Current Protocols in Cell Biology

Online ISBN: 9780471143031
DOI: 10.1002/0471143030

Table of Contents

32. Unit 3.30 Purification of Intact Chloroplasts from Arabidopsis and Spinach Leaves by Isopycnic Centrifugation
33. Unit 3.31 Isolation of Neuromelanin Granules
34. Unit 3.32 Isolation of Dense Core Secretory Vesicles from Pancreatic Endocrine Cells by Differential and Density Gradient Centrifugation
35. Unit 3.33 Isolation and Biochemical Characterization of Amyloid Plaques and Paired Helical Filaments
36. Unit 3.34 Isolation of Legionella-Containing Vacuoles by Immuno-Magnetic Separation
37. Unit 3.35 Isolation of Platelet Granules
38. Unit 3.36 Isolation of Nucleoli
39. Unit 3.37 Isolation of Cytotoxic T Cell and NK Granules and Purification of Their Effector Proteins
40. Unit 3.38 Isolation of Aggresomes and Other Large Aggregates
41. Unit 3.39 Isolation of Chromaffin Granules
42. Unit 3.40 Purification of Ribosomes from Human Cell Lines

6. Chapter 4 Microscopy

1. Introduction
2. Unit 4.1 Proper Alignment and Adjustment of the Light Microscope
3. Unit 4.2 Fluorescence Microscopy
4. Unit 4.3 Immunofluorescence Staining
5. Unit 4.4 Fluorescent Staining of Subcellular Organelles: ER, Golgi Complex, and Mitochondria
6. Unit 4.5 Basic Confocal Microscopy
7. Unit 4.6 Immunoperoxidase Methods for Localization of Antigens in Cultured Cells and Tissues
8. Unit 4.7 Cryo-Immunogold Electron Microscopy
9. Unit 4.8 Correlative Video Light/Electron Microscopy
10. Unit 4.9 Polarization Microscopy
11. Unit 4.10 Fluorescent Speckle Microscopy (FSM) of Microtubules and Actin in Living Cells
12. Unit 4.11 Two-Photon Excitation Microscopy for the Study of Living Cells and Tissues
13. Unit 4.12 Total Internal Reflection Fluorescence Microscopy for High-Resolution Imaging of Cell-Surface Events
14. Unit 4.13 Fluorescent Labeling of Yeast
15. Unit 4.14 Fluorescence Lifetime Imaging Microscopy
16. Unit 4.15 Biological Second and Third Harmonic Generation Microscopy
17. Unit 4.16 Analyzing Real-Time Video Microscopy: The Dynamics and Geometry of Vesicles and Tubules in Endocytosis
18. Unit 4.17 Scanning Electron Microscopy of Cell Surface Morphology
19. Unit 4.18 Fluorescence Imaging Techniques for Studying Drosophila Embryo Development
20. Unit 4.19 Quantitative Colocalization Analysis of Confocal Fluorescence Microscopy Images
21. Unit 4.20 Visualizing Protease Activity in Living Cells: From Two Dimensions to Four Dimensions
22. Unit 4.21 Photoactivated Localization Microscopy (PALM) of Adhesion Complexes
23. Unit 4.22 Culturing MDCK Cells in Three Dimensions for Analyzing Intracellular Dynamics
24. Unit 4.23 Interference Reflection Microscopy
25. Unit 4.24 Fluorescence Correlation Spectroscopy in Living Cells: A Practical Approach
26. Unit 4.25 Analysis of Mitochondrial Dynamics and Functions Using Imaging Approaches
27. Unit 4A Organelle Atlas: Appendix to Chapter 4

7. Chapter 5 Characterization of Cellular Proteins

1. Introduction
2. Unit 5.1 Overview of the Physical State of Proteins Within Cells
3. Unit 5.2 Determining the Topology of an Integral Membrane Protein
4. Unit 5.3 Determination of Molecular Size by Zonal Sedimentation Analysis on Sucrose Density Gradients
5. Unit 5.4 Analysis of the Association of Proteins with Membranes
6. Unit 5.5 Determination of Molecular Size by Size-Exclusion Chromatography (Gel Filtration)
7. Unit 5.6 Identification of Proteins in Complex Mixtures Using Liquid Chromatography and Mass Spectrometry
8. Unit 5.7 Determining Membrane Protein Topologies in Single Cells and High-Throughput Screening Applications

8. Chapter 6 Electrophoresis and Immunoblotting

1. Introduction
2. Unit 6.1 One-Dimensional SDS Gel Electrophoresis of Proteins
3. Unit 6.2 Immunoblotting and Immunodetection
4. Unit 6.3 Detection and Quantitation of Radiolabeled Proteins in Gels and Blots
5. Unit 6.4 Two-Dimensional Gel Electrophoresis
6. Unit 6.5 One-Dimensional Electrophoresis Using Nondenaturing Conditions
7. Unit 6.6 Staining Proteins in Gels
8. Unit 6.7 Agarose Gel Electrophoresis of Proteins

9. Unit 6.8 Fluorescence Detection of Glycoproteins in Gels and on Electroblots
10. Unit 6.9 Digital Electrophoresis Analysis
11. Unit 6.10 Two-Dimensional Blue Native Polyacrylamide Gel Electrophoresis
12. Unit 6.11 Measurement of Oxidatively-Induced Clustered DNA Lesions Using a Novel Adaptation of Single Cell Gel Electrophoresis (Comet Assay)

9. Chapter 7 Protein Labeling and Immunoprecipitation

1. Introduction
2. Unit 7.1 Metabolic Labeling with Amino Acids
3. Unit 7.2 Immunoprecipitation
4. Unit 7.3 Metabolic Labeling with Sulfate
5. Unit 7.4 Metabolic Labeling with Fatty Acids
6. Unit 7.5 Metabolic Labeling of Prenyl and Carboxyl-Methyl Groups
7. Unit 7.6 Metabolic Labeling and Immunoprecipitation of Yeast Proteins
8. Unit 7.7 Metabolic Labeling and Immunoprecipitation of Drosophila Proteins
9. Unit 7.8 Metabolic Labeling of Glycoproteins with Radioactive Sugars
10. Unit 7.9 Analysis of Oxidative Modification of Proteins
11. Unit 7.10 Radioiodination of Cellular Proteins

10. Chapter 8 Cell Cycle Analysis

1. Introduction
2. Unit 8.1 Overview of the Cell Cycle
3. Unit 8.2 Assays for CDK Activity and DNA Replication in the Cell Cycle
4. Unit 8.3 Methods for Synchronizing Cells at Specific Stages of the Cell Cycle
5. Unit 8.4 Determining Cell Cycle Stages by Flow Cytometry
6. Unit 8.5 Centrifugal Elutriation to Obtain Synchronous Populations of Cells
7. Unit 8.6 Dynamic Proliferation Assessment in Flow Cytometry

11. Chapter 9 Cell Adhesion

1. Introduction
2. Unit 9.1 Cell-Substrate Adhesion Assays
3. Unit 9.2 Quantitative Measurement of Cell Adhesion Using Centrifugal Force
4. Unit 9.3 Cadherin-Dependent Cell-Cell Adhesion
5. Unit 9.4 Analyzing Integrin-Dependent Adhesion
6. Unit 9.5 Analysis of Cell-Cell Contact Mediated by Ig Superfamily Cell Adhesion Molecules
7. Unit 9.6 Measurement of Adhesion Under Flow Conditions

12. Chapter 10 Extracellular Matrix

1. Introduction
2. Unit 10.1 Overview of Extracellular Matrix
3. Unit 10.2 Preparation of Basement Membrane Components from EHS Tumors
4. Unit 10.3 Preparation of Gelled Substrates
5. Unit 10.4 Preparation of Extracellular Matrices Produced by Cultured Corneal Endothelial and PF-HR9 Endodermal Cells
6. Unit 10.5 Purification of Fibronectin
7. Unit 10.6 Purification of Vitronectin
8. Unit 10.7 Proteoglycan Isolation and Analysis
9. Unit 10.8 Matrix Metalloproteinases
10. Unit 10.9 Preparation of Extracellular Matrices Produced by Cultured and Primary Fibroblasts
11. Unit 10.10 Purification and Analysis of Thrombospondin-1
12. Unit 10.11 Purification of SPARC/Osteonectin
13. Unit 10.12 Analysis of Fibronectin Matrix Assembly
14. Unit 10.13 Non-Radioactive Quantification of Fibronectin Matrix Assembly
15. Unit 10.14 Use of Hyaluronan-Derived Hydrogels for Three-Dimensional Cell Culture and Tumor Xenografts
16. Unit 10.15 Generation of Micropatterned Substrates Using Micro Photopatterning
17. Unit 10.16 Preparation of Hydrogel Substrates with Tunable Mechanical Properties
18. Unit 10.17 Engineering Three-Dimensional Collagen Matrices to Provide Contact Guidance during 3D Cell Migration
19. Unit 10.18 Imaging Cells in Three-Dimensional Collagen Matrix

13. Chapter 11 In Vitro Reconstitution

1. Introduction
2. Unit 11.1 Overview of Eukaryotic In Vitro Translation and Expression Systems
3. Unit 11.2 In Vitro Translation
4. Unit 11.3 In Vitro Analysis of Endoplasmic-Reticulum-to-Golgi Transport in Mammalian Cells

5. Unit 11.4 Cotranslational Translocation of Proteins into Canine Rough Microsomes
6. Unit 11.5 In Vitro Analysis of SV40 DNA Replication
7. Unit 11.6 In Vitro Transcription
8. Unit 11.7 Nuclear Import in Digitonin-Permeabilized Cells
9. Unit 11.8 In Vitro Translation Using HeLa Extract
10. Unit 11.9 Analysis of Eukaryotic Translation in Purified and Semipurified Systems
11. Unit 11.10 Preparation and Use of Interphase Xenopus Egg Extracts
12. Unit 11.11 Analysis of the Cell Cycle Using Xenopus Egg Extracts
13. Unit 11.12 Analysis of Apoptosis Using Xenopus Egg Extracts
14. Unit 11.13 Mitotic Spindle Assembly In Vitro
15. Unit 11.14 Analysis of RNA Export Using Xenopus Oocytes
16. Unit 11.15 In Vitro Analysis of Peroxisomal Protein Import
17. Unit 11.16 In Vitro Analysis of Chloroplast Protein Import
18. Unit 11.17 In Vitro RNA Splicing in Mammalian Cell Extracts
19. Unit 11.18 Endocytosis Assays in Intact and Permeabilized Cells
20. Unit 11.19 In Vitro Analysis of Yeast Mitochondrial Protein Import

14. Chapter 12 Cell Motility

1. Introduction
2. Unit 12.1 Chemotaxis Assays for Eukaryotic Cells
3. Unit 12.2 Invasion Assays
4. Unit 12.3 Cell Traction
5. Unit 12.4 Cell Wound Assays
6. Unit 12.5 Dictyostelium Cell Dynamics
7. Unit 12.6 Optical Microscopy–Based Migration Assay for Human Neutrophils
8. Unit 12.7 Actin-Based Motility Assay
9. Unit 12.8 In Vivo Marking of Single Cells in Chick Embryos Using Photoactivation of GFP

15. Chapter 13 Organelle Motility

1. Introduction
2. Unit 13.1 Microtubule/Organelle Motility Assays
3. Unit 13.2 In Vitro Motility Assay to Study Translocation of Actin by Myosin
4. Unit 13.3 Organelle Motility in Plant Cells: Imaging Golgi and ER Dynamics with GFP
5. Unit 13.4 Movement of Nuclei
6. Unit 13.5 Measuring Dynamics of Nuclear Proteins by Photobleaching
7. Unit 13.6 Functional Characterization of Proteins Regulating Actin Assembly

16. Chapter 14 Signal Transduction: Protein Phosphorylation

1. Introduction
2. Unit 14.1 Overview of Protein Phosphorylation
3. Unit 14.2 Immunological Detection of Phosphorylation
4. Unit 14.3 The Detection of MAPK Signaling
5. Unit 14.4 Labeling Cultured Cells with 32Pi and Preparing Cell Lysates for Immunoprecipitation
6. Unit 14.5 Phosphoamino Acid Analysis
7. Unit 14.6 Determination of Akt/PKB Signaling
8. Unit 14.7 Analyzing FAK and Pyk2 in Early Integrin Signaling Events
9. Unit 14.8 Rho GTPase Activation Assays
10. Unit 14.9 In Vitro GEF and GAP Assays
11. Unit 14.10 In Vivo Imaging of Signal Transduction Cascades with Probes Based on Förster Resonance Energy Transfer (FRET)
12. Unit 14.11 Biosensors for Characterizing the Dynamics of Rho Family GTPases in Living Cells
13. Unit 14.12 Analysis of Arf GTP-Binding Protein Function in Cells

17. Chapter 15 Protein Trafficking

1. Introduction
2. Unit 15.1 Overview of Protein Trafficking in the Secretory and Endocytic Pathways
3. Unit 15.2 Use of Glycosidases to Study Protein Trafficking
4. Unit 15.3 Endocytosis: Biochemical Analyses
5. Unit 15.4 Determining Protein Transport to the Plasma Membrane
6. Unit 15.5 Analysis of Membrane Traffic in Polarized Epithelial Cells
7. Unit 15.6 Analysis of Protein Folding and Oxidation in the Endoplasmic Reticulum
8. Unit 15.7 Measurements of Phagocytosis and Phagosomal Maturation
9. Unit 15.8 Analysis of Protein Transport to Lysosomes
10. Unit 15.9 Studies of the Ubiquitin Proteasome System
11. Unit 15.10 Measuring Retrograde Transport to the Trans-Golgi Network
12. Unit 15.11 Assays for Regulated Exocytosis of Mast Cell Granules

13. Unit 15.12 Analysis of Regulated Secretion Using PC12 Cells
14. Unit 15.13 Analysis of Endocytic Trafficking by Single-Cell Fluorescence Ratio Imaging
15. Unit 15.14 Quantitative Analysis of Endocytosis and Turnover of Epidermal Growth Factor (EGF) and EGF Receptor
16. Unit 15.15 Documenting GLUT4 Exocytosis and Endocytosis in Muscle Cell Monolayers

18. Chapter 16 Antibodies as Cell Biological Tools

1. Introduction
2. Unit 16.1 Production of Monoclonal Antibodies
3. Unit 16.2 Production of Polyclonal Antisera
4. Unit 16.3 Purification of Immunoglobulin G
5. Unit 16.4 Fragmentation of Immunoglobulin G
6. Unit 16.5 Antibody Conjugates for Cell Biology
7. Unit 16.6 Production of Antibodies That Recognize Specific Tyrosine-Phosphorylated Peptides

19. Chapter 17 Macromolecular Interactions in Cells

1. Introduction
2. Unit 17.1 Imaging Protein-Protein Interactions by Fluorescence Resonance Energy Transfer (FRET) Microscopy
3. Unit 17.2 Identification of Protein Interactions by Far Western Analysis
4. Unit 17.3 Interaction Trap/Two-Hybrid System to Identify Interacting Proteins
5. Unit 17.4 Mapping Protein-Protein Interactions with Phage-Displayed Combinatorial Peptide Libraries
6. Unit 17.5 Protein-Protein Interactions Identified by Pull-Down Experiments and Mass Spectrometry
7. Unit 17.6 Measuring Protein Interactions by Optical Biosensors
8. Unit 17.7 Chromatin Immunoprecipitation for Determining the Association of Proteins with Specific Genomic Sequences In Vivo
9. Unit 17.8 Isothermal Titration Calorimetry
10. Unit 17.9 Rational Design and Evaluation of FRET Experiments to Measure Protein Proximities in Cells
11. Unit 17.10 Identification and Analysis of Multiprotein Complexes Through Chemical Crosslinking
12. Unit 17.11 Visualization of RNA Using Fluorescence Complementation Triggered by Aptamer-Protein Interactions (RFAP) in Live Bacterial Cells

20. Chapter 18 Cellular Aging and Death

1. Introduction
2. Unit 18.1 Current Concepts in Cell Death
3. Unit 18.2 Analysis of Caspase Activation During Apoptosis
4. Unit 18.3 Assessment of Apoptosis and Necrosis by DNA Fragmentation and Morphological Criteria
5. Unit 18.4 Quantitative Fluorescence In Situ Hybridization (Q-FISH)
6. Unit 18.5 Analysis of Mitochondrial Dysfunction During Cell Death
7. Unit 18.6 Analysis of Telomeres and Telomerase
8. Unit 18.7 Nonisotopic Methods for Determination of Poly(ADP-Ribose) Levels and Detection of Poly(ADP-Ribose) Polymerase
9. Unit 18.8 Flow Cytometry of Apoptosis
10. Unit 18.9 Analysis of Cellular Senescence in Culture In Vivo: The Senescence-Associated β-Galactosidase Assay
11. Unit 18.10 High-Throughput Live Cell Imaging of Apoptosis

21. Chapter 19 Whole Organism and Tissue Analysis

1. Introduction
2. Unit 19.1 Overview of Metastasis Assays
3. Unit 19.2 Tail Vein Assay of Cancer Metastasis
4. Unit 19.3 Microanalysis of Gene Expression in Tissues Using T7-SAGE: Serial Analysis of Gene Expression After High-Fidelity T7-Based RNA Amplification
5. Unit 19.4 SAGE Analysis from 1 μg of Total RNA
6. Unit 19.5 The Chick Chorioallantoic Membrane as an In Vivo Angiogenesis Model
7. Unit 19.6 Experimental Metastasis Assays in the Chick Embryo
8. Unit 19.7 Imaging Tumor Cell Movement In Vivo
9. Unit 19.8 Embryonic Organ Culture
10. Unit 19.9 Three-Dimensional Tissue Models of Normal and Diseased Skin
11. Unit 19.10 Overview: Engineering Transgenic Constructs and Mice
12. Unit 19.11 Generation of Transgenic Mice
13. Unit 19.12 Overview: Generation of Gene Knockout Mice
14. Unit 19.13 Manipulation of Mouse Embryonic Stem Cells for Knockout Mouse Production
15. Unit 19.14 Generation of Gene Knockout Mice by ES Cell Microinjection

22. **Chapter 20 Expression and Introduction of Macromolecules into Cells**
    1. Introduction
    2. Unit 20.1 Direct Introduction of Molecules into Cells
    3. Unit 20.2 Protein Transduction: Generation of Full-Length Transducible Proteins Using the TAT System
    4. Unit 20.3 Calcium Phosphate Transfection
    5. Unit 20.4 Transfection Using DEAE-Dextran
    6. Unit 20.5 Transfection by Electroporation
    7. Unit 20.6 Transfection of Cultured Eukaryotic Cells Using Cationic Lipid Reagents
    8. Unit 20.7 Optimization of Transfection
    9. Unit 20.8 Inducible Gene Expression Using an Autoregulatory, Tetracycline-Controlled System
23. **Chapter 21 Fluorescent Protein Technology**
    1. Introduction
    2. Unit 21.1 Measuring Protein Mobility by Photobleaching GFP Chimeras in Living Cells
    3. Unit 21.2 Fluorescence Localization After Photobleaching (FLAP)
    4. Unit 21.3 Visualization of Protein Interactions in Living Cells Using Bimolecular Fluorescence Complementation (BiFC) Analysis
    5. Unit 21.4 Design and Use of Fluorescent Fusion Proteins in Cell Biology
    6. Unit 21.5 The Fluorescent Protein Color Palette
    7. Unit 21.6 Photoactivation and Imaging of Photoactivatable Fluorescent Proteins
24. **Chapter 22 Cell Biology of Chromosomes and Nuclei**
    1. Introduction
    2. Unit 22.1 Overview of Cytogenetic Chromosome Analysis
    3. Unit 22.2 Preparation of Cytogenetic Specimens from Tissue Samples
    4. Unit 22.3 Traditional Banding of Chromosomes for Cytogenetic Analysis
    5. Unit 22.4 Fluorescence In Situ Hybridization (FISH)
    6. Unit 22.5 Multi-Color FISH Techniques
    7. Unit 22.6 Comparative Genomic Hybridization
    8. Unit 22.7 Sister Chromatid Exchange
    9. Unit 22.8 Detection of Mitotic Figures and Components of the Mitotic Machinery
    10. Unit 22.9 Assembly and Micromanipulation of Xenopus In Vitro–Assembled Mitotic Chromosomes
    11. Unit 22.10 Replication Labeling with Halogenated Thymidine Analogs
    12. Unit 22.11 Assays for Ribosomal RNA Processing and Ribosome Assembly
    13. Unit 22.12 Visualization and Measurement of DNA Methyltransferase Activity in Living Cells
    14. Unit 22.13 Monitoring mRNA Export
    15. Unit 22.14 Analysis of DNA Replication in Saccharomyces cerevisiae by Two-Dimensional and Pulsed-Field Gel Electrophoresis
25. **Chapter 23 Stem Cells**
    1. Introduction
    2. Unit 23.1 Stem Cells: An Overview
    3. Unit 23.2 Mouse Embryonic Stem Cell Derivation, and Mouse and Human Embryonic Stem Cell Culture and Differentiation as Embryoid Bodies
    4. Unit 23.3 Maintenance and In Vitro Differentiation of Mouse Embryonic Stem Cells to Form Blood Vessels
    5. Unit 23.4 Differentiation of Mouse Embryonic Stem Cells and of Human Adult Stem Cells into Adipocytes
    6. Unit 23.5 Induction of ES Cell–Derived Cartilage Formation
    7. Unit 23.6 Hematoendothelial Differentiation of Human Embryonic Stem Cells
    8. Unit 23.7 Neural Differentiation of Human ES Cells
26. **Chapter 24 Lipids**
    1. Introduction
    2. Unit 24.1 Using Fluorescent Sphingolipid Analogs to Study Intracellular Lipid Trafficking
    3. Unit 24.2 Fluorescent Detection of Lipid Droplets and Associated Proteins
    4. Unit 24.3 Making Giant Unilamellar Vesicles via Hydration of a Lipid Film
    5. Unit 24.4 Visualization of Cellular Phosphoinositide Pools with GFP-Fused Protein-Domains
27. **Chapter 25 Nanotechnology**
    1. Introduction
    2. Unit 25.1 In Vivo Imaging Using Quantum Dot–Conjugated Probes
    3. Unit 25.2 Fabrication and Application of Nanofibrous Scaffolds in Tissue Engineering
28. **Chapter 26 Viruses**
    1. Introduction
    2. Unit 26.1 Production of Papillomavirus-Based Gene Transfer Vectors

3. Unit 26.2 BK Virus (BKV): Infection, Propagation, Quantitation, Purification, Labeling, and Analysis of Cell Entry
4. Unit 26.3 Methods Used to Study Respiratory Virus Infection
5. Unit 26.4 Compartmented Neuron Cultures for Directional Infection by Alpha Herpesviruses
6. Unit 26.5 HIV-1 Interactions with Cells: From Viral Binding to Cell-Cell Transmission

29. Chapter 26 Lipids

1. Unit 26.6 Methods for Monitoring Dynamics of Pulmonary RSV Replication by Viral Culture and by Real-Time Reverse Transcription–PCR In Vivo: Detection of Abortive Viral Replication

30. Chapter 27 RNA-Based Methods in Cell Biology

1. Introduction
2. Unit 27.1 Silencing of Gene Expression in Cultured Cells Using Small Interfering RNAs
3. Unit 27.2 Gene Down-Regulation with Short Hairpin RNAs and Validation of Specificity by Inducible Rescue in Mammalian Cells

31. Appendix 1 Useful Information and Data

1. 1A Useful Measurements and Data
2. 1B Compendium of Drugs Commonly Used in Cell Biology Research
3. 1C Identification of Motifs in Protein Sequences
4. 1D Safe Use of Radioisotopes
5. 1E Absorption and Emission Maxima for Common Fluorophores
6. 1F Importing Biological Materials
7. 1G Centrifuges and Rotors
8. 1H Internet Basics for Biologists

32. Appendix 2 Laboratory Stock Solutions and Equipment

1. 2A Common Stock Solutions, Buffers, and Media
2. 2B Medium Formulations
3. 2C Standard Laboratory Equipment

33. Appendix 3 Commonly Used Techniques

1. 3A Molecular Biology Techniques
2. 3B Spectrophotometric Determination of Protein Concentration
3. 3C Dialysis and Concentration of Protein Solutions
4. 3D Quantification of DNA and RNA with Absorption and Fluorescence Spectroscopy
5. 3E Silanizing Glassware
6. 3F Enzymatic Amplification of DNA by PCR: Standard Procedures and Optimization
7. 3G Micro RT-PCR
8. 3H The Colorimetric Detection and Quantitation of Total Protein

34. Appendix Suppliers

1. Selected Suppliers of Reagents and Equipment

PREFACE

The universe of cell biology is expanding. One way to sense this expansion is to attend a major meeting dedicated to the field, such as that of the American Society for Cell Biology. The poster sessions allow one to take a leisurely stroll through the exhibits and, even without stopping to look at any single poster, get a very good visceral feel for the scope of cell biology. For those who have taken such a stroll periodically over the past decade or two, the dynamic nature of cell biology and its explosive growth have been obvious—there is simply more and more about more and more. Once upon a time, poster sessions were dominated by images of cells fixed (literally) and captured in black and white by electron microscopists. While the electron microscope continues to contribute to our understanding of cell architecture, more recent poster sessions have witnessed the emergence of row upon row of television monitors where one can view computer-enhanced video images of living cells captured in the not-so-living colors of rhodamine red, fluorescein yellow, and the characteristic green that gives the now-famous fluorescent protein its name. Freeze-etching has been joined by freeze-frame. Furthermore, interspersed among the television sets and whirring VCRs are posters that document detailed molecular characterizations of a vast array of biochemical components that comprise the diverse cell types being investigated. Other posters record the latest genes to fall to the seemingly relentless onslaught of the cloners and sequencers, and still others offer functional insights obtained by knocking out these genes. Every point of the compass has its blot! Genetic studies in yeast, flies, and worms abound on the one hand, and on the other, a growing number of the presentations form bridges between basic research in cell biology and the practice of clinical medicine.

Clearly, the scientists who today identify themselves as cell biologists are a diverse community, and great value resides in that diversity. Borders that once separated research disciplines have faded, and cell biologists have come to appreciate that no single approach in isolation will open the profound mysteries of the cell. New techniques and new technologies come alongside the tried-and-true as the tools of cell biology expand along with the field. It is this changing face of cell biology and its methodologies that represented the greatest challenge in pulling together *Current Protocols in Cell Biology*. A foundational question addressed by the editors of this work involved where to draw the boundaries around the field of cell biology. Our decision has been to refuse to draw such boundaries—they are artificial at best and counterproductive at worst. Instead, we will attempt in this effort to match the diversity of our field. We will include "classic" methods that remain valuable tools for the modern cell biologist and will also provide protocols that we believe are destined to become tomorrow's classics.

There is no reason to suspect that the expanding universe of cell biology will cease expanding anytime soon. Indeed, part of the thrill of being a cell biologist is being constantly surprised by new innovations and discoveries. As a consequence, however, our community needs a reliable and user-friendly source of laboratory methods that is as expansive as the field itself. To begin to address this need, we have assembled a series of protocols that cover many aspects of cell biology. While this set of methods is incomplete, it can be considered a "starter toolbox" that includes many of the most versatile and essential instruments of our trade. This collection will expand as regular quarterly supplements are added to *Current Protocols in Cell Biology*. Through these supplements, the editors will endeavor to make the toolbox increasingly more useful over time. Because of the rapid pace of innovation and discovery in cell biology, we are expecting that our efforts will be met with some degree of very pleasant frustration as we strive to keep up with this fast-moving and exciting field.

Current Protocols in Cell Biology iii-vi, September 2010

HOW TO USE THIS MANUAL

Format and Organization

This publication is available in both looseleaf and CD-ROM format. For looseleaf purchasers, a binder is provided to accommodate the growth of the manual via the quarterly update service. This format allows easy insertion of new pages, units, and chapters that are added. The index and table of contents are updated with each supplement. CD-ROM purchasers receive a completely new disc every quarter and should dispose of their outdated discs. The material covered in the two versions is identical.

Subjects in this manual are organized by chapters, and protocols are contained in units. Protocol units, which constitute the bulk of the book, generally describe a method and include one or more protocols with listings of materials, steps and annotations, recipes for unique reagents and solutions, and commentaries on the "hows" and "whys" of the method. Other units present more general information in the form of explanatory text with no protocols. Overview units contain theoretical discussions that lay the foundation for subsequent protocols. Other discussion units present more general information.

Page numbering in the looseleaf version reflects the modular arrangement by unit; for example, page 1.2.3 refers to Chapter 1 (Cell Culture), *UNIT 1.2* (Media for Culture of Mammalian Cells), page 3 of that particular unit.

Many reagents and procedures are employed repeatedly throughout the manual. Instead of duplicating this information, cross-references among units are used and recipes for common reagents are supplied in *APPENDIX 2A*. Cross-referencing helps to ensure that lengthy and complex protocols are not overburdened with steps describing auxiliary procedures needed to prepare raw materials and analyze results.

Introductory and Explanatory Information

Because this publication is first and foremost a compilation of laboratory techniques in cell biology, we have included explanatory information where required to help readers gain an intuitive grasp of the procedures. Some chapters begin with special overview units that describe the state of the art of the topic matter and provide a context for the procedures that follow. Chapter and unit introductions describe how the protocols that follow connect to one another, and annotations to the actual protocol steps describe what is happening as a procedure is carried out. Finally, the Commentary that closes each protocol unit describes background information regarding the historical and theoretical development of the method, as well as alternative approaches, critical parameters, troubleshooting guidelines, anticipated results, and time considerations. All units contain cited references and many indicate key references to inform users of particularly useful background reading, original descriptions, or applications of a technique.

Protocols

Many units in the manual contain groups of protocols, each presented with a series of steps. One or more *basic* protocols are presented first in each unit and generally cover the recommended or most universally applicable approaches. *Alternate* protocols are provided where different equipment or reagents can be employed to achieve similar ends, where the starting material requires a variation in approach, or where requirements for the end product differ from those in the basic protocol. *Support* protocols describe additional steps that are required to perform the basic or alternate protocols; these steps are separated from the core protocol because they might be applicable to other uses in the manual, or because they are performed in a time frame separate from the basic protocol steps.

Reagents and Solutions

Reagents required for a protocol are itemized in the materials list before the procedure begins. Many are common stock solutions, others are commonly used buffers or media, while others are solutions unique to a particular protocol. Recipes for the latter solutions are provided in each unit, following the protocols (and before the commentary) under the heading Reagents and Solutions. It is important to note that the *names* of some of these special solutions might be similar from unit to unit (e.g., RIPA buffer) while the *recipes* differ; thus, make certain that reagents are prepared from the proper recipes. On the other hand, recipes for commonly used stock solutions and buffers are provided once in *APPENDIX 2A*. These universal recipes are cross-referenced parenthetically in the materials lists rather than repeated with every usage.

Commercial Suppliers

Throughout the manual, we have recommended commercial suppliers of chemicals, biological materials, and equipment. In some cases, the noted brand has been found to be of superior quality or it is the only suitable product available in the marketplace. In other cases, the experience of the author of that protocol is limited to that brand. In the latter situation, recommendations are offered as an aid to the novice in obtaining the tools of the trade. Experienced investigators are therefore encouraged to experiment with substituting their own favorite brands.

Addresses, phone numbers, and facsimile numbers of all suppliers mentioned in this manual are provided in the *SUPPLIERS APPENDIX*.

Safety Considerations

Anyone carrying out these protocols may encounter the following hazardous or potentially hazardous materials: (1) radioactive substances, (2) toxic chemicals and carcinogenic or teratogenic reagents, and (3) pathogenic and infectious biological agents. Check the guidelines of your particular institution with regard to use and disposal of these hazardous materials. Although cautionary statements are included in the appropriate units, we emphasize that users must proceed with the prudence and precaution associated with good laboratory practice, and that all materials must be used in strict accordance with local and national regulations.

Animal Handling

Many protocols call for use of live animals (usually rats or mice) for experiments. Prior to conducting any laboratory procedures with live subjects, the experimental approach must be submitted in writing to the appropriate Institutional Animal Care and Use Committee (IACUC) or must conform to appropriate governmental regulations regarding the care and use of laboratory animals. Written approval from the IACUC (or equivalent) committee is absolutely required prior to undertaking any live-animal studies. Some specific animal care and handling guidelines are provided in the protocols where live subjects are used, but check with your IACUC or governmental guidelines to obtain more extensive information.

Reader Response

Most of the protocols included in this manual are used routinely in the authors' laboratories. These protocols work for them; to make them work for you they have annotated critical steps and included critical parameters and troubleshooting guides in the commentaries to most units. However, the successful evolution of this manual depends upon readers' observations and suggestions. We encourage readers to send their comments to *CurrentProtocols@wiley.com*, or to go to any specific unit on our website at

http://www.currentprotocols.com, where you can post comments, ask questions, and see author updates.

ACKNOWLEDGMENTS

This manual is the product of dedicated efforts by many of our scientific colleagues who are acknowledged in each unit and by the hard work by the Current Protocols editorial staff at John Wiley and Sons. We are extremely grateful for the critical contributions by Kathy Morgan (Series Editor) who kept the editors and the contributors on track and played a key role in bringing the entire project to completion. Other skilled members of the Current Protocols staff who contributed to the project include Joseph White, Janet Blair, Kathy Wisch, Michael Gates, Demetra Kagdis, Alice Ro, and Scott Holmes. The extensive copyediting required to produce an accurate protocols manual was ably handled by Rebecca Barr, Allen Ranz, Elizabeth Harkins, Lisa Christenson, Connie Parks, Karen Hopkin, Monte Kendrick, and Cathy Lundmark, and electronic illustrations were prepared by Gae Xavier Studios.

CHAPTER 1
Cell Culture

INTRODUCTION

Cell biology traces its roots to the introduction of the concept of "cells" by Robert Hooke in the second half of the 17th century. However, not until nearly halfway through the 20th century were techniques for the culture of cells developed. In fact, 1998 marked the golden anniversary of the first continuous mammalian cell line. Cell culture has become such an integral part of cell biology that it is somewhat difficult to imagine the field in the B.C. ("Before Culture") era. Cell culture also represents the primary way in which cell biology reaches into related disciplines, since the maintenance and propagation of cells has become an important component of biochemistry, biophysics, genetics, immunology, physiology, molecular biology, and neuroscience. Accordingly, it is altogether fitting that the first chapter of *Current Protocols in Cell Biology* should present methods related to the culture of cells.

The immediate aim of cell culture is to maintain or expand a population of cells, and the single most important consideration is cell viability. Determining the number of cells and their viability is important in standardizing culture and experimental conditions. As viable cells replicate in culture, passaging of the cells allows their number to be expanded to meet experimental needs. The ability to freeze, store, and recover cells provides an essential safeguard against losing a cell line to contamination, incubator malfunction, or an error on the part of the investigator. In addition to preserving the cells, maintenance of a frozen stock is desirable to avoid cellular senescence and genetic drift. Chapter 1 therefore begins with protocols for passaging cells, freezing and thawing cells, and determining cell number and viability (*UNIT 1.1*).

Success in cell culture is highly dependent on the choice of a medium. At minimum, a medium must provide the nutritional requirements of the cells as well as any required growth factors, and maintain pH and osmolarity compatible with survival. The historical development of a wide variety of culture media has influenced significantly the types of cells that can be studied experimentally, since cell lines that proliferate in a particular environment are always selected at the expense of those that do not. The second unit of Chapter 1 therefore focuses on media used in culturing cells and provides descriptions of standard, serum-free, and selective media, as well as the use of soft agar for anchorage-independent growth (*UNIT 1.2*).

The next three units of this chapter deal with microbial contamination of cell cultures. *UNIT 1.3* describes basic aseptic techniques and the laminar flow hoods that are the main weapons in the constant battle against contamination. *UNIT 1.4* provides protocols related to sterilization, namely filtration and heat sterilization (e.g., autoclaving), as well as the use of disinfectants. *UNIT 1.5* describes methods for detecting microbial contaminants (bacteria, fungi, and mycoplasmas). While the best way to deal with such contamination may well be to review the previous unit on autoclaving and faithfully apply its precepts, situations do arise where an attempt to salvage a contaminated culture is warranted. *UNIT 1.5* details the use of antibiotics for this purpose.

Of course there are cell biologists who do not see the growth of fungi as an annoying contamination of their mammalian cell cultures but as a desirable goal. For scientists who

Contributed by Joe B. Harford
Current Protocols in Cell Biology (2003) 1.0.1-1.0.2

wish to propagate yeast, *UNIT 1.6* provides recipes for media and descriptions of some basic culture methodologies.

UNIT 1.7 represents the first unit of Chapter 1 dealing with culture of plants cells, specifically the culture and transformation of BY-2 cells derived from tobacco. BY-2 cells have been described as the HeLa cell of higher plants.

Future units in Chapter 1 will cover specialized systems for cell culture (e.g., cell cloning, polarized cells, and three-dimensional cultures), as well as additional units on the propagation of plant cells, cells from other so-called simpler organisms, and viruses.

For additional information on mammalian cell culture, readers are directed to Freshney (1993).

Basic Techniques in Mammalian Cell Tissue Culture

Mary C. Phelan[1]

[1]Molecular Pathology Laboratory Network, Maryville, Tennessee

ABSTRACT

Cultured mammalian cells are used extensively in cell biology studies. It requires a number of special skills in order to be able to preserve the structure, function, behavior, and biology of the cells in culture. This unit describes the basic skills required to maintain and preserve cell cultures: maintaining aseptic technique, preparing media with the appropriate characteristics, passaging, freezing and storage, recovering frozen stocks, and counting viable cells. *Curr. Protoc. Cell Biol.* 36:1.1.1-1.1.18. © 2007 by John Wiley & Sons, Inc.

Keywords: mammalian cells • tissue culture • aseptic technique • medium • passaging cells • freezing cells

Tissue culture technology has found wide application in the field of cell biology. Cell cultures are utilized in cytogenetic, biochemical, and molecular laboratories for research as well as diagnostic studies. In most cases, cells or tissues must be grown in culture for days or weeks to obtain sufficient numbers of cells for analysis. Maintenance of cells in long-term culture requires strict adherence to aseptic technique to avoid contamination and potential loss of valuable cell lines (see *UNIT 1.3*).

An important factor influencing the growth of cells in culture is the choice of tissue culture medium. Many different recipes for tissue culture media are available and each laboratory must determine which medium best suits its needs. Individual laboratories may elect to use commercially prepared medium or prepare their own. Commercially available medium can be obtained as a sterile and ready-to-use liquid, in a concentrated liquid form, or in a powdered form. Besides providing nutrients for growing cells, medium is generally supplemented with antibiotics, fungicides, or both to inhibit contamination. Medium preparation is discussed in *UNIT 1.2*.

As cells reach confluency, they must be subcultured or passaged. Failure to subculture confluent cells results in reduced mitotic index and eventually in cell death. The first step in subculturing is to detach cells from the surface of the primary culture vessel by trypsinization or mechanical means. The resultant cell suspension is then subdivided, or reseeded, into fresh cultures. Secondary cultures are checked for growth and fed periodically, and may be subsequently subcultured to produce tertiary cultures, etc. The time between passaging of cells varies with the cell line and depends on the growth rate.

The Basic Protocol describes subculturing of a monolayer culture grown in petri plates or flasks. Support Protocols describe freezing of monolayer cells, thawing and recovery of cells, counting cells using a hemacytometer, and preparing cells for transport. Alternate Protocols 1 and 2 describe the passaging and freezing of cells in suspension culture.

CAUTION: When working with human blood cells, or infective agents, appropriate biosafety practices must be followed.

NOTE: All solutions and equipment coming into contact with living cells must be sterile, and aseptic technique should be used accordingly.

ASEPTIC TECHNIQUE

It is essential that aseptic technique be maintained when working with cell cultures. Aseptic technique involves a number of precautions to protect both the cultured cells and the laboratory worker from infection. The laboratory worker must realize that cells handled in the lab are potentially infectious and should be handled with caution. Protective apparel such as gloves, lab coats or aprons, and eyewear should be worn when appropriate (Knutsen, 1991). Care should be taken when handling sharp objects such as needles, scissors, scalpel blades, and glass that could puncture the skin. Sterile disposable plastic supplies may be used to avoid the risk of broken or splintered glass (Rooney and Czepulkowski, 2001).

Frequently, specimens received in the laboratory are not sterile, and cultures prepared from these specimens may become contaminated with bacteria, fungus, or yeast. The presence of microorganisms can inhibit growth, kill cell cultures, or lead to inconsistencies in test results. The contaminants deplete nutrients in the medium and may produce substances that are toxic to cells. Antibiotics and antimycotics can be used to combat potential contaminants (see Table 1.1.1). The solutions can be used to wash specimens prior to culture or to rinse contaminated cultures, and can be added to medium used for tissue culture. Antibiotics (penicillin, streptomycin, kanamycin, neomycin, or gentamycin) can be used individually or in combinations (i.e., penicillin/streptomycin/neomycin and penicillin/streptomycin/gentamycin). Likewise, fungicides such as amphotericin B (Fungizone) and mycostatin (Nystatin) can be used alone or as antibiotic/antimycotic solutions (i.e., penicillin/streptomycin/Fungizone). Particular care should be taken when using Fungizone, as it is typically very toxic to cell cultures, and adequate data are not available regarding potential adverse effects on the growth of human cells. Antibiotics and antimycotics are available from a number of vendors including Invitrogen, Sigma-Aldrich, and BioWhittaker.

All materials that come into direct contact with cultures must be sterile. Sterile disposable dishes, flasks, pipets, etc., can be obtained directly from manufacturers. Reusable glassware must be washed, rinsed thoroughly, then sterilized by autoclaving or by dry heat before reusing. With dry heat, glassware should be heated 1.5 to 2 hr at 160°C to ensure sterility. Materials that may be damaged by very high temperatures can be autoclaved

Table 1.1.1 Working Concentrations of Antibiotics and Fungicides for Mammalian Cell Culture

Additive	Final concentration
Penicillin	50–100 U/ml
Streptomycin sulfate	50–100 μg/ml
Kanamycin	100 μg/ml
Gentamycin	50 μg/ml
Neomycin	50 μg/ml
Mycostatin (Nystatin)	20 μg/ml
Amphotericin B (Fungizone)	0.25 μg/ml
Pen/strep/neomycin[a]	1×

[a]Usually supplied as 100× concentrated stock solution, which is diluted to 1× concentration in the medium.

20 min at 120°C and 15 psi. All media, reagents, and other solutions that come into contact with the cultures must also be sterile; media may be obtained as a sterile liquid from the manufacturer, autoclaved if not heat-sensitive, or filter sterilized. Supplements can be added to media prior to filtration, or they can be added aseptically after filtration. Filters with 0.20- to 0.22-μm pore size should be used to remove small gram-negative bacteria from culture media and solutions.

Contamination can occur at any step in handling cultured cells. Care should be taken to maintain the sterility of petri plates, pipets, and flasks that are used for tissue culture. The use of disposable, sterile culture supplies is convenient and has virtually eliminated the need to flame-sterilize instruments and vessels used for tissue culture. The initial cost of purchasing these single-use supplies outweighs the expense associated with the time and effort of washing, packaging, and sterilizing nondisposables. Good sterile technique must be followed. For example, if a sterile pipet tip should come into contact with the benchtop or other nonsterile surface, the pipet tip should be discarded and a fresh one obtained. If disposables are not an option, the necks of sterile containers, such as bottles and flasks, and the tips of pipets should be passed through a flame before the pipet is introduced into the container. After pipetting, the neck of the bottle or flask should again be flamed.

Certain instruments used for tissue culture (forceps, scissors, scalpels, and in some instances, glass bottles) may require autoclave sterilization prior to initial use (see *UNIT 1.4*). The autoclave relies on pressurized steam to destroy microorganisms. Instruments to be autoclaved should be thoroughly washed and dried, then packaged if necessary to ensure that sterility will be maintained after removal from the autoclave until use. Indicator tape or autoclave bags with indicator strips should be used to document that the items have been autoclaved. The indicator tape demonstrates that the item has been autoclaved, but does not ensure sterility.

Historically, if instruments such as forceps, tweezers, scissors, or scalpels were going to be re-used to handle several sequential specimens, they were rapidly sterilized between uses by dipping in 70% alcohol and flaming. Other methods of rapid decontamination are now available. For example, the Germinator 500 (Cellpoint Scientific) is a small benchtop unit [height, 6.76 in. (~17 cm) × width, 5.25 in. (~13 cm) × depth 5.25 in. (~13 cm)] used in tissue culture labs for decontamination of metal dissecting instruments. Instruments must be clean, dry, and free of debris prior to sterilization. The instruments are inserted into a stainless steel well [inside dimensions: diameter, 2 in. (~ 5 cm) × depth, 4 in (~10 cm)] filled with glass beads that are maintained at a constant temperature of 500°F (~260°C). Dry heat decontamination occurs through heat transfer from the glass beads to the instruments. The inserted parts of small instruments are dry sterilized within ~15 sec, while larger instruments may take as long as 1 min. The Germinator 500 eliminates the need for alcohol and open flames for sterilization. Due to the lack of a method for routine monitoring of sterilization by glass beads, the Germinator 500 operating manual recommends that this equipment be used for research purposes only.

Although tissue culture work can be done on an open bench if aseptic methods are strictly enforced, many labs prefer to perform tissue culture work in a room or low-traffic area reserved specifically for that purpose. At the very least, biological safety cabinets are recommended to protect the cultures as well as the laboratory worker. In a laminar flow hood, the flow of air protects the work area from dust and contamination and acts as a barrier between the work surface and the worker. Many different styles of safety hoods are available, and the laboratory should consider the types of samples being processed and the types of potential pathogenic exposure in making a selection. Manufacturer recommendations should be followed regarding routine maintenance checks on air flow

and filters. For day-to-day use, the cabinet should be turned on for at least 5 min prior to beginning work. All work surfaces both inside and outside of the hood should be kept clean and disinfected daily and after each use. A 10% household bleach solution, 70% alcohol, an iodophor, a quarternary ammonium compound, or commercially available liquid disinfectants can be used (*http://www.ehs.cornell.edu/bio/cabinets.htm*, last updated December, 2000).

Some safety cabinets are equipped with ultraviolet (UV) lights for decontamination of work surfaces. However, UV lamps are not required in biological safety cabinets, and their effectiveness has been questioned (*http://www.niehs.nih.gov/odhsb/biosafe/bsc/section6.htm*; *http://www.ehs.cornell.edu/bio/cabinets.htm*). UV lamps may produce a false sense of security as they maintain a visible blue glow long after their germicidal effectiveness is lost. Effectiveness diminishes over time as the glass tube gradually loses its ability to transmit short UV wavelengths, and may also be reduced by dust on the glass tube, distance from the work surface, temperature, and air movement. Even when the UV output is adequate, the rays must directly strike a microorganism in order to kill it; bacteria or mold spores hidden below the surface of a material or outside the direct path of the rays will not be destroyed. Another rule of thumb is that anything that can be seen cannot be killed by UV. UV lamps will only destroy microorganisms such as bacteria, viruses, and mold spores; they will not destroy insects or other large organisms. Aside from their general ineffectiveness, UV lights pose a safety hazard, as exposure can cause damage to the eyes and skin (*http://www.yale.edu/oehs/cad2_0.htm*). A more reliable approach to eliminate contamination is the use of well-practiced microbiological procedures, good aseptic techniques, and standard operational procedures for working in a biological safety cabinet, including thorough decontamination with an effective disinfectant before and after use of the biological safety cabinet. The current recommendation is that work surfaces be wiped down with ethanol instead of relying on UV lamps, although some labs use the lamps in addition to ethanol wipes to decontaminate work areas. If UV lamps are used as a secondary method of disinfecting the work surface, their radiation output should be tested with a UV meter during the annual certification of the biological safety cabinet to ensure that the proper intensity of light is reaching the work surface. The radiation output should be at least 40 $\mu W/cm^2$ at 254 nm when measured with a UV flux meter placed in the center of the work surface. The UV lamps should be replaced when they fall below the minimum requirements for protection (*http://www.ehs.cornell.edu/bio/cabinets.htm*).

Cultures should be visually assessed on a routine basis for evidence of contamination (see *UNIT 1.5*). Indicators in the tissue culture medium change color when contamination is present: for example, medium that contains phenol red changes to yellow because of increased acidity. Cloudiness and turbidity are also observed in contaminated cultures. Once contamination is confirmed with a microscope, infected cultures are generally discarded. Keeping contaminated cultures increases the risk of contaminating other cultures. Sometimes a contaminated cell line can be salvaged by treating it with various combinations of antibiotics and antimycotics in an attempt to eradicate the infection. In this procedure, the tissue culture medium is aspirated from the affected cultures and discarded. The cultures are rinsed with fresh "wash" medium that has been prepared by supplementing the routinely used tissue culture medium with the appropriate concentration of antibiotic and/or antimycotic (Table 1.1.1). The petri dish or flask should be gently swirled so that the cell surface is bathed in the clean medium. The wash medium can be left on the cultures for 1 to 5 min. Due to the toxicity of Fungizone and amphotericin, it is recommended that cell exposure to these agents be limited to less than 2 min. Aspirate the wash medium, replace with fresh medium and return the cultures to the incubator. Even under the best conditions, such treatment may adversely affect cell growth and it is often unsuccessful in ridding cultures of contaminants.

Mycoplasma are small (0.2 to 0.3 μm) intracellular bacteria that attach to the cell membrane, inhibit cell growth, and eventually lead to cell death. Because these parasites do not have cell walls, do not grow in colonies, and do not change the pH of the medium, they are difficult to detect visually in cultures. Mycoplasma can multiply to very high concentrations (10^7 to 10^8 organisms/ml) and adversely affect cultures by altering cell growth characteristics, inhibiting cell metabolism, disrupting nucleic acid synthesis, inducing chromosome aberrations, changing cell membrane antigenicity, and altering transfection rates and viral susceptibility (*http://www.unc.edu/depts/tcf/mycoplasma.htm*).

Mycoplasma are spread by cross-contamination from infected cultures through aerosolization during pipetting, or via the transfer of contaminated cells or contaminated reagents used in cell culture (*http://www.unc.edu/depts/tcf/mycoplasma.htm*). There are several methods of detecting mycoplasma in cell cultures and in cell culture reagents (see *UNIT 1.5*). In the direct method, both cultures and reagents can be plated on agar in order to grow and thereby reveal the presence of mycoplasma. Disadvantages of this method are that some strains of mycoplasma cannot be cultivated on agar and that the results can take from 2 to 4 weeks to obtain (*http://www.lerner.ccf.org/services/cell/cellculture.php*). Several indirect methods are available and should be selected based on the capabilities of the laboratory and the needs of the laboratory in terms of sensitivity, specificity, and time requirements. The DNA staining method uses Hoechst 33258 to highlight the A-T rich DNA of mycoplasma, so that mycoplasma appear as bright extranuclear spots in the cytoplasm. Results are available in 24 hr, but this method is not as sensitive as the direct method and can be difficult to interpret due to background bacterial/yeast/fungal contamination, excess debris, reduced or absent live cells, and broken nuclei from dead cells. The addition of an indicator such as Vero (Sigma-Aldrich) increases the sensitivity of this method. PCR primers that selectively amplify part of the mycoplasma DNA are also available. Kits include the ELISA mycoplasma detection kit from Roche Applied Science, the Mycoplasma Detection kit from Minerva Biolabs, the Myco Alert Mycoplasma Detection Assay by Cambrex (with results available in $<$20 min using the Cambrex instrument), and the VenorGem Mycoplasma PCR Detection Kit from Sigma-Aldrich.

Good aseptic technique and routine testing are the most effective methods for preventing mycoplasma contamination. Most standard antibiotics are not effective in treating mycoplasma contamination, and many laboratories prefer to dispose of contaminated cultures. In the event that the cultures are valuable and backup cultures are not available, it is imperitive to attempt to salvage the contaminated cells. Agents such as Mynox Mycoplasma Elimination Reagent and Mycoplasma Removal Agent (MRA) are commercially available from ICN Flow, and usually require a single treatment to decontaminate cultures (*http://www.unc.edu/depts/tcf/mycoplasma.htm*).

CULTURE MEDIUM PREPARATION

Choice of tissue culture medium comes from experience. An individual laboratory must select the medium that best suits the type of cells being cultured. Chemically defined media are available in liquid or powdered form from a number of suppliers. Sterile, ready-to-use medium has the advantage of being convenient, although it is more costly than other forms. Powdered medium must be reconstituted with tissue culture–grade water according to manufacturer's directions. Distilled or deionized water is not of sufficiently high quality for medium preparation; double- or triple-distilled water or commercially available tissue culture water should be used. The medium should be filter-sterilized and transferred to sterile bottles. Prepared medium can generally be stored $\leq$1 month in a 4°C refrigerator. Laboratories using large volumes of medium may choose to prepare their own medium from standard recipes. This may be an economical approach, but it is time-consuming and the savings may not offset the time required.

Basic media such as Eagle minimal essential medium (MEM), Dulbecco's modified Eagle medium (DMEM; see recipe), Glasgow modified Eagle medium (GMEM), and RPMI 1640 and Ham F10 nutrient mixture (e.g., Invitrogen) are composed of amino acids, glucose, salts, vitamins, and other nutrients. A basic medium is supplemented by addition of L-glutamine, antibiotics (typically penicillin and streptomycin sulfate), and usually serum to formulate a "complete medium." Where serum is added, the amount is indicated as a percentage of fetal bovine serum (FBS) or other serum. Some media are also supplemented with antimycotics, nonessential amino acids, various growth factors, and/or drugs that provide selective growth conditions (see *UNIT 1.2*). Supplements should be added to medium prior to sterilization or filtration, or added aseptically just before use.

The optimum pH for most mammalian cell cultures is 7.2 to 7.4. Adjust pH of the medium as necessary after all supplements are added. Buffers such as bicarbonate and HEPES are routinely used in tissue culture medium to prevent fluctuations in pH that might adversely affect cell growth. HEPES is especially useful in solutions used for procedures that do not take place in a controlled CO_2 environment.

Fetal bovine serum (FBS; sometimes known as fetal calf serum, FCS) is the most frequently used serum supplement. Calf serum, horse serum, and human serum are also used; some cell lines are maintained in serum-free medium (Freshney, 2005). Complete medium is supplemented with 5% to 30% (v/v) serum, depending on the requirements of the particular cell type being cultured. Serum is obtained frozen, then is thawed, divided into smaller portions, and refrozen until needed.

There is considerable lot-to-lot variation in FBS. Most suppliers will provide a sample of a specific lot and reserve a supply of that lot while the serum is tested for its suitability. The suitability of a serum lot depends upon the use. Frequently the ability of serum to promote cell growth equivalent to a laboratory standard is used to evaluate a serum lot. Once an acceptable lot is identified, enough of that lot should be purchased to meet the culture needs of the laboratory for an extended period of time.

Although the use of heat-inactivated serum was once preferred, it is no longer standard, or may be standard in some labs simply because it is an established and routine practice (*http://www.unc.edu/depts/tcf/tech_tipsHI.htm*). Historically, heat inactivation was considered necessary to destroy complement protein due to its role in cell lysis. It has since been shown that the level of complement components in commercially available FCS was only 1% to 3% of adult levels, and that no significant cell lysis was detected with the use of commercially available FCS, even when undiluted (Triglia and Linscott, 1980). In addition, many researchers prewarm FBS to 37°C, which is enough to inactivate heat-labile complement components. Improvements in the filtration of serum products have also made the use of heat-inactivated serum nonessential for most cell types. In the past serum was filtered through 0.45-μm or 0.22-μm filters, raising concern that adventitious agents such as mycoplasma could persist. Today media suppliers use 0.1-μm or 0.04-μm porosity membranes to eliminate the need for heat inactivation (*http://www.unc.edu/depts/tcf/tech_tipsHI.htm*; Hyclone Labs, 1996). Not only is heat inactivation unnecessary for most cell types, it may sometimes be detrimental to cell growth. Heat inactivation not only destroys complement, it also degrades amino acids, vitamins, growth factors, and other nutrients that enhance cell growth. Furthermore, heat inactivation can increase the formation of precipitates that can be mistaken for microbial contamination (Hyclone Labs, 1996). Laboratories that continue the use of heat inactivation should conduct studies to determine whether this step is really indicated. Heat inactivation may be warranted when conducting immunologic studies or when culturing embryonic stem cells, insect cells, and smooth muscle cells. For cells obtained

from a commercial vendor such as ATCC, serum requirements are included in the cell descriptions.

Although FBS has historically been the serum of choice, many investigators are moving towards the use of alternative types of animal serum or to serum-free media. An increasing number of companies are offering serum-free media for a wide range of cell types. Focus on Alternatives (FOA) lists over 300 types of serum-free products along with their suppliers, applications, and the cell types supported for each product (*http://www.focusonalternatives.org.uk*, compiled in July, 2005). Although the term "serum-free" implies that a medium contains no serum, the medium may not be entirely free of serum-derived products. For example, bovine serum albumin may be used as the protein component of particular types of serum-free media (Newman, 2003). While some media are designed for culturing a particular cell type, others are general-purpose media that can support a variety of cell types.

Commercially prepared media containing L-glutamine are available, but many laboratories choose to obtain medium without L-glutamine, and then add it to a final concentration of 2 mM just before use. L-Glutamine is an unstable amino acid that, upon storage, converts to a form cells cannot use. Breakdown of L-glutamine is temperature- and pH-dependent. At 4°C, 80% of the L-glutamine remains after 3 weeks, but at near incubator temperature (35°C) only half remains after 9 days (Barch et al., 1991). To prevent degradation, 100× L-glutamine should be stored frozen in aliquots until needed.

Another option to prevent degradation is the use of a stabilized dipeptide form of L-glutamine such as GlutaMAX (Invitrogen), which is available both as a stand-alone medium and as a medium supplement. GlutaMAX media contain the dipeptide L-alanyl-L-glutamine, which is split by aminopeptidases in culture to release L-glutamime and L-alanine. This mechanism provides a controlled delivery of L-glutamine to the cells in culture. The GlutaMAX dipeptide is also available as a medium supplement to be used as a direct substitute for L-glutamine in cell culture medium preparations with minimal or no adaptation. Both GlutaMAX Media and Supplement are reported by the manufacturer to maximize cell performance, improve cell viability and growth, extend cell culture life, and minimize toxic ammonium build-up during cell culture (*http://www.invitrogen.com*).

In addition to practicing good aseptic technique, most laboratories add antimicrobial agents to medium to further reduce the risk of contamination. A combination of penicillin and streptomycin is the most commonly used antibiotic additive; kanamycin and gentamycin are used alone. Mycostatin and amphotericin B are the most commonly used fungicides (Rooney and Czepulkowski, 2001). Table 1.1.1 lists the final concentrations for the most commonly used antibiotics and antimycotics. Combining antibiotics in tissue culture media can be tricky, as some antibiotics are not compatible and one may inhibit the action of another. Furthermore, combined antibiotics may be cytotoxic at lower concentrations than the individual antibiotics. In addition, prolonged use of antibiotics may cause cell lines to develop antibiotic resistance. For this reason, some laboratories add antibiotics and/or fungicides to medium when initially establishing a culture but eliminate them from medium used in later subcultures.

Commercially available tissue culture media have been tested for sterility prior to release, and further testing within the research laboratory is generally not required. In clinical laboratories, sterility checks on tissue culture media are often performed as a quality-control monitor in compliance with requirements from the College of American Pathologists (CAP). A small aliquot from each lot of medium is incubated 48 hr at 37°C and monitored for evidence of contamination such as turbidity (infected medium will be cloudy) and color change (if phenol red is the indicator, infected medium will turn yellow). Any contaminated medium should be discarded.

BASIC PROTOCOL

TRYPSINIZING AND SUBCULTURING CELLS FROM A MONOLAYER

A primary culture is grown to confluency in a 60-mm petri plate or 25-cm^2 tissue culture flask containing 5 ml tissue culture medium. Cells are dispersed by trypsin treatment and then reseeded into secondary cultures. The process of removing cells from the primary culture and transferring them to secondary cultures constitutes a passage, or subculture.

Materials

Primary cultures of cells
HBSS (*APPENDIX 2A*) without Ca^{2+} and Mg^{2+}, 37°C
0.25% (w/v) trypsin/0.2% EDTA solution (see recipe), 37°C
Complete medium with serum: e.g., DMEM supplemented with 10% to 15% (v/v) fetal bovine serum (complete DMEM-10; see recipe), 37°C

Sterile Pasteur pipets
37°C warming tray or incubator
Tissue culture plasticware or glassware including pipets and 25-cm^2 flasks or 60-mm petri plates, sterile

NOTE: All incubations are performed in a humidified 37°C, 5% CO_2 incubator unless otherwise specified. Some media (e.g., DMEM) may require altered levels of CO_2 to maintain pH 7.4.

1. Remove all medium from primary culture with a sterile Pasteur pipet. Wash adhering cell monolayer once or twice with a small volume of 37°C HBSS without Ca^{2+} and Mg^{2+} to remove any residual FBS that may inhibit the action of trypsin.

   Use a buffered salt solution that is Ca^{2+}- and Mg^{2+}-free to wash cells. Ca^{2+} and Mg^{2+} in the salt solution can cause cells to stick together.

   If this is the first medium change, rather than discarding medium that is removed from primary culture, put it into a fresh dish or flask. The medium contains unattached cells that may attach and grow, thereby providing a backup culture.

2. Add enough 37°C trypsin/EDTA solution to culture to cover adhering cell layer.

3. Place plate on a 37°C warming tray 1 to 2 min. Tap bottom of plate on the countertop to dislodge cells. Check culture with an inverted microscope to be sure that cells are rounded up and detached from the surface.

   If cells are not sufficiently detached, return plate to warming tray for an additional minute or two.

4. Add 2 ml 37°C complete medium. Draw cell suspension into a Pasteur pipet and rinse cell layer two or three times to dissociate cells and to dislodge any remaining adherent cells. As soon as cells are detached, add serum or medium containing serum to inhibit further trypsin activity that might damage cells.

   If cultures are to be split 1/3 or 1/4 rather than 1/2, add sufficient medium such that 1 ml of cell suspension can be transferred into each fresh culture vessel.

5. Add an equal volume of cell suspension to fresh plates or flasks that have been appropriately labeled.

   Alternatively, cells can be counted using a hemacytometer (Support Protocol 3) or Coulter counter and diluted to the desired density so a specific number of cells can be added to each culture vessel. A final concentration of ~5×10^4 cells/ml is appropriate for most subcultures.

For primary cultures and early subcultures, 60-mm petri plates or 25-cm^2 flasks are generally used; larger petri plates or flasks (e.g., 150-mm plates or 75-cm^2 flasks) may be used for later subcultures.

Cultures dishes/flasks should be labeled with at least two unique identifiers, as well as date of culture and passage number.

6. Add 4 ml fresh medium to each new culture. Incubate in a humidified 37°C, 5% CO_2 incubator.

   If using 75-cm^2 culture flasks, add 9 ml medium per flask.

   Some labs now use incubators with 5% CO_2 and 4% O_2. The low oxygen concentration is thought to simulate the in vivo environment of cells and to enhance cell growth.

7. If necessary, feed subconfluent cultures after 3 or 4 days by removing old medium and adding fresh 37°C medium.

8. Passage secondary culture when it becomes confluent by repeating steps 1 to 7, and continue to passage as necessary.

PASSAGING CELLS IN SUSPENSION CULTURE

ALTERNATE PROTOCOL 1

Passaging of suspension cultures is somewhat less complicated than passaging of monolayer cultures. Because the cells are suspended in medium rather than attached to a surface, it is not necessary to disperse them enzymatically before passaging. However, before passaging, cells must be maintained in culture by feeding every 2 to 3 days until they reach confluency (i.e., until the cells clump together in the suspension and the medium appears turbid when the flask is swirled).

NOTE: All incubations are performed in a humidified 37°C, 5% CO_2 incubator unless otherwise specified. Some media (e.g., DMEM) may require altered levels of CO_2 to maintain pH 7.4.

For materials, see Basic Protocol.

1. Feed cells as follows every 2 to 3 days until the cultures are confluent:

   a. Remove flask of suspension cells from incubator, taking care not to disturb those that have settled to the flask bottom.

   b. Aseptically remove and discard about one-third of the medium from the flask and replace with an equal volume of prewarmed (37°C) medium. If the cells are growing rapidly, add an additional 10% medium by volume in order to maintain an optimum concentration of 1×10^6 cells/ml. Gently swirl flask to resuspend cells.

   c. Return flask to incubator. If there is <15 ml of medium in the flask, incubate flask in horizontal position to enhance cell/medium contact.

      At higher volumes of medium, the flask can be incubated in the vertical position.

      If using a 25-cm^2 flask, there should be 20 to 30 ml of medium in the flask at confluency.

2. On the days cultures are not being fed, check by swirling flask to resuspend cells and observing color changes from pink to yellow/orange in the medium, which indicate active cell metabolism.

3. When cultures are confluent (~2.5×10^6 cells/ml), passage culture as follows:

   a. Remove flask from incubator and swirl flask so that cells are evenly distributed in the medium.

b. Aseptically remove half of the volume of cell suspension and place into a fresh flask, retaining the other half of the cell suspension in the original flask.

Alternatively, the entire cell suspension can be removed from the original flask and divided equally into two fresh flasks. The original flask can be discarded, or if there is concern about the need for additional cells, the original flask can be retained and fed in an attempt to salvage any residual cells.

c. Feed each flask with 7 to 10 ml prewarmed medium and return flasks to incubator.

Some labs prefer to split the cells 1/3 or 1/4, although increasing the split ratio will result in a longer interval before subcultures reach confluency.

SUPPORT PROTOCOL 1

FREEZING HUMAN CELLS GROWN IN MONOLAYER CULTURES

It is sometimes desirable to store cell lines for future study. To preserve cells, avoid senescence, reduce the risk of contamination, and minimize effects of genetic drift, cell lines may be frozen for long-term storage. Without the use of a cryoprotective agent, freezing would be lethal to the cells in most cases. Generally, a cryoprotective agent such as dimethylsulfoxide (DMSO) is used in conjunction with complete medium for preserving cells at −70°C or lower. DMSO acts to reduce the freezing point and allows a slower cooling rate. Gradual freezing reduces the risk of ice crystal formation and cell damage.

Materials

Log-phase monolayer culture of cells in petri plate
Complete medium
Freezing medium: complete medium (e.g., DMEM or RPMI; see recipes) supplemented with 10% to 20% (v/v) FBS and 5% to 10% (v/v) DMSO, 4°C
Benchtop clinical centrifuge with 45° fixed-angle or swinging-bucket rotor

NOTE: All incubations are performed in a humidified 37°C, 5% CO_2 incubator unless otherwise specified. Some media (e.g., DMEM) may require altered levels of CO_2 to maintain pH 7.4.

1. Trypsinize cells from plate (see Basic Protocol, steps 1 to 4).

   It is best to use cells in log-phase growth for cryopreservation.

2. Transfer cell suspension to a sterile centrifuge tube and add 2 ml complete medium with serum. Centrifuge 5 min at 300 to 350 × *g* (~1500 rpm in Fisher Centrific rotor), room temperature.

   The benchtop centrifuge can be accessorized depending on the anticipated volume. A variety of brands are available, including Eppendorf, Thermo Electron, and Beckman, and can be obtained from Fisher Scientific, VWR, and other laboratory equipment vendors.

   Cells from three or more dishes from the same subculture can be combined in one tube.

3. Remove supernatant and add 1 ml of 4°C freezing medium. Resuspend pellet to obtain a density of 1×10^6 cells/ml.

4. Add 4 ml of 4°C freezing medium, mix cells thoroughly, and place on wet ice.

5. Count cells using a hemacytometer (see Support Protocol 3). Dilute with more freezing medium as necessary to get a final cell concentration of 10^6 or 10^7 cells/ml.

   To freeze cells from a nearly confluent 25-cm^2 flask, resuspend in roughly 3 ml freezing medium.

6. Pipet 1-ml aliquots of cell suspension into labeled 2-ml cryovials. Tighten caps on vials.

7. Place vials 1 hr to overnight in a −70°C freezer, then transfer to a liquid nitrogen storage freezer.

   Keep accurate records of the identity and location of cells stored in liquid nitrogen freezers. Cells may be stored for many years and proper information is imperative for locating a particular line for future use.

FREEZING CELLS GROWN IN SUSPENSION CULTURE

ALTERNATE PROTOCOL 2

Freezing cells from suspension culture is similar in principle to freezing cells from monolayer. The major difference is that suspension cultures need not be trypsinized.

NOTE: All incubations are performed in a humidified 37°C, 5% CO_2 incubator unless otherwise specified. Some media (e.g., DMEM) may require altered levels of CO_2 to maintain pH 7.4.

1. Transfer cell suspension to a centrifuge tube and spin 10 min at 300 to 350 × *g* (−1500 rpm in Fisher Centrific centrifuge), room temperature.
2. Remove supernatant and resuspend pellet in 4°C freezing medium at a density of 10^6 to 10^7 cells/ml.

   Some laboratories freeze lymphoblastoid lines at the higher cell density because they plan to recover them in a larger volume of medium and because there may be a greater loss of cell viability upon recovery as compared to other types of cells (e.g., fibroblasts).

3. Transfer 1-ml aliquots of cell suspension into cryovials and freeze as for monolayer cultures.

THAWING AND RECOVERING HUMAN CELLS

SUPPORT PROTOCOL 2

When cryopreserved cells are needed for study, they should be thawed rapidly and plated at high density to optimize recovery.

CAUTION: Protective clothing, particularly insulated gloves and goggles, should be worn when removing frozen vials or ampules from the liquid nitrogen freezer. The room containing the liquid nitrogen freezer should be well-ventilated. Care should be taken not to spill liquid nitrogen on the skin.

NOTE: All incubations are performed in a humidified 37°C, 5% CO_2 incubator unless otherwise specified. Some media (e.g., DMEM) may require altered levels of CO_2 to maintain pH 7.4.

Materials

Cryopreserved cells stored in liquid nitrogen freezer
70% (v/v) ethanol
Complete medium (e.g., DMEM or RPMI; see recipes) containing 10% to 20% FBS (see recipe), 37°C

1. Remove vial from liquid nitrogen freezer and immediately place it into a 37°C water bath. Agitate vial continuously until medium is thawed.

   The medium usually thaws in <60 sec. Cells should be thawed as quickly as possible to prevent formation of ice crystals that can cause cell lysis. Try to avoid getting water around the cap of the vial.

2. Wipe top of vial with 70% ethanol before opening.

   Some labs prefer to submerge the vial in 70% ethanol and air dry before opening.

3. Transfer thawed cell suspension into a sterile centrifuge tube containing 2 ml warm complete medium containing 20% FBS. Centrifuge 10 min at 150 to 200 × *g* (~1000 rpm in Fisher Centrific), room temperature. Discard supernatant.

Cells are washed with fresh medium to remove residual DMSO.

4. Gently resuspend cell pellet in small amount (~1 ml) of complete medium/20% FBS and transfer to properly labeled culture plate containing the appropriate amount of medium.

   Cultures are reestablished at a higher cell density than that used for original cultures because there is some cell death associated with freezing. Generally, 1 ml cell suspension is reseeded in 5 to 20 ml medium.

5. Check cultures after ~24 hr to ensure that cells have attached to the plate.

6. Change medium after 5 to 7 days or when pH indicator (e.g., phenol red) in medium changes color. Keep cultures in medium with 20% FBS until cell line is reestablished.

   If recovery rate is extremely low, only a subpopulation of the original culture may be growing; be extra careful of this when working with cell lines known to be mosaic.

SUPPORT PROTOCOL 3

DETERMINING CELL NUMBER AND VIABILITY WITH A HEMACYTOMETER AND TRYPAN BLUE STAINING

Determining the number of cells in culture is important in standardization of culture conditions and in performing accurate quantitation experiments. A hemacytometer is a thick glass slide with a central area designed as a counting chamber. Cell suspension is applied to a defined area and counted so cell density can be calculated.

The exact design of the hemacytometer may vary; the one described here is the Improved Neubauer from VWR (Fig. 1.1.1). The central portion of the slide is the counting platform, which is bordered by a 1-mm groove. The central platform is divided into two counting chambers by a transverse groove. Each counting chamber consists of a silver footplate on which is etched a 3 × 3–mm grid. This grid is divided into nine secondary squares, each 1 × 1 mm. The four corner squares and the central square are used for determining the cell count. The corner squares are further divided into 16 tertiary squares and the central square into 25 tertiary squares to aid in cell counting.

Accompanying the hemacytometer slide is a thick, even-surfaced coverslip. Ordinary coverslips may have uneven surfaces, which can introduce errors in cell counting; therefore, it is imperative that the coverslip provided with the hemacytometer be used in determining cell number.

Materials

70% (v/v) ethanol
Cell suspension
0.4% (w/v) trypan blue or 0.4% (w/v) nigrosin, prepared in HBSS (*APPENDIX 2A*)

Hemacytometer with coverslip (Improved Neubauer, Baxter Scientific)
Hand-held counter

NOTE: A disposable plastic hemacytometer, the C-Chip (DHC-N01), has exactly the same grid pattern as the Improved Neubauer. It is a single-use device available from INCYTO (*http://www.incyto.com*).

Prepare hemacytometer

1. Clean surface of hemacytometer slide and coverslip with 70% alcohol.

   Coverslip and slide should be clean, dry, and free from lint, fingerprints, and watermarks.

2. Wet edge of coverslip slightly with tap water and press over grooves on hemacytometer so the coverslip rests evenly over the silver counting area.

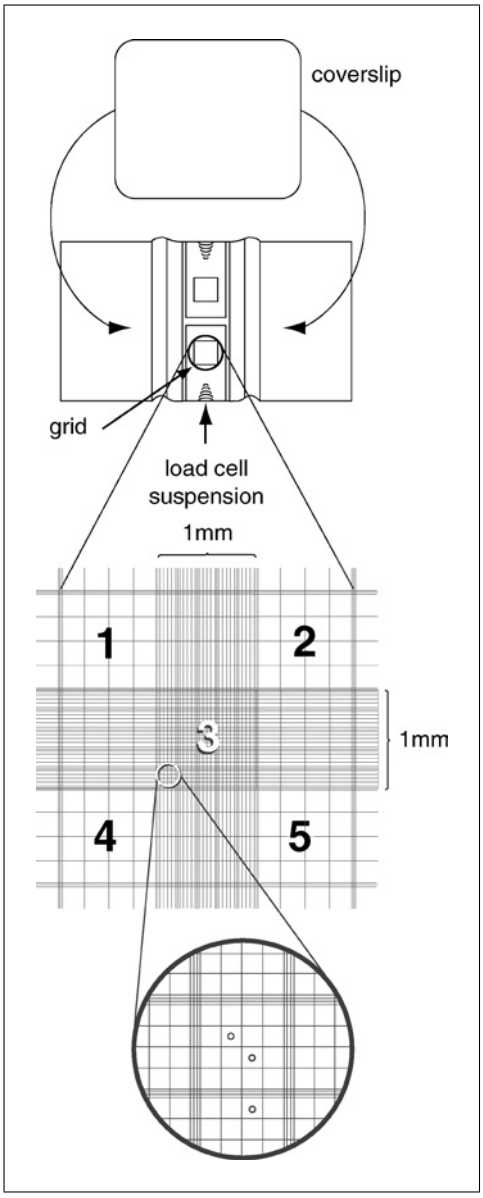

Figure 1.1.1 Hemacytometer slide (Improved Neubauer) and coverslip. Coverslip is applied to slide and cell suspension is added to counting chamber using a Pasteur pipet. Each counting chamber has a 3 × 3–mm grid (enlarged). The four corner squares (1, 2, 4, and 5) and the central square (3) are counted on each side of the hemacytometer (numbers added).

Prepare cell suspension

3. For cells grown in monolayer cultures, detach cells from surface of dish using trypsin (see Basic Protocol).

4. Dilute cells as needed to obtain a uniform suspension. Disperse any clumps.

   When using the hemacytometer, a maximum cell count of 20 to 50 cells per 1-mm square is recommended.

Load hemacytometer

5. Use a sterile Pasteur pipet to transfer cell suspension to edge of hemacytometer counting chamber. Hold tip of pipet under the coverslip and dispense one drop of suspension.

   Suspension will be drawn under the coverslip by capillary action.

   Hemacytometer should be considered nonsterile. If cell suspension is to be used for cultures, do not reuse the pipet and do not return any excess cell suspension in the pipet to the original suspension.

6. Fill second counting chamber.

Count cells

7. Allow cells to settle for a few minutes before beginning to count. Blot off excess liquid.

8. View slide on microscope with 100× magnification.

   A 10× ocular with a 10× objective = 100× magnification.

   Position slide to view the large central area of the grid (section 3 in Fig. 1.1.1); this area is bordered by a set of three parallel lines. The central area of the grid should almost fill the microscope field. Subdivisions within the large central area are also bordered by three parallel lines and each subdivision is divided into sixteen smaller squares by single lines. Cells within this area should be evenly distributed without clumping. If cells are not evenly distributed, wash and reload hemacytometer.

9. Use a hand-held counter to count cells in each of the four corner and central squares (Fig. 1.1.1, squares numbered 1 to 5). Repeat counts for other counting chamber.

   Five squares (four corner and one center) are counted from each of the two counting chambers for a total of ten squares counted.

   Count cells touching the middle line of the triple line on the top and left of the squares. Do not count cells touching the middle line of the triple lines on the bottom or right side of the square.

Calculate cell number

10. Determine cells per ml by the following calculations:

    cells/ml = average count per square × dilution factor × 10^4
    total cells = cells/ml × total original volume of cell suspension from which sample was taken.

    The volume correction factor for the hemacytometer is 10^4: each square is 1 × 1 mm and the depth is 0.1 mm.

Stain cells with trypan blue to determine cell viability

11. Determine number of viable cells by adding 0.5 ml of 0.4% trypan blue, 0.3 ml HBSS, and 0.1 ml cell suspension to a small tube. Mix thoroughly and let stand 5 min before loading hemacytometer.

    Either 0.4% trypan blue or 0.4% nigrosin can be used to determine the viable cell number. Nonviable cells will take up the dye, whereas live cells will be impermeable to it.

12. Count total number of cells and total number of viable (unstained) cells. Calculate percent viable cells as follows:

$$\%\ \text{viable cells} = \frac{\text{number of unstained cells}}{\text{total number of cells}} \times 100$$

13. Decontaminate coverslip and hemacytometer by rinsing with 70% ethanol and then deionized water. Air dry and store for future use.

SUPPORT PROTOCOL 4

PREPARING CELLS FOR TRANSPORT

Both monolayer and suspension cultures can easily be shipped in 25-cm^2 tissue culture flasks. Cells are grown to near confluency in a monolayer or to desired density in suspension. Medium is removed from monolayer cultures and the flask is filled with fresh medium. Fresh medium is added to suspension cultures to fill the flask. *It is essential that the flasks be completely filled with medium to protect cells from drying if flasks are inverted during transport*. It is also imperative that the flasks have nonvented caps. The

cap is tightened and taped securely in place. The flask is sealed in a leak-proof plastic bag or other leak-proof container designed to prevent spillage in the event that the flask should become damaged. The primary container is then placed in a secondary insulated container to protect it from extreme temperatures during transport. A biohazard label is affixed to the outside of the package. Generally, cultures are transported by same-day or overnight courier.

Cells can also be shipped frozen. The vial containing frozen cells is removed from the liquid nitrogen freezer and placed immediately on dry ice in an insulated container to prevent thawing during transport.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. Suitable suppliers for media and components include Invitrogen, Cambrex, Hyclone, and Sigma-Aldrich. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Complete DMEM

Dulbecco's modified Eagle medium, high-glucose formulation (e.g., Invitrogen), containing:

5%, 10%, or 20% (v/v) FBS (optional; see recipe)
1% (v/v) nonessential amino acids
2 mM L-glutamine (see recipe)
100 U/ml penicillin
100 μg/ml streptomycin sulfate
Filter sterilize and store ≤1 month at 4°C

Throughout this manual, the percentage of serum (usually fetal bovine serum) used in a protocol step is indicated by a numeral hyphenated to the base medium name. Thus, "complete DMEM-10" indicates that 10% FBS is used. Absence of a numeral indicates that no serum is used.

DMEM containing 4500 mg/liter D-glucose can be obtained from Invitrogen. DMEM is also known as Dulbecco's minimum essential medium.

Complete RPMI

RPMI 1640 medium (e.g., Invitrogen) containing:

2%, 5%, 10%, 15%, or 20% FBS (optional; see recipe)
2 mM L-glutamine (see recipe)
100 U/ml penicillin
100 μg/ml streptomycin sulfate
Filter sterilize and store ≤1 month at 4°C

FBS (fetal bovine serum)

Thaw purchased fetal bovine serum (shipped on dry ice and kept frozen at −20°C until needed). Store 3 to 4 weeks at 4°C. If FBS is not to be used within this time, aseptically divide into smaller aliquots and refreeze until used. Store ≤1 year at −20°C.

Repeated thawing and refreezing should be avoided as it may cause denaturation of the serum.

In some cases, heat inactivation may be warranted (see Culture Medium Preparation). To inactivate FBS, heat 30 to 60 min in a 56°C water bath. Alternatively, FBS may be inactivated through radiation treatment.

L-Glutamine, 0.2 M (100×)

Thaw frozen L-glutamine, aliquot aseptically into usable portions, then refreeze. For convenience, L-glutamine can be stored in 1-ml aliquots if 100-ml bottles of medium are used, and in 5-ml aliquots if 500-ml bottles are used. Store ≤1 year at −20°C.

Many laboratories supplement medium with 2 mM L-glutamine—1% (v/v) of 100× stock—just prior to use.

Trypsin/EDTA solution

Prepare in sterile HBSS (APPENDIX 2A) or 0.9% (w/v) NaCl:

0.25% (w/v) trypsin
0.2% (w/v) EDTA
Store ≤1 year (until needed) at −20°C

Most laboratories prefer to purchase trypsin/EDTA as a prepared solution, which is available from vendors including Sigma-Aldrich, Invitrogen, and Cambrex. This is a convenient and cost-effective alternative to preparing the solution within the laboratory. Trypsin/EDTA solution is available in various concentrations including 10×, 1×, and 0.25% (w/v). It is received frozen from the manufacturer and can be thawed and aseptically aliquotted into smaller volumes. Specific applications may require different concentrations of trypsin; the appropriate methods should be consulted for details.

EDTA (disodium ethylenediamine tetraacetic acid) is added as a chelating agent to bind Ca^{2+} and Mg^{2+} ions that can interfere with the action of trypsin.

COMMENTARY

Background Information

At its inception in the early twentieth century, tissue culture was applied to the study of tissue fragments in culture. New growth in culture was limited to cells that migrated out from the initial tissue fragment. Tissue culture techniques evolved rapidly, and since the 1950s culture methods have allowed the growth and study of dispersed cells in culture (Freshney, 2005). Cells dispersed from the original tissue can be grown in monolayers and passaged repeatedly to give rise to a relatively stable cell line.

Four distinct growth stages have been described for primary cells maintained in culture. First, cells adapt to the in vitro environment. Second, cells undergo an exponential growth phase lasting through ~30 passages. Third, the growth rate of cells slows, leading to a progressively longer generation time. Finally, after 40 or 50 passages, cells begin to senesce and die (Lee, 1991). It may be desirable to study a particular cell line over several months or years, so monolayer cultures can be preserved to retain the integrity of the cell line. Aliquots of early-passage cell suspensions are frozen, then thawed, and cultures reestablished as needed. Freezing monolayer cultures prevents changes due to genetic drift and avoids loss of cultures due to senescence or accidental contamination (Freshney, 2005).

Cell lines are commercially available from a number of sources, including the American Type Culture Collection (ATCC; *http://www.atcc.org*) and the Human Genetic Mutant Cell Repository at the Coriell Cell Repository (CCR; *http://www.coriell.org*). These cell repositories are a valuable resource for researchers who do not have access to suitable patient populations. An up-to-date listing of available cell lines will be provided upon request. The cell lines are preserved in liquid nitrogen, and information on the characteristics are supplied by the distributor. Immortalized cell lines can be maintained in culture indefinitely, while nontransformed cells have a limited life-span in vitro. For human fibroblasts, about 20 population doublings occur between the initial growth in the primary culture and the first subculture (Priest, 1997). About 50 to 60 population doublings is the standard rule for maintaining fibroblast cell lines in culture before risking the loss of cell lines through senescence, cytogenetic or biochemical changes, or contamination. If it is anticipated that these cells will be needed for future study, cells should be frozen at an early culture stage and retrieved for future use (Verma and Babu, 1995).

Critical Parameters

Use of aseptic technique is essential for successful tissue culture. Cell cultures can be contaminated at any time during handling, so precautions must be taken to minimize the chance of contamination. All supplies and reagents that come into contact with cultures must be sterile, and all work surfaces should be kept clean and free from clutter.

Cultures should be 75% to 100% confluent when selected for subculture. Growth in monolayer cultures will be adversely affected if cells are allowed to become overgrown. Passaging cells too early will result in a longer lag time before subcultures are established. Following dissociation of the monolayer by trypsinization, serum or medium containing serum should be added to the cell suspension to stop further action by trypsin that might be harmful to cells.

When subculturing cells, add a sufficient number of cells to give a final concentration of $\sim 5 \times 10^4$ cells/ml in each new culture of human cell lines. Optimal concentrations are cell-type specific. Package inserts provided with commercially available cell lines contain information on recommended cell density, culture media, and appropriate culture temperatures. Cells plated at too low a density may be inhibited or delayed in entry into growth stage. Cells plated at too high a density may reach confluence before the next scheduled subculturing; this could lead to cell loss and/or cessation of proliferation. The growth characteristics for different cell lines vary. A lower cell concentration (10^4 cells/ml) may be used to initiate subcultures of rapidly growing cells, and a higher cell concentration (10^5 cells/ml) may be used to initiate subcultures of more slowly growing cells. Adjusting the initial cell concentration permits establishment of a regular, convenient schedule for subculturing—e.g., once or twice a week (Freshney, 2005).

Cells in culture will undergo changes in growth, morphology, and genetic characteristics over time. Such changes can adversely affect reproducibility of laboratory results. Nontransformed cells will undergo senescence and eventual death if passaged indefinitely. The time of senescence will vary with cell line, but generally at between 40 and 50 population doublings fibroblast cell lines begin to senesce. Cryopreservation of cell lines will protect against these adverse changes and will avoid potential contamination.

Cultures selected for cryopreservation should be in log-phase growth and free from contamination. Cells should be frozen at a concentration of 10^6 to 10^7 cells/ml. Cells should be frozen gradually and thawed rapidly to prevent formation of ice crystals that may cause cells to lyse. Cell lines can be thawed and recovered after long-term storage in liquid nitrogen. The top of the freezing vial should be cleaned with 70% alcohol before opening to prevent introduction of contaminants. To aid in recovery of cultures, thawed cells should be reseeded at a higher concentration than that used for initiating primary cultures. Careful records regarding identity and characteristics of frozen cells as well as their location in the freezer should be maintained to allow for easy retrieval.

For accurate cell counting, the hemacytometer slide should be clean, dry, and free from lint, scratches, fingerprints, and watermarks. The coverslip supplied with the hemacytometer should always be used because it has an even surface and is specially designed for use with the counting chamber. Use of an ordinary coverslip may introduce errors in cell counting. If the cell suspension is too dense or the cells are clumped, inaccurate counts will be obtained. If the cell suspension is not evenly distributed over the counting chamber, the hemacytometer should be washed and reloaded.

Anticipated Results

Confluent cell lines can be successfully subcultured in the vast majority of cases. The yield of cells derived from monolayer culture is directly dependent on the available surface area of the culture vessel (Freshney, 2005). Overly confluent cultures or senescent cells may be difficult to trypsinize, but increasing the time of trypsin exposure will help dissociate resistant cells. Cell lines can be propagated to get sufficient cell populations for cytogenetic, biochemical, and molecular analyses.

It is well accepted that anyone can successfully freeze cultured cells; it is thawing and recovering the cultures that presents the problem. Cultures that are healthy and free from contamination can be frozen and stored indefinitely. Cells stored in liquid nitrogen can be successfully thawed and recovered in over 95% of cases. Several aliquots of each cell line should be stored to increase the chance of recovery. Cells should be frozen gradually, with a temperature drop of $\sim 1^\circ$C per minute, but thawed rapidly. Gradual freezing and rapid thawing prevents formation of ice crystals that might cause cell lysis.

Accurate cell counts can be obtained using the hemacytometer if cells are evenly dispersed in suspension and free from clumps. Determining the proportion of viable cells in a population will aid in standardization of experimental conditions.

Time Considerations

Establishment and maintenance of mammalian cell cultures require a regular routine for preparation of media and feeding and passaging cells. Cultures should be inspected regularly for signs of contamination and to determine if the culture needs feeding or passaging.

This site contains a comprehensive discussion of the use of biological safety cabinets, including operational procedures and the advantages and disadvantages of ultraviolet lights.

Media for Culture of Mammalian Cells

In culturing mammalian cells in vitro, one attempts to reproduce in a culture vessel the physiological environment and characteristic responses of individual cell types. This simple idea is not easily realized because the physiological environments of most cells are not yet completely characterized, and because the complex regulatory interactions between neighboring cells within tissues are still being elucidated. However, a body of knowledge about the survival and growth requirements of cells has been empirically derived over the past 90 years, making it possible to maintain and to propagate a variety of normal, immortalized, and transformed cell types in vitro. This received knowledge has directly influenced the compositions of culture media and culture substrata that are in use today, and it continues to evolve as the requirements of individual cell types become more explicitly defined. Part of this evolution may be founded on the ongoing discovery of novel growth factors, growth mediators, and survival factors that comes about as the range of specialized cells that can be propagated in vitro is extended. It may be further shaped by advances in understanding of the signaling mechanisms by which culture substrata and other external stimuli influence cells to proliferate, differentiate, become quiescent, or die.

At a minimum, the fluid medium in which cells are cultured must provide for their nutritional requirements, provide an energy source, maintain pH, and provide a level of osmolarity compatible with cell viability. In addition, the environment in which cultures are kept, typically a water-jacketed CO_2 incubator, must provide a constant temperature, humidity to prevent evaporation of medium, O_2 for respiration, and CO_2 for maintenance of the pH of bicarbonate-buffered medium. Culture media commonly used today consist of two parts: a basal nutrient medium and supplements. The basal nutrient medium, such as Dulbecco's modified Eagle's medium (DMEM; also known as Dulbecco's minimal

Table 1.2.1 Tissue Culture Products and Suggested Suppliers[a]

Supplier	Culture-related products
Bayer	Fatty acid–free BSA
Becton Dickinson Labware	Growth factors, hormones, Matrigel
Cell Systems	Specialized serum-free media
Chemicon International	Low-density lipoprotein
Clonetics	Specialized serum-free media
Corning Costar	Filter-sterilization apparatus, tissue culture vessles
Difco Laboratories	Agar
Gelman Sciences	Filter-sterilization apparatus
Life Technologies	Basal nutrient media, antibiotics
Hyclone Laboratories	Sera
J.T. Baker	Chemicals
Millipore	Water-purification system
Nalgene	Filter-sterilization apparatus
Research Organics	HEPES
Sigma Chemical	Inorganic and organic chemicals, BSA fraction V, FBS, sterols, antibiotics, growth factors, hormones, tissue culture vessels
Steraloids	Sterols
Upstate Biotechnology Inc. (UBI)	Insulin, transferrin, FBS, type I collagen, growth factors, hormones

[a]See *SUPPLIERS APPENDIX* for suppliers' addresses.

Current Protocols in Cell Biology (1998) 1.2.1-1.2.15

Eagle's medium), RPMI 1640, or Ham's F-12, is a buffered aqueous solution of inorganic salts, vitamins, amino acids and other anabolic precursors, energy sources such as glucose and glutamine, and trace elements. Supplements are either undefined, such as fetal bovine serum (FBS), tissue extracts, and conditioned medium, or defined, such as hormones and growth factors, transport proteins, and attachment factors. The compositions of basal nutrient media and medium supplements may vary considerably; however, both components of the complete medium are necessary for support of cell viability and proliferation.

The basic protocols in this unit describe the preparation of serum-supplemented medium (see Basic Protocol 1); serum-reduced or serum-free medium (see Basic Protocol 2); selective medium, such as HAT (see Basic Protocol 3) or cholesterol- and serum-free medium (see Alternate Protocol); and soft agar for anchorage-independent growth (see Basic Protocol 4). The support protocols discuss the use of pH buffers (see Support Protocol 1) and antibiotics (see Support Protocol 2) in culture media. Suppliers for culture products are listed in Table 1.2.1.

NOTE: For all solutions and media, use water purified using a reverse osmosis system (e.g., Milli-Q system from Millipore) and vessels that are thoroughly rinsed with water after use but never washed with detergent.

NOTE: All reagents and equipment coming into contact with live cells must be sterile, and aseptic technique should be used accordingly.

BASIC PROTOCOL 1

PREPARATION OF SERUM-CONTAINING MEDIA

Many cell types, especially fibroblasts and transformed cells, survive and proliferate to some extent when cultured in a basal nutrient medium supplemented with 5% to 20% (v/v) serum. The degree of cell proliferation achieved under these nonoptimized conditions may be sufficient for the goals of the experiment as long as the cellular properties of interest are not lost. It is worth remembering that if tissue samples consisting of more than one cell type are cultured, this culture environment may confer a growth advantage to fibroblasts. In addition, the medium may select against the propagation of some types of cells: a number of epithelial cell types cease proliferating and differentiate in the "physiological" Ca^{2+} concentrations of commonly used serum-supplemented basal media. Finally, a serum-supplemented nutrient solution does not approximate a physiological environment for any cells except those in a healing wound.

Materials

Basal nutrient medium, such as DMEM, Ham's F-12, or RPMI 1640 (*APPENDIX 2B*; see Critical Parameters for discussion of medium selection)
HEPES (e.g., Research Organics)
Sodium bicarbonate (e.g., J.T. Baker)
Glutamine and pyruvic acid (e.g., Sigma)
Penicillin G and streptomycin sulfate (e.g., Sigma)
5 N NaOH (e.g., J.T. Baker)
Serum (e.g., Hyclone, Sigma, UBI; see Critical Parameters for discussion of fetal bovine serum)

Filter sterilization units (e.g., Nalge Nunc, Corning, Gelman)
0.2-µm-pore-size filters (e.g., Nalge Nunc, Corning, Gelman)

Additional reagents and equipment for culture of mammalian cells (*UNIT 1.1*)

1. Dissolve powdered medium with constant stirring in a 0.8× to 0.9× volume of water.

   If a commercially prepared liquid medium is being used, add penicillin and streptomycin from commercial stock solutions and proceed to step 8.

2. Add an amount of HEPES that yields a concentration of 15 mM in the final volume of medium.

   Omit this step if the powdered medium is formulated with HEPES.

3. Add the amount of sodium bicarbonate recommended by the medium supplier for use in a CO_2-controlled atmosphere (e.g., 14 to 36 mM in 5% CO_2 atmosphere).

   Omit this step if the powdered medium contains sodium bicarbonate.

4. Add glutamine to give a final concentration of 2 mM and pyruvic acid to give a final concentration of 0.01% (w/v).

5. Add penicillin G to give a final concentration of 100 IU/ml and streptomycin to give a final concentration of 50 µg/ml.

   Other antibacterial agents or antifungal agents should not be routinely included in culture medium. Gentamicin at a final concentration of 50 µg/ml or kanamycin at 100 µg/ml may be useful in eliminating gram-positive and gram-negative bacteria from primary cultures or from irreplaceable cultures, but it is best to discard any cultures that are contaminated with bacteria, yeast, or fungi.

6. Adjust the pH of the medium to 7.4 with 5 N NaOH, and add water to achieve the final (1×) volume. Readjust the pH of the medium to 7.4, if necessary.

7. Sterilize the medium by filtration through a 0.2-µm filter. Store the medium at 4°C in the dark.

   Vacuum-operated filtering units or bottle-top filters are useful for small volumes of medium (0.1 to 2 liters), whereas filter capsules (2 to 5 liters) or filter stands (>10 liters) that are used under positive pressure are more suitable for larger volumes.

8. Add serum to the desired final concentration at the time of use.

   Basal nutrient medium and the serum supplement should be stored individually at 4°C, and the complete medium should be made up at the time of use and only in the volume necessary. Working volumes of serum should be stored at 4°C and used within several weeks. Serum should not be subjected to repeated freezing and thawing, but it can be stored for at least 2 years at −20°C with little deterioration in growth-promoting activity. In this way, medium components are not wasted, and the chances of detecting, isolating, and eliminating contamination with minimal losses are increased.

PREPARING MEDIA FOR REDUCED-SERUM OR SERUM-FREE GROWTH

BASIC PROTOCOL 2

The most obvious advantages of serum-free cell culture are that it costs less and it simplifies the purification of cell products. However, it is in the increased knowledge of cell physiology that the real value of serum-free medium lies. Both reduced-serum and serum-free media are intermediates in a continuum between completely undefined mixtures of biological fluids and chemically defined, protein-free medium. Although mixtures of biological fluids and protein-free medium have useful applications, neither extreme provides a suitable environment for studies of cellular physiology. At the current time, the most physiologically relevant culture medium for an isolated cell type is a defined, protein-supplemented medium consisting of required components at optimal concentrations and extracellular matrix constituents. This set of conditions can be approached for an increasing number of cell types, but for some cell types, a reduced-serum medium is the best that can be achieved. This state of affairs reflects incomplete knowledge of cell growth requirements, and it suggests that there are novel mediators of cell proliferation and differentiation that remain to be discovered.

Table 1.2.2 Components of Reduced-Serum and Serum-Free Medium[a]

Component	Final concentration	Stock concentration	Suggested supplier(s)
Undefined supplements			
Sera[b]	5% to 20% (v/v)	100% (v/v)	Hyclone, Sigma, or UBI
Pituitary extract	5 to 100 µg/ml	1 to 2 mg/ml	UBI, Clonetics
Conditioned medium	5% to 50% (v/v)	100% (v/v)	Not commercially available[c]
Energy sources			
Glucose	1 to 4.5 g/liter	None	Sigma
Glutamine	1 to 2 mM	None	Sigma
Attachment factors			
Collagen type I	10 to 50 µg/ml	3 to 4 mg/ml	UBI, Sigma
Fibronectin	1 to 10 µg/ml	0.5 to 1 mg/ml	Sigma
Vitronectin	1 to 10 µg/ml	0.5 to 1 mg/ml	Sigma
Hormone			
Insulin	1 to 10 µg/ml	1 mg/ml	Sigma, UBI
Carrier proteins			
Transferrin	5 to 30 µg/ml	1 mg/ml	Sigma, UBI
BSA, fatty acid–free	0.5 to 4 mg/ml	50 mg/ml	Bayer
Trace element			
Selenium, sodium salt	1 to 20 nM	2 µM	Sigma
Lipids and lipid precursors			
Ethanolamine	1 to 20 µM	2 mM	Sigma
Fraction V BSA	0.05 to 5 mg/ml	50 mg/ml	Sigma
Unsaturated fatty acids	1 to 10 µg/ml	20 to 50 mg/ml	Sigma
Sterols	1 to 20 µg/ml	2 to 4 mg/ml	Steraloids, Sigma
Low-density lipoprotein	1 to 20 µg/ml	1 to 2 mg/ml	Chemicon International

[a]Nonsterile stock solutions should be sterilized by filtration. Add glucose and glutamine as dry powder (or frozen aliquots that have been thawed) to reconstituted powdered medium.

[b]See Critical Parameters for discussion of FBS.

[c]Conditioned medium must be made in the investigator's laboratory, and the choice of cells used depends on the investigator's purpose.

If all the growth requirements of the cells of interest can be satisfied, the undefined medium supplement can be completely eliminated. The limitation of this approach is that not all of the cell growth regulators operating within tissues have been discovered. As the variety of cell types that can be cultured in vito for extended periods expands, new growth activities may be identified and novel growth factors purified.

Materials

Basal nutrient medium, such as DMEM, Ham's F-12, or RPMI 1640 (*APPENDIX 2B*; see Critical Parameters for discussion of medium selection)

Nutrients: inorganic salts, amino acids, and vitamins (e.g., Sigma)

Trace elements (e.g., Sigma)

Supplements: growth factors and hormones (e.g., Sigma, UBI, Becton Dickinson Labware) and other assorted medium components (Table 1.2.2)

Additional reagents and equipment for culture of mammalian cells (*UNIT 1.1*)

Optimize nutrient medium

1. Starting with a complete medium empirically determined to best support the growth of the cells of interest, reduce the concentration of the undefined medium supplement until cell proliferation is suboptimal but cell viability remains high.

2. Vary the concentrations of individual components of the nutrient medium in a cell proliferation assay. Vary the concentrations of components in the following groupings, which have been found to be limiting for proliferation of at least one cell type:

   a. energy sources (glucose and glutamine);
   b. trace elements and electrolytes (Na^+, Cl^-, K^+, Ca^{2+}, Mg^{2+}, Zn^{2+}, Cu^{2+}, Fe^{2+}, selenium, $H_2PO_4^-$, and HCO_3^-);
   c. amino acids (glutamine, cystine, cysteine, histidine);
   d. vitamins (biotin, vitamin B_{12});
   e. lipids and lipid precursors (oleic acid, linoleic acid, or cholesterol conjugated to fatty acid–free BSA; undefined lipids bound to fraction V BSA; low-density lipoprotein; ethanolamine or phosphoethanolamine).

   Determine the optimal concentration range for the most limiting factor, and fix its concentration in the center of that range. Repeat the growth assays to sequentially identify and optimize each limiting factor.

   Concentrations of 0.1×, 1×, and 10× those listed in the chosen medium formulation are initially useful to determine which components are limiting factors for proliferation.

3. Lower the concentration of the undefined supplement and repeat the optimization procedure. Continue optimizing the nutrient medium until reductions in the concentration of the undefined medium supplement can no longer be compensated for.

   Each new supplement concentration is tested on an individual culture for a finite period (3 to 10 days). The best concentration, supporting the most cell growth, is incorporated into the next round of testing on new cultures.

Optimize medium supplements

4. Optimize medium supplements such as growth factors, hormones, transport proteins, and attachment factors either independently of or in conjunction with the nutrient medium components.

   The set of defined supplements that are required for an individual cell type may be less complex in the presence of an optimized nutrient medium. If an optimized nutrient medium is not being used, then a nutrient-rich basal medium such as DMEM/F-12 (see recipe) is recommended for supplement optimization (see Critical Parameters). As with nutrient optimization, the strategy is to decrease the concentration of an undefined supplement to give suboptimal growth with high cell viability and then to restore proliferation with optimized concentrations of defined supplements.

PREPARATION OF SELECTIVE MEDIA: HAT MEDIUM

BASIC PROTOCOL 3

Culture medium can be used to intentionally select mammalian cells with desired properties from a mixed population of cells. This strategy is founded on the proven effectiveness of selective media in selecting strains of mutant microorganisms that, for example, cannot grow in minimal media but thrive in a medium supplemented with one particular nutrient. Although mammalian cells with desired characteristics proliferate in selective media, in this case selective pressure is applied to inhibit or, preferably, to kill cells that do not possess those characteristics. Thus, the efficacy of a selective medium depends on the efficiency with which it eliminates unwanted cells and on the degree to which the selected phenotypic trait is expressed. Because monoclonal antibodies are commonly used reagents in cell and molecular biology, the use of selective media that target differences in metabolic pathways is illustrated with two protocols for selecting hybridomas (see Background Information for further discussion). In both protocols, unfused spleen cells do not survive 7 to 10 days.

Materials

Spleen cell × myeloma fusion products (10:1)
RD medium (Life Technologies) with 10% FBS (Hyclone; see recipe)
4×10^{-5} M aminopterin (A solution; 100× stock in 0.1 N NaOH)
1×10^{-5} M hypoxanthine/1.6×10^{-3} M thymidine in water (HT solution; 100× stock)
HAT medium: RD/10% FBS/1× A solution/1× HT solution
96-well tissue culture plates

Additional reagents and equipment for culture of mammalian cells (*UNIT 1.1*)

1. Resuspend the fusion products in RD/10% FBS at a concentration of 1×10^6 myeloma cells per ml. Add 0.01× volumes of A and HT solutions to the cell suspension to make HAT selection medium.
2. Plate 0.1 ml of cell suspension per well into 96-well plates. Incubate the plates in a humidified 37°C, 5% CO_2 incubator.
3. Every 2 or 3 days, remove half the existing medium from the wells by aspiration and replace with fresh HAT medium.
4. After 21 days, screen hybridoma supernatants for the presence of the antibodies of interest.
5. Wean hybridomas stepwise from HAT medium by transferring them to HT-supplemented medium and then to RD/10% FBS over a 2-week period. Replace 50% of the medium with HT medium four times at 3-day intervals. Replace 50% of the medium with RD/10% FBS at 3-day intervals.

Aminopterin is toxic, so it is advisable to wean hybridomas from HAT medium as soon as possible.

ALTERNATE PROTOCOL

PREPARATION OF SELECTIVE MEDIA: CHOLESTEROL-FREE, SERUM-FREE MEDIUM

Most of the mouse myeloma cell lines survive in serum-supplemented medium, but they die in the absence of cholesterol (see Background Information for explanation). This conditional lethal defect has been exploited to create an alternative selection process for hybridomas using cholesterol-free medium. Because they are produced by fusion with spleen cells capable of producing cholesterol, NS-1 hybridomas survive in cholesterol-free medium, but the parent NS-1 myeloma cells are selected against. This selective medium allows for the outgrowth of up to 10 times as many hybridomas as HAT medium. This procedure can be used with any myeloma cell line that is unable to synthesize cholestrol.

Materials

Spleen cell × NS-1 myeloma fusion products (10:1)
RD medium with 5F supplement (see recipes)
100× BSA–oleic acid conjugate solution: fatty acid–free BSA (e.g., Bayer; 50 mg/ml) conjugated with oleic acid (e.g., Sigma; 500 μg/ml) in PBS
96-well tissue culture plates

Additional reagents and equipment for culture of mammalian cells (*UNIT 1.1*)

1. Make complete RD/5F medium by adding appropriate volumes of the stock solutions of insulin, transferrin, ethanolamine, 2-mercaptoethanol, and sodium selenite (e.g., Sigma) to RD medium. Supplement the medium with 1/100 vol of 100× BSA–oleic acid conjugate.

BSA–oleic acid acid conjugate is available from Sigma. For a protocol, see Kawamoto et al. (1983).

2. Resuspend fusion products at 2 or 3×10^5 NS-1 cells per milliliter of medium.
3. Plate 0.1 ml of cell suspension per well in 96-well plates. Incubate the plates in a humidified 37°C, 5% CO_2 incubator.
4. Add 0.5× volume of fresh medium to the wells every 2 or 3 days after removing half the existing medium by aspiration.
5. Screen hybridoma supernatants for antibodies of interest after 10 to 14 days. Maintain hybridomes in RD/SF medium supplemented with BSA–oleic acid.

GROWTH OF TRANSFORMED CELLS IN SOFT AGAR

BASIC PROTOCOL 4

Malignantly transformed cells can differ from their normal counterparts in a number of respects. Chief among these differences are a loss of contact-inhibited growth, the acquisition of an infinite life span, and the ability to form tumors in animal hosts. Freedman and Shin (1974) found that there was a general correlation between the tumorigenic potential of transformed cells in vivo and their ability to grow in an anchorage-independent manner in vitro. Although this generalization does not hold for every transformed cell, growth in soft agar can be used as a surrogate in vitro assay for transformation and tumorigenicity. The advantages of this method are that it is relatively easy, it may take much less time than an in vivo tumorigenesis assay, and it does not require the maintenance and care of experimental animals. However, if growth in soft agar is used as a measure of transformation of cells that have been manipulated in vitro, an in vivo tumorigenesis assay is required to determine whether the cells are malignantly transformed.

Materials

2% (w/v) agar (e.g., Difco; see recipe)
Basal nutrient medium, such as DMEM, Ham's F-12, or RPMI 1640 (*APPENDIX 2B*; see Critical Parameters for discussion of medium selection), with 24.6% and 20% FBS
Single-cell suspension
12-well culture plates (e.g., Corning Costar)
15-ml polycarbonate conical centrifuge tubes (e.g., Sarstadt), sterile

1. For each set of replicate wells, add 2.25 ml of 2% agar solution to 9.75 ml of medium containing 24.6% FBS to give a solution of 0.375% agar in 20% FBS. Dispense 2-ml aliquots into five sterile 15-ml polypropylene conical tubes and incubate at 45°C.
2. To separate tubes, add 50, 100, 200, 500, or 1000 cells to a final volume of 0.5 ml medium with 20% FBS. Prepare an additional set of tubes for each set of replicate cultures.
3. Add each cell suspension to an aliquot of agar solution, mix, and quickly pour into a well of a 12-well plate.
4. Incubate the plate at 37°C in a humid atmosphere of 5% CO_2 until cell colonies appear.
5. Count colonies >32 cells (five doublings) under phase contrast with an inverted microscope, and calculate colony formation efficiency (percentage of plated cells that formed colonies).

To prevent any cell attachment to the plastic substratum, cells in 0.3% agar can be overlaid on a preformed layer of 0.5 ml of 0.5% agar in medium supplemented with 20% FBS.

SUPPORT PROTOCOL 1

pH CONTROL IN MEDIA

Most cell lines proliferate in medium with a pH of 7.4, and they exhibit decreased viability and rates of proliferation as the medium becomes progressively more acidic or more basic (Eagle, 1973). Culture media must buffer the CO_2 and lactic acid produced as cells metabolize glucose and glutamine. Historically, bicarbonate, HCO_3^-, in conjunction with atmospheric CO_2, has been used as a buffering system. Each basal medium formulation has a recommended concentration for sodium bicarbonate, usually 20 to 40 mM, to maintain pH and osmolarity. Media that are to be incubated in an elevated CO_2 atmosphere contain higher concentrations of bicarbonate than those designed to be used at ambient CO_2 levels. Most cell culture media require an atmosphere of 5% CO_2 to maintain pH 7.4. However, certain media contain levels of bicarbonate that require different amounts of CO_2. For example, DMEM containing 3700 mg/liter of sodium bicarbonate equilibrates to ~pH 7.6 in a 5% CO_2 environment and requires 10% CO_2 to maintain pH 7.4. The low pK_a of bicarbonate (pK_a = 6.1) makes it a poor buffer around pH 7.4, and, in the absence of atmospheric CO_2, the breakdown of H_2CO_3 formed from bicarbonate releases CO_2 that comes out of solution, causing a rise in pH. With the development of Good buffers (Good et al., 1966), nontoxic buffering agents effective in the pH range of 6 to 8, such as PIPES (pK_a = 6.8), MOPS (pK_a = 7.2), TES (*N*-tris[hydroxymethyl]methyl-2-aminoethanesulfonic acid; pK_a = 7.5), and HEPES (pK_a = 7.55), became available to the research community. HEPES in a concentration range of 10 mM to 25 mM has become a standard buffer in serum-free medium, but it is used in addition to and not in place of the bicarbonate and CO_2 system. Phenol red is an indicator dye that is commonly added to medium to provide a visual assessment of pH. Red at pH 7.4, it becomes orange (pH 7.0) and then yellow (pH 6.5) as the pH decreases; it turns violet (pH 7.6) and purple (pH 7.8) as the pH rises. Culture medium should generally be replaced as the phenol red changes from orange to yellow, which reflects the accumulation of lactic acid.

Materials

Powdered medium without $NaHCO_3$ or HEPES
HEPES (e.g., Research Organics)
$NaHCO_3$ (e.g., J.T. Baker)

1. Dissolve powdered medium in water with gentle stirring.
2. Add HEPES (mol. wt. 238.3) to give a final concentration of 15 mM, and stir until dissolved.
3. Add $NaHCO_3$ to the recommended concentration for the basal nutrient medium being used and stir.
4. Add other medium components, and adjust the pH to 7.4 (see Basic Protocol 1).
5. Filter sterilize the medium (see Basic Protocol 1, step 7).

   Filtering medium under vacuum may cause the pH to increase slightly. A small change in pH need not be compensated because other factors such as medium supplements, temperature, atmospheric pressure, and atmospheric CO_2 levels can also affect pH.

6. Check the pH of the complete medium after it has equilibrated with incubator temperature and CO_2 atmosphere.

USE OF ANTIBIOTICS IN MEDIA

Antibiotics can be added to culture media to eliminate microbial contaminants (Perlman, 1979). The most common contaminants encountered are bacteria, yeast, other fungi, and mycoplasma, and the most common routes of contamination are operator error and nonsterile medium components. Of the common microbial contaminants, yeast and other fungi are very difficult to eradicate, and it is recommended that all heavily contaminated cultures be discarded unless the cells cannot be replaced. Thus, it is wise to maintain duplicate cultures of important cells and to cryopreserve cell lines as soon as possible. Penicillin and streptomycin are broad-spectrum antibacterial agents that are often added to culture media (see Basic Protocol 1 and Table 1.2.3). However, the routine use of antibiotics in media is not recommended, because when used to compensate for poor aseptic technique, they may select for antibiotic-resistant strains of microorganisms. Antibiotics may be used to best effect in primary cultures of cells for which the sterility of the tissue samples is in doubt. The antifungal agent amphotericin B should be used sparingly, as it is toxic to mammalian cells (Perlman, 1979), and it may select for the property of cholesterol auxotrophy (Sato et al., 1987). Mycoplasma and viruses are too small to be retained by 0.2-µm sterilization filters; mycoplasma can be treated with gentamicin or kanamycin, but viruses cannot be treated with antibiotics. There is no reliable method for eliminating viral contaminants from cell cultures.

To be effective in culture, antibiotics must have the following characteristics: they must completely eliminate the microbial contaminant; they must not affect the viability or metabolism of mammalian cells; and they must be compatible with medium components in an aqueous environment. In addition, because the identity of a contaminating species is usually unknown, antibiotics should act on a broad spectrum of mircoorganisms. A list of antibiotics commonly used in culture media is provided in Table 1.2.3.

Materials

Antibiotic
Sterile solvent
0.2-µm-pore-size sterilizing filter

1. Dissolve the antibiotic at a 100× or greater concentration in an appropriate sterile solvent. If it is highly soluble in an aqueous solvent, use water or PBS.
2. If the antibiotic was not obtained in a sterile form, filter the solution through a 0.2-µm filter.
3. Store the antibiotic solution at 4°C prior to use or at −20°C for long-term storage.
4. Add the antibiotic to medium immediately prior to use.

Table 1.2.3 Some Antibiotics Used in Culture Media and Their Microbial Targets

Antibiotic	Concentration	Microbial targets
Amphotericin B	2.5 µg/ml	Yeast and other fungi
Ampicillin	100 µg/ml	Gram-positive and -negative bacteria
Chloramphenicol	5 µg/ml	Gram-negative bacteria
Gentamicin	50 µg/ml	Gram-positive and -negative bacteria, mycoplasma
Kanamycin	100 µg/ml	Gram-positive and -negative bacteria, mycoplasma
Penicillin G	100 IU/ml	Gram-positive bacteria
Streptomycin	100 µg/ml	Gram-positive and -negative bacteria
Tetracycline	10 µg/ml	Gram-positive and -negative bacteria, mycoplasma

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Agar

Dissolve 2% (w/v) agar (e.g., Difco) in water by boiling it or heating it in a microwave. Maintain soft agar at 45°C.

DMEM/F12 medium, supplemented

Make 1:1 (v/v) mixture of DMEM and F-12. Filter sterilize the medium and store at 4°C. Add the appropriate volume of serum at the time of use.

Five factors (5F) supplement

Make the following 200× stock solutions:
2 mg/ml insulin in 10 mM HCl
2 mg/ml transferrin in PBS
2 mM ethanolamine in water
2 mM 2-mercaptoethanol in water
2 μM sodium selenite in water
Filter sterilize the stock solution and store at 4°C prior to use
Add 0.5 ml of each stock solution per 100 ml of medium

RD medium, supplemented

Make 1:1 (v/v) mixture of RPMI 1640 and DMEM. Add glutamine to 2 mM, penicillin G to 100 IU/ml, and streptomycin to 50 μg/ml. Filter sterilize the medium and store at 4°C. Add the appropriate volume of serum at the time of use.

COMMENTARY

Background Information

It is beyond the scope of this unit to describe all of the medium formulations that have been developed for mammalian cell culture. The following references, which provide surveys of media and conditions that have been used successfully to culture numerous cell lines and a variety of cell types, are recommended as sources of this information: Bottenstein et al. (1979); Jacoby and Pastan (1979); Barnes et al. (1984); Freshney (1987, 1992); Baserga (1989); Davis (1994); and Sato et al. (1994).

Because the immediate aim of the cell culturist is to maintain or expand a population of cells, culture media have been developed with an emphasis on maintaining cell viability and stimulating cell proliferation. These goals have necessarily led to culture media and culture conditions that select for cells that can proliferate at the expense of those that cannot. Thus, the choice of culture medium and the culture conditions used affect the properties and types of cells that can be studied in vitro. As an example of selection, normal rodent cells cultured on a plastic substratum in the presence of fetal bovine serum often go through a period of "crisis" in which a minority population of aneuploid cells survive and proliferate as immortalized but not completely transformed cells. Another example of unintentional selection through in vitro cell culture is the outgrowth of basal keratinocytes from cultured epidermal cells; this occurs because keratinocytes in the suprabasal layers of the epidermis differentiate and lose the ability to proliferate.

Conversely, for some applications, culture media have been developed to deliberately select for the survival of specific cell types of interest. Low-calcium, serum-free media developed for many epithelial cell types (Sato et al., 1994) are selective in that they promote the proliferation of epithelial cells but inhibit the outgrowth of fibroblasts in primary cultures; surviving fibroblasts are eliminated by dilution as the cultures are repeatedly passaged (*UNIT1.1*). Selective media are generally designed to exploit differences in susceptibility to metabolic inhibitors or differences in metabolic pathways. An example of a metabolic inhibitor as a selection agent is the use of the antibiotic G418 (geneticin) to kill nontransfected mammalian cells while allowing the growth of transfectants containing the bacterial gene for aminoglycoside phosphotransferase (*neo*^{r}; Southern and Berg, 1982).

Endogenous synthesis of purines and pyrimidines, which are essential components of nucleosides and nucleotides, can be blocked in mammalian cells by the folic acid analogue aminopterin (A). Such a block is circumvented in normal cells by salvage pathways that use hypoxanthine (H) and thymidine (T). However, cells deficient in the salvage pathway enzymes hypoxanthine-guanine phosphoribosyltransferase ($HGPRT^-$) and thymidine kinase (TK^-) cannot produce purines or pyrimidines by means of the salvage pathways in the presence of aminopterin, and die. Thus, HAT medium (Littlefield, 1964) selects for cells that contain functional HGPRT and TK enzymes, and it selects against cells that are $HGPRT^-$ or TK^-. This selection system has been made applicable to the selection of hybridomas by the generation of $HGPRT^-$ mouse myeloma cell lines. When these cells are fused with $HGPRT^+$ spleen cells from an immunized mouse, the resulting $HGPRT^+$ hybridomas survive in HAT medium, and the parental myeloma cells die.

Another example of the use of selective media takes advantage of cell line deficiencies. Most of the mouse myeloma cell lines that are commonly used to generate hybridomas (P3-X63-Ag8, NS-1-Ag4-1, X63-Ag8.653, and NS-0) are clonally derived from the MOPC21 tumor cell line P3 (Horibata and Harris, 1970), and they are all unable to synthesize cholesterol (Sato et al., 1984, 1987), which is an essential component of the plasma membrane. This trait is not a common characteristic of murine lymphoid cells or of mammalian cells in general, and it may have arisen from prolonged exposure to the antifungal agent amphotericin B (Sato et al., 1987). In all of these related myeloma cell lines, the defect in cholesterol biosynthesis has been traced to the enzyme 3-ketosteroid reductase (Sato et al., 1988). In cholesterol-free medium, NS-1 hybridomas are selected for while the cholesterol auxotrophic NS-1 parent cells are selected against (Myoken et al., 1989).

One must bear in mind that it is usually only after a population of cells has been expanded in culture that they can be characterized with respect to their physiological or differentiated properties. At one time it was thought that cells normally dedifferentiated in vitro and that culture techniques could not be used to study differentiated cellular functions. Subsequently, it was found that the dedifferentiation phenomenon resulted from the overgrowth of differentiated cells by contaminating fibroblasts. Once this problem was recognized, the first differentiated animal cell lines were established (Buonassisi et al., 1962; Yasumura et al., 1966). Thus, it is incumbent upon the cell culturist to choose culture media and culture conditions that not only support the viability and proliferation, if possible, of the cells of interest, but that allow those cells to manifest some or all of their differentiated properties in vitro.

From a historical viewpoint, it is of interest that early culture media consisted of undefined mixtures of biological fluids, tissue extracts, and simple salt solutions. The first continuous mammalian cell line, the mouse L cell fibroblast line (Sanford et al., 1948), was established from 20-methylcholanthrene-treated C3H mouse tissue explants grown in chicken plasma clots in 40% horse serum, 20% chick embryo extract, and 40% saline. The first continuous human cell line, the HeLa cervical adenocarcinoma line (Gey et al., 1952), was isolated in a mixture of chicken plasma, bovine embryo extract, and human placental cord serum. At about the same time, attempts were being made to make culture media more defined by creating synthetic nutrient media and by determining the nutritional requirements of cells in culture. An early synthetic nutrient medium, medium 199 (Morgan et al., 1950), was created to increase the longevity of primary chicken muscle cell cultures that were started as tissue explants in Earle's salt solution with 40% horse serum and 1% chick embryo extract. Medium 199 consisted of a salt solution with amino acids, vitamins, purines, pyrimidines, pentose sugars, adenosine triphosphate (ATP), adenylic acid, Tween 80 as a source of oleic acid, cholesterol, antioxidants, and iron in the form of ferric nitrate. Although medium 199 promoted the outgrowth of "large, flat and spindle-shaped" cells from the original tissue fragments, none of the medium components except glutamine clearly enhanced the life span of the cultures. The pioneering work of Eagle (Eagle, 1955) showed that L cells and HeLa cells had similar, demonstrable nutritional requirements for the thirteen essential amino acids, seven vitamins, glucose or other carbohydrates, and electrolytes. Strikingly, neither L cells nor HeLa cells would grow under these minimal essential conditions without the further addition of a small amount of dialyzed serum protein. Nonetheless, this research marked the beginning of concerted efforts to optimize basal nutrient media and to determine the growth requirements of cells in vitro.

Culture media for a number of normal, immortalized, and transformed cells have been

improved through the application of two complementary strategies. The approach of Ham and his colleagues has been to optimize the compositions of basal nutrient media for individual cell lines or cell types (Ham and McKeehan, 1979; Ham, 1984; Bettger and McKeehan, 1986) in the presence of ever-decreasing concentrations of dialyzed serum protein. These efforts gave rise to Ham's F-12 nutrient medium and the MCDB media, which are commonly used today. MCDB media are optimized basal media developed for specific call types by R. Ham and colleagues. In studying hormonally responsive cell lines in culture, Sato and his colleagues realized that a major role of serum in culture medium was to provide hormones and hormone-like growth factors that were required for cell proliferation and expression of differentiated functions (Bottenstein et al., 1979; Barnes and Sato, 1980; Barnes, 1987). This understanding led them to replace serum with purified hormones, growth factors, transport proteins, and attachment factors as supplements for preexisting nutrient media. In combination, these two experimental approaches demonstrated (1) that basal nutrient media could be optimized for individual cell types, but optimal cell proliferation required additional hormones or growth factors, transport proteins, and attachment mediators in the absence of serum, and (2) that the combinations of purified medium supplements for individual cell lines could be simplified when using an optimized basal medium.

General conclusions that can be drawn from the work of Ham and Sato are: (1) individual cell types require quantitatively balanced sets of nutrients, of which some are cell type specific; (2) cell proliferation and differentiated properties are regulated by hormones, growth factors, protein-bound nutrients, and attachment factors, of which many are present in serum and tissue extracts; (3) most cells in culture are growth stimulated by the serum components insulin and insulin-like growth factors, the iron-transporting protein transferrin, and unsaturated fatty acids or lipoproteins; and (4) because different cell types have similar but different growth requirements, it is unlikely that a single medium formulation will prove optimal for all cells.

Critical Parameters

When choosing or developing a cell culture medium, the single most important parameter is cell viability. This holds true whether the medium is used to maintain a population of differentiated cells, to stimulate cell proliferation, or to optimize the yield of a cellular product. An adequate serum-containing, serum-reduced, or serum-free medium formulation should promote a high degree of cell viability. Conversely, poor cell viability is a good indication that the culture medium or culture environment is deficient in one or more essential components. Suggestions for improving culture media are provided in Basic Protocols 1 and 2, and the reader is referred to *UNIT 1.1* for methods of assessing cell viability. On occasion, changes in culture conditions, such as a switch from serum-supplemented to serum-free medium, may cause the majority of cells in a culture to die, followed by the outgrowth of a surviving subpopulation of cells. Although this phenomenon has been referred to in the literature as adaptation or weaning, it is more likely to be a selective process in which the surviving cells differ phenotypically from the parental population. The investigator can reduce the chances of phenotypic changes becoming fixed in a population of cells by maintaining cells in culture medium that supports a high level of viability, by using low split ratios when passaging cells, and by periodically returning to cryopreserved stocks of low-passage-number cells.

The first choice for a basal nutrient medium should be one that other investigators have used successfully to culture the cells of interest and have reported in the literature. If for some reason that medium is not adequate for the purposes at hand, a number of basal media should be tested for the ability to support the proliferation of the cells of interest and to maintain their phenotypic properties. It is useful to start with basal media that have been used with similar or related cell types and in similar culture conditions (e.g., clonal or high-density cultures), but basal media developed for unrelated cell types may also yield good results (Ham, 1984). Commercially available basal media commonly used for continuous cell lines are DMEM; Ham's F-12 medium; a 1:1 mixture (v/v) of DMEM and Ham's F-12 medium (DMEM/F-12); and RPMI 1640, which was originally developed for lymphoid cells. The MCDB media were developed by Ham and his colleagues for individual types of normal cells, but they may also be effective on continuous cell lines. Most of these basal media are qualitatively similar but differ quantitatively. The basal medium selected based on empirical testing can be used as a starting point for further optimization. For excellent discussions on cel-

lular nutrition and procedures for optimizing basal nutrient medium see Ham and McKeehan, 1979; Ham, 1984; and Bettger and McKeehan, 1986.

The most commonly used serum supplement is fetal bovine serum (FBS). Less expensive alternatives to FBS are calf serum, newborn calf serum, calf serum fortified with transferrin or growth factors (available from Hyclone and Sigma), and horse serum. For normal human lymphocytes, the use of commercial human serum treated at 56°C for 30 min to inactivate complement may be appropriate. The most suitable serum supplement for the cells of interest should be determined empirically. Although variability in efficacy between batches of FBS owing to variations in composition is not as problematic as it once was, it is advisable to test batches of FBS at several concentrations for the ability to support the proliferation of cells of interest at low and high densities. Clonal growth assays are the most stringent tests of the efficacy of batches of serum, but acceptable batches of serum should also be able to support, at reasonable concentrations, the viability of high-density cultures.

A number of reduced-serum or serum-free media have been developed for continuous cell lines and nontransformed cells (Bottenstein et al., 1979; Jacoby and Pastan, 1979; Barnes et al., 1984; Freshney, 1987, 1992; Baserga, 1989; Davis, 1994; Sato et al., 1994), and most are optimized for a single cell line or cell type. However, the similarities between media developed for related cells are increasing the understanding of the nutritional and growth factor requirements of individual cell types, which in turn is making the development of serum-free medium a more rational process (Sato et al., 1994). As in choosing a basal nutrient medium for serum-supplemented medium, the best choice for a reduced-serum or serum-free medium is one that has been used by other investigators for the same or a related cell line or cell type. It is desirable to use a defined, serum-free medium whenever possible, as this affords the investigator the greatest degree of control over an in vitro culture–based experiment.

Proprietary serum-free media for specific cell types are commercially available from companies such as Clonetics and Cell Systems (see Table 1.2.1). If an optimized, preexisting serum-free medium is not available, then a serum-free or serum-supplemented medium that supports cell viability and suboptimal proliferation can be used as a starting point for further medium development. As described above (see Background Information), two complementary strategies for improving culture media are to optimize the components of the basal nutrient medium (Ham and McKeehan, 1979; Ham, 1984) and to replace serum or other undefined medium components with defined, purified protein and nonprotein supplements (Bottenstein et al., 1979; Barnes and Sato, 1980; Barnes, 1987; Sato et al., 1994). Under both strategies, concentrations of serum, dialyzed serum, or other undefined supplements are lowered stepwise to reduce the rate of cell proliferation, and the concentrations of defined medium components are individually manipulated until cell proliferation is restored. A completely defined culture medium or a much reduced serum-supplemented medium should be attained after a number of rounds of optimization. See Basic Protocol 2 for description of both these approaches.

Clues as to which defined supplements are likely to be growth stimulatory for the cells of interest are provided by the following sources: hormones or growth factors that act on the cell type of interest in vivo; autocrine factors that the cells have been found to produce in vitro; and defined supplements that have been included in serum-free media developed for similar or related continuous cell lines or cell types. Thus, the first place to search for potentially useful supplements is the literature. The following general suggestions are based on the serum-free media that have been developed over the past 20 years.

1. Most cells are growth stimulated by insulin or insulin-like growth factor I and require iron obtained by the iron-transporting protein transferrin.

2. Fatty acid–free BSA is a useful carrier protein for unsaturated fatty acids, sterols, and steroid hormones, which are insoluble in an aqueous solvent.

3. Cells of epithelial origin often respond to epidermal growth factor (EGF), acidic fibroblast growth factor (aFGF or FGF-1), and dexamethasone or hydrocortisone.

4. Mesenchymal cells respond to EGF, aFGF, basic FGF (bFGF or FGF-2), and platelet-derived growth factor (PDGF).

5. In the absence of serum-derived attachment mediators, treating tissue culture plastic with attachment factors, such as type I collagen (*UNIT 10.3*), fibronectin, vitronectin, and laminin (*UNIT 10.2*), or with an incompletely defined, natural extracellular matrix (e.g., Matrigel, from Becton Dickinson Labware; *UNIT 10.2*) may

enhance the plating efficiencies and growth rates of adherent cells.

It is important to use highly pure water in preparing media and medium additives. Double-distilled water was a standard ingredient in medium for many years, but it has been superseded by purification systems that incorporate reverse osmosis. In the Milli-Q system, locally supplied water is subjected to deionization, reverse osmosis, and filtration through activated charcoal and a sterilizing filter. Use a vessel that is thoroughly rinsed with water after use but never washed with detergent.

Anticipated Results

As the survival and growth requirements of individual cell lines and cell types become better understood, the routine culture conditions for cells of interest become more defined. When all of the growth requirements of cells of interest are understood, any undefined medium supplements that were previously required can be completely eliminated. Defined culture conditions afford the investigator the greatest degree of control over in vitro culture experiments, and they provide more accurate insights into cellular physiology in vivo.

Time Considerations

Optimizing a basal nutrient medium or developing a serum-free medium formulation is not a trivial undertaking, and it can be very time-consuming with no guarantee of success. Thus, the investigator should carefully consider how important defined culture conditions are to the experimental goals before taking on either task. However, as optimized and defined media are developed for a wider array of cell types, it is becoming easier and less time-consuming to create defined media for additional types of cells. The amount of time required to mix and sterilize 5- to 20-liter batches of medium should not exceed 2 to 4 hours.

Aseptic Technique for Cell Culture

This unit describes some of the ways that a laboratory can deal with the constant threat of microbial contamination in cell cultures. Microorganisms are ubiquitous. Bacteria can be isolated from nearly any surface including inanimate objects and human skin. Fungal spores and bits of vegetative hyphae drift into a laboratory from air conditioning ducts and open doors. Mycoplasma infections most frequently originate from improperly sterilized media or serum. At the risk of eliciting paranoia in the novice cell culture user who has no training in microbiological techniques, the possibility for microbial contamination exists everywhere. Inherent with successful manipulation of cell cultures is the basic understanding that everything that comes into contact with the cells must be sterile or noncontaminating. This includes media, glassware, and instruments, as well as the environment to which the cultures are briefly exposed during transfer procedures. Because cleaning up a contaminated culture is too frequently a disheartening and unsuccessful experience, the best strategy is to employ procedures to prevent microbial contamination from occurring in the first place.

This unit begins with a protocol on aseptic technique (see Basic Protocol 1). This catch-all term universally appears in any set of instructions pertaining to procedures in which noncontaminating conditions must be maintained. In reality, aseptic technique cannot be presented in one easily outlined protocol, but rather encompasses all aspects of environmental control, personal hygiene, equipment and media sterilization, and associated quality control procedures needed to ensure that a procedure is, indeed, performed with aseptic, noncontaminating technique. Although cell culture can theoretically be carried out on an open bench in a low-traffic area, most cell culture work is carried out using a horizontal laminar-flow clean bench (see Basic Protocol 2) or a vertical laminar-flow biosafety cabinet (see Alternate Protocol). Subsequent units within this chapter address these diverse considerations—e.g., sterilization and disinfection, use of antibiotics, and quality control. Where applicable, use presterilized, disposable labware and other equipment. The wide availability and reliability of these products has simplified cell culture, particularly for small-scale laboratory needs.

ASEPTIC TECHNIQUE

BASIC PROTOCOL 1

This protocol describes basic procedures for aseptic technique for the novice in cell culture technology. One basic concern for successful aseptic technique is personal hygiene. The human skin harbors a naturally occurring and vigorous population of bacterial and fungal inhabitants that shed microscopically and ubiquitously. Most unfortunately for cell culture work, cell culture media and incubation conditions provide ideal growth environments for these potential microbial contaminants. This procedure outlines steps to prevent introduction of human skin flora during aseptic culture manipulations.

Every item that comes into contact with a culture must be sterile. This includes direct contact (e.g., a pipet used to transfer cells) as well as indirect contact (e.g., flasks or containers used to temporarily hold a sterile reagent prior to aliquoting the solution into sterile media). Single-use, sterile disposable plastic items such as test tubes, culture flasks, filters, and pipets are widely available and reliable alternatives to the laborious cleaning and sterilization methods needed for recycling equivalent glass items. However, make certain that sterility of plastic items distributed in multiunit packages is not compromised by inadequate storage conditions once the package has been opened.

Current Protocols in Cell Biology (1998) 1.3.1-1.3.10

Ideally, all aseptic work should be conducted in a laminar cabinet (see Basic Protocol 2 and Alternate Protocol). However, work space preparation is essentially the same for working at the bench. Flame sterilization is used as a direct, localized means of decontamination in aseptic work at the open bench. It is most often used (1) to eliminate potential contaminants from the exposed openings of media bottles, culture flasks, or test tubes during transfers, (2) to sterilize small instruments such as forceps, or (3) to sterilize wire inoculating loops and needles before and after transfers. Where possible, flame sterilization should be minimized in laminar-flow environments as the turbulence generated by the flame can significantly disturb the sterile air stream.

Materials

Antibacterial soap
70% ethanol or other appropriate disinfectant
95% ethanol

Clean, cuffed laboratory coats or gowns
Latex surgical gloves
Clean, quiet work area
Shallow discard pans containing disinfectant
Bunsen burner or pilot-activated burner (e.g., Touch-o-Matic, VWR)

Take personal precautions

1. Just prior to aseptic manipulations, tie long hair back behind head. Vigorously scrub hands and arms at least 2 min with an antibacterial soap.

   Superficial lathering is more prone to loosening than removing flaking skin and microbial contaminants. Loosely adhering skin flora easily dislodge and can potentially fall into sterile containers.

2. Gown appropriately. For nonhazardous sterile-fill applications, wear clean, cuffed laboratory coats and latex gloves.

   Greater stringencies may be necessary depending upon laboratory regulatory requirements. Work with potentially hazardous agents certainly mandates additional considerations for safety. Front-closing laboratory coats are not recommended for work with hazardous biological agents. Safety glasses should be worn by laboratory personnel when manipulating biological agents outside the confines of a biosafety cabinet.

3. Frequently disinfect gloved hands with 70% ethanol while doing aseptic work.

   Although the gloves may initially have been sterile when first worn, they will no doubt have contacted many nonsterile items while in use.

   Note that 70% ethanol may not be an appropriate agent for latex glove disinfection when working with cultures containing animal viruses, as studies have shown that ethanol increases latex permeability, reducing protection for the wearer in the event of exposure. In this case, quarternary ammonium compounds are more appropriate.

4. Dispose of gloves by autoclaving after use. Do not reuse. Bag and autoclave single-use laboratory coats after use. Bag, autoclave (if necessary), and wash other laboratory coats within the laboratory facility or send out for cleaning at a laundry certified for handling biologically contaminated linens.

   Never take laboratory clothing home for washing.

5. Thoroughly wash hands after removing protective gloves.

Prepare and maintain the work area

6. Perform all aseptic work in a clean work space, free from contaminating air currents and drafts. For optimal environmental control, work in a laminar-flow cabinet (see Basic Protocol 2 and Alternate Protocol).
7. Clear the work space of all items extraneous to the aseptic operation being performed.
8. Wipe down the work surface before and after use with 70% ethanol or other appropriate disinfectant.
9. Wherever feasible, wipe down items with disinfectant as they are introduced into the clean work space. Arrange necessary items in the work space in a logical pattern from clean to dirty to avoid passing contaminated material (e.g., a pipet used to transfer cultures) over clean items (e.g., flasks of sterile media).
10. Immediately dispose of any small contaminated items into a discard pan.
11. When the aseptic task has been completed, promptly remove any larger contaminated items or other material meant for disposal (e.g., old culture material, spent media, waste containers) from the work space and place in designated bags or pans for autoclaving. Disinfect the work space as in step 8.

Flame sterilize the opening of a vessel

12. For a right-handed person, hold the vessel in the left hand at ~45° angle (or as much as possible without spilling contents) and gently remove its closure. Do not permit any part of the closure that directly comes in contact with the contents of the vessel to touch any contaminating object (e.g., hands or work bench).

    Ideally, and with practice, one should be able to hold the closure in the crook of the little finger of the right hand while still being able to manipulate an inoculating loop or pipettor with the other fingers of the hand.

    Holding the vessel off the vertical while opening will prevent any airborne particulates from entering the container.

13. Slowly pass the opening of the vessel over the top of (rather than through) a Bunsen burner flame to burn off any contaminating matter.

    Be careful when flaming containers of infectious material. Any liquid lodged in the threads of a screw cap container will spatter as it is heated. Aerosols thus formed may actually disseminate entrapped biological agents before the heat of the flame is hot enough to inactivate them.

14. While still holding the vessel at a slant, use a sterile pipet and pipettor to slowly add or remove aliquots to avoid aerosol formation.
15. Flame-sterilize again as in step 13, allow the container to cool slightly, and carefully recap the vessel.

Flame sterilize small hand instruments

16. Dip critical areas of the instrument (i.e., those that come into contact with the material of concern) in 95% ethanol.

    Make certain that the alcohol is in a container heavy enough to support the instrument without tipping over.

    CAUTION: *95% ethanol is flammable; keep the container at a safe distance from any open flame.*

17. Remove the instrument from the alcohol, being careful not to touch the disinfected parts of the instrument. Allow excess ethanol to drain off into the container.

18. Pass the alcohol-treated part of the instrument through the flame of a Bunsen burner and allow residual alcohol to burn off.

19. Do not let the sterilized portion of the instrument contact any nonsterile material before use. Let the heated part of the instrument cool for ~10 sec before use.

20. After use, return the instrument to the alcohol disinfectant until needed again.

Flame sterilize inoculating loops and needles

21. Hold the inoculating wire by its handle and begin in the center of the wire to slowly heat the wire with the flame of a Bunsen burner. Proceed back and forth across the wire's full length until it glows orange.

22. While still holding the handle, allow the inoculating wire to cool back to room temperature (~10 sec) before attempting any transfer of material.

    If tranfers are made while the inoculating wire is hot, cells will be killed by the hot wire, and aerosols created from spattering material can disperse biological material throughout the work space.

23. After the transfer is made, reheat the inoculating wire as in step 21 to destroy any remaining biological material. Let cool to room temperature before putting aside for next use.

BASIC PROTOCOL 2

USE OF THE HORIZONTAL LAMINAR-FLOW CLEAN BENCH

Laminar-flow cabinets (hoods) are physical containment devices that act as primary barriers either to protect the material being manipulated within the hood from worker-generated or environmental sources of contamination, or to protect the laboratory worker and laboratory environment from exposure to infectious or other hazardous materials that are present within the hood. Cell culture applications utilize two types of laminar-flow hoods: (a) the horizontal-flow clean bench (described here) and (b) the biological safety cabinet (see Alternate Protocol). Both types of hoods use a high-efficiency particulate air (HEPA) filter and blowers that generate a nonmixing stream of air.

The horizontal laminar-flow clean bench is used to provide a near-sterile environment for the clean (i.e., noncontaminating) handling of nonhazardous material such as sterile media or equipment. Because the air stream pattern directs the flow of air within the hood directly back to the hood operator and the room (Fig. 1.3.1), horizontal flow hoods are never to be used with infectious agents or toxic chemicals.

Materials

70% ethanol or other disinfectant
Horizontal laminar-flow hood, certified for use
Swabs (e.g., cheesecloth, paper towels)
Pilot light–activated Bunsen burner (e.g., Touch-o-Matic, VWR)

1. Completely clear the bench of the laminar-flow hood and disinfect the bench working surface and the left and right sides of the hood with 70% ethanol or other disinfectant. Do not spray the back (gridded) wall where the HEPA filter is housed.

   Resist the urge to leave frequently used items (e.g., pipet canisters or a bag of disposable plastic tissue culture flasks) in the hood between uses. Their presence makes thorough disinfection of the work space difficult.

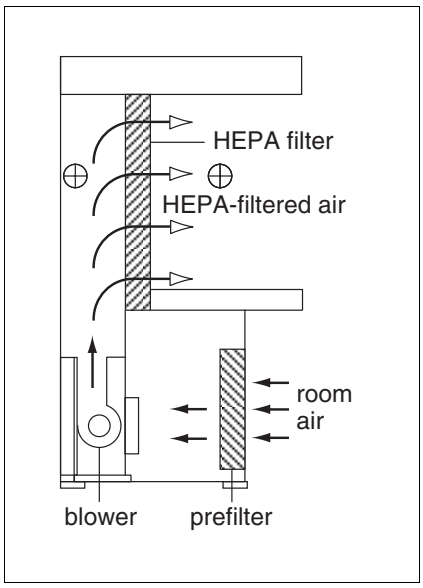

Figure 1.3.1 Horizontal laminar-flow clean cabinet. Solid arrows, dirty room air; open arrows, clean HEPA-filtered air; circled +, positive pressure with respect to room air.

2. Turn the hood blower and lights on and let the air circulate within the hood 10 min before use.
3. Place items needed for the specific procedure into the hood, wiping each item with 70% ethanol or other disinfectant just before introducing it into the laminar environment.

   Do not overcrowd the work space. For horizontal laminar-flow effectiveness, maintain a clear path between the work area and the back wall of the cabinet where the HEPA filter is located.

4. Wash hands well before working in the hood and wear a clean laboratory coat and surgical gloves to further protect the work from shedding of skin flora that can contaminant any product (see Basic Protocol 1).
5. While working in the hood, perform all work at least 4 in. back from the front opening, and avoid rapid movements that might disrupt the laminar air flow. Avoid moving materials or hands in and out of the cabinet as much as possible.
6. If flame sterilization is needed in the hood for a particular application, use a burner that can be activated by a pilot light when needed, rather than one that burns constantly.

   The open flame of a Bunsen burner causes turbulence that disrupts the unidirectional laminar air flow.

7. When work is completed, remove all material from the laminar work bench, clean any spills, and disinfect the bench working surface by wiping with 70% ethanol or other disinfectant.
8. Turn off hood blower and lights.

ALTERNATE PROTOCOL

USE OF THE VERTICAL LAMINAR-FLOW BIOSAFETY CABINET

Biological safety cabinets provide a clean, safe environment for both the worker and the product. The Class II, Type A biosafety cabinet (Fig. 1.3.2) is frequently encountered in cell culture laboratories, and this protocol describes the use of this type of barrier device. The Class IIA biosafety cabinet is suitable for work with low- to moderate-risk biological agents in the absence of toxic or radioactive chemicals.

Materials *(also see Basic Protocols 1 and 2)*

Class II, Type A Biosafety Cabinet (BSC), certified for use
Pilot light–activated Bunsen burner (e.g., Touch-o-Matic, VWR) or electronic incinerator (e.g., Bacti-Cinerator III, VWR)
Closed-front laboratory gowns (for personnel working with biological agents)

1. Turn the hood blower on and verify air flow by feeling (by hand) the current near the front grill of the work surface. Turn the germicidal UV light off if it is on. Turn the fluorescent light on.

   Before use, the cabinet should already be empty and clean from prior activity. The view window should be lowered to the proper operating height (normally 8 in.) or as specified by the cabinet manufacturer.

   UV light is effective only for decontaminating clean, solid surfaces with which it comes in contact. It is not effective in decontaminating the cabinet air flow. UV light is not effective against bacterial spores. UV germicidal light tubes should be replaced frequently (at least every 6 months for biosafety cabinets in use on a daily basis) to assure that they are emitting light at 254 nm and at an intensity appropriate for decontamination.

   CAUTION: *UV light is harmful to the eyes. Laboratory personnel should not be near the cabinet or looking at the UV light when it is in use.*

2. Wash and gown as required for the operation (see Basic Protocol 1, steps 1 to 5).
3. Wipe down the entire interior cabinet work surface area with 70% ethanol or other appropriate disinfectant.
4. Let blower run for 10 min to filter the cabinet air of any particulates.

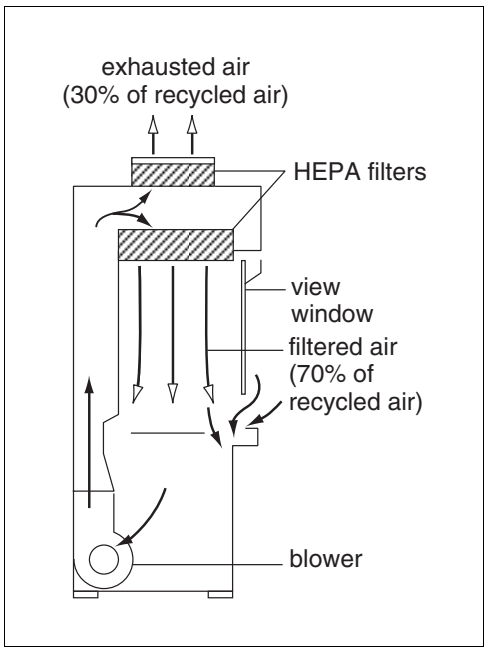

Figure 1.3.2 Biological safety cabinet, Class II, Type A. Note that filtered air is contaminated after passing through the work space, and is filtered again whether it is recycled to the workspace (70%) or exhausted (30%). Solid arrows, dirty (room/contaminated) air; open arrows, filtered air.

5. Raise the front view window as needed to bring necessary items into the cabinet. Wipe each item with 70% ethanol or other disinfectant as it is placed in the cabinet.

   Do not crowd the work space and make sure no air vents are blocked by supplies or equipment. Do not position material so that it obscures any of the air vents at the front edges of the laminar hood. One frequent source of air flow restriction in biosafety cabinets is "lost" paper towels that have been drawn into the air ducts at the back of the work surface.

6. Organize the work surface for a clean-to-dirty work flow. Place clean pipets, flasks, and sterile media bottles at one side of the cabinet; place discard pans, spent cultures, and other wastes on the other side.

7. Return the view window to the 8-in. operating level. Wait ~10 min for the blowers to filter the disturbed cabinet air before starting work.

8. While working, keep all material and perform work ≥4 in. back from the front opening of the cabinet, and minimize rapid movements or activity. Keep the view window opening as close to 8 in. as allows reasonable access to the work surface and equipment.

   These precautions assure that any drafts caused by arm movements will not disrupt air flow or churn room air currents into the clean work area.

9. If direct flame sterilization of items within the cabinet is necessary, use an electric burner or pilot light–activated flame burner located at the back of the work space.

   A constant open flame in the cabinet can disturb the laminar air flow.

10. At the end of the procedure, enclose all contaminated materials. Clean the cabinet work surface with 70% ethanol or other disinfectant, being especially careful to wipe any spills of culture suspensions or media that can serve as future contamination points. Clear all material from the cabinet.

11. Let the blower run for ≥10 min with no activity to remove any aerosols that were generated. During this period, turn off the fluorescent light and turn on the germicidal UV light. Allow the UV light to operate ≥30 min.

COMMENTARY

Background Information

Aseptic technique

The dictionary definition of asepsis simply implies freedom from pathogenic organisms. However, the practical definition of the term for cell biologists, as well as other biotechnologists working with pure cultures, has come to be synonymous with sterile or noncontaminating conditions. The successful manipulation of cell cultures under any circumstance inherently relies upon the ability to maintain rigorous aseptic (i.e., noncontaminating) working conditions. The concept of aseptic technique is simple in theory: prevention of sterile or uncontaminated material and objects from coming into contact with any nonsterile or contaminated material.

Practical application of the theory is often illusive for beginning students. However, breaches in aseptic technique can also cause significant problems for even well-experienced laboratories, particularly when the source of contamination is not readily evident. A single incident of culture contamination is frustrating in its own right, but repeated contamination (particularly by the same type of organism) invariably results in expensive losses and delays until the localization and source are identified.

The critical areas of concern with respect to successful aseptic technique include environmental conditions (laboratory or work space), source material (cell lines, media, and reagents), equipment (labware, instruments, and apparatuses), sterilization procedures and equipment (autoclave, dry heat, filtration), and human (laboratory personnel) considerations. Budgetary constraints aside, technological aids exist to greatly simplify the hardware needed

for aseptic work. Laminar-flow cabinets create clean working environments (see below); clean, certified cell lines are available from cell repositories; media manufacturers and biotechnology supply companies provide sterile media, sera and reagents; and presterilized disposable labware to satisfy most cell culture needs is available from any large distributor of scientific supplies.

Despite all the technological advances, the one weak link remaining in successful laboratory applications of aseptic technique is the human factor. Too frequently, contamination occurs because of the desire to work a little too quickly, the urge to eliminate an "unimportant" step, or lapses in concentration during mundane procedures. The only advice to offer as protection against the human factor is to work slowly and deliberately when performing procedures under aseptic conditions, don't eliminate procedural steps, and pay attention! Establishing a standard routine of procedures and of placement of materials can help prevent the omission of steps.

Laminar-flow cabinets

Laminar-flow cabinets or hoods have replaced the open laboratory bench for aseptic work in almost all cell culture and microbiology laboratories. Their effectiveness as physical barriers to contamination relies on a cabinet design incorporating high-efficiency particulate air (HEPA) filters to trap airborne contaminants, and blowers to move the filtered air at specified velocities and in a nonmixing (laminar) stream across a work surface.

As noted in each protocol for the particular type of laminar-flow application, the proper choice of cabinet is imperative. Horizontal laminar-flow cabinets are never used with biological or toxic chemical agents as they are not containment devices but rather serve to provide a strong stream of near-sterile air for particle-free working conditions. As this air is blown directly from the HEPA filter (at the back of the cabinet) across the work surface and out of the cabinet (directly into the operator's face and the room), the restricted use of the horizontal flow cabinet to nonhazardous material is obvious.

The Class IIA biosafety cabinet is a laminar containment device that (1) protects the material being manipulated within the cabinet by HEPA-filtered incoming air and (2) protects the operator and room environment from potentially hazardous material in the cabinet with an air curtain at the front of the cabinet (the view screen) and HEPA-filtered cabinet exhaust air. As Class IIA biosafety cabinets are not totally leak-proof, they cannot be used for high-risk biological agents (see current Center for Disease Control and NIH guidelines for the status of any biological material used in the laboratory; Richmond and McKinney, 1993). Because Class IIA cabinets operate with ~70% recirculated air within the cabinet (Fig. 1.3.2), the potential for accumulation of chemicals within the laminar work space limits use to low-level toxic or radioactive material.

Laminar-flow cabinets are not replacements for good microbiological aseptic technique and must be used in conjunction with standard concerns for asepsis if full efficiency of the equipment is expected. Similarly, there is a limit to the protection a laminar cabinet can provide if it is operated in an environment not conducive to clean work conditions. The cabinets should be installed and operated in a relatively clean, quiet laboratory environment. Laboratory doors should be kept closed while the cabinet is in use to minimize strong room air currents that could break the laminar air stream within the cabinet. The units should not be located directly near room air ducts or anywhere a strong environmental air flow exists. Additionally, air flow disturbance by personnel or equipment, particularly within a few feet in front of the cabinets, should be limited when the laminar device is in use.

Because of the critical nature of their function (particularly for the biosafety laminar cabinet), these devices must be certified at installation by professional laminar flow technicians in accordance with National Sanitation Foundation Standard No. 49 for Class II (laminar flow) Biohazard Cabinetry (NSF International, 1992) or other applicable regulatory and safety guidelines. As HEPA filters are brittle and will crack with normal usage of the unit, laminar cabinets must also be recertified annually or after 1000 hr use, and whenever they are moved.

Critical Parameters and Troubleshooting

Human sources of contamination

As noted above, bacterial shedding from human skin is a natural occurrence. However, under times of physiological or psychological stress, a human may shed so excessively that routine gowning procedures are inadequate. A clue to this condition can be the veteran technician who suddenly can't seem to transfer anything without contaminating it, especially when contamination is repeatedly bacterial and

by species of *Staphylococcus, Micrococcus*, or coryneforms.

Alleviation of the problem may be achieved by simply controlling the temperature of the laboratory. Gowned personnel sweat in 27°C (80°F) rooms, and people who sweat shed more than people who don't. Rigorous attention to gowning details as well as liberal washing of hands and arms with an antimicrobial soap just prior to aseptic work may alleviate the situation. If the problem involves psychological stress or physiological stress due to illness or medication, more rigorous gowning procedures may help. Use fresh, clean laboratory coats for each round of aseptic work and make sure laboratory coat sleeves are tucked inside gloves to prevent exposed wrists. Use disinfectants liberally. For worst-case incidences of excessive shedding, the only recourse may be to move the individual to nonaseptic procedures until the condition clears.

Decontamination of a laminar-flow cabinet

Any mechanical failure of a laminar cabinet must be evaluated by qualified, trained personnel. Increased incidences of microbial contamination (particularly by the same organism) could originate from (1) poor cleaning and disinfection of the cabinet work space, (2) a source of contamination lodged in the ducts within the cabinet (e.g., media or culture material spilled into the cabinet ducts), or (3) a crack in the HEPA filter.

Disinfect the catch basin if culture material has spilled through the vents in the work surface into the catch basin below. Use a strong disinfectant (such as 5% to 10% bleach in a sufficient volume to thoroughly contact the spilled material) and allow the disinfectant to stay in contact with the spill for 30 min. Drain the contents of the catch basin into a container suitable for final sterilization by autoclaving.

Visually inspect the working interior of the laminar cabinet for evidence of dried culture material or media, especially in the corners of the cabinet. Clean the interior of the cabinet with a laboratory detergent, rinse with water, dry, and treat the area with an appropriate disinfectant. Be very careful not to wet the exposed HEPA filter located on the back wall of horizontal flow cabinets, as this can compromise the filter integrity. Be careful not to let cleaning solutions enter any vents of the cabinet.

After thorough cleaning of the cabinet work surface, operate the cabinet (as detailed in Basic Protocol 2 or Alternate Protocol) using a control procedure for localizing the source of any remaining contamination. This can be achieved with a series of opened plates of trypticase soy agar and Emmons' modification of Sabouraud's agar systematically coded and placed across the work surface. Leave the media plates open and the cabinet operating for 30 min. Close the lids of the agar plates and incubate them at 26°C for 5 days. If significant microbial contamination appears in the plates, consult with a qualified laminar technician. The resolution to the problem will require either caulking leaks in the HEPA filter or sealing the cabinet for total interior decontamination of filter and ducts with formaldehyde gas.

A final source of frequent contamination in a laminar working condition can be the "sterile" equipment, labware, or solutions used. A poorly filter-sterilized phosphate-buffered saline solution can give rise to significant numbers of pseudomonad bacteria within weeks when stored at room temperature. Insufficiently processed autoclaved or dry heat–sterilized labware frequently results in contamination of cell culture material by spore-forming bacteria.

Anticipated Results

When proper aseptic techniques are used, it should be possible to maintain cell cultures without contamination.

Time Considerations

It takes ~1/2 hr to properly prepare oneself and the cell culture area for culture procedures and a similar amount of time to properly clean up afterward.

Sterilization and Filtration

This unit describes conditions and procedures for the use of the autoclave and the convection or gravity oven for sterilization of heat-stable laboratory materials, for depyrogenation by heat, and for decontamination of biological waste. Sterilization is not an absolute but rather a probability function. Terminal sterilization processes such as autoclaving or dry heat should have a 10^{-6} or less probability that an organism will survive treatment. The proper choice of sterilization method, well-maintained equipment, validated procedures, and adherence to protocol are all necessary to keep the statistics in one's favor.

This unit includes protocols for a variety of sterilization and decontamination methods. Moist-heat or steam sterilization is used for liquids, dry goods, and decontamination of biological wastes. Dry heat or depyrogenation is used to sterilize laboratory glassware and equipment. The efficacy of sterilization using these methods should be monitored using biological indicators. Disinfectants such as ethanol, quaternary ammonium compounds, and sodium hypochlorite are used for decontamination of facilities and equipment, and for clean up of certain spills. Vacuum or positive-pressure filtration is an alternative method for sterilization of liquids that do not withstand steam sterilization.

AUTOCLAVING LIQUIDS

BASIC PROTOCOL 1

The autoclave is used for sterilization by moist heat. The standard conditions for moist-heat sterilization are exposure to saturated steam under pressure at 121°C for 15 min, although other temperature/time specifications can be utilized for specialized needs. In general, materials suitable for autoclaving as a nondestructive sterilization process must meet the following criteria: (1) stable to the temperature and time of the autoclave cycle, (2) unaffected by moisture, (3) packaged to permit exposure to steam, and (4) hydrophilic, if liquid. Materials are sterilized by autoclaving only if they are wetted with the steam; thus, sealing gaskets on certain types of laboratory equipment may not be effectively sterilized if tightened in place during the autoclave cycle. Materials can be decontaminated by autoclaving providing criteria (3) and (4) are met.

The autoclave cycle is based on the time it takes the material being sterilized to be in contact with saturated steam at 121°C for 15 min, and not the time the autoclave itself has been selected to run at that temperature. As autoclave efficiency is machine specific, and steam penetration is container and volume dependent, autoclave cycles and load configurations should ideally be validated to assure that sterilization conditions are achieved. For many small laboratories, the purchase expense of temperature-monitoring thermocouples might be prohibitive. However, frequent use of biological indicators to monitor autoclave conditions (see Support Protocol 1) is strongly recommended for all laboratories, particularly when the machine is used for decontamination of biological waste. Table 1.4.1 lists suggested autoclave times for load configurations in an autoclave with a $20 \times 20 \times 38$–in. ($51 \times 51 \times 97$–cm) chamber.

Materials

Heat-resistant containers and vessels (e.g., borosilicate glass, high-grade stainless steel, noncytotoxic plastic)
Liquid to be autoclaved
Moisture-resistant labels
Paper or aluminum foil
Autoclave indicator tape

Contributed by Rosalie J. Coté
Current Protocols in Cell Biology (1999) 1.4.1-1.4.21

Autoclave
Autoclavable discard pans

1. Use a heat-resistant vessel that can hold twice the volume of the liquid to be autoclaved to assure that boiling encountered during the heating and cooling periods of the autoclave cycle do not result in a boil-over of the vessel contents.

   The most frequent laboratory frustrations with autoclaves and sterilization of liquids are boil-over of material or blow-off of closures. When volume-to-container relationships are acceptable, and when the solution is not overly viscous, the problem most often occurs because the autoclave's slow exhaust or liquid cycle is not properly functioning and the machine is exhausting the chamber pressure too quickly. Adjustments or repairs to the unit should be made by qualified personnel.

2. Fill the vessel to desired volume with liquid to be autoclaved. Indicate the contents of the container with permanent ink and a moisture-resistant label.

3. Loosely cover any opening to the vessel. Do not overtighten screw-cap closures, as this prevents adequate pressure/steam exchange. Overwrap and secure cotton-plugged flasks with paper or aluminum foil to prevent plugs from blowing off if the autoclave is exhausted too rapidly.

4. Affix a piece of autoclave indicator tape to each item or package, as a visual reference (following the autoclave cycle) that the material has been processed.

   The color change of autoclave tape indicates only that the tape has been exposed to a 121°C temperature, and not how long it has been held at that temperature. Thus, it is not an indicator of successful sterilization.

5. Load the autoclave with vessels of similar size, volume, and configuration. Place all liquid-containing vessels inside autoclavable discard pans inside the autoclave. Close and lock autoclave door.

   The discard pans should be large enough to contain all fluid or glass in the event of boiling over or breakage during autoclaving.

6. Set autoclave controls for liquids or slow exhaust.

7. Select and set autoclave controls for appropriate sterilization time (see Table 1.4.1).

Table 1.4.1 Suggested Autoclave Run Times and Configurations for 121°C Sterilization in a 20 × 20 × 38–in. Autoclave[a]

Vessel	Size	Volume (ml)	Minimum time (min)[b]	Maximum time (min)[b]
Test tubes	13 × 100 mm	4-6	18	20
	16 × 125 mm	5-10	18	20
	20 × 150 mm	12-20	18	20
Flasks	100 ml	25-50	20	26
	250 ml	75-100	24	28
	500 ml	250	26	30
	1000 ml	500	28	32
	2000 ml	1000	30	32
Media bottles	125 ml	50	20	22
	500 ml	250-500	30	32
Empty glassware	All	All	35	90

[a]Chamber dimensions (metric equivalent, 51 × 51 × 97 cm).

[b]Sterilization times indicated are actual autoclave timer settings. Material within the vessels will be exposed to 121°C for 15 min using these process times. See text for further explanantion.

8. Start and run autoclave cycle to completion.

   Any interruption in the cycle (e.g., a sudden drop in chamber pressure) invalidates the run, and the sterilization cycle must be rerun to assure efficacy of the process. This is problematical if the liquid has limited stability to prolonged or repeated autoclaving, such as the microbiological media used for quality control in cell culture work. In such cases, it is best to start over with new media.

9. Open the autoclave door only when chamber pressure registers 0 lb/in^2 (100°C or less).

   CAUTION: *Never stand in the path of escaping steam when opening an autoclave.*

10. Remove flasks or containers only when all bubbling has stopped.

    CAUTION: *Superheated liquids can easily boil violently if even slightly jostled. Resulting boil-over can badly scald laboratory personnel.*

11. Cool vessels to ambient or other prescribed temperature in a relatively clean area not subject to excessive air currents.

    This helps avoid suctioning of heavily contaminated environmental air into the container, which can sometimes occur when a vacuum forms within the container as the liquid cools.

AUTOCLAVING DRY GOODS

ALTERNATE PROTOCOL 1

Heat-stable dry materials (including stainless steel instruments, glassware, fabrics, and plasticware) can be effectively sterilized by autoclaving, providing all surfaces of the dry material come in contact with the saturated steam at 121°C. This can become problematical for small items (such as forceps) that must be packaged in an outer container or wrapping that impedes the flow of steam, or for folded fabrics that tend to harbor pockets of cooler air. For this reason, autoclaving times for dry goods sterilization often rely on overkill, as these materials generally have much higher heat resistance. As noted above, validation studies should be done to determine the most effective times and configurations for a given autoclave. For further information on general autoclaving considerations, see Basic Protocol 1 introduction. For default times for an autoclave with a $20 \times 20 \times 38$–in. ($51 \times 51 \times 97$–cm) chamber, see Table 1.4.1.

Additional Materials *(also see Basic Protocol 1)*

Items to be autoclaved
Shallow heat-resistant container

1. Loosely arrange small items in a shallow, heat-resistant outer container. Loosely cover the outer container's opening with paper or aluminum foil. If container has its own lid, apply it loosely so that steam and pressure can penetrate. Cap larger items such as bottles or flasks, making sure that all closures (e.g., screw caps) are loose enough to permit penetration of pressurized steam.

   Small items can also be individually wrapped in paper or foil.

2. Code each item or package with permanent ink and a moisture-resistant label identifying its contents. Affix a piece of autoclave indicator tape to each item or package as a visual reference (following the autoclave cycle) that the material has been processed.

   The color change of autoclave tape indicates only that the tape has been exposed to a 121°C temperature, and not how long it has been held at that temperature. Thus, it is not an indicator of successful sterilization.

3. Where feasible, add a small amount of deionized or distilled water to the outer container or the individual items to assure adequate moisture for effective sterilization.

4. Arrange material in the autoclave to avoid dense overpacking that will impede effective sterilization. Where possible, arrange items to permit downward displacement of cooler, heavier air (e.g., place empty bottles or flasks on their sides rather than upright in the autoclave).

   This prevents pockets of cool air from being trapped in the bottom of the containers as the hot, pressurized steam flows into the vessels.

5. Set autoclave for a fast exhaust cycle.

   If the sterilizer is so equipped, a drying cycle that removes moisture from the dry goods under vacuum at the end of the timed sterilization run can also be used.

6. Select and set autoclave controls for appropriate sterilization time (see Table 1.4.1).

7. Start and run autoclave cycle to completion.

   Note that any interruption in the cycle (e.g., a sudden drop in chamber pressure) invalidates the run, and the sterilization cycle must be rerun to assure efficacy of the process.

8. Open the autoclave door to remove items only when chamber pressure registers 0 lb/in^2 (100°C or less).

   CAUTION: *Never stand in the path of escaping steam when opening an autoclave.*

ALTERNATE PROTOCOL 2

AUTOCLAVING FOR DECONTAMINATION OF BIOLOGICAL WASTE

Biological laboratory waste is most frequently decontaminated by autoclaving unless it contains hazardous chemical materials that can volatilize in the sterilization process. In many mid- to large-sized laboratories, biological waste includes varying combinations of spent media, discarded cultures, and solid material. An autoclave load size or configuration can vary dramatically with each run. For this reason, autoclave cycles for decontamination most often employ the overkill approach. Validation studies prior to actual-use procedures must be performed to assure that selected operation procedures are adequate to achieve the desired conditions for successful decontamination. For further information on general autoclaving considerations, see Basic Protocol 1 introduction.

CAUTION: Do not dispose of biological material containing hazardous chemicals or radioactive isotopes in the waste stream designated for autoclaving.

Additional Materials *(also see Basic Protocol 1)*

Items for decontamination
Plastic (polyethylene or polypropylene) autoclavable bags for biohazardous waste

1. Place items for decontamination into plastic autoclavable bags clearly labeled as containing biohazardous material.

   For greater ease with postautoclaving cleanup procedures, segregate plastic disposable material from reusable labware in separate bags.

   CAUTION: *For the safety of laboratory personnel who sort the autoclaved waste for washing or disposal, do not dispose of sharps or pipets as loose items in the bags. These items must be segregated in their own containers (containing a disinfectant, if appropriate).*

2. Add ~500 ml water to bags containing only dry items (such as empty glassware or contaminated lab coats) to supply sufficient moisture for steam generation.

3. Support bags by placing them in large, shallow, leak-proof, autoclave-resistant discard pans to prevent tearing of the bags and release of contents.

   For the safety of personnel carrying the discard pans, use a maximum weight limit of 25 lb per pan.

4. Securely seal each bag to prevent leakage of material. Transport biological waste only in closed containers.

5. Code each bag with permanent ink and a moisture-resistant label to permit general identification of its contents or source-lab should an accident occur (e.g., mycoplasma testing lab; QC lab).

6. Affix a piece of autoclave indicator tape to each item or package as a visual reference (following the autoclave cycle) that the material has been processed.

   The color change of autoclave tape indicates only that the tape has been exposed to a 121°C temperature, but does not indicate the time held at that temperature. Thus, it is not an indicator of successful sterilization.

7. Transport the waste using a sturdy laboratory cart or autoclave carriage and dolly.

8. Load the discard pans loosely into the autoclave to allow steam to flow over and around the material. While loading, slit each individual bag open in several spots to allow direct exposure of the contents of the bags to the steam from the autoclave.

   Do not stack pans directly on top of each other.

9. Close and lock autoclave door.

10. Run autoclave cycle for 90 min at 121°C on a fast-exhaust, gravity cycle.

    The cycle time listed here is for a large (24 × 36 × 48–in.; 61 × 91 × by 122–cm) autoclave. With small loads and smaller-chamber autoclaves, 45 min may be sufficient. Any interruption in the cycle (e.g., a spurious drop in autoclave steam pressure) invalidates the run.

11. Open the autoclave door to remove items only when chamber pressure registers 0 lb/in^2 (100°C or less).

    CAUTION: *Never stand in the path of escaping steam when opening an autoclave.*

USE OF BIOLOGICAL INDICATORS FOR MONITORING AUTOCLAVE PROCESSES

SUPPORT PROTOCOL 1

Biological indicators are used to effectively monitor the efficacy of moist- or dry-heat sterilization processes. The indicators contain standardized preparations and concentrations of resistant endospores of specific strains of bacteria that will survive suboptimal sterilization conditions, and proliferate when subsequently incubated under normal growth conditions. For greatest control of sterilized material, biological controls should be included with every load. Under general laboratory conditions, biological indicators should be used for validation studies in conjunction with thermocouple temperature-sensing probes, and they should be used for frequently scheduled monitoring of the performance of sterilization equipment and procedures. Bioindicator sources listed in this unit are examples only; other products by other manufacturers can work well. Specific manufacturer instructions for product use supercede general instructions described in this protocol.

This protocol describes the use of biological indicator ampules for monitoring sterilization. For monitoring dry-heat sterilization, see Support Protocol 2.

Additional Materials *(also see Basic Protocol 1; see Alternate Protocols 1 and 2)*

Biological indicator ampules: standardized concentration of *Bacillus stearothermophilus* (ATCC #7953) spores suspended in growth medium containing bromcresol purple as a pH indicator (e.g., Prospore from Raven Biological Laboratories)
55° to 60°C incubator

1. Label the desired number of biological indicator ampules with permanent ink to indicate location and autoclave run number.
2. Place one or more ampules in the most difficult locations to sterilize in the autoclave, including (1) near the front drain of the autoclave, located on the chamber floor at the door of the autoclave, and (2) suspended within the item being sterilized. For liquids, suspend the ampule in the container of liquid by a string tied around the ampule neck and secured around the opening of the container. For dry goods, tuck the ampule within the samples being autoclaved.

   Manipulating test ampules in loads containing biohazardous waste must be performed by personnel trained for dealing with the potential hazards of the material.
3. Run autoclave cycle at prescribed conditions (see Basic Protocol 1; see Alternate Protocols 1 and 2) and retrieve ampules.

   CAUTION: *After sterilization, handle ampules with care if still hot, as they are under pressure and might burst if strongly jostled.*

   Validation studies should never be performed in routine process cycles; unfortunately, they are too often used interchangeably in small laboratories. If validation and processing are used simultaneously, the sterilized material must be quarantined until the results of the sterilization monitoring tests are confirmed.
4. Place autoclaved test ampules and a labeled, unautoclaved positive control ampule in a vertical position in a 55° to 60°C incubator.
5. Incubate 48 hr.
6. Analyze results by noting the color of the test ampules and positive control ampule.

   Growth of the positive control confirms lack of sterilization. The positive-control ampule exhibits a color change from purple (prior to sterilization) to yellow (postincubation), with or without turbidity.

   Growth of the test sample indicates failed sterilization, and is seen as a color change from purple (prior to sterilization) to yellow (postincubation). Positive sterilization is indicated by a purple-colored test ampule (postincubation). An intermediate yellowish color is suspicious and necessitates additional testing of the autoclave parameters. An intermediate grayish color, without turbidity, usually indicates heat destruction of the bromcresol pH indicator, resulting from prolonged autoclaving conditions.

BASIC PROTOCOL 2

DRY-HEAT STERILIZATION AND DEPYROGENATION

Dry heat is used for components and materials that are resistant to the 140° to 180°C temperatures needed for effective dry sterilization; it is most often used for the sterilization of laboratory glassware and stainless steel instruments. It is also used for sterilization of nonaqueous, heat-stable liquids such as mineral oil. Depyrogenation of heat-tolerant materials is done with ovens capable of operating at the required processing temperatures of 220° to 350°C. As with autoclaving, standard dry-heat sterilization and depyrogenation times refer to the time the material is held at the prescribed temperature and not to the time the oven has been set to run. Dry-heat sterilization using gravity ovens generally requires a longer time than does sterilization with convection ovens, which evenly

distribute the heated air throughout the chamber with blowers. In all instances, process validation of any dry-heat sterilization protocol is required. The frequent use of bacterial spore strips (see Support Protocol 2) is advantageous for routine monitoring of the efficacy of an established sterilization process.

Materials

Items to be sterilized
Heat-resistant outer containers (borosilicate glass or stainless steel) for small items
Aluminum foil
Heat-resistant labels or tape
Dry-heat indicator tape
Laboratory oven (operating temperature of 140° to 180°C for sterilization; 220° to 350°C for depyrogenation)

1. Place small items to be sterilized into heat-resistant outer containers. Use aluminum foil to cover any openings to larger, individually sterilized items, or to cover any openings to large items that do not have their own closures.
2. Code each item or package as to its contents with permanent ink and a heat-resistant label.
3. Affix a piece of dry-heat indicator tape to each item or package as a visual reference (following the oven cycle) that the material has been processed.

   The color change of indicator tape shows only that the material has been exposed to a prescribed sterilization temperature, but does not indicate the time held at that temperature. It is not an indicator of successful sterilization.

4. Loosely arrange material in the oven. Do not overpack, as this prevents efficient heat penetration to all items.
5. Close and secure oven door.
6. Select operating temperature and time (see Table 1.4.2 for general guidelines).

   Note that times designated in Table 1.4.2 do not include temperature buildup time, as this is equipment specific. The actual sterilization time begins when the oven chamber reaches the prescribed temperature. Heating times are long for dry-heat sterilization, and can actually be longer than the sterilization time itself. Thus, a load of material might require 2 hr to reach 180°C, while needing only 0.5 hr at that temperature to be effectively sterilized.

7. Run dry-heat sterilization cycle to completion.

   Any interruption in the cycle (e.g., opening the door to add just one more item to the load) invalidates the run.

Table 1.4.2 Time-Temperature Relationships for Dry-Heat Sterilization

Oven temperature (°C)	Sterilization time (hr)[a]
180	0.5
170	1.0
160	2.0
150	2.5
140	3.0

[a]Sterilization time indicated is the amount of time for which material should be raised to a given temperature and does not include heating time.

8. Turn oven heating element off and allow material to cool to room temperature before removing items from the oven.

   This can take several hours for large loads in gravity ovens.

SUPPORT PROTOCOL 2

USE OF BIOLOGICAL INDICATORS FOR MONITORING DRY-HEAT STERILIZATION

Biological indicator strips are used to monitor dry-heat sterilization. For a general discussion of biological indicators, see Support Protocol 1.

Additional Materials *(also see Basic Protocol 2)*

Biological indicator strips containing standardized concentrations of *Bacills subtilis* (ATCC #9372) spores (e.g., Spore-O-Chex; PyMaH, or VWR)
Trypticase soy broth (see recipe)
30°C incubator

1. Label the appropriate number of biological indicator strips with location and cycle number or date.
2. Place one or more strips in the most difficult-to-sterilize areas of the load.
3. Run sterilization cycle at prescribed conditions (see Basic Protocol 2) and retrieve strips when cool.
4. Aseptically open the outer wrapping of the indicator, remove the spore strip, and insert it into an appropriately labeled tube of trypticase soy broth (6 to 10 ml per tube).
5. Prepare a positive control by aseptically inserting an unsterilized spore strip into a separate tube of trypticase soy broth. Prepare an uninoculated tube of trypticase soy broth as a negative control.
6. Incubate tubes at 30°C for 4 days.
7. Analyze results by noting turbidity of the broth. Compare test samples with positive and negative control tubes. Resterilize any material in loads with positive test samples.

   Bacterial growth in the positive control, indicated by cloudy medium, confirms lack of sterilization. Growth should be absent in the negative control; the medium should remain clear, with no precipitate.

BASIC PROTOCOL 3

USE OF DISINFECTANTS: 70% ETHANOL

Ethanol is widely used in many laboratories for benchtop or laminar-space disinfection. The antimicrobial activity of the alcoholic solution is very much dependent upon the working concentration of the solvent, proper preparation, storage, and conditions of its use. Ethanol is an effective disinfectant against vegetative bacterial and fungal cells, but is totally ineffective in germicidal activity against bacterial spores. Ethanol is suitable for spraying or swabbing, but is not recommended for large-volume applications. Ethanol is highly flammable, and spills near the flame of a Bunsen burner are always a possible safety hazard. Similarly, an elevated concentration of vaporized ethanol in a liberally disinfected biosafety cabinet could ignite in the presence of a flame or spark. Furthermore, 70% ethanol is not recommended for use in discard pans or for decontamination of biological spills in the catch basins of biological safety cabinets.

Materials

100% denatured ethanol
Ethanol-resistant spray-type storage container

1. Add 700 ml of 100% denatured ethanol to 300 ml deionized or distilled water. Mix well by stirring.

   Denatured ethanol is absolute ethyl alcohol to which small amounts of chemicals have been added to render it unsuitable for human consumption. This does not interfere with most industrial uses.

2. Store working solution in a tightly closed container to retard evaporation.

   Choose a spray bottle rather than a squirt bottle to retard the evaporation of solvent that occurs with the larger opening of a squirt bottle neck.

3. *For lab benches or laminar-flow cabinets:* Liberally spray the alcoholic solution in a crisscross pattern over the work surface, making certain that the entire area is wetted. Let disinfectant remain in contact with the surface for ≥10 min. Wipe away excess solution with absorbent towels

4. *For objects (e.g., media bottles, culture flasks):* Wet absorbent towels (cheesecloth or paper towels) with the alcoholic solution. Thoroughly swab the object, being careful not to introduce any of the liquid into the threads of screw caps or other container closures. Let disinfectant remain in contact with the object for 3 to 5 min. Wipe away excess solution with absorbent towels

USE OF DISINFECTANTS: QUATERNARY AMMONIUM COMPOUNDS

ALTERNATE PROTOCOL 3

The discovery of the antimicrobial activity of quaternary ammonium compounds during the early 20th century was a major advancement in the development of effective germicides. The inherent antimicrobial activity of these compounds was soon shown to be significantly improved by the addition of long-chain alkyl groups to the nitrogen moiety of the quaternary compound. The various quaternary ammonium compounds commercially used as disinfectants today are chemical modifications of this original concept. The mode of action of quaternary ammonium compounds is as cationic surface-active agents, although this chemical property does not fully explain the germicidal activity of the compounds. All have broad-based antimicrobial activity and have proven effectiveness against algae, gram-positive bacteria, some gram-negative bacteria, fungi, and certain viruses, when used at the manufacturer's recommended concentrations (0.1% to 2.0% active ingredient, or 200 to 700 ppm). They are relatively nontoxic to humans when used according to manufacturer's instructions and are not chemically destructive to equipment under normal use. They can be autoclaved without formation of toxic vapors and thus are frequently used as disinfectants in discard pans.

The limitations of quaternary ammonium compounds include lack of effectiveness at low concentrations against some commonly encountered gram-negative bacteria (e.g., *Pseudomonas* sp.). Like many other disinfectants, they are quickly inactivated by the presence of heavy organic burden.

Materials

Quaternary ammonium compound disinfectant of choice: e.g., Roccal (Sterling Winthrop), Micro-Quat (Ecolab), Zephirol (Bayer)
Tightly closed containers
Spray bottles
1-gallon jugs

1. Dilute concentrated quaternary ammonium compound according to manufacturer's instructions in deionized or distilled water and stir well to mix.

   Depending upon use, normal working concentrations of 235 ppm active ingredient are used for sanitization purposes such as floor mopping, whereas concentrations of 470 to 700 ppm active ingredient are used for disinfection of laminar-flow cabinet work surfaces or for use in discard pans.

2. Store working solution in tightly closed containers to retard evaporation.

   Prepare fresh working solutions frequently (e.g., once a month; follow manufacturer's instructions).

3. *For work surfaces:* Liberally spray the working solution in a crisscross pattern over the work surface, making certain that the entire area is wetted. Let disinfectant remain in contact with the surface for >10 min. Wipe away excess solution with absorbent towels.

4. *For use in discard pans:* Prepare a solution containing 700 ppm quaternary ammonium compound. Fill discard pan about half full with disinfectant solution. Carefully place used pipets into the pans to avoid splashing. Securely cover pan when moving it.

   Volume of disinfectant must be enough to fully cover the pipets placed into the pan, but not so full that spilling could occur when the pan is filled with pipets or when it is moved.

ALTERNATE PROTOCOL 4

USE OF DISINFECTANTS: SODIUM HYPOCHLORITE

Chlorine, in various forms, has a long history of use as a powerful disinfectant, yet the exact mode of germicidal action is unclear. Hypochlorites are the most widely used chlorine compounds for disinfection. Commercial liquid bleach products (e.g., Clorox) are solutions containing 5.25% (w/v) sodium hypochlorite. Sodium hypochlorite is effective against vegetative microbial cells, most spores, and many viruses. It has some residual effect after the treated surface dries. It can be used in sanitization procedures for laboratory floors and in laboratory coat washing. It is strongly germicidal and can be used to decontaminate small- to mid-volume spills of biological material.

Despite their germicidal effectiveness, chlorine solutions are limited in their use as laboratory disinfectants because of their corrosiveness to metals and their human toxicity. They should not be routinely used in discard pans or in any solutions that are autoclaved, as the chlorine fumes liberated are significant skin and respiratory irritants. Frequent autoclaving of chlorine solutions will corrode the chamber interior of the sterilizer. One exception to this autoclave ban is the need to sterilize any biological spill material in which bleach was used as a disinfectant during the cleanup process. A solution of 10% (v/v) household bleach is a strongly germicidal, containing ~0.52% (w/v) sodium hypochlorite. Excess hypochlorite is needed in mopping up spills of biological agents, to supply additional chlorine to replace that consumed by the large amount of organic matter associated with the spill.

Sodium hypochlorite solutions can be inactivated by organic matter (which consumes the available free chlorine that constitutes microbiocidal activity), by exposure to UV light, and by inorganic chemical reducing agents (such as ferrous or manganese cations and hydrogen sulfide). Hypochlorite solutions should be stored away from heat to avoid deterioration.

Materials

Household liquid bleach (e.g., Clorox, Dazzle)
5% (w/v) sodium thiosulfate solution

1. Add 100 ml household bleach to 900 ml water to give a 10% (v/v) solution. Mix well. Store in the dark away from heat.
2. *For cleanup of open spills:* Soak paper towels with bleach and gently cover the spill, being careful not to enlarge the area of the spill. Let bleach stay in contact with the spill for ≥20 min. During this time, decontaminate any nearby areas that may have been subject to spatters from the original spill by swabbing with additional 10% bleach. Collect used paper towels in a suitable container and place in an autoclave bag.
3. *For autoclaving bleach-containing waste:* Add ~1 vol of 5% sodium thiosulfate solution to the bleach solution to help neutralize the chlorine. Seal the bag and autoclave. Prominently label the autoclave room door to warn laboratory personnel of the potential for irritating vapors. When the autoclave cycle is finished, crack the autoclave door slightly to allow remaining chlorine fumes to dissipate before removing the bags.
4. *For sanitizing solution:* Add 14.8 ml household bleach to 3.78 liter water (0.4%). Mix well.

   Solutions containing 0.4% (v/v) household bleach (200 ppm available chlorine) are suitable for soaking lab coats without being so strong as to harm the fabric. The solution is acceptable for routine floor maintenance.
5. *For disinfection solution:* Add 44.4 ml household bleach to 3.78 liter water (1.2%). Mix well. Liberally apply to surface with clean absorbent towels and let stand for >10 min. Dry surface with a separate clean towel.

   This concentration of bleach (600 ppm available chlorine) is suitable for disinfecting biosafety cabinets during scheduled weekly maintenance. More frequent use on stainless steel may not be recommended because of the corrosiveness of the bleach.

FILTER STERILIZATION OF SOLUTIONS

All solutions that come in contact with cell cultures must be sterile in order to prevent microbial contamination. This includes non-nutritive preparations such as distilled/deionized water and reagents (e.g., dimethyl sulfoxide used as a cryoprotectant). Although heat-stable solutions can be sterilized by autoclaving, many solutions used in cell culture contain one or more heat-labile components (e.g., antibiotics), or are chemically formulated with ingredients that will form deleterious precipitates if subjected to steam sterilization temperatures (e.g., phosphate-buffered salines). Membrane filtration is the most common cold sterilization method for these types of solutions.

Filter membranes with 0.2-µm pore size are used for general sterilization purposes; however, some environmentally stressed bacteria (e.g., *Pseudomonas* sp.) as well as mycoplasma can pass through filters of this porosity. To provide a greater degree of assurance for complete removal of these common tissue culture contaminants, cell culture media and sera should be sterilized using 0.1-µm filter membranes. Filter manufacturers offer many different types of membranes. With respect to cell culture applications, membranes fabricated from cellulose acetate or cellulose nitrate are used for general purpose filtration of aqueous solutions such as media and buffers, but may need prewashing with hot distilled water to remove extractable substances that may be cytotoxic. Nylon membranes are very low in extractable substances such as surfactants or wetting agents; polyethersulfone membranes are low in extractables and have very low protein binding.

The availability of presterilized, ready-to-use, disposable filter systems has eliminated much of the labor and risk of failure inherent with earlier filtration methods. Filter units come in a wide variety of sizes to handle small (≤10-ml) to large (≥20-liter) volumes. Disposable systems are available for either vacuum or positive-pressure filtration. Many manufacturers have filter systems designed specifically for cell culture applications: the sterilization membranes, housings, and receiving vessels are certified noncytotoxic and nonpyrogenic.

This section outlines selection of filters and filter-sterilization procedures for various types of liquids encountered in cell culture laboratories. The most common small-volume filtration technique is positive pressure using a syringe to force the liquid through the filter membrane (see Basic Protocol 5). Volumes ranging from 50 ml to 1 liter are most efficiently processed with a vacuum (see Basic Protocol 4). Larger volumes should be filter sterilized with positive pressure (see Alternate Protocols 5 and 6). The primary use of membrane filtration is in the preparation of tissue culture media; this topic is treated in depth in *UNIT 1.2*. This unit focuses on problematic filtration needs that often appear in cell culture applications, such as the need to filter sterilize a hazy solution like the serum/yeast extract additives used in mycoplasma media, or the chemically aggressive reagent dimethyl sulfoxide (DMSO). The methods outlined in this section are equally adaptable for the preparation of tissue culture media or stock solutions of additives such as glutamine or puruvate. For media preparation, use noncytotoxic cellulose acetate/nitrate membranes, or similar membranes specific to the application, and food-grade silicon tubing. For further details on the use of vacuum versus positive-pressure filtration, see Background Information.

BASIC PROTOCOL 4

Vacuum Filtration

Solutions that are initially clean preparations, in that they are free of particulate debris and are not proteinaceous, can be directly filter sterilized with no difficulty. Solutions with high particle load require centrifugation and/or nonsterile prefiltration through depth filters (see Background Information) and larger-porosity membranes prior to sterile 0.2-µm filtration. This protocol uses 200-ml to 1-liter disposable systems designed for the final vacuum filtration of media, sera, and other aqueous solutions. The protocol also describes nonsterile prefiltration for particulate removal from 200-ml to 2-liter volumes of filtrate.

Materials

Solution to be filtered
47-mm funnel/support assembly (optional; e.g., Kontes, Millipore) attached to a 1- to 2-liter vacuum filtration flask (Fig. 1.4.1)
47-mm glass fiber depth filters (optional; Gelman, Millipore)
47-mm membrane filters (optional; 0.45-µm and 0.2-µm pore sizes)
Disposable, sterile filter unit (e.g., Corning, Nalgene) including:
  Filter funnel, housing an integrally sealed 0.2-µm filter membrane
  Funnel dust cover
  Removable receiver bottle and cap
  Barbed tubing adapter
  Nonsterile depth prefilters (included by most manufacturers)
Vacuum source

NOTE: Perform all procedures using aseptic technique (*UNIT 1.3*).

1. If the solution to be sterilized is a hazy suspension or has a noticeable precipitate, centrifuge 30 min at 10,000 × g to clarify. Alternatively, use a funnel/filter assembly

to process the solution through a series of nonsterile prefilters: depth filter, followed by 0.45-µm membrane, followed by 0.2-µm membrane.

Depending upon the particulate load, the filter membranes may have to be replaced if they clog before all the solution is processed.

If a water aspirator is used as the vacuum source, include an in-line catch flask or hydrophobic filter to prevent any water from accidentally being drawn into the vacuum port and into the filtration flask.

2. Remove a disposable, sterile filter unit, barbed tubing adapter, and individual wrapped sterile receiver cap from the plastic bag.
3. Check to make certain that the filter funnel is firmly attached to the receiver. Hand tighten if necessary.
4. Attach barbed tubing adapter to the side vacuum port on the neck of the filter funnel. Attach the vacuum tubing to the adapter.

   If a water aspirator is used, include an in-line catch flask (see step 1).

5. Set the filter upright and provide support to avoid tipping the unit when it is top-heavy with liquid in the funnel.
6. Remove the funnel dust cover and slowly add solution (centrifuged or prefiltered if necessary) to the funnel. Slowly apply a slight vacuum—5 pounds per square inch gravity (psig)—to prevent excessive foaming of proteinaceous solutions.
7. When filtration is complete, turn the vacuum source off. Carefully disconnect the filter unit from the vacuum tubing.

   If the tubing is pulled off while the vessel is still under full vacuum, the room air rushes into the receiving vessel at a much higher velocity.

8. Using aseptic technique, carefully remove the filter funnel from the receiver bottle and seal the bottle with the sterile screw-cap closure provided with the filter unit.

   If the total volume of solution to be filtered exceeds the capacity of the receiver bottle supplied with the filter unit, the initial volume of sterile filtrate can be aseptically transferred to a secondary sterile storage vessel, and the filter funnel can be reattached to the original receiver to process a second volume of solution.

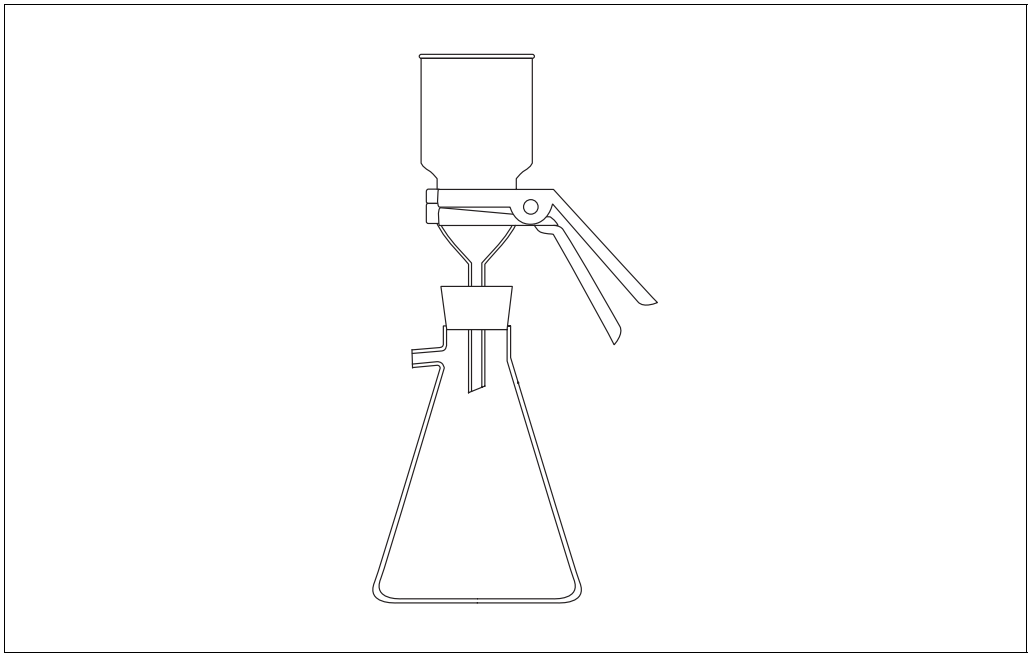

Figure 1.4.1 Funnel/support assembly for vacuum prefiltration.

BASIC PROTOCOL 5

Small-Volume Positive-Pressure Filtration of Nonaqueous Solutions

Dimethyl sulfoxide (DMSO) is used as the cryoprotectant for liquid-nitrogen preservation of cell cultures. The reagent is not stable to autoclaving conditions and must be filter sterilized. DMSO is an aggressive solvent that dissolves general-use filter membranes (such as cellulose acetate or cellulose nitrate) as well as the polystyrene filter units themselves. This protocol describes small-volume positive-pressure filtration using DMSO-resistant syringe-type filter units. For large volumes, see Alternate Protocols 5 and 6.

Materials

Dimethyl sulfoxide (DMSO)
Glass 25-ml syringe with Luer-lok tip
Sterile syringe filter: 25-mm-diameter nylon membrane, 0.2-µm pore size, polypropylene housing (Nalgene or equivalent)
Laminar-flow cabinet
Sterile amber glass storage vessels with polytetrafluoroethylene (Teflon, PTFE)–lined screw-cap closure

NOTE: Perform all procedures using aseptic technique (*UNIT 1.3*).

1. Load a glass 25-ml syringe with deionized or distilled water.
2. Aseptically remove a sterile syringe filter from its blister-package wrapper, being careful not to touch the outlet nipple.
3. Attach the inlet end of the filter to the syringe and finger tighten the Luer-lok connection.
4. Apply a firm, but not forceful, pressure to slowly discharge the water through the filter into a waste container.

   This initial step is necessary to wet the filter to permit flow of the DMSO through the nylon membrane.
5. Carefully remove the filter from the syringe, and rest the filter on the laminar-flow cabinet work surface, being careful to keep the outlet nipple facing up (i.e., not touching any surface).
6. Load the syringe with ~25 ml DMSO and replace the filter as in step 3.
7. Apply a firm, but not forceful, pressure to slowly discharge this first volume of DMSO into a waste container.

   This step clears any water remaining in the syringe and filter.
8. Reload the syringe with ~25 ml DMSO and discharge the filtrate into a suitable sterile amber glass storage vessel. Cap immediately with a PTFE-lined screw-cap closures. Store up to 6 to 9 months at room temperature.

ALTERNATE PROTOCOL 5

Large-Volume Positive-Pressure Filtration of Nonaqueous Solutions

This protocol uses a peristaltic pump to provide positive pressure for large-volume filtration. The setup is shown in Figure 1.4.2.

Materials

Dimethyl sulfoxide (DMSO)
Sterile filter capsule: 400-cm^2-surface-area nylon membrane, 0.2-µm pore size, polypropylene housing (Whatman Polycap 36AS or equivalent)
Glass 25-ml syringe with Luer-lok tip

Worm drive clamps
PTFE tubing: polytetrafluoroethylene (PTFE or Teflon) with 0.25-in. (6.4-mm) i.d., 0.06-in. (1.6-mm) wall thickness, 0.38-in. (9.5-mm) o.d. (Norton or equivalent)
Peristaltic pump assembly capable of providing an operating pressure of 15 to 20 lb/in.^{2}
Sterile amber glass storage vessels with PTFE-lined screw caps

NOTE: Perform all procedures using aseptic technique (*UNIT 1.3*).

1. Carefully remove a sterile capsule filter from its plastic bag.
2. Remove the nipple cover from the inlet barb.
3. Hold the filter over a waste container, and use a glass 25-ml syringe to carefully add water to the filter housing through the inlet barb. Fill the syringe as necessary and continue to flush the housing until water begins to drip from the sterile outlet side.

   This step wets the nylon membrane to allow the DMSO to pass through the filter.
4. Attach a piece of PTFE tubing to the inlet barb from the nonsterile DMSO reservoir. Using worm drive clamps, secure the tubing at all connections when working with positive pressure to prevent sudden blowing off of tubing in case of accidental overpressurization.
5. Secure the capsule filter to an upright support at a height with sufficient clearance to accept any receiving vessels.
6. Connect the tubing as shown in Figure 1.4.2, to the peristaltic pump head according to the pump manufacturer's instructions. Apply power to the pump and begin pumping.
7. Discharge the first 200 ml of DMSO filtrate to a waste container.

   This step clears any water remaining in the filter and tubing.
8. Collect sterile DMSO in suitable sterile amber glass storage vessels and cap immediately with PTFE-lined screw-cap closures. Store up to 6 to 9 months at room temperature.

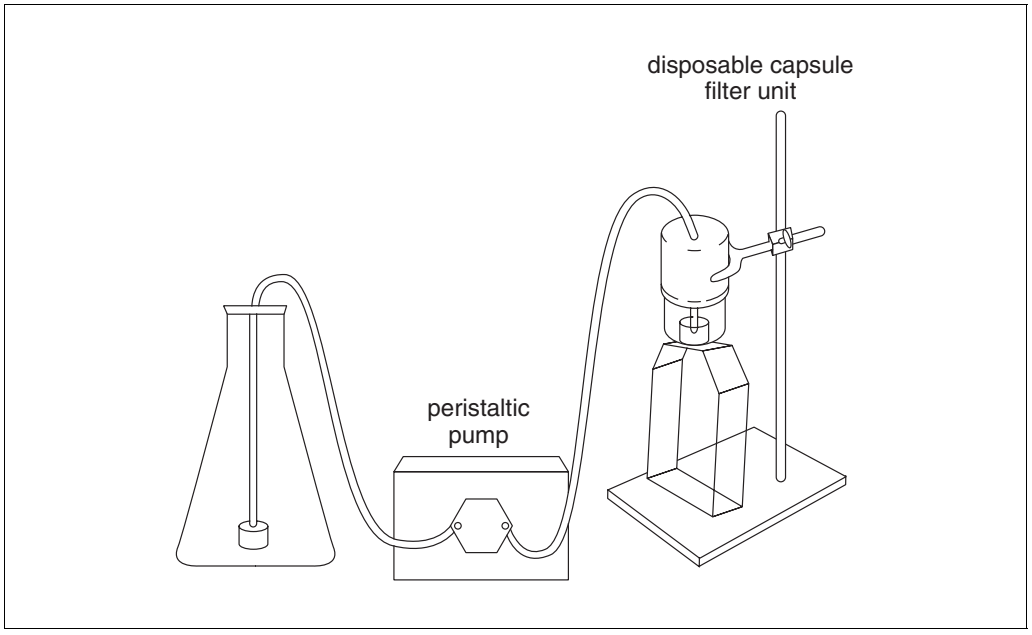

Figure 1.4.2 Positive-pressure filtration assembly for use with a peristaltic pump.

ALTERNATE PROTOCOL 6

Large-Volume Positive-Pressure Filtration Using Pressurized Nitrogen

This alternative method for large-volume filtration uses pressurized nitrogen to force the solvent through the filter membrane. It offers an advantage for filtration of DMSO in that it saturates the solvent with an oxygen-free gas phase that helps retard oxidation of the material during storage. The setup is shown in Figure 1.4.3.

Additional Materials *(also see Alternate Protocol 5)*

5-liter pressure vessel (or size to fit application; Gelman or Millipore)
Pressurized nitrogen tank
Additional tubing to fit pressure vessel and nitrogen tank

1. Prepare a capsule filter (see Alternate Protocol 5, steps 1 to 3).
2. Attach a piece of tubing to the filter inlet barb from the outlet barb of a 5-liter pressure vessel. Using worm drive clamps, secure the tubing at all connections when working with positive pressure to prevent sudden blowing off of tubing in case of accidental overpressurization.
3. Fill pressure vessel with DMSO. Close and secure pressure vessel lid. Open pressure relief valve on vessel.
4. Attach another piece of tubing from a pressurized nitrogen tank to the inlet barb on the pressure vessel and secure with a worm drive clamp.
5. Slowly open nitrogen feed valve and wait until gas can be heard escaping from the pressure relief valve.
6. Close pressure relief valve.

   Pressure will begin to rise in the vessel as indicated either on the pressure gauge included with the vessel, or by the gauges on the nitrogen tank regulator.

   To prevent bursting of the filter membrane, keep the operating pressure below the maximum rated pressure specified by the filter's manufacturer.
7. Collect sterile DMSO filtrate (see Alternate Protocol 5, steps 7 and 8).

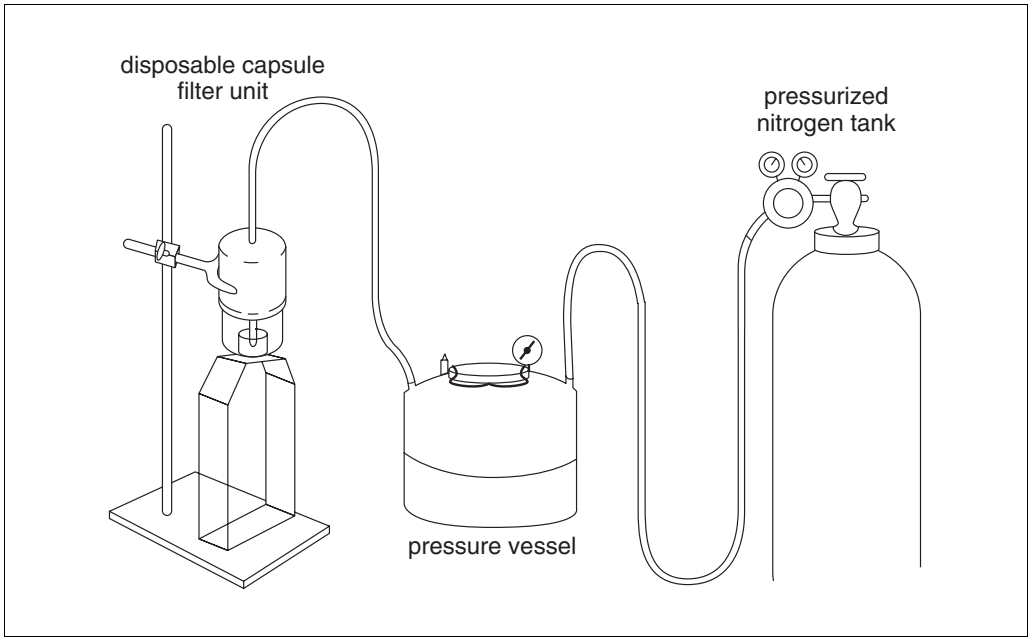

Figure 1.4.3 Positive-pressure filtration assembly for use with pressurized nitrogen.

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Trypticase soy broth

Suspend 30.0 g trypticase soy broth powder (BBL) in 1.0 liter water and stir to dissolve. Dispense 6 to 10 ml per 16 × 125–mm tube and cap loosely. Sterilize by autoclaving at 121°C for 15 min. Store prepared tubes at 4° to 8°C for up to 6 to 9 months.

COMMENTARY

Background Information

Autoclaving

Steam (autoclave) and dry heat are destructive terminal sterilization processes in which the effectiveness of the method is characterized by the rate of the microbial killing. As the order of death in a terminal sterilization process is a logarithmic function, mathematical calculations will never result in a zero survival rate. Thus, theoretically, complete sterilization is impossible. Therefore, rather than expecting an absolute, the effectiveness of terminal sterilization processes is mathematically expressed in terms of the decimal reduction time (*D* value), which is the time required at a given temperature to destroy 90% of survivors. A corollary term used in discussions of terminal sterilization is the *Z* value, which is the temperature at which a survival curve decreases by one log. Factors influencing these values include the concentration and type of microbial contaminants initially in the material to be sterilized, the physical nature of the material undergoing sterilization, and the performance characteristics of the sterilization equipment.

Disinfectants

The use of disinfectants in the cell culture laboratory is directed both to issues of personal safety as well as quality control. In most instances the distinction between the two considerations blurs; however, this unit discusses the use of disinfectants primarily as a means for prevention of microbial contamination from the standpoint of quality control (i.e., maintenance of noncontaminating conditions for cell culture manipulations). Human safety considerations are limited to brief notations regarding potential effects of misuse of specific disinfectants (e.g., chemical incompatibilities, lack of effectiveness against certain biological agents) rather than a reiteration of the need for disinfectants as a means of personal defense against etiologic agents.

The list of common disinfectants is lengthy: alcohols (ethanol or isopropanol), chlorine compounds (bleach), hydrogen peroxide, phenolics, and iodophores (povidone-iodine), to name a few. Yet from this broad list, there is no universal disinfectant solution that can work effectively for all laboratory situations. Thus, the concern for any laboratory is deciding upon its different needs for disinfection (e.g., spill cleanup, work surface disinfection, discard pan disinfection, routine floor cleaning, lab coat laundering), and then selecting the appropriate disinfectant and concentration for each purpose. It is beyond the scope of this unit to provide a lengthy treatise on all the commercially available liquid germicides. Focus is directed, instead, to the three most commonly encountered disinfectants utilized in tissue culture: 70% ethanol, quaternary ammonium compounds, and sodium hypochlorite (bleach).

Filtration

Filtration as a method of sterilization has been in use for over one hundred years. Early filters were designed to trap contaminants within the depths of a thick, tortuous maze of filter material. Scintered glass filters and the asbestos (later cellulose) Seitz filters commonly used in the 1950s and 1960s worked on the entrapment principle. These depth filters have significant loading capacity and can retain much particulate matter before clogging. The limitation of depth filters is the structural nature of the filter matrix. At best, the loose matrix of a depth filter permits only a nominal designation of particle size retention. Because the pores of a depth filter are of random size and shape, there is a real probability that small-sized contaminants will successfully channel through the filter through interconnecting pores. In addition, the effects of moisture and pressure associated with autoclave sterilization and/or use of

depth filters tends to result in a shifting of the filter material (media migration) that compromises the integrity of the fibrous filter matrix.

By the mid 1970s membrane filters had essentially replaced depth filters for sterile applications. Membranes are classified as screen filters: they are thin and the pores are uniformly sized and spaced across the sheet. This structural consistency allows predictable retention characteristics. Thus, membrane filters can be rated according to the minimal diameter of the smallest particle they will retain (e.g., 1.2-µm, 0.45-µm, 0.2-µm). Membrane filters have limited loading capacity (i.e., they quickly clog). For this reason, they are most effectively used in tandem with depth filters and membrane filters of larger porosity to conserve the filter surface area on the final sterilization membrane.

The type of filtration system, as well as the type of membrane used in the system, depends upon the nature of the filterable material and the volume of material being filtered. A wide variety of configurations is available in both presterilized disposable units containing integrated filter membranes, as well as membrane discs that can be used in conjunction with reusable glass or stainless steel filter housings. In the past, positive pressure was the preferred filtration method for cell culture media because it reduced the foaming and concomitant protein denaturation associated with vacuum filtration systems. Unfortunately, positive-pressure filtration systems are efficient only for small (syringe filtration) or large (pressure vessel) volumes. With recent technological advances in new membrane matrices and improved membrane supports for filter housings that eliminate excessive foaming, vacuum filtration with presterilized disposable units is now the easiest and most effective sterilization method for intermediate volumes (0.1 to 2 liters) of tissue culture media.

Filter membranes are made from a number of different materials. The most common filters featured in presterilized, disposable filtration units are those fabricated from esters of cellulose acetate or cellulose nitrate. These general-purpose hydrophilic membranes are suitable for aqueous solutions such as tissue culture basal media and supplements. These membranes can, however, bind proteins and may be of concern for certain critical applications. With the huge cell culture market as a direct target, filter manufacturers have, in recent years, begun to offer presterilized filtration units customized for cell culture, featuring noncytotoxic, low-protein-binding membranes (nylon or polyethersulfone).

Not every solution utilized in cell culture applications is truly aqueous or hydrophilic. Nonpolar liquids, such as DMSO, or chemically aggressive solutions, such as concentrated acids or bases, demand special chemically resistant membrane filters. Quite often, filters resistant to nonpolar solvents will need pretreatment with an appropriate wetting agent to quickly render the membrane filterable to a particular nonpolar liquid. For example, PTFE (Teflon) membrane filters require prewashing with methanol prior to use with DMSO. This poses no problem providing all traces of the cytotoxic alcohol are removed by washing prior to collection of any sterile, unadulterated DMSO filtrate. Where residual toxic wetting agents are a concern, nylon filters may be a more appropriate consideration. Nylon membranes, when wetted with water, readily accept DMSO.

With wide recognition of the detrimental effects of insidious mycoplasma contamination and the concern about absolute removal of these contaminants from a major point of entry (i.e., serum) into a cell culture system, much emphasis is now placed on 0.1-µm filtration of cell culture media and sera. Unfortunately, this pore size is not widely available in disposable filtration units. Gelman Sciences does, however, offer presterilized filter units with 0.1-µm polyethersulfone (Supor) membranes for small- to large-volume cell culture media sterilization. Expect slower flow rates with 0.1-µm filtration.

When lacking presterilized filtration units, a laboratory can turn to individual membrane discs of specified porosity and membrane type, available from major filter manufacturers. These can be sterilized by autoclaving as part of an integrated unit in a small-volume filter assembly (e.g., Fig. 1.4.1), or for large-volume needs in a 142- or 293-mm filter holder (Gelman or Millipore). If this route for sterile filtration is chosen, follow the manufacturer's instructions precisely with respect to membrane sterilization times, and use a slow exhaust cycle to avoid the membrane cracking that can occur with rapid pressure changes.

This unit outlines procedures that are suitable for any number of variations. Large volumes of tissue culture media can be processed with the peristaltic pump or pressurized nitrogen procedures providing a hydrophilic filter is used. Similarly, a hydrophilic syringe filter can be used to sterilize small volumes of media. Sterilization of DMSO is, however, limited to

those filter membranes and filter unit housings fabricated of materials resistant to the reagent.

Critical Parameters

Autoclaving

Successful autoclave sterilization is dependent upon the contents of a load coming into full contact with saturated steam at 121°C for 15 min. Many operational factors tend to work against these criteria. With respect to the sterilizer itself, if an autoclave is improperly maintained, problems can occur with inadequate removal of air from the chamber or with excessive moisture buildup. Either condition compromises sterilization parameters. Most autoclaves have cool spots that can move about in the chamber like a current depending upon load pattern and configuration. The nature of the load content also influences the time necessary to reach the time-temperature relationship. Small volumes will heat to sterilization temperatures faster than large volumes. Agar solutions that have solidified prior to sterilization will take longer than those that are loaded into the autoclave while still molten. Dry materials take longer to sterilize than those that are moist.

For any laboratory investing in as expensive a pursuit as tissue culture, sterilization equipment and procedures should be validated to assure that conditions for sterilization are met. Ideally a laboratory should invest in a thermocouple to monitor temperatures within areas of autoclave loads, in order to determine exactly how long it takes the material of concern to reach sterilization temperature. In many cases, the lag between the time an autoclave temperature gauge indicates 121°C in the autoclave chamber and the time the contents of a large flask or discard pan within the chamber reaches the same temperature is sobering. Where thermocouples are not available, the use of biological indicators can yield useful information about autoclave procedures and machine performance, although the time needed for incubation and interpretation of results is a drawback.

A final, but most important, consideration for autoclaving is the source of steam generation. Autoclaves used in the preparation of media or for sterilization of materials that come into contact with cell cultures must be supplied with clean steam (i.e., steam generated from purified water). Steam generated directly from general building physical plant sources (e.g., the building heating system) is frequently produced from water treated with potentially cytotoxic boiler amines and/or chemical softening agents.

Dry-heat sterilization

Hot dry air is an inefficient means of sterilization and should be reserved for those materials that cannot effectively be exposed to saturated steam in an autoclaving process. Sterilization by dry heat can be accomplished with temperatures as low as 140°C, but 170° to 180°C are more routine operating temperatures because of the difficulty in controlling the rate of heat penetration into the load. The time-temperature relationships for dry-heat sterilization noted in Table 1.4.2 indicate a requirement for longer times and higher temperatures than for autoclaving, because dry heat is less efficient than moist heat. Lag time for conduction of heat into the materials to be sterilized can be significant, as can cool-down periods for large, dense objects. Dry-heat sterilization is applicable only for materials resistant to 140° to 180°C, and thus is unsuitable for paper, many plastics, or rubber. As noted for autoclaving, a dry-heat sterilization procedure should be validated with thermocouples and biological indicators.

Disinfectants

The term disinfection refers to the treatment of surfaces with chemical solutions to reduce microbial presence. Exposure to a disinfectant may result only in bacteriostatic or fungistatic rather than microbiocidal conditions. Disinfection does not imply sterilization, and it should never be used as an alternative to appropriate sterilization methods (e.g., autoclaving, dry heat, ethylene oxide, incineration). Similarly, disinfectants are not detergents and they should not be used as the sole method for cleaning solid surfaces. Indeed, many disinfectants are quickly inactivated when burdened with organic matter. Thus, routine disinfection of work surfaces in laminar-flow cabinets first requires that the surface be washed with a good detergent to remove dried media or other dirt before application of the germicide.

Ethanol. A solution of 70% ethanol is not germicidal against bacterial spores. While freshly prepared solutions are normally free of spores, the working solutions can contain bacterial spores from cross-contamination and poor aseptic technique. Once the spores are separated from the physical presence of the disinfectant (i.e., when the ethanol volatilizes from a surface, leaving the dried spores behind), they can germinate in suitable growth conditions. Thus, fresh working solutions of

70% ethanol should be prepared frequently (e.g., weekly).

The efficacy of ethanol as a disinfectant is highly concentration dependent. The mode of action of alcohol as a disinfectant is protein denaturation. Thus, 95% ethanol is a poor disinfectant because there is not enough water in the preparation to permit effective denaturation of contaminant proteins. As ethanolic concentration drops below 70%, there simply isn't enough of the solvent present to adequately react with large concentrations of proteinaceous matter. Because of the dilution effect, 70% ethanol is not effective in disinfecting large spills of culture material.

Quaternary ammonium compounds. Quaternary ammonium compounds are not effective against spores and, in this aspect, should be used with the same cautions noted for ethanol. Quaternary ammonium compounds are quickly inactivated by organic matter. They must not be used for disinfection of large spills of culture material, nor should they be used for kill pans (see below).

Bleach. Chlorine compounds, most frequently sodium hypochlorite, are strongly germicidal. Yet their potential for human toxicity and strong corrosiveness limits their use.

Biological spills. Strong disinfectant solutions are the first line of defense in decontaminating small to moderate spills of biological agents in both open areas and biosafety cabinets. The choice and concentration of disinfectant is particularly critical in this application. Use of 70% ethanol would be a poor choice as its germicidal activity is highly concentration dependent and dilution effects associated with spill cleanup would diminish its effectiveness (see above). Quaternary ammonium compounds are germicidal against a broad range of microbes, but they are quickly chemically overwhelmed and inactivated by organic matter (e.g., the culture material or medium in a spill). Chlorine compounds are strongly germicidal.

Kill pans. A final note of caution regarding disinfectants is their use in discard pans or pipet pans. Too many laboratories consider these containers kill pans and use them as a convenient way to dispose of excess liquid cultures or other contaminated solutions. Discard pans should never be used in such a manner. Most general disinfectants are inactivated by excess organic matter and/or exhibit diminished germicidal effects with dilution. Kill pans should contain 10% (v/v) household bleach (0.525% sodium hypochlorite).

Filtration

When using disposable filtration units, replace the filter funnel immediately with a permanent receiving vessel closure once filtration is complete. If the funnel is left on the receiver, the filter membrane will crack as soon as it dries, thereby compromising the sterility of the filtrate.

Be prepared and willing to prefilter any hazy or precipitated suspension. The additional steps will much repay the effort when balanced against the significant monetary expense, time, and frustration spent dealing with prematurely clogged sterilization filters. If one repeatedly filter sterilizes the same type of suspension, a prefiltration scheme can be tailored according to the nature of the particulates. For example, if particulates are retained only by 0.2-µm porosity filters, then omit prefiltration with depth filters and 0.45-µm filters.

Process large volumes of slow-filtering liquids (such as serum or other proteinaceous substances) in a cold room, if possible, to retard proliferation of microbial growth during the sometimes time-consuming, nonsterile prefiltration steps.

Anticipated Results

If sterilization and disinfection procedures are effective and proper aseptic technique is used, it should be possible to initiate and maintain cell cultures without any incidence of contamination.

Time Considerations

Preparation of materials for autoclaving and the autoclaving itself should take 1 to 2 hr; cooling solutions and equipment may require several hours. Dry-heat sterilization should take less than half a day plus cooling time. Monitoring the efficacy of sterilization requires several days to allow time for contaminants to grow. Disinfection of space and equipment requires a variable amount of time. The time required for filter sterilization can be a few minutes to hours depending on the solution.

Assessing and Controlling Microbial Contamination in Cell Cultures

This unit describes procedures for the detection of bacterial, fungal, and mycoplasmal contaminants in cell cultures. Bacterial and fungal contaminants are detected by direct culture under conditions that specifically favor bacteria, mycelia, and yeast (see Basic Protocol 1). The direct method for detecting mycoplasma contamination similarly involves screening with microbiological media designed to encourage proliferation of mycoplasma (see Basic Protocol 2). The two indirect methods presented are (1) a slight modification of Barile's adaptation on the use of the Hoechst stain to detect mycoplasma by DNA fluorescence (see Alternate Protocol 1), and (2) the use of polymerase chain reaction in conjunction with a commercially available mycoplasma detection kit (see Alternate Protocol 2 and Support Protocol 1). In addition, a procedure is described for controlling microbial contamination through the use of antibiotics (see Basic Protocol 3).

Testing for microbial contamination should be integrated into a cell culture program as part of routine quality control. Microbial and mycoplasma testing should be performed upon arrival of all incoming cell lines and on lot samples of ampules prepared for master or working cell banks and seed stocks. Testing for microbial contamination should also be done whenever contamination is suspected (e.g., unusually slow growth rates for a particular cell line, aberrant appearance of cells). Indirect mycoplasma screening methods should also be done on new lots of serum used in media preparation when first received by the laboratory. Testing for microbial contamination should be performed after the cells have been cultured in the absence of antibiotics for several weeks.

TESTING FOR BACTERIAL AND FUNGAL CONTAMINANTS

BASIC PROTOCOL 1

The media and methods described in this protocol are suitable for detection of most bacteria and fungi that would be expected to survive as contaminants in cell lines. Brain heart infusion and trypticase soy agar with sheep blood are used for the cultivation of nutritionally fastidious bacteria of clinical origin that may be present in primary tissue cultures or in material contaminated by bacterial flora from human skin and poor aseptic technique. Fluid thioglycollate supports the growth of bacteria that require reduced oxygen tension; these microaerophilic or slightly anaerobic contaminants are frequently spore formers that originate from inadequately autoclaved or heat-sterilized materials. Soybean/casein digest broth is a general-purpose medium that supports the growth of a wide range of bacteria of human or environmental origin. HEPES/trypticase/yeast extract (HTYE) broth is also a general bacterial growth medium, but has the advantage of supporting growth of nutritionally or physiologically stressed bacteria not easily culturable with other media. These general types of bacteria are primarily environmental in origin and can be found in distilled water carboys, in fouled deionization systems, or as air-borne contaminants. Emmons' modification of Sabouraud's agar and YM agar are used for detection of filamentous fungi (molds) and yeasts, respectively. Molds are frequently environmental contaminants that can thrive under a wide variety of conditions. They often take residence in air-handling ducts to generate a constant microscopic rain of spores into a laboratory. Similarly, molds can often be found as films colonizing the dispensing tubing from distilled water reservoirs. The types of yeasts normally found as cell culture contaminants are human in origin.

Many of the media listed below may be purchased in their final configurations as sterile plates or test tubes from microbiological media manufacturers such as BBL or Difco, as well as other suppliers. Be that as it may, the cell culture user should carefully evaluate

Contributed by Rosalie Coté
Current Protocols in Cell Biology (1999) 1.5.1-1.5.18

the configurations, performance, and cost of any prepared quality control medium before commencing full-scale use in a cell culture laboratory.

Materials

Medium for bacterial detection: e.g., brain heart infusion (BBL, Difco), fluid thioglycollate medium (BBL, Difco), HTYE broth (see recipe), soybean/casein digest broth USP (e.g., trypticase soy broth, BBL; tryptic soy broth, Difco), or trypticase soy agar (BBL)
Medium for mycelial and yeast fungal detection: e.g., Sabouraud's dextrose agar (Emmon's modified; BBL, Difco), or YM agar (Difco)
Sterile, defibrinated sheep blood (e.g., Colorado Serum, Waltz Farm)
Cell culture test samples
Antibiotic-free culture medium (optional)

Conductivity meter (Corning model 162 or equivalent), if not integrated with the laboratory water purification system
50°C water bath
16 × 125–mm borosilicate screw-cap test tubes with rubber-lined caps
100 × 15–mm sterile plastic disposable petri dishes
Semiautomated repeat-volume filling unit to accurately dispense 5- to 24-ml aliquots (optional)
Incubators: 26°C, 35° to 37°C, and 37°C with 5% (v/v) CO_2

NOTE: To avoid inadvertent contamination of clean cell lines, bacterial and fungal testing should be segregated to a laboratory not used for general cell culture work.

Prepare media

For liquid (broth) media:

1a. Reconstitute brain heart infusion, HTYE broth, soybean/casein broth, and fluid thioglycollate medium per manufacturer's instructions, or per specific recipe instructions, in 10-megaohm (or higher) distilled or deionized water. Heat to ~50°C with frequent stirring to dissolve components. Heat to boiling with frequent stirring to dissolve any medium containing even small amounts of agar (e.g., fluid thioglycollate).

2a. Dispense medium into 16 × 125–mm borosilicate screw-cap test tubes at 10 ml/tube for fluid thioglycollate medium, and a 5 ml/tube for all other media.

3a. Cap tubes loosely, threading caps securely enough to prevent them from blowing off during autoclaving, but loosely enough to permit pressure exchange within the tube head space during the sterilization process.

Because of the large (10-ml) volume required with fluid thioglycollate medium, one should anticipate significant tube blow-outs upon autoclaving, and should prepare ~25% more tubes than required to compensate for the rejected material.

4a. Sterilize tubes by autoclaving at 121°C for 15 min under slow exhaust or liquid cycle.

Autoclaving times indicate the time necessary to hold the medium at the 121°C temperature for 15 min, not the time selected to run an autoclave cycle (UNIT 1.4; Table 1.4.1). Autoclave efficiency is very much machine and maintenance specific. However, an autoclave cycle of 20 min for a single 6 × 12 test tube rack of bacteriological medium, and a 32-min cycle for a 2-liter flask containing 1 liter of bulk medium, provide general guidelines for achieving the 121°C for 15 min sterilization criteria for these medium/vessel configurations.

5a. Remove tubes of medium from autoclave immediately after sterilization cycle is completed and/or when autoclave gauges indicate atmospheric pressure in the auto-

clave chamber. Allow medium to cool to ambient room temperature in a location not subject to excessive air currents or temperature fluctuations.

Oversterilization or prolonged holding of bacteriological media at elevated temperatures will severely affect performance. Cooling of just-autoclaved media in laboratory areas with significant temperature fluctuations or personnel movement can cause environmental contamination of otherwise sterile media.

6a. When tubes of medium reach ambient temperature, fully tighten screw caps and store tubes at 4° to 8°C until further quality control checks or until use (up to 6 to 9 months).

Fluid thioglycollate is a medium formulated to detect slightly anaerobic bacteria and contains a small amount of agar to retard atmospheric oxygen diffusion into the medium, cysteine as a reducing agent, and methylene blue as an oxygen indicator. Freshly prepared fluid thioglycollate will have a very small zone of aerobiosis at the medium surface/head space interface, as indicated by a slight purple to orange band of oxidized methylene blue. As oxygen slowly continues to permeate with prolonged storage of the medium, the pigmented, oxidized band will enlarge. Do not use the medium if the color has changed to orange in greater than the top 25% of the medium. Oxidized fluid thioglycollate may be rejuvenated, but only once, by steaming the tubed medium in a boiling water bath to purge gaseous oxygen from the medium, and then cooling just prior to use. Other bacteriological media cited here have a shelf life of 6 to 9 months when stored in the dark at 4° to 8°C.

Any of the liquid media cited above may be adapted for agar plate or test tube slant use by the addition of agar as the solidification agent as noted below.

For bulk agar media for plates:

1b. Reconstitute trypticase soy agar, Sabouraud's dextrose agar, and YM agar per manufacturer's instructions in 10-megaohm (or higher) distilled or deionized water. Use an autoclavable container capable of holding at least twice the volume of the medium being prepared (e.g., use a 2-liter Erlenmeyer flask to autoclave 1 liter of medium) to avoid boiling over during the auotclave cycle.

2b. Sterilize the bulk medium by autoclaving at 121°C for 15 min under slow exhaust or liquid cycle (see step 4a annotation).

3b. Cool in a water bath to ~50°C.

4b. Add 50 ml/liter (5%) defibrinated sheep blood aseptically to trypticase soy agar.

It is critical that medium be cooled to 45° to 50°C before sheep blood is added.

5b. Dispense medium aseptically in 24-ml aliquots to 100 × 15–mm sterile plastic disposable petri dishes.

A semiautomated repeat-volume filling unit fitted with a weight on the inlet line to sink the tubing to the bottom of the flask of medium will greatly alleviate drawing of surface foam from the bulk flask to the petri dishes. Surface bubbles most often occur when postautoclaving agitation of the bulk flask is necessary to incorporate heat-labile additives such as sheep blood. A small number of media bubbles can be removed from the plates by lightly passing the flame of a Bunsen burner across the surface of the plated medium as soon as it is dispensed.

6b. Place plates in stacks of 10 to 20 and allow to cool and solidify overnight at room temperature. Store in vented plastic bags at 4° to 8°C until quality control checks or use (up to 12 weeks).

Cooling the plates in stacks of 10 to 20 retards formation of excessive condensation on the lids of the plates.

Prepare test samples

7a. *For lot sample preparation of cryopreserved ampules:* Use a 1-ml serological pipet to pool and mix the contents of ~5% of the cell culture ampules prepared from each freeze lot.

7b. *For cell culture vessels:* Examine cell culture vessels individually under low power, preferably with phase contrast, using an inverted microscope. Look for aberrant growth or appearance of the cells. Aseptically remove 5-ml aliquots from suspect cultures to use for further examination and testing. Quarantine any suspect cultures or containers to ensure that they will not be inadvertently mixed with and cross-contaminate clean cultures.

Unless the cultures are heavily contaminated, microbial growth will not be readily evident under low-power magnification. Mycelial fungal contamination sometimes is first noticed macroscopically by the appearance of small "cottony" or "lint-like" debris in the culture vessel.

8. Prepare wet mounts for microscopic evaluation of test samples and examine under oil immersion with high-power objectives (≥1000× magnification).

Bacterial contamination is recognized by the presence of small, uniformly sized spheres, rods, or spirals scattered throughout the field. The organisms may be individual, in clusters, or in chains. Rod-shaped bacteria may contain bright, refractile spores. The bacteria may be motile. Fungal yeast contamination appears as ovoid, fairly regularly sized nucleated cells scattered throughout the microscopic field. The yeast may be individual, in the process of budding off smaller daughter cells, or in short chains. Mycelial fungal contamination is characterized by the presence of long filaments or pieces of broken filaments in the microscopic field. Fungal spores, frequently appearing as spherical objects covered with spines or other protrusions, might be observed. Low-level contamination may not be detected under the microscope even by a trained microbiologist, particularly if the cell culture sample contains much debris.

9. If culture contains antibiotics, wash prior to inoculation of microbiological test media by centrifuging at 2000 × *g* for 20 min (at room temperature or 4° to 8°C), removing the supernatant, and resuspending the pellet in an equal volume of antibiotic-free medium. Repeat for a total of three washes to eliminate traces of antibiotics that might interfere with microbial cultivation.

Inoculate microbiological media with test samples

10. For each test sample, inoculate each of the following with 0.3-ml aliquots of cell suspension:

    2 tubes of brain heart infusion
    2 tubes of fluid thioglycollate medium
    2 tubes of HTYE broth
    2 tubes of soybean/casein digest broth
    2 plates of trypticase soy agar with 5% sheep blood
    2 plates of Sabouraud's dextrose agar, Emmon's modified
    2 plates of YM agar.

11. Incubate one plate of trypticase soy agar (with 5% sheep blood) at 37°C aerobically and the other at 37°C under 5% CO_2.

12. Incubate one sample each of the other media at 26°C and the other sample at 35° to 37°C.

13. Examine all inoculated media daily for 14 days.

Usually, visual evidence of bacterial growth appears within 72 hr; fungal growth within 96 hr. Low-level contamination, or proliferation of contaminants previously stressed by the presence of antibiotics or other adverse culture conditions, may take longer to appear.

Positive bacterial and yeast growth appears as turbidity or the formation of a precipitate in liquid media. In an undisturbed test tube, growth may be restricted to a pellicle of growth at the surface of the liquid. On solid media, these bacteria and yeast appear as distinct, slightly convex, discretely isolated circular or confluent areas of microbial colonial proliferation, most often off-white or yellow in color. Filamentous fungal colonial growth is characterized by the appearance of typical cottony, whitish-gray to green to black mold on plates.

14. Autoclave and discard any general-use cell culture preparations that are positive for contamination.

If a cell culture that has tested positive is critical to maintain, repeat the microbial evaluation. If still positive, autoclave and discard the culture. If it is necessary to attempt to clean a microbially contaminated critical cell culture, see Basic Protocol 3.

Reusable glassware from discarded contaminated cultures should be decontaminated by autoclaving, cleaned, and depyrogenated by dry heat (UNIT 1.4).

TESTING FOR MYCOPLASMA CONTAMINATION BY DIRECT CULTURE

BASIC PROTOCOL 2

This protocol describes the direct detection of mycoplasma contamination by screening with microbiological media designed to encourage proliferation of mycoplasma. Total incubation time for this method is ~35 days. This schedule is necessary to detect low levels of mycoplasma contamination that might otherwise be scored as false negatives.

Materials

Cell line for testing
Mycoplasma broth medium (see recipe): 6 ml medium in 16 × 125–mm screw-cap test tubes
Mycoplasma agar plates (see recipe): 10 ml solidified medium in 60 × 15–mm petri dishes

37°C incubators: one without CO_2 and one humidified with 5% (v/v) CO_2
Inverted microscope with 100 to 300× magnification

NOTE: To avoid inadvertent contamination of clean cell lines, mycoplasma testing should be segregated to a laboratory not used for general cell culture work.

1a. *For adherent cultures:* Select a cell culture that is near confluency and has not received a fluid renewal within the last 3 days. Remove and discard all but 3 to 5 ml of the culture medium. Scrape a portion of the cell monolayer into the remaining culture medium using a sterile disposable scraper.

1b. *For suspension cultures:* Take the test sample directly from a heavily concentrated culture that has not received a fresh medium supplement or renewal within the last 3 days.

Samples can also be taken directly from thawed ampules that have been stored frozen.

2. Inoculate 1.0 ml of the test cell culture suspension into 6 ml mycoplasma broth medium in a 16 × 125–mm screw-cap test tube. Also inoculate 0.1 ml of the test sample onto the center of a 60 × 15–mm mycoplasma agar plate.

3. Incubate the broth culture aerobically at 37°C. Incubate the agar plate in a humidified 37°C, 5% CO_2 incubator. Observe broth culture daily for development of turbidity and/or shift in pH (medium becomes redder for alkaline shift, yellower for acid shift).

As an alternative, a self-contained anaerobic system such as the GasPak equipment (Becton Dickinson Microbiology Systems) can be used in conjunction with a standard 37°C incubator to provide proper CO_2 levels.

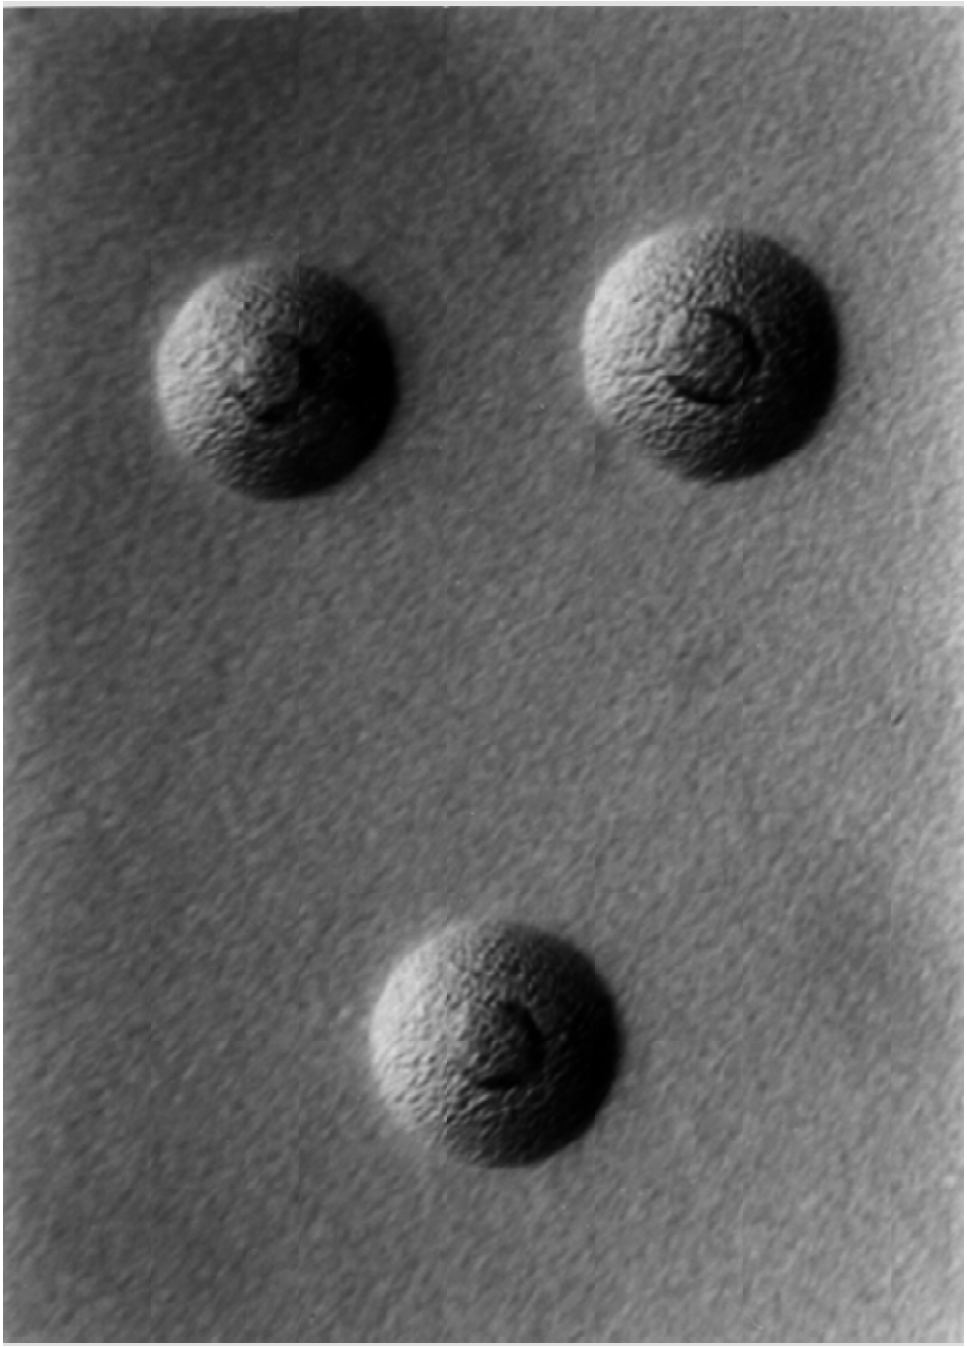

Figure 1.5.1 Mycoplasma colonies at 230× magnification. Figure provided by W. Siegel, Bio-Whittaker, Inc.

4. After 5 to 7 days of incubation and again after 10 to 14 days, remove a 0.1-ml sample from the broth culture and inoculate a fresh mycoplasma agar plate. Incubate these plates as in step 3.

5. Using an inverted microscope at 100 to 300× magnification, examine the agar plates weekly for at least 3 weeks for mycoplasma colony formation and growth.

   Mycoplasma colonies range from 10 to 55 μm in diameter and classically look like a fried egg, with the dense center of the colony embedded in the agar and the thinner outer edges of the colony on the surface of the substrate (Fig. 1.5.1). However, much variation in colony morphology occurs between species and culture conditions. Although colonies typically

appear within 4 days after inoculation, plates should be kept for the full incubation period before scoring them as negative.

6. To confirm presumptive mycoplasma colonies, subculture a small (~1 cm^2) section of the suspicious area of the agar plate into a tube of mycoplasma broth medium, incubate up to 14 days, and observe as in step 3.

   When other detection methods are not available, the ability to subculture presumptive mycoplasma colonies will help to differentiate authentic mycoplasma presence from artifacts such as air bubbles, tissue culture cells, or pseudocolonies.

INDIRECT TESTING FOR MYCOPLASMA BY STAINING FOR DNA

ALTERNATE PROTOCOL 1

The total time for this protocol, which includes the use of an indicator cell culture, is 6 days. The staining procedure itself takes ~1 hr. The use of an indicator cell culture provides a number of advantages. The indicator cell line supports the growth of more fastidious mycoplasma species. Both positive and negative controls are thus readily available for direct comparison with the culture samples being tested. Selection of a proper indicator cell is important to the success of this procedure. It must first have good viability. Transformed cell lines are not recommended as indicators as they produce significant nuclear background fluorescence, which interferes with interpretation of results. Cell lines that produce much debris, such as hybridomas, are also not recommended as indicator cells because of the amount of positive staining artifacts that confuse interpretation of results.

Materials

Complete EMEM-10: Eagle's minimum essential medium (EMEM) with Earle's salts (Life Technologies), 100 U/ml penicillin, 100 µg/ml streptomycin, and 10% (v/v) bovine calf serum (see *UNIT 1.2* for media preparation methods)
Indicator cell line: e.g., African green monkey cell line Vero (ATCC #CCL81) or 3T6 murine cell line (ATCC #CCL96)
Cell culture for testing
Mycoplasma hyorhinis (ATCC #29052) or a known mycoplasma-infected cell line to use as a positive control, actively growing
Fixative: 3:1 (v/v) absolute methanol/glacial acetic acid
Hoechst stain (see recipe)
Mounting medium (see recipe)

60 × 15–mm culture dishes, sterile
No. 1 or no. 1½ coverslips, sterilized by autoclaving (*UNIT 1.4*)
37°C, 5% (v/v) CO_2/95% air incubator

NOTE: To avoid inadvertent contamination of clean cell lines, mycoplasma testing should be segregated to a laboratory not used for general cell culture work.

Prepare indicator cell cultures

1. Aseptically place a sterile glass no. 1 or 1½ coverslip into each sterile 60 × 15–mm culture dish.

   Use two culture dishes for the positive control, two dishes for the negative control, and two dishes for each test sample.

2. Aseptically dispense 3 ml complete EMEM-10 into each culture dish.

   Make certain that each coverslip is totally submerged and not floating on top of the medium.

3. Prepare a single-cell suspension of the indicator cell line in complete EMEM-10 at a concentration of 1.0×10^5 cells per ml.

4. Inoculate 1 ml indicator cell suspension into each culture dish.
5. Incubate overnight at 37°C in a 5% CO_2/95% air incubator.
6. Microscopically examine cultures to verify that the cells have attached to the glass coverslip. Code the top of each culture dish for identification purposes (to record the test samples to be inoculated).

Inoculate test samples

7. Add 0.5 ml/dish complete EMEM-10 to two culture dishes for negative controls.

8a. *For adherent cultures:* Select a test cell culture that is near confluency and has not received a fluid renewal within the last 3 days. Remove and discard all but 3 to 5 ml of the culture medium. Scrape a portion of the cell monolayer into the remaining culture medium using a sterile disposable scraper.

8b. *For suspension cultures:* Take the test sample from a heavily concentrated culture that has not received a fresh medium supplement or renewal within the last 3 days.

Samples can also be taken directly from thawed ampules from frozen stocks.

9. For each test sample, add 0.2 to 0.5 ml/dish test sample to two culture dishes.
10. Add 0.5 ml/dish actively growing *Mycoplasma hyorhinis* to two culture dishes for positive controls.

CAUTION: *To prevent spread of mycoplasma, infected strains should be destroyed and removed as quickly as possible. Benches and incubators should be cleaned. For safety of the investigator, BSL 2 laboratory conditions are appropriate.*

Alternatively, a known mycoplasma-infected cell line can be used.

11. Return the cultures to the CO_2 incubator and allow to incubate undisturbed for 6 days.

Cultures should be at 20% to 50% confluent. Confluence can interfere with microscopic examination for mycoplasma.

Fix, stain, and mount coverslips

12. Remove cultures from incubator. Aspirate medium and immediately add 5 ml fixative to each culture dish. Incubate for 5 min.

Do not allow the culture to dry between removal of the culture medium and addition of the fixative.

13. Aspirate fixative from each culture dish and repeat fixation for 10 min.

These fixing times are minimal. Additional fixation time will not harm the procedure and can be beneficial for some preparations.

14. Aspirate the fixative and let the cultures air dry.

Dry completely and store in a 60-mm petri or tissue culture dish if samples are to be accumulated at this stage for later staining.

15. Add 5 ml Hoechst stain to each culture dish, cover, and let stand at room temperature for 30 min.
16. Aspirate the stain and rinse each culture three times with 5 ml distilled water.
17. Aspirate well so that the glass coverslip is completely dry. Let air dry if necessary.
18. Place a drop of mounting medium on a clean glass microscope slide.
19. Use forceps to remove the glass coverslip containing the fixed cells from the culture dish and place face up on top of the mounting medium, being careful to eliminate air bubbles.

20. Add a second drop of mounting medium onto the top of the specimen coverslip and cover with a larger clean coverslip, being careful to eliminate air bubbles.
21. Label each slide to identify the specimen.
22. Observe each specimen by fluorescence microscopy at 500× using immersion oil. Use a blue glass excitation filter (330/380 nm) in combination with a 440-nm barrier filter (see *UNIT 4.2*). Compare test samples to positive and negative controls.

    The nuclei of the indicator cells appear as large (~20 μm), ovoid fluorescing bodies. Mycoplasma will appear as small fluorescing particles (0.1 to 1.0 μm) that are regular in shape and size in the cytoplasm or in intercellular spaces. If infection is heavy, the particles may be tightly clustered in some areas. With low-level contamination, not all cells will be infected. Thus, all of the slide should be examined.

INDIRECT TESTING FOR MYCOPLASMA BY PCR

ALTERNATE PROTOCOL 2

Kits are now available from a number of manufacturers for the detection of mycoplasma in cell cultures or other material using PCR. The kits, although expensive and requiring the expertise and equipment needed for molecular procedures, provide advantages with quick results (1 day) and the ability to speciate the contaminant and thus potentially identify its source. The PCR kits are also useful for detecting mycoplasma in cultures prone to forming artifact debris that often obscures definitive interpretations with staining detection methods. The procedure described here uses primers from a commercially available kit and a nested PCR assay that amplifies the spacer region between the 16S and 23S rRNA genes of mycoplasmas. This specific protocol details procedures using cell cultures; however, instructions provided with the kit also explain how to make modifications for analyzing test samples of serum or frozen cells. The novice practitioner of PCR methodologies is strongly urged to consult Sambrook et al. (1989) for specific details (also see *APPENDIX 3*).

Materials

Cells for testing
10× PCR buffer (usually provided with *Taq* polymerase)
2.5 mM 4dNTP mix: 2.5 mM each dGTP, dCTP, dTTP, and dATP
25 mM $MgCl_2$
5 U/μl *Taq* DNA polymerase
Mineral oil (if needed for thermal cycler)
Mycoplasma detection kit (ATCC), containing first- and second-stage primer mixtures (total 7 primers), as well as two positive control mycoplasma DNAs (*Mycoplasma pirum*, *Acholeplasms laidlawii*)

Thin-wall microcentrifuge tubes
Aerosol-preventive micropipettor tips, sterile
Positive-displacement micropipettors
Picofuge
Thermal cycler

Additional reagents and equipment for agarose gel electrophoresis (see Support Protocol)

NOTE: To avoid inadvertent contamination of clean cell lines, mycoplasma testing should be segregated to a laboratory not used for general cell culture work.

NOTE: To avoid amplification of contaminating DNA from laboratory workers, room contaminants, or previous mycoplasma DNA amplifications, all PCR should be performed using aseptic technique (also see special considerations for PCR experiments in *APPENDIX 2A*).

Prepare test sample

1a. *For confluent monolayers:* Detach cell monolayer from flask surface with a cell scraper. Gently agitate the flask to dispense the cells in the medium. Transfer 0.5 ml cell suspension (~5×10^4 cells/ml) to a sterile 1.5-ml microcentrifuge tube.

1b. *For suspension cultures:* Mix the suspension culture by gently pipetting to obtain an even dispersal of cells in the medium. Transfer 0.5 ml of the suspension (~5×10^4 cells/ml) to a sterile 1.5-ml microcentrifuge tube.

2. Centrifuge at 12,000 × *g* for 10 min at 4°C.

3. Discard 400 µl supernatant and use a pipet to resuspend the cell pellet in the remaining 100 µl medium.

Pipet gently to avoid formation of bubbles. The 100-µl cell suspension is ready for PCR.

Run first-stage PCR

4. Using a permanent ink marker, label each thin-wall microcentrifuge tube (reaction tube) with appropriate test sample or control DNA codes.

5. Prepare a master mix of PCR reagents in sufficient quantity for all samples to be tested (*n* + 1 or 2 reactions) plus a minimum of two positive DNA controls and one negative control. Use the following volumes per reaction:

5 µl 10× PCR buffer
1 µl first-stage primer mixture
1 µl 2.5 mM 4dNTP mix
1 µl 25 mM $MgCl_2$ (see annotation)
0.2 µl 5 U/µl *Taq* DNA polymerase
Deionized water to 45 µl.

Store the mix on ice until it is aliquotted.

The optimal reaction conditions for this procedure are 10 mM Tris·Cl (pH 8.3 to 8.8), 50 mM KCl, 2.0 mM $MgCl_2$, 50 µM of each dNTP, and 1 U Taq polymerase. Check for the inclusion and final concentration of $MgCl_2$ in the 10× PCR buffer supplied with the Taq polymerase and adjust the volume of $MgCl_2$ in the reagent mix, if necessary, to give a final concentration of 2.0 mM. Adjust the amount of water in the mix accordingly for a final reaction mix volume of 45 µl.

NOTE: *In this and all subsequent steps, use positive-displacement micropipettors and sterile aerosol-preventive micropipettor tips to prevent contamination of the amplification reaction.*

6. Pipet 45 µl reaction mix into each sample and control reaction tube.

7. If the thermal cycler used requires mineral oil to minimize sample evaporation, add 40 to 60 µl of mineral oil to each tube.

Keep the reaction tubes closed, except when aliquotting into them, to avoid possible cross-contamination.

8. Add 5 µl test sample (step 3) to the appropriate reaction tube containing reagent mix (final reaction volume 50 µl). If reaction tubes contain mineral oil, pipet the samples directly into the mix below the mineral oil layer (final tube volume 90 to 110 µl).

9. Add 5 µl of each positive control mycoplasma DNA into separate positive control tubes.

10. Add 5 µl sterile deionized water into the negative control tube.

11. Mix each tube thoroughly by flicking it with a finger, and centrifuge the tube briefly in a picofuge.

12. Place all the tubes into a thermal cycler and perform amplification using the following program:

Initial step:	30 sec	94°C	(denaturation)
30 cycles:	30 sec	94°C	(denaturation)
	2 min	55°C	(annealing)
	2 min	72°C	(extension)
Final step:	5 min	72°C	(extension)
Chill:	indefinitely	4°C	(hold).

Store PCR products at 4°C or on ice until further use (2 to 3 weeks). For longer periods, store at −20°C.

Run second-stage PCR

13. Using a permanent ink marker, label each second-stage reaction tube with appropriate test sample or control DNA codes.

14. Prepare a master mix of reagents in sufficient quantity for all samples (n + 1 or 2 reactions), plus positive and negative controls, using the following volumes per reaction:

5 µl 10× PCR buffer
1 µl second-stage primer mixture
1 µl 2.5 mM 4dNTP mix
1 µl 25 mM $MgCl_2$ (see step 5 annotation)
0.2 µl 5 U/µl *Taq* DNA polymerase
Deionized water to 49 µl.

Store the mix on ice until it is aliquotted.

15. Pipet 49 µl reaction mix to each sample and control tube.

16. If the thermal cycler used requires mineral oil to minimize sample evaporation, add 40 to 60 µl of mineral oil to each tube.

Keep the reaction tubes closed, except when aliquotting into them, to avoid possible cross-contamination.

17. Carefully pipet 1 µl from the first-stage PCR reaction tube (step 12) into the second-stage reaction tube (final reaction volume 50 µl). If mineral oil was used, add the sample to the reagent mix below the oil layer (final tube volume 90 to 110 µl).

18. Mix each tube thoroughly by flicking it with a finger, and centrifuge the tube briefly in the picofuge.

19. Place all the tubes in the thermal cycler and run the program as above (step 12). Store PCR products at 4°C or on ice until further use (2 to 3 weeks). For longer periods, store at −20°C.

20. Analyze reaction products by agarose gel electrophoresis (see Support Protocol).

SUPPORT PROTOCOL

AGAROSE GEL ELECTROPHORESIS OF PCR PRODUCTS

Agarose gel electrophoresis is used to analyze the products of the second-stage PCR for the presence of mycoplasma sequences. The protocol is written for one 10-lane gel, which can accommodate up to four unknown samples, two positive controls, one negative PCR control, one negative electrophoresis control, and two molecular weight marker lanes. For additional samples, the procedure can be scaled by using a comb with additional wells, or additional gels can be run.

Materials

Agarose (e.g., NuSieve, FMC Bioproducts)
1× TBE electrophoresis buffer (*APPENDIX 2A*)
10 mg/ml ethidium bromide solution
Second-stage PCR products from test samples and controls (see Alternate Protocol 2)
6× electrophoresis sample buffer (see recipe)
Molecular weight marker (100-bp DNA ladder)

Electrophoresis apparatus with a 10 × 14–in. gel tray and a 1-mm, 10-tooth comb
Power supply
UV light box

Prepare 2.5% agarose containing ethidium bromide

1. Seal a 10 × 14–in. gel tray from an electrophoresis apparatus according to manufacturer's instructions and place on a level surface.
2. Weigh 2.25 g agarose and place in a 250-ml Erlenmeyer flask.
3. Add 90 ml of 1× TBE electrophoresis buffer, swirl to mix, and heat to boiling to completely dissolve agarose.
4. Add 5.4 µl of 10 mg/ml ethidium bromide solution, swirl to mix, and cool to ~55°C.

   CAUTION: *Ethidium bromide is a mutagen and a potential carcinogen. Gloves should be worn and care should be taken when handling ethidium bromide solutions.*

Cast gel

5. Pipet 80 ml agarose solution into the center of the gel tray. Remove any bubbles.
6. Gently place a 1-mm, 10-tooth comb into the gel mold. Allow gel to harden until it becomes milky and opaque in appearance (~1 hr).
7. Remove tape or sealers from the gel mold. Place gel into electrophoresis tank.
8. Pour ~950 ml of 1× TBE electrophoresis buffer into the electrophoresis tank.

   Gel should be totally submerged in buffer, but not covered more than 1 cm.

9. Gently remove the gel comb.

Prepare sample

10. Add 10 µl of each second-stage PCR product to a separate microcentrifuge tube containing 2.0 µl of 6× electrophoresis sample buffer. Mix well.
11. Add 5 µl of 100-bp DNA ladder to 2 µl of 6× electrophoresis sample buffer. Mix well.

Load and run the gel

12. Add 7 µl DNA ladder to each of the first and last wells (lanes 1 and 10) of the gel.
13. Add 12 µl of 6× electrophoresis sample buffer to one lane as a negative control.

14. Add 12 µl unknown test samples and positive and negative PCR controls to the remaining wells.

15. Connect a power supply and run the gel at 75 V for ~1 hr and 40 min.

16. View the gel on a UV light box.

    CAUTION: *UV light is damaging to eyes and exposed skin. Protective eyewear should be worn at all times while using a UV light source.*

    With the primers used in Alternate Protocol 2, the mycoplasmas commonly encountered as cell culture contaminants should generate a second-stage PCR DNA amplicon that ranges in size from 236 to 365 bp. In contrast, the A. laidlawii positive control should generate two amplicons of 426 bp and 219 bp, and the M. pirum positive control should generate a single 323-bp amplicon. No discrete amplicon band should be seen in the negative controls. Fuzzy bands <100 bp are sometimes observed in control and test samples and are probably primer multimer artifacts.

USE OF ANTIBIOTICS TO CONTROL MICROBIAL CONTAMINATION

BASIC PROTOCOL 3

The best way to deal with a contaminated cell culture is to autoclave it. Be that as it may, situations will undoubtedly occur when there is a need to attempt to salvage a microbially contaminated cell culture. This brief protocol describes the use of antibiotics in cell culture and cautions against misuse of these potent antimicrobial agents.

Materials

Contaminated cell culture
Sterile antibiotic stock solution(s) as appropriate (Table 1.5.1)

Additional reagents and equipment for identifying microbial contamination (see Basic Protocols 1 and 2; see Alternate Protocols 1 and 2)

1. Immediately quarantine the contaminated culture to prevent possible cross-contamination with other cultures in the laboratory.

2. Identify the microbial contaminant as to type: bacterial, fungal, or mycoplasmal (see Basic Protocols 1 and 2; see Alternate Protocols 1 and 2).

   If bacteriological expertise is available, identification of a bacterial contaminant to genus can help narrow antibiotic selection to one that is particularly effective against the contaminant.

3a. *For an identified microbial contaminant:* Select an appropriate antibiotic from the Table 1.5.1, and prepare and filter sterilize a stock solution.

3b. *For an unknown bacterial contaminant:* Prepare and filter sterilize the following 10× antibiotic cocktail:

    2500 U/ml penicillin
    2.5 mg/ml streptomycin sulfate
    2.5 mg/ml neomycin
    25 U/ml bacitracin

4a. *For monolayers:* Remove contaminated medium by suction and add fresh medium containing antibiotics. Add specific antibiotic stock solutions (step 3a) to fresh medium to give the appropriate working concentration (Table 1.5.1). Alternatively, add 1 vol of 10× antibiotic cocktail (step 3b) to 9 vol fresh medium.

    Do not add greater than the recommended amount of antibiotic. All of these chemical reagents are cytotoxic in that they have essentially the same metabolic effect on cells as they do on microorganisms if the concentration is great enough.

Table 1.5.1 Antibiotics[a]

Organism	Antibiotic	Solvent	Stability (days at 37°C)	Working concentration
Bacteria (gram-positive only)	Ampicillin	Water	3	100 mg/liter
	Erythromycin	2 M HCl	3	100 mg/liter
	Gentamicin sulfate	Water	5	50 mg/liter
	Kanamycin sulfate	Water	5	100 mg/liter
	Neomycin sulfate	Water	5	50 mg/liter
	Penicillin-G, K^+ salt	Water	3	10^5 U/liter
	Streptomycin sulfate	Water	3	100 mg/liter
	Tetracycline HCl	Water	4	10 mg/liter
Fungi (molds and yeasts)	Amphotericin B	DMSO; DMF[b]	3	2.5 mg/liter
	Nystatin	DMF	3	2.5×10^6 U/liter
Mycoplasma	Gentamicin sulfate	Water	5	50.0 mg/liter

[a]All antibiotics must be filter sterilized in the solvent noted. Antibiotics are meant only for short-term use; if contamination is not cleared after 14 days of treatment or two subcultures, discard culture.

[b]Abbreviations: DMF, dimethylformamide; DMSO, dimethyl sulfoxide.

4b. *For suspensions:* Centrifuge culture 10 min at 125 × *g*. Remove supernatant and resuspend cells in fresh medium containing antibiotics as described in step 4a.

5. Add additional antibiotic solution every 3 to 5 days to maintain the working concentration (note stability times at 37°C in Table 1.5.1). Continue treatment for 14 days.

   Change medium or passage cells as required during this time, being sure to maintain the antibiotic concentration.

6. Examine the contaminated culture microscopically during the treatment period; look for evidence of cytotoxicity as well as elimination of the contaminant.

7. If the antibiotic treatment is unsuccessful, destroy the culture by autoclaving. If culture appears to have been cleaned of the contaminant, inoculate into fresh, antibiotic-free medium.

   It is not recommended that cultures be maintained in media containing antibiotics. The chemicals may have adverse effects on cell characteristics and will also create the risk of selecting for a population of antibiotic-resistant contaminants that could pose a human health hazard.

8. Test for microbial and mycoplasma contamination (see Basic Protocols 1 and 2; see Alternate Protocols 1 and 2).

REAGENTS AND SOLUTIONS

*Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see **APPENDIX 2A**; for suppliers, see **SUPPLIERS APPENDIX**.*

Dextrose/arginine supplement

50.0 g dextrose
10.0 g L-arginine HCl

Dissolve ingredients with stirring and heating at 37°C in ~800 ml deionized, distilled water. Bring final volume of solution to 1.0 liter with water. Filter sterilize and dispense in convenient aliquots (e.g., 100-ml aliquots for making 1 liter of mycoplasma agar or broth). Store frozen (at −20° to −70°C) until needed (up to 12 months).

Electrophoresis sample buffer, 6×

2.5 ml 1% (w/v) bromphenol blue
2.5 ml 1% (w/v) xylene cyanol
5.0 ml glycerol
Store up to 6 months at 4°C in glass container

Hoechst stain

Stock concentrate:

5.0 mg bisbenzamide fluorochrome stain (Calbiochem)
10.0 mg thimerosal (Sigma)
100 ml 1× HBSS (*APPENDIX 2A*) without sodium bicarbonate or phenol red

Prepare in a brown bottle wrapped in aluminum foil. Mix thoroughly 45 min at room temperature using a magnetic stirrer. Store 1-ml aliquots up to 1 year at −20°C in the dark.

The stock concentrate is heat and light sensitive.

The concentrate can support microbial growth and should be examined periodically for contamination. Filter sterilization of the concentrate is not recommended as it diminishes fluorescence.

Working solution: In a brown bottle, dilute 1.0 ml stock concentrate in 100.0 ml HBSS without sodium bicarbonate or phenol red. Mix thoroughly 20 to 30 min at room temperature using a magnetic stirrer. Prepare fresh immediately before use.

HTYE (HEPES/trypticase/yeast extract) broth

5.0 g trypticase peptone (BBL)
2.0 g yeast extract
4.0 g HEPES acid
1.0 liter H_2O
Adjust to pH 7.1 ± 0.1 with NaOH
Dispense as required
Autoclave at 121°C for 15 min
Store up to 6 to 9 months at 4° to 8°C

Mounting medium

22.2 ml 0.1 M citric acid
27.8 ml 0.2 M Na_2HPO_4
50.0 ml glycerol
Adjust to final pH 5.5
Store up to 6 months at 2° to 8°C

Periodically check pH of prepared mounting medium, as pH is critical for optimal fluorescence.

Mycoplasma agar plates

23.8 g mycoplasma agar base (BBL)
600 ml deionized, distilled H_2O

Heat to boiling with constant stirring to dissolve all ingredients. Sterilize by autoclaving at 121°C for 15 min (*UNIT 1.4*, Basic Protocol 1). Cool to 50°C and aseptically add the following sterile solutions which have been equilibrated to 37°C:
200 ml horse serum (Life Technologies)
100 ml fresh yeast extract solution (Life Technologies)
100 ml dextrose/arginine supplement (see recipe)

Aseptically adjust to pH 7.2 to 7.4 and dispense in 10-ml aliquots to sterile 60 × 15–mm petri dishes. Store up to 6 weeks at 4°C to 8°C.

continued

Solutions should be prewarmed to 37°C before adding to the agar solution to avoid immediate gelling.

The sterile fresh yeast extract solution used in the preparation of the mycoplasma broth and agar media frequently contains large amounts of sediment that must be removed before it is used in media preparation. Sediment can be removed by coarse filtration followed by filter sterilization (UNIT 1.4) with a 0.2-μm membrane.

The formation of bubbles in agar plates should be avoided as it can confuse examination. When preparing medium, add and mix heat-labile supplements carefully to avoid formation of bubbles. As most of the bubbles are at the surface of the medium, they can be avoided during dispensing by using a semiautomatic dispensing apparatus, such as a peristaltic pump with a sinker attached to the inlet tubing to assure that the medium is being drawn from below the surface of the flask. If a few bubbles form when the medium is dispensed into the plates, they may be removed by lightly passing the flame of a Bunsen burner across the agar surface before the agar has solidified.

Mycoplasma broth medium

14.7 g mycoplasma broth base (BBL)
20.0 mg phenol red
600.0 ml deionized, distilled H_2O

Mix well to dissolve all ingredients. Sterilize by autoclaving at 121°C for 15 min (*UNIT 1.4*, Basic Protocol 1). Cool to room temperature and aseptically add the following sterile solutions:
200 ml horse serum (Life Technologies)
100 ml fresh yeast extract solution (Life Technologies)
100 ml dextrose/arginine supplement (see recipe)

Aseptically adjust to pH 7.2 to 7.4 and dispense in 6-ml aliquots to sterile 16 × 125–mm test tubes. Store up to 12 weeks at 4° to 8°C.

The sterile fresh yeast extract solution used in the preparation of the mycoplasma broth and agar media frequently contains large amounts of sediment that must be removed before it is used in media preparation. Sediment can be removed by coarse filtration followed by filter sterilization (UNIT 1.4) with a 0.2-μm membrane.

COMMENTARY

Background Information

Bacterial and fungal contamination

Bacterial and fungal contamination of cell cultures can originate from many sources. Lapses in aseptic technique at any stage of culture manipulation can introduce low-level contamination that may take days or weeks to proliferate to noticeable levels. Mechanical or operational failures with air handling, primary barriers (e.g., biosafety cabinets), water purification and storage, or sterilization systems utilized by the laboratory can give rise to contamination in spite of adequate aseptic practices during culture transfers. Commonly encountered contaminants of human origin include *Escherichia coli, Micrococcus* and *Staphylococcus* sp., and the fungal yeast *Candida* sp. Common contaminants from environmental sources include *Bacillus* sp., *Escherichia coli*, *Pseudomonas* sp. and allied genera, and the ubiquitous filamentous fungi *Aspergillus* sp., *Cladosporium* sp., and *Penicillium* sp. Testing procedures described in this unit detect most of the common organisms cited above as well as some less-frequently encountered microbial contaminants of cell cultures. None of the techniques listed, however, will detect all potential microbial cell culture contaminants. If microbial contamination is suspect but not culturable with these media, consultation with a reputable microbiology laboratory should be the course of action.

As an integral part of quality control in a cell culture lab, microbial testing should be performed on culture media, on incoming cultures, and on all seed stock and working cell banks.

Mycoplasma contamination

Mycoplasma contamination of cell cultures is a frequent occurrence that often goes unobserved because, unlike bacterial or fungal contamination, it is rarely visible to the naked eye. The presence of mycoplasma in cultures can

inhibit cell metabolism and growth, alter nucleic acid and protein syntheses, affect cell antigenicity, induce chromosomal alterations, interfere with virus replication, and mimic viral actions. Bovine serum (used in media preparation), laboratory personnel, original tissue samples, and other infected cell lines can be sources of mycoplasma contamination.

No one method, either direct or indirect, will detect all mycoplasma, particularly at low levels of infection. A good mycoplasma screening program will include both direct and indirect methods. Direct culture involves a long test period of over a month and may not detect mycoplasmal strains with nutritional requirements not satisfied by the growth medium. DNA fluorescence is an efficient method for screening mycoplasma contamination, but sometimes it takes experience to recognize the presence of contaminants amid background debris and artifacts. PCR is very fast and sensitive, but expensive in terms of both basic equipment and reagents.

Commercial mycoplasma testing services may be an option for laboratories without the experience or specialized equipment needed to fully screen a cell line for contamination with these microorganisms. A good testing service should be able to provide direct culture, indirect staining, and molecular (DNA/RNA hybridization or PCR) methods. Many of the larger reference culture collections with cell line holdings—e.g., American Type Culture Collection (ATCC), European Collection of Cell Cultures (ECACC), or German Collection of Microorganisms and Cell Culture (DSMZ)—offer mycoplasma testing services. Expect to pay approximately $100 U.S. per sample for direct culture methods and staining. PCR or other molecular techniques will increase the testing fee because of the cost of the reagents involved.

Mycoplasma testing, along with testing for bacteria and fungi, should be included in the routine quality control procedures for all cell culture laboratories. Tests should be performed on sera used in culture media, on incoming cultures, and on all seed stock and working cell banks.

Antibiotic treatment

Antibiotics are not substitutions for good aseptic technique and should not be routinely used as prophylactics against possible contamination. Antibiotics work by disrupting metabolic processes (e.g., protein synthesis) and the chemical mode of action does not always differentiate between microbial contaminants and cultured cells. Antibiotics can be cytotoxic, sometimes at working concentrations. The use of combined antibiotics can exert cytotoxic effects at lower concentrations than that of an individual antibiotic. Do not exceed the suggested working concentration for any antibiotic. As cytotoxicity is cell line dependent, it is necessary to monitor the effects of antibiotic use on cell characteristics as well as on the contaminant.

Critical Parameters

Because of the insidious nature of infection, mycoplasma testing should be segregated from rooms where routine cell culture work is conducted to avoid cross-contamination of clean cultures with mycoplasma-infected cell cultures or mycoplasma cultures being grown with the direct culture screening method. Any mycoplasma-infected material should be immediately destroyed by autoclaving.

It is important to note the stability of antibiotics at 37°C (Table 1.5.1). Antibiotic potency diminishes within days of incubation and additional antibiotic should be added during the 2-week treatment to ensure that working concentrations are maintained, in order to prevent development of antibiotic-resistant contaminants.

Anticipated Results

If contamination of cultures is suspected, careful application of these testing procedures should allow identification of most common microbial, fungal, and/or mycoplasma contaminants. Success rates for treatment of contaminated cultures cannot be generalized, as they depend on the type of contaminant and the severity of the infection.

Time Considerations

Testing for contamination can take a few minutes for visual inspection to several weeks for identification of contaminants such as mycoplasma. Treating contaminated cultures with antibiotics requires 14 days for treatment itself, plus additional days to weeks to verify that the culture is no longer contaminated.

Media and Culture of Yeast

This unit describes basic aspects of preparing media for and growing *Saccharomyces cerevisiae* cells. It also covers some aspects of handling yeast strains, such as growth, storage, and shipment. *Saccharomyces* has been one of the most extensively studied organisms in the laboratory, and an extensive repertoire of genetic and molecular biology methods have been developed, as described in this volume and elsewhere (see Key References). A large number of yeast strains with useful characteristics have been documented, and many can be obtained for a nominal cost from public collections including the Yeast Genetics Stock Center (YGSC; Rebecca Contopoulou, Curator; e-mail: *ygsc305@violet.berkeley.edu*) or the American Type Culture Collection (ATCC). For contact information for these collections, see Internet Resources and *SUPPLIERS APPENDIX*.

Culturing *Saccharomyces* is relatively straightforward and can be accomplished with readily available and inexpensive materials. Wild-type yeast are prototrophic for most nutrients; that is, they are capable of synthesizing most metabolites from inorganic salts and a carbon source for energy. However most laboratory strains carry mutations that make them auxotrophic for one or more metabolites, such as amino acids or nucleotides, that must be supplied in the growth medium. The auxotrophic mutations, or *markers*, are used in the maintenance of plasmids and in other genetic experiments.

The first part of this unit will discuss the preparation of media. General aspects of media preparation will be described followed by specific recipes. The second part of the unit will discuss the growth and handling of yeast strains.

NOTE: All incubations of yeast cells are performed at 30°C unless otherwise noted.

PREPARATION OF MEDIA

Yeast media are referred to as either *liquid* or *solid*. Liquid medium is self-explanatory. A solid medium typically contains 2% (w/v) Bacto Agar. Other comparable gelling agents can be used in special circumstances, but they are not discussed in this unit.

Liquid Media

Liquid media are prepared in the same way as solid media (described below) except that agar is not added. As a result, liquid media can be sterilized either by autoclaving or by filter sterilizing with a 0.22-µm filter. Filter sterilization is faster and eliminates the risk of heat inactivation of any medium ingredients. Liquid medium is prepared in either bottles or growth flasks. In flasks, medium should never exceed one-fifth the flask volume, so that maximum aeration can be achieved during shaking.

Solid Media

Solid media can be prepared in Erlenmeyer or Fernbach flasks; however, the most convenient container for pouring plates is the Fleaker (Corning). Heat-stable ingredients are mixed in water until completely dissolved (with the exception of the agar, which is added but will not dissolve). It is convenient to add a magnetic stir bar to the flask or Fleaker prior to autoclaving. The medium is autoclaved at 121°C on the liquids or slow exhaust program/setting at 15 psi for 15 min, after which it is placed on a stir plate at room temperature and stirred as it is allowed to cool to 60° to 65°C. Alternatively, the flasks or Fleakers can be placed in a 55°C water bath. Filter-sterilized, heat-sensitive ingredients are added at this point, and the medium is mixed completely prior to plate pouring. At this point the agar should be fully suspended within the medium.

Contributed by Simon R. Green and Charles M. Moehle
Current Protocols in Cell Biology (1999) 1.6.1-1.6.12

Most yeast medium recipes, including those described in this unit, should result in a pH between 5.5 and 7.0. If a more acid medium is prepared, care should be taken to minimize or avoid autoclaving agar at pH ≤4.8, as the agar will hydrolyze and fail to gel when cooled.

A pouring area should be prepared in a quiet place with minimal dust and airflow, and the bench surface should be wiped with 70% ethanol or another sterilizing agent. The appropriate number of bags of petri dishes (typically 15 × 100–mm or 15 × 95–mm) should be opened by carefully cutting off the top of the bags. The bags are overturned, allowing the plates to slide out in a stack. The bags are saved for storing the filled plates. The bottom of the plates are labeled, and the plates overturned and divided into stacks of eight. When the medium has cooled to 55° to 60°C, it can be carefully poured into the plates. When pouring, the Fleaker or flask of medium should be held in one hand, allowing the other hand to grab the stack of plates. The top seven plates are lifted as a stack, the medium is poured into the eighth (bottom) plate, and the stack is lowered. This process is then repeated by picking up the top six plates, pouring the seventh plate, and so on. Although this system of pouring is awkward at first, it has the advantages of being faster and taking up less space than pouring plates in stacks of one.

One liter of medium should generate 40 to 50 plates. Sometimes bubbles will be formed while pouring medium. These can be removed by quickly passing a bunsen burner flame over the surface of the molten agar. The lid should be placed on the plates as soon as possible to minimize the risk of contamination. After the agar hardens (20 to 45 min), the plates should be flipped so that the lids are on the bottom. Plates should be allowed to dry at room temperature for 2 to 3 days. Because they are more prone to collecting condensation, media for yeast are left to dry at room temperature for a longer time than are media for bacteria. Once dried, the plates are placed in plastic bags, and the bags are taped closed and stored at room temperature or at 4°C for extended periods of time. Most media will be stable for ≥3 months; if excessive drying and contamination can be avoided, most media are stable for up to one year. Sometimes it is helpful to make small slits in the plastic bags to let them "breathe." This reduces condensation, which in turn leads to the appearance of fewer contaminating organisms.

Defined Versus Complex Media

Yeast media are often referred to as either *defined* or *complex*. A defined medium is made with chemically defined components, such as salts, sugars, and amino acids. A complex, or rich, medium includes the addition of a complex lysate or hydrolysate, such as yeast extract or peptone. For the purpose of these definitions, agar-containing medium may still be referred to as defined. The following sections provide details about materials for media, and give recipes for specific complex and defined media. A number of special-purpose media are detailed.

Materials

Media should be prepared using distilled or deionized water. Most materials for media preparation should be of high grade, although the specific vendor is usually not important. However, yeast extract, peptone, agar, and yeast nitrogen base (YNB) should all be Bacto brand, sold by Difco. Difco products are carried by several scientific distributors.

Best results are obtained when the sugar component of a yeast medium (e.g., dextrose, sucrose, raffinose, galactose) is not autoclaved with the other components of the medium. If dextrose is included with other ingredients during the autoclaving process, it can caramelize. The standard alternative method is to autoclave or filter sterilize a concentrated stock solution of the sugar and add it to the medium after the other components have been autoclaved. For dextrose, a sterilized 40% (w/v) stock solution is added at 50

ml/liter to the autoclaved mixture of other medium components. Other sugars are typically made as 20% (w/v) stock solutions and added at 100 ml/liter.

Complex Media

Yeast extract/peptone/dextrose (YPD or YEPD) medium

This complex medium is the one most commonly used for the routine growth of yeast when no auxotrophic selection is required.

10 g Bacto yeast extract (1% w/v final)
20 g Bacto Peptone (2% w/v final)
20 g agar (2% w/v final)
950 ml H_2O
Autoclave
Add 50 ml 40% (w/v) dextrose (2% final; sterilized separately by autoclaving or filtering)

Many researchers prefer to add adenine to YPD medium, especially when working with adenine auxotrophs. Red-colored strains of Saccharomyces almost always lack either ade1 or ade2 gene function. To make YPAD, add 20 mg/liter adenine sulfate to YPD prior to autoclaving.

Similar media can be made by substituting other sugars for dextrose. Generally, Saccharomyces grows best on dextrose, but specific experiments may require replacement of dextrose with another sugar. The most common substitutes are YPF (2% w/v fructose), YPGal (2% w/v galactose), YPSuc (2% w/v sucrose), YPRaf (2% w/v raffinose), or YPMal (2% w/v maltose). Except for fructose, not all yeast strains are capable of growing on these alternative sugars. Growth on raffinose is sometimes facilitated by adding 0.05% (w/v) dextrose.

Yeast extract/peptone/glycerol (YPG) medium

Nonfermentable glycerol is the only defined carbon source in this complex medium. Because there is no fermentable carbon source, YPG does not support the growth of *petite* yeast strains (mutant strains that lack functional mitochondria).

10 g Bacto yeast extract (1% w/v final)
20 g Bacto Peptone (2% w/v final)
50 ml glycerol (5% v/v final)
20 g agar (2% w/v final)
950 ml H_2O
Autoclave

Some recipes call for 3% glycerol, but 5% gives better growth. Glycerol can be autoclaved with the medium. Other nonfermentable carbon sources can be used, including ethanol, acetate, or lactate, or combinations thereof. Glycerol is the most commonly used nonfermentable carbon source.

Yeast extract/peptone/dextrose/glycerol (YPDG) medium

This complex medium is used to determine the proportions of wild-type and *petite* cells. The different cells form large and small colonies respectively.

10 g Bacto yeast extract (1% w/v final)
20 g Bacto peptone (2% w/v final)
30 ml glycerol (3% v/v final)
20 g agar (2% w/v final)
970 ml H_2O
Autoclave
Add 2.5 ml 40% (w/v) dextrose (0.1% final; sterilized separately by autoclaving or filtering)

Special-Purpose Complex Media

Galactose indicator medium

Several gene expression systems used in yeast research rely on a *GAL* (galactose) promoter for regulated expression. When such a system fails to work as expected, one source of trouble is the use of yeast strains that are unable to respond to galactose. Strains that respond to galactose will ferment it and release acid into the medium. Acidification causes the indicator dye to change color from blue to yellow.

10 g Bacto yeast extract (1% w/v final)
20 g Bacto Peptone (2% w/v final)
20 g agar (2% w/v final)
930 ml H_2O
Autoclave
Add 50 ml 40% (w/v) galactose (2% final; sterilized separately by autoclaving or filtering)
Add 20 ml 0.4% (w/v) bromthymol blue (0.08% final; sterilized separately by filtering)

Sporulation medium

Saccharomyces strains can be maintained as either haploids or diploids. Most diploid strains will sporulate when grown on a poor source of carbon and nitrogen.

10 g potassium acetate (1% w/v final)
1 g Bacto yeast extract (0.1% w/v final)
0.5 g dextrose (0.05% w/v final)
20 g agar (2% w/v final)
1 liter H_2O
Autoclave

For this recipe dextrose can be added prior to autoclaving.

Presporulation (PSP) medium

Sporulation of some *Saccharomyces* strains is facilitated by growth on a rich medium prior to plating on sporulation medium.

8 g Bacto yeast extract (0.8% w/v final)
3 g Bacto Peptone (0.3% w/v final)
20 g agar (2% w/v final)
750 ml H_2O
Autoclave
Add 250 ml warm 40% (w/v) dextrose (10% final; sterilized separately by autoclaving or filtering)

The dextrose solution should be warmed to ~40° to 55°C before it is added, so that the agar does not harden prematurely.

Dissection agar

Preparation of dissection agar is frequently tailored to the configuration of the dissection apparatus. In general, thin slabs of YPD medium (10 ml per standard 15 × 100–mm petri plate) are used. Best results are obtained with light-colored (most transparent) medium, which can be facilitated by minimizing the length of time it is heated and by autoclaving the dextrose separately.

Defined Media

It is generally best to add inositol to all synthetic media. Although wild-type yeast strains are prototrophic for inositol, some laboratory strains bear an *ino1* mutation. Unfortunately, this mutation is sometimes forgotten in reporting the genotype because yeast nitrogen base (YNB) contains enough inositol that the effect of the mutation is not easy to see. However, the amount of inositol in YNB is not enough to fully supplement the auxotrophy, and selection for compensating mutations can occur.

Salts and dextrose (SD) medium

This minimal medium contains enough nutrients to support growth of prototrophic yeast strains (strains having no nutritional requirements).

6.7 g Bacto yeast nitrogen base (YNB) without amino acids (0.67% w/v final)
20 g agar (2% w/v final)
950 ml H_2O
Autoclave
Add 50 ml 40% (w/v) dextrose (2% final; sterilized separately by autoclaving or filtering)

Similar media can be made by substituting other sugars for dextrose. Generally, Saccharomyces grows best on dextrose, but specific experiments may require replacement of dextrose with another sugar. The most common substitutes are SGal (2% galactose) and SRaf (2% raffinose). Not all yeast strains are capable of growing on these alternative sugars. Growth on raffinose is sometimes facilitated by adding 0.05% (w/v) dextrose.

Vendors carry several similar types of YNB, e.g., with or without amino acids or ammonium sulfate. YNB in this recipe includes ammonium sulfate. Although ammonium sulfate is the preferred nitrogen source, Saccharomyces will grow on other nitrogen sources, albeit more slowly. For these media, YNB without ammonium sulfate and without amino acids is used at 1.7 g/liter. Nitrogen sources include ammonium sulfate (0.5% w/v), arginine (0.1% w/v), asparagine (0.1% w/v), or proline (0.1% w/v).

Most yeast strains require one or more nutrients that are not included in SD medium. These nutrients can be added in various ways (see supplemented SD medium and SC medium).

Supplemented SD medium

Add supplements (see Table 1.6.1) individually or in groups to SD medium. Alternatively, add supplements to individual plates by spreading, and allow one day for supplement(s) to permeate the medium. Add most supplements before autoclaving; add tryptophan and histidine, which are sensitive to heat, after autoclaving. Store tryptophan in the dark, as it is also sensitive to prolonged exposure to light.

Synthetic complete (SC) medium

As an alternative to adding individual nutrients to SD medium, add a dry mixture of the most common supplements. Combine the dry reagents listed in Table 1.6.1 and mix thoroughly using a coffee grinder or a mortar and pestle. Then add the mixture before sterilizing the medium, without tryptophan and histidine, which should be added after autoclaving.

Alternative mixtures can be constructed (e.g., SC minus tryptophan) by omitting specific ingredients. These mixtures are sometimes referred to as "dropout" media—e.g., SC –Trp dropout medium.

5-Fluoroorotic acid (5-FOA) medium

Selection for *URA3* function is used for the stable maintenance of many yeast plasmids. For some experiments, however, loss of the *URA3* gene is desired. The *URA3* gene product converts 5-FOA into a toxin. Therefore, strains that have lost the *URA3* gene can be identified by their resistance to 5-FOA.

continued

Solution 1:
1 g 5-FOA (0.1% w/v final)
500 ml H_2O
6.7 g yeast nitrogen base (YNB) – amino acids (0.67% w/v final)
50 mg uracil (50 µg/ml final)
20 g dextrose (2% w/v final)
Appropriate supplements (see Table 1.6.1)

Add 5-FOA, H_2O, and a stir bar to a 1-liter flask. Autoclave or stir over a low to medium heat ~1 hr to dissolve completely. Add YNB, uracil, glucose, and supplements. Choose supplements from Table 1.6.1 based on the genotype of the strain, but always add uracil. If supplements are added in liquid form, be sure to adjust the volume of H_2O accordingly. Dissolve completely (warming to 55°C is useful) and filter sterilize.

Solution 2:
20 g agar (2% w/v final)
500 ml H_2O

Mix agar and H_2O in a 2-liter flask, autoclave, and cool to ≤80°C.

5-FOA medium:
Mix solution 1 into cooled solution 2
Cool to 55°C
Pour into petri dishes

Table 1.6.1 Common Supplements Used In Defined Media

Nutrient	Stock concentration (g/100 ml)	Stock volume per liter medium (ml)	Final concentration (mg/liter)[a]	Stock volume to spread on plate (ml)
Adenine sulfate[b]	0.2	10	20	0.2
L-Arginine·Cl	1	2	20	0.1
L-Aspartic acid	1	10	100	0.2
L-Glutamic acid	1	10	100	0.2
L-Histidine·Cl	1	2	20	0.1
L-Isoleucine	1	3	30	0.1
L-Leucine	1	3	30	0.1
L-Lysine·Cl	1	3	30	0.1
L-Methionine	1	2	20	0.1
Myo-inositol[c]	3.6	1	36	0.02
L-Phenylalanine	1	5	50	0.1
L-Serine	8	5	400	0.1
L-Threonine	4	5	200	0.1
L-Tryptophan	1	2	20	0.1
L-Tyrosine	0.2	15	30	0.2
Uracil	0.2	10	20	0.2
L-Valine	3	5	150	0.1

[a]Mixtures of supplements can be made in advance by weighing out individual components in the ratio indicated by this column; mixing the dry reagents in a coffee grinder, mill, or mortar and pestle; and then weighing out the appropriate amount of the mixture.

[b]When working with *ade1* or *ade2* mutants, the amount of adenine should be increased three fold to prevent accumulation of red color.

[c]The traditional recipe for SC medium does not include inositol. Inositol is added as a precaution because some common laboratory strains contain the *ino1* mutation, which is not always documented. YNB contains enough inositol for significant, albeit incomplete, supplementation, which makes recognizing the presence of an *ino1* mutation difficult.

Xgal medium

Wild-type *Saccharomyces* strains lack endogenous β-galactosidase activity, which facilitates use of the *E. coli lacZ*-encoded β-galactosidase enzyme as a reporter activity. This plate assay provides a semi-quantitative assay for activity.

6.7 g yeast nitrogen base (YNB) − amino acids (0.67% w/v final)
Appropriate supplements (see Table 1.6.1)
20 g agar (2% w/v final)
850 ml H_2O
Autoclave
Cool to 65°C
Add 100 ml 0.7 M potassium phosphate, pH 7.0 (70 mM final; best if warmed prior to adding to agar)
Add 50 ml 40% (w/v) dextrose (2% final; sterilized separately by autoclaving or filtering)
Add 2 ml 20 mg/ml 5-bromo-4-chloro-3-indolyl-β-D-galactoside (Xgal) in 100% *N*,*N*-dimethylformamide (DMF)

Xgal can be prepared in advance, aliquoted, and stored as a frozen stock. Supplements are chosen from Table 1.6.1 based on the genotype of the strain. If supplements are added in liquid form, the volume of H_2O should be adjusted accordingly.

Xgal plates are frequently made as above, but without the substrate Xgal. Approximately 1 to 2 days prior to using the plates, 0.1 ml of 20 mg/ml Xgal stock is spread across the surface of the plate and allowed to diffuse through the agar.

GENERAL CONSIDERATIONS FOR CULTURING YEAST

For the most part, culturing *Saccharomyces* is fairly straightforward. Wild-type strains are typically grown at 30°C, although they are capable of growing at a wide range of temperatures. Many strains will grow to some extent at temperatures as low as 4°C and at least as high as 37°C. Liquid or solid media can be used. Liquid cultures grow better with aeration, but this is not required. For the most consistent results, it is important to maintain a reproducible level of aeration with each experiment by marking or taping the speed dial of the shaker.

Culturing Yeast in Liquid Media

Yeast strains are readily cultured in liquid media. For most experiments it is best to grow them with agitation, as this prevents them from settling to the bottom of the liquid. When cultures are grown in flasks, the liquid volume should be limited to 20% of the flask volume, although this guideline is sometimes exceeded. Another standard method is to grow 1- to 5-ml cultures in 18 × 150–mm glass tubes that are rotated on a tube roller (e.g., New Brunswick). Metal or plastic caps are readily available for these tubes. Many brands of tabletop or preparative centrifuges accommodate these tubes directly.

Yeast cells can be transferred from liquid or solid cultures to a new liquid culture by many methods. One popular method is to use sterile disposable 15-cm-long applicator sticks. The sticks can be autoclaved in capped culture tubes. Another popular method is to use nonflavored, noncolored wooden toothpicks, which can be autoclaved in their original boxes.

For any given set of conditions—namely, yeast strain, medium, temperature, and agitation—a generation time and saturation density can be readily determined. Most strains grown with agitation in YPD medium at 30°C will double every 80 to 100 min. An overnight culture seeded with ~3×10^4 to 1×10^5 cells or a ~1-mm colony will typically

grow to ~3×10^7 cells/ml. After two days the culture should reach ~5×10^8 cells/ml. When grown in SD or SC medium, the generation time will be on the order of 120 to 150 min. An overnight culture will typically grow to ~5×10^6 cells/ml.

The number of cells per milliliter of culture can be estimated using a spectrophotometer. With a standard 1-cm-path-length cuvette at 600 nm, an optical density (OD_{600}) of 1.0 is equal to ~2×10^6 cells/ml. Because this method relies on measuring light scattering and not true absorbance of the culture, this rule of thumb should be confirmed for each specific spectrophotometer. The conversion factor can vary widely depending on the configuration of the instrument. The spectrophotometer can be calibrated by comparing the OD_{600} reading with an accurate cell count obtained with a hemacytometer or by counting the number of colonies that can be grown from a diluted sample. Once an instrument is calibrated, however, the value should not change from day to day.

Culturing Yeast on Solid Media

Yeast strains are readily cultured on solid media. For most experiments it is best to use a 30°C incubator. While growth rates are hard to establish on solid media, colonies formed from single cells are generally visible to the unaided eye after 2 or 3 days and patches of cells are visible after one day. There are five common methods for transferring yeast cells to solid media: (1) spread plating a suspension of cells, (2) streaking cells with a toothpick or inoculating loop, (3) patching cells with a toothpick or inoculating loop, (4) replica plating from an existing plate, and (5) suspending cells in top agar and pouring them over an agar plate. Each of these is described below.

Spread plating cells

In this method, an appropriate number of yeast cells are calculated and suspended in a small volume of liquid, typically 0.05 to 0.25 ml. The appropriate cell number will depend on the nature of the experiment. It is generally desirable to produce 20 to 200 colonies per plate.

A glass rod can be fashioned into a spreader as follows. A roughly 30-cm length of 3-mm glass rod is cut and both ends are smoothed in a flame. Hold the rod over a bunsen burner flame ~5 cm from one end. When the glass is pliable, bend it ~45°. Hold the rod over the flame ~10 cm from the same end and bend it another 45°, so that one end has now formed a triangle. Optionally, the point at which the triangle section meets the shaft can be bent 30° from the plane of the triangle to make the spreader more ergonomic. Prior to use the spreader is sterilized by dipping the triangle end in 70% to 95% ethanol and igniting it in a flame. Before applying to a cell suspension, the spreader should be cooled by touching it onto the surface of the agar plate or onto the condensation that frequently collects on the lid of the plate. Alternatively, an unmodified sterile glass pipet can be used to spread cells, but this is more difficult. Plastic pipets are not recommended as they tear the agar.

Although not required, spread plating works better if an inoculating turntable (available from Fisher Scientific and other laboratory suppliers) is used. An inoculation turntable consists of a solid base and a freely rotating platform that is the approximate size of a petri plate.

The cells should be spread across the plate immediately after pipetting them onto the agar. If a turntable is used, give it a gentle push. If it is not used, the plate can be rotated frequently by hand. The flat part of the triangle is used to push the cells back and forth across the agar. The technique of spread plating yeast cells, especially with a turntable, differs from spread plating bacteria in one notable respect: yeast cells are more likely to be pushed to the periphery of the plate. To avoid this problem, gently push the "elbow" of the spreader into edge of the plate for a few rotations and then, while the plate is still

rotating, push the elbow back and forth across the plate in a chord that is roughly half way between the center and the edge of the plate.

Streaking cells

The streaking method is used for isolating single colonies of yeast. Single isolated colonies are desirable because, when the procedure is done properly, each colony is derived from a single cell, so that every cell in the colony is genetically identical.

In this method, the plate is divided into four pie-shaped sections and one sample of yeast cells is streaked for single colonies in each section. With practice and increasing skill, the plate can be divided into six or more sections. This method is best performed with sterile toothpicks. A minimal amount of yeast cells are picked with the toothpick and placed in a spot near the edge of the plate. A clean toothpick is used to smear the cells back and forth in a 4×10–mm patch with the long axis of the patch running roughly parallel to the lip of the plate. A third toothpick is drawn once across the short axis of the patch and for another ~15 mm towards the center of the plate. A fourth toothpick is dragged on the agar in an arc that parallels the plate edge and crosses the line made by the third toothpick; the toothpick is then drawn in a series of shorter and shorter arcs that parallel the plate edge and move consecutively towards the center of the plate. The plate is then incubated for 2 to 4 days until individual colonies are visible.

Patching cells

Once pure strains of yeast have been isolated, it is frequently useful to compile a set of the strains on a single agar plate, either for short-term storage or in preparation for testing them in parallel by replica plating. Between 30 and 100 patches can be arranged on a standard 100-mm petri plate.

Before patching yeast from one plate to another, an ordered grid is prepared on a piece of paper and is inserted in a clear plastic sleeve. A standard sheet of paper (A4 or 8×10–in.) can accommodate four identical grids for 100-mm petri plates. The agar plates are set on the grid with the lids facing up. The plates can be held in place with a piece of double-sided tape or with tape that has been rolled into a circle. Two pieces of tape are much more effective than one in holding the plates in place. Either sterile toothpicks or inoculating loops can be used for the patch technique, but toothpicks work better. The patches are made by barely touching a source colony with the end of the toothpick and then gently dragging the toothpick over a ~2-mm diameter spot on the recipient plate.

Replica plating cells

Replica plating is used for testing multiple strains or isolates in parallel. This technique requires three specialized pieces of equipment: a replica block, a locking ring, and velveteen cloth squares. All three are available commercially from Fisher Scientific, Cora Styles, and other suppliers. The diameter of the block must be designed for the diameter of the petri plates being used; 95-mm diameter plates will not work with a block designed for 100-mm plates. Having the correct type of cloth is also essential for replica plating to work.

Prior to the first use and after each subsequent use, the cloth squares are laundered in any standard washer and dryer with standard laundry detergent. If recombinant organisms are used, it is prudent to soak the contaminated squares in a disinfectant prior to laundering them. Care should be taken to monitor the lint screen during drying because a significant amount of lint is produced; failure to do this can damage the clothes dryer. After the squares are dried, excess lint can be removed with a standard lint brush, although this is not always necessary. The squares are sterilized by wrapping them in heavy-gage aluminum foil and autoclaving them. Depending on usage patterns, 5 to 50 squares can be stacked, soft-side down, on the center of a large piece of foil. The foil is then folded

around the stack to make a securely closed package that is held with a piece of tape. The package is then autoclaved on the dry cycle.

A *master* plate is made by spread plating, streaking, or patching cells. Typically, the master plate is incubated for 1 to 3 days before use. The master plate works best if the colonies are not extremely large and overgrown. Each good-quality master can be used to produce up to eight replicas.

The replica block and locking ring can be cleaned by squirting them with 70% ethanol and drying them with a paper towel. The package of velvets is carefully opened with the soft side of the cloth squares facing down. One velvet is picked up by the corner, turned over, and placed on the block. The package should then be partially closed to prevent contamination. The locking ring is pushed down so that the velvet is drawn tight. The master plate is gently but firmly pushed onto the surface of the velvet and then lifted up again. Each test plate is then pushed onto the velvet in the same manner.

Suspending cells in top agar

This is probably the least preferred method unless the yeast cell wall has been compromised and an osmotic support is needed. A stock of sterile Bacto agar is prepared in water or medium. The agar should be prepared so that the final concentration is between 0.5% and 1.0% after adding the yeast suspension. Once it has been sterilized, the agar stock solution can be melted any number of times in a boiling water bath. For a 100-mm plate, 3 to 10 ml of the melted agar is transferred to a sterile tube and cooled to 37°C. A small volume of yeast cells are added, and the suspension is mixed and poured over the surface of an agar plate. After a few minutes, the plates can be inverted and incubated for 2 to 4 days at 30°C.

Storage of Yeast Strains

Short-term storage of yeast strains

Most yeast strains will survive extended periods of storage at room temperature or 4°C; however, this type of storage should not be relied upon. Storage at these temperatures may result in loss of viability, or worse, selection of uncharacterized mutants that survive better under these conditions.

Long-term storage in glycerol

Two methods are commonly used for long-term storage of yeast strains: glycerol/water vials at −80°C and agar slants at room temperature or 4°C. The glycerol vials are the preferred method of storage.

Yeast strains can be stored indefinitely at −80°C in 15% (v/v) glycerol in water. Any glass vial may be used; however, 2-ml Wheaton vials (in a lab file) are an ideal size. These vials can be stored in standard freezer storage boxes (100 per box).

To prepare the vials, 1 ml of 15% glycerol solution is dispensed per vial, lids are placed loosely on the vials, and the vials are autoclaved. As soon as the vials are cool enough to handle, the lids are tightened. Prior to use, the vials may be stored at room temperature indefinitely.

To store the strain, the vials are labeled and a single colony is transferred using a sterile toothpick or inoculating loop from a fresh plate into each vial. Each vial is shaken until the colony is evenly distributed in the liquid. The vials are then transferred to a −80°C freezer. The best colonies are 1 to 3 days old, although older ones will work.

Labeling the vials can be difficult because some brands of label fall off at such cold temperatures and some inks run when they come in contact with freezer frost. One method

that works is to use good quality office labels and to cover the labels with one wrap of cellophane tape. The tape sticks to itself very well and protects the writing.

A sample of a liquid culture may be preserved by this method, although it is not recommended. If liquid cultures are to be preserved, the concentration of glycerol should be adjusted accordingly to allow for dilution by the liquid culture.

Long-term storage in YPAD slants

YPAD medium is prepared and the agar is dissolved into the medium in a boiling water bath. Portions of 1.5 ml are dispensed into 3-ml vials, screw cap lids are applied loosely, and the medium is autoclaved. After autoclaving, the vials are inclined so that the agar is just below the neck of the vial. After drying for 1 to 2 days, the lids are tightened.

A small sample of a fresh culture is transferred to the agar slant using a sterile toothpick or inoculating loop. The culture may be spread across the agar surface or it may be pushed into the agar. The screw-cap lid is tightened. Parafilm can be wrapped around the lid to improve the seal. The slants are stored in a cool (23°C) dark place. Viable yeasts can be recovered from the slants for ≥ 3 years.

Shipping Yeast Strains

Yeast strains can be shipped by any of several different methods. The shipped cultures may be dried, on agar, or in liquid as long as sterility is maintained. The simplest method is to use sterile swabs. Other methods generally involve more preparation time or are more vulnerable to damage in the mail.

Shipping yeast strains in sterile swabs

One convenient and safe method is to use sterile swabs for taking throat cultures, such as the Culturette system from Becton Dickinson. These systems contain a sterile swab and a saline solution housed in a leak-proof container that is resistant to rough handling. To use this system, the package is opened, a colony is swabbed from a fresh culture plate, the swab is inserted back into the package, and the package is labeled and taped or stapled shut. To revive the strain, the swab is removed and dabbed on a small area of a petri plate containing YPD or another appropriate medium. Toothpicks are then used to streak for single colonies and the plate is incubated.

Shipping yeast strains on filter paper

Yeast cultures can be dried onto filter paper and stored or transported. This method was developed by at the YGSC by John Bassel, and is best used for strains that are frequently sent out, because multiple filters may be prepared once and stored up to several years at 4°C. Sterile filter paper squares (Whatman no. 4, 1 × 1 cm) are prepared by packaging them in a sheet of heavy-duty aluminum foil (7 × 6 cm) and autoclaving the packages. The strain to be shipped is grown exponentially in YEPD and a 5-µl sample of culture is added to 0.2 ml evaporated milk. The milk is handled aseptically but is not sterilized. The filter paper squares are immersed in the milk suspension of cells and returned to the aluminum foil packet. The packets are folded only once and stored in a desiccator at 4°C for 2 to 3 weeks or until the liquid congeals into a hard, dry lump. Following desiccation, the packets are folded tightly and stored at 4°C in plastic boxes. To revive the strain, the filter paper is swiped on a petri plate of YPD or other appropriate medium and returned to its packet. Toothpicks are used to streak for single colonies and the plate is incubated.

Shipping yeast strains by other methods

Other methods include sending agar slants (described above) or petri plates. Care should be taken in packaging petri plates because they are easily broken in the mail.

BY-2 Cells: Culture and Transformation for Live Cell Imaging

This unit describes the production of stable transformants of tobacco Bright Yellow 2 (BY-2) cells with such fluorescent markers as the green fluorescent protein (GFP) from the jellyfish *Aequoria victoria* to study subcellular dynamics. These markers are increasingly used in plant cell biology, and the number of fluorescent proteins available for plant cell imaging and physiology is increasing almost exponentially (Brandizzi et al., 2002; Table 1.7.1).

BY-2 cells were initially established for mass production of raw material for cigarettes, but they have lately been described as the HeLa cell of the biology of higher plants (Nagata et al., 1992). This title is well deserved, as these cells are amenable to cell culture, transformation, and manipulation. BY-2 cells have a high synchronization efficiency and growth rate, and they are homogeneous. Because of their good size and the absence of autofluorescent chloroplasts, they are also easily transformed and imaged. When BY-2 cells are grown on solid medium they form calli. Calli are aggregated cells that arise from multiple divisions of a single cell—similar to a bacterial colony. The BY-2 calli are used as a way to keep a stock of cells that can be used to start suspension cultures as required.

Table 1.7.1 Examples of BY-2 Cellular Components Highlighted with Fluorescent Proteins[a]

Construct	Cellular location	Fluorescent protein	Reference
Korrigan (KOR1) and mutants	Golgi apparatus, growing cell plates	GFP	Zuo et al., 2000
Soybean α-1,2 mannosidase (Gm-Man1)	Golgi apparatus	GFP	Nebenführ et al., 2000
Rat sialyltransferase 1 (ST)	Golgi apparatus	GFP	Saint-Jore et al., 2002
N-acetylglucosaminyl transferase I (Nag)	Golgi apparatus and NE	RFP	Dixit and Cyr, 2002
ER-targeted GFP-HDEL	ER	GFP	Nebenführ et al., 2000
Arabidopsis thaliana RAN GTPase activating protein 1 (AtRanGAP1) and deletion clones	NE and other structures	GFP	Rose and Meier, 2001
Truncated lamin B receptor (LBR)	NE	GFP	Irons et al., 2003
Matrix attachment filament-like protein (MAF1)	Outer NE and other cellular structures	GFP	Rose and Meier, 2001
		CFP	Dixit and Cyr, 2002
Actin-binding domain of a mouse talin	Actin	GFP	Kost et al., 1998
Tubulin	Microtubules	GFP	Kumagai et al., 2001
Microtubule-binding domain (MBD)	Microtubule-binding domain	GFP	Granger and Cyr, 2000 Dixit and Cyr, 2002
Cyclin B1 and mutants	Cytoplasm and nucleus	GFP	Criqui et al., 2001

[a]Abbreviations: CFP, cyan fluorescent protein; ER, endoplasmic reticulum; GFP green fluorescent protein; NE, nuclear envelope; RFP, Red fluorescent protein.

Current Protocols in Cell Biology (2003) 1.7.1-1.7.16

Within a month a callus can grow to several centimeters in diameter, at which point a small piece (~2 to 5 mm^2 lump) should be transferred to fresh solid medium to keep the cells supplied with nutrients. If cells are already in suspension culture, stock plates can be made by plating 1 ml of suspension cells on solid medium. BY-2 calli are easily broken up by agitation in liquid medium. The establishment of a BY-2 suspension culture is described in Basic Protocol 1; Basic Protocol 2 describes their routine culturing.

Transient transformation of BY-2 cells may be achieved after protoplasting and electroporation (F.B. and C.H., unpub. observ.; *UNIT 20.5*) or directly by particle bombardment (An, 1985) and electroporation (Koscianska and Wypijewski, 2001; *UNIT 20.5*). Co-cultivation with *Agrobacterium tumefaciens* also easily leads to stable transformation.

BY-2 cells are readily susceptible to inducible expression systems such as the tetracycline repressor and, even more tightly, the glucocorticoid-inducible system, neither of which suffers from leakage of gene expression in the absence of the inducer (Criqui et al., 2000; David and Perrot-Rechenmann, 2001; Nishihama et al., 2001; Geelen et al., 2002). Besides chemical inducers, gene expression in the BY-2 cell system may be induced by heat shock. In this respect, the heat-sensitive promoter HSP18.2 may be used as an alternative to chemical inducers with fast kinetic responses (Yoshida et al., 1995; Shinmyo et al., 1998).

BY-2 cells can easily be used for following the cell cycle and for studying the effect of test compounds on its progression. As the authors describe in this unit, aphidicolin synchronization (Basic Protocol 3) may produce a good mitotic index. The current availability of cellular fluorescent markers opens the exciting possibility to follow the dynamics of organelles and the cytoskeleton during the cell cycle.

The transformation of BY-2 cells with *Agrobacterium* that contains a reporter construct in a suitable binary vector is an easy, quick, and very reliable method (Basic Protocol 4). In comparison with protoplast-based protocols, this method offers several advantages over transient transformation. These include working with a relatively unperturbed cellular environment, little variability of DNA expression among cells, longer imaging periods, amenability to synchronization of mitosis, and ease of handling. BY-2 cells can also be stably transformed with two constructs, each expressing a different fluorescent marker (Alternate Protocol).

When GFP is expressed as a chimeric protein either with selected peptide targeting sequences or with complete proteins that are resident in subcellular locations, expression of the chimeric constructs can be observed in living cells using conventional epifluorescence or, preferably, confocal laser scanning microscopes.

CAUTION: BY-2 cells are unlikely to survive outside the laboratory culture environment. It is, however, good laboratory practice to treat transformed BY-2 cells as biological hazards and therefore to dispose of them accordingly. The cells in culture should be killed by autoclaving.

NOTE: All procedures should be carried out under sterile conditions in a laminar flow hood sprayed with 70% (v/v) ethanol (and allowed to stand for 20 min before use). A heat bead sterilizer or flame should be used to sterilize metallic tools such as forceps and razor blades (tools must be cool before using on biological materials). All items placed in the hood should be sprayed with 70% (v/v) ethanol.

ESTABLISHING A BY-2 SUSPENSION CULTURE

This protocol describes the method to establish a BY-2 cell suspension from a BY-2 or another tobacco callus. Subculturing the cells is technically termed passaging (also see Basic Protocol 2). It is advisable to work in duplicate or even triplicate when establishing a suspension culture. This allows initiation of fresh suspensions of the same transformed cell line should any contamination occur.

Materials

Calli of wild-type and/or transformed BY-2 cells (available from various laboratories) grown on solid BY-2 medium (see recipe) in petri dish
50-ml conical flasks containing 20 ml liquid BY-2 medium (see recipe), covered with aluminum foil and autoclaved
Suitable filter-sterilized antibiotics, for culturing transformed BY-2 cells only

Razor blades, sterile
Packet of aluminum foil squares for covering flasks, sterile
Shaking incubator, 25°C

1. Cut a 2-cm^2 piece of wild-type or transformed BY-2 callus with a sterile razor blade directly on the petri dish on which the calli are growing.

2. Loosen aluminium foil from top of a sterile 50-ml conical flask containing 20 ml liquid BY-2 medium. Lightly flame neck of flask. Add suitable filter-sterilized antibiotics if needed. Open a sterile packet of aluminum foil squares so that they are readily accessible.

   This will aid the speed at which the items in the hood can be handled and hence will reduce the possibility of contamination.

   The flasks should be open for as short a time as possible to avoid contamination. Avoid passing anything (e.g., hands or sleeves) over the open flasks.

   The preparation and storage of antibiotics should be according to manufacturer's instructions. Antibiotics should be filter sterilized and handled as sterile material. To filter sterilize the antibiotic solution, a stock solution of the required concentration (usually 100×) is prepared. The antibiotic solution is aspirated into a sterile syringe without a needle. A 0.2-μm syringe filter is attached to the syringe, and the solution is pressed through the filter into a sterile tube.

3. Transfer the cut callus to the 50-ml flask with medium.

   When establishing suspension cultures it is best to begin in a small volume as the cells grow better. To encourage growth the authors have found that subculturing newly established suspensions 1 to 2 weeks after placing calli in liquid medium, the culture should be quite thick—like runny tomato ketchup. Passaging cultures at lower dilution ratio (1:10 instead of 1:20) can also encourage good suspension culture growth. Once the cells are growing well in the small volume they can be subcultured into larger volumes of medium.

4. Gently pipet the culturing medium up and down to break up callus.

5. Reseal the flask with a new square of aluminium foil.

6. Place cells in a shaking incubator set at 130 rpm and 25°C with illumination of choice.

   A flat-bed orbital platform in a 25°C culture room may also be used.

   BY-2 cell suspensions may be kept in the dark. An illumination regime of 16 hr light and 8 hr dark can also be used.

   Cells should be subcultured after 7 days (see Basic Protocol 2).

BASIC PROTOCOL 2

ROUTINE CULTURE OF BY-2 CELLS

This protocol describes the routine method to culture BY-2 cells and to maintain suspension and callus cultures. As described in Figure 1.7.1, the protocol requires liquid and solid media.

Materials

50-ml conical flasks containing 20 ml liquid BY-2 medium (see recipe), covered with aluminum foil and autoclaved
Suitable filter-sterilized antibiotics, for transformed BY-2 cells only
Wild-type or transformed stationary-phase BY-2 cells (i.e., 7-day-old cultures) grown in suspension (see Basic Protocol 1)

Packet of aluminum foil squares for covering flasks, sterile
Trimmed 1-ml pipet tips (i.e., 4 to 5 mm cut off from narrow end), sterile
Shaking incubator, 25°C

1. Loosen aluminium foil from top of a sterile 50-ml conical flask containing 20 ml liquid BY-2 medium. Lightly flame neck of flask. Add suitable filter-sterilized antibiotics if needed. Open a sterile packet of aluminum foil squares so that they are readily accessible.

   This will aid the speed at which the items in the hood can be handled and hence will reduce the possibility of contamination.

   The flasks should be open for as short a time as possible to avoid contamination. Avoid passing anything (e.g., hands or sleeves) over the open flasks.

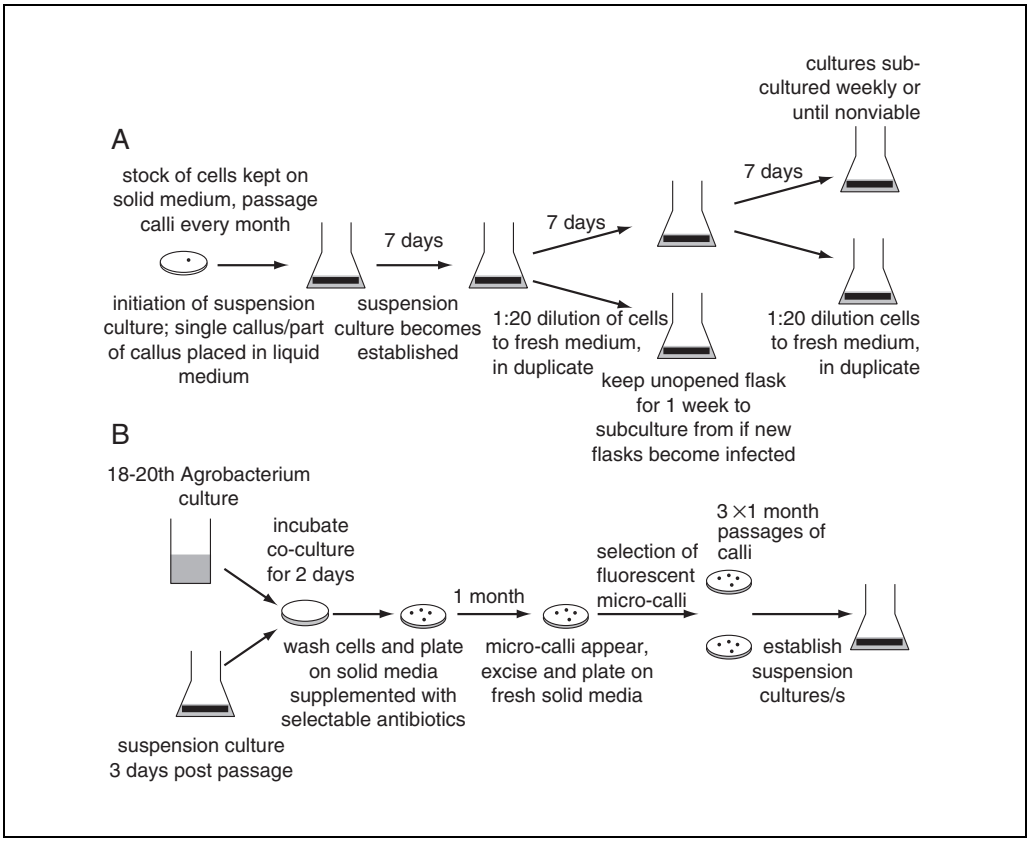

Figure 1.7.1 (**A**) Routine culture of BY-2 cells (see Basic Protocol 2). (**B**) Production of stable transformants (see Basic Protocol 4).

The preparation and storage of antibiotics should be according to manufacturer's instructions. Antibiotics should be filter sterilized and handled as sterile material. To filter sterilize the antibiotic solution, a stock solution of the required concentration (usually 100×) is prepared. The antibiotic solution is aspirated into a sterile syringe without a needle. A 0.2-μm syringe filter is attached to the syringe, and the solution is pressed through the filter into a sterile tube.

2. Use a trimmed 1-ml pipet tip to take a 1-ml aliquot of wild-type or transformed stationary-phase BY-2 cells from their flask.

   The ends of uncut tips will be too narrow to allow easy entry of cells. A razor blade can be used to cut the tips, and cut tips are autoclaved as normal.

   For larger volumes of cells, use 100 ml BY-2 medium in a 250-ml flask. For 100-ml suspension cultures, passage 10 ml cells into 100 ml fresh medium.

3. Remove foil from the new flask and pipet the cell aliquot directly into the fresh medium.

4. Cover the new flask with a new square of aluminum foil and seal firmly.

5. Place cells in a shaking incubator set at 130 rpm and 25°C with illumination of choice for 7 days.

   A flat-bed orbital platform in a 25°C culture room may also be used.

   BY-2 cell suspensions may be kept in the dark. An illumination regime of 16 hr light and 8 hr dark can also be used.

   After 7 days, cells should be passaged again.

6. Passage cells every 7 days.

APHIDICOLIN-MEDIATED SYNCHRONIZATION OF CELL CULTURES

BASIC PROTOCOL 3

Synchronization of cultures can be achieved by a variety of methods, which include mineral and hormone starvation, hydroxyurea treatment, heat shock, light-dark cycle control, or chemical inducers, such as aphidicolin. Aphidicolin is a toxin produced by the fungus *Cephalosporium aphidicolia*, and it acts as a specific and reversible inhibitor of DNA polymerase α (Ikegami et al., 1978). In the presence of this compound, cells are blocked in G1; when aphidicolin is washed out of the suspension, the cells are released from G1 and the cell cycle progresses to S phase (see Fig. 1.7.2; Menges and Murray, 2002).

The following describes how to synchronize BY-2 cells with aphidicolin. With this method it is possible to achieve a 40% mitotic index. Higher synchrony is possible using treatments such as propyzamide (1.6 mg/liter) 6 hr after aphidicolin release (Nagata et al., 1992). However, as this compound may perturb microtubule structure, its use may not be desirable if subcellular dynamics, such as the cell cycle, are being studied.

With the method described below, cells generally reach M phase 10 to 11 hr after the aphidicolin wash.

CAUTION: Aphidicolin is very toxic and should be handled with great care. Aphidicolin should be handled wearing gloves and in accordance with general good lab practice (i.e., with lab coat and eye protection). Inhalation of dust should be avoided. The chemical should be diluted in at least 1 liter of water and flushed down the drain.

Materials

50-ml conical flasks containing 20 ml liquid BY-2 medium (see recipe), covered with aluminum foil and autoclaved
5 mg/ml aphidicolin (Fisher) in dimethyl sulfoxide, store up to 1 yr at 4°C
Suitable filter-sterilized antibiotics, for transformed BY-2 cells only
Wild-type or transformed stationary-phase BY-2 cells (i.e., 7-day-old cultures) grown in suspension (see Basic Protocol 1)

Five 100-ml beakers, covered with aluminum foil and autoclaved
20-µm nylon filter mounted on a cut plastic autoclavable 50-ml beaker, sterile
Packet of aluminum foil squares for covering flasks, sterile
Trimmed 1-ml pipet tips (i.e., 4 to 5 mm cut off from narrow end), sterile
Shaking incubator, 25°C
1-liter liquid waste container

1. In a laminar flow hood, aliquot 80 ml BY-2 medium to each of five sterile 100-ml beakers.
2. Loosen aluminium foil from top of a sterile 50-ml conical flask containing 20 ml liquid BY-2 medium. Lightly flame neck of flask. Add 20 µl of 5 mg/ml aphidicolin and suitable filter-sterilized antibiotics, if needed. Open a sterile packet of aluminum foil squares so that they are readily accessible.

   This will aid the speed at which the items in the hood can be handled and hence will reduce the possibility of contamination.

   The flasks should be open for as short a time as possible to avoid contamination. Avoid passing anything (e.g., hands or sleeves) over the open flasks.

   The preparation and storage of antibiotics should be according to manufacturer's instructions. Antibiotics should be filter sterilized and handled as sterile material. To filter sterilize the antibiotic solution, a stock solution of the required concentration (usually 100×) is prepared. The antibiotic solution is aspirated into a sterile syringe without a needle. A 0.2-µm syringe filter is attached to the syringe, and the solution is pressed through the filter into a sterile tube.
3. Use a trimmed 1-ml pipet tip to take a 1-ml aliquot of wild-type or transformed stationary-phase BY-2 cells from their flask and transfer them to aphidicolin-supplemented medium.

   The ends of uncut tips will be too narrow to allow easy entry of cells. A razor blade can be used to cut the tips, and cut tips can be autoclaved as usual.
4. Cover the new flask with a new square of aluminium foil and seal firmly.
5. Place cells in a shaking incubator set at 130 rpm and 25°C and incubate 24 hr in the dark.
6. Hold a sterile 20-µm nylon filter mounted on a cut plastic 50-ml beaker over a sterile 1-liter liquid waste container and gently pour aphidicolin-treated cells onto the filter. Discard medium in liquid waste container.

   To construct the filter apparatus, the bottom end of a plastic beaker is cut off and discarded. A 2-cm section is cut from the bottom of the beaker. This ring is placed on top of the nylon filter, and then the filter and ring are inserted in the upper part of the beaker. In this way, the filter will be secured to the cut end of the beaker (see Fig. 1.7.2). The apparatus is wrapped in foil before autoclaving.
7. Quickly transfer filter with cells to a sterile 100-ml beaker containing 70 to 80 ml liquid BY-2 medium. Gently agitate cells in filter for 5 min.

   The transfers must be carried out quickly to prevent the cells from drying out.

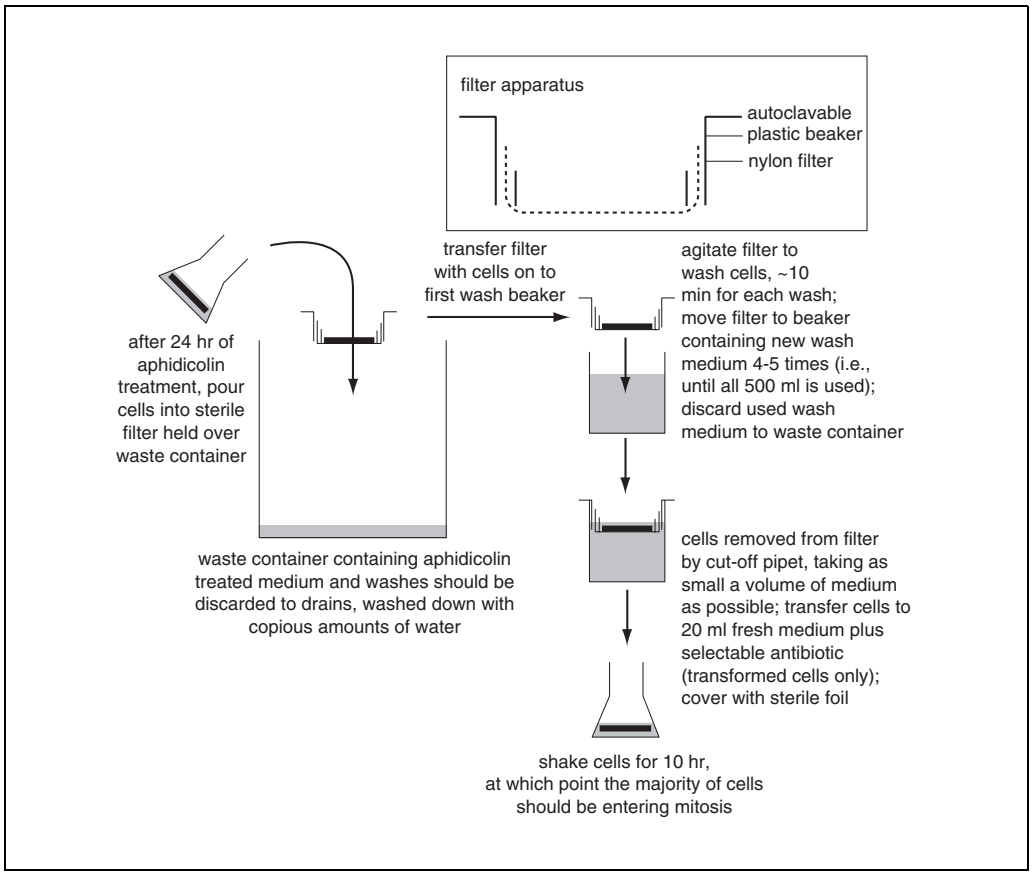

Figure 1.7.2 Aphidicolin synchronization of BY-2 suspension cultures.

8. Repeat transfer four more times, using a beaker with fresh medium each time. Discard used medium in liquid waste container.
9. Resuspend cells in new 50-ml flask containing 20 ml medium (with antibiotic if needed).
10. Shake cells 10 to 11 hr at 25°C.

At this point the majority of cells are entering into M phase.

STABLE TRANSFORMATION OF BY-2 CELLS MEDIATED BY *AGROBACTERIUM* FOR VISUALIZATION OF SUBCELLULAR ORGANELLES

BASIC PROTOCOL 4

This protocol involves the production of BY-2 lines that stably express GFP targeted to subcellular structures for subsequent live cell imaging (see Fig. 1.7.3). The procedures are suitable for other tobacco cell lines and may be modified for *Arabidopsis thaliana* suspension cells as well (Foreiter et al., 1997).

Stably transformed calli may be identified and selected directly on a petri dish with the aid of a portable UV lamp if the fluorescent protein used to transform cells has a UV peak excitation (such as the green fluorescent protein GFP5; Haseloff et al., 1997). Alternatively, a small portion of the callus may be analyzed with a conventional fluorescence microscope using the appropriate excitation-emission filter set to establish the positive transformation. In Figure 1.7.1B, a scheme of the production of stable transformants is given.

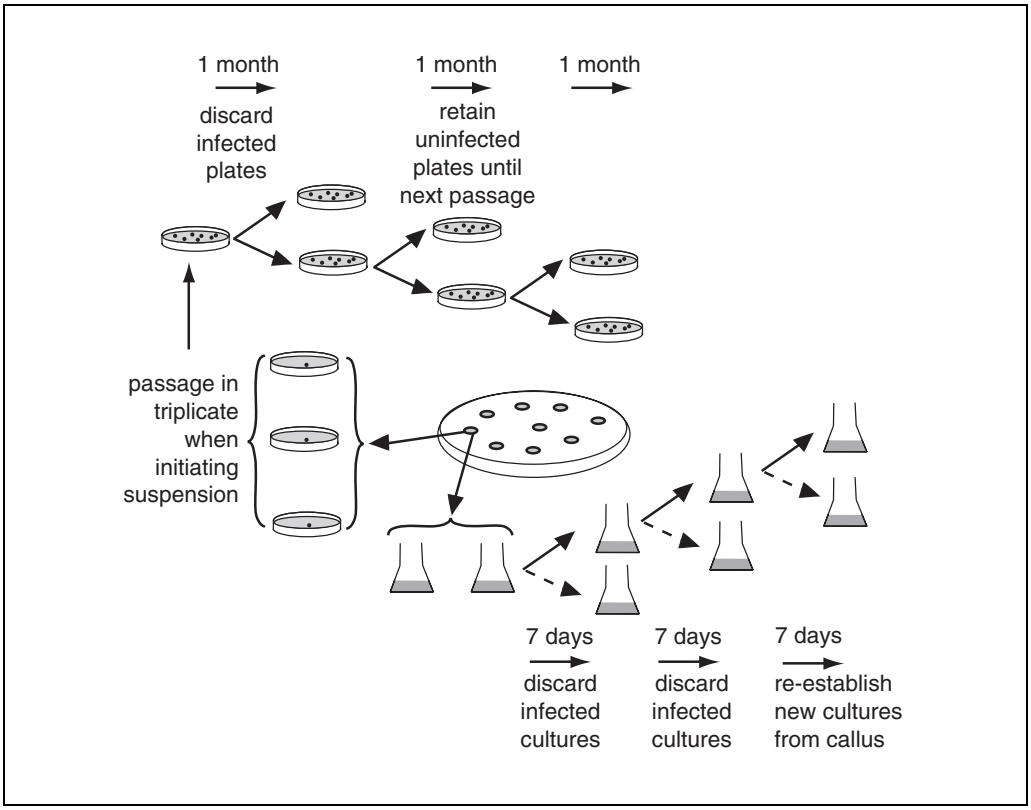

Figure 1.7.3 Passaging of stably transformed BY-2 cells.

NOTE: To transform BY-2 cells, a binary vector that can be transformed into agrobacteria is needed and can be the same as is used to transform tobacco and *Arabidopsis* plants. The binary vector, in which the fluorescent protein marker is subcloned, must carry two resistance markers (antibiotic resistance). One is a selectable marker for bacteria—to select positive transformants after bacterial transformation—and the other is a selectable marker for plants, which will allow the growth only of transformed plant cells. When working with these selection markers, it is very important to follow the manufacturer's instructions for the specific antibiotic in use. Factors such as light and pH, for example, may alter the properties of the antibiotics and thus affect the yield of stable transformants.

Materials

YEB medium (see recipe) containing appropriate filter-sterilized bacterial selection antibiotic

Agrobacterium tumefaciens transformed with vector containing appropriate GFP construct (e.g., strain GV3101::pMP90; Konez and Schell, 1986) transformed with another plasmid (e.g., pVKHI8En6, pBII21) which contains GFP and the insert of interest.

3-day-old wild-type BY-2 suspension culture (see Basic Protocol 1)

Liquid BY-2 medium (see recipe), sterile

Solid BY-2 medium (see recipe) plates with plant selectable antibiotic, 100 µg/ml carbenicillin (see recipe), and 20 µg/ml timentin (see recipe)

Shaking incubator, 25°C

Trimmed 1-ml pipet tips (i.e., 4 to 5 mm cut off from narrow end), sterile

5- and 10-cm petri dishes, sterile

1.5-ml microcentrifuge tubes, sterile

Forceps, sterile

Grow agrobacteria

1. Inoculate 5 ml YEB medium containing appropriate filter-sterilized bacterial selection antibiotic with a single colony of *Agrobacterium tumefaciens* transformed with a binary vector containing the appropriate GFP construct. Incubate 18 to 20 hr at 130 rpm and 25°C.

Transform BY-2 cells

2. Using a trimmed 1-ml pipet tip, transfer 1 ml of a 3-day-old wild-type BY-2 suspension culture to a sterile 5-cm petri dish.
3. Add 50 µl overnight *Agrobacterium* culture (step 1) and mix very gently with pipet tip.
4. Seal plate with Parafilm and incubate 2 days at 25°C in the dark without shaking.

   Alternatively, the plates may be wrapped in aluminium foil or placed in sealed boxes.

5. Add 1 ml fresh liquid BY-2 medium and collect the cells with a trimmed 1-ml pipet tip. Transfer cells to a sterile 1.5-ml microcentrifuge tube.

   Because the cell medium may have dried out during the 2-day incubation, 1 ml medium is added to facilitate collection of the cells.

   It may be necessary to divide cells between two tubes at this stage.

6. Allow BY-2 cells to settle to bottom of tube by gravity (2 min).
7. Remove excess medium and add 1 ml fresh liquid BY-2 medium. Resuspend cells by gently flicking the tube.
8. Repeat steps 6 and 7 two more times for a total of three washes.

Plate BY-2 cells

9. Resuspend cells with 1 ml fresh liquid BY-2 medium and use trimmed 1-ml pipet tip to transfer cells to solid BY-2 medium plates with plant selectable antibiotic, 100 µg/ml carbenicillin and 20 µg/ml Timentin.
10. Gently rotate plate to spread cells over the surface of the solid medium.
11. Seal plate with Parafilm and incubate in the dark at 25°C without shaking until microcalli appear (~1 month).
12. Use sterile forceps to excise individual microcalli and plate them onto fresh solid BY-2 medium plates with plant antibiotic. Place a maximum of nine calli per 10-cm plate.

    Calli can be screened, after excision and before passaging, for fluorescence using an UV lamp for constructs based on GFP5 (Haseloff et al., 1997); calli that have been successfully transformed will fluoresce.

13. Passage calli three times, allowing a 1-month interval between each passage, before establishing suspension cultures.

    Each passaging step except the first (when the microcalli are too small to divide) should be carried out in duplicate to ensure that, should one plate become contaminated, there is still another stock plate available. These passages are carried out to ensure that the cells are stably transformed.

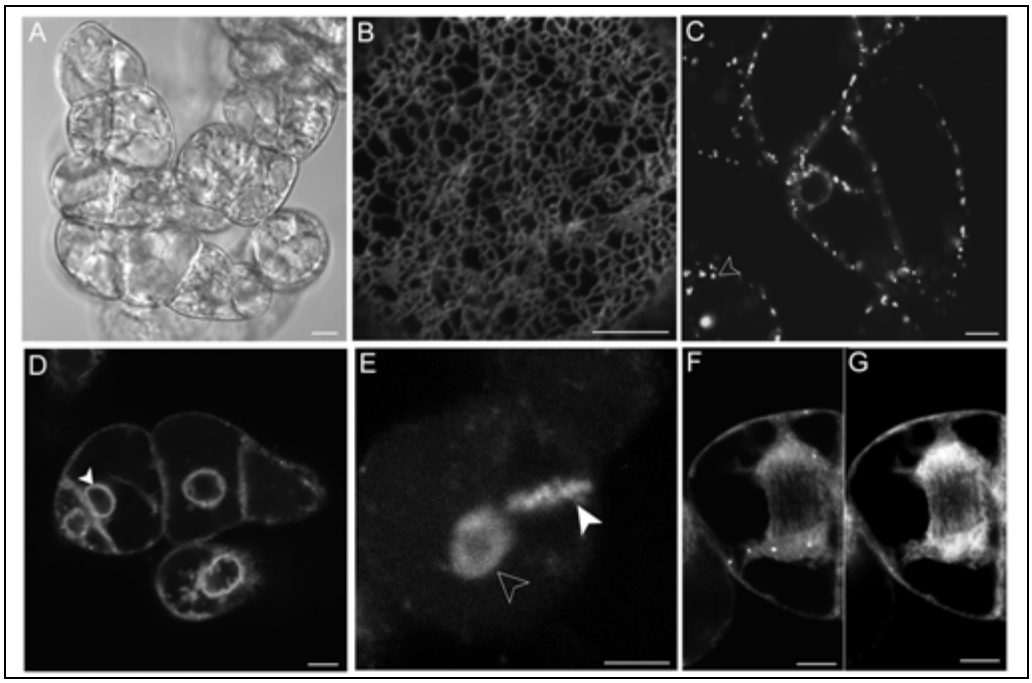

Figure 1.7.4 ((**A**) DIC image of BY-2 suspension culture. Membranous structures, nuclei, and vacuole are clearly visible. (**B**) Cortical endoplasmic reticulum (ER) visualized with yellow fluorescent protein (YFP) targeted and retained in a BY-2 cell stable transformant. This construct, SpYFP-HDEL, is composed of a sporamin signal peptide (to target the protein to the ER lumen), YFP, and the tetrapeptide HDEL to retain the protein in the lumen of the organelle (Irons et al., 2003). (**C**) To visualize the Golgi apparatus (arrowhead), the signal anchor of a rat sialyl transferase has been fused to green fluorescent protein (GFP) and expressed stably in BY-2 cells (Saint-Jore et al., 2002). (**D**) Nuclear envelope (arrowhead) of BY-2 cells stably expressing the amino terminus of the human lamin B receptor fused to GFP (LBR-GFP; Irons et al., 2003). (**E**) A histone-YFP (Boisnard-Lorig et al., 2001) construct highlights the chromatin in stably transformed cells. Cell in interphase (white arrowhead) and at metaphase (black arrowhead). (**F**,**G**) Stable BY-2 transformant co-expressing LBR-GFP (F) and SpYFR-HDEL (G) during cell division. Scale bars, 10 μm.

ALTERNATE PROTOCOL

STABLE TRANSFORMATION OF BY-2 CELLS WITH TWO CONSTRUCTS

BY-2 cells are also an amenable system for stably co-expressing two constructs (Fig. 1.7.4F, G). To achieve this, the fluorescent markers should be subcloned independently into a bacterial plasmid bearing the same antibiotic resistance. For the transformation, Basic Protocol 4 is carried out with the following changes. In step 1, two separate overnight cultures are grown for the two fluorescent marker constructs. In step 3, 50 μl of each bacterial population is added to 1 ml untransformed BY-2 cells. Following the transformation, calli are screened for co-expression of the two fluorescent markers using a fluorescent microscope with adequate excitation and emission filters to discriminate the two fluorochromes.

BASIC PROTOCOL 5

PREPARATION OF BY-2 CELLS FOR FLUORESCENCE MICROSCOPY

BY-2 cells are generally mounted in half-strength agarized medium to prevent excessive movement of the cells and are maintained in the culture medium to limit cellular stress. For longer observation (up to several days) of immobilized suspension culture cells, a chamber covered with the gas-permeable foil bioFOLIE (Vivascience) can be used as an alternative to the agar medium (J.W. Vos and A.M.C. Emons, Plant Cell Biology, Wageningen University; pers. comm.). BioFOILE allows gas exchanges at the junction of the gas and liquid phase and gently immobilizes cells.

Materials

Solid BY-2 medium (see recipe), for short-term observation only
Wild-type or transformed BY-2 suspension culture (see Basic Protocol 1)
70% (v/v) ethanol, for long-term observation only
Valap: 1:1:1 (w/w/w) Vaseline/lanolin/paraffin (*UNIT 13.1*)

Electrical tape, cut in 0.5-cm-wide strips, for short-term observation only
76 × 26–mm glass slides and 51 × 20–mm O thickness coverslips, for short-term observation only
Microwave oven, for short-term observation only
Trimmed 200-µl pipet tips (i.e., 4 to 5 mm cut off from narrow end), sterile
76 × 51–mm glass slides with 18-mm hole in the center and 24 × 24–mm O thickness coverslips, for long-term observation only
50°C oven, for long-term observation only
Double-sided tape, for long-term observation only
Scalpel, for long-term observation only
2.5 × 2.5–cm piece of bioFOLIE film (Vivascience), for long-term observation only
Sterile tissues, for long-term observation only

For short-term observation:

1a. Place two 0.5-cm-wide strips of electrical tape on a clean 76 × 26–mm glass slide perpendicular to the long sides of the slide. Place the strips of tape ~10 mm apart.

The electrical tape will prevent excessive compression of the cells.

2a. Warm a small amount of solid BY-2 medium in a microwave oven until melted but not boiling. Place 100 µl medium on the glass slide between the strips of tape and allow to cool.

3a. At the critical point at which the medium solidifies, use a trimmed 200-µl pipet tip to transfer 50 to 100 µl wild-type or transformed BY-2 suspension culture to the medium. Use the pipet tip to gently mix the cells and medium.

4a. Place a 51 × 20–mm O thickness coverslip over the sample prior to observing at the microscope.

The cells will be held in place by the pressure of the coverslip.

Cells should be observed within up to 4 hr. Discard after observing; autoclave the slide before discarding if the cells are transformed.

For long-term observation:

1b. Clean a 76 × 51–mm glass slide with an 18-mm hole in the center and a 24 × 24–mm coverslip with soap and hot tap water, rinse in distilled water, and dry in an oven at 50°C.

2b. Place two 3-cm-long strips of double-sided tape on the slide, to cover the surface of the slide, including the hole.

3b. Use a scalpel to remove the tape covering the hole.

4b. Clean a 2.5 × 2.5–cm piece of bioFOLIE film in 70% ethanol and allow to air dry.

5b. Mount the bioFOLIE film on the tape on the glass slide and remove excess tape and foil.

The bioFOLIE film is mounted on the underside of the glass slide.

6b. Clean with soap and water, rinse with 70% ethanol, and air dry in a laminar flow hood.

7b. Working under sterile conditions, use a trimmed 200-µl pipet tip to transfer 20 µl of a wild-type or transformed BY-2 suspension culture onto the bioFOLIE in the hole of the glass slide.

8b. Cover the hole with the coverslip. Blot excess fluid with a sterile tissue while gently pressing on the coverslip.

9b. Seal the slide with Valap to prevent drying and infection.

Cells should be observed within 2 to 3 days. Store the slides at 25°C during observations. Discard slides, autoclaving first if the cells are transformed.

REAGENTS AND SOLUTIONS

Use ultrapure distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Carbenicillin, 100 mg/ml

Dissolve 100 mg/ml carbenicillin disodium (Melford Laboratories) in ultrapure water. Filter sterilize with a 0.2-µm filter and store up to 6 to 8 weeks at −20°C.

To use at 100 µg/ml, add 100 µl to 100 ml medium.

2,4-Dichlorophenoxyacetic acid (2,4-D), 1 mg/ml

Dissolve 1 mg 2,4-D in 1 ml 70% (v/v) ethanol. Store up to 6 to 8 weeks at 4°C.

Liquid BY-2 medium

Place 750 ml water in a 1-liter beaker and add 30 g sucrose (AnalaR grade, BDH Chemicals). Stir until dissolved. Add 4.3 g Murashige and Skoog medium (without sucrose, indole acetic acid, kinetin, agar; ICN Biomedicals), 200 µl 1 mg/ml 2,4-D (see recipe), and 3.4 µl 100 mg/ml KH_2PO_4 (potassium dihydrogen orthophosphate; AnalaR grade, BDH Chemicals). Adjust pH to 5.8 with 0.1 M KOH (not NaOH), make up to 1000 ml with water, and mix well. Pour into flasks, cover with foil and autoclave 15 min at 121°C. Allow to cool and store up to 2 weeks at 4° to 8°C.

The final concentration of KH_2PO_4 in BY-2 medium is 540 mg/liter. BY-2 cells have a high phosphate usage, greater than that supplied in Murashige and Skoog medium alone (Nagata et al., 1992).

Solid BY-2 medium

Add 1% (w/v) low-melting-temperature agar (Bacto Agar; Difco) to liquid BY-2 medium (see recipe) in suitable flask. Autoclave 15 min at 121°C and allow to cool until flask can be held for pouring. Pour medium into sterile petri dishes (~25 ml/9-cm dish) in laminar flow hood. Allow plates to cool and store at 4° to 8°C.

If working with stable transformants, antibiotics should be added before pouring, and the flask should be swirled to mix them into the medium.

Timentin, 20 mg/ml

Dissolve 20 mg/ml Timentin (tricarcillin disodium salt/potassium clavunculate; Melford Laboratories) in ultrapure water. Filter sterilize with a 0.2-µm filter and store up to 6 to 8 weeks at −20°C.

An alternative to Timentin is ticarcillin/potassium clavulanate.

To use at 20 µg/ml, add 100 µl/100 ml medium.

YEB medium

In a 1-liter beaker dissolve 5 g beef extract (Difco), 1 g yeast extract (Merck), 5 g peptone (Difco), 5 g sucrose (BDH Laboratory), and 0.5 g $MgSO_4 \cdot 7H_2O$ in 0.8 liter water. Add water, while stirring continuously, up to 1 liter. Autoclave and store up to 4 to 6 weeks at room temperature.

The components may take some time to dissolve completely.

COMMENTARY

Background Information

The reader may find different protocols for BY-2 cell culture and transformation being used in different laboratories. This is because researchers tend to optimize a general protocol based on their experience with handling BY-2 cell lines.

The medium used for the same cell type sometimes differs between labs as a result of different working practices and preferences. Different suspension plant cell types have differing medium requirements. For example in the authors' experience carrot suspension cells grow optimally in M and S media supplemented with sucrose, coconut milk, zeatine, and 2,4-dichloro-phenoxyacetic acid (2,4-D), in comparison to BY-2 cells which require the addition of sucrose, KH_2PO_4, and 2,4-D only. In turn, *Arabidopsis* suspension cells proliferate in M and S supplemented with sucrose, NAA (naphthaleneacetic acid), and kinetin. The cells are all grown at the same temperature, with the same light and shaking regimes and are subcultured every 7 days.

There are several factors that have to be taken into consideration when working with transformed BY-2 cells. The expression of a fluorescent construct may vary among calli from the same transformation. Mistargeting of a protein may well be due to overexpression. Therefore, transgenic calli should be analyzed with a fluorescence microscope to ascertain the fidelity of the expression pattern. The authors have also found that levels of fluorescence of transformed BY-2 cells of a single line and patterns of expression may change after repeated passages. This may be due to aging of the culture, degradation of the fluorescent construct, and/or gene silencing.

Critical Parameters

The efficiency in obtaining transgenic calli may vary between experiments. This may be related to the quality of the BY-2 cells. In particular, cells that are in M and early G1 phase are more susceptible to transformation via *A. tumefaciens* than cells residing in G2 (Geelen and Inzé, 2001). Similarly, the strain of *Agrobacterium* used may affect the yield. For example, the *Agrobacterium* strain LBA4404, which constitutively expresses the *vir*G gene (van der Fits et al., 2000), has been found to be superior in generating transgenic calli (Geelen and Inzé, 2001).

Contamination of cultures may easily occur even if appropriate sterile procedures are followed. Therefore, to avoid wasted time and effort, it is preferable to work in duplicate or, in certain situations, in triplicate. This is to ensure that there is a backup stock of sterile material should infection occur at any point. The authors found that when routinely working with suspensions and calli (for the weekly and monthly passages, respectively), one should work in duplicate, but, when initiating a suspension culture, the calli should be passaged in triplicate. This is illustrated in Figure 1.7.3. When passaging calli and suspension cultures, the operator should discard infected plates. At each passage, new subcultures should be generated from one plate or flask only. It is advisable to retain the uninfected and unopened plates or flasks until the next passage to ensure a backup of material should contamination occur.

Once transformed lines are established, they can be passaged in a 7- to 14-day cycle. It is advisable, however, to maintain the line as calli on solid medium so that if expression levels decrease with time, a new suspension can be established. It is also the authors' experience that with some transformed lines, correct targeting of constructs is lost after three to four passages, and regular renewal from calli is then necessary (Fig. 1.7.3).

Troubleshooting

General rules for troubleshooting that apply in culturing and transforming of any plant cell line (Evans et al., 2003) apply for BY-2 cells.

In general, to enhance the possibility of a successful transformation, the operator should produce at least three initial plates of mixed agrobacteria and BY-2 cells.

There may be an absence of fluorescence in the transformed BY-2 cells. This may be due to several factors, including gene silencing, toxicity of the construct, mutation in the sequence of the fluorescent protein, degradation of gene product, or even misuse of the selectable markers. When cells are stably transformed via *Agrobacterium*, the DNA is integrated into the genome, hence resulting in an absence of a defined position effect. This may lead to silencing. The fidelity of a construct should always be checked by transient expression before attempting any stable transformation. Very often constructs may prove toxic to cells so that only lines with low levels of expression survive.

The gene product may not be tolerated by the cells and may be degraded. Nonspecific overproliferation of untransformed cells in calli may also occur. This may arise because of an impairment of antibiotic activity, for instance by temperature, light, or pH inactivation of the selective marker.

Anticipated Results

Transformation and culturing of BY-2 cells is a straightforward approach to set up an in vivo system to analyze cellular dynamics. This system is particularly well suited for investigation into cell cycle progression.

BY-2 cells are present in variable shapes from isodiametric to elongated and as single cells or concatamers (Fig. 1.7.4A). The large nucleus is suspended in a highly vacuolated cytoplasm. Numerous plastids are present in these cells, but they are not autofluorescent.

A variety of cellular organelles have been highlighted by in vivo fluorescent protein markers thanks to the ease of transformation of BY-2 cell and their ability to tolerate heterologous constructs based on green fluorescent protein (GFP) and its fluorescent derivatives (Table 1.7.1), including the actin cytoskeleton (Kost et al., 1998), microtubules (Granger and Cyr, 2000; Kumagai et al., 2001), and the Golgi (Nebenführ et al., 1999; Saint-Jore et al., 2002).

Figure 1.7.4B shows the endoplasmic reticulum (ER) of BY-2 cells stably expressing the yellow fluorescent protein targeted to the ER by an N-terminal sporamin signal peptide and retained by means of a C-terminal tetrapeptide, HDEL (SpYFP-HDEL). The Golgi apparatus can be visualized with a rat sialyl transferase membrane-anchoring domain GFP construct (Fig. 1.7.4C; Saint-Jore et al., 2002), and the nuclear envelope by the N-terminal domain of a mammalian lamin B receptor–GFP fusion (Fig. 1.7.4D; Irons et al., 2003). Chromatin can be visualized by a histone-YFP fusion (Fig. 1.7.4E, G; Boisnard-Lorig et al., 2001), which allows the visualization of chromosome dynamics in interphase and mitotic cells.

BY-2 cells are also an amenable system for stable co-expression of two constructs (Fig. 1.7.4F, G). Thus BY-2 cells may be used to express a double combination of fluorochromes for the analysis of organelle-organelle and protein-protein interactions.

Time Considerations

As shown in Figure 1.7.1B, production of stable cell lines of BY-2 cells may take about 4 months. Detection of fluorescence in calli may be possible after 1 month from transformation with agrobacteria. This may be useful to distinguish fluorescent calli from nonfluorescent ones and to propagate the former.

After inoculation of liquid medium with callus, it is advisable to let the culture establish for a minimum of 1 week before microscopy. This gives time for cells to divide and separate from clumps of callus.

CHAPTER 2
Preparation and Isolation of Cells

INTRODUCTION

Chapter 1 describes the techniques of cell culture, but, of course, to culture cells one must have cells. Many cell biologists, if asked where cells come from, would probably give the American Type Culture Collection (ATCC) as their answer. As important as such repositories are as a resource, cells really come from organisms, and Chapter 2 deals with the preparation and isolation of cells from their true source.

As indicated in the introduction to Chapter 1, 1998 marked the golden anniversary of the first continuous mammalian cell line. That line was the L cell fibroblast line established from a mouse tissue explant by Sanford et al. in 1948 (*J. Natl. Cancer Inst.* 9:229-246). Fibroblast lines continue to be important now, half a century after the establishment of the L cell line. Fibroblasts can be obtained from humans without sacrificing the individual (human skin fibroblasts are indeed available from the ATCC), and fibroblast cultures established from patients with inherited disorders have often been used to identify genetic abnormalities. Skin fibroblasts are also instrumental in characterization of functional abnormalities in transgenic or knockout animals. The methodologies of preparing and maintaining skin fibroblasts are described in *UNIT 2.1*.

Blood represents a "renewable resource" for obtaining human cells. *UNIT 2.2* describes procedures for the isolation and maintenance of human lymphocytes from peripheral blood. Relatively large numbers of these cells (1 to 2 million per milliliter of blood) can be isolated by techniques that are moderately simple and inexpensive. In addition to the basic protocol for lymphocyte preparation by density-gradient centrifugation, protocols by which various subfractions of the lymphocyte population can be separated are provided. Monocytes/macrophages are isolated (or depleted) by utilizing their tendency to adhere to plastic. Monoclonal antibodies recognizing the specific surface molecules are utilized together with magnetic beads to select positively or negatively for populations of T cells or B cells. These cells can also be used to generate continuously growing B cell lines via transformation with Epstein Barr virus.

In *UNIT 2.3*, we move from blood to the blood vessels, from which endothelial cells can be isolated. Endothelial cells have been used extensively to explore cell-cell and cell-matrix interactions. Endothelial cell function (or dysfunction) participates in pathological processes as diverse as coronary artery disease and tumor invasion, as well as in the inflammatory response. The expression of surface proteins and secretion of soluble mediators by the endothelium controls vascular tone and permeability, regulates coagulation and thrombosis, and directs the passage of leukocytes into areas of inflammation. Endothelial cells play a central role in angiogenesis, the formation of new blood vessels that is necessary for tumor growth. As such, endothelial cells are being extensively studied in the quest for antiangiogenic agents that might be used in cancer therapy. A basic protocol for the preparation of endothelial cells from human umbilical vein is provided in *UNIT 2.3*, along with alternative protocols for isolation of endothelial cells from retroperitoneal adipose tissue, nasal mucosa, and human foreskins.

UNIT 2.4 provides guidance for preparing immortalized B cell lines via transformation by Epstein-Barr virus. This methodology allows for the establishment and maintenance of

Contributed by Joe B. Harford
Current Protocols in Cell Biology (2006) 2.0.1-2.0.2

cell lines derived from resting human B lymphocytes obtained from blood samples, including those obtained from individuals with genetic changes leading to disease conditions (e.g., sickle cell anemia and cystic fibrosis).

Animal tissues are heterogenous because they are composed of mixtures of cell types. Analysis of the functions of these cells necessitates obtaining pure samples of the cells of interest. One recent approach to the daunting task of isolating homogenous morphologically identified cell populations is laser capture microscopy (LCM). The technique as described in *UNIT 2.5* is based on selective adherence of visually identified cells within a tissue section to a plastic membrane following activation by low-energy infrared laser. Although initially developed at the National Cancer Institute for separation of malignant or premalignant cells from surrounding normal tissue, LCM is being applied to a wide variety of cell types. Hundreds of papers have already appeared in the literature wherein DNA, RNA, and/or proteins have been extracted and analyzed from laser-captured cells.

UNIT 2.6 describes a method for establishing cultures of human keratinocytes. Although the source for the protocol described is human newborn foreskin from circumcision, the method may also be used to prepare keratinocyte cultures from skin biopsies, from other surgical procedures, or from cadavers.

The interaction between neurons and glial cells represents an important but complex aspect of brain development and function. In *UNIT 2.7*, protocols are provided for the isolation and coculture of these cell types. The methods described include procedures for a coculture system (sandwich coculture) in which the cells are maintained in the same culture dish but are not in physical contact with one another. This arrangement allows diffusion between the cell types of soluble factors that mediate the interplay between the two cocultured cell types.

In future supplements to Chapter 2, protocols for the isolation of additional cell types will be provided.

Joe B. Harford

Establishment of Fibroblast Cultures

This unit describes methods for establishing fibroblast cultures from skin. Because fibroblasts can be expanded to relatively large numbers from a small skin sample, they have been widely used to study basic aspects of cell biology as well as genomic, biochemical, and/or functional abnormalities in human patients and in transgenic or knockout animals. Two protocols are described for the development of fibroblast lines from human and mouse skin samples; the same protocols are also applicable, with slight modification, to other animals including rats and rabbits. The first technique (see Basic Protocol) employs an "skin explant" culture system in which fibroblasts grow out of skin specimens. The second technique (see Alternate Protocol) employs a dissociated fibroblast culture system in which fibroblasts are first released from skin specimens by enzymatic digestion and then placed in culture. In general, the explant culture system is technically simpler, requiring almost no special experience or reagents, whereas the dissociated fibroblast culture is more suitable for obtaining relatively large numbers of fibroblasts in a short period.

NOTE: All incubations are performed in a humidified 37°C, 5% CO_2 incubator unless otherwise specified. Some media (e.g., DMEM) may require altered levels of CO_2 to maintain pH 7.4.

NOTE: All solutions and equipment coming into contact with cells must be sterile, and proper sterile technique should be used accordingly. Surgical equipment may be sterilized by simply soaking in 70% ethanol; however, it is important to rinse in PBS before use since ethanol will "fix" the tissue.

SKIN EXPLANT CULTURE

BASIC PROTOCOL

When skin specimens are "transplanted" onto culture plates, fibroblasts (in dermis) and keratinocytes (in epidermis) migrate over the plastic surfaces, as they do in an ordinary skin graft. Because fibroblasts will eventually overgrow keratinocytes in conventional culture media, relatively pure fibroblast cultures can be obtained by simply placing small pieces of skin on tissue culture dishes. On the other hand, the optional enzymatic separation of the epidermis will ensure the absence of epidermal components from the resulting fibroblast cultures; it will also allow investigators to establish keratinocyte cultures from the same skin samples.

Materials

Skin specimen (see Commentary)
Phosphate-buffered saline (PBS; see recipe)
0.5% (w/v) dispase II (Boehringer-Mannheim) in PBS (store up to 3 months at −20°C; optional)
0.3% (w/v) trypsin (from bovine pancreas; Sigma) in PBS (store up to 3 months at −20°C; optional)
Complete growth medium (DMEM or RPMI; see recipe)
Trypsin/EDTA solution (see recipe)
0.4% (w/v) trypan blue in PBS (store up to 6 months at room temperature)
Freezing medium: 10% DMSO/90% FBS or 10% DMSO/90% complete DMEM

15-ml and 50-ml polypropylene centrifuge tubes
Lids from 100-mm tissue culture dishes
Eye forceps (2 pairs)
Surgical scalpel with disposable no. 22 blade

Contributed by Akira Takashima
Current Protocols in Cell Biology (1998) 2.1.1-2.1.12

35-mm tissue culture dishes or 6-well plates
22-mm glass coverslips (wrap several coverslips in aluminum foil and sterilize by autoclaving)
Hemacytometer
25-cm^2 tissue culture flasks
1.5-ml cryotubes (e.g., Nunc)
Liquid nitrogen freezer

CAUTION: When working with human blood, cells, or infectious agents, appropriate biosafety practices must be followed.

NOTE: Use Milli-Q water or equivalent in all protocol steps and for preparing all solutions.

Prepare skin sample

1. Wash skin samples in PBS by gently shaking or agitating in a 50-ml polypropylene centrifuge tube.

   When handling skin samples from mice, rats, or rabbits, it is easier to remove hair before excision. This can be achieved by applying 70% ethanol on skin and shaving with a single-edged razor blade (e.g., Personna Prep).

2a. *For relatively large skin samples (e.g., foreskin, surgically removed samples, or cadaver skin):* Place sample on the lid of a 100-mm tissue culture dish and spread it out with the epidermal side down. Remove the subcutaneous tissue by scraping the dermal side using two pairs of eye forceps. Cut skin into strips of ~0.5-cm width using a surgical scalpel.

2b. *For smaller skin samples (e.g., punch-biopsy samples):* Place the sample on a 100-mm tissue culture dish and excise the subcutaneous tissue using a surgical scalpel and a pair of forceps.

Remove epidermis (optional)

3a. *For human skin samples:* Incubate 45 min to 4 hr with 0.5% dispase/PBS in a 37°C water bath, then separate as an intact sheet mechanically by gentle agitation for 10 sec or by using two pairs of forceps.

   The incubation time required for epidermal separation varies depending upon the thickness of the skin specimen and the completeness of the subcutaneous tissue removal.

3b. *For mouse, rat, and rabbit skin samples (optional):* Incubate with 0.3% trypsin/PBS for 30 to 60 min in a 37°C water bath or overnight at 4°C. Place the sample on the lid of a 100-mm tissue culture dish with the epidermal side up and scrape off the epidermis mechanically using two pairs of forceps.

   In general, trypsin works better than dispase for skin with deep hair follicles.

4. Wash the dermal sample in PBS by gently shaking or agitating in a 50-ml polypropylene centrifuge tube.

Culture fibroblasts

5. Place the dermal sample on the lid of a 100-mm tissue culture dish and cut it into small (2- to 3-mm) squares.

   Fibroblast outgrowth occurs only from sharply cut edges. Thus, it is crucial to use a new, fine surgical scalpel; disposable surgical blades (no. 22) can be used for this purpose.

6. Place 5 to 10 skin pieces in the center of a 35-mm tissue culture dish or 6-well plate.

   The 6-well plates are more convenient for handling multiple fibroblast cultures in parallel.

7. Place a sterile 22-mm glass coverslip gently over the skin specimens (Fig. 2.1.1).

   Skin specimens need to be attached physically to the plate. This can be achieved most effectively by making a sandwich using a coverslip (Fig. 2.1.1). The coverslip also assists the growth of fibroblasts by maintaining the microenvironment.

8. Add a few drops of 4°C complete growth medium (DMEM or RPMI) into the space below the coverslip (by applying at the edge of the coverslip so that it is drawn under), then add 1 to 2 ml of 4°C complete medium to the dish or well, gently so as to avoid disturbing the skin specimens.

   Either complete DMEM or complete RPMI can be used for growing fibroblasts.

9. Place the culture in a humidified 37°C, 5% CO_2 incubator. Check the fibroblast outgrowth every 3 to 4 days under an inverted phase-contrast microscope and change medium every 3 to 4 days, taking care not to agitate the coverslip.

   Initial outgrowth should be detectable within 3 to 4 days (Fig. 2.1.2B). The coverslip should be left on the skin specimens until the culture becomes confluent. The original skin specimens may come off the plate spontaneously during culture and will be removed in step 10.

10. Upon confluency, remove the coverslips and wash the dish or wells twice with 4°C PBS.

    Fibroblasts sometimes migrate over the surface of the coverslip instead of the tissue culture plate. If this is the case (as judged by focusing up and down with the microscope) transfer the coverslip into a new dish, wash it with PBS as in this step, then harvest cells by trypsin treatment as in step 11.

    Washing with PBS is essential because trypsin (see step 11) does not work effectively in the presence of the FBS present in the culture medium.

    In the absence of epidermal separation, the cultures are often contaminated with outgrowing keratinocytes, which are readily distinguishable by their cobblestone-like appearance. Contaminating keratinocytes can be removed selectively by incubating 10 to 30 min with 0.5% dispase/PBS, because keratinocytes are much more sensitive than fibroblasts to this treatment. Keratinocytes will be detached, leaving the majority of fibroblasts attached to the plate.

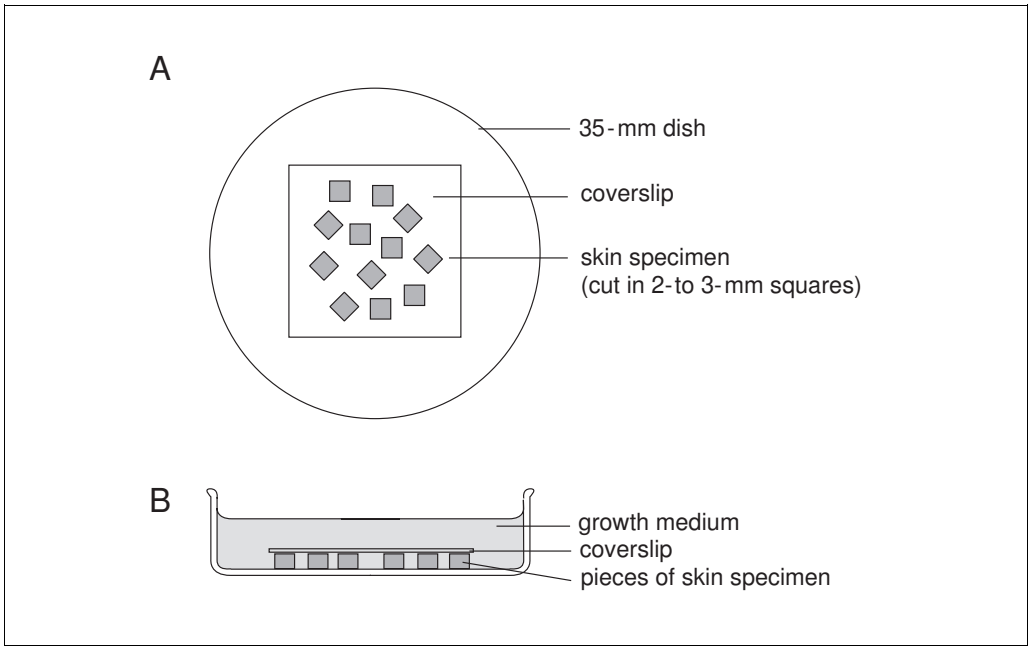

Figure 2.1.1 Skin explant culture: (**A**) top view; (**B**) side view.

11. Add 1 ml of 4°C trypsin/EDTA solution and incubate 3 to 5 min at room temperature while examining periodically under the inverted phase-contrast microscope. As soon as the fibroblasts round up, add 1 ml ice-cold complete growth medium (DMEM or complete RPMI) to inactivate trypsin and harvest cells by gentle pipetting.

    Avoid trypsinization for excessive periods of time and vigorous pipetting, which are the two common causes of the "low viability" problem (see Troubleshooting). Do not pipet the cells before the trypsin has been diluted by addition of complete culture medium.

    Harvest fibroblasts before they become overconfluent and form bundle-like alignments (Fig. 2.1.3B).

    The original skin specimens may be removed using forceps.

12. Collect fibroblast suspensions into a 15-ml polypropylene centrifuge tube and centrifuge 10 min at $150 \times g$, 4°C. Aspirate the supernatant, tap the pellet to dissociate the cells, and resuspend them in 100 to 200 µl of fresh 4°C complete growth medium.

13. Mix a 10- to 20-µl sample of the cell suspension with an equal volume of 0.4% trypan blue/PBS, then count total and viable cells under a microscope using a hemacytometer.

    The cell viability as measured by trypan blue exclusion should be >90%.

14. Plate $3–10 \times 10^4$ viable cells in 5 ml of fresh complete growth medium in a 25-cm^2 tissue culture flask.

    The cells will attach to a new flask within 2 to 3 hr and begin to exhibit the characteristic spindle shape in 24 hr.

    Contamination occurs less frequently in flasks than in dishes or multiwell plates

15. Change medium every 3 to 4 days until the culture becomes confluent. Harvest fibroblasts as described in steps 10 and 11.

    See Figure 2.1.4 for the typical growth rate of human fibroblasts; their doubling time varies from 24 to 72 hr, depending upon the culture conditions. Human fibroblasts can be passaged up to 10 times without significant changes in morphology or growth rates. It is recommended, however, that frozen stocks be prepared after the second or third passage (see step 16).

    Maximal fibroblast growth requires 5% to 10% FBS (Fig. 2.1.5A). It is technically challenging to grow fibroblasts in the absence of added serum. On the other hand, there is minimal, if any, variation among FBS batches purchased from different vendors in their capacity to promote the growth of human fibroblasts (Fig. 2.1.5B). Human fibroblasts also grow well in the presence of heat-inactivated human serum, which may be used instead of FBS (Fig. 2.1.5C).

16. To freeze cells, resuspend in ice-cold 10% DMSO/90% FBS or 10% DMSO/90% complete DMEM at $0.3–1 \times 10^6$ cells/ml. Dispense into 1.5-ml cryotubes at 1 ml/tube and freeze first at −20°C, then move on to −80°C, and finally place in liquid nitrogen.

    The −20°C and −80°C freezing steps may be performed in a styrofoam box to promote a gradual drop in temperature. Commercially available cell-freezing instruments may also be used for this purpose.

Figure 2.1.2 *(at right)* Microscopic appearance (magnification, 40×) of fibroblast cultures established from a newborn foreskin sample using the skin explant culture system (panels A to C) or the cell dissociation culture system (panels D to F). (**A**) Skin explant, day 1; (**B**) skin explant, day 5; (**C**) skin explant, day 14. (**D**) Dissociation culture, day 1; (**E**) dissociation culture, day 5; (**F**) dissociation culture, day 14. Note that fibroblasts migrate out from the edge of a skin specimen (panel B) and become confluent, except for the area where the original skin specimen was located (panel C). In dissociated-cell cultures, fibroblasts attach (panel D), spread on culture plates (panel E), and become confluent (panel F).

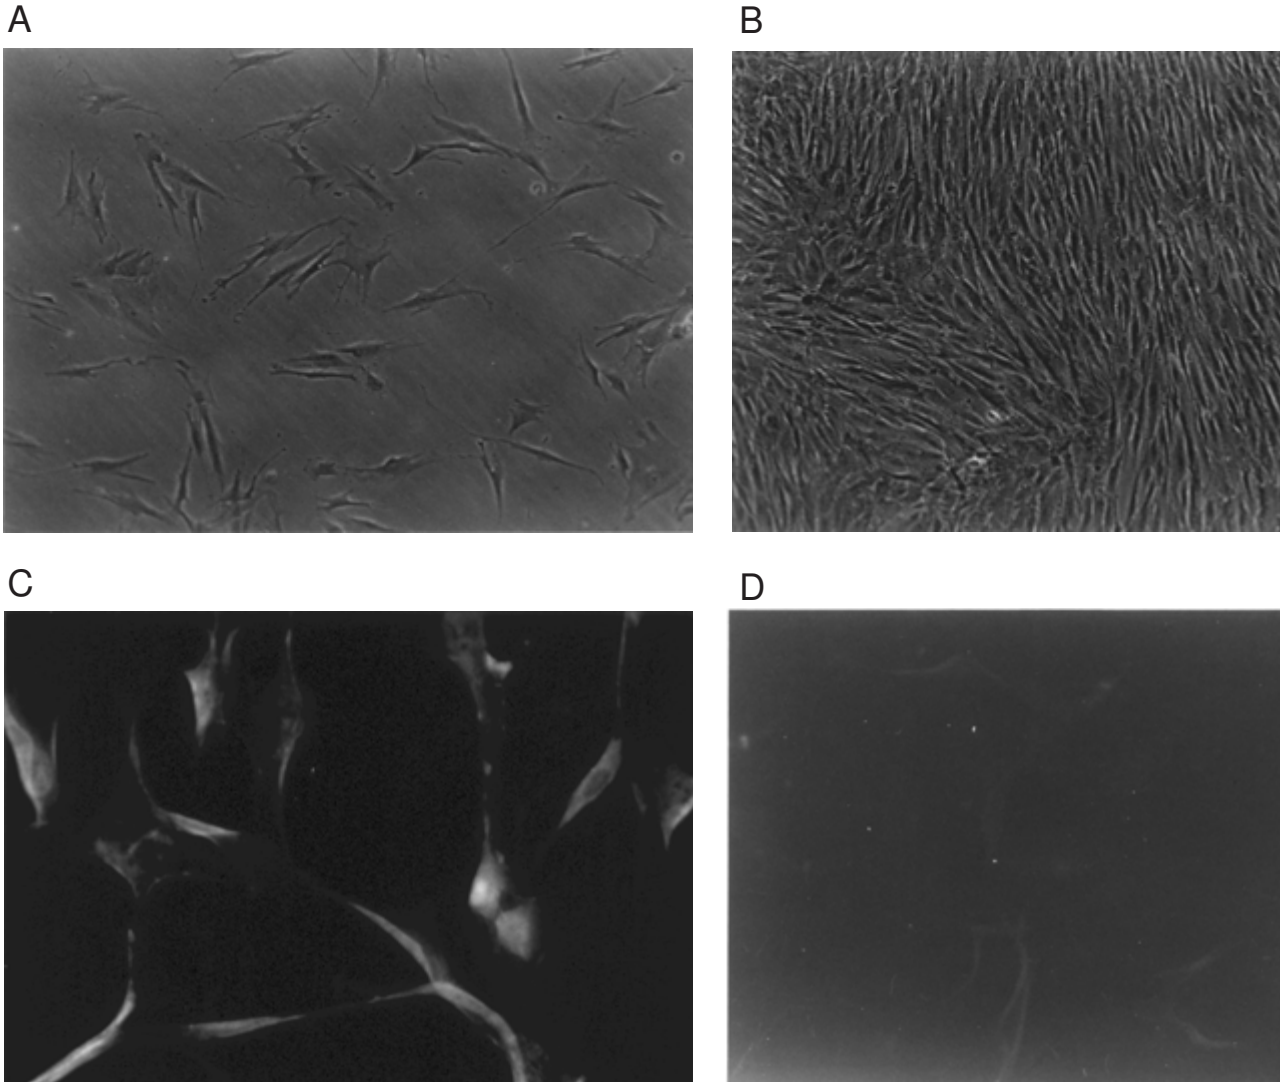

Figure 2.1.3 Identification of fibroblasts. Fibroblasts change their morphology depending upon the extent of confluency (or cell density). (**A**) Morphology at low density (10% to 20% confluence; magnification, 40×); (**B**) morphology at high density (100% confluence; magnification, 40×). (**C**) Indirect immunofluorescence staining of human fibroblast cultures with antibodies against type I collagen (magnification, 100×). (**D**) Indirect immunofluorescence staining of human fibroblast cultures with control antibodies (magnification, 100×). Briefly, fibroblasts were cultured for 2 days on LabTek chamber slides, fixed in 3% paraformaldehyde in PBS, permeabilized with 0.1% Triton X-100, and then subjected to immunofluorescence staining (*UNIT 4.3*) with rabbit anti-type I collagen (Chemicon), followed by labeling with FITC-conjugated anti-rabbit IgG (Jackson Immunoresearch).

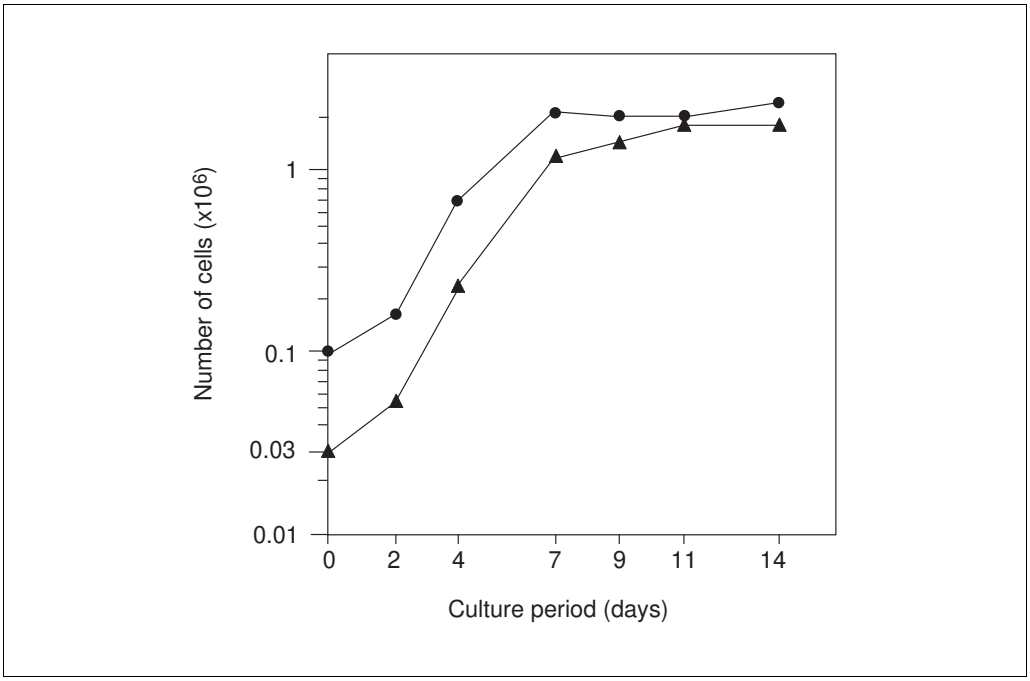

Figure 2.1.4 Fibroblast growth curve. A third passage of human fibroblast culture was plated on 35-mm dishes at either 30,000 (triangles) or 100,000 (circles) cells per dish, and cultured in complete RPMI. At the indicated time points, cultures were harvested by incubation with 0.3% trypsin/25 mM EDTA and counted to determine cell number. Note that cells grow relatively rapidly, with an approximate doubling time of 24 hr, and then stop dividing as they reach confluency.

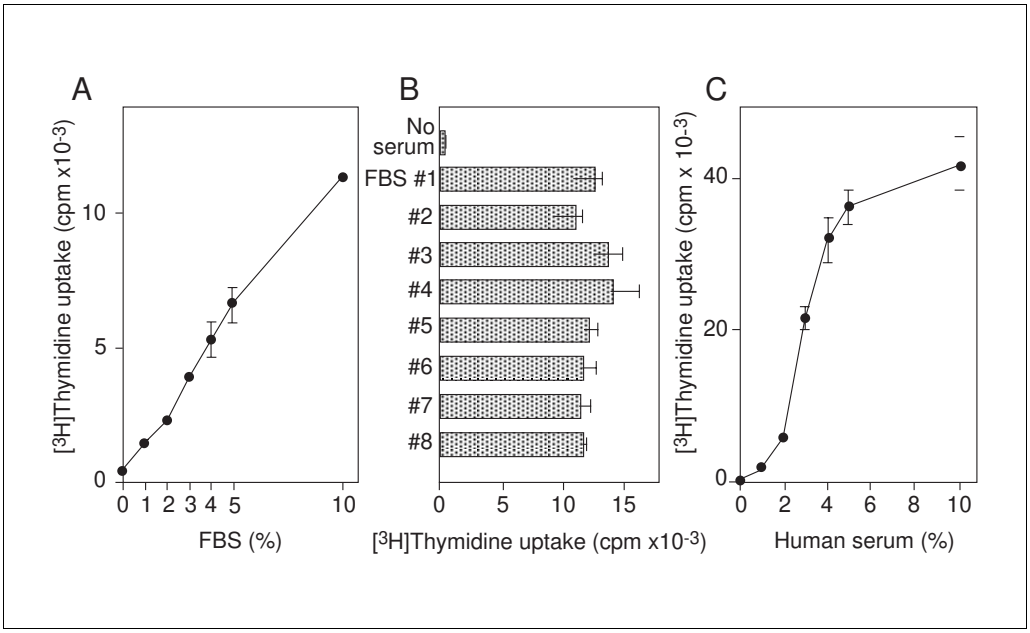

Figure 2.1.5 Serum requirement for fibroblast growth. A third passage of human fibroblasts (3000 cells/well) was cultured in flat-bottom 96-well plates, pulsed with [^{3}H]thymidine on day 3, and harvested on day 4 using an automated cell harvester. The culture media were supplemented with (**A**) different concentrations of FBS; (**B**) 10% FBS from different vendors; and (**C**) different concentrations of human serum. Data shown are the means and standard deviations from triplicate cultures.

ALTERNATE PROTOCOL

DISSOCIATED FIBROBLAST CULTURE

Although more complicated than the skin explant culture (see Basic Protocol), the dissociated fibroblast culture described in this protocol is more suitable for those experiments that require relatively large numbers of fibroblasts. After removal of the epidermis by dispase treatment, fibroblasts are released from the remaining dermis by enzymatic treatment with trypsin. The resulting dermal cells are then plated in suspension onto tissue culture plates. The most tricky step is the enzymatic digestion of dermal tissues. Investigators may need to compare various conditions (e.g., batches of trypsin, trypsin concentrations, and incubation periods) to maximize the cell yield while maintaining the cell viability. Alternatively, collagenase, which is less cytotoxic than trypsin, can be used for the same purpose.

Additional Materials *(also see Basic Protocol)*

1000 U/ml collagenase type IA in PBS (see recipe for PBS; store enzyme solution up to 3 months at −20°C)
Nylon mesh (85-µm mesh; Tetko; cut into 5-cm square, wrap in aluminum foil, and sterilize by autoclaving)

CAUTION: When working with human blood, cells, or infectious agents, appropriate biosafety practices must be followed.

NOTE: Use Milli-Q water or equivalent in all protocol steps and for preparing all solutions.

Prepare dissociated cell suspension

1. Wash skin samples in PBS, remove the subcutaneous tissues, remove the epidermis by enzymatic digestion, wash the dermal sample in PBS, and cut the sample into small squares (see Basic Protocol, steps 1 to 5).

   Since the trypsin that is used to digest the dermal connective tissue also dissociates epidermal cells, the epidermis must first be separated from dermal layer. Otherwise, the resulting cultures will be heavily contaminated by epidermal keratinocytes.

2. Place 10 to 20 dermal pieces in a 15-ml polypropylene tube with 3 ml of 0.3% trypsin/PBS and incubate 10 min in a 37°C water bath, inverting the tube several times every 2 to 3 min. Alternatively, incubate 10 to 20 dermal pieces 1 to 2 hr with 3 ml of 1000 U/ml collagenase at 37°C, agitating every 20 to 30 min.

3. Add 3 ml of ice-cold complete growth medium (DMEM or RPMI containing 10% FBS) to stop the reaction. Vortex the tube vigorously several times.

   Although fibroblasts detach from collagen fibers after treatment with trypsin or collagenase, mechanical agitation is required for releasing them into the solution. Do not vortex before the addition of complete medium.

4. Pass the fibroblast suspension through 85-µm nylon mesh (placed over the top of a tube) to remove dermal debris.

5. Centrifuge 10 min at 150 × *g*, 4°C. Aspirate the supernatant, then resuspend the pellet in 100 to 200 µl of complete growth medium.

6. Count total and viable cells (see Basic Protocol, step 13).

   The cell viability varies depending upon the conditions used for enzymatic digestion. Cutting skin sample into smaller sizes usually increases cell recovery as well as cell viability.

Culture fibroblasts

7. Plate 3–10 × 10^4 cells in 5 ml of complete growth medium in a 25-cm^2 tissue culture flask and begin incubation.

   Viable fibroblasts will attach to the flask within 24 hr and begin to exhibit the spindle-shape in 2 to 3 days (Fig. 2.1.2D and E).

8. Gently remove the medium containing nonadherent cells and add fresh medium on day 2.

   Because the presence of dead cells in culture affects the growth of viable fibroblasts, nonadherent, dead cells must be removed from the culture.

9. Change medium every 3 to 4 days until the culture becomes confluent.

   As fibroblasts become overconfluent, they appear as bundle clusters instead of spindle-shaped cells (Fig. 2.1.2 and Fig. 2.1.3). Harvest the cells before they reach this level.

10. Harvest fibroblasts by washing with PBS followed by incubation with trypsin/EDTA solution. Passage fibroblasts and prepare frozen stocks (see Basic Protocol, steps 10 to 16).

REAGENTS AND SOLUTIONS

Use Milli-Q water or equivalent in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Complete growth medium

500 ml DMEM or RPMI 1640 (Life Technologies or Sigma)
60 ml FBS (heat-inactivated 60 min at 56°C; *APPENDIX 2A*)
5 ml 1 M HEPES buffer solution (Life Technologies)
5 ml 100× nonessential amino acid mixture (Life Technologies)
5 ml 100× L-glutamine (Life Technologies)
5 ml 100× penicillin/streptomycin (Life Technologies)
5 ml 100× sodium pyruvate (Life Technologies)
Store up to 1 month at 4°C

Phosphate-buffered saline (PBS)

4 liters distilled water
32 g NaCl (140 mM final)
0.8 g KH_2PO_4 (1.5 mM final)
8.7 g $Na_2HPO_4 \cdot 7H_2O$ (8.1 mM final)
0.8 g KCl (2.7 mM final)
Adjust the pH to 7.4 with 1 N NaOH
Store indefinitely at room temperature

Trypsin/EDTA solution

Prepare the following stock solutions:
0.3% (w/v) trypsin (from bovine pancreas; Sigma) in PBS (see recipe for PBS)
1% (w/v) tetrasodium EDTA in PBS (see recipe for PBS)
Store stock solutions up to 3 months at −20°C

Combine 97.5 ml 0.3% trypsin/PBS and 2.5 ml 1% EDTA/PBS. Store trypsin/EDTA solution up to 1 week at 4°C.

COMMENTARY

Background Information

Fibroblasts are the major cellular component of connective tissues, where they play an important role in maintaining structural integrity. They produce and secrete a wide array of extracellular proteins, including proteinases, thereby regulating the biochemical composition and remodeling of tissues. Because biopsy samples can be easily obtained from skin, this tissue serves as a most convenient source of fibroblasts. Skin is composed of continually renewing multilayered squamous epithelium (the epidermis), connective tissue (the dermis), and subcutaneous (adipose) tissue. Human epidermis contains, in addition to keratinocytes (epithelial cells producing keratin intermediate filaments), relatively small numbers of Langerhans cells (antigen-presenting cells of the dendritic cell lineage) and melanocytes (which produce pigment granules called melanosomes). By contrast, mouse epidermis contains keratinocytes, Langerhans cells, and resident γδ T cells called "dendritic epidermal T cells." The dermis, in both human and mouse skin, is a fibrous and filamentous connective tissue that contains fibroblasts, endothelial cells, mast cells, macrophages, and occasionally other leukocyte populations. Despite the complexity of cellular composition, relatively pure fibroblast cultures can be obtained from skin specimens without sophisticated purification processes. This is primarily due to the fact that fibroblasts grow rapidly and continuously when cultured in the presence of serum, whereas other cell types require additional growth factors (e.g., epidermal growth factor or keratinocyte growth factor for keratinocytes), or show very little mitotic activity in vitro (Schuhmachers et al., 1995).

Morphological features—e.g., elongated cell bodies, oval nuclei, and linear or bundle-like alignment of cellular distribution—serve as conventional markers of fibroblasts in culture (Fig. 2.1.2 and Fig. 2.1.3). It is important to emphasize, however, that fibroblasts change their morphology dramatically depending upon the culture conditions, especially the extent of confluency (compare Fig. 2.1.3 panels A and B). Unfortunately, there is no antibody available that recognizes fibroblasts selectively. On the other hand, the absence of specific markers that are expressed by other dermal components (e.g., cytokeratin in keratinocytes, VCAM-1 on endothelial cells, IgE receptor on mast cells, and CD14 on macrophages) serves as a phenotypic marker of fibroblasts (Xu et al., 1995). Production of large amounts of type I collagen, as detected by immunofluorescence staining (Fig. 2.1.3C and D), can be used as a functional marker (Schuhmachers et al., 1995). Nevertheless, because the fibroblast cultures established by the standard protocols described in this unit are rarely "contaminated" by other cell types, especially after a few passages, it is generally accepted that they can be used as "fibroblasts" without further characterization.

Fibroblasts grow rapidly, with a doubling time of 24 to 72 hr (Fig. 2.1.4), and can be passaged successfully >10 times. Because of this outstanding mitotic potential, fibroblasts have been used for a variety of investigative purposes. For example, they serve as useful tools for studying the function and metabolism of extracellular matrix proteins as well as other fundamental aspects of cell biology. Fibroblast cultures established from patients with inherited disorders have often been used to identify genetic abnormalities. Moreover, autologous fibroblasts can be used as a "vector" in gene therapy to deliver transgenes into patients (Suhonen et al., 1996; Nolta and Kohn, 1997). Fibroblast lines generated from healthy human volunteers can be purchased from American Type Culture Collection (ATCC).

The protocols described in this unit are also applicable to other animal species. For example, in the author's laboratory, several fibroblast lines from rats and rabbits have been developed using the same protocols as described for mouse fibroblasts. After enzymatic separation of the dermal compartment, the remaining epidermal portion can be used to grow epidermal cells, such as keratinocytes and melanocytes.

As sources of human fibroblast cultures, newborn foreskin (obtained in circumcision), skin samples excised during surgical operations, cadaver skin (obtained from the transplantation unit), or skin biopsies are routinely used in the author's laboratory. Fibroblast cultures can be established from relatively small skin specimens; the author routinely uses 4-mm punch biopsies for this purpose (Pandya et al., 1995). It is also practical and feasible to establish fibroblast cultures without sacrificing experimental animals; mouse "ear punch" samples are used for this purpose by the author.

Critical Parameters

Because fibroblast outgrowth occurs predominantly from sharp edges of skin speci-

mens, it is crucial to use fine razor blades or surgical scalpels for cutting skin into small pieces. The author routinely uses disposable no. 22 surgical blades for this purpose. Drying of skin specimens is another common cause of poor fibroblast outgrowth. This can be avoided by adding a few drops of PBS while cutting skin specimens. If the surgical blades and forceps are to be soaked with 70% ethanol for sterilization, they should be rinsed well in PBS before use. When performed appropriately, outgrowing fibroblasts should become detectable within 3 to 4 days in skin explant cultures (Fig. 2.1.2B). In cell-dissociation cultures (see Alternate Protocol), the enzymatic digestion process is the most critical; if the viable cell count of resulting suspensions is <70% by trypan blue exclusion, this indicates overdigestion. When performed appropriately, the plated cells should attach firmly to culture plates within 24 hr and begin to spread in 2 to 3 days (Fig. 2.1.2D and E).

Fibroblasts can be frozen safely in 10% DMSO/90% FCS or 10% DMSO/complete DMEM and stored for >10 years in liquid nitrogen. Thus, it is suggested that several aliquots be frozen at a relatively early phase in culture (e.g., after the second or third passage). Because the original features of the cells may be altered during extended culture periods, it is not recommended that they be cultured continuously without experimental usage. If the cells suddenly stop dividing, or if the growth rate accelerates, the cultures need to be replaced. In the author's laboratory the original cultures are routinely discarded after the sixth passage and new cultures are started from a frozen stock.

Care should be taken in harvesting fibroblasts from culture plates. Although fibroblasts are more resistant to contact inhibition than other cell types (e.g., keratinocytes), it is suggested that cells be harvested during their exponential growth phase (Fig. 2.1.4). In the author's laboratory, after removal of culture medium, culture plates are routinely washed briefly with PBS, and then minimal amounts of 0.3% trypsin/25 mM EDTA are added. These plates can be incubated at room temperature under a microscope; as soon as the cells become rounded (before being released spontaneously from plates), the enzymatic reaction is stopped by the addition of ice-cold growth medium containing 10% FBS, and cells are harvested by tapping the culture vessel or gentle pipetting. These cells need to be centrifuged immediately to remove trypsin and EDTA. The cell viability should be >90% by trypan blue exclusion.

Troubleshooting

Bacterial or fungal contamination

Clean the skin well with 70% ethanol before taking a biopsy. Check all the culture media and reagents, including PBS, dispase, trypsin, collagenase, and complete growth medium. Sterilize surgical blades and forceps with 70% ethanol. Always keep the incubator clean.

Contamination by keratinocytes

Remove the epidermis before setting up the fibroblast cultures. Treat the contaminated cultures with 0.5% dispase for 10 to 30 min at 37°C to remove keratinocytes. Because keratinocytes usually require special growth factors for continuous growth, they will eventually disappear in the first or second passage.

Low cell yields or low cell viabilities after enzymatic digestion

Optimize the concentrations, batches of enzymes, and incubation periods. Cut skin into smaller pieces. Use freshly prepared trypsin (or collagenase) solutions; they will lose enzymatic activity gradually when kept at 4°C. Alternatively, prepare enzyme solutions in large quantities, divide them into 5- to 10-ml aliquots, and freeze them at –20°C.

Low cell viabilities during passage

Care must be taken not to overtrypsinize cultures. Wash the culture with PBS before trypsin treatment. Use freshly prepared trypsin solutions. Add ice-cold complete growth medium to stop the enzymatic reaction immediately after fibroblasts round up as determined by examination under a microscope. Avoid excessive pipetting.

Slow fibroblast growth

Increase FBS concentrations (up to 10%); most of the commercially available FBS batches work well for fibroblast cultures (Fig. 2.1.5). Check the temperature, CO_2 level, and humidity of the incubator. The growth rates of fibroblasts often slow down after >10 passages; thaw a frozen stock and start new cultures to avoid this.

Anticipated Results

In skin explant cultures, outgrowing fibroblasts become detectable within 3 to 4 days

and continue to grow thereafter. When skin pieces from one 4-mm punch-biopsy sample are plated in a 35-mm tissue culture dish, it usually takes 3 to 5 weeks to obtain a confluent culture. Starting from one newborn foreskin sample, one can obtain 5 to 10 confluent 35-mm dishes in 3 to 5 weeks. Approximately 1–2 $\times$ 10^6 cells can be harvested from a confluent 35-mm dish. Cell yields are usually higher in the dissociated fibroblast preparation (see Alternate Protocol); after enzymatic digestion with trypsin, ~1–3 $\times$ 10^5 cells can be harvested from a 4-mm punch-biopsy sample and 1–3 $\times$ 10^6 cells can be harvested from a newborn foreskin sample. The use of collagenase typically increases the yield up to 2-fold. When 1–2 $\times$ 10^5 cells are originally seeded in a 25-cm^2 flask, they will become confluent within 2 to 3 weeks, producing 2–3 $\times$ 10^6 cells. After the first passage to new culture plates, fibroblasts begin to grow much faster, with a typical doubling time of 24 to 72 hr (Fig. 2.1.4).

Time Considerations

Skin explant cultures can be set up in 30 to 60 min (without epidermal separation) or 2 to 4 hr (with epidermal separation). Dissociated fibroblast cultures take 3 to 4 hr, depending upon the extent of enzymatic digestion. Although it has been possible in the author's laboratory to establish fibroblast cultures from 1- to 2-day-old skin samples kept in complete growth medium at 4°C, it is highly recommended that cultures be set up immediately after taking biopsy samples. Subsequent passages can be made in 15 to 30 min.

Preparation and Culture of Human Lymphocytes

This unit describes procedures for preparation and culture of human lymphocytes and lymphocyte subpopulations obtained from peripheral blood. Because of ease of access, peripheral blood is the primary source of human lymphocytes (mononuclear leukocytes) used in most studies of lymphocyte function. Peripheral blood is a mixture of cells including lymphocytes, granulocytes, erythrocytes, and platelets. Density gradient centrifugation (see Basic Protocol 1) has proven to be an easy and rapid method for separation of lymphocytes from these other peripheral blood cell populations. Lymphocytes and platelets can be separated from granulocytes and erythrocytes according to their lower densities—they will float on top of a density gradient of Ficoll-Hypaque, whereas granulocytes and erythrocytes will traverse this fluid and collect at the bottom of the tube (Fig. 2.2.1). Monocytes/macrophages can then be separated from the other lymphoid-cell populations by adherence to plastic tissue culture vessels (see Basic Protocol 2). The procedures described in this section can be applied to the isolation of peripheral blood lymphocyte populations obtained either from whole blood or via a leukapheresis procedure.

Human lymphocyte subpopulations can be purified based on their cell-surface display of specific distinguishing molecules that can be recognized by monoclonal antibodies. The physical basis for such separation procedures involves the coupling of antibody reagents to magnetic beads, which permit the rapid sequestration of cells that have been bound by the specific antibodies. T and B cells can be positively selected using monoclonal antibody–coated magnetic beads (see Basic Protocol 3) or by exposing the cells to monoclonal antibody and then purifying cells that have bound the antibody using magnetic beads coated with anti–immunoglobulin G (anti-IgG; see Alternate Protocol 1).

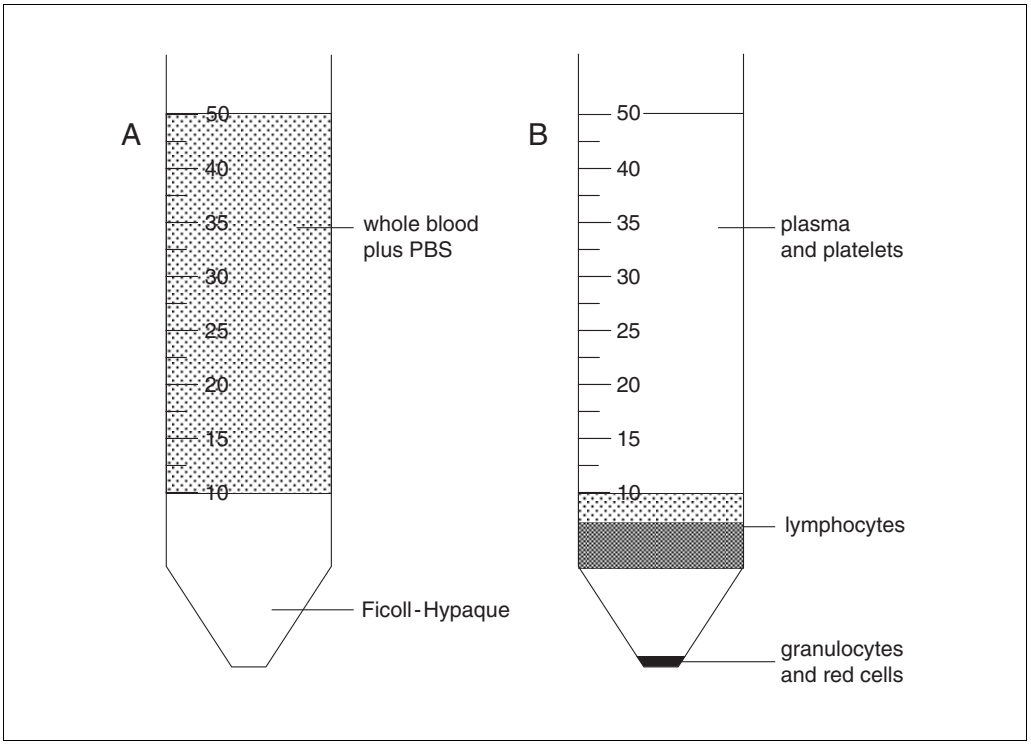

Figure 2.2.1 Isolation of human lymphocytes on a Ficoll-Hypaque gradient. (**A**) Before centrifugation; (**B**) after centrifugation.

Contributed by William E. Biddison
Current Protocols in Cell Biology (1998) 2.2.1-2.2.13

In addition, specific subpopulations can be isolated by negative selection, in which all unwanted subpopulations are removed using monoclonal antibodies and anti-IgG-coated magnetic beads (see Alternate Protocol 2).

CAUTION: When working with human blood, cells, or infectious agents, appropriate biosafety practices must be followed.

NOTE: All solutions and equipment coming into contact with living cells must be sterile, and proper aseptic technique should be used accordingly.

NOTE: All culture incubations are performed in a humidified 37°C, 5% CO_2 incubator unless otherwise specified. Some media (e.g., DMEM) may require altered levels of CO_2 to maintain pH 7.4.

BASIC PROTOCOL 1

PREPARATION OF LYMPHOCYTES BY FICOLL-HYPAQUE GRADIENT CENTRIFUGATION

In this procedure, whole blood or white blood cells from leukapheresis donors are centrifuged in the presence of a density gradient medium to separate lymphocytes from other peripheral blood cell populations.

Materials

Anticoagulated whole blood or white blood cells from leukapheresis donor
Phosphate-buffered saline (PBS), without calcium or magnesium (Bio-Whittaker), room temperature
Ficoll-Hypaque solution (see recipe), room temperature
Lymphocyte culture medium (LCM; see recipe), room temperature
Iscove's modified Dulbecco's medium (IMDM; Life Technologies) containing 20% heparinized human plasma
Freezing medium (see recipe)

50-ml conical centrifuge tubes
Sorvall RT-6000B centrifuge with H-1000 rotor (or equivalent)
1.5-ml cryotubes (e.g., Nunc)
Controlled-rate freezer (e.g., CryoMed from Forma Scientific)
Liquid nitrogen freezer

Additional reagents and equipment for counting cells and determining cell viability (*UNIT 1.1*) and flow cytometry (Robinson et al., 1998)

Prepare Ficoll-Hypaque gradient

For whole blood

1a. Pipet 15 ml of whole blood into a 50-ml conical centrifuge tube and add 25 ml room temperature PBS

2a. Using a 10-ml pipet, underlay with 10 ml room temperature Ficoll-Hypaque solution.

For leukapheresis preparation

1b. Pipet 10 ml of cell suspension from a leukapheresis preparation into a 50-ml conical centrifuge tube and add 30 ml room temperature PBS.

2b. Using a 10-ml pipet, underlay with 7.5 ml room temperature Ficoll-Hypaque solution.

Separate cells

3. Centrifuge 20 min at 800 × *g* (2000 rpm in H-1000 rotor), 20°C, with the brake off.

4. Aspirate most of the plasma- and platelet-containing supernatant above the interface band (granulocytes and erythrocytes will be in red pellet; Fig. 2.2.1). Aspirate the interface band (which includes the lymphocytes) along with no more than 5 ml of fluid above the pellet into a 10-ml pipet, then transfer to a new 50-ml conical centrifuge tube, combining the bands from 2 to 3 Ficoll-Hypaque gradients into one 50-ml tube. Add PBS to 50-ml mark.
5. Centrifuge 10 min at 600 × *g* (1500 rpm in H-1000 rotor), 20°C, with the brake on.
6. Aspirate supernatants and resuspend the pellet in each tube with 10 ml room temperature PBS. Combine resuspended pellets into as few 50-ml tubes as possible. Add PBS to 50-ml mark in each tube used.
7. Centrifuge 15 min 300 × *g* (750 rpm in H-1000 rotor), 20°C, with brake on.

   This low-speed centrifugation permits as many platelets as possible to remain above the pellet of lymphocytes.

Process cell pellet

8. Aspirate platelet-containing supernatant and resuspend lymphocyte pellet in room temperature LCM. Count cells and determine number of viable cells by trypan blue exclusion (*UNIT 1.1*).

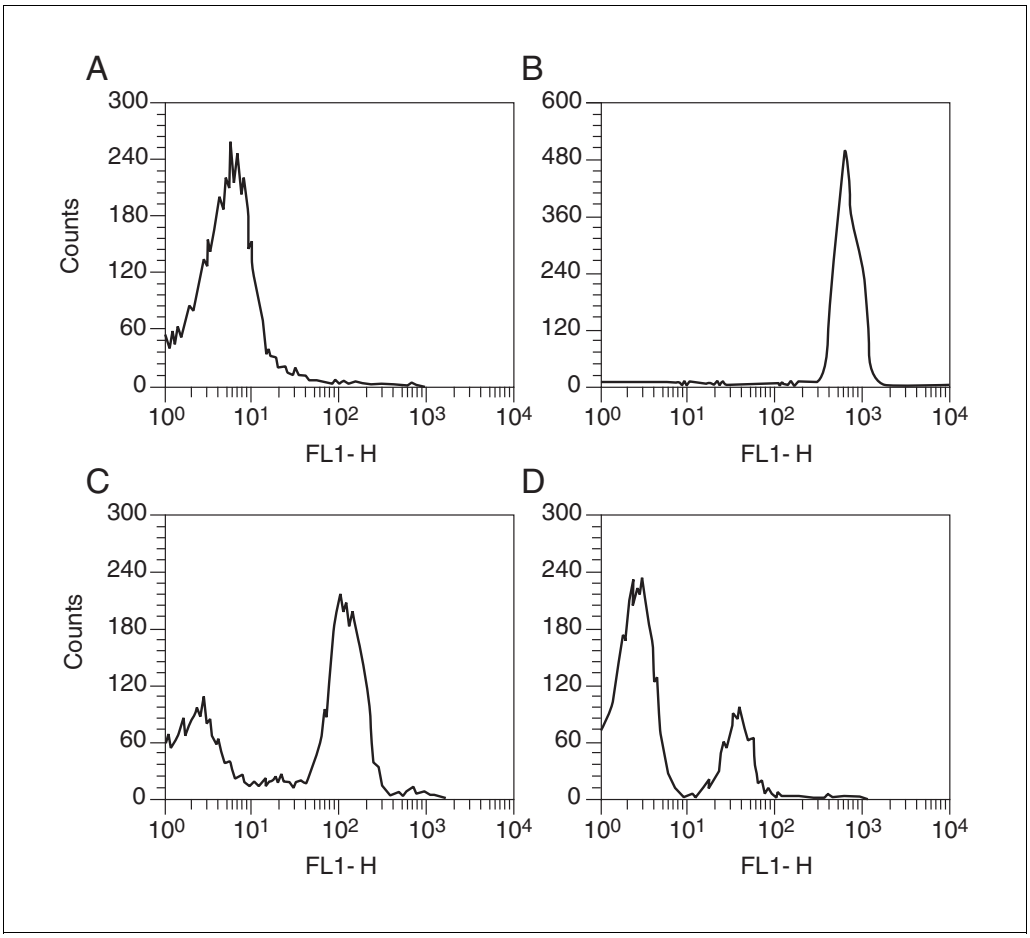

Figure 2.2.2 Flow cytometric analysis of human lymphocytes isolated by Ficoll-Hypaque density gradient centrifugation stained with (**A**) fluorochrome-labeled anti–mouse Ig antibody alone (negative control), (**B**) fluorochrome-labeled anti-CD45 monoclonal antibody, (**C**) fluorochrome-labeled anti-CD3 monoclonal antibody, and (**D**) fluorochrome-labeled anti-CD19 monoclonal antibodies. FL1-H refers to the pulse height for the fluorochrome.

9. Determine purity of lymphocyte preparation by flow cytometry (see, e.g., Robinson et al., 1998) using an anti-CD45 (anti–leukocyte common antigen) antibody (see Fig. 2.2.2 for typical results).

10. To cryopreserve cells, resuspend lymphocytes at twice the concentration desired in the freezing vials using MDM/20% human plasma. Add an equal volume of freezing medium, in increments, over a period of 1 to 2 min, mixing after each addition. Divide the cell suspension into 1-ml aliquots in 1.5-ml cryotubes, place cryotubes in a precooled 4°C controlled-rate freezer and freeze at −1°C/min until −50° or −60°C is attained. Finally, place cryotubes in the gaseous phase of a liquid nitrogen freezer.

BASIC PROTOCOL 2

PREPARATION OF MONOCYTES/MACROPHAGES AND "DENDRITIC-LIKE" CELLS FROM LYMPHOCYTE POPULATIONS

Monocytes/macrophages comprise 5% to 20% of the lymphocytes prepared by density gradient centrifugation (see Basic Protocol 1). To isolate this cell population, or to deplete these cells from the population of lymphocytes, the most expedient mechanism is to exploit the adherence property of monocytes/macrophages. By coating plastic tissue culture vessels with serum as a source of fibronectin and other components of the extracellular matrix, monocytes/macrophages, but not T and B cells, will adhere to these surfaces. This adherence can be significantly enhanced by the presence of recombinant human interleukin 3 (rhIL-3; Biddison et al., 1997). Cells with properties of dendritic cells and a markedly enhanced capacity for antigen processing and presentation can be generated from the monocyte/macrophage population by differentiation in the presence of rhIL-4 and granulocyte/macrophage colony stimulating factor (GM-CSF; Sallusto and Lanzavecchia, 1994).

Materials

Lymphocyte culture medium (LCM; see recipe), 37°C
Lymphocyte population (see Basic Protocol 1)
Recombinant human interleukin 3 (rhIL-3), interleukin 4 (rhIL-4), and GM-CSF (PeproTech)
5 mM tetrasodium EDTA in PBS (also available as Versene from Life Technologies), filter-sterilized using 0.22-µm Nalgene filter, prewarmed to 37°C
175-cm^2 tissue culture flasks
50-ml conical centrifuge tubes
Sorvall RT-6000B centrifuge with H-1000 rotor (or equivalent)
Additional reagents and equipment for counting cells and determining cell viability (*UNIT 1.1*) and flow cytometry (Robinson et al., 1998)

Allow monocyte/macrophage population to attach to plastic

1. Add 20 ml of 37°C LCM to 175-cm^2 tissue culture flasks. Incubate 30 min.

2. Add 500×10^6 lymphocytes in 10 ml LCM to each flask plus rhIL-3 to a final concentration of 200 U/ml.

3. Incubate 3 hr, gently rocking flasks every hour.

4. Remove nonadherent cells by aspirating the medium. Wash flasks twice, each time with 20 ml 37°C LCM.

Isolate macrophages/monocytes or "dendritic-like" cells

To isolate monocytes/macrophages

5a. Add 20 ml of 5 mM EDTA/PBS to each flask and incubate 20 min to release adherent monocytes/macrophages.

6a. Vigorously pipet medium up and down to detach adherent cells, then transfer to 50-ml centrifuge tube.

To generate and isolate "dendritic-like" cells

5b. Add 30 ml LCM containing 200 U/ml rhIL-4 and 200 U/ml GM-CSF to each flask and incubate 60 hr.

6b. Remove nonadherent cells and place in 50-ml centrifuge tubes, then add 20 ml of 5 mM EDTA/PBS to each flask and incubate 20 min to release adherent cells. Vigorously pipet medium up and down to detach adherent cells, then combine with nonadherent cells in 50-ml centrifuge tubes.

Separate and analyze isolated cells

7. Centrifuge 10 min at 600 × *g* (1500 rpm in Sorvall H-1000 rotor), room temperature. Aspirate supernatant and resuspend pellet in LCM.

8. Count cells and determine number of viable cells by trypan blue exclusion (*UNIT 1.1*).

9. Determine purity of the monocyte/macrophage or "dendritic-like" cell populations by flow cytometry (see, e.g., Robinson et al., 1998).

Monocytes/macrophages can be distinguished from T and B cells by the absence of cell-surface CD3 and CD19 and by the presence of CD14 or CD35. "Dendritic-like" cells can be distinguished from monocytes/macrophages by the presence of cell-surface CD1 molecules (Sallusto and Lanzavecchia, 1994).

POSITIVE SELECTION OF T AND B CELLS BY MONOCLONAL ANTIBODY–COATED MAGNETIC BEADS

BASIC PROTOCOL 3

In this procedure, T cells and B cells are positively selected based on their differential cell-surface expression of CD3 (T cells) or CD19 (B cells). Monoclonal anti-CD3 and anti-CD19 antibodies coupled to magnetic beads are commercially available. Aliquots of a lymphocyte population purified as described in Basic Protocol 1 are incubated in separate tubes with anti-CD3-coupled beads and anti-CD19-coupled beads. T cells and B cells will be bound by their specific antibody-coupled beads and are then physically separated from unbound cells by exposure of the tubes to a strong magnetic field. Unbound cells are removed and washed away, and the specifically bound cells are released by incubation with a soluble antiserum specific for mouse Fab fragments (Detachabead solution from Dynal) which competes with the bead-coupled monoclonal antibody that is bound to the surface of the cells and thus causes the cells to come off. The procedure here describes specific reagents for separation of T cells and B cells, but is directly applicable to separation of any lymphocyte subpopulation that can be distinguished by monoclonal antibody–coated beads—e.g., purification of $CD4^+$ and $CD8^+$ T cell populations with anti-CD4- and anti-CD8-coated magnetic beads.

Materials

Lymphocyte population (see Basic Protocol 1)
Anti-CD3 and anti-CD19 antibodies for flow cytometry (Becton-Dickinson or Coulter)
Anti-CD3- and anti-CD19-coated magnetic beads (Dynabeads M-450; Dynal)
PBS without calcium and magnesium (Bio-Whittaker)

PBS/HSA: PBS without calcium and magnesium (Bio-Whittaker) containing 0.5% (w/v) human serum albumin (American Red Cross Blood Services)

IMDM/HSA: Iscove's modified Dulbecco's medium (Life Technologies) containing 0.5% (w/v) human serum albumin

Polyclonal anti–mouse Fab antiserum (Detachabead; Dynal)

15-ml conical centrifuge tubes

Magnetic separation device (e.g., Dynal MPC-I or Advanced Magnetics Biomag Separator)

Platform rocker (e.g., Clay Adams Nutator, Becton Dickinson Primary Care Diagnostics)

Sorvall RT-6000B centrifuge with H-1000 rotor (or equivalent)

Additional reagents and equipment for flow cytometry (Robinson et al., 1998) and for counting cells and determining cell viability (*UNIT 1.1*)

Prepare and wash magnetic beads

1. Determine the approximate number of T cells and B cells in the starting population of lymphocytes by flow cytometry (or indirect immunofluorescence staining) using anti-CD3 and anti-CD19 antibodies, then determine the number of antibody-coated magnetic beads that will be required to purify the required number of T cells and B cells (5 to 10 beads will be needed for each specific target cell).
2. Based on the bead concentration supplied by the manufacturer, remove the required volume of anti-CD3- and anti-CD19-coated beads from the source vials and place each in a 15-ml conical centrifuge tube. Add PBS to the 14-ml mark and resuspend the beads.
3. Place tubes on magnetic separation device (vertical magnet) for 2 min, then gently aspirate supernatant, leaving beads clinging to one side of each tube.
4. Remove tubes from magnet. Add 10 ml PBS to each tube, resuspend beads, then place tubes on vertical magnet for 2 min. Aspirate PBS as in step 3.

Perform magnetic separation

5. Resuspend each tube of beads in 2 ml PBS/HSA. Put tubes on ice for 15 min.
6. Resuspend lymphocyte population ($\leq 200 \times 10^6$ cells) in 10 ml PBS/HSA. Place on ice for 15 min.
7. Add 5 ml of lymphocyte suspension to the tube with anti-CD3 beads and 5 ml to the tube with anti-CD19 beads.
8. Incubate 45 min with gentle tilting and rotation on a platform rocker at 4°C.
9. Place tubes on vertical magnet for 2 min. Aspirate nonadherent cells, taking care not to disturb the beads that are clinging to one side of each tube.
10. Add 5 ml IMDM/HSA to each tube. Gently resuspend beads, then place tubes on vertical magnet for 2 min. Aspirate nonadherent cells as in step 9.
11. Add 3 ml IMDM/HSA to each tube. Gently resuspend beads, then place tubes with their conical bottoms on the horizontal magnet. Incubate 2 min at room temperature.

Release T cells and B cells from beads

12. Carefully remove 2.5 ml of supernatant. Tap tubes gently to resuspend beads.
13. Add 200 µl Detachabead solution. Incubate 30 min at room temperature with gentle resuspension every 5 min.

Smaller volumes of Detachabead solution may be used when starting with smaller numbers of lymphocytes; see manufacturer's instructions.

14. Add 3 ml PBS/HSA to each tube and resuspend beads. Place tubes on vertical magnet for 2 min, then aspirate and save supernatant containing detached cells, taking care not to disturb the beads clinging to the side of each tube. Repeat this step four times, saving and combining detached cell–containing supernatants from each separation.

15. Centrifuge detached cells 10 min at 600 × *g* (1500 rpm in H-1000 rotor), room temperature.

16. Aspirate supernatants and resuspend cells in IMDM/HSA. Count cells and determine number of viable cells by trypan blue exclusion (*UNIT 1.1*).

17. Determine purity of the T cell and B cell populations by flow cytometry using anti-CD3 and anti-CD19 antibodies (see, e.g., Robinson et al., 1998).

POSITIVE SELECTION OF T AND B CELLS BY MONOCLONAL ANTIBODIES AND ANTI-IgG-COATED MAGNETIC BEADS

ALTERNATE PROTOCOL 1

This procedure differs from Basic Protocol 3 in that it does not require the acquisition of separate magnetic beads coupled with individual monoclonal antibodies. The procedure is described for T and B cell separation, but can be applied to any lymphocyte subpopulation that can be distinguished by monoclonal antibodies. The principle of the technique is that a human mixed lymphocyte population is separately exposed to saturating amounts of either anti-CD3 or anti-CD19 mouse IgG monoclonal antibodies, unbound antibodies are washed away, then the cells that have bound these antibodies are physically separated from unbound cells by magnetic beads coated with goat anti-mouse IgG. The cells that are specifically bound to the goat anti-mouse IgG–coated beads are then detached by exposure to soluble antiserum against mouse Fab fragments.

Additional Materials *(also see Basic Protocol 3)*

Anti-CD3 and anti-CD19 IgG monoclonal antibodies (Becton Dickinson or Coulter)
Goat anti-mouse IgG–coated magnetic beads (Dynabeads M-450; Dynal)

Prepare cells and antibodies

1. Determine the approximate number of T cells and B cells in the starting population of lymphocytes by flow cytometry using anti-CD3 and anti-CD19 antibodies (e.g., Robinson et al., 1998).

2. Determine the saturating concentration of the anti-CD3 and anti-CD19 antibodies to be used by flow cytometry. Prepare a solution of each antibody in PBS/HSA at ten times (10×) the saturating concentration.

Treat cells with antibodies

3. Resuspend the lymphocyte population (≤200 × 10^6 cells) in 9 ml PBS/HSA and add 4.5 ml of the suspension to each of two 15-ml conical centrifuge tubes. Add 0.5 ml of 10× anti-CD3 antibody to one tube and 0.5 ml of 10× anti-CD19 antibody to the other tube.

4. Incubate 45 min with gentle tilting and rotation on a platform rocker at 4°C.

5. Wash cells twice, each time by centrifuging 10 min at 600 × *g* (1500 rpm in H-1000 rotor), room temperature, removing the supernatant, resuspending in 10 ml PBS/HSA, and removing the supernatant. Finally, resuspend each tube in 5 ml PBS/HSA and put on ice for 15 min.

Prepare magnetic beads

6. Based on the number of T and B cells estimated in step 1, determine the number of goat anti-mouse IgG–coated magnetic beads that will be required to purify the required number of T and B cells (5 to 10 beads will be needed for each specific target cell).
7. Based on the bead concentration supplied by the manufacturer, remove two aliquots of the required volume of goat anti-mouse IgG–coated beads from the source vial and place in 15-ml conical centrifuge tubes. Add PBS to the 14-ml mark and resuspend the beads.
8. Wash beads (see Basic Protocol 3, steps 2 to 4).

Perform separation

9. Add 5 ml of anti-CD3-coated cells to one tube of washed anti-IgG-coated beads and 5 ml of anti-CD19-coated cell suspension to the other tube of anti-IgG-coated beads.
10. Perform magnetic separation to isolate T and B cells (see Basic Protocol 3, steps 8 to 17).

ALTERNATE PROTOCOL 2

ISOLATION OF T AND B CELL SUBPOPULATIONS BY NEGATIVE SELECTION

For certain experimental conditions, it is desirable to isolate lymphocyte subpopulations without antibody engagement of cell-surface molecules such as the immunoglobulin receptor on B cells and the CD3 complex on T cells. Therefore, negative selection procedures are followed that aim to maximize the elimination of all lymphocyte subpopulations except the desired one. For T cell isolation, the procedure involves elimination of B cells ($CD19^+$), monocytes/macrophages ($CD14^+$), and NK cells ($CD16^+$); for B cell isolation T cells ($CD3^+$), monocytes/macrophages, and NK cells are eliminated. The procedure is very similar to the above protocol for selection of T and B cells using anti-IgG–coated magnetic beads.

Additional Materials *(also see Basic Protocol 3)*

Anti-CD3, anti-CD14, anti-CD16, and anti-CD19 IgG monoclonal antibodies (Becton-Dickinson or Coulter)
Goat anti-mouse IgG–coated magnetic beads (Dynabeads M-450; Dynal)

Prepare cells and antibodies

1. Determine the approximate number of T cells, B cells, monocytes/macrophages, and NK cells in the starting population of lymphocytes by flow cytometry using anti-CD3, anti-CD19, anti-CD14, and anti-CD16 antibodies (e.g., Robinson et al., 1998).
2. Determine the saturating concentrations of the anti-CD3, anti-CD19, anti-CD14, and anti-CD16 antibodies to be used by flow cytometry. Prepare a solution of each antibody in PBS/HSA at ten times (10×) the saturating concentration.

Treat cells with antibodies

3. Resuspend the lymphocyte population ($\leq 200 \times 10^6$ cells) in 3.5 ml PBS/HSA in a 15-ml conical centrifuge tube.

4a. *For T cell isolation:* Add 0.5 ml each of 10× anti-CD19, 10× anti-CD14, and 10× anti-CD16 antibody preparations to the tube.

4b. *For B cell isolation:* Add 0.5 ml each of 10× anti-CD3, 10× anti-CD14, and 10× anti-CD16 antibody preparations to the tube.

5. Incubate 45 min with gentle tilting and rotation on a platform rocker at 4°C.
6. Wash cells twice, each time by centrifuging 10 min at 600 × *g* (1500 rpm in H-1000 rotor), room temperature, removing the supernatant, resuspending in 10 ml PBS/HSA, and removing the supernatant. Finally, resuspend cells in 5 ml PBS/HSA and put on ice for 15 min.

Prepare magnetic beads

7. Based on the number of cells of each subpopulation estimated in step 1, determine the number of goat anti-mouse IgG–coated magnetic beads that will be required to bind the required number of antibody-coated lymphocytes (5 to 10 beads will be needed for each specific target cell).
8. Based on the bead concentration supplied by the manufacturer, remove the required volume of goat anti-mouse IgG–coated beads from the source vial and place in a 15-ml conical centrifuge tube. Add PBS to the 14-ml mark and resuspend the beads.
9. Wash beads (see Basic Protocol 3, steps 2 to 4).

Perform separation

10. Add 5 ml of washed antibody-coated cells (from step 6) to the tube with the washed anti-IgG-coated beads.
11. Incubate 45 min with gentle tilting and rotation on a platform rocker at 4°C.
12. Place tube on vertical magnet for 2 min. Aspirate and save supernatant containing nonadherent cells, taking care not to disturb the beads clinging to the side of the tube.
13. Add 5 ml IMDM/HSA to tube. Gently resuspend beads.
14. Repeat steps 12 and 13 twice, saving and pooling nonadherent cells from each wash.
15. Centrifuge nonadherent cells 10 min at 600 × *g* (1500 rpm in H-1000 rotor), room temperature. Aspirate supernatant and resuspend cells in 5 ml IMDM/HSA. Count cells and determine number of viable cells by trypan blue exclusion (*UNIT 1.1*).
16. Determine purity of the T cell and B cell populations by flow cytometry using anti-CD3 and anti-CD19 antibodies (see, e.g., Robinson et al., 1998).

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Ficoll-Hypaque solution (density 1.07 to 1.08 g/ml)

Dissolve 6.2 g Ficoll (mol. wt. 400,000; e.g., Sigma) in 75 ml distilled water with slow stirring. Add 10.4 g sodium diatrizoate and stir until solution is clear. Add water to 100 ml. Filter-sterilize using 0.22-µm filter (Nalgene). Store up to 6 months at 4°C in the dark.

Alternatively, solutions can be purchased from commercial suppliers (e.g., Lymphocyte Separation Medium from Organon Teknika Cappel or equivalent product from Bio-Whittaker).

Freezing medium

Mix 20 ml Iscove's modified Dulbecco's medium (IMDM; Life Technologies) and 20 ml heparinized human plasma. Cool to 4°C. Slowly add 10 ml dimethylsulfoxide, mixing after each incremental addition. Cool to 4°C and filter sterilize using a 0.22-µm filter.

Lymphocyte culture medium (LCM)

Iscove's modified Dulbecco's medium (IMDM; Life Technologies) containing:
100 U/ml penicillin
100 µg/ml streptomycin
10% heparinized human plasma
Store up to 2 weeks at 4°C

COMMENTARY

Background Information

Density-gradient separation of lymphocytes

Isolation of human lymphocytes from peripheral blood by density gradient centrifugation provides the following advantages: it is a simple technique, it is relatively inexpensive, it does not require special laboratory equipment, sterility is easily maintained, and high yields of lymphocytes are provided (Boyum, 1968). A typical yield of lymphocytes from whole blood of healthy adult donors is $1–2 \times 10^6$ cells/ml. Figure 2.2.2 shows a typical result from flow cytometric analysis of density gradient–purified lymphocytes in which 98% of cells are $CD45^+$ (positive for common leukocyte antigen), 61% are $CD3^+$ (T cells), and 21% are $CD19^+$ (B cells). The non-T non-B cell population contains monocytes/macrophages and natural killer (NK) cells.

Monocytes/macrophages can be easily purified from the lymphocyte population based on their differential adhesiveness to immobilized components of the the extracellular matrix contained in human serum. A typical yield of monocytes/macrophages from a lymphocyte population is 5% to 10%. Flow cytometric analysis shows that ≥95% of these cells are HLA class I^+, HLA-DR^+, and $CD35^+$, and ≤1% are $CD3^+$ T cells (Fig. 2.2.3). A subset of these monocytes/macrophages can be differentiated into immature antigen-presentation-competent "dendritic-like" cells by culture in IL-4 and GM-CSF (Sallusto and Lanzavecchia, 1994). These "dendritic-like" cells have proven to be extremely useful antigen-presenting cells for the generation and cloning of rare self-reactive T cells (Biddison et al., 1997).

Magnetic-bead separation of lymphocytes

Cell-separation procedures based on magnetic-bead technology have the advantages of easy manipulation, safety from contamination with microorganisms, and avoidance of high shear forces that affect cell viability. The most direct procedures involve positive selection with specific monoclonal antibodies directly coupled to magnetic beads and the subsequent liberation of the bound cells by competing anti-Fab antibodies. This procedure also has the added advantage of providing a positively selected lymphocyte subpopulation free of any cell-bound selecting antibodies. A variation on this approach involves precoating the lymphocyte subpopulation of choice with a specific monoclonal IgG antibody and subsequent physical sequestration with anti-IgG-coated magnetic beads. In experimental situations in which specific antibody binding to cell-surface structures must be avoided, negative selection procedures are employed, wherein the lymphocyte subpopulations that are not desired are coated with specific IgG antibodies and are then removed by anti-IgG-coated magnetic beads. Each of these procedures has been used successfully to isolate human T cells, monocytes/macrophages, and B cells (Lea et al., 1986; Vartdal et al., 1987; Funderud et al., 1990).

Alternative procedures for positive selection are cell sorting of fluoresceinated antibody–coated cells with a flow cytometer and panning of antibody-coated cells on plastic surfaces containing immobilized anti-immunoglobulin reagents. This author's experiences with these techniques indicate that they present a much higher likelihood of contamination with microorganisms and subject the lymphocytes to conditions that can lead to more loss of viable cells than occurs with the magnetic-bead procedures. Cell sorting also has a major limitation in the number of cells that can be separated. Negative selection can also be provided by complement-fixing antibodies, but this approach involves the need to remove dead-cell debris before the remaining viable cells can be used for experimentation.

Critical Parameters and Troubleshooting

To maximize the yield and purity of lymphocytes using the density gradient protocol (see Basic Protocol 1), it is essential to harvest all of the cells at the interface between the

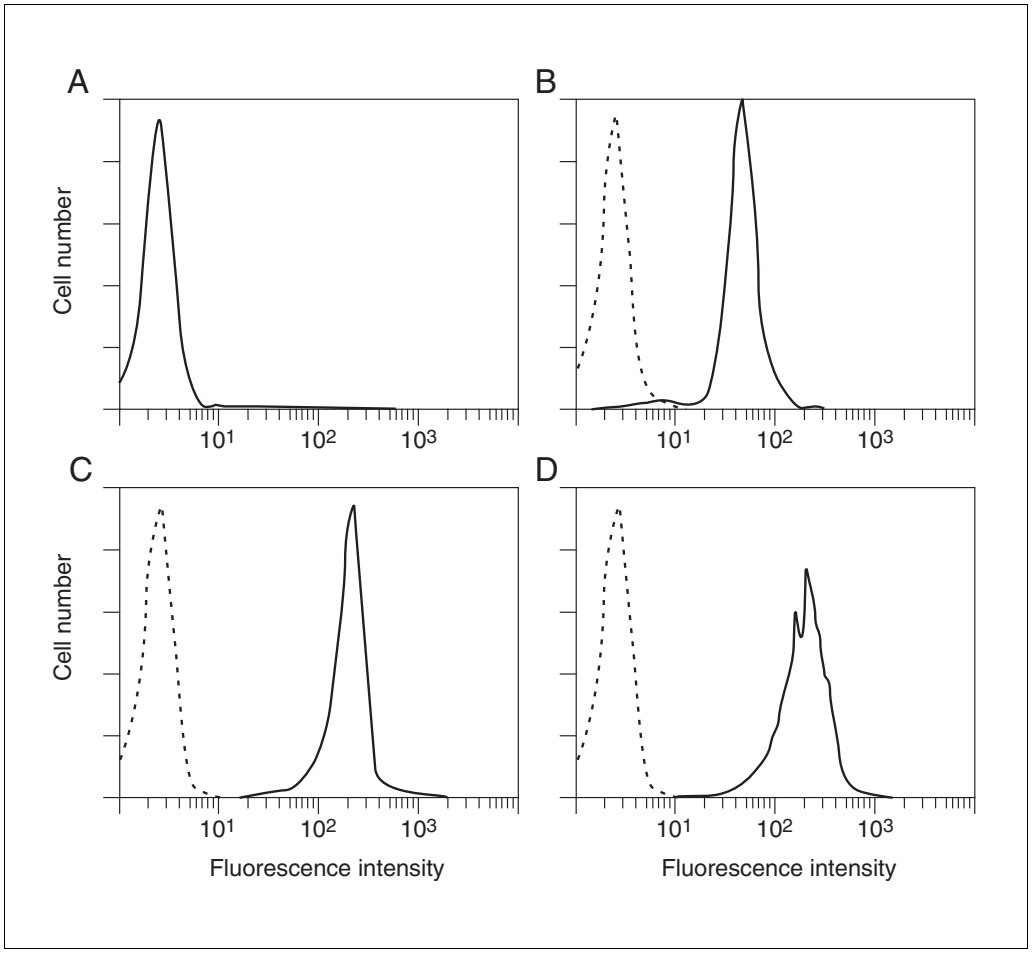

Figure 2.2.3 Flow cytometric analysis of isolated monocytes/macrophages. The solid lines represent cells stained with (**A**) fluorochrome-labled anti-CD3 monoclonal antibodies, (**B**) fluorochrome-labeled anti-CD35 monoclonal antibodies, (**C**) fluorochrome-labeled anti–HLA class I monoclonal antibodies, and (**D**) fluorochrome-labeled anti-HLA-DR monoclonal antibodies. The dotted lines in panels B, C, and D represent cells stained with fluorochrome-labeled anti–mouse IgG alone.

Ficoll-Hypaque solution and the plasma/platelet layer. This may require harvesting up to 5 ml of the underlying Ficoll-Hypaque solution. This is why it is recommended that at least 7.5 ml of this solution be used as an underlay for each tube. Great care should be taken not to disturb or harvest any of the pelleted granulocytes and erythrocytes. One common problem is the accumulation of platelets at the Ficoll-Hypaque interface, which produces clumping and contamination with platelets and erythrocytes. This problem can be partially avoided by further dilution of blood with PBS and by not centrifuging the cells at temperatures <20°C. The platelet-contamination problem can be alleviated in the subsequent washing steps. If significant cloudiness of the supernatant is observed (due to platelet contamination) following the 15-min centrifugation at 300 × *g* (see Basic Protocol 1, step 7), aspirate the supernatants, resuspend the cells in 50 ml PBS, and do another 15-min, 300 × *g* centrifugation to remove as many remaining platelets as possible.

Isolation of monocytes/macrophages by adherence is significantly enhanced by precoating the tissue culture flasks with serum-containing medium and including IL-3 during the adhesion incubation. No diminution in antigen-presenting function has been observed in the author's laboratory by cells cultured in IL-3. However, if the presence of IL-3 may add an unknown variable to other types of experiments, especially those that will utilize the nonadherent lymphocyte fraction, it is recommended that IL-3 not be included during the adherence step.

The specificity and avidity of the antibody reagents used in these cell-separation procedures are clearly of critical importance. Care must be taken to utilize appropriate concentrations of coating monoclonal antibodies to ensure that all specific target cells are coated with antibody. It is also crucial that, when precoating cells with soluble antibodies, all unbound antibodies are adequately removed during the washing steps. Another critical factor is the use of adequate numbers of antibody–coated magnetic beads to completely engage all appropriate available cells. The use of 5 to 10 beads per specific target cell helps to ensure a complete saturation of the available target cells. Certain pitfalls are relatively easy to avoid. Where called for in the protocols, be sure to do manipulations on cells that have been precooled and do appropriate incubations at 4°C. This will ensure that the selecting antibodies will not be removed by capping. Use of a sufficiently strong magnet will improve cell yields and purity and reduce the amount of time for each magnetic-selection step. This author's experience is that the Biomag Separator available from Advanced Magnetics is more than adequate for the task of selecting the Dynal Dynabeads. Also note that the protocols do not include use of fetal bovine serum (FBS) in any step. FBS and other heterologous sera should be avoided in all steps because they can produce unwanted activation of lymphocytes.

At the conclusion of each of the cell-separation procedures, the purity of the cell populations produced should be assessed by flow cytometry.

Anticipated Results

Whole blood from healthy adult donors will typically yield 1–2 $\times 10^6$ lymphocytes per ml of blood by the density gradient protocol. A typical leukapheresis in which lymphocytes are collected from 5 liters of blood will yield 4–6 $\times 10^9$ lymphocytes when processed by the density gradient protocol. Isolated lymphocytes should be ≥95% viable.

Isolation of monocytes/macrophages from 500×10^6 lymphocytes will usually yield 25–50 $\times 10^6$ cells with ≥95% viability. Generation of "dendritic-like" cells from the same number of starting lymphocytes will usually yield 5–10 $\times 10^6$ cells with ≥90% viability.

The lymphocyte subpopulations produced by the magnetic-bead techniques should be ≥95% pure and ≥95% viable by trypan blue dye exclusion. The overall yield of T and B cells from the starting lymphocyte preparation from peripheral blood should be 40% to 60%.

Time Considerations

Isolation of lymphocytes from peripheral blood (see Basic Protocol 1) usually takes 2 hr, depending on the volume of blood obtained or the number of lymphocytes collected by leukapheresis. Monocyte/macrophage isolation (see Basic Protocol 2) requires a subsequent 3.5-hr time period, and culture of the isolated monocytes/macrophages with IL-4 and GM-CSF requires an additional 60 hr of incubation time.

Positive selection using monoclonal antibody–coated magnetic beads (see Basic Protocol 3) requires 2 to 3 hr. The method using anti-IgG coated-beads (see Alternate Protocol 1) requires an additional hour for precoating of the cells with selecting antibodies.

Preparation of Endothelial Cells

This unit presents various approaches to obtaining endothelial cells from tissues for cell culture. The isolation of these cells from umbilical vein (see Basic Protocol) is particularly useful because the tissue source is readily available and the cells can be obtained in quantity. The isolated cells are generally pure and grow well. Although umbilical veins are the most frequently employed source, cells can be obtained from other vessels and from tissues—e.g., adipose tissue, nasal mucosa, and skin.

The isolation of human umbilical vein endothelial cells (HUVEC) is first described (see Basic Protocol). Additional protocols describe the isolation of microvascular endothelial cells from tissues with few contaminating cells (retroperitoneal adipose tissue and nasal mucosa; see Alternate Protocol 1) and from tissues with a significant number of contaminating cells (skin; see Alternate Protocol 2).

CAUTION: When working with human blood, cells, or infectious agents, appropriate biosafety practices must be followed.

NOTE: All solutions and equipment coming into contact with cells must be sterile, and proper sterile technique should be used accordingly.

NOTE: All culture incubations should be performed in a 37°C, 5% CO_2 incubator unless otherwise specified. Some media (e.g., DMEM) may require altered levels of CO_2 to maintain pH 7.4.

PREPARATION OF ENDOTHELIAL CELLS FROM HUMAN UMBILICAL VEIN

BASIC PROTOCOL

This protocol describes the isolation and culture of human umbilical vein endothelial cells (HUVEC).

Materials

Fresh human umbilical cord
RPMI 1640 medium, 4° and 37°C
Phosphate-buffered saline (PBS; Life Technologies)
5 mg/ml collagenase CLSII (Worthington) in PBS (filter sterilized), 37°C
HUVEC medium (see recipe), 37°C

250-ml wide-mouthed tissue culture flasks
Sterile pads and gauze
Sterile scissors, razors, hemostats, and non-toothed forceps
Syringes and yellow 200-µl pipet tips
50-ml conical centrifuge tubes
Tabletop centrifuge
Nunc T-75 tissue culture flasks *or* 75-cm^2 gelatin-coated flasks (see recipe)
150-mm-diameter Nunc tissue culture dishes

Additional reagents and equipment for trypsinization of cells (*UNIT 1.1*)

1. Place the umbilical cord in a 250-ml wide-mouthed flask containing RPMI 1640 medium and store at 4°C for no more than 24 hr after delivery.

   Cords older than 24 hr should be discarded. It is easiest to drop off the medium in a wide-mouth flask at the hospital ahead of time so the staff can deposit the cord as soon as it is available.

Contributed by Hynda K. Kleinman and Maria C. Cid
Current Protocols in Cell Biology (1998) 2.3.1-2.3.6

2. Working in a sterile tissue culture hood with sterile pads on the hood counter top, wash the cord with PBS. Using sterile gauze to hold the cord, cut the ends with a razor to yield a 10- to 15-cm segment.

   Wear a lab coat and two pairs of gloves. The cord is human tissue and could be infectious or pathogenic.

3. Dilate vein using non-toothed forceps.

   Dilate carefully to avoid tears.

4. Using a syringe with a yellow 200-µl pipet tip attached, flush 5 to 10 ml 37°C RPMI 1640 through the vein.

5. Using a fresh syringe with a yellow 200-µl pipet tip, flush 5 to 10 ml of 5 mg/ml collagenase through the vein.

6. Clamp one end of the cord with a hemostat and squeeze ~10 ml more collagenase solution into the vein. Clamp top of cord with a second hemostat and invert the cord several times to spread the collagenase solution.

7. Place the clamped umbilical cord in a 250-ml wide-mouthed flask with warm RPMI 1640 and incubate 15 min at room temperature.

8. Open one end of the cord over a 50-ml conical centrifuge tube to catch the effluent from the vein. Flush vein with 15 ml of 37°C HUVEC medium and collect the effluent.

   The HUVEC medium reduces the collagenase activity and helps the cells to remain viable.

9. Add enough additional HUVEC medium to fill the tube and centrifuge 5 min at 170 × *g* in a tabletop centrifuge, room temperature.

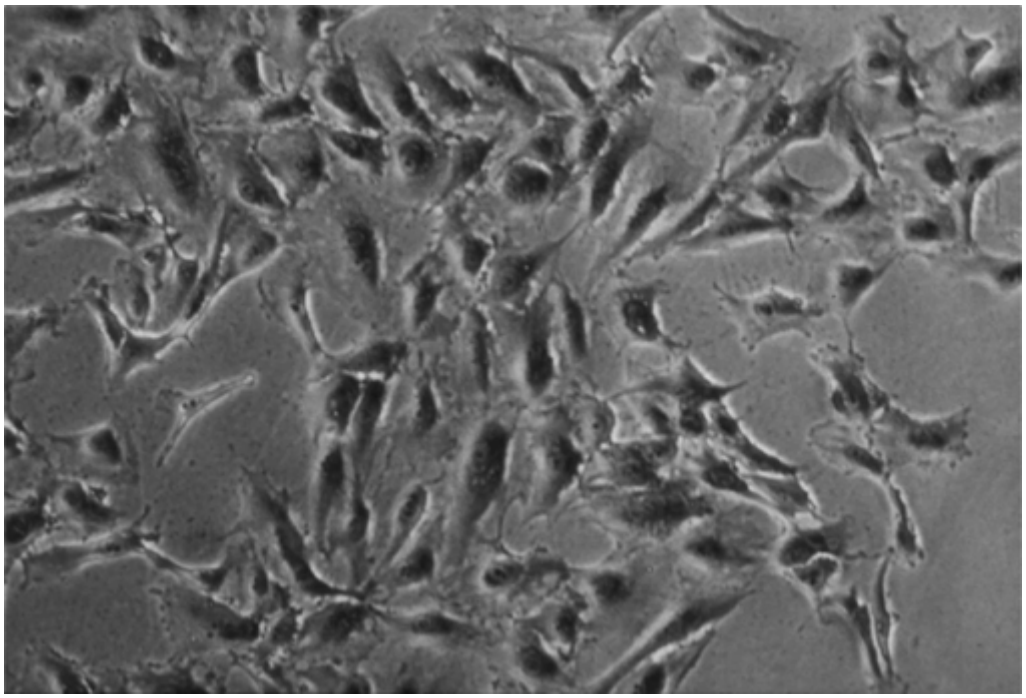

Figure 2.3.1 Culture of human umbilical vein endothelial cells 2 days after passaging. Passage 3 cells were at ~70% confluence and were fixed and stained, respectively, with Diff-Quik Fix and Solution II (Baxter). Cells were viewed using a Zeiss inverted microscope.

10. Decant and discard supernatant, tap tube to resuspend cell pellet, then add 15 ml 37°C HUVEC medium and transfer to two T-75 Nunc or 75-cm^2 gelatin-coated flasks. Incubate 1.5 hr.

    This is based on an average yield from a 10- to 15-cm cord.

11. After 1.5 hr, remove medium and add 15 ml fresh medium. Incubate 2 to 3 days (until confluent).

    The medium that is removed can be used to plate additional cells in another flask; after 1.5 hr, that medium should be removed and discarded, and fresh medium added. It is important with this second flask to be sure that there are not too many dead cells or fibroblasts (which can be detected microscopically on the basis of morphology).

12. When cells become confluent, split flask 1:4 into 150-mm Nunc tissue culture dishes.

    These cells are considered passage 1. Cells should not be used beyond passage 6. At passage 2, there should be 32 dishes. Some of the passage 2 cells can be frozen and stored in liquid nitrogen for future use (UNIT 1.1). Figure 2.3.1 shows a culture of endothelial cells with typical elongated morphology.

ISOLATION OF ENDOTHELIAL CELLS FROM RETROPERITONEAL ADIPOSE TISSUE OR NASAL MUCOSA

ALTERNATE PROTOCOL 1

It is well recognized that not all endothelial cells behave in a similar manner or have identical phenotypes. Preparations of endothelial cells from different tissue sources are often needed. Retroperitoneal adipose tissue or nasal mucosa can be obtained at the time of surgery. Usually, small pieces are provided from the normal edges of removed lesions such as polyps in the nasal mucosa.

Additional Materials *(also see Basic Protocol)*

Retroperitoneal adipose tissue or nasal mucosa
0.02% (w/v) collagenase A (Boehringer Mannheim) in PBS (filter sterilized)

Cell scraper
Laminin-coated 6-well tissue culture plates (see recipe)

Additional reagents and equipment for trypsinization of cells (*UNIT 1.1*)

1. Cut tissue into 2- to 4-mm-square pieces and wash with sterile PBS.
2. Incubate 3 to 5 tissue pieces for 30 min with enough 0.2% collagenase at 37°C to just cover the pieces.
3. Gently aspirate collagenase solution and wash the tissue once in PBS, discarding the supernatants.
4. Add 3 ml RPMI 1640 medium, squeeze tissue with a cell scraper, and collect cells in a 50-ml conical tube.
5. Filter through sterile gauze to remove tissue debris.
6. Centrifuge 5 min at 170 × *g* in a tabletop centrifuge, room temperature.
7. Discard supernatant, gently tap tube to resuspend cell pellet, and add 15 ml of room temperature HUVEC medium.
8. Plate 3 ml of cell suspension onto each well of a laminin-coated 6-well plate. Incubate 1 hr, then remove medium (along with unattached cells) and add 3 ml fresh medium.

    This step reduces the fibroblast contamination.

9. Incubate cells until confluent and passage as described above for HUVECs (see Basic Protocol).

ALTERNATE PROTOCOL 2

ISOLATION OF MICROVASCULAR ENDOTHELIAL CELLS FROM DERMIS

Human microvascular endothelial cells can be isolated from neonatal foreskins (Kubota et al., 1988). These cells are relatively easy to prepare and are widely used.

Additional Materials *(also see Basic Protocol and Alternate Protocol 1)*

Dermal tissue (e.g., neonatal foreskins)
Discontinuous Percoll gradient (see recipe)
5 mM tetrasodium EDTA in PBS (also available as Versene from Life Technologies), filter-sterilized using 0.22-μm Nalgene filter, prewarmed to 37°C

PBS containing 5% FBS, room temperature to 37°C (store up to 1 month at 4°C)
Laminin-coated 6-well tissue culture plates (see recipe)
Anti-CD31-coated petri dishes (see recipe)
Gelatin- or fibronectin-coated 6-well tissue culture plates (see recipes)

Additional reagents and equipment for trypsinization of cells (*UNIT 1.1*)

1. Prepare a cell suspension from dermal tissue as described for retroperitoneal adipose tissue or nasal mucosa (see Alternate Protocol 1, steps 1 to 6). Resuspend the pellet in 1 ml of RPMI 1640 medium.
2. Carefully layer 1 ml of the resuspended pellet on top of the discontinuous Percoll gradient. Centrifuge 20 min at 670 × *g* in a tabletop centrifuge, room temperature.
3. Collect each layer separately and transfer to individual tubes. Wash by centrifuging 5 min at 170 × *g*, room temperature, adding 10 ml RPMI 1640 medium, then centrifuging again and removing the supernatant.

   Endothelial cell fractions are usually in the 32% and 34% layers.

4. Resuspend pellets in HUVEC medium and culture each fraction in a well of a laminin-coated 6-well plate (see Alternate Protocol 1, steps 7 to 9).

   Usually the yield of cells is very low due to the small amounts of biopsy material available. All of the pellet obtained from each fraction should be placed in a well. The number of endothelial cell colonies will be small.

5. After 2 days, remove medium, wash cells with PBS, and detach cells by incubating ~5 min with 1.0 ml/well of 5 mM EDTA/PBS at room temperature.
6. Centrifuge 5 min at 170 × *g*, room temperature. Discard supernatant, tap tube to resuspend cell pellet, add 15 ml RPMI 1640 medium (prewarmed to 37°C), and incubate 1 to 3 hr on a CD31-coated dish at 37°C.
7. Gently aspirate the medium containing nonadherent cells and wash the dish twice gently with 15 ml of room temperature to 37°C PBS containing 5% FBS.
8. Wash dish gently with 15 ml of room temperature to 37°C PBS and release attached cells by trypsinization.

   The cells usually detach within a few minutes.

9. Centrifuge cells 5 min at 170 × *g*, room temperature. Discard the supernatant, tap the tube gently to resuspend the cell pellet, add HUVEC medium and culture on gelatin- or fibronectin-coated 6-well tissue culture plates (see Basic Protocol).

   Fibronectin is more expensive than gelatin.

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Anti-CD31-coated petri dishes

Prepare 10 µg/ml anti-CD31 monoclonal antibody in 50 mM Tris·Cl, pH 9.5 (store according to supplier's instructions). Add 10 ml of this solution to a 10-cm-diameter petri dish and incubate 1.5 hr at 37°C. Remove the solution and use it to coat two more dishes in the same way. Wash each dish three times with 0.15 M NaCl, then add 10 ml of 1 mg/ml bovine serum albumin (BSA) to each dish and incubate overnight at 4°C. Remove the liquid before adding the cells.

The anti-CD31 is available from several suppliers. Preparations without BSA work better. The coated plates should be used immediately.

Fibronectin-coated 6-well tissue culture plates

Prepare 333 µg/ml fibronectin in PBS (Life Technologies) and filter sterilize (store up to 1 week at 4°C). Add 0.3 ml to each well and incubate 30 min at 37°C just prior to addition of cells. Remove the solutions containing unbound fibronectin prior to addition of the cells.

Gelatin-coated tissue culture flasks and plates

Prepare 0.1% (w/v) gelatin in PBS (Life Technologies) and filter sterilize (store up to 1 month at 4°C). Incubate flasks with the gelatin solution 30 min at 37°C, then remove gelatin and rinse with sterile PBS. Store coated flasks up to 1 day at 4°C or air dry and use within 1 week.

HUVEC medium

500 ml RPMI-1640 medium
100 ml defined iron-supplemented calf serum (HyClone)
100 mg endothelial cell growth supplement (ECGS; Collaborative Biomedical)
2500 U heparin
5 ml 100× glutamine
5 ml 100× penicillin/streptomycin
5 ml 100× Fungizone
0.5 ml 1000× gentamicin
Store up to 1 month at 4°C

Laminin-coated 6-well tissue culture plates

Prepare 333 µg/ml laminin in PBS (Life Technologies) and filter sterilize (store up to 1 year at −80°C). Add 0.3 ml to each well and incubate 30 min at 37°C just prior to addition of cells. Remove the solutions containing unbound laminin prior to addition of the cells.

Percoll gradient, discontinuous

Prepare 30%, 34%, and 38% (v/v) Percoll in PBS
Prepare 32%, 36%, and 40% (v/v) Percoll in RPMI-1640 medium (with phenol red)

Pipet 2 ml of the 40% Percoll solution into a 15-ml round-bottom Nalgene centrifuge tube. Carefully layer 2 ml of the 38% Percoll on top of this, followed successively by the 36%, 34%, 32%, and 30% Percoll.

The Percoll solutions are prepared in an alternating fashion with PBS and (phenol red containing) RPMI 1640 to make it possible to distinguish the layers easily.

COMMENTARY

Background Information

Endothelial cells line blood vessels and are attached to each other (cell-to-cell) and to the underlying basement membrane matrix (cell-to-matrix). Various methods have been developed to isolate these cells in quantity for cell culture. Human umbilical vein is an ideal source because it is easy to obtain, cells can be isolated in quantity, and the cells are generally pure and grow well (Gimbrone, 1976; Jaffe, 1980). A disadvantage is the expensive medium needed to propagate the cells. The ECGS (endothelial cell growth supplement) is costly but can be prepared by the investigator if very large quantities are needed (Gordon et al., 1983). Newer media are under development and appear to maintain the survival of the cells. Previously, tumor-conditioned medium had been used (Folkman et al., 1979), but that material was somewhat variable and the results were not as reproducible as those observed with the HUVEC medium used in this unit (see Reagents and Solutions). Another disadvantage of HUVEC is that the cells cannot be used beyond passage 6, due to changes in the phenotype.

Other blood vessel and tissue sources have yielded endothelial cells for culture. For example, endothelial cells have been prepared from nasal mucosa (Fukuda et al., 1989), bovine capillary, pancreatic islet, mouse hemangioendothelioma (Folkman et al., 1979; Voest et al., 1995), adrenal cortex, and human dermis (Kubota et al., 1988).

Critical Parameters and Troubleshooting

Once the cells are isolated, their identity as endothelial cells can be confirmed by their characteristic cobblestone morphology or by specific markers such as factor VIII or uptake of acetylated LDL (Kubota et al., 1988; Kibbey et al., 1992). The type of dish used to culture the cells is important and the protocols should be followed exactly.

Because the cells are of human origin, full precautions for infectious and viral diseases must be employed. Gloves (at least two pair) should be used even after the cells have been in culture for several passages.

As compared with other types of primary cells, HUVEC are more "delicate" and problems with growth are observed with slight changes in the carbon dioxide or the temperature.

Umbilical cord or biopsy tissue should be stored at 4°C in medium and should not be used if it is >24 hr old.

Anticipated Results

One umbilical vein should yield two confluent T-75 flasks in 3 to 5 days. By passage 2 there should be 32 confluent 150-mm dishes with ~1 $\times 10^7$ cells per dish. The yield from tissues is less than that from umbilical vein.

Time Considerations

Preparation of the cells for all three methods should not take more than half a day.

Generation of Continuously Growing B Cell Lines by Epstein-Barr Virus Transformation

BASIC PROTOCOL

Epstein-Barr virus (EBV) has been widely used to transform human B cells in vitro and to produce continuously growing B cell lines for use in a variety of in vitro studies. Most human B cell lines that are transformed by EBV secrete little or no infectious viral particles. For this reason, a marmoset line transformed with the human Hawley strain of EBV, which secretes active infectious EBV into the culture supernatant, is used as a source of transforming virus (Miller and Lipman, 1973). This protocol explains how to prepare the marmoset-derived EBV and transform human B cells obtained from peripheral blood.

CAUTION: EBV is a known human pathogen. Appropriate biosafety practices must be followed.

Materials

Complete culture medium (see recipe), 37°C
B95-8 EBV-transformed marmoset cell line (ATCC #CRL 1612)
Anti-CD3 monoclonal antibody produced by OKT3 hybridoma (ATCC #CRL 8001)

25-cm^2 and 75-mm^2 tissue culture flasks
Sorvall RT-6000B centrifuge with H-1000 rotor (or equivalent refrigerated centrifuge and rotor) and 50-ml centrifuge tubes
0.45-µm sterile filter

Additional reagents and equipment for growing cells, determining cell viability by trypan blue exclusion, and cryopreservation of cells (*UNIT 1.1*) and preparation of peripheral blood lymphocytes (*UNIT 2.3*)

NOTE: All solutions and equipment coming into contact with cells must be sterile, and proper aseptic technique should be used accordingly.

NOTE: All culture incubations should be performed in a humidified 37°C, 5% CO_2 incubator unless otherwise specified. Some media (e.g., DMEM) may require altered levels of CO_2 to maintain pH 7.4.

1. Resuspend B95-8 cells in complete culture medium at 1×10^6 cells/ml and incubate in 75-mm^2 tissue culture flasks at 50 ml of culture per flask for 3 days (until ≥95% viable and in exponential growth phase; see *UNIT 1.1* for basic culture technique and determination of cell viability).

2. Transfer cultures to 50-ml centrifuge tubes. Centrifuge 10 min at $600 \times g$ (1500 rpm in H-1000 rotor), 4°C. Filter supernatant through 0.45-µm sterile filter, divide into 0.6-ml aliquots, and store at −70°C.

   The culture supernatants should contain 10^2 to 10^3 infectious units/ml (Miller and Lipman, 1973). Determination of EBV titers can be done by quantitative assessment of transformation of umbilical cord leukocytes (Miller and Lipman, 1973); however, because of the difficulty in obtaining such cells, this determination is usually omitted.

3. Prepare peripheral blood lymphocytes as described in *UNIT 2.3*. Resuspend lymphocytes in 37°C complete culture medium at 1×10^6 cells/ml, then place 5 ml of the lymphocyte suspension in an upright 25-cm^2 tissue culture flask.

4. Add anti-CD3 antibody to final concentration of 10 µg/ml. Incubate cells and anti-CD3 antibody for 1 hr with the flask in the upright position.

Contributed by William E. Biddison
Current Protocols in Cell Biology (1999) 2.4.1-2.4.3

5. Add 0.5 ml of the EBV-containing B95-8 supernatant (from step 2) to flask. Incubate with the flasks in the upright position for 1 to 2 weeks (until medium begins to turn orange/yellow and small clumps of cells become visible).
6. Add 5 ml of fresh 37°C complete medium, then incubate 2 to 3 days. After that period, remove 5 ml of the supernatant and add 5 ml of fresh 37°C complete medium and continue incubating. Repeat the feedings as described in this step until total cell number exceeds 5×10^6.
7. Transfer growing cells to 75-cm^2 flask in 50 ml of 37°C complete medium and incubate until cell concentration is $\geq 1 \times 10^6$/ml.
8. Cryopreserve aliquots of cells (*UNIT 1.1*) and maintain B cell line by splitting to 1×10^5 cells/ml in complete medium, incubating to 1×10^6 cells/ml, then splitting again.

   The cells can be maintained this way indefinitely in the absence of any contamination with microorganisms.

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Complete culture medium

RPMI 1640 medium containing:
5% fetal bovine serum (FBS, heat-inactivated; *APPENDIX 2A*)
100 U/ml penicillin
100 µg/ml streptomycin
100 µg/ml gentamycin
2 mM L-glutamine
10 mM HEPES
Store up to 2 weeks at 4°C

COMMENTARY

Background Information

EBV is able to transform a subset of human resting B cells from peripheral blood (Sugden and Mark, 1977; Aman et al., 1984). The outgrowth of EBV-transformed B cells is prevented by the presence of EBV-immune T cells contained within the peripheral blood lymphocyte population (Rickinson et al., 1979). For this reason, soluble anti-CD3 antibody is included in the transformation process to inhibit the ability of T cells to respond to EBV antigens presented by the transformed B cells. Other procedures to eliminate T cell reactivity that could be utilized include T cell depletion of the lymphocyte population (*UNIT 2.3*) and functional T cell inactivation by cyclosporin A (Tosato et al., 1982).

EBV-transformed B cell lines have proven useful in studies of the cell biology of antigen presentation (Roche and Cresswell, 1990) and in the production of large-scale protein preparations for characterization of MHC antigens (Orr et al., 1979) and MHC-bound peptides (Falk et al., 1991).

Critical Parameters

EBV-transformed B cells will not survive if there is an effective anti-EBV T cell response in the culture. It is essential that T cell functions be blocked with an adequate concentration of anti-CD3 antibody (10 µg/ml is sufficient). Also the number and viability of resting B cells in the culture must be sufficient to permit an efficient transformation by EBV (at least 5×10^6 peripheral blood lymphocytes are recommended). In addition, the titer of infectious EBV in the B95-8 culture fluid must be adequate for transformation. If transformation fails to occur, it will be necessary to obtain umbilical cord leukocytes to measure EBV infectivity (Miller and Lipman, 1973). Different batches of FBS have variable capacities for promoting the growth of EBV-transformed B cells. It is best to predetermine whether the available FBS can support the growth of existing EBV-trans-

formed B cell lines before using it for establishing new EBV-transformed lines. Great care should be taken to avoid contamination with mycoplasma (also see *UNIT 1.5*). Mycoplasma-containing EBV-transformed B cell lines will lose their capacity for continuous growth.

Anticipated Results

With the procedure described above, EBV-transformed B cell lines should be obtained which can maintain continuous growth indefinitely in the absence of contamination by microorganisms.

Time Considerations

Preparation of B95-8 culture supernatants requires a 3-day incubation. The establishment of the cultures for transformation takes 1 to 2 hr once the peripheral blood lymphocyte population has been obtained. Culture for 2 to 3 weeks is required to produce continuously growing EBV-transformed B cell lines.

Laser Capture Microdissection

This unit describes a method for isolating pure populations of cells for biochemical and molecular analysis, called laser capture microdissection (LCM; see Basic Protocol). A second protocol outlines procedures for staining frozen or paraffin-embedded tissue samples for LCM (see Support Protocol).

ISOLATION OF A PURE CELL POPULATION FROM TISSUE SECTIONS

BASIC PROTOCOL

Laser capture microdissection (LCM) provides the scientific community with a rapid and reliable method for obtaining pure cell populations from tissue sections under direct microscopic visualization. It incorporates both an inverted light microscope (with or without a fluorescent module) and a near-infrared laser to facilitate the visualization and procurement of cells. Briefly, a stained slide is placed under a microscope, and a specific adherence cap with an ethylene vinyl acetate (EVA) film is placed onto the tissue. The user moves the slide until the area of interest lies in the center of the microscope's field of view. When the cells of interest are located, a near-infrared laser is fired, which melts the EVA film in the targeted area. The EVA film expands into the void of the stained tissue and solidifies within 200 msec as it rapidly cools. The targeted tissue bonds to the EVA film, retaining the exact cellular morphology, DNA, RNA, and proteins intact. Both frozen and fixed tissue samples are successfully microdissected using LCM. Recovered cells can be analyzed for DNA, RNA, and protein content, and used to construct cell-specific cDNA libraries (Emmert-Buck et al., 1996; Krizman et al., 1996; Simone et al., 1998, 2000; Banks et al., 1999). LCM offers a quick means of procuring pure cell populations; however, it is necessary to follow strict protocols pertaining to fixation, preparation, and handling of tissue samples to be microdissected.

Materials

Stained tissue samples, either frozen or formalin paraffin-embedded, cut into 2- to 10-µm sections, and mounted on plain, uncharged microscope slides
PixCell II Laser Capture Microdissection System (Arcturus Engineering)
CapSure transfer film (Arcturus Engineering)
Compressed gas duster
CapSure pads (Arcturus Engineering)
Cap removal tool (Arcturus Engineering)

Setup LCM apparatus

1. Load the CapSure cassette module with a CapSure cartridge.
2. Move joystick into vertical position to properly position the cap in relation to the capture zone. Place the microscope slide containing the prepared and stained tissue sample on microscope stage. When the target zone for microdissection appears in the viewing area, turn on Vacuum on front of controller to hold slide in place.
3. Slide CapSure cassette backward or forward to place cap at Load position. Slide transport arm over CapSure cap, then lift transfer film transport arm and place cap onto slide.
4. To enable the PixCell II laser, turn the keyswitch located on front of the controller and press the Laser Enable button.

Figure 2.5.1 shows components of the PixCell II.

Current Protocols in Cell Biology (2001) 2.5.1-2.5.7

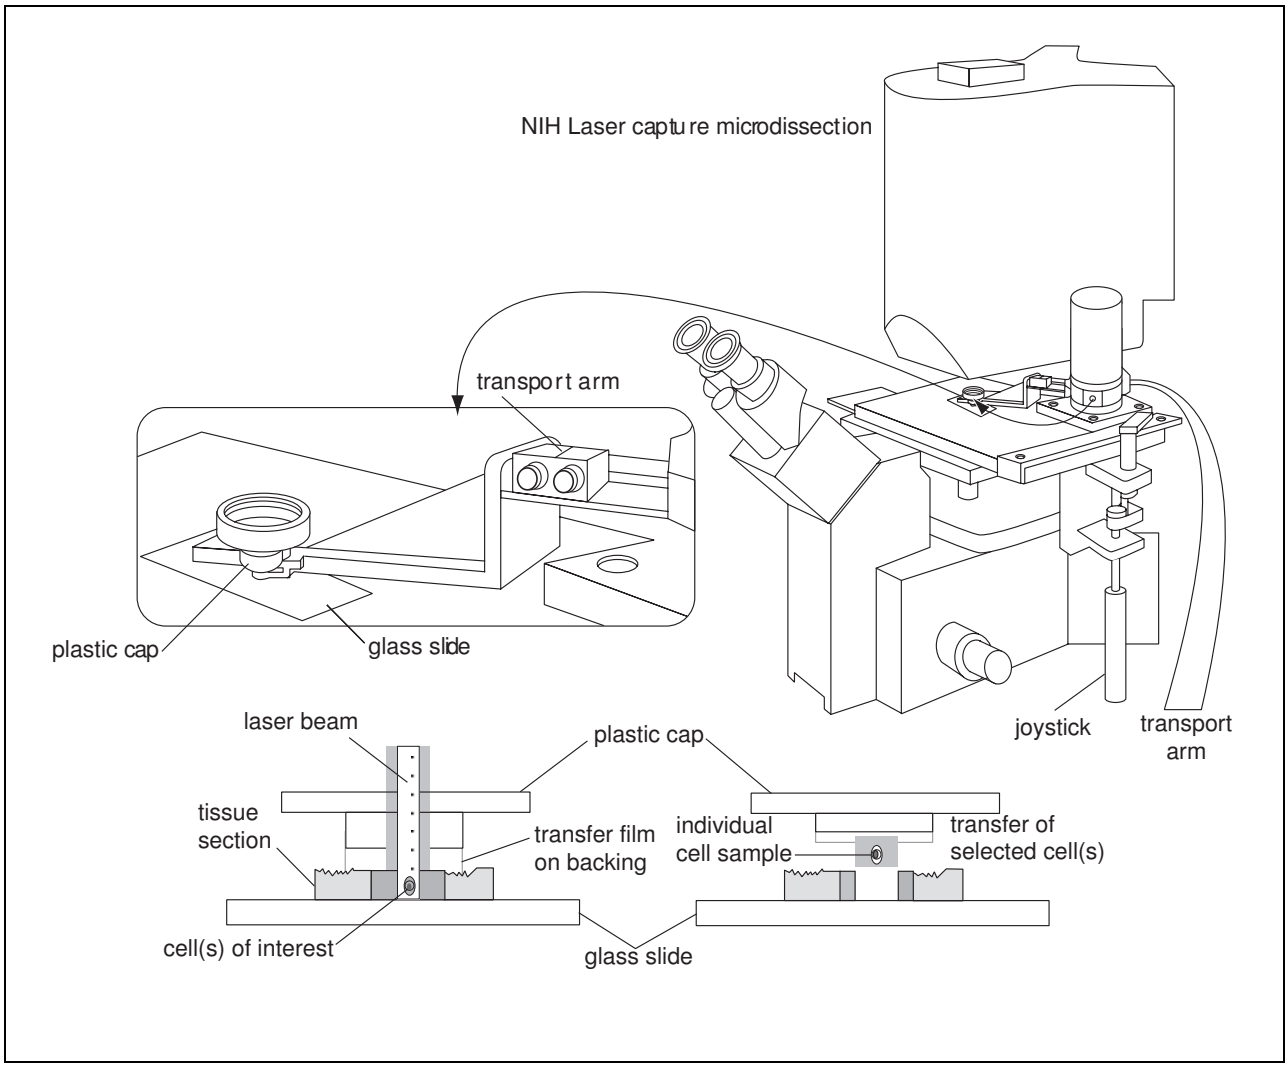

Figure 2.5.1 Schematic overview of the Laser Capture Microdissection Microscope. Through activation of a laser beam and under direct microscopic visualization, individual cells can be isolated for use in molecular analysis of any kind.

5. Verify that target beam is focused by selecting a spot size of 7.5 μm, using the Spot Size Adjust lever found on the left side of the microscope. Rotate microscope objectives until the 10× objective is in place. Reduce light intensity through the optics until field seen on the monitor appears almost dark and target beam is easily viewed. Using the Fine Focus Adjust located below the Spot Size Adjust lever, adjust target beam until it reaches the point of sharpest intensity and most concentrated light with little or no halo effect (Fig. 2.5.2).

   The laser is now focused for any of the three laser spot sizes.

6. Select the laser spot size suitable to perform the microdissection.

7. Adjust Power and Duration of the laser pulse on front of the controller to vary the diameter of the "capture zone", using target settings as a reference point. Adjust these settings up or down to customize the laser to the type and thickness of the tissue to be dissected. Suggested settings are listed in Table 2.5.1.

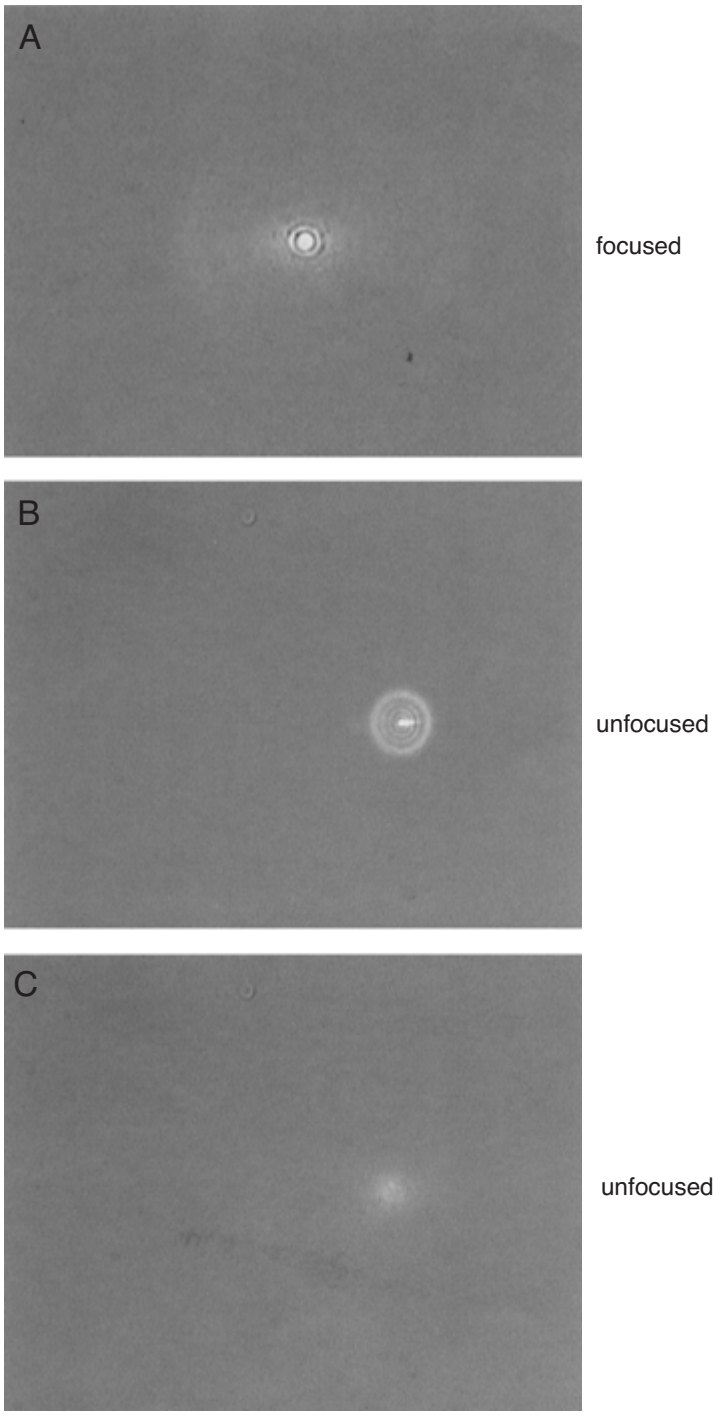

Figure 2.5.2 Focusing of the target beam. If transfer of cells to the cap is not adequate, improper focus may be the cause. Select a spot size of 7.5 μm using the Spot Size Adjust lever found on the left side of the microscope. Rotate the objectives of the microscope until the 10× objective is in place. Reduce the intensity of the light through the optics until the field viewed on the monitor is almost dark and the target beam is easily viewed. Compare the target beam with this figure. If the target is not focused, refocus the target beam as described (see Basic Protocol, step 2).

Table 2.5.1 Settings for LCM

Spot size	Power	Duration
7.5 µm	25 mW	3.0 msec
15 µm	30 mW	5.0 msec
30 µm	30 mW	8.0 msec

Perform LCM

8. Microdissect cells of interest. Guide microdissection with target beam and press Pendant switch for a single microdissection. To microdissect multiple shots, hold Pendant switch down.

   The tissue sample slide must contain no residual xylene, because it melts the transfer film, making microdissection impossible. Dry slide with a compressed gas duster before microdissection to remove residual liquid from staining procedure (see Support Protocol).

   To adjust the frequency interval, select Repeat on controller, then choose the desired time between laser pulses.

9. Observe wetting as the laser fires, maintaining a distinct clear circle surrounded by a dark ring (Fig. 2.5.3). If proper wetting is not observed, refocus the target beam (step 5).

Collect microdissected cells

10. After collecting the desired number of cells, lift cap from slide using the transport arm. Lift and rotate transport arm until cap reaches the Cap Removal Site. Lower transport arm, then rotate it back toward slide, leaving the cap in place at the removal site. Remove cap using the provided cap tool.
11. Blot polymer surface of CapSure transfer film with CapSure pads to remove nonspecific debris adhered to it.
12. Inspect slide and cap for successful microdissection (Fig. 2.5.3).
13. Insert polymer end of cap into top of a 500-µl microcentrifuge tube.

    The sample is ready for extraction of desired components or can be frozen at −80°C for later analysis.

SUPPORT PROTOCOL

HEMATOXYLIN AND EOSIN STAINING OF TISSUES FOR LCM

A reaction sequence for performing basic hematoxylin and eosin staining is outlined in Table 2.5.2. Although LCM is not limited to hematoxylin and eosin staining, it is probably the most versatile stain used. Staining can be done using Coplin jars or racks and dishes. DNA can be retrieved from frozen as well as paraffin-embedded tissue that has been fixed in formalin or ethanol. RNA and protein retrieval is best when frozen tissue is used or alternatively when ethanol-fixed paraffin-embedded tissue is used. RNA and protein are cross-linked when fixed in formalin. However, the morphology of formalin- or ethanol-fixed paraffin-embedded tissues is almost always better than that of frozen tissues, and this is often the deciding factor as to what tissue fixation to use.

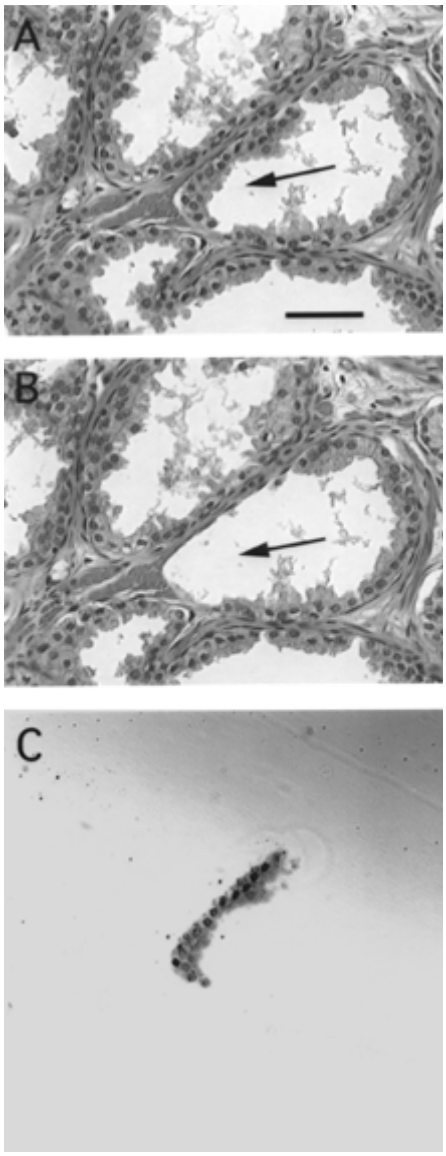

Figure 2.5.3 LCM capture of complex tissue structures. Successful transfer is achieved when nonspecific cells are absent on cap and when microdissection does not leave residual cells behind (see Critical Parameters and Troubleshooting). Example of good microdissection: (**A**) heterogeneous prostate tissue, (**B**) removal of normal epithelium, and (**C**) transfer to EVA film in <5 min.

COMMENTARY

Background Information

One of the problems encountered during the study of disease in actual pathologic lesions arises from the fact that cells in tissue do not exist in a vacuum, but rather interact with each other and neighboring cells in a complex environment. Components of this microenvironment—such as cell-to-cell contact, autocrine and paracrine growth factors, vascular and lymphatic circulation, among many others—influence growth and differentiation. Even more troublesome is the study of changes that occur during disease progression. Most solid tumors are comprised of a large variety of mixed cell populations. For example, a biopsy of breast tissue harboring a malignant tumor may also contain fat cells in the abundant adipose tissue surrounding the ducts, normal epithelium, myoepithelium in the branching ducts, fibroblasts and endothelial cells in the stroma and

Table 2.5.2 Reaction Sequence for Hematoxylin and Eosin Staining Frozen and Paraffin-Embedded Tissues for LCM

Reagent[a]	Frozen tissue	Paraffin-embedded tissue
Xylene	—	2 × 5 min
100% ethanol	—	30 sec
95% ethanol	—	30 sec
70% ethanol	5 sec	30 sec
Deionized water	10 sec	20 sec
Mayer's hematoxylin	30 sec	30 sec
Deionized water	10 sec	20 sec
Scott's tap water	10 sec	20 sec
70% ethanol	10 sec	20 sec
Eosin-Y	60 sec	60 sec
95% ethanol	2 × 10 sec	2 × 20 sec
100% ethanol	2 × 10 sec	2 × 20 sec
Xylene	30-60 sec	30-60 sec

[a]Mayer's hematoxylin and Eosin-Y are available from Sigma-Aldrich; Scott's tap water is available from Fisher.

blood vessels, premalignant carcinoma in situ lesions, and invasive carcinoma. Thus, one cannot simply grind up such tissue and hope to analyze molecular events taking place in premalignant lesions.

In the past, several approaches have been used to overcome this problem. The use of immunological techniques to visualize cells of interest or to deplete contaminating cells has been used to purify or at least enrich cell populations. Modern techniques, such as flow cytometry with cell sorting and affinity-labeled magnetic beads, allow separation of subpopulations from heterogeneous pools of single cells in suspension. However, these techniques are generally not practical when applied to tissue, as there is a requirement for the dissolution of intercellular adhesion and the formation of a suspension of individual cells. Alternatively, other approaches aim to imitate in vivo conditions such as cell cultures of specific cell populations. However, cultured cells may not accurately represent the molecular events taking place in the actual tissue they were derived from. Assuming methods are successful to isolate and grow the tissue cells of interest, the gene-expression pattern of the cultured cells is influenced by the culture environment and can be quite different from the genes expressed in the native tissue state. Another method of obtaining a pure or enriched cell population involves manual extraction of the cells from the tissue sections. This method has been widely used, but it requires a high level of manual dexterity and is often quite time consuming.

Laser capture microdissection (LCM) permits, under direct microscopic visualization, a quick and reliable means of procuring a selected cell population from a heterogeneous tissue, while maintaining the basic integrity of the RNA, DNA, and proteins within the cells (Emmert-Buck et al., 1996; Krizman et al., 1996; Simone et al., 1998, 2000; Banks et al., 1999).

Critical Parameters and Troubleshooting

Problems are rarely encountered during laser capture microdissection, but the most likely causes of difficulty are discussed below. The most probable cause for unsuccessful microdissection is improper handling of the tissue prior to microdissection. For best results, the use of plain uncharged and uncoated microscope slides is recommended. Although, some success has been achieved using positively charged slides, these are not recommended. Tissue sections should be flat and free of folds and wrinkles. The smallest of these imperfections in a prepared tissue section can prevent the proper seating of the polymer cap and limit effective cell capture.

Incomplete deparaffinization of embedded tissues also limits the amount of tissue transferred during microdissection. The times for deparaffinization listed in Table 2.5.2 are minimal and can be extended to allow for complete

removal of the paraffin from the sample, if necessary.

Incomplete dehydration of the tissue section prior to LCM will limit the operator's success in microdissection of the tissue. The xylene rinse, which is the final step of both staining protocols outlined in Table 2.5.2, is essential for the complete dehydration of the tissue on the slide. LCM is compatible with a wide range of immunohistochemical and fluorescent stains in addition to the outlined hematoxylin/eosin stain. It is necessary, however, for the final step of any staining protocol used to be a thorough dehydration step in xylene. If it is suspected that the slide is not completely dehydrated, allow it to sit in xylene for additional time.

Another cause for unsuccessful microdissection is improper focusing of the laser. To avoid this problem, the laser should be focused at the beginning of each LCM session, and whenever there is a change in the type of slide being used (see Basic Protocol).

Anticipated Results

Individual tissue cells can vary in their spacing density, shape, and volume. Therefore, the estimated cell yield is more precise when cells are collected using a greater number of laser pulses. Using the 30-µm laser spot size, the operator can expect to collect, on the average, five to six cells per laser pulse (Fig. 2.5.3).

Time Considerations

The output of LCM is the molecular information derived from analysis of the procured cells. Great care should be taken to ensure the stability of DNA, RNA, or protein molecules analyzed. Delays incurred during staining or while performing LCM can adversely affect molecule stability. DNA is by far the most stable of cellular components. The cellular material collected on the cap for DNA analysis is stable when refrigerated or stored at −20°C until testing is resumed. In contrast, samples microdissected for RNA or proteomic analysis are far less stable because of the endogenous RNases and proteinases. The amount of time that lapses between the start of the staining protocol and completion of microdissection should be closely monitored. Do not exceed 30 min from the time of thawing or deparaffinizing the tissue slide to refreezing of the final dissected sample at -80°C or immediate extraction.

Preparation of Human Epidermal Keratinocyte Cultures

BASIC PROTOCOL

This unit describes a protocol for establishing keratinocyte cultures from human newborn foreskins. The foreskins are incubated with trypsin to dissociate the dermis and epidermis. Keratinocytes are obtained from the epidermis as described in the steps below, and fibroblasts can be obtained from the dermis as described in *UNIT 2.1*.

NOTE: All incubations are performed in a humidified 37°C, 5% CO_2 incubator.

NOTE: All solutions and equipment coming into contact with cells must be sterile, and proper aseptic technique must be used.

Materials

Human newborn foreskin (for sources, see Background Information)
Betadine (Purdue Frederick) or 5% (v/v) Wescodyne (STERIS Corporation)
HEPES-buffered saline (see recipe)
0.25% (w/v) trypsin in HEPES-buffered saline
Keratinocyte primary culture medium (see recipe)
Hanks' balanced salt solution (HBSS; *APPENDIX 2A*)
Keratinocyte growth medium (either Keratinocyte-SFM from Invitrogen or KGM from Cambrex)
Trypsin/EDTA solution (Invitrogen) diluted 1:1 with Hanks' balanced salt solution (final 0.025% w/v trypsin, 0.26 mM EDTA)
10 mg/ml soybean trypsin inhibitor (Sigma) in Hanks' balanced salt solution
Freezing medium: 10% (v/v) DMSO/10% (v/v) heat-inactivated fetal bovine serum/80% (v/v) keratinocyte growth medium

100-mm sterile tissue culture dishes
Small curved forceps (4 pairs), sterile
Small sharp straight or curved scissors, sterile
Coarse filter such as a tea strainer or several layers of cheesecloth taped over the top of a 50-ml centrifuge tube, sterile
15- and 50-ml sterile disposable centrifuge tubes
75-cm^2 sterile tissue culture flasks
1-ml sterile cryotubes
Liquid nitrogen freezer

Additional reagents and equipment for cell culture (*UNIT 1.1*)

CAUTION: When working with human tissue, appropriate biosafety practices must be followed.

Prepare foreskin

1. Incubate foreskin in Betadine or 5% Wescodyne for 1 min.
2. Wash foreskin four times, each time by incubating for 30 sec in HEPES-buffered saline at room temperature, to remove the disinfectant.
3. Place foreskin in a 100-mm tissue culture dish and trim away as much subcutaneous tissue as possible by snipping it away with a small pair of sharp scissors. Cut the foreskin into 4- to 6-mm pieces, and float them, epidermis-side-up, in 5 ml of 0.25% trypsin in a 100-mm tissue culture dish overnight at 4°C.

   IMPORTANT NOTE: *The scissors used in this step must be sharp.*

Contributed by Susan S. Yamada
Current Protocols in Cell Biology (2003) 2.6.1-2.6.5

When the epidermis is ready to be removed (as described in step 4), there is a change from the shiny and transparent appearance of the fresh epidermis to a more dull and white/opaque surface. Alternatively, the trypsin incubation can be performed at 37°C for several hours. Exposure times must be carefully controlled to curtail trypsin damage to the cells (see Critical Parameters and Troubleshooting).

Remove epidermis

4. Using two pairs of forceps, peel the epidermis from the pieces of tissue and place the detached epidermis in a dish containing 5 ml keratinocyte primary culture medium.

   If the epidermis does not detach from the tissue, incubate as in step 3 for another 8 to 24 hr in fresh trypsin at 4°C. The dermis can be used to isolate fibroblasts (see UNIT 2.1).

5. Release cells from the epidermis by pipetting up and down ten times with a 5-ml disposable plastic pipet.

   The pieces of epidermis may have a tendency to stick to the inside of the pipet. Coating the inside of the pipet with serum proteins by rinsing it with keratinocyte primary culture medium may help prevent this problem.

6. Filter out the epidermal sheets and other debris by passing the cell suspension through a coarse filter such as a tea strainer or several layers of cheesecloth and collecting the filtrate in a 50-ml disposable centrifuge tube.

7. Centrifuge the filtered suspension 5 min at 200 × *g*, room temperature. Aspirate the supernatant and resuspend the cells in 10 ml keratinocyte primary culture medium. Plate the cells in a 75-cm^2 flask (see *UNIT 1.1* for basic cell culture techniques).

8. Place the culture in a humidified 37°C, 5% CO_2 incubator. The next day, inspect for cells attached to the flask.

   The cells may not spread overnight, but there should be some cells attached to the flask. If there are few or no cells attached after an overnight incubation, leave the culture in keratinocyte primary culture medium for up to 1 additional day before changing the medium. Many or most of the cells will never attach.

9. Wash the flask gently three times with Hanks' balanced salt solution and add 15 ml keratinocyte growth medium.

10. Incubate the flask, changing the medium every other day, until the keratinocytes have reached no more than 70% to 80% confluency.

    IMPORTANT NOTE: *Do not permit the cells to become confluent. Confluent cells are very difficult to remove and can begin to differentiate and stop dividing (see Critical Parameters and Troubleshooting).*

Subculture cells

11. To subculture the cells, wash the flask twice with Hanks' balanced salt solution. Add 5 ml trypsin/EDTA warmed to 37°C and incubate at room temperature for about 5 min or until most of the cells are rounded up. Rap the side of the flask against the palm of the hand to release the cells from the flask. If most of the cells do not come off, wait 1 to 2 min and rap again.

    Not all of the cells will detach easily, and it is better to leave a few behind than to overtrypsinize the rest. In general, keratinocytes are more difficult to remove than fibroblasts, and they are also more sensitive to being overtrypsinized (see Critical Parameters and Troubleshooting). It is therefore important that the trypsin/EDTA solution be very fresh. One may wish to freeze aliquots and defrost only as much as needed.

12. After the cells are released from the flask surface, add an equal volume of soybean trypsin inhibitor solution to the trypsinized cell suspension and transfer to a 15-ml disposable centrifuge tube. Centrifuge 5 min at 200 × *g*, at room temperature. Aspirate the supernatant and resuspend the pellet of cells in keratinocyte growth medium. Count cells (*UNIT 1.1*).

13. Plate at ~6×10^3 cells per cm^2 in 75-cm^2 tissue culture flasks.

    This represents about a 1:5 split ratio, and the cells will usually be ready to trypsinize again in about 4 or 5 days. At this split ratio, keratinocyte cultures will usually stop growing at around passage 10 or 11. However, other characteristics of the cultures may begin to change well before this time, and investigators should determine the maximum useful lifespan of these cells for their individual purposes.

14. Change the medium every other day.

Freeze cells and defrost at time of use

15. Resuspend the pellet of trypsinized cells in freezing medium. Dispense into 1-ml sterile cryotubes at 5×10^5 cells/ml, and place in a styrofoam box in a −80°C freezer overnight. Transfer the cryotubes to liquid nitrogen the next day.

16. To defrost cells, thaw a tube of cells in a 37°C water bath. As soon as the cell suspension is thawed, transfer to a 75-cm^2 tissue culture flask containing 15 ml keratinocyte growth medium and incubate at 37°C. As soon as most of the cells have attached, which should take several hours, wash gently several times with Hanks' balanced salt solution and add fresh keratinocyte growth medium.

    The addition of serum to the freezing medium ensures better survival of the frozen cells, but results in high calcium levels once they have been defrosted. Therefore, it is important to wash the cells and change into fresh keratinocyte growth medium as soon as they have attached.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

HEPES-buffered saline

480 ml water
0.5 ml 1 M HEPES buffer solution (1 mM final)
0.9 g glucose (10 mM final)
1.5 ml 1 M KCl (3 mM final)
1 ml 0.5 M $Na_2HPO_4 \cdot 7H_2O$ (1 mM final)
3.8 g NaCl (130 mM final)
0.1 ml 0.5% (w/v) phenol red solution (final 1 µg/ml)
Adjust the volume to 500 ml
Filter sterilize through a 0.22-µm filter
Store up to 1 year at 4°C

Keratinocyte primary culture medium

500 ml DMEM (*APPENDIX 2B*)
12 ml 1 M HEPES (20 mM final)
100 ml fetal bovine serum (FBS; heat-inactivated 30 min at 55°C)
0.6 ml 100 µg/ml EGF (Sigma-Aldrich; 10 ng/ml final)
0.6 ml 10^{-7} M cholera toxin (*Vibrio cholerae*, lyophilized powder; Sigma-Aldrich; 10^{-9} M final)

continued

2.4 ml 100 μg/ml hydrocortisone (Sigma-Aldrich; 0.4 μg/ml final)
6 ml 100× penicillin/streptomycin (100 U/ml penicillin G and 100 μg/ml streptomycin sulfate final)
0.6 ml 250 μg/ml amphotericin B (0.25 μg/ml final)
0.6 ml 10 mg/ml gentamicin (10 μg/ml final)
Store up to 1 month at 4°C in the dark

As an alternative to the 100 ml of FBS, it is possible to use 50 ml calf serum and 50 ml FBS, both heat-inactivated.

CAUTION: *Cholera toxin is very toxic. Use appropriate precautions when handling.*

COMMENTARY

Background Information

Early attempts to grow keratinocytes used medium supplemented with serum and frequently required fibroblast feeder layers (Rheinwald and Green, 1975). The development of serum-free MCDB 153 (Boyce and Ham, 1983) permitted keratinocyte culture without feeder layers. Both of the commercially available serum-free media recommended in this unit (Keratinocyte-SFM from Invitrogen and KGM from Cambrex) are modifications of MCDB 153. They feature low Ca^{2+} concentrations to inhibit keratinocyte differentiation and suppress fibroblast growth and are supplemented with bovine pituitary extract as the primary mitogen. If the undefined composition of bovine pituitary extract is a problem in the experimental system, a medium that replaces it with several defined mitogens is available (Defined Keratinocyte-SFM from Invitrogen).

This protocol can also be adapted to use biopsies or samples of skin from surgical operations or cadavers. A similar protocol has been used to obtain murine keratinocytes (Dlugosz et al., 1995). However, murine keratinocytes are difficult to passage successfully, which can limit their usefulness.

Neonatal human foreskins from circumcisions may be available locally, or they can be obtained through the Cooperative Human Tissue Network (*http://www-chtn.ims.nci.nih.gov/*). Foreskins can be stored immersed in HEPES-buffered saline or serum-free medium such as DMEM (*APPENDIX 2B*) with 100 U/ml penicillin G, 100 μg/ml streptomycin, and 0.25 μg/ml amphotericin B, at 4°C for up to 3 days before use.

Critical Parameters and Troubleshooting

This protocol specifies two media: keratinocyte primary culture medium and keratinocyte growth medium. Keratinocyte primary culture medium contains DMEM with 20% serum and is used initially to encourage the keratinocytes from the epidermis to attach. As soon as they attach, the medium is changed to keratinocyte growth medium, a commercially available low-calcium, serum-free medium, which is used in all subsequent cultures.

The concentration of calcium in the medium can regulate whether keratinocytes differentiate or continue to proliferate. The calcium levels in the recommended growth media are low: 0.09 mM in Keratinocyte-SFM from Invitrogen, and 0.15 mM in KGM from Cambrex. Raising the calcium concentration, either intentionally, e.g., by adding $CaCl_2$ to 1 mM, or unintentionally, e.g., by adding factors dissolved in solutions containing calcium, will cause keratinocytes to terminally differentiate. Their growth rate will greatly decrease and their morphology will change markedly (Fig. 2.6.1) from flattened cells with ruffled edges that associate only loosely with neighboring cells to more tightly packed and well-circumscribed colonies of less-spread cells. Differentiated cells are often more phase-dense by phase-contrast microscopy, with phase-bright borders where they contact neighboring cells because the cells are more closely packed and thicker. Ruffled cell margins, if present, are seen only in cells with free edges at the perimeter of colonies. Whereas cells in low calcium can be quite motile, particularly those with semicircular ruffles, cells in high calcium move much less and tend to associate strongly with other cells. Permitting the cells to become confluent will also signal them to slow their growth and differentiate, and cultures that have been allowed to grow to confluence should be replaced with new cells from a frozen stock.

Keratinocytes are relatively sensitive to overtrypsinization, so care should be exercised when passaging the cultures. Use fresh trypsin and expose the cultures for a minimal period.

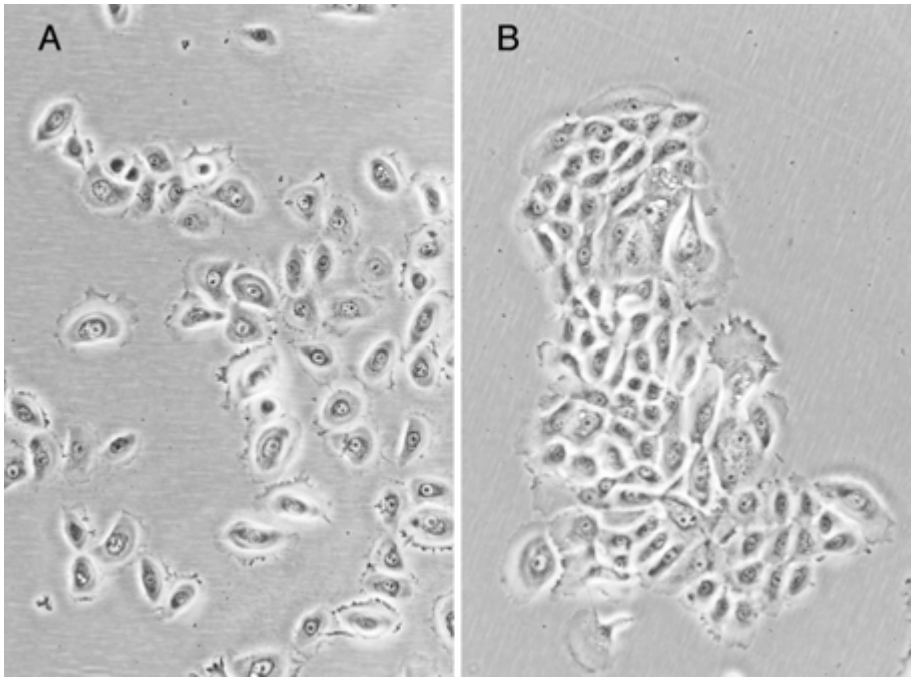

Figure 2.6.1 Human keratinocytes in culture (passage ~6) in: (**A**) low (0.09 mM) or (**B**) high (1 mM) calcium. Magnification: 130×.

Do not trypsinize until all the cells have been removed from the flask; there should always be some cells left attached. Immediately add soybean trypsin inhibitor solution to neutralize the trypsin.

Anticipated Results

After 1 to 2 days in keratinocyte primary culture medium, one should be able to see cells attached to the flask, although they may not be spread. After changing the medium to one of the low-calcium keratinocyte growth media, spread keratinocytes should be visible within 1 to 2 days. Cultures should be ready for passage within 1 or 2 weeks, depending on the initial yield. Early-passage cells should be frozen promptly. From a 75-cm^2 flask at about 80% confluence, it should be possible to harvest ~2 × 10^6 cells.

Time Considerations

Trimming of the foreskin and placing it into trypsin may take 1 to 2 hr, with another hour or less the next day to peel off the epidermis and place the cells into culture. If the epidermis cannot be separated from the dermis after overnight trypsinization, another 8- to 24-hr incubation may be necessary.

Preparation and Coculture of Neurons and Glial Cells

In the development and maintenance of the nervous system there is a complex interdependency between neurons and glial cells. This relationship is vital for their individual differentiation, development, and functionality but also seems to play an important role in progressive neurodegeneration and in the modulation of neurotoxic effects.

Glial cells maintain normal functioning of the nervous system both by controlling the extracellular environment and by supplying metabolites and growth factors. Neurons may interfere with the proliferation and maturation of glial elements (Steward et al., 1991; Gegelashvili et al., 1997) and dynamically regulate the glial signaling pathway through the release of substances such as glutamate (Bezzi et al., 1998). There is also evidence that glia can be neurotoxic both in vivo and in vitro and can exacerbate neuronal damage caused by a variety of agents (Brown et al., 1996; Meucci and Miller, 1996; Rogove and Tsirka, 1998; Viviani et al., 1998). This effect may be attributable not only to an altered supply of trophic factors to neurons, establishment of contacts, and an altered buffering of the extracellular microenvironment by glia, but also to direct release of substances toxic to neurons such as reactive oxygen species (ROS), glutamate, and some cytokines—e.g., interleukin-1β (IL-1β) and tumor necrosis factor-α (TNF-α).

Physiologically, the bidirectional communication existing between glia and other cells of the nervous system (i.e., neurons, other glial cells, and blood vessel cells) allows glia to link cells and structures that are not functionally connected and to continuously monitor and modulate their activity as a function of local needs (for a review, see Volterra and Meldolesi, 2005). The consequences of such interactions are the modulation of synaptic transmission, neuronal synchronization, and the regulation of cerebral blood flow. The recognition of this connection led to the definition of a new function—gliotransmission. The term gliotransmission describes the release of factors from physiologically stimulated glia; these factors are able to activate a rapid response in neighboring cells (Volterra and Meldolesi, 2005).

Cocultures of different cells of the nervous system (i.e., neurons, astrocytes, and microglia) represent the easiest approach to: (1) study intercommunication between the different cell populations of the nervous system, (2) evaluate its relevance in several physiological responses and/or propagation of the damage, and (3) study the molecular mechanisms involved. Other possible approaches are to use aggregate cultures of neural and glial cells and the more complex organotypic slices of hippocampus (Harry et al., 1998).

This unit describes procedures to set up a sandwich coculture system with a combination of neurons and glial cells (see Basic Protocol 1) or astrocytes and microglia cells (see Basic Protocol 2), as well as methods for the preparation of hippocampal neurons (see Support Protocol 1), glial cells (see Support Protocol 2), coated glass coverslips (see Support Protocol 4), and the separation of astrocytes and microglia from glial cells (see Support Protocol 3). A sandwich coculture is an in vitro cell system formed by two different cell populations growing on different surfaces, usually a coverslip and a petri dish. These surfaces are separated by small paraffin dots at the edges of the coverslip, on which one of the cell populations is seeded. In this way the two cell populations face each other without touching (Fig. 2.7.1), and soluble substances can diffuse between them. This cell system is therefore suitable for the study of biological responses that are due to the release of soluble mediators but not of those dependent on the contact of the two cell types.

Current Protocols in Cell Biology (2006) 2.7.1-2.7.21

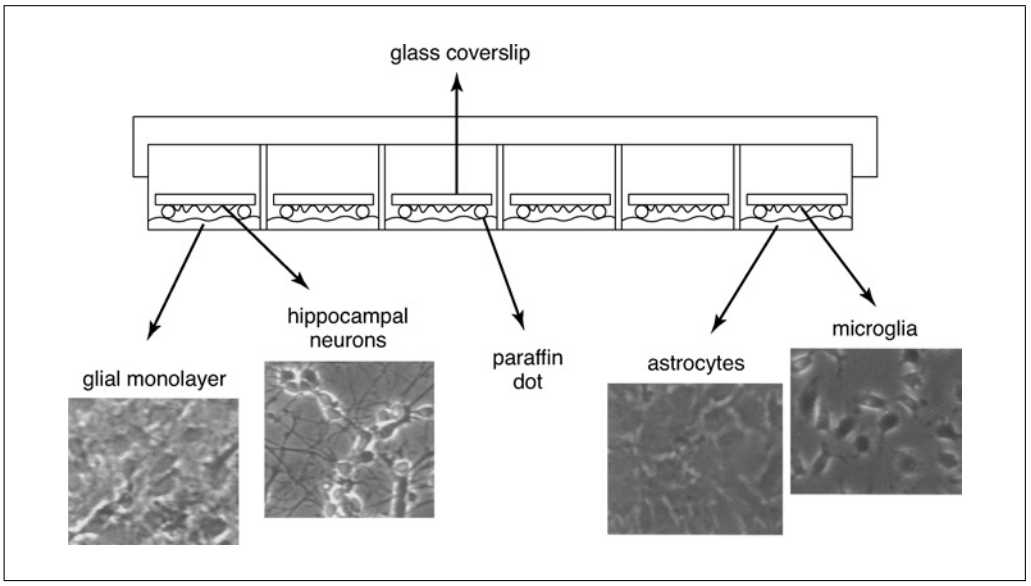

Figure 2.7.1 Scheme of a typical coculture (i.e., hippocampal neurons–glia or microglia-astrocytes) in a 24-well plate. Bright-field photographs are at 10× magnification. Note that cell populations are separated by paraffin dots on the edges of 12-mm round glass coverslips.

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) and must follow officially approved procedures for the care and use of laboratory animals.

NOTE: Working conditions must ensure the highest degree of sterility. Thus, brain tissues should be dissected and cells plated and grown in a laminar flow hood. Equipment must be sterilized before use and stored in 95% ethanol when not in use. All solutions and reagents that come into contact with tissues or cells must be sterile.

NOTE: All culture incubations should be performed in a 37°C, 5% CO_2 incubator with 95% relative humidity unless otherwise specified. As soon as prepared, cultures must be maintained in this type of incubator.

BASIC PROTOCOL 1

PREPARATION OF HIPPOCAMPAL NEURON-GLIA SANDWICH COCULTURES

In the author's laboratory, the neuron-glia sandwich coculture is used not only to study the interaction between glia and neural cells, but also to obtain a highly differentiated neural culture. Since glial cells are a valuable source of neurotrophic substances, cultures of cortical glial cells (see Support Protocol 2), consisting mainly of astrocytes and a small number of microglial cells, are prepared and allowed to reach confluence (∼10 days). These monolayers can be used for up to 1 month from their preparation. Next, cultures of hippocampal neurons are prepared by plating onto glass coverslips. These coverslips are then placed above the glial monolayer as shown in Figure 2.7.1. In the author's laboratory, the coculture is set up in 24-well plates, with one coverslip for each well. This avoids overlapping of different coverslips, which can occur if petri dishes are used. The main steps in preparing a neuron-glia sandwich coculture are summarized in Table 2.7.1. The dissection and culture techniques described here are largely based on the method of Goslin and Banker (1991) but have undergone minor changes in the author's laboratory.

Table 2.7.1 Preparation of Neuron-Glia Sandwich Coculture

Day	Action
1[a] (Thursday)	Prepare primary glial cultures (see Support Protocol 2)
8 (Friday)	Add paraffin dots and coat glass coverslips (see Support Protocol 4)
10 (Monday morning)	Wash and condition glass coverslips
	Substitute DMEM with SFM in glial cells
10 (Monday afternoon)	Prepare and seed hippocampal neurons (see Support Protocol 1)
11 (Tuesday)	Transfer coverslips with neurons over glial cells and add cytosine arabinoside to the coculture
18 (Tuesday)	Perform experiments

[a]Note this is 10 days before hippocampal dissection.

Materials

Confluent cortical glial monolayer in 24-well plates (see Support Protocol 2)
Serum-free medium (SFM; see recipe)
Coated glass coverslips seeded with hippocampal neurons (see Support Protocol 1)
2 mM cytosine arabinoside (see recipe)
Sharpened forceps

1. On the day hippocampal neurons are to be prepared (see Table 2.7.1), replace the medium in confluent cortical glial monolayers with 1 ml SFM and return them to the incubator overnight.

   The addition of SFM to glia prior to adding glass coverslips with hippocampal neurons allows conditioning to favor early phases of neural maturation. SFM is chosen because the ingredients are totally defined, and the absence of serum limits the growth of glial cells together with neurons on the glass coverslip.

   Since the author's laboratory usually prepares a number of 24-well glial plates, an amount sufficient for cocultivation with neurons produced over 1 month (i.e., more than will probably be used in one experiment), the medium is replaced only in wells that will receive a coverslip plated with neural cells the following day.

2. The next morning, use one tip of a pair of sharpened forceps to lift the edge of a coated glass coverslip plated with hippocampal neurons. Seize the coverslip with the forceps, and transfer and turn it over the glial monolayer. Repeat for each well to be used.

3. To each well containing neurons and glia, add 2 mM cytosine arabinoside to a final concentration of 5 μM to reduce the proliferation of glial cells.

   Addition of cytosine arabinoside, toxic to dividing cells, is important to block glial proliferation in the neuronal culture.

   In other workers' hands, cytosine arabinoside is usually added on the second to fourth day of culture. Under the experimental conditions used in the author's laboratory, such delayed addition of arabinoside did not satisfactorily reduce glial contamination. This is probably because of the large number of neural cells seeded by the author (160,000/coverslip), which enriches the cell suspension with rapidly dividing astrocytes. Addition of cytosine arabinoside immediately after neuronal cells are attached allows this laboratory to obtain a 98% pure neuronal culture on the glass coverslip, as assessed by immunocytochemistry of microtubule-associated protein 2 (a marker for neurons) and glial fibrillary acidic protein (a marker for astrocytes).

   Under these experimental conditions cytosine arabinoside is not toxic to neurons.

4. Maintain the cocultures, routinely feeding once every 7 to 10 days with SFM.

Neurons are very sensitive to temperature and environmental conditions. Thus, if the incubator is opened often during the day it is better to keep the plates towards the bottom where the temperature, percentage CO_2, and humidity are better preserved.

During feeding, it is important not to change the culture medium completely, since neurons depend upon glial cells to condition the medium for long-term survival. Thus, replace $\sim\frac{1}{3}$ of the medium each time. Under such conditions neurons survive for several weeks and become richly innervated.

These cells reach a high degree of maturation (i.e., developed neuronal network, functional glutamatergic system, and almost complete development of the post-synaptic density) after ~7 to 9 days of culture.

SUPPORT PROTOCOL 1

ISOLATION AND SEEDING OF HIPPOCAMPAL NEURONS

The author prepares hippocampal cultures from 18-day-old fetal rats (Table 2.7.1, day 10). At this stage, the generation of pyramidal neurons is complete while the generation of dentate granule cells has only just begun. Thus, the culture obtained will consist mainly of pyramidal neurons, which constitute the principal cell type in the hippocampus (85% to 90% of total neurons). From one litter of 18-day-old embryos (i.e., nine to twelve embryos), $\sim 7 \times 10^6$ cells for 30 to 40 coverslips 12 mm in diameter (160,000 cells/coverslip) are obtained. The number of coverslips is of course related to the plating density, which has to be chosen according to the experiment to be performed and the techniques available in the laboratory.

Low-density cultures suitable for the study of the development of individual cells and their synaptic interactions or the distribution of antigens within single cells require the application of microscopic techniques because of their sparse distribution. The author's group found that a plating density of 160,000 cells/coverslip yielded a highly differentiated hippocampal culture with a sufficient number of cells for the independent measurement of several parameters of neurotoxicity by nonmicroscopic and quantifiable techniques (Table 2.7.2).

Table 2.7.2 Parameters Measured in Hippocampal Cultures at Low and High Density

Parameter	Low-density cultures	High-density cultures
Neural cell death	Vital dye exclusion and count of living cells	MTT test (Denizot and Lang, 1986)
Apoptosis	Conformation of nuclei using Hoechst 33258 or propidium iodide dyes (Zhivotovsky et al., 1999)	Quantification of oligonucleosomal fragments
Intracellular Ca^{2+} homeostasis	Confocal microscopy (*UNIT 4.5*), video imaging	Spectrofluorimetric measurement in cell population stained with Fura-2 AM (Gunter and Gunter, 1999)
Reactive oxygen species production		Spectrofluorimetric measurement in cell population stained with 6-carboxy-2′,7′-dichlorohydro-fluorescein diacetate
Production of cytokines	Immunohistochemistry (Watkins et al., 2000)	Quantification by ELISA and/or RT-PCR (Bookout et al., 2006)

The procedures performed for isolating hippocampal neurons from rat embryos in the author's laboratory are similar to those described by Goslin and Banker (1991). This section provides an alternative for the dissociation of the hippocampi obtained and for growth in order to set up a sandwich coculture. The highest number of healthy neurons will be obtained by minimizing the total time between removal of uterine horns and dissociation of neurons, which must not exceed ~2 hr.

Materials

Pregnant female rats (Sprague-Dawley) at gestational day 18 (E18)
95% ethanol
HBSS (see recipe)
1× trypsin/EDTA solution (Sigma)
10 mg/ml DNase I stock solution (see recipe)
High-glucose MEM/10% (v/v) FBS (see recipe)
0.04% (w/v) trypan blue

Dissecting tools, sterile:
- Stainless steel scissors with ~4- and ~2-cm blades
- Curved forceps (2 pairs)
- Dumont forceps, no. 3c and no. 5

100- (two), 60- (one) and 35-mm (six) petri dishes
Dissecting microscope, e.g., Zeiss Stemi DV4
Anesthetizing chamber connected to a CO_2 tank
1.5-ml microcentrifuge tubes, sterile
1-ml and 200-µl pipet tips, sterile
24-well tissue culture plate containing coated coverslips (see Support Protocol 4)
75-cm^2 canted-neck flasks with screw caps

Additional reagents and equipment for determination of cell number and viability with a hemacytometer (*UNIT 1.1*)

Prepare for dissections

1. Arrange all the sterile dissecting tools on a sterile surface (e.g., sterile lid of a petri dish).
2. Fill all the petri dishes required for the preparation with the appropriate amount of HBSS (10 ml for 100-mm dishes, 5 ml for 60-mm dishes, and 2 ml for 35-mm dishes).
3. Set up the dissecting microscope.

Remove uterine horns and isolate embryo head

4. Sacrifice the day 18 pregnant animal by an officially approved procedure.

   Anesthetization is often required prior to decapitation. Anesthetize the pregnant rat in an anesthetizing chamber filled with CO_2. Wait until the rat has stopped breathing for a few seconds.

   Longer anesthesia is unnecessary and may result in damage to fetal neurons.

5. Remove the rat from the anesthetizing chamber and transfer it to a dissecting table, ventral side up, and sterilize the abdomen by pouring 95% ethanol over it.
6. Rinse forceps and scissor in ethanol, grasp the abdominal skin with forceps, and cut the abdomen completely open from the vagina to the thoracic cavity. Cut the diaphragm.

7. Gently grasp uterine horns at one of the constrictions and lift up. Remove the horns by cutting the attachments to the abdominal cavity and place them in a 100-mm petri dish filled with 10 ml cold HBSS. Keep on ice.

   Keeping embryos, brains, and later the hippocampi cold reduces metabolic activity and associated cellular damage.

   Typically there are ten to twelve fetuses in a Sprague-Dawley litter.

8. Remove the fetuses from the uterine horns and place them in a 100-mm petri dish with cold HBSS. Keep on ice.

   To remove fetuses grasp at the upper constriction of each yolk sac and cut along one side, the fetus will slip out of it.

9. Decapitate the fetuses with scissors and place the heads in a 60-mm petri dish with cold HBSS. Keep on ice.

Dissect out embryo brain

10. Place one head in a 35-mm petri dish (2 ml HBSS), with the neck down and the skullcap towards the operator. Under the dissection microscope, gently grasp the cut edges of skin and skull with both the Dumont no. 3c and no. 5 forceps and pull in opposite direction to expose the brain.

    Place anterior end of the head towards the top side of the petri dish and posterior end towards the bottom. This orientation will greatly facilitate the dissection.

11. Sever the cerebral hemispheres from the cerebellum and the spinal cord with Dumont no. 5 forceps.

12. Remove the brain by lifting upward out of the skull with curved-tip forceps and place it in a 60-mm petri dish with 5 ml HBSS. Keep on ice.

    Place the curved tips of the forceps under the brain and gently lift it upward.

13. Repeat steps 10 to 12 for each head.

Isolate hippocampi

14. Place the brain in a 35-mm petri dish (2 ml HBSS), with the dorsal side up and the posterior end toward the operator. Working under the dissecting microscope, place the two tips of Dumont no. 5 forceps along the brain midline under the cortices, one at the anterior and the other at the posterior end. Use a single cut to isolate the cortices from the brain stem. Repeat for the other hemisphere.

15. Discard the brainstem and orient one of the hemispheres with the medial surface upwards.

    The cerebral hemisphere is defined by a dorsal side that is much more rounded than the ventral side and usually by the olfactory bulb that projects anteriorly. The hippocampus is located in the medial-posterior part of the cerebral cortex on the back of the olfactory bulb. When the medial cortex is perfectly clean, the hippocampus is clearly visible as a C-shaped structure, with its dorsal margin separated from the adjoining cortex by a fissure while the ventral margin is free.

16. Gently remove meninges by pulling them off with Dumont no. 3c and no. 5 forceps.

17. To obtain the hippocampus, make a curving incision with Dumont no. 5 forceps along the dorsal hippocampal fissure. Release the hippocampus by cutting at the end of the curved incision.

18. Transfer the hippocampus to a 35-mm petri dish with 1 ml HBSS and keep on ice.

19. Repeat steps 14 to 18 for each brain.

Prepare hippocampi

20. Collect hippocampi isolated from rat embryos in a sterile 1.5-ml microcentrifuge tube.

21. Centrifuge 4 min at 100 to 150 × *g*, room temperature. Carefully remove the supernatant.

    Aspiration with a pipet is recommended over a vacuum system to avoid aspirating the hippocampi along with the medium.

Trypsinize hippocampi

22. Add 400 µl of 1× trypsin/EDTA solution and 80 µl of 10 mg/ml DNase I solution. Shake gently (do not vortex) and incubate 5 min at 37°C.

    DNase is added to prevent the DNA released by damaged cells from making the dissociation medium too viscous during digestion.

23. While hippocampi are incubating, prepare four 1.5-ml microcentrifuge tubes with 400 µl high-glucose MEM/10% FBS each.

24. Gently aspirate trypsin/DNase solution with a sterile 1-ml pipet (do not use vacuum). Add 400 µl MEM/10% FBS and shake until hippocampi are floating in the medium.

    The serum in the MEM inhibits residual trypsin and prevents overdigestion of the cells.

***Wash out trypsin and DN*ase**

25. Allow the hippocampi to pellet at the bottom of the tube.

26. Gently collect the pelleted hippocampi with a 1-ml pipet in the smallest possible volume of medium and transfer to the first of the four tubes containing MEM/10% FBS (step 23).

    Take care not to destroy the hippocampi during this and the immediately following steps.

27. Gently shake and allow the hippocampi to pellet at the bottom of the tube.

28. Repeat steps 26 and 27 another three times using the remaining tubes in succession.

    Repetitive passage through microcentrifuge tubes with fresh medium washes the hippocampi free from trypsin and DNase I.

Disaggregate and assess cell number and viability

29. In the last microcentrifuge tube, disaggregate the hippocampi by gently drawing up and down in a 1-ml pipet first and then a 200-µl pipet tip. Adjust the volume of the cell suspension to 1 ml using MEM/10% FBS.

    It is important to be very gentle in pipetting: too vigorous or extensive pipetting causes significant cell death. Pipetting in sequence through a 1-ml pipet and then a 200-µl pipet tip gradually yields a single-cell suspension. Note that pipet tips must be sterile.

30. Gently mix 10 µl cell suspension with 10 µl of 0.04% (w/v) trypan blue. Determine the total cell number and viability with a hemacytometer and an inverted phase-contrast microscope (see *UNIT 1.1*).

    Trypan blue is used to distinguish viable from dead cells. Viable cells exclude trypan blue while dead or damaged cells are stained (dark blue).

Plate and prepare hippocampal neurons for the sandwich coculture

31. Pipet 160,000 cells into each well of a 24-well plate containing a coated coverslip.

32. Incubate plates overnight and place the coverslip over the confluent glial monolayer the next morning.

Remember to keep the plates towards the bottom of the incubator where temperature, percentage CO_2, and humidity are better preserved. Neural cells will attach to the coverslip surface during this incubation.

Since seeding medium is not suitable for hippocampal neuron survival and differentiation, remember to transfer the coverslips the day after plating.

BASIC PROTOCOL 2

PREPARATION OF ASTROCYTE-MICROGLIA SANDWICH COCULTURES

Glia include three cell types: astrocytes, microglia, and oligodendrocytes. All glial subtypes can greatly influence not only neuronal, but also neighboring glial cell activity. Astrocytes, long considered to be primarily supportive of neurons, are now thought to be active participants in neural circuit functions. Recently it has been observed that astrocytes are organized in distinct territories and may influence the surrounding cells (including other glial cells) due to the release of diffusible extracellular signals (Volterra and Meldolesi, 2005). Thus, astrocytes influence spontaneous astrocytic excitation by releasing glutamate (Nett et al., 2002), which in turn may result in the excitation of neighboring neurons. The astrocytes may control the release of several modulators (i.e., TNF-α, SDF-1α, and glutamate) through the production of eicosanoids (Bezzi et al., 1998).

Under physiological conditions microglia have a "resting" phenotype adapted to the microenvironment of the central nervous system. However, microglia are able to respond quickly to a variety of signaling molecules. Activation at a very early stage in response to damage or alterations to the microenvironment that precede pathological changes is characteristic of microglia, and its activation often precedes reaction of any other cell type in the brain. The author has recently observed that microglial cells can influence the response of astrocytes in producing neurotoxic substances. For instance, the production of tumor necrosis factor-α (TNF-α) after a neurotoxic insult is much higher in a culture of astrocytes and microglia than with astrocytes or microglia alone (Viviani et al., 1998; Bezzi et al., 2001). Thus, the progression of neurodegenerative events is also modulated by glia-glia interactions.

On the basis of the experience gained by the author's group in coculturing neurons and glial cells (Basic Protocol 1), a similar coculture system of astrocytes and microglial cells has been set up in order to study the molecular mechanisms involved in communication between these two cell population. First, the MEM/FBS medium present in a 24-well plate seeded with astrocytes (see Support Protocol 3) is replaced with SFM (see recipe) 1 to 2 days after the preparation of the culture. Next, the tip of a pair of sharpened forceps is used to lift the corner of a coated glass coverslip seeded with microglia (see Support Protocol 3), seize it, and transfer it over the astrocyte monolayer. In this fashion, microglial cells are juxtaposed, without direct contact, with a monolayer of astrocytes. Note that in the author's laboratory, the astrocyte-microglia coculture is usually used within 48 hr of its preparation.

SUPPORT PROTOCOL 2

ISOLATING AND CULTURING CORTICAL GLIAL CELLS

Glial cells (astrocytes, microglia, and oligodendrocytes) are obtained by mechanical and enzymatic dissociation (e.g., trypsin) of cerebral tissue from 1- to 2-day-old old rat pups (Sprague Dawley; day 1, Table 2.7.1). The use of such young rats ensures the absence of viable neurons in the cell suspension. From one 2-day-old pup, the author usually obtains $\sim 5 \times 10^6$ cells.

The author uses confluent cultures of glial cells both to obtain astrocytes and microglia, and to cocultivate hippocampal neurons. Shaking a confluent glial culture makes it possible to separate astrocytes from microglial cells and obtain two purified cultures (see Support Protocol 3). For this purpose the author's laboratory seeds 4×10^6 glial cells in 75-cm^2 culture flasks. To obtain a glial monolayer for neuron-glia coculture, cells are seeded in 24-well plates at a density of 50,000 cells/ml per well. Both the cells seeded in the wells and those seeded in the flasks reach confluence in ~10 days.

Materials

1- to 2-day-old Sprague-Dawley rat pups.
95% (v/v) ethanol
HBSS (see recipe)
10× trypsin/EDTA (Sigma)
10 mg/ml DNase I (see recipe)
High-glucose MEM/10% and 20% (v/v) FBS (see recipe)
0.04% (w/v) trypan blue

Dissecting tools, sterile:
- Stainless steel scissors with ~4- and ~2-cm blades
- 2 pair curved forceps
- Dumont forceps, no. 3c and no. 5
- Bistoury (Aesculap)

100- (one), 60- (two) and 35-mm (four) petri dishes
Dissecting microscope, e.g., Zeiss Stemi DV4
100-μm nylon cell strainer (Falcon)
50-ml conical polystyrene centrifuge tubes
24-well tissue culture plates
75-cm^2 canted-neck tissue culture flasks with screw caps

Additional reagents and equipment for determining total cell number and viability with a hemacytometer (*UNIT 1.1*)

Prepare for dissections

1. Arrange all the sterile dissecting tools on a sterile surface (e.g., sterile lid of a petri dish).
2. Fill all the petri dishes required for the preparation with the appropriate amount of HBSS (10 ml for 100-mm dishes, 5 ml for 60-mm dishes, 2 ml for 35-mm dishes).
3. Set up the dissecting microscope.

Isolate heads from neonatal pups

4. Transport 1- to 2-day-old Sprague-Dawley pups from the cage to the laboratory.

   The authors order a number of pups, usually three, adequate to provide the amount of glial cells needed for 1 month of experiments.

   Neonatal rats can become hypothermic very quickly. To avoid this, place the pups in a nest of cotton in a small open box and cover them as much as possible to help maintain their body temperature.

5. Sacrifice the animal by an officially approved procedure.

   Anesthetization is often required prior to decapitation. To anesthetize pups, place a small piece of cotton wool soaked in halothane or other approved anesthetic in a tube. Place the pup into the tube until it is anesthetized. Replenish the anesthetic between uses if necessary.

6. Gently hold the pup with thumb and forefinger and rinse it with 95% ethanol.

7. Decapitate the pup with scissors over a 100-mm petri dish with 10 ml HBSS. Keep head on ice.

   Keeping head, brains, and later the cortices cold reduces metabolic activity and the associated cellular damage.

8. Repeat steps 5 to 7 for each pup.

   Sterile scissors should be placed on a sterile petri dish lid or in a beaker with 95% ethanol.

Dissect out brains

9. Place one head in a 35-mm petri dish with 2 ml HBSS. Secure the head by holding down the snout with a curved-tip forceps and cut skin and skull along the midline from the base of the skull to the snout with sharpened scissors. To ease removal of the brain, cut left and right side of the skull in the center perpendicularly to the midline.

   Place the head in the petri dish with neck down and skullcap towards the operator. Place anterior end of the head towards the top side of a petri dish and posterior end towards the bottom. This orientation will greatly facilitate the dissection.

   To avoid damaging the underlying brain tissue, place one scissors tip just under the skull bone and lift upward with the scissor blade while cutting.

10. Still keeping the head secured, remove the skull with a curved-tip forceps and expose the brain. Sever the olfactory bulbs at the anterior end of the brain and the spinal cord at the posterior end with Dumont no. 5 forceps.

11. Remove the brain with a curved-tip forceps and collect it in a 60-mm petri dish with 5 ml HBSS. Keep on ice.

    Place the curved tips of the forceps under the brain and gently lift it upward.

12. Repeat steps 9 to 11 for each head.

Isolate cortices

13. To separate the cortices from the rest of the brain, move one brain to a 35-mm petri dish with 2 ml HBSS. Working under the dissecting microscope, place the two tips of Dumont no. 5 forceps along the brain midline under the cortices, one at the anterior and the other at the posterior end. Use a single cut to isolate the cortices from the brain stem.

14. Repeat this step for each brain and store all the cortices on ice in a 60-mm petri dish with 5 ml HBSS.

15. Place one cortex in a 35-mm petri dish (2 ml HBSS) and, still working under the dissecting microscope, gently remove any extraneous tissue as well as the meningeal coverings on the cortical surface by pulling them off gently with Dumont no. 3c and no. 5 forceps. Take care not to destroy the tissue by pressing too hard with the forceps.

    A semitransparent tissue, the meninges, surrounds the surface of the cortex. They are recognizable for their slightly pink color due to the presence of blood vessels. When the meninges are completely removed, the surface of the cortex appears completely white.

16. Repeat step 15 for each cortex.

Disassociate cells

17. Place cortices from 1- to 2-day-old rat pups in a 35-mm petri dish on ice (no medium). To obtain a homogenate of finely minced cortices, accumulate them together in the center of the dish and cut several times in different directions with a bistoury.

18. Add 2 ml HBSS and resuspend the minced cortices by drawing the mixture in and out of a disposable, sterile, 2-ml plastic pipet.

19. Remove the suspension and transfer to a 50-ml centrifuge tube.

20. Repeat steps 2 and 3 twice more to collect all of the minced cortices from the dish. Resuspend minced cortices in 6 ml HBSS.

Trypsinize cells

21. Add 750 µl of 10× trypsin/EDTA and 750 µl of 10 mg/ml DNase I to the suspension.

    DNase is added to prevent the DNA released by damaged cells from making the dissociation medium too viscous during digestion.

22. Seal the capped tube with Parafilm. Vigorously agitate 15 min in a 37°C water bath to favor enzymatic digestion of the tissue. While the tube is being agitated, prepare a 50-ml centrifuge tube containing 12 ml high-glucose MEM/10% FBS.

23. After agitation, remove the tube from the shaking water bath and allow the undissociated tissue to collect at the bottom.

    Avoid centrifugation; dissociated cells must remain suspended so they can be collected.

24. Collect 5 ml dissociated cells with a disposable, sterile, plastic 12-ml pipet and transfer to the 50-ml centrifuge tube containing MEM/10% FBS (step 22).

    Take care not to include undissociated tissue pieces.

Repeat trypsinization and consolidate products

25. Add 6 ml HBSS, 750 µl of 10× trypsin, and 750 µl DNase I to the 50-ml tube containing the remaining undissociated tissue.

    The FBS in MEM (step 22) inhibits trypsin and thus prevents overdigestion of the dissociated cells.

26. Repeat steps 22 and 23, and add these dissociated cells to the 50-ml tube containing the cells from the first digestion as described in step 24.

***Remove trypsin and DN*ase**

27. Filter dissociated cells through a 100-µm nylon cell strainer and collect in a fresh 50-ml centrifuge tube.

    Filtration eliminates any pieces of tissue accidentally collected with dissociated cells.

28. Pellet pooled cells by centrifuging in a swinging-bucket rotor 5 min at 200 to 300 × *g*, room temperature.

29. Carefully remove the medium from the pelleted cells.

Disaggregate and assess cell number and viability

30. Disaggregate the pellet by first adding 2 ml MEM/10% FBS and then gently drawing in and out of a 2-ml disposable plastic pipet until the solution becomes homogeneous. Add an additional 3 ml MEM/10% FBS for a total resuspension volume of ~5 ml.

31. Gently add 100 µl cell suspension to 200 µl of 0.04% (w/v) trypan blue. Determine total cell number and viability with a hemacytometer and an inverted phase-contrast microscope (*UNIT 1.1*).

    Trypan blue is used to distinguish viable from dead cells. Viable cells exclude trypan blue while dead or damaged cells are stained (dark blue).

Plate and prepare glia for the sandwich coculture

32. From the 5-ml cell suspension (step 30) aspirate a volume containing a sufficient number of viable cells to prepare the desired number of 24-well plates at a ratio of 50,000 cells/well. Dilute the cell suspension to 50,000 cells/ml with high-glucose MEM/20% FBS.

    The author usually plates a sufficient number of wells for the cocultivation of neurons prepared over 1 month.

    Glial cells are plated and kept in MEM/20% FBS for 5 days, then the medium is changed to MEM/10% FBS. The cells are maintained in this medium up to 1 month.

33. Pipet 1 ml cell suspension into each well of a 24-well plate.

Plate and prepare glia to obtain astrocytes and microglia

34. From the 5-ml cell suspension (step 30), aspirate a volume containing a number of cells sufficient to prepare the desired number of 75-cm^2 canted-neck flasks with screw caps at a ratio of $\sim 4 \times 10^6$ cells/flask. Dilute 4×10^5 cells/ml in MEM/20% FBS.

    Astrocyte and microglial cells are obtained by shaking the glial culture to divide the two cell populations (see Support Protocol 3). Thus, it is important to use culture flasks having screw caps that can be completely tightened to prevent medium spillage during the shaking period.

35. Pipet 10 ml cell suspension into each flask.

Grow cultures to confluence

36. Incubate plates and flasks 24 hr.

37. To eliminate undetached cells, remove the medium and add 1 or 10 ml fresh MEM/20% FBS for each well or flask, respectively. Repeat 5 days later.

38. Five days later, remove MEM/20% FBS, replace with MEM/10% FBS, and continue to grow to confluence, changing the medium twice a week (e.g., Monday and Thursday or Tuesday and Friday).

    Confluence will be reached in ~10 days.

SUPPORT PROTOCOL 3

ISOLATION AND SEEDING OF CORTICAL ASTROCYTES AND MICROGLIA CELLS

The techniques described here to prepare and separate astrocytes and microglial cells are based on the methods of McCarthy and DeVellis (1980) and Giulian and Baker (1986), which have undergone some changes in this laboratory. The method is based on the selective detachment of microglial cells from astrocytes by shaking mixed glial cultures on an orbital shaker; taking advantage of the difference in degree of attachment of the two cell types to tissue-culture plastic. Astrocytes are then further depleted of microglial cells by treatment with L-leucine methyl ester (L-LME), which selectively kills microglia.

Both astrocytes and microglial cultures appear >97% pure, as assessed by immunocytochemistry of glial fibrillary acidic protein (GFAP), a cytoskeletal protein found only in astrocytes, and with *Griffonia simplicifolia* isolectin B4, a selective marker of both resting and activated microglia (Cheepsunthorn et al., 2001). From each flask of confluent glial cells the author's group usually obtains $\sim 5 \times 10^6$ astrocytes. The number of microglial cells separated from each flask is extremely variable and changes with different preparations (i.e., from $\sim 5 \times 10^5$ to $\sim 3 \times 10^6$ cells).

Materials

High-glucose MEM/10% and 15% FBS (see recipe)
0.04% (w/v) trypan blue solution
1× PBS (Sigma; *APPENDIX 2A*)
High-glucose MEM/10% FBS containing 5 mM L-LME (Sigma)
1× trypsin/EDTA solution (Sigma)
24-well plate containing coated glass coverslips (see Support Protocol 4)
Additional reagents and solutions for preparing confluent glial cultures in 75-cm^2 cantered-neck flasks (see Support Protocol 2) and determining cell number and viability with a hemacytometer (*UNIT 1.1*)

Detach microglia

1. Prepare confluent glial cultures in 75-cm^2 canted-neck flasks (see Support Protocol 2).

   Use culture flasks since the caps can be completely tightened to prevent medium spill during the shaking period.

   In the author's laboratory, usually ~4 × 10^6 cells are seeded per flask. Under these conditions glial cells reach confluence after 10 days (i.e., to obtain a confluent monolayer on Monday prepare glial cells on the Thursday two weeks before).

2. Use Parafilm to seal the flask caps and vigorously agitate on an orbital shaker 1.5 hr at 260 rpm, 37°C.

   Within 2 hr of shaking, most of the microglia can be detached from the glial monolayer and subcultured. Astrocytes remain adherent to the flask.

3. Collect the medium from the flasks in one or more 50-ml centrifuge tubes.

   Collect up to 50 ml in each tube; one 50-ml tube is enough for six flasks.

Equilibrate astrocytes and pellet microglia

4. Add 10 ml fresh high-glucose MEM/10% FBS to each flask with a sterile pipet.

5. To pellet the suspended cells, centrifuge the 50-ml tubes 5 min in a swinging-bucket rotor at 200 to 300 × *g*, room temperature. Meanwhile, transfer the flasks to an incubator for at least 1 hr.

   To obtain purified astrocytes, the flasks have to be shaken further overnight. Since it is usually impossible to shake the flasks in an incubator, it is better to allow the fresh medium to equilibrate before shaking again. This period usually suffices for the preparation of microglial cultures.

Disaggregate and assess cell number and viability

6. At the end of the centrifugation discard the supernatant, add 2 ml MEM/10% FBS to microglial-cell pellet using a sterile pipet and disaggregate by drawing up and down. Add an additional 3 ml MEM/10% FBS for a total of 5 ml and resuspend to obtain a homogeneous suspension.

7. Add 100 µl cell suspension to 200 µl of 0.04% trypan blue solution and mix gently. Determine total cell number and viability with a hemacytometer and inverted phase-contrast microscope (*UNIT 1.1*).

   Trypan blue is used to distinguish viable from dead cells. Viable cells exclude trypan blue while dead or damaged cells are stained (dark blue).

Prepare and plate microglia for the sandwich coculture

8. Gently resuspend sedimented cells, then dilute to 200,000 cells/ml with MEM/10% FBS.

9. Add 1 ml suspension to each well of a 24-well plate containing coated glass coverslips.
10. Incubate 30 min.

    This short incubation period allows the adhesion of chiefly microglial cells to the substrate.

11. Gently shake the plate, remove the medium, and wash once with 1× PBS.

    By shaking and washing, loosely adhering cells like oligodendroglia are removed.

12. Add 1 ml high-glucose MEM/15% FBS to each well and transfer plates to an incubator.

Purify astrocytes

13. Transfer the flasks containing partially purified astrocytes (step 5) to an orbital shaker and agitate overnight at 260 rpm, 37°C.
14. The next morning, remove the medium and wash the monolayer three times with 1× PBS.
15. Add 10 ml high-glucose MEM/10%FBS/5 mM L-LME to each flask.

    L-LME selectively kills microglial cells and is used to reduce any microglial contamination of astrocytes.

16. Incubate 2 hr.
17. Wash twice with PBS.

Trypsinize astrocytes

18. Add 2 ml of 1× trypsin/EDTA to each flask to detach astrocytes and gently rotate so that the trypsin can spread over the surface where astrocytes are attached. Incubate 5 min.

    Do not exceed this time, otherwise there is danger of overdigestion. If it is necessary to detach astrocytes from several flasks, do not add trypsin to all of them at the same time.

    To detach cells without using trypsin, incubate the monolayer 5 min in 5 ml PBS without calcium and magnesium, supplemented with 5 mM EDTA; however, this procedure gives lower cell recovery than trypsinization.

19. Detach astrocytes by gently shaking and washing the surface of the flask.
20. Transfer the trypsin solution containing astrocytes to a tube containing 2 ml MEM/10% FBS.

    The serum contained in the medium inactivates trypsin. Thus, to avoid overdigestion the cells resuspended in trypsin are immediately added to an equal volume of cell culture medium. If more than one flask is to be trypsinized, the cells can be pooled in a single tube containing cell culture medium. Add 1 ml of cell culture medium for each milliliter trypsin.

Prepare and plate astrocytes for the sandwich coculture

21. To pellet cells, centrifuge 10 min in a swinging bucket rotor at 100 to 200 × *g*, room temperature. Aspirate the medium and resuspend the pellet in 2 ml of MEM/10% FBS.
22. Repeat steps 7 and 8 with the astrocyte suspension.
23. Add 1 ml cell suspension to each well of a 24-well plate.
24. Transfer to an incubator.

    Astrocytes can be maintained up to 1 month.

PREPARATION OF GLASS COVERSLIPS FOR SANDWICH COCULTURES

SUPPORT PROTOCOL 4

Hippocampal neurons and microglial cells do not readily adhere to glass. Thus, to promote their attachment, maturation, and survival, coverslips are coated using poly-L-ornithine, or poly-L-lysine. In addition, three dots of paraffin are placed on each coverslip to create a narrow gap between the two cultivated cell populations.

The use of 24-well plates and 12-mm coverslips to obtain a coculture does not allow an open-face sandwich coculture. This is basically because the cell monolayer below the coverslip degenerates. In 24-well plates, where the well is slightly bigger than the coverslip, this means the destruction of the glial or astrocyte monolayer.

The coverslips are prepared at least one day before the hippocampal neurons (see Support Protocol 1) or microglial cells (see Support Protocol 2) are dissociated. In the author's laboratory, if hippocampi are dissected on Monday, coverslips are prepared the Friday before and kept in polyornithine at room temperature until Monday morning. Next they are washed and incubated in growth medium before being seeded with cells.

Materials

Paraffin wax
1× poly-L-ornithine solution (see recipe)
1× PBS (Sigma)
High-glucose MEM/10% FBS (see recipe)

12-mm glass coverslips
24-well tissue-culture plates
Microwave oven
5- to 10-ml sterile syringe with 0.95 × 40–mm needle
Germicide lamp (e.g., as equipped on a flow hood)

1. Place one 12-mm glass coverslip in each well of a 24-well tissue-culture plate.

   Each time, prepare the exact number of coverslips to be used. This will reduce the possibility of contamination.

2. Sterilize the coverslips by microwaving 10 min at the highest power setting.

3. Place the plates next to a beaker half full of water in order to avoid melting the plastic plates.

4. Heat paraffin wax to ∼100°C. Take an ∼2-ml aliquot in a 5- or 10-ml syringe and apply three small drops near the outer edge of each coverslip at roughly equal distances from each other.

   To melt paraffin, place four pieces in a beaker and place the beaker on a hot plate.

   By working rapidly, it is possible to place several dots over two to three coverslips. The temperature of the paraffin is very important. If it is too hot, it spreads too thin and wide, while if it is too cool, the dots do not adhere to the coverslip and will subsequently detach.

5. Resterilize the coverslips by UV irradiation for 30 min with a germicide lamp.

   The germicide lamp of a flow hood is sufficient. Avoid exposing coverslips to UV after they have been coated with polyornithine.

6. In a laminar flow hood, add 1 ml of 1× poly-L-ornithine solution in each well containing the coverslips.

   Check that the coverslips do not float in the well but are completely covered by polyornithine. To prevent floating, be sure to eliminate any air bubble under the coverslip by gently pressing over it.

7. Incubate the plates up to 2 days at room temperature or 2 hr at 37°C.

   When plates are out of the laminar flow hood, store them sealed with Parafilm in the dark.

8. Immediately before isolating cells (see Support Protocol 2), remove polyornithine and rinse twice with 1× PBS.

   To obtain the best result in the attachment of cells and their development do not let the coverslips dry at any stage.

9. After the final rinsing add 1 ml high-glucose MEM/10% FBS and incubate until the end of cell preparation.

   When isolated and dissociated, cells will be seeded in this same medium.

   The coverslips are now ready to be seeded. Add the desired number of cells over the coverslips without changing the incubation medium.

   In the author's laboratory unused coverslips are discarded.

REAGENTS AND SOLUTIONS

Use deionized, distilled water or equivalent for all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Cytosine arabinoside, 2 mM

Dissolve 2 mg cytosine-1-β-D-arabino-furanoside (cytosine arabinoside) in 5 ml water. Store up to 6 months at −20°C.

DNase I, 10 mg/ml

Dissolve 100 mg of 536 Kunitz units/mg DNase I (Sigma) in 10 ml HBSS (see recipe). Store up to 6 months in 1.5-ml aliquots at −20°C.

HBSS

To 850 ml H_2O add:
Hanks Balanced Salts powder (Sigma), enough for 1 liter
10 ml 10 mM HEPES (Sigma)
10 ml penicillin/streptomycin stock solution (Sigma)
Adjust volume to 1 liter with H_2O
Sterilize using a 0.22-μm cellulose-acetate disposable vacuum-filtration system (Millipore)
Store up to 1 month at 4°C

The stock solution of penicillin/streptomycin contains 10,000 U/ml penicillin and 10 mg/ml streptomycin. Store this stock solution up to reported expiration date in 5-ml aliquots at −20°C.

High-glucose MEM/10%, 15%, or 20% FBS

500 ml minimal essential medium with Earle's salts (MEM; Sigma)
0.6% (w/v) D(+)-glucose (Sigma)
5 ml penicillin/streptomycin stock solution (Sigma)
5 ml of 200 mM L-glutamine
Shake vigorously to dissolve glucose
10%, 15%, or 20% (v/v) FBS (Sigma)
Sterilize using a 0.22-μm cellulose-acetate disposable vacuum-filtration system (Millipore)
Store up to 1 month at 4°C

Do not add FBS before shaking, otherwise there is excessive foam formation.

continued

The stock solution of penicillin/streptomycin contains 10,000 U/ml penicillin and 10 mg/ml streptomycin (100 U and 100 μg/ml final, respectively). Store this stock solution up to indicated expiration date in 5-ml aliquots at −20°C.

See UNIT 1.1 for more information regarding preparation of medium.

Insulin, 5 mg/ml

100 mg insulin from bovine pancreas (Sigma)
20 ml sterile H_2O
100 μl glacial acetic acid
Store up to 6 months at 4°C

Poly-L-ornithine solution, 1×

Prepare a 100× stock solution by dissolving 10 mg poly-L-ornithine (Sigma) in 6.67 ml water. Store up to 6 months in 1-ml aliquots at −20°C. Dilute to 1× with water.

Progesterone, 0.1 mM

Dissolve 0.314 mg progesterone in 10 ml of ethanol. Store up to 6 months at −20°C.

Putrescine, 1 M

Dissolve 1.6 g putrescine (Sigma) in 10 ml water. Store up to 6 months at −20°C.

Serum free medium (SFM)

To 850 ml H_2O add:
Dulbecco's modified Eagle's medium nutrient mixture F-12 Ham powder (Sigma), enough for 1 liter
3.7 g $NaHCO_3$
0.11 g sodium pyruvate (1 mM final; Sigma)
1 ml 5 mg/ml insulin (see recipe)
100 mg >97% human apotransferrin (Sigma)
100 μl 1 M putrescine (1 μM final; see recipe)
120 μl 0.25 M sodium selenite (30 nM final; see recipe)
200 μl 0.1 mM progesterone (20 nM final; see recipe)
10 ml penicillin/streptomycin (100 U/ml and 100 μg/ml final, respectively; Sigma)
Adjust pH to 7.2
Adjust volume to 1 liter with H_2O
Sterilize using a 0.22-μm cellulose-acetate disposable vacuum-filtration system (Millipore)
Store for up to 1 month at 4°C.

See UNIT 1.1 for more information regarding preparation of culture medium.

Sodium selenite, 0.25 mM

Dissolve 1 mg sodium selenite (Sigma) in 10 ml water. Store up to 1 month at room temperature.

COMMENTARY

Background Information

Coculture systems provide an easy controlled way to study how a cell population can influence the function, viability, and response of another cell population. Other in vitro systems suitable for the study of the interactions between different cell populations are brain reaggregate cultures or organotypic explants. Brain reaggregate cultures are rotation-mediated aggregating cultures constructed from single-cell suspensions of fetal brain characterized by an organotypic cell association.

A more complex situation is represented by the organotypic cultures. These are derived from explants of undifferentiated embryonic brain and retain some of the structural and functional characteristics of the area of origin.

Both organotypic and reaggregate cultures differ from cocultures since they retain a three-dimensional organization. While a flat coculture system is particularly well suited to detect changes in cell function or differentiation and the interference of a compound on these parameters, organotypic and reaggregate cultures are designed to detect changes in cellular organization by morphological and electrophysiological features. Thus, the choice of the cell system largely depends on the question to be answered.

The great advantage of a sandwich coculture system in studies over the other in vitro systems is the possibility of separating the two cell populations at any time (e.g., prior to or after a treatment) while retaining their integrity. This allows the investigator to (1) manipulate the cell types differently before they are treated together, thus providing information on the involvement of specific mediators or biochemical pathways, (2) perform different biochemical measurements on the two cell populations separately at the end of the treatment, and (3) evaluate the activity on highly differentiated neurons in the presence or absence of the glial feeder layer. For example, the author used this system to study the molecular mechanisms involved in the glia-mediated neuronal death triggered by the human immunodeficiency virus glycoprotein 120 (gp-120). The question of whether the production of reactive oxygen species (ROS) induced by gp-120 in glial cells could be responsible for an increased production of IL-1β from glia and subsequent neural death was assessed (Viviani et al., 2001). For this purpose, glial cells were loaded with an antioxidant, washed, and exposed together with hippocampal neurons to gp-120. In this way, the ability of glial cells to produce ROS as a consequence of gp-120 exposure was blocked without altering the neural cells. As a control, hippocampal neurons and unloaded glia were exposed to gp-120. At the end of the treatment, glia and neurons were separated, neural cell death was assessed by the MTT test, and the results compared with the death rate of neurons exposed to gp-120 in the presence of an unloaded glial monolayer. The synthesis of IL-1β in glial cells was also measured by RT-PCR. It was observed that antioxidant pretreatment of glial cells reduced gp-120-induced production of IL-1β and neural cell death.

This model has also been used to monitor the influence of neural degeneration on glial response in modulating neural cell death (Viviani et al., 2000; Villa et al., 2003).

Because there is no contact between the cell populations, sandwich coculture allows one to study how different cell populations can reciprocally influence their functions/viability through the release of soluble mediators. The lack of contact between neurons and glia, or astrocytes and microglia may, however, represent a disadvantage since it does not mirror physiological conditions. Hippocampal neurons can be plated directly onto glial cells, as can microglia onto astrocytes, but the advantage of manipulating one of the two cell populations forming the coculture would be lost.

Critical Parameters and Troubleshooting

Three very important parameters to obtain successful primary cultures are sterility, rapidity in dissecting brain tissues and plating the obtained cells, and satisfactory reagents. Problems encountered during cell isolation and growth, their possible causes, and possible remedies are reported in Table 2.7.3.

Sterility

Working conditions must ensure the highest degree of sterility. This means that, wherever possible, cell isolation, culturing, and preparation of all solutions should be performed in a laminar flow hood. If nonsterile ingredients are added to a solution, the product has to be filtered through a 0.22-μm filter. To maintain sterility, solutions must never be opened outside the laminar flow hood and must be stored in small aliquots. The addition of antibiotics such as penicillin and streptomycin to the culture medium helps to avoid bacterial contamination.

The use of disposable materials for culturing cells reduces the possibility of contamination and is strongly recommended. All disposable materials (even plastic pipets) should be used only once.

Autoclave surgical instruments (i.e., 21 min at 121°C) to sterilize and store in 95% ethanol when not in use. If, during dissection, tools touch nonsterile surfaces or materials, spray them with 70% ethanol and let the ethanol evaporate before using again.

If any contamination occurs, it is wise to eliminate the contaminated cultures, prepare fresh reagents, and clean the laminar flow hood

Table 2.7.3 Troubleshooting Guide for Preparation and Coculture of Neurons and Glial Cells

Problem	Possible cause	Solution
Low cell viability	Prolonged dissection time	Never exceed 2 hr to obtain brain and dissect hippocampi or cortices
Poor neuronal differentiation	SFM incomplete (e.g., without apotransferrin)	Prepare fresh SFM and check that all ingredients are added
	L-Polyornithine lot unsatisfactory	Test different lots and choose the best
	Glial feeder layer too old	To cocultivate hippocampal neurons use a glial feeder layer within 3 to 4 weeks
	Damaged glial feeder layer	Check the morphology of glial cultures every time before adding neurons
Floating cells in cultures	Contamination	See Critical Parameters and Troubleshooting, Sterility

prior to new culture preparation. To clean the laminar flow hood, wash with a detergent first and then with 70% ethanol. Contaminated solutions can be filtered, but sterility has to be checked prior to use by incubating in culture dishes for a few days at 37°C.

Tissue dissection

Rapid dissection of both hippocampi and cortices is essential to obtain a successful neural or glial culture. In the author's experience the shorter the time of dissection the better the culture obtained. The author's group never exceeds 2 hr to obtain brains and dissect hippocampi and cortices. Preparation time for cultures can be considerably shortened by using a team of two people, one removing brains from the skull and the other cleaning, removing, and dissociating hippocampi or cortices.

Reagent lots

Lot-to-lot variability of reagents such as trypsin, poly-L-ornithine, and all the ingredients of SFM as well as FBS, influences the viability, development, and functionality of glia and particularly of hippocampal neurons. Wherever possible, it is better to test different lots of the same reagent before using it for the routine cultivation of glia and neurons. Measurements to identify the best lot are: the number of cells obtained after tissue dissociation (which can depend on the lot of trypsin used), growth rate of glial cells (dependent on serum), cell viability, and differentiation of neural cells (dependent on the poly-L-ornithine or the ingredients of SFM). If poor neural differentiation is observed, also check that all the requisite ingredients have been added to the culture medium.

Anticipated Results

Healthy hippocampal neurons readily attach to coated glass coverslips and are initially characterized as small round shapes. Within a day of coculture they extend short processes (Fig. 2.7.1). A well-developed network is clearly evident at the third or fourth day of coculture. In the following weeks, even if great morphological changes are not evident any more, hippocampal neurons develop a functional glutamatergic system and a complete post-synaptic density. Hippocampal neurons become sensitive to glutamate, showing an increase in cell death and intracellular calcium, starting from the eighth day of culture.

Glial cultures at confluence are characterized by the presence of an overwhelming percentage of astrocytes and ~5% of microglia. Astrocytes have a flat polygonal appearance and form a uniform layer over which small, dark microglial cells can be observed. Microglial cell numbers can increase considerably with aging of the culture. Once detached from astrocytes and plated on a glass coverslip, microglial cells acquire a round shape that tends to ramify as the number of days in culture increases. A "ramified" morphology is typical of resting microglia. The author's group observed no morphological difference in microglia or astrocytes cultivated alone or in coculture <48 hr from their preparation.

Time Considerations

Preparation of hippocampal neuron-glia sandwich cocultures (Basic Protocol 1) or of astrocyte-microglia sandwich cocultures (Basic Protocol 2) requires 35 to 45 min. Hippocampal neuron-glia cocultures can be maintained up to 3 to 4 weeks. In the author's laboratory, the astrocyte-microglia coculture is used within 48 hr from its preparation.

Isolation and seeding of hippocampal neurons (Support Protocol 1) require 1.5 hr to 2 hr. Hippocampal neurons seeded by following the described protocol can be maintained without glial cells up to a couple of days.

Isolating and culturing cortical glial cells (Support Protocol 2) require 2 hr. Cortical glial cells can be maintained up to 1 month.

Isolation and seeding of cortical astrocytes (Support Protocol 3) require 19 hr. Astrocytes can be maintained up to 1 month. Isolation and seeding of microglial cells (Support Protocol 3) require 2 hr. In the author's laboratory, microglia are maintained up to 48 hr from preparation.

Preparation of glass coverslips for sandwich cocultures (Support Protocol 4) requires 2 days when glass coverslips are incubated with poly-L-ornithine at room temperature or 3 hr when glass coverslips are incubated with poly-L-ornithine at 37°C.

CHAPTER 3
Subcellular Fractionation and Isolation of Organelles

INTRODUCTION

In the early 1700s, Leeuwenhoek noted that avian and amphibian blood cells contained a "clear area," almost certainly corresponding to the structure we now know as the nucleus. This represents probably the earliest recognition that eukaryotic cells are not simply sacs of protoplasm, but instead contain subcellular structures. Although the concept of the nucleated cell became firmly established in the 18th and 19th centuries, the real beginning of subcellular fractionation had to await the emergence in the mid-1940s of the art form known as electron microscopy. The electron microscope revealed much more complexity than Leeuwenhoek could have imagined. Concurrent with improvements in the techniques of electron microscopy was the development of methodologies for subcellular fractionation. Through the 1950s, these parallel approaches resulted in the discovery and isolation of the major organelles that comprise the eukaryotic cell. Finally, as biochemical functions were associated with specific subcellular compartments, a much clearer picture of the eukaryotic cell began to emerge, and with it the field of modern cell biology.

Chapter 3 is dedicated to methods for subcellular fractionation. The chapter begins with an overview of cell fractionation (*UNIT 3.1*) which covers some basic principles as well as the instrumentation of centrifugation. The various centrifugation media, ranging from sucrose to the newer media (Ficoll, Percoll, metrizamide, Nycodenz, and Iodixanol), are described.

Much of the earliest work in subcellular fractionation utilized rat liver as starting material. The second unit of Chapter 3 provides protocols for the isolation of plasma membrane sheets and domains from rat liver (*UNIT 3.2*). This method is used to isolate plasma membrane sheets in sufficient yield and purity to be suitable for a variety of analytical and preparative purposes. For example, these preparations can be used as starting material for the isolation of hepatocyte plasma membrane proteins. The sheets also serve as the starting material for the protocols within *UNIT 3.2* that yield the apical and basolateral domains comprising the polarized hepatocyte plasma membrane.

The densities of mitochondria, peroxisomes, and lysosomes are very similar, and as a result, these organelles cosediment in density gradients as the so-called "light mitochondrial fraction." The development of separation media has significantly improved the ability to separate these organelles from each other. *UNITS 3.3–3.6* deal with separation of these organelles.

UNITS 3.3 & 3.4 describe methods for isolating mitochondria from rat liver as well as other sources including other tissues, cultured mammalian cells, and yeast. *UNIT 3.3* focuses on methods involving differential centrifugation for rapid isolation of metabolically active mitochondria, whereas methods involving density-gradient centrifugation for further purification of mitochondria are described in *UNIT 3.4*.

UNIT 3.5 provides methods for the isolation of peroxisomes from mammalian tissues and cells in tissue culture. Also included in this unit are a method for preparation of

peroxisomes from yeast and descriptions of assays for assessing the success of subcellular fractionation of the various starting materials.

The yeast *Saccharomyces cerevisiae* contains all the membrane-bound subcellular organelles that are characteristic of higher eukaryotes, yet this organism has a haploid genome that is less than four times the size of that of *E. coli*. The availability of the entire *S. cerevisiae* genome sequence, together with the ease with which yeast are cultured (*UNIT 1.6*) and the simplicity with which genetic manipulations are performed have made this organism a popular model in eukaryotic cell biology. Indeed, it is yeast cell biology that may provide insights into the function of many yeast genes and their mammalian counterparts. While some attention to certain subcellular organelles from yeast is given in earlier units of this chapter, *UNIT 3.7* provides a comprehensive overview of yeast subcellular fractionation.

UNIT 3.8 describes centrifugation-based methods for isolating most of the major organelles of the yeast *Saccharomyces cerevisiae*. Most of these procedures begin with the preparation of spheroplasts as described in the Support Protocol near the beginning of the unit. Lysates for subcellular fractionation can also be generated by glass-bead lysis to disrupt intact yeast cells (also described). Because of the fragility of most yeast organelles, lysates of spheroplasts are best used for most protocols; however, glass-bead lysates can be used for preparation of cytosol and plasma membranes. Several of the protocols are analytical for assessing the distribution of proteins along exocytic, endocytic, and biosynthetic pathways in yeast cells. The unit also includes preparative methods for isolating yeast nuclei, vacuoles, mitochondria, peroxisomes, endoplasmic reticulum, plasma membranes, and cytosol.

The Golgi, an organelle named for the pioneering cell biologist, Camillo Golgi, was identified on the basis of a then current protocol developed by Golgi for fixing and staining tissues. Although observations of what he then referred to as the "internal reticular apparatus" probably date even earlier in the 19th century, the Golgi remains an intracellular site of intense investigation by today's cell biologists. *UNIT 3.9* describes the isolation of Golgi membranes on a preparative basis. Individual protocols describe isolation of dextrose-treated Golgi stacks from rat liver using a sucrose density barrier and by flotation from a light mitochondrial fraction. Isolation from cultured cells is also described, as is a method to assay for the Golgi marker enzyme, UDP-galactose galactosyl transferase.

UNIT 3.10 focuses on the "clear area" of Leeuwenhoek—the nucleus. As noted above, rat liver has been the most frequently used source of material for subcellular fractionation. This unit contains two protocols for isolation of nuclei from rat liver. The first utilizes a sucrose density barrier, whereas the second employs Nycodenz as a density medium. Although the vast majority of methods for preparing nuclei use soft tissue (e.g., liver), the protocols described in this unit can be applied to other source materials (e.g., cultured cells, plants), provided appropriate homogenization can be achieved. *UNIT 3.10* also contains two protocols for purification of nuclear membranes from isolated nuclei and Support Protocols describing methods for assaying DNA and RNA.

Free-flow electrophoresis (*UNIT 3.11*) provides opportunities for both analytical and preparative applications for isolating subcellular organelles such as rat endosomes. Endosome-enriched fractions are prepared from rat liver using discontinuous sucrose gradients, and these are used to prepare endosomal subpopulations by free-flow electrophoresis. The analytical approach can be used to study the kinetics and cellular subpopulations involved in endocytic traffic. Three distinct subpopulations of endosomes are revealed in such studies. Support Protocols include methods for analyzing markers for endosomal subpopulations and for demonstrating retention of endosomal function (acidification)

in vitro. Methods are also included for preparing and labeling ligands that traffic through endosomes.

UNIT 3.12 describes protocols for the isolation of synaptic vesicles—small, electron-lucent organelles contained within presynaptic nerve terminals. Synaptic vesicles function to store neurotransmitters and to release them into the synaptic cleft upon stimulation. Methods for the purification of synaptic vesicles take advantage of the vesicle's small size and low density. The first two protocols describe the use of differential centrifugation to enrich synaptic vesicles 8- to 10-fold relative to brain homogenate. The next three protocols allow further purification to ~20-fold using sedimentation velocity or chromatography on controlled-pore glass beads or Sephacryl S-1000. This unit ends with protocols for the sedimentation of synaptic vesicles at high speed, immunoisolation of synaptic vesicle subpopulations, and siliconization of tubes.

Transport of proteins, lipids, and other "cargo" molecules between different compartments of the secretory, endocytic and lysosomal targeting pathways is mediated by membrane-enclosed carriers. The best characterized of these carriers are clathrin-coated vesicles (CCVs), which play critical roles in endocytosis from the plasma membrane and sorting from the trans-Golgi network and endosomes. CCVs are small (50 to 100 nm in diameter) and are encased within a dense proteinaceous coat—properties that are the bases for their isolation by ultracentrifugation procedures. *UNIT 3.13* presents a series of protocols for the isolation of coated vesicles from different sources, including adult and developing rat brain, adult rat liver, and cultured cell lines. In addition, this unit contains a procedure for analyzing the purity of isolated CCVs by electron microscopy. The Commentary section shows representative electron micrographs of these preparations, as well as SDS-PAGE analyses of the protein composition of the purified CCVs.

UNIT 3.14 deals with melanosomes, which are membrane-bound organelles filled with the pigment melanin. These organelles are only found in specialized cell types such as melanocytes and retinal epithelial cells, and they function to protect cells and tissues from the harmful effects of ultraviolet radiation. Oncogenic transformation of melanocyte precursors results in melanomas, which are particularly aggressive cancers. This unit presents protocols for the isolation of melanosomes from melanoma cells and tissues. The biogenesis of melanosomes involves maturation of precursors through a series of well-defined stages; the protocols in this unit allow for the separation of early and late stage melanosomes by ultracentrifugation and free-flow electrophoresis. This unit also describes a method for monitoring the purification of melanosomes by measuring the activity of the melanosomal enzyme, tyrosinase. Finally, the unit lists antibody reagents to melanosomal proteins that can be used to monitor purification and assess the purity of the isolated melanosomes.

Most cells in culture contain discernable lipid droplets, although the size and number of these droplets vary depending on cell type and culture conditions. Lipid droplets can provide a source of metabolic energy and also play a role in cholesterol homeostasis required for membrane biogenesis. In steroidogenic cells, the lipid droplets provide substrates for hormone synthesis. *UNIT 3.15* describes the isolation of lipid droplets based on their high buoyancy, which is reflective of their low mass of protein and high relative mass of neutral lipids. At present, no specific enzyme markers have been localized exclusively to lipid droplets. The droplets do, however, contain certain characteristic structural proteins, and protocols for immunoblotting of these proteins are included for assessment of the isolated lipid droplets.

UNIT 3.16 describes the isolation of rat serosal mast cells by peritoneal lavage and the use of these cells as a source of mast cell granules. These granules are modified lysosomes that release their contents upon degranulation of the activated mast cells. Protocols

are provided for the isolation of mast cell granules enveloped in their perigranular membrane and of granule remnants released upon degranulation. Several protocols aimed at assessing mast cell activation are included, as is a protocol for verification of granule remnant morphology and purity via electron microscopy. A future unit in Chapter 3 will deal with the isolation of the analogous organelle from chromaffin cells (i.e., chromaffin granules).

All previous units in this chapter that deal with organelle isolation have described isolation of organelles that exist in multiple copies per cell. In contrast, *UNIT 3.17* provides protocols related to the isolation of centrosomes, of which there is only one per cell. As starting material for this challenging task, the protocols utilize early (0- to 3.5-hr) *Drosophila* embryos. Centrosomes are isolated by a protocol involving gradient centrifugation and a protocol for further enrichment via immunomagnetic purification. Protocols for assessing the centrosome preparation by immunofluorescence microscopy are included.

In contrast to the situation with the centrosome (one copy per cell), pancreatic zymogen granules have been estimated to constitute as much as 25% of the total cellular volume based on electron microscopy. The relative abundance of these organelles resulted in their being among the first to be the subject of cellular subfractionation protocols, dating to the mid-1950's. *UNIT 3.18* provides more modern protocols for the purification of these important cellular bodies from both rat and dog pancreas, using both sucrose and Percoll gradients. The pancreas contains other secretory granules in lower abundance, most notably the endocrine granules responsible for insulin release. A future unit of this chapter will provide protocols related to isolation of the insulin granules of the pancreas.

An early unit in this chapter (*UNIT 3.5*) deals with the organelles known as peroxisomes. Glyoxysomes represent a specialized form of the peroxisome found in the cotyledons of seedling plants. In this context, these organelles sequester the enzymes of the glyoxylate cycle that provides energy to the rapidly growing seedling. Later in plant development, the peroxisomes of the green leaves have a distinct complement of enzymes reflecting their role in photorespiration. *UNIT 3.19* provides protocols for growing pumpkin seedlings and for isolation of glyoxysomes from their cotyledons via density gradient centrifugation.

The glucose transporter isoform known as GLUT4 functions to facilitate uptake of glucose by both fat and muscle tisssues. GLUT4 is translocated in response to insulin from an intracellular compartment to the plasma membrane as the mechanism for insulin-mediated enhancement of glucose transport. The investigation of trafficking of GLUT4 has gained considerable attention since the discovery that GLUT4 translocation is compromised in type 2 diabetes. *UNIT 3.20* provides protocols for isolation of GLUT4 storage vesicles from primary rat adipocytes, cultured adipocytes, and skeletal muscle.

Another type of membrane vesicle is the subject of *UNIT 3.21*, which describes isolation of vesicles from intestinal brush border from three species (rat, pig, and cow). These vesicles are derived from the apical surface of the polarized epithelial cells of the small intestine, which also contain integral membrane proteins involved in glucose uptake. Whereas the GLUT4 vesicles of *UNIT 3.20* are part of a regulated trafficking of cellular membranes, those of *UNIT 3.21* represent spontaneous sealing of membrane fragments derived from the intestinal microvilli upon disruption of the tissue architecture. These vesicles can nonetheless be utilized for membrane transport studies.

The theme of isolation of membrane-derived vesicles continues in *UNIT 3.22*, which provides several protocols related to exosomes. These vesicles are derived from the plasma membrane via an endocytosis-exocytosis mechanism, but they are isolated from extracellular fluids (either tissue culture media or bodily fluids). Methods are provided whereby exosomes are isolated by either ultracentrifugation, ultrafiltration, or immunoisolation.

The protocols of *UNIT 3.22* should prove useful in studies aimed at understanding exosome function and the possible use of exosomes in therapeutic applications e.g., as immunogens in vaccines.

UNIT 3.23 describes the isolation of intermediate filaments from bovine spinal cord. Although intermediate filaments from different sources contain a diverse complement of intermediate filament proteins, all intermediate filaments share the property of being insoluble in conventional extraction buffers. It is this property that serves as the basis of the isolation protocol. Intermediate filaments can also be produced after assembly of a recombinant intermediate filament protein, and an Alternate Protocol describes this method. With intermediate filaments isolated from either tissue or assembled recombinant protein, it is possible to study the assembly process in vitro and to investigate, in vitro, possible interaction partners that participate in intermediate filament–mediated processes in vivo.

Skeletal and cardiac muscle cells contain an unusual system of tubular invaginations of their sarcolemma known as the transverse tubule (T-tubule), which are critical participants in the process of muscle contraction. *UNIT 3.24* provides a Basic Protocol that enables the isolation of highly purified T-tubules from muscle tissue using density gradient ultracentrifugation. A second, related Basic Protocol takes advantage of the glycoproteins in the membranes to separate sarcolemma membrane vesicles from T-tubule vesicles via aggregation of the former by wheat germ agglutinin. An Alternate Protocol involves immunoisolation T-tubule vesicles utilizing antibodies that recognize the intracellular domain of T-tubule integral membrane proteins (e.g., GLUT4).

Another very specialized membrane is the myelin sheath that surrounds vertebrate axons in both the central and peripheral nervous system. CNS myelin is elaborated as a plasma membrane extension by oligodendroglial cells of the brain and spinal cord, whereas PNS myelin is generated by Schwann cells. Methods for isolating myelin go back over three decades, and the methods of *UNIT 3.25* are in fact based on the classical isolation method of Norton and Podusulo published in 1973. The methods here are modified to minimize proteolysis and contamination with the axon plasma membrane. Although the protocols are related, separate protocols are provided for isolation of myelin from the CNS and from the PNS, reflecting the morphological and biochemical distinction in the two forms of myelin. In both cases, the relatively low density of myelin-derived membrane vesicles allows for a high degree of purification. A support protocol for assay of a marker enzyme is also included.

Brush borders also represent a specialization of the cell surface. In this case, rather than wrapping around axons in a spiral fashion as does myelin, the brush border is characterized by characteristic folds of the plasma membrane to form finger-like projections termed microvilli. These structures markedly increase the surface area of the membrane, which enables enhancement of absorption of substances. *UNIT 3.26* provides protocols for the isolation of brush borders from the kidney where the brush border structure participates in glomular filtration. The microvilli that make up the renal brush border are closely associated with actin filaments, explaining why brush borders have been utilized as a source of actin-binding proteins. It also accounts for the fact that brush borders are relatively resistant to homogenization, and this feature is exploited in the isolation protocols. Isolated brush borders can be further studied and purity/integrity assessed by flow cytometry, marker enzymes, and/or electron microscopy.

The boundary between the fields of virology and cell biology has always been blurry due to the fact that viruses infect cells. The cellular pathways of protein trafficking are among those that are "hijacked" by many viruses. Indeed, the trafficking of viral proteins has been instrumental in understanding these pathways. To localize and examine the

trafficking of the proteins of human cytomegalovirus (HCMV), the ability to isolate subcellular fractions from virally infected cells has proven to be highly informative. *UNIT 3.27* provides procedures for isolating mitochondria, endoplasmic reticulum, and mitochondria-associated membranes from primary fibroblasts and HeLa cells infected with HCMV. The unit also includes a protocol for visualization of the disruption of the mitochondrial network based on subcellular fractionation in Percoll gradients.

Amyloplasts are organelles wherein starch is synthesized and stored in plants. The starch in amyloplasts can subsequently be converted to sugar to meet the energy needs of the plant. Specialized amyloplasts are also thought to participate in gravitropism (sensing of gravity) that determines the growth of root tips. Much less is known about the biochemistry and function of these organelles than other, more studied plastids (e.g., chloroplasts). In *UNIT 3.28*, protocols are provided for the isolation of amyloplasts from maize endosperm and oilseed rape embryos as starting material. These methods could be adapted for other sources.

Microtubules are one of the components of the cytoskeleton. They are dynamic structures undergoing an assembly-disassembly process that contribute to cell motility, movement of organelles within the cell, and segregation of chromosomes into the daughter cells during mitosis. Microtubules are polymers of α-tubulin and β-tubulin with associated proteins (the microtubule-associated proteins or MAPs). The α-β heterodimer is the basic building block of microtubules, and a classical method for the isolation of the soluble heterodimer is provided in *UNIT 3.29*. Also described in this unit are protocols aimed at analysis of tubulin and MAPs. These protocols include the chromatographic and electrophoretic methods that have been traditionally employed, but they also include a new protocol for visualizing microtubules by atomic force microscopy.

Perhaps the best known organelle in plants is the chloroplast, which is responsible not only for energy production via photosynthesis but also for other critical metabolic functions, including synthesis of amino acids, vitamins, and lipids. *UNIT 3.30* provides protocols for the purification of chloroplasts from both *Arabidopsis* and spinach leaves. The purification is accomplished using differential centrifugation followed by Percoll gradient centrifugation and yields intact organelles suitable for additional characterization and experimentation. Whereas chloroplasts have been classically isolated from spinach leaves, the inclusion of an isolation protocol tailored for using *Arabidopsis* leaves as starting material is of significance, owing to the widespread use of this organism in plant genetics and molecular biology.

Melanins are pigmented polymers that occur widely in both plants and animals. Cutaneous melanin is responsible for skin color. Melanin in the brain has been termed neuromelanin and is located in the human midbrain region known as the substantia nigra pars compacta. Indeed the name of this portion of the brain is related to its pigmented nature (from the Latin meaning “black body”). This region of the brain is related to control of movement, and loss of the pigmentation in this region is a feature of Parkinson’s disease. Neuronal neuromelanin granules are distinct from melanosomes (see *UNIT 3.14*), which are located in melanocytes and are thought to be related to lysosomes. The neuromelanin granules exhibit a wider range of size than do melanosomes and have a distinct lipid composition. *UNIT 3.31* describes the isolation of neuromelanin granules with human midbrain as the starting material.

Dense core secretory vesicles (also termed secretory granules) are present in endocrine and neuroendocrine cells where they serve as storage sites for hormones (e.g., insulin), proteases, and signaling molecules. It appears that the intracellular sorting of peptide hormone precursors to the dense core secretory vesicles is an essential step in the bioactivation of these precursors. *UNIT 3.32* details the isolation of dense core vesicles from

pancreatic exocrine cells utilizing differential and density-gradient centrifugation. The unit describes isolation of the vesicles from pancreatic islets, as well as from tissue culture lines and transplantable tumors.

Alzheimer's Disease is characterized by lesions in the brain that contain deposits of amyloid-β protein (plaques) as well as neurofibrillary tangles consisting of abnormally phosphorylated microtubule-associated tau protein. A fuller understanding of these structures will help elucidate the pathology of the disease. *UNIT 3.33* provides protocols for the isolation, biochemical analysis, and characterization of both amyloid plaques and neurofibrilar tangles.

Legionella pneumophila is the bacterial pathogen responsible for the disease known as Legionnaire's disease. The name is based on an outbreak of deadly pneumonia at a convention of the American Legion in Philadelphia in 1976. The previously unknown bacterium was isolated the following year. This organism replicates intracellularly within phagocytes in a unique compartment that is called the *Legionella*-containing vacuole (LCV). It is now appreciated that the LCV is formed by hijacking the host signaling and vesicle trafficking pathways and involves a large number of bacterial effector proteins. The method of isolation of LCVs described in *UNIT 3.34* utilizes immunomagnetic separation using an antibody to one of the bacterial proteins on the surface of the vacuoles, followed by density gradient centrifugation. The unit also provides a means of monitoring the enrichment of the LCVs via fluorescence microscopy.

Immunomagnetic methods are also employed in one of the protocols of *UNIT 3.35* for the isolation of a distinct intracellular structure, the platelet granule. Platelets possess alpha granules that contain several growth factors, as well as dense (delta) granules. An alternative protocol utilizes more traditional differential centrifugation/sedimentation methodology. The degree of purification is monitored via immunoblotting using antibodies that recognize specific granule proteins.

Earlier in this chapter, there is a unit which is focused on isolation of nuclei from rat liver (see *UNIT 3.10*). Within nuclei, the nucleoli are non-membrane-bound structures composed of RNA and protein. These domains within the nucleus are involved in a number of important cellular functions, notably ribosome biogenesis and tRNA maturation. The purification of these relatively large and dense structures from the nuclei of cultured cells is described in *UNIT 3.36*.

Killer lymphocytes have been known for about 50 years, following their discovery in the context of transplant rejection in vivo. Two of the varieties of killer lymphocytes are cytotoxic T cells and natural killer cells. Each of these cell types contains cytotoxic granules, the contents of which are responsible for elimination of target cells. The protocols of *UNIT 3.37* describe purification of such granules utilizing Percoll density gradients following disruption of the killer lymphocytes. The unit also contains protocols for purification via liquid chromatography of key proteins involved in the cytolytic process.

Proteinaceous inclusion bodies formed when the cellular proteosome degradation mechanism is impaired are known as aggresomes. These structures form in the vicinity of the microtubule organizing center and centrosome and appear to be associated with intermediate filaments. The aggresomal response is thought to be a protective mechanism for dealing with abnormally high cytosolic loads of abnormal (e.g., misfolded) or damaged protein. Neuronal cytosolic inclusion bodies seen in Parkinson's disease are thought to be aggresomes. *UNIT 3.38* provides a protocol for isolating aggresomes from a yeast model.

Chromaffin cells are neuroendocrine cells found in the medulla of the adrenal gland. These cells contain secretory vesicles (granules) that contain a complex mixture of catecholamine neurotransmitters, peptide hormones, and a number of enzymes. Understanding of the molecular composition of chromaffin granules continues to evolve. The two protocols of *UNIT 3.39* should further this understanding as relatively large amounts of the granules can be obtained in a relatively short time. One protocol utilizes an iso-osmotic medium and differential centrifugation and yields intact granules. The second is used for isolation of chromaffin granule membranes or contents for further characterization.

CHAPTER 3
Subcellular Fractionation and Isolation of Organelles

INTRODUCTION

In the early 1700s, Leeuwenhoek noted that avian and amphibian blood cells contained a "clear area," almost certainly corresponding to the structure we now know as the nucleus. This represents probably the earliest recognition that eukaryotic cells are not simply sacs of protoplasm, but instead contain subcellular structures. Although the concept of the nucleated cell became firmly established in the 18th and 19th centuries, the real beginning of subcellular fractionation had to await the emergence in the mid-1940s of the art form known as electron microscopy. The electron microscope revealed much more complexity than Leeuwenhoek could have imagined. Concurrent with improvements in the techniques of electron microscopy was the development of methodologies for subcellular fractionation. Through the 1950s, these parallel approaches resulted in the discovery and isolation of the major organelles that comprise the eukaryotic cell. Finally, as biochemical functions were associated with specific subcellular compartments, a much clearer picture of the eukaryotic cell began to emerge, and with it the field of modern cell biology.

Chapter 3 is dedicated to methods for subcellular fractionation. The chapter begins with an overview of cell fractionation (*UNIT 3.1*) which covers some basic principles as well as the instrumentation of centrifugation. The various centrifugation media, ranging from sucrose to the newer media (Ficoll, Percoll, metrizamide, Nycodenz, and Iodixanol), are described.

Much of the earliest work in subcellular fractionation utilized rat liver as starting material. The second unit of Chapter 3 provides protocols for the isolation of plasma membrane sheets and domains from rat liver (*UNIT 3.2*). This method is used to isolate plasma membrane sheets in sufficient yield and purity to be suitable for a variety of analytical and preparative purposes. For example, these preparations can be used as starting material for the isolation of hepatocyte plasma membrane proteins. The sheets also serve as the starting material for the protocols within *UNIT 3.2* that yield the apical and basolateral domains comprising the polarized hepatocyte plasma membrane.

The densities of mitochondria, peroxisomes, and lysosomes are very similar, and as a result, these organelles cosediment in density gradients as the so-called "light mitochondrial fraction." The development of separation media has significantly improved the ability to separate these organelles from each other. *UNITS 3.3-3.6*, deal with separation of these organelles.

UNITS 3.3 & 3.4 describe methods for isolating mitochondria from rat liver as well as other sources including other tissues, cultured mammalian cells, and yeast. *UNIT 3.3* focuses on methods involving differential centrifugation for rapid isolation of metabolically active mitochondria, whereas methods involving density-gradient centrifugation for further purification of mitochondria are described in *UNIT 3.4*.

UNIT 3.5 provides methods for the isolation of peroxisomes from mammalian tissues and cells in tissue culture. Also included in this unit are a method for preparation of

Current Protocols in Cell Biology 3.0.1-3.0.7, June 2010

peroxisomes from yeast and descriptions of assays for assessing the success of subcellular fractionation of the various starting materials.

The yeast *Saccharomyces cerevisiae* contains all the membrane-bound subcellular organelles that are characteristic of higher eukaryotes, yet this organism has a haploid genome that is less than four times the size of that of *E. coli*. The availability of the entire *S. cerevisiae* genome sequence, together with the ease with which yeast are cultured (*UNIT 1.6*) and the simplicity with which genetic manipulations are performed have made this organism a popular model in eukaryotic cell biology. Indeed, it is yeast cell biology that may provide insights into the function of many yeast genes and their mammalian counterparts. While some attention to certain subcellular organelles from yeast is given in earlier units of this chapter, *UNIT 3.7* provides a comprehensive overview of yeast subcellular fractionation.

UNIT 3.8 describes centrifugation-based methods for isolating most of the major organelles of the yeast *Saccharomyces cerevisiae*. Most of these procedures begin with the preparation of spheroplasts as described in the Support Protocol near the beginning of the unit. Lysates for subcellular fractionation can also be generated by glass-bead lysis to disrupt intact yeast cells (also described). Because of the fragility of most yeast organelles, lysates of spheroplasts are best used for most protocols; however, glass-bead lysates can be used for preparation of cytosol and plasma membranes. Several of the protocols are analytical for assessing the distribution of proteins along exocytic, endocytic, and biosynthetic pathways in yeast cells. The unit also includes preparative methods for isolating yeast nuclei, vacuoles, mitochondria, peroxisomes, endoplasmic reticulum, plasma membranes, and cytosol.

The Golgi, an organelle named for the pioneering cell biologist, Camillo Golgi, was identified on the basis of a then current protocol developed by Golgi for fixing and staining tissues. Although observations of what he then referred to as the "internal reticular apparatus" probably date even earlier in the 19th century, the Golgi remains an intracellular site of intense investigation by today's cell biologists. *UNIT 3.9* describes the isolation of Golgi membranes on a preparative basis. Individual protocols describe isolation of dextrose-treated Golgi stacks from rat liver using a sucrose density barrier and by flotation from a light mitochondrial fraction. Isolation from cultured cells is also described, as is a method to assay for the Golgi marker enzyme, UDP-galactose galactosyl transferase.

UNIT 3.10 focuses on the "clear area" of Leeuwenhoek—the nucleus. As noted above, rat liver has been the most frequently used source of material for subcellular fractionation. This unit contains two protocols for isolation of nuclei from rat liver. The first utilizes a sucrose density barrier, whereas the second employs Nycodenz as a density medium. Although the vast majority of methods for preparing nuclei use soft tissue (e.g., liver), the protocols described in this unit can be applied to other source materials (e.g., cultured cells, plants), provided appropriate homogenization can be achieved. *UNIT 3.10* also contains two protocols for purification of nuclear membranes from isolated nuclei and Support Protocols describing methods for assaying DNA and RNA.

Free-flow electrophoresis (*UNIT 3.11*) provides opportunities for both analytical and preparative applications for isolating subcellular organelles such as rat endosomes. Endosome-enriched fractions are prepared from rat liver using discontinuous sucrose gradients, and these are used to prepare endosomal subpopulations by free-flow electrophoresis. The analytical approach can be used to study the kinetics and cellular subpopulations involved in endocytic traffic. Three distinct subpopulations of endosomes are revealed in such studies. Support Protocols include methods for analyzing markers for endosomal subpopulations and for demonstrating retention of endosomal function (acidification)

in vitro. Methods are also included for preparing and labeling ligands that traffic through endosomes.

UNIT 3.12 describes protocols for the isolation of synaptic vesicles—small, electron-lucent organelles contained within presynaptic nerve terminals. Synaptic vesicles function to store neurotransmitters and to release them into the synaptic cleft upon stimulation. Methods for the purification of synaptic vesicles take advantage of the vesicle's small size and low density. The first two protocols describe the use of differential centrifugation to enrich synaptic vesicles 8- to 10-fold relative to brain homogenate. The next three protocols allow further purification to ~20-fold using sedimentation velocity or chromatography on controlled-pore glass beads or Sephacryl S-1000. This unit ends with protocols for the sedimentation of synaptic vesicles at high speed, immunoisolation of synaptic vesicle subpopulations, and siliconization of tubes.

Transport of proteins, lipids, and other "cargo" molecules between different compartments of the secretory, endocytic and lysosomal targeting pathways is mediated by membrane-enclosed carriers. The best characterized of these carriers are clathrin-coated vesicles (CCVs), which play critical roles in endocytosis from the plasma membrane and sorting from the trans-Golgi network and endosomes. CCVs are small (50 to 100 nm in diameter) and are encased within a dense proteinaceous coat—properties that are the bases for their isolation by ultracentrifugation procedures. *UNIT 3.13* presents a series of protocols for the isolation of coated vesicles from different sources, including adult and developing rat brain, adult rat liver, and cultured cell lines. In addition, this unit contains a procedure for analyzing the purity of isolated CCVs by electron microscopy. The Commentary section shows representative electron micrographs of these preparations, as well as SDS-PAGE analyses of the protein composition of the purified CCVs.

UNIT 3.14 deals with melanosomes, which are membrane-bound organelles filled with the pigment melanin. These organelles are only found in specialized cell types such as melanocytes and retinal epithelial cells, and they function to protect cells and tissues from the harmful effects of ultraviolet radiation. Oncogenic transformation of melanocyte precursors results in melanomas, which are particularly aggressive cancers. This unit presents protocols for the isolation of melanosomes from melanoma cells and tissues. The biogenesis of melanosomes involves maturation of precursors through a series of well-defined stages; the protocols in this unit allow for the separation of early and late stage melanosomes by ultracentrifugation and free-flow electrophoresis. This unit also describes a method for monitoring the purification of melanosomes by measuring the activity of the melanosomal enzyme, tyrosinase. Finally, the unit lists antibody reagents to melanosomal proteins that can be used to monitor purification and assess the purity of the isolated melanosomes.

Most cells in culture contain discernable lipid droplets, although the size and number of these droplets vary depending on cell type and culture conditions. Lipid droplets can provide a source of metabolic energy and also play a role in cholesterol homeostasis required for membrane biogenesis. In steroidogenic cells, the lipid droplets provide substrates for hormone synthesis. *UNIT 3.15* describes the isolation of lipid droplets based on their high buoyancy, which is reflective of their low mass of protein and high relative mass of neutral lipids. At present, no specific enzyme markers have been localized exclusively to lipid droplets. The droplets do, however, contain certain characteristic structural proteins, and protocols for immunoblotting of these proteins are included for assessment of the isolated lipid droplets.

UNIT 3.16 describes the isolation of rat serosal mast cells by peritoneal lavage and the use of these cells as a source of mast cell granules. These granules are modified lysosomes that release their contents upon degranulation of the activated mast cells. Protocols

are provided for the isolation of mast cell granules enveloped in their perigranular membrane and of granule remnants released upon degranulation. Several protocols aimed at assessing mast cell activation are included, as is a protocol for verification of granule remnant morphology and purity via electron microscopy. A future unit in Chapter 3 will deal with the isolation of the analogous organelle from chromaffin cells (i.e., chromaffin granules).

All previous units in this chapter that deal with organelle isolation have described isolation of organelles that exist in multiple copies per cell. In contrast, *UNIT 3.17* provides protocols related to the isolation of centrosomes, of which there is only one per cell. As starting material for this challenging task, the protocols utilize early (0- to 3.5-hr) *Drosophila* embryos. Centrosomes are isolated by a protocol involving gradient centrifugation and a protocol for further enrichment via immunomagnetic purification. Protocols for assessing the centrosome preparation by immunofluorescence microscopy are included.

In contrast to the situation with the centrosome (one copy per cell), pancreatic zymogen granules have been estimated to constitute as much as 25% of the total cellular volume based on electron microscopy. The relative abundance of these organelles resulted in their being among the first to be the subject of cellular subfractionation protocols, dating to the mid-1950's. *UNIT 3.18* provides more modern protocols for the purification of these important cellular bodies from both rat and dog pancreas, using both sucrose and Percoll gradients. The pancreas contains other secretory granules in lower abundance, most notably the endocrine granules responsible for insulin release. A future unit of this chapter will provide protocols related to isolation of the insulin granules of the pancreas.

An early unit in this chapter (*UNIT 3.5*) deals with the organelles known as peroxisomes. Glyoxysomes represent a specialized form of the peroxisome found in the cotyledons of seedling plants. In this context, these organelles sequester the enzymes of the glyoxylate cycle that provides energy to the rapidly growing seedling. Later in plant development, the peroxisomes of the green leaves have a distinct complement of enzymes reflecting their role in photorespiration. *UNIT 3.19* provides protocols for growing pumpkin seedlings and for isolation of glyoxysomes from their cotyledons via density gradient centrifugation.

The glucose transporter isoform known as GLUT4 functions to facilitate uptake of glucose by both fat and muscle tisssues. GLUT4 is translocated in response to insulin from an intracellular compartment to the plasma membrane as the mechanism for insulin-mediated enhancement of glucose transport. The investigation of trafficking of GLUT4 has gained considerable attention since the discovery that GLUT4 translocation is compromised in type 2 diabetes. *UNIT 3.20* provides protocols for isolation of GLUT4 storage vesicles from primary rat adipocytes, cultured adipocytes, and skeletal muscle.

Another type of membrane vesicle is the subject of *UNIT 3.21*, which describes isolation of vesicles from intestinal brush border from three species (rat, pig, and cow). These vesicles are derived from the apical surface of the polarized epithelial cells of the small intestine, which also contain integral membrane proteins involved in glucose uptake. Whereas the GLUT4 vesicles of *UNIT 3.20* are part of a regulated trafficking of cellular membranes, those of *UNIT 3.21* represent spontaneous sealing of membrane fragments derived from the intestinal microvilli upon disruption of the tissue architecture. These vesicles can nonetheless be utilized for membrane transport studies.

The theme of isolation of membrane-derived vesicles continues in *UNIT 3.22*, which provides several protocols related to exosomes. These vesicles are derived from the plasma membrane via an endocytosis-exocytosis mechanism, but they are isolated from extracellular fluids (either tissue culture media or bodily fluids). Methods are provided whereby exosomes are isolated by either ultracentrifugation, ultrafiltration, or immunoisolation.

The protocols of *UNIT 3.22* should prove useful in studies aimed at understanding exosome function and the possible use of exosomes in therapeutic applications e.g., as immunogens in vaccines.

UNIT 3.23 describes the isolation of intermediate filaments from bovine spinal cord. Although intermediate filaments from different sources contain a diverse complement of intermediate filament proteins, all intermediate filaments share the property of being insoluble in conventional extraction buffers. It is this property that serves as the basis of the isolation protocol. Intermediate filaments can also be produced after assembly of a recombinant intermediate filament protein, and an Alternate Protocol describes this method. With intermediate filaments isolated from either tissue or assembled recombinant protein, it is possible to study the assembly process in vitro and to investigate, in vitro, possible interaction partners that participate in intermediate filament–mediated processes in vivo.

Skeletal and cardiac muscle cells contain an unusual system of tubular invaginations of their sarcolemma known as the transverse tubule (T-tubule), which are critical participants in the process of muscle contraction. *UNIT 3.24* provides a Basic Protocol that enables the isolation of highly purified T-tubules from muscle tissue using density gradient ultracentrifugation. A second, related Basic Protocol takes advantage of the glycoproteins in the membranes to separate sarcolemma membrane vesicles from T-tubule vesicles via aggregation of the former by wheat germ agglutinin. An Alternate Protocol involves immunoisolation T-tubule vesicles utilizing antibodies that recognize the intracellular domain of T-tubule integral membrane proteins (e.g., GLUT4).

Another very specialized membrane is the myelin sheath that surrounds vertebrate axons in both the central and peripheral nervous system. CNS myelin is elaborated as a plasma membrane extension by oligodendroglial cells of the brain and spinal cord, whereas PNS myelin is generated by Schwann cells. Methods for isolating myelin go back over three decades, and the methods of *UNIT 3.25* are in fact based on the classical isolation method of Norton and Podusulo published in 1973. The methods here are modified to minimize proteolysis and contamination with the axon plasma membrane. Although the protocols are related, separate protocols are provided for isolation of myelin from the CNS and from the PNS, reflecting the morphological and biochemical distinction in the two forms of myelin. In both cases, the relatively low density of myelin-derived membrane vesicles allows for a high degree of purification. A support protocol for assay of a marker enzyme is also included.

Brush borders also represent a specialization of the cell surface. In this case, rather than wrapping around axons in a spiral fashion as does myelin, the brush border is characterized by characteristic folds of the plasma membrane to form finger-like projections termed microvilli. These structures markedly increase the surface area of the membrane, which enables enhancement of absorption of substances. *UNIT 3.26* provides protocols for the isolation of brush borders from the kidney where the brush border structure participates in glomular filtration. The microvilli that make up the renal brush border are closely associated with actin filaments, explaining why brush borders have been utilized as a source of actin-binding proteins. It also accounts for the fact that brush borders are relatively resistant to homogenization, and this feature is exploited in the isolation protocols. Isolated brush borders can be further studied and purity/integrity assessed by flow cytometry, marker enzymes, and/or electron microscopy.

The boundary between the fields of virology and cell biology has always been blurry due to the fact that viruses infect cells. The cellular pathways of protein trafficking are among those that are "hijacked" by many viruses. Indeed, the trafficking of viral proteins has been instrumental in understanding these pathways. To localize and examine the

trafficking of the proteins of human cytomegalovirus (HCMV), the ability to isolate subcellular fractions from virally infected cells has proven to be highly informative. *UNIT 3.27* provides procedures for isolating mitochondria, endoplasmic reticulum, and mitochondria-associated membranes from primary fibroblasts and HeLa cells infected with HCMV. The unit also includes a protocol for visualization of the disruption of the mitochondrial network based on subcellular fractionation in Percoll gradients.

Amyloplasts are organelles wherein starch is synthesized and stored in plants. The starch in amyloplasts can subsequently be converted to sugar to meet the energy needs of the plant. Specialized amyloplasts are also thought to participate in gravitropism (sensing of gravity) that determines the growth of root tips. Much less is known about the biochemistry and function of these organelles than other, more studied plastids (e.g., chloroplasts). In *UNIT 3.28*, protocols are provided for the isolation of amyloplasts from maize endosperm and oilseed rape embryos as starting material. These methods could be adapted for other sources.

Microtubules are one of the components of the cytoskeleton. They are dynamic structures undergoing an assembly-disassembly process that contribute to cell motility, movement of organelles within the cell, and segregation of chromosomes into the daughter cells during mitosis. Microtubules are polymers of α-tubulin and β-tubulin with associated proteins (the microtubule-associated proteins or MAPs). The α-β heterodimer is the basic building block of microtubules, and a classical method for the isolation of the soluble heterodimer is provided in *UNIT 3.29*. Also described in this unit are protocols aimed at analysis of tubulin and MAPs. These protocols include the chromatographic and electrophoretic methods that have been traditionally employed, but they also include a new protocol for visualizing microtubules by atomic force microscopy.

Perhaps the best known organelle in plants is the chloroplast, which is responsible not only for energy production via photosynthesis but also for other critical metabolic functions, including synthesis of amino acids, vitamins, and lipids. *UNIT 3.30* provides protocols for the purification of chloroplasts from both *Arabidopsis* and spinach leaves. The purification is accomplished using differential centrifugation followed by Percoll gradient centrifugation and yields intact organelles suitable for additional characterization and experimentation. Whereas chloroplasts have been classically isolated from spinach leaves, the inclusion of an isolation protocol tailored for using *Arabidopsis* leaves as starting material is of significance, owing to the widespread use of this organism in plant genetics and molecular biology.

Melanins are pigmented polymers that occur widely in both plants and animals. Cutaneous melanin is responsible for skin color. Melanin in the brain has been termed neuromelanin and is located in the human midbrain region known as the substantia nigra pars compacta. Indeed the name of this portion of the brain is related to its pigmented nature (from the Latin meaning “black body”). This region of the brain is related to control of movement, and loss of the pigmentation in this region is a feature of Parkinson’s disease. Neuronal neuromelanin granules are distinct from melanosomes (see *UNIT 3.14*), which are located in melanocytes and are thought to be related to lysosomes. The neuromelanin granules exhibit a wider range of size than do melanosomes and have a distinct lipid composition. *UNIT 3.31* describes the isolation of neuromelanin granules with human midbrain as the starting material.

Dense core secretory vesicles (also termed secretory granules) are present in endocrine and neuroendocrine cells where they serve as storage sites for hormones (e.g., insulin), proteases, and signaling molecules. It appears that the intracellular sorting of peptide hormone precursors to the dense core secretory vesicles is an essential step in the bioactivation of these precursors. *UNIT 3.32* details the isolation of dense core vesicles from

pancreatic exocrine cells utilizing differential and density-gradient centrifugation. The unit describes isolation of the vesicles from pancreatic islets, as well as from tissue culture lines and transplantable tumors.

Alzheimer's Disease is characterized by lesions in the brain that contain deposits of amyloid-β protein (plaques) as well as neurofibrillary tangles consisting of abnormally phosphorylated microtubule-associated tau protein. A fuller understanding of these structures will help elucidate the pathology of the disease. *UNIT 3.33* provides protocols for the isolation, biochemical analysis, and characterization of both amyloid plaques and neurofibrilar tangles.

Legionella pneumophila is the bacterial pathogen responsible for the disease known as Legionnaire's disease. The name is based on an outbreak of deadly pneumonia at a convention of the American Legion in Philadelphia in 1976. The previously unknown bacterium was isolated the following year. This organism replicates intracellularly within phagocytes in a unique compartment that is called the *Legionella*-containing vacuole (LCV). It is now appreciated that the LCV is formed by hijacking the host signaling and vesicle trafficking pathways and involves a large number of bacterial effector proteins. The method of isolation of LCVs described in *UNIT 3.34* utilizes immunomagnetic separation using an antibody to one of the bacterial proteins on the surface of the vacuoles, followed by density gradient centrifugation. The unit also provides a means of monitoring the enrichment of the LCVs via fluorescence microscopy.

Immunomagnetic methods are also employed in one of the protocols of *UNIT 3.35* for the isolation of a distinct intracellular structure, the platelet granule. Platelets possess alpha granules that contain several growth factors, as well as dense (delta) granules. An alternative protocol utilizes more traditional differential centrifugation/sedimentation methodology. The degree of purification is monitored via immunoblotting using antibodies that recognize specific granule proteins.

Earlier in this chapter, there is a unit which is focused on isolation of nuclei from rat liver (see *UNIT 3.10*). Within nuclei, the nucleoli are non-membrane-bound structures composed of RNA and protein. These domains within the nucleus are involved in a number of important cellular functions, notably ribosome biogenesis and tRNA maturation. The purification of these relatively large and dense structures from the nuclei of cultured cells is described in *UNIT 3.36*.

Killer lymphocytes have been known for about 50 years, following their discovery in the context of transplant rejection in vivo. Two of the varieties of killer lymphocytes are cytotoxic T cells and natural killer cells. Each of these cell types contains cytotoxic granules, the contents of which are responsible for elimination of target cells. The protocols of *UNIT 3.37* describe purification of such granules utilizing Percoll density gradients following disruption of the killer lymphocytes. The unit also contains protocols for purification via liquid chromatography of key proteins involved in the cytolytic process.

Juan S. Bonifacino

Overview of Cell Fractionation

Cell fractionation has enjoyed widespread use among cell biologists for half a century. It continues to be a fruitful, if not essential, approach in the reductionistic efforts to define the composition and functions of the multiple compartments in eukaryotic cells. It also provides the essential ingredients for the increasing number of cell-free assays now being used in test-tube reconstructions of complex cellular events involving intercompartmental interactions. Much of the knowledge regarding the composition and function of cell organelles has resulted from fractionation of mammalian tissues, where cells are both abundant and highly differentiated (and thus organelle-rich). However, with new techniques in molecular biology and widened interest in combining studies of intact cells and functional reconstitution, interest in fractionation has spread to cultured cell lines and genetically tractable lower eukaryotic cells.

The goals of cell fractionation often differ depending on the nature of the experiments being conducted. In preparative procedures, in which the intent is to isolate quantities of a particular cell organelle for further study or for subfractionation, the emphasis is on purity and (secondarily) on yield. In analytical experiments, in which the intent is not isolation of organelles but evaluation of associations of selected macromolecules with particular organelles, the emphasis is on using one-step procedures that result in different distributions of various organelles (as defined by marker activities) rather than on separating organelles outright. Finally, in preparing organelles for cell-free reconstitution, the goal is to maintain them in a functional state. The investigator generally has developed a specific assay for intercompartmental interaction that does not rely on organelle purity, so the extent of contamination by irrelevant organelles is less important.

The separation of distinct organelles during cell fractionation results from their differing physical properties—size (and shape), buoyant density, and surface charge density—which reflect their differing compositions. Particular fractionation techniques capitalize on one or more of these properties. For example, gel filtration separates on the basis of size, centrifugation separates on the basis of size and density, and electrophoresis separates on the basis of surface charge density. As knowledge of the specific composition of particular organelles has developed, it has become possible to apply newer techniques such as affinity chromatography and selective density-shift perturbation. Whichever fractionation method is used, the procedures may have to be modified to adapt them to individual needs. Even isolation of a particular kind of organelle from different tissue or cell sources may necessitate adjustment of fractionation conditions. This also means that in addition to isolating the organelle of interest, one should also plan on confirming the identity of what has been isolated.

Centrifugation is the most widely used procedure in cell fractionation. It is the only approach commonly used to separate crude tissue homogenates (often having quite large volumes) into subfractions as starting material for more refined purification procedures. Further, the technology available, using rotors with a variety of geometries and diverse media that enable separation according to size, density, or both, now routinely permits refined separations on volumes ranging from submilliliter to several liters. No other technology is this versatile. Gel filtration is limited by the pore sizes of available resins, such that only regularly shaped vesicles with diameters <100 to 200 nm can be purified away from larger or irregularly shaped organelles. Use of electrophoresis for organelle purification, especially at the preparative level, is relatively recent, and, as with gel filtration, its success relies on generating starting material by centrifugation. Although it shows promise for purifying selected organelles (e.g., endosomes) that have been difficult to obtain otherwise, surface charge densities on most organelles may not be different enough (or able to be manipulated sufficiently) to make this a versatile procedure. For these reasons, the remaining comments in this overview focus primarily on fractionation of organelles by centrifugation. For more detailed coverage of each of the topics, the reader is referred to the excellent book edited by Rickwood (1984).

BASIC PRINCIPLES OF CENTRIFUGATION

One of the best ways to understand the rationale for various cell fractionation proce-

Current Protocols in Cell Biology (1998) 3.1.1-3.1.9

dures is to examine the Svedberg equation, which describes mathematically the sedimentation of a spherical particle in a viscous fluid:

$$\frac{dx/dt}{\omega^2 x} = \frac{2r^2 (\rho_p - \rho_m)}{9\eta}$$

where x is the distance from axis of rotation, t is time, ω is the angular velocity, r is the radius of the particle, ρ_p and ρ_m are the densities of the particle and medium, and η is the viscosity of the medium.

This equation states that the sedimentation velocity, dx/dt, per unit centrifugal field $\omega^2 x$ (which is set by the instrumentation) increases with the square of the particle radius and the difference in density between the particle and the medium, and decreases with increasing viscosity. In practical terms, when sedimentation is performed by differential velocity in a medium such as 0.25 M sucrose, which is less dense than all particles and has a low viscosity, the radius of the particle is the dominant factor that determines the sedimentation rate. In contrast, when isopycnic density gradient centrifugation is used, the density of the medium changes from top to bottom in the centrifugation tube, and the range of densities typically includes the buoyant densities of most particles (vesicles). Thus individual types of vesicles will sediment until $\rho_p = \rho_m$, and the vesicles will then stop at their isopycnic densities. Alternatively, in flotation procedures $\rho_p < \rho_m$ initially and dx/dt is negative, meaning that particles will move toward the axis of rotation (i.e., toward the top of the tube). Clearly, the equation also indicates that sedimentation or flotation, as the case may be, is slowed in media of higher viscosity. As discussed below, various media used in centrifugation are distinguished by their viscosities (and osmolarities) at high densities.

The Svedberg equation can also be used to discuss three other basic relationships encountered in using centrifugation. First, the velocity of a particle per unit centrifugal field (left side of the equation) is the sedimentation coefficient. Its dimensions are in seconds, and it is generally reported in units known as Svedbergs (S). 1 S = 10^{-13} sec, the same order of magnitude as the sedimentation coefficient of several biological macromolecules (e.g., 5S RNA). Second, the centrifugal field, $\omega^2 x$ is usually normalized to gravity and is expressed in the literature as a relative centrifugal force (RCF = $\omega^2 x/g$). Centrifugation conditions are best reported as $\times g$. RCF is usually expressed at the midpoint of the tube (g_{av}). The centrifugal field term includes the angular velocity in units of radians per second, which is easily converted to revolutions per minute (rpm), the unit most often given in the literature, as follows: RCF = 11.18 $r(N/1000)^2$, where N is rpm. Third, integration of the Svedberg equation over time yields the following relationship:

$$t = \frac{1}{s\omega^2} \ln\left(\frac{X_{max}}{X_{min}}\right) = \frac{k}{s}$$

$$\text{where} \quad k = \frac{1}{\omega^2} \ln\left(\frac{X_{max}}{X_{min}}\right)$$

This is a measure of the clearance time, the time required for a particle of given sedimentation coefficient to travel from the top to the bottom of the tube. Included in k are the geometry of the rotor (X_{max} and X_{min}) and the angular velocity. k-factors are reported in the printed information that accompanies most rotors. They are useful for estimating the length of centrifugation required to pellet a particular particle and for translating centrifugation conditions between two rotors. For a given particle or vesicle, k/t (rotor 1) = k/t(rotor 2).

INSTRUMENTATION

Several pieces of equipment must be available to carry out cell fractionation by centrifugation. These include homogenizers, centrifuges (generally one low-speed and one ultracentrifuge) with compatible rotors, a refractometer for measuring the refractive index of centrifugation media (before centrifugation) and gradient fractions (after centrifugation), a gradient-forming device for generating preformed density gradients, and a gradient-collecting device for unloading the gradients after the run. The refractometer, gradient-forming device, and gradient-collection device are very useful, if not essential, for density gradient and rate zonal sedimentation.

Centrifuges. Most organelle purification procedures require that samples be maintained at ≤4°C, so the centrifuges used need to be refrigerated. The low-speed centrifuge is used in the early steps of the typical purification procedure for sedimenting large particulates such as nuclei and unbroken cells, frequently from large volumes. The ultracentrifuge is used for subsequent spins at higher speeds and often with smaller volumes. These instruments have a vacuum system as the rotors are spun in an evacuated chamber to reduce friction (and thus heating).

Rotors. Commonly used rotors come in three configurations: fixed-angle, vertical (or near-vertical), and swinging-bucket (Fig. 3.1.1). Continuous-flow and zonal rotors, which are loaded and unloaded during the run, are less widely used. Fixed-angle rotors emphasize speed and capacity. Many of these rotors generate RCFs in excess of $600{,}000 \times g$, meaning low *k*-factors, and can handle a few hundred milliliters of solution at one time. As a result, they are used frequently for pelleting fractions, particularly from large volumes. Most fixed-angle rotors hold tubes in a fixed incline substantially away from the vertical. When the

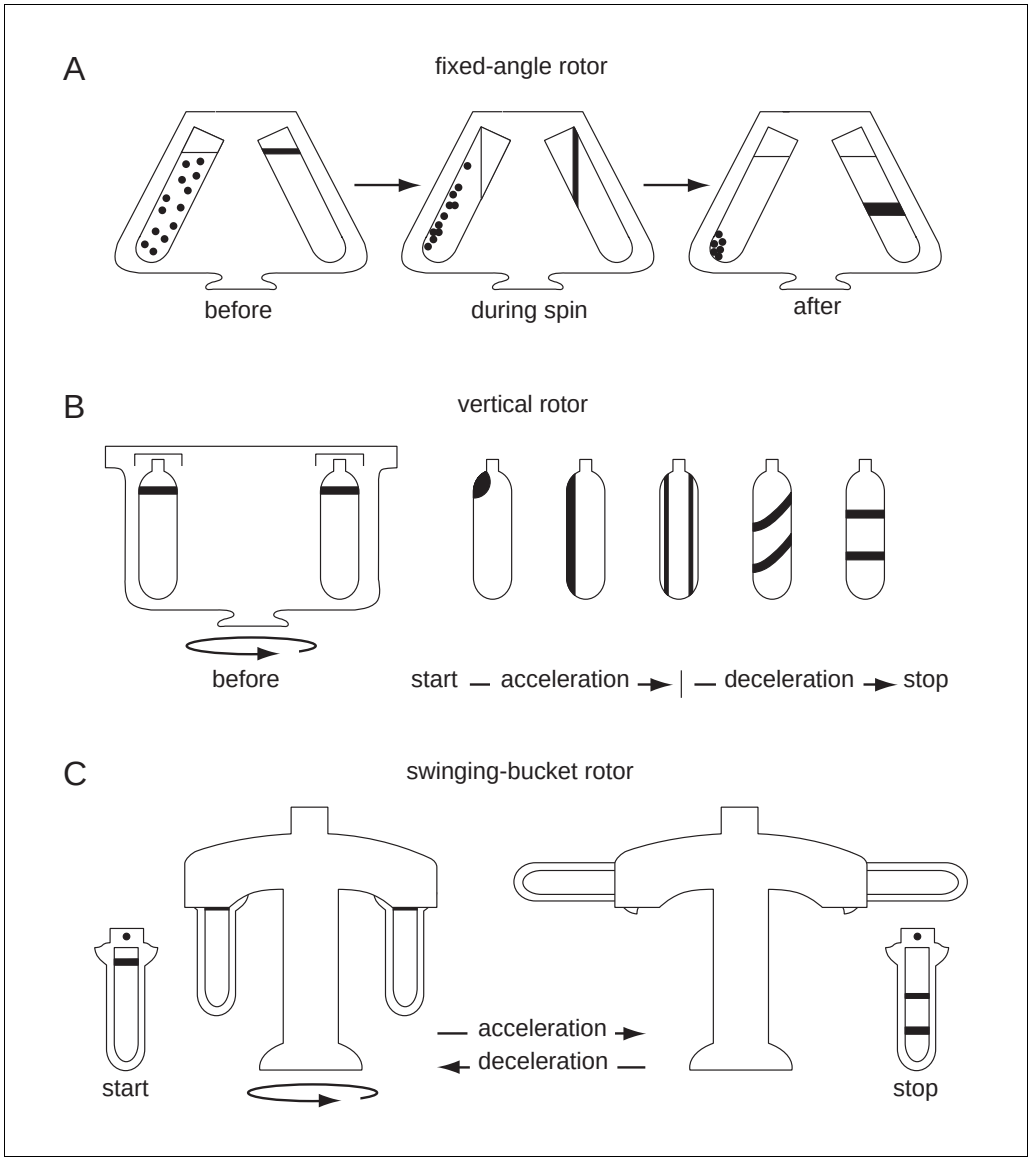

Figure 3.1.1 Rotors used in ultracentrifuges. (**A**) Fixed-angle rotor. In each profile, the tube on the left shows pelleting from a uniform suspension and the tube on the right shows sedimentation of a band layered at the top above a higher-density fluid. Sedimentation is radial (particles move toward the outer wall of the tube and then down this wall to the pellet). Note how the band in the right tube reorients during the spin and then again at the end of the run. (**B**) Vertical rotor. The rotor profile shows tubes with sample layered above a higher-density solution before a run. Note that during the run (successive tube profiles shown at right), the layer reorients along the inner wall of the tube and then the bands resolve vertically. During deceleration the bands reorient to a horizontal position. (**C**) Swinging-bucket rotor. Note the tube on the left in the upper profile has a sample layered at the top. The buckets are mounted vertically on the rotor. During the run, the buckets reorient to the horizontal position, and the bands separate along the length of the tube. Because sedimentation is radial, the particulates in the bands are more concentrated at the walls facing and away from the viewer than in the center of the tube. Toward the end of deceleration, the buckets reorient to the vertical position.

Table 3.1.1 Density and Refractive Index of Aqueous Sucrose Solutions at 20°C[a]

Percent (w/w)	Molarity	Density	Refractive index	Percent (w/w)	Molarity	Density	Refractive index

centrifugal force is applied, it is radial rather than along the length of the tube. Thus the path length is across the tilted tube and is reasonably short; particles travel outward until they hit the outer wall and then "slide" down the wall to form a pellet (see Fig. 3.1.1). In vertical rotors, the path is only the width of the tube. As is evident from the figure, in both fixed-angle and vertical rotors the solution in the tubes reorients from the horizontal to the vertical during acceleration and reverses during deceleration. These rotors can be advantageous for density gradients because equilibrium is reached quite rapidly with the short path, and the separation of bands of different density increases as the contents of the tube reorient during deceleration. With swinging-bucket rotors, the tube and its contents reorient from vertical to horizontal during acceleration and reverse during the end of deceleration. The centrifugal force in this case is along the length of the tube. Note, however, that because the force is directed radially, sedimenting particles tend to concentrate peripherally near the tube walls. Also, the long path length and the generally lower centrifugal forces required for these rotors mean that *k*-factors are usually much higher than with fixed-angle rotors. Thus these rotors have been used more for density gradient and rate zonal centrifugations and less for pelleting fractions.

Refractometers. A refractometer measures refractive indices of solutions used for organelle separations. Refractive index is linearly related to density, and tables relating these two parameters over a large range of concentrations have been prepared for sucrose (Table 3.1.1) and can readily be constructed for other gradient media by weighing aliquots of accurately prepared solutions of different concentrations. The measurement of refractive index/density is particularly useful for characterizing the position of organelles in gradients after centrifugation and for ensuring reproducibility of gradients from one experiment to another.

Gradient-forming devices. These devices consist of two chambers with an interconnecting channel along the bottom and an outlet from one chamber that connects to a peristaltic pump on its way to the centrifuge tube (see Fig. 3.1.2). The channel is gated by a stopcock. For linear gradients (the type most frequently used), the chambers have the same cross-sectional area. Solutions representing the extremes in density of the desired gradient are each placed in one chamber, and a stirring device is placed in the chamber with the outlet going to the tube. As

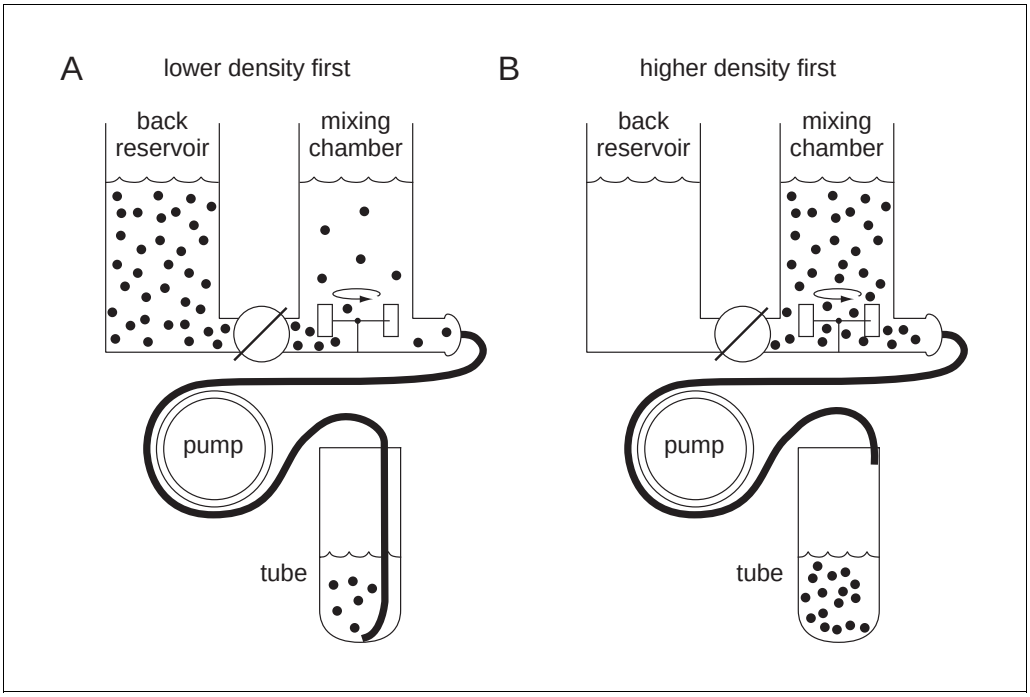

Figure 3.1.2 Linear gradient-forming device showing the back reservoir connected to the mixing chamber via a channel with a stopcock. A delivery tube leads from the mixing chamber to a peristaltic pump and then to the centrifuge tube. (**A**) Configuration used when the lower-density solution is delivered first; the lower-density solution is in the mixing chamber and the outlet is at the bottom of the centrifuge tube. (**B**) Configuration used when the higher-density solution is delivered first; the higher-density solution is in the mixing chamber and the outlet tube is always above the surface of the liquid entering the tube.

fluid is pumped out of the mixing chamber, fluid also flows through the connecting channel from the reservoir to maintain the same pressure head in the two chambers. Consequently, the density of the solution in the mixing chamber changes progressively. Gradients can be generated either highest density first, if the higher-density solution is placed in the mixing chamber, or lowest density first, if the lower-density solution is placed in the mixing chamber. Note that for highest density first, the delivery point must be located above the level of the solution filling the centrifuge tube, whereas for lowest density first, the delivery point must be at the bottom of the tube.

Gradient-collection devices. Gradient collection at the end of centrifugation requires a systematic and reproducible means of emptying the tube. Gradients can be collected from the top or from the bottom. With care, a pipettor (e.g., Pipetman, Rainin) of suitable volume can be used for manual collection from the top, taking care to withdraw equal-volume fractions from just below the meniscus. Alternatively, Buchler markets a pumping device (Autodensiflow) that continually adjusts to the height of the meniscus and withdraws gradients from the top, and both MSE Scientific and Nyegaard market devices that pump high-density solution beneath the gradient and progressively displace the gradient, which is again collected at the top. For collection from the bottom, the centrifuge tube is punctured with a needle and the gradient is collected dropwise.

FRACTIONATION MEDIA

Early in the development of centrifugation as a tool for purification of cellular organelles, it was established that nonelectrolyte-based media are preferable to electrolyte-based media for reducing organelle aggregation (Hogeboom et al., 1948). Most media used today are nonelectrolyte-based, although some do have a substantial electrolyte content (e.g., STKM medium, which contains 50 mM Tris·Cl, 25 mM KCl, and 5 mM $MgCl_2$ in addition to 0.25 M sucrose; Adelman et al., 1973). Moreover, media are generally isoosmotic or hyperosmotic as compared to 0.15 M NaCl. Organelles are osmometers, with water moving across their limiting membranes to maintain osmotic equilibrium; thus lysis can occur in hypoosmotic media.

The nonelectrolyte solute most commonly used in subcellular fractionation is sucrose. High-quality sucrose (free of RNase) is reasonably inexpensive, very soluble, and can be used readily to prepare solutions that span the range of densities of most biological organelles (Table 3.1.1). In addition, procedures have been developed for purifying most biological organelles in sucrose. Sucrose, however, has limitations; at higher concentrations solutions are quite viscous and hyperosmotic. Isoosmotic sucrose (0.25 M; ~9% w/v) has a density of only 1.03 g/ml, which is at the lower-density end for biological organelles. Thus all isopycnic density gradient centrifugation performed in sucrose constitutes hyperosmotic conditions; intraorganellar water redistributes to the surrounding medium, and the organelles shrink and increase in density. These changes are reversible for some, but not all, organelles.

Various sugar alcohols have been used in place of sucrose in some procedures. Glycerol is one, but although its viscosity is lower than that of sucrose, so is its density at a given concentration, and it also permeates some organelles. Mannitol has been used in a few procedures where the use of sucrose is not feasible—e.g., for isolation of epithelial brush border membranes that contain sucrase (Malathi et al., 1979)—and sorbitol has been a favorite for fractionating yeast, which secrete invertase (a form of sucrase; e.g., Walworth and Novick, 1987).

Polysaccharides have also been employed as substitutes for sucrose. Ficoll 400 (Pharmacia Biotech), a chemical polymer of sucrose with epichlorohydrin that has an average molecular weight of 400,000, has been a popular choice (a 70,000-MW form is also available, as Ficoll 70). At low concentrations, it has very low osmolarity, but as can be seen in Figure 3.1.3, the osmolarity rises sharply above 30% (w/v; density ~1.09 g/ml), and it is quite viscous at all concentrations above 10% (w/v). Ficoll has been used widely for separating different cell populations and is frequently most useful as an additive to media containing other density-modifying agents.

Iodinated nonelectrolytes increase the density of fractionation media through most of the range of biological organelles while maintaining reasonably low viscosity and osmolarity as compared to sucrose. Three popular and closely related compounds are metrizamide, Nycodenz, and iodixanol (OptiPrep; marketed by Nyegaard; Accurate Chemical—listed in the *SUPPLIERS APPENDIX*—is the U.S. outlet). As seen from Figure 3.1.3, 40% (w/v) solutions of both metrizamide and Nycodenz have a density >1.2 g/ml (above that of most organelles) and an osmolarity ≤400 mOsm with reasonable viscosity. 60% iodixanol has a density of 1.32 g/ml and an osmolarity of 260 mOsm with only moderate viscosity, making this medium especially useful for density gradient fractionation under isoosmotic conditions. With all these advantageous features, why aren't they used more? They are rather expensive, which certainly limits their use for large-scale work. In addition, they absorb in the UV and have been reported to inhibit selected enzyme activities.

A different alternative for achieving high densities at low viscosity and osmolarity involves the use of Percoll, colloidal silica coated with polyvinylpyrrolidone to reduce its adsorption to biological organelles. For fractionation of cellular organelles, Percoll is almost always used in combination with isoosmotic sucrose, because pure Percoll is only 10 mOsm. As can be seen from Figure 3.1.3, Percoll-containing media can achieve very high densities with reasonably low viscosities. Because Percoll particles have a significant size (range 30 to 150 Å) and density, they sediment during centrifugation. Thus, concentration gradients self-form fairly rapidly during a spin and the profile of density along the length of the tube continuously changes with time. The shallow gradients achieved with Percoll can be very advantageous in separating organelles whose densities differ only slightly; however, for reproducibility, the centrifugation conditions must be quite carefully set. Percoll also has its limitations: it absorbs in the UV, interferes with protein assays, precipitates in acid and organic solvents—do *not* attempt to precipitate Percoll-containing fractions with trichloroacetic acid (TCA) or acetone—is difficult to get rid of entirely.

EVALUATION OF FRACTIONATION

In setting up a procedure for separating or purifying cellular organelles, it is advisable to evaluate the steps of the protocol to confirm that the outcome is as desired and as stated. This means setting up assays for marker activities and protein and accounting for the totality of both throughout the procedure. This meticulousness enables the investigator to evaluate the homogenization, yield, fold purification, and extent of contamination by other undesirable organelles, and to account for 100% of the activity at each step. The extent of cell breakage

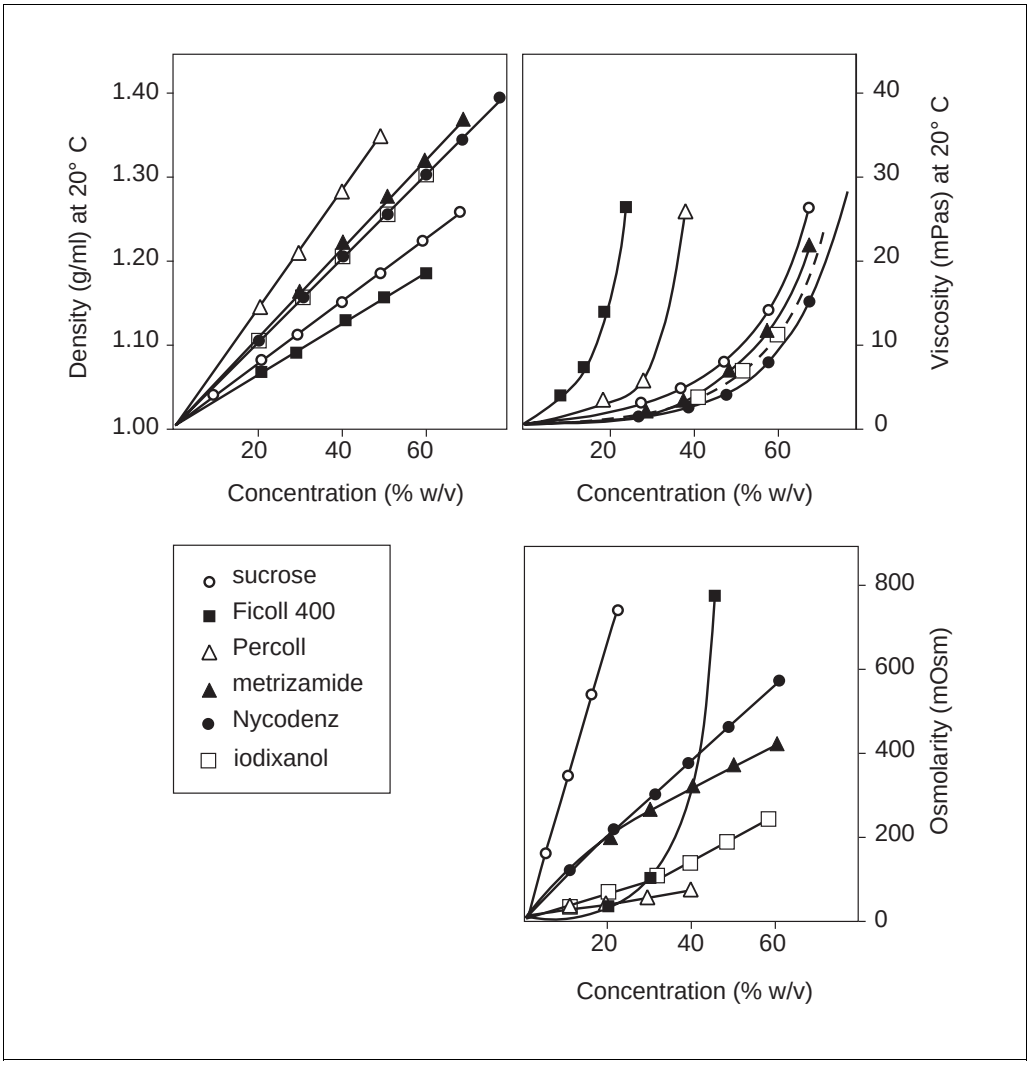

Figure 3.1.3 Plots of density, viscosity, and osmolarity of gradient media used to fractionate cellular organelles as a function of concentration. Data are shown for sucrose, Ficoll 400, Percoll, metrizamide, Nycodenz, and iodixanol. Modified from Rickwood (1984) by permission of IRL Press. Data for iodixanol by permission of Nycomed Pharma AS Diagnostics (Nycomed Pharma, 1996).

during homogenization can be estimated by determining the fraction of a marker activity of a particular organelle that pellets in the first low-speed centrifugation step (and is likely still to be associated with unbroken cells), while the extent of organelle breakage can be estimated by determining the fraction of the total amount of a soluble intraorganellar protein that is not sedimented by a high-speed spin that pellets all of the organelle. Following marker activity throughout purification enables the investigator to determine the yield of the desired organelle, and, if markers of other organelles are followed, the extent of residual contamination. Finally, if protein concentration is determined in parallel, calculation of the ratio of activity to protein (known as specific activity) at each step provides an estimate of fold purification or enrichment. In the event that analytical rather than preparative procedures are used, determination of marker activity in every fraction is essential for specifying the distribution of a particular organelle. Finally, it is very important to note that subcellular fractionation is never perfect! The entirety of a particular organelle is never obtained in completely pure form. In fact, the term "fraction" signifies both incomplete yield and incomplete purity. The careful investigator will always be cognizant of the limitations of the procedures and the consequent limitations of the results.

DEFINITIVE PROCEDURES

A useful starting point in isolating a particular cellular organelle may be to examine a procedure that has been designed for the spe-

Table 3.1.2 Preparing Organelle Fractions from Mammalian Tissues and Cells

cific organelle of interest. Table 3.1.2 lists references to procedures for purifying most of the membranous organelles found in eukaryotic cells. Unfortunately, it is not possible to make this listing comprehensive, but the procedures selected have achieved unusually good purity and in many cases have documented their achievement by bookkeeping of marker activities. Although several of the procedures are reasonably old, they have been used either as starting points for subfractionation (e.g., nucleus, endoplasmic reticulum, secretion granules, plasma membranes, lysosomes, mitochondria, and peroxisomes) or for functional studies in cell-free assays (e.g., Golgi, endoplasmic reticulum, and mitochondria). The adventurous investigator may want to consider the newer-generation reagent iodixanol (OptiPrep). The ability to fractionate under isoosmotic conditions over a large density range seems quite appealing. Sample procedures for various fractionations in iodixanol can be obtained from Nycomed/Accurate Chemical Co.

Isolation of Rat Hepatocyte Plasma Membrane Sheets and Plasma Membrane Domains

The plasma membrane of polarized epithelial cells is separated into discrete domains (apical and basolateral) that are functionally distinct. In polarized hepatocytes, the basolateral surface includes the sinusoidal front, which is specialized for the exchange of metabolites with the blood, and the lateral surface, which is adjacent to neighboring hepatocytes. The apical or bile canalicular plasma membrane domain is separated from the basolateral surfaces by tight junctions and is specialized for bile secretion. The functional and morphological differences between the two domains are matched by differing biochemical compositions. In order to examine the constituents of the hepatocyte plasma membrane, isolation of preparative amounts of this organelle is required.

This unit describes isolation of purified plasma membrane sheets from rat hepatocytes (see Basic Protocol 1). Since relatively high yields of plasma membrane sheets are obtained from this procedure, these preparations are suitable for a variety of analytical or preparative uses. For example, integral plasma membrane proteins can be extracted from preparative amounts of the sheets and further purified. The sheets also serve as the starting material for the separation of the two membrane domains (see Basic Protocol 2). The sheets are vesiculated by sonication, applied to continuous sucrose gradients, and centrifuged to equilibrium. The fractionation is generally an analytical procedure, and is useful for determining the distributions of plasma membrane–associated molecules between the two domains. The recovery and purity of plasma membrane sheets can be determined by measuring alkaline phosphodiesterase I activity (see Support Protocol 1); basolateral membrane recovery and purity can be assessed by measuring K^+-stimulated *p*-nitrophenylphosphatase activity (see Support Protocol 2); and apical membrane recovery and purity can be assessed by measuring 5′-nucleotidase activity (see Support Protocol 3). Distributions of proteins at the hepatocyte plasma membrane can also be determined morphologically (see Support Protocol 4). The large plasma membrane sheets readily adhere to glass coverslips and are easily processed for indirect immunofluorescent detection of specifically labeled antigens. The biochemical and morphological procedures described in this unit provide a relatively simple, yet powerful approach to examining molecules associated with the plasma membrane in rat hepatocytes.

ISOLATION OF PLASMA MEMBRANE SHEETS

BASIC PROTOCOL 1

This protocol describes a rapid and effective method for the purification of plasma membrane sheets from rat hepatocytes. Rat livers are first gently homogenized in buffered sucrose, and the plasma membrane sheets are separated from other intracellular compartments by a series of four differential centrifugations followed by a single flotation through a one-step sucrose gradient.

NOTE: All solutions and glassware should be prechilled to 4°C before the procedure, and kept on ice throughout.

Materials

125- to 150-g male Sprague-Dawley rats
Ether
0.9% (w/v) NaCl, ice cold (store 1 to 2 weeks at 4°C)
0.25 and 2.0 M STM solutions (see recipes), ice cold

continued

Contributed by Pamela L. Tuma and Ann L. Hubbard
Current Protocols in Cell Biology (1999) 3.2.1-3.2.16

Protease inhibitor solutions (see recipe)
0.25 M sucrose solution (see recipe), ice cold

40-ml Dounce homogenizer (Wheaton) with tight- and loose-fitting pestles (size A and B, respectively, although certain manufacturers reverse these designations)
Cheesecloth, grade 60
Abbe refractometer (Bausch and Lomb)
7-ml Dounce homogenizer (Wheaton) with loose-fitting pestle (size B)

Additional reagents and equipment for SDS-PAGE (*UNIT 6.1*), quantitative immunoblotting (*UNIT 6.2*), and densitometry (*UNIT 6.3*)

Subfractionate liver homogenate

1. Starve a 125- to 150-g male rat for 18 to 24 hr.

   For analytical work, one 6- to 8-g rat liver provides sufficient material. For preparative work, use up to 40 g of liver at a time (five to six rats and scale up solution volumes proportionally to number of livers used). The protocol described here and the volumes of sucrose solutions given (see Reagents and Solutions) are for the isolation of plasma membrane sheets from one rat liver.

2. Anesthetize the rat with ether and sacrifice by decapitation. Drain the blood from the animal under cold running water and carefully excise the liver.

3. Rinse the liver with ice-cold 0.9% NaCl to remove excess blood and hair. Using a squirt bottle, perfuse the liver with 0.9% NaCl via the portal vein until the liver is blanched. Quickly weigh the perfused liver and place it in a prechilled beaker on ice.

   This perfusion will remove any contaminating blood trapped within the liver. All subsequent steps are performed at 4°C.

4. Use scissors to mince the liver into ~0.5-cm^3 pieces and add 4.5 vol (4.5 ml/g tissue) of 0.25 M STM solution with protease inhibitors. Pour the mixture into a 40-ml Dounce homogenizer.

   If the liver weighs more than 8 g, divide it in half and homogenize separately.

5. Homogenize with 10 up-and-down strokes with the loose-fitting pestle (B).

   Avoid producing bubbles during homogenization by moving the pestle slowly and steadily. Wipe off any connective tissue that sticks to the pestle.

6. Filter homogenate into a graduated cylinder through a funnel lined with four layers of grade-60 cheesecloth premoistened with 0.25 M STM solution. Add 0.25 M STM solution to adjust the filtered volume to five times the original wet weight (5 ml/g) of the liver, producing a 20% (w/v) homogenate. Mix by gently inverting 3 to 5 times.

7. Pour 25- to 30-ml aliquots of homogenate into 50-ml conical tubes. Centrifuge 5 min at 260 × *g* (e.g., 1100 rpm in Beckman GS-6R), 4°C.

8. Carefully decant supernatant (S1) into a fresh tube, avoiding contamination from the soft pellet, and place on ice.

9. Resuspend pellet in one-half the original homogenate volume (step 6) of 0.25 M STM solution with protease inhibitors, using three strokes of the loose-fitting pestle (B) in a 40-ml Dounce homogenizer. Centrifuge as in step 7.

10. Decant supernatant and pool with supernatant from step 8 (S1). Centrifuge 25- to 30-ml aliquots of pooled supernatant per 50-ml conical tube, 10 min at 1500 × *g* (e.g., 2600 rpm in Beckman GS-6R), 4°C.

11. Pour off supernatant (S2).

    If assaying all fractions for recoveries, save S2 on ice and use on the same day.

Float plasma membrane sheets

12. Add two-thirds the original homogenate volume (step 6) of 0.25 M STM solution with protease inhibitors to the pellet (P2). Resuspend in a 40-ml Dounce homogenizer with three strokes of the loose-fitting pestle (B) followed by one stroke of the tight-fitting pestle (A).
13. Pour the suspension into a graduated cylinder and adjust to 2 times the original homogenate volume (step 6) with 2.0 M STM solution. Mix by gently inverting 3 to 5 times.
14. Check the density of the mixture with an Abbe refractometer, and adjust with either 0.25 M or 2.0 M STM solution until a density of 1.18 g/cm^3 (refractive index = 1.4016) is achieved.
15. Fill ultracentrifuge tubes equally with the resuspended P2 to ~90% total volume. Carefully overlay each tube to within a few millimeters from the top with ice-cold 0.25 M sucrose solution.

    For the Beckman SW28 rotor, 90% is 32 ml.

16. Centrifuge 60 min at 113,000 × *g* (e.g., 25,000 rpm in Beckman SW28 rotor), 4°C, in a swinging-bucket rotor with no brake.
17. Collect and pool the pellicules at the interface of each tube with a blunt-ended plastic transfer pipet.

    If assaying all fractions for recoveries, pour off and save the load fraction and resuspend the pellet (P3) to the desired volume (e.g., 5 to 10 ml).

18. Resuspend pellicules in 0.25 M sucrose solution at 0.8 to 1.0 times the original homogenate volume (step 6) and gently homogenize with three strokes of the loose-fitting pestle in the 40-ml Dounce homogenizer.
19. Check density of the suspension and adjust to ≤1.05 g/cm^3 (refractive index ≤1.3500) by diluting with 0.25 M sucrose solution, if necessary.

Recover and characterize plasma membrane sheets

20. Centrifuge 25- to 30-ml aliquots of resuspended pellicules per 50-ml conical tube, 10 min at 1500 × *g* (e.g., 2600 rpm in Beckman GS-6R), 4°C.
21. Carefully remove supernatant with a pipet and resuspend the pellet (plasma membrane sheets) in 1 to 2 ml of 0.25 M sucrose solution per liver in a 7.0-ml Dounce homogenizer with a loose-fitting pestle. Divide the purified plasma membrane sheets into 0.5- to 1.0-ml aliquots and save indefinitely at −80°C.

    Use caution when removing the supernatant, as this pellet is loose.

22. Apply ~20 µl of resuspended membrane sheets to a glass slide and examine at 25× magnification by phase-contrast microscopy.

    There should be relatively few small (≤1-µm) vesicles and membrane fragments, and an abundance of relatively large (20- to 40-µm), Y-shaped structures. If large (10-µm) spheres are also observed, these are nuclei. To avoid this form of contamination, pour less supernatant off of the pellet in step 8.

23. Check recovery and purity of an aliquot of the plasma membrane sheets by SDS-PAGE (*UNIT 6.1*) and immunoblotting (*UNIT 6.2*), assaying immunoreactivity with antibodies specific for various intracellular membrane marker proteins (see Table 3.2.1). Determine distributions by densitometric analysis (*UNIT 6.3*) of immunoreactive bands.

    Alternatively, recovery and purity can be checked by using the relatively simple colorimetric assay for the plasma membrane marker alkaline phosphodiesterase I (see Support Protocol 1) and by assaying protein concentration (APPENDIX 3).

Table 3.2.1 Recovery and Enrichment of Various Organellar Markers During the Isolation of Plasma Membrane Sheets[a]

Marker[b]	% Recovery	Fold-enrichment
Protein	0.4 ± 0.13	—
5′-nucleotidase (PM)	17.4 ± 6	39 ± 10
Alkaline phosphodiesterase I (PM)	17.0 ± 5.6	40 ± 9
Asialoglycoprotein binding activity (PM)	16.3 ± 6	47.8 ± 18
NADH-cytochrome *c* reductase (ER)	0.3 ± 0.2	1 ± 0.5
Glucose-6-phosphatase (ER)	0.5	0.8
β-*N*-acetylglucosaminidase (lysosomes)	0.22 ± 0.13	0.66 ± 0.3
Cytochrome oxidase (mitochondria)	0.12 ± 0.07	0.22 ± 0.1
DNA (nuclei)	0.26	0.3
Galactosyltransferase (Golgi)	1.0	1.9

SUPPORT PROTOCOL 1

ASSAY FOR ALKALINE PHOSPHODIESTERASE I ACTIVITY

Alkaline phosphodiesterase I is a plasma membrane–associated enzyme that distributes equally between the two surface domains. Since its enzymatic activity is easily assayed (Touster et al., 1970), alkaline phosphodiesterase is an excellent marker for total plasma membranes in biochemical subcellular fractions. In general, the assay described below is used to determine the recovery and purity of plasma membrane sheets in the preparative fractions obtained during the isolation procedure (Basic Protocol 1).

Materials

Preparative fractions and isolated plasma membrane sheets (see Basic Protocol 1)
Alkaline phosphodiesterase I reaction buffer (see recipe)
5% and 10% (w/v) trichloroacetic acid (TCA), ice cold
2 N NaOH
0.25 mM *p*-nitrophenol in 5% (w/v) TCA
1-cm-pathlength cuvettes

Analyze samples

1. Determine the necessary volume of alkaline phosphodiesterase I reaction buffer by multiplying the number of assay points plus one substrate blank by 0.8 ml (0.2 ml/assay tube × 4 tubes/fraction) and prepare it fresh.

   In general, all preparative fractions from the isolation of plasma membrane sheets, as well as the substrate blank, are assayed in duplicate for alkaline phosphodiesterase activity. Also, two incubation times are usually used.

   Substrate blanks are processed along with the other fractions and account for the amount of substrate hydrolyzed without added enzyme.

2. Set up four disposable glass tubes per fraction and substrate blank, and distribute 0.2 ml reaction buffer to each tube at room temperature.

3. Add 50 µl of each fraction (kept on ice until ready to assay) to the appropriate sample tubes and 50 µl water to the substrate blank tubes. Vortex gently.

4. Incubate fractions and blanks at 37°C in a shaking water bath, half for 30 min and half for 60 min.

5. Stop the reaction by adding 0.25 ml ice-cold 10% TCA. Gently vortex and let stand on ice.
6. Add 1.5 ml of 2 N NaOH to each tube and gently vortex.
7. Read A_{400} using a 1-cm-pathlength cuvette.

Analyze standards

8. Distribute 0, 0.1, 0.25, 0.3, 0.4, and 0.5 ml of 0.25 mM *p*-nitrophenol in 5% TCA to duplicate tubes.

   The corresponding amounts of p-nitrophenol are 0.0, 25.0, 62.5, 75, 100, and 125 nmoles/tube, respectively.

9. Adjust the volume of each tube to 0.5 ml with 5% TCA.
10. Add 1.5 ml of 2 N NaOH to each tube and read A_{400} as in step 7.

Perform calculations

11. Generate a standard curve by plotting A_{400} versus the amount of *p*-nitrophenol.
12. Subtract the substrate blank from each sample absorbance reading.
13. Determine the *p*-nitrophenol released in each sample tube from the standard curve.

    If the unknown alkaline phosphodiesterase activity is too high, dilute the fraction, assay a smaller aliquot, or generate another standard curve in a higher concentration range. Do the opposite if the activity is too low.

14. Calculate enzyme activity (μmoles substrate hydrolyzed/hr/ml) by multiplying the number of micromoles of *p*-nitrophenol in the samples by 20 (to correct the sample volume to 1.0 ml), by 2 (for the 30-min sample only, to correct the time to 1 hr), and by 1/dilution (if sample was diluted before addition to tube in the 50-μl aliquot).

ISOLATION OF PLASMA MEMBRANE DOMAINS

BASIC PROTOCOL 2

The isolated sheets prepared above (see Basic Protocol 1) are used as the starting material for the separation of the apical and basolateral domains, which constitute the intact rat hepatocyte plasma membrane. Gentle sonication of the plasma membrane sheets results in the formation of vesicles derived from either the apical or the basolateral domains. The two resultant vesicle populations are separated by equilibrium centrifugation on linear sucrose gradients and are identified by immunodetection of domain-specific antigens.

Materials

Plasma membrane sheets (see Basic Protocol 1)
0.25, 0.46, and 1.42 M sucrose solutions (see recipes)
Protease inhibitor solutions (see recipe)
Antibodies specific for apical and basolateral domains (e.g., anti–dipeptidyl peptidase IV for apical domain and CE9 antibody for basolateral domain; Hubbard et al., 1985)

Sonicating water bath (e.g., Laboratory Supplies)
Peristaltic pump
Gradient maker
Abbe refractometer (Bausch and Lomb)

Additional reagents and equipment for preparing and collecting sucrose gradients (*UNIT 5.3*), SDS-PAGE (*UNIT 6.1*), immunoblotting (*UNIT 6.2*), and densitometry (*UNIT 6.3*)

1. Dilute purified plasma membrane sheets to 1.0 mg protein/ml with 0.25 M sucrose solution containing protease inhibitors.

   If using a Beckman SW28 rotor, use 4 mg plasma membrane protein/32-ml gradient.

2. Sonicate 2.0-ml aliquots in 15-ml conical tubes using a sonicating water bath containing an ice/water slurry. Sonicate for 10-sec bursts with 1-min pauses on ice between bursts. Monitor vesiculation by phase-contrast microscopy (25× magnification; see Basic Protocol 1, step 22) every 1 to 5 bursts.

   Vesiculation is complete when no, or very few, large Y-shaped structures are observed. In general, this takes 3 to 20 bursts, depending on the strength of sonication. If a sonicating water bath is not available, vesiculation can also be achieved using a Polytron homogenizer (Brinkmann) fitted with a 12-mm tip at a setting of 8.

3. Pour linear gradients from 0.46 to 1.42 M sucrose (*UNIT 5.3*).

   If using a Beckman SW28 rotor, each gradient is 32.0 ml.

4. Layer the vesiculated plasma membrane sheets onto the gradients to within 2 to 5 mm from the top.

   If using a Beckman SW28 rotor, this volume is ~3.9 to 4.0 ml. Scale sucrose sample volumes proportionally for other types of tubes.

5. Centrifuge 16 to 20 hr at 72,000 × *g* (e.g., 38,000 rpm in Beckman SW28 rotor) with no brake at 4°C.

6. Collect fractions of desired volume (*UNIT 5.3*). Resuspend the pellet in 0.25 M sucrose to the same volume as the fractions. Invert each fraction to mix the sucrose solution and measure the refractive index of each with an Abbe refractometer. Store fractions indefinitely at −80°C.

   For 36-ml gradients, 3.0-ml fractions are usually collected.

7. Determine the distributions of apical and basolateral plasma membrane proteins by SDS-PAGE (*UNIT 6.1*) and quantitative immunoblotting (*UNIT 6.2*) with specific antibodies (e.g., dipeptidyl peptidase IV antibodies for the apical plasma membrane marker and CE9 antibodies for the basolateral), followed by densitometric analysis (*UNIT 6.3*) of immunoreactive bands.

   Alternatively, domain distributions can be determined by assaying for marker enzyme activities. For the basolateral vesicles, assay K^+-stimulated p-nitrophenyl phosphatase activity (see Support Protocol 2), and for the apical vesicles, assay 5′-nucleotidase activity (see Support Protocol 3).

   A typical plot of domain distribution is shown in Figure 3.2.1. For discussion, see Commentary.

SUPPORT PROTOCOL 2

ASSAY FOR K^+-STIMULATED *p*-NITROPHENYLPHOSPHATASE ACTIVITY

K^+-stimulated *p*-nitrophenylphosphatase activity is primarily associated with the basolateral plasma membrane in polarized epithelial cells. The assay outlined below (Stieger et al., 1986) is a straightforward method to determine the distribution of basolateral plasma membranes in sucrose gradient fractions containing vesiculated plasma membrane sheets (Basic Protocol 2). When used in combination with the assay for 5′-nucleotidase activity (Support Protocol 3), the distributions of both domains are easily determined for a single gradient.

Materials

Domain gradient fractions and resuspended pellet fraction (see Basic Protocol 2)
p-Nitrophenylphosphatase reaction buffer, with and without K^+ (see recipe)
Substrate mix (see recipe)

continued

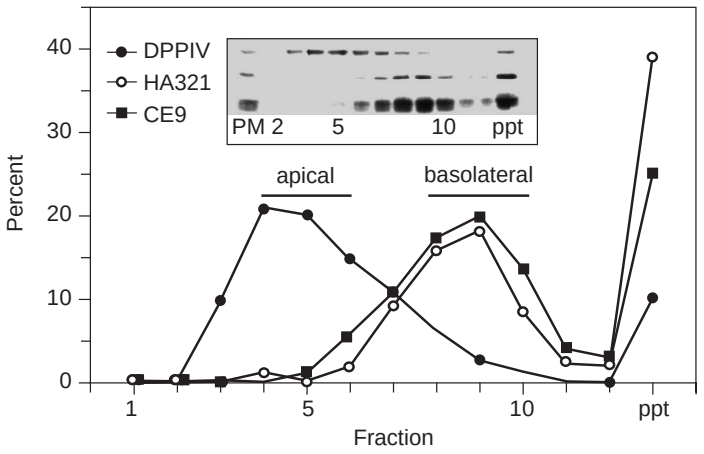

Figure 3.2.1 Distribution of one apical and two basolateral markers in the plasma membrane domain gradient. Isolated hepatocyte plasma membrane sheets were sonicated and the resulting vesicles separated on linear sucrose gradients. Collected fractions were analyzed by SDS-PAGE and quantitative immunoblotting with antibodies against known plasma membrane marker proteins. The data obtained from densitometry of the immunoreactive species detected in each fraction relative to the total recovered were plotted and indicated as percent distribution. The blotting data for each of the proteins are shown in the inset. The majority of the apical plasma membrane marker DPPIV was distributed to fractions 4 to 6, while the basolateral markers HA321 and CE9 were detected in fractions 8 to 10. The data shown are representative of three to ten experiments. Abbreviations: DPPIV, dipeptidyl peptidase IV; PM, plasma membrane; ppt, pellet. Reproduced from Fujita et al. (1998) by copyright permission of Portland Press.

1 and 10 N NaOH
0.25 mM *p*-nitrophenol in 1 N NaOH
1-cm-pathlength cuvette

Analyze samples

1. Determine the necessary volumes of K^+ and K^+-free *p*-nitrophenylphosphatase reaction buffers by multiplying the number of assay points plus one substrate blank by 3.28 ml (0.82 ml/assay tube × 4 tubes/fraction). Freshly prepare this volume of each reaction buffer.

   In general, all gradient fractions (including the resuspended pellet fraction) and a substrate blank are assayed in duplicate for both K^+-stimulated and K^+-independent activity. Also, two incubation times are usually used.

   Substrate blanks are processed along with the other fractions and account for the amount of substrate hydrolyzed without added enzyme.

2. Set up eight disposable glass tubes per fraction and substrate blank. Distribute 0.82 ml of each reaction buffer to four tubes/fraction. Distribute 0.87 ml of each reaction buffer to four substrate blank tubes.
3. Add 50 µl of each gradient fraction and the pelleted fraction (kept on ice until ready to assay) to the appropriate sample tubes and vortex gently.
4. Add 30 µl of substrate mix to all sample and blank tubes to begin the reaction. Incubate at 37°C in a shaking water bath, half for 30 min and half for 60 min.
5. Stop reaction by adding 100 µl of 10 N NaOH and vortex.
6. Read A_{405} using a 1-cm-pathlength cuvette.

Analyze standards

7. Distribute 0, 0.1, 0.25, 0.3, 0.4, and 0.5 ml of 0.25 mM *p*-nitrophenol in 1 N NaOH to duplicate tubes.

   The corresponding amounts of p-nitrophenol are 0, 25.0, 62.5, 75, 100, and 125 nmoles/tube, respectively.

8. Adjust the volume of each tube to 1.0 ml with 1 N NaOH and read A_{405} as in step 5.

Perform calculations

9. Generate a standard curve by plotting A_{405} versus the amount of *p*-nitrophenol.
10. Subtract the substrate blank from each sample absorbance reading.
11. Determine the *p*-nitrophenol released in each sample tube from the standard curve.

    If the unknown phosphatase activities are too high, dilute the fraction, assay a smaller aliquot, or generate another standard curve in a higher concentration range. Do the opposite if the activity is too low.

12. Calculate enzyme activity (μmoles substrate hydrolyzed/hr/ml) by multiplying the number of micromoles of *p*-nitrophenol in the samples by 20 (to correct the sample volume to 1.0 ml), by 2 (for the 30 min sample only, to correct the time to 1 hr), and by 1/dilution (if sample was diluted before addition to tube in the 50-μl aliquot).
13. To determine the K^+-stimulated *p*-nitrophenylphosphatase activity (the basolateral domain marker enzyme), subtract the values obtained using the buffer containing K^+ from those obtained using the K^+-free buffer.

SUPPORT PROTOCOL 3

ASSAY FOR 5′-NUCLEOTIDASE ACTIVITY

5′-nucleotidase is a plasma membrane–associated enzyme that distributes exclusively to the apical domain in many polarized epithelial cells. The assay described below (Widnell and Unkeless, 1968) serves as a straightforward means of determining the distributions of the apical plasma membranes in sucrose gradients containing vesiculated plasma membrane sheets (Basic Protocol 2).

Materials

Domain gradient fractions and resuspended pellet fraction (see Basic Protocol 2)
5′-Nucleotidase reaction buffer (see recipe)
5% and 30% (w/v) trichloroacetic acid (TCA), ice cold
10% (w/v) ascorbic acid, prepared fresh
0.42% (w/v) ammonium molybdate (see recipe)
0.1 mM KH_2PO_4 in 10% (w/v) TCA
1-cm-pathlength cuvette

Analyze samples

1. Determine the necessary volume of 5′-nucleotidase reaction buffer by multiplying the number of assay points plus one substrate blank by 1.8 ml (0.45 ml/assay tube × 4 tubes/fraction) and prepare it fresh.

   In general, all gradient fractions (including the resuspended pellet fraction) and the substrate blank are assayed in duplicate for 5′-nucleotidase activity. Also, two incubation times are usually used.

   A substrate blank consists of a mixture of 0.45 ml reaction buffer and 50 μl of H_2O also done in duplicate. These samples are processed along with the other fractions and account for the amount of substrate hydrolyzed without added enzyme. Two such blanks are required: one for the 30-min reaction and one for the 60-min reaction.

2. Set up four disposable glass tubes per fraction and substrate blank, and distribute 0.45 ml reaction buffer to each tube.
3. Add 50 µl of each gradient fraction (kept on ice until ready to assay) to the appropriate sample tubes and 50 µl water to the substrate blank tubes. Vortex gently.
4. Incubate at 37°C in a shaking water bath, half for 30 min and half for 60 min.
5. Stop reaction by adding 0.1 ml ice-cold 30% TCA and vortexing. Keep samples on ice.
6. Mix one part 10% ascorbic acid with six parts 0.42% ammonium molybdate (AA/AM).
7. To the tubes in step 4, add 1.5 ml AA/AM, cover with aluminum foil, and incubate an additional 20 min at 45°C.
8. Read A_{750} using a 1-cm-pathlength cuvette.

Analyze standards

9. Distribute 0, 0.05, 0.1, 0.2, 0.3, and 0.4 ml of 0.1 mM KH_2PO_4 in 10% TCA to duplicate tubes.

   The corresponding amounts of PO_4 are 0, 5, 10, 20, 30, and 40 nmoles/tube, respectively.

10. Adjust the volume of each tube to 0.6 ml with 5% TCA.
11. Add 1.5 ml AA/AM to each tube and incubate at 45°C as in step 6.
12. Read A_{750} as in step 8.

Perform calculations

13. Generate a standard curve by plotting A_{750} versus the amount of PO_4.
14. Subtract the substrate blank from each sample absorbance reading.
15. Determine the PO_4 released in each sample tube from the standard curve.

    If the unknown 5′-nucleotidase activity is too high, dilute the fraction, assay a smaller aliquot, or generate another standard curve in a higher concentration range. Do the opposite if the activity is too low.

16. Calculate enzyme activity (µmoles substrate hydrolyzed/hr/ml) by multiplying the number of micromoles of PO_4 in the samples by 20 (to correct the sample volume to 1.0 ml), by 2 (for the 30 min sample only, to correct the time to 1 hr), and by 1/dilution (if sample was diluted before addition to tube in the 50-µl aliquot).

INDIRECT IMMUNOFLUORESCENT DETECTION OF PROTEINS ASSOCIATED WITH PLASMA MEMBRANE SHEETS

SUPPORT PROTOCOL 4

The distribution of plasma membrane–associated molecules between the two domains can be easily determined by processing the purified sheets for indirect immunofluorescence. The sheets are settled onto glass coverslips by gravity and fixed with methanol at –20°C. The sheets are labeled with specific primary antibodies and visualized by indirect immunofluorescent detection of fluorophore-conjugated secondary antibodies. For additional discussion of immunofluorescent detection, see *UNIT 4.3*.

Materials

Plasma membrane sheets (see Basic Protocol 1)
0.25 M sucrose solution (see recipe)
PBS (*APPENDIX 2A*)

continued

Methanol, prechilled to −20°C
PBS/1% (w/v) BSA, prepared fresh
Primary antibody for marker protein
PBS/0.2% (w/v) BSA, prepared fresh
Fluorochrome-conjugated secondary antibody specific for Ig of the species of the primary antibody
Phenylenediamine mounting medium (see recipe)

Nail polish
22 × 22–mm glass coverslips

Adhere plasma membrane sheets to glass coverslips

1. Dilute plasma membrane sheets to 1.0 mg protein/ml with 0.25 M sucrose solution. Apply 100 to 200 µl to a 22 × 22–mm glass coverslip and distribute evenly across the surface with the side of a pipet tip.
2. Allow the plasma membrane sheets to settle onto the coverslip by gravity for 20 to 30 min at room temperature.

   The solution should not dry out during this time.

Prepare fixed samples

3. Wash off unattached plasma membrane sheets by rapidly dunking the coverslip 10 times in a small beaker of PBS. Remove excess liquid by touching an edge of the coverslip to a paper towel.
4. Quickly place the coverslip in prechilled (−20°C) methanol and incubate 5 min at −20°C.
5. Remove the coverslip from the methanol and rehydrate by washing three times in PBS for 5 min each.

   This and all subsequent steps are carried out at room temperature.

Stain samples for immunofluorescence

6. Block the plasma membrane sheets by incubating 15 min with PBS/1% BSA.
7. Remove excess blocking reagent as in step 3 and replace with 100 µl fresh PBS/1% BSA containing the desired primary antibody. Incubate 30 min.
8. Wash the coverslip three times with PBS/0.2% BSA, 5 min each, and remove excess wash buffer as in step 3.
9. Incubate 15 min in 100 µl PBS/1% BSA containing the desired concentration of fluorochrome-conjugated secondary antibody.
10. Wash coverslip as in step 8.
11. Place a drop of the phenylenediamine mounting medium in the middle of a glass slide. Place the coverslip with plasma membrane sheets face down on top of the drop.
12. Wick excess liquid with filter paper placed adjacent to the coverslip. Seal the coverslip into place with nail polish.
13. Allow specimen to dry at least 15 min and view with a fluorescent microscope equipped with a 63× or 100× objective.

REAGENTS AND SOLUTIONS

*Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see **APPENDIX 2A**; for suppliers, see **SUPPLIERS APPENDIX**.*

Alkaline phosphodiesterase I reaction buffer

5.0 ml 100 mM Na_2CO_3/$NaHCO_3$, pH 10.5 (40 mM final)
1.25 ml 1% (v/v) Triton X-100 (0.1% final)
1.0 ml 20 mM TMP solution (see recipe; 2 mM final)
H_2O to 10.0 ml
Prepare fresh and use at room temperature

This volume is sufficient for assaying all the preparative fractions and substrate blanks in duplicate for two incubation times (enough for 50 assay tubes).

Ammonium molybdate, 0.42% (w/v)

27.8 ml concentrated H_2SO_4 (1 N final)
4.2 g ammonium molybdate
H_2O to 1 liter
Store indefinitely at room temperature

p-Nitrophenylphosphatase reaction buffer, with and without K^+

5 ml 100 mM KCl (10 mM final)
1.5 ml 100 mM $MgCl_2$ (3 mM final)
25 ml 100 mM Tris·Cl, pH 7.4 (*APPENDIX 2A*; 50 mM final)
45 mg theophylline (5 mM final)
H_2O to 50 ml
Adjust pH to 7.4
Prepare fresh and use at room temperature

For buffer without K^+: Use 5 ml of 100 mM NaCl (10 mM final) in place of KCl.

This volume is sufficient for assaying all the gradient fractions and substrate blanks in duplicate for two incubation times (enough for 60 assay tubes).

5′-Nucleotidase reaction buffer

27.0 ml 100 mM Tris·Cl, pH 8.0 (*APPENDIX 2A*; 90 mM final)
3.0 ml 100 mM $MgCl_2$ (10 mM final)
15 mg adenosine-5′-monophosphate
Prepare fresh and use at room temperature

This volume is sufficient for assaying all the gradient fractions and substrate blanks in duplicate for two incubation times (enough for 66 assay tubes).

Phenylenediamine mounting medium

2.5 ml 2× TBS (see recipe)
2.5 ml glycerol
10 mg phenylenediamine (2 mg/ml final)

Adjust pH to between 9.5 and 10.5. Place medium in a 5-ml syringe, attach a 0.22-μm syringe-tip filter, and wrap in aluminum foil. Prepare fresh and keep on ice. Pass solution directly onto slide through the filter when needed.

This medium is very light sensitive.

Protease inhibitor solutions

Antipain: Prepare a 5-ml aqueous solution containing 5 mg antipain (1 mg/ml final) and 10% (v/v) dimethyl sulfoxide (DMSO). Divide into aliquots and store up to 1 year at −20°C. Add immediately before use at a 1:1000 dilution (1 μg/ml final).

continued

Aprotinin: Prepare a 10-ml aqueous solution containing 13.6 mg (1.36 mg/ml final) aprotinin. Store up to 1 year at 4°C. Add immediately before use at a 1:200 dilution (6.8 mg/ml final).

Benzamidine: Prepare a 10-ml aqueous solution containing 0.313 g benzamidine (200 mM final). Divide into aliquots and store up to 1 year at −20°C. Add immediately before use at a 1:200 dilution (1 mM final).

Leupeptin: Prepare a 5-ml aqueous solution containing 5 mg leupeptin (1 mg/ml final) and 10% (v/v) DMSO. Divide into aliquots and store up to 1 year at −20°C. Add immediately before use at a 1:1000 dilution (1 µg/ml final).

Phenylmethylsulfonyl fluoride (PMSF): Prepare a 10-ml solution of 100% ethanol containing 0.348 g PMSF (200 mM final). Store indefinitely at 4°C. Add immediately before use at a 1:200 dilution (1 mM final).

STM (sucrose/Tris/$MgCl_2$) solution, 0.25 M

17.12 g sucrose (0.25 M final)
2.0 ml 1.0 M Tris·Cl (*APPENDIX 2A*), pH 7.4 (10 mM final)
0.2 ml 1.0 M $MgCl_2$ (*APPENDIX 2A*; 1.0 mM final)
H_2O to 200 ml

Adjust to pH 7.4. Determine density (refractive index) at room temperature. Filter through a 0.2-µm nitrocellulose filter and store up to 48 hr at 4°C.

Refractive index = 1.3453 ± 0.0005. Solution can also be stored up to 1 year at −20°C, but density and pH should be checked before use.

STM solution, 2.0 M

Prepare as for 0.25 M STM solution (see recipe), but use 68.4 g sucrose per 100 ml (2.0 M final), and filter with a 1.2-µm nitrocellulose filter.

Refractive index = 1.4295 ± 0.0005.

Substrate mix

1.0 ml 10% (w/v) saponin (0.5% final)
0.92 g *p*-nitrophenylphosphate ditris salt (100 mM final)
H_2O to 20 ml
Store for up to 1 year at −20°C

Sucrose solution, 0.25 M

12.84 g sucrose
H_2O to 150 ml

Adjust to pH 7.4. Determine density (refractive index) at room temperature. Filter through a 0.2-µm nitrocellulose filter and store up to 48 hr at 4°C.

Refractive index = 1.3453 ± 0.0005. Solution can also be stored up to 1 year at −20°C, but density and pH should be checked before use.

Sucrose solution, 0.46 M

7.87 g sucrose
0.5 ml 1.0 M Tris·Cl (*APPENDIX 2A*), pH 7.5 (10 mM final)
H_2O to 50 ml

Adjust to pH 7.5. Determine density (refractive index) at room temperature. Filter through a 0.2-µm nitrocellulose filter and store up to 48 hr at 4°C.

Refractive index = 1.3557 ± 0.0005. Solution can also be stored up to 1 year at −20°C, but density and pH should be checked before use.

Sucrose solution, 1.42 M

Prepare as for 0.46 M sucrose solution (see recipe) but use 24.3 g sucrose.

Refractive index = 1.4016 ± 0.0005.

Thymidine-5′-monophospho-p-nitrophenyl ester (TMP), 20 mM

92 mg TMP
H_2O to 10.0 ml
Store up to 1 year at −20°C

Tris-buffered saline (TBS), 2×

2.42 g Tris base (100 mM final)
3.51 g NaCl (300 mM final)
H_2O to 200 ml
Adjust pH to 10.5 with concentrated HCl
Store indefinitely at 4°C

COMMENTARY

Background Information

The plasma membrane of polarized epithelial cells is divided into two functionally and compositionally distinct plasma membrane domains: the apical domain and the basolateral domain. In order to examine the biochemical constituents of each domain, isolation of highly purified plasma membranes is required. Not only must the preparations be pure, they must also contain each of the domains in similar amounts to that found in intact hepatocytes.

Early stereological studies revealed that the basolateral surface accounts for ~87% of the total plasma membrane surface area in hepatocytes; the apical domain for only ~13% (Weibel, 1976; Weibel et al., 1969; Blouin et al., 1977). However, early purification methods were deficient in substantial amounts of the basolateral surface, as discussed in Hubbard et al. (1983). This is largely due to the fact that the plasma membranes were vesiculated in the initial homogenization step, rendering the basolateral-derived vesicles both physically and morphologically indistinguishable from other intracellular vesicular structures. To circumvent this problem, the method presented here (first presented in Hubbard et al., 1983) avoids vesiculation of plasma membranes in the initial purification. Rather, using gentle homogenization, entire plasma membrane sheets are prepared and purified. These purified sheets retain both the apical and basolateral domains in near-normal surface area ratios (Hubbard et al., 1983), as well as a full complement of intercellular junctions and the subplasmalemmal cytoskeletal network (Hubbard and Ma, 1983).

This isolation procedure offers several other advantages over previously published methods. For one, this procedure is fast, taking a total of only 4 to 5 hr. It is also simple, requiring only four low-speed centrifugation steps and a single flotation through a one-step sucrose gradient. Perhaps most importantly, this method is effective, with routinely high yields and substantial enrichment of plasma membrane marker proteins (see Anticipated Results). This preparation also has substantially lower recoveries of membranes derived from other organelles, including the plasma membranes of other liver cell types (e.g., Kupffer and endothelial cells; see Table 3.2.1).

Once isolated, the plasma membrane sheets are useful for a variety of preparative and analytical procedures ranging from the identification of plasma membrane–associated molecules to their purification. Because domain-specific integral membrane proteins of the rat hepatocyte maintain their membrane localizations during isolation (Hubbard et al., 1983), the sheets are also useful as the starting material for purification of plasma membrane domains and determination of the distribution of molecules between domains. For this procedure, the plasma membrane sheets are vesiculated by sonication, applied to linear sucrose gradients, and centrifuged to equilibrium (Bartles et al., 1985). The basolateral-derived vesicles are more dense, probably due to associated cytoskeletal elements, and are readily separated from apical membrane vesicles. However, since the apical and basolateral vesicles partially overlap in the gradients (see Fig. 3.2.1), this method is only appropriate for analytical purposes.

The distributions of plasma membrane–associated molecules between domains can also be determined by processing isolated sheets for indirect immunofluorescence (Fujita et al., 1998). The large sheets readily adhere to uncoated glass coverslips and can be fixed in place with methanol. Conventional methods are then used to specifically label antigens with primary antibodies and visualize them with fluorophore-conjugated secondary antibodies. This method provides a much less time-consuming and labor-intensive alternative to density centrifugation followed

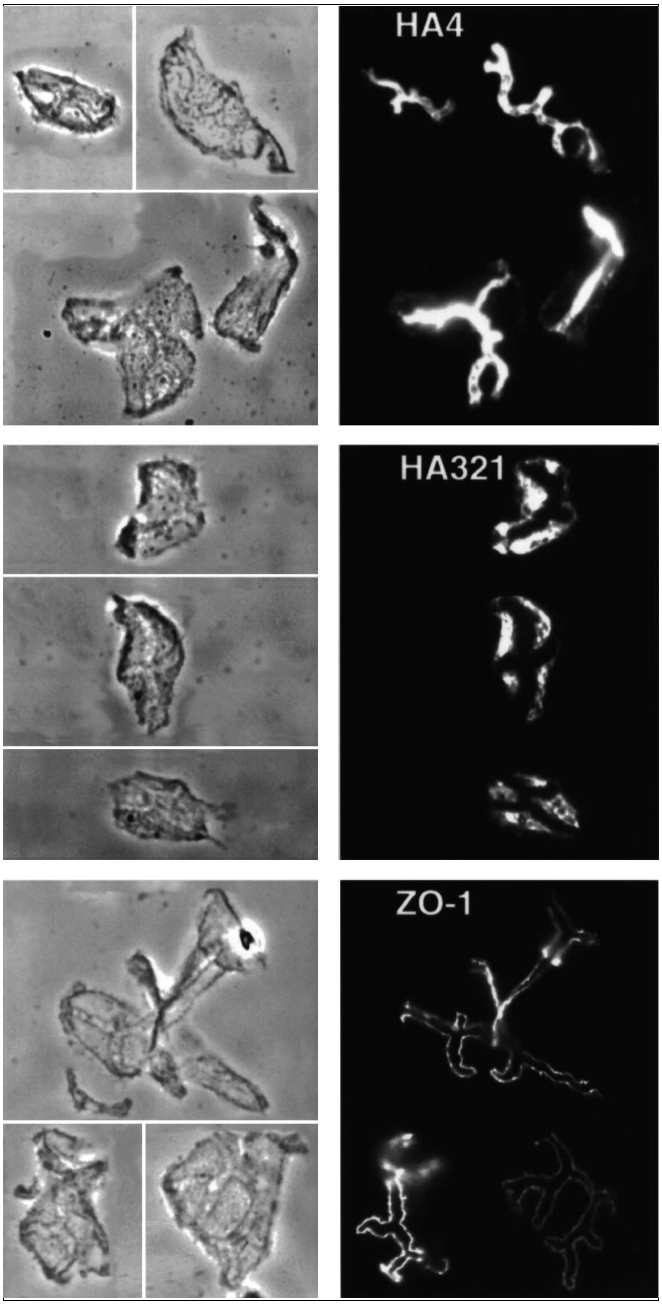

Figure 3.2.2 Immunofluorescent detection of domain-specific proteins and a tight junction–associated molecule in isolated plasma membrane sheets. Isolated plasma membrane sheets (~0.1 mg) were absorbed to glass coverslips, fixed with methanol for 5 min at –20°C, and processed for indirect immunofluorescence. (**A**), (**B**), and (**C**) are phase images of the plasma membrane sheets labeled for HA4 (**D**), HA321 (**E**), and ZO-1 (**F**), respectively. HA4 (an apical plasma membrane protein) was localized strictly to the bile canalicular area, whereas HA321 (a basolateral plasma membrane marker) was excluded from these membranes. The tight junctions, as indicated by ZO-1 staining, were detected in narrow regions immediately adjacent to the canalicular membranes. Reproduced from Fujita et al. (1998) by copyright permission of Portland Press.

by immunoblotting. In addition, the fluorescent staining patterns for domain-specific markers and tight junction components are dramatic and distinct (see Anticipated Results and Fig. 3.2.2). The authors have also found that plasma membrane proteins that were not observed in intact cells can often be detected in isolated sheets (Fujita et al., 1998). The reasons for this are not clear, but may be linked to increased accessibility of antigens for antibody binding. The sheets can also be processed for immunostaining by electron microscopy (Hubbard et al., 1983). However, the time and expertise required for ultrastructural analysis far exceed that required for light-level evaluation, making the latter approach much more accessible to the average experimenter.

Critical Parameters and Troubleshooting

Several features of the isolation procedure are essential to the successful preparation of purified plasma membrane sheets. To reduce aggregation of subcellular organelles by glycogen, rats must be starved at least 18 hr prior to sacrifice. Rat livers from younger rats (125 to 150 g) are preferable for isolation and should be used to avoid the increased amounts of connective tissue and plasma membrane–associated filaments found in preparations from larger rats. Homogenization of the perfused livers should be performed within 5 min of excision to avoid autolysis. To reduce both the vesiculation of the plasma membrane sheets and/or the production of membrane fragments, homogenization should be gentle, with minimal generation of bubbles or vacuum during the up and down strokes with the pestle. To reduce contamination by endoplasmic reticulum, it is recommended to resuspend the second pellet (P2, after centrifugation at 1500 × *g*) in twice the initial homogenate volume in preparation for flotation (see Basic Protocol 1, steps 12 and 13).

The most commonly encountered problem in the domain separation procedure is incomplete vesiculation of the membrane sheets resulting from undersonication. Incomplete vesiculation is characterized by >25% of the plasma membrane markers being found in the pelleted fraction and by the apical plasma membrane markers having more basolateral-like distributions. This problem can be corrected by increasing the number of sonication bursts until no Y-shaped membrane structures are visible by phase-contrast microscopy. Oversonication is a less prevalent problem, but results in basolateral markers having a more apical-like distribution in the gradient. This problem can be avoided by more closely monitoring vesiculation (e.g., after every sonication burst) by phase-contrast microscopy.

The assays to determine the recovery and purity of the plasma membrane sheets and of the two domains are relatively straightforward and easily interpreted. The most common problem is determining the appropriate dilution of the preparative fractions such that their activity levels fall within the values of the standard curve. In Table 3.2.2, suggested dilutions for preparative fractions are listed for both the enzyme assays and protein concentration determination using BCA reagent (Pierce). Alternatively, different standard curves can be prepared shifting the concentrations either higher or lower, or different incubation times can be used. In general, dilution of the domain gradient fractions is not suggested when assaying enzyme activities. Thus, altering the standard curve concentrations and incubation times are advised if problems are encountered.

Anticipated Results

The plasma membrane sheets purified according to Basic Protocol 1 are enriched 20- to 40-fold in plasma membrane markers. This preparation contains substantial amounts of both domains in continuity with each other in ratios approaching those of intact hepatocytes. The yield is 10% to 20% of total plasma membranes. The protein concentration of the purified sheets generally ranges from 1 to 2 mg/ml, corresponding to ~1 mg of plasma membrane protein/g of starting liver wet weight. The major contaminant of the isolated sheets is endoplasmic reticulum, which is enriched in these fractions 1-fold (see Table 3.2.1).

The vesicles derived from the apical and basolateral domains are partially resolved on the basis of differences in equilibrium density (see Fig. 3.2.1). The density profile for apical vesicles is characterized by a single peak with its center at a density of 1.10 g/cm^3 (refractive index = 1.3713). Basolateral vesicles have a bimodal distribution, with a peak centered at 1.14 g/cm^3 (refractive index = 1.3859) and a smaller (and variable) amount found in the pelleted fraction.

The apical and basolateral plasma membrane antigens, as well as tight junction components, exhibit distinct staining patterns in plasma membrane sheets. As shown in Fig. 3.2.2, the relatively intense staining for HA4 (an apical protein) is restricted to the bile canalicular membranes in an evenly distributed pattern. In contrast, staining for HA321 (a basolateral protein) is excluded from the canalicular structures and is detected in the surrounding membranes as a more diffuse and less intense signal. The tight junction protein ZO-1 is detected in regions immediately adjacent

Table 3.2.2 Suggested Dilutions for Analysis of Plasma Membrane Preparative Fractions

Fraction	Dilutions for enzyme assays[a]	Dilutions for BCA protein assay
H	1:50; 1:100	1:50; 1:100
S1	1:25; 1:50	1:25; 1:50
P1	1:50; 1:100	1:20; 1:40
S2	1:20, 1:40	1:25; 1:50
P2	1:10; 1:20	1:5; 1:10
I	1:10; 1:20	No dilution; 1:2
1.18 g/m^3	1:2; 1:4	1:2; 1:4
P3	1:5; 1:10	1:50; 1:100
S3	1:2; 1:4	No dilution
PM	1:50; 1:100	1:5; 1:10

[a]In these listings, "1:50" indicates 1 part enzyme in a total of 50 parts (i.e., 1 part enzyme plus 49 parts diluent).

to (outside) the apical plasma membrane in a ring-like pattern, indicating the location of the junctional complexes that form the barrier between plasma membrane domains.

Time Considerations

The isolation of plasma membrane sheets starting from the excision of the rat liver to the final plasma membrane pellet takes only 4 to 5 hr. Preparation of the sheets for density centrifugation by sonication generally takes 15 to 30 min. Each of the enzyme assays takes approximately 3 to 4 hr to perform, including setting up the assay, incubating the samples, reading the absorbances, and performing the calculations. Processing the sheets for indirect immunofluorescence is accomplished within 2 to 3 hr. SDS-PAGE also takes 2 to 3 hr and immunoblotting takes 18 to 24 hr.

Isolation of Mitochondria from Tissues and Cells by Differential Centrifugation

The protocols in this unit are simple and rapid methods for the isolation of a mitochondrial fraction from three different mammalian tissues (liver, heart, and skeletal muscle), from cultured cells, and from yeast. Unlike the protocols in *UNIT 3.4*, they only require routine differential centrifugation in low- and high-speed centrifuges and should be accessible to any laboratory. These mitochondrial fractions will be contaminated to varying degrees by smaller particles (lysosomes and peroxisomes), although the heavy mitochondrial fraction from rat liver is relatively pure (~90%). These preparations can be used as starting material for the density-gradient separations described in *UNIT 3.4*.

Basic Protocol 1 describes the isolation of the heavy mitochondrial fraction from rat liver; this fraction has high respiratory control and can be used in oxygen electrode studies for ≥4 hr after preparation. Centrifuging the postnuclear supernatant at only 3000 × *g* avoids significant contamination of the pellet by other more slowly sedimenting organelles (e.g., lysosomes, peroxisomes, endoplasmic reticulum). Contamination is reduced further by gently washing the 3000 × *g* pellet. A mannitol-containing buffer is the medium of choice for this preparation.

Other protocols describe methods for obtaining crude total mitochondrial fractions from bovine heart (see Basic Protocol 2), rat skeletal muscle (see Basic Protocol 3), cultured cells (see Basic Protocol 4), and yeast (see Basic Protocol 5). The major differences between these protocols is their mode of homogenization. Although the easy availability of rat liver in most laboratories makes it a popular choice as a source of mitochondria, those from bovine heart are also often used for respiratory studies. Indeed, they may even be more tightly coupled than liver mitochondria, and they can generally be stored for longer periods while maintaining good functional integrity. This may be allied to the lower levels of proteases and slower release of fatty acids in this tissue. Heart mitochondria also tend to provide better yields of the various structural components of electron transport and ATP synthesis. Basic Protocol 2 also provides a strategy for large-scale preparation. The increasing use of yeast as a model for mammalian membrane and organelle synthesis points to the importance of Basic Protocol 5. Although rat brain is another widely used source of mitochondria, they are rarely purified by differential centrifugation alone (see *UNIT 3.4*).

Methods for measuring succinate dehydrogenase, catalase, and β-galactosidase (as mitochondrial, peroxisomal, and lysosomal markers, respectively) in density-gradient fractions are given in *UNIT 3.4*, but they can also be applied to assessing the purity of mitochondria prepared by differential centrifugation.

Protease inhibitors (see *UNIT 3.4*, Reagents and Solutions) can be included in any or all of the media at the discretion of the investigator, except in the protease-containing solutions used in Basic Protocols 3 and 5.

NOTE: For all protocols, all *g* values are given as *g*.

PREPARATION OF THE HEAVY MITOCHONDRIAL FRACTION FROM RAT LIVER

BASIC PROTOCOL 1

Young adult male animals (150 to 200 g) are routinely used, providing livers of ~10 g wet weight. This protocol is designed for one such liver, but can be scaled up or down proportionally for different amounts of liver. The animals are normally deprived of food overnight to reduce the glycogen content of the liver; this facilitates the separation process.

Contributed by John M. Graham
Current Protocols in Cell Biology (1999) 3.3.1-3.3.15

A homogenization medium containing mannitol and sucrose, a chelating agent (either EGTA or EDTA), and a buffer (normally HEPES or MOPS) is best suited to respiratory studies.

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) or must conform to governmental regulations regarding the care and use of laboratory animals.

NOTE: All solutions, glassware, centrifuge tubes, and equipment should be precooled to 0° to 4°C and kept on ice throughout. When handling the glass vessel of the Potter-Elvehjem homogenizer, a thermally insulated glove or silicone rubber hand protector should be used, not only to avoid heat transfer from the skin, but also to protect the hand in the unlikely event that the vessel breaks.

Materials

150- to 200-g male Sprague-Dawley rat
Liver homogenization medium (LHM; see recipe), ice cold

Dissecting tools
Potter-Elvehjem homogenizer (~0.09-mm clearance; 25-ml working volume)
Overhead high-torque electric motor (thyristor-controlled)
Low-speed centrifuge with swinging bucket rotor and appropriate tubes
High-speed centrifuge with fixed-angle rotor and 40- to 50-ml polycarbonate tubes
Vacuum pump
Dounce homogenizer (30- to 40-ml volume) with loose-fitting pestle (Wheaton type B)

Isolate liver

1. Deprive a 150- to 200-g male Sprague-Dawley rat of food overnight.
2. Sacrifice the animal by cervical dislocation or decapitation.

   This must be supervised or carried out by an experienced animal technician.

3. Open the abdominal cavity and transfer the liver to a chilled beaker containing ~20 ml LHM.
4. Decant the medium and finely mince the liver using scissors.

   The pieces of liver should be no more than ~25 mm^3.

5. Agitate the minced tissue in ~30 ml ice-cold LHM and allow the pieces to settle out.
6. Decant the medium and replace with ~40 ml fresh medium.

Homogenize liver

7. Transfer half the suspension to the chilled glass vessel of a Potter-Elvehjem homogenizer.
8. Attach the cold pestle to an overhead high-torque electric motor and homogenize the minced liver using five to six up-and-down strokes of the pestle, rotating at ~500 rpm. Decant the homogenate into a beaker on ice.

   The motor should be securely mounted either to a wall, to a bench via a G clamp, or in a floor-standing cradle. Attachment to a free-standing retort stand is not adequate.

9. Rinse the homogenizer with medium and wipe the pestle to remove any adhering connective tissue. Repeat the procedure with the other half of the suspension.

Isolate mitochondria

10. Centrifuge the homogenate 10 min at 1000 × *g*, 4°C, in a swinging-bucket rotor using a low-speed centrifuge.

11. Aspirate the supernatant and transfer to 40- to 50-ml polycarbonate tubes.

    It is convenient to use a 20- to 30-ml syringe attached to a metal filling cannula (i.d. 0.8 to 1.0 mm) to aspirate supernatants that are to be recentrifuged.

12. Centrifuge the supernatant 10 min at 3000 × *g*, 4°C, in a fixed-angle rotor using a high-speed centrifuge.

13. Using a glass Pasteur pipet attached to some form of vacuum pump, aspirate the supernatant from each tube, keeping the tip of the pipet at the meniscus to remove as much of the floating lipid layer as possible. Also remove as much as possible of the loose-packed pinkish layer that overlies the brown mitochondria.

14. Wipe away any remaining lipid adhering to the wall of the tube with a paper tissue.

    Removal of this lipid is essential, as free fatty acids are potent uncouplers of phosphorylation from electron transport.

15. Add a small amount of LHM (~8 ml) to each pellet and crudely resuspend the pellet with a glass rod. Then resuspend fully using 3 to 4 very gentle strokes in a Dounce homogenizer.

16. Make up to the original volume with LHM, transfer to new tubes, and recentrifuge 10 min at 3000 × *g* in the high-speed centrifuge.

17. Repeat steps 13 to 16 twice more.

    For large-scale preparations, the total volume of LHM used to resuspend the pellet can be reduced by ~50% for the second and third washes.

18. Resuspend the purified mitochondria in a buffer whose composition is compatible with any subsequent analysis or processing; in many instances, LHM will be satisfactory.

    See Time Considerations for information about storage of mitochondria prior to further processing.

LARGE-SCALE PREPARATION OF MITOCHONDRIA FROM BOVINE HEART

BASIC PROTOCOL 2

It is important that fresh slaughterhouse material be used for this preparation, and that any adhering connective and adipose tissue be carefully removed. Because of the scale of the preparation and the size of the homogenization equipment, the procedure must be carried out in a cold room. The procedure is suitable for 500 to 600 g of material, and is adapted from Smith (1967) and Rice and Lindsay (1997).

NOTE: All solutions, glassware, centrifuge tubes, and equipment should be precooled to 0° to 4°C and kept on ice or in a cold room throughout.

Materials

Bovine heart, freshly isolated
Heart wash buffer (see recipe)
2.0 M Tris base
Sucrose/succinate solution (SS; see recipe)

Commercial mincer with a total capacity of 2 to 3 liters
Waring blender or other large-capacity rotating blades homogenizer
Cotton muslin
Low-speed centrifuge with swinging-bucket rotor and 250- to 750-ml bottles
High-speed centrifuge with fixed-angle rotor
Glass rod
Dounce homogenizer (50-ml volume) with loose-fitting pestle (Wheaton type B)

Prepare the heart

1. Cut freshly isolated bovine heart tissue into small cubes (~4 cm^3) and pass once through a commercial mincer.
2. Suspend in 800 ml ice-cold heart wash buffer. While stirring, adjust the pH to 7.8 by adding 2.0 M Tris base.
3. Pour through two layers of cotton muslin and then squeeze to remove as much of the liquid as possible.
4. Transfer minced tissue to a clean beaker and suspend in 800 ml ice-cold SS.

Homogenize the heart

5. Transfer half the suspension to a Waring blender and homogenize at high speed for 20 sec.
6. Readjust the pH to 7.8 using 2.0 M Tris base and then reblend for 60 sec.
7. Repeat the procedure with the other half of the suspension. Combine the two homogenates and dilute with ice-cold SS to ~2.2 liters.

Isolate mitochondria

8. Transfer homogenate to 250- to 750-ml centrifuge bottles and centrifuge 20 min at 800 × *g*, 4°C, in a swinging-bucket rotor using a low-speed centrifuge.
9. Carefully decant the supernatants and recentrifuge 20 min at 26,000 × *g*, 4°C, in a fixed-angle rotor using a high-speed centrifuge.

   A rotor such as the Sorvall SLA-1500 will allow this to be carried out in two centrifugations.

10. Decant and discard the supernatant.

    The pellet is clearly tripartite.

11. Tilting the bottles, gently pour ~10 ml SS on top of each pellet and gently swirl the contents to resuspend the top light-brown layer of partially disrupted mitochondria. Discard this material.
12. Crudely resuspend the remaining dark-brown mitochondria in ~20 ml SS using a glass rod, avoiding the almost-black hard-packed button at the bottom.
13. Completely resuspend mitochondria using 2 to 3 gentle strokes in a Dounce homogenizer.
14. Dilute the suspension to ~300 ml with SS and recentrifuge 20 min at 26,000 × *g*, 4°C.
15. Collect and resuspend the middle layer of the pellet as in steps 10 to 13.

    The upper and lower layers of this second pellet should be relatively minor components.

16. If the composition of the SS medium is incompatible with any subsequent analysis, centrifuge the suspension 20 min at 26,000 × *g* and resuspend the pellet in a suitable medium.

    See Time Considerations for information about storage of mitochondria prior to further processing.

PREPARATION OF MITOCHONDRIA FROM SKELETAL MUSCLE

This protocol uses a commercially available protease to facilitate the homogenization of the muscle tissue. Using this approach, the severity of the shear forces used to disrupt the tissue can be reduced, thus minimizing any damage to the mitochondria. The protocol is adapted from Bhattacharya et al. (1991). The protocol is designed for 4 to 5 g muscle tissue, but can be scaled up or down proportionally.

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) or must conform to governmental regulations regarding the care and use of laboratory animals.

NOTE: All solutions, glassware, centrifuge tubes, and equipment should be precooled to 0° to 4°C and kept on ice or in a cold room throughout. When handling the glass vessel of the Potter-Elvehjem homogenizer, a thermally insulated glove or silicone rubber hand protector should be used, not only to avoid heat transfer from the skin, but also to protect the hand in the unlikely event that the vessel breaks.

Materials

150- to 200-g male Sprague-Dawley rat
Muscle wash buffer (see recipe)
Muscle homogenization medium I (see recipe)
Muscle homogenization medium II (see recipe)

Dissecting tools
Potter-Elvehjem homogenizer (~0.3-mm clearance, 40-ml working volume)
Overhead high-torque electric motor (thyristor-controlled)
Fine nylon mesh (200-μm pore size)
Low-speed centrifuge with swinging-bucket rotor and appropriate tubes
High-speed centrifuge with fixed-angle rotor
Dounce homogenizer (30-ml volume) with loose-fitting pestle (Wheaton type B)

Isolate muscle tissue

1. Sacrifice a 150- to 200-g male Sprague-Dawley rat by cervical dislocation or decapitation.

   This must be supervised or carried out by an experienced animal technician.

2. Rapidly dissect out 4 to 5 g of striated leg muscle and wash it twice in ~50 ml muscle wash buffer.

3. Mince the muscle finely on a cold surface (e.g., a glass plate on crushed ice) using two scalpels.

   The muscle pieces should be <30 mm^3. The smaller the muscle pieces, the more efficient is the enzyme softening.

Homogenize tissue

4. Add 40 ml muscle homogenization medium I to the tissue and incubate for 5 min at 0° to 4°C.

5. Transfer to an ice-cold glass vessel of a Potter-Elvehjem homogenizer.

6. Attach the cold pestle to an overhead high-torque electric motor and homogenize using eight up-and-down strokes of the pestle, rotating at ~700 rpm.

   The motor should be securely mounted either to a wall, to a bench via a G clamp, or in a floor-standing cradle. Attachment to a free-standing retort stand is not adequate.

7. Incubate the homogenate with stirring for 5 min at 0° to 4°C.

8. Dilute with an equal volume of muscle homogenization medium II and rehomogenize as in step 6.

Isolate mitochondria

9. Filter the homogenate through fine nylon mesh and then centrifuge the filtrate 10 min at 2000 × *g*, 4°C, in a swinging-bucket rotor using a low-speed centrifuge.
10. Decant the supernatant and keep on ice.
11. Rehomogenize the pellet in 20 ml muscle homogenization medium II using three up-and-down strokes of the pestle, recentrifuge, and combine the supernatant with the first supernatant.
12. Centrifuge mitochondria 10 min at 10,000 × *g*, 4°C, in a fixed-angle rotor using a high-speed centrifuge.
13. Wash the pellet by resuspending in ~20 ml muscle homogenization medium II using 2 to 3 gentle strokes of the pestle in a Dounce homogenizer.
14. Repeat centrifugation as in step 12 and resuspend the pellet in a medium whose composition is compatible with any subsequent analysis or processing; in many instances muscle homogenization medium II or LHM (see recipe) will be quite satisfactory.

See Time Considerations for information about storage of mitochondria prior to further processing.

BASIC PROTOCOL 4

PREPARATION OF MITOCHONDRIA FROM CULTURED CELLS

This protocol, which is adapted from Attardi and Ching (1979) and Rice and Lindsay (1997), is designed for cultured cells (~2×10^8) grown as a monolayer. The method may also be satisfactory for suspension culture cells, as the homogenization medium is hypoosmotic. Inclusion of Mg^{2+} and K^+ in this medium is crucial; not only do these cations protect the nuclei from breakage, the KCl helps prevent some of the cytoplasmic proteins from forming a gel. To protect the released organelles from the hypoosmotic environment, the volume ratio of cells to medium should be as high as possible.

NOTE: All solutions (except PBS), glassware, centrifuge tubes, and equipment should be precooled to 0° to 4°C and kept on ice or in a cold room throughout. When handling the glass vessel of the Potter-Elvehjem homogenizer, a thermally insulated glove or silicone rubber hand protector should be used, not only to avoid heat transfer from the skin, but also to protect the hand in the unlikely event that the vessel breaks.

Materials

Confluent monolayer cultured cells (total 2×10^8)
PBS (*APPENDIX 2A*)
Cell homogenization medium (CHM; see recipe)
CHM containing 1 M sucrose
Sucrose/Mg^{2+} medium (see recipe)
Mitochondrial suspension medium I (see recipe)

Rubber policeman
Potter-Elvehjem homogenizer (~0.09-mm clearance, 10- to 15-ml working volume)
Overhead high-torque electric motor (thyristor-controlled)
Low-speed centrifuge with swinging-bucket rotor and appropriate tubes
High-speed centrifuge with fixed-angle rotor and appropriate tubes
Dounce homogenizer (5- to 10-ml volume) with loose-fitting pestle (Wheaton type B)

Prepare cells

1. Wash the monolayer cultures twice with ~60 ml PBS per wash at room temperature.
2. Using a rubber policeman, scrape the cells into 60 to 80 ml PBS and pellet the cells at 1000 × *g*, room temperature for 15 min.

   It is important to form a compact pellet so that all of the PBS can be removed in step 3.

3. Aspirate or decant all of the supernatant and resuspend the cells in ice-cold cell homogenization medium. Use a volume of medium equal to six times the volume of the pellet.
4. Leave on ice for 2 min.

Homogenize cells

5. Attach the cold pestle of a Potter-Elvehjem homogenizer to an overhead high-torque electric motor and homogenize the cells using five up-and-down strokes at 500 rpm. Confirm that ≥90% cell breakage has occurred by examining the homogenate under a phase-contrast microscope.

   The motor should be securely mounted either to a wall, to a bench via a G clamp, or in a floor-standing cradle. Attachment to a free-standing retort stand is not adequate.

   Some cells may require up to ten strokes of the pestle. If adequate cell breakage has not occurred at this stage, a tight-fitting Dounce homogenizer (Wheaton type A) should be used.

6. Add ⅓ vol ice-cold CHM containing 1 M sucrose (final 0.25 M) and mix gently by repeated inversion.

   Do not create foaming by rapid agitation.

Isolate mitochondria

7. Pellet nuclei by centrifuging 5 min at 1000 × *g*, 4°C, in a swinging-bucket rotor using a low-speed centrifuge.

   Washing the nuclear pellet to recover more mitochondria cannot be uniformly recommended for all cultured cells, as the nuclei of many cell lines tend to be rather fragile and may release DNA upon being resuspended.

8. Decant or aspirate the supernatant and centrifuge 10 min at 5000 × *g*, 4°C, in a fixed-angle rotor using a high-speed centrifuge.
9. Resuspend the pellet in ~10 ml ice-cold sucrose/Mg^{2+} medium using two to three gentle strokes of the pestle in a Dounce homogenizer.
10. Recentrifuge at 5000 × *g*, 10 min, 4°C. Resuspend the pellet in 2 to 3 ml ice-cold mitochondrial suspension medium I or other suitable medium for further processing.

    See Time Considerations for information about storage of mitochondria prior to further processing.

PREPARATION OF MITOCHONDRIA FROM YEAST (*SACCHAROMYCES CEREVISIAE*)

BASIC PROTOCOL 5

This protocol uses Zymolase to digest the tough outer coat of yeast to produce spheroplasts. It is probably best suited to the relatively small-scale cultures used in cell and molecular biology research. The rather harsh mechanical shear forces imposed by commercial homogenizers and ball mills that are often employed for large-scale cultures are not very well suited to the preparation of mitochondria. Zymolase works well with most wild-type yeast strains (e.g., D273-10B or KL14-4A). The yeast should be harvested in early- or mid-log growth phase, as the tougher coat that develops in late-log or stationary phase renders the enzyme digestion less satisfactory.

The yeast should be grown in YPD medium (*UNIT 1.6*) and washed in distilled water and a dithiothreitol-containing buffer. This common strategy seems to facilitate subsequent spheroplast formation (Goud et al., 1988). The protocol is adapted from Rice and Lindsay (1997).

Materials

Yeast cultures in early- to mid-log phase, grown in YPD medium (1% yeast extract/2% Bacto Peptone/2% glucose; see *UNIT 1.6*)
DTT buffer (see recipe)
Yeast sorbitol buffer (see recipe)
Zymolase-100T (from *Arthrobacter luteus*, 100,000 U/g; e.g., ICN Biomedicals, Sigma)
Spheroplast homogenization medium (see recipe), ice cold
Mitochondrial suspension medium II (see recipe), ice cold

Low-speed centrifuge with swinging-bucket rotor and appropriate tubes
High-speed centrifuge with fixed-angle rotor and appropriate tubes
30°C incubator
Dounce homogenizer (5- to 10-ml volume) with loose-fitting pestle (Wheaton type B)

Harvest yeast

1. Harvest yeast by centrifuging the culture (~1 liter) 10 min at 1000 × *g*, room temperature, in a swinging-bucket rotor using a low-speed centrifuge. Use a preweighed centrifuge tube, and calculate the wet weight of yeast by reweighing the tube after removing the supernatant.

   An early- to mid-log phase yeast culture is equivalent to an OD_{600} of ~0.6. Such a culture contains ~10^7 cells/ml.

2. Wash cells once in 3 to 4 vol distilled water, centrifuge again, and resuspend in 2 vol DTT buffer.

3. Incubate 30 min at 30°C and then centrifuge again.

4. Wash the cells once in 3 to 4 vol yeast sorbitol buffer and then resuspend in this medium at 0.15 g wet weight/ml.

Make spheroplasts

5. Stir in Zymolase-100T at 0.25 mg/100 g wet weight and incubate for ~1 hr at 30°C.

   Spheroplast formation can be checked by adjusting a small sample of the suspension to 0.1% (w/v) sodium dodecyl sulfate (SDS) to solubilize the spheroplasts and observing the remaining intact yeast cells under a microscope.

   Zymolase is sold by Sigma under the trade name Lyticase.

6. Harvest spheroplasts by centrifuging 10 min at 1000 × *g*, 4°C, and then wash the pellet once in 3 to 4 vol yeast sorbitol buffer.

Homogenize spheroplasts

7. Resuspend spheroplasts in 2 vol ice-cold spheroplast homogenization medium and carry out all subsequent operations at 0° to 4°C.

8. Homogenize in a Dounce homogenizer using no more than ten up-and-down strokes of the pestle.

Isolate mitochondria

9. Dilute homogenate with an equal volume of spheroplast homogenization medium and remove the nuclei and unbroken spheroplasts by centrifuging 10 min at 1000 × *g*, 4°C.

10. Decant or aspirate the supernatant and centrifuge 10 min at 6500 × *g*, 4°C, in a fixed-angle rotor using a high-speed centrifuge.

11. Wash the pellet once in ~40 ml ice-cold mitochondrial suspension medium II, recentrifuge, and resuspend in ~10 ml of the same buffer.

    See Time Considerations for information about storage of mitochondria prior to further processing.

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocols (except where indicated). For common stock solutions see ***APPENDIX 2A****; for suppliers see* ***SUPPLIERS APPENDIX****.*

Cell homogenization medium (CHM)

To 100 ml H_2O add:
30 µl 1 M $MgCl_2$ (150 mM final)
0.15 g KCl (10 mM final)
2.0 ml 1 M Tris·Cl (*APPENDIX 2A*; 10 mM final)
Adjust pH to 6.7
Add H_2O to 200 ml
Store up to 1 to 2 days at 4°C

For CHM containing 1 M sucrose, add 68.4 g sucrose to 200 ml CHM.

Dithiothreitol (DTT) buffer

To 100 ml H_2O add:
0.31 g dithiothreitol (10 mM final)
20 ml 1 M Tris base (0.1 M final)
Adjust pH to 9.3 with HCl
Add H_2O to 200 ml
Store up to 1 to 2 days at 4°C

Heart wash buffer

To 500 ml H_2O add:
85.5 g sucrose (0.25 M final)
10 ml 1 M Tris·Cl (*APPENDIX 2A*; 10 mM final)
Adjust pH to pH 7.8
Add H_2O to 1 liter
Store up to 1 to 2 days at 4°C

Liver homogenization medium (LHM)

To 250 ml H_2O add:
18.2 g mannitol (0.2 M final)
8.55.g sucrose (50 mM final)
0.37 g KCl (10 mM final)
5.0 ml 100 mM Na_2EDTA (1 mM final)
50 ml 100 mM HEPES (10 mM final)
Adjust pH to 7.4 with KOH
Add H_2O to 500 ml
Store up to 1 to 2 days at 4°C

Mitochondrial suspension medium I

To 50 ml H_2O add:
8.5 g sucrose (0.25 M final)
1.0 ml 1 M Tris base (10 mM final)
Adjust pH to 7.0 with acetic acid
Add H_2O to 100 ml
Store up to 1 to 2 days at 4°C

Mitochondrial suspension medium II

To 100 ml H_2O add:
21.9 g mannitol (0.6 M final)
40 ml 100 mM HEPES (20 mM final)
Adjust pH to 7.4 with KOH
Add H_2O to 200 ml
Store up to 1 to 2 days at 4°C

Muscle homogenization medium I

To 100 to <200 ml H_2O add:
6.84 g sucrose (0.1 M final)
0.686 g KCl (46 mM final)
20 ml 100 mM Na_2EDTA (10 mM final)
2.0 ml 1 M Tris·Cl (*APPENDIX 2A*; 10 mM final)
Adjust pH to 7.4
Add H_2O to 200 ml
Store up to 1 to 2 days at 4°C
Immediately before use, add 1.0 g bovine serum albumin (BSA; 0.5% w/v final) and 40 mg Nagarse (0.2 mg/ml final)

Sigma now markets Nagarse under the name Protease Type VII.

Muscle homogenization medium II

To 100 ml H_2O add:
6.84 g sucrose (0.1 M final)
0.686 g KCl (46 mM final)
20 ml 100 mM Na_2EDTA (10 mM final)
2.0 ml 1 M Tris·Cl (*APPENDIX 2A*; 10 mM final)
Adjust pH to 7.4
Add H_2O to 200 ml
Store up to 1 to 2 days at 4°C

Muscle wash buffer

To 100 ml H_2O add:
7.64 g mannitol (0.2 M final)
4.78 g sucrose (70 mM final)
0.2 ml 100 mM Na_2EDTA (0.1 mM final)
2.0 ml 1 M Tris·Cl (*APPENDIX 2A*; 10 mM final)
Adjust pH to 7.4
Add H_2O to 200 ml
Store up to 1 to 2 days at 4°C

Spheroplast homogenization medium

To 100 ml H_2O add:
21.9 g mannitol (0.6 M final)
40 ml 100 mM HEPES (20 mM final)
Adjust pH to 7.4 with KOH

continued

Add H_2O to 200 ml
Store up to 1 to 2 days at 4°C
Immediately before use add 1 ml 200 mM phenylmethylsulfonyl fluoride (PMSF; 1 mM final)

Sucrose/Mg^{2+} medium

To 100 ml H_2O add:
30 µl 1 M $MgCl_2$ (0.15 M final)
17.1 g sucrose (0.25 M final)
2 ml 1 M Tris·Cl (*APPENDIX 2A*; 10 mM final)
Adjust pH to 6.7
Add H_2O to 200 ml
Store up to 1 to 2 days at 4°C

Sucrose/succinate solution (SS)

To 1.5 liter H_2O add:
256.5 g sucrose (0.25 M final)
0.81 g disodium succinic acid hexahydrate (1 mM final)
6.0 ml 100 mM Na_2EDTA (0.2 mM final)
30 ml 1 M Tris·Cl (*APPENDIX 2A*; 10 mM final)
Adjust to pH 7.8
Add H_2O to 3 liters
Store up to 1 to 2 days at 4°C

Yeast sorbitol buffer

To 100 ml H_2O add:
43.7 g sorbitol (1.2 M final)
40 ml 100 mM KH_2PO_4 (20 mM final)
Adjust pH to 7.4 with KOH
Add H_2O to 200 ml
Store up to 1 to 2 days at 4°C

COMMENTARY

Background Information

Differential centrifugation is often used merely as a preliminary procedure to prepare a crude fraction of membranes or subcellular organelles prior to further purification in a density gradient. This technique separates particles according to their velocity of sedimentation (v), which depends principally on the diameter of the particle (d), although particle density (ρ_p) can also be important in some cases (e.g., nuclei). For the other parameters, ρ_l (the density of the liquid) and μ (its viscosity), are constant, and g is the applied centrifugal force.

$$v = \frac{d^2\left(\rho_p - \rho_l\right)}{18\mu} g$$

Table 3.3.1 gives the dimensions of some of the major particles in mammalian liver. Since v is proportional to d^2, it is clear from these values that the sedimentation rate of the majority of nuclei is much greater than that of the other particles, while only the largest mitochondria are likely to be separable from organelles such as lysosomes and peroxisomes. This is enhanced by the tendency of the larger mitochondria to be slightly more dense than lysosomes and peroxisomes. Thus centrifugation of a homogenate at 500 to 1000 × g for 5 to 10 min will pellet essentially all of the nuclei, a slightly higher relative centrifugal force (RCF) of 3000 × g for 10 min will pellet the "heavy" fraction of the mitochondria, and the considerably higher RCFs (e.g., 10,000 to 15,000 × g) required to pellet all of the smallest mitochondria will also pellet all lysosomes and peroxisomes.

The heterogeneity in the size of different organelles is bound to compromise separations of particles on the basis of sedimentation rate, but differential centrifugation (as opposed to rate-zonal centrifugation) imposes a further problem that arises from the sedimentation path length of the rotor and the radial increase in g

Table 3.3.1 Size (d) and d^2 of Major Organelles from Rat Liver

Particle	Size (μm)	d^2
Nucleus	4-12	16-144
Plasma membrane sheet[a]	3-20	9-400
Golgi membranes	1-2	1-4
Mitochondria	0.4-2.5	0.16-6.25
Lysosomes	0.4-0.8	0.16-0.64
Peroxisomes	0.4-0.8	0.16-0.64
Most vesicles	0.05-0.3	0.0025-0.09

[a]Only organized tissues such as liver produce plasma membrane sheets under certain homogenization conditions.

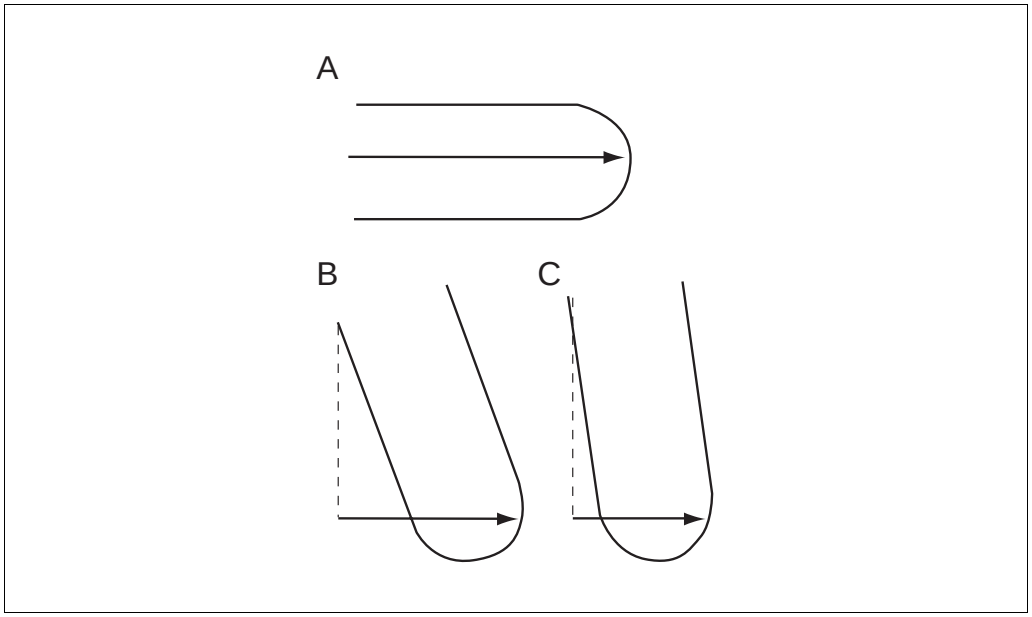

Figure 3.3.1 Sedimentation path length of rotors: (**A**) swinging-bucket; (**B**) high-angle fixed-angle; (**C**) low-angle fixed-angle. The sedimentation path length is indicated by the arrowed line.

force in the spinning rotor. If the homogenate fills the centrifuge tube, then the RCF at the top of the sample is considerably less than that at the bottom of the sample. On the other hand, particles at the top of the sample have the furthest distance to travel to form a stable pellet. The above equation shows that a particle with a diameter of 5 μm will sediment four times faster than one with a diameter of 2.5 μm and equal density. In such cases, all the smaller particles in the lower quarter of the centrifuge tube will sediment in the time taken for the larger particles, initially at the top of the tube, to pellet. Thus, in differential centrifugation, if a rotational speed and centrifugation time are chosen to allow all of the nuclei to pellet, then some the mitochondria towards the bottom of the tube—which are exposed to the highest RCF and have the shortest distance to travel—will also pellet. It is for this reason that "washing" of a differential centrifugation pellet is a common practice; resuspending any pellet in medium and repeating the centrifugation will reduce contamination by the smaller particles. However, it will also reduce the yield of the particle of interest.

The sedimentation path length and the difference in RCF between the top and bottom of the sample are both less in a fixed-angle rotor than in a swinging-bucket rotor of the same tube volume (Fig. 3.3.1). Thus, differential centrifugation should always be carried out in a fixed-angle rotor for maximum resolution, and the lower the tube angle the better. However, as the tube angle decreases, the pellet tends to spread up the wall of the tube and become less compact and sometimes less stable, making removal of the supernatant more difficult. In practice,

therefore, a tube angle of ~30° is probably a good compromise. It might, therefore, be surprising that in all of the protocols presented here, the first low-speed centrifugation to remove the nuclei is often executed in a swinging-bucket rotor. In this case, the difference in the rate of sedimentation between the bulk of the nuclei and the mitochondria is so great that a fixed-angle rotor offers no significant advantage. More information on the use of differential centrifugation for the isolation of subcellular organelles can be obtained from Evans (1992), Graham (1997), and Hinton and Mullock (1997).

For studies on oxidative phosphorylation, mitochondria prepared by simple differential centrifugation are often preferred to those purified by gradient centrifugation. Here the aim is not to achieve high recoveries, but to prepare the organelles as rapidly and as gently as possible in a medium known to promote the retention of a highly coupled state. Hence, it is best to avoid the use of time-consuming density gradients, which may also expose the mitochondria to potentially damaging high *g* forces and unsuitable media. Bovine heart (see Basic Protocol 2) and the heavy fraction from rat liver (see Basic Protocol 1) are widely used for this purpose. See Rice and Lindsay (1997) for a review of methods for the measurement of functions associated with electron transport and oxidative phosphorylation and the preparation of submitochondrial particles.

Purification of subcellular organelles such as mitochondria has been given fresh impetus recently from the increasing number of projects aimed at mapping all proteins within a tissue (proteomics).

Critical Parameters and Troubleshooting

The composition of solutions used for isolating mitochondria is very much dependent on the source material. While a mannitol/sucrose–containing medium (see Basic Protocol 1) appears to offer good retention of functional integrity for liver mitochondria, it is not apparently a universal requirement. Although the inclusion of divalent cations (e.g., Mg^{2+}) is usually avoided (indeed, addition of EDTA or EGTA is often beneficial), the selection of a suitable homogenization medium may be dictated by the choice of material. This is most clearly the case with cultured cells, which may require a hypoosmotic medium to effect cell breakage; in these instances, Mg^{2+} and K^+ are present to protect the nuclei from disruption. The medium used in Basic Protocol 4 is a good general-purpose medium for adherent cultured cells (Attardi and Ching, 1979) that may also be suitable for suspension cultured cells, its composition being not unlike that used by Goldberg and Kornfeld (1983) for isolating membrane compartments of the secretory system. The presence of KCl is quite compatible with the isolation of functionally intact mitochondria, and it is often included to solubilize proteins that tend to form gels in homogenates of cultured cells and skeletal muscle (Rice and Lindsay, 1997). However, some monolayer cells can be homogenized in an isoosmotic sucrose medium containing 0.25 M sucrose, 1 mM EDTA, 10 mM triethanolamine/acetic acid, pH 7.4 (Marsh et al., 1987; Graham, 1997). The efficacy of the medium is related to the particular buffer, for which there is a strict requirement. If a hypoosmotic Mg^{2+}-containing medium is used, the suspending medium must be made isoosmotic as soon as possible and the mitochondria suspended in a Mg^{2+}-free medium. Once the nuclei have been removed, it is acceptable to add EDTA to the postnuclear supernatant to chelate the Mg^{2+}.

Scaling up of procedures should always be accompanied by a proportional scaling up of the homogenization volume, but the volumes of buffer used for washing centrifugation pellets may be reduced. For example, in Basic Protocol 1, the ratio of liver to homogenization medium must be maintained at ~40 ml per 10 g of liver; for washing the $3000 \times g$ pellets, the volume of LHM can be reduced by about one third.

The centrifugation conditions used to isolate mitochondria from the postnuclear supernatant are tailored to individual tissues or cells; however, any RCF between 5,000 and $10,000 \times g$ is generally adequate, and the reason for using $26,000 \times g$ for bovine heart mitochondria (Smith, 1967) is not entirely clear. Lysosome and peroxisome contamination will tend to increase as the RCF increases, although the yields of mitochondria will also increase. The RCFs required for the pelleting of mitochondria from cultured cells may well depend on the type of cell and the homogenization schedule used. With this type of material, therefore, it may be prudent to determine the RCFs empirically by investigating the composition of pellets produced at a series of RCFs such as 500, 1000, 3000, 6000, 10,000, and $15,000 \times g$ (each for 10 min).

Respiratory studies on mitochondria are particularly demanding on the integrity of the product. Thus, at all stages in their preparation, great attention must be paid to the use of the mildest and gentlest of manipulations. It cannot be stressed too strongly that excessive shear forces during homogenization can be highly deleterious to these organelles, and the resuspension of mitochondrial pellets must be carried out with the very minimum of liquid shear forces.

Anticipated Results

The yield of succinate dehydrogenase in the heavy mitochondrial pellet from rat liver may be as much as 80% of the total, with relatively little contamination from lysosomes and peroxisomes. The contamination levels vary with the efficacy of the washing procedure, but 5% to 10% of the total is not uncommon. Levels are much higher in the unwashed material (20% to 25% of the total). Oxygen electrode studies on this fraction reveal that oxygen uptake in the presence of either succinate or glutamate plus malate is very low upon depletion of endogenous ADP, and that addition of exogenous ADP increases the rate of oxygen consumption by as much as ten to fifteen fold, indicating that they are highly coupled. Recoveries of mitochondria in the other protocols are routinely 90% to 95%. However, because the RCFs used to produce the mitochondrial pellet are higher, the contamination by peroxisomes and lysosomes is correspondingly higher (25% to 30%), and these levels are less easily reduced by washing.

Time Considerations

There are no points at which these relatively short protocols may be suspended. Indeed, rapid preparation is the key to the recovery of functionally intact mitochondria. All solutions can be made ahead of time and stored at 4°C for 1 to 2 days or frozen at −20°C for longer period (e.g., 2 to 3 months). Note that any enzymes, BSA, PMSF, or other protease inhibitors should be added immediately prior to use.

Basic Protocols 1, 3, and 4 should be accomplished in 2 to 3 hr, while Basic Protocol 5 will require ≥4 hr because of the two incubation steps. The time required for Basic Protocol 2 will depend on the availability of suitable large-capacity rotors; it may be necessary to split the material between two centrifugations, if the 2.2 liters cannot be accommodated in the rotor. Large-capacity rotors also decelerate slowly (up to 15 min) so the whole procedure may take ~3.5 hr.

Functional assays should be carried out on the mitochondria as soon as possible after their preparation: this applies particularly to studies on oxidative phosphorylation and other measurements which rely on the permeability properties of the mitochondrial membranes. Storage for up to 4 hr at 0° to 4°C (<8 hr for heart mitochondria) is permissible but not recommended. Other functional assays (e.g., the succinate dehydrogenase assay described in *UNIT 3.4*) which are less demanding on structural integrity may be performed on material stored at 0° to 4°C for <16 h. Such assays and compositional measurements may also be carried out on material frozen to −20°C or −80°C. There are, however, no general rules regarding the suitability of a particular storage regime, and it is strongly recommended that the validity of results on stored material be checked by comparison with those made on the fresh organelles.

NOTE: If the mitochondria are to be further purified using one of the Basic Protocols described in *UNIT 3.4*, this must be carried out without delay.

Purification of a Crude Mitochondrial Fraction by Density-Gradient Centrifugation

Metabolic studies of mitochondria are often carried out on organelles prepared by differential centrifugation (*UNIT 3.3*), avoiding the use of gradients, which extend the preparation time. However, to obtain high yields of mitochondria in a relatively pure form, or to determine the specificity of the localization of a particular component or function to mitochondria (as compared to other organelles), density-gradient centrifugation is the most obvious strategy. Most mitochondrial fractions produced by differential centrifugation, with the exception of the heavy fraction from some mammalian tissues (*UNIT 3.3*), are contaminated to a significant degree by other organelles—lysosomes, peroxisomes, tubular Golgi membranes, and small amounts of endoplasmic reticulum. The Basic Protocols in this unit are therefore aimed at the optimal resolution of mitochondria from these other membrane particles in density gradients that can be used either preparatively or analytically.

A continuous sucrose gradient system for mammalian liver mitochondria is described in Basic Protocol 1. Although discontinuous sucrose gradients seem to lack the resolution necessary for mammalian systems, they can be used for yeast (also see Basic Protocol 1). Because of the hyperosmotic nature of all sucrose gradient systems, they lack the resolution possible with media such as Nycodenz, iodixanol, and Percoll, which can form isoosmotic (or nearly isoosmotic) gradients. Basic Protocol 2 describes a discontinuous Percoll gradient as applied to the isolation of rat brain mitochondria. Although the Percoll gradient in this protocol is probably satisfactory for mitochondria from sources other than rat brain, an alternative discontinuous gradient designed for rat liver is also included (see Alternate Protocol). Basic Protocol 3 describes a self-generated Percoll gradient for rat liver mitochondria. Some of the variations of these Percoll-based methods are discussed later (see Commentary). Although iodixanol can also be used in self-generated mode, the *g* forces required are rather high ($\geq$180,000 $\times$ *g*); therefore, Basic Protocol 4 describes the use of a preformed continuous iodixanol gradient. All of the gradients covered in these protocols should be broadly applicable to most material sources; however, because the sedimenting properties and density of organelles from different tissues and cells can vary, it may be necessary to modulate either the density profile of the gradient or the centrifugation conditions.

With the exception of Basic Protocol 2 (for rat brain), the methods do not include homogenization schedules, and any differential centrifugation is designed for mammalian liver. Thus, the homogenization medium is also used for all stages of the differential centrifugation and for suspending the final crude mitochondrial fraction. This is often not the case with other material such as cultured cells, skeletal muscle, or yeast (*UNIT 3.3*). Therefore, the strategy and media recommended in *UNIT 3.3* should be used to prepare crude mitochondria from sources other than mammalian liver.

It should be pointed out that the precise composition of the homogenization medium, the medium used to suspend the crude mitochondrial pellet, and the medium used to prepare the gradients from Percoll and OptiPrep (Basic Protocols 2-4 and Alternate Protocol) can be adapted to subsequent operational requirements. For example, because Percoll itself has no significant osmotic activity, Reinhart et al. (1982) were able to use medium containing 0.21 M mannitol, 60 mM sucrose, 10 mM succinate, 10 mM KCl, 1 mM ADP, 0.25 mM DTT, 10 mM HEPES-KOH, pH 7.4, throughout the entire procedure. As OptiPrep has an osmolarity of approx 170 mOsm, it could also be diluted with a similar medium. Such media doubtless have many beneficial effects on the retention of respiratory competence by the organelles. Because of the high concentrations of sucrose used in the gradients of Basic Protocol 1, however, the use of mannitol in the homogenization and differential centrifugation stages is

Contributed by John M. Graham
Current Protocols in Cell Biology (1999) 3.4.1-3.4.22

probably of little benefit, although the inclusion of KCl, ADP, DTT in all the solutions might be worthwhile. If the aim of the gradient purification is to identify the localization of some functional or compositional parameter or it is a preliminary process to some subsequent extraction, then the use of a simple general-purpose medium throughout the preparation is probably satisfactory. In the following protocols therefore basic general-purpose media containing either sucrose or mannitol, a chelating agent, and an organic buffer have generally been recommended, but these may be adjusted by the investigator to include low concentrations ≤10 mM) of substrates, co-factors, and sulphydryl reagents. Note, also, that the relative centrifugal force (RCF) used to pellet this mitochondrial fraction can be between 6,000 and 20,000 × *g*, as the purpose of the gradient is to resolve mitochondria from contaminating lysosomes, peroxisomes, and Golgi, if present.

Support Protocols describe simple assays for succinate dehydrogenase (see Support Protocol 1), β-galactosidase (see Support Protocol 2), and catalase (see Support Protocol 3), which have been adapted specifically for the detection of mitochondria, lysosomes, and peroxisomes, respectively, in gradient fractions, but they can be used for any mitochondrial fraction.

NOTE: For all protocols, all *g* values are given as g_{au}.

BASIC PROTOCOL 1

RESOLUTION OF A RAT LIVER MITOCHONDRIAL FRACTION IN A CONTINUOUS SUCROSE GRADIENT

This protocol, adapted from Diczfalusy and Alexson (1988) and Vamecq and Van Hoof (1984), was designed for mitochondria from mammalian liver. A crude light mitochondrial fraction should be suspended in a medium that is suitable to mitochondria, but there is little merit in using a mannitol-containing medium, as the mitochondria will be exposed to high hyperosmotic concentrations of sucrose in the gradient. The protocol is best carried out on Triton WR1339–treated rats (see Background Information) in order to reduce the density of the lysosomes. Optimal resolution in these sucrose gradients is carried out in a large-volume vertical rotor. Although this protocol is designed for mitochondria from rat liver, it can be modified for other mammalian tissues and for yeast. In the latter case, discontinuous sucrose gradients are used in a swinging-bucket rotor according to the method of Beauvoit et al. (1989).

NOTE: All solutions, glassware, centrifuge tubes, and equipment should be precooled to 0° to 4°C and kept on ice throughout.

NOTE: Supplements (see recipe) to the media used in this protocol are optional and can be added to any or all of the solutions.

Materials

General-purpose homogenization medium (GHM; see recipe), ice cold
Sucrose gradient solutions (see recipe)
Sucrose cushion (see recipe)
Protease inhibitors (optional; see recipe)

Dounce homogenizer (5- to 10-ml with loose-fitting, Wheaton type B pestle)
Low-speed centrifuge with swinging-bucket rotor and appropriate tubes
High-speed centrifuge with fixed-angle rotor and appropriate tubes
Gradient maker (two-chamber or Gradient Master)
Ultracentrifuge (e.g., Beckman VTi 50 with vertical rotor) and 39-ml tubes
Gradient unloader (optional)

Additional reagents and equipment for preparing homogenates (*UNIT 3.3*)

1. Prepare rat liver homogenate as described in *UNIT 3.3* (Basic Protocol 1, steps 1 to 9), but use ice-cold GHM instead of LHM.

   For sources other than mammalian liver it may be necessary to use a different homogenization medium (see UNIT 3.3), in which case GHM should be used only for resuspending the final crude mitochondrial pellet (step 4 below).

2. Pellet nuclei by centrifuging 5 min at 1000 × *g*, 4°C, in a swinging-bucket rotor using a low-speed centrifuge. If desired, wash the nuclei once to maximize the recovery of mitochondria.

3. Pellet mitochondria from the postnuclear supernatant by centrifuging 10 min at 15,000 × *g*, 4°C in a fixed-angle rotor using a high-speed centrifuge.

4. Resuspend the mitochondrial pellet in ~8 ml ice-cold GHM using 3 to 4 gentle strokes of the Dounce homogenizer.

5. Using a two-chamber gradient maker, prepare linear 28-ml sucrose gradients from 34% and 64% (w/v) sucrose gradient solutions in 39-ml tubes for a Beckman VTi 50 ultracentrifuge. Underlay 4 ml sucrose cushion in each tube.

   Alternatively, a Gradient Master can be used to prepare the gradients.

6. Layer 7 to 8 ml sample on top of the gradients and centrifuge 65 min at 170,000 × *g*, 4°C.

   For a discontinuous gradient (yeast), layer 11 ml each of 30%, 40%, and 55% (w/v) sucrose gradient solutions (see recipe) in 38-ml centrifuge tubes for an ultracentrifuge swinging-bucket rotor (e.g., Beckman SW28 or 28.1, or Sorvall AH 629). Then layer 5 ml sample on top of the gradients and centrifuge 20 to 30 min at 150,000 × g, 4°C. For 17-ml tubes, use 5 ml of each sucrose solution and 2 ml mitochondrial fraction.

7. Collect the gradient in 1- to 2-ml fractions using a gradient unloader or harvest the brownish mitochondrial band just above the middle of the tube (continuous gradient).

   For discontinuous gradients, harvest mitochondria from the 40%/55% interface.

8. Dilute sample(s) with ≥2 vol ice-cold GHM.

9. Centrifuge 20 min at 20,000 × *g*, 4°C.

10. Resuspend pellet(s) in ice-cold GHM or another suitable medium at 1 to 5 mg protein/ml.

    Metabolic assays should be carried out as soon as possible upon preparation; some assays, such as those in Support Protocols 1 to 3, can be carried out after storage at 4°C for <16 hr. Many assays can be carried out on material frozen to –20°C or –80°C; always check that the measurements that are made are relatively unaffected by the storage conditions by comparing with measurements made on fresh material.

ISOLATION OF MITOCHONDRIA FROM RAT BRAIN USING A DISCONTINUOUS PERCOLL GRADIENT

BASIC PROTOCOL 2

Methods for isolating rat brain mitochondria rarely rely solely on differential centrifugation as a purification process, probably because of contamination by synaptosomes and myelin. This particular purification is thus aimed at the isolation of nonsynaptosomal mitochondria. The method, derived from Sims (1990), appears to work optimally when ≥500 mg of tissue is processed. A discontinuous Percoll gradient for liver is described in the Alternate Protocol.

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) or must conform to governmental regulations regarding the care and use of laboratory animals.

NOTE: All solutions, glassware, centrifuge tubes, and equipment should be precooled to 0° to 4°C and kept on ice throughout.

NOTE: Supplements (see recipe) to the media used in this protocol are optional and can be added to any or all solutions.

Materials

150- to 200-g Sprague-Dawley rats
Brain homogenization medium (BHM; see recipe), ice cold
Percoll solutions in BHM: 15% (v/v), 23% (v/v), and 40% (v/v) (see recipe)
Protease inhibitors (optional; see recipe)

10-ml Dounce homogenizer with tight-fitting and loose-fitting pestles (Wheaton type A and B, respectively)
Low-speed centrifuge with swinging-bucket rotor and appropriate tubes
High-speed centrifuge with fixed-angle rotor and appropriate tubes
Ultracentrifuge with swinging-bucket rotor for 12-ml tubes

Prepare homogenate

1. Starve 150- to 200-g Sprague-Dawley rats overnight and sacrifice by decapitation.

   This must be supervised or carried out by an experienced animal technician.

2. Dissect out brain tissue, place ~500 mg in ice-cold BHM, and wash in three changes of this medium.
3. After mincing the tissue finely with scissors, suspend it in ~5 ml BHM and homogenize using five up-and-down strokes with the loose-fitting pestle of a 10-ml Dounce homogenizer, followed by ten more up-and-down strokes with the tight-fitting pestle.
4. Centrifuge 3 min at 1300 × *g*, 4°C, in a swinging-bucket rotor using a low-speed centrifuge. Decant and retain the supernatant.
5. Resuspend the pellet up to the original volume with BHM and rehomogenize using 10 strokes with the tight-fitting pestle.
6. Repeat centrifugation, decant the supernatant, and combine it with the first (step 4).

Isolate mitochondria

7. Centrifuge 10 min at 21,000 × *g*, 4°C, in a fixed-angle rotor using a high-speed centrifuge.
8. Discard the supernatant and resuspend the pellet in 5 ml of 15% Percoll solution.
9. In a suitable tube for a swinging-bucket rotor, layer 4.0 ml each of 23% and 40% Percoll solutions in BHM. Layer 3 ml mitochondrial suspension on top and centrifuge 5 min at 31,000 × *g*, 4°C.

   Add additional BHM on top if necessary to fill the tube.

10. Harvest the mitochondria that band at the lowest interface, and dilute with 4 vol ice-cold BHM.
11. Centrifuge 10 min at 17,000 × *g*, 4°C in a fixed-angle rotor.

12. Remove the supernatant and resuspend the mitochondrial pellet as appropriate at 1 to 5 mg protein/ml.

Metabolic assays should be carried out as soon as possible upon preparation; some assays, such as those in Support Protocols 1 to 3, can be carried out after storage at 4°C for <16 hr. Many assays can be carried out on material frozen to −20°C or −80°C; always check that the measurements that are made are relatively unaffected by the storage conditions by comparing with measurements made on fresh material.

ISOLATION OF MITOCHONDRIA FROM RAT LIVER USING A DISCONTINUOUS PERCOLL GRADIENT

ALTERNATE PROTOCOL

A similar discontinuous Percoll gradient, covering a slightly higher density range, has been used by Reinhart et al. (1982) to isolate a mitochondrial fraction from a total rat liver homogenate; this approach eliminates the resuspension of a crude mitochondrial pellet which may damage the organelles. Presumably to avoid contamination of the gradient by erythrocytes, the authors perfused the liver with a standard balanced salt medium containing 1.3 mM $CaCl_2$. Alternatively a post-nuclear supernatant could be used from an unperfused liver (as described in this protocol). The method is restrictive inasmuch as only 2 ml of homogenate can be processed on a single gradient, and the authors used only the median lobe of the liver in a total homogenate volume of ~10 ml. The method is adapted from Reinhart et al. (1982).

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) or must conform to governmental regulations regarding the care of laboratory animals.

NOTE: All solutions, glassware, centrifuge tubes, and equipment should be precooled to 0° to 4°C and kept on ice throughout.

NOTE: Supplements (see recipe) to the media used in this protocol are optional and can be added to any or all solutions.

Materials

150- to 200-g Sprague-Dawley rats
Mannitol-sucrose homogenization medium (MSHM; see recipe), ice-cold
Percoll solutions in MSHM: 19%, 31%, 42%, and 52% (v/v) (see recipe)
Protease inhibitors (optional; see recipe) can be added to any or all of the solutions

Low-speed centrifuge with swinging-bucket rotor and appropriate tubes
High-speed centrifuge with fixed-angle rotor (e.g., Sorvall SS34) with ~14-ml tubes

Additional reagents and equipment for preparing liver homogenate (*UNIT 3.3*)

1. Prepare rat liver homogenate from the median liver lobe as described in *UNIT 3.3* (Basic Protocol 1, steps 1 to 9), but use ice-cold MSHM (10 ml) instead of LHM.

   For sources other than mammalian liver it may be necessary to use a different homogenization medium (see UNIT 3.3), in which case only use MSHM to prepare the Percoll solutions.

2. Pellet the nuclei by centrifuging 5 min at 1000 × *g*, 4°C, in a swinging-bucket rotor using a low-speed centrifuge.
3. Remove the postnuclear supernatant into a beaker and keep on ice
4. In a tubes for the ultracentrifuge swinging-bucket rotor layer 3 ml of each of the 31%, 42% and 52% Percoll solutions and 2 ml each of the 19% Percoll and post nuclear supernatant.

5. Centrifuge at 36,000 × *g* for 30 sec at speed.

   The acceleration time should be ~1.5 min and the deceleration time ~3 min.

6. Collect the mitochondria that band at the lowest interface and dilute with 4 vol of MSHM. Centrifuge 10 min at 17,000 × *g*, 4°C, in a fixed-angle rotor.

7. Remove the supernatant and resuspend the mitochondria as appropriate at 1 to 5 mg protein/ml.

   Metabolic assays should be carried out as soon as possible upon preparation; some assays, such as those in Support Protocols 1 to 3, can be carried out after storage at 4°C for <16 hr. Many assays can be carried out on material frozen to −20°C or −80°C; always check that the measurements that are made are relatively unaffected by the storage conditions by comparing with measurements made on fresh material.

BASIC PROTOCOL 3

RESOLUTION OF A MITOCHONDRIAL FRACTION IN A SELF-GENERATED PERCOLL GRADIENT

A mitochondrial fraction prepared by differential centrifugation is loaded on to a 30% (v/v) solution of Percoll containing 225 mM mannitol and any other additives that may be required for the retention of respiratory activity. Gradient formation is normally carried out in a fixed-angle rotor at 95,000 × *g*. The protocol for rat liver mitochondria is adapted from Hovius et al. (1990).

Mitochondria band at ~1.09 g/ml in Percoll. It is important that the differential centrifugation fraction that is used contain as little endoplasmic reticulum (ER) as possible, as the density of mitochondria and ER tend to overlap quite significantly in these gradients. It is therefore recommended that the centrifugation speed be no more than 10,000 × *g* to produce the crude mitochondrial fraction.

Compared to the discontinuous Percoll gradients described in Basic Protocol 2 and Alternate Protocol, the centrifugation time for self-generated gradients is considerably longer, but the time taken in the preparation of the gradients is much reduced and considerably more simple to execute. Self-generated gradients may therefore be the method of choice for large numbers of samples. The gradients that are formed by self-generation are also highly reproducible. Alternate Protocol allows the use of a whole homogenate but this necessarily restricts the amount of mitochondria which can be purified on one gradient.

NOTE: All solutions, glassware, centrifuge tubes, and equipment should be precooled to 0° to 4°C and kept on ice throughout.

NOTE: Supplements (see recipe) to the media used in this protocol are optional and can be added to any or all solutions.

Materials

Mannitol buffer A (see recipe), ice cold
30% (v/v) Percoll solution (see recipe), ice cold
Protease inhibitors (optional; see recipe)

Low-speed centrifuge with swinging-bucket rotor and appropriate tubes (~30 ml)
5- and 30-ml Dounce homogenizers with loose-fitting pestles (Wheaton type B)
High-speed centrifuge with fixed-angle rotor and appropriate tubes (~30 ml)
Ultracentrifuge with fixed-angle rotor (e.g., Beckman 60 Ti or Sorvall T-1250) and appropriate tubes

Additional reagents and equipment for preparing homogenates (*UNIT 3.3*)

Isolate light mitochondrial fraction

1. Prepare rat liver homogenate as described in *UNIT 3.3* (Basic Protocol 1, steps 1 to 9), but use ice-cold mannitol buffer A instead of LHM.

   For sources other than mammalian liver it may be necessary to use a different homogenization medium (see UNIT 3.3), in which case mannitol buffer A should be used only for resuspending the final crude mitochondrial pellet (step 9 below).

2. Centrifuge homogenate 10 min at 1000 × *g*, 4°C, in a swinging-bucket rotor using a low-speed centrifuge.

3. Aspirate supernatant into new centrifuge tubes and set aside.

4. Resuspend pellets in ~20 ml ice-cold mannitol buffer A using two to three gentle strokes in a 30-ml Dounce homogenizer.

5. Centrifuge 10 min at 1000 × *g*, aspirate supernatant, and combine with the supernatant in step 3.

6. Centrifuge supernatants 15 min at 10,000 × *g*, 4°C, in a fixed-angle rotor using a high-speed centrifuge.

7. Discard supernatant and resuspend pellet in ~20 ml ice-cold mannitol buffer A as in step 4.

8. Centrifuge 15 min at 10,000 × *g*, 4°C, and discard the supernatant.

9. Resuspend the light mitochondrial pellet in 5 ml mannitol buffer A using 2 to 3 gentle strokes in a 5-ml Dounce homogenizer.

Purify mitochondria

10. Transfer 20 ml of 30% Percoll solution into each of four tubes for a suitable fixed-angle rotor (e.g., a Beckman 60Ti or Sorvall T-1250) and layer the resuspended mitochondria on top.

11. Centrifuge 30 min at 95,000 × *g*, 4°C. During deceleration below 1000 rpm, either switch off the brake or use a controlled deceleration program (if available on the ultracentrifuge).

12. Collect the gradient in 1- to 2-ml fractions.

    The lower part of the dense brown/yellow band contains the bulk of the purified mitochondria; once their position has been confirmed, they can, in future separations, be recovered simply by aspiration. A syringe and long metal cannula is the best tool for this task.

13. Dilute the gradient fraction(s) with ≥2 vol ice-cold mannitol buffer A.

14. Pellet organelles by centrifuging 10 min at 6300 × *g*, 4°C, in a fixed-angle rotor using a high-speed centrifuge.

15. Wash the mitochondrial pellet at least twice with ~10 ml of this buffer and resuspend in a suitable medium at 1 to 5 mg protein/ml.

    Metabolic assays should be carried out as soon as possible upon preparation; some assays, such as those in Support Protocols 1 to 3, can be carried out after storage at 4°C for <16 hr. Many assays can be carried out on material frozen to −20°C or −80°C; always check that the measurements that are made are relatively unaffected by the storage conditions by comparing with measurements made on fresh material.

RESOLUTION OF A RAT LIVER MITOCHONDRIAL FRACTION IN AN IODIXANOL GRADIENT

Although this protocol is carried out with a light mitochondrial fraction, any appropriate differential centrifugation fraction can be used. The fraction is adjusted to $\rho = 1.177$ g/ml, layered beneath a shallow linear gradient of iodixanol $\rho = 1.124$ to 1.162 g/ml, and centrifuged 2 hr at $110{,}000 \times g$ in a swinging-bucket rotor. As an alternative (if preferred), the mitochondrial fraction can be layered on top in the homogenization medium.

This protocol has been devised for mammalian liver mitochondria in a general-purpose medium. Any of the mitochondrial fractions from other sources covered in *UNIT 3.3* should behave in a similar manner, although the detail of the organelle banding may vary slightly and require modulation for optimal results. See Commentary for variations of this separation strategy.

NOTE: All solutions, glassware, centrifuge tubes, and equipment should be precooled to 0° to 4°C and kept on ice throughout.

NOTE: Supplements (see recipe) to media used in this protocol are optional and can be added to any or all solutions.

Materials

Iodixanol buffer A (see recipe), ice cold
50% (w/v) iodixanol solution: 1 vol iodixanol buffer B (see recipe) in 5 vol OptiPrep (60% iodixanol; Nycomed Pharm, Life Technologies, Accurate Chemicals, Mediatech)
19% and 27% iodixanol solutions: dilute 50% iodixanol with iodixanol buffer A
Protease inhibitors (optional; see recipe)

Low-speed centrifuge with swinging-bucket rotor and appropriate tubes
5- and 20-ml syringes and metal cannulae (i.d. ~0.7 mm)
5- and 30-ml Dounce homogenizers with loose-fitting pestles (Wheaton type B)
High-speed centrifuge with fixed-angle rotor and appropriate tubes
Ultracentrifuge with swinging-bucket rotor (e.g., Beckman SW 28.1 or Sorvall AH-629) and appropriate tubes
Refractometer (optional)
Gradient maker: two-chamber or Gradient Master

Additional reagents and equipment for preparing homogenates (*UNIT 3.3*)

Isolate mitochondrial fraction

1. Prepare rat liver homogenate as described in *UNIT 3.3* (Basic Protocol 1, steps 1 to 9), but use ice-cold iodixanol buffer A instead of LHM.

   For sources other than mammalian liver it may be necessary to use a different homogenization medium (see UNIT 3.3), in which case iodixanol buffer A should be used only for resuspending the final crude mitochondrial pellet (step 10 below).

2. Centrifuge homogenate 10 min at $1000 \times g$, 4°C, in a swinging-bucket rotor using a low-speed centrifuge.

3. Transfer the supernatant to new centrifuge tubes using a 20-ml syringe and metal cannula, and set aside.

4. Resuspend pellets in ~20 ml ice-cold iodixanol buffer A using two to three gentle strokes in a 30-ml Dounce homogenizer.

5. Centrifuge 10 min at 1000 × *g*, remove supernatant, and combine with the supernatant in step 3.
6. Centrifuge supernatants 10 min at 3000 × *g*, 4°C, in a fixed-angle rotor using a high-speed centrifuge.

   This step can be omitted if the heavy mitochondrial fraction is not required as a separate fraction or if the source material does not exhibit such a fraction.

7. Remove supernatants and centrifuge 15 min at 15,000 × *g*, 4°C.
8. Discard supernatant and resuspend pellet in ~20 ml ice-cold iodixanol buffer A using three to four gentle strokes in the 30-ml Dounce homogenizer.
9. Centrifuge 15 min at 15,000 × *g*, 4°C, and discard the supernatant.
10. Resuspend the light mitochondrial pellet in 3 ml iodixanol buffer A using 2 to 3 gentle strokes in a 5-ml Dounce homogenizer.

Purify by Iodixanol gradient

11. Mix the suspension with 4.5 ml of 50% iodixanol solution by repeated inversion.

    Do not shake the tube vigorously to create foaming. If the sample is going to be loaded on top of the gradient rather than beneath it, then omit this step and the next.

12. Check that the refractive index is 1.3864 (± 0.0004) and adjust with 50% iodixanol solution or iodixanol buffer A, if necessary.
13. Prepare a linear iodixanol gradient in a ~17-ml centrifuge tube for a swinging-bucket rotor (e.g., a Beckman SW28.1 or a Sorvall AH-629) using 6 ml each of 19% and 27% iodixanol solution.

    If the gradient is prepared with a Gradient Master, use an 80° angle at 20 rpm and a time of 1 min 50 sec.

14. Underlayer the gradient with 3 ml sample (step 12), using a 5-ml syringe and a metal cannula.
15. Overlayer the gradient with 1 ml iodixanol buffer A.

    Alternatively, underlayer the gradient with 1 ml of 30% iodixanol (3 vol iodixanol stock solution plus 2 vol iodixanol buffer A), and then layer 3 ml sample on top of the gradient.

16. Centrifuge 1.5 hr at 110,000 × *g*, 4°C.
17. Collect the gradient in 1-ml fractions starting at the low-density end, using upward displacement with a dense liquid. Alternatively, collect the mitochondria that band just above the middle of the gradient using a syringe and cannula.
18. Dilute the sample with ≥2 vol iodixanol buffer A.
19. Centrifuge 20 min at 20,000 × *g*, 4°C, and resuspend the pellet in this buffer or another suitable medium at 1 to 5 mg protein/ml.

    Metabolic assays should be carried out as soon as possible upon preparation; some assays, such as those in Support Protocols 1 to 3, can be carried out after storage at 4°C for <16 hr. Many assays can be carried out on material frozen to –20°C or –80°C; always check that the measurements that are made are relatively unaffected by the storage conditions by comparing with measurements made on fresh material.

SUPPORT PROTOCOL 1

SUCCINATE DEHYDROGENASE ASSAY FOR MITOCHONDRIA

Although any component of the tricarboxylic acid cycle can be used as a functional marker for mitochondria, the most frequently used marker is succinate dehydrogenase with either the native electron acceptor (cytochrome *c*) or the artificial acceptor *p*-iodonitrotetrazolium violet (INT). Measuring the reduction of cytochrome *c* ideally requires a recording spectrophotometer, while the INT variant can be performed with a nonrecording instrument. INT is also far more stable than cytochrome *c* and avoids the use of cyanide, which is used to prevent reoxidation of cytochrome *c*. The INT method presented here is from Graham (1993).

Sample handling depends on the type of gradient and the concentration of mitochondria (and other organelles) in the fractions (see Commentary). Ideally, the protocol should be carried out on gradient fractions from which the gradient solute or Percoll has been removed by centrifugating as described in the final steps of each Basic Protocol. The gradient fractions should be resuspended in 0.25 M sucrose/10 mM HEPES-NaOH, pH 7.4, or an equivalent buffer.

Materials

Mitochondrial gradient fraction (see Basic Protocols 1 to 4)
Succinate solution (see recipe)
INT solution (see recipe)
Stop solution I (see recipe)
Spectrophotometer and glass cuvettes

1. Place 0.3 ml succinate solution in 1.5- to 2.0-ml microcentrifuge tubes, including a set of tubes to provide blanks for each fraction. Perform the assay in duplicate.

   As long as the protein content of each assay is approximately the same, a blank for each fraction may not be necessary. A single blank containing buffer instead of sample may suffice for many gradients. Alternatively, blanks may be prepared by adding stop solution to the gradient fraction before adding INT solution in step 3.

2. Add 10 to 20 μl of each gradient fraction to separate sample tubes. Incubate samples and blanks 10 min at 37°C.

   The sample should contain ~20 μg protein.

3. Add 0.1 ml INT solution and incubate for another 10 to 20 min at 37°C.
4. Terminate the reaction by adding 1 ml stop solution I.
5. Remove any precipitate by microcentrifuging for 2 min at maximum speed.
6. Using glass cuvettes, measure the absorbance at 490 nm against a suitable blank.
7. Calculate the enzyme activity as μmoles INT reduced per milligram protein.

   The molar extinction coefficient of reduced INT is 19,300 $cm^{-1}M^{-1}$.

SUPPORT PROTOCOL 2

β-GALACTOSIDASE ASSAY FOR LYSOSOMES

β-Galactosidase is one of several glycosidases that can be used to detect lysosomes. The assay is facilitated by the availability of *p*-nitrophenol derivatives of a number of monosaccharides, which mimic the native oligosaccharide substrates. It is linked to a simple spectrophotometric measurement of the released nitrophenol. The method is as described by Graham (1993).

Sample handling depends on the type of gradient and the concentration of lysosomes (and other organelles) in the fractions (see Commentary). Ideally, the protocol should be carried out on gradient fractions from which the gradient solute or Percoll has been removed by

centrifugation as described in the final steps of each Basic Protocol. The gradient fractions should be resuspended in 0.25 M sucrose/10 mM HEPES-NaOH, pH 7.4, or an equivalent buffer.

Materials

Mitochondrial gradient fraction (see Basic Protocols 1 to 4)
Substrate solution (see recipe)
Stop solution II (see recipe)
Spectrophotometer and plastic cuvettes

1. Add 20 to 40 µl of each gradient fraction (containing ~30 µg protein) to separate microcentrifuge tubes containing 0.5 ml substrate solution. Perform the assay in duplicate.
2. Prepare a blank for each fraction by adding 1 ml stop solution II before adding the gradient fraction.

   As long as the protein content of each assay is approximately the same, a blank for each fraction may not be necessary. A single blank containing buffer instead of sample may suffice for many gradients.
3. Incubate test samples 30 min at 37°C.
4. Add 1 ml stop solution II to test samples.
5. Remove any precipitate by microcentrifuging 1 to 2 min at maximum speed.
6. Using plastic cuvettes, measure the absorbance of tests at 410 nm against the chosen blank(s).

   The molar extinction coefficient of nitrophenol is 9620 $cm^{-1}M^{-1}$.

CATALASE ASSAY FOR PEROXISOMES

SUPPORT PROTOCOL 3

The titanium oxysulfate method, adapted from Baudhuin (1974), is the method of choice for peroxisomes and provides very reliable data. It is more sensitive than the permanganate-based method and is certainly easier to execute.

In peroxisomes from rat liver, catalase is an extremely active enzyme, and purified fractions from gradients may require dilution of up to 100 fold. Assays are usually carried out at 0°C. Sample handling depends on the type of gradient and the concentration of peroxisomes (and other organelles) in the fractions (see Commentary). Ideally, the protocol should be carried out on gradient fractions from which the gradient solute or Percoll has been removed by centrifuging as described in the final steps of each Basic Protocol. The gradient fractions should be resuspended in 0.25 M sucrose/10 mM HEPES-NaOH, pH 7.4, or an equivalent buffer.

CAUTION: Exercise care when handling titanium oxysulfate, as this reagent is extremely corrosive.

Materials

Mitochondrial gradient fraction (see Basic Protocols 1 to 4)
Stock peroxide solution (see recipe)
Tris/BSA solution (see recipe)
Titanium oxysulfate reagent (see recipe)
Sample buffer (see recipe)
Spectrophotometer

NOTE: Carry out all operations on ice in 2-ml microcentrifuge tubes.

1. Prepare substrate mixture by diluting 8.5 ml stock peroxide solution to 100 ml with Tris/BSA solution and keep at 0°C.
2. Add 1.0 ml titanium oxysulfate reagent to 0.5 ml substrate mixture and measure the absorbance at 405 nm.

   A_{405} should be ~1.5; if it is not, adjust the concentration of hydrogen peroxide accordingly.
3. Mix 10 µl gradient fraction with 30 µl sample buffer. Also set up a reagent control using 40 µl sample buffer. Perform assay in duplicate.

   With mammalian liver, because it is necessary to dilute the gradient fractions 10 to 100 fold, it is never necessary to set up blanks for each fraction. A single reagent blank is adequate. If a sample blank is necessary, replace 0.5 ml substrate mixture with buffer.

   Catalase activities in fractions from other sources may be much lower; test the pregradient mitochondrial fraction first.
4. Add 0.5 ml substrate mixture to all tubes. Do this in batches of 6 tubes, adding the assay mixture to successive tubes at timed 10-sec intervals.
5. After exactly 1 min, add 1.0 ml titanium oxysulfate reagent (also at 10-sec intervals).
6. Remove any precipitate by microcentrifuging 2 min at maximum speed, 4°C.
7. Transfer the tubes to room temperature and measure the absorbance at 405 nm against a blank containing 0.5 ml Tris/BSA solution and 1.0 ml titanium oxysulfate reagent.
8. Calculate the activity of the enzyme by deducting the test absorbance of each gradient fraction from that of the reagent control (see Commentary).

   Note that catalase is estimated by "back-titration"; i.e., the residual H_2O_2 is measured in the assay mixture after being acted on by the enzyme.

REAGENTS AND SOLUTIONS

*Use deionized or distilled water in all recipes and protocols (except where indicated). For common stock solutions see **APPENDIX 2A**; for suppliers see **SUPPLIERS APPENDIX**.*

Brain homogenization medium (BHM)

To 100 ml H_2O add:
21.9 g sucrose (0.32 M final)
2.0 ml 100 mM K_2EDTA (1 mM final)
2.0 ml 1 M Tris·Cl (*APPENDIX 2A*; 10 mM final)
Adjust pH to 7.4
Add H_2O to 200 ml
Store up to 1 to 2 days at 4°C

BHM, 2×

To 50 ml H_2O add:
21.9 g sucrose (0.64 M final)
2.0 ml 100 mM K_2EDTA (2 mM final)
2.0 ml 1 M Tris·Cl (*APPENDIX 2A*; 20 mM final)
Adjust to pH 7.4
Add H_2O to 100 ml
Store up to 1 to 2 days at 4°C

Citrate/phosphate buffer

Dissolve 0.71 g Na_2HPO_4 in 100 ml H_2O (50 mM final). Dissolve 0.96 g citric acid in another 100 ml H_2O (50 mM final). Add Na_2HPO_4 to citric acid to reach pH 4.3.
Store up to 1 to 2 days at 4°C

General-purpose homogenization medium (GHM)

To 100 ml H_2O add:
17.1 g sucrose (0.25 M final)
2.0 ml 100 mM Na_2EDTA (1 mM final)
2.0 ml 1 M Tris·Cl (*APPENDIX 2A*; 10 mM final)
Adjust pH to 7.4
Add H_2O to 200 ml
Store up to 1 to 2 days at 4°C

Iodixanol buffer A

To 100 ml H_2O add:
17.1 g sucrose (0.25 M final)
2.0 ml 100 mM Na_2EDTA (1 mM final)
20 ml 100 mM HEPES (10 mM final)
Adjust pH to 7.4
Add H_2O to 200 ml
Store up to 1 to 2 days at 4°C

Iodixanol buffer B

To 50 ml H_2O add:
8.55 g sucrose (0.25 M final)
6.0 ml 100 mM Na_2EDTA (6 mM final)
60 ml 100 mM HEPES (60 mM final)
Adjust pH to 7.4
Add H_2O to 100 ml
Store up to 1 to 2 days at 4°C

p-Iodonitrotetrazolium violet (INT) solution

25 mg INT (2.5 mg/ml final)
Phosphate buffer, pH 7.4 (see recipe), to 10 ml
Store up to 2 to 3 months at −20°C

Mannitol buffer A

To 100 ml H_2O add:
9.13 g mannitol (0.25 M final)
38 mg EGTA (0.5 mM final)
0.2 g bovine serum albumin (BSA; 0.1% w/v final)
10 ml 100 mM HEPES (5 mM final)
Adjust pH to 7.4
Add H_2O to 200 ml
Store 1 to 2 days at 4°C

Mannitol buffer B

To 100 ml H_2O add:
16.4 g mannitol (0.45 M final)
152 mg EGTA (2.0 mM final)
0.4 g BSA (0.2% w/v final)
100 ml 100 mM HEPES (50 mM final)
Adjust pH to 7.4
Add H_2O to 200 ml
Store up to 1 to 2 days at 4°C

Mannitol-sucrose homogenization medium (MSHM)

To 100 ml H_2O add:
7.64 g mannitol (0.21 M final)
4.10 g sucrose (60 mM final)
0.15 g KCl (10 mM final)
2.0 ml 1 M HEPES-KOH (10 mM final)
Adjust to pH 7.4
Add H_2O to 200 ml
Store up to 1 to 2 days at 4°C

MSHM, 4×

To 50 ml H_2O add:
15.3 g mannitol (0.21 M final)
8.2 g sucrose (60 mM final)
0.3 g KCl (10 mM final)
4.0 ml 1 M HEPES-KOH (10 mM final)
Adjust to pH 7.4
Add H_2O to 100 ml
Store up to 1 to 2 days at 4°C

Percoll solution, 30% (v/v)

3 vol Percoll
2 vol water
5 vol mannitol buffer B (see recipe)
Store up to 1 to 2 days at 4°C

Percoll solutions in BHM

Prepare a 50% (v/v) Percoll stock solution by adding 20 ml Percoll to 20 ml 2× BHM (see recipe). Store up to 1 to 2 days at 4°C

To prepare gradient solutions, dilute 50% Percoll stock with BHM to provide 15%, 23%, and 40% (v/v) Percoll. Store up to 1 to 2 days at 4°C

Percoll solution in MSHM

Prepare a 75% (v/v) Percoll solution by adding 30 ml Percoll to 10 ml of 4× MSHM (see recipe). Store up to 1 to 2 days at 4°C

To prepare gradient solutions, dilute Percoll (75% v/v) stock with MSHM to provide 19%, 31%, 42%, and 52% (v/v) Percoll. Store up to 1 to 2 days at 4°C

Phosphate buffer, pH 7.4

Dissolve 0.71 g Na_2HPO_4 in 100 ml water (50 mM final). Dissolve 0.68 g KH_2PO_4 in another 100 ml water (50 mM final). Add KH_2PO_4 to Na_2HPO_4 to reach pH 7.4. Store up to 1 to 2 days at 4°C

Protease inhibitors

Add the following to solutions as required so that the final concentrations are 1 mM for PMSF and 2.0 μg/ml for each of the other inhibitors.

PMSF:
0.348 g phenylmethylsulfonyl fluoride (200 mM final)
10 ml dried propan-2-ol or ethanol
Store up to 2 to 3 months at 4°C

Antipain:
10 mg antipain (1 mg/ml final)
10 ml 10% (v/v) dimethyl sulfoxide (DMSO)
Store in aliquots up to 2 to 3 months at −20°C

continued

Aprotinin:
10 mg aprotinin (1 mg/ml final)
10 ml H_2O
Store in aliquots up to 2 to 3 months at −20°C
Leupeptin:
10 mg leupeptin (1 mg/ml final)
10 ml of 10% (v/v) dimethyl sulfoxide (DMSO)
Store in aliquots up to 2 to 3 months at −20°C

Sample buffer

2 g Triton X-100 (2% w/v final)
H_2O to 100 ml
Mix 1 vol of this solution with 2 vol Tris/BSA solution (see recipe)
Store up to 1 to 2 days at 4°C

Stock peroxide solution

0.67 g 30% (w/w) H_2O_2 (30 mM final)
Tris/BSA solution (see recipe) to 200 ml
Prepare fresh

Stop solution I

10 g trichloroacetic acid
50 ml ethyl acetate
50 ml ethanol
Store up to 1 month at room temperature

Stop solution II

To 50 ml H_2O add:
1.87 g glycine (0.25 M final)
25 ml 1.0 M NaOH (0.25 M final)
Adjust pH to 10 (if necessary)
Add H_2O to 100 ml
Store up to 1 to 2 days at 4°C

Substrate solution

90 mg *o*-nitrophenyl β-D-galactopyranoside (6 mM final)
0.25 g Triton X-100 (0.5% w/v final)
Citrate/phosphate buffer (see recipe) to 50 ml
Store up to 1 to 2 days at 4°C

Succinate solution

0.27 g sodium succinic acid hexahydrate (10 mM final)
Phosphate buffer, pH 7.4 (see recipe), to 100 ml
Adjust to pH 7.4 if necessary
Store up to 1 to 2 days at 4°C

Sucrose cushion (continuous gradient only)

67 g sucrose (67% w/w final)
Dissolve the sucrose in 33 ml of 10 mM Tris·Cl, pH 7.4
Store up to 1 to 2 days at 4°C

Sucrose gradient solutions

Dilute 70% (w/v) sucrose stock (see recipe) with sucrose stock diluent (see recipe) to provide 34% and 64% (w/v) sucrose (continuous gradient); or 30%, 40%, and 54% (w/v) sucrose (discontinuous gradient)

Sucrose stock diluent

1.0 ml 100 mM Na_2EDTA (1 mM final)
1.0 ml 1 M Tris·Cl stock (10 mM final)
H_2O to 100 ml
Adjust pH to 7.4 after adding half the water
Store 1 to 2 days at 4°C

Sucrose stock solution, 70% (w/v)

70 g sucrose (70% w/v final)
1.0 ml 100 mM Na_2EDTA (1 mM final)
1.0 ml 1 M Tris·Cl stock (10 mM final)
H_2O to 100 ml
Adjust pH to 7.4 after adding most of the water
Store 1 to 2 days at 4°C

Supplements

0.27 g sodium succinic acid hexahydrate (10 mM final)
50 mg ADP (potassium salt) (1 mM final)
3.8 mg DTT (0.25 mM final)

Any or all of the above may be added to 100 ml of the homogenization, suspension, and gradient media, before adjusting the pH.

Titanium oxysulfate reagent

Dissolve 5.56 ml of 18 M H_2SO_4 in ~90 ml H_2O (1 M final). Add 0.225 g titanium oxysulfate (2.25 g/liter final). Bring to 100 ml with H_2O. Prepare fresh.

CAUTION: *Both the acid and the titanium oxysulfate are highly corrosive. Exercise great care when adding pure H_2SO_4 to water. Use a face mask and protective gloves (not disposable plastic gloves, as any splashes will cause them to "melt" and adhere to the skin).*

Tris/BSA solution

To 100 ml H_2O add:
0.2 g bovine serum albumin (1 g/liter final)
4.0 ml 1.0 M Tris·Cl (*APPENDIX 2A*; 20 mM final)
Adjust pH to 7.0
Add H_2O to 200 ml
Prepare fresh

COMMENTARY

Background Information

As a general rule, metabolic studies on liver, heart, or muscle mitochondria are carried out on organelles prepared by differential centrifugation (see *UNIT 3.3*). Density-gradient separations, although undoubtedly able to provide a more pure preparation, are frequently avoided simply because the speed of preparation is the prime consideration. With the exception of the heavy mitochondrial fraction (*UNIT 3.3*), however, these preparations contain significant contamination by other organelles (lysosomes, peroxisomes), sometimes by tubular Golgi elements (if present in the homogenate), and also by some of the more rapidly sedimenting endoplasmic reticulum vesicles. Such contamination can only be reduced by gradient centrifugation. The use of higher relative centrifugal forces (RCFs) to sediment the mitochondria from the postnuclear supernatant results in higher contamination. Gradients are also very useful if analytical work is to be carried out to determine the localization of a particular component or function. In this case, the distribution

Table 3.4.1 Density (g/ml) of Major Organelles from Mammalian Liver in Iodixanol, Sucrose, and Percoll

Particle	Density in iodixanol	Density in sucrose	Density in Percoll
Nuclei	1.23-1.25	>1.32	NA[a]
Peroxisomes	1.18-1.21	1.19-1.23	1.075-1.085
Mitochondria	1.14-1.16	1.17-1.21	1.085-1.100
Lysosomes	1.11-1.13	1.19-1.21	1.105-1.111
Golgi	1.03-1.08	1.05-1.12	1.03-1.105

[a]Not available.

of the component or function in the gradient is compared with known markers for the different organelles.

Table 3.4.1 compares the density of mammalian liver mitochondria and other organelles in sucrose, iodixanol, and Percoll. In sucrose, the density of mitochondria overlaps that of lysosomes and peroxisomes. As mitochondria (and lysosomes) sediment through a sucrose gradient, their densities rise to a limiting value as water is removed from their enclosed spaces by the high and rising osmolarity of the gradient. In other media that are true solutes (e.g., Nycodenz and iodixanol) and that can provide gradients of much lower osmolarity, the density of these organelles are lower and more distinctive (Ford et al., 1983; Graham et al., 1990, 1994). Peroxisomes present an exception to this rule; because they do not have an osmotic space in these media, their density is almost identical in sucrose, Nycodenz, and iodixanol (Graham et al., 1994). Although both Percoll and iodixanol can provide isoosmotic gradients over the entire density range of these organelles, the densities of organelles in Percoll are lower. In iodinated density-gradient media, the density of the major organelles always increases in the order lysosomes, mitochondria, peroxisomes. In Percoll the order is sometimes completely reversed (Symons and Jonas, 1987), and in other cases the mitochondria are denser than the lysosomes (Singh et al., 1987). The reason for these differences is not clear. Hence, the popularity of Percoll methods whose efficiency relies as much on the higher sedimentation rate of the mitochondria as on their banding density.

The continuous sucrose gradient system in a vertical rotor used by Vamecq and Van Hoof (1984) can resolve mitochondria and peroxisomes reasonably well. Lysosomes, however, band broadly between these two organelles unless their density can be reduced by prior injection of the animals with Triton WR1339 (85 mg/100 g body weight) 3 to 5 days before sacrifice (Leighton et al., 1968). Diczfalusy and Alexson (1988) used this approach, which makes the lysosomes significantly less dense than the mitochondria. A discontinuous sucrose gradient system was developed by Beauvoit et al. (1989) for yeast and might be applicable to other source materials (see Basic Protocol 1).

A major advantage of using Percoll for the density purification of mitochondria is that the medium forms self-generated gradients at relatively low *g* forces. Thus, the centrifugation conditions that are required are not unlike those used for purification through preformed gradients of other gradient media. One of the problems of using Percoll, however, is the significant overlap of mitochondria and endoplasmic reticulum (ER; Patel et al., 1991). The method of Hovius et al. (1990) uses a relatively low RCF (10,000 × *g* for 10 min) to produce the crude mitochondrial fraction in order to reduce the ER content (see Basic Protocol 3). In an alternative approach, Reinhart et al. (1982) separated the mitochondria principally on the basis of sedimentation rate in a preformed four-step discontinuous gradient of 19%, 31%, 42%, and 52% (v/v) Percoll (Alternate Protocol). Centrifugation was carried out at 37,000 × *g* for just 30 sec, so that the ER vesicles did not have time to reach their banding density. Although this method permits the use of a whole homogenate, only 2 ml can be loaded onto a single 11-ml gradient. A similar sedimentation rate approach was used by Sims (1990) for rat brain mitochondria (see Basic Protocol 2), and the slightly longer centrifugation time of 5 min is probably easier to standardize. Because of the speed of these Percoll systems, the mitochondria tend to display good respiratory control.

Generally speaking, although Percoll gradients can be tailored to the isolation of a particular organelle (e.g., mitochondria), they are less well suited to producing relatively pure fractions of other organelles simultaneously. Both Nycodenz and iodixanol are better suited to this

purpose. A linear gradient of iodixanol from 10% to 30% (w/v) was first developed by Graham et al. (1994), in which the crude mitochondrial fraction was loaded in 35% iodixanol beneath the gradient and centrifuged at ~50,000 × *g* for 1.5 hr. Although this may be a good starting point, it is now recognized that a more shallow gradient (19% to 27%) is probably better for resolving the mitochondria and lysosomes, and indeed this range of gradient concentration is not unlike the discontinuous metrizamide system used by Wattiaux et al. (1983). Note that the density of liver mitochondria in iodixanol is slightly lower than in Nycodenz (Graham et al., 1994).

A significant advantage of iodixanol (and Nycodenz) over Percoll is that, as long as the organelles are sufficiently concentrated in the gradient fractions, the gradient solute does not have to be removed prior to enzyme analysis using visible wavelength spectrophotometry. Because of the light-scattering properties of Percoll, this medium must be removed prior to such analysis, and since the RCFs required to pellet both Percoll particles and organelles are similar, significant loss of organelles can occur (Osmundsen, 1982).

Critical Parameters and Troubleshooting

Density-gradient centrifugation

See *UNIT 3.3* for information regarding the preparation of crude mitochondrial fractions by differential centrifugation.

The preparation of a preformed continuous gradient (see Basic Protocols 1 and 4) using a two-chamber gradient maker requires considerable practice to achieve highly reproducible gradients; some of the important points in operating such devices are covered by Dobrota and Hinton (1992). A Gradient Master, which involves simply layering the most dense and lightest solutions in the centrifuge tube, provides a more expensive but reproducible alternative. If neither of these are available, a discontinuous gradient constructed from three or four solutions spanning the required density range can be prepared and allowed to diffuse. Note that the time required for complete linearity to be achieved will depend on the tube diameter and the volume of each layer. Often this carried out at 4°C overnight without any consideration as to whether the timing is optimal. Always collect a blank gradient and check (by refractive index) that the gradient is indeed linear and covers the appropriate density range.

Although the sample is layered under the iodixanol gradient (see Basic Protocol 4), overlayering can be used as an alternative and may even be beneficial if the separation of the organelles needs to be carried out partly on the basis of sedimentation rate (as with Basic Protocol 2). However, with overlaying, care may be required to avoid overloading the gradient, especially if the top of the gradient is adjusted to a lower density in order to customize the method to a particular source material. Overloading occurs when the total density of the sample layer (liquid plus particles) is greater than that of the top of the gradient; as a consequence, the sample falls through the gradient as a droplet. This is very unlikely to occur in Basic Protocol 1, as the top of the gradient is quite dense.

Self-generated gradients (see Basic Protocol 3) form optimally in tubes of relatively short sedimentation path length. Use of a rotor and gradient volume other than those recommended will mean that the density profile of the gradient, and consequently the separation of the organelles, will be altered. For self-generated Percoll gradients, fixed-angle rotors with an angle of ~24° appear to be the best suited.

It is possible that the density of organelles from other sources (e.g., cultured cells) may be sufficiently different for sucrose gradients to provide some degree of resolution. Poor resolution of organelles may occur as a result of an inappropriate density gradient, but it is just as likely that the basic problem lies with the earlier homogenization and differential centrifugation. A homogenate containing 0.25 M sucrose/10 mM HEPES-NaOH, pH 7.4/1 mM EDTA is suitable; the presence of KCl is permissible, but buffers containing Mg^{2+} should be avoided. If Mg^{2+} is essential for the homogenization of a cultured cell, then the mitochondria should be treated as described in *UNIT 3.3*. It is particularly difficult to predict the precise density of organelles separated from cells that have been homogenized in hypoosmotic conditions. In such circumstances, the Basic Protocols should only be regarded as a suitable starting point.

Enzyme assays

Prior to the execution of an enzyme assay (or other measurement), it is common practice

to remove the gradient medium from each gradient fraction by dilution with 2 to 4 volumes of a low-density medium, centrifugation to pellet the organelles, and resuspension in the same low-density medium. The latter is often the homogenization medium or, if it is isoosmotic, a medium used for the subsequent assay. This practice eliminates any possible interference of the gradient medium on the subsequent procedure(s), and it is described in the final steps of each Basic Protocol. In many instances, however, the sample volumes used in the assay are sufficiently small (as in the Support Protocols), that the gradient solute is sufficiently diluted not to cause any interference in the assay, even at the highest density. Thus, so long as the concentration of organelles in the gradient fraction is high enough for the enzyme activity to be detectable, the assay may be performed directly without washing. If, however, either of these requirements are not met, then dilution, pelleting, and resuspension of the pellet in a smaller volume are unavoidable. In the case of Percoll gradients, it is essential to remove the gradient medium prior to any spectrophotometric analysis to avoid variable interference from light scattering. It should also be pointed out that during these postgradient manipulations losses of functional activity can occur. If the assays are carried out in microcentrifuge tubes (as in the Support Protocols) a convenient strategy, which minimizes these losses, is to dilute and centrifuge (maximum speed) the organelles from an appropriate volume of gradient fraction and to use the resuspended pellet directly in the assay.

The only notable source of error in the enzyme assays themselves concerns the β-galactosidase assay. The stop solution for this assay should not have a pH >10; higher pH causes hydrolysis of the substrate.

In order to determine specific activities of measured enzymes, it is also necessary to estimate the protein content of fractions. Most gradient media interfere to varying extents with methods using the Folin-Ciocalteu reagent, although as with the enzyme assays, if by using small volumes (≤100 µl) of fraction in a 1 to 2 ml assay volume the concentration of gradient solute in the assay solution is <10% (w/v), the interference is marginal. Methods based on Coomassie blue are generally unaffected by any concentration of gradient solute, although because of light-scattering problems, it is always advantageous to remove any Percoll.

With the sample volumes used in Support Protocols 1 to 3, the gradient solute is sufficiently diluted to not cause any inhibition of enzyme activity, even at the highest density. If the gradient fraction must be concentrated, the organelles must be pelleted after dilution of the fraction with 2 volumes of an isoosmotic buffer (buffered 0.25 M sucrose is normally adequate). As the assays are carried out in microcentrifuge tubes, a good and convenient strategy is to pellet the particles in a microcentrifuge for 15 to 20 min at 4°C, then suspend the pellet directly in the enzyme assay buffer.

Anticipated Results

Basic Protocol 1

With rat liver, Triton WR1339 shifts the density of lysosomes in sucrose to ~1.15 to 1.17 g/ml (~0.4 g/ml lower than in the normal animal; Table 3.4.1), while mitochondria and peroxisomes are unchanged at 1.17 to 1.21 g/ml and 1.19 to 1.23 g/ml, respectively. Typical separations that might be achieved from normal and Triton-treated animals are shown in Figure 3.4.1 and Figure 3.4.2, respectively. The lysosomes in the Triton WR1339–treated animals are clearly and significantly shifted to lower densities (Diczfalusy and Alexson, 1988) compared to those from the untreated animal (Vamecq and Van Hoof, 1984).

Basic Protocol 2 and Alternate Protocol

In the case of liver mitochondria (Reinhart et al., 1982), ~60% of total mitochondria band at the lowest interface. The major contamination is from peroxisomes and lysosomes (~10% of total; see Table 3.4.2), whereas there is essentially no contamination from either endoplasmic reticulum or plasma membrane. All the enzyme markers for organelles other than mitochondria are broadly distributed across the other interfaces. Although the corresponding band from rat brain (Sims, 1990) only contains ~12% of the total mitochondria, many of these are present in synaptosomes, which band at a much lower density. The author found only 0.3% of the total lactate dehydrogenase and 0.1% of the total 2′,3′-cyclic nucleotide-3′-phosphodiesterase in the bottom interfacial material, attesting to very low contamination by synaptosomes or myelin, respectively.

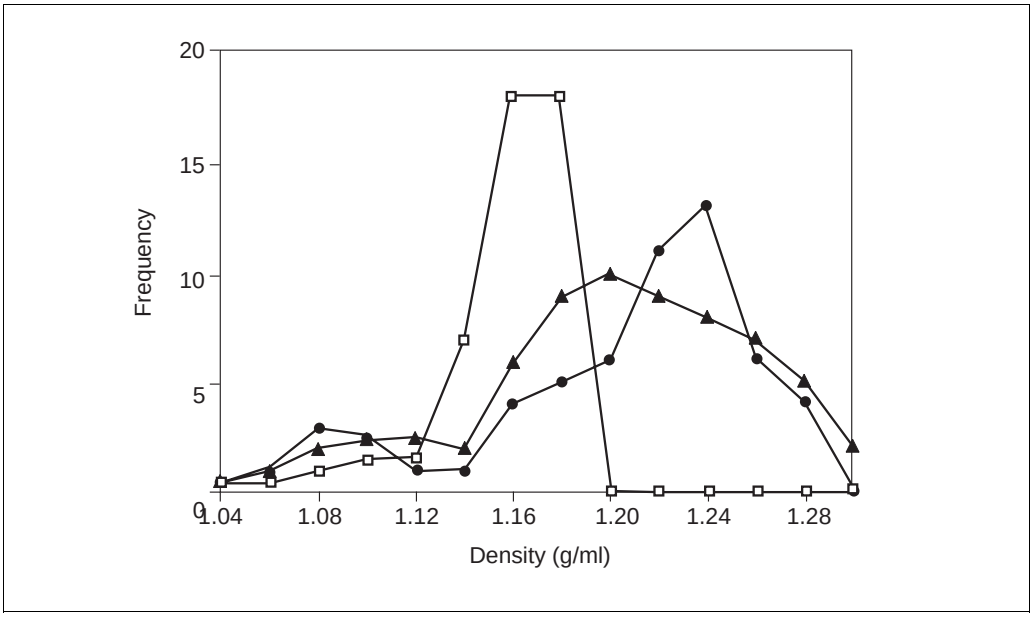

Figure 3.4.1 Frequency distribution of enzyme markers after separation of a crude mitochondrial fraction in a sucrose gradient. Cytochrome *c* oxidase (mitochondria; open squares); *N*-acetyl-β-glucosaminidase (lysosomes; filled triangles); catalase (peroxisomes; filled circles). Data from Vamecq and Van Hoof (1984). Frequency is the amount of enzyme in a fraction divided by the density interval covered by the fraction.

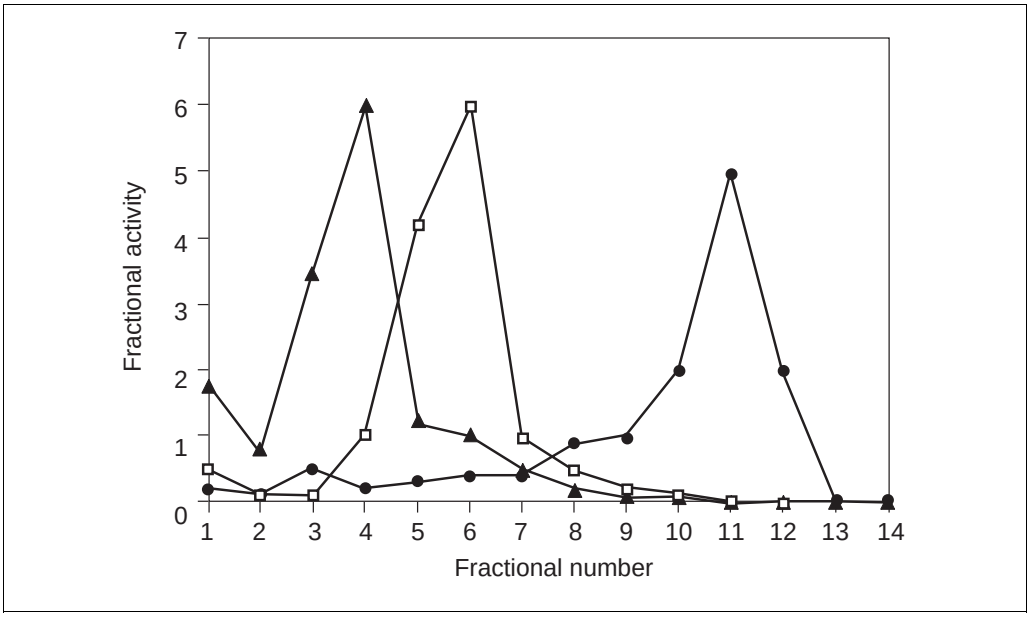

Figure 3.4.2 Fractional activity of enzyme markers after separation of a crude mitochondrial fraction from Triton WR1339–treated rats. Cytochrome *c* oxidase (mitochondria; open squares); *N*-acetyl-β-glucosaminidase (lysosomes; filled triangles); catalase (peroxisomes; filled circles). Fraction 1 is the top of the gradient; data from Diczfalusy and Alexson (1988).

Basic Protocol 3

An ~5-fold enrichment of succinate dehydrogenase is expected in the mitochondrial band over the homogenate, while marker enzymes characteristic of contaminating organelles are significantly depleted (Hovius et al., 1990).

Basic Protocol 4

Figure 3.4.3 describes a typical separation with rat liver on a preformed iodixanol gradient. Fractions 6 to 8 in the middle of the gradient contain >50% of the total mitochondria recovered from the gradient. This gradient also provides an excellent enrichment of lysosomes in fraction 2, and although the peroxisomes are rather broadly banded in the bottom of the gradient, the bottom five fractions contain very little contaminating enzyme markers. This gradient would therefore be very useful analytically as well as preparatively.

Time Considerations

There are no obvious points at which any of the Basic Protocols can be discontinued. Preformed gradients should be made up during the initial differential centrifugation of the homogenate and kept on ice until required. If they are prepared at room temperature, they must be given time to cool down to 4°C. The enzyme marker assays need not be carried out immediately; overnight storage of mitochondria at 4°C is permissible unless metabolic studies are also to be carried out. Enzyme markers can be measured on previously frozen material, but any concentration of the organelle fractions and/or removal of gradient medium must be carried out prior to freezing.

Table 3.4.2 Marker Enzyme Content of a Rat Liver Mitochondrial Fraction after Discontinuous Percoll Gradient Separation[a]

Enzyme marker	Percent of total recovered
Cytochrome *c* oxidase	55
Glucose-6-phosphatase	2
5′-Nucleotidase	4
Acid phosphatase	8
Catalase	11

[a]Data from Reinhart et al. (1982).

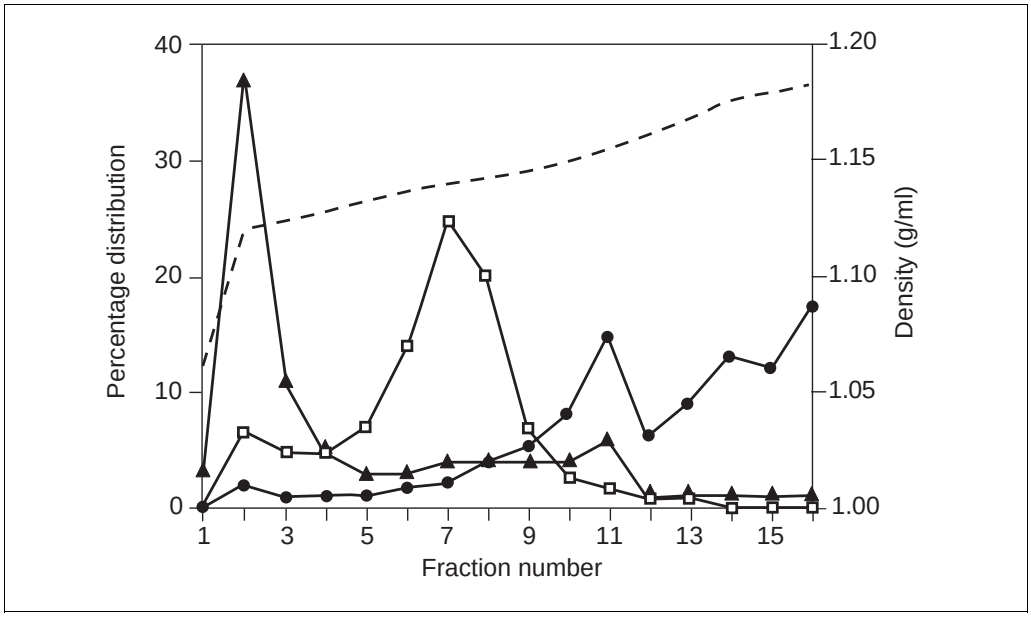

Figure 3.4.3 Percent distribution of enzyme markers after separation of a crude mitochondrial fraction in a preformed continuous iodixanol gradient. Succinate dehydrogenase (mitochondria; open squares); β-galactosidase (lysosomes; filled triangles); catalase (peroxisomes; filled circles).

The figures for the total time (given below) required to complete the gradient separation of mitochondria, include preparation of the homogenate (but omit the optional step of removing the gradient medium) and are calculated for a single rat liver. It is assumed that any preparation of either preformed or continuous gradients is carried out during the periods of differential centrifugation. With the exception of Basic Protocol 2 and Alternate Protocol, total preparation time is probably 3.5 to 4.5 hr. The very short gradient centrifugation times in Basic Protocol 2 and Alternate Protocol mean that overall times are reduced to 2 to 3 hr and 1 to 2 hr respectively. Although the number of pre-gradient operations in Alternate Protocol are also reduced, time has to be taken for preparing a larger number of multi-step discontinuous gradients.

Harvesting the banded organelles from the gradients with a syringe and metal cannula only takes a few minutes, while complete unloading of a single tube into a series of equivolume fractions will take 15 min per tube. Removal of the medium, by washing the pellet once, will add a further 0.5 to 1.0 hr depending on the number of fractions being handled.

All solutions can be made up ahead of time and stored at 4°C for 1 to 2 days or frozen to –20°C for longer periods (2 to 3 months). However, note that any enzymes, BSA, PMSF, or other protease inhibitors should be added immediately prior to use.

Isolation of Peroxisomes from Tissues and Cells by Differential and Density Gradient Centrifugation

Almost without exception, the purification of peroxisomes from a mammalian tissue homogenate is carried out in two stages: (1) differential centrifugation to produce a light mitochondrial fraction and (2) resolution of the light mitochondrial fraction in some form of density gradient. Iodinated density gradient media (e.g., iodixanol) are preferred for the second phase of the purification (see Commentary). Moreover, because the difference in density between mitochondria and peroxisomes is greater in iodixanol than in Nycodenz, and because the osmolarity of the gradients can be more easily controlled with iodixanol, it is the medium of choice. The much wider use of Nycodenz merely reflects the fact that it has been commercially available for more than 15 years, while iodixanol (OptiPrep) has only been available since 1994.

The unit first describes the homogenization and differential centrifugation process for the most commonly used source material—rat liver (see Basic Protocol 1). This protocol serves as a preliminary methodology for all of the density gradient separations subsequently outlined. Next described is a preformed, continuous iodixanol gradient system for isolation of peroxisomes (see Basic Protocol 2). Iodixanol can also be used as a self-generated gradient (see Alternate Protocol 1). Methods are also presented for the use of Nycodenz: a protocol for a continuous Nycodenz gradient (see Basic Protocol 3) and for a simple Nycodenz barrier (see Alternate Protocol 2) are included. The relative merits of these protocols are discussed in the Commentary. There are a large number of published methods based on Nycodenz and there is variation in both the precise density range covered by the gradients and the centrifugation conditions; some of these are described in the italicized annotations to the appropriate steps of the Nycodenz protocols.

Lastly, the unit describes the isolation of peroxisomes from yeast (see Basic Protocol 4) and cultured monolayer cells (see Basic Protocol 5). In the case of mammalian cultured cells, the differential centrifugation system is truncated and a post-nuclear supernatant is used as the gradient input.

After collecting the banded material in the gradients, the success of the fractionation is routinely measured by assaying for various marker enzymes: catalase (peroxisomes), succinate dehydrogenase (mitochondria), and acid phosphatase or a glycosidase such as β-galactosidase (lysosomes). These assays are provided in *UNIT 3.4*. Although the endoplasmic reticulum (ER) is not a major contaminant of the light mitochondrial fraction, some ER is always present, and therefore an assay for a suitable marker such as NADPH–cytochrome *c* reductase or glucose-6-phosphatase is recommended. This problem becomes more significant if a post-nuclear fraction is loaded on to the gradient.

NADPH–cytochrome *c* reductase is ubiquitously found in the ER, while glucose-6-phosphatase is only present in significant amounts in the ER from liver and kidney. NADPH–cytochrome *c* reductase is also considerably easier to measure than is glucose-6-phosphatase; a method is included for assay of this oxidoreductase (see Support Protocol).

BASIC PROTOCOL 1

ISOLATION OF A LIGHT MITOCHONDRIAL FRACTION FROM RAT LIVER

A standard homogenization medium such as 0.25 M sucrose/1 mM EDTA/10 mM HEPES-NaOH, pH 7.4, is satisfactory for a tissue such as liver, and may be chosen particularly if other organelles are to be isolated from the same homogenate. However if the aim is solely to isolate peroxisomes, the medium is supplemented with 0.1% ethanol to aid the recovery of functionally intact organelles, and the preferred buffer is often MOPS rather than HEPES (or Tris). Sometimes 1 to 5 mM KCl is also included, and the supplementation of any medium with protease inhibitors is at the discretion of the investigator. A standard three-step differential centrifugation system is described, although some workers use a two-step system (see Commentary for more information).

The following protocol is suitable for a single 10- to 12-g liver.

NOTE: All protocols using live animals must be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) or must conform to government regulations regarding the care and use of laboratory animals.

Materials

150- to 200-g Sprague-Dawley rats
Homogenization medium (HM; see recipe)
Protease inhibitors (optional; see recipe) added to any or all solutions at concentrations indicated in recipe

Dissecting equipment
Overhead high-torque electric motor (thyristor-controlled) for homogenizers
Potter-Elvehjem homogenizer (clearance ~0.09 mm), 25-ml working volume, prechilled
Dounce homogenizer (loose-fitting Wheaton type B pestle, ~30 ml), prechilled
Dounce homogenizer (loose-fitting Wheaton type B pestle, ~5 ml), prechilled
Low-speed refrigerated centrifuge with swinging-bucket rotor accommodating 50-ml tubes
40- to 50-ml polycarbonate centrifuge tubes
High-speed refrigerated centrifuge with fixed-angle rotors accommodating 50-ml tubes (e.g., Sorvall SS-34)

NOTE: All solutions, glassware, centrifuge tubes and equipment should be pre-cooled to 0° to 4°C and kept on ice throughout. Centrifuge rotors should be precooled to the same temperature. When handling the glass vessel of the Potter-Elvehjem homogenizer, a thermally insulated glove or silicone rubber hand protector should be used, not only to avoid heat transfer from the skin but also to protect the hand in the unlikely event of breakage of the vessel.

Isolate liver

1. Starve the animal overnight.
2. Sacrifice the animal by cervical dislocation or decapitation.

   This must be supervised or carried out by an experienced animal technician.

3. Open the abdominal cavity and remove the liver to a chilled beaker containing ~20 ml of ice-cold HM.
4. Decant the medium and finely mince the liver using scissors.

   The pieces of liver should be no more than ~25 mm^3 each.

Homogenize liver

5. Suspend the mince in ~40 ml of HM and transfer half of this suspension to the glass vessel of the Potter-Elvehjem homogenizer.

   The motor should be mounted either to a wall, via a G-clamp to the bench, or in a floor-standing cradle. Attachment to a free-standing retort stand is not adequate.

6. Attach the cold pestle to the electric motor and homogenize the liver mince using 4 to 5 up-and-down strokes of the pestle, rotating at ~500 rpm.

7. Decant the homogenate into a beaker on ice, and after rinsing the homogenizer with medium and wiping the pestle to remove any connective tissue that may be adhering, repeat steps 5 and 6 with the other half of the mince and combine the homogenates.

Isolate light mitochondrial fraction

8. Centrifuge the homogenate 10 min at 750 × *g*, 0° to 4°C, in the low-speed centrifuge.

   Steps 8 to 12 are omitted in the two-step protocol (see Commentary). Proceed directly to step 13, centrifuging the homogenate from step 7 in the high-speed centrifuge at 3500 × g.

9. Decant and retain the supernatant.

10. Resuspend the pellet in 20 ml of HM, first using a glass rod and then more completely using 3 to 4 gentle strokes of the pestle of the 30-ml Dounce homogenizer.

11. Centrifuge, decant, and retain the supernatant (steps 8 and 9).

12. Combine the supernatants from steps 9 and 11 and transfer to 40- to 50-ml polycarbonate tubes.

13. Centrifuge 10 min at 3500 × g, 0° to 4°C, in the high-speed centrifuge.

14. Decant and retain the supernatant.

    In the two-step method the pellet from this step should be resuspended in HM as in step 10, centrifuged at 3500 × g as in step 13, the supernatant decanted as in step 14, and the two supernatants combined.

Fractionate liver homogenate

15. Centrifuge the 3500 × *g* supernatant(s) from step 14 in the high-speed centrifuge, 20 min at 23,000 × *g*, 0° to 4°C.

16. Decant and discard the supernatant.

    If a microsomal fraction is required for complete bookkeeping, centrifuge this supernatant plus the supernatant from step 18 for 45 min at 100,000 × g.

17. Resuspend the light mitochondrial pellet (LMP) in HM (~20 ml) using a glass rod followed by 3 to 4 gentle strokes of the pestle of the 30-ml Dounce homogenizer.

18. Recentrifuge 20 min at 23,000 × *g*, 0° to 4°C, and discard the supernatant.

19. Resuspend the LMP in HM (~6 ml) using a glass rod and then 3 to 4 gentle strokes of the pestle of the 5-ml Dounce homogenizer (do this in two batches).

    This is equivalent to ~0.5 ml per gram of liver tissue. Use this for all subsequent density-gradient separations of rat liver peroxisomes.

BASIC PROTOCOL 2

ISOLATION OF PEROXISOMES FROM A RAT LIVER LIGHT MITOCHONDRIAL FRACTION USING A PREFORMED CONTINUOUS IODIXANOL GRADIENT

In the past, both metrizamide (e.g., Völkl and Fahimi, 1985; Wanders et al., 1986) and Nycodenz gradients (see Basic Protocol 3) have been used to purify peroxisomes from mammalian liver, but improved resolution can be achieved with iodixanol gradients (Graham et al., 1994; Van Veldhoven et al., 1996). Peroxisomes can be purified from a light mitochondrial fraction in preformed continuous 20% to 40% (w/v) iodixanol gradients at high yield (80% to 90%), with no detectable contamination from any other organelle. In this protocol, which is adapted from the method of Van Veldhoven et al. (1996), the gradient has been designed to be accurately isoosmotic over its whole range, by inclusion of an inverse gradient of sucrose. Because of the large difference in density between the peroxisomes and the other organelles, the separation can be carried out easily in open-topped tubes for a fixed-angle rotor. This considerably simplifies the loading procedures and also increases the capacity of the system. Since the peroxisomes are the densest organelle in the light mitochondrial fraction, it is normal practice to unload the gradient dense-end-first.

Materials

Iodixanol gradient solutions A, B, and C (see recipe)
Light mitochondrial pellet (LMP) suspension (see Basic Protocol 1)
Homogenization medium (HM; see recipe)
Protease inhibitors (optional; see recipe) added to any or all solutions at concentrations indicated in recipe

Gradient maker: two-chamber or Gradient Master (Accurate Chemical)
5-ml syringe with metal cannula (1-mm i.d.).
Ultracentrifuge and thick-walled polycarbonate tubes (30-ml) for a fixed-angle rotor (e.g., Beckman 60 Ti or Sorvall T-865)
Gradient unloader for dense-end-first collection (thin metal cannula connected to a peristaltic pump)

Additional reagents and equipment for protein assay (*APPENDIX 3B*)

NOTE: All solutions, glassware, centrifuge tubes and equipment should be precooled to 0° to 4°C and kept on ice throughout. Centrifuge rotors should be precooled to the same temperature.

1. Using the two-chamber gradient maker (or Gradient Master) prepare two linear gradients from 9 ml each of iodixanol gradient solutions B and C in the thick-walled polycarbonate tubes for the ultracentrifuge rotor.

   Alternatively, a continuous gradient can be generated from a discontinuous one by diffusion. Layer equal volumes of 20%, 25%, 30%, 35%, and 40% (w/v) iodixanol and let stand 16 hr at 4°C.

2. Using a syringe and metal cannula, underlayer each gradient with 2 ml of gradient solution A.

   If thin-walled tubes, which require complete filling, are used the volume of solution A may need to be increased.

3. Layer 3 ml of the LMP suspension over each gradient and ultracentrifuge 1 hr at 105,000 × *g*, 0° to 4°C.

   If the centrifuge has a slow acceleration facility use a program that allows the rotor speed to increase from 0 to 2000 rpm over a period of ~4 min.

4. Allow the rotor to decelerate from 2000 rpm without the brake (or on a controlled deceleration program) and collect the gradient in 1-ml fractions, dense-end-first, by aspiration using the gradient unloader.

   Thin-walled tubes may be unloaded by tube puncture.

   Peroxisomes have a median density of ρ *= 1.17 g/ml in iodixanol; the peak fraction is 7 to 8 ml from the bottom.*

5. Dilute the fraction(s) with ≥2 vol of HM and centrifuge 20 min at 30,000 × *g*, 0° to 4°C.

6. Perform a protein assay (*APPENDIX 3B*) on an aliquot of the pellet(s) resuspended in 1 to 2 ml of HM or other suitable medium, then adjust the volume to 1 to 5 mg protein/ml.

   Metabolic assays should be carried out as soon as possible upon preparation; some marker enzyme assays can be carried out after storage at 4°C for up to 16 hr. Many assays can be carried out on material frozen to –20° or –80°C; always check that any measurements are unaffected by the storage conditions by comparing with those made on fresh material.

ISOLATION OF PEROXISOMES FROM A RAT LIVER LIGHT MITOCHONDRIAL FRACTION IN A SELF-GENERATED IODIXANOL GRADIENT

ALTERNATE PROTOCOL 1

The LMP suspension is mixed with OptiPrep to a starting iodixanol concentration of 25% (w/v) and centrifuged in a vertical, near-vertical, or low-angle fixed-angle rotor in tubes of ~12 ml volume at ~180,000 × *g* for 2 to 3 hr (depending on rotor type). The protocol is adapted from Graham et al. (1994).

Additional Materials *(also see Basic Protocol 2)*

OptiPrep (60%, w/v iodixanol; Life Technologies, Accurate Chemical, Sigma, or Aldrich)
Diluent medium (DM; see recipe)
Vertical (e.g., Beckman VTi 65.1 or Sorvall 65V13), near-vertical (e.g., Beckman NVT 65), or low-angle (20° to 26°) fixed-angle rotor for an ultracentrifuge with 11- to 12-ml sealed tubes

NOTE: All solutions, glassware, centrifuge tubes, and equipment should be precooled to 0° to 4°C and kept on ice throughout. Centrifuge rotors should be precooled to the same temperature.

1. Make a 50% (w/v) iodixanol working solution by diluting 5 vol of OptiPrep with 1 vol of DM.

2. Mix equal volumes of 50% (w/v) iodixanol stock and LMP suspension by repeated gentle inversion.

3. Transfer to a suitable sealed tube.

4. Centrifuge 1.5 to 3 hr at 180,000 × *g*, 0° to 4°C, in vertical, near-vertical, or low-angle fixed angle rotor.

   The time will depend on the sedimentation path length of the rotor. For a vertical or near-vertical rotor with a path length of 17 to 25 mm, 1.5 hr will be sufficient; for longer path-length fixed-angle rotors the time will be up to 3 hr. The aim is to generate a gradient that is shallow in the middle to allow satisfactory separation of peroxisomes and mitochondria (see Commentary).

5. Decelerate the rotor from 2000 rpm to rest either using a controlled deceleration program or without the brake to allow a smooth reorientation of the gradient.
6. Collect the gradient, dense-end-first, in ~1-ml fractions by tube puncture or aspiration.

   The peroxisomes band in the bottom third of the gradient.
7. Dilute the fraction(s) with ≥2 vol of HM and centrifuge 20 min at 30,000 × *g*, 0° to 4°C.
8. Perform a protein assay (*APPENDIX 3B*) on an aliquot of the pellet(s) resuspended in 1 to 2 ml of HM or other suitable medium, then adjust the volume to 1 to 5 mg protein/ml.

   Metabolic assays should be carried out as soon as possible upon preparation; some marker enzyme assays can be carried out after storage at 4°C for up to 16 hr. Many assays can be carried out on material frozen to −20° or −80°C; always check that any measurements are unaffected by the storage conditions, by comparing with those made on fresh material.

BASIC PROTOCOL 3

ISOLATION OF PEROXISOMES FROM A RAT LIVER LIGHT MITOCHONDRIAL FRACTION USING A PREFORMED CONTINUOUS NYCODENZ GRADIENT

Because the difference in density between peroxisomes and mitochondria in Nycodenz is less than that in iodixanol, it is common practice to use the high resolving power of a vertical rotor. The short sedimentation path length of such rotors permits the use of relatively short centrifugation times at low relative centrifugal forces of 35,000 to 75,000 × *g*. This approach also reduces potential contamination of the peroxisomes by vesicles of the endoplasmic reticulum. Published methods use a variety of gradients and centrifugation conditions, and the following protocol is adapted from a number of these (Appelqvist et al., 1990; Kase and Björkhem, 1989; Prydz et al., 1988; Wilcke and Alexson, 1994).

Materials

20% (w/v) Nycodenz in homogenization medium (HM; see recipe)
50% and 60% (w/v) Nycodenz in high-density diluent (HD; see recipe)
Light mitochondrial pellet (LMP) suspension (see Basic Protocol 1)
Homogenization medium (HM; see recipe)
Protease inhibitors (optional; see recipe) added to any or all of the solutions at concentrations indicated in recipe

Gradient maker: two-chamber or Gradient Master (Accurate Chemical)
5-ml syringe with metal cannula (1-mm i.d.)
Ultracentrifuge with vertical rotor (e.g., Beckman VTi50 or Sorvall 50V39) with appropriate sealed tubes (~39 ml)
Gradient unloader for dense-end-first collection (tube-puncturing device or thin metal cannula connected to a peristaltic pump)

Additional reagents and equipment for protein assay (*APPENDIX 3B*)

NOTE: All solutions, glassware, centrifuge tubes, and equipment should be precooled to 0° to 4°C and kept on ice throughout. Centrifuge rotors should be precooled to the same temperature.

1. Using the two-chamber gradient maker (or Gradient Master) prepare linear gradients from 17 ml each of the 20% and 50% Nycodenz solutions in tubes appropriate for the vertical rotor of the ultracentrifuge.

Alternatively, a continuous gradient can be generated from a discontinuous one by diffusion. Layer equal volumes of 20%, 30%, 40% and 50% (w/v) Nycodenz and let stand for 16 hr at 4°C.

Variants of this gradient include 18% to 50% (Hartl et al., 1985); 13% to 48% (Kase and Björkhem, 1989); 15% to 48% (Prydz et al., 1988); and 25% to 50% (Wilcke and Alexson, 1994).

2. Using the syringe and metal cannula, underlayer the gradient with 2 ml of the 60% Nycodenz as a density cushion.

   A number of published methods used the nonaqueous, low-viscosity Maxidens as a density cushion, but this is no longer readily available commercially.

3. Layer 2 to 3 ml of the LMP suspension on top of the gradient.

4. Centrifuge 75 min at 60,000 × *g*, 0° to 4°C, using programmed acceleration and deceleration to ensure a smooth reorientation of the gradient in the tubes.

   If programmed deceleration is not available then turn off the brake below 2000 rpm.

   Variants of the centrifugation parameters include 20 min at 74,000 × g (Prydz et al., 1988) and 75 min at 35,000 × g (Appelqvist et al., 1990).

   If a vertical rotor is not available, use a swinging-bucket rotor for 2 hr at 70,000 × g (Hartl et al., 1985).

5. Collect the gradient, dense-end-first, in 1- to 2-ml fractions, using a gradient unloader.

   The peroxisomes band close to the bottom of the gradient.

6. Dilute the fraction(s) with ≥2 vol of HM and centrifuge 20 min at 30,000 × *g*, 0° to 4°C.

7. Perform a protein assay (*APPENDIX 3B*) on an aliquot of the pellet(s) resuspended in 1 to 2 ml of HM or other suitable medium, then adjust the volume to 1 to 5 mg protein/ml.

   Metabolic assays should be carried out as soon as possible upon preparation; some marker enzyme assays can be carried out after storage at 4°C for up to 16 hr. Many assays can be carried out on material frozen to −20° or −80°C; always check that any measurements are unaffected by the storage conditions by comparing with those made on fresh material.

ISOLATION OF PEROXISOMES FROM A RAT LIVER LIGHT MITOCHONDRIAL FRACTION USING A NYCODENZ BARRIER

ALTERNATE PROTOCOL 2

This is the simplest of all the systems. There is a tendency for the contamination from mitochondria to be slightly higher than with other systems, and the formation of a pellet rather than a band in a gradient may be detrimental to the integrity of the rather fragile organelles. The method is adapted from Ghosh and Hajra (1986).

Additional Materials *(also see Basic Protocol 3)*

30% (w/v) Nycodenz in high-density diluent (HD; see recipe)
Fixed-angle rotor with ~25-ml thick-walled polycarbonate tubes (e.g., Beckman 55.2 Ti or Sorvall T-865)

NOTE: All solutions, glassware, centrifuge tubes, and equipment should be precooled to 0° to 4°C and kept on ice throughout. Centrifuge rotors should be precooled to the same temperature.

1. Transfer 15 ml of 30% Nycodenz to a 25-ml polycarbonate centrifuge tube.

2. Layer 2 ml of the LMP suspension over the Nycodenz barrier.

3. Centrifuge 1 hr at 130,000 × *g*, 0° to 4°C.

4. Remove all of the supernatant carefully by aspiration and resuspend the pellet in 1 to 2 ml of HM.

   Do not decant the supernatant, since the pellet is not firmly packed.

   Metabolic assays should be carried out as soon as possible upon preparation; some marker enzyme assays can be carried out after storage at 4°C for up to 16 hr. Many assays can be carried out on material frozen to −20° or −80°C; always check that any measurements made are unaffected by the storage conditions by comparing with those made on fresh material.

BASIC PROTOCOL 4

ISOLATION OF PEROXISOMES FROM YEAST SPHEROPLASTS USING A PREFORMED CONTINUOUS NYCODENZ GRADIENT

Although wild-type yeast appears to contain rather few peroxisomes, they can be induced to proliferate, and there are a number of peroxisome gene–deletion strains of the organism (Thieringer et al., 1991; Watkins et al., 1998). Yeast has therefore become an increasingly popular means of investigating peroxisome development. In the following protocol, spheroplasts are homogenized in a sorbitol-containing medium using a Dounce homogenizer. Some variation exists in the sorbitol concentration in this medium; Watkins et al. (1998) used 0.6 M, while Crane et al. (1994) used 1.0 M. As with mammalian liver, a continuous Nycodenz gradient is used to fractionate a light mitochondrial fraction prepared from the homogenate. This method is adapted from Crane et al. (1994) and Watkins et al. (1998).

Materials

Yeast homogenization medium (YHM; see recipe)
15% (w/v) Nycodenz in yeast low-density diluent (YLD; see recipe)
42.5% and 50% (w/v) Nycodenz in yeast high-density diluent (YHD; see recipe)
Yeast low-density diluent (YLD; see recipe)
Yeast high-density diluent (YHD; see recipe)
Protease inhibitors (optional; see recipe) added to any or all solutions at concentrations indicated in recipe

Dounce homogenizer (Wheaton Type B, 40-ml)
Dounce homogenizer (Wheaton Type B, 5- to 10-ml)
Gradient maker: two-chamber or Gradient Master (Accurate Chemical)
5-ml syringe with metal cannula (1-mm i.d.)
Ultracentrifuge with vertical rotor (e.g., Beckman VTi65.1 or Sorvall 65V13) with appropriate sealable tubes (~13 ml)
Gradient unloader for dense-end-first collection (tube-puncturing device or thin metal cannula connected to a peristaltic pump)
High-speed refrigerated centrifuge with fixed-angle rotor to accommodate 50-ml tubes (e.g., Sorvall SS34)

Additional reagents and equipment for preparation of yeast spheroplasts (*UNIT 3.3*) and protein assay (*APPENDIX 3B*)

NOTE: All solutions, glassware, centrifuge tubes, and equipment should be precooled to 0° to 4°C and kept on ice throughout. Centrifuge rotors should be precooled to the same temperature.

Prepare light mitochondrial fraction from spheroplasts

1. Prepare spheroplasts from 1 liter of yeast culture, grown in YPD medium to an OD_{600} of 0.5 to 1.0 (*UNIT 3.3*).
2. Suspend the spheroplasts in 35 ml of yeast homogenization medium (YHM) and homogenize in the 40-ml Dounce homogenizer, using 10 up-and-down strokes of the pestle.

3. Centrifuge the homogenate 10 min at 1500 × *g*, 0° to 4°C.
4. Aspirate and retain the supernatant on ice.
5. Resuspend the pellet in 35 ml of YHM and repeat steps 2 to 4.
6. Combine the two supernatants and centrifuge 30 min at 25,000 × *g*, 0° to 4°C.
7. Resuspend the light mitochondrial pellet in 6 ml of YHM using 10 gentle strokes of the pestle of the small volume Dounce homogenizer.

Separate peroxisomes in Nycodenz gradient

8. Using a two-chamber gradient maker (or Gradient Master) prepare 10.5-ml linear gradients from equal volumes of the 15% and 42.5 % Nycodenz in tubes for the vertical rotor.

   Alternatively, a continuous gradient can be generated from a discontinuous one by diffusion. Layer equal volumes of 15%, 25%, 35%, and 45% (w/v) Nycodenz and let stand for 16 hr at 4°C.

9. Using a syringe and metal cannula, underlayer the gradient with a cushion of 0.5 ml of 50% Nycodenz.
10. Layer the yeast light mitochondrial pellet (step 7) on top to fill the tube.
11. Ultracentrifuge 75 min at 174,000 × *g*, 0° to 4°C. Use controlled acceleration and deceleration programs to ensure a smooth reorientation of the gradient. If these are not available turn off the brake below 2000 rpm.

    Alternative systems include 15% to 37% Nycodenz for 90 min at 118,000 × g in Beckman 50.2Ti rotor (McAlister-Henn et al., 1995) and 15% to 36% Nycodenz and 42% cushion, 1 hr at 100,000 × g in a Sorvall 865B vertical rotor (Thieringer et al., 1991).

12. Collect the gradient in 0.5-ml fractions, dense-end-first, using a gradient unloader.
13. Dilute the fraction(s) with ≥2 vol of YHM and centrifuge 20 min at 30,000 × *g*, 0° to 4°C.
14. Perform a protein assay (*APPENDIX 3B*) on an aliquot of the pellet(s) resuspended in 1 to 2 ml of YHM or other suitable medium, then adjust the volume to 1 to 5 mg protein/ml.

    Metabolic assays should be carried out as soon as possible upon preparation; some marker enzyme assays can be carried out after storage at 4°C for up to 16 hr. Many assays can be carried out on material frozen to −20° or −80°C; always check that any measurements are unaffected by the storage conditions by comparing with those made on fresh material.

ISOLATION OF PEROXISOMES FROM CULTURED CELLS (HepG2) USING A PREFORMED CONTINUOUS NYCODENZ GRADIENT

BASIC PROTOCOL 5

The cultured cells most widely used in peroxisome studies are the human hepatoblastoma line HepG2, and various skin fibroblast lines that are used in investigations into Zellweger syndrome. Both of these lines are grown routinely as a monolayer culture. In view of the fragility of peroxisomes from cultured cells, homogenization techniques such as nitrogen cavitation (Schrader et al., 1994) or the ball-bearing homogenizer (Watkins et al., 1991) devised by Balch and Rothman (1985) are to be preferred. If these are not available, a standard Potter-Elvehjem homogenizer (Cohen et al., 1992) may be used (see Commentary for more information). The following protocol is adapted from Cohen et al. (1992) and Watkins et al. (1991). The buffer used for all the solutions below is the same as that described for rat liver (i.e., MOPS) but Tris and HEPES are also commonly used with cultured cells. Some workers (Aikawa et al., 1991; Wanders et al., 1991; Cohen et al.,

1992) use a post-nuclear supernatant rather than a light mitochondrial fraction—in these cases a larger volume gradient may be necessary (see annotations to the corresponding steps below).

Materials

Suspension of cells (~10^8 cells) in 3 to 5 ml of homogenization medium (HM; see recipe)
Homogenization medium (HM; see recipe)
10% (w/v) Nycodenz in homogenization medium (HM; see recipe)
40% and 50% (w/v) Nycodenz in high-density diluent (HD; see recipe)
Protease inhibitors (optional; see recipe) added to any or all solutions at concentrations indicated in recipe

Ball-bearing homogenizer (see Balch and Rothman, 1985, for details of construction)
Low-speed centrifuge with swinging-bucket rotor to accommodate 10- to 20-ml tubes
Dounce homogenizer (5- to 10-ml, Wheaton type B)
High-speed centrifuge with fixed-angle rotor to accommodate 10- to 14-ml tubes (e.g., Sorvall SE12)
Gradient maker: two-chamber or Gradient Master (Accurate Chemical)
5-ml syringe with metal cannula (1-mm i.d.)
Ultracentrifuge with vertical rotor (e.g., Beckman VTi65.1or Sorvall 65V13) with appropriate sealable tubes (~13-ml)
Gradient unloader for dense-end-first collection (tube-puncturing device or thin metal cannula connected to a peristaltic pump)

Additional reagents and equipment for protein assay (*APPENDIX 3B*)

NOTE: All solutions, glassware, centrifuge tubes, and equipment should be precooled to 0° to 4°C and kept on ice throughout. Centrifuge rotors should be precooled to the same temperature.

Isolate the light mitochondrial fraction

1. Homogenize the cells using five passes from syringe to syringe in the ball-bearing homogenizer.

   Alternatives include a nitrogen cavitation vessel (e.g Artisan Industries) or a Potter-Elvehjem homogenizer (clearance ~0.09 mm), 10-ml working volume.With nitrogen cavitation, use 400 psi for 10 min; with the Potter-Elvehjem homogenizer use 50 up-and-down strokes of the pestle at 1000 rpm.

2. Check by phase-contrast microscopy that cell breakage is ≥90%.

3. Centrifuge the homogenate 5 min at 500 × *g*, 0° to 4°C, in the low-speed centrifuge.

4. Aspirate the supernatant and retain on ice.

5. Resuspend the pellet in HM using 4 to 5 strokes of the pestle of the Dounce homogenizer and repeat steps 3, 4, and 5.

6. Centrifuge the combined supernatants 10 min at 6000 × *g*, 0° to 4°C, in the high-speed centrifuge.

7. Aspirate and recentrifuge the supernatant 15 min at 20,000 × *g*, 0° to 4°C.

8. Aspirate and discard the supernatant and resuspend the light mitochondrial pellet in 3 to 4 ml of HM using 3 to 4 gentle strokes of the pestle of the Dounce homogenizer.

Separate the peroxisomes in Nycodenz gradient

9. Using the two-chamber gradient maker (or Gradient Master) prepare 10-ml linear gradients from equal volumes of the 10% and 40% Nycodenz in tubes for the vertical rotor.

   Alternatively a continuous gradient can be generated from a discontinuous one by diffusion. Layer equal volumes of 10%, 20%, 30% and 40% (w/v) Nycodenz and let stand for 16 hr at 4°C.

   If a post-nuclear supernatant is used rather than a light mitochondrial pellet, then prepare 34-ml gradients.

10. Using the syringe and metal cannula, underlayer the gradient with 0.5 ml of 50% Nycodenz.

11. Layer ~2 ml of the pellet suspension from step 8 on top of the gradient, to fill the tube.

    Alternatively use 4 to 5 ml of a post-nuclear supernatant on the larger gradients.

12. Centrifuge 25 to 35 min at 75,000 × *g*, 0° to 4°C. Use a controlled acceleration and deceleration programs to ensure a smooth reorientation of the gradient. If these are not available turn off the brake below 2000 rpm.

    For fibroblasts, Aikawa et al. (1991) used a 15% to 30% Nycodenz gradient and 1 hr at 305,000 × g in the same rotor.

13. Collect the gradient in 0.75-ml fractions, dense-end-first, using a gradient unloader.

    The peroxisomes band close to the bottom of the tube.

14. Dilute the fraction(s) with ≥2 vol of HM and centrifuge 20 min at 30,000 × *g*, 0° to 4°C.

15. Perform a protein assay (*APPENDIX 3B*) on an aliquot of the pellet(s) resuspended in 1 to 2 ml of HM or other suitable medium, then adjust the volume to 1 to 5 mg protein/ml.

    Metabolic assays should be carried out as soon as possible upon preparation; some marker enzyme assays can be carried out after storage at 4°C for up to 16 hr. Many assays can be carried out on material frozen to −20°C or −80°C; always check that any measurements made are unaffected by the storage conditions by comparing with those made on fresh material.

ASSAY FOR ENDOPLASMIC RETICULUM MARKER ENZYME NADPH-CYTOCHROME *c* REDUCTASE

SUPPORT PROTOCOL

NADPH cytochrome *c* reductase is an important oxidoreductase linked to the oxidative status of the biosynthetic pathways present in the endoplasmic reticulum. Most methods measure the production of reduced cytochrome *c* by monitoring the absorbance at 550 nm. Sometimes NADH is used as an alternative substrate to NADPH, in which case it is normal to include an inhibitor of the mitochondrial oxidation pathway—normally rotenone—to which the endoplasmic reticulum enzyme is insensitive. Indeed, the inclusion of rotenone in the assay is not uncommon when using NADPH as the substrate, to avoid any interference from mitochondrial electron transport. The method is taken from Graham (1993) and adapted from Williams and Kamin (1962).

Materials

Assay buffer (see recipe)
25 mg/ml cytochrome *c* in assay buffer (prepare fresh; keep on ice)
10 mM EDTA (dilute 1 ml 100 mM EDTA stock to 10 ml with H_2O)
1 mg/ml rotenone in ethanol (store up to 1 month at 4°C)
2 mg/ml NADPH in assay buffer (prepare fresh; keep on ice away from light)
Recording spectrophotometer (visible wavelength) with 1-ml cuvettes

1. Bring the assay buffer to room temperature and carry out all operations at this temperature.
2. Adjust the chart recorder to give a 0.2 absorbance unit full-scale deflection.
3. In a 1-ml cuvette, add 50 µl of cytochrome *c*, 10 µl 10 mM EDTA, and 10 µl of 1 mg/ml rotenone to 1 ml of assay buffer.
4. Add up to 50 µl of sample and mix well.

   Neither Nycodenz nor iodixanol interfere with this enzyme at the concentrations that are likely to occur in the assay mixture. If the gradient fractions need to be concentrated, they should be diluted with 2 vol of HM, sedimented by centrifuging 20 min at 35,000 × g, and resuspended in a smaller volume of HM.

5. Record the absorbance at 550 nm until the baseline is steady, then add 0.1 ml of NADPH.

   A double-beam recording spectrophotometer is ideal, but, as single-beam instruments are more commonly available, these steps are designed for such an instrument.

6. Mix well and continue to record the absorbance until a linear increase in value can be measured over a period of 1 to 2 min.
7. Calculate the activity of the enzyme (µmol cytochrome *c* reduced/min) by measuring the slope of the trace.

   The molar extinction coefficient of reduced cytochrome c is 27,000.

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Assay buffer

Dissolve 0.71 g Na_2HPO_4 in 100 ml water (50 mM final). Dissolve 0.68 g KH_2PO_4 in another 100 ml water (50 mM final). Add KH_2PO_4 to Na_2HPO_4 to reach pH 7.7. Store up to 1 to 2 days at 4°C.

Diluent medium (DM)

To 100 ml H_2O add:
12 ml 100 mM disodium EDTA (6 mM final)
60 ml 100 mM MOPS (see recipe; 30 mM final)
1.2 ml ethanol (0.6% v/v final)
Adjust to pH 7.2 with 1 M NaOH
Add H_2O to 200 ml
Store up to 1 to 2 days at 4°C

High-density diluent (HD)

To 100 ml H_2O add:
2 ml 100 mM disodium EDTA (1 mM final)
10 ml 100 mM MOPS (see recipe; 5 mM final)
0.2 ml ethanol (0.1% v/v final)
Adjust to pH 7.4 with 1 M NaOH
Add H_2O to 200 ml
Store up to 1 to 2 days at 4°C

Homogenization medium (HM)

To 100 ml H_2O add:
17.1 g sucrose (0.25 M final)
2 ml 100 mM disodium EDTA (1 mM final)
10 ml 100 mM MOPS (see recipe; 5 mM final)
0.2 ml ethanol (0.1% v/v final)
Adjust to pH 7.2 with 1 M NaOH
Add H_2O to 200 ml
Store up to 1 to 2 days at 4°C

Iodoxinol gradient solutions A, B, and C

These gradient solutions are prepared by mixing the following stock solutions at the volume ratios listed below:

OptiPrep (60% w/v iodixanol; available from Life Technologies, Accurate Chemical and Scientific, Sigma, and Aldrich)
Diluent medium (DM; see recipe)
1 M sucrose (see recipe)

Gradient solution A (50% w/v iodixinol):
5 vol OptiPrep
0.6 vol DM
0.4 vol 1 M sucrose

Gradient solution B (40% w/v iodixanol):
4 vol OptiPrep
0.6 vol DM
0.7 vol 1 M sucrose
0.7 vol H_2O

Gradient solution C (20% w/v iodixanol):
2 vol OptiPrep
0.6 vol DM
1.1 vol 1 M sucrose
2.3 vol H_2O

MES, 100 mM

4.16 g 2-(*N*-morpholino)ethanesulfonic acid (MES)
H_2O to 200 ml
Store up to 2 to 3 months at −20°C

MOPS, 100 mM

4.18 g 3-(*N*-morpholino)propanesulfonic acid (MOPS)
H_2O to 200 ml
Store 2 to 3 months at −20°C

Protease inhibitors

Add the following to solutions as required so that the final concentrations are: 1 mM PMSF and 2.0 µg/ml for each of the other inhibitors. Also see *APPENDIX 1B* for general information on these compounds. All of these stock solutions may be stored in aliquots up to 2 to 3 months at −20°C, except PMSF which should be stored at 4°C.

PMSF: Dissolve 0.348 g phenylmethylsulfonyl fluoride (PMSF; 200 mM final) in 10 ml of dried propan-2-ol or ethanol.

Antipain: Dissolve 10 mg antipain (1 mg/ml final) in 10 ml of 10% (v/v) dimethyl sulfoxide (DMSO).

Aprotinin: Dissolve 10 mg antipain (1 mg/ml final) in 10 ml water.

Leupeptin: Dissolve 10 mg leupeptin (1 mg/ml final) in 10 ml of 10% (v/v) dimethylsulfoxide (DMSO).

Sucrose, 1 M

34.2 g sucrose (1 M final)
Add H_2O to 100 ml
Store up to 1 to 2 days at 4°C

Yeast high-density diluent (YHD)

To 100 ml H_2O add:
8.55 g sucrose (0.125 M final)
15 mg KCl (1 mM final)
2 ml 100 mM disodium EDTA (1 mM final)
10 ml 100 mM MES (see recipe; 5 mM final)
0.2 ml ethanol (0.1% v/v final)
Adjust to pH 6.0 with 1 M NaOH
Add H_2O to 200 ml
Store up to 1 to 2 days at 4°C

Yeast homogenization medium (YHM)

To 100 ml H_2O add:
21.9 g sorbitol (0.6 M final)
15 mg KCl (1 mM final)
2 ml 100 mM disodium EDTA (1 mM final)
10 ml 100 mM MES (see recipe; 5 mM final)
0.2 ml ethanol (0.1% v/v final)
Adjust to pH 6.0 with 1 M NaOH
Add H_2O to 200 ml
Store up to 1 to 2 days at 4°C

Yeast low-density diluent (YLD)

To 100 ml H_2O add:
17.1 g sucrose (0.25 M final)
15 mg KCl (1 mM final)
2 ml 100 mM disodium EDTA (1 mM final)
10 ml 100 mM MES (see recipe; 5 mM final)
0.2 ml ethanol (0.1% v/v final)
Adjust to pH 6.0 with 1 M NaOH
Add H_2O to 200 ml
Store up to 1 to 2 days at 4°C

COMMENTARY

Background information

Differential centrifugation

As with most subcellular organelles, methods for the isolation of peroxisomes have come largely from work with rat liver. With the exception of nuclei and rough endoplasmic reticulum (RER), peroxisomes are the densest of the major subcellular organelles. Peroxisomes are also one of the major components of the light mitochondrial fraction, which is obtained from a homogenate by differential centrifugation. The "classical" differential centrifugation scheme involves four steps: 600 to 1000 × *g* for 10 min (nuclear pellet); 3000 to 4000 × *g* for 10 min (heavy mitochondrial pellet); 15,000 to 25,000 × *g* for 20 min (light mitochondrial fraction); and 50,000 to 100,000 × *g* for 45 min (microsomal pellet). There is considerable variation in the actual RCFs used for each step, and sometimes the isolation of the heavy mitochondrial fraction is omitted. Moreover since the size of peroxisomes is quite diverse (0.2 to 1.0 μm), and as there is evidence for subpopulations of these organelles (Schrader et al., 1994; van Roermund et al., 1995), it is not unusual for the homogenate to be centrifuged at 2000 × *g* for 10 min, followed by 22,000 to 25,000 × *g* for 20 min, in order to pellet as many of the peroxisomes as possible. Unavoidably, some of the more rapidly sedimenting microsomes will also be pelleted. This situation is exacerbated if the RCF is increased; Lyons et al. (1991) used 41,000 × *g* for 30 min to pellet the peroxisomes from a hepatoma homogenate. Although in this case most of the microsomes formed a layer on top of the main organelle pellet, which could be recovered separately, increased microsomal contamination of the light mitochondrial pellet is inevitable with this technique. Some protocols, notably those for cultured cells (e.g., Aikawa et al., 1991; Wanders et al., 1991; Cohen et al., 1992) often use a post-nuclear supernatant rather than a light mitochondrial fraction; in these cases all of the endoplasmic reticulum (ER) will also be present. This unavoidable contamination of the peroxisome-containing fraction by vesicles from the ER is a significant factor, since this influences the choice of density gradient medium.

Density gradient centrifugation

The densities of the major components of the light mitochondrial fraction in a variety of media are given in Table 3.5.1. In iodinated density gradient media such as Nycodenz or iodixanol, the density of peroxisomes is only slightly lower than that in sucrose; on the other hand the densities of the other organelles—mitochondria, lysosomes and Golgi membranes—are significantly higher in sucrose (Graham et al., 1994). The limiting membrane of peroxisomes is freely permeable to small solute molecules; these organelles therefore do not behave as osmotically sensitive particles in low-molecular mass solutes. Hence their observed density is relatively little affected by the osmolarity of the suspending solution and reflects only the macromolecular composition of the particle. The observed density of the mitochondria, lysosomes, and ER vesicles, on the other hand, includes the enclosed water component and is consequently dependent on the osmolarity of the gradient.

Although sucrose gradients are still occasionally used to purify peroxisomes from yeast (e.g., Crane et al., 1994), in the case of mammalian tissues and cells they have been totally superseded by iodinated density gradient media. In sucrose gradients, peroxisomes are significantly contaminated by lysosomes, and this can only be effectively reduced, in the case of rat liver, if the animals are injected with Triton

Table 3.5.1 Density of Organelles of the Light Mitochondrial Fraction in Different Gradient Media

	Density (g/ml)			
Organelle	Sucrose	Nycodenz	Iodixanol	Percoll
Endoplasmic reticulum	1.06-1.23	1.05-1.16	1.03-1.13	1.03-1.06
Golgi membranes	1.05-1.12	1.03-1.08	1.03-1.06	1.03-1.05
Lysosomes	1.19-1.21	1.12-1.15	1.11-1.14	1.06-1.12
Mitochondria	1.17-1.21	1.13-1.16	1.13-1.15	1.05-1.08
Peroxisomes	1.18-1.23	1.17-1.20	1.16-1.19	1.04-1.06

WR1339 to lower the density of the lysosomes (Leighton et al., 1968). Although contamination by mitochondria is less marked, the densest of these organelles consistently overlap the lighter peroxisomes. Consequently, the lower densities of both mitochondria and lysosomes in iodinated density gradient media make these media ideally suited to the purification of peroxisomes. Since about 1985, Nycodenz has been the gradient medium of choice, and the use of preformed gradients in vertical rotors has become an almost standard technique. Vertical rotors, with their short sedimentation path lengths, allow efficient and rapid separations of organelles. Moreover, the hydrostatic pressures in vertical rotors (and low-angle fixed-angle rotors) are much lower than those in swinging-bucket rotors, thus minimizing any potential deleterious effects on the organelles. Although the various published methods using Nycodenz show some minor differences in the density range of the gradient, generally they run from ~1.10 to 1.19 g/ml and include a cushion of density 1.22 to 1.26 g/ml to prevent any peroxisomes reaching the wall of the tube. This is essential for vertical rotors. The centrifugation conditions show the largest discrepancy, varying from 30,000 × *g* for 75 min (Kase and Björkhem, 1989; Appelqvist et al., 1990) to 309,000 × *g* for 60 min (Aikawa et al., 1991). Without exception, the gradients are top-loaded with the sample, and many gradients are centrifuged below 60,000 × *g* for <1 hr. At these relatively low RCFs and times, any endoplasmic reticulum vesicles will probably not reach their equilibrium density banding position, and this may virtually eliminate any potential contamination of the peroxisomes.

Although inverse gradients of sucrose are often used to balance the osmolarity of Nycodenz gradients, at concentrations above 30% w/v (~1.16 g/ml) any Nycodenz solution is hyperosmotic. Iodixanol solutions on the other hand can be made isoosmotic at all densities (Graham et al., 1994); consequently mitochondria and lysosomes have significantly lower densities (Table 3.5.1) in iodixanol than in Nycodenz, and the mitochondria in particular are easier to resolve from peroxisomes. Moreover, the latter are also isolated under isoosmotic conditions. Most organelle separations with iodixanol are carried out in preformed gradients. Although the formation of self-generated gradients of iodixanol is normally carried out at RCFs above 300,000 × *g*, gradients with a relatively shallow median section, which are ideal for peroxisome purification (see Anticipated Results), can be formed at RCFs of 180,000 × *g*, and although the centrifugation time maybe 1.5 to 3 hr (depending on rotor type), the method has the considerable merits of ease of sample preparation and high reproducibility (Graham et al., 1994).

Peroxisomes can also be isolated under isoosmotic conditions in Percoll gradients. Probably because Percoll is a colloidal suspension of silica, rather than a true solute, mammalian peroxisomes behave rather differently: they exhibit a much lower density than in sucrose, Nycodenz, or iodixanol, and they are generally well resolved from both mitochondria or lysosomes (see Table 3.5.1). However, why the density of the major organelles in iodinated density gradient media (lysosomes<mitochondria<peroxisomes) should be essentially reversed in Percoll is not clear. In some nonmammalian systems, however, for example the filamentous hemiascomycete *Ashbya gossypii* (Maeting, et al., 1999), peroxisomes are denser than mitochondria in Percoll.

Although the formation of Percoll gradients has the great merit of self-generation at low RCFs and centrifugation times, a major problem with these gradients is that endoplasmic reticulum vesicles in the light mitochondrial fraction from mammalian tissues always copurify with the peroxisomes (see Table 3.5.1), as evinced by the coincidence of catalase and glucose-6-phosphatase profiles (see for example Schepers et al., 1989). One other problem that is rarely considered is the potential contamination from Golgi membranes in Percoll gradients. In the case of liver in particular, a large proportion of the Golgi will sediment in the LMP. According to Schweizer et al. (1991) the Golgi membranes also band at a low density in Percoll, as they do in iodixanol and Nycodenz (see Table 3.5.1). In Percoll, therefore, they are likely to contaminate the peroxisomes, while in iodixanol (and Nycodenz), Golgi membranes band at the opposite end of the gradient from the peroxisomes.

Moreover, before spectrophotometric assays for peroxisomes (and other organelles) can be carried out, it is usually necessary to remove the Percoll by centrifugation, because of the light-scattering properties of this medium. During this procedure the peroxisomes will also sediment and they are recovered as a loose layer above the Percoll pellet. However Osmundsen (1982) established that this procedure accounted for an approximately 50% loss of the organelles. As long as the organelles are at a

sufficiently high concentration in the gradient fractions, removal of the medium is generally not a strict requirement for either Nycodenz or iodixanol gradients. If the peroxisomes do need to be concentrated or if the medium does interfere with some subsequent procedure, then a simple dilution of the fraction(s) with buffer to reduce the density, followed by pelleting of the organelles, will give high recoveries.

Critical Parameters and Troubleshooting

Homogenization

Only cultured cells may provide a significant homogenization problem. Many monolayer cells can be disrupted in an isoosmotic sucrose medium using relatively mild liquid shear conditions; this minimizes any damage to peroxisomes and loss of intra-organelle components. Watkins et al. (1991) observed that the standard liquid shear techniques of Dounce or Potter-Elvehjem homogenization led to the release of soluble peroxisomal macromolecules from HepG2 cells, and stressed the need to use the more gentle disruptive forces provided by the ball-bearing device of Balch and Rothman (1985). Nevertheless, other workers using the same cells have used up to 50 strokes of the pestle of a Potter-Elvehjem homogenizer (Wanders et al., 1991; Cohen et al., 1992). Nitrogen cavitation is another alternative and was used by Völkl and Fahimi (1985). If only Dounce or Potter-Elvehjem homogenizers are available, a homogenization medium of 0.25 M sucrose/1 mM EDTA/10 mM triethanolamine-acetic acid, pH 7.4 (Marsh et al., 1987), combined with no more than 10 strokes of the pestle of a tight-fitting Dounce homogenizer, has been found to be widely applicable to monolayer cells (and fibroblasts in particular). For a more complete discussion of these problems see Evans (1992) and Graham (1997).

Differential centrifugation

The aim of the homogenization should be to devise conditions such that ≥90% of cells are disrupted with the minimum release of peroxisomal markers into the medium. To check this out, all of the differential centrifugation fractions, including the microsomes and the cytosol (100,000 × *g*/45 min pellet and supernatant), should be assayed for organelle markers and proteins (see Anticipated Results). For tissues or cells other than those described in this unit, always carry out a more thorough differential centrifugation (e.g., 600 × *g*/10 min, 3000 × *g*/10 min, 15,000 × *g*/10 min; 25,000 × *g*/10 min, 40,000 × *g*/10 min) in order to devise the optimal protocol.

Density gradient centrifugation

For a tissue or cell other than one of those described in this unit, it may also be necessary to modulate some of the gradient and/or centrifugation conditions in the light of experience. For example, try making the gradient more or less dense at the bottom to take account of organelles that may be correspondingly more or less dense. Modifications will also need to be made if the type of rotor described in the protocol is not available. If a swinging-bucket or fixed-angle rotor is substituted for a recommended vertical rotor, then the centrifugation times will have to be increased to take account of the longer sedimentation path lengths.

The preparation of preformed continuous gradients using a two-chamber gradient maker requires considerable practice to achieve highly reproducible gradients, and some of the important points in operating such devices are covered by Dobrota and Hinton (1992). A Gradient Master, which involves simply layering the densest and lightest solutions in the centrifuge tube, provides a more expensive but reproducible alternative. If neither of these are available, then a discontinuous gradient constructed from three or four solutions, spanning the required density range, can be prepared and allowed to diffuse, usually overnight at 4ÉC. Note that the time required for complete linearity to be achieved will depend on the tube diameter and the volume of each layer. Always collect a blank gradient and check (using refractive index) that the gradient is indeed linear and covers the appropriate density range.

In self-generated gradients of iodixanol (Alternate Protocol 1), the light mitochondrial fraction is mixed with OptiPrep to a uniform starting concentration of 25% iodixanol; the gradient forms and the particles move to their banding density during the centrifugation. It is important that the gradient generated be relatively shallow in the middle of the gradient (ρ = 1.14 to 1.16 g/ml) to achieve a satisfactory linear separation between the mitochondria and peroxisomes (see Anticipated Results).

Enzyme and other assays

Prior to the execution of an enzyme assay (or other measurement), it is common practice to remove the gradient medium from each gradient fraction by dilution with 2 to 4 volumes of a low-density medium, followed by centrifugation to pellet the organelles and resuspension in

the same low-density medium. The latter is often the homogenization medium, or, if it is isoosmotic, a medium used for the subsequent assay. This practice eliminates any possible interference of the gradient medium on the subsequent procedure(s), and it is described in the final steps of each Basic Protocol. In many instances, however, the sample volumes used in the assay are sufficiently small (as in the Support Protocol) that the gradient solute is adequately diluted so as not to cause any interference in the assay, even at the highest density. Thus, so long as the concentration of organelles in the gradient fraction is high enough for the enzyme activity to be detectable, the assay may be performed directly without washing. If, however, either of these requirements are not met, then dilution, pelleting and resuspension of the pellet in a smaller volume are unavoidable.

In order to determine specific activities of measured enzymes, it is also necessary to estimate the protein content of fractions. Nycodenz and iodixanol interfere with methods using the Folin-Ciocalteu reagent; however, if small volumes (≤100 µl) of fraction are used in a 1- to 2-ml assay volume, the concentration of gradient solute in the assay solution is <10% (w/v) and the interference is marginal. Methods based on Coomassie blue are generally unaffected by any concentration of gradient solute.

The only significant interference of common peroxisome functional assays by Nycodenz (and by implication by iodixanol too) is phytanic acid α-oxidation (Singh et al., 1993).

Anticipated Results

Basic Protocol 1

The expected distribution of the major organelle enzyme markers in the nuclear, heavy mitochondrial, light mitochondrial, microsomal, and cytosolic fractions from a rat liver homogenate is given in Table 3.5.2. If the first 750 × *g* is omitted, the figures for the percent protein and percent enzyme content of the 3500 × *g* pellet will be the sum of the nuclear and light mitochondrial fractions. If the actual RCFs and times used are different from those in Basic Protocol 1, then the data will also be similarly different. Nevertheless, the overall pattern of enzyme content should remain the same. In the case of HepG2 cells, the percent of the total catalase in the light mitochondrial fraction is reported (Watkins et al., 1991) at 32%, and the mitochondria tend to be more prevalent in the heavy mitochondrial fraction (48%) compared to the nuclear fraction (16%). Organelles from a yeast homogenate also conform to this overall pattern.

Basic Protocol 2

Fractions 5 to 14 of the gradient (~10 ml) contain ~85% of the total catalase activity recovered from the gradient (Fig. 3.5.1). There is no detectable contamination from mitochondria, lysosomes, or endoplasmic reticulum in these fractions whatsoever.

Alternate Protocol 1

The bottom seven fractions of the gradient (~5 ml) contain nearly 90% of the total catalase activity recovered from the gradient (Fig. 3.5.2). There is no detectable contamination from mitochondria, lysosomes, or endoplasmic reticulum (not shown), which co-bands with the lysosomes in this gradient.

Basic Protocol 3

There will be some small differences in the precise banding position of the peroxisomes (in terms of the distance from the bottom of the tube) which reflect the density profile of the

Table 3.5.2 Protein and Enzyme Distribution in Rat Liver Differential Centrifugation Fractions[a,b]

	Percent (relative sp. act.)				
Fraction	Protein	Catalase	SDH	NADPH cyt *c* red	AP
Nuc	30-35	20-25 (<1.0)	50-60 (<2.0)	20-25 (<1.5)	20-25 (<2.0)
H Mit	15-25	7.5-12.5(<0.5)	20-25 (>3.0)	5-7.5 (<0.2)	10-12.5 (<1.0)
L Mit	7.5-12.5	20-25 (>3.0)	5-10 (<2.0)	5-10 (<1.0)	20-25 (>3.0)
Mic	12.5-17.5	1-2 (<0.2)	10-15 (<0.5)	50-55 (>3.0)	2-5 (<0.2)
Cytosol	25-30	25-30 (<1.0)	0	5-10 (<0.5)	20-25 (<1.5)

gradient, the concentration of Nycodenz cushion (if present), and the centrifugation conditions. Nevertheless there will be an overall similarity of organelle banding, with the peroxisome peak being very close to the bottom of the gradient. The example given in Figure 3.5.3 is from Wilcke and Alexson (1994) who used a 25% to 50% Nycodenz gradient, a 60% cushion, and 60,000 × *g* for 35 min in a vertical rotor. Approximately 70% of the total catalase

(1994) with permission of Academic Press.

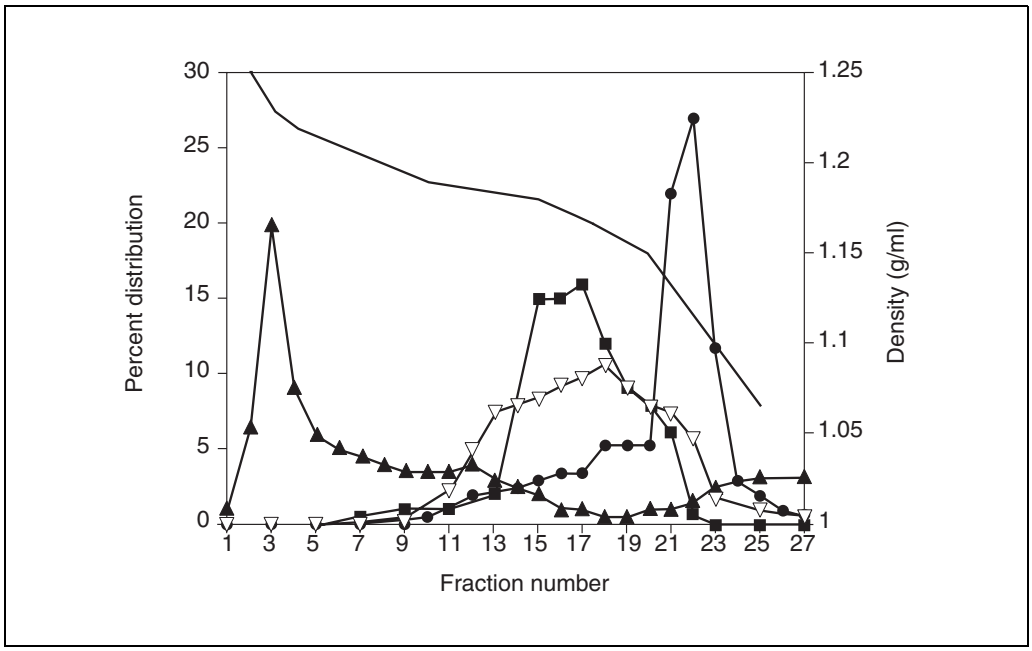

Figure 3.5.3 Isolation of peroxisomes in a 25% to 50% (w/v) Nycodenz gradient (60,000 × *g* for 35 min) in a vertical rotor. Fraction 1 is the dense end of the gradient. Distribution of enzymes: Cat, catalase (filled triangles); Cytox, cytochrome oxidase (filled squares); AP, acid phosphatase (open inverted triangles); Est, esterase (filled circles; endoplasmic reticulum marker). Data is adapted from Wilcke and Alexson (1994) with permission of European Journal of Biochemistry.

in the gradient is recovered from the first eleven fractions, with essentially no contamination from any other organelle. Compared to iodixanol, there is a greater tendency for some of the lighter peroxisomes to overlap the denser lysosomes and mitochondria.

Alternate Protocol 2

Because density barriers are less discriminating than continuous gradients, it is difficult to choose a single density that will give both good yields and lack of contamination by other organelles. Nevertheless the 30% Nycodenz barrier devised by Ghosh and Hajra (1986) should give a yield of ~50% of the catalase from the light mitochondrial fraction, with <2% of the lysosomes, mitochondria, and endoplasmic reticulum.

Basic Protocol 4

In this yeast protocol, ~55% of the total catalase is located in the bottom half of the gradient with no detectable contamination from mitochondria (Watkins et al., 1998). Unlike the mammalian systems, however, the rest of the lighter catalase-containing particles form a second well defined peak, which co-bands with the mitochondria. Moreover the median banding densities of all of the particles in Nycodenz gradients appear significantly lighter than their mammalian counterparts. Peroxisomes have a median density of ~1.16 g/ml and that of the mitochondria is as low as 1.12 g/ml (Thieringer et al., 1991).

Basic Protocol 5

The density of the organelles from HepG2 cells is almost identical to that of those from rat liver. Approximately 55% of the total catalase bands in the lowest third of the gradient; this peroxisome band is devoid of succinate dehydrogenase, but contains ~8% of the total ER in the gradient (Watkins et al., 1991). The overall distribution of enzyme markers is, however, essentially identical to that of Basic Protocol 3.

Time Considerations

There are no points at which any of the basic protocols can be discontinued. The light mitochondrial fraction produced in Basic Protocol 1 must be used immediately for any subsequent gradient separation. Preformed gradients should be made up during Basic Protocol 1 and kept on ice until required. If they are prepared at room temperature, they must be given time to cool down to 4°C.

Basic Protocol 1 should be accomplished in 2 to 2.5 hr. If the preformed iodixanol or Nycodenz gradients have been made up either the previous night (diffusion of discontinuous gra-

dients) or during Basic Protocol 1, Basic Protocols 2 and 3 should take ~3 hr. Alternate Protocol 1 will also take ~3 hr (depending on the rotor), but the preparations prior to centrifugation are considerably simpler and shorter. Basic Protocol 3 should take no more than 2 hr. Because of the ~4 hr spheroplast preparation time, Basic Protocol 4 will require in total ~7 hr. Basic Protocol 5 should be completed within 3.5 hr.

With experience and practice it may be unnecessary to unload the gradients in a series of equal fractions; instead the peroxisome band might be removed using a Pasteur pipet or syringe—this will save at least 15 min per tube.

Functional assays should be carried out as soon as possible after the preparation, but simple marker enzyme assays (such as described in this unit and in *UNIT 3.4*) can be carried out on material stored at 0° to 4°C for up to 16 hr without much loss of activity. These assays and compositional measurements may also be carried out on material frozen to −20° or −80°C. There are, however, no general rules regarding the suitability of a particular storage regime, and it is strongly recommended that the validity of results on stored material be checked by comparison with those obtained with the fresh organelles. Any concentration of the membrane fractions and/or removal of gradient medium must be carried out prior to freezing.

All the solutions can be made up ahead of time and stored at 4°C for 1 to 2 days or frozen to −20°C for longer periods. But note that any enzymes, as well as PMSF or other protease inhibitors, should be added immediately prior to use.

Isolation of Lysosomes from Tissues and Cells by Differential and Density Gradient Centrifugation

Lysosomes are widely studied organelles; they are an integral part of the complex traffic of membrane vesicles between intracellular and surface membranes. Most notably, they are the site of degradation of macromolecules which have been brought into the cell by endocytosis. Most of the biochemical and structural analysis of lysosomes has been carried out on organelles from rat liver. A Percoll gradient method for this still widely-used tissue is described in this unit (see Basic Protocol 1). In the italicized annotations to this protocol, there are some comments regarding the application to other mammalian tissues (i.e., brain and kidney). More recently, the study of lysosomes as part of the endocytic and synthetic processes has been performed on organelles from a wide range of cultured cells. Because of the diversity of homogenization procedures and minor variations in the Percoll centrifugation regime used for cultured cells, it is not practical to present each cell type in a detailed protocol. A second procedure (see Basic Protocol 2) describes the isolation of lysosomes from HL-60 cells and the italicized annotations, a few of the many variants. The Commentary also presents some of the protocol variations used for cultured cells.

Since lysosomes, mitochondria, and peroxisomes have similar and overlapping densities in sucrose gradients, in the past, density perturbation of the lysosomes by Triton WR1339 loading was a prerequisite to achieving satisfactory purification in these gradients. With the advent of low-osmolarity Percoll and Nycodenz gradient media, the use of sucrose gradients declined and they are little used today, being generally regarded as unsatisfactory for lysosome purification. Nevertheless, to obtain the highest yields and purities of lysosomes, density perturbation can improve the resolution of Percoll gradients. This approach is presented in Alternate Protocol 1. Alternate Protocol 2 describes the use of a discontinuous gradient of Nycodenz for rat liver lysosomes. None of these systems are recommended for concomitant purification of the other major organelles in the light mitochondrial fraction (mitochondria and peroxisomes); this is best carried out by flotation of the light mitochondrial fraction through a continuous iodixanol gradient, described in Alternate Protocol 3.

After collecting the banded material from the gradients, the success of the fractionation is routinely measured by assaying for various marker enzymes; acid phosphatase (see Support Protocol 1) or a glycosidase such as β-galactosidase (*UNIT 3.4*) are commonly used for lysosomes. For peroxisomes, mitochondria, and endoplasmic reticulum, respectively, catalase, succinate dehydrogenase (*UNIT 3.4*), and NADPH-cytochrome *c* reductase (*UNIT 3.5*) may be used as markers.

IMPORTANT NOTE: All solutions, glassware, centrifuge tubes, and equipment should be precooled to 0° to 4°C and kept on ice throughout. Centrifuge rotors should be precooled to the same temperature.

ISOLATION OF LYSOSOMES FROM RAT LIVER USING A SELF-GENERATED PERCOLL GRADIENT

BASIC PROTOCOL 1

From a mammalian tissue homogenate, the lysosomes are always purified from a light mitochondrial fraction (LMF), this is also occasionally true of cultured cell homogenates. Routinely, lower relative centrifugal forces (RCFs) are required to produce the LMF for lysosome purification than for peroxisome purification (*UNIT 3.5*). A medium containing

Contributed by John M. Graham
Current Protocols in Cell Biology (2000) 3.6.1-3.6.21

buffered 0.25 M sucrose and 1 mM EDTA is routinely used both for the homogenization and as the osmotic balancer for the Percoll gradient.

The LMF is either mixed with a Percoll stock solution or layered on top of a uniform concentration of Percoll, normally in the range 25% to 40% (v/v), and most commonly centrifuged in a fixed-angle rotor for 30 to 90 min at 20,000 to 35,000 × *g*. A gradient is generated by the centrifugal field and the lysosomes are the densest organelle in this system. The normal mode of harvesting the gradient is either tube puncture (for thin-walled centrifuge tubes only) or aspiration from the bottom of the gradient. In a technique requiring practice and experience, the principal lysosome band can be removed using a syringe attached to a long metal cannula. See Commentary for more information on the manner in which the lysosomes are banded in these gradients. The protocol below is adapted from Jonas (1986) and Symons and Jonas (1987).

Percoll must normally be removed from gradient fractions before any spectrophotometric assay for marker enzymes can be carried out, because of the light-scattering properties of the medium. It is also advisable to remove the medium before carrying out any electrophoresis.

While isolation from liver is the focus of this protocol, the use of both brain (Caimi et al., 1989) and kidney (Ohshita et al., 1992) tissues are described in the annotations where appropriate.

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) and must follow officially approved procedures for the care and use of laboratory animals.

NOTE: The following protocol is suitable for a single rat liver of wet weight 10 to 12 g.

Materials

150- to 200-g Sprague-Dawley rats
Homogenization medium (HM; see recipe)
Percoll stock solution (see recipe)

Dissecting equipment
~40- and ~5 ml Dounce homogenizers with loose-fitting Wheaton type B pestles (e.g., Kontes)
Low-speed centrifuge with swinging-bucket rotor to take 50-ml tubes
Sorvall RC series centrifuge and SE-12 and SS-34 rotors or equivalents
Gradient unloader: thin metal cannula connected to a peristaltic pump
Ultracentrifuge with fixed-angle rotor (e.g., Beckman 50 Ti or 70.1 Ti or Sorvall T-865.1)

NOTE: Protease inhibitors (*UNIT 3.4*) can be added to any or all of the solutions.

Isolate and homogenize liver

1. Starve the animal overnight.
2. Sacrifice the animal by cervical dislocation or decapitation.

   This must be supervised or carried out by an experienced animal technician.

3. Open the abdominal cavity and remove the liver to a chilled beaker containing ~20 ml of homogenization medium (HM).
4. Decant the medium and finely mince the liver using scissors.

   The pieces of liver should be no more than ~25 mm^3.

5. Suspend the mince in ~40 ml of HM and homogenize the liver using 15 to 20 strokes of the type B pestle of the 40-ml Dounce homogenizer.

   If only a smaller-volume Dounce homogenizer is available, carry out the homogenization in two batches. Brain tissue should be homogenized in 3 vol of HM containing a higher sucrose concentration (0.32 M) using a 50-ml Potter-Elvehjem homogenizer (0.2 mm clearance) with five gentle strokes at 500 rpm . For kidney tissue use 9 vol of HM (0.25 M sucrose) in a Potter-Elvehjem homogenizer.

Isolate light mitochondrial fraction

6. Centrifuge the homogenate 10 min at 750 × *g*, 0° to 4°C, in a low-speed centrifuge with a swinging-bucket rotor.
7. Decant and retain the supernatant.
8. Crudely resuspend the pellet in 20 ml of HM using a glass rod. Complete the resuspension using 3 to 4 gentle strokes of the type B pestle of the Dounce homogenizer
9. Repeat steps 6 and 7.
10. Combine the supernatants and transfer to ~50-ml high-speed centrifuge tubes.

    This is the post-nuclear supernatant (PNS).

11. Centrifuge 10 min at 20,000 × g in Sorvall RC series centrifuge and SS-34 or equivalent fixed-angle rotor, 0° to 4°C.
12. Decant and discard the supernatant
13. Suspend the light mitochondrial pellet (LMP) in ~40 ml HM using a glass rod followed by 3 to 4 gentle strokes of the pestle of the Dounce homogenizer.
14. Centrifuge 10 min at 20,000 × *g*, 4°C, and discard the supernatant.
15. Resuspend the LMP in ~6 ml HM using a glass rod. Complete resuspension with 3 to 4 gentle strokes of the pestle of the 5 ml Dounce homogenizer.

    The homogenate (light mitochondrial fraction; LMF) should contain ~25 mg/ml protein.

Purify lysosomes

16. Mix 4.5 ml of Percoll stock solution with 5.5 ml LMF from step 15.

    This is equivalent to ~40% (v/v) Percoll.

17. Transfer 10 ml of the Percoll/LMF mixture to each high-speed centrifuge tube and centrifuge 90 min at 35,000 × *g*, 0° to 4°C, in a Sorvall SE-12 or equivalent fixed-angle rotor.

    The gradient can also be generated in an ultracentrifuge fixed-angle rotor. Such a rotor is required to remove the Percoll particles from the gradient fractions (see step 19).

    Because the gradient reorients in the tube during deceleration from 2,000 rpm to rest, use a slow deceleration during the braking phase so deceleration occurs smoothly and disturbance of the gradient and the banded material is avoided.

    For brain lysosomes, layer 4 ml of LMF over 36 ml of 27% (v/v) Percoll and centrifuge 90 min at 20,000 × g. Kidney lysosomes: mix LMF with Percoll stock to 40% (v/v) Percoll and centrifuge 30 min at 47,000 × g.

18. Harvest the gradient (preferably dense-end-first) in ~1 ml fractions from the top using a gradient unloader; the lysosomes band in the bottom 1 to 2 ml.

    Alternatively, a syringe (1 to 2 ml) with metal cannula (i.d. 1 mm) can be used to collect equal-volume fractions from the top or bottom of the gradient. Thin-walled tubes can be unloaded by tube puncture.

19. Ultracentrifuge the fractions 1 hr at 100,000 × *g*, 0° to 4°C, and collect the turbid layer of lysosomes just above the Percoll pellet.

20. Perform metabolic assays for lysosomes (see Support Protocols 1 and 2), peroxisomes (*UNIT 3.4*), mitochondria (*UNIT 3.4*), or endoplasmic reticulum (*UNIT 3.5*) as soon as possible upon preparation.

    If necessary dilute the lysosomes to 1 to 5 mg protein/ml with HM.

    Some marker enzyme assays can be carried out after storage at 4°C for up to 16 hr. Many assays can be carried out on material frozen to −20°C or −80°C; however, always check that the measurements that are made are relatively unaffected by the storage conditions by comparing with results obtained from fresh material.

ALTERNATE PROTOCOL 1

ISOLATION OF LYSOSOMES FROM RAT LIVER USING DENSITY PERTURBATION AND A SELF-GENERATED PERCOLL GRADIENT

After intraperitoneal injection of the carbohydrate polymer dextran, the macromolecule is endocytosed by the liver and delivered to the lysosomes, thereby increasing their density. On the other hand, if the post-nuclear supernatant of a liver homogenate is made 1 mM with respect to Ca^{2+}, the mitochondria take up water and become considerably less dense. This bimodal density perturbation approach was devised by Arai et al. (1991) to improve the yield and resolution of lysosomes from mitochondria in Percoll gradients. These dextran-perturbed lysosomes are sometimes called dextranosomes. The following method is adapted from Arai et al. (1991).

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) and must follow officially approved procedures for the care and use of laboratory animals.

Additional Materials *(also see Basic Protocol 1)*

100 mg/ml dextran solution (see recipe)
Homogenization medium (HM; see recipe) without EDTA
100 mM $CaCl_2$ (see recipe)
Percoll stock solution (see recipe) without EDTA

2-ml syringe and 23-G needle
Beckman 70.1 Ti rotor

1. Inject rats intraperitoneally with 1 mg dextran per gram of body weight using a 2-ml syringe and 23-G needle.

   This must be carried out by a properly trained and licensed operative.

2. Sacrifice the animal by decapitation or cervical dislocation.
3. Blanch the liver by perfusion from the portal vein with 20 to 30 ml ice-cold HM.
4. Prepare the PNS (see Basic Protocol 1, steps 3 to 10).
5. Measure the volume of PNS; add 0.01 vol of 100 mM $CaCl_2$, and incubate 5 min at 37°C.
6. Cool the suspension back to 0° to 4°C and prepare the LMF (see Basic Protocol 1, steps 11 to 15).

7. Mix 5.5 ml of Percoll stock solution with 4.5 ml of the LMF and ultracentrifuge 15 min at 60,000 × g in a 70.1 Ti or equivalent fixed-angle rotor, 0° to 4°C.

   This is equivalent to ~50% (v/v) Percoll.

8. Collect the gradient and process the fractions as described (see Basic Protocol 1, steps 18 to 20).

   The dextranosomes band close to the bottom of the gradient.

ISOLATION OF LYSOSOMES FROM A RAT LIVER LIGHT MITOCHONDRIAL FRACTION IN A DISCONTINUOUS GRADIENT OF NYCODENZ

ALTERNATE PROTOCOL 2

The discontinuous metrizamide gradient devised by Wattiaux and Wattiaux-De Coninck (1983) has been superseded by a Nycodenz gradient covering the same density range (Olsson et al., 1989). The light mitochondrial fraction is adjusted to a high density and layered under the gradient; bottom-loading has been shown (Wattiaux and Wattiaux-De Coninck, 1983) to be preferable for isolation of lysosomes in this system.

As Nycodenz is a true solute, the gradient fractions do not require centrifugation at 100,000 × *g* (as for Percoll) to remove the gradient medium; if necessary the organelles can be pelleted 15 min at 20,000 × *g* after dilution of the fractions with 2 vol of HM.

Additional Materials *(also see Basic Protocol 1)*

45% Nycodenz stock solution (see recipe)
Ultracentrifuge with swinging-bucket rotor to take ~38-ml tubes (e.g., Beckman SW28, Sorvall AH629, or equivalent)
Gradient unloader: 1- to 2-ml syringe attached to metal cannula (i.d. 1 mm)

1. Prepare LMF as described (see Basic Protocol 1, steps 1 to 15). To keep the sample volume to a minimum, resuspend the LMP in 3 to 4 ml of HM.
2. To 1 vol of LMF add 2 vol 45% Nycodenz stock solution.
3. Prepare 19%, 24%, 26%, and 30% Nycodenz by dilution of 45% Nycodenz stock solution in HM.
4. Transfer 8 ml of 19% Nycodenz to a tube for the SW-28 rotor (or equivalent), and, using a syringe and metal cannula, underlayer 7 ml each of the other three gradient solutions in order of increasing density. Underlayer 9 ml of LMF in the bottom of the tube.
5. Ultracentrifuge 2 hr at 95,000 × *g*, 0° to 4°C.
6. Harvest the lysosomes from the 19%/24% interface using a syringe and metal cannula.
7. If required, dilute the fraction with ≥2 vol of HM and centrifuge 20 min at 30,000 × g, 0° to 4°C.
8. Resuspend the pellet in HM to 1 to 5 mg protein/ml.
9. Process the fractions as described (see Basic Protocol 1, step 20).

   Metabolic assays should be carried out as soon as possible upon preparation; some marker enzyme assays can be carried out after storage at 4°C for up to 16 hr. Many assays can be carried out on material frozen to −20°C or −80°C; always check that the measurements that are made are relatively unaffected by the storage conditions by comparing with results obtained with fresh material.

ALTERNATE PROTOCOL 3

FRACTIONATION OF A RAT LIVER LIGHT MITOCHONDRIAL FRACTION IN A CONTINUOUS IODIXANOL GRADIENT

Occasionally it is necessary to at least partially purify the other organelles in the light mitochondrial fraction (as well as the lysosomes), as, for example, when the localization of a particular component or function is being determined (i.e., a gradient is being used analytically rather than preparatively). In this case, none of the gradients described in Basic Protocol 1 or Alternate Protocols 1 and 2 are really suited to this task, because mitochondria, peroxisomes, and endoplasmic reticulum tend to copurify (particularly in Percoll gradients). The continuous iodixanol gradient described in this protocol overcomes this problem to a large extent. Bottom-loading of the sample in a dense medium is described, but top loading can be used.

Additional Materials *(also see Basic Protocol 1)*

OptiPrep diluent (see recipe)
OptiPrep (Accurate Chemical)
Dense gradient unloading liquid (e.g., Maxidens; Lipotek, U.K.)
Two-chamber gradient maker or Gradient Master

Gradient unloader
Ultracentrifuge with Beckman SW28.1 or equivalent swinging bucket rotor

1. Prepare the LMF (see Basic Protocol 1, steps 1 to 15), but suspend the final pellet in 3.5 ml HM.
2. Prepare 50% (w/v) iodixanol stock by combining 5 vol of OptiPrep (60% iodixanol) and 1 vol OptiPrep diluent. Mix 3.0 ml of LMF with 4.5 ml of 50% iodixanol stock by repeated inversion.

   NOTE: *Do not shake the tube so vigorously as to create foaming.*

   If the sample is going to be loaded on top of the gradient rather than beneath it, then omit this step.
3. Prepare a linear iodixanol gradient in the 17-ml centrifuge tubes from 6 ml each of 19% and 27% (w/v) iodixanol.

   If the gradient is prepared with a Gradient Master use an angle of 80°, 20 rpm, and a time of 1 min 50 sec.
4. Underlayer the gradient with 3 ml of the LMF/iodixanol from step 2, using a syringe and metal cannula.
5. Overlayer the gradient with 1 ml of HM.

   Alternatively underlayer the gradient with 1 ml of 30% iodixanol (3 vol iodixanol stock and 2 vol HM) and then layer 3 ml of LMF on top of the gradient.
6. Ultracentrifuge 2 hr at 110,000 × *g*, 0° to 4°C. Collect the gradient in 1-ml fractions, low-density end first by upward displacement with a dense liquid (e.g., Maxidens).

   The lysosomes band close to the top of the gradient.
7. If required, dilute the fraction with 2 vol of HM and centrifuge 20 min at 30,000 × *g*, 0° to 4°C.
8. Resuspend the pellet in HM to 1 to 5 mg protein/ml.
9. Process the fractions as described (see Basic Protocol 1, step 20).

   Metabolic assays should be carried out as soon as possible upon preparation; some marker enzyme assays can be carried out after storage at 4°C for up to 16 hr. Many assays can be carried out on material frozen to −20° or −80°C; always check that the measurements that are made are relatively unaffected by the storage conditions by comparing with results obtained with fresh material.

ISOLATION OF LYSOSOMES FROM HUMAN HL-60 CULTURED CELLS USING A SELF-GENERATED PERCOLL GRADIENT

This is an example of the use of a post-nuclear supernatant from a cultured cell homogenate. While similar homogenization media and centrifugation and analysis protocols, with minor modifications, have been applied to the isolation of lysosomes from a variety of cultured cells, the form of homogenization that has been used is extremely variable. The protocol below has been adapted from the method of Carlsson and Fukuda (1992), as these authors used the ball-bearing homogenizer of Balch and Rothman (1985), which causes very little damage to subcellular organelles. The homogenization procedures used for cultured cells are too diverse to be covered comprehensively in this text (see Graham, 1997 for more information), but a few alternatives are suggested in the italicized annotations and discussed more fully in the Commentary. Whatever homogenization method is used, the aim should be to produce ~90% cell breakage using the minimum shearing forces.

Materials

HL-60 cells (ATCC#CCL-240) in homogenization medium
Phosphate-buffered saline (PBS; *APPENDIX 2A*)
Homogenization medium (HM; see recipe)
10% (w/v) bovine serum albumin (BSA)
Percoll stock solution
10% (w/v) Nonidet-40 (NP-40) in water

Ball-bearing cell homogenizer (see Balch and Rothman, 1985, for more details)
Low-speed centrifuge with swinging-bucket rotor to take 10-ml tubes
Sorvall high-speed centrifuge with SE-12 and SS-34 or equivalent fixed-angle rotors
Beckman ultracentrifuge with 50Ti, 70Ti, T865 (Sorvall), or equivalent fixed-angle rotor
Gradient unloader: thin metal cannula connected to a peristaltic pump

NOTE: An ultracentrifuge rotor is required to pellet Percoll (step 12), but gradient formation (step 10) can be carried out in a high-speed centrifuge or ultracentrifuge.

NOTE: Protease inhibitors (*UNIT 3.4*) can be added to any or all of the solutions.

1. Wash 1-3 × 10^8 HL-60 cells once with 5 ml phosphate buffered saline (PBS), and again with 5 ml of HM, pelleting cells by centrifugation at 500 × *g* for 10 min.

   In some methods the EDTA is omitted from the homogenization medium (and the Percoll diluent). The inclusion of EDTA is dependent on the subsequent procedures to be done on purified lysosomes, and how well cells homogenize (some cells will not homogenize without EDTA). An alternative medium in which 10 mM triethanolamine-acetic acid, pH 7.4 replaces the HEPES buffer has been found to be suitable to many monolayer cultures (Marsh et al., 1987).

2. Suspend the cells in 3 ml of HM.

3. Homogenize in the ball-bearing homogenizer using 5 passes.

   See Balch and Rothman (1985), for more details on the use of ball-bearing homogenizers. A Dounce (Finley and Kornfeld, 1994; Lipman et al., 1990; Muno et al., 1990) or Potter-Elvehjem homogenizer (Akasaki et al., 1993), or nitrogen cavitation (Kelly et al., 1989) may be used if the ball-bearing homogenizer is not available.

4. Rinse the homogenizer with 0.5 ml of HM and add to the homogenate.

5. Pellet the nuclei, cell debris and any unbroken cells by centrifuging at 800 × g for 10 min in a low-speed centrifuge.
6. Decant or aspirate the supernatant and keep on ice.
7. Suspend the nuclear pellet in 1 ml of HM (use gentle vortexing). Repeat steps 5 and 6.
8. Combine the supernatants, adding adding HM to a final total volume of 3.5 ml if necessary.
9. Mix 3 ml of supernatant with 0.18 ml 10% bovine serum albumin (BSA), 1.0 ml of Percoll stock solution, and HM to a final volume of 4.5 ml.

   The final Percoll concentration is 20%.

   In some methods the post-nuclear fraction is layered over the Percoll solution and other Percoll concentrations that have been used are ~27% and 35% (v/v).
10. Ultracentrifuge 30 min at 36,000 × *g* in a Beckman 50 Ti rotor or equivalent fixed-angle rotor, 0° to 4°C.

    Centrifugation conditions vary from 60 min at 15,000 × g to 40 min at 62,500 × g and the gradient volume may be as high as 35 ml.

    The density profile required to achieve high resolution will depend on cell type and HM composition. Centrifugation conditions required to produce this profile will depend on rotor type.
11. Collect the gradient dense-end-first (0.4-ml factions) using a gradient unloader.

    The lysosomes band close to the bottom of the gradient.

    A thin metal cannula connected to a peristaltic pump can be used as a gradient unloader.
12. Add 10% Nonidet-40 (NP-40) to each gradient fraction (final concentration 0.5%) before pelleting the Percoll by ultracentrifuging 1 to 2 hr at 100,000 × *g*, 0° to 4°C.

    By adding a nonionic detergent to solubilize the organelles before the Percoll is pelleted, very high recoveries of lysosomal proteins may be obtained. If the aim, however, is to recover intact organelles, the detergent must be omitted.
13. Perform metabolic assays for lysosomes (see Support Protocols 1 and 2), peroxisomes (*UNIT 3.4*), mitochondria (*UNIT 3.4*), or endoplasmic reticulum (*UNIT 3.5*) as soon as possible upon preparation.

    Metabolic assays should be carried out as soon as possible upon preparation; some marker enzyme assays can be carried out after storage at 4°C for up to 16 hr. Many assays can be carried out on material frozen to –20° or –80°C; always check that the measurements that are made are relatively unaffected by the storage conditions by comparing with results obtained with fresh material.

SUPPORT PROTOCOL 1

ASSAY FOR ACID PHOSPHATASE

Acid phosphatase is an established marker for lysosomes. The assay is simple to execute and uses *p*-nitrophenyl phosphate as a substrate. The released nitrophenol is measured spectrophotometrically in an alkaline solution. *p*-Nitrophenyl phosphate is quite stable under alkaline conditions, thus if the reaction is terminated by addition of NaOH, background hydrolysis is negligible. Because of the ubiquity of nonspecific phosphatases, glycosidases such as β-galactosidase (e.g., Graham, 1997; *UNIT 3.4*) or β-*N*-acetylglucosaminidase (e.g., Berg et al., 1985; Support Protocol 2) are increasingly used today as markers.

Sample handling depends on the type of gradient and the concentration of lysosomes (and other organelles) in the fractions (see Commentary). Ideally, the protocol should be carried out on gradient fractions from which the gradient solute or Percoll has been removed and the gradient fractions suspended in 0.25 M sucrose, 10 mM HEPES/NaOH, pH 7.4 or equivalent.

Materials

Assay buffer I (see recipe)
Substrate solution I (see recipe)
Gradient fractions (see Basic Protocol 1 or 2 or Alternate Protocol 1 or 2)
0.25 M NaOH

1. Prepare assay solution by mixing equal volumes of assay buffer I and substrate solution I. Add 50 µl of each gradient fraction (containing ~20 µg protein) to separate microcentrifuge tubes containing 0.2 ml of assay solution. Perform the assay in duplicate.
2. Prepare a blank for each fraction by adding 0.2 ml of assay solution to 0.6 ml of 0.25 M NaOH before adding 50 µl gradient fraction.

   As long as the protein content of each assay is approximately the same, a blank for each fraction may not be necessary; a single blank containing buffer instead of sample may suffice for many gradients. This simple approach cannot be adopted for Percoll-containing fractions.
3. Incubate assay tubes at 37°C for 30 min.
4. Add 0.6 ml of 0.25 M NaOH to each test sample to stop the reaction.
5. Remove any precipitate by microcentrifuging 1 to 2 min at maximum speed.
6. Using plastic cuvettes, measure the absorbance of the assay reactions at 410 nm against the appropriate blank.

   The molar extinction coefficient of nitrophenol is 9620 $cm^{-1}M^{-1}$.

ASSAY FOR β-*N*-ACETYLGLUCOSAMINIDASE

SUPPORT PROTOCOL 2

This sensitive fluorometric method is based on the release of 4-methylumbelliferone from 4-methylumbelliferyl *N*-acetyl-β-D-glucosaminide at an acid pH followed by determination of the fluorescence of the aglycone at pH 10 or 11. It may be necessary to remove protein by precipitation with trichloroacetic acid before measuring the fluorescence. A less sensitive spectrophotometric method, which uses the *p*-nitrophenyl derivative, is also available (see β-galactosidase assay in *UNIT 3.4*).

Sample handling depends on the type of gradient and the concentration of lysosomes (and other organelles) in the fraction (see Commentary). Ideally, the protocols should be carried out on fractions from which the gradient solute or Percoll has been removed; the gradient fractions are resuspended in 0.25 M sucrose, 10 mM HEPES/NaOH, pH 7.4, or equivalent.

This method is adapted from Barrett and Heath (1977).

Materials

Assay buffer II (see recipe)
Substrate solution II (see recipe)
Bicarbonate buffer (see recipe)
1.2 mM (21 mg/100 ml) 4-methylumbelliferone, prepare fresh
Fluorimeter and appropriate cuvettes

1. Mix 0.5 ml each of assay buffer II and substrate solution II with 0.45 ml water.
2. Add 50 µl sample.

   It is strongly advised that some preliminary experimentation be carried out to determine the optimum range of protein concentrations that will provide a satisfactory fluorescent emission, detectable by the available instrument and falling on the standard curve (see step 5).

3. Prepare a blank for each fraction by repeating step 1, adding 3 ml bicarbonate buffer, and then adding 50 µl of sample.

   Unless the samples are clarified by the addition of TCA and sedimentation prior to fluorescent measurement (step 6), light scattering in the sample may require a separate blank for each sample. However, if the protein content of each clarified assay reaction is approximately the same, a blank for each fraction may be avoided, in which case a single blank containing 0.5 ml assay buffer, substrate solution, and water (and no sample) may suffice.

4. Incubate 30 to 60 min at 37°C.
5. Prepare a standard curve by diluting 1.2 mM 4-methylumbelliferone with water to make 1 ml standards from 1.2 to 12 nmol and adding 0.5 ml assay buffer II to each.
6. Add 3 ml bicarbonate buffer to all sample and standard reactions (not blanks). Measure the fluorescence emission at 448 nm using an excitation wavelength of 360 nm.

   If it is necessary to clarify the samples, add 1.5 ml of 3.3% (w/v) TCA to each tube. Let stand 5 min, then centrifuge 2 min in a microcentrifuge, to remove precipitate. To 2 ml of supernatant add 2 ml bicarbonate buffer and measure fluorescence.

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Assay buffer I

To 100 ml H_2O add:
2.94 g sodium acetate (180 mM final)
Adjust to pH 5.0 with glacial acetic acid
Add H_2O to 200 ml
Store up to 1 to 2 days at 4°C

Assay buffer II

To 100 ml H_2O add:
11.52 g citric acid (0.3 M final)
17.64 g trisodium citrate dihydrate (0.3 M final)
3.5 g NaCl (0.3 M final)
H_2O to 200 ml
Store 1 to 2 days at 4°C

Bicarbonate buffer

To 250 ml H_2O add:
26.5 sodium carbonate (0.5 M final)
21 g sodium bicarbonate (0.5 M final)
H_2O to 500 ml
The pH should be ~9.9
Store 1 to 2 weeks at 4°C

$CaCl_2$, 100 mM

To 50 ml H_2O add:
1.47 g $CaCl_2 \cdot 2H_2O$
Add H_2O to 100 ml
Store up to 3 months at 4°C

Dextran solution, 100 mg/ml

To 50 ml H_2O add:
0.85 g NaCl
10 g dextran (M_r = 60,000 to 90,000)
Add H_2O to 100 ml
Store up to 1 to 2 days at 4°C

HEPES, 1 M and 100 mM

23.83 g N-2-hydroxyethylpiperazine-N′-2-ethanesulfonic acid (HEPES)
Adjust volume to 100 ml with H_2O for 1 M and to 1000 ml for 100 mM HEPES.

Homogenization medium (HM)

To 100 ml H_2O add:
17.1 g sucrose (0.25 M final)
2 ml 100 mM Na_2EDTA (1 mM final)
20 ml 100 mM HEPES (10 mM final; see recipe)
Adjust to pH 7.0 with NaOH
Add H_2O to 200 ml
Store up to 1 to 2 days at 4°C

Nycodenz stock solution, 45% (w/v)

To 100 ml H_2O add:
90 g Nycodenz (Accurate Chemicals)
2 ml 100 mM Na_2EDTA (1 mM final)
20 ml 100 mM HEPES (10 mM final; see recipe)
Adjust to pH 7.4 with NaOH
Add H_2O to 200 ml
Store up to 3 months at −20°C

OptiPrep diluent

To 50 ml H_2O add:
8.55 g sucrose (0.25 M final)
6 ml 100 mM Na_2EDTA (6 mM final)
12 ml 1 M HEPES (120 mM final; see recipe)
Adjust to pH 7.4 with NaOH
Add H_2O to 100 ml
Store up to 1 to 2 days at 4°C

Percoll diluent

To 75 ml H_2O add:
171 g sucrose (2.5 M final)
20 ml 100 mM Na_2EDTA (10 mM final)
20 ml 1 M HEPES (100 mM final)
Adjust to pH 7.0 with NaOH
Add H_2O to 200 ml
Store up to 1 to 2 days at 4°C

For protocols where EDTA is omitted, replace with 20 ml water.

Percoll stock solution, 90% (v/v)

Combine 9 vol Percoll and 1 vol Percoll diluent (with or without EDTA depending on protocol). Store up to 1 to 2 days at 4°C.

Substrate solution I

To 100 ml H_2O add:
0.59 g *p*-nitrophenyl phosphate hexahydrate
Store up to 3 months at −20°C

Substrate solution II

To 100 ml H_2O add:
56.8 mg 4-methylumbelliferyl-N-acetyl-β-D-glucosaminide (1.5 mM final)
Prepare fresh

COMMENTARY

Background Information

Homogenization and differential centrifugation

For all mammalian tissues, a routine homogenization medium containing 0.25 M sucrose and 1 mM EDTA, usually buffered with HEPES, is used with no special supplements, although for brain tissue the sucrose concentration is invariably increased to 0.32 M (Caimi et al., 1989). This medium has also commonly been used for cultured cells, although sometimes the EDTA is omitted. Dounce homogenization of the cells is widely used, although nitrogen cavitation of human skin fibroblasts was used by Kelly et al. (1989) and a ball-bearing homogenizer (Balch and Rothman, 1985) by Carlsson and Fukuda (1992) for HL-60 cells. As with peroxisomes (*UNIT 3.5*), the gentlest possible homogenization protocol should be adopted, to avoid any potential damage to the organelles.

With tissues such as rat liver, the first stage of the lysosome purification is always the isolation of a light mitochondrial fraction (LMF), which is then further fractionated on some form of density gradient. This is also true of other tissues such as brain (Caimi et al., 1989; Ohshita and Kido, 1995) and kidney (Ohshita et al., 1992). In the case of cultured cells, a postnuclear supernatant (PNS) is often used as the source of crude lysosomes for gradient centrifugation. This was also used by Oliver et al. (1989) for rat parotid acinar cells. If a LMF is used, then it is normally sedimented from the PNS by centrifuging 10 to 15 min at 18,000 to 20,000 × *g*; slightly lower than that used for the purification of peroxisomes (*UNIT 3.5*) which is routinely 25,000 × *g* for 10 to 15 min. The reason for this may be that the smallest peroxisomes are ~0.2 μm, while the smallest lysosomes are ~0.4 μm. There are also a few examples of the use of much lower RCFs: 20 min at 12,500 × g for chicken liver (Nakabayashi and Ikezawa, 1988) and 20 min at 11,000 × g for macrophages (Muno et al., 1990). Since lysosomes contain many degradative enzymes, resuspension of any differential centrifugation pellets must be carried out as gently as possible; indeed the lack of any pellet resuspension is a clear advantage of using a PNS.

Density gradients

Sucrose gradients. Because the density of lysosomes is very similar to that of mitochondria and peroxisomes in sucrose gradients (Table 3.5.1), that method is now regarded as unsatisfactory for lysosome purification. Sucrose gradients can only achieve a partial resolution of lysosomes from other organelles, unless their density is reduced by loading them with Triton WR1339 (Leighton et al., 1968). This involves injection of the experimental animal with the detergent. It is now known that the lysosomes (or tritosomes) that are produced behave abnormally, particularly in regard to their enzyme composition (Wattiaux and Wattiaux-De Coninck, 1983). Therefore, it is now considered more acceptable to use one of the low-osmolarity media to isolate these organelles, because in such media the density of lysosomes is sufficiently different from that of the other organelles (see Table 3.5.1) to permit easy isolation. In iodinated density gradient media such as Nycodenz or iodixanol, lysosomes are less dense than either mitochondria or peroxisomes, while in Percoll they tend to be more dense; however, the reason for this is not clear. Because Percoll can be used as a self-generated gradient at relatively low RCFs (20,000 to 60,000 × *g* is common) and because

a band of lysosomes is invariably formed towards the bottom of the gradient with relatively little contamination from other organelles, the use of this medium is very popular.

Percoll gradients. In the handling of Percoll gradients, the osmolarity of the commercial medium (which is close to zero) has to be adjusted to ~290 mOsm by the addition of 0.1 vol of a solution containing 2.5 M sucrose. Normally this osmotic balancer is simply a 10× solution of the homogenization medium. In this way, the organelles are always exposed to the same isoosmotic medium. Usually, the final 90% (v/v) Percoll stock solution contains 0.25 M sucrose, 10 to 20 mM HEPES/NaOH, pH 7.0 to 7.4, with or without 1 mM EDTA (see recipe in Reagents and Solutions); however, as an alternative, 0.24 M mannitol, 10 mM MOPS/NaOH, pH 7.0 (Pisoni et al., 1987), and 1 mM EDTA, can be used instead.

As with all self-generated gradients, the centrifugation conditions which are used to produce the Percoll gradient control its profile. That is, lower RCFs and shorter centrifugation times will tend to produce sigmoidal gradients which are very shallow in the middle, while higher RCFs and times cause the gradient to become more linear (although a truly linear gradient is difficult to achieve with Percoll). Usually a fixed-angle rotor is used to create the gradient, but there are examples which use a vertical rotor (Kelly et al., 1989; Oliver et al., 1989). Oliver et al. (1989) included a cushion of 2.5 M sucrose, presumably to prevent any silica particles pelleting on to the vertical wall of the tube. RCFs normally vary from 20,000 to 65,000 × *g* and times from 30 to 90 min, although some methods fall outside these ranges. For lower RCFs, it is possible to use a high-speed centrifuge. The starting concentration of the Percoll, normally 20 to 40% (v/v), affects the density range of the gradient. The lower the starting concentration, the nearer the bottom of the tube the lysosomes will band. Some of the conditions for lysosome separation from cultured cells are summarized in Table 3.6.1.

The PNS or LMF is either simply mixed with the Percoll stock, or layered over a Percoll solution prepared from the Percoll stock and (usually) HM. Overlayering will minimize any contamination of the lysosomes by soluble proteins, which under the given centrifugation conditions will remain at the top of the gradient.

There are relatively few instances of Percoll being used in a non-self-generated gradient mode. Examples include PNS from guinea-pig alveolar cells fractionated on a preformed 0% to 50% Percoll gradient, 1 hr at 19,000 × *g* (12,000 rpm) in a Beckman SW-28 swinging-bucket rotor (Yamaguchi and Kaneda, 1988), and an 8% Percoll barrier used for pelleting the lysosomes from a K562 erythroleukemia cell PNS, 20 min at 19,000 × g (Bridges, 1987).

Nycodenz and iodixanol gradients. The discontinuous Nycodenz gradient (Olsson et al., 1989), based on the metrizamide system developed by Wattiaux and Wattiaux-De Coninck (1983), provides a useful alternative to Percoll. Nycodenz was also used by Graham et al. (1990) for isolation of organelles. Lack of a simple self-generated gradient protocol, however, is a disadvantage. Although iodixanol, which is a dimer of Nycodenz, forms self-generated gradients rather more quickly than Nycodenz and can be used to fractionate the organelles from a LMF (Graham et al., 1994), the RCFs required are in excess of 150,000 × *g*, with centrifugation times of 1 to 3 hr (depending on the RCF and the rotor). However, if it is a requirement that the separation system should adequately resolve both the mitochondria and peroxisomes, as well as the lysosomes, then a continuous iodixanol gradient can achieve this aim more effectively than Percoll.

Table 3.6.1 Percoll Centrifugation Conditions for Selected Cultured Cells

Cell type	% Percoll (v/v)	Volume (ml)	RCF/time	Reference
Human fibroblasts	27	35	35,000 × *g*/60 min	Kelly et al., 1989
	34	10	17,500 × *g*/35 min	Pisoni et al., 1987
Macrophages	35	7.5	62,500 × *g*/40 min	Muno et al., 1990
	27	30	15,000 × *g*/60 min	Lipman et al., 1990
Monkey COS	36	12	35,000 × *g*/90 min	Finley and Kornfeld, 1994
Rat hepatocytes	27	10	25,000 × *g*/40 min	Akasaki et al., 1993

Critical Parameters and Troubleshooting

Homogenization

As with all membrane fractionations, the use of cultured cells, rather than intact tissues, may provide problems in devising a suitable homogenization method. Although most monolayer cultured cells seem to homogenize reasonably effectively in the widely-used sucrose/EDTA/HEPES medium, the homogenization medium developed by Marsh et al. (1987) of 0.25 M sucrose, 1 mM EDTA, and 10 mM triethanolamine/10 mM acetic acid, pH 7.4, is more widely applicable (the triethanolamine-acetic acid buffer being the critically important component). This was used for the preparation of lysosomes from human fibroblasts (Pisoni et al., 1987), while for the J774 mouse macrophage-like cells, Lipman et al. (1990) used 0.25 M sucrose, 1 mM EGTA, 1 mM Mg^{2+}, 1 mM dithiothreitol, and 20 mM HEPES/NaOH, pH 7.4. If, upon homogenization, the cell homogenate acquires a gelatinous quality, this may be due either to nuclear breakage or to the release of proteins from cytoskeletal elements. Inclusion of 1 mM Mg^{2+} with or without DNase I (μg/ml) and/or 10 mM KCl may ameliorate the problems, although these measures should be regarded as a last resort.

Although a Dounce homogenizer is often used to break cultured cells, it is strongly recommended that the optimal conditions for disrupting the cells be thoroughly investigated. The aim must always be to use the minimum force to achieve ~90% cell breakage; therefore, protocols which use more than 20 strokes of the pestle should be avoided.

For cells that resist the liquid shear forces either of the Balch and Rothman (1985) ball-bearing homogenizer or of Dounce or Potter-Elvehjem homogenizers, nitrogen cavitation is probably the best option, as an isoosmotic sucrose medium can always be used. Standard conditions are 300 to 600 psi for 10 to 15 min, although Kelly et al. (1989) reported the use of much lower pressures. For a more complete discussion of these problems see Evans (1992) and Graham (1997).

Differential centrifugation

The aim of the homogenization should be to devise conditions such that 90% of cells are disrupted with the minimum possible release of organelle markers into the medium. To determine organelle integrity, all of the differential centrifugation fractions, including the microsomes and the cytosol (45 min, 100,000 × *g* pellet and supernatant) should be assayed for organelle markers and proteins (see Anticipated Results). For a tissue or cell other than those described in this unit, always carry out a more thorough differential centrifugation (e.g., 10 min at 600 × *g*, 10 min at 3000 × *g*, 10 min at 15,000 × *g*, 10 min at 25,000 × g, and 10 min at 40,000 × g) in order to devise the optimal protocol.

Density gradient centrifugation

For a tissue or cell other than those described in this unit, it may also be necessary to modulate some of the gradient and/or centrifugation conditions in the light of experience, for example, making the gradient more or less dense at the bottom to take account of organelles which may be correspondingly more or less dense. Modifications will also need to be made if the type of rotor described in this unit (see Basic Protocol 1) is not available. The sedimentation path length of the rotor will influence the shape of the density gradient profile—the longer the path length, the more shallow the gradient will be in the middle, and the steeper it will be at both ends (under the same centrifugation conditions). With Percoll, the density profile of the gradient can be checked by using colored density marker beads, which are available from Amersham-Pharmacia Biotech.

The preparation of preformed continuous gradients of iodixanol using a two-chamber gradient maker requires considerable practice to achieve highly reproducible gradients. Some of the important points in operating such devices are covered by Dobrota and Hinton (1992). A Gradient Master, which involves simply layering the densest and lightest solutions in the centrifuge tube, provides a more expensive but reproducible alternative. If neither of these is available, then a discontinuous gradient constructed from three or four solutions spanning the required density range can be prepared and allowed to diffuse, usually overnight at 4°C. Note that the time required to achieve complete linearity will depend on the tube diameter and the volume of each layer. Always collect a blank gradient and check (using refractive index) that the gradient is indeed linear and covers the appropriate density range.

Enzyme and other assays

Prior to the execution of an enzyme assay (or other measurement), it is common practice to remove Percoll, Nycodenz, or iodixanol from each gradient fraction. In the case of

Percoll, the silica colloid is normally pelleted from the gradient fraction at 100,000 × *g*, while the other two media are removed in the supernatant after dilution of the fraction with 2 to 4 vol of a low-density medium and centrifugation of the organelles 15 to 20 min at ~20,000 × *g*. These practices eliminate any possible interference of the gradient medium with the subsequent procedure(s) and are described in the final steps of the appropriate protocols. Osmundsen (1982) warned, however, that at least with peroxisomes, organelles may be lost into the Percoll pellet and that this loss may be as much as 50% of the total.

If the sample volumes used in an enzyme assay are sufficiently small (see Supports Protocol 1 and 2), the gradient solute may be adequately diluted so as not to cause any interference in the assay, even at the highest density. Thus, so long as the concentration of organelles in the gradient fraction is high enough for the enzyme activity to be detectable, the assay may be performed directly without removal. If, however, either of these requirements are not met, then dilution, pelleting, and resuspension of the pellet in a smaller volume are unavoidable. If Percoll is not removed from the gradient fraction, a blank containing the sample is essential.

In order to determine specific activities of measured enzymes, it is also necessary to estimate the protein content of fractions. Percoll, Nycodenz, and iodixanol interfere with methods using the Folin-Ciocalteu reagent, although, if by using small volumes of Nycodenz or iodixanol-containing fractions (<100 µl) in a 1 to 2 ml assay volume, the concentration of gradient solute in the assay solution is ≤10%, the interference is marginal. Methods based on Coomassie blue are generally unaffected by any concentration of these gradient media, while Percoll-containing fractions may be used so long an appropriate Percoll blank is used.

Anticipated Results

Basic Protocol 1

Differential centrifugation. Table 3.6.2 provides an analysis of the enzyme content of three principal differential centrifugation fractions. In particular it should be noted that values for acid phosphatase in the 20,000 × *g* supernatant, in excess of those in Table 3.6.2 might indicate that there is considerable lysosomal breakage during the homogenization. There will be some variation depending on the type of tissue or cell, and it is interesting that for brain tissue Caimi et al. (1989) reported only 4% of the acid phosphatase in a 17,500 × *g* supernatant. The authors used a very mild homogenization method using only 5 very slow strokes of the pestle of a Potter-Elvehjem homogenizer.

Density gradient. In Percoll in particular, the density of the lysosomes (Table 3.5.1) reveals a considerable heterogeneity, with the result that those lysosomes banding at a lower density in Percoll gradients overlap other organelles and are not recoverable in anything approaching a pure form. The profile of the lysosomal enzyme markers in the gradient, while always demonstrating this broad range of density banding, varies with the gradient-forming conditions and the enzyme. In the gradient system described in this protocol (Symons and Jonas, 1987) the β-hexosaminidase of rat liver lysosomes shows only one clear band in the bottom 2 ml of the gradient, while the enzyme is broadly distributed at a low level in the top 8 ml of the gradient; nevertheless, this represents ~40% of the total enzyme in the gradient (Fig. 3.6.1).

In the system of Nakabayashi and Ikezawa (1988), on the other hand, the lysosomal enzymes from chicken liver showed a very pronounced biphasic distribution (Fig. 3.6.2); moreover *N*-acetyl-β-D-glucosaminidase was concentrated in the dense band, while β-D-

Table 3.6.2 Enzyme Content in Differential Centrifugation Fractions

Enzyme/protein	Enzyme content (% of total in homogenate)		
	750 × *g* pellet	20,000 × *g* pellet	20,000 × *g* supernatant
Acid phosphatase	20-25	30-35	35-40
Catalase	20-25	35-40	25-30
NADPH-cyt *c* reductase	15-20	5-10	70-80
Protein	25-30	15-20	55-60
Succinate dehydrogenase	40-50	40-50	5-10

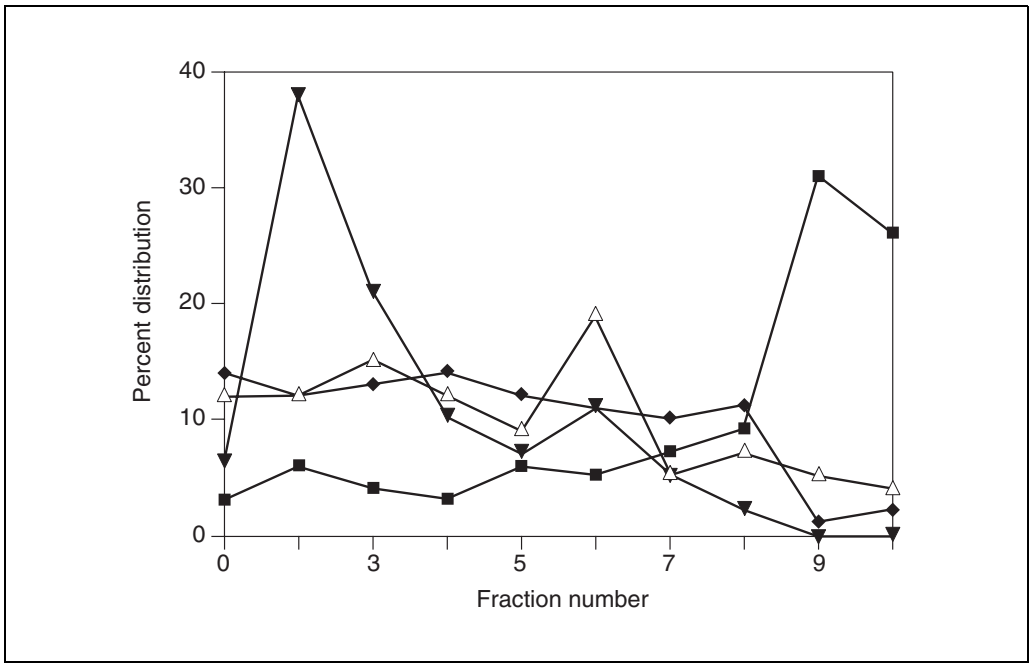

Figure 3.6.1 Isolation of rat liver lysosomes in a Percoll gradient: distribution of enzyme markers. Rat liver LMF in 40% Percoll was centrifuged for 90 min at 35,000 × g, 4°C. The gradient was collected low-density end first (1-ml fractions). β-hexosaminidase (filled squares); cytochrome oxidase (filled triangles); catalase (filled-diamonds); and glucose-6-phosphatase (filled inverted triangles). Data adapted from Symons and Jonas (1987) with kind permission.

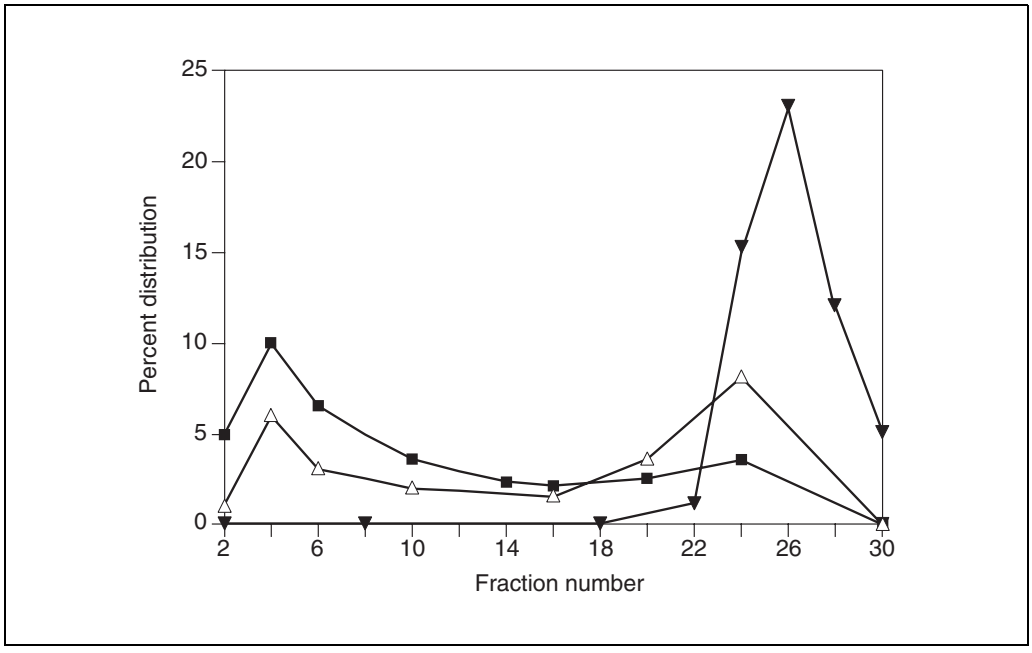

Figure 3.6.2 Isolation of chicken liver lysosomes in a Percoll gradient: distribution of enzyme markers. Chicken liver LMF in 36% Percoll was centrifuged 30 min for 25,000 × *g*, 4°C. The gradient was collected dense-end first. *N*-acetyl-β-glucosaminidase (filled squares); β-galactosidase (open triangles) and succinate dehydrogenase (filled inverted triangles). Data adapted from Nakabayashi and Ikezawa (1988) with kind permission.

galactosidase predominated in the light band. The actual enzyme profiles may be dictated by the gradient density profile, which in turn is controlled by the centrifugation conditions. At a low RCF and short centrifugation time (Nakabayashi and Ikezawa, 1988) the density profile is more sigmoidal (shallow in the middle), while at higher RCFs and longer times the profile will be more linear (Symons and Jonas, 1987).

Although there is clear heterogeneity of the lysosome population in Percoll gradients, it is most likely that the production of two distinct bands is an artifact of the gradient density profile. This was elegantly demonstrated by Draye et al. (1987), who banded rat liver lysosomes in a Percoll gradient and discovered that when the enzyme marker (*N*-acetyl-β-glucosaminidase) was plotted as a relative concentration (concentration in gradient fraction/theoretical concentration if homogenously distributed through the gradient) versus gradient volume, the typical biphasic profile was obtained (Fig. 3.6.3). When the data is replotted as frequency (enzyme activity/density interval of fraction) versus density, a single asymmetrical peak is obtained (Fig. 3.6.4). The authors confirmed this by banding the lysosomes in a linear gradient and obtained the same single asymmetrical peak.

The overall yield of lysosomes (as a percentage of the homogenate) in the Symons and Jonas (1987) gradient is ~20%, although for most Percoll gradients, the figure is closer to 15%. The relative specific activity (RSA) of lysosomal enzyme markers (specific activity in the fraction/specific activity in the homogenate) is ~60.

Alternate Protocol 1

When the lysosomes are density-perturbed with dextran, 70% to 80% of the total *N*-acetyl-β-glucosaminidase in the gradient is recovered in a single very sharp band in the bottom two fractions, and all of the $CaCl_2$-swollen mitochondria are at the top of the gradient (Arai et al., 1991). The RSA of lysosomal markers (~100) is accordingly higher than in Basic Protocol 1.

Alternate Protocol 2

The relative specific activity of lysosomal enzyme markers is ~100 (Olsson et al., 1989) in the 19%/24% Nycodenz interfacial material, while that for enzyme markers of mitochondria, peroxisomes, and endoplasmic reticulum is <0.5, showing a high degree of purification of the lysosomes. Typical yields of lysosomes (as a percent of the total homogenate) are ~10%. Thus, while the yield is lower than with the

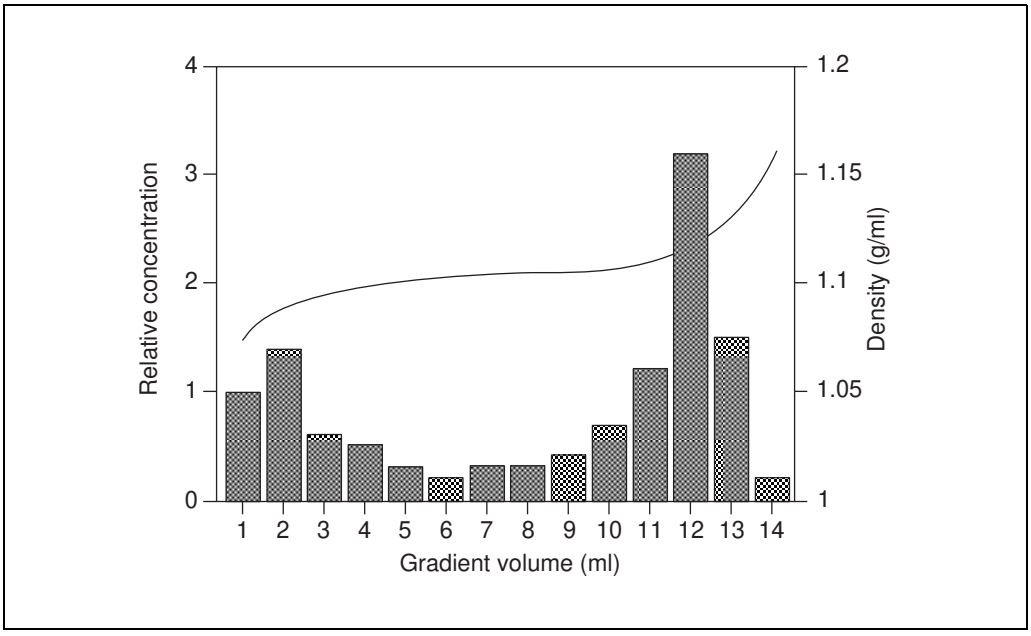

Figure 3.6.3 Biphasic banding of lysosomes in Percoll gradient. The bars show the relative concentration (concentration in gradient fraction/theoretical concentration if homogenously distributed through the gradient) of *N*-acetyl-β-glucosaminidase plotted against gradient volume. The continuous line is the density profile. Data from Draye et al. (1987) with kind permission.

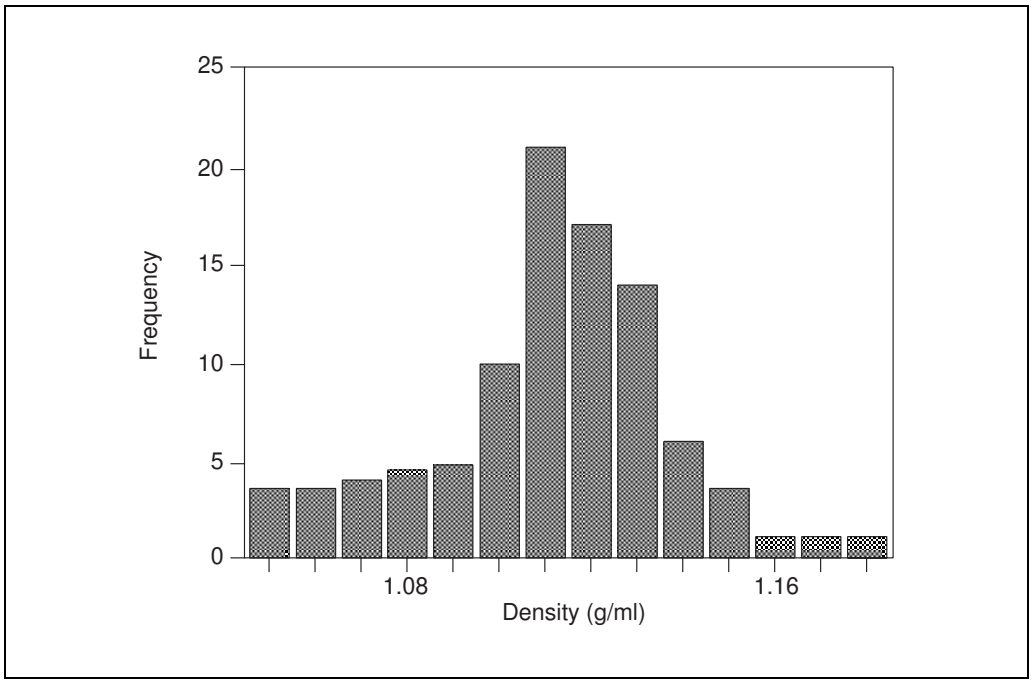

Figure 3.6.4 Real density heterogeneity of lysosomes in Percoll gradient. The data from Figure 3.6.3 were replotted as frequency (enzyme activity divided by density interval of fraction) versus density. Data from Draye et al (1987) with kind permission.

native lysosomes on a Percoll gradient, the purity is as high as that of dextranosomes.

Alternate Protocol 3

A typical separation of the organelles from the LMF on a continuous iodixanol gradient is shown in Figure 3.6.5. The lysosomes band at the top of the gradient and there is a concomitant separation of the mitochondria and peroxisomes in the lower density region of the gradient. Although the iodixanol gradient was designed primarily as an analytical gradient, it could be used preparatively for lysosomes.

Basic Protocol 2

Figure 3.6.6 shows the very satisfactory separation of lysosomes from plasma membrane (leukosialin) and Golgi membranes (galactosyl transferase) in the Percoll gradient (Carlsson and Fukuda, 1992). Approximately 50% of the total *N*-acetyl-β-hexosaminidase is recoverable in the bottom four fractions of the gradient. The mitochondria (not shown) band with the plasma and Golgi membranes.

Time Considerations

There are no points at which either of the basic protocols can be discontinued and then resumed. The light mitochondrial fraction produced in Basic Protocol 1 must be used immediately for any subsequent gradient separation. The preformed gradients in Alternate Protocols 2 and 3 should be made up during the preparation of the LMF in Basic Protocol 1, and kept on ice until required. If they are prepared at room temperature they must be given time to cool down to 4°C. The continuous iodixanol gradient of Alternate Protocol 3 can also be made from a discontinuous gradient the previous day and stored overnight at 4°C.

Basic Protocol 1 and Alternate Protocol 1 should be accomplished in ~4 hr. Because of the shorter density gradient centrifugation time, Basic Protocol 2 will take ~3.5 hr. As long as the gradients for Alternate Protocols 2 and 3 have been prepared ahead of time, these protocols will take ~4.5 hr. These values assume the use of a Percoll gradient. Protocols will take more or less time if one of the alternative gradients is chosen.

With experience and practice it may be unnecessary to unload the gradients in a series of equal fractions. Instead, the lysosome band might be removed using a Pasteur pipet or syringe and this will save ≥15 min per tube.

Functional assays should be carried out as soon as possible after the preparation, but for simple marker enzyme assay (such as described in this unit, and *UNIT 3.4*) material can be stored at 0° to 4°C for up to 16 hr without much loss of activity. These assays and compositional measurements may also be carried out on ma-

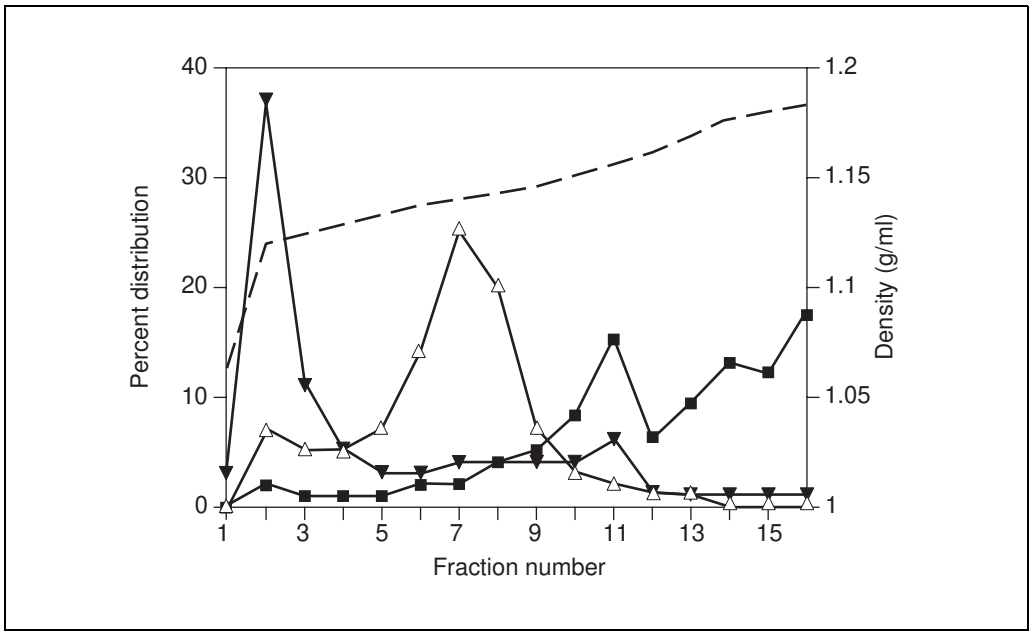

Figure 3.6.5 Fractionation of a rat liver LMF in a continuous iodixanol gradient. Rat liver LMF was centrifuged through a 19% to 27% iodixanol gradient for 2 hr at 110,000 × *g*, 4°C. Gradient collected in 1 ml fractions. β-galactosidase (filled inverted triangles); succinate dehydrogenase (open triangles), and catalase (filled squares). The discontinuous line is the density profile.

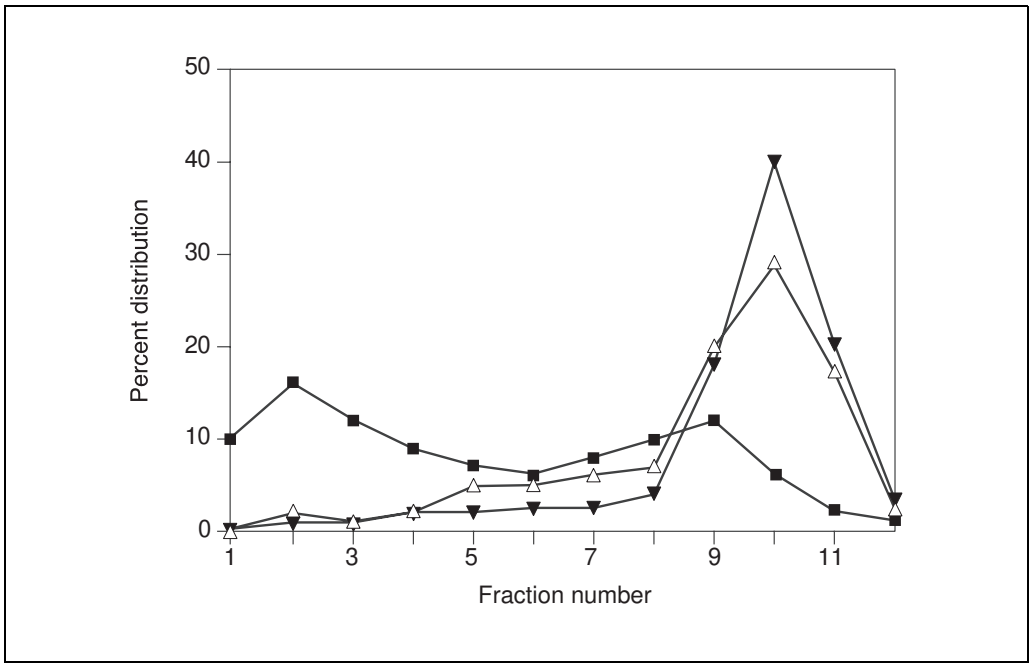

Figure 3.6.6 Isolation of HL-60 cell lysosomes in a Percoll gradient. PNS was layered over 20% Percoll and centrifuged 30 min at 36,000 × *g*, 4°C. The gradient was collected dense-end first in 0.38 ml fractions. β-*N*-acetylhexosaminidase (filled squares); galactosyl transferase (open triangles) and leukosialin (filled inverted triangles). Data from Carlsson and Fukuda (1992) with kind permission.

terial frozen to −20°C or −80°C. There are, however, no general rules regarding the suitability of a particular storage regime, and it is strongly recommended that the validity of results on stored material be checked by comparison with results obtained with the fresh organelles. Any concentration of the membrane fractions and/or removal of gradient medium must be carried out prior to freezing.

All of the solutions can be made up ahead of time and stored at 4°C for 1 to 2 days, or frozen to −20°C for longer periods, but note that any enzymes and PMSF (or other protease inhibitors) should be added immediately prior to use.

Overview of Subcellular Fractionation Procedures for the Yeast *Saccharomyces cerevisiae*

The budding yeast *Saccharomyces cerevisiae* is an excellent model organism for the study of eukaryotic cell biology. This unicellular organism shares many features with higher eukaryotic cells including all of the major membrane-bounded subcellular organelles. Accumulating evidence indicates that many cellular processes are mechanistically conserved between yeast and other eukaryotes. Despite the cellular complexity of *S. cerevisiae*, its haploid genome is only 3.5 times larger than that of *E. coli* and has been completely sequenced (Cherry et al., 1997; Clayton et al., 1997; Mewes et al., 1997). This incredible wealth of genetic information, together with powerful genetic and molecular biology techniques, has made *S. cerevisiae* an extremely valuable organism in eukaryotic cell biology (Botstein et al., 1997; Winzeler et al., 1999). The subcellular fractionation techniques for *S. cerevisiae* discussed in this unit are critical to the investigation of the molecular mechanisms of complex cellular functions.

The basic methods used to isolate and characterize organelles and organelle-derived membranes from *S. cerevisiae* are very similar to those used for animal cells and cells from other higher eukaryotes (see *UNITS 3.1-3.6*). This unit provides an overview of centrifugation-based fractionation procedures used to separate the subcellular components of *S. cerevisiae* according to their size and/or buoyant densities. The critical steps include: (1) cell growth under appropriate conditions, (2) preparation of the cell lysate with minimal damage to organelle integrity, (3) selection of a fractionation protocol that separates the subcellular components of interest into distinct sets of fractions, and (4) identification and characterization of the membranes/organelles in the resulting fractions.

Yeast cells are cultured using relatively simple, rapid, and inexpensive techniques (see *UNIT 1.6*). Vigorous strains grown in rich medium at 30°C have a doubling time of ~90 min. Yeast are very versatile. They can be maintained in either their haploid or diploid state and grown under either aerobic and anaerobic conditions. The abundance of certain enzymes and organelles that are subject to metabolic regulation can be manipulated by altering the nutrient composition of the medium. In contrast to animal cells, yeast cells have a thick cell wall that must be disrupted or removed to generate cell lysates. The released subcellular components are then subjected to one or more centrifugation steps, and their distribution among the resulting fractions is determined through their biochemical and morphological characteristics.

Disruption of the cell wall by shearing with glass beads is a rapid and effective method to prepare yeast cell homogenates for the isolation of cytosol or plasma membranes. However, glass-bead lysis is not suitable for most subcellular fractionation experiments, because strong mechanical forces damage the intracellular organelles and can disrupt critical protein and membrane interactions. To minimize the disruption of subcellular integrity, yeast cells are usually enzymatically converted to spheroplasts (yeast cells lacking cell walls) prior to cell lysis. For example, yeast cells can be incubated with enzyme preparations such as Zymolyase 100T (Seikagaku America, ICN), which destabilizes cell walls by cleaving the β-glucan linkages. Subsequently, the spheroplasts are lysed under iso- or hypoosmotic conditions, usually in combination with moderate mechanical force (e.g., several strokes in a Dounce homogenizer).

The most appropriate subcellular fractionation procedure depends on the goals of the particular experiment and the desired levels of organelle yield, purity, and function. Analytical protocols are primarily used to evaluate the subcellular location of one or more proteins. These techniques are designed to obtain discernible differences in the distribution of two or more organelles, while organelle purity, yield, and function are of secondary importance. Ideally, such procedures provide a relatively rapid and simple means to fractionate subcellular components and to subsequently compare the distribution of a protein of interest with the distribution of various organelle membranes. Preparative procedures are generally used to isolate specific organelles, mem-

Current Protocols in Cell Biology (2000) 3.7.1-3.7.25

branes, and/or cytosol. These protocols have a greater emphasis on purity, yield, and/or function than do most analytical protocols. For example, when preparing organelles for reconstitution of a cellular process in a cell-free system, the primary requirement is that the organelle(s) of interest remain functional, while organelle yield and purity are important secondary goals. In contrast, the analysis of the protein or lipid composition of a particular organelle requires that the preparation be of very high purity. If the isolated subcellular components will be fractionated further (e.g., for the separation of mitochondrial inner and outer membranes), and/or used in multiple subsequent experiments, then high yields become especially important.

The following sections provide an overview of several key techniques used during yeast subcellular fractionation experiments. The critical parameters, merits, and limitations of various procedures are discussed to facilitate the development and optimization of centrifugation-based fractionation strategies for yeast. Topics include yeast cell growth, cell lysate preparation, differential velocity centrifugation, density gradient centrifugation, and the analysis of subcellular fractions.

YEAST STRAIN SELECTION AND GROWTH CONDITIONS

Yeast Strains

All references to "yeast" within this unit refer to the budding yeast *S. cerevisiae*, unless otherwise indicated. Many of the protocols developed for *S. cerevisiae* are not directly applicable to other yeast (e.g., *Schizosaccharomyces pombe*) without significant modification. *S. cerevisiae* protocols can be applied to many different strains; however, variations among strains and growth conditions may require adjustments to a given protocol.

The desired *S. cerevisiae* strains can be generated using a variety of genetic and molecular biology techniques (Sherman, 1991). In addition, published strains can be obtained from centralized sources such as the Yeast Genetic Stock Center (*http://www.atcc.org/searchengine/ygsc.html*) or from the investigators that first generated the strain and described it in the literature. In many cases, a limited set of strains is used most frequently by a given laboratory or a group of investigators in a common field. If the strain used in a published protocol is available and compatible with the goals of the experiment, using it can minimize the need for protocol modifications. All other things being equal, it is usually best to use the healthiest strain and the most optimal growth conditions that meet the goals of the experiment.

For many subcellular fractionation procedures, it is best to use a strain that is deficient in vacuolar protease activity in order to minimize problems with proteolysis. The three major vacuolar proteases are proteinase A (PrA), proteinase B (PrB), and carboxypeptidase Y (CPY), which are encoded by the *PEP4, PRB1,* and *PRC1* genes, respectively (Jones, 1991a,b; Van Den Hazel et al., 1996). These proteases, as well as most other vacuolar hydrolases, are first synthesized as inactive precursors and are activated by the cleavage of their pro domain upon arrival in the acidic, protease-rich environment of the vacuole (Klionsky and Emr, 1989; Horazdovsky et al., 1995). The minimal requirement for low vacuolar protease activity is the deletion or inactivation of PrA, because this proteinase self-activates under acidic conditions and subsequently initiates the activation cascade for PrB, CPY, and multiple other vacuolar hydrolases (Zubenko et al., 1983; Jones, 1990, 1991a,b). Protease activity levels can be further reduced by eliminating PrB and CPY expression, as these proteases can become activated in the absence of PrA activity under certain conditions (Jones, 1991a,b; Romanos et al., 1992; Westphal et al., 1996).

Cell Culture Conditions

Most *S. cerevisiae* strains can be cultured with relatively little difficulty and expense (see UNIT 1.6; Sherman, 1991). Unless there are special nutritional indications, the medium of choice is a rich broth, such as yeast extract/peptone/dextrose (YPD; UNIT 1.6), that promotes rapid growth. Minimal or synthetic medium supplemented with dextrose (SD) and the appropriate amino acids is frequently used if plasmid maintenance is required. Alternate carbon sources can be used to enhance organelle function and proliferation (e.g., peroxisomes, mitochondria) or to regulate the expression of proteins under the control of certain inducible or repressible promoters. The growth of strains carrying mutations in the adenine deficiency genes *ADE1* or *ADE2* can be improved by adding adenine hemisulfate at 100 mg/liter, which minimizes the accumulation of the red metabolic intermediates. (The pH of the medium should be adjusted to 6.0 with NaOH after the addition of adenine hemisulfate.)

The optimal temperature for culturing yeast is 30°C, unless strains sensitive to high or low temperature are being used. Yeast growth is most vigorous under aerobic conditions. Adequate aeration is achieved by culturing yeast in an Erlenmeyer flask (filled to no more than one-fourth capacity) on a rotary shaker. If extensive foaming occurs, the cultures can be safely treated with a standard antifoam solution. Smaller cultures (2 to 10 ml) can be grown in tubes, which should be secured to a rotary shaker at an angle to allow greater movement of the culture. Fermenters can be used to culture the many cells required for large-scale preparations.

To ensure that a culture consists of a homogeneous population of vigorously growing cells, yeast should be cultured for ≥16 to 24 hr prior to the start of an experiment. This is often best achieved by inoculating a small volume (~5 to 10 ml) of rich medium with a single yeast colony from a fresh plate. Incubation of this initial culture, sometimes referred to as a preculture, allows viable cells to emerge from the stationary phase and enter the growth phase. Once the cell number has doubled at least twice (two generations), the preculture is used to inoculate a larger volume of medium with cells that will be cultured for an extended period (usually overnight) prior to the start of the experiment. If the culture surpasses its target cell density during the incubation period and its growth rate begins to slow, it is best to dilute the culture and allow the cells to grow for several hours (at least two generations) prior to harvesting.

Monitoring Growth Phase and Cell Titer

For most applications, yeast cells are harvested by centrifugation during their mid- to late-logarithmic growth phase. During this time, the cells are growing and dividing vigorously, and have reached a concentration that permits a reasonable yield. In addition, rapidly dividing cells have lower protease levels and thinner cell walls that are more susceptible to disruption than cells exiting or approaching stationary phase.

The cell concentration that correlates with the mid-logarithmic growth phase can vary considerably for different strains and culture conditions. For example, mutant strains with slower growth kinetics or strains grown in minimal medium will reach the logarithmic growth and stationary phases at significantly lower cell concentrations than heartier wild-type strains or strains grown in rich medium. Thus, growth curves should be generated for each strain and each set of culture conditions.

The approximate cell concentration of a culture can be determined using a microscope and hemacytometer (*UNIT 1.1*) or by measuring the optical density of the suspension at 600 nm (OD_{600}; *UNIT 1.6*). Although the latter technique provides only an estimate of the cell concentration, it is rapid and simple. The OD_{600} measurement of a culture, also referred to as the absorbance (A_{600}), is proportional to the number of cells and their size.

The relationship between the OD_{600} value, viable cell number, and growth phase is dependent on the strain and culture conditions. To generate a standard curve for each strain and culture condition to be used, remove samples of the culture at regular intervals throughout its growth and measure the OD_{600} value. The most linear range of the relationship between OD_{600} values and cell number is at OD_{600} values between 0.1 and 0.3; thus, it is usually recommended to measure a diluted culture sample (e.g., 1:5 to 1:10 dilution). Next, determine the corresponding viable cell number by plating appropriate dilutions onto YPAD plates (*UNIT 1.6*).

In general, each 0.1 OD_{600} unit corresponds to ~2–4 × 10^6 cells/ml for haploid cells and 0.5–2 × 10^6 cells/ml for diploid cells. An OD_{600} unit of haploid cells, defined as 1 ml of culture with an OD_{600} value of 1, typically represents 3 × 10^7 cells. In many cases, a haploid yeast culture (grown with appropriate preculturing as described above) will reach its mid-logarithmic growth phase when its OD_{600} value is between 0.4 and 0.9. However, these values are estimates, and it is strongly recommended that the correlation between the OD_{600} value, cell density, and growth phase be determined empirically for each strain and growth condition to be used.

An unusually rapid increase in the OD_{600} of a yeast culture, as well as an unpleasant odor, may indicate that the culture is contaminated with bacteria. Contamination can be confirmed by inspection with a phase-contrast microscope.

PREPARATION OF YEAST CELL LYSATES

The preparation of the cell homogenate is a crucial step in any subcellular fractionation procedure. The major aim of a homogenization

technique is to reproducibly achieve a high degree of cell breakage with a minimum of damage to the organelles or organelle membranes of interest. To analyze yeast organelle membranes, the cell must be stressed sufficiently to cause the disruption of the cell wall and plasma membrane to release the cytosol or the other subcellular components in an intact, dispersed state. Ideally, the cells are disrupted in such a way that the subcellular compartments and membranes: (1) retain their normal functional and structural integrity, (2) are freely suspended in the homogenate, and (3) are in a state that is compatible with the goals and techniques of the subsequent experiments.

The extent of cell lysis and the quality of a yeast cell homogenate depend largely on the culture conditions, cell lysis and homogenization techniques, and lysis buffer. Culture conditions have been discussed above (see Yeast Strain Selection and Growth Conditions), and should be standardized to ensure optimal and reproducible results. In addition, the experimental conditions to which cells are subjected (e.g., extended incubations on ice, treatment with energy poisons) should be noted and standardized.

All lysis and homogenization techniques cause some degree of membrane fragmentation, which reduces organelle integrity and exacerbates the preexisting problem of organelle heterogeneity. Some organelle membranes will rupture and release their lumenal contents; subsequently, the damaged membranes can also reseal and trap inappropriate constituents. The release of hydrolytic enzymes from the vacuole/lysosome can result in extensive protein degradation, while the release of DNA from nuclei increases the viscosity of the suspension and promotes aggregation. Moreover, the normal interactions between organelles and cytoskeletal elements, as well as the formation of aggregates during the homogenization process, can cause difficulties in the preparation of an optimal homogenate. Realistically, homogenization procedures are an imperfect compromise between complete homogenization and minimal damage to intracellular components.

Cell Lysis with Glass Beads

Mechanical disruption of the cell wall by shearing with glass beads is a simple and rapid method to prepare homogenates for the isolation of cytosol or plasma membranes (see Table 3.7.1). This technique is very flexible, as it can be applied to multiple small cultures using a vortex mixer, as well as to very large cultures using a Bead Beater (BioSpec). However, glass-bead lysis is not suitable for most subcellular fractionation experiments, as the strong mechanical forces damage the intracellular organelles and can disrupt critical protein and membrane interactions.

Spheroplast Preparation and Lysis

The optimal lysates for most subcellular fractionation experiments are prepared by enzymatically removing the yeast cell wall prior to lysis (see Table 3.7.1). Yeast cells lacking cell walls, referred to as spheroplasts, are fragile and can be lysed with far more gentle methods than can whole yeast cells. Thus, the preparation of lysates from spheroplasts causes much less damage to organelles, organelle membranes, protein complexes, and other intracellular components than does glass-bead lysis.

A number of hydrolytic enzyme preparations that rapidly and efficiently destabilize yeast cell walls are available. The key enzyme in these preparations is a glucanase that hydrolyzes the bonds between β1-3-linked glucans, the primary structural components of yeast cell walls. In addition, the enzymatic preparations have an alkaline protease activity that plays a more minor role in cell wall digestion. Hydrolysis of the cell walls is enhanced by treatment with dithiothreitol (DTT) or 2-mercaptoethanol (2-ME). These sulfhydral reagents break the disulfide bonds within cell wall proteins, thereby giving the β1-3-glucanase greater access to the glucan linkages. It is often beneficial to determine the optimal digestion conditions empirically in a small-scale experiment, as they can vary considerably with different yeast strains, culture conditions, and enzyme preparations.

The most widely used enzyme preparation is Zymolyase 100T (Seikagaku America, ICN), a highly purified β1-3-glucanase preparation derived from cultured filtrates of *Arthrobacter luteus*. Zymolyase 20T is also used, but its specific activity is one-fifth that of Zymolyase 100T. Several investigators use lyticase preparations to minimize costs, because it can be isolated from cultures of *Oerskovia xanthineolytica* using a straightforward protocol (Scott and Schekman, 1980) or purchased (Sigma). The use of crude enzyme preparations such as β-glucuronidase is usually not recommended for subcellular fractionation ex-

Table 3.7.1 Yeast Cell Lysis Techniques: Advantages and Disadvantages

Method	Advantages	Disadvantages
Glass-bead lysis	Rapid, efficient homogenization Can be applied to many small cultures (using a vortex mixer) or large cultures (using a Bead Beater) Glass beads are inexpensive and easy to prepare Does not require an incubation step prior to cell lysis Plasma membrane is not exposed to hydrolytic enzymes for extended times	Extensive damage to organelles and organelle membranes Agitation generates heat (increased proteolysis) and foam (due to protein denaturation) Can disrupt membrane and protein interactions Lysis efficiency is less reproducible than spheroplast lysis
Spheroplast preparation and lysis	Minimal damage to organelles and protein complexes, as spheroplasts readily lyse when exposed to osmotic and/or mechanical stress Spheroplast lysis is highly efficient and reproducible Multiple methods for lysing spheroplasts: DEAE-facilitated isoosmotic lysis (the most gentle method), exposure to hypoosmotic conditions (osmotic shock), Dounce homogenization, and/or multiple passes through a syringe needle or pipet tip The degree of lysis and homogenization can be easily adjusted (e.g., by changing number of strokes or pestle clearance when using a Dounce homogenizer) High-quality glucanase preparations are readily available (e.g., Zymolyase 100T) Lyticase is very economical if prepared in the laboratory	Takes longer than glass-bead lysis Extended incubation time (30-60 min) before cell lysis can conflict with the goals and steps of some experiments Spheroplasts are fragile; osmotic support and gentle handling are required to prevent premature lysis Enzyme preparations used to digest cell wall can damage some plasma membrane proteins Highly purified glucanase preparations (e.g., Zymolyase 100T) are relatively expensive Lyticase is more economical than Zymolyase, but time and effort are required to prepare it

periments, since they have much higher protease levels than do Zymolyase or lyticase preparations. For example, β-glucuronidase preparations ("snail-gut juice"), which are isolated from the alimentary canal of the Roman snail *Helix pomatia*, can have at least thirty different enzyme activities. Although Zymolyase and lyticase are highly purified preparations, even they can contain residual protease, phosphatase, and nuclease activities; thus, it is always important to wash the spheroplasts well prior to cell lysis.

Spheroplasts are very sensitive to mechanical and osmotic stress. They must be suspended in an isotonic solution during and after the digestion procedure to prevent lysis. The nonmetabolizable sugar sorbitol is frequently used at concentrations of 1.0 to 1.2 M (up to 1.5 M for particularly unstable strains) to provide osmotic support. In addition, spheroplasts must be handled with care to prevent premature cell lysis.

Spheroplasts can be lysed using several techniques. In many procedures, the spheroplasts are resuspended in a hypoosmotic solution, which causes them to swell and potentially lyse. A dramatic and rapid decrease in osmotic support is sufficient to promote cell lysis; however, it also promotes the lysis of intracellular organelles. To disrupt the plasma membrane with a minimum of damage to subcellular components, mild hypoosmotic conditions are used in combination with moderate homogenization techniques—e.g., glass/glass (Dounce) or glass/Teflon (Potter-Elvehjem) homogenization, or passage through a small-gauge syringe needle or pipet tip. Even milder conditions with very little osmotic and mechanical stress are required to maintain the integrity of a high percentage of very fragile

organelles (such as vacuoles). Cell lysis under isoosmotic conditions can be facilitated by incubating the spheroplasts with a cationic polymer such as DEAE-dextran, which interacts with the negatively charged phospholipids in the plasma membrane. Treatment with triethanolamine/acetic acid, pH 7, also improves cell lysis efficiency under mild hypotonic conditions.

Lysis Buffers

The optimal lysis buffer facilitates cell lysis and simultaneously protects the structural and functional integrity of the organelles, organelle membranes, and protein complexes of interest. Ideally, a lysis buffer should be isoosmotic to the organelles within the homogenate; however, most lysis buffers are hypoosmotic to some degree to facilitate efficient cell lysis. In some cases, the osmolarity of the buffer can be adjusted after cell lysis to protect organelles from extended osmotic stress. In addition to minimizing damage to subcellular components, the lysis buffer should interfere as little as possible with subsequent fractionation steps and biochemical assays.

The most appropriate buffer composition depends on the cell lysis method and the purpose for which the lysate is being prepared. Standard buffers consist of several components, including: (1) a suitable organic buffer to maintain a physiological pH, (2) sorbitol or another osmotic balancer to stabilize the organelle membranes, (3) salts to provide the appropriate ionic strength, and (4) a cocktail of protease inhibitors to minimize the damage caused by hydrolytic enzymes. Most lysis buffers include the cation chelator EDTA, as Mg^{2+} serves as a cofactor for several proteases and can promote membrane aggregation at high concentrations. However, in a few cases, Mg^{2+} is added to the lysis buffers to stabilize the composition, membrane association, and function of certain protein complexes and enzymes.

Protein degradation can be a severe problem during subcellular fractionation experiments. Subcellular components are inevitably exposed to degradative enzymes upon cell lysis and homogenization, as these manipulations disrupt the in vivo regulation and compartmentalization of hydrolase activities. The primary source of active degradative enzymes in cell lysates is usually the vacuole, which is an acidic lysosome-like compartment. A cocktail of protease inhibitors with a broad specificity range should be included in the lysis buffer and all subsequent solutions (even when using a vacuolar protease–deficient strain). Because protease inhibitors such as phenylmethylsulfonyl flouride (PMSF) are unstable in aqueous solutions, they should be added just before the solutions are to be used and should be replenished at multiple steps during the fractionation process. In addition, the lysis buffer and all other solutions and equipment required to process the lysate should be prechilled to 0° to 4°C before and during their use (unless otherwise indicated). Damage caused by hydrolytic enzymes can be minimized further by (1) working quickly to limit the potential exposure time to active hydrolases, (2) separating material of interest from the remaining cell lysate as soon as possible, (3) maintaining the integrity of the vacuole, and/or (4) using mutant yeast strains that lack most vacuolar hydrolase activities (e.g., *pep4*Δ*prb1*Δ yeast strains).

It is also critical to be aware that different lysis buffers can destabilize protein-protein interactions to varying degrees and promote the release of sensitive peripheral membrane proteins. The destabilization of protein-protein interactions can disrupt the function, composition, and other biochemical characteristics of subcellular components. In addition, the release of peripheral membrane proteins can change both the absolute and the relative densities of organelles and organelle membranes. It can be particularly difficult to determine the subcellular localization of a peripheral membrane protein, since these proteins can dissociate from their resident membranes during the fractionation procedure and thus cofractionate with soluble cytoplasmic proteins.

The buffer composition often needs to be optimized for a given purpose, since even a slight change can have dramatic effects. Certain buffer characteristics can be either advantages or disadvantages depending on the goals of the experiment. For example, the use of buffers with relatively high ionic strengths minimizes protein and membrane aggregation during cell lysis and homogenization; however, these buffers also tend to destabilize certain protein-protein interactions and promote the release of peripheral membrane proteins. Similarly, inclusion of triethanolamine in the lysis buffer facilitates spheroplast lysis under very mild hypoosmotic conditions, but it can also destabilize some protein-protein interactions.

ISOLATION OF SUBCELLULAR FRACTIONS: PROCEDURAL OPTIONS

Subcellular fractionation procedures capitalize on the differing physical properties of individual organelle and membrane types. The most versatile fractionation procedures are based on centrifugation techniques, which effectively exploit the differences in size, shape, and/or density of distinct organelles and membranes (see Table 3.7.2 and the text below). A number of more-specialized fractionation protocols use gel filtration, immunoisolation, or electrophoresis to separate certain subcellular components according to their size, surface antigen composition, or surface charge, respectively (see Table 3.7.3). However, even these alternate procedures usually begin with centrifugation-based steps to enrich the starting material with the subcellular components of interest and to remove some of the undesirable components.

The most appropriate fractionation procedure will depend on the primary goals of the particular experiment. Parameters to consider include: (1) the properties of the organelles/membranes of interest (e.g., their abundance, fragility, size, density), (2) the properties of the other subcellular components that need to be separated from the organelles/membranes of interest, (3) the required yield, (4) the required purity, (5) the degree to which certain contaminants are harmful, (6) the need for organelle integrity and function, (7) the need to maintain the association of peripheral membrane proteins with their resident compartments, and (8) the need to maintain enzymatic activity levels. The importance of each of these factors should be prioritized for a given experiment, since some desirable qualities will need to be sacrificed to meet the most important goals. For example, the yield of a given organelle within a fraction will generally decrease as its purity increases. Thus, fractionation procedures often need to be evaluated and modified to meet particular requirements.

Centrifugation-Based Subcellular Fractionation Techniques

There are three primary centrifugation procedures used for subcellular fractionation experiments: (1) differential centrifugation by velocity, (2) equilibrium density gradient centrifugation, and (3) rate-zonal gradient centrifugation. Centrifugation-based fractionation procedures separate organelles and membranes according to their sedimentation velocities and/or buoyant densities. These techniques are very versatile, since the sedimentation velocities and densities of subcellular components are determined both by their intrinsic properties and the characteristics of the surrounding medium. Some of the merits and limitations of these procedures are summarized in Table 3.7.2. Several excellent reviews on the theory and practice of centrifugation-based fractionation techniques are also available (Dobrota and Hinton, 1992; Evans, 1992; Hinton and Mullock, 1997).

The absolute densities of subcellular components, as well as their densities relative to one another, can vary with the composition of the surrounding solution. One cause of this variability is the semipermeable nature of membranes. While the mass of the membrane (i.e., the lipids and integral membrane proteins) and the nondiffusible components within the lumen remain constant, the mass of the water and diffusible solutes within the organelle can change as the diffusible molecules move into or out of the organelle to reach equilibrium. Also, the volume of the organelle will change as it swells with water in a hypoosmotic solution, shrinks in a hyperosmotic solution, or bursts due to osmotic or mechanical stress. The mass of an organelle is also dependent on the amounts of associated peripheral membrane proteins and macromolecular complexes (e.g., ribosomes), which can vary in different buffers and density media. For example, if a density medium destabilizes protein-protein interactions, peripheral membrane proteins may be released from their resident membranes, and the mass and density of the organelle will decrease.

The relative sedimentation velocities of subcellular components are primarily determined by the mass and shape of the components and by their density relative to that of the surrounding medium. If the organelles have significantly higher densities than the surrounding medium, their relative sedimentation velocities will be principally determined by their mass, so that larger organelles will have a faster sedimentation velocity than will smaller ones. Shape usually plays a more minor role. However, if the organelles are subjected to centrifugation in a density gradient, their sedimentation velocities will decrease as the density of the surrounding medium approaches their own density. The movement of

Table 3.7.2 Centrifugation-Based Subcellular Fractionation Techniques: Advantages and Disadvantages

Method	Advantages	Disadvantages
Differential centrifugation (basis: sedimentation velocity[a], primarily size)	Simple and rapid method to enrich membranes in fractions corresponding to broad size classes (Fig. 3.7.1) Effective separation of membranes with large size differences (see Table 3.7.4) Relatively high yield Initial low-speed centrifugation permits removal of unbroken cells and large aggregates Excellent preparation step for further fractionation: can enrich components of interest, remove unwanted material, and concentrate membranes from large lysate volumes Provides a rapid means to determine the potential subcellular location of a protein of interest (Table 3.7.4)	Low resolution and purity[a] Poor separation of membranes of similar sizes Pellets containing larger subcellular components will be contaminated with smaller ones[a] Pelleting of organelles and membranes can cause aggregation and structural damage (minimized by pelleting on a cushion) Isolation of particular membrane types requires further fractionation steps
Equilibrium density gradient (basis: density)	Extremely versatile: well suited for both preparative and analytical fractionation experiments Relative densities of organelles/membranes can vary in different gradient media (high flexibility and versatility) Gradients can be either continuous or discontinuous Not sensitive to changes in centrifugation times as long as equilibrium status is reached (good for overnight centrifugations)	Extended centrifugation times may be detrimental to labile organelles and enzyme activities (centrifugation times can be minimized by using a vertical tube rotor) Sample size should be relatively low to maximize resolution and minimize aggregation Very dense organelles/membranes may be exposed to hyperosmotic conditions (especially in sucrose gradients)
Rate-zonal (velocity) gradient (basis: sedimentation velocity and density[b])	Multiparameter separation based on size, shape, and density Well suited for the separation of multiple subcellular components of different sizes Superior to differential centrifugation for separation of components based on size and sedimentation velocities, since sample is layered on top of the gradient Results vary with centrifugation time and gradient composition and shape (high flexibility) Shorter centrifugation runs than for equilibrium gradients (lower risk of damage to subcellular components)	Results depend on centrifugation times and gradient shape and composition (can be more difficult to design and optimize) Less well suited for organelle/membrane purification unless procedure also includes equilibrium gradient fractionation step Sample size should be relatively low to maximize resolution and minimize aggregation Very large or dense components may be exposed to hyperosmotic conditions

[a]Relative sedimentation velocity in a buffer of low density and viscosity is primarily determined by size. Shape and density play a more minor role. The resolution is quite low because components are suspended throughout the medium prior to centrifugation, and thus have a range of migration distances to the bottom of the tube.

[b]Relative sedimentation velocity and final banding position in a nonequilibrium density gradient is determined by both particle size and density relative to the surrounding medium. Size is the primary determinant of sedimentation velocity when the density of the component is significantly greater than the surrounding medium. As the component approaches medium equal to its own density, the particle velocity will decrease. If the particle reaches medium with a density equal to its own, the particle will stop, and its final position within the gradient will be based on its buoyant density alone, irrespective of size or shape.

Table 3.7.3 Several Noncentrifugal Fractionation Techniques: Advantages and Disadvantages

Method	Advantages	Disadvantages
Gel filtration (basis: size and shape)	Excellent for purification of small spherical vesicles (<200 nm) from larger or irregularly shaped organelles High resolution	Not suited for fractionation of larger or irregularly shaped organelles/vesicles Poor separation of different vesicle types with similar sizes
Affinity isolation (basis: surface epitope)	Highly selective for compartment or membrane that has appropriate surface epitope (high purity) Relatively gentle, facilitates isolation of intact organelles	Highly specialized; may need extensive optimization Not well suited for large-scale preparations Limited by antibody specificity and avidity (controls for nonspecific interactions are critical) Limited by epitope accessibility
Electrophoresis (basis: surface charge and size)	Can be used after gel filtration to separate different vesicle types that are similar in size, shape, and density	Requires specialized, expensive equipment Not suitable for larger organelles Rarely used for yeast organelles (purification of mammalian endosomes has been the most common application)

a subcellular component will stop once the density of the surrounding medium is equal to its own density; in this case, the position of the component within the gradient is based on its density, irrespective of size.

The fractionation of subcellular components is never perfect or complete. Centrifugation-based fractionation procedures are limited by the fact that different organelle or membrane populations can have similar sizes and/or densities. In addition, members of a given organelle population vary to some degree both in mass and density. Both of these complications (i.e., the differences within an individual population and the similarities between different populations) are exacerbated by the organelle/membrane fragmentation caused by lysate preparation and fractionation procedures.

Differential centrifugation

Differential centrifugation protocols rapidly fractionate cell lysates into broad size classes through sequential centrifugation steps of increasing force and duration (Fig. 3.7.1). This technique is also referred to as differential pelleting. Because the subcellular components have a substantially higher density than the surrounding buffer, their relative sedimentation velocities are primarily determined by their mass; larger organelles and membranes will pellet faster and at lower centrifugal forces than will smaller organelles. Some of the merits and limitations of differential centrifugation are summarized in Table 3.7.2.

Differential centrifugation is particularly useful to generate fractions that are significantly enriched for the component(s) of interest. The use of enriched fractions (instead of crude cell lysates) facilitates subsequent purification or analysis by density gradient centrifugation and other fractionation techniques. Differential centrifugation is also a convenient way to assess the potential subcellular locations of a protein of interest.

The resolution of size separation by differential centrifugation is quite low, because subcellular components are randomly dispersed throughout the medium prior to centrifugation. Thus, the resulting separation of subcellular components is based both on their sedimentation velocity (which is proportional to their mass) and on their migration distance to the bottom of the centrifugation tube (a random characteristic). Small organelles with short migration distances (and relatively slow sedimentation velocities) will pellet with larger organelles that have faster sedimentation velocities. In other words, a pellet intended to consist of relatively large organelles will also contain smaller organelles that happened to be close to the bottom of the centrifugation tube. Some of the smaller organelles found in low-speed pellets can be removed by resuspending

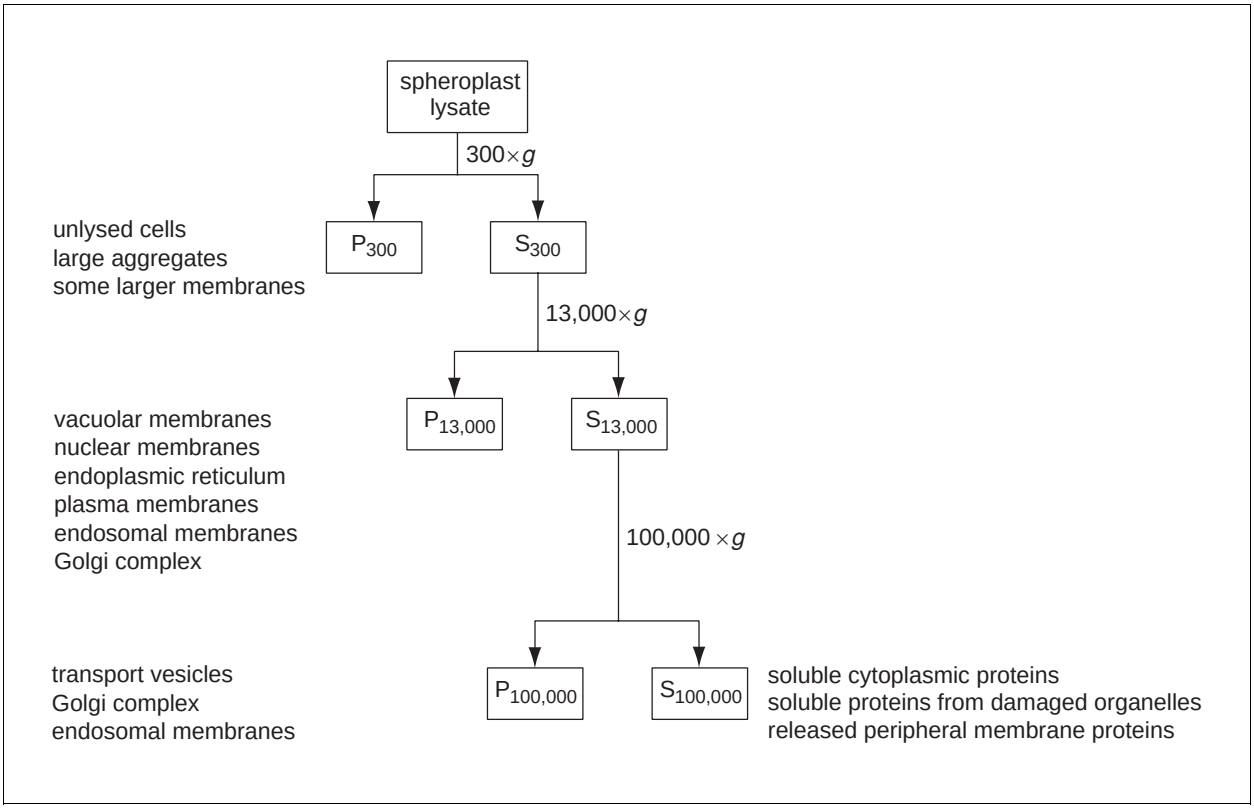

Figure 3.7.1 A procedure for differential centrifugation of yeast cells (see Table 3.7.4 for further details).

the pellet in fresh medium and repeating the centrifugation step, a technique often referred to as "washing" the pellet; however, this step also increases the likelihood of organelle damage.

A typical differential centrifugation scheme is a presented in Figure 3.7.1. First, the yeast cell lysates are subjected to a low centrifugal force (e.g., 300 × *g*) to pellet any unlysed cells and large aggregates. This centrifugation step is often referred to as a "clearing spin." The cleared lysate (S_{300}) is then subjected to sequential centrifugation steps to generate a 13,000 × *g* pellet ($P_{13,000}$), a 100,000 × *g* pellet ($P_{100,000}$), and a 100,000 × *g* supernatant ($S_{100,000}$). The resulting distribution of subcellular components is summarized in Table 3.7.4. The $P_{13,000}$ fraction primarily contains larger organelles and membranes (e.g., plasma membrane, vacuole, endoplasmic reticulum, mitochondria, nuclei, peroxisomes), while the $P_{100,000}$ fraction contains smaller compartments (e.g., Golgi, transport vesicles). Heterogeneous or moderate-sized organelles can distribute between the two fractions (e.g., endosomal membranes). The $S_{100,000}$ fraction contains soluble cytoplasmic proteins, soluble proteins released from the lumen of damaged organelles, and released peripheral membrane proteins.

Equilibrium density gradient centrifugation

Subcellular components can be separated according to their buoyant densities by centrifugation to equilibrium in a density gradient. This technique is referred to as equilibrium density gradient centrifugation or isopycnic gradient centrifugation. In response to centrifugation, a given organelle or membrane will migrate within the gradient until it reaches the region of the gradient that matches its own buoyant density. The subcellular component will then remain at this position for the duration of the centrifugation irrespective of its size, as there is no net force exerted on a particle that is suspended in a liquid of its own density (Archimedes' principle). Some of the merits and limitations of equilibrium density gradient centrifugation are summarized in Table 3.7.2.

Equilibrium density gradient centrifugation techniques are very versatile and are well suited for both analytical and preparative procedures. Often the material to be separated by equilibrium density gradient centrifugation is first subjected to differential centrifugation

Table 3.7.4 Distribution of Organelle Membranes after Cleared Yeast Spheroplast Lysate (S_{300}) is Subjected to Sequential Centrifugation at 13,000 × *g* and 100,000 × *g* [a]

Subcellular component	$P_{13,000}$	$P_{100,000}$
Endosomal membranes[b]	~30%-70%	~30%-70%
Endoplasmic reticulum[c]	>95%	
Golgi (*cis* cisternae)	~30%-60%	~40%-70%
Golgi (medial and *trans* cisternae)	~10%-30%	~70%-90%
Mitochondria	>95%	
Nuclei[c]	>95%	
Peroxisomes (oleate induced)	>95%	
Plasma membrane[c]	>95%	
Transport vesicles		>95%
Vacuolar membranes	>95%	

[a]Strain: SEY6210. Selected references: Gaynor et al. (1994); Marcusson et al. (1994); Cereghino et al. (1995); Zinser and Daum (1995); Rieder and Emr (1997); Babst et al. (1998).

[b]The endosomal membrane system is thought to consist of at least two distinct compartment types. The later prevacuolar endosomes appear to pellet at lower speeds than the earlier post-Golgi endosomal compartments.

[c]Up to 50% of these membranes may pellet during the clearing centrifugation step at 300 × *g*. Yields can be improved by resuspending and recentrifuging the 300 × *g* pellet material, but some loss is unavoidable.

and is thus enriched for components of the appropriate size. The combination of differential centrifugation and equilibrium density gradient centrifugation allows subcellular components to be fractionated according to both mass and buoyant density. The material to be fractionated can be loaded on the top, bottom, or middle of the density gradient, since the components will sediment or float until they reach the appropriate region of the gradient. (Loading a gradient at the bottom, however, may damage sensitive organelles if the gradient is hyperosmotic at the dense regions of the gradient.)

Rate-zonal gradient centrifugation

Rate-zonal gradient centrifugation is a nonequilibrium method in which subcellular components loaded on top of a density gradient move into enriched regions within the gradient. This technique is also referred to as velocity gradient centrifugation. The absolute and relative banding positions of subcellular components are primarily determined by each component's mass, the density of the component relative to the surrounding medium, the centrifugation time (duration), and the composition of the gradient. The mass is the primary determinant of the sedimentation velocity (and thus of position) when the density of the component is significantly greater than that of the surrounding medium. As the component approaches medium equal to its own density, its velocity will decrease. If the particle reaches medium with a density equal to its own, it will stop, and its final position within the gradient will be based on its buoyant density alone, irrespective of its mass or shape.

Like equilibrium density gradient centrifugation techniques, rate-zonal density gradient centrifugation techniques are very versatile and well suited for both analytical and preparative procedures. The separation between different subcellular components can be manipulated empirically to some extent by changing the length of centrifugation, the density limits of the gradient, or the gradient medium. Often the material to be separated by rate-zonal density gradient centrifugation is first subjected to differential centrifugation and is thus enriched for components of the appropriate size. Rate-zonal centrifugation procedures are particularly useful to fractionate subcellular components within a relatively short time, since the rate-zonal centrifugation times are typically much shorter than density equilibrium centrifugation times.

Continuous Versus Discontinuous Density Gradients

The density gradients used for density gradient centrifugation procedures can be either continuous or discontinuous. Some of the mer-

Table 3.7.5 Advantages and Disadvantages of Continuous and Discontinuous Density Gradients

Density gradients	Advantages	Disadvantages
Continuous gradient	Especially well suited for the separation of multiple organelle/membrane types Very versatile: useful for both analytical and preparative fractionation procedures Appropriate for both equilibrium and velocity density gradients Higher resolution than step gradients Less sensitive to overloading than step gradients	Fractions containing organelles of interest are usually not identifiable without monitoring distribution over several fractions Material of interest may be spread over several fractions and may require concentration Preparation is more time consuming
Discontinuous gradient (step gradient)	Gradient preparation is simple and rapid Especially well suited for preparative fractionation procedures to isolate a subcellular component of interest Concentrated organelle/membrane layers are often visible and may have distinguishing characteristics (e.g., color, "fluffiness") Subcellular components of interest can be rapidly harvested by collecting fractions at the appropriate region of the gradient. (All gradient fractions should be collected and examined to assess the success of the experiment.)	Lower resolution than continuous gradients Preliminary experiments using continuous density gradients are usually required to determine optimal densities Accumulation of membranes/organelles at an interface can block movement of other membranes/organelles Sample quantities loaded on gradients must be relatively low to minimize aggregation at interfaces Generally less well suited for analytical purposes (e.g., separation of multiple organelle types on a single gradient)

its and limitations of continuous and discontinuous density gradients are summarized in Table 3.7.5.

In continuous density gradients, the density of the medium changes gradually along the length of the gradient tube. Such gradients are particularly useful for equilibrium or rate-zonal centrifugation to analyze a complex mixture of subcellular components, some of which may have unique but overlapping distributions along the density gradient. The relationship between the density of the gradient medium and the positions of given densities along the gradient, sometimes referred to as the shape of the gradient, can be linear or nonlinear. The optimal shape depends on the densities of the key components that need to be separated from each other.

Discontinuous density gradients, also referred to as step gradients, consist of two or more layers of gradient media with significantly different densities. The interfaces between the layers should be very sharp; therefore, discontinuous gradients must be prepared just before use. Discontinuous density gradients are most frequently used for preparative procedures (e.g., the purification of a subcellular component of interest) but have also been used for analytical experiments. In most cases, the appropriate density and volume of the gradient layers (or steps) are determined by first examining the distribution of the subcellular components within a continuous density gradient. For preparative procedures, discontinuous density gradients are often designed in such a way that the components of interest accumulate in a small and easily identifiable region of the gradient (e.g., an interface between two layers), while other components either do not reach this region or pass through it.

Gradient Preparation

The accurate and reproducible preparation of density gradients is critical to the success of density gradient fractionation procedures. Continuous density gradients are often generated using a gradient maker that mixes two solutions of different densities in the appropriate proportions. Alternatively, continuous density gradients can be formed by preparing a multilayer step gradient and allowing the density medium to diffuse for several hours to eliminate the interfaces. Regardless of whether a continuous gradient is prepared with a gradient maker or by diffusion, it is best to analyze the density distributions of at least two test

gradients to ensure that the densities are as planned and are reproducible. A refractometer is the best way to accurately measure the densities of media that are true solutions (e.g., sucrose, Nycodenz, iodixinol).

Discontinuous gradients are prepared just before use by sequentially adding layers of gradient media with significantly different densities to the centrifugation tube. Some investigators prefer to start with the most dense layer, then gently add the subsequent layer of lower density on top (overlaying). Other investigators find it easier to add the least-dense layer first and then introduce layers of increasing density underneath it, using a very long, slim cannula or needle (underlaying). With either technique, it is critical that the interface between the layers remains sharp. If mixing between layers becomes apparent during gradient preparation, the gradient should be discarded and a new one should be made.

Gradient Media

The optimal density gradient medium should facilitate the separation of the subcellular components of interest into distinct sets of fractions. It should also protect the functional and structural integrity of the organelles and membranes, as well as the appropriate protein-protein and protein-membrane interactions, to the greatest extent possible.

The characteristics of several different density gradient media are summarized in Table 3.7.6. To generate the required density range of the gradient medium, the primary constituent is dissolved or suspended in a buffered solution at varying concentrations. Some density gradient media also contain sucrose to provide osmotic support for organelle membranes, a cocktail of protease inhibitors to minimize damage due to hydrolytic enzymes, and occasionally salts to provide the appropriate ionic strength.

The density gradient media listed in Table 3.7.6 are all very soluble in aqueous buffers and are nontoxic, chemically inert, transparent to visible light, and available at high purity. In addition, each of the media has one or more (but not all) of the following desirable characteristics: (1) has a low viscosity-to-density ratio to minimize the required centrifugation time and/or force, (2) has a low osmolarity-to-density ratio to minimize exposure of dense organelles to hyperosmotic conditions, (3) is transparent to UV light, (4) is inexpensive, (5) is not metabolized by yeast cells, (6) can be used to form gradients with osmolarity levels that support organelle membranes and vary by <10% across the gradient, (7) does not interfere with subsequent analyses of the resulting fractions, and (8) can be easily removed from isolated subcellular components if required.

For several decades, sucrose density gradients have been the most common method for separating organelles on the basis of both size and density. More recently, density gradient solutions prepared with nonionic iodinated compounds (e.g., metramizide, Nycodenz, iodixinol) have increased in popularity, since these solutions have lower viscosity and osmolarity levels than do sucrose solutions of equal density. Density gradients prepared from sucrose or nonionic iodinated compounds are well suited for analytical experiments designed to examine the distribution of multiple organelles and membranes along the same gradient, as well as for preparative experiments used to isolate a particular organelle or membrane type at higher yield and purity levels. In contrast, density gradients prepared from Percoll or Ficoll suspensions are primarily used for preparative procedures. Ficoll consists of highly branched polymers of sucrose and epichlorhydrin, while Percoll consists of colloidal silica beads coated with polyvinylpyrrolidone. Percoll and Ficoll suspensions both have low osmolarity and viscosity levels; in fact, sucrose is usually added to the suspensions to provide the required osmotic support. Density gradients prepared with sorbitol or glycerol, or with D_2O instead of H_2O as the solvent, are used less frequently.

The most appropriate density gradient composition depends on the purpose of the experiment. For example, certain protein-protein interactions will be more stable in one medium than in another. In addition, the absolute densities of organelles and membranes, as well as their densities relative to each other, depend on both the intrinsic characteristics of the organelles and the properties of the surrounding gradient medium. Important factors include differential levels of membrane permeability to gradient solutes, osmolarity of the density medium relative to the organelles, and degree of peripheral protein loss. Thus, subcellular components that are unresolvable in one gradient medium may be resolvable in another.

Ideally, the entire density gradient should be isoosmotic to the organelles within the homogenate. Hyperosmotic solutions tend to draw water out of organelles, and thus can

Table 3.7.6 Characteristics of Several Density Gradient Media: Advantages and Disadvantages

Medium	Advantages	Disadvantages
Sucrose	Most common medium, used for many years Inexpensive and available at high purity Many applications (preparative and analytical) Does not absorb UV light Differential membrane permeability to sucrose[a] Removed by centrifugation, dialysis, or ultrafiltration	High osmotic-pressure-to-density ratio Moderate to high viscosity Can disrupt some protein and membrane interactions Can pass through organelle membranes to some extent[a] Interferes with some enzyme assays
Nycodenz, iodixinol[b]	Exert moderate osmotic pressure (less than sucrose) Isoosmotic density gradients can be generated with osmotic balancers (e.g., sucrose, sorbitol, NaCl) Low to moderate viscosity Many applications (preparative and analytical) Iodixinol gradients can be formed through centrifugation Do not penetrate organelle membranes Removed by centrifugation, dialysis, or ultrafiltration	Moderate osmotic-pressure-to-density ratio Relatively expensive Can disrupt some protein and membrane interactions Moderate viscosity at high concentrations Absorb UV light Interfere with some enzyme assays
Ficoll 400[c]	Very low osmotic pressure at concentrations <25% Does not penetrate organelle membranes Generally used for preparative procedures Usually does not interfere with enzyme assays	Osmotic pressure increases rapidly at concentrations >25% High osmotic pressure at concentrations >30% High viscosity (longer centrifugation times) Cannot be removed by dialysis or ultrafiltration
Percoll[d]	Exerts essentially no osmotic pressure (required osmotic support is usually provided by adding sucrose) Very low viscosity (shorter centrifugation times) Continuous density gradients form during centrifugation Gradient shape is sensitive to changes in rotor geometry, centrifugation speed, and duration (offers flexibility) Permits simple, rapid isolation of larger organelles Does not penetrate organelle membranes	Adheres to membranes and is difficult to remove Cannot be removed by dialysis or ultrafiltration Absorbs UV light and interferes with some assays Gradient shape usually changes during centrifugation Gradient shape is sensitive to changes in centrifugation speed, time, and rotor (more difficult to design and reproduce) Generally not useful for evaluating multiple organelles Not suitable for small organelles or membrane vesicles

continued

change their size, shape, and density. Exposure to hyperosmotic conditions can also promote the loss of protein coats and other peripheral membrane proteins, thereby altering the composition, function, and density of the affected organelle membranes. In addition, organelles suspended in hyperosmotic solutions are more susceptible to lysis if subsequently transferred to a buffer of lower osmolarity. Organelles can also be damaged through exposure to hypoosmotic conditions, which can induce organelle swelling, membrane discontinuities, and organelle lysis. However, hypoosmotic conditions are rarely a practical problem during gradient fractionation, since osmotic balancers such as sorbitol or sucrose can be added to gradient solutions to increase their osmolarity.

Information booklets provided by the manufacturers of gradient media can serve as an excellent resource for details on gradient media

Table 3.7.6 Characteristics of Several Density Gradient Media: Advantages and Disadvantages, continued

Medium	Advantages	Disadvantages
Sorbitol	Advantages are similar to those of sucrose Unlike sucrose, sorbitol is not metabolizable Slightly less membrane permeable than sucrose[a]	Not used as frequently as sucrose More expensive than sucrose Other disadvantages are similar to those of sucrose
Glycerol	Used for separating large protein complexes Freely penetrates membranes (organelle/vesicle density primarily determined by membrane composition)[a] Removable by centrifugation, dialysis, or ultrafiltration	Rarely the best medium for membrane separations Very high viscosity (longer centrifugation times) Freely penetrates membranes (high banding densities) Interferes with some enzyme assays
D_2O solvent[e]	Lower osmolarity and viscosity levels than with H_2O-based media of equal density Extent of exchange between D^+/OD^- and H^+/OH^- molecules varies with membrane composition, changing their relative densities[a]	Expensive and benefits can be insignificant D^+/OD^- molecules can exchange with membrane- and protein-associated H^+/OH^- molecules, increasing the density of components

[a]The absolute densities of subcellular organelles/membranes, as well as their densities relative to each other, can change in different gradient media (e.g., because of differential levels of membrane permeability to the solute, osmolarity of the medium, or peripheral protein loss). Thus, components of interest that have overlapping densities in one medium can have differentiable densities in another gradient medium.

[b]Nycodenz (Nycomed Pharma) and iodixinol (Optiprep, Nycomed Pharma) are nonionic iodinated density compounds with similar characteristics. Nycodenz is a nonionic derivative of triiodobenzoic acid with three aliphatic side chains. Iodixinol is essentially a dimeric form of Nycodenz, and thus has a higher density-to-osmolarity ratio. These nonionic compounds have largely replaced the nonionic medium metramizide, as well as the ionic iodinated density compounds.

[c]Ficoll 400 is a neutral, highly branched polymer of sucrose and epichlorhydrin (average mol. wt. 400,000).

[d]Percoll consists of colloidal silica beads coated with polyvinylpyrrolidone (PVP).

[e]Preparation of gradient density media in heavy water (D_2O; 1.1 g/ml) instead of regular water (1.0 g/ml).

characteristics, gradient preparation techniques, and subcellular fractionation procedures. For example, Nycomed Pharma has several booklets that discuss Nycodenz and Optiprep (iodixinol) gradient media, centrifugation-based fractionation procedures, and several cellular and subcellular fractionation protocols. While the focus of these texts is on mammalian systems, many of the principles are also applicable to yeast fractionation experiments.

ANALYSIS OF SUBCELLULAR FRACTIONS

The specialized functions of subcellular organelles and their membranes are reflected by their unique protein compositions, enzymatic activities, and morphologies. These characteristics can be used to follow the distribution of particular organelles and membranes during the subcellular fractionation procedure, to characterize the resulting fractions, and to analyze the success of an experiment. The most common method used to monitor the distribution and integrity of particular organelles and membranes after subcellular fractionation is to analyze the distribution of their characteristic marker proteins and enzyme activities (Tables 3.7.7 and 3.7.8). To establish the purity and yield of an organelle preparation or the success of an analytical fractionation experiment, it is of central importance to determine the levels of the components of interest, as well as the levels of the potential contaminants. The distribution and integrity of fractionated organelles and membranes can also be characterized by examining their morphologies, functions, and overall protein compositions.

Marker Proteins and Enzymatic Activities

An optimal marker is a well-characterized protein and/or enzyme activity that (1) is associated with a single subcellular compartment or membrane type, (2) remains tightly associated with its resident compartment/membrane

throughout the fractionation experiment, and (3) can be detected by immunological or enzymatic techniques. Proteins that associate with more than one organelle can also serve as markers if they are subjected to compartment-specific posttranslational modifications (e.g., glycosylation, propeptide cleavage). An overview of compartment-specific posttranslational modifications is presented in Table 3.7.9.

Examples of marker proteins for various organelles are supplied in Table 3.7.7. The distribution of marker proteins within a series of fractions can be followed using immunoprecipitation (*UNIT 7.2*) or immunoblotting (*UNIT 6.2*) techniques. To ensure the highest possible accuracy, it is important to determine the relative protein levels among the fractions within the linear ranges of the detection methods.

Several enzyme activities that are characteristic of specific organelles are listed in Table 3.7.8. In most cases, the use of marker proteins to analyze the distribution of organelles/membranes is now favored over the use of enzyme activities if the appropriate antibodies are available. Enzyme activity levels are more sensitive than are protein levels to differing experimental conditions. For example, enzyme activities can be significantly impaired by the lysis buffer or gradient medium, the loss of a needed cofactor, or partial proteolysis.

Protein Profiles

The proteins found in several different highly purified yeast organelle preparations have been analyzed by SDS-PAGE (reviewed in Zinser and Daum, 1995; *UNIT 6.1*). The typical protein pattern (or protein profile) can be used to analyze the purity of an organelle preparation. In addition, the apparent molecular weights and isoelectric points of characterized resident proteins have been used to generate theoretical two-dimensional protein distributions for particular organelles (Yeast Protein Database; Hodges et al., 1998). Several two-dimensional profiles of *S. cerevisiae* proteins have been published (Singer-Kruger et al., 1993; Shevchenko et al., 1996; Garrels et al., 1997; Perrot et al., 1999), and it is likely that experimentally derived two-dimensional protein profiles for various organelle preparations will become increasingly available and informative in the near future.

Analysis of Protein Localization

To determine the subcellular localization of a novel protein (or a mutant form of a characterized protein), the distribution of the protein of interest is compared with the distribution of markers (proteins or enzyme activities) that have a well-characterized subcellular localization. The cofractionation of the protein of interest with a marker suggests, but does not prove, that the two components may be associated with the same organelle or membrane in vivo. A second method (e.g., immunofluorescence) should be used to confirm the steady-state localization of the protein of interest (Pringle et al., 1991; Hasek and Streiblova, 1996). In contrast, if the protein of interest fractionates away from a given marker protein, one can usually conclude that the two components have different subcellular distributions in vivo. However, this generalization does not apply when the protein of interest primarily cofractionates with soluble cytoplasmic marker proteins, because these data alone do not rule out the possibility that the protein is a released peripheral membrane protein or a soluble protein that normally resides within the lumen of an organelle instead of a native cytoplasmic protein.

Analysis of Organelles Along Protein Transport Pathways

The dynamic compartments along the secretory, endocytic, and vacuolar protein transport pathways can be particularly difficult to characterize (especially endosomes and transport vesicles), as they tend to have few proteins or enzyme activities that can serve as reliable steady-state markers. Many of the proteins associated with these organelles are either: (1) cargo molecules that transit along the transport pathways (e.g., newly synthesized membrane proteins, internalized components from the cell surface), (2) proteins that cycle between two or more of the compartments (e.g., cargo receptors, vesicle targeting molecules), or (3) molecules that only transiently associate with the compartment membranes (e.g., small GTPases, coat proteins).

Despite these complications, several techniques can be used to follow the organelles along the secretory, endocytic, and vacuolar protein transport pathways. For example, proteins that are actively retained within a compartment (and retrieved if they escape) have been used as markers for the endoplasmic reticulum (ER), Golgi complex, and plasma membrane, since their steady-state distribution strongly favors a single organelle type (see Table 3.7.7 for examples). In addition, proteins

that transit through multiple compartments can serve as transient markers for the transport intermediate of interest. Several techniques used to generate and monitor transient markers are summarized in Table 3.7.10. In some cases, the transit of a limited pool of proteins is followed until it reaches the compartment of interest. In addition, multiple investigators have successfully used temperature-sensitive mutants that block protein transport at specific steps and accumulate cargo molecules within a particular compartment. Multiple temperature-sensitive mutants that inhibit specific transport steps are available for the secretory pathway (e.g., *sec* mutants), the endocytic pathway (e.g., *end* mutants), and vacuolar protein transport pathway (e.g., *vps* mutants; see Table 3.7.10 for selected references). However, the results derived from mutant cells should only be extrapolated to normal cells after careful evaluation of the mutant cell properties and potential artifacts.

Analysis of Organelle Morphology, Integrity, and Function

The organelles and membranes within subcellular fractions can also be analyzed by electron microscopy. Some organelles, such as

[b]Peripheral membrane protein(s).

[c]Complex of peripheral and integral membrane proteins.

intact mitochondria, retain recognizable features after their isolation (e.g., Aris and Blobel, 1991; Glick and Pon, 1995). However, most organelles and membranes have similar tubular and/or vesicular appearances after homogenization and fractionation, and thus cannot be identified by their morphology alone. In these cases, analysis by immunocytochemistry, immunoelectron microscopy (*UNITS 4.3, 4.4 & 4.6*), or other marker-based techniques is advisable (e.g., Byers and Goetsch, 1991; Clark, 1991; Hasek and Streiblova, 1996; Rieder et al., 1996; Hicke et al., 1997; Prescianotto-Baschong and Riezman, 1998).

The structural integrity of an organelle can be monitored by measuring the latency of marker proteins or enzymes that normally reside within the lumen of an organelle. Morphological analysis can also reveal the integrity of certain organelles, especially mitochondria and nuclei. In addition, the integrity and orientation of organelle and vesicle membranes can be examined using protease- and antibody-accessibility experiments (see *UNIT 5.4*).

The intracellular functions of several organelles have been successfully reconstituted in a test tube (e.g., Daum et al., 1982a,b; Baker et al., 1988; Vida et al., 1990; Lazarow et al., 1991; Brodsky et al., 1993). These in vitro assays are essential tools for studying complex cellular processes, as the conditions and corresponding consequences can be manipulated and analyzed. In addition, in vitro assays can be used to monitor the functional integrity of the organelle of interest and thus the quality of an organelle preparation.

Table 3.7.9 Compartment-Specific Posttranslational Protein Modifications

Compartment	Posttranslational modification
Mitochondria:	
Intermembrane space	Heme attachment
	Membrane anchor cleavage
Matrix	Leader peptide cleavage
Endoplasmic reticulum:	
Lumen	Signal peptide cleavage
	Core N-linked[a] oligosaccharide addition
	Core O-linked[a] oligosaccharide addition
	Cleavage of glucose from N-linked oligosaccharides
Golgi:	
cis cisternae	Initial α1-6-linked oligosaccharide addition
	α1-6-linked oligosaccharide elongation
Medial cisternae	α1-3-linked oligosaccharide addition
	α1-2-linked oligosaccharide addition
	Elongation of O-linked oligosaccharides
trans cisternae	Lysine-arginine dibasic endoproteolysis
	Cleavage by dipeptidyl aminopeptidase A (DPAP-A)
Vacuoles:	
Lumen	Propeptide cleavage and activation of hydrolases

[a]N-linked, asparagine-linked; O-linked, serine- or threonine-linked.

Table 3.7.10 Application of Transient Markers to Identify Compartments Along the Secretory, Endocytic, and Vacuolar Protein Transport Pathways[a]

General principle	Specific techniques
Follow transit of limited protein pool until it reaches compartment of interest	Briefly label newly synthesized proteins with [^{35}S]cysteine/methionine and analyze compartments after appropriate chase times Briefly label cell surface proteins with ^{125}I and analyze endocytic compartments after appropriate chase times Follow radiolabeled ligand (e.g., [^{35}S]α-factor) to analyze endocytic compartments after appropriate chase times Transiently induce/derepress translation of protein known to transit through compartment(s) of interest Localize cargo proteins by analyzing their compartment-specific posttranslational modifications (Table 3.7.9)
Slow or block protein transport at specific step to accumulate cargo proteins in compartment of interest	Block protein transport at specific step along transport pathway using temperature-conditional mutants (e.g., *sec*, *end*, *vps* mutants) Slow protein transport through endosomal system by cooling cells to 15°C

Isolation of Subcellular Fractions from the Yeast *Saccharomyces cerevisiae*

The refinement of subcellular fractionation techniques for the budding yeast *Saccharomyces cerevisiae* has provided a valuable approach for investigating the molecular mechanisms of complex cellular functions. The protocols presented in this unit cover a range of centrifugation-based procedures used to fractionate subcellular components from *S. cerevisiae* according to their sizes and/or buoyant densities. The key goals and techniques of each protocol are summarized in Table 3.8.1. In addition, many other *S. cerevisiae* subcellular fractionation procedures and the corresponding references are listed in Table 3.8.2. An overview of centrifugation-based fractionation procedures for *S. cerevisiae* is presented in *UNIT 3.7*.

The basic methods used to isolate and characterize organelles from *S. cerevisiae* are very similar to those used for mammalian cells and other higher eukaryotes. The most appropriate subcellular fractionation procedure will vary with the goals of the particular experiment and the desired levels of organelle yield, purity, and function. The merits, limitations, and critical parameters of various *S. cerevisiae* techniques are discussed in *UNIT 3.7* to facilitate the development of successful subcellular fractionation experiments.

Yeast cells can be cultured using relatively simple techniques (*UNIT 1.6*) and are extremely versatile. For example, the abundance of certain enzymes and organelles that are subject to metabolic regulation can be manipulated by varying the nutrient composition of the medium. The optimal development of mitochondria and peroxisomes induced by growth on lactate or oleate, respectively, is critical to the effective isolation of these organelles (see Basic Protocols 6 and 7). In addition, the availability of mutant strains is also beneficial. For example, the use of a strain that is deficient in vacuolar protease activity can minimize problems with proteolysis.

In contrast to animal cells, yeast cells have a thick cell wall that must be disrupted or removed in order to generate cell lysates. The disruption of the cell wall by shearing with glass beads is a rapid and effective method to prepare yeast cell homogenates for the isolation of plasma membranes (see Basic Protocol 9) and cytosol (see Basic Protocol 10). However, glass bead lysis is not suitable for most subcellular fractionation experiments, since the strong shear forces required to disrupt the cell wall can also damage intracellular organelles and disrupt protein and membrane interactions. To minimize the disruption of subcellular integrity, yeast cells are usually first enzymatically converted to spheroplasts (yeast cells lacking cell walls) prior to cell lysis (see Support Protocol). Unlike intact yeast cells, spheroplasts are fragile and osmotically sensitive; thus they can be lysed under isoosmotic or hypoosmotic conditions, usually in combination with moderate shear force (e.g., several strokes in a Dounce glass homogenizer). Multiple enzyme preparations that digest the cell wall by cleaving the critical β-glucan linkages are available, such as Zymolyase 100T (see Support Protocol) and oxalyticase (see Basic Protocol 4).

NOTE: All references to "yeast" within this unit refer to the budding yeast *S. cerevisiae*. Many protocols developed for *S. cerevisiae* are not directly applicable to other yeasts (e.g., *Schizosaccharomyces pombe*) without significant modification. *S. cerevisiae* protocols can be applied to many different *S. cerevisiae* strains; however, variations among strains and growth conditions may require adjustments to a given protocol.

Current Protocols in Cell Biology (2000) 3.8.1-3.8.68

Table 3.8.1 Summary of the Primary Goals and Techniques of the Protocols[a]

Protocol	Primary goals	Key techniques
Basic Protocol 1	Separate lysate into a cytosol fraction and several membrane fractions (roughly according to size; see Table 3.7.2, Table 3.7.4, and Figure 3.7.1) Prepare enriched membrane fractions for subsequent procedures	Spheroplast preparation (Support Protocol) Dounce homogenization Sequential centrifugation steps
Support Protocol	Generate spheroplasts (for subsequent lysate preparation)	Cell culture Cell wall digestion (Zymolyase 100T)
Basic Protocol 2	Separate endosomal and Golgi membranes from vacuolar membranes	Spheroplast preparation (Support Protocol) Homogenization and centrifugation (Basic Protocol 1) Equilibrium Nycodenz gradients
Alternate Protocol	Separate endosomal and vacuolar membranes from Golgi membranes	Spheroplast preparation (Support Protocol) Homogenization and centrifugation (Basic Protocol 1) Equilibrium sucrose gradients
Basic Protocol 3	Subfractionate 13,000 × *g* pellet: separate PM and ER membranes from vacuolar and Golgi membranes	Spheroplast preparation (Support Protocol) Homogenization and centrifugation (Basic Protocol 1) Sucrose step gradients
Basic Protocol 4	Isolate intact vacuoles	Spheroplast preparation (oxylyticase) DEAE-isoosmotic spheroplast lysis Ficoll 400 step gradients
Basic Protocol 5	Isolate intact nuclei	Spheroplast preparation (Zymolyase 100T and Glusulase) Homogenization and differential centrifugation Ficoll 400 step gradients
Basic Protocol 6	Isolate lactate-induced mitochondria	Induction of mitochondria (lactate as carbon source) Spheroplast preparation (Zymolyase 20T) Homogenization and differential centrifugation Nycodenz step gradients
Basic Protocol 7	Isolate oleate-induced peroxisomes	Induction of peroxisomes (oleate as carbon source) Spheroplast preparation (Zymolyase 100T) Homogenization and differential centrifugation Sucrose step gradient
Basic Protocol 8	Isolate ER membranes	Spheroplast preparation (Support Protocol) Homogenization and differential centrifugation Sucrose step gradient
Basic Protocol 9	Isolate plasma membranes	Glass bead lysis Differential centrifugation Sucrose step gradient
Basic Protocol 10	Prepare “active” cytosol (e.g., for functional in vitro assays)	Glass bead lysis Centrifugation

[a]Abbreviations: ER, endoplasmic reticulum; PM, plasma membrane.

NOTE: Operations during and after cell lysis should be conducted at 0° to 4°C (unless otherwise indicated). In addition, solutions and equipment to be used during and after cell lysis should be chilled to 0° to 4°C prior to their use (unless otherwise indicated).

NOTE: Phenylmethylsulfonyl fluoride (PMSF) and other protease inhibitors are toxic and should be handled with care. They should be added to solutions just before use.

FRACTIONATION OF SPHEROPLASTS BY DIFFERENTIAL CENTRIFUGATION

BASIC PROTOCOL 1

The protocol presented below is a differential centrifugation protocol that separates subcellular components from yeast spheroplasts into several fractions, roughly according to their size. Differential centrifugation is a component of most subcellular fractionation experiments, since it provides a way to enrich for the organelle or membrane of interest, to deplete undesired components, and/or reduce the sample volume. Differential centrifugation is also used to analyze the potential subcellular location(s) of a protein of interest (see Table 3.7.4).

Yeast cells in their exponential growth phase are first converted to spheroplasts (see Support Protocol, steps 4 to 15). Alternate spheroplast preparation procedures can also be used; e.g., Basic Protocol 4, Basic Protocol 5, or numerous other protocols. The spheroplasts are lysed using a combination of osmotic shock and Dounce homogenization. Subsequently, the lysates are subjected to sequential centrifugation runs at increasing speeds (see Figure 3.7.1). The resulting fractions include the 300 × *g* pellet (P_{300}) and supernatant (S_{300}), the 13,000 × *g* pellet ($P_{13,000}$) and supernatant ($S_{13,000}$), and the 100,000 × *g* pellet ($P_{100,000}$) and supernatant ($S_{100,000}$) fractions.

If compatible with the goals of the experiment, protease-deficient strains can be used to minimize protein degradation (e.g., BJ3505, a *pep4 prb1* mutant yeast strain). The cell number required will depend on the goals of the experiment. This protocol is written for relatively small-scale experiments (10 to 40 OD_{600} units of cells) but can be adapted to experiments requiring more cells. When investigating the localization of a protein of interest, it is helpful to use enough cells so that one can set aside an aliquot of each fraction and monitor the yield of each centrifugation step.

Materials

Desired yeast cultures in their exponential growth
Stop solution or spheroplast medium B (see recipe; optional), ice cold
HEPES/potassium acetate (HEPES/KAc) lysis buffer (see recipe), ice cold
500× protease inhibitor cocktails A and B (500× PIC-A and 500× PIC-B; see recipes)
Protease inhibitor stock solutions A (see recipe)

Dounce glass homogenizer, tight-fitting pestle, prechilled to 4°C
1.6-ml microcentrifuge tubes, prechilled to 4°C
Microcentrifuge prechilled to 4°C
1.6-ml polycarbonate tubes for ultracentrifugation at 100,000 × *g*, prechilled on ice
Beckman refrigerated tabletop ultracentrifuge (or equivalent) and rotor (e.g., Beckman TLA100.3 or equivalent)

Additional reagents and equipment for growing yeast cells (see *UNIT 1.6*) and preparation of spheroplasts (see Support Protocol)

Prepare and harvest cells

1. Culture desired yeast strains and prepare spheroplasts (Support Protocol, steps 1 to 15).

   From this point on, keep samples on ice or at 4°C.

   Spheroplasts are fragile and must be handled very gently.

2. Resuspend the spheroplasts at a concentration of 5 to 10 OD_{600} units/ml in ice-cold stop solution, spheroplast medium B, or another solution with the appropriate osmotic support. Resuspend spheroplasts gently by swirling tube by hand, slowly stirring with a glass rod, or slowly pipetting with a wide bore pipet. Do not vortex. Keep suspension on ice until ready for the next step.

   The optimal solution will depend on the goals and subsequent steps of the experiment in which the spheroplasts will be used.

   Spheroplasts tend to stick to each other and thus can be difficult to resuspend. To facilitate resuspension, initially resuspend spheroplasts in a smaller volume of solution before adding the remaining solution.

   Stop solution contains two energy poisons (i.e., NaN_3 and NaF) that are toxic and should be handled with care. The inclusion of NaN_3 and NaF is not appropriate for all purposes (e.g., to isolate organelles for functional studies).

3. To harvest spheroplasts centrifuge 5 min at 1500 × *g*, 4°C. Aspirate or decant the supernatants.

   Use care while removing supernatants, because spheroplast pellets will be relatively loose and fluffy. In addition, the emergence of CO_2 bubbles from the spheroplasts can significantly disrupt the pellets.

Lyse spheroplasts

4. Gently resuspend spheroplasts at a concentration of 5 OD_{600} units/ml in ice-cold HEPES/KAc lysis buffer.

   The spheroplasts can also be lysed at higher concentrations (i.e., 5 to 15 OD_{600} units/ml) for large-scale preparations or if it is crucial to minimize the lysate volume.

5. Transfer spheroplast suspension to a Dounce homogenizer that has been prechilled in an ice bucket. Disrupt spheroplasts with 10 up-and-down strokes of a tight-fitting pestle.

   Keep the Dounce homogenizer on ice throughout this process. Move the pestle slowly and maintain contact between pestle and suspension to minimize foaming.

6. Transfer lysate to multiple prechilled 1.6-ml microcentrifuge tubes.

   It is often convenient to make 1-ml aliquots of the lysate (e.g., each containing 5 OD_{600} cell equivalents). Larger microcentrifuge tubes can also be used; however, the use of 1.6-ml microcentrifuge tubes and a refrigerated microcentrifuge is often faster and more convenient.

   In order to monitor recovery levels in the fractions generated by the subsequent microcentrifugation steps, it is often beneficial to set aside an aliquot of the lysate that will not be fractionated (e.g., 1 ml or 5 OD_{600} cell equivalents).

Clear lysates

7. Clear the lysates of unbroken cells, partially disrupted cells, and aggregates by centrifuging 5 min at 300 × *g*, 4°C.

8. Carefully withdraw the supernatant (S_{300}) without disturbing the very loose, fluffy pellet (P_{300}), and transfer to new prechilled 1.6-ml tubes. Record the volumes of the transferred S_{300}.

   Usually only ~80% of S_{300} can be harvested from each tube without disturbing the pellets.

   In order to monitor the recovery levels in the fractions generated by the subsequent centrifugation steps at 13,000 × g and 100,000 × g, it is often beneficial to set aside an aliquot of the S_{300} that will not be fractionated further.

   Also, it is critical to record the volume of harvested supernatant at each step (as it is never 100%) in order to follow the yield of each centrifugation step.

9. *Optional:* Resuspend the P_{300} by pipetting up and down ten times using a micropipettor with a 200-µl pipet tip. Add HEPES/KAc lysis buffer to a total volume of ~500 µl and mix with a cut pipet tip or by vortexing. Repeat steps 7 and 8. Pool the first and second S_{300} supernatants.

   Alternatively, the sample can be transferred to a clean, chilled Dounce homogenizer and dispersed with several gentle strokes.

   This washing step can improve the yield of intracellular membranes and purity of P_{300} fractions by removing some of the smaller organelles trapped within P_{300} pellets. This step is critical if the P_{300} will be retained for further analyses (e.g., to examine ER and plasma membrane distributions, since up to 50% of these membranes can pellet at 300 × g; see Table 3.7.4). However, it is not always recommended, since it increases the sample volume, processing time, and likelihood of organelle damage.

   The P_{300} pellets not required for subsequent analyses are often discarded since they contain a crude mixture of unlysed and partially disrupted cells, as well as a very heterogeneous mixture of intracellular membranes.

Prepare 13,000 × g fractions

10. Microcentrifuge S_{300} supernatants 10 min at 13,000 × *g*, 4°C.

11. Carefully transfer the supernatants ($S_{13,000}$) to prechilled 1.6-ml polycarbonate ultracentrifuge tubes and keep on ice.

    In order to monitor the recovery in the fractions generated by the subsequent centrifugation at 100,000 × g, it is often beneficial to set aside an aliquot of the $S_{13,000}$ that will not be fractionated further.

12. To remove any residual supernatant from the $P_{13,000}$ pellets and tube walls, microcentrifuge the tubes containing the $P_{13,000}$ samples ~30 sec at 13,000 × *g,* 4°C. Carefully remove any remaining $S_{13,000}$ above pellet.

    If the residual $S_{13,000}$ has a small volume (e.g., ≤10 µl), discard it; otherwise, add it to the appropriate $S_{13,000}$ fraction.

13. Add ice-cold HEPES/KAc lysis buffer (or another appropriate buffer) with freshly added protease inhibitors (PIC-A, PIC-B, protease inhibitor stock solution A) to the $P_{13,000}$ pellets. Briefly mix using a micropipettor or by vortexing. Cap tubes and store on ice. Quickly move on to step 14.

    The appropriate buffer and volume will depend on the goals and procedures of subsequent experiments. It is critical, however, that the buffer contain fresh protease inhibitors.

Prepare 100,000 × g fractions

14. Balance the $S_{13,000}$ samples by adding ice-cold HEPES/KAc lysis buffer as needed. Centrifuge $S_{13,000}$ samples 60 min at 100,000 × *g,* 4°C, in a fixed-angle rotor (e.g., 55,000 rpm for the Beckman TLA100.3 rotor).

15. *Optional:* During the 60-min centrifugation, process the $P_{13,000}$ pellets further as needed.

    If it is critical to disperse the membranes for subsequent fractionation steps, transfer the suspension to a small chilled Dounce homogenizer and apply several up-and-down strokes until the pellet is disrupted.

16. After ultracentrifugation, carefully transfer the supernatants ($S_{100,000}$) to clean, pre-chilled microcentrifuge tubes and store on ice.

17. To remove residual supernatant from pellets ($P_{100,000}$) and tube walls, centrifuge tubes with $P_{100,000}$ pellets ~30 sec at 13,000 × *g*, 4°C. Carefully remove and discard any remaining supernatant above the $P_{100,000}$ pellet.

18. Add ice-cold HEPES/KAc lysis buffer with freshly added protease inhibitors (or another appropriate buffer) to $P_{100,000}$ pellets. Quickly mix with a pipettor or vortexer. Keep on ice until needed.

    The appropriate buffer and volume will depend on the goals and procedures of subsequent experiments. It is critical, however, that the buffer be ice-cold and contain fresh protease inhibitors.

    The $P_{100,000}$ pellets are usually very difficult to resuspend. If it is critical to disperse the membranes for subsequent experiments, transfer the suspension to a small chilled Dounce homogenizer and apply several up-and-down strokes until the pellet is disrupted. It also can be helpful to allow the pellets to "soften" by incubating the pellets with buffer on ice. If the membranes do not need to be intact for further fractionation experiments, the pellet can be quickly resuspended in a small volume of buffer (~100 µl) using a water sonication bath.

SUPPORT PROTOCOL

PREPARATION OF YEAST SPHEROPLASTS USING ZYMOLYASE

The preparation of yeast spheroplasts through enzymatic digestion of the cell wall is the first step for most subcellular fractionation experiments. This protocol describes a method to prepare exponentially growing yeast cultures and convert yeast cells into spheroplasts using Zymolyase 100T, a β-glucanase preparation. Digestion of the cell wall is monitored by spectrophotometry and microscopy. This protocol can be adapted to any cell number or strain.

Additional Materials *(also see Basic Protocol 1)*

Exponentially growing yeast cell cultures in yeast extract/peptone/dextrose (YPD) medium (see *UNIT 1.6*) or appropriate medium
TSD reduction buffer (see recipe)
Spheroplast medium A (see recipe)
5 mg/ml Zymolyase 100T (ICN Immunobiochemicals) in spheroplast medium A, (store in aliquots at −20°C)
Spheroplast medium B (see recipe), ice cold

50-ml glass culture tubes *or* 100-ml Erlenmeyer flasks
Shaker platform at 30°C (or appropriate growth temperature of the strains being used)
250-ml centrifuge bottles
50-ml centrifuge tubes
Centrifuge and rotor (e.g., Sorvall GS-3 rotor)
30°C water bath

Additional reagents and equipment for culturing yeast cells (*UNIT 1.6*)

Preculture cells

1. In the morning, a day before the experiment, start precultures of the desired yeast strains by inoculating 10 ml YPD (or appropriate medium) with a single yeast colony from a fresh plate.

   The cultures can be grown in 50-ml glass culture tubes or 100-ml Erlenmeyer flasks.

   If using strains that grow very slowly or that have been stored on a plate at 4°C for more than a few days, it is advised that the preculture be started with a single colony the night before.

2. Culture cells throughout the day while shaking at 225 to 325 rpm at 30°C (or appropriate permissive temperature).

3. In the evening, a day before the experiment, determine cell density of the precultures by measuring the OD_{600}.

   For the most accurate measurement, dilute the culture at 1:5 or 1:10 in water, measure OD_{600}, and then multiply the reading by 5 or 10, respectively. The correlation between the cell number and the OD_{600} is usually most linear between an OD_{600} of 0.1 to 0.3 (see UNIT 3.7).

4. After completing the calculations below, use the appropriate amount of the preculture to inoculate fresh cultures for overnight growth.

   The suitable yeast cell concentration is determined by the growth rate of each strain (i.e., the doubling time), the desired incubation time (usually overnight), and the target cell density. For most applications, the target OD_{600} corresponds to the cell density when the cultures are in their mid-logarithmic growth phase. The culture OD_{600} during this rapid growth phase varies with the strain and growth conditions, but is often between 0.6 and 1.0. The required culture volumes will depend on the number of cells needed. It is best to start slightly larger cultures than required in case the cell density does not quite reach the expected level (see calculations below and UNITS 1.6 & 3.7).

   a. Calculate desired culture volume as follows:

   minimum culture volume (ml) = (required OD_{600} equivalents of cells/target OD_{600}) $\times$ 1.25

   Example: If 20 OD_{600} equivalents of a strain are required and the target cell density is at an OD_{600} of 0.8, then a 30-ml culture should be started, since (20/0.8) $\times$ 1.25 = 31.25 ml.

   b. Calculate the inoculation cell density (OD_{600}):

   inoculation OD_{600} = target $OD_{600} \times 2^{(\text{no. of doublings})}$

   Examples: A strain with a doubling time of 2.5 hr should be inoculated at an OD_{600} of ~0.008 in order to reach an OD_{600} of ~1 after 17.5 hr of growth (7 generations), since $1 \times 2^{-4} = 0.008$. A strain with a doubling time of 1.75 hr should be inoculated at an OD_{600} of ~0.001 in order to reach an OD_{600} of ~1 after 17.5 hr of growth (10 generations), since $1 \times 2^{-10} = 0.001$.

5. In the morning of the day that the spheroplasts are needed, measure the OD_{600} of cultures. Continue to culture the cells until they are within their target density range (i.e., mid-logarithmic growth phase).

   If the cultures have significantly exceeded the maximum target density (i.e., by >20%), dilute the cultures (e.g., 1:4 to 1:6 dilution in medium) and allow them to grow for at least two more generations before harvesting.

6. Harvest cells by centrifuging 5 min at 4000 $\times$ *g* (e.g., 5000 rpm in a Sorvall GS-3 rotor), room temperature, and carefully remove supernatant.

Prepare spheroplasts

7. Resuspend cells at 5 to 10 OD_{600} units/ml in TSD reduction buffer and incubate 10 min at room temperature.

   The DTT treatment facilitates cell wall digestion by breaking disulfide bonds and making the β-glucan linkages more accessible to the β-glucanase activity present in the Zymolyase preparation.

8. Harvest cells by centrifuging 5 min at ~4000 × *g*, room temperature. Aspirate supernatant.

9. Resuspend cells at ~20 to 30 OD_{600} units/ml in spheroplast medium A.

10. Remove 10 µl of each cell suspension and dilute in 990 µl water. Mix by briefly vortexing. Measure and record the OD_{600} value.

    The decrease in the OD_{600} value of the diluted cell suspension will be used to determine the efficiency of cell wall removal. In the absence of mechanical support (provided by the intact cell wall) or osmotic support (provided by sorbitol in the spheroplast medium), yeast cells will lyse and thus will no longer contribute to the optical density.

11. Add Zymolyase 100T (as 5 mg/ml stock) to the cell suspension at a concentration of 1 to 5 µg per OD_{600} unit of cells. Incubate at 30°C (or appropriate permissive temperature) for ~20 min.

    The optimal Zymolyase concentration and digestion time depend on the strains and growth conditions. Thus, these parameters should ideally be determined empirically for the specific strains and culture conditions to be used.

12. To monitor the efficiency of cell wall removal, dilute 10 µl cell suspension into 990 µl water. Mix by vortexing. After 1 or 2 min, mix again and then measure the OD_{600} value. Continue cell wall digestion until the OD_{600} measurement of the diluted cell suspension is <5% of the original value (step 9), indicating that over 95% of the cells have been converted to spheroplasts.

    The generation of spheroplasts can also be monitored by light microscopy. Spheroplasts will appear as spherical cells with bright halos, while yeast with intact cell walls will have a darker appearance and a slightly more oval shape. Spheroplast lysis can also be observed under the microscope by adding a drop of water to the sample.

Harvest and wash spheroplasts

13. Harvest spheroplasts by centrifuging 5 min at 1500 × *g*, room temperature.

    Spheroplasts are fragile and must be handled very gently.

    If working with a very osmotically sensitive strain, the sorbitol concentration can be increased to 1.2 M or even 1.5 M. In addition, the spheroplasts can be pelleted through a cushion of 1.1 M sorbitol/7.5% (v/v) Ficoll 400 to minimize damage during the following wash steps.

14. Aspirate or decant supernatants.

    Use care while removing the supernatants, since the spheroplast pellets will be relatively loose and fluffy. In addition, the emergence of CO_2 bubbles from the spheroplasts can significantly disrupt the pellets.

15. Resuspend spheroplasts at 1 to 5 OD_{600} units/ml in spheroplast medium B by gently swirling tube by hand or gently stirring with a glass rod.

    Spheroplasts tend to stick to each other and thus can be difficult to resuspend. To facilitate resuspension, initially resuspend spheroplasts in a smaller volume of solution before adding remaining solution.

    This washing step is critical to remove contaminating proteases and any other enzymes present in the Zymolyase preparation.

16. Harvest the spheroplasts by centrifuging 5 min at 1500 × *g,* 4°C. Decant or aspirate the supernatant.

17. *Optional:* Repeat steps 15 and 16 to ensure that the Zymolyase has been completely removed from the spheroplast preparation.

18. Resuspend spheroplasts in ice-cold spheroplast medium B, stop solution, or another solution with the appropriate osmotic support. Keep the suspension on ice.

    The optimal solution will depend on the goals and subsequent steps of the experiment in which the spheroplasts will be used.

    Stop solution contains two energy poisons (NaN_3 and NaF) that are toxic and should be handled with care. The inclusion of NaN_3 and NaF is not appropriate for all purposes (e.g., to isolate organelles for functional studies).

EQUILIBRIUM DENSITY GRADIENT FRACTIONATION USING NYCODENZ

BASIC PROTOCOL 2

In this protocol, equilibrium Nycodenz density gradient centrifugation is used to separate vacuolar membranes from endosomal and late Golgi compartments (Rieder and Emr, 1997). The distribution of subcellular components among the resulting fractions can be analyzed using marker proteins and activities (see *UNIT 3.7*). The fractions can also be used to analyze the subcellular localization of proteins of interest.

Yeast cells are first converted to spheroplasts (see Support Protocol). The spheroplasts are lysed using a combination of osmotic shock and Dounce homogenization. Subsequently, the lysates are subjected to centrifugation at 300 × *g* to remove unlysed cells and aggregates. These cleared cell lysates are loaded onto Nycodenz density gradients for overnight centrifugation.

About 15 to 20 OD_{600} units of cells in their mid-logarithmic growth phase are recommended for each gradient. If compatible with the goals of the experiment, protease-deficient strains can be used to minimize protein degradation (e.g., TVY614, a *pep4 prb1 prc1* mutant yeast strain). Since the membranes are not separated from the cytosol in this protocol, use of a protease-deficient strain is particularly advantageous to minimize damage by vacuolar hydrolases released from ruptured vacuoles.

Materials

20 OD_{600} units of cells in mid-logarithmic growth phase per gradient
HEPES/potassium acetate (HEPES/KAc) lysis buffer (see recipe), ice cold
50% (w/v) Nycodenz/sorbitol stock solution (see recipe)
37%, 31%, 27%, 23%, 20%, 17%, 13%, and 9% (w/v) Nycodenz in HEPES/KAc lysis buffer (see recipe), 4°C
500× protease inhibitor cocktails A and B (500× PIC-A and 500× PIC-B; see recipes)
Protease inhibitor stock solution A (see recipe)
100 mg/ml bovine serum albumin (BSA; optional)
Stop solution (see recipe) or another appropriate buffer, ice cold

Trimmed 1-ml pipet tips (cut ~5 to 10 mm from the tips to increase the size of the opening)
Clear 14 × 89–mm ultracentrifuge tubes (e.g., Ultraclear 14 × 89–mm tubes or equivalent) and rack
Centrifuge and microcentrifuge at 4°C
Dounce homogenizer with a tight-fitting pestle, prechilled

1.6-ml microcentrifuge tubes, prechilled

Refrigerated ultracentrifuge with swinging bucket rotor (e.g., Beckman SW41 Ti or equivalent), 4°C

Refractometer

Additional reagents and equipment for growing yeast cells (*UNIT 1.6*) and preparation of spheroplasts (Support Protocol)

Culture cells

1. On the day before the experiment, culture desired yeast strains (Support Protocol, steps 1 to 5).

   About 20 OD_{600} units of cells are usually needed for each gradient.

2. In the morning on the day of the experiment, dilute the cultures so that the cells will be ready to harvest in the early afternoon (see Support Protocol, step 4 for sample calculations).

Prepare gradients

3. In the morning on the day of the experiment, prepare gradients with a micropipettor and trimmed 1-ml pipet tips. Add protease inhibitors to each Nycodenz gradient solution. In a 14 × 89–mm ultracentrifuge tube carefully layer the following volumes of Nycodenz gradient media on top of one another in the following order:

   1 ml 37%
   1.5 ml 31%
   1.5 ml 27%
   1.5 ml 23%
   1.5 ml 20%
   1 ml 17%
   1 ml 13%
   1 ml 9%.

4. Store the gradients undisturbed for 2 to 3 hr at room temperature. After several hours, transfer gradients to 4°C so that they are chilled prior to use.

   During the storage time, the concentration differences at the interfaces decrease through diffusion, and the gradient becomes essentially continuous.

Prepare cleared spheroplast lysates (S_{300})

5. Once the cells have reached their target density, prepare spheroplasts (Support Protocol, steps 6 to 15).

   Spheroplasts are fragile and must be handled very gently.

6. Resuspend spheroplasts at a concentration of 1 to 5 OD_{600} units/ml in ice-cold stop solution, spheroplast medium B, or another solution with the appropriate osmotic support. Resuspend spheroplasts gently by swirling tube by hand, slowly stirring with a glass rod, or slowly pipetting with a wide bore pipet. Do not vortex. Keep suspension on ice until ready for the next step.

   The optimal solution will depend on the goals and subsequent steps of the experiment in which the spheroplasts will be used.

   Spheroplasts tend to stick to each other and thus can be difficult to resuspend. To facilitate resuspension, initially resuspend spheroplasts in a smaller volume of solution before adding the remaining solution.

   Stop solution contains two energy poisons (NaN_3 and NaF) that are toxic and should be handled with care. The use of NaN_3 and NaF is not appropriate for all purposes (e.g., to isolate organelles for functional studies).

7. Harvest spheroplasts by centrifuging 5 min at 2000 × *g*, 4°C. Aspirate the supernatant.

   From this point on, keep the samples on ice or at 4°C. Also, all solutions and equipment should be chilled to 0° to 4°C prior to as well as during use.

8. Resuspend spheroplasts at a concentration of ~15 OD_{600} units/ml in ice-cold HEPES/KAc lysis buffer with freshly added protease inhibitors (PIC-A, PIC-B, and protease inhibitor stock solutions A).

   The spheroplasts are lysed at a higher concentration than in Basic Protocol 1 in order to minimize the load volume for step 13.

9. Transfer the spheroplast suspension to a Dounce homogenizer that has been pre-chilled in an ice bucket. Disrupt the spheroplasts with 10 up-and-down strokes of a tight-fitting pestle.

   Keep Dounce homogenizer on ice throughout this process. Move the pestle slowly and maintain contact between pestle and suspension to minimize foaming.

10. Transfer lysate to multiple chilled 1.6-ml microcentrifuge tubes. Dispense convenient (~1.35-ml) aliquots of lysate (~20 OD_{600} cell equivalents) into each tube.

    Larger centrifugation tubes can also be used; however, use of 1.6-ml microcentrifuge tubes and a refrigerated microcentrifuge is often faster and more convenient.

    In order to monitor recovery levels in fractions generated by the subsequent centrifugation steps, it is often beneficial to set aside an aliquot of the lysate that will not be fractionated.

11. Clear the lysates of unbroken cells, partially disrupted cells, and aggregates by centrifuging 5 min at 300 × *g*, 4°C, in a microcentrifuge.

12. Carefully withdraw supernatants (S_{300}), without disturbing the very loose, fluffy pellet (P_{300}), and transfer them to new prechilled 1.6-ml tubes.

    Usually only ~80% of the S_{300} can be harvested from each tube without disturbing the pellets.

    In order to monitor the recovery levels in the gradient fractions, it is often beneficial to set aside a small aliquot of the S_{300} that will not be fractionated further.

    The yield of intracellular membranes can be improved by "washing" the P_{300} pellet; however, this practice increases the sample volume and handling times, and is not recommended for this protocol.

Fractionate lysate (S_{300}) on Nycodenz density gradients

13. Carefully layer supernatant (S_{300}) on the previously prepared gradient (step 4) using trimmed 1-ml pipet tip. Record volume of transferred S_{300}.

14. Balance appropriate pairs of buckets, gradients, and lids by adding a small amount of ice-cold HEPES/KAc lysis buffer to lighter tubes. Place the loaded gradient into prechilled buckets of the swinging bucket rotor.

    Slowly add buffer using a Pasteur pipet. Keep the tip near the surface of the gradient, when adding buffer, to minimize disruption of the gradient.

15. Centrifuge the gradients in a Beckman SW41 Ti rotor (or equivalent) 15 to 18 hr at 170,000 × *g*, 4°C, using the slow acceleration and deceleration settings to minimize disruption of the gradients.

Collect and process fractions

16. While the rotor is slowly decelerating, label 14 microcentrifuge tubes for the fractions to be collected from each gradient and place the tubes on ice.

    To prepare for manual fraction collection, cut ~5 to 10 mm off the tips of 1-ml pipet tips (~15 per gradient). Alternatively, an automated fraction collector system can be assembled.

17. After centrifugation is completed, carefully remove gradients from the rotor buckets and place them in a stable rack. Note any apparent membrane aggregation or other characteristics. While processing each gradient, store remaining gradients undisturbed at 4°C.
18. Collect ~14 fractions starting at the top of the gradient, using either a micropipettor and the trimmed 1-ml pipet tips or an automated fraction collector.

    If desired, 200 μg of BSA or another well-characterized protein source can be added to increase the protein concentration of the collected fractions.

19. Mix each sample well by vortexing. Centrifuge 15 sec at 13,000 × *g*, 4°C, to clear the sample droplets from lids. Transfer 30 to 40 μl of each fraction to new microcentrifuge tubes and set aside at room temperature (for step 21).
20. Process fractions as desired.

    For example, membranes can be collected by diluting the fractions 2- to 3-fold with ice-cold HEPES/KAc lysis buffer and then subjecting the samples to centrifugation ≥60 min at 100,000 × g, 4°C. The proteins in each fraction can be precipitated by adding trichloroacetic acid (TCA) to a final concentration of 10%, and subsequently analyzed using immunoprecipitation (UNIT 7.2) or immunoblotting (UNIT 6.2) techniques.

21. Determine Nycodenz density of each fraction by measuring refractive index of the 30- to 40-μl samples set aside in step 19.

ALTERNATE PROTOCOL

EQUILIBRIUM DENSITY GRADIENT FRACTIONATION USING SUCROSE

In this protocol, equilibrium sucrose density gradient centrifugation is used to separate vacuolar and endosomal membranes from late Golgi compartments (Becherer et al., 1996). The resulting fractions can be used to analyze the subcellular localization of proteins of interest.

Yeast cells are first converted to spheroplasts (see Support Protocol). The spheroplasts are lysed under hypoosmotic conditions with a glass Dounce homogenizer. Differential centrifugation is used to generate 13,000 × *g* pellet and supernatant fractions ($P_{13,000}$ and $S_{13,000}$, respectively). The $P_{13,000}$ and $S_{13,000}$ fractions are subsequently loaded onto sucrose density gradients for overnight centrifugation.

About 15 to 25 OD_{600} units of cells in their mid-logarithmic growth phase are recommended for each gradient set ($P_{13,000}$ and $S_{13,000}$). If compatible with the goals of the experiment, protease-deficient strains can be used to minimize protein degradation (e.g., TVY614, a *pep4 prb1 prc1* mutant yeast strain). Since the membranes in the $S_{13,000}$ fraction are not separated from the cytosol in this protocol, the use of a protease-deficient strain is particularly advantageous to minimize damage by vacuolar hydrolases released from ruptured vacuoles.

Additional Materials *(also see Basic Protocol 2 and Support Protocol)*

60% (w/v) sucrose stock solution, pH 6.8 (see recipe)
Sucrose solutions for equilibrium gradients (see recipe)
Refractometer

Prepare spheroplasts and sucrose gradients

1. Culture desired yeast strains (Support Protocol, steps 1 to 5).
2. Aliquot 37%, 34%, 32%, 29%, 27%, 22%, 10% (w/v) sucrose solutions for equilibrium gradients to separate 5-ml centrifuge tubes and add protease inhibitors just before preparing gradients.

    The volumes for these aliquots will depend on the number of gradients to be prepared. Always aliquot a bit more than the amount required.

3. In the morning on the day of the fractionation experiment, prepare the sucrose gradients in Ultra-Clear 14 × 89–mm tubes. Carefully layer the following sucrose solutions on top of each other with a trimmed 1-ml pipet tip:

   1 ml 60%
   1 ml 37%
   1.5 ml 34%
   2 ml 32%
   2 ml 29%
   1 ml 27%
   1.5 ml 22%
   0.5 ml 10% sucrose.

   Store, undisturbed at room temperature for 2 to 3 hr and then carefully transfer to 4°C.

4. Harvest ~20 OD_{600} units of cells in their mid-logarithmic growth phase for each gradient by centrifuging 5 min at ~5000 × *g*, room temperature.

5. Prepare spheroplasts (Support Protocol, steps 6 to 15).

   Spheroplasts are fragile and must be handled very gently.

6. Resuspend the spheroplasts at a concentration of 1 to 5 OD_{600} units/ml in ice-cold stop solution, spheroplast medium B, or another solution with the appropriate osmotic support. Resuspend spheroplasts gently by swirling tube by hand, slowly stirring with a glass rod, or slowly pipetting with a wide bore pipet. Do not vortex. Keep suspension on ice until ready for the next step.

   The optimal solution will depend on the goals and subsequent steps of the experiment in which the spheroplasts will be used.

   Spheroplasts tend to stick to each other and thus can be difficult to resuspend. To facilitate resuspension, initially resuspend spheroplasts in a smaller volume of solution before adding the remaining solution.

   Stop solution contains two energy poisons (NaN_3 and NaF) that are toxic and should be handled with care. The use of NaN_3 and NaF is not appropriate for all purposes (e.g., to isolate organelles for some functional studies).

Prepare spheroplast lysates and generate $P_{13,000}$ and $S_{13,000}$ fractions

7. Harvest spheroplasts by centrifuging 5 min at 2000 × *g*, 4°C. Aspirate the supernatant.

   From this point on, keep the samples on ice or at 4°C. Also, all solutions and equipment should be chilled to 0° to 4°C prior to as well as during use.

8. Gently resuspend spheroplasts at a concentration of ~15 OD_{600} units/ml in ice-cold HEPES/KAc lysis buffer with freshly added protease inhibitors.

9. Transfer spheroplast suspension to a Dounce homogenizer that has been prechilled in an ice bucket. Disrupt spheroplasts with 10 up-and-down strokes of a tight-fitting pestle.

   Keep the Dounce homogenizer on ice throughout this process. Move the pestle slowly and maintain contact between pestle and suspension to minimize foaming.

10. Transfer lysate to multiple chilled 1.6-ml microcentrifuge tubes.

    In order to monitor recovery levels in the fractions generated by the subsequent centrifugation steps, it is often beneficial to set aside an aliquot of the lysate that will not be fractionated.

11. Clear lysate of unbroken cells, partially disrupted cells, and aggregates by microcentrifuging 5 min at 300 × *g*, 4°C.

12. Carefully withdraw supernatant (S_{300}), without disturbing the very loose, fluffy pellets (P_{300}), and transfer to new chilled 1.6-ml microcentrifuge tube.

    Usually only ~80% of S_{300} can be harvested from each tube.

13. Microcentrifuge S_{300} supernatant 10 min at 13,000 × *g*, 4°C.

14. Transfer supernatant ($S_{13,000}$) to prechilled 1.6-ml microcentrifuge tube and store on ice.

    If desired, $S_{13,000}$ can be subjected to centrifugation 60 min at 100,000 × g, 4°C, to generate $P_{100,000}$ and cytosol $S_{100,000}$ fractions. $P_{100,000}$ membranes can then be fractionated on the density gradients. The $S_{13,000}$ fraction is used instead of the $P_{100,000}$ in this protocol, since membranes can be very difficult to resuspend after centrifugation at 100,000 × g.

15. To remove any residual supernatant from $P_{13,000}$ pellets and tube, centrifuge the tube containing $P_{13,000}$ sample ~45 sec at 13,000 × *g*, 4°C. Carefully remove any remaining liquid above pellet and discard.

16. Resuspend ~20 OD_{600} unit equivalents of $P_{13,000}$ membranes in ~800 µl ice-cold HEPES/KAc lysis buffer with freshly added protease inhibitors (PIC-A, PIC-B, and protease inhibitor stock solutions A). Pipet the suspension up-and-down at least 20 times to ensure complete dispersion of the $P_{13,000}$ pellet.

Fractionate $P_{13,000}$ and $S_{13,000}$ samples on sucrose density gradients

17. Carefully layer the $P_{13,000}$ and $S_{13,000}$ samples (i.e., products from steps 13 and 15) on separate previously prepared, separate sucrose gradients using trimmed 1-ml pipet tips.

18. Balance the appropriate pairs of gradients by adding a small amount of ice-cold HEPES/KAc lysis buffer to the lighter tubes. Place loaded gradient into the prechilled bucket of the swinging-bucket rotor.

19. Centrifuge the gradient in a Beckman SW41 Ti rotor (or equivalent) 15 to 18 hr at 170,000 × *g*, 4°C, using the slow acceleration and deceleration settings to minimize disruption of the gradients.

Collect and process fractions

20. While the rotor is slowly decelerating, label fourteen 1.6-ml microcentrifuge tubes for the fractions to be collected from each gradient and place tubes on ice.

    To prepare for manual fraction collection, cut ~5 to 10 mm from the pointed ends of 1-ml pipet tips (~15 per gradient). Alternatively, an automated fraction collector system can be assembled.

21. After centrifugation is completed, carefully remove gradients from the rotor buckets and place in a stable rack. Note any apparent membrane aggregation or other characteristics. While processing each gradient, store the remaining gradients, undisturbed, at 4°C.

22. Collect ~14 fractions from top of gradient, using either a micropipettor and trimmed 1-ml pipet tips or an automated fraction collector.

    If desired, 200 µg of BSA or another well-characterized protein source can be added to increase protein concentration of the collected fractions.

23. Mix each sample well with a vortexer. Centrifuge 15 sec at 13,000 × *g* to clear the sample droplets from the lids. Transfer 30 to 40 µl of each fraction to new 1.6-ml microcentrifuge tube and set aside at room temperature for step 25.

24. Process remaining fractions as desired.

    For example, membranes can be collected by diluting the fractions 3- to 10-fold with ice-cold HEPES/KAc lysis buffer and then subjecting samples to centrifugation ≥60 min at 100,000 × g, 4°C. The proteins in each fraction can be precipitated by adding trichloroacetic acid (TCA) to a final concentration of 10% (v/v) and subsequently analyzed using immunoprecipitation (UNIT 7.2) or immunoblotting (UNIT 6.2) techniques.

25. Determine sucrose density of each fraction by measuring refractive index of the 30- to 40-µl samples from step 22.

FRACTIONATION OF $P_{13,000}$ MEMBRANES ON SUCROSE STEP GRADIENTS

BASIC PROTOCOL 3

This protocol was designed to analyze the distribution of one or more proteins among vacuoles, plasma membrane (PM), early Golgi, and endoplasmic reticulum (ER) membranes (Gaynor et al., 1994). Yeast cells are converted to spheroplasts with the β-glucanase Zymolyase 100T (see Support Protocol). The spheroplasts are lysed under hypoosmotic conditions with a glass Dounce homogenizer. Differential centrifugation is used to generate a 13,000 × *g* pellet that is enriched for vacuoles, PM, early Golgi, and ER membranes ($P_{13,000}$). This membrane pellet is subsequently fractionated on a sucrose density step gradient.

About 30 OD_{600} units of cells in their mid-logarithmic growth phase are recommended for each gradient. If compatible with the goals of the experiment, protease-deficient strains can be used to minimize protein degradation (e.g., TVY614, a *pep4 prb1 prc1* mutant yeast strain).

Materials

Desired yeast strains (e.g., TVY614, a *pep4 prb1 prc1* mutant yeast strain)
Stop solution or spheroplast medium B, ice cold (see recipe; or another buffer with the appropriate osmotic support)
HEPES/potassium acetate (HEPES/KAc) lysis buffer, ice cold (see recipe)
500× protease inhibitor cocktails A and B (500× PIC-A and 500× PIC-B, see recipes)
Protease inhibitor stock solution A (see recipe)
1.2 and 1.5 M sucrose gradient solutions in sucrose gradient buffer (see recipe)

Ultra-clear 11 × 34–mm centrifuge tubes (e.g., Beckman or equivalent)
Benchtop refrigerated centrifuge and swinging bucket rotor, 4°C (e.g., Beckman TLS55 or equivalent)
Dounce homogenizer with a tight-fitting pestle, prechilled
1.6-ml microcentrifuge tubes
Microcentrifuge, 4°C
Trimmed 1-ml and 200-µl pipet tips (~5 to 10 mm cut from the tips)

Additional reagents and equipment for growing yeast cells (*UNIT 1.6*) and preparation of spheroplasts (Support Protocol)

Culture cells and prepare spheroplasts

1. Culture desired yeast strains (Support Protocol, steps 1 to 5).

   About 30 OD_{600} units of cells in their mid-logarithmic growth phase are recommended for each gradient.

2. Prepare spheroplasts (Support Protocol, steps 6 to 15).

   Spheroplasts are fragile and must be handled very gently.

3. Resuspend spheroplasts in ice-cold stop solution, spheroplast medium B, or another solution with the appropriate osmotic support. Resuspend spheroplasts gently by swirling tube by hand, slowly stirring with a glass rod, or slowly pipetting with a wide bore pipet. Do not vortex. Keep suspension on ice until ready for the next step.

   The optimal solution will depend on the goals and subsequent steps of the experiment in which the spheroplasts will be used.

   Spheroplasts tend to stick to each other and thus can be difficult to resuspend. To facilitate resuspension, initially resuspend spheroplasts in a smaller volume of solution before adding the remaining solution.

   Stop solution contains two energy poisons (NaN_3 and NaF) that are toxic and should be handled with care. The use of NaN_3 and NaF is not appropriate for all purposes (e.g., to isolate organelles for some functional studies).

Prepare lysates and generate $P_{13,000}$ membrane pellets

4. Harvest spheroplasts by centrifuging 5 min at 2000 × *g*, 4°C. Aspirate supernatant.

   From this point on, keep samples on ice or at 4°C. Also, all solutions and equipment should be chilled to 0° to 4°C prior to as well as during use.

5. Gently resuspend spheroplasts at a concentration of 5 OD_{600} units/ml in ice-cold HEPES/KAc lysis buffer.

6. Transfer spheroplast suspension to a Dounce homogenizer that has been prechilled in an ice bucket. Disrupt spheroplasts with 10 up-and-down strokes with a tight-fitting pestle.

   Keep Dounce homogenizer on ice throughout this process. Move pestle slowly and maintain contact between pestle and suspension to minimize foaming.

7. Transfer lysate to multiple chilled 1.6-ml microcentrifuge tubes.

   To monitor recovery levels in the fractions generated by subsequent centrifugation steps, it is often beneficial to set aside an aliquot of lysate that will not be fractionated (e.g., 1 ml or 5 OD_{600} cell equivalents).

8. Clear lysates of unbroken cells, partially disrupted cells, and aggregates by centrifuging 5 min at 300 × *g*, 4°C.

9. Carefully withdraw supernatant (S_{300}), without disturbing the very loose, fluffy pellets (P_{300}), and transfer to new chilled 1.6-ml tube.

   Usually only ~80% of the S_{300} can be harvested from each tube.

10. Resuspend P_{300} by pipetting up-and-down 10 times using a micropipettor and a 200-µl trimmed pipet tip. Add ice-cold HEPES/KAc lysis buffer to a total volume of 1 ml. Mix by pipetting up and down a few more times.

    Alternatively, the sample can be transferred to a clean, chilled Dounce homogenizer and dispersed with several gentle strokes.

    This washing step can improve the yield of intracellular membranes and the purity of the P_{300} fractions by removing some of the smaller organelles trapped within P_{300} pellets.

11. Repeat steps 8 and 9.

    The P_{300} pellets not required for subsequent analyses are often discarded since they contain a crude mixture of unlysed and partially disrupted cells, as well as a very heterogeneous mixture of intracellular membranes.

12. Pool the first and second S_{300} supernatants (from step 9 and 11) and mix. Transfer the pooled supernatant (S_{300}) to prechilled 1.6-ml microcentrifuge tube and place on ice.

13. Microcentrifuge the S_{300} supernatant 10 min at 13,000 × *g*, 4°C.

14. Remove the supernatant ($S_{13,000}$) to new 1.6-ml microcentrifuge tube. Store $S_{13,000}$ on ice until the gradient fractionation of $P_{13,000}$ membranes is in progress (step 20).

    Alternatively, the supernatants can be discarded.

    If desired, an aliquot (e.g., 5 OD_{600} units equivalents) of the $S_{13,000}$ can then be subjected to centrifugation 60 min at 100,000 × g, 4°C, to generate $P_{100,000}$ and cytosol $S_{100,000}$ fractions.

15. To remove any residual supernatant from $P_{13,000}$ pellet, centrifuge tubes containing $P_{13,000}$ samples ~45 sec at 13,000 × *g*, 4°C. Carefully remove any remaining liquid above pellet and discard.

16. Resuspend ~20 OD_{600} units equivalents of $P_{13,000}$ membranes in 200 µl ice-cold HEPES/KAc buffer with freshly added protease inhibitors (PIC-A, PIC-B, and protease inhibitor stock solutions A). Pipet each individual $P_{13,000}$ suspension up-and-down at least 20 times with a micropipettor and 200-µl pipet tip to ensure complete dispersion of $P_{13,000}$ pellet. Then combine pellets and mix by pipetting up-and-down a few more times.

Prepare and centrifuge sucrose step gradients

17. Carefully pipet 800 µl of 1.5 M sucrose step gradient solution into each ultra-clear 11 × 34–mm centrifuge tube. Using a trimmed 1-ml pipet tip, carefully layer 800 µl of 1.2 M sucrose step gradient solution on top of the 1.5 M sucrose layer.

    Prepare the sucrose gradients just prior to their use so that the interface remains crisp.

    If the interface is disturbed during or after preparation of the gradient, a new step gradient will need to be prepared.

18. Carefully layer 180 µl $P_{13,000}$ suspension (from step 16) over the 1.2 M sucrose solution with a trimmed 200-µl pipet tip.

19. Balance appropriate pairs of gradients by adding more of the $P_{13,000}$ suspension to the lighter tube if necessary. Put gradient tubes into prechilled buckets of the swinging bucket rotor.

20. Centrifuge gradients for 1 hr at 85,000 × *g*, 4°C (35,000 rpm for TLS55 rotor), using the slow acceleration and deceleration settings to minimize disruption of the gradients.

Collect and process fractions

21. While the rotor is slowly decelerating, prepare six labeled 1.6-ml microcentrifuge tubes for each gradient and keep on ice. Cut ~5 to 10 mm off the tips of 1-ml pipet tips (i.e., ~6 tips per gradient).

22. Carefully remove tubes from rotor buckets and place in a rack. Place gradients, undisturbed, at 4°C and process one gradient at a time. Make a note of position and appearance of bands and any other visible characteristics.

    Two discrete membrane bands should be visible, one in the 1.2 M sucrose layer and one at the interface between the 1.2 M and 1.5 M sucrose layers.

23. Collect the six fractions listed below with a micropipettor and cut 1-ml pipet tips. Store fractions in labeled microcentrifuge tubes on ice.

    Fraction 1: the top of gradient to just above the first membrane layer
    Fraction 2: first membrane band within the 1.2 M sucrose layer
    Fraction 3: sucrose solution between first membrane layer (Fraction 2) and second membrane layer (Fraction 4)
    Fraction 4: membrane band at the 1.2 M/1.5 M sucrose interface
    Fraction 5: 1.5 M sucrose solution below the interface
    Fraction 6: membrane pellet.

    The fractions will not have identical volumes.

    The vacuolar membranes are found in fractions 1 and 2; Golgi membranes are primarily in fraction 2; and ER membranes and the plasma membrane are split between fractions 2 (~35%) and 4 (~65%).

    If ER membranes and/or plasma membranes are the only features of interest, one can simply harvest the two membrane bands and discard the remaining solutions.

24. Increase the volume of each fraction to ~1.4 ml with ice-cold HEPES/KAc lysis buffer and mix.

25. Process fractions as desired.

    For example, the membranes can be collected by diluting the fractions 3- to 10-fold with ice-cold HEPES/KAc lysis buffer and then subjecting samples to centrifugation ≥50 min at 100,000 × g, 4°C. The proteins in each fraction can be precipitated by adding trichloroacetic acid (TCA) to a final concentration of 10% (v/v) and subsequently analyzed using immunoprecipitation (UNIT 7.2) or immunoblotting (UNIT 6.2) techniques.

BASIC PROTOCOL 4

ISOLATION OF INTACT VACUOLES USING FICOLL STEP GRADIENTS

This protocol was designed to purify intact, functional vacuoles from yeast spheroplasts (Haas, 1995). Yeast cells are converted to spheroplasts by incubation with oxalyticase, a β-glucanase preparation. The spheroplasts are lysed under isoosmotic conditions after treatment with the polybase DEAE-dextran. This gentle lysis procedure facilitates the isolation of intact vacuoles. Subsequently, the vacuoles are isolated through flotation on a Ficoll density step gradient.

The use of ~550 to 800 OD_{600} units of cells is recommended for each gradient. If compatible with the goals of the experiment, protease-deficient strains can be used to minimize protein degradation (e.g., TVY1, a *pep4* mutant yeast strain). The protocol is optimized for the yeast strains BJ3505 (a *pep4 prb1* mutant strain, deficient for most vacuolar hydrolase activities) and DKY6281 (a *pho8* mutant strain that does not express vacuolar alkaline phosphatase but has normal vacuolar protease activity levels).

Materials

Desired yeast strain
0.2× YPD (*UNIT 1.6*)
PIPES/DTT buffer (see recipe)
Oxalyticase buffer (see recipe)
Oxalyticase (45,000 U/mg, Enzogenetics; 0.5 to 1.0 mg/gradient) or an alternate β-glucanase enzyme (e.g., Zymolyase 100T; Support Protocol)
15%, 8%, 4%, and 0% (w/v) Ficoll solutions, 4°C (see recipe)
50× protease inhibitor cocktail (PIC, see recipe)
0.4 mg/ml dextran solution, freshly made (see recipe)
Protein assay reagent kit (e.g., BioRad; or an alternate technique, see *APPENDIX 3B*)

250-ml and 2-liter Erlenmeyer flasks
Shaker platform at 30°C (or appropriate growth temperature)
Centrifuge and rotor, room temperature and 4°C (e.g., Beckman JA-20 and JA-10 rotors or equivalents)
500-ml centrifuge bottles (e.g., for Beckman JA-10 rotor or equivalent)
10-ml glass pipets
30-ml glass Corex tubes (1 tube per gradient) or equivalent glass centrifugation tubes
Water bath at 30°C
Adapters for 30-ml glass Corex tubes (e.g., Beckman JA-20 rotor or equivalent)
Polyallomer centrifuge tubes, prechilled (e.g., 14 × 89–mm for SW41 Ti rotor)
Ultracentrifuge and rotor, 4°C (e.g., Beckman SW41 Ti rotor or equivalent)
200-µl pipet tips with ~5 to 8 mm trimmed off each tip
1.6-ml microcentrifuge tubes

Additional reagents and equipment for growing yeast cells (*UNIT 1.6*) and determining protein concentration (*APPENDIX 3B*)

Grow cells

1. In the morning, the day before the experiment, start precultures of desired yeast strains by inoculating 20-ml of YPD (or appropriate medium) in 250-ml Erlenmeyer flasks. Culture cells throughout the day at 30°C (or appropriate permissive temperature) while shaking at 225 to 350 rpm.

   It is best to start precultures with a single yeast colony from a fresh plate.

   If using a strain that grows very slowly or if using a strain that has been stored on a plate at 4°C for more than a few days, it is wise to start the preculture with a single colony the night before.

2. In the evening, the day before the experiment, measure and record the OD_{600} of precultures.

3. Inoculate 1 liter of fresh medium with an appropriate volume of each preculture.

   A 1-liter culture is required for each gradient, since 550 to 800 OD_{600} units of cells from a rapidly growing culture (e.g., OD_{600} of 0.6 to 0.8) are needed per gradient. The suitable yeast cell concentration at this inoculation step depends on the growth rate of each strain and length of the incubation time. See Support Protocol, step 3 for sample calculations.

   Example: Haas and coworkers recommend inoculating 1 liter of YPD with 0.25 OD_{600} equivalents of DKY6281 cells or 0.9 OD_{600} equivalents of BJ3505 cells when incubating for 16.5 hr. (Protease-deficient pep4 mutant strains grow more slowly than the corresponding wild-type strains.)

4. Culture cells overnight at 30°C (or appropriate permissive temperature) while shaking at 225 to 325 rpm.

Generate spheroplasts with oxalyticase treatment

5. In the morning, the day of the experiment, analyze cell density.

   If the OD_{600} is >1.2, dilute cultures to an OD_{600} of 0.2 and allow growth to an OD_{600} of 0.6 to 0.8.

   Ideally, cultures should have an OD_{600} of 0.6 to 0.8 to begin the experiment.

6. Harvest cells at an OD_{600} of 0.6 to 0.8 by centrifuging 5 min at 4000 × *g* (5000 rpm in JA-10 rotor), room temperature.

   As noted earlier, ~550 to 800 OD_{600} units are needed per vacuole isolation gradient.

7. Decant the supernatant. Resuspend pellet in freshly prepared PIPES/DTT buffer at a concentration of ~15 OD_{600} units/ml (i.e., ~50 ml of buffer per liter of original culture).

8. Pool or divide cell suspension for each gradient into an individual 500-ml centrifuge bottle (i.e., one bottle of cells per gradient).

9. Incubate the cells for 10 min in a 30°C water bath.

10. Harvest cells by centrifuging 5 min at 4000 × *g* (5000 rpm in a JA-10 rotor), room temperature.

11. Decant supernatants and gently resuspend each pellet in oxalyticase buffer at a concentration of ~40 OD_{600} units/ml (e.g., ~15 ml/liter of original culture) using a 10-ml glass pipet.

12. Transfer suspension from each centrifuge bottle into separate, labeled 30-ml glass Corex tubes (i.e., one glass tube per gradient).

    It is important to use glass tubes, since they allow for more rapid temperature changes than plastic tubes.

13. Transfer 10 µl from each cell suspension to a labeled microcentrifuge tube and set aside to use as controls in step 16.

14. Add oxalyticase (or an alternate β-glucanase enzyme) to a concentration of 1800 to 3600 U/ml.

    Oxalyticase is often supplied at 45,000 U/mg. The amount of oxalyticase required to efficiently digest the cell wall needs to be determined empirically for each strain and growth condition.

    For DKY6281 cells, 1800 U/ml of oxalyticase is usually sufficient to generate spheroplasts efficiently (i.e., ~0.04 mg/ml or 0.8 mg for each 1000 OD_{600} units of cells). However, a higher concentration of ~2700 U/ml of oxalyticase is recommended for BJ3505 cells (i.e., ~0.06 mg/ml or 1.2 mg for each 1000 OD_{600} units of cells).

15. Incubate 25 min in 30°C water bath (or appropriate permissive temperature). Prepare the fresh 0.4 mg/ml dextran solution during the oxalyticase digestion and keep on ice until ready to use.

16. To monitor the efficiency of cell wall removal, dilute 10 µl of each cell suspension with oxalyticase into 990 µl water and mix by briefly vortexing. Also, dilute the 10-µl control samples set aside at step 13. After 1 or 2 min, briefly vortex again and measure OD_{600} values of all samples.

    The decrease in OD_{600} values of diluted oxalyticase cell suspension indicates the extent of cell wall removal. In the absence of mechanical support (provided by the intact cell wall) or osmotic support (provided by sorbitol), spheroplasts will lyse and thus will no longer contribute to optical density.

    The extent of cell-wall digestion can also be examined by phase-contrast microscopy (Support Protocol, step 11).

17. Continue to incubate at 30°C (or appropriate permissive temperature) until ≥95% of cells have been converted to spheroplasts.

    The total incubation time for preparation of spheroplasts should be ≤60 min.

18. Place 30-ml glass Corex tubes in a JA-20 rotor with appropriate adapters. Harvest spheroplasts by centrifuging 1 min at 800 × *g* (2500 rpm in a JA-20 rotor), 4°C, followed by centrifugation for 1 min at 1500 × *g* (3500 rpm in a JA-20 rotor), 4°C.

    Spheroplasts are fragile and must be handled very gently.

19. *Optional:* Wash spheroplasts by gently resuspending each pellet in ~15 ml oxalyticase buffer. Resuspend by gently swirling tube by hand or by gently stirring with a glass rod. Do not vortex. Harvest spheroplasts as in step 18.

Perform dextran-mediated spheroplast lysis

20. Carefully decant supernatant and place tube on ice. Add 2.5 ml 15% Ficoll solution, 4°C, to each glass tube. Resuspend spheroplasts by gently swirling tube by hand or by gently stirring with a glass rod. Do not vortex.
21. Add 100 to 200 µl freshly made 0.4 mg/ml dextran solution to each tube. Immediately mix by gently swirling tubes by hand or by gently stirring with a glass rod. Do not vortex.

    The optimal amount of dextran for each strain needs to be determined empirically. (For DKY6281 strains, 100 µl per tube is recommended, while 180 to 200 µl per tube is recommended for BJ3505.)

22. Place tube on ice for 2 min to allow dextran to bind to the plasma membrane.
23. Disrupt the cell membrane by placing tube in a 30°C water bath for 60 to 75 sec, then immediately place tube on ice.
24. Examine cell lysates by phase contrast microscopy. Do not repeat the heat-shock step.

    Haas (1995) has found that lysates with one free-floating vacuole per 5 to 10 unlysed cells seem to yield the most vacuoles.

Prepare Ficoll step gradient

25. Transfer cell lysate from the glass tube to prechilled 14 × 89–mm polyallomer centrifuge tube and keep on ice.
26. Carefully layer 3 ml 8% Ficoll solution and 3.5 ml 4% Ficoll solution over cell lysate. Fill tube with 0% Ficoll solution (i.e., up to ~5 mm from top of tube).
27. Balance tubes using 0% Ficoll solution and place in prechilled ultracentrifuge rotor buckets (e.g., Beckman SW41 Ti).
28. Centrifuge 90 min at 110,000 × *g* (30,000 rpm for SW41 Ti rotor), 4°C. Use the slow acceleration and deceleration rate settings.

    To minimize mixing of the layers, allow the rotor to coast to a stop after slowing to 1000 rpm.

Collect and assess fractions

29. First, carefully remove top layer consisting of lipid with trimmed 200-µl tip and place in a microcentrifuge tube on ice (or discard).

    Remember to change the tip after each pipetting step.

    The vacuoles primarily accumulate in the interface between the 4% Ficoll and 0% Ficoll layers.

30. Carefully remove the vacuolar fraction from the 0% Ficoll/4% Ficoll interface using trimmed 200-µl tip and place in a microcentrifuge tube on ice.

    Avoid harvesting any of the 4% Ficoll layer, since Ficoll can interfere with subsequent steps. Collect a maximum of ~600 µl to avoid overdiluting the sample and to minimize Ficoll contamination.

31. Check for organelle integrity and purity by phase-contrast microscopy. Carefully mix 2 µl vacuole preparation with 10 µl 15% Ficoll solution for viewing.

    The vacuoles will appear as bright disks on a darker background, while lipid bodies that often associate with vacuolar membranes will appear as smaller dark spheres.

32. Determine protein concentration using 10 µl of each vacuole preparation and the BioRad protein assay reagent kit (or an alternate technique, see *APPENDIX 3B*).

Each sample of ~600 µl should have a protein concentration of ~0.25 to 0.9 mg/ml.

Vacuoles that will be used for functional assays should not be stored on ice for more than a few hours. Vacuoles remain functional in in vitro vacuole-vacuole fusion assays for up to several weeks if stored at –80°C as described in Haas (1995).

BASIC PROTOCOL 5

ISOLATION OF INTACT NUCLEI WITH FICOLL STEP GRADIENTS

This protocol was designed to isolate intact nuclei from yeast spheroplasts (Dove et al., 1998). Yeast cells are converted to spheroplasts by incubation with two β-glucanase preparations, Glusulase and Zymolyase 100T. The spheroplasts are lysed under hypoosmotic conditions. The lysate is cleared of unbroken cells and aggregates by centrifugation. Subsequently, the nuclei are isolated by fractionation on two sequential Ficoll step gradients.

The protocol is written for the preparation of nuclei from 6 liters of yeast culture in the exponential growth phase (i.e., ~3×10^{11} cells), but can be scaled up or down as needed. It has been optimized for the haploid strain BJ2168, which is deficient for vacuolar protease activity. BJ5465, another protease-deficient strain, also yields good results. Other strains can also be used; however, the yields will vary from strain to strain, and the protocol may need to be optimized (Aris and Blobel, 1991; Dove et al., 1998). If the nuclei will be used for functional studies, a recovery incubation after spheroplast preparation is needed for optimal activity.

Materials

Desired yeast strain
YPD medium (*UNIT 1.6*; or appropriate growth medium)
Sterile H_2O, ice cold
Pretreatment buffer (see recipe)
1.1 M sorbitol solution (see recipe), ice cold
Glusulase (NEN Life Science Products)
10 mg/ml Zymolyase 100 T (or 100,000 U/g yeast lytic enzyme can also be used; ICN)
Spheroplast recovery medium (optional; see recipe)
1000× protease inhibitor cocktail-D (1000× PIC-D; see recipe)
1000× protease inhibitor cocktail-W (1000× PIC-W; see recipe)
Ficoll cushion solution (see recipe), 4°C
20%, 30%, 40%, and 50% (w/v) Ficoll lysis solutions with 1× PIC (see recipe)
1× and 2× PM buffer (see recipe), 4°C
PSM 1 solution (see recipe)
TE/SDS solution (see recipe; optional)

Shaker platform in incubator at 30°C (or appropriate permissive temperature)
250-ml and 2-liter Erlenmeyer flasks
250-ml centrifuge bottles
Hemacytometer
Sorvall GSA rotor or equivalent; prechill to 4°C
1.6-ml microcentrifuge tubes
30°C water bath
50-ml polycarbonate centrifuge tubes (e.g., Oakridge or equivalent)
Swinging bucket rotor (e.g., Sorvall HB-4 rotor or equivalent), prechill to 4°C

Homogenizer (e.g., Potter-Elvehjem or a 40-ml glass Dounce homogenizer with a loose-fitting pestle), prechilled

Beckman Ultra-Clear 25 × 89–mm centrifuge tubes (or equivalent), prechill to 4°C

Beckman SW28 rotor (or equivalent), 2°C

20-ml syringes with 16-G needles

Additional reagents and equipment for growing yeast cells (*UNIT 1.6*) and determining protein concentration (*APPENDIX 3B*)

Grow cells

1. In the morning, 2 days before the experiment, start precultures of desired yeast strains by inoculating 5 ml YPD (or appropriate medium) with a single yeast colony from a fresh plate.

2. Culture cells throughout the day at 30°C (or appropriate permissive temperature) while shaking at 225 to 350 rpm.

3. In the evening, measure and record the OD_{600} of precultures. Use 5-ml preculture to inoculate 20 ml of growth medium in 250-ml Erlenmeyer flasks to yield a culture with an ~1 OD_{600} unit by the following morning.

   The suitable yeast cell concentration at this inoculation step depends on the growth rate of each strain and length of incubation time. See Support Protocol, step 3 for sample calculations.

   The doubling time of BJ2168 and BJ5465 in YPD at 30°C is ~110 min.

4. Culture cells overnight at 30°C (or appropriate permissive temperature) while shaking at 225 to 350 rpm.

5. In the morning, the day before the experiment, measure and record the OD_{600} of precultures. Use the 20-ml precultures to inoculate 50 ml of growth medium in 250-ml Erlenmeyer flasks so that the culture will reach an OD_{600} of 0.5 to 1.0 by the late afternoon.

6. Measure OD_{600} of the culture in the evening. Prewarm six 1-liter volumes of YPD to 30°C. Add appropriate volume of 50-ml preculture to each of six 1-liter volumes of YPD so that the cultures will reach an OD_{600} of 0.6 to 0.7 by morning. Culture cells overnight at 30°C while shaking at 225 to 350 rpm.

Harvest cells

7. Measure OD_{600} of 1-liter cultures in the morning of the experiment. Harvest cells when cultures reach an OD_{600} of 0.6 to 0.7.

   If cultures exceed an OD_{600} of 0.8, dilute cultures to ~0.15 and continue growth until cultures reach an OD_{600} of 0.6 to 0.7.

8. Chill cells by placing flasks in an ice-water bath with occasional swirling.

9. Transfer cells to 250-ml centrifuge bottles and harvest by centrifuging 5 min at ~4000 × *g* (Sorvall GSA rotor at 5000 rpm), 4°C.

   If a Pellicon (Millipore) or similar cell concentrator is available, it is convenient to concentrate cells before centrifugation.

10. Decant supernatant and place tubes on ice. Resuspend cell pellets in ice-cold water to a total of 200 ml.

11. Transfer cell suspension to a single, preweighed 250-ml centrifuge bottle. Centrifuge for 5 min at ~4000 × *g* (Sorvall GSA rotor at 5000 rpm), 4°C.

12. Decant supernatant and aspirate remaining supernatant. Determine wet weight of cell pellet.

    The cell pellet usually weighs ~9 g.

Pretreat cells

13. Resuspend pellet in freshly-prepared pretreatment buffer, using 4 ml for every gram of wet cell pellet (e.g., add 36 ml pretreatment buffer to a 9-g cell pellet). Incubate 10 min at room temperature with intermittent swirling.

14. Add ice-cold water to a final volume of 250 ml and mix well. Transfer 10 µl to a microcentrifuge tube and store on ice for step 16.

15. Centrifuge 5 min at ~4000 × *g* (Sorvall GSA rotor at 5000 rpm), 4°C.

16. During centrifugation, determine the cell yield (i.e., cell number) using a hemacytometer. Dilute the 10-µl sample in 990 µl water to facilitate counting.

    BJ2168 typically yields 1.6×10^{10} cells/g. The number of cells per gram varies with different strains, but is usually between 1.2 and 1.7×10^{10} cells/g.

17. Resuspend cells in ~200 ml ice-cold 1.1 M sorbitol solution. Centrifuge 5 min at ~4000 × *g* (Sorvall GSA rotor at 5000 rpm), 4°C.

18. Decant supernatant and aspirate remaining supernatant. For every 1×10^{11} cells, add 25 ml 1.1 M sorbitol solution (e.g., if there are 3×10^{11} cells, add 75 ml sorbitol solution). Disperse well by pipetting.

19. Remove 100 µl of cell suspension and transfer to a microcentrifuge tube. Store on ice until step 22.

    This sample will be used as a control when monitoring cell wall integrity.

Prepare spheroplasts

20. To digest cell wall, add 1.5 ml Glusulase (at concentration supplied by manufacturer) and 0.3 ml of 10 mg/ml Zymolyase 100T for every 1×10^{11} cells (e.g., if there are 3×10^{11} cells in 75 ml of sorbitol solution, add 4.5 ml Glusulase and 0.3 ml 10 mg/ml Zymolyase 100T). Mix cell suspension with a glass rod and loosely cap the bottle.

21. Incubate 1.5 to 2.5 hr in a 30°C water bath with gentle swirling. Monitor the digestion microscopically (under 400× magnification) every 15 to 20 min. Continue digesting until cells are round and clumped cells separate.

    After ~1 hr of digestion, cells should be spherical and show extensive clumping. After further digestion, the spheroplasts will separate.

22. To monitor the efficiency of cell wall removal, dilute 10 µl of each cell suspension into 990 µl water and mix by briefly vortexing. Also dilute the 9.4-µl samples stored at step 19 to serve as controls. After 1 or 2 min, briefly vortex again and measure the OD_{600} values.

    The decrease in the OD_{600} values of the digested cell suspensions indicate the extent of cell wall removal. In the absence of mechanical support (provided by the intact cell wall) or osmotic support (provided by sorbitol), spheroplasts will lyse and thus will no longer contribute to the optical density.

Wash spheroplasts with sorbitol

23. During cell-wall digestion and subsequent steps, prepare first set of Ficoll step gradients as time permits (see step 39).

24. *Optional:* If the nuclei will be used for functional studies, a recovery incubation is needed for optimal activity. Incubate spheroplasts in prewarmed spheroplast recovery medium for 30 min at 30°C with gentle swirling.

    Other growth media supplemented with sorbitol at a final concentration of 1 to 1.5 M can be used as well.

    Optimum recovery conditions should be determined empirically for each application.

Chill and wash spheroplasts

25. Divide spheroplast suspension into 50-ml polycarbonate centrifuge tubes adding 1×10^{11} cells per tube. Store on ice for 10 min to chill the cells.

26. Centrifuge in a swinging-bucket rotor for 5 min at ~4000 × *g* (e.g., Sorvall HB-4 rotor at 5000 rpm), 4°C. Aspirate supernatants.

27. Gently resuspend each pellet with ~25 ml ice-cold 1.1 M sorbitol solution. Use a glass rod to carefully resuspend pellet. Do not vortex.

28. Centrifuge in a swinging-bucket rotor 5 min at ~4000 × *g* (e.g., Sorvall HB-4 rotor at 5000 rpm), 4°C. Aspirate supernatant.

29. Resuspend each pellet with ~20 ml ice-cold 1.1 M sorbitol solution. Use a glass rod to carefully resuspend pellet. Do not vortex.

Prepare cushion solution and filter cells

30. Add 20 µl of each 1000× PIC-W and PIC-D to a 6-ml aliquot of Ficoll cushion solution and vortex. Carefully load 6 ml Ficoll cushion solution under spheroplast suspension using a Pasteur pipet or a syringe with a long needle or canula. Repeat for each tube.

    To load the Ficoll cushion solution, slowly move the pipet, needle, or canula through the lysate until the tip is at the bottom of the tube. Slowly expel 6 ml of the Ficoll cushion solution. Carefully remove the pipet, needle, or canula by lifting straight up.

31. Centrifuge spheroplasts through cushion solution 10 min at ~4000 × *g* (e.g., Sorvall HB-4 rotor at 5000 rpm), 4°C. Aspirate supernatants and store wet pellets on ice.

Isolate enriched nuclear fraction

32. To lyse spheroplasts, add 25 ml of 20% Ficoll solution (room temperature) to each pellet. Quickly disperse pellet with a 25-ml pipet.

    For optimal lysis, it is important that the Ficoll solution is at room temperature, not 4°C.

33. Immediately transfer suspension to a prechilled motorized Potter-Elvehjem homogenizer. Lyse cells with 5 strokes and a fast-spinning pestle using a motorized drive.

    Alternatively, cells can be lysed in a prechilled 40-ml Dounce homogenizer. Use 20 slow strokes with a loose-fitting pestle (3 to 4 min total).

34. Immediately transfer lysate to a 50-ml polycarbonate centrifuge tube that is submerged to the neck in ice.

    Work quickly so that each pellet is processed within 3 to 5 min.

35. Chill lysates on ice for 10 to 15 min. Examine lysates by microscopy (400× magnification).

    The spheroplasts should be completely disrupted. The nuclei will be relatively small, round, and dark. The edges may look slightly ruffled and the nucleolus may appear as a dark crescent. Released vacuoles will look larger and refractile.

36. Centrifuge lysate in a precooled swinging-bucket rotor for 5 min at 13,000 × *g* (e.g., Sorvall HB-4 rotor at 9000 rpm), 2°C.

37. Carefully transfer supernatant into new, prechilled 50-ml polycarbonate centrifuge tubes without transferring any of the loose pellet. Centrifuge supernatant 10 min at 13,000 × *g* (e.g., 9000 rpm in a Sorvall HB-4 rotor), 2°C.

    After centrifugation, a tight pellet should be visible.

38. Do not transfer supernatant; place tube on ice until step 40.

Prepare Ficoll step gradients

39. Prepare the first set of Ficoll step gradients as time permits during previous steps. Warm the 50%, 40%, and 30% Ficoll solutions to ~25°C. Transfer ~20 ml of each solution into a separate 50-ml tube. Add PIC-W and PIC-D solutions and vortex.

40. Place a 25 × 89–mm ultracentrifuge tube and support base on a balance. Tare. Slowly pipet 6.5 g of 50% Ficoll solution to the bottom of the tube. Place the first tube on ice and repeat for the remaining tubes.

    It is important to chill each Ficoll layer for a few minutes before adding another layer. At lower temperatures Ficoll increases in viscosity and it becomes less likely that addition of the next layer will disrupt the layer below.

41. Add 6.5 g of 40% Ficoll solution to each tube as in step 40. Chill tubes on ice.

42. Add 6.5 g of 30% Ficoll solution to each tube as in step 40. Chill gradients >10 min on ice before use.

    One gradient is needed for every 1×10^{11} cells. Typically, three gradients are needed for a 6-liter preparation.

    Ficoll solutions are very viscous so it is more accurate to aliquot by weight.

Purify and collect nuclei

43. Carefully layer ~25 ml supernatant from each tube (from step 38) onto each of the chilled Ficoll gradients. Do not transfer any of the pellet.

44. Fill and balance tubes with cold 1× PM buffer as necessary. Centrifuge the gradients 60 min at 58,400 × *g* (18,000 rpm in a Beckman SW28 rotor), 2°C.

45. During the last 30 min of centrifugation, prepare second set of Ficoll step gradients as in steps 39 to 42, except use 5.5 g of Ficoll solution. Chill on ice for ≥10 min before using gradients.

    Typically, two gradients are needed for a 6-liter preparation.

46. After centrifugation (step 44), inspect gradients and note any visible characteristics.

    Bands containing nuclei are usually visible at the 30%/40% and 40%/50% Ficoll interfaces. (Nuclei are also found throughout the 40% Ficoll layer.) A layer of white film should be visible at the top of the gradient. A thick layer should be visible at the 20%/30% interface. A small, halo-like pellet should occur at the bottom.

47. Collect nuclei with a 20-ml syringe and a 16-G needle. Insert needle through tube wall just below the 40%/50% Ficoll interface. With needle tip in the center of tube and the beveled edge facing up, carefully remove ~8 ml while slowly moving needle back and forth.

    Cold Ficoll solutions are quite viscous, so collection should be done smoothly and slowly. The 8-ml volume will include the 40% Ficoll layer and some of the 50% Ficoll layer. Avoid the 30% Ficoll layer.

    If an enriched (but less pure) preparation of nuclei is sufficient for the purposes of the experiment, one can collect ~6 ml from each gradient and omit the second Ficoll gradient. However, this is not recommended when purity is of importance.

48. Remove needle and slowly expel harvested nuclear suspension into a 150-ml glass beaker chilled on ice.

49. Repeat steps 46 to 48 for each gradient and pool harvested nuclei in the 150-ml beaker.

50. Dilute suspension with 1 volume of cold 1× PM buffer by gently stirring with a glass rod.

51. Carefully layer harvested nuclear suspension over two prechilled second set Ficoll step gradients (prepared in step 45). Fill and balance tubes with cold 1× PM buffer plus PIC as necessary.

52. Centrifuge gradients in a 60 min at 58,400 × *g* (18,000 rpm in a Beckman SW28 rotor), 2°C.

53. After centrifugation, collect ~10 ml from each gradient as described in step 47.

54. Pool harvested nuclei in a 50-ml tube on ice. Mix by stirring gently with a glass rod.

55. Transfer 50 µl nuclear preparation to a chilled microcentrifuge tube for protein determination. Store on ice until step 57.

    If the nuclei are not needed right away, aliquot harvested nuclei while still in Ficoll solution, freeze in liquid nitrogen, and store at −70°C.

56. To remove Ficoll solution, dilute nuclei in 10 vol cold 1× PM buffer plus PIC. Mix by gently stirring with a glass rod. Pellet nuclei by centrifuging 10 min at 10,000 × *g*, 4°C. Process nuclei as desired.

    For most purposes (e.g., TCA protein precipitation, SDS-PAGE analysis, functional assays), the Ficoll will need to be removed from harvested nuclei.

Determine protein concentration

57. To determine protein concentration, dilute 50 µl of harvested nuclei in 10 volumes PSM 1 solution and mix well. Centrifuge 30 min at 12,000 × *g*, 4°C. Resuspend pellet in 50 µl of water or TE/SDS solution. Determine protein concentration using a modified Lowry procedure or Bradford assay (e.g., *APPENDIX 3B*).

ISOLATION OF LACTATE-INDUCED MITOCHONDRIA USING NYCODENZ STEP GRADIENTS

BASIC PROTOCOL 6

This protocol is designed to isolate intact, functional mitochondria from lactate-grown D273-10B spheroplasts (Glick and Pon, 1995). Yeast cells are precultured in a glucose medium for a day and then transferred to a lactate medium to encourage optimal development of mitochondria. After ~15 hr in lactate medium, the cells are converted to spheroplasts using the β-glucanase preparation Zymolyase 20T and lysed by osmotic shock. Differential centrifugation is used to generate a mitochondria-enriched pellet. This

pellet is subsequently fractionated on a Nycodenz density step gradient to purify the mitochondria.

This protocol calls for four 1-liter cultures of lactate-grown D273-10B cells, but can be scaled-up or scaled-down as needed. Cells other than lactate-grown D273-10B cells can be used; however, the mitochondrial density and abundance will vary with strain and growth conditions, and thus the protocol may need to be optimized. If the mitochondria will be used for functional studies, a recovery incubation after spheroplast preparation may be needed for optimal activity.

Materials

D273-10B cells (e.g., or desired yeast strain)
Semi-synthetic lactate medium (see recipe)
TSD reduction buffer (see recipe)
Zymolyase 20T (e.g., ~75 mg)
Buffer A: 1.2 M sorbitol/20 mM potassium phosphate, pH 7.4 (see *APPENDIX 2A* for phosphate buffer), room temperature
Semi-synthetic lactate medium (see recipe) supplemented with 1.2 M sorbitol (optional)
200 mM phenylmethylsulfonyl fluoride (PMSF; 34.5 mg/ml) in absolute ethanol; prepare fresh
Buffer B: 0.6 M sorbitol/20 mM potassium MES (pH 6.0), ice cold
0.6% (w/v) SDS solution
2× Buffer B (see recipe)
Buffer C: 0.6 M sorbitol/20 mM potassium HEPES (pH 7.4), ice cold
18% and 14.5 % (w/v) Nycodenz solution (see recipe), prechilled
100 mg/ml fatty-acid free bovine serum albumin (BSA)

200-ml Erlenmeyer flask
Platform shaker, 30°C (or permissive growth temperature)
Sorvall GS-3 rotor (or equivalent)
250-ml centrifuge bottles (e.g., Sorvall GS-3 rotor or equivalent)
30°C water bath
1.6-ml microcentrifuge tubes
40- and 1-ml glass Dounce homogenizers with a tight-fitting pestles (or Teflon homogenizer), 4°C
40-ml centrifuge tubes (e.g., for Sorvall SS-34 rotor or equivalent)
Sorvall SS-34 rotor (or equivalent)
Clear ultracentrifuge tubes (e.g., Beckman SW-41 14 × 89–mm Ultra-Clear centrifuge tubes)
Beckman ultracentrifuge with a SW-41 rotor (or equivalent)
Cut 1-ml pipet tips

Additional reagents and equipment for growing yeast cells (*UNIT 1.6*) and determining protein concentration (*APPENDIX 3B*)

Grow D273-10B cells and induce mitochondrial development

1. In the evening, 2 days before fractionation experiment, start a preculture of D273-10B cells (or desired yeast strain) by inoculating 40 ml semi-synthetic lactate medium in a 200-ml Erlenmeyer flask.

   It is best to use a single colony from a fresh plate.

2. Culture cells for ~24 hr at 30°C while shaking at 225 to 325 rpm.

   Good aeration is critical for optimal cell growth and proliferation of mitochondria.

3. In the evening of the day before fractionation experiment, use 40-ml stationary-phase preculture to inoculate 4 liters semi-synthetic lactate medium (e.g., use 10 ml preculture per 1-liter culture).
4. Culture cells at 30°C overnight with good aeration until OD_{600} value is ~3.

   For strain D273-10B, cells should be grown for ~15 hr.

Harvest cells

5. In the morning, on the day of the experiment, check OD_{600} value of cultures. Allow cells to grow until OD_{600} reaches ~3.
6. Harvest cells by centrifuging 5 min at 4000 × *g* (5000 rpm in a Sorvall GS-3 rotor), room temperature, and removing the supernatant.
7. Resuspend cells in a total volume of 120 ml sterile water. Transfer suspension to a preweighed 250-ml centrifuge bottle.
8. Pellet cells by centrifuging 5 min at 2000 × *g* (3500 rpm in a Sorvall GS-3 rotor), room temperature.
9. Decant supernatant and weigh the wet pellet. Determine the wet weight of pellet by subtracting bottle weight.

   Four liters of a D273-10B culture at an OD_{600} of 3.0 usually yields ~30 g of packed cells.

Prepare spheroplasts

10. Resuspend cells in 40 ml freshly prepared reduction buffer.
11. Incubate cell suspension for 15 min in a 30°C water bath with gentle shaking. During this incubation, weigh out the required amount of Zymolyase 20T to add 2.5 mg Zymolyase 20 T per gram of packed cells.

    Alternatively, 0.5 mg Zymolyase 100T per gram of packed cells can be used.

12. Pellet cells by centrifuging 5 min at 2000 × *g* (3500 rpm in a Sorvall GS-3 rotor), room temperature. Remove supernatant.
13. Gently resuspend pellet in buffer A, using 2 ml buffer A per gram of packed cells (e.g., 60 ml buffer A for a 30-g cell pellet).
14. Remove 10 µl suspension and store in a 1.6-ml microcentrifuge tube on ice until step 18.
15. Pellet cells by centrifuging 5 min at 2000 × *g*, room temperature. During centrifugation, dissolve weighed Zymolyase 20T in buffer A at a concentration of 1.25 mg/ml.

    If using Zymolyase 100T, dissolve it in buffer A at a concentration of 0.25 mg/ml.

16. Decant supernatant and resuspend pellet in Zymolyase solution.
17. Incubate suspension for 30 min in a 30°C water bath with gentle shaking.
18. After 30 min, monitor the efficiency of cell wall removal. Dilute 10 µl of each cell suspension into 990 µl water and mix by briefly vortexing. Also dilute the 10-µl samples stored after step 14 to serve as controls. After 1 or 2 min, briefly vortex again and measure OD_{600} values.

    The decrease in OD_{600} values of diluted cell suspension indicates the extent of cell wall removal. In the absence of mechanical support (provided by the intact cell wall) or osmotic support (provided by sorbitol), spheroplasts will lyse and thus will no longer contribute to the optical density.

    The extent of cell-wall digestion can also be examined by phase-contrast microscopy as described in Support Protocol, step 11.

19. Continue incubation until >95% of cells have been converted to spheroplasts.

Wash spheroplasts

20. Centrifuge spheroplasts 5 min at 2000 × *g* (3500 rpm in a Sorvall GS-3), 4°C. Remove supernatant.

21. Gently resuspend spheroplast pellet in 30 ml buffer A. Pellet spheroplasts by centrifuging 5 min at 2000 × *g* (Sorvall GS-3 rotor, 3500 rpm), 4°C.

22. Wash the spheroplasts again by repeating step 21.

23. *Optional:* Incubate washed spheroplasts for 30 to 60 min at 30°C in semi-synthetic lactate medium supplemented with 1.2 M sorbitol (final concentration). Shake gently. Pellet spheroplasts (step 21).

    Optimal recovery conditions should be determined empirically for each application.

    Other growth media supplemented with sorbitol to a final concentration of 1 to 1.5 M can be used.

    A recovery period after cell wall removal is essential for optimal translation/transcription activity.

24. Prepare buffer B by adding 0.5 ml of 200 mM PMSF drop-wise to 200 ml of ice-cold buffer B while stirring. Filter through Whatman paper into a flask on ice.

    It is important to keep the suspensions, solutions, and equipment at 0° to 4°C from this step on.

Prepare spheroplast lysates

25. Resuspend spheroplasts in 40 ml ice-cold buffer B with PMSF. Divide suspension into two equal portions and keep on ice.

26. Homogenize each portion in an ice-cold 40-ml glass Dounce homogenizer, using 15 strokes with a tight-fitting pestle.

    Keep Dounce homogenizer on ice throughout this process. Move pestle slowly and maintain contact between pestle and suspension to minimize foaming.

27. Combine lysates in a prechilled beaker on ice. Add buffer B with PMSF to a total volume of 100 ml.

Collect mitochondria

28. Transfer lysate to four 40-ml centrifuge tubes. Centrifuge 5 min at 1500 × *g* (3500 rpm in a Sorvall SS-34 rotor), 4°C.

29. Carefully transfer supernatant to a prechilled beaker on ice, being careful to avoid the loose pellet. Store supernatants on ice until step 33.

30. Resuspend each pellet in 10 ml buffer B with PMSF. Combine suspensions in a single tube, swirl to mix, and then divide into two 20-ml portions.

31. Homogenize each 20-ml suspension in the 40-ml glass Dounce homogenizer, using 15 strokes with a tight-fitting pestle, without introducing air.

32. Combine lysates in a prechilled beaker on ice. Add buffer B with PMSF to a total volume of 100 ml.

33. Transfer lysate to four new 40-ml centrifuge tubes. Centrifuge 5 min at 1500 × *g*, 4°C.

34. Transfer supernatant to the beaker containing the stored supernatants (step 28), being careful to avoid the loose pellets. Discard pellets.

Isolate enriched mitochondrial fraction

35. Divide supernatants between six 40-ml centrifuge tubes. Centrifuge 10 min at 12,000 × *g* (10,000 rpm in Sorvall SS-34 rotor), 4°C.

36. Decant supernatants and resuspend each pellet in 7 ml ice-cold buffer B (without PMSF) and combine into two tubes.

37. Homogenize each suspension (gently, but thoroughly) in a clean, prechilled 40-ml glass Dounce homogenizer, using 5 to 10 slow strokes with a tight-fitting pestle.

38. Transfer suspensions to two clean 40-ml tubes. Centrifuge 5 min at 1500 × *g*, 4°C.

39. Transfer supernatants into two fresh 40-ml centrifuge tubes, avoiding the loose pellets. Centrifuge 10 min at 12,000 × *g* (10,000 rpm in a Sorvall SS-34 rotor), 4°C.

40. Decant supernatant and gently resuspend pellets in 0.5 ml ice-cold buffer B (without PMSF) using a prechilled 1-ml glass Dounce homogenizer or Teflon homogenizer. Transfer suspensions to 1.6-ml microcentrifuge tubes and store on ice.

    These suspensions are crude preparations that are enriched for mitochondria.

    The mitochondria prepared from lactate-grown D273-10B cells usually have a dark brown color but may also look orange or pink.

41. Estimate protein concentration by measuring A_{280} of 10 µl of crude mitochondrial suspension diluted in 990 µl of 0.6% SDS. Mix 10 µl buffer B with 990 µl of 0.6% SDS to use as a reference standard.

    An A_{280} value of 0.21 corresponds to ~10 mg/ml protein in the undiluted suspension. A 4-liter culture typically yields 120 mg of crude mitochondrial protein.

    If no further purification is desired, dilute the crude mitochondrial suspension to 15 ml with ice-cold buffer C. Centrifuge 10 min at 12,000 × g, 4°C. Gently resuspend crude mitochondrial pellet to the desired concentration in ice-cold buffer C.

Purify mitochondria

42. Centrifuge crude mitochondrial suspension generated in step 40 for 5 min at 3000 × *g*, 4°C, in a microcentrifuge, to remove aggregated material. Transfer supernatant to new microcentrifuge tube and store on ice.

43. Prepare two Nycodenz step gradients just before use. Transfer 5 ml prechilled 18% Nycodenz solution to each clear ultracentrifuge tube. Carefully add 5 ml prechilled 14.5% Nycodenz solution, taking care to obtain a sharp interface. Keep gradients on ice.

    Two Nycodenz gradients are usually sufficient for purifying mitochondria obtained from 4 liters of cells. For optimal separation, the amount of material loaded on each 10-ml gradient should not exceed 50 to 75 mg protein (as measured in step 41).

44. Gently layer ~1 ml crude mitochondrial preparation from step 42 onto each gradient.

45. Ultracentrifuge 30 min at 284,000 × *g* (40,000 rpm in Beckman SW-41 rotor), 2°C, using the slow acceleration and deceleration settings.

46. After centrifugation is completed, carefully remove gradient from the rotor buckets and place them in a stable rack. Note any apparent membrane aggregations and other characteristics. While processing each gradient, store remaining gradients undisturbed at 4°C.

The purified mitochondria should collect at the 18%/14.5% Nycodenz interface and form a brown band. The mitochondrial layer may also appear to be orange or pink.

Collect mitochondria

47. First remove buffer layer and most of the 14.5% Nycodenz layer using cut 1-ml pipet tips. Harvest mitochondrial layer with a cut 1-ml pipet tip and transfer to a 50-ml tube on ice.

    Change pipet tips with each pipetting step to minimize contamination.

    Alternatively, the mitochondrial layer can be recovered using a syringe with a 19-G needle. Place a piece of clear tape on each tube at the 18%/14.5% Nycodenz interface and puncture the side of each tube to collect mitochondria.

48. Pool harvested mitochondria and dilute to 15 ml with buffer C. Centrifuge 10 min at 12,000 × *g*, 4°C.

49. Discard supernatant and gently resuspend pellet in 0.5 ml ice-cold buffer C (0.25 ml buffer C per Nycodenz gradient), using a glass Dounce or Teflon homogenizer to resuspend mitochondria completely. Store suspension in a microcentrifuge tube on ice.

Determine protein concentration

50. To determine approximate protein concentration, dilute 10 µl purified mitochondrial suspension from step 49 in 0.5 ml buffer C. Centrifuge 3 min at 12,000 × *g*, 4°C.

    This centrifugation step is required to remove any residual Nycodenz from the mitochondrial suspension, since Nycodenz absorbs ultraviolet light and will distort the A_{280} measurements.

51. Discard supernatant, resuspend pellet in 1.0 ml of 0.6% SDS, and measure the A_{280}.

    For gradient-purified mitochondria, an A_{280} value of 0.12 corresponds to a protein concentration of ~10 mg/ml in the undiluted suspension.

52. To store mitochondria, dilute mitochondria with a combination of cold buffer C and cold buffer C plus BSA to yield final concentrations of 25 mg/ml mitochondrial protein and 10 mg/ml BSA. Aliquot, freeze in liquid nitrogen, and store at −70°C or −80°C. Just before use, rapidly thaw the mitochondrial suspension in a 30°C water bath and immediately place on ice.

    Alternatively, mitochondria can be frozen in a DMSO-mannitol solution as described by Yaffe (1991).

BASIC PROTOCOL 7

ISOLATION OF OLEATE-INDUCED PEROXISOMES USING SUCROSE STEP GRADIENTS

This protocol was designed to purify intact, functional peroxisomes from the wild-type yeast strain D273-10B after growth in oleate medium (Distel et al., 1996). Yeast cells are precultured in glucose medium for two days and then transferred to oleate medium to induce the proliferation and growth of peroxisomes. After 12 to 18 hr in oleate medium, they are converted to spheroplasts using the β-glucanase preparation Zymolyase 100T and lysed by osmotic shock. Differential centrifugation is used to generate a peroxisome-enriched pellet. This pellet is subsequently fractionated on a sucrose density step gradient to purify the peroxisomes.

The protocol presented here calls for a 1-liter culture of D273-10B cells in oleate medium, but can be scaled up or down as needed. The extent of peroxisome proliferation in response

to growth on oleate medium can vary significantly among different *S. cerevisiae* strains. If using a strain other than D273-10B, it is wise to conduct a pilot experiment and monitor peroxisome induction using peroxisomal enzyme activity assays and electron microscopy. If the peroxisomes will be used for functional studies, a recovery incubation after spheroplast preparation may be needed for optimal activity.

Materials

Rich growth medium (see recipe)
Yeast strain D273-10B (or another strain of interest)
Peroxisome induction medium (see recipe)
TSD reduction buffer (see recipe)
1.2 M sorbitol/phosphate solution (see recipe)
100,000 U/g Zymolyase 100T (ICN Biochemicals)
1.2 M sorbitol in MES buffer (see recipe for buffer), 4°C
MES buffer (see recipe), 4°C
0.65 M sorbitol/MES solution (see recipe), ice cold
20%, 30%, 40%, 44%, 46%, and 60% (w/w) sucrose/MES solution: ultrapure sucrose in MES buffer (see recipe), 4°C

100-ml and 2-liter flasks
50-ml centrifuge tubes
250-ml centrifuge bottles
1.6-ml microcentrifuge tubes
Sorvall GS-3 rotor
Centrifuge and Sorvall SS-34 rotor (or equivalent)
Dounce homogenizer with a loose-fitting pestle (optional), chilled
Beckman polyallomer Quick-seal tubes (25 × 89–mm) or equivalent
Vertical rotor (Beckman VTi 50 or equivalent), 4°C
30°C water bath
Syringe and wide-gauge needle

Additional reagents and equipment for growing yeast cells (*UNIT 1.6*) and determining protein concentration (*APPENDIX 3B*)

Preculture cells

1. Three to four days before fractionation, inoculate 10 ml of rich growth medium in a 100-ml flask with a single colony of desired yeast strain from a fresh plate. Culture cells overnight at 28°C with vigorous shaking.

2. Measure OD_{600} the following morning. Use preculture to inoculate 10 ml of rich growth medium (in a new 100-ml flask) to an OD_{600} of 0.15. Culture cells during the day at 28°C with vigorous shaking.

3. Once culture reaches an OD_{600} of 1.0 to 1.5, inoculate 10 ml of rich growth medium (in a new 100-ml flask) with cells to an OD_{600} of ~0.010 to 0.015 (i.e., a 1:100 dilution). Incubate at 28°C overnight with vigorous shaking.

4. *Optional:* Repeat steps 2 and 3.

   Extended preculturing will generate a relatively homogeneous population of healthy, rapidly dividing cells that will respond well when transferred to the peroxisome proliferation medium; however, the third day of preculturing is usually not necessary.

Culture and harvest cells

5. In the morning, the day before the fractionation experiment, measure the OD_{600} of the 100-ml preculture from step 3. Inoculate 300 ml of rich growth medium (in a

2-liter flask) to an OD_{600} of 0.15. Culture cells at 28°C with vigorous shaking until culture reaches an OD_{600} of 1.0.

6. Once the culture reaches an OD_{600} of 1.0, harvest cells by centrifuging 5 min at ~4000 × *g* (4900 rpm in Sorvall GS-3 rotor), room temperature.
7. Decant supernatant and resuspend cells in 10 ml induction medium. Transfer 5 ml suspension to a flask containing 1 liter induction medium. Incubate overnight at 28°C with vigorous shaking.

Prepare cells to generate spheroplasts

8. In the morning of the day of fractionation experiment, harvest cells by centrifuging 5 min at 4000 × *g*, room temperature.

   For best results, harvest cells 12 to 18 hr after the shift to induction medium.

9. Decant supernatant and resuspend cells in a total of ~100 ml sterile water. Pellet cells by centrifuging 5 min at ~4000 × *g*, room temperature.
10. Decant supernatant and resuspend cells in a total of 40 ml sterile water. Transfer suspension to a single preweighed 50-ml centrifuge tube. Pellet cells by centrifuging 5 min at ~4000 × *g*, room temperature.
11. Decant supernatant and aspirate any remaining liquid. Weigh centrifuge tubes containing pellets to determine the wet weight of cell pellet.
12. Resuspend cells in freshly prepared TSD reduction buffer at 0.125 g/ml (i.e., add 8 ml TSD reduction buffer per gram wet cell pellet). Incubate 15 min at 30°C with gentle shaking.
13. Harvest cells by centrifuging 5 min at ~3000 × *g* (e.g., 5000 rpm in Sorvall SS-34 rotor), room temperature.

Generate spheroplasts

14. Decant supernatant and resuspend cells with ~30 ml 1.2 M sorbitol/phosphate buffer. Harvest cells by centrifuging 5 min at ~3000 × *g*, room temperature.
15. Decant supernatant and resuspend cells to 0.125 g/ml in 1.2 M sorbitol/phosphate buffer. Transfer 10 µl cell suspension to a 1.6-ml microcentrifuge tube and store on ice until step 17.
16. Add Zymolyase 100T to a final concentration of 1 mg enzyme per gram of wet cell pellet. Incubate 20 min at 30°C with occasional gentle agitation.
17. After 20 min, monitor cell wall digestion. Dilute 10 µl of each cell suspension into 990 µl water and mix by briefly vortexing. Also dilute the 10-µl samples stored after step 15 to serve as controls. After 1 or 2 min, briefly vortex again and measure the OD_{600} values.

    The decrease in OD_{600} values of diluted cell suspension indicates the extent of cell wall removal. In the absence of mechanical support (provided by the intact cell wall) or osmotic support (provided by sorbitol), spheroplasts will lyse and thus will no longer contribute to the optical density.

    The extent of cell-wall digestion can also be examined by phase-contrast microscopy as described in Support Protocol, step 11.

18. Continue incubation until >95% of cells have been converted to spheroplasts, which usually takes 30 to 60 min. Harvest spheroplasts by centrifuging 5 min at ~1000 × *g* (e.g., 3000 rpm in Sorvall SS-34 rotor), room temperature.

19. Decant supernatant and carefully resuspend pellet in ice-cold 1.2 M sorbitol/MES buffer by swirling and gently mixing with a glass rod. Do not vortex, as spheroplasts are fragile.

    All subsequent steps are performed at 4°C with prechilled solutions and equipment.

20. Pellet spheroplasts by centrifuging 5 min at 1000 × *g*, 4°C. Transfer cell suspension to a preweighed centrifuge tube. Repeat steps 19 and 20.

21. *Optional*: Incubate spheroplasts 30 to 60 min at 28° to 30°C in rich growth medium supplemented with sorbitol to a final concentration of 1.2 M. Shake gently. Pellet spheroplasts by centrifuging 5 min at ~1000 × *g*, 4°C.

    Optimal recovery conditions should be determined empirically for each application.

    Other growth media supplemented with sorbitol to a final concentration of 1 to 1.5 M can be used.

22. Repeat steps 19 and 20.

Isolate enriched peroxisome fraction

23. Decant supernatant and weigh wet pellet. Gently resuspend spheroplasts in ice-cold 1.2 M sorbitol/MES buffer to a concentration of 0.125 g/ml (i.e., add 8 ml of solution per g wet cell pellet determined in step 11). Resuspend with a glass rod. Do not vortex.

24. To generate hypoosmotic conditions, slowly add ice-cold MES buffer with freshly added PMSF dropwise to spheroplast suspension while gently stirring until the final sorbitol concentration is 0.65 M.

    The required volume ice-cold MES buffer will need to be calculated based on the volume of 1.2 M sorbitol/MES added in step 23.

25. Monitor the degree of cell lysis microscopically.

    If >20% of the spheroplasts remain intact after several minutes, induce further lysis with a few gentle strokes in a chilled Dounce homogenizer with a loose-fitting pestle.

26. Centrifuge homogenate 10 min at 2000 × *g* (e.g., 4100 rpm in Sorvall SS-34), 4°C, to remove unlysed cells and large aggregates. Transfer supernatant to a new tube and store on ice until step 28.

27. Using a pipet, resuspend pellet in ice-cold 0.65 M sorbitol/MES solution with PMSF to a concentration of 0.125 g/ml. Centrifuge 10 min at 2000 × *g*, 4°C.

28. Pool supernatants from steps 26 and 27 in a 50-ml centrifuge tube prechilled on ice.

29. Pellet peroxisomes (as well as mitochondria and other organelles) from pooled supernatants by centrifuging 30 min at 20,000 × *g* (e.g., 13,000 rpm in Sorvall SS-34 rotor), 4°C.

30. After 30-min centrifugation, aspirate supernatant. Carefully resuspend the organelle pellet in 2 ml cold 30% sucrose/MES solution and store organelle suspension on ice.

    In order to minimize damage to the fragile peroxisomes, resuspend pellet using a glass rod or a pipet with a wide tip opening.

Determine protein concentration

31. Determine approximate protein concentration of organelle suspension by any standard method (e.g., *APPENDIX 3B*).

32. Add cold 30% sucrose/MES solution to organelle suspension to reach a final protein concentration of ~5 mg/ml. Carefully mix with a glass rod or a pipet with a wide tip opening.

Purify peroxisomes

33. Carefully prepare sucrose step gradients in Quick-seal centrifuge tubes by layering 5 ml of 60% sucrose/MES solution, 12 ml of 46% sucrose/MES solution, 12 ml of 44% sucrose/MES solution, and 5 ml of 40% sucrose/MES solution. Cool on ice for ≥10 min.

    It is important that gradients be prepared <30 min before use and interfaces between sucrose layers are sharp.

    One gradient will be needed for every 2 ml of organelle suspension.

34. Apply 2 ml suspension from step 30 to each sucrose step gradient. Fill and balance tubes with cold 20% sucrose/MES solution and carefully seal tubes.

35. Centrifuge 2.5 hr at 34,500 × *g*, 4°C, in a vertical rotor (Beckman VTi 50 or equivalent), using the slow acceleration and deceleration modes.

36. After centrifugation is completed, carefully remove gradient from the rotor buckets and place them in a stable rack. Note any apparent membrane aggregations and other characteristics. While processing each gradient, store remaining gradients undisturbed at 4°C.

    Two bands will be visible in the gradient: (1) a narrow band at the 60%/46% sucrose interface consisting primarily of peroxisomes, and (2) a broader band at the 46%/44% sucrose interface consisting primarily of mitochondria.

37. Collect peroxisomes at the 60%/46% sucrose interface using a syringe with a wide-gauge needle.

    Alternatively, collect 2-ml fractions with an automated collector or a cut 1-ml pipet tip. Ideally the membrane layers at the 60%/46% and 46%/44% sucrose interfaces should each be in a single fraction.

    If the peroxisomes are not immediately needed, the sucrose fraction(s) can be rapidly frozen in liquid nitrogen and stored at −80°C.

BASIC PROTOCOL 8

ISOLATION OF ENDOPLASMIC RETICULUM USING SUCROSE STEP GRADIENTS

This protocol was designed to isolate functional ER membranes from yeast spheroplasts (Wuestehube and Schekman, 1992). Yeast cells are converted to spheroplasts with the β-glucanase Zymolyase 100T as in Support Protocol. The cells are lysed under hypoosmotic conditions with a motor-driven Potter-Elvehjem homogenizer (or a glass Dounce homogenizer). Differential centrifugation is used to generate a pellet that is enriched for ER membranes. This pellet is subsequently fractionated on a sucrose density step gradient to isolate ER membranes.

The protocol presented here calls for 5000 OD_{600} units of cells in mid-logarithmic growth phase, but it can be scaled-up or scaled-down as needed. If compatible with the goals of the experiment, protease-deficient strains can be used to minimize protein degradation (e.g., TVY614, a *pep4 prb1 prc1* mutant yeast strain).

Materials

Desired yeast strain (~5000 OD_{600} units of cells in exponential growth phase)
HEPES lysis buffer (see recipe), 4°C
1 M DTT
Protease inhibitor stock solutions B (see recipe)
1.5 M and 1.2 M sucrose/HEPES solution (see recipe)

250-ml centrifugation bottles
Motor-driven Potter-Elvehjem homogenizer (or a glass Dounce homogenizer)
1.6-ml centrifuge tubes
1.6-ml polycarbonate ultracentrifuge microcentrifuge tubes, prechilled
Sorvall GS-3 rotor
Trimmed 1-ml and 200-µl pipet tips (i.e., ~5 to 10 mm cut from the tips)
4-ml Dounce homogenizer, prechilled
Beckman Ultraclear 11 × 34–mm centrifuge tubes (or equivalent), prechilled
Swinging bucket rotor (e.g., Beckman SW 50.1 or equivalent), 4°C

Additional reagents and equipment for growing yeast cells (*UNIT 1.6*), spheroplast preparation (see Support Protocol), and Lowry assay for proteins (*APPENDIX 3B*)

Culture cells and prepare spheroplasts

1. Culture desired yeast strains as described in Support Protocol, steps 1 to 4 (also see *UNIT 1.6*).

2. Harvest ~5000 OD_{600} units of cells in mid-logarithmic growth phase by centrifuging 5 min at ~4000 × *g* (5000 rpm in Sorvall GS-3 rotor), room temperature.

3. Prepare spheroplasts as described in Support Protocol, steps 5 to 15.

   Alternatively, spheroplasts can be prepared as in Basic Protocol 4 or by other methods.

   Spheroplasts are fragile and must be handled very gently.

4. Resuspend spheroplasts in ~100 ml ice-cold cold stop solution, spheroplast medium B, or another solution with the appropriate osmotic support. Resuspend spheroplasts gently by swirling tube by hand, slowly stirring with a glass rod, or slowly pipetting with a wide bore pipet. Do not vortex. Keep suspension on ice until ready for the next step.

   The optimal solution will depend on the goals and subsequent steps of the experiment in which the spheroplasts will be used.

   Spheroplasts tend to stick to each other and thus can be difficult to resuspend. To facilitate resuspension, initially resuspend spheroplasts in a smaller volume of solution before adding the remaining solution.

   Spheroplasts can be stored at −80°C. Resuspend at 1000 OD_{600} units/ml in 0.7 mM sorbitol/20 mM HEPES (pH 7.4). Slowly freeze to −80°C in an insulated container and then store at −80°C.

Prepare spheroplast lysates

5. Harvest spheroplasts by centrifuging 5 min at 1500 × *g*, 4°C, and aspirate supernatant.

   From this point on, keep samples on ice or at 4°C. Also, all solutions and equipment should be chilled to 0° to 4°C prior to as well as during use.

6. Resuspend spheroplasts at a concentration of 1000 OD_{600} units/ml in ice-cold HEPES lysis buffer with freshly-added DTT and protease inhibitors.

7. Prepare lysate with a motor-driven Potter-Elvehjem homogenizer (i.e., 4 to 10 strokes). Keep lysate at 4°C.

   Alternatively, spheroplasts can be disrupted with 10 up-and-down strokes of a tight-fitting pestle in an ice-cold Dounce homogenizer. Keep Dounce homogenizer on ice throughout this process. Move pestle slowly and maintain contact between pestle and suspension to minimize foaming.

8. Inspect 10 µl of the lysate by phase microscopy.

   Intact spheroplasts have characteristic bright halos that are easily distinguished from lysed spheroplast and spheroplast fragments.

   Usually, >95% lysis is achieved.

9. Transfer lysate to multiple chilled 1.6-ml centrifuge tubes.

10. Clear lysate of unbroken cells, partially disrupted cells, and aggregates by microcentrifuging 10 min at 1000 × *g*, 4°C.

11. Carefully withdraw supernatants (S_{1000}) and transfer to new chilled tubes, taking care not disrupt loose pellets (P_{1000}).

    Usually only 80% to 90% of S_{1000} can be harvested from each tube.

12. Resuspend P_{1000} in ~2.5 ml ice-cold HEPES lysis buffer. Repeat homogenization and low-speed centrifugation (steps 7 to 10).

    This second homogenization step can improve the yield of intracellular membranes by ~30%.

Prepare $P_{27,000}$ membrane pellets

13. Pool the first and second S_{1000} supernatants (steps 11 and 12). Mix and transfer the pooled supernatants (S_{1000}) to polycarbonate ultracentrifuge tubes, chilled on ice.

    When not required for subsequent analyses, the P_{1000} pellets are usually discarded since they contain a crude mixture of unlysed and partially disrupted cells, as well as a very heterogeneous mixture of intracellular membranes.

14. Centrifuge the S_{1000} supernatants 10 min at 27,000 × *g*, 4°C. Remove the supernatants ($S_{27,000}$).

    The $S_{27,000}$ can either be saved for analysis or discarded.

15. To remove any residual supernatant from $P_{27,000}$ pellets, centrifuge tubes containing $P_{27,000}$ samples ~45 sec at 13,000 × *g*, 4°C. Carefully remove any remaining liquid above pellet and discard.

16. Resuspend $P_{27,000}$ membranes in 1.0 ml HEPES lysis buffer (~5000 OD_{600} equivalents per ml). Use five strokes in a Dounce homogenizer to ensure complete dispersion of $P_{27,000}$ pellet.

Prepare and run sucrose step gradients

17. Prepare four sucrose step gradients just prior to use so that the interface remains crisp. Carefully pipet 1.0 ml of 1.5 M sucrose/HEPES solution into each 11 × 34–mm ultracentrifuge tube. Using a trimmed 1-ml pipet tip, carefully layer 1.0 ml of 1.2 M sucrose/HEPES solution on top of the 1.5 M sucrose layer.

    If the interface is disturbed during or after preparation of gradient, a new step gradient will need to be prepared.

18. Carefully layer $P_{27,000}$ suspension (step 16) over the four sucrose gradients using a trimmed 200-µl pipet tip.

    Distribute the $P_{27,000}$ suspension among the four gradients so that they are loaded with similar volumes. Up to 0.5 ml of suspension can be loaded on each gradient.

19. Balance the appropriate pairs of gradients by adding ice-cold lysis buffer as necessary. Put gradient tubes into the prechilled buckets of the swinging bucket rotor (e.g., SW 50.1 rotor or equivalent).

20. Centrifuge gradient 1 hr at 100,000 × *g*, 4°C, using the slow acceleration and deceleration settings to minimize disruption of gradients.

Collect and process fractions

21. Carefully remove tubes from the rotor buckets and place in a rack. Make a note of the position and appearance of bands and any other visible characteristics.

    Two discrete membrane bands should be visible, one in the 1.2 M sucrose layer and one at the interface between the 1.2 M and 1.5 M sucrose layers.

22. Collect ER membranes at the 1.2 M/1.5 M sucrose interface. First remove the load layer and most of the 1.2 M sucrose layer by aspiration. Then collect the band at the interface.

    Alternatively, all of the gradient can be harvested as described in Basic Protocol 3, step 23.

23. Dilute ER membrane suspension 10-fold in ice-cold HEPES lysis buffer.

24. Harvest membranes by centrifuging 10 min at 27,000 × *g*, 4°C. Remove supernatant and process pellet fractions as desired.

25. Determine the protein concentration with the Lowry assay (*APPENDIX 3B*) after resuspending a small amount of the preparation in 1% SDS.

    Typically, this protocol yields ~7 mg of protein per 5000 OD_{600} units of cells.

ISOLATION OF PLASMA MEMBRANES FROM WHOLE YEAST CELLS USING SUCROSE STEP GRADIENTS

BASIC PROTOCOL 9

This protocol is an efficient method to isolate plasma membranes from intact yeast cells (Panaretou and Piper, 1996). Yeast cells are rapidly disrupted by vortexing with glass beads. The resulting lysate is fractionated by differential centrifugation to generate a pellet enriched for plasma membrane. The plasma membrane–enriched pellet is then fractionated on a sucrose density step gradient.

The protocol presented here calls for a 1-liter culture of yeast cells in exponential growth phase, but it can be scaled-up or -down as needed. If compatible with the goals of the experiment, it is often beneficial to use a strain that is deficient in vacuolar protease activity to minimize protein degradation (e.g., TVY1, a *pep4* mutant yeast strain), especially when working with heat-shocked cells.

Materials

1-liter culture of desired yeast cells in exponential growth phase
0.4 M, 1.1 M, 1.65 M, 2.25 M sucrose/imidazole solutions (see recipe), 4°C
Protease inhibitor stock solutions C (see recipe)
Breakage buffer (see recipe), 4°C
Plasma membrane storage buffer (optional; see recipe)

250-ml centrifuge bottles
50-ml polycarbonate centrifuge tubes
Acid-washed glass beads (0.45-mm diameter; see recipe), prechilled to 4°C
Sorvall GS-3 rotor
Sorvall SS-34 rotor (or equivalent) and appropriate centrifugation tubes, 4°C
14 × 89–mm Beckman Ultra-clear centrifugation tubes
Beckman SW41 or SW40Ti rotor (or equivalent), 4°C
Beckman 50 Ti rotor (or equivalent)

Additional reagents and equipment for growing yeast cells (*UNIT 1.6*) and culture preparation (Support Protocol)

Grow cells

1. Prepare a 1-liter yeast culture in exponential growth phase (see Support Protocol, steps 1 to 4).
2. Harvest cells by centrifuging 5 min at 5000 × *g* (5000 rpm in Sorvall GS-3 rotor), 4°C.

   All subsequent steps should be performed at 4°C with prechilled solutions and equipment.

3. Decant supernatant and resuspend cells in 80 ml cold 0.4 M sucrose/imidazole solution with freshly added protease inhibitors.
4. Transfer cell suspension to two 50-ml polycarbonate centrifuge tubes. Centrifuge 10 min at 5000 × *g* (e.g., 6500 rpm in Sorvall SS-34 rotor), 4°C.

Perform glass-bead lysis

5. Decant supernatant and add two times the pellet volume of prechilled glass beads to pellets. Add sufficient cold 0.4 M sucrose/imidazole solution to just cover pellet and glass beads.
6. Vortex 5 min at maximum speed. Keep lysate cold by alternating between 30 sec of vortexing followed by 30 to 60 sec in an ice-water bath.

   Ice can be used instead of an ice-water bath; however, an ice-water bath will cool the lysates more efficiently.

7. Monitor degree of cell breakage under a microscope.

   The percentage of lysed cells should be between 50% and 80%. If the lysis efficiency is significantly below 50%, repeat step 6.

8. Place tubes on ice ~2 min to allow glass beads to settle and cool the lysate. Transfer supernatant to a new tube and store on ice.
9. Add ~2 times volume of cold 0.4 M sucrose/imidazole solution to glass beads. Vortex for 30 sec. Allow glass beads to settle while the tube is on ice.
10. Remove supernatant and pool with the supernatant collected in step 8. Repeat steps 9 and 10.

Isolate enriched plasma membrane fraction

11. Clear the pooled lysate of unbroken cells, cell wall debris, and aggregates by centrifuging 20 min at 530 × *g* (2150 rpm in Sorvall SS-34 rotor), 4°C.
12. During the centrifugation step, prepare two sucrose step gradients in 14 × 89–mm Beckman Ultra-clear centrifugation tubes. Add 4 ml of 2.25 M sucrose/imidazole solution to each tube. Then carefully overlay 4 ml of 1.65 M sucrose/imidazole solution, followed by 4 ml of 1.1 M sucrose solution. Chill gradients on ice until ready for use.

    Crisp interfaces are essential to the success of the experiment.

13. Transfer supernatant from step 11 to fresh centrifuge tubes. Centrifuge 30 min at 22,000 × *g* (13,500 rpm in Sorvall SS-34 rotor), 4°C, to obtain a pellet that includes plasma membranes (as well as nuclei, mitochondria, and vacuoles).
14. Carefully remove supernatant and resuspend pellet in 2 ml cold breakage buffer by vortexing for 30 sec at slow-medium speed.

    The use of <2 ml breakage buffer is not recommended, as membranes will tend to clump.

Purify plasma membranes

15. Carefully layer 1 ml resuspended membranes onto each of the two sucrose step gradients (prepared in step 12). Balance tubes with breakage buffer.

16. Centrifuge 14 hr at 80,000 × *g* (~22,000 rpm in Beckman SW-41 rotor), 4°C.

    Alternatively, centrifuge for 6 hr at 284,000 × g (~40,000 rpm in Beckman SW-41 rotor).

17. After centrifugation is completed, carefully remove gradient from the rotor buckets and place them in a stable rack. Note any apparent membrane aggregations and other characteristics. While processing each gradient, store remaining gradients undisturbed at 4°C.

    A layer primarily consisting of plasma membrane should form at the 2.25 M/1.65 M sucrose solution interface; this band represents up to two-thirds of the plasma membranes loaded onto the gradient. The remaining plasma membranes will colocalize with mitochondria at the 1.65 M/1.10 M sucrose solution interface.

18. Collect membranes at the 2.25 M/1.65 M sucrose interface using a Pasteur pipet. Dilute membranes with 4 vol cold breakage buffer and store on ice.

    If desired, the other fractions can also be harvested and analyzed.

19. Transfer suspensions to centrifuge tubes. Pellet membranes by centrifuging 40 min at 30,000 × *g* (~17,000 rpm in Beckman 50 Ti rotor), 4°C.

20. Decant supernatant and resuspend pellet in desired buffer for immediate use.

    For storage, resuspend the pellet in plasma membrane storage buffer and store at −80°C.

21. *Optional*: Determine protein concentration by indirect means (*APPENDIX 3B*).

PREPARATION OF CYTOSOL FROM WHOLE YEAST CELLS

BASIC PROTOCOL 10

This protocol is designed to prepare cytosol from intact yeast cells (Haas, 1995). Yeast cells are rapidly disrupted by vortexing with glass beads. The resulting lysate is subjected to high-speed centrifugation to separate the cytosol from membrane components.

The protocol presented here calls for 2000 OD_{600} units of yeast cells grown to a concentration of 1 to 2 OD_{600} units/ml, but it can be scaled up or down as needed. If compatible with the goals of the experiment, it is often beneficial to use a strain that is deficient in vacuolar protease activity to minimize protein degradation (e.g., TVY1, a *pep4* mutant yeast strain).

Materials

Desired yeast strains
YPD (*UNIT 1.6* or appropriate growth medium)
PIPES lysis buffer (see recipe), prechilled
50× protease inhibitor cocktail (50× PIC; see recipe) or equivalent
Acid-washed glass beads (~0.45-mm diameter; BDH or Sigma; see recipe), prechilled to 4°C
Methylene blue
BioRad protein assay reagent kit (or equivalent)

250-ml and 2-liter Erlenmeyer flasks
Platform shaker, 30°C (or appropriate permissive temperature)
Centrifuge rotors (e.g., Beckman JA-10 and JA-20 rotors or equivalents)
500-ml centrifuge bottles
30-ml glass Corex tubes (1 tube per cytosol preparation), prechilled

Ice-water bath
Adapters for 30-ml glass Corex tubes (for Beckman JA-20 rotor or equivalent)
Ultracentrifuge tubes, 4°C
Ultracentrifuge rotor (Beckman TLA 100.2 rotor or equivalent)
Tabletop ultracentrifuge, 4°C
Microcentrifuge tubes, prechilled

Additional reagents and equipment for growing yeast cells (*UNIT 1.6*) and determining protein concentration (*APPENDIX 3B*)

Grow cells

1. In the morning, the day before the experiment, start precultures of desired yeast strains by inoculating 20-ml of YPD (or appropriate medium) in 250-ml Erlenmeyer flasks. Grow throughout the day at 30°C (or appropriate permissive temperature) shaking at 225 to 335 rpm.

   It is best to start with a single yeast colony from a fresh plate.

   If using a strain that grows very slowly or if using a strain that has been stored on a plate at 4°C for more than a few days, it is wise to start the preculture with a single colony the night before.

2. In the evening, the day before the experiment, measure and record the OD_{600} values of precultures.

3. Inoculate two 1-liter cultures (in 2-liter Erlenmeyer flasks) with the appropriate volume of each preculture.

   Cultures of 1 to 2 liters are recommended for each strain, since 2000 OD_{600} units of cells at 1 to 2 OD_{600} units/ml are needed for each batch of cytosol. The suitable yeast cell concentration at this step depends on the growth rate of each strain and the length of incubation time. See Support Protocol step 3 for sample calculations.

   For some purposes, cytosol can be prepared from yeast cell cultures with a higher cell density (OD_{600} of 2 to 6); however, cytosol preparations from lower-density cultures (OD_{600} 1 to 2) generally seem to have higher activities as determined by vacuolar fusion assays (Haas, 1995).

4. Culture cells overnight at 30°C (or appropriate permissive temperature) while shaking at 225 to 325 rpm. In the morning, the day of experiment, analyze cell density.

   Ideally the cultures should have an OD_{600} of 1 to 2 to begin the experiment.

5. Harvest 2000 OD_{600} units of cells in 500-ml centrifugation bottles by centrifuging 5 min at 4400 × *g* (5000 rpm in JA-10 rotor), room temperature. Decant and discard supernatants.

Prepare cell lysates using glass beads

6. Resuspend pellets in a total of 50 ml prechilled PIPES lysis buffer (50 ml per 2000 OD_{600} units of cells). Transfer cells to smaller centrifuge tubes and vortex at maximum speed for 15 sec. Transfer cell suspensions to a single 500-ml centrifugation bottle.

7. Harvest the washed cells by centrifuging 5 min at 4400 × *g* (e.g., 5000 rpm in JA-10 rotor), room temperature. Decant and discard supernatants.

8. Resuspend cells in 2 ml prechilled PIPES lysis buffer (2 ml per 2000 OD_{600} units of cells). Add 80 µl 50× PIC to each 2-ml suspension and mix by vortexing.

9. Transfer the cell suspension into a prechilled, labeled 30-ml glass Corex tube (one tube/2000 OD_{600} units suspension). Add 3 g prechilled acid-washed glass beads. Seal tubes tightly with Parafilm and keep tubes 2 min in an ice-water bath.

10. Vortex at maximum speed for 30 sec. Then immediately return to ice-water bath for 1 min. Repeat 15 times for each tube.

    Ice can be used instead of an ice-water bath; however, an ice-water bath will cool the lysate more efficiently.

11. Monitor the degree of cell lysis by phase-contrast microscopy. Dilute 10 µl cell lysate in 90 µl PIPES lysis buffer. Add ~5 µl methylene blue and mix. View lysate to determine the percentage of cells that stain with the reagent.

    The stained cells have been lysed. Ideally, 80% of the cells should be lysed. If <50% of cells are lysed, repeat step 10.

Prepare cytosol

12. Clear lysate of unlysed cells, larger aggregates, and glass beads by centrifuging 10 min at 3000 × g (5000 rpm in JA-20 rotor with adapters for the Corex tubes), 4°C.

13. Carefully transfer supernatant to prechilled ultracentrifuge tubes (~1.2 ml per tube).

    If required, balance tubes using cold PIPES lysis buffer.

14. Centrifuge samples 1 hr at 150,000 × *g* (65,000 rpm in Beckman TLA 100.2 rotor), 4°C.

15. Carefully remove and discard the lipid layer visible on top of each sample. Then transfer supernatant to prechilled microcentrifuge tubes, being careful not to include any of the pellet.

16. Determine protein concentration of each cytosol sample using the BioRad protein assay reagent kit (or equivalent; see *APPENDIX 3B*). Prepare several dilutions of cytosol in water (e.g., 1:10 to 1:100; 10 µl total).

    The cytosol preparations usually have protein concentrations of 10 to 30 mg/ml.

    If the cytosol is not needed immediately, aliquot cytosol in prechilled tubes (e.g., 100 µl per 0.6-ml microcentrifuge tube). Quickly freeze the samples in liquid nitrogen and store at −80°C. Haas and coworkers (1995) have found that cytosol can be stored for months at −80°C and still support an in vitro vacuole-vacuole fusion assay.

REAGENTS AND SOLUTIONS

Use double-distilled water and Ultrapure reagents in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Acid-washed glass beads

For yeast glass bead lysis, it is best to use glass beads between 0.4 and 0.5 mm (BDH or Sigma). Soak the glass beads in concentrated nitric acid or 1 M hydrochloric acid for 2 hr in a fume hood (use caution; wear safety goggles, nitrile gloves, and a long lab coat). During incubation, carefully mix beads a few times using a long glass stirring rod. Wash beads extensively with deionized water. Continue washing until the water has the same pH before and after addition to the beads (it is helpful to use a filter apparatus for the washing). Transfer beads to a glass dish or metal tray. Place them in a vacuum oven at ~200°C. Stir a few times to ensure that all of the beads will dry completely. Once the beads are completely dry and have cooled to room temperature, store them in a glass bottle at 4°C.

Breakage buffer

2 mM EDTA
25 mM imidazole-HCl, pH 7.0
Store up to a few weeks at 4°C

Just before use, add PMSF and *N*-tosyl-L-phenylalanine chloromethyl ketone (TPCK) to a final concentration of 1 mM each. Also add pepstatin A to a final concentration of 2.5 µg/ml (see recipe for protease inhibitor stock solutions C).

Keep buffer at 4°C, not 0°C, to prevent precipitation of protease inhibitors.

Buffer B, 2×

1.2 M sorbitol
40 mM potassium MES, pH 6.0
Filter sterilize
Store up to several weeks at 4°C

Dextran solution, 0.4 mg/ml (Basic Protocol 4)

Dissolve 2 mg dextran in 5 ml of 15% Ficoll solution (see recipe). Mix by vortexing. Prepare fresh and keep on ice until ready to use.

Less than 0.3 ml is required for each gradient.

Ficoll cushion solution (Basic Protocol 5)

5.5 g sorbitol
1.25 g Ficoll 400
H_2O to 25 ml
Prepare fresh and store at 0° and 4°C until used

Ficoll gradient buffer (Basic Protocol 4)

10 mM PIPES/KOH, pH 6.8
200 mM sorbitol
Store a few weeks at 4°C
Add 50× PIC and PMSF (1 mM; see recipes) just before use

Ficoll solutions

0% Ficoll solution: Ficoll gradient buffer (see recipe) without Ficoll. Add 50× protease inhibitor cocktail (50× PIC; see recipe) and 1 mM PMSF (from 100 mM stock; see recipe for protease inhibitor stock solutions) just before use.

4% (w/v) Ficoll solution: Dissolve 4 g Ficoll 400 in 50 ml Ficoll gradient buffer (see recipe); adjust final volume to 100 ml with Ficoll gradient buffer. Add 50× PIC (see recipe) and 1 mM PMSF (from 100 mM stock; see recipe for protease inhibitor stock solutions) just before use.

8% (w/v) Ficoll solution: Dissolve 8 g Ficoll 400 in 50 ml Ficoll gradient buffer (see recipe); adjust final volume to 100 ml with Ficoll gradient buffer. Add 50× PIC (see recipe) and 1 mM PMSF (from 100 mM stock; see recipe for protease inhibitor stock solutions) just before use.

15% (w/v) Ficoll solution: Dissolve 15 g Ficoll 400 in 50 ml Ficoll gradient buffer (see recipe); adjust final volume to 100 ml with Ficoll gradient buffer. Add 50× PIC (see recipe) and 1 mM PMSF (from 100 mM stock; see recipe for protease inhibitor stock solutions) just before use.

Prepare solutions on the day before the experiment (or earlier) since Ficoll takes a long time to dissolve. To minimize clumping, slowly add the indicated amount of Ficoll 400 to the Ficoll gradient buffer while stirring. Continue to stir the Ficoll solutions without heat. Once Ficoll has dissolved, adjust final volume of each solution to 100 ml with Ficoll gradient buffer. Sterilize by filtration. Store up to a few weeks at 4°C.

Ficoll lysis solutions (Basic Protocol 5)

50% (w/v) Ficoll lysis solution. Heat 100 ml 2× PM buffer (see recipe) and 30 ml water in a 400-ml beaker to ~60°C (not boiling). Slowly add 100.0 g Ficoll 400 with continuous, rapid stirring over a period of 5 to 10 min. Keep solution hot (but avoid boiling) and cover with a glass petri dish. Continue moderate stirring and gentle heating until Ficoll has completely dissolved (often takes ~1 hr). Allow the solution to cool to room temperature. Transfer Ficoll solution to a clean glass 250-ml cylinder. Use multiple washes with water to transfer all of Ficoll from beaker to cylinder. Once all of the bubbles have reached the surface, add water to cylinder to a final volume of 200 ml. Carefully seal cylinder with Parafilm and tape. Mix on a rotator until Ficoll stock is completely homogeneous (30 to 60 min). Aliquot into five sterile, plastic 50-ml tubes and store at −20°C. Remember to mix well after thawing. Warm to room temperature and add 1000× protease inhibitor cocktails (1000× PICs; see recipe) PIC-W and PIC-D at 1:1000 (1× final) just before use.

It is critical to prepare the 50% Ficoll lysis stock solution accurately.

20% (w/v) Ficoll lysis solution. Mix 40.0 ml of 50% Ficoll lysis solution (see recipe) and 30 ml of 2× PM buffer (see recipe), and add water to 100 ml. Warm to room temperature and add 1000× protease inhibitor cocktails (1000× PICs; see recipe) PIC-W and PIC-D at 1:1000 (1× final) just before use.

30% (w/v) Ficoll lysis solution. Mix 27.0 ml of 50% Ficoll lysis solution (see above) and 9.0 ml of 2× PM buffer (see recipe), and add water to 45 ml. Warm to room temperature and add 1000× protease inhibitor cocktails (1000× PICs; see recipe) PIC-W and PIC-D at 1:1000 (1× final) just before use.

40% (w/v) Ficoll lysis solution. Mix 36.0 ml of 50% Ficoll lysis solution (see above) and 4.5 ml of 2× PM buffer (see recipe), and add water to 45 ml. Warm to room temperature and add 1000× protease inhibitor cocktails (1000× PICs; see recipe) PIC-W and PIC-D at 1:1000 (1× final) just before use.

HEPES/KAc lysis buffer (Basic Protocols 1, 2, 3, and Alternate Protocol)

20 mM HEPES/KOH, pH 6.8
50 mM potassium acetate
200 mM sorbitol
1 mM EDTA
Autoclave and store up to 1 month at 4°C

Just before use, aliquot the desired amount of HEPES/KAc lysis buffer to a tube. Add 500× protease inhibitor cocktails A and B (PIC-A and PIC-B, see recipes) to a final concentration of 1×. Add 1 mM PMSF and 5 μg/ml α-macroglobulin (final concentrations; protease inhibitor cocktail stock solutions A, see recipe). If desired, add DTT to 1 mM but omit α-macroglobulin.

HEPES lysis buffer (Basic Protocol 8)

20 mM HEPES/KOH, pH 6.8
50 mM potassium acetate
100 mM sorbitol
2 mM EDTA

Autoclave and store up to 1 month at 4°C

Add DTT and protease inhibitors just before use at final concentrations of 1 mM DTT, 1 mM PMSF, 1 μg/ml pepstatin, and 1 μg/ml leupeptin (see recipe for protease inhibitor stock solutions B).

MES buffer (Basic Protocol 7)

5 mM 2-(*N*-morpholino)ethanesulfonic acid (MES), pH 5.5
1 mM EDTA
1 mM KCl
Store up to 1 month at 4°C

Nycodenz solutions for equilibrium gradients (Basic Protocol 2)

Prepare the following solutions by diluting the 50% (w/v) Nycodenz/sorbitol stock solution (see recipe) with the appropriate volume of HEPES/KAc lysis buffer (see recipe): 37%, 31%, 27%, 23%, 20%, 17%, 13%, and 9% (w/v) Nycodenz solutions. Just before use, aliquot the desired volume of each Nycodenz solution to individual 15-ml tubes. Add 500× protease inhibitor cocktails A and B (PIC-A and PIC-B, see recipes) to a final concentration of 1×. Add 1 mM PMSF and 5 µg/ml α-macroglobulin (final concentrations; protease inhibitor cocktail stock solutions A, see recipe). If desired, add DTT to 1 mM but omit α-macroglobulin.

Alternatively, each solution can be prepared in a manner similar to 60% sucrose stock solution (see recipe).

Nycodenz stock solution, 50% (w/v) (Basic Protocol 6)

Dissolve 50% (w/v) Nycodenz (Life Technologies) in sterile water by slowly adding powder while stirring. Store several months at −20°C.

It may take several hours for the Nycodenz to dissolve completely.

Nycodenz/sorbitol stock solution, 50% (w/v)

50% (w/v) Nycodenz powder
50 mM HEPES/KOH, pH 6.8
1 mM EDTA
200 mM sorbitol
Aliquot and store several weeks at −20°C

Prepare well in advance because Nycodenz powder can take several hours to dissolve. To minimize formation of clumps, stir while adding Nycodenz powder.

Nycodenz step gradient solutions

18% (w/v) Nycodenz step gradient solution: Mix 10 ml of 2× buffer B (see recipe) with 7.2 ml of 50% Nycodenz stock solution (see recipe). Adjust final volume to 20 ml with water. Prepare fresh. Add PMSF to 1 mM final concentration just before use.

14.5% Nycodenz step gradient solution: Mix 10 ml of 2× buffer B (see recipe) with 5.8 ml of 50% Nycodenz stock solution (see recipe). Adjust final volume to 20 ml with water. Prepare fresh. Add PMSF to 1 mM final concentration just before use.

Oxalyticase buffer (Basic Protocol 4)

7.5 ml 1 M potassium phosphate buffer, pH 7.5 (*APPENDIX 2A*)
22.5 ml 4 M sorbitol
120 ml 0.2× YPD medium (*UNIT 1.6*)
Store up to a few weeks at 4°C

Final concentrations are 50 mM potassium phosphate, pH 7.5, 0.6 M sorbitol, and 0.16× YPD. About 15 ml is required for each gradient.

Peroxisome induction medium (Basic Protocol 7)

0.5% (w/v) Bacto peptone
0.3% (w/v) yeast extract
0.12% (w/v) oleic acid
0.2% (v/v) Tween 40

continued

0.5% (w/v) KH_2PO_4
Adjust to pH 6.0 with NaOH
Autoclave
Store up to several weeks at room temperature

At least 1.1 liter of induction medium will be needed per strain.

This medium is best prepared within a few days of use.

PIPES/DTT buffer (Basic Protocol 4)

Prepare 100 mM PIPES/KOH (pH 9.4) and 1 M DTT stock solutions in sterile water at room temperature. Mix 10 ml of 1 M PIPES/KOH (pH 9.4), 1 ml of 1 M DTT, and water for a final volume of 100 ml. Prepare fresh before use.

About 50 ml is required for each gradient.

PIPES lysis buffer (Basic Protocol 10)

20 mM PIPES/KOH (pH 6.8)
250 mM sorbitol
100 mM potassium acetate
50 mM KCl
5 mM $MgCl_2$
Store several weeks at 4°C
Just before use, add DTT, PMSF, and 50× PIC to final concentrations of 2 mM, 1 mM, and 2× respectively

Prepare for sterile components or filter sterilize.

PM buffer, 2× and 1× (Basic Protocol 5)

For 2×:
2.5 ml 1 M K_2HPO_4
5.5 ml 1 M KH_2PO_4
0.4 ml 1 M $MgCl_2$
H_2O to 200 ml
Filter sterilize
Store up to several weeks at 4°C

For 1×: Dilute 2× PM buffer 1:1 with water. Chill to 4°C. Add 1000× protease inhibitor cocktails PIC-W and PIC-D (see recipe) at 1:1000 just before use.

PMSF, 200 mM

Dissolve 34.5 mg phenylmethylsulfonyl fluoride (PMSF) in 9 ml absolute ethanol. Prepare fresh or store aliquots at −20°C for a few weeks.

Pretreatment buffer (Basic Protocol 5)

100 mM Tris·Cl, pH 9.4
50 mM DTT
5 mM EDTA, pH 9.0
Prepare fresh at room temperature from sterile stock solutions

Protease inhibitor cocktail (PIC), 50× (Basic Protocols 4 and 10)

10 µl leupeptin (0.5 mg/ml in water)
50 µl 1,10-phenanthroline (500 mM in ethanol)
25 µl pepstatin A (1 mg/ml in methanol)
50 µl Pefabloc (100 mM in water)
865 µl sterile water
Mix thoroughly, dispense into 1-ml aliquots, and store several months at −80°C
Dilute 1:50 or 1:25 in the indicated buffers just before use

Protease inhibitor cocktails (PICs), 500× and 1000× (Basic Protocols 1, 2, 3, and Alternate Protocol)

500× PIC-A: Dissolve 5 mg/ml antipain, 1 mg/ml leupeptin, and 1 mg/ml aprotinin in water. Prepare 1-ml aliquots and store several months at −20°C.

500× PIC-B: Dissolve 5 mg/ml pepstatin A and 5 mg/ml chymostatin in methanol. Prepare 1-ml aliquots and store several months at −20°C.

1000× PIC-D: Dissolve 880 mg phenylmethylsufonyl fluoride (PMSF; final concentration 0.5 M), 10 mg pepstatin A, and 10 mg chymostatin in 10 ml dimethylsulfoxide (DMSO). Prepare ten 1-ml aliquots and store up to several months at −20°C.

1000× PIC-W: Dissolve 1.5 g benzamidine (final concentration 1 M), 131 mg ε-aminocaproic acid (final concentration 1 M), 5 mg bestatin, and 5 mg leupeptin in 10 ml water. Prepare ten 1-ml aliquots and store up to several months at −20°C.

Dilute PIC solutions at 1:1000 in the indicated buffers solutions just before use. Add PIC-D below the surface of the solution while rapidly stirring to minimize precipitation.

Protease inhibitor cocktail solutions A

5 mg/ml α-macroglobulin in H_2O (optional; omit if using DTT)
200 mM PMSF in absolute ethanol (200×)
Store a few weeks at −20°C

Protease inhibitor cocktail solutions B

100 mM PMSF in absolute ethanol (100×)
1 mg/ml pepstatin in methanol (1000×)
1 mg/ml leupeptin in water (1000×)
Store a few weeks at −20°C

Protease inhibitor stock solutions C (Basic Protocol 9)

Prepare 100 mM PMSF in absolute ethanol

Prepare 100 mM *N*-tosyl-L-phenylalanine chloromethyl ketone (TPCK) in absolute ethanol

Prepare 2.5 mg/ml pepstatin A in methanol (1000×)
Store protease inhibitor stocks in aliquots up to several months at –20°C

PSM 1 solution (Basic Protocol 5)

1.6 ml 1 M K_2HPO_4
2.4 ml 1 M KH_2PO_4
0.2 ml 1 M $MgCl_2$
17.12 g ultrapure sucrose (final concentration 250 mM)
H_2O to 200 ml
Filter sterilize
Store up to several weeks at 4°C

Rich growth medium (Basic Protocol 7)

0.67% (w/v) yeast nitrogen base without amino acids
0.1% (w/v) yeast extract
0.3% (w/v) glucose

Autoclave. Add required amino acids (usually to a final concentration of 20 µg/ml) once medium has cooled. Store up to a few weeks at room temperature.

At least 350 ml of growth medium will be needed per strain.

Semi-synthetic lactate medium (Basic Protocol 6)

In a total volume of 2.5 liters, mix:
15 g yeast extract
2.5 g glucose
2.5 g $CaCl_2 \cdot 2H_2O$
2.5 g NaCl
3 g $MgCl_2 \cdot 2H_2O$
5 g KH_2PO_4
5 g NH_4Cl
220 ml 90% (w/v) DL-lactic acid
40 g NaOH
Adjust volume to 5 liters with water
Autoclave
Store up to several weeks at room temperature

This medium is best prepared within a few days of use.

1.2 M Sorbitol/phosphate solution (Basic Protocol 7)

50 mM potassium phosphate, pH 7.5 (*APPENDIX 3B*)
1 mM EDTA, pH 7.5
Prepare with sterile stock solutions, autoclave, or filter sterilize
Store several months at 4°C

Sorbitol solution, 1.1 M (Basic Protocol 5)

Dissolve 50 g ultrapure sorbitol in water and dilute to 250 ml. Autoclave. Store up to a few months at 4°C.

Spheroplast medium A, pH 7.5 (Support Protocol)

1× yeast nitrogen base (YNB; Difco)
2% (w/v) glucose
1× amino acids
1 M sorbitol
20 mM Tris·Cl, pH 7.5
Store up to a few weeks at room temperature

Prepare from sterile stock solutions or filter sterilize.

Spheroplast medium B (Support Protocol, optional for other protocols)

1× yeast nitrogen base (YNB; Difco)
2% (w/v) glucose
1× amino acids
1 M sorbitol
Store up to a few weeks at room temperature

Spheroplast recovery medium (Basic Protocol 5, optional)

1 M sorbitol
1% (w/v) Bacto peptone (Difco)
1% (w/v) glucose
0.5% (w/v) Bacto yeast extract (Difco)
20 mM potassium phosphate, pH 6.5 (*APPENDIX 2A*)
Store up to a few weeks at room temperature

Stop solution (Support Protocol, optional for other protocols)

1 M sorbitol
20 mM NaN_3
20 mM NaF
Prepare shortly before use and chill to 4°C

Stop solution contains two energy poisons (NaN_3 and NaF) that are toxic and should be handled with care. The use of NaN_3 and NaF is not appropriate for all purposes (e.g., to isolate organelles for functional studies).

Sucrose gradient buffer (Basic Protocol 5)

50 mM potassium acetate
20 mM HEPES, pH 6.8
2 mM EDTA
Autoclave
Store up to several weeks at room temperature

Sucrose gradient solutions, 1.2 M and 1.5 M in sucrose gradient buffer (Basic Protocol 3)

Stock solutions: Prepare 1.516 M and 1.213 M sucrose solutions in sucrose gradient buffer (see recipe). Filter sterilize. Store up to several weeks at room temperature. Chill prior to use.

Working solutions: Prepare required amounts of 1.5 M and 1.2 M sucrose solutions on day of the experiment by adding 1 M DTT and 100 mM PMSF to a final concentration of 1 mM each (i.e., for 3 ml of 1.5 M sucrose, add 3 µl 1 M DTT and 30 µl 100 mM PMSF).

Sucrose/HEPES gradient solutions, 1.5 M and 1.2 M (Basic Protocol 8)

Prepare 1.516 M and 1.213 M stock sucrose solutions in HEPES lysis buffer (see recipe). Filter sterilize. Store at room temperature. Chill prior to use. Prepare required amounts of 1.5 M and 1.2 M sucrose solutions just before use by adding 1 M DTT and 100 mM PMSF to a final concentration of 1 mM each (i.e., for 3 ml of 1.5 M sucrose, add 3 µl 1 M DTT and 30 µl 100 mM PMSF).

Sucrose solutions for equilibrium gradients (Alternate Protocol)

Prepare the following sucrose solutions by diluting 60% sucrose stock solution (see recipe) with the appropriate volume of HEPES/KAc lysis solution (see recipe): 37%, 34%, 32%, 29%, 27%, 22%, and 10% (w/v) sucrose solutions. Just before use, aliquot the desired volumes of solutions to individual 15-ml tubes. Add 500× protease inhibitor cocktails A and B (PIC-A and PIC-B, see recipes) to a final concentration of 1×. Add 1 mM PMSF and 5 µg/ml α-macroglobulin (final concentrations; protease inhibitor cocktail stock solutions A, see recipe). If desired, add DTT to 1 mM but omit α-macroglobulin.

Alternatively, each solution can be prepared in a manner similar to 60% sucrose stock solution (see recipe).

Sucrose stock solution, 60% (w/v; Alternate Protocol)

60% (w/v) ultrapure sucrose
20 mM HEPES/KOH, pH 6.8
50 mM potassium acetate
1 mM EDTA
1 mM DTT (optional)
Store up to several months at −20°C

Sucrose/imidazole solutions (Basic Protocol 9)

0.4 M sucrose/imidazole solution: 0.4 M sucrose/2 mM EDTA/25 mM imidazole·HCl (pH 7.0)
1.1 M sucrose/imidazole solution: 1.1 M sucrose/2 mM EDTA/25 mM imidazole·HCl (pH 7.0)
1.65 M sucrose/imidazole solution: 1.65 M sucrose/2 mM EDTA/25 mM imidazole·HCl (pH 7.0)
2.25 M sucrose/imidazole solution: 2.25 M sucrose/2 mM EDTA/25 mM imidazole·HCl (pH 7.0)
Store up to several weeks at 4°C
Prechill to 4°C
Add protease inhibitor stock solutions C (see recipe) just before use

TE/SDS solution (Basic Protocol 5, optional)

10 mM Tris·Cl, pH 8 (*APPENDIX 2A*)
1 mM EDTA
0.1% (w/v) SDS
Store at up to several months at room temperature

100 mM Tris·SO_4, pH 9.4

Solubilize 12.11 g Tris in water. Adjust pH to 9.4 with sulfuric acid (H_2SO_4). Adjust final volume to 1 liter with water. Autoclave or filter sterilize. Store up to several months at room temperature.

TSD reduction buffer

0.1 M Tris sulfate, pH 9.4 (see recipe)
10 mM DTT added just before use

COMMENTARY

Background Information

A range of centrifugation-based subcellular fractionation procedures have been successfully applied to the yeast *Saccharomyces cerevisiae*. This unit includes several analytical procedures that are primarily designed to analyze the distribution of proteins along the exocytic, endocytic, and biosynthetic protein transport pathways (see Basic Protocols 1 to 3; Alternate Protocol). Preparative protocols for the isolation of yeast nuclei, vacuoles, mitochondria, peroxisomes, endoplasmic reticulum, plasma membrane, and cytosol are also presented (see Basic Protocols 4 to 10). In addition, numerous alternative *S. cerevisiae* subcellular fractionation procedures and the corresponding references are listed in Table 3.8.2.

These centrifugation-based fractionation procedures separate organelles and membranes according to their sedimentation velocities and/or buoyant densities. An overview of yeast subcellular fractionation procedures and the key considerations are presented in *UNIT 3.7*. In addition, several excellent reviews on yeast subcellular fractionation techniques (Walworth et al., 1989; Zinser and Daum, 1995) and on the theory and practice of centrifugation-based fractionation techniques (Dobrota and Hinton, 1992; Evans, 1992; Hinton and Mullock, 1997) are available.

Most yeast subcellular fractionation procedures begin with spheroplast preparation (i.e., the enzymatic removal of the yeast cell wall) in order to facilitate cell lysis and minimize damage to cellular components (e.g., see Support Protocol). Lysates can also be prepared by agitating intact yeast cells with glass beads. While glass bead lysis works well for the isolation of plasma membrane and cytosol (see Basic Protocols 9 and 10), this technique is not recommended for other fractionation procedures because the strong shear forces required to break the cell wall also damage subcellular components. Once cell lysates are prepared, most protocols then utilize differential centrifugation (e.g., see Basic Protocol 1) in order to enrich the starting material with the components of interest and to remove some of the undesirable components. Further fractionation is achieved by density gradient centrifugation (see Tables 3.8.1 and 3.8.2). Density gradient separation techniques are especially versatile,

since the sedimentation velocities and densities of subcellular components are determined both by their intrinsic properties and the characteristics of the surrounding medium. Thus, the optimal density gradient medium, density range, and shape will vary depending on which components one is trying to separate.

Preparation of yeast spheroplasts using Zymolyase

Most subcellular fractionation procedures begin with preparation of spheroplasts. Standard spheroplast preparation protocols include a reduction step (i.e., with DTT or 2-mercaptoethanol) to break disulfide bonds, followed by incubation with a glucanase enzyme preparation that disrupts the critical β-glucan linkages of the cell wall. Multiple glucanase preparations are commercially available (e.g., Zymolyase, lyticase). In addition, lyticase can be prepared in the laboratory (Scott and Schekman, 1980).

The conditions for optimal cell wall digestion will vary with the strain and growth conditions and thus often need to be determined empirically. The choice of a spheroplast preparation is primarily a matter of preference and expertise of the lab. Zymolyase and oxalyticase are generally preferred since they are highly purified. In contrast, Glusulase is very effective but is much less pure and consequently, contaminating proteases are more of a concern. In Support Protocol, DTT and Zymolyase treatment are used to prepare spheroplasts. Similar methods are used in Basic Protocols 6 and 7. Oxalyticase is used to digest the cell wall in Basic Protocol 4, while a combination of Zymolyase and Glusulase is used in Basic Protocol 5. In all cases, it is wise to monitor the cell wall digestion process by microscopy and/or optical density (OD_{600}) (lysis in water due to osmotic shock) as described in the Support Protocol.

Fractionation of spheroplasts by differential centrifugation

Differential centrifugation protocols rapidly fractionate cell lysates into broad size classes through sequential centrifugation steps with each step increasing in force and duration. The relative sedimentation velocities of the subcellular components are primarily determined by their mass; thus larger organelles and membranes will pellet faster and at lower centrifugal forces than smaller organelles. Differential centrifugation is particularly useful to generate fractions that are significantly enriched for the component(s) of interest and thus facilitates the subsequent fractionation steps. Differential centrifugation is also a convenient way to assess the potential subcellular locations of a protein of interest.

The resolution of the size separation by differential centrifugation is quite low, since the subcellular components are randomly dispersed throughout the medium prior to centrifugation. While the low-speed and medium-speed pellets will primarily consist of relatively large components, they will contain smaller components that were near the bottom of the tube before the centrifugation began.

Equilibrium density gradient fractionation

Basic Protocol 2, Basic Protocol 3, and Alternate Protocol are used to analyze the distribution of one or more proteins among the dynamic compartments of the exocytic, endocytic, and biosynthetic protein transport pathways. The protocols separate these subcellular components into sets of distinct, yet often overlapping fractions.

Basic Protocol 2 was designed to separate vacuolar membranes from endosomal and late Golgi compartments using equilibrium Nycodenz density gradient centrifugation (Rieder and Emr, 1997). The cleared cell lysate is loaded onto gradients, this minimizes the manipulation of lysate and the potential for membrane aggregation. However, abundant cytosolic proteins and unneeded membrane fractions can increase the potential for contamination and can limit the amount of the organelle of interest that can be loaded on a gradient. Thus it is often beneficial to use differential centrifugation (see Basic Protocol 1) to prepare a sample for density gradient fractionation. Pelleting of the membranes allows the removal of cytosolic proteins and can achieve some separation of membrane-bound organelles. A disadvantage to this approach is that it can be difficult to resuspend pelleted membranes well.

The samples can also be loaded onto the bottom of the density gradient if a concentrated Nycodenz stock is added to the sample to increase its density. Singer and co-workers have been able to differentiate between two different endocytic transport intermediates using Nycodenz floatation gradient (Singer and Riezman, 1990). The purification of endosomes, however, has been difficult. Endosome-enriched fractions contain significant levels of other membranes (e.g., ER and Golgi; Singer-Kruger et al., 1993), and the identification of new endosomal proteins using endosome-enriched fractions has remained elusive.

The equilibrium sucrose density gradient centrifugation protocol (Alternate Protocol) is particularly useful to separate vacuolar and endosomal membranes from late Golgi membranes (monitored using mALP, Pep12p, and Vps10p, respectively; see Table 3.7.9); however, the endosomal and vacuolar membranes overlap significantly (Becherer et al., 1996). In contrast, the Nycodenz gradient presented in Basic Protocol 2 can separate vacuolar membranes from endosomal and late Golgi membranes, but in this case the vacuolar and endosomal membranes overlap (Rieder and Emr, 1997). A similar sucrose equilibrium density gradient has been used to separate plasma membranes, ER membranes, and Golgi membranes into distinct sets of fractions (Bowser and Novick, 1991).

Fractionation of $P_{13,000}$ membranes on sucrose step gradients

Basic Protocol 3 was designed to analyze the distribution of one or more proteins among vacuoles, plasma membrane, early Golgi, and ER membranes (Gaynor et al., 1994). The sucrose step gradient is especially useful to determine whether a protein is associated with ER or Golgi compartments. The protocol is very similar to Basic Protocol 8, but on a smaller scale. A continuous sucrose velocity gradient has also been used to obtain discernible differences in the distribution of Golgi, ER, and vacuolar membranes (Antebi and Fink, 1992).

Isolation of intact vacuoles using Ficoll step gradients

Yeast vacuoles are acidic, lysosome-like compartments that occupy ~25% of the cell volume. These single-membrane-bound organelles harbor numerous hydrolases (e.g., proteases, phosphatases, lipases), as well as metabolites (e.g., basic amino acids, polyphosphates, and *S*-adenosylmethionine). Yeast vacuoles are very fragile and are easily damaged during subcellular fractionation experiments. This has two key consequences: (1) it is difficult to isolate intact vacuoles unless very gentle lysis and fractionation techniques are used (see Basic Protocol 4); and (2) the active hydrolases released from ruptured vacuoles can cause significant problems with protein degradation and other damage to subcellular components. Difficulties with protein degradation by vacuolar enzymes can be minimized by using yeast strains with deficient protease activity (e.g., *pep4 prb1* strains; see UNIT 3.7).

Basic Protocol 4 was designed to isolate intact, functional vacuoles. The spheroplasts are lysed with a dextran-mediated isoosmotic lysis procedure, a more gentle lysis technique that allows the isolation of intact vacuoles. However, even with this technique, some of the vacuoles inevitably rupture. The vacuoles and vacuolar membranes are isolated by floatation on a Ficoll gradient. The buoyant density of vacuoles is due to their relatively low protein density and the association of lipid particles or lipid storage granules with the vacuolar membrane (Zinser and Daum, 1995).

An alternate protocol for the isolation of vacuoles uses an hypoosmotic spheroplast lysis and two sequential Ficoll gradients (Roberts et al., 1991; Uchida et al., 1988). The hypoosmotic lysis procedure disrupts the integrity of the majority of vacuoles, as indicated by the loss of lumenal contents and the relatively small size of the isolated vacuoles (Uchida et al., 1988). However, the vacuoles are primarily right-side-out and still functional in several enzyme and transport assays.

Isolation of intact nuclei with Ficoll step gradients

The yeast nucleus is a relatively large (~1 μm), dense organelle that consists of a crescent-shaped nucleolus, chromatin, RNA, and numerous nuclear proteins surrounded by the nuclear envelope. The nuclear envelope is composed of two membrane bilayers that are interconnected at the nuclear pores. The outer membrane is continuous with portions of the rough ER (RER); indeed the nuclear envelope represents ~30% of the functional RER. Thus it is not possible to completely separate ER membranes and nuclei.

Basic Protocol 5 was designed to isolate intact nuclei from yeast spheroplasts using Ficoll step gradients (Dove et al., 1998). Nuclei have also been isolated using Ficoll-glycerol gradients and sucrose gradients (see Table 3.8.2). For example, Kalinich and co-workers developed a protocol that includes cytochalasin B treatment to minimize the interactions between nucleus and the cytoskeleton, followed by glycerol/Ficoll-glycerol step gradients to isolate the nuclei (Kalinich and Douglas, 1989).

Isolation of lactate-induced mitochondria using Nycodenz step gradients

Mitochondria are double-membrane-bound organelles that play a key role in eukaryotic cell metabolism. The enzymes of the electron transport and oxidative phosphorylation pathways are localized to mitochondria, which also contain mitochondrial DNA and the enzymes re-

quired for its replication, transcription, and translation. Growth of yeast on non-fermentable carbon sources such as lactate allows for optimal development of mitochondria. In contrast, the proliferation of mitochondria is repressed under anaerobic conditions, and the formation of pro-mitochondria is observed instead (Pon et al., 1989).

Basic Protocol 6 was designed to isolate intact mitochondria from lactate-grown D273-10B cells on Nycodenz step gradients. (Glick and Pon, 1995). If using cells other than lactate-grown D273-10B cells, it may be necessary to modify the Nycodenz density gradient procedure, as mitochondrial characteristics can vary between yeast strains. In addition, density of the mitochondria can vary significantly depending on growth conditions of the cells, such as the carbon source, temperature, and growth phase. A continuous Nycodenz gradient fractionation procedure to empirically determine the optimal Nycodenz concentrations for a step density gradient is presented by Glick and Pon (1995). Alternatively, mitochondria can be purified using Percoll gradients (Yaffe, 1991), as well as other gradients (see Table 3.8.2). Isolated mitochondria can be fractionated further into outer membrane, inner membrane, intermembrane space and matrix fractions (see Table 3.8.2).

Isolation of oleate-induced peroxisomes using sucrose step gradients

Peroxisomes are single-membrane-bound organelles that range from 0.1 to 1 μm in diameter. The enzymes of the β oxidation and glyoxylate pathways are localized to peroxisomes, as well as enzymes that generate and degrade hydrogen peroxide. The abundance, size, and protein composition of peroxisomes can vary dramatically in response to the cells' environment. When *S. cerevisiae* are grown under standard conditions on a fermentable carbon source (e.g., glucose), peroxisomes and their proteins are barely detectable. In contrast, when *S. cerevisiae* are cultured on fatty acids (e.g., oleate), the expression of peroxisomal proteins is induced and the peroxisomes proliferate and increase in size (Veenhuis et al., 1987).

Basic Protocol 7 was designed to purify intact peroxisomes from D273-10B cells (Distel et al., 1996). The peroxisomes are induced by growth on oleate medium and purified on sucrose step gradients. Alternatively, peroxisomes can be purified on continuous Nycodenz gradients, Nycodenz step gradients, or continuous sucrose gradients (see Table 3.8.2). Some researchers have found that peroxisomes purified on continuous Nycodenz gradients have slightly higher activities and lower levels of contamination with mitochondria than peroxisomes purified on sucrose gradients (Kunau et al., 1993). If an especially pure peroxisome preparation is required, peroxisomes can be purified on two sequential gradients, a sucrose gradient followed by a Nycodenz/sucrose gradient (Erdmann and Blobel, 1995).

Isolation of endoplasmic reticulum using sucrose step gradients

The endoplasmic reticulum (ER) is a complex network of compartments that plays a key role in the transport, folding, and post-translational modification of proteins, as well as in lipid metabolism and several other processes. ER compartments cannot be isolated in a completely intact state, and thus ER preparations primarily consist of ER membrane vesicles, often referred to as microsomes. Basic Protocol 8 was developed to isolate ER membranes for an in vitro protein transport assay (Wuestehube and Schekman, 1992). The protocol is very similar to Basic Protocol 3, but on a larger scale. Rough ER membrane vesicles can be separated from smooth ER vesicles using density gradients, since the ribosomes associated with the rough ER membranes increase their density relative to smooth ER membranes (Sanderson and Meyer, 1991).

Isolation of plasma membranes from whole yeast cells using sucrose step gradients

The plasma membrane forms a selective barrier between the cell's surroundings and its interior. Plasma membrane contains many signaling molecules, as well as transport proteins and channels that move molecules in and out of cells. The plasma membrane is very dynamic, due to the fast growth and division rates of yeast and the continuous exocytic and endocytic transport processes. Like ER membranes, plasma membrane preparations consist of vesicles and sheets.

Basic Protocol 9 provides a method to isolate plasma membranes from intact yeast cells after glass bead lysis (Panaretou and Piper, 1996). The use of intact yeast cells instead of spheroplasts has several benefits beyond ease and speed of the technique. Plasma membranes isolated from glass-bead cell lysates tend to have lower levels of ER contamination. In addition, Zymolyase and other β-glucanase preparations are contaminated with low levels

of proteases that could damage cell surface proteins. Indeed, plasma membrane preparations from spheroplasts have a slightly lower density than those prepared from whole cells.

Plasma membranes can also be successfully prepared from yeast spheroplasts, which are osmotically lysed and subjected to density gradient fractionation (see Table 3.8.2). Several of these procedures specifically alter the sedimentation properties of the plasma membrane. For example, a procedure using cationic silica beads that specifically bind to the plasma membrane is well suited for large-scale isolation of plasma membranes (Panaretou and Piper, 1996). In addition, researchers have used the lectin concanavalin A to facilitate the separation of plasma membrane from other cellular components (e.g., Ziman et al., 1996). Concanavalin A interacts with the glycoproteins found on the cell surface, thereby increasing the plasma membrane density and also minimizing its vesiculation.

Preparation of cytosol from whole yeast cells

The preparation of yeast cytosol is critical to the success of in vitro functional assays. Basic Protocol 10 is a simple and efficient method to prepare cytosol from yeast cells lysed by agitation with glass beads (Haas, 1995). The resulting lysate is subjected to high-speed centrifugation to separate the cytosol from cell wall fragments and membrane components. This cytosol preparation supports an in vitro vacuole-vacuole fusion assay and is likely to support other functional assays as well (Haas, 1995). Cytosol is also frequently prepared from spheroplast lysates (see Table 3.8.2). In addition, a large number of intact yeast cells can be processed by freezing them in liquid nitrogen and then disrupting the cells in a blender or with a mortar and pestle (see Table 3.8.2). Small molecules, such as residual ATP or ions, can be removed from cytosol by passing it over a Sephadex G-25 column (e.g., Wuestehube and Schekman, 1992).

Critical Parameters and Troubleshooting

Subcellular fractionation experiments share several key steps, including, (1) cell growth under appropriate conditions; (2) preparation of cell lysate with minimal damage to subcellular components; (3) selection of a fractionation protocol that separates subcellular components of interest into distinct sets of fractions; and (4) identification and characterization of the membranes/organelles in the resulting fractions. Table 3.8.3 summarizes some of the important factors that are relevant to most subcellular fractionation experiments. Many of these points are discussed in more detail in *UNIT 3.7*. Table 3.8.4 provides a summary of problems that can arise during subcellular fractionation experiments and suggestions for potential solutions. Some key steps that are especially important for the preparative protocols presented in this unit are summarized below.

Isolation of intact vacuoles

In Basic Protocol 4, vacuoles are isolated from spheroplast lysates prepared using a dextran-mediated isoosmotic lysis technique. This lysis procedure is more gentle than hypoosmotic lysis, leaving more of the vacuoles intact. The timing and temperature shifts are critical to the success of this lysis technique. It is important to use glass tubes, since they allow for more rapid temperature changes than plastic tubes. After adding the freshly prepared dextran and swirling to mix, the tubes are placed on ice for 2 min to allow the dextran to bind to the plasma membrane. The optimal amount of dextran for each strain needs to be determined empirically. The cell membrane is disrupted by placing tubes in a 30°C water bath for 60 to 75 sec and the tubes are then immediately placed on ice again. This heat-shock step should not be repeated.

After Ficoll gradient centrifugation, it is important to collect the vacuoles without harvesting the Ficoll solution. Ficoll can be difficult to remove and interferes with many subsequent analyses. If necessary, the Ficoll can be removed by dilution and centrifugation as described in Basic Protocol 5.

Isolation of intact nuclei

For optimal results, the cell cultures need to be in their early log growth phase. The extensive incubation time with glucanase preparations is important to maximize yields. The digestion should be continued until the cells are round and the clumped cells have separated. The lysis buffer should be at room temperature, not 4°C as in most other protocols. Lysis at low temperature will reduce the yield by 50%. However, after the lysis step, the preparation should be kept at 4°C. If the nuclei will be used for functional experiments, it is critical to allow the spheroplasts to recover from the glucanase treatment by incubating in spheroplast recovery medium (or another rich medium supplemented with 1.2 M sorbitol). Optimal conditions for the recovery often need to be determined empirically. For most purposes (e.g.,

Table 3.8.3 Critical Parameters Common to Most Subcellular Fractionation Experiments

Procedure	Critical parameters
Strain selection and growth	The use of a vacuolar protease deficient strain can minimize proteolysis
	If available and compatible with goals of the experiment, use the strain(s) that the protocol was optimized for, as results can vary with strain and growth conditions
	Inoculate the culture with a single colony from a fresh plate (ideally prepared from frozen stock within the past week)
	Determine the correlation between the growth phase, OD_{600} value, and viable cell number for the strains, growth conditions, and spectrophotometer in use
	To generate a homogeneous, active cell population, culture the cells so that they are in their exponential growth phase at least 16 to 24 hr
	For the purification of peroxisomes and mitochondria, preculture cells in the appropriate induction medium prior to harvesting (i.e., oleate or lactate medium)
	Harvest cells in their mid-logarithmic growth phase (unless otherwise indicated)
Reagents and equipment	Use Ultrapure (or equivalent) reagents and double-distilled water for all solutions
	Be sure that glassware is clean and completely free of detergents
	Prepare reagents and solutions ahead of time (unless otherwise indicated)
	Bring reagents to the appropriate temperature in advance
	Label tubes ahead of time to save time and minimize mistakes
	Reserve critical equipment and prechill as needed
Spheroplast preparation	Start with a homogeneous population of dividing cells (unless otherwise indicated)
	Optimal conditions may need to be determined for each strain and growth condition in a small-scale pilot experiment
	Pretreat cells with DTT or 2-ME to break disulfide bonds within the cell wall
	Provide sufficient osmotic support (usually with 1 to 1.5 M sorbitol)
	Digest cell wall with Zymolyase 100T or another glucanase preparation
	Handle the spheroplasts gently (e.g., do not vortex)
	Monitor cell wall digestion by microscopy or lability in water (Support Protocol)
	Wash spheroplasts to remove residual glucanase and contaminating enzymes before continuing to the cell lysis step
Glass bead cell lysis	Use acid-washed beads of ~0.45 mm diameter
	Prechill beads to 4°C
	Resuspend the cell pellet in buffer before adding glass beads
	Use ~1:1 ratio of cell suspension to bead volume
	Cool the lysate every 30 to 45 sec in an ice-water bath
	Minimize foaming. If agitating the sample with a vortexer, be aware of how speed, pressure, and angle affect foaming
	Monitor lysis by microscopy (and methylene blue treatment)
	A Bead Beater is recommended for larger volumes (2 to 200 ml) as there is better heat dissipation and less foaming

continued

Table 3.8.3 Critical Parameters Common to Most Subcellular Fractionation Experiments, continued

Procedure	Critical parameters
Lysate preparation	Keep samples at 0° to 4°C (unless otherwise indicated)
	Add fresh protease inhibitors to solutions just before use
	Use a buffer with the appropriate composition and osmotic support (may need to be determined empirically)
	Use a homogenization technique that balances the need for cell lysis and the need for intact subcellular components
	Minimize foaming
	Handle the lysate gently as many subcellular components are fragile (e.g., avoid narrow pipet tips, vigorous pipetting, mixing with a vortexer)
Fractionation	Set aside samples at each step in order to monitor the recovery levels and marker distribution at each step
	Work as quickly, carefully, and consistently as possible
	Keep samples at 0° to 4°C (unless otherwise indicated)
Gradient preparation	Test whether gradient medium will disrupt protein interactions of interest
	Prepare mock gradients and measure their densities to ensure accuracy and reproducibility of gradient preparation
	Chill the gradients to 4°C before using
	Prepare step gradients just before use so that interface is sharp
	Use the slow acceleration and deceleration rate settings. To minimize mixing of layers, allow the rotor to coast to a stop after slowing to 1000 rpm
Gradient harvesting	Note any bands, pellets, and other characteristics before unloading the gradient
	Save all fractions until confident that they are not needed
	Save a small amount of each fraction to test its density
	When unloading one gradient, store the others at 4°C in a safe place
	If harvesting with a pipettor, change the pipet tip with every fraction
	If the organelles need to be intact, handle the fractions gently (e.g., avoid narrow pipet tips, vigorous pipetting, mixing with a vortexer)
	Work as quickly, carefully, and consistently as possible
Analysis of fractions	Determine the distribution and enrichment factors of multiple markers (see Tables 3.7.8 and 3.7.9)
	Remove gradient medium if it will interfere with subsequent analyses (e.g., by centrifugation)
	If the organelles need to be intact, handle the fractions gently (e.g., avoid narrow pipet tips, vigorous pipetting, mixing with vortexing)
	Remember that colocalization of subcellular components in a given fraction does not necessarily mean they colocalize in vivo
	Optional: examine the fractions for organelle integrity and/or function
	Ideally, confirm results and interpretations using an alternate technique

Table 3.8.4 Troubleshooting Yeast Fractionation

Problem	Potential causes	Potential solutions[a]
Inefficient cell wall digestion	Presence of older and/or stationary-phase cells (which have thicker cell walls)	Generate growth curves for strains and conditions being used
		Dilute or restart cultures and allow cells to grow for several generations until the desired growth phase is reached
	Bacterial contamination	Check for contamination by light microscopy
		If necessary, start a new yeast culture with sterile reagents
	Insufficient enzyme activity levels or incubation times	Purchase and/or prepare a fresh enzyme stock if required
		Determine the optimal conditions in small-scale experiments (e.g., enzyme concentration, duration of treatment with reducing agent, duration of digestion)
	The use of strains with especially thick, strong cell walls (e.g., mutant cells, cells approaching stationary growth phase)	Determine the optimal conditions in small-scale experiments
Inefficient cell lysis (spheroplasts)	Inefficient cell wall digestion	See above
	Insufficient mechanical force to disrupt spheroplasts and/or too much osmotic support	Increase the homogenization intensity and/or duration (e.g., tighter-fitting pestle; more strokes; different lysis technique; buffer with less osmotic support). However, these steps will tend to increase damage to intracellular components
Inefficient cell lysis (whole cells)	Glass beads not of proper size	Glass beads for cell lysis should be 0.45 to 0.55 mm in diameter
	Cells not resuspended before the addition of the glass beads	Resuspend the cell pellet in the lysis buffer before adding glass beads
	Excessive foaming	Determine the optimal conditions with test samples. Changing the angle of the tube or the vortex used can make a difference
	Insufficient intensity or duration of agitation	Increase the duration of agitation (with intermittent chilling on ice). Determine the optimal conditions with test samples
	Glass bead to cell ratio not optimal	Usually a 1:1 ratio of cell suspension to glass beads works well. The cell suspension is ~1:1 cells to buffer
	Presence of older and/or stationary-phase cells (which have thicker cell walls)	Generate growth curves for strains and conditions being used
		Dilute or restart cultures and allow cells to grow for several generations until the desired growth phase is reached
	The use of strains with especially thick, strong cell walls (e.g., mutant cells, cells in stationary growth phase)	Determine the optimal conditions in small-scale experiments

continued

Table 3.8.4 Troubleshooting Yeast Fractionation, continued

Problem	Potential causes	Potential solutions[a]
Proteolysis	Exposure to temperatures >4°C after cell lysis	Keep samples at 0° to 4°C as much as possible. Prechill all solutions and equipment to 0° to 4°C. Use ice and ice-water baths as possible
	Inadequate levels or specificity range of protease inhibitors	Increase levels or change composition of protease inhibitor cocktail
		Add inhibitor cocktail to all solutions during and after cell lysis
		Add PMSF more than once (as it has a short half-life in aqueous solutions)
		Prepare fresh protease inhibitor stocks (if older or improperly stored)
	Extended exposure to hydrolytic enzymes	Work as quickly as possible and keep samples ice cold
		Use a vacuolar protease–deficient strain (e.g., *pep4 prb1*)
		Minimize vacuole lysis (especially important with *PEP4* strains) by using a more gentle homogenization technique, increasing osmotic support in the lysis buffer, and/or treating samples gently throughout the experiment
		Separate components of interest from proteases as soon as possible (e.g., limit exposure to cytosol containing released vacuolar enzymes)
Poor separation on density gradients	Gradients overloaded	Decrease sample amount loaded onto gradients
	Membrane aggregation	See below
	Inadequate cell lysis	See above
	Gradient density medium, density range and/or shape are not ideal for the application	Determine more optimal conditions in small-scale experiments
Membrane aggregation	Insufficient resuspension of pelleted membranes	Pellet membranes onto a cushion (instead of against tube wall)
		Minimize the number and/or intensity of pelleting steps
		Increase intensity and/or duration of resuspension step (e.g., resuspend membranes in a small Dounce homogenizer or by passage through a small pipet tip or needle)
		Allow resuspended membranes to sit on ice in buffer
	Too much material	Use less material or more buffer
	Omission of a clearing step	The low-speed spin clears the lysate of partially-lysed cells (e.g., 500 × *g*)

continued

Table 3.8.4 Troubleshooting Yeast Fractionation, continued

Problem	Potential causes	Potential solutions[a]
	Buffer composition not optimal	Buffer composition can contribute to aggregation (e.g., high Mg^{2+} levels). Aggregation can be minimized to some extent with the addition of 1-2 mM DTT or 2-ME. EDTA can also be helpful
	Insufficient homogenization	Increase the homogenization intensity and/or duration (e.g., tighter-fitting pestle; more strokes; different lysis technique; buffer with less osmotic support). However, these steps will tend to increase damage to intracellular components
	Release of DNA from nuclei	Minimize damage to nuclei by handling samples gently (see below)
		If required, add DNase to 10 µg/ml
Damage to subcellular components	Insufficient osmotic support or rapid change in osmotic support	Increase osmotic support. Avoid rapid buffer changes
	High levels of proteolysis	See above
	Loss of peripheral membrane proteins and/or disruption of protein complexes	Use an alternate buffer or gradient medium. Some buffers and gradient media can destabilize protein interactions. Determine the optimal conditions in small-scale experiments
	Repeated pipetting, pelleting, and/or resuspension	Pellet membranes onto a cushion (instead of the tube wall)
		Handle suspension gently (e.g., cut pipet tip to enlarge the opening, initially resuspend by gently tapping the tube, pipet slowly, etc.)
		Minimize pelleting steps required
	Homogenization technique not gentle enough	Avoid cell lysis with agitated glass beads
		Use a more gentle method to lyse and homogenize spheroplasts (e.g., DEAE-facilitated isoosmotic lysis, a Dounce homogenizer with greater clearance)
		Monitor the appearance of the lysate with a light microscope
Low recovery of proteins and/or enzyme activities	Exposure to active hydrolases	See above
	Damage to membrane integrity and loss of lumenal contents	See above
	Loss of peripheral membrane proteins and/or disruption of protein complexes	Use an alternate buffer or gradient medium. Some buffers and gradient media can destabilize protein interactions
	Gradient media may interfere with enzymatic assays and/or liquid scintillation assays	Remove gradient media from fractions with an appropriate technique (e.g., centrifugation, dialysis). If necessary, choose an alternative gradient medium
	Low recovery of membranes	See below

continued

Table 3.8.4 Troubleshooting Yeast Fractionation, continued

Problem	Potential causes	Potential solutions[a]
Low recovery of membranes	Inefficient cell lysis	See above
	Inadequate homogenization	Increase the homogenization intensity and/or duration (e.g., tighter-fitting pestle; more strokes; different lysis technique; buffer with less osmotic support). However, these steps will tend to increase damage to intracellular components
		Repeat homogenization of low-speed pellet
	Membrane aggregation	See above
	Poor recovery of spheroplasts due to premature spheroplast lysis	Increase osmotic support (up to 1.5 M sorbitol)
		Handle spheroplasts gently (e.g., pellet spheroplasts onto a cushion or through a cushion, cut pipet tips to increase bore size, resuspend cells by swirling, pipet very slowly and gently, do not vortex)

[a]These potential solutions are not compatible with the goals of all experiments; thus they are only recommended if there are no conflicts with subsequent steps and the desired final result. In most cases, the problems cannot be entirely eliminated. Furthermore, pilot experiments may be needed to determine to optimum conditions for a particular purpose.

TCA protein precipitation, SDS-PAGE analysis, functional assays), Ficoll will need to be removed from the harvested nuclei.

Isolation of lactate-induced mitochondria

Basic Protocol 6 was optimized for lactate-grown D273-10B cells. If using cells other than lactate-grown D273-10B cells, it may be necessary to modify the Nycodenz density gradient procedure (Glick and Pon, 1995). The density of the mitochondria can vary significantly with the strain, growth conditions of the cells—e.g., carbon source, temperature—and growth phase.

Good aeration is critical for optimal cell growth and proliferation of mitochondria. A recovery period after cell wall removal is essential for optimal mitochondrial transcription/translation activity. It is critical that high-quality deionized sorbitol be used in the reagents, since lower quality grades contain trace metal contaminants that can damage mitochondria.

Isolation of oleate-induced peroxisomes

The isolation of intact peroxisomes from *S. cerevisiae* is more difficult than from other yeast strains (e.g., *Pichia*, *Candida*). In *S. cerevisiae*, the peroxisomes do not proliferate as readily and are especially fragile. For optimal peroxisome induction, cells must be dividing rapidly prior to the shift to oleate medium. Thus, extended preculturing (i.e., 2 to 3 days) is recommended in order to generate a relatively homogeneous population of healthy, rapidly-dividing cells that will respond well when transferred to the oleate medium. The cells should then be harvested 12 to 18 hr after the shift to induction medium for optimal results. If working with a strain other than D273-10B, it is wise to do a pilot experiment and monitor peroxisome induction using peroxisomal enzyme activity assays and electron microscopy.

In order to isolate intact peroxisomes from *S. cerevisiae*, it is critical that all buffers used during the isolation procedure be adjusted to a low pH (5.5 to 6.0; Thieringer and Kunau, 1991). The sucrose step gradients need to be prepared shortly before use and must have a sharp interface between the sucrose layers. Since peroxisomes are especially fragile, the density gradients used for the purification of peroxisomes are often centrifuged in a vertical rotor to decrease the required centrifugation time.

Isolation of endoplasmic reticulum

In order to maximize yield, the pellet from the first 1000 × *g* clearing spin should be homogenized a second time. This second homogenization step can improve the yield of intracellular membranes by ~30%. The sucrose step

gradients need to be prepared shortly before use and must have a sharp interface between the sucrose layers.

Isolation of plasma membranes from whole yeast cells

The plasma membranes are isolated from yeast cells after glass bead lysis. For efficient cell lysis, the ratio of glass beads to cell suspension is important. It is also critical to keep the lysate cold by alternating between vortexing and incubation in an ice-water bath. Ice can be used instead of an ice-water bath; however, an ice-water bath will cool the lysate more efficiently. The step gradients need to be prepared shortly before use and must have a sharp interface between the sucrose layers.

Preparation of cytosol from whole yeast cells

In Basic Protocol 10, cytosol is isolated from yeast cells cultured to an OD_{600} of 1 to 2. Cytosol can also be prepared from yeast cell cultures with a higher cell density (OD_{600} of 2 to 6); however, these cytosol preparations tend to have lower activity levels as determined by in vitro vacuolar fusion assays (Haas, 1995). For efficient cell lysis, the ratio of glass beads to cell suspension is important. It is also critical to keep the lysate cold by alternating between vortexing and incubation in an ice-water bath. The tubes need to be sealed tightly with Parafilm. The use of glass tubes allows the lysate to be cooled more rapidly.

A high-speed centrifugation step is used to separate cytosol from cell wall fragments, cellular membranes, and larger protein complexes and assemblies. The lipid layer that forms on top of each sample needs to be carefully removed and discarded. The supernatant should then be transferred to a prechilled microcentrifuge tube with a clean pipet, being careful not to include any of the pelleted material.

Use of protease inhibitors

It is critical to include protease inhibitors in all solutions for every step during and after cell lysis. In most cases a number of different inhibitors are included to ensure that a broad range of protease types are inactivated. The protocols described in this unit require a number of different protease combinations that have been recommended by the authors of published methods. Other combinations may be equally or even more appropriate for a particular application. Also convenient premixed protease inhibitor cocktails are commercially available (e.g., Boehringer-Mannheim, Sigma).

Anticipated Results

The unique protein compositions, enzymatic activities, and morphologies of subcellular organelles can be used to follow their distribution among the resulting fractions and analyze the success of an experiment. The most common method used to monitor the distribution and integrity of particular subcellular components is to analyze the distribution of characteristic marker proteins and enzyme activities (see *UNIT 3.7*, see Tables 3.7.7 and 3.7.8). The fractionated subcellular components can also be characterized by examining their morphologies, functions, and overall protein compositions. In order to establish the purity and yield of an organelle preparation or the success of an analytical fractionation experiment, it is important to determine the levels of the components of interest, as well as the levels of the potential contaminants.

The fractionation of subcellular components is never perfect or complete. Centrifugation-based fractionation procedures are limited by the fact that different organelle or membrane populations can have similar sizes and/or densities. In addition, members of a given organelle population vary both in mass and density to some degree. Both of these complications are exacerbated by the additional fragmentation caused by the lysate preparation and fractionation procedures.

Fractionation of spheroplasts by differential centrifugation

Basic Protocol 1 is a typical differential centrifugation method used to separate subcellular components into three membrane pellet fractions and a cytosol fraction. A schematic is presented in Figure 3.7.1. First, yeast cell lysates are subjected to a low centrifugal force (e.g., $300 \times g$) to pellet any unlysed cells and large aggregates. The lysate (S_{300}) is then subjected to sequential centrifugation at $13,000 \times g$ and $100,000 \times g$ to generate $P_{13,000}$ and $P_{100,000}$ pellets, respectively. The distribution of subcellular components in the resulting fractions is summarized in Table 3.7.4. The $P_{13,000}$ primarily contains large membrane structures, such as vacuolar membranes, plasma membrane, endoplasmic reticulum, mitochondria, and nuclei, while the $P_{100,000}$ fraction contains Golgi membranes and transport vesicles (Marcusson et al., 1994). Endosomal membranes containing the syntaxin-homolog Pep12p is distributed between the $P_{13,000}$ and $P_{100,000}$ pellets (Becherer et al., 1996). Soluble cytoplasmic proteins, soluble proteins released from the lumen of dam-

aged organelles, and released peripheral membrane proteins are found in the $S_{100,000}$ fraction. The P_{300} pellet will contain significant amounts of the larger organelles (e.g., plasma membrane, endoplasmic reticulum). The P_{300} and $P_{13,000}$ pellets will contain some smaller organelles that happen to be close to the bottom of the centrifuge tube or that are trapped within partially lysed cells and larger membrane structures. Some of these smaller organelles found in low-speed pellets can be removed by resuspending the pellet in fresh medium and repeating the centrifugation step.

Preparation of yeast spheroplasts

The optimal conditions for digesting the cell wall will vary with the strains, growth conditions, and glucanase enzyme preparation. It is wise to monitor the digestion process by microscopy or lability in water (Support Protocol). For most applications, at least 95% of the cells should be converted to spheroplasts within 20 to 40 min.

Equilibrium density gradient fractionation using Nycodenz

Basic Protocol 2 is particularly useful to separate vacuolar and endosomal membranes from late Golgi membranes (monitored using mALP, Pep12p, and Vps10p, respectively; see Table 3.7.9); however, the endosomal and late Golgi membranes overlap significantly (Rieder and Emr, 1997). The vacuolar membranes migrate to the top region of the gradient, while the endosomal and Golgi membranes localize to the more central fractions of the Nycodenz gradient.

Equilibrium density gradient fractionation using sucrose

The Alternate Protocol is particularly useful to separate vacuolar and endosomal membranes from late Golgi membranes (monitored using mALP, Pep12p, and Vps10p, respectively; see Table 3.7.9); however, the endosomal and vacuolar membranes overlap significantly (Becherer et al., 1996). The vacuolar and endosomal membranes migrate to the top fractions of the gradient, while the Golgi membranes localize to the more central fractions of the sucrose gradient.

Fractionation of $P_{13,000}$ membranes

Basic Protocol 3 was designed to analyze the distribution of one or more proteins among vacuoles, plasma membranes, early Golgi, and ER membranes (Gaynor et al., 1994). Six fractions of unequal volume are collected (summarized below). Vacuolar membranes are found in fractions 1 and 2. Golgi membranes are primarily in fraction 2. ER membranes and the plasma membrane vesicles are split between fractions 2 (~35%) and 4 (~65%; Gaynor et al., 1994).

Isolation of intact vacuoles

Basic Protocol 4 was designed to purify intact vacuoles that are functional in an in vitro vacuole-vacuole fusion assay (Haas, 1995). The resulting vacuole preparation is ~50-fold enriched in vacuolar proteins with respect to the total cell protein of the spheroplast lysate. Cytosolic and ER markers are found in the vacuole preparation in only trace amounts. The level of endosome contamination has not been investigated and may be significant.

The yield is <5% of the total vacuoles. Each gradient with material from ~500 OD_{600} cell equivalents yields a ~600-µl vacuole preparation with a protein concentration of ~0.25 to 0.9 mg/ml. One of the most prominent proteins in the vacuole preparation is Vph1p, a 95-kDa integral membrane protein that is part of the vacuolar ATPase. It is sensitive to proteolysis, so it also can appear as a 75-kDa fragment on SDS-PAGE gels. Isolated vacuoles can be viewed by staining with the vital dyes carboxydichlorofluorescein diacetate (CDC-FDA; lumen) or *N*-(3-triethylammoniumpropyl)-4-6-(diethylammino)phenyl) hexatrienyl)pyridinium dibromide (FM 4-64; membrane) in the presence of ATP (Roberts et al., 1991; Vida and Emr, 1995).

Isolation of intact nuclei

Basic Protocol 5 was designed to isolate intact nuclei from yeast spheroplasts (Dove et al., 1998). The preparation also contains ER membranes, as well as very low levels of plasma membrane, vacuoles, and sometimes mitochondria. The most prominent proteins include the histones and fibrillarin, the 38-kDa nuclear envelope protein. Six liters of yeast culture grown as described usually yield ~75 mg total nuclear protein. Only 2% to 5% of all nuclei are recovered after Ficoll gradients (Aris and Blobel, 1991). Yield and purity of nuclei can vary depending on strain, carbon source, and life stage. Quality of the preparation can be followed by microscopy due to characteristic size and shape of nuclei. Under a light microscope, the nuclei are uniformly gray with slightly rough edges. A small aliquot of the preparation can also be stained with DAPI (4′,6-diaminidino-2-phenylindone) to monitor the purification. This

protocol yields primarily intact nuclei. The nuclei are functional in several in vitro assays. The nuclei can be fractionated further to isolate nucleoli or nuclear envelope preparations (see Table 3.8.2; Dove et al., 1998).

Isolation of lactate-induced mitochondria

Basic Protocol 6 is designed to isolate intact, functional mitochondria from lactate-grown D273-10B spheroplasts (Glick and Pon, 1995). Cells other than lactate-grown D273-10B cells can be used; however, the mitochondrial density and abundance will vary with the strain and growth conditions, and thus the protocol may need to be optimized. The mitochondria will usually have dark brown color but may also look orange or pink. The gradient-purified mitochondrial preparation usually contains only trace amounts of the marker proteins for vacuoles, nuclei, endoplasmic reticulum, plasma membrane, cytosol, or cytosolic ribosomes. Some of the residual microsomal membranes (that associate with the mitochondrial surface) can be removed with an acidic wash as described in Zinser and Daum (1995). When examined by electron microscopy, the gradient-purified mitochondria preparation primarily consists of mitochondria; however, a minor population of unidentified membranes is present. Common mitochondrial marker proteins include porin (outer membrane), cytochrome *c* (inner membrane), cytochrome b_2 (intermembrane space), and citrate synthase (matrix). A typical yield from four 1-liter cultures of lactate-grown D273-10B cells is 20 to 25 mg of mitochondrial protein. These mitochondria are suitable for organelle translation studies, in vitro protein import studies, and other in vitro assays (Daum et al., 1982). If the mitochondria will be used for functional studies, a recovery incubation after spheroplast preparation may be needed for optimal activity.

Isolation of oleate-induced peroxisomes

Basic Protocol 7 was designed to purify intact, functional peroxisomes from the wild-type yeast strain D273-10B after growth in oleate medium (Distel et al., 1996). Strains other than D273-10B can be used; however, it is wise to conduct a pilot experiment and monitor peroxisome induction and isolation steps. Peroxisomal fractions are highly enriched with peroxisomal proteins, such as catalase A, thiolase, and acyl-CoA oxidase. Contamination of the peroxisomal fraction with proteins from mitochondria, vacuoles, ER, and plasma membrane is low. Only a fraction of the initial peroxisome population is recovered after the sucrose density gradient steps. A substantial proportion of the peroxisomes are unavoidably lost in the low-speed pellet. A 1-liter culture of oleate-grown D273-10B cells typically yields 5 to 15 mg of peroxisomal protein. By electron microscopy, a homogenous population of single-membrane bound organelles should be visible. The isolated peroxisomes are functional for in vitro protein-import studies. If the peroxisomes will be used for functional studies, a recovery incubation after spheroplast preparation may be needed for optimal activity.

Isolation of endoplasmic reticulum

Basic Protocol 8 was designed to isolate endoplasmic reticulum (ER) membranes from yeast spheroplasts (Wuestehube and Schekman, 1992). These membranes are functional in in vitro protein import and transport studies. The gradients are similar to those used in Basic Protocol 3. The ER membranes distribute in a membrane layer within the 1.2 M sucrose solution and at the 1.2 M/1.5 M sucrose interface. Both of these fractions have significant amounts of plasma membrane vesicles. Since the membrane band in the 1.2 M sucrose solution also contains vacuolar membranes and Golgi membranes, only the ER vesicles at the 1.2 M/1.5 M sucrose interface are harvested. Typically, this protocol yields ~7 mg of protein per 5000 OD_{600} units of cells.

Isolation of plasma membranes

Basic Protocol 9 isolates plasma membranes from yeast cells that are rapidly disrupted by vortexing with glass beads (Panaretou and Piper, 1996). Glass bead lysis protocols typically lyse 50% to 80% of the cells. The isolated plasma membrane preparation consists of vesicles in both the right-side-out and inside-out orientations. Vacuolar markers are usually not detected, while low levels of mitochondrial, ER, and Golgi markers are found. The plasma membrane vesicles isolated from disrupted whole cells tend to have lower levels of ER contamination than plasma membrane vesicles prepared from spheroplasts. Plasma membranes obtained from ruptured spheroplasts tend to have a lower density, presumably due to degradation of surface glycoproteins. The most prominent plasma membrane protein is the 100-kDa PM-ATPase. This Mg^{2+}-dependent ATPase activity is inhibited by orthovanadate, while the ATPase activities of mitochondria and vacuoles are inhibited by KNO_3 and bafilomycin A1, respectively. The activity of the plasma membrane ATPase can be sensitive to gradient medium, so protein analy-

sis is recommended in addition to enzymatic analysis.

Preparation of cytosol

Basic Protocol 10 is a simple and efficient method to prepare cytosol from yeast cell lysates prepared by glass bead lysis (Haas, 1995). Glass bead lysis protocols typically lyse 50% to 80% of the cells. The resulting cytosol is enriched 10- to 15-fold over the crude lysate in cytosolic proteins. ~2000 OD_{600} units of cells yield 25 to 60 mg of cytosolic protein at a concentration of 10 to 30 mg/ml.

Cytosol prepared by this technique supports in vitro vacuole-vacuole fusion and is likely to be functional in other in vitro assays. The cytosol should be tested and titrated for functional activity every time a fresh batch is prepared. Typically, cytosol prepared from cultures in their early- to mid-logarithmic growth phase has a higher specific activity than that prepared from cultures at later growth stages. Small molecules (e.g., ions, ATP) can be removed by passing the cytosol over a G25-Sephadex column.

Time Considerations

For best results, desired yeast strains should be obtained from glycerol stocks (stored at −80°C) and streaked onto fresh plates 2 to 3 days prior to starting the first cultures. Precultures should be started with a single colony from fresh plates 1 to 3 days before the fractionation experiment. Extensive preculturing (i.e., 2 to 3 days) is especially important prior to the induction of peroxisomes (see Basic Protocol 7). A full day should be allowed for each fractionation experiment, especially when doing the experiment for the first time. Some of the experiments will require several more hours on the following day to harvest fractions from gradients subjected to centrifugation overnight (see Basic Protocol 2, Alternate Protocol, and Basic Protocol 9).

It is wise to prepare well for fractionation experiments, since it is critical to work as quickly as possible once the cells have been lysed. Prepare all the solutions ahead of time (unless otherwise indicated) and store at the appropriate temperature. Reserve the necessary equipment and prechill if required. Prelabel tubes to the extent that it is possible. Minimize the number of strains used, especially when doing the experiment for the first time. It is often helpful to do small pilot experiments to determine the optimal experimental conditions for a given strain and growth regimen.

Isolation of Golgi Membranes from Tissues and Cells by Differential and Density Gradient Centrifugation

Golgi membranes from actively secreting tissues form a major defined organelle and are relatively easy to isolate so long as the method of tissue disruption is as mild as possible, such that fragmentation of the Golgi stacks is minimized. As a general rule, if the Golgi membranes retain their in vivo tubular structure, they will sediment when centrifuged at 10,000 to 15,000 × *g* for 10 to 20 min. They can thus be purified from a light mitochondrial fraction by flotation through a discontinuous sucrose gradient (see Basic Protocol 2). Alternate Protocol 1 adapts this method to a self-generated iodixanol gradient. This may be of particular use for multiple samples because of the simplicity of gradient preparation. In mammalian liver, not only can the homogenization conditions be tailored to the retention of Golgi tubules, but, by inclusion of dextran in the homogenization medium, the entire Golgi stack may be retained so that it sediments at a relative centrifugal force (RCF) as low as 5000 × *g* (see Basic Protocol 1). This not only promotes a high recovery of Golgi membranes but also reduces possible contamination by other membrane particles. Isolation of Golgi membranes is facilitated by their having a distinctively low density, lower than any other membrane except possibly the *trans*-Golgi network and some plasma membranes. Thus, even if the Golgi membranes are present in a homogenate in a vesicular form (e.g., those from cultured cells), they can be isolated either in a discontinuous sucrose density gradient (see Basic Protocol 3), a continuous iodixanol gradient (see Alternate Protocol 2), or a self-generated iodixanol gradient (see Basic Protocol 4). Again the latter may be of particular use for multiple samples.

The aim of the protocols described in this unit is to isolate the Golgi in a preparative manner; the unit does not specifically address the requirements for an analytical investigation of the secretory process, which requires the simultaneous fractionation of a series of membrane compartments through a continuous gradient. Strategies for these studies (including the partial resolution of the *cis*-, medial, and *trans*-Golgi domains; *trans*-Golgi network; and various vesicular intermediates) will be given in a future unit. It is worth noting, however, that the protocols for the isolation of Golgi vesicles (particularly Basic Protocol 4 and Alternate Protocol 2) also permit the simultaneous isolation of other vesicular fractions and can therefore also be used in an analytical mode.

This unit also includes a routine method (see Support Protocol) for the assay of the UDP-galactose galactosyltransferase, which, although strictly a *trans*-Golgi enzyme, is the most commonly used marker in any preparative Golgi method.

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) and must conform to governmental regulations for the care and use of laboratory animals.

RAPID ISOLATION OF GOLGI MEMBRANES FROM RAT LIVER USING A SUCROSE DENSITY BARRIER

BASIC PROTOCOL 1

The use of dextran in the homogenization medium and a mechanical shear means of homogenization, as opposed to liquid shear, favors the retention of intact Golgi stacks. This permits the recovery of the Golgi membranes in a relatively low-speed pellet (5000 × *g* for 15 min). In the bipartite pellet that is formed, the Golgi forms a quite distinct upper layer, which can be resuspended independently of the much more well-packed material

Current Protocols in Cell Biology (2001) 3.9.1-3.9.24

(containing nuclei, some plasma membrane sheets, and mitochondria) in the lower layer (Morré et al., 1972). Purification of the Golgi is then achieved using a simple sedimentation on a 1.2 M sucrose density barrier. Because dextran effectively cross-links the Golgi tubules, these membranes cannot be further subfractionated into the *cis*-, medial, and *trans*-Golgi domains unless they are unstacked by hydrolyzing the dextran with a mixture of amylases. The unstacking procedure of Hartel-Schenk et al. (1991) is presented below as an option.

If the presence of dextran is undesirable, then one of the alternative methods described in Basic Protocol 2 and Alternate Protocol 1 should be used. The following protocol is adapted from Morré et al. (1972).

NOTE: All solutions, glassware, centrifuge tubes, and equipment should be precooled to 0° to 4°C and kept on ice throughout. Centrifuge rotors should be precooled to the same temperature.

Materials

150- to 200-g Sprague-Dawley rat
DHM (see recipe)
1.2 M sucrose density barrier (see recipe)
HM (see recipe), optional
Crude α-amylase Type X-A from *Aspergillus oryzae* (Sigma Aldrich Co.), optional
α-Amylase Type VIII-A from barley (Sigma Aldrich Co.), optional

Dissecting tools, including scissors, razor blade, and forceps
Polytron homogenizer (Brinkmann Instruments)
Phase-contrast microscope
High-speed centrifuge with swinging-bucket rotor and 30- to 50-ml clear plastic tubes
10-ml syringes with long metal cannulas (i.d. ~1 mm) or Pasteur pipet attached to an aspirator
Glass rod
Ultracentrifuge with swinging-bucket rotor (Beckman SW 28.1, Sorvall AH629, or equivalent) and 17-ml tubes

Additional reagents and equipment for determining protein concentration (*APPENDIX 3B*)

NOTE: Protease inhibitors (*UNIT 3.4*) can be added to any or all solutions.

Isolate and mince liver

1. Starve a 150- to 200-g Sprague-Dawley rat overnight.
2. Sacrifice the animal by cervical dislocation or decapitation.

   This must be supervised or carried out by an experienced animal technician.

3. Open the abdominal cavity and remove liver to a chilled beaker containing ~20 ml DHM. Record weight of the liver.

   This protocol is suitable for a 10- to 12-g liver.

4. Decant medium and finely mince liver using scissors or a razor blade.

   The pieces of liver should be no more than ~25 mm^3.

Isolate intact stacked Golgi

5. Suspend liver mince in ~20 ml DHM.

6. Set suspension on ice and homogenize with a Polytron homogenizer set at 10,000 rpm (setting 1) for 40 sec, using 10-sec pulses and 10-sec rests. Check for completeness of tissue disruption by phase-contrast microscopy.
7. Centrifuge 15 min in a high-speed centrifuge at 5000 × *g*, 4°C.

   The brake should not be used to decelerate the rotor; rapid changes in rpm may disturb the layering of the pellet.
8. Very carefully remove most of the supernatant using a 10-ml syringe with a long metal cannula or a Pasteur pipet attached to an aspirator. Leave 0.5 to 1.0 ml supernatant.

   The supernatant should not be decanted.

   The Golgi membranes are contained in the upper (yellow-brown) portion of the bipartite pellet.
9. Resuspend upper portion of pellet in the residual supernatant by very gentle stirring with a glass rod.

   Resuspension of the lower part of the pellet, which contains nuclei and whole cells, must be avoided.
10. Transfer resuspended Golgi material to a 10-ml measuring cylinder using the syringe and cannula.
11. Adjust concentration of the suspension with DHM to 6 ml per 10 g liver and layer over 2 vol of 1.2 M sucrose density barrier in a 17-ml tube.
12. Centrifuge 30 min in an ultracentrifuge at 120,000 × *g*, 4°C.
13. Remove Golgi membranes, which collect at the interface, with a fresh syringe and cannula.
14. If required, dilute fraction with ≥2 vol DHM (or HM) and centrifuge 20 min at 10,000 × *g*, 4°C.
15. Determine protein concentration (*APPENDIX 3B*) and resuspend pellet in DHM (or HM) to 1 to 5 mg protein/ml.

    Metabolic assays should be carried out as soon as possible upon preparation; some marker enzyme assays can be carried out after storage at 4°C for ≤16 hr. Many assays can be carried out on material frozen to –20° or –80°C. Measurements that are made with frozen material should be compared with those made on fresh material to confirm that they are relatively unaffected by storage conditions.

Unstack Golgi (optional)

If a subsequent aim is to attempt to resolve various domains of the Golgi membranes, it is necessary to hydrolyze the dextran in order to unstack the Golgi. The following is adapted from Hartel-Schenk et al. (1991).

16. Incubate 4 to 5 ml Golgi membrane suspension with 3 mg each of crude α-amylase Type X-A from *Aspergillus oryzae* and α-amylase Type III-A from barley at 4°C for 45 min.
17. Use gentle liquid shear to complete the destacking process by repeatedly (5 to 6 times) drawing suspension into and expelling it from a Pasteur pipet (1-mm tip i.d.) or a 10-ml syringe with a long metal cannula.

    The success of the destacking process can only be monitored by electron microscopy or by comparing the banding pattern of cis-, medial, and trans-Golgi markers in a suitable density gradient or in some other separative technique before and after treatment.

BASIC PROTOCOL 2

ISOLATION OF GOLGI MEMBRANES FROM A RAT LIVER LIGHT MITOCHONDRIAL FRACTION BY FLOTATION THROUGH A DISCONTINUOUS SUCROSE GRADIENT

If the use of dextran to maintain the stacked format of the Golgi apparatus, as described in Basic Protocol 1, is unacceptable, then a light mitochondrial fraction from a liver homogenate can be used to overcome several of the problems associated with the fragmentation of the Golgi. The relatively gentle homogenization technique used in this protocol is aimed at retaining the tubular structure of the Golgi membranes and avoiding excessive fragmentation. In this manner, at least some of the Golgi membranes will sediment at ~15,000 × *g*, thus facilitating the separation procedure. Purification of Golgi vesicles from vesicles produced from other smooth membrane compartments of the cell (plasma membrane, *trans*-Golgi network, smooth endoplasmic reticulum, and some endocytic structures) may be more problematic. In a microsomal fraction the Golgi vesicles will be both denser and lighter than some of the other vesicle populations. By processing the light mitochondrial fraction rather than a microsomal fraction (or some other microsome-containing fraction) these problems are minimized, as the Golgi is the least dense component of this fraction. This method works very satisfactorily for rat liver but its applicability to other tissues (and to cultured cells) will depend on the behavior of the Golgi membranes during homogenization and differential centrifugation. For the method to be suitable for a particular tissue or cell type, a significant amount of a Golgi marker (e.g., galactosyltransferase) should be recovered in the light mitochondrial fraction rather than the microsomes. The method is adapted from Fleischer and Fleischer (1970) and Graham and Winterbourne (1988).

NOTE: All solutions, glassware, centrifuge tubes, and equipment should be precooled to 0° to 4°C and kept on ice throughout. Centrifuge rotors should be precooled to the same temperature.

Materials

150- to 200-g Sprague-Dawley rat
HM (see recipe)
2.0, 1.33, 1.2, 1.1, 0.77, and 0.25 M sucrose gradient solutions (see recipe)

Dissecting tools, including scissors or razor blade
Potter-Elvehjem homogenizer, ~0.09-mm clearance, 40-ml working volume (Fisher Scientific), with chilled pestle
Overhead high-torque electric motor, thyristor controlled (Fisher Scientific)
Low-speed centrifuge with swinging-bucket rotor and 50-ml tubes
~5- and ~30-ml Dounce homogenizers (Wheaton) with loose-fitting type-B conical pestles
High-speed centrifuge with 8 × 50–ml fixed-angle rotor (e.g., Sorvall SS34)
10-ml syringe and metal cannula
Refractometer
Ultracentrifuge with swinging-bucket rotor (Beckman SW 28.1, Sorvall AH629, or equivalent) and 17-ml tubes

Additional reagents and equipment for determining protein concentration (*APPENDIX 3B*)

NOTE: Protease inhibitors (*UNIT 3.4*) can be added to any or all solutions.

Isolate and mince liver

1. Starve a 150- to 200-g Sprague-Dawley rat overnight.
2. Sacrifice the animal by cervical dislocation or decapitation.

   This must be supervised or carried out by an experienced animal technician.

3. Open the abdominal cavity and remove liver to a chilled beaker containing ~20 ml HM.

   This protocol is suitable for a 10- to 12-g liver.

4. Decant medium and finely mince liver using scissors or a razor blade.

   The pieces of liver should be no more than ~25 mm^3.

Homogenize liver

5. Suspend mince in ~40 ml HM and transfer half of this suspension to the glass vessel of a Potter-Elvehjem homogenizer.
6. Attach the cold homogenizer pestle to an overhead high-torque electric motor and homogenize liver mince using four to five up-and-down strokes of the pestle, rotating at ~500 rpm.

   The motor should be mounted either to a wall via a G clamp, to the bench, or in a floor-standing cradle. Attachment to a free-standing retort stand is not adequate.

7. Decant homogenate into a beaker on ice and rinse homogenizer with HM, wiping pestle to remove any connective tissue that may be adhering.
8. Repeat the procedure with the other half of the mince.

Prepare light mitochondrial fraction

9. Transfer homogenate to a 50-ml conical tube and centrifuge 10 min at $1000 \times g$, 4°C, in a low-speed centrifuge to pellet nuclei.
10. Decant supernatant and place on ice.
11. Transfer nuclear pellet to an ~30-ml Dounce homogenizer in ~20 ml HM. Use four gentle strokes of the loose-fitting pestle to resuspend pellet.
12. Transfer suspension to a clean 50-ml tube and recentrifuge 10 min at $1000 \times g$, 4°C.
13. Combine supernatants from steps 10 and 12, and centrifuge 10 min at $3000 \times g$, 4°C, to pellet the heavy mitochondria.
14. Transfer supernatant to a clean 50 ml tube and centrifuge 20 min at $17{,}000 \times g$, 4°C, in a high-speed centrifuge.
15. Aspirate supernatant using a 10-ml syringe and metal cannula, and discard.

Isolate Golgi membranes

16. Resuspend light mitochondrial pellet in 1 to 2 ml HM by vortex mixing, then add 8 ml of 2.0 M sucrose gradient solution (final concentration ~1.55 M). Transfer to an ~5-ml Dounce homogenizer and homogenize using gentle strokes of the loose-fitting pestle.
17. Use a refractometer to check that the refractive index is 1.4080 and adjust, if necessary, with either HM or 2.0 M sucrose.

    If a refractometer is not available, check that the suspension will layer beneath the 1.33 M sucrose solution.

18. Transfer 5 ml light mitochondrial suspension to a 17-ml tube and overlay it with the following sucrose gradient solutions:

    4.0 ml 1.33 M sucrose
    2 ml 1.2 M sucrose
    2 ml 1.1 M sucrose
    2 ml 0.77 M sucrose
    0.25 M sucrose to fill the tube

19. Centrifuge 1 hr in an ultracentrifuge at 100,000 × *g*, 4°C.

Harvest light Golgi membranes

20. Harvest material that bands at the 0.77 M/1.1 M and 1.1 M/1.2 M sucrose interfaces and any intervening material.

21. If required, dilute fraction with ≥2 vol HM and centrifuge 20 min at 10,000 × *g*, 4°C.

22. Determine protein concentration (*APPENDIX 3B*) and resuspend pellet in HM to 1 to 5 mg protein/ml.

    Metabolic assays should be carried out as soon as possible upon preparation; some marker enzyme assays can be carried out after storage at 4°C for ≤16 hr. Many assays can be carried out on material frozen to −20°C or −80°C. Measurements that are made with frozen material should be compared with those made on fresh material to confirm that they are relatively unaffected by storage conditions.

ALTERNATE PROTOCOL 1

ISOLATION OF GOLGI MEMBRANES FROM A RAT LIVER LIGHT MITOCHONDRIAL FRACTION IN A SELF-GENERATED GRADIENT OF IODIXANOL

In this variation, the light mitochondrial fraction from mammalian liver is suspended in a medium containing 15% iodixanol and centrifuged in a vertical, near-vertical, or low-angle fixed-angle rotor at >180,000 × *g* for 1 to 3 hr. The centrifugation conditions are chosen to produce a slightly sigmoidal density profile; the relatively shallow gradient in the middle of the tube is used to provide a large linear separation between the Golgi membranes (low density) and the other organelles (high density). The precise gravitational forces and times will depend on the rotor type. In high-performance vertical rotors, which can produce ~350,000 × *g*, the separation will take only 1 hr. The method is adapted from Graham et al. (1994). It should be applicable to other tissues and cells, although the iodixanol concentration (step 3) may need to be modulated.

NOTE: All solutions, glassware, centrifuge tubes, and equipment should be precooled to 0° to 4°C and kept on ice throughout. Centrifuge rotors should be precooled to the same temperature.

Additional Materials *(also see Basic Protocol 2)*

HME (see recipe), optional
OptiPrep
ODB solution (see recipe)
IWS solution (see recipe)
High-density cushion (20%, w/v, iodixanol): 2:3 (v/v) IWS/HME (or HM)
Ultracentrifuge with vertical (e.g., Beckman VTi 65.1, Sorvall 65V13), near-vertical (e.g., Beckman NVT 65) rotor and ~11-ml sealable ultracentrifuge tubes or low-angle fixed-angle rotor (~20°; e.g., Beckman 50.3Ti) and ~5-ml sealable ultracentrifuge tubes.

NOTE: Protease inhibitors (*UNIT 3.4*) can be added to any or all solutions.

1. Isolate a rat liver, homogenize, and prepare a light mitochondrial fraction as described (see Basic Protocol 2, steps 1 to 15) in either HM or HME.

   The sample can be prepared in the presence (HME) or absence (HM) of EDTA (see Background Information, discussion of homogenization).

2. Resuspend light mitochondrial pellet in HME or HM to a total volume of 14 ml.

3. Add 6 ml IWS to the suspension (15% w/v iodixanol final).

   EDTA may be omitted from the OptiPrep dilution buffer (ODB) used to make IWS.

4. Transfer 9.5 ml to an ~11-ml sealable ultracentrifuge tube or a 4.5- to 5.0-ml sealable tube.

5. Underlayer suspension with 0.5 ml high-density cushion; omit cushion with fixed-angle rotor.

   The cushion prevents the densest organelles (peroxisomes) from pelleting against the wall of the tube and making unloading difficult. This is particularly important if a vertical rotor is used.

6. Fill the tube by layering HME or HM on top, seal the tube, and centrifuge 1 to 3 hr in an ultracentrifuge at 180,000 to 350,000 × *g*, 4°C.

   The precise centrifugation conditions depend on the rotor type and tube sedimentation path length. In a vertical rotor such as the VTi 65.1, 1 hr at 350,000 × g will be sufficient, while at 180,000 × g, 3 hr will be needed. Longer path-length rotors may need 3 hr at 350,000 × g. Fixed-angle rotors with these tube volumes are not ideal for rapid formation of self-generated gradients because of their relatively long sedimentation path lengths. Many Beckman rotors that are capable of high speeds (e.g., 80 Ti and 90 Ti) can, however, be adapted to accommodate smaller-volume g-Max tubes that have suitable path lengths. Ford et al. (1994) and the Axis-Shield Density Gradient Media Catalog (Axis-Shield, 2000) provide more information on the preparation of self-generated iodixanol gradients.

7. During deceleration below 2000 rpm, either use a programmed deceleration or turn off the brake.

8. Harvest the Golgi membranes, which band near the top of the gradient.

ISOLATION OF GOLGI MEMBRANES FROM CULTURED CELLS BY FLOTATION THROUGH A DISCONTINUOUS SUCROSE GRADIENT

BASIC PROTOCOL 3

This protocol, devised by Balch et al. (1984), is applicable to any cell homogenate (primarily from cultured cells) in an isoosmotic sucrose medium. The whole homogenate is adjusted to 1.4 M sucrose and layered under a discontinuous sucrose density gradient of 1.2 M and 0.8 M sucrose. During centrifugation, the Golgi membranes, which have a much lower density than those of the other membrane particles (with the exception of the *trans*-Golgi network and possibly the plasma membrane), float upwards to band at the 1.2 M/0.8 M sucrose interface. By including a layer of 1.6 M sucrose beneath the homogenate it is also possible to resolve (at least partially) some of the endoplasmic reticulum (ER) from the other denser organelles (mitochondria, lysosomes, peroxisomes, and nuclei), which will sediment into or through this layer (the smooth ER in particular will remain in the load zone). The advantage of this procedure is not only the speed of preparation but the elimination of differential centrifugation; resuspending the pellets also minimizes any comminution of the subcellular organelles. A similar discontinuous sucrose gradient consisting of 8.4% (0.25 M), 32.5% (0.95 M), and 45.2% (1.33 M) sucrose, with the sample (an 11,000 × *g* supernatant) loaded beneath the gradient in ~51% (1.5 M) sucrose, was devised by Macintyre (1992). In Alternate Protocol 2, the use of a continuous iodixanol gradient is described.

The homogenization procedure should be as gentle as possible (in a medium containing 0.25 M sucrose) to avoid excessive fragmentation of internal organelles. A ball-bearing device ("cell cracker") of the type designed by Balch and Rothman (1985) is recommended; it certainly causes the least amount of damage to organelles. A tight-fitting Dounce homogenizer is a possible alternative. The method may also be used for a tissue such as rat liver, but volumes will need to be scaled up (see annotations). The following protocol is adapted from Balch et al. (1984).

NOTE: All solutions, glassware, centrifuge tubes, and equipment should be precooled to 0° to 4°C and kept on ice throughout. Centrifuge rotors should be precooled to the same temperature.

Materials

Cultured cells
HM (see recipe)
0.8, 1.2, 1.6, and 2.0 M sucrose gradient solutions (see recipe)

Ball-bearing homogenizer
5-ml syringe and metal cannula
Ultracentrifuge with swinging-bucket rotor (Beckman SW 28.1, Sorvall AH629, or equivalent) and ~17-ml tubes, 4°C

Additional reagents and equipment for determining protein concentration (*APPENDIX 3B*)

NOTE: Protease inhibitors (*UNIT 3.4*) can be added to any or all solutions.

1. Wash 1–3 × 10^8 cultured cells twice in 5 ml HM, resuspend in 3 ml HM, and homogenize in a ball-bearing homogenizer using five passes.

   Alternatively use ten to fifteen strokes of a tight-fitting pestle (0.025- to 0.075-mm clearance) in a Dounce homogenizer.

   For a tissue such as rat liver, the liver mince (see Basic Protocol 1, steps 1 to 4) should be suspended in 20 ml HM and homogenized using ten strokes of a loose-fitting pestle in a Dounce homogenizer.

2. Make the homogenate 1.4 M with respect to sucrose by adding 2 vol of 2.0 M sucrose gradient solution.

3. Transfer 6 ml to an ~17-ml tube.

   Use ~2.2× this volume (here and in step 4) for rat liver. A larger-volume rotor will also be required (~38-ml tubes).

4. Overlay sample with 6 ml of 1.2 M sucrose gradient solution and 3 ml of 0.8 M sucrose gradient solution.

5. Use a 5-ml syringe and metal cannula to underlay sample with 2 ml of 1.6 M sucrose gradient solution.

6. Centrifuge 2 hr in an ultracentrifuge at 110,000 × *g*, 4°C.

7. Harvest the Golgi band from the 0.8 M/1.2 M sucrose interface.

   If required, harvest the ER, which bands within the 1.4 M sucrose layer.

8. If required, dilute fraction(s) with ≥2 vol HM and centrifuge 30 min at 100,000 × *g*, 4°C.

9. Determine protein concentration (*APPENDIX 3B*) and resuspend pellet in HM to 1 to 5 mg protein/ml.

   Metabolic assays should be carried out as soon as possible upon preparation; some marker enzyme assays can be carried out after storage at 4°C for ≤16 hr. Many assays can be carried out on material frozen to −20°C or −80°C. Measurements that are made with frozen material should be compared with those made on fresh material to confirm that they are relatively unaffected by storage conditions.

ISOLATION OF GOLGI MEMBRANES FROM CULTURED CELLS IN A CONTINUOUS GRADIENT OF IODIXANOL

ALTERNATE PROTOCOL 2

Yang et al. (1997) devised a continuous iodixanol (0% to 26%, w/v) gradient to study the localization of UBC6 ubiquitin-containing protein in COS-7 cells, and Zhang et al. (1998) used a similar gradient (1% to 20%, w/v) to study the localization of presenilins to the ER or Golgi membranes of CHO cells. Sufficient resolution of the Golgi was obtained that these methods could be used to prepare Golgi on a preparative basis. The following protocol is based on these two published methods and may be used in one of three sample-handling modes: (1) layering a postnuclear fraction (or postmitochondrial supernatant) on top, (2) layering a microsomal fraction on top, or (3) layering any fraction (including a homogenate) at the bottom (see annotations to this protocol). The method also allows simultaneous purification of the ER and plasma membrane. See Commentary for more information on the relative advantages and disadvantages of the three types of sample handling.

NOTE: All solutions, glassware, centrifuge tubes, and equipment should be precooled to 0° to 4°C and kept on ice throughout. Centrifuge rotors should be precooled to the same temperature.

Additional Materials *(also see Basic Protocol 3)*

Cellular homogenate (see Basic Protocol 3, step 1)
25% (w/v) iodixanol: 1:1 (v/v) IWS solution (see recipe) and HM (see recipe)

Low-speed centrifuge with swinging-bucket rotor and 10- to 15-ml tubes, all at 4°C
Ultracentrifuge with fixed-angle rotor and 5- to 10-ml tubes (optional), all at 4°C
5- to 10-ml Dounce homogenizer (Wheaton) with loose-fitting type-B pestle (optional)
Two-chamber gradient maker or Gradient Master (e.g., BioComp Instruments)
Gradient unloader (upward displacement; Axis-Shield)
Refractometer

Additional reagents and equipment for determining protein concentration (*APPENDIX 3B*)

NOTE: Protease inhibitors (*UNIT 3.4*) can be added to any or all solutions.

1. Transfer a cellular homogenate to a 10- to 15-ml centrifuge tube and centrifuge 10 min at 2000 × *g*, 4°C, in a low-speed centrifuge. Save supernatant.

   This step should be omitted if the whole homogenate is to be layered under the gradient.

2. *Optional:* Transfer supernatant to a 5- to 10-ml tube and centrifuge 40 min at 100,000 × *g*, 4°C, in the fixed-angle rotor of an ultracentrifuge. Resuspend microsomal pellet in 4 to 8 ml HM using a 5- to 10-ml Dounce homogenizer with a loose-fitting pestle.

   This step should be omitted if either the homogenate or the 2000 × g supernatant is used as gradient input.

3. Prepare a 14-ml continuous gradient from 7 ml each HM and 25% iodixanol solution in a 17-ml tube for a swinging-bucket rotor using a two-chamber gradient maker or Gradient Master.

4. Layer 3 ml of 2000 × *g* supernatant (step 1) or resuspended microsomes (step 2) on top of the gradient and centrifuge 2 to 3 hr at 200,000 × *g*, 4°C.

   Alternatively, the homogenate (or any of the other fractions) can be adjusted to 30% (w/v) iodixanol with IWS solution and layered beneath the gradient.

5. Collect gradient in 0.75-ml fractions using a gradient unloader. Check the density of the fractions with a refractometer.

   The Golgi bands between 1.040 and 1.065 g/ml. With practice it is possible to use a syringe or Pasteur pipet to remove the Golgi-containing gradient zone (see Commentary for more details).

6. If required, dilute Golgi fractions with ≥2 vol HM and centrifuge 30 min at 100,000 × *g*, 4°C.

7. Determine protein concentration (*APPENDIX 3B*) and resuspend pellet in HM to 1 to 5 mg protein/ml.

   Metabolic assays should be carried out as soon as possible upon preparation; some marker enzyme assays can be carried out after storage at 4°C for ≤16 hr. Many assays can be carried out on material frozen to −20°C or −80°C. Measurements that are made with frozen material should be compared with those made on fresh material to confirm that they are relatively unaffected by storage conditions.

BASIC PROTOCOL 4

ISOLATION OF GOLGI MEMBRANES FROM A MICROSOMAL FRACTION OF HEPATOCYTES IN A SELF-GENERATED GRADIENT OF IODIXANOL

Cartwright et al. (1997) developed a rapid method for the fractionation and subfractionation of the smooth and rough endoplasmic reticulum (SER and RER) from a microsomal fraction of rabbit hepatocytes. The method used a self-generated gradient of iodixanol (starting concentration 20%, w/v) at ~350,000 × *g* for 2 hr in a vertical rotor and was used to study the synthesis of very low density lipoproteins (VLDL) from radiolabeled precursors. Later, Plonné et al. (1999) adapted this method to the simultaneous isolation of Golgi, SER, and RER membranes from both isolated hepatocytes and intact liver. Although it is possible to make the gradient more shallow in the low-density region by increasing the centrifugation time to 3 hr and thus improve the resolution of the Golgi membranes from other intracellular particles, Plonné et al. (1999) preferred an alternative method of generating the gradient from equal volumes of 15% and 20% (w/v) iodixanol without increasing the centrifugation time. Although both layers can contain the microsomal fraction, if it is restricted to the denser 20% iodixanol layer, any residual contaminating soluble proteins remain in this layer and the Golgi membranes float into the soluble-protein-free lower-density region. The following protocol is adapted from Plonné et al. (1999) and uses collagenase-prepared rat hepatocytes as the source material. Some comments regarding the use of rat liver are given in the annotations.

NOTE: With the exception of the Dulbecco's modified Eagle medium with BSA (DMEM/BSA), all solutions, glassware, centrifuge tubes, and equipment should be precooled to 0° to 4°C and kept on ice throughout. Centrifuge rotors should be precooled to the same temperature.

Materials

95% O_2/5% CO_2 gas mixture
DMEM/BSA: Dulbecco's modified Eagle medium (*APPENDIX 2A*) with 1.0% (w/v) BSA
Collagenase-prepared rat hepatocytes (Plonné et al., 1999)
PBS (*APPENDIX 2A*), 4°C
10 mM HEPES-NaOH buffer, pH 7.8
HB (see recipe)
SB (see recipe)
OptiPrep (Axis-Shield, Life Technologies, Accurate Chemicals)
30% (w/v) iodixanol: 1:1 (v/v) OptiPrep/SB
15% (w/v) iodixanol: 1:3 (v/v) OptiPrep/SB

Low-speed centrifuge with swinging-bucket rotor and 50-ml conical tubes, all at 4°C
~10-ml Dounce homogenizer (Wheaton) with tight-fitting type-A pestle
High-speed centrifuge with fixed-angle rotor and ~15-ml tubes (e.g., Sorvall SE12), 4°C
Ultracentrifuge with the following, all at 4°C:
Fixed-angle rotor (e.g., Beckman 50Ti, SorvallT865.1) and ~10-ml tubes
Vertical rotor (e.g., Beckman VTi 65.1, Sorvall 65V13), near-vertical rotor (e.g., Beckman NVT 65), with ~11-ml sealable tubes or a low-angle fixed-angle rotor (~20°; e.g., Beckman 50.3Ti) and ~5-ml sealable ultrcentrifuge tubes.
~10-ml Dounce homogenizer (Wheaton) with loose-fitting type-B pestle
Gradient unloader (upward displacement; e.g., Axis-Shield)

Additional reagents and equipment for determining protein concentration (*APPENDIX 3B*)

NOTE: Protease inhibitors (*UNIT 3.4*) can be added to any or all solutions.

Homogenize hepatocytes

1. Bubble a 95% O_2/5% CO_2 gas mixture through DMEM/BSA for 20 min, and then suspend collagenase-prepared rat hepatocytes in this medium at $0.5–1 \times 10^7$ cells/ml.
2. Incubate ≥30 min at 37°C in a shaking incubator with continuous gassing.
3. Transfer cells to a preweighed 50-ml conical tube and centrifuge 2 min in a low-speed centrifuge at 800 × *g*, 4°C, to pellet cells. Discard supernatant and record weight of cell pellet.
4. Wash cell pellet twice in ~20 ml PBS at 4°C.
5. Remove all PBS after last wash and resuspend cells in 10 mM HEPES buffer (5 ml/g cells).
6. Allow cells to swell at 4°C for ~10 min and then centrifuge 2 min at 800 × *g*, 4°C, to pellet cells.
7. Remove and discard 70% of buffer and then add a volume of HB equal to residual supernatant.
8. Resuspend cells and homogenize using 30 strokes of a tight-fitting pestle in an ~10-ml Dounce homogenizer.

For intact liver, isolate and homogenize as described (see Basic Protocol 2, steps 1 to 8) using SB as the homogenization medium.

Isolate microsomal fraction

9. Transfer homogenate to a 15-ml centrifuge tube and add protease inhibitors, if required.
10. Centrifuge homogenate 20 min at 8000 × *g*, 4°C, in a high-speed centrifuge.
11. Transfer supernatant to an ~10-ml tube and centrifuge in the fixed-angle rotor of an ultracentrifuge 40 min at 150,000 × *g*, 4°C, to pellet microsomes.
12. Resuspend microsomes in SB (~2.5 ml/g cells) using the loose-fitting pestle of an ~10-ml Dounce homogenizer.

Purify Golgi

13. Mix 4 vol microsome suspension with 2 vol OptiPrep (20% w/v iodixanol final).
14. Transfer 4.5 ml to an ~11-ml sealable tube for a vertical, near-vertical, or low-angle fixed-angle rotor. Underlayer with 1.8 ml of 30% iodixanol and overlayer with 4.5 ml of 15% iodixanol. Seal tube.

    In fixed-angle rotors the 30% iodixanol may be omitted; fill the tube with equal volumes of the two iodixanol solutions.

    Fixed-angle rotors with these tube volumes are not ideal for rapid formation of self-generated gradients because of their relatively long sedimentation path lengths. Many Beckman rotors that are capable of high speeds (e.g., 80 Ti and 90 Ti) can, however, be adapted to accommodate smaller-volume g-Max tubes that have suitable path lengths. Ford et al. (1994) and Axis-Shield Density Gradient Media Catalog (Axis-Shield, 2000) provide more information on the preparation of self-generated iodixanol gradients.

15. Centrifuge 2 hr at 350,000 × *g*, 4°C.
16. Use a gradient unloader to unload into 1-ml sample tubes by upward displacement in ~0.5-ml fractions.

    The Golgi bands in the top 7 ml of the gradient, smooth ER in the median 8 to 14 ml, and rough ER in the bottom third.

17. If required, dilute Golgi fractions with ≥2 vol SB and centrifuge 30 min at 100,000 × *g*, 4°C.
18. Determine protein concentration (*APPENDIX 3B*) and resuspend pellet SB to 1 to 5 mg protein/ml.

    Metabolic assays should be carried out as soon as possible upon preparation; some marker enzyme assays can be carried out after storage at 4°C for ≤16 hr. Many assays can be carried out on material frozen to −20°C or −80°C. Measurements that are made with frozen material should be compared with those made on fresh material to confirm that they are relatively unaffected by storage conditions.

SUPPORT PROTOCOL

ASSAY FOR UDP-GALACTOSE GALACTOSYLTRANSFERASE

The domains of the Golgi (*cis*, medial, and *trans*) are involved in the post-translational modification of oligosaccharide residues of glycoproteins and proteoglycans. As such, any of the enzymes that characterize these reactions can be used as markers. They all have their active sites directed towards the cisternal space of the Golgi, and if a glycoprotein is used as an acceptor molecule in the assay, it is normal practice to include a mild detergent in the medium to allow access of the acceptor to the enzyme. The most commonly used marker is UDP-galactose galactosyltransferase, which is really a marker for the *trans*-Golgi, but in total Golgi membrane preparations it is used as a general marker for these membranes.

UDP-galactose galactosyltransferase can be measured using as an acceptor a suitable glycoprotein (normally) that has had its terminal *N*-acetylneuraminic acid and galactose residues removed chemically (Kim et al., 1971). To avoid this rather lengthy procedure, two alternative acceptors are more commonly used today: *N*-acetylglucosamine (the terminal sugar residue, which is the acceptor in vivo) or ovalbumin (a commercially available glycoprotein, which can be used as an artificial acceptor without modification). With *N*-acetylglucosamine as acceptor, the radiolabeled product, *N*-acetyllactosamine, is separated from UDP-galactose by passage through a small Dowex ion-exchange resin (Fleischer et al., 1969); this is a simple but very tedious technique with large numbers of samples. The ovalbumin method is easier to carry out and is described below (Beaufay et al., 1974).

CAUTION: When working with radioactivity (UDP-gal), take appropriate precautions to avoid contamination of the experimenter and the surroundings (*APPENDIX 1D*). Carry out the experiment and dispose of wastes in an appropriately designated area, following the guidelines provided by the local radiation safety officer.

Materials

10% (w/v) trichloroacetic acid (TCA)
Acceptor solution (see recipe)
UDP-gal solution (see recipe)

2.4-cm filter paper discs
Polystyrene board
Pins

1. Prepare two 2.4-cm filter paper discs per sample (numbered lightly with a pencil).
2. Use pins to attach discs to a polystyrene board, making sure that the discs do not touch the board.
3. Place 250 ml of 10% TCA in a beaker on ice.
4. In a 0.5-ml tube in an ice/water bath, mix 50 µl acceptor solution with 50 µl sample and add 10 µl UDP-gal solution.
5. At time zero and after a 20-min incubation at 37°C, transfer 50 µl incubation mixture to a filter disc.
6. Plunge disc into the ice-cold 10% TCA.

   If the disc is dropped onto the surface of the TCA, the pencilled number is liable to lift off.
7. Leave for 2 to 3 hr, swirling discs occasionally.
8. Wash discs with several changes of distilled water and leave to dry overnight at room temperature.
9. Count radioactivity in any commercial scintillant for non-aqueous samples.

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Acceptor solution

To 5 ml assay buffer (see recipe) add:
55 mg Na_2ATP (10 mM final)
0.5 g ovalbumin (5% final)
Add assay buffer to 10 ml
Prepare fresh

Assay buffer

To 50 ml H_2O add:
0.19 g $MnCl_2 \cdot 4H_2O$ (10 mM final)
0.23 g 2-mercaptoethanol (30 mM final)
0.2 g Triton X-100 (0.2% v/v final)
1.6 g sodium cacodylate (0.1 M final)
Adjust to pH 6.2 with 1 M HCl
Add H_2O to 100 ml
Store up to 1 month at 4°C

Dextran-containing homogenization medium (DHM)

To 100 ml H_2O add:
34.2 g sucrose (0.5 M final)
2 g dextran (mol. wt. 225,000; 1% final)
1.21 g Tris base (50 mM final)
1.16 g maleic acid (50 mM final)
Adjust pH to 6.4 with 50 mM Tris base or 50 mM maleic acid as required
Add H_2O to 200 ml
Store up to 1 to 2 days at 4°C

Homogenization medium (HM)

To 100 ml H_2O add:
17.1 g sucrose (0.25 M final)
2 ml 1 M Tris·Cl, pH 7.4 (*APPENDIX 2A*; 10 mM final)
Adjust to pH 7.4 with 1 M Tris or 1 M HCl if required
Add H_2O to 200 ml
Store up to 1 to 2 days at 4°C

Homogenization medium with EDTA (HME)

Prepare as for HM (see recipe), but add 2 ml 100 mM Na_2EDTA (*APPENDIX 2A*; 1 mM final) before adjusting pH. Store 1 to 2 days at 4°C.

Hyperosmotic buffer (HB)

To 100 ml H_2O add:
41 g sucrose (0.6 M final)
20 ml 100 mM HEPES (10 mM final)
Adjust to pH 7.8 with NaOH
Add H_2O to 200 ml
Store up to 1 to 2 days at 4°C

Iodixanol working stock (IWS) solution

Dilute 5 vol OptiPrep (Axis-Shield, Life Technologies, Accurate Chemicals) with 1 vol ODB (see recipe) to give a final iodixanol concentration of 50% (w/v). Store up to 1-2 days at 4°C.

OptiPrep dilution buffer (ODB)

To 100 ml H_2O add:
17.1 g sucrose (0.25 M final)
12 ml 100 mM Na_2EDTA (6 mM final)
12 ml 1 M Tris·Cl, pH 7.4 (*APPENDIX 2A;* 60 mM final)
Adjust to pH 7.4 with 1 M Tris or 1 M HCl if required
Add H_2O to 200 ml
Store up to 1 to 2 days at 4°C

Sucrose density barrier, 1.2 M

To 50 ml H_2O add:
41.0 g sucrose (1.2 M final)
0.61 g Tris base (50 mM final)
0.58 g maleic acid (50 mM final)
Adjust pH to 6.4 with 50 mM Tris base or 50 mM maleic acid
Add H_2O to 100 ml
Store up to 1 to 2 days at 4°C

Sucrose gradient solutions

2.0 M solution:
To 45 ml H_2O add:
69 g sucrose (2.0 M final)
1 ml 1 M Tris·Cl, pH 7.4 (*APPENDIX 2A;* 10 mM final)
Adjust to pH 7.4 with 1 M Tris or 1 M HCl if required
Add H_2O to 100 ml
Store up to 1 to 2 days at 4°C

For other concentrations: Dilute as needed with 10 mM Tris·Cl, pH 7.4 (*APPENDIX 2A*). Store up to 1 to 2 days at 4°C.

For 1.33 M sucrose, dilute 1.33:0.67, v/v; for 1.2 M, dilute 1.2:0.8, v/v; for 1.1, dilute 1.1:0.9, v/v; and for 0.77 M, dilute 0.77:1.23, v/v.

Suspension buffer (SB)

To 100 ml H_2O add:
17.1 g sucrose (0.25 M final)
20 ml 100 mM HEPES (10 mM final)
Adjust to pH 7.8 with NaOH
Add H_2O to 200 ml
Store up to 1 to 2 days at 4°C

Uridine-5′-diphospho[6-^{3}H]galactose (UDP-gal) solution

To 5 ml H_2O add:
76 mg uridine 5′-diphosphogalactose, disodium salt (12.5 mM final)
10 µl uridine 5′-diphospho[6-^{3}H]galactose (70 kBq/ml)
Add H_2O to 10 ml
Store up to 1 month at −80°C

COMMENTARY

Background Information

Homogenization

Most published methods describing the isolation of Golgi membranes from mammalian tissues and cells employ a standard buffered sucrose solution as homogenization medium, although there is apparently no rigorous requirement for the presence of some chelating agent such as EDTA. In this respect, the isolation of the Golgi membranes from a light mitochondrial fraction is different from the isolation of other organelles from this fraction (e.g., mitochondria, lysosomes, peroxisomes), where inclusion of EDTA facilitates the recovery of highly purified and functionally competent organelles. Indeed, the inclusion of EDTA in the homogenization medium is actually detrimental to the isolation of Golgi membranes from a microsomal fraction using the self-generated iodixanol gradient described in Basic Protocol 4 (J.A. Higgins, pers. comm.). Moreover, in those methods that use gradient purification, any fraction containing microsomal material (an actual microsomal fraction, a postnuclear or postmitochondrial supernatant, or a homogenate), the presence of EDTA may also destabilize the ribosomes on the rough endoplasmic reticulum (RER), thus causing these membranes to band anomalously. Such an effect would be particularly undesirable if the density gradient was being used for the simul-

taneous purification of one or more components of the ER system. This is much less of a problem if a light mitochondrial fraction is used as a Golgi source for a density gradient; indeed, inclusion of EDTA will reduce contamination of this fraction by the RER.

The only major exceptions to the use of a standard isoosomotic sucrose homogenization medium are: (1) the method of Morré et al. (1972), where dextran is included in a slightly hyperosmotic (0.5 M) sucrose medium to promote the maintenance of Golgi stacks (from rat liver) during homogenization; and (2) for the isolation of Golgi from yeast, where it is common to use higher concentrations of sorbitol (~0.8 M) for lysis of spheroplasts (Bowser and Novick, 1991).

Rat liver may be homogenized in either a Potter-Elvehjem (four to five strokes of the pestle rotating at ~500 rpm) or in a loose-fitting Dounce homogenizer (ten to fifteen strokes), although in the method of Morré et al. (1972) the use of a Polytron homogenizer (or some similar means of providing controlled mechanical shear) is an absolute requirement, as otherwise the stacks of Golgi tend to fragment unpredictably. Hepatocytes are best homogenized in a tight-fitting Dounce homogenizer. For the often smaller volumes of cultured-cell suspensions, a ball-bearing homogenizer ("cell cracker"), repeated passages through a fine needle of a 1- to 2-ml syringe, or a tight-fitting Dounce homogenizer are commonly used techniques. It is strongly recommended that for any cell suspension (either from cultured cells or from a disaggregated tissue), the homogenization procedure be thoroughly investigated so that ≥90% of the cells can be disrupted reproducibly in the shortest time.

Differential centrifugation

Generally, it is only the Golgi membranes from an intact tissue such as mammalian liver that form highly organized and extensive cytoplasmic structures. When dextran is included in the homogenization medium (Morré et al., 1972) stacked tubules will sediment along with nuclei and heavy mitochondria at 5000 × *g*; otherwise, so long as the homogenization procedure is gentle, tubular elements will sediment in the light mitochondrial fraction (10,000 to 15,000 × *g*). On the other hand, the Golgi from most cultured cells will form fragments and vesicles of a variety of sizes. Hence, in the interest of maximum recovery, it is common to use either a total homogenate or, more commonly, a postnuclear or post–heavy mitochondrial supernatant for gradient fractionation of these cells. Although use of a microsomal fraction (centrifugation of a light mitochondrial supernatant at 100,000 to 150,000 × *g* for 30 to 40 min) may result in the loss of some of the larger fragments in earlier fractions of a differential centrifugation scheme, the elimination of both the majority of large organelles and the cytosolic proteins may be an advantage. The volume of medium required to suspend the microsomes will also be considerably less than that of the homogenate or postnuclear or postmitochondrial supernatant, thus facilitating sample and gradient handling. This may be of particular importance with intact tissues or hepatocytes where volumes tend to be large.

Density gradients

In sucrose gradients (Table 3.9.1), the density of Golgi membranes is predominantly in the range of 1.07 to 1.12 g/ml (although densities as low as 1.05 g/ml are possible). Because Golgi membranes are considerably lighter than other organelles in the light mitochondrial fraction (mitochondria, peroxisomes, and lysosomes), which have densities in sucrose >1.16 g/ml, discontinuous gradients for purifying Golgi membranes were successfully developed by a number of workers between 1970 and

Table 3.9.1 Density (g/ml) of Membrane Fractions from Rat Liver in Sucrose and Iodixanol

Particle	Density in sucrose	Density in iodixanol
Nuclei	>1.32	1.23-1.25
Peroxisomes	1.19-1.23	1.18-1.21
Rough endoplasmic reticulum	1.18-1.26	1.14-1.20
Mitochondria	1.17-1.21	1.14-1.16
Lysosomes	1.19-1.21	1.11-1.13
Smooth endoplasmic reticulum	1.10-1.17	1.08-1.12
Golgi	1.07-1.12	1.04-1.07
Plasma membrane	1.07-1.14	1.02-1.03

1980 (e.g., Fleischer and Fleischer, 1970; Ehrenreich et al., 1973). These have formed the basis for most of the technology based on sucrose (e.g., Basic Protocol 2). Later these methods were adapted to the use of the iodinated density gradient medium metrizamide (Graham and Winterbourne, 1988) and more recently to iodixanol (Graham et al., 1994; Yang et al., 1997; Zhang et al., 1998). Because solutions of iodinated density gradient media have a significantly lower osmolarity than those of sucrose, osmotically sensitive subcellular particles exhibit a much lower density in gradients of these media compared to those of sucrose (Table 3.9.1). The density of Golgi fragments in iodixanol, for example, is principally in the range 1.04 to 1.07 g/ml. As in sucrose, there are some variations: Plonné et al. (1999), for example, reported the same density range for most of the Golgi membranes in rat hepatocytes, but a small fraction of galactosyltransferase activity was observed at ~1.10 g/ml.

The variation in density may at least be partly explained by the fact that the Golgi membranes, and indeed the other membranes of the synthetic and secretory systems, are involved in post-translational modification of proteins and lipids that are destined either for incorporation into other membranes or for secretion. The density of these membranes (or of certain domains of these membranes) will be influenced by the density of the macromolecules (and macromolecular complexes) within them. Thus, the presence of particles such as VLDL, which are synthesized by hepatocytes, will tend to make membrane vesicles containing them have a relatively low density, while the presence of heavily glycosylated molecules (carbohydrate is normally very dense) will have the reverse effect. This may not be true of all glycosylated molecules: many proteoglycans, for example, are highly hydrated, giving them a relatively low density in isoosmotic gradients (Ford et al., 1983), but possibly not in a hyperosmotic medium such as sucrose.

The choice of medium may be influenced less by the attainable resolution, which is very satisfactory in both sucrose and iodixanol, than by the ease of handling, notably the commercial availability of iodixanol as a 60% (w/v) solution (OptiPrep) and the avoidance of the need to prepare highly viscous solutions of sucrose. Iodixanol may also be used as a self-generated gradient (Alternate Protocol 1 and Basic Protocol 4). In a self-generated gradient system, the sample is loaded into the centrifuge tube as a dilute suspension; this practice, together with the absence of any density interfaces, reduces aggregation of particles and promotes high resolution. It is also highly reproducible and facilitates the handling of large numbers of samples. Generation of a suitable density gradient profile depends on the use of an appropriate type of rotor. Vertical, near-vertical, or low-angle fixed-angle rotors can be used. Because the separation of the Golgi from a light mitochondrial fraction (Alternate Protocol 1) requires a gradient containing a relatively shallow median region, g forces as low as $180{,}000 \times g$ are permissible. For more information on the production and use of self-generated gradients, see Ford et al. (1994) and the Axis-Shield Density Gradient Media Catalog (Axis-Shield, 2000). In any system it may be necessary to modulate the density range of the gradients according to the median density of the Golgi membranes.

By using homogenization conditions that allow the Golgi from rat liver to retain its in vivo stacked form, Morré et al. (1972) were able to use a simple density barrier to purify the intact Golgi from the upper layer of a $5000 \times g$ pellet. Yields also tend to be higher than in other methods that use a light mitochondrial fraction (Basic Protocol 2 and Alternate Protocol 1) and in which the size of the Golgi fragments is variable. The only disadvantage of the method is that because the stacking is maintained by the inclusion of dextran in the homogenization medium, this fraction has to be hydrolyzed enzymatically if further subfractionation into domains is to be attempted (see Basic Protocol 1).

As to the separation of Golgi membrane vesicles from other vesicles of the secretory system and from plasma membrane, the situation is rather less clear with sucrose. Although the density in sucrose gradients of the RER is clearly considerably greater than that of the Golgi (Table 3.9.1), the lighter smooth-ER (SER) vesicles clearly overlap the denser Golgi membranes. The overlap of the Golgi with the ER is less significant in iodixanol gradients (Table 3.9.1), making iodixanol the gradient medium of choice for the isolation of Golgi membranes from a microsomal fraction, postnuclear (or postmitochondrial) supernatant, or homogenate (see Anticipated Results).

The advantage of using either a whole homogenate or a postnuclear supernatant for the isolation of Golgi membranes is that the response of the Golgi tubules to the homogenization procedure is irrelevant as all of the membranes will be applied to the gradient. If a homogenate is used, then it is certainly advis-

able to adjust its density such that it can be layered under the gradient; if it were layered on top, the presence of rapidly sedimenting nuclei might disturb the gradient. The situation with a postnuclear supernatant or with a microsomal fraction is less critical, and top-loading is permissible. Nevertheless, it is often considered an advantage, especially when isolating the least-dense membrane from much larger populations of denser particles, that bottom loading provides better resolution (Hinton and Mullock, 1997). In this mode the densest particles either remain in or float very slowly into the gradient from the load zone. The disadvantage to this approach is that there is an increase in sample volume when the sample density is adjusted by adding a high-density solution, and this may require that more gradients be set up to accommodate the volume.

In top loading a fraction that also contains the cytosolic fraction (i.e., any fraction except a resuspended microsomal pellet), it is inevitable that soluble proteins will also move into the gradient due to sedimentation and diffusion. If discrimination of cytosolic proteins from any membrane fraction is important, then bottom loading should alleviate this problem as the proteins will tend to remain in the load zone. Although cytoplasmic proteins may also be subsequently removed by pelleting the membranes from the gradient fractions, this additional step may be undesirable.

Use of a pelleted microsomal fraction will not only remove most of the cytosolic proteins (although, unless the pellet is washed, there will always be some residual contamination), it will also permit reduction of the fluid volume. On the other hand, when the pellet is resuspended, liquid shear forces may cause some transient damage to the membrane vesicles and consequent leakage of their contents.

Critical Parameters and Troubleshooting

Homogenization

Homogenization of the commonly used rat liver is covered in these protocols, and the methodology should be applicable to other soft tissue such as kidney. The homogenization procedures are unsatisfactory for hard tissues such as skeletal or cardiac muscle. These tissues require special treatment, and it is strongly recommended that methods that employ severe mechanical shear be avoided, as they tend to cause organelles such as lysosomes to be disrupted. Use of a protease (Nagarse, marketed by Sigma-Aldrich as Proteuse Type VII) to soften the tissue allows its subsequent homogenization by more gentle means in a Dounce or Potter-Elvehjem homogenizer. For more information see Bhattacharya et al. (1991) and Graham (1997).

Hepatocytes, CHO cells, and COS-7 cells can be homogenized either in a tight-fitting Dounce homogenizer or a ball-bearing homogenizer using a routine homogenization medium (i.e., 0.25 M sucrose with or without 1 mM EDTA, buffered with either Tris or HEPES). Although most monolayer cultured cells seem to homogenize reasonably effectively in this medium, the medium developed by Marsh et al. (1987), in which the buffer was changed to 10 mM triethanolamine/10 mM acetic acid, pH 7.4, is more widely applicable. The triethanolamine/acetic acid buffer is the critically important component. If, upon homogenization, the cell homogenate acquires a gelatinous quality, this may be due either to nuclear breakage or to the release of proteins from cytoskeletal elements. Inclusion of 1 mM Mg^{2+} with or without DNase I (10 μg/ml) and/or 10 mM KCl may alleviate the problems.

For cultured cells, the device of choice that seems to provide the least damage to intracellular organelles is the ball-bearing homogenizer, first described by Balch and Rothman (1985). A Dounce homogenizer (or passage through a fine syringe needle) is often used as an acceptable alternative, but for cells other than those described in this unit, it is strongly recommended that the optimal conditions for disrupting the cells be thoroughly investigated. The aim must always be to use the minimum force to achieve ~90% cell breakage, and protocols, for example, that use more than 20 pestle strokes of a Dounce homogenizer should be avoided, if at all possible.

For cells that resist disruption by liquid shear forces, nitrogen cavitation is probably the best option, as an isoosmotic sucrose medium can always be used. Standard conditions are 300 to 600 psi for 10 to 15 min, although Kelly et al. (1989) reported the use of much lower pressures. For a more complete discussion of these problems, see Evans (1992) and Graham (1997).

Ideally the Polytron homogenizer used in Basic Protocol 1 should not be substituted by any other homogenization device. If another device is used, the homogenate should be centrifuged at 5000 × *g* for 15 min and the supernatant recentrifuged at 100,000 × *g* for 30 min. The recovery of galactosyltransferase in the

5000 × *g* pellet should be ≥50% of the total (Morré et al., 1972).

Density gradient centrifugation

Use of tissues or cells other than those for which the protocols were designed may require some modification to the density range of gradients; this can only be determined by experimentation. In those protocols in which preformed continuous or discontinuous gradients are used, the use of swinging-bucket rotors with tube volumes other than those recommended in the protocols is permissible so long as the volume ratios of sample and gradient are maintained and the rotors are capable of similar relative centrifugal forces (RCFs). However, use of alternative rotors for self-generated gradients is not recommended unless it is first established that the rotor can be used to form a gradient of the correct density profile (see Anticipated Results). The sedimentation path length and maximum RCF of the rotor are the critical factors; generally speaking, path lengths of >30 mm and RCFs <180,000 g_{av} are unacceptable. The gradient-forming capacity of any rotor should be checked by running a blank gradient, fractionating the gradient either by upward displacement or tube puncture, and determining the density of the gradient fractions by refractometry. In the case of iodixanol, density (ρ) and refractive index (η) of solutions produced by diluting OptiPrep with a medium containing 0.25 M sucrose are related by the following equation: $\rho = 3.4713\eta - 3.6393$.

Enzyme and other assays

If the sample volumes from sucrose or iodixanol gradient fractions used in an enzyme assay are sufficiently small (compared to the assay volume), the gradient solute may be adequately diluted so as not to cause any interference in the assay, even at the highest density. Indeed, it is well established that neither iodixanol nor sucrose exhibits any significant inhibition of the standard enzyme markers (Ford et al., 1994). Thus, so long as the concentration of organelles in the gradient fraction is high enough for the enzyme activity to be detectable, the assay may be performed directly without washing. If, however, either of these requirements is not met, or if it is important to suspend the membrane fractions in a medium of constant composition, then dilution, sedimentation, and resuspension of the pellet in a smaller volume of an appropriate medium is the recommended method. In the case of sucrose, dialysis is an acceptable alternative, although any residual dextran in a gradient fraction from Basic Protocol 1 is not dialyzable. For iodixanol, ultrafiltration using a microcentrifuge cone filter can be used.

In order to determine specific activities of measured enzymes, it is also necessary to estimate the protein content of fractions. Both iodixanol and, to a lesser extent, sucrose interfere with methods using the Folin Ciocalteu reagent. However, if the concentration of gradient solute in the assay solution can be reduced to <10%, i.e., by using small volumes of gradient fractions (≤100 µl) in a 1- to 2-ml assay volume, the interference is marginal. Methods based on Coomassie blue are generally unaffected by any concentration of these gradient media.

Any electrophoretic and electroblotting technique can also be carried out on sucrose- or iodixanol-containing fractions without prior removal of the medium, again, as long as the concentration of membrane in the sample is sufficiently high for the analytical procedure.

Anticipated Results

Basic Protocol 1

According to the data of Morré et al. (1972), 40% to 70% of the total *N*-acetylglucosamine galactosyltransferase activity originally in the rat liver homogenate should be recoverable in the material harvested from the top of the 1.2 M sucrose density barrier. The recovery from other tissues or cells will depend very much on the existence of a well-organized Golgi apparatus in the cell and the behavior of the Golgi membranes during homogenization. The fraction purity should be ≥80% with a relative specific activity (ratio of specific activity of N-acetylglucosamine galactosyltransferase in the Golgi fraction to that in the homogenate) of ~90.

Basic Protocol 2

The following information is taken from Fleischer and Fleischer (1970). The Golgi membranes at the 0.77 M/1.1 M sucrose interface should contain the highest activity of galactosyltransferase activity (a specific activity of ~120 relative to that of the homogenate), while the slightly denser membranes should have lower activity (~70). Total yield of galactosyltransferase in the two bands is 30% to 35% of that in the homogenate, while only ~0.3% of the total protein is recovered in these two bands.

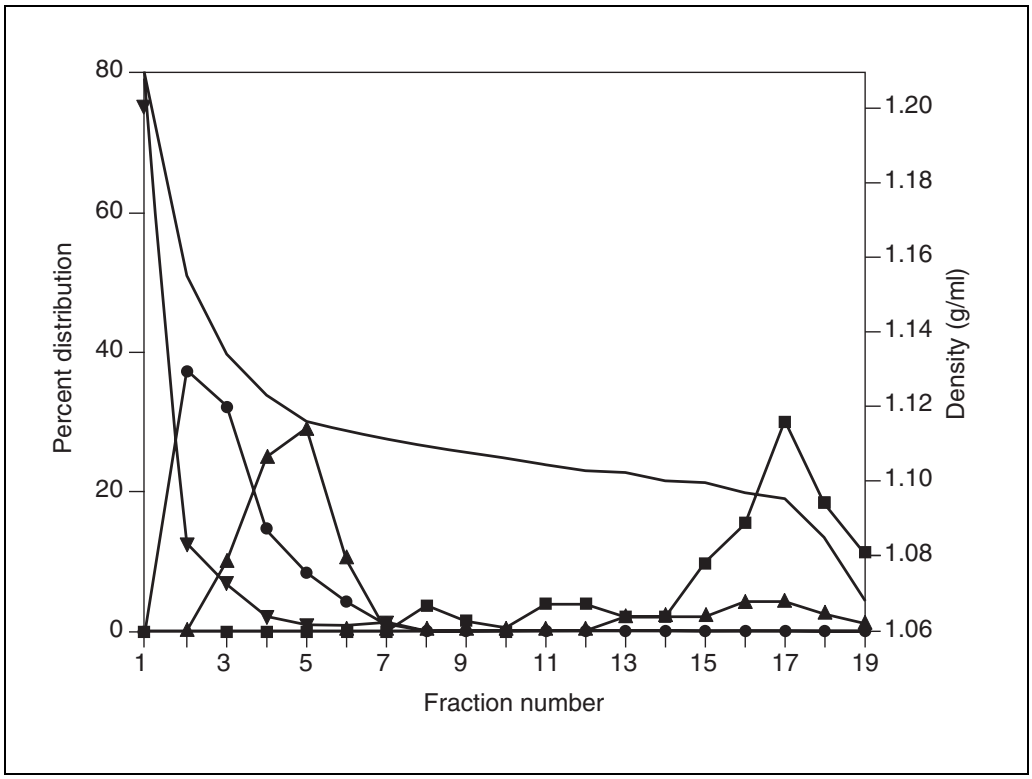

Figure 3.9.1 Fractionation of a light mitochondrial fraction (mouse liver) in a self-generated gradient of iodixanol: percent distribution of enzyme markers (symbols) and density profile (—). Light mitochondrial fraction adjusted to 15% (w/v) iodixanol and centrifuged at 180,000 × *g* for 3 hr in a 20° fixed-angle rotor. Organelle markers and symbols: catalase for peroxisomes (filled inverted triangle), succinate dehydrogenase for mitochondria (filled circle), β-galactosidase for lysosomes (filled triangle), and galactosyltransferase for Golgi (filled square). Adapted from Graham et al. (1994) with permission from Academic Press.

Alternate Protocol 1

Figure 3.9.1 shows a typical distribution of marker enzymes in the iodixanol gradient. At least 80% of the total galactosyltransferase present in the light mitochondrial fraction from mouse liver should be recovered from the top five fractions. The same fractions should contain <10% of any lysosomal marker (β-galactosidase) and negligible amounts of enzyme markers for other organelles (Graham et al., 1994). The relative specific activity of galactosyltransferase (specific activity in gradient fraction relative to that in the light mitochondrial fraction) in the peak Golgi fraction should be ~20.

Basic Protocol 3

Some typical recoveries of Golgi (*N*-acetylglucosamine galactosyltransferase) and ER (glucosidase I) markers are given in Table 3.9.2

Table 3.9.2 Marker Enzyme Activity in Isolated Fractions from CHO Cells Processed by Flotation Through a Discontinuous Sucrose Gradient[a]

Fraction	Protein recovery (%)	*N*-Acetylglucosamine galactosyltransferase		Glucosidase I	
		Total activity	Specific activity	Total activity	Specific activity
Postnuclear supernatant	NA[b]	164	2.3	0.6	0.008
Golgi	3.6	70	26.8	0.026	0.01

[a]Data from Balch et al. (1984).

[b]Abbreviation: NA, not applicable.

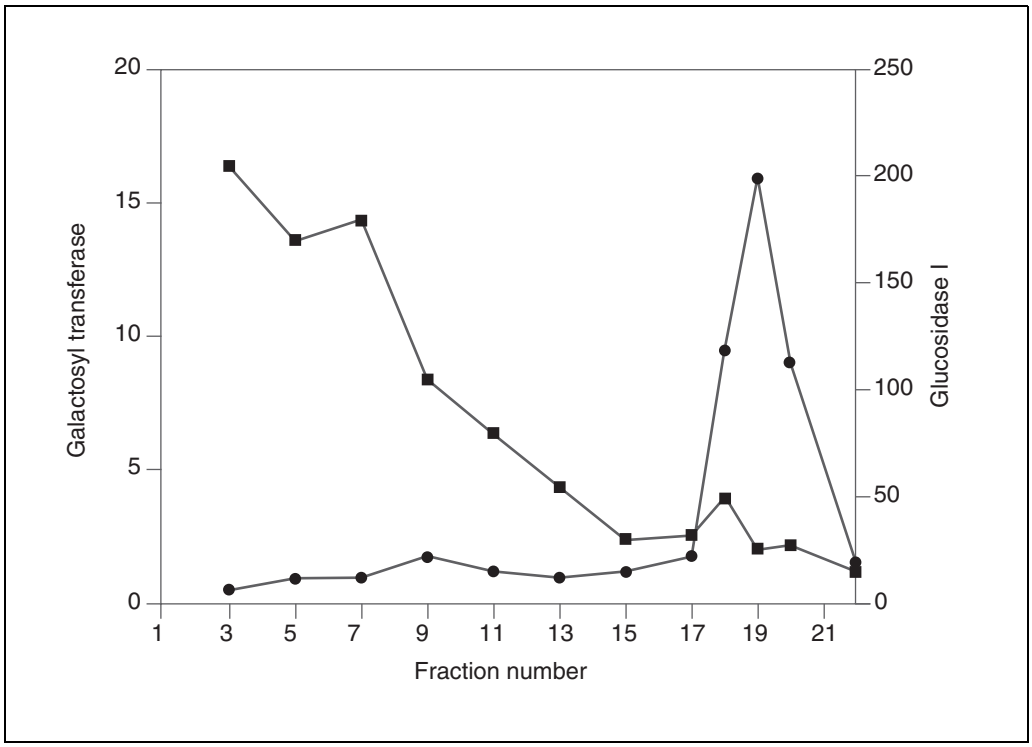

Figure 3.9.2 Fractionation of a homogenate of CHO cells in a 0.8 to 2.0 M discontinuous sucrose gradient: distribution of Golgi (galactosyltransferase) and endoplasmic reticulum (ER; glucosidase I) markers. Gradients were unloaded dense-end first. Activity of galactosyltransferase (filled circle) expressed as cpm $\times 10^{-2}$; activity of glucosidase I (filled square) expressed as cpm. Adapted from Balch et al. (1984) with permission from Elsevier Science.

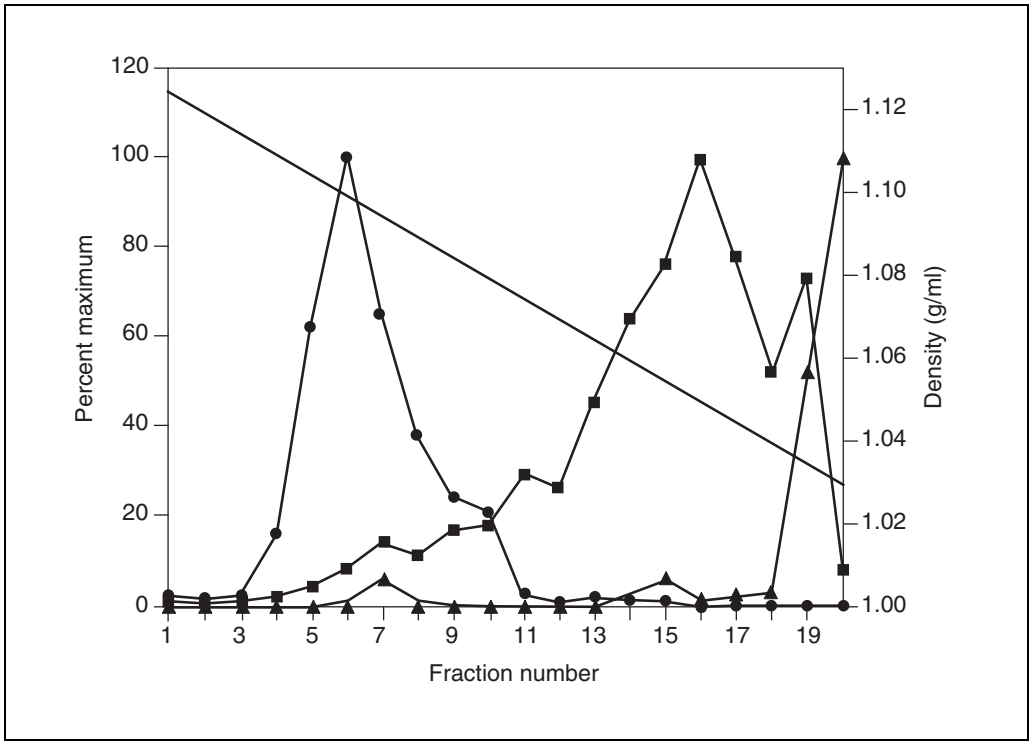

Figure 3.9.3 Fractionation of a postnuclear supernatant from CHO cells on a preformed continuous 0% to 26% (w/v) iodixanol gradient: distribution of markers (symbols) and density profile (—). Activities in each fraction expressed as a percentage of the maximum fraction. Organelle markers and symbols: ribophorin for endoplasmic reticulum (ER; filled circle), galactosyltransferase for Golgi (filled square), and biotinylated surface proteins for plasma membrane (filled triangle). Adapted from Yang et al. (1997) with permission from the American Society for Biochemistry and Molecular Biology.

(Balch et al., 1984). The Golgi fraction contains ~40% of the total *N*-acetylglucosamine galactosyltransferase of the postnuclear supernatant but only ~4% of the glucosidase I. Figure 3.9.2 shows that essentially all of the ER is distributed quite broadly in the bottom half of the gradient, while the Golgi bands sharply at the 0.8 M/1.2 M sucrose interface.

Alternate Protocol 2

Distribution of the Golgi and ER markers (Yang et al., 1997) in the continuous iodixanol gradient (Fig. 3.9.3) is not unlike that observed in the discontinuous sucrose gradient (Basic Protocol 3), but the rather broader distribution of the Golgi may provide some potential for subfractionation of the Golgi into light and dense populations. Moreover, some small contamination of the Golgi by the ER is evident in the sucrose gradient (the specific activity of glucosidase I is indeed slightly raised in the Golgi fraction over the postnuclear supernatant; Table 3.9.2). In the iodixanol gradient, on the other hand, no contamination whatsoever is apparent. If the two lightest fractions containing plasma membrane are discarded, then ≥80% of the galactosyltransferase in the gradient is recovered in a highly purified manner.

Basic Protocol 4

Figure 3.9.4 shows a typical result of the self-generated iodixanol gradient (Plonné et al., 1999): ~80% of the galactosyltransferase is contained in the top seven fractions of the gradient. The system can also be used for the simultaneous isolation of smooth ER (fractions 9 to 13) and rough ER (fractions 15 to 20).

Time Considerations

There are no points at which any of the basic or alternate protocols can be discontinued. The light mitochondrial fraction produced in Basic Protocol 2 must be used immediately for any subsequent gradient separation. Discontinuous gradients may be made up immediately prior to use and underlayered with the dense light mitochondrial fraction (Basic Protocol 2) or homogenate (Basic Protocol 3). Preformed continuous gradients (Alternate Protocol 2) may be made up during the preparation of the postnuclear supernatant and kept on ice until required. If these continuous gradients are prepared at room temperature they must be given time to cool down to 4°C. Alternatively, they can be made from a discontinuous gradient the previous day and stored overnight at 4°C to allow diffusion to occur. Always check that a

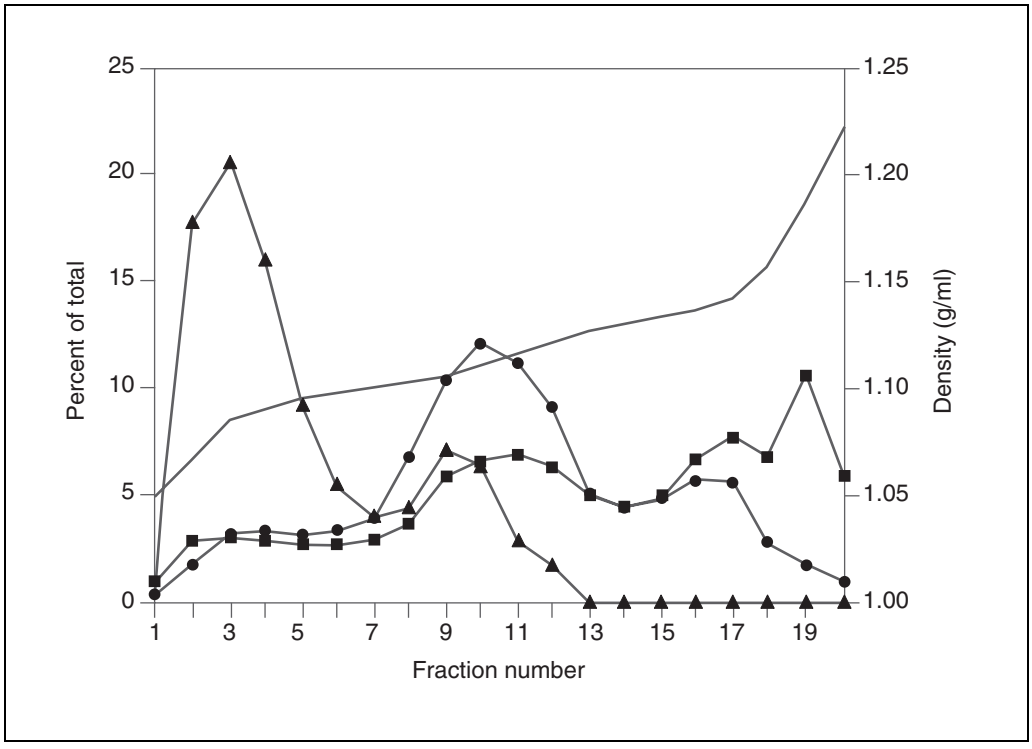

Figure 3.9.4 Fractionation of a rat hepatocyte microsomal fraction in a 15%/20% self-generated iodixanol gradient: percent distribution (symbols) and density profile (—). Centrifugation was carried out in a Beckman VTi 65.1 vertical rotor at 350,000 × *g* for 2 hr. Organelle markers and symbols: NADPH-cytochrome c reductase for ER (filled circle), galactosyltransferase for Golgi (filled triangle), and protein (filled square). Adapted from Plonné et al. (1999) with permission from Academic Press.

continuous gradient has been formed by measuring the refractive index of fractions from a blank gradient.

Basic Protocol 1 is a rapid procedure and Morré et al. (1972) considered that the livers from as many as ten to twelve rats could be processed in 2 hr. Preparation of the light mitochondrial fraction (Basic Protocol 2), which forms the input for gradients described in the same protocol and in Alternate Protocol 1, should take no more than 1 hr for one to two rat livers. Forming, centrifuging, and harvesting the discontinuous gradients (Basic Protocol 2) will take ~2 hr for two tubes. Tube preparation for self-generated gradients (Alternate Protocol 1) is much faster than is the construction of preformed gradients, but because of the longer acceleration and deceleration times, the overall time will be similar if the centrifugation is carried out at 350,000 × *g*. Basic Protocol 3 will take ~3 hr, as will Alternate Protocol 2 if the shorter centrifugation time is used. If hepatocytes are used, the overall time for Basic Protocol 4 will be ~5 hr, but for liver this will be nearer to 4 hr.

For the first couple of preparations it is probably advisable to unload continuous gradients in a number of equivolume fractions (fraction volume should be ~5% of gradient volume). With experience and practice, however, it will be possible to remove the Golgi-containing fractions with a syringe or Pasteur pipet.

Functional assays should be carried out as soon as possible after the preparation. The Support Protocol should take ~4 hr for 20 to 30 samples. For simple marker enzyme assays (such as described in this unit), material can be stored at 0° to 4°C for ≤16 hr without much loss of activity. These assays and compositional measurements may also be carried out on material frozen to −20° or −80°C. There are, however, no general rules regarding the suitability of a particular storage regime, and it is strongly recommended that the validity of results on stored material be checked by comparison with those made on the fresh organelles. Any concentration of the membrane fractions and/or removal of gradient medium must be carried out prior to freezing.

All solutions, except the acceptor solution (Support Protocol), can be made up ahead of time and stored at 4°C for 1 to 2 days or frozen to −20°C for longer periods (e.g., 5 months). Any enzymes or protease inhibitors should be added immediately prior to use.

Isolation of Nuclei and Nuclear Membranes From Animal Tissues

The vast majority of methods for the isolation of nuclei and nuclear membranes use soft mammalian tissues (particularly rat liver) as the biological source; however, the protocols described in this unit should be applicable generally to any tissue type, cultured cells, or cells of lower eukaryotes or plants, so long as a suitable homogenization method is available. Generally, a buffered isoosmotic medium containing KCl and $MgCl_2$ is used to stabilize the nuclei of mammalian tissues. Some of the media used for cultured animal cells and nonmammalian sources are described later in the unit (see Commentary). Purification using a sucrose barrier of 2.3 M sucrose is described (see Basic Protocol 1). The use of such dense sucrose solutions has several disadvantages, notably the high viscosity, meaning that particles sediment very slowly through the medium; therefore, the procedure requires an ultracentrifuge. The high osmolarity may also be detrimental to the intranuclear structure, and certainly the organelles loose water and shrink considerably in size. The use of OptiPrep (iodixanol; Axis-Shield) overcomes both the viscosity and osmolarity problems (see Alternate Protocol 1) and permits the use of a high-speed centrifuge and much shorter centrifugation times. A series of alternate steps are given for plant cell (i.e., wheat germ) nuclei, since the dense layer of iodixanol used in this method is able to resolve nuclei from the denser starch granules (see Commentary for more details).

The centrifugation of any subcellular particle through an aqueous medium tends to lead to loss of some proteins that may be important for proper functioning of the organelle. Although nonaqueous media can overcome this problem, they are generally avoided, since they often pose more problems than they solve. Nuclei are probably the only organelle that might benefit from such an approach, so a method employing a gradient of Nycodenz (Axis-Shield) in ethylene glycol is described (see Alternate Protocol 2).

The isolation of nuclear membranes from purified nuclei has been approached via diametrically opposite strategies. High-ionic-strength media generally give high yields of nuclear membranes, and the hollow membranous spheres that are formed seem well suited to permeability studies (see Basic Protocol 2). Low-ionic-strength media produce highly purified nuclear envelopes, which are particularly good for compositional studies (see Basic Protocol 3).

Two simple chemical methods for estimating DNA and RNA (see Support Protocols 1 and 2) and a fluorometric method for measuring both nucleic acids (see Support Protocol 3) are also provided.

ISOLATION OF NUCLEI FROM RAT-LIVER HOMOGENATE USING A SUCROSE DENSITY BARRIER

BASIC PROTOCOL 1

In this procedure the tissue is homogenized in an isoosmotic medium containing 0.25 M sucrose, 25 mM KCl, 10 mM $MgCl_2$, and 10 mM Tris·Cl, pH 7.4 (Blobel and Potter, 1966). Variations for other tissues, cultured cells, or nonmammalian material are described elsewhere (see Commentary). Filtration of the homogenate is often included to avoid contamination of the subsequent crude nuclear pellet, produced by centrifugation of the homogenate at 800 × *g* for 10 min, by connective tissue and unbroken cells; the connective tissue may also make resuspension of the pellet difficult. The pellet is then resuspended in ~1.6 M sucrose and layered over 2.3 M sucrose. After centrifugation at 100,000 × *g* for 1 hr, the nuclei form a pellet at the bottom of the tube, while any

Contributed by John M. Graham
Current Protocols in Cell Biology (2001) 3.10.1-3.10.19

contaminating material remains in the load zone. In some methods (Widnell and Tata, 1964), the lower barrier is eliminated and the nuclei are simply pelleted from the dense crude nuclear suspension. This alternative is given in the annotations to the respective steps.

If the exposure of the nuclei to such a vastly hyperosmotic medium is undesirable, then a method using an isoosmotic discontinuous gradient of iodixanol can be used (see Alternate Protocol 1). These gradients are also much less viscous and the centrifugation can be carried out at much lower RCFs in a high-speed centrifuge. A gradient that is nonaqueous can also be used (see Alternate Protocol 2). The following protocol is adapted from Blobel and Potter (1966).

Materials

150- to 200-g Sprague-Dawley rats
Nuclear isolation medium (NIM; see recipe)
Sucrose density barrier (SDB; see recipe)

Scissors or razor blade
~30-ml Potter-Elvehjem homogenizer with 0.1-mm clearance and loose-fitting pestle
75-µm pore size nylon gauze or cheesecloth (muslin)
Glass rod
Refrigerated low-speed centrifuge with swinging-bucket rotor and appropriate 50-ml polypropylene or polystyrene tubes
~30-ml Dounce homogenizer with loose-fitting Wheaton Type B pestle
Refractometer
Ultracentrifuge with swinging-bucket rotor (e.g., Beckman SW40Ti, Sorvall TH641) and appropriate 14-ml tubes

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) and must follow officially approved procedures for the care and use of laboratory animals.

NOTE: All solutions, glassware, centrifuge tubes, and equipment should be precooled to 0° to 4°C, and kept on ice throughout. Centrifuge rotors should be precooled to the same temperature.

NOTE: Protease inhibitors (*UNIT 3.4*) may be added to any or all solutions.

Isolate and homogenize the liver

1. Starve a 150- to 200-g Sprague-Dawley rat overnight.
2. Sacrifice the animal by cervical dislocation or decapitation.

   This must be supervised or carried out by an experienced animal technician.

3. Open the abdominal cavity and remove the liver to a chilled beaker containing ~20 ml nuclear isolation medium (NIM).
4. Decant the medium and finely mince the liver using scissors or a razor blade.

   The pieces of liver should be no more than ~25 mm^3.

5. Suspend the mince in ~40 ml NIM and transfer half of this suspension to the glass vessel of the ~30-ml Potter-Elvehjem homogenizer.

   The motor should be mounted either to a wall, via a G-clamp to the bench, or in a floor-standing cradle. Attachment to a free-standing retort stand is not adequate.

6. Attach the precooled pestle to the electric motor and homogenize the liver mince using 4 to 5 up-and-down strokes of the pestle, rotating at ~500 rpm.
7. Decant the homogenate into a beaker on ice. After rinsing the homogenizer with NIM, and wiping the pestle to remove any connective tissue that may be adhering, perform the procedure (i.e., steps 5 to 7) with the other half of the mince.

Prepare crude nuclear pellet

8. Filter the homogenate through a single layer of nylon gauze (pore size of 75 μm), or three layers of cheesecloth (muslin) to remove unbroken cells and any connective tissue.

   Do not force the homogenate through the filter; assist filtration only by stirring with a glass rod.

9. Dilute the homogenate with at least an equal volume of NIM.

   For cultured cells that have been homogenized in a hypoosmotic medium, add an equal volume of buffer containing 0.5 M sucrose. If there is neither KCl nor $MgCl_2$ in the homogenate, double the concentration of these salts in the added buffer.

10. Distribute the suspension equally between two 50-ml centrifuge tubes and centrifuge in a low-speed centrifuge with a swinging-bucket rotor 10 min at 800 × *g*, 4°C.
11. Decant the supernatant, discarding as much of the upper, loosely packed brown layer as possible. Resuspend the pellet in 40 ml NIM using the ~30-ml Dounce homogenizer.
12. Repeat the centrifugation as described in step 10.
13. Decant the supernatant and make a crude resuspension of the combined pellets in NIM, using a glass rod, so that the final volume is ~8 ml.

    If the crude nuclear suspension itself is to be adjusted to ~2.2 M sucrose and centrifuged without layering over a barrier, do not resuspend the pellets in NIM.

Purify nuclei

14. Add 2 vol sucrose density barrier (SDB) to the crudely resuspended nuclear pellet and mix very thoroughly using the Dounce homogenizer.

    Alternatively, resuspend the pellets from step 13 directly in ~9 vol SDB. This critical step is quite difficult because of the viscosity of the SDB. It may be easier to use the Potter-Elvehjem homogenizer rotating at 1000 rpm.

15. Check that the refractive index of the suspension is 1.4117 ± 0.0004, using a refractometer. Adjust concentration with SDB, if necessary, to attain this refractive index.
16. Transfer 9 ml suspension to a 14-ml ultracentrifuge tube. Underlayer with 2.3 M sucrose to fill the tube. Ultracentrifuge in a swinging-bucket rotor 1 hr at 100,000 × *g*, 4°C.

    In the alternative method, simply fill the tubes with the resuspended nuclei and centrifuge in a swinging-bucket or fixed-angle rotor.

17. Remove any material that has floated to the meniscus with a spatula, then decant all the liquid from above the pellet. Leave the tubes inverted for a few minutes to drain as much of the viscous sucrose layer as possible.
18. While the tube is inverted, wipe off as much of the liquid from the walls of the tube as possible, using a tissue wrapped around forceps.

19. Resuspend the pellet in NIM, or other suitable medium compatible with the next process, to ~5 mg protein/ml.

Metabolic assays should be carried out as soon as possible upon preparation; some enzyme assays can be carried out after storage at 4°C for up to 16 hr. Assays can often be carried out on material frozen to –20° or –80°C. Always check that the measurements made are relatively unaffected by the storage conditions by comparing with those made on fresh material. Note however that thawing a frozen suspension of nuclei may cause release of DNA, and consequently almost irreversible aggregation of the particles.

ALTERNATE PROTOCOL 1

ISOLATION OF NUCLEI FROM ANIMAL OR PLANT (WHEAT GERM) CELLS USING AN IODIXANOL GRADIENT

If elimination of any potential damage to the nucleoprotein complexes is important, then the alternative iodixanol gradient described in this protocol might be relevant. Using these gradients it is possible to isolate nuclei by isopycnic banding in an isoosmotic nonionic environment (Graham et al., 1994; Provost et al., 1996). Because the nuclei retain their normal hydration, their density (ρ = 1.20 to 1.22 g/ml) is much lower than in sucrose (>1.32 g/ml). Buoyant density banding thus requires much lower concentrations of iodixanol; consequently the viscosity of the medium is much lower, as are the centrifugation forces and times needed to purify the nuclei. Also, unlike using a sucrose gradient (see Basic Protocol 1), it is not necessary to produce a crude nuclear fraction first. After the whole homogenate is adjusted to 25% (w/v) iodixanol, this is loaded directly on to a discontinuous iodixanol gradient; therefore, the method is quicker and simpler to execute. The protocol below is adapted from Graham et al. (1994). Ford et al. (1998) reported that a comparable iodixanol gradient is also able to separate the nuclei and starch granules from wheat germ (see alternative steps). This is not possible with sucrose gradients, since both pellet through the 2.3 M sucrose.

Additional Materials *(also see Basic Protocol 1)*

Filtered homogenate (animal cells or tissue; see Basic Protocol 1) or wheat germ
50% (w/v) iodixanol (see recipe; animal cells or tissue)
30% and 35% (w/v) iodixanol gradient solutions (see recipe; animal cells or tissue)
25% and 40% (w/v) iodixanol gradient solutions (see recipe; wheat germ)
Wheat germ medium (WGM; see recipe)
High-speed centrifuge with a swinging-bucket rotor and appropriate 50-ml tubes

NOTE: All solutions, glassware, centrifuge tubes, and equipment should be precooled to 0° to 4°C, and kept on ice throughout. Centrifuge rotors should be precooled to the same temperature.

NOTE: Protease inhibitors (*UNIT 3.4*) may be added to any or all solutions.

For animal cells or tissue

1a. Prepare the filtered homogenate as described (see Basic Protocol 1, steps 1 to 8).

2a. Mix the homogenate with an equal volume of 50% iodixanol.

3a. In a 50-ml centrifuge tube, layer 15 ml each of 35% and 30% iodixanol solutions, and sample.

If it is necessary to reduce the number of tubes used for this centrifugation, the volume of 35% iodixanol per tube may be reduced to 7.5 ml while increasing the volume of homogenate by a corresponding amount.

4a. Centrifuge in a high-speed centrifuge with a swinging-bucket rotor 20 min at 10,000 × *g*, 4°C.

The nuclei from some tissues or cells may be smaller and/or less dense than those from mammalian liver; therefore, it may be necessary to increase the RCF to 20,000 × g and/or modulate the concentration (w/v) of iodixanol in the three layers (e.g., 20%, 25%, and 30%).

5a. Harvest the nuclei from above the 35% iodixanol and dilute with 2 vol of NIM.

For wheat germ

1b. Make a crude suspension of nuclei by vigorously shaking ~5 g of wheat germ in ~50 ml WGM.

2b. Allow the debris to settle for 10 min. Carefully decant the supernatant.

3b. Layer 20 ml crude nuclear suspension over 5 ml each 25% and 40% iodixanol gradient solutions.

4b. Centrifuge in a high-speed centrifuge with a swinging-bucket rotor 30 min at 5600 × *g*, 4°C.

5b. Harvest the nuclei, which band above the 40% iodixanol.

The starch granules form a pellet.

Concentrate nuclei

6. Centrifuge 10 min at 2000 × *g*, 4°C in a low-speed centrifuge with a swinging-bucket rotor. Resuspend the pellet in NIM (animal cells or tissue) or WGM (wheat germ), or other suitable medium compatible with the next process, to ~5 mg protein/ml.

Metabolic assays should be carried out as soon as possible upon preparation; however, some enzyme assays can be carried out after storage at 4°C for up to 16 hr. Many assays can be carried out on material frozen to –20° or –80°C. Always check that the measurements made are relatively unaffected by the storage conditions by comparing with those made on fresh material. Thawing a frozen suspension of nuclei may cause release of DNA, and consequently almost irreversible aggregation of the particles.

ISOLATION OF NUCLEI FROM RAT-LIVER HOMOGENATE IN A NONAQUEOUS MEDIUM

ALTERNATE PROTOCOL 2

It may be beneficial to use homogenization and gradient media that are nonaqueous in order to eliminate, as far as possible, any loss of proteins from the external surface of the nuclei, or the leaching out of proteins from the matrix. This approach, in particular, eliminates loss of DNA polymerase from the nuclei. The method, developed by Rickwood et al. (1997), in which an aqueous sucrose medium is replaced by ethylene glycol, permits the use of standard Potter-Elvehjem homogenization techniques. Moreover, Nycodenz (Axis-Shield) is freely soluble in the same solvent so purification in a density gradient is also possible.

Additional Materials *(also see Basic Protocol 1)*

Ethylene glycol homogenization medium (EGHM; see recipe)
10% and 40% (w/v) Nycodenz (Axis-Shield; available from Accurate Chemicals) in EGHM
Two-chamber gradient maker or Gradient Master (BioComp Instruments)

NOTE: All solutions, glassware, centrifuge tubes, and equipment should be precooled to 0° to 4°C, and kept on ice throughout. Centrifuge rotors should be precooled to the same temperature.

NOTE: Protease inhibitors (*UNIT 3.4*) may be used in any or all solutions.

1. Prepare a filtered homogenate as described (see Basic Protocol 1, steps 1 to 8), except omit the use of NIM for washing the liver (step 3), replacing the ~40 ml NIM (step 5) with ~50 ml EGHM, and increasing the number of strokes of the pestle from 4 to 5 to 6 to 9 (step 6).
2. Centrifuge in a low-speed centrifuge with a swinging-bucket rotor 10 min at 1000 × *g*, 4°C.
3. Discard the supernatant and resuspend the pellet in 10% (w/v) Nycodenz in EGHM (~2 ml/g liver), using a Dounce homogenizer.
4. Prepare 12-ml continuous gradients from equal volumes 10% and 40% Nycodenz in EGHM in a 14-ml ultracentrifuge tube using a two-chamber gradient maker or Gradient Master, and layer 2 ml resuspended nuclear pellet on top.
5. Ultracentrifuge in a swinging-bucket rotor 90 min at 80,000 × *g*, 4°C.
6. Remove the white band of nuclei from the middle of the gradient (i.e., ~22% Nycodenz) using a syringe or pipet.
7. Dilute the suspension with 2 vol EGHM. Centrifuge in a low-speed centrifuge with a swinging-bucket rotor 10 min at 1000 × *g*, 4°C.
8. Resuspend in EGHM or some other medium appropriate to further analysis.

Metabolic assays should be carried out as soon as possible upon preparation; however, some enzyme assays can be carried out after storage at 4°C for up to 16 hr. Many assays can be carried out on material frozen to –20°C or –80°C. Always check that the measurements made are relatively unaffected by the storage conditions, by comparing with those made on fresh material. Note that thawing a frozen suspension of nuclei may cause release of DNA, and consequently almost irreversible aggregation of the particles.

BASIC PROTOCOL 2

ISOLATION OF NUCLEAR MEMBRANES: HIGH-IONIC-STRENGTH METHOD

High-ionic-strength methods for removing chromatin from the nucleus were first developed by Monneron et al. (1972), and more recently, high concentrations (i.e., 1.6 M) of NaCl were used by Kaufmann et al. (1983). In these methods, nucleus-sized hollow spheres are produced that are good for permeability studies. DNase I and RNase are also commonly included to digest the nucleic acids, and phenylmethylsulfonyl fluoride (PMSF) is included as a protease inhibitor.

As with the preparation of nuclei, most nuclear membrane methods are also based on rat liver and application to nuclei from other sources will need to be approached empirically to determine which, if any, of the current methods are suitable. This protocol is adapted from Kaufmann et al. (1983).

Materials

200 mM PMSF (*APPENDIX 2A*)
Nuclei suspension medium (NSM; see recipe)
DNase I
RNase
Incubation buffer (IB; see recipe)
High-NaCl buffer (HNB; see recipe)
2-mercaptoethanol
Nuclear membrane storage medium (NMSM; see recipe)

~20-ml Dounce homogenizer with loose-fitting Wheaton Type B pestle
Refrigerated low-speed centrifuge with swinging-bucket rotor

1. Prepare the nuclei (see Basic Protocol 1 or Alternate Protocol 1), using 1 mM PMSF in all media, diluted from a 200 mM stock.
2. Suspend the nuclei in nuclear suspension medium (NSM) at a concentration of 5 to 8 mg DNA/ml (see Support Protocols 1 and 3), using 3 to 4 gentle strokes of the ~20-ml Dounce homogenizer.
3. Add DNase I and RNase to a final concentration of 250 μg/ml and stir gently for 1 hr at 4°C.
4. Sediment the nuclei in a low-speed centrifuge with a swinging-bucket rotor for 10 min at 1000 × *g*, 4°C. Resuspend the pellet in the same volume incubation buffer (IB) to a concentration of 5 to 8 mg DNA/ml.
5. While stirring at 4°C, add 4 vol high-NaCl buffer (HNB) dropwise. Add 2-mercaptoethanol to a final concentration of 1% (v/v).

   Make sure each drop of HNB is well mixed before adding the next.
6. Stir for a further 15 min, then pellet the nuclear envelopes in a low-speed centrifuge with swinging-bucket rotor for 30 min at 1600 × *g*, 4°C.
7. Resuspend the pellet in IB and repeat steps 5 and 6, but omit the 2-mercaptoethanol.
8. Harvest the membranes by centrifugation in a low-speed centrifuge with swinging-bucket rotor for 30 min at 1600 × *g*, 4°C.
9. If the membranes are not to be analyzed immediately, suspend in nuclear membrane storage medium (NMSM) and maintain at –20°C.

   Metabolic assays should be carried out as soon as possible upon preparation; however, some enzyme assays can be carried out after storage at 4°C for up to 16 hr. Many assays can be carried out on material frozen to –20°C or –80°C. Always check that the measurements made are relatively unaffected by the storage conditions by comparing with those made on fresh material.

ISOLATION OF NUCLEAR MEMBRANES: LOW-IONIC-STRENGTH METHOD

BASIC PROTOCOL 3

The low-ionic-strength method described in this protocol uses 0.1 mM $MgCl_2$ and is relatively rapid. This method produces fragments that range from incomplete "ghosts" to much smaller pore-sized fragments that retain the lamina and pores and are good for compositional studies (Kay et al., 1972; Harris and Milne, 1974; Rickwood et al., 1997). The protocol is adapted from Kay et al. (1972).

The application of this and other methods to nuclei from sources other than mammalian liver will need to be approached empirically to determine which of these protocols are suitable.

Materials

200 mM PMSF (*APPENDIX 2A*)
Low-ionic-strength suspension medium (LISM; see recipe)
1.0 mg/ml DNase I
Sucrose buffer, pH 7.4 and 8.5 (SB7.4 and SB8.5; see recipe)
NMSM (see recipe)
~10-ml Dounce homogenizer with loose-fitting Wheaton Type B pestle
High-speed centrifuge with fixed-angle rotor for 15-ml tubes

NOTE: All centrifugations are carried out at 4°C and all incubations are at 22°C.

1. Prepare the nuclei (see Basic Protocol 1, Alternate Protocol 1, or Alternate Protocol 2), using 1 mM PMSF in all media, diluted from a 200 mM stock.
2. Suspend the nuclei in low-ionic-strength suspension medium (LISM) to a concentration of 3 to 4 mg DNA/ml (see Support Protocols 1 and 3), using 4 to 5 gentle strokes of the pestle of the ~10-ml Dounce homogenizer.
3. Add DNase I to a final concentration of 5 µg/ml from the 1 mg/ml stock and add 4 vol sucrose buffer, pH 8.5 (SB8.5).
4. Incubate with gentle stirring for 15 min at 22°C and then add an equal volume ice-cold distilled water.
5. Transfer to an appropriate centrifuge tube and centrifuge in a high-speed centrifuge with fixed-angle rotor 15 min at 38,000 × *g*, 4°C.
6. Resuspend the pellet in the same volume of sucrose buffer, pH 7.4 (SB7.4), and add DNase I to a final concentration of 1 µg/ml.
7. Incubate 15 min with gentle stirring at 22°C and then add an equal volume ice-cold distilled water.
8. Centrifuge 15 min at 38,000 × *g*, 4°C. If the membranes are not to be analyzed immediately, resuspend in NMSM and store at –20°C.

   Metabolic assays should be carried out as soon as possible upon preparation; however, some enzyme assays can be carried out after storage at 4°C for up to 16 hr. Many assays can be carried out on material frozen to –20°C or –80°C. Always check that the measurements that are made are relatively unaffected by the storage conditions by comparing with those made on fresh material.

SUPPORT PROTOCOL 1

DIPHENYLAMINE ASSAY FOR DNA

This well-established chemical method for quantifying DNA, devised by Schneider (1957), is still probably one of the best, simplest, and most reliable assays. It measures the deoxyribose released by acid hydrolysis; however, because of interference by other carbohydrates, the DNA of samples in sucrose or any other gradient medium containing a sugar residue (e.g., metrizamide), must be first precipitated with trichloroacetic acid (TCA). Although a later method based on the use of the dye methyl green (Peters and Dahmus, 1979) does not require hydrolysis of the nucleic acid and is compatible with most gradient media, it is necessary to extract the methyl green with chloroform to remove contaminating crystal violet, and some sources of methyl green do not give consistent results (Graham and Ford, 1983).

Materials

500 µg/ml DNA standard solution
5%, 10%, and 20% (w/v) trichloracetic acid (TCA), ice-cold
Samples
Diphenylamine reagent (see recipe)

1. Dilute the 500 µg/ml DNA standard to give 0 to 200 µg DNA in 1.0 ml of 5% (w/v) TCA, diluted from a 20% (w/v) stock.
2. *Optional:* For samples in sucrose, precipitate the DNA by adding an equal volume ice-cold 20% (w/v) TCA.

   Although this is not strictly necessary for iodixanol-containing fractions, it is a useful way of concentrating dilute fractions. Omit steps 2 to 4 if precipitating DNA is not necessary.
3. After 10 min on ice, sediment the DNA by centrifuging in a low-speed centrifuge with a swinging-bucket rotor 20 min at 1000 × *g*, 4°C.
4. Wash the pellet twice in ice-cold 10% TCA.
5. Hydrolyze the DNA in the standards, membrane suspensions, or pellets in 5% (w/v) TCA (1 ml final volume), 20 min at 90°C.
6. Centrifuge 2 min at full speed in a microcentrifuge.
7. To 0.5 ml of each supernatant (and a blank containing 0.5 ml 5% TCA), add 1 ml diphenylamine reagent and heat 10 min at 100°C.
8. Cool to room temperature and measure the absorbance at 595 nm.

ORCINOL ASSAY FOR RNA

SUPPORT PROTOCOL 2

Like the diphenylamine assay for DNA, this simple method was devised by Schneider (1957) and measures the ribose released from RNA by acid hydrolysis. Gradient media (e.g., sucrose, metrizamide) containing carbohydrate residues must be removed by precipitation of the nucleic acid with trichloroacetic acid (TCA) prior to hydrolysis. As the deoxyribose from DNA also interferes, standard curves for both DNA and RNA should be constructed.

Materials

500 µg/ml DNA and RNA standard solutions
5%, 10%, and 20% (w/v) TCA
Samples
Orcinol reagent (see recipe)

1. Dilute the 500 µg/ml RNA and DNA standards to give 0 to 200 µg nucleic acid in 0.5 ml water.
2. *Optional:* For samples in sucrose, precipitate the nucleic acids by adding an equal volume ice-cold 20% TCA.

   Although this is not strictly necessary for iodixanol-containing fractions, it is a useful way of concentrating dilute fractions. Omit steps 2 to 5 if precipitating the DNA is not necessary.
3. After 10 min on ice, sediment the DNA by centrifuging in a low-speed centrifuge with a swinging-bucket rotor 20 min at 1000 × *g*, 4°C.
4. Wash the pellet twice in ice-cold 10% TCA.
5. Resuspend the pellet in 0.5 ml water.
6. To 0.5 ml standards, membrane suspensions, or resuspended pellets, add 0.1 ml water and 0.2 ml 20% (w/v) TCA.
7. Hydrolyze the nucleic acids 20 min at 90°C.

8. Microcentrifuge for 2 min at full speed.
9. To 0.6 ml of all supernatants and a blank containing 0.6 ml of 5% TCA, add 0.6 ml orcinol reagent and heat 20 min at 100°C.
10. Cool to room temperature and measure the absorbance at 660 nm.

To obtain an accurate value of the RNA content of a gradient fraction the contribution of the deoxyribose to the total absorbance must be subtracted. Determine the amount of DNA in the fraction using the diphenylamine method (see Support Protocol 1) and using the orcinol DNA standard curve convert this to an A_{660} value. Deduct this value from the A_{660} of the sample.

SUPPORT PROTOCOL 3

ETHIDIUM BROMIDE ASSAY FOR DNA AND RNA

This very sensitive fluorometric method devised by Karsten and Wollenberger (1972, 1977), although very simple to execute, does require a large number of controls. Although the method avoids the use of the strong acids needed for the chemical method (see Support Protocols 1 and 2), ethidium bromide is extremely toxic. The characteristic fluorescence is produced by the ethidium bromide intercalating the DNA, which therefore indicates that ethidium bromide is a strong mutagen. The alternative fluorescent method (Brunk et al., 1979) using diamidinophenylindole (DAPI) is less potentially harmful, but the binding of the DAPI is highly specific for A-T base pairs, and it is therefore essential that the standard and sample have the same base composition (Graham and Ford, 1983). Both methods are compatible with any gradient medium.

NOTE: Use phosphate-buffered saline with Ca^{2+} and Mg^{2+} (PBSCM) to make all solutions and dilutions in this protocol.

Materials

Phosphate-buffered saline with Ca^{2+} and Mg^{2+} (PBSCM; see recipe)
25 µg/ml DNA standard solution: store at –20°C for 2 to 3 months
25 µg/ml heparin
Sample
50 µg/ml RNase: heat at 100°C for 10 min to denature DNase
25 µg/ml ethidium bromide

3-ml cuvettes
Spectrophotofluorometer with an emission wavelength of 580 nm and an excitation wavelength of 360 nm

CAUTION: Ethidium bromide is a mutagen and should be handled, stored, and disposed of with appropriate care.

1. Just before use, dilute 25 µg/ml DNA standard with an additional 4 vol PBSCM.
2. In 3-ml cuvettes, labeled a to f, make up the following mixtures:
   a. standard: 0.5 ml of 5 µg/ml DNA standard, 0.5 ml heparin solution and 1.0 ml PBSCM
   b. blank I: 0.5 ml heparin solution and 1.5 ml PBSCM
   c. blank II: 2.5 ml PBSCM
   d. sample (DNA + RNA): 0.5 ml sample, 0.5 ml heparin solution and 1.0 ml PBSCM
   e. sample (DNA): 0.5 ml sample, 0.5 ml heparin solution, 0.5 ml 50 µg/ml RNase, 0.5 ml PBSCM
   f. sample blank: 0.5 ml sample, 2.0 ml PBSCM

   Dilute samples as required with PBSCM, in order to dilute the DNA to a level compatible with the assay.

3. Incubate all cuvettes at 37°C for 20 min.
4. Add 0.5 ml 25 µg/ml ethidium bromide to all cuvettes except c and f.
5. Stir the contents before measuring the fluorescence at an emission wavelength of 580 nm and an excitation wavelength of 360 nm.

   The fluorescence of the standard (a) should be set at 100 and the temperature should remain constant (±0.5°C) during the measurements. Measurements should be made at least 1 min after adding the ethidium bromide, but within an hour. Check the RNase solution for fluorescence and subtract if necessary.
6. Calculate the mass of DNA in the sample using the following equation:

$$A_{DNA} = \frac{A_{std}\left(F_e - F_b - F_f + F_c\right)}{F_a - F_b}$$

Calculate the mass of RNA according to the following equation:

$$A_{RNA} = \frac{A_{std}\left(F_d - F_e\right)}{0.46 \times \left(F_a - F_b\right)}$$

where A_{DNA} is the mass of DNA in sample mixture, A_{RNA} is the mass of RNA in sample mixture, A_{std} is the mass of DNA in standard mixture, and F is the fluorescence intensity.

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Diphenylamine reagent

To 100 ml glacial acetic acid add 1 g diphenylamine (1% w/v final) and 2.75 ml concentrated sulfuric acid (H_2SO_4). Store up to 1 month at room temperature.

CAUTION: *Take care when adding the H_2SO_4 and use safety goggles.*

Ethylene glycol homogenization medium (EGHM)

To 100 ml ethylene glycol add 20 mg $MgCl_2 \cdot 6H_2O$ (1 mM final). Store up to 1 month at 4°C.

High-NaCl buffer (HNB)

To 100 ml H_2O add:
23.4 g NaCl (2.0 M final)
40 µl 1 M $MgCl_2$ (*APPENDIX 2A;* 0.2 mM final)
2 ml 1 M Tris·Cl (*APPENDIX 2A;* 10 mM final)
Adjust to pH 7.4 if necessary
Add H_2O to 200 ml
Store 2 to 3 days at 4°C
Immediately before use, add 1 ml of 200 mM PMSF (*APPENDIX 2A*)

continued

Incubation buffer (IB)

To 100 ml H_2O add:
40 µl 1 M $MgCl_2$ (*APPENDIX 2A;* 0.2 mM final)
2 ml 1 M Tris·Cl (*APPENDIX 2A;* 10 mM final)
Adjust to pH 7.4 if necessary
Add H_2O to 200 ml
Store 2 to 3 days at 4°C
Immediately before use, add 1 ml of 200 mM PMSF (*APPENDIX 2A*)

Iodixanol, 50% (w/v)

Dilute 5 vol OptiPrep (60% iodixanol; Axis-Shield; available from Accurate Chemical) with 1 vol OptiPrep diluent for nuclei (ODN; see recipe). Store 2 to 3 days at 4°C.

Iodixanol gradient solution, 30% and 35% (animal cells or tissues)

For 30% and 35% iodixanol, dilute 50% (w/v) iodixanol (see recipe) with NIM (see recipe) at a ratio of 6:4 and 7:3 by volume, respectively. Store 2 to 3 days at 4°C.

Iodixanol gradient solutions, 25% and 40% (wheat germ)

For 25% and 40% iodixanol, dilute OptiPrep (60% iodixanol; Axis-Shield; available from Accurate Chemical) with WGM (see recipe) at a ratio of 2.5:3.5 and 4:2 by volume, respectively. Store 2 to 3 days at 4°C.

Low-ionic-strength suspension medium (LISM)

To 200 ml H_2O, add 20 µl 1 M $MgCl_2$ (*APPENDIX 2A;* 0.1 mM final). Store up to 2 weeks at 4°C.

Nuclear isolation medium (NIM)

To 100 ml H_2O add:
17.1 g sucrose (0.25 M final)
0.37 g KCl (25 mM final)
1 ml 1 M $MgCl_2$ (*APPENDIX 2A;* 5 mM final)
2 ml 1 M Tris·Cl (*APPENDIX 2A;* 10 mM final)
Adjust to pH 7.4 if necessary
Add H_2O to 200 ml
Store 2 to 3 days at 4°C

Nuclear membrane storage medium (NMSM)

To 100 ml H_2O add:
40 ml glycerol (20% v/v final)
2 ml 100 mM disodium EDTA (*APPENDIX 2A;* 1 mM final)
2 ml 1 M Tris·Cl (*APPENDIX 2A;* 10 mM final)
Adjust to pH 7.5 if necessary
Add H_2O to 200 ml
Store 2 to 3 days at 4°C

Nuclei suspension medium (NSM)

To 100 ml H_2O add:
17.1 g sucrose (0.25 M final)
1 ml 1 M $MgCl_2$ (*APPENDIX 2A;* 5 mM final)
10 ml 1 M Tris·Cl (*APPENDIX 2A;* 50 mM final)
Adjust to pH 7.4 if necessary
Add H_2O to 200 ml
Store 2 to 3 days at 4°C
Immediately before use add 1 ml of 200 mM PMSF (*APPENDIX 2A*)

OptiPrep diluent for nuclei (ODN)

To 100 ml H_2O add:
17.1 g sucrose (0.25 M final)
2.22 g KCl (150 mM final)
6 ml 1 M $MgCl_2$ (*APPENDIX 2A;* 30 mM final)
12 ml 1 M Tris·Cl (*APPENDIX 2A;* 60 mM final)
Adjust to pH 7.4 if necessary
Add H_2O to 200 ml
Store 2 to 3 days at 4°C

Orcinol reagent

To 50 ml concentrated HCl, add 0.5 g orcinol (1% w/v final) and 0.25 g $FeCl_3 \cdot 6H_2O$ (0.5% w/v final). Make up fresh and keep on ice until required.

Phosphate-buffered saline with Ca/Mg (PBSCM)

To 100 ml H_2O add:
0.026 g $CaCl_2 \cdot 2H_2O$ (0.9 mM final)
0.04 g KCl (2.68 mM final)
0.04 g KH_2PO_4 (1.47 mM final)
100 µl 1 M $MgCl_2$ (*APPENDIX 2A*; 0.5 mM final)
0.16 g NaCl (0.137 M final)
0.23 g Na_2HPO_4 (8.1 mM final)
Adjust to pH 7.5 with NaOH or HCl
H_2O to 200 ml
Store up to 1 week at 4°C

Sucrose buffer, pH 7.4 (SB7.4), pH 8.5 (SB8.5)

Sucrose buffer, pH 8.5 (SB8.5)
To 100 ml H_2O add:
20.5 g sucrose (0.3 M final)
20 µl 1 M $MgCl_2$ (*APPENDIX 2A;* 0.1 mM final)
78 mg 2-mercaptoethanol (5 mM final)
0.37 g triethanolamine (10 mM final)
Adjust to pH 8.5 with HCl
Add H_2O to 200 ml
Store 2 to 3 days at 4°C

Sucrose buffer, pH 7.4 (SB7.4)
Prepare as SB8.5, but adjust to pH 7.4

Sucrose density barrier (SDB)

To 95 ml H_2O add:
157 g sucrose (2.3 M final)
0.37 g KCl (25 mM final)
1 ml 1 M $MgCl_2$ (*APPENDIX 2A;* 5 mM final)
2 ml 1 M Tris·Cl (*APPENDIX 2A;* 10 mM final)
Adjust to pH 7.4 if necessary
Add H_2O to 200 ml
Store 2 to 3 days at 4°C

(continued)

Wheat germ medium (WGM)

To 100 ml H_2O add:
27.4 g sucrose (0.4 M final)
0.37 g KCl (25 mM final)
1 ml 1 M $MgCl_2$ (*APPENDIX 2A*; 5 mM final)
0.39 g 2-(*N*-morpholino)sulfonic acid (MES; 10 mM final)
Adjust pH to 6.2 with NaOH
Add H_2O to 200 ml
Store 2 to 3 days at 4°C

COMMENTARY

Background Information

Isolation of nuclei from a mammalian tissue homogenate has proved to be one of the easier tasks of sucrose density gradient separation technology. In a homogenate the nuclei are generally regarded as the largest organelle (4 to 12 μm in diameter), although some plasma membrane sheets, often present in a tissue homogenate but not in homogenate from cultured cells, may be up to 20 μm in length. Consequently a "low-speed" or "nuclear" pellet, produced by centrifugation of a homogenate at 500 to 1000 × *g* for 10 min, will contain these two components, plus some of the largest mitochondria. Unbroken tissue, cells, and connective tissue also sediment under these conditions, and this is the reason why nuclear isolation methods invariably preface the low-speed centrifugation with a filtration step to remove these elements which would otherwise contaminate the nuclear pellet and compromise the subsequent gradient fractionation. Smaller subcellular particles will also contaminate the pellet because of entrapment and the inefficiency of differential centrifugation (*UNIT 3.3*). These can be partially removed by washing the pellet, but this might be regarded as superfluous, as any subsequent gradient will resolve these contaminants, since the density of nuclei (>1.32 g/ml in sucrose) is also greater than that of any other major subcellular component.

It is also possible to purify the nuclei from a low-speed pellet by washing the crude nuclei in a medium containing 0.5% Triton X-100 in order to solubilize contaminating membranes (Hoffmann and Chalkley, 1978); however, the method tends to make the nuclear membrane rather more fragile, the nuclei prone to aggregation, and endogenous nuclease activity can be activated (Rickwood et al., 1997). Thus, density barrier centrifugation is the most widely used technique. As the nuclei are the largest and densest of all the subcellular organelles, simple density barriers or discontinuous gradients are usually effective for their purification.

Sucrose solutions are not dense enough to band nuclei (ρ > 1.32 g/ml in sucrose) within a gradient; thus, pelleting through a 2.2 to 2.3 M sucrose density barrier is the only option. Because of the high viscosity of the sucrose density barrier, the sedimentation of the particles is very slow and the nuclei lose much of the water from their internal space due to the osmotic gradient across the membrane. This process may disrupt the macromolecular structures, which are normally highly hydrated. Nevertheless, the nuclei do rehydrate when they are transferred back to an isoosmotic medium, and the method is still widely used. After centrifugation of sucrose barriers at 100,000 to 200,000 × *g* (for up to 1 hr), the nuclei are recovered as a pellet. Because resuspension of the pellet is sometimes difficult (aggregation of the nuclei is often a problem), banding the organelles at an interface offers some significant benefits.

Although both CsCl and sodium diatrizoate can provide solutions of sufficient density to band nuclei at an interface, their ionic strength can cause disruption of the nucleoprotein structure, unless the chromatin is first fixed using a cross-linking agent such as formaldehyde to prevent dissociation of the protein from DNA (Gollin and Wray, 1984). However, the nonionic iodinated density gradient media can be used in this mode. With iodixanol, the gradient is isoosmotic, so the nuclei do not become condensed. Consequently, they have a much lower density (i.e., 1.20 to 1.22 g/ml), and the lower viscosity of the density gradient allows the separation to be carried out at much lower RCFs (i.e., 10,000 × *g* for 20 min) than with sucrose. It is also considered unnecessary to produce a crude nuclear fraction first. The recommended strategy is to adjust the homogenate with OptiPrep, or a high-density working solution produced from it, to a density that is higher than most organelles (ρ = ~1.16 g/ml), and layer

it over a double iodixanol barrier (ρ = 1.175 and 1.20 g/ml, respectively). In mammalian cells, the only other organelles that have a density approaching that of nuclei are peroxisomes (Graham et al., 1994), but, as they are much smaller, only the nuclei have the size and density to band above the densest layer at the relatively-low *g* forces (i.e., 10,000 × *g*) and short times (i.e., 20 min) used in this method (Graham et al., 1994; Provost et al., 1996).

Early methods that attempted to use nonaqueous media for the isolation of organelles relied on organic solvents such as benzene and carbon tetrachloride and the preparation of lyophilized cells and tissues, so it is hardly surprising that they never attained any degree of popularity whatsoever (see Rickwood et al., 1997 for more information). Nevertheless, a method such as homogenization of lyophilized cells in pure glycerol (Gurney and Foster, 1977) may be useful for analysis of inorganic ions and soluble proteins which are normally leached out by the normal aqueous media. However, the method developed by Rickwood et al. (1997), in which the liver is homogenized in ethylene glycol and the nuclei are purified in gradients of Nycodenz in the same solvent, probably provides a much more acceptable manner for avoiding the use of aqueous media (see Alternate Protocol 2).

Critical Parameters and Troubleshooting

Homogenization

For mammalian tissues, inclusion of divalent cations in the homogenization medium, usually in the form of $MgCl_2$ ($CaCl_2$ is generally avoided because of the problem of Ca^{2+}-stimulated phospholipases), as well as KCl in buffered 0.25 M sucrose, helps to stabilize and preserve nuclear structure (e.g., the 0.25 M sucrose/25 mM KCl/5 mM $MgCl_2$/10 mM Tris·Cl, pH 7.4 medium; see Basic Protocol 1). This buffer was devised by Blobel and Potter (1966). While KCl is sometimes omitted, inclusion of $MgCl_2$ is invariant; Widnell and Tata (1964), for example, used 0.25 M sucrose/5 mM $MgCl_2$/10 mM Tris·Cl, pH 7.4. For nuclei from nonmammalian sources, inclusion of Mg^{2+} is also common, although the details of the homogenization medium are generally specific for the organism. Yeast spheroplasts have been homogenized in 8% polyvinylpyrrolidone (PVP; M_r 40,000)/1 mM $MgCl_2$/0.02 M KH_2PO_4/0.02% Triton X-100, while for intact yeast cells an Mg^{2+}-free medium has been used (i.e., 1 M sorbitol/20% glycerol/5% PVP), and for plant cells the media are even more diverse. For a review of these media see Rickwood et al. (1997).

With mammalian liver, KCl and $MgCl_2$ can be present at all stages of the procedure, including homogenization. On the other hand, homogenization media for hard tissues (e.g., skeletal muscle) may contain KCl, but they may also contain EDTA rather than Mg^{2+}. In such circumstances, isolation procedures need to be developed empirically. If adequate homogenization does not occur in the absence of EDTA, or in the presence of Mg^{2+}, then a compromise must be reached in which the tissue or cells are homogenized in a suitable medium and then an isoosmotic medium containing KCl and/or $MgCl_2$ might be added to the homogenate. Alternatively the nuclei can be pelleted and then resuspended in a KCl/$MgCl_2$ medium.

The same problem applies to cultured cells in which it is common to use media that are not ideally suited to nuclei (e.g., 0.25 M sucrose/1 mM EDTA/10 mM triethanolamine-acetic acid, pH 7.4 medium; Marsh et al., 1987). If the cells do not disrupt readily in an isoosmotic Mg^{2+}-containing medium, then it may be better to use a hypoosmotic medium such as 15 mM KCl/1.5 mM magnesium acetate/1 mM dithiothreitol/10 mM HEPES-KOH, pH 7.5 (Goldberg and Kornfeld, 1983; Dunphy and Rothman, 1985). Birnie (1978) recommended a swelling medium of 10 mM NaCl/1.5 mM $MgCl_2$/10 mM Tris·Cl, pH 7.4. After homogenization, the medium is returned to isoosmoticity by adjusting to 0.25 M sucrose. With cultured-cell nuclei, it is also common to include a number of washing steps prior to centrifugation through 2.2 to 2.3 M sucrose. Moreover, Birnie (1978) used a Ca^{2+}-containing buffer (0.25 M sucrose/3 mM $CaCl_2$/10 mM Tris·Cl, pH 7.4) as a wash medium; apparently Ca^{2+}-stimulated phospholipases are less of a problem with cultured cells (i.e., as compared to liver).

For cells and tissues that do not homogenize satisfactorily in any of these media, the method adopted by Wray et al. (1977) may be useful. Homogenization of liver in 0.5 M hexylene glycol (2 methyl-2,4-pentanediol)/1.0 mM $CaCl_2$/50 mM PIPES, pH 7.5, allowed the isolation of nuclei with good functional integrity. Although this method only produced a yield of 40% to 50%, it was applicable to a very wide range of tissues, including those which do not respond well to the normal sucrose-based meth-

Table 3.10.1 Enzyme Content of Nuclear Membranes[a]

	Glucose-6-phosphatase activity (μmol phosphate/hr/mg/protein)	NADHCR[b] activity (μmol cytochrome *c* reduced/hr/mg/protein)	DNA polymerase activity (pmol TMP incorporated/min/mg protein)

[b]NADHCR = NADH cytochrome *c* reductase.

ods (e.g., Novikoff hepatoma cells and mouse brain).

Selection of a suitable nonaqueous system is a difficult problem, and the approach adopted by Rickwood et al. (1997) is something of a compromise in that, although the homogenization medium is nonaqueous, water will be present in the tissue since lyophilization is not used. Although such an approach cannot remove cytosolic water, the water in the liver vasculature can be eliminated by perfusion with ethylene glycol prior to homogenization, if this is regarded as important. Use of a nonaqueous medium generally makes homogenization more difficult, and the liver should be minced very finely before using the Potter-Elvehjem homogenizer; indeed it may be advantageous to use a small mincer rather than scissors.

Isolation of mammalian nuclei by sucrose density gradient centrifugation

At the high concentrations of sucrose used in the first protocol of this unit (see Basic Protocol 1), the extreme viscosity is a major problem, not only in preparing the solutions, but also in accurate dispensing of aliquots into centrifuge tubes. It may be easier to make up the solutions on a weight/weight basis, rather than to try and dissolve the sucrose in a smaller volume than the final, and then make up to the volume (e.g., 2.2 and 2.3 M sucrose are equivalent to 59% and 61% w/w, respectively). However, it should be noted that the liquid used to dissolve the sucrose should contain approximately twice the required concentrations of buffer and salts to allow for "dilution of the water by the sucrose." If the crude nuclear pellet is resuspended directly in 2.3 M sucrose rather than in 0.25 M sucrose first (see Basic Protocol 1, step 14), great care has to be taken to ensure that the pellet is properly resuspended; using such a viscous medium in an homogenizer is technically difficult.

Isolation of mammalian nuclei by iodixanol density gradient centrifugation

For material other than mammalian liver it may be necessary to modulate the density of the three layers of iodixanol and/or increase the time of centrifugation (see Alternate Protocol 1). This separation is based to some extent on the sedimentation rate of the nuclei as well as their density. In dense hyperosmotic sucrose, all nuclei shrink and attain the same limiting density irrespective of their real size and density. In isoosmotic iodixanol gradients, the organelles retain their native size and density; therefore, the rate at which they sediment and their banding density may vary with the material source.

Gradient purification of nonmammalian nuclei

Nuclei from plant cells pose additional problems in that other subcellular particles such as chloroplasts and starch granules sediment at low RCFs and are as dense or denser than nuclei in sucrose gradients. Consequently, sucrose gradients are ineffective for resolving and purifying plant cell nuclei; however, since nuclei are much less dense in iodixanol than in sucrose, the opportunity exists for resolution in these gradients. Ford et al. (1998) reported that starch granules are able to pellet through an iodixanol solution of density 1.234 g/ml, and that centrifugation of a crude nuclear preparation over a discontinuous gradient of iodixanol (i.e., 1.167 and 1.234 g/ml) produces nuclei free of starch granules at the lower interface. It is not known at what density chloroplasts band in this system. Rickwood et al. (1997) also noted that the melanin granules of *Xenopus* liver also pellet with the nuclei in sucrose and that only a 58% (w/v) metrizamide barrier (i.e., 10,000 × *g* for 20 min) was effective in separating these particles (the melanin granules pellet). At this concentration, metrizamide is hyperosmotic

and it may be possible to use a lower concentration of iodixanol.

Nuclear membranes

In the 1970s, two quite different strategies were evolved for the isolation of nuclear envelopes from mammalian liver nuclei. One used high concentrations of $MgCl_2$ (i.e., 0.5 to 0.7 M) to disrupt the nuclear chromatin (Monneron et al., 1972) while the other used low-ionic-strength media (Kay et al., 1972; Harris and Milne, 1974). Since that time, these two basic strategies have been developed almost in parallel, with some workers favoring high ionic strength and others low ionic strength.

There are no particular technical problems associated with either method of nuclear membrane preparation (see Basic Protocols 2 and 3). Either method works well for rat liver; only experimentation will reveal whether this is true for other tissues and cells. Choice of methodology depends to some extent on the subsequent studies to be carried out on the envelopes. The high-ionic-strength method produces nucleus-sized hollow spheres, which are good for permeability studies. The yield of envelopes is very high and they are intact, retaining the lamina and pores. Low-ionic-strength procedures tend to produce high-purity fragments of the nuclear membrane, with intact pores and lamina, and are particularly good for compositional studies. The fragments of membrane have a variety of sizes ranging from incomplete "ghosts" to much smaller pore-sized fragments; therefore, a high-speed centrifuge is required to harvest the membranes in high yield. The high-ionic-strength procedure, on the other hand, in which the whole envelope is retained, requires only a low-speed centrifuge. All the modern methods incorporate the use of enzymes to digest the released nucleic acids.

Assays

Determination of the purity of a nuclear preparation can be assessed by phase-contrast microscopy (i.e., absence of any particles other than nuclei) and measurement of DNA and RNA. The chemical methods that measure the content of either deoxyribose or ribose (Schneider, 1957) are probably the most widely used. Neither Nycodenz nor iodixanol interferes significantly, but sucrose, metrizamide, and other sugar-containing molecules do. The newer fluorometric methods (Karsten and Wollenberger, 1972, 1977) are certainly more sensitive and are unaffected by most gradient media. There are no easily measurable enzyme markers for the nuclear membrane, but enzymes that are characteristic of the endoplasmic reticulum (ER) are found in nuclear and nuclear-membrane preparations. Since there is evidence for some continuity between the outer nuclear membrane and the ER, this is probably not surprising, but the levels of enzymes such as glucose-6-phosphatase, NADH cytochrome *c* reductase, and NADPH cytochrome *c* reductase (*UNIT 3.5*) observed in nuclear membrane preparations suggest that they are true components, rather than merely a reflection of the presence of some "attached" ER. It is more common to express the purity of nuclei in terms of the DNA and RNA content and in addition, protein and phospholipid, for nuclear membrane fractions (see Anticipated Results).

Anticipated Results

Nuclei

The yield of nuclei is measured in terms of percentage recovery of DNA from the homogenate, and for both the sucrose and iodixanol methods a figure of at least 90% is expected. Approximately 4% of the total RNA is recovered in the nuclear pellet, and the DNA/RNA ratio should be ~0.11. By phase-contrast microscopy, the nuclei should appear as characteristic dark-gray structures, 4 to 12 μm in diameter, and although smaller organelles cannot be discerned at the levels of magnification achievable by this technique, there should be a complete absence of any "stippled" background. In neither method can any marker enzymes of any other membrane be detected, except those of the ER (e.g., glucose-6-phosphatase and NADH cytochrome *c* reductase), which may be present at specific activities that are characteristically 10% to 15% of the levels in microsomes.

Nuclear membranes

Because the preparation of nuclear membranes is always made from previously purified nuclei, it is common to express efficacy of the membrane separation procedure in terms of the percentage recovery of protein, DNA, RNA, and phospholipid from the nuclei. Typical values are 8% to 12%, 0.6% to 2%, 6% to 8%, and 55% to 60%, respectively (Kay et al., 1972; Monneron et al., 1972). Phospholipid is only present in the membrane, so 55% to 60% is also a measure of the overall recovery of nuclear membranes. The relative amounts of each of these four components in the membrane is

typically 73%, 0.6%, 3%, and 20%, respectively, by weight.

Table 3.10.1 gives the specific activity of some typical enzyme markers in the nuclear membranes, and, for comparison, levels in the nuclei and in the microsomes (Kay et al., 1972). There is a clear enrichment in the nuclear membrane (i.e., compared to the nuclei) of the two enzyme markers, which are generally regarded as characteristic of the endoplasmic reticulum (glucose-6-phosphatase and NADH cytochrome *c* reductase). The specific activity of the glucose-6-phosphatase, in particular, is close to that of the microsomes, and thus this enzyme would appear to be a true component of the nuclear membrane rather than a result of contamination by the ER. It should be noted that in some preparations the levels of glucose-6-phosphatase are much lower (for a review of this data, see Harris and Agutter, 1976). The situation with the NADH cytochrome *c* reductase is rather less clear, in as much as the membranes contained <10% of the protein present in the nuclei, but the specific activity of this enzyme only increased approximately twofold. Again the reported levels for this enzyme vary considerably (Harris and Agutter, 1976).

Time Considerations

There are no points at which any of the basic or alternate protocols can be interrupted. The crude nuclear fraction (see Basic Protocol 1) must be used immediately for any subsequent density barrier or gradient separation. Discontinuous (see Alternate Protocol 1) and continuous gradients (see Alternate Protocol 2) should be made up immediately prior to use, although time can be saved by preparing these gradients during the immediately previous step or steps. Basic Protocol 1 and Alternate Protocol 2 will take about 2.5 hr, while the shorter centrifugation time and avoidance of use of an ultracentrifuge means that Alternate Protocol 1 can be accomplished in less time (i.e., ~1.75 hr).

Nuclear membrane preparations should be executed as soon as possible upon purification of the nuclei. Basic Protocol 2 will take about 3.15 hr, while Basic Protocol 3 is more rapid (i.e., ~1.75 hr).

Functional assays should be carried out as soon as possible after the preparation, but for simple marker-enzyme assay, material can be stored at 0° to 4°C for up to 16 hr without much loss of activity. Enzyme assays may be carried out on nuclear membrane preparations frozen to –20° or –80°C, but when frozen nuclei are thawed, the tendency to leak DNA may cause serious aggregation. There are no general rules regarding the suitability of a particular storage regime, and it is strongly recommended that the validity of results on stored material be checked by comparison with those made on fresh organelles. Chemical assays for DNA and RNA, which may take up to 3 hr if the DNA is precipitated first, can be carried out on frozen material, although again the aggregation that can occur when frozen suspensions of nuclei are thawed may cause sampling errors. The ethidium bromide assay for DNA and RNA is very rapid and will take no more than 1 hr, and this is also best carried out on unfrozen material. Any concentration of the membrane fractions and/or removal of gradient medium must be carried out prior to freezing.

All the solutions can be made ahead of time and stored at 4°C for 1 to 2 days or frozen to –20°C for longer periods; however, note that any enzymes, PMSF, or other protease inhibitors, should be added immediately prior to use.

Free-Flow Electrophoretic Analysis of Endosome Subpopulations of Rat Hepatocytes

Endosomes constitute a functionally, morphologically, and biochemically heterogeneous population of intracellular organelles that play a major role in sorting of incoming ligands, receptors, membrane, and content. To characterize their composition and properties, highly purified endosomes are required. Given the heterogeneity of endosomes and the lack of a general and suitable marker, endosome subpopulations have to be specifically labeled by pulse-chase internalization of ligands routed to the pathway of interest. However, due to their heterogeneity and similarity in buoyant density to other intracellular organelles, isolation procedures using standard cell fractionation techniques usually do not result in sufficient purification and adequate resolution of the endosome population of interest. Thus, alternative protocols have to be used for endosome purification. These involve the selective modification of the density of endosomes, immunoisolation, and free-flow electrophoresis (FFE). The latter technique has been applied to isolate highly purified and, most importantly, functional endosomes from cultured cells and tissues (Marsh et al., 1987). Furthermore, endosome subpopulations can be resolved by FFE, allowing for the kinetic analysis of ligand transport through distinct endosome compartments (Schmid et al., 1988).

This unit describes the application of FFE for analysis of endosome subpopulations of polarized rat hepatocytes (see Basic Protocol). As a prerequisite, endosomes involved in transport to lysosomes and transcytosis have to be labeled. In rat liver, asialoorosomucoid (ASOR) and polymeric immunoglobulin A (pIgA) can be used as ligands to selectively label the lysosomal and transcytotic route in hepatocytes. The respective receptors—i.e., the asialoglycoprotein receptor (ASGPR) and the pIgA receptor (pIgR)—are expressed in parenchymal but not in other cells in the liver. Procedures for preparation of ASOR, fluorescein isothiocyanate (FITC)-ASOR, and [^{125}I]pIgA are detailed in Support Protocols 4, 5, and 6, respectively. In vivo labeling of rat liver endosomes is achieved by intravenous injection of the ligands. As starting material for the FFE separation, endosome-enriched fractions have to be prepared from rat liver homogenates. The FFE protocol (see Basic Protocol) can be extended for the preparative isolation of endosomes from rat liver (see Alternate Protocol). The characterization of the endosome-containing FFE-fractions with respect to contamination by other intracellular organelles and the analysis of the protein composition are outlined in Support Protocols 1 and 2, respectively. Highly purified endosomes obtained by FFE are fully functional with respect to in vitro endosome acidification as described in Support Protocol 3.

FREE-FLOW ELECTROPHORESIS OF HEPATOCYTE ENDOSOMES

BASIC PROTOCOL

Endosome subpopulations of rat hepatocytes can be most accurately labeled in the isolated perfused liver using single-pass perfusion and a pulse-chase protocol (Mueller and Hubbard, 1986; Perez et al., 1988). This method, however, requires a skillful person trained in this specific operating technique and the instruments (e.g., pumps, drop counter, bile flow recorder) for the isolated perfusion of the liver. For a detailed description of the method see Exton (1975). Alternatively, markers can be injected into the rat for in vivo endosome labeling (Hoppe et al., 1985). However, using in vivo marker injection, a detailed pulse-chase protocol for two or more endocytic markers is not applicable and consequently the labeling of distinct endosome subpopulations is less precise in comparison to the isolated perfused liver. Nevertheless, the endosomes are well resolved from the

Contributed by Renate Fuchs and Isabella Ellinger
Current Protocols in Cell Biology (2002) 3.11.1-3.11.31

main protein peak and the kinetics of marker transport through distinct subcompartments can also be analyzed.

For FFE separation of rat liver endosomes, the sample injected into the FFE apparatus must already be considerably enriched in endosomes with respect to the original homogenate. This can be achieved by differential centrifugation of the initial homogenate, preparation of microsomes, and flotation of microsomes in discontinuous sucrose density gradients. The protocol for preparation of endosome-enriched fractions described below (also see Fig. 3.11.1) is a modification of the method used by Khan et al. (1986) and has been successfully used as starting material for FFE isolation of rat liver endosomes (Fuchs et al., 1989; Stefaner et al., 1997).

Endosome-enriched fractions prepared from rat liver are used as the starting material for the separation of endosome subpopulations from each other—and from contaminating organelles such as plasma membrane, endoplasmatic reticulum, and lysosomes—by free-flow zone electrophoresis, also known as continuous flow electrophoresis (the

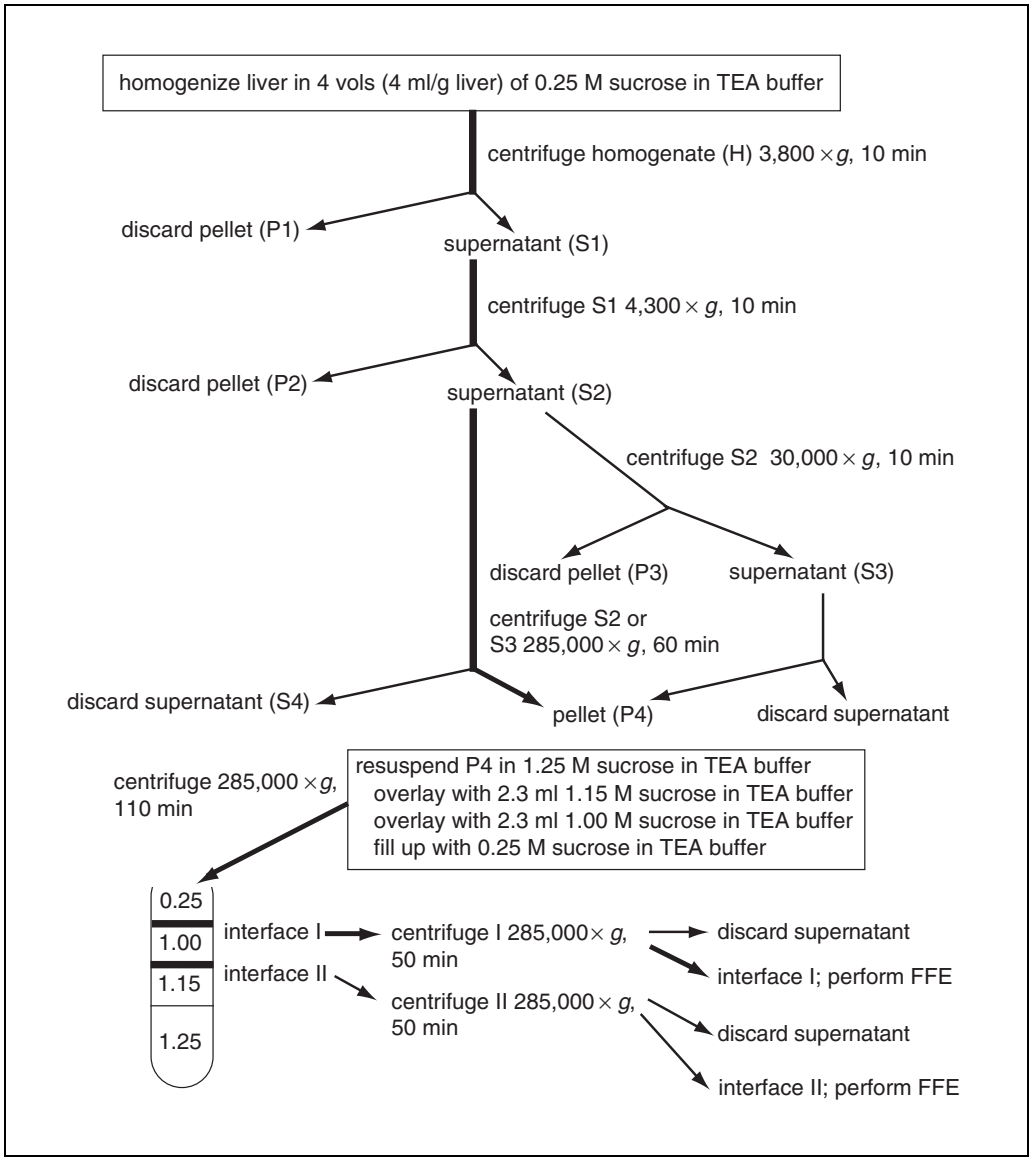

Figure 3.11.1 Flow chart of the fractionation protocol applied to prepare endosome-enriched fractions (interface I and interface II) from rat liver. Interface I and II are subsequently subjected to separation by free-flow electrophoresis (FFE).

abbreviation FFE is used in this protocol for this specific type of free-flow electrophoresis). The starting membrane material is treated with trypsin, a procedure which alters the electrophoretic mobility of endosomes and lysosomes (Marsh et al., 1987). Samples are then injected as a fine jet into the chamber of the FFE apparatus, where they are subjected to separation by the laminar flow of the chamber buffer and an high-voltage electrical field. Endosomes are deflected more towards the anode from the flow direction of the medium and contaminating organelles such as plasma membranes and endoplasmic reticulum. Among the endosome subpopulations, late endosomes are more deflected towards the anode than transcytotic or early endosomes, respectively (Schmid et al., 1988; Stefaner et al., 1997). Once the samples have reached the end of the separation chamber at the top, they can be fractionated continuously and collected by means of a 96-fold splitting device. The presence of endosomes and other organelles in these fractions is then identified by determination of endosomal markers and organelle-specific marker enzyme activities.

Carrier-free high voltage electrophoresis involves high-tech instruments. The user must have well-founded knowledge with regard to the theory and practice of the method and operation of the instrument. The protocol described below has been established for the Elphor VaP 22, Bender and Hobein, FFE apparatus. Application of the protocol to other free-flow electrophoresis instruments (e.g., Octopus) might require modifications with respect to buffer volumes, chamber buffer flow, sample flow rate, and voltage/current.

CAUTION: Wear gloves and carry out experiments in radioactivity-certified areas. This procedure must be performed in a laboratory certified for work with ^{125}I-labeled material. All personnel using radioactive material must be properly trained. Make sure that all radioactive waste (including the rat corpse and perfusion buffer) is disposed appropriately (also see *APPENDIX 1D*).

NOTE: All solutions, rotors, centrifuge tubes and glassware should be prechilled to 4°C and kept on ice throughout the isolation procedure. All manipulations and centrifugations following step 17 are carried out at 4°C.

NOTE: All protocols using live animals must be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) and must conform to government regulations regarding the care and use of laboratory animals. Anesthesia, surgery, and killing of the rats should be supervised or carried out by an experienced animal technician.

Materials

150- to 200-g male Sprague-Dawley rats (e.g., Taconic Farms, The Jackson Laboratory)

Urethane anesthetic solution: 10 g urethane ethyl carbamate/10 ml 0.9% (w/v) NaCl (prepare immediately before use)

0.25 M, 1 M, 1.15 M, and 2.5 M sucrose in TEA buffer, ice cold (see recipes)

Endocytic tracers: 220 µg FITC-ASOR (see Support Protocols 4 and 5) and 1.4×10^6 cpm [^{125}I]pIgA (see Support Protocol 6) per 500 µl phosphate-buffered saline (PBS; *APPENDIX 2A*)

Protease inhibitor solutions (*UNIT 3.4*)

1× TEA buffer (see recipe)

FFE chamber buffer (see recipe)

FFE electrode buffer (see recipe)

1 mg/ml trypsin solution (trypsin-TPCK treated; Worthington), freshly prepared

2 mg/ml trypsin inhibitor solution (trypsin inhibitor, Type I-S, from soybean; Sigma-Aldrich), freshly prepared

2-ml syringes and 25-G needles

Plastic dissecting trays (~15 cm width × 30 cm length) with legs (~8 cm height)
Plastic basins (~35 cm width × 35 cm height × 15 cm depth)
500-ml buffer reservoir with outlet at bottom and connecting tube to fit the 18-G cannula (e.g., 500 ml squibb, separatory pear-shaped funnel with stopcock; Cole Parmer No. P-34506-04) or 500 ml aspirator bottle)
Cannula (e.g., 18-G plastic cannula)
Dissecting instruments including: microscissors, scissors, and curved forceps
4-0 surgical silk
15-ml and 40-ml Dounce homogenizers (Kontes Glass) with loose- and tight-fitting pestles (size A and B, respectively)
50-ml thick-walled polycarbonate centrifuge tubes for Beckman J6-B centrifuge
Low-speed centrifuge with swinging bucket-rotor for 50-ml tubes (e.g., Beckman J6-B)
30-ml thick-walled polycarbonate centrifuge tubes for Sorvall SS-34 rotor
High-speed centrifuge (e.g., Sorvall RC-5B) with fixed-angle rotor (e.g., Sorvall SS-34 rotor) for 30-ml tubes
14-ml Ultraclear ultracentrifuge tubes
Ultracentrifuge (e.g., Beckman L8-55) with swinging-bucket rotor (e.g SW 40 or equivalent)
1-ml and 2-ml syringes with blunt-ended 1.8 × 18–mm needles (for underlaying gradients)
Zeiss Refractometer
5-ml syringe with blunt-ended 1.8 × 10–mm needle (for collecting fractions from gradients)
2-ml syringe with 0.6 × 30–mm blunt-ended needle (for resuspending pellets)
Conductivity meter
FFE apparatus (e.g., Elphor VaP 22, Bender and Hobein)

Additional reagents and equipment for determining the protein concentration according to Bradford (*APPENDIX 3B*)

Label hepatocellular endosomes in situ

1. Starve a 150-to 200-g male Sprague-Dawley rat overnight.

   For analytical separation, one 7- to 10-g liver provides sufficient material. For preparative work (see Alternate Protocol), use up to 30 g of liver at a time (three to four rats and scale up volumes proportionally to number of livers used).

2. Anesthetize rats by an intraperitoneal injection of urethane anesthetic solution (1 ml per 100 g body-weight), using an 25-G needle.

3. Shave abdomen of rat.

4. Fasten animal on a plastic tray (~15 cm × 30 cm with legs ~8 cm in height) using adhesive tape and place the tray in a plastic basin (~35 cm × 35 cm × 15 cm) to collect blood and perfusion buffer contaminated with ^{125}I.

   Make sure that the dimensions of the plastic basin are large enough to collect the entire fluid dropping from the plastic tray.

Perfuse the liver

5. Place a buffer reservoir with an outlet at the bottom ~50 cm above the animal. Fix a tube to the outlet that is long enough to allow for connection to a cannula (e.g., an 18-G plastic cannula) to be placed later into the portal vein of the rat (step 9). Fill the reservoir and the tube with ~500 ml ice-cold 0.25 M sucrose in TEA buffer.

6. Open the abdomen widely by a midline incision without injuring liver or diaphragm. Expose the liver by gently moving intestines to the left side of the rat to gain easy access to the liver, the portal vein, and the inferior vena cava.

7. Prepare two ligatures of 4-0 silk in loose knots around the portal vein 1 to 2 cm and 4 to 5 cm, respectively, before the vessel enters the liver. Leave bile duct exterior to the ligatures.

8. Inject endocytic tracers (e.g., 220 µg FITC-ASOR and 1.4×10^6 cpm ^{125}I-pIgA in 500 µl PBS) into the saphenous vein using a 2-ml disposable syringe with a 25-G needle.

   The endocytic tracers FITC-ASOR and [^{125}I]-pIgA can be injected simultaneously in 500 µl PBS or successively (e.g., each tracer in 500 µl PBS) to label the endosome subpopulation of interest. Due to variability of the animals, the injection procedure and the resulting labeling of the individual endosome subpopulation, injection of two or more tracers in the same animal is required.

   If labeling is carried out for more than 5 min, the body temperature of the animal should be stabilized by e.g., covering the body with paper towels and placing the animal under a 60 W light bulb.

9. At the end of the labeling time (1 to 20 min), hold the portal vein with forceps and incise on the ventral surface with a fine pair of scissors between the two prepared ligations. Lift and steady the vein and insert the cannula into the hepatic portal vein. Immediately remove the needle and place the tip of the cannula ~3 mm before the first bifurcation of the portal vein to ensure perfusion of all lobes. Fix the cannula with the ligature proximal to the liver and then also tie the distal ligature.

10. Remove any air bubble at the end of the cannula by adding ice-cold 0.25 M sucrose in TEA buffer from a syringe with a 25-G needle immediately before it is connected to the tube. Then rapidly connect the cannula air bubble-free to the tube and start to perfuse the liver with ice-cold 0.25 M sucrose in TEA buffer by gravity.

    When labeling endosomes, a rapid subsequent perfusion with ice-cold 0.25 M sucrose in TEA buffer is important to halt endocytic processes. In addition, this perfusion will remove any contaminating blood and extracellular marker trapped within the liver. Since binding of ASOR to the ASGPR is calcium dependent, plasma membrane bound FITC-ASOR is also removed using this calcium-free and EDTA-containing TEA buffer.

11. Cut the inferior vena cava soon after connecting the cannula to the tube.

    If this is not done, back-pressure will damage the liver. The perfusion fluid is allowed to drain from the vena caba into the body and then drain into the basin. The fluid remaining in the corpse after removing the liver should be drainedi nto the basin before disposal of the corpse.

12. After perfusion, cut the diaphragm and immediately proceed to prepare endosome-enriched fractions, beginning with step 13.

    All subsequent steps are performed at 4°C.

Isolate and mince liver

13. After in vivo labeling of hepatocyte endosomes and perfusion of the liver with ~500 ml ice-cold 0.25 M sucrose in TEA buffer, carefully excise the liver and cut away connective tissue.

14. Determine the liver weight and place the liver in a prechilled beaker containing 4 vol (4.0 ml/g liver) of 0.25 M sucrose in TEA buffer (i.e., 28 ml) with protease inhibitors on ice.

For the case of 150- to 200-g male Sprague-Dawley rats, the range of liver weight is 7 to 10 g. The conditions described below are based on a liver weight of 7 g.

15. Use scissors to mince the liver into ~0.5-cm^3 pieces. Pour the mixture into a 40-ml Dounce homogenizer.

    If the liver weighs more than 10 g, divide it into two equal portions and homogenize separately.

Homogenize the liver

16. Homogenize the liver with eight up-and-down strokes with loose-fitting pestle (A), followed by three up-and-down strokes with a tight-fitting pestle (B). Measure total volume of the homogenate (H) and remove an aliquot (~100 µl) for determination of radioactivity, fluorescence, protein, and enzymes.

    To avoid producing bubbles during homogenization, move the pestle slowly and steadily. Wipe off any connective tissue that sticks to the pestle.

Prepare microsomes

17. Pour homogenate into 50-ml thick-walled polycarbonate tubes (1 to 2 tubes/liver). Centrifuge 10 min at 3800 × *g*, 4°C, in a low-speed centrifuge to pellet nuclei and unbroken cells. Remove supernatant (S1) and discard pellet (P1).

18. Transfer supernatant (S1) into a another 50-ml thick-walled polycarbonate tube, and centrifuge for 10 min at 4300 × *g*, 4°C, in a low-speed centrifuge. Remove supernatant (S2) and discard pellet (P2).

    These two centrifugation steps remove nuclei and unbroken cells. Furthermore, the resulting supernatant (S2) is depleted in marker for mitochondria and plasma membranes.

19. Measure volume of supernatant S2 and remove an aliquot (~100 µl) for analysis. Continue endosome preparation either at step 20a or step 20b.

20a. *To prepare "microsomes":* Transfer S2 to a 30-ml thick walled polycarbonate tube (one tube per 10 g liver, maximum) and centrifuge 10 min at 30,000 × *g*, 4°C, in a high-speed centrifuge to pellet lysosomes and mitochondria. Discard the pellet and transfer the supernatant (S3) to 14-ml ultraclear ultracentrifuge tubes. Proceed directly to step 21.

    This additional centrifugation step results in a higher enrichment of endosomal markers in the microsomal pellet (P4; see step 24) and consequently in endosome-enriched fractions due to removal of the majority of lysosomes and mitochondria. As a further consequence, the amount of trypsin required to achieve separation of endosomes by free-flow electrophoresis can be reduced from 3% to 0.3% (see steps 39b and 40b). This is of major importance when the acidification properties of the isolated endosomes are analyzed (see Support Protocol 3).

20b. *To prepare "total microsomes":* Transfer S2 to 14-ml Ultraclear ultracentrifuge tubes and proceed directly to step 21.

    If this alternative is chosen, centrifugation of S2 at 30,000 × g is omitted. For quantitative analysis of endosome subpopulations total microsomes are used.

21. Place a 1.3-ml cushion of 2.5 M sucrose in TEA buffer at the bottom of each of the tubes (containing either S2 or S3) using a 2-ml syringe equipped with a 1.8 × 18–mm needle with a blunted end.

    The high-density cushion prevents the breakage of organelles, and therefore the loss of endocytic markers or vesicular content, by preventing the organelles from being pelleted against the walls of the tube. In addition, gentle resuspension of the pellet is facilitated.

22. To prepare total microsomes (i.e., from S2, where step 20a has not been performed) or microsomes (i.e., from S3, where step 20a has been performed), respectively, centrifuge either supernatant S2 or S3 for 50 min at 285,000 × *g* (40,000 rpm in an SW 40 rotor), 4°C.

23. Discard supernatant (S4).

24. Transfer the pellet (P4) and the cushion to a 15-ml Dounce homogenizer. Rinse tube with 2 to 3 ml of 0.25 M sucrose in TEA buffer.

25. Resuspend the membranous material by using 10 up-and-down strokes with a tight-fitting pestle (B). Monitoring with a Zeiss refractometer, adjust the sucrose concentration with 2.5 M sucrose (in TEA buffer) to 1.25 M (refractive index = 1.3934) and to a final volume of 1.3 to 1.5 ml per gram liver.

If assaying all fractions for yield and enrichment, save them on ice and use on the same day.

Prepare endosome-enriched fractions

26. Transfer 5 ml of resuspended total microsomes (or microsomes) to a 14-ml ultraclear ultracentrifuge tube (for 10 g liver, three tubes are required). Overlay with 2.3 ml of 1.15 M sucrose in TEA buffer, then overlay that with 2.3 ml of 1.0 M sucrose in TEA buffer. Finally, fill up tube to 3 mm below the top with 0.25 M sucrose in TEA buffer.

Figure 3.11.1 contains a diagram of the preparation of the sucrose gradient.

27. Centrifuge gradients for 110 min at 285,000 × *g*, 4°C.

28. Using a 5-ml syringe with a blunt-ended 1.8 × 10–mm needle, collect and pool the endosome-enriched fractions at the 0.25/1.0 M sucrose interface (interface I) and the fractions at the 1.0/1.15 M interface (interface II), from each tube. Transfer the pooled interface I fractions and the pooled interface II fractions into separate 14-ml Ultraclear centrifuge tubes.

For a 7-g liver, one tube for the pooled interface I fraction and another tube for the pooled interface II fraction are sufficient.

29. Determine refractive index of the pooled interface I fraction and of the pooled interface II fraction and add TEA buffer to bring the sucrose concentration to 0.25 M in each fraction.

30. Fill up tubes to ~14 ml with 0.25 M sucrose in TEA buffer and underlay each tube with 100 µl 2.5 M sucrose in TEA buffer using a 1-ml syringe with a 1.8 × 18–mm needle with a blunted end.

Concentrate endosome-enriched fractions by centrifugation

31. Ultracentrifuge tubes for 50 min at 285,000 × *g*, 4°C, to concentrate material in the sucrose cushion.

32. Carefully remove the supernatants, add 500 µl of 0.25 M sucrose in TEA buffer, and resupend the pellets and the sucrose cushion using a 2-ml syringe with a 0.6 × 30–mm needle.

33. Determine the sucrose concentration of the resuspended material using a refractometer and adjust the sucrose concentration with TEA buffer to 0.25 M (refractive index = 1.3453).

Adjust protein concentrations of enriched fractions

34. Determine the protein concentration of each fraction using the Bradford method (*APPENDIX 3B*).

    From a 7 g liver, one may expect to obtain ~2.5 mg protein in the final interface I fraction and 7 mg in the final interface II fraction. To quantitate yield and enrichment, remove aliquots of all supernatants and pellets (~100 µl to 500 µl) and also of the fractions applied to the free-flow electrophoresis apparatus (designated interface 1 and interface II). Furthermore, determine and record the volumes of the respective fractions. Either keep fractions at 4°C and assay immediately or store at −20°C.

35. Adjust the protein concentration to 1 mg/ml by adding 0.25 M sucrose in TEA buffer.

    High protein concentrations (>1 mg/ml) result in reduced separation of endosomes from other subcellular organelles by FFE. Low protein concentrations (<1 mg/ml) complicate detection of markers in the FFE fractions.

Set up instrument

36. Make sure that the FFE instrument is assembled correctly, and the conductivities of the chamber and electrode buffers are correct. Fill chamber with FFE chamber buffer without inclusion of air bubbles, and add FFE electrode buffer to the electrodes.

    Degass chamber buffer using a vacuum pump immediately before use. Fill the chamber slowly to prevent generation of air bubbles during filling. Carefully read the manufacturer's manual on how to avoid air bubbles during filling of the chamber.

37. Before turning on the high voltage (and injecting sample), make sure that all 96 collecting tubes are not clogged.

    For the separation profile, a continuous dropping of buffer from all collecting tubes is of great importance. Due to the presence of sucrose in the chamber buffer, the tubes tend to clog as a result of limited washing after the run.

38. Follow the manufacturer's instructions for starting the instrument. Set the following parameters and maintain constantly:

    Chamber buffer flow: 2.0 to 2.5 ml/hr/fraction
    Chamber temperature: 6°C
    Voltage: ~1400 to 1550 V
    Current: ~120 to 135 mA.

    Values indicated have been established for the Elphor VaP 22 (Bender and Hobein) FFE apparatus, and might need to be retested in other systems.

    Stabilization of voltage and current requires that the FFE instrument be run with the settings listed above for 1 to 2 hr before sample injection. This should be considered in the time schedule. For the stability of the field, the conductivities of electrode buffer (~7.2 mS) and chamber buffer (~720 µS) are of great importance and need to be verified.

Treat endosome-enriched fractions with trypsin

For analysis of "total microsomes" (i.e., where step 20a has not been performed)

39a. Immediately before injection of samples into the FFE apparatus, treat interfaces I and II obtained from total microsomes with 3% trypsin (0.03 mg trypsin/mg protein; added from 1 mg/ml trypsin solution) for 5 min at 37°C.

    The amount of trypsin is "standardized as percent trypsin/mg protein; 0.03 mg trypsin/mg protein is therefore equal to 3% trypsin.

40a. Stop the reaction by adding 6% soybean trypsin inhibitor (0.06 mg soybean trypsin inhibitor/mg protein; added from 2 mg/ml soybean trypsin inhibitor solution), and cooling immediately to 4°C.

For analysis of "microsomes" (i.e where step 20a has been performed)

39b. Immediately before injection of samples into the FFE apparatus, treat interfaces I and II derived from microsomes with 0.3% trypsin (0.003 mg trypsin/mg protein) for 5 min at 37°C.

40b. Stop the reaction by adding 0.6% soybean trypsin inhibitor (0.006 mg soybean trypsin inhibitor/mg protein; added from 2 mg/ml soybean trypsin inhibitor solution), and cooling immediately to 4°C.

Subject samples to separation by FFE

41. Inject trypsin-treated sample into the FFE apparatus at a rate of 1 to 1.5 ml/hr and 4°C.

Avoid introducing an air bubble into the chamber. Wash sample inlet with FFE chamber buffer after injection of sample.

Turn off the room light and try to visualize the sample jet in the FFE- chamber using a flashlight. Splitting of the jet into two unequal beams will give a first indication for separation of endosomes (thin beam, deflected more towards the anode) from the majority of other organelles (thick beam, majority of protein). By watching the sample in the chamber one knows when the fraction collection has to be started and stopped, to avoid unnecessary dilution of the fractions.

42. Begin collecting the fractions when the sample reaches the top of the separation chamber. Collect FFE fractions on ice during the entire run.

Keep an eye on the volume in the tubes collecting the 96 fractions. Try to avoid clogged tubes. Usually, ~2 to 3 ml/fraction are obtained from the FFE separation of interface I or II from one rat liver.

Analyze samples

43. At the end of the run, immediately analyze the collected fractions for protein concentration (e.g., Bradford assay; *APPENDIX 3B*), endosomal marker, and marker enzymes (see Support Protocol 1).

Turn off the FFE instrument by exactly following the manufacturer's instructions. Wash extensively with water to prevent deposition of sucrose or salt in the apparatus.

PREPARATIVE FFE

ALTERNATE PROTOCOL

Usually, one rat liver yields enough material to analyze FFE fractions for marker enzymes, for kinetic analysis of transport through endosomal compartments, or for functional studies such as in vitro acidification of endosomes. However, to characterize the composition of endosomes and identify endosomal proteins or lipids—by, e.g., SDS-PAGE (*UNIT 6.1*) and immunoblotting (*UNIT 6.2*) or by immunoprecipitation (*UNIT 7.2*), larger quantities of purified fractions are required than what are obtained from one rat liver. To avoid the labeling of endosomes in all livers subjected to fractionation, endosomes from one liver are labeled with the appropriate marker (see the Basic Protocol), and two to four livers that have been flushed with buffer by in situ perfusion without prior endosome labeling are processed in parallel.

For materials, see Basic Protocol.

Table 3.11.1 Suggested Dilutions and Volumes Used for Protein, Endocytic Marker, and Marker Enzyme Determination

Fraction[a]	Dilution/volume used			
	Protein (Bradford)	[^{125}I]IgA	FITC-ASOR	Enzymes
H	1:20/5 µl	No dilution/50 µl	-	1:20/10 to 100 µl
S2	1:10/5 µl	No dilution/50 µl	-	1:10/10 to 100 µl
P4	1:10/5 µl	No dilution/5 µl	No dilution/5 µl	1:10/10 to 100 µl
Interface I	No dilution/5 µl	No dilution/10 µl	No dilution/5 µl	No dilution - 1:5/10 to 60 µl
Interface II	No dilution/5 µl	No dilution/10 µl	No dilution/5 µl	No dilution - 1:5/10 to 60 µl
FFE fractions	No dilution/300 µl	No dilution/500 to 1000 µl	No dilution/500 µl	No dilution/60 to 200 µl

[a]See Basic Protocol and Figure 3.11.1 for explanations of the terms used for the various fractions. Abbreviations: H, homogenate; P4, pellet 4; S2, supernatant 2.

1. Label endosomes of one rat liver and halt endocytosis by ice-cold perfusion with 0.25 M sucrose in TEA buffer (see Basic Protocol, steps 1 to 12).
2. Flush one to four livers by in situ perfusion with ice-cold 0.25 M sucrose in TEA buffer (see the Basic Protocol, steps 1 to 12, but omit pulsing with endocytic tracers at step 8)
3. Prepare endosome-enriched fractions from labeled and unlabeled livers, respectively (see Basic Protocol, steps 13 to 35). Prepare the FFE apparatus (see Basic Protocol, steps 36 to 38).
4. Pool interfaces derived from unlabeled livers.
5. Trypsinize interface I or II that contain labeled endosomes (see Basic Protocol, steps 39 to 40).
6. Subject the interfaces containing labeled endosomes (e.g., FITC-ASOR and [^{125}I]pIgA) to FFE separation, and collect the 96 fractions (see Basic Protocol, steps 41 to 42).
7. Trypsinize pooled interface I or II from unlabeled livers (see Basic Protocol, steps 39 to 40).
8. Immediately after the FFE separation of the labeled samples (step 6 of this Alternate Protocol), inject the pooled fractions of the unlabeled samples (step 7 of this Alternate Protocol) and subject to FFE. Collect the 96 fractions.

   According to the amount of livers used, the duration of separation as well as the fraction volumes will be increased.
9. During FFE of unlabeled samples, analyze labeled fractions for protein (*APPENDIX 3B*) and endosome marker distribution (see Support Protocol 1).
10. Analyze FFE fractions of unlabeled samples for the distribution of proteins (see *APPENDIX 3B* and Support Protocol 1).

    The localization of the major protein peak and the endosome marker proteins should be identical in FFE-separations carried out under the same condition.

    Fractions containing endosomes derived from the unlabeled livers can be identified by comparison to the separation profile of labeled fractions.
11. Pool fractions of interest and continue with analysis (see, e.g., Support Protocol 2).

DETERMINATION OF PROTEIN, ENDOSOMAL MARKER, AND MARKER ENZYMES

SUPPORT PROTOCOL 1

The amount and dilution used for analysis of individual fractions is listed in Table 3.11.1. Protein concentration is determined using the Bradford assay (*APPENDIX 3B*). The enrichment of and purity of [^{125}I]pIgA-labeled endosomes is determined by γ counting of individual fractions. Since the liver homogenate and most fractions obtained from it are colored and have a high level of autofluorescence, an accurate determination of the FITC-ASOR concentration and the enrichment of FITC-ASOR labeled endosomes is difficult and requires the parallel analysis of rat liver fractionation where endosome labeling was omitted. Nevertheless, the distribution of FITC-ASOR in interface I and II and in free-flow fractions can be carried out following this protocol. Furthermore, ATP-dependent acidification can be used to determine the enrichment of FITC-ASOR labeled compartments in free-flow fractions in comparison to P3 or P4 (see Support Protocol 3). In order to determine the enrichment of ASOR-labeled endosomes with respect to the initial homogenate it is preferable to use ^{125}I-labeled ASOR.

The following organelle-specific markers can be used to determine the degree of contamination of the endosomal fraction after free-flow electrophoresis. For the apical and basolateral plasma membrane, alkaline phosphodiesterase I (APDE I), which is localized at both plasma membrane domains, is determined (see Support Protocol 1, *UNIT 3.2*). NADPH cytochrome *c* reductase is an oxidoreductase present in the endoplasmic reticulum and is determined according to the Support Protocol in *UNIT 3.5*. As a marker enzyme for lysosomes, β-*N*-acetylglucosaminidase can be assayed using the less sensitive *p*-nitrophenyl derivative as substrate instead of 4-methylumbelliferyl *N*-acetyl-β-D-glucosaminide (see Support Protocol 2 in *UNIT 3.6*; also see *UNIT 3.4*). It has to be pointed out that lysosomal enzymes are also found in endosomes en route to lysosomes. Furthermore, lysosomal enzymes are also found in the biosynthetic pathway (e.g., Golgi) where they can be partially active. As the *cis, medial,* and *trans* Golgi are involved in glycoprotein and proteoglycan modification carrying out distinct modifications at distinct sites in the Golgi stack, the respective enzymes involved in these modifications exhibit a site-specific localization. Most commonly, UDP-galactose galactosyltransferase, a marker of the *trans*-Golgi, is used to determine contamination by Golgi membranes (see Support Protocol in *UNIT 3.9*). Since most of the enzymes are facing the interior of the organelles and many substrates for the enzymes are membrane impermeable, it is important to include detergents in the reaction mixture. For pratical considerations of the assay procedure see *UNIT 3.4-3.9*.

Materials

FFE fractions enriched in endosomes or other organelles (see Basic Protocol or Alternate Protocol)
Phosphate-buffered saline (PBS; *APPENDIX 2A*), pH 7.4
PBS, pH 7.4 (*APPENDIX 2A*) containing 0.2% (v/v) Triton X-100
0.25 M sucrose in TEA buffer (see recipe)

Disposable plastic cuvettes for spectrofluorometer
Spectrofluorometer (e.g., Jasco FP 777)
2.0 ml scintillation vials
γ-counter

Determine FITC-ASOR fluorescence

1. When required (Table 3.11.1), dilute fractions with PBS, pH 7.4.
2. Use 300 µl to 500 µl of each free-flow fraction and add PBS containing 0.2% (v/v) Triton X-100 up to 2 ml.

3. Use 300 µl to 500 µl of 0.25 M sucrose in TEA buffer as blank.
4. Determine fluorescence of the fractions using a spectrofluorimeter at 485 nm excitation (excitation slit, 10 nm) and at 515 nm emission wavelength (emission slit, 10 nm).
5. Subtract blank.

Calculate and present data

6. To determine the distribution of marker enzymes and endosome subpopulations (radioactivity of [^{125}I]pIgA and FITC-ASOR fluorescence) in free-flow fractions, set the total amount of the respective marker recovered in all free-flow fractions (in arbitary units) to 100% and express the activity in individual fractions, counted in 2-ml scintillation vials in a γ-counter in percent of the total amount.
7. Plot the percent of marker in individual fractions versus fraction number.

SUPPORT PROTOCOL 2

CHARACTERIZATION OF PROTEINS IN ENDOSOME SUBPOPULATIONS

The distribution of proteins of interest associated with endosome subpopulations (or other organelles) separated by FFE can be determined by processing the FFE fractions obtained for SDS-PAGE (*UNIT 6.1*) and immunoblotting with specific antibodies (*UNIT 6.2*). FFE fractions are pooled and concentrated, and proteins are dissolved in SDS sample buffer. In order to detect a protein of interest, the effect of trypsin on its antigenicity needs to be tested, as the cytoplasmic portions of proteins can be cleaved by trypsin during preparation for FFE.

Materials

1 mg/ml trypsin
2 mg/ml soybean trypsin inhibitor
FFE fractions enriched in endosomes or other organelles (Interfaces I and II; see Basic Protocol or Alternate Protocol)
0.25 M sucrose in TEA buffer, ice cold (see recipe)
1× SDS sample buffer (*UNIT 6.1*)
Ultracentrifuge with swinging-bucket rotor (e.g., Beckman SW 40 or equivalent) and 14-ml Ultraclear tubes
Additional reagents and equipment for protein determination (*APPENDIX 3B*), SDS-PAGE (*UNIT 6.1*), and immunoblotting (*UNIT 6.2*)

Determine effect of trypsin on the integrity of proteins by immunoblotting

The incubation of endosome-enriched fractions with trypsin is an absolute requirement for separation of endosomes from other organelles; however, when dealing with a membrane-associated or membrane-spanning protein, the trypsin incubation and the resulting degradation of the protein of interest might result in a loss of antigenicity. Test endosome-enriched fractions (i.e., interfaces I, II) for the effect of trypsin on the protein of interest before subjecting them to FFE separation. When starting the protocol, the conditions for SDS-PAGE and immunoblotting required to detect the protein of interest with the antibody should be known.

1. Prepare endosome-enriched fractions (interfaces I, II; see Basic Protocol, step 29, including step 20a).
2. Determine protein concentration in the interfaces (e.g., Bradford assay, *APPENDIX 3B*).

3. If necessary, adjust protein concentrations of interfaces as described (see Basic Protocol, steps 34 to 35).

4. Digest, e.g., 100 µg protein from interfaces with increasing concentrations of trypsin (e.g., 0%, 0.1%, 0.2%, 0.3%, 0.4%, 0.5%; see Basic Protocol, step 39) from 1 mg/ml trypsin stock.

   The amount of trypsin is "standardized as % trypsin/mg protein; 0.003 mg trypsin/mg protein is therefore equal to 0.1% trypsin.

5. Stop incubation as described in Basic Protocol, step 40 by addition of 0%, 0.2%, 0.4%, 0.6%, 0.8%, and 1% soybean trypsin inhibitor from 2 mg/ml.

   The results obtained from immunoblotting the samples treated with various concentrations of trypsin should indicate whether trypsin treatment does or does not interfere with detection of the protein of interest by immunoblotting.

Process FFE fractions for SDS-PAGE

6. Determine the protein concentration of pooled FFE fractions of interest (e.g., Bradford assay, *APPENDIX 3B*) and measure the total volume. Calculate total amount of protein in the pooled fractions.

7. Load 14-ml Ultraclear ultracentrifuge tubes with the pooled fractions. Fill up tubes with 0.25 M sucrose in TEA buffer.

8. Ultracentrifuge 50 min at 285,000 × *g* (e.g., 40,000 rpm in Beckman SW 40 rotor), 4°C, to concentrate material.

9. Carefully remove the supernatants and add a small volume (e.g., 50 µl) of 1× SDS sample buffer to the pellet.

10. Perform SDS-PAGE (*UNIT 6.1*) and immunoblotting (*UNIT 6.2*).

IN VITRO ACIDIFICATION OF ISOLATED ENDOSOMES

SUPPORT PROTOCOL 3

Endosomes purified by free-flow electrophoresis maintain their functional integrity. In vivo, endosomes are acidified by a proton ATPase (so called vacuolar or V-ATPase) resulting in the generation of a pH gradient across the endosomal membrane (Mellman et al., 1986). Due to passive proton efflux, this pH gradient can only be sustained by constant proton influx energized by the proton ATPase. This functional property of endosomes is also found in vitro. Thus, a cell-free acidification assay can be applied to characterize proton transport and ion permeabilities of the isolated endosomes, taking advantage of the pH-dependent fluorescence of FITC-labeled ligands (such as FITC-ASOR), whereby lowering the pH from 7.4 to 5.0 results in a pH-dependent quenching of the fluorescence intensity of FITC. In the absence of permeable ions (such as in 0.25 M sucrose in TEA buffer) the in vivo acidic pH of the endosomes is not dissipated during the isolation procedure and purified endosomes are therefore still acidic. Consequently, this pH gradient has to be dissipated by incubation with permeable cations and anions (e.g., in KCl-containing buffers). Subsequently, ATP is added, and a rapid decrease in the initial fluorescence is indicative of ATP-dependent intravesicular acidification.

Due to trypsinization of the interface I fraction (with 0.03 mg trypsin/mg interface I protein) prior to free-flow electrophoresis, the proton permeability of the endosomes is increased, and, as a consequence, ATP-dependent acidification is decreased. Thus, for acidification experiments, endosome-enriched fractions are prepared that have been depleted in mitochondria and lysosomes (by centrifugation of S2 at 30,000 × *g*; see Fig. 3.11.1). For such endosome fractions (interface I) the amount of trypsin required can be

reduced to 0.003 mg trypsin/mg protein to achieve separation by free-flow electrophoresis. 0.003 mg trypsin/mg protein does not affect ion permeabilities and acidification properties of free-flow purified endosomes (Fuchs et al., 1989).

Materials

FFE fractions from microsomes (Interface I, see Basic Protocol, step 20a) containing FITC-ASOR labeled endosomes (see Basic Protocol), treated with reduced quantity of trypsin (see Basic Protocol, steps 39b and 40b)
Acidification buffer (see recipe)
pH calibration buffers (see recipe)
ATP stock (see recipe)
500 µM nigericin stock (see recipe)
1 mg/ml rabbit anti-fluorescein antibody: IgG(H+L)-fraction (Molecular Probes)

Spectrofluorometer (e.g., Jasco FP 777)
Disposable plastic cuvettes for spectrofluorometer (e.g., Sarstedt)

Generate pH calibration curve of internalized FITC-ASOR

1. Add 0.2 to 10 µl interface I endosome fraction (0.2 to 10 µg protein) to 2 ml of pH calibration buffer (pH 5.0, 5.5, 6.0, 6.5, 7.0, 7.4) in disposable plastic cuvettes.

   FITC-ASOR labeled endosomes are mainly enriched at interface I, regardless of whether endosomes were labeled by injection of markers for 1 min or 10 min.

2. Add 1 µM nigericin (from 500 µM stock) and 1 µl anti-fluorescein antibody.

   The K^+/H^+ ionophore nigericin results in pH equilibration between the pH calibration buffer and the interior of the vesicle. Any FITC-ASOR that leaks out during incubation is quenched by the anti-fluorescein antibody and therefore does not contribute to the fluorescence measurements.

3. Incubate for 2 to 3 hr at room temperature in the dark to equilibrate extra- and intravesicular pH.

4. Transfer cuvettes into spectrofluorometer and determine the fluorescence intensities at 485 nm excitation (excitation slit, 10 nm) and at 515 nm emission wavelength (emission slit, 10 nm).

5. Generate a pH calibration curve by setting fluorescence intensitiy at pH 7.4 to 100% and plotting pH versus fluorescence intensities (in percent), to obtain a calibration curve of internalized FITC-ASOR.

Dissipate initial acidic endosomal pH

6. Add endosome fraction (0.1 to 10 µl of interface I; 100 to 500 µl of free-flow fraction) to 2 ml acidification buffer in a plastic cuvette.

7. Add 1 µl anti-fluorescein antibody.

8. Place cuvette into spectrofluorometer and continuously record the fluorescence until it reaches a steady-state level.

   Dissipation of the initial pH to neutrality requires 30 min to 1 hr.

Acidify endosomes

9. Add 10 µl ATP stock (final concentration 2.5 mM) to the cuvette and mix rapidly by carefully pipetting up and down.

10. Record fluorescence decrease until steady-state level is obtained.

Usually, ATP-dependent acidification results in a fluorescence decrease at least to the initial fluorescence prior to pH dissipation. Steady-state low pH is obtained after ~15 min. If a fluorescence increase is then observed, the amount of ATP added was insufficient and must be increased. Due to other ATPases present in the fraction, the ATP concentration decreases, and this may result in insufficient levels to provide the driving force for the V-ATPase.

11. Add 4 µl of 500 µl nigericin stock (final concentration, 1 µM), mix rapidly by carefully pipetting up and down, and record the rapid fluorescence increase.

Nigericin leads to an immediate dissipation of the intravesicular pH. The fluorescence value upon nigericin addition should be identical to the value prior to ATP addition (i.e., neutral pH inside the endosomes).

Caclulate initial endosomal pH and the pH obtained after ATP addition

12. Express initial fluorescence in percent of the value obtained after dissipation of the pH gradient (i.e., after the intravesicular pH has reached 7.4).

13. Express ATP-dependent fluorescence-decrease in percent of the value prior to ATP addition (i.e., at intravesicular pH of 7.4).

14. Use pH calibration curve to calculate the initial (acidic) endosomal pH and the pH obtained after ATP-dependent acidification.

The pH obtained after in vitro acidification amounts to 6.5 to 6.0 for early endosomes and to 5.0 to 5.5 for late FITC-ASOR labeled endosomes, and is comparable to the initial pH. Peak fractions from free-flow fractions have the highest capacity for ATP-dependent acidification/µg protein, demonstrating a high level of enrichment of these fractions.

PREPARATION OF ASIALOOROSOMUCOID (ASOR)

SUPPORT PROTOCOL 4

The unique and high expression of a galactose-specific receptor, i.e., asialoglycoprotein receptor (ASGPR) at the sinusoidal (basolateral) plasma membrane of rat hepatocytes leads to uptake and removal of desialylated glycoproteins from the circulation (Wall et al., 1980). Many desialylated proteins with terminal galactose residues bind to this receptor. High binding affinities are exhibited by proteins such as ASOR that expose at least three terminal galactose residues. ASOR can be obtained by enzymatic desialylation of α1-acid glycoprotein (orosomucoid; Wall et al., 1980), as described in this protocol. Subsequent conjugation of ASOR to fluorescein isothiocyanate (FITC) is described in Support Protocol 5.

Materials

Insoluble neuraminidase (type X-A, attached to beaded agarose; Sigma-Aldrich)
0.1 M sodium acetate buffer, pH 5.5 (*APPENDIX 2A*)
2% (w/v) sodium azide in H_2O, prepare before use
Human α1-acid glycoprotein (Sigma-Aldrich)
0.1 M sodium borate buffer, pH 9.3

Sephadex G-25 M column (prepacked; Pharmacia Biotech PD-10; bed volume 9.1 ml)
Low-speed centrifuge with swinging bucket rotor for 50-ml tubes (e.g., Beckman JA-20 rotor or equivalent)
50-ml conical centrifuge tubes

Prepare neuraminidase

1. Resuspend 0.25 U insoluble neuraminidase in 1.5 ml of 0.1 M sodium acetate buffer, pH 5.5, in a 2.0-ml microcentrifuge tube at room temperature.

2. Microcentrifuge for 10 min at maximum speed, (16,000 × *g*) room temperature.
3. Remove and discard supernatant.
4. Resuspend the pellet of insoluble neuraminidase in 1.5 ml of 0.1 M sodium acetate buffer, pH 5.5.
5. Pellet insoluble neuraminidase by centrifugation as in step 2.
6. Repeat steps 4 and 5 once more.

Desialylate α1-acid glycoprotein with insoluble neuraminidase

7. Dissolve 100 mg α1-acid glycoprotein in 2 ml of 0.1 M sodium acetate buffer, pH 5.5, containing 0.02% (w/v) sodium azide (added from a 2% w/v stock solution).
8. Add this α1-acid glycoprotein solution to the pellet of neuraminidase and incubate 48 hr under rotation at 37°C.
9. Pellet neuraminidase by microcentrifuging 10 min at maximum speed, at room temperature.
10. Remove supernatant containing ASOR and free sialic acid in 0.1 M sodium acetate buffer, pH 5.5 for subsequent spin desalting. Use this solution in 1-ml aliquots for spin desalting (steps 11 – 15).

Spin desalt ASOR

11. Equilibrate prepacked Sephadex G-25 M column with two bed volumes (20 ml) of 0.1 M sodium borate buffer, pH 9.3.

    One column is needed to exchange the buffer and remove free sialic acid from 1 ml of ASOR solution.

12. Centrifuge column for 5 min at 2500 × *g* (in JA-20 rotor) at room temperature to remove excess liquid.

    Centrifugation can be done by cutting a hole in the screw cap of a 50-ml conical plastic tube to fix the column at the top of the tube. Excess liquid is then collected at the bottom of the tube and discarded. It is important to allow liquid to be removed by centrifugation without back-flow into the column, otherwise the protein solution subsequently applied cannot be quantitatively removed by the centrifugation step below.

13. Insert the column into a new 50 ml conical plastic tube and place a 2.0-ml microcentrifuge tube under the outlet of the Sephadex G 25 column at the bottom of the 50-ml centrifuge tube.
14. Apply 1 ml of ASOR solution (in sodium acetate buffer, pH 5.5; see step 10) to the column.
15. Centrifuge column for 5 min at 2500 × *g*, at room temperature, to collect the ASOR in 1 ml 0.1 M sodium borate buffer, 9.3 in the 2.0-ml microcentrifuge tube. Cool ASOR solution to 4°C.

    Since excess liquid has been removed from the column by centrifugation (step 12) the 1 ml ASOR in 0.1 M sodium acetate buffer, pH 5.5, applied should be recovered as ASOR in 1 ml of 0.1 M sodium borate buffer, pH 9.3.

16. Use an aliquot (20 mg) of this solution for FITC-labeling (see Support Protocol 5) and store remaining aliquots (20 mg) at −20°C.

COUPLING OF FLUORESCEIN ISOTHIOCYANATE (FITC) TO ASOR

To follow endocytosis and to determine the endosomal pH, FITC conjugates of various ligands or fluid-phase markers have been used (van Renswoude et al., 1982). The fluorescence intensity of FITC is pH dependent and the fluorophore can be easily conjugated to the protein of interest. Specific receptor binding of FITC-ligands has to be verified by competing internalization using a 10- to 100-fold excess of unconjugated ligand.

Materials

20 mg ASOR (see Support Protocol 4) in 1 ml of 0.1 M sodium borate buffer, pH 9.3
40 mg FITC on celite (Isomer I on celite; ~10% FITC; Sigma-Aldrich): use 2 mg FITC on celite/mg protein for coupling
TBS, pH 7.38 (see recipe)
PBS, pH 7.38 (*APPENDIX 2A*)

Thermomixer for microcentrifuge tubes (e.g., Eppendorf thermomixer)
Dialysis tubing (Spectra/Por 2; 0.32 ml/cm; MWCO, 12,000 to 14,000 Da)
Sephadex G-25 M column (prepacked; Pharmacia Biotech PD-10; bed volume 9.1 ml)
Spectrofluorometer (e.g., Jasco FP 777)
Microcuvettes for spectrofluorometer

Additional reagents and equipment for dialysis (*APPENDIX 3C*)

Label ASOR with FITC

1. Add 40 mg FITC on celite to 20 mg ASOR in 1 ml 0.1 M sodium borate buffer, pH 9.3, at 4°C, in a 1.5-ml microcentrifuge tube.
2. Incubate under constant mixing at maximum mixing frequency in an Eppendorf Thermomixer in the dark for 40 min at 4°C.
3. Pellet celite by microcentrifuging 10 min at maximum speed, (16,000 × *g*), 4°C.
4. Remove supernatant containing FITC-ASOR and free unconjugated FITC with a plastic transfer pipet and transfer this solution into a prewetted (*APPENDIX 3C*) dialysis tubing.

   Avoid aspiration of any celite, which is not removed during dialysis and which would otherwise interfere with the endocytosis of FITC-ASOR.

5. Dialyze supernatant (*APPENDIX 3C*) against eight 2-hr changes of 1 liter TBS at 4°C in the dark.
6. Finally, dialyze against 1 liter PBS at 4°C in the dark.
7. Remove FITC-ASOR (~1 ml of 40 mg/ml in PBS) from the dialysis tubing, determine the coupling ratio (steps 8 to 10), and store aliquots (e.g., 100 µg) at −20°C.

Determine the FITC/ASOR ratio (coupling ratio)

8. Determine the protein concentration of the conjugate using the Bradford method (*APPENDIX 3B*).
9. Dilute the FITC-ASOR solution (~1:40) with PBS, pH 7.38, and measure the absorbance of the conjugate at 496 nm (maximal FITC absorbance, A_{496}).

   It is important to adjust the pH of the PBS to exactly 7.38, as the fluorescence of FITC is strongly pH dependent.

10. Calculate the amount (μg) FITC bound to ASOR (mg) using the following equations (coupling ratio; Jobbágy and Király, 1966):

    μg FITC/mg ASOR = cFITC/cASOR

    cFITC (FITC content of the conjugate; μg/ml) = $6.09 \times A_{496} \times$ dilution

    cASOR = concentration of ASOR in the conjugate (mg/ml)

    Following this protocol, the authors found that ~18 μg FITC bound to 1 mg ASOR; this corresponds to a molar ratio of FITC:ASOR of 2:1. The FITC-to-ASOR ratio should not exceed 8 mol FITC per mol ASOR to ensure specific binding to the ASGP receptor.

Analyze the purity of the FITC-ASOR conjugate by chromatography on Sephadex G-25

11. Equilibrate Sephadex G-25 column with two bed volumes (20 ml) of PBS.
12. Apply 100 μl of diluted (1:100 in PBS) FITC-ASOR solution to the column.
13. Elute column with PBS and collect 2-ml fractions of the eluate.
14. Determine fluorescence of individual fractions in a spectrofluorometer at excitation and emission wavelengths of 485 nm and 515 nm, respectively (slit, 10 nm).

    The FITC-ASOR conjugate elutes at fraction 2, whereas the peak of free FITC, if present, is found in fractions 10 to 11. In the case of free FITC, the conjugate can be further purified by chromatography on Sephadex G-25 (follow steps 11 to 14 of this protocol using undiluted FITC-ASOR as starting material).

    Specific binding of FITC-ASOR can be demonstrated by competing binding and internalization by a 10-fold excess of unlabeled ASOR; under this condition no fluorescence signal in isolated endosomes is obtained (Fuchs et al., 1989).

SUPPORT PROTOCOL 6

PREPARATION OF ^{125}I-LABELED HUMAN POLYMERIC IMMUNOGLOBULIN A ([^{125}I]pIgA)

The pIgA-receptor (pIgR) on rat hepatocytes efficiently transports pIgA from the circulation into bile via vesicular transcellular transport. To label transcytotic endosomes in rat liver, rat, human or mouse pIgA can be used as unmodified or radiolabeled ligand (Hoppe et al., 1985; Giffroy et al., 1998).

CAUTION: When working with radioactive materials, take appropriate precautions to avoid contamination of the experimenter and the surroundings. Carry out the experiment and dispose of wastes in an appropriately designated area, following guidelines provided by the local radiation safety officer (also see *APPENDIX 1D*).

CAUTION: This procedure must be performed in a hood certified for radioiodination. All personnel performing iodinations or using radioactive materials must be properly trained.

Materials

Phosphate-buffered saline (PBS; *APPENDIX 2A*) containing 0.1% (w/v) bovine serum albumin (BSA)
Phosphate-buffered saline (PBS; *APPENDIX 2A*)
Iodo-Beads (iodination reagent; Pierce)
Na[^{125}I] (17 mCi/ml; NEN Life Sciences)
Human polymeric immunoglobulin A (pIgA), purified from human myeloma serum (Vaerman and Lemaitre-Coelho, 1979) and kindly provided by Jean-Pierre Vaerman and Pierre J. Courtoy (Catholic University of Louvain, Brussels, Belgium).

TBS (*APPENDIX 2A*)
10% (w/v) trichloroacetic acid (TCA)

Pre-packed anion-exchange cartridges (e.g., Bio-Rad Econo-Pac Q; bed volume 5 ml)
5-ml conical-bottom screw-cap glass reaction vials
2.0-ml scintillation vials
γ counter (e.g., Beckman Instruments)

Prepare the anion exchange column

1. Equilibrate the prepacked anion-exchange column with three bed volumes (15 ml) of PBS/0.1% (w/v) BSA to reduce nonspecific protein absorption.
2. Remove excess BSA with 1 bed volume (5 ml) PBS.

Radiolabel pIgA

3. Wash one Iodo-Bead with 500 µl PBS and dry bead on filter paper.
4. Put 100 µl PBS containing 1 mCi (2.2×10^9 cpm) Na[^{125}I] in a 5-ml glass reaction vial.
5. Add Iodo-Bead to the vial, cap vial, and incubate in the hood for 10 min at room temperature.
6. Add 50 µg pIgA (in 5 µl PBS) to the vial and incubate for 30 min at room temperature in the hood.

   Alternatively, mouse pIgA can be used. The polymer forms of mouse IgA can be purified from clarified ascites (Sigma-Aldrich) or from the purified myeloma immunoglobulin (Sigma-Aldrich) of a plasmacytoma cell line (TEPC) as described by Hoppe et al., 1985.

7. Stop the iodination reaction by applying the mixture to the anion-exchange column.
8. Rinse the vial with 100 µl PBS and transfer the rinse to the anion-exchange column.
9. Elute iodinated pIgA with 100 µl portions of PBS at room temperature and collect ~100-µl fractions in pre-chilled microcentrifuge tubes on ice.

Analyze labeling

10. Quantify radioactivity by counting 3-µl aliquots of each fraction in a γ-counter.
11. To determine protein-bound radioactivity, place a 5-µl sample of each fraction in a microcentrifuge tube and add 1 ml ice cold 10% (w/v) TCA, mix, and incubate on ice for 30 min.
12. Pellet precipitated proteins by microcentrifuging 10 min at maximum speed, 4°C.
13. Remove and count 500 µl of the supernatant (i.e., TCA-soluble radioactivity) as well as the remaining 500 µl containing soluble and precipitable (^{125}I-labeled pIgA) radioactivity.
14. Determine cpm in a γ counter and calculate free (soluble) and precipitable cpm.

    This procedure should yield pIgA with a specific activity of ~1.5 µCi/µg pIgA (3.3×10^6 cpm/µg pIgA).

15. Use the fractions with at least 95% to 98% TCA-precipitable counts for in vivo endosome labeling. Store ^{125}I-labeled pIgA in 50-µl aliquots for up to 1 month at 4°C in a lead container.

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Acidification buffer

5.6 g KCl (150 mM final)
3.4 g HEPES (*N*-[2-Hydroxyethyl]piperazine-N′-[2-ethanesulfonic acid]; 20 mM final)
616.2 mg $MgSO_4.7H_2O$ (5 mM final)
H_2O to 500 ml (final volume)
Adjust pH with tetramethylammonium hydroxide to pH 7.4
Filter through a qualitative filter paper (e.g., Whatman no. 4)
Store up to 1 month at 4°C

ATP stock

2917 mg adenosine 5′-triphosphate (dipotassium salt; Sigma-Aldrich; 500 mM final)
H_2O to 10 ml (final volume)
Adjust pH with 1 M KOH (prepared freshly) to 7.4
Store aliquots (100 µl) indefinitely at −20°C

FFE chamber buffer

Prepare 5 liters of 1× TEA buffer from 10× stock solution (see recipe). Adjust pH to 7.4. Add 427.9 g sucrose (250 mM final) to a final volume of 5 liters of 1× TEA buffer, stir overnight, filter through a qualitative filter paper (e.g., Whatman no. 4) before use, and determine conductivity (should be 720 µS). Prepare fresh and use at 4°C

With a chamber buffer flow rate of 2.0 to 2.5 ml/h/fraction, this volume is sufficient to run the FFE for at least 20 hr nonstop. The FFE separation of one interface by the Elphor Vap 22 takes ~45 to 60 min.

FFE electrode buffer

10× TEA buffer (see recipe), room temperature
Determine conductivity before use (conductivity: 7.2 mS)
Prepare 5 liters for one FFE run

Nigericin stock, 500 µM

5 mg nigericin, sodium salt (Sigma-Aldrich; 500 µM final)
Ethanol to 13.4 ml
Store 1-ml aliquots up to 1 year at −20°C

pH calibration buffers

Mix solution A (see recipe) with solution B (see recipe) until the desired pH (5.0, 5.5, 6.0, 6.5, 7.0, and 7.4) is obtained. Prepare 100 to 200 ml of each buffer. Store up to 1 month at 4°C

Solution A for pH calibration buffer

11.2 g KCl (150 mM final)
9.8 g MES (2-[*N*-Morpholino]ethanesulfonic acid; 50 mM final)
H_2O to 1000 ml (final volume)
Adjust pH with KOH to 5.0
Filter through a qualitative filter paper (e.g., Whatman no. 4)
Store up to 1 month at 4°C

Solution B for pH calibration buffer

11.2 g KCl (150 mM final)
16.9 g HEPES (*N*-[2-Hydroxyethyl]piperazine-N′-[2-ethanesulfonic acid]); 50 mM final)
H_2O to 1000 ml (final volume)
Adjust pH with KOH to 7.4
Filter through a qualitative filter paper (e.g., Whatman no. 4)
Store up to 1 month at 4°C

Sucrose in TEA buffer, 0.25 M

171.2 g sucrose (250 mM final)
1× TEA buffer (prepare from 10×; see recipe) to 2000 ml (final volume)
Adjust to pH 7.4

To control the molarity of the solution, check the refractive index (refractive index = 1.3453 ± 0.0005) at room temperature. Filter through a qualitative filter paper (e.g., Whatman no. 4) and store up to 48 hr at 4°C.

Sucrose in TEA buffer, 1.00 M

85.6 g sucrose (1.0 M final)
1× TEA buffer (prepare from 10×; see recipe) to 250 ml (final volume)
Adjust to pH 7.4

To control the molarity of the solution, check the refractive index (refractive index = 1.3816 ± 0.0005) at room temperature. Filter through a qualitative filter paper (e.g., Whatman no. 4) and store up to 48 hr at 4°C.

Sucrose in TEA buffer, 1.15 M

98.4 g sucrose (1.15 M final)
1× TEA buffer (prepare from 10×; see recipe) to 250 ml (final volume)
Adjust to pH 7.4

To control the molarity of the solution, check the refractive index (refractive index = 1.3888 ± 0.0005) at room temperature. Filter through a qualitative filter paper (e.g., Whatman no. 4) and store up to 48 hr at 4°C.

Sucrose in TEA buffer, 2.5 M

214.0 g sucrose (2.5 M final)
1× TEA buffer (prepare from 10×; see recipe) to 250 ml (final volume)
Adjust to pH 7.4

To control the molarity of the solution, check the refractive index (refractive index = 1.4528 ± 0.0005) at room temperature. Filter through a qualitative filter paper (e.g., Whatman no. 4) and store up to 1 month at 4°C.

TEA buffer, 10×

66.6 ml triethanolamine, free base (100 mM final)
28.6 ml acetic acid (glacial; 100 mM final)
100 ml 500 mM EDTA (*APPENDIX 2A*; 10 mM final)
H_2O to 5000 ml (final volume)
Adjust pH to 7.4 with NaOH
Store at room temperature

Using the FFE instruments available from Elphor VaP 22, Bender and Hobein, this volume is sufficient for the FFE electrode buffer volume required for one FFE run. An additional 500 ml to 1000 ml will be needed to prepare the FFE chamber buffer and the solutions containing sucrose in TEA buffer used.

continued

Tris-buffered saline (TBS)

87.7 g NaCl (150 mM final)
24.2 g Tris base (20 mM final)
H_2O to 10,000 ml (final volume)
Adjust pH with HCl to 7.38
Store indefinitely at 4°C

This volume is sufficient to dialyze 20 mg FITC-ASOR.

COMMENTARY

Background Information

Free-flow electrophoresis (FFE) is an efficient method providing both analytical capabilities and the opportunity for continuous operation on a preparative scale. The range of substances to be separated is wide, including small ions, proteins, membrane particles, and even viable cells, and the recoveries of membrane and proteins are high (~90%). FFE separates membranous cell components and organelles (e.g., endosomes) based on surface charge (Morré et al., 1994). As the procedure is non-

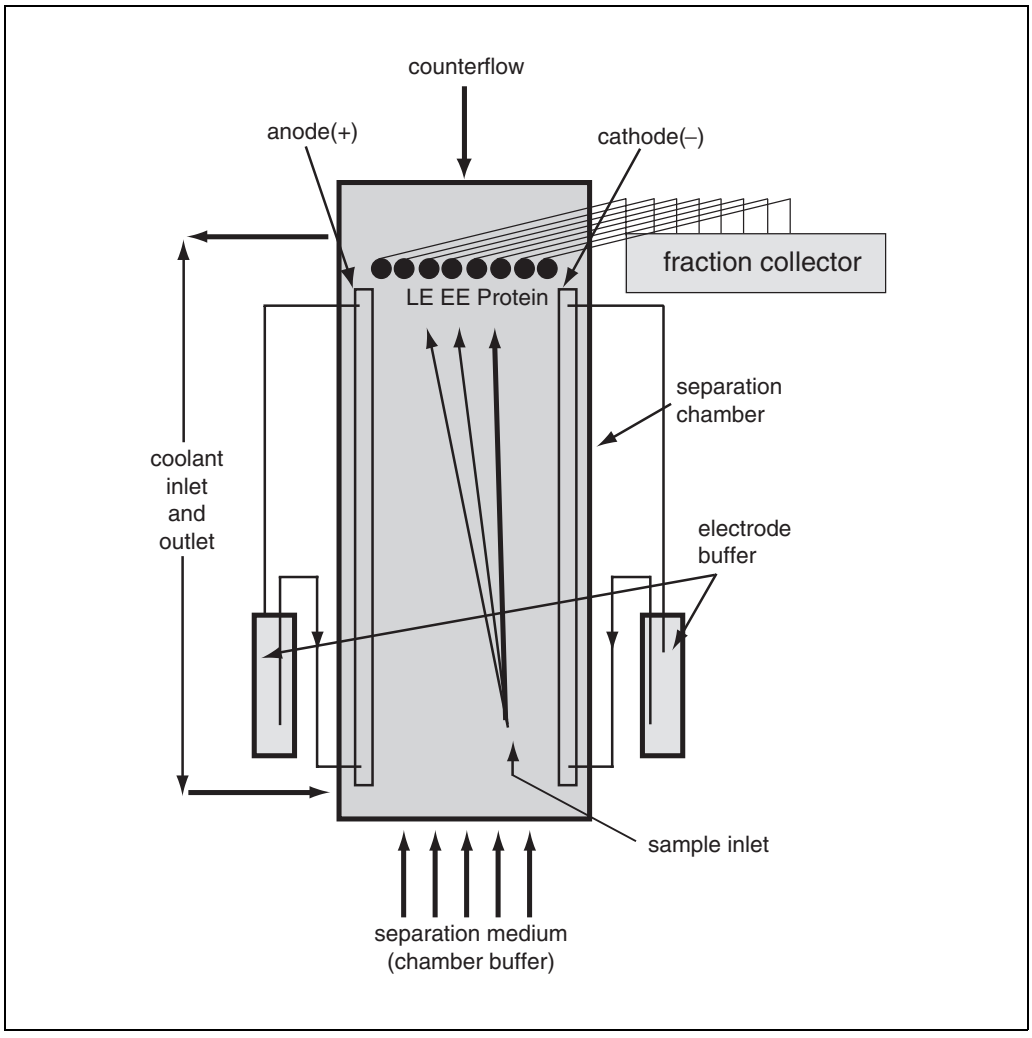

Figure 3.11.2 Basic principle of endosome separation by free-flow zone electrophoresis, referred to as free-flow electrophoresis (FFE), represented in a schematic view. A basic electrolyte with defined pH (chamber buffer) is continuously pumped through the chamber. A fine stream of sample is injected into the laminar flow of the chamber buffer. Due to their different electrophoretic mobilities the different organelles exhibit different angles of deflection and can be collected in different fractions. Early endosomes (EE) are less deflected towards the anode than late endosomes (LE) and the main protein peak elutes nearly undeflected.

destructive and fractions obtained retain full in vitro function, organelles such as endosomes isolated by FFE can be subsequently analyzed for their characteristic functions (e.g., acidification).

A mixture of components to be separated is injected as a fine jet into a separation buffer moving perpendicular to the field lines of an electric field (see Fig. 3.11.2). The electric field leads to deflection of membranes bearing different electrical charge densities according to their mobility or isoelectric point. The sample and the separation buffer enter the separation chamber at one end. On the opposite side, the fractionated sample and the separation buffer are collected. Though FFE can be performed in various modes depending on the electrolyte system applied (e.g., isotachophoretic mode, isoelectric focusing mode), the simplest and most widely used free-flow electrophoresis technique is free-flow zone eletrophoresis, also known as continuous flow electrophoresis. In this mode, the chamber buffer has a constant composition, pH, and conductivity, and the electrically charged components of the samples (e.g., organelles) are deflected from the flow direction of the medium to a defined angle, which is determined by flow velocity and by electrophoretic migration speed (separation according to the size-to-charge ratio).

With regard to the isolation of intracellular organelles from rat liver, FFE has been applied (Krivankova and Bocek, 1998) for the isolation of lysosomes (Stahn et al., 1970), peroxisomes

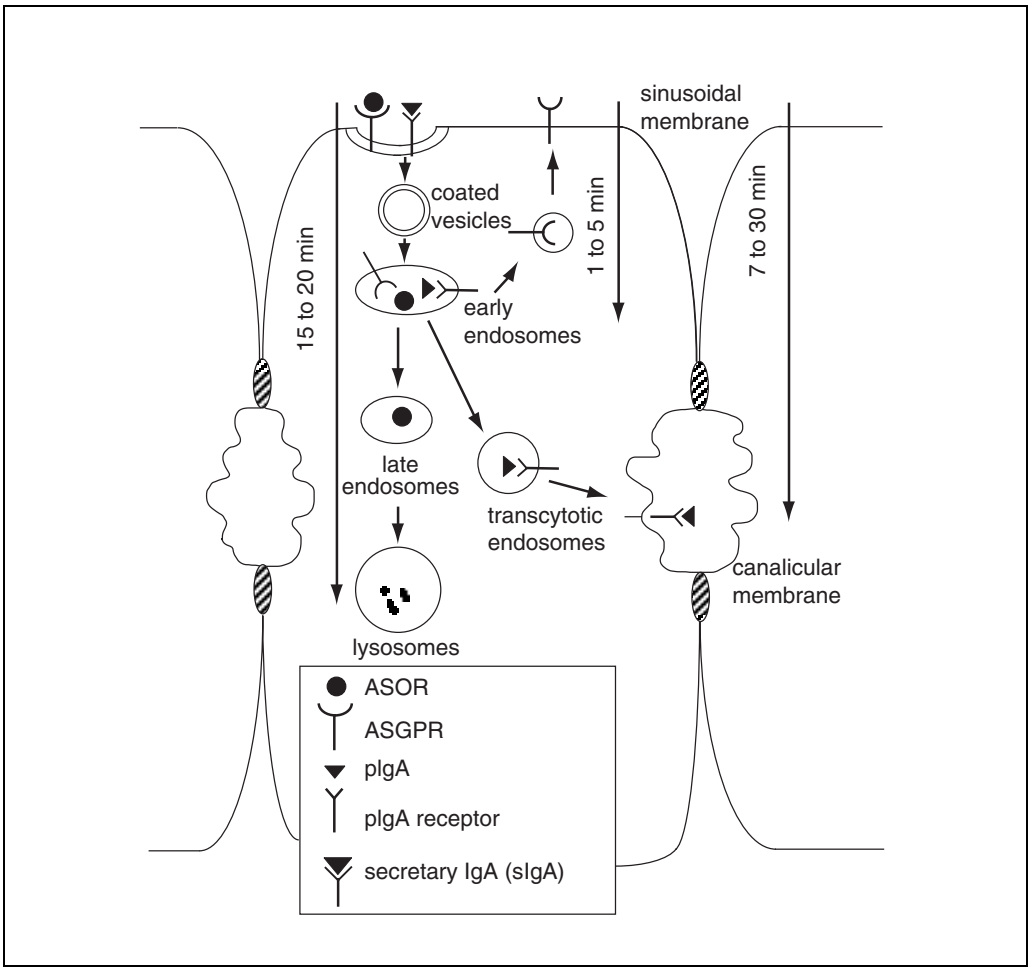

Figure 3.11.3 Kinetics of ASOR and pIgA transport through endocytic compartments in rat hepatocytes. Endocytic subcompartments of rat hepatocytes can be selectively labeled by cointernalization of FITC-ASOR and [^{125}I]pIgA. Within 1 to 5 min after in vivo injection, both ligands can be localized in a common early endosomal compartment. Thereafter, pIgA is sorted into the transcytotic pathway and is secreted into bile (as secretory IgA) 7 to 30 min after injection. In contrast, ASOR is dissociated from its receptor in acidic early endosomes and transported via late endosomes to lysosomes. Lyosomal degradation of ASOR is observed 15 to 20 min after uptake. The authors therefore labeled (common) early endosomes by injection of both markers for 1 min. Late endosomes and transcytotic endosomes are preferentially labeled when the markers are injected for 10 min.

(Volkl et al., 1997) and for subfractionation of the Golgi apparatus (Morré et al., 1983). The buffer system and FFE conditions described in this protocol can also be used for the purification of lysosomes, and with some modifications for peroxisome isolation, and for subfractionation of the Golgi apparatus. In any case, an organelle-enriched fraction is subjected to separation by FFE. Although trypsination is omitted, the starting material is, for example, treated with amylase (Morré, 1998) or reacted with antibodies (Volkl et al., 1997). As marker enzymes β-*N*-acetylglucosaminidase (lysosomes), urate oxidase (peroxisomen), thiamine pyrophosphatase and UDP-galactose galactosyltransferase (trans-Golgi) can be used to follow the organelle purification and enrichment.

An important application of FFE is the isolation and analysis of endosomes and endosome subpopulations. Although endosomes per se are not separated from contaminating material (e.g., endoplasmic reticulum, plasma membranes, mitochondria) when subjected to FFE, separation can be achieved by mild trypsin treatment of the sample, which results in a dose-dependent increase in separation (Marsh et al., 1987). Although the effect of trypsin is still obscure, the electrophoretic mobility of endosomes and lysosomes is enhanced after trypsinization. Applying this technique, it was demonstrated that late endocytic compartments are more shifted to the anode than early compartments (Schmid et al., 1988). Migration of late endosomes to the anode appear to correlate with the internal lower (more acidic) pH of late compartments as compared to the higher (less acidic) pH of early compartments. This lead Morré et al. (1994) to suggest that ATP-dependent vesicle (endosome) acidification generates an outside negative membrane potential and as a consequence results in a more anodal migration of vesicles with a lower internal pH, as compared to those maintaining a higher pH. ATP-dependent acidification was then applied to achieve endosome separation by FFE without the need for trypsinization (Morré et al., 1994). In the authors' experience, rat liver endosomes maintain their initial low internal pH during the isolation procedure; nevertheless no separation is achieved without trypsinization (Fuchs et al., 1989).

FFE has been widely used to characterize endocytic pathways and compartments in non-polarized cells, primarily in tissue culture cells. The isolation of endosomes from polarized tissue culture cells requires the culture of the cells on permeable filters in sufficient quantities to permit subcellular fractionation. This is time-consuming and costly. Alternatively, the rat liver provides a tissue where trafficking in polarized hepatocytes can be studied and where sufficient material is provided from one liver to isolate intracellular organelles. Therefore, the authors describe a protocol for the labeling of endosomal subcompartments of rat hepatocytes and the subsequent FFE isolation and analysis of endosomal fractions.

Polarized hepatocytes express many receptors also commonly found in other cell types (e.g., transferrin receptor, LDL receptor, insulin receptor) and in addition exhibit unique receptor expression (e.g., ASGPR) at their basolateral surface (Courtoy, 1991). Furthermore, hepatocytes are involved in selective transcytosis and secretion of serum proteins (e.g., pIgA) into bile. After internalization via clathrin-coated vesicles, internalized ASGPs are first delivered to kinetically early endosomes that maintain a mildly acidic intravesicular pH. In these compartments, ligands and receptors are sorted into distinct pathways: ASGPs dissociate from their receptors in the acidic endosomal milieu and are transported via kinetically late endosomal compartments to lysosomes, where they are rapidly degraded. Similar to the transferrin receptor, the ASGPR is recycled to the sinusoidal membrane. Although the pIgA-receptor complex is initially delivered via clathrin-coated vesicles to the same early endosomal compartment as ASGPs, the complex is subsequently sorted into transcytotic endosomes and pIgA/pIgR is transported to the canalicular (apical) plasma membrane. Due to proteolytic cleavage near or at the canalicular membrane, the extracellular (ligand-binding) domain of the pIgR (now called secretory component) still bound to pIgA is secreted into bile (hence the term secretory IgA, or sIgA). Although hepatocytes internalize membrane and extracellular material at the canalicular surface (Tuma et al., 1999), this pathway is less characterized due to experimental inaccessibility of the canalicular domain.

Based on the kinetics of ASOR transport through early (receptor-positive) and late (receptor-negative) compartments and its arrival and immediate degradation in lysosomes, early or late endosomes en route to lysosomes can be labeled in a time-dependent manner (see Fig. 3.11.3). Similarly, early and late compartments involved in transcytosis of pIgA from the sinusoidal to the canalicular domain can be marked by short or prolonged internalization

of [^{125}I]pIgA. The labeling procedure applied in the Basic Protocol is based on in vivo studies and cell fractionation experiments reported by various laboratories (Courtoy, 1991; Hoppe et al., 1985; Mueller and Hubbard, 1986; Perez et al., 1988; Sztul et al., 1991; Stefaner et al., 1997). Early endosomes were labeled by coinjection of FITC-ASOR and [^{125}I]pIgA for 1 min, whereas late compartments of the transcytotic and lysosomal pathway, respectively, were labeled by coinjection of the markers for 10 min.

Critical Parameters and Troubleshooting

Due to variability of the animals, the injection procedure and the resulting labeling of the individual endosome subpopulation, injection of two or more tracers in the same animal is required. To obtain reproducible endosome labeling by in vivo marker injection, rapid cooling of the liver by in situ perfusion is very important, especially when early compartments have to be labeled, since markers are rapidly sorted (within 1 to 5 min) from these compartments. Furthermore, the livers have to be processed (minced, homogenized) immediately after cooling. The entire isolation procedure (including homogenization) is carried out in isotonic buffers to maintain the integrity of the organelles and to prevent loss of endocytic markers. Thus, care has to be taken during homogenization, and protease inhibitors are included in the buffer to inhibit damage due to release of proteases. It is also critical for subsequent FFE separation to use the 0.25 M sucrose in TEA buffer, which is also used as FFE chamber buffer, throughout the entire isolation procedure. Most tissue culture cells, and also liver cells, are effectively broken up in this buffer.

To obtain good separation of samples by free-flow zone electrophoresis in general, an accurate preparation of FFE electrode and chamber buffer is of major importance. The composition, the pH, and the conductivity of these buffers are critical parameters; therefore, pH and conductivity should be tested prior to every run. In general, all parameters (buffer composition, coolant volume, filter membranes) directly or indirectly influencing the high-voltage field must be regularly checked. To avoid loss of essential samples, a constant electrical field should be maintained for at least 1 hr before the sample is injected. This might allow one to observe and find a reason for any

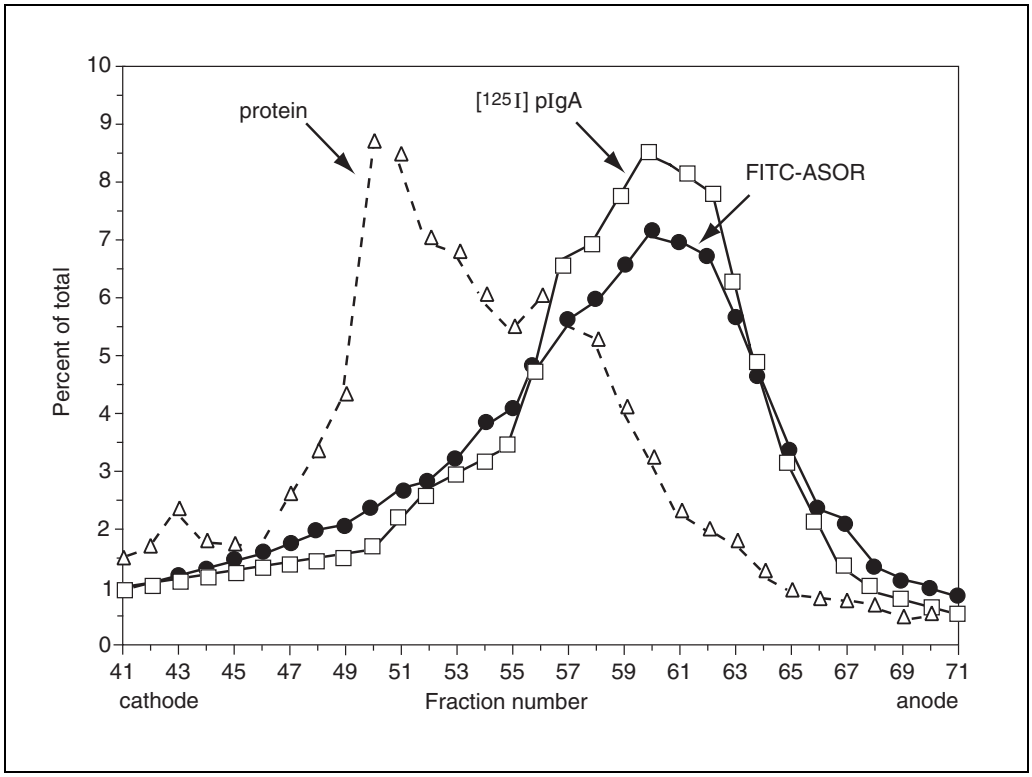

Figure 3.11.4 Distribution of protein and endocytic marker after free-flow electrophoresis of interface I after in vivo injection of FITC-ASOR and [^{125}I]pIgA for 1 min. Endosome-enriched fractions were prepared. Material at the 0.25/1.0 M sucrose interface was collected, trypsin-treated, and subjected to FFE.

problem before the sample is lost. Filtering of chamber buffer is essential, too, as small particles introduced into the thin chamber can disturb the separation by, e.g., deflecting the jets of separated substances. For the same reason, it is essential to accurately clean the chamber before it is filled and to avoid the introduction of small air bubbles either during filling of the chamber with chamber buffer or during injection of the sample. Separated samples are collected via 96 tubes. Clogged tubes (especially several clogged tubes in series) severely alter the separation profile. It is therefore critical to extensively wash the chamber and all connecting tubes with water after every run to remove the sucrose. Tubes blocked at the beginning of a run might be forced to flow again by applying a vacuum (e.g., sucking with a large syringe). Also wash the sample inlet immediately after sample injection with TEA/0.25 M sucrose buffer to prevent clogging. Separation of endosomes from other organelles requires brief trypsinization. As demonstrated by Marsh et al. (1987), even a small increase or decrease in the trypsin concentration can alter the separation profile. Therefore, the amount of trypsin added, the incubation time of samples with trypsin at 37°C, and an exact determination of the protein concentration in the interfaces are critical parameters. The amount of trypsin is "standardized" as percent trypsin per milligram protein. Since the amount of trypsin required to separate endosomes depends on the enrichment of endosomes in the sample, the optimal trypsin concentration has to be experimentally determined, whenever the fractionation protocol is modified. The adjustment of a certain protein concentration (1 mg/ml) in the loading sample has important implications: lower concentrations make it difficult to detect marker proteins in fractions; high concentrations cause broadening of jets and reduced separation of organelles. When the expected separation (~10 fractions) of endosomal markers from the major protein peak is not obtained (e.g., with a new instrument), alter the relevant conditions (sample flow rate, chamber buffer flow rate, trypsin concentration, voltage/current) one by one.

When two different endosome-labeling conditions (e.g., 1 min versus 10 min labeling) are analyzed, these two livers should be processed in parallel and subjected to FFE on the same day, one after another, to have comparable isolation and FFE conditions. When individual FFE runs at different days and liver preparations are compared, the actual fraction num-

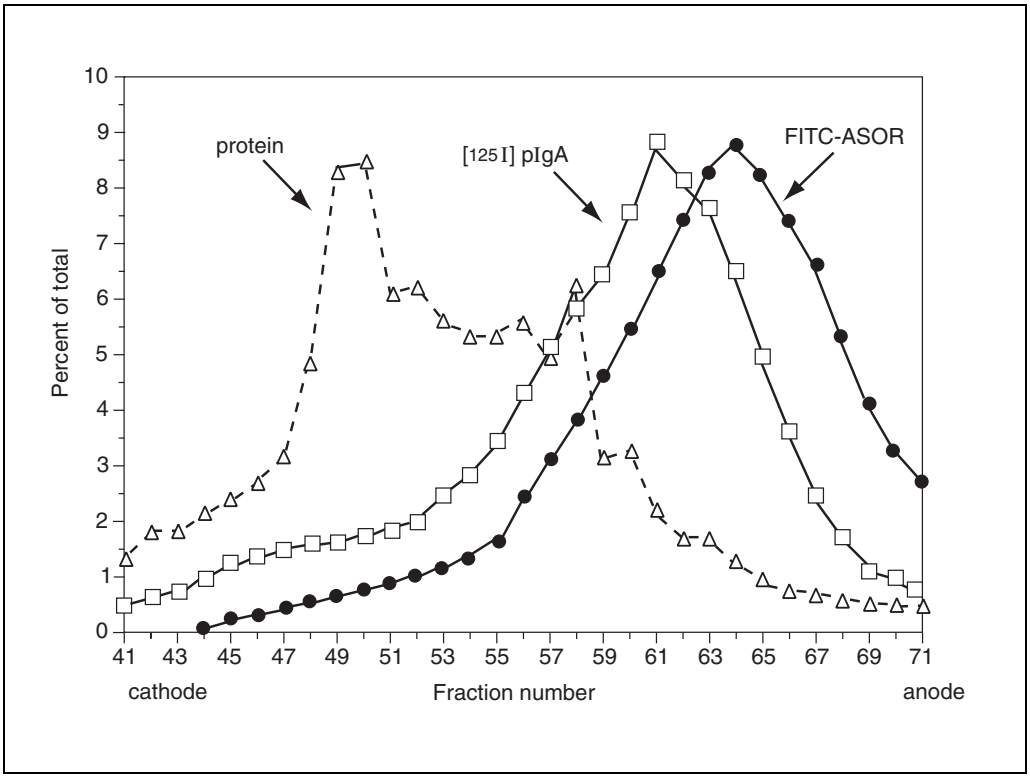

Figure 3.11.5 Distribution of protein and endocytic marker after free-flow electrophoresis of interface I. FITC-ASOR and [^{125}I]pIgA were injected for 10 min. Endosome-enriched fractions were prepared. Material at the 0.25/1.0 M sucrose interface was collected, trypsin-treated, and subjected to FFE.

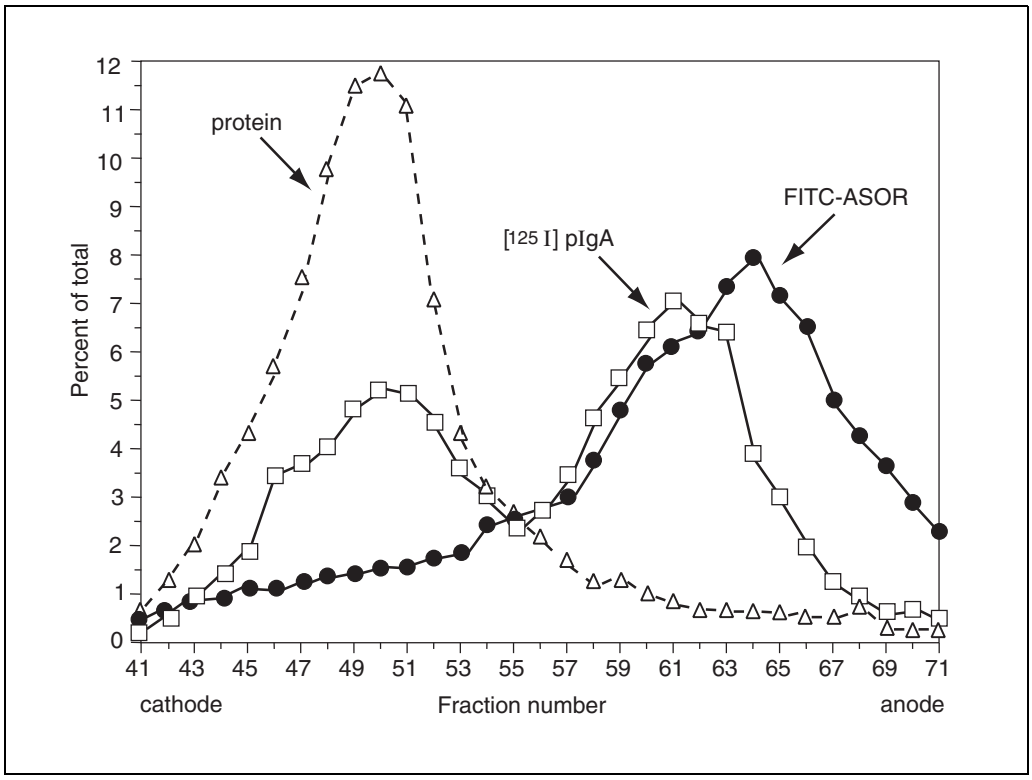

Figure 3.11.6 Distribution of protein and endocytic marker after free flow electrophoresis of interface II. FITC-ASOR and [^{125}I]pIgA were injected for 10 min. Endosome-enriched fractions were prepared. Material at the 1.0/1.15 M sucrose interface was collected, trypsin-treated, and subjected to FFE.

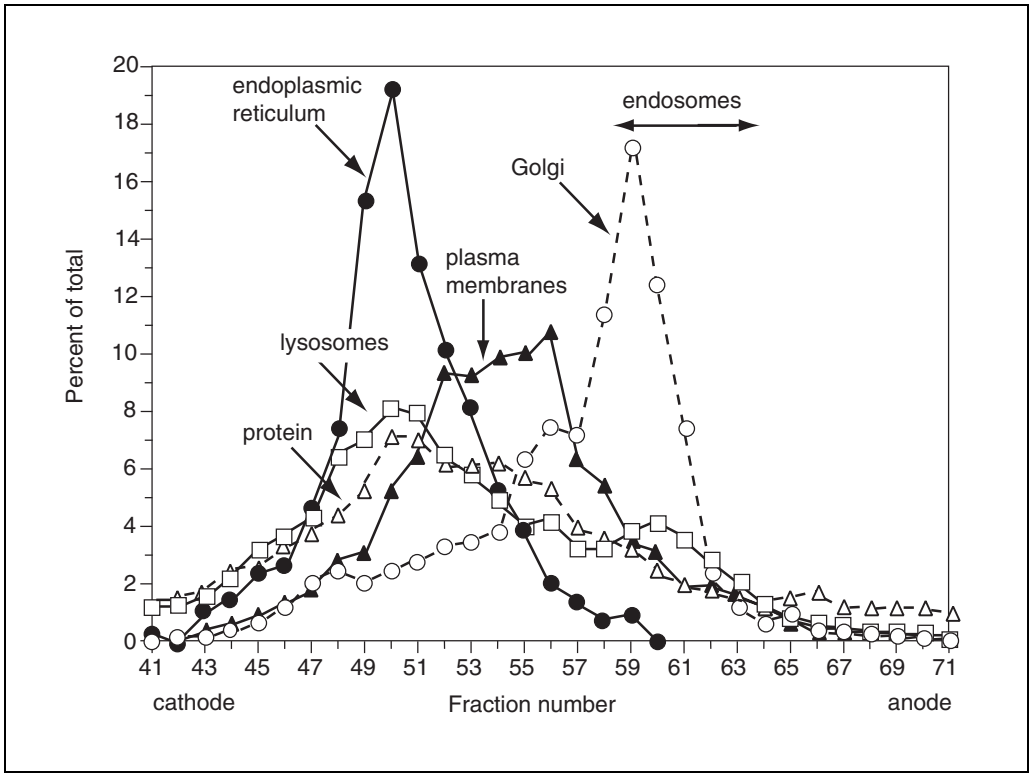

Figure 3.11.7 Distribution of protein and marker enzymes after free-flow electrophoresis of interface I. The following marker enzymes were determined: NADPH cytochrome *c* reductase (endoplasmic reticulum); alkaline phosphodiesterase I (plasma membranes); β-*N*-acetylglucosaminidase (lysosomes); UDP-galactose galactosyltransferase (*trans*-Golgi).

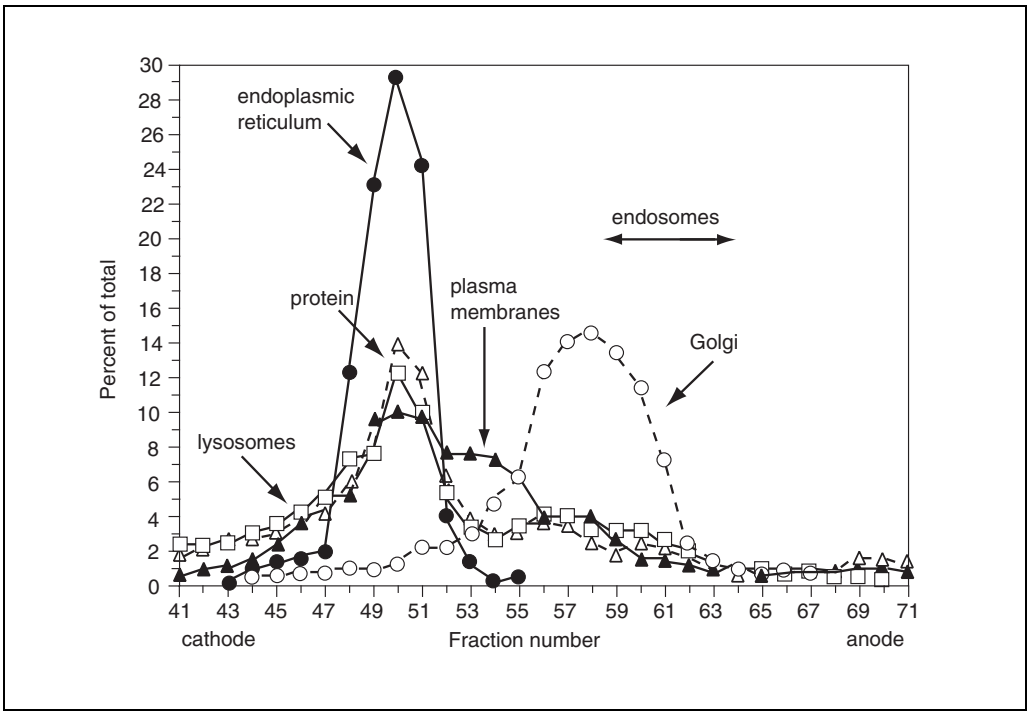

Figure 3.11.8 Distribution of protein and marker enzymes after free flow electrophoresis of interface II. The following marker enzymes were determined: NADPH cytochrome *c* reductase (endoplasmic reticulum); alkaline phosphodiesterase I (plasma membranes); β-*N*-acetylglucosaminidase (lysosomes); UDP-galactose galactosyltransferase (*trans*-Golgi).

ber—i.e., the position at which protein and endosomal peaks elute—varies, but separation (number of fractions between endosomal and protein peaks, and between endosome subcompartments) is fairly constant.

Anticipated Results

Basic Protocol

Preparation of endosome-enriched fractions. Rat liver endosomes are mainly enriched in so-called Golgi fractions that can be obtained by flotation of microsomes or total microsomes (see Fig. 3.11.1) in discontinuous sucrose density gradients. According to the Basic Protocol, a "Golgi fraction" is prepared that corresponds to a combined Golgi light, intermediate, and heavy fraction as described by Khan et al. (1986). The combined Golgi fraction, here called interface I (interface 0.25/1.0 M sucrose), is primarily enriched in endosomes labeled with ASOR. In contrast, pIgA is equally distributed between interfaces I and II (1.0/1.15 M interface) and also within the 1.15 M sucrose layer. Nevertheless, due to the higher amount of protein-contaminating material (primarily endoplasmic reticulum and plasma membranes) present in interface II, pIgA is less enriched in interface II as compared to interface I. Both interface I and interface II have been analyzed by FFE to demonstrate that the distribution and separation of endosome subcompartments is very similar in these interfaces and therefore independent of their density properties. For further functional studies, endosomes derived from interface I are preferentially used. These endosome-enriched fractions are mainly contaminated by the Golgi apparatus, which is highly enriched at interface I. Although the majority of plasma membranes are removed by the initial low-speed centrifugation steps, interfaces I and II are slightly enriched in APDE I with a higher enrichment found in interface II as compared to interface I. This becomes apparent when FFE fractions of interface I and II are compared (see below) and plasma membrane localization of pIgA is evident in interface II but not in interface I. For a detailed characterization (yield, enrichment, purity) of endosome–enriched gradient fractions and FFE fractions see previous reports (Fuchs et al., 1989; Khan et al., 1986; Marsh et al., 1987; Schmid et al., 1988; Stzul et al., 1991; Stefaner et al., 1997).

FFE separation of endosome-enriched fractions: To analyze the kinetics and potential subcompartments involved in endocytic transport, analytical FFE can be applied. For these separations, the distribution of marker enzymes

is first determined to ensure the resolution of the technique. For subsequent analysis, the distribution of protein and endosomal markers is determined. The quality of the separation is usually estimated from the number of fractions between the main protein peak and the endosome peak fractions. Since early endosomes are less deflected to the anode than transcytotic and late endosomes, a separation is considered as "good" if the protein and early endosome peaks are 9 to 10 fractions apart. Late endosomes are separated by 13 to 15 fractions from the protein peak, at best. In general, the separation of rat liver endosomes is usually less when compared to the separation of endosomes from tissue culture cells.

Early endosomes were labeled by coinjection of FITC-ASOR and [^{125}I]pIgA for 1 min. Since ~1 to 2 min are required to cool the liver and halt endocytosis, both ligands are internalized for ~2 to 3 min. The FFE separation of the endosome-enriched fraction at interface I is shown in Figure 3.11.4. The major protein peak elutes at fraction 50, whereas endosomes are deflected towards the anode and are well resolved from the protein peak. As expected, the major peak of ASOR and pIgA-labeled endosomes are localized in the same fraction (60).

Internalization of FITC-ASOR and [^{125}I]pIgA for 10 min and FFE separation of interface I and interface II is shown in Figures 3.11.5 and 3.11.6. In comparison to early endosomes labeled with ASOR, late ASOR-labeled compartments are more deflected to the anode, and the peak fraction of the late ASOR-labeled endosomes now elutes at fraction 64. In contrast, labeling of late transcytotic compartments with pIgA leads to a small but reproducible shift of the peak fraction from 60 (see Fig. 3.11.4) to 61 (see Fig. 3.11.5 and 3.11.6). Similar results were obtained by labeling early, late, and transcytotic endosomes in the isolated perfused liver (Stefaner et al., 1997). The second peak of [^{125}I]pIgA at fraction 50 after FFE separation of interface II (Fig. 3.11.6) is due to pIgA still present in the plasma membrane. This also demonstrates the higher contamination of interface II fractions by plasma membranes, since this peak is largely absent in interface I fractions (see Fig. 3.11.5). In contrast to ASOR, binding of pIgA to its receptor is neither calcium- nor pH-dependent and plasma membrane–associated pIgA is not displaced from the plasma membrane during isolation.

The distribution of marker enzymes after FFE separation of interface I and II (see Fig. 3.11.7 and 3.11.8) is very similar with respect to elution of peak fractions. The major protein peak consists of endoplasmic reticulum and plasma membranes. Lysosomes are a minor contaminant and the lysosomal enzyme activity found in the FFE fractions from rat liver does not colocalize with endosomal fractions, in contrast to FFE of endosomes from tissue culture cells (Marsh et al., 1987). Similar to endosomes, marker for the *trans*-Golgi is also shifted to the anode, eluting at fraction 59. Thus, it is primarily early endosomes that are contaminated by Golgi membranes. Due to removal of the majority of the protein (i.e., endoplasmic reticulum, plasma membranes), upon FFE the enrichment of the endosomal peak fractions is further increased 2- to 4-fold as compared to the starting material (interface I and II).

In conclusion, FFE separation of endosome-enriched fractions from rat liver results in the identification of three distinct endosomal subcompartments: (common) early, late, and transcytotic endosomes. When the acidification properties of these three peak fractions is analyzed using Support Protocol 3, these populations are functional with respect to ATP-dependent proton transport and differ in their internal pH.

Time Considerations

In contrast to the FFE purification of endosomes from tissue culture cells, the isolation procedure for rat liver endosomes (see Basic Protocol) is time-consuming and connot be interrupted at any time. The following time requirements have to be calculated for individual steps (preparation of buffers, ligands, and solutions is not included in this timetable):

In vivo endosome labeling, and liver perfusion: 1 hr;

Preparation of endosome-enriched fractions ready for FFE separation: ~8 to 9 hr;

FFE-set up before separation: 2 to 3 hr (this can be done in parallel during the centrifugation procedure);

Endosome separation: calculate ~1 to 1.5 hr/sample to obtain material for analytical purpose; at least two samples are analyzed, i.e., 2 to 3 hr; For preparative endosome isolation: 3 to 5 hr;

Analysis of protein and endosomal marker in FFE fractions: ~1 to 2 hr; For analysis of marker enzymes the fractions can be frozen and assayed when appropriate;

Enzyme assays: 1 to 2 days.

It has to be pointed out that the result of the separation and the reproducibility largely depend on how fast endosome-enriched fractions ready to be used for the FFE are prepared. Since the entire protocol, starting at marker injection into the rat in the morning and ending after FFE fractions are obtained, has to be carried without interruption, at least 13 to 14 hr must be allotted. When cell-free acidification assays are carried out for functional analysis, these assays have to be performed immediately after analysis of the FFE fractions for endosomal markers and for protein. This functional assay is similarly time-consuming. To dissipate the initial pH gradient and to subsequently acidify endosomes, ~1 hr is required. In most cases, dissipation of the initial gradient does not have to be determined in each fraction, and fractions can be pre-equilibrated consecutively while determining ATP-dependent acidification of the preceding samples. Nevertheless, ~5 hr are required to carry out these assays.

For preparative isolations, at least 15 hr must be allotted. In the case of analysis of endosomes by SDS-PAGE and immunoblotting, protein and endosomal markers have to be analyzed immediately after FFE separation in order to pool the fractions of interest and to concentrate the membranes by centrifugation (2 to 3 hr). Thereafter, the endosomal (membrane) pellets can be stored frozen for further analysis (e.g., SDS-PAGE and immunoblotting: 1 to 2 days).

Isolation of Synaptic Vesicles

Neurons communicate through synaptic contacts organized in presynaptic and postsynaptic domains (see Fig. 3.12.1). A central aspect of synapse organization is that the presynaptic and postsynaptic domains are separated by a cleft. The presence of this synaptic cleft between neurons restricts the nature of their communication to diffusible chemicals called neurotransmitters. Presynaptic terminals are characterized by their capacity to store and secrete neurotransmitters in small packets or quanta. These packets contain a discrete and relatively homogenous number of neurotransmitter molecules. Ultrastructural studies of the presynaptic terminal suggested that the quantal nature of synaptic transmission is due to the presence of numerous synaptic vesicles that are highly regular in size.

Synaptic vesicles are probably the most abundant vesicular organelle. The function and molecular composition of these vesicles is understood in detail largely because they can be purified to a great degree. At the electron microscopic level, synaptic vesicles are spherical, with a characteristic cross-sectional diameter of ~40 nm ± 4% to 9%

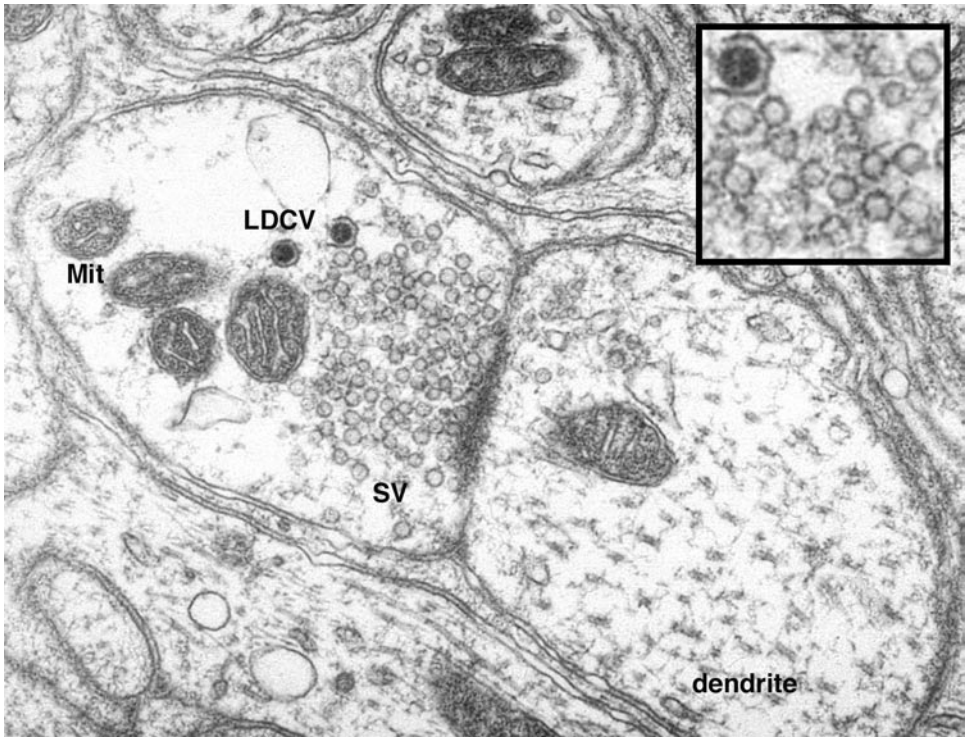

Figure 3.12.1 Ultrastructure of a rat brain synapse. The figure depicts a transmission electron micrograph of the presynaptic (left side of the panel) and the post-synaptic (dendrite, right side of the panel) elements that constitute a typical synapse. Two classes of secretory organelles are present in the presynaptic element, synaptic vesicles (SV) and large dense core vesicles (LDCV). Note the difference in the size and the luminal content between these organelles as well as their abundance. Synaptic vesicles are very homogenous in size, with a clear center (see text). Mitochodria (Mit) are present in both pre and post-synaptic terminals. Insert shows a magnification of vesicles. An LDCV is present on the upper left-hand corner of the insert. (Kim et al., 2000). Synaptic vesicles can be visually identified in electron micrographs because they have an electron-lucent appearance, which is due to the absence of protein or peptides in their lumen. These characteristics (size and density) are used in almost all the protocols designed to isolate synaptic vesicles. The synaptic vesicle purification methods that are described here take advantage of the characteristic density and size of these organelles. Combinations of differential centrifugation, density-based sedimentation, and size fractionation have been used in several synaptic vesicle isolation procedures, including those presented here. In the past, the efficacy of these synaptic vesicle purification procedures was confirmed by electron microscopy. Today, the degree of synaptic vesicle purification can be easily determined by immunoblot using various antibodies that recognize synaptic-vesicle proteins.

Two synaptic vesicle isolation procedures, developed, respectively, by Clift-O'Grady et al. (1990) and Huttner et al. (1983), are described. Both of these utilize rat brain as the source of tissue. Although both protocols rely on similar biophysical principles to isolate vesicles, they differ in (1) the way the tissue is homogenized; (2) the buffer in which homogenization is performed; and (3) the method of fractionation. Clift-O'Grady's method (see Basic Protocol 1) is performed in buffered physiological saline. In contrast, Huttner's protocol (see Alternate Protocol 1) is performed in the absence of salt, resulting in a lower vesicle yield. However, synaptic vesicles purified by the Huttner protocol retain loosely associated peripheral proteins such as synapsins (Huttner et al., 1983). Thus, the reader is referred to Basic Protocol 1 or Alternate Protocol 1, depending on purification needs. The biochemical and biophysical foundations of these protocols can be found in the classical work of Whittaker and Kelly (Whittaker et al., 1972; Nagy et al., 1976; Carlson et al., 1978; Wagner et al., 1978). Once the synaptic vesicles have been isolated, they can be enriched (Basic Protocol 2 or Alternate Protocol 2 or 3). They can be sedimented at high speed (Support Protocol 1) or immunoprecipitated (Support Protocol 2). Silanized glassware and plasticware (Support Protocol 3) are used for synaptic-vesicle purifications.

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) and must conform to governmental regulations regarding the care and use of laboratory animals.

NOTE: The authors recommend that all surfaces coming in contact with purified vesicles be siliconized (see Support Protocol 3). As one proceeds further into the purification protocols, the vesicles will have a tendency to adsorb to plastic and glass.

BASIC PROTOCOL 1

CLIFT-O'GRADY METHOD OF SYNAPTIC VESICLE ISOLATION

This is a 2-day protocol. Brain tissue is disrupted in a Waring Blendor in a physiological salt buffer; thus, synaptic vesicles are released from whole brain and do not from a crude synaptosomal preparation as in the Huttner method (Alternate Protocol 1). All procedures, buffers, tubes, and equipment must be maintained at 4°C to perform the purification. Microcentrifuge tubes and glass tubes as well as pipets used to collect and handle synaptic vesicles should be siliconized with Sigmacote (see Support Protocol 3). This is particularly critical at the later stages of purification because synaptic vesicles adsorb strongly to untreated glass and plastic surfaces. Addition of carrier protein to the purified vesicles is not recommended. At each fractionation step, keep a record of the approximate volume of the fractions and collect an aliquot of material to determine protein concentration and content of synaptic vesicle antigens by immunoblot (refer to Table 3.12.1 for a list of commonly used antibodies; also see *UNIT 6.2*). With these figures, it will be possible to estimate the enrichment and recovery of synaptic vesicle markers.

Membranes and vesicles fractions should be stored at −80°C after flash freezing in liquid nitrogen.

Table 3.12.1 Antibodies Used to Immunoisolate Synaptic Vesicles

Antigen	Name and isotype	Reactivity	Performance with[a]		Supplier
			Immunomagnetic isolation	Immunoblotting	
VAMP II	69.1/IgG1	Human, mouse, rat	++++	+++	Synaptic Systems
Synaptophysin	SY38/IgG1	Human, mouse, rat	++++	++++	Chemicon
SV2	10H4/IgG1	Human, mouse, rat, frog, fish	+++	++++	Iowa Hybridoma Bank
Rab3a	42.1/IgG1	Mouse, rat	+++	+++	Synaptic Systems
Vacuolar ATPase	P116 rabbit	Mouse, rat	NT	+++	Synaptic Systems
Vglut1/BNP1	Rabbit	Mouse, rat	++	+++	Synaptic Systems
VGAT	Rabbit	Mouse, rat	++	+++	Synaptic Systems

[a]Symbols: ++++, best performance; ++ good performance; NT, not tested.

Materials

200- to 250-g female rats (22 animals needed)
Buffer A (see recipe) prepared in H_2O (light water), with and without 1× protease inhibitors
1000 × protease inhibitors (see recipe) *or* Boehringer Complete protease inhibitor tablets (Roche Applied Science)
Buffer A (see recipe) prepared in 80% (v/v) H_2O/20% D_2O (deuterium oxide, 99% isotopic purity), with and without 1× protease inhibitors
320 mM sucrose/4 mM HEPES, pH 7.4, prepared with 100% D_2O
320 mM sucrose/4 mM HEPES, pH 7.4, prepared with 85% (v/v) D_2O/15% H_2O
320 mM sucrose/4 mM HEPES, pH 7.4, prepared with 70% (v/v) D_2O/30% H_2O

Dissecting instruments
Waring Blendor with small glass cup (kept in cold room)
Refrigerated centrifuge with Sorvall SS-34 rotor (or equivalent), and corresponding polycarbonate centrifuge tubes
Beckman ultracentrifuge with 45 Ti rotor (or equivalent), and corresponding Oak Ridge ultracentrifuge tubes
Small Teflon-coated spatula
Tight-clearance Teflon/glass Potter-Elvehjem homogenizer, ~50 ml
Beckman ultracentrifuge with SW 41 Ti rotor (or equivalent) and corresponding polyallomer ultracentrifuge tubes
Loose-clearance Teflon/glass Potter-Elvehjem homogenizer, ~2 ml
SG series gradient maker (Hoefer Scientific)
Loose-clearance Teflon/glass Potter-Elvehjem homogenizer, ~1 ml

NOTE: Carry out all procedures at 4°C using solutions prechilled to that temperature.

Homogenize rat brains

1. Euthanize 22 rats by CO_2 asphyxiation (Donovan and Brown, 1995). Decapitate rats, dissect out brains, and quickly place them in ice-cold buffer A without protease inhibitors. Wash brains in ice-cold buffer A without protease inhibitors extensively to remove blood.

   Rats should be euthanized two to three at a time and the brains removed so as to minimize the time at room temperature.Wash brains by swirling the cold buffer with a metal spatula, avoiding mechanical damage to the brains.

2. Drain off the buffer used for washing and bring the 22 brains to a final volume of 110 ml with ice-cold buffer A containing 1× protease inhibitors.

3. In the cold room, blend for 2 min in a Waring Blendor with a small glass cup at maximum speed.

Prepare cytosolic suspension

4. Pour the homogenate into six to eight 50-ml polycarbonate SS-34 Sorvall tubes and centrifuge 30 min at 20,250 × *g*, 4°C.

5. Pool all supernatants in a separate tube and bring the volume up to 94 ml with ice-cold buffer A containing 1× protease inhibitors.

Isolate membranes

6. Layer a pad of 20 ml of buffer A prepared in 80% H_2O/20% D_2O, containing 1× protease inhibitors, in each of four to six Oak Ridge ultracentrifuge tubes appropriate for a 45 Ti rotor. Carefully overlay the supernatant from step 5 on top of the pads, distributing it evenly among the tubes. Balance the tubes with chilled buffer A.

7. Ultracentrifuge 4 hr at 225,000 × *g*, 4°C, with centrifuge acceleration and brake set to the maximum setting.

8. Aspirate and discard the supernatants and collect the pellets.

   Pellets are sticky, so the best method of collecting them is to use a Teflon-coated small spatula to slice each pellet in three pieces and scoop them out of the tubes.

Fractionate membranes

9. Transfer pellet pieces to a tight-clearance 50-ml Potter-Elvehjem (Teflon/glass) homogenizer and bring the volume up to 30 ml with buffer A (prepared with light water) containing 1× protease inhibitors. Resuspend pellets with 12 strokes at 600 to 800 rpm. Try to avoid bubble formation.

10. Layer the following consecutively from bottom to top in four SW 41 Ti polyallomer tubes to prepare step gradients:

    Layer 1: 1.5 ml 320 mM sucrose/4 mM HEPES, pH 7.4, prepared with 100% D_2O
    Layer 2: 1.5 ml 320 mM sucrose/4 mM HEPES, pH 7.4, prepared with 85% D_2O/15% H_2O
    Layer 3: 1.5 ml of 320 mM sucrose/4 mM HEPES, pH 7.4, 70% D_2O/30% H_2O.

    Layer 8 to 9 ml of the membrane suspension obtained in step 9 on top of each step gradient.

    Fill tubes completely; otherwise they will collapse during the run.

11. Ultracentrifuge 1.5 hr at 225,000 × *g*, 4°C.

12. Collect the sedimented material in layer 3 and at the interface between layer 3 and layer 2.

13. Transfer the material collected to a 45 Ti Oak Ridge centrifuge tube. Bring the total volume up to 68 ml with buffer A (prepared with light water) containing 1× protease inhibitors. Centrifuge overnight at 225,000 × *g*, 4°C.

Isolate synaptic vesicles

14. Discard the supernatant and collect the pellet as in step 8. Resuspend pellets in 1.6 ml of buffer A containing 1× protease inhibitors and transfer to a 2-ml Potter-Elvehjem homogenizer using the technique described in step 9 and homogenize.

15. Using an SG series gradient maker, prepare four 10-ml continuous gradients in SW 41 Ti polyallomer ultracentrifuge tubes, each containing 5.8 ml of buffer A prepared with 80% H_2O/20% D_2O (without protease inhibitors) and 6.2 ml of 320 mM sucrose/4 mM HEPES, pH 7.4, prepared with 100% D_2O.

    See Basic Protocol 2, step 1, for preparation of continuous gradients using the SG series gradient maker.

16. Layer the membrane suspension obtained in step 14 over the gradients at 1 ml per gradient. Centrifuge 3 hr at 274,000 × *g*, 4°C.

    After this centrifugation step, membranes appear as a white fluffy material distributed all along the gradient.

17. Using a 1-ml automatic pipettor, take the uppermost 2 ml of each gradient and discard. Collect the next 8 ml from each tube and pool. Discard the pellet at the bottom of the tube.

18. Dilute the pooled membranes to 136 ml with buffer A (prepared with light water) containing 1× protease inhibitors. Divide between two 45 Ti Oak Ridge tubes and ultracentrifuge at least 3 hr at 225,000 × *g*, 4°C.

19. Collect each pellet as described in step 8. Transfer to a 1-ml Potter-Elvehjem homogenizer. Resuspend in 0.6 ml of buffer A containing 1× protease inhibitors as described in step 9.

20. Immediately clarify the resuspended membranes by microcentrifuging 4 min at maximum speed, 4°C.

21. Proceed to enrichment of synaptic vesicles (see Basic Protocol 2 or Alternate Protocol 2 or 3).

HUTTNER METHOD OF SYNAPTIC VESICLE ISOLATION

ALTERNATE PROTOCOL 1

This is a 2-day protocol. Brain tissue is disrupted gently with a loose-clearance Potter-Elvehjem (Teflon/glass) homogenizer. The initial differential fractionation steps (steps 1 to 6 below) generate a crude synaptosomal fraction that contains intact presynaptic terminals. Vesicles are released by hyposmotic shock. As mentioned in Basic Protocol 1, all procedures, buffers, tubes, and equipment must be kept at 4°C during the course of the purification. Microcentrifuge and glass tubes, as well as pipets used to collect and handle synaptic vesicles should be siliconized with Sigmacote (see Support Protocol 3). At each fractionation step, keep record of the approximate volume of the fractions and collect an aliquot of material to determine protein concentration and synaptic vesicle content by immunoblot, using the antibodies described in Table 3.12.1. With these figures it will be possible to estimate the enrichment and recovery of synaptic vesicle markers.

Membranes and vesicle fractions should be stored at −80°C after flash freezing in liquid nitrogen.

Additional Materials *(also see Basic Protocol 1)*

200- to 250-g female rats (14 animals needed)
SB buffers (see recipe), with and without 1× protease inhibitors
1 M HEPES buffer, pH 7.4
Loose clearance Potter-Elvehjem (Teflon/glass) homogenizer, ~50 ml
10-ml syringe with 25-G needle
Beckman ultracentrifuge with SW 28 rotor (or equivalent), and corresponding Ultraclear centrifuge tubes

NOTE: Carry out all procedures at 4°C using solutions prechilled to that temperature.

Homogenize rat brains

1. Euthanize 14 rats by CO_2 axphyxiation (Donovan and Brown, 1995). Decapitate rats, dissect out brains, and quickly place them in ice-cold buffer A without protease inhibitors. Wash brains in ice cold SB320 without protease inhibitors extensively to remove blood.
2. Drain off the buffer used for washing and bring the 14 brains to a final volume of 100 ml in ice-cold SB320 containing 1× protease inhibitors.
3. Transfer brains to a 50-ml loose-clearance Potter-Elvehjem (Teflon/glass) homogenizer and homogenize with 12 strokes at 600 to 800 rpm.

   Since the brains are in a 100-ml volume, the homogenization will be done in two installments.

Perform initial fractionation

4. To the (pooled) homogenate generated in step 3, add 40 ml SB320 containing 1× protease inhibitors. Split volume evenly into four SS-34 tubes, then centrifuge 10 min at 1000 × *g*, 4°C.
5. With a pipet, collect the supernatants and pool them in a separate tube. Bring the volume to 100 ml with SB320 containing 1× protease inhibitors. Split volume evenly into four new SS-34 tubes, then centrifuge 15 min at 13,200 × *g*, 4°C.
6. With a pipet, remove and discard the supernatant. Resuspend the pellet, bringing the volume to 13 ml with SB320 containing 1× protease inhibitors.

   The pellet at this stage is almost 13 ml in volume, so be careful not to add too much buffer.

Fractionate synaptosome preparation

7. Add 117 ml of ice-cold double-distilled water containing 1× protease inhibitors and homogenize in a 50-ml tight-clearance Potter-Elvehjem (Teflon/glass) homogenizer with three strokes at 600 to 800 rpm.
8. Add 1 ml of 1 M HEPES buffer pH 7.4, and incubate on ice for 30 min.
9. Transfer to four SS-34 tubes and centrifuge 20 min at 33,000 × *g*, 4°C.
10. Collect the supernatants with a pipet and transfer to two 45 Ti Oak Ridge tubes. Ultracentrifuge at least 5.5 hr at 213,000 × *g*, 4°C.

    This step can be prolonged to overnight.

11. Collect the pellets in a total volume of 6 ml of SB40 containing 1× protease inhibitors.
12. Pass the material in and out through a 25-G needle five times using a 10-ml syringe.
13. In two Ultraclear SW 28 tubes pour a discontinuous gradient by sequentially layering 16 ml of SB800, then 19 ml of SB50.
14. Load the resuspended homogenate from step 12 and layer carefully on top of the gradients, distributing it evenly among the tubes. Centrifuge 5 hr at 95,000 × *g* in SW 28 rotor, 4°C.

    IMPORTANT NOTE*: This is not an equilibrium gradient; it is a velocity sedimentation. Therefore changes in the time of the run or the angular velocity will affect the vesicle sedimentation.*

15. Collect the faint hazy band that extends from approximately half-way to two-thirds of the way down the tube. Discard the top portion of the gradient.

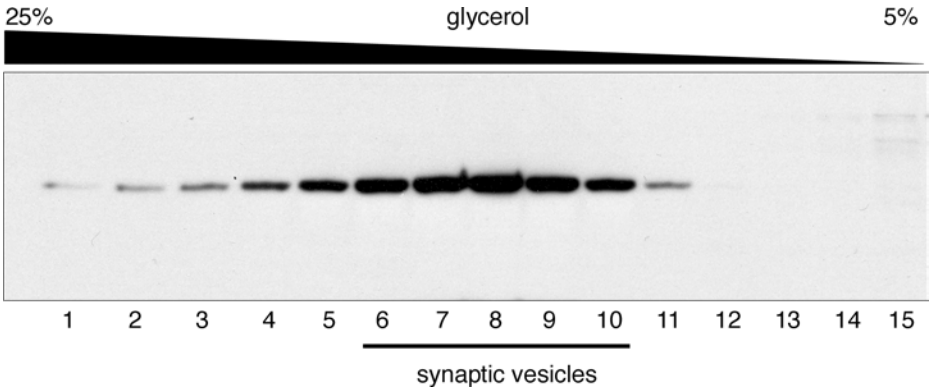

Figure 3.12.2 Size fractionation of brain synaptic vesicles. Synaptic vesicles were purified according to the protocol of Clift-O'Grady and size fractionated in glycerol velocity gradients as described in Basic Protocol 2. Vesicles were resolved in 10% polyacryloamide (PAA)–SDS gel and the presence of synaptic vesicles was determined by immunoblot using the antibody SY38 directed against synaptophysin, also known as p38. Synaptophysin (p38) is one of the most abundant proteins in synaptic vesicles. A vesicle peak is evident between fractions 6 and 10. Electron microscopic examination confirmed that these vesicles possess the features of synaptic vesicles found in nerve tissue.

16. Proceed to enrichment of synaptic vesicles (see Basic Protocol 2 or Alternate Protocol 2 or 3).

If vesicles will be purified by size fractionation they can be loaded directly onto the columns, but if glycerol sedimentation is going to be used, vesicles should be sedimented to wash away the sucrose (see Support Protocol 1).

SYNAPTIC VESICLE ENRICHMENT

Basic Protocol 1 and Alternate Protocol 1 yield membrane preparations in which SV are enriched ~8 to 10 times over brain homogenate. The protocols below take advantage of the uniformity in SV size and their small diameter to further purify these vesicles. These steps increase the yield to ~20 fold over the starting homogenate. Basic Protocol 2 utilizes velocity sedimentation (see Fig. 3.12.2) and Alternate Protocols 2 and 3 each employ a chromatography approach. The chromatography protocols differ in the protein capacity of the column as well as the ease of preparation and maintenance of the different chromatographic media.

NOTE: Carry out all procedures at 4°C using solutions prechilled to that temperature.

SYNAPTIC VESICLE ENRICHMENT BY GLYCEROL VELOCITY SEDIMENTATION

BASIC PROTOCOL 2

Materials

5% and 25% (v/v) glycerol in buffer A (see recipe for buffer)
Synaptic vesicle preparation (see Basic Protocol 1 or Alternate Protocol 1)

SG series gradient maker (Hoefer Scientific)
Transi-stir motor (Talboys Engineering Corp.)
Beckman ultracentrifuge with SW 55 Ti rotor (or equivalent) and corresponding polyallomer centrifuge tubes
Tube-piercing apparatus (Brandel)

1. Layer a pad of 0.5 ml of 50% sucrose in buffer A in an SW 55 Ti polyallomer centrifuge tube. On top of the pad, layer a 5% to 25% continuous glycerol gradient in buffer A as follows. On a SG series gradient maker, first close the communication vessel between chambers. Place 2.2 ml of 25% glycerol solution in the heavy solution chamber. Place 2.2 ml of 5% glycerol solution in the other chamber. Place a stirring rod connected to a Transi-stir motor in the heavy solution chamber. Slightly tilt the gradient maker so the heavy solution is below the level of the light solution. Stir the solution and open the connection between chambers.

   As the gradient is flowing dropwise into the SW 55 Ti tube, the volume of both chambers should come down evenly. The linearity of the gradient can be tested by refractometry. This procedure is highly consistent and reproducible and the linearity of the gradient is optimal.

2. Place the gradients on ice for 20 to 30 min to chill. Gradients can be prepared the night before the experiment and kept at 4°C. Once prepared cover them with Parafilm.
3. Load 200 to 250 μl of the synaptic vesicle preparation (100 to 500 μg of total protein) on top of the gradient.
4. Ultracentrifuge 75 min at 218,309 × *g*, 4°C.
5. Collect gradients from the bottom into sixteen 6-drop fractions using a tube-piercing apparatus.

   Fractions can also be collected from the top using a 1-ml automatic pipettor; collect ~250- tp 270-μl fractions. Synaptic vesicles migrate in fractions 7 to 12 in the middle of the gradient.

6. Flash freeze the fractions in liquid nitrogen and store at −80°C.

ALTERNATE PROTOCOL 2

SYNAPTIC VESICLE ENRICHMENT BY CONTROLLED PORE GLASS (CPG) CHROMATOGRAPHY

Materials

Glycerol-coated controlled pore glass (glyceryl-CPG) beads, 3000 Å particle size (CPG, Inc.)
300 mM glycine/5 mM HEPES, pH 7.4, containing 1× protease inhibitors (see recipe for protease inhibitors)
Synaptic vesicle preparation (see Basic Protocol 1 or Alternate Protocol 1)
Buffer A (see recipe) containing 1× protease inhibitors (see recipe)

85 × 1.6–cm glass chromatography column, siliconized (see Support Protocol 3)
Wall-mounted column rack
Peristaltic pump and fraction collector, with appropriate tubing and connections
Additional reagents and equipment for protein assay (*APPENDIX 3B* or *APPENDIX 3H*) and concentration of protein solutions (*APPENDIX 3C*)

1. Resuspend CPG beads in distilled water and degas.
2. Place an 85 × 1.6–cm i.d. glass chromatography column in a wall-mounted column rack with the bottom part of the column in contact with a Vortex mixer.

   The glass column should be sturdy enough to withstand extensive vortexing.

3. With the vortexer at maximum speed, apply the CPG slurry very slowly, to avoid the formation of settled zones. Once finished pouring the slurry, keep vortexing the column for at least 30 to 60 min to settle all the beads.
4. Attach column to peristaltic pump. Equilibrate column with 10 volumes of 300 mM glycine/5 mM HEPES, pH 7.4.

5. Load the synaptic vesicle preparation (do not exceed 15 mg protein).
6. Run the column at 50 to 80 ml/hr and collect 4-ml fractions.
7. Check protein elution by monitoring the column eluate by spectrophotometry at 280 nm (*APPENDIX 3B*) or by a protein assay (*APPENDIX 3H*).

   There should be two overlapping peaks. The second peak corresponds to a preparation of highly purified synaptic vesicles.

8. Depending on the application, flash freeze vesicles in liquid nitrogen or concentrate using a centrifugal concentrator (*APPENDIX 3C*).

SYNAPTIC VESICLE ENRICHMENT BY GEL-FILTRATION CHROMATOGRAPHY IN SEPHACRYL S-1000

ALTERNATE PROTOCOL 3

Materials

Sephacryl S-1000 resin (Amersham Biosciences)
Buffer A (see recipe) containing 25% (v/v) glycerol and 1× protease inhibitors *or* 300 mM glycine/5 mM HEPES, pH 7.4, containing 1× protease inhibitors (see recipe for protease in hibitors)
Synaptic vesicle preparation (see Basic Protocol 1 or Alternate Protocol 1)
15 × 1–cm plastic chromatography column, siliconized (see Support Protocol 3)

Additional reagents and equipment for concentrating protein solutions (*APPENDIX 3C*)

1. Pour Sephacryl S-1000 into a 15 × 1–cm plastic chromatography column to make an 11-ml packed bed column.
2. Equilibrate column with 5 volumes of 25% glycerol in buffer A or 300 mM glycine/5 mM HEPES, pH 7.4, containing 1× protease inhibitors.
3. Equilibrate with ten volumes of either buffer A or 300 mM glycine 5 mM HEPES, pH 7.4.
4. Apply the synaptic vesicle preparation (1.5 mg protein) and run column by gravity.
5. Collect 0.5-ml fractions in siliconized microcentrifuge tubes.
6. Microcentrifuge the fraction-containing tubes at maximum speed, 4°C, and retain the supernatants.
7. Depending on the application, flash freeze vesicles in liquid nitrogen or concentrate by ultracentrifugation (*APPENDIX 3C*).

SYNAPTIC VESICLE SEDIMENTATION AT HIGH SPEED

SUPPORT PROTOCOL 1

After chromatography, vesicles are diluted in a large volume. Although their concentration may be good for immunoblotting or SDS-PAGE, if larger amounts of concentrated material are needed, vesicles can be concentrated by sedimentation. Tabletop ultracentrifuges or airfuges are appropriate for this purpose. Remember that if vesicles are obtained from a gradient they may have already reached their equilibrium buoyancy. Therefore, the solution in which the vesicles are present ought to be diluted at least 1:1. Failure to do this will result in the vesicles staying in suspension despite the time and g-force applied to sediment them. If the vesicles are in a solution that contains soluble proteins, it should be taken into account that, at the g-force applied here, many protein complexes will also sediment with the vesicles, irrespective of whether or not these proteins interact with synaptic vesicles.

Materials

Synaptic vesicle preparation (see previous protocols)
Buffer A (see recipe)
1000 × protease inhibitors (see recipe) *or* Boehringer Complete protease inhibitor tablets (Roche Applied Science)
Beckman ultracentrifuge with TLA 120.2 rotor (or equivalent), and corresponding ultracentrifuge tubes

NOTE: Carry out all procedures at 4°C using solutions prechilled to that temperature.

1. If required, dilute vesicles in buffer A. Keep all the solutions at 4°C and add protease inhibitors to concentration of 1×.
2. Place the diluted vesicles in siliconized tubes for the TLA 120.2 rotor. Mark the site in which the membrane pellet should be found (i.e., the outermost side of the tube bottom in a fixed-angle rotor).

   This is an important consideration, as the pellet is crystalline and hard to visualize.
3. Centrifuge 1 hr at 200,000 × *g*, 4°C.
4. Carefully remove supernatant with a pipet.
5. Add a small volume of buffer A (~0.2 ml) to wash the pellet. Carefully aspirate.
6. Depending on the use of the vesicles store them at −80°C or resuspend in the appropriate buffer (e.g., buffer A containing 1× protease inhibitors).

SUPPORT PROTOCOL 2

IMMUNOPURIFICATION OF SV SUBPOPULATIONS

Synaptic vesicles or their subpopulations can be isolated by immunoadsortion. Beads coated with antibodies specific to the cytosolic tails of universal synaptic vesicle markers like VAMP II (Baumert et al., 1989) or SV2 (Floor and Feist, 1989) can retrieve synaptic vesicles selectively and with high efficiency. This procedure is helpful to determine if a new antigen suspected to be in synaptic vesicles is indeed present, and not just a protein present in an unidentified membrane population comigrating with synaptic vesicles. Furthermore, the use of transporter-specific synaptic vesicles allows the purification of vesicle subpopulations that contain specific neurotransmitters like glutamate (VGlut1-containing vesicles; Takamori et al., 2000a), GABA (VGAT-containing vesicles; Takamori et al., 2000b; see Table 3.12.1 for antibodies), or zinc (Salazar et al., 2004). A critical element in this protocol is the purity of the vesicles. Crude membrane fractions are not recommended, since some synaptic vesicle antigens might be present in nonsynaptic vesicle membranes as they traffic through different compartments. Also, nonspecific membrane background is substantially higher in cruder membrane preparations.

Materials

Phosphate-buffered saline (PBS; *APPENDIX 2A*) containing 5% (w/v) BSA (fraction V, Boehringer Mannheim)
1000 × protease inhibitors (see recipe) *or* Boehringer Complete protease inhibitor tablets (Roche Applied Science)
Size-purified synaptic vesicles (Basic Protocol 2 or Alternate Protocol 2 or 3)
Primary antibody to protein of interest (Table 3.12.1)
Magnetic bead slurry (Dyanal): e.g., Dynabeads M450 sheep anti-mouse IgG–coated *or* Dynabeads M2800 sheep anti-rabbit IgG–coated beads, depending on species from which primary antibody was derived
Phosphate-buffered saline (PBS; *APPENDIX 2A*)
Laemmli sample buffer (*UNIT 17.3*)

Rotating platform
Dynal MPC-S magnetic stand
Beckman tabletop ultracentrifuge with TLA 120.2 rotor (or equivalent), and corresponding polycarbonate ultracentrifuge tubes

Prepare beads

1. Add 0.5 ml of PBS/5% BSA to a 1-ml screw-cap microcentrifuge tube.

   Snap-cap tubes should be avoided because they have the tendency to trap beads in between the cap and the tube.

2. Add 40 µl of the magnetic bead slurry plus the desired amount of primary antibody.

   Note that the great majority of the bead slurry is buffer. Check that the beads are coupled to the right antibody to recognize the species from which the immunoglobulin of the primary antibody was derived. The anti–synaptic vesicle antibody should be tested at different concentrations. Use a preimmune antibody or an unrelated IgG at the same concentration to determine nonspecific membrane binding to beads. If planning to perform immunoblot on the isolated membranes, set up one tube without any antibody to determine cross-reactivity between the immunoglobulins bound to the beads and the secondary antibodies used in the immunoblot procedure.

3. Incubate at room temperature for 2 hr with slow agitation on a rotating platform.

   Alternatively, incubate overnight at 4°C.

   Prebinding is performed to avoid having free antibody compete with the bead-bound antibody.

4. Microcentrifuge for 2 to 5 sec at maximum speed to remove the beads from the cap.

   This step is not intended to sediment all the beads but rather to avoid losing them on the cap.

5. Put the tubes in the magnetic stand at 4°C. Aspirate and add 1 ml of PBS/5% BSA and wash with slow agitation on a rotating platform for 10 min. Repeat wash.

   IMPORTANT NOTE*: After aspiration, new buffer should be added immediately to avoid drying the beads.*

Bind vesicles

6. Prepare tubes containing 0.5 ml of PBS/5% BSA containing 1× protease inhibitors. Add size-purified synaptic vesicles and the prebound beads from step 5.

   Do not use membrane preparations that have not been size-purified, since the nonspecific background will greatly increase. Between 1 and 5 µg of vesicles is appropriate to start with, but the optimal concentration of vesicles should be determined for each antibody.

7. Incubate with slow rotary agitation for 3 hr at 4°C. Repeat steps 4 and 5 but perform at 4°C.

8. Recover supernatant and save it. Keep supernatant on ice.

9. Add 1 ml of ice cold PBS/5% BSA and rotate beads for 10 min at 4°C. Centrifuge and put in the magnetic stand as described in steps 4 and 5.

10. Repeat washes for a total number of three.

11. Perform a last wash of 10 min in ice-cold PBS to remove the excess BSA.

Prepare samples for storage

12. Add 10 to 40 μl Laemmli sample buffer to the beads and store at −80°C.

13. Transfer supernatants from step 8 to a TLA tabletop ultracentrifuge polycarbonate tube. Dilute the supernatant with 1 volume of PBS and centrifuge 1 hr at 200,000 × *g*, 4°C, to sediment the unbound synaptic vesicles. Add 10 to 40 μl Laemmli sample buffer to pellet and store at −80°C.

SUPPORT PROTOCOL 3

TUBE SILICONIZATION

The authors recommend siliconizing all the surfaces that will be in contact with the purified vesicles. Further into the purification protocol, vesicles will have a tendency to adsorb to plastic and glass. Sigmacote is a special silicone solution in heptane that readily forms a covalent, microscopically thin film that is water resistant.

Materials

Sigmacote (Sigma)
Glass- or plasticware to be siliconized

1. In a fume hood, evenly cover the plastic or glass surface and recover the solution to apply to the next piece of glassware or plasticware.

2. Let stand overnight in a chemical fume hood to dry.

For ultracentrifugation tubes, the authors recommend siliconizing polycarbonate tubes. Microcentrifuge tubes and glass pipets can be autoclaved before use.

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Buffer A

Prepare 10× stock:
100 mM HEPES, pH 7.4
1.5 M NaCl
10 mM EGTA
1 mM $MgCl_2$
Autoclave
Store up to several months at room temperature
1 × working solution: Dilute to 1× with water just before use.

Protease inhibitors, 1000×

Prepare the following together in H_2O:
5 mg/ml leupeptin
10 mg/ml aprotinin
1 mg/ml chymostatin
Store up to 2 to 3 months at −20°C
Separately prepare the following stocks:
10 mM benzamidine in ethanol (store up to 2 to 3 months at −20°C)
2 mg/ml antipain in H_2O (store up to 2 to 3 months at −20°C)
5 mg/ml pepstatin in methanol (store up to 2 to 3 months at −20°C)
1 mM phenylmethylsulfonyl fluoride (PMSF) in ethanol (prepare fresh)
Add to solutions at 1× concentration as recommended in the protocols. PMSF is very sensitive to water, so it should be added fresh to the solutions just before contact with biological material.

SB buffers

SB40:
5 mM HEPES, pH 7.4
40 mM sucrose
SB50:
5 mM HEPES, pH 7.4
50 mM sucrose
SB320:
5 mM HEPES, pH 7.4
320 mM sucrose
SB800:
5 mM HEPES pH 7.4
800 mM sucrose
Prepare fresh

COMMENTARY

Background Information

Synaptic vesicles are the most abundant membrane-enclosed organelle in vertebrate cells. It has been estimated that each neuron possesses, on average, 10^6 synaptic vesicles, and that the total number in the mammalian central nervous system is $\sim 10^{17}$ (Jahn and Sudhof, 1993). About 5% of total nerve tissue protein is associated with synaptic vesicles, implying that these organelles can be enriched ~20 fold over the homogenate. In fact, the enrichment estimated through measurements of the peripherally associated synaptic vesicle protein synapsin I (15.5 fold; Huttner et al., 1983), the integral membrane protein SV2 (18 fold; Floor et al., 1988), or vesicle acetylcholine content (28 fold; Nagy et al., 1976) are in agreement with theoretical calculations.

The above protocols are based on the pioneering work of Whittaker and Kelly (Whittaker et al., 1972; Nagy et al., 1976; Carlson et al., 1978; Wagner et al., 1978). The authors of this unit recommend exploring those papers because of the detailed description of the procedural aspects of vesicle purification. Two chracteristic features of synaptic vesicles are central to all purification protocols. Synaptic vesicles do not contain secretory proteins because they are constantly fusing and rapidly reforming at the presynaptic plasma membrane (Murthy and De Camilli, 2003). The lack of protein in the lumen of a synaptic vesicle results in a density that is lower compared to other organelles (see *UNIT 3.5*, Background Information). Synaptic vesicle density depends on the source of tissue analyzed and the centrifugation medium. However, the density of synaptic vesicles ranges from 1.045 ± 0.002 g/cm^3 by isoosmotic sucrose sedimentation (Carlson et al., 1978) to 1.11 ± 0.003 g/cm^3 by hyperosmotic sucrose sedimentation (Clift-O'Grady et al., 1990). This low density results from the fact that 74% of the synaptic vesicle mass is water, 14% is phospholipids, and only 2.6% is protein (Wagner et al., 1978).

The second characteristic utilized in purification procedures is synaptic vesicle size. Synaptic vesicles are small and highly uniform in size. Morphometric analysis of electron micrographs of fixed synaptic vesicles revealed diameters of ~30 to 50 nm (Kim et al., 2000). The values determined by electron microscopy of fixed tissue have been elegantly confirmed by biophysical analysis of freshly purified synaptic vesicles (Wagner et al., 1978). Vesicle size varies depending on the species in which synaptic vesicles are analyzed and the type of nerve terminal the vesicles are derived from. For example, synaptic vesicles from the *Drosophila* neuromuscular junction differ in size depending on the muscle that they innervate (Karunanithi et al., 2002). The synaptic vesicle's small and uniform size has facilitated size-purification approaches that greatly enhance the purity of these vesicles. Basic Protocol 2 and Alternate Protocols 2 and 3 take advantage of the size of synaptic vesicles.

Homogenization of the tissue is a variable that was extensively analyzed in earlier work on the *Torpedo* fish electric organ (Whittaker et al., 1972; Carlson et al., 1978). Measurements of membrane-enclosed ATP or acetylcholine indicated that blending in the Waring Blendor is more efficient in releasing vesicles than Potter-Elvehjem homogenization. Yield can be increased further by freeze-thawing followed by use of the Waring Blendor (Carlson et al., 1978). Blending of tissue in the Waring Blendor is the basis of Basic Protocol 1, which

was purposely designed to avoid hypotonic lysis of synaptosomes. Tissue is homogenized in a buffer of physiological ionic strength to minimize the nonspecific adsorption of soluble proteins to synaptic vesicles. When vesicles isolated by this procedure are size fractionated by Sephacryl-1000 chromatography, vesicles elute as a peak whose polypeptide composition (by protein gel staining) appears to be similar to that obtained via the Huttner procedure (see Alternate Protocol 1 and Clift-O'Grady et al., 1990). However, Basic Protocol 1 removes loosely associated proteins such as synapsin I from the vesicle's cytoplasmic surface, a process that occurs at ionic strengths as low as 10 mM salt (Huttner et al., 1983).

Basic Protocol 1 can be used with mammalian brain tissue and fish electric organ. The size-purification procedures are universal because the morphological and biophysical features of synaptic vesicles are conserved from invertebrates to humans. In fact glycerol sedimentation has been used in *Drosophila* (van de Goor et al., 1995) as well as neuroendocrine cell lines to identify this type of vesicle (Clift-O'Grady et al., 1990).

Critical Parameters

The two synaptic vesicle purification protocols described here differ in vesicle yield, due to differences in the technique of tissue homogenization and the buffer in which purification is performed. The Huttner method (low salt and gentle homogenization) results in lower yield compared to the Grady protocol, but has an advantage in that it preserves low-affinity protein interactions with synaptic vesicle membranes. In contrast, the Clift-O'Grady protocol utilizes a physiological salt buffer and homogenization is performed in a Waring Blendor. Thus, the Clift-O'Grady protocol results in a higher synaptic-vesicle yield, but proteins that are loosely associated with vesicle membranes are lost. Both protocols are capable of purifying integral membrane proteins residing in synaptic vesicles. However, if there is no available information as to how a protein of interest associates with the membrane, the authors of this unit recommend performing pilot experiments in which the tissue is homogenized in either buffer A or SB40 buffer. Follow steps 1 to 4 of Basic Protocol 1, then sediment the supernatant from step 4 in a TLA centrifuge (see Support Protocol 1). The resulting pellet contains a crude small vesicle membrane fraction that can be tested for the presence of the protein of interest. Proteolytic sensitivity and biological activity of the protein should also be tested to determine if the protein of interest can withstand a 2-day purification procedure.

An equally important consideration is the tendency for synaptic vesicles to adsorb to glass and plastic surfaces. During the initial steps of purification, the high concentration of cytosolic proteins and cellular membranes reduces synaptic vesicle adsorption. However, as synaptic vesicles become increasingly purified, adsorption increases and can compromise the final yield. To avoid this problem the authors recommend siliconizing all glass and plastic materials that will come in contact with synaptic vesicles. To minimize adsorption to the CPG column, it is recommended that glycerol-coated beads, which are available pre-coated from the supplier, be used.

If greater yield is desired, the authors definitely do not recommend increasing the amount of protein loaded into the gradients or changing tissue/buffer ratios. When additional yield is desired, the user is encouraged to perform additional purifications and pool the vesicles.

Assessing vesicle purity

The synaptic vesicle purification protocols presented in this unit have been extensively characterized both for the enrichment of synaptic vesicle markers as well as for the uniformity of the isolated vesicles by electron microscopy (see Fig. 3.12.3). Early work by Whittaker explored whether classical enzymatic markers of mitochondria, ER, and lysosomes were present in the synaptic-vesicle fraction. Although these markers are excluded from purified synaptic vesicles, fractions containing vesicles should not be considered absolutely pure, but rather highly enriched. Other vesicle intermediaries present in brain tissue cells may have identical biophysical properties to synaptic vesicles and could possibly copurify with synaptic vesicles. Users should test whether their preparations contain other vesicles or organelles in which the protein of interest is suspected to be present. Alternatively, immunoisolation of vesicles using synaptic vesicle–specific antibodies can provide a solid indication as to the presence of a certain protein in synaptic vesicles.

The authors strongly encourage the user to characterize the final vesicle preparation not only for the enrichment of synaptic vesicles using the antibodies described in Table 3.12.1, but also to ensure that other organelle markers are absent. A good collection of compartment-specific antibodies available commercially can be found at *http://www.bdbiosciences.com*.

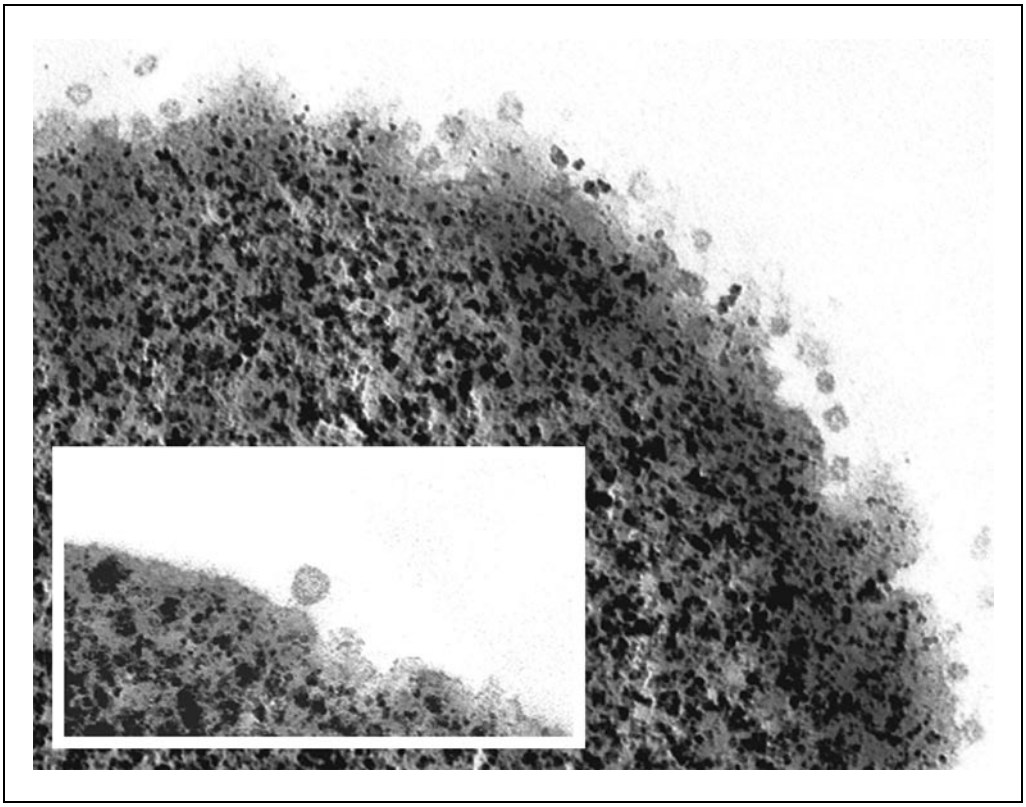

Figure 3.12.3 Electron microscopy of purified synaptic vesicles. Synaptic vesicles isolated by glycerol velocity sedimentation (fractions 6 to 10) were incubated with magnetic beads coated with antibodies against the cytosolic tail of synaptophysin (SY38) as described in Support Protocol 2. Beads were extensively washed and processed for transmission electron microscopy. The dark and granular circular profile that covers two thirds of the image and extends from the lower left-hand corresponds to a sectioned magnetic bead. Note the presence of multiple vesicle profiles of ~40 nm in diameter on the bead horizon. Control beads with mouse IgG do not display synaptic vesicles on their surface. Insert shows a magnification of an archetypical synaptic vesicle.

Anticipated Results

The outcome of the purification should be an enrichment of synaptic vesicle antigens to about 20- to 30-fold over the starting homogenate. A good record of the volumes and protein concentrations of all the fractions should be maintained. The preparations yielded by the protocols described here have been analyzed for the presence of contaminant membranes using electron microscopy and biophysical criteria, as well as for the presence of classical enzymatic markers of plasma membrane, mitochondria, and endoplasmic reticulum. Although these protocols are well established and characterized, users should determine whether the synaptic vesicles obtained contain contaminant membranes. The use of antibodies against compartment-specific antigens is strongly encouraged. It should be noted that for accurate immunoblot analysis it is important to maintain sample integrity throughout the procedure. Always maintain protease inhibitors in all buffers and store fractions at −80°C. After adding sample buffer, samples must under no circumstances be boiled, because many synaptic vesicle proteins form aggregates that do not efficiently enter the gel or that run as smears. In the authors' laboratory, samples are routinely heated to 70°C for 5 min. In addition, some antigens (SV2, for example) electrophorese differently due to species, post-translational modifications (Buckley et al., 1983; Buckley and Kelly, 1985), or differential isoforms (Bajjalieh et al., 1994; Janz and Sudhof, 1999).

Table 3.12.2 tabulates proteins identified in size-purified synaptic vesicles.

Isolation of Clathrin-Coated Vesicles by Differential and Density Gradient Centrifugation

Endocytosis of nutrients, signaling receptors, and other cell surface regulatory proteins via clathrin-coated vesicles (CCVs) is essential for normal cellular function. CCVs are also involved in the transport of proteins, such as lysosomal hydrolases, from the *trans*-Golgi network to the endosomal/lysosomal system. CCVs are relatively uniform in size and, at 50 to 100 nm in diameter, they are among the smallest membranous organelles. Moreover, they are encased in a dense, proteinaceous coat, which contributes to the formation of the vesicular structure. Protocols for isolating CCVs take advantage of the small size and high density of these organelles by using differential centrifugation coupled with velocity and equilibrium gradients to separate CCVs from contaminating membranes.

The first reliable protocol for isolating CCVs was described by Pearse (1975), working with pig brain. CCVs were enriched in a microsomal fraction prepared by differential centrifugation. They were subsequently separated from larger and less dense membranes using velocity and equilibrium sedimentation, respectively, on linear sucrose gradients. Pearse (1982) later introduced a protocol (for purification of CCVs from human placenta) in which Ficoll and D_2O were substituted for sucrose. Most protocols currently in use are derived from these original protocols.

In Basic Protocol 1, the authors describe a procedure for isolating CCVs from adult rat brain. This procedure, which is based on the protocol of Maycox et al. (1992), uses differential centrifugation coupled with Ficoll and D_2O-sucrose density gradient centrifugation. The application of an additional step involving velocity sedimentation in linear sucrose gradients, as originally described by Wasiak et al. (2002), is also outlined. In Alternate Protocols 1 and 2, the authors describe how the same basic approach can be applied to the isolation of CCVs from developing rat brain and cell lines, respectively.

When applied to other tissues, such as rat liver, the steps outlined in Basic Protocol 1 yield CCV preparations that exhibit only modest enrichment and purity. In Basic Protocol 2, therefore, the authors describe a fractionation procedure that has been used to purify CCVs from rat liver. This protocol, based on that of Pilch et al. (1983), involves differential centrifugation coupled with velocity and equilibrium centrifugation using discontinuous sucrose gradients.

Following fractionation, it is necessary to characterize CCV enrichment and purity. One important method for doing so is the analysis of equal protein aliquots of the various subcellular fractions by SDS-PAGE (*UNIT 6.1*) using Coomassie blue staining and/or immunoblotting (*UNIT 6.2*) with antibodies against specific CCV proteins (e.g., clathrin). Thus, for each protocol, we indicate fractions from which aliquots should be retained for analysis. The purity of CCVs is best assessed by electron microscopy (EM). In the Support Protocol, we describe an EM procedure, based on that of Baudhuin et al. (1967), that involves filtration of the isolated vesicle fractions onto nitrocellulose filters. This procedure ensures a random sampling of membranes in the pellet fraction and is thus appropriate for quantitative evaluation of CCV purity.

NOTE: All protocols using live animals must first be approved by an Institutional Animal Care and Use Committee (IACUC) and must conform to governmental regulations for laboratory animal care and use.

Current Protocols in Cell Biology (2005) 3.13.1-3.13.31

NOTE: All prepared solutions, glassware, centrifuge tubes, and equipment should be precooled, and samples should be kept on ice throughout unless otherwise noted.

NOTE: It is recommended that the purification of CCVs be monitored using clathrin as a marker. Each fraction that should be included in subsequent analyses is named, and the need to reserve aliquots of various fractions in screw-cap tubes is indicated throughout the protocols that follow. All reserved aliquots should be snap-frozen in liquid nitrogen and stored at −70°C.

BASIC PROTOCOL 1

ISOLATION OF CCVs FROM ADULT RAT BRAIN USING DIFFERENTIAL AND DENSITY GRADIENT CENTRIFUGATION

In this protocol, adult rat brains are homogenized in MES buffer at pH 6.5 (buffer A) using a glass-Teflon homogenizer. Figure 3.13.1 provides a flow chart summarizing the subsequent steps used to isolate CCVs. A microsomal fraction is first generated from the homogenate by performing two differential centrifugation steps. Next, the CCVs are separated from larger microsomal contaminants by velocity sedimentation through a Ficoll-sucrose solution. The CCVs are subsequently separated from less dense membranes by pelleting through a sucrose cushion prepared in D_2O. These steps represent the basic procedure as described by Maycox et al. (1992). The D_2O pellets are further fractionated on linear sucrose gradients (20% to 50%) as originally described by Wasiak et al. (2002).

Materials

10 Sprague-Dawley rats (150 to 200 g each)
1× buffer A (see recipe) containing protease inhibitors (see recipes)
Ficoll-sucrose solution (see recipe)
Deuterium oxide (D_2O; heavy water)–sucrose solution (see recipe)
20% and 50% sucrose solutions in 1× buffer A (see recipe)

Glass-Teflon homogenizers (assorted sizes; Wheaton) fitted to a power head
Sorvall high-speed centrifuge equipped with SS-34 fixed-angle rotor (or equivalent)
Battery-operated pipet filler
Ultracentrifuge with fixed-angle (Sorvall T-865, Beckman 45Ti, or equivalent) and swinging-bucket (Sorvall AH-629, Beckman SW-28, or equivalent) rotors
25-G, $\frac{5}{8}$-in. needle
13-ml thin-walled centrifuge tubes
2-mm-diameter glass capillary tubes
Two-chamber gradient maker
Peristaltic pump

Additional reagents and equipment for standard protein assays (*APPENDIX 3H*)

NOTE: Protease inhibitors are added (to a concentration of 1×) to 1× buffer A within 30 min of buffer use, except for PMSF, which should be added immediately after the buffer comes into contact with a protein sample.

Prepare a crude homogenate

1. Sacrifice 10 Sprague-Dawley rats (150 to 200 g), by decapitation or, alternatively, by CO_2 asphyxiation followed by decapitation.

   The sacrificing of rats must be supervised or carried out by an experienced animal technician according to specific animal care protocols at the investigator's institution.

2. Open the rats' skulls with scissors, and remove and weigh the brains. After weighing, transfer the brains to a beaker and add enough ice-cold 1× buffer A so that they are completely covered.

   Ten rat brains typically weigh 15 to 20 g.

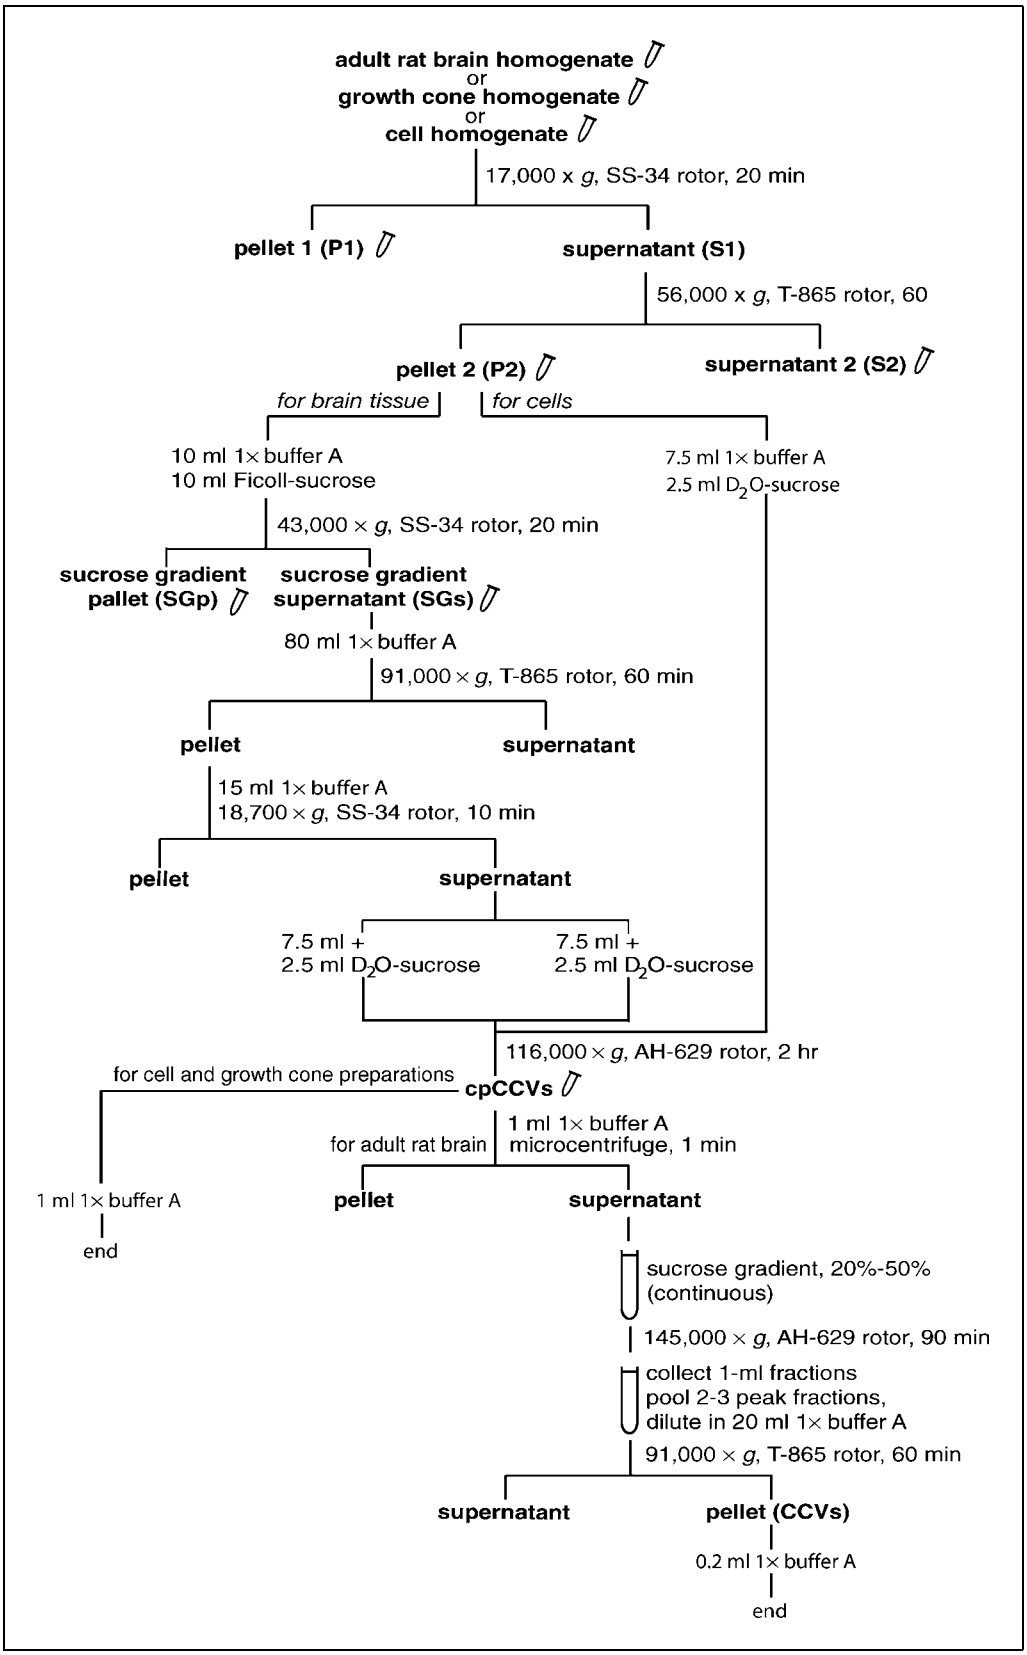

Figure 3.13.1 Flow chart summarizing Basic Protocol 1 and Alternate Protocol 2. The flow chart also covers Alternate Protocol 1 after the lysis of growth cones. The stylized microcentrifuge tube denotes fractions from which an aliquot should be retained for analysis by SDS-PAGE. CCVs, clathrin-coated vesicles; cpCCVs, cusion-pellet clathrin-coated vesicles.

3. Once all of the brains have been removed and weighed, decant and discard the 1× buffer A and transfer the brains to the mortar of a 55-ml glass-Teflon homogenizer.

   A large glass-Teflon homogenizer generally has a capacity of 50 ml, so it is likely that multiple homogenizations will be required to process all of the rat brains that have been collected.

4. Add 5 ml of 1× buffer A for every gram of rat brain in the homogenizer. Homogenize using 10 strokes of the Teflon pestle with the power head set at 1500 rpm.

5. Pool homogenates in a 250-ml graduated cylinder and add ice-cold 1× buffer A to a final volume of 10 ml for every gram of rat brain present (e.g., if 20 g of rat brain is present, add ice-cold 1× buffer A to a final volume of 200 ml). Reserve a 0.5-ml aliquot of the pooled homogenate, but do not discard the rest.

Prepare a microsomal (P2) fraction by differential centrifugation

6. Transfer pooled homogenate to six 40-ml centrifuge tubes and centrifuge 20 min at 17,000 × *g*, 0° to 4°C, in a Sorvall SS-34 fixed-angle rotor.

7. Using a pipet filler and pipet, remove the supernatant (S1) from each tube, being careful not to disturb the pellet, and combine all supernatants in a 250-ml glass beaker on ice.

8. Resuspend one of the pellets (P1; step 6) in 10 ml of 1× buffer A by pipetting up and down using a pipet filler and pipet. Transfer the suspension to the mortar of a 35-ml glass-Teflon homogenizer. Prepare an even suspension using 5 strokes of the Teflon pestle with the power head set at 1500 rpm. Reserve a 0.5-ml aliquot of the suspension and discard the rest.

9. Transfer S1 (step 7) to eight 25-ml centrifuge tubes and centrifuge 60 min at 56,000 × *g*, 0° to 4°C, in a Sorvall T-865 fixed-angle rotor.

10. Using a pipet filler and pipet, remove the supernatant (S2) from each tube. Reserve a 0.5-ml aliquot of S2 from one of the tubes and discard the rest.

11. Combine all pellets (P2; step 9) and use a pipet filler and pipet to resuspend in a total of 10 ml of 1× buffer A.

    The head of a small Teflon homogenizer can be used to scrape the pellets out of their individual centrifuge tubes so that they can be combined.

12. Transfer the resuspended P2 pellets to the mortar of a 35-ml glass-Teflon homogenizer and prepare an even suspension using 5 strokes of the Teflon pestle with the power head set at 1500 rpm.

13. Transfer the homogenized material to a syringe barrel equipped with a 25-G, $\frac{5}{8}$-in. needle. Pass the material once through the needle by slowly and evenly applying pressure to the plunger. Reserve a 0.25-ml aliquot of the P2 suspension, but do not discard the rest.

Centrifuge microsomal fraction on a Ficoll-sucrose density gradient

14. Add 10 ml ice-cold Ficoll-sucrose solution to the P2 suspension (∼10 ml) and gently mix by pipetting up and down. Transfer to a 40-ml centrifuge tubes.

15. Centrifuge 20 min at 43,000 × *g*, 0° to 4°C, in a Sorvall SS-34 fixed-angle rotor.

16. Using a pipet filler and pipet, remove the supernatant (sucrose gradient supernatant, or SGs) and transfer to a 100-ml graduated cylinder.

17. Resuspend the pellet (sucrose gradient pellet, or SGp) in 5 ml of 1× buffer A by pipetting up and down. Transfer the suspension to the mortar of a 10-ml glass-Teflon

homogenizer. Generate an even suspension using 5 strokes of the Teflon pestle with the power head set at 1500 rpm. Reserve a 0.5-ml aliquot of the suspension and discard the rest.

18. Dilute the SGs from step 16 (20 ml) by adding 80 ml ice-cold 1× buffer A. Transfer to six 25-ml centrifuge tubes.

19. Centrifuge diluted SGs 60 min at 91,000 × *g*, 0° to 4°C, in a Sorvall T-865 fixed-angle rotor.

20. Using a pipet filler and pipet, remove and discard all supernatants.

21. Combine all pellets and use a pipet filler and pipet to resuspend in a total of 15 ml of 1× buffer A.

    The head of a small Teflon homogenizer can be used to scrape the pellets out of their individual centrifuge tubes so that they can be combined.

22. Transfer the resuspended material to the mortar of a 30-ml glass-Teflon homogenizer and homogenize using 5 strokes of the Teflon pestle with the power head set at 1500 rpm.

23. Transfer the homogenized material to a syringe barrel equipped with a 25-G, $\frac{5}{8}$-in. needle. Pass the material once through the needle by slowly and evenly applying pressure to the plunger, and collect in a 40-ml centrifuge tube.

24. Centrifuge 10 min at 18,700 × *g*, 0° to 4°C, in a Sorvall SS-34 fixed-angle rotor.

25. Using a pipet filler and pipet, remove the supernatant (still referred to as the SGs) and transfer to a 50-ml graduated cylinder. Reserve a 0.5-ml aliquot and discard pellet.

Pellet CCVs through sucrose cushion

26. Split SGs into 2 aliquots of 7.5 ml and transfer each aliquot to a 13-ml thin-walled centrifuge tube designed for a Sorvall AH-629 swinging-bucket rotor.

27. Underlay each SGs sample with 2.5 ml D_2O-sucrose solution in the following way.

    a. Use a piece of Tygon tubing to attach a 5-ml syringe barrel to a 2-mm-diameter glass capillary tube.

    b. Load the 5-ml syringe barrel with D_2O-sucrose solution.

    c. Gently position the exposed end of the attached capillary tube so that it rests at the bottom of the centrifuge tube containing the 7.5-ml sample.

    d. Slowly eject 2.5 ml D_2O-sucrose solution into the centrifuge tube from the syringe.

28. Centrifuge samples 2 hr at 116,000 × *g*, 0° to 4°C, in a Sorvall AH-629 swinging-bucket rotor.

29. Using a pipet filler and pipet, remove and discard the supernatants.

30. Combine pellets (cushion-pellet CCVs, or cpCCVs) and resuspend in a total of 1 ml of 1× buffer A.

    The head of a small Teflon homogenizer can be used to scrape the pellets out of their individual centrifuge tubes so that they can be combined.

31. Transfer suspension to the mortar of a 3-ml glass-Teflon homogenizer.

32. Generate even cpCCV suspensions using 3 strokes of a Teflon pestle (from the glass-Teflon homogenizer) with the power head set at 1500 rpm. After homogenization, transfer the suspended material to a single microcentrifuge tube. Reserve a 100-µl aliquot of the homogenized suspension, but do not discard the rest.

The protocol can be stopped at this point, with the cpCCVs having been collected; if so, the cpCCV suspension can be divided into aliquots (to eliminate the need for repeated freezing/thawing in the future), transferred to screw-cap tubes, snap-frozen in liquid nitrogen, and stored at −70°C for up to 1 year. Otherwise, proceed to linear sucrose gradient fractionation.

Perform linear sucrose gradient fractionation

33. Transfer the cpCCV suspension to a syringe barrel equipped with a 25-G, $\frac{5}{8}$-in. needle. Pass the suspension once through the needle by slowly and evenly applying pressure to the plunger, and collect suspension in a microcentrifuge tube.

34. Microcentrifuge the cpCCV suspension 1 min at maximum speed, 0° to 4°C.

35. In a 13-ml thin-walled centrifuge tube designed for a Sorvall AH-629 swinging-bucket rotor, prepare a 12-ml linear gradient from equal volumes of 20% and 50% sucrose in 1× buffer A using a two-chamber gradient maker. Use a peristaltic pump to ensure an even flow rate (from the gradient maker to the centrifuge tube) of ∼2 to 3 ml/min.

36. Using a Pasteur pipet, remove the supernatant and gently layer it onto the top of the linear gradient. Discard pellet.

37. Centrifuge 90 min at 145,000 × *g*, 0° to 4°C, in a Sorvall AH-629 swinging-bucket rotor.

38. Collect approximately twelve fractions of 1 ml from the centrifuged gradient in the following way.

    a. Use a piece of Tygon tubing to attach a 2-mm-diameter glass capillary tube to a peristaltic pump.
    b. Gently position the exposed end of the capillary tube so that it rests on the bottom of the tube containing the centrifuged sucrose gradient.
    c. Activate the peristaltic pump and collect each fraction at a flow rate of ∼2 to 3 ml/min.

39. Use a standard protein assay (*APPENDIX 3H*) to determine which of the isolated fractions yield the highest protein signals.

    The highest protein signals should be found near the middle of the gradient (around fractions 6 to 8). The peak protein signal is directly correlated with the peak concentration of CCVs.

40. Pool the 2 to 3 fractions that yield the highest protein signals and dilute to a total volume of 20 ml in 1× buffer A. Transfer to a 25-ml centrifuge tube.

41. Centrifuge the pooled and diluted sample 60 min at 91,000 × *g*, 0° to 4°C, in a Sorvall T-865 fixed-angle rotor.

42. Decant and discard supernatant. Resuspend pellet (which contains CCVs) in 0.2 ml of 1× buffer A.

43. Transfer the resuspended CCVs to the mortar of a 1-ml glass-Teflon homogenizer and generate an even suspension using 5 strokes of the Teflon pestle with the power head set at 1500 rpm.

44. Transfer the suspension to a screw-cap tube, snap-freeze in liquid nitrogen, and store at −70°C for up to 1 year.

    This CCV suspension can be divided into aliquots before freezing to eliminate the need for repeated freezing/thawing in the future.

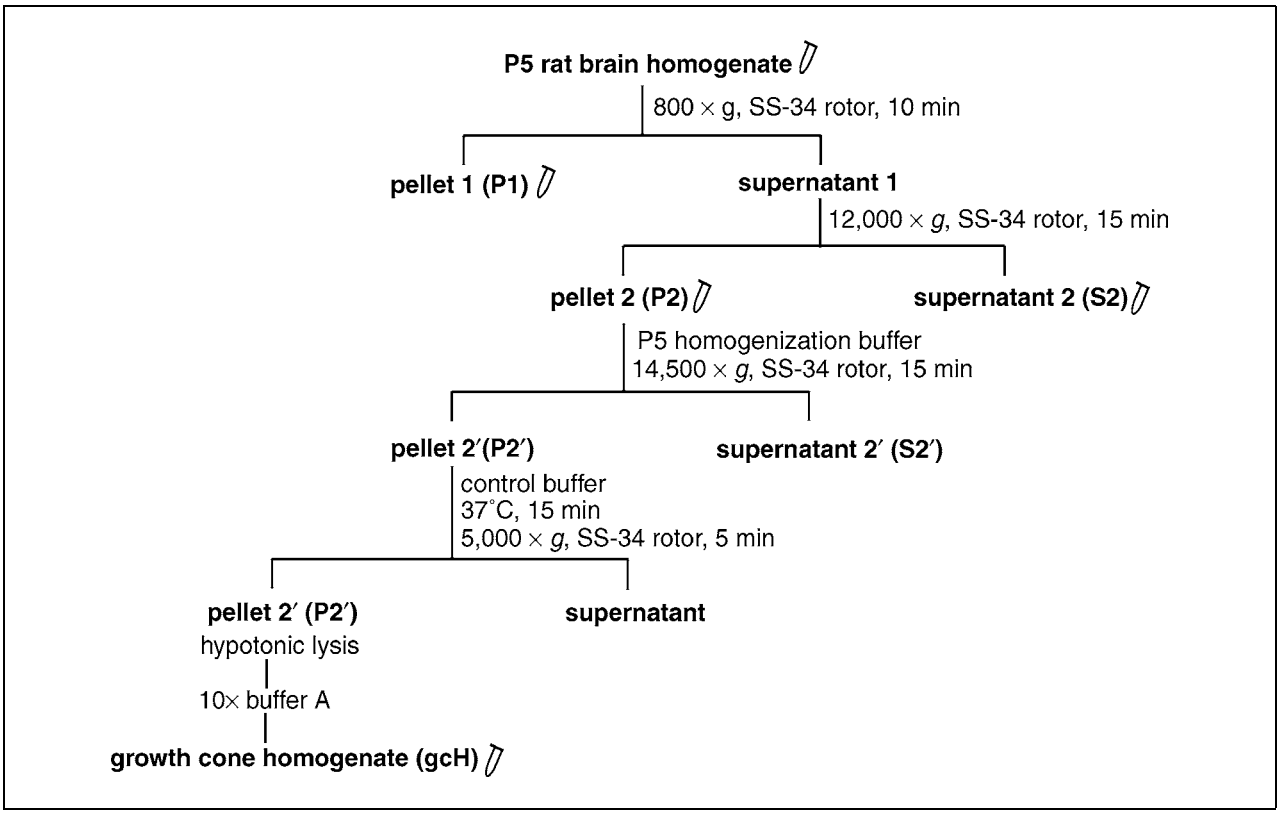

Figure 3.13.2 Flow chart summarizing the generation of crude growth cones in Alternate Protocol 1. The stylized microcentrifuge tube denotes fractions from which an aliquot should be retained for analysis by SDS-PAGE.

ISOLATION OF CCVs FROM DEVELOPING RAT BRAIN USING DIFFERENTIAL AND DENSITY GRADIENT CENTRIFUGATION

ALTERNATE PROTOCOL 1

This protocol is similar to Basic Protocol 1. It is derived from a procedure developed by Maycox et al. (1992) to isolate CCVs from synaptosomes, nerve terminals that are pinched off during homogenization. However, because Alternate Protocol 1 starts with P5 (postnatal day 5) rat brains, CCVs are being isolated primarily from growth cones, nerve terminal structures that guide growing neurites prior to synapse formation (Saito et al., 1992). Figure 3.13.2 presents a flow chart for the initial steps of the protocol. P5 rat brains are homogenized in HEPES buffer containing 0.3 M sucrose (P5 homogenization buffer). With gentle homogenization and isotonic conditions, the growth cones remain intact and are pelleted out at moderately low *g* forces. Next, the crude growth cones are lysed by hypotonic shock to release CCVs, and buffer A is added to stabilize the clathrin coats. The lysate is then subjected to a series of differential and density gradient centrifugation steps as described in Basic Protocol 1 and outlined in Figure 3.13.1.

Additional Materials *(also see Basic Protocol 1)*

15 litters of P5 rat pups
P5 homogenization buffer (see recipe) containing protease inhibitors (see recipes)
Control buffer (see recipe) containing protease inhibitors (see recipes)
10× buffer A (see recipe)

NOTE: Protease inhibitors are added (to a concentration of 1×) to P5 homogenization buffer, control buffer, and 1× buffer A within 30 min of buffer use, except for PMSF, which should be added to a given solution immediately after the solution comes into contact with protein samples.

Prepare crude growth cones

1. Sacrifice 15 litters of P5 rat pups by decapitation or, alternatively, by CO_2 asphyxiation followed by decapitation.

   The sacrificing of rats must be supervised or carried out by an experienced animal technician according to specific animal care protocols at the investigator's institution.

2. Open the rats' skulls with scissors, and remove and weigh the brains. After weighing, transfer the brains to a beaker and add enough ice-cold P5 homogenization buffer so that they are completely covered.

   In 15 litters, there will be ~200 pups total. The total wet weight of the brains collected will be ~110 g.

3. Once all brains have been removed and weighed, decant and discard the P5 homogenization buffer and transfer the brains to the mortar of a 55-ml glass-Teflon homogenizer.

   A large glass-Teflon homogenizer generally has a capacity of 50 ml, so it is likely that multiple homogenizations will be required to process all of the rat brains that have been collected.

4. Add 5 ml P5 homogenization buffer for every gram of rat brain in the homogenizer. Homogenize using 10 strokes of the Teflon pestle with the power head set at 900 rpm.

5. Pool homogenates in a 1000-ml graduated cylinder. Reserve a 0.5-ml aliquot of the pooled homogenate.

6. Transfer pooled homogenate to sixteen 40-ml centrifuge tubes and centrifuge 10 min at 800 × *g*, 0° to 4°C, in a Sorvall SS-34 (or equivalent) fixed-angle rotor.

   The SS-34 rotor fits eight tubes, so two rounds of centrifugation will be necessary.

7. Using a pipet filler and pipet, remove the supernatant (S1) from each tube, being careful not to disturb the pellet, and combine all supernatants in a glass beaker on ice.

   It is recommended that the supernatants be removed at the centrifuge, as transport of the tube can disturb the pellet, which is very soft.

8. Resuspend one of the pellets (P1; step 6) in 5 ml P5 homogenization buffer. Transfer the suspension to the mortar of a 10-ml glass-Teflon homogenizer. Generate an even suspension using 5 strokes of the Teflon pestle with the power head set at 1500 rpm. Reserve a 0.5-ml aliquot of the suspension and discard the rest.

9. Transfer S1 to sixteen 40-ml centrifuge tubes and centrifuge 15 min at 12,000 × *g*, 0° to 4°C, in a Sorvall SS-34 fixed-angle rotor.

   The SS-34 rotor fits eight tubes, so two rounds of centrifugation will be necessary.

10. Using a pipet filler and pipet, remove the supernatant (S2) from each tube. Reserve a 0.5-ml aliquot from one of the tubes and discard the rest.

11. Combine all pellets (P2; step 9) and use a pipet filler and pipet to resuspend in a total of 400 ml P5 homogenization buffer. Reserve a 0.5-ml aliquot of the P2 suspension.

12. Transfer the P2 suspension to sixteen 40-ml centrifuge tubes and centrifuge 15 min at 14,500 × *g*, 0° to 4°C, in a Sorvall SS-34 fixed-angle rotor.

13. Using a pipet filler and pipet, remove and discard all supernatants.

14. Gently pipet 10 ml control buffer up and down over each pellet until only the soft, beige outer component of the pellet (P2′) is resuspended, leaving behind a dense, red core. Pool all of these suspensions in a 500-ml beaker and add control buffer up to a total volume of 200 ml.

The soft, beige outer component, which is weakly adherent to the walls of the centrifuge tube, contains the growth cones. The dense, red core that is left behind is mainly mitochondrial and is strongly adherent to the walls of the tube.

15. Incubate the pooled P2′ suspension 15 min in a 37°C water bath.

Lyse growth cones

16. Transfer the P2′ suspension to sixteen 40-ml centrifuge tubes and centrifuge 5 min at 5000 × *g*, 0° to 4°C, in a Sorvall SS-34 fixed-angle rotor.

17. Using a pipet filler and pipet, remove and discard all supernatants.

18. Combine all pellets and resuspend in a total of 20 ml of 1× buffer A.

19. Transfer suspension to a 500-ml graduated cylinder and add 160 ml ice-cold water. Immediately thereafter, homogenize the diluted suspension (in aliquots not exceeding the capacity of the homogenizer mortar) in a 55-ml glass-Teflon homogenizer using 10 strokes of the Teflon pestle with the power head set at 1500 rpm. Pool homogenized aliquots in a 500-ml graduated cylinder.

    All 160 ml of ice-cold water should be added at once in order to rapidly dilute the sample and lyse the growth cones.

    A large glass-Teflon homogenizer generally has a capacity of 50 ml, so it is likely that multiple homogenizations will be required to process the entire suspension.

20. Immediately after homogenization, add 20 ml of 10× buffer A to the suspension. Reserve a 0.5-ml aliquot of this suspension (referred to as the growth cone homogenate, gcH), but do not discard the rest.

    The addition of 10× buffer A stabilizes the clathrin coats that are present in the sample.

21. Proceed from Basic Protocol 1, step 6 through step 32, treating the gcH as if it were the homogenate suspension obtained in Basic Protocol 1, step 5. Reserve aliquots as directed throughout this portion of the Basic Protocol.

ISOLATION OF CCVs FROM CELL LINES

ALTERNATE PROTOCOL 2

In this protocol, as in Basic Protocol 1, cells are homogenized in 1× buffer A. As outlined in the flow chart in Figure 3.13.1, differential centrifugation is used to generate a microsomal fraction, and enrichment for CCVs is performed by centrifuging this microsomal fraction through a sucrose cushion prepared in D_2O.

Additional Materials *(also see Basic Protocol 1)*

HEK-293, COS-7, or HeLa cells
Phosphate-buffered saline (PBS; *APPENDIX 2A*)
Rubber stopper cut in half lengthwise (to yield straight edges along top and bottom)
Additional reagents and equipment for mammalian cell culture (*UNIT 1.1*)

NOTE: Protease inhibitors are added (to a concentration of 1×) to 1× buffer A within 30 min of buffer use, except for PMSF, which is added immediately after the buffer comes into contact with a protein sample.

Prepare a cell extract

1. Grow 5 dishes (diameter, 10 cm) of HEK-293, COS-7, or HeLa cells to confluence in a 37°C incubator (*UNIT 1.1*).

2. Remove confluent cells from incubator. Using a vacuum source, aspirate culture medium from cells.

3. Wash cells twice, each time by gently adding 10 ml room temperature PBS to each dish of cells and then using a vacuum source to aspirate the PBS.

4. Add 4 ml of 1× buffer A to each plate. Detach cells from plate surface by scraping the bottom of the plate with the straight edge of the cut rubber stopper (i.e., the edge where the flat face that results from cutting and the bottom face of the stopper meet).

5. Transfer cell suspensions to the mortar of a 55-ml glass-Teflon homogenizer and homogenize using 10 strokes of the Teflon pestle with the power head set at 1500 rpm. Reserve a 0.5-ml aliquot of the homogenate.

Prepare a microsomal (P2) fraction

6. Transfer the homogenate to one to two 40-ml centrifuge tubes and centrifuge 20 min at 17,000 × *g*, 0° to 4°C, in a Sorvall SS-34 fixed-angle rotor.

7. Using a pipet filler and pipet, remove the supernatant (S1) from each tube, being careful not to disturb the pellet, and combine all supernatants in a glass beaker on ice.

8. Resuspend one of the pellets (P1; step 6) in 5 ml of 1× buffer A. Transfer the suspension to the glass mortar of a 10-ml glass-Teflon homogenizer. Generate an even suspension using 5 strokes of the Teflon pestle with the power head set at 1500 rpm. Reserve a 0.5-ml aliquot of the suspension and discard the rest.

9. Transfer S1 to two 25-ml centrifuge tubes and centrifuge 60 min at 56,000 × *g*, 0° to 4°C, in a Sorvall T-865 fixed-angle rotor.

10. Using a pipet filler and pipet, remove the supernatant (S2) from each tube. Reserve a 0.5-ml aliquot from one of the tubes and discard the rest.

11. Combine all pellets (P2; step 9) and use a pipet filler and pipet to resuspend in a total of 7.5 ml of 1× buffer A.

12. Transfer the resuspended P2 pellets to the mortar of a 10-ml glass-Teflon homogenizer and generate an even suspension using 5 strokes of the Teflon pestle with the power head set at 1500 rpm.

13. Transfer the homogenized material to a syringe barrel equipped with a 25-G, $\frac{5}{8}$-in. needle. Pass the suspension through the needle once by slowly and evenly applying pressure to the plunger, and collect in a 13-ml thin-walled centrifuge tube designed for a Sorvall AH-629 swinging-bucket rotor. Reserve a 0.25-ml aliquot.

Pellet CCVs through sucrose cushion

14. Underlay the sample with 2.5 ml D_2O-sucrose solution in the following way.

    a. Use a piece of rubber tubing to attach a 5-ml syringe barrel to a 2-mm-diameter glass capillary tube.

    b. Load the 5-ml syringe barrel with D_2O-sucrose solution.

    c. Gently position the exposed end of the attached capillary tube so that it rests at the bottom of the centrifuge tube containing the 7.5-ml sample.

    d. Slowly eject 2.5 ml D_2O-sucrose solution into the centrifuge tube from the syringe.

15. Centrifuge sample 2 hr at 116,000 × *g*, 0° to 4°C, in a Sorvall AH-629 swinging-bucket rotor.

16. Using a pipet filler and pipet, remove and discard the supernatant. Resuspend the pellet (CCVs) in 0.25 ml of 1× buffer A.

17. Transfer the resuspended CCV pellet to the mortar of a 1-ml glass-Teflon homogenizer and generate an even suspension using 5 strokes of the Teflon pestle with the power head set at 1500 rpm.

18. Transfer the suspension to a screw-cap tube, snap-freeze in liquid nitrogen, and store at −70°C for up to 1 year.

    This CCV suspension can be divided into aliquots before freezing to eliminate the need for repeated freezing/thawing in the future.

ISOLATION OF CCVs FROM ADULT RAT LIVER USING DIFFERENTIAL AND DENSITY GRADIENT CENTRIFUGATION

BASIC PROTOCOL 2

In this protocol, adult rat livers are homogenized in HEPES buffer, pH 7.4, containing 0.25 M sucrose (liver homogenization buffer) using a glass-Teflon homogenizer. Figure 3.13.3 provides a flow chart summarizing the subsequent steps used to isolate CCVs. First, a microsomal fraction is obtained from the homogenate by two differential centrifugation steps. (MES buffer, pH 6.5, is added after the first centrifugation step in order to stabilize the clathrin coat.) Next, CCVs are separated from larger microsomal contaminants by velocity sedimentation through discontinuous sucrose gradients. The CCVs are subsequently separated from less dense membranes by equilibrium sedimentation on discontinuous sucrose gradients, and they can be further purified by performing an additional velocity sedimentation step.

Basic Protocol 2 is based on the procedure described by Pilch et al. (1983), as modified from Blitz et al. (1977).

Materials

Ten Sprague-Dawley rats (150 to 200 g)
Liver homogenization buffer (see recipe) containing protease inhibitors (see recipes)
10× and 1× MES buffers (see recipes) containing protease inhibitors (see recipes)
5%, 10%, 20%, 30%, 40%, 45%, 50%, and 55%, and 60% (w/v) sucrose solutions in 1× MES buffer (see recipe)
Glass-Teflon homogenizers (assorted sizes; Wheaton) fitted with power heads
Sorvall high-speed centrifuge equipped with SS-34 fixed-angle rotor (or equivalent)
Battery-operated pipet filler
Ultracentrifuge with fixed-angle (Sorvall T-865, Beckman 45Ti, or equivalent) and swinging-bucket (Sorvall AH-629, Beckman SW-28, or equivalent) rotors
16- and 36-ml polypropylene tubes for Sorvall AH-629 (or equivalent) swinging-bucket rotor
2-mm-diameter glass capillary tubes

NOTE: Protease inhibitors are added to liver homogenization buffer and 1× MES buffer within 30 min of buffer use, except for PMSF, which is added to a given solution immediately after the solution comes into contact with protein samples.

Prepare crude homogenate

1. Starve 10 Sprague-Dawley rats overnight. After overnight starvation, sacrifice rats by decapitation or, alternatively, by CO_2 asphyxiation followed by decapitation.

   The starvation and sacrificing of rats must be supervised or carried out by an experienced animal technician in accordance with specific animal care protocols at the investigator's institution.

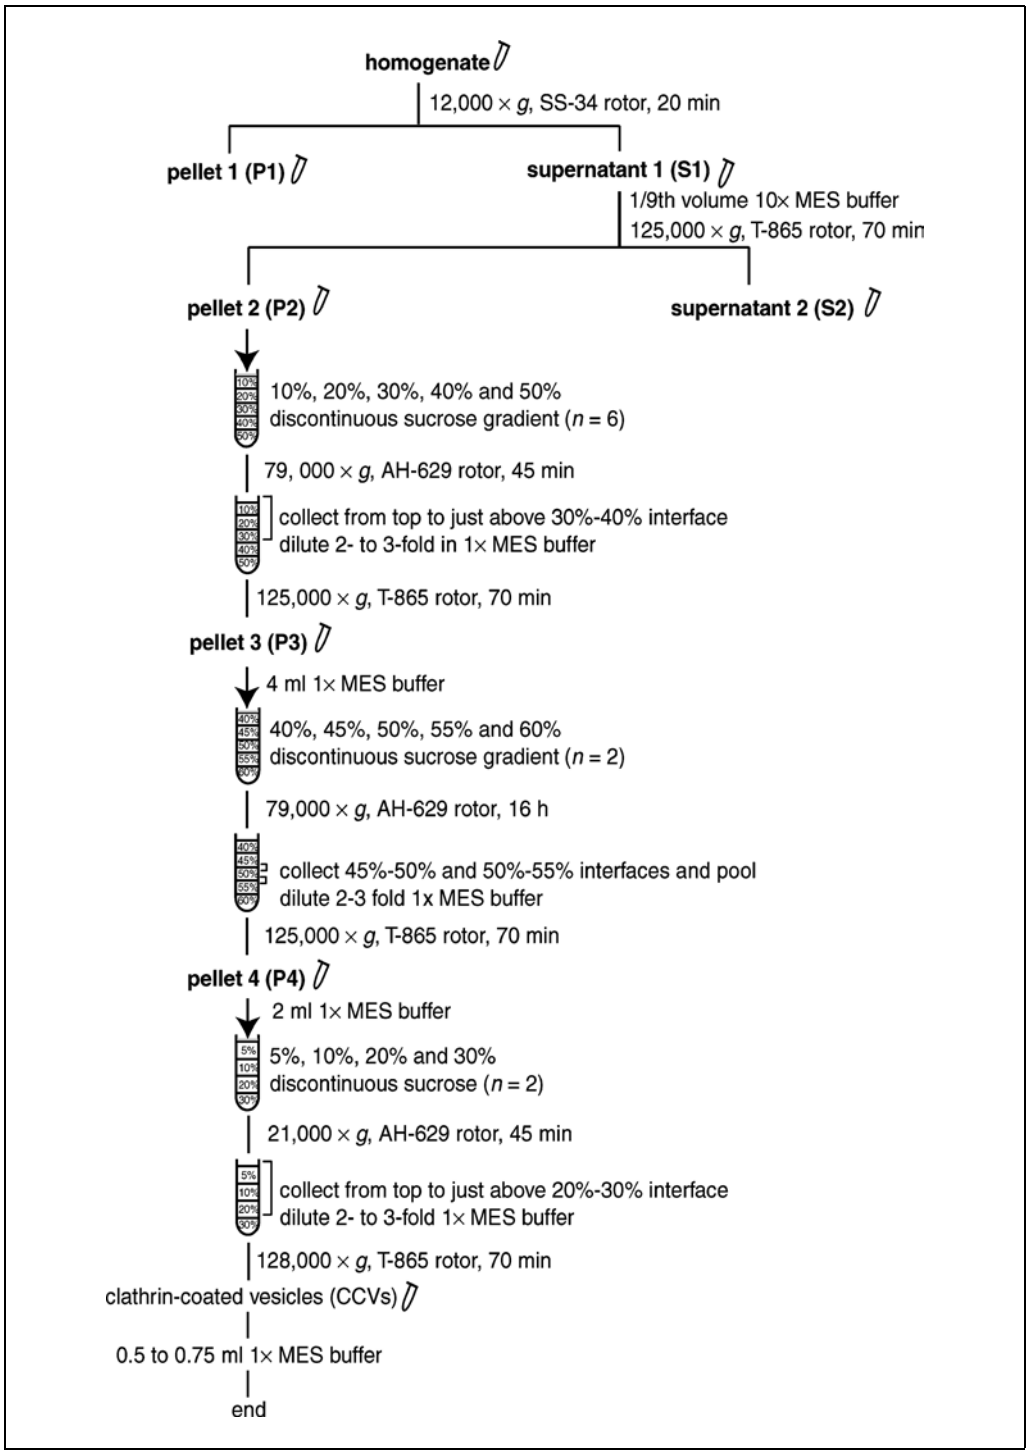

Figure 3.13.3 Flow chart summarizing Basic Protocol 2. The stylized microcentrifuge tube denotes fractions from which an aliquot should be retained for analysis by SDS-PAGE.

2. Open the rats' abdominal cavities and remove their livers. Transfer the livers to a chilled beaker containing ~100 ml liver homogenization buffer.
3. Once all brains have been removed and weighed, decant and discard the liver homogenization buffer. Cut the livers into small pieces with scissors and weigh.

   Ten rat livers typically weigh 60 to 100 g.

4. Transfer the liver tissue to the mortar of a 55-ml glass-Teflon homogenizer.

   A large glass-Teflon homogenizer generally has a capacity of 50 ml, so it is likely that multiple homogenizations will be required to process all of the rat liver tissue that has been collected.

5. Add 2 ml liver homogenization buffer for every gram of rat liver in the homogenizer. Homogenize using 10 to 15 strokes of the Teflon pestle with the power head set at 1500 rpm.

6. Pool homogenates in a 500-ml graduated cylinder and add ice-cold liver homogenization buffer to a final volume of 4 ml for every gram of rat liver present (e.g., if 100 g of rat liver is present, add ice-cold liver homogenization buffer to a final volume of 400 ml). Reserve a 0.5-ml aliquot of the pooled homogenate, but do not discard the rest.

Prepare a microsomal (P2) fraction by differential centrifugation

7. Transfer the pooled homogenates to eight to ten 25-ml centrifuge tubes and centrifuge 20 min at 12,000 × *g*, 0° to 4°C, in a Sorvall SS-34 fixed-angle rotor.

8. Using a pipet filler and pipet, remove the supernatant (S1) from each tube, being careful not to disturb the pellet, and combine all supernatants in a 500-ml graduated cylinder on ice.

9. Resuspend one of the pellets (P1; step 7) in 25 ml of 1× MES buffer. Transfer the suspension to the mortar of a glasss-Teflon homogenizer. Generate an even suspension using 5 to 10 strokes of the Teflon pestle with the power head set at 1500 rpm. Reserve a 0.5-ml aliquot of the suspension and discard the rest.

10. Add 1/9th volume of 10× MES buffer to the pooled S1 from step 8. Reserve a 0.5-ml aliquot.

11. Transfer the pooled S1 (with MES buffer added) to eight to ten 25-ml centrifuge tubes and centrifuge 70 min at 125,000 × *g*, 0° to 4°C, in a Sorvall T-865 fixed-angle rotor.

    The SS-34 rotor fits eight tubes, so two rounds of centrifugation may be necessary.

12. Using a pipet filler and pipet, remove the supernatant (S2) from each tube. Reserve a 0.5-ml aliquot from one of the tubes and discard the rest.

13. In the following way, combine the pellets (P2; step 11) and resuspend them in a maximum of 30 ml of 1× MES buffer.

    a. Scrape the pellets out of their centrifuge tubes using the head of a small Teflon homogenizer (adding a combined total of 15 to 20 ml of 1× MES buffer to the tubes to facilitate pellet removal), and transfer the pellets (along with the added 1× MES buffer) to a chilled beaker. Resuspend the transferred pellets using a 1-ml pipet tip.

    b. Add a combined total of 10 to 15 ml of 1× MES buffer to the tubes from which the P2 pellets were removed, use the head of a small Teflon homogenizer to scrape the remnants of the pellets from the walls of these tubes, and then transfer the contents of the tubes to the chilled beaker from substep a.

       This procedure ensures maximum recovery of the P2 pellet, which is very thick.

14. Transfer the P2 suspension to the mortar of a 30-ml glass-Teflon homogenizer. Generate an even suspension using 5 strokes of the Teflon pestle with the power head set at 1500 rpm. Reserve a 0.25-ml aliquot of the homogenized P2 suspension.

Isolate CCVs from P2 microsomes

15. Prepare six discontinuous sucrose gradients (sucrose concentrations: 10%, 20%, 30%, 40%, and 50%; 5 ml per layer), with each gradient being constructed in the following way.

    a. To a 36-ml polypropylene tube designed for a Sorvall AH-629 swinging-bucket rotor, add 5 ml of a 10% sucrose solution.

    b. Use a piece of Tygon tubing to attach a 10-ml syringe barrel to a 2-mm-diameter glass capillary tube.

       Alternatively, a syringe equipped with a blunt-end pipetting needle can be used to dispense the gradient solutions.

    c. Load the syringe barrel with the 20% sucrose solution.

    d. Gently position the exposed end of the attached capillary tube so that it rests at the bottom of the 36-ml polypropylene tube in which the sucrose gradient is being constructed.

    e. Slowly eject 5 ml of the 20% sucrose solution. Discard the sucrose solution remaining in the syringe barrel.

    f. Repeat substeps c to e three times, first using a 30% sucrose solution, then using a 40% sucrose solution, and finally using a 50% sucrose solution.

    g. Mark all interfaces with an indelible marker.

       It is important to mark all interfaces with an indelible marker, as this will facilitate sample recovery.

16. Using a Pasteur pipet, gently layer 5 ml of the P2 suspension on top of each of the six discontinuous sucrose gradients prepared in step 15.

17. Centrifuge gradients 45 min at 79,000 × *g*, 0° to 4°C, in a Sorvall AH-629 swinging-bucket rotor.

18. For each gradient, using a Pasteur pipet and starting from the top of the tube, collect all of the liquid down to (but not including) the interface between the 30% and 40% sucrose solutions. Transfer collected liquid to a 250-ml graduated cylinder.

19. Add sufficient 1× MES buffer to dilute the collected sample 2- to 3-fold.

20. Transfer diluted sample to eight to twelve 25-ml centrifuge tubes and centrifuge 70 min at 125,000 × *g*, 0° to 4°C, in a Sorvall T-865 fixed-angle rotor.

21. Decant and discard all supernatants. Resuspend pellets (P3) in a total of 4 ml of 1× MES buffer and combine.

    The head of a small Teflon homogenizer can be used to scrape the pellets from their individual centrifuge tubes so that they can be combined.

22. Transfer P3 suspension to the mortar of a 10-ml glass-Teflon homogenizer and generate an even suspension using 3 to 5 strokes of the Teflon pestle with the power head set at 1500 rpm. Reserve a 0.25-ml aliquot of the P3 suspension.

23. Prepare two discontinuous sucrose gradients (sucrose concentrations: 40%, 45%, 50%, 55%, and 60%; 5.5 ml per layer) using the procedure outlined in step 15.

    Note that the gradients constructed in this step differ from those constructed in step 15 only in terms of their layer volumes and sucrose concentrations.

24. Using a Pasteur pipet, layer 2 ml of the P3 suspension on top of each of the two discontinuous sucrose gradients.

25. Centrifuge gradients 16 hr at 79,000 × *g*, 0° to 4°C, in a Sorvall AH-629 swinging-bucket rotor.

26. From each gradient, collect the interface between the 45% and 50% sucrose solutions and the interface between the 50% and 55% sucrose solutions in the following way.

    a. Using a Pasteur pipet and starting from the top of the tube, remove and discard all of the contents of the tube down to a point just above the interface between the 45% and 50% sucrose solutions.

    b. Gently remove the material at the interface between the 45% and 50% sucrose solutions and transfer it to a glass beaker on ice.

    c. Continue by removing and discarding the contents of the tube down to a point just above the interface between the 50% and 55% sucrose solutions.

    d. Gently remove the material at the interface between the 50% and 55% sucrose solutions and add it to the material from the interface between the 45% and 50% sucrose solutions.

    e. Determine the volume of the collected material using a pipet filler and pipet, and then return the material to the glass beaker.

27. Dilute the sample 2- to 3-fold with 1× MES buffer.

28. Transfer diluted sample to four to eight 25-ml centrifuge tubes and centrifuge 70 min at 125,000 × *g*, 0° to 4°C, in a Sorvall T-865 fixed-angle rotor.

29. Decant and discard supernatants. Resuspend pellets (P4) in a total of 2 ml of 1× MES buffer and combine.

    The head of a small Teflon homogenizer can be used to scrape the pellets from their individual centrifuge tubes so that they can be combined.

30. Transfer P4 suspension to the mortar of a 10-ml glass-Teflon homogenizer and generate an even suspension using 3 to 5 strokes of the Teflon pestle with the power head set at 1500 rpm. Reserve a 0.25-ml aliquot of the P4 suspension.

31. Prepare two discontinuous sucrose gradients (sucrose concentrations: 5%, 10%, 20%, and 30%; 3.0 ml per layer), with each gradient being constructed in the following way.

    a. To a 16-ml polypropylene tube designed for a Sorvall AH-629 swinging-bucket rotor, add 3.0 ml of a 5% sucrose solution.

    b. Use a piece of Tygon tubing to attach a 10-ml syringe barrel to a 2-mm-diameter glass capillary tube.

        Alternatively, a syringe equipped with a blunt-end pipetting needle can be used to dispense the gradient solutions.

    c. Load the syringe barrel with the 10% sucrose solution.

    d. Gently position the exposed end of the attached capillary tube so that it rests at the bottom of the 16-ml polypropylene tube in which the sucrose gradient is being constructed.

    e. Slowly eject 3.0 ml of the 10% sucrose solution. Discard the remaining sucrose solution in the syringe barrel.

f. Repeat substeps c to e twice, first using a 20% sucrose solution and then using a 30% sucrose solution.

g. Mark all interfaces with an indelible marker.

It is important to mark all interfaces with an indelible marker, as this will facilitate sample recovery.

32. Using a Pasteur pipet, layer 1 ml of the P4 suspension on top of each of the two discontinuous sucrose gradients.

33. Centrifuge gradients 45 min at 21,000 × *g*, 0° to 4°C, in a Sorvall AH-629 swinging-bucket rotor.

34. For each gradient, using a Pasteur pipet and starting from the top of the tube, collect the contents of the tube down to a point just above the interface between the 20% and 30% sucrose solutions. Transfer collected material to a 100-ml graduated cylinder.

35. Dilute the sample 2- to 3-fold with 1× MES buffer.

36. Transfer diluted sample to two to four 25-ml centrifuge tubes and centrifuge 70 min at 128,000 × *g*, 0° to 4°C, in a Sorvall T-865 fixed-angle rotor.

37. Decant and discard supernatants. Using a pipettor, resuspend pellets (CCVs) in a total of 0.5 to 0.75 ml of 1× MES buffer and combine.

38. Transfer the suspension to a screw-cap tube, snap-freeze in liquid nitrogen, and store at −70°C for up to 1 year.

This CCV suspension can be divided into aliquots before freezing to eliminate the need for repeated freezing/thawing in the future.

SUPPORT PROTOCOL

ANALYSIS OF CCV PURITY BY ELECTRON MICROSCOPY

This protocol is derived from the method of Baudhuin et al. (1967). It is specifically designed to analyze subcellular particles generated by centrifugation and to ensure random sampling throughout a membrane pellet. Isolated membrane fractions that have been enriched for CCVs are fixed using glutaraldehyde and then applied to Millipore filters, generating very thin pellicles of packed particles. The CCVs and contaminating membranes in these samples are further fixed with osmium tetroxide and stained with tannic acid and uranyl acetate (Simionescu and Simionescu, 1976), after which the filters are embedded in Epon for EM analysis.

Materials

Fresh CCVs in 1× buffer A or 1× MES buffer (see Basic Protocol 1, Basic Protocol 2, Alternate Protocol 1, or Alternate Protocol 2)
1× buffer A (see recipe), filtered
1× MES buffer (see recipe), filtered (use only if CCVs were prepared using Basic Protocol 2)
25% (w/v) glutaraldehyde solution
Nitrogen gas
Sodium cacodylate buffer (see recipe), 4°C
Osmium tetroxide solution (see recipe), 4°C
Tannic acid solution (see recipe), 4°C
Sodium sulfate solution (see recipe), 4°C
Uranyl acetate solution (see recipe), 4°C, filtered
Maleate buffer (see recipe), 4°C

50%, 70%, 90%, 95%, and 100% (all v/v) ethanol
Propylene oxide
Epon solution (see recipe)
3:1, 1:1, and 1:3 (all w/w) Epon solution (see recipe)/propylene oxide
Platform rocker
Filter unit (Baudhuin et al., 1967; also see annotation to step 3), including 13-mm-diameter Millipore filter discs (pore size, 0.22 μm)
Glass vial
Small paraffin-coated polypropylene containers (Peel-A-Way disposable embedding molds; Polysciences) with (see recipe) and without a coating of hardened Epon on the inside bottom surface

NOTE: Osmium tetroxide, glutaraldehyde, and propylene oxide must be handled and disposed of in accordance with protocols approved by Institutional Chemical Safety and Chemical Waste Committees. Uranyl acetate is radioactive and therefore must be handled and disposed of in accordance with protocols approved by an Institutional Radiation Safety Committee, as well as in accordance with protocols approved by Institutional Chemical Safety and Chemical Waste Committees.

NOTE: All steps involving propylene oxide should be performed in a fume hood, as this compound is highly volatile.

Fix sample in glutaraldehyde

1. Add 0.2 mg of CCV fractions (as measured using a standard protein assay; *APPENDIX 3H*) to a microcentrifuge tube. Dilute to a final volume of 0.9 ml in ice-cold, filtered 1× buffer A or ice-cold, filtered 1× MES buffer, depending on which buffer the CCV fractions are suspended in.

2. Add 100 μl of ice-cold 25% glutaraldehyde solution. Incubate sample overnight at 4°C with gentle rocking.

   Once the glutaraldehyde solution has been added, the sample can be kept at 4°C for up to 72 hr.

   The authors have only processed fresh CCV fractions using this protocol; thus, they perform steps 1 and 2 immediately following the preparation of CCVs.

Filter sample

3. Wash the filter unit with double-distilled water.

   The filter unit is a custom-built apparatus modeled on the one described by Baudhuin et al. (1967). In brief, a Millipore filter is placed between two Teflon O-rings and then seated on top of a support screen at mid-height in a stainless steel centrifuge tube, and a Plexiglas chamber with a cylindrical opening of matching diameter is fitted to the top of this tube. After the sample of interest has been applied to the filter, the Plexiglas chamber can be closed with a plug (held securely to the Plexiglas chamber by a screw) that allows the filter unit to be connected to a tank of nitrogen gas.

4. Install a 13-mm-diameter Millipore filter (pore size, 0.22 μm) in the filter unit.

5. Apply 1× buffer A to the filter, and adjust the nitrogen flow rate such that 2 ml of the buffer passes through the filter in 30 sec.

6. Apply the fixed sample from step 2 to the filter.

7. Using a Pasteur pipet, gently layer 4 ml of 1× buffer A on top of the fixed sample.

   The 1× buffer A must be layered on top of the fixed sample very gently. The difference in density between the 1× buffer A and the fixed sample prevents mixing of the two layers.

8. Close the filter unit and apply constant nitrogen pressure (using the flow rate determined in step 5). When 2 ml of liquid has passed through the filter (as estimated by eye), cut off the nitrogen flow and open the filter unit.

   Allowing 2 ml of liquid to pass through the filter will ensure that the fixed membranes are collected on the filter while also ensuring that the filter does not dry out. As membranes collect on the filter, the rate at which liquid passes through will decrease to as low as 2 ml every 20 to 30 min.

9. Add 2 to 4 ml ice-cold sodium cacodylate buffer to a glass vial kept at 4°C. Using forceps, transfer the filter to this glass vial such that the sample side faces up.

   In this step and all subsequent steps, take care to ensure that the filter does not dry out.

10. Wash the filter three times, each time by adding 2 to 4 ml ice-cold cacodylate buffer, incubating 15 min at 4°C, and then removing the buffer.

    To avoid damaging the filter, add and remove the cacodylate buffer gently.

    All wash and incubation times presented here are intermediate recommended times and can be changed by ~30% without affecting sample preparation.

Fix sample in osmium tetroxide

11. After removing the last cacodylate buffer wash, add 2 ml ice-cold osmium tetroxide solution. Incubate 1 hr at 4°C, and then remove the solution.

12. Wash the filter three times, each time by adding 2 ml ice-cold cacodylate buffer, incubating 10 min at 4°C, and then removing the buffer.

Treat with tannic acid

13. After removing the last cacodylate buffer wash, add 2 ml ice-cold tannic acid solution. Incubate 1 hr at 4°C, replacing the old 2-ml aliquot of tannic acid solution with a new 2-ml aliquot every 20 min. At the end of the incubation period, remove all of the tannic acid solution.

14. Wash the filter twice, each time by adding 2 ml ice-cold sodium sulfate solution, incubating 10 min at 4°C, and then removing the solution.

Treat sample with uranyl acetate

15. After removing the last sodium sulfate wash, add 2 ml ice-cold, filtered uranyl acetate solution. Incubate in the dark for 2 hr at 4°C, and then remove the solution.

    Precipitate particles will appear as dark spots when the sample is viewed under EM. Thus, it is critical that the uranyl acetate solution be passed through a 0.22-μm filter prior to use. It is also critical that the sample be kept in the dark throughout the course of the incubation, as uranyl acetate will precipitate if it is exposed to light.

16. Wash the filter twice, each time by adding 2 to 4 ml ice-cold maleate buffer, incubating 10 min at 4°C, and then removing the buffer.

    During these two washes, handle the sample under the assumption that it is contaminated with uranyl acetate.

17. Add 2 to 4 ml ice-cold maleate buffer. Incubate overnight at 4°C, and then remove the buffer.

Dehydrate sample

18. Add 2 to 4 ml of ice-cold 50% ethanol to the vial containing the filter. Incubate 10 min at 4°C.
19. Replace the 50% ethanol with 2 to 4 ml of ice-cold 70% ethanol. Incubate 10 min at 4°C.
20. Replace the 70% ethanol with 2 to 4 ml of ice-cold 90% ethanol. Incubate 10 min at 4°C.
21. Replace the 90% ethanol with 2 to 4 ml of ice-cold 95% ethanol. Incubate 10 min at 4°C, and then remove the ethanol solution.
22. Wash the filter twice more, each time by adding 2 to 4 ml of ice-cold 95% ethanol to the vial, incubating 10 min at 4°C, and then removing the ethanol solution.
23. Add 2 to 4 ml of ice-cold 100% ethanol to the vial. Incubate 10 min at 4°C, and then remove the ethanol.
24. Wash the filter once by adding 2 to 4 ml of ice-cold 100% ethanol to the vial, incubating 10 min at 4°C, and then removing the ethanol.

Treat sample with propylene oxide

25. Wash the filter once more by adding 2 to 4 ml of ice-cold 100% ethanol to the vial and incubating 10 min at 4°C. At the end of the 10-min incubation period, fill a small, paraffin-coated polypropylene (Peel-A-Way) disposable embedding mold with propylene oxide and transfer the filter to this mold.

    Do not transfer the filter to an empty mold and then add propylene oxide, as this will cause the filter to fragment.

26. Incubate the filter in propylene oxide for 1 to 2 hr at room temperature.

    Propylene oxide is highly volatile. Therefore, the propylene oxide in the mold will need to be replenished periodically to replace any liquid that has evaporated over the course of the incubation.

    Incubation in propylene oxide makes the filter extremely fragile, and in many cases, the filter will break into pieces as a result. In the remaining steps, the filter should be treated very gently, so as to minimize fragmentation.

Embed samples

27. Gently pour the filter and propylene oxide into a Peel-A-Way embedding mold whose inside bottom surface has been coated with a layer of hardened Epon.
28. Replace the propylene oxide solution in the Epon-coated mold with 2 to 4 ml of 1:3 (w/w) Epon solution/propylene oxide. Incubate 1 hr at room temperature.
29. Replace the 1:3 Epon solution/propylene oxide with 2 to 4 ml of 1:1 (w/w) Epon solution/propylene oxide. Incubate 1 hr at room temperature.
30. Replace the 1:1 Epon solution/propylene oxide with 2 to 4 ml of 3:1 (w/w) Epon solution/propylene oxide. Incubate 1 hr at room temperature.
31. Replace the 3:1 Epon solution/propylene oxide with 2 to 4 ml Epon solution. Incubate 76 hr at 60°C to generate a hard block surrounding the sample.
32. Trim the block, and then section and analyze using standard EM protocols (Baudhuin et al., 1967).

REAGENTS AND SOLUTIONS

Use deionized distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Buffer A

For 10× stock

To 80 ml H_2O, add:
19.52 g 2-(*N*-morpholino)ethanesulfonic acid (MES; 1 M final)
5 ml of 200 mM ethylene glycol bis(β-aminoethylether)-*N,N,N′,N′*-tetraacetic acid (EGTA; 10 mM final)
0.25 ml of 2 M $MgCl_2$ (5 mM final)
Adjust to pH 6.5 with 10 N NaOH
Add H_2O to 100 ml
Store up to 4 weeks at 4°C

For 1× working solution

To 400 ml H_2O, add 50 ml of 10× buffer A
Adjust to pH 6.5 with 1 N NaOH if necessary
Add H_2O to 500 ml
Store up to 2 days at 4°C

To prevent the appearance of dust or other particles in the sample to be analyzed, pass 1× buffer A through a 0.22-μm filter before use.

Control buffer

To 400 ml H_2O, add:

10 ml of 1 M HEPES, pH 7.4 (20 mM final)
16 ml of 4 M NaCl (128 mM final)
0.6 ml of 2.5 M KCl (3 mM final)
0.3 ml of 2 M $MgCl_2$ (1.2 mM final)
0.05 ml of 1 M $CaCl_2$ (0.1 mM final)
18.8 g glucose (11 mM final)
Add H_2O to 500 ml
Store up to 24 hr at 4°C

D_2O-sucrose solution

To 5 ml deuterium oxide (D_2O; heavy water), add:

0.8 g sucrose (8% w/v final)
1 ml of 10× buffer A (see recipe)
Add D_2O to 10 ml
Prepare fresh and use immediately

Epon solution

12.6 g Epon 812 resin (specific density, 1.256 g/cm^3; MECA Lab)
6.7 g dodecenylsuccinic anhydride (specific density, 1.024g/cm^3; MECA Lab)
6.6 g nadic methyl anhydride (specific density, 1.237 g/cm^3; MECA Lab)
0.3 g 2,4,6-tris[(dimethylamino)methyl]phenol (DMP30; specific density, 0.977 g/cm^3; MECA Lab)
Make solution fresh and use immediately

With the exception of DMP30, the components used to make Epon are very viscous and thus hard to measure by volume. Therefore, in the preparation of Epon, measurement of these components by weight is recommended.

The recipe provided here yields 26.2 g Epon, which is sufficient for the preparation of four samples in the Support Protocol.

Ficoll-sucrose solution

To 20 ml of 1× buffer A (see recipe), add:
3.75 g sucrose (12.5% w/v final)
3.75 g Ficoll 400 (12.5% w/v final)
Add 1× buffer A to 30 ml
Stir or gently rock until sucrose and Ficoll 400 are completely dissolved
Prepare fresh and use immediately

Liver homogenization buffer

To 800 ml H_2O, add:
10 ml of 1 M HEPES, pH 7.4 (10 mM final)
85.6 g sucrose (0.25 M final)
Adjust to pH 7.4 if necessary
Add H_2O to 1000 ml
Store up to 24 hr at 4°C

Maleate buffer

To 400 ml H_2O, add:
4 g NaOH
11.6 g maleic acid (50 mM final)
Adjust pH to 6 with 1 N HCl
Add H_2O to 500 ml
Store up to 3 months at 4°C

MES buffer

For 10× stock
To 150 ml H_2O, add:
39.04 g MES (1 M final)
20 ml of 200 mM EGTA (20 mM final)
1.5 ml of 2 M $MgCl_2$ (15 mM final)
Adjust to pH 6.5 with 10 N NaOH
Add H_2O to 200 ml
Store up to 4 weeks at 4°C

For 1× working solution
To 400 ml H_2O, add 50 ml of 10× MES buffer
Adjust to pH 6.5 with 1 N NaOH
Add H_2O to 500 ml
Store up to 2 days at 4°C

Osmium tetroxide solution

To 1 ml of 4% (w/v) osmium tetroxide, add (in the order presented):
2 ml of 3% (w/v) potassium ferrocyanide
1 ml of 0.2 M sodium cacodylate buffer (see recipe)
Prepare fresh and use immediately

P5 homogenization buffer

To 800 ml H_2O, add:
10 ml of 1 M HEPES, pH 7.4 (10 mM final)
102.9 g sucrose (0.3 M final)
Add H_2O to 1000 ml
Store up to 24 hr at 4°C

Peel-A-Way disposable embedding mold with Epon-coated inside bottom surface

Add just enough Epon solution (see recipe) to cover the bottom of a Peel-A-Way disposable embedding mold (Polysciences). Incubate 76 hr at 60°C.

Protease inhibitors

Aprotinin, 10,000× stock:
To 1 ml H_2O, add 5 mg aprotinin powder (5 mg/ml final)
Store up to 6 months at −20°C
Benzamidine, 100× stock:
To 100 ml H_2O, add 1 g benzamidine powder (64 mM final)
Pass solution through a 0.22-μm filter
Store up to 6 months at 4°C
Leupeptin, 10,000× stock:
To 1 ml H_2O, add 5 mg leupeptin powder (5 mg/ml final)
Store up to 6 months at −20°C
Phenylmethylsulfonyl fluoride (PMSF), 500× stock:
To 100 ml of 100% ethanol, add 1 g PMSF powder (10 mg/ml final)
Store up to 3 months at room temperature

Sodium cacodylate buffer

To 400 ml H_2O, add:
21.4 g sodium cacodylate (0.2 M)
Adjust pH to 7.4 with 1 N HCl
Add H_2O to 500 ml
Store up to 3 months at 4°C
Dilute 1:1 with H_2O immediately prior to use in the Support Protocol (final sodium cacodylate concentration, 0.1 M)

Sodium sulfate solution

To 80 ml of 0.1 M sodium cacodylate buffer (see recipe), add 1 g sodium sulfate (1% w/v final). Add 0.1 M sodium cacodylate buffer to 100 ml. Prepare fresh and use immediately.

Sucrose solution, 20% or 50% (w/v), in 1× buffer A

To a 50-ml conical tube containing 25 ml of 1× buffer A (see recipe), add 10 g (20% final) or 25 g (50% final) sucrose. Add 1× buffer A to 50 ml. Stir or gently rock until sucrose is completely dissolved. Prepare fresh and use immediately.

Sucrose solutions in 1× MES buffer

Add the following amounts of sucrose to individual 50-ml conical tubes, each containing 25 ml of 1× MES buffer (see recipe).
2.5 g (5% final)
5 g (10% final)
10 g (20% final)
15 g (30% final)
20 g (40% final)
22.5 g (45% final)
25 g (50% final)
27.5 g (55% final)
Add 1× MES buffer to 50 ml
Prepare fresh and use immediately

Tannic acid solution

To 80 ml of 0.1 M sodium cacodylate buffer (see recipe), add:
1 g tannic acid (1% w/v final)
0.1 M sodium cacodylate buffer to 100 ml
Prepare fresh and use immediately

Uranyl acetate solution

To 100 ml H_2O, add:
25 ml maleate buffer (see recipe)
2 g uranyl acetate (2% w/v final)
Store up to 3 months at 4°C in the dark

To prevent the appearance of dust or other particles in the sample to be analyzed, pass uranyl acetate solution through a 0.22-μm filter prior to use.

COMMENTARY

Background Information

Homogenization and differential centrifugation

CCVs are generally purified in 2-(*N*-morpholino)ethanesulfonic acid (MES) buffers at mildly acidic pH, as originally described by Pearse (1975). These buffers usually contain $MgCl_2$ and EDTA, although the inclusion of these chemicals appears to be primarily a matter of convention (Daiss and Roth, 1983). MES buffers are used at mildly acidic pH, as the stability of the clathrin coat is sensitive to pH. Clathrin coats are also sensitive to protonated amines, and Tris-containing buffers are therefore avoided (Keen et al., 1979). In fact, Tris-containing buffers are routinely used to strip clathrin coats following the isolation of CCVs; this technique is useful in determining whether a protein of interest is associated with the coat or with the vesicle fraction. Moreover, Tris-mediated stripping of clathrin from isolated CCVs is often used in the purification of clathrin. Keen et al. (1979) describe protocols for stripping clathrin coats from CCVs using Tris and other buffers.

Due to their small size, CCVs are resistant to shear forces, and high–shear force methods of homogenization are therefore acceptable (Daiss and Roth, 1983). Protocols originally described by Pearse (1975) used a Waring blender for the homogenization of pig brain tissue. Subsequent protocols for isolating CCVs from placental and lymphoma cells (Pearse, 1976; Pearse, 1982), calf brain (Blitz et al., 1977), rat liver (Pilch et al., 1983), and bovine adrenal cortex (Mello et al., 1980) used similar homogenization techniques. The protocols presented in this unit call for a Wheaton glass-Teflon homogenizer, as previously described by Maycox et al. (1992).

For adult brain and cultured cells, homogenization is performed directly in 100 mM MES, pH 6.5, containing 1 mM $MgCl_2$ and 0.5 mM EDTA (buffer A). The homogenizer power head is set at 1500 rpm, and the pestle is pushed through the sample rapidly and forcefully. These conditions are sufficient to lyse cultured cells and, in the case of brain tissue, to lyse nerve terminals as well as cell somata. When P5 rat brain samples are used, CCVs are isolated from crude growth cones using a protocol derived from the one described by Maycox et al. (1992) for purifying CCVs from synaptosomes. Thus, the homogenization step in that protocol is designed to lyse the somata of neurons but to leave growth cones (or synaptosomes) intact. To this end, homogenization is performed in isotonic sucrose using a glass-Teflon homogenizer. The power head is set at 900 rpm, and the pestle is passed through the sample slowly, using little force. Thus, populations of CCVs and other membrane components, as well as soluble proteins, are trapped inside the growth cones or synaptosomes. Spins of moderate force (12,000 to 14,500 × *g* in sucrose, 5000 × *g* in isotonic saline) are sufficient to pellet these membranes, whereas CCVs and other microsomal components from cell bodies are not pelleted at such *g* forces. After separation from membranes, the growth cones/synaptosomes are washed of peripherally associated vesicles and lysed using hypotonic shock. In Basic Protocol 2, homogenization is performed as in Basic Protocol 1, except that a neutral-pH homogenization buffer containing 0.25 M sucrose is initially employed, with MES buffer (100 mM

MES, pH 6.5; 2 mM $MgCl_2$; 1.5 mM EGTA) being added to the supernatant from the first centrifugation step.

In each protocol, the first step of purification involves differential centrifugation to generate crude microsomes, which are enriched for CCVs. Thus, the homogenates (or lysed growth cones, when P5 brain samples are used) are centrifuged at moderate *g* forces (12,000 to 17,000 × *g*), and the supernatants are collected and centrifuged at 56,000 to 125,000 × *g* (Figs. 3.13.1 to 3.13.3). These steps reduce contamination by nuclei, mitochondria, and other large organelles, such that the majority of CCV contamination comes from vesiculated endoplasmic reticulum, Golgi bodies, membranes of the endosomal/lysosomal system, and other transport vesicles, including synaptic vesicles when brain tissue samples are used.

Density gradients

The various forms of density gradient centrifugation employed in these protocols all take advantage of the small size and high density of CCVs to separate these vesicles from contaminating membranes present in the crude microsomal fractions. Pearse (1975) developed the first protocols of this type. In those protocols, microsomal membranes were applied to 5%-to-60% linear sucrose gradients and centrifuged at 50,000 × *g* for 2 hr (Pearse, 1975). Under velocity sedimentation conditions such as these, organelles will separate based on their size, and CCVs, because of their small size, have a low sedimentation rate. Pearse (1975) found that CCVs banded near the middle of the gradient, with larger contaminating membranes appearing at the bottom of the gradient. Once the CCVs were recovered by pelleting, they were centrifuged for 16 hr at 50,000 × *g* through a linear 20%-to-60% sucrose gradient (Pearse, 1975). Under equilibrium sedimentation conditions such as these, organelles have time to reach their isopycnic points and are thus separated based primarily on their densities. Because of their protein coat, CCVs have a high density (1.20 to 1.25 mg/ml; Daiss and Roth, 1983). Thus, as observed by Pearse (1975), they equilibrate at ~50% to 55% sucrose. Many of the small microsomal vesicles not removed in the velocity gradient step will equilibrate at lower sucrose concentrations and remain above the CCVs in the equilibrium gradient. Basic Protocol 2 takes advantage of these principles using an equilibrium sedimentation step sandwiched between two velocity sedimentation steps on discontinuous sucrose gradients.

One potential problem with sucrose density gradients is that osmotic stress encountered by an organelle at high sucrose concentrations can cause partial disruption of membranes. In fact, it was reported that the sucrose density gradient procedures originally described by Pearse (1975) caused partial disruption of CCVs, with some loss of contents (Pearse, 1982). Pearse (1982) thus introduced techniques for purifying CCVs using Ficoll and D_2O gradients. Maycox et al. (1992) adapted these procedures for the purification of CCVs from rat brain. As described in Basic Protocol 1 and Alternate Protocol 1, microsomal membranes are first fractionated by centrifugation in a Ficoll-sucrose solution in which the sucrose concentration is 12.5%. Centrifugation at 43,000 × *g* for 20 min leads to pelleting of larger microsomal membranes, while CCVs remain in the supernatant. The CCVs are then collected by centrifugation and pelleted through a cushion of 8% sucrose in D_2O. Only dense CCVs are pelleted under these conditions. This step is particularly important when working with brain tissue, since synaptic vesicles, which are abundant in brain, are major contaminating organelles in microsomal fractions. Maycox et al. (1992) were able to determine that these Ficoll-sucrose and D_2O-sucrose centrifugation steps were effective in separating CCVs from synaptic vesicles.

EM analysis of CCVs

Negative-stain electron microscopy (EM) is used routinely to examine CCV purity following subcellular fractionation (Pearse, 1975). Typically, a drop of a resuspended pellet is placed on a carbon-coated copper grid and negatively stained with 1% uranyl acetate, as originally described by Huxley (1963). However, the purity of CCVs may be overestimated using this procedure, as protein-coated vesicles are selectively retained on the grid (Daiss and Roth, 1983). Specimens prepared by fixing pellets prior to embedding and sectioning give a more faithful representation of the purity of CCVs (Daiss and Roth, 1983). However, as noted by Baudhuin et al. (1967), when particles in a given preparation have differing sedimentation coefficients or densities, the distribution of those particles within a pellet will be far from homogeneous. Thus, in the Support Protocol, we describe a procedure for analyzing CCV purity that is based on protocols developed by Baudhuin et al. (1967) and Simionescu and Simionescu (1976). Resuspended CCV fractions are fixed in glutaraldehyde and then passed through Millipore

nitrocellulose filters using nitrogen pressure (Baudhuin et al., 1967). This generates very thin pellicles of packed particles, with fraction heterogeneity solely in the direction perpendicular to the filter surface. The vesicles on the filters are then processed using osmium tetroxide and tannic acid treatments prior to staining with uranyl acetate (Simionescu and Simionescu, 1976). This procedure better preserves membranes as the samples go through the dehydration and embedding steps and results in increased contrast, especially for membranes, on EM (Simionescu and Simionescu, 1976). Taking pictures of large numbers of random EM fields and determining the percentages of CCVs in these fields should yield an unbiased estimate of CCV purity (Blondeau et al., 2004). However, it is possible that the Support Protocol leads to underestimation of CCV purity, since CCVs are small, and larger membranes may be preferentially retained on the filters.

Critical Parameters and Troubleshooting

Tissue source

The species of animal used for CCV preparations is an important consideration. The authors have isolated CCVs exclusively from rat. Rat is a convenient laboratory source of tissue, and the animals are easy to manipulate experimentally; for example, CCVs can be prepared from tissues following the injection of drugs or receptor ligands of interest. Moreover, rat proteins are more likely to be reactive with a broad range of commercial or investigator-generated antibodies. The authors recently performed a proteomic analysis of CCVs isolated from rat brain, with that study being aided by the relative completeness of rat databases (Blondeau et al., 2004). However, CCVs have been successfully isolated from a variety of species. For example, CCVs have also been isolated from the brains of rabbits, cows, and pigs (Pearse, 1975; Blitz et al., 1977; Woods et al., 1978); one advantage of using these species is that large amounts of tissue can be obtained. The use of human tissues is limited, given the relatively large amount of starting material required, although CCVs have been prepared from human placenta (Pearse, 1982).

Another advantage to using rat is that an extensive array of frozen tissues are available. The protocols described here use fresh tissue. However, the authors have also used commercially available frozen tissue from adult rat brain and liver. Based on Coomassie blue staining and immunoblot analysis of subcellular fractions, no obvious differences between fresh and frozen tissue in terms of the protein profiles of the CCVs isolated have been observed. However, Daiss and Roth (1983) have noted that fresh tissue yields a better product for studies of the assembly and disassembly of clathrin coats.

Vesicle isolation

Overall, the protocols presented here are reliable and reproducible. However, there are several points to note. Given the importance of mildly acidic pH to the stability of clathrin coats, the pH of each buffer should be checked immediately prior to starting the preparations. Tissues other than brain should be minced before homogenizing with a glass-Teflon homogenizer. During homogenization, the glass mortar should be held in such a way that the investigator does not warm the tissue with his or her hands. Also, when starting with adult brain synaptosomes (Maycox et al., 1992) or P5 growth cones (Alternate Protocol 1), the pestle should be moved through the sample with limited force in order to minimize shear forces. For the lysis of these structures, water should be added quickly to ensure hypotonic shock, and the pestle should then be passed through the samples forcefully.

Ensure that pellets are completely scraped from the walls of centrifuge tubes. The head of a Teflon pestle is useful in this regard, and the authors generally rinse the walls of the tube with the resuspension buffer as well. Certain pellets, as noted in the protocols, are very soft, and it is important to remove the supernatant from these pellets at the centrifuge in order to avoid disturbing the pellet. Step gradients are easy to prepare, and with some practice, linear gradients can also be generated reproducibly using a conventional two-chamber gradient maker. When using high concentrations of sucrose, ensure that the solution in the front chamber of the gradient maker (i.e., the chamber with the exit port) is adequately stirred. An automatic gradient maker (for example, the BioComp system) that generates linear gradients following the layering of the densest and lightest solutions in a centrifuge tube can also produce reliable gradients.

EM analysis

When following the Support Protocol for the analysis of CCVs by EM, it is important to remember that several of the reagents are somewhat dangerous and must be handled with care. In addition, as noted in the annotation

to step 26, the filter becomes translucent and very fragile once treated with propylene oxide. Thus, it must be handled carefully to avoid losing sample. Even if the filter does fragment, keep all of the pieces that show a spot of brown color (the sample). Finally, do not exceed the recommended nitrogen flow rate, as doing so can cause the filter to collapse.

Anticipated Results

Basic Protocol 1

Using 10 rat brains with a combined wet weight of 15 to 20 g, Basic Protocol 1 yields approximately 0.5 mg of CCVs. The protocol can be stopped following the D_2O-sucrose cushion step (step 32), yielding 1 mg of cushion-pellet CCVs (cpCCVs). Figure 3.13.4A demonstrates the enrichment of clathrin heavy chain (CHC; as seen on Coomassie blue staining and immunoblotting) going from the crude homogenate to the cpCCV fraction. Other components of the clathrin coat, including the α-, β-, γ-, and μ-adaptin subunits of the AP-1 and AP-2 clathrin adaptor complexes, as well as the clathrin light chain (CLC), are readily detectable in the cpCCV fractions. Cosedimentation of these components is seen when the cpCCVs are fractionated by velocity sedimentation on linear 20%-to-50% sucrose gradients (Fig. 3.13.4B). These patterns are highly reproducible and can be used to easily and rapidly assess the quality of the preparation.

Figure 3.13.4C shows an EM image (Support Protocol) of CCVs following linear sucrose gradient centrifugation. When randomly chosen EM images from multiple preparations were counted, cpCCVs and CCVs were found to represent 64.9% ± 1.2% and 72.7% ± 1.7% (mean ± SD; $n = 3$ CCV preparations), respectively, of all membrane profiles (Blondeau et al., 2004). On sensitive tandem mass spectrometric analysis, CCVs prepared using this protocol were found to be essentially free of contamination by endoplasmic reticula, nuclei, mitochondria, Golgi bodies, endosomes, peroxisomes, and lysosomes (Blondeau et al., 2004).

Alternate Protocols 1 and 2

The Coomassie blue staining pattern of retained fractions from P5 rat growth cone CCV (gcCCV) preparations (Alternate Protocol 1) is shown in Figure 3.13.5A. As with adult CCV preparations, clathrin coat components, including α-, β-, γ-, and μ-adaptin and CLCs, are readily detectable in the gcCCVs. Immunoblotting for CHC in the same fractions shows clathrin enrichment (Fig. 3.13.5A). An EM image of gcCCVs is presented in Figure 3.13.5B. Counting of randomly sampled fields revealed that these vesicle fractions were 79% ± 2.3% (mean ± SD; $n = 4$ CCV preparations) pure. The exact same protocol applied to adult rat brain synaptosomes yields similar clathrin enrichment (data not shown). The authors routinely process the brains of P5 pups from ~15 litters (combined weight of brain tissue, ~110 g); doing so yields ~0.3 mg of gcCCVs.

Rothman and Fine (1980) have developed a protocol for the purification of CCVs from cultured CHO cells using the procedure of Pearse (1975). This procedure requires approximately 40 g of packed cells, corresponding to 24 liters of CHO cells in culture (Rothman and Fine, 1980). The procedure for the isolation of CCVs described in Alternate Protocol 2 is valuable, because it can be performed using as few as five plates of cells. The protocol can thus easily be applied to transfected cells to obtain valuable information regarding the mechanisms by which a given protein associates with CCVs (see Metzler et al., 2001, for example). This protocol, which leads to membranes that are significantly enriched for clathrin (Metzler

Figure 3.13.4 *(at right)* Summary of results from Basic Protocol 1. (**A**) Analysis of adult rat brain fractions on a Coomassie-stained gel (top) and on immunoblot with a clathrin heavy chain (CHC) antibody (bottom). The migratory positions of CHC, clathrin light chains (CLCs), and the α-, β-, γ-, and μ-adaptin subunits of the AP-1 and AP-2 clathrin adaptor protein complexes are indicated. P1, P2, and S2 are fractions obtained before isolation of the final clathrin-coated vesicle (CCV) fraction; see Basic Protocol 1 for additional details. (**B**) Cushion-pellet CCVs (cpCCVs) were prepared and fractionated on linear 20%-to-50% sucrose gradients, and 1-ml fractions were collected from the bottom of each gradient as described in Basic Protocol 1. Proteins from aliquots of fractions 1 through 11 were separated by SDS-PAGE and analyzed by Coomassie blue staining. The migratory positions of CHC, CLCs, and the α-, β-, γ-, and μ-adaptin subunits of AP-1 and AP-2 are indicated. (**C**) Fractions that yielded peak protein signals (i.e., CCV fractions; see Basic Protocol 1) were analyzed by EM as described in the Support Protocol. A representative image is shown. H, crude homogenate; SGp, suspension of pellet from Ficoll-sucrose density gradient centrifugation; SGs, supernatant from Ficoll-sucrose density gradient centrifugation.

(**A**) Analysis of adult rat liver fractions on a Coomassie-stained gel (top) and on immunoblot with a clathrin heavy chain (CHC) antibody (bottom). The migratory positions of CHC, clathrin light chains (CLCs), and the α-, β-, γ-, and μ-adaptin subunits of the AP-1 and AP-2 clathrin adaptor protein complexes are indicated. P1, S1, P2, S2, P3, and P4 are fractions obtained before isolation of the final clathrin-coated vesicle (CCV) fraction; see Basic Protocol 2 for additional details. (**B**) Liver CCVs were analyzed by EM as described in the Support Protocol. A representative image is shown. H, crude homogenate.

et al., 2001), has been applied to COS-7 and HeLa cells, as well as HEK-293 cells. Five plates of confluent cells should yield ~0.5 mg of relatively crude CCVs.

Basic Protocol 2

Basic Protocol 2 starts with 10 rat livers (combined wet weight, 60 to 100 g) and yields 2 to 3 mg of CCVs. Figure 3.13.6A shows a Coomassie blue–stained gel of the fractions from a typical preparation. Major components of CCV coats, including CHCs, CLCs, and the various subunits of the AP-1 and AP-2 protein complexes, are easily detected in the CCV fraction. Enrichment for CHC throughout the preparation is monitored by Coomassie staining and immunoblotting (Fig. 3.13.6A). EM analysis of the CCV fraction revealed a nearly homogeneous CCV population (Fig. 3.13.6B), and random sampling of EM images showed that the fraction had a CCV purity of 89.2% ± 3.2% (mean ± SD; $n = 6$ CCV preparations).

Basic Protocol 2, which closely resembles the protocol originally described by Pearse (1975), should be applicable to the isolation of CCVs from a wide variety of tissues. The authors have used it to purify CCVs from rat kidney and brain, and they have observed similar enrichment for CHC in both cases. Similar or identical protocols have been used successfully to isolate CCVs from rabbit and calf brain (Blitz et al., 1977), human placenta (Pearse, 1982), lymphoma and CHO cells (Pearse, 1976; Rothman and Fine, 1980), and adrenal medulla and cortex (Pearse, 1976; Mello et al., 1980).

Time Considerations

There is no point at which any of the CCV purification protocols can be stopped and then resumed. Basic Protocol 1 will take ~14 hr, although this is shortened to ~10 hr if the last linear sucrose gradient step is omitted. Basic Protocol 2 takes ~35 hr. However, this includes a 16-hr (overnight) equilibrium sucrose gradient centrifugation. Basic Protocol 2 is thus very manageable over a 2-day period. Alternate Protocol 2 is the most straightforward and can be completed in ~6 hr, including the 2-hr centrifugation step. The most problematic protocol in terms of time management is Alternate Protocol 1. This protocol takes ~16 hr but contains no extended centrifugation steps. An important consideration with regard to this protocol is the time required to sacrifice and dissect brains from nearly 200 P5 rat pups.

The Support Protocol requires 6 days, not including the time needed for sectioning and EM observation. However, this time estimate includes 2 overnight incubations and 1 incubation of 76 hr. Days 2 and 3 both require hands-on time, with day 2 requiring ~8 hr for filtration and multiple wash steps.

Isolation of Melanosomes

Melanosomes are specific membrane-bound organelles that are produced only by melanocytes and retinal pigment epithelial cells, both types of cells being derived from the embryonic neural tube. Melanosomes are specialized intracellular organelles in which the biopolymer pigment melanin is synthesized and stored. Melanosomes have been shown to be closely related to lysosomes and platelet dense bodies, primarily because of the effects of certain diseases, such as Hermansky-Pudlak syndrome (HSP) and Chediak-Higashi syndrome (CHS), on the function of all three of these types of organelles (Dell'Angelica et al., 2000; Raposo and Marks, 2002). Pigmentation of the hair, skin, and eyes results from the concerted action of a number of melanocyte-specific enzymes required for the biosynthesis of melanin, most of which are localized in the melanosomes. Melanin protects underlying cells and tissues from the harmful effects of ultraviolet radiation.

Mammalian pigmentation is regulated directly or indirectly by more than 120 distinct genes, and many of the corresponding gene products modulate the quality or quantity of melanin produced, the structure of the melanosomes, and/or the processing and distribution of melanosomes. Melanosomal proteins can be structural proteins, such as Pmel17/gp100, or enzymatic proteins, such as tyrosinase (TYR), tyrosinase-related protein 1 (TYRP1), and tyrosinase-related protein 2 (DCT/TYRP2). TYR, which is absolutely required for melanogenesis, catalyzes the rate-limiting reactions in melanin synthesis, converting tyrosine to dopaquinone and subsequently oxidizing 5,6-dihydroxyindole to indole-5,6-quinone (Wakamatsu and Ito, 2002). Pmel17/gp100 has been identified as a specific marker for melanoma and is processed by proteolysis. It is localized within fibrils in the melanosomal lumen (Kwon et al., 1991; Kobayashi et al., 1994; Kushimoto et al., 2001).

The biogenesis of melanosomes and the regulation of melanin synthesis have been studied extensively by means of electron microscopy, as well as by biochemical and immunohistochemical methods. On the basis of their morphology and degree of pigmentation, melanosomes have been classified into four developmental stages. Stage I melanosomes, originally termed premelanosomes, are characterized by a poorly organized internal structure and lack melanin. Stage II melanosomes display a well organized structure and exhibit lumenal fibrillar striations. In stage III melanosomes, some deposition of electron-opaque melanin on the fibrillar striations becomes evident, while stage IV melanosomes are fully melanized and have all of their internal structure obscured by this pigment (Fig. 3.14.1; Seiji et al., 1963a; Marks and Seabram, 2001; Dell'Angelica, 2003; Kushimoto et al., 2003). During their maturation, melanosomes are transported toward the tips of the dendrites and, in the skin, are then transferred to keratinocytes by an as yet poorly understood mechanism.

The protocols in this unit are simple and relatively rapid methods for isolating melanosomes of different stages from melanoma cells in culture and from melanoma tissues. These protocols describe the isolation of early (stage I and II) and late (stage III and IV) melanosomes from pigmented melanoma cells in culture (see Basic Protocol 1; Kushimoto et al., 2001; Basrur et al., 2003) and from pigmented melanoma tissues (see Basic Protocol 2; Seiji et al., 1963b; Araki et al., 2000). Alternate Protocol 1 describes a method for obtaining early-stage melanosomes from pigmented or nonpigmented melanoma cells in culture (Basrur et al., 2003; Watabe et al., 2004). Early melanosomes can be contaminated to varying degrees by lysosomes and by other

subcellular organelles, whereas late melanosomes can be completely separated from other membrane-bound organelles by virtue of their high density, which is caused by melanin deposition. To isolate early melanosomes from other smaller vesicular components (lysosomes and endosomes) and other organelles (late melanosomes and mitochondria), the authors describe the use of free-flow electrophoresis (FFE; see Alternate Protocol 2; Kushimoto et al., 2001; Basrur et al., 2003). The fractions obtained can be analyzed for various types of enzymatic activity, with tyrosinase activity being the most specific (see Support Protocol); immunohistochemistry using various melanosome-specific antibodies is also useful (see Table 3.14.1). These approaches provide essentially pure melanosome fractions, the likes of which have yielded important clues to melanosome biogenesis and function.

Table 3.14.1 Melanosome-Specific Antibodies[a]

Antigen	Antibody name[b]	Source[c]
Tyrosinase	αPEP7, αPEP7h	—[d]
	T311	Novocastra Labs
	C-19	Santa Cruz Biotechnology

NOTE: All solutions and equipment coming into contact with cells must be sterile, and proper aseptic technique should be used accordingly.

NOTE: All tissue culture incubations should be performed in a humidified 37°C, 5% incubator unless otherwise specified. Some media (e.g., DMEM) may require altered levels of CO_2 to maintain pH 7.4.

NOTE: All solutions, glassware, centrifuge tubes, centrifuge rotors, and other equipment should be precooled to 0 to 4°C, and samples should be kept on ice throughout processing.

NOTE: Some marker enzyme assays (e.g., TYR; see Support Protocol) can be carried out using material that has been stored at 4°C for up to 1 to 2 days. Many assays can be performed on material frozen to −20°C or −80°C for storage; however, care should be taken to ensure that the measurements made using such materials are relatively unaffected by the storage conditions. This can be confirmed by comparing results with those obtained using fresh material.

BASIC PROTOCOL 1

PREPARATION OF EARLY AND/OR LATE MELANOSOMES FROM CULTURED MELANOMA CELLS BY DENSITY GRADIENT CENTRIFUGATION

Cultured melanoma cells are collected, homogenized, and then fractionated on a sucrose step gradient to allow isolation of early and/or late melanosomes.

Materials

MNT-1 human melanoma cells
Dulbecco's modified Eagle medium (DMEM), supplemented (see recipe)
PBS (*APPENDIX 2A*)
Cell homogenization medium–1 (CHM-1; see recipe)
Sucrose step gradient, 1.0 to 2.0 M (see recipe)
Melanosome wash buffer (MWB; see recipe)
150-cm^2 culture dishes (Becton Dickinson Labware)
Tabletop centrifuge, 4°C
Dounce glass/glass homogenizer
15-ml centrifuge tubes
36.5-ml polyallomer centrifuge tubes (Seton)
Beckman SW-28 swinging-bucket rotor
3-in., 20-G needle attached to a 12-ml syringe
50-ml Oak Ridge centrifuge tubes (Nalge Nunc)
Sorvall SS-34 centrifuge rotor
Additional reagents and equipment for mammalian cell culture (*UNIT 1.1*)

Culture MNT-1 cells

1. Using 150-cm^2 culture dishes and supplemented DMEM, grow MNT-1 cells to confluent monolayers (*UNIT 1.1*).

   Inoculating with 1 × 10^6 cells will result in a confluent monolayer in 7 to 10 days.

   MNT-1 cells are highly pigmented human melanoma cells (Kushimoto et al., 2001). Other pigmented cultured melanocytes or melanoma cells can also be used, but MNT-1 cells have been shown to consistently give high yields

   This protocol typically calls for a minimum of 30 culture dishes of MNT-1 cells and will yield ~1 × 10^7 cells/dish.

Homogenize cultured cells

2. Wash confluent monolayers of MNT-1 cells once with PBS (10 ml/dish). Harvest cells by incubating with trypsin/EDTA (6 ml/dish; see *UNIT 1.1*) for 2 to 3 min, and then adding serum-containing medium (6 ml/dish) to stop the reaction. Pool cells in suitable tubes or flasks. Centrifuge the resulting cell suspensions 5 min at 700 × *g*, 4°C. Remove supernatant.

3. Wash each pellet once with 10 ml CHM-1 and centrifuge for 10 min at 1000 × *g*, 4°C. Remove supernatant. Resuspend each pellet in 10 ml CHM-1 and homogenize on ice using 20 strokes in 2 min with a Dounce glass/glass homogenizer.

Isolate postnuclear supernatant

4. Using a pipettor, transfer homogenates (~10 ml each) from step 3 to 15-ml centrifuge tubes and centrifuge for 10 min at 1000 × *g*, 4°C.

Isolate melanosomes

5. Recover supernatants (~8 ml per tube) from step 4. Using a pipettor, gently layer each supernatant on top of a 1.0 to 2.0 M sucrose step gradient (sucrose concentrations, from top to bottom: 1.0, 1.2, 1.4, 1.5, 1.6, 1.8, and 2.0 M; 4 ml each) in a 36.5-ml polyallomer centrifuge tube.

   A permanent marker can be used to mark the outside of the tube to make subsequent identification of gradient fractions easier.

6. Centrifuge gradients 1 hr at 100,000 × *g*, 4°C, in a Beckman SW-28 swinging-bucket rotor.

7. After centrifugation, carefully recover each layer of the sucrose gradient from the top of the tube (e.g., using a 3-in., 20-G needle attached to a 12-ml syringe). Transfer each recovered layer to a 36.5-ml polyallomer centrifuge tube.

8. Resuspend each recovered layer in 30 ml melanosome wash buffer (MWB), transfer to a 50-ml Oak Ridge centrifuge tube, and centrifuge 30 min at 12,000 × *g*, 4°C, in a Sorvall SS 34 rotor. Remove supernatant.

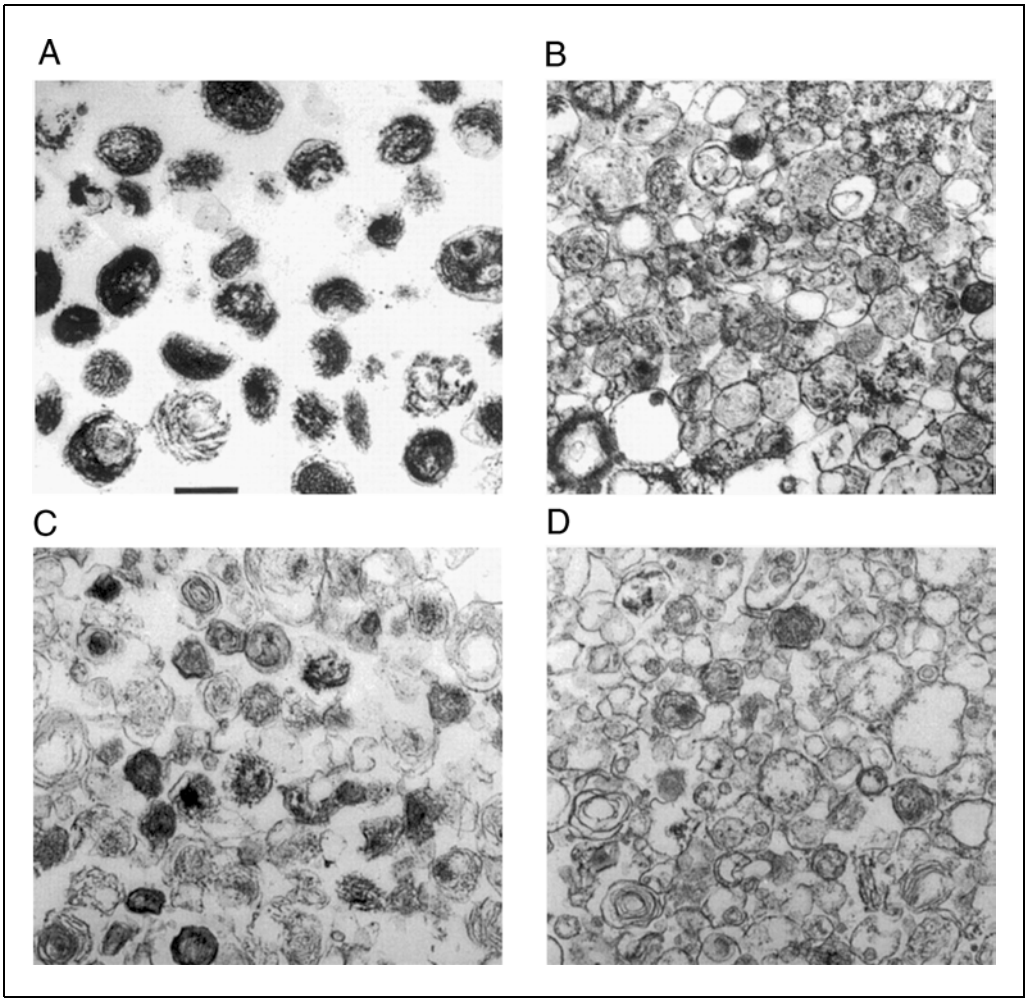

Figure 3.14.2 Ultrastructural appearance of melanosomes in the sucrose density gradient and in free-flow electrophoresis (FFE) fractions purified from the 1.0 M layer of the sucrose density gradient. (**A**) 1.8 M sucrose fraction. (**B**) 1.0 M sucrose fraction. (**C**) FFE fraction II. (**D**) FFE fraction I. Bar = 0.5 μm. Adapted from: Kushimoto et al. (2001).

9. Resuspend each pellet in 1 ml PBS. Wash once with 5 ml PBS, centrifuge 20 min at 5000 × *g*, 4°C, and then remove supernatant. Analyze resulting pellets using enzyme assays, electron microscopy (Fig. 3.14.2A,B), and/or immunoblotting (*UNIT 6.2*) as necessary.

ALTERNATE PROTOCOL 1

PREPARATION OF EARLY MELANOSOMES FROM CULTURED MELANOMA CELLS BY INVERSE DENSITY GRADIENT CENTRIFUGATION

In this protocol, early melanosomes are isolated from cultured cells using an inverse sucrose step gradient.

Additional Materials *(also see Basic Protocol 1)*

MNT-1 human melanoma cells or SK-MEL-28 amelanotic human melanoma cells (American Type Culture Collection)
DMEM, supplemented (for MNT-1 cells; see recipe), or minimal essential medium, supplemented (for SK-MEL-28 cells; see recipe)
2.0 M sucrose (see recipe)
Sucrose step gradient, 0.25 to 1.8 M (see recipe)
Sucrose step gradient, 0.25 to 1.4 M (see recipe)

Culture MNT-1 or SK-MEL-28 cells

1. Using 150-cm^2 culture dishes and supplemented DMEM, grow MNT-1 cells to confluent monolayers. Alternatively, using 150-cm^2 culture dishes and supplemented minimal essential medium, grow SK-MEL-28 cells to confluent monolayers (*UNIT 1.1*).

   This protocol typically calls for a minimum of 30 culture dishes of MNT-1 cells.

Homogenize cultured cells

2. Wash confluent monolayers of cells once with PBS (10 ml/dish). Harvest cells by incubating with trypsin/EDTA (6 ml/dish; see *UNIT 1.1*) for 2 to 3 min, and then adding serum-containing medium (6 ml/dish) to stop the reaction. Pool cells in suitable tubes or flasks. Centrifuge the resulting cell suspensions 5 min at 700 × *g*, 4°C. Remove supernatant.

3. Wash each pellet once with 10 ml CHM-1 and centrifuge 10 min at 1000 × *g*, 4°C. Remove supernatant. Resuspend each pellet in 10 ml CHM-1 and homogenize on ice using 20 strokes in 2 min with a Dounce glass/glass homogenizer.

Isolate postnuclear supernatant

4. Using a pipettor, transfer homogenates (~10 ml each) from step 3 to 15-ml centrifuge tubes and centrifuge 10 min at 1000 × *g*, 4°C.

Isolate early melanosomes

5. Recover supernatants (~8 ml each) from step 4, transfer to 50-ml Oak Ridge centrifuge tubes, and centrifuge 30 min at 19,000 × *g*, 4°C, in a Sorvall SS-34 rotor. Remove supernatant.

6. Resuspend each pellet in 8 ml of 2.0 M sucrose. Using a pipettor, gently layer each of the resulting suspensions onto the bottom of a 0.25 to 1.8 M sucrose step gradient (sucrose concentrations, from top to bottom: 0.25, 1.0, 1.2, 1.4, 1.5, 1.6, and 1.8 M sucrose; 4 ml each) in a polyallomer centrifuge tube.

   A permanent marker can be used to mark the outside of the tube to make subsequent identification of gradient fractions easier.

7. Centrifuge gradients 1 hr at 100,000 × *g*, 4°C, in a Beckman SW-28 swinging-bucket rotor.
8. After centrifugation, carefully recover each sucrose layer (~4 ml each) of each gradient from the top of the tube (e.g., using a 3-in., 20-G needle attached to a 12-ml syringe). Transfer each recovered layer to a suitable tube or flask.
9. Layer each 1.0 M fraction (volume, ~4 ml) into the middle (i.e., between the 0.8 and 1.0 M layers) of a 0.25 to 1.4 M sucrose step gradient (sucrose concentrations, from top to bottom: 0.25, 0.8, 1.2, and 1.4 M; 8 ml each) in a 36.5-ml polyallomer centrifuge tube.
10. Centrifuge gradients 1 hr at 100,000 × *g*, 4°C, in a Beckman SW-28 swinging-bucket rotor.
11. After centrifugation, carefully recover the 1.0 M sucrose fraction from the top of the tube as in step 8. Transfer each recovered layer to a suitable tube or flask.
12. Resuspend each recovered layer in 30 ml MWB, transfer to a 50-ml Oak Ridge centrifuge tube, and centrifuge 30 min at 12,000 × *g*, 4°C, in a Sorvall SS-34 rotor. Remove supernatant.
13. Resuspend each pellet in 1 ml PBS. Wash once with 5 ml PBS, centrifuge 20 min at 5000 × *g*, 4°C, and then remove supernatant. Analyze resulting pellets using enzyme assays, electron microscopy (Fig. 3.14.2A,B), and/or immunoblotting (*UNIT 6.2*) as necessary.

PREPARATION OF EARLY MELANOSOMES FROM CULTURED PIGMENTED MELANOMA CELLS BY DENSITY GRADIENT CENTRIFUGATION AND FREE-FLOW ELECTROPHORESIS (FFE)

ALTERNATE PROTOCOL 2

In this protocol, cultured melanoma cells are homogenized, and the melanosomes within are isolated on a sucrose step gradient. Early melanosomes are further purified by free-flow electrophoresis.

Additional Materials *(also see Basic Protocol 1)*

0.3% (w/v) trypsin
0.6% (w/v) soybean trypsin inhibitor
FFE chamber buffer: 0.25 M sucrose in 1× TEA, pH 7.4 (see recipe for 100×)
Octopus-PZE FFE apparatus (FFE Weber)

Culture MNT-1 cells

1. Using 150-cm^2 culture dishes and supplemented DMEM, grow MNT-1 cells in confluent monolayers (*UNIT 1.1*).

This protocol typically calls for a minimum of 30 culture dishes of MNT-1 cells.

Homogenize cultured cells

2. Wash confluent monolayers of MNT-1 cells once with PBS (10 ml/dish). Harvest cells by incubating with trypsin/EDTA (6 ml/dish; see *UNIT 1.1*) for 2 to 3 min, and then adding serum-containing medium (6 ml/dish) to stop the reaction. Pool cells in suitable tubes or flasks. Centrifuge the resulting cell suspensions 5 min at 700 × *g*, 4°C. Remove supernatant.
3. Wash each pellet once with 10 ml CHM-1 and centrifuge for 10 min at 1000 × *g*, 4°C. Remove supernatant. Resuspend each pellet in 10 ml CHM-1 and homogenize on ice using 20 strokes in 2 min with a Dounce glass/glass homogenizer.

Isolate postnuclear supernatant

4. Using a pipettor, transfer homogenates (~10 ml each) from step 3 to 15-ml centrifuge tubes and centrifuge 10 min at 1000 × *g*, 4°C.

Isolate melanosomes

5. Recover supernatants (~8 ml per tube) from step 4. Using a pipettor, gently layer each supernatant on top of a 1.0 to 2.0 M sucrose step gradient (sucrose concentrations, from top to bottom: 1.0, 1.2, 1.4, 1.5, 1.6, 1.8, and 2.0 M; 4 ml each) in a 36.5-ml polyallomer centrifuge tube.

   A permanent marker can be used to mark the outside of the tube to make subsequent identification of gradient fractions easier.

6. Centrifuge gradients 1 hr at 100,000 × *g*, 4°C, in a Beckman SW-28 swinging-bucket rotor.

7. After centrifugation, carefully recover each 1.0 M sucrose layer from the top of the tube (e.g., using a 3-in., 20-G needle attached to a 12-ml syringe). Transfer each recovered layer to a suitable tube or flask.

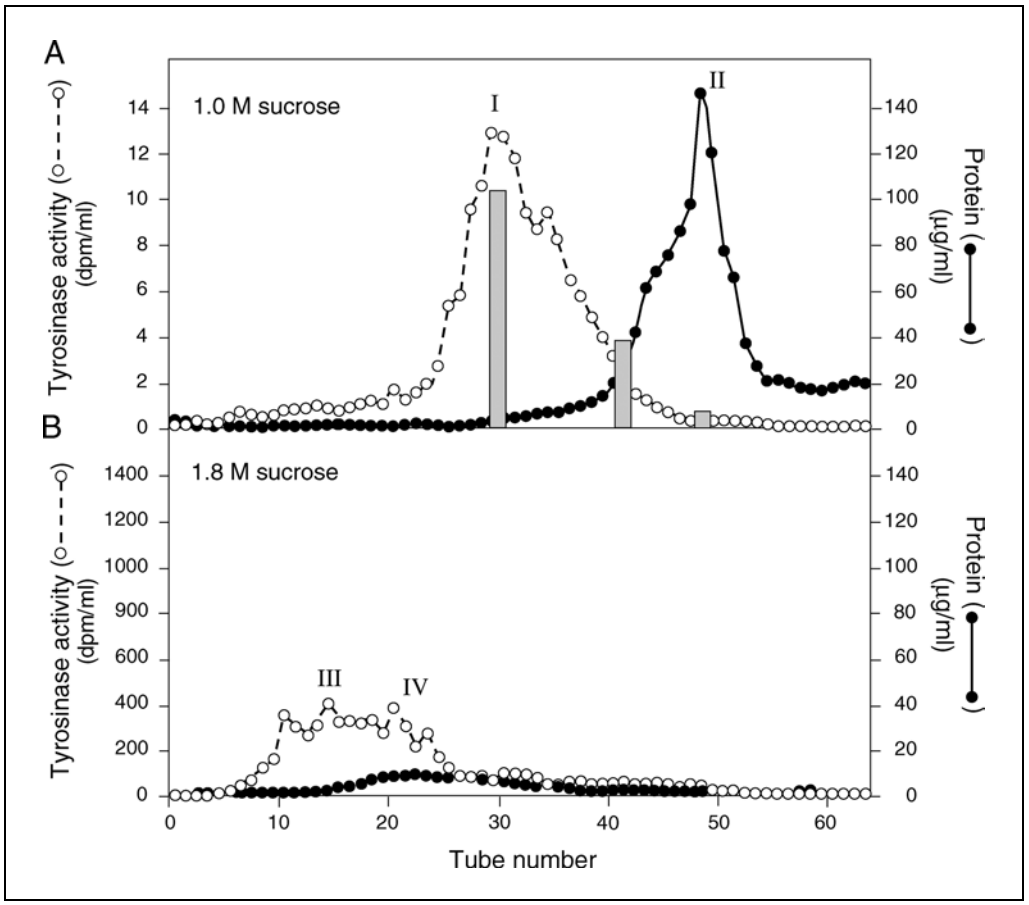

Figure 3.14.3 Distribution curves for tyrosinase (TYR), tyrosinase-related protein 2 (DCT), and other proteins after purification by free-flow electrophoresis (FFE). Elution of the (**A**) 1.0 M and (**B**) 1.8 M sucrose fractions after separation by FFE is shown. Broken lines with open symbols represent TYR enzyme activity, bars represent DCT enzyme activity, and solid lines with closed symbols represent protein content. Enzyme activity data in dpm/ml; protein concentration data in µg/ml. Adapted from: Kushimoto et al. (2001).

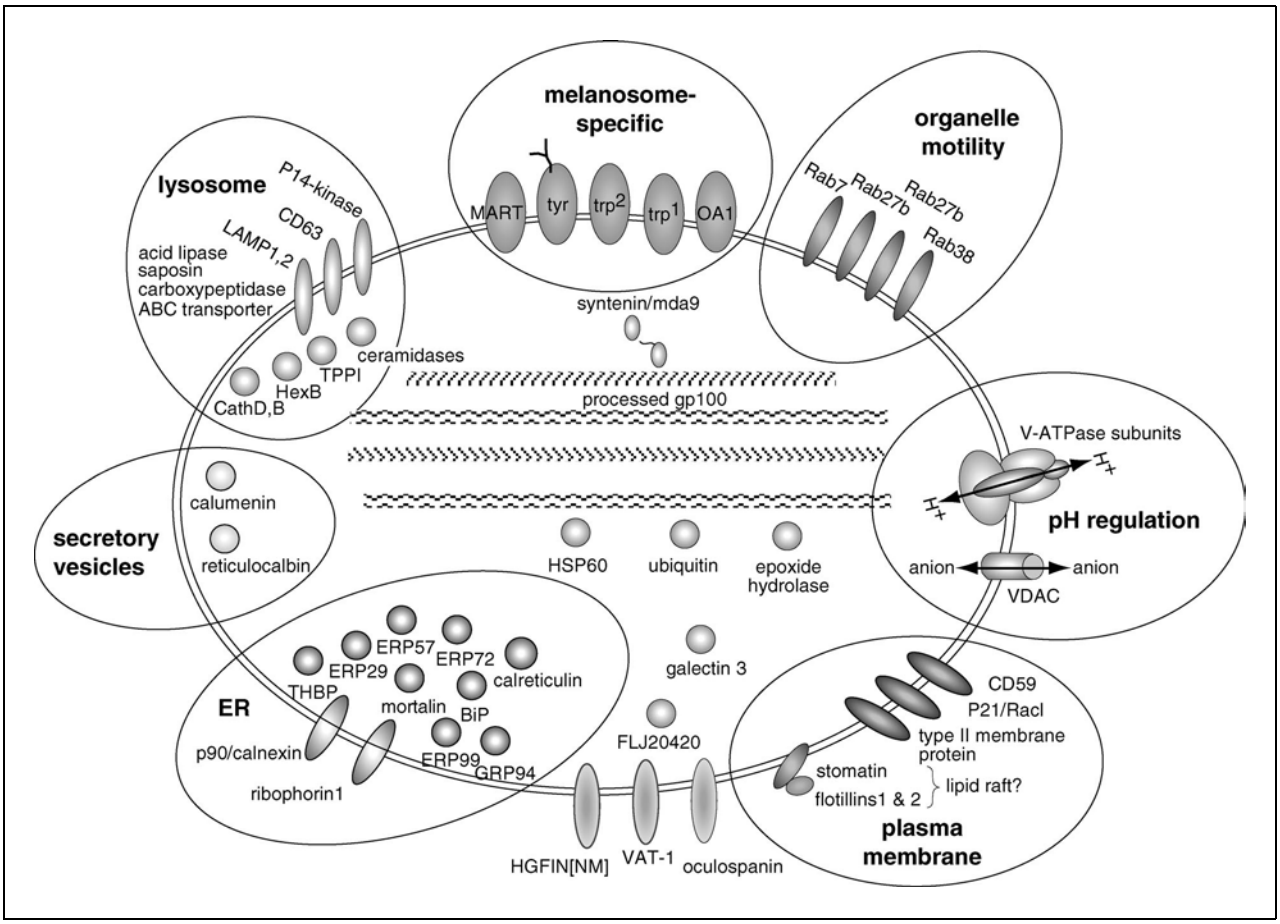

Figure 3.14.4 Proteomic analysis in early melanosomes. Proteins detected in the 1.0 M sucrose fraction after separation by free-flow electrophoresis (FFE) and in fraction I as analyzed by mass spectrometry are shown. Adapted from: Basrur et al. (2003).

8. Resuspend each sample in 30 ml MWB, transfer to a 50-ml Oak Ridge centrifuge tube, and centrifuge 30 min at 12,000 × *g*, 4°C, in a Sorvall SS-34 rotor. Remove supernatant.

9. Resuspend each pellet in 1 ml PBS. Wash once with 5 ml PBS, centrifuge 20 min at 5000 × *g*, 4°C, and then remove supernatant.

Isolate early melanosomes using free-flow electrophoresis (FFE)

10. Immediately before injection into the FFE apparatus, treat each sample from step 9 with 0.5 ml of 0.3% trypsin and incubate at 37°C. After 5 min, stop the reaction by adding 0.5 ml of 0.6% soybean trypsin inhibitor, and immediately cool each sample to 4°C.

11. Taking care not to introduce air bubbles into the FFE chamber, inject the early melanosome fractions into the right inlet of an Octopus-PZE FFE apparatus at a rate of 2.0 ml/hr. After injection, wash the sample inlet by injecting FFE chamber buffer. Perform FFE at 1000 to 1100 V and ~110 to 125 mA, with an elution flow rate of 3 to 4 ml/hr and a chamber temperature of 10°C.

12. Once the sample has reached the top of the separation chamber, begin collecting fractions in 5-ml plastic tubes on ice. Analyze fractions using enzyme assays (Fig. 3.14.3), electron microscopy (Fig. 3.14.2C, D), immunoblotting (*UNIT 6.2*), and/or mass spectrometry (Fig. 3.14.4) as necessary.

PREPARATION OF EARLY AND/OR LATE MELANOSOMES FROM MELANOMA TISSUES BY DENSITY GRADIENT CENTRIFUGATION

In this protocol, melanoma cells are injected into a mouse host. When the resulting tumor is of sufficient size, the tumor tissue is harvested. Tissue fragments are subsequently homogenized, and melanosomes are isolated using a sucrose step gradient.

Materials

B16 melanoma cells
Eagle's minimal essential medium (Sigma) containing 10% (v/v) heat-inactivated FBS (*UNIT 1.2*; HyClone)
C57BL/6 mice
PBS (*APPENDIX 2A*)
Cell homogenization medium–2 (CHM-2; see recipe)
Sucrose step gradient, 1.0 to 2.0 M (see recipe)
MWB (see recipe)
150-cm^2 culture dishes (Bacton Dickinson Labware)
Potter-Elvehjem glass homogenizer
15-ml centrifuge tubes
Tabletop centrifuge, 4°C
36.5-ml polyallomer centrifuge tubes (Seton)
Beckman SW-28 swinging-bucket rotor
3-in., 20-G needle attached to a 12-ml syringe
50-ml Oak Ridge centrifuge tubes (Nalge Nunc)
Sorvall SS-34 centrifuge rotor
Additional reagents and equipment for mammalian cell culture (*UNIT 1.1*)

NOTE: All protocols using live animals must first be reviewed and approved by an institutional animal care and use committee (IACUC) and must conform to governmental regulations regarding the care and use of laboratory animals.

Culture melanoma cells

1. Using 150-cm^2 culture dishes, culture B16 melanoma cells in Eagle's minimal essential medium containing 10% (v/v) heat-inactivated FBS (*UNIT 1.1*).

   B16 melanoma cells are pigmented mouse melanoma cells. Other pigmented melanoma cells can be used in a similar manner.

Homogenize cultured cells

2. Harvest B16 melanoma cells (Basic Protocol 1, step 2). Implant cells (10^6 per mouse) by injecting subcutaneously (Donovan and Brown, 1995) into the flanks of C57BL/6 mice.

3. When a tumor reaches 1 cm in size, sacrifice the mouse using an approved protocol (preferably CO_2 asphyxiation) and excise the tumor with scissors and forceps. Wash the excised tumor twice, using at least 50 ml PBS for each wash.

4. For each excised tumor, use small scissors to carefully trim away excess connective tissue, and then cut the tumor into small pieces (~1 mm^3) using a sterile surgical blade.

5. For each tumor, resuspend the small pieces in a total of 10 ml CHM-2 and homogenize on ice using 20 strokes of a Potter-Elvehjem glass homogenizer.

Isolate postnuclear supernatant

6. Using a pipettor, transfer homogenates from step 5 (~10 ml per mouse) to 15-ml centrifuge tubes and centrifuge 10 min at 700 × *g*, 4°C.

Isolate melanosomes

7. Recover supernatants from step 6 (~8 ml each). Using a pipettor, gently layer each supernatant on top of a 1.0 to 2.0 M sucrose step gradient (sucrose concentrations, from top to bottom: 1.0, 1.2, 1.4, 1.5, 1.6, 1.8, and 2.0 M; 4 ml each) in a 36.5-ml polyallomer centrifuge tube.

   A permanent marker can be used to mark the outside of the tube to make subsequent identification of gradient fractions easier.

8. Centrifuge sucrose gradients 1 hr at 100,000 × *g*, 4°C, in a Beckman SW-28 swinging-bucket rotor.

9. After centrifugation, carefully recover each layer of each gradient from the top of the tube (e.g., using a 3-in., 20-G needle attached to a 12-ml syringe). Transfer each recovered layer to a 36.5-ml polyallomer centrifuge tube.

10. Resuspend each sample in 30 ml MWB, transfer to a 50-ml Oak Ridge centrifuge tube, and centrifuge 30 min at 12,000 × *g*, 4°C, in a Sorvall SS-34 rotor. Remove supernatant.

11. Resuspend each pellet in 1 ml PBS. Wash once with 5 ml PBS, centrifuge 20 min at 5000 × *g*, 4°C, and then remove supernatant. Analyze resulting pellets using enzyme assays, electron microscopy (Fig. 3.14.2A,B), and/or immunoblotting (*UNIT 6.2*) as necessary.

TYROSINASE ASSAY

SUPPORT PROTOCOL

In this support protocol, the melanosome fractions isolated in the protocols described above are exposed to radiolabeled tyrosine. Because tyrosinase catalyzes the rate-limiting steps in the eventual conversion of tyrosine to melanin, tyrosinase activity can be evaluated by monitoring the appearance of radiolabeled melanin in the assay mixture.

Materials

Melanosome fractions to be assayed (see Basic Protocols 1 and 2 and Alternate Protocols 1 and 2)
Extraction buffer (see recipe)
Tyrosinase assay buffer (see recipe)
25 μCi/ml L-[U-^{14}C]tyrosine solution (100 mCi/mmol)
0.1 N HCl
1 g/liter unlabeled tyrosine in 0.1 N HCl
95% ethanol
Acetone
Scintillation fluid

Vortex mixer
96-well microtiter plates
2.5-cm Whatman 3MM filter paper discs
1-liter Erlenmeyer flasks
Liquid scintillation counter
Scintillation vials

1. Resuspend melanosome fractions in extraction buffer. Mix thoroughly using a vortex mixer, and then store at 4°C for at least 1 hr.

   The volume of extraction buffer added depends on the number of cells used to prepare the sample. Typically, a ratio of ~1 ml/10^6 cells or 1 ml/1 mg protein is used.

2. Transfer samples to microcentrifuge tubes. Centrifuge 2 min at 10,000 × *g*, 4°C. Recover supernatants for tyrosinase assays.

3. For each melanosome fraction, add 30 µl supernatant from step 2, 10 µl tyrosinase assay buffer, and 10 µl of 2.5 µCi L-[U-^{14}C]tyrosine solution to a well in a 96-well microtiter plate. Mix thoroughly by pipetting the resulting solution up and down in the microtiter well. Incubate for 1 hr at 37°C.

   Samples are routinely run at least in duplicate or triplicate.

   Longer incubation times are possible for samples with low tyrosinase activity.

4. Using a pipettor, remove 40 µl from each microtiter well. Apply each 40-µl aliquot to a separate 2.5-cm disc of Whatman 3MM filter paper, and allow filter paper to air dry.

5. Remove unincorporated background label by washing filters (with gentle agitation) in 1-liter beakers (50 filters/liter), using the following washing fluids in sequence:

   200 ml of 0.1 N HCl containing 1 g/liter unlabeled tyrosine (once, for 15 min)
   200 ml of 0.1 N HCl (twice; 15 min per wash)
   100 ml of 95% ethanol (twice; 5 min per wash)
   100 ml acetone (once, for 5 min).

6. Allow filters to dry in air, transfer each filter to a scintillation vial containing 10 ml scintillation fluid, and then assay sample radioactivity using a liquid scintillation counter.

7. Calculate tyrosinase activity using the following standard parameters: time, protein amount, and pmol of product ([^{14}C]melanin) generated (Hearing and Ekel, 1976).

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Cell homogenization medium–1 (CHM-1)

42.79 g sucrose (0.25 M final)
5 ml 1 M *N*-2-hydroxyethylpiperazine-*N*′-2-ethanesulfonic acid (HEPES; Invitrogen; 10 mM final)
Add H_2O to 500 ml
Adjust pH to 7.5 with 5 N NaOH
Store up to 1 week at 4°C
Immediately before use, add 1 tablet complete protease inhibitor cocktail (Roche) per 50 ml of solution
Filter using a 0.45-µm filter unit

Cell homogenization medium–2 (CHM-2)

42.79 g sucrose (0.25 M final)
5 ml 1 M HEPES (Invitrogen; 10 mM final)
1 ml 0.5 M EDTA (1 mM final)
Add H_2O to 500 ml
Adjust pH to 7.5 with 5 N NaOH
Store up to 1 week at 4°C
Immediately before use, add 1 tablet complete protease inhibitor cocktail (Roche) per 50 ml of solution
Filter using a 0.45-µm filter unit

Dulbecco's modified Eagle medium (DMEM), supplemented

Dulbecco's modified Eagle medium (DMEM; Invitrogen) containing:
20% (v/v) heat-inactivated FBS (Atlanta Biologicals)
10% (v/v) AIM V medium (Life Technologies)
20 mM *N*-2-hydroxyethylpiperazine-*N*′-2-ethanesulfonic acid (HEPES; Invitrogen)
0.1 mM nonessential amino acids (Invitrogen)
1 mM sodium pyruvate (Invitrogen)
2 mM L-glutamine (Invitrogen)
3.7 μg/ml sodium bicarbonate (Invitrogen)
Store up to 1 month at 4°C

The addition of these supplemental ingredients to DMEM helps to maximize the growth and pigmentation of the cells to be cultured.

Extraction buffer

1% (v/v) Nonidet P-40 (NP-40)
0.01% (w/v) SDS
0.1 M Tris·Cl, pH 7.2 (*APPENDIX 2A*)
1 μg/ml aprotinin
100 μM phenylmethylsulfonyl fluoride (PMSF)
Store up to 1 month at 4°C

Melanosome wash buffer (MWB)

42.79 g sucrose (0.25 M final)
5 ml 1 M Tris·Cl, pH 7.5 (10 mM final; *APPENDIX 2A*)
Add filtered H_2O to 500 ml
Store up to 1 week at 4°C
Immediately before use, add 1 tablet complete protease inhibitor cocktail (Roche) per 50 ml of solution
Filter using a 0.45-μm filter unit

Minimal essential medium, supplemented

Minimal essential medium (Invitrogen) containing:
10% (v/v) heat-inactivated FBS (Atlanta Biologicals)
0.1 mM nonessential amino acids (Invitrogen)
1 mM sodium pyruvate (Invitrogen)
2 mM L-glutamine (Invitrogen)
2.8 μg/ml sodium bicarbonate (Invitrogen)
Store up to 1 month at 4°C

See Watabe et al. (2004).

The addition of these supplemental ingredients to minimal essential medium helps to maximize the growth and pigmentation of the cells to be cultured.

Sucrose stock solution, 2 M

To 200 ml H_2O, add:
136.92 g sucrose (2 M final)
Adjust pH to 7.5 with 5 N NaOH
Filter using a 500-ml filter system (pore size, 0.45 μM)
Store up to 1 week at 4°C

Table 3.14.2 Composition of Sucrose Step Gradient Solutions

Step concentration (M)	Composition of step solution		
	2 M sucrose stock solution (ml)	H_2O (ml)	1 M HEPES[a] (μl)
2.0	20	—	—
1.8	18	1.8	200
1.6	16	3.8	200
1.5	15	4.8	200
1.4	14	5.8	200
1.2	12	7.8	200
1.0	10	9.8	200
0.8	8	11.8	200
0.25	2.5	17.3	200

[a]HEPES, *N*-2-hydroxyethylpiperazine-*N*′-2-ethanesulfonic acid.

Sucrose step gradient

Make appropriate sucrose step gradient solutions (see Table 3.14.2)
Immediately before use, add complete mini protease inhibitor tablets (1 tablet/50 ml)
Store individual solutions up to 1 week at 4°C

To construct the gradient, layer the appropriate volume of each sucrose step gradient solution into a 36.5-ml polyallomer tube, beginning with the most concentrated solution in the gradient and proceeding in order of decreasing concentration. During layering, take care not to allow adjacent layers to mix with one another.

TEA stock solution, 100×

66.6 ml triethanolamine (1 M final)
28.75 ml acetic acid (1 M final)
100 ml 0.5 M EDTA (100 mM final)
Add H_2O to 500 ml
Adjust pH to 7.4 with 5 N NaOH
Filter using a 500-ml filter system (pore size 0.46 μm)
Store up to 3 months at 4°C

Tyrosinase assay buffer

0.1 M sodium phosphate buffer (APPENDIX 2A), pH 7.2, containing:
0.25 mM L-3,4-dihydroxyphenylalanine
0.1 mg/ml cycloheximide
0.1 mg/ml chloramphenicol
0.1 mg/ml BSA
100 units/ml penicillin
Store up to 1 month at −20°C

COMMENTARY

Background Information

Homogenization

Most published methods describing the isolation of melanosomes from melanoma tissues and cells employ standard buffered sucrose solution as the homogenization medium, although there is apparently no rigorous requirement for the presence of a chelating agent such as EDTA. For mammalian tissues, a routine homogenizing buffer containing 0.25 M sucrose/1 mM EDTA, usually buffered with HEPES, is used without additional supplementation. This buffer has also commonly been used for cultured melanoma cells or melanocytes, although EDTA is sometimes omitted. Melanoma cells and melanocytes are best homogenized in a tight-fitting Dounce homogenizer. Melanoma tissues may be homogenized in a Potter-Elvehjem homogenizer.

Density gradient centrifugation

Melanosomes are one of the major components of pigmented melanoma tissues and cultured melanoma cells, and they are obtained from cell homogenates by sucrose density gradient centrifugation. The classical density gradient centrifugation scheme involves two steps: 1000 × *g* for 10 min (nuclear pellet), and 100,000 × *g* for 60 min (pellet containing melanosomes and other membrane-bound organelles). The density of late melanosomes (stages III and IV) is very similar to that of mitochondria in a sucrose gradient, and as a result, the classical method is now regarded as unsatisfactory for melanosome purification. On the other hand, the inverse density gradient centrifugation scheme involves four steps—1000 × *g* for 10 min (nuclear pellet), 19,000 × *g* for 30 min (pellet containing late-stage melanosomes and mitochondria), 100,000 × *g* for 60 min, and 100,000 × *g* for 60 min (pellet containing early melanosome fraction)—because the density of early melanosomes is significantly lower than that of late melanosomes and mitochondria in the sucrose gradient. However, the density of early melanosomes is very similar to that of lysosomes in the sucrose gradient, because the structures of both of these organelles are closely related, and because both initially evolve via the same biogenesis pathway.

Free-flow electrophoresis (FFE)

FFE is an efficient method that provides both analytical capabilities and the opportunity for continuous operation on a preparative scale. The range of substances that can be separated is wide, including small ions, proteins, membrane particles, and even viable cells, and yields of recovered membrane and protein are high. FFE separates membranous cell components and organelles, such as melanosomes, lysosomes, and endosomes, based on their surface charge. This method allows the recovery of organelles and their constituent proteins in a form suitable for studying enzyme activity, morphology, and cytochemistry, among other features.

Critical Parameters and Troubleshooting

Care must be taken to include protease inhibitors in all solutions and to keep these solutions at 4°C; melanosomes contain most, if not all, proteases normally found in lysosomes, and degradation of the sample can occur quickly. The procedures outlined work equally well for purifying melanosomes from normal skin or other pigmented tissue or for purifying these organelles from normal melanocytes in tissue culture, although the amounts recovered from cultured cells will be dramatically reduced compared with the amount recovered from melanoma cells.

Anticipated Results

The purified fraction of melanosomes can be used for enzymatic and/or proteomic analyses or for structural characterization. Despite the fact that the pigmentation of cells and fractions can look very dark, small amounts of melanin can cause very dense pigmentation. Recoveries of early and late melanosomes are usually very low, and significant protein levels in the purified fractions usually indicate poor purity. As a guideline, 30 confluent 150-cm^2 dishes of heavily pigmented MNT-1 melanoma cells (usually 1–2 × 10^8 cells) will usually provide only 30 μg of protein from late (stage III or IV) melanosomes and only 2 μg from early (stages I or II) melanosomes.

Time Considerations

There is no point at which any of these relatively short protocols may be suspended. Indeed, rapid preparation is the key to the recovery of functionally intact melanosomes. All solutions can be made ahead of time and stored at 4°C for 1 week or frozen at −20°C for longer periods (up to 1 month).

Basic Protocols 1 and 2 can be carried out in 2 to 3 hr each, while Alternate Protocol 1 will require ~4 hr because of the additional centrifugation step. FFE assays should be performed as soon as possible after melanosome purification and will require a total of ~7 hr. The tyrosinase asasay (Support Protocol) requires ~4 hr.

Isolation of Lipid Droplets from Cells by Density Gradient Centrifugation

Lipid droplets are organelles found in most cultured cells, particularly when the cells have been cultured in medium containing serum or exogenous fatty acids (see Fig. 3.15.1). Due to a relatively low protein content and the presence of a neutral lipid core composed of primarily triacylglycerol or cholesterol esters, lipid droplets are more buoyant than other cellular compartments and can be isolated easily by centrifugation. Brief low-speed centrifugation can rapidly float lipid droplets, but other cellular membranes and particularly mitochondria may adhere to the lipid droplets. This unit describes a method to isolate a highly purified lipid droplet fraction with minimal contaminating membranes (see Basic Protocol). The unit also describes an alternate method to disrupt cells while maintaining the integrity of lipid droplets (see Alternate Protocol), a method for loading cells with lipid (see Support Protocol 1), and two methods for solubilizing lipid droplet membrane proteins (see Support Protocols 2 and 3).

ISOLATION OF LIPID DROPLETS FROM CULTURED CELLS BY DENSITY GRADIENT CENTRIFUGATION

BASIC PROTOCOL

Nuclei are removed by low-speed centrifugation and the density of the post-nuclear supernatant is adjusted with sucrose prior to flotation of the lipid droplets through a single discontinuous sucrose gradient. The lipid droplet fraction is characterized by immunoblotting of component proteins.

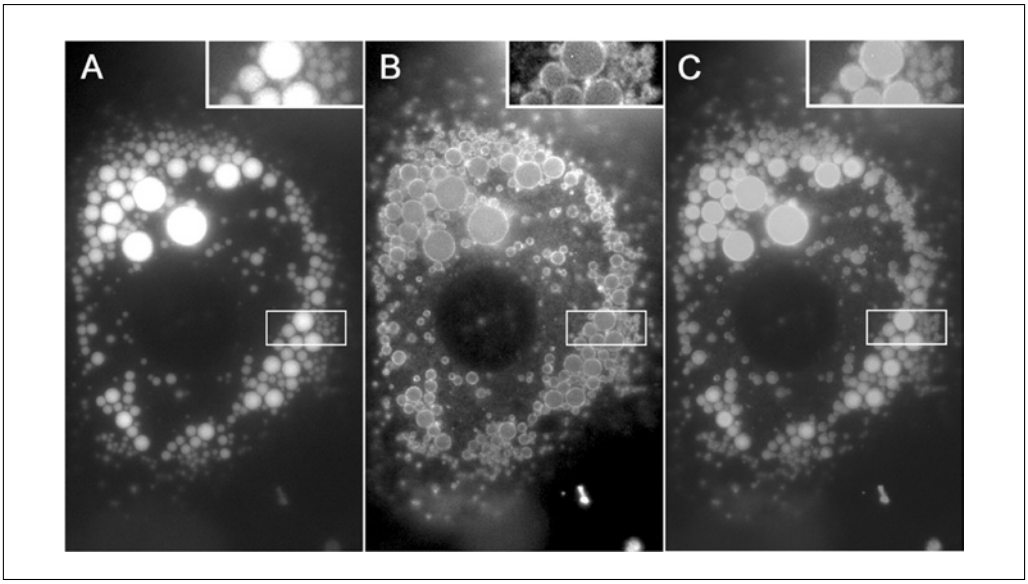

Figure 3.15.1 Cultured 3T3-L1 adipocyte labeled with fluorescent fatty acids (**A** and **C**: green) and stained for perilipin (**B** and **C**: red). Cultured 3T3-L1 adipocytes were differentiated for 6 days with the addition of a BODIPY-labeled 12-carbon fatty acid (Molecular Probes, Invitrogen detection technologies, D3822, BODIPYFL C_{12}) for the final 18 hr. Cells were fixed with 2% paraformaldehyde in PBS prior to staining with guinea pig polyclonal antibody to perilipin (Research Diagnostics, Inc., RDI-PROGP29) followed by AlexaFluor 594 goat anti-guinea pig IgG (Molecular Probes, Invitrogen detection technologies, A11076). Images were captured with a Zeiss Axioplan-2 microscope equipped with a Hamamatsu Orca CCD camera. For the color version of this figure go to *http://www.currentprotocols.com.*

Current Protocols in Cell Biology (2005) 3.15.1-3.15.12

NOTE: Protease inhibitors (*UNIT 3.4*) may be included in any or all of the media at the discretion of the investigator.

NOTE: All solutions and glassware should be prechilled to 4°C before the procedure, and kept on ice throughout. Centrifuges, centrifuge rotors, and buckets should be precooled to the same temperature.

Materials

4 to 10 100-mm dishes containing confluent monolayer cells (1–2.5 × 10^7 cells)
Phosphate-buffered saline (PBS; *APPENDIX 2A*), ice cold
Hypotonic lysis medium (HLM; see recipe), ice cold
HLM containing 60% and 5% (w/w) sucrose (see recipes), ice cold
Rubber policeman or cell-scraper
15-ml plastic tubes with caps
Potter-Elvehjem tissue homogenizer with loose-fitting Teflon pestle (Wheaton), 4-ml capacity, 0.01 to 0.02 cm clearance
Low-speed refrigerated centrifuge with swinging-bucket rotor and appropriate centrifuge tubes
Beckman or Sorvall ultracentrifuge with SW41Ti or Th-641 swinging-bucket rotor
13.2-ml thin-walled polyallomer or polycarbonate ultracentrifuge tubes
Beckman tube slicer with two metal shim rings and two rubber rings to fit ultracentrifuge tubes
Additional reagents and equipment for SDS-PAGE (*UNIT 6.1*) and immunoblotting (*UNIT 6.2*)

Prepare cells

1. Wash cells two times with 10 ml ice-cold PBS per dish.
2. Using a rubber policeman or cell scraper, scrape cells from all dishes into 10 to 15 ml ice-cold PBS in a single 15-ml plastic tube with cap and pellet cells by centrifuging 10 min at 1000 × *g*, 4°C.
3. Remove the supernatant with a pipet to a new 15-ml plastic tube with cap and gently and thoroughly resuspend the cells in ice-cold HLM by pipetting the cells up-and-down using a pipet tip with a wide opening. Use a volume of about five times the cell pellet volume.

   Total volume will be 1.5 to 2.5 ml.

4. Incubate the suspended cells on ice for 10 min.

Homogenize cells

5. Transfer the resuspended cells to a Potter-Elvehjem tissue homogenizer on ice. Keeping the homogenizer on ice, insert the Teflon pestle and slowly homogenize the cells by six to eight gentle strokes with the hand-driven pestle. Transfer the homogenate to a 15-ml tube.
6. Centrifuge the cell lysate 10 min at 1000 × *g*, 4°C.
7. Collect the supernatant and the floating fat layer into a separate 15-ml tube.
8. Add 1/3 volume of ice-cold HLM containing 60% sucrose (final 20% sucrose), and mix by gentle pipetting using a pipet tip with a wide opening until aggregates of lipid droplets are finely and thoroughly dispersed.

Isolate lipid droplets

9. Layer density adjusted cell lysate into the bottom of a 13.2-ml ultracentrifuge tube for an SW41Ti rotor, or equivalent.

		Rabbit polyclonal	610059	BD Transduction Laboratories

[a] Band numbers refer to gels A and B depicted in Figure 3.15.2.
[b] Listed antibodies may not work well for all applications.
[c] Additional antibodies are available from sources that are not listed.

10. Gently layer 5 ml ice-cold HLM containing 5% sucrose over sample.
11. Gently add 5 to 6.5 ml ice-cold HLM over the sucrose layers to fill the tube.
12. Centrifuge tube 30 min at 28,000 × *g*, 4°C. Allow rotor to coast to a stop.

    A balance tube containing equivalent volumes of the solutions and equal mass will be required if a single sample is prepared.

Collect lipid droplets

13. Remove ultracentrifuge tubes from ultracentrifuge rotor and place into Beckman tube slicer with blade placement 5 to 8 mm below the floating opaque lipid droplet layer. Slice tube firmly and steadily.
14. Collect the lipid droplet fraction from the top chamber of the tube slicer using ice-cold HLM to rinse residual lipid droplets from the sides of the tube and surface of the cutting blade.

Characterize lipid droplets

15. Check recovery and purity of an aliquot of the lipid droplet fraction by SDS-PAGE (*UNIT 6.1*) of solubilized proteins (see Support Protocol 2) and immunoblotting (*UNIT 6.2*), assaying for immunoreactivity against lipid droplet–associated proteins including adipophilin (~47 kDa for mouse) for all types of cells except differentiated adipocytes, and perilipin (~57 kDa for mouse) for differentiated adipocytes.

    The sizes of the two proteins adipophilin and perilipin A provided here, ~47 kDa and ~57 kDa, respectively, pertain to mouse proteins. These protein sizes vary between species.

16. Check for contamination of lipid droplet fractions with other membranes by immunoreactivity with antibodies specific for various intracellular membrane marker proteins.

ALTERNATE PROTOCOL

ISOLATION OF LIPID DROPLETS WITH LYSIS OF CELLS USING A CELL DISRUPTION BOMB

Nitrogen cavitation is particularly effective in lysing cells while keeping lipid droplets intact.

Additional Materials *(also see Basic Protocol)*

Suspended cells in HLM (see Basic Protocol, step 4)
45-ml cell disruption bomb (Parr)
15- and 50-ml plastic tubes

1. Transfer suspended cells in HLM into the chamber of a cell disruption bomb. Pressurize the chamber with nitrogen at 450 psi for 15 min.
2. Release the sample dropwise and collect in a 50-ml plastic tube.
3. Centrifuge tube 5 min at 100 × *g*, 4°C, to collect the sample at the bottom of the tube; transfer to a 15-ml plastic tube with cap.
4. Continue with Basic Protocol, step 6.

SUPPORT PROTOCOL 1

LIPID LOADING OF CULTURED CELLS

Many cultured cells store very low mass of neutral lipids in lipid droplets. To promote the synthesis of triacylglycerols and the formation of lipid droplets, the culture medium can be supplemented with 100 μM to 1 mM fatty acids complexed to albumin. Oleic acid is commonly used for lipid loading of cells because it is a good substrate for triacylglycerol biosynthesis (Coleman and Lee, 2004). The most critical step of the procedure is to assure complete complexation of fatty acids to the albumin to prevent detergent effects of unbound fatty acids. One mole of albumin may bind up to 7 mol of fatty acids, depending upon the acyl chain length of the fatty acid (Petitpas et al., 2001); the accompanying procedure guides complex formation of 6 mol of fatty acids to 1 mol of bovine serum albumin. The starting albumin must be fatty acid–free to avoid the addition of an excess of fatty acids. The formation of complexes is accompanied by a visible clearing of the solution; cloudy solutions contain aggregates of uncomplexed fatty acids.

Materials

Fatty acid–free bovine serum albumin
0.1 M Tris·Cl, pH 8.0
Oleic acid
50-ml screw-capped polypropylene tubes
Rotisserie shaker
0.2- or 0.45-μm filter unit

1. Dissolve 3.36 g fatty acid–free bovine serum albumin in 24 ml of 0.1 M Tris·Cl, pH 8.0.
2. Transfer 84 mg oleic acid into a clean 50-ml screw-capped tube using a pipet tip with a wide opening.

   A wide-opening tip should be used because the oleic acid is viscous and difficult to pipet.
3. Add 24 ml of albumin solution to the oleic acid, and mix using a rotisserie shaker, or by gentle inversion and swirling to avoid excessive foaming.

   Complex formation is complete when cloudiness in the solution disappears and there is no visible uncomplexed oleic acid on the side or bottom of the tube.
4. Sterile filter the solution through a 0.2- or 0.45-μm filter unit.
5. Add solution to culture medium to a final concentration of 100 μM to 1 mM oleic acid.

SOLUBILIZATION OF LIPID DROPLET–ASSOCIATED PROTEINS FOR IMMUNOBLOTTING

SUPPORT PROTOCOL 2

Lipid droplet fractions contain a low mass of protein, but high relative mass of neutral lipids, including either triacylglycerols or cholesterol esters, in addition to phospholipids. The high lipid content of the samples interferes with the resolution of proteins by SDS-PAGE. When the lipid droplet fractions are fresh and have not been frozen, the component proteins can be solubilized using detergent solutions with warming and sonication of the sample.

Materials

10% (w/v) sodium sodecyl sulfate (SDS; see recipe)
Fresh lipid droplet fraction (see Basic Protocol)
2× SDS sample buffer (for discontinuous systems; see *UNIT 6.1*)
Sonicating water bath with adjustable temperature
Vortex mixer
1.5-ml microcentrifuge tubes
Gel-loading pipet tip or wide-guage needle attached to a small syringe
Additional reagents and equipment for a discontinuous SDS-PAGE gel (see *UNIT 6.1*)

1. Add 1 vol of 10% SDS to the fresh (not frozen) lipid droplet fraction in HLM. Incubate for at least 1 hr at 37°C in a sonicating water bath. Remove the sample every 5 to 10 min and agitate on a vortex mixer before returning to the bath.
2. Transfer the sample to a 1.5-ml microcentrifuge tube and microcentrifuge 10 min at maximum speed, room temperature.
3. Use a gel-loading pipet tip or a wide-gauge needle attached to a small syringe to collect the infranatant containing the solubilized proteins from beneath the floating lipid layer without removing any of the opaque floating lipid or any precipitated insoluble material from a visible pellet. Transfer to a new 1.5-ml microcentrifuge.

   If the floating lipid layer becomes disrupted, repeat microcentrifugation to consolidate the lipid layer.
4. Add an equivalent volume of 2× SDS sample buffer, and boil the sample for 10 min prior to loading onto a discontinuous SDS-PAGE gel (see *UNIT 6.1*).

DELIPIDATION AND SOLUBILIZATION OF LIPID DROPLET–ASSOCIATED PROTEINS

Alternatively, frozen lipid droplet fractions, or fractions containing excessive lipid can be delipidated using solvents, and the precipitated proteins solubilized in concentrated detergent solutions with warming and sonication. The extent of solvent delipidation required is dependent upon the lipid content of the sample; whereas most samples require only a single delipidation step, lipid droplets isolated from adipocytes and highly lipid-enriched cells require multiple solvent delipidation steps.

Materials

Acetone, −80°C and room temperature
Frozen lipid droplet fraction, thawed
1:1 (v/v) acetone/ether
Ether
2× SDS sample buffer (for discontinuous systems; see *UNIT 6.1*)
Extra reducing reagent (e.g., β-mercaptoethanol or dithiothreitol)

Polypropylene screw-capped centrifuge tubes (Sarstedt)
High-speed refrigerated centrifuge with Sorvall SS34 rotor and tube adapter sleeves, or equivalent
Sonicating water bath with adjustable temperature
1.5-ml microcentrifuge tubes

NOTE: All procedures using organic solvents should be carried out in a fume hood. Tubes should be tightly capped before removing samples from the fume hood for incubation or centrifugation steps. Glass pipets and storage containers should be used to transfer solvents, because disposable polystyrene laboratory pipets will dissolve in many organic solvents. Solvent waste should be disposed of in accordance with institutional policy.

Delipidate sample with acetone

1. Add at least 10 vol of cold acetone that has been stored at −80°C to the thawed or fresh lipid droplet fraction in a screw-capped polypropylene tube. Cap the tube and mix the sample thoroughly by inversion.
2. Incubate the sample overnight at −20°C, or for 4 hr on dry ice.
3. Mix the sample by inversion and centrifuge 1 hr at 4300 × *g*, 4°C.
4. Carefully remove acetone from the loose pellet by pouring off the solvent, or removing with a glass pipet. Discard the acetone in a suitable container.

If samples do not require additional delipidation

5a. Remove residual solvent residue from the pellet using a gentle stream of nitrogen in a fume hood. Continue to step 12.

If additional delipidation is required (adipocyte lipid droplet fractions and samples yielding large fluffy appearing pellets)

5b. Check the tube carefully for stress fractures. Add 10 vol of room temperature acetone to the protein pellet and vortex to mix. Centrifuge 30 min at 4300 × *g*, 4°C.

6b. Carefully remove acetone from the loose pellet by pouring off the solvent, or removing with a glass pipet. Discard the solvent in an appropriate container.

7b. Add 10 vol of 1:1 acetone/ether to the protein pellet at room temperature and vortex to mix. Centrifuge 30 min at 4300 × *g*, 4°C.

8b. Carefully remove the solvent from the loose pellet. Discard the solvent in an appropriate container.

9b. Add 10 vol ether to the pellet at room temperature and vortex to mix. Centrifuge 30 min at 4300 × g, 4°C.

10b. Carefully remove the solvent from the loose pellet. Discard the solvent in an appropriate container.

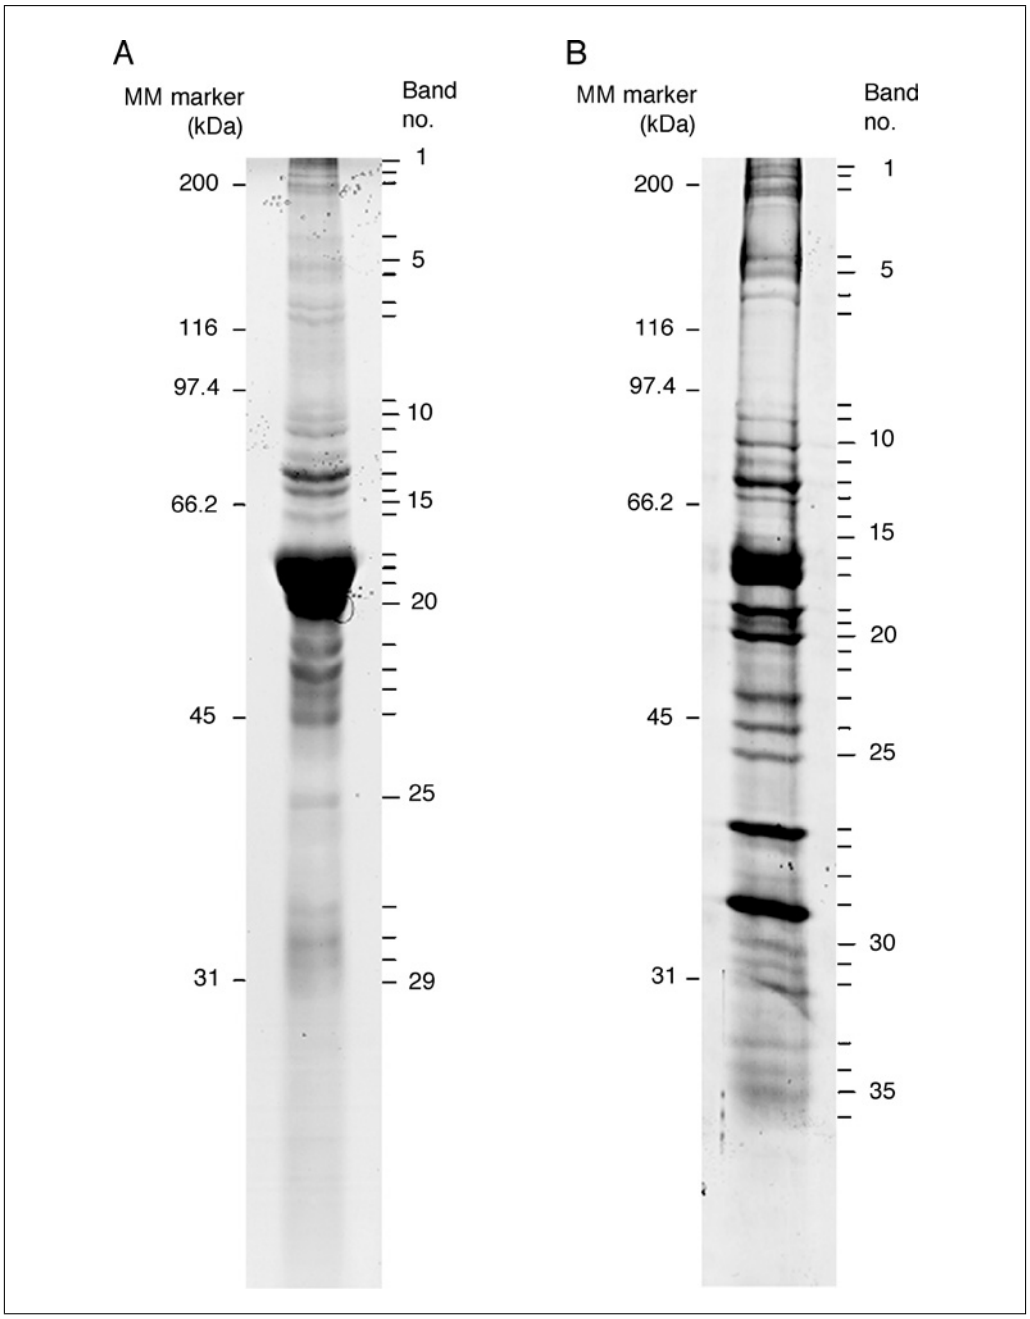

Figure 3.15.2 Coomassie Blue-stained proteins of lipid droplets isolated from 3T3-L1 adipocytes incubated under basal, lipid-storing conditions (**A**) and lipolytically stimulated conditions (**B**). Positions of molecular mass markers and stained bands are depicted on the left and right sides of the panels, respectively. Figure reprinted with permission of *The Journal of Biological Chemistry*, from "Proteomic Analysis of Proteins Associated with Lipid Droplets of Basal and Lipolytically Stimulated 3T3-L1 Adipocytes," Dawn L. Brasaemle, Georgia Dolios, Lawrence Shapiro, and Rong Wang, Vol. 279 (2004) 46835-46842 (original manuscript); Correction Vol. 280 (2005) 4004; permission conveyed through Copyright Clearance Center, Inc.

11b. Remove residual solvent residue using a gentle stream of nitrogen in a fume hood.

Prepare samples for SDS-PAGE gel

12. Add 2× SDS sample buffer to the dry pellet using the largest volume that will fit into sample wells of gel; do not further dilute 2× SDS sample buffer to a 1× concentration.

13. Incubate sample 4 to 6 hr at 60°C in a sonicating water bath. Remove the sample every 5 to 15 min and agitate vigorously using a vortex mixer before returning to the water bath.

14. Transfer the sample to a 1.5-ml microcentrifuge tube and microcentrifuge 10 min at 14,000 × *g*, room temperature.

    The presence of a pellet indicates incomplete solubilization of proteins. Repeat sonication at 60°C, if necessary.

15. Add sufficient additional reducing reagent (e.g., β-mercaptoethanol or dithiothreitol) to replace the majority of reducing reagent in the initial volume of 2× SDS sample buffer (much of the reagent will have been lost during solubilization of the proteins). Load samples onto an SDS-PAGE gel in 2× SDS sample buffer without dilution. Run the gel.

    All samples and molecular weight standards must contain the same volume and 2× concentration of SDS sample buffer.

    Samples may be boiled prior to loading, or loaded onto gels without further processing.

    A full-size SDS-PAGE gel is recommended rather than a mini-gel due to the larger size of the sample wells; it is advantageous to use as large a volume of 2× SDS sample buffer as possible to fully solubilize delipidated lipid droplet proteins. Failure to adequately delipidate the samples will result in one of two possible outcomes: (1) proteins within the samples will be retarded in the wells or stacking gel, and will not migrate sufficiently into the gel, or (2) vertical streaking or smearing of the samples will occur, yielding poor resolution of protein bands. Insufficient solubilization of the samples will yield a low signal of lipid droplet–associated proteins.

    See Figure 3.15.2 for a gel showing proteins associated with lipid droplets and Table 3.15.1 for antibodies to those proteins and their suppliers.

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

HLM containing 5% (w/w) sucrose

2.54 g sucrose
48.34 g HLM (see recipe)
Store 1 to 2 days at 4°C

HLM containing 60% (w/w) sucrose

38.6 g sucrose
25.73 g HLM (see recipe)
Store 1 to 2 days at 4°C

Hypotonic lysis medium (HLM)

1 ml 1 M Tris·Cl, pH 7.4 (20 mM final)
100 µl 0.5 M EDTA (1 mM final)
1 ml 0.5 M sodium fluoride (10 mM final; *optional*)

continued

Protease inhibitors (see *UNIT 3.4*)
H_2O to 50 ml
Prepare fresh and keep on ice

Sodium fluoride is a general phosphatase inhibitor.

Sodium dodecyl sulfate (SDS) 10% (w/v)

10 g SDS
H_2O to 100 ml
Store 1 month at room temperature

COMMENTARY

Background Information

Most cultured cells and many types of cells within tissues have lipid droplets composed of a core of neutral lipids surrounded by a membrane monolayer of phospholipids and cholesterol, into which proteins are embedded. The majority of cells have a few tiny lipid droplets of 0.5 to 5 μm in diameter and containing cores of primarily cholesterol esters, whereas adipocytes store triacylglycerol in large lipid droplets that can reach diameters of 100 μm. In adipocytes and muscle cells, triacylglycerol stored in lipid droplets serves as an important source of energy, whereas in the majority of cells, stored cholesterol esters serve a role in the maintenance of cellular cholesterol homeostasis and are used for membrane synthesis and repair. In steroidogenic cells found in the adrenal cortex, testes, and ovaries, stored cholesterol esters are a source of substrate for steroid hormone synthesis. In stellate cells of the liver and in the retina of the eye, lipid droplets are enriched with retinyl esters.

Identification of the PAT family of lipid droplet–associated proteins (perilipin, adipophilin, also called ADRP, and TIP47; also including S3-12) that contain highly conserved sequences of amino acids has created interest in the proteomics of lipid droplets and the study of lipid droplets as a dynamic metabolic compartment.

Additionally, several enzymes required for the biosynthesis of sterols and for acylation of neutral lipids and phospholipids have been localized to lipid droplets (Caldas and Herman, 2003; Ohashi et al., 2003; Brasaemle et al., 2004; Fujimoto et al., 2004; Liu et al., 2004; Umlauf et al., 2004).

In general, the culture medium used to promote the growth of most cell lines contains a relatively low concentration of fatty acid and cholesterol substrates for neutral lipid synthesis. Under these conditions, most cell lines display few or no lipid droplets per cell, when visualized by staining of cells with the lipophilic dyes Nile Red (Greenspan et al., 1985), or Bodipy 493/503 (Gocze and Freeman, 1994). The addition of either decimillimolar concentrations of fatty acids complexed to albumin, or a combination of fatty acids bound to albumin and cholesterol delivered via liposomes or cyclodextrins promotes increased synthesis of neutral lipids and subsequent storage of these lipids in lipid droplets.

The isolation of lipid droplets relies upon the buoyant density of lipid droplets, which is <1 g/cm^3. Two low-speed centrifugation steps and a single ultracentrifugation step using a discontinuous density gradient will collect >95% of the lipid droplets from a cell lysate. The isolated lipid droplets may be used as a source of lipid substrates for studying the activities of lipid metabolic enzymes. To date, no specific enzyme activities have been localized exclusively to lipid droplets. The PAT family proteins adipophilin and perilipin are structural proteins that are used as specific markers of the lipid droplet compartment in immunoblotting and indirect immunofluorescence applications. The use of isolated lipid droplet fractions for proteomics studies necessitates the washing of the initial lipid droplet fraction through several additional centrifugation steps to remove traces of contaminating membranes including microsomes, mitochondria, and fragments of plasma membranes. The described methods may also be scaled up and used to isolate lipid droplets from tissue samples, following the digestion of the tissue to yield a uniform suspension of intact, disaggregated cells.

Critical Parameters and Troubleshooting

The isolation of lipid droplets by centrifugation is a relatively simple procedure. A very low protein-to-lipid ratio renders lipid droplets more buoyant than all other subcellular structures; lipid droplets can be separated from

more dense subcellular compartments using discontinuous density gradients. The most critical step in the isolation of lipid droplets is making an appropriate choice for the method of cell disruption to keep the droplets intact, particularly when working with cells containing very large lipid droplets. Gentle disruption of cells is required to preserve lipid droplet structure. The use of rotor-stator homogenizers or sonication to lyse cells will disrupt and emulsify lipid droplets. Likewise, the extrusion of cells or isolated lipid droplets through small openings exerts sufficient shear force to disrupt lipid droplets. Gentle homogenization using a hand-operated homogenizer with a loose-fitting Teflon pestle, or the use of a nitrogen cavitation bomb will yield better results.

The buoyant density of lipid droplets facilitates flotation during centrifugation of any aqueous medium. The use of solutions lacking electrolytes may reduce the aggregation of lipid droplets with other subcellular organelles; the use of hypotonic solutions does not compromise the integrity of lipid droplets because they have no aqueous compartment. Since segments of endoplasmic reticulum and numerous mitochondria are often closely apposed to the droplets in intact cells, isolated lipid droplet fractions contain low levels of these membranes. Contamination of lipid droplets with these membranes can be minimized by layering density-adjusted cell lysates beneath one or two layers of decreasing density in a discontinuous gradient prior to centrifugation. The movement of the lipid droplets upwards through the layers of the gradient reduces the adherence of contaminant membranes to the droplets and resolves the droplets from soluble proteins. Further removal of contaminating membranes may be enhanced by flotation of the isolated lipid droplets through additional discontinuous density gradients, which may include solutions containing a low concentration of glycerol, 100 mM to 1 M sodium chloride, or 100 mM sodium carbonate, pH 11.5 (Fujiki et al., 1982). The use of sodium carbonate wash solutions, however, may remove loosely adherent proteins that normally localize to the outer membrane monolayer of lipid droplets, and may denature the proteins. While lipid droplets can be isolated using tubes with volumes smaller than those described, and with correspondingly reduced volumes of the gradient solutions, higher levels of contaminating membranes may be floated with the lipid droplet fraction. Wide-diameter tubes are not recommended for the isolation of lipid droplets from relatively small numbers of cells, because the lipid droplet layer will be diffuse and more easily disrupted during sample collection. Additionally, swinging-bucket rotors are recommended to band the floating lipid droplets compactly at the top of the tube; rotors should be allowed to coast to a stop through the final deceleration to minimize disruption of the lipid droplet layer.

Following centrifugation, lipid droplets will appear as a milky layer at the top of the tube. If there is a clear oily layer at the top of the tube, the lipid droplets have broken during sample preparation; this is indicative of a poor isolation. Gentle homogenization with fewer strokes and slower insertion of the pestle will reduce disruption of the lipid droplets. There will be a pellet containing dense membranes at the bottom of the tube and one or two translucent bands of membranes at the interfaces of the density phases. If these bands appear very cloudy and white, this indicates breakage and emulsification of the lipid droplets, and a poor preparation of lipid droplets. A portion of the floating droplet fraction will adhere to the sides of the tube, and to the surfaces of any pipetting device used to collect the fraction. Additionally, if the layer is disrupted during handling of the tube or collection of the samples, some of the droplets may swirl down into the top layer of the gradient, making sample collection more difficult.

The best way to collect the majority of the lipid droplet fraction in a small volume is to use a Beckman tube slicer in combination with thin-walled polyallomer or polycarbonate tubes. The tube is inserted into the tube slicer to position the cutting blade several millimeters below the lipid droplet layer. The steady and firm insertion of the blade through the tube isolates the lipid droplet layer in a small volume of the top gradient solution in the sliced top portion of the tube. Rubber rings within the tube slicer form a seal with the blade, keeping the top solution from leaking out. Use of a tube slicer facilitates the most efficient collection of the lipid droplets in a minimal volume, and it permits rinsing of the surfaces of the blade and tube with additional solution to more completely collect the fraction. When a tube slicer is unavailable, the lipid droplet fraction can be collected using either a pipetting device or a syringe with a wide-bore needle; however, it is more difficult to collect the entire lipid droplet layer in a minimal volume. Additionally, there

will be significant loss of lipid droplets that are adherent to the sides of the tube. Gradient collectors that puncture the bottoms of tubes and collect the most dense fractions first are unsuitable for the collection of lipid droplets, because the majority of the lipid droplets will adhere to the sides of the tube as the volume of liquid drops.

Lipid droplets from chordates are characterized by their content of neutral lipids and by the presence of one or more members of the PAT family of proteins. The neutral lipid content may be assessed by quantitative thin layer chromatography (Brasaemle et al., 1997a) of solvent extracts of lipids (Bligh and Dyer, 1959), or by the adaptation of commercially available clinical assays for the quantitation of triacylglycerol or cholesterol for use with extracted lipids. The content of PAT family proteins is best assessed by immunoblotting of proteins extracted from lipid droplet fractions. Since lipid droplets have an extremely low content of protein relative to lipid, it is imperative to remove the excess lipid before applying samples to SDS-PAGE gels (see Support Protocols 2 and 3). Detergent solubilization of proteins in preparation for SDS-PAGE must be conducted using freshly isolated lipid droplet fractions; the recovery of PAT family proteins from frozen and thawed samples of lipid droplets is significantly reduced. A buffered solution containing 1% Triton X-100 and 0.5% sodium deoxycholate can substituted for the SDS-containing sample buffer. Lipid droplet fractions that have been frozen and thawed can be delipidated with solvents and the proteins solubilized in 2× concentrated sample buffer; the higher content of SDS and reducing reagent in undiluted 2× sample buffer helps to solubilize the relatively insoluble component proteins. Effective solubilization of precipitated proteins requires extensive warming and sonication of the samples; however, the use of a probe sonicator will cause foaming of the sample and should be avoided. Solubilization of samples for several hours at 60°C with sonication in a bath sonicator is more effective than brief boiling of the samples. Samples should be loaded on gels immediately after the solubilization steps to avoid precipitation of the component proteins. For most types of cells, immunoblotting for adipophilin will identify lipid droplets; however, immunoblotting for perilipin is required for lipid droplets isolated from mature adipocytes, since adipophilin is excluded from the droplets when the expression of perilipin is induced during adipose differentiation (Brasaemle et al., 1997b).

Anticipated Results

This procedure will yield a lipid droplet fraction that contains >95% of the total neutral lipid content of the cells, and >95% of adipophilin or perilipin. The lipid droplet fraction will contain an extremely low protein mass relative to that of lipid; the relative protein mass will vary with the size of the lipid droplet and type of cell used. The lipid droplet fraction will also contain low levels of contamination with mitochondria and membrane fragments from endoplasmic reticulum and plasma membrane. Typical preparations of adipocyte lipid droplets using this procedure contain ≤5% of the total content of calnexin, a marker for endoplasmic reticulum, when assessed by immunoblotting. The relative purity of the lipid droplet fraction will be influenced by several factors including the size of the lipid droplets and the number of lipid droplets in the cell lysate. Lower levels of contaminants may be anticipated when isolating lipid droplets from cells that have very small lipid droplets, and when centrifugation of the cell lysates yields a distinct, but relatively thin lipid layer.

If the isolated lipid droplets are being used to establish the relative content in lipid droplets of a protein that is found in other subcellular compartments, then it is essential to characterize the levels of contaminant membranes using either immunoblotting methods, or marker enzyme assays. When analyzing the distribution of a protein that localizes to both lipid droplets and another subcellular compartment, care must be taken to make appropriate comparisons. Lipid droplets contain an extremely low protein content relative to lipid, whereas other membrane compartments are relatively protein dense. Thus, comparing lipid droplets to other membrane fractions on the basis of total protein content of the compartments is inappropriate, as it will require the use of lipid droplets from 20- to 100-fold greater cell mass than for the other subcellular compartments. It is more appropriate to compare a volume of the lipid droplet fraction that represents an equivalent fraction of the whole cell lysate.

Time Considerations

The isolation of intact lipid droplets requires fresh and not frozen cell or tissue samples. It is necessary to proceed from harvest of

cells through the collection of lipid droplets without storage of samples at intermediate steps of the procedure. Since the centrifugation steps are relatively brief, all steps from the harvest of cells through the initial collection of the lipid droplet fraction can be completed within 4 hr. Additional washes of the lipid droplet fraction should be done on freshly isolated material, immediately following the initial isolation. The lipid droplet fraction can then be stored for several hours at 4°C, or several weeks at −80°C.

Assessment of lipid droplet components can be performed upon frozen and thawed samples of isolated lipid droplets, although recovery of proteins using the detergent solubilization procedure will be reduced for samples that have been stored at −80°C. Protein precipitation by solvent delipidation, and the subsequent solubilization of the proteins will require at least 8 hr, if a one-step delipidation is completed. SDS-PAGE may be completed in 2 to 4 hr and transfer of proteins to membranes and subsequent immunoblotting takes 10 to 24 hr.

Isolation of Mast Cell Granules

This unit describes the means to isolate and use rat serosal mast cell granules in experiments aimed at determining the role of mast cell activation and degranulation in disease. Upon activation, mast cells exocytose, through an energy-requiring process, cytoplasmic secretory granules into their extracellular microenvironment. These granules are modified lysosomes containing preformed mast cell mediators, such as histamine, neutral proteases, cytokines, and growth factors embedded in a heparin proteoglycan matrix (Fig. 3.16.1). Isolated rat serosal mast cells are activated by compound 48/80 (Thon and Uvnäs, 1967), a commercially available basic polyamine (a condensation product of *N*-methyl-*p*-methoxyphenethylamine with formaldehyde) that has been shown to activate mast cells through activation of G protein–coupled receptors (Aridor et al., 1990). Upon activation, a part of the secretory granules become swollen and their individual perigranular membranes fuse to form a tubular channel in which the granules to be exocytosed lie in chains. The outer end of a degranulation channel fuses with the plasma membrane, and a pore connecting the tubule with the extracellular fluid is formed (Fig. 3.16.2B). The outermost granules are expelled, whereas the innermost granules remain in the degranulation channel. The soluble components of the granules exposed to the extracellular fluid, such as histamine, diffuse away, whereas the heparin proteoglycans and the mast cell–specific neutral proteases (e.g., chymase) remain tightly bound to each other, forming proteolytically active intra- and extracellular granule remnants (Fig. 3.16.3; Kovanen, 1993; Kokkonen et al., 1995). The whole process of degranulation, from stimulation to exocytosis, occurs within a few minutes. This unit focuses on the preparation of serosal mast cells from the peritoneal and pleural cavities of rats for the isolation of mast cell granules (Kokkonen and Kovanen, 1985). It also describes a procedure to obtain intact cytoplasmic granules, which are enveloped by their individual perigranular membranes (Krüger et al., 1980; Lindstedt et al., 1992). These protocols concern rat serosal mast cells only.

The first step in the procedure is isolation of rat serosal mast cells (see Basic Protocol 1). Rat serosal mast cell granules can be isolated by different procedures. One involves mast cell activation and degranulation, i.e., mimicking the in vivo situation of granule secretion (see Basic Protocol 2). Upon exposure to the extracellular fluid containing physiological levels of ions, the soluble components loosely bound to the negatively charged proteoglycan component of the granules (also those remaining within the degranulation channels) diffuse away due to lost ionic interactions (Bergendorff and Uvnäs, 1972). The heparin proteoglycan protease–containing residues are called granule remnants. Furthermore, intact mast cell granules enveloped by their individual perigranular membranes, i.e., containing both heparin proteoglycan–bound and soluble mediators, can be isolated using a mild sonication procedure (see Alternate Protocol 1). The isolation of intact membrane-covered granules allows one to study all preformed granule mediators, i.e., both bound and soluble, present within the granule organelle. In addition, mast cell granules can be isolated simply by disruption of mast cells using freezing and thawing, and isolation of the granule remnants by a combination of low- and high-speed centrifugations (see Alternate Protocol 2). Since activation of mast cells with compound 48/80 only leads to release of a fraction of the cytoplasmic granules, the advantage of using the freezing and thawing method is a higher yield of isolated granule remnants. The composition of the granule remnants is, however, identical whether the remnants have been isolated after mast cell stimulation or by the freezing and thawing method. Assays for histamine (see Support Protocol 1), lactate dehydrogenase (LDH, see Support

Protocol 2), granule morphology and purity (see Support Protocol 3), heparin proteoglycans (see Support Protocol 4), and chymase activity (see Support Protocol 5) are included to assess degranulation of mast cells.

BASIC PROTOCOL 1

ISOLATION OF RAT SEROSAL MAST CELLS

Loosely associated serosal mast cells are isolated from the peritoneal and pleural cavities of male rats by gentle lavage with albumin-containing phosphate buffer. Typically, ~15% of the cells are mast cells, and ~85% are macrophages. The obtained cell suspension is then plated on plastic petri dishes in the presence of rat serum to allow the contaminating macrophages to adhere to the plastic. The purity of the nonadherent cells, i.e., mast cells, is then checked by staining with Moore & James stain, and normally exceeds 90% to 95%.

Materials

Male Wistar rats, 300 to 500 g
CO_2 gas
Ethanol
Buffer A (see recipe)
Heparin (Sigma)
Medium A (see recipe)
PBS with magnesium and calcium (GIBCO)
Moore & James staining solution (see recipe)

Glass tank with cover
Sterilized scissors and forceps (surgical and anatomical)
20- and 10-ml syringes
10-ml disposable pipets
18-G needles
15- and 50-ml centrifuge tubes
56°C water bath
Centrifuge (e.g., Eppendorf 5810R)
150 × 15–mm petri dishes
37°C, 5% CO_2 humidified incubator
Hemacytometer

NOTE: Treat the mast cells gently throughout the protocol to avoid spontaneous degranulation and loss of granules.

Isolate rat serosal cells

1. Sacrifice male Wistar rats weighing 300 to 500 g by CO_2-asphyxiation in a covered glass tank followed by cervical dislocation.
2. Spray the abdomen and breast area with ethanol and remove the fur from the sprayed area by lifting the dermis with surgical forceps and cutting with scissors in a longitudinal direction.
3. Lift the abdominal muscles with surgical forceps and make a small incision through the abdominal wall with the scissors. Carefully inject 20 ml of buffer A containing 0.05 mg/ml heparin into the peritoneal cavity using a 20-ml syringe (without a needle). Keep the injection site lifted with forceps and gently massage the abdomen by hand for 30 sec.
4. Open the abdomen by cutting with surgical scissors in a longitudinal direction and carefully aspirate the buffer containing the peritoneal cells using a disposable 10-ml pipet. To recover most of the injected buffer A from the peritoneal cavity, carefully lift the intestines out of the peritoneal cavity with anatomical forceps.

Avoid touching the internal organs with the pipet because it may cause damage to the liver or intestines and contaminate the mast cell suspension.

5. Make a small incision in the upper part of the diaphragm avoiding visible blood vessels and inject 10 ml of buffer A containing 0.05 mg/ml heparin into the pleural cavity. Again, gently massage the torso for 30 sec by hand, and aspirate the mast cell–containing buffer with a disposable 10-ml pipet.

Prepare rat serum

6. Puncture the heart with a 10-ml syringe equipped with an 18-G needle and draw blood into a 15-ml centrifuge tube. Allow the blood to coagulate at room temperature for 10 min and centrifuge 10 min at 700 × *g*, room temperature.

7. Recover the serum, inactivate it 30 min at 56°C, and add it (final concentration 5% v/v) to medium A when plating the mast cells (step 9).

Remove macrophages

8. Pool the cells from the peritoneal and pleural cavities in 50-ml centrifuge tubes. Sediment the cells by centrifuging 5 min at 150 × *g*, room temperature. Gently resuspend the cells in 15 ml of medium A.

9. Seed aliquots of the cells (1×10^6 mast cells) onto plastic petri dishes in medium A with 5% rat serum (step 7) and incubate 1 hr in a 37°C, 5% CO_2 humidified incubator to allow contaminating macrophages to adhere to the plastic.

10. Recover the non-adherent cells (mast cells) by shaking the petri dishes for 30 sec and transfering the mast cells into a new 50-ml centrifuge tube.

Wash the mast cells

11. Carefully wash the recovered mast cells two times by adding 10 ml PBS and centrifuging 5 min at 150 × *g*, 22°C, avoiding spontaneous activation.

12. Resuspend 1×10^6 mast cells in 200 µl PBS by gently flicking the tube with a finger.

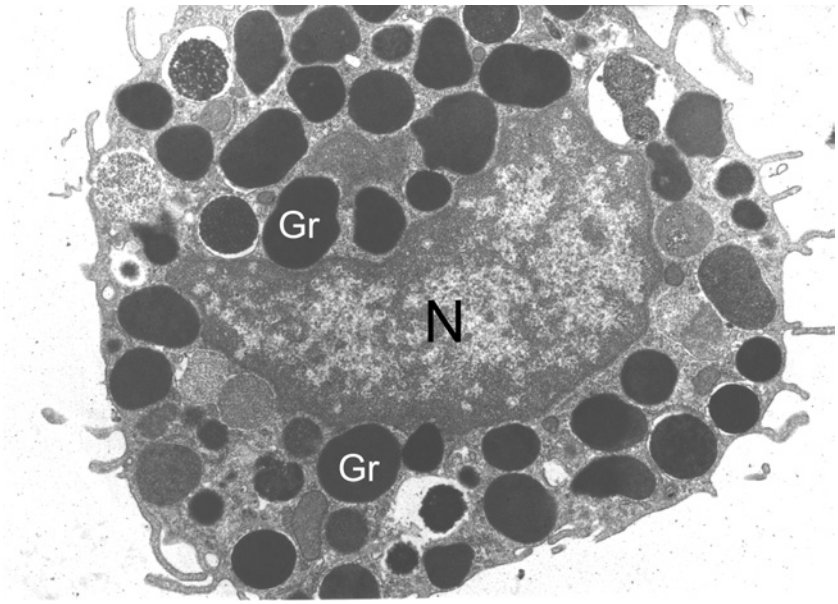

Figure 3.16.1 A transmission electron micrograph showing an isolated rat serosal mast cell filled with cytoplasmic electron dense granules (black spheres, Gr). One rat serosal mast cell typically contains ~1000 secretory granules. N = nucleus; Gr = granules

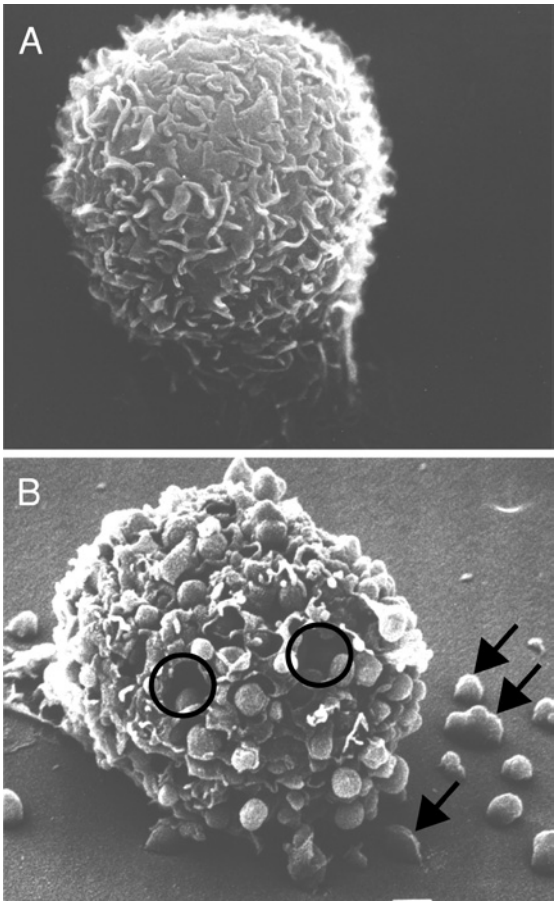

Figure 3.16.2 Scanning electron micrographs of isolated rat serosal mast cells. (**A**) Resting mast cell. (**B**) Activated and degranulated mast cell. Arrows point to expelled granule remnants. Two open degranulation channels showing intracellular granule remnants are encircled.

13. Judge the purity of the mast cell suspension by adding 5 µl of the mast cell suspension to 5 µl Moore & James staining solution and immediately count an aliquot on a hemacytometer.

    One should find 90% to 95% of the cells to be mast cells (see Fig. 3.16.1), the remaining cells are lymphocytes, eosinophils, and occasional macrophages.

BASIC PROTOCOL 2

ISOLATION OF MAST CELL GRANULES

Mast cell granules are isolated from activated or disrupted mast cells by low- and high-speed centrifugation steps (Thon and Uvnäs, 1966; Kokkonen and Kovanen, 1985). All centrifugation steps are performed using 1.5-ml microcentrifuge tubes and a microcentrifuge.

Mast cells can be activated to release a fraction of their granules by several distinct mechanisms. IgE-mediated activation is the classical pathway known to activate mast cells in vivo in, for example, allergic reactions. It involves the crosslinking of cell surface–bound antigen-specific IgE by the respective antigens or by anti-IgE antibodies. Mast cell activation can also be accomplished using a commercially available activator, compound 48/80, which causes extensive mast cell degranulation by activating G protein–coupled receptors (Aridor et al., 1990). Because compound 48/80 mimicks the physiological pathway of activation, it has been used in this unit for isolation of mast cell granules.

Materials

Mast cells (see Basic Protocol 1)
PBS with magnesium and calcium (GIBCO), cold and room temperature
Compound 48/80 (Sigma)

1.5-ml microcentrifuge tubes
Microcentrifuge
37°C, 5% CO_2 humidified incubator

Activate mast cells

1. For the standard assay, preincubate 1×10^6 mast cells in 200 μl of PBS in a 1.5-ml microcentrifuge tube 15 min in a 37°C, 5% CO_2 humidified incubator.
2. Stimulate the mast cells to degranulate by adding compound 48/80 to a final concentration of 1 μg/ml.
3. Continue incubation for 5 min in a 37°C, 5% CO_2 humidified incubator to allow the mast cells to completely activate and degranulate.
4. Sediment the cells by centrifuging 5 min at 150 × *g*, 4°C. Save the supernatant.
5. Determine the histamine contents of both supernatant and sediment as described in Support Protocol 1.

Recover granules and remnants

6. Recover any extracellular granules loosely associated with the stimulated mast cells by gently resuspending the sediment ten times in 200 μl of PBS using a micropipet.
7. Sediment the cells by centrifuging 5 min at 150 × *g*, 4°C. Collect the supernatant.
8. Determine intactness of the mast cells by measuring the presence of lactate dehydrogenase in the supernatants from steps 4 and 7 (see Support Protocol 2).
9. Pool the supernatants from steps 4 and 7. Recover the granule remnants by centrifuging the supernatants 5 min at 15,000 × *g*, 4°C. Wash one time with 200 μl deionized water and repeat centrifugation.
10. Resuspend the granule remnants in 200 μ1 of deionized water and determine the amounts of protein, heparin proteoglycans, and chymase (see Support Protocol 5).

ISOLATION OF MEMBRANE-COVERED GRANULES

ALTERNATE PROTOCOL 1

Intact mast cell granules enveloped by their individual perigranular membranes, i.e., containing both heparin proteoglycan bound and soluble mediators can be isolated using a mild sonication procedure. The isolation of intact membrane-covered granules allows for the study of all preformed granule mediators, i.e., both insoluble and soluble mediators, present within the granule organelle.

Materials

Purified mast cells (see Basic Protocol 1)
Buffer B (see recipe)
0.1% (v/v) Triton X-100 in buffer B (see recipe for buffer B)
PBS with magnesium and calcium (GIBCO)

1.5-ml microcentrifuge tubes
Sonicator (e.g., Model Pul 125, Kerry Ultrasonics)

1. Wash purified mast cells (5–10 × 10^6) three times with 4 ml buffer B, centrifuging 5 min at 150 × *g*, 22°C. Resuspend the cells in 500 µl buffer B in a 1.5-ml microcentrifuge tube.
2. Subject the mast cell suspension to mild sonication in a Kerry water bath sonicator for 30 sec at 4°C. Determine the duration of sonication necessary to rupture the plasma membranes but leave the membrane-covered granules intact by checking an aliquot of the cells with a light microscope at intervals.
3. Sediment cellular debris by centrifuging 10 min at 150 × *g*, 4°C.
4. Transfer the supernatant containing the membrane-covered granules to a new 1.5-ml microcentrifuge tube.
5. Treat 250 µl of membrane-covered granules with 1 ml of 0.1% Triton X-100 in buffer B for 10 min at room temperature to remove the granule membranes.
6. Obtain membrane-free granule remnants by centrifuging 5 min at 15,000 × *g*, 4°C.
7. Analyze the insoluble granule remnants and the soluble granule remnant–free supernatant for their individual components using various techniques, e.g., SDS-PAGE, western blotting, and others.

ALTERNATE PROTOCOL 2

BULK PREPARATION OF MAST CELL GRANULES

If mast cell granules are used for experiments involving the effects of chymase and heparin proteoglycans, they can also be prepared in advance (in bulk) and stored for up to 6 months at –20°C.

Materials

Purified mast cells (see Basic Protocol 1)
0.3 M sucrose
Liquid nitrogen
Buffer A (see recipe)
1.5-ml microcentrifuge tubes
37°C water bath
Additional reagents and equipment for determination of protein concentration by the method of Lowry (*APPENDIX 3H*)

1. Resuspend purified mast cells isolated from ten rats in 1 ml of 0.3 M sucrose in a 1.5-ml microcentrifuge tube.
2. Lyse the cells by six freeze/thaw cycles using liquid nitrogen and a 37°C water bath.

   The freeze/thaw cycles should include freezing samples thoroughly (~5 sec) in liquid nitrogen and thawing (~10 sec) in the 37°C water bath.
3. Sediment the cellular debris from the lysate by centrifuging 5 min at 450 × *g*, 22°C.
4. To obtain a practically pure granule fraction, transfer the supernatant to a new 1.5-ml microcentrifuge tube and centrifuge 20 min at 3000 × *g*, 22°C.
5. Wash the granule pellet two times in 1 ml buffer A by centrifuging 5 min at 15,000 × *g*, 22°C. Resuspend the granule pellet in 100 µl of deionized water.
6. Measure the protein concentration by the method of Lowry (*APPENDIX 3H*) and express the quantity of granules in terms of micrograms granule proteins per milliliter.

HISTAMINE ASSAY

SUPPORT PROTOCOL 1

The yield of granules obtained during the process of mast cell degranulation (see Basic Protocol 2) is dependent on the degree of mast cell activation. This can easily be measured by analyzing the amount of soluble histamine both in the supernatant and in the remaining cell pellet.

Materials

Activated mast cells (see Basic Protocol 2)
Trichloroacetic acid (TCA)
Orthopthalaldehyde (OPTA, Fluka)
Methanol
Histamine (Sigma)
0.01, 0.05, and 2 N H_2SO_4
1 N NaOH

1.5-ml microcentrifuge tubes
Fluorometer (340-nm excitation and 443-nm emission filters)

1. After mast cell activation, transfer 200 µl (1×10^6 mast cells) to a 1.5-ml microcentrifuge tube. Centrifuge 5 min at 150 × *g*, 4°C.
2. Remove the supernatant by pipetting it into a new 1.5-ml microcentrifuge tube. Incubate the cell pellet with 200 µl deionized water 30 min at room temperature to lyse the cells.
3. Treat 50 µl of the supernatant and 50 µl of the resuspended pellet with 11 µl of ice-cold 50% TCA (10% final concentration), shake the tubes vigorously and incubate 20 min at 4°C.
4. Sediment the precipitated material by centrifuging 10 min at 12,000 × *g*, 4°C.
5. Determine the histamine content by fluorometry according to the method of Bergendorff and Uvnäs (1972). Briefly, prepare a fresh solution of 10 mg/ml fluorescent OPTA by dissolving it in methanol.
6. Dissolve the histamine standard in 0.05 N H_2SO_4 at 100 ng/µl and prepare a 1 ng/µl histamine working solution by diluting the stock solution in water.
7. Incubate samples and histamine standards (0 to 300 ng histamine) in a mixture of 2 ml of 0.1 N H_2SO_4, 400 µl of 1 N NaOH, and 100 µl of 10 mg/ml OPTA 4 min at room temperature.
8. Add 200 µl of 2 N H_2SO_4 and incubate 5 min at room temperature. Measure the fluorescence using a 340-nm excitation filter and a 443-nm emission filter.
9. Calculate the percentage of histamine released from the mast cells into the incubation medium by using the following formula: histamine release (%) = $S/(S + P) \times 100$, where *S* is the histamine content of the supernatant and *P* is the histamine content of the mast cell pellet.

A concentration of 1×10^6 mast cells contains ~14 µg of histamine.

QUANTIFICATION OF LACTATE DEHYDROGENASE USING THE CYTOTOXICITY DETECTION KIT (ROCHE)

SUPPORT PROTOCOL 2

To verify that the mast cells have been properly activated, resulting in the release of physiological mast cell mediators and not components released due to cell rupture or damage, the level of lactate dehydrogenase (LDH) in the cell-free supernatant is measured. In this protocol, a commercially available Roche kit is used for LDH-measurement, but the assay

may also be performed using a standard method for LDH and reagents prepared in the laboratory. The assay is a colorimetric assay for the quantification of cell death and cell lysis based on the measurement of LDH activity released from the cytosol of damaged cells into the supernatant. The percentage of cytotoxicity is determined by calculating the average absorbance values of triplicates and subtracting from each of these the value obtained in the background control (LDH activity present in the assay medium). Low control absorbance provides the spontaneous LDH released from untreated cells and high control absorbance provides the maximum LDH released from lysed cells. The following equation is used for calculating cytotoxicity: cytotoxicity (%) = [experimental value – low control/(high control – low control)] × 100.

Materials

Cell-free supernatant from mast cells (see Basic Protocol 2; 1×10^6 activated mast cells)
PBS
Cytotoxicity detection kit (Roche) containing:
Catalyst: diaphorase/NAD^+ mixture and lyophilizate, stabilized
Dye solution: iodotetrazolium chloride (INT) and sodium lactate

96-well microtiter plates with flat-bottomed wells
Microtiter plate reader (490 nm)

1. Transfer 10 µl of cell-free supernatant per well of a 96-well clear flat-bottomed microtiter plate. Add PBS up to 100 µl. Prepare samples in triplicate.
2. Prepare the reaction mixture from the cytotoxicity detection kit as follows: add 1 part of catalyst to 45 parts of dye solution. Add 100 µl of the reaction mixture to each well.
3. Incubate ~10 to 30 min at room temperature until color is visible. Protect the plate from light during the incubation.
4. Measure absorbance at 490 nm using a microtiter plate reader and calculate cytotoxicity (see protocol introduction).

SUPPORT PROTOCOL 3

VERIFICATION OF GRANULE MORPHOLOGY AND PURITY

The morphology and purity of the isolated mast cell granules can be verified using transmission electron microscopy (TEM).

Materials

Mast cell granules (see Basic Protocol 2)
2.5% (v/v) glutaraldehyde/100 mM sodium phosphate buffer, pH 7.2
1% (w/v) osmium tetroxide/100 mM sodium phosphate buffer, pH 7.2
50%, 70%, 94%, and 99% ethanol
LX-112 embedding medium (Ladd Research)
Uranyl acetate (Ultrostain I, Leica)
Lead citrate (Ultrostain II, Leica)

Ultramicrotome
Automated Leica EMStain apparatus (Leica)
Electron microscope

1. Fix 10 µg mast cell granules 60 min at 22°C in 200 µl of 2.5% glutaraldehyde/100 mM sodium phosphate buffer, pH 7.2
2. Postfix the sample 30 min at 22°C in 200 µl of 1% osmium tetroxide/100 mM sodium phosphate buffer, pH 7.2.

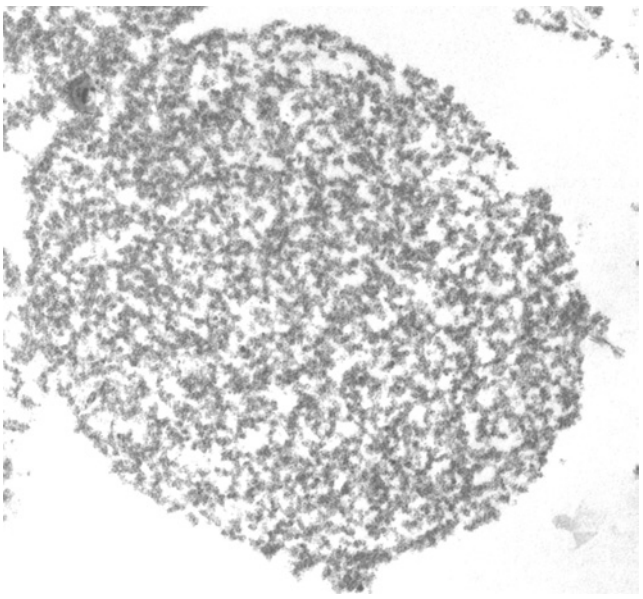

Figure 3.16.3 A transmission electron micrograph showing an isolated rat serosal mast cell granule remnant.

3. Dehydrate samples in an increasing ethanol series: 5 min in 50% ethanol, 10 min in 70% ethanol, 20 min in 94% ethanol, and 45 min in 99% ethanol. Embed in LX-112 embedding medium.
4. Cut 70- to 90-nm sections for analysis with an ultramicrotome.
5. Using an automated Leica EMStain staining apparatus, post stain sections with Ultrostain I 30 min at 20°C and Ultrostain II 1.2 min at 20°C with water wash in between the stainings.
6. Visualize the preparation using a transmission electron microscope.

Figure 3.16.3 shows a typical granule remnant isolated from rat serosal mast cells visualized by the transmission electron microscopic technique.

DETERMINATION OF HEPARIN PROTEOGLYCANS

SUPPORT PROTOCOL 4

This method of determining the amount of proteoglycans in mast cell granules and fragments is adapted from Bartold and Page (1985).

Materials

Sepraphore III cellulose polyacetate electrophoresis strips (2.5 × 15.2–cm, Pall Corporation)
Heparin standards (Sigma)
Mast cell granule remnants (see Basic Protocol 2)
0.2% (w/v) Alcian blue staining solution (see recipe)
Destaining solution (see recipe)
DMSO

10-ml disposable plastic tubes (DMSO-resistant)
Platform shaker
Whatman no. 3 filter paper
Spectrophotometer

1. Mark a Sepraphore III cellulose polyacetate electrophoresis strip in 2-cm sections with a soft pencil.
2. Apply heparin standards (1.25 and 2.5 μg) and granule remnants (10 to 30 μl), in duplicate, onto the middle of the marked strip and let them air dry. Include two empty sections for blanks.
3. Stain the strip in 10 to 100 ml of 0.2% Alcian blue staining solution 30 min at room temperature on a platform shaker.
4. Destain strip through three changes, 15 min each, in 10 to 100 (depending on the container used) ml destaining solution on a platform shaker.
5. Dry the strip using Whatman no. 3 filter papers.
6. Cut the marked strips into 2-cm pieces. Place into 10-ml disposable plastic tubes and dissolve the pieces in 2 ml of DMSO by vigorous vortexing. Repeat the vortexing until the pieces have dissolved completely.
7. Measure the absorbance at 678 nm in a spectrophotometer.
8. Calculate the amount of heparin proteoglycan in the granule remnants using the known concentrations of the heparin standards.

SUPPORT PROTOCOL 5

MEASUREMENT OF CHYMASE ACTIVITY

A major protein component in the granule remnants is the neutral serine protease, chymase, which constitutes ~30% of the total granule remnant protein. The proteolytic activity of chymase in the isolated granule remnants can be determined spectrophotometrically using *n*-benzoyl-L-tyrosine ethyl ester (BTEE; Sigma) as substrate (Woodbury et al., 1981).

Materials

Isolated mast cell granules (see Basic Protocol 2)
0.5 mM *n*-benzoyl-L-tyrosine ethyl ester (BTEE; Sigma) in 100 mM NaCl/50 mM Tris·Cl, pH 7.4
Spectrophotometer (256 nm)

1. Resuspend 1 to 5 μg of isolated mast cell granule protein in 2.9 ml of 100 mM NaCl/50 mM Tris·Cl (pH 7.4) and add 100 μl of BTEE substrate immediately before starting the measurement.
2. Measure the change in absorbance at 256 nm for 5 min at room temperature using 30-sec measuring intervals.
3. Calculate the activity (arbitrary U/min) as the change in absorbance measured as the Δ-slope value × 1000, and using purified or recombinant chymase as a standard.

REAGENTS AND SOLUTIONS

Use deionized distilled water in all recipes and protocol steps. For common reagents, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Alcian blue staining solution, 0.2% (w/v)

200 mg Alcian blue
100 ml destaining solution (see recipe)
Filter using a piece of Whatman no. 3 filter paper
Store up to 2 weeks at 4°C

Buffer A

PBS (GIBCO) supplemented with:
0.5 mg/ml bovine serum albumin
5.6 mM glucose, pH 7.3
Prepare fresh and keep at 4°C

Buffer B

PBS (GIBCO) supplemented with:
1.75 mg/ml bovine serum albumin
5.6 mM glucose
Prepare fresh and keep at 4°C

Destaining solution

0.05 M $MgCl_2$
0.025 M sodium acetate
50% (v/v) ethanol
Store up to 2 weeks at 4°C

Medium A

RPMI 1640 (with 25 mM HEPES) supplemented with:
10 mg/ml bovine serum albumin
5% (v/v) fresh rat serum
25 mM NaCl
100 IU/ml penicillin
2 mM L-glutamine
Store up to 2 weeks at 4°C

Moore & James staining solution

4 ml 0.05% (w/v) toluidine blue in 0.9% (w/v) NaCl
100 μl saturated saponin (Merck) in 5% methanol
1.1 ml 95% ethanol
Filter through Whatman no. 3 filter paper
Store up to 2 months at 22°C
Use the stain by mixing 1:1 (v/v) with cell suspension.

COMMENTARY

Background Information

The mast cell is a multipotent inflammatory cell, which has been shown to participate in the pathogenesis of a variety of diseases, such as immediate hypersensitivity reactions, arthritis, atherosclerosis, and heart failure. Mast cells are long-lived cells (weeks to months) that under normal conditions are present in tissues in a resting, i.e., non-degranulating, state. Their localization at cutaneous and mucosal surfaces where exogenous antigens penetrate the organism has suggested a role as sentinels at the interface of the host and the environment for mast cells. The sentinel function of mast cells is essentially accomplished through an energy requiring process of activation, in which they release preformed cytoplasmic granules into their microenvironment. These secretory granules consist of a heparin proteoglycan matrix embedded with preformed mediators, such as histamine, neutral proteases, growth factors, and cytokines, which together trigger acute allergic and ensuing sustained inflammatory reactions. Mast cell activation in vivo or in vitro occurs by exogenous triggers, including IgE-mediated crosslinking of FcεRI (high affinity IgE receptors), histamine-releasing factors secreted by neighboring T-lymphocytes or macrophages, and anaphylatoxin components of the complement system (C3a, C5a). Upon activation, a part of the secretory cytoplasmic granules become swollen, and their individual membranes fuse to form tubular channels in which the granules to be secreted lie in chains.

The degranulation channels then rapidly open to the extracellular fluid and some of the peripheral granules are expelled. The soluble components of the granules, such as histamine, diffuse away, whereas the heparin proteoglycans and the mast cell–specific neutral proteases (e.g., chymase and carboxypeptidase A) remain tightly bound to each other through ionic interactions, forming proteolytically active extracellular granule remnants. The extracellular remnants are eventually phagocytosed by macrophages, smooth muscle cells, fibroblasts, or even endothelial cells in the close vicinity of the activated mast cells. Finally, the granule remnants remaining in the degranulation channels are converted into individual membrane-covered mature granules, when the lost preformed mediators are replenished through a rapid onset of de novo synthesis. Depending on the tissue and type of stimulation, the degree of mast cell degranulation may greatly vary from being almost complete, i.e., involving most of the granules as in anaphylactic shock, to being only minimal and directed only towards the site of activation.

Critical Parameters

The procedure to isolate rat mast cell granules is straightforward and only few critical parameters exist. To obtain uncontaminated mast cells, all media injected into the cavities and all instruments need to be sterile, and the mast cells need to be recovered without perforating the bowel, and thus, avoiding

Table 3.16.1 Amounts of Granule Components in 1×10^6 Mast Cells

		Experimental yield	
Granule component	100% recovery	Compound 48/80	Freezing and thawing
Protein	50 μg	~20 μg (~40%)	~45 μg (~90%)
Heparin proteoglycan	18 μg	~7 μg (~40%)	~16 μg (~89%)
Chymase	15 μg	~6 μg (~ 40%)	~13 μg (~87%)

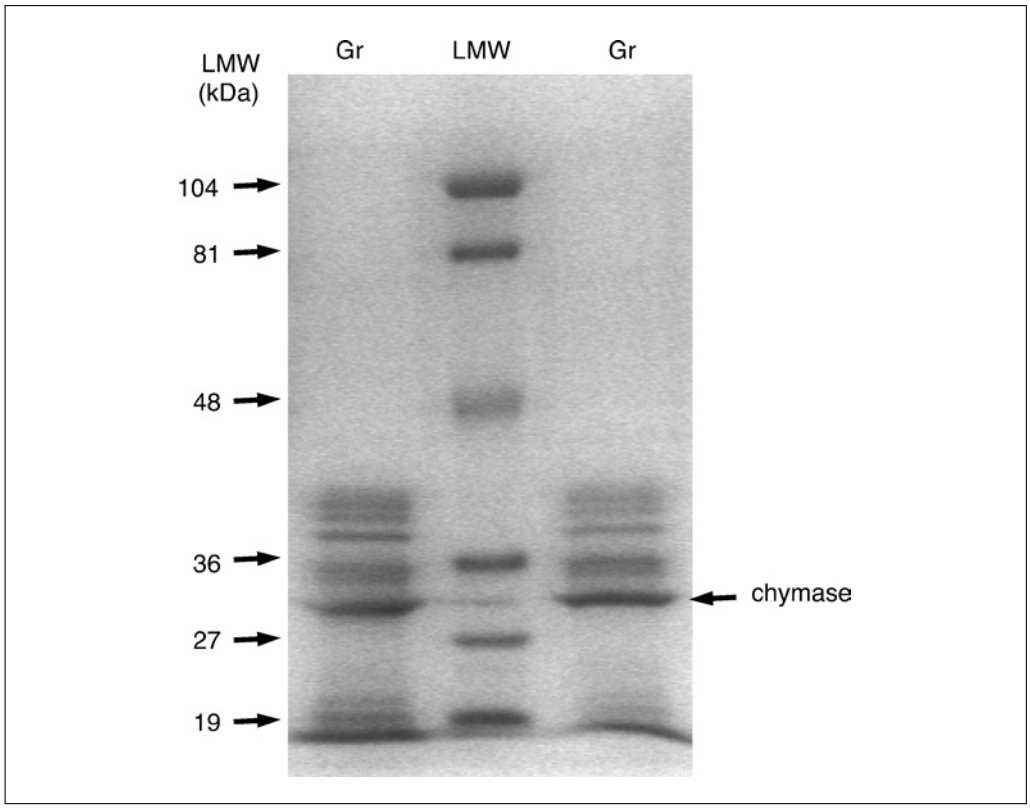

Figure 3.16.4 A Coomassie blue–stained SDS-PAGE (4% to 20%) gel describing the protein composition of isolated mast cell granule remnants (Gr, 5 μg/lane). The size of the low-molecular weight standard (LMW, Bio-Red) is indicated on the left side of the gel and the major granule protein, chymase, is indicated on the right side of the gel.

contamination with enteric bacteria. Throughout the isolation procedure, the mast cells have to be treated gently not to induce spontaneous degranulation. When isolating granules using the physiological method of mast cell activation, a confirmation of mast cell activation can easily be performed with a microscope. The process of degranulation is clearly visible in a microscope at low magnification immediately after the addition of compound 48/80. To isolate intact granules embedded within perigranular membranes, the sonication time is critical, since it depends on the efficiency of the sonication apparatus used. The optimal time interval needs to be determined empirically in each laboratory.

Troubleshooting

Low yield of mast cells: Use older and heavier animals and improve the lavage of the cavities. Use prewarmed buffer A and aim at maximal recovery of the buffer.

Low purity of mast cells: Do not use the cell-suspension if it is yellow or reddish, which is a sign of contamination. Increase the plating time for more efficient removal of macrophages.

Low yield of granules: Check the level of histamine release. It should be high (up to 80%). Repeat the stimulation and check the process of degranulation visually by microscopy.

Anticipated Results

A successful isolation of mast cells will give $\sim 1 \times 10^6$ mast cells/rat.

After plating, the purity of mast cells in the suspension will be ~90% to 95%. Table 3.16.1 describes the amount of granule components in 1×10^6 mast cells. See Figure 3.16.4 for a Coomassie blue–stained SDS-PAGE gel with low-molecular-weight standards and 20 μg of granule protein.

Time Considerations

The whole procedure can be performed within 1 working day. The isolated granules can be rapidly frozen in liquid nitrogen and stored up to 6 months at –20°C to be analyzed later for their content of protein, heparin proteoglycans, and protease activities.

Immunoisolation of Centrosomes from *Drosophila melanogaster*

The isolation of centrosomes from cells has been, for a long time, a challenging task. The main reason is that this small organelle (~0.3 μm in diameter in mammalian cells) is present only in a single copy in the cell and therefore represents only a minuscule part of the whole cell proteome. Another technical difficulty is that the density of this organelle ($\rho > 1.32$ g/ml) is too high for it to be purified in a continuous gradient using isopycnic density centrifugation. Hence, step-gradient centrifugation has been the method of choice for most of the isolation approaches used to date. Both Ficoll and sucrose density gradients, as well as a combination of the two, have been employed. Most recent methods use sucrose gradient centrifugation only. Density gradient centrifugation is followed by immunofluorescence assays, microtubule nucleation assays, or electron microscopy to evaluate enrichment of cell organelles in particular fractions of the gradient.

Currently, isolation of centrosomes from *Drosophila* embryos, although relatively inefficient (i.e., only ~10% of total centrosomes present in starting material are isolated), results in some of the best total yields compared to isolation of centrosomes from other organisms. In short, this method permits production of excellent quantities for many biochemical, functional, and structural studies.

The method described here focuses on the isolation of centrosomes from the syncytial stages of the early *Drosophila* embryo (0 to 3.5 hr). This has the particular advantage that cell organelles are not bounded by cellular membranes and that lysis can be performed on a relatively small scale, keeping the resulting volume low. This is an essential factor for subsequent gradient centrifugation steps, because ultracentrifugation of large buffer volumes is impractical. The abundance of pericentriolar material of these centrosomes isolated from the highly mitotic embryos produces excellent total protein yields. Moreover, maintenance of large fly populations that produce grams of starting material within a few hours is relatively cost efficient.

Basic Protocol 1 describes isolation of centrosomes from early-syncytial-stage *Drosophila* embryos by sucrose step gradient centrifugation. Basic Protocol 2 details an immunomagnetic isolation procedure for further purification of the centrosomes isolated in Basic Protocol 1. Support Protocol 1 details an immunofluorescence microscopy procedure for quantitatively tracking the gradient purification of centrosomes, and, finally, Support Protocol 2 describes fluorescence microscopy to assess the purification of the immunomagnetically isolated centrosome preparations.

ISOLATION OF CENTROSOMES FROM THE EARLY SYNCYTIAL STAGES OF THE *DROSOPHILA* EMBRYO USING SUCROSE STEP GRADIENT CENTRIFUGATION

BASIC PROTOCOL 1

This protocol outlines the production of *Drosophila* embryo extract as starting material for the isolation of centrosomes. Embryos are homogenized in homogenization buffer (HB), centrifuged at low speed, and filtered twice to remove large aggregates of membranes, debris, and other cell organelles. The two consecutive low-speed centrifugations also eliminate the large quantities of lipids that float on top of the embryo extract; these lipids need to be carefully removed to avoid contamination in subsequent isolation steps. The first two steps of density centrifugation serve to pool centrosomes for the subsequent immunoisolation, rather than to enrich cell organelles in a particular fraction. The

Current Protocols in Cell Biology (2005) 3.17.1-3.17.13

affinity-isolation step then removes contaminants that copurify in the sucrose gradient to obtain a high degree of purity.

This protocol was adapted from Moritz et al. (1995) and Moritz and Alberts (1999) for use with the immunoisolation protocols developed by the authors of this unit.

Materials

Large population of *Drosophila* (e.g., ~250,000 strain W118 flies) maintained in large environmental incubator or temperature- and humidity-controlled room with fixed day (12 hr) and night (12 hr) cycles (Greenspan, 1997; Bonte and Becker, 1999; Sullivan et al., 2000)
Apple juice/molasses agar plates (see recipe)
Yeast paste: ordinary baker's yeast dissolved in warm water to form a paste
Embryo wash: 0.7% (w/v) NaCl/0.04% (v/v) Triton X-100
3% (v/v) sodium hypochlorite in embryo wash (see above)
Homogenization buffer (HB, see recipe)
Liquid N_2
5× BRB80 with 100 mM KCl (see recipe), diluted to 1×
25% (v/v) Triton X-100
100× protease inhibitor mix (PIM, see recipe)
55% and 70% (w/v) sucrose solutions (see recipes)
Fine strainer
Filter unit fitted onto vacuum flask
Motor-driven Wheaton homogenizer with tight-fitting Teflon pestle (60-ml volume)
50-ml conical polypropylene centrifuge tubes
Refrigerated low-speed centrifuge
Miracloth (Calbiochem)
15-ml snap-cap polypropylene tubes for freezing and storage of supernatants
39-ml thin-walled polyallomer ultracentrifuge tubes (e.g., Beckman)
Large-volume ultracentrifuge (e.g., Beckman) with swinging-bucket rotor (e.g., Beckman SW 32)
Additional reagents and equipment for assessing purify of centrosome fractions from gradient (see Support Protocol 1)

Homogenize embryo material

1. Collect 30 to 50 g of 0- to 3.5-hr-old *Drosophila* embryos by placing a fresh apple juice/molasses agar plate with a lump of yeast paste on the surface into the population cage every 3 hr.

   Depending on the size of the fly population, three collections of 3 hr each will be needed in order to obtain a total of ~30 to 50 g of embryo material.

2. After the 3-hr collection period for each plate, wash embryos off the plate with embryo wash using a paint brush to aid in removing the embryos, collecting them in a fine strainer, and store the embryos in ice-cold embryo wash until all embryos have been collected.

3. Remove the chorion layer by stirring embryos for 3 min in 250 ml of 3% sodium hypochlorite solution.

4. Intensively wash the embryos with a forceful stream of cold tap water, then three times with a total volume of 1 liter of ice-cold distilled, deionized water, on a filter unit fitted onto a vacuum flask. Determine the dry weight after removing all excess water.

5. Resuspend dechorionated embryos in HB at a ratio of 1:5 (w/v).

6. Homogenize material on ice using five strokes of the motor-driven Wheaton homogenizer at a speed of 1500 rpm in a cold room.

CAUTION: *Wear protective gloves and goggles when using the homogenizer.*

Remove lipids and prepare/store HSS

7. Transfer homogenate to 50-ml conical polypropylene centrifuge tubes. Centrifuge 10 min at 1800 × *g*, 4°C. Remove floating lipids by aspirating with a suction pump and filter supernatant through Miracloth. Repeat the centrifugation, lipid removal, and filtration a second time.

8. Divide the resulting supernatant (referred to as HSS: i.e., "homogenate, supernatant, supernatant") into 10-ml aliquots in 15-ml conical polypropylene tubes, snap-freeze in liquid nitrogen, and store at −80°C until further use.

   The extract can be conveniently frozen at this stage if the isolation procedure must be interrupted. Freezing also gives the opportunity to produce stockpiles of embryo extracts without affecting the functional and structural integrity of the centrosome.

Perform sucrose-gradient purifications

9. Prepare six 50-ml conical polypropylene centrifuge tubes, each containing:

   20 ml 70% (w/v) sucrose
   1 ml 1× BRB80 with 100 mM KCl
   640 µl 25% Triton X-100
   400 µl 100× PIM.

10. Drop the contents of each 15-ml tube containing a frozen 10-ml HSS aliquot into one of the 50-ml tubes containing the mixture prepared in the previous step, and thaw on ice. Collect a 30-µl aliquot for immunofluorescence microscopy (see below).

11. For each of the extract mixtures prepared in the previous step, pour a sucrose gradient in a 39-ml thin-walled polyallomer ultracentrifuge tube by carefully overlaying 3 ml of 70% sucrose solution with 4 ml of 55% sucrose, and, finally, at the top, the HSS mixture from the preceding step. Mark the upper margin of the 55% sucrose layer of the sucrose gradient on the plastic wall of the tube.

12. Centrifuge samples for 1.5 hr at 100,000 × *g* in a SW 32 rotor with slow acceleration and slow braking.

    Slow acceleration and braking correspond to "setting 4" on the Beckman instrument.

13. Aspirate the supernatant above the marked line with a vacuum aspirator. Pool the gradients (all of the sucrose solutions below the mark; Pool 1) and discard the pellets. Take a 30-µl sample for immunofluorescence microscopy.

14. Dilute the ~35 to 40 ml Pool 1 to 70 ml with 1× BRB80 containing 100 mM KCl and add 100× PIM to a final concentration of 1×.

15. Prepare two sucrose gradients in 39-ml thin-walled polyallomer tubes ultracentrifuge tubes by carefully overlaying 3 ml of 70% sucrose solution with 1 ml of 55% sucrose solution. Split the diluted Pool 1 (step 14) into two equal portions, and carefully overlay each of these portions over the 55% sucrose layer in each of the two respective tubes. Mark the upper margin of the 55% sucrose layer of the sucrose gradient on the plastic wall of the tube.

16. Ultracentrifuge the gradients 1 hr at 100,000 × *g*, 4°C. Remove the supernatant from each tube with a vacuum aspirator and discard the pellets. Pool the sucrose gradients (resulting in Pool 2). Take a 30-µl sample for immunofluorescence microscopy.

17. Assess the sample aliquots from each purification stage by immunofluorescence microscopy (see Support Protocol 1). Use the remainder of Pool 2 for further purification by immunoisolation (Basic Protocol 2).

In principle, these enriched preparations can also be used for functional in vitro microtubule nucleation assays and for standard immunofluorescence colocalization studies. However, the preparations are too crude to be used for biochemical analysis of centrosome composition. For convenience, samples can also be snap-frozen in liquid nitrogen until used in Basic Protocol 2.

SUPPORT PROTOCOL 1

IMMUNOFLUORESCENCE MICROSCOPY OF ISOLATED CENTROSOMES

This protocol is used to assess the enrichment and yield of aliquots from the intermediate steps in preparation of centrosomes.

Materials

30-µl aliquots from Pool 1 and Pool 2 (see Basic Protocol 1)
PBS-T: phosphate-buffered saline (PBS; *APPENDIX 2A*), pH 7.4, containing 0.003% (v/v) Triton X-100
Methanol, −20°C
Primary antibody: anti-γ-tubulin (Sigma)
Secondary antibody: fluorochrome-conjugated antibody specific for IgG of the species from which the primary anti-γ-tubulin antibody was obtained
Mounting medium (e.g., Mowiol from Calbiochem, or 50% v/v glycerol)
20 mg/ml (10×) *p*-phenylendiamine in H_2O
Nail polish

Plastic inserts to support a 11-mm round glass coverslip (Evans et al., 1985)
15-ml Corex tubes
11-mm round glass coverslips (grade 1)
Refrigerated centrifuge with swinging-bucket rotor (e.g., Sorvall HB-6 or Beckman JS 13.1, or equivalent) and adapters
24-well tissue culture plates
Spatula bent at the tip for removing the plastic insert
Needle with bent tip
Forceps
Microscope slides
Epifluorescence microscope equipped with immunofluorescence filters and appropriate optics

NOTE: To avoid staining artifacts, never allow the coverslips to dry out at any point during the following protocol.

Centrifuge centrosome sample onto coverslip

1. Resuspend the 30-µl aliquot of *Drosophila* centrosomes from HSS mix Pool 1 or Pool 2 in 11 ml PBS-T.

   Keep samples on ice until centrifugation.

2. Place a pair of plastic inserts into a 15 ml-Corex glass tube to support a 11-mm round glass coverslip.

3. Transfer the 11-ml diluted centrosome sample into a 15-ml Corex tube and centrifuge onto the coverslips for 15 min at 15,000 × *g*, 4°C.

4. Remove the coverslip by lifting the top insert out of the Corex tube with a spatula bent at the tip. Transfer the coverslip with a pair of forceps immediately into −20°C methanol in a well of a 24-well tissue culture plate and incubate at least 5 min at −20°C to fix the sample.

5. Aspirate methanol and rehydrate sample in the well by covering with 1.5 ml PBS-T and incubating 15 min at room temperature. Aspirate PBS-T.

Stain with antibodies

6. Add ~80 μl of the anti-γ-tubulin primary antibody, appropriately diluted in PBS-T (e.g., 1:400 for polyclonal antisera, depending on antibody used), to each coverslip-containing well. Incubate 1 hr at room temperature in a moist environment.

7. Wash four times, each time by filling the sample-containing well(s) with an excess (e.g., 1.5 ml) of PBS-T, incubating 2 min at room temperature, and aspirating the solution.

   Apply the PBS along the wall of each well and not directly onto the sample, to avoid rinsing the centrosomes away.

8. Add ~80 μl of the fluorophore-labeled secondary antibody diluted in PBS-T according to the manufacturer's recommendations to each coverslip-containing well. Incubate 45 min at room temperature in the dark in a moist environment.

   The antibody dilution will vary; e.g., anti-mouse IgG whole-molecule dilutions will range between 1:400 and 1:2000.

Mount coverslip on slide and examine centrosome preparation

9. Remove coverslip(s) from well(s) with a bent needle and a pair of forceps and dip each coverslip briefly in water to rinse off excess PBS.

   Coverslips can more easily be removed from the plastic wells using a needle with a slightly bent tip.

10. Add 20-mg/ml *p*-phenylenediamine to the mounting medium (e.g., Mowiol or 50% glycerol) for a final concentration of 1 mg/ml. Mount each coverslip on a microscope slide with 6 μl of the phenylenediamine-containing mounting medium. Carefully remove excess mounting medium with tissue, and allow to set for 20 min at room temperature in the dark. Seal with nail polish.

11. Check preparations under a fluorescence microscope or store at 4°C in the dark until samples are viewed.

    The centrosomes should be homogenous in size and shape, and should be enriched through each step of the isolation procedure.

IMMUNOPURIFICATION OF CENTROSOMES WITH MAGNETIC BEADS

BASIC PROTOCOL 2

Prepare magnetic beads cross-linked with affinity-purified anti-γ-tubulin antibody. For negative control, magnetic beads are cross-linked with the relevant preimmune antibody. Centrosomes should be well enriched and quite similar in size. A ratio of 1:6 (v/v) between beads and centrosomes is recommended.

Materials

Protein G magnetic bead suspension (Dynal)
Phosphate-buffered saline (PBS; *APPENDIX 2A*)
0.2 M triethanolamine, pH 8.2, with and without 20 mM dimethyl pimelidate dihydrochloride (DMP); prepare fresh
Anti-γ-tubulin antibody (anti-peptide antibody; not commercially available; affinity-purified; Tavosanis et al., 1997)
Tris·Cl, pH 7.5 (*APPENDIX 2A*)
PBS (*APPENDIX 2A*) containing 0.1% (v/v) Tween 20
PBS (*APPENDIX 2A*) containing 0.1% (v/v) Tween 20 and 0.02% (w/v) thimerosal
Pool 2 of centrosomes (see Basic Protocol 1)
Dilution buffer (see recipe), 4°C

PBS-T: phosphate-buffered saline (PBS; *APPENDIX 2A*), pH 7.4, containing 0.003% (v/v) Triton X-100, 4°C

Methanol, −20°C

SDS sample buffer (*UNIT 6.1*)

Magnetic particle collector (magnet and magnetic stand) suitable for 1.5-ml microcentrifuge tubes (e.g., Dynal)

End-over-end rotator

Additional reagents and equipment for SDS-PAGE (*UNIT 6.1*) and determining purity of centrosome preparations from immunomagnetic purification (see Support Protocols 1 and 2)

Prepare the antibody-coated magnetic beads

1. Place 120 μl of protein G magnetic bead suspension in a 1.5-ml microcentrifuge tube. Place the tube on the magnetic stand to immobilize the beads with the magnet according to the manufacturer's documentation, and remove the supernatant. Add 100 μl of PBS, resuspend the beads, and immobilize the beads on the magnet again. Repeat this wash four times.
2. Remove the supernatant and add 100 μg of anti-γ-tubulin antibody to the washed protein G beads. Incubate 45 min on an end-over-end rotator at room temperature. Immobilize beads and remove supernatant.
3. Wash the beads three times, each time with 1 ml of 0.2 M triethanolamine, pH 8.2, by immobilizing the beads on the magnet.
4. Cross-link by incubating the antibody-coupled beads with 1 ml of freshly prepared 0.2 M triethanolamine, pH 8.2, containing 20 mM DMP, on an end-over-end rotator at room temperature for 30 min.
5. Place tube on the magnetic stand and remove supernatant. Add 1 ml of 50 mM Tris·Cl, pH 7.5, and incubate on an end-over-end rotator at room temperature for 15 min.
6. Remove supernatant and wash beads three times, each time with 1 ml PBS containing 0.1% Tween 20, by immobilizing the beads on the magnet. Store antibody-coupled beads at 4°C in the original bead-suspension volume of PBS containing 0.1% Tween 20 and 0.02% thimerosal.

   Antibody binding and cross-linking efficiency can be checked by SDS-PAGE (UNIT 6.1) of 20-μl samples of beads before and after cross-linking.

Perform immunomagnetic separation

7. Take 120 μl antibody-coupled beads suspension and wash twice, each time with 1 ml wash buffer using the technique described above. Take a sample of 20 μl for later analysis by SDS-PAGE (*UNIT 6.1*).
8. Thaw 0.5 ml of centrosome Pool 2 on ice, then mix with 0.5 ml dilution buffer. Take a 20-μl sample for further analysis (see Support Protocol 1).
9. Add the 1 ml of diluted centrosomes to 100 μl washed, cross-linked beads. Mix gently by inverting the tube. Incubate 1 hr at 4°C on an end-over-end rotator. Immobilize the beads on the magnetic collector and carefully remove the supernatant. Keep the supernatant on ice for later analysis.
10. Wash beads three times, each time with 1 ml cold wash buffer, using the technique described above.
11. Wash beads twice, each time with 1 ml cold PBS-T, using the technique described above. Resuspend in 80 μl (original bead volume) of PBS-T. Remove an aliquot of 10 μl for immunofluorescence microscopy and an aliquot of 20 μl for SDS-PAGE.

12. Remove the PBS-T from the bead suspension with bound centrosomes (50 µl), resuspend in 55% sucrose solution, snap-freeze in liquid nitrogen, and store at −80°C.

    The purified centrosome preparation is used subsequently in various assays. These include, for example, functional tests such as microtubule nucleation assay, electron microscopic study of centrosome morphology, antigen localization, or antigen for the generation of monoclonal or polyclonal antibodies, and biochemical assays.

13. Fix the 10-µl aliquot of beads reserved for immunofluorescence microscopy for at least 5 min in 1 ml of −20°C methanol and store at −20°C until analyzed according to Support Protocol 2.

Assess purity

14. Immobilize beads and remove supernatant as described above. Add SDS sample buffer, and boil 5 min. Perform magnetic collection to remove beads and run the supernatant on a 10% SDS-PAGE gel (*UNIT 6.1*).

15. Assay diluted centrosome fractions before (see Support Protocol 1) and after immunomagnetic separation (see Support Protocol 2) by fluorescence microscopy.

IMMUNOFLUORESCENCE MICROSCOPY OF IMMUNOPURIFIED CENTROSOMES ON MAGNETIC BEADS

SUPPORT PROTOCOL 2

Materials

Centrosomes immunopurified on magnetic beads (see Basic Protocol 2)
Methanol, −20°C
PBS-T: phosphate-buffered saline (PBS; *APPENDIX 2A*), pH 7.4, containing 0.003% (v/v) Triton X-100
Primary antibody: anti-γ-tubulin (Sigma)
PBS-T containing 0.1% (w/v) bovine serum albumin (BSA)
Secondary antibody: fluorochrome-conjugated antibody specific for IgG of the species from which the primary anti-γ-tubulin antibody was obtained
Mounting medium: Mowiol (Calbiochem)
20 mg/ml (10×) *p*-phenylendiamine in H_2O
Clear nail polish

Magnetic particle collector (magnet and magnet stand) suitable for 1.5-ml microcentrifuge tubes (e.g., Dynal)
End-over-end rotator
Microscope slides
Round coverslips (grade 1, 11 mm diameter)
Epifluorescence microscope equipped with immunofluorescence filters and appropriate optics

NOTE: Handle samples with care and avoid vigorous mixing or vortexing.

1. Fix a 10-µl magnetic bead–centrosome sample in 1 ml −20°C methanol by incubating for at least 5 min at −20°C. Place the test tube containing the beads on the magnetic stand, immobilize the beads with the magnet as described in the manufacturer's documentation, and remove the supernatant.

2. Add 1 ml PBS-T to the beads in the tube. Mix gently by inverting the tube, then incubate 15 min on an end-over-end rotator. Collect beads and remove supernatant as described above.

3. Dilute the anti-γ-tubulin primary antibody 1:500 in PBS-T containing 0.1% BSA. Add 300 µl of the diluted primary antibody to the beads in the tube and mix gently

by inversion. Incubate 1 hr at room temperature with gentle rotation. Collect beads and remove supernatant as described above.

4. Wash beads four times, each time by immobilizing the beads on the magnet, removing the supernatant, resuspending the collected beads in 1 ml PBS-T, then removing the supernatant.
5. Dilute the fluorochrome-conjugated secondary antibody appropriately in PBS-T containing 0.1% BSA. Add 300 µl of the diluted secondary antibody to the beads in the tube and mix gently by inverting the tube. Incubate 45 min at room temperature on an end-over-end rotator in the dark (cover tubes with aluminum foil). Collect beads and remove supernatant as described above.
6. Wash beads four times, each time with 1 ml PBS-T using the technique described in step 4.
7. Add 20 mg/ml *p*-phenylenediamine to Mowiol mounting medium for a final concentration of 2 mg/ml. Add ~30 µl of this medium to the tube and mix gently by inverting the tube (solution is viscous).
8. Place 6 µl of bead/Mowiol-mix on a microscope slide and carefully mount a coverslip on top. Let set for ~20 min at room temperature in the dark. Seal the edges of the coverslip with nail polish.
9. Examine preparation under the epifluorescence microscope or store at 4°C in the dark until samples are viewed.

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Apple juice/molasses agar plates

For 200 plates:
11.5 liters H_2O
5 liters apple juice
750 ml molasses
500 g agar
420 ml 10% (w/v) Nipagin (Fluka) in absolute ethanol

BRB80, 5×

To 100 ml H_2O add:
24.2 g PIPES (400 mM final)
2 ml 0.5 M EGTA (5 mM final)
1 ml 1 M $MgCl_2$ (5 mM final)
Adjust pH to 6.8 with KOH pellets.
Add H_2O to 200 ml
Store up to 2 months at 4°C

Dilution buffer

To 200 ml phosphate-buffered saline (PBS; APPENDIX 2A) add:
0.4 g bovine serum albumin (BSA, fraction V; 0.2% w/v final)
100× protease inhibitor mix (see recipe) to 2× final
20 mg/ml stock of DNase I, RNase free to final concentration of 20 µg/ml (stock stored at −20°C)
Prepare fresh just prior to use

Homogenization buffer

To 140 ml H_2O add:
40 ml 5× BRB80 (1× final)
20 ml 1 M KCl (100 mM final)
28 g sucrose (14% w/v final)
100× protease inhibitor mix (see recipe) to 2× final
Prepare fresh

Protease inhibitor mix (PIM), 100×

To 3 ml of methanol add:
4 ml of 1 mg/ml aprotinin (dissolved in H_2O)
4 ml of 1 mg/ml leupeptin (dissolved in H_2O)
4 ml of 1 mg/ml pepstatin A (dissolved in methanol)
5 ml of 100 mg/ml Pefabloc SC (Roche; dissolved in H_2O)
Store up to 2 weeks at −20°C

Sucrose solution, 55% (w/v)

To 140 ml H_2O add:
40 ml 5× BRB80 (1× final)
20 ml 1 M KCl (100 mM final)
110 g sucrose (55% w/v final)
Store up to 2 months at 4°C

Sucrose solution, 70% (w/v)

40 ml 5× BRB80 buffer (1× final)
20 ml 1 M KCl (100 mM final)
140 g sucrose (70% w/v final)
H_2O to 200 ml
Heat without boiling to dissolve
Store up to 2 months at 4°C

Wash buffer

To 200 ml phosphate-buffered saline (PBS; APPENDIX 2A), add:
0.2 g bovine serum albumin (BSA, fraction V; 0.1% w/v final)
100× protease inhibitor mix (see recipe) to 1× final
20 mg/ml stock of DNase I, RNase free to final concentration of 20 μg/ml (stock stored at −20°C)
Prepare fresh just prior to use

Yeast Paste

For 90 plates:
220 ml H_2O
150 g baker's yeast
1.4 ml propionic acid (Merck)

COMMENTARY

Background Information

Protocols for the isolation of centrosomes from higher eukaryotic cells are classically based on cell organelle enrichment via gradient centrifugation. Various successful protocols have been described that isolate centrosomes from mammalian tissue culture cells (Mitchison and Kirschner, 1986; Bornens et al., 1987; Blomberg-Wirschell and Doxsey, 1998; Bornens and Moudjou, 1999), tissue (Komesli et al., 1989; Lange and Gull, 1995), clam oocytes (Palazzo and Vogel, 1999), *Drosophila* (Moritz and Alberts, 1999; Lange et al., 2000), and yeast

(Wigge et al., 1998), to mention only some of the more frequently used sources. Most of the employed methods involve a lysis step in a low-ionic-strength buffer followed by density gradient centrifugation. The material thus produced is used subsequently in various assays. These include functional tests such as microtubule nucleation assay, electron microscopic study of centrosome morphology, antigen localization, or antigen production for the generation of monoclonal or polyclonal antibodies. Furthermore, centrosomal preparations have been used for the characterization of protein content of the organelle (protein complex); this application requires preparations in which the centrosomes are both highly enriched and present in biochemically meaningful quantities—i.e., micrograms of centrosomes for subsequent gel electrophoresis and mass spectrometry analysis (Wigge et al., 1998; Lange et al., 2000; Andersen et al., 2003).

Critical Parameters and Troubleshooting

Lysis and homogenization

Correct lysis and homogenization are critical for yield as well as for purity of centrosome preparations. Alternative methods using either tissue or mammalian tissue culture cells as starting material carry out the lysis in a low-ionic-strength buffer. Pretreatment of cells with anti-actin (e.g., cytochalasin B) and anti-microtubule drugs (e.g., nocodozole) has been employed in order to release the nuclear-centrosome interaction; this technique was initially proposed to efficiently dissociate the centrosome from the cytoskeleton and nuclei. However, cytochalasin treatment might not be an essential prerequisite for cytoskeletal dissociation (Bornens and Moudjou, 1999). Here, for *Drosophila* lysis and homogenization, buffer conditions are derived from the classical PIPES-based microtubule reassembly buffer (BRB80) but are modified (Moritz and Alberts, 1999) to include additional salt and sucrose, probably bringing them closer to isotonic conditions. An additional condition determining the outcome of the preparations is the efficient removal of the outer protective chorion layer of *Drosophila* embryos using washes with sodium hypochlorite solution. Incomplete removal can cause blockage or overheating of the tight-fitting Teflon pestle and render the material produced nearly useless.

Isolation of centrosomes by density gradient centrifugation

In the protocol developed by Moritz and Alberts (1999) for the isolation of *Drosophila* centrosomes, cell organelles are enriched in a single sucrose step gradient. The isolated centrosomes have been used in structural assays (electron microscopy) and functional assays (in vitro microtubule nucleation). Here centrifugation is carried out in two consecutive rounds, which represent concentration steps rather than purifications. These steps are then followed by affinity immunoisolation of centrosomes to remove co-migrating contaminants. Other groups employ, albeit for mammalian centrosome isolation, Ficoll gradients in a concentration step (Michison and Kirschner, 1986) or a rapid isolation step (Blomberg-Wirschell and Doxsey, 1998). This step can be followed by a purifying sucrose gradient centrifugation. The gradient is then fractionated and assayed by immunofluorescence microscopy using an anti-γ-tubulin antibody (Support Protocol 1) to select for the most enriched fractions for subsequent experiments. In the protocol in this unit, this assay is used to calculate the yield and determine the quality of isolated organelles. To perform this calculation, the number of centrosomes per relative area of the coverslip are counted, i.e., a given volume of the preparation is centrifuged down onto the coverslip, the count is performed, and the results extrapolated to the total volume of the preparation. A similar assay, though based on electron microscopy negative staining, can also be employed for rapidly checking the quality and structural integrity of centrosome preparations (Lange and Gull, 1996).

Purification of centrosomes by immunoaffinity purification

Because the avenue of density banding of centrosomes is blocked due to the high density of the organelle, the purity of most of the current centrosome isolation protocols is limited. Therefore, the authors of this unit developed a protocol for the affinity purification of centrosomes. The critical parameter here is the quality of the antibody that is used for the immunoprecipitation. Each antibody will need to be tested to determine if the antibody will or will not work under certain buffer or detergent concentrations and antibody concentrations, and protocols will have to be adapted accordingly. The initial protocol for affinity isolation

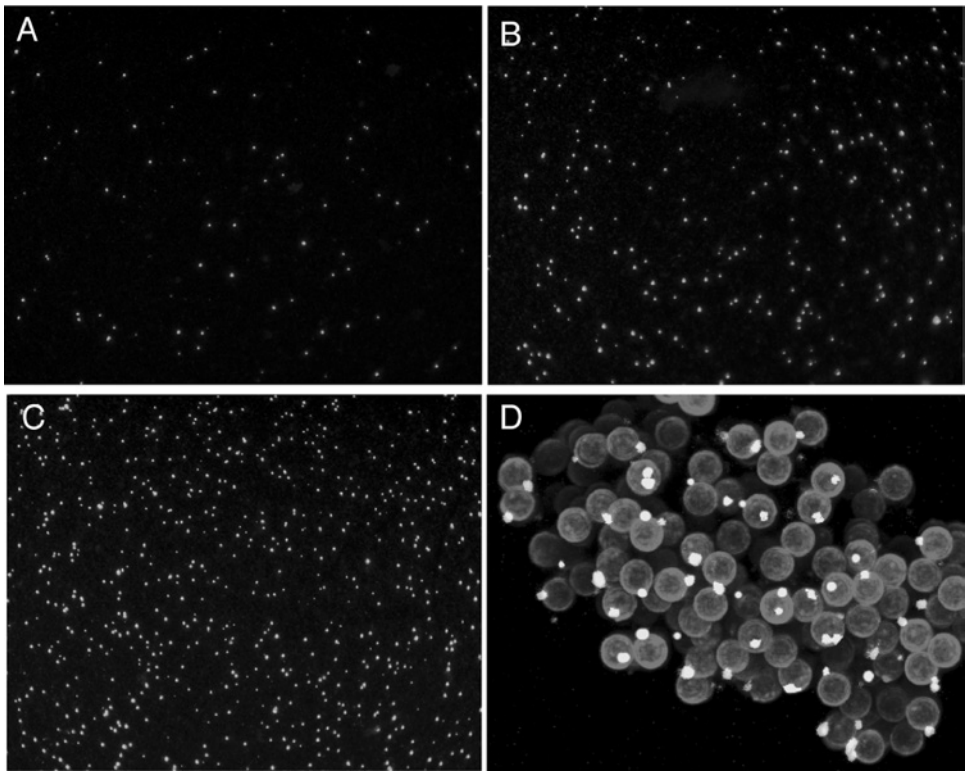

Figure 3.17.1 These images show the consecutive isolation steps assayed by immunofluorescence microscopy (Support Protocols 1 and 2) using an anti-γ-tubulin antibody to evaluate number and integrity of isolated centrosomes. (**A**) Centrosomes in embryo homogenate; (**B**) Pool 1; (**C**) Pool 2; (**D**) immunopurified centrosomes. Centrosomes are shown in yellow, beads are shown in red. For the color version of this figure go to *http://www.currentprotocols.com*.

of centrosomes was based on an indirect affinity method (Lange et al., 2000). In this technique, centrosomes were first coated with antibody, then anti-immunoglobulin beads were employed to isolate the centrosomes in a second step. In the protocol described in this unit, the authors use direct coupling of antibodies to magnetic beads to affinity purify centrosomes from enriched sucrose gradient fractions. This reduces the number of steps involved and consequently improves the yield.

Anticipated Results

With the described method microgram quantities of centrosomal protein can easily be obtained from ~10 g of embryo extract. Centrosomes should be intact as assayed by immunofluorescence microscopy (Support Protocols 1 and 2) and electron microscopy (Lange and Gull, 1996). Immunofluorescence images of centrosomes from consecutive isolations steps labeled with an anti-γ-tubulin antibody (see Fig. 3.17.1, panels A to D) are quantified to control enrichment and yield. In the Coomassie-stained SDS-PAGE analysis (see Fig. 3.17.2) of the immunopurified preparations, a major band should be CNN, a centrosomal protein of about 130 kD (see Fig. 3.17.2, asterisk) indicating the level of enrichment of the preparations.

Time Considerations

In well maintained fly populations, large quantities of embryo material can be obtained almost on a daily basis. Collection of material and production of embryo extract can be streamlined so that extracts are stockpiled for future use. The actual preparation of centrosomes by density gradient centrifugation can be easily achieved within 4 hr, and samples can be safely frozen without losing microtubule nucleation activity. Affinity purification, including all of the washing and coupling steps, will consume ~4 hr, not taking into account buffer and antibody preparation time. Assays monitoring the quality of the

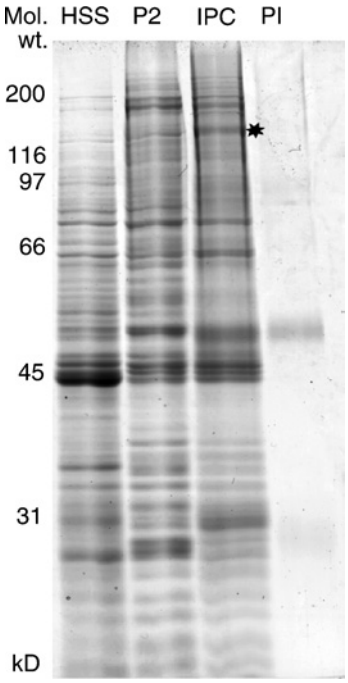

Figure 3.17.2 Isolation profile showing the protein composition of samples from the major consecutive steps in a Coomassie-stained gel. Abbreviations: HSS, homogenate supernatant supernatant; P2, Pool 2; IPC, immunopurified centrosomes; PI, preimmune isolation negative control. The asterisk at ~130 kDa labels the position of one of the major centrosome components (CNN) that is enriched throughout the isolation process.

preparation using immunofluorescence microscopy and SDS-PAGE are performed within 3 to 4 hr, not including microscope viewing time. Most solutions can be made ahead of time and stored either at 4°C or −20°C as indicated. Some solutions, such as proteinase inhibitors and DNase, must be added fresh from stock solutions to the solutions prior to use.

Isolation of Zymogen Granules from Rat Pancreas

Zymogen granules are storage organelles in pancreatic acinar cells that contain digestive enzymes to be released into the pancreatic duct for eventual transport, along with bile salts from the liver, to the small intestine where they aid in digestion (see Fig. 3.18.1). The content proteins include amylase, the most abundant protein in the granules, as well as trypsinogen, chymotrypsinogen, carboxypeptidases, esterases, and lipases. The membranes of the granules contain proteins involved in granule exocytosis as well as enzymes that are released into the pancreatic juice. Many of the enzymes are stored in the granules as inactive proenzymes. Conversion of trypsinogen to trypsin occurs in the small intestine via a proteolytic cleavage by enterokinase, an enzyme of the duodenal mucosa. Activated trypsin, in turn, proteolytically cleaves and activates the other zymogen enzymes. The major stimuli for release of the contents of the granules from the cells, which occurs soon after ingestion of food, are cholecystokinin and acetylcholine.

This unit includes protocols for the isolation of crude zymogen granules from rat pancreas, further purification on sucrose gradient (see Basic Protocol) and/or Percoll gradient (see

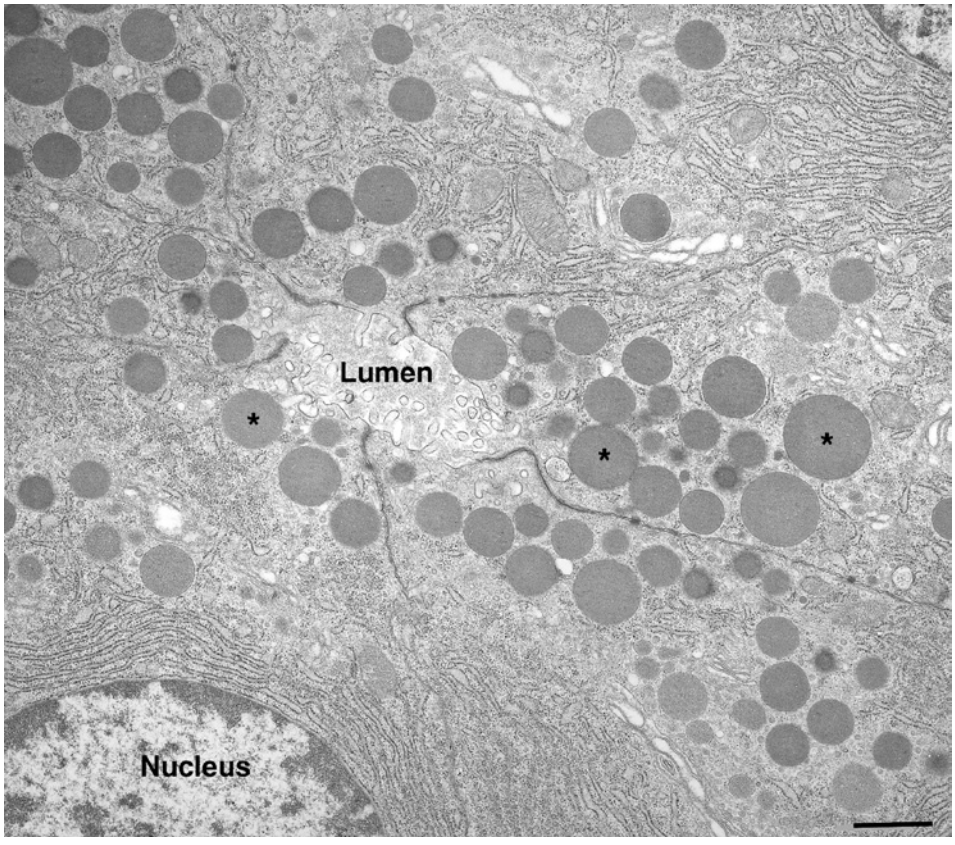

Figure 3.18.1 Electron micrograph of exocrine pancreas. Mouse pancreas was fixed and processed for conventional electron microscopy. Shown are exocrine cells containing abundant large zymogen granules near their apical plasma membrane (asterisks). Secretory contents are released into the acinar lumen and transported to the duodenum via the pancreatic ducts. Courtesy of H. Plesken and Dr. David Sabatini, NYU School of Medicine. Bar = 1 μm.

Current Protocols in Cell Biology (2005) 3.18.1-3.18.16

Alternate Protocol 1), and purification of granule contents and membranes (see Alternate Protocol 2). There is also a protocol for purification of zymogen granules from dog pancreas (see Alternate Protocol 3). Additional protocols are provided for preparing a continuous sucrose gradient (see Support Protocol 1) and using a refractometer to assess the density of gradient fractions (see Support Protocol 2).

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) or must conform to governmental regulations regarding the care and use of laboratory animals.

BASIC PROTOCOL

ISOLATION OF ZYMOGEN GRANULES FROM RAT PANCREAS

The early steps of this protocol can be used to prepare crude zymogen granules from rat pancreas. These granules are useful for structural and functional studies. If a higher degree of purity is required, the sucrose gradient fractionation steps described further along in the protocol can be used (see Fig. 3.18.2).

Materials

Rats (>200 g; Sprague-Dawley)
Phosphate-buffered saline (PBS; *APPENDIX 2A*)
Homogenization buffer (see recipe)
30-ml continuous sucrose gradients in 25 × 89–mm Beckman Ultraclear centrifuge tubes (0.8 to 2 M sucrose; see Support Protocol 1)
Homogenization buffer (see recipe) containing 1 mM EDTA
CO_2 tank and vented chamber for inducing narcosis
Rat guillotine
Dissecting instruments including:
  Dissecting scissors and small scissors
  Scalpels or single-edge razor blades
150- and 250-ml beakers
Glass plates, clean
Balance accurate to 0.1 g
30-ml piston-type glass homogenizer-tissue grinder with Teflon pestle (Thomas) powered by variable-speed rotary drill (Wheaton Instruments)
15- and 50-ml conical polypropylene screw-cap centrifuge tubes
Eppendorf 5810C centrifuge (or equivalent low-speed refrigerated centrifuge) with swinging-bucket rotor
150-ml Erlenmeyer flask
Nitex 20-μm nylon mesh (Fisher)
30-ml glass Sorvall centrifuge tubes
Sorvall RC-5B centrifuge with SS-34 rotor (or equivalent)
7-ml Dounce homogenizer with B pestle (Kontes Glass)
Optima L-90K ultracentrifuge with SW-28 rotor (Beckman Coulter) or equivalent ultracentrifuge with swinging-bucket rotor
Additional reagents on equipment for preparing a sucrose gradient (Support Protocol 1) and using a refractometer (Support Protocol 2)

NOTE: Wear a laboratory coat and gloves throughout the procedure. All steps should be performed at 4°C, in a cold room if possible.

Collect pancreas

1. Feed 6 to 12 rats ad libitum (or starve overnight if required).

   The procedure may be scaled up or down to accommodate from 1 to 36 rats.

2. Anesthetize the first rat by CO_2 narcosis, then decapitate using a guillotine.

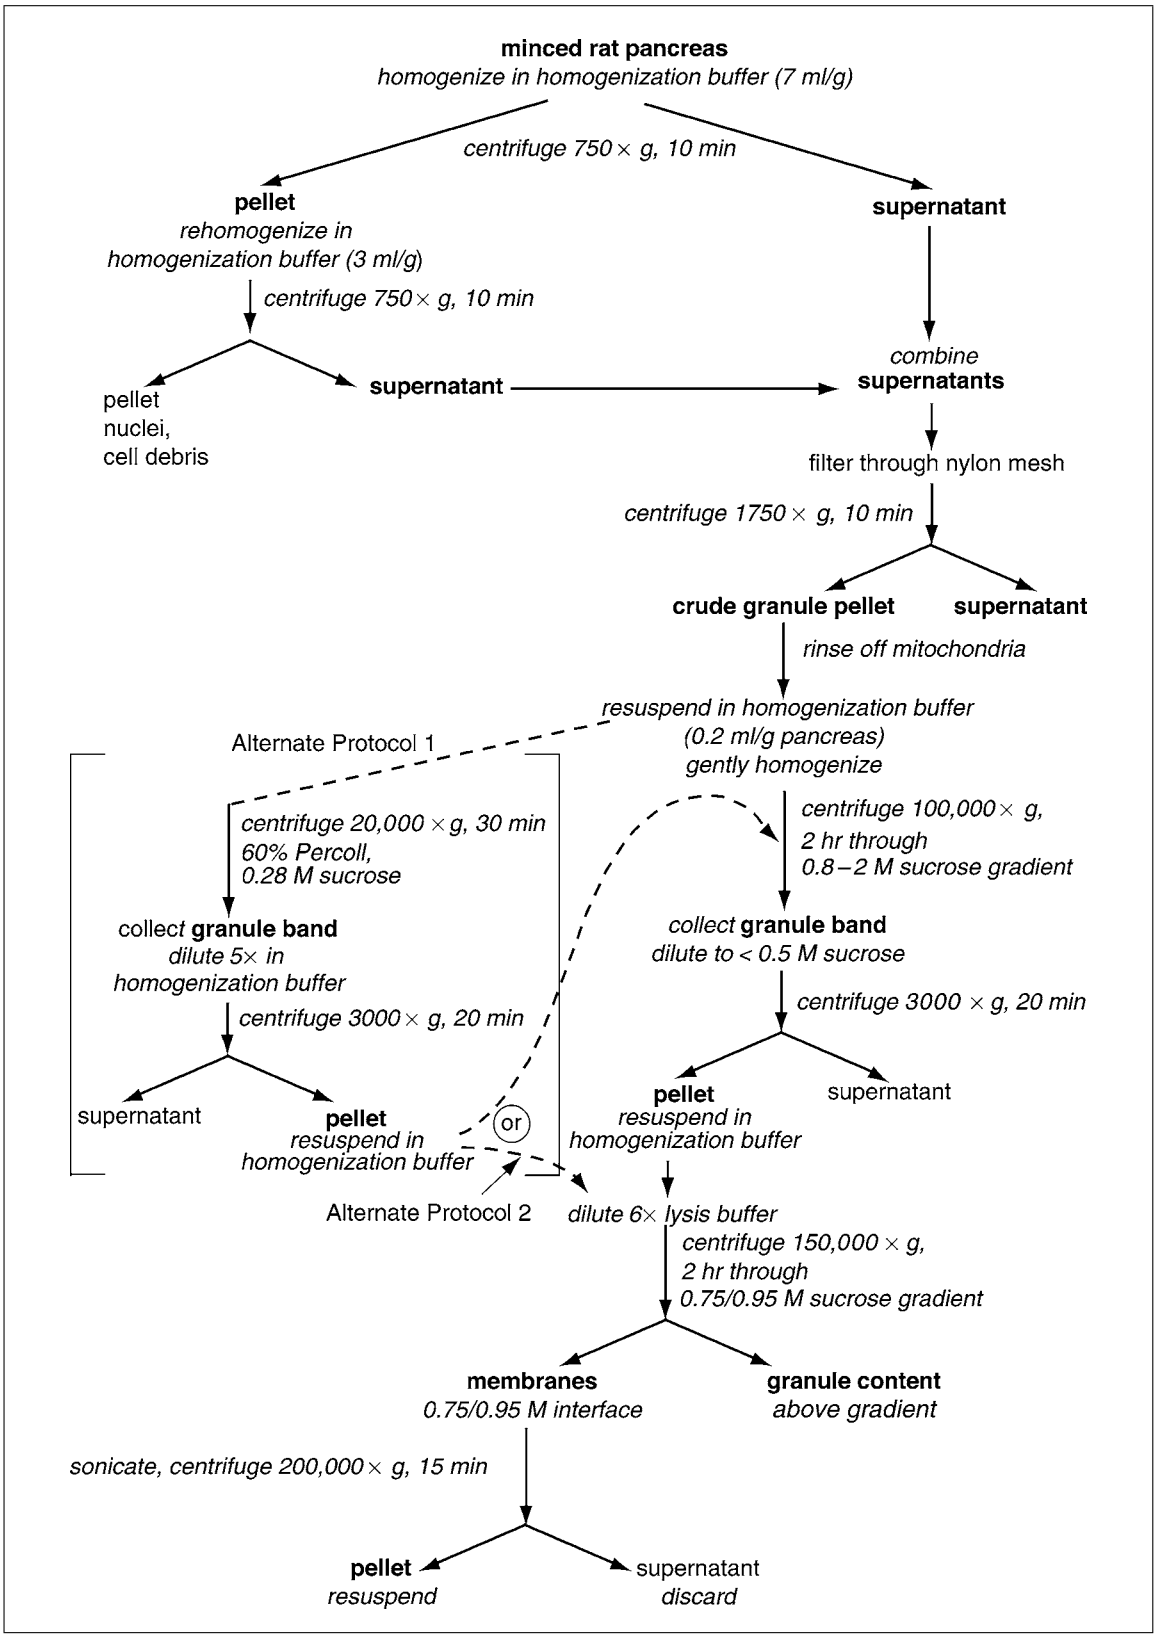

Figure 3.18.2 Flowchart of Basic and Alternate Protocols 1 and 2, providing a schematic summary of the major steps (described in detail in the text) of the protocols for purification of zymogen granules from rat pancreas and for separation of content and membrane proteins.

3. Excise pancreas (~1 g wet weight per animal) within 10 min. Using dissecting scissors make a vertical incision in the midline through the skin and underlying abdominal wall up to the thorax, then make lateral incisions just beneath the rib cage.

   This will allow access to the abdominal cavity. The pancreas in rats and mice is located in the mesogastrium just inferior to the stomach, also attached to the spleen and the duodenum.

4. Using small scissors, cut along the edge of the spleen and continue cutting along the inferior edge of the stomach and duodenum. Remove the entire mesentery, which contains the pancreas.

5. Place the pancreas in ice-cold PBS (10 ml per pancreas) in a 250-ml beaker.

6. Repeat steps 1 to 5 for each rat. When finished with all of the animals, transfer the pancreata to the same amount of fresh ice-cold PBS in another beaker.

Weigh pancreas

7. Prepare a 250-ml beaker containing 10 ml homogenization buffer per pancreas and obtain the tare weight to an accuracy of 0.1 g. Transfer each pancreas to a clean glass plate and trim away the fat and mesentery using a scalpel, then place the trimmed pancreas in the tared beaker. When finished, weigh the beaker to determine the amount of pancreas present.

   Protease inhibitors (present in the homogenization buffer; see Reagents and Solutions) are critical in the isolation procedure to prevent spontaneous activation of the inactive protease precursors, e.g., trypsinogen and chymotrypsinogen, to their active forms. It is possible to substitute a commercial protease inhibitor cocktail (Roche Biomedical).

Homogenize pancreas

8. Remove one or two pancreata at a time and place on another glass plate in the cold room or on ice. Mince finely, first with two scalpels or razor blades and subsequently with fine scissors.

9. Gather the minced material in a 150-ml beaker containing 7 ml homogenization buffer for each 1 g of pancreas

10. Homogenize with three strokes of a 30-ml Teflon/glass homogenizer powered by a variable-speed rotary drill at 3000 rpm. Repeat until all of the material has been homogenized.

    CAUTION: *Wear safety glasses or goggles during this procedure.*

    Smaller homogenizers can be used if only one or two animals are sacrificed.

Collect PNS

11. Transfer homogenate to disposable 15-ml (10 ml homogenate per tube) or 50-ml (40 ml homogenate per tube) conical polypropylene screw-cap centrifuge tubes. Centrifuge 10 min at 750 × *g*, 4°C, in an Eppendorf 5810C centrifuge with a swinging-bucket rotor (or equivalent) to sediment unbroken cells, nuclei, and large particles.

12. Remove as much of the floating fat and debris as possible from each tube with a pipet. Collect the remaining post-nuclear supernatant (PNS) carefully from each tube and pool all of the supernatants in a 150-ml Erlenmeyer flask.

13. Resuspend and pool pellets in 3 vol of homogenization buffer by pipetting up and down. Rehomogenize the pellets using three strokes of the Teflon/glass homogenizer at 3000 rpm. Centrifuge homogenate 10 min at 750 × g, 4°C.

14. Collect the PNS as above and combine with the first. Filter the PNS through a layer of 20-μm nylon mesh by covering the top of the Erlenmeyer flask and inverting over a 250-ml beaker.

For comparison or quantification purposes, it is useful to take an aliquot (e.g., 50 to 100 μl) of the PNS. To determine if a protein is present in zymogen granules, its enrichment in the purified granule fraction can be compared to that of amylase and other granule proteins.

Isolate zymogen granules

15. Transfer the filtrate to 15- or 30-ml glass Sorvall tubes. Centrifuge 20 min at 1750 × *g*, 4°C, in a Dupont Sorvall RC-5B with an SS-34 rotor, to sediment the zymogen granules.

16. Remove supernatants. Add 2 ml homogenization buffer to each pellet and swirl briefly to mobilize and dislodge the upper tan layer of mitochondria. Remove the supernatants by aspiration. Repeat the procedures in this step for a second rinse.

A small amount of the white granule pellet will be lost and not all the mitochondria will be removed.

17. Resuspend the pellets in a small volume of homogenization buffer (0.2 ml per g of pancreas) by manually shaking the tubes. Do not vortex.

This can take 15 to 30 min and is best done in a cold room. If necessary, pellets can be dislodged and crushed gently with a Teflon policeman during resuspension.

18. Gently homogenize the resuspended pellet (crude granule fraction) with five strokes of a 7-ml Dounce homogenizer with a loosely fitting (B) pestle.

This crude granule fraction is >90% pure. For many purposes, this may be sufficient. If not proceeding further, store granules at −80°C. after flash freezing in liquid nitrogen.

Further purify zymogen granules

19. Load 7 ml of resuspended granules onto the top of a continuous 30-ml sucrose gradient (0.8 to 2 M sucrose).

Alternatively, a step gradient using 0.2 M sucrose increments can be used (4.3 ml per step).

20. Ultracentrifuge gradient(s) 2 hr at 100,000 × *g*, 4°C, in an SW-28 rotor (or equivalent).

21. Collect the white granule layer about three-quarters of the way down the tube.

It is helpful to remove most of the gradient first and collect the band with a Pasteur pipet. It is also possible to collect the fraction by carefully puncturing the tube from the side with a syringe needle just below the granule layer and quickly collecting the granules in the syringe.

22. After collecting the granules, dilute them slowly in 3 vol of homogenization buffer containing 1mM EDTA.

It is best to put a small magnetic stirring bar in the tube and stir slowly while adding the homogenization buffer. If necessary, check sucrose concentration on a refractometer (see Support Protocol 2).

23. Transfer the diluted granules to 30-ml Sorvall tubes. Centrifuge the diluted granules 20 min at 3000 × *g*, 4°C, in an RC-5B centrifuge with SS-34 rotor.

24. Discard the supernatants. Resuspend the pellets in 2 ml homogenization buffer. Further purify zymogen granules (see Alternate Protocol 1) and/or separate content

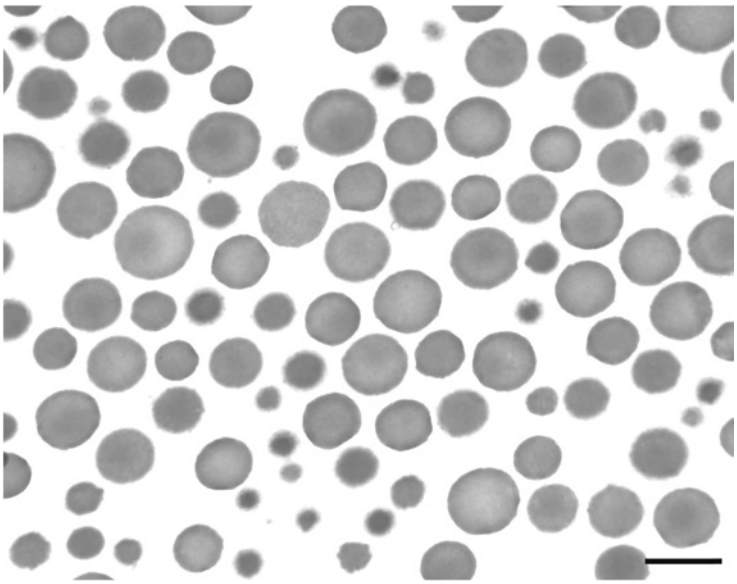

Figure 3.18.3 Electron micrograph of zymogen granule preparation. Granules prepared by the Basic Protocol, including the sucrose gradient fractionation, were fixed in a mixture of paraformaldehyde and glutaraldehyde and processed for electron microscopy. Courtesy of H. Plesken and Dr. David Sabatini, NYU School of Medicine. Bar = 1 μm.

and membrane fractions (see Alternate Protocol 2), or, if not proceeding further, freeze granules in liquid nitrogen and store at −80°C.

After this step, the granules appear to be pure by electron microscopy (Fig. 3.18.3).

SUPPORT PROTOCOL 1

POURING A CONTINUOUS SUCROSE GRADIENT

Continuous sucrose gradients are used to purify zymogen granules. They are poured using an Auto Densi-Flow device from Buchler Instruments. This device has an electric eye probe controller that senses the air/water interface and provides for precise gradient formation.

Materials

0.8 and 2 M sucrose gradient solutions (see recipe)
39-ml, 25 × 89–mm Beckman Ultraclear centrifuge tube
Auto Densi-Flow device (Buchler Instruments)
Peristaltic pump (Buchler Instruments)
Gradient maker (Hoefer Instruments SG30)
Magnetic stirrer and stir bars
Parafilm

1. Clamp a 39-ml, 25 × 89–mm Beckman Ultraclear centrifuge tube into the Auto Densi-Flow device.
2. Set the device on "Up" and manually lower the sensor so that it is almost touching the bottom of the tube.
3. Attach the device to the tubing of a peristaltic pump and connect the pump tubing to the outflow spout of a gradient maker on top of a magnetic stirrer.
4. With the stopcocks closed, add 15 ml of 0.8 M sucrose solution to the far chamber and 15 ml of 2 M sucrose solution, along with a small stirring bar to the outflow chamber of the gradient maker.

5. Set the stirrer to spin at a medium speed.
6. Open the outflow stopcock with the pump set ~5 ml/min flow. After a few seconds, open the stopcock between the chambers and check for free flow between the chambers.

   If the flow is not present, apply slight pressure to the outer chamber by covering it Parafilm and pressing down with a finger or thumb.
7. Allow the gradient to pour slowly, and keep at 4°C (up to 24 hr) until use.

USING A REFRACTOMETER

SUPPORT PROTOCOL 2

A refractometer is used to check the density of gradient fractions.

Materials

Sucrose gradient fractions (Basic Protocol)
Refractometer (Bausch & Lomb)

1. First calibrate the refractometer to zero by pipetting 50 μl water onto the quartz surface.
2. Close the chamber and read the refractive index.
3. Wipe the quartz surface clean with tissue paper (e.g., Kimwipes).
4. Read 50 μl of each sample from the sucrose gradient.
5. Convert the refractive index reading to density or molarity using a standard table.

   Among other sources, Beckman Coulter publishes a chart in the back of their ultracentrifuge brochure.

FURTHER PURIFICATION OF ZYMOGEN GRANULES ON A PERCOLL GRADIENT

ALTERNATE PROTOCOL 1

This protocol adds a Percoll gradient step to the purification procedures described in the Basic Protocol, instead of the sucrose gradient, in order to allow the isolation of granules of a slightly higher purity. Either the Percoll or the sucrose gradient, or both, can be used, in any order. The granules obtained from the Percoll gradient can also be used directly in assays, such as measurements of ion transport, where the high concentrations of sucrose are undesirable. Other investigators have reported methods to separate zymogen granules effectively from mitochondria using 40% Percoll gradients (De Lisle et al., 1984). The gain in purity is minor but there is a decrease in contaminant levels.

Additional Materials (see Basic Protocol)

Crude zymogen granule fraction (Basic Protocol, step 18)
Percoll gradient solution (see recipe)

50 ml, 29 × 102–mm flanged polycarbonate tubes centrifuge tubes (Fisher)
Sorvall RC-5B with SS-34 rotor or equivalent centrifuge with fixed-angle rotor

1. Prepare and resuspend the crude zymogen granule fraction (see Basic Protocol, steps 1 to 18).
2. Load 1 to 5 ml of the resuspended granules on top of 20 ml of Percoll gradient solution in a 29 × 102–mm thick-walled polycarbonate tube.

3. Centrifuge 30 min at 20,000 × *g*, 4°C, in an RC-5B centrifuge with an SS-34 rotor.

   Percoll forms a gradient when centrifuged. This procedure allows for only a shallow gradient to form, so that the lighter organelles remain in the top half of the tube.

4. Collect the white granule band near the bottom of the gradient and dilute slowly five-fold with homogenization buffer in a 30-ml glass Sorvall centrifuge tube.

   The lighter-density mitochondrial layer can be collected and sedimented to produce a mitochondria-enriched fraction.

5. Centrifuge the diluted granules 20 min at 3000 × *g*, 4°C, using an RC-5B centrifuge with SS-34 rotor.

   If it is necessary to remove Percoll entirely, this centrifugation can be repeated after resuspension of the white granule pellet in step 6.

6. Remove the supernatant and gently resuspend the pellet in 2 ml homogenization buffer without dissolving the Percoll below the pellet.

7. *Optional.* If greater purity is desired, continue with steps 19 to 24 of the Basic Protocol.

8. *Optional.* If desired, proceed with Alternate Protocol 2 for separating content and membrane fractions.

9. Freeze the granule fraction in liquid nitrogen and store at −80°C.

ALTERNATE PROTOCOL 2

ISOLATION OF ZYMOGEN GRANULE CONTENT AND MEMBRANE FRACTIONS

Content and membrane fractions can be separated on sucrose step gradients after granule lysis. Zymogen granules spontaneously lyse when the pH is raised to pH 8. This gentle procedure has the advantage of not disturbing other organelles that might be very minor contaminants, such as rough endoplasmic reticulum and mitochondria, which will sediment during centrifugation of the lysed granules.

Additional Materials *(also see Basic Protocol)*

Percoll-purified zymogen granules (Alternate Protocol 1)
Lysis buffer (see recipe)
0.75 M and 0.95 M sucrose gradient solutions (see recipe)
25 mM Tris·Cl, pH 7.5 containing 1 mM EDTA

13.2 ml, 14 × 89–mm Ultraclear centrifuge tubes
Beckman ultracentrifuge with SW-41 rotor (or equivalent)
15-ml conical polypropylene centrifuge tubes
Probe sonicator (Heat Systems Ultrasonics Model 185 or equivalent) with pencil probe
Beckman TL-100 centrifuge and TLA 100.3 rotor (or equivalent)
13 × 31–mm thick-walled polycarbonate centrifuge tubes or polyallomer microcentrifuge tubes

1. In a beaker, dilute resuspended gradient-purified granules slowly with 6 vol of lysis buffer while stirring slowly with a magnetic stirrer and a small stir bar. Incubate at least 45 min at 4°C.

   The solution should clarify with time. 0.2 M $NaHCO_3$, pH 8.3 (with protease inhibitors), can be substituted for the lysis buffer.

2. Prepare a step gradient by layering 3 ml of 0.75 M sucrose gradient on top of 3 ml of 0.95 M sucrose gradient solution in a 14 × 89–mm Ultraclear centrifuge tube. Mark

the interface to facilitate collection. Layer 6.5 ml of the diluted, lysed granules on top of the gradient and centrifuge 2 hr at 150,000 × *g*, 4°C, using an SW-41 rotor.

3. Collect the granule lysate (soluble content) above the gradient. Store at −80°C.
4. Collect the membranes at the 0.75/0.95 M sucrose interface and transfer to a 15-ml centrifuge tube. Dilute the membranes 1:1 in lysis buffer and sonicate using a probe sonicator with a pencil tip for 5 sec at maximum power.
5. Recover membranes by centrifuging 15 min at 200,000 × *g*, 4°C, in 13 × 31–mm thick-walled polycarbonate tubes (or microcentrifuge polyallomer tubes) in a Beckman TL-100 centrifuge with a TLA 100.3 rotor.
6. Discard the supernatants and resuspend the pellets by brief sonication (see step 4) in 0.1 ml 25 mM Tris·Cl, pH 7.5/1 mM EDTA. Freeze at −80°C for storage.

Expect a yield of <1% of the total granule protein.

ISOLATION OF ZYMOGEN GRANULES FROM DOG PANCREAS

ALTERNATE PROTOCOL 3

Zymogen granules can be isolated from dog pancreas, which is a more abundant source of material, using procedures similar to those described in this unit for rat pancreas. With canine pancreas, the connective tissue in the organ makes the procedure more cumbersome. It is necessary to use a tissue press and scale up the procedure, because the pancreas can be 100 g or more depending on the size of the animal. Otherwise, the procedure here makes use of the sucrose and Percoll gradient procedures described in the protocols above.

Additional Materials *(also see Basic Protocol)*

Dog, newly sacrificed
1-liter beakers
Tissue press consisting of a piston that drives the tissue through a 1-mm stainless steel mesh (a good-quality garlic press may be substituted)
250-ml disposable plastic conical screw-cap centrifuge tubes (Corning)
Sorvall RC-5B centrifuge with GSA rotor (or equivalent refrigerated centrifuge with fixed-angle rotor)
40-ml Dounce homogenizer with B pestle

Obtain and mince pancreas

1. From a newly sacrificed dog, dissect out the pancreas. Place in 500 ml ice-cold PBS in a 1-liter beaker to wash away blood and other debris.

Generally, animals used for experiments in open-heart surgery or other medical procedures are sacrificed at the end of the procedure. Control animals not treated with drugs or subjected to invasive procedures are preferred. The pancreas should be excised within 20 min of sacrifice. If the animal must be sacrificed in the laboratory, check with the institutional animal facility for the best procedures.

2. Remove the pancreas from PBS and cut away fat and large blood vessels with scissors and scalpels. Cut tissue into 2 to 3-cm pieces and put into a 1-liter beaker with 500 ml homogenization buffer.
3. Remove pancreas pieces from beaker one piece at time, cut the tissue into small fragments, and mince with scalpels or razor blades.

Press tissue and perform first homogenization

4. Prepare a 1-liter beaker containing 500 ml homogenization buffer and obtain the tare weight to an accuracy of 1 g. Put minced pieces in tissue press and force through the

press over the tared beaker. Repeat until all pieces have been pressed, cleaning out the screen mesh in between uses.

It can take a great deal of pressure to force the tissue through the press. Connective tissue will clog the mesh. Clean the press frequently.

5. Reweigh the beaker to determine the amount of tissue. Dilute to a volume of 10 ml per g of tissue using homogenization buffer.

6. Homogenize using three to five strokes of a 30-ml piston-type Teflon/glass homogenizer powered by a variable-speed rotary drill at 2500 rpm. Repeat until all the tissue is homogenized. Combine homogenates.

Even after the tissue press step, there will be considerable amounts of connective tissue present which will make homogenization difficult. Be very careful in the homogenization not to force the pestle down to the base of the glass vessel, as this may cause the homogenizer to shatter. Wear safety goggles.

An alternative is to use a Polytron homogenizer (Brinkmann Instruments) at a medium speed setting. Insert the head of the Polytron directly into the beaker and homogenize until the solution is uniformly pink. Connective tissue can also clog the Polytron, so it is important to check and clean the probe if it does not function effectively.

Obtain and PNS

7. Transfer homogenate to disposable plastic 50-ml (40 ml homogenate per tube) conical polypropylene screw-cap tubes or to 250-ml conical centrifuge tubes. Centrifuge 10 min at 750 × *g*, 4°C, in an Eppendorf 5810C centrifuge with a swinging-bucket rotor (or equivalent).

8. Remove as much of the floating fat and debris as possible with a pipet. Collect the remaining post-nuclear supernatant (PNS) carefully from each tube and pool all of the supernatants in a 500-ml Erlenmeyer flask.

Because of the large amount of PNS obtained and the fact that there will be connective tissue in the pellet, it is neither necessary nor desirable to rehomogenize the pellet.

Collect zymogen granules

9. Filter the PNS through a layer of 20-µm nylon mesh by covering the top of the Erlenmeyer flask and inverting it over a 500-ml beaker.

10. Transfer the filtrate to 250-ml plastic centrifuge tubes (<200 ml filtrate/tube) and centrifuge 30 min at 1750 × *g*, 4°C, in a fixed-angle (e.g., GSA) rotor, to bring down the zymogen granules.

11. Discard supernatant. Add 10 ml homogenization buffer and swirl briefly to remove the upper tan layer of mitochondria from the pellet. Remove the solution. Repeat.

A small amount of the white granule pellet will be washed away.

Further homogenize and purify zymogen granules

12. Resuspend the pellet in a small volume (0.2 ml per g of pancreas) of homogenization buffer by manually shaking the tubes. Dislodge the pellets and mash them gently with a Teflon policeman during resuspension. Do not vortex.

13. Gently homogenize the resuspended pellet (crude granule fraction) with five strokes of a loosely fitting Dounce homogenizer with a loosely fitting (B) pestle.

14. Further purify the granules according to Alternate Protocol 1, steps 1 to 8.

REAGENTS AND SOLUTIONS

Use deionized distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Homogenization buffer

0.3 M sucrose
2 mM MOPS, pH 6.8
1× protease inhibitors (see recipe for 1000×)
1 mM EDTA
Prepare fresh

Lysis buffer

150 mM KCl
25 mM HEPES, pH 8
1 mM EDTA
1× protease inhibitors (see recipe for 1000×)
Prepare fresh

Percoll gradient solution

60% (v/v) Percoll (Amersham Biosciences)
0.28 M sucrose
20 mM MOPS, pH 6.8
1 mM EDTA
1× protease inhibitors (see recipe for 1000×)
Store up to 2 hr at 4°C

Percoll consists of colloidal silica coated with polyvinylpyrrolidone.

Protease inhibitors, 1000×

Prepare the following 1000× solutions separately:
10 mg/ml aprotinin in H_2O (store up to 3 months at −20°C)
5 mg/ml pepstatin in methanol (store up to 3 months at −20°C)
0.5 M phenylmethylsulfonyl fluoride (PMSF) in DMSO (prepare fresh)
Add inhibitors to solutions at 1× concentration as recommended

PMSF is unstable in water and should be added to the solutions just prior contact with biological material.

Sucrose gradient solutions, 0.75 M, 0.8 M, 0.95 M, and 2 M

Solutions for purification of zymogen granules (see Basic Protocol; see Support Protocol 1 for continuous gradient preparation):
0.8 M sucrose
10 mM HEPES, pH 6.8
1 mM EDTA
1× protease inhibitors (see recipe for 1000×)
Store up to 24 hr at 4°C

2 M sucrose
10 mM HEPES, pH 6.8
1 mM EDTA
1× protease inhibitors (see recipe for 1000×)
Store up to 24 hr at 4°C

Solutions for separation of zymogen granule content and membranes (see Alternate Protocol 2):
0.75 M sucrose
25 mM HEPES, pH 8

(continued)

1 mM EDTA
1× protease inhibitors (see recipe for 1000×)
Store up to 24 hr at 4°C

0.95 M sucrose
25 mM HEPES, pH 8
1 mM EDTA
1× protease inhibitors (see recipe for 1000×)
Store up 24 hr at 4°C

COMMENTARY

Background Information

Pancreatic zymogen granule isolation procedures were first reported by Hokin (1955) for dog pancreas and later extended to bovine and guinea pig pancreas by Palade and collaborators (Greene et al., 1963; Tartakoff et al., 1974). These procedures were similar to the crude granule preparation outlined in the early steps of the Basic Protocol of this unit. Sucrose gradient fractionation was later introduced (Paquet et al., 1982). All of the procedures to purify zymogen granules take advantage of their large size and density as compared to other cellular organelles. Variations on the theme include procedures that use sucrose/Ficoll gradients for granule isolation (Cameron et al., 1986). These procedures are similar to those used to purify secretory granules from salivary glands, whose granules resemble those of the pancreas and have exocrine secretions that include amylase and several other proteins also found in the pancreatic zymogen granules. Percoll gradient fractionation has been useful for preparing zymogen granules competent for ion transport because Percoll, unlike sucrose, has very low osmolality (De Lisle et al., 1984). Zymogen granules are more susceptible to lysis after being exposed to high concentrations of sucrose.

Zymogen granules lyse as the pH is raised above 7 and the content proteins become soluble (Hokin, 1955). The pH-dependent solubilization of the granule content correlates with the physiological function of the pancreatic duct as a secretor of bicarbonate to neutralize stomach acid in the duodenum. Thus, the granule content, which is in an acidic environment as long as the granules remain within the cells in order to ensure that the zymogens remain inactive and in a condensed state, is exposed to a pH of ∼8 in the lumen of the duct after release from the acinar cells.

Acinar cells, whose exocrine products are secreted into the pancreatic juice, are the predominant cells in the pancreas. However, there are also pancreatic duct cells, connective tissue cells, vascular endothelial cells, and islets of Langerhans, whose cells secrete endocrine hormones such as insulin and glucagon. The islet cells contain secretory granules, but constitute a minor percentage of the total pancreatic volume (∼1% in rats; Bonner-Weir et al., 1989). Hence zymogen granules will be far more abundant than any other type of granule, including the Weibel-Palade bodies of the endothelial cells. The question arises as to whether endocrine granules are present in the zymogen granule preparations. Because the endocrine granules are smaller than the zymogen granules, they do not sediment efficiently at 1750 × g. Indeed, procedures for preparing insulin granules take advantage of the fact that zymogen granules sediment at 3000 × g while the insulin granules do not (Rhodes et al., 1987). Although the endocrine contamination is minimal, in order to determine if a protein is a bona fide zymogen granule protein, it is essential to compare its enrichment in the granule fractions with known zymogen granule content proteins.

Table 3.18.1 lists the major proteins of the zymogen granule. Amylase is the most abundant. Figure 3.18.4 shows the pattern of Coomassie blue staining of a SDS/PAGE gel with some of the major proteins indicated. Two-dimensional SDS/PAGE has been used to identify many of the proteins listed in Table 3.18.1 (Scheele, 1981; Kleene et al., 1999).

Critical Parameters

The pancreatic zymogen granules include proteases that may become activated at a low rate during granule isolation. Thus, it is essential to keep the samples at 4°C and to use protease inhibitors.

Contaminants are the major concern. Nuclei are quantitatively eliminated in the initial low-speed centrifugation. However, the crude granule fraction will be contaminated with mitochondria, as previously mentioned, and by some large fragments of the rough endoplasmic reticulum (ER), which is abundant

Table 3.18.1 Major Proteins Identified in Pancreatic Zymogen Granules

Protein	Mol. wt. (kDa)
Secreted proteins (content and peripheral membrane)	
Amylase isoforms	56
Carboxyl ester hydrolase/lysophospholipase/bile salt–dependent lipase	70–78
Chymotrypsinogen isoforms	26
Colipase	10
DNase I	35
Kallikrein I (glandular)	30
Lipase Related Protein 1 (PLRP1)	45–53
GP3/GPIII/PLRP2	54
Pancreatic lipase (triacylglycerol lipase)	53
Pancreatic thread protein (stone protein, reg, lithostathine)	14–19
Phospholipase A2	14
Procarboxypeptidase (PCP) A1, A2, B/ZAP47 isoforms	44–47
Proelastase (proteinase E) isoforms	32
RNase	50
Serglycin proteoglycan	>300
Serpin (ZG46)	46
Serpin (ZP21p)	21
Syncollin	18
Trypsinogen I (cationic), II (anionic), III (cationic), VB	25
ZG16p	16
ZG29	29
Integral membrane proteins	
CLCA-1 (calcium-activated HCO_3^- channel)	90
GP2 (luminal domain released into content)	78–90
ITMAP (luminal domain released into content)	110
Multi-drug resistance transporter MDR-related protein	65
Muclin/CRP-ductin/DBMT1/hensin/gp-340 (luminal domain released)	300
Rab 3D	27
Syntaxin 3	35

in pancreas. These organelles are not as dense as zymogen granules and therefore can be separated from granules during sucrose and/or Percoll gradient fractionation. Mitochondria will appear as a tan layer above the white granules. The rough ER is more variable in density but will also be in lighter fractions. It is important to gently resuspend the crude granule pellet and homogenize with a Dounce homogenizer so as to minimize nonspecific absorption of these organelles to the outside of the granules. Mitochondrial contamination can be monitored using mitochondrial enzyme assays, such as succinate dehydrogenase (Pennington, 1961; *UNIT 3.4*). Mitochondrial enzyme–specific activity is usually below the threshold of detectability in granules purified through sequential Percoll and sucrose gradient steps. ER contamination can be measured by immunoblotting with antibodies to rough ER marker proteins, such as BiP/GRP78, available commercially through a number of sources.

The ER is difficult to eliminate entirely, especially from granule membrane fractions. Granule content is generally highly purified,

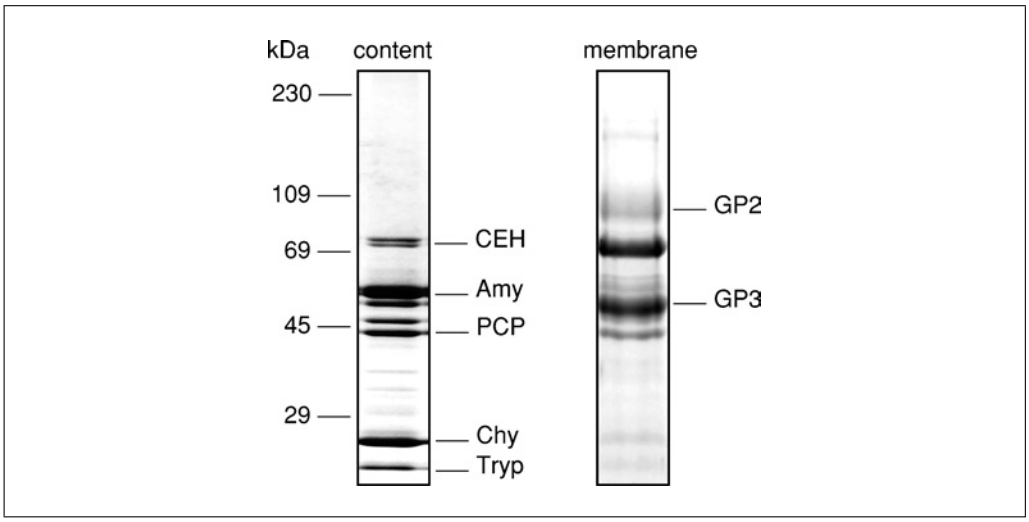

Figure 3.18.4 Profile of content and membrane proteins. Zymogen granules from rat pancreas were prepared according to the Basic Protocol, including sucrose gradient steps, and Alternate Protocol 1 (the Percoll gradient procedure). Membranes and content fractions (30 μg) were subjected to SDS/PAGE on 10% gels and stained with Coomassie blue. The migration positions of some of the major content proteins, including amylase (Amy), procarboxypeptidase (PCP), chymotrypsinogen (Chy), trypsinogen (Try), and carboxyl ester hydrolase (CEH, also known as lysophospholipase and bile salt–dependent lipase) are indicated. The migration positions of two of the major membrane proteins, GP2 and GP3, are indicated in the right panel.

but membranes are much less so. This is because the contaminants, such as ER and even mitochondrial remnants, often adhere nonspecifically to the granule membranes, which represent <1% of the total zymogen granule protein. Even when the membranes are isolated on a step gradient, contaminants can remain with them. However, all of the major proteins visible upon staining of polyacrylamide gels with Coomassie blue or silver after SDS-PAGE are granule membrane proteins or content proteins; hence the contamination is usually very minor and will not be detected unless very sensitive methods are used.

In addition, lysosomes are large and dense organelles. Some of them are large enough to cosediment in the crude granule pellet and to remain in the high-density granule fraction of the sucrose and/or Percoll gradients. Lysosomal enzyme assays such as that of aryl sulfatase, β-hexosaminidase (*UNIT 15.8*), or β-glucuronidase can be monitored to assess lysosomal contamination (a protocol for the assay of β-glucuronidase is available from Worthington Biochemical at *http://www.worthington-biochem.com/GL/default.html*). In general, lysosomes are represented in the isolated gradient-purified granule fraction to about the same extent as they are in the initial homogenate, whereas zymogen granules will be enriched ~4 fold, as noted above.

Granule content proteins are present in the granule membrane fraction and vice versa. In the case of the content, a number of major membrane proteins, including the major membrane protein GP2, are known to be enzymatically cleaved from the membrane and released in a soluble form in the pancreatic juice (Rindler and Hoops, 1990). In addition, several granule peripheral membrane proteins are also known to be present in the granule content, including GP-III/PLRP2 (Wagner et al., 1994). Therefore, their presence in the granule content is expected. However, the presence of major content proteins in the membrane fraction is more complex. In part, their presence could represent trapping of soluble proteins as granules lyse and their membranes subsequently reseal after incubation at pH 8. After isolation of these membranes on the sucrose step gradient, the protocol calls for the membranes to be sonicated and sedimented. This eliminates much of the nonspecific trapping as the large granule membrane ghosts are broken up into smaller vesicles. However, even if these sonication and washing steps are repeated, amylase and other content proteins can be observed in the membrane fraction. Their presence may be related to the mechanisms by which granules form in the *trans*-Golgi network (TGN), and similar findings have been reported for endocrine granules. During granule formation in the TGN, aggregating content proteins need to

interact with membrane proteins prior to immature granule detachment (Rindler, 1992). Zymogen granule content proteins as well peripheral membrane proteins can be extracted by sonication in 0.1 M $NaCO_3$, pH 11 (Rindler and Hoops, 1990).

Anticipated Results

Assessment of the efficacy of purification is essential in any cell fractionation scheme. Aliquots of the homogenate, PNS, crude granule pellet, and purified granules are saved for this purpose. Because amylase and other major granule content proteins are easily identified after staining polyacrylamide gels with Coomassie blue, it is relatively easy to assess the extent of purification using SDS-PAGE. After determining the protein content of each fraction by standard methods (e.g., Bradford; *APPENDIX 3H*), equal amounts of protein are run in parallel lanes on the gel. The intensity of the content protein bands can be quantitated using the NIH Image computer program (*http://rsb.info.nih.gov/nih-image/*) and digitally scanned images of the gels. Generally, a ~4 fold enrichment in the specific activity of the content proteins is expected in the granule preparations during purification because the granules constitute ~25% of the total cellular volume in electron micrographs. However, the procedures are designed for high purity rather than maximum yields, which can be low (<20% for the entire procedure including the Percoll gradient step) because many granules lyse during the homogenization procedure and subsequent steps.

Classically, the specific activity of amylase has been used to monitor the purification. Enzymatic activity is based on the ability of α-amylase to hydrolyze starch and release maltose. There have been a number of methods used to quantify this. A spectrophotometric assay based on detection of reducing groups liberated from starch using 3,5-dinitrosalicylic acid has been commonly used. It is inexpensive, but cumbersome and linear only in a relatively narrow range (see the Worthington Enzyme Manual, *http://www.worthington-biochem.com/AA/default.html*, and references therein). Alternatively, a diagnostic kit using a *p*-nitrophenyl maltoheptaside derivative as a substrate is available from Sigma (cat no. 568-20) and can be scaled down to use on 96-well plates and read on a standard plate reader at 405 nm. Recently, a BODIPY-derivatized starch has been used as an enzyme substrate (Molecular Probes). This assay is sensitive and easy to use but is costly and requires a fluorescent plate reader.

Time Considerations

The time that the procedure requires depends critically on the number of animals used. For a standard preparation using 12 rats, it should take ~2 hr to obtain a PNS and an additional 1 hr to sediment and resuspend the crude granule pellet. Further purification on sucrose gradients will add an additional 3 hr, and a Percoll gradient step will add 1 hr. If membranes and content proteins are separated, then allow 3 additional hr. Hence, a high-purity preparation of content and membrane fractions would take ~10 hr to prepare.

It is possible to centrifuge sucrose gradients longer than the recommended times, even overnight, without adverse effects. This applies both to the initial continuous gradients and the step gradients used to separate membrane from content proteins. If pressed for time, this course would be appropriate. Granules cannot be fractionated after being frozen. While membrane and content proteins can be separated readily from frozen and thawed granules by Alternate Protocol 3, this is not recommended because other organelles that may be minor contaminants of the preparation, like lysosomes and mitochondria, will lyse, and their proteins will further contaminate the preparations.

Isolation of Glyoxysomes from Pumpkin Cotyledons

The isolation of organelles is essential for a variety of biochemical procedures. The Basic Protocol in this unit delineates the efficient isolation and purification of glyoxysomes from pumpkin cotyledons. It has been used, with minor modifications, to isolate peroxisomes from multiple plant tissues and species. In addition, effective means to quantify and determine the integrity of the isolated organelles are discussed. A Support Protocol for growing pumpkin seedlings for use in the Basic Protocol is also provided.

ISOLATION OF GLYOXYSOMES

BASIC PROTOCOL

Glyoxysomes are found in germinating seedlings and contain the enzymes of the glyoxylate cycle. They are isolated by differential and density gradient centrifugation.

Materials

5- to 7-day, dark-grown pumpkin seedlings (Support Protocol)
1× grinding buffer working solution (see recipe)
2 M sucrose
28% (v/v) Percoll/resuspension buffer solution (see recipe)
1× resuspension buffer working solution (see recipe)

250-ml beakers
Balance accurate to 0.1 g
Waring blender (2-speed) and 500-ml blender cup, precooled to 4°C
Miracloth (Calbiochem)
Glass funnel, precooled to 4°C
50-ml round-bottom polypropylene centrifuge tubes
Sorvall RC5C centrifuge with HB-6 swinging-bucket rotor (or equivalent refrigerated centrifuge and rotor)
15-ml Corex tubes, cooled to 4°C
Small, soft paintbrush (natural hair)
UV spectrophotometer

NOTE: Keep all equipment and all solutions cold (4°C) for the duration of the procedure.

Prepare cotyledons

1. Record the age and growth conditions of the pumpkin seedlings.
2. Harvest the pumpkin cotyledons (Fig. 3.19.1) in dim room light by manually separating the cotyledons from the hypocotyls. For very small seedlings, remove the seed coat and radicle as well.
3. Preweigh a 250-ml beaker to the nearest 0.1 g, cool the beaker on ice, then place the cotyledons inside the beaker. Reweigh the beaker, and record the tissue weight to the nearest 0.1 g.

   Be sure to keep the tissue cold. Avoid exposure to bright light, as this will cause the cotyledons to become green. Normal room lighting can be resumed during the first centrifugation step.

Current Protocols in Cell Biology (2005) 3.19.1-3.19.8

Figure 3.19.1 Five-day-old dark-grown pumpkin seedlings**.** 1, seed coat; 2, cotyledons; 3, hypocotyl; 4, radicle.

Homogenize the tissues

4. Put the tissue and enough 1× grinding buffer working solution (with BSA) to cover the tissue (usually about 150 to 170 ml) in the blender cup. Homogenize the tissue with the Waring Blender, using three short bursts of ∼3 sec each, on low speed. Do not overgrind.

5. Filter the homogenate through a piece of Miracloth that has been folded in half and used to line the inside of a precooled funnel placed over a 250-ml beaker on ice. Collect the filtered homogenate in the beaker below the funnel. Squeeze the macerated tissue inside the Miracloth bag gently, to extract all the liquid. Discard the remaining tissue and used Miracloth.

6. Distribute the filtrate evenly between four 50-ml round-bottom polypropylene centrifuge tubes and centrifuge in a swinging-bucket rotor 10 min at 3000 × *g*, 4°C.

7. Remove the thick lipid layer floating on top of each supernatant using a Kimwipe wrapped around the wide end of a 1000-µl plastic pipet tip.

8. Decant the supernatant into a second set of four clean 50-ml round-bottom polypropylene centrifuge tubes.

9. Centrifuge this supernatant in a swinging-bucket rotor 20 min at 10,500 × *g*, 4°C. Carefully decant and discard the supernatant from each tube, retaining the pellets (keep on ice).

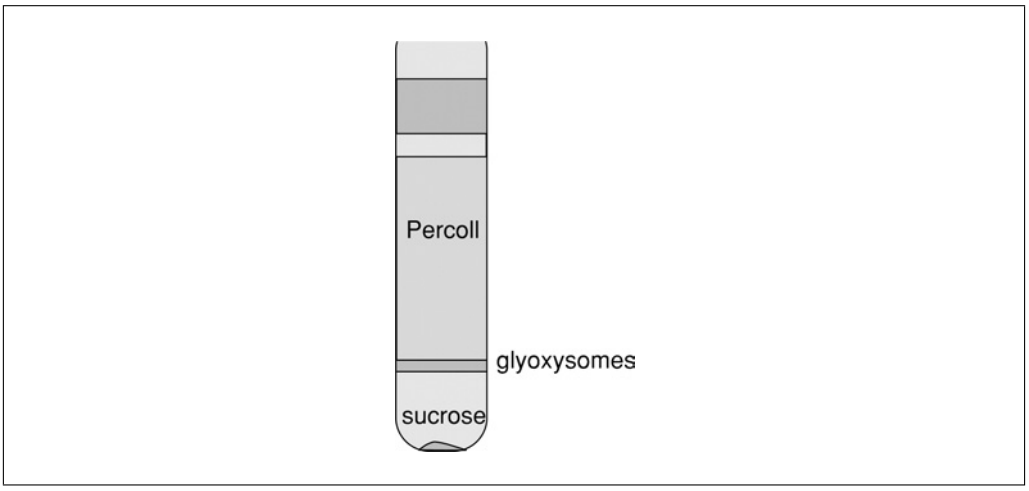

Figure 3.19.2 Percoll gradient separation of glyoxysomes.

Centrifuge the homogenate

10. Prepare a Percoll gradient by placing 1.5 ml of 2 M sucrose solution in a chilled 15-ml Corex tube. Carefully overlay with 10 ml 28% Percoll/1× resuspension buffer solution, being very careful not to mix the sucrose and Percoll layers.

11. Using a small paintbrush, gently resuspend each pellet (from step 9) in 250 µl of 1× resuspension buffer working solution. Pool the resulting suspension in one tube and swirl gently to mix.

12. Carefully overlay the pooled suspension on to the top of the prepared Percoll gradient.

13. Centrifuge the supernatant in a swinging-bucket rotor 30 min at 18,000 × *g*, 4°C, without the brake.

    Using the brake on this step will disturb the gradient and greatly diminish the final glyoxysome yield.

Purify the glyoxysomes

14. Carefully remove the upper layers of lipid and broken organelles in the gradient with a Pasteur pipet (Fig. 3.19.2). Finally, carefully collect and transfer the glyoxysomes (the visible yellowish band at the Percoll/sucrose interface) with a clean pipet to a 15-ml Corex tube.

    Removing too much Percoll or sucrose cushion will reduce the purity of the glyoxysomes, while removing too little will decrease the overall yield.

15. Dilute the glyoxysomes 3- to 5-fold with 1× resuspension buffer (usually ~8 ml is required).

16. Centrifuge glyoxysomes in a swinging-bucket rotor 16 to 20 min at 7000 × *g*, 4°C, with the brake on.

    A shorter (16-min) centrifugation will result in a soft organelle pellet, making it harder to remove all of the supernatant without losing part of the pellet. A longer (20-min) centrifugation will yield a tighter pellet.

17. Carefully remove and discard the supernatant. Gently resuspend the pellet of purified glyoxysomes in 100 µl of 1× resuspension buffer.

18. To approximate the yield, take an aliquot of the glyoxysome suspension, dilute it 1:500 with 1× resuspension buffer, and measure the absorbance at A_{280} and A_{235}. Use these values in the equations below to obtain the approximate concentration and yield.

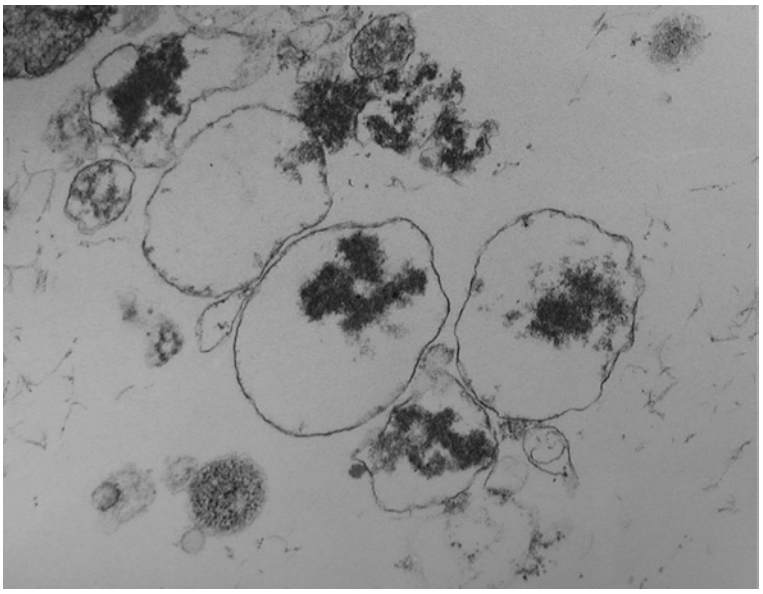

Figure 3.19.3 Electron micrograph of purified pumpkin glyoxysomes. Magnification, 10,000× (micrograph by Mary Alice Webb, Purdue University).

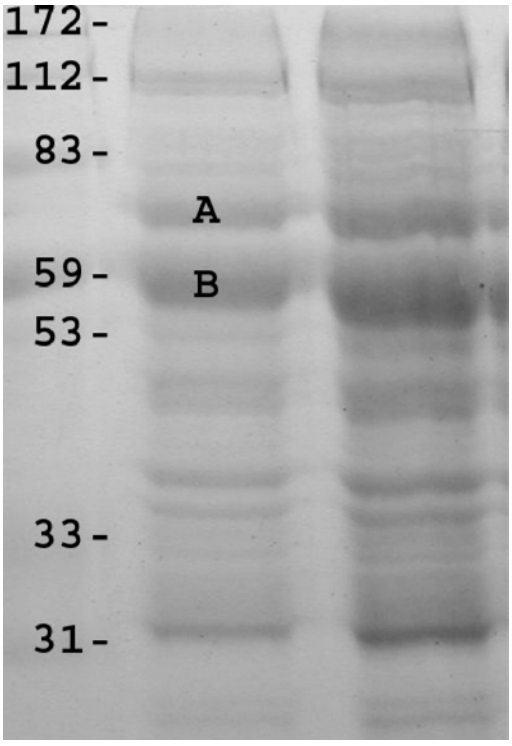

Figure 3.19.4 Coomassie blue–stained gel of proteins from purified pumpkin glyoxysomes. Proteins from freeze-thawed, lysed glyoxysomes were separated by 10% SDS-PAGE: left lane, 25 μg; right lane 50 μg. The major glyoxysomal protein bands indicated in the figure are: (**A**) isocitrate lyase (64 kDa) and (**B**) catalase (55 kDa).

Approx. conc. (mg protein/ml) $= [(A_{235} - A_{280})/2.51] \times 500$

Approx. yield (mg total protein) = (mg protein/ml)
× (final resuspension volume in ml).

These numbers are only approximate, but they are quick and easy to obtain and are consistent between organelle preparations. The authors use this calculation to standardize the amount of glyoxysomes used in each experiment. If more accurate protein concentrations are needed, one can do a biochemical protein assay, such as Pierce's BCA assay or any other protein assay of choice (APPENDIX 3H).

19. Determine integrity of the organelle preparation.

In addition to morphological analysis by electron microscopy (Fig. 3.19.3), there are many enzymatic assays that can be used to verify the presence of intact glyoxysomes, including catalase assays (Cooper and Beevers, 1969; Aebi, 1984; also see UNIT 3.4) and isocitrate lyase assays (Cooper and Beevers, 1969). Mitochondrial contamination can be assessed by performing fumarase assays (Cooper and Beevers, 1969; Hatch, 1978). The intactness of the organelles can be determined by performing the enzyme assays in the presence (to disrupt the membrane) and absence of 0.5% (v/v) Triton X-100. Though substantially enriched for glyoxysomes, the final organelle pellet usually contains some mitochondrial contamination. The proteins can be analyzed by SDS-PAGE and Coomassie blue staining (Fig. 3.19.4).

GROWING SEEDLINGS FOR GLYOXYSOME ISOLATION

SUPPORT PROTOCOL

Seedlings are required for isolation of the glyoxysomes.

Materials

Pumpkin seeds (or other plant seeds depending on desired organelle source)
Medium-coarse vermiculite (available from gardening supply stores)
Flat for germination (available from gardening supply stores)
Plastic wrap

1. Place ~75 ml pumpkin seeds on about 2 cm of medium-coarse vermiculite in a germination flat and sprinkle with a thin layer of vermiculite just sufficient to cover the seeds. Water the seeds liberally and cover the flat loosely with plastic wrap to maintain high humidity for germination.

The amount of seeds may need to be adjusted for other plant types to generate 25 to 35 g of tissue.

2. Germinate pumpkin seeds (or desired organelle source) in the dark at 22° to 25°C.

Optimize the temperature for the particular tissue source.

Germination and growth routinely takes 5 to 7 days, depending on the time of year (shorter during the summer months).

3. Water the seedlings 3 to 4 days after planting to promote germination.

4. Harvest the seedlings when they are ~5 to 8 cm tall.

Seeds that have just begun to germinate can also be harvested, as long as the seed coat is removed prior to grinding.

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Grinding buffer

2× stock solution:
17.844 g tetrasodium pyrophosphate (40 mM final)
0.744 g EDTA (2 mM final)
109.32 g D-mannitol (0.6 M final)
Add 950 ml H_2O
Adjust pH to 7.5 with glacial acetic acid
Add H_2O to 1 liter final volume
Sterilize through 0.45-μm filter
Store up to 6 months at 4°C
1× working solution (170 ml): Add 85 ml of 2× grinding buffer stock solution to 85 ml water. Add 170 mg BSA (1 mg/ml) to the buffer and mix well. Make fresh working solution for each glyoxysome preparation.

The final concentrations in the working solution are 20 mM tetrasodium pyrophosphate, 1 mM EDTA, and 0.3 M D-mannitol.

Percoll, 28% (v/v)/resuspension buffer, 1×

28 ml Percoll
50 ml 2× resuspension buffer stock solution (see recipe)
22 ml H_2O
Store up to 6 months at 4°C

Resuspension buffer

2× stock solution:
4.776 g HEPES (20 mM final)
109.32 g D-mannitol (0.6 M final)
Add 950 ml H_2O
Adjust pH to 7.2 with KOH
Adjust volume to 1 liter with H_2O
Sterilize through 45-μm filter
Store up to 6 months at 4°C
1× working solution (20 ml): Add 10 ml of 2× resuspension buffer stock solution to 10 ml distilled water. Make fresh working solution for each glyoxysome preparation.

The final concentrations in the working solution are 10 mM HEPES and 0.3 M D-mannitol.

Sucrose, 2 M

Dissolve 85.575 g sucrose in water. Bring final volume to 125 ml. Filter the solution through a 45-μm filter. Store up to 6 months at 4°C.

Filtration can be tricky because of the high viscosity of the solution. A vacuum or syringe filter may be used. Filtering may be easier if the solution is warm.

COMMENTARY

Background Information

In the late 1960s, cell biologists determined that the spherical particles observed in plant cell electron micrographs were in fact classes of a distinct and vital organelle, the peroxisome (Tolbert, 1971). Peroxisomes derive their name from their critical function in the metabolism of hydrogen peroxide. For example, the degradation of hydrogen peroxide is catalyzed by the matrix protein catalase, arguably the most abundant peroxisomal enzyme. Catalase is also a major constituent of the distinctive peroxisomal core or crystalline inclusion that is sometimes observed in

plant peroxisomes (Heinze et al., 2000). Peroxisomes are small organelles that are bound by a single phospholipid membrane. They can range in size from 0.5 to 1.5 μm. Although they have been observed in a variety of shapes, they are most commonly spherical. While all plant peroxisomes have some enzymes in common (e.g., catalase, thiolase), they are typically divided into several classes based upon their physiological roles, as defined by spatial and temporal parameters (Olsen and Harada, 1995; Beevers, 2002). For example, cotyledons of oilseeds, such as pumpkins, contain a special class of peroxisomes, called glyoxysomes. These sequester all of the enzymes required for the glyoxylate cycle, to supply the growing seedling with energy. In contrast, peroxisomes found later in leaf development have a partially different enzyme complement because of their function in other pathways, including photorespiration (Olsen, 1998).

An interesting feature of peroxisomes is their lack of an organellar genome. This means that nuclear genes encode all constituent proteins. Peroxisomal proteins are synthesized in the cytoplasm and are post-translationally translocated into peroxisomes (Brickner et al., 1997). The biogenesis of peroxisomes most likely involves the growth and division of preexisting peroxisomes (Olsen, 1998; Purdue and Lazarow, 2001). Intense study has elucidated the molecular machinery (PEX proteins) required for the interrelated processes of peroxisome biogenesis and protein import. Import of peroxisomal matrix proteins occurs through two receptor-mediated import pathways. Each pathway is defined by one of two peroxisome targeting signals (PTS1, PTS2) on the cargo proteins that the receptors recognize and transport. Thus, there are two cytosolic receptors (Pex5p, Pex7p) that recognize the targeting signals and bind to the cargo proteins (Subramani, 1996; Johnson and Olsen, 2001; Brown and Baker, 2003). In vitro protein import assays have been invaluable in studies of the dynamics of peroxisomal protein import, addressing questions about the interactions between the receptors and cargo proteins, the energy requirements, the roles of protein chaperones, and the molecular mechanisms of translocation (Mori and Nishimura, 1989; Behari and Baker, 1993; Brickner et al., 1997; Brickner and Olsen, 1998; Crookes and Olsen, 1998; Johnson and Olsen, 2003). The success of these assays relies on the reproducible purification and manipulation of intact peroxisomes and the presence of the relevant protein cargo, receptors, and other biochemical constituents.

In addition to questions of organelle biogenesis, peroxisome biochemistry and function has received recent attention. Many previously uncharacterized enzymes, including alanine aminotransferase, alanine:glyoxylate aminotransferase, and sarcosine oxidase, have been localized to plant peroxisomes (Liepman and Olsen, 2001, 2003; Goyer et al., 2004). A role for peroxisomal β-oxidation in auxin metabolism has been extensively studied (e.g., Zolman et al., 2000, 2001; Zolman and Bartel, 2004). An isozyme of 12-oxophytodienoate reductase, OPR3, which catalyzes the final step of jasmonate biosynthesis, also possesses a peroxisomal targeting signal, suggesting a role for peroxisomes in jasmonic acid signaling (Sanders et al., 2000; Stintzi and Browse, 2000). Thus, peroxisomes have many critical physiological functions throughout the life cycle of plants.

Critical Parameters and Troubleshooting

There are several critical points for consideration during the glyoxysome purification procedure. Care must be taken to ensure that plants are grown in the dark, that the seedlings are ~5 to 8 cm tall, and that exposure to light during harvesting is minimized to get a good yield of glyoxysomes. This is because, when seedlings begin greening and producing the first true leaves, some glyoxysomes transition into leaf peroxisomes while others are probably degraded (there are fewer peroxisomes present in leaves than there are glyoxysomes present in cotyledons). The tissue must remain cold throughout the protocol to help reduce endogenous protease activities that can cause the degradation of glyoxysomes and glyoxysomal peripheral membrane proteins. The tissue should not be overground during the homogenization step. Instead subject the tissue to just enough homogenization needed to break up the majority of the tissue. When homogenization is done correctly, there should be no large chunks of intact tissue evident after homogenization, though smaller pieces of ground tissue should be present.

Anticipated Results

A preparation of 25 g of pumpkin cotyledons should yield 100 μl of glyoxysomes with an approximate protein concentration of 100 mg/ml. The yield largely depends on the successful removal of the glyoxysome layer from the Percoll gradient.

Time Considerations

An efficient glyoxysome preparation should be completed within 2 to 2.5 hr. Purified glyoxysomes can be stored on ice, but will lose structural and metabolic integrity within hours. Intact glyoxysomes do not survive freezing, though many glyoxysomal enzymes will continue to have measurable activity.

Isolation of GLUT4 Storage Vesicles

The regulation of blood glucose following a meal is achieved by the insulin-dependent mobilization of the glucose transporter isoform GLUT4, which resides primarily (>95%) in intracellular membranes in the basal state. In response to insulin it moves to the cell surface where it can then function to transport glucose into fat and muscle, the tissues that express GLUT4. In type 2 diabetes this process of GLUT4 translocation is compromised. For this and other fundamental reasons, there is considerable interest in GLUT4 trafficking.

The process is similar to two other well-studied vesicular trafficking paradigms: (1) the cellular itinerary of nutritional receptors such as those for transferrin and LDL and (2) synaptic vesicle movement. However, unlike the former, GLUT4 movement is highly insulin dependent, and unlike the latter, it has a relatively slow time course of ~20 min to complete a journey from its intracellular storage site to the cell surface and back again. It is thought that ~50% of GLUT4 represents the immediately mobilizable pool, called GLUT4 storage vesicles (GSVs), although these have not yet been isolated on a preparative scale sufficient for proteomic analysis.

Nevertheless, the isolation procedures described in this unit for all GLUT4 pools and their subsequent biochemical analysis has been instrumental to our understanding of GSV trafficking (see Fig. 3.20.1). The Basic Protocol describes immunoisolation of GLUT4 pools using primary rat adipocytes where the majority of this work has been performed. Alternate Protocols 1 and 2 describe appropriate adjustments to the Basic Protocol for cultured adipocytes and primary skeletal muscle.

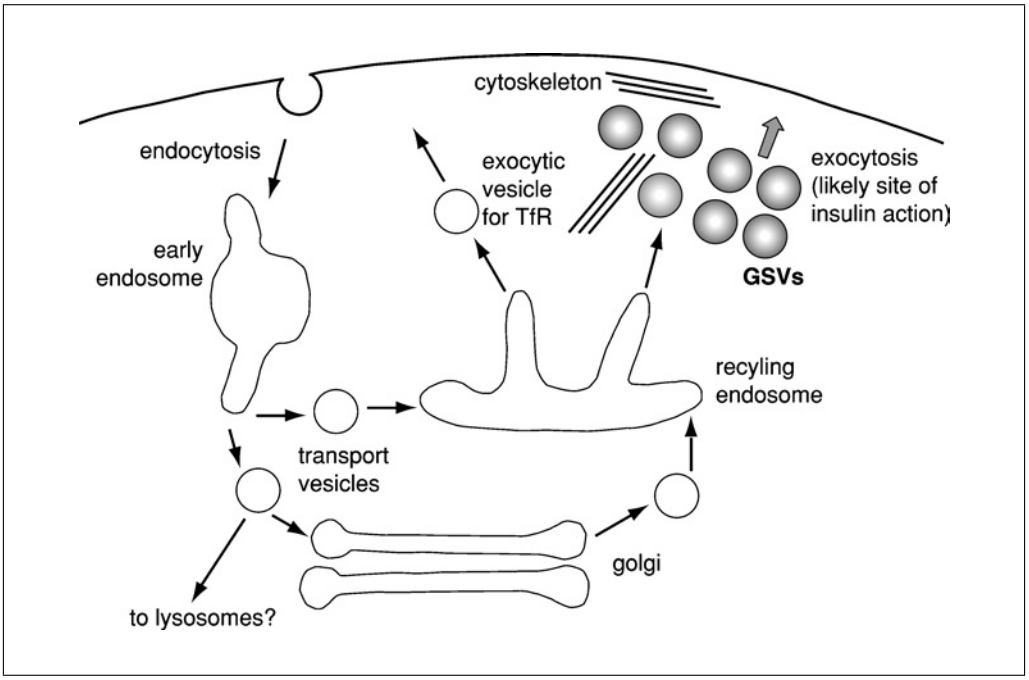

Figure 3.20.1 Known and speculative features of GLUT4 trafficking. Some steps are depicted as being unidirectional although they may operate bidirectionally (Karylowski et al., 2004). Abbreviations: GSVs, GLUT4 storage vesicles; TfR, transferrin receptor.

Current Protocols in Cell Biology (2006) 3.20.1-3.20.13

IMMUNOISOLATION OF GLUT4 VESICLES FROM RAT ADIPOSE CELLS

Primary rat adipocytes are highly insulin responsive cells that can be isolated in exceptional purity (<98%) and sufficient quantity (4 to 25 ml packed cells, density <0.9g/ml) for extensive biochemical characterization. They are easily fractionated into relatively pure membrane compartments enriched, respectively, in plasma membrane, light membranes containing Golgi markers and GSVs, and heavier membranes containing ER markers. Thus, they are a particularly good tissue source for the isolation of GSVs and analysis of their component proteins and lipids.

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) and conform to governmental regulations regarding the care and use of laboratory animals.

Materials

1 mg/ml protein A–purified mouse monoclonal anti-GLUT4 antibody (e.g., R & D Systems 1F8) in 0.1 M sodium borate, pH 8.6 (see James et al., 1988)
1 mg/ml protein A–purified nonspecific mouse IgG in 0.1 M sodium borate, pH 8.6
Reacti-Gel (GF-2000) beads (Pierce)
PBS (*APPENDIX 2A*)
PBS (*APPENDIX 2A*)/0.02% (w/v) NaN_3
Male Sprague-Dawley rats, 150 to 175 g
KRH buffer (see recipe), 37°C
Type I collagenase specified for adipocyte isolation (Worthington) or equivalent
PBS with inhibitors (see recipe), 37°C, 18°C to 20°C, and 4°C
PBS (*APPENDIX 2A*)/1% (w/v) BSA
PBS (*APPENDIX 2A*)/1% (v/v) Triton X-100
Laemmli SDS-PAGE sample buffer without reducing agents (*UNIT 6.1*)
CO_2 chamber (or other equipment for IACUC-approved protocols for sacrificing rats)
Dialysis tubing
1.5-ml microcentrifuge tubes or cryovials
−80°C freezer
Sharp scissors
50-ml plastic vials with tight caps
37°C water bath with orbital and reciprocal shaker
Low-speed medical centrifuge
300-μm nylon mesh
Long-tip, 9-in. Pasteur pipets
Vacuum pump with trap
50-ml centrifuge tube
Motor-driven tissue grinder with a Teflon pestle (Potter-Elvehjem type, Thomas model #3431, size B or C)
High-speed centrifuge (e.g., Sorvall RC-5C with SA-600 rotor)
Gel-loading tip (optional)
Spectrophotometer
1.5-ml microcentrifuge tubes
Tube rotator in a 4°C incubator
Additional reagents and equipment for protein quantification (*APPENDIX 3B & 3H*) and SDS-PAGE (*UNIT 6.1*) or immunoprecipitation (*UNIT 7.2*) and immunoblotting (*UNIT 6.2*)

Prepare antibody-coupled beads

1. Couple protein A–purified 1F8 antibody and non-specific mouse IgG, in separate reactions, to Reacti-Gel beads according to manufacturer's instructions.

   The resulting beads should contain ~0.8 to 1.0 mg of either 1F8 or IgG per ml.

2. Remove the beads by centrifuging 10 sec at 300 × *g*, collect unbound 1F8, dialyze the antibody against three changes of PBS, measure the protein concentration (*APPENDIX 3B & 3H*), separate the stock into 200-µl aliquots, and store at −80° for unlimited periods of time (>10 years).

   This residual antibody can be used for immunoblotting (UNIT 6.2) at 2 µg/ml.

3. Prepare 50% suspension of immunobeads in PBS/0.02% (w/v) NaN_3 and store them at 4°C for up to 1 year.

Prepare tissue

4. Sacrifice male rats using a chamber with CO_2 or another IACUC-approved protocol.

5. Dissect epididymal fat pads from 10 to 12 rats (5 to 10 g of tissue) and place them pooled together into a plastic vial with ~20 ml warm KRH.

Isolate cells

6. Use scissors to mince fat pads into small (<1-mm^3) pieces. Add dry collagenase to 1.75 mg/ml, place vials into a 37°C shaking water bath, adjust speed to achieve intense but gentle shaking, and incubate vials for 45 min.

   The time and concentration of collagenase digestion may vary with the lot and should be adjusted to yield a smooth suspension of adipocytes; also see next step.

7. Filter cells through 300-µm nylon mesh. Gently mix cells with an equal volume of warm KRH in a 50-ml centrifuge tube and centrifuge 10 sec at 100 to 300 × *g*, room temperature.

   Lipid-filled fat cells will float because their buoyant density is less than water. A Pasteur pipet should be inserted through the cell layer to the bottom of the tube and the buffer should be carefully aspirated from underneath the cells.

   Handle primary cells with extreme care. A lipid layer on top of adipocytes after the centrifugation step indicates that a significant number of cells have been broken due to either harsh handling or low temperature that causes solidification of intracellular lipids and cell lysis. Certain batches of collagenase can also cause this problem.

8. Resuspend the cell layer (not the pellet) in warm KRH and aspirate KRH with a long-tip Pasteur pipet attached to a vacuum pump with a trap. Repeat wash three times, then incubate cells 45 min at 37°C.

9. Aspirate KRH and wash cells by adding three volumes of PBS with inhibitors warmed to room temperature (18°C to 20°C).

10. Add 2 vol warm (18°C to 20°C) PBS with inhibitors (twice the volume of lightly packed adipocytes), place cells in a 50-ml centrifuge tube, and spin 20 min at 16,000 × *g*, 4°C.

    Primary adipocytes will break open without homogenization. Alternatively, homogenize cells with seven strokes in a motor-driven Potter-Elvehjem homogenizer with a Teflon pestle (Simpson et al., 1983).

Collect the homogenate

11. Place cell homogenate on ice immediately.

    Another protocol for subcellular fractionation of adipocytes without homogenization is described in Lee et al. (1999).

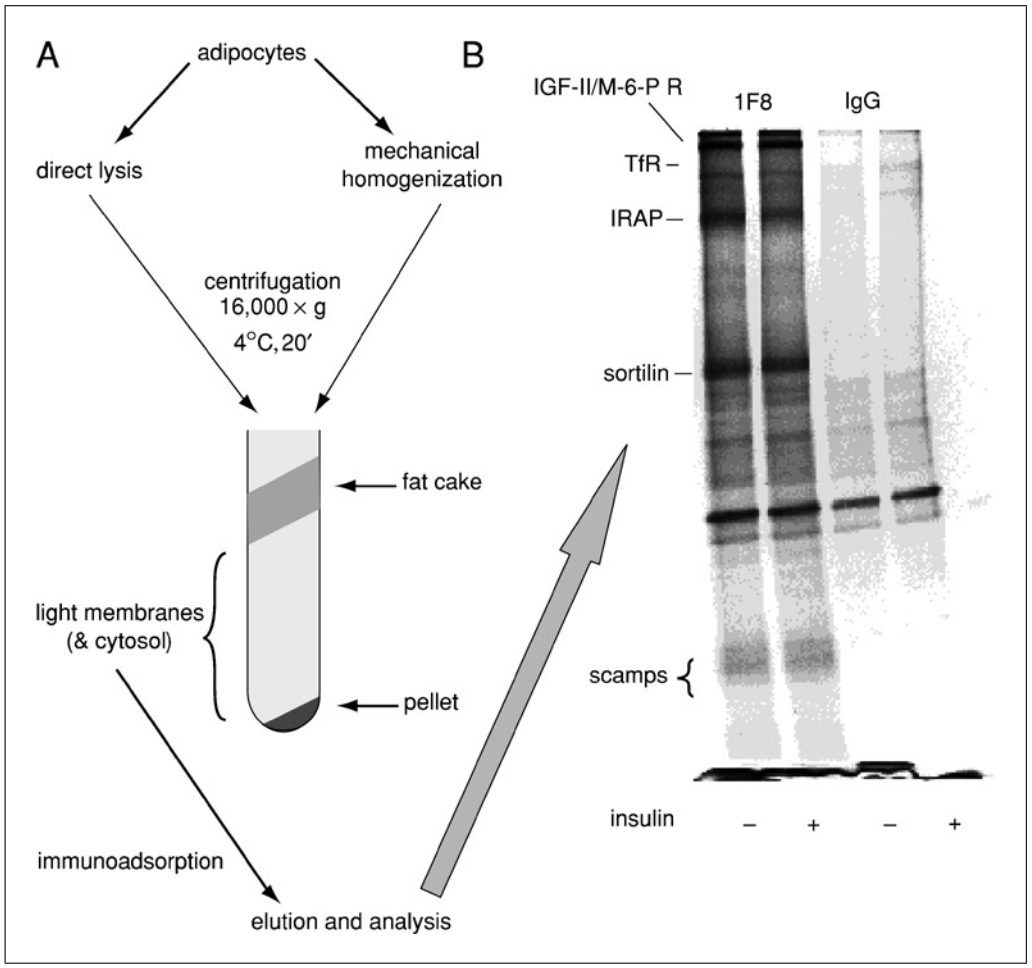

Figure 3.20.2 Vesicle isolation scheme (**A**) and the results of silver staining of proteins eluted with Triton X-100 (**B**). The identity of the bands in this experiment was determined by immunoblotting with corresponding antibodies and has been confirmed by protein sequencing in other experiments (Laurie et al., 1993; Thoidis et al. 1993; Kandror et al., 1994, 1995; Keller et al., 1995; Kandror and Pilch, 1996, 1998; Lin et al., 1997; Morris et al., 1998; Larance et al., 2005). The proteins listed on the left of panel B are discussed in Background Information, along with additional proteins implicated in vesicle association.

12. Centrifuge homogenized cells 20 min at 16,000 × *g*, 4°C.

    The triglycerides will form a congealed fat cake on top, and the heavy membrane will pellet (Fig. 3.20.2A). Centrifugation for 20 min at 16,000 × g results in pellets that contain the heavier GLUT4-containing membranes such as the plasma membrane and endosomes. The substantial majority of GLUT4 in the 16,000 × g supernatant is localized in homogenous 60 to 80 S vesicles. In addition to these vesicles, the 16,000 × g supernatant contains light membranes (LM) that do not contain GLUT4 and all soluble proteins from the cytosol.

13. Using a gel-loading tip or a Pasteur pipet and with minimum disturbance of the fat cake and pellet, collect as much as possible of the light membranes plus cytosol from below the fat cake and above the pellet.

14. Measure the protein concentration (*APPENDIX 3B & 3H*) in the light membranes plus cytosol fraction (LM + cytosol) which will be applied to the beads for immunoadsorption.

Block antibody-bound beads

15. Calculate the amount of immunobeads required for the experiment based on a ratio of ~1 mg of the starting material (LM + cytosol) to 15 μg of immobilized antibody. Resuspend immunobeads in 1 ml PBS/1% BSA in 1.5-ml microcentrifuge tubes and rotate for 30 min at 4°C.

    Blocking beads with BSA is required in order to decrease nonspecific sorption of protein and membrane material on the beads.

16. Rinse blocked beads with PBS three times, centrifuging 10 sec at 300 × *g*, room temperature, between rinses.

Isolate GLUT4 storage vesicles

17. Add LM + cytosol to the beads in the amounts calculated in step 15. Gently rotate immunobeads with the LM overnight at 4°C.

    Use same amounts of the starting material for specific and nonspecific immunobeads. Save an aliquot (25 to 50 μg) of the starting material for analysis of the efficiency of immunoadsorption (see step 18).

18. At the end of the overnight incubation, place microcentrifuge tubes in a rack and wait till the beads sediment to the bottom of the tubes.

    This process should take about a minute and may be expedited by a 4–5 sec centrifugation at ~1000 × g in a microcentrifuge. Avoid high speed centrifugation, which can lead to contamination of the settled beads with membranes and protein aggregates.

19. Collect postadsorptive supernatant, which contains unbound material.

    The volume and the total protein concentration of the postadsorptive supernatant should be equal to the volume and the protein concentration of the starting material because the GLUT4 protein represents such a small portion of the total material that the difference is undetectable.

20. Wash immunobeads four times with 1 ml cold PBS by gentle mixing and microcentrifuging 10 sec at 300 × *g*, room temperature.

    Avoid vortexing and high-speed centrifugation of the beads. Wash the beads at room temperature, but use cold PBS.

21. Add at least 3 bead vol of PBS/1% Triton X-100 to washed beads and elute bound material by rotating the tubes 1 hr at 4°C.

22. Collect the Triton eluate for SDS-PAGE (*UNIT 6.1*) or immunopreciptation (*UNIT 7.2*).

    1% Triton X-100 will solubilize the vesicular membrane and elute vesicular proteins with the exception of GLUT4 itself, which will remain bound to immobilized antibody. Alternatively, all protein can be eluted with SDS (Laemmli) sample buffer.

23. Rinse the beads with 1 ml PBS/1% Triton X-100, then with 1 ml PBS alone with centrifugation 10 sec at 300 × *g*, room temperature, after each rinse.

24. Add Laemmli SDS-PAGE sample buffer without reducing agents to the beads. Vortex the beads five times and collect SDS eluate that contains GLUT4.

    For convenience sake, use the same volume of Laemmli sample buffer as the volume of the starting material and postadsorptive supernatant. Do not add reductants such as β-mercaptoethanol or DTT to Laemmli sample buffer in order to avoid dissociation of the immobilized antibody and elution of the heavy and light antibody chains from the beads. The IgG heavy chain migrates in SDS-PAGE immediately above GLUT4, and if immunoblotting is performed with other mouse antibodies, they will interfere with it.

Analyze the fractions

25. Analyze the starting material, postadsorptive supernatant, Triton eluate, and SDS eluate by SDS-PAGE (*UNIT 6.1*) and immunoblotting (*UNIT 6.2*) with 1F8 antibody.

    If volumes of all these fractions are similar, the distribution of GLUT4 between the fractions will immediately show the efficiency of immunoadsorption (see Fig. 3.20.2B).

ALTERNATE PROTOCOL 1

IMMUNOISOLATION OF GLUT4 VESICLES FROM CULTURED ADIPOSE CELLS

Cultured adipocytes are similar to primary cells in that they are highly insulin responsive and can be relatively easily fractionated for biochemical analysis of GSVs. Moreover, they can be more easily manipulated genetically (e.g. by transfection) than primary cells, and this potentially allows new avenues for understanding GSV composition and behavior. One disadvantage is the large number of cell culture dishes needed to obtain the cultured cells compared to the few animals needed to obtain primary cells. In addition, the GLUT4 content of cultured adipocytes is significantly less than in primary cells.

Additional Materials *(also see Basic Protocol)*

3T3-L1 preadipocytes (ATTC CL-173; Green and Kehinde, 1976) or other adipocyte cell lines (Gross et al., 2004)
DMEM supplemented with 10% (v/v) bovine calf serum (DMEM-10)
Differentiation medium (see recipe)
Maintenance medium (see recipe)
1 mg/ml protein A–purified mouse monoclonal anti-GLUT4 antibody (1F8) in 0.1 M sodium borate, pH 8.6
1 mg/ml protein A–purified nonspecific mouse IgG in 0.1 M sodium borate, pH 8.6
Reacti-Gel (GF-2000) beads (Pierce)
PBS with inhibitors (see recipe)
Cell scraper
Ball-bearing homogenizer (Isobiotec; Heidelberg, Germany) with a 12-μm clearance.
Tube rotator
Additional reagents and equipment for tissue culture (*UNIT 1.1*)

NOTE: All solutions and equipment coming into contact with cells must be sterile, and proper aseptic technique should be used accordingly.

NOTE: All culture incubations should be performed in a humidified 37°C, 5% CO_2 incubator unless otherwise specified. Some media, e.g., DMEM, require higher levels of CO_2 to maintain pH 7.4.

1. Grow 3T3-L1 pre-adipocytes (Green and Kehinde, 1976) in DMEM-10 until confluent.
2. Wait 48 hr after confluence and replace the medium with the differentiation medium. Continue incubation.
3. After 48 hr, replace the differentiation medium with the maintenance medium and change it every 48 hr. Use differentiated cells after 5 to 8 days of differentiation.
4. Using a cell scraper, harvest differentiated cells in PBS with inhibitors (0.8 to 1 ml per 10-cm dish).

    Up to four 10-cm plates may be harvested and combined in 1 ml.

5. Homogenize the cells with 10 strokes using a ball-bearing homogenizer with a 12-μm clearance. Rinse the homogenizer with 0.2 to 0.4 ml PBS with inhibitors and combine this fraction with the homogenate.

   The Potter-Elvehjam tissue grinder described in the Basic Protocol is also suitable for this purpose.

6. Isolate GLUT4 as in Basic Protocol beginning with step 6.

IMMUNOISOLATION OF GLUT4 VESICLES FROM RAT SKELETAL MUSCLE

ALTERNATE PROTOCOL 2

The major source of GLUT4 in animals is skeletal muscle where >80% of glucose is transported after a meal. Therefore, it is quantitatively the most important target tissue for insulin action, but it has been relatively less studied with regard to its GSV content. This is largely due to the lack of well defined and accepted muscle-fractionation protocols similar to those extant for adipocytes for over 20 years. The procedures described in this protocol (from Kandror et al. 1995) result in the isolation of highly enriched GSVs for comparison to those from adipocytes and possible identification of muscle-specific GSV components.

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) and conform to governmental regulations regarding the care and use of laboratory animals.

Materials

Male Sprague-Dawley rats, 150 to 175 g
PBS with inhibitors (see recipe)
1 mg/ml protein A–purified anti-GLUT4 antibody (e.g., R & D Systems 1F8) in 0.1 M sodium borate, pH 8.6
1 mg/ml protein A–purified non-specific mouse IgG in 0.1 M sodium borate, pH 8.6
Reacti-Gel (GF-2000) beads (Pierce)
10% to 30% (w/w) linear sucrose gradients
Chamber with CO_2 or other equipment for IACUC-approved protocol for sacrificing rats
Sharp scissors
Polytron homogenizer, 0.5 in. generator
50-ml centrifuge tubes
High-speed centrifuge (e.g., Sorvall RC-5C)
Ultracentrifuge with SW-55Ti rotor and 5-ml tubes, or comparable
Peristaltic pump
1.5-ml collection tubes

Dissect and process muscles

1. Sacrifice two rats using a chamber with CO_2 or another IACUC-approved protocol.
2. Remove gastrocnemius and/or soleus muscles from rat hindlimb.
3. Trim muscles of connective tissue, fat, and nerves, pool them in a 50-ml centrifuge tube, mince with scissors into small pieces, and rinse three times with PBS with inhibitors.

Homogenize muscle tissue

4. Homogenize in 10 ml PBS with inhibitors on ice three times (10-sec each) using a Polytron homogenizer set at 13,500 rpm.
5. Remove nonhomogenized tissue by centrifuging 10 min at 2000 × *g*, 4°C, and collect the supernatant.

Fractionate the homogenate

6. Centrifuge supernatant 20 min at 9000 × *g*, 4°C. Collect supernatant in a fresh 50-ml tube.

   The pellet of this second centrifugation step contains muscle fibers, cell nuclei, mitochondria, and large fragments of sarcolemma.

7. Resuspend the pellet in 1 ml PBS with inhibitors and store up to 7 days at 4°C for further analysis.

8. Centrifuge the second supernatant 90 min at 180,000 × *g*, 4°C. Solubilize the pellet in 0.25 ml PBS with inhibitors using a flattened yellow pipet tip.

   This is an important step. Try to resuspend the pellet as thoroughly as possible with at least 60 strokes of the pipet tip. The resulting solution should be completely homogeneous.

9. Load solubilized pellet (3 to 4 mg of protein in a total volume of 0.2 ml) on a 5-ml 10% to 30% (w/w) linear sucrose gradient and centrifuge 55 min at 48,000 rpm (250,000 × *g*) in a Beckman SW-55Ti rotor.

   Because skeletal muscle is not fractionated as readily as adipocytes by differential centrifugation, sucrose gradient centrifugation is required in order to separate GSVs from other GLUT4-containing intracellular membranes.

Identify GLUT4-containing fractions

10. Separate each gradient into ~25 fractions using a peristaltic pump. Collect the pellet formed during gradient centrifugation.

    This pellet contains most of the plasmalemma and T-tubules.

11. Analyze the 9000 × *g* pellet from step 6 and gradient fractions and pellets by SDS-PAGE (10% gel; *UNIT 6.1*) and immunoblotting (*UNIT 6.2*) with 1F8 antibody.

    GLUT4 is a 55 kDa protein.

12. Combine GLUT4-containing fractions and use this material for immunoadsorption beginning with step 7 of the Basic Protocol.

ALTERNATE PROTOCOL 3

IMMUNOISOLATION OF GLUT4-CONTAINING VESICLES USING MAGNETIC BEADS

The use of antibody-coupled magnetic beads rather than acrylic beads may offer some advantages in obtaining vesicles of higher purity and/or ease of manipulation.

Additional Materials *(also see Basic Protocol)*

Dynabead M-280-sheep anti-mouse IgG (Dynal Biotech)

Magnetic bead separator (Dynal Biotech)
Tube rotator

1. Incubate protein A–purified 1F8 antibody and nonspecific mouse IgG (2 μg each), in separate reactions, with 30 μl Dynabeads M-280 sheep anti-Mouse IgG according to manufacturer's instructions.

2. Prepare the cell extract for immunoadsorption (Basic Protocol, steps 4 to 14).

3. Block the beads by incubating with PBS/1% BSA for 30 min with rotation at 4°C as in the Basic Protocol, steps 15 and 16.

4. Wash the beads three times with PBS, centrifuging 10 sec at 300 × *g*, room temperature.

5. Use 800 μg of the cell extract per 30 μl of either specific or nonspecific beads. Rotate immunobeads with the starting material overnight at 4°C.

6. Isolate GLUT4-containing vesicles as in Basic Protocol, steps 14 to 24 *except* use a magnetic holder to separate the beads form the liquid phase during the wash steps.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Differentiation medium

DMEM containing:
10% (v/v) fetal bovine serum
0.5 mM 3-isobutyl-1-methylxanthine
1 μM dexamethasone
1.7 μM insulin
Prepare on day of use

KRH buffer

12.5 mM HEPES
120 mM NaCl
6 mM KCl
1.2 mM $MgSO_4$
1 mM $CaCl_2$
0.6 mM Na_2HPO_4
0.4 mM NaH_2PO_4
2.5 mM D-glucose
2% (w/v) bovine serum albumin

Add the glucose and bovine serum albumin on the day of use, and adjust to pH 7.4 with HCl

Maintenance medium

DMEM containing:
10% (v/v) fetal bovine serum
Prepare on day of use

PBS with inhibitors

PBS (phosphate-buffered saline; APPENDIX 2A) containing:
1 μM aprotinin (American Bioanalytics)
2 μM leupeptin (American Bioanalytics)
1 μM pepstatin (American Bioanalytics)
5 mM benzamidine (Sigma)
1 mM PMSF (phenylmethylsulfonyl fluoride; Sigma; 100× in ethanol stock or see *APPENDIX 2A*)
10 mM Na_3VO_4 (Sigma)
50 mM NaF
1 mM β-glycerophosphate
1 mM sodium pyrophosphate
Add inhibitors on day of use

COMMENTARY

Background Information

In adipose and skeletal muscle cells, insulin, within minutes, dramatically increases glucose uptake. This effect of insulin is caused by translocation of the glucose transporter isoform 4 (GLUT4) from the intracellular storage pool to the plasma membrane. In basal adipocytes ~75% of the total GLUT4 pool is accumulated in small (<100 nm in diameter) 60S to 80S membrane vesicles (GLUT4 storage vesicles, or GSVs) with the rest of the transporter being present in ubiquitous intracellular transport vesicles and large (120 to 500 nm) rapidly sedimenting intracellular membranes that are likely to represent endosomes and, possibly, TGN (*trans*-Golgi network) structures (Slot et al., 1991; Ploug et al., 1998; Shewan et al., 2003). Upon insulin administration, GSVs rapidly fuse with the plasma membrane thus increasing the amount of GLUT4 molecule at the cell surface (Bryant et al., 2002) and allowing enhanced glucose uptake. The precise mechanism of insulin-dependent translocation of GSVs is currently under intense investigation in numerous laboratories around the world.

In addition to GLUT4 itself, several integral membrane proteins have been found in the GSVs in adipose cells. The most abundant of these is the insulin-regulated aminopeptidase (IRAP; Kandror et al., 1994; Keller et al., 1995), which is actually more abundant than GLUT4 (Kupriyanova et al., 2002) and serves as a surrogate marker for GSVs (Gross et al., 2004). Why this protein is such a major component of GSVs remains unclear. Other cargo proteins found in GSVs include receptors for transferrin (Kandror and Pilch, 1998) and IGFII (insulin-like growth factor)/ mannose 6-phosphate (Kandror and Pilch, 1996), sortilin (a sorting receptor; Lin et al., 1997; Morris et al., 1998), the tetraspanners called secretory compartment-associated membrane proteins (SCAMPs; Laurie et al., 1993; Thoidis et al., 1993), vesicle-associated membrane proteins VAMP2 (Cain et al., 1992), and VAMP3 (Volchuk et al., 1995). VAMP2 appears to be the v-snare (vesicular soluble-NSF-attaching protein receptor) required for fusion of the GSVs with the plasma membrane (Cheatham et al., 1996), and sortilin functions in GSV formation (Shi and Kandror, 2005). The exact biochemical/physiological role of the rest of the GSV proteins in the context of GSVs is not so clear, although a teleological argument can be made that iron uptake via the transferrin receptor makes sense as a postprandial, insulin-dependent event.

Peripheral membrane proteins must also associate with the GSVs and play a role in vesicle formation and targeting. These may include vesicle tethers such as p115 (Hosaka et al., 2005), TUG (tether, containing the UBX domain, for GLUT4; Bogan et al., 2003) and others (Kao et al., 1999; Chi and Lodish, 2000), rab proteins (Cormont et al., 1991), adaptors (Gillingham et al., 1999; Li and Kandror, 2005), motors (Bose et al., 2002; Semiz et al., 2003) and probably others. The biological significance of these associations is also a topic of much current investigation.

Along with synaptic vesicles, GSVs from adipose cells represent a well-characterized and widely used cell biological model for the study of membrane compartmentalization, sorting, and trafficking.

Critical Parameters

Basic Protocol

Preparation of immunobeads is extremely important for the success of vesicle immunoisolation. For experiments on a small scale (0.5 to 2 mg of light microsomes plus cytosol), use Alternate Protocol 3 with magnetic beads. For the preparative isolation of GLUT4-vesicles, use covalently immobilized antibody (Basic Protocol). An important difference between the two protocols is that SDS will elute the primary antibody from magnetic beads. This result should be minimal when the antibody is covalently coupled to the beads, but some antibody leakage commonly occurs. When choosing the beads for coupling with the antibody, remember that acrylamide beads, such as Reacti-Gel GF-2000, tend to have less nonspecific adsorption, than agarose (Sepharose) beads. Do not use immunobeads that have less than 0.5 mg of antibody per ml, which may lead to unacceptable levels of nonspecific adsorption.

Thorough mincing of fat pads with sharp scissors prior to addition of collagenase (as well as the good quality of the enzyme itself) is absolutely required for the efficient collagenase digestion. In general, it is better to spend more time on the preparation of the tissue, than to prolong incubation with collagenase which can be damaging to cells. Too vigorous shaking and/or prolonged collagenase treatment may trigger translocation of the intracellular GLUT4-vesicles to the plasma

membrane, thus complicating data analysis. Be sure to reequilibrate the cells for 45 min after collagenase digestion to avoid this artifactual translocation.

Alternate Protocol 1

When working with cultured adipocytes, make sure that the cells are well differentiated. Keep in mind that different lines of 3T3-L1 cells may express different amounts of GLUT4 and differentiate at various rates. A good cell line is a key to success, along with using cells passaged <12 times. In preliminary experiments, make sure that cells express sufficient amounts of GLUT4 and increase their glucose uptake at least 5- to 6-fold in response to insulin stimulation (day 6 to 10 after initiation of differentiation).

Alternate Protocol 2

As is the case with adipocytes, tissue preparation and homogenization are very important steps for isolation of GSVs from skeletal muscle. Usually, the results of sucrose-gradient centrifugation show whether or not homogenization has gone well and the experiment may be continued. GLUT4-vesicles should form a distinct peak in the middle of the gradient and be well separated from the bulk of protein and heavy GLUT4-containing membranes in the gradient pellet (Kandror et al., 1995).

Troubleshooting

Insufficient yield of GLUT4

The most common reason for the problem of insufficient yield of GLUT4 is a low ratio between 1F8 antibody and the amount of GLUT4 in the starting material. Try to use more immunobeads, keeping in mind, however, that an increase in the bead volume is likely to increase nonspecific adsorption as well.

High level of nonspecific adsorption

To avoid a high level of nonspecific adsorption, increase stringency of the washing step by elevating the ionic strength of washing buffer to 200 to 250 mM NaCl and/or by performing two to three additional washes.

Most likely, not all of the proteins isolated by immunoadsorption are components of GSVs. Immunoadsorption will isolate all GLUT4-containing membranes regardless of their biological origin. Thus, if intracellular membranes, such as endosomes, are fragmented during homogenization, these membrane fragments will also be isolated. Although artificial fragmentation of membranes does not appear to be a significant factor upon proper cell homogenization (Kupriyanova et al., 2002), this possibility should not be overlooked. In addition, a significant fraction of GLUT4 is localized in ubiquitous intracellular transport vesicles that do not demonstrate insulin responsiveness (Lee et al., 1999; Kupriyanova et al., 2002).

Thus, additional approaches, such as sucrose gradient centrifugation, are required in order to determine whether or not the protein of interest is indeed localized in the GSVs. Also, if a protein is localized in the GSVs, it should be translocated to the cell surface in response to insulin stimulation. This is routinely assessed by immunofluorescence staining (*UNIT 4.3*) and/or cell surface labeling (*UNITS 7.10 & 15.4*).

Anticipated Results

Immunoisolation procedures allow for isolation of 80% to 90% of GLUT4-vesicles, ~0.1% to 0.2% of the total protein content of adipocytes. One can then calculate what quantity of adipocytes will provide sufficient material for various studies, e.g., proteomic analysis, although small-scale analytical experiments are always a good idea to start with, and scale-up seems to be a linear function of starting material and beads. For analytical-scale experiments, the protein yield is too low to bother measuring, as it will use up too much material. For example, for a scaled-up protocol for proteomic analysis, adipocytes from ten or more animals or more than ten 100-cm dishes of cultured cells will yield 50 to 100 μg of immunoadsorbed membrane protein. The amount of GLUT4 in the eluate from nonspecific beads (Triton eluate + SDS eluate) should be <5% of its amount in the starting material. Because some of the membrane material may be lost during washing steps, the protein balance between the starting material, postadsorptive supernatant, and eluates may not always be complete. Usually, recovery of 80% to 90% of any individual protein is within acceptable range.

IRAP (see Background Information) represents a good alternative marker for GSVs, and the yield of IRAP is usually equal to the yield of GLUT4. Note that IRAP and other vesicular proteins are present in the Triton eluate from immunobeads (Fig. 3.20.2). Thus, one can test for the presence of candidate proteins in GSVs by immunoblotting, using either GLUT4 or IRAP as monitors for the specificity and yield of the protocol.

When analyzing the purity of the immunoisolated vesicles, keep in mind that immunoblotting is more specific than silver staining. In other words, it is quite common to have a good and specific yield of GLUT4, IRAP, and other vesicular proteins by immunoblotting and to see relatively small differences in the total protein composition between 1F8- and IgG-bound material when analyzed by protein staining (see Troubleshooting section). The use of sufficient starting material for immunoadsorption, e.g., as in Figure 3.20.2, will minimize this problem.

Time Considerations

The whole procedure from obtaining the rats to the isolation of the light microsomes plus cytosol fraction will take one person ~4 to 6 hr, depending on the nature of the experiment. The addition of the albumin and glucose to the KRH should be done on the day of the experiment and the pH adjusted. Then, ~3 hr are required for preparation, digestion, and resting of the adipocytes, 1 hr or more for experimental manipulation, if needed (addition of insulin, inhibitors, etc.), and 45 to 60 min. for centrifugation and fractionation. It is convenient, therefore, to carry out immunoadsorption overnight at the end of the day and to run the gel next morning; however, the time for immunoadsorption can be reduced to 5 to 6 hr without noticeable changes in yield, and therefore, the whole procedure of vesicle immunoisolation can be achieved in one day.

For preparations from skeletal muscle, homogenize the tissue and perform gradient centrifugation on the first day and run the gel with gradient fractions overnight. Carry out immunoblotting during the second day and perform immunoadsorption overnight. The results of immunoadsorption should be available by the end of day 3. Alternatively, gradient fractions may be kept at 4°C (do not freeze them!) for 2 to 3 days.

Isolation of Intestinal Brush-Border Membranes

This unit describes how to prepare isolated brush-border membrane vesicles from the small intestine of rat, pig, and cow. The procedure is based upon cation precipitation which causes intracellular organelles to coalesce and takes ~3 hr to complete (Hopfer et al., 1973). Membranes isolated in this way can be used for the identification of integral membrane proteins found at the apical pole of the intestinal epithelium or for transport assays because the microvilli spontaneously form sealed membrane vesicles. The technique does not require much specialized equipment apart from a high-speed centrifuge and a Polytron homogenizer. The enrichment of apical membrane proteins is about twenty-fold and will be a product primarily of the enterocyte (absorptive cell) population which makes up ~80% of the cells. There will also be a small contribution from endocrine and mucus-secreting cells.

The Basic Protocol describes isolation of brush-border membranes from rat, while Alternate Protocols 1 and 2 describe isolation of the same material from pig and cow intestines, respectively. A Support Protocol describes methods for assessing the enrichment of the membrane fraction.

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) and conform to governmental regulations regarding the care and use of laboratory animals.

NOTE: Maintain all solutions at 4°C during preparations. Increased stability of rat membranes has been reported by including phospholipase inhibitors in the initial homogenization medium (Maenz et al., 1991), and the inhibitors should also be used in the initial homogenization of pig and cow membranes.

ISOLATION OF INTESTINAL BRUSH-BORDER MEMBRANES FROM RAT

BASIC PROTOCOL

This protocol provides the procedure for taking mucosal scrapings from the small intestine and isolating the apical (brush-border) membranes (see Fig. 3.21.1) from the epithelial cells with minimal contamination of intracellular or basolateral membranes.

Materials

Anesthetic (e.g., sodium pentobarbital; MTC Pharmaceuticals, Ontario, Canada)
Rats (e.g., male Sprague-Dawley rats, ~300 g)
Isotonic saline (0.9% w/v NaCl) containing 0.1 mM phenylmethylsulfonyl fluoride (PMSF), ice-cold
Water, ice cold
Rat collection solution A (see recipe)
Formaldehyde
100 mM $MgCl_2$
Rat homogenization solution B (see recipe)
Final suspension medium (see recipe)

1-ml syringe with 26-G needle
Surgical instruments for laproscopic surgery: scissors and forceps
30 × 20–cm Plexiglas or other flat plate, chilled on ice
Glass microscope slides, chilled on ice

Contributed by Chris I Cheeseman and Debbie O'Neill
Current Protocols in Cell Biology (2006) 3.21.1-3.21.10

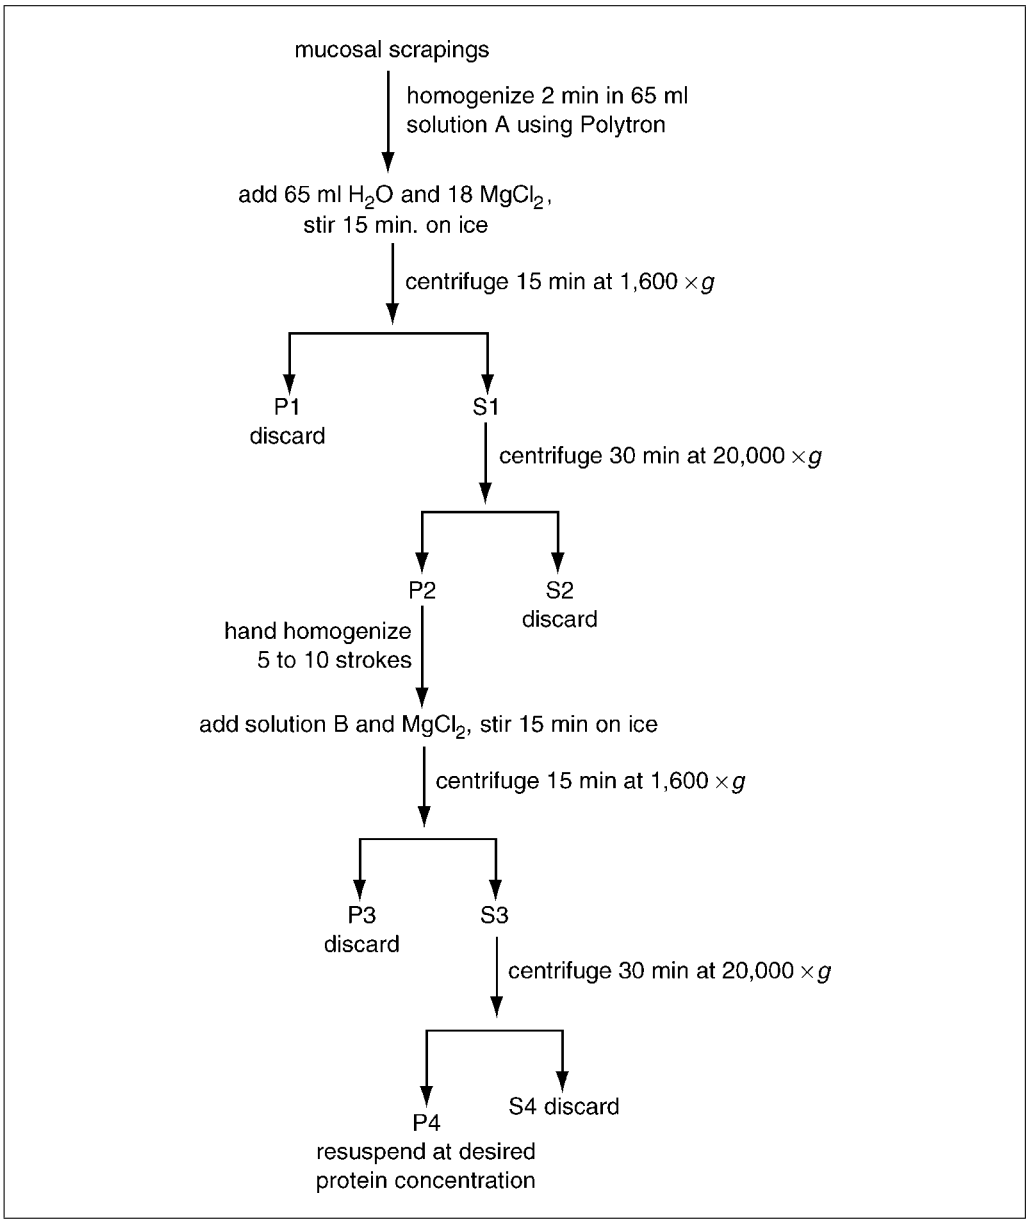

Figure 3.21.1 Flow chart for procedures to isolate rat intestinal brush-border membranes. Pig and bovine preparations differ in the details (see text).

100- and 250- ml beakers
Polytron homogenizer (Brinkmann) or equivalent
Magnetic stirrer and stir bar
50-ml polycarbonate centrifuge tube
High-speed centrifuge capable of generating 20,000 × *g* and handling samples up to 50 ml
15-ml hand held glass homogenizer
Additional materials for determination of protein concentration (*APPENDIX 3H*) and fixing, sectioning, and staining tissue for light microscopy (optional)

Prepare rat intestinal mucosa

1. Anesthetize each rat using sodium pentobarbital, 45 mg/kg body weight, for intraperitoneal injection with a 1-ml syringe with 26-G needle.

   The strain, weight, and sex of the rats will vary, depending on the objectives of a particular study.

The authors use Somnotol (sodium pentobarbital), but the choice of anesthesia will depend upon the jurisdiction and local animal regulations.

If the animals are fasted overnight there will be less lumenal content and the remaining material can be removed more easily. However, it must be remembered that fasting may change the expression of surface enzymes and integral membrane proteins.

2. Expose the small intestine by laproscopic surgery, allowing for blood flow to be maintained.

   Rat intestine is very sensitive to anoxia, and membranes are best prepared from tissue that has the blood flow interrupted as late as possible.

3. Identify the region of interest (small intestine) and make small incisions at both ends of the required section (normally no longer than 30 cm).

   The best way to remove the epithelium from the underlying tissues (muscle, neuronal, and connective tissue) is to take mucosal scrapings (see below).

4. Flush the lumen gently, in situ, with ~15 to 30 ml ice-cold isotonic saline containing 0.1 mM PMSF.

   It is necessary to cool the tissue in this way while maintaining the blood flow in order to reduce stress and avoid possible reinternalization of membrane proteins. It is essential to have the protease inhibitor present at this initial step or the resulting isolated membranes will degrade very rapidly. It is also essential that cooling proceed rapidly and that no delays occur once this procedure has started.

5. Remove the section of intestine from the animal and place it on an ice-cold plate.

   A piece of Plexiglas, sitting on ice, will serve this purpose very well.

   The rat is killed, after the dissection with an anesthetic overdose.

6. Open up the intestine along its antimesenteric border, i.e., along the surface opposite to the blood and nerve supply.

7. Lay this sheet of tissue flat, but avoid touching the exposed mucosal surface.

Collect and homogenize mucosal cells

8. Scrape off the mucosa using an ice-cold glass slide held at a 45° angle.

   This is best done using short strokes.

9. Shake the collected cells into a 100-ml beaker containing 65 ml of collection solution A. Proceed along the length of the sheet of intestine.

   This procedure takes practice to achieve the degree of harvesting required. A light pressure and a few strokes will result in harvesting only the villus tips. More pressure and a greater number of strokes will remove cells from further down the villi towards the crypts.

10. Determine the extent of harvesting the epithelium by fixing the remaining tissue overnight with formaldehyde, sectioning (with basic paraffin sectioning technique), staining with hematoxylin and eosin, and examining by conventional light microscopy.

    Microscopic examination need not be performed for every preparation but is useful when establishing the technique. Only the villi should be harvested without cells being taken from the crypts.

11. Homogenize the cell suspension from step 9 using a Polytron homogenizer 2 min at setting 5, on ice.

    For enrichment assays (see Support Protocol) hold back a 1-ml sample of this initial homogenate.

Precipitate intracellular and basolateral membranes

12. Add 65 ml ice-cold double distilled water and 18 ml of 100 mM $MgCl_2$ to the homogenate. Keep this solution on ice for 15 min and gently stir continuously using a stir bar and a magnetic stirrer.

    The magnesium will cause a large proportion of the intracellular and basolateral membranes to aggregate.

13. Pellet these membranes by centrifuging the solution for 15 min at 1600 × *g*, 4°C.

14. Collect the supernatant (S1 in Fig. 3.21.1) in a 50-ml centrifuge tube. Discard the pellet (P1). Centrifuge S1 30 min at 20,000 × *g*, 4°C. Discard the resulting supernatant (S2).

15. Homogenize the pellet (P2) with a hand-held 15-ml glass homogenizer in 2 to 3 ml homogenization solution B, using 10 strokes.

16. Add up to 30 ml homogenization solution B and repeat the magnesium precipitation step by adding 4 ml of 100 mM $MgCl_2$ to the suspension and stirring on ice for another 15 min.

17. Pellet the aggregated membranes by centrifuging 15 min at 1,600 × *g*, 4°C. Collect the supernatant (S3) and discard the pellet (P3).

Isolate brush-border membranes

18. Pellet the brush-border membranes in S3 by centrifuging this supernatant 30 min at 20,000 × *g*, 4°C.

19. Finally, resuspend the resulting pellet, P4, in the required final resuspension medium and determine the protein concentration using standard protocols (see *APPENDIX 3H*).

    These isolated brush-border membranes spontaneously form vesicles with a trapped volume normally of about 1.5 to 2.0 μl per mg protein.

    If these vesicles are to be used for rapid filtration flux studies a maximum protein concentration of 8 mg/ml is recommended or the filters clog, lengthening filtration time and making flux assays inaccurate.

20. Proceed to the Support Protocol to analyze membrane enrichment.

    Membranes can now used for enzyme assays, flux studies with rapid filtration, or for protein identification with (western) immunoblotting.

SUPPORT PROTOCOL

ASSESSMENT OF MEMBRANE ENRICHMENT

There are several methods which can be used to determine the degree of enrichment of the resulting membrane preparation, most of which rely on enzyme assays. Sucrase-isomaltase and alkaline phosphatase are both enzymes associated with the intestinal brush-border membrane. Assays for these enzymes can be used to determine the level of enrichment of the isolated membranes (Fredricksen and Wirsen, 1956; Tsuboi et al., 1985). Normally, the degree of enrichment is about fifteen- to twenty-fold compared to the original homogenate.

ALTERNATE PROTOCOL 1

ISOLATION OF INTESTINAL BRUSH-BORDER MEMBRANES FROM PIG

This is a modification of the procedure employed for rat tissue. It requires slightly different solutions and takes account of the greater yield. Pig BBM vesicles are ideal for use in rapid filtration uptake assays because they are very robust and give very reproducible data.

Additional Materials *(also see Basic Protocol)*

Pig intestine (freshly isolated from slaughter or animal house)
Pig and cow collection solution A, ice cold
Pig and cow homogenization solution B

25-G needle
10-ml syringe
−70°C freezer

Isolate membranes

1. Flush the intestinal lumen of freshly isolated pig intestine pieces (30 cm long) with 60 to 70 ml ice-cold isotonic saline containing 0.1 mM PMSF.

   Intestine can be collected at the slaughter or animal house and must be chilled immediately. Ideally it should be sectioned and flushed, with mucosal scrapings taken on site and kept in ice-cold saline until they can be used. If mucosal scrapings cannot be prepared immediately, flush out the lumenal contents of the intestinal segments with ice-cold saline and keep the tissue on ice in the saline for no more than 2 hours.

   Note that the flow chart in Figure 3.21.1 does not fully match the isolation steps for pig or cow.

2. Open up the intestine along its antimesenteric border, i.e., along the surface opposite to the blood and nerve supply and lay it flat on an ice-cold plate or piece of Plexiglas.

Collect and homogenize mucosal cells

3. Take mucosal scrapings, as for rat tissue (Basic Protocol, step 8), using a microscope slide held at 45° angle.

4. Collect the scrapings in ice-cold pig and cow collection solution A, at a ratio of ∼20 ml solution for each gram of tissue.

5. Homogenize the suspension from step 4 with a Polytron homogenizer 90 sec at setting 5, on ice.

Remove intracellular and basolateral membranes

6. Centrifuge this suspension (in 50-ml tubes) 15 min at 1,600 × *g*, 4°C. Collect the supernatant (S1) and discard the pellet (P1).

7. Add the 100 mM $MgCl_2$ to S1 bringing the magnesium concentration to a final concentration of 10 mM and stir 15 to 20 min on ice.

8. Centrifuge the suspension 15 min at 1,600 × *g*, 4°C.

9. Collect the supernatant (S2) discarding the pellet (P2). Centrifuge S2 30 min at 20,000 × *g*, 4°C. Retain pellet (P3). Discard supernatant (S3).

10. To resuspend P3 effectively, add 1 ml of ice-cold pig and cow homogenization solution B and draw the solution back and forth 5 to 10 times through a 25-G needle on a 10-ml syringe.

    At this stage aliquots of this samples can be frozen up to 4 months at −70°C with little deterioration.

Isolate brush-border membranes

11. Dilute the 1 ml of P3 suspension to 35 ml with pig and cow homogenization solution B and centrifuge 30 min at 20,000 × *g*, 4°C. Retain P4 and discard S4.

12. Resuspend P4 in a small volume of homogenization solution B, measure the protein concentration (see *APPENDIX 3H*) and then dilute to the required protein concentration in final suspension medium.

    The desired concentration for rapid filtration assays is 6 to 8 mg/ml.

ISOLATION OF INTESTINAL BRUSH-BORDER MEMBRANES FROM COW

Clearly, the tissue cannot be flushed *in situ* as with smaller species but, tissue samples store well for subsequent membrane isolation.

Additional Materials *(also see Basic Protocol)*

Cow intestine
Phosphate-buffered saline (PBS; *APPENDIX 2A*) containing 0.1 mM PMSF and 0.1 mM aprotonin
Pig and cow collection solution A (see recipe)
Pig and cow homogenization solution B (see recipe)
Aluminum foil or plastic vials suitable for freezing
Liquid nitrogen or −70°C freezer
25-G needle
10-ml syringe

Collect intestinal tissue

1. Cut the intestine into 10-cm lengths. Flush pieces of intestine with 30 ml ice-cold PBS containing 0.1 mM PMSF and 0.1 mM aprotonin. Place in flask containing ice-cold flushing solution and transport rapidly to preparation site.

   Tissue will keep for a couple of hours on ice.

2. Blot the pieces and wrap in aluminum foil before dropping into liquid nitrogen for storage.

   Alternatively mucosal scrapings can be prepared as below and then placed in plastic vials for rapid freezing under liquid nitrogen. These will store well under liquid nitrogen for several weeks. If they are subsequently kept at −70°C they will only keep for 1 week.

Isolate membranes

3. Thaw samples on ice and collect mucosal scrapings as in Basic Protocol, step 8. Add 1 g of mucosal scrapings to 20 ml of pig and cow collection solution A.
4. Homogenize the material with a Polytron homogenizer 2 min at setting 5, on ice.
5. Then centrifuge the suspension for 15 min at 1,600 × *g*, 4°C. Retain supernatant (S1) and discard the pellet (P1).

Precipitate intracellular and basolateral membranes

6. Add stock 100 mM $MgCl_2$ to a final concentration of 10 mM $MgCl_2$. Stir the solution slowly on ice for 15 to 20 min.
7. Centrifuge 15 min at 1,600 × g, 4°C. Collect S2 and discard P2.
8. Centrifuge S2 30 min at 20,000 × *g*, 4°C, and retain P3 while discarding S3.

Homogenize brush-border membranes

9. Wash P3 with 1 ml ice-cold pig and cow homogenization solution B and mix by drawing back and forth through a 25-G needle on a 10-ml syringe five to ten times.

   At this stage aliquots of this sample can be frozen up to 4 months at −70°C with little deterioration.

Isolate brush-border vesicles

10. Dilute the 1 ml of P3 suspension to 35 ml in pig and cow homogenization solution B and centrifuge 30 min at 20,000 × g, 4°C. Retain P4 and discard S4.

11. Resuspend P4 in a small volume of pig and cow homogenization solution B, measure the protein concentration (see *APPENDIX 3H*) and then dilute to the required protein concentration using final suspension medium.

For rapid filtration assays, 6 to 8 mg protein/ml is the desired concentration for rapid filtration assays.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Final suspension medium

Using solution C (see recipe), add components, including protease inhibitors, buffers at the appropriate pH, and chemicals to provide the ionic composition that will be required for the experiment to be performed. Store up to 1 week at 4°C.

The composition of this solution will determine what the vesicles contain because this is the point at which they seal and equilibrate. Mannitol is often used as the osmolyte so that the effects of different extravesicular cations can be tested on transport processes; however, the disadvantage of using the sugar is that the ionic strength is not maintained across the membrane.

Pig and cow collection solution A

For 500 ml: 50 mM mannitol
2 mM Tris base, pH 7.4
Store up to 1 month at 4°C
Add 200 µl of 250 mM PMSF just before use (0.1 mM. final)

Pig and cow homogenization solution B

30 ml 500 mM mannitol (300 mM final)
5 ml of 500 mM HEPES (50 mM final), adjusted to pH 7.4 with Tris base
H_2O to 50 ml
Store up to 1 month at 4°C

Rat collection solution A

300 mM mannitol
5 mM EGTA
12 mM Tris·Cl
Adjust to pH 7.4 with 5 M NaOH
0.1 mM PMSF (add just before use; see *APPENDIX 2A* for stock solution recipe)
Store up to 1 month at 4°C

Rat homogenization solution B

150 mM mannitol
2.5 mM EGTA
6 mM Tris·Cl
Adjust to pH 7.4 with 5 M NaOH
0.05 mM PMSF (added just before use)
Store up to 1 month at 4°C

Solution C

300 mM mannitol
5 mM Tris·Cl, pH 7.4
Store up to 1 month at 4°C

COMMENTARY

Background Information

Polarized epithelial cells, such as those of the small intestine, have two distinct membrane domains. The basolateral membrane (BLM) bounds the sides and basal surface of the epithelial cells while the apical surface is often referred to as the brush-border membrane (BBM). This name comes from the appearance of this surface as bristles of a brush under a low-power light microscope. These bristles are formed by the plasma membrane having numerous uniform projections called microvilli, which have a very complex cytoskeletal structure in their core (Fig. 3.21.2A and 3.21.2B). A key feature of polarized cells is their asymmetrical expression of membrane proteins which allows them to mediate vectorial transport of numerous solutes and ions. In the case of the small intestine, amino acid and hexose absorption is achieved by the expression in the BBM of proteins like SGLT1 (sodium-coupled glucose transporter) and GLUT5 (a facilitated fructose transporter). These proteins are not expressed in the BLM; instead we find GLUT2, a low-affinity glucose and fructose facilitated transporter, and sodium/potassium ATPase, which pumps sodium out of the cell into the blood stream. This differential expression then promotes the uptake of fructose and the coupled entry of glucose and sodium, followed by the exit of these hexoses via GLUT2 and the pumping out of sodium by the ATPase. The end result is the absorption of hexoses and sodium from the lumen into the blood stream.

The isolation of BBMs then allows one, using a variety of biochemical and molecular techniques, to determine the expression of proteins at the apical surface of the epithelial cells. The intestine is a very plastic tissue, varying the expression of numerous proteins in response to environmental conditions, e.g., starvation, alterations in diet, and some disease states like diabetes. In addition, there is evidence for regulatory processes in which transport proteins are rapidly inserted or removed from the BBM. Isolated BBMs permit quantification of the degree of changes in protein expression and also allow for measurement of the time course of expression or turnover. The major technique for determining transporter protein expression would be immunoblotting (*UNIT 6.2*) with densitometric scanning (*UNIT 6.3*) which allows for at least semiquantitative analysis. Confirmation of the identity of proteins expressed in the BBM can also be achieved by using mass spectrometry. In addition to the embedded membrane proteins, the intestine also expresses a number of surface enzymes which are anchored by a single membrane-spanning domain (Hauser and Semenza, 1983). Their activity can be assayed using isolated BBMs and a variety of substrates depending upon the enzyme to be assayed, e.g., sucrase-isomaltase (Tsuboi et al., 1985).

The second major use of these isolated BBMs is for transport studies. During the homogenization processes the individual microvilli are sheared off from the cells producing tubes of plasma membrane containing microtubules. The majority of these individual microvilli then seal at their base by the fusion of the lipid bilayer around the cytoskeleton. During the final centrifugation the suspension medium equilibrates with the intramicrovillus space giving vesicles containing a solution of known composition. The trapped volume of these isolated BBM vesicles is usually in the range of 1 to 2 μl per mg membrane protein. If these vesicles are then suspended in a medium containing a radiolabeled substrate of known concentration, incubated for a few seconds and then separated from the medium by filtration, it is possible to measure the functional activity of transport proteins expressed in the BBM.

Critical Parameters and Troubleshooting

This protocol is based upon the principle of divalent cation precipitation (calcium or magnesium) and can be used to isolate BBMs from a variety of different species (Hopfer et al., 1973). The initial description is for rat small intestine with later protocols indicating modifications for pig and cow. It must be recognized that the intestinal epithelium is heterogeneous, with ~20% of the cells being non-epithelial, including endocrine cells, mucus secreting goblet cells, and immunoreactive Paneth cells. Thus, any preparation will at best have a contribution of 80% from intestinal epithelial cells (enterocytes). Potential contamination from basolateral and intracellular membranes must also be allowed for.

Rat BBM vesicles are quite labile and are best used fresh, although they can be frozen under liquid nitrogen for up to a week or so. Pig BBMs are far more robust and will store well under liquid nitrogen for extended periods. Bovine material can be stored frozen as tissue, scrapings, or fully isolated

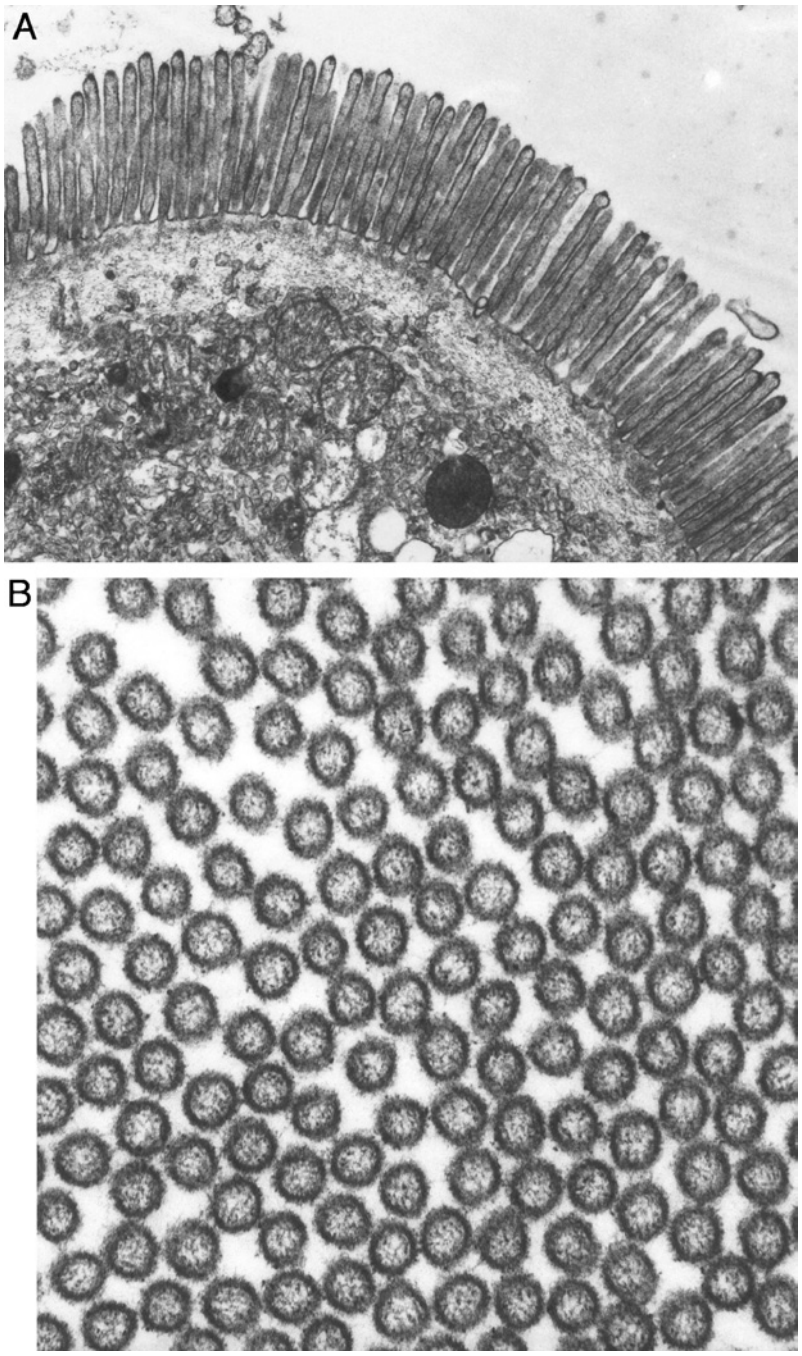

Figure 3.21.2 (**A**) Low-power electron micrograph of isolated rat enterocytes (intestinal epithelial cells) showing highly specialized apical membrane organized into microvilli. (**B**) Cross-section electron micrograph of intestinal microvilli showing plasma membrane surrounding a core of structural filaments.

membranes. It should be noted that a new protocol has been reported using polyethylene glycol (PEG) which may produce vesicles with a better phospholipid profile than is obtained with the divalent cation method (Prabhu and Balasubramanian, 2001). This may be a consequence of the possible stimulation of cation-dependent phospholipases when using the divalent cation precipitation method, and it may be avoided using PEG precipitation.

The isolated membranes are sheared-off microvilli, which will seal spontaneously at their bases forming vesicles that are almost invariably oriented outside out (Hearn et al., 1981); thus, they can be used for rapid uptake experiments. They usually trap ~1 to 2 μl per

mg protein, and so even with a suspension of 8 to 10 mg protein/ml the total trapped volume is negligible compared to the extravesicular suspension volume. The sealing process and equilibration of intravesicular medium with the suspension medium takes place during the final centrifugation of S3. Thus, in these protocols the vesicles will contain an isotonic mannitol medium. If a different composition is required, an additional step is required in which P4 is resuspended in 10 ml of the medium of choice, mixed by repeated flushing through a plastic pipet tip, and then given a final 15-min centrifugation at 20,000 × *g*, 4°C. Discard the supernatant and resuspend in the same solution using a minimal volume (~ 500 µl) to allow for final dilution to the required protein concentration. If the yield cannot give 8 to 10 mg protein/ml for flux assays it is possible to go as low as 5 mg/ml. However, the transport assays will not be as reliable.

When designing an uptake experiment where the composition of the intravesicular medium may be different from that of the uptake medium, it is necessary to take into account the ratio of intravesicle medium versus uptake medium to determine the actual final concentration of substrates and electrolytes. Normally, the ratio of vesicle suspension to uptake medium is in the range of two to five parts uptake medium to one part vesicles.

Anticipated Results

The yield of isolated BBMs varies significantly among species. Three 30-cm pieces of rat jejunum will yield ~8 to 10 mg membrane protein. The ileum will give a slightly lower yield, but there is ~70 cm available in the adult animal. The BBMs can be suspended to the desired protein concentration depending upon whether they are to be used for vesicle transport assays, enzyme assays, or immunoblotting. Normally, for transport assays 8 to 10 mg protein would be resuspended in 1 ml incubation medium. A higher concentration will clog the filters used in the assay.

One 30-cm segment of pig small intestine will generate up to 5 to 6 mg isolated BBM membrane protein.

One 30-cm segment of cow small intestine will generate up to 5 to 6 mg isolated BBM protein.

Time Considerations

Total preparation time from harvesting of the tissue to the final suspension of purified material takes 4 to 5 hr. Ideally, preparation should be commenced at the start of the day and the experiments with the isolated membranes can then be performed in the afternoon.

Isolation and Characterization of Exosomes from Cell Culture Supernatants and Biological Fluids

Exosomes are small vesicles secreted by most cell types in culture. Exosomes form intracellularly by inward budding of the limiting membrane of endocytic compartments, leading to vesicle-containing endosomes, called multivesicular bodies (MVBs). MVBs eventually fuse with the plasma membrane, thus releasing their internal vesicles (i.e., exosomes) into the extracellular medium. What, then, may the physiological function of exosomes be? On one hand, exosome secretion could be a function per se, e.g., exosome secretion by reticulocytes allows the elimination of proteins such as transferrin receptor or integrins, which are useless in differentiated red blood cells (Pan et al., 1985; Vidal et al., 1997). On the other hand, exosomes could be involved in intercellular communication, allowing exchange of proteins and lipids between the exosome-producing cells and target cells. Such a function has been exemplified in the immune system where exosomes allow exchange of antigen or major histocompatibility complex (MHC)-peptide complexes between antigen-bearing cells and antigen-presenting cells (e.g., dendritic cells; Wolfers et al., 2001; Andre et al., 2002, 2004; Théry et al., 2002). Nevertheless, the physiological functions of exosomes remain a matter of debate.

The purpose of this unit is to give simple and reliable methods for purifying and characterizing exosomes. Cell culture supernatants (conditioned media; CM) contain several types of shed membrane fragments and vesicles; therefore, before performing any functional analysis, it is critical to ensure that the purified vesicles are exosomes and not other contaminating material. The first part of this unit describes the most common protocols used to purify exosomes from cell culture conditioned media or from physiological fluids, and the second part describes different methods for characterizing and assessing the purity of the isolated exosomes.

Exosomes have been successfully purified from cell culture conditioned medium or bodily fluids. Support Protocols 1 and 2 provide all details and precautions to take in collecting materials from which exosomes will be purified. Starting from this material, the original and most commonly used protocol for exosome purification (Raposo et al., 1996) is described in Basic Protocol 1. It involves several centrifugation and ultracentrifugation steps. In some cases, the first centrifugation steps can be replaced by a single filtration step: this option is described in an Alternate Protocol. A slightly modified version of Basic Protocol 1, designed for purifying exosomes from viscous fluids (e.g., plasma) is described in Basic Protocol 2. An extra purification step that provides extremely pure exosomes can be added to these protocols, and is described in Support Protocol 3. A different purification procedure, involving trapping exosomes on beads bearing an antibody specific for exosomal surface molecules, has more recently been described (Clayton et al., 2001) and is provided in Basic Protocol 3. It is easy to use and useful for rough characterization of exosomes, but it is not intended for purification of large amounts of exosomes. An additional new method for purifying exosomes by ultrafiltration instead of ultracentrifugation is not described in this unit. This method employs ultrafiltration cartridges and pumps and is especially useful for purifying exosomes from large volumes (>1 liter) of conditioned medium. It is suitable for clinical applications of purified exosomes, but it is not the easiest option for laboratory applications. Interested readers should see Lamparski et al. (2002) for details.

Current Protocols in Cell Biology (2006) 3.22.1-3.22.29

Identification of membrane vesicles as exosomes requires morphological analysis. Given their small size (50 to 90 nm), exosomes can be visualized only with an electron microscope; thus, evaluation of the purity of exosome preparations as well as their characterization should be determined by electron microscopy (see Support Protocols 4, 5, and 6). Separation of exosomes by SDS-PAGE, followed by Coomassie blue staining of all exosomal proteins also gives an idea of the quality of the exosome preparation: exosomes should contain a large number of proteins, i.e., at least a few dozen, many of which are distinct from the proteins detected in whole cell lysates. Further characterization involves analysis of the physical properties of exosomes on a continuous sucrose gradient (Support Protocol 7) and of protein quantity (Support Protocol 9) and composition by immunoblotting (Support Protocol 8) and FACS analysis (Support Protocol 10).

BASIC PROTOCOL 1

PURIFICATION OF EXOSOMES BY DIFFERENTIAL ULTRACENTRIFUGATION

The general idea of exosome purification by ultracentrifugation is depicted in Figure 3.22.1. The first steps are designed to eliminate large dead cells and large cell debris by successive centrifugations at increasing speeds (steps 1 to 5 below). At each of these steps, the pellet is thrown away, and the supernatant is used for the following step (Fig. 3.22.1). The final supernatant is then ultracentrifuged at 100,000 × *g* to pellet the small vesicles that correspond to exosomes. The pellet is washed in a large volume of PBS, to eliminate contaminating proteins, and centrifuged one last time at the same high speed.

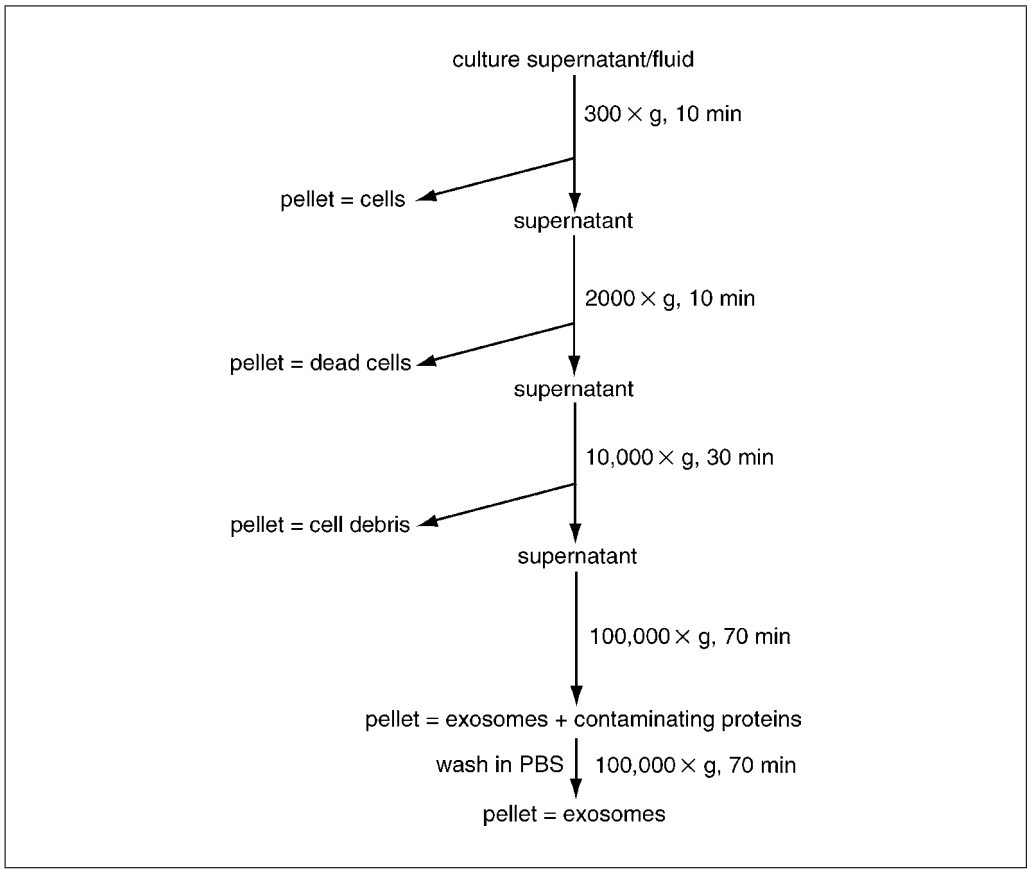

Figure 3.22.1 Flow chart for the exosome purification procedure based on differential ultracentrifugation. The speed and length of each centrifugation are indicated to the right of the arrows. After each of the first three centrifugations, pellets (cells, dead cells, cell debris) are discarded, and the supernatant is kept for the next step. In contrast, after the two 100,000 × *g* centrifugations, pellets (exosomes + contaminant proteins, exosomes) are kept, and supernatants are discarded.

Table 3.22.1 Ultracentrifuge and Rotor Information for Exosome Purification

Rotor (Beckman)	Tubes (Beckman)	Max vol/tube (ml)	Max vol/rotor (ml)	rpm for 10,000 × *g*	rpm for 12,000 × *g*	rpm for 100,000 × *g*	rpm for 110,000 × *g*
SW 41 or 40 (swinging bucket)	Polyallomer	12	72	7,500	8,200	24,000	25,000
SW 28 or 32 (swinging bucket)	Polyallomer	30	180	7,500	8,200	24,000	25,000
70 Ti	Polycarbonate bottle	22	180	10,000	11,000	31,000	32,000
45 Ti	Polycarbonate bottle	68	400	9,000	10,000	30,000	31,000
TLA-100.3	Thick-walled	3	18	13,000	15,000	43,000	45,000
TLA-110	polycarbonate	5	40				

Materials

Conditioned medium (Support Protocol 1, step 5), cleared
Phosphate-buffered saline (PBS; *APPENDIX 2A*)
Tris-buffered saline (TBS; *APPENDIX 2A*), optional

Refrigerated centrifuge
50-ml polypropylene centrifuge tubes
Ultracentrifuge and fixed-angle or swinging-bucket rotor (see Table 3.22.1)
Polyallomer tubes or polycarbonate bottles, appropriate for the ultracentrifuge rotor (see Table 3.22.1)
Micropipettor (e.g., Pipetman)
Tabletop ultracentrifuge (e.g., Beckman TL-100)
–80°C freezer

NOTE: All centrifugations should be performed at 4°C.

NOTE: It is only necessary to use sterile equipment if the final use of exosomes is going to require sterility (e.g., functional in vivo or in vitro assay). If only biochemical analyses will be performed (e.g., immunoblot, proteomics, FACS analysis), very clean, but not necessarily sterile, tubes are required.

NOTE: If sterility is required, sterile centrifuge and ultracentrifuge tubes must be used, and all steps up to the time when CM-containing tubes or tube holders are closed must be performed in a tissue culture hood. To sterilize ultracentrifuge tubes, wash the clean tubes and their lids briefly in 70% ethanol, rinse twice in sterile PBS, pour PBS off, and drain the remaining drops of PBS with a pipet before use. The rotor lid (45Ti rotor) or the lid for each tube holder (SW41, SW28 rotors) must also be cleaned with 70% ethanol before closing the rotors.

Remove cells, dead cells, and cellular debris

1. Transfer the cleared, conditioned medium to 50-ml centrifuge tubes.
2. Centrifuge 20 min at 2,000 × *g*, 4°C.
3. Pipet off the supernatant, and transfer it to polyallomer tubes or polycarbonate bottles appropriate for the ultracentrifugation rotor to be used.

Ensure that none of the pellet is collected and contaminates the supernatant. Use a pipet, rather than pouring off the supernatant, and leave behind half a centimeter of liquid above the pellet.

4. Mark one side of each ultracentrifuge tube with a waterproof marker, orient the tube in the rotor with the mark facing up, and centrifuge 30 min at 10,000 × *g*, 4°C (see Table 3.22.1).

   The mark is a reference for the location of a pellet at the end of the centrifugation.

Collect exosome fraction

5. Transfer the supernatant to a fresh tube or bottle the same size as in step 3.

   Ensure that none of the pellet is collected and contaminates the supernatant.

   There will probably not be a visible pellet at this step. For swinging-bucket rotors, the pellet is at the bottom of the tube. For fixed-angle rotors, the pellet is on the side of the tube facing up (marked by the marker pen) near the bottom of the tube.

   When removing the supernatant with the pipet, hold the tube at an angle, so that the pellet is always covered with supernatant, and stop removing supernatant when half a centimeter of liquid is still covering the pellet.

6. Centrifuge at least 70 min at 100,000 × *g*, 4°C.

   For this high-speed centrifugation, all tubes should be at least three-quarters full. If one of the tubes is not three-quarters full, add PBS.

   Centrifugation time is calculated to allow a full hour at 100,000 × g, i.e., ~10 min for the centrifuge to reach 100,000 × g plus 1 hr at the final speed. A longer time (up to 3 hr) will not damage the exosomes.

7. Remove the supernatant completely.

   For fixed-angle rotors, at this step, pour off the supernatant rather than use a pipet.

   For swinging-bucket rotors, remove the supernatant with a pipet and leave 2 mm of supernatant above the pellet.

Wash exosomes

8. Resuspend the pellet in each tube in 1 ml PBS, using a micropipettor. Pool the resuspended pellets from all the tubes containing materials from the same cells in a single centrifuge tube. Then add PBS to fill the tube completely.

   There will probably not be a visible pellet at this step. For fixed-angle rotors, resuspend by flushing up and down where the pellet should be (upper side of the tube, towards the bottom). For swinging-bucket rotors, flush the bottom of the tube.

9. Centrifuge 1 hr at 100,000 × *g*, 4°C.

10. Remove the supernatant as completely as possible. For fixed-angle rotors, pour off the supernatant, keep the tube upside down, and aspirate the remaining liquid on the sides and the mouth of the tube with a micropipettor. Proceed to step 11a or step 11b

11a. *To resuspend the pellet* (*i.e., exosomes)*: Add a small volume (50 to 100 µl) of PBS or TBS and resuspend.

   If the final volume of exosomes is too large (>1/2000 of the initial volume of conditioned medium) or if there was no visible pellet at step 10, use step 11b instead.

11b. *To concentrate the exosome preparation*: Centrifuge the supernatant (step 10) 1 hr at 100,000 × *g*, 4°C in a tabletop ultracentrifuge, using a TLA-100.3 rotor and the corresponding thick-walled polycarbonate tubes. Remove most of the PBS above the visible pellet and resuspend exosomes in 20 to 50 µl of fresh PBS.

12. Store exosomes up to 1 year at –80°C in 100-µl aliquots. Avoid repeated freezing and thawing.

ELIMINATION OF LARGE CELL DEBRIS AND MEMBRANES BY FILTRATION

ALTERNATE PROTOCOL

For some cells (e.g., mouse dendritic cells) it is possible to replace steps 1 to 6 of Basic Protocol 1 with a single filtration step using a 0.22-µm filter; this will eliminate dead cells and large debris while keeping small membranes for further purification by ultracentrifugation. To determine whether this Alternate Protocol can be used, perform Basic Protocol 1 once using the same volume of conditioned medium obtained from the same cells at the same time in parallel with this protocol, to compare the yields and the quality of exosomes by electron microscopy and immunoblotting (Support Protocols 4, 5, 6, 7, 8, 9, and 10), to ensure that the exosome preparations are identical.

Materials *(also see Basic Protocol 1)*

0.22-µm filter sterilization device (e.g., Steritop; Millipore)
100-ml to 1-liter glass bottle, sterile

1. Filter sterilize the conditioned medium by passing through a vacuum-connected 0.22-µm filter on top of a sterile bottle, using a vacuum.
2. Store the filtered supernatant up to 1 week at 4°C before proceeding to exosome purification (Basic Protocol 1, steps 8 to 12).

COLLECTING CULTURE SUPERNATANTS FOR EXOSOME PURIFICATION

SUPPORT PROTOCOL 1

The exosome-containing conditioned medium from cultured cells is used as the starting material for exosome purification. Total cell lysate of the cells that produce the conditioned medium is prepared at the same time and is used later in parallel with exosomes for immunoblot analysis (Support Protocol 8).

Materials

Cells in culture (*UNIT 1.1*)
Exosome-production medium (Support Protocol 2)
Phosphate-buffered saline (PBS; *APPENDIX 2A*)
Cell lysis buffer (see recipe)

Refrigerated centrifuge
50-ml polypropylene centrifuge tubes
500-ml or 1-liter glass bottle, sterile
1.5-ml microcentrifuge tubes

Additional materials for growing and counting cells in culture (*UNIT 1.1*) and clearing conditioned medium by filtration (Alternate Protocol; optional)

Collect and clear conditioned medium

1. Grow cells of interest under the usual conditions (see *UNIT 1.1*) until they reach 70% to 80% confluency for adherent cells, or 60% to 70% of their maximum concentration for cells grown in suspension.

   Use as many cells as necessary to produce at least 70-ml of conditioned medium (i.e., a minimum of seven 10-cm dishes and up to twenty 15-cm dishes); it is always better to purify exosomes from large volumes of conditioned medium because the yield of the purification procedure increases with the starting volume.

2a. *For adherent cells:* Remove the culture medium, and replace it with a similar volume of exosome-production medium.

2b. *For cells in suspension:* centrifuge cells 10 min at 300 × *g*, 4°C, pour off the supernatant, and resuspend cells in the same volume of exosome-production medium.

3. Return the cells to the incubator for 24 to 48 hr.

Cells that grow fast may be overconfluent and start dying after 48 hr. In this case, take the conditioned medium after 24 hr.

Cells that are very sensitive may not like growing in exosome production medium or in FBS-free medium. In this case, take the supernatant after 24 hr. For instance, dendritic cells tend to mature spontaneously if kept for 48 hr in exosome-production medium.

4a. *To clear conditioned medium from adherent cells:* Collect the conditioned medium with a pipet and transfer to 50-ml polypropylene centrifuge tubes. Centrifuge cells 10 min at 300 × *g*, 4°C, and collect the conditioned medium with a pipet.

4b. *To clear conditioned medium from cells in suspension:* Centrifuge cells 10 min at 300 × *g*, 4°C, and collect the conditioned medium with a pipet and transfer to 50-ml polypropylene centrifuge tubes.

The centrifugations will pellet the cells from suspension cultures or remove the large dead cells from adherent cultures.

5. Transfer the conditioned medium to a sterile glass bottle. Pool supernatants from all dishes or flasks containing the same cell type into a single bottle and store up to 1 week at 4°C.

Once supernatant is collected, the authors strongly recommend proceeding with exosome purification (Basic Protocol 1, Basic Protocol 3, or Alternate Protocol) as soon as possible. Keeping the supernatant at 4°C for up to a week may lead to loss of some exosomes (C. Théry and S. Amigorena, unpub. observ.). Alternatively, some investigators have successfully isolated exosomes from supernatants kept at −80°C for several months, but this also probably leads to exosome loss and should be avoided.

Prepare total cell lysate

6a. *To collect adherent cells:* Trypsinize adherent cells from one to two dishes and count cells with a hemacytometer (see *UNIT 1.1*).

6b. *To collect cells in suspension:* Use cells from the pellet remaining in the tube after step 4b. Resuspend and count cells with a hemacytometer (see *UNIT 1.1*).

7. Put 1–5 × 10^7 cells in a microcentrifuge tube. Centrifuge 5 min at 300 × *g*, 4°C, discard supernatant, and resuspend the cell pellet in 1-ml of PBS. Centrifuge and repeat the PBS wash and centrifugation.

8. Add 200-µl (for 1 × 10^7 cells) or 1-ml (for 5 × 10^7 cells) of cell lysis buffer to the cell pellet and incubate 20 min on ice, vortexing at the beginning and end of the incubation.

9. Centrifuge 20 min at 20,000 × *g*, 4°C. Collect the supernatant in a fresh microcentrifuge tube. Store up to 6 months at −20°C.

The total cell lysate is used in parallel with exosomes for immunoblot analysis (Support Protocol 8).

PREPARING EXOSOME-PRODUCTION MEDIUM

Exosomes are present in the serum generally used for tissue culture. To avoid contamination by these exosomes, culture medium used to grow cells for conditioned media from which the cell-derived exosomes will be purified must be depleted of the contaminating exosomes. There are two options for depleting medium of serum-derived exosomes: (1) if the cells grow in the absence of serum, exosome production-medium can be the basal culture medium, supplemented with all the nutrients and antibiotics, but no fetal bovine serum (FBS). If the cells need some proteins to survive, 1% (w/v) bovine serum albumin (BSA) can be added instead of FBS. (2) If the cells do not survive in serum-free conditions, predeplete the FBS-derived exosomes from FBS-containing medium following this protocol to obtain FBS-exosome-free, exosome-production medium.

Materials

Culture medium complete with required nutrients (e.g., antibiotics, L-glutamine, HEPES, 2-mercaptoethanol, FBS
Ultracentrifuge and fixed-angle or swinging-bucket rotor (see Table 3.22.1)
Polyallomer tubes or polycarbonate bottles, appropriate for the ultracentrifuge rotor (see Table 3.22.1)
0.22-μm filter-sterilization device (e.g., Steritop; Millipore)
100-ml to 1-liter glass bottle, sterile

1. Prepare medium supplemented with all nutrients, plus 20% (v/v) FBS.
2. Centrifuge the medium overnight at 100,000 × *g*, 4°C.

   Follow the same general instructions for centrifugation as explained in the exosome purification section;. i.e., mark a side of each tube with a waterproof marker, and orient the tubes in the centrifuge with mark facing up, indicating where to look for a pellet at the end of the centrifugation.

   If using reusable centrifuge tubes, keep a specific batch of centrifuge tubes for medium depletion, and another different batch for exosome purification to avoid potential contamination with serum endosomes.

3. Filter sterilize the supernatant (i.e., depleted medium) by pouring the contents of each tube into a vacuum-connected 0.22-μm filter on top of a sterile bottle.

   Keep an eye on the pellet (on the marked side of the tube), to make sure that it does not become loose. If it does, stop pouring and throw away the medium remaining in the tube.

4. Dilute the depleted medium with medium supplemented with all the nutrients and antibiotics, but no FBS, in order to reach the final FBS concentration required to make the exosome production medium.

   For instance, if the cells are normally cultured in 10% FBS, dilute 1 vol depleted medium with 1 vol FBS-free medium.

   Depleting medium with 20% FBS allows depletion of a large volume of culture medium in a single round of centrifugation.

   Do not deplete pure FBS because the viscosity of pure FBS will cause elimination of many proteins and factors, which will pellet as aggregates. The cells may not like it!

5. Store exosome-depleted medium after step 4 (sterilized, but not diluted) or step 5 (sterilized and diluted) up to 4 weeks at 4°C.

BASIC PROTOCOL 2

PURIFYING EXOSOMES FROM VISCOUS FLUIDS

To purify exosomes from bodily fluids (e.g., urine, broncho-alveolar lavage, serum, plasma, tumor ascites), simply collect the fluid by the usual means. Store up to 5 days at 4°C in a glass bottle until proceeding with exosome purification.

The principle for exosome purification is the same as when starting from tissue culture conditioned media, but because of the viscosity of some fluids it is necessary to dilute them, and to increase the speed and lengths of centrifugations. This protocol has been used in the authors' laboratories for purification of exosomes from human plasma (Caby et al., 2005).

All precautions indicated in Basic Protocol 1 apply to this protocol as well.

Materials

Fluid (e.g., plasma: separate from blood cells by Ficoll centrifugation; lymph, serum, urine, bronchiolar lavage, or tumor ascites)
Phosphate-buffered saline (PBS; *APPENDIX 2A*)

Refrigerated centrifuge
50-ml polypropylene centrifuge tubes
0.22-μm filter device (e.g., Steritop, Millipore)
Ultracentrifuge and fixed-angle or swinging-bucket rotor (see Table 3.22.1)
Polyallomer tubes or polycarbonate bottles, appropriate for the ultracentrifuge rotor (see Table 3.22.1)

NOTE: All centrifugations should be performed at 4°C.

1. Dilute fluid with an equal volume of PBS. Transfer diluted fluid in 50-ml tubes. Centrifuge 30 min at 2,000 × *g*, 4°C.
2. Carefully transfer supernatant to ultracentrifuge tubes or bottles without pellet contamination (see Basic Protocol 1, step 3 annotation). Centrifuge 45 min at 12,000 × *g*, 4°C.
3. Carefully transfer supernatant to ultracentrifuge tubes or bottles (See Table 3.22.1 for tubes to choose according to the volume of fluid handled.). Centrifuge 2 hr at 110,000 × *g*, 4°C.
4. Resuspend pellets in 1 ml PBS and pool them in one of the tubes. Fill the tube with PBS to dilute the resuspension in a large volume.
5. Filter the suspension through a 0.22-μm filter, and collect in a fresh ultracentrifuge tube or bottle.
6. Centrifuge 70 min at 110,000 × *g*, 4°C. Pour off the supernatant.
7. Resuspend the pellet in 1 ml PBS, and then fill the tube with PBS. Centrifuge 70 min at 110,000 × *g*, 4°C. Pour off the supernatant.
8. Resuspend pellet in 50 to 200 μl PBS. Store up to 1 year at −80°C.

SUPPORT PROTOCOL 3

PREPARATION OF EXOSOMES ON A 30% SUCROSE CUSHION

Although Basic Protocols 1 and 2 provide reasonably pure exosomes, for some applications it may be advisable to include an extra purification step using a sucrose cushion. This step eliminates more contaminants, such as proteins nonspecifically associated with exosomes, or large protein aggregates, which are sedimented by centrifugation but do not float on a sucrose gradient.

Materials

Partially purified exosome pellet (Basic Protocol 1, step 10 or Basic Protocol 2, step 7)
Phosphate-buffered saline (PBS; *APPENDIX 2A*)
Tris/sucrose/D_2O solution (see recipe)

Ultracentrifuge with SW 28 and 45 Ti rotors
Polyallomer tubes appropriate for the SW 28 rotor (Table 3.22.1)
Thick-walled polycarbonate tubes appropriate for the 45 Ti rotor (Table 3.22.1)
5-ml syringe
18-G needle

NOTE: All centrifugations should be performed at 4°C.

1. Resuspend partially purified exosome pellet in 25 ml PBS total.
2. Load 4 ml of Tris/sucrose/D_2O solution at the bottom of a SW 28 tube, to make a cushion.
3. Add the diluted exosomes gently above the sucrose cushion without disturbing the interface. Centrifuge 75 min at 100,000 × *g*, 4°C.
4. With a 5-ml syringe fitted with an 18-G needle, collect ~3.5 ml of the Tris/sucrose/D_2O cushion, which now contains exosomes, from the side of the tube.
5. Transfer the exosomes to a fresh ultracentrifuge tube. Dilute exosomes to 60 ml with PBS. Centrifuge 70 min at 100,000 × *g*, 4°C, in a 45 Ti rotor.
6. Resuspend the pellet in 50 to 100 µl PBS.

PURIFICATION OF EXOSOMES BY IMMUNOISOLATION

BASIC PROTOCOL 3

A simple and rapid method, suitable for the routine isolation and analysis of exosomes, is based upon immuno-magnetic extraction of exosomes bearing human MHC Class II molecules as described by Clayton et al. (2001). (See Table 3.22.2 for exosome markers that are not immune or MHC molecules.). This method has been used by the authors and others (Rabesandratana et al., 1998; Wubbolts et al., 2003; Caby et al., 2005) using magnetic beads coated with antibodies directed against proteins exposed on exosomal membranes. It is, therefore, a mode of isolating exosomes without the need for ultracentrifugation. Furthermore, this method demonstrates colocalization of the protein recognized by the antibody-coated beads with other identified proteins, strengthening the evidence that the analysis is that of exosomes and not, for example, soluble contaminating proteins present in the exosome preparation.

There are several advantages and some disadvantages to this approach. The bead-exosome complexes can be analyzed by flow cytometry, using fluorophore-conjugated antibodies; this facilitates a rapid semiquantitative characterization of the exosome surface phenotype. Alternatively, bead-exosome complexes can be incubated in SDS sample buffer and analyzed by immunoblot (Support Protocol 8). In addition, the loaded beads can be processed for electron microscopy, which allows investigation of the morphology of the adsorbed membranes. Given their size, beads can only be observed after sectioning, which can be accomplished with standard electron microscopy methods such as resin embedding and ultrathin sectioning or, preferably, ultracryomicrotomy to avoid dehydration steps (Raposo et al., 1997). Do not use Support Protocols 4 and 5 for electron microscopy of exosome-bead complexes.

The choice of exosome marker for immobilization is a key issue. For MHC Class II–positive cells, the use of beads precoated with a pan class II–specific antibody is ideal. However, this marker is unsuitable for exosome isolation from non antigen-presenting cells which are MHC class II–negative. In theory, a good candidate marker would be MHC Class I molecules expressed on most if not all exosomes. Unfortunately, MHC class I molecules are also shed from the plasma membrane as a soluble molecule, especially in certain cancerous cells, so that the MHC class I–capturing antibody on the bead surface captures soluble class I as well as exosomally expressed class I molecules, significantly reducing the efficiency of exosome capture. Some suggested alternative exosome-capture molecules include members of the tetraspanin family such as CD81 or CD63, for MHC class II–negative cells (Table 3.22.2). Dynal products (available now from Invitrogen) provide naked beads for coating with antibodies of choice. There are at least 2 types: M-450 Epoxy and M-450 Tosylactivated. Other manufacturers make beads of a similar size, which may also be suitable.

Although selecting exosomes from a conditioned medium based on chosen exosome-expressed proteins is an advantage in several ways, it is important to be aware that this approach may isolate only a subpopulation of marker-positive exosomes, so that subsequent analysis does not reflect the exosome population as a whole. Immunoisolation is not appropriate for purification of large amounts of exosomes. Finally, once captured on beads, exosomes retaining full functionality may not be successfully eluted from the bead surface.

Materials

Conditioned medium from cultured cells (Support Protocol 1)
Phosphate-buffered saline (PBS; *APPENDIX 2A*) containing 3 mg/ml bovine serum albumin (BSA), filter sterilized and stored up to 1 month at 4°C
50-ml centrifuge tubes, sterile
Refrigerated centrifuge
4.5 μM paramagnetic Dynabeads M-450 (Dynal), ready-coated with antibodies (e.g., anti-human MHC II)
Magnet (Dynal)
Test tube rolling machine holding 50-ml tubes

1. Transfer the conditioned medium (Support Protocol 1, step 5) to 50-ml centrifuge tubes. Centrifuge 10 min at 2,000 × *g*, 4°C.
2. Transfer supernatant to fresh 50-ml tubes, and centrifuge again.
3. Wash the antibody-coated Dynabeads as recommended by the manufacturer (i.e., five times in 5 ml of PBS containing 3 mg/ml BSA) using magnetic separation.
4. Pellet the beads using the magnet, and remove all buffer. To this pellet add the supernatant from step 2.

   The easiest method for defining conditions for bead saturation is to perform a dilution series (of cell numbers or of exosome-rich supernatant), and to capture exosomes using a fixed number of beads, in a fixed volume of medium. After washing, beads are stained (preferably with direct-conjugated antibody against a strongly expressed exosome protein e.g., MHC Class I), and the fluorescence intensity measured by flow cytometry. A plot of bead:cell ratio versus mean fluorescence intensity should be drawn, and from this graph, it should be clear at around which point a maximum (plateau) is reached—i.e., adding more exosomes to the beads results in no further increase in signal because the bead surface is already completely saturated. Examples are shown in Clayton et al. (2001).

   For cells such as B cells, which produce abundant exosomes, cells are typically seeded at 1–5 × 10^6 cells/ml and allowed to condition the medium for 24 to 48 hr. About 10 to

50 ml of precleared supernatant is added to 0.5–5 × 10^6 beads. (A half million beads is usually sufficient for the analysis of 10 to 20 different surface markers i.e., 10 to 20 FACS tubes, each representing staining with a particular antibody). For nonimmune cells, start with the same ratio as for B cells and adjust as necessary.

Dynal provides the concentration of the bead stock (usually 400,000 beads/ml). The beads can also be counted using a hemacytometer.

5. Incubate 24 hr at room temperature or at 4°C (to limit proteolysis) on a test tube rolling machine to allow complete bead saturation.

   Do not use a test tube rotating shaker because it may be very harsh and encourage formation of bubbles in protein rich supernatants. The bubbles will trap the magnetic beads and make it difficult to pull them into a pellet using a magnet.

   In almost all situations, it is desirable to obtain beads that are completely saturated with exosomes (for examples of the possible use of partially coated beads see Clayton et al., 2001). Subsequent analysis of exosome-bead complexes, will therefore give the maximum possible signal. It is especially important to be sure that the saturating condition has been achieved if comparing exosome phenotypes from different cell lines, for example. Two key factors dictate the bead coupling efficiency: (1) the coupling time and (2) the ratio of beads to exosomes.

   For an exosome in solution to bind to the surface of a bead it is essential that the exosome makes contact with the bead. If the coupling time is long, the likelihood that such an interaction occurs is increased; hence, long coupling times result in better bead coating.

   However, coupling is entirely dependent on the concentration of exosomes in the supernatant, and beads reach saturation more quickly in exosome-rich medium. In practical terms, the authors have found that an overnight coupling gives the best bead-coating results and extending the time beyond 27 hr has no beneficial effect on the extent of bead coating. If time is short, however, incubations of ~1 to 3 hr give ~50% to 70% bead saturation. If the exosomes are particularly dilute (i.e., cell density is low, or cells produce few exosomes) extending the coupling time will be of little benefit. Optimal bead saturation occurs if there is a vast excess of exosomes present in the supernatant relative to beads.

   In practice, use only as much of the bead preparation as is required (~20,000 to 50,000 beads per flow cytometry antibody, or 5–10 × 10^6 beads per well for immunoblotting), and condition the medium with as many cells as possible. As a guide, the authors suggest using at least 100 cells for every bead, but this ratio will vary considerably among different cell types and with duration of cell culture.

6. Collect the beads with the magnet, and wash at least three times with 2 to 10 ml PBS containing 3 mg/ml BSA to remove material that is nonspecifically bound.
7. Finally, wash once in ~10 ml PBS as in step 6 to reduce BSA content.
8. Resuspend beads in 100 µl of PBS for FACS (Support Protocol 10) or continuous sucrose gradient (Support Protocol 7) analysis, SDS sample buffer for immunoblotting (Support Protocol 8), or fixative for electron microscopy (Clayton et al. 2001).

ELECTRON MICROSCOPE ANALYSIS OF WHOLE-MOUNTED EXOSOMES

SUPPORT PROTOCOL 4

Standard electron microscopic (EM) methods requiring fixation, dehydration, resin embedding, and ultrathin sectioning that are currently used for tissues, cells, and subcellular fractions are, in the authors' opinions, difficult to apply to exosomes and do not give a representative view of the preparation because membranes may be lost during dehydration and repeated centrifugation steps related to dehydration and embedding. This protocol describes a quick and reliable contrasting and embedding method that permits EM analysis of whole-mount exosome preparations.

Materials

100,000 × *g* exosome pellet or frozen concentrated exosome preparations (Basic Protocol 1 or Support Protocol 3)
2% or 4% (w/v) paraformaldehyde (PFA; see recipe)
Phosphate-buffered saline (PBS; *APPENDIX 2A*)
1% glutaraldehyde (see recipe)
Uranyl-oxalate, pH 7 (see recipe)
Methyl cellulose-UA, pH 4: 9 parts 2% methyl cellulose (see recipe) and 1 part 4% uranyl acetate (see recipe) mixed just before use
Formvar-carbon coated EM grids (Support Protocol 6; also see Video 11 for *UNIT 4.7* at *http://www.currentprotocols.com*)
Parafilm
Forceps (Dumont no. 5), clean
Glass dish
Stainless steel loops (homemade; see Video 1 for *UNIT 4.7* at *http://www.currentprotocols.com*), slightly larger than grids
Whatman no. 1 filter paper
Grid storage boxes (e.g., PELCO; *http://tedpella.com*)
Transmission electron microscope (TEM)

Fix exosomes on electron-microscope grids

1. Resuspend the 100,000 × *g* exosome-containing pellet in 50 to 100 µl of 2% PFA.

   Purified concentrated exosomes frozen at –20°C or –80°C are thawed and mixed with an equal volume of 4% PFA.

   Exosomes in 2% PFA can be stored up to 1 week at 4°C before proceeding further.

2. Deposit 5 µl resuspended pellets on Formvar-carbon coated EM grids. Prepare two or three grids for each exosome preparation. Cover and let the membranes adsorb for 20 min in a dry environment.

   Alternatively, put a drop of 5 to 10 µl of exosome suspension on clean Parafilm. In this case float the grids on the drop with their coated side facing the suspension.

3. Put 100-µl drops of PBS on a sheet of Parafilm. Transfer the grids (membrane side down) to drops of PBS with clean forceps to wash.

   IMPORTANT NOTE: *It is important to keep the grids wet on the side of membrane adsorption during all steps, but dry on the opposite side.*

   Subsequent procedures are performed in the same manner: placing drops of reagents on a sheet of Parafilm and transferring the grids from drop to drop with forceps.

   Grids with the same sample can be handled in the same drop.

4. Transfer the grids to a 50-µl drop of 1% glutaraldehyde for 5 min.

5. Transfer to a 100-µl drop of distilled water and let grids stand for 2 min. Repeat seven times for a total of eight water washes.

Contrast and embed samples

6. Transfer grids to a 50-µl drop of uranyl-oxalate solution, pH 7, for 5 min.

   Samples are contrasted first in a solution of uranyl oxalate, pH 7 and then contrasted and embedded in a mixture of 4% uranyl acetate and 2% methyl cellulose in a ratio of 100µl/900µl, respectively.

7. Transfer grids to a 50-µl drop of methyl cellulose-UA for 10 min on ice.

   To keep the grids cold; use a glass dish covered with Parafilm on ice.

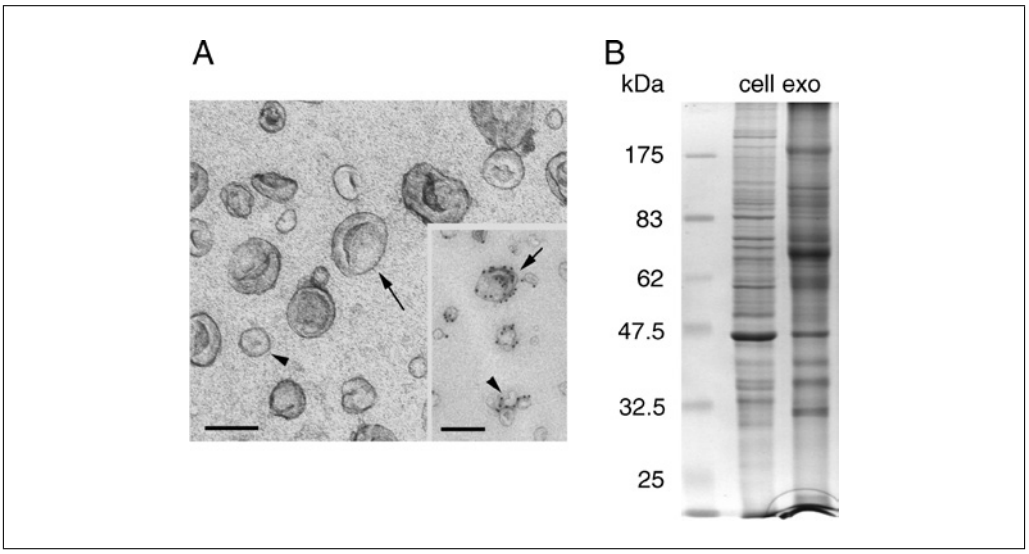

Figure 3.22.2 Typical characteristics of exosomes. (**A**) Electron-microscopic observation of whole-mounted exosomes purified from mouse dendritic cells. Arrows indicate exosomes, arrowheads point to smaller nonexosomal vesicles. Insert: Immunogold labeling of MHC class II molecules (10-nm gold particles). Scale bar = 100 nm. (**B**) Coomassie blue–stained SDS polyacrylamide gel after separation of 30 μg of total cell lysates (Cell) or exosomes (Exo) from mouse dendritic cells. Molecular weight markers were loaded in the first lane (kDa).

This contrasting and embedding procedure ("positive-negative" contrast) was originally developed for ultrathin cryosections. This method is reproducible and combines both increase in contrast and stabilization of the membranes.

8. Remove the grids with stainless steel loops and blot excess fluid by gently pushing the loop sideways on Whatman no. 1 filter paper so that a thin film is left behind over the exosome side of the grid. (See Video 3 of *UNIT 4.7* at *http://www.currentprotocols.com.*)

   It is essential to control the thickness of the methyl-cellulose film. The final thickness of the film is critical in obtaining optimal contrast and fine structure preservation. This can be controlled by the speed of adsorption onto the filter paper (the faster this goes the thicker the film). In the authors' laboratory a sheet of Whatman no. 1 filter paper is placed on top of Parafilm to avoid contamination of the bench with uranyl acetate.

   Loops are slightly larger than the grids and are generally mounted on 1-ml plastic micropipettor tips.

9. Air dry the grid 5 to 10 min while still on the loop.

   After drying, a blue-gold interference color is indicative of a homogeneous and appropriate thickness of the methyl-cellulose film.

10. Store the grids in appropriate grid storage boxes for many years.

11. Observe under the electron microscope at 80 kV.

    Electron microscopy of negatively stained exosomes reveals cup-shaped membrane vesicles of 50 to 90 nm (Fig. 3.22.2). Often, smaller 10- to 20-nm lipid particles are also observed within the same preparations. It is possible that the morphological appearance of exosomes may be influenced by chemical fixation and/or embedding and contrasting with methyl cellulose and uranyl acetate. Unpublished observations of cryo-fixed no-contrasted exosomes visualized with cryo-electron microscopy reveal rather round membrane vesicles.

    Analysis of the 100,000 × g pellets at the electron microscopic level is also essential in evaluating contamination of exosome preparations by other membranes that may be present in culture supernatants as a consequence of cell lysis and may be pelleted during centrifugation.

SUPPORT PROTOCOL 5

IMMUNOGOLD LABELING OF WHOLE-MOUNT EXOSOMES

For further characterization of exosomes, immunolabeling with antibodies against proteins known to be exposed on exosomal membranes is recommended before electron microscopy. A standard immunolabeling procedure is difficult to establish because each antibody/antigen combination may require a slightly different approach.

The most commonly used single antigen-specific labeling procedures are specific antibody + Protein A–gold (PAG) or specific antibody + bridging antibody + PAG. IgG conjugated to gold probes can also be used. The specific antibody can be either a monoclonal or a polyclonal antibody, the bridging antibody or IgG conjugated to the gold probe must originate from a different species. A bridging antibody can be used either to amplify the signal or in situations where the specific antibody does not react with PAG or the IgG-gold. The labeling efficiency, specificity, and background of bridging antibodies depend on the source and should be tested when handling antibodies from different manufacturers.

Multiple antigen-specific immunolabeling procedures can be accomplished using two or more consecutive single-labeling procedures. Up to three different antigens can be visualized (double- and triple-immunolabeling). When performing double or triple immunolabeling, one should consider the best choice of the size of gold particles to be used in the first, second, or third step and for the sequence of gold probes and antibodies. This should be tested first in a single-labeling procedure. Also take into account that, given the small size of exosomes, steric hindrance may hide epitopes and give a negative result.

The procedure described in this protocol was used by Escola et al. (1998), Raposo et al. (1996), Théry et al. (1999), Van Niel et al. (2001), and Zitvogel et al. (1998), to localize proteins exposed at the surface of exosomes. To visualize proteins on the cytosolic side of exosomes (e.g., Tsg101) one may introduce a permeabilization step with saponin after the fixation procedure and during incubation with antibodies and PAG (Fevrier et al., 2004). However, permeabilization of exosomal membranes is difficult to control and may affect exosome morphology.

Materials

100,000 × *g* exosome pellet (Basic Protocol 1)
2% or 4% (w/v) paraformaldehyde (PFA; see recipe)
Phosphate-buffered saline (PBS; *APPENDIX 2A*)
PBS/50 mM glycine *or* PBS/50 mM NH_4Cl
Blocking buffer: PBS/5% (w/v) BSA, PBS/10% (v/v) fetal calf serum (FCS), *or* PBS/1% (w/v) cold-water fish skin gelatin (CFG; Sigma Aldrich)
Primary antibody
Antibody diluent: PBS/1% (w/v) BSA, PBS/5% (v/v) FCS, *or* PBS/1% (w/v) cold-water fish skin gelatin
Washing buffer: PBS/0.1% (w/v) BSA, PBS/0.1% (v/v) FCS, *or* PBS/0.1% (w/v) CFG
Secondary (bridging) antibody (optional; e.g., Dakopatt)
PBS/0.5% (w/v) BSA
Protein A–gold conjugates (Cell Microscopy Center, Utrecht, The Netherlands)
1% glutaraldehyde (see recipe)
Formvar-carbon coated EM grids (Support Protocol 6 or Pelco International, *http://www.pelcoint.com*)
Parafilm
Clean forceps (Dumont no. 5)
Additional reagents and equipment for contrasting, embedding, and electron microscopy (Support Protocol 4)

Adsorb exosomes on electron-microscope grids

1. Resuspend the 100,000 × *g* exosome-containing pellet in 50 to 100 µl of 2% PFA.

   Purified concentrated exosomes frozen at –20°C or –80°C are thawed and mixed with an equal volume of 4% PFA.

   Exosomes in 2% PFA can be stored up to 1 week at 4°C before proceeding further.

2. Deposit 5 µl of the resuspended pellets on Formvar-carbon coated electron-microscopy grids. Prepare two or three grids for each exosome preparation. Cover and let the membranes adsorb for 20 min in a dry environment.

   Alternatively, put a drop of 5 to 10 µl of exosome suspension on clean Parafilm. In this case float the grids on the drop with their coated side facing the suspension.

3. Put 100-µl drops of PBS on a sheet of Parafilm. Transfer the grids to drops of PBS with clean forceps.

   IMPORTANT NOTE: *It is important to keep the grids wet on the side of membrane adsorption during all steps, but dry on the opposite side.*

   Grids with the same sample can be handled in the same drop.

   The immunolabeling procedure is performed by floating the exosome-coated electron-microscope grids on successive drops of washing, blocking, and labeling solutions disposed on a Parafilm sheet. Each rinsing step is performed on drops of at least 100 µl, while 5-µl drops are sufficient for immunoreagents.

   The following steps proceed by floating grids on 100- to 200-µl droplets of solutions.

Wash and block exosomes on grids

4. Transfer grid to PBS and wash twice for 3 min.

5. Transfer grid to PBS/50 mM glycine for 3 min. Repeat transfers to fresh drops of PBS/50 mM glycine three times for a total of four washes.

   The glycine quenches free aldehyde groups. As an alternative use a 50 mM solution of ammonium chloride (NH_4Cl).

6. Transfer grids to a drop of blocking buffer for 10 min

   Bovine serum albumin (BSA) and other proteins saturate nonspecific binding sites. Alternative blocking solutions are 10% fetal calf serum (FCS) or 1% cold-water fish skin gelatin (CFG) in PBS.

   Diluents and washing buffers in following steps should contain the same proteins as the blocking buffer.

Incubate exosomes with antibodies

7. Transfer the grid to a 5-µl drop with the first antibody diluted in the appropriate antibody diluent for the blocking solution and incubate 30 min.

   Test a range of antibody dilutions from 2 to 20 µg/ml.

   As in any labeling procedure it is critical to avoid contamination of solutions. Buffers should be freshly prepared, and antibody dilutions can be kept from 1 week to 1 month, depending on the antibody.

8. Transfer grids to the appropriate washing buffer and wash 3 min. Repeat transfers to fresh drops of washing buffer five times for a total of six washes.

   It is important to keep the grids wet on the specimen side during all steps, but dry at the opposite side. When the samples are allowed to dry during the immunoincubation, high background levels or other contamination can result.

If the first antibody is not directly reactive with protein A (for example mouse monoclonal IgG1, rat monoclonals, goat polyclonals), use a bridging antibody: for example, rabbit anti-mouse IgM, rabbit anti-goat IgG, rabbit anti-rat (commercially available from Dakopatt).

9. (*Optional*): If it is necessary to perform bridging, incubate 30 min with a secondary antibody diluted in the appropriate blocking solution.

10. Transfer grids to 100-µl drops of PBS/0.5% BSA (blocking buffer) and wash 3 min. Repeat transfers to fresh drops of PBS/0.5% BSA five times for a total of six washes.

Label exosomes with protein A-gold conjugates

11. Incubate in 5-µl drops of protein A-gold conjugates diluted in the appropriate blocking buffer 20 min.

    For a single labeling the authors generally use 10-nm gold particles.

    Protein A-gold of excellent quality with appropriate dilutions indicated by the supplier can be purchased from Cell Microscopy Center, Department of Cell Biology, Utrecht University, The Netherlands. These reagents are extremely pure, the dilutions have been perfectly controlled, and the same batches (made four times a year) are used by different labs.

    The authors recommend a 1:200 dilution when using Dako bridging antibodies.

12. Transfer grids to 100-µl drops of PBS and wash 2 min. Repeat transfers to fresh drops of PBS seven times for a total of eight washes.

13. Transfer grids to 50-µl drops of 1% glutaraldehyde for 5 min.

    This step is necessary to stabilize the immunoreaction.

14. Transfer grids to 100-µl drops of water and wash 2 min. Repeat transfers to fresh drops of water seven times for a total of eight washes.

    This step is necessary to remove ions responsible for precipitates during contrast enhancement.

    When performing a double labeling, proceed with steps 3 to 14 with the second label.

Prepare labeled exosomes for electron microscopy

15. Contrast and embed the grids as in Support Protocol 4, steps 6 to 10.

16. Observe under the electron microscope at 80 kV. See Figure 3.22.2.

SUPPORT PROTOCOL 6

PREPARATION OF FORMVAR-CARBON COATED GRIDS

The successful adsorption of exosomal membranes onto grids depends on the quality of the support film. Commercially available Formvar-carbon coated grids can be purchased from Leica or Pelco International (*http://www.pelcoint.com*). This protocol describes a method that is currently used in several laboratories to prepare clean and strong Formvar films. (Also see Video 11 for UNIT 4.7 at *http://www.currentprotocols.com*.)

Materials

Ethanol
Acetone
Formvar powder (Agar Scientific, *http://www.agarscientific.com*)
Chloroform
EM grids, 200 mesh/copper-palladium, hexagonal specimen (e.g., PELCO; *http://tedpella.com*)
Warming plate or 37°C drying oven

100-ml volumetric flask: rinse with chloroform before use
Funnel-shaped glass column with a stopcock (e.g., PELCO; *http://tedpella.com*; Electron Microscopy Sciences): rinse with chloroform before use
Glass microscope slides
Lens tissue
Deep glass dish: rinse with chloroform before use
Clean forceps
Razor blades
Adhesive label (e.g., address label) or Parafilm
Petri dishes with tops
Filter paper
Carbon vacuum evaporator (Bal-tec, *http://www.bal-tec.com*)

Create Formvar film on microscope slide

1. Clean EM grids in a 200 ml glass flask, by rinsing them ~5 min with ethanol and then three times, ~3 min each, in acetone. Remove acetone.
2. Dry over a 37°C warming plate or in a drying oven.
3. Put 1.2 g Formvar powder into a 100-ml volumetric flask and add 100 ml chloroform with stirring. Let stand overnight wrapped in aluminum foil to protect from light.

   In order to prepare a clean solution all materials should be previously rinsed with chloroform.

4. Clean a glass slide with ethanol and dry it immediately with lens tissue.
5. Fill the glass column with Formvar solution. Using clean forceps, introduce the clean slide upright in the solution.

   The glass column is funnel-shaped and specially designed to accommodate the slide. The column should be previously rinsed with chloroform.

6. Open the stopcock to allow the Formvar to drain over the slide.

   This leaves a thin film of Formvar on the slide. The draining time determines the thickness of the film, and is usually 12 to 15 sec.

7. Remove the slide from the funnel and let the slide dry vertically.

Transfer Formvar film to EM grid

8. Fill a deep glass dish with water and place a light so that it reflects on the water surface. Clean the water surface by passing a piece of lens tissue over the surface.
9. Cut the edges of the dry Formvar film around the slide with a razor blade.
10. Put the slide on a water surface in an upright position. Push the slide gently into the water to allow the film to be released from the slide and to float on the water surface.

    The thickness of the film can be judged by its color, which ideally should be grey/white. If the films are yellow-purple, they are too thick. Either dilute the solution with chloroform or decrease the speed of draining with the stopcock.

11. Place the grids on the film floating on the water surface.
12. Remove the grids/film from the water by putting a microscope slide covered with an adhesive label in an upright position on the edge of the film, and pushing it downwards into the water.

    The film with the grids will stick to the label. Clean Parafilm can be used instead of the label.

13. Place the slides filled with grids in plastic dishes over a filter paper and let dry overnight at room temperature.

14. Evaporate a thin layer of carbon on the grids using a carbon-vacuum evaporator according to the manufacturer's instructions. Store in a covered petri dish.

SUPPORT PROTOCOL 7

DETERMINATION OF THE DENSITY OF AN EXOSOME PREPARATION ON A CONTINUOUS SUCROSE GRADIENT

This method measures the density of exosomes in a sucrose gradient. Exosomes have been found to float at densities ranging from 1.15 to 1.19 g/ml on continuous sucrose gradients. By comparison, vesicles purified from the endoplasmic reticulum float at 1.18 to 1.25 g/ml, and vesicles from the Golgi at 1.05 to 1.12 g/ml.

Since exosomes are usually spread among three to five fractions of the sucrose gradient, it is best to perform this separation on at least five times the amount of exosomal proteins needed to detect exosomes after this procedure. For example, to perform an immunoblot on the sucrose-gradient fractions using an antibody that detects its target among 3 μg of exosomal proteins, perform the sucrose gradient on 15 to 20 μg of exosomal proteins. To visualize exosomal proteins in the sucrose-gradient fractions by Coomassie blue staining on gels, use 100 μg of exosomal proteins, to obtain about 20 μg in each exosomal sucrose gradient fraction.

Materials

Exosome preparation (Basic Protocol 1, step 12 or Basic Protocol 2, step 8)
HEPES/sucrose stock solution (see recipe)
HEPES stock solution (see recipe)
4× SDS sample buffer (*APPENDIX 2A*)

30-ml gradient maker
Ultracentrifuge with SW 41 rotor
3-ml ultraclear tubes
Tabletop ultracentrifuge with TLA-100.3 rotor
3-ml thick-walled polycarbonate ultracentrifuge tubes
Refractometer

Additional reagents and equipment for SDS-PAGE (*UNIT 6.1*), protein staining (*UNIT 6.6*), and immunoblotting (*UNIT 6.2*)

Prepare and pour exosome-containing sucrose gradient

1. For each gradient (i.e., each exosome preparation to be analyzed) prepare 5 ml of 2 M sucrose solution by mixing 4 ml HEPES/sucrose stock solution and 1 ml HEPES stock solution.

2. For each gradient, prepare 5 ml of 0.25 M sucrose solution by mixing 0.5 ml HEPES/sucrose stock solution and 4.5 ml HEPES stock solution.

3. Resuspend exosomes in 2 ml of HEPES/sucrose stock solution.

4. Pour exosomes at the bottom of an SW 41 centrifuge tube.

5. In the gradient maker with all shutters closed, load 5 ml of 2 M sucrose solution in the proximal compartment with a magnetic stir bar, and 5 ml of 0.25 M sucrose solution in the distal compartment.

6. Put the gradient maker on a high shelf, on a magnetic stir plate. Open shutter between proximal and distal compartments and turn on the magnetic stir plate.

7. Place the outer tubing in the SW 41 tube, just above the 2 ml of exosomes.
8. Open the outer shutter, and slowly pour a continuous 2 M (bottom) to 0.25 M (top) sucrose gradient on top of the exosomes.

   Lower the SW 41 tube as the gradient is poured, so that the tubing is always slightly above the top of the liquid.

   It is often worth pouring a test gradient on top of non-exosome-containing sucrose first, to get used to the procedure.
9. Balance all tubes containing gradient with each other, or with other tubes containing the same weight of sucrose solutions.

Centrifuge gradients and collect fractions

10. Centrifuge the gradients overnight (≥14 hr) at 210,000 × *g*, 4°C, in the SW 41 swinging-bucket rotor with the brake set on low.

    Total centrifugation time must be at least 14 hr. Set the centrifuge on hold in the evening, and turn it off on arrival in the morning
11. With a micropipettor, collect eleven 1-ml fractions, from top to bottom. Put each fraction in a 3-ml tube for the TLA-100.3 rotor

Measure refractive index

12. Set aside, in separate wells of a 96-well plate, 50 µl of each fraction to use to measure the refractive index. Cover the plate with adhesive foil to prevent evaporation. Store up to 1 hr at room temperature.
13. Use a refractometer to measure the refractive index (hence the sucrose concentration, and the density) of 10 to 20 µl of each fraction from the material saved in the 96-well plate.

    A table for converting the refractive index into g/ml is available in the ultracentrifugation catalog downloadable from the Beckman website.

Prepare fractions for analysis by SDS-PAGE

14. Add 2 ml of 20 mM HEPES, pH 7.4, to each 1-ml gradient fraction, and mix by pipetting up and down two to three times.
15. Mark one side of each tube with a permanent marker, and place the tubes marked side up in a TLA-100.3 rotor.
16. Centrifuge the 3 ml-tubes containing diluted fractions 1 hr at 110,000 × *g*, 4°C.

    The TLA-100.3 rotor holds six tubes, so it is necessary to perform two centrifugations for each gradient. Keep the other tubes at 4°C until they can be centrifuged.
17. Aspirate the supernatant from each of the 3-ml tubes, leaving a drop on top of the pellet.

    The pellet most probably is not visible, but its location can be inferred from the mark on the tube. See Basic Protocol 1.
18. Resuspend the invisible pellet and transfer to microcentrifuge tube.
19. Store half of each resuspended fraction up to 1 year at −80°C. To the other half of each resuspended fraction add one third of that volume of 4× SDS sample buffer.

    This will result in a 1 × final concentration of SDS sample buffer.

    The stored fractions can be used for other purposes (e.g. functional analysis, or further purification by immunoisolation, step 22) once gel analysis (step 21) has revealed which fractions contain exosomes.

20. Heat samples in SDS sample buffer from step 19a to 70°C for 10 min or 95°C for 5 min, and load half onto a 10% or 12% SDS-PAGE gel for further analysis (*UNIT 6.1*).

21. Analyze the gel by immunoblotting (*UNIT 6.2*) to visualize different exosome markers (Table 3.22.2), or Coomassie blue staining (*UNIT 6.6*) to visualize all proteins.

    Most proteins should be recovered in fractions with densities of 1.15 to 1.20 g/ml. Contaminants that are not specifically associated with exosomes will be recovered in the densest fractions collected from the bottom of the tube (>1.25 g/ml)

Purify fractions by immunoisolation

22. Thaw frozen fractions from step 19 on ice, and pool exosome-containing gradient fractions (as determined in step 21). Dilute to 1.5 ml final with PBS.

23. In one microcentrifuge tube, combine 750 µl of the pooled fractions with 200 µl of antibody-coated Dynabeads (8×10^7 beads). In another microcentrifuge tube, combine 750 µl with 200 µl of goat anti mouse IgG-coated Dynabeads as a negative control.

24. Proceed further as in Basic Protocol 3.

    See Wubbolts et al., 2003 for more details.

SUPPORT PROTOCOL 8

IMMUNOBLOT ANALYSIS OF EXOSOMES

The overall protein composition of exosomes from various cellular sources has been investigated by several groups, using extensive proteomic analysis, immunoblotting (western blots), or FACS. Exosome sources include various immortalized cell lines or tumor cells (Clayton et al., 2001; Skokos et al., 2001; Blanchard et al., 2002; Van Niel et al., 2003; Wubboltz et al., 2003; Amzallag et al., 2004; Fevrier et al., 2004; Hegmans et al., 2004; Mears et al., 2004; Segura et al., 2005), primary cells (Heijnen et al., 1999; de Gassart et al., 2003), or bodily fluids (Bard et al., 2004; Pisitkun et al., 2004; Caby et al., 2005). Several proteins were consistently found in exosomes from many of these different sources.

To characterize the purified vesicles as exosomes, it is important to show that most of the common exosomal proteins are present. Immunoblotting is a convenient way to accomplish this. Table 3.22.2 gives an overview of the exosomal proteins that can be identified by immunoblotting. To show that a given protein is specifically enriched in exosomes, it is important to compare on the same gel identical amounts of protein from exosomes and from total lysates prepared from the producing cells. To give a more accurate quantification and to allow detection of proteins which are not very abundant in either exosomes or cells, two different amounts of exosomal or total cell proteins are run side by side on the SDS-gel for subsequent immunoblot analysis.

Materials

Exosomes (pellet from Basic Protocol 1, step 10; Basic Protocol 2, step 8; or Basic Protocol 3, step 8)
Whole cell lysates: prepared from same cell source as exosomes (Support Protocol 1, step 8)
Phosphate-buffered saline (PBS; *APPENDIX 2A*)
4× SDS sample buffer, reducing or nonreducing (i.e., with or without DTT or 2-mercaptoethanol; *APPENDIX 2A*)

Additional reagents and equipment for quantifying protein (Support Protocol 9), SDS-PAGE (*UNIT 6.1*); and western blots (immunoblotting; *UNIT 6.2*)

Table 3.22.2 Characteristic Protein Markers of Exosomes, as Assessed by Immunoblot

Protein	MW (kDa)	Cells types with exosomes containing the protein[a]	Enrichment in exosomes	Remarks
Alix	96	DC, M, U	Medium	MVB marker
Annexin II	38	DC, M, IEC, MC, Mov, U	Low	
B7-2	80	DC, B, Mast	High	Not all cells express B7-2
Calnexin	96		Absent in exosomes	Endoplasmic reticulum marker
CD9	25	DC, IEC, U, P	High	Do not use 2-mercaptoethanol or DTT in samples
CD63, CD81	50-60	Human: DC, B, IEC	High	Do not use 2-mercaptoethanol or DTT in samples
Clathrin	192	DC, IEC, B, HEK	Medium	
Flotillin-1	48	DC, Mov, U, Ret	Medium	Associated with lipid rafts
Gi2α	40	DC, Mov, U, B, Ret	Medium	
Grp94 (or gp96)	96		Absent in exosomes	Endoplasmic reticulum marker
Hsc70	70	DC, M, MC, Mov, U, B, Ret, Mast	Low	
ICAM-1	90	Mature DC, B	Variable, depending on the cell type	Do not use 2-mercaptoethanol or DTT in samples
Lamp-1 or 2	90	DC, B	Low	Enrichment of lamp-1 or lamp-2 on exosomes depends on the cell type
MFG-E8	70 + 60	DC, IEC, Mov	Very high (not detectable in cell lysates)	Not all cells express MFG-E8
MHC I	47	DC, IEC, MC, U, B, T, HEK	Medium	
MHC II	30 (α chain)	DC, IEC, B, T, Mast	High	Not all cells express MHC II
Transferrin receptor	90	DC, Mov, Ret	Variable, depending on the cell type	
Tsg101	44	DC, Mov, U	Medium	MVB marker

[a]Abbreviations for cell types: B, B cells; DC, dendritic cells; HEK, human embryonic kidney cells; IEC, intestinal epithelial cells; Mast, mast cells; M, melanoma cells; MC, mesothelioma cells; Mov, immortalized Schwann cells; MVB, multivesicular bodies; P, platelets; Ret, reticulocytes; T, T cells; U, urine.

1. Quantify the protein content of all the samples (exosomes and cell lysates) in the same assay (Support Protocol 9).
2. For each sample, prepare a tube with 10 μg and a tube with 3 μg of cell lysate, a tube of 3 μg and a tube of 10 μg (if possible) of exosomes.
3. Add PBS to a final volume of 20 μl in each tube.
4. Add 6 μl of 4× SDS sample buffer to each tube.
5. Heat to 70°C for 10 min or 95°C for 5 min.
6. Load samples on a 10% or 12% gel, putting the two exosome samples and the two lysate samples next to each other.

   See UNIT 6.1 for more information about SDS-PAGE.

7. Run the gel, transfer to a nylon membrane, and analyze by immunoblots (*UNIT 6.2*) with antibodies specific for exosomes markers, as listed in Table 3.22.2.

SUPPORT PROTOCOL 9

MEASURING THE PROTEIN CONTENT OF EXOSOMES USING THE BRADFORD ASSAY

Measuring the amount of total proteins present in the exosome preparations gives a rough idea of the amount of exosomes secreted by the cells. When performing immunoblots with exosomes and total cell lysates, or when comparing different exosome preparations on the same immunoblot, it is important to perform the protein quantification by the Bradford assay on all the samples at the same time. The protocol given below is a classical version of the assay adapted to a large number (≤80) of precious samples (it uses only 10 μl of each sample). It allows accurate quantification of many samples at once, by running them side by side with a standard BSA dilution curve. (Also see *APPENDIX 3H.*)

Materials

BSA standards (see recipe)
Phosphate-buffered saline (PBS; *APPENDIX 2A*)
Cell lysates (Support Protocol 1, step 8)
Exosome preparations (Basic Protocol 1, step 12 or Basic Protocol 2, step 8)
Bradford concentrate solution (Bio-Rad)

0.5-ml microcentrifuge tubes
Flat-bottom 96-well plates
Microplate reader with 590 nm filter

1. Thaw a set of BSA standards, and store up to 2 weeks at 4°C.

2a. *For Bradford assay of total cell lysates*: Thaw the cell lysate in ice and dilute 10 μl in 90 μl PBS (i.e., 1/10).

   This step will reduce the detergent used to lyse cells to a level that will not interfere with the color reaction of the Bradford assay.

2b. *For Bradford assay of exosome preparations*: Thaw exosomes on ice.

3. In a flat-bottom 96-well plate, load 10 μl of PBS in the first well (blank) and 10 μl of each standard BSA dilution in the eight following wells.

   Perform all protein determinations for standards and samples in duplicate.

4. Load 8 μl of PBS to each well for cell lysate samples, and 6 μl of PBS to each well for exosome samples.

5. Add 2 μl of cell lysates to the wells containing 8 μl PBS.
6. Homogenize each exosome sample by pipetting up and down several times, then load 5 μl in the wells containing 5 μl PBS.
7. Dilute Bradford concentrate solution 1/5 in distilled water. Prepare enough for 200 μl per well.
8. Add 200 μl of diluted Bradford solution to each blank, standard, and sample well.

   The color changes immediately. If the color of some samples is obviously out of line with the BSA standard curve, prepare new wells immediately with more or less sample, PBS to 10 μl, and 200 μl of diluted Bradford solution.

9. Read OD at 590 nm within 10 min.
10. Estimate the amount of exosomes purified per cell number based on the standard curve.

    The authors usually obtain 0.5 μg exosomes/10^6 immature dendritic cells in 24 hr. The amounts are quite variable with other cell lines.

ANALYSIS OF EXOSOMES BY FACS OF LABELED EXOSOMES BOUND TO BEADS

SUPPORT PROTOCOL 10

Exosomes are too small to be reliably analyzed by direct cell sorting. To overcome this problem, exosomes are fixed to beads of a size that is in the detection range of a flow cytometer. The exosomes are then labeled with fluorophore-conjugated antibodies and analyzed by FACS.

Materials

Purified exosomes (Basic Protocol 1, step 12; or Basic Protocol 2, step 8; or Basic Protocol 3)
3.9-μm latex beads, surfactant-free aldehyde/sulfate, 4% solids (Interfacial Dynamics 12-4000; *http://www.idclatex.com*)
Phosphate-buffered saline (PBS; *APPENDIX 2A*)
PBS/1 M glycine
PBS/0.5% (w/v) BSA
Fluorochrome-conjugated primary or secondary antibodies

Test tube rotator wheel for 1.5-ml microcentrifuge tubes
Microcentrifuge
Flow cytometer (e.g., FACScan; BD)

1a. *To analyze exosomes purified by antibody-coated bead*: Proceed directly to step 8.

1b. *To analyze exosomes purified by ultracentrifugation*: Incubate 5 μg purified exosomes as measured by Bradford assay (Support Protocol 9) with 10 μl latex beads 15 min at room temperature, in a 1.5-ml microcentrifuge tube.

   A nonspecific adsorption of all exosomal proteins to the latex beads occurs in this step.

2. Add PBS to a final volume of 1 ml, and incubate on a test tube rotator wheel 2 hr at room temperature.

   Overnight incubation at 4°C is also possible.

3. Add 110 μl of 1 M glycine (i.e., 100 mM final), mix gently and let stand on the bench at room temperature for 30 min.

   The purpose of this step is to saturate any remaining free binding sites on beads.

4. Microcentrifuge 3 min at 4000 rpm, room temperature. Remove the supernatant and discard.

5. Resuspend the bead pellet in 1 ml PBS/0.5% BSA and microcentrifuge 3 min at 4000 rpm, room temperature. Remove the supernatant and discard.

   If not enough proteins are used to coat beads, the bead pellet may be spread along the side of the tube. In this case, resuspend the beads by flushing the side of the tube with PBS/0.5% (w/v) BSA; the pellet will become visible after the next centrifugation

6. Resuspend the bead pellet and microcentrifuge as in step 5 to wash two more times.

7. Resuspend beads in 0.5 ml PBS/0.5% BSA.

8. Incubate 10 µl coated beads with 50 µl anti-exosomal protein antibody diluted in PBS/0.5% BSA 30 min at 4°C. Wash twice with 150 µl PBS/0.5% BSA. If necessary, incubate with 50 µl secondary antibody diluted in PBS/0.5% BSA 30 min at 4°C. Wash twice in PBS/BSA, resuspend in 200 µl of PBS/BSA.

   Use fluorophore-coupled primary antibodies, or noncoupled primary antibodies followed by fluorophore-coupled secondary antibodies. Always perform negative-control staining on another 10 µl of beads, using an irrelevant isotype-matched primary antibody.

   When analyzing exosomes purified with antibody-coated beads (Basic Protocol 3), use directly conjugated fluorescent antibodies for FACS, rather than antibodies requiring a secondary antibody step.

   If the fluorescence signal is weak with antibodies specific for abundant exosomal proteins (e.g., MHC II on dendritic cell exosomes), try to increase the amount of exosomes and/or decrease the amount of beads in step 1.

9. Analyze antibody-stained exosome-coated beads on a flow cytometer. Adjust the forward scatter (FSC) and side scatter (SSC) to see both single beads and bead doublets. Gate on both single and doublet beads to analyze fluorescence. Compare fluorescence obtained with specific antibody and with irrelevant isotype control.

   When performing flow cytometric analysis of exosome-coated Dynal beads it is important to be aware that these paramagnetic beads may cause blockages in certain flow cytometric instruments. This is due to the use of electro-magnetic valves controlling the fluidics of certain instruments. This may present a problem for some instruments including BD FACScalibur range and BD FACScanto. The authors have never experienced any such problems when using BD FACScan.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

BSA standards

Prepare a set of standard dilutions with BSA, starting with 500 µg/ml, performing two-fold dilutions in PBS to 4 µg/ml (seven dilutions). Dispense 100-µl aliquots of the diluted BSA standard curve solutions into microcentrifuge tubes and store up to 6 months at –20°C.

Cell lysis buffer

300 mM NaCl
50 mM Tris, pH 7.4 (adjust pH of Tris base with drops of 6 N HCl)
0.5% Triton X-100 or NP-40
Store up to 1 year at room temperature
Add antiproteases cocktail (Roche) just before use

Glutaraldehyde, 1% (v/v)

Dilute EM-grade glutaraldehyde fixatives (commercially available as 8%, 25% or 70% aqueous solutions; Polysciences or Sigma) in 0.1 M sodium phosphate buffer, pH 7.4 (*APPENDIX 2A*), to the appropriate dilution. Store up to 6 months at −20°C or up to 1 week at 4°C after thawing.

0.1 M PIPES or HEPES can also be used. The buffers used to prepare fixatives need to have a good buffering capacity to maintain a pH of about 7.4 during fixation.

HEPES stock solution

2.4 g *N*-2-hydroxyethylpiperazine-*N*′-2-ethanesulfonic acid (HEPES; 20 mM final)
300 H_2O
Adjust pH to 7.4 with 10 N NaOH, added slowly
Adjust volume to 500 ml with H_2O
Sterilize by passing through a 0.22-μm filter
Store up to 2 years at 4°C

HEPES/sucrose stock solution

2.4 g hydroxyethylpiperazine-*N*′-2-ethanesulfonic acid (HEPES; 20 mM final)
428 g protease-free sucrose (ICN; 2.5 M final)
150 ml H_2O
Adjust pH to 7.4 with 10 N NaOH
Adjust volume to 500 ml with H_2O
Store up to 2 years at 4°C

Methyl cellulose, 2% (w/v)

Heat 196 ml of distilled water to 90°C and add 4 g methyl cellulose (Sigma, 25 centipoise, M-6385) with stirring. Rapidly cool on ice with stirring, until the solution has reached 10°C. Continue slow stirring overnight at 4°C. Stop stirring and allow the solution "ripen" for 3 days at 4°C. Bring to a final volume of 200 ml with water. Centrifuge using polycarbonate centrifuge bottles with cap assemblies 95 min at 100,000 × *g*, 4°C. Collect the supernatant and store up to 3 months at 4°C.

Paraformaldehyde (PFA), 2% and 4% (w/v)

Dissolve 4 g of PFA powder (Polysciences) in 90 ml of 0.1 M sodium phosphate buffer (see *APPENDIX 2A*) and heat to 65°C while stirring, If needed, add drops of 1 N NaOH until the solution becomes clear. Bring to 100 ml with 0.1 M sodium phosphate buffer. Cool and filter. Store at −20°C in 4- to 10-ml aliquots. Use thawed aliquots immediately and do not refreeze. To make 2% glutaraldehyde, dilute 4% glutaraldehyde with 0.1 M sodium phosphate buffer.

Tris/sucrose/D_2O solution

30 g protease-free sucrose
2.4 g Tris base
50 ml D_2O
Adjust pH to 7.4 with 10 N HCL drops
Adjust volume to 100 ml with D_2O
Sterilize by passing through a 0.22-μm filter
Store up to 2 months at 4°C

Uranyl acetate (4% w/v), pH 4

Weigh 2 g of uranyl acetate (Polysciences) and dissolve in 50 ml distilled water. Store up to 4 months at 4°C, in a 20-ml plastic syringe protected from light. Just before use, filter the amount needed of uranyl solution with a 0.22-μm filter.

CAUTION: *Radioactive materials require special handling. See the institutional Radiation Safety Office for guidelines concerning proper handling and disposal.*

The uranyl acetate crystals are difficult to dissolve and it may be necessary to use a rotating wheel for mixing.

Uranyl-oxalate, pH 7

Mix 4% uranyl acetate, pH 4 (see recipe) with 0.15 M solution of oxalic acid (0.945 g in 50 ml distilled water), in a 1:1 ratio. Adjust the pH to 7 by adding 25% (w/v) NH_4OH in drops to prevent formation of insoluble precipitates. Store in the dark up to 1 month at 4°C.

COMMENTARY

Background Information

The purification of exosomes from cell culture supernatants or other biological fluids is not trivial. The most characteristic feature of exosomes that should be used both for their purification and characterization is their density. The most usual way of determining exosomes' density is on continuous sucrose gradients. A buoyant density of 1.23 to 1.16 g/liter, together with the presence of endocytic markers (e.g., tsg101 or alix), and images in whole-mount electron microscopy showing the characteristic cup shaped morphology are good evidence that one is dealing with exosomes. Some groups have argued that the ultrafiltration method (Lamparski et al., 2002) is less harmful and more reliable than the ultracentrifugation method described in this unit. The authors have compared the two preparation methods for the same dendritic cell supernatants side by side, using biochemical, morphological, and functional assays for exosomes. They found no significant differences. The ultrafiltration method is advisable mainly for clinical-grade applications of exosomes, because it allows rigorous control of the environment during the purification procedure.

The issue of exosome quantification also deserves some attention. Two approaches to quantifying the amount of exosomes in a given preparation have been used. One is to quantify the amount of a particulate exosomal protein using ELISA or immunoblotting. The main limitation of this approach is that it is very hard to distinguish between a modification of the number of molecules per exosome (e.g., the proportion of exosomes expressing any given marker) and a real modification in the amount of exosomes. The other approach for quantifying exosomes is to measure the protein concentration in the exosome preparations. In the authors' experience, if the FBS used for the production of the conditioned media is properly cleared and if one carries out the experiment carefully, the protein concentration has proven to be a reliable and reproducible approach to quantification.

Recent work on exosomes from antigen-presenting cells has caused renewed interest in this controversial field. It is the authors' feeling that the study of exosomes is now in a critical phase of scientific development. Their identity as a bone fide secreted subcellular compartment is established. The challenge for the next few years is to understand their physiological mode of action and to learn how to use them in therapeutic strategies (e.g., vaccination).

Critical Parameters and Troubleshooting

When preparing exosomes from cell culture supernatants, it is important to make sure that the cells are healthy (including no contamination with mycoplasma) and viable at the end of the exosome production period. If not, the product will be heavily contaminated with membrane fragments that are not exosomes. Fragments of apoptotic cells are bigger than exosomes when observed by whole-mount EM, do not migrate at the proper density on sucrose gradients, and contain high amounts of nuclear proteins, such as histones (Théry et al., 2001).

When designing experiments involving exosome purification, it is important to make sure that there is an assay to characterize the preparations and show that they contain exosomes and no other contaminants. Whole-mount

EM combined with immunoblotting is the best choice.

Aggregates of exosomes can often be observed in preparations obtained by ultracentrifugation. Resuspending the pellet in PBS containing EDTA may help, but it can also be detrimental if exosomes are subsequently used in functional assays.

Particular attention should be given to the centrifugation tubes used to prepare exosomes. Exosomal membranes may stick to some ultracentrifugation tubes, such as ultraclear tubes from Beckman (W. Stoorvogel, Faculty of Veterinary Medicine, Utrecht University, pers. comm.).

Anticipated Results

The amount of exosomes produced varies with the cell type. The authors usually obtain 0.3 to 0.5 μg of exosomes per 10^6 dendritic cells in 24 hr (Segura et al., 2005). Amounts of exosomes obtained from most murine tumor cell lines (e.g., fibrosarcomas, melanomas, carcinomas) are in the same range. In contrast, very small amounts of exosomes seem to be produced by a mouse mastocytoma (P815) or thymoma (EL4; C. Théry, A. Clayton, S. Amigorena, and G. Raposo, unpub. observ.) Intestinal epithelial adenocarcinoma cell lines seem to produce slightly fewer exosomes (~0.05 μg/10^6 cells; Van Niel et al., 2001). Given the lack of details in the literature, it is difficult to say today whether all cell types produce exosomes and at what level, but exosome production seems to be a rather general mechanism, and an average level of production of ~0.1 μg/10^6 cells may be taken as a rough general estimate.

Purified exosomes should appear by EM as 50- to 100-nm vesicles surrounded by a lipid layer with a cup-shaped morphology (Fig. 3.22.2A) and exosomal proteins on their surfaces. Smaller vesicles (<50 nm), not displaying the cup-shaped morphology, are sometimes observed in preparations of exosomes, especially if the centrifugation is performed at >100,000 × *g*. Such vesicles cannot be considered exosomes.

When separating 30 to 50 μg of exosomal proteins on 10% or 12% SDS-gels, there should be a pattern of bands ranging from the largest to the smallest sizes, different from the pattern obtained with whole cell lysates (Fig. 3.22.2B). Be aware that exosome preparations showing mainly one band at ~60 kDa cannot be considered as good preparations because they probably contain mostly BSA from the culture medium.

Time Considerations

Exosome purification

The time required to produce cell culture conditioned medium from which exosomes will be purified is 24 to 48 hr after the cells have reached about 70% confluency (which varies greatly with the cell type). The time required to prepare the exosome collection medium is 14 hr (overnight). It takes ~30 min to 1 hr to collect the conditioned medium, depending on the number of different cells and the volume of conditioned medium. The conditioned medium can then be stored for up to a week at 4°C. From this conditioned medium, the whole procedure to purify exosomes by ultracentrifugation takes ~4 hr (Basic Protocol 1). If it has been demonstrated that Alternate Protocol can be used, the whole exosome purification procedure will take 3 hr instead of 4 hr. For the extra sucrose-cushion step (Support Protocol 3), allow an extra 2.5 to 3 hr. To purify exosomes from viscous fluids (Basic Protocol 2) it takes 6 hr in total. Purification of exosomes by immunoisolation (Basic Protocol 3) requires 1 hr the first day and 45 min the next day (with a 24-hr incubation in between).

Exosome analysis

Preparation of whole-mounted exosomes for EM analysis takes a maximum of 1.5 hr. Immunohistochemical staining of exosomes for EM requires 2.5 hrs for single labeling. If the primary antibody is not directly recognized by protein A, an extra 1 hr is required for the use of a bridging antibody. For double labeling the time required is doubled. Analysis of exosomes by immunoblotting takes ~1 hr to prepare the samples, plus the time required to perform SDS-PAGE followed by electrotransfer and antibody incubations; the total time varies depending on the systems used and the laboratory's preferred protocols. For exosomes analysis by FACS, it takes 2.5 hr to prepare exosome-coated beads, followed by the time required for incubation in antibodies (30 to 60 min) and flow cytometric analysis (30 min to 1 hr).
