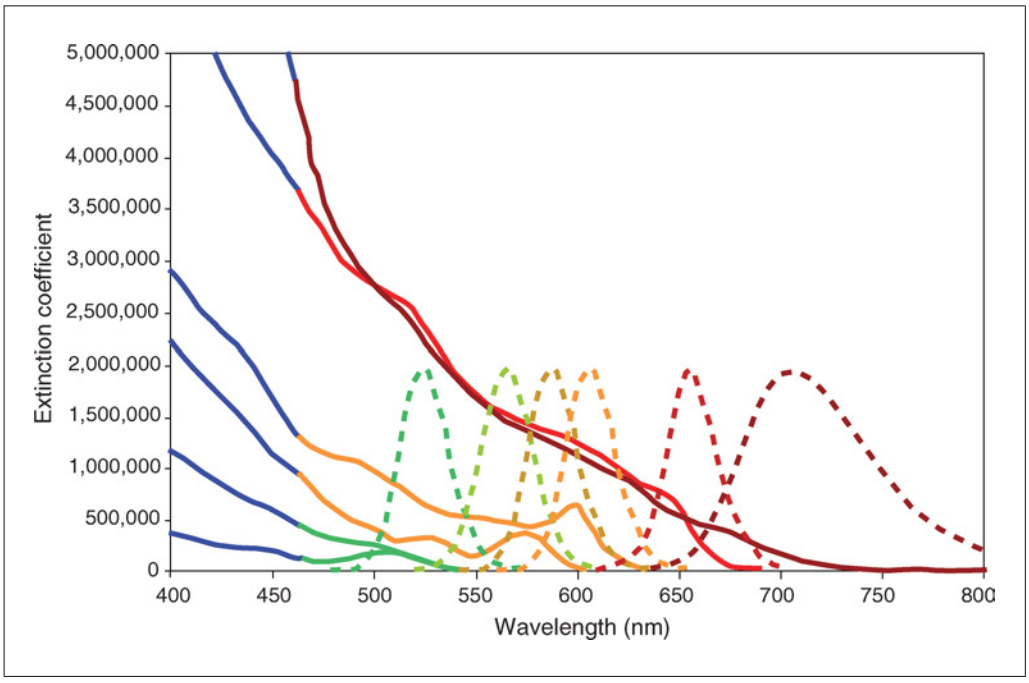

Figure 25.1.1 Excitation and emission spectra of CdSe core QDs. For color version of this figure see *http://www.currentprotocols.com*.

conjugate that emits by bioluminescence resonance energy transfer in the absence of external excitation has been prepared by coupling carboxylate-presenting quantum dots to a mutant of the bioluminescent protein *Renilla reniformis* luciferase (So et al., 2006).

Differences between QDs as probes and small or conventional fluorophores

Most conventional fluorophores have relatively broad absorption and emission bands with a small to medium Stokes' shift (the difference in wavelength between their excitation and emission maxima). For information on the excitation and emission maxima for many small molecule fluorophores see *http://probes.invitrogen.com/handbook*. Genetically encoded fluorophores (VFPs, visible fluorescent proteins) have small Stokes' shifts except for the recently described Keima (Chudakov et al., 2005; Shaner et al., 2005; Kogure et al., 2006). Thus, it is more difficult to excite several conventional fluorophores with a single wavelength. For excitations in the visible wavelengths many conventional fluorophores have higher extinction coefficients than QDs and with their shorter fluorescent lifetimes will appear 'brighter' to the observer. However, these dyes are much less photostable than QDs. This latter fact makes QDs the probe of choice for in vivo imaging over extended time periods.

Instrumentation

Microscopy

Macromolecular dynamics, localization, and aggregation state can be directly visualized in the living cell using fluorescence microscopy [see units on basic fluorescence microscopy (*UNIT 4.2*), FRAP (*UNIT 21.1*), FRET (*UNITS 17.1 & 17.9*) and fluorescence correlation spectroscopy (FCS)]. Commercial confocal microscopes allow for multi-laser excitation and the imaging of several different fluorophores simultaneously. Recent advances in multispectral fluorescence imaging, where the emission spectrum of the sample is measured in each sampled point, have made it possible to further increase the number of fluorophores that can be monitored (Fountaine et al., 2006). Commercial systems include the Zeiss LSM 510META and Live systems, Nikon Digital Eclipse C1si, Leica TCS SP5, Olympus Fluoview, and Olympus DSU spinning disk. QDs are particularly suited to simultaneous multi-color labeling of different macromolecules in the same sample due to their broad excitation spectra and narrow emission spectra, which allows for single line excitation of multiple QDs and separation of spectrally distinct QD emissions using filter-based or multispectral imaging.

In addition to confocal imaging, high spatial and time resolution can be achieved using a wide-field microscope and a sensitive CCD camera (see *UNIT 4.2*). The brightness and photostability of QDs make it possible to track individual protein dynamics in living cells at video rate or faster using the new generation electron multiplying (em) CCD cameras (Andor iXon, Roper Scientific Cascade, Hamamatsu C9100-02). The high quantum efficiency of CCD cameras extending into the NIR makes them far superior for detecting QDs with emissions >600 nm compared with PMT-based imaging systems.

Flow cytometry

Flow cytometry is a complementary technique to imaging microscopy. The authors include a discussion of it here to demonstrate its power for quantitative determination of binding constants, numbers of binding sites, as well as kinetic or dissociation constants with high statistical precision. Flow cytometry has both advantages and disadvantages compared to microscopy. It can record the fluorescence and light scattering of hundreds or thousands of cells in a second, but speed comes at the price of losing subcellular resolution. Although some flow cytometers are capable of multi-laser excitation, in the simplest and probably most wide-spread bench-top flow cytometers the number of excitation wavelengths is limited. Similarly as in the imaging microscope, the fact that several different types of QDs can be excited by a single laser line makes

multi-color labeling possible and easily detected in different fluorescence channels of the flow cytometer (Mattheakis et al., 2004; Chattopadhyay et al., 2006). The photostability of QDs is less valuable in flow cytometry due to the limited amount of time the cells are illuminated, but their relatively large extinction coefficient (especially with UV excitation) makes the labeling of cells with low numbers of binding sites more reliable.

BASIC PROTOCOL 1

IN VIVO, IN SITU LABELING OF CELLS WITH QD-LIGAND CONJUGATES FOR FLUORESCENCE MICROSCOPIC IMAGING

This method describes the general procedure for preparing cells for live imaging in order to follow the fate of the QD-ligands interacting with membrane-bound receptors (see Fig. 25.1.2). The methods can be used with a confocal laser scanning microscope or a wide-field microscope. The use of LabTek chambers (Nunc) requires the use of an inverted microscope. Other manufacturers such as Electron Microscopy Services (*http://www.emsdiasum.com/microscopy/products/preparation/dish.aspx*) make holders that accommodate coverslips of various dimensions that are equally suitable. With live-cell imaging, dynamic events (i.e., QD-ligand binding/internalization or endosomal trafficking) can be monitored by acquiring an image series over the time range of interest.

If quantitative analysis of data is desired care must be taken to acquire the images such that no pixels have intensities of 0 or less nor values above the range of the detector (8-bit, 12-bit, or 16-bit for example.)

Controls for the specificity of the QD-receptor interaction are important. It is absolutely essential to show that the signal that is acquired is specifically associated with the presumed receptor and that it reflects the behavior of the receptor without QDs attached. The researcher must do binding experiments with unconjugated QDs, and QD-ligand binding in the presence of competitive excess free ligand, determine if down-stream signaling is affected as expected (e.g. phosphorylation profiles are the same with QD-ligand compared with ligand alone), and demonstrate that there is no binding on cells that do not express the receptor.

If one wishes to perform single-particle tracking of individual receptors, it may be desirable to use the QD simply as a tracer of the molecule of interest. This may be done

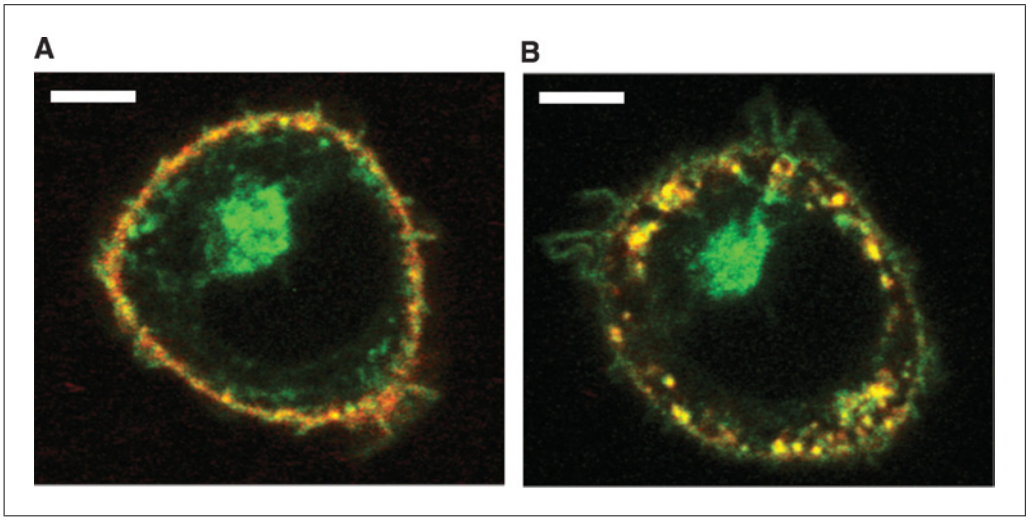

Figure 25.1.2 QD-EGF (red) bind to the surface of Chinese hamster ovary cells expressing EGFR-GFP (green) (**A**) and undergo endocytosis within minutes (**B**). Colocalization (yellow) of the QDs and receptor are seen at the membrane and after internalization in endosomes. Images acquired using a Zeiss LSM510-META system. Scale bar = 10 μm. For color version of this figure see *http://www.currentprotocols.com*.

by using a very low concentration of QD-ligand mixed with an excess of free ligand (Lidke et al., 2005a) or by binding the biotinylated-ligand (Alternate Protocol) followed by a tracer amount of SAvQDs (Echarte et al., 2007).

Materials

Logarithmically growing cells (*UNIT 1.1*)
Trypsin
Cell culture medium appropriate for the particular cell line
Tyrode's buffer plus (see recipe)
Preformed QD-ligands (Support Protocol 1 or 2)

LabTek 8-well coverslip chambers (Nunc)
Emission filters for specific QD emission wavelengths (Chroma or Omega, also available from the microscope manufacturers)

Additional reagents and equipment for culture of cells (*UNIT 1.1*)

Plate cells

1. One or two days before the experiment, trypsinize logarithmically growing cells (*UNIT 1.1*).

2. Plate the cells in LabTek 8-well coverslip chambers in complete culture medium at the appropriate density (one typically desires ~50% confluency on the day of the experiment).

   In the case of experiments with receptors that are sensitive to serum factors, the cells can be serum-starved for 4 to 16 hr prior to the experiment to reduce signaling induced by the serum in the medium.

Prepare sample for live-cell imaging with QD-ligand complexes

3. At the time of the experiment, wash the cells once with 200 µl Tyrode's buffer plus and maintain in this buffer.

   Culture medium without phenol red, containing 1% (w/v) BSA can be used for very long imaging periods (in place of Tyrode's buffer plus).

4. Place the chamber on the microscope stage and equilibrate to the desired temperature.

   The authors recommend an objective heating collar as the most effective way to keep the cells at the desired temperature during the duration of the experiment. An inexpensive and efficient setup can be purchased from Cell MicroControls (HLS8 × 0.8P and mTCII) and consists of an adjustable, flexible heating strip that can be secured around any objective with a strip of Velcro and a battery powered controller. For very long (hours to days) experiments a system having CO_2 input is necessary as well.

5. Dilute the QD-ligand complex (Support Protocol 1 or 2) to twice the desired final concentration in Tyrode's buffer plus.

   Dilute the ligand-SAvQD complex from PBS/1% BSA into Tyrode's plus just before use since the SAvQDs can aggregate with time in buffers containing divalent cations. Do not store this dilution for use on another day.

6. Add an equal volume (200 µl) of QD-ligand in Tyrode's buffer plus to the cells in the well under observation to a final concentration of 0.005 to 2 nM.

   The final concentration should be adjusted for the specific protein-ligand interaction and the known binding constants. Also, the concentration will depend on whether one wants to observe many or only a few of the receptors at one time (i.e., single-molecule tracking or measuring binding and uptake). The two-step labeling procedure is recommended if a maximal cellular response but single-molecule resolution are desired. This procedure allows using the QDs as tracers of the behavior of the macromolecule of interest.

Image acquisition

7. Initiate image acquisition either before or just after addition of the QD-ligand.

That is, when using preformed complexes, the QD-ligand can be added to the sample after images at several time points have already been acquired, taking care not to disturb the position of the sample during addition of the QD-ligand. Typically, addition of large volumes (e.g., addition of 200 μl of QD-ligand to 200 μl of buffer in chamber) results in rapid mixing without additional pipetting. The QD-ligand should also be kept at the same temperature as the imaging chamber to avoid focal drift due to temperature fluctuations. The time between images and duration of the time series acquisition is dependent on the events being monitored and must be determined by the researcher.

A 63× or 40× 1.2 NA water immersion objective is recommended.

In confocal imaging systems, simultaneous excitation of VFP and various QDs can be achieved by using different laser combinations. QDs having emissions of 605 nm and above can be excited well by 488 nm or higher wavelengths whereas lower wavelength QDs are more efficiently excited by 458-nm or 407-nm lasers. An imaging system with at least two detectors, allows the simultaneous collection of eGFP and QD signals with appropriate filters (eg., 520/20 bandpass and the appropriate QD emission bandpass filters). Single QD imaging requires high laser powers and pixel dwell times of about 6 μsec. Thus, whole 512 × 512 image acquisitions take seconds. Fast-tracking of single QDs requires more sensitive acquisition systems (see next section). For the most efficient separation of different emitting QDs in the same sample, selective QD emission filters or a spectral unmixing device should be used (Fountaine et al., 2006; Miskoski et al., 2006; see Fig 25.1.3).

Wide-field systems equipped with a mercury arc lamp most efficiently excite the QDs at 436 nm without cell damage. Image splitters and multispectral analysis systems can separate many QD and VFP labels simultaneously (Miskoski et al., 2006). EmCCD cameras can easily detect QD emission from single bound QDs with acquisition times of 50 ms or less (see Fig. 25.1.4).

Image analysis is specific to the particular question being addressed and therefore, must be developed by the researcher. There are many commercial and noncommercial resources available for image processing. Two of the most popular platforms are ImageJ, a stand-alone software available through NIH (http://rsb.info.nih.gov/ij/) and DIPimage, a

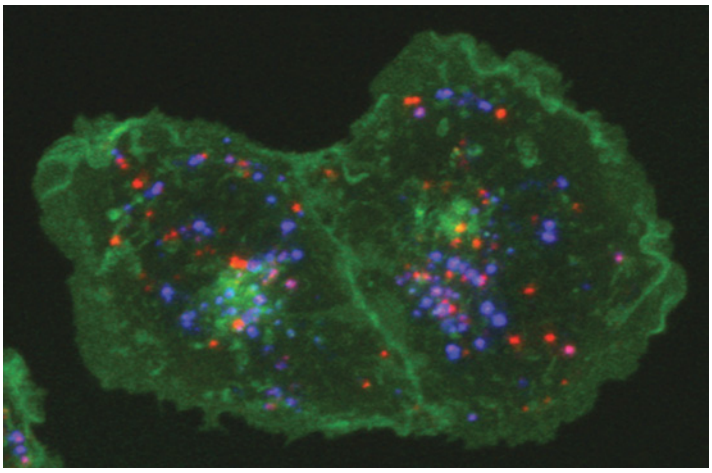

Figure 25.1.3 In a 'pulse-chase' experiment, two different colors of QD-EGF (red and blue) added to a cell expressing erbB1-eGFP (green) are used to monitor vesicle fusion. First, red QD-EGF is added and allowed to internalize. At a time point 15 min later, the blue QD-EGF is added. At a time point 22 min after addition of the blue QD-EGF, colocalization of red and blue QDs are seen in endosomes (purple), indicating that receptors activated later in time can 'catch-up' to the same compartment as those that were internalized earlier. Image acquired using a Zeiss LSM510-META system. For color version of this figure see *http://www.currentprotocols.com*.

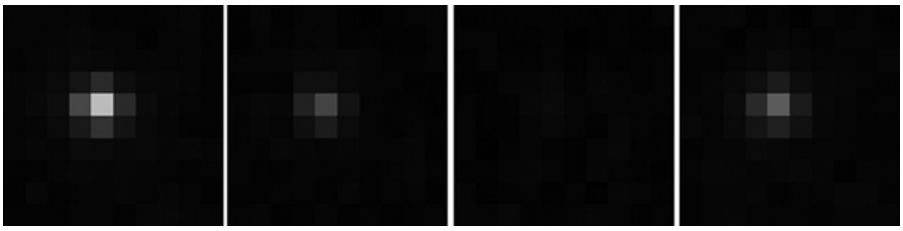

Figure 25.1.4 Single QD Blinking. Selected images from a time series showing the intermittent fluorescence of an individual QD. Time series acquired using an Olympus IX71 microscope with an Andor iXon emCCD camera. Excitation: 472-nm diode laser; emission: 655/40 QD filter. 60 msec between images, 20 msec integration time (see Lidke et al., 2005b).

scientific image processing toolbox for Matlab available from Delft University of Technology (http://www.ph.tn.tudelft.nl/DIPlib/). These two programs are free to University staff and students. A large number of plug-ins or scripts have been developed for both packages, such as masking operations, tracking algorithms, colocalization or 2-D histograms, and are freely available to the public.

LABELING CELL SURFACE RECEPTORS IN A TWO-STEP PROCEDURE

ALTERNATE PROTOCOL

In some cases, the presence of the QD may sterically hinder the QD-ligand binding to the cell surface membrane receptor. If one does not observe binding of the preformed complex, the following two-step protocol may be useful. The authors have successfully used this procedure with EGF, transferrin, and NGF receptors (Grecco et al., 2004; Lidke et al., 2004; Echarte et al., 2007).

Materials

Cells cultured in chambers or on coverslips (Basic Protocol 1)
Tyrode's buffer plus (see recipe), cold
Bio-ligand
Streptavidin-conjugated Quantum Dots (SAvQD; Invitrogen)
4% (w/v) paraformaldehyde
Tris-saline buffer
Phosphate-buffered saline (PBS; see recipe)
10° to 12°C water bath

1. Put chambers or coverslips containing cells on ice or float chamber in a water bath maintained at 10° to 12°C (recommended for cells of the immune system which are sensitive to extreme cold).
2. Wash cells once with cold Tyrode's plus and maintain in this buffer for the experiment.
3. Incubate cells with bio-ligand for 10 to 30 min.

   The concentration of bio-ligand and incubation times should be adjusted according to the binding constant of the protein-ligand interaction.

4. Wash with cold Tyrode's plus several times.
5. Add 0.05 to 2 nM cold SAvQD (diluted in Tyrode's plus) for 5 to 15 min.
6. Wash the cells several times with cold Tyrode's plus.
7. Mount for imaging.

   a. For live-cell imaging, immediately place cells on the microscope stage with appropriate temperature control and image (for more detail see Basic Protocol 1).

b. For snapshots of the behavior of the QD-ligand complex at different time points, incubate cells grown on coverslips at the appropriate temperatures and times and fix in 4% paraformaldehyde for 15 min on ice to prevent redistribution of the QDs. After fixation, wash the coverslips with Tris-saline buffer for 10 min several times and mount in PBS for imaging.

SUPPORT PROTOCOL 1

COUPLING MONOBIOTINYLATED LIGANDS TO STREPTAVIDIN-QDS

This method describes how to conjugate ligands to QDs via a biotin-streptavidin interaction. The authors have successfully used this protocol for several biotinylated ligands, including epidermal growth factor (EGF; Lidke et al., 2005a) and nerve growth factor (NGF; Echarte et al., 2007).

This protocol can be used with most ligands and proteins (such as antibodies) that have a single biotin moiety attached. The protocol uses QDs from Invitrogen that have 3 to 4 streptavidin molecules covalently bound to the QD bioconjugate shell (SAvQD). The authors recommend for most applications the PEG 2000 coated QDs since they show reduced nonspecific binding to cells and cell substrates such as polylysine or collagen.

The reader is reminded that each streptavidin can have up to four binding sites for biotin. The multi-valency of the SAvQDs can be an advantage in that it allows for the stochiometry of the QD-ligand complex to be varied by simply changing the ligand:QD ratio. A monovalent biotinylated ligand, where the biotin is conjugated to a single known residue or position, is preferred since the properties of the QD-ligand complex can be better controlled and potential cross-linking of the QDs via the ligand is avoided (see Support Protocol 2 for ligands with multiple biotins). By mixing SAvQDs, biotinylated ligand and free biotin at specific molar ratios, one can create QDs with the desired average number of attached ligands, assuming a Poisson distribution (Lidke et al., 2004).

After formation of the QD-ligand complex, unbound ligands that are smaller than the QDs can be removed from the conjugate by passing the mixture over a size exclusion column. For PEG-QDs cross-linked dextran size exclusion columns (eg, Sephadex G-25) are recommended, and for QDs without a PEG coating, polyacrylamide bead exclusion columns are most efficient (eg, Bio-gel P).

Materials

Streptavidin-conjugated Quantum Dots (SAvQD; Invitrogen)
Phosphate-buffered saline (PBS)/1% (w/v) BSA (see recipe)
Biotinylated-Ligand (bio-ligand)
PBS (see recipe)
1% (w/v) BSA

Shaker
Gel filtration spin columns, NAC-5

Prepare QD-ligand preformed complexes

1. Dilute SAvQD to 20 nM in 100 µl PBS/1% BSA.
2. Dilute bio-ligand to 20 to 60 nM in 100 µl PBS/1% BSA.

   The above concentration will yield a Poisson distribution of 1:1 to 3:1 ligands per QD. The reader should determine the valency of ligand desired for his/her particular experiment.

3. Add SAvQDs to ligand, mix with a micropipet, and vortex for 1 sec.

   Thoroughly mix the SAvQDs and ligand in equal volumes so that the stoichiometry does not vary throughout the solution at the time of mixing.

4. Incubate for at least 30 min at 4°C with gentle agitation or rotation.

Purify QD-ligand conjugates

5. Swell and pour the column material according to the manufacturer's instructions.

   For PEG-coated QDs coupled to small peptide ligands as described above, Sephadex G-25 medium-grade gel filtration is recommended; the QD-ligand complex will elute in the void volume. Use a 1:20 ratio of sample to column volume to ensure separation. Spin columns can be used for sample volumes of 50 μl or less. For non-PEG SAvQDs, Bio-gel P20 is recommended; the QDs appear in the void volume. To remove excess macromolecules from QD conjugations, ultra filtration units with 100-kDa or 200-kDa regenerated cellulose membranes are recommended (see Millipore Corporation for small volume ultracel or microcon units).

6. Equilibrate the column in PBS by washing with at least 3 column volumes.

7. Allow the buffer to just enter the top of the gel bed before adding the sample. Avoid air bubbles.

8. Add the sample to the top of the gel bed, allow the sample to enter the gel, and add PBS to elute the sample.

9. Collect the fractions containing the QDs. Add 1% (w/v) BSA (final concentration) to final product

   The purified QD-ligand complexes are stable for 4 weeks when stored at 4°C.

PREPARATION OF PREFORMED COMPLEXES OF QDS WITH LIGANDS WITH MULTIPLE BIOTINS

SUPPORT PROTOCOL 2

Some ligands must be multivalent for proper recognition by their receptors. The ligand may thus also be multi-biotinylated. The following protocol has been successfully used with such ligands and avoids cross-linking of QDs by the ligand by blocking excess biotin binding sites on SAv-QDs with free biotin shortly after addition of the ligand (see Cambi et al., 2007 for an example).

Materials

Streptavidin-conjugated Quantum Dots (SAvQD; Invitrogen)
PBS/1% (w/v) BSA (see recipe)
Bio-ligand

1. Dilute SAvQD to 20 nM in 100 μl PBS/1% BSA.

2. Dilute bio-ligand to the appropriate molarity in 100 μl PBS/1% BSA and mix with the QDs for 15 min with agitation.

   After addition of free biotin, the ligand-QD complexes can be purified as described above (Support Protocol 1, steps 3 and 4) or used directly if the free biotin and potentially free ligand do not interfere with receptor recognition.

   The absolute concentration of the ligand should be carefully determined. The number of biotins per ligand should also be determined.

   The authors recommend adding the ligand at a concentration such that the final dilution has a ratio of approximately three to six ligands to one QD and allowing binding to proceed with agitation for only 15 min followed by the addition of a 10-fold excess of free biotin to saturate any remaining streptavidin binding sites.

   The success of this procedure will depend to some extent upon the nature of the ligand. The authors assume that there are at least two available biotin binding sites for each streptavidin. Due to the geometries of the QDs, the nature of the ligand, as well as how the biotins are arrayed on its surface, not all biotins will be able to bind to the QD surface. The authors have found that polymeric ligands of ~30 to 40 kDa with approximately three biotins per polymer show no detectable cross-linking of QDs when added to the QDs at a polymer to QD ratio of 3:1 followed by excess biotin (Cambi et al., 2007).

FLOW CYTOMETRIC DETERMINATION OF THE BINDING CONSTANTS OF LIGANDS OR ANTIBODIES

Ligand binding to its receptor is the first step in transmembrane signaling. The easiest way to characterize this interaction is to determine the equilibrium binding curve, i.e., ligand binding as a function of ligand concentration. Fluorescence has largely replaced the use of radioactivity in such experiments. This protocol describes how fluorescent QDs can be used for the determination of dissociation constants.

Materials

Biotin-coupled ligand or antibody
Avidin-coated QD (Invitrogen or Evident Technologies) suitable for excitation with the flow cytometer available
Trypsin
Phosphate-buffered saline (PBS)/1% (w/v) BSA (see recipe)

Flow cytometry tube
Flow cytometer
Flow cytometric analysis software

Additional reagents and equipment for coupling the ligand or antibody of interest to QDs (Support Protocol 1) and culture of cells (*UNIT 1.1*)

1. Couple the ligand or antibody of interest to QDs (see Support Protocol 1).
2. Trypsinize cells (*UNIT 1.1*), resuspend them in PBS/1% BSA at a concentration of 5×10^6/ml.
3. Prepare a 2-fold dilution series of QD-ligand. Add 1000 µl of the highest concentration of QD-ligand made in PBS/1% BSA to a flow cytometry tube. Prepare dilutions starting from a concentration ~10× higher than the anticipated K_d. Mix thoroughly. Keep all the tubes on ice during the entire labeling procedure. Pipet 500 µl from this solution to another tube into which 500 µl of PBS/1% BSA is added yielding the second highest concentration. Repeat this procedure until the lowest concentration is reached.

   Be aware that in the presence of ligand concentration 9× higher than the K_d, 90% of the binding sites will be occupied, if binding is noncooperative.

   At the end of this step flow cytometry tubes will be filled with 500 µl of different concentrations of the QD-ligand on ice.
4. Add 20 µl of the cell suspension to each tube and incubate for 30 to 60 min on ice with regular mixing.

   The QD-ligand is diluted negligibly by the 20 µl cell suspension, since 500 µl >20 µl.
5. Measure the samples with a flow cytometer.

   Keep the cells on ice until measurement. Alternatively, samples can be fixed in 1% formaldehyde after removing unbound QD-ligand by washing twice with PBS.

   Measure a nonlabeled cell sample too, the fluorescence intensity of which will be subtracted from the mean fluorescence intensities of each sample. Pay attention to the fact that all cells in the brightest and darkest samples have to be on scale, otherwise the means will be distorted.
6. Using a flow cytometric analysis software, determine the mean fluorescence intensities of each sample gated on the FSC-SSC dot plot.
7. Plot the autofluorescence-corrected mean fluorescence intensities as a function of the total QD-ligand concentration (assumed to be equal to the free ligand concentration).

8. Fit the following, so-called Hill equation to the measured data points:

$$I = I_{\max} \frac{c^n}{c^n + K_d^n}$$

where I is the fluorescence intensity in the presence of QD-ligand concentration of c, K_d is the dissociation constant required to half-saturate the binding sites, and n is the Hill coefficient characterizing the cooperativity of binding.

If there is good reason to believe that there is no cooperativity (e.g., if one ligand binds to a monomeric receptor species), it can be assumed that $n = 1$, and a simpler equation can be used:

$$I = I_{\max} \frac{c}{c + K_d}$$

In this case K_d has real meaning characterizing the binding event, e.g., it is equal to the ratio of the dissociation and association rate constants. If $n \neq 1$, K_d lacks any direct molecular implications. Indeed, the Hill coefficient itself cannot be translated into a real molecular model, since the Hill equation is the result of a reductionist view of the molecular events taking place during complex formation.

FLOW CYTOMETRIC QUANTITATION OF THE NUMBER OF ANTIBODY BINDING SITES

BASIC PROTOCOL 3

The number of binding sites for a ligand or antibody, i.e., the total number of expressed antigens is a significant issue: for example, it has predictive value in cancer diagnosis. Flow cytometry has obvious advantages over cell suspension-based methods (e.g., radioactive binding analysis), since it is capable of resolving heterogeneity and eliminates the influence of dead cells and cell debris. The idea behind the calibration procedure is to run a series of reference beads with calibrated number of antibody binding sites or fluorescence intensities. Three approaches are widely used:

1. Beads with calibrated fluorescence intensities (e.g., Quantum FITC MESF beads from Bangs Laboratories). The kit contains several bead populations each corresponding to the fluorescence intensity of a calibrated number of fluorophores. The company provides a calibration software (QuickCal) for the calculations, which can also be easily carried out with a spreadsheet program. Different beads are available for different fluorophores. To the best of our knowledge, no such beads are available for the calibration of QD fluorescence intensities, therefore the authors will not provide a detailed protocol.

2. The Qifikit calibration kit (Dako) contains a series of beads coated with different, calibrated numbers of mouse monoclonal antibody molecules. The beads have to be labeled by the secondary antibody used for labeling of the cells. A plot of the fluorescence intensity of the beads against the number of binding sites will be constructed.

3. The Quantum Simply Cellular kit (Bangs Laboratories) contains subpopulations of beads with calibrated binding capacities for the Fc region of mouse or human antibodies. The beads have to be labeled with a primary antibody followed by a secondary, fluorochrome-conjugated antibody in the same way as the cells. A calibration plot of fluorescence intensity versus number of binding sites can be constructed.

Materials

Cells being investigated
Primary unlabeled antibody

Secondary QD-conjugated antibody against the primary antibody (Quantum Dot Corporation or Evident Technologies)
Phosphate-buffered saline (PBS)/1% (w/v) BSA (see recipe)

Qifikit calibration kit (Dako)
Vortex
Qifikit calibration beads (Dako-Cytomation, *www.dako.com*) or Quantum Simply Cellular beads (Bangs Laboratories, *www.bangslabs.com*)
Flow cytometer
Quantum Simply Cellular kit (Bangs Laboratories)

For Qifikit

1a. Label the cells under investigation with saturating concentration of the primary unlabeled antibody.

2a. After washing the cells twice with 2 ml PBS, label them with the secondary, QD-conjugated secondary $F(ab')_2$. Include a cell sample which is only labeled by the primary antibody for background correction.

Cells and beads should be labeled with secondary antibody at the same time (see step 4a).

3a. After vortexing remove 100 µl from the Setup and Calibration bead vials, centrifuge the beads 4 min at 1400 × g, 4°C, after adding 3 ml of PBS/1% BSA.

The Qifikit beads are coated with primary mouse antibodies, and can only be used for the calibration of secondary antibody binding to cells labeled by primary mouse antibodies.

4a. Remove the supernatant and label the bead pellet with the secondary QD-conjugated secondary $F(ab')_2$ under the same conditions as the cells.

This step should be done at the same time as step 2a.

5a. Run the cells and the two Qifikit bead samples (Setup and Calibration) on the flow cytometer.

6a. Subtract the fluorescence intensity of the sample labeled by the primary antibody only from the intensity of the sample labeled by both the primary and secondary antibodies (background-corrected intensity).

7a. Analyze the fluorescence of the unlabeled bead population in the Setup sample and the five subpopulations in the Calibration sample. Subtract the mean fluorescence intensity of the unlabeled bead population from the fluorescence intensities of the calibration beads. Plot the background-corrected fluorescence intensities of the calibration bead subpopulations as a function of the number of binding sites which is included in the manual for the kit. Fit a line to the data points.

8a. Find the number of antibody binding sites on the cells based on their background-corrected fluorescence intensity using the calibration line.

For Quantum Simply Cellular beads (secondary labeling)

1b. Combine one drop of each of the beads with graded number of binding sites for human or mouse antibodies.

The blank bead with no capacity for antibody binding can also be combined with the others, or can be processed separately.

The Quantum Simply Cellular beads can capture a calibrated number of mouse or human monoclonal antibodies by their Fc domain allowing them to be used for the calibration of both primarily or secondarily labeled cells. The authors have provided a protocol for the use of these beads with secondary labeling, but the principle can easily be adapted for primary labeling.

2b. After mixing the beads vortex them. Label both the cells and the beads with saturating concentration of the primary unlabeled antibody.

3b. Add 5 to 10 ml PBS, centrifuge 4 min at 1400 × *g*, 4°C, and repeat washing step once more. Label the cells and the beads with the secondary, QD-conjugated secondary $F(ab')_2$. Include a cell sample which is only labeled by the primary antibody for background correction.

4b. Add 5 to 10 ml PBS and centrifuge the samples 4 min at 1400 × *g*, 4°C. Repeat the washing step once more before running the samples on the flow cytometer.

5b. Subtract the mean fluorescence intensity of the blank bead population from the fluorescence intensities of the labeled beads. Plot the background-corrected fluorescence intensities of the calibration bead subpopulations as a function of the number of binding sites. Fit a line to the data points.

6b. Find the number of antibody binding sites on the cells based on their background-corrected fluorescence intensity using the calibration line.

The company provides an online program, QuickCal (www.bangslabs.com/flow/quickcal), which can perform the above calculations automatically.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Paraformaldehyde (PFA) fixative

Prepare a fresh 4% (w/v) solution of paraformaldehyde, analytical grade in PBS (see recipe). Use only for 1 day, keep on ice.

A 40% solution can be prepared and kept in small aliquots at −20°C. Thaw at 50°C and immediately dilute in PBS (see recipe) before use.

Phosphate-buffered saline (PBS)

137 mM NaCl
2.7 mM KCl
7.9 mM Na_2HPO_4
1.5 nM KH_2PO_4
Adjust pH to 7.3 using NaOH or HCl, if necessary
Autoclave

Store up to 6 months at room temperature

PBS/1% (w/v) BSA

Add 1% BSA to PBS (see recipe) just before use.

Tyrode's buffer

135 mM NaCl
10 mM KCl
0.4 mM $MgCl_2$
1 mM $CaCl_2$
10 mM HEPES
Adjust pH to 7.2 using NaOH
Autoclave

Store up to 6 months at room temperature

Tyrode's buffer plus

Add 20 mM glucose and 0.1% (w/v) BSA to Tyrode's buffer (see recipe) just before use.

COMMENTARY

Background Information

Published results of in-vivo QD imaging

QD are not "brighter" than conventional fluorophores since they have relatively long fluorescence emission lifetimes. Also, due to their large size (dictated by the necessity of several layers of material for passivation and biocompatibility beyond the emitting core), there may be steric hindrance to binding compared to small fluorophores in applications such as in situ hybridization or labeling to arrays like cytoskeletal components. They are most important for their extreme photostability and thus have been used most effectively as labels for in vivo imaging. In particular, their application to the study of the behavior of cell surface receptors has brought new insights at single-molecule resolution (Dahan et al., 2003; Lidke et al., 2005a; Arndt-Jovin et al., 2006; Courty et al., 2006; Echarte et al., 2007; Hagen et al., 2007). An area beyond the scope of these protocols is the application of QDs to tracking and homing in whole animal studies (see Lim et al., 2003; Ballou et al., 2004; Kim et al., 2004; Smith et al., 2006). A number of recent reviews refer to uses of QDs in imaging, flow cytometry, and immunoassays (Bruchez and Hotz, 2006; Fu et al., 2005; Michalet et al., 2005; Mulder et al., 2006; Pinaud et al., 2006; Portney and Ozkan, 2006; Prasad, 2006; Smith et al., 2006; Weng and Ren, 2006).

Special characteristics and behaviors of QDs

One of the most powerful ways to determine local proximity of biologically relevant molecules is through FRET (Förster resonance energy transfer; *UNITS 17.1 & 17.9*) between a donor and an acceptor fluorophore attached to the two molecules of interest. In the case of QDs, the large passivation and conjugation shells surrounding the fluorescent core make it difficult to use QDs for such measurements since the efficiency of transfer varies inversely with the 6th power of the distance between donor and acceptor. Additionally, the broad excitation spectrum of QDs prohibits their use as FRET acceptors since it is not possible to selectively excite the donor, resulting in a relatively small enhancement of acceptor fluorescence due to FRET. An exception is the use of a bioluminescent donor for QD-BRET as mentioned in the beginning of this unit (So et al., 2006). QDs can act as donors in a FRET pair when the acceptor lies in close proximity to the passivation shell (see Lidke et al., 2005a; Clapp et al., 2006; Pons et al., 2006). In this case the QD should not have a large bio-shell such as PEG conjugation.

Single QDs exhibit 'blinking' behavior or intermittent fluorescence (see Fig. 25.1.4). Although proper passivation of the semiconductor core reduces blinking, it is generally not possible to suppress this phenomenon completely. The blinking follows an inverse power law, as predicted for (1) an exponential distribution of trap depths or (2) a distribution of tunneling distances between QD core/interface state (Kuno et al., 2000; Shimizu et al., 2001). Hohng and Ha (2004) were able to reduce blinking of single QDs by treating them with high concentrations of thiols, a procedure that is incompatible with live-cell imaging. When tracking individual QDs attached to cell surface receptors or the cytoskeleton using high-speed acquisitions in the 20 to 50 msec range, correction for the blinking behavior must be made to avoid improper segmentation of the loci or jumping of the track between different QDs (Dahan et al., 2003; Arndt-Jovin et al., 2006). However, this blinking behavior can be used to advantage to localize individual QDs with super resolution (Lidke et al., 2005b; Hagen et al., 2007).

An advantageous property of QDs is the CdSe electron dense core that can be detected by transmission electron microscopy (Dahan et al., 2003; Nisman et al., 2004). This makes possible correlative dynamic fluorescence and high-resolution TEM studies on the same sample.

Critical Parameters and Troubleshooting

The "tail wagging the dog" problem: Quantum Dot size and valency considerations

The size of a QD is comparable to that of an antibody. Therefore, since the binding properties or biological activity of a ligand can be influenced by its conjugation to a QD, careful control experiments (such as flow cytometry

to characterize QD-ligand binding constants) must be made to establish that there is no steric influence of the QD.

QDs are multivalent, such that several ligands can be coupled to each QD. This can result in a single QDs binding multivalently to multiple receptors (Cambi et al., 2007). The researcher has to decide whether this is a concern for his or her particular problem. If so, the ligand should be coupled to the QD in a nearly 1:1 ratio (Lidke et al., 2004) and preblocking of excess binding sites with free biotin may be necessary (see Support Protocol 1).

Fixation

PFA (4%) is the preferred fixation solution for samples labeled with QDs. The QD fluorescence is destroyed by freezing or fixation in −20°C methanol. In addition, the use of various mounting mediums must be tested to ensure that the medium does not degrade the QD fluorescence. As QDs degrade, their emission gradually shifts to lower wavelength and this can be particularly precarious when several spectrally distinct QDs are present. To avoid such problems, store fixed samples in PBS at 4°C, mount fixed samples in PBS, and image within 24 hr of fixation.

Nonspecific binding

The authors recommend the PEG 2000-coated QDs for most cellular applications since they show reduced nonspecific binding to cells and cell substrates, such as polylysine or collagen. In addition, the presence of high concentrations of BSA and the use of a higher pH will help to reduce nonspecific binding. The reader is reminded that stock solutions of QDs are maintained by Invitrogen in 1 M trimethylglycine at pH 8.5 and dilution into buffers containing divalent cations will, over time, result in aggregation and precipitation of the QDs.

Controls

It is essential to prove that the QD signal is reflective of the uncoupled ligand's interaction with the receptor of interest and that the QDs do not interfere, when appropriate, with the ligand's physiological activity. Controls for such behavior include showing that (1) unconjugated QDs do not bind to the cell surface, (2) QD-ligands do not bind to cells not expressing the membrane protein of interest, (3) presaturation of the cell surface receptors with unlabeled ligand blocks QD-ligand binding, and (4) addition of QD-ligand mimics unconjugated ligand. In addition, flow cytometry (Basic Protocols 2 and 3) can be used to characterize QD-ligand binding constants and correlation with free ligand binding (Lidke et al., 2004).

Other bioconjugation techniques

As described above, many types of QDs with different bioconjugation are available. In addition, manufacturers sell kits for alternative bio-coupling methods. See the manufacturers' Web sites for more information (*http://probes.invitrogen.com/p1roducts/qdot* and *http://www.evidenttech.com*). For a review of other labeling methods see Smith et al. (2006).

Flow cytometric determination of binding constants

Antibodies and ligands typically induce the internalization of their receptor. In order to prevent this from happening, both the cell suspension and the ligand solutions have to be kept on ice for the duration of the experiment. If samples are not fixed before measurement, internalization can take place in the instrument as well. The sample can spend a significant amount of time at room temperature in flow cytometers into which multiple samples are loaded simultaneously (e.g., with a sample loader or on a 96-well plate). In such cases, the samples should be fixed before measurement. Before fixation the unbound ligand has to be removed by washing with excess PBS. Dissociation of bound ligands starts immediately after the ligand concentration drops in the medium. Therefore, washing can introduce errors into the measurement. Consequently, it is best to use flow cytometers into which single tubes are loaded one-by-one, and use unfixed cells without washing. This can be done since most flow cytometers are equipped with a constant background subtraction algorithm, therefore the contribution of extracellular fluorescence is reliably removed.

The authors strongly advise against using the Scatchard analysis, i.e., a plot of the ratio of bound ligand concentration to free ligand concentration as a function of bound ligand concentration, for fitting. In flow cytometric experiments the measured fluorescence intensities can be used instead of the bound ligand concentration. Before nonlinear regression programs became widely available, scientists transformed data to make linear plots. If the Scatchard plot can be fitted with a single line, the x intercept and the slope of the line correspond to the maximum number of binding sites (maximum fluorescence intensity) and the negative reciprocal value of the K_d, respectively. Although the shape of a Scatchard

plot reveals potentially important information about the nature of binding (positive or negative cooperativity in the case of concave down and concave up Scatchard plots, respectively), the fitting results will be distorted due to error propagation inherent in the transformation leading to the Scatchard plot.

If the fluorescence intensity does not saturate, the following possibilities have to be investigated:

1. Nonspecific binding: nonspecific binding sites are usually very difficult to saturate. Dead cells may have significant non-specific binding.

2. Ligand depletion: in most analyses it is assumed that the amount of bound ligand is negligible compared to the total amount available. If the number of binding sites is high, this assumption does not hold, and the free ligand concentration can be significantly lower than the total (ligand depletion). In such a case saturation of binding takes place at a much higher total ligand concentration than without ligand depletion. The ligand can also bind to the wall of the flow cytometric tube leading to a similar phenomenon.

3. Ligand binding can be compromised by coupling to QD.

Flow cytometric determination of the number of antibody binding sites

In the Quantum Simply Cellular kit the same primary antibody is used for labeling the beads and the cells whereas the Qifikit beads are coated with a mouse monoclonal antibody. Since secondary antibodies may show slight variation with regard to binding to primary antibodies, there is some advantage to the Quantum Simply Cellular in that the secondary antibody binds to the same primary antibody on both cells and beads. In most cases (especially if the same isotype is used for labeling the cells and coating the bead), this is unlikely to be a major source of error. On the other hand, the primary antibody is captured by its Fc domain by the Quantum Simply Cellular beads, a different orientation from when the Fab domain binds to its epitope. It is unknown to us whether the different orientation of the primary antibodies has any influence on the binding of the secondary antibody.

If the calibration line is prepared using the background-corrected fluorescence intensities of the calibration beads (as described in the above protocols), the calibration line should cross the origin of the plot, or have a *y* intercept very close to zero. The calibration curve is expected to be strictly linear, i.e., a correlation coefficient of >0.98 and no splaying at high concentrations. If the curve is nonlinear or it does not cross the *y* axis at zero, nonspecific binding of the antibody or incomplete labeling of the beads may have happened. Check the quality of the antibodies used and whether the beads were mixed regularly during labeling.

If the fluorescence intensity of the cells is higher than that of the brightest bead population, the calibration line can be extrapolated. But it has to be kept in mind that at very high densities antibody binding may not be strictly proportional to the number of antibody binding sites. Although the number of antibody binding sites on the different bead population may show batch-to-batch variation, the range of the Qifikit beads usually extends higher ($\sim 5 \times 10^5$) than that of the Quantum Simply Cellular beads ($\sim 2 \times 10^5$).

Anticipated Results

Support Protocols 1 and 2: Collection of eluted fractions from the size exclusion column or recovery of the QD fraction after filtration should result in a purified QD-ligand complex. The presence of QDs can be confirmed by recording an absorbance or emission spectrum. Concentration of QDs can be calculated from the peak absorbance value if one knows the extinction coefficient (available from the manufacturer) for that particular QD.

Basic Protocol 1: During the imaging times series, the researcher should observe a strong QD signal localized at the position of the receptor (either on the membrane or internalized in vesicles). Addition of unlabeled QDs should not result in QD binding to the cell surface. Large aggregates should not be seen in the images—this would indicate cross-linking of the QDs by ligand and the complex formation conditions should be adjusted as discussed in the Alternate Protocol.

For all of the basic protocols, detection limits depend on the imaging conditions. Under the right conditions and with sensitive emCCD cameras one can detect single QD binding as indicated in the Background Information section and literature cited therein. It is difficult to detect single QDs in raster scanning confocal microscopes in live samples, but possible in fixed material with long pixel dwell times and line averaging.

Time Considerations

Support Protocol 1. Preparation and mixing of reagents to form QD-ligand complexes should take 15 to 20 min. Complexes should incubate for at least 30 min. The time for

purification depends on whether spin columns, filters, or gravity columns are used, between 30 min to 2 hr is usual.

Basic Protocol 1. Replating of cells into imaging chambers takes ~30 min. The time for an imaging experiment is dependent on the processes being observed and the length of the time series acquired. Quantitative image analyses of image time series can be run as batch jobs once the conditions of the experiments have been standardized and macros or plug-ins to the basic image processing software have been concatenated. Tracking of individual QDs must normally be controlled by operator intervention to avoid analysis of false traces.

Basic Protocols 2 and 3. The labeling and the flow cytometric experiment can be carried out in ~2 hr and analysis typically takes ~1 hr.

Acknowledgements

The authors would like to thank Thomas M. Jovin for discussions and expert advice and Alessandra Cambi and Keith Lidke for results from collaborations.

ABSTRACT

Nanofibers fabricated by electrospinning are morphological mimics of fibrous components of the native extracellular matrix, making nanofibrous scaffolds ideal for three-dimensional cell culture and tissue engineering applications. Although electrospinning is not a conventional technique in cell biology, the experimental setup may be constructed in a relatively straightforward manner, and the procedure can be carried out by individuals with limited engineering experience. Here, we detail a protocol for electrospinning of nanofibers and provide relevant specific details concerning the optimization of fiber formation (Basic Protocol 1). The protocol also includes conditions required for preparing biodegradable polymer solutions for the fabrication of nonwoven and aligned nanofibrous scaffolds suitable for various cell/tissue applications. In addition, information on effective cell loading into nanofibrous scaffolds and cellular constructs grown in a bioreactor is provided (Basic Protocol 2). Instructions for building the electrospinning apparatus are also included (see the Support Protocol). *Curr. Protoc. Cell Biol.* 42:25.2.1-25.2.12.

Keywords: nanofiber • electrospinning • scaffold • tissue engineering • three-dimensional culture

INTRODUCTION

Recent advances in nanotechnology and increasing recognition of the potential of nanomaterials as biocompatible and biomimetic scaffolds for cells have provided new tools for tissue engineering and the development of three-dimensional (3D) cell cultures (Christenson et al., 2007). In a native tissue environment, cells are embedded within and are in contact with the extracellular matrix (ECM), which acts both as a structural supporter, as well as a regulator of cell activities. Biochemical and mechanical signals derived from cell-ECM interactions are critical to cell survival and functions. Similarly, in vitro, cells interact intimately with and respond to cues from their matrix environment, further highlighting that cell activities are strongly influenced by the physical and chemical properties of the culture environment (Berrier and Yamada, 2007). A 3D, highly porous substrate that mimics the native ECM can form unique spatial interactions with cells, and is thought to more accurately replicate cell-matrix interactions in vivo, compared to two-dimensional (2D) substrates commonly used for tissue culture (Griffith and Swartz, 2006). To meet the requirements for various tissue engineering applications, a variety of 3D scaffolds of different compositions have been developed. Nanofibers produced by electrospinning represent a promising candidate scaffold biomaterial for tissue engineering (Li et al., 2005). These fibers possess unique physical characteristics, such as high surface area to volume ratio and improved mechanical strength, compared to their micro-scaled counterparts. Nanofibrous scaffolds also morphologically resemble the fibrillar components of the native ECM, enhance adsorption of cell adhesion molecules, induce favorable cell-ECM interactions, maintain cell phenotype, support differentiation

of stem cells, and promote cell-matrix adhesion and activate appropriate cell signaling pathways (Fig. 25.2.1; Li et al., 2006b).

What Is Electrospinning?

The electrospinning technique uses a high electric field to produce ultra-fine polymeric fibers with diameters ranging from a few nanometers to a few micrometers. The mechanism of electrospinning nanofibers is based on a complex electro-physical activity between polymer solution and electrostatic force. In this procedure, a high-voltage electric field is set up between the injection needle and the collecting screen using a power supply and electrodes. When the polymer solution is extruded slowly from the syringe, a semispherical polymer solution droplet is formed at the tip of the needle. With increasing voltage, the charged polymer droplet elongates to form a conical shape known as the Taylor cone (Taylor, 1969), and the surface charge on the polymer droplet increases with time. Once the surface charge overcomes the surface tension of the polymer droplet, a polymer jet is initiated (Taylor, 1964). The solvent in the polymer jet evaporates during its travel to the collecting screen, increasing the surface charge on the jet. This increase in surface charge induces instability in the polymer jet as it passes through the electric field. To compensate for this instability, the polymer jet divides geometrically, first into two jets, and then into many more as the process repeats itself. The formation of nanofibers results from the action of the spinning force provided by the electrostatic force on the continuously splitting polymer droplets. Nanofibers are deposited layer-by-layer on the metal target plate, forming a nonwoven nanofibrous mat. During the electrospinning process,

both extrinsic and intrinsic parameters are known to affect the structural morphology of the nanofibers (Doshi and Reneker, 1995). Specifically, extrinsic parameters, such as environmental humidity and temperature, and intrinsic parameters, including applied voltage, working distance, and conductivity and viscosity of the polymer solution, need to be optimized to produce uniform nanofibers. The two major structures usually found in the nanofibrous mat are a uniform, continuous fibrous structure or a bead-containing fibrous structure. Variation in the relative abundance of these two structures is determined by the relative contributions of the parameters during the electrospinning process.

Nanofibrous biomaterials, by virtue of their structural and morphological characteristics, are well suited as tissue engineering scaffolds for various tissue types, particularly musculoskeletal tissues such as cartilage, bone, tendon, and ligament. In principle, the structural functions of ECM components, such as collagen fibers, can be fulfilled by the morphologically similar nanofibers in the engineered tissues. Nanofiber-based 3D biomaterials may also serve as biomimetic substrates to culture normal and transformed cells for cell biology research.

STRATEGIC PLANNING

To fabricate nanofibrous scaffolds, an electrospinning apparatus is required. Given that this is not commercially available, one must construct the apparatus. This unit provides a straightforward, do-it-yourself protocol for constructing an electrospinning apparatus (see Support Protocol). Although relatively simple in design, the electrospinning apparatus described here is capable of producing high-quality nanofibers for experimental applications. The nanofiber electrospinning process starts with the preparation of biodegradable or nonbiodegradable, natural/synthetic polymer solutions. Polymer solutions are prepared by mixing the chosen polymer with the suitable solvent(s). The solvent can be either a single chemical component or a mixture of multiple chemicals, depending on the chemistry of the chosen polymer. In general, the solvent must be capable of completely dissolving the polymer and carrying an applied charge. This unit will focus on how to fabricate nanofibrous scaffolds with a non-woven or an aligned fiber structure, composed of clinically used, Food and Drug Administration (FDA) approved synthetic biodegradable polymers (see Basic Protocol 1).

The four intrinsic parameters mentioned above—applied voltage, working distance, and conductivity and viscosity of the polymer solution—must be adjusted and optimized to produce a uniform fiber. These parameters are dependent on the nature of the polymer used and thus vary with different polymers. After electrospinning, the finished nanofibrous scaffold needs to be sterilized before use for cell culture. Heat or γ–irradiation cannot be used to sterilize nanofibers since the fibers are likely to be damaged by these treatments. Nanofibrous scaffolds can be effectively sterilized by ultraviolet light (UV) and ethanol. The step-by-step procedure detailing effective cell seeding into nanofibrous scaffolds, including aspiration using bibulous filter paper to increase cell-infiltration efficiency, is described in Basic Protocol 2. To enhance nutrient access to cell-seeded nanofibrous constructs, rotary wall vessel (RWV) bioreactors are used to facilitate nutrient/metabolic waste exchange in and out of the 3D construct; the procedure for culturing cellular nanofibrous constructs in a bioreactor is described in Basic Protocol 2.

FABRICATION OF NANOFIBROUS SCAFFOLDS

BASIC PROTOCOL 1

A number of polymers, both natural and synthetic, which may be biodegradable or nonbiodegradable, may be used as raw biomaterials to fabricate nanofibrous scaffolds. With the discovery and synthesis of new polymers, the list of candidate polymers suitable for electrospinning continues to grow. Synthetic biodegradable polymers can be tailored to have the specified, desired properties, including degradation profile and mechanical

properties, over those of natural polymers. Biodegradable poly(α-hydroxy esters) are the most widely used polymers for the fabrication of tissue engineered scaffolds, given their FDA approval and well-documented biocompatible properties (Gunatillake and Adhikari, 2003). In addition to each member of the poly(α-hydroxy esters) family having defined chemical and physical properties, the addition option of mixing or co-polymerizing two or more of poly(α-hydroxy esters) at varying ratios to generate materials with a wide spectrum of properties is another attractive characteristic of the poly(α-hydroxy esters).

There are currently six FDA-approved poly(α-hydroxy esters), including poly(glycolic acid) (PGA), poly(L-lactic acid) (PLLA), poly(D,L-lactic acid) (PDLLA), poly(D,L-lactic-*co*-glycolic acid 50:50) (PLGA5050), poly(D,L-lactic-*co*-glycolic acid 85:15) (PLGA8515), and poly(ε-caprolactone) (PCL), that have been successfully used to produce nanofibers. However, only PLLA and PCL have slow degradation rates suitable for cell culture applications (Li et al., 2006a). In this section, fabrication of PLLA and PCL nanofibrous scaffolds will be described in the step-by-step protocol. Besides nonwoven fibrous scaffolds, the electrospinning technique is also capable of producing aligned fibrous scaffolds using an alternative setup (Theron et al., 2001). The matrix of aligned synthetic nanofibers mimics that of uni-axial collagen fibers found in native tissues and is suitable for growing of tissues with anisotropic structure, such as striated muscle and tendon/ligament. Typically, nanofibrous scaffolds are characterized on the basis of fiber morphology, observed using scanning electron microscopy, degradation profile, porosity, and mechanical properties.

Materials

PLLA (mol. wt. 50,000; Polysciences)
N,N-Dimethyformamide (DMF; Fisher Scientific)
Chloroform (Fisher Scientific)
PCL (mol. wt. 80,000; Aldrich)
Tetrahydrofuran (THF; Fisher Scientific)

Glass threaded vials
Analytical balance
Parafilm
Vortex mixer
Aluminum foil
Electrospinning apparatus (see Support Protocol)
Glass slides
Glass coverslips
10-ml glass syringe fitted with an 18-G blunt needle
Sharp surgical blade
Vacuum desiccator

Prepare polymer solution

1. Dissolve 1.6 g of PLLA polymer in 11 ml of chloroform/DMF (10:1) in a glass vial.

   More polymer solution can be made using the same proportions if desired.

2. Dissolve 2 g of PCL polymer in 14 ml of THF/DMF (1:1) in a glass vial.

   More polymer solution can be made using the same proportions if desired.

   NOTE: *Raw polymers before use should be stored at 4°C in a tight container within a sealed bag. When taking out of storage, allow the container to reach room temperature before opening to prevent moisture condensation.*

3. Screw the cap of the glass vial tight and wrap the vial cap with Parafilm.

4. Vortex the polymer solution in the glass vial overnight.

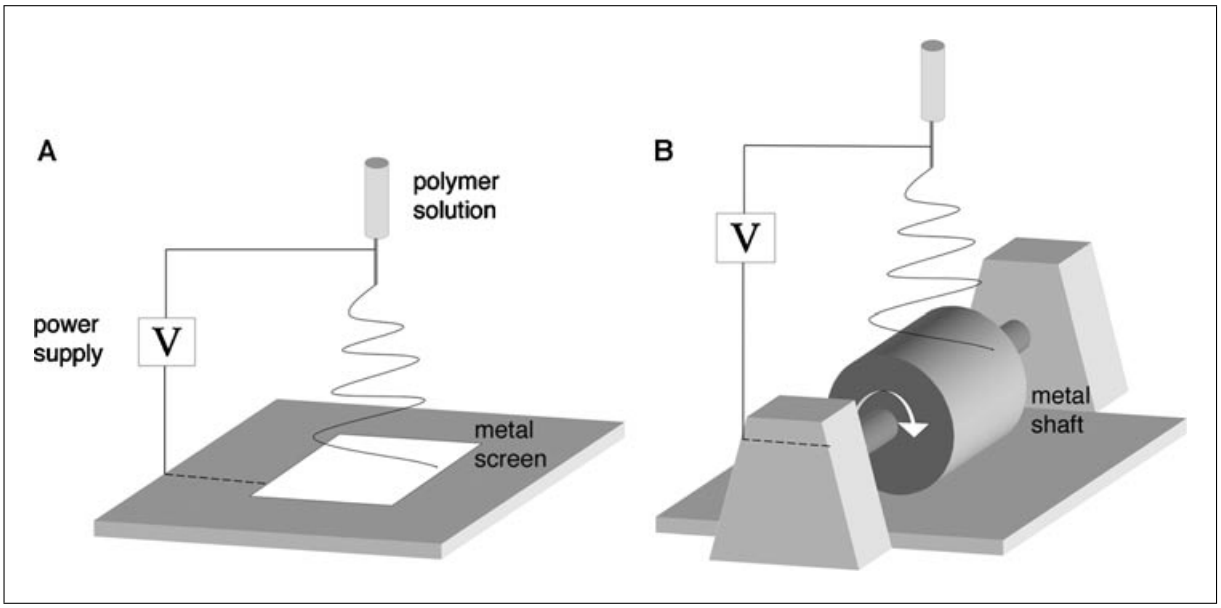

Figure 25.2.2 Two basic setups of electrospinning apparatus. Nonwoven nanofibrous scaffolds can be produced and collected on a flat metal plate (**A**), whereas aligned nanofibrous scaffolds can be collected onto a rotary metal shaft (**B**).

Electrospin a nonwoven nanofibrous scaffold

5a. Place a sheet of aluminum foil onto the fiber collection screen in the bottom of the electrospinning apparatus (see Fig. 25.2.2A).

The sheet of aluminum foil used to collect nanofibers should be wrinkle-free since the wrinkled surface results in uneven fiber deposition. The sheet of aluminum foil must be handled with care.

To directly coat nanofibers onto glass slides or coverslips, use clean forceps to pick up the slides/coverslips and place them onto the surface of the aluminum foil sheet with only a small distance separating them.

6a. Mount the 10-ml glass syringe fitted with an 18-G blunt needle vertically in the electrospinning apparatus, and transfer the homogeneously mixed polymer solution into the syringe.

7a. Adjust the distance between the tip of the needle and the fiber collection screen to 20 cm.

8a. Turn on the high-voltage power supply and set the voltage at 16 kV for PLLA or 12 kV for PCL.

Unwanted non-uniformed polymer droplets form before the voltage is correctly established. Use a sheet of paper towel to cover the collection screen and then remove it after the desired voltage is reached.

The fiber spinning process usually requires a period of several hours. Check the process periodically. The needle can become clogged if undissolved polymer or impurity is present. When this happens, turn off the power and then unclog the needle.

9a. Using a sharp surgical blade, cut the nanofibrous sheet and gently remove it from the fiber collection screen.

For nanofiber-coated glass slides or coverslips, cut the fibers along the edge of the slides or coverslips. Make sure that all the excess, connected nanofibers are excised from the edges of the slides/coverslips and cut clean before they are separated from each other.

10a. Place the nanofibrous sheet or the nanofiber-coated glass slides/coverslips in a vacuum desiccator for 2 days to remove the organic solvent residue.

Electrospin an aligned nanofibrous scaffold

5b. Remove the stationary copper plate collection screen and replace with the rotary metal shaft or mandrel (see Fig. 25.2.2B).

6b. Place a sheet of aluminum foil to fully cover the shaft.

The sheet of aluminum foil used to collect nanofibers should be wrinkle-free since the wrinkled surface results in uneven fiber deposition. The sheet of aluminum foil must be handled with care.

To directly coat nanofibers onto glass slides or coverslips, use clean forceps to pick up the slides/coverslips and place them onto the surface of the aluminum foil sheet with only a small distance separating them. Secure the slides/coverslips with adhesive tape to the surface of the rotary shaft. In addition, a protective plastic shield should be set up in the front of the electrospinning apparatus to contain accidental, flying objects.

7b. Mount the 10-ml glass syringe fitted with an 18-G blunt needle vertically in the electrospinning apparatus, and transfer the homogeneously mixed polymer solution into the syringe.

8b. Adjust the distance between the tip of the needle and the fiber collection shaft to 20 cm.

9b. Adjust the rotation of the rotary shaft to the desired speeds(s) with the variable rheostat transformer.

The rotation speed determines the extent of the fiber alignment. The faster the rotation speed the greater the extent of alignment. Under the conditions described here, >90% fiber alignment is achieved when the linear speed of the shaft exceeds 9.3 meters/sec.

10b. Turn on the high-voltage power supply and set the voltage at 16 kV for PLLA or 12 kV for PCL.

Unwanted non-uniformed polymer droplets form before the voltage is correctly established. Place a sheet of paper towel between the needle and the rotary shaft to cover the fiber collection surface and then remove it after the desired voltage is reached.

11b. Using a sharp surgical blade, cut the nanofibrous sheet and gently remove it from the fiber collection surface of the shaft.

For nanofiber-coated glass slides or coverslips, cut the fibers along the edge of the slides or coverslips. Make sure that all the excess, connected nanofibers are excised from the edges of the slides/coverslips and cut clean before they are separated from each other.

12b. Place the nanofibrous sheet or the nanofiber-coated glass slides/coverslips in a vacuum desiccator for 2 days to remove the organic solvent residue.

The nanofibrous sheets/slides/coverslips should be used for experiments as soon as they are produced. If storage is needed, the product should be stored in a vacuum desiccator.

BASIC PROTOCOL 2

NANOFIBROUS SCAFFOLDS FOR CELL CULTURING

Cell seeding into a 3D, porous biomaterial scaffold is the first and critical step for the formation and growth of tissue engineered constructs in vitro. Because of the complex 3D structure that makes cell infiltration difficult, cell seeding into a 3D scaffold is more challenging and less effective compared to conventional monolayer culturing. For nanofiber-coated surfaces, such as glass slides or coverslips, cell seeding by natural gravity is a convenient and practical approach. However, cell seeding into a 3D nanofibrous scaffold constructed with interwoven ultrafine fibers requires different methods to

improve efficiency. One preferred method uses bibulous filter paper to aspirate cells into the 3D scaffold in a guided manner.

Bioreactors are culture devices that circulate the culture medium to promote cell and tissue growth via enhanced nutrient transport and mechanical stimulation (Martin et al., 2004). Tissues cultured in appropriate bioreactors show increased weight and enhanced cellular phenotype, compared to tissues grown in static cultures, e.g., in tissue culture dishes, plates, or flasks (Martin et al., 2000). Various bioreactor designs have been developed and used for tissue engineering applications. The rotary wall vessel (RWV) bioreactor, originally developed to simulate microgravity by randomizing gravity (Martin et al., 2004), is a commercially available device (Synthecon), and is suitable for growing large-sized engineered tissue in vitro. Constructs cultured in a RWV bioreactor encounter low shear stress when the rotation speed of the culture chamber is set to balance the weight of the construct and the hydrodynamic force (Lappa, 2003). The randomized gravity environment inside the chamber permits the cultured tissue construct to undergo continuous free-fall with maximal enhancement of medium diffusion into the construct.

Materials

Graded ethanol series [70% (v/v), 50% (v/v), and 25% (v/v) ethanol, see recipe]
Sterile distilled water
Hank's Balanced Salt Solution (HBSS), sterile
Cell suspension in 10% serum-containing culture medium (cell density = 20×10^6/ml; see recipe for culture medium)
Serum-containing culture medium (see recipe)

Surgical blade
Nanofibrous sheet/scaffolds (see Basic Protocol 1)
Petri dish
UV light source
Bibulous filter paper (Whatman 3 MM)
Pipettor
Multi-well culture plate
Tissue culture incubator
Rotary wall vessel (RWV) bioreactor (Synthecon)

Prepare nanofibrous scaffolds for cell seeding

1. Using a surgical blade, cut the nanofibrous sheet (1-mm thick) into the desired shape and size.

   The use of scissors should be avoided because the compressive cutting force will deform the edges of the scaffolds.

2. Gently remove the fibrous scaffolds from the aluminum foil and place them in the clean petri dish.

3. Sterilize the nanofibrous scaffolds under UV irradiation of each side for 30 min in a sterile, laminar-flow hood.

4. Soak the nanofibrous scaffolds in 70% (v/v) ethanol for 30 min.

   Air bubbles often are trapped inside the nanofibrous scaffold. To ensure complete sterilization and hydration, trapped air bubbles must be removed, which can be done by gently rolling a sterile glass rod over the nanofibrous scaffold to squeeze out the air bubbles.

5. Remove the 70% (v/v) ethanol and hydrate the nanofibrous scaffolds with sequential washes of 50% (v/v) ethanol, 25% (v/v) ethanol, sterile distilled water, and finally sterile HBSS for 30 min each.

6. Store the nanofibrous scaffolds in the HBSS while preparing cells for seeding.

7. Place the nanofibrous scaffold onto a sterile piece of bibulous filter paper.
8. Seed the desired number of cells by quickly pipetting the cell suspension onto the nanofibrous scaffold, as the solution is being aspirated into the scaffold.

   The ideal cell seeding density in a nanofibrous scaffold depends on cell types and applications. For example, the density of 400,000 cells/cm^2 is used to study chondrogenesis of mesenchymal stem cells.

9. Place the cell-loaded nanofibrous scaffold into wells of the multi-well culture plate.

   The nanofibrous scaffold may become dry if left on the filter paper too long. Cell seeding into the scaffolds should be done one at a time, with other scaffolds kept in HBSS.

   Replace the wet filter paper as needed to maintain an efficient absorption capability.

10. Maintain the culture plate in the tissue culture incubator. Add a small volume of additional cell medium periodically during the next 2 hr to prevent desiccation.
11. Add appropriate amount of culture medium into the wells for regular static culture. For cultures to be maintained in the RWV bioreactor, culture the cell-seeded scaffolds in culture plates for 3 days before transferring to the bioreactor.

Culture cellular nanofibrous constructs in RWV bioreactor

12. Gently transfer the cell-based nanofibrous constructs to the sterilized RWV bioreactor chamber and reassemble the chamber.

    The choice of the RWV chamber size is based on the dimension of the samples being cultured. The internal space of the chamber should be large enough for the samples to move freely. Multiple samples may be placed in a single chamber, provided that the constructs do not collide with one another when the chamber is rotating.

13. Fill the chamber completely with culture medium and purge all air bubbles.
14. Mount the chambers to the bioreactor base and adjust the rotation speed until the samples appear to be suspended in the culture medium.
15. Maintain cellular constructs in the bioreactor for at least 21 days to allow maturation of the engineered tissue.
16. Collect the cultured tissue from the bioreactor and analyze it using cellular and molecular biology techniques.

SUPPORT PROTOCOL

CONSTRUCTION OF AN ELECTROSPINNING APPARATUS

The construction and setup of an electrospinning apparatus is presented here. The electrospinning apparatus is composed of three major components: a high-voltage power supply, a polymer solution reservoir (e.g., a syringe, with a small diameter needle) and an accessory flow control pump, and a metal collecting screen. The high-voltage power supply with several independent adjustable controls and independently functioning DC outputs should be capable of providing multiple power levels up to 50-kV. A syringe is used to store the polymeric solution and a metal needle is connected to the electrodes of the power supply to deliver a charged polymer jet. Polymer flow can be driven by gravity when the syringe is placed vertically. However, a syringe pump is usually used for precise control of flow rate. The fiber-collecting screen should be conductive and can be either a stationary plate or a rotary platform. As described above, the plate is used to obtain nonwoven fibers, while a rotary platform is used to obtain aligned fibers.

There are two basic electrospinning setups, vertical and horizontal. In the former, nanofibers move downwards vertically to the fiber collection screen, whereas in the latter, nanofibers travel horizontally to the target plate. Both setups function well in the production of nanofibers, and the selection of the setup is a matter of preference. With

computer-controlled automation, the setup can be transformed into a more sophisticated one capable of fabricating complex nanofibrous structures. For example, controlled delivery using multiple jets can be used to fabricate a single nanofibrous scaffold that is composed of multiple layers, with each layer derived from a different polymer. In addition, the multiple jet setup is more efficient for the production of a large quantity of scaffolding material. Generally, a basic setup is sufficient for the purpose of making nanofibrous scaffolds for tissue engineering and 3D culture experiments in the laboratory. The protocol described here is for constructing a basic model of the vertical electrospinning apparatus.

An isolated or low-traffic space in the laboratory is needed to set up the electrospinning apparatus, since a high-voltage charge is utilized during electrospinning, and this is potentially hazardous. To enhance safety, a protective casing, made of nonconductive plastic, is commonly used to enclose the entire electrospinning apparatus. The enclosure also minimizes variations in environmental factors, such as temperature and humidity, which affect nanofiber formation. In addition, proper venting via a chemical hood is required to remove vapor from volatile chemical solvents.

Materials

High-density polyethylene (HDPE) plate
Polycarbonate plate
HDPE square rods
Wooden plate (20-in. × 20-in.)
Copper plate (10-in. × 10-in.)
Teflon plate (20-in. × 20-in.)
Glass syringe
18-G blunt metal needle
High-voltage DC power supply

Construct closed apparatus box

1. Build the electrospinning apparatus box (20-in. × 20-in. × 30-in.; Fig. 25.2.3) by assembling the top (see A in Fig. 25.2.3), the bottom (see B in Fig. 25.2.3), the back (see C in Fig. 25.2.3), and the two side (see D & E in Fig. 25.2.3) HDPE panels.

   Black or dark color plastic is preferred to construct the back panel of the enclosure box, to provide better observation of fiber formation, since electrospun nanofibers are seen as white ultra-fine fibers.

2. Install the transparent polycarbonate front door (see F in Fig. 25.2.3).

   The transparent door provides protected observation of the electrospinning process.

3. Attach the two adjustable-length HDPE arms (see G in Fig. 25.2.3) onto the inside of the top panel of the box.

   Each of the HDPE arms, with one end attached to the top, is composed of three interconnecting square rods.

   The free end of the arms has a drilled hole to function as the syringe holder.

   The length of the arms should be adjustable to permit a distance range of 5 to 30 cm between the tip of the needle and the fiber collection screen.

4. Place the wooden plate (see H in Fig. 25.2.3), with a 5-cm hole at the center to allow the negative/ground wiring to pass through, on the bottom plastic plate

5. Place the copper plate (see I in Fig. 25.2.3), which serves as the fiber-collecting screen, on top of the wooden plate.

   The copper plate functions as the negative/ground target that needs to be connected to the negative/ground charge of the power supply during electrospinning. A connector, such as

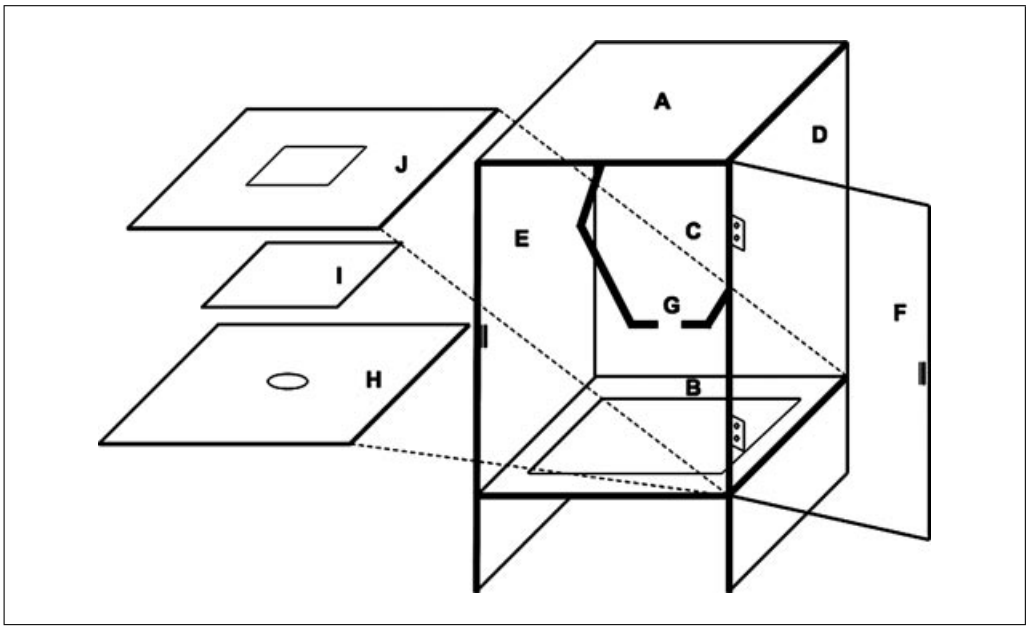

Figure 25.2.3 Schematic of electrospinning apparatus box. The box is constructed with HDPE plates representing the top (A), bottom (B), back (C), and two side (D&E) panels, and the front polycarbonate door (F). Each of the HDPE arms (G), with one end attached to the top, is composed of three inter-connecting square rods, and is flexible for height adjustment of the syringe holder. Inside the box, a Teflon plate (J) is placed on top of the copper plate (I) that is on top of the wooden plate (H).

a banana socket, may be installed at the center of the copper plate to connect with the negative/ground charge.

6. Place a Teflon plate (see J in Fig. 25.2.3), the same size as the wooden plate and with a square opening in the center, on top of the copper plate,

   The Teflon plate is nonconductive and is used to electrically mask the copper plate underneath, such that nanofibers are only allowed to deposit on the exposed area of the copper plate defined by the opening. The area of the opening thus determines the size of the finished electrospun nanofibrous sheet.

7. Place the needle-attached syringe in the holder.

8. Connect the positive charge output to the needle and the negative charge to the copper plate.

   See Critical Parameters for guidelines to operating the electrospinning apparatus.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Graded ethanol series

25% ethanol in sterile, distilled water
50% ethanol in sterile, distilled water
70% ethanol in sterile, distilled water
Store at room temperature until used to sterilize the nanofibers in the preparation process for cell seeding

Serum-containing culture medium

DMEM culture medium containing 10% fetal bovine serum
Store up to 2 weeks at 4°C and warm to 37°C in water bath before use

COMMENTARY

Background Information

Electrospinning was developed based on the "electrospray" phenomenon first described by Lord Rayleigh in 1882 (Rayleigh, 1882). He discovered that a highly charged droplet would break down into smaller droplets when passing through a voltage gradient, as the result of Coulombic repulsion disrupting the droplet surface tension. Instead of producing small droplets in the electrospraying process, electrospinning produces continuous long fibers. In 1934, Formhals was granted a series of U.S. patents on the applications of using the technique to make fine fibers from a cellulose acetate solution (Formhals, 1934). Recently, the surging interest in nanotechnology and tissue engineering has engendered renewed attention to this technology.

Critical Parameters and Troubleshooting

Electrospinning is a complex electrophysical process in which both extrinsic and intrinsic parameters affect nanofiber formation (Doshi and Reneker, 1995). Uniform nanofibers are produced only under optimal conditions where both extrinsic and intrinsic parameters work together seamlessly. In general, the intrinsic parameters are more critical in determining the nanofiber structure than the extrinsic parameters.

Polymer solution viscosity

Viscosity of a polymer solution, directly proportional to polymer concentration, is the most critical parameter influencing nanofiber uniformity and size (Fong et al., 1999). Every polymer solution has its specific viscosity range in which uniform nanofibers can be produced, and the range varies with the polymer or solvent types (Liu and Hsieh, 2002). Therefore, each polymer solution needs to be individually characterized to assess the optimal viscosity range. In addition, viscosity affects fiber size; a more viscous polymer solution makes larger fibers (Deitzel et al., 2001).

Applied voltage and working distance

Applied voltage is the electro-driving force for nanofiber spinning, and usually a voltage of at least 5 kilovolts DC is required for electrospinning. Working distance is defined as the distance between the syringe tip and the fiber collection screen, and together with applied voltage, can determine the strength of applied charge in the electro-static field. Similar to polymer solution viscosity, charge strength also has to be optimized to a range appropriate for uniform nanofiber formation.

Polymer solution conductivity

Polymer solution conductivity is primarily determined by the nature of the polymer and solvent, and the availability of ionizable salts. It has been shown that a more conductive polymer solution carrying a more electric charge during electrospinning, with the as-spun fibers generating a stronger repulsive force, tends to produce more uniform nanofibers. Different approaches, such as using dipolar aprotic solvents (Lee et al., 2003) and adding conductive agents (Zong et al., 2002) in the polymer solution are applied to enhance polymer solution conductivity.

The biggest challenge with electrospinning is finding the optimal combination of polymer solution viscosity and conductivity, applied voltage, and working distance for electrospinning. If the optimal combination is not reached, the electrospun structure turns into beads or bead-strings, instead of fibers. When bead-containing structures occur, increasing polymer solution viscosity should be the first parameter to vary in order to improve fiber formation. Increasing polymer solution conductivity can also be tested for the purpose of reducing bead formation.

Anticipated Results

Support Protocol. A basic, functioning electrospinning apparatus box should be assembled for electrospinning nonwoven or aligned nanofibers.

Basic Protocol 1. After overnight mixing by vortexing, the polymer solution turns into a homogeneously viscous and transparent liquid. During electrospinning, the researcher should observe that the polymer solution comes out of the needle, transforms into nanofibers, and deposits onto the fiber collection screen. A white nanofibrous mesh spot should be observed on the screen, gradually increasing its dimensions and eventually covering the entire screen. After electrospinning, a thick fabric-like nanofibrous mat is produced.

Basic Protocol 2. Both PLLA and PCL nanofibrous scaffolds are hydrophobic but should be completely hydrated by immersion in a graded series of ethanol solutions. After the hydration step, the researcher should observe that the nanofibrous scaffolds are easily hydrated in HBBS. Using labeled cells and subsequently microscopy, cells should

be observed adhering to nanofibers after cell seeding and culturing in serum-containing medium.

Time Considerations

Support Protocol. The electrospinning apparatus box can be constructed by a skilled mechanic in a few days.

Basic Protocol 1. It takes <10 min to prepare the polymer solution for vortexing and both PLLA and PCL can be completely dissolved overnight. The time needed for electrospinning nanofibers depends on the amount and the conductivity of polymer solutions. In general, it takes 8 hr for PLLA and 35 hr for PCL. After a nanofibrous mat is produced, placement for 2 days in a vacuum desiccator is preferred for the complete removal of harmful chemical residue.

Basic Protocol 2. The preparation of nanofibrous scaffolds for cell seeding takes ~4 hr, including 1 hr for sample cutting and 3 hr of sterilization/hydration using UV irradiation and a graded ethanol series. The time needed for cell seeding varies, depending on sample number. It takes ~40 seconds to complete the cell seeding per scaffold. To optimize cell viability, cell seeding should be controlled within the 40-sec time frame, if possible.

CHAPTER 26
Viruses

INTRODUCTION

Although Jenner, in the 1790's, and Pasteur in the 1880's, developed methods for protecting people from smallpox and rabies, respectively, the nature of the agents causing these diseases remained obscure. In the late 1800's, it was demonstrated that tobacco mosaic disease could be transmitted by filtrates of diseased tobacco plants even after passing through filters fine enough to exclude the then smallest known living organisms. It became clear that the disease-causing agent was not merely a liquid toxin but something that "grew" in its host. This same virus, the tobacco mosaic virus, some 50 years later became the first virus whose structure was elucidated in detail.

Over 100 years ago, Peyton Rous suggested that a virus could cause cancer. A number of other diseases, most notably yellow fever, influenza, and polio, were subsequently shown to have viral etiologies. Later still, hepatitis, AIDS, and cervical cancer were added to the list of viral diseases. Given the linkage to important human and animal diseases, it is no wonder that the field of virology blossomed throughout the 20th century.

Virology has been considered traditionally as a branch of microbiology, but its impact has been truly far-reaching. Viruses, in particular bacteriophage, were critical tools in the emerging field of molecular biology owing to their ability to move genetic material from one host cell to another. Because viruses infect and utilize the cellular machinery of their hosts for replication, no small measure of what we know about that machinery has come from studying the viral "hijacking" of it. Because viruses infect cells, the boundary between the fields of virology and cell biology has always been blurry. Knowledge gained about the pathogen invariably led to increased understanding of the host and vice versa. In this chapter of *Current Protocols in Cell Biology*, the methods of virology will be described with a focus on those methods that are most closely related to cell biology.

Like bacteriophage, eukaryotic viruses can also be utilized in the movement of genetic material by design. In *UNIT 26.1*, the methods involved in the production of gene transfer vectors based on papillomaviruses are presented. The papillomaviruses are a diverse group of viruses that infect the skin and mucosal tissues. They have perhaps gained most notoriety for being the causal agent of cervical cancer, the incidence of which is second only to breast cancer in women worldwide. *UNIT 26.1* focuses on the production and propagation of pseudoviruses based on papillomaviruses that have utility as gene-delivery vehicles both in vitro and in vivo.

The BK virus (BKV) is a member of the polyomavirus family, to which many in the population have been exposed, usually without adverse consequences. However the BKV can cause nephritis in renal transplant patients on immunosuppressive medications. Little is known concerning the means of BKV transmission, but in renal transplant patients, it may be transferred with the transplanted organ. *UNIT 26.2* describes handling, propagation, and assessment of infectivity of BKV, as well as the labeling of the virus to analyze cell entry.

Viruses can be studied in tissue culture, but certain types of studies are facilitated by animal models. Respiratory viruses represent a major class of human pathogens affecting millions of individuals worldwide. *UNIT 26.3* describes a number of protocols related to

Current Protocols in Cell Biology 26.0.1-26.0.2, June 2010
Published online June 2010 in Wiley Interscience (www.interscience.wiley.com).
DOI: 10.1002/0471143030.cb2600s47

utilizing a mouse model for the study of respiratory viruses. Protocols are included for introducing viruses into the lungs of mice and assessing the impact of the infection on the lungs. Tissue sampling methods are described along with procedures for virus quantification and isolation. Methods for lung histology, immunocytochemistry, and in situ hybridization of the infected lungs are also provided.

The ability to study viral infection in culture systems varies widely. For example, it is possible to culture neurons in a trichambered system that allows the cell bodies to be in one chamber and the axons growing from the cell bodies to be in another. This physical isolation allows the cell body and axons to be independently exposed to viruses. Such a culture system is the subject of *UNIT 26.4*. The assembly of the trichambered system is described along with its use in exploring viral spread using immunofluorescence and electron microscopy.

Characterization of HIV-1 interactions with host cells is critical for cell biology studies of HIV-1. *UNIT 26.5* describes a set of methods and protocols to perform quantitative assays of HIV-1 binding, internalization, infection, and cell-cell transmission. Protocols are included for generating viral stocks and conducting HIV-1 binding and internalization assays as well as for quantification of the viral infection and assays for cell-to-cell transmission of the virus. These protocols provide tools enabling HIV-1 infection and transmission on a quantitative basis.

Monitoring respiratory syncytial virus (RSV) replication is described in *UNIT 26.6*. This unit contains protocols that range from the design of animal infection protocols, to extracting viruses for culture, to RNA extraction and quantification by quantitative real-time PCR. The unit provides methods of quantifying viral infection via simultaneous viral culture and PCR, two approaches that are often used independently. This combination reveals certain features of RSV replication, such as abortive replication, that would not be revealed with either of the methods in isolation.

Joe B. Harford

Production of Papillomavirus-Based Gene Transfer Vectors

Christopher B. Buck[1] and Cynthia D. Thompson[1]

[1]National Cancer Institute, Center for Cancer Research, Bethesda, Maryland

ABSTRACT

Papillomaviruses are a diverse group of pathogens that infect the skin and mucosal tissues of humans and various animal species. The viral genome is a circular, double-stranded DNA molecule ~8-kb in length. The non-enveloped papillomavirus capsid is composed of a virally encoded major coat protein, L1, and a minor coat protein, L2. L1 and L2 co-assemble when expressed in mammalian cells, and can promiscuously encapsidate essentially any <8-kb plasmid present in the cell nucleus. In the last several years, there has been rapid development of techniques for intracellular production of papillomavirus-based gene transfer vectors (also known as pseudoviruses). This unit outlines the production and propagative amplification of papillomaviral vectors. The system represents a highly tractable method for converting pre-existing mammalian expression plasmids into infectious virus stocks. The resulting vectors have utility for in vitro, as well as in vivo gene delivery applications. *Curr. Protoc. Cell Biol.* 37:26.1.1-26.1.19. © 2007 by John Wiley & Sons, Inc.

Keywords: papillomavirus • HPV • pseudovirus • pseudovirion • virus-like particle • VLP

INTRODUCTION

The papillomavirus capsid proteins L1 and L2 can, when co-expressed in mammalian cells, co-assemble and package heterologous nonviral DNA into infectious particles that resemble authentic papillomavirus virions (Buck et al., 2004, 2005). Essentially any transfected <8-kb expression plasmid present in the cell nucleus can be encapsidated. The high degree of promiscuity of packaging makes it possible to convert transfected reporter plasmids into papillomaviral vector stocks capable of delivering the encapsidated plasmid to a wide variety of cultured cell types. Until recently, such papillomaviral vectors (also known as pseudoviruses) have primarily been used for analysis of papillomavirus neutralization and infectious entry pathways. However, papillomaviral vectors are beginning to show promise as tractable general-purpose gene transfer vehicles. Applications include high-level overexpression of genes of interest in cultured cells, as well as in vivo gene delivery in mouse model systems (Roberts et al., 2007).

The production system relies on a human embryonic kidney cell line, 293TT, which expresses high levels of the simian virus 40 (SV40) large T antigen (Buck et al., 2004). In primate cell lines, SV40 T antigen drives high-level replication of plasmids carrying the SV40 early promoter/origin of replication (*ori*), which is present on a wide variety of commercially available mammalian expression plasmids. In Basic Protocol 1, an expression plasmid encoding a gene or genes of interest, as well as the SV40 *ori*, is co-transfected into 293TT cells along with a second plasmid, p16L1L2, that drives expression of the L1 and L2 proteins of human papillomavirus type 16 (HPV16). After transfection, both the expression plasmid of interest and p16L1L2 are taken up (encapsidated) into infectious L1/L2 capsids. The resulting viral seed stock can be used to infect fresh 293TT cells, permitting high-yield, low-cost amplification of the vector (Basic Protocol 2; Buck et al., submitted). Although crude vector stocks can be used for a variety of applications, it

Current Protocols in Cell Biology 26.1.1-26.1.19, December 2007
Published online December 2007 in Wiley Interscience (www.interscience.wiley.com).
DOI: 10.1002/0471143030.cb2601s37

is also possible to purify infectious capsids by ultracentrifugation (Support Protocol 1) or gravity-flow gel filtration (Support Protocol 2). Fractions containing capsids can be screened by the BCA assay, agarose gel electrophoresis (Support Protocol 3), or SDS-PAGE (*UNIT 6.1*). Although it should not generally be necessary to do so, purified capsids can be concentrated by dialysis against a concentrating reagent (Support Protocol 4).

If the plasmid being packaged expresses a fluorescent protein, the infectivity of the vector stock can readily be titered using flow cytometry or fluorescent microscopy (Support Protocol 5). Alternative Protocols 1 and 2 cover, respectively, the production of amplification-incompetent papillomaviral vectors (see Fig. 26.1.1) and bulk production of papillomavirus capsids.

NOTE: All solutions and equipment coming into contact with cells must be sterile, and proper aseptic technique should be used accordingly.

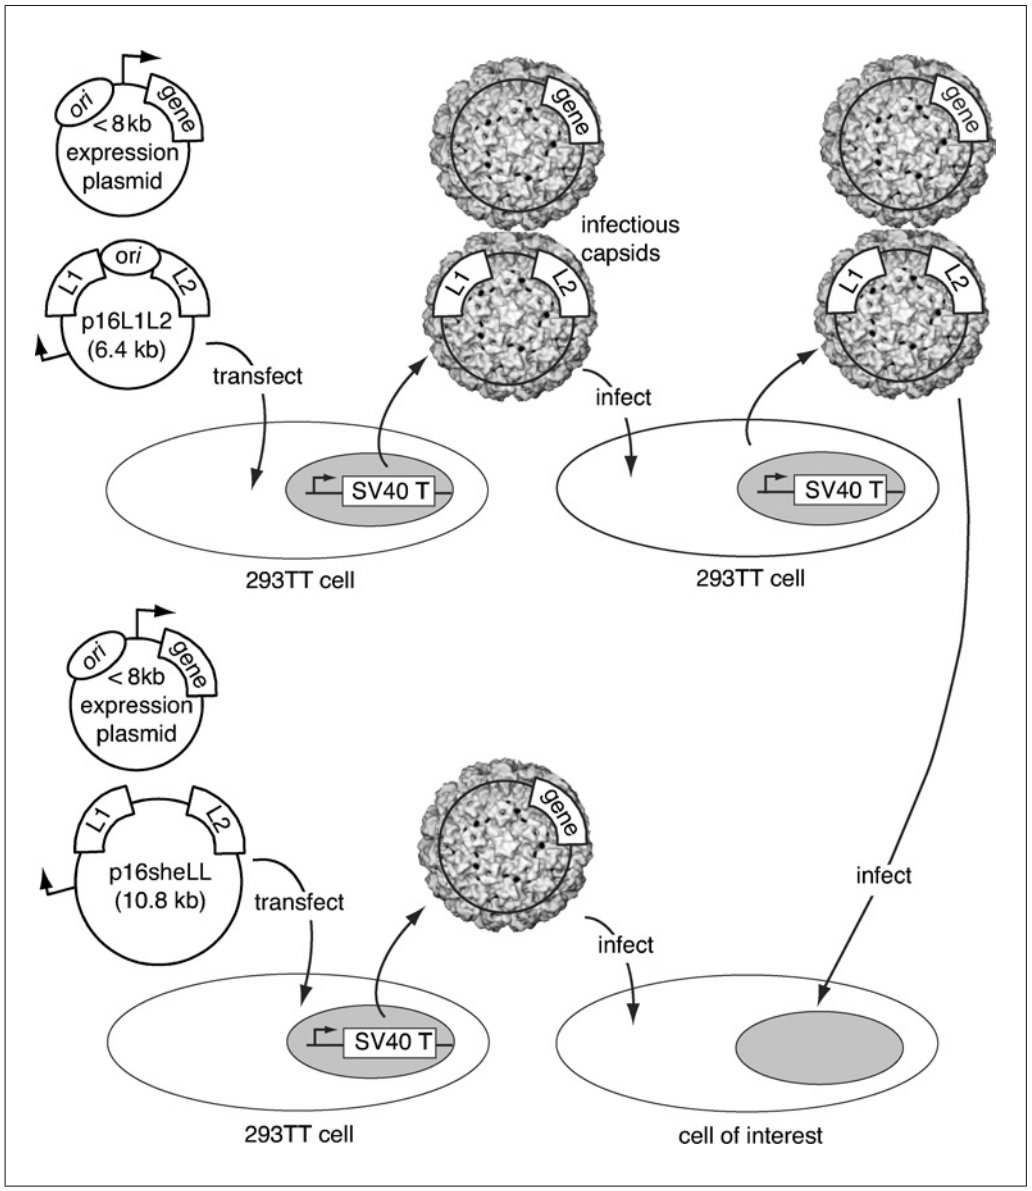

Figure 26.1.1 Amplification competent (top) versus incompetent (bottom) vector production.

GENERATION OF A PAPILLOMAVIRAL VECTOR STOCK BY TRANSFECTION

An initial vector seed stock is generated by co-transfecting an HPV16 L1/L2 expression plasmid, p16L1L2, together with an expression plasmid of interest into 293TT cells. After transfection, p16L1L2 and the expression plasmid are each replicated to high-copy number and packaged separately into L1/L2 capsids. Note that Alternate Protocol 2 discusses the use of a different L1/L2 expression plasmid, p16sheLL, which cannot be packaged into L1/L2 capsids and thus allows production of amplification-incompetent papillomaviral vector stocks. Capsids are harvested by lysing the cells with Brij-58 (a nonionic detergent) 48 hr after transfection. The resulting cell lysate must be allowed to mature for 24 hr, then can be diluted and used directly as an infectious vector stock or purified as described in Support Protocol 1 or 2. In some instances it may be useful to amplify the vector stock by using it to infect fresh 293TT cells (Basic Protocol 2).

Materials

DMEM (Dulbecco's modified Eagle medium) with 10% (v/v) FBS (DMEM-10)
Fetal bovine serum, heat-inactivated at 56°C for 30 min (FBS)
293TT cells
0.05% (w/v) trypsin/EDTA solution (Invitrogen or other supplier)
2× freeze medium: 82% (v/v) FBS/18% (v/v) dimethylsulfoxide
50 mg/ml hygromycin B stock (Roche)
Lipofectamine 2000 (Invitrogen)
OptiMEM-I (Invitrogen)
p16L1L2 plasmid
<8-kb mammalian expression plasmid with SV40 *ori* (see Commentary)
DPBS-Mg (see recipe)
10% (v/v) Brij-58 (see recipe)
RNase A/T1 cocktail (Ambion, no. AM2286) or RNase A stock

225-cm^2 and 75-cm^2 cell culture flask
Humidified 37°C, 5% CO_2 incubator
37°C water bath
2-ml gasketed cryovials
Cryocooler (e.g., Nalgene Mr. Frosty isopropanol bath) chilled to 4°C
Liquid nitrogen freezer
15-ml conical centrifuge tubes
1.5-ml siliconized centrifuge tubes, preferably screw-cap (e.g., VWR, no, 60828-818)
Siliconized pipet tips (optional)

Establish the 293TT cell culture

1. Dispense 27 ml of DMEM-10 into a 225-cm^2 flask. Add 3 ml of FBS for a final FBS concentration of 20%. Place the flask in a humidified 37°C 5% CO_2 incubator and loosen the cap. Allow the flask to equilibrate for at least 10 min.

   It is important to omit hygromycin B (see below) from the culture medium during recovery from thawing.

   The Laboratory of Cellular Oncology (http://home.ccr.cancer.gov/LCO/) freely distributes 293TT cells to nonprofit researchers.

2. Thaw a frozen vial of 293TT cells in a 37°C water bath. Immediately upon thawing, pipet the cells into the flask.

   It is not necessary to spin the cells out of their freeze medium. Like other human embryonic kidney 293-derived cell lines, 293TT cells do not adhere tightly to plastic. Placing the cells in a relatively small volume with large surface area promotes attachment, which may take up to two days.

3. Incubate the cells in a humidified 37°C, 5% CO_2 incubator for 2 to 3 days.

4. Remove the supernatant and gently wash cells with 1 to 2 ml of trypsin/EDTA. Remove trypsin wash and replace with 1 to 2 ml of fresh trypsin/EDTA. Return the flask to the incubator, loosen the cap, and incubate for at least 5 min, gently rocking the flask once or twice. Neutralize the trypsin by suspending the cells in 9 ml of DMEM-10.

   Although 293TT cells are easily dislodged from plastic, the cells can adhere to one another fairly tightly. If the cells are not fully trypsinized, the resulting cell clumps may be partially lysed by shear forces during resuspension. Insufficient trypsinization also results in the appearance of unhealthy piles of cells after replating.

5. On the first or second passage, retain enough cells to freeze archive vials in liquid nitrogen. When trypsinizing the cells, retain some of the spent culture medium. After trypsinization, resuspend the cells in the retained spent medium. Gently mix the suspended cells 1:1 with 2× freeze medium. Distribute the suspension as 1-ml aliquots in cryovials (roughly 2 to 5 × 10^6 cells per vial). Transfer the vials to a cryocooler and freeze at −80°C overnight. Transfer the frozen cells to a liquid nitrogen freezer for long-term storage.

6. For routine passaging, split the culture 1:10 or 1:20 every 2 to 3 days. After recovery from thawing, supplement the culture medium with hygromycin B at a final concentration of 400 μg/ml to promote maintenance of SV40 T antigen expression.

Transfect 293TT cells

7. Preplate 7.5 × 10^6 293TT cells in a 75-cm^2 flask in 20 ml of DMEM-10 without hygromycin B. Incubate the cells overnight in a humidified 37°C, 5% CO_2 incubator.

   A 75-cm^2 flask is used as an example, but the transfection can easily be scaled up or down based on the surface area of the culture vessel. See the Lipofectamine 2000 package insert for details.

8. Transfect the cells with Lipofectamine 2000, essentially according to package insert. Mix 80 μl of Lipofectamine 2000 reagent with 2 ml of OptiMEM-I in a 15-ml tube. Incubate 10 min.

9. In a separate 15-ml tube, mix 19 μg each of p16L1L2 and expression plasmid of interest in 2 ml of OptiMEM-I.

10. Combine the Lipofectamine 2000 and DNA mixtures and incubate 20 to 30 min to form lipid/DNA complexes.

11. Add the complexes directly to the preplated cells and incubate 6 hr.

    IMPORTANT NOTE: *From this point forward, the culture should be handled under proper biosafety conditions approved by an institutional biosafety committee (see Biosafety heading in the Commentary section).*

    It is essential that the cells be <50% confluent at the time of transfection. Higher levels of confluency tend to reduce the transfection efficiency for 293TT cells. Ideally, the cells should be preplated late in the day, then transfected the next morning. It is not necessary to change the medium on the cells before adding the lipid/DNA complexes, provided the cells were preplated in DMEM-10 without antibiotics or selective agents. Incubation of the cells with the lipid/DNA complexes for 4 to 8 hr gives similar results.

12. Carefully remove the supernatant from the culture and add 20 ml of fresh DMEM-10 prewarmed to 37°C.

    Care should be taken not to dislodge the cells when adding fresh medium. For example, it may help to turn the flask upside-down and add the medium to the top surface of the flask. Medium can be supplemented with antibiotics (e.g., pen-strep) at this point, although this is not generally necessary.

13. Return the transfected cells to the incubator for 2 days.

    It should not be necessary to split the culture.

Harvest capsids

14. Remove supernatant from the culture.

    Generally, there will be very few detached cells and the supernatant can be discarded. If there are substantial numbers of floating cells, recover them by centrifugation.

15. Harvest cells by trypsinization (see step 4 above). Transfer suspended cells to a 15-ml conical centrifuge tube. Collect residual cells by rinsing the flask with 4 ml of fresh DMEM-10. Pool rinse in the same 15-ml conical tube. Pellet the cells by centrifuging 10 min at 200 × *g*, 4°C.

16. Remove the supernatant and resuspend the cells in 0.5 ml of DPBS-Mg. Transfer the suspension to a 1.5-ml siliconized tube. Rinse the 15-ml conical tube with 0.5 ml of fresh DPBS-Mg. Pool rinse into the 1.5-ml siliconized tube. Pellet the cells by centrifuging 10 min at 200 × *g*, 4°C.

    Papillomavirus capsids interact nonspecifically with polypropylene and other types of surfaces (Shi et al., 2005). Siliconized tubes appear to be less prone to disruptive nonspecific interactions with the capsids. Blocking of polypropylene surfaces with excess protein or detergent also helps prevent capsid-plastic interactions. Thus, the use of siliconized tubes is desirable but not absolutely essential for the purposes of Basic Protocols 1 and 2. The use of siliconized tubes becomes more important when handling purified capsids (Support Protocols 1 and 2), particularly if the capsids are to be stored for extended periods of time at 4°C. Although siliconized screw-cap tubes can be difficult to obtain, they are easier to keep sterile than more widely available flip-cap siliconized tubes. The use of siliconized pipet tips is optional.

17. Carefully remove the supernatant. Estimate the volume occupied by the cell pellet by side-by-side comparison to fluid in a dummy tube.

    Pellet volume for a 75-cm^2 flask of cells is typically 60 to 80 μl.

18. Add 1.5× cell pellet volumes of DPBS-Mg. For example, add 120 μl of DPBS-Mg to a cell pellet of 80 μl (total volume of about 200 μl). Resuspend the cells by gently vortexing or flicking the tube.

    It is critical that the cells be suspended at a density of at least 100 × 10^6 cells/ml. Lower-density lysates can suffer from nonspecific protein aggregation that reduces the purity of capsid stocks and can also reduce titer yield. Estimating suspension density based on pellet size is safer and more reliable than performing hemacytometer counts.

19. Add 10% Brij-58 to achieve a final concentration of ∼0.35%.

    For example, add 7 μl of 10% Brij-58 to 200 μl cell suspension.

20. Add ∼1 μl of RNase A/T1 cocktail (or ∼5 RNase A units) and mix.

    Intact ribosomes are large enough to partially co-purify with capsids. Digestion of ribosomes with RNase thus facilitates purification (see Support Protocols 1 and 2). The suggested amount of RNase stock is more than enough enzyme to adequately digest ribosomes—lower doses of enzyme stock are also effective.

21. Allow capsids to mature by incubating the lysate at 37°C for 24 hr.

Although this step of the protocol may seem counterintuitive, it is essential to allow the capsids to undergo a slow process of maturation, in which disulfide bonds between neighboring L1 molecules stabilize the structure of the capsid (Buck et al., 2005). Prior to maturation, capsids are infectious but physically fragile, such that immature capsids lose infectivity during purification or freeze-thaw cycles. The maturation process also renders the capsid more soluble, allowing clarification of the lysate (step 22).

It may be helpful to gently mix the lysate once or twice during the maturation period. Note that effective sterile technique is critical during harvest of capsids, since contaminating microbes have ample opportunity to grow during the capsid maturation period.

22. After maturation, chill the lysate on ice for 5 to 10 min. Clarify the chilled lysate by centrifuging 10 min at 5,000 × *g*, 4°C. The resulting clarified supernatant is the vector stock. Freeze at −80°C in 20 to 50 µl aliquots or proceed to purifying the stock (Support Protocols 1 and 2).

The clarified supernatant can be used directly as a crude papillomaviral vector stock to infect cells of interest. The residual Brij-58 in the lysate is not toxic to most cell types, provided the stock is diluted least 1:500 (final dilution in culture well). The clarified lysate can also be used as a seed for amplifying the vector in fresh 293TT cells (Basic Protocol 2). Although amplification allows high-yield production of a more concentrated vector stock, initial seed stocks are usually of sufficient titer for use in most applications.

BASIC PROTOCOL 2

PROPAGATIVE AMPLIFICATION OF A PAPILLOMAVIRAL VECTOR STOCK

In this protocol, the vector seed stock from Basic Protocol 1 is amplified by infection of fresh 293TT cells. In principle, the amplified vector stock can in turn be further amplified by additional rounds of infection of 293TT cells. However, as the viral stock is passaged, smaller collapsed plasmid recombinants begin to dominate the propagated plasmid swarm. By the third passage, ~3 kb collapsed species are predominant and, as a consequence, titer yield begins to decline.

Materials

293TT cells
DMEM with 10% (v/v) FBS
Vector seed stock (Basic Protocol 1)

225-cm^2 flask
Humidified 37°C 5% CO_2 incubator

1. Plate 12 × 10^6 293TT cells in 50 ml of DMEM-10 in a 225-cm^2 flask. Incubate overnight in a humidified 37°C, 5% CO_2 incubator.

2. Infect the preplated cells by adding 20 µl of vector seed stock (Basic Protocol 1). Return the flask to the incubator. Incubate the culture with the vector inoculum for 20 to 40 hr, then change the cells into fresh DMEM-10.

Rocking the flask occasionally during the first 2 hr of incubation will help to promote virus attachment.

The change of medium may improve infectious titer yield, but can be considered optional.

3. About 72 hr after initial infection, harvest capsids from the cells as described in Basic Protocol 1, steps 14 to 22. Freeze the clarified supernatant at −80°C in 100-µl aliquots or purify the vector stock (Support Protocols 1 and 2).

PRODUCTION OF AMPLIFICATION-INCOMPETENT VECTOR STOCKS

ALTERNATE PROTOCOL 1

For some applications, co-delivery of p16L1L2 along with the expression plasmid of interest may be undesirable. An alternative strategy is to produce an amplification-incompetent vector stock by transiently co-transfecting an expression plasmid of interest together with the packaging plasmid p16sheLL. In contrast to p16L1L2, p16sheLL lacks the SV40 *ori* and is too large to be packaged within papillomavirus capsids. Thus, when p16sheLL is co-transfected with an expression plasmid of interest, only the expression plasmid is packaged into nascent infectious capsids.

A variety of other papillomavirus types have been adapted to the "sheLL" format and are freely available to nonprofit researchers. Note that the L1 and L2 open reading frames in these plasmids have been "codon-modified" (subjected to extensive silent mutation) in order to eradicate expression-inhibitory elements present in native papillomavirus L1 and L2 genes (Leder et al., 2001). Amplification-incompetent vectors can be produced using the methods outlined in Basic Protocol 1 by simply substituting p16sheLL (or other sheLL series plasmid) for p16L1L2. See the Web page *http://home.ccr.cancer.gov/LCO/packaging.htm* for maps of available packaging plasmids.

Because of their relatively large size, sheLL series plasmids are occasionally subject to recombinant collapse during re-growth in bacteria. The chance of inadvertent recombination can be reduced by using STBL2 (Invitrogen) or other reduced-recombination bacterial strains. Alternatively, standard bacterial subcloning strains can be grown at 30°C during recovery from transformation and during growth on selective agar plates. Growth of bacteria at 30°C tends to result in maintenance of ColE1-based plasmids at lower copy number, thus reducing the chance of recombination. Subsequent liquid culture scale-up of a single colony at 37°C improves plasmid yield and has not resulted in detectable amounts of plasmid collapse in our hands.

BULK PRODUCTION OF PAPILLOMAVIRUS CAPSIDS

ALTERNATE PROTOCOL 2

The promiscuity of DNA packaging by HPV16 L1 and L2 applies not just to various expression plasmids, but also to cellular DNA. At the time of cell lysis, at least 90% of the proto-capsids present in the cell nucleus exist in complex with cellular DNA. In the basic protocols, most capsid/cellular DNA complexes sediment away from the vector stock during the lysate clarification step. However, if DNases are added to the cell suspension during cell lysis, capsids associated with cellular DNA are liberated with an encapsidated 8-kb linear fragment of cellular DNA (Buck et al., 2005). For applications aimed using infectious reporter capsids, the presence of "cold" (reporter-less) capsids containing cellular DNA is undesirable, since the cold capsids may compete against the infectivity reporter capsids. The infectious delivery of random fragments of 293TT cell DNA to target cells also presents a theoretical biosafety risk.

In this protocol, the addition of DNases to the cell lysate allows for recovery of capsids containing linear fragments of cellular DNA. This boosts the yield of capsids by at least 10-fold, making this approach desirable when the production of virus-like particles, rather than titerable infectious units, is the primary goal.

In some instances it may be desirable to produce L1 capsids that do not contain L2. HPV16 L1 particles can encapsidate a limited amount of DNA in the absence of L2, but are at least 10,000-fold less infectious than L1/L2 capsids. A limited seed stock for production of L1-only capsids can be generated by co-transfecting p16sheLL together with a packageable L1 expression plasmid, such as p16L1-GFP. The resulting seed stock can be used for a single-round infection of fresh 293TT cells. The infected cells will be transduced only with the L1 expression plasmid and will thus produce capsids lacking L2.

Additional Materials *(also see Basic Protocol 1)*

Benzonase endonuclease (~250 U/μl; Sigma-Aldrich or other supplier)
Plasmid Safe ATP-Dependent DNase (10 U/μl; Epicentre)
5 M NaCl

Additional reagents and equipment for production of an initial vector seed stock (Basic Protocol 1)

1. Follow Basic Protocol 1 for production of an initial vector seed stock, omitting the expression plasmid of interest and transfecting with p16L1L2 alone.
2. Amplify the vector seed stock using Basic Protocol 2. Instead of adding RNase to the cell lysate (Basic Protocol 1, step 20), add Benzonase and Plasmid Safe stocks to a final concentration of ~0.25% each. Mature the lysate for 24 hr (Basic Protocol 1, step 21).

   Benzonase is an RNA/DNA endonuclease, while Plasmid Safe is a processive exo-DNase. The two nucleases act in concert to "slice and dice" any DNA outside the protective environment of the capsid. There is enough residual ATP in the lysate to support Plasmid Safe's ATP-dependent exonuclease activity. Final nuclease stock concentrations of 0.05% to 0.1% each are also adequate for effective fragmentation of unencapsidated DNA.

3. After maturation, chill the matured lysate on ice for 5 to 10 min. Add 0.17 volume of 5 M NaCl to achieve a final NaCl concentration of ~0.85 M. Incubate on ice 10 min, mixing once or twice.

   Treating the lysate with high salt helps solubilize the lysate, facilitating the purification of capsids. It is not possible to add high salt to the lysate prior to clarification in the basic (DNase-less) protocols, because the salt would solubilize the undigested cellular DNA, rendering the lysate too viscous to handle.

4. If desired, purify capsids out of the clarified lysate using Support Protocols 1 or 2.

SUPPORT PROTOCOL 1

PURIFICATION OF VECTOR STOCKS USING OPTIPREP GRADIENTS

Although clarified cell lysates can serve as useful vector stocks, the residual Brij-58, undigested DNA, and expressed proteins of interest in the lysate may cause problems for some applications. This protocol outlines the use of ultracentrifugation to purify vector stocks. Virologists have traditionally relied on two main ultracentrifugation strategies to purify capsids: buoyant density ultracentrifugation, which typically employs CsCl solutions, and velocity ultracentrifugation, which typically employs concentrated sucrose solutions. The method described here makes use of a newer ultracentrifugal gradient medium called Optiprep (iodixanol). Optiprep is a relatively nontoxic iodinated di-hexanol compound used clinically as an injectable X-ray contrast agent. It has the useful feature of being both high-density (like CsCl solutions) and high-viscosity (like sucrose solutions). It is thus possible to employ Optiprep for velocity and buoyant density ultracentrifugation simultaneously in a single tube. The clarified capsid-containing cell lysate is layered on top of a preformed Optiprep step-gradient. At the top of the gradient, the relatively large size of the capsids allows them to rapidly sediment through the upper portion of the gradient while other, smaller diameter solutes in the lysate traverse the gradient slowly. Once the capsids reach the middle portion of the gradient, their migration is dominated by buoyancy. This allows separation of empty capsids from DNA-containing capsids.

Ultracentrifugation is a relatively advanced laboratory technique and should not be attempted without the guidance of an experienced operator. Although Optiprep purification is a highly effective way to purify papillomaviral vector stocks, the simpler gel filtration strategy described in Support Protocol 2 also gives reasonable purity and would be a

better choice for investigators lacking easy access to the equipment or expertise required for ultracentrifugation.

The protocol describes the use of a Beckman SW-55 rotor. Other types of rotors can be used successfully, although some adjustment of spin time may be necessary. An SW32 rotor at 32,000 rpm (125,000 × *g*) for 5.75 hr or an SW40.1ti rotor at 40,000 rpm (200,000 × *g*) for 4.75 hr work reasonably well.

Additional Materials *(see also Basic Protocol 1)*

46% (v/v) Optiprep/DPBS (see recipe)
DPBS/0.8 M NaCl (prepare by adding 0.15 volume of 5 M NaCl to DPBS)

Thin-wall 1/2 × 2–in. Polyallomer tubes (Beckman, no. 326819) or appropriate ultracentrifuge tubes
3-ml syringe fitted with a 2-in. or longer large-bore (~16-G) needle
Parafilm
Ultracentrifuge
Beckman SW-55 ultracentrifuge rotor (or other swing-bucket rotor)
Ring stand with tube clamp
Siliconized collection tubes
~25-G needle

Prepare a 27%, 33%, and 39% Optiprep step gradient by underlayering

1. Dilute 46% Optiprep/DPBS to 27%, 33%, and 39% using DPBS/0.8 M NaCl

   Although our laboratory has traditionally used DPBS as a dilution medium, Optiprep gradients prepared using plain PBS (lacking $CaCl_2$, $MgCl_2$, and KCl) are probably equally effective. Use of high (0.8 M) NaCl concentrations in the gradient results in more effective separation of the capsids from cellular proteins, but gradients prepared with physiologic (0.15 M) NaCl concentrations can give acceptable results.

2. Set up a minimum of two ultracentrifuge tubes: one for the clarified lysate, one for balance.

3. Using a pipet, add 1.5 ml of 27% Optiprep to each tube.

   A gradient with three 1.5 ml steps will leave enough room for about 0.5 ml of lysate. Up to 3 ml of lysate can be loaded into a single tube by shortening the gradient to 0.7 ml per step.

4. Load the 3 ml syringe with 33% Optiprep. Eject any bubbles. Insert the syringe until the needle is gently touching the bottom of the tube. Gently eject 1.5 ml of 33% Optiprep beneath the 27% step.

5. Remove the syringe from the tube and eject residual Optiprep (or use a fresh syringe). Repeat step 4 with 39% Optiprep.

6. Cover the tubes with Parafilm and incubate 1 to 4 hr at room temperature.

   Letting the gradients stand at room temperature allows the steps to partially diffuse into one another. The partly linearized gradient results in a slightly better-focused capsid band.

Perform the ultracentrifugation

7. Gently layer the clarified cell lysate (or DPBS in the balance tube) onto the top of the gradient. Seat the tubes into opposing rotor buckets.

8. Add DPBS/0.8 M NaCl to the top of the tube until the meniscus is above the surrounding metal rim of the bucket. Balance buckets to within 5 mg.

   It is critical that the tubes be filled to near the rim and that the buckets be balanced. Underfilled tubes can collapse, resulting in imbalances. Imbalances can result in destruction of the ultracentrifuge rotor and containment drum.

9. Hang the buckets on the rotor, being sure that both hooks catch. Spin 3.5 hr at 234,000 × *g* (50,000 rpm for an SW-55ti rotor), 16°C.

Fractionate the gradient

10. Remove the tube from the bucket and place in the tube clamp.

    An opalescent band of capsids may be visible roughly a third of the way up the gradient. Visualization of the band is easier if a dark object is held behind the tube.

11. Set up and uncap twelve siliconized collection tubes. Position the collection tubes beneath the ultracentrifuge tube.

12. Puncture the bottom of the ultracentrifuge tube slightly off center using a 25-G (or similar diameter) needle. Rock the needle in a circular motion to slightly expand the hole.

    Use of sharp objects when handling biohazardous agents obviously presents some risk. This step of the protocol should be performed very carefully. Discard the needle directly into an appropriate sharps container (do not attempt to re-cap the needle).

13. Collect a single large first fraction until the rate of drops begins to increase (~750 µl collected). For each subsequent fraction, collect 5 to 8 drops (~200 µl) per fraction. Repeat for twelve fractions. The fractions should encompass the bottom 1/2 to 2/3 of the gradient. Discard the top portion of the gradient.

    The first few drops will emerge very slowly.

14. Screen gradient fractions for the presence of capsids (Support Protocol 3). Pool appropriate fractions, divide into 100-µl aliquots, and store at −80°C.

    Optiprep is nontoxic to cell cultures and can be injected into mice without apparent negative effects. It is therefore not necessary to exchange capsids out of Optiprep in most cases. If removal of Optiprep (or the high salt present in the gradient fractions) is desired, Support Protocol 2 presents an effective method for exchanging capsids into other buffers. Note that Optiprep is resistant to dialysis (see Support Protocol 4).

SUPPORT PROTOCOL 2

PURIFICATION OF VECTOR STOCKS USING AGAROSE GEL FILTRATION

The simple size-exclusion chromatography (gel filtration) purification method described in this protocol makes use of the fact that papillomavirus capsids are larger than nearly all other macromolecular complexes in the clarified lysate. The agarose beads used in the protocol have a pore size slightly smaller than the papillomavirus capsid. Thus, papillomavirus capsids are excluded from the beads and run rapidly through the void volume of the column, while other solutes in the cell lysate take a slower, circuitous path through the bead matrix. Although the purity of gel filtered capsids is not quite as high as for Optiprep-purified capsids (Support Protocol 1), gel filtration does effectively remove most contaminants and is safer and less technically demanding than ultracentrifugal methods. Agarose gel filtration can also be used as a buffer exchange method for removing Optiprep or other solutes from purified vector stocks.

Additional Materials *(see Basic Protocol 1)*

DPBS-BSA (see recipe)
DPBS/0.5 M NaCl (prepare by adding 0.075 volume of 5 M NaCl to DPBS)
Benzonase nuclease (Sigma; optional)
0.05% (w/v) NaN_3 or other preservative

Vacuum source (optional)
Bell jar or side-arm vacuum flask for degassing solutions (optional)
Ring stand with clamp
5 ml gravity-flow columns with caps and frits (Pierce or other supplier)

1- or 5-ml pipet
2% (w/v) agarose beads (50- to 150-μm diameter; Agarose Bead Technologies, no. A-1020-S) *or* 1.4% agarose beads (Bioscience Beads)
Parafilm

Prepare an agarose gel filtration column

1. De-gas the DPBS-BSA solution by exposure to vacuum.

   This step is optional. See the package insert that comes with Pierce gravity-flow column kit for additional information.

2. Clamp the column to a ring stand. Put the bottom cap on and add 5 ml of DPBS/0.5 M NaCl.

3. Remove the bottom cap to eject any bubbles. Recap and add more DPBS/0.5 M NaCl. Fill to near the top of the column.

4. Float a frit on the surface. Gently tap the frit to dislodge any air bubbles. Tap frit down to the bottom of the column using a 1- or 5-ml pipet (or the serum separator provided with the column kit).

5. Remove the bottom cap and drain out most of the fluid.

6. Suspend the agarose beads by gently swirling and inverting the bottle. Pour bead slurry into the column. Fill the column to the rim.

7. Remove the bottom cap. Partially exchange the beads into room-temperature DPBS-BSA by repeatedly allowing the column to drip to near dryness then pouring on more DPBS-BSA.

8. Replace the bottom cap. Cover the top of the column with Parafilm. Suspend beads by repeated gentle inversion of the column. Return the column to the clamp and allow blocking and settling overnight at room temperature.

   Preblocking the column overnight with 1% BSA reduces capsid aggregation by blocking nonspecific protein binding sites on the bead matrix and column walls. Although it is generally not as effective as BSA, Tween 80 at a final concentration of 0.01% (v/v) can also be used as a blocking agent. Like BSA, the detergent partially prevents nonspecific interactions that can lead to capsid aggregation (Shi et al., 2005). Tween 80 is a relatively mild detergent and can be added to cell cultures at final concentrations of up to 0.1% (v/v) without noticeable toxicity. The use of high (0.5 M) NaCl concentrations also helps block nonspecific interactions that can lead to capsid denaturation and aggregation.

   It is important to allow the beads to settle slowly after equilibration with room temperature (preferably de-gassed) buffer. Chilled solutions contain more dissolved oxygen, which can form bubbles upon re-warming to room temperature. Trapped bubbles create disruptive vortexes in the liquid flow through the gel bed.

9. Remove Parafilm. Float a frit on the fluid surface and gently tap down to within a few mm of the bed surface.

10. Remove the cap from the bottom of the column. Wash the column with at least 10 column volumes of DPBS/0.5 M NaCl.

    It is helpful to use the conical reservoir included with the Pierce column kit. The washing process may take as long as long as an hour. Washing with only 4 column volumes may result in contamination of the capsids with residual BSA. The gel bed will compact some during the washing. Tap the frit down to within a few millimeters of the bead surface. Do not compress the gel bed. After washing, the column is ready to use.

Perform gel filtration

11. *Optional:* If capsids are being purified out of crude cell lysate (Basic Protocols 1 and 2) add 1 µl of Benzonase nuclease and incubate 10 to 30 min at 37°C to digest any residual unencapsidated DNA.

    It may be beneficial to adjust the salt concentration of the crude lysate to 0.5 M NaCl after Benzonase digestion.

    Although the addition of Benzonase is optional, it helps improve the purity of the stock by digesting large DNA molecules that, like capsids, are too large to enter the pores in the agarose beads. A small fraction of cellular DNA-associated capsids will remain present in the clarified lysate. The addition of Benzonase will therefore liberate some capsids carrying 8-kb linear fragments of cellular DNA. Most of the Benzonase will be removed by the gel filtration process. If capsids have been purified using an Optiprep gradient, they have already been separated from unencapsidated DNA and addition of Benzonase is unnecessary. Also note that Benzonase is inhibited by high-salt concentrations (such as the 0.8 M NaCl used for Optiprep gradients).

12. Add 0.5 ml or less (i.e., less than 1/10 of the agarose bed volume) of clarified lysate (or capsids in Optiprep) to the washed agarose gel filtration column.

13. Apply 0.25 ml of DPBS/0.5 M NaCl to the top of the column. Collect column eluate in a siliconized 1.5-ml tube. Repeat this for a total of 12 0.25-ml fractions.

    See notes for step 13 of Basic Protocol 1 for information about use of siliconized tubes.

14. Screen fractions for encapsidated DNA, as described in Support Protocol 3.

    A peak of purified capsids usually emerges from the gel filtration column at about 1/3rd of the column volume. In other words, typically fraction 7, if 0.25 ml fractions were collected. A histogram of capsid content may be spread over as many as four fractions.

15. Regenerate columns for re-use by washing the column with 10 column volumes of DPBS/0.5 M NaCl, then exchanging into DPBS-BSA supplemented with 0.05% (w/v) NaN_3 or other preservative. Store the column at room temperature for several days.

    Columns can be stored for longer periods at 4°C, but oxygen bubbles may form in the column upon re-warming. If bubbles form, remove the top frit and resuspend the beads by inverting the column.

SUPPORT PROTOCOL 3

SCREENING FRACTIONS FOR THE PRESENCE OF CAPSIDS

If enough capsids are present in the starting lysate, it is possible to screen Optiprep or agarose gel filtration fractions by simple BCA protein assay (Pierce). Screening fractions for the appearance of L1 (55 kDa) in stained SDS-PAGE gels (see *UNIT 6.1*) is also feasible. If SDS-PAGE is used for screening, fractions containing L1 and peak amounts of ~15 kDa histone bands (indicating the presence of encapsidated DNA) should be chosen. Optiprep has a strong light absorbance peak at ~250 nm. This makes it impossible to screen Optiprep fractions using UV absorbance.

If the papillomaviral vector carries a convenient reporter gene, fractions can also be screened by titration of infectivity (Support Protocol 4). If siliconized tubes (see note for step 13 of Basic Protocol 1) have been used for fraction collection, stock titer is generally stable at 4°C for 48 hr.

The fraction screening technique described below is based on the visualization of encapsidated DNA and has the advantage of rapidly identifying fractions containing even relatively low levels of encapsidated plasmid. For more information on agarose gel electrophoresis see Voytas (2000).

Additional Materials *(see Basic Protocol 1)*

Electrophoresis-grade agarose
Tris-acetate-EDTA (TAE) electrophoresis buffer (or other agarose gel electrophoresis buffer, see *APPENDIX 2A*)
Phosphate-buffered saline (*APPENDIX 2A*), optional
Proteinase K (e.g., Qiagen, no. 19131)
0.5 M EDTA
10% SDS
DNA loading dye (Voytas, 2000)
DNA marker ladder (kilobase-range; Invitrogen or other supplier)
1 to 10 ng sample of supercoiled p16L1L2 and/or 1 to 10 ng of the expression plasmid of interest
SYBR Green-I (Invitrogen/Molecular Probes or other supplier)

UV (or blue light) gel documentation imaging device
16- × 16–cm tray
12-well combs
Agarose gel electrophoresis apparatus (see *APPENDIX 3A*)

1. Add 0.8 g of electrophoresis-grade agarose to 80 ml of TAE buffer. Melt by microwaving.
2. Cast molten agar into a 16- × 16–cm tray with one or two 12-well combs. Allow gel to cool.

   Other sizes of casting tray can be used. It is helpful if the gel is relatively shallow (<5 mm thick). SYBR Green-I stain penetrates the gel relatively slowly. If the sample extends up to the surface of the gel, the shorter diffusion distance allows for faster staining.
3. Make a master mix with 100 µl of water (or PBS) and 5 µl each proteinase K, 0.5 M EDTA and 10% SDS. Distribute 5 µl of master mix to an appropriate number of microcentrifuge tubes. Add a 15 µl sample of each gradient or column fraction to separate tubes. Vortex the tubes then incubate 10 to 30 min at 56°C.

   Proteinase K digestion liberates the encapsidated plasmid DNA from the capsid/histone complex. This allows the encapsidated DNA to migrate properly during electrophoresis.
4. Add 5 µl of DNA loading dye to each tube. Load 20 µl of each sample into the gel. Include a lane with 100 ng of DNA marker ladder (i.e., ~10 ng of DNA per ladder band). Also include a 1 to 10 ng sample of supercoiled p16L1L2 and/or 1 to 10 ng of the expression plasmid of interest. Run the gel at 120 V for ~60 min (or an appropriate voltage and time for the electrophoresis device being used).

   The presence of Optiprep and/or salt in the sample may distort the migration of the loading dye, but migration of the DNA is not dramatically affected. It is possible to purify encapsidated DNA away from the proteinase K-digested fraction material using silica spin columns, for example Qiaquick PCR Purification columns (Qiagen, no. 28104). The purified DNA can then be positively identified by digestion with restriction enzymes prior to electrophoresis.
5. Stain the gel for 20 min in SYBR Green-I diluted 1:10,000 in TAE.
6. Image the gel using an appropriate imaging device (see SYBR Green-I package insert).

   The encapsidated plasmid should be predominantly supercoiled, although some nicked and linearized species may appear, particularly if Benzonase was added to the sample (step 1 in Support Protocol 2). Benzonase liberates capsids containing linear fragments of cellular DNA, which will appear as a wide ~8-kb band. See Alternate Protocol 2 for details about capsids containing cellular DNA.

7. Choose fractions with peak plasmid content. Pool the fractions, divide into 100-µl aliquots, and freeze at −80°C.

SUPPORT PROTOCOL 4

CONCENTRATION OF VECTOR STOCKS

It should not generally be necessary to concentrate capsid stocks. However, it is possible to do so using Pierce Slide-A-Lyzer dialysis cassettes and Slide-A-Lyzer Concentrating Solution, following manufacturer's instructions. Unfortunately, Optiprep does not readily pass through dialysis membranes. Therefore, capsids must be exchanged out of Optiprep (using gel filtration, Support Protocol 2) prior to concentration. Addition of high NaCl concentrations (0.5 M to 1.0 M final) and Tween 80 (0.001% – 0.01% (v/v)) to the sample prior to concentration will help prevent capsid aggregation during the concentration process (see notes for Support Protocol 2, step 8). If necessary, the NaCl and Tween 80 can then be dialyzed away after concentrating the stock.

SUPPORT PROTOCOL 5

TITERING THE INFECTIVITY OF PAPILLOMAVIRAL VECTOR STOCKS

Authentic papillomaviruses are released into the environment by the spontaneous disruption of cells at the surface of stratified squamous epithelia. This process, referred to as desquamation, is a normal feature of healthy skin and mucosal surfaces. Perhaps as a consequence of their exploitation of desquamation as a release mechanism, papillomaviruses are not known to employ an active cell-lysis program, as do other nonenveloped viruses. Thus, classical viral plaque assays that rely on viral lysis of infected cells are not useful for titration of papillomaviral vectors.

If a fluorescent protein is expressed by one or more of the packaged plasmids, the stock can readily be titered by flow cytometric analysis of cells treated with varying doses of vector stock (see *Current Protocols in Cytometry*). Intracellular immunostaining [for example, using a Cytofix/Cytoperm Kit (BD Biosciences)] coupled with flow cytometry may also be a feasible method for titering the expression of proteins of interest. If flow cytometry is not available, assessment of fluorescent protein expression (or fluorescent staining of a protein of interest) can be performed using fluorescence microscopy. Some plasmids, for example p16L1-GFP, express enhanced green fluorescent protein (GFP) under control of the SV40 promoter, while a protein of interest (in this case HPV16 L1) is expressed from the stronger EF1α promoter. 293TT cells are useful for titering vector stocks because the incoming plasmid is rapidly replicated to high copy number by SV40 T antigen, thus promoting high-level expression of proteins or reporter genes of interest.

Typically, adding 1 µl of vector stock to 10^6 293TT cells will result in bright fluorescence of nearly 100% of the cells, if GFP is used as a reporter. The infectability of other cell lines varies and should be tested empirically, preferably using a reporter plasmid with GFP under control of a strong promoter, such as CMV immediate early promoter (e.g., pCIneo-GFP) or human EF1α promoter (e.g., pfwB). See Commentary for further information on selecting reporter plasmids.

Materials

Cells, e.g., 293TT
DMEM-10
Vector stocks to be tested
Dulbecco's phosphate-buffered saline (DPBS) supplemented with 1% (v/v) FBS
ι-carrageenan (e.g., Sigma, no. C4014)

24-well plate
2.5-µl pipettor
1000-µl pipettor
Fluorescent microscope

1. Plate 1×10^5 293TT cells (or other cell type of interest) per well in a 0.5 ml volume of DMEM-10 in a 24-well plate. Incubate overnight in a humidified 37°C, 5% CO_2 incubator.

   Cells should be ~25% confluent.

2. Perform four 10-fold serial dilutions (i.e., 1:10 to 1:10,000) of the papillomaviral vector stock, for example by serially adding 2 µl of stock to 18 µl of DMEM-10.

3. Using a 2.5 µl pipettor, add 1 µl of diluted virus stocks to individual wells. Include a well of mock-treated cells. Perform the titration in replicate wells. Include a negative control by adding the papillomavirus-neutralizing agent ι-carrageenan to the cell culture at a final concentration of 1 µg/ml just prior to virus inoculation (Buck et al., 2006). Incubate cells 48 hr in a humidified 37°C, 5% CO_2 incubator.

   It is not necessary to change the medium on the cells.

   Papillomavirus infectious entry is a relatively slow process. 48 hr represents an adequate time period for infection of 293TT cells, but peak infection rates may occur at closer to 72 hr.

4. Remove the supernatant and trypsinize (as described in step 4 of Basic Protocol 1, using a few drops of trypsin per well) infected cells. Using a 1000 µl pipettor, thoroughly resuspend the cells in 0.5 ml DPBS supplemented with 1% FBS. Subject cells to flow cytometric analysis. Alternatively, count the fraction of cells expressing GFP using a fluorescent microscope.

5. To analyze GFP expression by flow cytometry, adjust an FL1 marker window to exclude 99.8% of the mock-transduced cells. Choose a vector stock dilution showing between 1% and 25% of cells FL1-positive. Use the formula [1000 µl/ml] × [stock dilution] × [200,000 cells at time of infection] × [fraction of cells FL1-positive] to calculate the number of infectious units per ml.

   Typical seed stocks for most GFP plasmids should contain at least 3×10^9 infectious units per ml.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Brij-58, 10% (w/v)

Dissolve Brij-58 (polyoxyethylene 20 cetyl ether) at 10% (w/v) in Dulbecco's phosphate-buffered saline (DPBS; e.g., Invitrogen, no. 14040-141). Store up to 1 month at 4°C.

Dissolve the Brij-58 by gently rocking the tube at room temperature for an hour or by storing overnight at 4°C. It is not necessary to filter the solution. The gradual appearance of a cloudy layer near the surface of the stored solution is normal. Mix the solution by gentle inversion of the tube prior to use.

DPBS-BSA

Combine the following in a 50-ml tube:
23 ml of Dulbecco's phosphate-buffered saline (DPBS; e.g., Invitrogen, no. 14040-141)
1.75 ml of 5 M NaCl
0.25 g of bovine serum albumin fraction V (BSA)
Filter using a 0.45-µm filter device (optional)

Dissolve the BSA by rocking at least 30 min. Solution can be kept overnight at room temperature.

DPBS-Mg

100 ml Dulbecco's phosphate-buffered saline (DPBS; e.g., Invitrogen, no. 14040-141), sterile
475 µl of sterile-filtered 2 M $MgCl_2$
1 ml of 100× antibiotic/antimycotic stock (Invitrogen, no. 15240062 or comparable broad-spectrum antibiotic from other suppliers)

Solution is stable for several months stored at 4°C. Keep sterile.

Optiprep/DPBS 46%

30.7 ml of 60% iodixanol solution (Optiprep; Sigma-Aldrich or other supplier)
4 ml of 10× PBS (Invitrogen or other supplier)
5.2 ml of 5 M NaCl
18 µl of 2 M $CaCl_2$
10 µl of 2 M $MgCl_2$
84 µl of 1 M KCl
Store up to one month at room temperature

It is helpful to briefly mix the solution after addition of the 10× PBS to avoid formation of $CaPO_4$ precipitates upon addition of the $CaCl_2$ stock.

Optiprep (60% iodixanol solution) is available from Sigma-Aldrich and other suppliers. Although the term Optiprep is technically a trade name for a 60% aqueous solution of iodixanol, this unit uses the term Optiprep colloquially as a synonym for iodixanol in order to be consistent with other published literature.

COMMENTARY

Background Information

Viral vectors are useful for efficient introduction of genes into mammalian cell types that are difficult to transfect. There is also substantial interest in the development of viral vectors for use as genetic vaccine vehicles or for various in vivo gene therapy applications. Papillomaviral vectors have a number of appealing features, such as their relatively tractable production and purification, which should make them useful as general-purpose gene delivery vehicles. The papillomaviral vectors described in this unit are a recent addition to the viral vector toolbox. To date, the vectors have been used primarily for analysis of the biology of papillomaviruses. However, the vector system also has utility for high-efficiency gene delivery to cultured cell lines and represents a promising new tool for in vivo gene delivery and genetic vaccination.

Other viral vectors, such as retroviral, adenoviral, or AAV-based systems, require that a gene of interest be flanked by viral packaging signals or other elements critical for production of infectious virions. A unique feature of papillomaviral vectors is that the packaging of plasmids within the cell nucleus is highly promiscuous, such that a variety of commercially available mammalian expression plasmids carrying the SV40 promoter [which contains the SV40 origin of replication (*ori*)] can be packaged efficiently. For example, pCDNA3.1 (Invitrogen) and pCIneo (Promega) plasmids expressing enhanced green fluorescent protein (GFP; BD Clontech) can be converted into purified papillomaviral vector stocks with titers of up to 10^{11} GFP-transducing units per ml.

Critical Parameters

This unit describes the production of papillomaviral vector stocks by two different methods: by direct transfection of cells (Basic Protocol 1) and infectious amplification of the transfection-derived stock (Basic Protocol 2). The yield of the initial transfection-derived stock is likely to be sufficient for most in vitro applications. The higher yields of propagated vector stocks may be appealing for in vivo studies, which generally require higher infectious doses.

At the outset of the protocol, a decision must be made whether to produce an amplification-competent or -incompetent vector stock (see Fig. 26.1.1). Amplification-competent stocks utilize p16L1L2, which carries the SV40 origin of replication and is small enough to be packaged into capsids. The p16L1L2 plasmid can be used to co-propagate expression plasmids of interest as

part of a viral swarm. Although this allows high-yield amplification of the vector stock, it has the drawback that the p16L1L2 plasmid will be co-delivered to target cell populations together with the expression plasmid of interest. This problem can be avoided by production of an amplification-incompetent vector stock, using p16sheLL in place of p16L1L2 (Fig. 26.1.1). p16sheLL does not carry an SV40 *ori* and is too large to become packaged. Infectious titer yields for p16sheLL-derived stocks are typically at least several-fold lower than for p16L1L2 transfection-derived stocks, but for most applications the reduced titer yield should not be a major impediment.

For reasons that are not yet clear, some expression plasmids are more amenable to packaging into papillomaviral vectors than others. In some instances, packaging may be impaired by the cytotoxic effects of high-level over-expression of a gene of interest in the producer 293TT cells. Even for relatively nontoxic genes, the plasmid context can affect titer yield. For example, use of pEGFP-N1 (Clontech) results in about ten-fold lower GFP-transducing titer yield compared to vector stocks made using pCDNA3.1-GFP or pCIneo-GFP. The suitability of a given plasmid for packaging should be tested empirically in an initial small-scale transfection-based stock (Basic Protocol 1). If the infectious titer (Support Protocol 4) of stocks made using a particular plasmid of interest is poor, it may be worth considering moving the gene of interest into a different expression plasmid backbone.

Plasmids using the human elongation factor 1-α (EF1α) promoter, for example the GFP expression plasmid pfwB or the L1-expression plasmid p16L1-GFP, have generally worked well in our hands. Variants of these EF1α promoter-based expression plasmids, such as phGf or pGwf (see *http://home.ccr.cancer.gov/Lco/support.htm* for maps), have been adapted for the Gateway cloning system (Invitrogen). p16L1-GFP and the Gateway-adapted variants also carry GFP under control of the SV40 promoter, which facilitates titration of the infectivity of the vector stock.

293TT cells rapidly replicate plasmids carrying the SV40 *ori* to high copy number in the cell nucleus. In general, it appears that this over-replication only modestly enhances the expression of genes under control of the human cytomegalovirus immediate early promoter (CMV promoter). In contrast, most genes under control of the EF1α promoter exhibit a more pronounced dose-response relationship between plasmid copy number and expression level. For some genes, for example HPV16 L1, expression from the EF1α promoter can yield milligram amounts of protein from a single flask of 293TT cells. If the ultimate goal is the high-level production of a protein of interest in 293TT cells, the EF1α promoter is probably a better choice than the CMV promoter.

Plasmids lacking the SV40 *ori* can be packaged using direct transfection (Basic Protocol 1), but titer yields for SV40 *ori*-negative plasmids are generally a minimum of 10-fold lower than comparable plasmids with the SV40 *ori*. The lack of an SV40 *ori* also precludes amplification of the vector stock (Basic Protocol 2). Addition of a previously reported minimal SV40 *ori* (construct pC139H; Okuley et al., 2003) to a plasmid of interest effectively enhances conversion of the plasmid into a papillomaviral vector stock.

Efficient transfection of 293TT cells during the production of a seed stock is a critical parameter of the production system. In our hands, the transfection reagent Lipofectamine 2000 is reliable, provided the cell density is relatively low at the time of transfection. However, Lipofectamine 2000 is very expensive and other, less expensive transfection methods, such as calcium phosphate (see *UNIT 20.3*) or PEI (see Choi et al., 2007), can be used to transfect 293TT cells, if cost is of primary concern.

A commercial version of the 293TT cell line, known as 293FT, is available from Invitrogen (no. R700-07). 293FT cells appear to perform reasonably well for production of transfection-derived papillomaviral vector stocks, but for unknown reasons they appear not to perform as well for titration or infectious amplification of stocks. The widely available 293T line, on which the 293TT line is based, expresses very low levels of SV40 T antigen (Fu and Manley, 1987) and therefore performs poorly for production of papillomaviral vectors.

Papillomaviral vectors can infect cell lines derived from a wide range of tissue types. However, the efficiency of infection can vary from line to line within a given tissue type and cell lines should be tested to determine their infectability. Ideally, cell infectability studies should be performed using flow cytometric analysis of cells infected with papillomaviral vectors carrying GFP under control of a strong promoter such as CMV or EF1α.

Biosafety

Like other types of mammalian gene delivery vehicles, there is a risk that papillomaviral vectors could endanger laboratory personnel if handled improperly. Papillomaviral vectors are a relatively new gene delivery technology and have not yet been subjected to controlled in vivo safety testing. One theoretical biosafety risk is that vector-delivered plasmids, or random fragments of 293TT cell DNA (see introduction to Alternative Protocol 2), might be oncogenic in human cells. Investigators should seek approval from an appropriate institutional biosafety committee (or comparable body within the investigator's institution) prior to engaging in the production of viral vectors. It is important to note that papillomaviruses are thought to be able to withstand a wide range of temperature and pH conditions, and remain infectious after desiccation (Roden et al., 1997). Thus, environmental exposure to papillomaviral vectors may be of greater concern than for other types of viral vectors.

An additional potential risk posed by papillomaviral vectors is that the L1/L2 packaging plasmid could, in principle, recombine with 293TT genomic DNA segments encoding SV40 T antigen. Such recombination events could result in the formation of an entirely novel autonomous tumor virus. It is important to note that SV40 T antigen cannot drive efficient replication of SV40 ori^+ DNA in murine cells (Smith et al., 2002). It is therefore unlikely that mice would be permissive for in vivo amplification of SV40 T antigen-based viruses.

Several safety modifications are currently under development in our laboratory. A 293 cell line carrying a T antigen mutant with diminished capacity to inactivate the pRb and p53 tumor suppressor genes (Cooper et al., 1997) may become a useful, theoretically safer, alternative to 293TT cells. The co-propagation of separate L1 and L2 expression plasmids (together with expression plasmids of interest) might also be an effective method for reducing the theoretical risk of the development of recombinant autonomous tumor viruses.

Troubleshooting

A critical first step in the production process is efficient transfection of the 293TT cells. Production of a GFP-expressing vector stock allows easy flow cytometric or fluorescent microscopic analysis of the transfected vector-producing cells to determine transfection efficiency. A minimum of 75% of the cells should be brightly GFP-positive if the transfection has worked well. The harvested cell pellet should contain enough GFP that it appears green to the naked eye.

The initial health of the cells is a critical factor in achieving good transfection efficiency. 293TT cultures should not be allowed to become confluent or form regions of piled up cells. It is also essential that the cells be preplated at a low enough density to be <50% confluent at the time of transfection.

The optimal dose of vector stock to use for amplification can vary substantially. The guidelines given in Basic Protocol 2 should result in a very high multiplicity of infection (i.e., many infectious events for each cell in culture) for a good vector stock. Lower-titer stocks might require a higher dose to ensure that both p16L1L2 and the expression plasmid of interest are co-delivered to a majority of cells in culture. Small-scale tests using 6-well plates or 25-cm^2 flasks can be performed to determine optimal stock dose for the amplification step. The time of harvesting the infected cells can also be varied. Again, such tests are facilitated by the presence of an easily scored reporter gene, such as GFP.

Anticipated Results

The initial transfection-based production described in Basic Protocol 1 should yield at least 100 μl of clarified cell lysate with at least 3×10^9 GFP-transducing units per ml. The great majority of the infectious titer should be recoverable after purification by ultracentrifugation or gel filtration, although the purification may dilute the stock somewhat. The subsequent amplification of the stock (Basic Protocol 2) should yield at least 300 μl of clarified lysate with at least 2×10^{10} GFP-transducing units per ml.

Time Considerations

293TT cells can be slow to attach and recover after thawing. It may take more than a week to establish the culture at adequate health for efficient transfection.

Attempts to incubate 293TT cells with Lipofectamine 2000/DNA complexes overnight often results in unacceptable levels of cytotoxicity. It takes some planning to accomplish the 6-hr incubation of the cells with the lipid/DNA complexes, as suggested in Basic Protocol 1, during an 8-hr workday.

Basic Protocols 1 and 2 can be performed in series and still accommodate weekends, provided the procedure is begun on a Monday and the feeding step for the infected amplification culture (Basic Protocol 2, step 3) is omitted. From start to finish (including titration of the amplified stock) the two protocols take 10 days to accomplish in series.

Although crude cell lysates should not be frozen prior to maturation (see notes for step 21 of Basic Protocol 1), clarified crude vector stocks withstand freeze-thaw well. This represents a reasonable stopping point prior to purification of the stock. With some advance planning, it is possible to perform Optiprep purification (Support Protocol 1) in a single day.

The infectious entry process for papillomaviruses is quite slow and asynchronous compared to many other virus types. For most cell types, harvesting the titration (Support Protocol 5) 3 days post-infection results in higher apparent titers. Support Protocol 5 suggests a shorter 48 hr period of incubation primarily in the interest of saving time.

BK Virus (BKV): Infection, Propagation, Quantitation, Purification, Labeling, and Analysis of Cell Entry

Takahito Moriyama[1, 2] and Andrey Sorokin[1]

[1]Medical College of Wisconsin, Milwaukee, Wisconsin
[2]Tokyo Women's Medical University, Tokyo, Japan

ABSTRACT

BK virus (BKV) can cause BKV nephritis in renal transplant patients and has become a significant reason for graft loss in this decade. BKV is latent in the urogenital tract and most likely is transported with the donor kidney to recipients. BKV replication occurs in the nucleus of human renal proximal tubular cells (HRPTEC) and daughter viruses are delivered to other cells to spread infection. A few in vitro studies have been reported about the mechanism and kinetics of BKV infection. However, there are still a lot of unknown factors regarding BKV infection. This unit describes the handling of BKV, BKV propagation, determination of titer and ability to infect cells, as well as purification and labeling of BKV in order to analyze BKV cell entry. *Curr. Protoc. Cell Biol.* 42:26.2.1-26.2.13. © 2009 by John Wiley & Sons, Inc.

Keywords: BK virus • human renal proximal tubular epithelial cells • infection • propagation • quantitation • purification • labeling

INTRODUCTION

BKV is a small DNA virus with a 40- to 44-nm sized icosahedral capsid. This capsid contains a 5000-base-pair genome that encodes three capsid proteins, viral proteins 1, 2, and 3 (VP-1, VP-2, and VP-3), and two nonstructural polypeptides, large tumor antigen (T-Ag) and small tumor antigen (t-Ag; Ahsan and Shah, 2006). Antibody against T-Ag is useful to detect BKV infection. The other method to identify BKV infection is to detect viral DNA using PCR. Even though it is possible to detect BKV infection by western blot (immunoblot) analysis using antibodies against VP-1, these antibodies are not commercially available.

Other well studied viruses that belong to Polyomaviridae are simian virus 40 (SV40), JC virus (JCV), and mouse polyoma virus (mPy). JCV has been reported to cause progressive multifocal leukoencephalopathy. BKV infection is relatively slow in comparison to infection with other polyoma viruses. BKV particles are most frequently found in caveolae at 4 hr after infection (Moriyama et al., 2007), are transported along microtubules after caveolar endocytosis, and reach the endoplasmic reticulum 6 to 10 hr after infection (Moriyama and Sorokin, 2008). At least 36 hr are necessary to detect high levels of T-Ag and VP-1 expression by immunoblot, and 48 hr are necessary for detection of viral DNA by Southern blot (Low et al: 2004).

To elucidate precise mechanisms and kinetics of BKV's invasive pathway, the precipitating cause of BKV nephritis, factors and signaling related to BKV nephritis, and efficient therapeutic strategy, it is beneficial to use human renal proximal tubular epithelial cells (HRPTEC). These are the main natural targets of BKV infection; viral life cycles could be different in other cell types.

Current Protocols in Cell Biology 26.2.1-26.2.13, March 2009
Published online March 2009 in Wiley Interscience (www.interscience.wiley.com).
DOI: 10.1002/0471143030.cb2602s42

For that reason, this unit describes the standard techniques suggested for the propagation (Basic Protocol 1), titration (Support Protocol 1), purification (Support Protocol 2), labeling (Support Protocol 3), and infection of BKV in HRPTEC (Basic Protocol 2), to facilitate easy handling of BKV by any investigator.

NOTE: All solutions and equipment coming into contact with living cells must be sterile, and aseptic technique should be used accordingly.

NOTE: All cell culture incubations should be carried out in a 37°C, 5% CO_2 humidified incubator.

BASIC PROTOCOL 1

VIRAL PROPAGATION OF BKV

Before starting experiments, sufficient quantities of BKV must be prepared to support the studies for the complete length of the project. The following method is a straightforward way to increase viral stock (Liu and Atwood, 2001; Eash et al., 2004, 2005). Even though this method is rather time consuming, it generates a large amount of viral stock.

For example, if the plan is to carry out weekly experiments that include incubation of BKV at a multiplicity of infection (MOI) of 0.5 FFU (fluorescence forming units)/cell with 5.0×10^5 cells in ten 60-mm cell culture dishes and 7.2×10^5 (24 wells $\times$ 3.0×10^4 cells/well) in a 24-well tissue culture plate, the required amount of BKV is at least 1.5×10^8 FFU per year.

Materials

HRPTEC (Cambrex Bio Science Inc.), passage 6
REBM containing 5% FBS (see recipe)
BKV stock (ATCC no. VR-837), titered by fluorescent focus assay (Support Protocol 1)
2.5% (w/v) deoxycholic acid

75-cm^2 tissue culture flasks
Refrigerated centrifuge
Cell scrapers
Sonicator (e.g., Sonic Dismembrator 550; Fisher Scientific), with microtip

Propagate BKV

1. Seed $2.0–2.5 \times 10^6$ HRPTEC in 15 ml REBM with 5% FBS per 75-cm^2 tissue culture flask.

   $2.0–2.5 \times 10^6$ HRPTEC will result in about 70% to 80% confluency in 75-cm^2 tissue culture flasks. Knowing the exact number of cells in the flask is necessary because the amount of BKV used for infection is determined based on the number of cells available.

2. Prepare 3 ml of REBM with 5% FBS containing BKV at a multiplicity of infection (MOI) of 0.5 FFU (fluorescence forming units)/cell (see Support Protocol 1 for determination of viral titer). Add an aliquot of BKV containing the corresponding amount of BKV particles directly from frozen stock to medium using barrier tips.

   Gardner strain was used for all described procedures described in this unit.

3. Incubate cells with 3 ml of REBM containing BKV for 1 hr, rocking the flasks by hand several times every 15 min to distribute the virus/inoculum evenly in the medium.

4. Add 7 ml of fresh REBM/5% FBS without removing the inoculum (10 ml total).

   To maintain the appropriate amount of HRPTEC for 4 weeks, REBM/5% FBS is recommended. REBM/10% FBS will result in overgrowth, and REBM/0.5% FBS will result in a severe reduction of cell number with cytopathic effect (CPE) of BKV.

5. Incubate cells for 4 weeks, changing medium and collecting the supernatant every week. Centrifuge the collected supernatant 15 min at 960 × *g*, 4°C, and resuspend the cell pellet in 1/10 of the collected supernatant (discard rest of supernatant). Store the resuspended supernatant at −80°C.

   Collected supernatant contains detached cells resulting from CPE caused by BKV.

Harvest the virus

6. At 4 weeks after incubation, collect the supernatant and harvest cells by scraping. Centrifuge 15 min at 1960 × *g*, 4°C, and resuspend in 1/10 of the collected supernatant.

7. Combine with the previously harvested cells and supernatant collected when changing medium. Freeze at −80°C and thaw at 37°C three times.

   About 4 to 5 ml of combined stock will have be obtained from one 75-cm^2 flask at this step.

8. Sonicate three times, each time for 30 sec in a Sonic Dismembrator 550 with microtip, at an output setting of 4, continuous operation, approximate power output of 20%, on ice.

   This process is very important for releasing BKV from cytoplasm and nucleus in HRPTEC.

9. Add 2.5% deoxycholic acid to the cell suspension to achieve a final concentration of 0.25% and incubate in 37°C water bath for 15 min.

10. Centrifuge the lysate and medium mixture 30 min at 1960 × *g*, 4°C.

11. Collect supernatant, divide into 100-µl aliquots, and store at −80°C.

    Repeat freezing and thawing of the viral samples should be avoided. Virus can be stored for >1 year at −80°C.

VIRAL TITRATION USING THE FLUORESCENT FOCUS ASSAY

SUPPORT PROTOCOL 1

It is necessary to determine the titer of the virus stock so as to carry out each experiment under identical conditions. The fluorescent focus assay (FFA) is an improved version of the standard plaque assay for quantification of BKV. What distinguishes FFA from the plaque assay is the detection of a number of infected cells by antibody against BKV large T-Antigen (T-Ag) in indirect immunofluorescence analysis (Low et al., 2004; Abend et al., 2007). Also see *UNIT 4.3* for general principles of immunofluorescence assays. A description of FFA for other viruses can be found in Lonardo et al. (2002), and Payne et al. (2006).

Materials

70% ethanol
HRPTEC (Cambrex Bio Science Inc.), passage 6
REBM containing 0.5% FBS (see recipe)
BKV stock (ATCC no. VR-837) for titration (Basic Protocol 1)
Phosphate-buffered saline (PBS; *APPENDIX 2A*)
100% methanol
Tris-buffered saline with 0.1% (v/v) Tween (TTBS; see recipe)
TTBS (see recipe) containing 3% (v/v) FBS
TTBS (see recipe) containing 1% (v/v) FBS
Primary antibody: antibody (mouse PA 416) against SV40 T-antigen, recognizing BKV T-Ag (Calbiochem)
Secondary antibody: goat antibody against mouse Ig, conjugated to Alexa Fluor 350 (detect blue color as nuclei in BKV-infected cells), Alexa Fluor 488 (green color), and Alexa Fluor 680 (red color), all from Invitrogen

Mounting medium: SlowFade Antifade Kit (Molecular Probes) *or* 70% (v/v) glycerol/30% (v/v) PBS (see *APPENDIX 2A* for PBS; store up to 1 year at 4°C)
Clear nail polish

13-mm-diameter glass coverslips
24-well tissue culture plates
Fluorescence microscope (*UNIT 4.2*) with FITC filters (which are a match for Alex Fluor 488)

Infect cells with BKV

1. Flame the coverslips after dipping in 70% ethanol to sterilize. Transfer a coverslip into each well of a 24-well tissue culture plate.
2. Seed 3.0×10^4 HRPTEC cells in 200 µl REBM medium/0.5% FBS per well of a 24-well tissue culture plate with a coverslip in each well, and cultivate until cells reach about 70% confluence.
3. Incubate for 72 hr with 10-fold serial dilutions of prepared BKV stock solution in a final volume of 200 µl per well of REBM/0.5% FBS.

   According to the authors' experience, the dilution should cover 10 FFU/cell to 10^{-4} FFU/cell. Triplicates should be used for incubation with each dose of 10–fold serial dilutions of BKV to determine the precise titer.

4. Add 300 µl of REBM/0.5% FBS (without removing the virus/medium inoculum) for a final concentration of 500 µl/well, and incubate for another 48 hr.

Block and expose to primary antibody

5. Wash the coverslips in the wells once by incubating for 1 min with 500 µl PBS.
6. Incubate coverslips in the wells with 500 µl 100% methanol for 20 min at –20°C to fix the cells.
7. Wash coverslips three times, each time for 5 min with 500 µl of TTBS. Incubate each coverslip in the wells with TTBS containing 3% FBS for 30 min at room temperature, for blocking.
8. Incubate with 1 µl/well of primary antibody (anti–SV40 T-antigen mouse monoclonal antibody PA416) diluted 1:200 in TTBS with 1% FBS for 1 hr at room temperature, and then wash three times, each time by incubating for 5 min with 500 µl/well of TTBS at room temperature.

Expose to secondary antibody

9. Incubate with 1 µl/well of secondary antibody (Alexa Fluor 488–conjugated goat anti–mouse IgG) diluted 1:200 in TTBS with 1% FBS for 40 min at room temperature, and then wash three times, each time by incubating for 5 min with 500 µl/well of TTBS.

   This procedure should be done with protection from the direct light.

10. Wash the coverslips once with 500 µl of distilled water (simply add the water and then aspirate it) and mount the coverslips, cell-side-down, with one drop of mounting medium on the slide.
11. Seal with clear nail polish along the edge of the coverslip to prevent drying.
12. Analyze the cells with the fluorescent microscope immediately (see Fig. 26.2.1).

    If immediate analysis is not possible, slides can be kept in the dark box at 4°C. However analysis should be carried out within a few days.

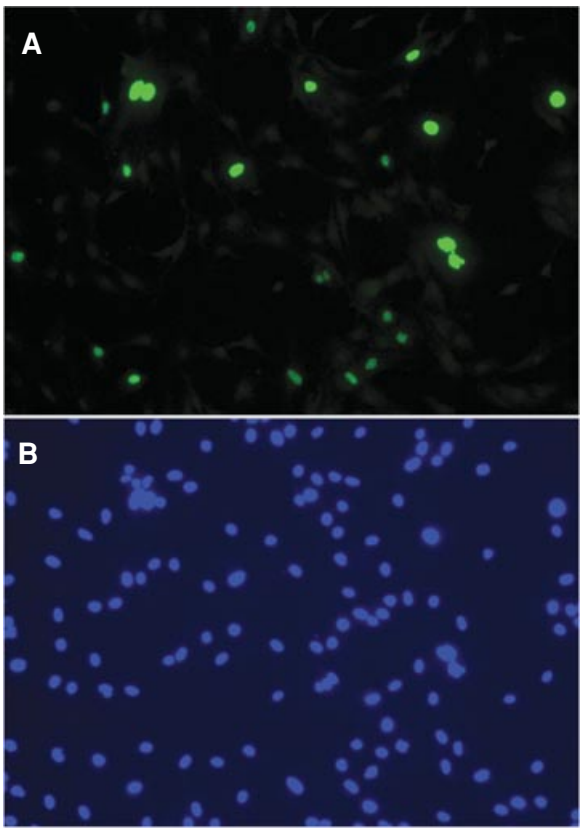

Figure 26.2.1 Detection of HRPTEC BKV infection by immunofluorescence. HRPTEC are either stained with anti-T-Ag antibodies (**A**) or stained with 4′,6-diamidino-2-phenylindole dilactate (DAPI) (**B**). HRPTEC were incubated with BKV (MOI, 0.5 FFU/cell). After 72 hr, fresh medium was added and the cells were incubated for another 48 hr. After incubation, cells were fixed and blocked. Next, cells were incubated with primary antibody [5 μl of PA 416 (Calbiochem) in 1 ml of TTBS with 1% FBS] and secondary antibody [1:200 diluted Alexa Fluor 488 goat anti-mouse IgG (H+L); (Molecular Probes) in TTBS with 1 % FBS]. To stain nuclei, cells were incubated with 300 nM DAPI (Molecular Probes) for 5 min and washed three times with PBS. Cells were observed by fluorescent microscopy (Nikon Eclipse E600) with 20× objective lens, and images were captured by SPOT version 4.0.9 (Diagnostic Instruments).

Calculate fluorescence-forming units (FFU)

13. At a magnification of 20×, count the number of infected cells from five different fields on each coverslip and calculate the average.

14. Calculate the number of infected cells in the whole well from the average of the number of infected cells in each field.

    For example, if the average number of infected cells in the field of BKV diluted at 10^{-4} is 10, and the area of the field is 1.5386 mm^2, the number of infected cells in the well is 1000 (=10 × 153.86/1.5386), where the area of one well of the 24-well plate is 153.86 mm^2 (=7 mm × 7 mm × 3.14).

15. Multiply the number of infected cells in each well by the reciprocal of the volume of sample added to the well, and multiply by the reciprocal of the dilution factor.

    For example, if the number of infected cells in the well of BKV diluted at 10^{-4} is 1000 and the volume of the diluted BKV sample is 0.2 ml, the calculation is $1000 \times 5 \times 10^4 = 5.0 \times 10^7$ FFU/ml. In this calculation, 1000 = the number of infected cells; 5 = 1/0.2 (reciprocal of the volume of BKV diluted sample); and $10^4 = 1/10^{-4}$ (reciprocal of the dilution factor).

This calculation is expected to show the same titer at each dilution point, because 10-fold serial dilution of BKV should cause 1/10-fold cell-killing activity. For example, the number of infected cells in the well of 10^{-3}-diluted BKV has to be 10000 ($10000 \times 5 \times 10^3 = 5.0 \times 10^7$ FFU/ml). Similarly, the number of infected cells in the well of 10^{-5}-diluted BKV has to be 100 ($100 \times 5 \times 10^5 = 5.0 \times 10^7$ FFU/ml). If the results do not meet this condition, there may be an error and the titration should be repeated.

SUPPORT PROTOCOL 2

PURIFICATION OF BKV

Observation of the viral particle itself is valid for the investigation of the kinetics and traffic of virus. However, viral stocks may contain a lot of other proteins besides BK viral proteins, after propagation of BKV. Therefore, purifying BKV from viral stocks is necessary for the labeling of BKV particles. Moreover, viral purification is also capable of preventing contamination with other viruses and bacteria (Eash et al., 2004; Sawa and Komagome, 2005).

Materials

Virus-containing supernatant (Basic Protocol 1)
20% (w/v) sucrose in reassociation buffer (see recipe for buffer)
Buffer A (see recipe)
1.40 g/ml and 1.20 g/ml cesium chloride (CsCl) solutions in distilled water
Slide-A-Lyzer dialysis cassette (MWCO 10,000, Pierce)

Ultracentrifuge
10-ml and 20-ml ultracentrifuge tubes
Sonicator (e.g., Sonic Dismembrator 550; Fisher Scientific), with microtip
5-ml syringe
18-G needle

Purify virus

1. In a 20-ml ultracentrifuge tube, gently layer 10 to 18 ml of virus-containing supernatant at the top of 2 ml of 20% sucrose in reassociation buffer and centrifuge 2 hr at 100,000 × *g*, 4°C.
2. Discard supernatant and dissolve pellets in 3 ml of buffer A. Sonicate three times each time for 30 sec in a Sonic Dismembrator 550 with microtip, at an output setting of 4, continuous operation, approximate power output of 20%, on ice.
3. Add 3 ml of 1.40 g/ml CsCl solution to a 10-ml ultracentrifuge tube and then overlay 3 ml of 1.20 g/ml CsCl solution.
4. Overlay 3 ml of viral sample above the 1.20 g/ml CsCl solution. Centrifuge overnight at 120,000 × *g*, 16°C.
5. Use a 5-ml syringe with an 18-G needle to extract the viral fraction (bottom white-colored fraction between the low and high density of CsCl), and transfer to a fresh 10-ml tube. Dilute the fraction with buffer A to a final volume of 3 ml.

   Insert the needle through the side of the tube 5 mm below the viral band.
6. Centrifuge the viral sample on a CsCl gradient again as described in steps 3 and 4.
7. Extract the viral fraction as in step 5 and dialyze against 500 ml of buffer A at 4°C overnight in a 10,000 MWCO Slide-A-Lyzer cassette.
8. Divide the viral sample into 100 µl aliquots and store at −80°C.

   Repeated freezing and thawing of the viral sample should be avoided. It can be stored for more than 1 year.

LABELING PURIFIED VIRUS

SUPPORT PROTOCOL 3

The icosahedral capsid of BKV contains a 5000 base-pair genome that encodes three capsid proteins, viral protein 1 (VP1), viral proteins 2 and 3 (VP2 and VP3), and two nonstructural polypeptides: the large tumor antigen (T-Ag) and small tumor antigen (t-Ag). The major capsid protein, VP1 (mol. wt. 42 kDa), is likely to be a target of the labeling procedure. Protein labeling kits (Invitrogen) are simple and handy tools to label proteins, and different kits are available depending on the amount of purified protein for labeling and desired fluorochrome for detection. The proper kit should be selected according to the manufacturer's suggestion. The general information about Alexa Fluor dye series can be found at *http://probes.invitrogen.com/media/publications/150.pdf*.

Comparison of Invitrogen kits for labeling proteins can be found at *http://probes.invitrogen.com/handbook/sections/0102.html*.

Description of Alexa Fluor dyes spanning the visible and infrared spectrum can be found at *http://probes.invitrogen.com/handbook/sections/0103.html*.

In this unit we describe Alexa Fluor 488 Microscale protein labeling kit for 20 to 100 μg protein which we use to label BKV particles (*http://probes.invitrogen.com/media/pis/mp30006.pdf*).

Materials

Alexa Fluor 488 Microscale Protein Labeling Kit (Invitrogen) containing:
- Alexa Fluor 488 tetrafluorophenyl (TFP) ester (Component A), 3 vials
- Sodium bicarbonate (Component B), 84 mg
- Reaction tubes (Component C), 3 tubes
- Spin filters (Component D) Nanosep MF 0.2-μm centrifugation devices, 3 tubes
- Purification resin (Component E) Bio-Gel P-6 fine resin suspended in PBS, 3 ml

Purified BKV (Support Protocol 2)

Label BKV

1. Calculate the amount of reactive dye (Component A) to add to labeled BKV according to the formula shown below.

Amount of reactive dye (μl) = [(μg protein/protein mol. wt.) × 1000] × [dye:protein molar ratio (MR)]/11.3

Protein mol. wt. is the molecular weight of VP-1 (42,000 Da).

MR is the optimal degree of labeling of VP-1 from manufacturer's manual (60).

11.3 is the concentration of the reactive dye stock solution (see step 4 below).

For example, to label of 24 μg of BKV (VP-1):

[(24/42,000) × 1000] ×(60/11.3) = 3.0 μl of dye.

2. Add 1 ml of distilled water to the vial of sodium bicarbonate (Component B) and vortex or pipet up and down until the reagent is fully dissolved.

This bicarbonate solution is 1 M, pH ∼8.3.

Store at 4°C up to 2 weeks and −20°C for longer periods.

3. Transfer 20 to 100 μl of purified BKV to a reaction tube (Component C), add 1/10 volume (2 to 10 μl) of sodium bicarbonate, and mix by pipetting up and down several times.

4. Add 10 µl of distilled water to Alexa Fluor 488 TFP ester (Component A) and pipet up and down until the reagent is fully dissolved

   The concentration of this reactive dye stock solution is 11.3 mM.

5. Add the appropriate volume of reactive dye solution according to the formula shown above (see step 1) to a reaction tube (Component C), mix by pipetting up and down, and incubate for 15 min at room temperature.

6. During the 15-min incubation, prepare the resin bed by adding ~800 µl of gel resin (Component E) to the spin filter (Component D), and centrifuging the spin filter 15 sec at 16,000 × *g*, room temperature.

   A fixed-angle rotor will make the resin bed tilt, and the lower side should be 2 to 3 mm above the bottom of the upper chamber for appropriate labeling. A swinging-bucket rotor will make the resin bed horizontal and 5 mm above the bottom of the upper chamber.

7. Transfer 50 µl of purified BKV sample with reactive dye solution from reaction tube (Component C) to the top of the center of the resin bed on the spin filter (Component D), and centrifuge 1 min at 16,000 × *g*, room temperature.

   If the amount of sample is over 50 µl, divide it and purify by separate spin filters with resin bed.

8. Divide the purified and labeled viral sample into 100 µl aliquots and store at −80°C.

   Before experiments, labeled virus must be titrated again (Support Protocol 1).

BASIC PROTOCOL 2

BKV INFECTION OF HUMAN RENAL PROXIMAL TUBULAR EPITHELIAL CELLS (HRPTEC)

In this unit, the method of BKV infection in HRPTEC is described. BKV infection in HRPTEC is relatively slow. The virus is most frequently trapped in caveolae at 4 hr after incubation, reaches the endoplasmic reticulum at from 6 to 10 hr after incubation, and high levels of T-Ag expression detected by immunoblots require at least 36 hr of infection (Low et al., 2004; Moriyama et al., 2007; Moriyama and Sorokin, 2008). It is important to prevent contamination by bacterium and cell detachment from wells or dishes by CPE of BKV, because the incubation period is long.

Materials

HRPTEC (Cambrex Bio Science Inc.), no later than passage 6
REBM containing 0.5% FBS (see recipe)
BKV stocks, titrated (Support Protocol 1), purified (Support Protocol 2), and labeled (Support Protocol 3, for observing virus particles)
60-mm tissue culture dishes *or* 24-well tissue culture plates with glass coverslip in each well (see Support Protocol 1, step 1)
Cell scrapers
Sonicator (e.g., Sonic Dismembrator 550; Fisher Scientific) with microtip

Infect cells with BKV

1. Seed 5.0×10^5 HRPTEC in REBM medium containing 0.5% FBS on a 60-mm tissue culture dish or 3.0×10^4 HRPTEC/well on a 24-well tissue culture plate with a coverslip in each well (see Support Protocol 1, step 1), 1 day prior to incubation with BKV.

   To calculate MOI for BKV infection correctly, it is important to know how many cells are incubated with virus.

   5.0×10^5 HRPTEC provides 70% of confluence at 60-mm tissue culture dish and 3.0×10^4 HRPTEC provides 60% to 70% confluence in one well of 24-well tissue culture plate on the day after seeding.

2. Calculate the required amount of BKV.

   According to our experience, the appropriate MOI of BKV against HRPTEC is 0.5 FFU/cell, because higher MOI and the long incubation period sometimes cause the detachment of cells by CPE (Moriyama et al., 2007).

   If the titer of BKV is 5.0×10^7 FFU/ml (see Support Protocol 1), the required amount of BKV is 5 μl [$=2.5 \times 10^5$ FFU ($=0.5 \times 5.0 \times 10^5 = MOI \times$ number of HRPTEC)] for a 60-mm tissue culture dish and 0.3 μl [$=1.5 \times 10^4$ FFU ($=0.5 \times 3.0 \times 10^4 = MOI \times$ number of HRPTEC)] for a 24-well tissue culture plate.

3. Dilute BKV stocks with REBM containing 0.5% FBS.

4. Remove growth medium from cells and add an equal volume of the medium containing the BKV. Incubate HRPTEC with medium containing BKV for 72 hr.

5. Discard medium and wash three times with REBM containing 0.5% FBS, each time by adding 3.0 ml (for 60-mm dish) or 500 μl (for well of 24-well plate) of REBM/0.5% FBS, and then aspirating the medium. Add fresh medium and incubate for another 48 hr.

   Add 3 ml fresh medium to 60-mm tissue culture plate and 500 μl to 24-well tissue culture plate.

   The first 72 hr are for BKV infection and the next 48 hr are to allow BKV infection to spread to the other cells.

6. After a total of 5 days incubation, harvest cells for analysis as follows:

   a. Discard medium containing with BKV and wash plate three times with PBS on the ice, using the technique described in step 5.

   b. Scrape the cells from the plate surface using a cell scraper.

      The authors do not use trypsin.

   c. Collect the scraped cells in microcentrifuge tubes.

   d. Sonicate three times, each time for 30 sec in a Sonic Dismembrator 550 with microtip, at an output setting of 4, continuous operation, approximate power output of 20%, on ice.

      Cells can be subjected to SDS-PAGE and western blot analysis as described in Moriyama et al. (2007).

ANALYSIS OF BKV ENTRY AND INTRACELLULAR TRAFFICKING PATHWAY IN HRPTEC USING CONFOCAL MICROSCOPE AND MetaVue IMAGING SYSTEM

BASIC PROTOCOL 3

To understand precise mechanisms and kinetics of BKV invasive pathway, investigation of co-localization of BKV particles with target organelles in HRPTEC is a useful method. The co-localization rate of purified and labeled BKV with target organelles indicates the intracellular trafficking pathway and time course of BKV invasion.

Materials

HRPTEC (Cambrex Bio Science Inc.), no later than passage 6
REBM containing 0.5% FBS (see recipe)
Purified and labeled BKV (Support Protocol 3)
Primary antibody against target organelle
Secondary antibody with a fluorophore different from that of the virus

24-well tissue culture plates with glass coverslip in each well
Confocal microscope (*UNIT 4.5*)
MetaVue Imaging System (Molecular Devices) or other image-analysis program

Additional reagents and equipment for indirect immunofluorescence assay (Support Protocol 1)

Incubate HRPTEC with purified and labeled BKV

1. Seed 3.0×10^4 HRPTEC/well in REBM medium containing 0.5% FBS on a 24-well tissue culture plate with a coverslip in each well (see Support Protocol 1, step 1), 1 day prior to incubation with BKV.

2. Calculate the required amount of BKV.

   According to our experience, the appropriate MOI of purified and labeled BKV to use in HRPTEC to observe viral particles is 5 FFU/cell.

   If the titer of BKV is 1.0×10^7 FFU/ml, the required amount of BKV is 15 μl $\{=1.5 \times 10^5$ FFU $(=5.0 \times 3.0 \times 10^4 = MOI \times$ number of HRPTEC$)\}$ for a 24- well tissue culture plate.

3. Dilute BKV stocks with REBM containing 0.5% FBS.

4. Remove growth medium from cells and add an equal volume of the medium containing the BKV. Incubate HRPTEC with medium containing BKV for the target period.

   According to our experience, BKV are most frequently trapped in caveolae at 4 hr after incubation, transported along microtubules, and reach the endoplasmic reticulum from 6 to 10 hr after incubation (Moriyama et al., 2007; Moriyama and Sorokin, 2008).

5. Observe cells by indirect immunofluorescent assay (see Support Protocol 1) using primary antibody against target organelle and secondary antibody with a fluorophore different from that of the virus.

   Co-localization of labeled BKV particles with endoplasmic reticulum markers is shown in Figure 26.2.2.

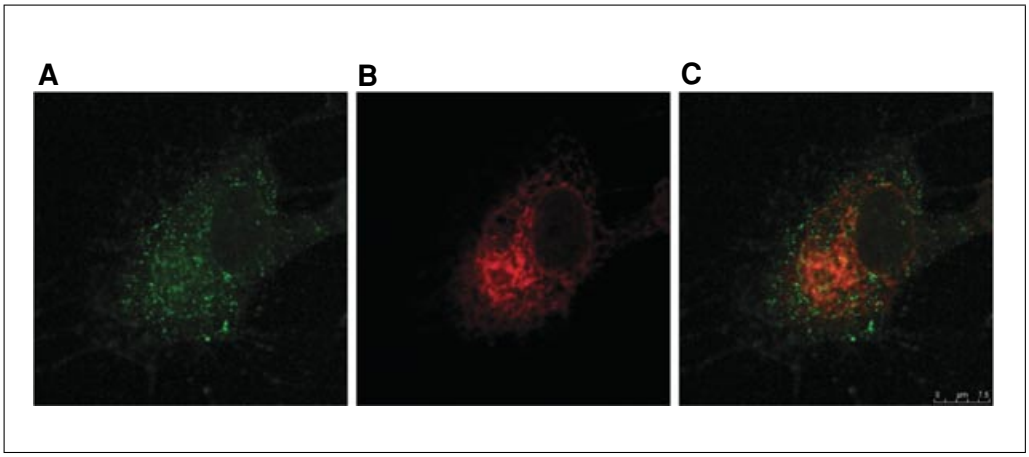

Figure 26.2.2 Localization of labeled BKV particles in HRPTEC. (**A**) Fluorescence of Alexa Fluor 488–labeled BKV particles in HRPTEC. (**B**) Staining for endoplasmic reticulum (ER) in HRPTEC. (**C**) Co-localization of purified and labeled BKV with ER marker. HRPTEC were incubated with purified and labeled BKV for 6 hr. After incubation, cells were fixed and blocked. Then cells were incubated with primary antibody [1:100 dilution of PDI (Abcam) as ER marker against TTBS with 1% FBS] and secondary antibody [1:200 diluted Alexa Fluor 680 goat anti-mouse IgG (H+L) (Molecular Probes) in TTBS with 1% FBS]. Cells were analyzed by confocal microscope (Leica TCS SP5) with 63× objective lens and images were captured by Leica application suite (advanced fluorescence). Bar = 10 μm.

Use MetaVue Imaging System to analyze interaction of BKV with target organelles

6. After observing HRPTEC by confocal microscope and capturing images, use MetaVue Imaging System (or other image-analysis program) for analysis of co-localization.

   If purified BKV is labeled with a green fluorophore (wavelength ~500 nM), the secondary antibody against a target organelle should be labeled with a red (wavelength ~650 nM) or blue (wavelength ~350 nM) fluorophore.

7. Fix the boundary between BKV particles or target organelle and background according to the intensity of pixels, and measure the area of BKV particles and co-localization area of BKV particles with target organelles.

   According to the BKV-uninfected cells, the intensity of background will be calculated. Once the threshold is fixed, the MetaVue Imaging System recognizes and measures area from all pictures regularly and automatically.

8. Calculate the co-localization rate by using formula shown below and the average of all the cells.

   Co-localization rate = Area of BKV particles co-localized with target organelle (mixed color of green with red or blue)/area of total BKV particles (green color).

   To prevent bias, many cells randomly selected from different wells in several independent experiments must be analyzed to obtain the average value. We calculated the average of at least 100 cells from three independent experiments.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Buffer A

1 M Tris·Cl, pH 8 (*APPENDIX 2A*)
5 M sodium chloride
0.1 M calcium chloride
Store up to 1 year at 4°C

Reassociation buffer

TTBS (see recipe) containing:
1 mM calcium chloride
Store up to 1 year at 4°C

REBM/10%, 5%, and 0.5% FBS medium

Add renal epithelial growth medium SingleQuots (Cambridge Bio Science, Inc., containing human epidermal growth factor, insulin, hydrocortisone, gentamicin/amphotericin B-1000, epinephrine, triiodothyronine, transferrin), 5 ml of 100 U/ml penicillin G (Invitrogen), and 50 ml (for REBM/10% FBS), 25 ml (for REBM/5% FBS), or 2.5 ml (for REBM/0.5% FBS) of fetal bovine serum (FBS) to 500 ml of renal epithelial basal medium (REBM; Cambrex Bio Science Inc.). Store at 4°C.

Tris-buffered saline (TBS), 10×

1.5 M (87.66 g) sodium chloride
0.2 M (24.22 g) Tris base
Add distilled H_2O to final volume 1000 ml and adjust pH to 7.5 using NaOH or HCl
Store at room temperature

Tris-buffered saline with Tween (TTBS)

Dilute TBS 10× stock solution to 1× working solution with distilled water and add Tween 20 to 0.1% (v/v)

For example, to prepare 1 liter, one would combine 100 ml 10× TBS 899 ml distilled water, and 1 ml Tween 20.

COMMENTARY

Background Information

BK virus is a nonenveloped double-stranded DNA virus which belongs to family Polyomaviridae. It was initially isolated from the urine of renal transplant patients with ureteric obstruction in 1971, and named after the initials of this patient (Gardner et al., 1971).

Primary BKV infection occurs by the upper respiratory route until age 10, without any obvious symptoms. More than 80% of the population is infected with BKV, and ∼50% of healthy native kidneys contain latent BKV. BKV mainly persists in the urogenital tract and enters latent phase in the renal tubular epithelial and urothelial cells. In this decade, BKV has become a severe problem in allograft failure among renal transplant patients, because latent BKV, likely transported with donor kidney, progresses to BKV nephritis in immunocompromised hosts, particularly in renal transplant patients. After renal transplantation, 35% to 60% of patients have BKV viruria and 5% to 30% of patients have BKV viremia. The prevalence of BKV nephropathy is about 10% of renal transplant patients, and about half of them have been reported to progress to irreversible allograft failure within 1 year after diagnosis (Nickleit et al., 2003).

Rapid progress is required to analyze BKV infection against HRPTEC, because the precise mechanism and kinetics of BKV infection are still not clearly understood and efficient antiviral therapies have not been established yet. This unit will be useful for the in vitro analysis of BKV infection in HRPTEC.

Critical Parameters and Troubleshooting

The most important factor for BKV experiments is to determine the appropriate dose of BKV and incubation period to cause efficient BKV infection in HRPTEC (30% to 40% of all cells). The highest titer and longest incubation period may not always cause the most efficient BKV infection. If the percentage of BKV infection is below 30% by indirect immunofluorescent analysis, or T-Ag expression is extremely low, several titers of BKV and several incubation periods should be examined to determine appropriate dose and incubation period. A point to notice is that another 48-hr incubation period to spread BKV infection to the other cells is required after initial BKV infection. The appropriate dose is different between purified and labeled BKV and untreated BKV. After purification and labeling, it is necessary to measure the viral titer and to determine the appropriate dose and period for infection. According to the author's observations, the appropriate titer of BKV without purification and labeling is MOI 0.5 FFU/cell and the optimal incubation period is 5 days (72 hr for primary infection and 48 hr for spreading) for the most efficient BKV infection; the appropriate dose of purified and labeled BKV is MOI 5 FFU/ml with a 24-hr incubation.

Biosafety

BKV belongs to agents of moderate potential hazard to personnel and the environment. This class includes agents which may produce disease of varying degrees of severity from accidental inoculation or injection but which are contained by ordinary laboratory techniques (Biosafety Level 2 standards of practice and facility). The guidelines for handling this kind of agent can be found in Biosafety in Microbiological and Biomedical Laboratories (BMBL, 4th ed.), available online at *http://www.cdc.gov/OD/ohs/biosfty/bmbl4/bmbl4toc.htm*.

Anticipated Results

Described protocols are generally straightforward, but require several days of procedures. However more than 1.0×10^7 FFU/ml BKV should be obtained after propagation, and these viruses will cause infection of more than 30% of cells as detected by indirect immunofluorescent analysis. Appearance of prominent T-Ag and VP-1 bands in immunoblot analysis and viral DNA detected by PCR will provide additional evidence of BKV infection. Purified and labeled virus will be useful for experiments dealing with analysis of BKV infection of its natural target HRPTEC.

Time Considerations

As we describe in this unit, viral propagation takes about 1 month. However BKV, once propagated by this method, provides a high amount of BKV. Titration of BKV using FFA takes 5 days, a time period similar to that required to cause the infection in HRPTEC for the immunoblots (*UNIT 6.2*) and indirect immunofluorescent analysis (*UNIT 4.3*). Viral purification requires 3 days and labeling requires about 2 hr.

Methods Used to Study Respiratory Virus Infection

Emilio Flaño,[1] Nancy A. Jewell,[1] Russell K. Durbin,[1] and Joan E. Durbin[1]

[1]Center for Vaccines and Immunity, The Research Institute at Nationwide Children's Hospital, Ohio State University, Columbus, Ohio

ABSTRACT

This unit describes protocols for infecting the mouse respiratory tract, and assaying virus replication and host response in the lung. Respiratory infections are the leading cause of acute illness worldwide, affecting mostly infants and children in developing countries. The purpose of this unit is to provide a basic strategy and protocols to study the pathogenesis and immunology of respiratory virus infection using the mouse as an animal model. The procedures include: (1) basic techniques for mouse infection, tissue sampling, and preservation, (2) determination of viral titers, isolation and analysis of lymphocytes and dendritic cells using flow-cytometry, and (3) lung histology, immunohistochemistry, and in situ hybridization. *Curr. Protoc. Cell Biol.* 43:26.3.1-26.3.28. © 2009 by John Wiley & Sons, Inc.

Keywords: respiratory viruses • pathology • immunohistochemistry • immunology • respiratory syncytial virus • influenza • murine γ-herpesvirus 68 • lung • lymphoid organs • T lymphocytes • dendritic cells

INTRODUCTION

The respiratory tract is remarkable for its extensive surface area (70 m^2 in adult humans), which is in continuous contact with the external environment. The lung samples ~10,000 liters of air every day and is exposed to a vast array of foreign particles. As a consequence, the respiratory system is a major portal by which microorganisms enter the body. When studying infection and immunity in this tract, the structurally and functionally distinct compartments must be appreciated, as each compartment has distinct populations of both immune and parenchymal cells. The nasopharynx, or uppermost airway, is lined by both respiratory and olfactory epithelium. The respiratory epithelium of the mouse nasopharynx is columnar to cuboidal with cilia and scattered goblet cells. The tracheal lining is similar but, unlike the human trachea, has a high percentage (50% to 60%) of non-ciliated, secretory Clara cells. The right lung of the mouse is divided into five lobes; the left lung is not divided. The lower respiratory tract is comprised of branching conducting airways, which extend from the trachea to the terminal bronchioles, which open into the alveolar ducts. The bronchi and bronchioles of the mouse are lined predominantly with Clara cells, which are relatively rare in the human airway (Sternberg, 1997). This altered cell distribution must be kept in mind as it will alter the pattern of infection with some viral respiratory pathogens. Goblet cells are not found in the uninfected mouse lung. The bulk of the lung volume is made up of alveoli, where gas exchange occurs. The alveolar ducts and spaces are lined primarily by flat type I pneumocytes overlying capillaries. The rare, plump type II cells produce surfactant and are thought to be the source of new type I cells (Maronpot et al., 1999).

Because efficient gas exchange requires that the alveoli be relatively free of fluid and inflammatory cells, the respiratory mucosal immune system must maintain a fine balance between eliminating pathogens and inhibiting inflammatory pathology. This requires discriminating between innocuous airborne antigens and pathogen-associated antigens,

Current Protocols in Cell Biology 26.3.1-26.3.28, June 2009
Published online June 2009 in Wiley Interscience (www.interscience.wiley.com).
DOI: 10.1002/0471143030.cb2603s43

and inducing tolerance or immunity, respectively. Surveillance is maintained by a layer of dendritic cells underlying the mucosa of the larger conducting airways (Vermaelen and Pauwels, 2005; Weslow-Schmidt et al., 2007), and alveolar macrophages present within the air spaces of the lung. Additional inflammatory cells are recruited by chemokines secreted by epithelial and immune cells when pathogens are detected. The mouse model is permissive for some but not all human respiratory pathogens, and among those viruses that will infect both mouse and man, disease in the mouse may not necessarily mirror disease in the human host. This is an important consideration when undertaking infection experiments to model human diseases in the murine host.

This unit describes protocols for infecting the mouse respiratory tract, and assaying virus replication and host response in the lung.

NOTE: All procedures involving viral pathogens and infected tissues must be carried out in a biosafety cabinet prior to fixation.

NOTE: All experiments using live animals must first be approved by the Institutional Animal Care and Use Committee and conform to governmental regulations for the care and use of laboratory animals.

BASIC PROTOCOL 1

INTRANASAL INFECTION OF MICE

Most intranasal infection protocols use relatively large volumes (30 to 100 μl) of inoculum, resulting in intratracheal delivery of virus. This protocol discusses intranasal inoculation using both small and large volumes. Choice of route will vary with the virus studied, and the interest of the investigator in upper versus lower airway infection.

Materials

Mice
Avertin anesthesia (see Support Protocol 5)
Viral inoculum diluted in PBS (see recipe) or HBSS (Cellgro) to a volume of 30 to 100 μl/dose

1-ml syringes and 25- to 27-G needles (BD)
Positive displacement pipets and tips (Rainin)

1. Restrain the mouse in dorsal recumbency by picking it up by the scruff of the neck between the index finger and thumb. Hold the tail against the hand with the little finger.

2. Insert the 1-ml syringe (filled with anesthetic) with attached needle into the caudal 2/3 of the right side of the abdomen, taking care to avoid internal organs. After the needle is inserted, draw the syringe back (if anything is aspirated, the viscera has been hit). Withdraw and attach a new needle to the syringe before trying again. Inject Avertin (200 to 250 μl, 25 mg/kg), pausing briefly before withdrawing the needle so that liquid does not seep out.

3. Monitor anesthesia by testing the mouse toe pinch reflex.

   Inadequate anesthesia increases the probability that the mouse will sneeze or swallow the virus.

4. When the mouse is fully anesthetized, inoculate the mouse by placing the pipet tip containing the inoculum at the opening of the nares. Slowly expel the virus preparation from the tip, checking that the mouse is inhaling (not swallowing) the solution.

The use of a positive displacement pipet prevents aerosol contamination and isolates the virus sample from the pipet body. This precaution is extremely important if different virus mutants, strains, or virus species are being used.

Changing the titer of the inoculum is possible by altering the amount of stock virus used and/or by adjusting the volume of diluent accordingly. The authors normally use volumes between 30 and 100 μl for mice 6 weeks of age or older, smaller volumes may be needed for younger animals.

5. Allow the mouse to recover for 5 to 10 min. Observe the mouse until it regains consciousness and breathing returns to normal.

   The mouse will have an increased respiratory rate for some minutes after intranasal inoculation. If a proper dose of anesthesia has been used, the mouse will regain consciousness and breathing will return to normal within 15 to 30 min.

INFECTION OF THE UPPERMOST AIRWAY

ALTERNATE PROTOCOL 1

This is a modification of the intranasal infection protocol (see Basic Protocol 1). In this method, an inoculum is delivered specifically to the upper airway by using a smaller volume and administering the inoculum over several minutes (Visweswaraiah et al., 2002; Gitiban et al., 2005). Materials required are listed in Basic Protocol 1, except that the viral inoculum should be prepared such that each dose is contained within a 20-μl volume. A timer is also required for this protocol.

1. Anesthetize mice with Avertin as in Basic Protocol 1, steps 1 to 3.
2. Place anesthetized animals on a flat surface, in a dorsal recumbent position with the nose facing you.
3. Administer 2 μl of inoculum to each naris of a mouse at 0, 2, 7, 9, and 11 min.
4. Allow the mouse to recover.

DETERMINING VIRUS TITER: PLAQUE ASSAY

BASIC PROTOCOL 2

The optimal method for determining virus titer will depend upon the virus being used. In this protocol, general applicable techniques for obtaining samples for testing, and examples of titering methods used for two viruses commonly used in the authors' laboratory, RSV and influenza A virus, are outlined.

Any virus recovered from the mouse respiratory tract will, presumably, replicate to some degree in mouse cells. Different viruses, however, vary widely in the degree to which they produce plaques (countable lesions) on a cell monolayer. RSV, for instance, normally produces no obvious cytopathology in cultured mouse cells, and has historically been assayed on monolayers of human HEp2 cells or monkey Vero cells. This protocol is specific for RSV; specifics will vary for other viruses. The plaque assay is performed on STAT1-deficient NY3 mouse fibroblasts, which are extremely sensitive to many viruses.

Materials

Dry ice
Mice
70% ethanol
Decarbonated Dulbecco's modified Eagle medium (dcDMEM; see recipe)
Susceptible cell line
10 mM HEPES supplemented with 5% fetal calf serum
Earle's balanced salt solution (Invitrogen) supplemented with 10 mM, pH 7.4 (HEBSA)

Overlay medium (see recipe)
Fixative/stain (see recipe)

2-liter beaker (Nalgene)
Styrofoam insert (3- to 5-cm thick, equal to the beaker in circumference)
Parafilm
Dissecting scissors, forceps
5-ml sterile, plastic snap-cap tubes, preweighed
Tissue homogenizer (e.g., PowerGen model 125, Fisher Scientific)
Scale
24-well plates
37°C, 5% CO_2 incubator
96-well multiwell plate
Dissecting microscope

Euthanize and prepare animal

1. Assemble an asphyxiation chamber by placing dry ice at the bottom of a 2-liter beaker, and covering with a Styrofoam insert constructed from packing material. Cover the beaker with Parafilm until enough gas is generated such that the Parafilm begins to bulge outward.

   This primitive CO_2 generation chamber is convenient because it can be sterilized after use, is portable, and can be placed within the biosafety cabinet.

2. Place the mouse to be sacrificed onto the Styrofoam platform and recover the beaker.

   The mouse will lose consciousness within ~2 min.

3. Place the unresponsive animal in a supine position, wet the fur over the thorax with 70% ethanol, open the skin, and remove the chest plate. Remove the lungs, which are salmon pink in color.

   If the trachea is to be collected, the neck, in addition to the chest, must be opened. The trachea with its distinctive cartilaginous rings sits just below the esophagus, which can be peeled off and discarded.

   CAUTION: *To avoid contamination of samples, clean and disinfect dissecting tools between animals. The chemical sterilization method outlined in Support Protocol 1 can be used in the biosafety cabinet.*

   Lung tissue (and adjacent lymph nodes if desired) harvested in this manner can be used for many purposes, but must be processed or frozen quickly to maintain its integrity.

   For determination of virus titers or cytokine levels, lungs should be placed in a sterile, plastic snap-cap tube (without liquid) and frozen immediately on dry ice. These samples can later be transferred to a −80°C freezer for storage.

4. Place the tissue sample (lung, etc.) in a tared 5-ml plastic snap-cap tube.

Homogenize tissue

5. Reweigh the tared tubes containing samples to determine the tissue mass so that titers can be expressed in terms of pfu/g of tissue.

6. Add carefully measured dcDMEM (~5 to 10 ml/g tissue), and homogenize each sample in tube at full speed for 30 sec until tissue is completely macerated. Sterilize the homogenizer between samples by chemical sterilization (see Support Protocol 1).

7. Centrifuge 5 min at 2000 × *g*, 4°C, to clarify. Carefully remove the clear supernatant to a new 5-ml tube, avoiding pellet and flocculent material at the bottom of the tube, and any insoluble fatty material floating on top.

It is important that samples do not undergo repeated freeze-thaw cycles before virus titers are determined. Homogenize samples the day they are collected, then freeze (−80°) for assay at a later time, or freeze the samples as they are being collected and prepare homogenates at a later time and set up the plaque assay on the same day. Viruses differ with respect to their ability to tolerate freezing, some pathogens may lose as much as a log of infectivity with each freeze-thaw cycle.

Perform plaque assay

8. Prepare a ~5×10^5 susceptible cells/ml suspension in DMEM, 10 mM HEPES, and 5% fetal calf serum.
9. Plate 0.4 ml into each well of a 24-well plate.
10. Allow cells to adhere and spread 2 to 16 hr in a 37°C, 5% CO_2 incubator.

    Monolayers should be >80% confluent; sensitivity to virus infection declines as the monolayer ages.

11. Prepare serial dilutions of virus samples in a 96-well multiwell plate. Prefill the appropriate number of wells with 180 µl HEBSA. Dilute 20 µl homogenate or BAL (see Basic Protocol 3) into the first well and mix well. Transfer 20 µl from that well into the next well, etc.

    It is important that the dilution series be carried out as accurately as possible, since systematic errors will be amplified exponentially. For this reason, care must be taken to avoid bubbles, and pipet tips changed between transfers. Ensure that the pipet tips do not carry any extra liquid as drops cling to the outside of the tip. HEBSA should be at room temperature, since a temperature differential between pipet tip and medium introduces systematic inaccuracy. A multichannel pipettor can be used, but the aforementioned cautions must be observed with respect to each of the pipet tips at each step.

12. Aspirate the medium from each well of the 24-well plate, and replace it with 100 µl/well serially diluted lung homogenate.
13. Incubate plate 2 hr in a 37°C, 5% CO_2 humidified incubator, keeping the liquid distributed over the monolayer by periodic (at least every 15 min) shaking of the plate.
14. Aspirate the inoculum and replace it with 0.4 ml/well of the overlay solution.

    In all steps, it is important to prevent the monolayers from drying out—aspirate with a minimum of suction, avoid exposing the cells to rushing air, and remove/replace medium from no more than a few wells at a time.

15. Incubate 5 days in a 37°C, 5% CO_2 incubator.
16. Aspirate medium, replace with fix/stain (~0.5 ml/well), and incubate 30 min at room temperature. Rinse plate briefly by immersion in cold tap water.
17. Count plaques with a dissecting microscope.

Make calculation of concentration of infectivity

18. Estimate the concentration of infectivity (commonly, but not quite correctly, referred to as "titer") as follows:

$$\text{titer} = (\text{no. of plaques/well/volume of inoculum/well}) \times \text{dilution}$$

    For example, if the well inoculated from the 4th well in the dilution series above shows 35 plaques, inoculum volume = 0.100 ml, and dilution = 10^4, then concentration of infectious virus = (35/0.100) × 10^4 = 3.5 × 10^6.

Estimate uncertainty

19. Estimate the standard error as the ratio as the square root of the total number of plaques counted. The relative standard error (i.e., expressed as a fraction of the concentration) is therefore the inverse of the square root of the number of plaques counted.

    In the above example, the standard error is $(35)^{-1/2} = 16.9\%$.

    If duplicate wells had been inoculated, yielding 34 and 36 plaques, for example, the estimated concentration would be the same, but the error would be reduced to $(70)^{-1/2} = 12.0\%$.

ALTERNATE PROTOCOL 2

DETERMINING VIRUS TITER: FLUORESCENT FOCUS ASSAY

Many viruses (e.g., influenza virus, parainfluenza virus 5, Newcastle disease virus) do not produce visible plaques. Estimation of the infectivity of such viruses can be done by following the procedure given in Basic Protocol 2 with the additional staining of the infected monolayers with fluorescent or enzymatically tagged antibodies. The procedure for immunofluorescent detection is outlined here. The procedure for enzyme-linked antibodies is similar, but details vary with the specific enzyme used.

***Additional Materials** (also see Basic Protocol 2)*

Virus-infected cells (see Basic Protocol 2, step 10)
PBSTA (see recipe)
Primary antibody against viral antigen (e.g., rabbit anti-influenza)
Fluorophore-tagged secondary antibody (e.g., FITC-goat anti-rabbit IgG)
PBS (see recipe)
Inverted fluorescent microscope

1. After the infection has been allowed to progress, fix the monolayer as for plaque assay, except use 0.5 ml/well fixative without dye for 30 min at room temperature.

   Often 24 hr of infection will suffice for fluorescent staining, since infection of a single cell is detectable, eliminating the need to allow time for spread to adjacent cells.

2. After fixation, wash wells two times with PBSTA by pipetting 300 µl PBSTA and then aspirating it.

   The detergent in this solution permeabilizes the cells, exposing intracellular antigens to recognition by antibody.

3. Dilute primary antibody against the virus in PBSTA. Add a sufficient volume of diluted antibody to cover the monolayer (~0.15 ml/well of a 24-well plate) and incubate at least 30 min at room temperature.

   Optimal dilutions are determined empirically as the dilution giving an optimal foreground/background ratio; typically in the range of 200 to 2000 fold.

4. Remove the primary antibody, wash wells two times with PBSTA (as in step 2).

5. Add the secondary antibody tagged with fluorophore diluted in PBSTA, and incubate 1 hr at room temperature in the dark.

   Exposure to light should be minimized for fluorescently tagged antibodies.

   If an enzyme-conjugated secondary antibody is used, after the incubation, wash and develop with the appropriate visualization substrate.

6. Remove the secondary antibody, and replace it with PBS.

7. Count fluorescent foci using an inverted fluorescent microscope.

8. Estimate the concentration of infectivity as in the plaque assay, but report as fluorescent focus forming units/ml (ffu/ml).

CHEMICAL STERILIZATION

SUPPORT PROTOCOL 1

It is important to assure that biologically active organisms and molecules be reliably eliminated from all surfaces that will contact subsequent samples. In processing any significant number of samples, sterilization by autoclaving is impractical. This protocol describes how to clean an apparatus and destroy any trace residual biologically active protein, nucleic acid, or lipid.

Materials

0.1% (w/v) SDS/0.006 M sodium hypochlorite (commercial chlorine bleach diluted 1:100)
0.1% (w/v) SDS/0.001% (w/v) Coomassie blue
70% ethanol
Phosphate-buffered saline (PBS; see recipe), sterile

Homogenizer
Sterile 50-ml tissue culture tubes

1. Run the homogenizer with the following solutions. Run two cycles (30 sec each) with 0.1% SDS/0.006 M sodium hypochlorite solution, making sure that any visible tissue residue has been removed. Take care that the liquid covers all surfaces that will potentially contact subsequent samples.

   For stainless steel homogenizers, prolonged contact with hypochlorite will be corrosive. However, at the specified dilution, followed immediately by the rest of the cleaning cycle, corrosion is not significant.

2. Run one cycle with 0.1% SDS/0.001% Coomassie blue.

   The dye is included as a sensitive indicator for residual hypochlorite; if the dye is bleached, this cycle should be repeated.

3. Run two cycles with 70% ethanol to remove residual SDS.

   The dye serves as a visible proxy for the detergent; make sure all traces of dye have been eliminated.

4. Rinse with sterile PBS to remove any residual ethanol, which may damage the next sample. After the last sample, omit the PBS wash to avoid salt precipitation during storage of the apparatus.

LEUKOCYTE ISOLATION

BASIC PROTOCOL 3

This protocol outlines the procedures for sampling and processing mouse tissues to obtain single-cell suspensions that can be used for flow cytometry or other assays (ELISpots, migration assays, proliferation assays, and purification of cell subsets). The method used to process the organs differs depending on the cell population of interest. For the analysis of T cell lymphocytes, the authors use mechanical digestion, which is quick and convenient. For the analysis of dendritic cells, collagenase digestion is recommended. This procedure is necessary to separate dendritic cells from the extracellular matrix, and is followed by a short incubation in an EDTA solution, which helps to disrupt multicellular complexes.

Materials

Mice
Avertin solution (see Support Protocol 5)
70% ethanol
HBSS/heparin: one vial heparin (Sigma) to 50 ml HBSS
HBSS without $MgCl_2$, $MgSO_4$, or $CaCl_2$ (Cellgro)
5 mg/ml collagenase A in MEM (see recipe)
Gey's solution (see recipe)

Trypan blue (MP Biomedicals)
80% Percoll (see recipe)
Assorted 1-ml syringes and needles (BD)
15- and 50-ml centrifuge tubes (BD)
Forceps, scissors
Terumo Surflo i.v. catheter 186 × 1¼–in.
70-μm cell strainers (BD Falcon)
Tissue culture dishes (100-mm; Falcon)
37°C water bath
Centrifuge (e.g., Sorvall Legend RT)
Hemacytometer (Hausser Scientific)
Microscope (e.g., Zeiss Axiostar plus)

Dissect mouse

1. Anesthetize mouse with Avertin solution (25 mg/kg i.p.).
2. Wet animal down using 70% ethanol. Place mouse in dorsal recumbency on two to three layers of paper towels.
3. Bleed the mouse and collect blood in a 15-ml tube containing 5 ml HBSS/heparin.

   Draw blood from the heart by sticking the 26-G needle of a 1-ml syringe into the apex of the left ventricle or by axillary bleed using a Pasteur pipet.

Perform bronchoalveolar lavage (BAL)

4. Perform BAL by using forceps to hold the skin of the neck and cutting along the neck from the chin to the thorax. Expose the trachea and make a small incision using sharp scissors or a needle with a beveled edge.
5. Insert only the plastic sleeve of an i.v. catheter into the trachea, and using a 1-ml syringe, flush lungs three times with 1 ml HBSS. Repeat two additional times using a total of 3 ml HBSS. Collect fluid in a 15-ml tube.

   Work slowly to avoid collapsing the lungs.

   If the BAL specimen is to be used for cytokine assays, use only 1 ml of lavage fluid to maximize the concentration of mediators present.

6. As a general rule, pool the lavage from the mice that belong to the same experimental group.

   Pooling lavage from the same group is done because of the limited number of lymphocytes found in the airways.

Collect organs

7. To harvest lung and draining lymph nodes, cut the skin of the mouse from the abdomen to the top of the thorax. Open the abdominal wall below the ribcage. Lift the sternum with tweezers and cut the diaphragm.
8. Then cut away the lower part of the ribcage to expose the heart and lungs. Using fine tweezers, harvest the lymph nodes and place in a labeled 15-ml tube containing 5 ml HBSS.

   The mediastinal lymph nodes are located ventral to the trachea at the level of the thymus. The bronchial lymph nodes are situated at the bifurcation of the trachea.

9. Next, harvest the lung and place in a labeled 15-ml tube containing 5 ml HBSS.
10. Harvest spleen, which lies adjacent to the greater curvature of the stomach, and place it in a labeled tube containing 5 ml HBSS.

Prepare single-cell suspensions

11a. *For analyzing lymphocytes:* Mechanically disrupt the tissues—spleen, lymph nodes, and lung—by pressing them gently through a cell strainer with a syringe plunger to achieve a single-cell suspension. Rinse the strainer repeatedly with HBSS to recover as many lymphocytes as possible. Transfer the sample to a 15-ml conical tube.

11b. *For analyzing dendritic cells:* Perform enzymatic digestion of the organ(s) by mincing the organ(s) in a solution of 5 mg/ml collagenase A in MEM in a small tissue culture dish. Incubate 30 min at 37°C (see Support Protocol 3). Transfer the sample to a 15-ml conical tube.

The BAL samples do not need processing. All the samples are transferred to 15-ml conical tubes if they are not already in one.

12. Centrifuge all single cell suspensions 10 min at 375 × *g*, 8°C.

13. Remove the supernatant from the cell pellet via aspiration. Flick the cell pellets to break up cell clumps.

Lyse erythrocytes

14. Add 3 ml Gey's solution to the spleen and lung cells, 1 ml to the lymph nodes and BAL samples, and 10 ml to the peripheral blood cells. Mix gently.

15. Incubate 3 to 5 min in a 37°C water bath.

16. Top off tubes with cold HBSS to achieve a final volume of 10 ml. Centrifuge 10 min at 375 × *g*, 8°C.

17. Discard the supernatants, disrupt cell pellets by flicking tube with fingers, and resuspend cells in HBSS. Further purify lung cells using a gradient; resuspend lung cells in 1.0 ml of 80% Percoll (see Support Protocol 2).

A volume of 5 ml for spleen and 1 ml for lymph nodes and BAL is used.

Count cells

18. While the lung cells are spinning, count viable cells in the rest of the samples using a hemacytometer and trypan blue exclusion (*UNIT 1.1*) or using an automatic cell counter. Count lung cells when the gradient is done.

Samples with low cell numbers such as BAL and lymph nodes must be counted using the hemacytometer. This is a tedious and time-consuming process, but it is essential in order to calculate absolute numbers of cells in each tissue using the frequencies obtained after flow cytometry analysis.

PERCOLL GRADIENT FOR LUNG TISSUE

SUPPORT PROTOCOL 2

Percoll solutions cannot be filtered, so be extra careful and keep sterile. The authors use the same gradient to process liver cells.

Materials

Percoll (GE Health Care) solutions (see recipe)
HBSS without $MgCl_2$, $MgSO_4$, or $CaCl_2$ (Cellgro)

Vortexer
Centrifuge
Pasteur pipets
50-ml conical tubes

1. Allow Percoll solutions to warm to room temperature.
2. Resuspend the lung cells in 2 ml of 80% isotonic Percoll. Vortex 3 sec.
3. Carefully layer 2 ml of 40% isotonic Percoll on top and centrifuge 25 min at 600 × *g*, 20°C.
4. Transfer cells from the 80%/40% Percoll interface using a Pasteur pipet and place into a 50-ml conical tube filled with HBSS without $MgCl_2$, $MgSO_4$, or $CaCl_2$.
5. Centrifuge all single-cell suspensions 10 min at 375 × *g*, 8°C.
6. Resuspend in 1 ml HBSS without $MgCl_2$, $MgSO_4$, or $CaCl_2$ and count viable cells (*UNIT 1.1*).

SUPPORT PROTOCOL 3

COLLAGENASE DIGESTION

Collagenase A digestion is used to disrupt the structure of organs (such as spleen and lung) to prepare single-cell suspensions.

Materials

Organ (spleen or lung)
Collagenase A solution (see recipe)
HBSS
HBSS/2 mM EDTA solution (see recipe)
Percoll

Tissue culture dishes (60-mm)
1- and 3-ml syringes
Razor blades
37°C tissue culture incubator
50-ml tubes
Cell strainer (70-μm)
Cell scraper
Centrifuge

Disrupt organ structure

1. Place organ (spleen, lung) in a small tissue culture dish with 5 ml collagenase A solution.

   If lymph nodes need to be digested, transfer organs to a 5-ml FACS tube with 200 μl collagenase A solution, smash it up with a 1-ml syringe plunger, and incubate as indicated in step 5.

2. Inject the organs with 1 ml collagenase A using a 1-ml syringe with a 26-G needle attached.
3. Mince the organs with a razor blade.
4. Pass the tissue through a 3-ml syringe to break it up.
5. Incubate the tissues for 30 min in a 37°C tissue culture incubator. Pass the tissues through the 3-ml syringe every 5 to 10 min.

Prepare single-cell suspension

6. Transfer the cells to a 50-ml tube through a 70-μm cell strainer. Use HBSS and a cell scraper to recover cells attached to the plastic.
7. Centrifuge 10 min at 375 × *g*, 8°C.

8. Resuspend the pellets in 10 ml HBSS/2 mM EDTA. Incubate 10 min at room temperature.
9. Centrifuge 10 min at 375 × *g*, 8°C.
10. Resuspend pellet in HBSS or Percoll solution as needed and follow the tissue processing protocols.

FLOW CYTOMETRY STAINING AND ANALYSIS OF ANTIGEN-SPECIFIC CD8 T CELL LYMPHOCYTES IN LUNG

BASIC PROTOCOL 4

This protocol describes staining of tissue lymphocytes to analyze antigen-specific CD8 T cells using flow cytometry. CD8 T cell responses are key for the control of viral infections (Doherty and Christensen, 2000; Wong and Pamer, 2003). The T cell receptor (TCR) on the surface of CD8 T cells recognizes peptides derived from viral antigens complexed with major histocompatibility complex (MHC) class I molecules on the surface of infected cells. CD8 T cells express a broad range of effector mechanisms that mediate resistance to infection, such as (1) direct cytolysis of target cells mediated by perforin, granzymes, and Fas; (2) secretion of cytokines such as TNFα and IFN-γ; and (3) secretion of chemokines that attract inflammatory cells at sites of infection. A prominent characteristic of respiratory virus infections, such as those mediated by influenza or respiratory syncytial virus, is that viral replication is limited to the lung epithelium. Thus, for viral clearance, the immune system must specifically target the mucosal surfaces of the respiratory tract. To accomplish this, antigen presenting cells migrate to the draining lymph nodes where they initiate a program of T cell proliferation and differentiation (Vermaelen et al., 2001; Legge and Braciale, 2003). Newly generated effector T cells return to the respiratory tract, complete their differentiation process, and terminate the infection (Cerwenka et al., 1999; Lawrence and Braciale, 2004). The effector CD8 T cells and memory cells that remain in the lung, once infection is cleared, are functionally different from their counterparts in lymphoid tissues (Hikono et al., 2006).

Fluorescence-activated flow cytometry is one of the most broadly used technologies in cell biology, immunology, hematology, and oncology. It allows the simultaneous and rapid analysis of multiple parameters of each cell in a suspension. This technology provides the means to define and analyze specialized subpopulations of cells that may carry out distinct functions. In addition, the availability of MHC class I–tetrameric reagents (Altman et al., 1996), which can label epitope-specific CD8 T cells, allows for the analysis of antigen-specific T cells at the single-cell level. Immunologists now routinely use "tetramers" to track and analyze T cell responses with a level of detail that was unimaginable 15 years ago.

Materials

Single-cell suspension from lung, spleen, or lymph nodes (see Basic Protocol 3 or Support Protocol 3)
Antibodies: Fc-Block (anti-mouse CD16/CD32 Fc II/III), anti-CD8α (FITC, Alexa 700, APC), anti-KLRG1 FITC (eBiosciences or BD Biosciences)
Staining wash buffer (SWB; see recipe)
Tetrameric reagent: γHV68 ORF6$_{487\text{-}495}$ /K^b APC (NIH Tetramer Core Laboratory)
10% (w/v) paraformaldehyde (see recipe)

96-well round-bottom plates
Centrifuge with plate rotor
1.1-ml microtubes (National Scientific Supply Co.)
Flow cytometer (e.g., FlowJo, TreeStar)

Prepare cells

1. Add 10^6 cells/well to a 96-well, round-bottom plate from the single-cell suspension derived from lung, spleen, or lymph node (see Basic Protocol 3 or Support Protocol 3). Set up as many single-color control wells as there are fluorochromes in the staining panel, and also a negative control well (use spleen cells for the control wells).

   For the authors staining panel, four control wells are necessary.

2. Centrifuge the plate 3 min at 450 × *g*, 8°C. Flick and gently vortex the plate.

Block cells

3. Add 50 µl Fc-Block diluted 1:200 in SWB to each well and incubate 10 min on ice.
4. Add 150 µl of SWB to each well.
5. Centrifuge plate 3 min at 450 × *g*, 8°C. Flick and gently vortex the plate.

Expose cells to tetramer

6. Add 50 µl/well of the appropriate dilution of the tetramer, which has been diluted in SWB. Mix by pipetting up and down (never vortex a tetramer).
7. Incubate 1 hr at room temperature in the dark.
8. Add 150 µl of SWB to each well.
9. Centrifuge plate 3 min at 450 × *g*, 8°C. Flick and gently vortex the plate.

Expose cells to antibody

10. Add 50 µl/well of the appropriate dilution of antibodies (anti-CD8α Alexa 700, anti-KLRG1 FITC) in SWB to the experimental samples. Add control antibodies as follows:

    a. Negative control: SWB alone
    b. FITC control: anti-CD8α FITC
    c. APC control: anti-CD8α APC
    d. Alexa 700 control: anti-CD8α Alexa 700.

11. Incubate 20 min on ice in the dark.
12. Add 150 µl/well of SWB to each well.
13. Centrifuge plate 3 min at 450 × *g*, 8°C. Flick and gently vortex the plate.

Wash cells

14. Add 200 µl/well of SWB to each well.
15. Centrifuge plate 3 min at 450 × *g*, 8°C.
16. While the plate is spinning, add 20 µl of 10% paraformaldehyde to the appropriate number of 1.1-ml microtubes.
17. Flick plate and vortex gently.

Fix cells

18. Add 180 µl/well of SWB to each well, pipet up and down to resuspend the cells, and transfer them into the 1.1-ml microtubes containing 20 µl of 10% paraformaldehyde solution.

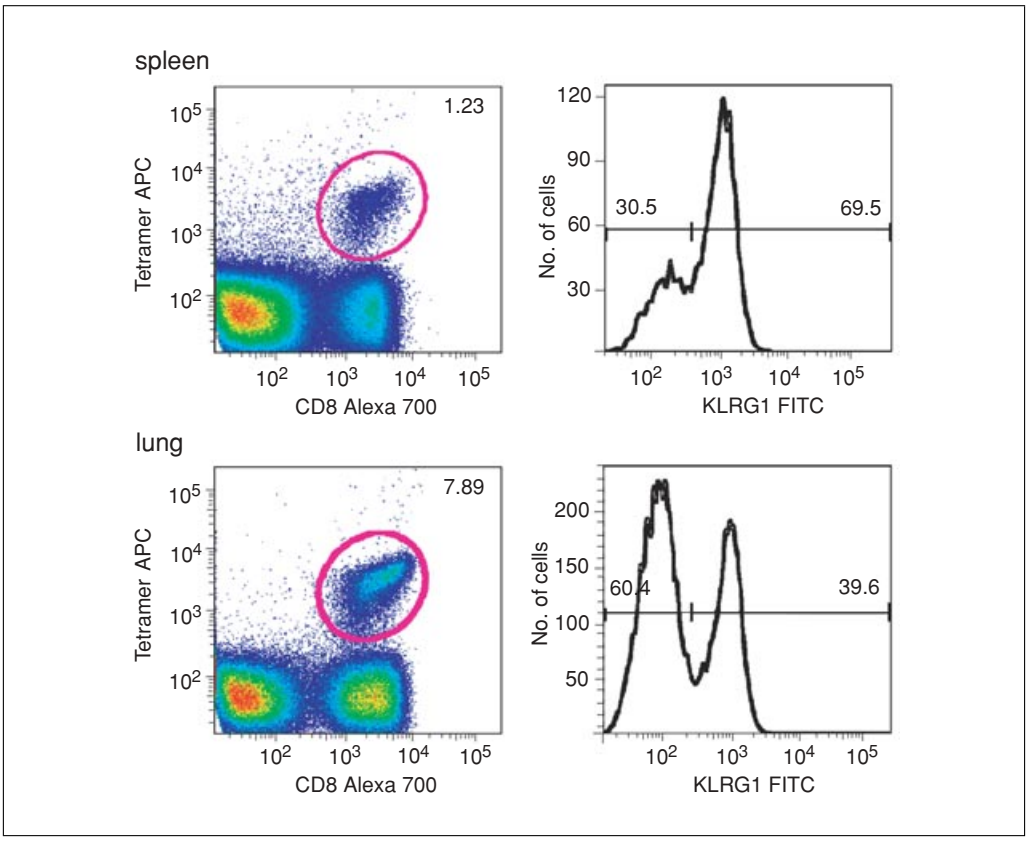

Figure 26.3.1 Flow cytometry staining of spleen and lung cells from a γHV68-infected mouse on day 16. Antigen-specific CD8 T cells are gated using the tetrameric reagent ORF6$_{487\text{-}495}$/K^b to show the expression profile of KLRG1. KLRG1 is a killer inhibitory receptor that is used to define terminally differentiated short-lived effector T cells. For color version of this figure go to *http://www.currentprotocols.com*.

Analyze cells

19. Keep the tubes on ice or at 4°C (no more than 2 to 3 days) and in the dark until running on a flow cytometer.

20. Analyze data on FlowJo (TreeStar).

The flow cytometry analysis in Figure 26.3.1 shows antigen-specific CD8 T cells gated using the tetrameric reagent ORF6$_{487\text{-}495}$/K^b, a murine γ-herpesvirus 68 (γHV68) peptide recognized by CD8 T cells when complexed with the MHC class I allele K^b. This gate is used to plot histograms showing the expression profile of KLRG1 (killer lectin receptor G1). KLRG1 is a killer inhibitory receptor that is used to define terminally differentiated short-lived effector T cells (SLECs). As observed, the distribution of SLECs is different in lung and spleen: the majority of SLECs concentrate in spleen because by day 14 after γHV68 infection acute respiratory infection has been cleared and the virus infection is at the peak of latency phase establishment in the spleen in B cells, macrophages, and dendritic cells (Flano et al., 2000).

FLOW CYTOMETRY STAINING AND ANALYSIS OF DENDRITIC CELLS IN LUNG

ALTERNATE PROTOCOL 3

Dendritic cells are professional antigen presenting cells essential for the generation of adaptive immune responses. Dendritic cells develop from bone marrow–derived precursors and are recruited from blood circulation to peripheral organs, where they continuously sample their environment for foreign substances. Dendritic cells are found through the airways forming a network through the epithelium and also constitute a small fraction of the cells in the BAL (Vermaelen and Pauwels, 2005). They are able to take up and

process antigens and migrate to the draining lymph nodes where they contribute to the initiation of adaptive immune responses. Pulmonary dendritic cells are key regulators of the local immune response to airborne pathogens, antigens, and allergens (Holt et al., 2008).

In mice, the dendritic cells in the respiratory tract express high levels of MHC class II and CD11c (Wikstrom and Stumbles, 2007). They can be distinguished from the lung macrophages because dendritic cells are less autofluorescent and express higher levels of class II molecules on their cell surface (Jakubzick et al., 2006). As their secondary lymphoid organ counterparts, respiratory dendritic cells can be divided into two main subsets: conventional dendritic cells ($CD11c^+B220^-$) and a very small fraction of plasmacytoid dendritic cells ($CD11c^+B220^+$; Weslow-Schmidt et al., 2007). Conventional respiratory dendritic cells can be further divided into two subsets on the basis of CD11b expression, with the predominant subset expressing high levels of CD11b. None of these subsets has been characterized extensively, but there is some evidence to suggest that they are functionally and phenotypically distinct (Julia et al., 2002; Belz et al., 2004; von Garnier et al., 2005). Other dendritic cell markers such as CD103, CD205, or CD8α can also be used to further define these populations.

Figure 26.3.2 presents a comparison between dendritic cells from spleen and lung stained with the same panel of fluorochrome-conjugated antibodies. The staining

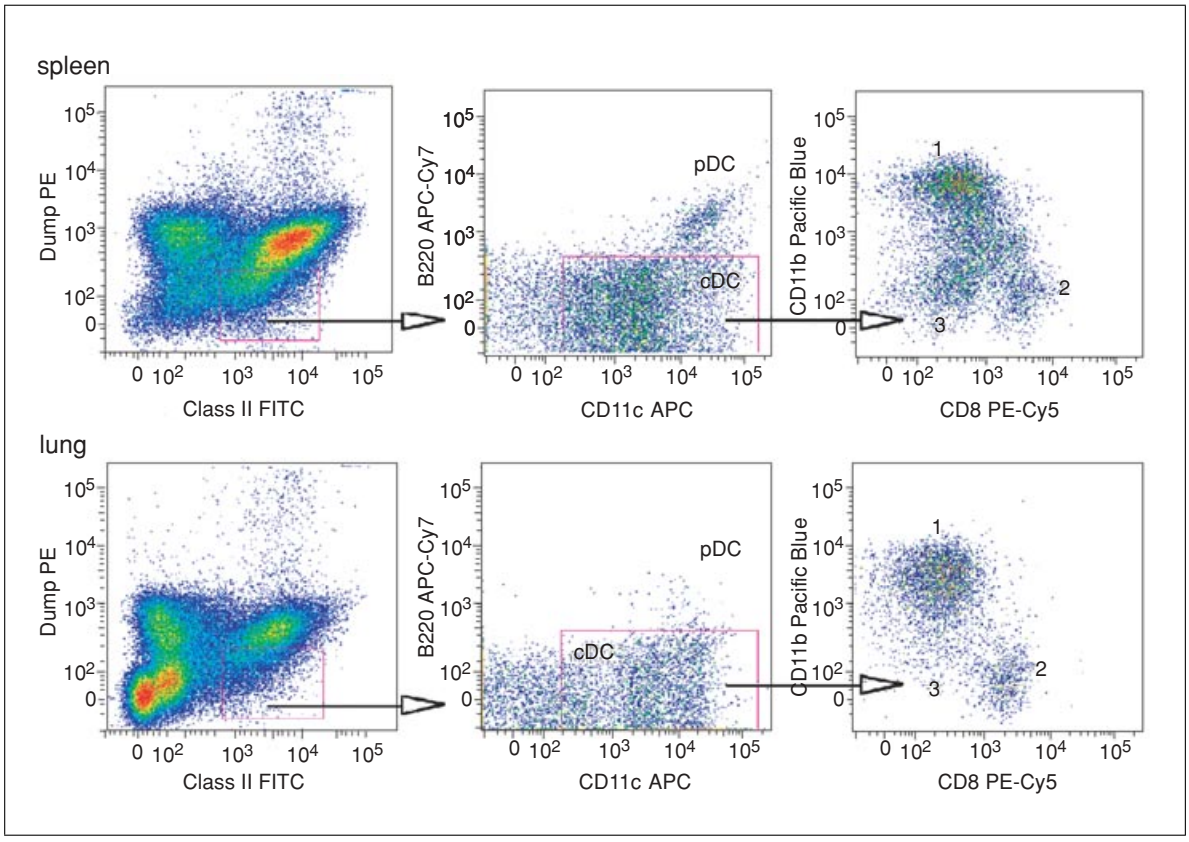

Figure 26.3.2 Analysis of dendritic cell subpopulations in lung and spleen of a γHV68-infected mouse on day 7. Lineage-positive cells are gated out using a dump channel (CD3, CD19, and NK1.1). Conventional dendritic cells (cDC) are defined as class $II^+CD11c^+B220^-$ and further divided into subsets: $CD11b^+$ (population 1), $CD8a^+$ (population 2), and $CD11b^-CD8a^-$ (population 3). Plasmacytoid dendritic cells (pDC) are class $II^+CD11c^+B220^+$. For color version of this figure go to *http://www.currentprotocols.com*.

procedure is performed as described in Basic Protocol 4, eliminating steps 6 to 9, which are specific for tetramer staining. As dendritic cells are a minor fraction of the total cells, the authors' staining panel uses a dump channel with a mixture of antibodies (CD3, CD19, and NK1.1) to gate out lineage-positive cells (T cells, B cells, and natural killer cells, respectively). The level of class II expression helps to differentiate dendritic cells from pulmonary macrophages. Then, conventional dendritic cells ($CD11c^+$) are plotted against plasmacytoid dendritic cells (B220) and further analyzed using expression of CD11b versus CD8α. CD11b expression defines a subpopulation formerly known as "myeloid" dendritic cells, and CD8α is expressed on "lymphoid" dendritic cells. The distribution of the subpopulations of dendritic cells is different between lung and spleen.

The following is the respiratory dendritic cell staining antibody panel: MHC class-II-FITC; CD3-PE, CD19-PE, NK1.1-PE; CD8α-PE-Cy5; CD11c-APC; B220-APC-Cy7; and CD11b-Pacific Blue.

HISTOLOGY

BASIC PROTOCOL 5

Examination of infected tissues under the microscope allows the investigator to assess many aspects of inflammation and disease that cannot be discerned from tissue homogenates. Standard hematoxylin and eosin (H&E)–stained sections provide information about trafficking and localization of inflammatory cells, as well as the extent of necrosis/apoptosis.

Materials

Mice
10% (v/v) buffered formalin (Fisher Scientific)

Tissue cassettes (Fisher Scientific)
No. 2 pencil
Histology laboratory

Additional reagents and equipment for removing lungs (see Basic Protocol 2)

1. Open the thorax and remove the lungs from a CO_2-anesthetized mouse as described in Basic Protocol 2.
2. Fix the lungs with 10% buffered formalin. Inflate the lung with formalin by gently injecting the lung tissue with a syringe and small-gauge needle until tissue is filled, but not taut, and place the inflated lungs or lung lobes into appropriately labeled tissue cassettes. Be sure to label the cassettes with a pencil as many inks or "permanent" markers will wash off during processing.

   The buffered formalin volume should be more than ten times the volume of the harvested tissues in a closed container.

   Good lung histology requires that the lung tissue be inflated with formalin at the time of fixation.

3. Fix tissue for at least 4 hr, but not more than 72 hr, before it is processed by the histology laboratory.

   The processor usually runs overnight, and the next day the histotechnologist will embed the tissue contained in each cassette within a paraffin block. If the tissue orientation is not correct, the block can be melted and the tissue re-embedded at a later time.

   Extended formalin fixation will inhibit binding of both antibodies and nucleic acid probes to tissue sections. Once fixed tissue is processed and embedded in paraffin, it is stable for many years at room temperature.

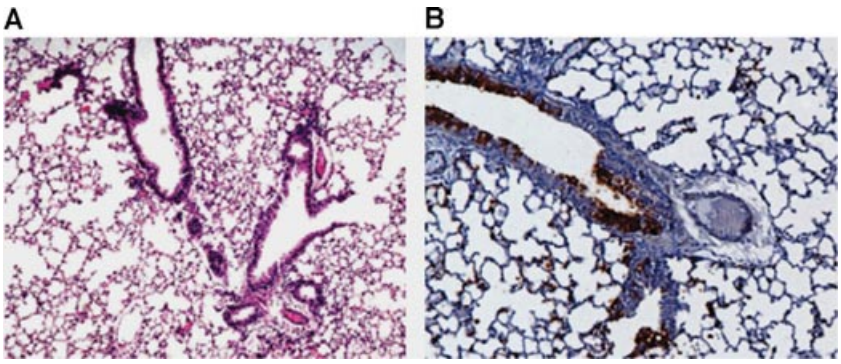

Figure 26.3.3 Much information can be gained from examining the histology of infected lungs. **A** is a standard H&E stained section photographed at low power (50×). The large conducting airways branching into the smaller bronchioles and finally alveolar spaces can be clearly seen. This animal was infected 24 hr previously with a high dose (10^6 pfu) of influenza A virus, but no evidence of pathology is appreciable at this early time point. (**B**) A higher magnification image (100×) shows that, despite the lack of inflammatory cells at this early time point, many airway lining cells (shown as red) already show evidence of infection. The slide shown in B was stained using polyclonal rabbit serum raised against whole virus, and the method described in Basic Protocol 6. This level of staining was obtained without antigen retrieval. For color version of this figure go to *http://www.currentprotocols.com*.

4. Order H&E-stained paraffin sections from the histology laboratory. Request additional sections for immunohistochemistry (IHC) or in situ hybridization (ISH) at the same time, but specify the purpose of these additional sections so that the appropriate glass slides can be used.

   Slides for IHC or ISH are coated with a polyanion such as poly-L-lysine to increase tissue adherence.

   It is best to rely on the histology laboratory for the standard H&E stain as it requires many solutions that must be renewed often.

   An example of an H&E stained lung section is shown in the left-hand panel of Figure 26.3.3 and demonstrates the anatomy of the lung infected 24 hr earlier with influenza A virus. At this low magnification (photomicrograph is taken through a 5× objective), the anatomy of the lung can be clearly seen with large airways branching into smaller airways, and finally opening into the alveolar ducts and space. Very little inflammation can be appreciated at this time point.

BASIC PROTOCOL 6

BAL CYTOLOGY

Characterization of the different types of inflammatory cells within the airspaces of the lung may be necessary, and this can be done by using a portion of the BAL fluid, obtained as described in Basic Protocol 3, to make cytospins.

Materials

BAL fluid (see Basic Protocol 3)
Acetone (Fisher Scientific), cold
TBS (see recipe)

Hemacytometer
Microscope
Cytoslides (Thermo Scientific)
Disposable cytofunnels (Thermo Scientific)
Cytocentrifuge (Thermo Scientific)

1. Determine cell concentration in each BAL sample using a hemacytometer. Adjust concentration such that no more than 10^4 cells are added to each slide. Make sure a sample volume of at least 150 µl is obtained before loading each sample.

   Interpretable data can also be obtained with fewer than 10^4 cells as only the edges are readable when the cell pellet is thick.

2. Attach cytoslides with a raised circle to contain the pelleted cells to the cytofunnels following the manufacturer's instructions, and load the 150-µl samples into individual funnels before they are inserted into the cytocentrifuge.

3. Centrifuge samples 6 min at 113 × *g*, room temperature.

4. For a differential cell count to determine the make up of the specimen (i.e., % lymphocytes, % eosinophils, % monocytes/macrophages), allow the slides to air dry for several hours and request a Wright-Giemsa stain from the pathology laboratory.

   This stain is done routinely to examine blood smears in a hospital setting and it is highly recommended to use a pathology laboratory given the limited sample size.

5. To use slides for immunohistochemistry (IHC), fix in cold acetone for 5 min, rinse in TBS for 5 min, and continue on to Basic Protocol 7, step 3 (IHC protocol).

IMMUNOHISTOCHEMISTRY

BASIC PROTOCOL 7

Immunohistochemistry (IHC) relies upon the availability of specific antibodies that can bind with high affinity to antigens in tissue sections. This technique involves incubating tissues with a primary, antigen-specific antibody, followed by a conjugated secondary antibody that will bind to the Fc region of the primary antibody. For example, when mouse IgG is used to stain human tissue, a biotinylated secondary antibody recognizing mouse IgG can be used to detect the bound primary antibody. Avidin bound to horseradish peroxidase will specifically bind to biotin, and when chromogen is added, it will be deposited at sites where primary antibody is bound.

Materials

4-µm tissue sections on Plus slides (Surgipath)
Xylenes
95% and 100% ethanol
3% (v/v) H_2O_2 (McKesson)
Superblock (Scytek)
TBS (see recipe)
Primary antibody (determined by investigator)
Primary antibody dilution buffer (Biomedia/Fisher Scientific) *or* TBS (see recipe) with 1% (w/v) BSA (fraction V, Fisher Scientific)
Biotinylated secondary antibody (determined by investigator)
Streptavidin-enzyme and substrate kits (Scytek or Dako)
Mayer's hematoxylin (Dako)
0.25% (v/v) ammonium hydroxide
Crystal/Mount (Biomedia)
Permaslip (Alban Scientific)

65°C oven
Coplin jars (Fisher Scientific)
Pap pen (Biocare Medical)
Humidified chamber
Coverslips

1. Incubate 4-µm sections on slides prepared by the histology laboratory in a 65°C oven for 1 hr prior to staining to improve tissue adherence.

2. Deparaffinize sections from conventional paraffin blocks and rehydrate before staining. Set up (in a chemical hood) a series of baths in Coplin jars, and incubate the slides as follows:

   a. Xylene: two times, 3 min each time
   b. Xylene: one time, 5 min
   c. 100% ethanol: three times, 2 min each time
   d. 95% ethanol: one time, 1 min
   e. Rinse in deionized water, 1 min.

3. Place slides in 3% H_2O_2 for 15 min to reduce background staining, and then rinse with deionized water for 2 min.

4. Circle tissue section to be stained with a pap pen so that the staining reactions can be carried out in a small volume, i.e., within the circle, while slides sit in a humidified chamber.

   Such chambers can be purchased, or made from a plastic container (e.g., Tupperware) containing moist paper towels and spacers to hold the slides away from the wet paper towel surface.

5. Incubate slides 5 min at room temperature with 100 to 200 µl Superblock, and then rinse with TBS for 1 min.

6. Incubate tissue sections with the appropriate dilution of primary antibody solution for 2 hr at room temperature or overnight at 4°C.

   The appropriate dilution of each primary antibody must be determined empirically and may vary from 1:50 to 1:5000.

7. Wash 10 min in TBS. Apply the biotinylated secondary antibody and incubate 10 to 20 min at room temperature. Following this incubation, wash a second time with TBS.

8. Stain using additional incubations, first with streptavidin-enzyme reagents, followed by substrate.

   Kits are available from a number of companies; the authors generally use the streptavidin/HRP system from Scytek, and follow the manufacturer's directions.

9. Rinse slides with TBS, then water. Counterstain in hematoxylin (15 sec to 1 min, depending on the batch of stain) followed by bluing (just a few dips) in 0.25% ammonium hydroxide. Wash with deionized water for 30 sec.

10. Once slides are dry, cover the tissue with one to two drops of Crystal/Mount, incubating at 65°C until dry. Use Permaslip to attach the cover slip.

    This protocol is the most flexible, allowing the use of many different sources of primary and secondary antibody. Nonetheless, a more sensitive methodology is being utilized where, rather than using a biotinylated secondary antibody and enzyme-conjugated avidin, an enzyme-linked polymer conjugated to a secondary antibody is used. The EnVision reagents from DAKO make use of this system, and although compatible reagents are not yet available for all primary antibodies, enhanced foreground and decreased background are routinely obtained with this technique.

SUPPORT PROTOCOL 4

MAXIMIZING SIGNAL: ANTIGEN RETREIVAL

This protocol describes a number of approaches to increasing the signal obtained with a particular primary antibody. As reagents are often limited when working with rodent models, it is often necessary to optimize results obtained with the antibodies available. For a detailed discussion of options available, consult a manual devoted to the subject (Renshaw, 2007).

If a primary antibody gives a poor signal using the standard IHC protocol outlined in Basic Protocol 7, antigen retrieval using a pressure cooker to heat the tissue sections may increase the foreground.

Materials

4-μm section slides
0.5 M Tris·Cl, pH 10 (see recipe)
Pressure cooker (any)

Additional reagents and equipment for deparaffinizing slides (see Basic Protocol 7)

1. After the sections are deparaffinized, as in Basic Protocol 7, steps 1 and 2, place the slides in a Coplin jar filled with 0.5 M Tris·Cl, pH 10, and place the jar in a pressure cooker with sufficient boiling water to heat, but not leak into, the container. Heat for 3 to 15 min at a pressure of 15 to 17 psi.
2. Cool the pressure cooker by running under cool tap water for 10 min. Remove the Coplin jar and allow the contents to cool for 30 min at room temperature.
3. Wash the slides in TBS for 30 sec, then water, and proceed to Basic Protocol 7, step 3.

These conditions work for many antigens, but some will require less heat or more acidic conditions for optimal unmasking. Optimal conditions for a particular antigen must be determined empirically.

IHC USING FROZEN SECTIONS

ALTERNATE PROTOCOL 4

Sometimes it is possible to use monoclonal antibodies to stain frozen tissues even when they are unable to detect antigen in fixed tissue sections.

Materials

Mice
Tissue Tek Cryo-OCT embedding compound (Fisher Scientific)
Acetone (Fisher Scientific), cold
Desiccant
TBS (see recipe)

Terumo Surflo i.v. catheter 186 × $1^{1/4}$-in.
Cryostat
Cryostat chuck (obtained from cryostat manufacturer)
Plus slides (Surgipath)
Coplin jars (Fisher Scientific)

1. Inflate the lungs with warm (37°C) Cryo-OCT by cannulating the trachea as described for the BAL (see Basic Protocol 3), and instilling 0.5 ml OCT as gently as possible, then separating individual lung lobes for individual embedding.

When harvesting lung tissue for this purpose, it is still necessary to inflate the lung tissue as much as possible with a water-soluble embedding compound (e.g., Cryo-OCT), which is very thick and difficult to manipulate. The viscosity is temperature dependent, so heating an aliquot to 37°C before using to inflate the lungs is necessary.

2. Use a cryostat to freeze, embed, and section frozen tissues. Place a thin layer of OCT medium onto a cold cryostat chuck, and before it completely solidifies, quickly add a tissue section and cover it with additional OCT. Cut sections as soon as the medium is completely frozen, or store embedded samples in a sealed bag for months to years at −70°C.

3. Cut 4- to 7-μm frozen sections on the cryostat.

   Cutting sections may be difficult for the novice; therefore, seeking help from a histotechnologist is recommended.

4. Place sections on Plus slides, and allow to dry for 1 to 3 hr at room temperature. Fix in cold acetone for 5 min, and store with desiccant at −70°C if the slides are not stained immediately.

5. To stain slides, rinse in TBS for 5 min, and proceed with Basic Protocol 7, step 3.

BASIC PROTOCOL 8

IN SITU HYBRIDIZATION

This method describes the use of a non-radioactive RNA probe to detect mRNA in paraffin-embedded tissue sections. For this procedure, a probe that is labeled with digoxigenin (DIG) is needed. The authors use the DIG RNA labeling kit (Roche) to prepare the riboprobe and test its labeling efficiency. The following protocol takes 2 days to complete. For the first day, all reagents and containers must be RNase free. Either treat all solutions with DEPC or prepare the solutions with DEPC-treated water. DEPC-treated solutions are no longer necessary after the hybridization overnight at 42°C.

Materials

4-μm section slides
Diethylpyrocarbonate (DEPC)-treated water
PBS (see recipe)
100 mM glycine (Fisher Scientific)
Triton X-100 (Sigma)
5 μg/ml proteinase K (Sigma) in PBS
4% paraformaldehyde (Electron Microscopy Sciences; see recipe), 4°C
100 mM triethanolamine, pH 8
Acetic anhydride (Sigma)
Prehybridization buffer (see recipe)
Digoxigenin (DIG)-labeled riboprobe
Hybridization buffer (see recipe)
20× SSC (see recipe)
ISH buffers 1, 2, and 3 (see recipes)
Goat serum (Invitrogen)
Anti-DIG alkaline phosphatase Fab fragment (Roche)
NBT/BCIP tablets (Roche)
Fast green FCF (see recipe)
Crystal/Mount (Biomedia)

Pap pen (Biocare Medical)
37°C slide warmer
Coplin jars (Fisher Scientific)
Humidified chamber (e.g., Tupperware container)
37°, 42°, and 65°C incubator/hybridization oven
80°C heating block
37°C water bath
Shaking/orbital rocker at 37°C
15-ml conical tubes
Coverslips

Additional reagents and equipment for deparaffinizing slides (see Basic Protocol 7)

NOTE: All buffers and reagents should be prepared in DEPC-treated water.

Prepare slides

1. Deparaffinize and rehydrate 4-μm tissue sections as described in Basic Protocol 7, but using DEPC-treated water to prepare solutions and for rinsing slides.
2. Wash slides two times, 5 min each wash, in PBS.
3. Incubate slides two times, 5-min incubations, in 100 mM glycine.
4. Incubate slides in PBS containing 0.3% (v/v) Triton X-100 for 15 min.
5. Wash slides two times, 5 min each wash, in PBS.
6. Encircle tissue section using a Pap pen. Permeabilize with 5 μg/ml proteinase K in PBS for 30 min at 37°C, followed by two 5-min washes in PBS.

Post-fix sections

7. Post-fix tissue section in cold (4°C) 4% paraformaldehyde in PBS for 5 min, followed by two 5-min washes in PBS.

Acetylate sections

8. Acetylate tissue section with two 5-min incubations in fresh 100 mM triethanolamine, pH 8, containing 0.25% (w/v) acetic acid anhydride.

   Add the acetic anhydride to the TEA buffer just before use, and use a clean Coplin jar for the second incubation.

Prehybridize sections

9. Incubate sections in a Coplin jar with 50 ml prehybridization buffer in a humidified chamber for at least 10 min in a 37°C incubator/hybridization oven.
10. During prehybridization, add 60 ng of DIG-labeled riboprobe, prepared and tested according to manufacturer's instructions, to 100 μl of hybridization buffer. Denature riboprobe 10 min at 80°C then place on ice.

Hybridize samples

11. Blot off the prehybridization buffer from each slide by placing the end of the slide onto absorbent paper towels, and re-encircle the tissue section with the Pap pen.
12. Add the hybridization buffer with the DIG-labeled riboprobe to the encircled tissue. Incubate the slide in a humidified chamber overnight at 42°C.
13. Blot off the probe from each slide taking care not to disturb the tissue section.
14. Wash tissue sections in 2× SSC for 5 to 10 min at room temperature.
15. Wash tissue sections in 2× SSC for 15 min in a 37°C water bath.
16. Wash tissue sections in 1× SSC for 15 min in a 37°C water bath.
17. Wash tissue sections in 0.1× SSC for 30 min at 37°C with shaking.
18. Incubate slides with ISH buffer 1, two times, 10 min each time.

Visualize probe

19. Place slides flat in the humidified chamber, block with 100 μl of ISH buffer 1 containing 0.1% Triton X-100 and 2% goat serum for 30 min at room temperature.
20. Blot off blocking solution, and cover the tissue section with 100 μl of a 1:500 dilution of anti-DIG-alkaline phosphatase in ISH buffer 1 containing 0.1% Triton X-100 and goat. Incubate 2 hr at room temperature.

21. Wash two times in a Coplin jar filled with ISH buffer 1, 10 min each wash, followed by two 10-min incubations in ISH buffer 2.
22. During the 2nd incubation in ISH buffer 2, prepare the substrate solution by placing half of an NBT/BCIP tablet in 5 ml water in a 15-ml conical tube.
23. Place slides in the humidified chamber, and cover each tissue section with 200 µl of substrate solution. Incubate from 1 to 24 hr in the dark, monitoring the color development of positive controls to determine when the reaction should be stopped.
24. Stop the reaction by placing slides in a Coplin jar containing ISH buffer 3 for 5 min.

Counterstain slide

25. Dip slides briefly in water, counterstain tissue section in 0.02% fast green FCF for 1 min, and then wash in water for 5 min.
26. Blot the excess water from each slide, and add enough Crystal/Mount to cover the section. Dry at 65°C and then add a coverslip.

SUPPORT PROTOCOL 5

PREPARATION OF AVERTIN SOLUTION

Avertin (tribromoethanol 20 mg/ml) is a short-acting anesthetic that is not available commercially and must be prepared. Sterile preparation procedures are essential. If Avertin is improperly prepared or stored in the light or at room temperature, it will break down within 24 hr into dibromoacetic acid and hydrobromic acid, which are lethal. Freshly mixed solutions are strongly recommended for safe use. The solution can be kept as long as 4 months if stored in the dark at 4°C. Ensure that the solution has a pH of >5.

Materials

Tert-amyl-alcohol (Fisher)
2,2,2-Tribromoethanol (Sigma)

2-liter glass Erlenmeyer flask
Magnetic stirrer
Hot plate with stirrer
Aluminum foil
Bottle-top filter (0.22-µm; Millipore)
50-ml dark glass bottles

1. Working in a fume hood, add 10 ml tert-amyl-alcohol into a 2-liter glass Erlenmeyer flask.
2. Add 10 g of 2,2,2-tribromoethanol to the tert-amyl-alcohol. Stir 2 hr at room temperature until the solid goes into solution.
3. Transfer to a hot plate on low heat.
4. Very slowly add 250 ml distilled water to flask while stirring. Make sure that solutes stay in solution before adding more water.

   This process takes several hours.

5. Bring solution up to 500 ml with distilled water.
6. Turn off the hot plate when all of the solid has gone into solution. Cover flask with aluminum foil to protect from the light, and stir overnight.
7. Check that the 2,2,2-tribromoethanol has not precipitated overnight. If necessary, return the flask to the hot plate and stir again on low heat until the solid has gone back into solution.

8. Check pH.
9. Filter with 0.22-μm bottle-top filter.
10. Dispense into 50-ml glass bottles (darkened glass or foil-covered).
11. Store up to 4 months at 4°C in the dark.
12. Test solution on mice.

The effective dose in mice is on the order of 25 mg/kg (~200 to 250 μl/animal) but this will vary by strain with 129 mice being very susceptible and requiring a lower dose, and C57BL6 mice requiring a higher dose. The optimal dose is best determined empirically with each new batch of Avertin made and each mouse strain used.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Collagenase A, 5 mg/ml

Collagenase A (Roche)
Culture medium (MEM, Cellgro)
Filter sterilize through a 0.22-μm filter
Dispense into 5-ml aliquots
Store up to 1 year at −20°C

D5HS

DMEM buffered with 25 mM HEPES (Invitrogen cat. no. 12320) and supplemented with 5% fetal calf serum. Store up to 3 months at 4°C.

Decarbonated Dulbecco's modified Eagle medium (dcDMEM)

The standard formulation of DMEM is buffered with bicarbonate, and therefore becomes alkaline when exposed to ambient atmosphere. For this reason, the medium used for the extended manipulations called for in these protocols is not supplemented with bicarbonate (Invitrogen). Adjust pH to neutral with NaOH. Store up to 3 months at 4°C.

Fast green FCF, 0.02% (w/v)

0.01 g fast green FCF (Fluka)
50 ml ddH_2O
Vortex
Filter to remove particulate matter with 3-mm Whatman paper
Store up to 1 week at room temperature

Fixative/stain

0.003% (w/v) crystal violet
5% (v/v) formalin
50 mM sodium phosphate, pH 7.4 (*APPENDIX 2A*)
Store up to 3 months at room temperature

Gey's solution (buffered ammonium chloride)

24.9 g NH_4Cl
3 g $KHCO_3$
3 ml 0.5% (w/v) phenol red
ddH_2O to a final volume of 3 liters
Filter sterilize with a 0.22-μm filter
Store up to 1 year at 4°C

Hybridization buffer

40% (w/v) deionized formamide
10% (w/v) dextran sulfate
1× Denhardt's solution
4× SSC
10 mM DTT
1 mg/ml yeast tRNA
1 mg/ml denatured and sheared salmon sperm DNA
ddH_2O

Hybridization solution can be made up without salmon sperm DNA and stored at −20°C.

When making up the hybridization buffer, dissolve the dextran sulfate in the water and formamide before adding the other components.

ISH buffer 1

100 mM Tris·Cl, pH 7.5 (*APPENDIX 2A*)
150 mM NaCl
Store up to 1 year at room temperature

ISH buffer 2

100 mM Tris·Cl, pH 9.5 (*APPENDIX 2A*)
100 mM NaCl
50 mM $MgCl_2$
Store up to 1 year at room temperature

ISH buffer 3

10 mM Tris·Cl, pH 8.1 (*APPENDIX 2A*)
1 mM EDTA
Store up to 1 year at room temperature

Methylcellulose in MEM, 1% (w/v)

Place 5 g of methylcellulose (Sigma-Aldrich cat. no. M0512) in an autoclavable bottle. Add 435 ml distilled water, preheated to >70°C. Before it cools, sterilize by autoclaving. Cap tightly and keep the bottle shaking, e.g., by automatic rotator, as it cools for at least 60 min at room temperature. Transfer the bottle to an ice bath, and keep shaking it until the methylcellulose dissolves, forming a clear viscous solution. Add 50 ml of 10× MEM, and mix thoroughly. (It will take some time and effort, since the solution is very viscous.) Add 14 ml of sterile 7.5% sodium bicarbonate. Clear the solution of insoluble material by centrifuging 30 min at 3000 × *g*, room temperature. Store up to 3 months at 4°C.

IMPORTANT NOTE: *Methylcellulose will form intractable "clots" in cold water.*

The room temperature cooling is to lower the temperature to the point where immersion in ice will not crack the glass bottle. The shaking is to prevent the (still insoluble) methylcellulose from settling.

The solution should be orange to cherry-red in color. If the pH becomes too high (fuchsia colored), it can be adjusted by gassing the bottle with (sterile) CO_2.

Overlay medium

Mix equal volumes of growth medium (DMEM, 25 mM HEPES, 5% fetal calf serum plus antibiotics) and 1% methylcellulose in MEM (see recipe). Mix thoroughly by repeated pipetting, to eliminate pockets of low viscosity. Prepare fresh.

continued

Since the source of the virus—a live animal—cannot be "sterile", there is possibility of bacterial and fungal contamination. Antibacterial agents (e.g., penicillin/streptomycin) and antifungal agents (e.g., amphotericin B) may be added to prevent these from overgrowing the cultures.

Paraformaldehyde, 4% (pH 7)

To prepare 200 ml:
8 g paraformaldehyde (Electron Microscopy Sciences)
20 ml 10× PBS (see recipe)
Drops of 2 N NaOH
ddH_2O

Heat deionized, distilled water in glass beaker with stirrer on hot plate to 60°C in fume hood. Add paraformaldehyde powder and keep at 60°C. Add 2 drops of 2 N NaOH, and the solution should clear within a few minutes. Remove from heat and let cool to room temperature. Add 20 ml of 10× PBS and bring volume up to 200 ml with ddH_2O. Filter sterilize through a 0.22-μm filter and store up to 3 months at 4°C.

PBS, pH 7.4

140 mM NaCl
2.7 mM KCl
10 mM Na_2HPO_4
1.8 mM KH_2PO_4
Adjust pH to 7.4 with HCl
Store up to 1 year at room temperature

PBSTA

PBS (see recipe) with:
0.1% (v/v) Triton X-100
0.1% (w/v) bovine serum albumin
0.1% (w/v) sodium azide
Store up to 1 year at room temperature

Percoll solutions

100% (v/v) isotonic Percoll: 90 ml Percoll and 10 ml 10× HBSS
80% (v/v) isotonic Percoll: 80 ml of 100% isotonic Percoll and 20 ml HBSS
40% (v/v) isotonic Percoll: 40 ml of 100% isotonic Percoll and 60 ml HBSS
Store up to 1 year at 4°C

Prehybridization buffer

50% deionized formamide in 4× SSC (see recipe for SSC)
Store up to 1 year at 4°C

SSC, 20×

3 M NaCl
300 mM sodium citrate
Adjust pH to 7.4 with HCl
Store up to 1 year at room temperature

Staining wash buffer (SWB)

60 ml 10× PBS (see recipe)
6 ml 10% (w/v) sodium azide
12 ml newborn calf serum
522 ml ddH_2O
Store up to 1 year at 4°C

Tris·Cl, 0.5 M (pH 10)

60.57 g Tris base
900 ml ddH_2O
Adjust pH with 1 M NaOH
Make up to final volume of 1 liter with ddH_2O
Store up to 1 year at room temperature

TBS, pH 7.6

0.05 M Tris·Cl (see recipe)
0.15 M NaCl
Adjust pH to 7.6
Store up to 1 year at room temperature

COMMENTARY

Background Information

The study of virus infections in vivo requires the analysis of many parameters by a large number of different methods. Because a single unit cannot encompass all of these methods in detail, this unit focuses on providing the reader with protocols for harvesting the relevant samples. The recommended methods for detection of infectious virus, flow cytometry, and histology are given as examples of how the samples might be assayed. The assay techniques outlined here are relatively general, as the authors have chosen the most widely applicable techniques and reagents. It is up to the individual investigator to tailor these assays to meet their specific needs.

Critical Parameters

Measuring cytokines and chemokines

Although not explicitly described in this unit, cytokine assays can be carried out using either BAL specimens (see Basic Protocol 4) or lung homogenates. The same homogenate can be used to assay both virus titers and cytokines, although the authors have found that BAL samples generally have a lower background for cytokine measurement than do whole lung homogenates. ELISA assays are commercially available for many mouse cytokines and chemokines. A biological assay for IFN-α or -β activity is described in detail by Vogel et al. (1991), and this method can be used to assay lung BALs and homogenates, as well as serum samples.

Flow-cytometry

Successful flow cytometry analysis of a given cell population requires the knowledge and experience to calibrate the instrument, standardize procedures and settings, and to analyze the data with a software package. However, the most important requirements are a good single-cell suspension and a proven staining panel/protocol. The correct choice of reagents requires certain knowledge of the characteristics of each fluorochrome and of the antigens of interest. However, the basic approach described here can be used for multiple extracellular antigens, cell subpopulations, and tissues with minor modifications.

Histology

High quality H&E sections are best obtained from a pathology core or hospital laboratory, as production of formalin-fixed, paraffin-embedded tissue blocks and slides from these blocks require a major investment in equipment and training, which is not appropriate for most research laboratories. Nonetheless, if fixed tissue samples are submitted to the histotechnologist in tissue cassettes, taking care to explain the orientation needed for optimal slide interpretation, high quality H&E stained sections can easily be obtained. Additional sections for immunohistochemistry (IHC) or in situ hybridization (ISH) studies can also be prepared from these tissue blocks. IHC using virus-specific antibodies allows the investigator to visualize the extent of virus spread, and the cell type(s) targeted by a particular virus. This method can also be used to visualize the appearance of immune cell types in infected tissues over time, although this type of experiment may require the use of unfixed, frozen tissue sections. ISH is an alternative method if specific antibodies are not available, or the investigator wishes to determine the source of a secreted protein.

Immunohistochemistry

For human tissues, there are a large number of commercially available monoclonal antibodies that can serve this purpose, and

work well for staining formalin-fixed, paraffin-embedded tissue sections. Unfortunately, this is not the case for mouse tissues, as there is a relatively small demand for these reagents. Many monoclonal antibodies that work well for staining cell suspensions prior to FACS analysis will not work well for staining tissue sections. The manufacturer selling the antibody may specify this, but usually this must be determined empirically. In some cases, this can be overcome by using frozen sections rather than paraffin sections of fixed tissues; however, frozen tissues are difficult to cut and the resulting histology is often suboptimal. In addition to the problem of low foreground signal, most monoclonal antibodies are made in mice, and background staining results when the anti-mouse secondary antibody recognizes endogenous antibody bound to mouse tissues or B cells. "Mouse to mouse" blocking reagents are available from a number of companies, but do not always solve the background problems. The authors' best results in mouse tissue have been obtained using polyclonal antisera raised in a non-mouse species such as hamster, goat, or rabbit. Fortunately, many such antisera, specific for a large number of viruses, are available from Millipore, and can be used to visualize infected cells in tissues using Basic Protocol 6. The right-hand panel of Figure 26.3.3 demonstrates the utility of this technique with evidence of many infected airway lining cells (seen as red) following infection 24 hr earlier with a high dose (10^6 pfu) of influenza A virus. This is a demonstration of a robust infection prior to the onset of visible pathology at early times post-inoculation.

Troubleshooting

Included here are a variety of different protocols to study respiratory virus infections. Because of the many manipulations that are required in these protocols and the diverse technologies used, there are many different things that can go wrong. Thus, the investigator should refer to the specific protocols or to a manual specific for each subject for more detailed information.

Anticipated Results

In these protocols, as with any in vivo experimental model, there will be variability between experiments and between individual animals at a given time point. As this is unavoidable, it is important to use sufficient numbers of animals such that a meaningful statistical analysis can be done. Typically, between five and ten animals are used for each data point, and this is important for both objective measures such as cytokine production, as well as the more subjective evaluation of histopathology. When comparing more than two cohorts of animals, a simple student *t*-test is often not sufficient, and an analysis of variance must be performed to determine significance. For histologic analysis, differences between groups of animals will often be a matter of degree rather than a +/− situation, so it is important to examine the slides blindly. This is done so by labeling each slide with only a number, and asking an unbiased examiner to determine whether the samples appear to segregate into groups. When no clear differences are present between two groups, it is concluded that those groups are not significantly different. Although this system has worked well for the authors, it is important to use both qualitative and quantitative measures whenever possible, e.g., comparing BAL cytology and/or FACs analysis with the pattern of inflammation seen on tissue sections at each time point.

Time Considerations

In planning an infection experiment, it is important to determine in advance which samples can be frozen (e.g., lungs for virus titers or BALs for ELISA), and which must be analyzed on the day that they are harvested. Tissues for histology must be fixed immediately, but cannot be processed until they have been fixed in formalin for several hours, but no more than 2 days. Lymphocyte analysis must be done immediately. Isolating immune cells from tissue samples and setting up FACS-staining will take from 4 to 12 hr depending on the number of tissue samples and the complexity of the staining. The samples can be run at the end of the day or, if fixed, during the following day. An ISH analysis will take at least 1 week, including the time needed to harvest, fix, process, and section tissues, with 2 days needed for staining.

Compartmented Neuron Cultures for Directional Infection by Alpha Herpesviruses

Dušica Curanović,[1] Toh Hean Ch'ng,[1, 2] Moriah Szpara,[1] and Lynn Enquist[1]

[1]Department of Molecular Biology, Princeton University, Princeton, New Jersey
[2]University of California at Los Angeles, Los Angeles, California

ABSTRACT

Compartmented neuronal cultures allow experimenters to establish separate fluid environments for neuronal axons and the soma from which they emanate. Physical isolation of cell bodies and axons is achieved by culturing neurons in tri-chambered Teflon rings. Dissociated ganglia are plated in one end compartment of the trichamber, and axonal growth is guided underneath watertight silicone grease barriers into a separate compartment. Since the axons and cell bodies are located in different compartments, they can be infected and assayed separately. We describe the assembly and use of compartmented neuronal cultures for in vitro study of directional infection of neurons by alpha herpesviruses. Selective application of viral inoculum to only one compartment ensures that the remainder of the neuron is not contaminated by input inoculum. This allows for quantification of viral spread, and unambiguous interpretation of immunofluorescence and electron microscopy images. *Curr. Protoc. INTRODUCTION

This unit describes the assembly and use of compartmented neuron cultures for the in vitro study of directional infection by alpha herpesviruses. The trichamber system we describe is based on the compartmented cultures developed by R.B. Campenot (Campenot, 1977, 1992). In the trichamber system, neuronal cell bodies and their axons are maintained in separate compartments, enabling the experimenter to establish unique fluid environments across the length of the neuron. Thus, a viral inoculum can be applied either to the compartment with neuronal cell bodies or to the compartment containing distal axons. If infection is initiated at axons, viral particle motion along microtubules is minus-end-directed and is termed retrograde transport. In contrast, viral particle motion that is plus-end-directed is termed anterograde. The efficiency of directional viral transport and subsequent spread can be determined by a combination of different techniques and assays including, but not limited to, viral titering, immunofluorescence imaging, and electron microscopy.

To study anterograde transport and neuron-to-cell transmission of infection, viral inoculum is applied to neuronal cell bodies, and the infection is transmitted via axons to detector cells plated in the axon compartment. Retrograde transport and axon-mediated infection of neurons are studied by applying the viral inoculum to the axonal compartment and titering the neuronal cell bodies at the appropriate time points after infection. Immunofluorescence and electron microscopy can be performed on infected samples after either type of infection. The trichamber system confers a major advantage for these experiments over non-compartmentalized cultures: the input inoculum is applied and

Current Protocols in Cell Biology 26.4.1-26.4.23, June 2009

DOI: 10.1002/0471143030.cb2604s43

restricted to only one compartment, and therefore does not confound measurements or imaging performed on the remainder of the sample; in addition, the direction of viral transport during infection is known.

NOTE: All incubations are performed in a humidified 37°C, 5% CO_2 incubator unless otherwise specified.

NOTE: Chamber assembly, dissection of ganglia, and all work with live virus and neurons should be performed under sterile conditions and aseptic technique should be used accordingly.

BASIC PROTOCOL 1

ASSEMBLING THE TRICHAMBER SYSTEM

Basic features of the trichamber system

The trichamber system consists of three compartments: the soma (S)-compartment, where the neuronal cell bodies are cultured; the methocel (M)-compartment, where the axons first emerge after penetrating underneath the initial barrier; and the neurite (N)-compartment, where the axons emerge from the M-compartment (see Fig. 26.4.1 for a diagram of the trichamber). Spatially, the Teflon trichamber is symmetrical and the S- and N-compartments are identical. However, for nomenclature purposes, we designate the S-compartment as the location where the neuron cell bodies are plated.

To assemble the trichamber system, we first apply a thin coat of silicone grease on one face of the trichamber and allow the chamber to form a watertight seal on a 35-mm plastic tissue culture dish. Silicone grease is viscous enough to prevent diffusion of liquids between compartments, but allows axons to penetrate underneath the chamber barrier. Once the chamber is affixed to the dish, freshly dissected and dissociated neurons are plated in the S-compartment. After 2 weeks, the axons emanating from the cell bodies in the S-compartment will have penetrated underneath the Teflon barriers, across the M-compartment, and into the N-compartment.

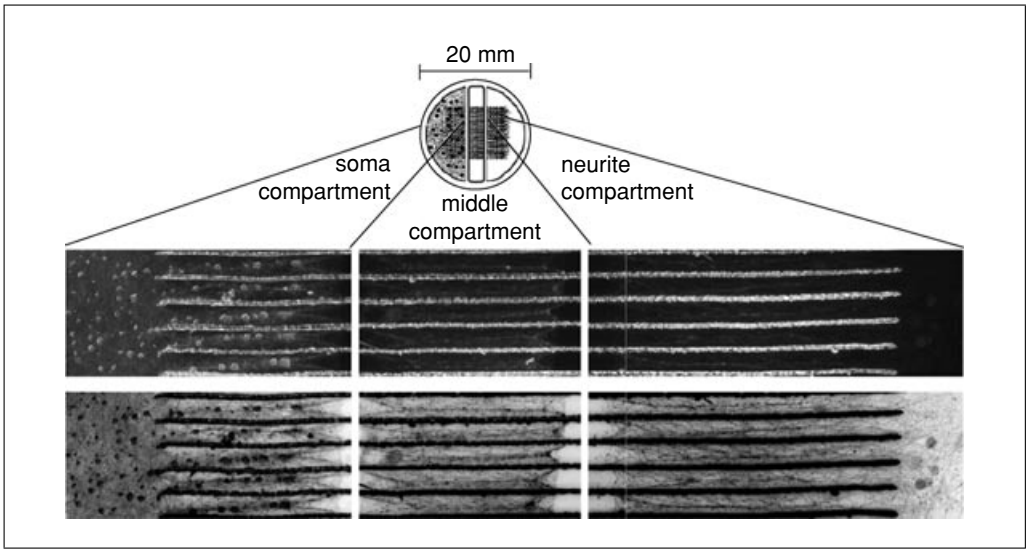

Figure 26.4.1 Diagram of trichamber setup, with images of neurons and axons passing through five inter-groove spaces. The trichamber is 20-mm across, and consists of a soma (S) compartment, middle (M) compartment, and neurite (N) compartment. These images show mouse SCG neurons after 3 weeks in trichamber culture. The Teflon trichamber has been removed to facilitate imaging. The top row of images is phase-contrast microscopy. The bottom row presents the same images, after inversion and contrast-adjustment in Photoshop, to better present the axon structure. The circular gray shadows visible in the N-compartment after image inversion are from silicone grease that floats on the surface of the medium after trichamber removal.

Preparing the trichamber components

Prior to dissecting neurons, the trichambers must be cleaned and sterilized. In addition, the tissue culture dishes must be coated with cell adhesion molecules to promote neuronal attachment and axonal growth. We regularly use poly-DL-ornithine and laminin as extracellular substrates. With respect to incubation times, this protocol must begin at least 1 day before neuronal dissection and plating is planned. This treatment may vary depending on the neuronal culture methods used in different laboratories or for different cell types.

Assemble chambers just before the dissections in a sterile environment; using a laminar flow hood for this step is highly recommended. We commonly culture rat or mouse superior cervical ganglia neurons in the S-compartment. Videos 1 and 2 provide visual demonstration of trichamber setup (see Videos 1 and 2 at *http://www.currentprotocols.com*).

Materials

Poly-DL-ornithine (Sigma) diluted in borate buffer
Tissue culture–grade water
Laminin (BD Biosciences)
HBSS without Ca^{2+} and Mg^{2+} (CMF-HBSS; HyClone)
Silicone high-vacuum grease, Dow Corning (VWR, cat. no. 59344-055)
70% ethanol
Neuronal medium containing 1% (v/v) methocel (see recipe)
Neuronal medium (see recipe)

Teflon trichambers (Tyler Research; see recipe)
Pin rake (homemade or Tyler Research)
35-mm plastic tissue culture dishes
15-cm non-tissue culture-treated dishes (optional)
Disposable 3-ml syringe
Machine-sawed 18-G hypodermic needle or truncated 200-µl pipet tip
Autoclave
Hemostat (e.g., Roboz RS-7293)

Additional reagents and equipment for cleaning the Teflon chambers (Support Protocol 1)

Prepare the chamber

1. Clean the Teflon chambers thoroughly before assembly (see Support Protocol 1).
2. Use a pin rake to etch 16 parallel, evenly spaced grooves in the middle of a 35-mm tissue culture dish. See Figure 26.4.2A for view of a pin rake.

   This homemade pin rake is constructed from 16 insect pins (size 00) arranged in a row such that sharp ends of the pins are aligned. Truncate the blunt ends of the pins with a wire cutter and fix the pins to a plastic holder with epoxy resin. A microcentrifuge tube opener can be used as the plastic holder. Always sterilize the pin rake with 70% ethanol (never autoclave). See Campenot (1992) for additional instructions on making a pin rake. Alternatively, a stainless-steel pin rake can be purchased from Tyler Research Corporation.

3. Make a notation at the side of the dish with a marker to determine the relative orientation of the dish with regards to the trichamber.

   When preparing multiple 35-mm dishes at once, it is useful to hold eight at a time by placing them within a 15-cm petri dish

4. Add 1 ml of 500 µg/ml of poly-DL-ornithine diluted in borate buffer to the dish. Incubate the dish for at least 6 hr.

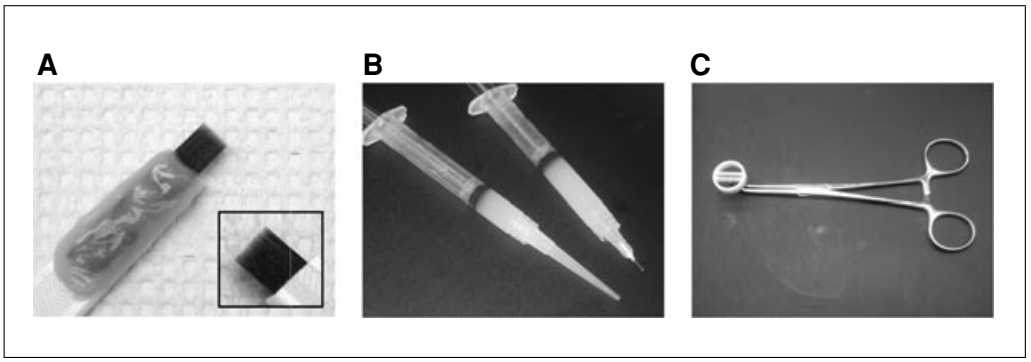

Figure 26.4.2 Tools for trichamber assembly. (**A**) Close-up of pin rake for making grooves in the trichamber dish. The pin rake is assembled from insect pins, epoxy, and a plastic handle. Inset shows close-up view of pins from the reverse side. (**B**) Two types of syringes for dispensing grease. The inner diameter of the needle or plastic tip determines the width of the grease strip. (**C**) Curved hemostat clamped onto trichamber, prior to addition of silicone grease.

5. Remove the dish from the incubator, aspirate poly-DL-ornithine and wash three times, each time with 1 ml tissue culture–grade water.
6. Add 1 ml of 10 μg/ml laminin in CMF-HBSS to the dish and incubate overnight.
7. Load silicone grease in a 3-ml disposable syringe. Fill the barrel of the syringe $^2/_3$ of the way through with silicone grease. Attach a truncated 18-G hypodermic needle, or a truncated 200-μl pipet tip, onto the syringe. Autoclave the silicone grease–loaded syringe, the trichambers, and tools for dissection. See Figure 26.4.2B for a view of grease-loaded syringes.

   The purpose of truncating the needle or the pipet tip is to dispense the silicone grease easily and evenly. If truncating a pipet tip, aim for a diameter equivalent to that of an 18-G needle.

Assemble the trichamber system

8. Aspirate laminin from dishes, wash twice with 1 ml CMF-HBSS and air-dry briefly.

   To facilitate drying, keep the dishes tilted. Do not over-dry laminin-coated plates because the protein may degrade.

9. As the dishes are drying, remove the Teflon chambers and silicone grease–loaded syringe from the autoclave. Cool briefly and sterilize syringe tip with 70% ethanol. Eject a small amount of silicone grease from the syringe to remove any air pockets formed at the tip of the needle during autoclaving.
10. Use a sterile hemostat to clamp one of the two central barriers of a Teflon trichamber. Flip the hemostat over and place it flat, so that the chamber is facing upward. See Figure 26.4.2C for a view of the hemostat and trichamber clamped together and see Video 1 at *http://www.currentprotocols.com*.
11. Apply a thin strip of silicone grease around the entire chamber, starting with the two central barriers followed by the outer circular ring. See Video 1 at *http://www.currentprotocol.com*.

    It is crucial to maintain the continuity of the strip of silicone grease, particularly in the central barriers, since a break in the strip will cause leakage between compartments.

12. Set the clamped hemostat aside. Add a 50-μl drop of neuronal medium with 1% methocel in the middle of the laminin-coated dish, on top of the etched grooves (see Video 1 at *http://www.currentprotocols.com*).

    The drop of methocel provides moisture for the seal between the chamber and the dish. Without methocel, the barrier is devoid of liquid, which deters axon penetration.

13. Flip the dish over and gently place it on the Teflon chamber, centering the grooves directly over and perpendicular to the chamber barriers. Lift the hemostat and view the trichamber assembly through the bottom-side of the dish. Tilt the hemostat slightly to allow light to hit the dish at different angles.

    This will reveal whether or not a seal has started to form between the chamber and the dish. If the seal has formed at very few locations, touch the edges of the dish very lightly until seal formation is observed.

    The seal does not need to be continuous at this point. It is only necessary for sufficient adhesion to ensure that the dish will not fall free of the hemostat when it is inverted in the next step.

14. Flip the hemostat over and gently release the clamp close to the surface of the bench, thus freeing the dish.

    Avoid letting the assembled trichamber and dish come in contact with the bench prior to releasing the clamp, since this may inadvertently disrupt the silicone grease strip and cause a breach in the barrier.

15. Wait for the seal to become continuous; while waiting, proceed with the assembly of the remaining chambers. Check for seal formation by lifting each 35-mm dish, inverting it, and allowing light to hit the bottom surface at different angles. If after 10 min the seal has not yet formed, apply gentle pressure to the chamber to complete the seal.

    If too much pressure is applied, axon penetration underneath the barriers will be hindered.

16. Add 200 μl of neuron medium to the M-compartment and wait 1 min; note whether the medium leaks from this compartment. If no leaks are detected, apply 300 μl of medium to the S-compartment and 400 μl to the N-compartment.

    By adding only 300 μl to the S-compartment, up to 100 μl volume of dissociated neuron suspension can be added (see below).

    Approximately 300 to 400 μl volume is sufficient for the S- and N-compartments, and 200 μl volume for the M-compartment.

PLATING AND MAINTAINING DISSOCIATED NEURONS IN THE TRICHAMBER SYSTEM

BASIC PROTOCOL 2

We routinely culture and plate peripheral neurons from the sympathetic ganglia (SCG) of embryonic rats and mice in the trichamber system. In this protocol, we provide a streamlined method for culturing mouse embryonic SCG neurons in the trichamber system. These dissociation and medium conditions work equally well for rat SCG neurons. Protocols for dissection of embryonic rat SCG neurons can be found in Ch'ng et al. (2005).

While different types of neurons can be cultured in the trichamber system, the success of this system depends on the robust outgrowth of the axonal or neuritic projections from the cell bodies. In general, embryonic neurons work better in the trichamber system than older neurons, and peripheral nervous system neurons display more robust outgrowth than central nervous system neurons. The trichamber system can be optimized for different neuronal cell types by modifying the cell adhesion substrates, medium, or other cell culture parameters.

Materials

Pregnant mouse, E14 or E15
HBSS (HyClone)
HBSS without Ca^{2+} and Mg^{2+} (CMF-HBSS; HyClone)
2.5 mg/ml trypsin in HBSS (see recipe)

1 mg/ml DNase in neurobasal medium (see recipe)
2 mg/ml soybean trypsin inhibitor (SBTI) in neurobasal medium (see recipe)
Neuronal medium (see recipe)
Cytosine β-D-arabinofuranoside hydrochloride (AraC; see recipe)

15-ml conical tubes
Water bath at 37°C
Flame-polished glass Pasteur pipet
Hemacytometer
Teflon trichambers (Tyler Research; see recipe)

Additional reagents and equipment for counting cells using a hemacytometer (*UNIT 1.1*)

Prepare neurons

1. Dissect ganglia in standard HBSS from embryonic day 14 (E14) or E15 mouse embryos, using the approaches previously described for rat superior cervical ganglion neurons (Johnson, 2001; Ch'ng et al., 2005).

2. Transfer dissected ganglia to a 15-ml conical tube and dilute with 5 ml CMF-HBSS. Allow the ganglia to settle, and then remove all but 800 µl of the buffer.

   CMF-HBSS is preferable at this step for optimal trypsin activity.

3. To digest the ganglia, add 100 µl of 2.5 mg/ml trypsin in HBSS and 100 µl of 1 mg/ml DNase in neurobasal medium, and incubate the tube for 15 min in a 37°C water bath. Swirl the tube once during this time.

4. During this time, flame-polish a glass Pasteur pipet by holding the open end in a flame for ~5 to 10 sec.

   The goal is to smooth the jagged edges of the glass pipet opening to minimize cell damage.

   We also coat the inner glass surface of the Pasteur pipet with a sterile 2% BSA in PBS solution. This prevents neurons from adhering to the glass surface.

5. After 15 min, add an additional 100 µl DNase in neurobasal medium, and 650 µl SBTI in neurobasal medium. Incubate the tube for an additional 5 min in a 37°C water bath.

   The enzyme solutions are optimized to give the desired final concentration in this volume. The final concentrations are: trypsin, 0.25 mg/ml; DNase, 0.2 mg/ml; and SBTI, 0.8 mg/ml.

   DNase aids in trituration by digesting genomic DNA released from lysed cells.

6. Dilute the ganglia-enzyme mix with additional CMF-HBSS to 10 ml. Centrifuge 1 min at 3000 × *g* in a tabletop centrifuge, room temperature. Remove all but 200 µl volume, then add 1.5 ml of neuronal medium.

7. Use trituration to mechanically dissociate the ganglia. Pipet the resuspended ganglia up and down with the flame-polished glass pipet until the neuronal suspension is free of clumps.

Plate neurons

8. Count a small aliquot of the resulting neuronal suspension in a hemacytometer (*UNIT 1.1*). Plate 20,000 to 25,000 mouse superior cervical ganglion cells in each trichamber S-compartment. Place the cultures in a 37°C, 5% CO_2 humidified incubator.

   We plate approximately the same number of neurons in the S-compartment whether using mouse SCG neurons or rat SCG neurons.

20,000 to 25,000 cells is approximately a whole ganglion obtained from an E14-E15 mouse embryo, or half of a superior cervical ganglion obtained from an E15.5 rat embryo.

Counting SCG neurons before plating is complicated by the presence of non-neuronal cells (satellite cells and/or fibroblasts from neighboring tissue). These cells will die during subsequent treatment with AraC. In addition, SCG neurons will divide for a short time in culture (DiCicco-Bloom and Black, 1988; DiCicco-Bloom et al., 1990). We have empirically observed that the neuron number at 2 weeks post-plating is ~1/4 the number of plated cells. Thus, plating 20,000 cells will yield ~5,000 mature neurons by the time of experimental infection.

Note that the S- and N-compartments each hold a maximum of 400 μl of medium, so the amount of dissociated neuron suspension added must not exceed this capacity.

9. Allow the neuronal cultures to grow for 2 days before adding an antimitotic drug to the S-compartment.
10. After 2 days, add AraC to 1 μM in the existing S-compartment medium to eliminate any mitotic, non-neuronal cells. Incubate overnight.
11. Remove AraC-containing medium after overnight incubation and replace with fresh, warm neuronal medium.

    Fluid volumes are 300 to 400 μl for the S- and N-compartments and 200 μl for the M-compartment.

    Always change medium with slow and gentle pipetting. Do not remove all of the medium and let the cells dry; instead, always leave a small volume at the bottom of the dish.

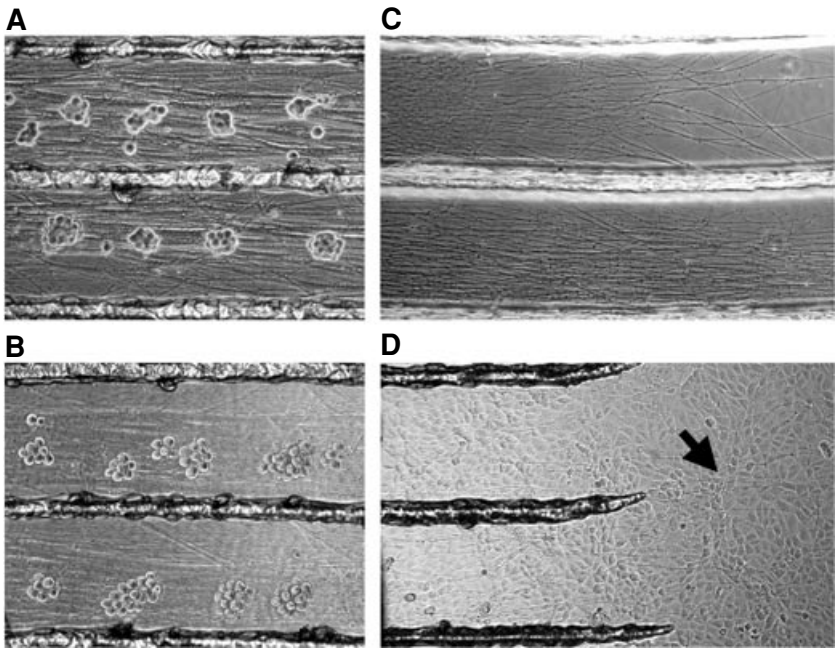

Figure 26.4.3 Highlights of trichamber culture features. (**A**) Enlarged view of mouse SCG neurons in the S compartment of a 3-week-old culture. The clusters of cell bodies are tightly packed. (**B**) At 24 hr after alpha herpesvirus infection (e.g., PRV or HSV-1), the clusters of SCG neurons are less tightly packed, and axons become grainy. (**C**) Enlarged view of dense axon growth in the N-compartment of a 2-week-old culture of rat SCG neurons. (**D**) View of the N-compartment 24 hr after plating of a monolayer of PK15 detector cells. Arrow highlights mouse SCG axons visible among the PK15 cells.

We recommend selecting one edge of the chambers (for instance, the top edge) from which to always add or remove medium. The force of fluid motion is enough to rip or lift the neurons from the dish. The top edge is far from the grooves and it will thus minimize effects on axon penetration through the compartments. In addition, by consistently choosing the same spot, the neuronal disruption is contained to only one part of the chamber.

If non-neuronal cells are still abundant 2 to 3 days after AraC treatment, repeat the treatment on the evening before a scheduled medium change.

12. Change neuronal medium in all three compartments every 2 to 3 days.

Figure 26.4.3 shows mature neuron cell bodies and axon outgrowth in the trichamber setup after 3 weeks of growth. Figure 26.4.3A,B provides a close-up view of neuron cell bodies in the S-compartment, and Figure 26.4.3C of neurites in the N-compartment.

In general, older cultures require more frequent medium changes. Observe the phenol red indicator found in most media formulations (including Neurobasal). The pH of the medium can fluctuate rapidly in small volumes, and the health of the neuronal cultures can drop dramatically if the medium becomes too acidic.

It is important not to bump or put pressure on the trichamber setup during medium changes, since this can tear the neurites or compress the silicone grease seal.

SUPPORT PROTOCOL 1

DISASSEMBLING AND CLEANING THE TRICHAMBERS: ROUTINE CLEANING

The Teflon trichambers are durable and can be cleaned and reused. However, the silicone vacuum grease must be removed entirely before assembling new cultures. With proper care, these chambers can last for many experiments. Traditionally, the chambers are soaked in concentrated sulfuric acid to remove residual silicone grease (Campenot, 1992). We currently use ethanol as a gentler solvent, reserving sulfuric acid for occasional strong cleaning. This protocol describes cleaning the trichambers with ethanol.

Materials

Distilled water
200-proof (absolute) ethanol

Trichambers that need cleaning
Blunt forceps
Paper towels
Kimwipes
Autoclave
10-cm glass petri dish (optional)

1. Upon the conclusion of an experiment, aspirate all residual medium from the compartments. Disassemble the trichamber setup by lifting the chamber from the tissue culture dish using a pair of blunt forceps.

Using sharp forceps will damage the Teflon.

2. Blot each trichamber onto a paper towel: apply gentle pressure and then lift again to leave additional grease behind on the paper towel. Remove any residual silicone grease by carefully wiping the chamber with Kimwipes.

It is crucial to remove most of the silicone grease before further treatment.

3. Rinse the chambers in distilled water and blot dry with paper towels.

4. Soak the chambers in 200 proof ethanol for 24 hr or longer. Swirl or shake the solution occasionally to aid in dissolution of any grease residue on the chambers.

5. Rinse the chambers with distilled water several times, then boil them in distilled water for 30 min.
6. Air dry and autoclave the chambers.

We use a 10-cm glass petri dish to hold the trichambers for autoclaving and storage.

DISASSEMBLING AND CLEANING THE TRICHAMBERS: OCCASIONAL CLEANING

SUPPORT PROTOCOL 2

Periodically (after 3 to 4 uses), the trichambers should be cleaned with stronger reagents to thoroughly clean it. This protocol describes the use of concentrated sulfuric acid to remove residual silicone grease (Campenot, 1992).

***Additional Materials** (also see Support Protocol 1)*

Concentrated sulfuric acid

1. Disassemble trichambers and remove grease as described in Support Protocol 1 (steps 1 to 3).
2. Soak the chambers in concentrated sulfuric acid for 24 hr. Swirl the acid solution occasionally.

Longer incubation will not result in damage.

3. Rinse the chambers with distilled water several times before boiling them in distilled water for 30 min.

Boiling the chambers should remove any residual sulfuric acid trapped within the Teflon.

4. Air dry and autoclave the chambers.

STUDYING THE SPREAD OF VIRAL INFECTION: ANTEROGRADE TRANSPORT AND NEURON-TO-CELL TRANSMISSION OF INFECTION

BASIC PROTOCOL 3

This assay was developed to study the spread of viral infection initiated in the neuron cell body (S-compartment) to axonally contacted epithelial detector cells plated in the N-compartment. Inoculum is applied to the S-compartment, and the titer of infectious virus in the N-compartment is indicative of viral spread from the soma, through axons, to the detector cells, which amplify viral titer. Because diffusion of viral particles is prohibited by the methocel-containing middle compartment and two watertight silicone grease seals, neuron-to-cell transmission of infection is mediated exclusively via neuronal axons that span all three compartments. By co-plating different cell types in the N-compartment, various axon-cell interactions can be established. For instance, if a standard tissue culture cell line that is permissive for viral infection is plated in the N-compartment, these cells serve as sensitive detectors and amplifiers for the axonal transmission of infection. Alternatively, if neurons are co-plated in the N-compartment, then the spread of infection from pre- to post-synaptic neurons can be studied. In this protocol, we describe the plating of a porcine kidney cell line (PK15), a commonly used detector and amplifier of Pseudorabies virus (PRV) infection.

Materials

Two-week-old neuron cultures in the trichamber system (Basic Protocol 2)
A confluent monolayer of tissue culture cells (e.g., PK15 cells)
Trypsin (Invitrogen)
Dulbecco's Modified Eagle Medium (DMEM; Invitrogen)
Fetal bovine serum (HyClone)
Neuronal medium containing 1% (v/v) methocel (see recipe)
Viral stock to be studied (e.g., 10^7 to 10^8 PFU/ml PRV)

Disposable protein gel-loading tip (Rainin)
−80°C freezer

1. Culture dissociated neurons in the S-compartment for ~2 weeks prior to the actual experiment.

   After 2 weeks, axons are easily visible in the N-compartment.

2. Score the axonal densities in the N-compartment from 1 to 4, with chambers scoring a 4 having the densest network in the N-compartment, and those with a score of 1 having little to no axonal penetration.

   An alternative method to score the N-compartment is by counting how many of the inter-groove spaces (there are 15 of these made by a 16-pin rake) are filled by penetrating axons. Another criterion is length of penetration into the N-compartment.

   Only chambers with a score of 3 or 4 are used in experiments; these chambers are evenly distributed among the different experimental variables.

3. One the day prior to infection, plate the detector cells (e.g., tissue culture cells such as PK15s) in the N-compartment.

   These cells settle on top of and in contact with the axons in the N-compartment (see Fig. 26.4.3D).

   For example, dissociate a 90% confluent monolayer of tissue culture cells with 1 ml of trypsin and bring the total volume of the dissociated cells up to 10 ml with neuronal medium. Add ~66 μl of the trypsinized cells into the N-compartment. Add fetal bovine serum to a final concentration of 1% in the N-compartment to facilitate cell attachment and growth.

   The goal is to plate enough tissue culture cells to form a confluent monolayer ~24 hr post-plating. Examples of detector cells for other viruses (e.g., Herpes simplex virus 1 or West Nile virus) can be found in Ch'ng et al. (2007) and Samuel et al. (2007). We plate ~6.6×10^3 PK15 cells per N-compartment.

   Neurons can also be plated in the N-compartment 2 to 3 days before their intended use (Feierbach et al., 2007; Samuel et al., 2007). This short time frame prevents axon growth from the newly plated neurons into the M-compartment.

4. On the day of infection, replace existing medium in the M-compartment with 200 μl of neuronal medium with 1% methocel. Return the dish to the incubator for 30 min to allow the methocel to settle to the bottom of the dish.

   The viscous, methocel-containing neuronal medium serves as an additional barrier to diffusion between the trichamber-compartments.

5. Dilute the viral inoculum in neuronal medium, to a final volume of 50 μl. Remove medium from the S-compartment, and add the viral inoculum.

   Keeping the volume of infection to only 50 μl is important for efficient viral adsorption.

   When preparing to use this system in your laboratory, it is important to characterize the amount of virus needed to synchronously infect all cells in the S-compartment. This can be empirically determined by applying a titration series of inoculum amounts to several trichambers. Assay infection by immunofluorescence at an early point in infection. Choose an inoculum concentration that adequately infects all cells.

   For PRV strains in our laboratory, we generally add 10^5 plaque-forming units (PFU) into the S-compartment, which is approximately a multiplicity of infection (MOI) of 20.

6. Incubate the trichambers with viral inoculum for 1 hr.

7. Gently remove the viral inoculum from the S-compartment with a pipet and replace it with 300 to 400 μl of neuronal medium. Place the chamber back in the incubator.

8. At the appropriate time post-infection, remove the trichamber dish from the incubator, and separately scrape and harvest the contents of the S- and N-compartments for later titering on the appropriate cell types.

   Use a sterile object to scrape the cells in the compartments for titering; we use a disposable protein gel-loading pipet tip for this purpose. The neurons should peel off easily as a sheet. The detector cells often adhere tightly and they must be scraped thoroughly.

   In anterograde-mediated infections (where inoculum is added to the S-compartment), both the S- and N-compartments are typically harvested for titering. Collecting the contents of the S-compartment also informs the experimenter about the titer of input inoculum and replication in neurons.

9. Freeze all harvested samples at −80°C before titering.

STUDYING THE SPREAD OF VIRAL INFECTION: RETROGRADE TRANSPORT AND AXON-MEDIATED INFECTION OF NEURONS

ALTERNATE PROTOCOL 1

Some neuroinvasive viruses, such as rabies virus and alpha herpesviruses, enter neurons at axon termini or growth cones and undergo retrograde axonal transport toward the cell body, where replication occurs. The trichamber system can be used to study this form of entry, and subsequent infection of neuron cell bodies. In addition, because not all neurons in the S-compartment send axons into the M- and N-compartments, this assay can be used to study secondary spread among S-compartment neurons (Curanović et al., in preparation). If the S-compartment is assayed 24 hr post-infection of the N-compartment with PRV, for instance, the titer obtained comes from both the initially infected neurons (primary infection), and also from secondary spread to additional neurons in the S-compartment (secondary infection/spread).

Materials

Two-week-old neuron cultures in the trichamber system
Neuronal medium containing 1% methocel (see recipe)
Viral stock to be studied (e.g., PRV)

Disposable protein gel-loading pipet tip (Rainin)
−80°C freezer

1. Grow dissociated neurons in the S-compartment for at least 2 weeks prior to any infection.

2. Score the axonal densities in the N-compartment (see Basic Protocol 3, step 2).

   Since viral particles are entering neurons via distal axons, it is critical that the axonal density in the N-compartment is robust and comparable among all chambers.

3. On the day of infection, replace medium in the M-compartment with 200 µl of neuronal medium containing 1% methocel. Return the dish to the incubator for 30 min, to allow the methocel to settle to the bottom of the dish.

4. Dilute the viral inoculum in neuronal medium, to a final volume of 50 µl. Remove medium from the N-compartment, and add the viral inoculum.

   Keeping the volume of infection to only 50 µl is important for efficient viral adsorption

   We use the same PFU for retrograde-mediated infection as for anterograde-mediated infections. See above for description of how to determine the appropriate amount of viral inoculum for your system.

   The terminal field densities and the number of infectious virions placed in the N-compartment are critical. Reproducible results are obtained only when inoculum titer is carefully controlled.

5. After 1 hr of incubation, gently remove the inoculum with a pipet and replace with 300 to 400 µl of neuronal medium. Place the chamber back in the incubator.

6. At the appropriate time post-infection, scrape and harvest the infected neuronal cell bodies in the S-compartment.

   We routinely use a sterile, disposable protein gel-loading pipet tip to scrape the neuron cell bodies.

   In retrograde-mediated infections, the goal is to measure the ability of a viral strain to undergo transport to the cell soma, replicate, and/or spread among neurons in the S-compartment. There is no local virus production in the axon; thus, only the S-compartment is harvested.

7. Freeze the harvested samples at −80°C until ready to titer.

BASIC PROTOCOL 4

VISUALIZING INFECTION IN THE TRICHAMBER SYSTEM: IMMUNOFLUORESCENCE

Visualizing neurons grown in the trichamber system via immunofluorescence or transmission electron microscopy requires slight modification of existing protocols. The trichambers are assembled on a plastic surface called Aclar. This flexible, thermoplastic fluoropolymer film is biochemically inert and exhibits no detectable autofluorescence; it can be molded or cut into any shape desired, and treated like a coverslip. However, unlike a glass coverslip, Aclar can be etched to produce grooves that are required for guiding axonal penetration into the N-compartment.

The basic steps of any protocol for fixation and antibody incubation can be adapted to the trichamber system. Here, we describe our preferred particular fixation and antibody incubation times, along with notes about handling that are particular to Aclar and the trichamber setup. Users are encouraged to adapt their own immunofluorescence staining protocols to this system.

Materials

Poly-DL-ornithine (Sigma)
Laminin (BD Biosciences)
Phosphate-buffered saline (PBS; HyClone, cat. no. SH30028.03)
3.2% (w/v) paraformaldehyde in PBS (store up to 2 weeks, in the dark, at 4°C)
PBS/BSA: 3% (w/v) bovine serum albumin (BSA) in PBS (HyClone store solution up to 6 months at 4°C)
PBS/BSA/SAP: PBS (HyClone)/3% (w/v) bovine serum albumin (BSA; Roche)/0.5% (v/v) saponin solution (Sigma; store solution up to 6 months at 4°C)
Primary antibody
Fluorophore-conjugated secondary antibody
Tissue culture–grade water
Mounting medium (e.g., Aqua Poly/Mount from Polysciences)

Aclar (EM Sciences)
UV source for sterilization
Pin rake (Tyler Research or homemade)
35-mm tissue culture dish
Blunt forceps
Sharp forceps
Spatula
Dissection scissors, optional
Microscope slide
Microscope coverslip

Additional reagents and equipment for assembling the trichamber (Basic Protocol 1) and plating dissociated neurons, maintaining the cultures, scoring axon penetration, and subsequent infection assays (Basic Protocol 2 and 3 and Alternate Protocol 1)

1. UV-sterilize a sheet of Aclar in the tissue culture hood. Cut a circular piece of Aclar that is slightly larger than the trichamber but smaller than a 35-mm tissue culture dish.

   The size of a standard United States quarter works well.

2. Etch 16 parallel grooves in the middle of the Aclar strip using a pin rake.

   Since Aclar is transparent, it can be challenging to determine which side of Aclar contains the etched grooves. Make a small mark or notch on the Aclar strip to determine orientation.

3. Place the Aclar in a 35-mm tissue culture dish and assemble the trichamber (Basic Protocol 1).

   Aclar is very hydrophobic. It is necessary to increase the volume of poly-DL-ornithine to 3 ml, and that of laminin to 2 ml per dish to ensure that the Aclar is completely submerged.

   Similarly, increase the volume of washing solutions to 2 to 3 ml. Aclar remains adhered to the tissue culture dish owing to a thin liquid film generated between the surfaces during poly-DL-ornithine and laminin incubations and wash steps.

4. Carry out all steps of plating dissociated neurons, maintaining the cultures, scoring axon penetration, and subsequent infection assays (Basic Protocols 2 and 3 and Alternate Protocol 1) in the same way for trichambers on Aclar as for the usual trichamber setup.

Fix cells

5. At the desired time point after infection, wash all compartments once with 300 to 400 µl PBS per compartment and fix the cells with 300 to 400 µl of 3.2% paraformaldehyde in PBS for 10 min at room temperature.

   As with medium changes, use the same edge of the trichambers for all fluid changes in this protocol. This will minimize neuronal damage during the washes.

6. Remove the fixative from all compartments and wash the samples three times, each time with 1 ml PBS containing 3% BSA (PBS/BSA). After the final wash, flood the entire 35-mm dish with 3 ml of PBS-BSA.

   Be gentle with the multiple rinses described in this protocol. Use a pipet to slowly flow solutions down the sides of the chamber. If the neuronal network starts to peel off due to washes, wash twice instead of three times. Infected neurons are especially likely to peel off during processing.

Remove the chamber

7. Using a pair of serrated, blunt forceps, grasp the central barrier and gently lift the trichamber upwards. To anchor the Aclar on the surface of the dish, apply the same downward force on the Aclar in the M-compartment with a pair of sharp forceps.

   Using the sharp end of the forceps in the M-compartment will minimize damage done to the sample. Avoid applying pressure sideways when lifting the chambers from the Aclar as this will disrupt the neuronal network. If the correct force is applied during this process, the majority of the silicone grease will come off together with the trichamber.

8. Remove excess silicone grease on the surface of Aclar.

   We find that spatulas or pipet tips work well to remove the excess silicone grease, which prevents the Aclar from floating to the surface of the antibody solution. An uneven Aclar surface will also hinder proper mounting on a coverslip.

9. *Optional:* Trim and discard the excess Aclar surrounding the chamber using dissection scissors.

Permeabilize the cells

10. To permeabilize the sample, add 1 ml of PBS containing 3% bovine serum albumin and 0.5% saponin (PBS/BSA/SAP) in the well. Incubate the sample 10 min at room temperature.

    Preparation and treatment of samples for immunofluorescence can vary. We often use 0.1% (v/v) Triton X-100 instead of 0.5% saponin.

    To perform immunofluorescence on nonpermeabilized samples, omit detergents from all solutions.

    In place of bovine serum albumin, 10% goat serum can be used as a blocking reagent.

Stain the cells for immunofluorescence

11. Remove PBS/BSA/SAP and replace with 1 ml of primary antibody solution diluted in PBS/BSA/SAP. Incubate 1 hr at room temperature or overnight at 4°C.

    Some laboratories prefer to use the drop method by inverting the Aclar and placing it on a drop of antibody solution; however, this may not be as gentle on the axons.

    Dilutions vary and they should be optimized for each antibody.

12. After the appropriate time, remove the primary antibody solution and rinse the well three times, each time with 1 ml PBS/BSA/SAP.

13. Add 1 ml of fluorophore-conjugated secondary antibody solution diluted in PBS/BSA/SAP and incubate 1 hr at room temperature.

    If the secondary antibody is fluorescent, be sure to carry out this incubation in the dark.

14. After the appropriate time, remove the secondary antibody and rinse the well three times, each time with 1 ml PBS and once with 1 ml distilled water.

Mount the samples

15. Using a pair of forceps, carefully pick up the Aclar and blot away the excess liquid by touching the edge of the Aclar to a Kimwipe.

16. Mount the Aclar on a microscope slide, cell side up, and place a coverslip over the sample.

    We routinely use Aqua Poly/Mount as the mounting medium. Place a drop of Aqua Poly/Mount on the cover slide and place the Aclar cell-side up. Make sure that that the Aclar is firmly in place. Next, place a drop of Aqua Poly/Mount on the Aclar and place a coverslip over the sample.

    If the Aclar is mounted cell-side down, the thickness of the Aclar may hinder proper viewing of the sample when using certain oil objectives that have a shorter focal plane.

17. Allow the samples to set overnight before doing any microscopy.

ALTERNATE PROTOCOL 2

VISUALIZING INFECTION IN THE TRICHAMBER SYSTEM: ELECTRON MICROSCOPY OF TRICHAMBER SYSTEM SAMPLES

One of the more challenging aspects of electron microscopy is preserving the ultrastructure of the sample, particularly the fragile neuronal network, during separation of the polymerized resin from the substrate. Often, the resin is bound tightly to the surface of the dish and the sample is damaged during separation. Aclar is an excellent substrate to use for electron microscopy because it is more hydrophobic than glass or plastic—hence, the resin tends to bind less tightly to Aclar (Kingsley and Cole, 1988). These protocols for transmission electron microscopy (TEM) were initiated and developed by

Margaret Bisher, of the Princeton Confocal and Electron Microscopy Core Facility, and Lisa Pomeranz (Pomeranz et al., unpub. observ.).

Materials

Two-week-old cultures in the trichamber system, set up on Aclar (Basic Protocol 4)
Phosphate-buffered saline (PBS; HyClone)
2% (v/v) glutaraldehyde in sodium cacodylate buffer (see recipe)
0.2 M sodium cacodylate buffer, pH 7.2 (see recipe)
1% (w/v) osmium tetraoxide in sodium veronal buffer (see recipe)
Sodium veronal buffer (see recipe)
0.25% (w/v) toluidine blue in sodium cacodylate buffer (see recipe)
0.05 M sodium maleate buffer, pH 5.1 (see recipe)
2% (w/v) uranyl acetate in sodium maleate buffer (see recipe)
Ethanol solutions of 30%, 50%, 70%, 90%, 95%, and 100%
Epon resin (Embed812; see recipe)

BEEM capsules
Fine-tipped forceps
60°C oven
Ultramicrotome (e.g., Leica UC6)
200-mesh hexagonal copper grid (EM Sciences)
Zeiss 912AB TEM with an Omega Energy Filter

Fix samples

1. At the desired time post-infection, wash all compartments twice, each time with 300 to 400 µl PBS per compartment and fix with 300 to 400 µl 2% glutaraldehyde solution 4 hr at room temperature.

   As with medium changes described in Basic Protocol 2, use the same edge of the trichambers for all fluid changes in this protocol. This will minimize neuronal damage during the washes.

2. After 4 hr, remove the trichambers and clean the Aclar as described in Basic Protocol 4 (steps 7 and 8). Do not trim the Aclar.

3. Remove the fixative and wash twice, each time with 3 ml 0.2 M sodium cacodylate buffer. Post-fix cells with 4 ml 1% osmium tetraoxide solution for 1 hr on ice.

Stain sample

4. Rinse the sample four times, each time with 4 ml sodium veronal buffer. Incubate sample with 4 ml of 0.25% toluidine blue solution 1 hr at room temperature.

   Toluidine blue is used to visualize the sample and identify areas of interest.

5. Remove the toluidine blue and rinse the sample four times, each time with 4 ml sodium veronal buffer.

6. Rinse the sample four times, each time with 4 ml of 0.05 M sodium maleate buffer.

7. Incubate the sample overnight in the dark with 4 ml of 2% uranyl acetate solution.

8. Rinse the sample four times, each time with 4 ml sodium maleate buffer.

Dehydrate sample

9. Dehydrate the sample by incubating in 4 ml of 30%, 50%, 70%, 90%, 95%, and two treatments of 100% ethanol, for 10 min each.

Embed sample

10. Replace the 100% ethanol with a 2:1 dilution of ethanol:resin for 2 hr, then 1:1 ethanol: resin overnight at room temperature.

11. The next day, replace with 100% resin and incubate for most of the day.

12. Meanwhile, fill BEEM capsules with 100% resin and allow the resin to slightly overfill the capsule. Make sure that there are no bubbles in the resin.

    It is a good idea to fill the capsules early in the day and allow them to degas for a few hours

13. Using a pair of fine-tipped forceps, gently pull the Aclar sample, sitting in resin, out of the well. Prop it on its edge at a slight angle, and allow most of the resin to slide off the Aclar.

14. Holding on the sample with the forceps, flip it onto the slightly overfilled top of the BEEM capsule (cell-side down, into the resin) to form a seal.

    Sections can be obtained separately from all three compartments of the chamber, by using a pair of fine-tipped scissors to cut the sample into pieces.

15. Place the BEEM capsule, with the Aclar top, into the 60°C oven and allow polymerizing for about 24 hr.

16. The next day, let the resin cool to room temperature, and then use a pair of forceps to pull the Aclar off the top of the BEEM capsule.

    The cells should be in the resin, away from the Aclar.

Section and view the sample

17. Obtain 70-µm sections using a Leica UC6 ultramicrotome and mount on a 200-mesh hexagonal copper grid.

18. Image using a Zeiss 912AB TEM with an Omega Energy Filter.

    To enhance contrast of cellular membranes, sectioned samples can be post-stained with lead citrate for 2 min, washed twice with water, and incubated another 2 min in 2% uranyl acetate.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Cytosine β-D-arabinofuranoside hydrochloride (AraC)

Prepare AraC (from powder; Sigma) as a 5 mM stock in DMEM. Dilute this to a 500 µM working stock in DMEM. Protect AraC stocks from light. Store up to 1 year, in the dark, at 4°C.

DNase, 1 mg/ml in Neurobasal medium

Dissolve DNase (Sigma) in Neurobasal medium (Invitrogen) at 10 mg/ml concentration. Filter-sterilize using a 0.2-µm filter. Excess stock can be stored (−80°C) at this high concentration. Dilute stock to 1 mg/ml in Neurobasal medium. Divide into 200-µl aliquots and store frozen up to 1 year at –80°C.

Epon Resin (Embed812)

Part A:	5 ml EMbed812 (EM Sciences)
	8 ml dodecenyl succinic anhydride (DDSA; EM Sciences
Part B:	8 ml EMbed812
	7 ml nadic methyl anhydride (NMA EM Sciences)
Part C:	0.47 ml tris(dimethylaminomethyl)phenol (DMP30; EM Sciences)

continued

Part A and Part B can be prepared in advance and stored at 4°C. Bring both parts to room temperature before use. Mix Part A with Part B first, then add Part C. Mix well on a gentle rocker for ~1 hr.

Do not store mixed resin. Aliquots of Parts A/B/C can be stored for up to 6 months at 4°C.

Glutaraldehyde, 2% (v/v), in sodium cacodylate buffer

10 ml ampoule of 10% glutaraldehyde (EM Sciences, cat. no. 16120)
Prepare fresh, by diluting 10% glutaraldehyde 1:5 with 0.2 M sodium cacodylate buffer (see recipe)
Prepare fresh

Methylcellulose (methocel), 2% (w/v), in DMEM

4 g methylcellulose
100 ml distilled water
100 ml 2× DMEM (make from powder using tissue culture–grade water; Invitrogen)

Weigh out 4 g methylcellulose, add to glass bottle, then add 100 ml distilled water (powder will remain clumpy).

NOTE: This initial solution is 4% (w/v) methocel.

Autoclave on liquid setting. Remove from autoclave, add a sterile stir bar, and stir overnight at 4°C. Add 100 ml 2× DMEM, for a final solution that is 2% methocel in 1× DMEM. If clumps remain, stir overnight again. Store up to 1 year at 4°C.

Neuronal medium

Neurobasal medium (Invitrogen)
1× glutamine/penicillin/streptomycin solution (Invitrogen)
1× B-27 medium supplement (Invitrogen)
NGF to 100 ng/ml (Invitrogen, cat. no. 13257-019)
Mix all components except NGF, and filter-sterilize using a 0.2-μm filter
Add NGF last
Store up to 10 days at 4°C

Neurobasal medium with B-27 supplement provides essentially the same medium formulation previously used by our laboratory for rat superior cervical ganglia cultures (Brewer et al., 1993; Ch'ng et al., 2005). This straightforward formulation works equally well for rat and mouse SCG cultures. The final concentration of glutamine is 2 mM, with 100 U/ml penicillin and 100 μg/ml streptomycin.

Neuronal medium containing 1% methocel

Prepare appropriate volume (e.g., 10 ml) of Neurobasal medium (Invitrogen) with 2× glutamine/penicillin/streptomycin (Invitrogen) and 2× B-27 medium supplement (Invitrogen). Filter-sterilize using a 0.2-μm filter. Add NGF (Invitrogen, cat. no. 13257-019) to 200 ng/ml.

Combine this 2× Neurobasal mix with an equal volume (e.g., 10 ml) of 2% methocel in DMEM (see recipe). Mix by pipetting or inverting tube several times.

Store up to 10 days at 4°C.

Osmium tetraoxide (OsO_4), 1%, in sodium veronal buffer

4% aqueous solution of OsO_4 (EM Sciences, cat. no. 19170)
Dilute OsO_4 with freshly made sodium veronal buffer (see recipe) to make a 1% solution
Prepare fresh; do not store

Sodium veronal buffer is recommended for superior membrane preservation with OsO_4 (Hayat, 2000).

Sodium cacodylate buffer (pH 7.2), 0.2 M

42.80 g sodium cacodylate
1000 ml distilled water
Mix all ingredients until dissolved
Adjust pH to 7.2 using 0.1 N HCl
Store up to 6 months at 4°C
Check for clarity before using.

CAUTION: *Cacodylate contains arsenic. Avoid skin contact and inhalation. Avoid strong reducing agents such as aluminum, zinc, sodium borohydride, sulfur dioxide.*

Sodium maleate buffer (pH 5.1), 0.05 M

36 ml 0.1 N NaOH
125 ml 0.2 M maleic acid
339 ml distilled water
Mix solution
Adjust pH to 5.15 using 0.1 N NaOH
Store up to 6 months at room temperature

Sodium veronal buffer (veronal acetate buffer)

Stock solution
2.94 g sodium veronal (sodium 5,5-diethylbarbiturate)
1.94 g sodium acetate
3.40 g sodium chloride
100 ml distilled water stock solution can be stored up to 6 months at room temperature
Working solution
5 ml stock solution (see recipe)
13 ml distilled water
0.25 ml 1.0 M $CaCl_2$
~7 ml 0.1 M HCl
Add the HCl dropwise until the required pH (between 4.2 and 5.2) is obtained
Prepare the buffer fresh every time; do not store

Soybean trypsin inhibitor, 2 mg/ml in Neurobasal medium

Dissolve soybean trypsin inhibitor (SBTI; Sigma) in Neurobasal medium (Invitrogen) at a concentration of 10 mg/ml. Pass through a 0.45-μm filter, then a 0.2-μm filter. Excess stock can be stored (−80°C) at this high concentration. Dilute stock to 2 mg/ml in Neurobasal medium. Divide into 650-μl aliquots and store frozen up to 1 year at –80°C.

Teflon trichambers

Tyler Research Corporation- Edmonton, Canada.

The trichambers are called Camp3A, which is essentially the catalog Camp3 chamber, scaled down to 20-mm diameter (www.tylerresearch.com).

Toluidine blue, 0.25 (w/v), in sodium cacodylate buffer

1 g of toluidine blue
400 ml 0.2 M sodium cacodylate buffer (see recipe)
Mix all ingredients well
Pass solution through a 0.22-μm syringe filter
Store up to 6 months at room temperature

Trypsin, 2.5 mg/ml in HBSS

Dissolve trypsin (Sigma) in Hank's balanced salt solution (HBSS; HyClone) at 10 mg/ml concentration. Pass solution through a 0.2-μm filter. Excess stock can be stored (−80°C) at this high concentration. Dilute stock to 2.5 mg/ml in HBSS. Divide into 100-μl aliquots and store frozen up to 1 year at –80°C.

This method of freezing highly concentrated enzyme stocks, while more dilute enzyme stocks are frozen in single-use aliquots, is both economical and prevents enzyme degradation during multiple freeze-thaw cycles.

Uranyl acetate, 2% (w/v), in sodium maleate buffer

0.5 g of uranyl acetate
25 ml 0.05 M sodium maleate buffer (see recipe)
Mix thoroughly to dissolve
Pass through 0.22-μm syringe filter
Store up to 6 months at room temperature, in the dark
Check clarity of solution before use

COMMENTARY

Background Information

Alpha herpesviruses are neuroinvasive pathogens that spread in a bidirectional, transneuronal fashion through the nervous system of the infected host. When viral particles are moving via plus-end directed microtubule transport in the axons of infected neurons, we term this motion anterograde transport; movement in the opposite direction is termed retrograde. When viral transport leads to viral movement from a presynaptic to a post-synaptic neuron, we call this anterograde spread.

Viral spread has been studied extensively in vivo: inoculum is injected into specific structures of the peripheral or central nervous system of an animal, and the extent of spread is determined by detecting viral antigen in anatomical sections. Because alpha herpesviruses spread between synaptically connected neurons, such experiments are valuable for elucidating neural circuit architecture and connectivity. However, for the purpose of studying large numbers of viral mutants, or defining the exact timing of viral transport within and between cells, it is much easier and less tedious to have a facile in vitro system.

Robert Campenot established a system for compartmentalization of neurons for studying neurite development after modulation of somatic or axonal media environments (Campenot, 1977). These chambers have since been modified, and their application extended to a variety of model systems, including other models of alpha herpesvirus infection (Ziegler and Herman, 1980; Lycke et al., 1984; Penfold et al., 1994; Mikloska and Cunningham, 2001; Karten et al., 2002, 2005). The trichamber cultures we describe differ structurally from the original Campenot chambers: in the original setup, the middle compartment is open to the environment outside the chamber; neurons are plated here, and axonal outgrowth is directed into both side-compartments. In the modified version, the middle compartment is not open to the external environment; dissociated ganglia are plated in one side compartment, from which axons first emerge into the middle, and then the opposite side compartment. Plating neurons in this fashion puts a greater distance between soma and axonal termini; furthermore, placing methocel-containing medium into the middle compartment serves to ensure that no appreciable fluid exchange can occur between the soma- and neurite-containing compartments.

For these reasons, the modified Campenot culture system offers an ideal in vitro

setup for examining the efficiency of directional transport and the spread of viral infection. By co-plating epithelial cells with axons, the efficiency of neuron-to-cell transmission of infection can be investigated. Conversely, retrograde-directed infection can be studied by applying the inoculum to axons, and measuring viral content of the neuronal cell bodies. Because only one-half to one ganglion per chamber (~5000 mature cell bodies) is required to achieve dense, experimentally viable neuronal cultures, the system yields more data in less time than in vivo animal infection experiments.

Performing immunofluorescence and electron microscopy on infected neurons can yield information regarding the mechanisms of directional infection. When imaging experiments are performed on infections of standard dissociated neuronal cultures, the site being observed by microscopy may also contain viral particles from the original inoculum. These conditions complicate data interpretation. Compartmentalization of neurons provides a solution, since the input inoculum is confined to a single-chamber compartment. Furthermore, the direction of viral transport is defined, enabling investigators to confidently describe anterograde-bound or retrograde-bound particles.

Critical Parameters

Not all of the neurons plated in the S-compartment extend axons that reach the N-compartment; additionally, the efficiency of axonal penetration underneath the Teflon barriers will vary. Therefore, if treatment is applied to the neurite compartment, only a subpopulation of cells in the soma compartment will respond to it directly. For this reason, it is crucial to plate the same number of cells in each S-compartment, and to score the efficiency of axonal penetration for each trichamber. After designating axonal density scores, the trichambers must be distributed evenly among the variables being tested.

It is also critical to establish ahead of time the amount of viral inoculum required to infect all cells in the S-compartment synchronously. This can be done with a titration series and immunofluorescence assays, and can be applied to all subsequent experiments involving the same virus and cells. If anterograde-mediated infection is incomplete or asynchronous, it will confound interpretation of the data.

When detector cells are plated in the neurite compartment, it is critical to supplement the cells with 1% fetal bovine serum. In the absence of serum, these cultured cells will not adhere to the bottom of the compartment. While the neuronal medium overall is serum-free, it should be noted that the N-compartment axons are necessarily exposed to serum whenever detector cells are plated there.

Troubleshooting

Axons hit the first barrier, turn away, and never penetrate into the M-compartment

Grooves etched into the bottom of the 35-mm tissue culture dish must be deep enough to generate rough, physical barriers that axons cannot cross. If the grooves are too shallow and smooth, they will not provide sufficient guidance for axonal penetration; the solution is to etch deeper grooves.

During assembly of the trichambers, do not apply too much force on the trichambers to create the watertight seal. Also, take care not to hit the chambers during subsequent medium changes. Either of these mistakes may inhibit axon penetration.

Alternatively, the type of neurons being cultured may not exhibit the robust growth necessary for barrier penetration. Neurons that have been successfully cultured in trichambers include embryonic and newborn rat superior cervical ganglia (SCG; Campenot, 1977; Ch'ng et al., 2005), embryonic mouse SCG neurons (Szpara and Enquist, unpub. observ.), and adult rat dorsal root ganglia (DRG; Kimpinski et al., 1997). Neuronal cultures grown in the original Campenot chambers, where axonal penetration under only one barrier is required, include newborn mouse SCG (Manning et al., 1987), rat DRG (Bi et al., 2006), and rat retinal ganglion cells (Hayashi et al., 2004). A modified Campenot chamber has also been used on cultured hippocampal neurons to study local neurite degeneration (Ivins et al., 1998). To our knowledge, neurites extended by neuron-like cell lines (e.g., PC12 cells) do not robustly penetrate the Teflon barriers in the trichamber system.

Neurons die 2 to 3 days after being plated

Optimization of adhesion substrates and/or neuronal medium is required. It is also possible that the incorrect ganglia are being isolated during dissection; for an example, it can be difficult to distinguish between the embryonic rat nodose ganglion and the superior cervical ganglion due to their physical proximity and morphological similarities. Low neuronal viability can result from treating the ganglia

too harshly during dissociation and trituration. Test the plate-coating, dissection, dissociation, and culturing methods by culturing neurons in 35-mm dishes without the trichamber setup. Make sure that neurons grow successfully in noncompartmented, dissociated cultures before moving on to trichambers.

Infection yields low titer

Infections of either the soma or neurons that produce low titers may result if the axonal density of cultures used in the experiment is low. One solution is to maintain the trichamber cultures several days longer to achieve denser axonal penetration into the N-compartment. Check your conditions by performing the experiment with a viral strain (e.g., wild-type PRV) that has been shown to infect cultured neurons efficiently. Another important control is to check the titer of the S-compartment cell bodies after S-compartment infection.

Neurons are fragile when processed for immunofluorescence

Standard immunofluorescence protocol options apply to the trichamber system. Wash steps and antibody incubations can be lengthened to increase sensitivity and/or decrease background. Care must always be taken to wash gently so that the network of neurons does not peel away. This is especially true late in infection by alpha herpesviruses. While removing the excess silicone grease, work carefully to avoid disrupting the neuronal networks, but swiftly to avoid drying out the sample.

No sample seen in EM

The neuronal network is both fragile and highly interconnected. While the edges may tear during wash steps, they can also lift off and eventually pull the entire neuronal network off the Aclar. Be cautious in wash steps and check that the sample is present throughout all incubations and washes, up to embedding in resin.

If imaging axons in the N-compartment, it may be difficult to find areas of axonal growth dense enough to capture via electron microscopy. The area closest to the Teflon barrier generally contains denser axonal networks.

Anticipated Results

The in vitro development of neurons isolated from embryonic rat or mouse superior cervical ganglia is consistent and predictable. Neurite outgrowth is detectable 1 day after the dissociated neurons are plated. Axons are visible in the M-compartment 3 to 4 days post-plating; they reach the N-compartment 10 to 12 days post-plating. High axonal density in the N-compartment can be achieved by 14 to 21 days. Under these growth conditions, the mature neurons will have only axons in the neurite compartment and not dendrites, which can be confirmed by immunofluorescence. For instance, the axonal marker Tau should be visible throughout cell bodies and all neurites, where the somatodendritic marker microtubule-associated protein 2 (Map2) should only be visible in the neuron soma.

When studying neuron-to-cell spread of wild-type PRV with PK15 detector cells in the N-compartment, the yield in the N-compartment will be $\sim 10^7$ PFU/ml at 24 hr post-infection. Infection of axons, which leads to retrograde transport and virus production by neuron cell bodies in the S-compartment, typically yields 10^5 PFU/ml in the S-compartment at 24 hr post-infection. Virus yield depends on the type of virus used in the study [e.g., PRV, herpes simplex virus 1 (HSV-1), etc.], degree of spread, and duration of infection (e.g., higher titers with more time for replication and/or spread).

Time Considerations

Setting up the trichamber system requires extensive planning and preparation. The average time from set up to initiating an experiment is 2 weeks. The intensive set up phase begins with coating the plates early on the day before a dissection is planned. Dissection tools and silicone grease are autoclaved late in the day or early the next morning. Trichambers are greased and assembled on the morning of a dissection. Neurons are dissected, dissociated, and plated later in the same day. To gain some flexibility in the schedule, plates can be coated with poly-ornithine and/or laminin for longer periods of time (overnight or over several nights). However, trichambers should be assembled no earlier than the evening before a dissection.

During the maintenance phase, the trichamber cultures are treated with an anti-mitotic agent (AraC) 2 days after dissection, and the medium changed for the first time on day 3. Thereafter, medium must be changed every 2 to 3 days. It is advisable to change medium in all the compartments even prior to axonal penetration to the M- and N-compartments. Axonal penetration to the middle compartment is visible within days, although the fine neuronal

processes can be difficult to observe by phase-contrast microscopy. Axons typically reach the second barrier and begin to penetrate into the third compartment around 1 week. By 2 weeks, the axonal penetration in the neurite compartment will likely be sufficient for use; cultures may be maintained as long as 4 weeks if more time for axon growth is needed. However, in some cases, neuronal viability may start to decline after more than 3 weeks in culture.

It is important to assemble extra trichambers, since success of axon penetration is variable, and some chambers will not have adequate penetration even at 2 to 3 weeks post-plating. It is common for novice users to have 50% or less of their trichambers succeed in having good axonal penetration.

Neuronal infections may take several hours or days, depending on the virus, time points examined, and other experimental parameters. Absorption of viral inoculum to the cells or axons is typically performed for 1 hr. Although one should be meticulous when scraping the S- or N-compartment for titering, collecting the contents of one compartment typically takes <1 min.

Immunofluorescence experiments require several wash steps and incubations, 10-min fixation and permeabilization steps, and sequential 1-hr incubations with primary and secondary antibodies. With the required wash steps, the entire procedure for a single sample can take 3 hr. Because processing samples for electron microscopy requires more than one overnight incubation, the procedure can require 3 or more days.

HIV-1 Interactions with Cells: From Viral Binding to Cell-Cell Transmission

Alicia M. Janas[1] and Li Wu[1]

[1]Department of Microbiology and Molecular Genetics, Medical College of Wisconsin, Milwaukee, Wisconsin

ABSTRACT

Characterization of HIV-1 interactions with host cells is critical for cell biology studies of HIV-1. This unit describes a set of methods and protocols to perform quantitative assays of HIV-1 binding, internalization, infection, and cell-cell transmission. The protocols include: (1) generating infectious single-cycle or replication-competent HIV-1 stocks, (2) an HIV-1 binding and internalization assay, (3) HIV-1 infection of target cells and quantification of viral infection, and (4) HIV-1 cell-cell transmission assays. These functional assays provide useful tools to quantitatively study HIV-1 infection and viral transmission. *Curr. Protoc. Cell Biol.* 43:26.5.1-26.5.20. © 2009 by John Wiley & Sons, Inc.

Keywords: human immunodeficiency virus type 1 (HIV-1) • binding • internalization • infection • viral transmission • interactions

INTRODUCTION

Human immunodeficiency virus type 1 (HIV-1) is the etiological agent of acquired immune deficiency syndrome (AIDS), the leading infectious disease worldwide. Despite great efforts and tremendous progress in HIV-1 and AIDS studies, eradication of HIV-1 infection and treatment of AIDS remain a long-term challenge (Fauci, 2007; Karlsson Hedestam et al., 2008). Understanding the multifaceted interactions between HIV-1 and host cells can potentially facilitate the development of therapeutic interventions against HIV-1 infection (Wu and KewelRamani, 2006; Goff, 2007). Quantitative analysis of HIV-1 interactions with host cells represents a critical aspect in the cell biology studies of HIV-1 infection and dissemination. In this unit, the use of a set of quantitative assays to measure HIV-1 binding (see Basic Protocols 1 and 2), endocytosis (see Basic Protocol 2), infection in target cells (see Basic Protocol 3), and cell-cell viral transmission (see Basic Protocol 4) are described. These quantitative assays provide useful tools to study HIV-1 interactions with host cells.

STRATEGIC PLANNING

Biosafety Precautions

Infection of replication-competent HIV-1 can cause AIDS in humans. In general, performing experiments that involve using infectious HIV-1 should carefully follow the *Virology Manual for HIV Laboratories* (available for download from the Web site listed in Internet Resources). This manual was developed by the Division of AIDS, National Institute of Allergy and Infectious Diseases, National Institutes of Health (NIH) and collaborating investigators. The manual addresses the biosafety issues of HIV laboratories in detail, and provides recommendations for specimen processing, storage, shipping, etc. Based on the manual, the following areas of the biosafety guidelines should be followed to effectively eliminate or minimize accidental exposure to HIV-1: (1) the use of universal precautions; (2) establishing appropriate engineering controls; (3) implementing appropriate work practice controls; (4) using necessary personal protective equipment; and (5) implementing appropriate housekeeping procedures.

HIV Research Reagents

The NIH AIDS Research and Reference Reagent Program is a unique worldwide resource of state-of-the-art reagents for HIV and other pathogens. The program provides registered researchers with a variety of valuable reagents for studying HIV and other retroviruses. Many of the expression plasmids, cell lines, and other reagents described in this unit can be obtained from the program. Refer to the Web site listed in Internet Resources for details.

BASIC PROTOCOL 1

GENERATING INFECTIOUS SINGLE-CYCLE OR REPLICATION-COMPETENT HIV-1 STOCKS

This method describes cellular transfection with HIV-1 proviral DNA as a common protocol to generate HIV-1 stocks. Replication-competent HIV-1 can be generated by transfection of human or animal cell lines with a full-length HIV-1 proviral construct (Adachi et al., 1986). Additionally, human $CD4^+$ T cells or activated human peripheral blood mononuclear cells can be infected with replication-competent HIV-1 derived from transfection, and then expanded viral stocks can be obtained from the supernatants several days after the infection (Freed et al., 1995; Dong et al., 2007). Single-cycle reporter HIV is an infectious HIV vector that can establish an integrated provirus but cannot undergo additional cycles of replication, owing to an inactivated viral envelope gene. The viral genome encodes a reporter gene, which is expressed in infected permissive cells, enabling measurement of infectivity.

To generate single-cycle HIV-1, an *env*-deleted/inactivated HIV-1 proviral DNA and a construct expressing HIV-1 envelope glycoproteins (Env) can be cotransfected into cells (Aiken, 1997; Wu et al., 2002b: Dong et al., 2007; Wang et al., 2007a,b; Janas et al., 2008). This method is also termed as HIV-1 pseudotyping. Based on different experimental purposes, various viral Env proteins from different tropic HIV-1 strains, simian immunodeficiency virus, or vesicular stomatitis virus G protein (VSV-G) can be incorporated in HIV-1 particles to generate single-cycle HIV-1 vectors (Aiken, 1997; Wu et al., 2002a; Dong et al., 2007; Janas et al., 2008). VSV-G-pseudotyped HIV-1 efficiently enters a broad range of cell types through a low-pH-dependent endocytic pathway (Aiken, 1997; Dong et al., 2007; Janas et al., 2008).

Materials

2.5 M $CaCl_2$
Tissue-culture-grade double distilled water
2× BES-buffered saline (BBS; see recipe)
Human embryonic kidney cell line HEK293T cells (a gift from Dr. V. KewalRamani, *vineet@ncifcrf.gov*; Wang et al., 2007a,b)
HEK293T cell culture medium (see recipe), 37°C
HIV-1 proviral DNA pHIV-Luc (pLai3ΔenvLuc2) *env*-deleted and *nef*-inactivated viral genome with a luciferase reporter insertion, and contains all other viral genes (Yamashita and Emerman, 2004; gifts from Michael Emerman, Fred Hutchinson Cancer Research Center; *memerman@fhcrc.org*)
HIV-1 full-length proviral construct pNL4-3 and pNLAD8 (Freed et al., 1995; gifts from Eric Freed, National Cancer Institute, Frederick, Maryland)
Expression plasmids: R5-tropic Env of HIV-1_{JRFL} (pJRFL) or HIV-1_{ADA} (pADA), X4-tropic Env of HIV-1_{HXB2} (pHXB2), and VSV-G-expressing pVSV-G (gifts from Vineet KewalRamani, National Cancer Institute, Frederick, Maryland; Dong et al., 2007; Wang et al., 2007a,b)
Green fluorescent protein–expressing HIV-1 vector (pHIV-GFP) generated from a pNL4-3-based HIV-1 provirus with deletions in the *env*, *vif*, *vpr*, *vpu*, and *nef* genes; the *GFP* gene was inserted in place of the *nef* open reading frame (Unutmaz et al., 1999)

Human $CD4^+$ T cell line Hut/CCR5 cells (a gift from Dr. V. KewalRamani, *vineet@ncifcrf.gov*; Wang et al., 2007a,b)

0.2-μm sterile filters
Tissue culture plates (standard 10-cm diameter dishes or 6-well plates)
37°C water bath
5- ml round-bottom, polystyrene tubes (Falcon cat. no. 2058)
37°C, 5% CO_2 cell culture incubator designated for HIV-1 infections
15-ml conical tubes
Refrigerated centrifuge
2-ml cryotubes (sterile)

Additional equipment and reagents for cell culture (*UNIT 1.1*)

CAUTION: Follow biosafety protocol and use 10% bleach to inactivate HIV-1 in the plates, tubes, plastic pipets, etc.

Prepare transfection reagents

1. To prepare 0.25 M $CaCl_2$, dilute 2.5 M stock with tissue culture quality water. Sterilize the solution using a 0.2-μm sterile filter, and freeze 10-ml aliquots at −20°C.

2. Prepare 2× BES-buffered saline (BBS), filter sterilize using a 0.2-μm filter, and freeze 10-ml aliquots at −20°C.

   The solution pH should be 6.96 with a ± 0.02 variance. Adjust pH with 10 M NaOH if necessary. The $CaCl_2$ and BBS solutions can be stored upto 6 months at −20°C.

   Alternatively, commercially available transfection kits (e.g., Mammalian Transfection Kit, Stratagene cat. no. 200385) can be used.

Plate cells

3. The day before transfection, seed HEK293T cells in 10 cm-diameter plates at 2.5–3 × 10^6 cells in 10 ml cell culture medium.

   Alternatively, for transfections in 6-well plates, seed 3.0 × 10^5 cells/well in 2 ml of culture medium. Cells should reach ∼80% confluence 24 hr later. The authors recommend not to plate cells that have been overly confluent for >1 day.

Transfect with HIV

4. Replace culture medium with fresh culture medium 1 to 3 hr before transfection.

   This step is optional if medium of cultured cells appear to be fresh. Cold medium should be prewarmed to 37°C. Use extra caution when replacing medium since cells can easily detach.

5. Quickly thaw 2× BBS and 0.25 M $CaCl_2$ aliquots in a 37°C water bath and leave at room temperature after thawing.

6. Prepare appropriate amounts of DNA that will be used in transfection according to Table 26.5.1.

   When using full-length HIV-1 proviral DNA (pNL4-3 or pNLADA, etc.) to generate replication-competent HIV-1, do not add Env-expressing vectors to the transfection mixture.

7. Dispense appropriate proviral vector DNA and desired Env-expressing vector DNA into 5-ml polystyrene tubes.

8a. For 10-cm diameter plates, combine 875 μl of 0.25 M $CaCl_2$ with prepared DNA and mix.

8b. For each sample well of a 6-well plate, combine 175 μl of 0.25 M $CaCl_2$ with prepared DNA and mix.

Table 26.5.1 Amount of HIV Proviral DNA and Env-Expressing Vectors Used for Transfection[a]

Cell culture plates (cell number)	HIV proviral DNA(μg) (pHIV-Luc, pHIV-GFP, or pNL4-3, etc.)	Envelope (Env)-expressing vectors[b] (one of the following expressing vector)	
		HIV Env-expressing vectors (μg) (pJRFL or pHXB2, etc.)	pVSV-G (μg)
10-cm plate (2.5×10^6)	10	10	5
6-well plate (3.0×10^5/well)	2	2	1

[a]All DNA used in transfection should be prepared with Qiagen DNA purification kits or equivalent products to ensure the purity of DNA and minimal endotoxin contamination.

[b]When using full-length HIV-1 proviral DNA (pNL4-3 or pNLADA, etc.) to generate replication-competent HIV-1, there is no need to add Env-expressing vectors.

9. Add 2× BBS (pH 6.95) to the 0.25 M $CaCl_2$ and DNA mixture.

   For 10-cm diameter plates, add 875 μl of 2× BBS. For each well of a 6-well plate, add 175 μl of 2× BBS. Add 2× BBS drop wise to the $CaCl_2$ and DNA mixture, and then gently vortex the transfection mixture for 2 to 5 sec. The solution should turn cloudy from precipitation.

10. After 13 to 15 min, gently and evenly add transfection mixture drop wise to HEK293T cells.

    It is recommended not to exceed the 15-min incubation time period.

11. Place cells in a 37°C, 5% CO_2 incubator designated for HIV-1 infections overnight.

    DNA precipitation will form slowly and evenly overnight.

12. On the next day, gently aspirate supernatants of HEK293T cells, and replace with prewarmed (37°C) cell culture medium.

    The authors recommend replacing medium 16 to 20 hr post-transfection. Replacing the medium will reduce the number of cells that may detach from the plate. Use appropriate biosafety precautions when replacing HIV-containing medium; supernatant is now infectious. All tissue culture work from here on should be performed in a biosafety hood using appropriate biosafety precautions.

Harvest viral stocks

13. Two days post-transfection, collect supernatants in 15-ml conical tubes, and centrifuge 5 min at 270 × *g*, 4°C.

14. Carefully transfer supernatants to a fresh tube, avoid disturbing cell pellet.

    Cellular debris can be further removed via filtering the supernatant through a 0.45-μm filter.

15. Dispense viral supernatant to 2-ml cryotubes (0.5 to 1 ml/vial), and then quickly freeze in a −80°C freezer.

16. Generate replication-competent HIV-1 by infecting $CD4^+$ T cells.

    Alternatively, to expand replication-competent HIV-1 stocks in $CD4^+$ T cells, Hut/CCR5 cells or activated peripheral blood lymphocytes (1×10^6) can be infected with HEK293T-derived HIV-1_{NLAD8} (5 ng p24 equivalent), and supernatants will be harvested 5 days post-infection. Refer to steps 13 to 15 for harvesting viral supernatants.

    HIV-1 Gag p24 protein concentrations of HIV-1_{NLAD8} stocks can be measured using an enzyme-linked immunosorbent assay (ELISA) according to the kit instruction.

HIV-1 BINDING AND INTERNALIZATION ASSAYS

BASIC PROTOCOL 2

HIV-1 can bind to cells through the viral receptor CD4 and multiple cellular attachment factors (Turville et al., 2001, 2002; Geijtenbeek et al., 2002; Gummuluru et al., 2003). A C-type lectin, dendritic cell-specific intercellular adhesion molecule 3 grabbing non-integrin (DC-SIGN), functions as an attachment factor of HIV-1 and facilitates HIV-1 binding, infection, and viral transmission (Geijtenbeek et al., 2000; Wu and KewalRamani, 2006). DC-SIGN also mediates HIV-1 internalization in cells (Kwon et al., 2002; Wu and KewalRamani, 2006; Wang et al., 2007a). This protocol describes HIV-1 binding and internalization assays using Raji/DC-SIGN cells as an example. Raji/DC-SIGN cells are derived from a human Raji B cell line and stably express high levels of exogenous human DC-SIGN (Wu et al., 2004 a,b; Wang et al., 2007a). CD4- and DC-SIGN-negative parental Raji cells are used as a background control.

HIV-1 incubated with Raji/DC-SIGN cells at 4°C primarily remains on the cell surfaces. After several washes, a cell surface–bound virus can be measured by quantifying cell-associated HIV-1 Gag p24 (Wang et al., 2007a). In contrast, Raji/DC-SIGN cells incubated with HIV-1 at 37°C can bind virus on cell surfaces and internalize HIV-1 intracellularly. When cells are incubated with HIV-1 at 4°C, and then washed and treated with a proteolysis reagent, such as trypsin, the majority of cell surface–bound HIV-1 can be stripped (Wang et al., 2007a,b). When cells are incubated with HIV-1 at 37°C, washed, and then treated with trypsin, the cell-associated HIV-1 represents internalized virus as well as cell-surface-bound viruses that are protected from the proteolysis (Wang et al., 2007a,b).

To examine the cell-HIV-1 interactions in the absence of potentially confounding effects of productive viral infection, aldrithiol-2 (AT-2)-inactivated HIV-1 can be used in the binding and internalization assays (Rossio et al., 1998; Wang et al., 2007a). Inactivation of HIV-1 with AT-2 modifies the essential zinc fingers in the viral nucleocapsid protein, but does not alter virion Env, thereby maintaining HIV-1 binding and fusion with target cells (Rossio et al., 1998). Thus, AT-2-inactivated HIV-1 is conformationally authentic and interacts with cells similarly to infectious HIV-1 (Rossio et al., 1998; Frank et al., 2002; Wang et al., 2007a,b). Depending on different experimental purposes, p24-quantified infectious HIV-1 and different cell types can also be used to measure viral binding and internalization in similar assays.

Materials

Raji cells, Raji/DC-SIGN cells or another appropriate cell type (NIH AIDS Research and Reference Reagent Program, Raji cells cat. no. 9944, Raji/DC-SIGN cells cat. no. 9945; *http://www.aids.reagent.org/index.cfm*)
Sterile PBS without Ca^{2+} and Mg^{2+} (CMF-PBS; *APPENDIX 2A*), cold
Cell culture media (see recipes)
AT-2–inactivated R5-tropic HIV (Bal/Supt1-CCR5 cl30; from Jeffery Lifson, AIDS Vaccine Program, SAIC-Fredrick)
RPMI-1640 medium with 10% (v/v) fetal bovine serum (FBS)
0.25% (w/v) trypsin without EDTA
1× cell lysis buffer (see recipe)
10% (v/v) Triton X-100
HIV-1 p24 ELISA kit (anti-p24-coated plates from the AIDS Vaccine Program, SAIC, Frederick, Maryland) or p24 ELISA kit (PerkinElmer)

1.5-ml screw-cap tubes and microcentrifuge tubes
Refrigerated microcentrifuge (e.g., rotor model F241.5P in Beckman Coulter microcentrifuge 22R centrifuge)
37°C water bath or incubator

Additional equipment and reagents for cell culture (*UNIT 1.1*)

Prepare cells and virus for incubation

1. Dispense Raji cells and Raji/DC-SIGN cells (3×10^5 per sample) into 1.5-ml microcentrifuge tubes. Centrifuge cells 3 min at ~900 × *g*, room temperature. Remove supernatant carefully.

   Sample numbers are dependent on specific experimental needs.

2. Wash cells with 0.5 ml CMF-PBS. Centrifuge cells 3 min at 900 × *g*, room temperature. Remove supernatant carefully.

3. Resuspend cells in culture medium containing 20 ng of p24-equivalent AT-2-inactivated HIV-1.

   The authors recommend that the final volume be raised to 200 μl using RPMI-1640 medium with 10% FBS. For cells being incubated at 4°C, the medium should be chilled. Also, warm medium can be used for the samples that will be incubated at 37°C.

4. Incubate 2 hr at desired temperature (4°C or 37°C).

   The screw-cap tubes should be slightly loosened during virus incubation. Incubation of samples at 4°C can be performed on ice in a 4°C refrigerator.

Wash, trypsinize, and lyse cells

5. After virus incubation, centrifuge cells 3 min at 900 × *g*, room temperature. Carefully remove supernatant and then wash the cells as in step 2, with 1 ml of CMF-PBS three to five times to remove unbound cell-free HIV-1.

6. Treat desired samples with 0.25% trypsin, and incubate cells 4 min at room temperature.

   The trypsin concentration and incubation time should be predetermined and adjusted when using different cell types.

7. Neutralize trypsin with cell culture medium containing 10% FBS. For samples not being treated with trypsin, incubate in cell medium only.

8. Centrifuge cells 3 min at 900 × *g*, 4°C. Remove supernatant carefully, avoiding disruption of the pellet.

9. Resuspend the pellet in 1 ml cold CMF-PBS, centrifuge cells 3 min at 900 × *g*, 4°C and remove supernatant carefully. Wash three to five times.

Lyse cells

10. Resuspend cell pellet with 200 μl of 1× cell lysis buffer. Add 20 μl of 10% Triton X-100 (1/10 vol) to each sample to release p24 according to the ELISA kit manufacturer's instructions.

11. Incubate samples 1 hr at 37°C to inactivate virus, if infectious HIV-1 stocks are used.

12. Analyze samples by p24 ELISA assay according to kit instructions.

    Alternatively, samples can be stored up to 6 months at −80°C, and analyzed in the future.

BASIC PROTOCOL 3 HIV-1 INFECTION OF TARGET CELLS AND QUANTIFICATION OF VIRAL INFECTION

Stable cell lines that express a reporter gene upon HIV-1 infection can be used to titrate HIV-1 infectivity. This protocol describes a flow cytometry based HIV-1 titration assay using GHOST cells, which are human osteosarcoma cells expressing high levels of CD4 and CCR5. These cells contain a *GFP* gene under the control of the long terminal repeat (LTR) promoter of HIV-2, which is expressed during HIV-1 infection via Tat

transactivation, acting as a sensitive indicator of HIV-1 infection (Cecilia et al., 1998; *UNIT 20.2*). GHOST cells expressing the CXCR4 and CCR5 coreceptor are referred to as GHOST/X4/R5 cells (Cecilia et al., 1998; Wu et al., 2002b). Approximately 40% of GHOST/X4/R5 cells are positive for CD4; 84% of the cells are positive for CXCR4; 66% of the cells are positive for CCR5. The parental GHOST cells are 3.8% positive for CXCR4 and 0.8% positive for CCR5 (Cecilia et al., 1998).

Materials

HIV indicator cell line: GHOST/X4/R5 cells (available from NIH AIDS Research and Reference Reagent Program cat. no. 3942 or from Dr. Vineet KewalRamani, National Cancer Institute, Frederick, Maryland)
Cell culture medium (see recipe)
Infectious HIV-1 stocks
Sterile PBS without Ca^{2+} and Mg^{2+} (CMF-PBS; *APPENDIX 2A*)
Sterile 1 mM EDTA
0.05% (w/v) trypsin with 0.2 g/liter EDTA, optional
4% (w/v) paraformaldehyde
CMF-PBS/2% (v/v) FBS

12-well tissue culture plate
37°C incubator
Centrifuge with plate rotor
Flow cytometer

Additional reagents and equipment for cell culture (*UNIT 1.1*)

CAUTION: Follow the biosafety protocol and use 10% bleach to inactivate HIV-1 in the plates, tubes, plastic pipets, etc.

Plate cells

1. The day before infection, plate 2×10^4 cells per well in a 12-well plate.

   Cells can be plated in nonselective culture medium for single-round infection experiments. To maintain high level expression of receptor and coreceptors, GHOST/X4/R5 cells should be cultured in selective medium.

Infect with virus

2. Add appropriate volumes of HIV-1 to GHOST/X4/R5 cells for incubation (day 1).

   Use appropriate biosafety precautions when handling virus stocks, and perform experiment in a designated biosafety cabinet. When titering virus pseudotyped with JRFL or HXB2, use 50, 100, and 200 μl of viral stocks for infections. When titering virus pseudotyped with VSV-G, use 12.5, 25, and 50 μl of viral stocks for infection. It is recommended not to use more than 50 μl of HIV-VSV-G for titration due to the cytotoxic effects of VSV-G. For replication-competent virus, 25 to 100 μl of viral stocks can normally be used in infections. Infections can be performed in a final volume of 300 μl per well of a 12-well plate. Alternatively, 10 μg/ml of polybrene can be added in the infection to enhance the infection efficiency. It is important that a mock control (no virus input) is always included in the experiment.

3. After incubating the virus 2 hr at 37°C, raise the volume to 1 ml with cell culture medium.

   Alternatively, supernatant can be replaced with 1 ml of medium, or infections can be performed in a 0.5-ml final volume overnight (not recommended for VSV-G-pseudotyped HIV-1 due to cytotoxicity).

4. Replace medium 24 hr post-infection (day 2).

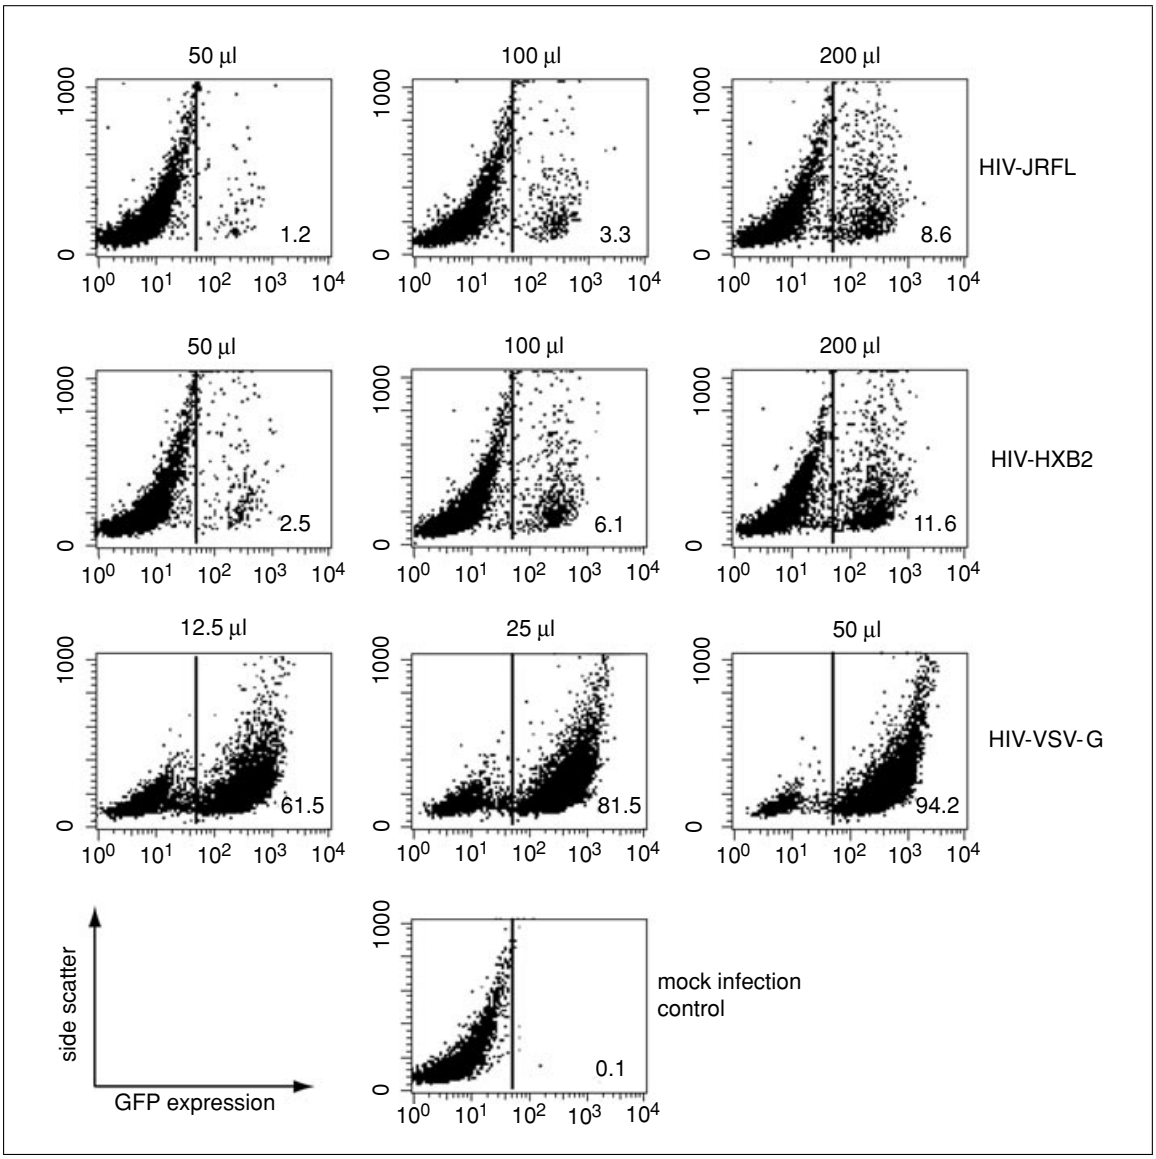

Figure 26.5.1 Infectivity titration of HIV-1 pseudotyped with different envelope proteins. HIV-1 indicator cells (GHOST/X4/R5) were infected with various single-cycle HIV-1 pseudotypes with different viral inputs. GFP-positive cells were measured 3 days post-infection by flow cytometry (FACSCalibur, BD Bioscience) and analyzed with CellQuest Pro program (BD Bioscience). GFP-positive cell populations were determined based on the settings of mock control, which used medium instead of virus in the infection assay. A total of 10,000 cells per sample were acquired and analyzed. The amounts of viral input are labeled on the top of each dot plot. The percentages of GFP-positive cells are shown in the bottom right corner of each dot plot.

Harvest infected cells

5. One or two days after replacing the medium, harvest infected GHOST/X4/R5 cells (day 3 or 4) by gently washing cells two times with PBS as follows: add 300 µl of PBS containing 1mM EDTA to each well, and place on a shaking platform for 15 min at room temperature.

   Alternatively, cells can be trypsinized (0.05% trypsin with EDTA), and neutralized with 10% FBS-containing DMEM.

6. Before proceeding to step 7, wash cells with 1 ml CMF-PBS. To calculate the virus titer, count and calculate the average total cell number/sample when harvesting cells. Also count the mock control.

Table 26.5.2 Summary Results of Single-Cycle HIV-1 Titration Assay[a]

Viral input (μl/sample)[c]	GFP-positive cells (%) [viral titer infectious unit per ml (IU/ml)][b]					Average titer[d] (IU/ml)
	12.5	25	50	100	200	
HIV-1 types HIV-JRFL (R5-tropic)	ND	ND	1.16 [3.22 × 10^5]	3.34 [4.64 × 10^5]	8.56 [5.95 × 10^5]	4.60 × 10^5
HIV-HXB2 (X4-tropic)	ND	ND	2.46 [6.84 × 10^5]	6.06 [8.42 × 10^5]	11.60 [8.06 × 10^5]	7.77 × 10^5
HIV-VSV-G	61.52 [6.84 × 10^7]	81.54 [4.53 × 10^7]	94.22 [2.62 × 10^7]	ND	ND	4.66 × 10^7

[a]GHOST/X4/R5 cells and single-cycle HIV-1 pseudotypes were used in the titration assay (see Basic Protocol 3).

[b]Values in brackets denote individual virus titer calculated as the following:
virus titer [infectious unit (IU)/ml] = cell number × %GFP-positive cells × dilution factor. The dilution factor = 1000 μl/viral input (μl). ND, not determined.

[c]Average cell number, 1.39 × 10^6/sample.

[d]Average titer of the results derived from the three different viral inputs.

Fix cells

7. Resuspend samples in 300 μl of CMF-PBS. Add 300 μl of 4% paraformaldehyde to each sample for a final concentration of 2% paraformaldehyde.

   The authors recommend thoroughly pipetting up and down to mix cells in paraformaldehyde solution to prevent cell clumping.

8. Incubate cells on ice for at least 1 hr.

   The authors recommend not exceeding 6 hr of incubation time.

9. After incubation, add 1 ml of CMF-PBS to wash cells and centrifuge cells 15 sec at ~4000 × *g*, room temperature.

10. Resuspend cells in 200 μl of CMF-PBS/2% FBS.

Detect GFP expression in infected cells

11. Analyze cells by flow cytometry for GFP expression.

    There should be approximately over a ten-fold shift in the mean GFP-fluorescence of infected cells over the mock control. See Figure 26.5.1 for examples.

12. Calculate virus titer based on the following equation:

infectious units (IU)/ml = (cell number) × (%GFP-positive cells) × (dilution factor)

For example, using 200 μl of HIV-JRFL sample, the calculation would be as follows: (1.39 × 10^6) × 8.56% × 5 = 5.95 × 10^5 IU/ml. Refer to Table 26.5.2 for calculated virus titers as examples.

VIRAL INFECTION AND QUANTIFICATION USING REPORTER HIV-1

ALTERNATE PROTOCOL 1

Rather than using HIV-1 indicator cell lines in viral infection assays, a reporter gene such as *luciferase* or *GFP* engineered into the HIV-1 genome can be expressed in infected cells and be used as a marker for viral infection (Unutmaz et al., 1999; Wu et al., 2002b). These virally expressed reporters in the infected cells can be measured to quantify HIV-1 infection. Additionally, when using wild-type, replication-competent HIV-1 in infection assays, HIV-1 p24 in the supernatant of infected cells can be measured to quantify

viral production (Dong et al., 2007; Wang et al., 2007a). These assays are presented as an alternative method of HIV-1 infection assays, in which, Hut/CCR5 cells, a human $CD4^+$ T cell line that expresses high levels of CD4, CXCR4, and CCR5, are used as an example. Now that the virus stocks have been quantified, cells can be infected at a specific multiplicity of infection (MOI).

Materials

HIV-1 stocks with known viral infectivity (see Basic Protocol 3)
Hut/CCR5 cells (available from Dr. Vineet KewalRamani, *vineet@ncifcrf.gov*; Wang et al., 2007a,b)
Cell culture medium (see recipes)

1.5-ml screw-cap microcentrifuge tubes
24-well culture plates
37°C incubator

Additional equipment and reagents for cell culture (*UNIT 1.1*)

Infect cells with virus

1. To calculate the volume of virus used at a specific MOI, use the following equation:

MOI = [(virus stock IU/ml) × (volume of virus used)]/(number of cells in infection)

An example calculation is: 1×10^5 Hut/CCR5 cells are infected at a 0.5 MOI by a virus stock with a titer of 1.67×10^6 IU/ml. Therefore determine the amount of virus needed to infect 1×10^5 cells at a 0.5 MOI as follows: [(1.67×10^6 IU/ml) × (volume of virus used)]/(1×10^5 cells) = 0.5 MOI, where the volume equals 30 μl per sample.

2. Before adding virus, wash cells once with 1 ml CMF-PBS in 1.5-ml screw-cap microcentrifuge tubes. Centrifuge cells (1×10^5) 3 min at ~900 × *g*, room temperature. Remove supernatant. Resuspend cell pellet in 1 ml of PBS. Centrifuge again, and carefully remove supernatant.

   If using adherent cells, see Basic Protocol 3, use of GHOST/X4/R5 cells, for further details. Hut/CCR5 cells can be cultured in nonselective culture medium for single-round infection experiments. To maintain high level expression of receptor and coreceptors, Hut/CCR5 cells should be cultured in selective medium.

3. Add desired amount of virus to cells and mix well by pipetting up and down.

   Depending on the volume of virus used, the authors recommend a final incubation volume between 200 μl and 500 μl for optimal infection conditions. Prewarmed cell culture medium can be added so that the final volume for the virus incubation is within the recommended incubation volume. Additionally, incubations should be performed in 1.5-ml screw-cap tubes. Always include a mock control (no virus) with all virus infection experiments.

4. Incubate cells 1.5 to 2 hr in a 37°C incubator.

   The authors recommend loosening the caps of samples during incubation. Alternatively, viral incubation can be performed using 24-well culture plates.

5. After virus incubation, wash the samples three times with 1 ml PBS as in step 2.

6. Resuspend cells in 1 ml culture medium using 24-well culture plates and place cells in culture (the seeding density is ~1×10^5 cells/ml).

7. Harvest cells 3 days after infection. Use harvested cells for detection of viral infection using Support Protocol 1 or 2.

DETECTION OF LUCIFERASE ACTIVITY IN INFECTED CELLS

SUPPORT PROTOCOL 1

If using luciferase reporter HIV-1, viral infection can be detected by measuring luciferase activity in infected cell lysates.

Materials

Cell samples
PBS (*APPENDIX 2A*)
5× passive lysis buffer (Promega)
Luciferase assay kit (Promega)

1.5-ml screw-cap microcentrifuge tubes
Microcentrifuge (e.g., rotor model F241.5P in Beckman Coulter microcentrifuge, 22R centrifuge)
Platform shaker
96-well black plate (Thermo)
Chemluminescence microplate reader (Wallac 1420 VICTOR2 Multilabel Plate Reader)

Wash cells

1. Transfer each sample of cells (2×10^5 cells) to a 1.5-ml screw-cap microcentrifuge tube, and centrifuge 3 min at ~900 × *g*, room temperature.
2. Remove supernatant, and resuspend pellet in 1 ml of PBS to wash cells.
3. Centrifuge 3 min at 900 × *g*, room temperature. Remove supernatant.
4. Resuspend cell pellet in 100 µl of 1× passive lysis buffer.

   The 1× passive lysis buffer should rapidly inactivate HIV-1. As an extra precaution, lysates can be transferred to a fresh tube to ensure that sample does not contain any infectious virus.

5. Shake samples for 5 min at room temperature.

   Incubation time can be increased to 10 min if using more than 5×10^4 cells per sample.

6. Centrifuge samples 2 min at ~4000 × *g*, room temperature.
7. If storing samples up to 6 months at −80°C to run luciferase assay in the future, transfer supernatant to a fresh microcentrifuge tube. Otherwise, transfer samples (40 µl in duplicate) directly to a 96-well black plate for detection of luciferase activity.

   Do not disrupt the pellet when dispensing.

8. Perform the luciferase assay according to manufacturer's instructions. Dispense luciferase substrate in 100-µl volumes to each well of the 96-well plate.
9. Detect luciferase activity of cell lysates on a microplate reader according to manufacturer's instructions.

GFP DETECTION IN INFECTED CELLS

SUPPORT PROTOCOL 2

If using GFP reporter HIV-1, viral infection can be detected by measuring GFP expression in infected cells.

Materials

Infected cells
4% (w/v) paraformaldehyde
Sterile PBS without Ca^{2+} and Mg^{2+} (CMF-PBS; *APPENDIX 2A*)
CMF-PBS/2% (v/v) FBS

1.5-ml screw-cap microcentrifuge tubes
Microcentrifuge (e.g., rotor model F241.5P in Beckman Coulter microcentrifuge, 22R centrifuge)
Flow cytometer

1. Transfer infected cells (2×10^5 cells) to a 1.5-ml screw-cap microcentrifuge tube and centrifuge 3 min at $900 \times g$, room temperature. Wash infected cells with 1 ml of PBS.
2. Resuspend the samples in 300 µl of PBS. Add 300 µl of 4% paraformaldehyde to each sample for a final concentration of 2% paraformaldehyde.

   The authors recommend thoroughly pipetting up and down to mix cells in paraformaldehyde solution to prevent cell clumping.
3. Incubate cells for at least 1 hr on ice.

   The authors recommend not exceeding 6 hr of incubation time.
4. After incubation, add 1 ml of CMF-PBS to wash cells and centrifuge cells 15 min at $\sim$4000 $\times$ g, room temperature.
5. Resuspend cells in 200 µl of CMF-PBS/2% FBS.
6. Analyze for GFP expression by flow cytometry.

   Include a positive control and a mock infection control. There should be approximately a 10- to 20-fold shift in the mean GFP-fluorescence of efficiently infected cells over the mock control.

SUPPORT PROTOCOL 3

HIV-1 P24 DETECTION IN SUPERNATANTS OF INFECTED CELLS

If using a replication-competent HIV-1 that does not encode a reporter gene, viral infection and production can be quantified by measuring HIV-1 p24 in cell supernatants.

Materials

Infected cells
10% (w/v) Triton X-100
HIV-1 p24 ELISA kit (anti-p24-coated plates from the AIDS Vaccine Program, SAIC, Frederick, Maryland) or p24 ELISA kit (PerkinElmer)

Refrigerated centrifuge
1.5-ml screw-cap microcentrifuge tubes
37°C incubator

Detect HIV-1 p24

1. Centrifuge infected cells ($\sim 2 \times 10^5$) 5 min at $\sim 900 \times g$, 4°C. Collect supernatant carefully, avoiding disruption of the pellet.
2. Transfer supernatant to a fresh 1.5-ml screw-cap microcentrifuge tube.
3. Add 1/10 vol of 10% Triton X-100 to each sample according to HIV-1 p24 ELISA kit manufacturer's instructions.
4. Incubate samples 1 hr at 37°C.
5. Analyze samples by p24 ELISA assay according to kit manufacturer's instructions.

   Alternatively, samples can be stored up to 6 months at −80°C, and analyzed in the future.

HIV-1 CELL-CELL TRANSMISSION ASSAYS

BASIC PROTOCOL 4

Cell-cell transmission can enhance HIV-1 infection 100 to 1000-fold compared with cell-free viral infection (Dimitrov et al., 1993). Elucidating the mechanisms of cell-cell transmission–mediated HIV-1 infection can facilitate the understanding of viral pathogenesis and potentially aid in HIV-1 interventions (Wu and KewalRamani, 2006; Piguet and Steinman, 2007). HIV-1-pulsed dendritic cells efficiently transmit HIV-1 to co-cultured $CD4^+$ T cells (Wu and KewalRamani, 2006), which has been used as an in vitro model to study the mechanisms underlying cell-cell transmission (Cameron et al., 1992; Pope et al., 1994; Geijtenbeek et al., 2000; Wu et al., 2002a,b; Dong et al., 2007; Wang et al., 2007a,b). Exogenous DC-SIGN expressed on certain types of cells can mediate efficient HIV-1 *trans*-infection of cocultured $CD4^+$ T cells (Wu et al., 2004a,b; Wang et al., 2007a,b). As an example, this protocol describes an HIV-1 transmission assay using Raji/DC-SIGN cells as donor cells and Hut/CCR5 T cells as targets. CD4- and DC-SIGN-negative parental Raji cells are used as background controls. The viral transmission assay is referred to as the HIV-1 capture assay, which is performed when virus donor cells are preincubated with HIV-1 and washed to remove cell-free virus, after which $CD4^+$ T cells were added in co-culture as infection targets.

Materials

Raji/DC-SIGN cells
Sterile PBS without Ca^{2+} and Mg^{2+} (CMF-PBS; *APPENDIX 2A*)
Inhibitors: anti-DC-SIGN or mannan, optional
Single-cycle luciferase reporter HIV-1 stocks (see Basic Protocol 3)
Cell culture medium (see recipe)
Hut/CCR5 target cells
Polybrene
RPMI-1640 with 10% FBS

1.5-ml screw-cap microcentrifuge tubes
Refrigerated microcentrifuge (e.g., rotor model F241.5P in Beckman Coulter microcentrifuge, 22R centrifuge)
37°C incubator
24-well tissue culture plates

Additional reagents and equipment for cell culture (*UNIT 1.1*)

CAUTION: Follow the biosafety protocol and use 10% bleach to inactivate HIV-1 in the plates, tubes, plastic pipets, etc.

Incubate donor cells with HIV-1

1. Dispense 2.5×10^5 Raji/DC-SIGN cells (donor cells) per sample into 1.5-ml screw-cap microcentrifuge tubes. Use Raji cells as a background control.
2. Centrifuge cells 3 min at ~$900 \times g$, room temperature. Remove supernatant carefully, avoiding disruption of the pellet.
3. Resuspend cell pellet in 1 ml of CMF-PBS to wash cells. Centrifuge cells 3 min at $900 \times g$, room temperature. Remove supernatant carefully.
4. (Optional) If using inhibition agents, such as anti-DC-SIGN (10 μg/ml) or mannan (20 μg/ml), preincubate cells with the inhibitors for 30 min at 37°C (Wu et al., 2002b).

   These inhibitors can be added in 100 μl of medium for 2×10^5 cells (2×10^6 cells/ml).

5. Resuspend cells in 0.2 to 0.4 MOI (~1 × 10^5 IU) of HIV-1.

   See Basic Protocol 3 for direct infection and calculation of MOI. Based on viral input, the incubation volume should be 200 to 400 μl with culture medium.

6. Incubate cells in 1.5-ml screw-cap microcentrifuge tubes for 2 hr at 37°C.

   Loosening the caps during incubation is recommended.

Wash donor cells and prepare target cells

7. Centrifuge 2 min at 900 × *g*, 4°C. Remove supernatant carefully.
8. Wash each sample with 1 ml of CMF-PBS and centrifuge 2 min at 900 × *g*, 4°C. Remove supernatant carefully.
9. Prepare Hut/CCR5 target cells (5 × 10^5 cells/ml). To enhance viral transmission efficiency, add polybrene (8 to 10 μg/ml) to target cells. When using adherent cells as target cells, plate cells in 24-well plate 1 day before the co-culture assay.

Co-culture donor cells with target cells

10. Resuspend HIV-1-pulsed Raji/DC-SIGN cell pellets (from step 8) with 200 μl of the prepared Hut/CCR5 cells (1 × 10^5 cells) from step 9.

    As a background control, include HIV-pulsed donor cells without co-culture of target cells. When using adherent cells as target cells, remove medium in 24-well plate, resuspend Raji/DC-SIGN cells with medium (200 μl/sample), and then transfer them into each well of the adherent target cells.

11. Incubate suspension cells in screw-cap tubes for 1 to 2 hr at 37°C.

    Loosening caps during incubation is recommended. Alternatively, co-culture adherent cells in a 24-well plate.

12. Transfer cells from each tube to a new 24-well plate. Adjust the final volume of medium to 1 ml per sample per well with RPMI-1640 with 10% FBS.
13. Incubate 2 to 3 days in an incubator designated for HIV-1-infected cells.
14. Refer to Support Protocol 1 on quantifying viral infection of target cells when harvesting cells.

ALTERNATE PROTOCOL 2

HIV-1 ENHANCEMENT ASSAY

As an alternative method of HIV-1 cell-cell transmission assay, a viral enhancement assay can be used. This assay is performed using a smaller HIV-1 inoculum during incubation with donor cells, and target cells are added directly to the co-culture without removing the virus present in the culture medium (Wu et al., 2004b).

For materials, see Basic Protocol 4.

CAUTION: Follow the biosafety protocol and use 10% bleach to inactivate HIV-1 in the plates, tubes, plastic pipets, etc.

Incubate donor cells with HIV-1

1. Dispense 2.5 × 10^5 Raji/DC-SIGN cells (donor cells) per sample into 1.5-ml screw-cap microcentrifuge tubes. Use Raji cells as a background control.
2. Centrifuge cells 3 min at 900 × *g*, room temperature. Remove supernatant carefully, avoiding disruption of the pellet.
3. Resuspend pellet in 1 ml of CMF-PBS to wash cells.
4. Centrifuge cells 3 min at 900 × *g*, room temperature. Remove supernatant carefully.

5. (Optional) If using inhibition agents, such as anti-DC-SIGN (10 μg/ml) or mannan (20 μg/ml), preincubate cells with the inhibitors for 30 min at 37°C (Wu et al., 2002b).

   These inhibitors can be added in 100 μl of medium for 2×10^5 cells (2×10^6 cells/ml).

6. Resuspend cells with 100 μl of nonselective cell culture medium.

7. Add 0.02 to 0.04 MOI ($\sim 1 \times 10^4$ IU) of HIV-1 to donor cells. Adjust the incubation volume to 200 μl with culture medium.

   See Basic Protocol 3 for direct infection and calculation of MOI.

8. Incubate cells in 1.5-ml screw-cap microcentrifuge tubes for 2 hr at 37°C.

   Loosening caps during incubation is recommended.

Prepare target cells and co-culture with donor cells

9. Prepare Hut/CCR5 target cells (5×10^5 cells/ml). To enhance viral transmission efficiency, add polybrene (8 to 10 μg/ml) to target cells.

   When using adherent cells as target cells, plate cells 1 day before the co-culutre assay.

10. Co-culture HIV-1-incubated Raji/DC-SIGN cells (from step 7) with 200 μl of the prepared Hut/CCR5 cells (1×10^5 cells) from step 8.

    As a background control, include HIV-incubated donor cells without co-culture of target cells. When using adherent cells as target cells, remove medium in 24-well plate, resuspend Raji/DC-SIGN cells with medium (200 μl/sample), and then transfer them into each well of the adherent target cells.

11. Incubate the cells in screw-cap tubes for 1 to 2 hr at 37°C.

    Loosening caps during incubation is recommended. Alternatively, co-culture cells in a 24-well plate.

12. Transfer cells from each tube to a new 24-well plate (the final volume of medium should be 1 ml per sample per well).

    Use non-selective culture media (see recipe). For adherent target cells, cells can be continuously incubated in the plate.

13. Incubate 2 to 3 days in an incubator designated for HIV-infected cells.

14. Refer to Support Protocol 1 on quantifying viral infection of target cells when harvesting cells.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

BES-buffered saline (BBS), 2× (pH 6.96 ± 0.02)

5.6 ml 5 M NaCl
5.0 ml 1 M BES
150 μl 1 M Na_2HPO_4
Tissue-culture quality sterile ddH_2O to a final volume of 100 ml
Filter sterilize through a 0.2-μm filter
Store 10-ml aliquots up to 6 months at −20°C

Cell culture media

Cell lysis buffer, 1×
1% (v/v) NP40 (Sigma cat. no. IGEPAL CA-630)

continued

100 mM NaCl, dilute from 5 M stock (*APPENDIX 2A*; 50×)
10 mM Tris·Cl, pH 7.5, dilute from 1 M stock (*APPENDIX 2A*; 100×)
1 mM EDTA, dilute from 0.5 M stock (*APPENDIX 2A*; 500×)

Alternatively, a 10× lysis buffer stock solution can be prepared and stored at 4°C, so that 1× fresh lysis buffer can be conveniently diluted with water for the assay.

Dulbecco phosphate buffered saline (DPBS, 1×)
137.9 mM NaCl
2.7 mM KCl
1.5 mM KH_2PO_4
8.1 mM Na_2HPO_4
Adjust pH to 7.3 using NaOH or HCl, if necessary
Autoclave solution
Store up to 6 months at room temperature

GHOST/X4/R5 cell medium
Dulbecco's modified Eagle's medium (DMEM)
10% (v/v) FBS
Neomycin (500 μg/ml)
Hygromycin B (50 μg/ml)
Puromycin (1 μg/ml)

(Optional) Add penicillin (100 U/ml) and streptomycin (100 μg/ml) to the medium. Store up to 6 months at 4°C. All cell-culture grade reagents are available from Invitrogen.

HEK293T cell medium
DMEM
10% (v/v) FBS

(Optional) Add penicillin (100 U/ml) and streptomycin (100 μg/ml) to the medium. Store up to 6 months at 4°C.

Hut/CCR5 cell medium
RPMI-1640
10% (v/v) FBS
Neomycin (500 μg/ml)
Puromycin (1 μg/ml)

(Optional) Add penicillin (100 U/ml) and streptomycin (100 μg/ml) to the medium. Store up to 6 months at 4°C.

Paraformaldehyde fixative, 4% (pH 7.2)

Prepare a fresh 4% (w/v) solution of analytical-grade paraformaldehyde in DPBS (see recipe). Adjust the pH of the solution to pH 7.2 with HCl. Store up to 3 months at 4°C in the dark.

Use caution when handling; formaldehyde is a carcinogen. The solution should be prepared in a fume hood.

PBS/2% (v/v) FBS

Add 2% FBS to 1× DPBS (see recipe) just before use.

Raji/DC-SIGN cell medium

RPMI-1640
10% (v/v) FBS

(Optional) Add penicillin (100 U/ml) and streptomycin (100 μg/ml) to the medium. Store up to 6 months at 4°C.

COMMENTARY

Background Information

In this unit, a set of methods to perform quantitative assays of HIV-1 binding, internalization, infection, and cell-cell transmission is described. Although not mentioned in this unit, many other assays and protocols have been described in the literature. Based on various experimental purposes and requirements, numerous different methods can be used to study HIV-1 interactions with host cells. For instance, a flow cytometry based HIV-1 binding assay using GFP-tagged virus has been used in $CD4^+$ primary T cells and cell lines (Schaeffer et al., 2004). A sensitive and specific enzyme-based assay has been reported to detect HIV-1 virion fusion in primary T lymphocytes (Cavrois et al., 2002). LTR promoter–based HIV-1 indicator cell lines have been widely used in measuring HIV-1 infectivity or viral infection (Cecilia et al., 1998; Derdeyn et al., 2000). However, a background transcriptional activity of the LTR promoter that is independent of HIV-1 infection and Tat expression could exist. Moreover, cellular activation states can also influence the activity of the LTR promoter. To overcome these potential caveats, a Rev-dependent HIV-1 indicator T cell line using GFP as a reporter has been recently produced (Wu et al., 2007). This $CD4^+$ T cell line appears to be sensitive to both CCR5- and CXCR4-tropic HIV-1 and shows no measurable background of GFP expression (Wu et al., 2007).

Although various reporter-expressing HIV-1 vectors provide convenient tools to measure viral infection (Connor et al., 1995; Unutmaz et al., 1999), the reverse transcriptase assay (Adachi et al., 1986; Freed et al., 1995) remains as a reliable and sensitive method to measure HIV-1 replication (Hatziioannou et al., 2006). Moreover, quantitative real-time PCR to measure HIV-1 reverse transcription, integration, and gene transcription is an important tool in dissecting molecular mechanisms of viral replication (Butler et al., 2001; Wu and Marsh, 2001; Dong et al., 2007). For the HIV-1 cell-cell transmission assay, the method described in this unit may need to be adjusted according to the cell types used in the experiments. In addition to DCs (Wu and KewalRamani, 2006), macrophages can mediate HIV-1 transmission to $CD4^+$ T cells (Sharova et al., 2005). Furthermore, efficient cell-cell transmission of HIV-1 also occurs between $CD4^+$ T cells (Jolly et al., 2007a,b; Sowinski et al., 2008).

Critical Parameters and Troubleshooting

Generating virus stocks

When generating virus stocks, it is imperative that all transfection reagents are at the appropriate pH. When mixing the transfection reagents, do not incubate the transfection mixture for longer than 20 min. To maximize the efficiency of transfection, use an earlier passage of HEK293T cells; the seeded cells should not be overly confluent before the transfection. Additionally, replace medium when specified to ensure high-titer and yield of the virus stock. Lastly, the DNA being used in transfection reactions should be of high quality. If experiencing difficulty with generating virus of appropriate titer, check the pH of the transfection solutions, the passage number of HEK293T cells, and the quality of the DNA preparations. For the DNA concentrations, it is recommended to use a ~1 mg/ml stock, because too dilute a stock may potentially alter the pH of the transfection reaction.

HIV-1 binding and internalization assay

When performing the binding assay, keep consistent temperatures of sample incubation at 4°C or 37°C. The samples that are incubated at 4°C and treated with trypsin represent background levels of the assay. The concentration of trypsin should be titrated for different cell types since some cells might be more sensitive to proteolysis. After trypsin treatment, use caution when removing the supernatant after washes since the sample can be very fragile. Lastly, include a parental cell line as a control if looking at specific attachment factors transduced in a cell line (e.g., comparing HIV binding in parental Raji cells and Raji/DC-SIGN cells). For p24 ELISA detection, see manufacturer's instructions.

HIV-1 infection and cell-cell transmission

For direct infection of target cells, cell viability and the quality of the virus stock will affect the quality of the assay. If the stock is too dilute, larger than desired incubation volumes will have to be used, and the infectivity of the virus may not be as high when compared to a more concentrated virus stock at the same MOI. Low-titer viral stocks can be concentrated by ultracentrifugation or ultrafiltration. Furthermore, if performing infections with different HIV-1 pesudotypes in parallel, it is important to maintain the same incubation volumes if directly comparing the virus

infections. Always include a mock infection control for background levels.

These critical parameters should also apply for the HIV cell-cell transmission assays. Another important control in viral transmission assays is to use donor cells with HIV-1 incubation, but without the co-culture of target cells. Donor cells that are negative for HIV-1 receptor or appropriate coreceptors should not be directly infected by HIV-1, and therefore should have similar values as compared to the mock control. Notably, when using HIV-1-permissive donor cells, such as immature dendritic cells, HIV-1-pulsed dendritic cells can become infected 3 to 5 days post-infection if high viral inputs are used (Dong et al., 2007).

Anticipated Results

Generating HIV-1 stocks

For HIV pseudotyped with HIV-1 Env, such as HXB2 or JRFL, the titer of the virus generated from transfection should range between 2×10^5 and 5×10^5 infectious units (IU)/ml, whereas HIV pseudotyped with VSV-G has a titer ranging from 1×10^6 to 10×10^6 IU/ml. A 10- to 20-fold shift in GFP expression should be expected when titrating the virus stocks by flow cytometry assay. See Figure 26.5.1 and Table 26.5.2 for viral titration examples.

HIV-1 binding and internalization assay

HIV-1 binding and internalization can be enhanced around two-fold in Raji/DC-SIGN cells, relative to parental Raji cells (Wu et al., 2004b). When using 20 ng of p24-equivelent HIV-1 with 3×10^5 of Raji/DC-SIGN cells, the p24 detection in cell lysates should be ~500 pg/ml (Wang et al., 2007a). Notably, cell-associated p24 values will vary based on the cell types, virus input, incubation temperature and time, and the proteolysis treatment after viral incubation (Wu et al., 2004b; Dong et al., 2007; Wang et al., 2007a,b).

HIV-1 infection assays

The level of infection detected in target cells will be dependent upon the number of cells used, the virus input, as well as the type of virus and cells that are used in the infection. Using luciferase reporter HIV-1 in the viral infection assay (see Alternate Protocol 1 and Support Protocol 1), the background levels were ~100 counts/sec for the mock control. As an example, 2×10^5 Hut/CCR5 cells infected with HIV-1-VSV-G at an MOI of 0.1, and harvested 3 days post-infection, had luciferase activity ~330-fold higher relative to that of the mock control. In contrast, Hut/CCR5 cells infected with HIV-1-JRFL had luciferase activity 39-fold higher compared to the mock control (Janas et al., 2008; Janas and Wu, unpub. observ.).

HIV-1 cell-cell transmission assays

If using the HIV-1 capture assay (see Basic Protocol 4), when compared to the negative control (HIV-pulsed Raji/DC-SIGN cells without target cells), Raji/DC-SIGN cell-mediated HIV-1-JRFL transmission to Hut/CCR5 target cells can be ≥350-fold higher (Wu et al., 2004b; Wang et al., 2007a). If using the HIV-1 enhancement assay (see Alternate Protocol 2), expect to see ~10-fold enhancement of viral infection in the co-cultures. Notably, the relative efficiency of HIV-1 cell-cell transmission may vary depending on the cell types and viruses (Wang et al., 2007b).

Time Considerations

Generating virus stocks

For virus stock generation, plan for 4 days. Day 1 will consist of plating cells. The transfection will be performed on the second day, and will take ~25 to 30 min, depending on how much virus stock is being generated. On day 3, the medium is replaced. The virus is harvested on day 4, and will take ~1 hr.

HIV-1 binding and internalization assay

The binding assay should take ~3 to 4 hr to perform, depending on the sample number (not including virus inactivation). The p24 ELISA detection normally takes ~6 hr.

HIV-1 infection of target cells

For virus titrations, the experiment will span 4 days. On day 1, the cells will be plated. On the second day, the cells are infected. On the third day, cell medium is replaced. On the fourth day, the cells can be harvested for GFP analysis by flow cytometry. Sample preparation for flow cytometry analysis can take from 1.5 to 6 hr, depending on how long the investigator chooses to fix the cells in paraformaldehyde. When performing other direct infections of target cells, anticipate ~4 hr on the day of infection (and 5 hr for transmission assay), and an additional 2 to 3 days until the cells are harvested for analysis. Harvesting the cells takes ~1 hr for the luciferase assay, and may be shorter if collecting cell supernatants for p24 analysis.

Acknowledgements

The authors thank Michael Emerman, Eric Freed, Jeffery Lifson, Vineet KewalRamani, and the AIDS Research and Reference Reagent Program, NIAID, NIH, for the kind gift of reagents. Methods for Monitoring Dynamics of Pulmonary RSV Replication by Viral Culture and by Real-Time Reverse Transcription–PCR In Vivo: Detection of Abortive Viral Replication

Marina S. Boukhvalova,[1] Kevin C. Yim,[1] Gregory A. Prince,[1] and Jorge C.G. Blanco[1]

[1]Virion Systems, Rockville, Maryland

ABSTRACT

Viral infection is normally detected either by viral culture or by PCR methods. Rarely is a combination of the two techniques used in the same study. Yet, when applied simultaneously, viral culture and PCR may reveal important features of viral biology, such as an abortive replication, as in the case of respiratory syncytial virus (RSV) infection. In this unit, we describe methods for detecting abortive RSV replication in a cotton rat model by using the plaque-forming unit assay and the real-time reverse-transcription PCR (qRT-PCR) assay. All steps of the process of monitoring viral replication in vivo are described, starting from the design of animal infection protocols. We continue on to the methods for extracting and processing lung samples for viral culture and RNA extraction, and finish with the actual methods of viral titration by the qRT-PCR and the plaque-forming unit assays. *Curr. Protoc. Cell Biol.* 46:26.6.1-26.6.19. © 2010 by John Wiley & Sons, Inc.

Keywords: abortive replication • RSV • cotton rat

INTRODUCTION

This unit describes methods for detecting abortive viral replication in vivo in an animal model. Viral culture has long been considered the "gold standard" for laboratory diagnosis of respiratory viral infections in humans and for analysis of viral replication in animal models. Over the years, other techniques such as PCR have proven to be specific and sensitive methods for viral detection, with real-time reverse-transcription PCR (qRT-PCR) particularly well-suited for analysis of respiratory RNA viruses (Bustin and Mueller, 2005). The rate of identification of viral infections in humans by viral culture is often lower than that detected by PCR and qRT-PCR (Mackay et al., 2003; van Kraaij et al., 2005). This finding is normally attributed to higher sensitivity of the PCR technique, but may also reflect cases when virus establishes an abortive infection in which viral genetic material is replicated, but production of infectious viral particles is impaired. Undetected by viral culture, this type of replication can only be documented by measuring viral gene expression and genome replication in infected humans and laboratory animals by PCR.

One of the viruses for which both productive and abortive infections have been documented is Respiratory Syncytial Virus (RSV; Boukhvalova et al., 2007). RSV is a negative-strand RNA virus that is a major cause of bronchiolitis and viral pneumonia in children (Shay et al., 2001). RSV effectively establishes productive infection in naïve cotton rats (*Sigmodon hispidus*), a preferred small animal model of human RSV disease (Niewiesk and Prince, 2002; Openshaw and Tregoning, 2005). When cotton rats are challenged with RSV for the second time, however, only abortive infection develops.

Current Protocols in Cell Biology 26.6.1-26.6.19, March 2010

DOI: 10.1002/0471143030.cb2606s46

The key for detecting all possible types of RSV replication in vivo is to analyze infection in dynamics by applying methods that allow virus monitoring both at microbiological (infectious virus generation) and molecular (replication of viral genetic material) levels. This type of analysis will constitute the scope of this unit. We will cover all steps of the process of monitoring viral replication in vivo starting from the design of animal infection protocols (Strategic Planning) and continuing on to the methods for harvesting lung samples for viral culture and RNA extraction (Support Protocol 1). We will describe the actual methods of viral titration by plaque assay (Basic Protocol 1) and qRT-PCR measurements of RSV replication (Basic Protocol 2), and discuss the ways to analyze and to interpret the data. Moreover, we will describe a simple method for RSV infection of epithelial cells in vitro (Support Protocol 2) which can be used to fine tune the plaque assay and qRT-PCR techniques in the reader's laboratory.

STRATEGIC PLANNING

To detect abortive viral replication, one has to have the ability to monitor viral infection in dynamics and to compare viral replication in naïve animals to viral replication in animals immune to the virus. The abortive replication in the case of RSV infection is detected in animals that have been rendered immune to RSV by prior RSV infection. So, the experiment has to include two groups of animals: the first group is composed of naïve animals that have never been infected with RSV before. These animals encounter RSV for the first time at the beginning of the experiment (primary infection). The second group includes animals that have been challenged with RSV once and then rechallenged again 21 days later (secondary infection). When cotton rats are challenged with RSV twice over the period of 21 days, no virus is detected by culture in the lungs of animals after the second infection. Even though no virus is detected in the lungs of rechallenged cotton rats by viral culture, replication of virus takes place and can be measured by qRT-PCR.

The samples must be collected for viral load analysis at various time points after viral challenge: the first and only challenge in primary RSV infection, and the second viral challenge in secondary RSV infection. Animals are sacrificed and lungs are collected over a time span that includes the time of maximum virus replication in naïve animals (day 4 post-infection), as well as the time points before and after the peak viral replication. Because abortive viral replication is more rapid than productive viral replication, early time points post-infection have to be included in analysis. We find that collecting lungs at 6 and 12 hr, and at days 1, 2, 4, 7, and 14 post-infection works best for detection of abortive RSV replication in the cotton rat model. The same time points are used for both primary and secondary infection to allow parallel analysis of samples.

Two different methods for detection of abortive viral replication are required: viral culture (Basic Protocol 1) and the qRT-PCR method (Basic Protocol 2). Replication is abortive when there is a discrepancy between the amount of viral genetic material accumulated (detected by qRT-PCR) and the amount of progeny virus released (detected by viral culture). It is thus important to be able to quantify extent of viral load by qRT-PCR and by viral culture assays in the same sample and to correlate the data yielded by the two techniques.

BASIC PROTOCOL 1

PLAQUE-FORMING UNIT ASSAY OF RSV PRODUCTION

This protocol describes the method for determining viral load in the lungs of RSV-infected animals by a plaque-forming unit assay (plaque assay). Monolayers of HEp-2 cells are inoculated with the homogenates of lung tissue. The infected monolayers are incubated in semi-solid methyl cellulose medium for several days to allow formation of plaques. Because semi-solid medium prevents spread of the virus (otherwise seen in liquid medium), infection of cells is localized and virus released from an infected cell

can infect only cells in the immediate surroundings of the originally infected one, thus producing a plaque. The plaques are visualized against the background of healthy cells stained with crystal violet stain. One plaque corresponds to one plaque-forming unit of RSV, and the total number of plaques reflects the amount of infectious virions present in the original lung sample.

NOTE: All solutions and equipment coming into contact with living cells must be sterile, and aseptic technique should be used accordingly.

NOTE: All cell culture incubations should be carried out in a 37°C, 5% CO_2 humidified incubator.

Materials

HEp-2 cells (ATCC #ccL23)
HEp-2 growth medium (see recipe)
Lung homogenates (Support Protocol 1)
Eagle minimal essential medium (EMEM) with Earle's Balanced Salt Solution (BSS)
Methyl cellulose overlay medium (see recipe)
Crystal violet fixative/stain (see recipe)

24-well tissue culture plates
Dissecting microscope

Additional reagents and equipment for basic cell culture techniques (*UNIT 1.1*)

Prepare HEp-2 monolayers

1. Seed HEp-2 cells on 24-well tissue culture plates at 1×10^5 cells/well in 1 ml HEp-2 growth medium per well.

   UNIT 1.1 provides protocols for basic cell culture techniques.

2. Incubate the plates until the cell monolayers achieve confluency.

   It takes 2 to 3 days for the HEp-2 monolayer to achieve confluency.

Prepare samples for titrations

3. Thaw lung homogenates (prepared as described in steps 13 to 15 of Support Protocol 1) at room temperature.
4. Prepare 1:10 and 1:100 serial dilutions of homogenate samples in EMEM with Earle's BSS.

Inoculate HEp-2 monolayers

5. Aspirate half of the medium from each well of the HEp-2 seeded 24-well culture dishes.
6. Inoculate wells with 50 µl of neat, 1:10, and 1:100 dilutions of each sample in duplicate.
7. Incubate the inoculated 24-well culture dishes for 1 hr.
8. After the incubation period, aspirate the remaining medium from each well of the culture dishes.
9. Overlay each well with 1 ml of the methyl cellulose overlay medium at 37°C.
10. Incubate the plates for 4 days in the incubator.

Stain and read the titration

11. Remove the overlay from each well.

12. Add 0.5 ml of crystal violet fixative/stain to each well. Allow plates to incubate with crystal violet stain for no less than 20 min at room temperature.
13. Remove stain by rinsing each plate two to three times under cold water by filling all of the wells with water, then inverting the plate and tapping it on a paper towel.
14. Place the plate upside-down to air dry.

    The plates have to be completely dry prior to reading.
15. Under a dissecting microscope count the number of plaque-forming units (pfu) per well. Select the sample dilution that yields a reasonable number of plaques (5 to 50 per well).
16. Calculate the corresponding RSV titer in plaque-forming units (pfu) per gram of tissue using the following equation:

$$\frac{\#\text{pfu well 1} + \#\text{pfu well 2}}{0.1\text{ ml total volume}} \times \text{dilution factor} \times \frac{1.5\text{ ml HBSS}}{0.15\text{ g tissue}} = \text{pfu/g of tissue}$$

    where the 0.1 ml total volume consists of 50 μl of sample inoculated onto cells in duplicate = 50 μl + 50 μl, and the dilution factor from processing the tissue remains at a constant of 10×. The limit of the sensitivity of the assay is 1×10^2 pfu/g lung tissue.
17. Determine the geometric mean ±SEM for all animals in a group at a given time

BASIC PROTOCOL 2

REAL-TIME REVERSE TRANSCRIPTION PCR (qRT-PCR) ANALYSIS OF RSV INFECTION

Real-time PCR analysis has been used in the past to detect RSV infection (Falsey et al., 2002, 2003; Hu et al., 2003; Perkins et al., 2005). However, this method has never been used to monitor dynamics of RSV infection in progression. We have established conditions for measuring expression of RSV genes and production of RSV genome/antigenome in vivo and in vitro (Boukhvalova et al., 2007). This protocol will describe steps required to analyze RSV infection in the lungs of cotton rats using qRT-PCR assay. Viral RNA is extracted from the lungs and reverse-transcribed. Expression of individual viral genes is measured. RSV amplicons NS1, N, M, G, F, M2, and L are targeted for quantification. All amplicons are less than 100 nucleotides in size, with primers defining them shown in Table 26.6.1.

Materials

RNeasy Midi kit (Qiagen) including:
- RLT buffer
- RNeasy Midi columns
- Reagents for DNase treatment

RLT/ME buffer: RLT buffer from the RNeasy kit supplemented with 10 μl/ml 2-mercaptoethanol
Frozen lung tissue for analysis (Support Protocol 1), including tissue from two animals sacrificed on day 4 after primary RSV infection for construction of standard curve
70% ethanol
DEPC-treated H_2O (*APPENDIX 2A*)
0.5 μg/ml oligo(dT) primer
10× PCR buffer (without $MgCl_2$; Invitrogen)
50 mM $MgCl_2$ (Invitrogen)

Table 26.6.1 Primers Used for the Real-Time PCR Analysis of RSV Amplicons

Viral gene	Forward primer[a]	Reverse primer[a]	Start of forward primer[b]	Amplicon length
NS1	CACAACAATGCCAGTGCTACAA	TTAGACCATTAGGTTGAGAGCAATGT	231	83
N	AAGGGATTTTTGCAGGATTGTTT	CTCCCCACCGTAGCATTACTTG	719	66
M	ATGTGCTAATGTGTCCTTGGATGA	TGATTTCACAGGGTGTGGTTACA	270	68
G	CGGCAAACCACAAAGTCACA	TTCTTGATCTGGCTTGTTGCA	191	64

M2	CATGAGCAAACTCCTCACTGAACT	TCTTGGGTGAATTTAGCTCTTCATT	294	80
L	CACTCTACAAAACAAAAAGACACAATCA	AGGATGCTGCATTGAACACATT	529	72
β-actin[c]	TATGCCAACACAGTGCTGTCT	TCTGCATCCTGTCGGCAAT	880	64

[a]Primers were designed using Primer Express software (Applied Biosystems).
[b]The number of nucleotides from the first nucleotide in the start codon (ATG) to the beginning of the amplicon.
[c]Expression of β-actin mRNA is measured in each sample for normalization purposes.

10 mM dNTP mix (Invitrogen)
200 U/μl SR II reverse transcriptase (Invitrogen)
iQ SYBR Green Supermix (BioRad)
10 μM forward and reverse PCR primers (Table 26.6.1)

14-ml polypropylene round-bottom tubes
OMNI TH homogenizer with 7-mm stainless-steel generator probe (OMNI International)
15-ml conical polypropylene tubes
Centrifuge with plate carriers
96-well PCR plates
Thermal cycler
Bio-Rad iCycler with iQ5 software
iQ 96-well PCR plates (BioRad)
Microseal 'B' adhesive seals (BioRad)

Extract RNA from lungs

1. Place 3.5 ml RLT/ME buffer into a 14-ml polypropylene tube. Add a frozen piece of lung to the solution and homogenize it using a probe homogenizer in two to three short bursts. Immediately freeze the homogenized lung on dry ice and transfer to the −80°C freezer.

   This step can be performed several days before the actual RNA extraction.

   The size of the lung piece sufficient for RNA extraction should be more or equal to ∼1/6th of the entire lung. We normally use one of the three lobes of the right lung, or a half of the upper lobe of the left lung for RNA extraction.

   IMPORTANT NOTE: *Lung tissue has to be frozen in liquid nitrogen immediately after extraction (see Support Protocol 1). Otherwise, the quality of the RNA preparation may be compromised.*

   Wash the probe well between the samples to prevent cross-contamination. We find that brief bursts of the homogenizer probe in two separate 50-ml tubes with 50 ml distilled water in each and an additional burst in 30 ml RLT/ME buffer between samples is sufficient to prevent cross-contamination of samples.

2. On the day of the RNA extraction, thaw lung homogenates in 37°C water bath for 15 min.

3. Centrifuge the homogenates for 10 min at 4000 × *g*, room temperature.
4. Transfer 2 ml of supernatant to a prepared 15-ml conical polypropylene tube with 2 ml 70% ethanol.

   Avoid upper phase when withdrawing supernatants.

5. Mix by inverting the tube vigorously five to seven times, then load the mixture onto the RNeasy Midi column.
6. Centrifuge the column and proceed with the protocol as specified in the RNeasy Midi kit instructions. Include the DNase treatment step as specified in the RNeasy Midi kit instructions.

   Omitting the DNase treatment step would result in an RNA preparation contaminated with genomic DNA, which may compromise accuracy of the qRT-PCR analysis.

7. Elute RNA from the RNeasy Midi column with 150 µl distilled water. Repeat elution with 50 µl distilled water. Determine RNA concentration by measuring the absorbance at 260 nm in a spectrophotometer. Also determine the ratio between the absorbance values at 260 nm and 280 nm to estimate RNA purity (a ratio value ≥1.8 is acceptable).

Prepare cDNA

8. Combine 1 µg of total RNA with 1 µl of 0.5 µg/µl oligo(dT) primer in 20 µl total reaction volume in a 96-well PCR plate. Set up one reverse transcription (RT) reaction for each animal. Use DEPC-treated water to bring final reaction volume to 20 µl.

   Oligo(dT) primer should be used for analysis of RSV gene expression and for the measurements of housekeeping gene β-actin mRNA. For the analysis of the amount of RSV genome or antigenome, use primer 5′-CAATGAACTAGGATATCAAGAC-3′ or primer 5′-GTCTTGATATCCTAGTTCATTG-3′, respectively (1 µl of 10 µM stock solution). The sequences of the last two primers correspond to the positive and negative strands within the intergenic region between SH and G genes of RSV.

9. Set up two additional RT reactions as in the previous step, using RNA from two animals sacrificed on day 4 after primary RSV infection.

   These two cDNAs will be used for the standard curve construction. Animals sacrificed 4 days after primary RSV infection are chosen as the source of RNA for standard curve because of the highest level of RSV replication is observed on that particular day in the cotton rat model.

10. Cover the plate and incubate it at 70°C for 10 min in a thermal cycler.
11. Remove the plate from the thermal cycler. Add to each well:

    10× PCR buffer for a final concentration of 1×
    50 mM $MgCl_2$ for a final concentration of 2.5 mM
    10 mM dNTP mix for a final concentration of 0.5 mM each dNTP
    DTT for a final concentration of 10 mM
    200 U/µl SR II reverse transcriptase for 200 U per reaction, final.

    Cover the plate and mix the contents of the plate by vortexing.

    To perform this step, a cocktail should be prepared for the number of required reactions plus two or three extra to account for pipetting errors.

12. Briefly centrifuge the plate at 800 × *g* to bring the solution to the bottoms of the wells, and return it to the thermal cycler for 60 min at 42°C, followed by 15 min at 70°C.
13. Upon completion of cDNA synthesis, add 80 µl of distilled water to each well.

Prepare standard curve cDNA

14. After the cDNA synthesis is complete and 80 μl of distilled water is added to each well, combine the contents of the two extra reactions that were set up using RNA from animals sacrificed day 4 post-primary-RSV infection into the same well (resulting volume, 200 μl).

    This will be the first cDNA in a dilution series of the standard curve samples.

15. Serially dilute this cDNA 1:2, 1:4, 1:8, 1:16, and 1:32 with distilled water, and use the dilutions in real-time PCR to compose a standard curve.

    Store the cDNA plate at −20°C in between uses. Multiple freeze-thaw cycles are permissible.

    Individual standard curves should be constructed for each gene analyzed.

Set up real-time PCR reactions

16. Before beginning to set up real-time PCR reactions, turn on the lamp on the Bio-Rad iCycler, as it takes time to warm up for the run.

17. Obtain an iQ 96-well PCR plate.

18. Prepare a premix by combining (per reaction):

    12.5 μl SYBR Green Supermix
    1.25 μl of each primer (from 10 μM stock) in an appropriate primer pair given in Table 26.6.1
    7 μl distilled H_2O.

    Mix enough for all animal samples to be run in duplicate and for the standard curve reactions to be run in duplicate, allowing for two to three extra reactions. Aliquot 22 μl of premix into each well of an iQ 96-well PCR plate.

    A 64-nucleotide amplicon in the β-actin transcript is amplified using primers shown in Table 26.6.1

19. Add 3 μl of cDNA to 22 μl of premix in the appropriate wells of the 96-well PCR plate.

    Use a multichannel pipettor to transfer cDNA from the cDNA plate to a plate containing PCR premix.

20. Cover the plate with Microseal 'B' adhesive seal, making sure it is firmly and uniformly attached throughout the plate.

21. Vortex the plate and briefly centrifuge at 800 × *g* to bring contents of the wells down to the bottom.

22. Place the plate into the BioRad iCycler.

23. Run the following program:

1 cycle:	3 min	95°C	(initial denaturation)
40 cycles:	10 sec	95°C	(denaturation)
	10 sec	60°C	(annealing)
	15 sec	72°C	(extension).

    There is no need to run melting curves for the primer pairs given in Table 26.6.1, as we have completed melting curves for each primer pair used in this work, and no nonspecific amplification has been noted under the conditions tested.

    If amplifying a certain gene product not specified here, program the PCR machine to add a melting curve at the end of the PCR reaction to check that particular primer pair for a potential to amplify multiple products.

Analyze real-time PCR assay results

The baseline cycles and cycle threshold (Ct) will be calculated automatically by the iQ5 software in the PCR Base Line Subtracted Curve Fit mode.

24. Plot the average Ct values for the standard curve samples against $\log_{10}$ cDNA dilution factor.

25. Use this curve to convert the average Ct values obtained for different samples to relative expression units. Normalize these relative expression units to the level of β-actin mRNA (housekeeping gene) expressed in the corresponding sample.

26. Calculate β-actin normalization values for each animal:

    a. Select the lowest β-actin relative expression unit value by comparing units obtained for different animals.

    b. Divide the β-actin relative expression units obtained for all animals by that lowest β-actin relative expression unit.

    For the animal selected in step 26a, the β-actin normalization value would equal 1.

27. Divide relative expression units obtained for genes other than β-actin by the β-actin normalization values.

28. For groups of animals, express mRNA levels as the geometric mean ±SEM for all animals in a group at a given time.

    Further normalization relative to the highest level of expression of the gene of interest (assigned relative value of 1) can be done (see Commentary).

SUPPORT PROTOCOL 1

INFECTION OF COTTON RATS WITH RSV AND HARVESTING AND PROCESSING OF LUNGS

Several animal models of RSV disease exist (Byrd and Prince, 1997). Among the ones most faithfully representing RSV disease manifestation in humans are the cotton rat, African green monkey, and the calf models of bovine RSV. The cotton rat is the preferred small animal model of RSV infection (Siber et al., 1994; Johnson et al., 1997; Maggon and Barik, 2004). Cotton rats are highly permissive for RSV infection and display histopathological features of the disease similar to that observed in humans (Prince et al., 1986, 1999). In this unit we describe a method for establishing RSV infection of cotton rats and for obtaining samples for analysis of RSV replication in the lungs. For all our experiments we use cotton rats *S.hispidus* from an inbred colony maintained at Virion Systems, Inc.

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) and conform to governmental regulations regarding the care and use of laboratory animals.

Materials

Cotton rats (*S.hispidus*, 4 to 8 weeks old; from a colony maintained at Virion Systems, Inc.)
RSV A/Long stock solution ($>10^7$ pfu/ml: original strain was obtained from ATCC (#VR26); virus was serially plaque purified to reduce defective-interfering particles)
Phosphate-buffered saline, pH 7.4 (*APPENDIX 2A*)
Liquid nitrogen
Homogenization medium (see recipe)

Isoflurane anesthesia chamber (Davis, 2008)
1-ml syringes
21-G needles
CO_2 chamber (Donovan and Brown, 2006)
Dissecting forceps
Dissecting scissors
Sterile Tenbroeck tissue homogenizers
Sterile polystyrene round-bottom tubes with caps, 12 × 75 mm
Centrifuge, refrigerated
Sterile 4-ml glass sample vials with caps

Additional reagents and equipment for isoflurane anesthesia in rodents (Davis, 2008) and euthanasia of rodents by CO_2 asphyxiation (Donovan and Brown, 2006)

Inoculate cotton rats with RSV

1. Obtain young (4- to 8-week-old) *S.hispidus* cotton rats.

   Young animals are required to reproduce dynamics of viral replication described in the Commentary. Cotton rats older than 6 months of age have delayed viral clearance from the lungs (Curtis et al., 2002; Boukhvalova et al., 2007).

2. Dilute RSV stock solution with PBS, pH 7.4. to obtain $10^{6.6}$ pfu/ml. Keep diluted virus on ice.

3. Anesthetize cotton rats in isoflurane chamber (see Davis, 2008).

   CAUTION: *Take necessary precautions when catching cotton rats and placing them into anesthesia chamber. Cotton rats behave very differently from common laboratory mice, in that cotton rats are more aggressive and very fast. Make sure to wear thick gloves when handling alert cotton rats to prevent being bitten. Quick reflexes on behalf of an investigator are a must!*

4. Draw viral solution into a 1-ml syringe with 21-G needle attached.

5. Remove the animal from the anesthesia chamber and inoculate it with 100 μl viral solution from the syringe by depositing drops of solution at the nostril openings, alternating nostrils for each consecutive drop.

   CAUTION: *Wear goggles and protective clothing.*

   Hold the animal in one hand, placing it belly-up on a palm and supporting the back of its head with four fingers. Use a thumb of that hand to push up on the chin of the animal to ensure that the mouth is closed. This will force the animal to aspirate viral solution through the nose. Animals have to be well anesthetized prior to virus inoculation. If it awakens during the inoculation process, the animal can puff the viral solution out, compromising efficiency of infection and spreading virus around the work area.

6. After infection, place the animal back into the cage, monitoring it for several minutes to ensure that the animal successfully wakes up from the anesthesia.

   If it takes longer than a few minutes for the animal to wake up, gently massage the sides of its chest cavity with one hand.

7. For secondary RSV infection studies, reinfect cotton rats 21 days later in the same manner as described in steps 2 to 6.

   When carrying an experiment with both secondary and primary RSV infection, do not infect the group of animals for primary infection studies until 21 days into the experiment. Infect the animals for secondary infection studies on days 0 and 21. Infect the animals for primary infection studies on day 21. All animals (for both secondary and primary infections studies) should be age-matched on day 0. This way, they will be age-matched at the time of sacrifice.

Sacrifice cotton rats

8. Sacrifice groups of animals via carbon dioxide asphyxiation (Donovan and Brown, 2006) at 6 hr, 12 hr, day 1, 2, 4, 7, and 14 after RSV inoculation (≥4 animals per time point).

   This will be the first RSV inoculation for the primary RSV infection group and the second RSV inoculation for the secondary RSV infection group.

9. Sacrifice one group prior to infection (0 hr) to serve as control.

Harvest lungs

10. Remove the lungs from the thorax using dissecting scissors and forceps.

11. Separate the left lung from the right lung.

    The right lung will be used for the qRT-PCR analysis and the left lung will be used for the RSV titration by plaque assay.

Allocate lungs for the RNA extraction

12. Trisect the right lung into individual lobes. Place each lobe in a separate cryotube and snap-freeze the tubes in liquid nitrogen. Transfer the tubes to dry ice and then to −80°C freezer.

    Work fast. Minimizing the time between the lung extractions and freezing the lung pieces in liquid nitrogen is crucial for ensuring a good-quality RNA preparation later on.

Process lungs for the plaque assay

13. Place the entire left lung into a sterile Tenbroeck tissue homogenizer with 10 parts (w/v) of homogenization medium. Homogenize in two to three short bursts, then place tubes on ice.

    The entire left or right lung weighs ∼0.15 g; therefore, it should be homogenized in 1.5 ml medium.

14. Following homogenization, pour samples into individually labeled sterile polystyrene round-bottom tubes with caps and centrifuge specimens 10 min at 770 × *g*, 4°C.

15. Transfer supernatants using sterile glass Pasteur pipets into 4-ml sterile glass sample vials and quick freeze aliquot specimens on dry ice. Store specimens at −80°C until assayed.

SUPPORT PROTOCOL 2

RSV INFECTION OF A549 EPITHELIAL CELLS

Respiratory epithelial cells are the primary target of RSV infection in vivo. Because of the complicated nature of in vivo experiments, RSV infection studies are often carried in vitro in epithelial cell cultures. These experiments provide important clues to the mechanism of RSV action, and also allow fast and efficient production of RSV-infected material. In this protocol we describe the method for RSV infection of alveolar epithelial cells A549, which provides a large amount of sample for RSV quantification by plaque assay and by real-time PCR. These samples can be used to fine tune techniques described in this unit in order to best adapt them to a particular laboratory setting.

Materials

Human alveolar epithelial type II cell (A549) culture (ATCC #CCL185)
A549 growth medium (see recipe)
RSV A/Long stock solution (>10^7 pfu/ml): original strain was obtained from ATCC (#VR26); virus was serially plaque purified to reduce defective-interfering particles

DMEM medium (serum-free; e.g., Invitrogen)
RNeasy Midi kit (Qiagen) including:
RLT buffer
RNeasy Midi columns
Reagents for DNase treatment
RLT/ME buffer: RLT buffer from the RNeasy Midi kit (Qiagen) supplemented with 10 μl/ml 2-mercaptoethanol
70% ethanol
PCR primers for viral genes and β-actin (Table 26.6.1)

75- to 175-cm^2 tissue culture flasks
6-well tissue culture plates

Additional reagents and equipment for basic cell culture techniques (*UNIT 1.1*), plaque assay (Basic Protocol 1), and preparation/PCR amplification of cDNA (Basic Protocol 2)

NOTE: All solutions and equipment coming into contact with living cells must be sterile, and aseptic technique should be used accordingly.

NOTE: All cell culture incubations should be carried out in a 37°C, 5% CO_2 humidified incubator.

Prepare A549 cells for infection

1. Propagate A549 cells in A549 growth medium in a humidified incubator in 75- to 175-cm^2 tissue culture flasks.

   UNIT 1.1 provides protocols for basic cell culture techniques. Cells should be seeded at 1×10^5 cells/ml in 12 or 25 ml per 75- or 175-cm^2 tissue culture flask, respectively. Cells should passaged, on average, twice a week using trypsin to facilitate cell detachment from the original flask, with the fresh medium added to a new flask upon completion of splitting. A 1:3 to 1:5 ratio for splitting is recommended.

2. Dilute cells to 2×10^5 cells/ml in A549 growth medium and plate on 6-well plates at 2 ml/well (2 ml/well of a 2×10^5 cell/ml suspension). Leave the plate in the incubator for 2 days.

Infect A549 cells with RSV

3. Trypsinize the cells in one well, mix a 20-μl aliquot of cells with an equal volume of trypan blue dye solution, and count viable cells using a hemacytometer.

   Trypsinization of cells and counting viable cells by trypan blue exclusion are described in UNIT 1.1.

4. Dilute RSV in plain DMEM medium to yield various MOIs (0.001 to 0.1).

   The calculations should be based on the fact that 500 μl of viral solution per well will be used for infection.

5. Wash the cells twice with PBS, pH 7.4, by adding 2 ml PBS to each well, swirling solution around the well, and aspirating PBS.

   Washing the cells with PBS removes traces of FBS present in A549 growth medium. Residual FBS may reduce efficiency of infection.

6. Add viral solution to the wells of cells to be infected (each treatment should be done in duplicate) and place the plate into the incubator for a total of 1 hr. During that hour, rock the plate every 15 min to uniformly cover the cells with viral solution.

   A small volume of viral solution, barely covering the cell monolayer, is crucial for efficient infection.

7. Aspirate viral solution and replace it with 2 ml A549 growth medium. Return the plate to the incubator.

Collect supernatants for RSV titrations by the plaque-forming unit assay

8. Harvest cell supernatants into 1.5-ml microcentrifuge tubes at various times post-infection.

9. Microcentrifuge supernatants 5 min at 500 × *g*, 4°C, and freeze cleared supernatants at −80°C for further analysis.

Determine viral titer in the supernatants by the plaque-forming unit assay

10. Titrate supernatants as described in Basic Protocol 1 with the following modifications:

    a. Prepare 1:10, 1:100, and 1:1000 dilutions of supernatants for titration.

    b. Use the following formula to calculate viral titers:

$$\frac{\#\text{pfu well 1} + \#\text{pfu well 2}}{0.1\text{ ml total volume}} \times \text{dilution factor} = \text{pfu/ml}$$

Collect cells for RSV replication analysis by real-time PCR assay

11. Collect cells in the wells from which supernatants were harvested for viral titration by plaque assay for RNA extraction. Remove traces of medium from the wells by aspiration and add 400 µl RLT/ME buffer per well. Resuspend the cells in RLT/ME by pipetting up and down at least seven to ten times.

    Considerable attention should be given to cell pipetting in RLT/ME buffer. At least seven to ten rounds have to be performed to ensure successful RNA isolation later on. Avoid generating foam in the solution when resuspending.

    The plate can be frozen at −80°C after RLT/ME buffer is added to the wells. Thaw the plate at room temperature on the day of RNA extraction.

12. Add 400 µl 70% ethanol to each well. Mix with the contents of a well by pipetting up and down two to three times, then load the mixture onto an RNeasy Mini kit column.

13. Proceed with the RNA extraction using RNeasy Mini kit. Include the DNase treatment step as specified in the RNeasy instructions.

Analyze RSV replication in A549 cells by real-time PCR assay

14. Prepare cDNA from 1 µg total RNA as described in Basic Protocol 2.

15. Use RNA from highly-infected cells (e.g., wells infected with RSV at MOI 1 for 24 hr) to prepare cDNA for the standard curve.

16. Amplify viral genes and β-actin using primers described above (Table 26.6.1) and the PCR conditions described in Basic Protocol 2.

    Because of the high sequence similarity between human and cotton rat β-actin gene, the same set of primers is used for the β-actin amplification in A549 cells and in the cotton rat lung samples.

17. Use the standard curve to obtain relative expression units for all genes and normalize them by the β-actin mRNA expression level as described in Basic Protocol 2.

18. Express mRNA levels as the mean ±SEM for two different wells of cultures.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

A549 growth medium

Dulbecco's modified Eagle's medium (DMEM) supplemented with:
10% (v/v) fetal bovine serum (FBS)
100 IU/ml of penicillin
100 μg/ml streptomycin
2 mM L-glutamine
Store up to 2 months at 4°C

Crystal violet fixative/stain

0.067% (w/v) crystal violet
1.25% (v/v) glutaraldehyde
Store up to 1 year at room temperature

HEp-2 growth medium

EMEM with Earle's BSS, supplemented with:
10% (v/v) FBS
2 mM L-glutamine
50 μg/ml gentamicin
2.5 μg/ml Fungizone
1× penicillin/streptomycin
Store up to 2 months at 4°C

Homogenization medium

Hanks' balanced salt solution (HBSS; *APPENDIX 2A*)
0.218 M sucrose
4.4 mM glutamate
3.8 mM KH_2PO_4
7.2 mM K_2HPO_4
Store up to 2 months at 4°C

Methyl cellulose overlay medium

EMEM containing:
0.75% (w/v) methyl cellulose
1% (v/v) FBS
2 mM L-glutamine
50 μg/ml gentamicin
2.5 μg/ml Fungizone
Store up to 2 months at 4°C

COMMENTARY

Background Information

RSV is an enveloped, nonsegmented, negative-strand RNA virus that belongs to the family *Paramyxoviridae*. The RSV genome contains 10 genes in the order NS1, NS2, N, P, M, SH, G, F, M2, L from the 3′ end; these genes give rise to 11 proteins (M2 ORF encodes two proteins: M2-1 and M2-2). RSV proteins include three transmembrane surface proteins G, F, and SH; the virion matrix protein M; the nucleocapsid proteins L, N, P, M2-1, and M2-2; and the two putative nonstructural proteins NS1 and NS2. RSV genes are transcribed sequentially from the 3′ end of the genome, with promoter-proximal genes transcribed more frequently than downstream genes (Collins and Wertz, 1983). This results in a transcription gradient characteristic

also of other mononegaviruses. Upon accumulation of virally expressed proteins in infected cells, RSV begins a replicative cycle in which a positive-strand copy of genome, the antigenome, is synthesized as an intermediate. Both genomic and antigenomic RNA get packaged into completed virions, in a process dependent on ongoing viral protein synthesis (Huang and Wertz, 1982).

Respiratory syncytial virus (RSV) is a major cause of bronchiolitis and viral pneumonia in young children, and the primary viral cause of death in infants (Shay et al., 2001; Thompson et al., 2003). Bronchiolitis caused by RSV affects most infants during their first and second months of life, but reinfection (often occurring with milder symptoms or asymptomatic) is common. By the age of 2, almost all children have been infected with RSV at least once, and half of the children had been reinfected (Glezen et al., 1986). RSV infection in children is associated with recurrent wheezing later in life, pointing to a link between RSV and inflammatory-allergic disorders (Stein et al., 1999; Sigurs et al., 2000; Schauer et al., 2002). Animal studies in the cotton rat model indicate that inflammatory changes in the lung are elicited in animals immune to RSV, even in the absence of detectable virus production (Prince et al., 1986). One likely explanation for that phenomenon could be abortive viral replication triggering an inflammatory response in the lung.

Abortive replication of RSV may indicate that reinfection with RSV occurs more frequently than currently appreciated. Typically, RSV infection is diagnosed by the isolation of virus from respiratory secretions of infected individuals. These cases would represent children infected with RSV for the first time, as well as children and adults reinfected with RSV after a certain period of time sufficient for the immune protection against virus to wane. However, our results suggest that reinfections might also occur shortly after previous challenge and happen at a time when immune response is sufficiently strong to suppress productive infection, but not abortive replication of the virus. Clinically, these reinfections would be characterized by expression of viral antigens in the absence of virus production, and may go undetected if viral cultures are used to monitor disease. Notably, results of several recent human studies support the possibility of frequent "abortive" RSV infections. These studies, in which respiratory secretions were analyzed for RSV presence by viral culture and by RT-PCR, revealed that consistently more samples test positive for RSV by RT-PCR than by culture (Falsey et al., 2002, 2003; Hu et al., 2003; Perkins et al., 2005). These results may indicate that some individuals with RSV detected by RT-PCR, but not by culture, might have recently recovered from RSV and are currently undergoing reinfection accompanied by abortive replication of the virus.

Critical Parameters and Troubleshooting

The critical parameter for abortive viral replication is establishing immunity strong enough to suppress productive replication of the virus in the lung. In the cotton rat, infection of animals with less that $\sim 10^4$ pfu RSV/animal produces only partial immunity, and virus can be recovered from the lungs of animals reinfected with RSV 21 days later. In this case, abortive replication of RSV would be masked by the production and release of infectious virions in the lung. If this situation occurs after following the protocols described here, an experimenter should recheck the titer of the RSV virus stock used in the lab to ensure the stock is of the correct concentration. If the titer turns out to be lower than the expected value, the amount of viral inoculum needs to be increased in the priming and rechallenge doses accordingly.

If using an animal model other than cotton rat to monitor abortive replication of RSV, one would need to determine the amount of viral inoculum establishing sterilizing immunity (as defined by the absence of infectious virions in the lungs after re-challenge) in the lungs of that particular animal. In order to do that, animals have to be inoculated with various doses of RSV at time 0, reinfected with $\sim 10^5$ to 10^6 pfu RSV/animal 21 days later, and sacrificed at the time of peak RSV replication. The dose of RSV causing sterilizing immunity in the lung should be used in all experiments on abortive RSV replication.

The critical parameters and troubleshooting relating to Basic Protocols 1 and 2 and Support Protocols 1 and 2 are addressed in the corresponding sections.

Anticipated Results

Each primer pair given in Table 26.6.1 can be expected to successfully amplify the appropriate DNA fragment, with efficiencies between primer pairs being nearly identical (98% to 99%; Fig. 26.6.1A). This is best demonstrated when a standard curve is developed using serial 10-fold dilutions of plasmid containing entire RSV antigenome (correlation

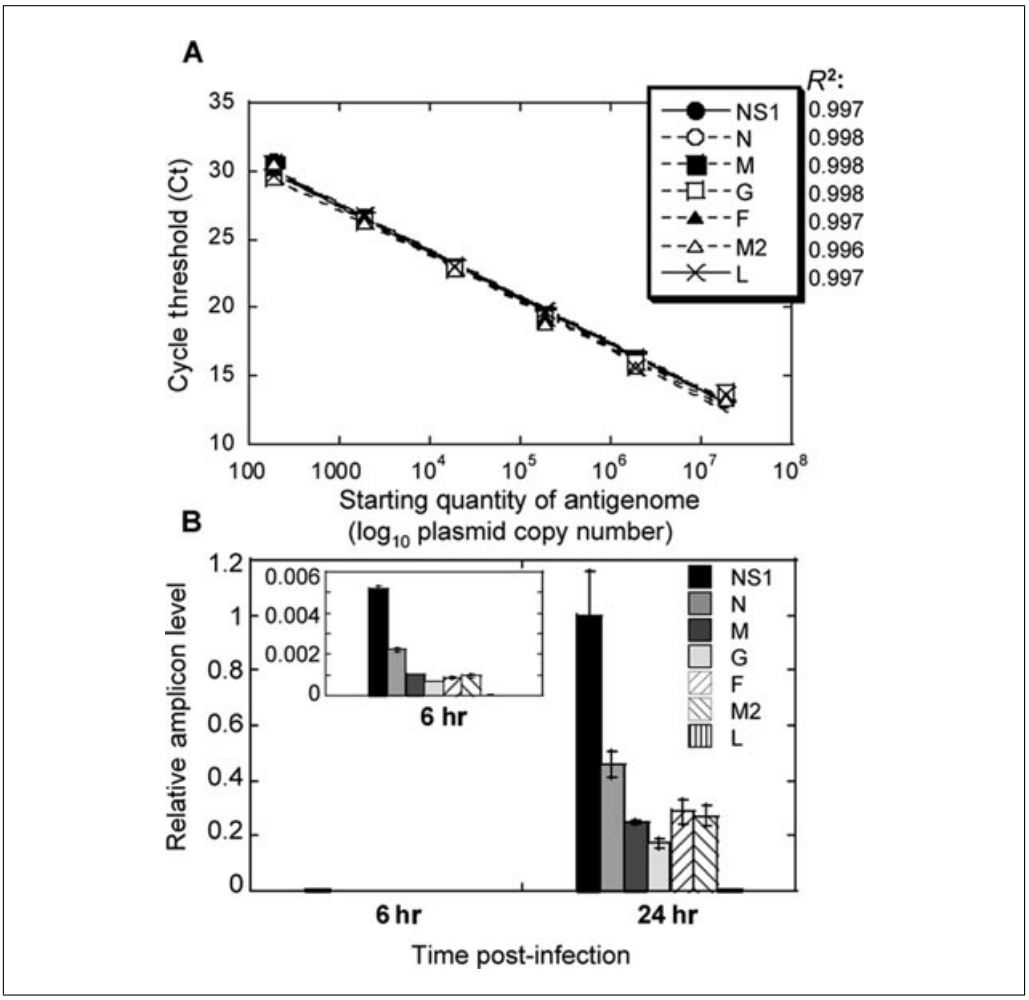

Figure 26.6.1 Establishing real-time PCR assay of RSV replication. (**A**) Amplification of various RSV genes from RSV antigenome inserted into a vector. Six 10-fold dilutions of antigenome-containing vector were used to generate a standard curve. Ct values were plotted against $\log_{10}$ quantity of antigenome used as a template. Correlation coefficients (R^2) of the best fit are shown next to the symbols corresponding to the 7 RSV genes analyzed. Each point on this graph includes symbols for all 7 genes. (**B**) Expression of RSV genes in infected A549 cells. A549 cells were infected with RSV at MOI 0.1. At time points 6 and 24 hr after infection, total RNA was extracted from infected cells and reverse transcribed using oligo(dT) primer. Expression of mRNA for each RSV gene indicated was measured by qRT-PCR. The relative level of each amplicon was normalized by β-actin mRNA level (also measured by qRT-PCR) in the corresponding sample, and expressed relative to the level of NS1 amplicon at 24 hr. The insert shows a gradient of RSV gene expression at 6 hr on an adjusted *y* -scale to highlight differences between levels of various amplicons. The results represent the mean ±SEM for two different wells per time point.

coefficients of 0.996 to 0.998). When used for analysis of RSV replication in vitro (see Support Protocol 2), the qRT-PCR assay described in Basic Protocol 2 accurately reflects viral load as estimated by the plaque assay (Basic Protocol 1). We have addressed this issue using cultures of alveolar epithelial cells A549 infected with RSV (see Support Protocol 2). As shown in Figure 26.6.1B, infection of A549 cells is slow, with transcripts of RSV genes appearing at 6 hr and accumulating considerably by 24 hr post-infection, consistent with reports of RSV infection of epithelial cells measured by other methods (Bermingham and Collins, 1999). A pronounced gradient of RSV gene expression is apparent in infected A549 cells, with amounts of transcripts diminishing dramatically in the order from NS1 to L. Reverse transcription with oligo dT primer, used in this and other similar experiments, results in a cDNA pool that contains not only reverse-transcribed copies of individual mRNAs produced during RSV transcription, but also copies of the RSV antigenome. However, because antigenome would be represented similarly in reactions

Table 26.6.2 Comparison of RSV Detection by Viral Culture and qRT-PCR in RSV-Infected Epithelial Cells

	MOI 0.001[a]	MOI 0.01	MOI 0.1
Viral yield (log_{10} pfu/ml)	2.24 ± 0.06	3.26 ± 0.20	4.77 ± 0.25
RSV gene expression level[b]	0.004 ± 0.001	0.069 ± 0.005	1 ± 0.1909
RSV genome level[c]	0.0009 ± 0.0002	0.020 ± 0.003	1 ± 0.117
RSV antigenome level[c]	0.0003 ± 0.0002	0.005 ± 0.002	0.269 0.057

[a]A549 alveolar epithelial cells were infected with RSV at MOI 0.001 to 0.1. At a point 48 hr after infection, cell supernatants were collected for quantification of viral yield by plaque assay, while cells themselves were lysed and used as a source of RNA for qRT-PCR analysis of RSV transcripts.

[b]Expression of RSV NS1 amplicon was analyzed by qRT-PCR, normalized by the expression of β-actin in the corresponding cell culture, and presented relative to the amount of NS1 amplicon in MOI 0.1–infected culture (assigned relative value of 1).

[c]Expression of RSV genome and antigenome was analyzed by qRT-PCR, normalized by the level of β-actin in the corresponding cell culture, and presented relative to the amount of genome in MOI 0.1-infected culture (assigned relative value of 1).

for different RSV genes, the differences between amplicon levels measured by RT-PCR here are attributed to differences in gene expression levels. Therefore, fluctuations in the different RSV amplicons' levels measured in oligo dT cDNA can be expressed as the gene-expression differences.

The RT-PCR assay of RSV replication described above can be expected to accurately quantify viral load in infected cells. To verify that, we inoculated A549 cells with RSV at various MOIs (0.001 to 0.1). At a time point 48 hr after infection, cell supernatants were collected for viral titrations, while the cells themselves were lysed for RNA extraction. Viral yield in supernatants of A549 cells accurately represented the level of infection (Table 26.6.2). Cells infected with the 10-fold-increasing amounts of RSV release virus in quantities that also differ by ∼10-fold. When viral RNA from these cells is analyzed by RT-PCR using primers for RSV NS1 gene, the difference in the amount of NS1 amplicon detected in A549 cells also differs by ∼10-fold between cultures infected with RSV at MOIs of 0.001, 0.01, and 0.1, respectively. The level of negative-sense (genome) and positive-sense (antigenome) RNA can also be measured in RSV-infected cells (Table 26.6.2). For that, total RNA of infected cells is reverse-transcribed using forward or reverse primer annealing to the genomic or antigenomic strand of RSV, respectively. The amount of reverse-transcribed product can then be measured by real-time PCR using primers specific for RSV amplicons G or M, proximal to the start of genome or antigenome fragment prepared, respectively. In infected A549 cells, the amount of genome and antigenome increases progressively between samples infected with increasing amounts of RSV, similar to the pattern of viral gene expression (Table 26.6.2), although less precisely reflecting differences between MOIs of infection and viral yield in infected cells. Real-time PCR analysis of extracts of cells infected with RSV indicates that RSV genome is ∼3- to 4-fold more abundant in infected cells than antigenome, consistent with reports for other paramyxoviruses, in which the antigenome constitutes only 10% to 40 % of genome in infected cells (Robinson 1970; Kolakofsky et al., 1974; Kolakofsky and Bruschi, 1975).

In vivo replication of RSV can also be accurately assessed by qRT-PCR. Infection of naïve cotton rats with RSV (primary RSV infection) results in efficient virus replication in the lungs that reaches peak on day 4 post-infection and disappears by day 7 (Fig. 26.6.2A). Genome and antigenome synthesis in primary RSV infection (Fig. 26.6.2B) increases progressively following RSV challenge, reaching its peak on day 4 post-infection and diminishing after that. This pattern of genome/antigenome production parallels the amount of infectious viral particles detected in the lungs of animals with primary RSV infection (Fig. 26.6.2A) on corresponding days. The only difference is seen for day 7, when no virus can be recovered from the lungs, and yet

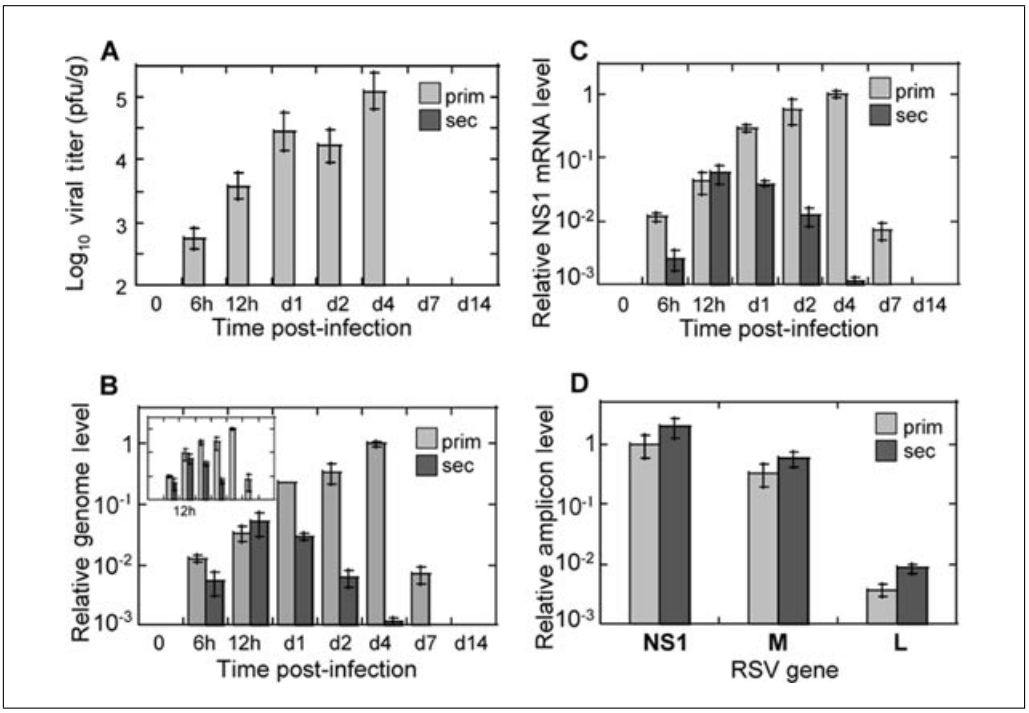

Figure 26.6.2 RSV replication in vivo: evidence of abortive replication in the reinfection model. Cotton rats were infected with RSV once for primary infection studies or twice (with an interval of 21 days) for secondary infection studies. At the indicated time points after the final challenge, lungs were collected for viral titer determination by plaque assay (**A**) or for analysis of RSV replication by qRT-PCR (**B, C, D**). (**A**) Pulmonary viral titers in cotton rats with primary RSV infection ("prim", light gray bars) and secondary RSV infection ("sec", no virus detected). Viral titers were determined by plaque assay as previously described (Prince et al., 1978; limit of detection 2 $\log_{10}$ pfu/g). (**B**) RSV genome and antigenome replication in primary and secondary RSV infection. RNA was extracted from the lungs of infected animals and reversed transcribed using primers complementary to the genomic or antigenomic strand of RSV. Relative genome (and antigenome, insert) amounts were determined by qRT-PCR, normalized by the β-actin mRNA level in the corresponding sample, and expressed relative to the level of genome (antigenome, for insert) detected in the lungs of animals with primary RSV infection on day 4. (**C**) Expression of RSV genes during primary and secondary RSV infection. RNA extracted from animals described above was reverse-transcribed using oligo (dT) primer. Expression of NS1 mRNA was measured by qRT-PCR, normalized by β-actin as described above, and expressed relative to the level of NS1 mRNA detected in the lungs of animals with primary RSV infection on day 4. (**D**) Gradient of RSV gene expression at 12 hr post-infection in primary and secondary RSV disease. NS1, M, and L amplicon levels were measured by qRT-PCR in cDNA prepared using oligo(dT) primer. Expression of each amplicon was normalized by β-actin, and expressed relative to the level of NS1 mRNA detected in the lungs of animals with primary RSV infection. The results represent the mean ±SEM for four animals per time point for each primary and secondary infection.

genomic and antigenomic strands of RSV can still be detected.

If animals inoculated with RSV once are kept for 21 days and then rechallenged with RSV (secondary RSV infection), no virus is detected in the lungs of such animals by viral culture (Fig. 26.6.2A). Viral RNA expression in secondary RSV infection, however, is strong. As Figure 26.6.2B shows, secondary RSV infection of cotton rats is accompanied by efficient synthesis of both genomic and antigenomic strands of RSV. It reaches peak at 12 hr post-infection and declines afterwards to an undetectable level by day 7. Production of genomic/antigenomic RNA is indistinguishable between primary and secondary RSV infection at 12 hr post-infection. After that, the amount of viral RNA in animals with secondary infection starts to decrease, and the differences between primary and secondary infection increase in magnitude with each subsequent time point as infection progresses. Because the scales of changes in viral titer and RSV RNA production in Figures 26.6.2A and 26.6.2B were set to be comparable (spanning 3 orders of magnitude each), the large

discrepancy in the extent of viral RNA replication and production of infectious viral particles during secondary RSV infection can be easily appreciated. For example, while the amount of infectious viral particles on day 1 in primary RSV infection is at least 288-fold higher than in secondary RSV infection (taking 2 $\log_{10}$ pfu/g detection limit into account and allowing for the possibility of the presence of some undetectable virus in the lungs of secondarily infected animals), the difference in RSV RNA level between primary and secondary infection is only 8-fold.

Expression of individual RSV genes during RSV infection in vivo can also be analyzed during primary and secondary RSV infection of cotton rats. The dynamics of RSV gene expression changes can be expected to be very similar to those of genome/antigenome variations noted above, and are exemplified by changes in the NS1 amplicon level shown in Figure 26.6.2C. NS1 gene expression in secondary RSV infection increases between 6 and 12 hr, and declines afterwards, while NS1 expression in primary infection increases progressively past the 12-hr time point, reaches a peak on day 4 post-infection, and declines afterwards. M and L amplicons follow identical patterns of time-dependent changes after RSV infection (data not shown). Similarly to the genome/antigenome changes, expression of RSV genes between primary and secondary infection is very similar at 12 hr post-infection for each particular gene analyzed. Overall, RSV re-infection of animals infected 21 days earlier results in increasing expression of viral transcripts and genome replication, but does not lead to production of detectable progeny virus. This type of replication, therefore, can be termed "abortive," as RSV is capable of entering the cells in the lungs of immune animals, yet production of progeny viruses is impaired. This is in contrast to the primary RSV infection, where accumulation of both viral genetic material and progeny viruses is detected in the lungs.

Time Considerations

Viral titrations by qRT-PCR and by plaque assay take ~1 week each, from the time of lung sample processing to the time of reading final results. Animal experiments are the most time-consuming part of the described protocols. A period of 21 days is needed between the primary and secondary RSV challenge, and an additional 2 weeks are needed for collection of samples after the final RSV inoculation.

CHAPTER 27
RNA-Based Methods in Cell Biology

INTRODUCTION

The initial demonstration in *C. elegans* that double-stranded RNAs (dsRNAs) can direct the degradation of messenger RNAs (mRNAs) that share their sequence has touched off a revolution in many fields of biology, including cell biology. It would be difficult to exaggerate either the speed or the significance with which these changes have occurred. It is now understood that virtually all animals and plants utilize small RNA molecules to control protein expression, to regulate the structure of their genomes, and to respond to viral infection. This chapter will include applications through which our emergent understanding of non-coding RNAs may be utilized by cell biologists.

The capacity of short dsRNAs to silence gene expression in mammalian cells was quickly exploited for the development of reverse-genetic methods in cultured mammalian cells. Among the first applications of this kind was the use of small interfering RNAs (siRNAs) to obtain potent, long-lasting post-transcriptional silencing of chosen genes through the active degradation of their encoded mRNAs (*UNIT 27.1*). In this application, chemically synthesized oligonucleotides with 21- to 25-nucleotide RNA duplex regions and 2-nucleotide 3′overhangs are directly transfected into cells. One strand of this duplex region is complementary to the target mRNA of interest. After incorporation into a multiprotein complex, called the RNA-induced silencing complex (RISC), this complementary sequence guides the endonucleolytic cleavage of targeted mRNAs. The length of RNA duplexes is largely determined by the fact that longer RNA duplexes trigger sequence-nonspecific attenuation of gene expression. siRNAs of this size are sufficient to provide a high degree of specificity, since even a few mismatches within the duplex can prevent target mRNA recognition. Nevertheless, the efficiency of knockdown should be monitored carefully because it can vary between different siRNAs targeting the same mRNA, and a series of controls must be utilized to ensure that observed phenotypes do not result from the unintended destabilization of other mRNAs.

As this chapter develops, there will be enormous scope for discussion of alternative methods for RNA interference through different methods of dsRNA production, as well as for the use of RNA-based methods in other cell biological contexts. Finally, studies of how different small RNAs are produced and of the processes through which they regulate physiological events are burgeoning fields of cell biology, producing important and fundamental physiological insights at a breathtaking rate.

Silencing of Gene Expression in Cultured Cells Using Small Interfering RNAs

Kumi Sakurai,[1] Pritsana Chomchan,[1] and John J. Rossi[1]

[1]Beckman Research Institute of City of Hope, Duarte, California

ABSTRACT

The discovery of RNA interference (RNAi) and related small RNA–mediated regulatory pathways has significantly altered the understanding of gene regulation in eukaryotic cells. In the RNAi pathway, small interfering RNAs (siRNAs) ~21 to 23 nucleotides in length serve as the regulatory molecules that guide and induce sequence-specific gene silencing. The use of siRNA-mediated silencing as a tool for investigating gene function is well established in cultured mammalian cells. This unit provides basic approaches to explore the field of RNAi, and hopes to address the importance of optimizing transfection conditions after empirical determinations in order to understand various degrees of silencing efficiency. *Curr. Protoc. Cell Biol.* 47:27.1.1-27.1.28. © 2010 by John Wiley & Sons, Inc.

Keywords: RNAi • small silencing RNAs • gene silencing • transfection • mammalian cell culture

INTRODUCTION

Since the first demonstration of RNA interference in cultured mammalian cells in 2001 (Elbashir et al., 2001a), small interfering RNA (siRNA)–mediated sequence-specific gene silencing has been widely used as a tool for investigating gene function, and has initiated a new wave of reverse genetics in mammalian systems. The siRNA-mediated silencing provides fast, target-specific down-regulation of gene expression. The extent to which one can successfully carry out the silencing for determination of gene function depends on the potency of siRNAs, transfection conditions, duration of analysis, and screening methods. This unit describes design of siRNAs, transfection of siRNAs into cultured cells, and testing and validation of gene knockdown.

The silencing efficiency is based on degree of susceptibility of target transcripts to siRNA-mediated RNA-induced silencing complex (RISC) activity. It is important to design multiple siRNAs and screen for siRNAs that are highly potent in silencing a given gene. There are several online siRNA design programs available, providing predicted siRNA sequences and opportunities to explore and compare the siRNA sequences generated by different design methods. Once several siRNA sequences with high prediction scores are obtained (Basic Protocol 1), one should carefully design and evaluate siRNA transfection conditions (Basic Protocol 2).

Transfection of mammalian cells typically utilizes reagents that enhance the uptake of nucleic acids (e.g., plasmid DNA or siRNAs) by cultured cells. Transfection methods commonly used are: (1) cationic liposomes—a complex of the genetic materials and/or siRNAs with a cationic lipid—inducing fusion with the cell plasma membrane; (2) electroporation via destabilization of the cell plasma membrane; and (3) calcium phosphate/nucleic acid precipitate uptake. In this unit, we describe the use of liposomes to deliver siRNAs to cultured mammalian cells for silencing gene expression.

Current Protocols in Cell Biology 27.1.1-27.1.28, June 2010
Published online June 2010 in Wiley Interscience (www.interscience.wiley.com).
DOI: 10.1002/0471143030.cb2701s47

As previously mentioned, it is desirable to test several siRNAs against a given gene and screen for efficacy. Target-site screening is tricky, but necessary to validate and observe outcomes that accurately reflect the effect of siRNAs. Currently, screening heavily relies on experimental observations such as monitoring phenotypic changes, detection of changes in reporter protein expression (e.g., fluorescence for GFP-target fusion proteins), RT-PCR (Support Protocol 1), or western blot analysis (Support Protocol 2). As fundamental processes for the validation of the siRNA-mediated silencing, we describe RNA isolation and protein collection following transfections. In addition, a dual-reporter system can be used for rapid and reliable screening for siRNA sequences (Support Protocol 3). The psiCHECK-2 vector system (Promega) incorporates expression of a fluorescent reporter protein (e.g., *Renilla* luciferase) and a control fluorescent protein (e.g., firefly luciferase) from a single vector, enabling one to evaluate the efficiency of siRNAs by comparing expression levels of reporter proteins. Support Protocols 4 and 5 are intended to supplement Basic Protocol 1 when a siRNA is obtained in single-stranded format.

STRATEGIC PLANNING

siRNA Design Algorithms

The sequence of an siRNA can be by far the most important determinant of silencing efficiency. The identification and selection of highly potent siRNA sequences against a given gene prior to any experimental determinations can be overwhelming. To facilitate the designing process, there are several databases that archive siRNA sequences tested in mammalian RNAi experiments (Chalk et al., 2005; Shah et al., 2007; Ren et al., 2009). Validated siRNAs can also be found in commercial resources such as the Stealth RNAi siRNAs from Invitrogen, the *Silencer* validated siRNA from Ambion, and HP validated siRNAs from Qiagen. These vendors and Dharmacon also provide predesigned siRNAs and custom design services, making siRNA designing easier and providing a good starting point. However, many, if not most, siRNA-mediated RNAi assays require experimental validation for optimization of conditions to meet specific aims.

NOTE: Throughout the protocols, RNA-handling techniques (*APPENDIX 2A*) should be practiced and aseptic cell culture conditions should be maintained to avoid accidental introduction of nucleases, cross-contamination of samples, and potential loss of cell culture.

BASIC PROTOCOL 1

DESIGN OF 21-NUCLEOTIDE-LONG siRNA (21-MER)

If no matches are found for a given gene of interest in the literature and available siRNA databases, siRNAs can be designed using Web-based siRNA design programs. There are several siRNA selection algorithms to help predict siRNA sequences for effective silencing. Users need to provide the target messenger RNA sequence and are able to create some user-defined design criteria such as thermodynamic stability and AU/GC base pair contents that will influence the overall efficiency of predicted siRNAs. Each algorithm has a unique emphasis on design features, but fundamentally most of the algorithms provide siRNA sequences with scores or ranks for users to further analyze for specificity and select candidate siRNAs that meet their needs. Some algorithms are specialized in determining off-target effects of predicted siRNA sequences (Chalk and Sonnhammer, 2008; Gong et al., 2008) to reduce unwanted side effects. Once selected, siRNAs can be synthesized in-house or obtained from several siRNA-licensed vendors such as Ambion, Dharmacon, and Qiagen.

While many of the siRNA design algorithms provide siRNAs in the form of 19 base pairs with 2 nucleotide overhangs at the 3′ end on each strand, siRNAs can be generated by processing longer double-stranded RNAs (dsRNAs) by the RNase III Dicer enzyme.

One may find the use of such dsRNAs for target gene silencing advantageous, since transfecting 25- to 27-nt siRNAs showed improved silencing efficiency (Rose et al., 2005). Hannon and colleagues also reported similar observations with short hairpin RNAs with 29-bp stems (Siolas et al., 2005). These observations together with others suggest that the Dicer processing of its substrates results in better programming of RISC (Elbashir et al., 2001c; Liu et al., 2003; Gregory et al., 2005).

While the 21-nt siRNAs often show a wide range of potency (Amarzguioui et al., 2003; Reynolds et al., 2004; Ui-Tei et al., 2004), transforming a 21-nt siRNA to a 27-nt Dicer substrate siRNA may improve the silencing efficiency. Furthermore, the structural modification that mimic secondary structure of existing Dicer substrates (e.g., pre-microRNAs) will introduce the defined polarity of Dicer processing, leading to preferential incorporation of the desired guide strand (Rose et al., 2005). Alternatively, D-siRNA sequences can be selected using an algorithm that provides fully automated D-siRNA designs using the mRNA target sequence (RNAi Design; Owczarzy et al., 2008; *http://www.idtdna.com/Scitools/Applications/RNAi/RNAi.aspx*).

Materials

Gene of interest
Web-based siRNA design program (e.g., Table 27.1.1)
Web-based specificity program (e.g., SpecificityServer; Table 27.1.1)

Design siRNA

1. Obtain the most updated mRNA sequence of the gene of interest from the UCSC Genome Browser (*http://genome.ucsc.edu/cgi-bin/hgGateway*).

2. Use an online siRNA design program to enter the mRNA sequence. To increase the chances of designing highly potent siRNAs, include the 5′ and 3′ untranslated regions (UTRs) in the inquiry as well. Follow the Web site instructions to further define the siRNAs.

   Examples of Web-based siRNA design tools are listed in Table 27.1.1.

3. Analyze the target sequence of the candidate siRNAs for specificity using available Web servers (e.g., SpecificityServer). Utilize several online siRNA design tools to compare and select up to five candidate siRNAs with high prediction scores.

Design Dicer substrate siRNA (D-siRNA)

4. Obtain a 21-nt siRNA sequence using the Web-based siRNA design tools.

   An example of a sequence is shown in step 5.

Table 27.1.1 List of Web-Based siRNA Design Tools

Tools	URLs
siRNA Target Finder	*http://www.ambion.com/techlib/misc/siRNA_finder.html/*
BLOCK-IT RNAi Designer	*http://rnaidesigner.invitrogen.com/rnaiexpress/*
GeneAssist siRNA Workflow Builder	*http://www5.appliedbiosystems.com/tools/sirna/*

siRNA Target Designer	*http://www.promega.com/siRNADesigner/*
SpecificityServer	*http://informatics-eskitis.griffith.edu.au/SpecificityServer/*

5. Extend the sequence of the sense strand to 25 nt and antisense strand to 27 nt, making one end of the duplex blunt-ended with 2 deoxy 3′ terminal end to block the Dicer entry.

   An example of a target sequence and siRNA are shown below.

   Target
   5′-AAGCUG**ACCCUGAAGUUCAUCUGCACC**ACCGGC-3′
   siRNA
   Sense: **ACCCUGAAGUUCAUCUGCACC**
   Antisense: ACUGGGACUUCAAGUAGACGU
   D-siRNA
   Sense: ACCCUGAAGUUCAUCUGCACCACCG
   Antisense: ACUGGGACUUCAAGUAGACGUGGUGGC

6. Exchange the last two ribonucleotides of the sense strand to corresponding deoxyribonucleotides.

   For instance, change the ribonucleotides to dCdG (shown in lowercase below) if the last two sequences are CG.

   Sense: **ACCCUGAAGUUCAUCUGCACC**ACcg
   Antisense: ACUGGGACUUCAAGUAGACGUGGUGGC

7. Once selected, synthesize siRNAs in-house or obtain from several siRNA-licensed vendors such as Ambion, Dharmacon, and Qiagen.

   When an siRNA is obtained in single-stranded format, the sense and antisense strands need to be annealed, and the integrity and quality of annealed double-stranded RNA need to be determined. These procedures are described in Support Protocols 4 and 5.

BASIC PROTOCOL 2

DETERMINING OPTIMAL TRANSFECTION CONDITIONS

In order to set up experiments with the designed siRNAs, several experimental conditions need to be optimized. First, it is important to determine the optimal cell density at the time of transfection. Transfection efficiency varies based on the cell density and concentrations of siRNAs, in addition to variations in transfection reagents used in the reaction. Second, optimal siRNA-lipid concentrations should be determined while screening for potent siRNAs to verify the most effective siRNA duplexes and the lowest concentration that results in efficient silencing of target gene without toxicity. Finally, it is recommended to empirically determine which reagent works best for your cell line. A variety of proprietary transfection reagents are available, and the efficiency of siRNA delivery to a particular cell line will slightly differ among the reagents. In this protocol, we describe a transfection procedure using Lipofectamine 2000 reagent (Invitrogen), which showed high transfection efficiency with commonly used mammalian cell lines (e.g., HEK293, HeLa, and HCT116 cells).

Procedures described here are for adherent cells grown in monolayer. For suspension cells, the same procedures will apply, except that detaching cells from the surface of culture dishes is not necessary. Otherwise, deviations in the procedures will be noted accordingly.

For successful gene silencing by transfecting mammalian cells with siRNAs, it is strongly recommended to determine the optimal cell density of your cell line, and optimal siRNA concentrations, before your experiments. To find an optimal cell density, perform transfections with at least two different levels of confluency. In accordance with the recommended

Table 27.1.2 Recommended Percent Confluence for Transfection

Cell types	Source	Recommended % confluence[a,b]
HEK293	Human embryonic kidney	90%
HeLa	Human cervical carcinoma	70%-80%
HCT116	Human colon carcinoma	50%
A549	Human lung carcinoma	60%
D3	Mouse embryonic stem cells	Transfect cells at the time of plating
3T3L1	Mouse fibroblast	60%-70%

[a]The listed cell densities are for 16 to 24 hr incubation. Adjust the seeding cell density so that cells reach confluency at the end of incubation if a longer interval between transfection and harvesting cells is necessary.
[b]Information also found at Invitrogen Web site *http://www.invitrogen.com*.

Table 27.1.3 Reagent Mixes for Transfection with Six Different Concentrations of siRNAs (12-well plates)

siRNA final conc. (nM)[a]	siRNA per well (ng)[b]	Stuffer DNA plasmid (ng)[c]	Total nucleic acid amount (μg)
0	0 (μg)	1100	1.1
1.0	1 pmol (13.37 ng)	1087	1.1
5.0	5 pmol (66.85 ng)	1033	1.1
25	25 pmol (334.3 ng)	765.7	1.1
50	50 pmol (668.5 ng)	431.5	1.1
75	75 pmol (1003 ng)	97.21	1.1

[a]siRNA concentrations were calculated for the final volume of 1 ml per well of a 12-well plate.
[b]siRNA (ng) was calculated with a dsRNA, mol. wt. = 1.34×10^4 g/mol.
[c]Any cloning vectors not containing eukaryotic promoters (e.g., pBluescript, pCR2.1, etc) can be used to adjust the total amount of nucleic acid.

percent confluence of adherent cells shown in Table 27.1.2, seed the cells in multiple-well plates at a minimum of two different densities 1 day prior to transfection.

In this protocol, 75% seeding density is used to plate four 12-well plates to perform a transfection with two siRNAs, an irrelevant siRNA as a negative control, and a Cy3-labeled siRNA as a positive control, at six different concentrations for an assay period of 24 hr. It is strongly recommended to perform another round of transfection with adjusted cell density to optimize the transfection conditions for your experiment. Cells with shorter doubling times should be seeded at a lower density so that cells reach confluency at the end of the assay period (e.g. HCT116, ∼16 hr; HEK293, ∼22 to 24 hr; HeLa, ∼ 24 hr). Within a well of a 12-well plate, you should be able to collect sufficient amounts of total RNA and proteins for your silencing analyses (Support Protocols 1 to 3). If the target gene expression is relatively low, consider plating in 6-well plates instead.

When you are analyzing gene function by knocking down gene expression with siRNA transfection, it is strongly recommended to verify the highly potent siRNA duplexes among siRNAs that you designed, and to identify the lowest concentration that results in efficient silencing of the target gene and is least toxic to cell culture. Procedures described below refer to transfection of cells seeded on four 12-well plates to determine optimal cell density for transfection with two siRNAs against the same target transcript. When more than two siRNAs are designed, adjust the number of plates to have enough wells for experimental determinations. To find optimal siRNA concentrations, one should test at least six different concentrations (e.g., 0, 1, 5, 25, 50, and 75 nM) in duplicate for

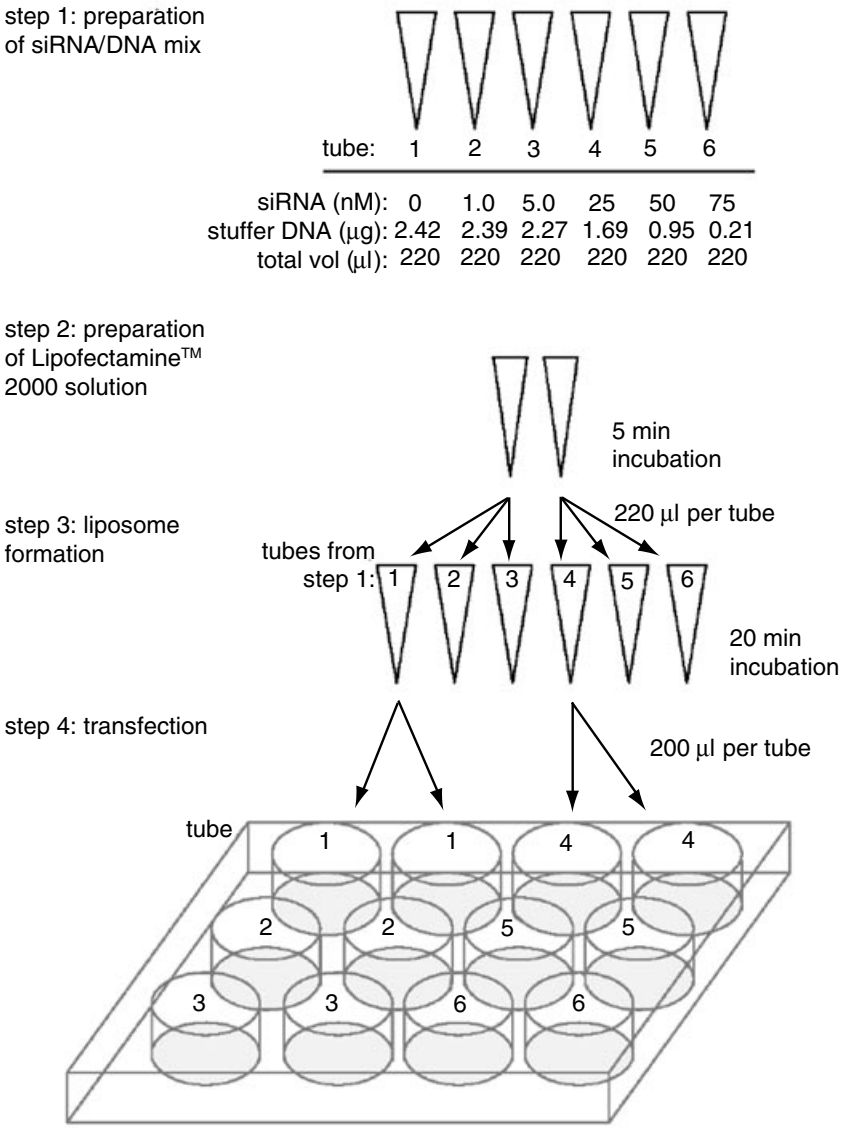

Figure 27.1.1 Transfection of mammalian cells with siRNAs. Stepwise description of transfection of mammalian cells seeded onto a 12-well plate a day prior to transfection is shown above. After choosing five different concentrations of siRNAs to transfect the cells, mix siRNA and stuffer DNA in the Opti-MEM (or a serum-free medium) to bring the volume to 220 μl (step 1). Next, prepare the proper amount of Lipofectamine 2000 solution (two tubes of 720 μl for six tubes of siRNA/DNA mixes, step 2). After 5 min incubation, add 220 μl of Lipofectamine 2000 solution to each siRNA/DNA mix (step 3). Incubate for 20 min to let liposome formation, then add 200 μl of the liposome solution to transfect the cells (step 4). Transfection reagent preparations should be done in a tissue culture hood.

each siRNA as a starting point. Also, the use of a fluorescent dye–labeled siRNA as a transfection control (e.g., FITC, Cy3) will help visualize the transfection efficiency at different concentrations of an siRNA. See below for reagents contained in each transfection reaction (Table 27.1.3). A brief summary of the procedure is also shown in Figure 27.1.1.

NOTE: It is desirable to use early-passage-number cells if available. The effects vary among cell lines; however, passage number of the cells at the time of transfection may have impact on the efficiency of liposome uptake and may result in cellular toxicity.

NOTE: In the case of transfection with suspension cells, adjust the cell numbers accordingly.

NOTE: Transfection reagent preparations should be done in a tissue culture hood.

NOTE: The use of stuffer DNA plasmid will adjust the final amounts of nucleic acid to be consistent throughout the experiment; hence, maintaining the volume of Lipofectamine 2000 used in the reaction. We have often observed inconsistency in knockdown levels of target genes that result from varying the volume of cationic lipid solution for delivery of different concentrations of an siRNA. Hence, maintaining the volume of Lipofectamine 2000 throughout the experiment will not only prevent variation in transfection efficiencies among the six siRNA concentrations, but also will rectify cellular toxicity, which may be caused by the different amounts of cationic lipid used in the reaction. Any cloning vectors not containing eukaryotic promoters, such as pBluescript and pCR2.1, can be used as a stuffer DNA plasmid to adjust the total amount of nucleic acid.

Materials

Mammalian cell line cultured in the appropriate growth medium in 10-cm^2 dishes
Calcium- and magnesium-free Dulbecco's phosphate-buffered saline (CMF-DPBS; Cellgro, cat. no. 21-031 CV, or see *APPENDIX 2A*), 37°C
1× trypsin/EDTA solution (e.g., Invitrogen; also see *UNIT 1.1*), 37°C
Complete DMEM with 10% (v/v) FBS (see recipe), 37°C
Complete DMEM with 10% (v/v) FBS (see recipe), without antibiotics, 37°C
Trypan blue staining solution (*UNIT 1.1*)
10 μM siRNA working solution (Basic Protocol 1)
10 μM irrelevant siRNA as a negative control
10 μM fluorescent dye (e.g., Cy3 or FITC)–labeled siRNA as a transfection control
250 ng/μl stuffer DNA plasmid (e.g., pBluescript, pCR2.1; Clontech, Invitrogen)
Opti-MEM I (a reduced-serum medium from Invitrogen), or serum-free growth medium
Lipofectamine 2000 (Invitrogen)

Microscope
Hemacytometer with coverslip (Figure 1.1.1)
12-well tissue culture plates
Standard microscope and UV lamp or fluorescence microscope

Additional reagents and equipment for basic cell culture techniques including trypsinization and counting viable cells on a hemacytometer by trypan blue exclusion (*UNIT 1.1*)

NOTE: All solutions and equipment coming into contact with living cells must be sterile, and aseptic technique should be used accordingly.

NOTE: All cell culture incubations should be carried out in a 37°C, 5% CO_2 humidified incubator.

Seed cultured cells 1 day prior to transfection

1. For adherent cells grown at subconfluency on 10-cm^2 dishes, rinse with 5 ml 1 CFM-DPBS and add 2 ml of 1× trypsin/EDTA solution per dish to detach cells from surface.

   This will be enough to cover the monolayer culture.

   In order to seed four 12-well plates at 75% cell confluency, prepare two 10-cm^2 dishes of cells at ~80% confluency.

   UNIT 1.1 includes protocols for basic cell culture techniques including trypsinization.

2. After 2 min incubation at 37°C, gently tap bottom of dish to dislodge cells. Also check culture under a microscope to see that cells are detached from the surface.

   The cells should look rounded up.

   For cells grown in suspension, skip steps 1 and 2. First centrifuge the cell culture 5 min at 200× g, room temperature, aspirate medium, and follow steps 3 to 9.

3. Gently resuspend cells by adding ~5 ml of complete DMEM/10% FBS and pipetting up and down.

   The addition of the serum-containing medium will inhibit further trypsin digestion.

4. Transfer the cell suspension to a sterile 50-ml centrifuge tube, and centrifuge for 3 min at 200 × *g* room temperature.

5. Aspirate medium and resuspend the cells with 10 ml complete DMEM/10% FBS without antibiotics, so that maximum cell count will be ~50 cells per 1 mm^2 .

   If cells on a 10-cm dish are below 80% confluency, lower the volume of medium to adjust the maximum cell count to ~50 cells per 1 mm^2.

6. Add 10 µl of trypan blue staining solution and a 10-µl aliquot of cell suspension to a 1.5-ml microcentrifuge tube. Mix thoroughly and dispense 10 µl of the mix gently to edge of hemacytometer counting chamber by placing the tip of pipet under the coverslip.

   UNIT 1.1 includes a protocol for viable cell counting using trypan blue and a hemacytometer.

7. Count cells under a microscope and calculate cell numbers as follows (also see *UNIT 1.1*):

   Cell numbers (cells/ml) = average count per square × 2 × 10^4
   Total cells = cell numbers (cells/ml) × volume of medium used to dilute cells
   where 2 is the dilution factor, and 10^4 is the volume correction factor.

8. Determine cell viability by counting total number of viable (unstained) cells.

   % viable cells = [number of unstained cells/total number of cells] × 100

   To plate cells at 75% seeding density on four 12-well plates, you will need a total of ~1.5 × 10^7 viable cells.

9. Plate cells at a seeding density of 3.0 × 10^5 cells (initial 75% confluence) in 0.8 ml medium into wells of four 12-well plates. Make sure to distribute cells uniformly across the well to ensure even uptake of liposomes.

   On the day of transfection (i.e., the next day), cells with slow doubling time will reach ~85% to 90% confluency. After the transfection efficiency is determined, scale up or down the seeding density and perform another round of transfection.

   For different cell lines, the numbers of cells at seeding should be adjusted so that they will reach confluency at harvesting. For instance, seed 4.0 × 10^5 HEK293 cells to obtain 90% confluency for a 24-hr assay period. Also refer to Table 27.1.2 for the recommended % confluency at transfection for different cell lines so that the optimal seeding density can be empirically determined.

10. Incubate the cells at 37°C, 5% CO_2 for subsequent transfection.

    Do not add antibiotics to the medium during transfection. If complete DMEM/10% FBS is used to seed cells, exchange the medium to complete DMEM/10% FBS without antibiotics once the cells are attached to wells, or at the latest 4 to 6 hr prior to transfection.

Prepare siRNA/DNA mixes

11. Prepare 40 µl of 1 µM siRNA by diluting 4 µl of the 10 µM siRNA working solution in 36 µl of Opti-MEM I (or serum-free medium) so that there are two different concentrations for a given siRNA. Using the same technique, prepare 1 µM solutions for three other siRNAs—the second siRNA to be tested, one Cy3-labeled siRNA, and one irrelevant control siRNA.

    It is recommended that you use serum-free medium to dilute siRNAs, to prevent potential reduction in transfection efficiency.

    It is not necessary to perform annealing (Support Protocol 4 and 5) if the siRNA is obtained in the double-stranded form. If the siRNA is purchased based on the match in the literature and available siRNA databases, it will be still ideal to determine the transfection efficiency (Support Protocols 1 to 3) to evaluate technical skills/conditions.

    One can interpret an irrelevant siRNA control as an siRNA whose sequence cannot be found in the system that the investigator tests with. An irrelevant/control siRNA can be purchased from several siRNA-licensed vendors such as Ambion, Dharmacon, and Qiagen. The sequences of such control siRNAs may not be available, for proprietary reasons.

    For the fluorescently labeled siRNA, in an ideal experimental setting, one should obtain the same siRNA that was designed in Basic Protocol 1, but with a fluorescent label. This can be done by custom ordering from the vendor. However, synthesizing the fluorescently labeled siRNA for each siRNA designed in Basic Protocol 1 is not cost-effective. Instead, one can purchase a fluorescently labeled control siRNA from vendors such as Invitrogen.

12. Prepare six 1.7-µl microcentrifuge tubes with proper labeling (0, 1, 5, 25, 50, 75 nM) for each siRNA, add each reagent as described in Table 27.1.3, and bring the final volume to 100 µl per tube with Opti-MEM I. Mix gently.

    It is strongly recommended to perform transfection in duplicate.

    From this point forward, volumes of reagents are calculated for duplicate reactions and shown on the right-hand side of Table 27.1.4 and Figure 27.1.1.

Table 27.1.4 Reagent Mixes for 0, 1, 5, 25, 50, and 75 nM of siRNA (12-well plates)

		Per well				For 2.2x			
		siRNA per well[b]				siRNA per well			
Tubes	siRNA final conc. (nM)[a]	1 µM (µl)	10 µM (µl)	Stuffer DNA plasmid (ng)[c]	Total volume per well (µl)	1 µM (µl)	10 µM (µl)	Stuffer DNA plasmid (ng)	Total volume per well (µl)[d]
1	0	–	–	1100	100	–	–	2420	220
2	1.0	2.0	–	1087	100	4.4	–	2391	220
3	5.0	10.0	–	1033	100	22.0	–	2273	220
4	25	–	5.0	765.7	100	–	11.0	1685	220
5	50	–	10.0	431.5	100	–	22.0	949.3	220
6	75	–	15.0	97.2	100	–	33.0	213.8	220

[a] siRNA concentrations were calculated for the total volume of 1 ml per well of a 12-well plate.

[b] siRNA (ng) was calculated with a dsRNA, mol. wt. = 1.34×10^4 g/mol.

[c] Any cloning vectors not containing eukaryotic promoters (e.g., pBluescript, pCR2.1, etc) can be used to adjust the total amount of nucleic acid.

[d] The 220 µl of siRNA/DNA mixes contains a 0.2× volume excess to the actual volume for a well. (220 µl = 100 µl × 1.2 × 2 wells).

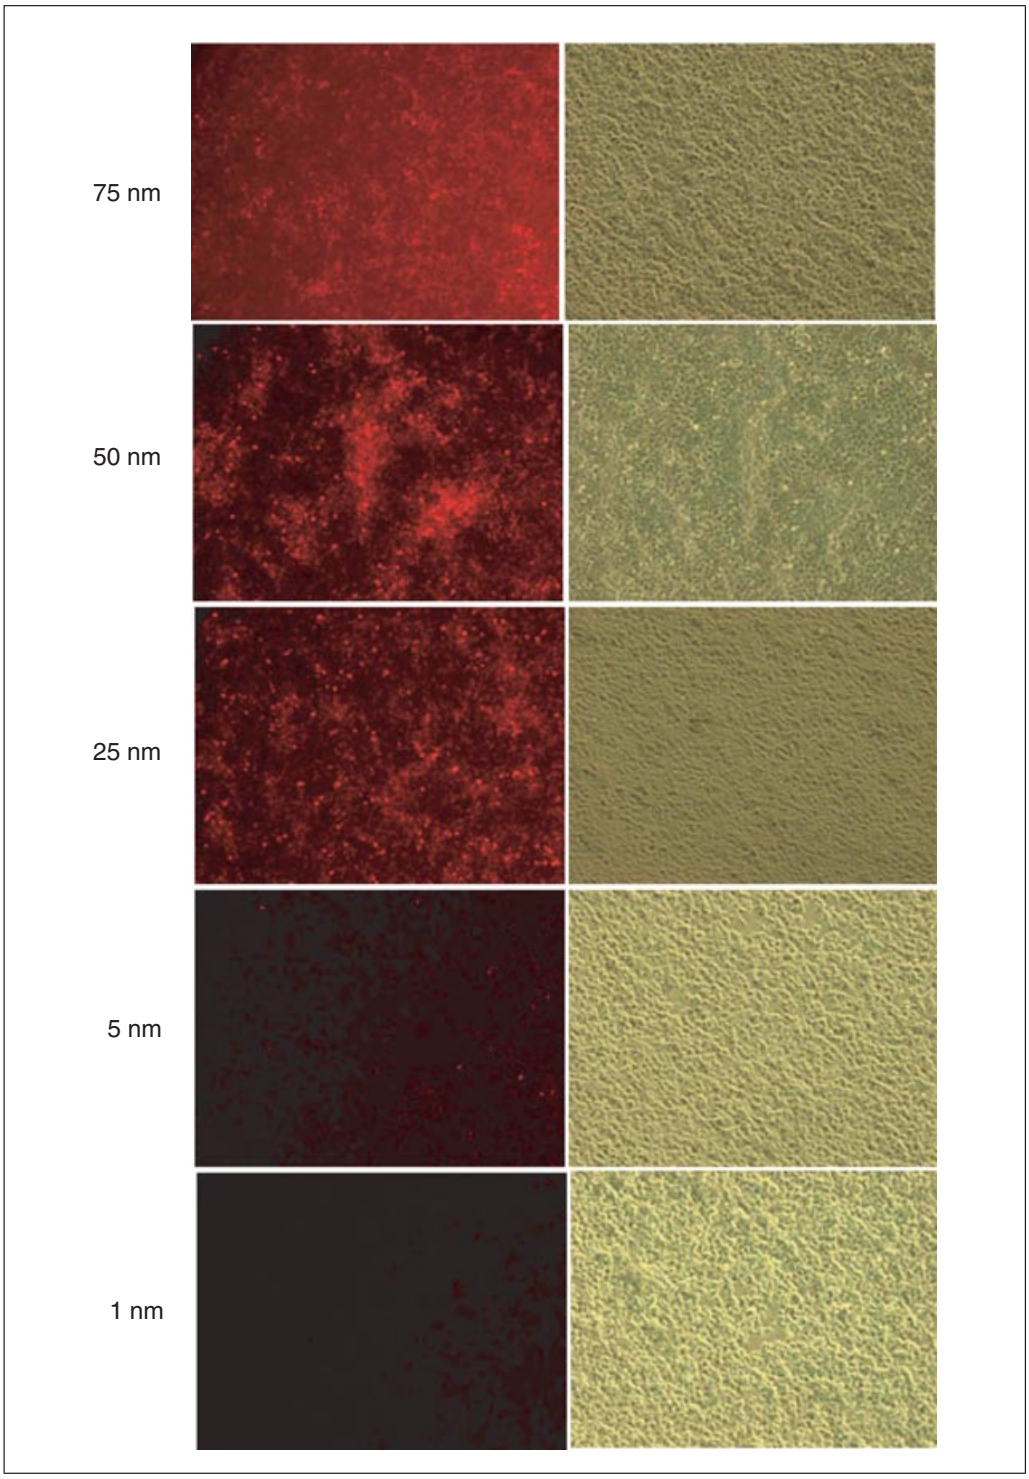

Figure 27.1.2 Detection of Cy3-labeled siRNA uptake by HEK293 cells. After 24 hr incubation, the transfection efficiency of 0, 1, 5, 25, 50, and 75 nM Cy3-labeled siRNAs were observed under a microscope with a UV lamp. Excitation wavelength of Cy3 is ~550 nm and emission wavelength is ~570 nm. Representative results are shown. For the color version of this figure go to *http://www.currentprotocols.com/protocol/cb2701*.

Prepare Lipofectamine 2000 solution

13. Mix Lipofectamine 2000 gently and microcentrifuge briefly to bring the solution to the bottom of the tube.

14. Dilute 2.0 µl Lipofectamine in 100 µl Opti-MEM I per well. For six different concentrations of a siRNA (for 12 wells), prepare 1440 µl of Lipofectamine 2000 solution in two tubes (=14.4 µl Lipofectamine 2000 in 720 µl Opti-MEM I per tube). Prepare three more sets for other siRNA/DNA mixes (total of eight tubes) (step 2, Fig. 27.1.1).

    The 1440 µl of Lipofectamine 2000 solution contains a 0.091× volume excess of the volume for six tubes of the siRNA/DNA mixes (tubes 1 to 6 in the table; 1440 µl =220 µl × 1.091 × 6 siRNA/DNA mixes).

15. Mix gently and incubate for 5 min at room temperature.

Form liposomes

16. Prepare DNA-siRNA-lipid complex (liposome) by adding 220 µl of the Lipofectamine 2000 solution to 220 µl of the siRNA/DNA mix. Mix gently and incubate for 20 min at room temperature for liposome formation (step 3, Fig. 27.1.1).

Transfect cells

17. Add 200 µl of the liposome solution dropwise to each well containing cells and 0.8 ml medium (step 4, Fig. 27.1.1). Mix gently by rocking the plate back and forth, left to right several times.

18. Incubate the cells at 37°C, 5% CO_2 until cells are ready for harvesting.

    Generally the assay period is 24 to 48 hr.

19. At the end of incubation, observe transfection efficiency with the Cy3-labeled siRNA under a microscope with a UV lamp or fluorescence microscope.

    The excitation wavelength of Cy3 is ~550 nm and the emission wavelength is ~570 nm. Representative results are shown in Figure 27.1.2.

    Under some experimental conditions (e.g., multiple cycles of transfection for a prolonged assay period), growth medium may be replaced after 4 to 6 hr of incubation without loss of transfection activity; this helps to reduce cellular toxicity.

    After 24 hr transfection, one can perform one of following procedures to estimate/measure transfection efficiency (should include a positive control for Cy3 fluorescence detection); approaches are listed in order from estimations to accurate measurements:

    Visual observation: Observe Cy3 fluorescence cells under a microscope with a UV lamp/fluorescence microscope and compare and estimate a ratio Cy3 fluorescence cells to total cells.

    Counting cell numbers: In a visual field under the microscope, count Cy3 fluorescence cell numbers and total cell numbers, and take a ratio. Transfection efficiency = Cy3 fluorescing cells/total cells.

    FACS analysis: Count cell numbers of negative control cells, positive control cells, and transfected cells, and take a ratio. Transfection efficiency = Cy3 fluorescing cells/total cells).

20. Once you optimize the transfection conditions, perform your experiment with the most potent siRNAs at an optimal cell density and siRNA concentration and using Lipofectamine 2000 at least three times for validating the reproducibility.

    Once the potent siRNAs are evaluated on 12-well plates, we run scaled-up experiments on 6-well plates to obtain sufficient samples for subsequent analyses.

21. Assess the results of transfection by PCR (Support Protocol 1), immunoblotting (Support Protocol 2), or a dual-reporter system (Support Protocol 3).

SUPPORT PROTOCOL 1

ASSESSING siRNA TRANSFECTION EFFICIENCY BY RT-PCR

The importance of detection of target transcript levels after siRNA treatment is often overlooked. Potentially, the target gene might express a protein with a long half-life; therefore, the effect of the siRNA treatment may not be apparent by immunoblot analyses (described in Support Protocol 2). Thus, following a short period of time post-transfection, it is recommended to validate the effect of designed siRNAs at the transcript level. The efficiency of down-regulation of target gene expression by siRNAs can be determined by real-time quantitative RT-PCR (qRT-PCR) or end-point RT-PCR reactions. Here, we describe the isolation of total RNA from siRNA-treated cells, and cDNA preparation, in detail. Reagents available for RNA extraction are RNA STAT-60 (TEL-TEST, INC.) or TRIzol (Invitrogen), and procedures for both reagents are very similar. In this protocol, we will describe the use of RNA STAT-60 in total RNA isolation.

Materials

siRNA-treated cells on 12-well plates (Basic Protocol 2)
RNA STAT-60 (Tel-Test, Inc., *http://www.tel-test.com/*) at 4°C
Chloroform
75% ethanol made with nuclease-free or diethylpyrocarbonate (DEPC)-treated H_2O (see *APPENDIX 2A* fro DEPC treatment)
Nuclease-free or DEPC-treated water (*APPENDIX 2A*)
2 U/μl DNase I (RNase-free) and 10× DNase buffer (Ambion)
1 U/μl RNase inhibitor (RNasin, Promega)
Random hexamer primers [or oligo$(dT)_{12\text{-}18}$]
10 mM dNTP mix(10 mM dATP, dCTP, dGTP, and dTTP)
5× first-strand buffer (Invitrogen)
0.1 M DTT
MMLV reverse transcriptase (Invitrogen)
Forward and reverse PCR primers
iQ SYBR Green Supermix (for real time qPCR; BioRad)

Refrigerated centrifuge
NanoDrop 1000 (Thermo Fisher Scientific) or UV/Vis spectrophotometer
PCR tubes
65° and 80°C water baths or heating block

Additional reagents and equipment for spectrophotometric determination of RNA concentration (*APPENDIX 3D*), standard PCR (Kramer and Coen, 2001), and real-time qPCR (Bookout et al., 2006)

Collect total RNA from siRNA treated cell culture

1. At the end of siRNA treatment (Basic Protocol 2), aspirate medium from the cell culture.

   Do not wash cells with CMF-DPBS, since this may result in RNA degradation.

   For cells grown in suspension, centrifuge the suspension and collect the cell pellet.

2. Lyse the cells by directly adding RNA STAT-60 (1 ml/2.5 to 5 × 10^6 cells; e.g., 300 μl of RNA STAT-60 per well on a 12-well plate) and pipetting up and down with a 200-μl pipet tip until the viscosity disappears.

   If the viscosity persists, add 50-μl increments of RNA STAT-60 until the lysate becomes transparent. It is critical to lyse cells thoroughly to extract RNA of high quality.

3. Transfer the lysate to a 1.7-ml microcentrifuge tube.

   In the case of collecting lysates from a 10-cm dish, use a 2.0-ml microcentrifuge tube or aliquot the lysate into multiple tubes. However, aliquotting into multiple tubes may cause RNA extraction efficiency to vary among tubes.

Extract RNA

4. Let the lysate stand for 5 min at room temperature to let nucleoprotein complexes dissociate.
5. Add 0.2 vol of chloroform to the RNA STAT-60 (i.e., 0.2 ml of chloroform to the 1 ml of RNA STAT-60 solution).
6. Cap tightly and vortex for 15 sec. Let it stand for 2 to 3 min at room temperature.
7. Centrifuge 15 min at 12,000 ×g, 4°C.
8. Transfer the upper aqueous phase to a 1.7-ml microcentrifuge tube.

   The volume of the aqueous phase will be ~0.6 vol of RNA STAT-60 used for cell lysis.

   DNA and proteins remain in the interphase and organic phase. While you are pipetting out the aqueous phase, be careful not to disturb the white debris.

Precipitate RNA

9. Add 0.5 volume of isopropanol (with respect to the volume of RNA STAT-60 used, i.e., 150 µl of isopropanol when 300 µl of RNA STAT-60 is used). Mix by pipetting up and down and let stand 5 min at room temperature.
10. Centrifuge 10 min at 12,000 × g, 4°C.

    You will see RNA precipitated as a white pellet at the bottom of the tube.

11. Discard supernatant, and add 1 vol of 75% ethanol made with DEPC-treated water to wash the RNA pellet. Mix by inverting the tube a couple of times.
12. Centrifuge 5 min at 7500 × g, 4°C.
13. Carefully discard supernatant and air-dry the RNA pellet.

    It is important to avoid drying the pellet completely, since that will reduce its solubility.

14. Dissolve the RNA pellet in nuclease-free water (or DEPC-treated water) so that the concentration of total RNA will be around 1 to 2 µg/µl.

    Generally, you will obtain about 5 to 10 µg of total RNA from 0.4 × 10^6 cells.

    Adding 15 µl of nuclease-free water to the RNA pellet will be enough to dissolve the RNA pellet.

15. Measure the concentration and check the quality of the total RNA using a NanoDrop assay or a spectrophotometer with UV lamp.

    APPENDIX 3D includes protocols for spectrophotometric determination of RNA concentration.

    The quality of the RNA can be estimated by measuring absorbance at 260 nm and 280 nm and take a ratio 260/280 for purity. In general, a ratio ≥1.8 is considered to be good quality for real-time PCR analysis (with 2.0 being the highest).

Treat with DNase I

16. For a 15-µl reaction, mix the following reagents in a PCR tube at room temperature (15 µl total volume). Prepare two tubes per sample so that one tube will be used for reverse transcription (RT) negative control.

    4.0 µl 0.5 µg/µl total RNA
    1.5 µl 10× DNase buffer
    1.0 µl 2 U/µl RNase-free DNase I
    0.5 µl 1 U/µl RNase inhibitor
    8.0 µl RNase-free water (or DEPC-treated water).

17. Mix, then microcentrifuge briefly to bring the mixture to the bottom of the tube. Incubate the reaction mix at 37°C for 60 min.
18. Heat-inactivate the DNase I by incubating the reaction mix at 80°C for 10 min. Immediately place the tube on ice and leave it for 3 min.
19. Centrifuge the tube briefly to bring the solution to the bottom of the tube.
20. Store the reaction mix at −20°C if necessary.

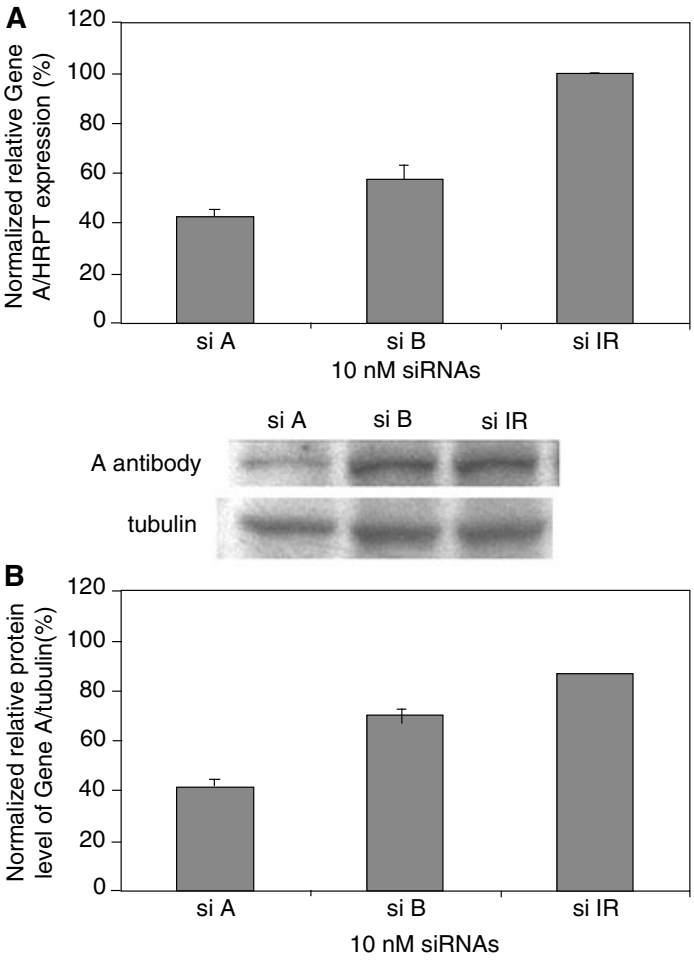

Figure 27.1.3 Effects of siRNA target gene down-regulation. (**A**) Determination of siRNA silencing efficiency by real-time qRT-PCR. Silencing of Gene A by si A or si B (10 nM) was determined with qRT-PCR. An irrelevant siRNA, si IR, was used as a negative control and used to normalize the Gene A expression level. The expression levels of the gene A was also analyzed relative to HRPT expression level set as 100%. The effects of siRNAs were determined in three independent transfections, and qRT-PCR reactions were performed in duplicate. (**B**) Determination of siRNA silencing efficiency by immunoblot analyses. Silencing of a gene A by si A or si B (10 nM) was determined at protein level. Quantification of protein expression levels are shown. An irrelevant siRNA, si IR, was used as a negative control and used to normalize the Gene A expression level. The expression levels of the Gene A was also analyzed relative to tubulin expression level set as 100%. The effects of siRNAs were determined in three independent transfections, and immunoblot analyses were performed independently.

Synthesize cDNA

21. Add following reagents to the 15-µl DNase I reaction mix in PCR tubes (18 µl total volume):

    2.0 µl 50 ng/µl random hexamers
    1.0 µl 10 mM dNTP mix.

22. Incubate the reaction mix at 65°C for 5 min. In the meantime, prepare the solution described in step 23. After 5 min incubation, immediately place tubes on ice.

23. Add the following reagents to the 18-µl reaction mix (27 µl total volume). For RT negative control, add 1.0 µl of DEPC-treated water in place of the MMLV-RT.

    5.0 µl 5× first-strand buffer
    2.5 µl 0.1 M DTT
    0.5 µl 1 U/µl RNase inhibitor
    1.0 µl MMLV-RT.

24. Incubate the 27-µl cDNA synthesis mix at 27°C for 10 min and 37°C for 50 min.

25. Heat-inactivate MMLV-RT by incubating the synthesis mix at 70°C for 15 min. Immediately place on ice and add 173 µl DEPC-treated water to bring the final volume to 200 µl.

Perform PCR

26. Perform either end-point PCR (standard PCR, e.g., Kramer and Coen, 2001, with determination of reaction product on a gel) or real-time qPCR (Bookout et al., 2006) to enable one to determine the gene silencing levels after siRNA treatment. In a PCR reaction, use 10 µl of synthesized cDNA to assess target RNA levels.

    Representative qRT-PCR results are shown in Figure 27.1.3A.

ASSESSING siRNA TRANSFECTION EFFICIENCY BY IMMUNOBLOTTING

SUPPORT PROTOCOL 2

Protein levels of target genes after siRNA treatments are often determined to validate the effects of designed siRNAs. To fully describe the effect of siRNA on protein levels, it is important to know the half-life of the target protein. With a protein that has a long half-life, you may adjust the length of incubation with siRNAs and/or numbers of transfections during the assay period or perform multiple cycles of transfection for a long-term assay to see the effects of siRNAs at the protein level. Here, we describe cell lysis for collecting total proteins for further analysis. Refer to *UNIT 6.2* for immunoblotting procedures. Prepare total protein from siRNA-treated cells for determination of the effects of transfection experiments, and mock-treated cells as a control for protein detection.

Materials

siRNA-treated cell culture in 12-well plate (Basic Protocol 2)
Mock-treated cell culture
Calcium- and magnesium-free Dulbecco's phosphate-buffered saline (CMF-DPBS; Cellgro, cat. no. 21-031 CV, or see *APPENDIX 2A*), 4°C
RIPA buffer (see recipe) with freshly added 1× protease inhibitor cocktail (Roche), ice cold
End-over-end rotator (e.g., Labquake from Thermo Scientific)
Additional reagents and equipment for Bradford protein assay (*APPENDIX 3H*) and immunoblotting (*UNIT 6.2*)

Lyse cells

1. At the end of siRNA treatment (Basic Protocol 2), aspirate medium from the cell culture. Wash cells once with 0.5 ml ice-cold CMF-DPBS. Keep the plate on ice. Also perform this and all subsequent steps on a mock-transfected culture as a control.

   For cells grown in suspension, collect the cell suspension, centrifuge 5 min at 200 × g, 4°C, and collect cell pellet. Wash the pellet with 1 ml ice-cold CMF-DPBS, and centrifuge again at 4°C.

2. Lyse the cells by directly adding ice-cold RIPA buffer with freshly added 1× protease inhibitor cocktail (1 ml per 2–5 × 10^6 cells, e.g., 300 µl per well on a 12-well plate). Let it sit ∼ 2 min on ice so that the cells detach from the surface.

3. Collect cells with a pipettor and 1000-µl pipet tip by tilting the plate on ice, and transfer to a cold 1.7-ml microcentrifuge tube.

   It is critical to keep cells on ice to prevent protein degradation.

   If necessary, use a scraper to collect cells. Adding more RIPA buffer may lower total protein concentrations.

4. Incubate the cells for 15 min at 4°C with gentle agitation on an end-over-end rotator.

5. Microcentrifuge 15 min at 14,000 rpm, 4°C, and transfer supernatant to a new, cold 1.7-ml tube.

6. Measure total protein concentration with Bradford assay (*APPENDIX 3H*), and aliquot the lysate into several tubes at ∼50 or 100 µl/tube to avoid multiple freeze-thaw cycles. Store the aliquots at −80°C. 7. Perform immunoblotting (*UNIT 6.2*).

   Representative results are shown in Figure 27.1.3B.

SUPPORT PROTOCOL 3

ASSESSING siRNA TRANSFECTION EFFICIENCY BY A DUAL-REPORTER ASSAY SYSTEM

Prevalidation of siRNA potency and optimization of transfection efficiency can be performed by developing reporter genes fused to a target gene. For instance, green fluorescent protein (GFP) fluorescence in cell culture can be quantified by flow cytometry, or a FLAG epitope tag can be used to detect the change in protein expression levels by immunoblot analysis. However, the former method requires that a FACS facility be readily available, and the latter tends to be time consuming. Conversely, a dual-luciferase reporter assay system by Promega accelerates the identification of potent siRNAs among designed siRNAs in 24 to 48 hr by detecting changes in expression of a reporter gene. With this system, the transfection of the dual-luciferase reporter vectors (psiCHECK vectors, Promega), carrying the target sequence, into mammalian cell lines leads to expression of the target sequence fused to the reporter gene, which is translated into the functional *Renilla* luciferase (*http://www.promega.com*). The catalytic activity of *Renilla* luciferase measured by bioluminescent reactions is used to determine how effective siRNAs initiate RNAi by observing reductions in the enzymatic activity.

Simultaneous transfection of two plasmids, one expressing a target gene and another expressing a control protein, can provide evaluation of siRNA potency by normalizing expression levels of the reporter protein to the control protein at time of transfection. However, results may vary from transfection to transfection due to inconsistent transfection efficiencies between the reporter and control plasmids. The psiCHECK-2 (Fig. 27.1.4, Promega) contains an additional internal control reporter gene that improves the reproducibility and that enables evaluating well-to-well variation of transfection (*http://www.promega.com*). The *Renilla* luciferase is expressed from the vector

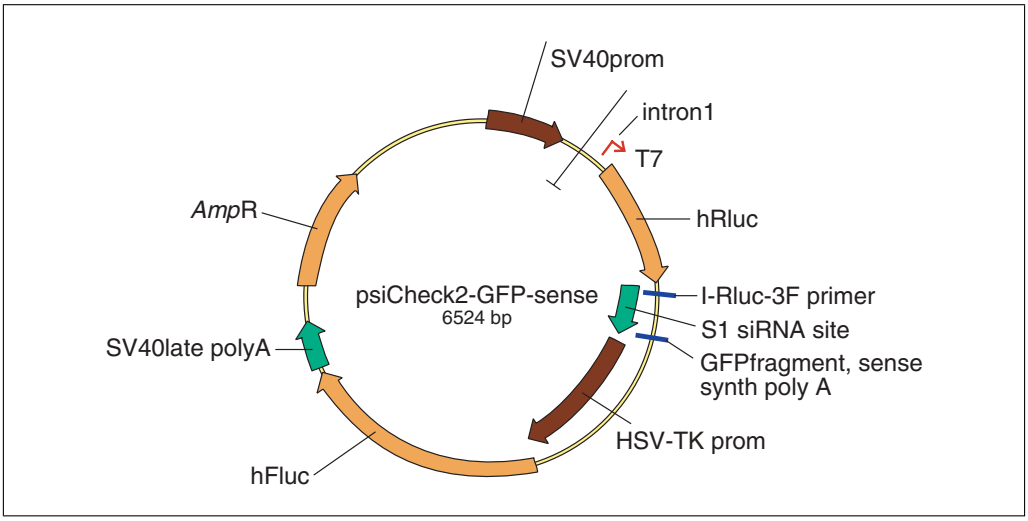

Figure 27.1.4 A reporter plasmid psiCHECK-2 (Promega) containing a target site GFP S1. A reporter plasmid psiCHECK2-GFP-sense was prepared by cloning a PCR fragment that contains the target sequence complementary to siRNAs into the multiple cloning region of the psiCHECK-2 (S1 siRNA site). The psiCHECK-2 contains an additional internal control reporter gene, firefly luciferase (*hluc+*), which is used to normalize the *Renilla* luciferase activity. Depending on experimental settings, the siRNAs can be either cotransfected or transfected sequentially. Small interfering RNA silencing efficiency was evaluated by measuring the activities of firefly and *Renilla* luciferases sequentially from a single sample using a luminometer (*http://www.promega.com*).

containing the target gene sequence cloned into the multiple cloning site located in the 3′ untranslated region (UTR) of a humanized *Renilla* luciferase (*hRluc*) reporter gene (*http://www.promega.com*). The firefly luciferase (*hluc+*) expressed from the same vector is used to normalize the *Renilla* luciferase activity, serving as the baseline response (*http://www.promega.com*). Depending on experimental settings, the siRNAs can be either cotransfected or transfected sequentially. In this protocol, cotransfection of siRNAs and the psiCHECK-2 vector is described in detail.

Prepare a reporter plasmid by cloning a PCR fragment that contains the target sequence complementary to siRNAs into the multiple cloning region of the psiCHECK-2 (S1 siRNA site, Fig. 27.1.4). The efficiency of siRNA silencing is evaluated by measuring the activities of firefly and *Renilla* luciferases sequentially from a single sample using a manual luminometer or a luminometer with one or two reagent injectors. Promega provides the Dual-Luciferase Reporter Assay system, containing reagents necessary for cell lysis and measuring *Renilla* and firefly luciferase activities. Refer to the manufacturer's protocol for more information (*http://www.promega.com*).

In this section, we describe cotransfection of mammalian cell culture with psiCHECK-2 reporter plasmid containing a target sequence and siRNAs for validation of the most effective siRNA duplexes among siRNAs, and the lowest concentration that results in efficient silencing. To find optimal siRNA concentrations, one should test at least six different concentrations (e.g., 0, 0.05, 0.5, 1.0, 20, and 45 nM) for each siRNA with a constant amount of the reporter plasmid as a starting point. The procedure described here refers to transfection of cells seeded in 48-well plates at two different levels of confluence (one at 75% and another at 90% confluency) with the reporter plasmid in addition to the siRNAs. See below for the summary of compositions for transfection reaction mixes shown in Table 27.1.5. Transfection procedures deviating from the previous section (with 12-well plates) are emphasized in this section (see the flow chart in Fig. 27.1.5). Once the conditions are optimized, you may perform transfection in a different format (e.g., 6- or 12-well plates) to accommodate your subsequent

Table 27.1.5 Transfection Reaction Mixes for Six Different siRNA Concentrations (48-Well Plates)

siRNA final conc. (nM)[a]	siRNA per well (ng)[b]	psiCHECK reporter plasmid (ng)	Stuffer DNA plasmid[c]	Total nucleic acid amount (ng)
0	0 (0 ng)	40	120.00	160
0.05	10 fmol (0.134 ng)	40	119.87	160
0.5	100 fmol (1.34 ng)	40	118.66	160
1.0	200 fmol (2.67 ng)	40	117.30	160
20	4 pmol (53.5 ng)	40	66.50	160
45	9 pmol (120 ng)	40	0	160

[a]siRNA concentrations were calculated for the total volume of 200 µl per well of a 48-well plate.
[b]siRNA (ng) was calculated with a dsRNA, mol. wt. = 1.34×10^4 g/mol.
[c]Any cloning vectors not containing eukaryotic promoters (e.g., pBluescript, pCR2.1, etc) can be used to adjust the total amount of nucleic acid.

experimental procedures (e.g., when collecting total proteins for immunoblot analyses or isolating total RNA for qRT-PCR, seed cells in 6- or 12-well plates while keeping the optimal percent confluency and optimal siRNA concentrations consistent at the time of transfection).

NOTE: Transfection reagent preparations should be carried out in a tissue culture hood.

Materials

10 µM siRNA working solution (Basic Protocol 1)
10 µM irrelevant siRNA as negative control
psiCHECK-2 vector with target cloned into the MCS (psiYTC)
Stuffer DNA plasmid (see Basic Protocol 2)
Opti-MEM I (a reduced-serum medium from Invitrogen), or serum-free growth medium
Lipofectamine 2000 (Invitrogen)
Mammalian cells seeded in two 48-well plates
Complete medium with 10% FBS (e.g., complete DMEM/10% FBS; see recipe), without antibiotics, 37°C
Dual-Luciferase Reporter Assay System (Promega)
Orbital shaker
Luminometer (e.g., Veritas Microplate Luminometer)

NOTE: All solutions and equipment coming into contact with living cells must be sterile, and aseptic technique should be used accordingly.

NOTE: All cell culture incubations should be carried out in a 37°C, 5% CO_2 humidified incubator.

Prepare DNA master mixes

1. Prepare six tubes properly labeled (0, 0.05, 0.5, 1.0, 20, 45 nM) for each corresponding siRNA mix, add each reagent as described in Table 27.1.6 and step 1 in Fig. 27.1.5, and bring the final volume to 16 µl per well with Opti-MEM I. Mix gently.

   It is strongly recommended to perform transfections in duplicate. From this point forward, volumes of reagents are calculated for duplicate transfections.

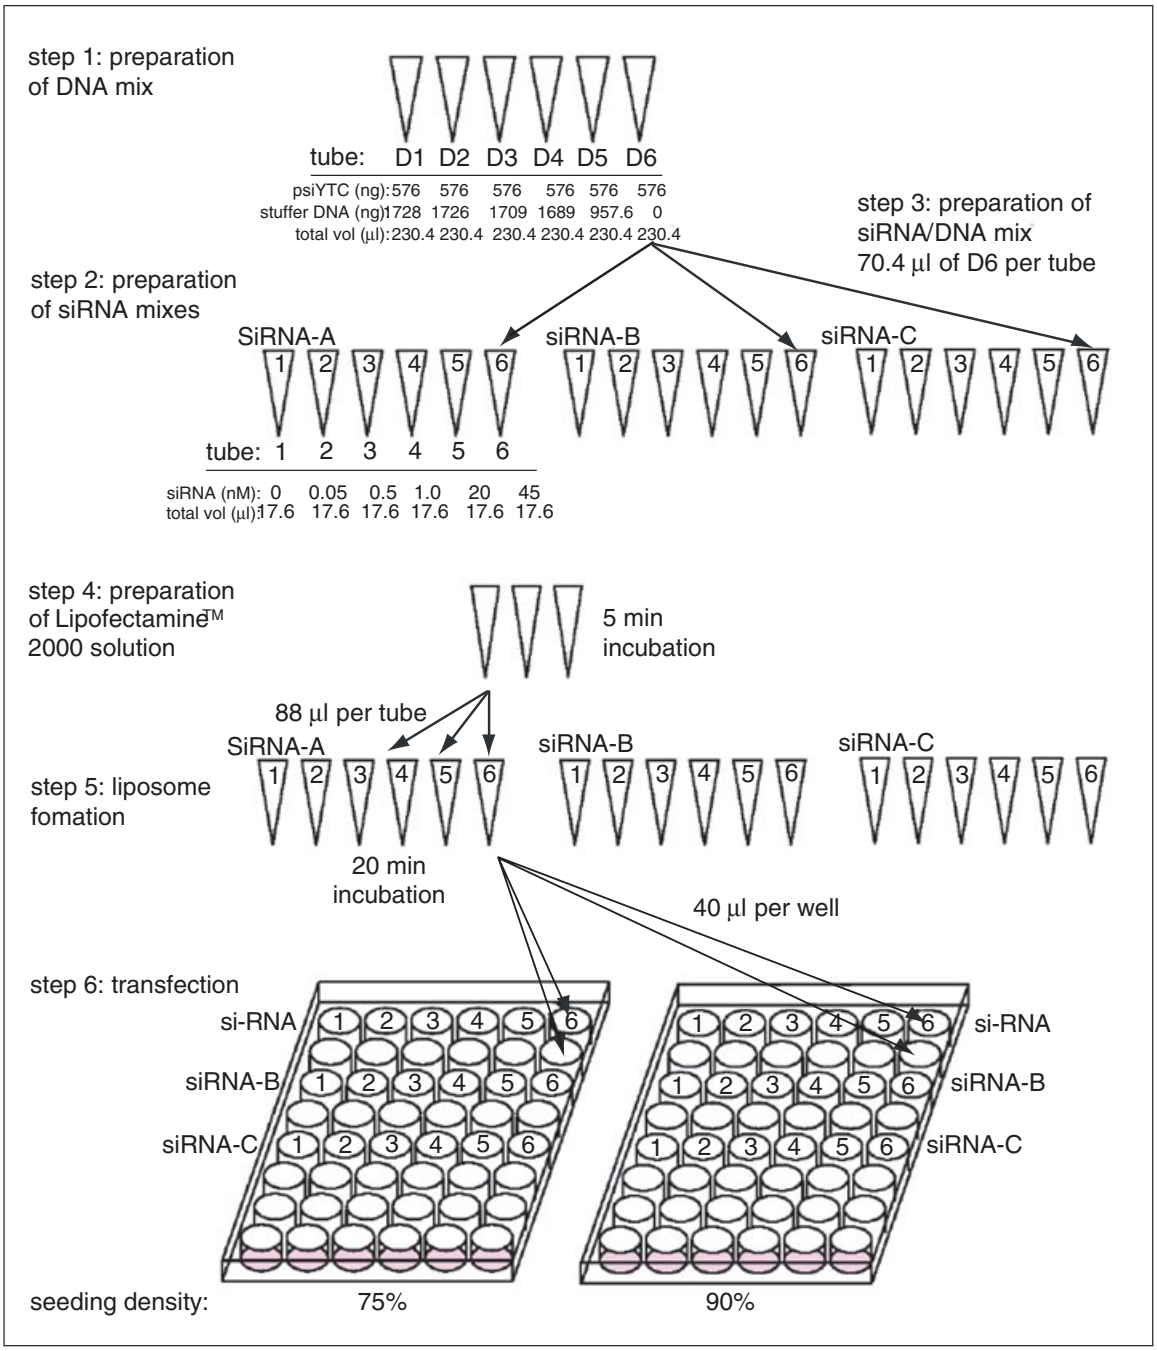

Figure 27.1.5 Transfection of mammalian cells with psiCHECK2-GFP-sense and siRNAs (48-well plates). Stepwise procedures of transfection of mammalian cells seeded at two different cell densities (75% and 90%) a day prior to transfection are shown. After choosing five different concentrations of siRNAs (0 to 45 nM) to transfect the cells, prepare DNA master mixes and siRNA mixes separately in the Opti-MEM (or a serum-free medium) as indicated (steps 1 and 2). Next, add 70.4 µl of D1 to tubes containing 0 nM of siRNAs A, B, or C (tubes A1, B1, and C1). Repeat with D2 to D6 to prepare siRNA/DNA mixes (step 3). Prepare proper amount of Lipofectamine 2000 solution (three tubes of 576 µl for six tubes of siRNA/DNA mixes, step 4). After 5 min incubation, add 88 µl of Lipofectamine 2000 solution to each siRNA/DNA mix (step 5). Incubate for 20 min to allow liposome formation, then add 40 µl of the liposome solution to two wells on the 75% seeding density plate and two wells on the 90% seeding density plate (step 6). Transfection reagent preparations should be done in a tissue culture hood.

Table 27.1.6 DNA Master Mixes for 0, 0.05, 0.5, 1.0, 20, and 45 nM siRNAs for Dual Reporter Assays

Tube	For siRNA final conc. (nM)[a]	Per well			For 14.4×		
		psiYTC reporter plasmid (ng)[b]	Stuffer DNA plasmid (ng)[c]	Total volume per well (μl)	psiYTC reporter plasmid (ng)[b]	Stuffer DNA plasmid (ng)[c]	Total volume per well (μl)
D1	0	40	120.00	16	576	1728	230.4
D2	0.05	40	119.87	16	576	1726	230.4
D3	0.5	40	118.66	16	576	1709	230.4
D4	1.0	40	117.30	16	576	1689	230.4
D5	20	40	66.50	16	576	957.6	230.4
D6	45	40	0	16	576	0	230.4

[a]siRNA concentrations were calculated for the total volume of 200 μl per well of a 48-well plate.
[b]The optimal amount of psiCHECK-2 vector with your target site (psiYTC) should also be experimentally determined. Here an example of 40 ng of psiYTC is used.
[c]Any cloning vectors not containing eukaryotic promoters (e.g., pBluescript, pCR2.1, etc) can be used to adjust the total amount of nucleic acid.

Table 27.1.7 siRNA Mixes for Six Different siRNA Concentrations

Tube	For siRNA final conc. (nM)[a]	Per well			For 14.4×		
		psiYTC reporter plasmid (ng)[b]	Stuffer DNA plasmid (ng)[c]	Total volume per well (μl)	psiYTC reporter plasmid (ng)[b]	Stuffer DNA plasmid (ng)[c]	Total volume per well (μl)
D1	0	40	120.00	16	576	1728	230.4
D2	0.05	40	119.87	16	576	1726	230.4
D3	0.5	40	118.66	16	576	1709	230.4
D4	1.0	40	117.30	16	576	1689	230.4
D5	20	40	66.50	16	576	957.6	230.4
D6	45	40	0	16	576	0	230.4

[a]siRNA concentrations were calculated for the total volume of 200 μl per well of a 48-well plate.

2. For three siRNAs—two test siRNAs and an irrelevant siRNA—and two 48-well plates with different cell densities, prepare 230.4 μl (14.4× volume) of DNA master mix per tube.

   The 230.4 μl of DNA master mix per tube contains 0.091× volume excess of the volume of the DNA mix added per siRNA mix tube (230.4 μl = 17.6 μl × 1.091 × 4 wells ×3 siRNA concentrations).

Prepare siRNA mixes

3. Prepare 20 μl of 0.1 and 1 μM siRNA by diluting 2 μl of the 10 μM siRNA working solution in 18 μl of Opti-MEM I and 2 μl of the 1 μM siRNA solution in 18 μl of Opti-MEM I so that you have three different concentrations for each siRNA.

4. Prepare three sets of six tubes properly labeled (0, 0.05, 0.5, 1.0, 20, 45 nM) for a set per siRNA, add reagents to each tube as described in Table 27.1.7 and step 2 in

Fig. 27.1.5, and bring the final volume with Opti-MEM I to 17.6 µl per well. Mix gently.

To perform transfections in duplicate, and since the cells are seeded in two 48-well plates with different cell densities, prepare 17.6 µl (4.4 × volume) of siRNA mix for 4 wells.

The 17.6 µl of siRNA/DNA mix per tube contains 0.1× volume excess of the actual volume of siRNA mix used for a well (17.6 µl = 4.0 µl × 1.1 × 4 wells).

Prepare siRNA/DNA mixes

5. Add 70.4 µl of DNA master mixes to corresponding siRNA mixes [i.e., add 70.4 µl of the DNA master mix for 45 nM siRNA (tube D6) to tubes containing 17.6 µl of 45 nM siRNA-A, siRNA-B, and irrelevant siRNA (siRNA-C) so that the total volume now is 88 µl per tube]. Add other DNA master mixes for 0, 0.05, 0.5, 1, and 20 nM to corresponding siRNA mix tubes (step 3 in Fig. 27.1.5).

Prepare Lipofectamine 2000 solution

6. Mix Lipofectamine 2000 gently and centrifuge briefly to bring the solution to the bottom.

7. Dilute 0.5 µl in 20 µl Opti-MEM I per well.

   For six different concentrations of an siRNA at four wells per concentration, prepare 576 µl of Lipofectamine 2000 solution (=14.4 µl Lipofectamine 2000 in 576 µl Opti-MEM I) for 24 wells (=6 siRNA concentrations × duplicate × 2 plates). Prepare two more tubes of the Lipofectamine 2000 solution for other siRNAs as well (total of three tubes; step 4, Fig. 27.1.5).

   The 576 µl of Lipofectamine 2000 solution contains 0.091× volume excess of the volume of the Lipofectamine 2000 solution to be added to the siRNA/DNA mix per tube (576 µl = 88 µl × 1.091 × 6 siRNA concentrations).

8. Mix gently and incubate for 5 min at room temperature.

Form liposomes

9. Prepare DNA/siRNA/lipid complex (liposome) by adding 88 µl of the Lipofectamine 2000 solution to 88 µl of the siRNA/DNA mix. Mix gently and incubate for 20 min at room temperature for liposome formation (step 5, Fig. 27.1.5).

Transfect cells

10. Add 40 µl of the liposome solution drop-wise to each well containing cells and 160 µl medium (step 6, Fig. 27.1.5A). Mix gently by rocking the plate back and forth, and left to right several times.

11. Incubate the cells at 37°C, 5% CO_2 until cells are ready for harvesting.

    Generally the cells are harvested at 24 to 48 hr.

Lyse cells

12. Prepare ~8 ml of 1× passive lysis buffer from 5× passive lysis buffer stock, which is part of the Dual-Luciferase Reporter Assay System (Promega) for 96 wells (=75 µl/well × 48 wells × 2 plates + extra).

13. Add 75 µl per well and shake the culture plates on an orbital shaker for 15 min at room temperature.

    The rocking motion will ensure covering the cells evenly and completely with the 1× passive lysis buffer.

14. Immediately proceed to dual-luciferase assays (using kit from Promega and luminometer) or store samples at −80°C.

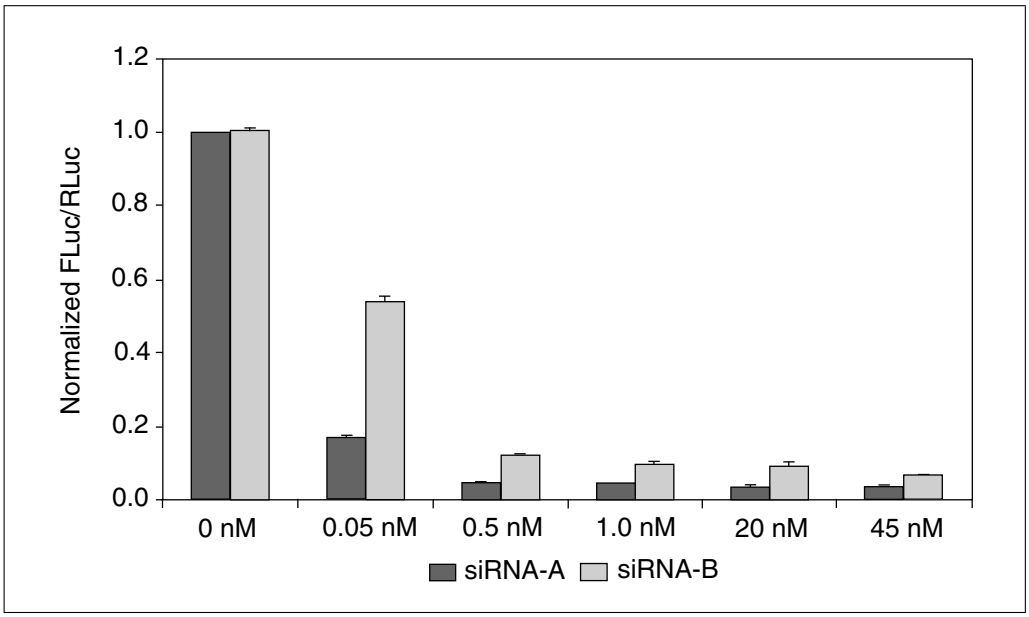

Figure 27.1.6 Determination of transfection efficiency by the dual-luciferase assays. The efficiency of siRNA silencing was evaluated by measuring the activities of firefly and *Renilla* luciferases. The relative luminescence units were normalized to the negative control (0 nM) set as 100%. Results showed concentration dependent silencing efficiency of the two siRNAs A and B. Once an optimal concentration of a siRNA is determined, perform your experiment with the highly potent siRNA(s) at optimal cell density and concentrations at least three times to assess reproducibility.

15. Once you optimize the transfection conditions, perform your experiment with the most potent siRNAs at optimal cell density and concentrations at least three times to assess reproducibility.

    Representative results are shown in Figure 27.1.6.

SUPPORT PROTOCOL 4

ANNEALING SINGLE-STRANDED OLIGOS FOR A DOUBLE-STRANDED RNA

Depending upon the purpose of the experiments (e.g., siRNA structural modifications, chemical modifications on siRNA strands, etc), you may obtain siRNAs as single-stranded RNA oligos or duplex siRNAs. When single-stranded oligos are obtained, you should anneal equal amounts of each single-stranded oligo to generate a double-stranded RNA.

NOTE: Gloves and plastic ware (no glass) should be used to avoid RNA degradation and cross-contamination of samples.

Materials

Lyophilized single-stranded sense and antisense oligos (Basic Protocol 1)
RNase-free (e.g., DEPC-treated) H_2O or TE buffer (*APPENDIX 2A*)
10× annealing buffer (see recipe)
Nuclease-free (e.g., DEPC-treated) H_2O

95°C heat block
NanoDrop 1000 (Thermo Fisher Scientific) or UV/Vis spectrophotometer

Additional reagents and equipment for spectrophotometric determination of RNA concentration (*APPENDIX 3D*)

Prepare for annealing

1. Dissolve the single-stranded RNA oligos in nuclease-free water or TE buffer to a final concentration of 100 μM. Make sure the oligos are completely dissolved. Place them on ice.

   It is recommended to measure actual concentrations of single-stranded oligos after dissolving by measuring A_{260} with a NanoDrop or a spectrophotometer with UV lamp (APPENDIX 3D) and assess the purity of your RNA oligos before use.

Anneal the oligos

2. For a 50-μl total volume reaction, mix the following reagents in a 1.7-ml sterile microcentrifuge tube at room temperature to generate a 25 μM dsRNA solution.

   12.5 μl 100 μM sense RNA oligo
   12.5 μl 100 μM antisense RNA oligo
   5 μl 10× annealing buffer
   Nuclease-free H_2O for 50 μl.

3. Incubate the reaction mix at 95°C for 4 min.

4. Microcentrifuge the tube briefly to bring the solution to the tube bottom, and remove the heat block from the heat source and set on your lab benchtop.

   Protect the surface of the bench top from heat by placing an insulator between the heat block and the bench top.

5. Place the tube back in the heat block to slowly cool to room temperature by allowing the heat block to reach ambient temperature.

   This will gradually anneal the single-stranded oligos to dsRNA. It will take about 1.5 to 2 hr to reach room temperature.

6. Briefly mix and centrifuge the solution and place on ice.

7. Dilute the dsRNA to 10 μM with RNase-free water and use as a working solution. Store the remaining sample up to 6 months at −20°C or 2 to 3 years at −80°C as the master stock.

   Double-stranded siRNA is diluted in RNase-free water for short-term storage or 1× RNase-free siRNA buffer (100 mM potassium acetate, 30 mM HEPES, pH 7.5) for long-term storage. The siRNA buffer can also be purchased from various vendors.

   It is strongly recommended to verify the quality of the annealed dsRNA using polyacrylamide gel electrophoresis (see Support Protocol 5).

CHECKING THE INTEGRITY OF dsRNAs

SUPPORT PROTOCOL 5

Before proceeding to transfection, it is strongly recommended to verify the integrity of the dsRNA annealed above using non-denaturing polyacrylamide gel electrophoresis. The presence of free single-stranded oligos will not only reduce the amount of siRNAs used in the transfection but also, more significantly, it will affect the silencing efficiency.

Materials

10× TBE buffer (*APPENDIX 2A*)
40% (w/v) 19:1 acrylamide:bisacrylamide (AC:BC) solution
TEMED
10% (w/v) ammonium persulfate (APS) solution
Annealed dsRNAs (Support Protocol 4)
4× native gel loading dye (see recipe)
10 mg/ml ethidium bromide solution

14 × 16–cm gel electrophoresis apparatus
Power supply
Flat gel loading tips
UV lamp

NOTE: When a minigel is used, adjust the volume and time of gel running.

Prepare gel apparatus

1. Assemble a glass plate sandwich on a clean surface. Make sure the plates are properly aligned with spacers to avoid leakage.
2. Prepare 35 ml of 8% polyacrylamide nondenaturing solution by mixing the following:

   24.5 ml Milli-Q water
   3.5 ml 10× TBE buffer
   7 ml 40% (w/v) AC:BC
   15 μl TEMED.

3. Add 150 μl of 10% APS solution to the gel solution and mix quickly, but thoroughly, by swirling and avoid foaming.

   To avoid polymerization while casting the gel, make sure to prepare the solution at room temperature.

4. Working quickly, fill the gel mold (without the comb) to 1 mm below the top of the smaller piece of glass using a disposable transfer pipet. Hold the tip of the pipet against the large piece of glass and at the end of the glass so the solution fills along the spacer. Insert the comb to its fully seated position. Allow gel to polymerize 10 to 15 min.

   This will cause some of the solution to overflow. Add more if necessary.

5. Assemble the 8% nondenaturing polyacrylamide gel into the running apparatus and pre-run for ∼0.5 hr at 200 V.
6. Prepare dsRNA samples by diluting part of the 10 μM working solution to a final concentration of 1 μM.
7. In a 1.7-ml tube, mix 1 μl of 10 μM dsRNA with 2 μl 1× TBE buffer and 1 μl 4× native gel loading dye. In another tube, mix 1 μl of 1 μM dsRNA with 2 μl 1× TBE and 1 μl 4× native gel dye.

Run and analyze the gel

8. Load samples at the bottom of the wells with flat gel loading tips.
9. Run the gel for 1.5 to 2 hr at 200 V.
10. Disassemble the gel and stain with 0.4 μg/ml ethidium bromide solution (prepared from 10 mg/ml stock) for 20 min.
11. Visualize dsRNA samples under a UV lamp.

    You should avoid leaving the gel in the stain solution too long because RNA samples will diffuse out from the gel and may no longer be detectable under the UV lamp.

    You should see results similar to those shown in Figure 27.1.7 when you perform nondenaturing polyacrylamide gel analysis.When the annealing is successful, you should see a detectable higher-molecular-weight band, which represents annealed dsRNA, and no remaining single-stranded oligo, which is seen as a lower-molecular-weight band, not shown in the figure.

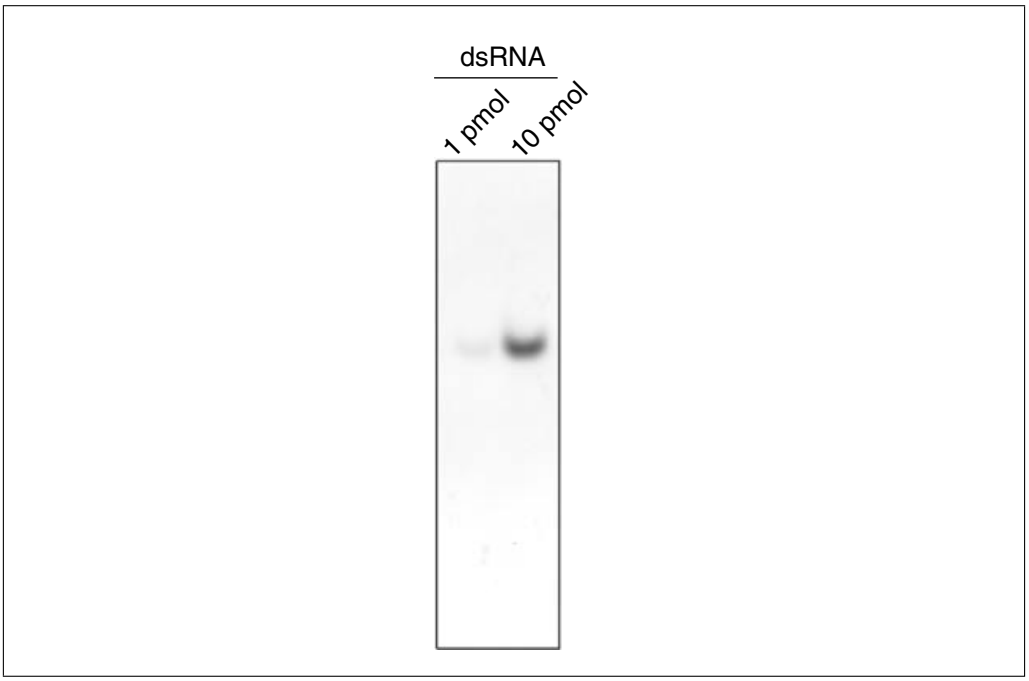

Figure 27.1.7 Verification of dsRNA integrity. The integrity of double-stranded RNAs was determined by gel electrophoresis. Either 1 pmol or 10 pmol of a 21-nt long dsRNA were loaded on a 8% non-denaturing polyacrylamide gel. Successful dsRNA annealing should result in a detectable higher-molecular-weight band and no remaining single-stranded oligo as a low-molecular-weight band, which was not detected in the gel.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Annealing buffer, 10×

100 mM Tris·Cl, pH 8.0 (*APPENDIX 2A*)
1.5 M NaCl
Store up to 2 to 3 years at 4°C

Complete DMEM/10% (v/v) FBS

Dulbecco's modified Eagle medium, high-glucose formulation supplemented with:
10% (v/v) FBS
2 mM L-glutamine
1 mM sodium pyruvate
100 U/ml penicillin
100 μg/ml streptomycin
Store up to 3 months at 4°C

For complete DMEM/10% FBS without antibiotics, omit adding penicillin and streptomycin.

Native gel loading dye, 4×

0.1% (w/v) bromphenol blue
0.1% (w/v) xylene cyanol FF
0.1% (w/v) Orange G
1 mM EDTA
10 mM Tris·Cl, pH 7.5 (*APPENDIX 2A*)
40% (v/v) glycerol
Store up to 2 to 3 years at 4°C (or long-term at −20°C)

RIPA buffer

150 mM NaCl
50 mM Tris·Cl, pH 8.0 (*APPENDIX 2A*)
1% (v/v) NP-40
0.25% (v/v) sodium deoxycholate
0.1% (w/v) SDS
1× protease inhibitor cocktail (Roche), added fresh
Adjust pH to 8.0
Store up to 1 year at 4°C

COMMENTARY

Background Information

The mechanism of RNA interference (RNAi) was first described in detail in *Caenorhabditis elegans* by Andrew Fire and Craig C. Mello (Fire et al., 1998), who later shared the Nobel Prize in Physiology or Medicine in 2006. Soon after, approximately 21 nucleotide-long small interfering RNAs (siRNAs) were shown to mediate sequence-specific gene silencing mammalian cells and *Drosophila* (Zamore et al., 2000; Elbashir et al., 2001b). The selective and immediate effect of RNAi on the gene silencing within living cells made it a valuable tool for investigating gene function and initiated a new wave of reverse genetics.

The RNAi pathway is found in many eukaryotes including plants and animals. It is a small RNA–mediated gene silencing process controlled by the RNA induced silencing complex (RISC) activity at the post-transcriptional level. In living cells, small RNAs have been shown to participate in: (1) regulating gene expression, (2) maintaining genome integrity, (3) controlling cell growth, differentiation, and cellular metabolism, and (4) defending from viral invasion. Biochemical analysis of the RNAi pathway led us to realize that introducing double-stranded RNAs (dsRNAs) with sequences complementary to target transcripts can elicit an RNAi response, demonstrating the versatility of the process in cells.

RNAi can be described as having at least two well defined steps: the initiation step, where the ribonuclease (RNase) III enzyme Dicer processes dsRNAs into 21- to 22-nucleotide (nt)–long duplexes (Bernstein et al., 2001), and the effector step, in which Argonaute 2 (Ago 2), a core endonuclease of the RISC, executes RNAi (Liu et al., 2004; Meister et al., 2004; Rivas et al., 2005). With exogenously introduced 21-nt siRNAs, the Dicer processing step is skipped and directly incorporated into RISC, where Ago2 carries out cleavage of the target transcript. Conversely, dsRNAs longer than 25 bp can be used to trigger RNAi response by undergoing Dicer processing. It is apparent that not only siRNA sequences that recruit RISC to target transcripts, but also incorporation of siRNAs into RISC, become critical determinants for the RNAi efficiency.

The protocol presented here describes basic approaches that one can use as a starting point. It is important to optimize transfection conditions after empirical determinations.

Critical Parameters

siRNA sequences

It is common to observe various degrees of silencing efficiency among designed siRNAs. This could simply be due to insufficient incorporation of siRNA into RISC, or it could be due to poor interaction between the siRNA and target transcript that might form secondary structure, making RISC inaccessible to the target sequence. To find target sequences that are readily accessible, it is advisable to design multiple siRNAs targeting different sites and assay the siRNAs at several concentrations. Some poorly designed siRNAs can still elicit RNAi when they are used in extremely high concentrations, a potential cause of cellular toxicity. In this protocol, 75 nM of siRNAs are included as an example to determine the gene-silencing efficiency. If designed siRNAs show some knockdown effects only at higher concentrations, you may consider redesigning siRNAs for the abovementioned reasons. Also there are siRNA design algorithms that consider the secondary structure of target transcripts (Ding et al., 2004; Yiu et al., 2005), e.g., siRNA Site selector (Heale et al., 2005; *http://www1.infosci.coh.org/hpcdispatcher/*).

Although an siRNA is designed against a specific target mRNA site, it can cause silencing of unspecific genes, termed off-target effects. If a sequence match is found between

a guide strand and an mRNA in the 3′ UTRs, the first 6 to 7 nucleotides of the guide strand can lead to translational inhibition via the microRNA-mediated pathway. Each strand of the siRNA has the potential to be assembled into RISC as a guide, so that it doubles the chance of creating off-target effects. If this is suspected, the psiCHECK-2 vector with the target sequence inserted in the antisense orientation can be used for the assessment.

Design of Dicer substrate siRNAs (D-siRNAs; Rose et al., 2005) described in this unit emanated from ideas of (1) inducing Dicer processing to increase the possibility of assembly into RISC, and (2) reducing a likelihood of passenger-strand incorporation by introducing structural asymmetry. However, it is difficult to completely eliminate all the potential off-targets. There are chemical and structural modifications such as 2′ O-methyl at a few positions that reduce the off-target effects.

Transfection conditions

In this protocol, the use of Lipofectamine 2000 has been described as a transfection reagent. Certain cell types may not achieve high levels of transfection efficiency with this reagent. If so, there are several other transfection reagents available from Invitrogen (e.g., Lipofectamine RNAiMax) and Mirus (e.g., *Trans*IT-siQUEST reagent), to name a few. It is also important to adjust the seeding density for optimization of the transfection condition.

Validations of siRNA silencing efficiency

To validate the silencing efficiency of the designed siRNAs, it is critical to assess the level of the target mRNA, since there could be a lag between degradation of mRNA and actual reduction in protein level. If necessary, you may need to perform multiple cycles of transfection to observe effects of siRNAs at the protein level. It is also strongly recommended to perform validations on both mRNA and protein levels (Support Protocols 1 and 2, respectively).

Anticipated Results

Well designed siRNA-mediated silencing of a given gene of interest can result in greater than 95%, if not 100%, reduction in the mRNA and protein levels.

Time Considerations

Synthesis of siRNA from ordering to receiving may take ∼1 week, while annealing and verification take ∼4.5 to 5 hr. Seeding cells in multiple-well plates takes ∼1 hr, and transfection reagent preparation and transfection takes ∼1.5 hr. Time for maintaining cultured cells varies. For dual-luciferase reporter assays, allow ∼1.5 hr from cell lysis to bioluminescence measurements.

For RT-PCR, it will take ∼1 hr for RNA extraction, ∼1 hr for DNase treatment, ∼1.5 hr for cDNA synthesis, and ∼2.5 hr for real-time PCR. For immunoblotting, time considerations are ∼1 hr for preparation of SDS-PAGE gel, ∼1.5 to 3 hr for electrophoresis, ∼2 hr for protein transfer, and ∼4 to 5 hr for blocking a PVDF membrane and antibody incubation.

The total time required to identify a valid siRNA for a gene can be ∼ 2 weeks.

Gene Down-Regulation with Short Hairpin RNAs and Validation of Specificity by Inducible Rescue in Mammalian Cells

Hoi Tang Ma[1] and Randy Y.C. Poon[1]

[1]Division of Life Science, Hong Kong University of Science and Technology, Clear Water Bay, Hong Kong

ABSTRACT

The principal problem with RNA interference (RNAi) experiments is off-target effects. The most vigorous demonstration of the specificity is the rescue of the RNAi effects with an RNAi-resistant target gene. By combining the expression of short hairpin RNA (shRNA) and rescue cDNA in the same vector, both the validation of shRNA specificity and the generation of shRNA-expressing cell lines can easily be accomplished. If the compensatory cDNA is under the control of an inducible promoter, stable shRNA-expressing cells can be generated before the knockdown phenotypes are studied, by conditionally turning off the rescue protein. The use of model systems is detailed in these protocols. *Curr. Protoc. Cell Biol.* 49:27.2.1-27.2.12. © 2010 by John Wiley & Sons, Inc.

Keywords: inducible expression • RNA interference • short hairpin RNA

INTRODUCTION

RNA interference (RNAi) by means of short hairpin RNA (shRNA) has developed into a powerful tool for loss-of-function analysis in mammalian cells. The principal problem in RNAi experiments is off-target effects. The most vigorous demonstration of the specificity of shRNA is the rescue of the RNAi effects with a shRNA-resistant target gene. Owing to the sequence-specific nature of RNAi, shRNA-resistant target genes can be generated by introducing several silent mutations in the region of the shRNA targeting sequence of the cDNA. The silent mutations confer resistance to the shRNA but do not change the protein sequence of the target. This method presents its own problems, including both the unpredictable relative expression of shRNA and rescue cDNA in individual cells and the difficulty in generating stable cell lines.

A solution to the above problems is to combine the expression of shRNA and rescue cDNA in the same vector. The use of a model vector system called pKAR1 (for Knockdown And Rescue) is described here. In addition to facilitating the validation of shRNA specificity, this system also considerably simplifies the generation of shRNA-expressing cell lines. Since the compensatory cDNA is under the control of an inducible promoter, stable shRNA-expressing cells can be generated before the knockdown phenotypes are studied by conditionally turning off the rescue protein. Conversely, the rescue protein can be activated after the endogenous protein is completely repressed. This approach is particularly suitable when prolonged expression of either the shRNA or the compensatory cDNA is detrimental to cell growth. This system allows convenient one-step validation of shRNA and generation of stable shRNA-expressing cells (Fig. 27.2.1).

This unit contains a method for generating a model shRNA-expressing plasmid (Basic Protocol 1). A method for evaluating the ability of the shRNA to down-regulate the protein expression in culture cells is also described (Support Protocol). Construction

Current Protocols in Cell Biology 27.2.1-27.2.12, December 2010

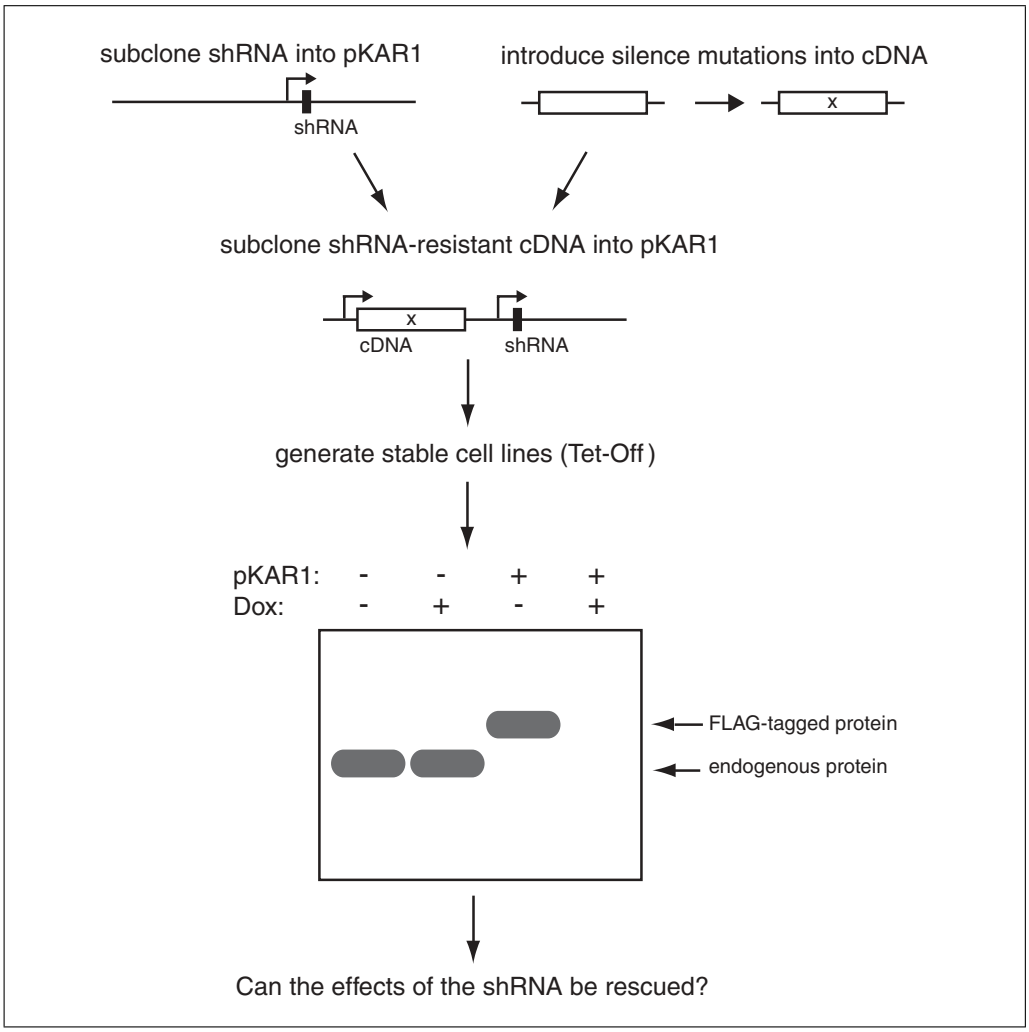

Figure 27.2.1 Plan for knockdown with shRNA and rescue experiments. An annealed duplex oligonucleotide that encodes for the shRNA is ligated into pKAR1/PUR. Silent mutations are introduced into the cDNA to render it resistant to the shRNA. The cDNA is now put into pKAR1/PUR and transfected into Tet-Off cell lines. Stable clones are selected and the expression of the target protein is analyzed—it should be suppressed (the diagram represent an immunoblot with specific antibody against the target protein). The expression of the recombinant rescue protein can be turned off with doxycycline (Dox) to reveal the knockdown phenotype.

of plasmids that coexpress both shRNA and cDNA is described in Basic Protocol 2. The generation of stable cell lines expressing shRNA and cDNA is overviewed in Basic Protocol 3.

BASIC PROTOCOL 1

DOWN-REGULATION OF GENE EXPRESSION WITH SHORT HAIRPIN RNA

Two 56-mer DNA oligonucleotides are to be synthesized. After annealing, the oligonucleotides form a double-stranded DNA that encodes the shRNA, with overhangs that are compatible with *Bbs*I- and *Xba*I-cut vector (Fig. 27.2.2A). The expected structure of the shRNA produced is shown in Figure 27.2.2B. The shRNA is processed into siRNA in the cell (see Background Information). The loop used in this design is based on that developed for the pSUPER plasmid system (Brummelkamp et al., 2002). Programs such as the freeware iRNAi (version 2.1; *http://mekentosj.com*) developed by Alexander Griekspoor and Tom Groothuis (The Netherlands Cancer Institute) can be used to assist the design of the primers.

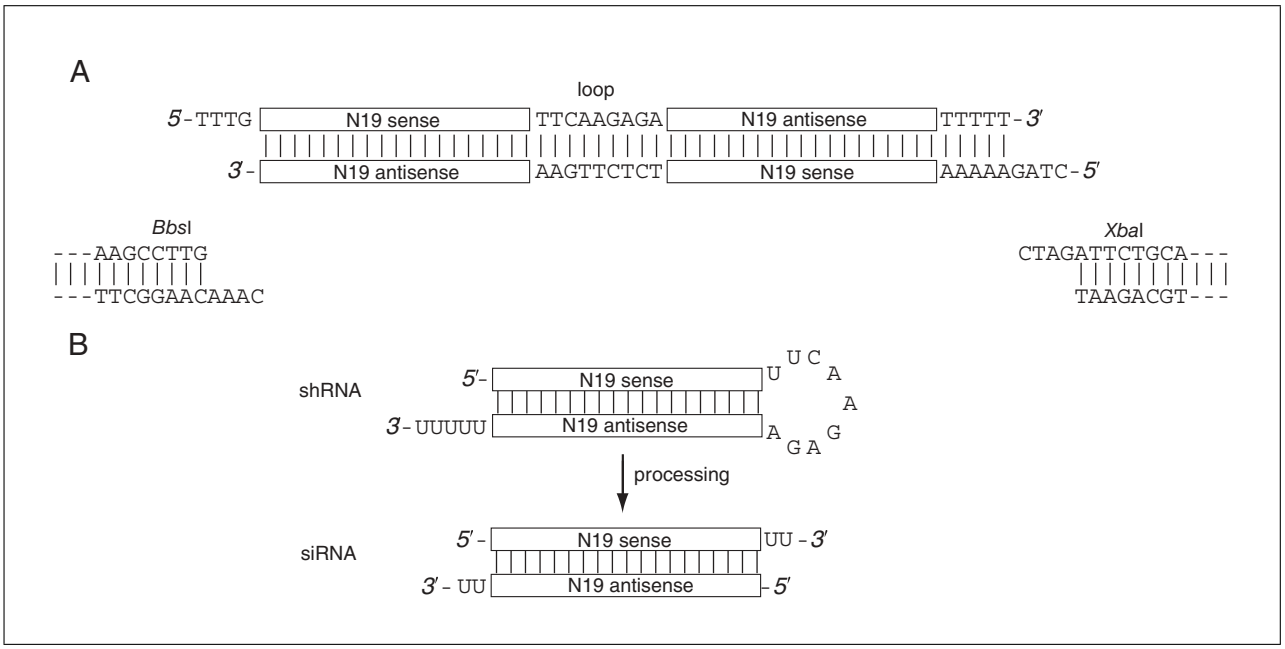

Figure 27.2.2 Cloning and expression of shRNA. (**A**) Schematic diagram of the annealed duplex oligonucleotides and the compatible sites from the *Bbs*I- and *Xba*I-cut vector. (**B**) Predicted structure of the shRNA and siRNA. After transcription from the RNA polymerase III promoter, the sense and antisense sequence form a stem that is linked by a loop of 8 nucleotides. The shRNA is believed to undergo processing by Dicer in the cell to produce a siRNA.

Materials

pKAR1 or pKAR1/PUR vectors (Addgene)
*Bbs*I and *Xba*I enzymes (New England Biolabs)
NEBuffer 2 (New England Biolabs; also see recipe)
QIAquick Gel Extraction Kit (Qiagen) or equivalent
10× annealing buffer: 100 mM Tris·Cl pH 7.4 (*APPENDIX 2A*) containing 1 M NaCl.
T4 DNA ligase and 10× ligation buffer (Fermentas)
dam$^-$ *E. coli* (e.g., GM2163 from Fermentas)
LB agar plates (*APPENDIX 2A*) with 50 μg/ml ampicillin
LB liquid medium (*APPENDIX 2A*) 50 μg/ml ampicillin
PCR primers (Invitrogen):
U6 FOR primer: 5′-CTCACCCTAACTGTAAAGTAATTG-3′
M13 REV primer: 5′-CAGGAAACAGCTATGACCATG-3′

Floating rack
16°C water bath (optional)

Additional reagents and equipment for DNA oligonucleotide synthesis (Ellington and Pollard, 1998), transforming competent *E. coli* (Thomason et al., 2007), PCR (*APPENDIX 3F*), agarose gel electrophoresis (Voytas, 2000), and DNA sequencing (Ausubel et al., 2010, Chapter 7)

Design shRNA targeting sequences

1. Select a sequence of 19 nucleotides in length (N19) that is flanked by AA and TT.

   AA(N19)TT is preferred to AA(N19)xx which is better than xx(N19)xx (x=any type of nucleotide).

2. Ensure that the 3′ end of the antisense stand is more stable (with higher free energy, ΔG) than the 5′ end.

3. Ensure that no more than four consecutive T (U) are present anywhere within the hairpin, otherwise the RNA polymerase III will terminate transcription.

4. Check that the GC content is close to 50%.
5. Avoid more than three G's in a row [as poly(G) sequences can hyperstack].
6. If the target sequence is in the ORF, avoid sequences that encode methionine and tryptophan.

   Since silent mutations are to be introduced into the shRNA-targeting region of the cDNA later, care should be made to avoid sequences that encode methionine and tryptophan (both are encoded by a single type of codon).

7. Check the sequence with BLAST to ensure that similar sequences are not present in other genes.

   Both ORF and UTRs can be used for designing targeting sequences. The use of the UTRs simplifies the generation of shRNA-resistant cDNA later.

8. Synthesize the DNA oligonucleotides (Ellington and Pollard, 1998) that will form the double-stranded DNA that encodes the shRNA.

   The authors usually use the oligonucleotide synthesis service from Invitrogen.

Prepare BbsI- and XbaI-cut vector

The shRNA is cloned into either pKAR1 or pKAR1/PUR. The difference between the two plasmids is that the latter contains a puromycin resistance gene between the two *Hin*dIII sites (Fig. 27.2.3A,B). The vectors are to be cut with *Bbs*I and *Xba*I to create compatible ends for ligation with the shRNA-encoding oligonucleotides.

9. Cut pKAR1 or pKAR1/PUR vector with *Bbs*I and *Xba*I in NEBuffer 2 at 25°C.

   Cleavage with XbaI may be blocked when the DNA is methylated by dam methylase. Dam$^-$ strains of E. coli should be used to prepare the plasmid.

10. Subject the cut plasmid to agarose gel electrophoresis (Voytas, 2000). Purify the cut plasmid with QIAquick Gel Extraction Kit (Qiagen) or similar product.

    A 761-bp fragment is removed, and the size of the cut vector is 3843 bp (pKAR1) or 4908 bp (pKAR1/PUR).

    The cut vectors can be stored at −20°C and used multiple times.

Anneal the oligonucleotides

11. Resuspend the DNA oligonucleotides (from step 8) in water to a concentration of 0.25 mM.

    The authors simply dilute the oligos according to the concentration information provided by the manufacturer (e.g., the oligonucleotide synthesis service from Invitrogen). Oligonucleotides do not need to be phosphorylated or purified.

12. Mix the following solutions in reaction tubes:

    20 µl Oligonucleotide 1
    20 µl Oligonucleotide 2
    5 µl 10× annealing buffer
    5 µl H_2O.

    The final concentration of each oligonucleotide should be 100 µM.

13. Heat 500 ml of water to 85° to 95°C in a microwave oven.
14. Immediately place the tube of annealing mixture from step 12 in a floating rack into the water and allow it to cool slowly to room temperature (usually over 1 to 2 hr).

    The annealed oligonucleotides can be stored at −20°C.

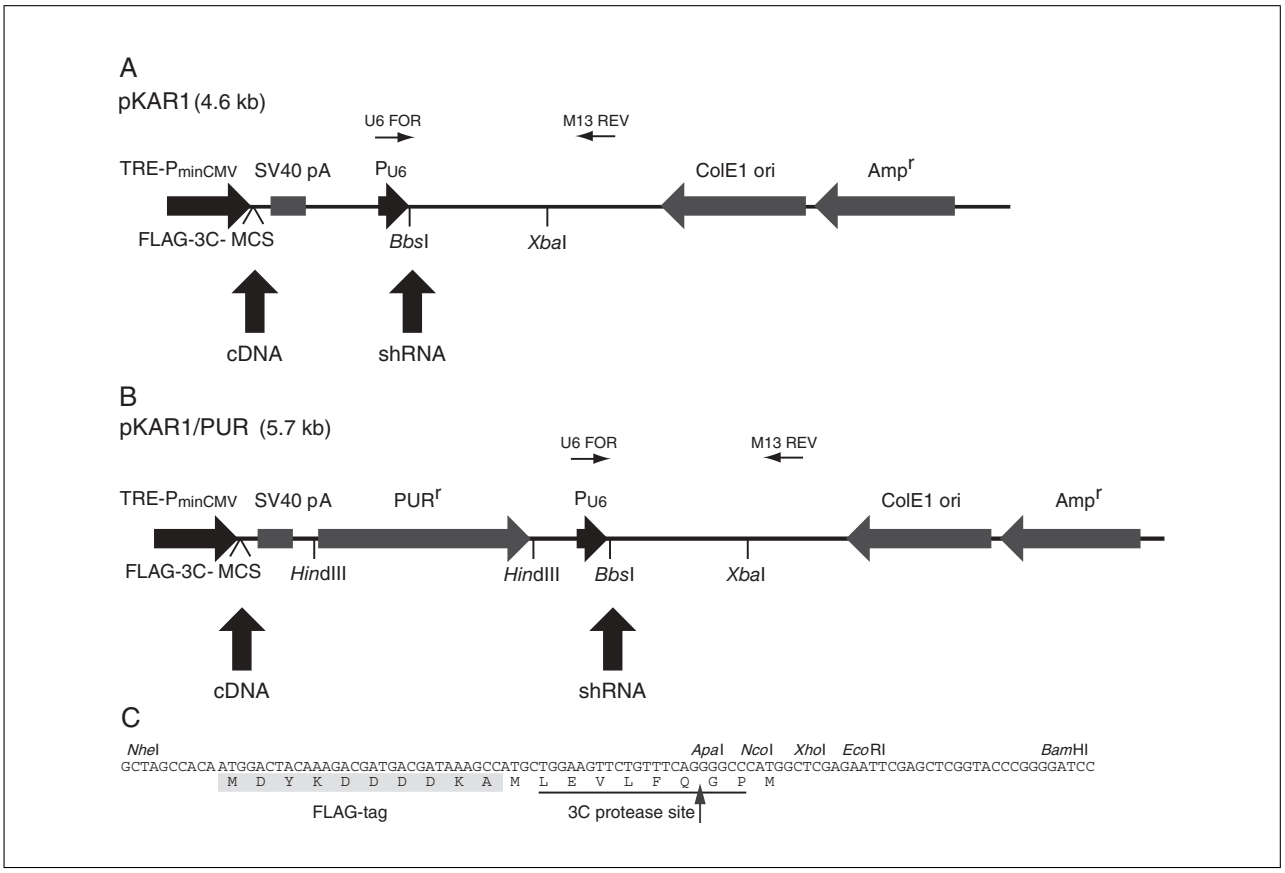

Figure 27.2.3 A model vector for coexpression of shRNA and shRNA-resistant cDNA. (**A**) Schematic diagram of pKAR1. The various elements are shown to scale: TRE, tetracycline response element; P_{min}CMV, minimal immediate early cytomegalovirus (CMV) promoter; FLAG-3C-MCS, multiple cloning sites; SV40 pA, SV40 polyadenylation signal; PU6, mouse U6 RNA promoter; Amp^r, ampicillin-resistant gene; ColE1 ori, ColE1 replication origin. The shRNA is first inserted between *Bbs*I-*Xba*I, and the shRNA-resistant cDNA is cloned into the multiple cloning sites (see panel C). The positions of the U6 FOR and M13 REV primers are indicated. (**B**) Schematic diagram of pKAR1/PUR. This vector is similar to pKAR1 except for the presence of a puromycin-resistant gene (PUR^r) inserted between the two *Hin*dIII sites. (**C**) The cDNA cloning region of pKAR1 or pKAR1/PUR. The protein sequence of the NH_2-terminal tag is shown. After cloning of the shRNA, the cDNA can be inserted in frame into the unique *Apa*I, *Nco*I, *Xho*I, *Eco*RI, and *Bam*HI sites. The untagged version can be cloned using the *Nhe*I site. The FLAG-tag is highlighted, the 3C protease recognition sequence is underlined, and the arrow indicates the site of cleavage.

Ligate oligos and plasmid

15. Dilute 1 μl of the annealed oligonucleotides into 4 ml of 0.5× annealing buffer.

16. Take 1 μl of the diluted annealed oligonucleotides from step 15 and ligate by combining the following reagents:

    1 μl diluted oligonucleotides
    50 ng *Bbs*I- and *Xba*I-cut vector (from step 10)
    1 μl 10× ligation buffer
    1 U T4 DNA ligase
    H_2O to 10 μl.

17. Incubate for 1 hr at room temperature or overnight at 16°C.

18. Transform competent *dam*$^-$ *E. coli* (Thomason et al., 2007) and plate on LB plates containing 50 μg/ml ampicillin.

Screen colonies

19. Pick several colonies and grow in 1 ml of LB supplemented with 50 μg/ml ampicillin (*APPENDIX 2A*).

20. Screen clones by PCR (*APPENDIX 3F*) with the U6 FOR primer and M13 REV primer. Analyze the products by agarose gel electrophoresis (Voytas, 2000).

    Expect an ~400 bp band if correct and an ~1130 bp for the recircularized parental vectors (see Fig. 27.2.3A,B for the relative positions of the primers).

21. Sequence clone DNA using the M13 REV primer (Ausubel et al., 2010, Chapter 7).

    The shRNA sequence is ~280 bp from the primer.

    Note that owning to the secondary structure, the hairpin region may be difficult to be sequenced properly.

SUPPORT PROTOCOL

TESTING OF THE DOWN-REGULATION OF PROTEIN BY shRNA USING IMMUNOBLOTTING

Various methods can be used to see if the shRNA is effective in down-regulating the endogenous protein. Described here is a procedure involving transient transfection of mammalian cells and detection of the endogenous target protein by immunoblotting. The presence of non-transfected cells in the final cell lysates prevents proper evaluation of the efficacy of the shRNAs. To increase the population of transfected cells, a brief treatment with antibiotics is used.

NOTE: All solutions and equipment coming into contact with the cells must be sterile, and proper aseptic technique should be used accordingly.

Materials

HeLa cells (ATCC no. CCL-2)

HeLa cell growth medium (DMEM containing 10% *APPENDIX 2B*); test batches of calf serum to ensure that there are no traces of tetracycline

pKAR1 or pKAR1/PUR plasmid bearing shRNA plus gene of interest (Basic Protocol 1) and blank plasmids as controls

Plasmid expressing blastacidin-resistance gene and histone H2B-GFP (available from the authors; can also use similar constructs such as pBOS-H2BGFP from BD Pharmingen)

Blasticidin: stock 5 mg/ml in H_2O, filter sterilized and stored as small aliquots at −20°C

Puromycin: stock 1.5 mg/ml in H_2O, filter sterilized and stored as small aliquots at −20°C

Antibodies that are capable phosphate-buffered saline (PBS; *APPENDIX 2A*) cell lysis buffer (e.g., Invitrogen) of detecting the target protein by immunoblotting

100-mm tissue culture plates

Additional reagents and equipment for mammalian cell tissue culture, including trypsinization (*UNIT 1.1*), calcium phosphate transfection (*UNIT 20.3*), determining protein concentration (*APPENDIX 3B*), SDS-PAGE (*UNIT 6.1*), and immunoblotting (*UNIT 6.2*)

1. Plate 2×10^6 HeLa cells in 100-mm plates in HeLa cell growth medium (*UNIT 1.1*).
2. Co-transfect the HeLa cells at ~25% confluence with 10 μg of the shRNA-expressing plasmid and 1 μg of a plasmid expressing a blasticidin-resistance gene and histone H2B-GFP, using the calcium phosphate precipitation method.

    Other methods such as Lipofectamine (UNIT 20.6) and electroporation (UNIT 20) may be required for obtaining a high transfection efficiency for some cell lines.

    It is essential to set up a control reaction with blank pKAR1 or pKAR1/PUR.

3. Allow the cells to grow for 6 hr (after removing the calcium phosphate-containing medium) and adding fresh HeLa cell growth medium.

4a. For blasticidin selection: Add blasticidin to a final concentration of 5 μg/ml and incubate the cells for 24 hr.

4b. For puromycin selection: Add puromycin to a final concentration of 2 μg/ml and incubate the cells for 24 hr.

Blasticidin is used for cells transfected with plasmids expressing a blasticidin-resistance gene and histone H2B-GFP. If pKAR1/PUR is used to express the shRNA, and it is possible to use puromycin for selection without the cotransfection of blasticidin-resistance plasmid in step 2. The concentration of both blasticidin and puromycin should be determined empirically for different cell lines.

5. Aspirate the medium and add 10 ml of HeLa cell growth medium.

6. Incubate for another 24 hr.

7. Harvest the cells and prepare cell-free extracts:

   a. Harvest cells by trypsinization (*UNIT 1.1*).
   b. Resuspend the cells with 1 ml PBS and transfer to a microcentrifuge tube.
   c. Microcentrifuge 1 min at 16,000 × *g*.
   d. Aspirate the PBS and store the microcentrifuge tube at –80°C.
   e. Add ~2 pellet volumes of cell lysis buffer to the microcentrifuge tube. Vortex to mix.
   f. Incubate on ice for 30 min.
   g. Centrifuge at 16,000 g at 4°C for 30 min.
   h. Transfer the supernatant to a new tube.
   i. Measure the protein concentration of the lysates (*APPENDIX 3B*). Dilute to 1 mg/ml with SDS sample buffer (*UNIT 6.1*).

   The transfection efficiency can be indicated by analyzing the percentage of cells expressing the histone H2B-GFP by fluorescence microscopy before harvest.

8. Detect the target protein by SDS-PAGE (*UNIT 6.1*) and immunoblotting (*UNIT 6.2*).

RESCUING RNA INTERFERENCE EFFECTS WITH TARGET GENES

BASIC PROTOCOL 2

Three to four silent mutations are to be introduced into the region targeted by the shRNA, causing the mRNAs to be resistant to the knockdown. Mutations should be introduced to the central region of the shRNA targeting sequence. Typically, the wobble positions of three consecutive codons are mutated. There is no need to generate silent mutations in the cDNA if the shRNA is against the UTRs (see Commentary). The use of HeLa cells expressing the tTA tetracycline repressor chimera is described. The expression of rescue cDNAs is repressed in the presence of doxycycline. Other tetracycline-responsive cell lines (such as Tet-On or Tet-Off cell lines from Clontech) can be used. For Tet-On cells, the expression of the cDNA is turned on by doxycycline.

Materials

QuickChange site-directed mutagenesis kit (Stratagene)
Target cDNA
shRNA-containing pKAR1 or pKAR1/PUR (Basic Protocol 1)
HeLa cells (see discussion in protocol introduction, above)
Doxycycline hydrochloride: 1 mg/ml in H_2O, filter sterilized and stored as small aliquots at −20°C
Antibody against FLAG peptide (M2 monoclonal antibody from Sigma)
Antibody against target protein

Additional reagents and equipment for DNA sequencing (Ausubel et al., 2010), Preparing cell-free extracts (Support Protocol, step 6), SDS-PAGE (*UNIT 6.1*), and immunoblotting (*UNIT 6.2*)

Generate shRNA-resistant cDNA in pKAR1

1. Use QuickChange site-directed mutagenesis kit or a similar product to introduce silent mutations into the target cDNA.
2. Confirm the mutagenesis by DNA sequencing (Ausubel et al., Chapter 7).
3. Clone the cDNA into the shRNA-containing pKAR1 or pKAR1/PUR generated in Basic Protocol 1 (Thomason et al., 2007).

   Several unique sites can be used to clone the cDNA in frame with both the FLAG epitope tag and the 3C protease cleavage site (Fig. 27.2.3C). Note that most of these cloning sites only become unique after the shRNA has been cloned into BbsI/XbaI-cut vector. Hence the shRNA should be cloned into the vector before the cDNA.

   IMPORTANT NOTE: *Do not include the UTR if the shRNA is against UTR.*

Test the expression of cDNA and shRNA with transient transfection

4. Transfect two identical plates of HeLa cells and transiently select with antibiotics (see Support Protocol, steps 1 to 4).
5. Add doxycycline to a final concentration of 2 μg/ml to one plate and incubate for 24 hr.

   Longer incubation may be needed for proteins with long half-lives.

6. Harvest cells and prepare cell-free extracts:

   a. Harvest cells by trypsinization (*UNIT 1.1*).
   b. Resuspend the cells with 1 ml PBS and transfer to a microcentrifuge tube.
   c. Microcentrifuge 1 min at 16,000 × *g*.
   d. Aspirate the PBS and store the microcentrifuge tube at –80°C.
   e. Add ~2 pellet volumes of cell lysis buffer to the microcentrifuge tube. Vortex to mix.
   f. Incubate on ice for 30 min.
   g. Centrifuge at 16,000 g at 4°C for 30 min.
   h. Transfer the supernatant to a new tube.
   i. Measure the protein concentration of the lysates (*APPENDIX 3B*). Dilute to 1 mg/ml with SDS sample buffer (*UNIT 6.1*).

      The transfection efficiency can be indicated by analyzing the percentage of cells expressing the histone H2B-GFP by fluorescence microscopy before harvest.

7. Detect the target protein by SDS-PAGE (*UNIT 6.1*) and immunoblotting (*UNIT 6.2*) using monoclonal antibody against FLAG (M2).
8. In a separate blot, detect the target protein by immunoblotting (*UNIT 6.2*) using specific antibodies.

   The shRNA-resistant cDNA should be slightly larger than the endogenous protein (due to the introduction of FLAG tag and 3C protease cleavage site). Control lysates without shRNA expression should also be loaded side-by-side to see if the endogenous protein is down-regulated.

GENERATION OF STABLE CELL LINES EXPRESSING BOTH shRNA AND RESCUE cDNA

Materials

HeLa Tet-Off cells (Clontech)
pKAR1/PUR expressing shRNA and cDNA (Basic Protocol 2)
HeLa cell growth medium (DMEM containing 10% calf serum; *APPENDIX 2B*); test batches of calf serum to ensure that there are no traces of tetracycline
Puromycin: stock 1.5 mg/ml in H_2O, filter sterilized and stored as small aliquots at −20°C

10-cm tissue culture plates
Stainless steel cloning rings (internal diameter: 6 mm, thickness: 1 mm, height: 10 mm)
Autoclaved high vacuum grease silicone lubricant (Dow Corning)

Additional reagents and equipment for transfecting HeLa cells and testing for expression (Basic Protocol 2) and mammalian cell culture techniques including trypsinization (*UNIT 1.1*)

1. Transfect HeLa Tet-Off cells with pKAR1/PUR expressing shRNA and cDNA (Thomason et al., 2007; see Basic Protocol 2).

   If pKAR1 is used instead of pKAR1/PUR, an antibiotic-resistant gene expression cassette should be put into the plasmid.

2. Split the cells into two 10-cm plates, one containing 90% and the other with 10% of the cells.

   Plating the cells at two densities will ensure that the densities of the colonies will not be too high.

3. Grow the cells for 24 hr in complete HeLa cell growth medium.

4. Change medium and supplement with 2 μg/ml final of puromycin.

   Optimum dose of puromycin should be identified for different cell line empirically.

5. Grow the cells in the puromycin-containing selection medium. Change medium every 3 days (maintaining the selection) until single colonies appear.

   This will take 2 to 3 weeks. Take care not to disturb the colonies when changing the medium. The medium should only be gently added to the side the dishes.

6. Identify single colonies.

   About ten well-separated colonies are to be isolated (each ∼5 mm diameter). They can be seen by eye and marked with a pen on the underside of the dishes.

7. Isolate single colonies using cloning rings.

   Home-made stainless steel cloning rings can be used (internal diameter: 6 mm, thickness: 1 mm, height: 10 mm). After coating with an autoclaved high vacuum grease silicone lubricant (Dow Corning), the rings are placed on top of the colonies to make sealed chambers. Trypsin solution (UNIT 1.1) is placed into the rings to transfer the cells to new plates.

8. Propagate cells in the absence of puromycin.

9. Test expression of shRNA and cDNA (see Basic Protocol 2).

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

NEBuffer 2

10 mM Tris·Cl, pH 7.9 (*APPENDIX 2A*)
50 mM NaCl
10 mM $MgCl_2$
1 mM dithiothreitol
Store up to 2 years at −20°C

This buffer is also available from New England Biolabs.

COMMENTARY

Background Information

RNA interference (RNAi) is an evolutionarily conserved gene-silencing process triggered by double-stranded RNAs (dsRNAs; Hannon, 2002). The use of RNAi as a technique for analyzing loss-of-function phenotypes has revolutionized research in mammalian cells. One way to induce RNAi in mammalian cells is by transfection of synthetic small interfering RNAs (siRNAs). These siRNAs are 19-base-pair (bp) dsRNAs with 2-nucleotide (nt) 3′ overhangs (Elbashir et al., 2001), and mimic the structure of microRNA (miRNA) intermediates found in the natural processing of longer dsRNA by RNase III. One strand of the siRNA or miRNA duplexes (called the guide strand) is incorporated into the RNA-induced silencing complex (RISC), where it directs RISC to bind to complementary mRNA. It is believed that the other strand of the siRNA or miRNA (called the passenger strand) is not incorporated into RISC and is destroyed. RISC cleaves the mRNAs at a site 10 nt upstream of the nucleotide complementing the 5′-most nucleotide of the guide strand. The mRNA fragments are then degraded by other nucleases, resulting in knockdown of expression (Meister and Tuschl, 2004). The shRNA hairpin structure is cleaved by the cellular machinery into siRNA, which is then bound to the RNA-induced silencing complex (RISC). This complex binds to and cleaves mRNAs that match the siRNA that is bound to it. For more information about RNA interference, refer to *UNIT 27.1*.

An alternative way to induce RNAi in mammalian cells is by expression plasmids or viral vectors. A common approach involves the transcription of shRNAs from RNA polymerase III promoters. The shRNAs consist of a stem of 19 to 29 bp linked by a small terminal loop (Brummelkamp et al., 2002; Yu et al., 2002; Paddison et al., 2002). The prevailing view is that shRNAs mimic the structure of a miRNA intermediate generated by the RNase III enzyme Drosha. Another RNase III enzyme called Dicer acts on the shRNAs to produce siRNA/miRNA duplexes, which are then loaded onto RISC to mediate silencing (Cullen, 2004).

The use of shRNA offers several important advantages over siRNA (Hannon and Rossi, 2004). First, more delivery options are available for shRNA, including transfection, electroporation, and infection with viral vectors. Second, shRNA is less expensive to generate than siRNA. Furthermore, while silencing using siRNA is inevitably transient, shRNA-expressing constructs can be stably integrated into the genome. Finally, while the effects of siRNA after delivery are only constitutive, both constitutive and inducible systems can be used for shRNA after delivery.

It is generally accepted that the major problem with using shRNAs (as well as siRNAs) for experimentation is the possibility of off-target effects (Jackson et al., 2003; Pei and Tuschl, 2006). Several methods are utilized to confirm the specificity of the RNAi results, including the use of shRNAs against irrelevant targets and the use of multiple shRNAs against the same gene. However, the ultimate control for a shRNA experiment is the rescue of the RNAi effects by expressing the target gene in a form refractory to the shRNA (Editorial, 2003; Cullen, 2006). This is usually achieved by introducing one or more silent point mutations into the region of the cDNA that is targeted by the shRNA. The rescue of RNAi phenotypes using shRNA-resistant cDNA itself may present several problems. It is likely that individual cells may take up different amount of shRNA versus cDNA-expressing constructs, triggering a spectrum of phenotypes within a

population. Moreover, it is not trivial to obtain stable expression of both shRNA and cDNA at the same time.

Vectors that can express shRNA and the respective rescue cDNA together are useful for validating the specificity of RNAi. The pKAR1 vector proves to be a good model for subcloning shRNA and the rescue cDNA simultaneously, as well as for generating stable cell lines (Ma et al., 2007). pKAR1 was based on pUHD-P1/3C (Fung et al., 2005), which was in turn based on the tetracycline-inducible system pUHD10-3 developed by Dr. Hermann Bujard's group (University of Heidelberg, Germany; Gossen and Bujard, 1992), and mU6pro developed by Dr. David Turner's group (University of Michigan, MI; Yu et al., 2002). The shRNA was expressed from a mouse U6 RNA promoter, and the rescue cDNA was expressed under the control of tetracycline or one of its derivatives (e.g., doxycycline). Similar constructs based on the same principle as pKAR1 that combine the expression of the shRNA and the rescue cDNA should also be used.

This pKAR1 system is particularly useful when the prolonged expression of either the shRNA or the compensatory cDNA is cytotoxic (Ma et al., 2007). In the first scenario, the shRNA can be allowed to completely knockdown the endogenous proteins in the presence of the rescue cDNA; the rescue cDNA can then be turned off to attain the knockdown phenotypes. In the second scenario, the rescue cDNA can be turned on only after the endogenous proteins are completely eliminated.

Critical Parameters

Expression of the shRNA

Following the criteria set out in Basic Protocol 1 does not guarantee that the shRNA will be effective in gene down-regulation. Various methods can be used to evaluate if the shRNA is effective. At the mRNA level, real-time PCR can be performed to see the reduction of the target mRNA relative to controls such as actin. Knockdown of a cotransfected target gene can also be a useful indication of the effectiveness of an shRNA. Similar reporter-based analyses such as the luciferase system (Brasier and Fortin, 2001) also serve as alternatives. If the effects of the gene knockdown are known, they can also be used as indicators of the effectiveness of the shRNA. Nevertheless, the ability of the shRNA to reduce the expression of the endogenous protein is generally regarded as the most desirable test. The Support Protocol describes a method for transient transfection followed by a brief selection with the very rapidly acting antibiotic blasticidin. Knockdown of the protein is then detected by immunoblotting. Depending on the capability of the antibodies, other methods for detecting the target protein such as flow cytometry and immunostaining (*UNIT 4.3*) can also be used. For HeLa cells, this transient selection approach can typically enrich the transfected cells to >90%.

A critical parameter for shRNA is the time required to achieve down-regulation of the protein. This depends on the effectiveness of the shRNA (and the stability of the plasmid in the cell), the abundance of the mRNA, and the stability of the protein. It is possible that a longer duration after transfection may be required to down-regulate some proteins.

Rescue of shRNA effects with cDNA

Due to the slight increase in size conferred by the FLAG epitope tag, both the endogenous protein to be silenced and the ectopically expressed version can be detected simultaneously. The tag also allows the recombinant protein to be specifically detected either by immunoblotting (*UNIT 6.2*) or immunoprecipitation (*UNIT 7.2*). Agarose conjugated with the monoclonal antibody M2 (Sigma) is effective in immunoprecipitating FLAG-tagged recombinant protein from cell lysates. Furthermore, the epitope tag can be removed using 3C proteases.

Here, examples are provided of a cell line expressing the tTA tetracycline repressor chimera, causing the expression of the rescue cDNA to be repressed by doxycycline. Likewise, cell lines expressing the reverse tTA (Gossen et al., 1995) can also be adopted to turn on the rescue cDNA with doxycycline.

The pKAR1 system is particularly suitable for generating stable cell lines. An example is the knockdown of cyclin A2 (Ma et al., 2007). Probably due to the toxicity of both cyclin A2 shRNA and cyclin A2 cDNA, all the colonies isolated lacked endogenous cyclin A and expressed FLAG-cyclin A. Furthermore, clones that grew at a normal rate tended to express the rescue cyclin A at a level similar to that in control cells. Thus, this method appears to have an additional advantage of isolating clones that express the rescue protein at a comparable level to the endogenous protein.

Time Considerations

Basic Protocol 1: ~2 weeks.
Basic Protocol 2: ~2 weeks.
Basic Protocol 3: ~2 months.

Compendium of Drugs Commonly Used in Cell Biology Research

The following appendix includes an alphabetical list of drugs commonly used to examine various cell biological processes. Table A.1B.1 lists the drugs by activity and provides recent references. Indicated under each drug listed is its mode of action, generally including several specific experimental examples; solvent(s) used to solubilize the drug; stock and working concentrations or ranges; storage conditions; and duration of incubation with cells to achieve the desired effects. Except where indicated, the majority of drugs in this list are cell-permeant. However, despite the well characterized selectivity of many of the following drugs in vitro, the corresponding effects upon their intracellular targets may not be precisely determined directly by their extracellular concentrations, since their cell-permeation properties are not known. Therefore, several different concentrations of any particular drug, as well as alternative methods of determining drug selectivity, should be examined.

Several of these drugs are members of large families, such as those targeting protein kinases and phosphatases, as well as those that affect intracellular Ca^{2+} levels. Many of these family members have different selectivities and potencies toward similar targets, and a complete listing is not included here. The reader may consult catalogs from the following companies, which have several of these family members available: Sigma, Alexis Biochemicals (including LC Laboratories), Calbiochem, Biomol, Molecular Probes, Boehringer Mannheim, Oxford Glycosystems, and Avanti Polar Lipids.

Although not specifically indicated, many of the following drugs are hazardous and should be handled with extreme care. Material Safety Data Sheets (MSDSs) are often provided for products that are hazardous or toxic. In some cases, these products are new and have not been tested for toxicity. Thus, care should be taken to ensure the safe handling of all products.

DRUGS COMMONLY USED IN CELL BIOLOGY

A23187

Calcium ionophore; forms stable complexes with divalent cations and increases their passage across biological membranes. Useful tool for increasing intracellular calcium concentration. The effectiveness of A23187 is dependent on the presence of extracellular calcium. Can be used as a fluorescent probe for investigating protein hydrophobicity. 4-Bromo-A23187 is a nonfluorescent derivative.
Soluble in: DMSO, methanol
Stock concentration: 100 mM (store at 4°C protected from light)
Working concentration: 0.1 to 20 μM
Duration of incubation: 2 min to 24 hr

Aggregates over time in aqueous systems.

Actinomycin D

Inhibits transcription by complexing with deoxyguanosine residues on DNA and blocking the movement of RNA polymerase. A potent inducer of apoptosis in many cell lines. However, actinomycin D has also been shown to suppress programmed cell death of PC12 cells induced by the topoisomerase II inhibitor etoposide.
Soluble in: Methanol
Stock concentration: 100 mM (store at 4°C)
Working concentration: 1 to 5 μM
Duration of incubation: 5 min to 24 hr

α-Amanitin

Acts as a potent and specific inhibitor of mRNA synthesis by binding preferentially to RNA polymerase II. At high concentrations also inhibits RNA polymerase III.
Soluble in: Methanol, water
Stock concentration: 2 to 10 mg/ml (store at 4°C protected from light)
Working concentration: 1 to 10 μg/ml (pol II) to 200 μg/ml (pol III)
Duration of incubation: 15 to 60 min

Ammonium chloride (NH_4Cl)

Permeant weak base. Used to neutralize acidic endomembrane compartments. Inhibits synthesis of sphingoid bases.
Soluble in: Water (freely soluble)
Stock concentration: 5 M (store at 4°C)
Working concentration: 1 to 50 mM
Duration of incubation: Effective within 15 sec

Anisomycin

Inhibits protein synthesis by blocking the peptidyl transferase step during translation. Activates p54 (JNK2) and MAP kinases. May be a useful tool to study cytoplasmic signals that result in nuclear signaling and *c-fos* and *c-jun* induction. Also known to induce apoptosis in U937 cells.
Soluble in: DMSO
Stock concentration: 100 μg/ml (store at 4°C)
Working concentration: 50 ng/ml to 1 μg/ml.
Duration of incubation: 30 min to 16 hr, depending on properties studied

Aphidicolin

Cell synchronization reagent. Reversible inhibitor of DNA polymerase α and δ; blocks cell cycle at early S phase. Potentiates apoptosis induced by arabinosyl nucleosides in leukemia cell lines.
Soluble in: DMSO, methanol
Stock concentration: 2 mg/ml (store at 4°C)
Working concentration: 0.5 to 100 μg/ml.
Duration of incubation: 12 to 24 hr

Ara-C (cytosine arabinoside)

Inhibits DNA synthesis. S-phase-toxic reagent whose active metabolite (ara-CTP) is a substrate for DNA polymerases and is incorporated into DNA. Anticancer, antiviral agent that is especially effective against leukemias. Induces apoptosis in human myeloid leukemia cells and in rat sympathetic neurons.
Soluble in: Water
Stock concentration: 20 mg/ml (store at 4°C)
Working concentration: 0.1 to 1 μg/ml
Duration of incubation: >3 hr

Bafilomycin A_1

A potent and specific inhibitor of vacuolar-type H^+-ATPases. Valuable tool for distinguishing different types of ATPases. Blocks lysosomal trafficking in macrophages.
Soluble in: DMSO
Stock concentration: 50 μM (store at −20°C protected from light)
Working concentration: 10 to 100 nM
Duration of incubation: 10 min to 2 hr

BAPTA

Ca^{2+} chelator with a 10^5-fold greater affinity for Ca^{2+} than for Mg^{2+}; can be used to control the level of both intracellular (using its membrane-permeant AM ester) and extracellular Ca^{2+}.
Soluble in: DMSO
Stock concentration: 1 to 10 mM (store at −20°C in aliquots, protected from light; avoid repeated freeze-thawing)
Working concentration: (BAPTA-AM): 1 to 20 μM
Duration of incubation: 15 to 60 min at 20° to 37°C

Before incubation with BAPTA, wash cells 2 to 3 times with serum-free medium (serum may contain esterase activity). The cell-loading medium should also be free of amino acids or buffers containing primary or secondary amines that may cleave the AM esters and prevent loading.

Bisindolylmaleimide I (GF 109203X)

A highly selective cell-permeant protein kinase C (PKC) inhibitor that is structurally similar to staurosporine, but has higher selectivity. May inhibit protein kinase A at high concentrations. Acts as a competitive inhibitor for the ATP-binding site of the PKC catalytic domain. Since ATP levels are generally very high in cells, the potency of bisindolylmaleimide I is reduced accordingly in whole-cell assays.
Soluble in: DMSO
Stock concentration: 2 mM (store at ≤4°C)
Working concentration: 20 nM to 1 μM
Duration of incubation: 15 min to 6 hr

Water-soluble salts are available.

Brefeldin A

Inhibits GTP nucleotide exchange onto several members of the ARF (ADP ribosylation factor) family. Inhibits binding of the cytosolic coatomer (COPI) complex to Golgi membranes; induces the rapid redistribution of the Golgi apparatus into the ER; blocks transport out of the ER in a number of cell lines. Reversible.
Soluble in: Methanol
Stock concentration: 1 to 20 mM (store at −20°C)
Working concentration: 1 to 5 μM
Duration of incubation: 5 min to 24 hr; effects are rapid (30 sec)

8-Bromo–cyclic AMP

Cell-permeant cyclic AMP analog. Activates protein kinase A. Increased resistance to degradation by cellular phosphodiesterases as compared to cyclic AMP.
Soluble in: Water
Stock concentration: 100 mM (store at −20°C)
Working concentration: 10 to 500 μM
Duration of incubation: Up to 24 hr

Calpain inhibitor I (ALLN)

Inhibitor of calpain I, calpain II, cathepsin B, and cathepsin L. Peptide aldehyde; inhibits neutral cysteine proteases and the proteosome. Protects against neuronal damage caused by hypoxia and ischemia. Inhibits proteolysis of IkB by the ubiquitin-proteosome complex. Inhibits cell-cycle progression at G_1/S and metaphase/anaphase in CHO cells by inhibiting cyclin B degradation. Membrane-permeant due to low molecular weight and lack of charged residues.
Soluble in: DMSO, methanol, dimethylformamide
Stock concentration: 25 mM (store at 4°C)
Working concentration: 25 to 100 μM
Duration of incubation: 1 to 18 hr

Calphostin C

Potent and highly selective inhibitor of protein kinase C (PKC; K_i = 50 nM). Competes with phorbol esters and diacylglycerol for binding to the PKC regulatory domain. Does not compete with Ca^{2+} or phospholipids. At higher concentrations inhibits myosin light chain kinase (K_i > 5 μM), protein kinase A (K_i > 50 μM), protein kinase G (K_i > 25 μM), and $p60^{v\text{-}src}$ (K_i > 50 μM).
Soluble in: DMSO
Stock concentration: 1 mM (store 4°C protected from light)
Working concentration: 10 nM to 3 μM
Duration of incubation: 15 to 60 min

Brief exposure to visible light in the presence of PKC is required for PKC inhibition by calphostin C. See Table 1 (Selectivity of Selected Kinase Inhibitors) in the Biomol Catalog and Handbook, 5th ed., and Technical Note #11 from Alexis Biochemicals for additional information.

Calyculin A

Potent cell-permeant inhibitor with high specificity for the Ser/Thr protein phosphatases 1 and 2A. Calyculin A is 20 to 300 times more potent than okadaic acid as a PP-1 class phosphatase inhibitor. Stimulates contraction of smooth muscle, induces intracellular protein phosphorylation in cultured human keratinocytes, and inhibits apoptosis.
Soluble in: DMSO, ethanol
Stock concentration: 10 μM (store at −20°C protected from light and moisture)
Working concentration: 0.5 to 50 nM
Duration of incubation: 15 min to 2 hr

See Technical Note #19 from Alexis Biochemicals for additional information.May cause cell rounding.

Camptothecin

A reversible DNA topoisomerase I inhibitor. Induces breaks at replication forks by binding to and stabilizing the topoisomerase-DNA covalent complex. Causes S-phase cytotoxicity. Posesses anti-leukemic and anti-tumor properties. Inhibits *tat*-mediated transactivation of HIV-1.
Soluble in: DMSO
Stock concentration: 1 to 10 mM (store at 4°C)
Working concentration: 0.1 to 10 μM
Duration of incubation: Literature shows use from 15 min to 24 hr

Castanospermine

Inhibitor of α- and β-glucosidases; inhibitor of glycoprotein processing. Prevents calnexin and calreticulin binding to N-linked glycans on newly synthesized glycoproteins. Inhibits HIV infectivity.
Soluble in: Water
Stock concentration: 1 mM (store at 4°C)
Working concentration: 1 to 5 μM
Duration of incubation: 15 min to 3 hr

CCCP (carbonyl cyanide-m-chlorophenyl hydrazone)

Proton ionophore. Uncoupling agent for oxidative phosphorlyation that inhibits mitochondrial function. Approximately 100 times as effective as 2,4-dinitrophenol at collapsing membrane potential. Inhibits transport processes and depresses growth.
Soluble in: DMSO, ethanol
Stock concentration: 1 to 10 mM (store at 4°C)
Working concentration: 1 to 5 μM
Duration of incubation: 5 to 15 min

Chelerythrine chloride

Potent, selective, cell-permeant inhibitor of protein kinase C (K_i = 0.66 μM). Acts on the catalytic domain. Chelerythrine shows competitive kinetics with PKC substrates, but is not competitive with ATP. Thus, the high concentration of ATP within cells should not lower the potency of chelerytherine in whole cells as compared with that seen in purified enzyme preparations. Inhibits thromboxane formation and phosphoinositide metabolism in platelets. Induces apoptosis in HL-60 cells.
Soluble in: DMSO
Stock concentration: 10 mM (store at –20°C)
Working concentration: 1 μM
Duration of incubation: 15 min to 2 hr

See Technical Note #8 from Alexis Biochemicals for additional information.

Chloroquine

Tertiary amine that accumulates within and neutralizes the pH of acidic organelles; various effects on phagosome-endosome and phagosome-lysosome fusion. Antimalarial drug that works via carrier-mediated uptake in *P. falciparum*. May activate protein kinases.
Soluble in: Water
Stock concentration: 1 to 10 mg/ml (store at room temperature)
Working concentration: 10 to 200 μg/ml
Duration of incubation: 15 min to 2 hr

Cholera toxin

Contains a single A subunit (mol. wt. = 29 kDa) and a B subunit (mol. wt. = 55 kDa) containing five B polypeptide chains. The B subunit binds to GM_1 ganglioside receptors on the surface of cells and facilitates transport of the A subunit through the membrane. The A subunit catalyzes the ADP-ribosylation of an arginine residue on the α subunit of heterotrimeric G proteins (primarily G_s), reducing its intrinsic GTPase activity. Toxicity results from activation of membrane-bound adenylate cyclase. Consequently, increased intracellular cAMP levels result in increased electrolyte transport out of the cell and water loss. Cholera toxin requires ADP-ribosylation factor (ARF) for maximal activity.
Soluble in: Water
Stock concentration: 1 mg/ml (store at 4°C, do not freeze)
Working concentration: 100 ng/ml to 2 μg/ml
Duration of incubation: 2 to 24 hr

Colcemid

Cell synchronization agent. Depolymerizes microtubules and limits microtubule formation. Low concentrations inactivate spindle dynamics. Induces apoptosis by blocking mitosis in HeLa S3 cells. Colcemid is a less toxic derivative of colchicine.
Soluble in: Ethanol
Stock concentration: 1 mM (store at or below room temperature)
Working concentration: 1 to 10 μM
Duration of incubation: 1 to 24 hr, depending on process studied

Colchicine

Inhibitor of mitosis, used in cell-division studies. Disrupts microtubules and inhibits tubulin polymerization. Induces apoptosis in PC 12 cells and in cerebellar granule cells.
Soluble in: Ethanol
Stock concentration: 1 mM (store at or below room temperature protected from light and moisture)
Working concentration: 1 to 10 μM
Duration of incubation: 1 to 24 hr, depending on process studied

Concanamycin B

Highly specific and sensitive inhibitor of vacuolar-type H^+-ATPases (K_i = 20 pM). Related to concanamycin A (folimycin). More potent and specific than bafilomycin A_1. Inhibits acidification of organelles such as lysosomes and the Golgi apparatus. Blocks cell-surface expression of viral glycoproteins without affecting their synthesis.
Soluble in: Methanol, ethanol
Stock concentration: 10 μM (store at −20°C protected from light)
Working concentration: 50 nM
Duration of incubation: 5 min to 1 hr

Cycloheximide

Inhibits protein synthesis in eukaryotes but not prokaryotes. Blocks the translocation step during translation. Induces apoptosis in a number of cell types. However, it inhibits DNA cleavage in rat thymocytes treated with thapsigargin and ionomycin.
Soluble in: Water, ethanol, methanol
Stock concentration: 10 mg/ml (store at or below room temperature)
Working concentration: 1 to 100 μg/ml, depending on cell type
Duration of incubation: Effective within 10 min

To achieve >90% inhibition of protein synthesis, only 1 to 10 μg/ml is required in CHO and HeLa cells, but 100 μg/ml is required in COS cells.

Cyclosporin A (CsA)

Cyclic oligopeptide with immunosuppressant properties. Induces apoptosis in some cell types, while inhibiting apoptosis in others. A complex of cyclosporin A and cyclophilin inhibits protein phosphatase 2B (calcineurin) with affinity at the nanomolar level. Inhibits nitric oxide synthesis induced by interleukin-1α, lipopolysaccharides, and TNFα.
Soluble in: Ethanol, methanol
Stock concentration: 1 to 5 mM (store at 4°C)
Working concentration: 0.1 to 10 μM
Duration of incubation: Used anywhere from 15 min to 24 hr

Cytochalasin B

Cell-permeant fungal toxin that blocks the formation of contractile microfilaments. Shortens actin filaments by blocking monomer addition at the barbed (fast-growing)

continued

end of polymers. Inhibits cytoplasmic division, cell movement, phagocytosis, platelet aggregation, and glucose transport.
Soluble in: DMSO, ethanol
Stock concentration: 10 mM (store at −20°C protected from light)
Working concentration: 1 to 20 μM
Duration of incubation: 15 min to 2 hr

Cytochalasin D

Approximately 10-fold more potent than cytochalasin B in inhibiting actin filament function. Does not inhibit sugar transport in cells. Modulates CD4 cross-linking in T lymphocytes and increases intracellular Ca^{2+}. Exhibits antitumor activity.
Soluble in: DMSO
Stock concentration: 10 mM (store at −20°C protected from light)
Working concentration: 1 to 20 μM
Duration of incubation: 15 min to 2 hr.

Desferrioxamine (DFO)

Iron-chelating agent. Commonly used in therapy as a chelator of ferric iron in iron overload disorders. Protects against dopamine-induced cell death. Also interferes with hydroxy-radical formation. Shows an antiproliferative effect on vascular smooth muscle cells.
Soluble in: DMSO; slightly soluble in water
Stock concentration: 10 to 50 mM (store at 4°C)
Working concentration: 10 μM to 2 mM
Duration of incubation: Up to 18 hr

2-Deoxyglucose

Nonmetabolizable derivative of glucose. Competes with glucose for the GLUT-2 transporter; phosphorylation of 2-deoxyglucose by hexokinase effectively inhibits glucose flux through the glycolytic pathway. Used in combination with sodium azide or oligomycin to reduce cellular ATP levels. Blocks inhibition of IL-1 release by high glucose levels in RAW 264.7 cells.
Soluble in: Water
Stock concentration: 1 M (store at 4°C)
Working concentration: 5 to 50 mM
Duration of incubation: 15 min to 3 hr

Deoxymannojirimycin

Competitive α-mannosidase I inhibitor that blocks conversion of high mannose forms to complex oligosaccharides. Inhibits mammalian Golgi α-mannosidase I (an α-1,2-mannosidase). Other rat liver mannosidases are not significantly affected (α-1,2–specific ER mannosidase is only inhibited 2% to 5% by 100 mM deoxymannojirimycin, and Golgi α-mannosidase II is inhibited ~14%).
Soluble in: Water
Stock concentration: 100 mM (store at −20°C)
Working concentration: 1 to 5 mM
Duration of incubation: Anywhere from 30 min to 24 hr

Deoxynojirimycin

Specific glucosidase inhibitor. Inhibits endoplasmic reticulum trimming glucosidases I and II, which sequentially remove three glucose residues from $Glc_3Man_9GlcNAc_2$ in N-linked glycan biosynthesis. Prevents calnexin and calreticulin binding to N-linked glycoproteins within the ER.

continued

Soluble in: Water
Stock concentration: 100 mM (store at 4°C)
Working conditions: 1 to 5 mM.
Duration of incubation: 15 min to 24 hr

At concentrations >1 mM, deoxynojirimycin may inhibit lipid-linked oligosaccharide biosynthesis as well as trimming. In such cases, N-methyldeoxynojirimycin may be a more effective inhibitor, possibly owing to an increased ability to cross cell membranes, afforded by the N-methyl group.

Dibutyryl cyclic AMP

Highly membrane-permeant cAMP analog resistant to phosphodiesterase cleavage. Constitutive activator of protein kinase A. This product releases butyrate due to intracellular and extracellular esterase action. Butyrate may have its own distinct biological effects (see sodium butyrate).
Soluble in: DMSO, ethanol
Stock concentration: 1 M (store at −20°C)
Working concentration: 100 μM to 1 mM
Duration of incubation: Anywhere from 1 to 48 hr

Dithiothreitol (DTT; Cleland's reagent)

Cell-permeant protective agent for SH groups; maintains monothiols completely in the reduced state and reduces disulfides quantitatively. DTT interferes with the folding and export of proteins located in the endoplasmic reticulum, but it does not prevent the transfer from the intermediate compartment to the Golgi complex. Reversible.
Soluble in: Water, ethanol
Stock concentration: 1 M (store at 4°C)
Working concentration: 1 to 10 mM
Duration of incubation: 1 min to several hours

E-64

Irreversible inhibitor of cysteine proteases (papain and cathepsins B and L). Has no action on cysteine residues in other proteins.
Soluble in: Water
Stock concentration: 1 mg/ml (store at −20°C)
Working concentration: 0.5 to 10 μg/ml
Duration of incubation: Up to 24 hr

Emetine

Irreversibly blocks protein synthesis by inhibiting movement of ribosomes along mRNA. Stimulates rapid and differential phosphorylation of the stress-activated protein kinase/c-Jun kinase (SAPK/JNK) pathway. Prevents apoptosis in several cell lines. In primary rat hepatocytes, the relative potency of inhibition of several protein synthesis inhibitors is in the order: emetine > anisomycin > cycloheximide > puromycin, with puromycin exhibiting only marginal inhibition at a concentration of 1 μM. In fact, 90% to 95% inhibition of protein synthesis was achieved only with emetine and anisomycin, at 10 μM concentrations. Cycloheximide and puromycin exerted only 80% and 60% inhibition, respectively, at a similar concentration.
Soluble in: Ethanol
Stock concentration: 10 to 100 mM (store at 4°C protected from light)
Working concentration: 10 to 20 μM
Duration of incubation: 15 to 30 min; can incubate 24 hr

Etoposide (VP-16)

Topoisomerase II inhibitor. Stabilizes the covalent complexes of topoisomerase II with DNA. Has major activity against a number of tumors, including germ cell neoplasms, small cell lung cancer, and malignant lymphoma. Induces apoptosis in mouse thymocytes and HL-60 cells. Activates PKCα.
Soluble in: DMSO
Stock concentration: 100 to 500 mM (store at room temperature)
Working concentration: 50 to 200 μM
Duration of incubation: 1 to 24 hr

Filipin

A cholesterol-binding fluorochrome. Specific for unesterified cholesterol. Binds and removes cholesterol from cell surface membranes. Reversibly disassembles caveolae.
Soluble in: Methanol
Stock concentration: 500 μg/ml (store 4°C protected from light)
Working concentration: 5 to 50 μg/ml
Duration of incubation: 1 hr

Forskolin

Activates adenylate cyclase by interacting directly with the catalytic subunit. Leads to an increase in the intracellular concentration of cAMP. Several forskolin derivatives are available having different and improved properties. Enhances detoxification of brefeldin A.
Soluble in: DMSO, ethanol
Stock concentration: 10 to 100 mM (store at 4°C)
Working concentration: 10 μM (to increase cAMP levels); 100 μM to inhibit brefeldin A
Duration of incubation: Depending on assay, incubate cells 15 min to 12 hr

Fumonisin B_1

Inhibits sphingolipid biosynthesis via inhibition of sphingosine *N*-acyltransferase (ceramide synthase). Sphingomyelin biosynthesis is preferentially inhibited versus glycosphingolipids in neuronal cells. Inhibits the butyric acid–induced increase in transport of cell-associated Shiga toxin to the Golgi apparatus and the ER. Induces apoptosis in monkey kidney cells.
Soluble in: methanol
Stock concentration: 10 to 100 mM (store at 4°C)
Working concentration: Anywhere from 1 to 100 μM
Duration of incubation: 15 min to 18 hr, depending on process studied

Geneticin (G418)

Aminoglycoside toxic to bacteria, yeast, higher plants, protozoa, and mammalian cells. Used for the selection and maintenance of eukaryotic cells stably transfected with the neomycin (*neo*) resistance genes from transposons Tn*5* and Tn*601*.
Soluble in: Water or culture medium
Stock concentration: 2 mg/ml (active G418) in cell culture medium, adjust pH to ~7.4 (store at 4°C)
Working concentration: Usually 50 to 1000 μg/ml (optimal concentration must be determined experimentally and varies with the cell type used)
Duration of incubation: >1 week

In cell types with relatively stable genomes (e.g., CHO), continuous incubation in geneticin is not generally necessary once stable cells have been selected. Expression in stable cells with down-regulated viral promoters can be enhanced with sodium butyrate.

Genistein

Inhibits protein tyrosine kinases by acting as a competitive inhibitor of ATP. Prevents EGF-stimulated tyrosine phosphorylation in A431 cells, as well as inhibiting kinases in other cultured cells.
Soluble in: DMSO
Stock concentration: 100 to 500 mM (store at −20°C)
Working concentration: 50 to 300 μM
Duration of incubation: 15 min to 1 hr

See Table II (Selectivity of Tyrosine Protein Kinase Inhibitors) in the Biomol Catalog and Handbook, 5th ed.

H-7

A broad-based, cell-permeant serine/threonine kinase inhibitor. Inhibits protein kinase C (K_i = 6.0 μM), protein kinase A (K_i = 3.0 μM), protein kinase G (K_i = 5.8 μM), and myosin light chain kinase (K_i = 97 μM). Induces apoptotic DNA fragmentation and cell death in HL-60 cells. Numerous analogs with different selectivities are available.
Soluble in: Water
Stock concentration: 100 mM (store at 4°C)
Working concentration: 10 to 100 μM
Duration of incubation: 15 min to 3 hr

See Table I (Selectivity of Selected Kinase Inhibitors) in the Biomol Catalog and Handbook, 5th ed., and Technical Note #10 from Alexis Biochemicals.

Herbimycin A

An irreversible and selective cell-permeant protein tyrosine kinase inhibitor; reacts with thiol groups. It is effective on Src, Yes, Fps, Ros, Abl, and ErbB oncogene products. Inhibits PDGF-induced phospholipase D activation in a dose-dependent manner.
Soluble in: DMSO
Stock concentration: 10 mM (store at −20°C protected from light)
Working concentration: 1 to 10 μM
Duration of incubation: 15 min to 1 hr

Hydroxyurea

Antineoplastic reagent. Blocks DNA synthesis by inhibiting ribonucleotide reductase; accumulates cells at G1/S interface.
Soluble in: Water
Stock concentration: 1 M (store at 4°C)
Working concentration: 50 μM to 1 mM
Duration of incubation: Up to 24 hr

Hygromycin

Inhibitor of both prokaryotic and eukaryotic protein synthesis; inhibits at the translocation step on 70S ribosomes and causes misreading of mRNA. The *E. coli hph* hygromycin B–resistant gene is widely used for selection of recombinant clones in a variety of cell types.

Hygromycin B is sold as an aqueous solution. Actual activity and concentration are given for each lot of product. Concentrations used must be experimentally determined.

Ionomycin

Ca^{2+} ionophore. Useful for increasing intracellular Ca^{2+} concentrations and in measurement of cytoplasmic free Ca^{2+}. More effective than A23187 and is nonfluorescent.
Soluble in: DMSO and methanol
Stock concentration: 1 mM (store at 4°C protected from light)

continued

Working concentration: Usually 1 μM
Duration of incubation: 15 to 30 min.

KN-62

Potent and selective inhibitor of Ca^{2+}/calmodulin kinase II (K_i = 0.9 μM), displaying a K_i for CaM kinase II more than 2 orders of magnitude lower than those for protein kinase C, protein kinase A, and myosin light chain kinase. A second inhibitor of CaM kinase II, KN-93, is more soluble in water and equally selective for CaM kinase II (K_i = 0.3 μM). Prevents agonist-mediated activation of Ins(1,4,5)P_3 3-kinase. Inhibits differentiation of 3T3-L1 embryonic fibroblasts to adipocytes. Inactive analogs are available.
Soluble in: DMSO
Stock concentration: 10 mM (store at 4°C)
Working concentration: 2 to 10 μM
Duration of incubation: 30 min (can incubate cells up to 48 hr)

Lactacystin

A cell-permeant and irreversible proteosome inhibitor. Blocks proteosome activity by targeting the catalytic β subunit. Induces neurite outgrowth in Neuro 2A mouse neuroblastoma cells and inhibits progression of synchronized Neuro 2A cells and MG-63 human osteosarcoma cells beyond the G_1 phase of the cell cycle. Inhibits NFκB activation. Has revealed the role of the proteosome in the degradation of many ER proteins.
Soluble in: DMSO
Stock concentration: 10 mM (store at −20°C)
Working concentration: 10 to 20 μM
Duration of incubation: 1 to 12 hr

Latrunculin A

Inhibits actin polymerization and disrupts microfilament organization as well as microfilament-mediated processes; 10 to 100-fold more potent than cytochalasins. Whereas cytochalasins induce dissolution of F-actin and stress-fiber contraction in fibroblasts in culture, the latrunculins (A and the less potent B) cause a shortening and thickening of stress fibers. In addition, the latrunculins sequester actin monomers, whereas with the cytochalasins, actin remains in an oligomer form. Thus, the two classes of compounds may have different target sites. Reversible.
Soluble in: DMSO, ethanol
Stock concentration: 10 mg/ml (store at −20°C)
Working concentration: 0.2 to 10 μg/ml
Duration of incubation: 1 to 12 hr

Leptomycin B

A potent and specific inhibitor of the NES-dependent nuclear export of proteins; binds to the export receptor CRM1. Exhibits antifungal and antitumor effects, inhibits the nucleo-cytoplasmic translocation of the human immunodeficiency virus type 1 regulatory protein Rev, and exhibits significant antiproliferative activity.
Soluble in: Ethanol
Stock concentration: 100 μM to 1 mM (store at −20°C)
Working concentration: 10 to 100 nM
Duration of incubation: 30 min to 3 hr

Leupeptin

A reversible inhibitor of trypsin-like and cysteine proteases (including trypsin, plasmin, proteinase K, papain, thrombin, and cathepsin A and B). Inhibits activation-induced programmed cell death in T lymphocytes.
Soluble in: Water
Stock concentration: 1 to 10 mM (store at −20°C)
Working concentration: 10 to 100 μM
Duration of incubation: 15 min to several hours

Lovastatin

An antihypercholesterolemic agent and inhibitor of 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase; depletes endogenous pools of mevalonic acid, thereby blocking protein isoprenylation and cholesterol synthesis. Has a number of cellular effects. Blocks *N-ras* oncogene–induced neuronal differentiation, inhibits growth factor signaling and causes cells to arrest in late G_1 phase.
Soluble in: DMSO, ethanol
Stock concentration: 4 mg/ml (store at −20°C)
Working concentration: 20 μM
Duration of incubation: 6 to 24 hr

Lysophosphatidic acid (LPA)

Activates a number of signaling pathways and processes via heterotrimeric G proteins (primarily G_i and G_q) including: inhibition of adenylate cyclase, activation of Ras and the Raf/MAP kinase pathway, stimulation of phospholipases C and D, and stress-fiber formation through the activation of Rho.

Solubility: A stock solution may be prepared at 10 mg/ml in 95:5:5 chloroform/methanol/acetic acid (gives a clear solution). Solubility in dimethysulfoxide (DMSO) or ethanol is limited. The sodium salt of oleoyl-LPA is reported to be readily soluble at 5 mg/ml (~11 mM) in calcium and magnesium-free buffers (Jalink et al., 1990). Solubilization has also been achieved (Seufferlein and Rozengurt, 1994) in phosphate-buffered saline (PBS), pH 7.4, or calcium- and magnesium-free Dulbecco's PBS (CMF-DPBS), pH 7.4 (see *APPENDIX 2A* for recipes), at up to 3 mM (0.14 mg/ml) in the presence of 0.1% (w/v) BSA (essentially fatty-acid free).

Storage. LPA should be stable in solution under neutral conditions. Freezer storage is recommended for solutions or aqueous preparations. Maintaining the product under an inert atmosphere (nitrogen or argon) may be appropriate for some applications.

Working concentration. Anywhere from 500 nM (1-hr incubation) to 100 μM (15-min incubation).

LY294002 (PI 3-kinase inhibitor)

Reversible inhibitor of phosphatidylinositol-3-kinase that acts on the ATP-binding site of the enzyme. Does not affect the activity of EGF receptor kinase, MAP kinase, PKC, PI4-kinase, S6 kinase, and *c-src*. Blocks proliferation of cultured rabbit aortic smooth muscle cells without inducing apoptosis. Wortmannin is more selective and more potent, but is irreversible.
Soluble in: DMSO and ethanol
Stock concentration: 1 to 10 mM (store in aliquots at −20°C)
Working concentration: 1 to 2 μM
Duration of incubation: 15 min to 3 hr

Mastoparan

Relatively cell-permeant synthetic peptide capable of directly activating pertussis toxin–sensitive G proteins by a mechanism analogous to that of G-protein-coupled receptors. Acts preferentially on G_i and G_o rather than G_s. Stimulates insulin secretion in permeabilized cells, and can increase intracellular Ca^{2+} levels. Inhibits calmodulin and activates phospholipase A_2.
Soluble in: Water
Stock concentration: 1 mM (store −20°C)
Working concentration: 10 to 50 μM
Duration of incubation: 15 min to 1 hr

Microcystin-LR

Cyclic heptapeptide; potent inhibitor of protein phosphatases 1 and 2A (PP-1 and PP-2A). Unlike okadaic acid, microcystin-LR is equally effective on both PP-1 (K_i = 1.7 nM) and PP-2A (K_i = 0.04 nM). Has no effect on protein kinases, making it useful for reducing the effect of contaminating phosphatases in protein kinase assays. It is not cell-permeant, but can enter hepatocytes via the multispecific organic anion transporter.
Soluble in: DMSO, ethanol, methanol
Stock concentration: 1 mM (store at −20°C)
Working concentration: 1 to 5 μM in hepatic cells; 10 μM in vitro
Duration of incubation: 15 min to 1 hr

MG-132

A potent, reversible and cell-permeant proteosome inhibitor. Reduces the degradation of ubiquitin-conjugated proteins by the 26S complex without affecting its ATPase or isopeptidase activities. Has been used to implicate the proteosome in the breakdown of membrane proteins, including the CFTR, within the ER (see also lactacystin). Inhibits NFκB activation.
Soluble in: DMSO
Stock concentration: 10 to 100 mM (store at −20°C)
Working concentration: 20 to 200 μM
Duration of incubation: 30 min to 24 hr

ML-7 (MLCK inhibitor)

Potent, cell- permeant, and selective inhibitor of myosin light chain kinase (K_i = 300 nM). Inhibits protein kinase A (K_i = 21 μM) and protein kinase C (K_i = 42 μM) at much higher concentrations.
Soluble in: DMSO, ethanol, water
Stock concentration: 100 to 500 mM (store at 4°C protected from light)
Working concentration: 10 to 50 μM
Duration of incubation: 15 min to 1 hr

See Table I (Selectivity of Selected Kinase Inhibitors) in the Biomol Catalog and Handbook, 5th ed

L-Mimosine

An inhibitor of DNA replication that may act by preventing the formation of replication forks. L-mimosine blocks the camptothecin-induced apoptosis of PC12 cells, whereas aphidicolin does not.
Soluble in: Water
Stock concentration: 10 mM (store at room temperature)
Working concentration: 25 to 400 μM
Duration of incubation: 2 to 24 hr

Monensin

Polyether antibiotic that functions as an Na^+ ionophore. Forms stable complexes with monovalent cations that are able to cross cell membranes. Inhibits glycoprotein secretion by blocking transport through the Golgi. Neutralizes acidic endomembrane compartments. Reduces sphingomyelinase activity.
Soluble in: DMSO, methanol
Stock concentration: 2 to 30 mM (store at 4°C)
Working concentration: 1 to 30 μM
Duration of incubation: Effective within seconds; use up to 3 hr.

Nigericin

Dual antiporter ionophore that acts as a K^+/H^+ exchanger. Stimulates Ca^{2+} release from mitochondrial stores by disruption of membrane potential. Allows adjustment of cytoplasmic pH (when combined with K^+ ionophore such as valinomycin).
Soluble in: Ethanol
Stock concentration: 1 mg/ml (store at 4°C)
Working concentration: 1 to 10 μM
Duration of incubation: Effective within 2 to 5 min

Nocodazole

Has specific antimicrotubular activity for mammalian cells in culture. Promotes microtubule depolymerization. Nanomolar concentrations alter microtubule dynamics and interfere with fibroblast locomotion without affecting polymer levels. Arrests cells in mitosis.
Soluble in: DMSO
Stock concentration: 10 to 30 mM (store at room temperature)
Working concentration: 50 nM (low concentrations) to 30 μM (for effective microtubule depolymerization)
Duration of incubation: For rapid depolymerization of microtubules, preincubate cells on ice with nocodazole for 15 min; use up to 24 hr.

Okadaic acid

Potent inhibitor of protein phosphatases, especially the PP-1 class (K_i = 10-15 nM) and PP-2A class (K_i = 0.1 nM), in numerous cell types. Does not affect the activity of acid or alkaline tyrosine phosphatases. It mimics the effects of insulin, enhances neurotransmitter release, causes vasodilation, and is a potent tumor promoter. Induces dispersal of the Golgi apparatus. Okadaic acid is a useful tool for studying cellular processes regulated by serine/threonine phosphorylation.
Soluble in: DMSO, ethanol, methanol
Stock concentration: 1 mM (store at –20°C protected from light)
Working concentration: 50 to 200 nM
Duration of incubation: 15 min to 2 hr

May cause cell rounding. See Technical Note #18 from Alexis Biochemicals for additional information.

Olomoucine

Adenine derivative that acts as a competitive inhibitor for ATP binding and inhibits $p34^{cdc2}$/cyclin B (K_i = 7 μM) as well as several other CDKs at low concentrations. Does not significantly affect the activity of other protein kinases at 1 mM. Inhibits DNA synthesis in IL-2 stimulated T lymphocytes. Also used to synchronize cells in G_1. Can affect microtubule dynamics at higher concentrations.
Soluble in: DMSO
Stock concentration: 100 mM (store in aliquots at –20°C)
Working concentration: Usually 10 μM (up to 100 μM)

continued

Duration of incubation: 15 min to 24 hr, depending on process studied.

See Technical Note #25 from Alexis Biochemicals for additional information.

Ouabain

Selective Na^+/K^+-ATPase inhibitor. Causes net influx of Ca^{2+}; also initiates the rapid protein kinase C–dependent inductions of early-response genes.
Soluble in: Water
Stock concentration: 100 mM (store at –20°C protected from light)
Working concentration: 1 to 100 µM
Duration of incubation: 30 min to 24 hr

PDMP

Useful tool for studying the effects of cellular glycosphingolipid depletion. Blocks ceramide glucosylation by inhibiting UDP-glucose:ceramide glucosyltransferase (glucosylceramide synthetase). Has antitumor activity; arrests 3T3 cells at both G_1/S and G_2/M. Prevents sensitization of A431 cells to Shiga toxin. Slows the rate of both anterograde vesicular traffic and endocytosis in CHO and BHK-21 cells. Redistributes *cis*-Golgi proteins to the ER.
Soluble in: Ethanol
Stock concentration: 10 to 100 mM (store at 4°C)
Working concentration: 20 to 100 µM
Duration of incubation: 1 to 18 hr, depending on process studied

PD 98059 (MEK Inhibitor)

Potent and selective inhibitor of MAP kinase kinase (MEK or MAPK/ERK kinase). Blocks the activity of MEK, thereby inhibiting the phosphorylation and activation of MAP kinase. Inhibits cell growth and reverses the phenotype of *ras*-transformed 3T3 mouse fibroblasts and rat kidney cells. Inhibits Golgi reassembly in vitro. Cell-permeant.
Soluble in: DMSO
Stock concentration: 50 mM (store at –20°C protected from light)
Working concentration: 10 to 50 µM
Duration of incubation: 30 min to 2 hr

PMSF (phenylmethanesulfonyl fluoride)

Inhibits serine proteases like chymotrypsin, trypsin, and thrombin, as well as acetylcholinesterase and the cysteine protease papain (reversible by DTT treatment). PMSF inhibits serine proteases by sulfonating serine residues at the active site. Does not inhibit metalloproteases, most cysteine proteases, or aspartic proteases.
Soluble in: Anhydrous isopropanol at 35 mg/ml with heating, resulting in a clear to very slightly hazy, colorless to faint yellow solution, or in anhydrous (100%, not 95%) ethanol
Stock concentration: 17 mg/ml (store at room temperature)
Working concentration: 17 to 170 µg/ml
Duration of incubation: 15 min to 1 hr

PMSF is very unstable in the presence of water. The half-life of aqueous PMSF at 25°C at pH 7.0, 7.5, and 8.0 is 110, 55, and 35 min, respectively.

Pepstatin A

Inhibitor of aspartyl proteases, including pepsin, renin, cathepsin D, and HIV-1 protease. Inhibits degradation of ApoB in rat hepatocytes; inhibits cytokine-induced programmed cell death. Accelerates amyloid fibril formation in mice.
Soluble in: DMSO
Stock concentration: 10 to 35 mM (store at –20°C)

Working concentration: 50 to 100 μM in cells
Duration of incubation: 30 min to 2 hr

Pertussis toxin

Protein endotoxin that catalyzes ADP-ribosylation of GDP-bound α subunits of the G proteins G_i, G_o, and G_t. Uncouples G proteins from receptors, thereby keeping the G protein in the inactive state. Used in the study of adenylate cyclase regulation and the role of G_i proteins. Consists of an enzymatically active A protomer subunit (S-1) which posesses both NAD^+ glycohydrolase and ADP-ribosylation activities and a B oligomer subunit (S-2, S-3, S-4, and S-5) that is responsible for cell surface attachment.

Stock solution: Reconstitute commercial preparation in water. Generally, commercially available pertussis toxin (Alexis Biochemicals, Biomol, Calbiochem) contains 50 μg of protein in 10 mM sodium phosphate buffer, pH 7.0/50 mM sodium chloride after being resuspended in 0.5 ml water. It is an insoluble protein that should be shaken gently before use. Store stock solutions at 4°C. Do not freeze.

Working concentration: 50 to 100 ng/ml
Duration of incubation: 2 to 24 hr

Phenylarsine oxide (PAO)

A cell-permeant phosphotyrosine phosphatase inhibitor (K_i = 18 μM). Induces a dose-dependent increase in the free Ca^{2+} intracellular concentration in rat peritoneal macrophages, human foreskin fibroblasts, and cultured human endothelial cells, without affecting intracellular stores. Inhibits insulin activation of phosphatidylinositol 3′-kinase. Dithiol cross-linking agent.

Soluble in: DMSO and chloroform
Stock concentration: 50 mM (store at room temperature)
Working concentration: 10 to 50 μM
Duration of incubation: Anywhere from 15 sec to 2 hr

Phorbol esters

An example is phorbol myristate acetate (PMA). Extremely potent tumor promoters. Activate protein kinase C by mimicking diacylglycerols (DAGs), causing a wide range of effects in cells and tissues.

Soluble in: DMSO
Stock concentration: 1 mM (store at –20°C)
Working concentration: 50 nM to 3 μM
Duration of incubation: Cells can be incubated anywhere from 5 min to 48 hr; stable in cells; results in long-term activation of PKC. However, long-term treatment may cause down-regulation of certain PKC subtypes.

See Technical Notes #13 and #14 from Alexis Biochemicals for additional information.

Piceatannol

At low concentrations, inhibits the receptor-mediated activation of the protein tyrosine kinase Syk as compared to the Src family in mast cells and B cells. Inhibits FcεR1-mediated signaling in RBL-2H3 cells.

Soluble in: DMSO, ethanol
Stock concentration: 10 to 50 mg/ml (store at 4°C protected from light)
Working concentration: 10 to 30 μg/ml
Duration of incubation: 1 hr

Puromycin

Protein synthesis inhibitor. Causes premature release of nascent polypeptide chains by its addition to the growing chain end; structural analog of aminoacyl-tRNA.
Soluble in: Water
Stock concentration: 100 mM (store at –20°C)
Working concentration: 10 to 100 μM
Duration of incubation: 5 min to 1 hr

Rapamycin

Member of a family of macrolide immunosuppressants that binds to and inhibits the peptidylproline *cis-trans* isomerase (PPIase) activity of the immunophilin FKBP12; effectors include a large protein termed FRAP (FKBP12 rapamycin-associated protein). FKBP12-rapamycin binds to but does not inhibit the activity of the Ca^{2+}/calmodulin–dependent serine/threonine phosphatase calcineurin. Blocks signaling, leading to the activation of p70 S6 kinase.
Soluble in: DMSO, methanol, ethanol
Stock concentration: 2 mM (store at –20°C)
Working concentration: 1 to 20 nM
Duration of incubation: 30 min to 1 hr

Sodium azide (NaN_3)

Inhibits mitochondrial ATPases; generally used to deplete ATP levels within cells (often in combination with 50 mM 2-deoxyglucose).
Soluble in: Water
Stock concentration: 1 M (store at room temperature)
Working concentration: 10 to 20 mM
Duration of incubation: 15 to 90 min

Sodium butyrate

A physiologically produced short-chain fatty acid that is generally used to increase expression of transfected genes with viral promoters (inhibits histone deacetylation). Blocks serum-stimulated DNA synthesis via a G_1 block. Induces apoptosis in colon carcinoma cell lines by a p53-independent process. Interferes with signal-transduction processes, including the release of Ca^{2+} from intracellular stores.
Soluble in: Water
Stock concentration: 5 M (store at –20° C)
Working concentration: 2 to 5 mM
Duration of incubation: Usually >12 hr

Sodium orthovanadate

Broad-spectrum inhibitor of protein tyrosine phosphatases. Also inhibits other ATPases, by mimicking the γ phosphate of ATP, including Na^+/K^+ ATPase, acid and alkaline phosphatases, and adenylate cyclase. Vanadate is also a strong inhibitor of lysosomal proteolysis in hepatocytes, the effect being ascribed to a direct inhibition of lysosomal enzymes. Stimulates pp60 (v-src) kinase activity in intact cells. It also stimulates amino acid transport activity in skeletal muscle, in a rapid and concentration-dependent manner.

Simple aqueous solutions of $(VO_4)^{3-}$ ion involve a dozen or more ionic species, both monomeric and oligomeric, whose abundances depend upon pH and $[VO_4]^{3-}$ concentration. See Fohr et al. (1989), as well as *UNIT 13.1* for directions on preparing monomeric orthovanadate. It is unclear how readily vanadate ions enter cells (likely through anion transporters). At the concentration required for maximum inhibition, vanadate may have side effects that limit its application in cell culture. Can be combined

continued

with hydrogen peroxide (forming peroxyvanadate) to facilitate cell entry (combine 100 µl 0.1 M orthovanadate, 900 µl water, and 3.3 µl 30% H_2O_2; use 1:100 dilution of this on cells). However, the effect of hydrogen peroxide itself should be tested.

Soluble in: Water

Stock concentration: 100 mM (store at room temperature). To ensure the presence of monomers, the solution is heated to boiling until translucent and the pH is readjusted to 10. Solutions can be divided into aliquots, stored in plastic, and frozen. The orange color observed before boiling is due to decavanadate. At pH 10 this will slowly depolymerize over several hours to the colorless monovanadate. Vanadyl, metavanadate, orthovanadate, and decavanadate will interconvert in aqueous solution without suitable precautions (i.e., control of pH, oxidation state, complexing compounds, and concentration).

Working concentration: 200 µM to 2 mM

Duration of incubation: 15 min to 2 hr

Staurosporine

A potent cell-permeant inhibitor of protein kinases, most potently protein kinase C (K_i = 0.7 nM), protein kinase A (K_i = 7 nM), and myosin light chain kinase (K_i = 1.3 nM). Interaction is with the ATP binding site. Induces apoptosis, but not DNA fragmentation in MCF-7 cells. Arrests normal cells at the G_1 checkpoint.

Soluble in: DMSO, methanol

Stock concentration: 1 mM (store at −20°C protected from light)

Working concentration: 10 to 200 nM

Duration of incubation: 30 min to 24 hr, depending on the assay used

See Table I (Selectivity of Selected Kinase Inhibitors) in the Biomol Catalog and Handbook, 5th ed

Taxol (Paclitaxel)

Antitumor and antileukemic agent. Promotes assembly of microtubules and inhibits microtubule disassembly. Bundles microtubules after several hours. Similar to nocodazole, taxol can inhibit microtubule dynamics without affecting overall polymer levels at nanomolar concentrations. Blocks cells at the G_2/M stage. Induces apoptosis in several cell types.

Soluble in: DMSO, methanol

Stock concentration: 20 mM (store at −20°C protected from light)

Working concentration: 10 nM to 20 µM

Duration of incubation: Taxol works rapidly to stabilize microtubules (within several minutes), although bundling takes several hours (this may be facilitated by first depolymerizing the polymer pool with ice treatment and/or washout of low levels of nocodazole)

Thapsigargin

Potent inhibitor of sarcoplasmic reticulum (SR)/endoplasmic reticulum (ER) Ca^{2+}-ATPases. Induces IP_3-independent release of Ca^{2+} from the endoplasmic reticulum, causing an increase in intracellular Ca^{2+}. Depletion of Ca^{2+} from intracellular stores induces stress response and defects in protein folding and processing. Induces apoptosis in rat thymocytes and in human hepatoma cells. Irreversible.

Soluble in: DMSO, ethanol

Stock concentration: 1 mM (store at −20°C in aliquots, protect from light)

Working concentration: 20 nM to 1 µM

Duration of incubation: 15 sec to 2 min produces rise in intracellular Ca^{2+}; longer incubations may be used, depending on effect to be analyzed

See Technical Note #15 from Alexis Biochemicals for additional information.

Trifluoperazine

Calmodulin antagonist. At 10 μM, potentiates rise in cytosolic calcium induced by agonists. Antagonizes calmodulin at higher concentrations. Inhibits IL-2 production in activated Jurkat T cells. Structurally distinct from W-7.
Soluble in: Water (dihydrochloride salt)
Stock concentration: 10 mM (store at 4°C)
Working concentration: 10 to 50 μM
Duration of incubation: 10 min to 3 hr

Tunicamycin

Nucleoside antibiotic that inhibits N-linked glycosylation, specifically by blocking the transfer of *N*-acetylglucosamine-1-phosphate from UDP-*N*-acetylglucosamine to dolichol monophosphate; has no effect on other glycosylation forms, such as Ser/Thr-linked oligosaccharides. Causes misfolding and retention of numerous glycoproteins in the endoplasmic reticulum, which induces synthesis of ER chaperones.
Soluble in: DMSO, ethanol
Stock concentration: 10 mg/ml (store at –20°C)
Working concentration: 1 to 10 μg/ml
Duration of incubation: Cells can be treated from 1 to 24 hr

Tyrphostins

Large family of protein tyrosine kinase inhibitors. Inhibits receptors such as EGF receptor and PDGF receptor.
Soluble in: DMSO, ethanol
Stock concentration: 20 to 100 mM (store at –20°C protected from light)
Working concentration: 10 to 150 μM
Duration of incubation: Anywhere from 1 to 48 hr
See Technical Note #22 from Alexis Biochemicals for additional information. Also see Table II (Selectivity of Tyrosine Protein Kinase Inhibitors) in the Biomol Catalog and Handbook, 5th ed.

Valinomycin

Potassium ionophore. Decreases ATP synthesis by decreasing membrane potential at mitochondrial membranes. Reported to inhibit NGF-induced neuronal differentiation. Used with nigericin to adjust cytoplasmic pH.
Soluble in: DMSO
Stock concentration: 1 mM (store at room temperature)
Working concentration: 1 to 20 μM
Duration of incubation: Normally 15 min to 2 hr

Vinblastine

Vinca alkaloid; antitumor drug. Inhibitor of cell proliferation that acts by disrupting spindle microtubule function. Binds tubulin and suppresses microtubule dynamics. Depolymerizes microtubules at higher concentrations. Induces apoptosis in cultured hepatocytes and human lymphoma cells. Similar, but not identical effects observed with another vinca alkaloid, vincristine.
Soluble in: Methanol
Stock concentration: 20 mM (store at 4°C protected from light)
Working concentration: <10 nM (suppresses microtubule dynamics); 100 nM to 1 μM (depolymerizes microtubules); >10 μM (forms non-microtubule polymers)
Duration of incubation: 30 min to 24 hr

W-7

Member of a family of calmodulin antagonists, inhibiting calcium/calmodulin regulated enzyme activity. W-7 inhibits the Ca^{2+}/calmodulin–induced activation of myosin light chain kinase (K_i = 51 μM) and phosphodiesterase (K_i = 28 μM). Inhibits membrane tubulation in cells treated with brefeldin A.
Soluble in: Water
Stock concentration: 10 to 100 mM (store at 4°C protected from light)
Working concentration: 10 to 100 μM
Duration of incubation: 30 min to 2 hr

Wortmannin

Selective and potent phosphatidylinositol 3-kinase (PI 3-kinase) inhibitor; forms covalent associations with the kinases and is, therefore, irreversible. Abolishes PDGF-mediated Ins(3,4,5)P_3 formation in fibroblasts. Blocks the metabolic effects of insulin in isolated rat adipocytes without affecting the insulin receptor tyrosine kinase activity. Inhibits the formation of constitutive transport vesicles from the TGN. In human fetal undifferentiated cells, wortmannin induces morphological and functional endocrine differentiation.
Soluble in: DMSO
Stock concentration: 1 to 20 mM (store at −20°C in aliquots, protected from light)
Working concentration: 10 to 100 nM
Duration of incubation: 30 min to 4 hr

At nanomolar concentrations, wortmannin is specific to PI 3-kinases, while at higher concentrations other kinases are affected. Once diluted into aqueous solutions, wortmannin is less stable and should be made fresh daily.

Identification of Motifs in Protein Sequences

Many biologists are not sure how to best analyze a newly determined protein sequence for the presence of functional motifs. This brief appendix is meant to guide researchers during their protein sequence analyses. Several database search engines that can be accessed via the World Wide Web (WWW) are described. Such computerized searches have become the preferred method to scan large sequence and motif databases, as the searches are efficient and the databases are updated frequently. A short list of sorting signals is also included, since these motifs often cannot be predicted reliably by a computer search.

The first step in predicting the function of an unknown protein is to perform a sequence similarity search in which the protein query sequence is compared pairwise to all other previously determined sequences. Popular programs for this include BLAST (Basic Local Alignment Search Tool; Altschul et al., 1997) and FASTA (Pearson et al., 1997). Such analyses identify the overall most similar proteins and often provide a good indication about the function of the protein. Table A.1C.1 lists some URLs through which such sequence databases can be searched.

Searching a database of protein motifs or domains will likely provide further information about the function of the protein. Such databases, which are manually collated and annotated collections, may shed light on the domain structure of the unknown protein, provide more detailed information on particular motifs, and detect domains that were missed in a pairwise database search. Protein motifs and domains are discovered as researchers find similar sequences shared by proteins that carry out similar functions. A number of popular databases that contain a large number of motifs or domains, and are accessible via the WWW, are also listed in Table A.1C.1.

It should be emphasized that the results from any sequence similarity or motif search should serve as a guide to future experiments, not as definitive proof that the protein carries out a particular function. Each match in a database search is given a score that indicates its significance and relative strength. In search programs that calculate the probability of finding a match by chance, a threshold of $P<10^{-5}$ is commonly used as rule of thumb for statistical significance that can be trusted biologically. For search programs that do not calculate the probability, empirically derived thresholds have to be used to estimate biological significance. The presence of a particular sequence motif is no guarantee that the protein will function as predicted. Conversely, the absence of a motif match may mean that the motif was not included in a particular database or had diverged too far to be detected. Thus, it is important to scan a few of the motif databases and integrate the results carefully with those obtained from a sequence similarity search. The WWW has brought a variety of sequence analysis tools directly into the laboratory. Researchers are encouraged to take advantage of them.

DATABASES AND SERVERS ON THE WWW

Table A.1C.1 lists general-purpose servers that are useful for sequence analysis and allow the user to submit a query sequence for analysis over the WWW. All are available without charge, and all have some on-line documentation, although in some cases, the documentation is minimal. Nevertheless, the databases are easy to use, as the query sequence is normally pasted into a box on the WWW page. Table A.1C.1 lists four types of servers. The first section lists servers useful for an initial sequence similarity search against all known sequences. This will return pairwise alignments between the query sequence and its closest relatives. The second section contains servers that allow users to search specialized databases for the presence of motifs or domains. Since such a search will return a concise list of the motifs present in the query sequences, the results are usually easier to interpret. In addition, searching motif databases may also be more sensitive. The table also lists servers that can help detect sorting signals, subcellular localization, and structural features such as transmembrane domains and coiled coils, as well as a few sites that provide links to other relevant servers not listed here.

One of the most commonly used sequence similarity search tools is BLAST. The servers for sequence similarity searching listed in the first part of Table A.1C.1 use different implementations of the BLAST algorithm (Recipon et al., 1995; Altschul et al., 1997). The results from the different servers are generally similar but are presented in different ways. An example

of a BLAST search result obtained at the National Center for Biotechnology Information (NCBI) is shown in Figure A.1C.1. The Baylor College of Medicine (BCM) search launcher also provides access to other search programs such as FASTA, SSEARCH, and BLITZ (Pearson, 1996). The two main types of BLAST are the gapped and ungapped varieties. The newer, gapped version introduces gaps in either sequence to generate one long alignment of the entire similarity region, while the ungapped version would report a series of separate ungapped alignments. There are different BLAST programs depending on whether the query and database sequences are protein or DNA. For a protein query, two programs are available: BLASTP, which searches a protein database, and TBLASTN, which searches the six-frame translation of a DNA database. For completeness, both types of searches should be performed.

Identification of Motifs in Protein Sequences

The second section of Table A.1C.1 lists databases of protein motifs or domains. Although the terms motif and domain are often used interchangeably, a *motif* is a characteristic pattern of functionally important residues and a *domain* is an autonomous protein region, i.e., a complete folding unit. For example, a motif

constitutes the catalytic residues involved in proteolysis, while a protein domain spans a much larger region, including structurally important residues. A *pattern* is a short string of residues, for example, R/L-X_5-H/Q-L. A *block* is an alignment of segments from multiple sequences. No gaps are allowed within segments of a block, and all segments have the same length. Such blocks represent highly conserved regions and are typically 20 to 40 residues wide. Domains are usually defined by multiple blocks. *Profiles* and *hidden Markov models (HMMs)* are representations of multiple alignments of sequence segments, where the segments can have gaps and can therefore span larger regions, often entire domains.

Popular protein motif and domain databases include the pattern-based Prosite (Bairoch et al., 1997), the block-based Prints (Attwood et al., 1998) and Blocks (Henikoff et al., 1998), and the HMM-based Pfam (Sonnhammer et al., 1998). Prosite also contains a number of profiles. Because these databases are maintained by different groups and were created using different methods, the results obtained are usually different but complementary. Prosite, Blocks, and Prints provide extensive functional annotation for each domain family, while the Pfam annotations are usually shorter but linked to other sources of annotation. Blocks uses the domain family definitions and annotations directly from Prosite, while Prints families were defined and annotated independently. Most of the families in both Prints and Pfam correspond to a Prosite domain family, but the details may differ substantially.

A pattern search in Prosite may identify highly conserved functional residues, while more widespread global similarity is generally easier to detect with a profile or HMM method. The block-based methods used by Blocks and Prints fall between the pattern and profile/HMM methods. The pattern method suffers from two drawbacks: first, motifs may be missed if the pattern definition is too stringent, and second, at positions where more than one residue is allowed, patterns do not provide for a quantitative description of the relative preference for different amino acids. The multiple alignment methods, on the other hand, can assign a score to a sequence when compared to any domain family. Thus, even weak matches, which may constitute distant similarities, can be reported. Again, it must be stressed that statistically insignificant matches must be treated with caution and usually require additional support (e.g., partial knowledge of protein function) to be considered biologically relevant.

It is also often useful to predict the localization and structural features of a protein. This is particularly valuable if no similar sequences were found in the previously described searches, but may also complement functional information based on sequence similarity. A number of servers for such analyses are listed in the third section of Table A.1C.1, which includes servers for prediction of signal peptides, subcellular localization, transmembrane helices, and secondary structure. The list includes multiple transmembrane helix prediction programs. These programs use distinct algorithms and may produce different results; careful interpretation of the output is therefore necessary.

ANALYSIS EXAMPLE

To illustrate how these servers can be used, sample results using the *C. elegans* protein R151.5 (Wormpep accession no. CE00743; Swissprot accession no. P98060) are shown. Figure A.1C.1 shows part of the output from the NCBI BLAST server, which lists the highest-scoring matches. The matches are shown as a graphical schematic and as a ranked list; the pairwise alignments for each match are also provided. Most of the highest-scoring matches span the entire query sequence. However, some matches are confined to regions near the C terminus (approximately residues 500 to 600) and near the N terminus (~100 to 350), suggesting that these may be separate domains. Browsing the annotations of these sequences reveals that the C-terminal domain is a thrombospondin type 1 domain, and the N-terminal domain is a zinc-dependent metalloprotease domain.

As an example of searching a domain database, Figure A.1C.2 shows the output from a Pfam search of the same query sequence. Compared to BLAST, the output is more concise and directly shows the location of the domains in a graphical diagram. This search confirms the existence of the metalloprotease and thrombospondin type 1 domains found by BLAST, and in addition detects an epidermal growth factor (EGF) domain and a CUB (c1r/c1s, Uegf, Bmpt) domain.

A schematic of the search results for *C. elegans* R151.5 against the four motif/domain databases is shown in Figure A.1C.3. All four searches detect the zinc-dependent metalloprotease motif, and Prints finds additional similarities to the astacin subfamily of zinc-dependent metalloproteases. Pfam, Blocks, and Prosite

Figure A.1C.1 *(at right)* Sample output from a BLASTP search on the NCBI BLAST server, showing the highest scoring hits of the *C. elegans* protein R151.5. The graphical display draws a shaded bar for each database sequence; multiple matches to the same sequence are attached with a hatched bar. Matches to multiple sequences may be packed on one line for compactness. The shading of each bar reflects the score of the match according to the key on top. By pointing the cursor on a bar, the description of the matching sequence is shown in the text box above (thrombospondin). The bottom of the figure shows a list of the hits. Clicking on a link in the left column leads to the record for that sequence, while following a link on the right gives the alignment of the query sequence with that hit.

find the EGF domain, and Pfam and Blocks report the CUB domain. Only Pfam detects the thrombospondin type 1 domain. In this example, Prints, Blocks, and Prosite reported several matches to clearly unrelated domains. These matches are shown as half-height uncolored boxes in Figure A.1C.3. Such background noise is common in these types of searches and can be recognized by one or more of the following criteria: (1) only one of many blocks that define a particular domain has a high score, (2) the match overlaps with other higher-scoring domains, and/or (3) the match is weak and is only reported by one of the database searches.

This analysis illustrates the point that one should not rely on the output of only one of the servers. In this case, Pfam provides the most extensive annotation for the EGF, CUB, and thrombospondin type 1 domains, while Prints provides the most extensive annotation of the metalloprotease domain. However, other examples may differentially accentuate the relative predictive powers of the databases.

R151.5 was further analyzed using the servers described in the third section of Table A.1C.1, for the presence of subcellular sorting signals and structural features. The programs predict that the protein contains a signal peptide, but no transmembrane segments, and is likely to be extracellular.

SORTING SIGNALS

Because the signals that govern subcellular localization are often weak, programs that predict such signals may be inaccurate, and it is often hard to judge the validity of the results. In many cases, the context in which a pattern occurs can affect its relevance. Further, because there are no programs available for many signals, text descriptions of the most common sorting signals are provided.

Signal Peptides

Proteins that are initially imported into the endoplasmic reticulum (ER)—e.g., those secreted or transported to the plasma membrane or lysosomes, as well as those retained in the ER or Golgi apparatus—contain a characteristic N-terminal presequence, or signal peptide. Signal peptides are usually cleaved off in the ER by signal peptidase I. A similar signal sequence is also present in precursors of proteins imported into the bacterial periplasm. Signal peptides are usually 15 to 40 residues long and contain, in N- to C-terminal order, a region of 2 to 5 positively charged residues, a region of 7 to 15 hydrophobic residues, and a cleavage region consisting of 3 to 7 neutral but often polar residues. The residues at positions −3 and −1 from the signal peptidase cleavage site are normally occupied by small and neutral residues, preferentially Ala. The program SignalP (Nielsen et al., 1997), which can be used via the WWW, can predict the presence of signal peptides and their cleavage sites for eukaryotic and prokaryotic proteins with an accuracy of ~75% (Table A.1C.1). Additional signal peptide prediction methods are reviewed in Claros et al. (1997).

Localization Signals in the Secretory Pathway

Proteins that contain a signal peptide and that enter the secretory pathway may contain an additional motif that causes localization to one compartment of the pathway. A motif sufficient for localization of luminal proteins in the ER is X-D-E-L at the C terminus. Within this motif there are general motif preferences: K-D-E-L in multicellular eukaryotes (also H-D-E-L in plants), H-D-E-L in budding yeast, and A-D-E-L in fission yeast (Gomord et al., 1997). A different localization signal, K-K-X-X- or K-X-K-X-X at the C terminus, is found in many ER transmembrane proteins whose C terminus is exposed to the cytosol (Jackson et al., 1990). Proteins retained in the Golgi do not appear to share any common sequence motif, but may instead be retained due to a common transmembrane domain structure (Colley, 1997). Lysosomal targeting of soluble proteins is accomplished by attachment of mannose-6-

The score threshold had to be lowered slightly from the default of 15 bits to detect the EGF domain. The E value given in the top bar gives the number of matches expected at the indicated score(s).

phosphate groups; no sequence motif is known for this, although attachment likely requires one or more lysine residues (Tikkanen et al., 1997).

A protein without a retention signal will be transported through the entire secretory pathway and will either be secreted or remain attached to the plasma membrane. A number of sorting signals mediate rapid internalization of plasma membrane proteins from the cell surface or targeting to lysosomes either directly from the *trans*-Golgi network or by internalization from the plasma membrane via the endocytic pathway. The sequence motifs for these signals are generally very short and too weak for predictive purposes. The most studied motifs are N-P-X-Y, Y-X-X-hydrophobic, and L-hydrophobic (Chen et al., 1990; Trowbridge et al., 1993; Sandoval and Bakke, 1994; Marks et al., 1997).

Attachment to the Plasma Membrane

Proteins are most often attached to the plasma membrane by one or more transmembrane segements, which are typically 15 to 35 residues long and consist mainly of hydrophobic residues. The presence of transmembrane helices can be predicted from a sequence by using one of the WWW servers listed in Table A.1C.1. A different type of plasma membrane attachment is by glycosylphosphatidylinositol (GPI) linkage (Udenfriend and Kodukula, 1995). Here, a C-terminal GPI-anchoring signal directs cleavage of the protein and attachment of the GPI anchor to the new carboxy terminus. The general cleavage motif is G/A/S/C/D/N↓X-G/A, followed by a 5- to 7-residue spacer rich in charged residues and Pro, followed by 15 to 30 hydrophobic residues.

Mitochondrial Transit Peptide

Most nuclear-encoded proteins targeted to the mitochondrion have an N-terminal presequence of 20 to 80 residues that is typically rich in basic and hydroxylated residues and poor in acidic residues. The transit peptide forms an

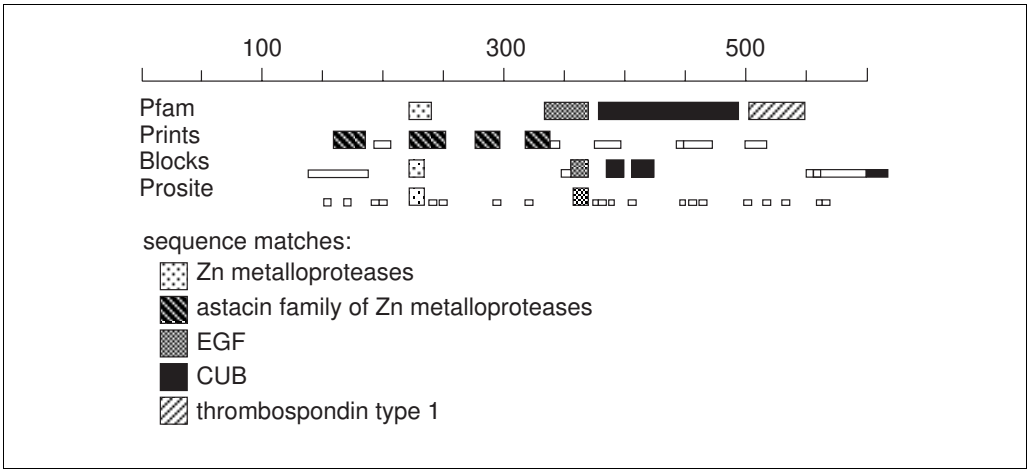

Figure A.1C.3 Schematic combined representation of results from searching protein domains in R151.5 with Pfam, Prints, Blocks, and Prosite. Matches to zinc-metalloproteases (Zn, including the astacin subfamily of zinc-metalloproteases), EGF, CUB, and thrombospondin type 1 (tsp-1) are indicated. Half-height boxes mark matches that were deemed false after manual inspection, and quarter-height boxes mark matches to Prosite patterns known to occur spuriously, such as phosphorylation and myristylation sites. For the sake of comparison, only matches to entries in the Blocks database are shown on line three; the Blocks WWW server can also report matches to Prints families. Likewise, only matches to Prosite patterns are shown here; the Prosite server also contains profile entries for the CUB and thrombospondin type 1 domains.

amphiphilic helix with one hydrophobic and one positively charged side (Claros et al., 1997). Of several known cleavage site motifs, the most diagnostic is RXY↓S/A (Gavel and von Heijne, 1990a). Additional sorting signals may be present to target the protein to mitochondrial subcompartments (Schwarz and Neupert, 1994; Dalbey et al., 1997; Neupert, 1997). The program MitoProt (Claros, 1995) can be used to predict the presence of mitochondrial transit peptides (Table A.1C.1).

Chloroplast Transit Peptide

Most nuclear-encoded proteins targeted to the chloroplast have an N-terminal presequence of 20 to 100 residues that is usually rich in hydroxylated residues and poor in acidic residues. The transit peptide has three domains: ~10 neutral residues at the N terminus, with Ala usually following the initial Met; a central Ser-rich domain; and a positively charged C-terminal domain (Cline and Henry, 1996; Claros et al., 1997). The most common cleavage site is V/I-X-A/C↓A, which is found in ~30% of sequences (Gavel and von Heijne, 1990b). After the cleavage site, a second transit peptide, similar to the generic signal peptide, may target subsequent import into the thylakoid (Dalbey et al., 1997).

Nuclear Localization Signals

Unlike the above signals, nuclear localization signals are not located in a particular region of the sequence and are not removed from the mature protein. No generic motif has been identified that can discriminate, with high accuracy, proteins that are imported into the nucleus, but overall the proteins tend to be rich in basic residues, and about half of the known examples contain the motif R/K-R/K-X_{10}-R/K$_{(3/4\ of\ 5)}$ (von Heijne, 1996; Corbett and Silver, 1997).

Microbody Targeting Signals

The C-terminal motif SKL-COOH has been shown to be necessary and sufficient to import proteins into peroxisomes (Keller et al., 1991). This motif, called peroxisome-targeting signal 1 (PTS1), is also found in proteins targeted to other microbodies, such as glycosomes and glyoxysomes, but this is often less conserved (Sommer and Wang, 1994). A second peroxisome-targeting signal, PTS2, has the motif R-L-X_5-H/Q-L at the N terminus; sometimes it is cleaved off after import (Blattner et al, 1995; Waterham and Cregg, 1997).

Safe Use of Radioisotopes

The use of radioisotopes to label specific molecules in a defined way has greatly furthered the discovery and dissection of biochemical pathways. The development of methods to inexpensively synthesize such tagged biological compounds on an industrial scale has enabled them to be used routinely in laboratory protocols, including many detailed in this manual. Although most of these protocols involve the use of only microcurie (μCi) amounts of radioactivity, some (particularly those describing the metabolic labeling of proteins or nucleic acids within cells; see *UNIT 7.1*) require amounts on the order of millicuries (mCi). In all cases where radioisotopes are used, depending on the quantity and nature of the isotope, certain precautions must be taken to ensure the safety of the scientist. This appendix outlines a few such considerations relevant to the isotopes most frequently used in biological research.

In designing safe protocols for the use of radioactivity, the importance of common sense, based on an understanding of the general principles of isotopic decay and the importance of continuous monitoring with a hand-held radioactivity monitor (e.g., Geiger counter), cannot be overemphasized. In addition, it is also critical to take into account the rules, regulations, and limitations imposed by each specific institution. These are usually not optional considerations: an institution's license to use radioactivity normally depends on strict adherence to such rules.

Many of the protocols described have evolved (and are evolving still) over the years. The authors are indebted to those who have trained them in the safe use of radioactivity, in particular to the members of the Salk Institute Radiation Safety Department. Most of the designs for the shields and other safety equipment shown in Figures A.1D.2A, A.1D.3, and A.1D.4 were created at the Salk Institute in collaboration with Dave Clarkin and Mario Tengco. Safety equipment of similar design is available from several commercial vendors, including CBS Scientific and Research Products International.

BACKGROUND INFORMATION

The Decay Process

As anyone who has taken a basic chemistry course will remember, each element is characterized by its atomic number, defined as the number of orbital electrons or the number of protons in the nucleus of that atom. Isotopes of a given element exist because some atoms of each element, while by definition having the same number of protons, have a different number of neutrons and therefore a different nuclear weight. It should be noted that the number of electrons outside the nucleus remains the same for all isotopes of a given element, and so all isotopes of a given element are equivalent with respect to their chemical reactivity.

Radioactive decay occurs when subatomic particles are released from the nucleus of an atom of a heavy isotope. This often results in the conversion of an atom of one isotope to an isotope of a different element, because the original isotope's atomic number changes after decay. The subatomic particles released from naturally occurring radioisotopes are of three basic types: α and β particles and γ rays (see Table A.1D.1).

An α particle is essentially the nucleus of a helium atom, or two protons plus two neutrons. It is a relatively large, heavy particle that moves slowly and usually only across short distances before it encounters some other atom with which it interacts. These particles are released from isotopes with large nuclei (atomic number >82; e.g., plutonium or uranium); such isotopes are not commonly used in biological research.

In contrast to α particles, β particles are light, high-speed charged particles. Negatively charged β particles are essentially electrons of nuclear origin that are released when a neutron is converted to a proton. Release of a β particle thus changes the atomic number and elemental status of the isotope.

γ radiation has both particle and wave properties; its wavelength falls within the range of X-ray wavelengths. The distinction between γ rays and X rays was made when primitive X-ray machines produced X rays with a wavelength longer than those of the γ rays produced naturally by radioisotopes. Modern X-ray machines produce a much broader spectrum of wavelengths, including γ radiation; currently this sort of X-ray radiation is termed γ when it is of nuclear origin. Unlike β-particle release, the release of γ radiation by itself produces an isotopic change rather than an elemental one; however, the resultant nuclei are unstable and often decay further, releasing β particles.

Table A.1D.1 Physical Characteristics of Commonly Used Radionuclides[a]

Nuclide	Half-life	Emission	Energy, max (MeV)	Range of emission, max	Approx. specific activity at 100% enrichment (Ci/mg)	Atom resulting from decay	Target organ
^{3}H	12.43 years	β	0.0186	0.42 cm (air)	9.6	$^{3}_{2}He$	Whole body
^{14}C	5370 years	β	0.156	21.8 cm (air)	4.4 mCi/mg	$^{14}_{7}N$	Bone, fat
^{32}P[b]	14.3 days	β	1.71	610 cm (air) 0.8 cm (water) 0.76 cm (Plexiglas)	285	$^{33}_{16}S$	Bone
^{33}P[b]	25.4 days	β	0.249	49 cm	156	$^{33}_{16}S$	Bone
^{35}S	87.4 days	β	0.167	24.4 cm (air)	43	$^{35}_{17}Cl$	Testes
^{125}I[c]	60 days	γ	0.27–0.035	0.2 mm (lead)	14.2	$^{125}_{52}Te$	Thyroid
^{131}I[c]	8.04 days	β	0.606	165 cm (air)	123	$^{130}_{54}Xe$	Thyroid
		γ	0.364	2.4 cm (lead)			

[a]Table compiled based on information in Lederer et al. (1967) and Shleien (1987).
[b]Recommended shielding is Plexiglas; half-value layer measurement is 1 cm.
[c]Recommended shielding is lead; half-value layer measurement is 0.02 mm.

The energy of all α particles and γ rays (measured in electron volts) is fixed, because they are of specific composition or wavelength. The energy of β particles, however, varies depending on the atom they originate from (and with concomitant release of neutrinos or antineutrinos that serve to balance the conservation of energy aspect of the decay equation). Thus there are (relatively) high-energy β particles released during the decay of ^{32}P and low-energy β particles released when tritium (^{3}H) decays.

Isotopic decay usually involves a chain or sequence of events rather than a single loss of a particle, because the resultant, equally unstable atoms try to achieve equilibrium. During this course of decay, secondary forms of radiation can be generated that may also pose a hazard to workers. For example, when high-energy β particles released during the decay of ^{32}P encounter the nuclei of atoms with a large atomic number, a strong interaction occurs. The β particle loses some energy in the form of a photon. Such photons are called Bremsstrahlung radiation; they are detectable using a monitor suitable for the detection of γ or X rays.

Following their release, α, β, and γ emissions (as well as secondary forms of radiation) travel varying average distances at varying average speeds, depending on their energy and the density of the material through which they are moving. The distance they actually travel before encountering either the electrons or nucleus of another atom is termed their degree of penetrance. This value is expressed as an average for each type of particle. The energy of the particles released (and therefore their potential penetrance) thus dictates what type of shielding, if any, is necessary for protection against the radiation generated by the decay of a given isotope. α, β, and γ emissions all have the potential, upon encountering an atom, to knock out its electrons, thereby creating ions. Thus, these three types of emissions are called ionizing radiation. The formation of such ions may result in the perturbation of biological processes: therein lies the danger associated with radioactivity!

Measuring Radioactivity and Individual Exposure to It

The radioactivity of a given substance is measured in terms of its ionizing activity. A Curie by definition is the amount of radioactive material that will produce 3.4×10^{10} disintegrations per second (see Table A.1D.2). This, not coincidentally, happens to be the number of disintegrations that occur during the decay of one gram of radium and its decay products. Exposure to such radiation is measured as the amount of energy absorbed by the recipient, which, of course, is directly related to the potential damage such radiation may cause. One rad is the dose of radiation that will cause 100 ergs of energy to be absorbed per gram of irradiated material. Another unit commonly used to measure radiation doses is the rem; this is related to the rad but takes into account a "quality factor" based on the type of ionizing radiation being received. For β particles and γ or X rays this factor is 1; therefore, rems β equal

Table A.1D.2 Conversion Factors for Radioactivity

Measurement of Radioactivity

The SI unit for measurement of radioactivity is the Becquerel:

1 Becquerel (Bq) = 1 disintegration per second

The more commonly encountered unit is the Curie (Ci):

1 Ci = 3.7×10^{10} Bq
= 2.22×10^{12} disintegrations per minute (dpm)
1 millicurie (mCi) = 3.7×10^{7} Bq = 2.22×10^{9} dpm
1 microcurie (μCi) = 3.7×10^{4} Bq = 2.22×10^{6} dpm

Conversion factors:

1 day = 1.44×10^{3} min = 8.64×10^{4} sec
1 year = 5.26×10^{5} min = 3.16×10^{7}sec
counts per minute (cpm) = dpm × (counting efficiency)

Measurement of Dose

The SI unit for energy absorbed from radiation is the Gray (Gy):

1 Gy = 1 joule/kg

Older units of absorbed energy are the rad (r) and Roentgen (R):

1 r = 100 ergs/g = 10^{-2} Gy
1 R = 0.877 r in air = 0.93 – 0.98 r in water and tissue

The SI unit for radiation dosage is the Sievert (Sv), which takes into account the empirically determined relative biological effectiveness (RBE) of a given form of radiation:

dosage [Sv] = RBE × dosage [Gy]

$$\text{RBE} = \frac{\text{(biological effect of a dose of standard radiation [Gy])}}{\text{(biological effect of a dose of other radiation [Gy])}}$$

RBE = 1 for commonly encountered radionuclides

The older unit for dosage is the rem (Roentgen-equivalent-man):

1 rem = 0.01 Sv

rads β. In contrast, the quality factor associated with α particles is 20, so an exposure of one rad due to α particles would be recorded as 20 rem.

The amount or dose of radiation received by materials (cells, scientists, etc.) near the source depends not only on the specific type and energy (penetrance) of the radiation being produced, but also on the subject's distance from the source, the existence of any intervening layers of attenuating material (shielding), and the length of time spent in the vicinity of the radiation source. To best measure such doses, every person working with or around radioactivity should wear an appropriate type of radiation detection badge (in addition to carrying a portable radiation monitor that can give an immediate, approximate reading.) This is normally a requirement for compliance with an institution's license to use radioisotopes. Such badges are usually furnished by the safety department and collected at regular intervals for reading by a contracted company. At most institutions, the old-style film badges have been replaced with the more accurate TLDs (thermoluminescent dosimeters). These take advantage of chemicals such as calcium or lithium fluorides which, following exposure to ionizing radiation, will luminesce at temperatures below their normal thermal luminescence threshold. Different types of badges are sensitive to different types of radiation: always be sure to wear one that is appropriate for detecting exposure to the isotope being used! In most places pregnant women are asked to wear a more sensitive (and more expensive) dosimeter to better monitor their (and the developing fetus') exposure. Most often workers will be asked to wear a radiation detection badge on the labcoat lapel in order to measure whole-body radiation. When working with ^{32}P or ^{125}I it is also advisable to wear a ring badge to measure exposure to the unshielded extremities (fingers). The limit set for "acceptable" exposure to whole-body radiation is several-fold less than the limit set for extremities. Nevertheless, we have found that the exposure recorded on ring badges is often significant with respect to the limit for extremities set by our institution.

Table A.1D.3 Shielding Radioactive Emission[a]

β emitters

Energy (MeV)	Mass (mg)/cm^2 to reduce intensity by 50%	Thickness (mm) to reduce intensity by 50%			
		Water	Glass	Lead	Plexiglas
0.1	1.3	0.013	0.005	0.0011	0.0125
1.0	48	0.48	0.192	0.042	0.38
2.0	130	1.3	0.52	0.115	1.1
5.0	400	4.0	1.6	0.35	4.2

γ emitters

Energy (MeV)	Thickness of material (cm) to attenuate a broad beam of γ-rays by a factor of 10			
	Water	Aluminum	Iron	Lead
0.5	54.6	20.3	6.1	1.8
1.0	70.0	24.4	8.2	3.8
2.0	76.0	32.0	11.0	5.9
3.0	89.0	37.0	12.0	6.4

[a]From Dawson et al. (1986). Reprinted with permission.

What is known about the effects on humans of exposure to low levels of radiation (i.e., levels which would be received when briefly handling mCi or μCi amounts of radioactivity)? Not much, for the obvious reason that direct studies have not been undertaken. Accordingly, guidelines for exposure levels are set using extrapolations—either by extrapolating down from population statistics obtained following accidents or disasters (the Chernobyl meltdown, atomic bombings) or by extrapolating up from numbers obtained from animal experiments. Each form of extrapolation is subject to caveats, and given that predictions based on such extrapolations cannot be perfect, most health and safety personnel aim for radiation exposure levels said to be ALARA or "as low as reasonably achievable." Further discussion of exposure limits and the statistics on which they are based may be found in B. Shleien's health physics text (Shleien, 1987). Limiting exposure to radiation can be accomplished by adjusting several parameters of the exposure: the duration of exposure, distance from the source, and the density of the material (air, water, shielding) between the individual and the source.

Time is of the essence

When designing any experiment using radioactivity, every effort should be made to limit the time spent directly handling the vials or tubes containing the radioactive material. Speed should be encouraged in all manipulations, though not to the point of recklessness! Have everything needed for the experiment ready at hand before the radioactivity is introduced into the work area.

Distance helps to determine dose

When possible, experiments involving radioactivity should be performed in an area separate from the rest of the lab. Many institutions require that such work be performed in a designated "hot lab"; however, if many people in the laboratory routinely use radioisotopes, it is less than feasible to move them all into what is usually a smaller space. No matter where an individual is working, it is his or her responsibility to monitor the work area and ensure his or her own safety and the safety of those working nearby by using adequate shielding. Obviously, when handling the radioactive samples, it is necessary to work rapidly behind any required shielding. To protect bystanders, remember that the intensity of radiation from a source (moving through air) falls off in proportion to the square of the distance. Thus, if standing 1 foot away from a source for 5 min would result in an exposure of 45 units, standing 3 feet away for the same amount of time would result in an exposure $(1/3)^2$ of 45 units, or 5 units. This factor is also relevant when considering the storage of large amounts of radioactivity, particularly ^{125}I or ^{32}P, as no amount of shielding can completely eliminate radiation.

Shielding is the key to safety

As mentioned above, the energy of the particle(s) released during the decay of an isotope

determines what, if any, type of shielding is appropriate (see Table A.1D.3). β particles released during the decay of ^{14}C and ^{35}S possess roughly ten times the energy of those released when ^{3}H decays. All three β particles are of relatively low energy, do not travel very far in air, and cannot penetrate solid surfaces. No barriers are necessary for shielding against this type of β radiation. The major health threat from these isotopes occurs through their accidental ingestion, inhalation, or injection.

β particles released during the decay of ^{32}P have 10-fold higher energy than those released from ^{14}C and pose a significant threat to workers. (One reported hazard is the potential for induction of cataracts in the unshielded eye.) The fact that these high-energy beta particles can potentially generate significant amounts of Bremsstrahlung radiation is the reason that low-density materials are used as the primary layer of shielding for ^{32}P β radiation. Water, glass, and plastic are suitable low-density materials (as opposed to lead). Obviously water is unsuitable as a shielding layer for work on the bench, although it does a reasonable job when samples are incubating in a water bath. Shields made from a thickness of glass sufficient to stop these particles would be extremely heavy and cumbersome (as well as dangerous if dropped). Fortunately, plastic or acrylic materials—variously called Plexiglas, Perspex, or Lucite—are available for shielding against ^{32}P β radiation. Shields as well as storage boxes constructed of various thicknesses of Plexiglas are necessary equipment in laboratories where ^{32}P is used. When mCi amounts of ^{32}P are used at one time it is necessary to also block the Bremsstrahlung radiation by adding a layer of high-density material (such as 4 to 6 mm lead) to the outside of the Plexiglas shield (covering the side farthest from the radioactive source).

γ rays released during the decay of ^{125}I have much higher penetrance than the β particles from ^{32}P decay; this radiation must be stopped by very-high-density material, such as lead. Lead foil of varying thicknesses (2 to 6 mm) can be purchased in rolls and can be cut and molded to cover any container, or taped to a Plexiglas shield (used in this instance for support). Obviously this latter arrangement has the disadvantage that it is impossible to see what one is doing through the shield. For routine shielding of manipulations involving ^{125}I, it is useful to purchase a lead-impregnated Plexiglas shield that is transparent, albeit inevitably very heavy (as well as relatively expensive).

Although it seems logical that the use of more radioactivity necessitates the use of thicker layers of shielding, it is also true that no shielding material is capable of completely stopping all radiation. When deciding how thick is "thick enough," consult the half-value layer measurement for each type of shielding material. This number gives the thickness of a given material necessary to stop half the radiation from a source; Table A.1D.3 lists half-value layer measurements for the β particles released from isotopes commonly used in the biology laboratory. In general, 1 to 2 cm of Plexiglas and/or 0.02 mm of lead are sufficient to shield the amounts of radioactivity used in most experiments.

GENERAL PRECAUTIONS

Before going on to a discussion of specific precautions to be taken with individual isotopes, a short list of general precautions to be taken with all isotopes seems pertinent:

1. Know the rules. Be sure that each individual is authorized to use each particular isotope and uses it in an authorized work area.

2. Don the appropriate apparel. Whenever working at the lab bench, it is good safety practice to wear a labcoat for protection. Disposable paper/synthetic coats of various styles are commercially available: at $4 each these may be conveniently thrown out if contaminated with radioactivity during an experiment, rather than held for decay as might be preferable with cloth coats costing about $30 each. As an alternative, disposable sleeves can be purchased and worn over those of the usual cloth coat. Other necessary accessories include radiation safety badges, gloves, and protective eyewear. It's handy to wear two pairs of gloves at once when using radioactivity; when the outer pair becomes contaminated, it is possible to strip it off and continue working without interruption.

3. Protect the work area as well as the workers. Lab benches and the bases of any shields used should be covered with some sort of disposable, preferably absorbent, paper sheet. Underpads or diapers (the kind normally used in hospitals) are convenient for this purpose.

4. Use appropriate designated equipment. It is very convenient, where use justifies the expense, to have a few adjustable pipettors dedicated for use with each particular isotope. Likewise, it is good practice to use only certain labeled centrifuges and microcentrifuge rotors for radioactive samples so that all the lab's

rotors do not become contaminated. Although such equipment should be cleaned after each use, complete decontamination is often not possible. A few pipettors or a single microcentrifuge can easily be stored (and used) behind appropriate shielding. Actually, contamination of the insides and tip ends of pipettors can be greatly reduced by using tips supplied with internal aerosol barriers; these have recently become very popular for setting up PCR reactions and are available to fit a variety of pipettors. To prevent contamination of the outside of the pipettor's barrel, simply wrap the hand-grip in Parafilm, which can be discarded later. Several manufacturers sell disposable paper inserts for their microcentrifuges that protect the wall of the rotor chamber from contamination that might spin off the outside of sample tubes. Trying to fashion homemade liners of this sort is not recommended, as we have had disastrous experiences using laminated adhesive paper that "unstuck" during microcentrifuge spins. These liners would get caught by the rotor, shattering sample tubes and creating an even bigger mess!

5. Know where to dispose of radioactive waste, both liquid and solid. Most institutions require that radioactive waste be segregated by isotope. This is done not only so that appropriate shielding can be placed around waste containers, but so that some waste can be allowed to decay prior to disposal through normal trash channels (see Table A.1D.4 and Fig. A.1D.1). With a decreasing number of radioactive waste disposal facilities able or willing to accept radioactive waste for burial (and a concomitant increase in dumping charges from those that still do), this practice of on-site decay can save an institution thousands of dollars a year in disposal charges.

6. Label your label! It is only common courtesy (as well as common sense) to alert coworkers to the existence of anything and everything radioactive that is left where they may come in contact with it! A simple piece of tape affixed to the sample box—with the investigator's name, the amount and type of isotope, and the date written on it—should do the trick. Yellow hazard tape printed with the international symbol for radioactivity is commercially available in a variety of widths.

7. Monitor radioactivity early and often. Portable radiation detection monitors are essential equipment for every laboratory using radioactivity. No matter how much or how little radioactivity is being used, the investigator should keep a hand-held monitor nearby—and it should be on! Turn it on before touching any radioactivity to avoid contaminating the monitor's switch. Use a monitor with the appropriate detection capacity (β for ^{35}S and ^{32}P; γ for ^{125}I) before, during, and after all procedures. The more frequently fingers and relevant equipment are monitored, the more quickly a spill or glove contamination will be detected. Such timely detection will keep both the potential mess and the cleanup time to a minimum. Because low-energy β emitters such as ^{3}H cannot be detected using such monitors, wipe tests of the bench and equipment used are necessary to ensure that contamination of the work area did not occur.

SPECIFIC PRECAUTIONS

The following sections describe precautions to be taken with individual isotopes in specific forms. Although the sections dealing with ^{35}S- or ^{32}P-labeling of proteins in intact cells are presented in terms of mammalian cells, most of the instructions are also pertinent (with minimal and obvious modifications) to the labeling of proteins in other cells (bacterial, insect, etc.).

Working with ^{35}S

Using ^{35}S to label cellular proteins and proteins translated in vitro

As discussed above, the β radiation generated during ^{35}S decay is not strong enough to make barrier forms of shielding necessary. The risk associated with ^{35}S comes primarily through its ingestion and subsequent concentration in various target organs, particularly the testes. Although willful ingestion of ^{35}S seems unlikely, accidental or unknowing ingestion may be more common. As reported several years ago (Meisenhelder and Hunter, 1988), ^{35}S-labeled methionine and cysteine, which are routinely used to label proteins in intact cells and by in vitro translation, break down chemically to generate a volatile radioactive component. The breakdown occurs independent of cellular metabolism. Thus the radioactive component is generated to the same extent in stock vials as in cell culture dishes. The process seems to be promoted by freezing and thawing ^{35}S-labeled materials. The exact identity of this component is not known, although it is probably SO_2 or CH_3SH. What is known is that it dissolves readily in water and is absorbed by activated charcoal or copper.

The amount of this volatile radioactive component released, despite stabilizers added by the manufacturers, is about 1/8000 of the total radioactivity present. The amount of this radio-

Table A.1D.4 Decay factors for calculating the amount of radioactivity present at a given time after a reference date. For example, a vial containing 1.85 MBq (50 μCi) of a ^{35}S-labeled compound on the reference date will have the following activity 33 days later: 1.85 × 0.770 = 1.42 MBq; 50 × 0.770 = 38.5 μCi.

Figure A.1D.1 Correlation of loss of radioactivity with elapsing half-lives of an isotope.

activity that a scientist is likely to inhale while using these compounds is presumably even smaller. Nevertheless, such a component can potentially contaminate a wide area because of its volatility, and also tends to concentrate in target organs. Thus, it is advisable to thaw vials of ^{35}S-labeled amino acids in a controlled area such as a hood equipped with a charcoal filter. This charcoal filter will become quite contaminated and should be changed every few months. If such an area is not available, the stock vial should be thawed using a needle attached to a charcoal-packed syringe to vent and trap the volatile compound.

Anyone who has ever added ^{35}S-labeled amino acids to dishes of cells for even short periods knows that the incubator(s) used for such labelings quickly become highly contaminated with ^{35}S. Such contamination is not limited to the dish itself, nor to the shelf on which the dish was placed. Rather, the radioactive component's solubility in water allows it to circulate throughout the moist atmosphere of the incubator and contaminate all the inside surfaces of the incubator. For this reason, in laboratories where such metabolic labelings are routine, it is highly convenient to designate one incubator to be used solely for working with ^{35}S-labeled samples. Such an incubator can be fitted with a large honeycomb-style filter, the size of an incubator shelf, made of pressed, activated charcoal. These filters are available from local air-quality-control companies. Such a filter will quickly become quite contaminated with radioactivity and should therefore be monitored and changed as necessary (usually about every three months if the incubator is used several times a week). The water used to humidify the incubator will also become quite "hot" (contaminated with radioactivity); keeping the water in a shallow glass pan on the bottom of the incubator makes it easy to change it after every use, thus preventing contamination from accumulating. Even with the charcoal filter and water as absorbents, the shelves, fan, and inner glass door of the incubator will become contaminated, as will the tray on which the cells are carried and incubated. Routine wipe tests and cleaning when necessary will help to minimize potential spread of this contamination.

If such labelings are done infrequently or there is no "spare" incubator, dishes of cells can be placed in a box during incubation. This box should be made of plastic, which is generally more easily decontaminated than metal. Along with the dishes of cells, a small sachet made of activated charcoal wrapped loosely in tissue (Kimwipes work well) should be placed in the box. If the box is sealed, it will obviously need to be gassed with the correct mixture of CO_2; otherwise small holes can be incorporated into the box design to allow equilibration with the incubator's atmosphere. In either case, the incubator used for the labeling should be carefully monitored for radioactivity after each experiment.

Working with ^{32}P

µCi amounts of ^{32}P

The amount of ^{32}P-labeled nucleotide used to label nucleic acid probes for northern or Southern blotting is typically under 250 µCi, and the amount of [γ-^{32}P]ATP used for in vitro phosphorylation of proteins does not usually exceed 50 µCi for a single kinase reaction (or several hundred µCi per experiment). However, handling even these small amounts, given the time spent on such experiments, can result in an unacceptable level of exposure if proper shielding is not employed. With no intervening shielding, the dose rate 1 cm away from 1 mCi ^{32}P is 200,000 mrads/hr; the local dose rate to basal cells resulting from a skin contamination of 1 µCi/cm^2 is 9200 mrads/hr (Shleien, 1987). Such a skin contamination could be easily attained though careless pipetting and the resultant creation of an aerosol of radioactive microdroplets, because the concentration of a typical stock solution of labeled nucleotide may be 10 µCi/µl.

For proper protection during this sort of experiment, besides the usual personal attire (glasses, coat, safety badges, and gloves) it is necessary to use some form of Plexiglas screen between the body and the samples (see Fig. A.1D.2A). Check the level of radiation coming through the outside of the shield with a portable monitor to be sure the thickness of the Plexiglas is adequate. Hands can be shielded from some exposure by placing the sample tubes in a solid Plexiglas rack, which is also useful for transporting samples from the bench to a centrifuge or water bath (see Fig. A.1D.2B).

Experiments of these types often include an incubation step performed at a specific temperature, usually in a water bath. Although the water surrounding the tubes or hybridization bags will effectively stop β radiation, shielding should be added over the top of the tubes (where there is no water)—e.g., a simple flat piece of Plexiglas. If the frequency of usage justifies the expense, an entire lid for the water bath can be

constructed from Plexiglas. When hybridization reactions are performed in bags, care should be taken to monitor (and shield) the apparatus used to heat-seal the bags.

The waste generated during the experiments should also be shielded. It is convenient to have a temporary waste container right on the bench. Discard pipet tips and other solid waste into a beaker lined with a plastic bag and placed behind the shield. This bag can then be emptied into the appropriate shielded laboratory waste container when the experiment is done. Liquid waste can be pipetted into a disposable tube set in a stable rack behind the shield (see Fig. A.1D.2C).

When radiolabeled probes or proteins must be gel-purified, it may be necessary to shield the gel apparatus during electrophoresis if the samples are particularly hot. Be advised that the electrophoresis buffer is likely to become very radioactive if the unincorporated label is allowed to run off the bottom of the gel; check with a radiation safety officer for instructions on how to dispose of such buffer. It is also prudent to check the gel plates with a portable detection monitor after the electrophoresis is completed, because they sometimes become contaminated as well.

mCi amounts of ^{32}P

In order to study protein phosphorylation in intact mammalian cells, cells in tissue culture dishes are incubated in phosphate-free medium with ^{32}P-labeled orthophosphate for a period of several hours or overnight to label the proteins. The amount of ^{32}P used in such labelings can

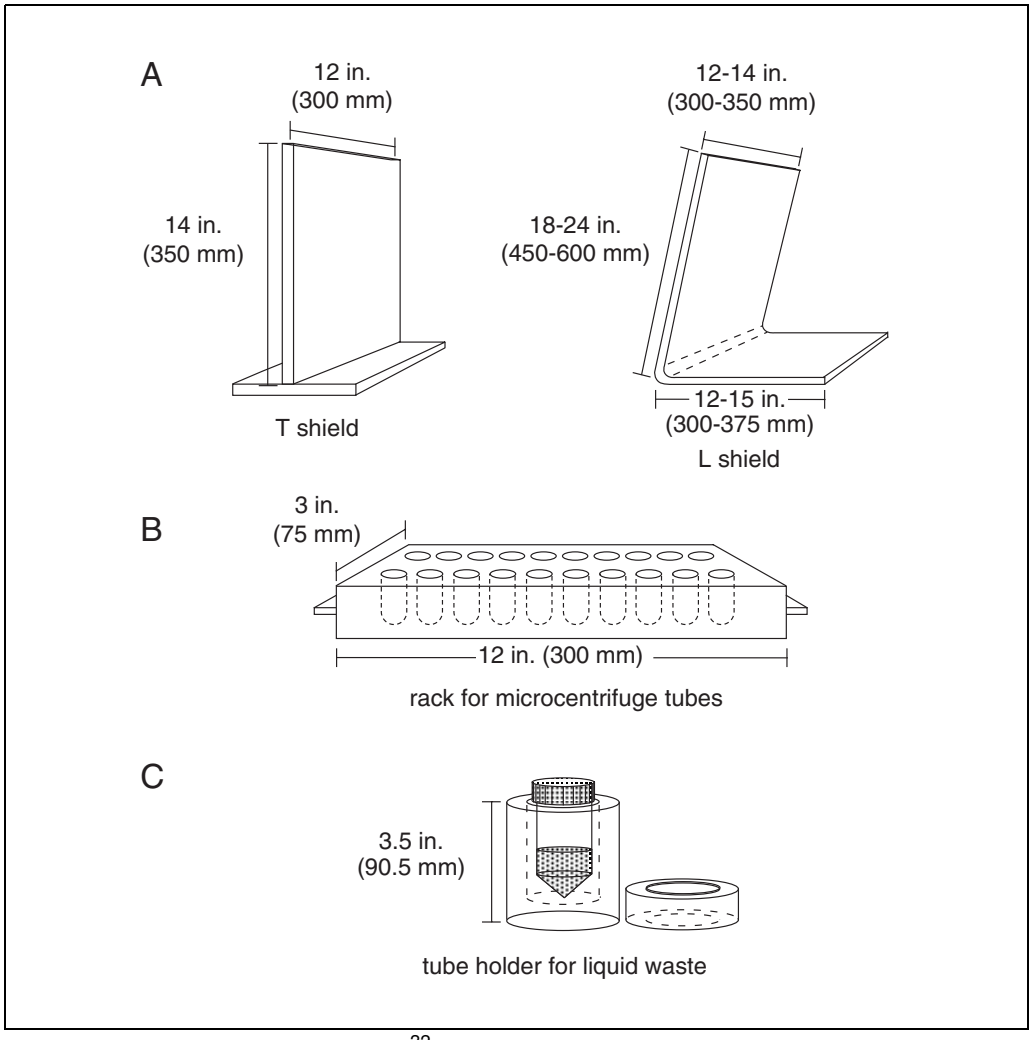

Figure A.1D.2 Plexiglas shielding for ^{32}P. (**A**) Two portable shields (L and T design) made of 0.5-in. Plexiglas. Either can be used to directly shield the scientist from the radioactivity he or she is using. Turned on its side, the L-shaped shield can be used to construct two sides of a cage around a temporary work area, providing shielding for other workers directly across or to the sides of the person working with ^{32}P. (**B**) Tube rack for samples in microcentrifuge tubes. (**C**) Tube holder for liquid waste collection.

be substantial. Cells are normally incubated in 1 to 2 mCi of ^{32}P/ml labeling medium; for each 6-cm dish of cells, 2.5 to 5 mCi ^{32}P may be used. When this figure is multiplied by the number of dishes necessary per sample, and the number of different samples in each experiment, it is clear that the amount of ^{32}P used in one experiment can easily reach 25 mCi or more. Because so much radioactivity is used in the initial labeling phase of such experiments, it is necessary for a researcher to take extra precautions in order to adequately shield him or herself and coworkers.

When adding label to dishes of cells, it is important to work as rapidly as possible. An important contribution to the speed of these manipulations is to have everything that will be needed at hand before even introducing the label into the work area. Prepare the work area, arranging shielding and covering the bench with diapers, in advance. Set out all necessary items, including any pipettors and tips needed, a portable detection monitor, extra gloves, and a cell house (see Fig. A.1D.3A).

Work involving this much radioactivity should be done behind a Plexiglas shield at least ¾ in. (2 cm) thick; the addition of a layer of lead to the outside lower section of this shield to stop Bremsstrahlung radiation is also needed. If one shield can be dedicated to this purpose at a specific location, a sheet of lead several centimeters thick can be permanently screwed to the Plexiglas (as shown in Fig. A.1D.3B); however, this lead makes the shield extremely heavy and therefore less than portable. If space constraints do not permit the existence of such a permanent labeling station, a layer or two of lead foil can be taped temporarily to the outside of the Plexiglas shield.

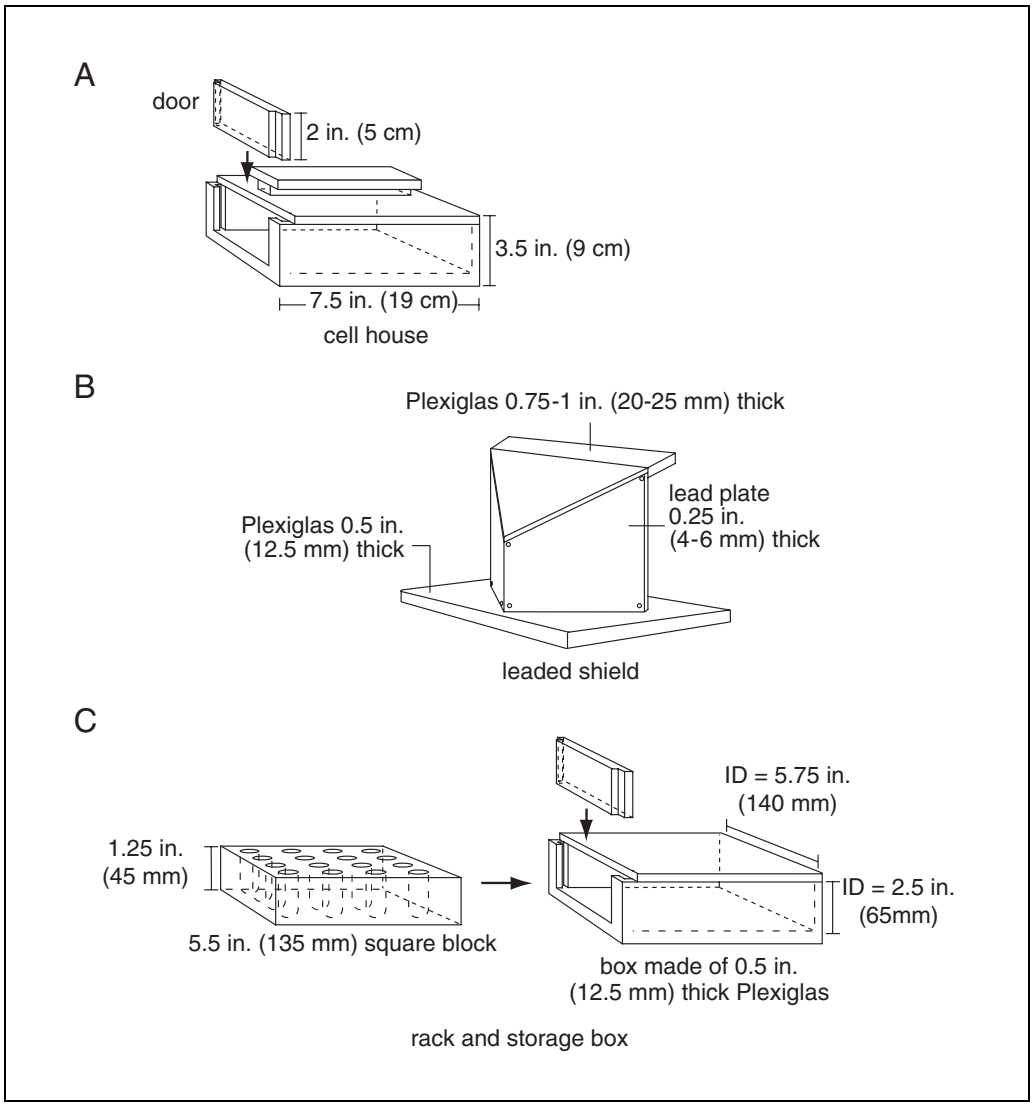

Figure A.1D.3 (**A**) Box for cell incubation (a "cell house"). (**B**) Stationary leaded shield. (**C**) Sample storage rack and box made of 0.5-in. Plexiglas. Abbreviations: ID, interior dimension.

Again, each worker should take care to shield not only him or herself, but bystanders on all sides. Handling of label should be done away from the central laboratory if possible to take maximum advantage of distance as an additional form of shielding. It is also advisable not to perform such experiments in a tissue culture room or any other room that is designed for a purpose vital to the whole laboratory. An accident involving this much ^{32}P would seriously inconvenience future work in the area, if not make it altogether uninhabitable! If care is taken to minimize the amount of time the dish of cells is open when adding the label, use of a controlled air hood to prevent fungal or bacterial contamination of the cells should not be necessary.

Once the label has been added to the dishes of cells, they will also need to be shielded for transport to and from the incubator and other work areas. Plexiglas boxes that are open at one end (for insertion of the dishes) and have a handle on top (for safe carrying) make ideal "cell houses" (see Figure A.1D.3A). A Plexiglas door that slides into grooves at the open end is important to prevent dishes from sliding out if the box is tilted at all during transport. If this door is only two-thirds the height of the house wall, the open slot thus created will allow equilibration of the CO_2 level within the house with that in the incubator. Obviously, this slot will also allow a substantial stream of radiation to pass out of the cell house, so the house should be carried and placed in the incubator with its door facing away from the worker (and others)!

Following incubation with label and any treatments or other experimental manipulations, the cells are usually lysed in some type of detergent buffer. It is during this lysis procedure that a worker's hands receive their greatest exposure to radiation, because it is necessary to directly handle the dishes over a period of several minutes. It is therefore very important to streamline this procedure and use any shielding whenever possible. If the cell lysates must be made at 4°C, as required by most protocols, working on a bench in a cold room is preferable to placing the dishes on a slippery bed of ice. In either case, make the lysate using the same sort of shielding (with lead if necessary) that was used when initially adding the label. Pipet the labeling medium and any solution used to rinse unincorporated radioactivity from the cells into a small tube held in a solid Plexiglas holder (shown in Fig. A.1D.2C). The contents of this tube can later be poured into the appropriate liquid waste receptacle. If possible, it is a good practice to keep this high-specific-activity ^{32}P liquid waste separate from the lower-activity waste generated in other procedures so that it can be removed from the laboratory as soon as possible following the experiment. If it is necessary to store it in the laboratory for any time, the shielding for the waste container should also include a layer of lead.

The solid waste generated in the lysis part of these experiments (pipet tips, disposable pipets, cell scrapers, and dishes) is very hot and should be placed immediately into some sort of shielded container to avoid further exposure of the hands. A Plexiglas box similar in design to that in Figure A.1D.4 is convenient; placed to the side of the shield and lined with a plastic bag, it will safely hold all radioactive waste during the experiment and is light enough to be easily carried to the main laboratory waste

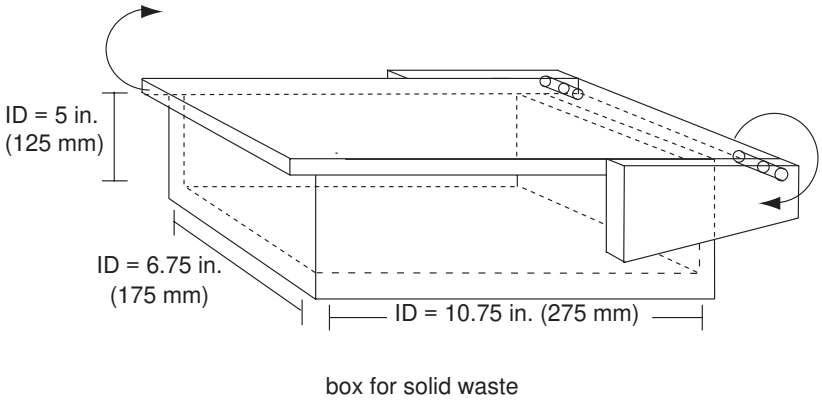

Figure A.1D.4 Box for solid waste collection made of 0.5-in. Plexiglas. Abbreviation: ID, interior dimension.

container where the plastic bag (and its contents) can be dumped after the experiment is done. If the lid of the box protrudes an inch or so over the front wall, it can be lifted using the back of a hand, thus decreasing the possibility of contaminating it with hot gloves.

When scraping the cell lysates from the dishes, it is good practice to add them to microcentrifuge tubes that are shielded in a solid Plexiglas rack; this will help to further reduce the exposure to which the hands are subjected. At this point, the lysates are usually centrifuged at high speed (>10,000 × *g*) to clear them of unsolubilized cell material. Use screw-cap tubes for this clarification step, as these will contain the labeled lysate more securely than flip-top tubes, which may open during centrifugation. No matter what type of tube is used, the rotor of the centrifuge often becomes contaminated, most probably due to tiny drops of lysate (aerosol) initially present on the rim of the tubes that are spun off during centrifugation. Monitor the rotor and wipe it out after each use.

The amount of ^{32}P taken up by cells during the incubation period varies considerably, depending on the growth state of the culture as well as on the cell type and its sensitivity to radiation. This makes it difficult to predict the percentage of the radioactivity initially added to the cells that is incorporated into the cell lysate; however, this figure probably does not exceed 10%. Thus, the amount of radioactivity being handled decreases dramatically after lysis, making effective shielding much simpler. However, at least ten times more radioactivity than is usual in other sorts of experiments is still involved! It is easy to determine if the shielding is adequate—just use both β and γ portable monitors to measure the radiation coming through it. Again, be sure to check that people working nearby (including those across the bench) are also adequately shielded. It is sometimes necessary to construct a sort of cage of Plexiglas shields around the ice bucket that contains the lysates.

At the end of the day or the experiment, it may be necessary to store radioactive samples; in some experiments, it may be desirable to save the cell lysates. These very hot samples are best stored in tubes placed in solid Plexiglas racks that can then be put into Plexiglas boxes (see Fig. A.1D.3C). Such boxes may be of similar construction to the cell houses described above; however, they should have a door that completely covers the opening. Be sure to check the γ radiation coming through these layers and add lead outside if necessary.

Working with ^{33}P

Using ^{33}P-labeled nucleotides to label nucleic acid probes or proteins

Several of the major companies that manufacture radiolabeled biological molecules have recently introduced nucleotides labeled with ^{33}P (both α- and γ-labeled forms). ^{33}P offers a clear advantage over ^{32}P with respect to ease of handling, because the energy of the β particles it releases lies between that of ^{35}S and ^{32}P and thus its use does not require as many layers of Plexiglas and lead shielding as for ^{32}P. In fact, the β radiation emitted can barely penetrate through gloves and the surface layer of skin, so the hazard associated with exposure to even millicurie amounts of ^{33}P is thought to be insignificant (as reported in the DuPont NEN product brochure). Gel bands visualized on autoradiographs of ^{33}P-labeled compounds are sharper than bands labeled with ^{32}P because the lower-energy β radiation does not have the scatter associated with that from ^{32}P. The half-life of ^{33}P is also longer (25 days compared to 14 days for ^{32}P). Despite its higher cost, these features have led many researchers to choose ^{33}P-labeled nucleotides for use in experiments such as band/gel shift assays where discrimination of closely-spaced gel bands is important.

The best way to determine what degree of shielding is needed when using ^{33}P is to monitor the source using a portable β monitor and add layers of Plexiglas as necessary.

Working with ^{125}I

Using ^{125}I to detect immune complexes (Immunoblots)

^{125}I that is covalently attached to a molecule such as staphylococcal protein A is not volatile and therefore is much less hazardous than the unbound or free form. Most institutions do not insist that work with bound ^{125}I be performed in a hood, but shielding of the γ radiation is still necessary. Lead is a good high-density material for stopping these γ rays; its drawbacks are its weight and opacity. Commercially available shields for ^{125}I are made of lead-impregnated Plexiglas—though heavy, these are at least see-through. Alternatively, a piece of lead foil may be taped to a structural support, although this arrangement does not provide shielding for the head as a worker peers over the lead!

Incubations of the membrane or blot with the [^{125}I] protein A solution and subsequent washes are usually done on a shaker. For shielding during these steps, a piece of lead foil may

simply be wrapped around the container. Solutions of ^{125}I can be conveniently stored for repeated use in a rack placed in a lead box.

Using ^{125}I to label proteins or peptides in vitro

Any experiments that call for the use of free, unbound ^{125}I should be done behind a shield in a hood that contains a charcoal filter to absorb the volatile iodine. Most institutions require that such experiments be done in a special hot lab to which access is limited. Ingested or inhaled iodine is concentrated in the thyroid; a portable γ monitor should therefore be used to scan the neck and throat before beginning and after completing each experiment. Similar scans should routinely be performed on all members of any laboratory in which unbound iodine is used.

DEALING WITH ACCIDENTS

Despite the best intentions and utmost caution, accidents happen! Accidents involving spills of radioactivity are particularly insidious because they can be virtually undetectable yet pose a significant threat to laboratory workers. For this reason it is best to foster a community spirit in any laboratory where radioisotopes are routinely used—a sense of cooperativity that extends from shielding each other properly to helping each other clean up when such accidents occur.

The specific measures to be taken following an accident involving radioactivity naturally depend on the type and amount of the isotope involved, the chemical or biological hazards of the material it is associated with, and the physical parameters of the spill (i.e., where and onto what the isotope was "misplaced"). However, following any accident there are several immediate steps that should be taken:

1. Alert coworkers as well as Radiation Safety personnel to the fact that there has been an accident. This will give them the opportunity to shield themselves if necessary—and to help clean up as well!

2. Restrict access to and away from the site of the accident to ensure that any uncontained radioactive material is not spread around the laboratory. When leaving the site be sure to monitor the bottoms of the shoes as well as the rest of the body.

3. Take care of all contaminated personnel first, evacuating others if necessary. If anyone's skin is contaminated, first use a portable monitor to identify specific areas of contamination. Then wipe these areas with a damp tissue to remove as much surface radioactivity as possible. Try to scrub only small areas at a time to keep the contamination localized. If the contamination is not easily removed with paper tissues, try a sponge or an abrasive pad, but be careful not to break the skin! Sometimes soaking is required: do this only after all easily removed contamination is gone and keep the soaked area to a minimum. Contaminated strands of hair can be washed (or perhaps a new hairstyle may be in order).

4. When attempting to clean any contaminated equipment, floors, benches, etc., begin by soaking up any visible radioactive liquid with an absorbent material. Use a small amount of soap and water to clean the contaminated area, keeping the area wiped each time to a minimum to avoid smearing the contamination over an even greater surface. Many surfaces prove resistant to even Herculean cleaning efforts; in these instances the best that can be done is to remove all contamination possible and then shield whatever is left until the radioactivity decays sufficiently for safety.

Importing Biological Materials

Scientific cooperation is no longer confined to laboratories at the same institution, nor between laboratories within the boundaries of the United States. More than ever, scientists are forming collaborations with their peers outside the U.S., leading not only to the exchange of knowledge and ideas, but also to the exchange of biological reagents. Thus, investigators need to be aware that an import permit may be required to obtain purified proteins, chemically synthesized materials, cell lines, tissues, and other biological materials from abroad. Before requesting any biological material from a laboratory outside the U.S., it is the responsibility of the "receiver" to ascertain whether an import permit is required, to apply for the permit if one is determined to be necessary, and to provide the "shipper" with an official copy of the permit to be included with the shipped material.

There are two government agencies in place to issue permits for the importation of most biologicals. Materials derived from all animals are subject to regulations set forth by the United States Department of Agriculture (USDA) and must be cleared by USDA inspectors at the port of arrival before entry into the United States is authorized. In general, an import permit issued by the USDA is necessary for receipt of any animal-derived material or any biological material (including proteins) that has been in contact with materials of animal origin. The USDA does not have regulatory authority over the importation of human or nonhuman primate material unless it is produced via tissue culture, due to the use of bovine material (fetal bovine serum or calf serum) in tissue culture. The U.S. Public Health Service (UPHS) has jurisdiction over human and nonhuman primate materials. According to UPHS regulations, any etiologic agent, animal host, or vector of human disease may not be imported in the United States nor distributed after importation without being accompanied by a permit issued by the Director of the Centers for Disease Control. Failure to obtain the appropriate import permit will result in the shipment being held at the port of entry until a permit is applied for and issued (a 4- to 6-week process), or it may result in shipment confiscation and destruction by the quarantine officer present.

IMPORTING RESTRICTED BIOLOGICAL MATERIALS

The following is a list of restricted biological materials requiring an import permit: proteins, monoclonal and polyclonal antibodies, antisera, immunoglobins, recombinant products, enzymes, hormones, immunoassay components or kits, animal tissues, blood, cells, cell lines, RNA/DNA extracts, plasmids, vectors, microorganisms—e.g., fungi, bacteria, viruses—and other products that are derived from or have been in contact with animal-derived materials. In addition, materials received from countries shown not to be free of foot-and-mouth disease (see Title 9, code of Federal Regulations, Part 94.1) require an import permit. Note that the USDA will not permit the importation of cell cultures, monoclonal antibodies, ascites fluid, or bovine serum from countries where rinderpest and foot-and-mouth disease are present unless the imported materials are determined to be virus-free. Cell cultures being imported into the U.S. must have been grown only with fetal bovine serum of U.S., Canadian, New Zealand, or Australian origin. Material exposed to bovine products originating in the United Kingdom, Switzerland, Ireland, France, or Portugal may NOT be used, either directly or indirectly, in any animals due to the presence of bovine spongiform encephalopathy (BSE) in those countries, and the material is restricted to in vitro uses only.

CRITERIA FOR HANDLING IMPORTED RESTRICTED MATERIALS

An import permit is only valid for transfer of the material(s) listed on the permit (a permit can cover more than one item), and for shipment between the two laboratories listed on the permit. Therefore, for each laboratory abroad from which biological materials are to be imported, a separate import permit is required. Once biological materials have been received from abroad, the import permit still imposes regulations on how the materials are handled by the receiver. Import permits do not usually authorize direct or indirect exposure of domestic animals—work is limited to in vitro uses only. In addition, permits are only valid for work conducted or directed by the permit holder at his or her facilities. Materials cannot

Contributed by Paula Wolf Bryant

Current Protocols in Cell Biology (2000) A.1F.1-A.1F.3

be removed to another location, nor distributed to others, without USDA authorization. There is one exception: monoclonal antibodies produced by hybridoma cell lines may be commercially distributed for in vitro uses.

IMPORTING NONRESTRICTED BIOLOGICAL MATERIALS

Any of the restricted materials that do not contain animal- or cell culture-derived products or additives such as albumin, serum, or gelatin, or were not exposed to any infectious agents of agricultural concern, do not need an official import permit. However, an accompanying declaration is required with each shipment to indicate that the material does not contain any animal- or cell culture-derived products or additives. This information should be supplied with each shipment in a clear and concise manner, and be available for the USDA Port of Entry Inspector's review. A separate memo or letter should be included with the shipping documents, such as U.S. Customs declaration and invoice. Note, whether a particular biological material requires an import permit cannot be decided by the investigator; the investigator must contact the USDA for a decision well in advance of making arrangements for importing the material.

PACKAGING BIOLOGICAL MATERIALS FOR IMPORTATION

Imported biological materials are subject to packaging and shipping requirements of various federal and international regulations. Proper packaging is the primary consideration and of utmost importance in the safe transportation of hazardous materials. If the biological material being shipped is infectious or radioactive, this information has to be noted on the outside of the package. In addition, if dry ice is used for shipment, that must be clearly stated on the package. It is of course advantageous to the investigator that the shipped material be packaged in the most efficient way possible, as well as in a form which will ensure its stability. If proteins are to be shipped, it may be better to send the samples lyophilized or blotted on a membrane, rather than in liquid form. This will omit the need for dry ice or ice packs in the packaging, which will save on shipping costs as well as ensure the samples will be stable if receipt of the package meets with unforeseen delays. If sending materials that require dry ice or ice packs, such as antibodies or antisera, there must be enough dry ice to allow the package to maintain the appropriate temperature during shipping for approximately 5 days. This requires utilizing much larger packaging boxes than are normally used to ship the same material within the United States. When shipping cell lines, sometimes it is better to send cells in culture, rather than frozen aliquots. To send cells in culture, the tissue culture flask containing the live cells must be filled to the very top with the appropriate medium, tightly capped, and the seal secured with parafilm. If the tissue culture flask is not completely filled with medium, the resulting air pockets will cause the flasks to explode in flight. Thus, the packaging of any biological material for shipping is an important consideration to ensure success of the scientific collaboration!

OBTAINING AN IMPORT PERMIT APPLICATION

The Division of Veterinary Services of the USDA Animal and Plant Health Inspection Service (APHIS) administers regulatory programs to control the import/export of biological materials. Import permits can be obtained from either local USDA port offices or from APHIS directly: USDA, APHIS, Veterinary Services, National Center for Import-Export Products Program, 4700 River Road Unit 40, Riverdale, MD 20737-1231, Tel: (301) 734-7830, Fax: (301) 734-8226.

When submitting an import application, (1) obtain the import permit well in advance of the proposed shipping date; (2) inform the supplier of the USDA's requirements, and do not allow shipment of materials until an import permit has been issued and the supplier has received a copy of the permit; (3) list all the potential U.S. ports of entry; (4) specify whether the material is for in vitro or in vivo use and whether it is for commercial distribution or for research in one's own laboratory; (5) list any treatments the material has undergone, such as processing and purification steps involving pH, heat, chromatography, or other methods; and (6) indicate the source(s) of nutrient factors in culture media, cell line designation and history, whether enzymes were used, and what types of viruses (if any) are being studied in the laboratory of origin (all must be listed).

RESOURCES

APHIS Web Site

More information regarding APHIS programs and import/export can be obtained on

their internet home page at *http://www.aphis.usda.gov.*

Fax Service of Veterinary Services, National Center for Import-Export

By calling (301) 734-4952, the investigator can access an automated document retrieval system and arrange to have an import application faxed directly, and choose from a menu of documents that describe general instructions for completing the application, as well as information regarding the importation of biological materials from 18 distinct categories.

Centrifuges and Rotors

Centrifugation runs described in this book usually specify a relative centrifugal force (RCF; measured in $\times g$), corresponding to a speed (in rpm) for a particular centrifuge and rotor model. As available equipment will vary from laboratory to laboratory, the investigator must be able to adapt these specifications to other centrifuges and rotors.

The relationship between RCF and speed (rpm) is determined by the following equation:

$$RCF = 1.12r\ (rpm/1000)^2$$

where r is the rotating radius between the particle being centrifuged and the axis of rotation. In most cases, an accurate conversion from speed to relative centrifugal force (or vice versa) can be obtained using the maximum value of r—or r_{max}—equal to the distance between the axis of rotation and the bottom of the centrifuge tube as it sits in the well or bucket of the rotor.

Table A.1G.1 provides r_{max} values for commonly used rotors manufactured by Sorvall, Beckman Coulter, Fisher, and IEC. There are situations (e.g., where an adapter is used to fit a smaller tube into a larger rotor well) where r_{max} will not accurately represent the effective rotating radius. In such cases, the manual for the rotor should be consulted to obtain the appropriate value of r. The most current information is available on the manufacturer's home page (see Internet Resources).

As an alternative to use of the above equation, the nomograms in Figures A.1G.1 and A.1G.2 make it possible to determine the RCF where speed and r_{max} are known, or the speed where RCF and r_{max} are known. This is done by aligning a ruler across the two known values and reading the unknown value at the point where the ruler crosses the remaining column. Figure A.1G.1 should be used for centrifuge runs <21,000 rpm, while Figure A.1G.2 should be used for faster speeds.

NOTE: In this manual, for spins involving microcentrifuges built to the Eppendorf standard, a shortened style of reference including only the speed (in rpm) may be used. All of these instruments have approximately the same rotating radius; hence the same speed will yield the same RCF value from machine to machine. Microcentrifuge spins may also be described as at "top speed" or "maximum speed," meaning 12,000 to 14,000 rpm, which is the maximum speed for all Eppendorf-type microcentrifuges.

CAUTION: Do not exceed maximum rotor speed! For Beckman Coulter ultracentrifuges, the maximum speed for each rotor is denoted by its name, e.g., the maximum speed of the Beckman VTi 80 rotor is 80,000 rpm. This speed refers only to centrifugation of solutions below a particular allowed density, which differs among rotors (see user manual). For centrifugation of high-density solutions, rotor maximum speed can be determined as: reduced rpm = $rpm_{max}(A/B)^{1/2}$, where A = allowed density and B = density of solution. A = 1.7 g/ml for several vertical rotors (including VTi 80 and VTi 50), and 1.2 g/ml for several swinging-bucket rotors (including SW 55 Ti, 28, 28.1, 40 Ti, 50.1). For gradients using heavy salts such as CsCl, particularly at low temperatures, maximum rpm should be reduced to prevent precipitation (see user manual).

Table A.1G.2 describes centrifuge tube materials and their properties, including optical properties, appropriate methods for sterilization, and chemical resistances (tolerance to various media, organic solvents, and alcohols).

Current Protocols in Cell Biology (2000) A.1G.1-A.1G.7

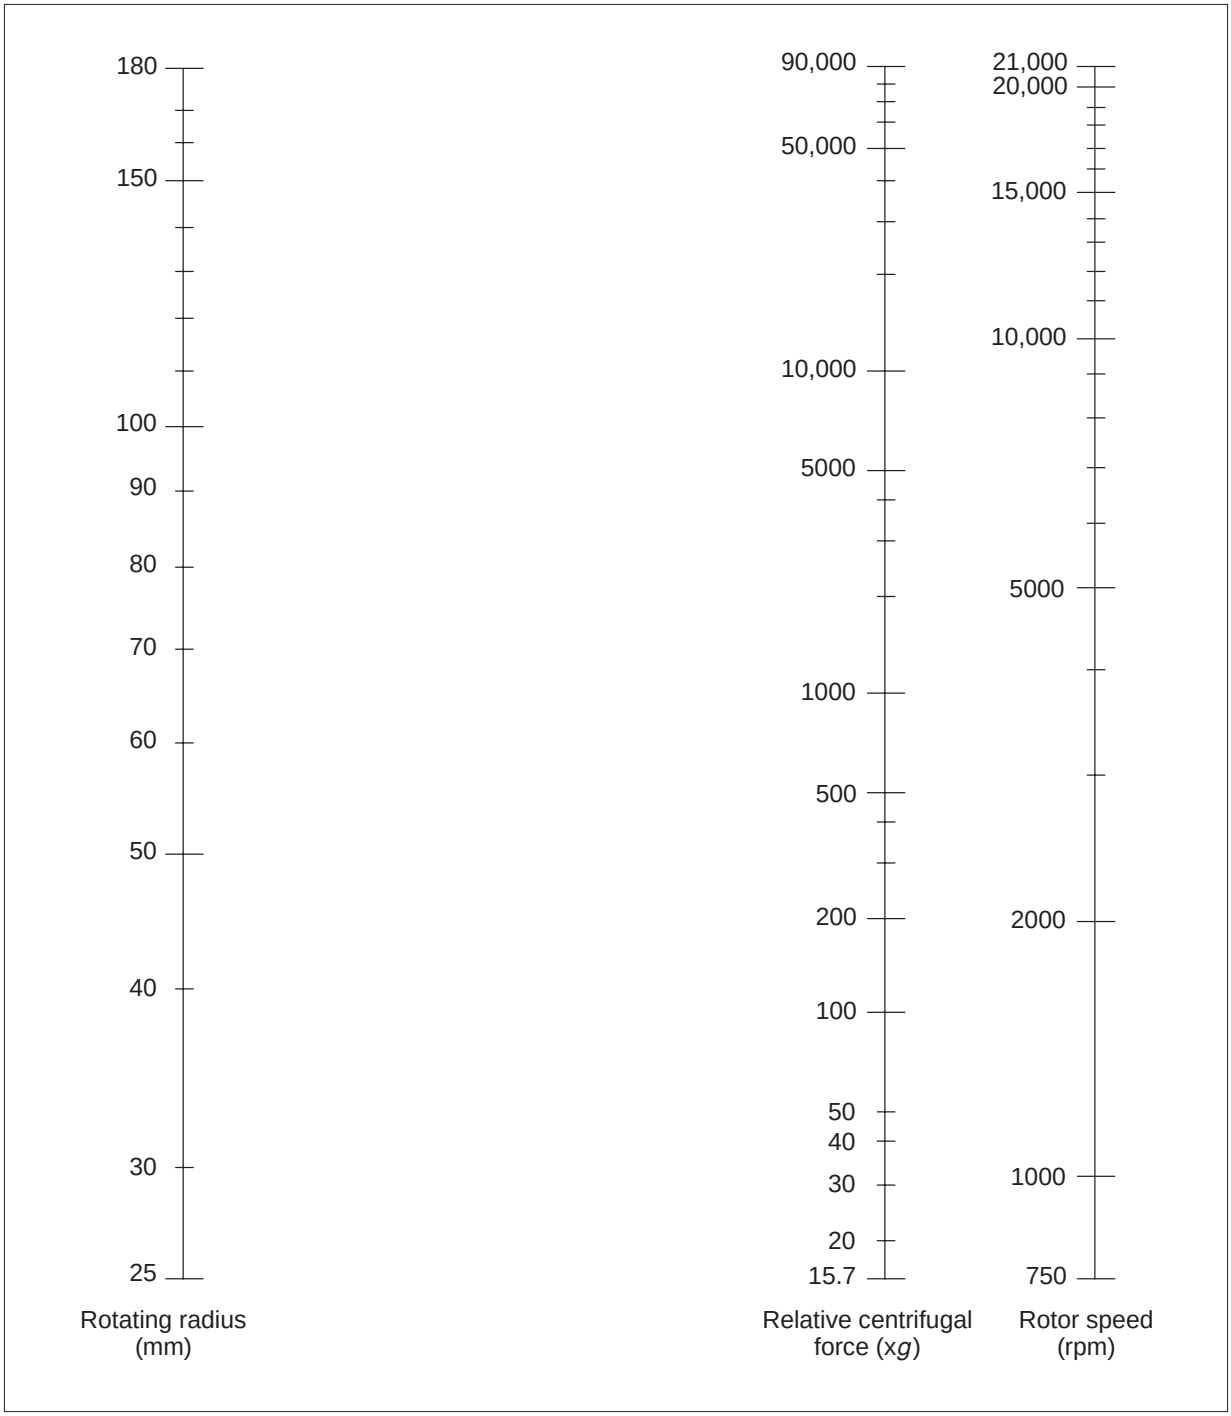

Figure A.1G.1 Nomogram for conversion of relative centrifugal force to rotor speed in low-speed centrifuge runs. To determine an unknown value in a given column, align ruler through known values in other two columns. Desired value is found at the intersection of the ruler with the column of interest. For faster centrifugations, use Figure A.1G.2. A more precise conversion can be obtained using the equation at the beginning of this appendix. See Table A.1G.1 for rotating radii of commonly used rotors.

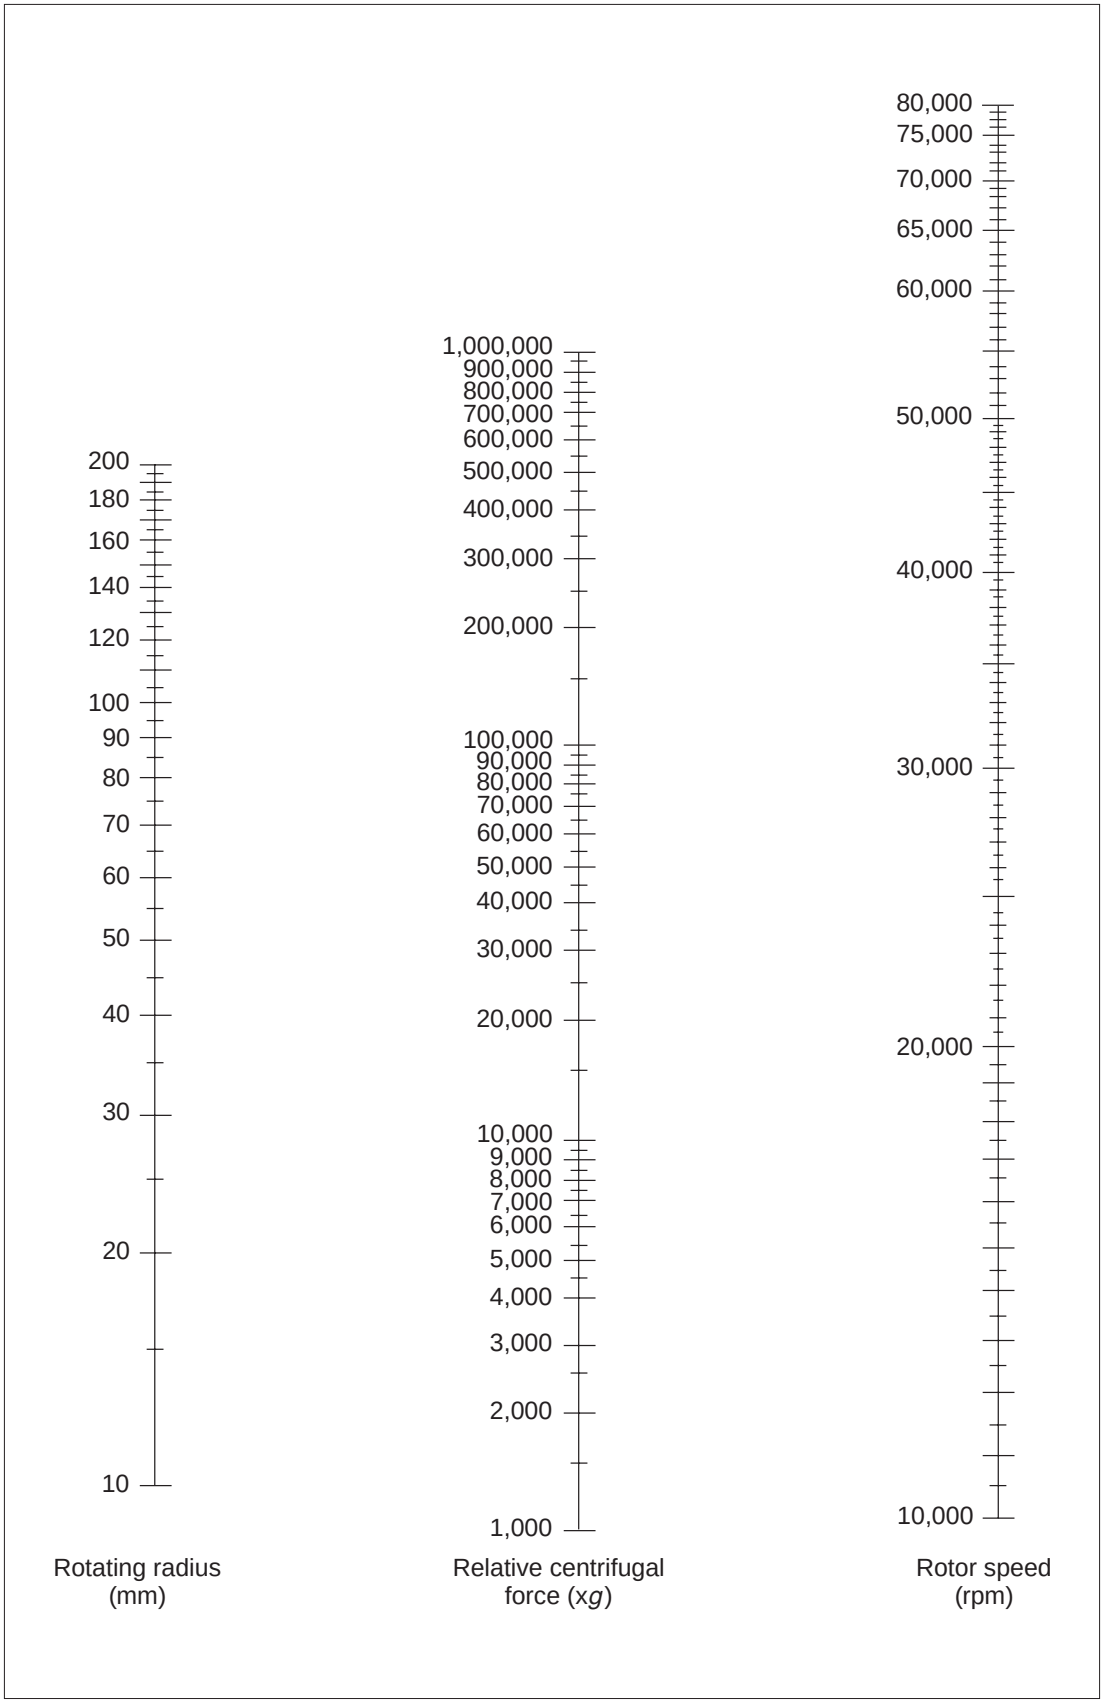

Figure A.1G.2 Nomogram for conversion of relative centrifugal force to rotor speed in high-speed centrifuge runs. For slower centrifugations and instructions for using the nomogram, use Figure A.1G.1. A more precise conversion can be obtained using the equation at the beginning of this appendix. See Table A.1G.1 for rotating radii of commonly used rotors.

[a]If your rotor is not listed here, consult the manufacturer's home page for the most up-to-date information. Sorvall, *www.sorvall.com*; Beckman Coulter, *www.beckmancoulter.com*; *beckman/biorsh/prodinfo/cntrifug/centuser.asp*; Fisher, *www.fishersci.com*; IEC, *www.labcentrifuge.com*.

[b]Sorvall centrifuges and rotors are a product of Du Pont Company Medical Products, Beckman centrifuges are a product of Beckman Coulter Instruments, IEC centrifuges are a product of International Equipment Co., Clay Adams Dynac centrifuges are a product of Becton Dickinson Labware, and Fisher centrifuges are a product of Fisher Scientific. For ordering information see *SUPPLIERS APPENDIX*.

[c]These instruments are often loosely referred to as "clinical," "tabletop," or "low-speed" centrifuges.

[d]These instruments accept a wide range of trunnion-ring rotors with variable rotating radii, as well as fixed-angle and swinging-bucket rotors that in turn accept a variety of adapters making it possible to spin different numbers of tubes of various sizes. For instance, the commonly used IEC 958 trunnion-ring rotor may be adjusted to radii ranging from 137 to 181 mm, depending on the trunnion-ring chosen. It is therefore necessary to consult the manual for the specific system being used to obtain an accurate speed to RCF conversion.

Table A.1G.2 Centrifuge Tube Materials and Their Properties[a]

Type	Optical property	Puncturable	Sliceable	Reusable	Sterilization methods	Chemical resistances[b]
Ultra-Clear thin-walled	Transparent	Yes	Yes		Cold sterilization only, but not with alcohol	Good tolerance to all gradient media except alkaline ones (>pH 8). Satisfactory for most weak acids and a few weak bases. Unsatisfactory for DMSO and most organic solvents, including all alcohols.
Standard tubes				Yes		
Quick-Seal tubes				No		
Polyallomer thin-walled	Translucent	Yes	Yes		Can be autoclaved on a test tube rack at 121°C	Good tolerance to all gradient media, including alkaline ones. Satisfactory for most acids, many bases, many alcohols, DMSO, and some organic solvents.
Standard tubes				Yes		
Quick-Seal tubes				No		
Polyallomer thick-walled	Translucent				Can be autoclaved on a test tube rack at 121°C	Good tolerance to all gradient media, including alkaline ones. Satisfactory for most acids, many bases, many alcohols, DMSO, and some organic solvents.
Tubes		No	No	Yes		
Bottles		No	No	Yes		
Polycarbonate thick-walled	Transparent	No	No		Cold sterilization recommended, but not with alcohol. Can be autoclaved at 121°C, but tube life may be reduced.	Good tolerance to all gradient media except alkaline ones (>pH 8). Satisfactory for some weak acids. Unsatisfactory for all bases, alcohols, and other organic solvents.
Tubes				Yes		
Bottles				Yes		
Cellulose propionate tubes	Transparent	No	No	Yes	Cold sterilization only, but not with alcohol	Good tolerance to all gradient media, including alkaline ones. Unsatisfactory for most acids, bases, alcohols, and other organic solvents.
Polypropylene	Translucent	No	No		Can be autoclaved at 121°C	Good tolerance to all gradient media, including alkaline ones. Satisfactory for many acids, bases, and alcohols. Unsatisfactory for most organic solvents.
Tubes				Yes		
Bottles				Yes		
Stainless steel tubes	Opaque	No	No	Yes	Can be autoclaved. Dry thoroughly before storage.	Good tolerance to many organic solvents. Marginal with many gradient media and salts. Unsatisfactory for most acids and many bases.
Polyethylene tubes	Translucent	No	No	Yes	Can be autoclaved at 121°C	Good tolerance to a wide range of chemicals. Suitable for use with strong acids and bases. Unsatisfactory for most organic solvents.
Corex/Pyrex	Transparent	No	No		Can be autoclaved at 121°C	Good tolerance to a wide range of gradient media. Corex has greater resistance to bases and acids.
Tubes				Yes		
Bottles				Yes		

[a]Table reproduced by permission of Beckman Coulter Instruments.

[b]Chemical resistances are described here in general terms, and are not meant by Beckman Coulter Instruments or John Wiley & Sons to express or imply any guarantee of safety based on these recommendations or resistances. If there is any doubt about a particular solution, it should be tested under actual operating conditions to evaluate the performance of a tube material. For more detailed information regarding specific media and solvents, consult Beckman Coulter Instruments. High-vapor-pressure inflammable solvents should not be handled in close vicinity to centrifuges because of possible ignition by sparking switches, relay contacts, or motor brushes.

Internet Basics for Biologists

With the explosion of sequence and structural information available to researchers, the field of bioinformatics is playing an increasingly large role in the study of fundamental biomedical problems. The challenge facing computational biologists will be to aid in gene discovery and in the design of molecular modeling, site-directed mutagenesis, and experiments of other types that can potentially reveal previously unknown relationships with respect to the structure and function of genes and proteins. This challenge becomes particularly daunting in light of the vast amount of data that has been produced by the Human Genome Project and other systematic sequencing efforts to date.

We begin with a review of the Internet and its terminology, also discussing major classes of Internet protocols, without becoming overly engaged in the engineering minutiae underlying these protocols. A more in-depth treatment on the inner workings of these protocols may be found in a number of well-written reference books intended for the lay audience (Krol and Klopfenstein, 1996; Rankin, 1996; Kennedy, 1999). This unit will also discuss matters of connectivity, ranging from simple modem connections to digital subscriber lines (DSL). Finally, we will address one of the most common problems that has arisen with the proliferation of Web pages throughout the world—i.e., finding useful information on the World Wide Web.

INTERNET BASICS

Despite the impression that the Internet is a single entity, it is actually a network of networks, composed of interconnected local and regional networks in more than 100 countries. While work on remote communications began in the early 1960s, the true origins of the Internet lie with a research project on networking at the Advanced Research Projects Agency of the U.S. Department of Defense in 1969 named ARPANET. The original ARPANET connected four nodes on the West Coast, with the immediate goal of being able to transmit information on defense-related research between laboratories. A number of different network projects subsequently surfaced, with the next landmark developments coming over ten years later. In 1981, BITNET ("Because It's Time") was introduced, providing point-to-point connections between universities for the transfer of electronic mail and files. In 1982, ARPA introduced the Transmission Control Protocol (TCP) and Internet Protocol (IP); TCP/IP allowed different networks to be connected to and communicate with one another, creating the system that is in place today.

A number of references chronicle the development of the Internet and communications protocols in detail (Quarterman, 1990; Froehlich and Kent, 1991; Krol and Klopfenstein, 1996). Most users, however, are content to leave the details of *how* the Internet works to their systems administrators; the relevant fact to most is that it *does* work.

Once the machines on a network are connected to one another, there needs to be some way to unambiguously specify a single computer so that messages and files find their intended recipient. To accomplish this, all machines directly connected to the Internet have an **IP number**. IP numbers are unique, identifying one and only one machine. The IP number is made up of four numbers separated by periods; for example, the IP number for the main file server at the National Center for Biotechnology Information (NCBI) at the National Institutes of Health (NIH) is *130.14.25.1*. The numbers themselves represent, from left to right, the domain (*130.14* for the NIH), the subnet (*.25* for the National Library of Medicine at NIH), and the machine itself (*.1*). While the use of IP numbers aids the computers in directing data, they are obviously very difficult for users to remember.

Contributed by Andreas D. Baxevanis and B.F. Francis Ouellette
Current Protocols in Cell Biology (2001) A.1H.1-A.1H.16

Therefore, an IP number often has a **fully-qualified domain name** (FQDN) associated with it, which is dynamically translated in the background by a **domain name server**. Going back to the NCBI example, instead of using *130.14.25.1* to access the NCBI computer, a user could instead use *ncbi.nlm.nih.gov* and achieve the same result. Reading from left to right, the IP number goes from least to most specific, while the FQDN equivalent goes from most specific to least. The name of any given computer can then be thought of as taking the general form *computer.domain*, with the top-level domain (the portion coming after the last period in the FQDN) falling into one of the six broad categories shown in Table A.1H.1. Outside the United States, the top-level domain names may be replaced with a two-letter code specifying the country where the machine is located (e.g., *.ca* for Canada and *.uk* for the United Kingdom).

In an effort to anticipate the needs of Internet users in the future, as well as to try to erase the arbitrary line between top-level domain names based on country, the now-dissolved International Ad Hoc Committee (IAHC) was charged with developing a new framework of generic top-level domains (gTLD). The new, recommended gTLDs were set forth in a document entitled *The Generic Top Level Domain Memorandum of Understanding* (gTLD-MOU); these gTLDs are overseen by a number of governing bodies and are also shown in Table A.1H.1.

The most concrete measure of the size (and, thereby, the success) of the Internet lies in actually counting the number of machines physically connected to it. The Internet Software Consortium conducts an Internet Domain Survey twice each year to count these machines, otherwise known as **hosts**. In performing this survey, ISC considers not only how many hostnames have been assigned, but how many of those are actually in use; a

Table A.1H.1 Top-Level Domain Names

Top-level domain names	
Inside the United States	
.com	Commercial site
.edu	Educational site
.gov	Government site
.mil	Military site
.net	Gateway or network host
.org	Private (usually not-for-profit) organizations
Examples of top-level domain names used outside the United States	
.ca	Canadian site
.ac.uk	Academic site in the United Kingdom
.co.uk	Commercial site in the United Kingdom
Generic top-level domains proposed by IAHC	
.firm	Firms or businesses
.shop	Businesses offering goods to purchase (stores)
.web	Entities emphasizing activities relating to the World Wide Web
.arts	Cultural and entertainment organizations
.rec	Recreational organizations
.info	Information sources
.nom	Personal names (e.g., *yourlastname.nom*)

hostname might be issued, but the requestor may be holding the name in abeyance for future use. To test for this, a representative sample of host machines are sent a probe (a "ping"), with a signal being sent back to the originating machine if the host was indeed found. The rate of growth of the number of hosts has been phenomenal; from a paltry 213 hosts in August 1981, the Internet has in excess of 60 million hosts now. The doubling time for the number of hosts is on the order of 18 months. Most of this growth has come from the commercial sector, capitalizing on the growing popularity of multimedia platforms for advertising and communications such as the World Wide Web.

CONNECTING TO THE INTERNET

Of course, before being able to use all of the resources that the Internet has to offer, one needs to actually make a physical connection between one's own computer and "the information superhighway." For purposes of this discussion, the elements of this connection have been separated into two discrete parts: the actual, physical connection (meaning the "wire" running from one's computer to the Internet backbone) and the service provider, who handles issues of routing and content once connected. Keep in mind that, in practice, these are not necessarily treated as two separate parts—for instance, one's service provider may also be the same company that will run cables or fibers right into one's home or office.

Copper Wires, Coaxial Cables, and Fiber Optics

Traditionally, users who were attempting to connect to the Internet away from the office have had one and only one option—a modem, which uses the existing copper twisted-pair cables carrying telephone signals to transmit data. Data transfer rates using modems are relatively slow, allowing for data transmission in the range of 28.8 to 56 kilobits per second (Kbps). The problem with using conventional copper wire to transmit data lies not in the copper wire itself, but in the switches that are found along the way that route information to their intended destinations. These switches were designed for the efficient and effective transfer of voice data, but were never intended to handle the high-speed transmission of data. While most people still use modems from their homes, a number of new technologies are already in place and will become more and more prevalent for accessing the Internet away from hard-wired Ethernet networks. The maximum speeds at which each of the services that are discussed below can operate are shown in Figure A.1H.1.

The first of these "new solutions" is the integrated services digital network, or ISDN. While the advent of ISDN was originally heralded as the way to bring the Internet into the home in a speed-efficient manner, it required that special wiring be brought into the home. It also required that users be within a fixed distance from a central office, on the order of 20,000 feet or less. The cost of running this special, dedicated wiring, along with a per-minute pricing structure, effectively placed ISDN out of reach of most individuals. While ISDN is still available in many areas, this type of service is quickly being supplanted by more cost-effective alternatives.

In looking at alternatives that did not require new wiring, cable television providers began to look at ways in which the coaxial cable already running into a substantial number of households could be used to also transmit data. Cable companies are able to use bandwidth that is not being used to transmit television signals (effectively, unused channels) to push data into the home at very high speeds, up to 4.0 megabits per second (Mbps). The actual computer is connected to this network through a cable modem, which uses an Ethernet connection to the computer and a coaxial cable to the wall. Homes in a given area all share a single cable, in a wiring scheme very similar to that by which individual computers are connected via the Ethernet in an office or laboratory setting. While this branching

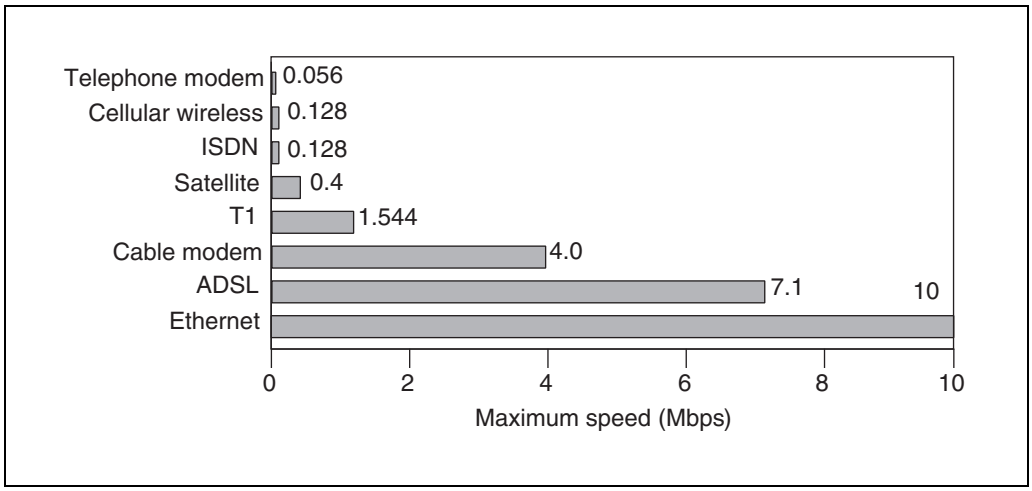

Figure A.1H.1 Performance of various types of Internet connections, by maximum throughput (in megabits per sec). The numbers indicated in the graph refer to peak performance; often the actual performance of any given method may be on the order of one-half slower, depending on configurations and system conditions.

arrangement can serve to connect a large number of locations, there is one major disadvantage—as more and more homes connect through their cable modems, service effectively slows down as more signal attempts to pass through any given node. One way of circumventing this problem is the installation of more switching equipment and reducing the size of a given "neighborhood."

Since the local telephone companies were the primary ISDN providers, they quickly turned their attention to ways in which the existing, conventional copper wire already in the home could be used to transmit data at high speed. The solution here is the digital subscriber line, or DSL. By using new, dedicated switches that are designed for rapid data transfer, DSL providers can circumvent the old voice switches that slowed down transfer speeds. Depending on the user's distance from the central office and whether a particular neighborhood has been wired for DSL service, speeds are on the order of 0.8 to 7.1 Mbps. The data transfers do not interfere with voice signals, and users can use the telephone while connected to the Internet; the signals are "split" by a special modem that passes the data signals to the computer and a microfilter that passes voice signals to the handset. There is a special type of DSL called **asynchronous DSL**, or ADSL. This is the variety of DSL service that is becoming more and more prevalent. Most home users download much more information than they send out, so systems are engineered to provide super-fast transmission in the "in" direction, with transmissions in the "out" direction being 5 to 10 times slower. Using this approach maximizes the amount of bandwidth that can be used without necessitating new wiring. One of the advantages of ADSL over cable is that ADSL subscribers effectively have a direct line to the central office, meaning that they do not have to compete with their neighbors for bandwidth. This, of course, comes at a price; at the time of this writing, ADSL connectivity options were on the order of twice as expensive as cable Internet.

Some of the newer technologies involve wireless connections to the Internet. These include using one's own cell phone or a special cell phone service (such as Ricochet) to upload and download information. These cellular providers can provide speeds on the order of 28.8 to 128 Kbps, depending on the density of cellular towers in the service area. Fixed-point wireless services can be substantially faster, since the cellular phone does not have to "find" the closest tower at any given time. Along these same lines, satellite providers are also coming on-line. These providers allow for data download directly to a

satellite dish with a southern exposure, with uploads occuring through traditional telephone lines. While the satellite option has the potential to be amongst the fastest of the options discussed, current operating speeds are only on the order of 400 Kbps.

Content Providers Versus ISPs

Once an appropriately fast and price-effective connectivity solution is found, users will then need to actually connect to some sort of service that will enable them to traverse the Internet space. The two major categories in this respect are **on-line services** or **Internet service providers** (**ISPs**). On-line services such as America Online (AOL) and CompuServe offer a large number of interactive digital services, including information retrieval, electronic mail (e-mail), bulletin boards, and "chat rooms" where users who are on line at the same time can converse with each other about any number of subjects. While the on-line services now provide access to the World Wide Web (see discussion of The World Wide Web), most of the features and services available through these systems reside within a proprietary, closed network; once a connection is made between the user's computer and the on-line service, accessing the special features, or content, of these systems does not require ever leaving the on-line system's host computer. Specialized content can range from access to on-line travel reservation systems to encyclopedias that are constantly being updated—items that would not be available to anyone unless they subscribed to that particular on-line service.

Internet service providers, or ISPs, take the opposite tack. Instead of focusing on providing content, the ISPs provide the tools necessary for users to send and receive e-mail, upload and download files, and navigate around the World Wide Web to find information at remote locations. The major advantage of ISPs is connection speed; ISPs often provide faster connections than the on-line services. Most ISPs charge a monthly fee for unlimited use.

The line between on-line services and ISPs has already begun to blur. AOL's now monthly flat fee pricing structure allows users to obtain all of the proprietary content found on AOL as well as all of the Internet tools available through ISPs, often at the same cost as a simple ISP connection. The extensive AOL network puts access to AOL as close as a local phone call in most of the United States, providing access to e-mail no matter where the user is located—a feature that small, local ISPs cannot match.

Not to be outdone, many of the major national ISP providers now also provide content through the concept of **portals**. Portals are Web pages that can be customized to the needs of the individual user and which serve as a jumping-off point to other sources of news or entertainment on the Net. In addition, many national firms such as Mindspring are able to match AOL's ease of connectivity on the road, and both ISPs and online providers are becoming more and more generous in providing users the capacity to publish their own Web pages. Developments such as this, coupled with the move of local telephone and cable companies into providing Internet access through new, faster fiber optic networks, foretell major changes in how people will access the Net in the future, changes that should favor the end-user both in price and performance.

ELECTRONIC MAIL

Most people are introduced to the Internet through the use of electronic mail (**e-mail**). The use of e-mail has become practically indispensable in many settings owing to its convenience as a medium for sending, receiving, and replying to messages. Its advantages are many:

It is much quicker than postal, or "snail mail." Messages tend to be much clearer and more to the point than is the case in typical telephone or face-to-face conversations.

Recipients have more flexibility in deciding whether a response needs to be sent immediately, relatively soon, or at all, giving individuals more control over workflow.

It provides a convenient method by which messages can be filed or stored.

There is little or no cost involved in sending an e-mail message.

While these and other advantages have pushed e-mail to the forefront of interpersonal communication in both industry and the academic community, users should be aware of several major disadvantages. First is the issue of security. As mail travels towards its recipient, it may pass through a number of remote nodes. The message could be intercepted and read at any one of those nodes by someone with high-level access, such as a systems administrator. Second is the issue of privacy. In industrial settings, e-mail is often considered to be an asset of the company for use only in official communication and, as such, is subject to monitoring by supervisors. The opposite is often true in academic, quasi-academic, or research settings; for example, National Institutes of Health policy encourages personal use of e-mail within the bounds of certain published guidelines. The key words here are "published guidelines"; no matter what the setting, users of e-mail systems should always be informed as to their organization's policy regarding the appropriate use and confidentiality of e-mail so that they may use the tool properly and effectively. An excellent, basic guide to the effective use of e-mail is highly recommended (Rankin, 1996).

Sending E-Mail

E-mail addresses take the general form *user@computer.domain,* where *user* is the name of the individual user and *computer.domain* specifies the actual computer that the e-mail account is located on. Like a postal letter, an e-mail message is comprised of an **envelope** or **header**, showing the e-mail addresses of the sender and recipient, a line indicating the subject of the e-mail, and information about how the e-mail message actually travelled from the sender to the recipient. The header is followed by the actual message, or **body**, analogous to what would go inside the postal envelope. Figure A.1H.2 illustrates all the components of an e-mail message.

E-mail programs vary widely, depending on both the platform and the needs of the users. Usually the characteristics of the local area network (LAN) dictate what types of mail programs can be used, and the decision is often left to systems administrators rather than individual users. Among the most widely used e-mail packages with a graphical user interface are Eudora for the Macintosh and both Netscape Messenger and Microsoft Exchange for Macintosh, Windows, and UNIX platforms. Text-based e-mail programs, which are accessed by logging into a UNIX-based account, include Elm and Pine.

Bulk E-Mail

As with postal mail, there has been an upsurge in "spam" or "junk e-mail," where companies compile bulk lists of e-mail addresses for use in commercial promotions. Since most of these lists are compiled from on-line registration forms and similar sources, the best defense for remaining off of these bulk e-mail lists is to be selective as to whom e-mail addresses are provided. Most newsgroups keep their mailing lists confidential; if in doubt and this is a concern, one should ask.

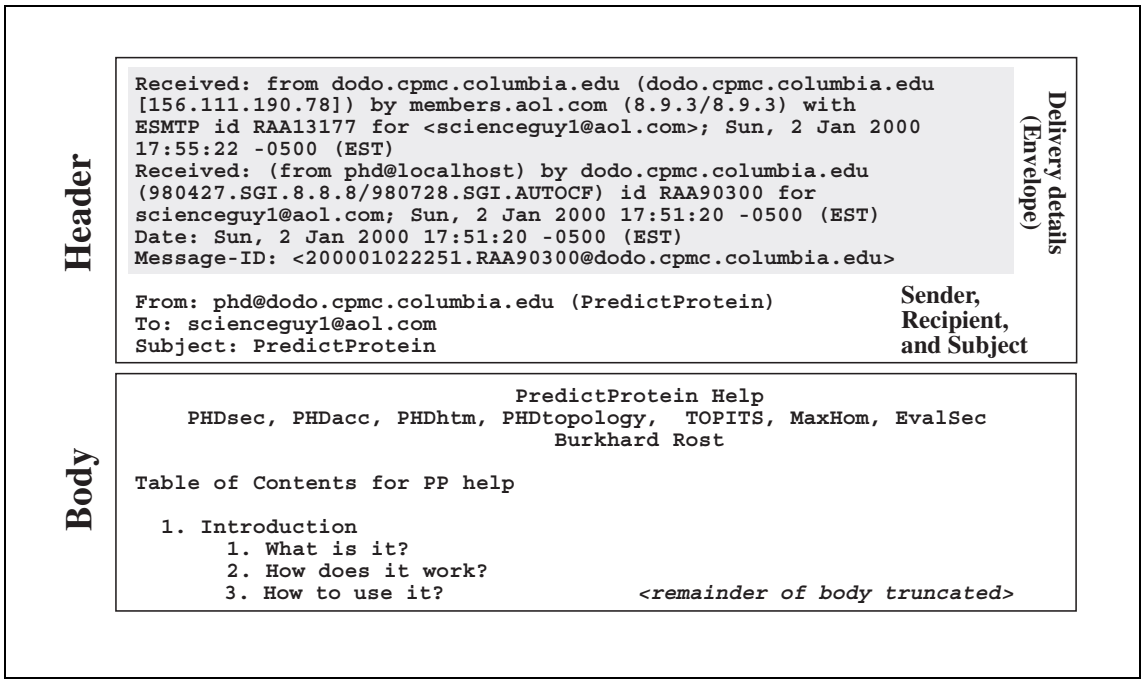

Figure A.1H.2 Anatomy of an e-mail message, with relevant components indicated. This message is an automated reply to a request for help file for the PredictProtein E-mail server.

E-Mail Servers

Most often, e-mail is thought of as a way to simply send messages, whether it be to one recipient or many. It is also possible to use e-mail as a mechanism for making biological predictions or retrieving records from biological databases. Users can send e-mail messages in a predefined format, defining the action to be performed for remote computers known as **servers**; the servers will then perform the desired operation and e-mail back the results. While this method is not interactive (in that the user cannot adjust parameters or have control over the execution of the method in real time), it does place the responsibility of hardware maintenance and software upgrades on the persons maintaining the server, allowing users to concentrate on their results instead of on programming. For most servers, sending the message *help* to the server e-mail address will return a detailed set of instructions for using that server, including the way in which queries need to be formatted.

Aliases and Newsgroups

In the example in Figure A.1H.2, the e-mail message is being sent to a single recipient. One of the strengths of e-mail is that a single piece of e-mail can be sent to a large number of people. The primary mechanism for doing this is through **aliases**; a user can define a group of people within their mail program and give the group a special name, or alias. Instead of using the individual e-mail addresses for all of the people in the group, the user can just send the e-mail to the alias name, and the mail program will handle broadcasting the message to each person in that group. Setting up alias names is a tremendous time-saver even for small groups; it also ensures that all members of a given group actually receive all e-mail messages intended for the group.

The second mechanism for broadcasting messages is through **newsgroups**. This model works slightly differently in that the list of e-mail addresses is compiled and maintained on a remote computer through subscriptions, much like magazine subscriptions. For example, the BIOSCI newsgroups are amongst the most highly-trafficked, offering a

forum for discussion or the exchange of ideas in a wide variety of biological subject areas. To begin receiving the messages posted to the automated sequencing discussion group within BIOSCI, a user would send a message to *biosci-server@net.bio.net* with the wording *subscribe autoseq* in the body of the message. The user would then receive all future postings to that group and be able to participate in the discussions. If a user wished to be removed from the group, a message would be sent to the same address, but this time, the body of the message would read *unsubscribe autoseq*. For more information on BIOSCI, including a complete list of discussion groups, an e-mail message can be sent to *biosci-server@net.bio.net*; in this case the subject line should be left blank and the words *info faq* typed in the body of the message. The BIOSCI server will then return a copy of the Frequently Asked Questions (FAQ) in response, with detailed information on each newsgroup overseen by BIOSCI.

It is also possible to participate in newsgroups without having each and every piece of e-mail flood into one's private mailbox. Instead, interested participants can use newsreading software, such as NewsWatcher for the Macintosh, which provides access to the individual messages making up a discussion. The major advantage is that the user can pick and choose which messages to read by scanning the subject lines; the remainder can be discarded by a single operation. NewsWatcher is an example of what is known as a **client-server application**—the client software (here, NewsWatcher) runs on a client computer (a Macintosh), which in turn interacts with a machine at a remote location (the server). Client-server architecture is interactive in nature, with a direct connection being made between the client and server machines.

Once NewsWatcher is started, the user is presented with a list of newsgroups available to them (Fig. A.1H.3); this list will vary, depending on the user's location, as systems administrators have the discretion to allow or block certain groups at a given site. From the rear-most window in the figure, the user double-clicks on the newsgroup of interest (here, *bionet.genome.arabidopsis*), which spawns the window shown in the center. At the top of the center window is the current unread message count, and any message within the list can be read by double-clicking on that particular line. This, in turn, spawns the last window (in the foreground), showing the actual message. If a user decides not to read any of the messages, or is done reading individual messages, the balance of the messages within the newsgroup (center) window can be deleted by first choosing *Select All* from the *File* menu, then selecting *Mark Read* from the *News* menu. Once the newsgroup window is closed, the unread message count is reset to zero. Every time NewsWatcher is restarted, it will automatically poll the news server for new messages that have been created since the last session.

As with most of the tools that will be discussed in this unit, news-reading capability is built into Web browsers such as Netscape Navigator and Microsoft Internet Explorer.

FILE TRANSFER PROTOCOL

Despite the many advantages afforded by e-mail in transmitting messages, experienced e-mail users have no doubt experienced frustration in trying to transmit files (**attachments**) along with an e-mail message. The mere fact that a file can be attached to an e-mail message and sent does not mean that the recipient will be able to detach, decode, and actually use the attached file. While more cross-platform e-mail packages such as Microsoft Exchange are being developed, the use of different e-mail packages by people at different locations means that sending files via e-mail is not an effective, foolproof method, at least in the short term. One solution to this problem is through the use of a **file transfer protocol** (or **FTP**). The workings of FTP are quite simple—a connection is made

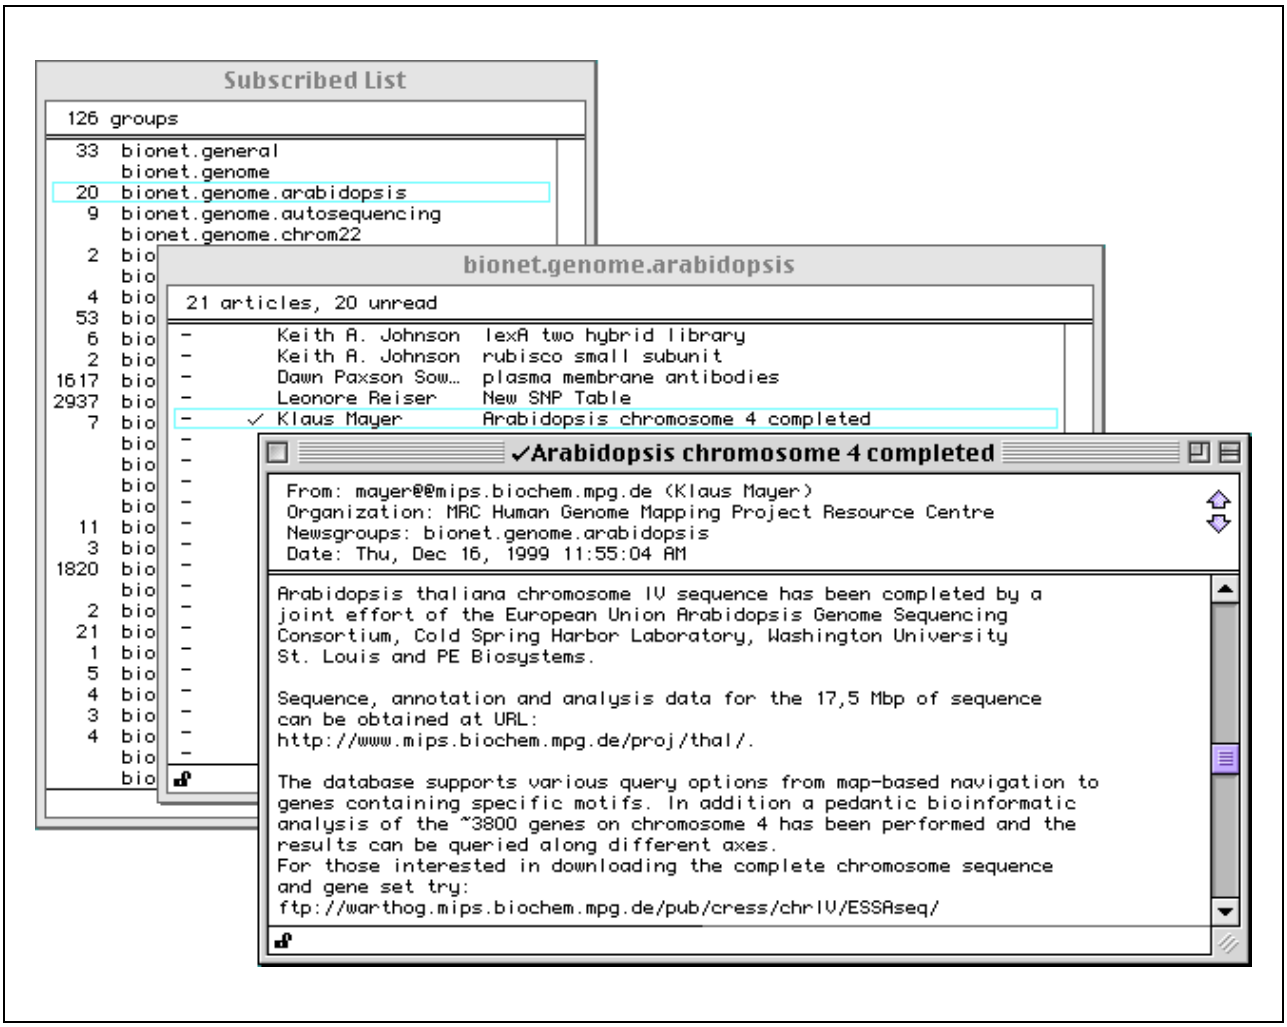

Figure A.1H.3 Using NewsWatcher to read postings to newsgroups. The list of newsgroups that the user has subscribed to is shown in the *Subscribed List* window (*left*). The list of new postings for the highlighted newsgroup (*bionet.genome.arabidopsis*) is shown in the center window. The window in the foreground shows the contents of the posting selected from the center window.

between a user's computer (the **client**) and a remote server, and that connection remains in place for the duration of the FTP session. File transfers are very fast, at rates on the order of 5 to 10 kilobytes per second, with speeds varying with time of day, distance between the client and server machines, and overall traffic on the network.

In the ordinary case, making an FTP connection and transferring files requires that a user have an account on the remote server. However, there are many files and programs that the academic community makes freely available, and access to those files does not require having an account on each and every machine where these programs are stored. Instead, connections are made using a system called **anonymous FTP**. Under this system, the user connects to the remote machine, and instead of entering a username/password pair, types *anonymous* as the username and enters an e-mail address in place of a password. Providing one's e-mail address allows the server's systems administrator to compile access statistics which may, in turn, be of use to those actually providing the public files or programs. An example of an anonymous FTP session using UNIX is shown in Figure A.1H.4.

Figure A.1H.4 Using UNIX FTP to download a file. An anonymous FTP session is established with the molecular biology FTP server at the University of Indiana to download the ClustalW alignment program. The user inputs are shown in boldface.

Although FTP occurs within the UNIX environment, Macintosh and PC users can employ programs that utilize graphical user interfaces (GUI, pronounced “gooey”) to navigate through the UNIX directories on the FTP server. Users need not have any knowledge of UNIX commands to download files; they can instead rely on pop-up menus and the ability to point-and-click their way through the UNIX file structure. The most popular FTP program on the Macintosh platform for FTP sessions is Fetch.

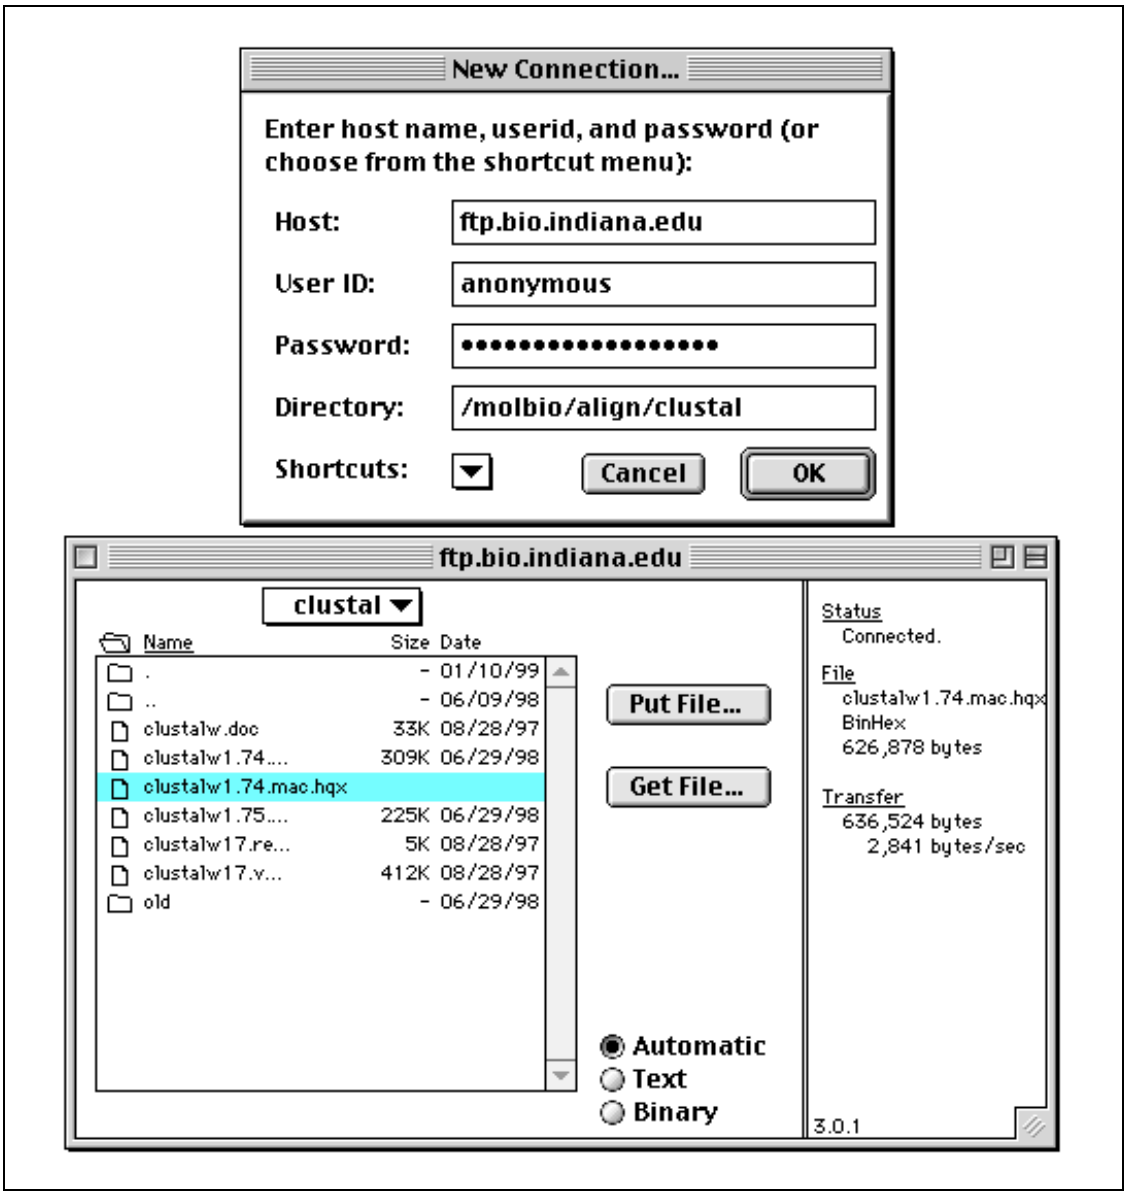

Figure A.1H.5 Using Fetch to download a file. An anonymous FTP session is established with the molecular biology FTP server at the University of Indiana (top) to download the ClustalW alignment program (bottom). Notice the difference between this GUI-based program and the UNIX equivalent illustrated in Figure A.1H.4.

A sample Fetch window is shown in Figure A.1H.5 to illustrate the difference between using a GUI-based FTP program and the equivalent UNIX FTP in Figure A.1H.4. In the figure, notice that the *Automatic* radio button (near the bottom of the second window under the *Get File* button) is selected, meaning that Fetch will determine the appropriate type of file transfer to perform. This may be manually overridden by selecting either *Text* or *Binary*, depending on the nature of the file being transferred. As a rule, text files should be transferred as *Text*, programs or executables as *Binary*, and graphic format files such as PICT and TIFF files as *Raw Data*.

THE WORLD WIDE WEB

While FTP is of tremendous use in the transfer of files from one computer to another, it does suffer from some limitations. When working with FTP, once a user enters a particular directory, they can only see the names of the directories or files. In order to actually view what is within the files, it is necessary to physically download them onto one's own computer. This inherent drawback led to the development of a number of **distributed document delivery systems** (DDDS), interactive client-server applications that allowed information to be viewed without having to perform a download. The first generation of DDDS development led to programs like Gopher, which allowed plain text to be viewed directly through a client-server application. From this evolved the most widely known and widely used DDDS, namely the World Wide Web. The Web is an outgrowth of research performed at the European Nuclear Research Council (CERN) in 1989 that was aimed at sharing research data between several locations. That work led to a medium through which text, images, sounds, and videos could be delivered to users on demand, anywhere in the world.

Navigation on the World Wide Web

Navigation on the Web does not require advance knowledge of the location of the information being sought. Instead, users can navigate by clicking on specific text, buttons, or pictures. These clickable items are collectively known as **hyperlinks**. Once one of these hyperlinks is clicked, the user is taken to another Web location, which could be at the same site or halfway around the world. Each document displayed on the Web is called a **Web page**, and all of the related Web pages on a particular server are collectively called a **Web site**. Navigation strictly through the use of hyperlinks has been nicknamed "Web surfing."

Users can take a more direct approach to finding information by entering a specific address. One of the strengths of the Web is that the programs used to view Web pages (appropriately termed **browsers**) can be used to visit Gopher and FTP sites as well, somewhat obviating the need for separate Gopher or FTP applications. As such, a unified naming convention was introduced to indicate to the browser program both the location of the remote site and, more importantly, the type of information at that remote location so that the browser could properly display the data. This standard-form address is known as a **uniform resource locator** (**URL**), and takes the general form *protocol://computer.domain*, where *protocol* specifies the type of site and *computer.domain* specifies the location (Table A.1H.2). The *http* used for the protocol in World Wide Web URLs stands for *hypertext transfer protocol*, the method used in transferring Web files from the host computer to the client.

Table A.1H.2 Uniform Resource Locator (URL) Format for Each Type of Transfer Protocol

Site	URL format (example)
General form	*protocol://computer.domain*
FTP site	*ftp://ftp.ncbi.nlm.nih.gov*
Gopher site	*gopher://gopher.iubio.indiana.edu*
Web site	*http://www.nhgri.nih.gov*

Browsers

Browsers, which are used to look at Web pages, are client-server applications that connect to a remote site, download the requested information at that site, display the information on the user's monitor, then disconnect from the remote host. The information retrieved from the remote host is in a platform-independent format called **hypertext markup language** (**HTML**). HTML code is strictly text-based, and any associated graphics or sound for that document exist as separate files in a common format. For example, images may be stored and transferred in GIF format, developed by CompuServe for the quick and efficient transfer of graphics; while GIF format is most commonly used for graphics, other formats such as JPEG and BMP may also be used. Because of this, a browser can display any Web page on any type of computer, whether it be a Macintosh, IBM-compatible, Linux, or UNIX machine. The text is usually displayed first, then the remaining elements are placed on the page as they are downloaded. With minor exceptions, a given Web page will look the same when the same browser is used on any of the above platforms.

The two major players in the area of browser software are Netscape, with their Communicator product, and Microsoft, with Internet Explorer. As with many other areas where multiple software products are available, the choice between Netscape and Internet Explorer comes down to one of personal preference. While the computer literati will debate the fine points of difference between these two packages, for the average user, both packages perform equally well and offer the same types of features, adequately addressing the Web-browser needs of most users.

It is worth mentioning that, while the Web is by definition a visually based medium, it is also possible to travel through Web space and view documents without the associated graphics. For users limited to line-by-line terminals, a browser called Lynx is available. Developed at the University of Kansas, Lynx allows users to use their keyboard arrow keys to highlight and select hyperlinks, using their return key the same way that Netscape and Internet Explorer users would click their mouse.

Internet Versus Intranet

The World Wide Web is normally thought of as a way to communicate with people at a distance, but the same infrastructure can be used to connect people within an organization. Such **intranets** provide an easily accessible repository of relevant information, capitalizing on the simplicity of the Web interface. It also provides another channel for broadcast or confidential communication within the organization. Having an intranet is of particular value when members of an organization are physically separated, whether it be in different buildings or different cities. Intranets are protected in such a way that people who are not on the organization's network are prohibited from accessing the internal Web pages; additional protections through the use of passwords are also common.

Finding Information on the World Wide Web

Most people find information on the Web the old fashioned way—by word of mouth either by using lists such as Table A.1H.3 or by simply following hyperlinks put in place by Web authors. Continuously clicking from page to page can be a highly ineffective way of finding information, especially when the information sought is of a very focused nature. One way of finding interesting and relevant Web sites is to consult **virtual libraries**, which are curated lists of Web resources arranged by subject. Virtual libraries of special interest to biologists include the WWW Virtual Library, maintained by Keith Robison at Harvard and the EBI BioCatalog, based at the European Bioinformatics Institutes. The URLs for these sites can be found in Table A.1H.3.

Table A.1H.4 Number of Hits Returned for Four Defined Search Queries on Some of the More Popular Search and Meta-Search Engines

Search term	Search engine			Meta-search engine		
	HotBot	Excite	Infoseek	Lycos	MetaCrawler	SavvySearch
genetic mapping	478	1,040	4,326	9,395	62	58
human genome	13,231	34,760	15,980	19,536	42	54
positional cloning	279	735	1,143	666	40	52
prostate cancer	14,044	53,940	24,376	33,538	60	57

It is also possible to directly search the Web by using **search engines** such as Alta Vista and Excite, among others. A search engine is simply a specialized program that can perform full-text or keyword searches on databases that catalog Web content. The result of a search is a hyperlinked list of Web sites fitting the search criteria from which the user can visit any or all of the found sites. However, search engines use slightly different methods in compiling their databases. One variation is the attempt to capture most or all of the text of every Web page that the search engine is able to find and catalog ("Web crawling"). Another technique is to catalog only the title of each Web page rather than its entire text. A third is to consider words that must appear next to each other or only relatively close to one another. Because of these differences in search-engine algorithms, the results returned by issuing the same query to a number of different search engines can produce wildly different results (Table A.1H.4). It may also be noted from Table A.1H.4 that most of the numbers are exceedingly large, reflecting the overall size of the World Wide Web. Unless a particular search engine ranks its results by relevance (for example, by scoring words in a title higher than words in the body of the Web page), the results obtained may not be particularly useful. It is also necessary to keep in mind that, depending on the indexing scheme that the search engine is using, the found pages may actually no longer exist, leading the user to the dreaded "404 Not Found" error.

Compounding this problem is the issue of **coverage**—the number of Web pages that any given search engine is actually able to survey and analyze. A comprehensive study by Lawrence and Giles (1998) indicates that the coverage provided by any of the search engines studied is both small and highly variable. For example, the HotBot engine produced 57.5% coverage of what was estimated to be the size of the "indexable Web," while Lycos had only 4.41% coverage, a full order of magnitude less than HotBot. The most important conclusion from this study was the extent of coverage increased as the number of search engines are increased and the results from those individual searches are combined. Combining the results obtained from the six search engines examined in this study produced coverage approaching 100%.

To address this point, a new class of search engines called **meta-search engines** have been developed. These programs will take the user's query and poll anywhere from five to ten of the "traditional" search engines. The meta-search engine will then collect the results, filter out duplicates, and return a single, annotated list to the user. One big advantage is that the meta-search engines take relevance statistics into account, returning much smaller lists of results. Even though the hit list is substantially smaller, it is much more likely to contain sites that directly address the original query. Since the programs must poll a number of different search engines, searches conducted this way obviously take longer to perform, but the higher degree of confidence in the compiled results for a given query outweighs the extra few minutes (sometimes only seconds) of search time. Reliable and easy-to-use meta-search engines include SavvySearch and MetaCrawler (see Table A.1H.3).

LABORATORY STOCK SOLUTIONS AND EQUIPMENT

APPENDIX 2

Common Stock Solutions, Buffers, and Media

APPENDIX 2A

RECIPES

This section describes the preparation of buffers and reagents used in this manual for cell culture, manipulation of tissue, and cell biological methods. When preparing solutions, use deionized or distilled water and reagents of the highest available grade. Sterilization—by filtration through a 0.22-μm filter or by autoclaving—is recommended for most solutions stored at room temperature and is essential for cell culture applications. Where storage conditions are not specified, store up to 6 months at room temperature. Discard any reagent that shows evidence of contamination, precipitation, or discoloration.

Acid, concentrated stock solutions

See Table A.2A.1.

Acid precipitation solution

1 M HCl
0.1 M sodium pyrophosphate

Nucleic acids can also be precipitated with a 10% (w/v) solution of trichloroacetic acid (TCA); however, this recipe is cheaper, easier to prepare, and just as efficacious.

Ammonium hydroxide, concentrated stock solution

See Table A.2A.1.

Ammonium acetate, 10 M

Dissolve 385.4 g ammonium acetate in 150 ml H_2O
Add H_2O to 500 ml

Ammonium sulfate, saturated

76 g ammonium sulfate
100 ml H_2O
Heat with stirring to just below boiling point
Let stand overnight at room temperature

Table A.2A.1 Molarities and Specific Gravities of Concentrated Acids and Bases[a]

Acid/base	Molecular weight	% by weight	Molarity (approx.)	Specific gravity	1 M solution (ml/liter)
Acetic acid (glacial)	60.05	99.6	17.4	1.05	57.5
Ammonium hydroxide	35.0	28	14.8	0.90	67.6
Formic acid	46.03	90	23.6	1.205	42.4
		98	25.9	1.22	38.5
Hydrochloric acid	36.46	36	11.6	1.18	85.9
Nitric acid	63.01	70	15.7	1.42	63.7
Perchloric acid	100.46	60	9.2	1.54	108.8
		72	12.2	1.70	82.1
Phosphoric acid	98.00	85	14.7	1.70	67.8
Sulfuric acid	98.07	98	18.3	1.835	54.5

[a]*CAUTION:* Handle strong acids and bases carefully.

Current Protocols in Cell Biology (1998) A.2A.1-A.2A.10

ATP, 100 mM

1 g ATP (adenosine triphosphate)
12 ml H_2O
Adjust pH to 7.0 with 4 M NaOH
Adjust volume to 16.7 ml with H_2O
Store in aliquots indefinitely at −20°C

Base, concentrated stock solutions

See Table A.2A.1.

BSA (bovine serum albumin), 10% (w/v)

Dissolve 10 g BSA (e.g., Sigma) in 100 ml H_2O. Filter sterilize using a low-protein-binding 0.22-μm filter. Store indefinitely at 4°C.

Lower-concentration stock solutions (e.g., 1%), which are useful for various applications, can be made by diluting 10% stock appropriately with sterile water.

BSA is available in various forms that differ in fraction of origin, preparation, purity, pH, and cost; the most commonly used is fraction V. Use the form that is appropriate for the application; this may need to be optimized empirically.

$CaCl_2$, 1 M

147 g $CaCl_2 \cdot 2H_2O$
H_2O to 1 liter

Carbonate buffer

1.6 g Na_2CO_3 (15 mM final)
2.9 g $NaHCO_3$ (35 mM final)
0.2 g NaN_3 (3.1 mM final)
H_2O to 1 liter
Adjust to pH 9.5

CAUTION: *Sodium azide is poisonous; follow appropriate precautions for handling, storage, and disposal.*

CMF-DPBS (calcium- and magnesium-free Dulbecco's phosphate-buffered saline)

8.00 g NaCl (0.137 M)
0.20 g KCl (2.7 mM)
2.16 g $Na_2HPO_4 \cdot 7H_2O$ (8.1 mM)
0.20 g KH_2PO_4 (1.1 mM)
H_2O to 1 liter
Store at room temperature

DEPC (diethylpyrocarbonate)-treated solutions

Add 0.2 ml DEPC to 100 ml of the solution to be treated. Shake vigorously to dissolve the DEPC. Autoclave the solution to inactivate the remaining DEPC.

CAUTION: *Wear gloves and use a fume hood when using DEPC, as it is a suspected carcinogen.*

Many investigators keep the solutions they use for RNA work separate to ensure that "dirty" pipets do not go into them.

Do not treat solutions containing Tris with DEPC, as Tris inactivates the DEPC.

DMEM (Dulbecco's modified Eagle medium), supplemented

Dulbecco's modified Eagle medium, high-glucose formulation (see APPENDIX 2B; e.g., Life Technologies), containing:
5%, 10%, or 20% (v/v) FBS, heat inactivated (optional; see recipe below)
1% (v/v) nonessential amino acids
2 mM L-glutamine

continued

100 U/ml penicillin
100 µg/ml streptomycin sulfate
Filter sterilize if anything nonsterile has been added
Store up to 1 month at 4°C

DMEM containing this set of additives is sometimes called "complete DMEM." The percentage of serum used is indicated after the medium name—e.g., "DMEM/5% FBS." Absence of a number indicates no serum is used. DMEM is also known as Dulbecco's minimum essential medium.

Ham's F-12 nutrient mixture (APPENDIX 2B; available commercially, e.g., from Life Technologies), is sometimes added to DMEM; the resulting medium is known as DMEM/F-12.

Because of the higher bicarbonate content, DMEM requires ~10% CO_2 to maintain pH 7.4.

Culture media containing glutamine and penicillin should be warmed to 37°C as few times as possible since components, especially glutamine, degrade rapidly at 37°C.

DPBS (Dulbecco's phosphate-buffered saline)

8.00 g NaCl (0.137 M)
0.20 g KCl (2.7 mM)
0.20 g KH_2PO_4 (1.1 mM)
0.10 g $MgCl_2 \cdot 6H_2O$ (0.5 mM)
2.16 g $Na_2HPO_4 \cdot 7H_2O$ (8.1 mM)
0.10 g anhydrous $CaCl_2$ (0.9 mM)
H_2O to 1 liter

DTT (dithiothreitol), 1 M

Dissolve 1.55 g DTT in 10 ml water and filter sterilize. Store in aliquots at −20°C.

EDTA (ethylenediaminetetraacetic acid), 0.5 M (pH 8.0)

Dissolve 186.1 g disodium EDTA dihydrate in 700 ml water. Adjust pH to 8.0 with 10 M NaOH (~50 ml; add slowly). Add water to 1 liter and filter sterilize.

Begin titrating before the sample is completely dissolved. EDTA, even in the disodium salt form, is difficult to dissolve at this concentration unless the pH is increased to between 7 and 8.

FBS (fetal bovine serum)

Thaw purchased fetal bovine serum (shipped on dry ice and kept frozen until needed). Store 3 to 4 weeks at 4°C. If FBS is not to be used within this time, aseptically divide into smaller aliquots and refreeze until used. Store ≤1 year at −20°C. To heat inactivate FBS, heat serum 30 min to 1 hr in a 56°C water bath with periodic gentle swirling during the first 10 to 15 min to ensure uniform heating.

Repeated thawing and refreezing should be avoided, as it may cause denaturation of the serum.

Heat-inactivated FBS (FBS that has been treated with heat to inactivate complement protein and thus prevent an immunological reaction against cultured cells) is useful for a variety of purposes. It can be purchased commercially or made in the lab as described above.

HBSS (Hanks' balanced salt solution)

0.40 g KCl (5.4 mM final)
0.09 g $Na_2HPO_4 \cdot 7H_2O$ (0.3 mM final)
0.06 g KH_2PO_4 (0.4 mM final)
0.35 g $NaHCO_3$ (4.2 mM final)
0.14 g $CaCl_2$ (1.3 mM final)
0.10 g $MgCl_2 \cdot 6H_2O$ (0.5 mM final)
0.10 g $MgSO_4 \cdot 7H_2O$ (0.6 mM final)
8.0 g NaCl (137 mM final)

1.0 g D-glucose (5.6 mM final)
0.2 g phenol red (0.02%; optional)
Add H_2O to l liter and adjust pH to 7.4 with 1 M HCl or 1 M NaOH
Filter sterilize and store up to 1 month at 4°C

HBSS may be made or purchased without Ca^{2+} and Mg^{2+} (CMF-HBSS). These components are optional and usually have no effect on an experiment; in a few cases, however, their presence may be detrimental. Consult individual protocols to see if the presence or absence of these components is recommended.

Bottles should be kept tightly closed to prevent CO_2 loss and subsequent alkalinization.

HCl, 1 M

Mix in the following order:
913.8 ml H_2O
86.2 ml concentrated HCl

HeBS (HEPES-buffered saline) solution, 2×

16.4 g NaCl
11.9 g HEPES acid
0.21 g Na_2HPO_4
800 ml H_2O
Titrate to pH 7.05 with 5 M NaOH
Add H_2O to 1 liter
Filter sterilize through a 0.45-µm nitrocellulose filter
Store in 50-ml aliquots at −20°C

If the solution is to be used for transfection, the pH should be between 7.05 and 7.12, and should be tested for transfection efficiency.

KCl, 1 M

74.6 g KCl
H_2O to 1 liter

LB medium

Per liter:
10 g tryptone
5 g yeast extract
5 g NaCl
1 ml 1 M NaOH
Autoclave 25 min

Although the pH is adjusted to near 7 with NaOH, the medium is not very highly buffered, and the pH of a culture growing in the medium drops as the culture nears saturation.

The medium may also contain antibiotics (e.g., 50 µg/ml ampicillin, 12 µg/ml tetracycline), galactosides (e.g., 20 µg/ml Xgal, 0.1 mM IPTG), or other nutritional supplements added after the medium has been autoclaved.

To make LB agar for LB plates, add 5 g/liter agar or agarose.

$MgCl_2$, 1 M

20.3 g $MgCl_2 \cdot 6H_2O$
H_2O to 100 ml

$MgSO_4$, 1 M

24.6 g $MgSO_4 \cdot 7H_2O$
H_2O to 100 ml

NaCl, 5 M

292 g NaCl
H_2O to 1 liter

NaOH, 10 M

Dissolve 400 g NaOH in 450 ml H_2O
Add H_2O to 1 liter

PBS (phosphate-buffered saline)

8.00 g NaCl (0.137 M)
0.20 g KCl (2.7 mM)
0.24 g KH_2PO_4 (1.4 mM)
1.44 g Na_2HPO_4 (0.01 M)
H_2O to 1 liter

PCR amplification buffer, 10×

500 mM KCl
100 mM Tris·Cl, pH 8.3 (see recipe below)
x mM $MgCl_2$
0.1% (w/v) gelatin
Store in aliquots at −20°C

This solution can be sterilized by autoclaving. Alternatively, it can be made from sterile water and stock solutions, and the sterilization omitted.

15 mM $MgCl_2$ is the concentration (x) used for most PCR reactions. However, the optimal concentration depends on the sequence and primer of interest and may have to be determined experimentally (see APPENDIX 3).

PMSF (phenylmethylsulfonyl fluoride), 100 mM

Dissolve 0.174 g PMSF in 10 ml of 100% ethanol, isopropanol, or methanol. Store in aliquots up to 2 years at −20°C.

CAUTION: *Phenylmethylsulfonyl fluoride is toxic.*

Make fresh dilutions from the alcohol stock for each use, because the half-life of PMSF in aqueous solution is <30 min at room temperature and a few hours on ice.

If PMSF is being added to a solution without detergent, the solution should be stirred vigorously during PMSF addition because PMSF has a tendency to form an insoluble precipitate in aqueous solution.

Polylysine-coated tissue culture surfaces

Prepare a stock solution by dissolving 100 mg polylysine in 100 ml water (poly-L-lysine or poly-D-lysine can be used; check specific protocol for choice of isomer) and filter sterilize through a 0.22-μm filter. Store in 5-ml aliquots at −20°C. When ready to use, dilute 1 part stock solution with 19 parts water to prepare a 50 μg/ml working solution.

To coat culture dishes, multiwell plates, or chamber slides: Fill tissue culture dishes, multiwell plates, or slide wells with the working solution and incubate 1 hr in a 37°C incubator, then remove solution by vacuum aspiration and allow surface to dry.

To coat coverslips: Sterilize coverslips by autoclaving or by incubating them in 95% ethanol and drying before coating. Place coverslips in a single layer in a petri dish containing working solution and incubate 1 hr at 37°C. Remove coverslips using sterile forceps and allow surface to dry.

Store coated tissue culture ware up to 3 months at 4°C. Use diluted solutions only once.

Potassium acetate buffer, 0.1 M

Solution A: 11.55 ml glacial acetic acid per liter (0.2 M) in water.

Solution B: 19.6 g potassium acetate ($KC_2H_3O_2$) per liter (0.2 M) in water.

continued

Table A.2A.2 Preparation of 0.1 M Sodium and Potassium Acetate Buffers[a]

Desired pH	Solution A (ml)	Solution B (ml)
3.6	46.3	3.7
3.8	44.0	6.0
4.0	41.0	9.0
4.2	36.8	13.2
4.4	30.5	19.5
4.6	25.5	24.5
4.8	20.0	30.0
5.0	14.8	35.2
5.2	10.5	39.5
5.4	8.8	41.2
5.6	4.8	45.2

[a]Adapted by permission from CRC (1975).

Referring to Table A.2A.2 for desired pH, mix the indicated volumes of solutions A and B, then dilute with water to 100 ml. Filter sterilize if necessary. Store up to 3 months at room temperature.

This may be made as a 5- or 10-fold concentrate by scaling up the amount of sodium acetate in the same volume. Acetate buffers show concentration-dependent pH changes, so check the pH by diluting an aliquot of concentrate to the final concentration.

To prepare buffers with pH intermediate between the points listed in Table A.2A.2, prepare closest higher pH, then titrate with solution A.

Potassium phosphate buffer, 0.1 M

Solution A: 27.2 g KH_2PO_4 per liter (0.2 M final) in water.

Solution B: 34.8 g K_2HPO_4 per liter (0.2 M final) in water.

Referring to Table A.2A.3 for desired pH, mix the indicated volumes of solutions A and B, then dilute with water to 200 ml. Filter sterilize if necessary. Store up to 3 months at room temperature.

This buffer may be made as a 5- or 10-fold concentrate simply by scaling up the amount of potassium phosphate in the same final volume. Phosphate buffers show concentration-dependent changes in pH, so check the pH of the concentrate by diluting an aliquot to the final concentration.

To prepare buffers with pH intermediate between the points listed in Table A.2A.3, prepare closest higher pH, then titrate with solution A.

Saponin, 10% (w/v)

Dissolve 1 g saponin in 10 ml PBS (see recipe above)
Store in 500-µl aliquots at –20°C

Once thawed, the 10% solution is stable for several months when stored at 4°C.

SDS, 20% (w/v)

Dissolve 20 g SDS (sodium dodecyl sulfate or sodium lauryl sulfate) in H_2O to 100 ml total volume with stirring. Filter sterilize using a 0.45-µm filter.

It may be necessary to heat the solution slightly to fully dissolve the powder.

Table A.2A.3 Preparation of 0.1 M Sodium and Potassium Phosphate Buffers[a]

Desired pH	Solution A (ml)	Solution B (ml)	Desired pH	Solution A (ml)	Solution B (ml)
5.7	93.5	6.5	6.9	45.0	55.0
5.8	92.0	8.0	7.0	39.0	61.0
5.9	90.0	10.0	7.1	33.0	67.0
6.0	87.7	12.3	7.2	28.0	72.0
6.1	85.0	15.0	7.3	23.0	77.0
6.2	81.5	18.5	7.4	19.0	81.0
6.3	77.5	22.5	7.5	16.0	84.0
6.4	73.5	26.5	7.6	13.0	87.0
6.5	68.5	31.5	7.7	10.5	90.5
6.6	62.5	37.5	7.8	8.5	91.5
6.7	56.5	43.5	7.9	7.0	93.0
6.8	51.0	49.0	8.0	5.3	94.7

[a]Adapted by permission from CRC (1975).

SDS electrophoresis buffer, 5×

15.1 g Tris base
72.0 g glycine
5.0 g SDS
Distilled, deionized H_2O to 1 liter
Store up to 1 month at 0° to 4°C
Dilute to 1× before use

Do not adjust the pH of the stock solution; the pH is 8.3 when diluted to 1×.

Use purified SDS if appropriate.

SDS sample buffer

See Table A.2A.4.

Table A.2A.4 Preparation of SDS Sample Buffer

Ingredient	2×	4×	Final conc. in 1× buffer
0.5 M Tris·Cl, pH 6.8[a]	2.5 ml	5.0 ml	62.5 mM
SDS	0.4 g	0.8 g	2% (w/v)
Glycerol	2.0 ml	4.0 ml	10% (v/v)
Bromphenol blue	20 mg	40 mg	0.1% (w/v)
2-Mercaptoethanol[b,c]	400 µl	800 µl	~300 mM
H_2O	to 10 ml	to 10 ml	—

[a]See recipe below.
[b]Alternatively, dithiothreitol (DTT), at a final concentration of 100 mM, can be substituted for 2-mercaptoethanol.
[c]Add just before use.

Sodium acetate, 3 M

Dissolve 408 g sodium acetate trihydrate ($NaC_2H_3O_2 \cdot 3H_2O$) in 800 ml H_2O
Adjust pH to 4.8, 5.0, or 5.2 (as desired) with 3 M acetic acid (see Table A.2A.1)
Add H_2O to 1 liter
Filter sterilize

Sodium acetate buffer, 0.1 M

Solution A: 11.55 ml glacial acetic acid per liter (0.2 M) in water.

Solution B: 27.2 g sodium acetate ($NaC_2H_3O_2 \cdot 3H_2O$) per liter (0.2 M) in water.

Referring to Table A.2A.2 for desired pH, mix the indicated volumes of solutions A and B, then dilute with water to 100 ml. Filter sterilize if necessary. Store up to 3 months at room temperature.

This may be made as a 5- or 10-fold concentrate by scaling up the amount of sodium acetate in the same volume. Acetate buffers show concentration-dependent pH changes, so check the pH by diluting an aliquot of concentrate to the final concentration.

To prepare buffers with pH intermediate between the points listed in Table A.2A.2, prepare closest higher pH, then titrate with solution A.

Sodium phosphate buffer, 0.1 M

Solution A: 27.6 g $NaH_2PO_4 \cdot H_2O$ per liter (0.2 M final) in water.

Solution B: 53.65 g $Na_2HPO_4 \cdot 7H_2O$ per liter (0.2 M) in water.

Referring to Table A.2A.3 for desired pH, mix the indicated volumes of solutions A and B, then dilute with water to 200 ml. Filter sterilize if necessary. Store up to 3 months at room temperature.

This buffer may be made as a 5- or 10-fold concentrate by scaling up the amount of sodium phosphate in the same final volume. Phosphate buffers show concentration-dependent changes in pH, so check the pH by diluting an aliquot of the concentrate to the final concentration.

To prepare buffers with pH intermediate between the points listed in Table A.2A.3, prepare closest higher pH, then titrate with solution A.

TAE (Tris/acetate/EDTA) electrophoresis buffer, 10×

24.2 Tris base
5.71 ml glacial acetic acid
3.72 g $Na_2EDTA \cdot 2H_2O$
H_2O to 1 liter

TBE (Tris/borate/EDTA) electrophoresis buffer, 10×

108 g Tris base (890 mM)
55 g boric acid (890 mM)
960 ml H_2O
40 ml 0.5 M EDTA, pH 8.0 (20 mM final; see recipe above)

TBS (Tris-buffered saline)

100 mM Tris·Cl, pH 7.5 (see recipe below)
0.9% (w/v) NaCl
Store up to several months at 4°C

TE (Tris/EDTA) buffer

10 mM Tris·Cl, pH 7.4, 7.5, or 8.0 (or other pH; see recipe below)
1 mM EDTA, pH 8.0 (see recipe above)

TEA (triethanolamine) solution

50 mM triethanolamine, pH ~11.5
0.1% (v/v) Triton X-100
0.15 M NaCl

Add Triton X-100 from a 10% stock (see recipe below).

TEN (Tris/EDTA/NaCl) solution

40 mM Tris·Cl, pH 7.5 (see recipe below)
1 mM EDTA, pH 8.0 (see recipe above)
150 mM NaCl

Tris·Cl, 1 M

Dissolve 121 g Tris base in 800 ml H_2O
Adjust to desired pH with concentrated HCl
Adjust volume to 1 liter with H_2O
Filter sterilize if necessary
Store up to 6 months at 4°C or room temperature

Approximately 70 ml HCl is needed to achieve a pH 7.4 solution, and ~42 ml for a solution that is pH 8.0.

IMPORTANT NOTE: *The pH of Tris buffers changes significantly with temperature, decreasing approximately 0.028 pH units per 1°C. Tris-buffered solutions should be adjusted to the desired pH at the temperature at which they will be used. Because the pK_a of Tris is 8.08, Tris should not be used as a buffer below pH ~7.2 or above pH ~9.0.*

Triton X-100, 10% (w/v)

1 g Triton X-100
H_2O to 10 ml
Stir to dissolve
Filter sterilize through a 0.45-μm filter
Store protected from light up to 6 months at room temperature

TTBS (Tween 20/TBS)

Dissolve 0.1% (w/v) polyoxyethylenesorbitan monolaurate (Tween 20) in TBS (see recipe above). Store up to several months at 4°C.

SPECIAL CONSIDERATIONS FOR PCR EXPERIMENTS

Because the polymerase chain reaction (PCR) is designed to detect very small amounts of DNA, only a few molecules of contaminating DNA will produce unwanted amplification products. Ideally, PCR should not be carried out in the same room where large quantities of DNA are handled. Even where such spatial separation is not practical, the following housekeeping procedures will help avoid contamination with extraneous DNA (H.D. Kay, pers. comm.).

1. Keep laboratory surfaces clean by swabbing with 5% to 10% chlorine bleach. Put fresh absorbent paper bench protectors on bench before beginning PCR.
2. Wear disposable gloves and change them frequently while setting up PCRs.
3. Use only sterile disposable plasticware.
4. Keep a separate set of pipetting devices for setting up PCRs. If possible, use these instruments only with cotton-plugged tips to minimize transfer of DNA by aerosol. A separate microcentrifuge for PCR work is also desirable.
5. Whenever possible, set up PCRs in a laminar-flow hood or Class II biological safety cabinet to help prevent contamination by airborne DNA particles. A UV light within the hood or cabinet will help inactivate contaminating DNA.
6. Handle microcentrifuge tubes aseptically. Do not touch the interior of the hinged cap; if this happens, discard the tube. Microcentrifuge tubes briefly before opening to pellet drops around the cap and help keep reagents and reaction mixtures away from potentially contaminating fingers. Have only one tube open at a time, and open each

tube away from the remaining tubes. Hand-held microcentrifuge tube openers (e.g., USA/Scientific Plastics) are available to facilitate aseptic technique.

7. Include negative controls (i.e., no primer and no template) in all PCRs.

SPECIAL CONSIDERATIONS FOR WORKING WITH RNA

RNA is susceptible to degradation by ribonucleases, which are ubiquitous, very stable, and generally require no cofactors to function. Therefore, it is very important when working with RNA to take precautions against RNase contamination.

1. Treat all water and salt solutions except those containing Tris with DEPC (diethylpyrocarbonate; see recipe above). DEPC inactivates ribonucleases by covalent modification (however, it cannot be used with Tris solutions because Tris inactivates DEPC).

   CAUTION: *DEPC is hazardous and a suspected carcinogen; follow appropriate precautions for handling, storage, and disposal.*

2. If possible, make separate stock solutions to use for working with RNA and keep separate to ensure that "dirty" pipets do not come in contact with them.

3. Bake glassware 4 hr at 150°C. Rinse plasticware in chloroform or use directly out of the package (when it is generally free from contamination). Autoclaving will not fully inactivate many RNases.

4. Wear disposable gloves.

Medium Formulations

COMMON TISSUE CULTURE MEDIA

Table A.2B.1 lists the formulations for four common tissue culture media. These and related media with a variety of additions are available from a number of commercial suppliers in liquid or powder form, in a variety of concentrations—e.g., 1× and 10×.

CO_2 in air must be used to maintain the pH of these tissue culture media, all of which are buffered with bicarbonate. Although most media require 5% CO_2 to maintain a pH of ~7.4, Dulbecco's modified Eagle medium (DMEM) is routinely used with 10% CO_2 because it contains elevated levels of bicarbonate. If DMEM is incubated in 5% CO_2, the pH remains at roughly pH 7.6 for at least several days, until the bicarbonate buffer equilibrates. In 7.5% to 10% CO_2, the pH remains at ~7.4. Additional buffering capacity can be provided by supplementing media with 25 mM HEPES.

For additional discussion of tissue culture media in general, see Ham and McKeehan (1979) and *UNIT 1.2*.

Table A.2B.1 Tissue Culture Medium Formulations[a]

Ingredient	Amount per liter			
	DMEM[b]	Ham's F-12 nutrient mixture	MEM[c]	RPMI 1640[d]

[a]Abbreviations: DMEM, Dulbecco's modified Eagle medium; MEM, minimal essential medium (after Eagle); RPMI, Roswell Park Memorial Institute.

[b]This formulation is for the high-glucose version with L-glutamine; DMEM is also available as a low-glucose version containing 1000 mg/liter. Other variations include: +HEPES, +sodium pyruvate, +pyridoxine·HCl, –inositol, –sodium phosphate, –L-glutamine, –phenol red, –L-methionine, –L-cysteine, –calcium chloride.

[c]This formulation contains L-glutamine. Other variations include: +Earle's salts, –L-glutamine, –sodium bicarbonate, –sodium phosphate, +D-valine (–L-valine), +inositol, +Hanks' salts, +nonessential amino acids. The α version of MEM is available with or without ribonucleotides and deoxyribonucleotides, and in other variations.

[d]This formulation contains L-glutamine. Other variations include –phenol red, –L-leucine, –L-methionine, –sodium phosphate, –glucose, –sodium bicarbonate, +HEPES, –folate, +L-alanine, –L-glutamine.

OTHER MEDIA

HAT supplement (see recipe) is used in hybrid selection to eliminate unfused or self-fused HGPRT$^-$ parental cells (*UNIT 1.2*).

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

HAT supplement, 100×

10 mM sodium hypoxanthine
40 µM aminopterin
1.6 mM thymidine
Store at 4°C protected from the dark
Rehydrate before use and add to medium to 1× final concentration

CAUTION: *This supplement is hazardous; avoid mouth pipetting and contact with skin.*

Standard Laboratory Equipment

Listed below are pieces of equipment that are standard in the modern cell biology laboratory—i.e., items used extensively in this manual and thus not usually included in the individual materials lists. No attempt has been made to list all items required for each procedure in the Materials list of each protocol; rather, those lists note those items that might not be readily available in the laboratory or that require special preparation. See *SUPPLIERS APPENDIX* for contact information for commercial vendors of laboratory equipment.

Applicator, cotton-tipped and wooden

Autoclave

Bag sealer

Balances, analytical and preparative

Beakers

Bench protectors, plastic-backed (including "blue" pads)

Biohazard disposal containers and bags

Biosafety cabinet, tissue culture or laminar flow hood; filters air and maintains air flow pattern to protect cultured cells from investigator and vice versa

Bottles, glass, plastic, and squirt

Bunsen burners

Centrifuges, low-speed (to 20,000 rpm) refrigerated, ultracentrifuge (20,000 to 80,000 rpm), large-capacity low-speed, tabletop, with appropriate rotors and adapters

Centrifuge tubes and bottles, plastic and glass, various sizes

Clamps

Conical centrifuge tubes, plastic and glass

Containers, assortment of glass and plastic, for gel and membrane washes

Coplin jars, glass, for 25 × 75–mm slides

Cryovials, sterile (e.g., Nunc)

Cuvettes

Desiccator and desiccant

Dry ice

Electrophoresis equipment, agarose and acrylamide, full-size and mini, with power supplies

Film developing system and darkroom

Filtration apparatus

Forceps

Fraction collector

Freezers, –20°C, –70°C, and liquid nitrogen

Fume hood

Geiger counter

Gel dryer

Gloves, disposable plastic and heat resistant

Graduated cylinders

Heating blocks, thermostatically controlled for test tubes and microcentrifuge tubes

Hemacytometer and/or electronic cell counter

Homogenizer

Humidified CO_2 incubator

Ice bucket

Ice maker

Immersion oil for microscopy

Lab coats

Laboratory glassware

Light box

Liquid nitrogen

Lyophilizer

Magnetic stirrer, with and without heater, and stir bars

Markers, including indelible markers, china-marking pens, and luminescent markers

Microcentrifuge, Eppendorf-type with 12,000 to 14,000 rpm maximum speed

Microcentrifuge tubes, 0.2-, 0.5-, 1.5-, 2-ml

Microscope slides, glass, 25 × 75–mm, and coverslips

Microscope with camera, upright, inverted, fluorescence, phase-contrast, dissecting

Microtiter plate reader

Mortar and pestle

Ovens, drying and microwave

Paper cutter, large

Paper towels

Parafilm

Pasteur pipets and bulbs

PCR thermal cycler and tubes

pH meter

pH paper

Pipets, graduated

Current Protocols in Cell Biology (1998) A.2C.1-A.2C.2

Pipettors, adjustable delivery, 0.5- to 10-µl, 10- to 200-µl, and 200- to 1000-µl

Polaroid camera or video documentation system

Power supplies, 300-V for polyacrylamide gels, 2000- to 3000-V for other applications

Racks, test tube and microcentrifuge tubes

Radiation shield, Lucite or Plexiglas

Radioactive waste containers for liquid and solid wastes

Refrigerator, 4°C

Ring stand and rings

Rubber policemen or plastic scrapers

Rubber stoppers

Safety glasses

Scalpels and blades

Scintillation counter, β

Scissors

Shakers, orbital and platform, room temperature or 37°C

Spectrophotometer, visible and UV range

Speedvac evaporator

Syringes and needles

Tape, masking, electrician's black, autoclave, and Time tape

Test tubes, glass and plastic, various sizes, with and without caps

Timer

Toolbox with common tools

Trays, plastic and glass, various sizes

Tubing, rubber and Tygon

UV light sources, long- and short-wavelength

UV transilluminator

UV transparent plastic wrap (e.g., Saran Wrap)

Vacuum desiccator

Vacuum oven

Vacuum supply

Vortex mixers

Waring blendor

Water bath with adjustable temperature

Water purification system

X-ray film cassettes and intensifying screens

COMMONLY USED TECHNIQUES

Molecular Biology Techniques

Protocols described in *Current Protocols in Cell Biology* may include molecular biology techniques and biochemical techniques that are not fully described in this book. Although it may be reasonable to assume that cell biologists have at least a basic understanding of these techniques, there are times when a full step-by-step description of the procedure is helpful. For that reason we have included the following table (Table A.3A.1), which lists techniques mentioned in this manual and provides cross-references to specific units in *Current Protocols in Molecular Biology* (CPMB) that describe the methods in detail. Protocols for some of these techniques will be added to this appendix in future supplements. Alternatively, the reader may wish to consult any of the many texts and manuals specifically devoted to recombinant DNA technology and biochemical analysis.

Spectrophotometric Determination of Protein Concentration

This unit describes spectrophotometric methods for measuring the concentration of a sample protein in solution. In Basic Protocol 1, absorbance measured at 280 nm (A_{280}) is used to calculate protein concentration by comparison with a standard curve or published absorptivity values for that protein (a_{280}). In the Alternate Protocol, absorbance measured at 205 nm (A_{205}) is used to calculate the protein concentration. The A_{280} and A_{205} methods can be used to quantitate total protein in crude lysates and purified or partially purified protein. Both of these methods are simple and can be completed quickly. The A_{280} method is the most commonly used. The A_{205} method can detect lower concentrations of protein and is useful for dilute protein samples, but is more susceptible to interference by reagents in the protein sample than the A_{280} method. Basic Protocol 2 uses a spectrofluorometer or a filter fluorometer to measure the intrinsic fluorescence emission of a sample solution; this value is compared with the emissions from standard solutions to determine the sample concentration. The fluorescence emission method is used to quantitate purified protein. This simple method is useful for dilute protein samples and can be completed in a short amount of time.

USING A_{280} TO DETERMINE PROTEIN CONCENTRATION

BASIC PROTOCOL 1

Determination of protein concentration by measuring absorbance at 280 nm (A_{280}) is based on the absorbance of UV light by the aromatic amino acids, tryptophan and tyrosine, and by cystine, disulfide-bonded cysteine residues, in protein solutions. The measured absorbance of a protein sample solution is used to calculate the concentration either from its published absorptivity at 280 nm (a_{280}) or by comparison with a calibration curve prepared from measurements with standard protein solutions. This assay can be used to quantitate solutions with protein concentrations of 20 to 3000 µg/ml.

Materials

3 mg/ml standard protein solution (see recipe; optional)
Sample protein
Spectrophotometer with UV lamp

1. For calibrating with standards, use the 3 mg/ml standard protein solution to prepare dilutions of 20, 50, 100, 250, 500, 1000, 2000, and 3000 µg/ml in the same solvent as used to prepare the sample protein. Prepare a blank consisting of solvent alone.

   Ideally, for purified or partially purified protein, the protein standard should have an aromatic amino acid content similar to that of the sample protein. For the total protein of a crude lysate, bovine serum albumin (BSA) is a commonly used standard for spectrophotometric quantitation of protein concentration. A 3 mg/ml solution of BSA should have an A_{280} of 1.98, based on an A_{280} of 6.61 for a 1% (w/v) solution.

2. Turn on the UV lamp of the spectrophotometer and set the wavelength to 280 nm. Allow the instrument to warm up 30 min before taking measurements.

3. Zero the spectrophotometer with the solvent blank.

4. Measure the absorbance of the protein standard and unknown solutions.

   If the A_{280} of the sample protein is >2.0, dilute the sample further in the same solvent and measure the A_{280} again.

Contributed by Michael H. Simonian
Current Protocols in Cell Biology (2002) A.3B.1-A.3B.7

5a. *If the a_{280} of the protein is known:* Calculate the unknown sample concentration from its absorbance value using Equation A.3B.1.

In this equation a_{280} has units of ml/mg cm and b is the path length in cm.

$$\text{concentration}\left(\text{mg/ml}\right) = \frac{A_{280}}{a_{280} \times b}$$

Equation A.3B.1

5b. *If standard solutions are used for quantitation:* Create a calibration curve by either plotting or performing regression analysis of the A_{280} versus concentration of the standards. Use the absorbance of the sample protein to determine the concentration from the calibration curve.

ALTERNATE PROTOCOL

USING A_{205} TO DETERMINE PROTEIN CONCENTRATION

Determination of protein concentration by measurement of absorbance at 205 nm (A_{205}) is based on absorbance by the peptide bond. The concentration of a protein sample is determined from the measured absorbance and the absorptivity at 205 nm (a_{205}). This assay can be used to quantitate protein solutions with concentrations of 1 to 100 µg/ml protein.

Additional Materials *(also see Basic Protocol 1)*

Brij 35 solution: 0.01% (v/v) Brij 35 (Sigma) in an aqueous solution appropriate for dissolving or diluting the sample protein

1. Dissolve or dilute the protein sample in Brij 35 solution.
2. Turn on the UV lamp of the spectrophotometer and set the wavelength to 205 nm. Allow the instrument to warm up 30 min before taking measurements.
3. Zero the spectrophotometer with the Brij 35 solution alone.
4. Measure the absorbance of the sample protein.

5a. *If the a_{205} of the protein is known:* Use Equation A.3B.1 to calculate the concentration of the sample protein *except* substitute the appropriate values for A_{205} and a_{205}.

5b. *If the a_{205} is not known:* Estimate the concentration of the sample protein from its measured absorbance using Equation A.3B.2.

$$\text{concentration}\left(\text{mg/ml}\right) = \frac{A_{205}}{31 \times b}$$

Equation A.3B.2

In this equation, the absorptivity value, 31, has units of ml/mg cm and b is the path length in cm.

USING FLUORESCENCE EMISSION TO DETERMINE PROTEIN CONCENTRATION

Protein concentration can also be determined by measuring the intrinsic fluorescence based on fluorescence emission by the aromatic amino acids tryptophan, tyrosine, and/or phenylalanine. Usually tryptophan fluorescence is measured. The fluorescence intensity of the protein sample solution is measured and the concentration calculated from a calibration curve based on the fluorescence emission of standard solutions prepared from the purified protein. This assay can be used to quantitate protein solutions with concentrations of 5 to 50 µg/ml.

Materials

Standard protein solution prepared using the purified protein (see recipe)
Sample protein
Spectrofluorometer *or* filter fluorometer with an excitation cutoff filter ≤285 nm and an emission filter >320 nm

1. Prepare dilutions of the purified protein at 5, 7.5, 10, 25, and 50 µg/ml in the same solvent as the sample protein. Prepare a blank consisting of solvent alone.
2. Turn on the lamp of the instrument and allow it to warm up 30 min before taking measurements.

   If a spectrofluorometer is used, set the excitation wavelength to 280 nm and the emission wavelength to between 320 and 350 nm. If the exact emission wavelength is not known, determine it empirically by scanning the standard solution with the excitation wavelength set to 280 nm. If the instrument is a filter fluorometer, use an excitation cutoff filter ≤285 nm and an emission filter >320 nm.
3. Zero the instrument with the solvent blank.
4. Measure the fluorescence of the protein standard and sample protein solutions.
5. Create a calibration curve by either plotting or performing regression analysis of the fluorescence intensity versus concentration of the standards. Using the fluorescence intensity of the sample protein, determine the concentration from the calibration curve.

   Fluorescence emission is a linear function of concentration only over a limited range.

REAGENTS AND SOLUTIONS

Use deionized distilled water for the preparation of all recipes and in all steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Standard protein solution, 3 mg/ml

Weigh out dry protein and prepare a stock solution at a concentration of 3 mg/ml in the same solvent as used for the sample protein. Store up to 3 months at −20°C.

To prepare calibration standard solutions, dilute the stock solution in solvent to give the desired final concentrations for the standard curve.

Bovine serum albumin (BSA, fraction V; Sigma) is frequently used for a protein standard solution. A 3 mg/ml solution of BSA should have an A_{280} of 1.98, based on an A_{280} of 6.61 for a 1% (w/v) solution.

For quantitation of a purified or partially purified protein, if possible, the protein standard should have an aromatic amino acid content similar to that of the sample protein.

COMMENTARY

Background Information

Measuring absorbance at 280 nm (A_{280}) is one of the oldest methods for determining protein concentration (Warburg and Christian, 1942; Layne, 1957). This method is still widely used because it is simple and does not require incubating the sample with exogenous chromophores. However, the detection limit is higher than colorimetric methods and therefore higher concentrations of protein are necessary. The A_{280} method requires that the protein being quantitated have aromatic amino acids, primarily tryptophan. Because of the variability in aromatic amino acid content among different proteins, their absorptivity at 280 nm (a_{280}) also varies. Therefore, if calibration standards are used for quantitation, the aromatic amino acid content of the standard must be similar to that of the sample protein for accurate results. For many previously studied proteins, the a_{280} is known and can be obtained from the literature (Fasman, 1989).

If the absorptivity is not known but the amino acid composition is known, the molar absorptivity at 280 nm (ε_{280}) can be predicted from Equation A.3B.3 (Pace et al., 1995):

$$\varepsilon_{280} = (\text{no. of Trp})(5500) + (\text{no. of Tyr})(1490) + (\text{no. of cystine})(125)$$

Equation A.3B.3

In this equation, the number of tryptophan (Trp), tyrosine (Tyr), and cystine residues are each multiplied by an estimated ε_{280} value for each residue. This equation was derived for folded proteins in water. With the DNA sequence for many proteins now available, the predicted ε_{280} can be derived for newer proteins where this value is not published. However, there are caveats that should be considered if the predicted ε_{280} in Equation A.3B.3 is used. First, the predicted ε_{280} is most reliable if the protein contains tryptophan residues and less so if there are no tryptophan residues. Second, the number of cystine residues must be accurately known and one cannot presume that all cysteine residues, to an even number, are involved in disulfide bonds. Alternatively, there are methods for measuring the ε_{280} value that are reliable (Pace et al., 1995).

Accordingly, the quantitation of proteins by peptide bond absorption at 205 nm (A_{205}) is more universally applicable among proteins. Furthermore, the absorptivity for a given protein at 205 nm is several-fold greater than that at 280 nm (Scopes, 1974; Stoscheck, 1990). Thus lower concentrations of protein can be quantitated with the A_{205} method. The disadvantage of this method is that some buffers and other components absorb at 205 nm (Stoscheck, 1990).

In addition to the aromatic amino acids, several others have absorption maxima in the UV range. Table A.3B.1 shows the wavelengths of absorption maxima and corresponding molar absorptivity (ε) for the amino acids with appreciable absorbance in the UV range. Only tryptophan has an absorption maximum at 280 nm,

Table A.3B.1 Absorption Maxima and Molar Absorptivity (ε) of Amino Acids[a]

Amino acid	Wavelength maxima (nm)	$\varepsilon \times 10^{-3}$ (l/mol cm)
Cysteine	250	0.3
Histidine	211	5.9
Phenylalanine	188	60.0
	206	9.3
	257	0.2
Tryptophan	219	47.0
	279	5.6
Tyrosine	193	48.0
	222	8.0
	275	1.4

[a]Values are for aqueous solutions at pH 7.1 (Freifelder, 1982; Fasman, 1989).

Table A.3B.2 Molar Absorptivity (ε) of Amino Acids at 280 nm[a]

Amino acid	$\varepsilon \times 10^{-3}$ (l/mol cm)
Cystine	0.110
Phenylalanine	0.0007
Tryptophan	5.559
Tyrosine	1.197

[a]Values are for aqueous solutions at pH 7.1 except for cystine, which is for water (Fasman, 1989).

Table A.3B.3 Fluorescence Properties of Aromatic Amino Acids[a]

Amino acid	Excitation wavelength	Emission wavelength	Quantum yield
Phenylalanine	260 nm	283 nm	0.04
Tryptophan	285 nm	360 nm	0.20
Tyrosine	275 nm	310 nm	0.21

[a]Values are for aqueous solutions at pH 7 and 25°C (Hawkins and Honigs, 1987; Fasman, 1989).

although, tyrosine and cystine will also slightly absorb. The ε_{280} for tryptophan is nearly five-fold greater than that for tyrosine and 50-fold greater than that for cystine (Table A.3B.2). The contribution to the absorbance at 280 nm of the third aromatic amino acid, phenylalanine, and cysteine are negligible. Several amino acids other than those in Table A.3B.1 absorb light below 205 nm (Fasman, 1989), but either the molar absorptivities are too low to be significant or the wavelengths are too short for practical absorbance measurements.

The aromatic amino acids also have fluorescence emissions when excited by light in the UV range. Table A.3B.3 gives the excitation wavelength, fluorescence emission wavelength, and quantum yield (Q) for tryptophan, tyrosine, and phenylalanine. The quantum yield is the ratio of photons emitted to photons absorbed. Typically, phenylalanine fluorescence is not detected in the presence of tyrosine and tryptophan due to low Q. Furthermore, tyrosine fluorescence is nearly completely quenched if the tyrosine residue is ionized or near an amino group, a carboxyl group, or a tryptophan residue (Teale, 1960; Freifelder, 1982). Therefore, tryptophan fluorescence is what is customarily measured.

Measurement of intrinsic fluorescence by aromatic amino acids is primarily used to obtain qualitative information (Freifelder, 1982). However, with a protein standard whose aromatic amino acid content is similar to that of the sample, intrinsic fluorescence can be used for quantitation (Hawkins and Honigs, 1987). An additional consideration is that the tertiary structure of a protein will influence the fluorescence, e.g., adjacent protonated acidic groups in a protein molecule will quench tryptophan fluorescence (Freifelder, 1982).

Critical Parameters and Troubleshooting

A 1-cm path length quartz cuvette is most often used to make absorbance measurements. However, quartz cuvettes with shorter path lengths, 0.01 to 0.5 cm, are available (e.g., from Hellma Cells or Beckman); these shorter path length cuvettes allow higher concentrations of protein solutions to be measured. Equation A.3B.1 and Equation A.3B.2 assume the cuvette has a path length of 1 cm; when cuvettes of shorter path length are used, the correct value for b must be substituted in the equation.

The solvent pH and polarity will affect the absorbance and fluorescence properties of a protein. A notable example of pH effects on absorbance is seen with tyrosine residues, where a change in pH from neutral to alkaline results in a shift of the absorbance maximum to a longer wavelength and an increase in absorptivity due to dissociation of the tyrosine phenolic hydroxyl group (Freifelder, 1982; Fasman, 1989). An example of solvent polarity effects on fluorescence is observed with tryptophan, where a decrease in solvent polarity

Table A.3B.4 Concentration Limits of Interfering Reagents for A_{205} and A_{280} Protein Assays[a]

Reagent[b]	A_{205}	A_{280}
Ammonium sulfate	9% (w/v)	>50% (w/v)
Brij 35	1% (v/v)	1% (v/v)
DTT	0.1 mM	3 mM
EDTA	0.2 mM	30 mM
Glycerol	5% (v/v)	40% (v/v)
KCl	50 mM	100 mM
2-ME	<10 mM	10 mM
NaCl	0.6 M	>1 M
NaOH	25 mM	>1 M
Phosphate buffer	50 mM	1 M
SDS	0.10% (w/v)	0.10% (w/v)
Sucrose	0.5 M	2 M
Tris buffer	40 mM	0.5 M
Triton X-100	<0.01% (v/v)	0.02% (v/v)
TCA	<1% (w/v)	10% (w/v)
Urea	<0.1 M	>1 M

[a]Values from Stoscheck (1990).

[b]Abbreviations: DTT, dithiothreitol; EDTA, ethylenediaminetetraacetic acid; 2-ME, 2-mercaptoethanol; SDS, sodium dodecyl sulfate; TCA, trichloroacetic acid.

results in a shift in fluorescence emission to shorter wavelengths and an increase in intensity (Freifelder, 1982). Because of these effects, the following precautions should be taken for accurate results: (1) when calibration curves are used for quantitation by absorbance or fluorescence, standards must be in the same solvent as the samples; and (2) when a published absorptivity at a given wavelength is used for quantitation, the solvent composition of the sample must be the same as that used in obtaining the published data.

Many buffers and other reagents can interfere with A_{280} and A_{205} spectrophotometric measurements. Stoscheck (1990) lists the concentration limits for many such reagents used in these spectrophotometric methods. The more commonly used reagents that absorb at 280 and 205 nm are listed in Table A.3B.4. In addition, reagents that contain carbon-carbon or carbon-oxygen double bonds can interfere with the A_{205} method.

Because stray light can affect the linearity of absorbance versus concentration, absorbance values >2.0 should not be used for sample proteins measured by the A_{280} or A_{205} method. Samples with absorbance >2.0 should be diluted further in the appropriate buffer to obtain absorbances <2.0.

Nucleic acids have substantial absorbance at 280 nm and can interfere with A_{280} quantitation of protein in crude samples. To resolve the protein concentration in such samples, measure the absorbance at 260 nm and 280 nm and calculate the protein concentration as follows (Warburg and Christian, 1942; Layne, 1957): protein concentration (mg/ml) = $1.55 \times A_{280} - 0.76 \times A_{260}$.

This estimation of protein concentration is valid up to 20% (w/v) nucleic acid or an A_{280}/A_{260} ratio <0.6.

Anticipated Results

Depending on the protein, the concentration range for the A_{280} method is 20 to 3000 µg/ml, for the A_{205} method is 1 to 100 µg/ml, and for the fluorescence emission method is 5 to 50 µg/ml.

Published absorptivities of proteins at 280 nm are usually given as the absorbance for a 1% (w/v) protein solution per cm, $A^{1\%}$, or as the molar absorptivity, ε, which has units of l/mol cm. To convert these published coeffi-

cients to units of mg/ml, use either Equation A.3B.4 or Equation A.3B.5.

$$\text{concentration}\left(\text{mg/ml}\right) = \frac{A_{280} \times 10}{A^{1\%} \times b}$$

Equation A.3B.4

Molecular weight in Equation A.3B.5 is the molecular weight of the protein.

$$\text{concentration}\left(\text{mg/ml}\right) = \frac{A_{280} \times \text{molecular weight}}{\varepsilon_{280} \times b}$$

Equation A.3B.5

Time Considerations

When the absorptivity for a protein is known, the A_{280} and A_{205} measurements require <30 min depending on the number of samples. When standards are used for quantitation with these assays or for intrinsic fluorescence quantitation, 1 hr is required.

Dialysis and Concentration of Protein Solutions

DIALYSIS

Conventional dialysis separates small molecules from large molecules by allowing diffusion of only the small molecules through selectively permeable membranes. Dialysis is usually used to change the salt (small-molecule) composition of a macromolecule-containing solution. The solution to be dialyzed is placed in a sealed dialysis membrane and immersed in a selected buffer; small solute molecules then equilibrate between the sample and the dialysate. Concomitant with the movement of small solutes across the membrane, however, is the movement of solvent in the opposite direction. This can result in some sample dilution (usually <50%).

This unit describes dialysis of large- and small-volume samples using cellulose membranes with pore sizes designed to exclude molecules above a selected molecular weight (Basic Protocol 1 and Alternate Protocol). The Support Protocol describes preparation of membranes for dialysis and discusses issues related to the selection of membranes including commercial kits. Solutions of proteins or peptides can be concentrated using commercially available reagents (see Basic Protocol 2).

Large-Volume Dialysis

BASIC PROTOCOL 1

This protocol describes the use of membranes, prepared using the support protocol, for dialysis of samples in large, easily handled volumes, typically 0.1 to 500 ml.

Materials

Dialysis membrane (see Support Protocol)
Clamps (Spectra/Por Closures, Spectrum, or equivalent)
Macromolecule-containing sample to be dialyzed
Appropriate dialysis buffer

1. Remove dialysis membrane from ethanol storage solution and rinse with distilled water. Secure clamp to one end of the membrane or knot one end with double-knots.

   Always use gloves to handle the dialysis membrane because the membrane is susceptible to cellulolytic microorganisms.

   See Support Protocol for a discussion of commercially available membranes and preparation and storage procedures.

   Clamps are less likely to leak than knots, but either type of closure should be carefully tested as described in steps 2 and 3.

2. Fill membrane with water or buffer, hold the unclamped end closed, and squeeze membrane. A fine spray of liquid indicates a pinhole in the membrane; discard and try a new membrane.

   Pinholes are rare but cause traumatic sample loss. Hard squeezing will cause some liquid to seep from the bag; this is normal.

3. Replace the water or buffer in dialysis membrane with the macromolecule-containing sample and clamp the open end. Again, squeeze to check the integrity of the membrane and clamps.

   If dialyzing a concentrated or high-salt sample, leave some space in the clamped membrane; there will be a net flow of water into the sample, and if sufficient pressure builds up the membrane can burst.

Contributed by Sarah M. Andrew, Julie A. Titus, and Louis Zumstein
Current Protocols in Cell Biology (1999) A.3C.1-A.3C.5

4. Immerse dialysis membrane in a beaker or flask containing a large volume (relative to the sample) of the desired buffer. Dialyze at least 3 hr at the desired temperature with gentle stirring of the buffer.

   Dialysis rates are dependent on membrane pore size, sample viscosity, and ratio of membrane surface to sample volume. Temperature has little effect on dialysis rate, but low temperatures (i.e., 4°C) are usually chosen to enhance macromolecule stability. Common salts will equilibrate across a 15,000-MWCO membrane (see Support Protocol) in ~3 hr with stirring.

   Some compounds, especially detergents above their critical micelle concentration (CMC), dialyze very slowly.

5. Change dialysis buffer as necessary.

   Usually two to three dialysis buffer changes are sufficient. For example, when 100 mM Tris·Cl is removed from a protein for sequence analysis or other amino-reactive chemistry, two equilibrations against a 1000-fold volume excess of buffer will decrease the Tris concentration 10^6-fold, to 100 nM; three dialyses will decrease the concentration to 100 pM.

6. Remove dialysis membrane from the buffer. Hold the membrane vertically and remove excess buffer trapped in end of membrane outside upper clamp. Release upper clamp and remove the sample with a Pasteur pipet.

ALTERNATE PROTOCOL

Small-Volume Dialysis

For solution volumes less than ~100 µl, the use of dialysis membrane as described above can result in unacceptable sample loss. The method described below can easily dialyze volumes as small as 10 µl. The sample is held in a 0.5-ml microcentrifuge tube, with dialysis membrane covering the open end of the tube.

Additional Materials *(also see Basic Protocol 1)*

0.5-ml microcentrifuge tube
Pasteur pipet
Cork borer

1. Puncture the lid of each microcentrifuge tube using a heated glass Pasteur pipet (wide end heated) or cork borer to completely remove the center part of the lid (see Fig. A.3C.1). Open lid and place a single layer of dialysis tubing over top of tube, then close lid to hold dialysis tubing in place.

   The success of this protocol is dependent on a tight-fitting cap, so make sure the cap is well-seated. On the other hand, an excessively tight-fitting cap can rip the membrane when it is inserted.

   Alternatively, some researchers use a microcentrifuge tube without a cap. The sample is placed in the microcentrifuge tube, a dialysis membrane is placed over the top of the tube, and the membrane is secured with a rubber band. With this method, however, there is a risk that a small sample—e.g., 10 to 20 µl—may be lost around the edge of the tube.

2. Turn tube upside down and shake reaction mixture onto the membrane surface. Tape each tube, dialysis surface down, to the side of a beaker, then fill the beaker with PBS or buffer of choice. Dialyze 2 hr at 4°C with stirring.

   Alternatively, place the tube in a styrofoam or foam sheet (e.g., foam microcentrifuge rack, Fisher) then place, with the tube inverted, on the surface of the dialysis buffer.

   Make sure the dialysis surface is in contact with the buffer and that no bubbles exist. This can be accomplished by gently centrifuging the tube in an inverted position in a tabletop centrifuge.

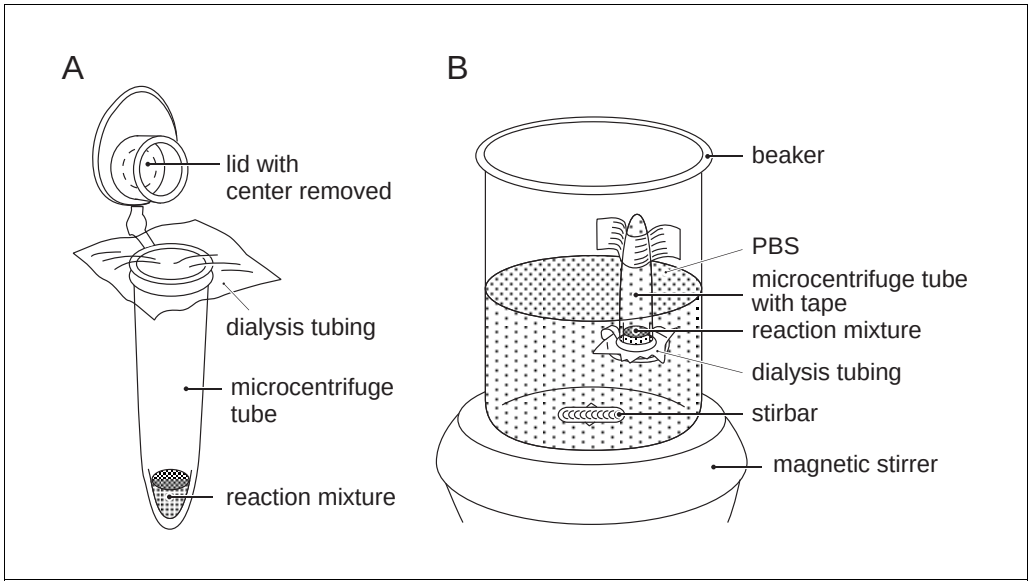

Figure A.3C.1 Making a microdialysis chamber. (**A**) Remove the center of the cap of a microcentrifuge tube with a heated Pasteur pipet (wide end). Place reaction mixture to be dialyzed into the tube. Place a piece of softened dialysis membrane loosely over top of tube. (**B**) Invert tube, shake sample down onto dialysis membrane (or centrifuge the tube inverted, if the sample is small), and tape tube into a beaker of buffer. Check that no bubbles are caught under the membrane.

The microdialysis method can be used for volumes of 50 to 500 µl (larger volumes can be dialyzed using a 1.5-ml microcentrifuge tube). The protein concentration is not important but should be 0.1 to 10 mg/ml. Most dialysis is complete after 2 hr but because proteins have a high buffering capacity, use 4 hr for a high protein concentration.

3. To recover the sample, remove microcentrifuge tube from the buffer and centrifuge briefly right-side-up.

Commercially available alternatives to this method include use of individual hollow-fiber filters from Spectrum (with sample capacities of 1 to 140 µl), and many different microdialysis machines, both single-sample and multisample (Spectrum, Cole-Parmer, Hoefer Pharmacia, and others).

Selection and Preparation of Dialysis Membrane

SUPPORT PROTOCOL

Dialysis membranes are available in a number of thicknesses and pore sizes. Thicker membranes are tougher, but restrict solute flow; thus equilibrium is reached more slowly. Pore size is defined by "molecular weight cutoff" (MWCO)—i.e., the size of the smallest particle that cannot penetrate the membrane. The MWCO designation should be used only as a very rough guide; if accurate MWCO information is required, it should be determined empirically (see Craig, 1967, for a discussion of parameters affecting MWCO). Knowledge of the precise MWCO is usually not required; it is necessary only to use a membrane with a pore size that is much smaller than the macromolecule of interest. For most plasmid and protein dialyses, a MWCO of 12,000 to 14,000 is appropriate, whereas a MWCO of 3500, 2000, or even 1000 is appropriate for peptides.

Most dialysis membranes are made of derivatives of cellulose. They come in a wide variety of MWCO values, ranging from 500 to 500,000, and also vary in cleanliness, sterility, and cost. Spectrum has the most impressive inventory. The least expensive membranes come dry on rolls; these contain glycerol to keep them flexible as well as residual sulfides and traces of heavy metals from their manufacture. If glycerol, sulfur compounds, or small amounts of heavy metals are problematic, cleaner membranes should be purchased or

membranes should be prepared as described below. Protein dialysis should only be done with clean membranes.

It should be noted that several commercial kits for performing either large-scale or microdialysis are also available. For example, use of microdialysis cassettes (Slide-A-Lyzer, Pierce; or Dispo-Dialyzer, Spectrum) eliminates the need for boiling or presoaking dialysis tubing as well as the cumbersome task of clamping the dialysis tubing. Other vendors provide vessels for dialyzing multiple samples simultaneously. Selection of the best dialysis approach to be used will depend on a number of factors including the volumes to be dialyzed, the MWCO appropriate for the sample, and, of course, costs when considering the use of kits.

Materials

Dialysis membrane
10 mM sodium bicarbonate
10 mM Na_2EDTA, pH 8.0
20% to 50% (v/v) ethanol

1. Remove membrane from the roll and cut into usable lengths (usually 8 to 12 in.).

   Always use gloves to handle dialysis membrane, as it is susceptible to a number of cellulolytic microorganisms. Membrane is available as sheets or preformed tubing.

2. Wet membrane and boil it for several minutes in a large excess of 10 mM sodium bicarbonate.
3. Boil several minutes in 10 mM Na_2EDTA. Repeat.

   Boiling speeds up the treatment process but is not necessary. A 30-min soak with some agitation can substitute for the boiling step.

4. Wash several times in distilled water.
5. Store at 4°C in 20% to 50% ethanol to prevent growth of cellulolytic microorganisms.

   Alternatively, bacteriostatic agents (e.g., sodium azide or sodium cacodylate) may be used for storage; however, ethanol is preferred for ease and convenience.

BASIC PROTOCOL 2

CONCENTRATION

Because it is usually more convenient to store antibodies or other proteins at >1 mg/ml, it may be necessary to concentrate the solution. In addition, concentration of protein solutions is often necessary to decrease the volume of a sample; e.g., to load onto a size-exclusion column when the volume must be ≤5 ml.

There are several simple and relatively inexpensive methods for concentrating protein solutions. Dialysis against Aquacide 11A (Calbiochem), which removes water through the dialysis tubing, may be used. After concentration, the solution must be redialyzed into the appropriate buffer. Another method is to use Immersible-CX Ultrafilters (Millipore) which, when connected to a vacuum, remove everything below their molecular weight cutoff (MWCO).

Alternatively, centrifugal concentrators which are operated with the aid of ordinary laboratory centrifuges may be used. Centricon microconcentrators (Amicon), which are available in different MWCO sizes, are very useful for concentrating small amounts of material in small volumes. Follow the instructions from the manufacturer when using these devices. Centriprep Centrifugal Filter Devices (Millipore) are disposable ultrafiltration devices used for purifying, concentrating, and desalting biological samples in the 2 to 15 ml volume range and are designed for use with most centrifuges that can accommodate 50-ml centrifuge tubes. Further description of these devices and instructions for their use are available at *http://www.millipore.com*.

Quantification of DNA and RNA with Absorption and Fluorescence Spectroscopy

Reliable quantitation of nanogram and microgram amounts of DNA and RNA in solution is essential to researchers in cell and molecular biology. In addition to the traditional absorbance measurements at 260 nm (see Basic Protocol), two more sensitive fluorescence techniques (see Alternate Protocols 1 and 2) are presented below. These three procedures cover a range from 5 to 10 ng/ml DNA to 50 μg/ml DNA (see Commentary and Table A.3D.3 therein).

Absorbance measurements are straightforward as long as any contribution from contaminants and the buffer components are taken into account. Fluorescence assays are less prone to interference than A_{260} measurements and are also simple to perform. As with absorbance measurement, a reading from the reagent blank is taken prior to adding the DNA. In instruments where the readout can be set to indicate concentration, a known concentration is used for calibration and subsequent readings are taken in ng/ml or μg/ml DNA.

DETECTION OF NUCLEIC ACIDS USING ABSORPTION SPECTROSCOPY

BASIC PROTOCOL

Absorption of the sample is measured at several different wavelengths to assess purity and concentration of nucleic acids. A_{260} measurements are quantitative for relatively pure nucleic acid preparations in microgram quantities. Absorbance readings cannot discriminate between DNA and RNA; however, the ratio of *A* at 260 and 280 nm can be used as an indicator of nucleic acid purity. Proteins, for example, have a peak absorption at 280 nm that will reduce the A_{260}/A_{280} ratio. Absorbance at 325 nm indicates particulates in the solution or dirty cuvettes; contaminants containing peptide bonds or aromatic moieties such as protein and phenol absorb at 230 nm.

This protocol is designed for a single-beam ultraviolet to visible range (UV-VIS) spectrophotometer. If available, a double-beam spectrophotometer will simplify the measurements, as it will automatically compare the cuvette holding the sample solution to a reference cuvette that contains the blank. In addition, more sophisticated double-beam instruments will scan various wavelengths and report the results automatically.

Materials

1× TNE buffer (see recipe)
DNA sample to be quantitated
Calf thymus DNA standard solutions (see recipe)

Matched quartz semi-micro spectrophotometer cuvettes (1-cm pathlength)
Single- or dual-beam spectrophotometer (ultraviolet to visible)

1. Pipet 1.0 ml of 1× TNE buffer into a quartz cuvette. Place the cuvette in a single- or dual-beam spectrophotometer, read at 325 nm (note contribution of the blank relative to distilled water if necessary), and zero the instrument. Use this blank solution as the reference in double-beam instruments. For single-beam spectrophotometers, remove blank cuvette and insert cuvette containing DNA sample or standard suspended in the same solution as the blank. Take reading. Repeat this process at 280, 260, and 230 nm.

   It is important that the DNA be suspended in the same solution as the blank.

Current Protocols in Cell Biology (2000) A.3D.1-A.3D.8

2. To determine the concentration (C) of DNA present, use the A_{260} reading in conjunction with one of the following equations:

$$\textit{Single-stranded DNA}: \quad C\ (\text{pmol}/\mu\text{l}) = \frac{A_{260}}{10 \times S}$$

$$C\ (\mu\text{g}/\text{ml}) = \frac{A_{260}}{0.027}$$

$$\textit{Double-stranded DNA}: \quad C\ (\text{pmol}/\mu\text{l}) = \frac{A_{260}}{13.2 \times S}$$

$$C\ (\mu\text{g}/\text{ml}) = \frac{A_{260}}{0.020}$$

$$\textit{Single-stranded RNA}: \quad C\ (\mu\text{g}/\text{ml}) = \frac{A_{260}}{0.025}$$

$$\textit{Oligonucleotide}: \quad C\ (\text{pmol}/\mu\text{l}) = A_{260} \times \frac{100}{1.5\,N_{\text{A}} + 0.71\,N_{\text{C}} + 1.20\,N_{\text{G}} + 0.84\,N_{\text{T}}}$$

where S represents the size of the DNA in kilobases and N is the number or residues of base A, G, C, or T.

For double- or single-stranded DNA and single-stranded RNA: These equations assume a 1-cm-pathlength spectrophotometer cuvette and neutral pH. The calculations are based on the Lambert-Beer law, $A = \varepsilon Cl$, where A is the absorbance at a particular wavelength, C is the concentration of DNA, l is the pathlength of the spectrophotometer cuvette (typically 1 cm), and ε is the extinction coefficient. For solution concentrations given in mol/liter and a cuvette of 1-cm pathlength, ε is the molar extinction coefficient and has units of $M^{-1}cm^{-1}$. If concentration units of μg/ml are used, then ε is the specific absorption coefficient and has units of $(\mu g/ml)^{-1}cm^{-1}$. The values of ε used here are as follows: ssDNA, 0.027 $(\mu g/ml)^{-1}cm^{-1}$; dsDNA, 0.020 $(\mu g/ml)^{-1}cm^{-1}$; ssRNA, 0.025 $(\mu g/ml)^{-1}cm^{-1}$. Using these calculations, an A_{260} of 1.0 indicates 50 μg/ml double-stranded DNA, ~37 μg/ml single-stranded DNA, or ~40 μg/ml single-stranded RNA (adapted from Applied Biosystems, 1989).

For oligonucleotides: Concentrations are calculated in the more convenient units of pmol/μl. The base composition of the oligonucleotide has significant effects on absorbance, because the total absorbance is the sum of the individual contributions of each base (Table A.3D.1).

3. Use the A_{260}/A_{280} ratio and readings at A_{230} and A_{325} to estimate the purity of the nucleic acid sample.

Ratios of 1.8 to 1.9 and 1.9 to 2.0 indicate highly purified preparations of DNA and RNA, respectively. Contaminants that absorb at 280 nm (e.g., protein) will lower this ratio.

Table A.3D.1 Molar Extinction Coefficients of DNA Bases[a]

Base	$\varepsilon^{1M}_{260\ nm}$
Adenine	15,200
Cytosine	7,050
Guanosine	12,010
Thymine	8,400

[a]Measured at 260 nm; see Wallace and Miyada, 1987.

Table A.3D.2 Spectrophotometric Measurements of Purified DNA[a]

Wavelength (nm)	Absorbance	A_{260}/A_{280}	Conc. (μg/ml)
325	0.01	—	—
280	0.28	—	—
260	0.56	2.0	28
230	0.30	—	—

[a]Typical absorbancy readings of highly purified calf thymus DNA suspended in 1× TNE buffer. The concentration of DNA was nominally 25 μg/ml.

Absorbance at 230 nm reflects contamination of the sample by phenol or urea, whereas absorbance at 325 nm suggests contamination by particulates and dirty cuvettes. Light scatter at 325 nm can be magnified 5-fold at 260 nm (K. Hardy, pers. comm.).

Typical values at the four wavelengths for a highly purified preparation are shown in Table A.3D.2.

DNA DETECTION USING THE DNA-BINDING FLUOROCHROME HOECHST 33258

ALTERNATE PROTOCOL 1

Use of fluorometry to measure DNA concentration has gained popularity because it is simple and much more sensitive than spectrophotometric measurements. Specific for nanogram amounts of DNA, the Hoechst 33258 fluorochrome has little affinity for RNA and works equally well with either whole-cell homogenates or purified preparations of DNA. The fluorochrome is, however, sensitive to changes in DNA composition, with preferential binding to AT-rich regions. A fluorometer capable of an excitation wavelength of 365 nm and an emission wavelength of 460 nm is required for this assay.

Additional Materials *(also see Basic Protocol)*

Hoechst 33258 assay solution (working solution; see recipe)
Dedicated filter fluorometer (e.g., Amersham Pharmacia Biotech DQLOO) *or* scanning fluorescence spectrophotometer (e.g., Shimadzu model RF-5000 or Perkin-Elmer model LS-5B or LS-3B)
Fluorometric square glass cuvettes *or* disposable acrylic cuvettes (Sarstedt)
Teflon stir rod

1. Prepare the scanning fluorescence spectrophotometer by setting the excitation wavelength to 365 nm and the emission wavelength to 460 nm.

   The dedicated filter fluorometer has fixed wavelengths at 365 and 460 nm and does not need adjustment.

2. Pipet 2.0 ml Hoechst 33258 assay solution into cuvette and place in sample chamber. Take a reading without DNA and use as background.

   If the fluorometer has a concentration readout mode or is capable of creating a standard curve, set instrument to read 0 with the blank solution. Otherwise note the readings in relative fluorescence units. Be sure to take a blank reading for each cuvette used, as slight variations can cause changes in the background reading.

3. With the cuvette still in the sample chamber, add 2 μl DNA standard to the blank Hoechst 33258 assay solution. Mix in the cuvette with a Teflon stir rod or by capping and inverting the cuvette. Read emission in relative fluorescence units or set the concentration readout equal to the final DNA concentration. Repeat measurements with remaining DNA standards using fresh assay solution (take background zero reading and zero instrument if needed).

If necessary, the DNA standards should be quantitated by A_{260} measurement (Basic Protocol) before being used here.

Small-bore tips designed for loading sequencing gels minimize errors of pipetting small volumes. Prerinse tips with sample and make sure no liquid remains outside the tip after drawing up the sample.

Read samples in duplicate or triplicate, with a blank reading taken each time. Unusual or unstable blank readings indicate a dirty cuvette or particulate material in the solution, respectively.

4. Repeat step 3 with unknown samples.

A dye concentration of 0.1 μg/ml is adequate for final DNA concentrations up to ~500 ng/ml. Increasing the working dye concentration to 1 μg/ml Hoechst 33258 will extend the assay's range to 15 μg/ml DNA, but will limit sensitivity at low concentrations (5 to 10 ng/ml). Sample volumes of ≤10 μl can be added to the 2.0-ml aliquot of Hoechst 33258 assay solution.

ALTERNATE PROTOCOL 2

DNA AND RNA DETECTION WITH ETHIDIUM BROMIDE FLUORESCENCE

In contrast to the fluorochrome Hoechst 33258, ethidium bromide is relatively unaffected by differences in the base composition of DNA. Ethidium bromide is not as sensitive as Hoechst 33258 and, although capable of detecting nanogram levels of DNA, will also bind to RNA. In preparations of DNA with minimal RNA contamination or with DNA samples having an unusually high guanine and cytosine (GC) content where the Hoechst 33258 signal can be quite low, ethidium bromide offers a relatively sensitive alternative to the more popular Hoechst 33258 DNA assay. A fluorometer capable of an excitation wavelength of 302 or 546 nm and an emission wavelength of 590 nm is required for this assay.

Additional Materials *(also see Basic Protocol)*

Ethidium bromide assay solution (see recipe)

1. Pipet 2.0 ml ethidium bromide assay solution into cuvette and place in sample chamber. Set excitation wavelength to 302 nm or 546 nm and emission wavelength to 590 nm. Take an emission reading without DNA and use as background.

If the instrument has a concentration readout mode or is capable of creating a standard curve, set instrument to read 0 with the blank solution. Otherwise note the readings in relative fluorescence units.

The excitation wavelength of this assay can be either in the UV range (~302 nm) using a quartz cuvette or in the visible range (546 nm) using a glass cuvette. In both cases the emission wavelength is 590 nm.

2. Read and calibrate these samples as described in step 3 of the Hoechst 33258 assay.

3. Read emissions of the unknown samples as in step 4 of the Hoechst 33258 assay.

A dye concentration of 5 μg/ml in the ethidium bromide assay solution is appropriate for final DNA concentrations up to 1000 ng/ml. 10 μg/ml ethidium bromide in the ethidium bromide assay solution will extend the assay's range to 10 μg/ml DNA, but is only used for DNA concentrations >1 μg/ml. Sample volumes of up to 10 μl can be added to the 2.0-ml aliquot of ethidium bromide assay solution.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Calf thymus DNA standard solutions

Kits containing calf thymus DNA standard for fluorometry are available (Fluorometry Reference Standard Kits, Hoefer). Premeasured, CsCl-gradient-purified DNA of defined GC content, for use in absorption and fluorometric spectroscopy, is available from Sigma (e.g., calf thymus DNA, 42% GC; *Clostridium perfringens* DNA, 26.5% GC).

Ethidium bromide assay solution

Add 10 ml of 10× TNE buffer (see recipe) to 89.5 ml H_2O. Filter through a 0.45-µm filter, then add 0.5 ml of 1 mg/ml ethidium bromide.

Add the dye after filtering, as ethidium bromide will bind to most filtration membranes.

CAUTION: *Ethidium bromide is hazardous; wear gloves and use appropriate care in handling, storage, and disposal.*

Hoechst 33258 assay solutions

Stock solution: Dissolve in H_2O at 1 mg/ml. Stable for ~6 months at 4°C.

Working solution: Add 10 ml of 10× TNE buffer (see recipe) to 90 ml H_2O. Filter through a 0.45-µm filter, then add 10 µl of 1 mg/ml Hoechst 33258.

Hoechst 33258 is a fluorochrome dye with a molecular weight of 624 and a molar extinction coefficient of $4.2 \times 10^4\ M^{-1}cm^{-1}$ *at 338 nm.*

The dye is added after filtering because it will bind to most filtration membranes.

CAUTION: *Hoechst 33258 is hazardous; use appropriate care in handling, storage, and disposal.*

TNE buffer, 10×

100 mM Tris base
10 mM EDTA
2.0 M NaCl
Adjust pH to 7.4 with concentrated HCl
As needed, dilute with H_2O to desired concentration

COMMENTARY

Background Information

In deciding what method of nucleic acid measurement is appropriate, three issues are critical: specificity, sensitivity, and interfering substances. Properties of the three assays described in this section are listed in Table A.3D.3. The traditional method for determining the amount of DNA in solution is by measuring absorbance at 260 nm. Because many potential contaminants of DNA and RNA preparations also absorb in the UV range, absorption spectroscopy is a reliable method to assess both the purity of a preparation and the quantity of DNA or RNA present. Absorption spectroscopy does have serious limitations. Relatively large amounts of DNA are required to get accurate readings—for example, 500 ng/ml DNA is equivalent to only 0.01 A_{260} units. Furthermore, the method cannot discriminate between RNA and DNA, and UV-absorbing contaminants such as protein will cause discrepancies.

The assay using Hoechst 33258 dye (Alternate Protocol 1) is the only procedure in common use that is specific for DNA (i.e., it does not measure RNA). This assay is the method of choice for rapid measurement of low quantities of DNA, with a detection limit of ~1 ng DNA. Concentrations of DNA in both crude cell lysates and purified preparations can be quantified (Labarca and Paigen, 1980). Because the assay quantifies a broad range of DNA concentrations—from 10 ng/ml to 15 µg/ml—it is useful for the measurement of both small and large amounts of DNA (e.g., in verifying DNA

Table A.3D.3 Properties of Absorbance and Fluorescence Spectrophotometric Assays for DNA and RNA

Property	Absorbance (A_{260})	Fluorescence	
		H33258	EtBr
Sensitivity (μg/ml)			
DNA	1-50	0.01-15	0.1-10
RNA	1-40	n.a.	0.2-10
Ratio of signal (DNA/RNA)	0.8	400	2.2

concentrations prior to performing electrophoretic separations and Southern blots). The Hoechst 33258 assay is also useful for measuring products of the polymerase chain reaction (PCR) synthesis.

Upon binding to DNA, the fluorescence characteristics of Hoechst 33258 change dramatically, showing a large increase in emission at ~458 nm. Hoechst 33258 is nonintercalating and apparently binds to the minor groove of the DNA, with a marked preference for AT sequences (Portugal and Waring, 1988). The fluorochrome 4′,6-diamidino-2-phenylindole (DAPI; Daxhelet et al., 1989) is also appropriate for DNA quantitation, although it is not as commonly used as Hoechst 33258. DAPI is excited with a peak at 344 nm. Emission is detected at ~466 nm, similar to Hoechst 33258.

Ethidium bromide is best known for routine staining of electrophoretically separated DNA and RNA, but it can also be used to quantify both DNA and RNA in solution (Le Pecq, 1971). Unlike Hoechst 33258, ethidium bromide fluorescence is not significantly impaired by high GC content. The ethidium bromide assay (with excitation at 546 nm) is ~20-fold less sensitive than the Hoechst 33258 assay.

Critical Parameters

Care should be taken when handling sample cuvettes in all spectrophotometric procedures. Fluorometers use cuvettes with four optically clear faces, because excitation and emitting light enter and leave the cuvette through directly adjacent sides. Thus, fluorometric cuvettes should be held by the upper edges only. In contrast, transmission spectrophotometers use cuvettes with two opposite optical windows, with the sides frosted for easy handling. It is important to check that the optical faces of cuvettes are free of fingerprints and scratches. In addition, for accurate absorbance readings, spectrophotometer cuvettes must be perfectly matched.

Proteins in general have A_{280} readings considerably lower than nucleic acids on an equivalent weight basis. Thus, even a small increase in the A_{280} relative to A_{260} (i.e., a lowering of the A_{260}/A_{280} ratio) can indicate severe protein contamination. Other commonly used buffer components absorb strongly at 260 nm and can cause interference if present in high enough concentrations. EDTA, for example, should not be present at ≥10 mM.

Sensitivity of the Hoechst 33258 fluorescence assay decreases with nuclease degradation, increasing GC content, or denaturation of DNA (Labarca and Paigen, 1980; Stout and Becker, 1982). Increased temperature of the assay solution and ethidium bromide contamination also decrease the Hoechst 33258 signal. Sodium dodecyl sulfate (>0.01% final concentration) also interferes with accurate readings (Cesarone et al., 1979). The pH of the assay solution is critical to sensitivity and should be pH ~7.4 (Stout and Becker, 1982; Labarca and Paigen, 1980). At a pH <6.0 or >8.0 the background becomes much higher and there is a concomitant loss of fluorescence enhancement.

High-quality double-stranded DNA is recommended, although single-stranded genomic DNA also works well with this assay. However, with very small fragments of DNA, the Hoechst 33258 dye binds to double-stranded DNA only. Thus, the assay will not work with single-stranded oligomers. Linear and circular DNA give approximately the same levels of fluorescence (Daxhelet et al., 1989). When preparing DNA standards, an attempt should be made to equalize the GC content of the standard DNA and that of the sample DNA. In most situations, salmon sperm or calf thymus DNA is suitable. An extensive list of estimated GC content for various organisms is available (Marmur and Doty, 1962). Eukaryotic cells vary somewhat in GC content but are generally in the range of 39% to 46%. Within this range, the fluorescence per microgram of DNA does not vary substantially. In contrast, the GC content of

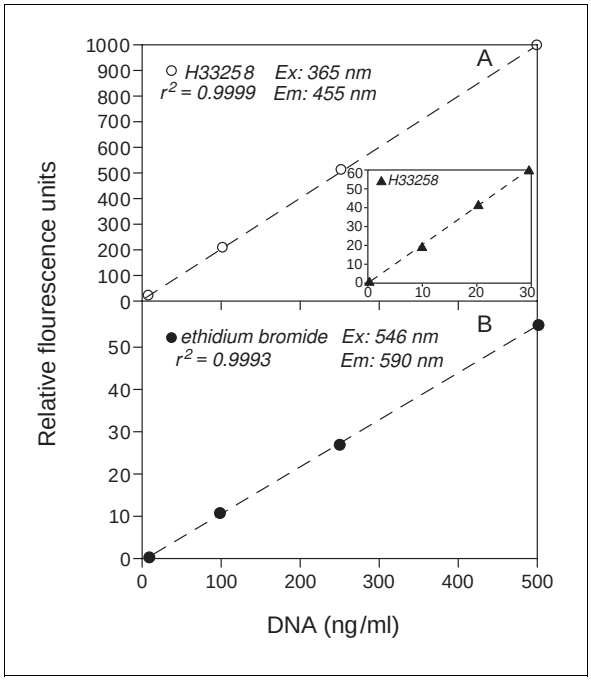

Figure A.3D.1 Fluorochrome Hoechst 33258 (H33258) (**A**) and ethidium bromide (**B**) DNA concentration standard curves. Assays were performed as described in alternate protocols, at indicated excitation and emission wavelengths. The concentrations of H33258 and ethidium bromide were 0.1 and 5 μg/ml, respectively. Assays contained the indicated concentrations of calf thymus DNA standards suspended in a final volume of 2.0 ml. Inset shows low DNA concentration curve for the H33258 assay. Note that, under these conditions, H33258 produces ~20 times more relative fluorescence units than ethidium bromide. A Shimadzu RF-5000 scanning fluorescence spectrometer was used for both assays.

prokaryotes can vary from 26% to 77%, causing considerable variation in the fluorescence signal. In these situations, the sample DNA should be first quantitated via transmission spectroscopy and compared to a readily available standard (e.g., calf thymus DNA). Future measurements would then use calf thymus as a standard, but with a correction factor for difference in fluorescence yield between the two DNA types. For further troubleshooting information, see Van Lancker and Gheyssens (1986), in which the effects of interfering substances on the Hoechst 33258 assay (and several other assays) are compared.

In the ethidium bromide assay, single-stranded DNA gives approximately half the signal as double-stranded calf thymus DNA. Ribosomal RNA also gives about half the fluorescent signal as double-stranded DNA, and RNase and DNase both severely decrease the signal. Closed circular DNA also binds less ethidium bromide than nicked or linear DNA. Further critical parameters of the ethidium bromide assay are described by Le Pecq (1971).

Anticipated Results

The detection limit of absorption spectroscopy will depend on the sensitivity of the spectrophotometer and any UV-absorbing contaminants that might be present. The lower limit is generally ~0.5 to 1 μg nucleic acid. Typical values for a highly purified sample of DNA are shown in Table A.3D.2.

For the Hoechst 33258 and ethidium bromide assays, a plot of relative fluorescence units or estimated concentration (*y* axis) versus actual concentration (*x* axis) typically produces a linear regression with a correlation coefficient (r^2) of 0.98 to 0.99 (Fig. A.3D.1). Table A.3D.3 provides a comparison of the sensitivities and specificities of the three assays.

Time Considerations

The three assays described can be performed in a short period of time. In a well-planned series of assays, 50 samples can be prepared and read comfortably in 1 hr. Although some error might be introduced, DNA samples can be sequentially added to the same cuvette containing working dye solution. The increase in fluorescence with each sample is noted and subtracted from the previous reading to give relative fluorescence or concentration of the new sample, eliminating the need to change solutions for each sample. Be certain that the final amount of DNA does not exceed the linear portion of the assay.

Silanizing Glassware

BASIC PROTOCOL

Glassware is silanized (siliconized) to prevent adsorption of solute to the glass surface or to increase its hydrophobicity. This is particularly important when dealing with low concentrations of particularly "sticky" solutes such as single-stranded nucleic acids or proteins or cells.

Materials

Chlorotrimethylsilane *or* dichlorodimethylsilane
Vacuum pump
Desiccator, equipped with a valve

1. In a fume hood, place glassware or equipment to be silanized into desiccator along with a beaker containing 1 to 3 ml of chlorotrimethylsilane or dichlorodimethylsilane.

   CAUTION: *Chlorotrimethylsilane and dichlorodimethylsilane vapors are toxic and highly flammable.*

2. Connect desiccator to vacuum pump until silane starts to boil and close connection to pump (maintaining vacuum in desiccator). Leave the desiccator evacuated and closed until liquid silane is gone (~1 to 3 hr).

   During the incubation the silane will evaporate, be deposited on the surface of the glassware, and polymerize. Do not leave the desiccator attached to the vacuum pump. This will suck away the silane, minimizing deposition and damaging the pump.

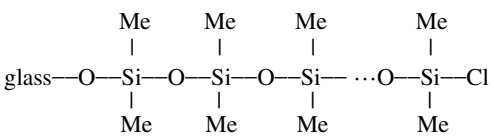
3. Open desiccator in a fume hood, and leave open for several minutes to disperse silane vapors.

4. If desired, bake or autoclave the glassware or apparatus.

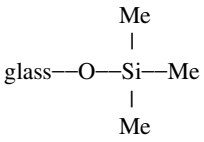
   Autoclaving or rinsing with water removes the reactive chlorosilane end of the dimethylsiloxane polymer generated by dichlorodimethylsilane.

COMMENTARY

Untreated glass contains silicate and silanol groups that can act as ion-exchange and nucleophilic centers. To mask these groups and decrease the hydrophilicity of the surface, various reactive silanes are frequently used to coat the glass surface. The same or related chemistries can be used to introduce functional groups, including large molecules, onto the glass surface. On contact with a silanol (SiOH) group, chlorosilanes react to give HCl and a siloxane Si-O-Si linkage. For most applications "silanizing" or "siliconizing" a piece of glassware or equipment means introducing onto the glass surface either a short polymer of dimethylsiloxane



using dichlorodimethylsilane, or a trimethylsiloxane cap



using chlorotrimethylsilane. Polydimethylsiloxane is silicone oil; the use of dichloromethylsilane essentially gives a light coating of oil to the glassware. The polymerization of dichlorodimethylsilane is mediated by residual water adsorbed to the glass surface; chlorosilanes also react with water and alcohols to give HCl and silanol or alkoxysilane, respectively. Thus, in the polymerization reaction, the residual water reacts with the chloride endgroup to give HCl and a silanol, which then reacts with more dichlorodimethylsilane and more water to give

Current Protocols in Cell Biology (2000) A.3E.1-A.3E.2

polymers. Chlorotrimethylsilane just gives a trimethyl cap to the silanol or silicate group.

Items too large to fit in a desiccator can be silanized by briefly rinsing with or soaking in a solution of approximately 5% dichlorodimethylsilane in various volatile organic solvents such as chloroform or heptane. The organic solvent is removed by evaporation, depositing the dichlorodimethylsilane on the surface. This approach is particularly useful for treating glass plates for denaturing polyacrylamide sequencing gels.

CAUTION: If a flammable solvent is used, do not bake the glassware until the solvent is completely evaporated.

Enzymatic Amplification of DNA by PCR: Standard Procedures and Optimization

BASIC PROTOCOL

This unit describes a method for amplifying DNA enzymatically by the polymerase chain reaction (PCR), including procedures to quickly determine conditions for successful amplification of the sequence and primer sets of interest, and to optimize for specificity, sensitivity, and yield. The first step of PCR simply entails mixing template DNA, two appropriate oligonucleotide primers, *Taq* or other thermostable DNA polymerases, deoxyribonucleoside triphosphates (dNTPs), and a buffer. Once assembled, the mixture is cycled many times (usually 30) through temperatures that permit denaturation, annealing, and synthesis to exponentially amplify a product of specific size and sequence. The PCR products are then displayed on an appropriate gel and examined for yield and specificity.

Many important variables can influence the outcome of PCR. Careful titration of the $MgCl_2$ concentration is critical. Additives that promote polymerase stability and processivity or increase hybridization stringency, and strategies that reduce nonspecific primer-template interactions, especially prior to the critical first cycle, generally improve amplification efficiency. This protocol, using *Taq* DNA polymerase, is designed to optimize the reaction components and conditions in one or two stages. The first stage (steps 1 to 7) determines the optimal $MgCl_2$ concentration and screens several enhancing additives. Most suppliers of *Taq* and other thermostable DNA polymerases provide a unique optimized $MgCl_2$-free buffer with $MgCl_2$ in a separate vial for user titration. The second stage (steps 8 to 13) compares methods for preventing pre-PCR low-stringency primer extension, which can generate nonspecific products. This has come to be known as "hot start," whether one omits an essential reaction component prior to the first denaturing-temperature step or adds a reversible inhibitor of polymerase. Hot-start methods can greatly improve specificity, sensitivity, and yield. Use of any one of the hot-start approaches is strongly recommended if primer-dimers or other nonspecific products are generated or if relatively rare template DNA is contained in a complex mixture, such as viral nucleic acids in cell or tissue preparations. This protocol suggests some relatively inexpensive methods to achieve hot start, and lists several commercial hot-start options which may be more convenient, but of course more expensive.

Materials

Sterile H_2O
15 mM (L), 30 mM (M), and 45 mM (H) $MgCl_2$
10× $MgCl_2$-free PCR amplification buffer (see recipe)
25 mM 4dNTP mix (see recipe)
50 µM oligonucleotide primer 1: 50 pmol/µl in sterile H_2O (store at −20°C)
50 µM oligonucleotide primer 2: 50 pmol/µl in sterile H_2O (store at −20°C)
Template DNA: 1 µg mammalian genomic DNA or 1.0 to 100.0 pg of plasmid DNA
5 U/µl *Taq* DNA polymerase (native or recombinant; many suppliers)
Enhancer agents (optional; see recipe)
TaqStart Antibody (Clontech)
Mineral oil
Ficoll 400 (optional)
Tartrazine dye (optional)

Thin-walled PCR tubes
Automated thermal cycler

H_2O	—	To 90 µl	To 360	To 360	To 360	To 360

[a]Total volume = 360 µl (enough for $n + 1$ reactions).

[b]Template DNA volume ("vol") is generally 1 to 10 µl.

[c]If 2 mM 4dNTP mix is preferred, use 10 µl per reaction, or 40 µl for each master mix; adjust the volume of water accordingly.

[d]Substitute with other enhancer agents (see recipe in Reagents and Solutions) as available.

Additional reagents and equipment for DNA preparation (*APPENDIX 3*), agarose gel electrophoresis (*APPENDIX 3*), nondenaturing PAGE (*UNIT 6.5*), or sieving agarose gel electrophoresis (*APPENDIX 3*), restriction endonuclease digestion (*APPENDIX 3*), and Southern blotting and hybridization (*APPENDIX 3*)

NOTE: Do not use DEPC to treat water, reagents, or glassware.

NOTE: Reagents should be prepared in sterile, disposable labware, taken directly from its packaging, or in glassware that has been soaked in 10% bleach, thoroughly rinsed in tap water followed by distilled water, and if available, exposed to UV irradiation for ~10 min. Multiple small volumes of each reagent should be stored in screw-cap tubes. This will then serve as the user's own optimization "kit." Thin-walled PCR tubes are recommended.

Optimize reaction components

1. Prepare four reaction master mixes according to the recipes given in Table A.3F.1.

   Enhancing agents probably work by different mechanisms, such as protecting enzyme activity and decreasing nonspecific primer binding. However, their effects cannot be readily predicted—what improves amplification efficiency for one primer pair may decrease the amplification efficiency for another. Thus it is best to check a panel of enhancers during development of a new assay.

2. Aliquot 90 µl master mix I into each of three 0.5-ml thin-walled PCR tubes labeled I-L, I-M, and I-H. Similarly, aliquot mixes II through IV into appropriately labeled tubes. Add 10 µl of 15 mM $MgCl_2$ into one tube of each master mix (labeled L; 1.5 mM final). Similarly, aliquot 10 µl of 30 mM and 45 mM $MgCl_2$ to separate tubes of each master mix (labeled M and H, respectively; 3.0 and 4.5 mM final concentrations respectively).

It is helpful to set the tubes up in a three-by-four array to simplify aliquotting. Each of the three Mg^{2+} concentrations is combined with each of the four master mixes.

3. Overlay the reaction mixture with 50 to 100 µl mineral oil (2 to 3 drops).

To include hot start in the first step, overlay reaction mixes with oil before adding the $MgCl_2$, heat the samples to 95°C in the thermal cycler or other heating block, and add the $MgCl_2$ once the elevated temperature is reached. Once the $MgCl_2$ has been added, do not allow the samples to cool below the optimum annealing temperature prior to performing PCR.

Choose cycling parameters

4. Using the following guidelines, program the automated thermal cycler according to the manufacturers' instructions.

30 cycles:	30 sec	94°C	(denaturation)
	30 sec	55° (GC content ≤50%) *or*	
		60°C (GC content >50%)	(annealing)
	~60 sec/kb		
	product sequence	72°C	(extension)

Cycling parameters are dependent upon the sequence and length of the template DNA, the sequence and percent complementarity of the primers, and the ramp times of the thermal cycler used. Thoughtful primer design will reduce potential problems (see Commentary). Denaturation, annealing, and extension are each quite rapid at the optimal temperatures. The time it takes to achieve the desired temperature inside the reaction tube, i.e., the ramp time, is usually longer than either denaturation or primer annealing. Thus, ramp time is a crucial cycling parameter. Manufacturers of the various thermal cyclers on the market provide ramp time specifications for their instruments. Ramp times are lower with thin-walled reaction tubes. The optimal extension time also depends on the length of the target sequence. Allow ~1 min/kb for this step for target sequences >1 kb, and as little as a 2-sec pause for targets <100 bases in length.

The number of cycles depends on both the efficiency of the reaction and the amount of template DNA in the reaction. Starting with as little as 100 ng of mammalian genomic DNA (~10^4 cell equivalents), after 30 cycles, 10% of the reaction should produce a band that is readily visible on an ethidium bromide–stained gel as a single predominant band. With more template, fewer cycles may suffice. With much less template, further optimization is recommended rather than increasing the cycle number. Greater cycle numbers (e.g., >40) can reduce the polymerase specific activity, increase nonspecific amplification, and deplete substrate (nucleotides). Many investigators lengthen the time for the last extension step—to 7 min, for example—to try to ensure that all the PCR products are full length.

These guidelines are appropriate for most commercially available thermal cyclers. For rapid cyclers, consult the manufacturers' protocols.

Analyze the product

5. Electrophorese 10 µl from each reaction on an agarose, nondenaturing polyacrylamide, or sieving agarose gel appropriate for the PCR product size expected. Stain with ethidium bromide.

For resolution of PCR products between 100 and 1000 bp, an alternative to nondenaturing polyacrylamide gels or sieving agarose is a composite 3% (w/v) NuSieve (FMC Bioproducts) agarose/1% (w/v) SeaKem (FMC Bioproducts) agarose gel. SeaKem increases the mechanical strength of the gel without decreasing resolution.

An alternative to ethidium bromide, SYBR Gold Nucleic Acid Gel Stain (Molecular Probes), is 25 to 100 times more sensitive than ethidium bromide, is more convenient to use, and permits optimization of 10- to 100-fold lower starting template copy number.

6. Examine the stained gel to determine which condition resulted in the greatest amount of product.

Minor, nonspecific products may be present even under optimal conditions.

Table A.3F.2 Master Mixes for Optimizing First-Cycle Reactions

Components	Final concentration	Master mix (µl)			
		A	B	C	D
10× PCR buffer	1×	10	10	10	10
$MgCl_2$ (L, M, or H)	Optimal	10	10	10	10
Primer 1	0.5 µM	1.0	1.0	1.0	1.0
Primer 2	0.5 µM	1.0	1.0	1.0	1.0
Additive	Optimal	V[a]	V[a]	V[a]	V[a]
Template DNA	—[b]	V[a]	V[a]	V[a]	V[a]
25 mM 4dNTP mix[b]	0.2 mM	0.8	0.8	0.8	0.8
Taq polymerase	2.5 U	0.5	0.5	—	—
Taq pol + TaqStart	2.5 U	—	—	—	1.0
H_2O	To 100 µl	V[a]	V[a]	V[a]	V[a]
Preparation temperature		Room temperature	Ice slurry	Room temperature	Room temperature

[a]V, variable amount (total volume should be 100 µl).

[b]Use undiluted or diluted template DNA based on results obtained in step 6.

7. To ensure that the major product is the correct one, digest an aliquot of the reaction with a restriction endonuclease known to cut within the PCR product. Check buffer compatibility for the restriction endonuclease of choice. If necessary, add Na^+ or precipitate in ethanol (*APPENDIX 3*), then resuspend in the appropriate buffer. Electrophorese the digestion product on a gel to verify that the resulting fragments have the expected sizes.

   Alternatively, transfer the PCR products to a nitrocellulose or nylon filter and hybridize with an oligonucleotide derived from the sequence internal to the primers. With appropriately stringent hybridization and washing conditions, only the correct product (and possibly some minor related products) should hybridize.

Optimize the first cycle

These optional steps optimize initial hybridization and may improve efficiency and yield. They are used when primer-dimers and other nonspecific products are detected, when there is only a very small amount of starting template, or when a rare sequence is to be amplified from a complex mixture. For an optimal reaction, polymerization during the initial denaturation and annealing steps should be prevented. *Taq* DNA polymerase activity can be inhibited by temperature (reaction B), physical separation (reaction C), or reversible antibody binding (reaction D). PCR without hot start is performed for comparison (reaction A).

8. Prepare four reaction mixtures using the optimal $MgCl_2$ concentration and additive requirement determined in step 6. Prepare the mixes according to the recipes in Table A.3F.2. Use the following variations for addition of *Taq* polymerase.

   a. Prepare reactions A and C at room temperature.

   b. Chill all components of reaction B in an ice slurry before they are combined.

   c. For reaction D, combine 1.0 µl TaqStart antibody with 4.0 µl of the dilution buffer provided with the antibody, add 1.0 µl *Taq* DNA polymerase (for 1:4:1 mixture of these components), mix, and incubate 5 to 10 min at room temperature before

adding to reaction mixture D (glycerol and PMPE are compatible with TaqStart antibody but DMSO will interfere with antibody binding).

To ensure that the reaction does not plateau and thereby obfuscate the results, use the smallest amount of template DNA necessary for visualization of the PCR product by ethidium bromide staining. Use the results from step 6 to decide how much template to use. If the desired product stains intensely, dilute the starting material as much as 1/100. If only a faint signal is apparent, use undiluted sample.

9. Overlay each reaction mixture with 50 to 100 µl mineral oil.

10. Heat all reactions 5 min at 94°C.

    It is most convenient to use the automated thermal cycler for this step and then initiate the cycling program directly.

11. Cool the reactions to the appropriate annealing temperature as determined in step 4. Add 0.5 µl *Taq* DNA polymerase to reaction C, making sure the pipet tip is inserted through the layer of mineral oil into the reaction mix.

    Time is also an important factor in this step. If the temperature drops below the annealing temperature and is allowed to remain low, nonspecific annealing will occur. Taq DNA polymerase retains some activity even at room temperature.

12. Begin amplification of all four reactions at once, using the same cycling parameters as before.

13. Analyze the PCR products on an agarose gel and evaluate the results as in steps 5 and 6.

14. Prepare a batch of the optimized reaction mixture, but omit *Taq* DNA polymerase, TaqStart antibody, PMPE, and 4dNTP mix—these ingredients should be added fresh just prior to use. If desired, add Ficoll 400 to a final concentration of 0.5% to 1% (v/v) and tartrazine to a final concentration of 1 mM.

    Adding Ficoll 400 and tartrazine dye to the reaction mix precludes the need for a gel loading buffer and permits direct application of PCR products to agarose or acrylamide gels. At these concentrations, Ficoll 400 and tartrazine do not decrease PCR efficiency and do not interfere with PMPE or TaqStart antibodies. Other dyes, such as bromphenol blue and xylene cyanol, do inhibit PCR. Tartrazine is a yellow dye and is not as easily visualized as other dyes; this may make gel loading more difficult.

    Ficoll 400 and tartrazine dye may be prepared as 10× stocks and stored indefinitely at room temperature.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Enhancer agents

For a discussion of how to select enhancer agents, see Commentary.

5× stocks:
25% acetamide (20 µl/reaction; 5% final)
5 M *N,N,N*-trimethylglycine (betaine; 20 µl/reaction; 1 M final)
40% polyethylene glycol (PEG) 8000 (20 µl/reaction; 8% final)

10× stocks:
Glycerol (concentrated; 10 µl/reaction; 10% final)

continued

20× stocks:

Dimethylsulfoxide (DMSO; concentrated; 5 µl/reaction; 5% final)
Formamide (concentrated; 5 µl/reaction; 5% final)

100× stocks:

1 U/µl Perfect Match Polymerase Enhancer [Strategene; 1 µl (1 U) per reaction, final]
10 mg/ml acetylated bovine serum albumin (BSA) or gelatin (1 µl/reaction; 10 µg/ml final)
1 to 5 U/µl thermostable pyrophosphatase [PPase; Boehringer Mannheim; 1 µl (1 to 5 U) per reaction, final]
5 M tetramethylammonium chloride (TMAC; betaine hydrochloride; 1 µl/reaction; 50 mM final)
0.5 mg/ml *E. coli* single-stranded DNA-binding protein (SSB; Sigma; 1 µl/reaction; 5 µg/ml final)
0.5 mg/ml Gene 32 protein (Amersham Pharmacia Biotech; 1 µl/reaction; 5 µg/ml final)
10% Tween 20, Triton X-100, or Nonidet P-40 (1 µl/reaction; 0.1% final)
1 M $(NH_4)_2SO_4$ (1 µl/reaction; 10 mM final; use with thermostable DNA polymerases other than *Taq*)

$MgCl_2$-free PCR amplification buffer, 10×

500 mM KCl
100 mM Tris·Cl, pH 9.0 (at 25°C; see *APPENDIX 2A*)
0.1% Triton X-100
Store indefinitely at −20°C

This buffer can be obtained from Promega; it is supplied with Taq DNA polymerase.

4dNTP mix

For 2 mM 4dNTP mix: Prepare 2 mM each dNTP in TE buffer, pH 7.5 (*APPENDIX 2A*). Store up to 1 year at −20°C in 1-ml aliquots.

For 25 mM 4dNTP mix: Combine equal volumes of 100 mM dNTPs (Promega). Store indefinitely at −20°C in 1-ml aliquots.

COMMENTARY

Background Information

The theoretical basis of the polymerase chain reaction (PCR; see chapter introduction) was probably first described in a paper by Kleppe et al. (1971). However, this technique did not excite general interest until the mid-1980s, when Kary Mullis and co-workers at Cetus developed PCR into a technique that could be used to generate large amounts of single-copy genes from genomic DNA (Saiki et al., 1985, 1986; Mullis et al., 1986; Embury et al., 1987).

The initial procedure entailed adding a fresh aliquot of the Klenow fragment of *E. coli* DNA polymerase I during each cycle because this enzyme was inactivated during the subsequent denaturation step. The introduction of thermostable *Taq* DNA polymerase from *Thermus aquaticus* (Saiki et al., 1988) alleviated this tedium and facilitated automation of the thermal cycling portion of the procedure. *Taq* DNA polymerase also permitted the use of higher temperatures for annealing and extension, which improved the stringency of primer–template hybridization and thus the specificity of the products. This also served to increase the yield of the desired product.

All applications of PCR depend upon an optimized PCR. The basic protocol in this unit optimizes PCR for several variables, including $MgCl_2$ concentration, enhancing additives—dimethyl sulfoxide (DMSO), glycerol, or Perfect Match Polymerase Enchancer (PMPE)—and prevention of pre-PCR mispriming. These and other parameters can be extremely important, as every element of PCR can affect the outcome; see Critical Parameters and Trou-

bleshooting for discussion of individual parameters.

There are several PCR optimization kits and proprietary enhancers on the market (Table A.3F.3). Optimization kits generally provide a panel of buffers in which the pH, buffer, nonionic detergents, and addition of $(NH_4)_2SO_4$ are varied, $MgCl_2$ may be added at several concentrations, and enhancers (e.g., DMSO, glycerol, formamide, betaine, and/or proprietary compounds) may be chosen. The protocol presented here is aimed at keeping the costs low and the options broad.

Critical Parameters and Troubleshooting

$MgCl_2$ concentration

Determining the optimum $MgCl_2$ concentration, which can vary even for different primers from the same region of a given template (Saiki, 1989), can have an enormous influence on PCR success. In this protocol three test concentrations are suggested—1.5 mM (L), 3.0 mM (M), and 4.5 mM (H). If further optimization is necessary, the $MgCl_2$ range can be extended or narrowed around the most successful concentration.

A 10× buffer optimized for a given enzyme and a separate vial of $MgCl_2$ are typically provided with the polymerase, so that the user may titrate the $MgCl_2$ concentration for their unique primer-template set. Note that some enhancers may broaden the $MgCl_2$ optimal range.

Reagent purity

For applications that amplify rare templates, reagent purity is the most important parameter, and avoiding contamination at every step is critical.

To maintain purity, store multiple small volumes of each reagent in screw-cap tubes.

For many applications, simply using high-quality reagents and avoiding nuclease contamination is sufficient. However, avoid one common reagent used to inactivate nucleases—diethylpyrocarbonate (DEPC). Even the tiny amounts of chemical left after treatment of water and autoclaving are enough to ruin a PCR.

Primer selection

This is the factor that is least predictable and most difficult to troubleshoot. Simply put, some primers just do not work. To maximize the probability that a given primer pair will work, pay attention to the following parameters.

General considerations. An optimal primer set should hybridize efficiently to the sequence of interest with negligible hybridization to other sequences present in the sample. If there are reasonable amounts of template available, hybridization specificity can be tested by performing oligonucleotide hybridization. The distance between the primers is rather flexible, ranging up to 10 kb. There is, however, a considerable drop-off in synthesis efficiency with distances >3 kb (Jeffreys et al., 1988). Small distances between primers, however, lessen the ability to obtain much sequence information or to reamplify with nested internal oligonucleotides, should that be necessary.

Design primers to allow demonstration of the specificity of the PCR product. Be sure that there are diagnostic restriction endonuclease sites between the primers or that an oligonucleotide can detect the PCR product specifically by hybridization.

Several computer programs can assist in primer design. These are most useful for avoiding primer sets with intra- and intermolecular complementarity, which can dramatically raise the effective T_m. Given the abundance of primers relative to template, this can preclude template priming. Computer primer design is not foolproof. If possible, start with a primer or primer set known to efficiently prime extensions. In addition, manufacturers' Web sites offer technical help with primer design.

Complementarity to template. For many applications, primers are designed to be exactly complementary to the template. For others, however, such as engineering of mutations or new restriction endonuclease sites, or for efforts to clone or detect gene homologs where sequence information is lacking, base-pair mismatches will be intentionally or unavoidably created. It is best to have mismatches (e.g., in a restriction endonuclease linker) at the 5′ end of the primer. The closer a mismatch is to the 3′ end of the primer, the more likely it is to prevent extension. If cloned template is available, primers can be checked for suitability by using them in a sequencing reaction with *Taq* DNA polymerase.

The use of degenerate oligonucleotide primers to clone genes where only protein sequence is available, or to fish out gene homologs in other species, has sometimes been successful—but it has also failed an untold (and unpublished) number of times. When the reaction works it can be extremely valuable, but it can also generate seemingly specific products that require much labor to identify and yield no

Table A.3F.3 PCR Optimization Products

Optimization goal	Supplier	Product
Optimization support	ABI-Perkin-Elmer	Technical information in appendix to catalog
Optimization support	Promega	PCR troubleshooting program on the Internet: *http://www.promega.com/amplification/assistant*
Optimization kits	Boehringer-Mannheim, Invitrogen, Stratagene, Sigma, Epicentre Technologies, Life Technologies	Several buffers, Mg^{2+}, and enhancers which may include DMSO, glycerol, formamide, $(NH_4)_2SO_4$, and other unspecified or proprietary agents
Quick startup	Amersham Pharmacia Biotech	Ready-To-Go Beads "optimized for standard PCR" and Ready-To-Go RAPD Analysis Beads (buffer, nucleotides, *Taq* DNA polymerase)
Quick startup	Fisher	EasyStart PCR Mix-in-a-Tube—tubes prepackaged with wax beads containing buffer, $MgCl_2$, nucleotides, *Taq* DNA polymerase
Quick startup	Life Technologies	PCR SuperMix—1.1× conc.—premix containing buffer, $MgCl_2$, nucleotides, *Taq* DNA polymerase
Quick startup	Marsh Biomedical	Advanced Biochemicals Red Hot DNA Polymerase—a new rival for *Taq* polymerase with convenience features
Hot-start/physical barrier	Fisher, Life Technologies	Molecular Bio-Products HotStart Storage and Reaction Tubes—preadhered wax bead in each tube; requires manual addition of one component at high temperature
Hot-start/separate $MgCl_2$	Invitrogen	HotWax Mg^{2+} beads—wax beads contain preformulated $MgCl_2$ which is released at first elevated-temperature step
Hot-start/separate $MgCl_2$	Stratagene	StrataSphere Magnesium Wax Beads—wax beads containing preformulated Mg^{2+}
Hot Start/separate polymerase	Promega	TaqBead Hot Start Polymerase—wax beads encapsulating *Taq* DNA polymerase which is released at first elevated-temperature step
Hot-start/reversible inactivation of polymerase by antibody binding	Clontech	TaqStart Antibody, TthStart Antibody—reversibly inactivate *Taq* and *Tth* DNA polymerases until first denaturation at 95°C
Hot-start/antibody binding	Life Technologies	PlatinumTaq—contains PlatinumTaq antibody
Hot-start/antibody binding	Sigma	JumpStart Taq—contains TaqStart antibody
Hot-start/reversible chemical modification	ABI-Perkin-Elmer	AmpliTaq Gold—activated at high temperature
Hot-start/reversible chemical modification	Qiagen	HotStarTaq DNA Polymerase—activated at high temperature
Enhancer	Boehringer Mannheim, New England Biolabs	*Tth* pyrophosphatase, thermostable
Enhancer	Clontech	GC-Melt (in Advantage-GC Kits)—proprietary
Enhancer	CPG	Taq-FORCE Amplification System and MIGHTY Buffer—proprietary
Enhancer	Fisher	Eppendorf MasterTaq Kit with TaqMaster Enhancer—proprietary
Enhancer	Life Technologies	PCRx Enhancer System—proprietary
Enhancer	Promega	*E.coli* Single Stranded Binding Protein (SSB)
Enhancer	Qiagen	Q-Solution—proprietary
Enhancer	Stratagene	Perfect Match Polymerase Enhancer—proprietary
Enhancer	Stratagene	TaqExtender PCR Additive—proprietary

useful information. The less degenerate the oligonucleotides, especially at the 3′ end, the better. Caveat emptor.

Primer length. A primer should be 20 to 30 bases in length. It is unlikely that longer primers will help increase specificity significantly.

Primer sequence. Design primers with a GC content similar to that of the template. Avoid primers with unusual sequence distributions, such as stretches of polypurines or polypyrimidines as their secondary structure can be disastrous. It is worthwhile to check for potential secondary structure using one of the appropriate computer programs that are available.

"Primer-dimers." Primer-dimers are a common artifact most frequently observed when small amounts of template are taken through many amplification cycles. They form when the 3′ end of one primer anneals to the 3′ end of the other primer, and polymerase then extends each primer to the end of the other. The ensuing product can compete very effectively against the PCR product of interest. Primer-dimers can best be avoided by using primers without complementarity, especially in their 3′ ends. Should they occur, optimizing the $MgCl_2$ concentration may minimize their abundance relative to that of the product of interest.

Template

Aside from standard methods for preparing DNA (*APPENDIX 3*), a number of simple and rapid procedures have been developed for particular tissues (Higuchi, 1989). Even relatively degraded DNA preparations can serve as useful templates for generation of moderate-sized PCR products. The two main concerns regarding template are purity and amount.

A number of contaminants found in DNA preparations can decrease the efficiency of PCR. These include urea, the detergent SDS (whose inhibitory action can be reversed by nonionic detergents), sodium acetate, and, sometimes, components carried over in purifying DNA from agarose gels (Gelfand, 1989; Gyllensten, 1989; K. Hicks and D. Coen, unpub. observ.). Additional organic extractions, ethanol precipitation from 2.5 M ammonium acetate, and/or gel purification on polyacrylamide rather than agarose, can all be beneficial in minimizing such contamination if the simplest method (precipitating the sample with ethanol and repeatedly washing the pellet with 70% ethanol) is not sufficient.

Clearly the amount of template must be sufficient to be able to visualize PCR products using ethidium bromide. Usually 100 ng of genomic DNA is sufficient to detect a PCR product from a single-copy mammalian gene. Using too much template is not advisable when optimizing for $MgCl_2$ or other parameters, as it may obscure differences in amplification efficiency. Moreover, too much template may decrease efficiency due to contaminants in the DNA preparation.

Amount of template, especially in terms of the amount of target sequence versus nonspecific sequences, can have a major effect on the yield of nonspecific products. With less target sequence, it is more likely that nonspecific products will be seen. For some applications, such as certain DNA sequencing protocols where it is important to have a single product, gel purification of the specific PCR product and reamplification are advisable.

Taq and other thermostable DNA polymerases

Among the advantages conferred by the thermostability of *Taq* DNA polymerase is its ability to withstand the repeated heating and cooling inherent in PCR and to synthesize DNA at high temperatures that melt out mismatched primers and regions of local secondary structure. The enzyme, however, is not infinitely resistant to heat, and for greatest efficiency it should not be put through unnecessary denaturation steps. Indeed, some protocols (e.g., and the "hot start" method described here) recommend adding it after the first denaturation step.

Increasing the amount of *Taq* DNA polymerase beyond 2.5 U/reaction can sometimes increase PCR efficiency, but only up to a point. Adding more enzyme can sometimes increase the yield of nonspecific PCR products at the expense of the product of interest. Moreover, *Taq* DNA polymerase is not inexpensive.

A very important property of *Taq* DNA polymerase is its error rate, which was initially estimated at 2×10^{-4} nucleotides/cycle (Saiki et al., 1988). The purified enzyme supplied by manufacturers lacks a proofreading 3′→5′ exonuclease activity, which lowers error rates of other polymerases such as the Klenow fragment of *E. coli* DNA polymerase I. For many applications, this does not present any difficulties. However, for sequencing clones derived from PCR, or when starting with very few templates, this can lead to major problems. Direct sequencing of PCR products, sequencing numerous PCR-generated clones, and/or the use of appropriate negative controls can help overcome these problems. Alternatively, changing reaction conditions (Eckert and

Kunkel, 1990) or changing to a non–*Taq* DNA polymerase (with greater fidelity) may be useful.

Another important property of *Taq* DNA polymerase is its propensity for adding nontemplated nucleotides to the 3′ ends of DNA chains. This can be especially problematic in cloning PCR products. It is frequently necessary to "polish" PCR products with enzymes such as other DNA polymerases before adding linkers or proceeding to blunt-end cloning. Conversely, addition of a nontemplated A by *Taq* DNA polymerase can be advantageous in cloning.

Table A.3F.4 lists currently available thermostable DNA polymerases by generic and trade names, the original source of native and recombinant enzymes, the supplier, the end generated (3′A addition versus blunt), and associated exonuclease activities. A 3′ to 5′ exonuclease activity is proofreading. Removal of the 5′ to 3′ exonuclease activity of *Taq* DNA polymerase (N-terminal deletion) is reported to produce a higher yield. A 5′ to 3′ exonuclease activity may degrade the primers somewhat. Proofreading enzymes synthesize DNA with higher fidelity and can generate longer products than *Taq*, but tend to generate low yields. Enzyme blends (Table A.3F.5) have been optimized for increased fidelity and length along with sensitivity and yield.

Hot start

What happens prior to thermal cycling is critical to the success of PCR. *Taq* DNA polymerase retains some activity even at room temperature. Therefore, under nonstringent annealing conditions, such as at room temperature, products can be generated from annealing of primers to target DNA at locations of low complementarity or having complementarity of just a few nucleotides at the 3′ ends. The latter would in effect create new templates "tagged" with the primer sequences. Subsequent cycles amplify these tagged sequences in abundance, both generating nonspecific products and possibly reducing amplification efficiency of specific products by competition for substrates or polymerase. Thus conditions preventing polymerization prior to the first temperature-controlled steps are desirable. In this protocol, three methods of inhibiting polymerization prior to the temperature-controlled step are compared. These include physical separation of an essential reaction component prior to the first denaturation step, cooling reagents to 0°C, and reversibly blocking enzymatic activity with an antibody.

Denaturation of the template before *Taq* polymerase or $MgCl_2$ is added to the reaction provides a dramatic improvement in specificity and sensitivity in many cases (Chou et al., 1992). The main drawback of this method is that it requires opening the reaction tubes a second time to add the essential missing component. This creates both an inconvenience and an increase in the risk of contamination, an important consideration when testing for the presence of a given sequence in experimental or clinical samples.

Cooling all components of the reaction mixture to 0°C prior to mixing is more convenient and the least expensive method but is also the least reliable. Transferring the PCR reaction tubes from the ice slurry to a 95°C preheated thermocycler block may improve the chance of success.

Reversible inhibition of *Taq* DNA polymerase by TaqStart antibody (Clontech) is the most convenient and very effective (Kellogg et al., 1994). Complete reactions can be set up, overlaid with oil, and stored at 4°C for up to several hours prior to thermal cycling with no loss of sensitivity or specificity compared to the other hot start methods (M.F.K. and D.M.C., unpub. observ.). Cycling is initiated immediately following 5-min denaturation of the antibody at 94°C. DMSO inhibits antibody binding and should not be used with TaqStart.

Several hot-start products are now commercially available (Table A.3F.3). Success with each may depend on strict adherence to the manufacturer's protocols, even on a specific thermocycler. Wax barrier and reversible antibody binding methods are more forgiving, while chemical modifications have more stringent activation temperature requirements.

Deoxyribonucleoside triphosphates

In an effort to increase efficiency of PCR, it may be tempting to increase the concentration of dNTPs. Don't. When each dNTP is 200 μM, there is enough to synthesize 12.5 μg of DNA when half the dNTPs are incorporated. dNTPs chelate magnesium and thereby change the effective optimal magnesium concentration. Moreover, dNTP concentrations >200 μM each increase the error rate of the polymerase. Millimolar concentrations of dNTPs actually inhibit *Taq* DNA polymerase (Gelfand, 1989).

The protocol in this unit calls for preparing 4dNTPs in 10 mM Tris·Cl/1 mM EDTA (TE buffer), pH 7.4 to 7.5. This is easier and less

Table A.3F.4 Thermostable DNA Polymerases

DNA polymerase		Biological source	Supplier	Product ends	Exonuclease activity
Generic name	Trade name				
Pfu	—	*Pyrococcus furiosus*	Stratagene, Promega	Blunt	3′-5′ (proofreading)
Pfu (exo-)	—	*Pyrococcus furiosus*	Stratagene	Blunt	No

prone to disaster than neutralization with sodium hydroxide. However, EDTA also chelates magnesium, and this should be taken into account if stocks of dNTPs are changed. Alternatively, to lower the risk of contamination, a 4dNTP mix can be made by combining equal volumes of commercially prepared stocks.

Enhancers

Enhancers are used to increase yield and specificity and to overcome difficulties encountered with high GC content or long templates. Nonionic detergents (Triton X-100, Tween 20, or Nonidet P-40) neutralize charges of ionic detergents often used in template preparation, and should be used in the basic reaction mixture, rather than as optional enhancers. Higher yields can be achieved by stabilizing/enhancing the polymerase activity with enzyme-stabilizing proteins (BSA or gelatin), enzyme-stabilizing solutes such as betaine or betaine·HCl (TMAC), enzyme-stabilizing solvents (glycerol), solubility-enhancing solvents (DMSO or acetamide), molecular crowding solvents (PEG), and polymerase salt preferences [$(NH_4)SO_4$ is recommended for polymerases other than *Taq*]. Greater specificity can be achieved by lowering the T_M of dsDNA (using formamide), destabilizing mismatched-primer annealing (using PMPE or hot-start strategies), and stabilizing ssDNA (using *E. coli* SSB or Gene 32 Protein). Amplification of high-GC-content templates can be improved by decreasing the base pair composition depend-

Table A.3F.5 Thermostable DNA Polymerase Blends

Product (trade name)	Supplier	Thermostable DNA polymerases and other components
Expand High Fidelity, Expand Long Template, and Expand 20kb PCR Systems	Boehringer Mannheim	*Taq* + *Pwo*
KlenTaq LA Polymerase Mix	Clontech, Sigma	KlenTaq-1 (5′-exonuclease deficient *Taq*) + unspecified proofreading polymerase
Advantage-HF PCR Kit	Clontech	KlenTaq-1 + unspecified proofreading polymerase + TaqStart Antibody
Advantage-cDNA and Advantage-GC cDNA Polymerase Mixes and Kits	Clontech	KlenTaq-1 + unspecified proofreading polymerase + TaqStart Antibody; GC Kit contains GC Melt
Advantage Genomic and Advantage-GC Genomic Polymerase Mixes and Kits	Clontech	*Tth* + unspecified proofreading polymerase + TthStart Antibody; GC Kit contains GC Melt

OmniBase Sequencing Enzyme Mix	Promega	Unspecified proofreading polymerase(s) with thermostable pyrophosphatase
AccuTaq LA DNA Polymerase Mix	Sigma	*Taq* + unspecified proofreading polymerase
TaqPlus Long and TaqPlus Precision PCR Systems	Stratagene	*Pfu* + *Taq*; TaqPlus Precision Reaction Buffer (proprietary)
Accurase Fidelity PCR Enzyme Mix; Calypso High Fidelity Single Tube RT-PCR System	Tetralink	*Thermus sp*. + *Thermococcus sp*.; Calypso also contains AMV-RT

ence of the T_M of dsDNA (with betaine; Rees et al., 1993). Betaine is an osmolyte widely distributed in plants and animals and is nontoxic, a feature that recommends it for convenience in handling, storage, and disposal. Betaine may be the proprietary ingredient in various commercial formulations. For long templates, a higher pH is recommended (pH 9.0). The pH of Tris buffer decreases at high temperatures, long-template PCR requires more time at high temperatures, and increased time at lower pH may cause some depurination of the template, resulting in reduced yield of specific product. Inorganic phosphate (PPi), a product of DNA synthesis, may accumulate with amplification of long products to levels that may favor reversal of polymerization. Accumulation of PPi may be prevented by addition of thermostable PPase. When large numbers of samples are being analyzed, the convenience of adding PCR products directly to a gel represents a significant time savings. Some companies combine their thermostable polymerase with a red dye and a high density component to facilitate loading of reaction products onto gels without further addition of loading buffer.

Thermal cycling parameters

Each step in the cycle requires a minimal amount of time to be effective, while too much time can be both wasteful and deleterious to the DNA polymerase. If the amount of time in each step can be reduced, so much the better.

Denaturation. It is critical that complete strand separation occur during the denaturation step. This is a unimolecular reaction which, in itself, is very fast. The suggested 30-sec denaturation used in the protocol ensures that the tube contents reach 94°C. If PCR is not working, it is well worth checking the temperature inside a control tube containing 100 µl water. If GC

content is extremely high, higher denaturation temperatures may be necessary; however, *Taq* DNA polymerase activity falls off quickly at higher temperatures (Gelfand, 1989). To amplify a long sequence (>3 kb), minimize the denaturation time to protect the target DNA from possible effects, such as depurination, of lowered pH of the Tris buffer at elevated temperatures.

Annealing. It is critical that the primers anneal stably to the template. Primers with relatively low GC content (<50%) may require temperatures lower than 55°C for full annealing. On the other hand, this may also increase the quantity of nonspecific products. For primers with high GC content, higher annealing temperatures may be necessary. It can be worthwhile, although time-consuming, to experiment with this parameter. Two manufacturers have thermal cyclers on the market which are capable of forming a temperature gradient across the heating units, thus permitting annealing temperature optimization in one run. These are Stratagene's Robocyclers, and Eppendorf's Master Cycler. As with denaturation, the time for this step is based mainly on the time it takes to reach the proper temperature, because the primers are in such excess that the annealing reaction occurs very quickly.

Extension. The extension temperature of 72°C is close to the optimal temperature for *Taq* DNA polymerase (~75°C), yet prevents the primers from falling off. Indeed, primer extension begins during annealing, because *Taq* DNA polymerase is partially active at 55°C and even lower temperatures (Gelfand, 1989).

The duration of extension depends mainly on the length of the sequence to be amplified. A duration of 1 min per kb product length is usually sufficient.

Certain protocols, including others in this chapter, end the PCR with a long final extension time in an attempt to try to make products as complete as possible.

Ramp time. Ramp time refers to the time it takes to change from one temperature to another. Using water baths and moving samples manually from temperature to temperature probably gives the shortest ramp times, which are mainly the time required for the tube's contents to change temperature. Different thermal cyclers have different ramp times; basically, the shorter the better.

The Stratagene Robocycler uses a robotic arm to move samples from one constant-temperature block to another, virtually eliminating block ramp time, but a ramp time for tube contents must be calculated (~1 sec/°C) and added to denaturation, annealing, and extension times. Rapid cyclers that utilize positive-displacement pipet tips or capillary tubes for the PCR reactions dramatically reduce the ramp times.

Generally, the more "high-performance" thermal cyclers with short ramp times are proportionally more costly. There are many new thermal cyclers on the market priced below $5000, which perform quite well (Beck, 1998).

Anticipated Results

Starting with ≥100 ng mammalian DNA (≥10^4 molecules), the basic protocol can be used to determine which $MgCl_2$ concentration, enhancing additive, and initial conditions will yield a predominant PCR product from a single-copy sequence that is readily visible on an ethidium bromide–stained gel. It is possible that other minor products will also be visible.

Time Considerations

The basic protocol can be completed in a single day. Assembly of the reaction mixtures should take ~1 hr. Cycling should take less than 3 hr. Preparing, running, and staining the gel should take another few hours. Further checks on specificity of the product such as restriction endonuclease digestion or Southern blot hybridization will take another few hours or days, respectively.

Micro RT-PCR

Newly developed technologies allow investigators to isolate specific subpopulations of disease-relevant cells from actual tissue under direct microscopic visualization (*UNIT 2.5*). This opens the opportunity to determine specific subsets of biologically-relevant mRNA and DNA that mediate the physiology of normal and diseased cells; however, these pertinent cells only represent a fraction of the total cell repertoire, often comprising only a few hundred in number. Thus, new methods have been developed to analyze the small DNA and RNA contents from these cells.

The following represents a collection of protocols for the microisolation (see Support Protocol), manipulation, and amplification of the RNA content of microdissected cells (see Basic Protocol). Even though emphasis in these protocols is given for microdissected cells, these protocols have successfully been used for bulk tissue (i.e., <10 µg) (see Internet Resources). Laser-capture microdissection (LCM) is described in *UNIT 2.5*.

MICRO RT-PCR

BASIC PROTOCOL

Following the isolation of RNA (see Support Protocol), oligo(dT)- or random hexamer–primed single-stranded cDNA is synthesized by reverse transcription. In the reaction, all four dNTPs are present in 250 µM concentrations and 10 µM random-hexamer primers or oligo(dT) are included. After first strand synthesis, the sample is directly diluted into PCR reaction buffer and amplified at 94°C for 2 min, followed by 35 cycles of 45 sec at 50°C to anneal, 2 min at 72°C to extend, and 2 min at 94°C to denature. PCR products are separated on a 2% (w/v) agarose gel and stained with ethidium bromide (*UNIT 1.5*).

CAUTION: When working with radioactivity, take appropriate precautions to avoid contamination of the experimenter and the surroundings. Carry out the experiment and dispose of wastes in an appropriately designated area, following the guidelines provided by your local radiation safety officer (also see *APPENDIX 1A*).

Materials

DEPC-treated H_2O (*APPENDIX 2A*)
20 U/µl RNase inhibitor (ABI-Perkin Elmer)
RNA pellet, dry (Support Protocol)
5× RT buffer (GenHunter)
250 µM dNTPs (GenHunter)
10 µM random-hexamer or oligo(dT) primers (ABI-Perkin Elmer)
100 U/µl MMLV reverse transcriptase (Stratagene)
10× PCR buffer (Perkin Elmer): 500 KCl/15 mM $MgCl_2$/1 mg/ml gelatin in 100 mM Tris·Cl, pH 8.4 (*APPENDIX 2A*)
10 µM upstream primer
10 µM downstream primer
5 U/µl *Taq* DNA polymerase (ABI-Perkin Elmer)
10 mCi/ml ^{32}P-dCTP or ^{33}P-dCTP (~300 Ci/mmol)

12-µl PCR tubes, RNase-free
Thermal cycler

Additional reagents and equipment for agarose gel electrophoresis (*UNIT 1.5*)

CAUTION: DEPC is a suspected carcinogen and must be handled with caution.

Current Protocols in Cell Biology (2001) A.3G.1-A.3G.6

Suspend RNA pellet

1. Add 24 µl DEPC-treated water and 1 µl RNase inhibitor to the dried RNA pellet.

   It is highly recommended to split the reaction mixture in order to determine whether the primers used for PCR could be amplifying any residual DNA—i.e., the RT(−) reaction.

2. Split suspended RNA into two 12-µl RNase-free PCR tubes, labeled RT(+) and RT(−), respectively.

For random hexamers

3a. To each tube, add 4 µl 5× RT buffer, 2 µl 250 µM dNTP, and 1 µl 10 µM random hexamers.

4a. Incubate for 5 min at 65°C and 10 min at 25°C.

5a. Add 1 µl 100 U/µl MMLV reverse transcriptase to the RT(+) tube. Add 1 µl DEPC-treated water to the RT(−) tube to maintain equal volume.

6a. *For random hexamers:* Incubate 10 min at 25°C, 40 min at 37°C, and 5 min at 95°C.

For oligo(dT)

3b. To each tube, add 4 µl 5× RT buffer, 2 µl 250 µM dNTP, and 2 µl 10 µM oligo(dT).

4b. Incubate 5 min at 65°C and 10 min at 37°C.

5b. Add 1 µl 100 U/µl MMLV reverse transcriptase to the RT(+) tube. Add 1 µl DEPC-treated water to the RT(−) tube to maintain equal volume.

6b. Incubate 50 min at 37°C and 5 min at 95°C.

Prepare and perform PCR

7. Place 1.5 µl RT(+) and RT(−) cDNA mixture into appropriately labeled RNase-free microcentrifuge tubes and add the following to each:

   1.0 µl 10× PCR buffer
   0.8 µl 250 µM dNTP mix
   0.2 µl 10 µM upstream primer
   0.2 µl 10 µM downstream primer
   0.2 µl 5 U/µl *Taq* DNA polymerase
   0.2 µl ^{32}P-dCTP or ^{33}P-dCTP
   5.9 µl DEPC-treated water.

   Heat reaction mixture for 2 min at 94°C in a thermal cycler.

   Taq DNA polymerase is usually supplied as 5 U/µl. If Taq DNA polymerase is supplied at a different dilution, dilute in PCR buffer to desired enzyme concentration.

   Radioactivity is necessary to allow visualization using a denaturing acrylamide gel. This protocol usually results in visible products in <2 hr.

8. Run 35 cycles in a thermal cycler as follows to amplify cDNA:

45 sec	94°C	(denaturation)
45 sec	50°C	(annealing)
2 min	72°C	(extension)
2 min	94°C	(denaturation)

   Hold at 4°C until use.

Analyze results

9. Separate 10 µl RT(+) and RT(−) on a 2% agarose gel (e.g., NaSieve precast gel) and stain with ethidium bromide.

NOTE: *Adjust the relative amounts of buffer and agarose in UNIT 1.5 to make a 2% agarose gel. Also see APPENDIX 3A for agarose-gel electrophoresis techniques.*

MICROISOLATION OF RNA

SUPPORT PROTOCOL

Transcriptional analysis and profiling of disease-related states depend upon the ability to isolate specific pure RNA from tissue cells. Fundamentally, the following protocol lyses microdissected cells (*UNIT 2.5*) in a guanidinium thiocyanate buffer and separates DNA and proteins by extraction with water-saturated phenol and chloroform/isoamyl alcohol. Subsequently, the extracted RNA (aqueous phase) is placed into a second RNase-free tube and precipitated with isopropyl alcohol. The RNA pellet is cleaned from contaminating cDNA by DNase treatment for 2 hr at 37°C.

Results in the authors' laboratory have shown that the Stratagene Micro RNA Isolation kit provides the best recovery of mRNA isolated for laser capture microdissected cells (*UNIT 2.5*). It also avoids the CsCl gradient step that was traditionally used to separate RNA from DNA and proteins.

Materials *(also see Basic Protocol)*

Tissue
Micro RNA Isolation kit (Stratagene):
  Denaturing solution
  2-mercaptoethanol
  H_2O-saturated phenol
  2 M sodium acetate, pH 4.0
  1 µg/µl glycogen
  Isopropanol, cold
  49:1 (v/v) chloroform/isoamyl alcohol
60% ethanol/40% DEPC-treated H_2O (*APPENDIX 2A*)
DEPC-treated H_2O (*APPENDIX 2A*)
Message Clean kit (GenHunter):
  RNase inhibitor
  10× reaction buffer
  10 U/µl mg/ml DNase
RNase Away (Molecular Bio-Products)
RNase-free tubes (Eppendorf)

Additional reagents and equipment for microdissection (*UNIT 2.5*)

CAUTION: DEPC is a suspected carcinogen and must be handled with caution.

NOTE: Because the starting material is only between 10 and 100 ng, it is of absolute necessity to use only DEPC-treated water to inactivate ribonucleases, to use only labware certified "RNase free," and to always wear gloves.

Extract RNA from cells

1. Microdissect a minimum of 1000 cells from tissue (*UNIT 2.5*) and place in an RNase-free tube.

Bulk tissue can also be used for this protocol. Typically between 10 and 100 ng RNA are required for good recovery.

The number of cells needed depends on the quality of the RNA in the tissue.

2. Lyse cells in 200 µl denaturing buffer and 1.6 µl 2-mercaptoethanol. Add lysate to RNase-free tubes and vortex vigorously.

   Observation of lysing can be confirmed by a pinkish discoloration in the lysing buffer from the H&E stained microdissected cells.

   To avoid contamination by RNases, it is recommended that all equipment be either certified RNase free or treated with RNase Away before use.

Phenol/chloroform extract RNA

3. Add 220 µl water-saturated phenol, 60 µl of 49:1 chloroform/isoamyl alcohol, and 20 µl of 2 M sodium acetate, pH 4.0 to the lysate. Vortex vigorously for 1 min. Place the tube on wet ice for 15 min followed by microcentrifugation for 30 min at 12,000 rpm, 4°C.

   The organic layer (phenol) is the bottom phase.

4. Transfer aqueous (upper) phase to a new RNase-free tube, paying special attention not to transfer any of the organic (bottom) layer.

Purify RNA by isopropanol precipitation

5. Add 2 µl of 1 µg/µl glycogen to the new tube.

   Glycogen acts as a carrier during this step. It is solely used to visualize the RNA pellet. Alternatively 2 µl of 1 µg/µl tRNA can be used.

6. Add 200 µl cold isopropanol and place on dry ice for 30 min.

7. Microcentrifuge 30 min at 12,000 rpm, 4°C.

   Visualization of the RNA pellet can be difficult. It helps to place the cap outward, which places the pellet away from the cap insertion.

8. Carefully remove supernatant by wicking.

Purify RNA by ethanol precipitation

9. Add 400 µl of 60% ethanol/40% DEPC-treated water. Microcentrifuge 5 min at 12,000 rpm, 4°C. Remove supernatant. Repeat once.

10. Dry the RNA pellet using a SpeedVac evaporator.

    The pellet can be stored at −80°C until further use.

Remove residual DNA (optional)

It is likely that RT-PCR may also amplify contaminating DNA. To ensure the purity of the RNA product, DNase treatment of the isolated RNA is highly recommended. If additional removal of the DNA is not warranted, any manipulations of the isolated RNA (i.e., steps 11 to 22), may be skipped.

11. Add 15 µl DEPC-treated water, 1 µl RNase inhibitor, and 2 µl of 10× reaction buffer.

12. Incubate 3 min at 50°C.

13. Add 2 µl of 10 U/µl DNase and incubate 2 hr at 37°C.

14. Add 22 µl water-saturated phenol, 6 µl of 49:1 chloroform/isoamyl alcohol, and 2 µl of 2 M sodium acetate, pH 4.0. Place on wet ice for 15 min.

15. Microcentrifuge 10 min at 12,000 rpm, 4°C.
16. Transfer upper layer to a new RNase-free tube.
17. Add 2 µl of 1 µg/µl glycogen to the new tube.
18. Add 200 µl cold isopropanol and place on dry ice for 30 min.
19. Microcentrifuge 30 min at 14,000 rpm, 4°C.
20. Carefully remove the supernatant by wicking.
21. Add 400 µl of 60% ethanol/40% DEPC-treated water. Microcentrifuge 5 min at 14,000 rpm, 4°C. Remove supernatant by wicking.
22. Remove any residual liquid using a SpeedVac evaporator.

Pellet can be stored overnight at –80°C.

COMMENTARY

Background Information

The development of rational approaches to the diagnosis and treatment of diseases are dependent on identifying and understanding the molecular mechanisms that underlie its progression. The understanding of cell type specific gene regulation is essential for this task; however, until recently it could not be analyzed due to the difficulty of isolating single cell types. Laser-capture microdissection (*UNIT 2.5*) allows for the direct procurement of cell populations under direct microscopic visualization (Emmert-Buck et al., 1996). RT-PCR from microdissected tissue has successfully been used for preparing cDNA libraries from specific subpopulations such as prostatic intraepithelial neoplasia (Krizman et al., 1996).

Although there are many approaches to the isolation, purification, and amplification of mRNA, the protocol presented here (see Basic Protocol) has been optimized for mRNA procured by laser-capture microdissection (*UNIT 2.5*). Following the isolation of RNA, oligo(dT)-primed or random hexamer–primed single-strand cDNA is synthesized by reverse transcription. All four dNTP's are present in 250 µM concentrations with 10 µM random-hexamer primers or oligo(dT). After first-strand synthesis the sample is directly diluted into the PCR reaction buffer and amplified at 94°C for 2 min, followed by 35 cycles of 45 sec at 50°C to anneal, 2 min at 72°C to extend, and 2 min at 94°C to denature. PCR products are separated on a 2% (w/v) agarose gel and stained with ethidium bromide (*UNIT 1.5*). The first application of PCR to the analysis of mRNA studied point mutations within the mouse ornithine transcarbamylase gene (Veres et al., 1987).

The denaturing buffer, which contains guanidinium isothiocyanate and mild detergents, lyses the microdissected cells instantaneously and inactivates ribonucleases. DNA and proteins are subsequently separated by extraction with water-saturated phenol and chloroform/isoamyl alcohol. The extracted RNA (aqueous phase) is placed into a second tube and precipitated with isopropyl alcohol.

The use of guanadinium isothiocyanate was first described for the purification of RNA in endogenous ribonucleases (Ullrich et al., 1977; Chirgwin et al., 1979). Organic extraction of proteins by phenol has been previously described by Kirby (1968). An excellent review and updated methods to recover and analyze mRNA from microdissected tissue samples are on the Cancer Genome Anatomy's (CGAP) website at *http://cgap-mf.nih.gov*.

Critical Parameters and Troubleshooting

The quality of the RNA in the tissue affects the number of cells required for the assay. It requires only a minute amount of DNA to provide a false positive signal. The RT(–) tube acts as a negative control and is designed to show any contaminating DNA products in this reaction mixture. If there is a positive band resulting from the RT(–) reaction mixture, there is genomic DNA contamination. Make sure the integrity of the mRNA is valid. A thorough DNase treatment of the sample might be necessary (see Support Protocol).

Any success of RNA isolation from minute tissue sample depends on the complete elimination of ribonucleases. The denaturing agent used herein is designed to eliminate any RNase activity while liberating the cell lysate. Likely sources of poor yields are probable introduction of foreign RNases into the reaction mixture. Contaminating RNases may be introduced either by using contaminated labware or from the user. If general labware such as microcentrifuge tubes or disposable plastic pipets are not certified "RNase free", glassware can be baked at 180°C for 8 hr, while plasticware can be decontaminated by rinsing it with chloroform and subsequently autoclaving it. Disposable gloves should be worn throughout the entire procedure.

Anticipated Results

Amplification of mRNA should only produce one discreet band of discrete length when stained with ethidium bromide on an agarose gel.

Between 10 and 100 ng of RNA should be isolated using 1000 microdissected cells.

Time Considerations

Synthesis of single-stranded cDNA takes 1.5 hr, while amplification by RT-PCR using a thermal cycler for 35 cycles takes ~2.5 hr. Visualization on a NuSieve 2% agarose gel takes ~1 hr.

Allow ~3 hr until the first ethanol precipitation of the RNA pellet. If additional DNA removal is desired allow an extra 5 hr for the DNase treatment and further purification of RNA. The RNA pellet can be stored until further use at −80°C after any of the ethanol precipitation steps.

The Colorimetric Detection and Quantitation of Total Protein

Protein quantification is an important step for handling protein samples for isolation and characterization, and is a prerequisite step before submitting proteins for chromatographic, electrophoretic, or immunochemical analysis and separation. The methods included in this unit are colorimetric measurements, whose procedures are fast and simple.

This unit describes four of the most commonly used total protein assay methods. Three of the four are copper-based assays to quantitate total protein: the Lowry method (see Basic Protocol 1 and Alternate Protocols 1 and 2), the bicinchoninic acid assay (BCA; see Basic Protocol 2 and Alternate Protocols 3 and 4), and the biuret method (see Basic Protocol 3 and Alternate Protocol 5). The fourth is the Coomassie dye binding or Bradford assay (see Basic Protocol 4 and Alternate Protocols 6 and 7), which is included as a simple and sensitive assay, although it sometimes gives a variable response depending on how well or how poorly the protein binds the dye in acidic pH. A protein assay method should be chosen based on the sensitivity and accuracy of method as well as the condition of the sample to be analyzed.

STRATEGIC PLANNING

Colorimetric Protein Assays

The four colorimetric methods for the detection and quantitation presented in this unit have withstood the test of time. They are all well-characterized robust assays that consistently work well. The methods were introduced over the past 15 to 50 years. They collectively represent the state of the art for colorimetric detection and quantitation of total proteins in the microgram to milligram range.

When confronted with the need to determine the total protein concentration of a sample, one of the first issues to consider is selection of a protein assay method. The choice among the available protein assays usually is made based upon consideration of the compatibility of the method with the samples to be assayed. The objective is to select a method that requires the least manipulation or pretreatment of the samples due to the presence of substances that may interfere. If the total protein concentration in the samples is high (i.e., in the range of 5 to 160 mg/ml), the biuret total protein reagent is the best choice. If the total protein concentration in the samples is low (i.e., in the range of 1 to 2000 μg/ml), then any one of the other three (i.e., the Lowry, the Coomassie Plus, or the BCA method) would be suitable. If the sample contains reducing agents or copper-chelating reagents, the Coomassie Plus Protein Assay Reagent (Pierce) would be the best choice. If the sample contains one or more detergents (at concentrations up to 5%), the BCA Protein Assay Reagent is the best choice.

Sometimes the sample contains substances that make it incompatible with any of the protein assay methods. In those cases, some pretreatment of the sample is necessary.

Each method has its advantages and disadvantages. No one method can be considered to be the ideal or best protein assay method. Because of this, most researchers keep more than one type of protein assay reagent available in their laboratory.

Current Protocols in Cell Biology (2002) A.3H.1-A.3H.28

Selection of the Protein Standard

The selection of a protein standard is potentially *the* greatest source of error in any protein assay. Of course, the best choice for a standard is a highly purified version of the predominant protein found in the samples. This is not always possible nor always necessary. In some cases, all that is needed is a rough estimate of the total protein concentration in the sample. For example, in the early stages of purifying a protein, identifying which fractions contain the most protein may be all that is required. If a highly purified version of the protein of interest is not available or it is too expensive to use as the standard, the alternative is to choose a protein that will produce a very similar color response curve with the selected protein assay method.

For general protein assay work, bovine serum albumin (BSA) works well as the choice for a protein standard, because it is widely available in high purity and relatively inexpensive. Although it is a mixture containing several immunoglobulins, bovine gamma globulin (BGG) is also a good choice for a standard when determining the concentration of antibodies, since BGG produces a color response curve that is very similar to that of immunoglobulin G (IgG).

For greatest accuracy of the estimates of the total protein concentration in unknown samples, it is essential to include a standard curve in each run. This is particularly true for the protein assay methods that produce nonlinear standard curves (e.g., Lowry method, Coomassie dye–binding method). The decision about the number of standards used to define the standard curve and the number of replicates to be done on each standard depends upon the degree of nonlinearity in the standard curve and the degree of accuracy required of the results. In general, fewer points are needed to construct a standard curve if the color response curve is linear. For assays done in test tubes, duplicates are sufficient; however, triplicates are recommended for assays performed in microtiter plates due to the increased error associated with microtiter plates and microtiter plate readers.

Preparation of the Samples

Before a sample can be analyzed for total protein content, it must be solubilized, usually in a buffered aqueous solution. The entire process is usually done in the cold, with additional precautions taken to inhibit microbial growth or to avoid casual contamination of the sample by foreign debris such as hair, skin, or body oils. When working with tissues, cells, or solids, the first step of the solubilization process is usually disruption of the sample's cellular structure by grinding and/or sonication, or by the use of specially designed reagents containing surfactants to lyse the cells (i.e., the "POPPERS" line of products, available from Pierce). This is done in a cold aqueous buffer containing one or more surfactants (to aid the solubilization of the membrane-bound proteins), one or more biocides (to prevent microbial growth), and protease inhibitors (to minimize or prevent digestion of the proteins into peptide fragments by endogenous proteases). After filtration or centrifugation (to remove the cellular debris), additional steps such as sterile filtration, removal of lipids, or further purification of the protein of interest from the other sample components may be necessary.

Calculation of the Results

If calculating the protein concentrations manually, it is best to use point-to-point interpolation. This is especially true if the standard curve is nonlinear. Point-to-point interpolation refers to a method of calculating the results for each sample using the equation for a linear regression line obtained from just two points on the standard curve. The first point is the standard that has an absorbance just below that of the sample and the second point is the standard that has an absorbance just above that of the sample. In this way, the

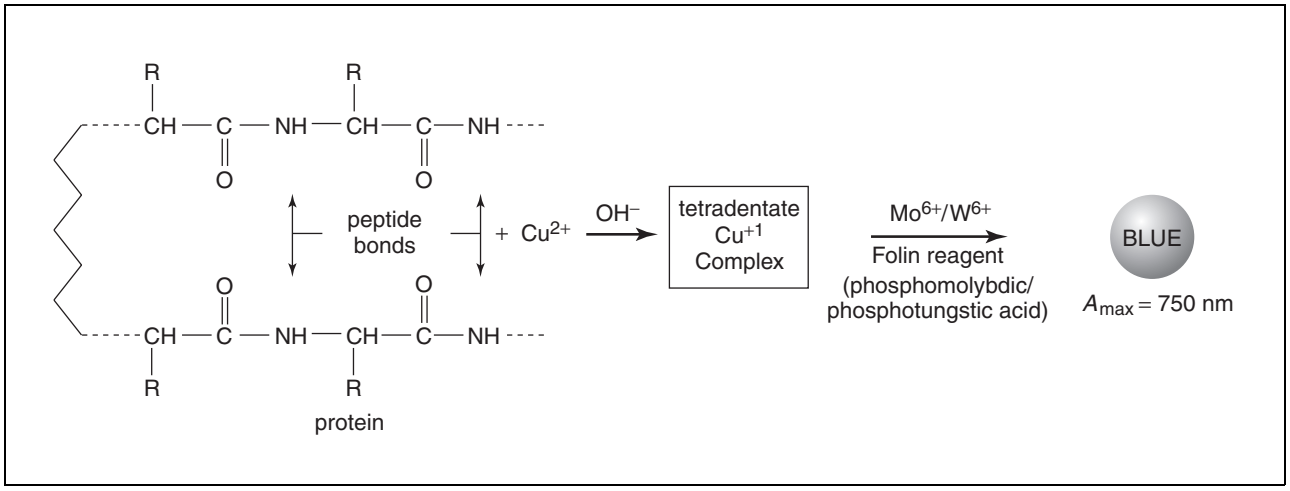

Figure A.3H.1 The reaction schematic for the Lowry Protein Assay.

concentration of each sample is calculated from the most appropriate section of the whole standard curve. The average total protein concentration for each sample is determined from the average of its replicates. If multiple dilutions of each sample have been run, the results for the dilutions that fall within the most linear portion of the working range are averaged.

If using a computer program, use a quadratic curve fit for the nonlinear standard curve to calculate the protein concentration of the samples. If the standard curve is linear or if the absorbance readings for the samples fall within the linear portion of the standard curve, the total protein concentrations of the samples can be estimated using the linear regression equation.

Most software programs will allow the experimenter to construct and print a graph of the standard curve as well as calculate the protein concentration for each sample and display statistics for the replicates. Typically, the statistics displayed will include the average of the absorbance readings (or the average of the calculated protein concentrations), the standard deviation (SD), and the coefficient of variation (CV) for each standard or sample. If multiple dilutions of each sample have been run, average the results for the dilutions that fall in the most linear portion of the working range.

THE LOWRY PROTEIN ASSAY FOR DETERMINATION OF TOTAL PROTEINS

BASIC PROTOCOL 1

In 1951, Oliver H. Lowry introduced this colorimetric total protein assay method. It offered a significant improvement over previous protein assays, and his paper became one of the most cited references in the life-science literature (Lowry, 1951). The Lowry assay is easy to perform since the incubations are done at room temperature and the assay is sensitive enough to allow the detection of total protein in the low microgram per milliliter range. It is one of three copper chelation chemistry–based methods presented in this unit. Essentially, the Lowry protein assay is an enhanced biuret assay (see Basic Protocol 3). After a short incubation, Lowry's reagent C (Folin phenol) is added for enhanced color development (Fig. A.3H.1). The Lowry assay requires fresh (daily) preparation of two reagents and a meticulously timed incubation step. The two reagents are combined just before use to make a buffered alkaline cupric sulfate working solution. The addition of sodium dodecyl sulfate (SDS) to Lowry's reagent D (i.e., Lowry's reagent D′) allows the method to be used with samples that contain detergents.

Materials

Standard protein: 2 mg/ml BSA (see recipe)
Sample buffer or solvent
Protein sample(s)
Lowry's Reagents C and D or D′ (see recipes)

1. Dispense 0 to 100 µl standard protein to appropriately labeled tubes and bring the total volume to 100 µl with sample buffer or solvent to prepare a dilution series from 10 to 100 µg.

   These concentrations of albumin should produce A_{750} readings from ~0.10 to 1.0 AU in 1-cm cuvettes.

2. Dispense ≤100 µl protein sample(s) to separate labeled tubes and adjust the final volume to 100 µl using the same buffer or solvent used to prepare the sample.

3. Add 1 ml reagent D (or reagent D′) to each of the standards and unknown samples. Vortex the tubes immediately to develop optimum color. Incubate for precisely 10 min at room temperature.

   If samples contain detergent, use reagent D′ to eliminate the interference associated with up to 1% of various detergents. If a precipitate forms in reagent D′, warm the reagent and vortex before addition.

4. While mixing, add 0.1 ml reagent C. Vortex the tubes immediately. Incubate for 30 min at room temperature.

5. Measure the color at 750 nm (A_{750}) on a spectrophotometer zeroed with deionized water.

   Read samples within 10 min, as samples continue to develop color. Samples incubated >60 min should be discarded.

   If the absorbance reading of the sample is higher than that of the highest concentration of standard, dilute the sample with buffer and repeat the procedure on the diluted sample.

6. Plot a standard curve by graphing the average net or blank-corrected A_{750} values for each standard versus its protein concentration in milligrams per milliliter.

7. Determine sample protein concentration by interpolating from the standard curve (see Strategic Planning).

ALTERNATE PROTOCOL 1

MODIFIED LOWRY PROTEIN ASSAY FOR DETERMINATION OF TOTAL PROTEINS

Preformulated, stabilized, modified versions of the Lowry reagent are now commercially available from Pierce (the Modified Lowry Protein Assay Reagent) or from Bio-Rad (the DC Protein Assay). The assay can be performed in test tubes or a microtiter plate (see Alternate Protocol 2). The working range of this assay is 1 to 1500 µg/ml if the Pierce reagent is used, or 200 to 1400 µg/ml if the Bio-Rad reagent is used. Table A.3H.1 is a brief troubleshooting guide for this technique.

Additional Materials *(also see Basic Protocol 1)*

Modified Lowry Protein Assay Kit (Pierce) containing:
2 mg/ml BSA in 0.9% (w/v) NaCl/0.05% (w/v) sodium azide
2 N Folin-Ciocalteu reagent: dilute fresh to 1 N
Modified Lowry's Reagent

Table A.3H.1 Troubleshooting Guide for the Modified Lowry Protein Assay

Problem	Possible cause	Solution
No color in any tubes	Sample contains a chelating agent (e.g., EDTA, EGTA)	Dialyze or dilute the sample
		Precipitate the protein with TCA and dissolve the pellet in modified Lowry reagent
Blank A_{750} is normal, but standards show less color than expected	Sample changed the pH of the reagent	Dialyze or dilute the sample
	Color measured at the wrong wavelength	Measure the color at 750 nm
Precipitate forms in all tubes	Sample contains a surfactant (detergent)	Dialyze or dilute the sample
	Sample contains potassium ions	Precipitate the protein with TCA, dissolve the pellet in Modified Lowry Reagent
All tubes (including the blank) are dark purple	Sample contains a reducing agent	Dialyze or dilute the sample
	Sample contains a thiol	Precipitate the protein with TCA, dissolve pellet in Modified Lowry Reagent
Need to read color at a different wavelength	Colorimeter does not have 750-nm filter	Color may be read at any wavelength between 650 nm and 750 nm

1. Prepare a dilution series of 2 mg/ml BSA (e.g., the standard provided in the Modified Lowry Protein Assay Kit) in buffer to cover the range 2.0 to 1500 µg/ml.

   If possible, use the same diluent or buffer cocktail for the blanks and for diluting the stock BSA standard that was used with the samples.

2. In duplicate, add 200 µl diluted standard, sample, or buffer (blank) into appropriately labeled test tubes.

   If possible, use the same diluent or buffer cocktail for the blanks and for diluting the stock BSA standard that was used with the samples.

3. At 15-sec intervals, add 1.0 ml Modified Lowry Protein Assay Reagent to each of the tubes. Vortex 2 to 3 sec to mix the contents of the tube and incubate at room temperature for *exactly* 10 min.

4. At the end of the first tube's 10-min incubation, add 100 µl freshly diluted 1 N Folin-Ciocalteu reagent (freshly diluted from a 2 N stock). Immediately vortex the tube for 2 to 3 sec. Continue to maintain the 15-sec intervals from step 3 for addition of the reagent to the remaining tubes.

5. Allow each of the tubes to incubate for 30 min at room temperature.

6. Measure the color at 750 nm (A_{750}) on a spectrophotometer zeroed with deionized water.

7. Plot a standard curve by graphing the average net or blank-corrected A_{750} values for each BSA standard versus its concentration in micrograms per milliliter.

   Example color response curves for BSA and BGG are shown in Figure A.3H.2.

8. Determine the sample concentration by interpolating from the plot (see Strategic Planning). Determine the average total protein concentration for each sample from the average of its replicates.

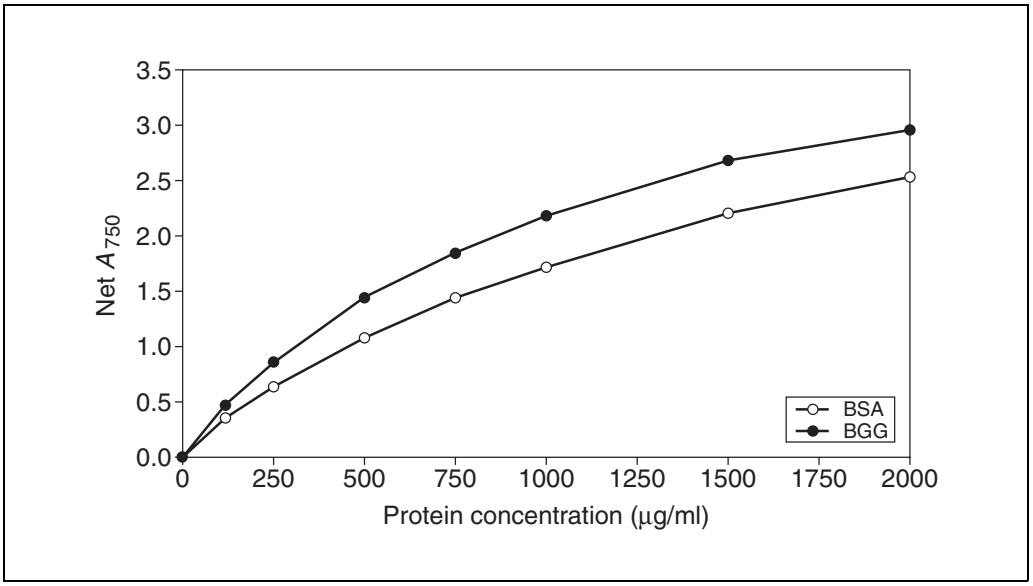

Figure A.3H.2 Graph of the color response curves obtained with Pierce's Modified Lowry Protein Assay Reagent using bovine serum albumin (BSA) and bovine gamma globulin (BGG). The standard tube protocol was performed and the color was measured at 750 nm in a Hitachi U-2000 spectrophotometer.

ALTERNATE PROTOCOL 2

MICROTITER PLATE MODIFIED LOWRY ASSAY FOR TOTAL PROTEIN

The modified Lowry assay can also be done in a 96-well microtiter plate format. The assay has a working range of 1 to 1500 μg/ml.

Additional Materials *(also see Alternate Protocol 1)*

Microtiter plate and cover or tape seals
200-μl multichannel pipettor
Microtiter plate reader for 750 nm

1. Draw a template for placement of samples and standards on the microtiter plate.

   Blanks, standards, and samples should be prepared in triplicate.

2. Add 40 μl of each diluted BSA standard (see Alternate Protocol 1, step 1), sample, or diluent (blank) to the appropriate wells of a 96-well plate.

   If possible, use the same diluent or buffer cocktail for the blanks and for diluting the stock BSA standard that was used with the samples.

3. Using a multichannel pipettor, quickly add 200 μl Modified Lowry Protein Assay Reagent to each of the wells. Mix immediately on a plate mixer for 30 sec.

4. Allow the plate to incubate at room temperature for *exactly* 10 min.

5. Using a multichannel pipettor, quickly add 20 μl freshly diluted 1 N Folin-Ciocalteu reagent to each well. Immediately mix on a plate mixer for 30 sec.

6. Cover the plate (to prevent evaporation) and incubate 30 min at room temperature.

7. Mix the plate again and measure the color (absorbance) of each well in a microtiter plate reader at 750 nm.

8. Plot a standard curve by graphing the average net or blank-corrected A_{750} values for each standard versus its protein concentration in micrograms per milliliter.

9. Determine the sample concentration by interpolating from the plot (see Strategic Planning). Calculate the average total protein concentration for each sample from the average of its replicates.

THE BICINCHONINIC ACID (BCA) FOR DETERMINATION OF TOTAL PROTEIN

BASIC PROTOCOL 2

Smith et al. (1985) introduced the bicinchoninic acid (BCA) protein assay reagent. In one sense, it is a modification of the Lowry protein assay reagent. The mechanism of color formation with protein for the BCA protein assay reagent is similar to that of the Lowry reagent, but there are several significant differences. The BCA protein assay reagent combines the reduction of Cu^{2+} to Cu^{+} by protein in an alkaline medium (i.e., the biuret reaction; see Basic Protocol 3) with the highly sensitive and selective colorimetric detection of the cuprous cation (Cu^{+}) by bicinchoninic acid. The purple-colored reaction product of this method is formed by the chelation of two molecules of BCA with one cuprous ion (Fig. A.3H.3). The BCA/copper complex is water-soluble and exhibits a strong linear absorbance at 562 nm with increasing protein concentrations. The primary advantage of the BCA protein assay reagent is that most surfactants, even if present in the sample at concentrations up to 5% (v/v), are compatible with this method. Table A.3H.2 is a brief troubleshooting guide for this technique.

Materials

Protein standard: 2 mg/ml BSA (see recipe)
Sample buffer or solvent
Protein sample
BCA working reagent: mix 100 parts BCA reagent A with 2 parts reagent B (see recipes for each reagent)

1. Prepare a dilution series of 2 mg/ml BSA in sample buffer or diluent to cover a range from 125 to 2000 µg/ml.
2. Add 100 µl sample, diluted standard, or buffer (blank) into appropriately labeled tubes.
3. Add 2 ml BCA working reagent mix to each tube. Vortex immediately.

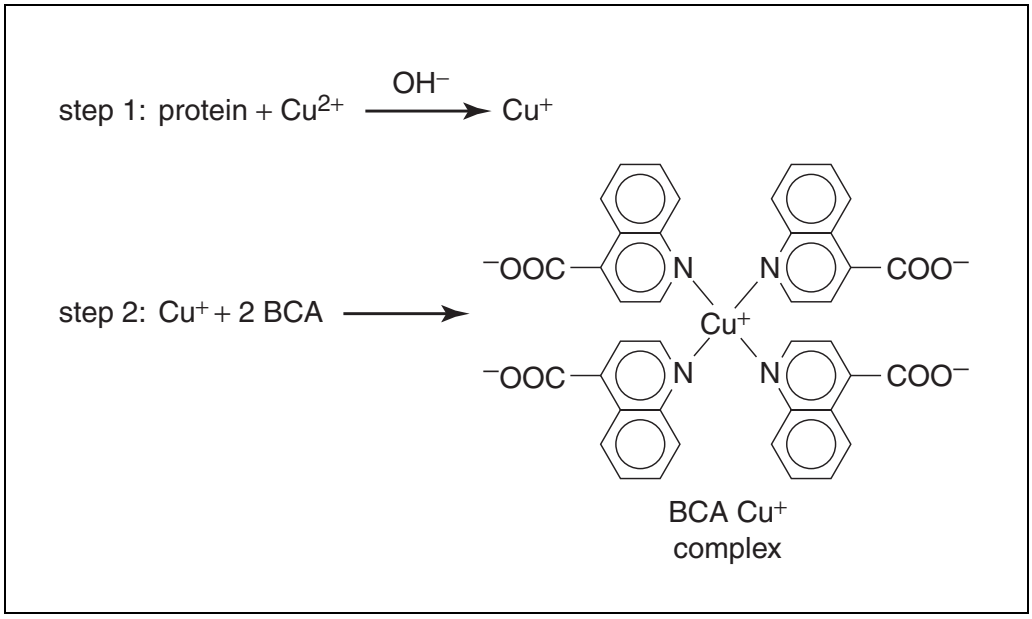

Figure A.3H.3 The reaction schematic for the BCA Protein Assay.

Table A.3H.2 Troubleshooting Guide for BCA Protein Assay

Problem	Possible cause	Solution
No color in any tubes	Sample contains a copper chelating agent	Dialyze or dilute the sample
		Increase the copper concentration in the working reagent (use 48 parts reagent A and 2 parts reagent B)
Blank A_{562} is normal, but standards and samples show less color than expected	Strong acid or alkaline buffer, alters working reagent pH	Dialyze or dilute the sample
	Color measured at the wrong wavelength	Measure the color at 562 nm
Color of samples appear darker than expected	Protein concentration is too high	Dilute the sample
	Sample contains lipids or lipoproteins	Add 2% (w/v) SDS to the sample to eliminate interference from lipids
All tubes (including the blank) are dark purple	Sample contains a reducing agent	Dialyze or dilute the sample
	Sample contains a thiol	Precipitate the protein with trichloroacetic acid (TCA) and deoxycholate (DOC), dissolve pellet in BCA working reagent
	Sample contains biogenic amines (catecholamines)	Treat the sample with iodoacetamide (for thiols)
Need to read color at a different wavelength	Colorimeter does not have 562-nm filter	Color may be read at any wavelength between 550 nm and 570 nm

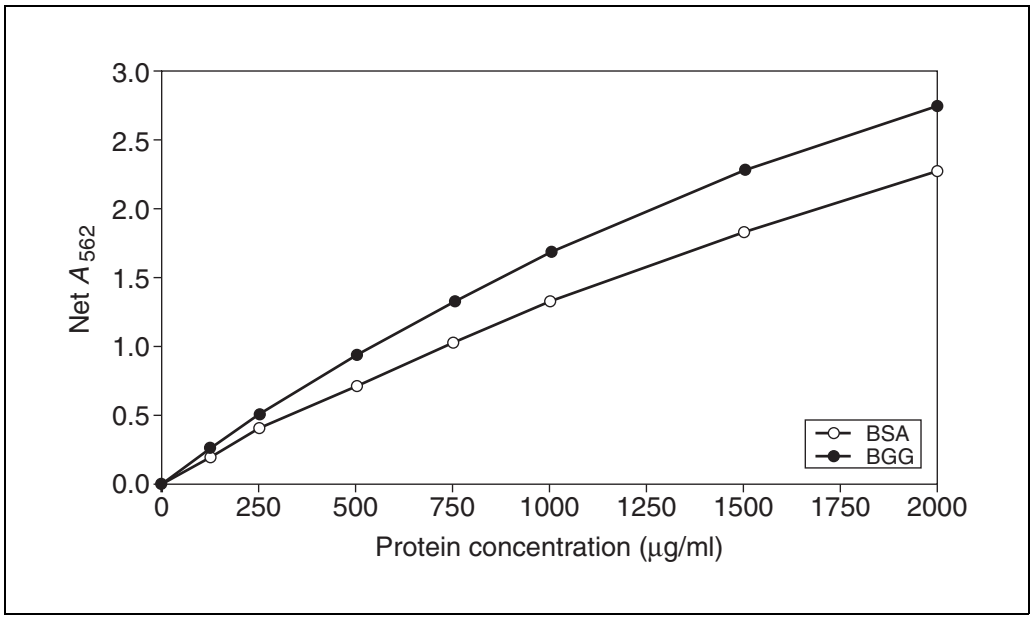

Figure A.3H.4 Graph of the color response curves obtained with Pierce's BCA Protein Assay Reagent using bovine serum albumin (BSA) and bovine gamma globulin (BGG). The standard tube protocol was performed and the color was measured at 562 nm in a Hitachi U-2000 spectrophotometer.

4. Incubate samples and standards for 30 min at 37°C, then cool to room temperature.
5. Measure the color at 562 nm (A_{562}) on a spectrophotometer zeroed with deionized water.
6. Plot a standard curve by graphing the average net or blank-corrected A_{750} values for the standards versus protein concentration in micrograms per milliliter.

   Example color response curves for BSA and BGG are shown in Figure A.3H.4.

7. Determine the protein concentration of the sample by interpolation from the plot (see Strategic Planning).

USING KITS FOR BCA MEASUREMENTS OF TOTAL PROTEIN

ALTERNATE PROTOCOL 3

Preformulated versions of the BCA reagent are now commercially available from Pierce (BCA Protein Assay Reagent) or Sigma (Bicinchoninic Acid Kit for Protein Determination). This assay can be performed in test tubes or microtiter plates (see Alternate Protocol 4), and has a working range of 20 to 2000 µg/ml.

Additional Materials

BCA Protein Assay Reagent Kit (Pierce) or Bicinchoninic Acid Kit (Sigma) containing:
2 mg/ml BSA in 0.9% NaCl/0.05% sodium azide (also see recipe)
BCA reagent A (also see recipe)
BCA reagent B (also see recipe)
37°C water bath

1. Prepare a dilution series of BSA standard in buffer to cover the range 125 to 2000 µg/ml.

   If possible, use the same diluent or buffer cocktail for the blanks and for diluting the stock BSA standard that was used with the samples.

2. Prepare sufficient BCA working reagent (a minimum of 2 ml/tube or 20 ml/96-well microtiter plate) by adding 2 parts BCA reagent B to 100 parts of BCA reagent A.

   After mixing, the BCA working reagent is clear and apple green in color.

3. In duplicate, add 100 µl standard, sample, or buffer (blank) into appropriately labeled test tubes.
4. Add 2.0 ml BCA working reagent to each tube. Mix well by vortexing each tube 2 to 3 sec.

5a. *Standard tube protocol:* Incubate all tubes in a 37°C water bath for 30 min.

5b. *Enhanced assay protocol:* Alternatively, incubate all tubes in a 60°C water bath for 30 min.

   Increasing the incubation temperature to 60°C lowers the minimum detection level to 5 µg/ml and narrows the working range of the assay to a maximum of 250 µg/ml. This is known as the enhanced BCA assay.

6. After incubation, cool all tubes to room temperature.

   Since the BCA reagent does not reach a true end point, color development will continue even after cooling to room temperature; however, the rate of color development is very slow after cooling to room temperature, so no significant error is introduced if the A_{562} readings of all the tubes can be read within ~10 min.

7. Before reading, mix each tube again and measure the amount of color produced in each tube with a spectrophotometer at 562 nm (A_{562}) versus deionized water.
8. Plot a standard curve by graphing the average net or blank-corrected A_{562} values for the standards versus protein concentration in micrograms per milliliter.
9. Determine the sample concentration by interpolating from the plot (see Strategic Planning). Calculate the average sample concentration from its replicates.

ALTERNATE PROTOCOL 4

MICROTITER PLATE ASSAY FOR BCA MEASUREMENT OF TOTAL PROTEIN

BCA assays can be run in 96-well microtiter plates. The assay has a working range of 125 to 2000 µg/ml.

Additional Materials *(also see Alternate Protocol 3)*

96-well microtiter plate with cover or tape seal
200-µl multichannel pipettor
Microtiter plate shaker
37°C dry-heat incubator
Microtiter plate reader

1. Draw a template for the placement of samples and standards on a microtiter plate.

   Blanks, standards, and samples should be prepared in triplicate.

2. Add 10 µl of each diluted BSA standard (see Alternate Protocol 3, step 1), sample, or diluent (blank) to the appropriate wells.
3. Using a multichannel pipettor, add 200 µl BCA working reagent (see Alternate Protocol 3, step 2) to each well. Mix well on a microtiter plate shaker for 30 sec.
4. Cover the plate and incubate in a 37°C dry-heat incubator for 30 min.
5. After incubation, allow the plate to cool to room temperature.
6. Mix the plate again, remove the plate cover and measure the color in each well of the plate at 562 nm (A_{562}) in a microtiter plate reader.
7. Plot a standard curve by graphing the average net or blank-corrected A_{562} values for each BSA standard versus its concentration in micrograms per milliliter.
8. Determine the sample concentration by interpolating from the plot (see Strategic Planning). Calculate the average total protein concentration for each sample from the average of its replicates.

BASIC PROTOCOL 3

THE BIURET ASSAY FOR DETERMINING TOTAL PROTEIN

All proteins are composed of amino acids joined by peptide bonds in a linear sequence. There are ~20 naturally occurring amino acids found in proteins. The amino acids are joined to each other by peptide bonds formed by a condensation reaction that occurs between the terminal amine of one amino acid and the carboxyl end of the next. Peptides containing three or more amino acid residues will form a colored chelate complex with cupric ions in an alkaline environment containing sodium potassium tartrate. A similar colored chelate complex forms with the organic compound biuret (NH_2–CO–NH–CO–NH_2) and the cupric ion. The reaction in which a colored chelation complex is formed with peptide bonds in the presence of an alkaline cupric sulfate solution became known as the biuret reaction (Fig. A.3H.5). Thus, the biuret protein assay reagent gets its name

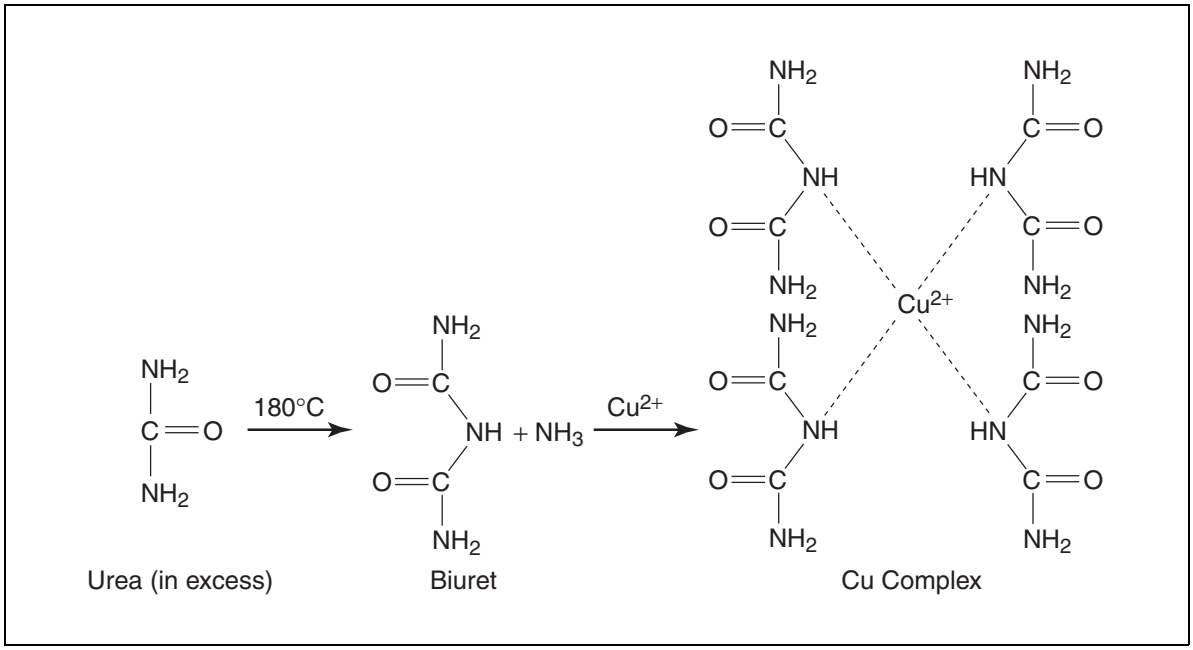

Figure A.3H.5 The schematic of the biuret reaction.

Table A.3H.3 Troubleshooting Guide for Biuret Protein Assay

Problem	Possible cause	Solution
No color in any tubes	Sample contains copper chelating agent	Dialyze or dilute the sample
Blank A_{540} is normal, but standards show less color than expected	Color measured at the wrong wavelength	Measure the color at 540 nm
All tubes (including the blank) are dark purple	Sample contains a reducing agent	Dialyze or dilute the sample

from the above reaction even though it does not actually contain the organic compound biuret. Single amino acids or dipeptides do not give the biuret reaction, but tripeptides and larger polypeptides or proteins will react to produce the light-blue to violet complex that absorbs light at 540 nm. One cupric ion forms the colored coordinate complex with 4 to 6 nearby peptides bonds. The intensity of the color produced is proportional to the number of peptide bonds participating in the reaction. Thus, the biuret reaction is the basis for a simple and rapid colorimetric method of quantitatively determining total protein concentration.

Because the working range for the biuret assay is from 5 to 160 mg/ml, the biuret reagent has found utility in the clinical laboratories for the quantitation of total protein in serum. The formulation employed in the biuret total protein reagent (Sigma Diagnostics) was developed by Doumas et al. (1981) as a candidate reference method for the determination of serum total protein in the clinical lab. Using Sigma's biuret reagent, the expected range for total protein in serum is from 63 to 83 mg/ml. Bilirubin, lipids, hemoglobin, and dextran are known to interfere in the biuret assay for total serum protein. Outside of this application, other copper chelating agents such as EDTA, EGTA, citrate, Tris, imino-

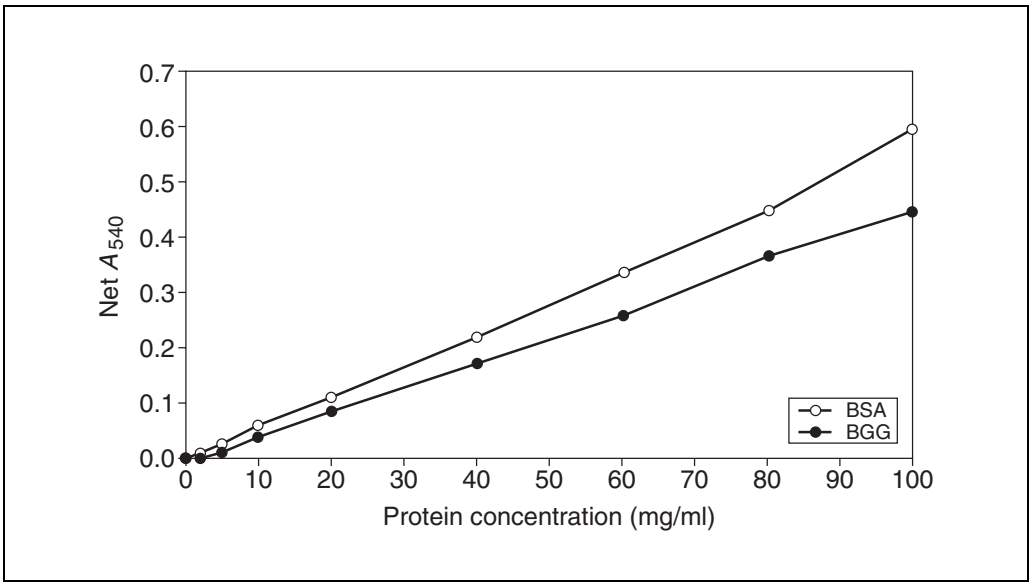

Figure A.3H.6 Graph of the color response curves obtained with Sigma's Biuret Total Protein Reagent using bovine serum albumin (BSA) and bovine gamma globulin (BGG). The standard tube protocol was performed and the color was measured at 540 nm in a Hitachi U-2000 spectrophotometer.

diacetic acid, and nitrilotriacetic acid will interfere. The working range of this assay is 5 to 160 mg/ml. Table A.3H.3 is a brief troubleshooting guide for this technique.

Materials

Standard protein (also see Commentary)
Sample (unknown) protein
Biuret total protein reagent (Sigma Diagnostics; also see recipe)

1. Select a protein to use as the standard (see Strategic Planning) and prepare a dilution series with buffer to cover the range 10 to 160 mg/ml.

   If possible, use the same diluent or buffer cocktail for the blanks and for diluting the standard that was used with the samples.

2. In duplicate, add 20 µl standard, sample, or diluent (blank) to appropriately labeled test tubes.
3. Add 1.0 ml biuret reagent to each tube. Mix well by vortexing 2 to 3 sec.
4. Incubate tubes at ambient room temperature (18° to 26°C) for 10 min.
5. Measure the color of each tube with a spectrophotometer at 540 nm (A_{540}). Compare to the blank.
6. Plot a standard curve by graphing the blank-corrected A_{540} values for the standards versus protein concentration in milligrams per milliliter.

   Example color response curves for BSA and BGG are shown in Figure A.3H.6.

7. Determine the sample concentration by interpolation from the standard curve (see Strategic Planning).

MICROTITER PLATE BIURET ASSAY FOR TOTAL PROTEIN

ALTERNATE PROTOCOL 5

The biuret assay can be performed in a 96-well microtiter plate and has a working concentration of 10 to 160 mg/ml.

Additional Materials *(also see Basic Protocol 3)*

96-well microtiter plate and cover or tape sealer
250-µl multichannel pipettor and appropriate tips
Microtiter plate mixer
Microtiter plate reader

1. Draw a template for placement of samples and standards on the microtiter plate.
2. Select a protein to use as the standard (see Strategic Planning). Prepare a dilution series with the same buffer used to dilute the samples to cover the range of 10 to 160 mg/ml.
3. In triplicate, add 5.0 µl of each diluted standard or sample into the appropriate microtiter plate wells. Use the buffer or diluent that was used to dilute the standard and samples for the blank wells.
4. Using a multichannel pipettor, add 250 µl biuret reagent to each well. Mix well on a plate shaker for 30 sec.
5. Cover the plate and incubate at room temperature for 10 min.
6. Mix again. Remove the plate cover and measure the color in each well of the plate at 540 nm (A_{540}) in a microtiter plate reader.
7. Prepare a standard curve by graphing the average net or blank-corrected A_{540} values for each standard versus its concentration in milligrams per milliliter.
8. Determine the sample concentration by interpolating from the plot (see Strategic Planning).

THE COOMASSIE DYE–BINDING (BRADFORD) ASSAY FOR DETERMINING TOTAL PROTEIN

BASIC PROTOCOL 4

The Coomassie dye–based protein-binding assays have the advantage of being the fastest and the easiest to perform (Fig. A.3H.7). In addition, the assay is performed at room temperature and no special equipment, other than a spectrophotometer, is required. Briefly, the sample is added to the ready-to-use reagent and, following a short incubation, the resultant blue color is measured at 595 nm versus deionized water.

In 1976, Marion Bradford introduced the first Coomassie dye–based reagent for the rapid colorimetric detection and quantitation of total protein. The Coomassie dye (Bradford) protein assay reagents have the advantage of being compatible with most salts, solvents, buffers, thiols, reducing substances, and metal chelating agents encountered in protein samples.

Materials

Sample buffer or solvent
Protein standard (e.g., 2 mg/ml BSA; see recipe)
Protein sample
Coomassie dye reagent (Pierce or Bio-Rad; also see recipe)

1. Prepare a dilution series from protein standard (e.g., 2 mg/ml BSA) and sample buffer to cover the range 100 to 1000 µg/ml.

   Bovine serum albumin (BSA) is often used as a calibration standard, but it has greater general dye-binding capacity than most proteins (Bradford, 1976).

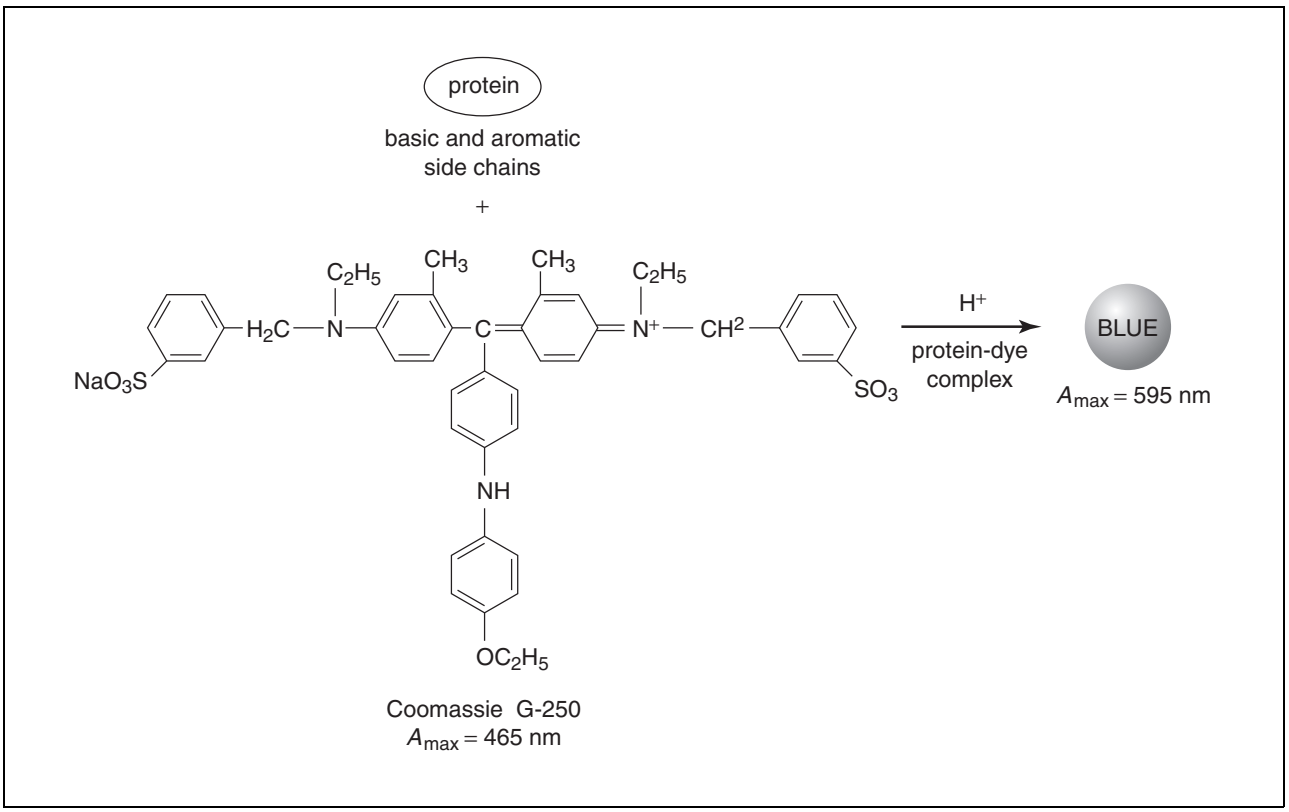

Figure A.3H.7 The reaction schematic for the Coomassie Protein Assay.

2. Dispense 0.1 ml standard, sample, or buffer to appropriately labeled tubes.

   If commercially prepared Coomassie reagent is used, follow the manufacturer's instructions. Commercial reagents tend to produce less turbidity and more consistent results.

3. Add 5 ml Coomassie dye reagent. Vortex immediately.
4. Incubate 10 min at room temperature.
5. Vortex each tube just before measuring the absorbance at 595 nm (A_{595}).
6. Plot a standard curve by graphing the average net or blank-corrected A_{595} values for the standard versus its protein concentration in micrograms per milliliter.
7. Determine the sample concentration by interpolation from the standard curve (see Strategic Planning).

ALTERNATE PROTOCOL 6

THE COOMASSIE PLUS PROTEIN ASSAY FOR DETERMINATION OF TOTAL PROTEIN

Several companies offer modified Bradford Coomassie dye–based protein assay reagents. Perhaps the most popular such reagent is the Protein Assay Reagent available from Bio-Rad. The Coomassie Plus Protein Assay Reagent available from Pierce is another modification of the Bradford formulation. In addition to the attributes cited above, the Coomassie Plus Protein Assay Reagent has the unique advantage of producing a linear response curve within a portion of its working range. For BSA, the response curve is linear from 125 to 1000 µg/ml and for bovine gamma globulin (BGG), the response curve is linear from 125 to 1500 µg/ml. The complete working range of the assay covers the concentration range from 100 to 2000 µg/ml for the tube protocol and from 1 to 25 µg/ml for the microtiter protocol (see Alternate Protocol 7).

Table A.3H.4 Troubleshooting Guide for Coomassie Plus Protein

Problem	Possible cause	Solution
Blank A_{595} is normal, but standards show less color than expected	Improper reagent storage	Store reagent refrigerated
	Reagent still cold	Warm to room temperature before use
	Color measured at the wrong wavelength	Measure the color at 595 nm
Blank and standards are normal, but samples show little color	Low molecular weight of sample protein (<3000 kDa)	Use the BCA (see Basic Protocol 2) or Lowry protein assay (see Basic Protocol 1)
A precipitate forms in all tubes	Sample contains a surfactant (detergent)	Dialyze or dilute the sample
		Precipitate the protein with TCA, dissolve pellet in 50 mM NaOH
All tubes (including the blank) are dark blue	Strong alkaline buffer or reagent raises reagent's pH	Dialyze or dilute the sample
	Sample volume too large, reagent pH raised	Maximum of 1 part sample and 1 part reagent
Need to read color at a different wavelength	Colorimeter does not have 595 nm filter	Color may be read at any wavelength between 575 nm and 615 nm

The main disadvantage of all Bradford-type protein assay reagents is that they are not compatible with surfactants at concentrations routinely used to solubilize membrane proteins. With some exceptions, the presence of a surfactant in the sample, even at low concentrations, causes precipitation of the reagent. Table A.3H.4 is a brief troubleshooting guide for this technique.

Additional Materials *(also see Basic Protocol 4)*

Coomassie Plus Protein Assay Reagent Kit (Pierce) containing Coomassie Plus Protein Assay Reagent

1. Prepare a dilution series with 2 mg/ml BSA and buffer to cover a range from 100 to 2000 µg/ml.

   If possible, use the same diluent or buffer cocktail for the blanks and for diluting the stock BSA standard that was used with the samples.

2. Allow the Coomassie Plus Protein Assay reagent to come to room temperature. Mix the assay reagent well by gentle inversion before use.
3. In duplicate, dispense 50 µl standard, sample, or diluent (blank) into appropriately labeled test tubes.
4. Add 1.5 ml Coomassie Plus Protein Assay Reagent to each tube. Mix each tube well by vortexing 2 to 3 sec.
5. Let the tubes stand 10 min at room temperature.
6. Mix each tube again just before measuring the absorbance at 595 nm (A_{595}).

   Disposable polystyrene cuvettes eliminate the job of cleaning dye-stained quartz or glass cuvettes.

7. Plot a standard curve by graphing the average net or blank-corrected A_{595} reading for each standard versus its concentration in micrograms per milliliter.

   Example color response curves for BSA and BGG are shown in Figure A.3H.8.

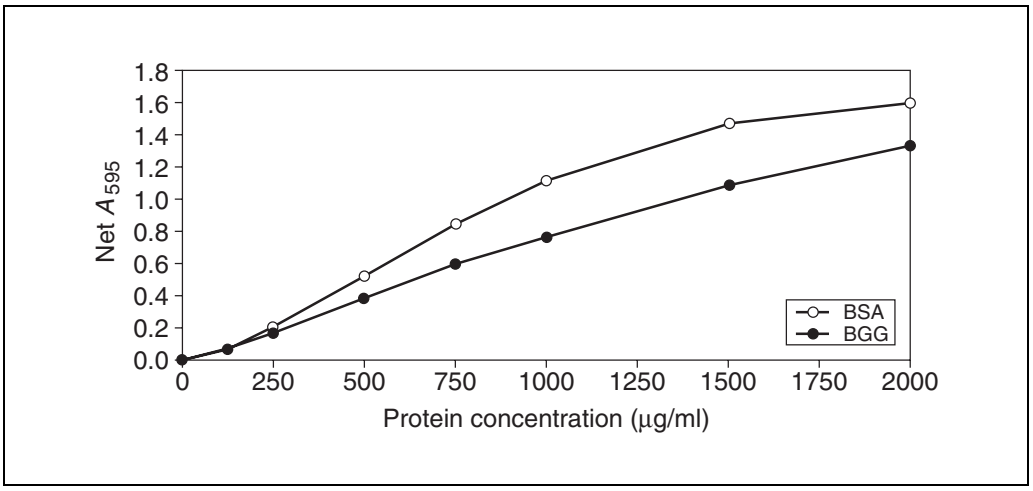

Figure A.3H.8 Graph of the color response curves obtained with Pierce's Coomassie Plus Protein Assay Reagent using bovine serum albumin (BSA) and bovine gamma globulin (BGG). The standard tube protocol was performed and the color was measured at 595 nm in a Hitachi U-2000 spectrophotometer.

8. Determine the protein concentration for each sample by interpolating from the standard curve (see Strategic Planning). Calculate the average total protein concentration for each sample from the replicates.

ALTERNATE PROTOCOL 7

MICROTITER PLATE COOMASSIE ASSAY FOR TOTAL PROTEIN

This microtiter plate assay has a working range of 1 to 25 µg/ml.

Additional Materials *(see Basic Protocol 4)*

Coomassie Plus Protein Assay Reagent Kit (Pierce) containing Coomassie Plus Protein Assay reagent
96-well microtiter plate
300-µl multichannel pipettor
Microtiter plate mixer
Microtiter plate reader

1. Allow the Coomassie Plus Protein Assay Reagent to come to room temperature. Once the reagent is at room temperature, mix the reagent well by gentle inversion of the bottle.
2. Draw a template for placement of samples and standards on a 96-well microtiter plate.
3. In triplicate, dispense 10 µl of each diluted BSA standard, sample, or diluent (blank) into the appropriate wells of a 96-well microtiter plate.

   If possible, use the same diluent or buffer cocktail for the blanks and for diluting the stock standard that was used with the samples.

4. Dispense 300 µl Coomassie Plus Protein Assay reagent into each well with a multichannel pipettor. Mix the plate well on a plate shaker for 30 sec.
5. Let the plate incubate 10 min at room temperature.
6. Just before reading, mix the plate again, then measure the absorbance at 595 nm (A_{595}) on a plate reader.

7. Prepare a standard curve by graphing the average net or blank-corrected A_{595} values for each standard versus its concentration in micrograms per milliliter.

8. Determine the sample concentration by interpolating from the standard curve (see Strategic Planning). Calculate the average total protein concentration for each sample from the replicates.

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

BCA reagent A

1 g 4,4′-dicarboxy-2,2′-biquinoline, disodium salt (Na_2BCA; Pierce or Sigma; 1% w/v final)
2 g $Na_2CO_3 \cdot H_2O$ (2% w/v final)
160 mg sodium tartrate dihydrate (0.16% w/v final)
0.4 g NaOH (0.4% w/v final)
0.95 g $NaHCO_3$ (0.95% w/v final)

Dissolve all of the above chemicals except the sodium bicarbonate in deionized water and adjust the final volume to 100 ml. Adjust the pH to 11.25 by adding the sodium bicarbonate a little at a time. Store this alkaline reagent in a plastic container 1 to 3 weeks at room temperature, longer at 4°C.

Only the disodium salt of Na_2BCA is soluble at neutral pH; the free acid is not readily soluble.

BCA reagent B

4 g $CuSO_4 \cdot 5H_2O$ (4% w/v final)
100 ml H_2O
Store up to 6 months at room temperature

Biuret total protein reagent

0.6 mol/liter sodium hydroxide
12.0 mmol/liter copper sulfate
31.9 mmol/liter sodium potassium tartrate
30.1 mmol/liter potassium iodide
Store up to 6 months at room temperature

This reagent is based upon the candidate reference method for the determination of total protein in serum developed by Doumas et al. (1981). It is available from Sigma Diagnostics.

BSA, 2 mg/ml (w/v)

200 mg BSA (crystallized or lyophilized or one of the Cohn Fraction V preparations which are 96% to 98% protein and 3% to 4% water) in 100 ml of 0.9% saline containing 0.05% (w/v) sodium azide. Store up to 6 months at 4°C.

Coomassie dye reagent

100 mg Coomassie Brilliant Blue G-250 (0.01% w/v final)
50 ml 95% ethanol (4.7% (w/v) final)
100 ml 85% (w/v) phosphoric acid (8.5% w/v final)

In a small container, dissolve the dye in ~25 ml ethanol, add the dye/ethanol solution to 800 ml of deionized water. Use the remaining ethanol to rinse the dye/ethanol container and add the rinses to the formulation. While mixing, slowly add the acid to the formulation and adjust the final volume to 1000 ml with deionized water. Filter the reagent through a single pad of Whatman no. 2 filter paper. Store up to 1 month at room temperature in a glass container.

continued

Coomassie Brilliant Blue G-250 (color index 42655) is available from a number of different suppliers (e.g., ACROS, Aldrich, AMRESCO, Bio-Rad, Fisher Biotech, Fluka, ICN Biomedicals, J.T. Baker, Research Organics, Serva, Sigma, or USB).

Lowry's reagent A

21.2 g sodium carbonate (2% w/v)
40 ml 1 N NaOH (or 4.0 g NaOH; 0.1 N final)
Add distilled or deionized water to 1 liter
Make fresh daily

Lowry's reagent B

0.5 g $CuSO_4 \cdot 5H_2O$ (0.5% final)
1 g sodium tartrate (1% final)
Make fresh daily

Sodium tartrate may be replaced with disodium tartrate, potassium sodium tartrate, or sodium citrate for better solubility.

Lowry's reagent C (1 N Folin phenol reagent)

Dilute 2 N Folin phenol (Sigma, Fisher, or VWR) with an equal volume water. Prepare immediately before use.

Lowry's reagent D (reagent A and B mix)

Mix 1 vol Lowry's reagent B and 50 vol Lowry's reagent A (see recipes). Prepare immediately before use.

Lowry's reagent D′

Add 2 ml of 10% (w/v) sodium dodecyl sulfate (SDS; *APPENDIX 2A* for 20% solution) in deionized water to each 100 ml Lowry's reagent D (see recipe). Prepare immediately before use.

COMMENTARY

Background Information

The Modified Lowry Protein Assay

Although the exact mechanism of color formation reaction in the Lowry protein assay remains poorly understood, it is known that the color producing reaction with protein occurs in two distinct steps. As seen in Figure A.3H.1, protein is first reacted with alkaline cupric sulfate in the presence of tartrate during a 10-min incubation at room temperature. During this incubation, a tetradentate copper complex forms from four peptide bonds and one atom of copper. The tetradentate copper complex is light blue in color (this is the "biuret reaction"). Following the 10-min incubation, Folin phenol reagent is added. It is believed that color enhancement occurs when the tetradentate copper complex transfers electrons to the phosphomolybdic/phosphotungstic acid complex (i.e., the Folin phenol reagent).

The reduced phosphomolybdic/phosphotungstic acid complex produced by this reaction is intensely blue in color. The Folin phenol reagent loses its reactivity almost immediately upon addition to the alkaline working reagent/sample solution. The blue color continues to intensify during a 30-min room temperature incubation. It has been suggested by Lowry et al. (1951) and by Legler et al. (1985) that during the 30-min incubation, a rearrangement of the initial unstable blue complex leads to the stable final blue colored complex, which has higher absorbance.

For small peptides, the amount of color increases with the size of the peptide. The presence of any of five amino acid residues (tyrosine, tryptophan, cysteine, histidine, and asparagine) in the peptide or protein backbone further enhance the amount of color produced, because they contribute additional reducing equivalents for further reduction of the phosphomolybdic/phosphotungstic acid complex. With the exception of tyrosine and tryptophan, free amino acids will not produce a colored product with the Lowry reagent; however, most dipeptides can be detected. In the absence of any of the five amino acids listed above, proteins containing proline residues have a lower

color response with the Lowry reagent because it interferes with complex formation.

The final blue color is optimally measured at 750 nm, but it can be measured at any wavelength between 650 nm and 750 nm with little loss of color intensity. Dr. Lowry (1951) recommended reading the color at 750 nm because few other substances absorb light at that wavelength. The amount of light absorbed at 750 nm is directly proportional to the amount of protein in the sample, but the color response curve produced is nonlinear.

The sensitivity of the Modified Lowry Protein Assay Reagent is greatly enhanced over that of the biuret total protein reagent. The working range of the method covers the total protein range from 1 to 1500 μg/ml. In comparison, the working range for the biuret assay is from 5 to 160 mg/ml.

The Modified Lowry Protein Assay Reagent will form precipitates in the presence of surfactants or potassium ions. The problem of precipitation that is caused by the presence of potassium ions in the sample can sometimes be overcome by centrifuging the tube and reading the color in the supernatant. Most surfactants will cause precipitation of the reagent even at very low concentrations. One exception is sodium dodecyl sulfate (SDS), which is compatible with the reagent at concentrations up to 1% (w/v) in the sample. Chelating agents interfere because they bind copper and thus prevent formation of the copper-peptide bond complex. Reducing agents and free thiols interfere, as they reduce the phosphotungstate-phosphomolybdate complex, immediately forming an intensely blue colored product upon their addition to the Modified Lowry Protein Assay Reagent.

The Coomassie Plus Protein Assay

The primary advantage of the Coomassie Plus Protein Assay is that it is generally compatible with most of the buffers and reagents found in samples and is unaffected by the presence of chelating agents, reducing agents, or free sulfhydryls in the sample.

The development of color in the Coomassie dye-binding methods has been associated with the presence of certain basic amino acids (primarily arginine, lysine, and histidine) in the protein. Van der Waals forces and hydrophobic interactions also participate in the binding of the dye by protein. The number of Coomassie dye ligands bound to each protein molecule is approximately proportional to the number of positive charges found on the protein. In the acidic environment of the Coomassie Plus Protein Assay Reagent, protein binds to the Coomassie dye. This results in a spectral shift of the reagent from the reddish/brown form of the dye, with an absorbance maximum at 465 nm, to the blue form of the dye, with an absorbance maximum at 610 nm (see Fig. A.3H.7).

The difference between the two forms is greatest at 595 nm; therefore, this is the optimal wavelength to measure the blue color from the Coomassie dye–protein complex. If desired, the blue color can be read at any wavelength between 575 and 615 nm. At the two extremes (575 and 615 nm) there is a loss of ~10% in the measured amount of color (absorbance) compared to the value obtained at 595 nm.

Free amino acids, peptides, and low molecular weight proteins do not produce color with the Coomassie Plus Protein Assay Reagent. In general the molecular weight of the peptide or protein must be at least 3000 Da to be assayed with this reagent. In some applications this can be an advantage. The reagent has been used to measure "high molecular weight proteins" during fermentation in the beer brewing industry.

One disadvantage of any Coomassie dye–based protein assay is that surfactants in the sample will cause precipitation of the reagent. Another disadvantage is that the Coomassie Plus Protein Assay Reagent shows almost twice as much protein-to-protein variation as that obtained with the protein-copper chelation–based assay reagents (the Lowry Protein Assay Reagent or the BCA Protein Assay Reagent). While this is true, the reagent exhibits the least protein-to-protein variation of all Coomassie dye–based (Bradford) reagents. Since the Coomassie dye reagent is highly acidic, a small number of proteins cannot be assayed with this reagent due to poor solubility. In addition, the glass or quartz cuvettes routinely used to hold the solution in the spectrophotometer while the color intensity is being measured are stained by Coomassie dye–based reagents.

The BCA Protein Assay

The BCA Protein Assay is a modification of the Lowry protein assay in which enhanced color production is due to the reaction of reduced copper with bicinchoninic acid (BCA). This reagent has a unique advantage over the Lowry Protein Assay Reagent and the Coomassie Plus Protein Assay Reagent because it is compatible with samples that contain up to 5% (v/v) surfactants (detergents). Unlike the Lowry protein assay, all reactants needed are present in the BCA working reagent. Large

numbers of tubes can be run without regard to the limits imposed in the Lowry assay by the need to add a second reagent at a precise time interval.

The working range of the BCA Protein Assay Reagent is from 20 to 2000 µg/ml for both the standard tube and the standard microtiter plate protocols. Since the color reaction is not a true end-point reaction, this allows more protocol flexibility. By increasing the incubation temperature, the sensitivity of the reagent can be increased. When using the enhanced tube protocol (incubating at 60°C for 30 min), the working range for the assay shifts to 5 to 250 µg/ml and the minimum detection level becomes 5 µg/ml.

Although the mechanism of color formation with protein for the BCA Protein Assay Reagent is similar to that of the Lowry reagent, there are several significant differences. The BCA Protein Assay combines the well-known reduction of Cu^{2+} to Cu^{+} by protein in an alkaline medium (the so-called biuret reaction) with the highly sensitive and selective colorimetric detection of the cuprous cation (Cu^{+}) by bicinchoninic acid. The purple-colored reaction product of this assay is formed by the chelation of two molecules of BCA with one cuprous ion (see Fig. A.3H.3). The resultant BCA/Cu^{+} complex is water-soluble and exhibits a strong linear absorbance maximum at 562 nm with increasing protein concentrations. If desired, the purple color may be measured at any wavelength between 550 nm and 570 nm with minimum (<10%) loss of signal.

The reaction that leads to BCA color formation as a result of the reduction of Cu^{2+} is also strongly influenced by the presence of any of four amino acid residues (tyrosine, tryptophan, cysteine, or cystine) in the amino acid sequence of the protein. Unlike the Coomassie dye–binding (Bradford) methods, which require a minimum mass of protein to be present for the dye to bind, the presence of only a single amino acid residue in the sample may result in the formation of a colored BCA-Cu^{+} chelate. This is true for any of the four amino acids cited above. Studies done with di- and tripeptides indicate that the total amount of color produced is greater than can be accounted for by the simple addition of the color produced with each BCA-reactive amino acid, so the peptide backbone must contribute to the reduction of copper as well.

The rate of color formation is dependent on the incubation temperature, the types of protein present in the sample, and the relative amounts of reactive amino acids contained in the proteins. The recommended protocols do not result in end-point determinations, so the incubation periods were chosen to yield maximal color response in a reasonable time frame.

The protein-to-protein variation in the amount of color produced with the BCA Protein Assay Reagent (CV = 15% for the group of 14 proteins at 1000 µg/ml in the standard tube protocol) is similar to that observed for the Modified Lowry Protein Assay Reagent.

The biuret total protein assay

Riegler (1914) introduced the biuret reaction as a method for the estimation of albumin in urine in 1914. Modifications and improvements to the biuret method were made by Autenrieth and Mink (1915), Hiller (1926), and Fine (1935). All of these early methods required the separate addition of a sodium hydroxide solution and the separate addition of a copper sulfate solution to the sample. The methods suffered from poor precision due to ineffective mixing and variation in reaction time during mixing. The first "one solution" biuret reagent was introduced by Kingsley (1942) for use in measuring total protein, albumin, and globulin in human serum. Weichselbaum (1946) and Gornall et al. (1949) modified Kingsley's biuret reagent by decreasing the sodium hydroxide concentration to prevent the formation of precipitates and by adding sodium potassium tartrate to stabilize the reagent. Potassium iodide was added to prevent the autoreduction of Cu^{2+}. Goa (1953) published on the use of the biuret reagent for determining total protein in human cerebrospinal fluid.

Sigma Diagnostic's biuret total protein reagent is based upon the candidate reference method formulation used for the determination of total protein in serum developed by Doumas et al. (1981). Because the primary application for this reagent is the determination of total protein in serum, most of the studies regarding assay precision, assay linearity, and interfering substances have been done on clinical samples. On samples with total protein concentrations in the range of 26 to 121 mg/ml, within-run and between-run precision was found to be excellent (CV's ranged from 4.2% to 1.4%). Lipids, bilirubin, hemoglobin, dextran, and certain drugs have been shown to interfere with the total protein results obtained with the biuret Total Protein Reagent. Interference caused by the presence of lipid in the sample is due to turbidity. Interference caused by the presence of bilirubin or hemoglobin is small, almost

negligible. Dextran causes precipitation in the reaction mixture during color development; however, centrifuging the reaction mixture before reading the color can minimize this. The biuret Total Protein Reagent contains 0.6 mol/liter sodium hydroxide, 12.0 mmol/liter copper sulfate, 31.9 mmol/liter sodium potassium tartrate, and 30.1 mmol/liter potassium iodide. It should be stored at ambient room temperature until the expiration date shown on the label. Certain drugs and other substances are known to influence circulating levels of total protein (Young, 1990).

Critical Parameters

The Modified Lowry Protein Assay Reagent

The Modified Lowry Protein Assay Reagent must be refrigerated for long-term storage. If the entire bottle of reagent will be used within a reasonable time, the reagent may be stored at ambient room temperature (18° to 26°C) for up to 1 month. Reagent that has been left at room temperature for more than a month may show lower color response with protein, especially at the higher end of the working range. If the reagent has been stored refrigerated, it must be warmed to room temperature before use. The use of cold Modified Lowry Protein Assay Reagent will result in low A_{750} values.

The protocol requires that the Folin phenol reagent be added to each tube precisely at the end of the 10-min incubation. At the alkaline pH of the Lowry reagent, the Folin phenol reagent is almost immediately inactivated; therefore, it is best to add the Folin phenol reagent at the precise time while simultaneously mixing each tube. Because it is somewhat cumbersome, it requires some practice to do the assay well. From a practical point of view, it also limits the total number of tubes that can be done in a single run. If a 10-sec interval between tubes is used, the maximum number of tubes that can be done within 10 min is 60 (10 sec/tube × 60 tubes = 600 sec or 10 min).

The Coomassie Plus Protein Assay Reagent

The Coomassie Plus Protein Assay Reagent must be refrigerated for long-term storage. If the entire bottle of reagent will be used within a reasonable time, the reagent may be stored at ambient room temperature (18° to 26°C) for up to 1 month. Reagent that has been left at room temperature for more than a month may show lower color response with protein, especially at the higher end of the working range. If the reagent has been stored refrigerated, it must be warmed to room temperature before use. The use of cold Coomassie Plus Protein Assay Reagent will result in low A_{595} values.

The Coomassie Plus Protein Assay Reagent must be mixed gently by inversion just before use. The Coomassie dye in the reagent spontaneously forms loosely associated dye-dye aggregates upon standing. These aggregates may become visible after the reagent has been standing for as little as 60 min. Gentle mixing of the reagent by inversion of the bottle will uniformly disperse the dye-dye aggregates. After binding to protein, the dye also forms protein-dye-protein-dye aggregates. Fortunately, these aggregates can be dispersed easily by mixing the reaction tube. This is common to all Coomassie dye–based (Bradford) protein assay reagents. Since these aggregates form relatively quickly, it is a good idea to routinely mix (vortex for 2 to 3 sec) each sample just before measuring the color.

Bradford-type reagents containing Coomassie dye will leave a blue stain on glass or quartz cuvettes. The stain can be removed by washing the cuvettes in a dilute detergent solution in hot tap water, rinsing with water, then washing with methanol or ethanol, and finally rinsing with deionized water. Disposable plastic (polystyrene) cuvettes are strongly recommended because they eliminate the need to clean; however, these cuvettes are not compatible with samples containing organic solvents (e.g., acetone, DMF, acetonitrile).

The BCA Protein Assay Reagent

Since the BCA Protein Assay is not a true end-point assay, the amount of color produced varies with the incubation time and the incubation temperature. While this allows considerable flexibility in optimizing the BCA assay for each application, it also requires that the optimized procedure be followed exactly every time the assay is done.

At room temperature, following an initial lag phase, the rate of color formation remains relatively constant for hours. If the incubation time alone is increased, the total amount of color produced by a given mass of protein increases.

If the incubation temperature is increased, the rate of color formation increases and the total amount of color produced by a given mass of protein increases. After cooling the reaction mixture back to room temperature, the rate of color development slows from its initial rate. As both time and temperature are increased, the total amount of color produced by a given mass

of protein approaches a maximum. This is apparent from the dramatic decrease in the rate of color formation upon cooling to room temperature following incubation at 60°C for 30 min.

Above 75°C, a black precipitate forms in the BCA reaction mixture and the absorbance at 562 nm of the blank increases dramatically. This appears to be caused by the formation of copper oxide at high temperature.

For greatest accuracy and precision when comparing sets of data from multiple runs, a set of standards must be included with each run, and the standards and the samples must be treated exactly the same.

The biuret total protein reagent

The biuret total protein reagent is considerably less sensitive to total protein than the other three protein assay reagents discussed in this unit. This limits the applications in which the biuret reagent can be used. Since the primary use of the biuret reagent has been for serum total protein in the clinical laboratory, there is little published information about its compatibility with substances and reagents common to nonclinical samples.

Anticipated Results

Standard curves

Typical standard curves are shown in Figures A.3H.2, A.3H.4, A.3H.6, and A.3H.8 for each of the four assay methods. In each case, the tube protocols were performed in duplicate on diluted BSA or BGG standard. The color in each tube was measured at the appropriate wavelength in a dual-beam spectrophotometer. The net absorbance for each sample was plotted versus its protein concentration.

Figure A.3H.2 shows the color response curves obtained with the Modified Lowry Protein Assay Reagent using BSA and BGG. The graph shows the net absorbance at 750 nm versus the protein concentration at seven concentrations from 125 to 2000 µg/ml for each protein. Note that the response curve for BGG is higher than the response curve for BSA.

Figure A.3H.4 shows the color response curves obtained with the BCA Protein Assay Reagent using BSA and BGG. The graph shows the net absorbance at 562 nm versus the protein concentration at seven concentrations from 125 to 2000 µg/ml for each protein. Note that the response curve for BGG is higher than the response curve for BSA.

Figure A.3H.6 shows the color response curves obtained with the biuret total protein reagent using BSA and BGG. The graph shows the net absorbance at 540 nm versus the protein at eight concentrations from 5 to 100 mg/ml.

Figure A.3H.8 shows the color response curves obtained with the Coomassie Plus Protein Assay Reagent using BSA and BGG. The graph shows the net absorbance at 595 nm versus the protein concentration at seven concentrations from 125 to 2000 µg/ml for each protein. Note that the color response curve for BGG is lower than the response curve for BSA.

Protein-to-protein variation

Each protein in a sample is unique and can demonstrate that individuality in protein assays as variation in the color response. Such protein-to-protein variation refers to differences in the amount of color (absorbance) that are obtained when the same mass (microgram or milligram) of various proteins are assayed concurrently (i.e., in the same run) by the same method. These differences in color response relate to differences among proteins due to amino acid sequence, isoelectric point (pI), secondary structure, and the presence of certain side chains or prosthetic groups.

To analyze protein-to-protein variation for each method, a group of fourteen proteins was assayed in duplicate using the standard tube protocol in a single run. The net (blank-corrected) average absorbance for each protein was calculated. To make it easier to interpret, the net absorbance for each protein was expressed as a ratio to the net absorbance for BSA. If a protein has a ratio of 0.80, it means that the protein produces ~80% of the color that is obtained for an equivalent mass of BSA.

Table A.3H.5 demonstrates the relative degree of protein-to-protein variation that can be expected with the different protein assay methods. This differential may be a consideration in selecting a protein assay method, especially if the relative color response ratio of the protein in the samples is unknown. As expected, the protein assay methods that share the same basic chemistry show similar protein-to-protein variation.

The protein-to-protein variation observed with the various protein assay methods makes it obvious why the largest source of error for protein assays is the choice of protein for the standard curve. If the sample contained IgG as the major protein and BSA was used for the standard curve, the estimated total protein concentration of the sample will be inaccurate. Whether the concentration was underestimated or overestimated depends upon which total pro-

Table A.3H.5 Protein-to-Protein Variation[a]

Protein tested	Ratios obtained with the BCA method	Ratios obtained with the Coomassie plus method	Ratios obtained with the modified Lowry method
Albumin, bovine (BSA)	1.00	1.00	1.00
Aldolase, rabbit	0.85	0.74	0.94
α-Chymotrypsinogen, bovine	1.14	0.52	1.17
Cytochrome C, horse	0.83	1.03	0.94
Gamma globulin, bovine	1.11	0.58	1.14
IgG, bovine	1.21	0.63	1.29
IgG, human	1.09	0.66	1.13
IgG, mouse	1.18	0.62	1.20
IgG, rabbit	1.12	0.43	1.19
IgG, sheep	1.17	0.57	1.28
Insulin, bovine pancreas	1.08	0.67	1.12
Myoglobin	0.74	1.15	0.90
Ovalbumin	0.93	0.68	1.02
Transferrin, human	0.89	0.90	0.92
Average ratio	1.02	0.73	1.09
Standard Deviation (SD)	0.15	0.12	0.13
Coefficient of Variation	0.15	0.29	0.12

[a]The protein-to-protein variation in color response was measured at 1000 µg/ml for each protein in duplicate using the standard tube protocol. Within each assay, the average net or blank-corrected absorbance was determined for each protein. The average net absorbance for each protein was divided by the average net absorbance obtained with BSA and expressed as a ratio. The standard deviation (SD) and the coefficient of variation (CV) is presented for the fourteen proteins assayed on the three methods. By comparing the CV's, the relative degree of protein-to-protein variation to be expected with the three methods can be assessed.

tein assay method was used. If the Coomassie Plus Protein Assay Reagent was used, the total protein (IgG) concentration in the sample would be underestimated by ~40%. (From Table A.3H.5, the response ratio for IgG is ~0.58 for IgG compared to 1.00 for BSA.) If the BCA Protein Assay Reagent was used, the total protein (IgG) concentration in the sample would be overestimated by ~15%. (From Table A.3H.5, the response ratio for IgG is ~1.15 for IgG compared to 1.00 for BSA.) On the other hand, if BGG had been used for both standard curves, the total protein estimates for the sample would have been in much greater agreement between the two methods.

While Table A.3H.5 is useful because it provides an estimate of the protein-to-protein variation in color response that can be expected with each method, it does not tell the whole story. Because the comparisons were done at a single protein concentration, it is not apparent that the color response ratio also varies with changes in protein concentration.

Compatible and incompatible substances

An extensive list of substances that have been found to be compatible with each of the reagents is shown in Table A.3H.6. Each substance was assayed in duplicate using the standard tube protocol for each reagent. In addition to adding the substance to a sample containing 1000 µg/ml BSA, a blank sample containing only the substance was tested. When added to the sample, a substance was deemed to be compatible with a reagent if the blank-corrected absorbance for the sample containing the substance was within 10% of the blank-corrected absorbance for the sample containing only BSA (also at 1000 µg/ml).

Time Considerations

The amount of time required to complete a total protein assay will vary for the four colorimetric total protein assay methods described. For the purpose of providing an estimate of the amount of time required to perform a run by each method, it was assumed that the run included twenty samples and eight standards (including the blank) and that each sample or standard was assayed in duplicate using the

Table A.3H.7 Estimated Time Requirements

Method	Incubation time(s)	Estimated total assay time
Modified Lowry Reagent	10 and 30 min	110 min (1 hr, 50 min)
Coomassie Plus Reagent	10 min	80 min (1 hr, 20 min)
BCA Reagent	30 min	100 min (1 hr, 40 min)
Biuret Reagent	10 min	80 min (1 hr, 20 min)

standard tube protocol. The estimates do not include the time spent obtaining the samples or the time it takes to prepare the samples for analysis, but they do include the incubation time(s) plus an estimate of the time it takes to do the following:

1. Prepare (dilute) the standard protein in the diluent buffer (10 min).
2. Organize the run and label the tubes (5 min).
3. Pipet the samples and reagents into the tubes (10 min).
4. Mix or incubate the tubes or plates (varies).
5. Measure the color produced in the tubes (15 min).
6. Graph the standard curve, calculate, record, and report the results (30 min).

For each of the four methods, a run of 20 samples (unknowns) and the standard curve (each done in duplicate) can be completed in the time estimated in Table A.3H.7.

Describes a procedure using trichloroacetic acid and sodium deoxycholate to precipitate protein and thus remove soluble substances in the sample that would otherwise interfere in the BCA protein assay.

Compton, S.J. and Jones, C.G. 1985. Mechanism of dye response and interference in the Bradford protein assay. *Anal. Biochem.* 151:369-374.

Found that the anionic form of the Coomassie dye reacts primarily with arginine residues within the macromolecular protein. Coomassie dye reacts to a lesser extent with other basic amino acid residues (His, Lys) and aromatic residues (Try, Tyr, Phe) present in macromolecular proteins, but not with the free amino acids. Dye binding is attributed to van der Waals forces and hydrophobic interactions. The interference seen with bases, detergents, and other compounds can be explained by their effects upon the equilibrium between the three dye forms (cationic, neutral, anionic).

Crowley, L.V. 1969. Interference with certain chemical analyses caused by dextran. *Am. J. Clin. Pathol.* 51:425.

Dextran at high concentrations causes a slight overestimation of the total protein concentration with the biuret reagent.

Peterson, G.L. 1977. A simplification of the protein assay method of Lowry, et al. Which is more generally applicable? *Anal. Biochem.* 83:346-356.

A deoxycholate-trichloroacetic acid protein precipitation technique that provides for rapid recovery of soluble and membrane-bound proteins from interfering substances. Interference by lipids and nonionic or cationic detergents is alleviated by adding SDS.

Peterson, G.L. 1979. Review of the Folin phenol protein quantitation method of Lowry, Rosebrough, Farr and Randall. *Anal. Biochem.* 100:201-220.

A thorough review article that examines the reaction mechanism involved when protein reacts with the Lowry reagent. An extensive list of possibly interfering substances is presented along with methods of coping with those interfering substances. Finally, the method of Lowry is compared to other methods. There is an extensive list of references.

A direct scale-down of the BCA method for test tubes that is suitable for microtiter plates.

Tal, M., Silberstein, A., and Nusser, D. 1980. Why does Coomassie Brilliant Blue interact differently with different proteins? *J. Biol. Chem.* 260:9976-9980.

Analysis of Scatchard plots showed that the number of Coomassie dye ligands bound to each protein is approximately proportional to the number of positive charges on the protein. About 1.5 to 3 dye molecules are bound to each positive charge on the protein.

Watters, C. 1978. A one-step biuret assay for protein in the presence of detergent. *Anal. Biochem.* 88:695-698.

A modified biuret reagent was formulated (sodium tartrate replaces sodium potassium tartrate, the sodium hydroxide concentration is reduced, and potassium iodide was deleted). When the modified biuret reagent was mixed with samples containing 2% detergent (SDS or sodium cholate or Triton X-100), it resulted in less protein-to-protein variation among six proteins.

Weichselbaum, 1946. See above.

Used sodium potassium tartrate as a stabilizer and added potassium iodide to prevent autoreduction of the biuret reagent; however, this reagent was found to be unstable after long storage.

Wiechelman, K., Braun, R., and Fitzpatrick, J. 1988. Investigation of the bicinchoninic acid protein assay: Identification of the groups responsible for color formation. *Anal. Biochem.* 175:231-237.

Cysteine, cystine, tryptophan, tyrosine, and the peptide bond are capable of reducing Cu^{2+} to Cu^{+}, but the extent of color formation is not simply the sum of the contributions from the various color producing functional groups. At 60°C, tryptophan, tyrosine, and the peptide bond are more completely oxidized than they are at 37°C, which is observed by the much greater extent of color developed at the higher temperature.
