When thawing the proteins, quick thawing at 37°C is recommended to decrease the chances of precipitation and shearing from ice crystals. Immediately after the quick thaw, keep the proteins on ice until they are added to the medium. The thawed protein can be kept on ice at 4°C for up to 1 week with no significant loss of transducibility. Continual storage of the protein at 4°C will eventually result in protein precipitation, and is therefore not recommended for long-term storage.

Addition of the fusion proteins to tissue culture system

Because of the efficiency of this transduction system, it may be important to add the fusion protein to the culture medium prior to

addition of the medium to the cells. Therefore, after plating the cells at the appropriate density for the experimental procedure, wash the cells once in fresh medium. Add the appropriate volume of fusion protein to the required volume of tissue culture medium—i.e., 0.2 ml to 1.8 ml of DMEM containing 10% fetal bovine serum and 1× penicillin/streptomycin per well of 6-well dish—and then add this volume to the cells. It is important that the volume of fusion protein not exceed 10% of the tissue culture volume. Toxic effects and slowing of the cell cycle have been observed in some cases when greater volumes were used.

Dose and toxicity of the fusion proteins

It is virtually impossible to predict possible toxicity of the fusion protein in certain cell culture systems. If toxicity is noticed, several options are available. First, one can decrease the molar concentration of the fusion protein to the cells. In general, concentrations of >200 nM fusion protein are not necessary. The working range of these proteins vary from 50 to 200 nM. In a rare case, 1 μM was necessary (Ezhevsky et al., 1997). Therefore, the range in which a protein can be used must be decided on a fusion-to-fusion basis. Second, changing the buffer in which the protein is stored may be necessary (see Alternate Protocols 2 and 3).

The final concentration of cells used in a transduction experiment is critical. The concentration of transducing protein that is required to observe an effect is dependent upon the starting cell population. The smaller the target cell population, the greater the intracellular concentration will be. Studies using FITC-labeled TAT-p16 in normal diploid fibroblasts have showed greater fluoresecence intensity of the fusion when fewer cells were plated (M. Becker-Hapak, unpub. observ.). Therefore, in suspension cultures or adherent cells, it is generally recommended that the lowest possible concentration of cells be used when fusion protein concentrations are limited.

Half-life of fusion proteins

The authors have observed dramatic differences in the half-lives of fusion proteins. Degradation of the fusion protein can be determined by immunoblotting extracts of the trypsinized and washed cells. Generally, if the transducing protein is to be incubated for longer than 24 hr, addition of supplemental protein is suggested. The necessity for supplementary additions of any protein of interest must also be experimentally determined.

Troubleshooting

Established clone is no longer expressing fusion protein

In some cases, the bacteria may stop expressing the fusion protein. If this occurs, simply go to another one of the backup clones or retransform the plasmid into fresh BL-21 (DE3)pLysS and rescreen for high-expressing clones.

Poor expression of the fusion protein

It may be necessary to induce the fusion protein of interest. Bl-21 cells, carry an IPTG-inducible, T7 polymerase (DE3) and a T7 polymerase specific protease (pLysS) under a chloramphenicol resistance marker. The pLysS keeps the T7 polymerase at a negligible concentration until the organism goes into log phase (during IPTG induction). If the expression of the specific fusion protein is low, induce the T7 polymerase by adding 2 μg/ml IPTG when the 200 ml overnight culture is added to 1 liter of LB-ampicillin medium. Culture as described in the protocols above.

Another factor affecting the protein expression levels is the choice of supplier for the LB medium. In the authors' experience, LB medium purchased from certain vendors have produced more recombinant protein than others, so it is recommended that various vendors and lots be tested for maximal yield of any protein of interest. One may, at the same time, culture the fusion in a richer medium such as Terrific Broth (TB). However, the routine use of this medium is not recommended because some fusions have proven to express more robustly in LB than TB.

Many T7 promotor–driven fusions can be expressed in a multitude of BL-21(DE3) derivatives. The authors have found a single source of many of these hosts. Novagen provides a reasonably priced set of competent DE3 derivatives (cat. no. 71032-3) which are very helpful in expression of various eukaryotic proteins that cannot be efficiently expressed in BL-21 (DE3) pLysS. Transformation of the pure plasmid into a panel of these hosts and side-by-side detection via immunoblotting can show dramatic differences in host-to-host differences in fusion expression.

Ion-exchange chromatography

Difficulties encountered during any standard ion-exchange procedure are also observed with TAT-fusion proteins. The authors highly recommend the batch test tube procedure outlined in Amersham Pharmacia Biotech's ion-exchange

handbook (Amersham Biosciences, 2002) to rapidly identify binding and elution protocols.

Protein seems to be degrading during the purification procedure

Be sure to use the protease inhibitor cocktail described in Reagents and Solutions. This cocktail should be added at every step of the purification when a new buffer is used. If the protein was sonicated in PBS maintain the sonicate at 4°C at all times and perform the chromatographic steps in the cold.

Protein precipitates after dialysis

The concentration of the protein may be too high. Dilute the protein in buffer Z to a concentration of <1 mg/ml before applying it to the dialysis cassette.

Try using the PD-10 column to remove the urea. However, the authors have noticed that if the protein precipitates during dialysis, it is likely to precipitate during the PD-10 step as well. Therefore, the only way to ensure soluble protein is to use the ion-exchange method of achieving soluble proteins.

No biological effect with wild-type protein

The transduced protein, may require a concentration higher than 200 nM (working concentrations with in cell culture varies from 50 to 200 nM, but can require upwards of 1 μM) to obtain the specific effect. For example, the authors have observed that in wild-type cells (i.e., SiFTs) that have an already high concentration of p16 (later passage), less TAT-p16 wt is required to achieve a G1 arrest, than in those expressing low concentrations of the protein.

Another factor that can affect function of the TAT-fusion protein is the position of the TAT-leader. The authors have observed that the TAT-leader inhibits the ability of p16 to bind to TAT-CDK4, but the leader has no effect on TAT-CDK2. In such cases, Cé terminal fusions should help.

Check if the protein is active after freeze-thaw. Some proteins cannot be frozen at any step of the purification from bacterial harvesting to storage. If this is the case, store the protein on ice at 4°C. BSA may also be required to help keep the protein from precipitating or degrading.

Unknown serum factors can inhibit, inactivate, or degrade exogenously added fusion proteins causing negative results. To examine if this is occurring with the fusion, simply dilute the pure protein into cell-free culture medium (usually in the presence of 10% v/v fetal bovine serum) at 37°C for varying amounts of time, then immunoblot for the pure protein. Nonspecific proteolytic degradation can be minimized by the addition of specific protease inhibitors. However, solutions to these types of problems are most likely found by the preparation of point-specific mutants.

Choice of tags

While the pTAT-HA vector utilizes the hemagglutinin tag to allow one to detect the fusion, other popular tags used concomitantly can inhibit transduction of the purified protein. It is presumed that the very acidic nature of tags such as FLAG can associate with the TAT domain and very effectively negate the transducibility of the fusion (M. Becker-Hapak, unpub. observ.).

Anticipated Results

Protein yield

The quantity of protein yielded by a 1-liter LB-ampicillin culture will vary depending upon the construct. For example, TAT-β-galactosidase will yield 4 to 6 mg of total protein, whereas TAT-caspase 3 only yields 500 μg. In general non-cytotoxic constructs, such as TAT-p27, yield 1 to 2 mg of protein per liter of LB-ampicillin medium.

Fluorescein-labeled fusion proteins

The efficiency of fluorescein labeling will vary from day to day and protein to protein. One can quantitate the fluorescence intensity using a fluorometer prior to addition of the label to the cell culture. When comparing fluorescently labeled TAT-fusion versus the nontransducing pure protein by confocal microscopy, TAT-fusion proteins will show an even fluorescence intensity throughout the cell, with some punctate staining in the nucleoli (Fig. 20.2.4). The nontransducing protein will show a lower intensity "rim" fluorescence due to nonspecific sticking of the labeled protein to the cell membrane. If examining transduction by immunohistochemistry, typical results show detection of the transducing protein after as little as 5 min and peaking between 4 and 6 hr after transduction, when incubated at 37°C. Early time points will show the protein nonspecifically distributed throughout the whole cell, while the later time points will show a more specific staining pattern. The putative nuclear localization sequence will not prevent the fusion from going in and out of the nucleus. For example, TAT-p27 WT shows a ubiquitous distribution when transduced into HepG2 cells in the first 12 hr, then concentrates in the nucleus 24 hr after introduction of the fusion protein. However, if HepG2 cells are

cultured in the presence of HGF, TAT-p27 is shuttled out of the nucleus and into the cytoplasm over a 24 hr period (S.S. McAllister and S.F. Dowdy, unpub. observ.).

Biological activities of transduced TAT-fusion proteins

The activities expected of the TAT-fusion proteins vary with application. Consequently, phenotypic readouts vary as well. In general, the time frame in which the phenotype can be recorded can vary from 5 min (enzymatic assays) to days (morphological changes). Table 20.2.1 shows some results obtained from various classes of TAT-fusion molecules. The table details the dose of fusion that was required, biological effect observed, and time frame in which the result was measured. To expand on examples of the utilization of TAT-full length fusion technology, examples of selected fusions are shown in Table 20.2.2. The table not only lists the TAT-fusion created and the function, but it also summarizes some other cell types that were not used in transduction experiments listed in Table 20.2.1.

Time Considerations

Total time required

Identification of protein and determining necessity of IPTG induction requires 2 days

Isolation of protein requires 1 to 2 days.

Detection of protein transduction requires 1 to 2 days.

For biological readouts the time required is pathway/protein–dependent.

Stopping points

In general, one should consider any protein left at room temperature as being susceptible to degredation. Therefore, if one wishes to stop at any point during the protein purification, one should consider freezing the preparation if the duration will be longer than overnight. Alternatively, store the protein at 4°C on ice overnight, if the protein of interest is sensitive to freeze/thaw. For example; TAT-β-gal, whose enzymatic activity is abolished if frozen at any point but it retains transducibility, must be stored at 4°C in the presence of 0.1% BSA to remain active for up to one month on ice at 4°C.

Calcium Phosphate Transfection

This unit presents two methods of calcium phosphate–based eukaryotic cell transfection that can be used for both transient and stable transfections. In these protocols, plasmid DNA is introduced to monolayer cell cultures via a precipitate that adheres to the cell surface. A HEPES-buffered solution is used to form a calcium phosphate precipitate that is directly layered onto the cells (see Basic Protocol). For some cells, shocking the cells with glycerol or DMSO (see Support Protocol) improves transfection efficiency. In the alternate high-efficiency method, a BES-buffered system is used that allows the precipitate to form gradually in the medium and then drop onto the cells (see Alternate Protocol). The alternate method is particularly efficient for stable transformation of cells with circular plasmid DNA. For transformation with linear plasmid or genomic DNA, or for transient expression, however, the Alternate Protocol is comparable to the Basic Protocol. Both methods of transfection require very high-quality plasmid DNA. Factors that can be optimized for calcium phosphate transfections are presented in *UNIT 20.7*. Additional details of mammalian cell culture are given in *UNIT 1.1*.

TRANSFECTION USING CALCIUM PHOSPHATE–DNA PRECIPITATE FORMED IN HEPES

BASIC PROTOCOL

A precipitate containing calcium phosphate and DNA is formed by slowly mixing a HEPES-buffered saline solution with a solution containing calcium chloride and DNA. This precipitate adheres to the surface of cells and should be visible in the phase contrast microscope the day after transfection. Depending on the cell type, up to 10% of the cells on a dish will take up the DNA precipitate through an as yet undetermined mechanism. Glycerol or dimethyl sulfoxide shock increases the amount of DNA absorbed in some cell types (see Support Protocol).

Materials

Exponentially growing eukaryotic cells (e.g., HeLa, BALB/c 3T3, NIH 3T3, CHO, or rat embryo fibroblasts)
Complete medium (depending on cell line used)
CsCl-purified plasmid DNA (10 to 50 µg per transfection)
2.5 M $CaCl_2$ (see recipe)
2× HEPES-buffered saline (HeBS; see recipe)
PBS (*APPENDIX 2A*)

10-cm tissue culture dishes
15-ml conical tube

Additional reagents and equipment for ethanol precipitation (*APPENDIX 3A*) and mammalian cell tissue culture (*UNIT 1.1*)

NOTE: All solutions and equipment coming into contact with cells must be sterile, and proper sterile technique should be used accordingly.

NOTE: All culture incubations are performed in a humidified 37°C, 5% CO_2 incubator unless otherwise specified.

1. Split exponentially growing eukaryotic cells into 10-cm tissue culture dishes the day before transfection. Feed cells with 9.0 ml complete medium 2 to 4 hr prior to precipitation.

   When transfecting adherent cells that double every 18 to 24 hr, a 1:15 split from a confluent dish generally works well. On the day of the transfection, it is important that cells are thoroughly separated on the dish, as the ability to take up DNA is related to the surface

Contributed by Robert E. Kingston, Claudia A. Chen, and Hiroto Okayama
Current Protocols in Cell Biology (2003) 20.3.1-20.3.8

area of the cell exposed to the medium. Cells should be split in a manner that accomplishes this.

The desired density of cells on dishes to be transfected will vary with cell type and the reason for doing the transfection. The optimal density is that which produces a near confluent dish when the cells are harvested or split into selective medium.

2. Ethanol precipitate the DNA to be transfected and air dry the pellet by inverting the microcentrifuge tube on a fresh Kimwipe inside a tissue culture hood. Resuspend the pellet in 450 µl sterile water and add 50 µl of 2.5 M $CaCl_2$.

   The amount of DNA that is optimal for transfection varies from 10 to 50 µg per 10-cm plate, depending on the cell line to be transfected.

   DNA to be transfected should be purified twice by CsCl gradient centrifugation. DNA can also be prepared using column procedures. Some column procedures produce DNA that does not transfect well, so column-purified DNA should be tested and compared to CsCl-purified DNA for transfection efficiency. Supercoiled DNA works well in transfections. Impurities in the DNA preparation can be deleterious to transfection efficiency. A description of how to optimize the amount of DNA to transfect and other parameters of calcium phosphate–mediated transfection is provided in the discussion of optimization of transfection (UNIT 20.7).

   Ethanol precipitation sterilizes the DNA to be transfected. For transfections that will be harvested within 3 to 4 days (transient analysis), this is not necessary. For transient experiments, many researchers make a 450-µl aqueous solution containing the DNA directly, without ethanol precipitation. If this is done, care should be taken to keep the amount of Tris in the solution to a minimum, as Tris may alter the pH of the precipitate and therefore reduce transfection efficiency.

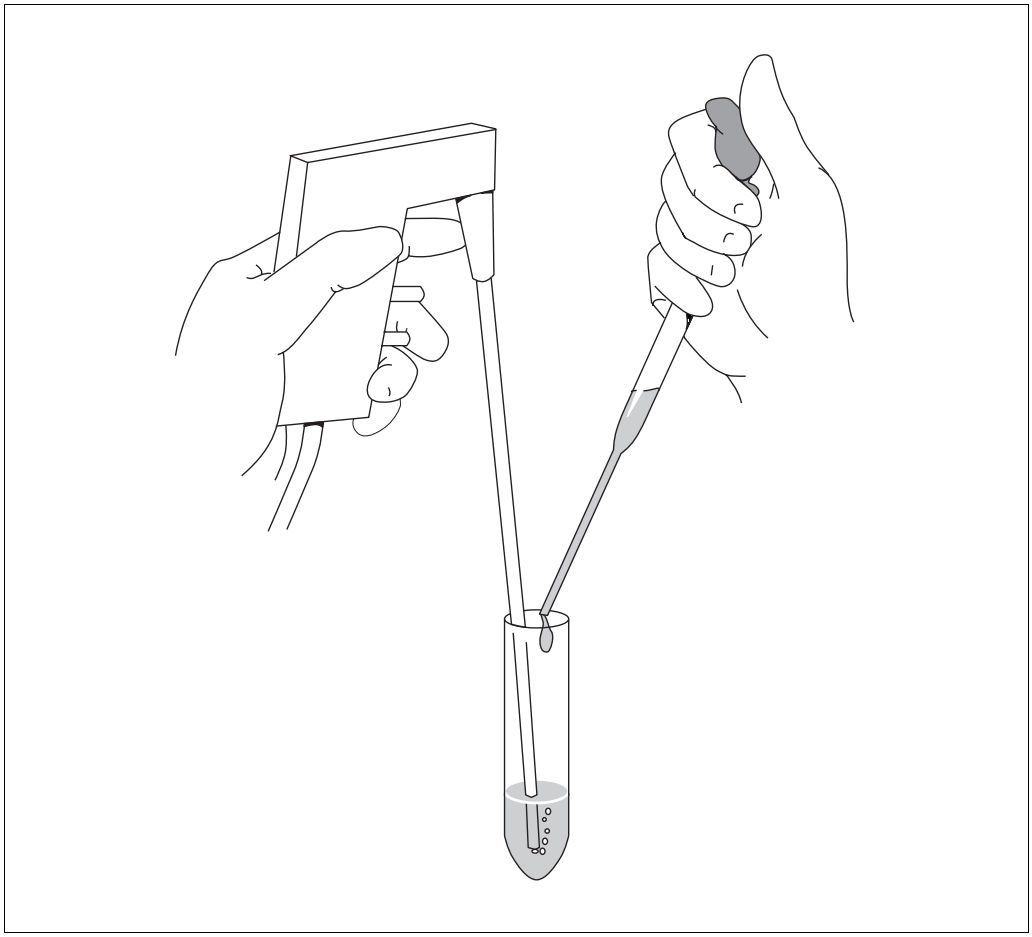

Figure 20.3.1 Formation of calcium phosphate precipitate.

3. Place 500 µl of 2× HeBS in a sterile 15-ml conical tube. Use a mechanical pipettor attached to a plugged 1- or 2-ml pipet to bubble the 2× HeBS and add the DNA/$CaCl_2$ solution dropwise with a Pasteur pipet (see Fig. 20.3.1). Immediately vortex the solution for 5 sec.

   If no mechanical pipettor is available, the solution can be bubbled by blowing through rubber tubing that is attached to a pipet via a filter. The filter is necessary to maintain sterility. This does not give as reproducible results as the mechanical pipettor.

4. Allow precipitate to sit 20 min at room temperature.

5. Use a Pasteur pipet to distribute the precipitate evenly over a 10-cm plate of cells and gently agitate to mix precipitate and medium.

6. Incubate the cells 4 to 16 hr under standard growth conditions. Remove the medium. Wash cells twice with 5 ml PBS and feed cells with 10 ml complete medium.

   The amount of time that the precipitate should be left on the cells will vary with cell type. For hardy cells such as HeLa, NIH 3T3, and BALB/c 3T3, the precipitate can be left on for 16 hr. Other cell types will not survive this amount of exposure to the precipitate. See discussion of optimization of transfection (UNIT 20.7) for optimization of this step as well as for a discussion of how to determine whether glycerol shock is useful.

7. For transient analysis, harvest the cells at the desired time point. For stable transformation, allow the cells to double twice before plating in selective medium.

GLYCEROL/DMSO SHOCK OF MAMMALIAN CELLS

SUPPORT PROTOCOL

The Basic Protocol works well for cell lines such as HeLa, BALB/c 3T3, NIH 3T3, and rat embryo fibroblasts. Transfection efficiency in some cell lines, such as CHO DUKX, is dramatically increased by "shocking" the cells with either glycerol or DMSO. Precipitates are left on the cell for only 4 to 6 hr, and the cells are shocked immediately after removal of the precipitate.

Additional Materials *(also see Basic Protocol)*

10% (v/v) glycerol solution or DMSO in complete medium, sterile
PBS (*APPENDIX 2A*), sterile

Replace step 6 of the Basic Protocol with the following:

6a. Incubate the cells 4 to 6 hr and remove the medium. Add 2.0 ml of a sterile 10% glycerol solution. Let the cells sit 3 min at room temperature.

   Alternatively, 10% or 20% DMSO can be used. DMSO tends to be somewhat less harmful to the cells, but also may not work as well.

6b. Add 5 ml of PBS to the glycerol solution on the cells, agitate to mix, and remove the solution. Wash twice with 5 ml of PBS. Feed the cells with complete medium.

   It is important to dilute the glycerol solution on the cells with PBS before removing the glycerol solution so the cells do not stay in glycerol too long. Excessive exposure to glycerol will kill cells.

ALTERNATE PROTOCOL

HIGH-EFFICIENCY TRANSFECTION USING CALCIUM PHOSPHATE–DNA PRECIPITATE FORMED IN BES

A solution of calcium chloride, plasmid DNA, and *N,N*-bis(2-hydroxyethyl)-2-aminoethanesulfonic acid (BES) buffer, pH 6.95, is added to a plate of cells containing culture medium. The plates are incubated overnight while a calcium phosphate–DNA complex forms gradually in the medium under an atmosphere of 3% CO_2. With this method, 10% to 50% of the cells on a plate stably integrate and express the transfected DNA. Transient expression under these conditions is comparable to that obtained with the Basic Protocol. Glycerol or DMSO shock does not increase the number of cells transformed.

Materials

Exponentially growing mammalian cells (see Critical Parameters)
Complete medium: Dulbecco modified Eagle medium containing 10% (v/v) fetal bovine serum (FBS)
CsCl-purified plasmid DNA
TE buffer, pH 7.4 (*APPENDIX 2A*)
2.5 M $CaCl_2$ (see recipe)
2× BES-buffered solution (BBS; see recipe)
PBS (*APPENDIX 2A*)
Selection medium (*APPENDIX 3A*; optional)

10-cm tissue culture dishes
35°C, 3% CO_2 humidified incubator
35° to 37°C, 5% CO_2 humidified incubator
Fyrite gas analyzer (optional; Fisher Scientific or Curtin Matheson)

NOTE: All solutions and equipment coming into contact with cells must be sterile, and proper sterile technique should be used accordingly.

1. Seed exponentially growing mammalian cells at 5×10^5 cells/10-cm tissue culture dish in 10 ml complete medium the day prior to transfection.

   There should be <10^6 cells/dish just prior to infection. Enough surface area should remain on the plate for at least two more doublings.

2. Dilute CsCl-purified plasmid DNA with TE buffer to 1 µg/µl. Store the DNA solution at 4°C.

   Purity of the plasmid DNA is critical.

   The optimum amount of plasmid to use can be determined by transfecting three dishes of cells with 10, 20, and 30 µg of plasmid DNA and incubating overnight. The dishes should then be examined with a microscope at 100×. A coarse, clumpy precipitate will form at DNA concentrations that are too low, a fine (almost invisible) precipitate will form at concentrations that are higher than optimal, and an even, granular precipitate will form with optimal DNA concentrations.

3. Prepare 0.25 M $CaCl_2$ from 2.5 M stock. Mix 20 to 30 µg plasmid DNA with 500 µl of 0.25 M $CaCl_2$. Add 500 µl of 2× BBS, mix well, and incubate 10 to 20 min at room temperature.

4. Add the calcium phosphate–DNA solution dropwise onto the medium-containing plate while swirling the plate. Incubate 15 to 24 hr in a 35°C, 3% CO_2 incubator.

   Level of carbon dioxide is critical. Use a Fyrite gas analyzer to measure percent CO_2 prior to incubation.

5. Wash the cells twice with 5 ml PBS, and add 10 ml complete medium. For stable transformation, incubate overnight in a 35° to 37°C, 5% CO_2 incubator. For studies involving transient expression, incubate the cells for 48 to 72 hr after adding the DNA.
6. Split the cells 1:10 to 1:30, depending on the growth rate of the host cell, before beginning to select stable transformants. Incubate overnight in a 35° to 37°C, 5% CO_2 incubator.
7. Start selection by changing the medium to selection medium or by incubating cells under appropriate selection conditions.

REAGENTS AND SOLUTIONS

*Use deionized, distilled water or equivalent for all recipes and protocol steps. For common stock solutions, see **APPENDIX 2A**; for suppliers, see **SUPPLIERS APPENDIX**.*

BES-buffered solution (BBS), 2×

50 mM *N,N*-bis(2-hydroxyethyl)-2-aminoethanesulfonic acid (BES; Calbiochem-Novabiochem)
280 mM NaCl
1.5 mM Na_2HPO_4, pH 6.95
800 ml H_2O
Adjust to pH 6.95 with 1 N NaOH, room temperature
Add H_2O to 1 liter
Filter sterilize through a 0.45-µm nitrocellulose filter (Nalgene)
Store in aliquots at −20°C

As discussed in the Commentary, the pH of this solution is critical (pH 6.95 to 6.98). When a new batch of 2× BES buffer is prepared, its pH should be checked against a reference stock prepared (and tested) earlier.

This solution can be frozen and thawed repeatedly.

$CaCl_2$, 2.5 M

183.7 g $CaCl_2 \cdot 2H_2O$ (Sigma; tissue culture grade)
H_2O to 500 ml
Filter sterilize through a 0.45-µm nitrocellulose filter (Nalgene)
Store at −20°C in 10-ml aliquots

This solution can be frozen and thawed repeatedly.

HEPES-buffered saline (HeBS) solution, 2×

16.4 g NaCl (0.28 M final)
11.9 g HEPES (N-2-hydroxyethylpiperazine-*N*′-2-ethanesulfonic acid; 0.05 M final)
0.21 g Na_2HPO_4 (1.5 mM final)
800 ml H_2O
Titrate to pH 7.05 with 5 N NaOH
Add H_2O to 1 liter
Filter sterilize through a 0.45-µm nitrocellulose filter
Test for transfection efficiency
Store at −20°C in 50-ml aliquots

An exact pH is extremely important for efficient transfection. The optimal pH range is 7.05 to 7.12.

There can be wide variability in the efficiency of transfection obtained between batches of 2× HeBS. Efficiency should be checked with each new batch. The 2× HeBS solution can be rapidly tested by mixing 0.5 ml of 2× HeBS with 0.5 ml of 250 mM $CaCl_2$ and vortexing. A fine precipitate should develop that is readily visible in the microscope. Transfection efficiency must still be confirmed, but if the solution does not form a precipitate in this test, there is something wrong.

COMMENTARY

Background Information

Calcium phosphate transfection was first used to introduce adenovirus DNA into mammalian cells by Graham and van der Eb (1973). It was later found to be possible to integrate exogenous DNA into mammalian chromosomes using this technique (Wigler et al., 1978). The protocol described here has evolved from these methods; in particular, the order of addition of the HEPES-buffered saline solutions (HeBS) to calcium chloride is different. In addition, many investigators have found that it is not necessary to add chromosomal DNA as carrier when doing a transfection. Transfections work well if only plasmid DNA, such as pUC vectors, is used.

This HEPES-based approach has been used to analyze replication and promoter function using "transient" protocols, in which cells are harvested 48 to 60 hr after the transfection is started. It also is presently the most widely used technique for producing cell lines in which transfected DNA is stably integrated into the chromosome, although the BES-based technique (see Alternate Protocol) is gaining widespread use for production of stable transformants. Calcium phosphate–mediated transfection tends to work much better than DEAE-dextran-mediated transfection (*UNIT 20.4*) in formation of stable cell lines. It is believed that this is because cells in a calcium phosphate transfection pick up more DNA than DEAE-dextran-transfected cells. Electroporation (*UNIT 20.5*) and liposome-mediated transfection (*UNIT 20.6*) can also be successfully used to produce stable cell lines.

Another major strength of calcium phosphate transfection is that transfected cells generally contain a representative sampling of the various plasmids in the precipitate. Hence, one can prepare a 10:1 ratio of two plasmids and expect that the plasmids will be present in that ratio in the transfected cells.

The BES-based high-efficiency calcium phosphate transfection (see Alternate Protocol) is a modification of the standard calcium phosphate method that employs a buffer system originally developed for phage particle–mediated gene transfer (Ishiura et al., 1982). With this buffer system the calcium phosphate–DNA precipitate forms gradually in the culture medium, dropping gently onto the cells over a 15- to 24-hr period. This method can stably transform most common mammalian fibroblast and epithelial cell lines 10- to 100-fold more efficiently than other methods. For transient expression, it is no better than the standard method.

Critical Parameters and Troubleshooting

Calcium phosphate transfections are finicky—they are not difficult to do, they just do not always work—even in the hands of people who routinely do them. In the Basic Protocol, the most common reason for failure is a 2× HeBS solution that is no longer at the appropriate pH. The optimum pH range for transfection is extremely narrow (between 7.05 and 7.12; Graham and van der Eb, 1973). The pH of the solution can change during storage and an old 2× HeBS solution may not work well. Some investigators also have noticed that the 2.5 M $CaCl_2$ solution can go bad over time. Both solutions should be made fresh if transfections have stopped working well.

A second problem is that the pH of the medium can turn acidic while the transfection is in progress. This results in an extremely heavy precipitate (making the medium resemble orange juice) and generally results in cell death. Care should be taken to maintain a pH of 7.2 to 7.4 and CO_2 concentrations in the incubator as listed in the protocols. Incubator and medium conditions that are fine for routinely growing cells may not suffice for calcium phosphate transfection.

Many factors can influence the efficiency of HEPES-buffered calcium phosphate–mediated transfection. A description of experiments that can be done to optimize transfection efficiency using both this procedure and the BES procedure can be found in the discussion of optimization of transfection (*UNIT 20.7*).

Several parameters are crucial to achieve high efficiency with the Alternate Protocol: pH of the 2× BES-buffered saline (BBS), percentage of carbon dioxide in the incubator during formation of precipitate, and form and amount of DNA used.

A pH curve of the 2× BBS buffer should be made because minor variations in pH can have substantial effects on transfection efficiency. Perform pilot experiments with buffers of varying pH. The optimal pH is within a very narrow range (6.95 to 6.98). Once the optimal buffer is found, use it as a reference to prepare buffer stocks. If no precipitate forms, the concentration of calcium chloride or 2× BES solution (BBS) may be wrong. Be sure to mix reagents

thoroughly before adding them to the DNA. Crystal formation upon the addition of calcium chloride indicates incorrect calcium chloride concentration, and the transfection must be repeated.

The first overnight incubation should be at 3% CO_2, but a variation of 0.5% may be acceptable. After overnight incubation at 3% CO_2 the culture medium should be alkaline (pH 7.6). Measure the CO_2 levels of the incubator before using. A Fyrite device is recommended for this.

Only plasmid DNA gives high efficiencies of gene transfer with the Alternate Protocol. Efficiency is also dependent on the purity and concentration of the DNA. Toxicity that often occurs with common fibroblasts and epithelial cell lines is usually caused by impure DNA, not calcium phosphate. DNA prepared by cesium chloride gradient centrifugation is rarely toxic to cells. The optimal DNA concentration varies among plasmid preparations as well as with different cells and media. Each new plasmid preparation and each new cell line being transfected should be tested for optimum DNA concentration.

If it is suspected that a particular plasmid preparation is toxic, use a control plasmid—one known not to be toxic to these cells—to test for toxicity. If the plasmid DNA is toxic, prepare new DNA.

Cotransfection efficiency is 10- to 20-fold better with the BES method (see Alternate Protocol) than with the Basic Protocol, although efficiencies vary with the plasmid and marker gene used. A 1:10 ratio of selectable marker to nonselected gene is recommended, but the efficiency of transfection will depend on optimum DNA dose. Glycerol shock or DMSO treatment will not increase the number of cells transfected with this method.

The BES protocol (see Alternate Protocol) has been optimized for use with cells that grow in Dulbecco modified Eagle medium containing 10% (v/v) fetal bovine serum (FBS). RPMI and minimal essential mediumα (MEMα) have also been demonstrated to give good results under the stated conditions. The FBS must be tested before use by examining the growth, plating efficiency, and transformation efficiency of at least two cell lines. (Serum is tested without heat inactivation.) Because FBS is very costly, 10% (v/v) newborn calf serum and 5% (v/v) FBS can be added to the medium (a total of 75 ml serum/500 ml medium) instead of 10% FBS. This gives equivalent efficiencies of stable transformation. The lots of newborn calf serum also must be tested for growth and plating efficiencies, as these have been found to vary. If horse or other serum or medium is required, optimum conditions may need to be rechecked.

The Alternate Protocol works well for most established cell lines that grow as monolayers, including mouse, rat, hamster, monkey, and human. It does not seem to work well for neuronal lines. This may be due to the deleterious effect of the calcium on these cells. Cells that grow in suspension are transfected rather poorly by this method, but their stable transformation frequencies seem to be better than those obtained by the Basic Protocol and almost comparable to those obtained by electroporation.

Anticipated Results

The efficiency that can be obtained with calcium phosphate–mediated transfection varies with cell type and other parameters as described. Methods for optimizing these parameters are presented in the discussion of optimization of transfection (*UNIT 20.7*). Up to 10^3 colonies can be obtained by transfecting 1 μg of a plasmid containing a dominant selectable marker into 10^6 cells by the HEPES-based protocol. Efficiencies for stable transformants are generally >10- to 100-fold higher when the BES-based protocol is used, with 10% to 50% of the cells on a plate stably transformed (Chen and Okayama, 1987). Transient expression is comparable in the Basic and Alternate Protocols (Chen and Okayama, 1988).

Time Considerations

For the Basic Protocol, preparation of twelve DNA precipitates and addition of the precipitates to the cells takes 1 to 2 hr. Without the ethanol precipitation step, the procedure can be done in 1 hr. With practice, the actual mixing of the $CaCl_2$ and 2× HeBS solutions will take ~1 min. This means that up to eighteen precipitates can be made before the first precipitate is ready to apply to the cells.

For the Alternate Protocol, no ethanol precipitation step has been necessary for either transient or stable transfections. It takes slightly less time than the Basic Protocol because the 2× BBS does not need to be added dropwise to the calcium chloride–DNA solution.

Transfection Using DEAE-Dextran

Transfection of cultured mammalian cells using diethylaminoethyl (DEAE)-dextran/DNA can be an attractive alternative to other transfection methods in many circumstances. The major advantages of the technique are its relative simplicity and speed, limited expense, and remarkably reproducible interexperimental and intraexperimental transfection efficiency. Disadvantages include inhibition of cell growth and induction of heterogeneous morphological changes in cells. Furthermore, the concentration of serum in the culture medium must be transiently reduced during the transfection. Any of these factors may adversely affect or be incompatible with some bioassays or experimental goals. In addition, for nonstandard cell types there may be a requirement for extensive preliminary investigation of optimal transfection conditions. Together, these factors influence the suitability of this technique to specific purposes. In general, DEAE-dextran DNA transfection is ideal for transient transfections with promoter/reporter plasmids in analyses of promoter and enhancer functions, and is suitable for overexpression of recombinant protein in transient transfections or for generation of stable cell lines using vectors designed to exist in the cell as episomes. The procedure may also be used for expression cloning (Aruffo and Seed, 1987; Kluxen and Lubbert, 1993; Levesque et al., 1991), although electroporation is usually preferred for this purpose (Puchalski and Fahl, 1992).

This unit presents a general description of DEAE-dextran transfection (see Basic Protocol) as well as two more specific protocols for typical experimental applications (see Alternate Protocols 1 and 2).

The Basic Protocol is suitable for transfection of anchorage-dependent (attached) cells. For cells that grow in suspension, electroporation (*UNIT 20.5*) or lipofection (*UNIT 20.6*) is usually preferred, although DEAE-dextran-mediated transfection can be used (Fregeau and Bleackley, 1991). For suspension cells, the transfection step should be performed on collected cells that have been resuspended at 10^7 cells/ml in transfection medium, using reagents and conditions that are otherwise similar to those of the Basic Protocol.

NOTE: All reagents and equipment coming into contact with live cells must be sterile, and proper aseptic technique should be followed accordingly.

NOTE: All culture incubations are performed in a 37°C, 5% CO_2 incubator unless otherwise specified.

GENERAL PROCEDURE FOR DEAE-DEXTRAN TRANSFECTION

BASIC PROTOCOL

Cultured cells are incubated in medium containing plasmid DNA and DEAE-dextran, which form complexes that are taken up by cells via endocytosis. Chloroquine can be included to inhibit degradation of plasmid DNA. Cells are exposed transiently to DMSO or another permeabilizing agent to increase DNA uptake (DMSO "shock"). Important variables include the concentration of DEAE-dextran, the ratio of DNA to DEAE-dextran, the duration of transfection, and the presence and timing of chloroquine exposure (see Critical Parameters). This protocol is suitable for transfection of COS and CV1 cells; Alternate Protocols 1 and 2 describe two examples of transfection experiments.

Materials

Cells to be transfected and appropriate culture medium (e.g., complete DMEM; *UNIT 1.1*) with and without 10% FBS

100 mM (1000×) chloroquine diphosphate in PBS, filter-sterilized (store at 4°C)

Plasmid DNA(s), prepared by CsCl density-gradient centrifugation or affinity chromatography

TE buffer (*APPENDIX 2A*)

Contributed by Tod Gulick

Current Protocols in Cell Biology (2003) 20.4.1-20.4.10

10 mg/ml DEAE-dextran stock solution (see recipe)
10% (v/v) dimethyl sulfoxide (DMSO) in PBS, filter-sterilized (store up to 1 month at room temperature)
Phosphate-buffered saline (PBS; *APPENDIX 2A*)

Appropriate-sized tissue culture vessels (Table 20.4.1)
Inverted microscope

Additional reagents and equipment for mammalian cell culture (*UNIT 1.1*)

1. Plate cells at a density that will achieve 50% to 75% confluence on the target day for transfection. For COS or CV1 cells, perform a 1:10 split 2 days prior to transfection.

   The surface area of various cell culture vessels given in Table 20.4.1 can be used to determine how to split cells to the desired density.

   Some cell types including many primary cells show particular sensitivity to the toxicity of DEAE-dextran. These cells should be plated at higher density or transfected after reaching near-confluence.

2. Determine the total volume of medium to be used in the transfection based on the number of culture vessels containing cells to be transfected and the volume per vessel shown in Table 20.4.1. Make up this amount of medium (plus some excess) to contain 2.5% FBS by combining 1 part medium containing 10% FBS with 3 parts serum-free medium.

   DEAE-dextran can precipitate in the presence of high medium protein, necessitating use of a low FCS concentration. Alternatively, NuSerum (Collaborative Research), which contains only ~30% serum, can be used at a final concentration of 10%.

3. Add 100 mM (1000×) chloroquine diphosphate stock solution to the 2.5%-FBS-containing transfection medium prepared in step 2 to achieve a final concentration of 100 µM. Warm transfection medium to 37°C.

   Chloroquine is toxic to all cells, so exposure time should be limited to <4 hr. If longer transfection times are required for optimal transfection of a particular cell type, chloroquine should be added during the final hours of the transfection.

Table 20.4.1 Surface Areas of Commonly Used Tissue Culture Vessels and Corresponding Appropriate DEAE-Dextran Transfection Medium Volumes

Vessel	Area (cm^2)	Appropriate vol. DEAE-dextran medium[a] (ml)
T175 flask	175	
T150 flask	150	
T75 flask	75	
T25 flask	25	
150-mm dish	148[b]	10
100-mm dish	55[b]	4
60-mm dish	21[b]	2
35-mm dish	8[b]	1
6-well plate (35-mm wells)	9.4[b]	1
12-well plate (22-mm wells)	3.8[b]	0.5
24-well plate (15.5-mm wells)	1.9[b]	0.25

[a]These volumes are roughly a linear function of vessel surface area. To ensure that cells are completely covered by medium during the transfection, small wells require proportionately larger volumes due to annular sequestration of medium because of surface tension at the periphery.
[b]Costar; other manufacturer products may deviate slightly.

4. Dilute plasmid DNA in TE buffer or distilled water to between 1.0 and 0.1 µg/µl, depending on the quantity to be transfected. Add the DNA solution directly to the warmed transfection medium to a final concentration of 1.0 µg/ml.

   DNA solution(s) should comprise <1% of the total volume of transfection medium, so that the concentration of medium components is not significantly altered. Optimal DNA concentration in the transfection medium may have to be determined experimentally.

   Maintaining dilute stock DNA solutions for dedicated use in transfections reduces interexperimental variation as well as the time required to set up transfection experiments.

5. Warm the 10 mg/ml DEAE-dextran stock solution to 37°C and mix thoroughly by inversion. Add to the DNA-supplemented transfection medium to a final concentration of 100 µg/ml DEAE-dextran and mix by inversion.

   The order of addition to the transfection medium is critical. Adding plasmid DNA to medium that has already been supplemented with DEAE-dextran can result in precipitation, seen as a ropy white glob. Optimal DEAE-dextran concentration in the transfection may have to be determined experimentally.

6. Aspirate medium from the 50% to 70% confluent cell cultures (see step 1) and replace with the appropriate volume of 37°C DEAE-dextran/DNA-supplemented transfection medium (see Table 20.4.1). Incubate 4 hr.

   Uniformity of transfection efficiency may be improved by placing culture vessels on a rocker platform within the incubator during the transfection to ensure even exposure of cells to DEAE-dextran/DNA in the medium and to avoid dessication of cells in the center of the vessel. Optimal transfection time may have to be determined experimentally.

7. Examine cells with an inverted microscope.

   Cells may appear granular, some cell nuclei may appear pyknotic, and some cell borders may be somewhat ragged. An efficient DEAE-dextran transfection is usually associated with 25% to 75% cell death.

8. Warm the 10% DMSO/PBS to 37°C. Aspirate the transfection medium, note the volume, and replace with 2 to 3 volumes of 37°C DMSO/PBS. Incubate at room temperature for >2 but <10 min. Aspirate the DMSO/PBS and wash the cell layer with a volume of PBS equal to the amount of DMSO/PBS removed. Aspirate and replace with a standard amount of complete medium containing 10% FBS.

   Loss of firm cellular anchorage to the culture vessel may occur. Medium exchange and cell washing should therefore involve careful aspiration and pipetting, perhaps by holding the tip of the pipet against a wall of the culture dish or well. It is sometimes advisable to omit the PBS wash (as in the experiment described in Alternate Protocol 1, step 8) and simply add the complete medium, then change the medium a second time several hours after the DMSO shock when cells have recovered and are more firmly adherent.

9. Continue incubating the cells and analyze at times appropriate to the bioassay or intended purpose of the experiment.

   The onset and duration of expression of the transfected gene varies from one cell type to another, and especially with the expression vector used. It is advisable to perform a parallel transfection with a readily assayable reporter gene in the identical vector to assess the temporal features of expression. A reporter that is secreted by the cell into the culture medium, such as human growth hormone or secreted alkaline phosphatase, is ideal for this purpose, since aliquots of medium from a single transfection sample can be collected at serial time points. This parallel transfection can also be used in preliminary experiments to optimize transfection conditions.

ALTERNATE PROTOCOL 1

SAMPLE EXPERIMENT: TRANSFECTION TO TEST PROMOTER FUNCTION

In this protocol for a typical application of DEAE-dextran transfection, a thyroid hormone–response element in a hormone-responsive gene promoter will be mapped. Thyroid hormone (T_3) modulates transcription by activating the thyroid hormone receptor (TR), a transcription factor that binds to specific response elements in target-gene promoters as a heterodimer with the retinoid X receptor (RXR). Expression of TR, but not RXR, is minimal and limiting in fibroblasts, such that overexpression of TR using an expression vector significantly increases transcriptional response to T_3 in these cells. In this example, four promoter/reporter constructs will be tested, representing a promoter 5′ deletion series. The hormones, retinoids, and fatty acids in fetal bovine serum (FBS) can interfere with or cause high background in transcription assays in transfected cells. These moieties can be removed from FBS by charcoal treatment (see Support Protocol).

This protocol corresponds step-for-step with Basic Protocol; variations from the original procedure and reagents specific to this particular experiment are noted.

Additional Materials *(also see Basic Protocol)*

CV-1 cells (ATCC #CCL 70) growing in 100-mm dish
Complete DMEM medium (*UNIT 1.2*) with and without 10% FBS
Complete DMEM medium (*UNIT 1.2*) with 10% charcoal-treated FBS (see Support Protocol)
Plasmid DNAs:
  Control reporter plasmid (e.g., β-galactosidase, secreted alkaline phosphatase, or growth hormone, driven by a viral promoter)
  Four test promoter constructs (promoter/CAT or promoter/luciferase)
  Expression plasmid with TR gene insert (pTR)
  No-insert expression plasmid (p[–])
Complete DMEM medium (*UNIT 1.2*) with 10% charcoal-treated FBS (see Support Protocol), supplemented with 10 nm thyroid hormone (T_3)

12-well tissue culture plates
100-ml tissue culture dishes

Additional reagents and equipment for trypsinizing and subculturing monolayer cells (*UNIT 1.1*) and analyzing reporter gene activity (*APPENDIX 3A*)

1. Two days prior to the transfection, trypsinize and suspend CV1 cells from a confluent 100-mm dish in 36 ml complete DMEM medium/10% FBS. Place 1 ml complete DMEM/10% FBS in each well of four 12-well plates, then add 250 µl of the cell suspension to each of these wells. Plate the residual cells in 100-mm dishes for later use, or discard. 12 to 24 hr before the transfection, change medium to complete DMEM/10% charcoal-treated FBS.

   The sensitivity of most reporter assays permits use of many fewer cells/transfection conditions than are generally used, with consequent cost savings. CV1 cells in a well of a 12-well plate will provide sufficient reporter-gene activity for most promoter/reporters. In this protocol, triplicate wells for each condition will be analyzed. Four promoter/CAT or promoter/luciferase reporters will be tested. Cells will include or exclude pTR cotransfection. Transfected cells will be incubated in the presence or absence of T_3. Thus, four 12-well plates are required for the experiment—i.e., 3 wells (triplicates) × 4 wells (four reporters) × 2 wells (with and without pTR cotransfection) × 2 wells (with and without T_3) = 48 wells. These 48 wells include ~180 cm^2 (see Table 20.4.1) such that approximately one-third of the cells on one 100-mm (55 cm^2) dish will be used in order to achieve a 1:10 split.

Addition of suspended cells to empty tissue culture plates or wells results in an uneven distribution of adherent cells, which can introduce undesirable intersample variability; hence medium is added to the wells first.

Preincubation in medium supplemented with charcoal-stripped FBS (see Support Protocol) ensures that any hormones of interest are absent from medium bathing the control cells during subsequent experiments.

2. Add 7 ml DMEM/10% charcoal-treated FBS to 21 ml serum-free DMEM to make 28 ml of DMEM/2.5 % FBS.

   In this experiment, the FBS in the DMEM/10 has been stripped of low molecular weight hydrophobic moieties, including T_3, using charcoal.

   The amount here was calculated as 48 wells multiplied by 0.5 ml/well, and a small excess was added. In experiments in which the transfection medium will be divided into multiple aliquots carrying different plasmids or plasmid combinations, it is useful to carry a volume excess throughout the preparation of the separate transfection media to adjust for pipet-calibration errors.

3. Add 28 µl 100 mM chloroquine diphosphate to the medium and place the tube in a 37°C water bath.

4. Dilute the reporter plasmids (control and test promoter constructs) in TE buffer to 1 µg/µl; dilute the TR (pTR) and no-insert (p[–]) expression plasmids in TE buffer to 0.2 µg/µl. Add 14 µl of the diluted reporter plasmid to the transfection medium (final concentration, 0.5 µg/ml). Divide this medium into four equal 6.6-ml aliquots and add 6.6 µl of a test promoter construct to each separate tube (final concentration, 1 µg/ml). Divide each of these into two tubes, each containing 3.2 ml. Add 8 µl pTR to one set of four tubes and 8 µl p[–] to the other set of four tubes (final concentration, 0.5 µg/µl). Use each of these eight transfection medium samples to transfect cells within six wells in step 6, below.

   All cells will be transfected with a control reporter—e.g., β-galactosidase, secreted alkaline phosphatase, or growth hormone—driven by a viral promoter. Each of the four test promoter/reporters will be transfected into cells within 12 wells. A TR expression vector will be transfected into 6 of each of these sets of 12 wells. Cells in triplicate wells in each of these conditions will be cultured in medium supplemented with T_3, while those in the other triplicate wells will be cultured in medium devoid of T_3.

   Plasmids that are included in more than one transfection condition are added prior to division of medium into separate aliquots to ensure that these samples receive equivalent amounts of plasmid DNA. The final concentration of DNA in each transfection medium sample should be equivalent. For this and other reasons, an "empty vector" should be used as described for p[–] above.

5. Warm the stock DEAE-dextran to 37°C, mix by inversion, and add 32 µl to each of the eight tubes containing DNA-supplemented transfection medium (final DEAE-dextran concentration, 100 µg/ml). Mix by gentle inversion.

6. Aspirate medium from six wells on one plate, and replace with one of the eight transfection-medium samples prepared in step 4 at 500 µl per well. Repeat for each of the different transfection-medium samples. Incubate 4 hr.

7. Examine cells with inverted microscope.

8. Aspirate medium from wells in one plate and add 1 ml DMSO/PBS per well. Repeat for each plate. Return to the first plate, aspirate the DMSO/PBS and replace with 1 ml/well complete DMEM/10% charcoal-treated FBS. Incubate cells for 4 to 12 hr. Aspirate medium from wells and replace the medium from one set of triplicate wells for each transfection condition with 1 ml/well T_3-supplemented DMEM/10% char-

coal-treated FBS and the other set of triplicate wells for each transfection condition with (T_3-unsupplemented) DMEM/10% charcoal-treated FBS.

9. Incubate cells 24 to 48 hr. Aspirate 500 µl of medium from each separate well and save for control reporter activity determinations in order to normalize test reporter activities. Wash wells with PBS and harvest cells for CAT or luciferase activity measurements.

   Reporter activity is used to confirm and quantitate promoter T_3 responsiveness ($+T_3$ /$-T_3$), to verify a direct transcriptional response mediated by the TR (augmentation of response to T_3 in pTR-cotransfected cells), and to map the T_3-responsive region of the promoter (region present in a T_3-responsive promoter/reporter and absent in an unresponsive one).

   The use of a control reporter permits normalization for transfection efficiency and for nonspecific-stimulus effects on gene expression. In many cases, when using this transfection technique, adequate and informative preliminary experiments can be conducted without this control (since transfection efficiency is so uniform), thereby saving time and expense. This is seldom possible when using other transient-transfection techniques, especially calcium phosphate coprecipitation (UNIT 20.3), where transfection efficiency varies markedly within an experiment. Of course, initial experiments should be performed to exclude nonspecific stimulus effects.

ALTERNATE PROTOCOL 2

SAMPLE EXPERIMENT: TRANSFECTION TO TEST ENZYME STRUCTURE/ACTIVITY RELATIONSHIPS

In this experimental application of DEAE-dextran transfection, an enzyme and several enzyme mutants are overexpressed in COS cells to provide material for kinetic analyses in a structure/activity analysis. A vector designed for high-level expression that replicates in SV40-transformed cells (e.g., CDM8) will be used.

This protocol corresponds step-for-step with Basic Protocol; variations from the original procedure and reagents specific to this particular experiment are noted.

Additional Materials *(also see Basic Protocol)*

COS cells (ATCC #1650) growing in 100-mm dish
Complete DMEM medium (*UNIT 1.2*) with and without 10% FBS
Control plasmid containing reporter gene (e.g., luciferase, CAT, or secreted alkaline phosphatase)
CDM8 vectors containing gene for wild-type enzyme and genes for four mutant enzymes
100-ml tissue culture dishes
Additional reagents and equipment for analyzing reporter gene activity (*APPENDIX 3A*) and analysis of recombinant proteins (*APPENDIX 3A*)

1. Two days prior to the transfection, split five 100-mm dishes of confluent COS cells into fifty 100-mm dishes.

   Ten 100-mm dishes of COS cells will provide sufficient recombinant enzyme activity for kinetic analyses. Recombinant wild-type enzyme and four mutant enzymes will be overexpressed. Thus, fifty dishes are required for this experiment.

2. Add 50 ml DMEM/10% FBS to 150 ml serum-free DMEM to make 200 ml DMEM/2.5% FBS.

   This was calculated as fifty dishes at 4 ml/100-mm dish (see Table 20.4.1).

3. Warm the transfection medium in a 37°C water bath. Do not add chloroquine diphosphate.

Chloroquine treatment increases DEAE-dextran transfection efficiency, but may reduce the amount of recombinant protein produced by the transfected cells. It is advisable to test this in early pilot experiments.

4. Dilute the reporter gene plasmid and each of the CDM8/enzyme expression vectors to 1 µg/µl in TE buffer. Add 20 µl reporter plasmid to the transfection medium and mix (final concentration, 0.1 µg/ml). Divide the medium into five aliquots of 40 ml. Add 160 µl of one CDM8/enzyme expression plasmid to one aliquot (final concentration, 4 µg/ml) and repeat this for each of the CDM8/enzyme expression plasmids.

   All cells will be transfected with a control plasmid containing a reporter gene such as luciferase, CAT, or secreted alkaline phosphatase to evaluate transfection efficiency. Each of the five enzyme expression vectors will be used to transfect cells in ten dishes.

   If the COS cells have an endogenous activity identical or similar to the activity of the recombinant protein to be overexpressed, it may be prudent to include cells that are transfected with "empty vector" in experiments of this type to permit parallel assays of endogenous COS cell activities for "background" subtraction.

   Plasmids may compete for replication and/or transcription factors. The control reporter plasmid can be included at low concentration because the reporter has a very sensitive assay.

5. Warm the stock DEAE-dextran to 37°C, mix by inversion, and add 800 µl to each of the tubes containing DNA-supplemented transfection medium (final DEAE-dextran concentration, 200 µg/ml). Mix by gentle inversion.

6. Aspirate medium from ten dishes and replace with 4 ml of the appropriate DEAE-dextran/DNA-supplemented transfection medium. Repeat for each set of ten dishes. Incubate 3 hr.

7. Examine cells with inverted microscope. Continue the transfection until some cells appear slightly granular.

8. Aspirate transfection medium from one of the sets of ten dishes and replace with 10 ml/dish DMSO/PBS. After 2 min, aspirate the DMSO/PBS and wash gently with 10 ml PBS. Aspirate PBS and add 10 ml DMEM/10 FBS. Repeat for each set of ten dishes.

9. Incubate cells 48 to 96 hr. Harvest cells as appropriate for recombinant protein assays. Save aliquots of culture medium (for secreted control reporter) or cell extract (intracellular reporter) to determined transfection efficiency.

   Normalization for transfection efficiency may not be necessary, particularly in circumstances where an independent assay for recombinant protein production is available, as might be provided by a specific antibody.

CHARCOAL STRIPPING OF FETAL BOVINE SERUM

SUPPORT PROTOCOL

Activated charcoal is used to remove low-molecular-weight lipophilic compounds from serum including hormones, retinoids, and fatty acid ligands of nuclear receptor transcription factors.

Materials

Fetal bovine serum (FBS), heat-inactivated (*UNIT 1.1*)
Activated charcoal, acid-washed (Sigma)
Ultracentrifuge with Beckman SW 28, JA-20.1, or equivalent swinging-bucket rotor

1. Add 2 g activated charcoal per 100 ml heat-inactivated FBS. Add a stir-bar and place on a stir plate in a 4°C cold room or refrigerator. Stir for 2 hr.

   Although it is difficult to maintain aseptic conditions during charcoal stripping, care should be taken to avoid flagrant contamination and to keep the serum at 4°C.

2. Collect serum in centrifuge tubes and centrifuge 30 min at 72,000 × *g* (20,000 rpm in SW 28 rotor) *or* 60 min at 51,500 × *g* (20,000 rpm in JA-20.1), 4°C.

3. Gently pour off serum from each centrifuge tube into a sterile beaker, divide into aliquots in sterile conical tubes, and store frozen at −20°C.

   Some residual charcoal may be present but the serum should be only lightly peppered with charcoal after centrifugation.

4. Prior to use, thaw a tube of charcoal-stripped medium and use immediately to supplement complete medium. Filter sterilize the medium using a 0.22-µm bottletop filter and collect in a sterile bottle. Store at 4°C.

   The serum is filtered after it is added to the medium because the undiluted serum is too viscous to filter readily.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

DEAE-dextran stock solution, 10 mg/ml (100×)

Make a 10 mg/ml stock solution of diethylaminoethyl (DEAE)-dextran (mol. wt. ~500,000 Da; Sigma) in tissue culture–quality PBS (*APPENDIX 2A*). Mix well, filter sterilize using an 0.22-µm filter, mix again, divide into aliquots, and store up to 3 months at 4°C.

Warm to 37°C and mix well by inversion immediately before each use.

COMMENTARY

Background Information

The mechanism by which cells take up DNA in DEAE-dextran-mediated transfection appears to involve endocytosis after adsorption of DNA/DEAE-dextran complexes onto cells. The advantages of the technique relate largely to the relative simplicity, limited expense, and lack of interexperiment and intraexperiment variability in transfection efficiency.

Critical Parameters

There are several crucial parameters in the transfection procedure, and the weight of importance of each differs for different cell types. Furthermore, maximizing efficiency of a transfection (percent of cells transfected) does not necessarily correspond with optimizing the desired goal of the transfection, such as production of recombinant protein (Kluxen and Lubbert, 1993) or maintenance of colony-forming potential of cells containing transfected DNA (Puchalski and Fahl, 1992). Systematic analyses of variables in DEAE-dextran/DNA transfection for particular cell types have been reported (Fregeau and Bleackley, 1991; Puchalski and Fahl, 1992; Kluxen and Lubbert, 1993; Yang and Yang, 1997), and these studies provide useful information. However, the existence of numerous variables and their mutual codependence makes interpolation, extrapolation, or guessing transfection conditions toward any specific end for any particular cell type difficult to extract from literature reports. Thus, the investigator should carry out a modest set of pilot experiments to optimize conditions.

The major variables that influence DEAE-dextran/DNA transfection include: (1) DEAE-dextran concentration; (2) DNA concentration and the ratio of DNA concentration to DEAE-dextran concentration; (3) duration of transfection; (4) use of chloroquine; (5) use of permeabilizing agents; and (6) serum concentration. The influence of each of these factors on the various goals of DNA transfection will be addressed.

The concentration of DEAE-dextran used in transfections varies from 50 to 500 μg/ml. There is an inverse relationship between the concentration used and the duration of exposure prior to onset of cytotoxicity for all cell types. In initial experiments, it may be best to use a low concentration (100 or 200 μg/ml) to provide an adequate temporal window to evaluate cytotoxicity microscopically. Lethal cytotoxicity can precede microscopic evidence of the same, such that transfections with high concentrations of DEAE-dextran can result in near-complete cell loss even when most cells appear healthy at the end of the transfection period.

The DNA concentration used depends in part on the vector, cell type, and the purpose of the transfection. For maximal cell adsorption of complexes and maximal transfection efficiency, the ratio of transfection-medium DEAE-dextran concentration to DNA concentration should be 40:1 to 50:1, perhaps because of the existance of an optimal electrostatic cell membrane/DEAE-dextran/DNA-complex interaction (Yang and Yang, 1997). Thus, at a DEAE-dextran concentration of 200 μg/ml, plasmid DNA should be included at 4 to 5 μg/ml. Since this ratio influences transfection efficiency, "empty vector" should be included in controls at the same concentration as test vectors. This ideal [DEAE-dextran]/[DNA] ratio may depend on transfection-medium serum concentration.

The amounts of DNA to be used in cotransfection experiments again depend on the intended purpose of each component transfection. When a control reporter plasmid is used to simply normalize for transfection efficiency, it is often possible and desirable to include a low concentration of the plasmid, since reporter enzyme assays are generally exquisitely sensitive. In experiments in which simultaneous cotransfection of single cells with two plasmids is a goal, it is appropriate to add the plasmids at the same or similar concentrations. Furthermore, transfection efficiency is of paramount importance in this circumstance, since the percentage of cells that take up both plasmids is a fraction of those that take up each alone. This is particularly important in a case like that presented in Alternate Protocol 1, where coexistence of the transcription-factor expression vector and the promoter/reporter plasmid in a single cell is important.

DEAE-dextran-mediated cytotoxicity is a function of exposure time. In general, efficient transfections can be achieved with a 4-hr incubation if other parameters are adjusted appropriately. This is a convenient transfection duration since it corresponds to the maximal allowable period of cell exposure to chloroquine. Shorter transfection times may be appropriate for some cell types.

The utility of chloroquine in increasing the efficiency of DEAE-dextran transfection is well documented. However, there may be an attenuation in the amount of transfected gene expression (Kluxen and Lubbert, 1993) and increased cell loss and disruption of cellular morphology (Puchalski and Fahl, 1992) when this reagent is included. Thus, use of chloroquine is appropriate for purposes where transfection efficiency is a dominant priority. In other cases, preliminary experiments should evaluate the impact of this agent on the bioactivity desired. While some investigators add chloroquine in the final stage of (or after) a longer transfection, it is generally easier to increase the DEAE-dextran concentration in this circumstance to permit a single 4-hr transfection in medium containing all components.

Using a final cell "shock" with a permeabilizing agent markedly increases DEAE-dextran transfection efficiency without additional cytotoxicity (Lopata et al., 1984) and should be used universally, unless this manipulation somehow interferes with the desired bioactivity. DMSO at a concentration of 10% is generally used, although 15% glycerol may be more effective for some cell types. Enhancement of transfection efficiency increases as a function of permeabilizing-agent exposure time up to 2 min, after which there is no additional impact (Sussman and Milman, 1984). Since longer exposure, up to 5 to 10 min, produces no negative effect, the "shock" should be for >2 min, but need not be rigorously timed or reproduced, even between transfected samples within an experiment.

Use of transfection medium supplemented with 10% FBS results in formation of macroscopic protein/DEAE-dextran/DNA complexes that are not compatible with efficient transfection. Serum-free medium can be used during the transfection, as can medium supplemented with either 2.5% FBS or 10% NuSerum. The concentration of serum in the transfection medium affects the extent of DEAE-dextran-mediated and chloroquine-mediated cytotoxicity, with a protective effect provided by the serum. FBS concentration may also influence the optimal ratio of [DEAE-dextran]/[DNA].

Anticipated Results

The efficiency of DEAE-dextran-mediated transfection varies considerably among cell types. One can expect to achieve 20% to 60% transfection efficiency with many cells using this procedure if proper attention is paid to optimization of transfection conditions. Following transfection using this technique, there are generally significant morphological changes in cells, and some of these may weigh against the use of this technique for certain purposes.

Time Considerations

Splitting cells into the required number of plates several days prior to the transfection may take ~30 min. Depending on the complexity of the transfection, preparing transfection media may take 5 min to 1 hr. If stock solutions of DNA, DEAE-dextran, chloroquine, and DMSO/PBS are prepared in advance, 30 min should be adequate for this phase, even in a moderately complex transfection experiment like that presented in Alternate Protocol 1. During the subsequent transfection, cells should be monitored using a microscope periodically after 3 hr. The DMSO or glycerol shock, cell wash, and medium replacement requires only ~10 min. Thus, with minimal but careful planning of experimental design, a transfection can readily be completed in 5 hr.

Transfection by Electroporation

Electroporation—the use of high-voltage electric shocks to introduce DNA into cells—is a procedure that is gaining in popularity. It can be used with most cell types, yields a high frequency of both stable transformation and transient gene expression, and, because it requires fewer steps, can be easier than alternate techniques (*UNITS 20.3, 20.4 & 20.6).*

The Basic Protocol describes the electroporation of mammalian cells. The alternate protocol outlines modifications for preparation and transfection of plant protoplasts.

ELECTROPORATION INTO MAMMALIAN CELLS

BASIC PROTOCOL

Electroporation can be used for both transient and stable transfection of mammalian cells. Cells are placed in suspension in an appropriate electroporation buffer and put into an electroporation cuvette. DNA is added, the cuvette is connected to a power supply, and the cells are subjected to a high-voltage electrical pulse of defined magnitude and length. The cells are then allowed to recover briefly before they are placed in normal growth medium. Factors that can be varied to optimize electroporation effectiveness are discussed in *UNIT 20.7*.

Materials

Mammalian cells to be transfected
Complete medium (*UNIT 1.2*) without and with appropriate selective agents (*APPENDIX 3A*)
Electroporation buffer, ice-cold (see recipe)
Linear or supercoiled, purified DNA preparation (see step 7)

Beckman JS-4.2 rotor or equivalent
Electroporation cuvettes (Bio-Rad #165-2088) and power source

Additional reagents and equipment for stable transformation in selective medium and for harvesting transfected cells (*APPENDIX 3A*)

Prepare the cells for electroporation

1. Grow cells to be transfected to late-log phase in complete medium.

   Each permanent transfection will usually require 5×10^6 cells to yield a reasonable number of transfectants. Each transient expression may require $1–4 \times 10^7$ cells, depending on the promoter.

2. Harvest cells by centrifuging 5 min at $640 \times g$ (1500 rpm in a JS-4.2 rotor), 4°C.

   Adherent cells are first trypsinized (UNIT 1.1) and the trypsin inactivated with serum.

3. Resuspend cell pellet in half its original volume of ice-cold electroporation buffer.

   The choice of electroporation buffer may depend on the cell line used. See Critical Parameters for a complete discussion.

4. Harvest cells by centrifuging 5 min as in step 2.

5. Resuspend cells at 1×10^7/ml in electroporation buffer at 0°C for permanent transfection. Higher concentrations of cells (up to 8×10^7) may be used for transient expression.

6. Transfer 0.5-ml aliquots of the cell suspension into desired number of electroporation cuvettes set on ice.

Contributed by Huntington Potter
Current Protocols in Cell Biology (2003) 20.5.1-20.5.6

Add DNA and electroporate the cells

7. Add DNA to cell suspension in the cuvettes on ice.

   For stable transformation, DNA should be linearized by cleavage with a restriction enzyme that cuts in a nonessential region and purified by phenol extraction and ethanol precipitation. For transient expression, the DNA may be left supercoiled. In either case, the DNA should have been purified through two preparative CsCl/ethidium bromide equilibrium gradients followed by phenol extraction and ethanol precipitation. The DNA stock may be sterilized by one ether extraction; the (top) ether phase is removed and the DNA solution allowed to dry for a few minutes to evaporate any remaining ether. See APPENDIX 3A for cross-references to these procedures.

   For transient expression, 10 to 40 μg is optimal. For stable transformation, 1 to 10 μg is sufficient. Cotransfection, although not recommended because of the work required to select and test transformants, can be done with 1 μg of a selectable marker containing DNA and 10 μg of the DNA containing the gene of interest.

8. Mix DNA/cell suspension by holding the cuvette on the two "window sides" and flicking the bottom. Incubate 5 min on ice.

9. Place cuvette in the holder in the electroporation apparatus (at room temperature) and shock one or more times at the desired voltage and capacitance settings.

   The number of shocks and the voltage and capacitance settings will vary depending on the cell type and should be optimized (Critical Parameters; see also UNIT 20.7).

10. After electroporation, return cuvette containing cells and DNA to ice for 10 min.

Culture and harvest the transfected cells

11. Dilute transfected cells 20-fold in nonselective complete medium and rinse cuvette with this same medium to remove all transfected cells.

12a. *For stable transformation:* Grow cells 48 hr (about two generations) in nonselective medium, then transfer to antibiotic-containing medium.

   Selection conditions will vary with cell type. For example, neo selection generally requires ~400 μg/ml G418 in the medium. XGPRT selection requires 1 μg/ml mycophenolic acid, 250 μg/ml xanthine, and 15 μg/ml hypoxanthine in the medium.

   It is often convenient to plate adherent cells at limiting dilution immediately following the shock, or suspension cells at the time of antibiotic addition.

12b. *For transient expression:* Incubate cells 50 to 60 hr, then harvest cells for transient expression assays.

   Transfected cells can be visualized by standard transient expression assays.

ALTERNATE PROTOCOL

ELECTROPORATION INTO PLANT PROTOPLASTS

This is a modification of the Basic Protocol that is intended for use with plant cells. Plant cells are stripped of their cell walls and DNA is introduced into the resulting protoplasts.

Additional Materials *(also see Basic Protocol)*

5-mm strips (1 g dry weight) sterile plant material
Protoplast solution (see recipe)
Plant electroporation buffer (see recipe)

80-μm-mesh nylon screen
Sterile 15-ml conical centrifuge tube

Additional reagents and equipment for plant RNA preparation (*APPENDIX 3A*)

1. Obtain protoplasts from carefully sliced 5-mm strips of sterile plant material by incubating in 8 ml protoplast solution for 3 to 6 hr at 30°C on a rotary shaker.
2. Remove debris by filtration through an 80-µm-mesh nylon screen.
3. Rinse screen with 4 ml plant electroporation buffer. Combine protoplasts in a sterile 15-ml conical centrifuge tube.
4. Centrifuge 5 min at 300 × *g* (1000 rpm in a JS-4.2 rotor). Discard supernatant, add 5 ml plant electroporation buffer, and repeat wash step. Resuspend in plant electroporation buffer at $1.5–2 \times 10^6$ protoplasts/ml.

   Protoplasts can be counted with a hemacytometer (UNIT 1.1).

5. Carry out electroporation as described for mammalian cells (steps 6 to 11 of the Basic Protocol). Use one or several shocks at 1 to 2 kV with a 3- to 25-µF capacitance as a starting point for optimizing the system.

   Alternatively, use 200 to 300 V with 500 to 1000 µF capacitance if the phosphate in the electroporation buffer is reduced to 10 mM final.

6. Harvest cells after 48 hr growth and isolate RNA, assay for transient gene expression, or select for stable transformants.

   Protoplasts can also be selected and grown into full transgenic plants (Rhodes et al., 1988).

REAGENTS AND SOLUTIONS

Use deionized distilled water for all recipes and protocol steps. For common solutions, see ***APPENDIX 2A****; for suppliers see* ***SUPPLIERS APPENDIX****.*

Electroporation buffers

Choice of electroporation buffer depends on the cells being used in the experiment (see Critical Parameters). The following buffers (stored at 4°C) can be used:

1. PBS (*APPENDIX 2A*) *without* Ca^{2+} or Mg^{2+}
2. HEPES-buffered saline (HeBS; *UNIT 20.3*)
3. Tissue culture medium *without* FBS (*UNIT 1.1*)
4. Phosphate-buffered sucrose: 272 mM sucrose/7 mM K_2HPO_4 (adjusted to pH 7.4 with phosphoric acid)/1 mM $MgCl_2$

Plant electroporation buffer

Prepare in PBS (APPENDIX 2A):
0.4 M mannitol
5 mM $CaCl_2$
Store at 4°C

Protoplast solution

2% (w/v) cellulase (Yakult Honsha)
1% (w/v) macerozyme (Yakult Honsha)
0.01% (w/v) pectylase
0.4 M mannitol
40 mM $CaCl_2$
10 mM 2-[*N*-morpholino]ethanesulfonic acid (MES), pH 5.5
Prepare fresh before use

COMMENTARY

Background Information

DNA transfection by electroporation is a technique that is applicable to perhaps all cell types. It yields a high frequency of stable transformants and has a high efficiency of transient gene expression. Electroporation makes use of the fact that the cell membrane acts as an electrical capacitor that is unable to pass current (except through ion channels). Subjecting membranes to a high-voltage electric field results in their temporary breakdown and the formation of pores that are large enough to allow macromolecules (as well as smaller molecules such as ATP) to enter or leave the cell. The reclosing of the membrane pores is a natural decay process that is delayed at 0°C.

During the time that the pores are open, nucleic acid can enter the cell and ultimately the nucleus. Linear DNA with free ends is more recombinogenic and more likely to be integrated into the host chromosome to yield stable transformants. Supercoiled DNA is more easily packaged into chromatin and is generally more effective for transient gene expression.

The use of high-voltage electric shocks to introduce DNA into cells was first performed by Wong and Neumann using fibroblasts (Neumann et al., 1982; Wong and Neumann, 1982). The technique was then generalized (Potter et al., 1984) to all cell types—even those such as lymphocytes that, unlike fibroblasts, cannot be transfected with other procedures (e.g., calcium phosphate or DEAE-dextran DNA coprecipitates). Although whole plants or leaf tissue have been reported to be transfectable by electroporation, plant cells must generally be made into protoplasts before DNA can be easily introduced into them (Alternate Protocol; Fromm et al., 1985; Ou-Lee et al., 1986). Like mammalian cells, plant protoplasts may be electroporated under a variety of electrical conditions (Critical Parameters). Both high voltage with low capacitance (short pulse duration) or low voltage with high capacitance (long pulse duration) have been used to achieve successful gene transfer (Chu et al., 1987).

The wide use of electroporation has been made possible in large part by the availability of commercial apparatuses that are safe and easy to use and that give extremely reproducible results. Designs of these machines vary substantially, but fall into two basic categories that use different means of controlling pulse duration and voltage (the two electrical parameters that govern pore formation). One kind uses a capacitor discharge system to generate an exponentially decaying current pulse, and the other generates a true square wave (or an approximation thereof). The capacitor discharge instruments charge their internal capacitor to a certain voltage and then discharge it through the cell-DNA suspension. Both the size of the capacitor and the voltage can be varied. Because the current pulse is an exponentially decaying function of (1) the initial voltage, (2) the capacitance setting of the instrument, and (3) the resistance of the circuit (including the sample), changing the capacitor size to allow more (or less) charge to be stored at the voltage will result in longer (or shorter) decay times and hence a different effective pulse duration. In contrast, square wave generators control both the voltage and pulse duration with solid-state switching devices. They also can produce rapidly repeating pulses.

Most of our electroporation experiments have used the Bio-Rad Gene Pulser, a capacitor discharge device, but are directly applicable to other capacitor discharge devices, and with some adjustment to square wave generators. Capacitor discharge devices are also available from Life Technologies, BTX, Hoeffer Scientific, and International Biotechnologies (see *SUPPLIERS APPENDIX* for suppliers' addresses). These machines, either in a single unit or through add-on components, can deliver a variety of electroporation conditions suitable for most applications. Square wave generators are available from BTX or Baekon and offer great control over pulse width, allow multiple, rapid pulses, and can be more effective for cells that are very sensitive or otherwise difficult to transfect. These machines are generally more expensive. It has become apparent that alternating current pulses at ~100 kHz may be the most effective wave form for electroporation and possibly electrofusion (Chang, 1989). However, dedicated electroporation devices utilizing such waves are not yet commercially available and must be constructed from components. For a complete discussion of electroporation instruments, see Potter (1988).

Electroporation can be easier to carry out than alternative techniques, which is why it is becoming popular. Its drawback for use with transient analysis is that almost five-fold more cells and DNA are needed than with either calcium phosphate– or DEAE-dextran-mediated transfection (*UNITS 20.3 & 20.4*). The main difference between electroporation and cal-

cium phosphate coprecipitation procedures is the state of the integrated DNA after selection in appropriate antibiotic media. In the case of calcium phosphate, the amount of DNA taken up and integrated into the genome of each transfected cell is in the range of 3×10^6 bp. As a result, the transfected DNA often integrates as large tandem arrays containing many copies of the transfected DNA. This would be an advantage when transfection of genomic DNA into recipient cells and selection for some phenotypic change such as malignant transformation is desired; here a large amount of DNA integrated per recipient cell is essential. In contrast, electroporation can be adjusted to result in one to many copies of inserted DNA per recipient cell. This would be an advantage for gene expression studies, as the identity of the particular copy responsible for the gene expression can be controlled.

Critical Parameters

As discussed above, the two parameters that are critical for successful electroporation are the maximum voltage of the shock and the duration of the current pulse (see also *UNIT 20.7*). The voltage and capacitance settings must be optimized for each cell type, with the resistance of the electroporation buffer being critical for choosing the initial instrument settings. The guidelines presented in this unit are meant to be adapted according to the manufacturers' instructions and the individual investigator's needs. Optimal stable and transient transformations occur at about the same instrument settings, so transient expression can be used to optimize conditions for a new cell type.

For low-resistance (high-salt) buffers such as PBS, HeBS, or tissue culture medium, start with a capacitor setting of 25 μF and a voltage of 1200 V for 0.4-cm cuvettes, then increase or decrease the voltage until optimal transfection is obtained (usually at ~40% to 70% cell viability as detected by trypan blue exclusion; *UNIT 1.1*). For many cell types, the choice between PBS, HeBS, and tissue culture medium is arbitrary. However, some cells (especially primary cells) are very easily killed and thus electroporate poorly at the high voltages needed for PBS or HeBS electroporation buffers. Particularly sensitive cells seem to prefer tissue culture medium, though it has been shown that the calcium and magnesium ions in the medium lower the electroporation efficiency (Neumann et al., 1982). Phosphate-buffered sucrose has the advantage that it can be optimized at voltages several hundred volts below those used with PBS or HeBS. Alternatively, Chu et al. (1987) found many sensitive cells were electroporated more effectively in HeBS with a low voltage/high capacitance setting that resulted in at least 10-fold longer pulse duration. For these conditions, start at 250 V/960 μF and change the voltage up to 350 V or down to 100 V in steps to determine optimal settings.

Keeping cells on ice (at 0°C) often improves cell viability and thus results in higher effective transfection frequency, especially at high power which can lead to heating (Potter et al., 1984). However, Chu et al. (1987) found that under low voltage/high capacitance conditions, some cell lines electroporate with higher efficiency at room temperature. Therefore, steps 6 to 10 of the Basic Protocol should be carried out separately at both temperatures to determine the optimum conditions for a new cell line.

Another factor contributing to cell death appears to be the pH change that results from electrolysis at the electrodes. This problem can be reduced by replacing some of the ionic strength of the PBS with extra buffer (e.g., 20 mM HEPES, pH 7.5).

Optimal parameters for plant electroporation differ depending on whether tissue culture cells or various parts of the whole plant are used as a source of protoplasts. In particular, the high salt in PBS can be damaging to protoplasts freshly produced from plant tissue. Replacing the NaCl in PBS with 135 mM LiCl may increase CAT transient gene expression in electroporated plant protoplasts 4- to 70-fold (Saunders et al., 1989). Alternatively, an electroporation buffer of 0.6 M mannitol/25 mM KCl for leaf cells, or 0.7 M mannitol/40 mM KCl/4 mM MES (pH 5.7)/1 mM 2-ME added for root and stem cells, is recommended (Sheen, 1990). In addition, 0.1% BSA/15 mM 2-ME/1 mM $MgCl_2$ can be added to either protoplast isolation buffer and the $CaCl_2$ reduced to 1 mM final. A low salt concentration in the electroporation buffer reduces the optimal capacitance setting to 200 μF.

Anticipated Results

The efficiency of transfection by electroporation is dependent upon cell type. For fibroblasts, which are easily transfected by calcium phosphate or DEAE-dextran coprecipitation (*UNITS 20.3 & 20.4*), electroporation gives a stable transformation frequency of 1 in ~10^3 to 10^4 live cells—approximately that obtainable by the above traditional procedures. For cells refractory to traditional methods, electropora-

tion gives a stable transformation frequency between 1 in 10^4 to 10^5 for most cell types. Occasionally a cell line (e.g., some T lymphocytes) will transfect poorly under our standard conditions (1 in 10^6), and even this frequency is sufficient to obtain significant numbers of transfectants. In general, cells that transfect efficiently for stable transformants also do so for transient gene expression. Increasing the number of cells and the amount of DNA used in the electroporation for studying transient gene expression can circumvent problems of low transfection efficiency and low promoter/enhancer efficiency.

For plant protoplast electroporation, the frequency of stable transformants is between 1 in 10^2 and 1 in 10^3 dividing cells.

Time Considerations

The entire process of electroporation of mammalian cells will take <1 hr. Electroporation of plant cells requires ≤6 hr to prepare the protoplasts and <1 hr for the actual electroporation process. As with other transfection procedures, the experiment should be planned to allow for harvest or splitting of the cells 1 to 2 days after transfection.

Transfection of Cultured Eukaryotic Cells Using Cationic Lipid Reagents

The development of high-efficiency methods for the introduction of functional genetic material into eukaryotic cells using cationic lipid–based transfection reagents has accelerated biology research in the studies of gene expression, control of cell growth, and cell lineage. Cationic lipid–mediated transfection techniques are commonly used in industrial protein production as well as in some clinical gene therapy protocols.

Most natural lipids are either neutral or negatively charged (anionic). Positively charged (cationic) lipids were first introduced in 1987 (Felgner et al., 1987). The cationic lipids function by spontaneous electrostatic interaction of their positive charges with the negative charges in the backbone of DNA, RNA, or oligonucleotides, condensing the extended macromolecules to a compact structure. The cationic charges and the lipophilic nature of the cationic lipids then allow the condensed aggregates to interact with and cross the negatively charged and hydrophobic cell membrane and enter the target cells. It is also possible to deliver some proteins into cells using cationic lipids (Sells et al., 1995). Most (but not all) cationic lipid reagents used for transfection consist of mixtures of cationic and neutral lipids (e.g., DOPE, cholesterol) that are formulated in water to yield noncovalent structures called liposomes—hollow spheres with aqueous cores and a diameter of 100 to 400 nm (Felgner et al., 1987). Some are dissolved in ethanol and form micelles (Behr et al., 1989). There are many cationic lipid reagents available (see Background Information and Table 20.6.1). They perform with various efficiencies in different applications and target cells.

This unit describes cationic lipid–mediated transfection of a variety of cell types. DNA transfection is presented for adherent mammalian cells (cell lines as well as primary cultures; see Basic Protocol 1), along with a modified protocol for enhanced transfection (see Alternate Protocol). DNA transfection of suspension mammalian cells (lymphoid, myeloid, and leukemic-derived cells) is also presented (see Basic Protocol 2). For adherent mammalian cells, RNA transfection is also covered (see Basic Protocol 3). Finally, DNA transfection is presented for insect cells (see Basic Protocol 4). To determine

the best transfection conditions for a particular reagent, use the optimization/fine-tuning procedure (see Support Protocol).

NOTE: There are minor differences among the recommended protocols for the various commercially available cationic lipid reagents. The appropriate product profile sheets should be consulted before beginning an experiment.

NOTE: All culture incubations for mammalian cells should be performed in a humidified 37°C, 5% CO_2 incubator. Some media may require altered levels of CO_2 (e.g., for growth of CHO cells in suspension, 8% CO_2 is preferable) to maintain pH 7.4. Insect cells are cultured at 27°C.

BASIC PROTOCOL 1

CATIONIC LIPID–MEDIATED TRANSFECTION OF ADHERENT MAMMALIAN CELLS WITH DNA

This protocol describes the procedure for transfection of DNA into most adherent mammalian cell lines or cultures of primary cells grown attached to culture vessels (Fig. 20.6.1). DNA and lipid reagent are diluted into separate aliquots of serum-free medium, and are then mixed together and allowed to form complexes. Complexes and transfection medium (which may contain serum) are added to the cells in one of two ways. Either the complexes are diluted with transfection medium and this mixture is added to cells that have been rinsed and aspirated (as shown in Fig. 20.6.1), or complexes are added directly to transfection medium that has already been added to the cells (with or without washing). The cells and complexes are incubated together for several hours. After transfection, the volume of the medium is increased if necessary to prevent drying, serum is added if the transfection was serum free, and cells are incubated an additional day or two to allow expression of the transgene.

It is advisable to optimize the conditions for transfection using the Support Protocol. Suggested starting ranges for optimizing the various components of these mixtures are given in Table 20.6.2 for six different popular culture vessel sizes. Transfections can be scaled up to other vessel sizes by increasing the amounts of lipid, DNA, and medium in

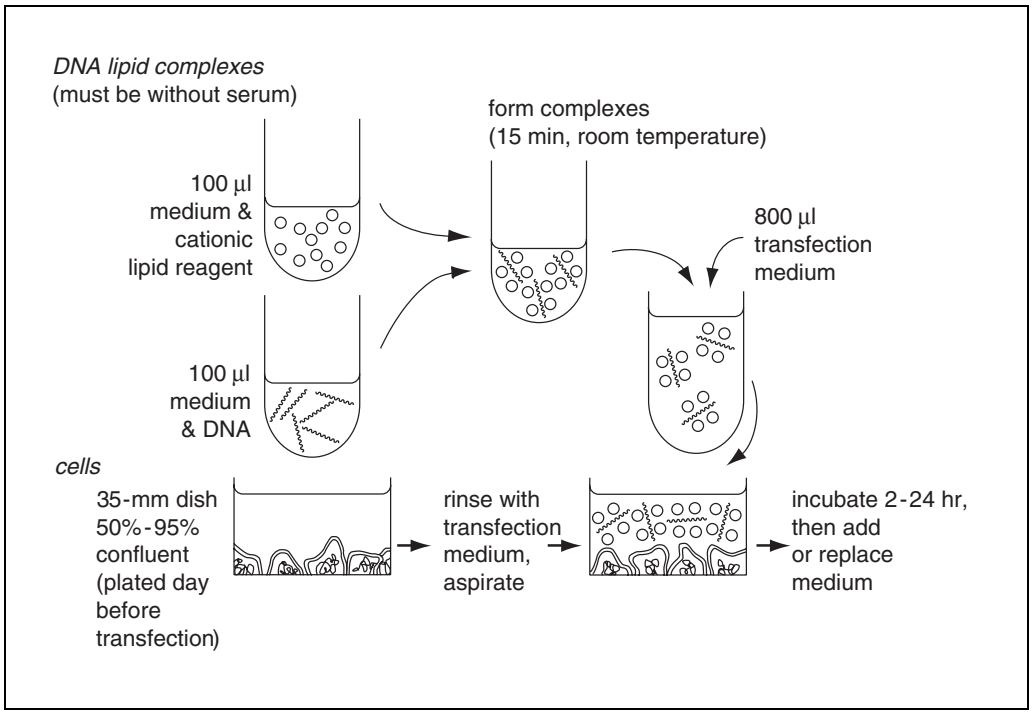

Figure 20.6.1 Diagram of cationic lipid–mediated transfection procedure.

proportion to the difference in surface area. Table 20.6.3 shows the surface areas of several popular culture vessels.

Materials

Adherent cells
Cell culture medium with serum (e.g., complete DMEM, *UNIT 1.2*)
Dilution medium: serum-free cell culture medium or specialized medium for lipid-mediated transfection (e.g., Opti-MEM I, Life Technologies)
Plasmid DNA, purified by anion-exchange chromatography (e.g., Concert High Purity columns, Life Technologies; or see Goldsborough et al., 1998), cesium chloride density gradient, or alkaline lysis (*UNIT 1.6*)
Cationic lipid reagent (see Table 20.6.1)
Polystyrene or polypropylene tubes

Additional reagents and equipment for trypsinization and counting of cells (*UNIT 1.1*), Xgal staining, and selection of stable transformants (*APPENDIX 3A*)

1. The day before transfection, trypsinize and count adherent cells (*UNIT 1.1*). Plate cells in cell culture medium with serum so that they are 50% to 95% confluent on the day of transfection. Avoid antibiotics at the time of plating and during transfection.

   The single most important factor in reproducible, high-efficiency transfection is a consistent number of healthy, proliferating cells. Transfection is most efficient when the cells are maintained in mid-log growth. Because transfection efficiency is sensitive to culture

Table 20.6.2 Suggested Starting Ranges of Reagents for Lipid-Mediated Transfection[a]

Culture vessel	DNA (µg)	Dilution medium (µl)	Cationic lipid reagent (µl)	Transfection medium (ml)	Transfection volume (ml)
	Step 2	Steps 2 & 3	Step 3	Step 5	Step 6
96-well	0.05-0.4	10-25	0.075-1.5	0.08-0.1	0.1-0.15
24-well	0.2-1.6	25-50	0.5-10	0.2-0.5	0.25-0.6
12-well	0.4-3.2	50-100	1-20	0.4-1	0.5-1.2
6-well	1-8	100-250	2.5-50	0.8-2.5	1-3
60-mm	2-16	250-500	5-100	2-5	2.5-6
100-mm	6-48	750-1500	15-300	5-15	6.5-18

[a]Step numbers are indicated from Basic Protocol 1. Volumes have been optimized for LipofectAmine 2000. See Support Protocol for additional optimization strategies.

Table 20.6.3 Surface Areas of Commonly Used Culture Vessels

Culture vessel	Surface area (cm^2)
96-well	0.3
24-well	2
12-well	4
6-well	10
35-mm	8
60-mm	20
100-mm	60
150-mm	140
T25	25
T75	75
T150	150

confluency, cultures should be maintained carefully and passaged frequently, and a standard seeding protocol should be followed from one experiment to the next. Antibiotics may cause some toxicity if present during transfection. For some transfection reagents, the higher cell density is recommended (90% to 95%).

Multiwell cell culture dishes are the easiest to use. Some cells are weakly adherent. If necessary, increase adherence by plating cells on polylysine-coated wells (0.1 mg/ml poly-L-lysine, Sigma; poly-D-lysine-precoated plates, Becton Dickinson).

This protocol is written without specific amounts of reagents. Table 20.6.2 gives the recommended starting amounts for several popular vessels. See Support Protocol for fine tuning the reagent volumes for highest transfection efficiency.

2. On the day of transfection, dilute plasmid DNA into dilution medium in a polystyrene or polypropylene tube and mix. Prepare in bulk for multiple transfections.

   Although DNA prepared by anion-exchange chromatography or CsCl gradients yield the best results, DNA prepared by alkaline lysis (miniprep) will work with lower efficiency.

   Commercial medium that is specialized for lipid-mediated transfection (e.g., Opti-MEM I) yields the highest efficiency, but other serum-free media may be used.

   Polystyrene or polypropylene tubes work well for dilutions. For small-scale transfections, round-bottom 96-well plates with covers are suitable.

3. Dilute cationic lipid reagent into dilution medium in a second tube and mix. Prepare in bulk for multiple transfections.

   See Table 20.6.1 for a partial listing of commercially available reagents. A preparation of the cationic lipid DDAB with the neutral lipid DOPE can be made in the laboratory (Rose et al., 1991), although efficiency may be lower than with some commercial preparations.

   If using Lipofectin, dilute into Opti-MEM I and allow to incubate at room temperature for 30 to 45 min (Ciccarone and Hawley-Nelson, 1995). If using LipofectAmine 2000, dilute into Opti-MEM I and allow to incubate no more than 30 min (Ciccarone et al., 1999).

4. Combine diluted DNA and diluted cationic lipid reagent, mix, and incubate for 15 min at room temperature.

   Incubation times >15 min (up to 6 hr for some reagents) work just as well.

5. While complexes are forming, replace medium on the cells with the appropriate volume of fresh transfection medium.

   This step is not necessary if the complexes are diluted with transfection medium or if using LipofectAmine 2000 (see step 6).

   This medium can be the same as the dilution medium. It is possible to use serum in the transfection medium at this step.

6. Add DNA-lipid complexes to each well containing cells. Mix complexes into the medium gently, holding the plate at a slant. Incubate 5 hr at 37°C in 5% CO_2.

   Adding transfection medium directly to the cells (as described in the steps) helps prevent cells in multiwell plates from drying out, as transfection medium can be added to multiple wells rapidly. Alternatively, complexes can be diluted with the appropriate volume of fresh transfection medium and added to cells from which the cell culture medium has been aspirated (with or without washing, see Fig. 20.6.1). If using LipofectAmine 2000, fresh transfection medium is not required. Undiluted complexes can be added directly to the cell culture medium.

   The exposure time may be >5 hr (up to overnight). Be sure that there is sufficient medium to prevent the cells from drying out (it is not necessary to increase other components if this is done). If necessary to maximize cell growth, replace the medium containing complexes with fresh complete medium after 5 hr incubation.

7. After 5 hr incubation, add cell culture medium to reach normal volume and add serum to bring the final concentration to that of normal cell culture medium.

   This step is omitted in some protocols, especially when serum is present during transfection and volumes are adequate to prevent drying.

8a. *For transient expression analysis:* Assay cell extracts or stain cells in situ 24 to 48 hr after the start of transfection, depending on cell type and promoter activity.

8b. *For stable expression analysis*: Passage cells into fresh culture medium 1 day after the start of transfection. At 2 days posttransfection, add the appropriate antibiotic to select for expression of the transfected antibiotic-resistance gene.

   Several days or weeks of selection are required for stable expression.

ENHANCED CATIONIC LIPID–MEDIATED TRANSFECTION OF ADHERENT MAMMALIAN CELLS WITH DNA

ALTERNATE PROTOCOL

This is an efficient and reproducible protocol for transfection of DNA into most adherent mammalian cell lines or cultures of primary cells grown attached to culture vessels (Dube, 1997; Shih et al., 1997; Fig. 20.6.2). The procedure is essentially as described in Basic Protocol 1, except that DNA is diluted into serum-free medium along with a proprietary enhancing reagent and incubated for 15 min, allowing the formation of precomplexed DNA before addition to the diluted cationic lipid reagent.

The protocol that follows was developed for LipofectAmine Plus, which is composed of two reagents: LipofectAmine (the cationic lipid reagent) and Plus reagent (the enhancer). One of the main advantages of the Plus enhancer is a high plateau of transfection activity

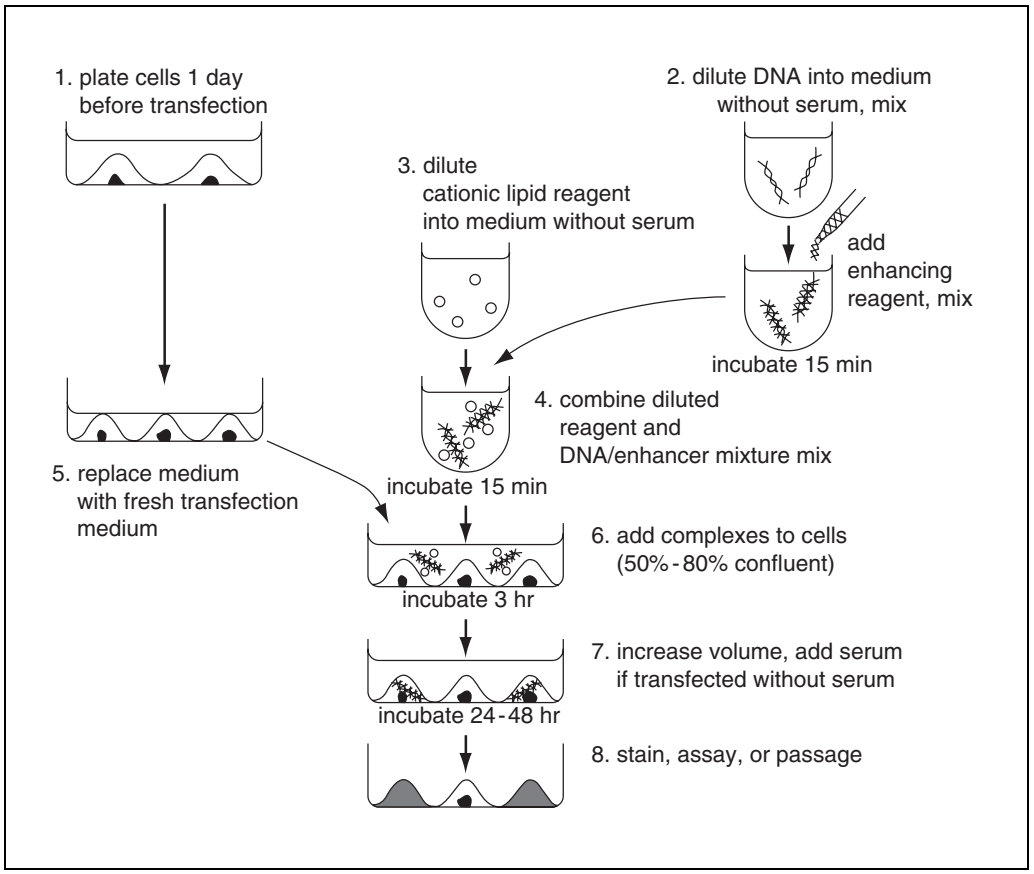

Figure 20.6.2 Diagram of enhanced cationic lipid–mediated transfection procedure.

Table 20.6.4 Suggested Starting Amounts of Reagents for Transfection with LipofectAmine Plus[a]

Culture vessel	DNA (µg)	Plus reagent (µl)	Dilution medium (µl)	LipofectAmine (µl)	Transfection medium (ml)	Transfection volume (ml)
	Step 2	Step 2	Steps 2 & 3	Step 3	Step 5	Step 6
96-well	0.1	1	10	0.5	0.08	0.1
24-well	0.4	4	25	1	0.2	0.250
12-well	0.7	5	50	2	0.4	0.5
6-well	1	6	100	4	0.8	1.0
60-mm	2	8	250	12	2	2.5
100-mm	4	20	750	30	5	6.5

[a]Step numbers indicated from Alternate Protocol. It is possible to fine tune transfections by testing a range of lipid and DNA concentrations to obtain optimal efficiency; however, the peak activity is usually a broad plateau with this reagent.

across a broad range of lipid and DNA concentrations. This decreases the necessity for optimization and allows the recommendation of specific starting conditions (Table 20.6.4). Transfections can be scaled up to other vessel sizes by increasing the amounts of lipid, DNA, enhancer, and medium in proportion to the difference in surface area (see Table 20.6.3).

The other commercially available enhanced cationic lipid reagent is Effectene (Qiagen, see Table 20.6.1). If using this product, consult the appropriate product profile sheets before beginning the experiment.

NOTE: Consult annotations of the standard transfection procedure (see Basic Protocol 1) for additional details, which also apply to this protocol.

Additional Materials *(also see Basic Protocol 1)*

Cationic lipid reagent and enhancer (e.g., LipofectAmine Plus, including LipofectAmine and Plus reagents; Life Technologies)

1. The day before transfection, trypsinize and count adherent cells (*UNIT 1.1*). Plate cells in cell culture medium with serum so that they are 50% to 80% confluent on the day of transfection. Avoid antibiotics at the time of plating and during transfection.

   For this protocol, refer to Table 20.6.4 for recommended amounts of reagents in different vessels.

2. On the day of transfection, dilute plasmid DNA into dilution medium in a polystyrene or polypropylene tube and mix well. Add enhancer, mix, and incubate 15 min at room temperature.

   DMEM is preferred over Opti-MEM I in this protocol. It is important to add the DNA first and mix well before adding the Plus reagent to avoid precipitation of the DNA. Incubation times >15 min (up to an hour) work just as well.

3. Dilute cationic lipid reagent into dilution medium in a second tube and mix.

4. Combine precomplexed DNA and diluted cationic lipid reagent, mix, and incubate for 15 min at room temperature.

   Incubation times >15 min (up to an hour) work just as well when LipofectAmine is the cationic lipid and Plus reagent is the enhancer.

5. While complexes are forming, replace medium on the cells with the appropriate volume of fresh transfection medium.

   The medium can be the same as the dilution medium. It is possible to use serum in the transfection medium at this step. In some cells (e.g., HeLa and NIH 3T3), transfection in medium containing serum is as efficient or more efficient than in medium without serum.

6. Add DNA-enhancer-lipid complexes to each well containing cells. Mix complexes into the medium gently, holding the plate at a slant. Incubate at 37°C in 5% CO_2 for several hours.

   The exposure time with LipofectAmine Plus may be as short as 3 hr or up to overnight. Be sure there is sufficient medium to prevent the cells from drying out (it is not necessary to increase other components if this is done).

7. After incubation, add cell culture medium to reach normal volume and add serum to bring the final concentration to that of normal cell culture medium.

8. Perform transient or stable expression analysis (see Basic Protocol 1, steps 8a and 8b).

CATIONIC LIPID–MEDIATED TRANSFECTION OF SUSPENSION CELLS WITH DNA

BASIC PROTOCOL 2

This protocol is essentially the same as for adherent cells (see Basic Protocol 1) in that lipid and DNA are diluted separately into dilution medium, mixed, and allowed to form complexes before exposing to cells. However, complexes are formed in the wells of multiwell culture plates, and cells are then distributed into the wells containing complexes and allowed to transfect.

Materials

Dilution medium: cell culture medium without serum or specialized medium for transfection (e.g., Opti-MEM I, Life Technologies)
Cationic liposome reagent (e.g., DMRIE-C or LipofectAmine 2000, Life Technologies; also see Table 20.6.1)
Plasmid DNA, purified by anion-exchange chromatography or Goldsborough et al., 1998), cesium chloride density gradient, or alkaline lysis
Cell suspension: 1×10^7 cells/ml in normal cell culture medium without serum or antibiotics
Cell culture medium (e.g., complete DMEM; *UNIT 1.2*)
Serum
6-well tissue culture plates

1. To each well of a 6-well tissue culture plate add 0.5 ml dilution medium.

   Commercial medium that is specialized for lipid-mediated transfection (e.g., Opti-MEM I), without serum or antibiotics, gives the best results. However, other serum-free media may also be used.

   When transfecting in different-sized culture plates, change the amounts of DNA, cationic lipid reagent, and medium in proportion to the difference in surface area (see Table 20.6.3).

2. Add 0, 2, 4, 6, 8, or 12 µl cationic lipid reagent to each well and mix gently by swirling the plate.

   DMRIE-C was found to give high efficiency transfection of DNA in Jurkat (human T cell lymphoma), K562 and KG-1 (human myeologenous leukemia), and MOLT-4 (human lymphoblastic leukemia) cell lines. It is a lipid suspension that may settle with time. To ensure that a homogenous sample is taken, mix thoroughly by inverting the tube 5 to 10 times before removing a sample for transfection.

3. Add 0.5 ml dilution medium containing 4 µg plasmid DNA to each well. Mix by swirling plate.

   The amount of DNA should be optimized for each cell line.

4. Incubate at room temperature for 15 to 45 min to allow formation of lipid-DNA complexes.

5. Add 0.2 ml cell suspension (2×10^6 cells) to each well and mix gently.

   The single most important factor in reproducible, high-efficiency transfection is a consistent number of healthy, proliferating cells. Transfection is most efficient when the cells are maintained in mid-log growth.

6. Incubate several hours at 37°C in a 5% CO_2 incubator.

   A 4-hr incubation is adequate for DMRIE-C transfections.

7. To each well add 2 ml cell culture medium containing 1.5× the usual amount of serum.

   For Jurkat and MOLT-4 cells, addition of 1 μg/ml phytohemagglutinin (PHA) and 50 ng/ml phorbol myristate acetate (PMA) enhances promoter activity and gene expression. For K562 and KG-1 cells, PMA alone enhances promoter activity.

8. Assay the cells at 24 or 48 hr post-transfection for transient or stable expression (see Basic Protocol 1, step 8a or 8b).

BASIC PROTOCOL 3

CATIONIC LIPID–MEDIATED TRANSFECTION OF ADHERENT CELLS WITH RNA

In this protocol, lipid is first diluted into dilution medium and mixed. RNA is then mixed directly into the diluted lipid and immediately added to cells (which have been rinsed with serum-free medium), and cells are incubated for transfection.

Materials

Adherent cells
Cell culture medium with serum (e.g., complete DMEM; *UNIT 1.2)*
Dilution medium: serum-free cell culture medium or specialized medium for transfection (e.g., Opti-MEM I, Life Technologies)
Cationic lipid reagent (e.g., DMRIE-C, Life Technologies; also see Table 20.6.1)
mRNA (see *APPENDIX 3A*)

6-well or 35-mm tissue culture plate
12 × 75–mm polystyrene tubes

Additional reagents and equipment for trypsinizing, counting, and plating cells (*UNIT 1.1*)

1. The day before transfection, trypsinize and count adherent cells (*UNIT 1.1*). In each well of a 6-well tissue culture plate, or in six 35-mm tissue culture plates, seed ~2–3 $\times 10^5$ cells in 2 ml of the appropriate cell culture medium supplemented with serum.

   Transfection is most efficient when the cells are growing rapidly. Cultures should be maintained carefully and passaged frequently. As transfection efficiency may be sensitive to culture confluency, it is important to maintain a standard seeding protocol from experiment to experiment.

2. Incubate at 37°C in a 5% CO_2 incubator until the cells are ~80% confluent.

   This will usually take 18 to 24 hr, but the time will vary among cell types.

3. On the day of transfection, wash the cells in each well with 2 ml dilution medium at room temperature.

   Commercial medium that is specialized for lipid-mediated transfection (e.g., Opti-MEM I), without serum or antibiotics, gives the best results. However, other serum-free media may also be used.

4. Add 1.0 ml dilution medium to each of six 12 × 75–mm polystyrene tubes.

5. Add 0, 2, 4, 6, 8, or 12 µl cationic lipid reagent to each tube and mix or vortex briefly.

   DMRIE-C was found to give high-efficiency transfection of RNA in adherent cell lines (Ciccarone et al., 1995). It is a lipid suspension that may settle with time. To ensure that a homogenous sample is taken, mix thoroughly by inverting the tube 5 to 10 times before removing a sample for transfection.

6. Add 2.5 to 5.0 µg RNA to each tube and vortex briefly.

   mRNA that is capped and polyadenylated is translated more efficiently and is more stable within the cell.

7. Immediately add lipid-RNA complexes to washed cells and incubate 4 hr at 37°C in a 5% CO_2 incubator.

   The time of exposure of cells to lipid-RNA complexes, as well as the amount of RNA added to the cells, should be adjusted for each cell type.

8. Replace transfection medium with cell culture medium containing serum.

9. Allow cells to express the RNA for 16 to 24 hr and analyze them for expression of the transfected RNA as appropriate for the transgene used.

CATIONIC LIPID–MEDIATED TRANSFECTION OF ADHERENT *Sf*9 AND *Sf*21 INSECT CELLS WITH BACULOVIRUS DNA

BASIC PROTOCOL 4

As for transfecting mammalian cells (see Basic Protocol 1), cationic lipid reagent and nucleic acid are diluted separately into serum-free medium and then mixed and allowed to form complexes. Complexes are then diluted with fresh transfection medium and added to the cells for transfection. After the cells are fed and incubated, budded virus can be isolated from the medium.

Materials

Insect cells: *Sf*9 or *Sf*21 cells
Insect medium (e.g., Sf-900 II SFM, Life Technologies) with and without serum and antibiotics
Baculovirus DNA: purified DNA or bacmid DNA miniprep (Anderson et al., 1995)
Cationic lipid reagent (Table 20.6.1)

6-well tissue culture plate
27°C incubator
12 × 75–mm polystyrene tubes, sterile

Additional reagents and equipment for culturing insect cells and harvesting baculovirus from cell supernatants (*APPENDIX 3A*)

1. In each well of a 6-well tissue culture plate, seed ~9×10^5 insect cells in 2 ml insect medium without serum or antibiotics.

   Insect cells must be plated when they are in mid-log growth phase. Cells that have reached stationary phase transfect and infect at very low efficiency. Therefore, it is advisable to maintain a standard cell passage protocol that keeps the cells in log growth. For Sf9 or Sf21 cells adapted in Sf-900 II SFM, cells are passaged twice weekly to a density of 3×10^5 *cells/ml in suspension, and plated for transfection on the third day postseeding, when they are in mid-log phase. For other cell culture media and growth conditions, adjust conditions to maintain similar growth characteristics.*

   For culture of insect cells, use 50 units/ml penicillin and 50 µg/ml streptomycin (half the usual final concentration). For transfection, it is preferable to omit antibiotics from the medium to avoid toxicity.

2. Allow cells to attach at 27°C for ≥1 hr.
3. For each transfection, dilute 1 to 2 µg baculovirus DNA into 100 µl insect medium without serum or antibiotics in a 12 × 75–mm polystyrene tube.
4. For each transfection, dilute 1.5 to 9 µl cationic lipid reagent into 100 µl insect medium without serum or antibiotics in a separate 12 × 75–mm polystyrene tube.

   The suggested amount is 6 µl, but this should be optimized for each system.

   CellFectin gives high-efficiency transfection of DNA in insect cell lines (Anderson et al., 1995). It is a lipid suspension that may settle with time. To ensure that a homogenous sample is taken, mix thoroughly by inverting the tube 5 to 10 times before removing a sample for transfection.
5. Combine the two solutions, mix gently, and incubate at room temperature for 15 to 45 min to form lipid-DNA complexes.
6. For each transfection, add 0.8 ml insect medium without serum or antibiotics to each tube containing lipid-DNA complexes and mix gently.
7. Aspirate medium from cells and overlay diluted lipid-DNA complexes onto the washed cells.

   Alternatively, the medium on the cells can be replaced with 0.8 ml fresh insect medium and the undiluted complexes can be added directly to the fresh medium on the cells.
8. Incubate cells for 5 hr in a 27°C incubator. Protect plates from evaporation by putting them in a humidified container.
9. Remove transfection mixture and add 2 ml insect medium containing antibiotics and serum, if desired. Incubate cells in a 27°C incubator for 72 hr.
10. Harvest baculovirus from cell supernatants.

    Gene expression may also be evaluated in the cells after removal of virus-containing medium.

SUPPORT PROTOCOL

FINE TUNING OR OPTIMIZING CONDITIONS FOR CATIONIC LIPID REAGENT TRANSFECTIONS

This protocol provides an example of a simple one-step procedure for determining conditions conducive to high-efficiency transfections using cationic lipid reagents in any target cell type. A matrix of DNA and lipid reagent concentrations is used on transfections performed in a multiwell plate (Fig. 20.6.3). Once the best conditions have been determined, the transfections may be scaled up to larger vessels using the relative surface area (see Table 20.6.3) to increase the amounts of all reagents proportionately. This protocol can be modified for use with any transfection protocol.

Additional Materials *(also see Basic Protocol 1 and Alternate Protocol)*

24-well tissue culture plates
96-well round-bottom plates (sterile, with lid)

1. The day before transfection, trypsinize and count cells (*UNIT 1.1*). Plate cells in each well of a 24-well tissue culture plate using normal cell culture medium with serum, so that they are 50% to 95% confluent on the day of transfection. Avoid antibiotics at the time of plating and during transfection.

   The single most important factor in high-efficiency transfection is healthy, proliferating cell cultures. Antibiotics may cause some toxicity if present during transfection.

   In a 24-well plate, seeding 4×10^4 to 2×10^5 cells per well will usually give good plating density. Any type of plate may be used by scaling the reagent and cell amounts in proportion to the relative surface area (see Table 20.6.3).

2. Dilute DNA into dilution medium (appropriate for the lipid being optimized) without serum or antibiotics in four microcentrifuge tubes. Use a range of DNA concentrations, and use a volume of dilution medium that is 7× the appropriate protocol volume (see Basic Protocol 1, step 2, and Table 20.6.1). Mix gently after each addition.

   This makes enough DNA per tube for seven wells on a 24-well plate. Good ranges include 0.2 to 1.6 μg DNA per well.

   If the Plus enhancer is being used, include it in the diluted DNA tubes, using 10 μl Plus reagent per μg DNA. Add the Plus reagent to the diluted DNA after mixing well. If the Plus reagent is added first, precipitation may occur.

3. Dilute cationic lipid reagent into dilution medium without serum or antibiotics in six microcentrifuge tubes. Use a range of DNA concentrations, and use a volume of dilution medium that is 5× the appropriate protocol volume (see Basic Protocol 1, step 3, and Table 20.6.1). Mix gently after each addition.

   Be sure to observe timing that works best for the cationic lipid reagent being used.

   This makes enough diluted lipid per tube for five wells on a 24-well plate. Good ranges include 0.5 to 5 μl lipid reagent per well.

4. Pipet equal per-well volumes of diluted DNA and diluted cationic lipid reagent into the wells of a 96-well plate in a matrix corresponding to the wells on the 24-well plate (Fig. 20.6.3). Mix the complexes with the pipet tip by triturating. Cover the plate and incubate for 15 min at room temperature.

   Incubation times >15 min (up to an hour) work just as well, but be sure the complexes do not dry by covering them well.

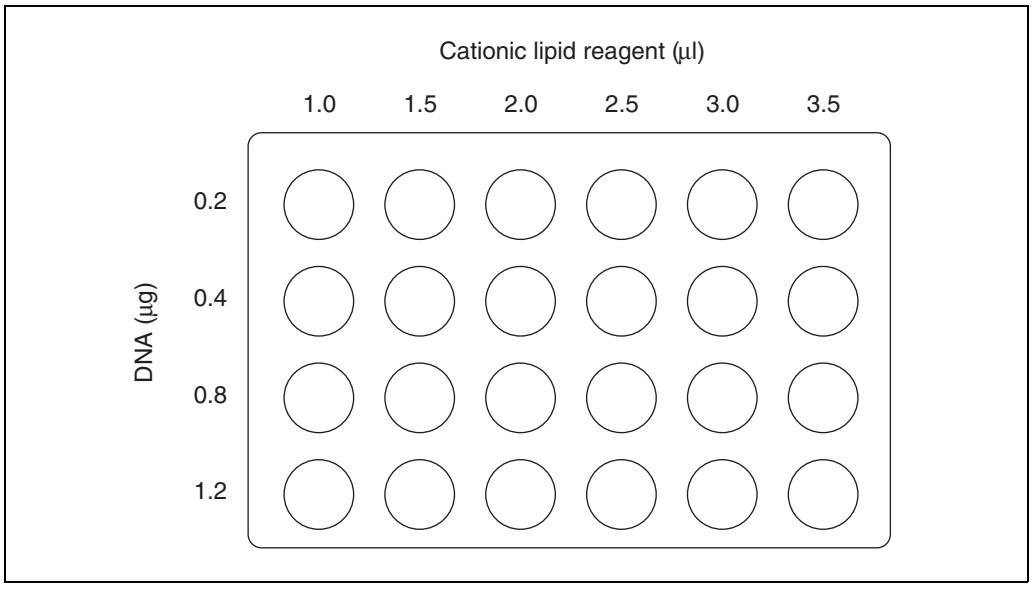

Figure 20.6.3 A sample matrix for fine tuning (optimizing) transfection reagent efficiencies using cationic lipid reagents.

5. While complexes are forming, replace medium on the cells with fresh transfection medium.

   See Basic Protocol 1, steps 5 and 6, for alternate procedures for combining complexes, medium, and cells. The medium can be the same as the serum-free dilution medium. It is possible to use serum in the transfection medium at this step. It is also possible to omit this step when using LipofectAmine 2000.

6. Add aliquots of DNA-lipid complexes (total volume from wells in step 4) to each well containing cells with fresh transfection medium. Mix complexes into the medium gently, holding the plate at a slant. Incubate at 37°C in 5% CO_2 for 5 hr.

   The exposure time may be >5 hr (up to overnight). Be sure there is sufficient medium to prevent the cells from drying out (it is not necessary to increase other components if this is done). If using the Plus enhancer, a 3-hr exposure is sufficient.

7. After 5 hr incubation, add cell culture medium to reach normal volume and add serum to bring the final concentration to that of normal cell culture medium.

   If necessary to maximize cell growth, replace the medium containing the complexes with fresh complete medium after 5 hr incubation. This step may be omitted entirely for some protocols.

8. Check expression as described (see Basic Protocol 1, steps 8a and 8b).

   If peak activity is found to occur on the edge of the matrix of concentrations tested, adjust the concentrations to include the observed peak at the center of a new matrix and repeat the transfection.

COMMENTARY

Background Information

There are currently at least eight companies that market cationic lipid–based transfection reagents. A partial listing of companies and products may be seen in Table 20.6.1. Many companies offer more than one type of reagent. Among the more popular ones are LipofectAmine 2000 and LipofectAmine Plus (Life Technologies), DOTAP and FuGENE 6 (Roche), and Effectene (Qiagen). Some of the structures are proprietary. The structures that are published can be classified into two general categories based on the number of positive charges in the lipid headgroup. The first cationic lipid (DOTMA) has a single positive charge per molecule and is used in Lipofectin (Life Technologies; Felgner et al., 1987). Several other cationic lipid–based transfection reagents such as DOTAP liposomal transfection reagent (Roche) and DMRIE-C (Life Technologies) also make use of singly charged cationic lipid molecules. Increasing the number of positive charges per cationic lipid molecule to as many as five improved transfection efficiency dramatically in most cell types. This can be seen in the examples of DOGS, the cationic lipid in Transfectam (Promega; Behr et al., 1989); DOSPA in LipofectAmine (Life Technologies; Hawley-Nelson et al., 1993); and TMTPS in CellFectin (Life Technologies; Anderson et al., 1995). Further increase in transfection efficiency can sometimes be achieved by precomplexing DNA with a proprietary enhancer. Two commercially available transfection kits with enhancers are LipofectAmine Plus (Life Technologies; Shih et al., 1997) and Effectene (Qiagen).

Life Technologies has designed cationic lipid reagents with specialized applications such as high-efficiency transfection of insect cells (see Basic Protocol 4) or delivery of RNA (see Basic Protocol 3). Lipofectin has high activity for endothelial cell transfection (Tilkins et al., 1994).

Basic Protocol 1 and the Alternate Protocol described in this unit are the procedures with the highest potential for efficient DNA transfection of adherent mammalian cells (Shih et al., 1997; Ciccarone et al., 1999). LipofectAmine 2000 has a simple protocol that yields the highest transfection efficiencies in many cell types. Using the enhancer reagent results in more reproducible transfections without extensive optimization because of the overall high activity. Prior to the availability of enhanced cationic liposome transfections (e.g., using

LipofectAmine 2000 and Effectene), the most effective procedure for transfection of adherent mammalian cells with DNA was with other polycationic reagents (e.g., LipofectAmine; Hawley-Nelson et al., 1993) following Basic Protocol 1. In order to achieve high-efficiency transfections with Basic Protocol 1, it is necessary to optimize lipid and DNA concentrations with the target cells at the desired plating density using a procedure similar to that described in the Support Protocol. Many cationic lipid reagents, as well as transfection reagents based on other chemistries, are available that can be used in Basic Protocol 1 for adherent mammalian cell DNA transfection, but they may yield lower efficiencies than the Alternate Protocol with the enhancer. Optimization using the Support Protocol is highly recommended when not using the enhancer, and the protocol can be modified for use with any cationic lipid reagent.

Critical Parameters

The most critical parameter for successful transfection is cell health. Cells should be proliferating as rapidly as possible at the time they are plated for transfection. On the day of transfection, mitoses should be abundant in healthy cultures. Fresh cultures with a finite life span should be used at the earliest possible passage.

For reproducible transfection results, it is critical to plate the same number of healthy cells for each transfection. Cells should always be counted, preferably using a hemacytometer and trypan blue (*UNIT 1.1*).

Although optimization is not required for high-efficiency transfection when using an enhancer (see Alternate Protocol), it is essential for success without the enhancer, and may improve efficiency even with the enhanced method.

The medium used to dilute and form complexes between the cationic liposomes and the DNA must not contain serum. Serum contains sulfated proteoglycans and other proteins, which compete with the DNA for binding to the cationic lipids. The medium should also not contain antibiotics. There is toxicity to the cells when cationic lipid reagents are used in the presence of antibiotics.

The dilution medium/plating medium for the cells may have some influence on transfection efficiency. Some proprietary serum-free media contain components that inhibit transfection and should be replaced with Opti-MEM I, DMEM, or other media without serum during transfection (Hawley-Nelson and Ciccarone, 1996).

Serum may be present in the medium on the cells during transfection. For most cationic lipid reagents, on most cell types, transfection activity is not inhibited in the presence of serum provided the complexes were formed in serum-free medium (Brunette et al., 1992; Ciccarone et al., 1993, 1999; Shih et al., 1997).

The specific serum-free medium used to dilute the lipid and DNA can have a slight effect on the efficiency of transfection. For the enhanced protocol (Alternate Protocol), normal culture medium such as DMEM is recommended. For the standard procedure (Basic Protocols 1, 2, and 3), Opti-MEM I medium works best. The improvements resulting from using the recommended media are less than two fold. When using Lipofectin, dilution in Opti-MEM I followed by a 30- to 45-min incubation is recommended (Ciccarone and Hawley-Nelson, 1995). With LipofectAmine 2000, the reverse is true: extended incubation (>30 min) of LipofectAmine 2000 in Opti-MEM prior to addition of DNA results in lower transfection activity (Ciccarone et al., 1999).

High-purity DNA will increase transfection efficiency. Miniprep DNA does work, however, when efficiency is not critical. A wide range of sizes of polynucleotides may be transfected, from 18-mer single-stranded oligonucleotides (Chiang et al., 1991; Bennett et al., 1992; Yeoman et al., 1992; Wagner et al., 1993) to 400-kb YAC DNAs (Lamb et al., 1993). Excess vortexing of complexes or DNA solutions may result in some shearing, especially with larger molecules. The concentration of EDTA in the diluted DNA should not exceed 0.3 mM.

Transgene expression may be increased in some cell types by inducing the promoter. This is observed in Jurkat cells when phytohemagglutinin and phorbol myristate acetate are added following transfection to activate the cytomegalovirus promoter (Schifferli and Ciccarone, 1996).

Troubleshooting

The most common complaints surrounding transfections include decreased transfection efficiency and low cell yield. Decreases in efficiency often result from changes in the target cell line. Cultured cell lines are usually aneuploid and often consist of a mixture of genotypes and phenotypes that can be subject to selection in the laboratory environment. Primary cultures, although usually genotypically uniform, often consist of a mixture of phenotypes from different tissues and can change their population characteristics in response to

their environment. Whenever a decrease in transfection efficiency is observed, the first thing to try is to work with a freshly thawed culture or isolate (Hawley-Nelson and Shih, 1995). Be sure the same number of cells is plated in each experiment, since plating density affects efficiency and peak position (Hawley-Nelson et al., 1993).

Low cell yield often results from the use of too much DNA or cationic lipid reagent. Use lower concentrations of these two components and examine the results for transfection efficiency as well as cell yield. Acceptable efficiency can usually be obtained with higher cell yield by using lower concentrations of lipid and DNA (Hawley-Nelson et al., 1993; Life Technologies, 1999).

Cell yield can also be improved in several other ways. (1) Increasing the plating density. This usually requires adjustment of lipid and DNA amounts, but often the transfection efficiency as well as the cell yield increases with higher plating input (Life Technologies, 1999). (2) Decreasing time of exposure of the cells to cationic lipid–DNA complexes. This can be done by increasing volume and adding back serum at earlier times or by removing the complexes from the cells at the end of transfection. (3) Performing the transfection in the presence of serum. Most cationic lipid reagents work

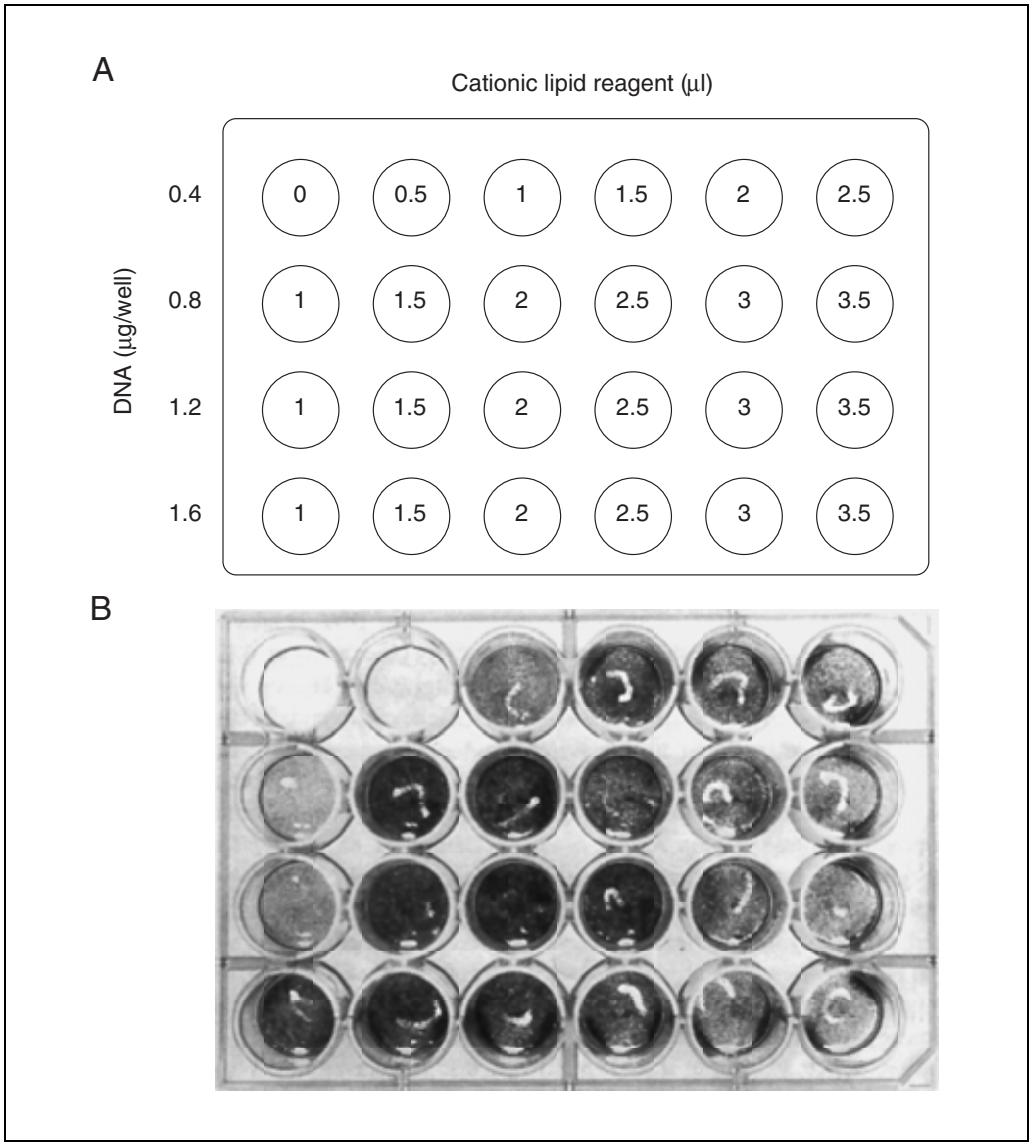

Figure 20.6.4 Results of fine-tuning or optimizing conditions for transfection. Before transfection, 293 H cells were plated at 2×10^5/well in a 24-well plate precoated with poly-D-lysine. The following day, cells were transfected with pCMV·SPORTβgal DNA using LipofectAmine 2000 as described (see Support Protocol). One day posttransfection, cells were fixed and stained with Xgal. (**A**) Amounts of DNA and lipid reagent used. (**B**) Results of Xgal staining.

Table 20.6.5 Activity for a Scaled-up Transfection Using LipofectAmine Plus in BHK-21 Cells

Plate	Surface area ratio to 24-well plate	Cells/well ($\times 10^4$)	DNA/well (μg)	Plus reagent (μl)	LipofectAmine reagent (μl)	β-gal (ng/cm^2)[a]
24-well	1	4	0.4	2	2	188 ± 5
12-well	2	8	0.8	4	4	193 ± 12
6-well	5	20	2	10	10	179 ± 27
60-mm	10	40	4	20	20	171 ± 16
100-mm	28	112	11.2	560	56	157

[a]Results are the mean of three transfections ± the standard deviation.

well in transfection medium containing serum (Brunette et al., 1992; Ciccarone et al., 1993, 1999; Shih et al., 1997). One exception is LipofectAmine without the Plus enhancer.

Some cationic lipid solutions are naturally cloudy. Sometimes cloudiness is observed when complexes are made with DNA. Usually this does not interfere with transfection efficiency. Most cationic liposome solutions (especially DMRIE-C and CellFectin) should be mixed gently by inversion just before use to produce a uniform suspension. With Plus reagent, it is possible to precipitate the DNA when the Plus reagent is diluted first into the DMEM and DNA is added second. Always dilute the DNA into DMEM and mix well before adding Plus reagent.

Anticipated Results

Transfection should be observed for most adherent mammalian cells transfected with DNA using Basic Protocol 1. Efficiencies vary with cell type. For example, 293, COS-7, and CHO-K1 cells yield 95% or more blue cells following Xgal staining of cells transfected with pCMVSPORTβgal plasmid DNA using LipofectAmine 2000. The authors have noted efficiencies of other cell types as high as 49% for SK-BR3 breast cancer cell lines, 77% for BE(2)C human neuroblastoma cells, and 43% for MDCK canine kidney cells (Ciccarone et al., 1999). Efficiencies also vary for suspension cells. The authors note that while LipofectAmine Plus is relatively inefficient for transfecting Jurkat cells, DMRIE-C can yield up to 85% blue cells following pCMV·SPORTβgal plasmid DNA transfection, gene activation

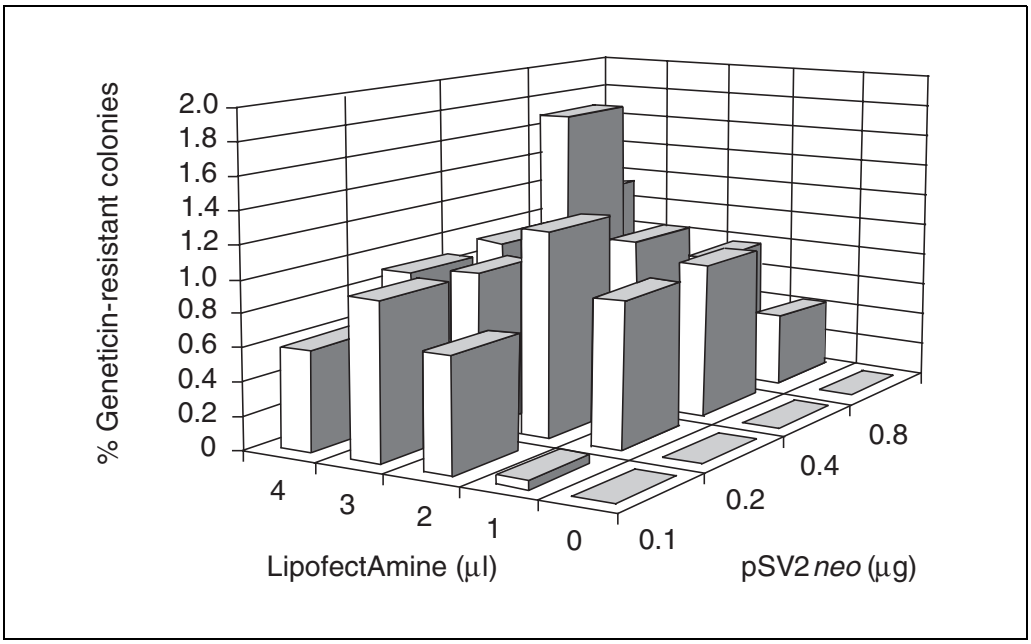

Figure 20.6.5 Stable transfection of NIH 3T3 cells. Cells were plated at 6×10^4 cells/well in 24-well plates. The day after plating, cells were transfected with LipofectAmine Plus complexed with pSV2*neo* DNA. The following day, cells were passaged at a total dilution of 1/150. Cells were exposed to 0.6 mg/ml Geneticin antibiotic from day 3 to day 13, and were then washed once with PBS and stained with 0.2% toluidine blue in PBS with 10% formalin.

with phytohemagglutinin and phorbol myristate acetate, and Xgal staining (Ciccarone et al., 1995, Schifferli and Ciccarone, 1996).

The result of a typical fine-tuning/optimization protocol is shown in Figure 20.6.4. The transfection reagent was LipofectAmine 2000, the DNA was pCMV·SPORTβgal, the cells were 293 H. Cells were stained the day following transfection and were allowed to stain overnight at 37°C. A selection of transfection conditions can be made.

Conditions found to be advantageous for transfection in small wells may be scaled up, the results of a typical scale-up are given in Table 20.6.5.

The results of a stable transfection of NIH 3T3 cells with pSV2*neo* DNA using an enhancer reagent (LipofectAmine Plus) are shown in Figure 20.6.5. The transfection was done on 24-well plates, the cells were passaged onto 6-well plates the following day, and selection with geneticin was done for 10 days. The figure shows optimization of conditions and the generally high efficiency that can be achieved using this method.

Time Considerations

Counting and plating the cells should be done the day before transfection and will usually require <1 hour. Transfection is usually done in the morning. Depending on the number of conditions being evaluated, it may require all morning plus a short period in the afternoon to increase medium volume or feed the cells. The total time required is <1 day.

Optimization of Transfection

When embarking upon any transfection procedure, a critical first step is to optimize conditions. Every mammalian cell type has a characteristic set of requirements for optimal introduction of foreign DNA; there is a tremendous degree of variability in the transfection conditions that work, even among cell types that are very similar to one another. Often, an experimenter must screen a wide variety of cell types for a desired regulatory trait, such as an appropriate response to a particular effector molecule. It is thus helpful to have a straightforward, systematic approach to optimizing transfection efficiency. Transient assay systems are particularly useful for this purpose. A fusion gene that is known to function in mammalian cells can be transfected into cells under a variety of conditions, and transfection efficiency can be easily monitored by assaying for the fusion gene product. The human growth hormone (hGH) assay system is particularly useful for this purpose because both harvest and assay take very little time. However, any reporter system can be used to optimize transfection efficiency.

The single most important factor in optimizing transfection efficiency is selecting the proper transfection protocol. This usually comes down to a choice among calcium phosphate–mediated gene transfer (*UNIT 20.3*), DEAE-dextran-mediated gene transfer (*UNIT 20.4*), electroporation (*UNIT 20.5*), and liposome-mediated transfection (*UNIT 20.6*). Fusion techniques such as protoplast fusion and microinjection may also be considered. Cells are variable with respect to which transfection protocol is most efficient. It is recommended that any adherent cell line under investigation be tested for transfection ability with DEAE-dextran, calcium phosphate, and liposome-mediated transfection. Nonadherent cell lines can be transfected by electroporation and liposome-mediated transfection. Generally, if a cell can be grown in culture, it can be transfected.

CALCIUM PHOSPHATE TRANSFECTION

The primary factors that influence efficiency of calcium phosphate transfection (*UNIT 20.3*) are the amount of DNA in the precipitate, the length of time the precipitate is left on the cell, and the use and duration of glycerol or DMSO shock. A calcium phosphate optimization is shown in Table 20.7.1. Generally, higher concentrations of DNA (10 to 50 μg) are used in calcium phosphate transfection. Total DNA concentration in the precipitate can have a dramatic effect on efficiency of uptake of DNA with calcium phosphate–mediated transfection. With some cell lines, more than 10 to 15 μg of DNA

Table 20.7.1 Optimization of Calcium Phosphate Transfection

Dish (10-cm)	pXGH5 (μg)	pUC13 (μg)	Exposure to precipitate (hr)	Glycerol shock (min)
1	5	5	6	—
2	5	15	6	—
3	5	35	6	—

Current Protocols in Cell Biology (2003) 20.7.1-20.7.4

added to a 10-cm dish results in excessive cell death and very little uptake of DNA. With other cell types, such as primary cells, a high concentration of DNA in the precipitate is necessary to get any DNA at all into the cell on a routine basis. For example, with human foreskin fibroblasts, transfection of 5 μg of a reporter plasmid with 5 μg of carrier DNA (e.g., pUC13) gives significantly less expression than does transfection of 5 μg of reporter plasmid with 35 μg of carrier DNA. Presumably, this is because the amount of DNA affects the nature of the precipitate and thus alters the fraction of the applied DNA that is taken up into cells.

The optimal length of time that the precipitate is left on cells varies with cell type. Some cell types, such as HeLa or BALB/c 3T3, are efficiently transfected by leaving the precipitate on for 16 hr. Other cell types cannot survive this length of exposure to the precipitate. Transfection efficiency of some cell types, such as CHO DUKX BII, is dramatically increased by glycerol or DMSO shock (*UNIT 20.3*). The pilot experiment listed will indicate whether the cell type is tolerant to long exposure to a calcium phosphate precipitate and whether glycerol shock should be used. Once the results of this experiment are in hand, finer experiments can be done to further optimize conditions. For example, if shocking with 10% glycerol for 3 min enhances transfection efficiency, an experiment varying the time of glycerol shock or also trying 10% and 20% DMSO shock might be done.

Once optimal conditions for transfection are found, extensive DNA curves varying the amount of reporter plasmid should be prepared. The total amount of DNA should be kept constant at the optimal level determined in the first experiment. The amount of reporter plasmid DNA (e.g., pXGH5) should be varied, and carrier DNA (e.g., pUC13) should be used to make up the difference. This is to ensure that transfections are performed under conditions where the amount of reporter plasmid in the cell is not saturating the cellular transcription and translation machinery.

DEAE-DEXTRAN TRANSFECTION

There are several factors that can be varied in DEAE-dextran transfection (*UNIT 20.4*). The number of cells, concentration of DNA, and concentration of DEAE-dextran added to the dish are the most important to optimize. To a first approximation, most cell types that can be transfected using DEAE-dextran will have a preference for 1 to 10 μg DNA/10-cm dish and for 100 to 400 μg DEAE-dextran/ml of medium. Table 20.7.2 shows how the dishes in an optimization might be chosen. The 20-dish experiment consists of two sets of 10 dishes; one set is plated at 5×10^5 cells/dish, the other is plated at 2×10^6 cells/dish. Each set contains dishes that will be transfected with 1 to 10 μg of a reporter plasmid and

Table 20.7.2 Optimization of DEAE-Dextran Transfection

5×10^5 cells/10-cm dish:			2×10^6 cells/10-cm dish:		
Dish	pXGH5 (μg)	DEAE-dextran (μg/ml)	Dish	pXGH5 (μg)	DEAE-dextran (μg/ml)
1	1	400	11	1	400
2	1	200	12	1	200
3	1	100	13	1	100
4	4	400	14	4	400
5	4	200	15	4	200
6	4	100	16	4	100
7	10	400	17	10	400
8	10	200	18	10	200
9	10	100	19	10	100
10	0	200	20	0	200

100 to 400 μg/ml DEAE-dextran. If an hGH expression vector such as pXGH5 is used, a time course of expression under each condition can be determined by removing 100-μl aliquots of the medium 2, 4, and 7 days posttransfection (with a medium change after the day 4 aliquot is removed).

With the results of this pilot experiment in hand, a second experiment using a narrower range of DEAE-dextran concentrations and a wider range of DNA doses should be undertaken. For example, if the cells appear to express more hGH at 100 μg/ml DEAE-dextran than at higher concentrations in the pilot experiment, the second experiment should cover from 25 to 150 μg/ml DEAE-dextran. Because DEAE-dextran is toxic to some cells, a brief exposure to small concentrations may be optimal. The wide range of added DNA in this experiment is crucial in two respects. First, it is valuable to know the smallest amount of the transfected reporter gene that can give a readily detectable signal. Second, the linearity of the dose of DNA with the amount of reporter gene expression generally decays for large amounts of input DNA. When excessive (i.e., nonlinear) amounts of DNA are used in transfection experiments, it is possible that the effects observed are dose-response effects rather than the phenomenon intended for study. This serious and common problem can be eliminated by doing a careful DNA dose–response curve as above.

ELECTROPORATION

Perhaps because it is not a chemically based protocol, electroporation (*UNIT 20.5*) tends to be less affected by DNA concentration than either DEAE-dextran- or calcium phosphate–mediated gene transfer. Generally, DNA amounts in the range of 10 to 40 μg/10^7 cells work well, and there is a good linear correlation between the amount of DNA present and the amount taken up. The parameter that can be varied to optimize electroporation is the amplitude and length of the electric pulse, the latter being determined by the capacitance of the power source. The extent to which this can be varied is determined by the electronics of the power supply used to supply the pulse. The objective is to find a pulse that kills between 20% and 60% of the cells. This generally is in the range of 1.5 kV at 25 μF. If excessive cell death occurs, the length of the pulse can be lowered by lowering the capacitance. Settings between 3 and 25 μF can be tried.

LIPOSOME-MEDIATED TRANSFECTION

Three primary parameters—the concentrations of lipid and DNA and incubation time of the liposome-DNA complex—affect the success of DNA transfection by cationic liposomes (*UNIT 20.6*). These should be systematically examined to obtain optimal transfection frequencies.

Concentration of Lipid

In general, increasing the concentrations of lipid improves transfection of four cell lines examined (CV-1 and COS-7 with Lipofectin, and HeLa and BHK-21 with TransfectACE; see *UNIT 20.6*). However, at high levels (>100 μg), the lipid can be toxic. For each particular liposome mixture tested, it is important to vary the amount as indicated in Table 20.7.3.

Concentration of DNA

In many of the cell types tested, relatively small amounts of DNA are effectively taken up and expressed. In fact, higher levels of DNA can be inhibitory in some cell types with certain liposome preparations. In the optimization protocol outlined in Table 20.7.3, the standard reporter vector pSV2CAT is used; however, any plasmid DNA whose expression can be easily monitored would be suitable.

Table 20.7.3 Optimization of Liposome-Mediated Transfection

Dish (35-mm)	pSV2CAT (μg)	Liposomes (μl)	Dish (35-mm)	pSV2CAT (μg)	Liposomes (μl)
1	0.1	1	11	5	5
2	0.1	2	12	5	10
3	0.1	4	13	5	15
4	0.1	8	14	5	20
5	0.1	12	15	5	30
6	0.5	1	16	10	5
7	0.5	2	17	10	10
8	0.5	4	18	10	15
9	0.5	8	19	10	20
10	0.5	12	20	10	30

Time of Incubation

When the optimal amounts of lipid and DNA have been established, it is desirable to determine the length of time required for exposure of the liposome-DNA complex to the cells. In general, transfection efficiency increases with time of exposure to the liposome-DNA complex, although after 8 hr, toxic conditions can develop. HeLa or BHK-21 cells typically require ~3 hr incubation with the liposome-DNA complex for optimal tranfection, while CV-1 and COS-7 cells require 5 hr of exposure.

Inducible Gene Expression Using an Autoregulatory, Tetracycline-Controlled System

Tetracycline-regulated gene expression systems have been developed to overcome some of the obstacles encountered using other strategies for inducible gene expression in mammalian cells. These difficulties include pleiotropic, nonspecific effects or toxicity of inducing agents or treatments, and high uninduced background levels of expression. This unit describes protocols for using a modified tetracycline-regulated system in which a transcriptional transactivator drives expression of itself and a target gene in cultured cells and, to some extent, in transgenic mice. This transactivator (tTA) is a fusion protein consisting of the tetracycline-repressor of *E. coli* and the transcriptional activation domain of the VP16 protein of herpes simplex virus. In the absence of tetracycline, tTA binds to and activates genes preceded by a heptamerized version of the tetracycline-resistance operator of Tn*10* plus a minimal CMV promoter (here collectively referred to as Tet P). Binding of tTA to Tet P and subsequent gene activation are blocked in the presence of tetracycline. The plasmid pTet-Splice (Fig. 20.8.1A) contains Tet P upstream, and SV40 splice and polyadenylation signals downstream, of a multiple cloning site into which sequences encoding the open reading frame (ORF) of a target gene of choice is easily inserted. Autoregulatory tTA expression is driven from the plasmid pTet-tTAk (Fig. 20.8.1B), in which the tTA ORF (including an optimal sequence for initiation of translation according to Kozak) has been inserted into pTet-Splice.

The protocols in this unit describe the transfection of adherent cells and the testing of resultant clones for inducible transactivator or target gene protein expression. Stably transfected fibroblast cell lines expressing transactivator and target gene(s) can be derived by first cotransfecting pTet-tTAk and a plasmid encoding a selectable marker and obtaining stable lines with inducible transactivator expression (see Basic Protocol). These lines are subsequently stably cotransfected with plasmids encoding the target gene(s) and a second selectable marker. The procedure may also be used to cotransfect pTet-tTAk with the target gene–encoding plasmid(s) and a single selectable marker plasmid. The choice of method depends upon the feasibility of screening for the protein products of the target genes. While the consecutive method is more systematic, cotransfection may be faster given a relatively straightforward screening method for expression of the target gene (see Critical Parameters).

A Support Protocol also describes methods to test stably transfected cell lines for inducible gene expression, for transient transfection and induction of tet-regulated plasmids, and for detection of the tTAk gene in cells (or transgenic mice).

CALCIUM PHOSPHATE-MEDIATED STABLE TRANSFECTION OF NIH3T3 CELLS WITH pTET-tTAk AND TETRACYLINE-REGULATED TARGET PLASMIDS

BASIC PROTOCOL

This protocol describes the stable transfection of adherent cells with pTet-tTAk for the derivation of cell lines expressing inducible tTA. In the first round of transfection stable cell lines expressing inducible tTA alone are produced. The single transfection procedure may also be used for stable cotransfection of pTet-tTAk and plasmids expressing the target gene(s). In the second round of transfection tTA-expressing lines are transfected with plasmids expressing the target gene(s).

Current Protocols in Cell Biology (2005) 20.8.1-20.8.10

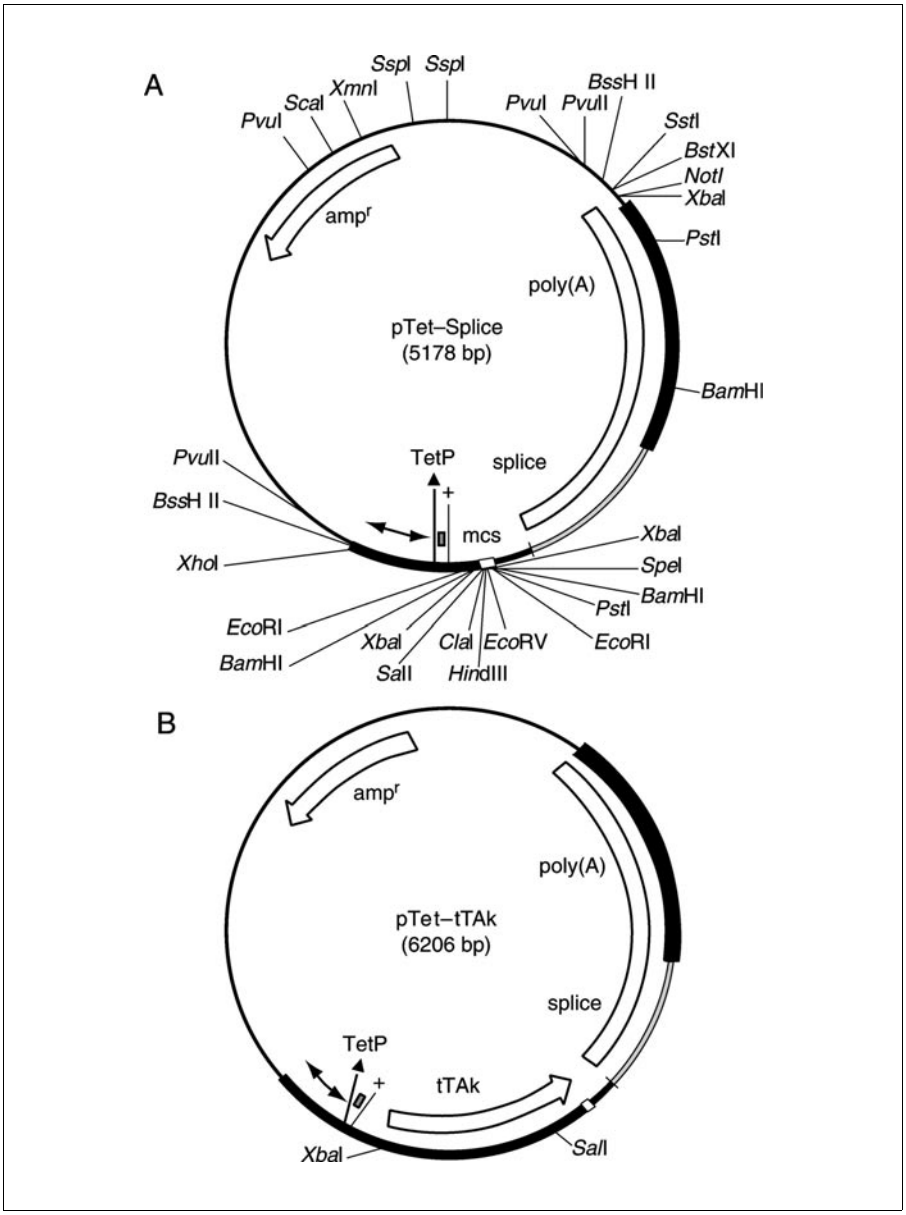

Figure 20.8.1 (**A**) The plasmid pTet-Splice (Shockett et al., 1995) is designed to drive tetracycline-regulated expression of a target gene inserted into the multiple cloning site (mcs). The tetracycline-regulated promoter (TetP) consists of a heptamerized tetracycline operator (double-ended arrow) upstream of a minimal human CMV promoter that includes bases −53 (triangle) to +75. The transcriptional start site (+) and TATAA box (small rectangle) are also indicated. This TetP fragment is an *Xho*I-*Sal*I fragment derived from pUHC13-3 (Gossen and Bujard, 1992). SV40-derived sequences downstream of the MCS drive mRNA splicing and polyadenylation. The backbone of the plasmid is from Bluescript II KS+ (Stratagene) and carries the ampicillin resistance gene (*amp*^{r}). (**B**) pTet-tTAk (Shockett et al., 1995) consists of the tTAk open reading frame inserted into the *Hin*dIII-*Eco*RV sites of pTet-Splice.

Materials

NIH3T3 cells
Complete DMEM-10 medium (see recipe)
Complete DMEM/tet: complete DMEM-10 medium (see recipe) containing 0.5 μg/ml tetracycline hydrochloride (Sigma; dilute 10 mg/ml stock in 70% ethanol and store protected from light at −20°C)
Selection medium (see recipe) containing 125 μM, 250 μM, or 500 μM L-histidinol
Plasmids for first-round or cotransfection procedure: pTet-tTAk (Life Technologies) and plasmids containing target gene ORF(s) cloned into pTet-Splice (Life Technologies), pSV2-His, or another selectable marker plasmid; purified by CsCl banding or anion-exchange chromatography
Plasmids for second round transfection procedure: plasmids containing target gene ORF(s) cloned into pTet-Splice, pPGKPuro, or another selectable marker plasmid; purified by CsCl banding or anion-exchange chromatography
2 M $CaCl_2$
HEPES-buffered saline (HeBS; see recipe)
10 mg/ml chloroquine (19 mM; optional; Sigma); dilute in water and store at −20°C
85% (v/v) HeBS/15% (v/v) glycerol, prewarmed to 37°C
3 mg/ml puromycin (Sigma) diluted in PBS (*APPENDIX 2A*)
Phosphate-buffered saline (PBS; *APPENDIX 2A*)
1× trypsin/EDTA (Invitrogen)
10-cm and 6-cm tissue culture plates
4-ml polystyrene tubes (Falcon)
24-well and 6-well tissue culture plates

NOTE: All tissue culture incubations are performed in a humidified 37°C, 5% CO_2 incubator.

Grow the cells

1a. *First round only:* Grow cells in complete DMEM-10 medium. The day before transfection split cells into 10-cm tissue culture plates in complete DMEM/tet to achieve one-third confluence on the day of the transfection.

From this point on cells are kept in the presence of 0.5 μg/ml tet.

One plate per transfection is needed at this stage. A typical experiment might include one plate for tTA only, one for tTA plus target gene, and one to serve as the untransfected control plate.

1b. *Second round only:* Grow stable cell lines that inducibly express autoregulatory tTA in selection medium/500 μM L-histidinol. The day before transfection split into 10-cm plates in this same medium to achieve one-third confluence on the day of transfection.

Transfect the cells

2. Linearize plasmids prior to transfection and adjust concentration to ≥0.5 mg/ml.

See Damke et al. (1995) for discussion of other selectable markers. All plasmids should be purified by CsCl banding (APPENDIX 3A) or on a Qiagen column.

3a. *First round only:* Mix 10 to 20 μg of pTet-tTAk (in the presence or absence of an equimolar amount of target gene plasmids) plus 1 to 2 μg pSV2-His (a molar ratio of ~10:1 of each tet plasmid to selectable marker plasmid) with 500 μl HeBS in a clear 4-ml polystyrene tube.

A control mock transfection should be performed with no DNA added to the transfection. All of these cells should die in the selection medium/125 μM L-histidinol introduced in step 14.

3b. *Second round only:* Mix 10 to 20 μg each of target gene plasmid(s) plus 1 to 2 μg pPGKPuro (a molar ratio of ~10:1 of each tet plasmid to selectable marker plasmid) with 500 μl HeBS in a clear 4-ml polystyrene tube.

A control mock transfection should be performed with no DNA added to the transfection. All of these cells should die in the presence of the puromycin introduced in step 14. The optimal killing concentration for puromycin (lowest dose between 0.1 μg/ml to 10 μg/ml that kills all untransfected cells within a few days) should be determined empirically prior to the transfection and varies with the cell type.

4. Add 32.5 μl of 2 M $CaCl_2$ to plasmid DNA and mix immediately by gentle vortexing. With occasional gentle mixing, allow precipitate to form for 15 to 30 min at room temperature or until solution is visibly cloudy when compared to a tube containing water.

5. Aspirate all of the medium from cells, doing one plate at a time. Mix precipitate a few times by pipetting with a Pasteur pipet, and apply dropwise and evenly over cells.

6. Incubate 30 min, gently rocking the plate after 15 min to ensure even coverage over entire plate.

7a. *First round only:* Add 10 ml complete DMEM/tet, with or without 25 μM chloroquine (final), to each plate.

Although the use of chloroquine may further reduce cell integrity during the glycerol shock (step 9), it can improve transfection efficiency.

7b. *Second round only:* Add 10 ml selection medium/500 μM L-histidinol, with or without 25 μM chloroquine (final), to each plate.

8. Incubate 4 to 5 hr.

The optimal length of incubation may vary for different cell types.

9. Gently aspirate medium from cells with minimal disruption of the precipitate that has settled onto the cells. Shock cells by adding dropwise 2.5 ml of prewarmed 85% HeBS/15% glycerol.

It is normal for the cells to look somewhat ragged before and especially after glycerol shock. Two to four plates may be shocked at one time, depending on the speed of the researcher.

10. Aspirate HeBS/glycerol after exactly 2.5 min. Work quickly, as glycerol can be very toxic to the cells.

The length of time cells are exposed to glycerol solution can be varied and increased up to 4 to 5 min to optimize transfection efficiency for different cell types. Cells should be shocked the maximal length of time which results in the least cell death.

11a. *First round only:* Immediately, gently, and quickly wash cells twice by adding 10 ml complete DMEM/tet and immediately aspirating.

Because cells tend to come loose from the plate after glycerol addition, add all medium to a single spot on the plate.

11b. *Second round only:* Immediately, gently, and quickly wash cells twice by adding 10 ml selection medium/500 μM L-histidinol and immediately aspirating.

Again, add medium to a single spot on the plate to avoid loosening the cells.

12a. *First round only:* Add 10 ml complete DMEM/tet. Incubate cells overnight.

12b. *Second round only:* Add 10 ml selection medium/500 μM L-histidinol. Incubate cells overnight.

13a. *First round only:* The morning after the transfection, aspirate the medium and replace with 10 ml complete DMEM/tet. Continue incubation.

13b. *Second round only:* The morning after the transfection, aspirate the medium and replace with 10 ml selection medium/500 μM L-histidinol. Continue incubation.

Select and clone transfected cells

14a. *First round only:* At 48 hr posttransfection, split cells into selection medium/125 μM L-histidinol at several dilutions ranging from 3×10^4 to 1×10^6 cells per 10-cm plate. Make more than one plate in the mid-range that corresponds to an approximate split from one confluent plate of 1:16 to 1:32.

14b. *Second round only:* At 48 hr posttransfection, split cells as above, using selection medium/500 μM L-histidinol containing 3 μg/ml puromycin (final).

The optimal killing concentration for puromycin (lowest dose between 0.1 μg/ml to 10 μg/ml that kills all untransfected cells within a few days) should be determined empirically prior to the transfection and varies with the cell type. The concentration of 3 μg/ml puromycin is sufficient for selection of transfected NIH3T3 cells.

15a. *First round only:* Refeed cells 4 days later with selection medium/125 μM L-histidinol. When colonies have formed, increase the concentration of L-histidinol in the selection medium to 250 μM.

L-histidinol is normally toxic to cells. The concentration of L-histidinol in the selection medium is therefore kept low initially and is raised as the number of cells expressing pSV_2-His at high levels reaches a critical mass.

15b. *Second round only:* Refeed cells 4 days later with selection medium/500 μM L-histidinol/puromycin.

16. When colonies are well established (at about day 12 to 14 of selection), circle their borders with a marker. Aspirate medium from plate and place a plastic cloning ring (autoclaved upright in vacuum grease) on the plate to surround an individual clone. Wash clones quickly with ~100 μl PBS and add 2 drops of trypsin (~100 μl) for 30 sec to 1 min.

Pick cells from plates on which individual colonies are moderately spaced and can easily be distinguished.

17a. *First round only:* Loosen cells by pipetting up and down with a Pasteur pipet and transfer colonies to wells of a 24-well plate into 1 ml selection medium/250 μM L-histidinol.

17b. *Second round only:* Loosen cells as for first round, transferring them into 1 ml selection medium/500 μM L-histidinol/puromycin.

18a. *First round only:* When cells are heavy in wells, split into 6-cm dishes in selection medium/500 μM L-histidinol.

18b. *Second-round only:* When cells are heavy in wells, split into 6-cm dishes in selection medium/500 μM L-histidinol/puromycin.

All trypsinization is performed by standard methods (UNIT 1.1), involving a quick PBS wash, a 1 to 3 min trypsin/EDTA incubation (2 ml per confluent 10-cm plate), and using 3rd selection medium/500 μM L-histidinol (± puromycin) and containing 10% calf serum to dilute and stop the trypsin.

19a. *First round only:* Expand cells for testing in selection medium/500 μM L-histidinol. Freeze aliquots of cells for storage in liquid nitrogen and grow in selection medium/500 μM L-histidinol from this point on. Test for tTA or target gene expression (if applicable; see Support Protocol for methods that may be used). Or, if applicable, repeat transfection procedure with target gene plasmid(s), following steps 1 to 18 and using the options listed for second-round transfection.

19b. *Second round only:* Test for target gene expression by northern or immunoblotting (*UNIT 6.2*) after induction (see Support Protocol). Freeze aliquots for storage in liquid nitrogen and grow in selection medium/500 μM L-histidinol/puromycin from this point on.

SUPPORT PROTOCOL

ANALYSIS OF TARGET GENE PROTEIN EXPRESSION

This protocol outlines methods for the analysis of target gene expression and inducibility. Instructions for inducing stable cell lines, for examining transient target gene expression with and without induction, and for PCR amplification of the tTA gene are included, with references to detection procedures such as Southern, northern, and immunoblotting (*UNIT 6.2*) techniques.

Induction of Stable Cell Lines

Stable cell lines can be tested for tTA or target gene expression by comparing induced to uninduced cells for tTA mRNA or target gene mRNA (see Detection of tTA Transgene in Cellular or Tail DNA by Southern Blotting), or protein expression or protein activity. Multiple lines may be screened at a time.

The night before induction, the cells are plated in selection medium/500 μM L-histidinol (see recipe) containing 3 μg/ml puromycin at an appropriate density such that cells will be subconfluent to confluent at the time of harvest. Cells are washed three times with PBS (*APPENDIX 2A*), with gentle swirling. Immediately, the medium is replaced with selection medium *without* 0.5 μg/ml tetracycline hydrochloride (tet). (For tet^+ controls, simply aspirate medium and replace with fresh selection medium containing tet.) Cells are incubated 6 to 48 hr in a humidified 37°C, 5% CO_2 incubator, then trypsinized (*UNIT 1.1*) and harvested at 4°C, and an aliquot of 0.15–0.4 $\times$ 10^6 cells is analyzed by immunoblotting (see *UNIT 6.2*).

Alternatively, cells may be grown in selection medium in the presence of tet, transferred to tubes [with a quick wash with cold PBS followed by trypsinization (*UNIT 1.1*) and stopping of the trypsin by addition of selection medium containing tet], washed three times with PBS (or just pelleted, for tet^+ controls), and replated into selection medium with and without tet at an appropriate density such that the cells will be subconfluent to confluent at the time of harvest.

Induction of Gene Expression in Transiently Transfected Cells

Transient transfection of tet-regulated plasmids is useful in several situations, including the initial testing of the autoregulatory system in a given cell line, screening stable tTA expressors for inducible expression, and biological applications where transient expression is specifically desired.

The night before the transfection, cells are split into medium containing 0.5 μg/ml tetracycline hydrochloride; the following day they are then transfected by methods appropriate for the cells being used (*UNITS 20.3–20.6*). Cells are induced by washing them three times in medium without tet. For $CaPO_4$ transfection, washes are incorporated into those normally performed after glycerol shock (see Basic Protocol, step 11). Uninduced cell controls are

washed with medium containing tet. Medium with and without tet is added to the appropriate plates, then the cells are incubated for 12 to 48 hr in a humidified 37°C, 5% CO_2 incubator. The cells are harvested at 4°C and, if trypsinized (*UNIT 1.1*), cold medium containing 10% FBS (with and without tet, as appropriate) is used to stop the action of the trypsin. Cells are pelleted for freezing or lysis, and tTA or target gene (experimental or reporter) expression can be analyzed by northern blotting, immunoblotting (*UNIT 6.2*), or by an appropriate activity assay (see Commentary).

Detection of tTA Transgene in Cellular or Tail DNA by PCR

PCR is routinely used to detect the Tet-tTAk transgene in candidate transgenic mouse tail DNA. The forward primer derives from the minimal human CMV promoter, CMV-F1:

5′-TGACCTCCATAGAAGACACC-3′

The reverse primer, TTA-REV1, is specific for the tTA ORF:

5′-ATCTCAATGGCTAAGGCGTC-3′

Hot-start PCR (*APPENDIX 3F*) is performed on 150 ng of each tail DNA to be analyzed in a reaction mix containing 1.5 mM $MgCl_2$, 0.5 μM each primer, and 0.2 mM each dNTP. PCR cycling conditions are as follows:

1 cycle:	3 min	94°C	
		80°C	(pause) add *Taq* polymerase
30 cycles:	45 sec	94°C	(denaturation)
	45 sec	58°C	(annealing)
	90 sec	72°C	(extension)
1 cycle:	10 min	72°C	(extension)
		80°C	(end).

Products are analyzed on a 1% to 1.3% agarose gel; the main product of interest is visible as a 290-bp band after ethidium bromide staining.

Detection of tTA Transgene in Cellular or Tail DNA by Southern Blotting

The tTA transgene may also be detected by Southern blot analysis (*APPENDIX 3A*). Tail DNA is digested with *Eco*RI and blots are probed with a 761-bp *Xba*I-*Sal*I tTA insert from pTet-tTA. This fragment detects a 1094-bp tTA fragment of the transgene. This probe may also be used to detect tTA mRNA by northern blotting (*APPENDIX 3A*).

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Complete DMEM-10

Dulbecco's minimal essential medium containing:
10% (v/v) donor bovine calf serum (JRH Biosciences)
100 U/ml penicillin/100 μg/ml streptomycin (Invitrogen)
2 mM glutamine (Invitrogen)

All DMEM complete medium used in this unit (with or without selection reagents or 0.5 μg/ml tetracycline hydrochloride) may be stored protected from light ~1 month at 4°C).

Fetal bovine serum (FBS) may also be used in place of donor bovine calf serum, but the latter is less expensive.

HEPES-buffered saline (HBS)

6 mM dextrose
137 mM NaCl
5 mM KCl
0.7 mM $Na_2HPO_4 \cdot 7H_2O$
21 mM HEPES (free acid)
Adjust final pH to 7.05 with NaOH
Filter sterilize and store in aliquots at −20°C

Selection medium

Complete histidine-free DMEM (Irvine Scientific, purchased without glutamine), containing:
10% (v/v) donor bovine calf serum (JRH Biosciences)
100 U/ml penicillin/100 μg/ml streptomycin (Invitrogen)
2 mM glutamine (Invitrogen)
0.5 μg/ml tetracycline·HCl (Sigma; dilute 10 mg/ml stock in 70% ethanol and store protected from light at −20°C)
125 μM, 250 μM, or 500 μM L-histidinol (Sigma, dilute in water as a 125 mM stock and store at −20°C)

COMMENTARY

Background Information

Inducible, tetracycline-regulated gene expression systems were initially developed to allow the controlled expression in eukaryotic cells of foreign genes not tolerated constitutively in cultured cells or during the development of transgenic animals. The general features of tetracycline-regulated gene expression strategies and their improvements over previous inducible expression systems have been addressed in current review articles (Gossen et al., 1993; Barinaga, 1994; Damke et al., 1995; Shockett and Schatz, 1996). The autoregulatory tTA system used in this protocol derives directly from a constitutive tTA system described by Gossen and Bujard (1992). Although tight regulatory control and high inducibility was achieved with the original system in HeLa cells, the inability to detect clones expressing moderate to high levels of tTA by immunoblotting suggested that the tTA was toxic when expressed constitutively. The autoregulatory tTA system was designed to overcome possible toxic effects of constitutive tTA expression by making tTA expression itself tetracycline regulated. Autoregulated tTA expression theoretically allows for the selection of clones expressing higher levels of tTA via an autoregulatory feed-forward mechanism that is activated only in the absence of tetracycline. In the presence of tetracycline, low-level tTA and target gene expression are driven from the minimal human CMV promoter. However, any tTA produced is unable to bind to tet operators upstream of the tTA or target gene. Conversely, when tetracycline is removed from the system, the small amounts of tTA protein expressed from the minimal promoter can bind the *tet* operators upstream of the tTA gene, driving higher levels of tTA (for controlled periods of time) and, subsequently, target gene expression.

The theoretical benefits of the autoregulatory tTA system have been confirmed by experiments in stably transfected NIH3T3 cell lines (Shockett et al., 1995). In these experiments, expression of the recombination activating genes *RAG-1* and *RAG-2*, and subsequent DNA recombination activated by these proteins, was higher and more frequently detected among stable transfectants expressing autoregulatory tTA than in constitutive tTA expressors. In transgenic mice expressing a luciferase reporter target transgene, the levels of expression appear to be 1 to 2 orders of magnitude greater with the autoregulatory system, although the uninduced levels also appear to be higher. Several studies have successfully used the autoregulatory tTA system for regulated gene expression in cell lines or transgenic animals (for examples, see Sheehy and Schlissel, 1999; Sikes et al., 1999; Chen et al., 2002; Shockett et al., 2004).

Since the description of the early tTA systems, several laboratories have created modified vectors, including streamlined versions containing both tTA and the target gene, viral vectors, and vectors in which

expression of two different target genes may be differentially or co-regulated. Some of these systems and their applications have recently been reviewed (Shockett and Schatz, 1996; Blau and Rossi, 1999).

Critical Parameters and Troubleshooting

Cell lines stably expressing both autoregulatory tTA and target genes have been derived at fairly high efficiencies by simultaneous transfection of all plasmids. This method may be faster, but it may require the screening of more clones than if stable lines with low basal and high induced levels of tTA are first derived and subsequently transfected with plasmids encoding the target genes. For the derivation of these clones, any selectable marker combination should theoretically work for consecutive cotransfection. Additionally, although the Basic Protocol describes calcium phosphate–mediated transfection of adherent fibroblast cell lines, the procedure can be adapted for other cell types using their optimal methods of transfection and selection. The protocol can also be scaled down to require fewer cells by using smaller dishes or wells and reducing all components proportionately.

Using the autoregulatory tTA system, tTA mRNA induction appears to be a good indicator of induced tTA expression (see Support Protocol). Alternatively, the vector pUHC13-3 (Life Technologies) encoding luciferase under tet control may be transiently transfected into putative stable tTA expressors as previously described (see Support Protocol and Damke et al., 1995). Cells are then cultured for 12 to 48 hr in the presence and absence of tetracycline. Luciferase activity is easily measured in cell lysates using a kit (Luciferase Assay System and Dual-Luciferase Reporter Assay System; Promega) in which luciferase activity in cell lysates is normalized either to total protein determined using a Bradford protein assay (*APPENDIX 3H*), or to a transfection control, respectively. Although basal expression of target plasmids tends to be higher when transiently transfected and luciferase detection is extremely sensitive, this method can be useful for the initial testing of the system in a given cell type (Damke et al., 1995).

It is imperative after stable transfection with pTet-tTAk that cells be maintained in medium containing 0.5 μg/ml tetracycline to prevent any toxic effects of tTA expression and subsequent selection against clones expressing high levels of tTA.

Anticipated Results

In the authors' experience with stably transfected NIH3T3 cells, expression of induced tTA and target gene has been observed by 6 hr and peaks at ~12 hr after induction. In cells that stably express tTA, transient target gene expression has been observed by 12 hr. In cells transiently expressing tTA and a tet-sensitive luciferase reporter (pUHC13-3), luciferase activity induced by 2 orders of magnitude has been observed by 20 hr.

Time Considerations

Starting with the plasmid vectors and following the transfection protocols above, stable clones expressing tTA (or tTA + target gene(s) if cotransfecting) are obtained in ~12 to 14 days. Approximately 2 additional weeks are required for expansion and testing of candidate clones. Subsequent transfection of a stable inducible tTA clone with vectors expressing target genes will require the same amount of time. Transient transfection and inducible gene expression may be achieved within 48 hr.

CHAPTER 21
Fluorescent Protein Technology

INTRODUCTION

The development of fluorescent proteins as molecular tags over the past decade has provided an essential new tool for understanding biological systems by allowing proteins to be visualized in living cells. The fluorescent proteins can be fused to a protein of interest and then expressed within cells to visualize, track, and quantify the behavior of a protein, providing fundamentally new insights into protein function and cellular processes in the complex environment of the cell. The fluorescent protein that has been most widely used in this regard is green fluoresent protein (GFP) from the jellyfish *Aequorea victoria*. GFP is a β-barrel-shaped protein of ~27 kDa that contains an amino acid triplet (Ser-Tyr-Gly) located in its center that functions as a fluorophore. Molecular engineering of the GFP coding sequence has resulted in optimized expression of GFP in different cell types, as well as the generation of GFP variants with optimal spectral properties, including increased brightness, relative resistance to the effects of pH, and photostability. When expressed within cells, GFP fusion proteins are bright and they are resistant at low illumination to photobleaching, which is the photo-induced alteration of a fluorophore that abolishes its fluorescence. These characteristics allow GFP chimeras expressed within cells to be imaged with low illumination levels over many hours, providing a simple method for visualizing the dynamics and behavior of the tagged protein.

Time-lapse observations of fluorescently tagged proteins can provide information about the steady-state distribution of the protein over time, but they usually do not reveal a protein's kinetic properties. These properties include whether a protein undergoes free or restricted diffusional motion, how rapidly it binds to and releases from other molecules, and whether it undergoes directed movement between compartments. One way to obtain this type of information with fluorescently tagged proteins is to utilize the technique of photobleaching. In this approach, a selected pool of fluorescent proteins is photobleached with a high-intensity laser pulse and the movement of unbleached molecules from neighboring areas into the bleached area is recorded by time-lapse microscopy. Analysis of the observed recovery kinetics can then be used to determine the diffusion coefficient of the fluorescent protein, its binding properties, or its transport routes. *UNIT 21.1* describes the use of fluorescent proteins in photobleaching techniques. Several specific applications of photobleaching are detailed, including fluorescence recovery after photobleaching (FRAP), fluorescence loss in photobleaching (FLIP), and selective photobleaching. The unit also describes how to extract kinetic parameters from the photobleaching data, including a protein's diffusion coefficient and its $t_{1/2}$ and mobile fraction. Use of these techniques provides a powerful method for characterizing the movement of proteins and their interactions with cellular components in the environment of the living cell.

UNIT 21.2 describes the technique known as fluorescence localization after photobleaching (FLAP), which allows localized photolabeling of proteins and subsequent tracking of these molecules in living cells. This technique, like FRAP and FLIP described in *UNIT 21.1*, overcomes the limitations of conventional fluorescence localization by revealing the relocation of molecules during dynamic, steady-state processes such as diffusion and polymerization/depolymerization. The principle underlying FLAP is simple and relies

Current Protocols in Cell Biology 21.0.1-21.0.2, March 2008

DOI: 10.1002/0471143030.cb2100s38

on photobleaching to label the targeted molecules. This is accomplished by labeling the molecular species of interest with two different fluorophores that can be imaged independently but simultaneously by fluorescence microscopy. Then one of the fluorophores is rapidly photobleached at a chosen location. Because the unbleached (reference) fluorophore remains co-localized with the target fluorophore, the subsequent fate of the photobleached molecules can be revealed by processing simultaneously acquired digital images of the two fluorophores. The FLAP method thus overcomes one drawback of FRAP and FLIP by enabling the bleached as well as unbleached molecules to be tracked in an experiment.

UNIT 21.3 describes the technique of bimolecular fluorescence complementation analysis (BiFC), which can be used to visualize protein interactions in living cells. It is based on complementation between non-fluorescent fragments of the yellow fluorescent protein (YFP) when they are brought together by an interaction between proteins fused to different fragments. This produces a fluorescent protein that allows the direct visualization of protein interactions within living cells and the site of this interaction. The unit also describes a multicolor BIFC assay that allows competition between interactive partners to be tested in cells. In this approach, fragments of different fluorescent proteins are attached to different proteins capable of interacting. The molecules are then allowed to compete with each other for binding with the read-out being a fluorescent signal. In this way, the multicolor BiFC assay allows comparison of the subcellular locations of different protein interactions in the same cell, as well as analysis of the competition among mutually exclusive interaction partners for complex formation with a common partner.

The advent of green fluorescent protein technology—in which proteins can be tagged with naturally fluorescent proteins derived from marine organisms and visualized in cells—is revolutionizing the field of cell biology. *UNIT 21.4* describes how to design fluorescent fusion proteins as probes of cell structure and function. Strategies for the selection of a fluorescent protein and for attaching it to a protein of interest using molecular biology techniques are described. Finally, assays are presented for testing whether the fusion protein maintains its function after being expressed in a living cell. *UNIT 21.5* extends the topic of green fluorescent protein technology to the color palette that fluorescent proteins offer as reporter molecules. Starting with an historical background of GFP development, the unit then delves into the details of the physical and chemical characteristics of GFP's unique chromophore, discussing its brightness, maturation, photostability, and oligomeric properties. The unit then discusses the broad range of fluorescent protein genetic variants that have been developed, including blue, cyan, green, yellow, orange, and red fluorescent proteins. Also discussed in *UNIT 21.5* are optical highlighter fluorescent proteins. These molecules have the advantage of being able to be "switched on" in response to a specific wavelength of light. The unit concludes with a discussion of future developments of fluorescent proteins aimed at making variants optimized for use in different imaging techniques, such as resonance energy transfer and multiphoton excitation.

UNIT 21.6 discusses the recent advance of photoactivation microscopy involving the use of fluorescent proteins that have the capacity to be "switched on" by photoactivation. These fluorescent proteins are invisible at the imaging wavelength until activated by a different wavelength of light. This unit discusses technical aspects regarding how to use the photoactivatable fluorescent proteins, including which laser lines should be used for photoactivation versus imaging, how to avoid photobleaching, and how to identify particular objects prior to photoactivation. Finally, specific applications of phtoactivation as they relate to cell imaging are discussed.

Jennifer Lippincott-Schwartz

Measuring Protein Mobility by Photobleaching GFP Chimeras in Living Cells

This unit describes photobleaching methods used in combination with green fluorescent protein (GFP) chimeras to analyze protein and organelle dynamics in living cells. Photobleaching is the photoinduced alteration of a fluorophore that abolishes the fluorophore's fluorescence signal. The diffusive characteristics of fluorescently tagged proteins or organelles in the cell can be studied by photobleaching a selected region of a fluorescently labeled cell with intense light and then quantitating the movement of nonbleached fluorescent molecules into the photobleached area using an attenuated light source (Lippincott-Schwartz et al., 1999, 2001; Meyvis et al., 1999). Other processes that lead to fluorescesce recovery into the bleached area (including vesicle transport or flow-based movement) also may be quantitated and studied by this method. Insights into a variety of aspects of protein and organelle dynamics thus can be addressed using photobleaching. These include: (1) estimation of the diffusion coefficient, *D*, of a fluorescent protein, (2) determination of the fraction of fluorescent molecules able to move under different cellular conditions, (3) assessment of continuity or discontinuity of an organelle, and (4) characterization of protein rates to or from an organelle (Ellenberg et al., 1997; Hirschberg et al., 1998; Partikian et al., 1998 Dayel et al., 1999; Marguet et al., 1999; Nehls et al., 2000). Photobleaching can also be used to reduce fluorescence from background noise to reveal faint populations of fluorescent proteins.

The usefulness of photobleaching methodologies depends on the availability of fluorescently labeled molecules. Until recently, these were limited to fluorescent dyes and to fluorescently labeled antibodies, which only permitted labeling of the plasma membrane, unless microinjected into cells. With the advent of GFP, a naturally fluorescent protein from the jellyfish *A. victoria* (Tsien, 1998), this has changed. Virtually any protein of interest can be tagged with GFP. When expressed within cells, these proteins usually retain their parent protein-targeting behavior. An important property of GFP is that it can be bleached without detectable damage to the surrounding environment. This is presumably because the GFP's cage-like structure, which surrounds a small cyclic peptide fluorophore (Prendergast, 1999), shields the external environment from any damaging effects caused by reactive photobleaching intermediates. These characteristics of GFP chimeras make them ideal reagents in photobleaching experiments.

In this unit, two photobleaching techniques for confocal laser scanning microscopes (CLSM) are described: FRAP (fluorescence recovery after photobleaching; see Basic Protocol 1 and Alternate Protocol 1) and FLIP (fluorescence loss in photobleaching; see Basic Protocol 2). In FRAP, a distinct region of interest in a cell expressing a GFP chimera is briefly photobleached with a high-intensity laser, and the movement of unbleached fluorescent molecules into the bleached region is followed with low-intensity laser light. FRAP is useful for determining a protein's diffusion coefficient (*D*), which measures the random movement or Brownian motion of a molecule. Knowing a protein's *D* can be used, in turn, to obtain information about the viscosity of a protein's environment and whether the protein is part a of much larger complex. FRAP also can be used to determine the fraction of molecules capable of recovering into a photobleached area, referred to as the mobile fraction (M_f). FLIP differs from FRAP in that photobleaching is repeated several times, alternating each photobleach with a low-laser-intensity image of the whole cell. FLIP reveals the connectedness of cellular compartments and whether immobile pools of proteins are spatially segregated.

Contributed by Erik L. Snapp, Nihal Altan, and Jennifer Lippincott-Schwartz
Current Protocols in Cell Biology (2003) 21.1-21.1.24

The protocols are described for mammalian cells, and the concepts can apply to other systems, including plant cells, yeast cells, and bacteria. Basic Protocols 1 and 2 (FRAP and FLIP, respectively) and Alternate Protocol 1 (FRAP with older confocal laser scanning microscopes) describe photobleaching techniques that can be used to visualize and quantitate protein mobility and organelle dynamics. Alternate Protocol 2 is a selective photobleaching protocol, which can be applied to the study of protein trafficking and protein flux through organelles. Support Protocol 1 discusses some practical issues of expressing and imaging GFP chimeras in living cells. In that protocol, preparation of transfected mammalian cells for imaging on a CLSM and setup of the CLSM is described. Data processing for FRAP is described in Support Protocol 2. Support Protocol 3 describes a simulation of inhomogeneous diffusion that can be used to obtain the diffusion coefficient *D*.

BASIC PROTOCOL 1

QUANTITATIVE FRAP BY STRIP PHOTOBLEACHING USING A LASER SCANNING CONFOCAL MICROSCOPE CAPABLE OF SELECTIVE PHOTOBLEACHING

Fluorescence recovery after photobleaching (FRAP) can be performed by irreversibly photobleaching a fluorescent marker in a region of a cell with a high-intensity laser beam and then following diffusion of unbleached fluorescent proteins into the bleached region by imaging with nonbleaching attenuated laser light (Fig. 21.1.1A). Several forms of FRAP or FPR (fluorescence photobleaching recovery) have been described. Popular methods include spot bleaching, pattern photobleaching, polarized photobleaching, and strip bleaching. The protocols in this unit will focus on the strip photobleach method for confocal laser scanning microscopes. Strip photobleaching permits imaging of the whole cell while monitoring the fluorescence recovery into the photobleached region of interest (ROI). It allows the investigator to readily determine information concerning the spatial distribution of fluorescence. It also can reveal whether the cell, stage, or focus have moved during imaging, events that make FRAP analysis difficult.

There are two types of strip FRAP protocols: quantitative and qualitative. Using the quantitative FRAP protocol, it is possible to obtain an effective diffusion coefficient, *D*, and to calculate the mobile fraction, M_f, of a fluorescent protein. Images are acquired rapidly and the data can be used to plot a recovery curve from which *D* can be determined (Fig. 21.1.1B). The qualitative protocol is used to obtain high-quality images for visualizing the diffusion process in a single cell. Because the images are obtained by line averaging and slow scan speeds, they take longer to acquire and therefore are usually unsuitable for calculation of *D*, which requires time points immediately after bleaching.

This FRAP protocol has been designed for the Zeiss LSM 510 microscope (using the physiology software package) and for other laser scanning confocal microscopes capable of selective photobleaching (e.g., from Leica and Bio-Rad). FRAP can also be performed using older laser scanning confocal microscopes without the selective photobleaching capacity (see Alternate Protocol 1). Selective photobleaching means that the investigator can bleach any shape or size of ROI. Specific settings will vary for each microscope. The user must determine conditions for photobleaching and postbleach recovery imaging that do not result in significant photobleaching of the cell (steps 1 to 6). The actual FRAP experiment is described in steps 7 to 9, and data analysis is described in the FRAP data-processing section (see Support Protocol 2).

Materials

Cell samples expressing GFP chimeric protein of interest (Support Protocol 1)
Confocal laser scanning microscope capable of selective photobleaching (e.g., Zeiss LSM 510)

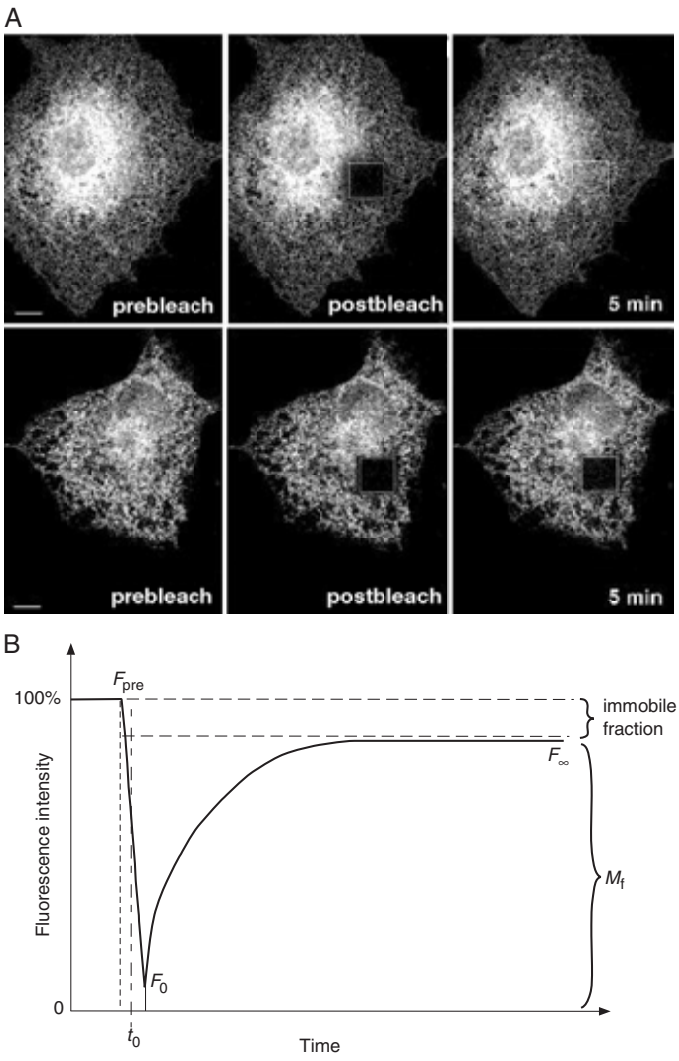

Figure 21.1.1 Photobleaching techniques. (**A**) Example of FRAP. Cells expressing VSVG-GFP were incubated at 40°C to retain VSVG-GFP in the ER under control conditions (untreated, upper row) or in the presence of tunicamycin (lower row). FRAP revealed VSVG-GFP was highly mobile in ER membranes at 40°C but was immobilized in the presence of tunicamycin. (**B**) Plot of fluorescence intensity in a ROI versus time after photobleaching a fluorescent protein. The prebleach (F_{pre}) is compared with the asymptote of the recovery (F_∞) to calculate the mobile and immobile fractions. Information from the recovery curve (from F_0 to F_∞) can be used to determine D of the fluorescent protein.

Additional reagents and equipment for preparing imaging chambers and microscope for photobleaching experiments (Support Protocol 1)

Establish FRAP conditions

1. Set up the microscope and prepare cells in imaging chamber with imaging medium as described in Support Protocol 1. Prewarm the imaging stage to 37°C or other desired temperature and warm up the microscope lasers for at least 5 min to avoid power fluctuations during imaging.

2. Identify the cell of interest on the confocal microscope. Bring it to the desired focus. Scan an image of the whole cell at the desired excitation light intensity, line averaging,

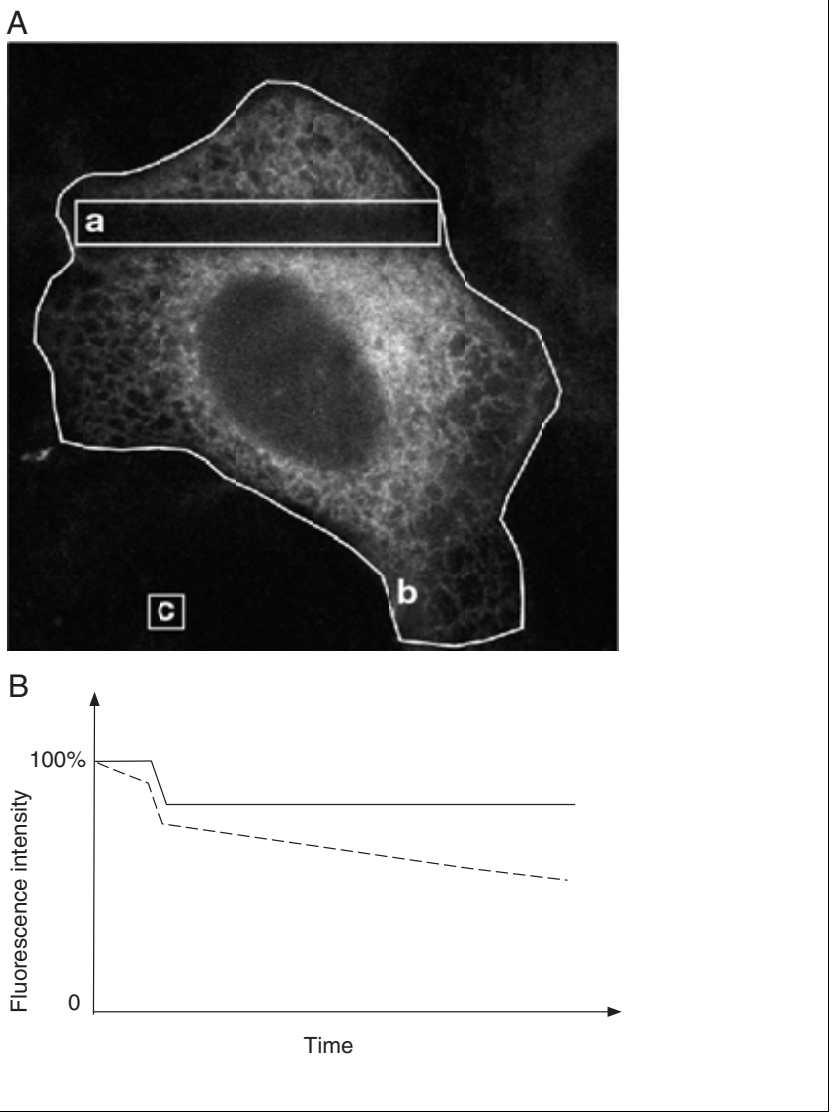

Figure 21.1.2 Defining ROIs and illustrating bleaching during imaging. (**A**) Example of ROIs, where *a* is the bleach ROI, *b* is the whole cell ROI, and *c* is the background ROI. (**B**) Plot of whole cell fluorescence (ROI *b*) versus time. The solid line represents an ideal plot in which the prebleach intensity of the cell does not change with time and where after the photobleach there is a drop in mean cellular fluorescence. There is no further loss of fluorescence. The dashed line represents a problematic plot of ROI *b*. The prebleach intensity steadily decreases with time, suggesting that the cell is being imaged at too high a laser power, resulting in photobleaching of the whole cell. The fluorescence loss continues after the photobleach of ROI *a*. The investigator must establish new imaging conditions.

zoom, and other parameters. Modify pinhole and detector gain for maximal fluorescence signal with no pixel saturation (pixel intensities that exceed the detector scale, i.e., >255 for an 8-bit image).

Saturated pixels only register as the maximum detector value, 255, so the true intensity of the pixel cannot be calculated under these conditions. Detector gain and offset will vary depending on the concentration of the fluorophore, the laser power, and the width and thickness of the fluorescently labeled organelle or region. The imaging parameters used for this image should be used for the fluorescence recovery time series. It may be useful to

record the detector gain settings to compare recoveries in cells expressing high versus low amounts of fluorescent protein.

3. Define a region-of-interest (ROI) for the photobleach (see Fig 21.1.2A), usually a 2- to 4-μm strip across the width of the cell.

   For soluble proteins that diffuse rapidly, the photobleach ROI may need to be relatively large (i.e., one-third to one-half of the cell). When performing FRAP on a discrete organelle, such as the nucleus or the Golgi complex, the photobleach ROI does not need to extend across the entire cell. It is sufficient for the edges of the strip to extend beyond the edges of the structure being analyzed. Note that larger photobleach ROIs will require longer recovery times.

4. Empirically determine photobleaching conditions (i.e., scan speed, zoom, laser power, microscope objective, and the minimal number of laser iterations required for photobleaching) so that after photobleaching, the fluorescent signal of the photobleach ROI decreases to within background intensity levels. Use imaging software to quantitate fluorescence intensity in the photobleach ROI and the whole cell prior to bleaching (Fig. 21.1.2A)

   It is necessary to know the fluorescence intensities in the whole cell and ROI prior to bleaching in order to determine the extent to which the photobleach ROI and the whole cell undergo bleaching during the course of imaging (Fig. 21.1.2B).

   It is useful to establish photobleaching conditions on fixed samples, as rapidly diffusing species may be impossible to bleach to background levels. Fix the plated GFP-expressing cells (either on a coverslip or in a Lab-Tek chamber) for 15 min in PBS (APPENDIX 2A) containing 4% formaldehyde at room temperature. Wash twice with PBS and then either place the coverslip on an imaging chamber with imaging medium or fill the Lab-Tek chamber with imaging medium. Under no circumstances must an antifade reagent (such as Fluoromount-G or phenylenediamine) be used, because this will significantly alter the photobleaching properties of the fluorophore. Image the fixed cells in imaging medium.

   Typical bleaching conditions require a 100 to 1000-fold increase in laser power (decrease in attenuation) for 1 to 5 bleach iterations (roughly 0.01 to 0.5 sec) for many organelles. If an ROI requires >20 sec to photobleach, a more powerful laser is necessary (see below).

   To ensure that bleaching laser power does not damage the cell, it is useful to repeat FRAP on the same ROI for the same cell. The diffusion coefficient (see discussion of data processing under Support Protocol 2) now should not change, but the mobile fraction (see Support Protocol 2) should be close to 100%. This is because any immobile fluorophores in the first FRAP will have been bleached and therefore will not contribute to the percent recovery observed in the second photobleach.

5. For acquisition of fluorescence recovery time points, empirically determine imaging conditions that do not significantly photobleach the cell outside of the bleach ROI (Fig. 21.1.2B)

   Recommended conditions for photobleaching with a 40-mW 488/514 nm argon or 25-mW argon laser are 45% to 60% power with 100% transmission. For acquisition of recovery time points, use the same power with 0.1% to 1.0% transmission. For quantitative FRAP, the whole cell is usually scanned at scan speed 8 to 10 (0.798 to 3 sec per 512 × 512 frame) with either two-line averaging or no-line averaging. In qualitative FRAP experiments, where the goal is to obtain high-quality images, the intervals at which images are collected during recovery need not be rapid (3- to 10-sec intervals, for membrane proteins). Soluble and lumenal proteins tend to diffuse rapidly and both quantitative and qualitative FRAP may require the bleaching of a large ROI and very rapid imaging conditions.

Collect FRAP data

6. To perform data analysis of a FRAP experiment, collect a prebleach image of the cell, a series of postbleach images of the whole cell that extend from an immediate

postbleach image to several images after the bleach ROI fluorescence intensity reaches a plateau, and a table of fluorescence intensity values including the photobleach ROI, the whole-cell ROI, and a background ROI. Note the corresponding time for each image and the pixel size in microns.

For the Zeiss 510 microscope, the physiology software contains several windows which permit the user to determine the number of images to collect, laser intensities for bleaching and imaging, number of bleach iterations, how many images to collect before bleaching, and drawing of the photobleach ROI. Other microscopes may possess their own software packages or may require writing macros for the photobleach time series.

7. Collect multiple prebleach images to establish the prebleach fluorescence intensity and to confirm that the prebleach fluorescence intensities of the cell and the bleach ROI do not fluctuate significantly.

8. Using the conditions determined in step 4, photobleach the ROI with intense laser illumination. Continue to image the whole cell at low laser illumination (the same conditions as the prebleach images) until the recovery process has reached a steady state.

   This must be determined quantitatively, as the human eye is incapable of distinguishing small differences in intensity. Typically, a 4-μm wide bleach ROI strip will recover within 90 to 120 sec for most freely mobile soluble lumenal proteins and within 350 sec for membrane proteins in the plasma membrane, endoplasmic reticulum, or Golgi. Cytoplasmic proteins may recover as rapidly as 5 to 20 sec. In this way, the investigator can establish conditions to obtain data sufficient for estimation of $t_{1/2}$ and M_f (see Support Protocol 2). The investigator should not attempt to refocus a cell during a FRAP experiment, because the fluorescence intensities will shift and the recovery curves will no longer be smooth. Time series that contain a shift in focal plane should be discarded.

   If a protein has a high protein diffusion coefficient (e.g., 5 μm^2/sec), the investigator may not observe a defined bleach region following the photobleach. Rapidly diffusing fluorescent proteins may appear homogeneously distributed immediately following a photobleach. The investigator must either: (1) increase the image collection rate, by changing the scan speed or reducing the size of the total frame to be collected, (2) increase the bleach ROI size, (3) increase the laser power, or employ a combination of these suggestions.

   To ensure that FRAP did not damage the area that was being scanned, repeat FRAP on the same area and compare the diffusion coefficients obtained from both experiments. D should remain the same but the mobile fraction should now be close to 100%. This is because the immobile fraction was bleached in the previous experiment.

9. Collect at least 10 to 20 data sets for each fluorescently labeled protein and treatment for statistical analysis.

   A fraction of the data sets are usually discarded because of problems that potentially bias imaging results (e.g., recovery was not complete, the focal plane shifted, or the recovery curve-fitting method failed).

   In Lippincott-Schwartz et al. (1999), a method for imaging the bleach ROI alone for rapid collection of a large number of data points is described. The caveat of the method is that the cell may shift in focus or position during the course of imaging. Imaging the whole cell offers the advantage of visualizing any movement of the cell or focal plane, thus allowing the researcher to reject unusable data upon visual inspection.

FRAP WITH CONFOCAL LASER SCANNING MICROSCOPES WITHOUT THE CAPACITY FOR SELECTIVE PHOTOBLEACHING

ALTERNATE PROTOCOL 1

FRAP (see Basic Protocol 1) can also be performed with older confocal laser scanning microscopes. Photobleaching is accomplished by zooming in on a small region of the cell and scanning with full laser power. The procedure for photobleaching is described below. The actual FRAP protocol is otherwise identical to Basic Protocol 1. For quantitative FRAP experiments for determining D, images should be acquired rapidly after the bleach, and this is best done if fluorescence is collected from the ROI only. If the investigator acquires a prebleach and a postrecovery image of the whole cell, it will be possible to calculate the M_f and D.

Additional Materials *(also see Basic Protocol 1)*

Confocal laser scanning microscope without capacity for selective photobleaching (e.g., Zeiss LSM 410)

Photobleach by zooming

1. Define a region of interest (ROI) for the photobleach. Define the ROI to be bleached at the highest zoom possible (usually zoom 8).

   At high zooms the laser will dwell longer on an ROI per line scan and thus will deliver more bleaching radiation.

2. To photobleach the ROI, set laser power at maximum and remove all neutral density filters from the path of the laser beam. Scan (photobleach) the ROI.

3. Bleach a desired ROI with high-intensity light and then rapidly and reliably switch to scanning the ROI with low levels of light and collect emission.

   A photobleaching macro can be written for the confocal system to perform bleaching and recovery imaging automatically.

CELL TRANSFECTION AND IMAGING SETUP

SUPPORT PROTOCOL 1

Cells first must be transfected with a construct in which DNA for GFP is linked to the protein of interest. Then the cells must be prepared for imaging. Transiently transfected adherent cells can be grown and imaged in a LabTek chambered slide or on a coverslip. Transfected suspension cells must be attached to a coated coverslip for imaging.

Materials

Eukaryotic cells of interest
Vector for expression of GFP chimeric protein: most laboratories today use the enhanced GFP (EGFP) variant (Clontech); although spectral variants of GFP are available, EGFP is best suited for photobleaching experiments; see Commentary for details
Cell culture medium (e.g., DMEM with serum) appropriate for cells of interest
Imaging medium (see recipe)
Silicon grease (optional)
5 to 10 mg/ml poly-L-lysine (Sigma) in PBS (see *APPENDIX 2A* for PBS)
Phosphate-buffered saline (PBS; *APPENDIX 2A*)

Confocal laser scanning microscope equipped with a filter set for GFP and a 488-nm excitation laser that is at least 10 mW and preferably ≥25 mW
Imaging chamber: chambered coverglass system (LabTek from Nalgene) *or* glass coverslips and silicon rubber gasket for constructing silicon rubber chamber (see recipe in *UNIT 4.4*; also see Fig. 4.4.1)
Immersion oil (for oil-immersion microscope objectives)

Stage heater (e.g., Model ASI 400 Air Stream Stage Incubator, Nevtek; for cells that grow at 37°C)

Temperature probe: e.g., Thermolyne pyrometer (Cole-Parmer)

Computer system capable of processing large image files: 350 MHz or faster processor, multiple gigabyte hard drive, and at least 128 MB RAM

Image processing software (i.e., NIH Image or Metamorph)

Additional reagents and equipment for transfection of eukaryotic cells by electroporation (*UNIT 20.5*) or use of lipid transfection reagents (*UNIT 20.6*)

Transfect cells

1. To enhance the probability of having multiple cells to choose from, transfect cells with GFP chimeric protein vector using a high-efficiency transfection method, such as electroporation (*UNIT 20.5*) or a lipid transfection reagent—e.g., FuGENE6 (Roche) or LipofectAMINE 2000 (Invitrogen)—as described in *UNIT 20.6*.

   The cell density for imaging depends on cell type, cell size, and experimental design.

   Before performing a photobleaching protocol, the investigator must ensure that there is sufficient GFP fluorescence in the expressing cell to maintain a significant fluorescent signal relative to background noise after photobleaching. Most standard transfection protocols are sufficient to provide bright specimens. Stable transfectants express lower levels of protein. Transient transfectants usually express higher levels of proteins; this sometimes results in overexpression artifacts, such as protein aggregation or saturation of protein targeting machinery, which lead to inappropriate localization. Whichever transfection method is selected, the investigator needs several usable cells for each experiment.

   Adherent cells should be transiently transfected 16 to 36 hr prior to the experiment. The commercially available GFP expression vectors are under the control of a very strong promoter, the CMV promoter, so cell toxicity or mislocalization of GFP chimeras to other regions of the cell should always be a concern.

2. Determine the optimal level of expression and timing of imaging empirically for each sample and condition.

Set up imaging system

3. Set up the confocal laser scanning microscope and its associated hardware.

   It is assumed that the investigator is familiar with the basic operation of a confocal microscope. The investigator should understand both the concept and the operation of a pinhole, as well as the considerations related to scan speed, zoom, detector gain, laser power, photobleach, and collection of a time series.

Set up the imaging chamber

To image adherent cells on chambered slides

4a. Plate adherent cells on LabTek chambered coverglass.

   The cell density for imaging depends on cell type, cell size, and experimental design.

   These chambers consist of wells with a cover glass bottom, which permits the use of high-numerical-aperture oil objectives for viewing.

5a. Fill the wells to the rim with imaging medium and place on the stage of an inverted microscope.

   This ensures that cells have sufficient nutrients during the imaging session. For experiments that will last longer than 1 hr, the top cover of the chamber should be sealed onto the chamber using petroleum jelly or silicon grease. These steps prevent rapid evaporation of the medium above the cells and decrease the alkalinization of the medium by preventing room air from entering the chamber.

To image adherent cells in silicon rubber chambers

4b. Plate cells on glass coverslips.

The cell density for imaging depends on cell type, cell size, and experimental design.

5b. Invert the cell-containing coverslips on rubber gaskets that have a hole punched in them to form silicon rubber chambers (see *UNIT 4.4* and Fig. 4.4.1).

These gaskets are mounted on glass slides with petroleum jelly or silicon grease. The hole is filled with imaging medium and the coverslips are inverted and pressed onto the hole allowing the cells to face the medium. The coverslip adheres to the gasket by capillary action. Excess liquid from the top of the coverslip is wicked away with absorbant tissue. See UNIT 4.4 for full details.

To image suspension cells

4c. Precoat LabTek chambers or clean coverslips 5 to 10 mg/ml poly-L-lysine in PBS. Incubate for 15 min. Wash twice with PBS or distilled water.

The coating is usually good for up to 1 week.

5c. Wash suspension cells three times in PBS, then place them on the poly-L-lysine-coated surface and incubate 2 to 5 min. Remove nonadhering cells by washing twice with PBS. Finally, immerse the cells in imaging medium.

The cell density for imaging depends on cell type, cell size, and experimental design.

6. Keep cells warm on the microscope stage using a stage heater, and use a temperature probe to confirm that the proper temperature is maintained at the coverslip/chamber.

In addition to the chambers described above, Bioptechs offers a completely closed chamber with built-in perfusion. This type of setup permits the maintenance of cells on the microscope stage for extended periods of time (>24 hours) with minimal loss in viability. In addition, the investigator can perfuse drugs, dyes, and other reagents with controlled precision throughout the experiment. Thermal collars for objectives are another option for heating/maintaining the temperature of the chamber/coverslip. Thermal collars are available from Bioptechs.

Collect data

7. Collect FRAP data as described in Basic Protocols 1 or 2 or Alternate Protocols 1 or 2.

Many laser scanning confocal microscopes provide the investigator with a number of options for data collection, including but not limited to image size (e.g., 512 × 512 or 1024 × 1024, pixels), range of data collection (8-bit or 12-bit), and file formats. It is worth determining the requirements for image-analysis software in advance. For example, some image-analysis programs (see, e.g., Support Protocol 3) cannot process 12-bit images or only process PGM (portable graymap) image files, not TIFF (tagged-image file format) files.

See Support Protocol 2 for processing of FRAP data.

FRAP DATA PROCESSING

SUPPORT PROTOCOL 2

After collecting FRAP data using either Basic Protocol 1 or Alternate Protocol 1, the data need to be processed for quantitation. The three parameters that can be determined are the mobile fraction (M_f) of the fluorescent fusion protein, its diffusion coefficient (D), and the $t_{1/2}$ of the fluorescence recovery. When first performing FRAP experiments, it is an excellent idea to perform calibration experiments with a fluorescent protein whose D and M_f have been previously characterized (see Table 21.1.1).

Table 21.1.1 Diffusion Rates of GFP and GFP Chimeras Using FRAP[a]

Molecule	D_{eff} (μm²/sec)	References
GFP in water	87	Swaminathan et al. (1997)
GFP in cytoplasm	25	Swaminathan et al. (1997)
GFP in the ER lumen	5-10	Dayel et al. (1999)
Elastase-GFP in the ER lumen	0.5	Subramanian and Meyer (1997)
GFP in the mitochondrial matrix	20-30	Partikian et al. (1998)
Nucleoplasm		
GFP-HMG-17	0.45	Phair and Misteli (2000)
GFP-SF2/ASF	0.24	Phair and Misteli (2000)
GFP-fibrillarin	0.53	Phair and Misteli (2000)
Endoplasmic reticulum membrane		
Lamin B receptor–GFP (in ER)	0.35	Ellenberg et al. (1997)
GFP–MHC class I (murine)	0.46	Marguet et al. (1999)
TAP1-GFP (murine)	0.12	Marguet et al. (1999)
Galactosyltransferase-GFP (in ER)	0.48	Nehls et al. (2000)
Signal recognition particle β subunit–GFP	0.26	Nehls et al. (2000)
KDEL receptor–GFP (+BFA)	0.43	Cole et al. (1996)
VSVG-GFP ts045 (in ER+BFA, 32°C)	0.49	Nehls et al. (2000)
VSVG-GFP ts045 (in ER, 40°C)	0.45	Nehls et al. (2000)
Cytochrome P450-GFP	0.03-0.06	Szczesna-Skorupa et al. (1998)
Golgi apparatus membrane		
Galactosyltransferase-GFP (in Golgi)	0.54	Cole et al. (1996)
Mannosidase II–GFP	0.32	Cole et al. (1996)
KDEL receptor–GFP	0.46	Cole et al. (1996)
Plasma membrane		
E-cadherin-GFP	0.03-0.04	Adams et al. (1998)
GFP-Ki-Ras (12V)	0.19	Niv et al. (1999)
GFP-aquaporin (1 and 2)	0.009	Umenishi et al. (2000)
Lutenizing hormone receptor–GFP	0.16	Horvat et al. (1999)
Endosomal membrane		
GFP-rab5	0.1	Roberts et al. (1999)
E. coli cytoplasm		
GFP	7.7	Elowitz et al. (1999)
Maltose D–GFP	2.5	Elowitz et al. (1999)

[a]Abbreviations: BFA, brefeldin A; ER, endoplasmic reticulum; GFP, green fluorescent protein; MHC, major histocompatibility complex; TAP, transporter associated with antigen processing; VSVG, vesicular stomatitis virus G protein.

Mobile fraction (M_f)

M_f refers to the percentage of fluorescent proteins capable of diffusing into a bleached ROI during the time course of the experiment (see Fig. 21.1.1B). M_f and D are distinct parameters and must be understood as such. D is a characteristic of the mobile pool of fluorescent proteins. The proteins in the immobile fraction do not diffuse.

An approximation of M_f can be calculated using the following equation, based on Feder et al. (1996), with the inclusion of a photobleaching correction (Lippincott-Schwartz et al., 1999):

$$M_f = 100 \times \frac{F_{\text{precell}} - F_{\text{background}}}{F_{\infty\text{cell}} - F_{\text{background}}} \times \frac{(F_{\infty\text{cell}} - F_{\text{background}}) - (F_0 - F_{\text{background}})}{(F_{\text{pre}} - F_{\text{background}}) - (F_0 - F_{\text{background}})}$$

Equation 21.1.1

where F_{precell} is the whole cell prebleach intensity, F_{pre} is the bleach ROI prebleach intensity, $F_{\infty\text{cell}}$ is the asymptote of fluorescence recovery of the whole cell, $F_{\text{background}}$ is the mean background intensity, F_∞ is the bleach ROI asymptote, and F_0 is the bleach ROI immediate postbleach intensity.

In the above equation, the bleach ROI and whole cell ROIs are background-subtracted. Next, the bleach ROI data are transformed such that the prebleach fluorescence intensity is defined as 100% fluorescence intensity. The equation includes a correction for the loss of total cellular fluorescence (due to the photobleach of the ROI and bleaching of the whole cell during imaging). The correction is calculated by determining the prebleach fluorescence intensity of the whole cell ROI (F_{precell}) and dividing it by the whole cell ROI intensity at time t. Without this bleach correction, the bleach ROI intensity can never recover to 100% of the prebleach fluorescence because the photobleach depletes 5% to 20% of the total cellular fluorescence. Finally, to convert the fraction to a percentage, it is multiplied by 100.

The F_0 value is an approximation for the fluorescence intensity immediately following the photobleach. For conditions in which the ROI is bleached to near background levels, F_0 will be relatively accurate. However, for rapidly diffusing proteins or for narrow bleach ROIs, the immediate postbleach ROI intensity may be closer to 30% to 40% of the prebleach fluorescence intensity. This can lead to the appearance of an artificial immobile fraction. The true F_0 may be much lower and can potentially be derived by rapidly collecting images of the bleach ROI alone, or by attempting to determine F_0 by nonlinear regression analysis.

Diffusion Analysis

The diffusion coefficient, D, reflects the mean-square displacement (usually μm^2/sec or cm^2/sec) that a protein explores through a random walk (i.e., Brownian motion) over time. It is important to recognize that D is not a simple linear rate (see Fig. 21.1.3). That is, the time required to cover increasing distances will not increase in a linear fashion. Time increases as the square of the distance covered divided by the D. The primary constraints on protein diffusion are the viscosity of the environment, whether the protein is soluble or integrated into a membrane, and, to a lesser extent, the molecular radius of the protein. Protein-protein interactions and collisions with other molecules also hinder free diffusion. By measuring D, the investigator can obtain information related to a protein's environment and in some cases, whether the protein is interacting with large complexes.

Several groups have derived a number of equations and computer simulations to determine D. The majority of available equations have been written for spot photobleaching. Related equations and simulations are available for strip photobleaching, including those described in Ellenberg et al. (1997) and Wey and Cone (1981). These equations, however, make several assumptions about the experimental system that may or may not be met. For example, the equation from Ellenberg et al. (1997) assumes that the bleach is complete, that there is no immobile fraction, that the cell is a uniform rectangle, and that the width of the bleach ROI is much less than the distance to either end of the cell. D values calculated with this equation can differ by 50% or more from an assumed D. Given these concerns, investigators are cautioned in the use this equation.

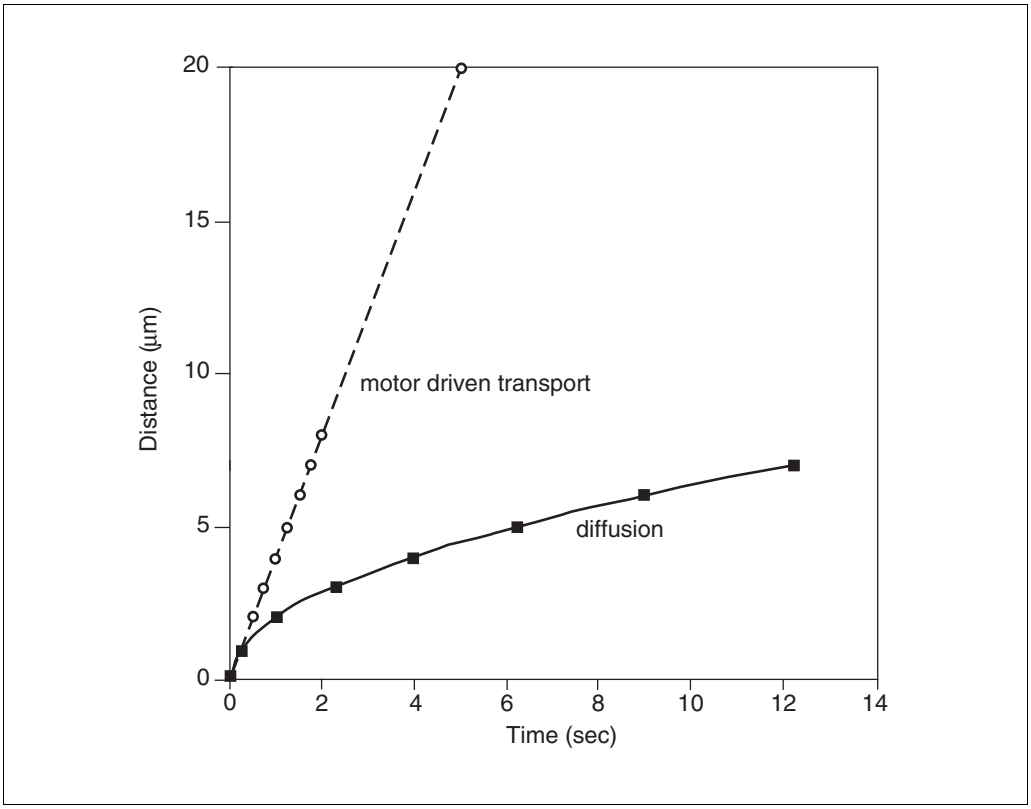

Figure 21.1.3 Diffusion versus linear movement. Plot of distance versus time for a protein, such as a motor protein, that moves directionally at a linear rate of 4 μm/sec (open circles, dashed line) and a protein that diffuses with a diffusion coefficient of 4 μm^2/sec (filled squares, solid line). Note that a protein travels 4 μm in 1 sec for the linear rate, but statistically takes 4 secs to travel the same distance by diffusion.

The best method the authors have found for obtaining *D* is through simulation of diffusive recovery into a strip bleach (Siggia et al., 2000). The Siggia simulation models inhomogeneous diffusion of nonbleached proteins in the cell into the photobleach ROI. The simulation then compares the simulated recovery to the actual data to determine *D* (Siggia et al., 2000). The program has been used for ER membrane proteins (Ellenberg et al., 1997; Zaal et al., 1999) and has been used to calculate *D* values comparable to values observed by other laboratories using different methods. Like other methods for determining *D*, simulation encounters difficulties when a significant fraction of the fluorescent protein is immobilized (Siggia et al., 2000). In such cases, the simulation either fails to fit the simulation data to the experimental recovery data or the simulation cannot calculate *D*. The Siggia simulation can be obtained by contacting Dr. Eric Siggia at *siggia@eds1.rockefeller.edu*. The simulation has been written for Unix systems and has been compiled for Macintosh computers. After signing the licensing agreement with Dr. Siggia, the Macintosh-compiled simulation can be obtained from the authors of this unit. Support Protocol 3 is a simple user's guide to the simulation.

After running any simulation or calculating a least-squares fit to determine *D*, it is essential to compare the simulation or fit data to the experimental data by plotting the data sets in a spreadsheet program. Even if a program or equation produces *D*, a poor fit means that *D* is questionable at best. "Goodness of fit" describes how well the simulation or equation data overlap the experimental data. The majority of the experimental data must overlap the simulation or equation plot. If the simulation misses the experimental data, the calculated *D* is questionable, at best. If there are any doubts about "goodness of fit," the user should consider another method of calculating the *D*.

A number of potential errors may occur in the course of data fitting. These errors are not unique to D calculations. They are part of the general problem of nonlinear regression analysis. Individuals that anticipate performing diffusion analysis are encouraged to become familiar with nonlinear regression analysis. An excellent introduction to the theory and problems of nonlinear regression analysis has been written by Dr. Harvey Motulsky and is available as a free download at *http://www.graphpad.com/www/nonlin.pdf*.

$t_{1/2}$

The mobilities of some proteins depend on complex behaviors, such as binding and release or populations with multiple D values. Such conditions complicate the analysis of D and may prevent fitting of data by traditional diffusion analysis. When a diffusion equation or simulation is unable to fit fluorescence recoveries, the $t_{1/2}$ measure can be used to compare relative recovery rates between samples. The $t_{1/2}$ is the time required for the fluorescence intensity in the bleach ROI to recover to 50% of the asymptote or plateau fluorescence intensity. This measure is independent of the prebleach ROI fluorescence intensity. In addition, it should be emphasized that while the $t_{1/2}$ can be a useful tool, it is only relevant for the user's system and conditions. It cannot be used to relate to $t_{1/2}$ values obtained from other experiments, since the $t_{1/2}$ value is relative to a particular experimental setup. The $t_{1/2}$ value requires two data manipulations: (1) conversion of time with the half-time of the bleach as time zero (t_0), and (2) conversion of bleach ROI recovery data into fractional fluorescence. Note that fluorescence recovery into a photobleach ROI must plateau or $t_{1/2}$ analysis cannot be performed. The $t_{1/2}$ can be determined visually or by solving the following equation (Feder et al., 1996):

$$F(t) = 100 \times [F_0 + F_\infty (t / t_{1/2})] / [1 + (t / t_{1/2})]$$

Equation 21.1.2

where t is the time for each ROI intensity value, usually in seconds or milliseconds, $t_{1/2}$ is the time required for the bleach ROI to recover to 50% of the asymptote (see discussion of $t_{1/2}$, below), and the remaining variables are defined as for Equation 21.1.1.

Fractional Fluorescence

To directly visualize and determine the $t_{1/2}$, transform the fluorescence intensity [$F(t)$] data to a 0% to 100% scale (see Fig. 21.1.4). The measurement is independent of the prebleach intensity and is not bleach corrected, as the relevant data occur after the photobleach. It is critical that the bleach ROI fluorescence recovery reaches a true plateau for accurate measurements. It is also important to have a large signal difference between the first postbleach intensity and the plateau. If the signal difference is too small, the plotted recovery will tend to be very broad and difficult to interpret. The following equation will convert the bleach ROI fluorescence recovery into fractional fluorescence data:

$$F_2(t) = 100 \times [F(t) - F_0] / [F_\infty - F_0]$$

Equation 21.1.3

where $F(t)$ is the bleach ROI fluorescence intensity at time t and the remaining variables are defined as for Equation 21.1.1. Time t must be rescaled relative to t_0, as described above. The $F_2(t)$ data are then plotted versus time (in seconds) to determine $t_{1/2}$.

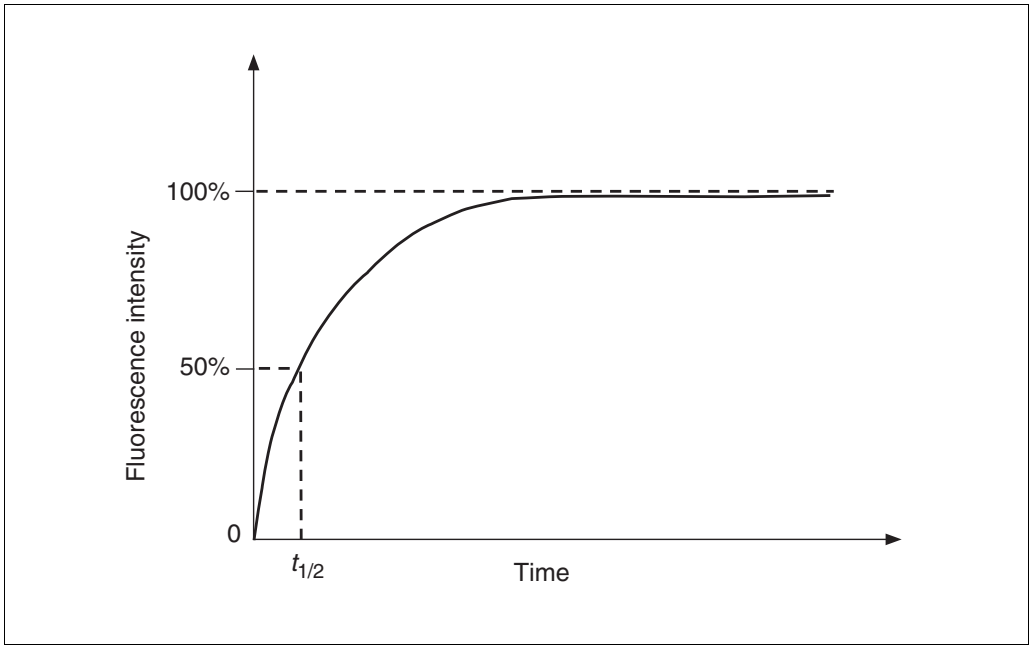

Figure 21.1.4 Fractional fluorescence. A plot of fractional fluorescence can be used to determine $t_{1/2}$, the time at which the fluorescence has recovered to 50% of the asymptote. The recovery data points (from F_0 to F_∞ in Fig. 21.1.1B) have been transformed to a scale of 0% to 100%.

The measurement is sensitive to the initial time (or t_0) of the bleach. When varying the size of the bleach ROI, the time to bleach the ROI will change. Practically, this means that the time for collection of the first postbleach image will vary between samples with different-sized bleach ROIs, which will alter the start time for data collection for each sample. Different groups define t_0 slightly differently. For this unit, t_0 is defined as the half-time of the bleach. To modify the time, subtract t_0 from each time value, where t_0 is defined by the following equation:

$$t_0 = \{[(t_{post} - t_{pre}) - (\text{time per image frame})]/2\} + t_{pre}$$

Equation 21.1.4

where t_{post} is the time of first image after photobleach and t_{pre} is the time of image immediately prior to photobleach.

ALTERNATE PROTOCOL 2

SELECTIVE PHOTOBLEACHING TO ENHANCE DIM STRUCTURES WHILE IMAGING OR TO VISUALIZE AND MEASURE NONDIFFUSIVE TRANSPORT INTO AN ORGANELLE

Photobleaching has additional uses besides those defined in Basic Protocols 1 and 2 and Alternate Protocol 1. For example, a GFP chimera may localize to two organelles in close proximity. One organelle may accumulate a substantial amount of the protein, while the adjacent organelle is dim. The bright organelle can be photobleached to permit imaging of the dim structure. Another application is to use photobleaching to visualize trafficking or flux through an organelle. For example, the Golgi complex (Nichols et al., 2001) or lysosomes can be photobleached, and then fluorescence recovery—either of fluorescence into the photobleached organelle or fluorescence trafficking out of the unbleached organelle into the photobleached area surrounding the organelle—can be imaged for both qualitative and quantitative analysis. Selective photobleaching essentially follows the FRAP protocol (see Basic Protocol 1). Instead of a strip, the investigator defines an ROI

appropriate to the organelle or structure of interest. Imaging conditions must be determined to photobleach either the structure of interest or around the structure of interest and to avoid bleaching of the overall cell during the course of imaging. When bleaching a bright structure to visualize dimmer structures, the conditions need to be set such that the dim structure or structures are sufficiently bright, but not saturating. The bright structure can be saturated, as it will be photobleached.

SIMULATION OF INHOMOGENOUS DIFFUSION

SUPPORT PROTOCOL 3

This simulation (Siggia et al., 2000) is a method for obtaining the diffusion coefficient *D* through diffusive recovery into a strip bleach (also see Support Protocol 2, discussion of Diffusion Analysis). The Siggia simulation can be obtained by contacting Dr. Eric Siggia at *siggia@eds1.rockefeller.edu*. The simulation has been written for Unix systems and has been compiled for Macintosh computers. After signing the licensing agreement with Dr. Siggia, the Macintosh compiled simulation can be obtained from the authors of this unit. Before running this simulation on a Macintosh computer (note the authors collect all of their data on a PC system with the confocal microscope and process diffusion data using a Macintosh), a substantial amount of RAM (50 to 100 Mb) should be allotted to the program. When running the simulation, other programs will run very slowly; therefore it is suggested that other programs be turned off. Before running the simulation, determine the time interval between frames and the size of each pixel.

1. To run the simulation, convert the TIFF (tagged-image file format) files to PGM (portable graymap), a format recognized by the simulation program.

   TIFF files can be converted to PGM files with the Macintosh program Graphic Converter (http://www.lemkesoft.de/us_gcabout.html). The authors recently discovered a bug in version 4.04 of the program, available online. The program will create PGM files; however, the simulation program does not recognize these files. The authors have used version 4.01 without incident. To run the simulation, the simulation program must be in the same folder as the PGM files. All files generated by the simulation will appear in this folder.

2. Open the first postbleach image and move the cursor to determine the coordinates of the smallest region that contains the whole cell. Write down the coordinate numbers (*x*, *y*), which should be in the range between 0 and 511, for the upper left corner of the box and the lower right corner of the box. Repeat for the photobleach ROI.

3. Start the simulation program.

   The program is designed to be user-friendly. The first few steps are self explanatory.

4. Enter the name of prebleach file (include full name, e.g., b009.pgm). If any colored saturation pixels are present in the images, the program will request that the user choose a channel (r, g, or b). Assuming the user has used GFP, enter g.

5. When asked Is this is a FRAP? and Are you supplying a series of postbleach images?, answer y for each question.

6. When asked Do you want to supply a background value?, answer n .

   Usually the simulation determines an accurate number, though the user is free to change the value.

7. When asked to enter the *x*,*y* coordinates of the ROI (note that the program is referring to the whole cell ROI, not the photobleach ROI), enter each coordinate for the upper left-hand corner of the box defined in step 2 (first *x* and then *y*) separated by a space (no parentheses or commas). Press the Return key and then enter the lower right-hand coordinates, each separated by a space.

8. When asked if one wants to monitor diffusion in individual rectangles, if one desires to use this option, open the postbleach_grid.pnm file and select grid rectangles of interest.

   The coordinates for each rectangle are determined by numbering the rectangles (0 to 9) across and down from the upper left corner of the grid. Each rectangle will correspond to x y, entered with a single space and no punctuation. The user may opt for this method to measure diffusion differences in different regions of the cell. However, the rectangle grid generated by the program will not necessarily align with the photobleach ROI. In addition, D values will be different for different regions of the cell. This information can be useful, but the time required for equilibration of a region of the cell some distance from the photobleach ROI is often much longer than the equilibration time in the photobleach ROI.

9. To obtain *D* in the bleach box ROI, type n and hit the Return key. Next, enter the coordinates (x y) of the bleach box ROI that were determined using graphic converter or NIH Image. Enter a single space between coordinates with no punctuation.

10. For time, unless one has used different times between frames, type y (without punctuation) if the time intervals between postbleach frames are the same. Next, enter the time between frames in seconds.

    Decimals (e.g., 0.798) are permitted.

11. Hit the Return key to run the simulation.

    The program takes 3 to 10 min to run depending on computer speed, the size of the cell ROI, and the number of images to be processed. The program becomes especially slow after the words "Starting inhomogeneous diffusion" appear. Finally, the program will state the effective diffusion constant for the photobleach ROI or the rectangles selected.

    IMPORTANT NOTE: *At the end of the program, the user is asked, "Do you wish to plot the simulation data with a different D_eff (yes or no)? The user must answer y or "n, and hit the Return key or the program will not create the experimental data file. Without this file, the user cannot compare the experimental recovery relative to the simulated recovery.*

12. Compare the sim001.dat versus the exp001.dat data files by simultaneously plotting both in a spreadsheet program.

    It is essential to plot the simulation data to determine whether the diffusion recovery has been accurately modeled. If the simulation misses the experimental data, the calculated diffusion rate is questionable, at best. The majority of the experimental data must overlap the simulation plot. A simulation that only overlaps with the initial steep rise or only with the later more gradual rise is not correct, and these D values should not be used. It is important to use all of the recovery data because removing parts of the recovery can significantly alter the calculated D. However, if the photobleach ROI fluorescence intensity has reached a genuine plateau and then rises or drops due to a focal shift or photobleaching, then the images after the plateau may be excluded from the analysis by simply removing them from the folder.

13. If the simulation quits before stating that *D* cannot be determined, recheck to see if incorrect coordinates have been entered (e.g., by placing the photobleach ROI outside of the whole cell ROI). Repeat the simulation, with the correct coordinates (be sure to remove any files generated by the previous run of the simulation).

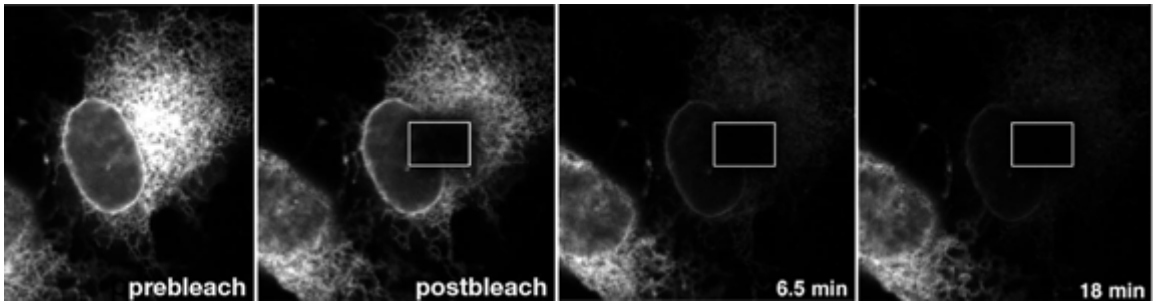

Figure 21.1.5 Example of FLIP. Protein fluorescence in a small area of the cell (box) is bleached repetitively. Loss of fluorescence in areas outside the box indicates that the fluorescent protein diffuses between the bleached and unbleached areas. Repetitive photobleaching of an ER GFP-tagged membrane protein reveals the continuity of the ER in a COS-7 cell. Image times are indicated in the lower right corners. The postbleach image was obtained immediately after the first photobleach. The cell was repeatedly photobleached in the same box every 40 sec. After 18 min, the entire ER fluorescence was depleted, indicating that all of the GFP-tagged protein was highly mobile and that the entire ER was continuous with the region in the bleach ROI.

FLIP USING A LASER SCANNING CONFOCAL MICROSCOPE CAPABLE OF SELECTIVE PHOTOBLEACHING

BASIC PROTOCOL 2

FLIP (fluorescence loss in photobleaching) is similar to FRAP (see Basic Protocol 1) in that an ROI is photobleached with a high-power laser. However, in FLIP, the ROI is repeatedly bleached over time to examine the behavior of the entire fluorescent pool. If the fluorescent molecules are completely mobile and have access to the photobleaching ROI, the entire fluorescent pool will be depleted (see Fig. 21.1.5). Results from FLIP experiments therefore provide information about the connectedness of structures containing GFP chimeras.

For FLIP analysis, the user must obtain a prebleach image, an immediate postbleach image following the first photobleach, and images following successive photobleaches (often 2 to 3 images following each photobleach) until the entire cell is depleted of fluorescence, or until several successive photobleaches do not further deplete cell fluorescence. The time for each image, pixel size, and fluorescence intensity values for the whole cell and the background intensity must also be determined.

Materials

Cell samples expressing GFP chimeric protein of interest (Support Protocol 1)
Confocal laser scanning microscope capable of selective photobleaching (e.g., Zeiss LSM 510)

Additional reagents and equipment for preparing imaging chambers and microscope for photobleaching experiments (Support Protocol 1)

1. Set up the microscope and prepare cells in imaging chamber with imaging medium as described in Support Protocol 1. Prewarm the imaging stage to 37°C or other desired temperature and warm up the microscope lasers for at least 5 min to avoid power fluctuations during imaging.

2. Identify the cell of interest on the confocal microscope.

   The ideal situation is to have two adjacent cells of similar fluorescence intensity in the imaging field. The cell that is not bleached provides a control to ensure that the imaging conditions do not cause nonspecific photobleaching of all fluorescence in the field of view. It is essential that imaging conditions do not significantly photobleach any adjacent cells during the experiment.

3. Bring the desired cell into focus. Scan an image of the whole cell at the desired excitation light intensity, averaging, and other parameters. Modify pinhole and detector gain for maximal fluorescence signal and minimal pixel saturation.

   Detector gain and offset will vary depending on the concentration of the fluorophore, the laser power, and the width and thickness of the fluorescently labeled organelle or region. The imaging parameters used for this image should be used for the fluorescence recovery time series.

4. Define a region-of-interest (ROI) for the photobleach, which should be between 5% and 20% of the structure of interest.

   The bleach ROI does not need to be a strip. A square is equally appropriate.

5. Determine imaging and photobleaching conditions (i.e., scan speed, zoom, laser power, number of laser iterations required for photobleaching, and microscope objective) that photobleach 90% or more of the fluorescent signal in the ROI, without causing significant photobleaching of the cell outside the photobleach ROI.

   A 40-mW 488/514 nm argon laser can be used at 45% to 60% power with 100% transmission for photobleaching and 1% transmission for imaging. Usually, cells are scanned at 0.8 to 3 sec per image with two- to eight-line averaging.

6. Collect three to five prebleach images to establish the prebleach fluorescence intensity and to confirm that the prebleach fluorescence intensity does not significantly fluctuate.

7. Collect two to five prebleach images and then photobleach the bleach ROI. Collect two to four images of the whole cell and photobleach the ROI again. Repeat the process until the fluorescent structure intensity is similar to background.

   The pauses allow unbleached molecules to diffuse into the photobleached ROI. In addition, collecting images between bleaches permits monitoring of progress and confirms that the cell remains in focus and has not moved. As this protocol requires longer time periods, the focal plane may shift. It is acceptable to refocus the cell during the experiment. However, if the cell or focus moves such that the region being photobleached also moves laterally, then the experiment should be aborted. Successful FLIP requires that the bleach ROI position within the cell is stable. If the cell migrates during the course of the experiment, then the data will be unusable.

8. Execute a quantitative FLIP.

   This procedure can be automated with a macro to program the bleaching and imaging timing. A FLIP macro for the Zeiss 510 laser scanning microscope (the advanced time-series macro in combination with the physiology software package) is available from Zeiss. It is also possible to perform FLIP manually. To do this, photobleach the bleach ROI in cells for several (i.e., 20 to 50) bleach iterations. Next, collect three images of the cell. Repeat the bleach and image collection many times, up to 15 to 20 min (or longer). If the proteins are mobile and the fluorescent structure is continuous, the total structure fluorescence will be depleted. If the protein diffuses relatively slowly, the investigator can modify the routine to include a time delay between images, to reduce overall photobleaching due to laser scanning of the cell.

9. Collect at least three to five data sets for each fluorescently labeled protein and treatment.

   A fraction of data sets may be unusable because the focal plane shifted, the cell moved, or other reasons.

   For CLSMs that are unable to perform selective photobleaching of an ROI, it is possible to perform FLIP using essentially the same protocol as that described above. The primary differences are the need to photobleach the cell by zooming (see Alternate Protocol 1) and

the requirement for a macro to automate the FLIP experiment. Essentially, the protocol must alternate between photobleaching the ROI and scanning images of the whole cell between photobleaching. The photobleaching and imaging scans must be performed at regular time intervals such that it will be possible to directly compare the rates of fluorescence depletion between two cells. For a more extensive discussion on writing this macro, see the review by Lippincott-Schwartz et al. (1999). Some FLIP experiments may not need to be quantitative and it is possible to manually perform FLIP.

REAGENTS AND SOLUTIONS

Use deionized , distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Imaging medium

Phenol-red free medium (e.g., RPMI or DMEM)
10% (v/v) fetal bovine serum (FBS)
2 mM glutamine
25 mM HEPES, pH 7.4
Prepare fresh

COMMENTARY

Background Information

Diffusion is defined as the rate of movement or flux of particles due to random or Brownian motion. An example of diffusion is the mixing of a drop of dye in a liquid solution. Random movements of proteins in a lipid bilayer (lateral diffusion), in the cytosol, or within an organelle are all examples of diffusion in a cell. Diffusion primarily depends on the viscosity of the environment and the size of the molecule. For soluble spherical molecules, the diffusion coefficient, *D*, is inversely proportional to the cube root of the radius of the molecule (Stokes-Einstein equation). This means that a molecule must increase 8- to 10-fold in size to decrease *D* by one-half. The size dependence of *D* for membrane proteins relates primarily to the radius of the transmembrane segments, rather than aqueous domains. This is because the lipid bilayer is more viscous than cytoplasm or organelle lumena. Other factors, such as protein-protein interactions or binding to a matrix can also profoundly affect the *D* of a protein.

Since Frye and Edidin (1970) demonstrated that proteins on the plasma membrane of cells move by diffusion, investigators have sought to directly measure diffusion coefficients of cellular proteins in their cellular context. Poo and Cone (1974) and Liebman and Entine (1974) performed some of the first FRAP experiments by photobleaching retinal rod outer segments; these experiments successfully measured the *D* value of the transmembrane protein rhodopsin. The analytical equations and methodology that form the basis of FRAP were described originally by Axelrod et al. (1976). Labeling of proteins that are exposed to the extracellular face of the plasma membrane of living cells, using fluorescent antibodies, has been the primary labeling method for FRAP studies for 20 years. However, with that method, studies were restricted primarily to proteins on the cell surface, leaving all of the vesicles, organelles, and cytoskeletal components of cells unexplored. Some researchers have exploited microinjection techniques to place fluorescent antibodies or fluorescently labeled proteins in the cytoplasm. However, standard microinjection does not deliver proteins to the lumena of organelles, leaving these important cell environments unprobed. An additional barrier to investigating protein mobility was that traditional FRAP methodology required a dedicated custom microscope (Wolf, 1989).

Today, the combination of advances in fluorescence imaging methods, user-friendly commercially available laser scanning microscopes, and powerful cost-effective computing resources has made it possible for nonspecialists to exploit GFP chimeras and to probe their mobilities and interactions. For examples and more information, the reader is referred to several reviews of FRAP theory and techniques (Edidin, 1992; Ellenberg et al., 1997; Lippincott-Schwartz et al., 1999, 2001; Meyvis et al., 1999; White and Stelzer, 1999; Nichols et al., 2001).

Critical Parameters and Troubleshooting

The critical parameters for data collection are described in the protocols. There are several considerations for data analysis and interpretation that require additional emphasis. The major concerns are discussed below.

EGFP is better suited than other spectral variants for photobleaching experiments

Photoconversion and reversible photobleaching are phenomena that can seriously complicate photobleaching analysis by generating artificially high *D* values. Photoconversion is the process by which a fluorophore is excited and becomes transiently or permanently altered in its fluorescence excitation and emission spectra. Reversible photobleaching occurs when a fluorophore's excitation state is changed by intense illumination, which appears to an observer as destruction of the fluorophore. However, the fluorophore reverts to its native excitation and emission spectra and becomes fluorescent again. While many fluorophores exhibit varying degrees of both phenomena, photoconversion and reversible photobleaching are minimal for enhanced green fluorescent protein (EGFP). In contrast, wild-type GFP readily undergoes photoconversion. Thus, FRAP experiments using wild-type GFP chimeras should be avoided.

Correct for photobleaching due to bleaching of the ROI and repeated scanning of the cell

One method to measure the amount of photobleaching is to directly measure the change in the fluorescence of the whole cell used in an experiment. A decrease in fluorescence can be used for data correction and can also help the investigator modify imaging conditions to achieve minimal sample bleaching. In addition, this method offers an additional advantage in that the investigator can monitor fluorescence changes in every frame and can be alerted to cell movement and focal drift, which can change the apparent fluorescence recovery. Alternatively, the investigator can fix the sample (using 4% formaldehyde in PBS for 15 min) and acquire the time-lapse images of the fixed sample using exactly the same imaging parameters (e.g., excitation light intensity, duration, zoom, and number of images) as in living cells. Loss of fluorescence under these conditions will be due only to photobleaching and not to biological degradation processes. Once the photobleaching rate has been determined, the experimental values obtained from living cells can be corrected.

Photobleaching experiments must produce recoveries with a true plateau or asymptote

M_f and $t_{1/2}$ calculations cannot be performed reliably when the asymptote has not been reached. Often, in the course of data processing, what appears to be a flat plateau with raw data may become an incomplete recovery following data processing. This result emphasizes the importance of determining the optimal imaging time to obtain a true plateau.

D and M_f must be interpreted in the context of the cell

Data analysis requires a commitment on the part of the investigator not to blindly accept numbers generated by the equations without attempting to determine whether the results are biologically and physically reasonable. For example, a *D* of 2 μm^2/sec for an integral membrane protein exceeds the highest recorded diffusion coefficient (0.4 to 0.5 μm^2/sec) for a membrane protein in a cell by four-fold. Such a number could indicate that a protein is no longer membrane-associated or that the GFP chimera is incorrectly processed or targeted. Another less likely possibility is that processes besides diffusion are occurring (e.g., flow; Sciaky et al., 1997) that do not exhibit diffusive behavior.

Interpretation of D and M_f can be confounded by the connectedness of fluorescent structures

The problem concerning compartment connectedness is not always readily apparent. That is, an organelle or compartment may appear connected at the light level, but not actually be connected. This situation will result in a low apparent mobile fraction since fluorescent molecules in nearby but unconnected areas will be unable to diffuse into the recovery box. One way to clarify whether a structure is continuous or disconnected is to perform FLIP and check to see whether fluorescence of an otherwise mobile protein is depleted from all areas of the compartment (indicating connectivity) or only specific areas (indicating a lack of connectedness). If the molecule being studied resides within a discontinuous compartment, it will be difficult to estimate its *D*, since the equations and simulation programs used for calculating *D* assume free diffusion throughout a compartment.

Table 21.1.2 Troubleshooting Guide for Photobleaching

Problem	Possible cause and solution
Autofluorescence noise	Lysosomes are notorious for autofluorescence when excited with light between 400 and 488 nm. To decrease autofluorescence, lower the intensity of the excitation beam and use narrower-bandpass emission filters. Also, avoid phenol red and high serum concentrations (>20%) in the medium.
Fluorophore bleaches too rapidly during acquisition	Decrease the excitation light intensity using either neutral density filters or by lowering the voltage to the Acousto-Optical Modulator and increase the gain on the detector side to collect light more efficiently. If this does not work try adding Oxyrase[a], an oxygen scavenger, to the medium.
Cells round up during imaging	This could be due to gross photodamage to the cells from long periods of exposure to an intense excitation beam. To correct, decrease the intensity of excitation light. Alternatively, the cells may have depleted some nutrient in the medium due to remaining in coverslip chambers for too long. Replenishing the imaging medium should help.
Cells are excited with a constant light intensity, but the fluorescence intensity varies over time	If this is not due to a biologically relevant process such as recruitment/degradation of fluorophore, then either the focus is shifting during acquisition or the laser power output is unstable. Maintain the focus either manually or by using autofocus software, which is available for some CLSMs. If laser output is a concern, then check it by exciting fluorescent beads and quantifying the emission over time. Fluctuating laser output may be due to the laser being operated at low power output. Increasing the power output to 50% may help. If this fails to correct the problem, then contact your confocal service representative.
Focus drifts	Try using relatively flat cells (i.e., COS-7) which may alleviate the problem. Try imaging with the pinhole partly or entirely open and use lower-NA objectives. Be sure to pre-equilibrate the sample to the temperature of the objective, as this will prevent expansion/contraction of the coverslip/chamber during imaging. Make sure that the stage insert is mounted securely and that the sample is seated properly in the holder.
D values of two subsequent experiments of the same ROI in the same cell do not match	This suggests the area that has been photobleached has been damaged. Try using a different GFP variant that requires a lower (and less damaging) wavelength of laser light, such as YFP. Note that YFP may reversibly photobleach.
Slow recovery or lack of recovery after bleaching	Either the fluorophore is relatively immobile or there are discontinuities within the structure where the fluorophore is located. This is relevant for isolated membrane structures with little connection between membranes, such as structures of the endocytic system (e.g lysosomes and endosomes).
Recovery is significantly faster than expected	A faster than expected *D* for a membrane protein may indicate that the protein is no longer correctly assembled or inserted in the membrane. This can be tested by performing immunofluorescence colocalization with a marker for the organelle of interest or performing immunoblotting to determine whether the GFP chimera has become partially degraded. Another condition that may affect fluorescence recovery is loss of cell integrity or viability.

continued

Table 21.1.2 Troubleshooting Guide for Photobleaching, *continued*

Problem	Possible cause and solution
Nondiffusive behavior	A failure to fit recovery-curve data by a simulation or to a least squares fit equation may suggest that the protein is not moving by simple diffusion. There are conditions that cannot be described by equations for simple diffusion, e.g., in the case of anomalous diffusion[b] and when there are multiple populations diffusing at different rates.[c]

[a]Product of Oxyrase Inc.; see *SUPPLIERS APPENDIX*.

[b]Potential mechanisms of anomalous diffusion include binding and collisional interactions with mobile and immobile obstacles (Periasamy and Verkman, 1998) and recovery due to vesicular transport.

[c]The labeled protein in the FRAP experiments may alternate between multiple states, i.e., different-sized oligomers or bound and unbound to a membrane or complex. These conditions pose significant problems to diffusion analysis. Gordon et al. (1995) describe the mathematical difficulties of separating multiple *D* coefficients. The main problem is that the investigator does not usually know the fraction of each population or the actual number of populations. It is worth noting that at least one group has successfully teased out multiple diffusing populations (Marguet et al., 1999). In this example, the group independently determined the *D* coefficients for the two populations and biochemically determined the relative percentages of each population.

Troubleshooting

A number of common problems that may arise in photobleaching experiments and potential solutions for them are presented in Table 21.1.2.

Anticipated Results

The methods described in this unit should permit the investigator to obtain and interpret fluorescence intensity recovery data following photobleaching of GFP chimeras with a CLSM. The investigator should be able to calculate the M_f and either the D or $t_{1/2}$ of fluorescence recovery of a protein in a cell. The investigator should also be able to perform a FLIP experiment to determine the connectivity of GFP-labeled cellular compartments and organelles. Finally, the investigator may take advantage of selective photobleaching either to reveal dimmer fluorescent structures obscured by bright structures or to visualize dynamic processes under steady-state conditions, such as vesicular trafficking.

Time Considerations

Creation of GFP chimeras involves standard cloning procedures and biochemical or genetic assays to confirm that the properties of the chimera are similar to those of the parent protein. Preparation for photobleaching experiments consists of transferring cells to coverslips or imaging chambers and transfecting the cells with a GFP construct 16 to 48 hr prior to imaging. The initial setup for photobleaching experiments requires a time investment of a few hours to determine conditions for each protein to be bleached. The actual FRAP experiments can be very rapid, ranging from 90 sec for the recovery of a soluble lumenal ER protein into a 4-μm bleach ROI, to 6 min for a membrane protein. FLIP experiments often take 10 to 20 min. FRAP experiments require at least 5 (and preferably 10) data sets for useful statistics to compare *D* values. Data processing depends on the method used and the power of the computer. The Siggia simulation will process a 250-image data series in 2 to 3 min on a Macintosh G4 450 MHz computer. Due to the large numbers of data sets to be processed, data analysis can be time consuming.

Fluorescence Localization After Photobleaching (FLAP)

Fluorescence localization after photobleaching (FLAP) is a new method for localized photolabeling and subsequent tracking of specific molecules within living cells. The molecular species to be located carries two different fluorophores that can be imaged independently but simultaneously by fluorescence microscopy. For the method to work, these two fluorophores should be accurately colocalized throughout the cell so that their images are closely matched. One of the fluorophores (the target fluorophore) is then rapidly photobleached at a chosen location. The unbleached (reference) fluorophore remains colocalized with the target fluorophore; thus the subsequent fate of the photobleached molecules can be revealed by processing simultaneously acquired digital images of the two fluorophores. For example, an absolute FLAP image, which shows the location of the photobleached molecules, is calculated simply by subtracting the target intensity from the reference intensity at each pixel. This image is effectively the same as images obtained directly by photoactivation methods, so absolute FLAP can be considered to be a method of virtual photoactivation. In addition, however, a relative FLAP image can be calculated to show the photobleached fraction of molecules within each pixel. This useful information is not available with other methods.

The Basic Protocol in this unit demonstrates the simplicity and effectiveness of the FLAP method in revealing both fast and slow molecular dynamics in living cells. As an example, cDNA fusion constructs of β-actin with yellow and cyan fluorescent proteins (YFP and CFP) are microinjected into the nuclei of transformed rat fibroblasts. Using a Zeiss LSM 510 laser-scanning microscope, the authors show that it is possible to follow simultaneously the fast relocation dynamics of monomeric (globular) G-actin and the much slower dynamics of polymeric (filamentous) F-actin in expressing cells.

In order to give a step-by-step protocol for the FLAP method, it is necessary to focus on a particular configuration of fluorophores and microscopy methods. CFP-actin and YFP-actin fusion proteins have been chosen as the fluorescent molecules, since YFP can be efficiently and rapidly photobleached. Moreover, the predominance of native actin in the cell means that noise-free images can be obtained at low relative expression levels of the tagged molecules. Using wide-field fluorescence microscopy, it is possible to separate the emission spectra of these two fluorophores and thus obtain simultaneous images. For this, both fluorophores are excited simultaneously, and a commercially available arrangement of fixed dichroic mirrors and filters (Cairn Research Ltd.) enables the two images to be projected side-by-side onto a single CCD chip. However, in view of the large overlap of emission spectra of CFP and YFP, laser scanning microscopy, which permits alternately exciting the two fluorophores line-by-line and yields images that are effectively simultaneous, has been chosen for the Basic Protocol. Some laser scanning microscopes, such as the Zeiss LSM 510 used here, have the further advantages of versatile choice of size, shape and location of the bleach region, and rapid resumption of image scanning after bleaching. Time-lapse recording using no intervals between scanned frames will reveal rapid diffusion dynamics, whereas intervals of several seconds or longer may be required to reveal the movements of polymerized or bound molecules without excessive fading of the fluors.

Current Protocols in Cell Biology (2004) 21.2.1-21.2.16

FLAP OF ACTIN IN LIVING CELLS

This protocol describes the FLAP method using transformed rat fibroblasts of the lines K2 and T15 (Pavel Vesely, Institute of Molecular Genetics, Academy of Sciences of the Czech Republic, Flemingovo nam. 2, 166 37 Prague 6 Dejvice, Czech Republic; e-mail, *pvy@zeus.img.cas.cz*). Many other cell types that the authors have tried work equally well. A notable exception is the Swiss 3T3 line, which shows significant autofluorescence on the YFP channel. Extensive details on preparation of constructs, cell culture, and microinjection methods will not be given, as these are standard procedures. Also a basic familiarity with the software and operation of the Zeiss LSM 510 upright microscope will be assumed. Once the microscope and software have been prepared (Support Protocol 1), there are two main sequential stages to the Basic Protocol: (1) preparation of cells and setting up the microscope (steps 1 to 4) and (2) microscopy (steps 5 to 17). Post-processing and analysis of images (Support Protocol 2) can be performed later.

Materials

Rat fibroblast cell line K2 or T15
Hanks' Minimal Essential Medium (MEM; Cancer Research UK; *daniel.zicha@cancer.org.uk*) containing 10% bovine serum and no antibiotics
cDNA constructs of eCFP-β-actin and eYFP-β-actin (see recipe)
Experimental reagents of interest (e.g., myosin light chain kinase inhibitor, ML-7)
Hot wax mixture (see recipe)
Non-toxic immersion oil optimized for 37°C, refractive index 1.515 (Cargille Labs)
18 × 18–mm glass coverslips
35-mm plastic petri dishes (Costar)
Microinjection system (also see *UNITS 4.10 & 17.1*) including:
  5171 micromanipulator (Eppendorf)
  5246 transjector (Eppendorf)
Zeiss Axiovert 35 microscope
Microneedles (GC120TF-10, Harvard Apparatus)
P97 Flaming/Brown micropipette puller (Sutter)
Optical chambers (see recipe)
Zeiss upright LSM 510 microscope (see Support Protocol 1 for full configuration) contained within a 37°C environmental control incubator (e.g., Microscope Temperature Control System, Life Imaging Services) *or* a similar apparatus assembled in house (Fig. 21.2.1)
Software:
  Zeiss LSM 510 operating software for image acquisition
  Zeiss LSM Reader for image review (free download; see Internet Resources)
Additional reagents and equipment for cell culture (*UNIT 1.1*), microinjection (see *UNITS 4.10 & 17.1*), and use of LSM 510 operating software (see Support Protocol 1)

NOTE: All solutions and equipment coming into contact with living cells must be sterile and aseptic technique should be used accordingly.

NOTE: All culture incubations should be performed in a humidified 37°C, 5% CO_2 incubator unless otherwise specified. Some media (e.g., DMEM) require altered levels of CO_2 to maintain pH 7.4.

Prepare cells and set up microscope

1. Seed cells at the required density onto the 18 × 18–mm coverslips in 35-mm plastic petri dishes and flood with Hanks' Minimal Essential Medium/10% bovine serum (see *UNIT 1.1* for basic cell culture techniques). Incubate 72 hr.

Figure 21.2.1 Zeiss upright LSM 510 microscope contained within a 37°C environmental control incubator. In the authors' laboratory, the enviromental control chamber is a specially built Plexiglass box with access hatches (Cancer Research UK workshop). The essential components for the heater and control system are a centrifugal fan (part no. 40BTFL from Air Flow Developments), and a temperature controller (208-2739), thermocouple type T (219-4680), box (584-615), mini-3-pole plug (449-269), mini-3-pole socket (449-275), fuse holder (418-603), optical relay (394-535), type T panel socket (219-4860), type T line plug (219-4876), enclosed heater (224-565), and thermocouple connector (219-4876), all from RS Components. A similar commercially available system (Microscope Temperature Control System) may be obtained from Life Imaging Services (see Internet Resources).

MEM has been optimized by the authors at Cancer Research UK for the cell lines used here. However, it might be possible to obtain satisfactory results with the MEM formulation supplied by Sigma.

In the authors' laboratory, experiments usually require that the cell density still be well below confluence (~50%) after this incubation.

2. Microinject the two cDNA constructs at concentrations of 50 ng/μl (YFP-actin) and 75 ng/μl (CFP-actin) into the nuclei of 20 to 30 cells located near the center of each coverslip. Return to incubator for 2 to 3 hr.

   Expression and folding times may vary widely with other fluorescent protein constructs.

3. During the incubation, switch environmental heating and argon laser on the LSM 510 to on and open a database with previous software settings (see Support Protocol 1).

4. Assemble a coverslip culture (from step 2) onto an optical chamber filled with medium and any experimental reagents. Seal chamber with hot wax mixture, wash outside of chamber with clean distilled water, and blow dry before placing on the stage of the LSM 510.

Perform microscopy

5. Restore settings for tile scanning by selecting the previous tile scan from the saved database and reusing the settings (Support Protocol 1). Check that scan rate is now at fastest setting and laser power settings are correct.

Tile scanning provides a montage of adjacent fields acquired sequentially in order to overview a large area for identification of expressing cells.

6. Use the stage control joystick to locate the center of the chamber on the microscope axis, switch to direct viewing using a low-power phase objective (5× to 25×), change phase setting of condenser as necessary, and focus on cells manually.

7. Start Tile scan in Stage controls.

   The authors generally use a 4 × 4 tile array with 256 × 256 pixel images.

8. Mark the expressing cells. Create an image database and use Save As to store the tile scan.

9. Restore software settings for FLAP imaging by selecting a FLAP sequence from the saved database and reusing the settings (Support Protocol 1). Use the stage-control joystick to move the chamber away from objective, apply immersion oil, and recentralize chamber by moving to the first marked cell. Switch to high-aperture oil-immersion objective (63× Plan apochromat Ph3) and change phase setting of condenser as necessary.

   CAUTION: *Do not attempt to switch objectives automatically unless it has been ascertained that they are accurately parfocal (Support Protocol 1) and that the lower surface of the upper coverslip is in focus. The high-power objective may have a very short working distance and any error could cause a disastrous crash between the objective and the specimen.*

10. Start a fast scan while displaying split channels and manually focus on a cell.

    The interference reflection microscopy (IRM) image will brighten suddenly when one is focused on the lower surface of the upper coverslip. A small distance below this surface (turn top of fine focus knob away from you) will usually be the optimal setting with maximal brightness of the fluorescence images.

11. If necessary, centralize the cell in image field using the X/Y buttons and the nudge wheel on the joystick control. Cease fast scanning as soon as possible.

    Note that the IRM image will often be out of focus at the optimal setting for fluorescence imaging; a compromise is necessary if good IRM images are required.

12. Select orientation and zoom factor (the authors usually keep a standard zoom of 2) and do a single scan.

    When it is critical to record fast molecular dynamics immediately after bleaching, note that the top of the reoriented image will be scanned first.

13. Click the use ROI button to set up region of interest (ROI) if required in order to reduce scan times.

    It is sometimes advantageous to image the whole cell for accurate estimates of fluorophore fade during imaging (Support Protocols 2). Note that the top one or two scan lines will sometimes show a defective match between channels and should be avoided (see Troubleshooting).

14. Do a single scan while displaying split channels. Switch to the custom Hall palette (Support Protocol 1). Using a minimal number of further scans, adjust laser gains and offsets so that the two fluorescence channels are accurately matched with no saturation and with a low but finite background intensity. Adjust settings for the other two channels if necessary. Return to the no palette display.

    If matched, the fifth combined image should show the fluorescent regions as pure white (Fig. 21.2.2). The phase-contrast and IRM channels should show good contrast.

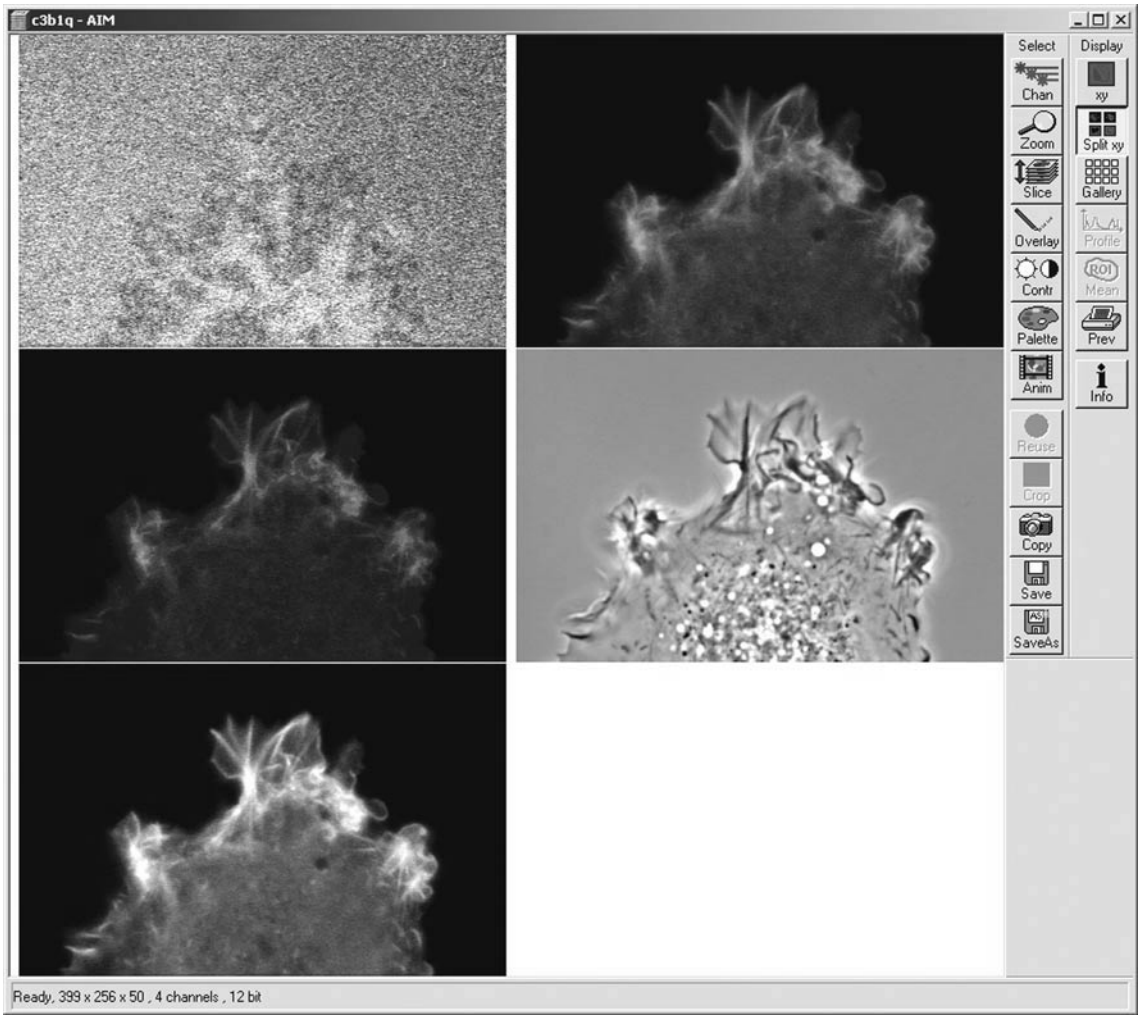

Figure 21.2.2 Window from Zeiss LSM software showing four channels and fifth combined channel after setting gains and offsets and laser powers. Courtesy of Carl Zeiss, Germany; reprinted with permission of Zeiss UK. *This black and white facsimile of the figure is intended only as a placeholder; for full-color version of the figure go to http://www.currentprotocols.com/colorfigures.*

15. Select the bleach panel, choose a bleach region, and change the bleach parameters if necessary.

    The authors use 50 bleach scans at the full-power laser setting. Note that bleach times depend on the height of the bleach region (regardless of its shape) but not on its width, so a horizontal narrow strip will bleach a large area rapidly.

16. Select the time series panel and change the time-lapse parameters if necessary. Do one single scan to check that everything is still OK (i.e., that the current setup still provides a satisfactory image of the selected cell). Choose the number of scans to average and start the recording.

    The authors normally average four scans per frame and record two frames before bleaching and 50 afterwards with no time-lapse interval. Recording of the FLAP signal is best monitored in a large window showing the combined image. After bleaching, the bleach-labeled molecules will then show as a bluish color against a white background (Fig. 21.2.3). Avoid transmitting any vibrations to the microscope during recording.

17. Save the recorded sequence if satisfactory, export the bleach region image for later reference (showing the bleach region and with the zoom aspect set to 1:1) as a

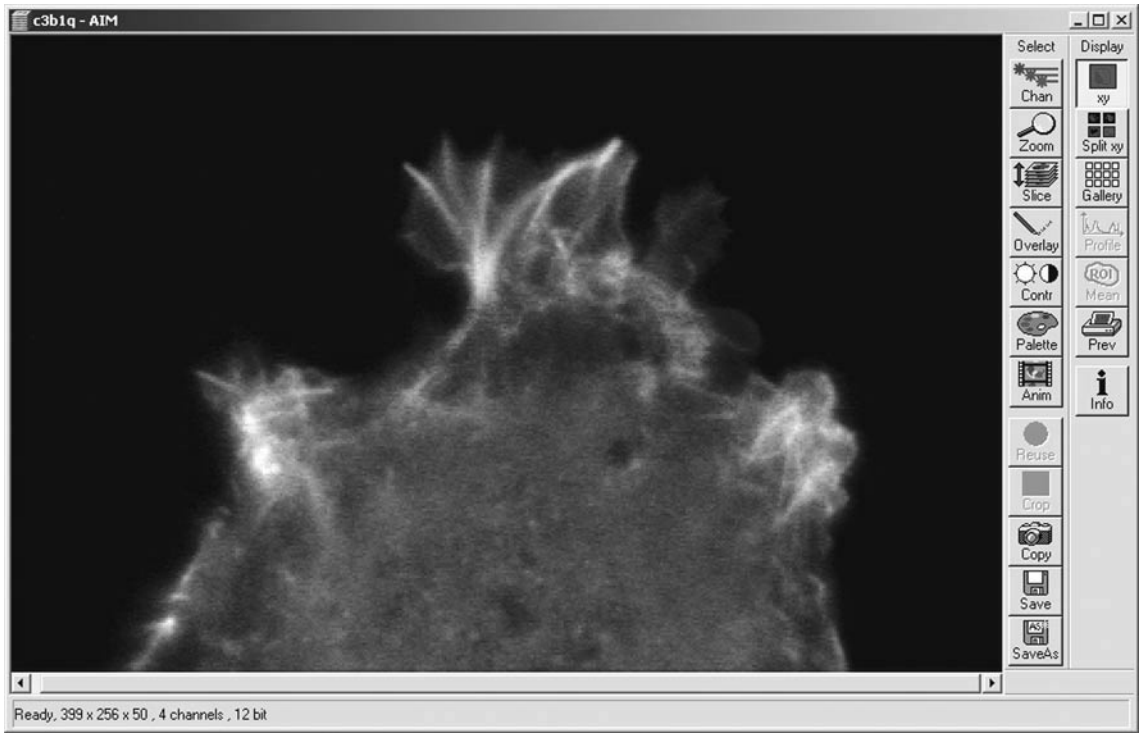

Figure 21.2.3 Window from Zeiss LSM software showing only the combined channel after bleaching during data recording. Courtesy of Carl Zeiss, Germany; reprinted with permission of Zeiss U K. *This black and white facsimile of the figure is intended only as a placeholder; for full-color version of the figure go to http://www.currentprotocols.com/colorfigures.*

single-image TIFF file, reset the scan averaging to 1, move to the next marked cell using the stage-control panel, and repeat steps 10 through 16 for all marked cells. Return to step 5 to start a new culture chamber.

SUPPORT PROTOCOL 1

SETTING UP THE LSM 510 AND ITS SOFTWARE

It is important that the microscope be configured optimally—e.g., pinhole alignment should be set correctly. Optimization of settings for tile scans and FLAP imaging will require a trial run through the Basic Protocol.

Materials

Zeiss upright LSM 510 microscope and software (see Basic Protocol 1)
Small beads (e.g., TetraSpeck microspheres, 0.2 μm; Molecular Probes)

1. Make sure that the objectives to be used are accurately parfocal using small beads and Parfocal Settings from the `CLM32.EXE` program.
2. Define the pseudocolor lookup table (LUT) for the custom Hall palette (Fig. 21.2.4) to be used for gain and offset adjustments and for viewing fully processed FLAP images.

   Other preferred LUTs may be used, but it is critical that minimum and maximum gray levels be easily distinguishable from the rest.

3. For tile scans, use three channels (CFP fluorescence, YFP fluorescence, and phase contrast), a low number of pixels (256 × 256), and fast scanning.

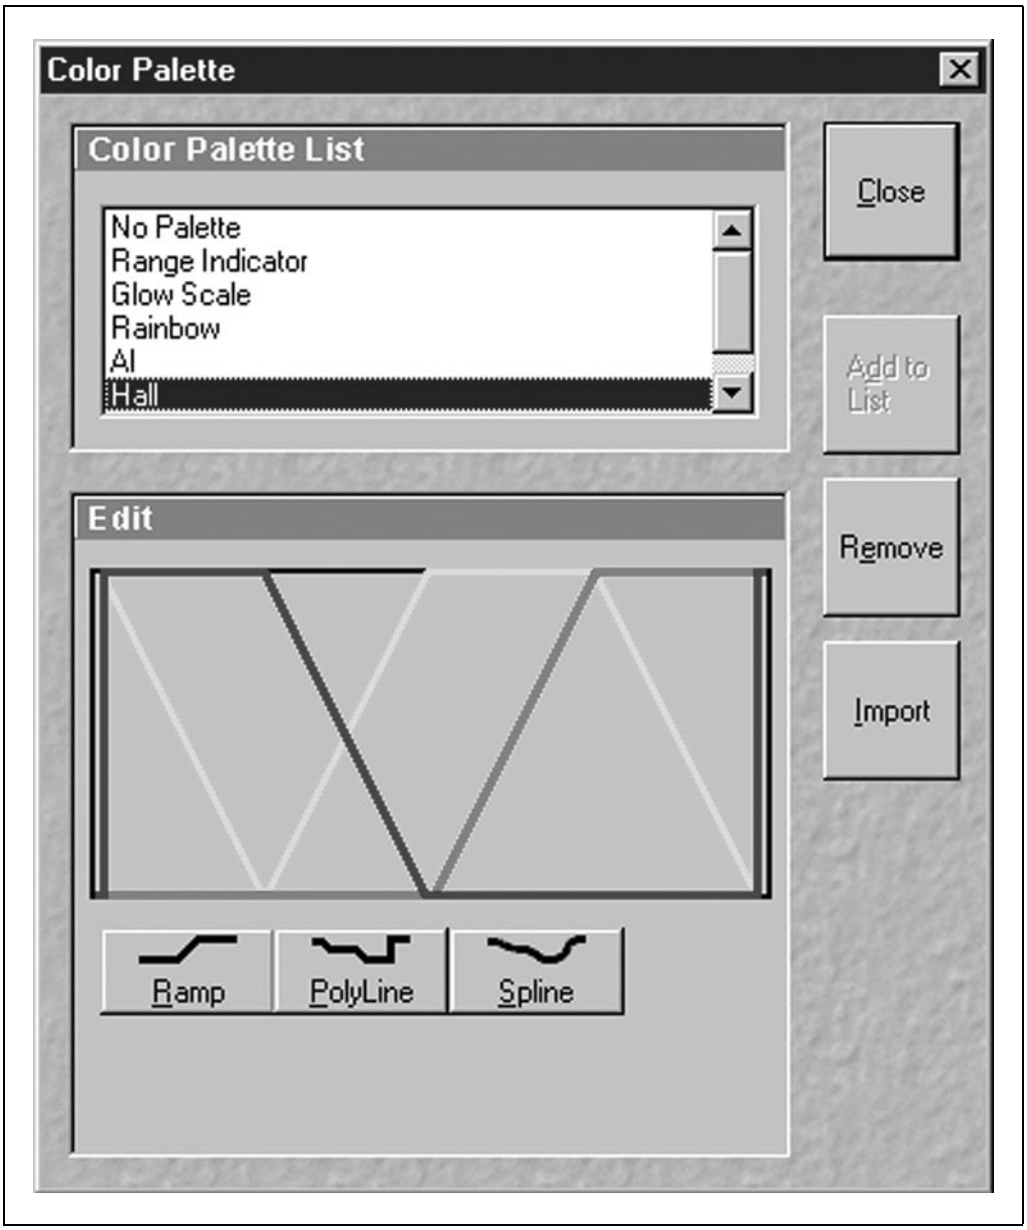

Figure 21.2.4 Window from Zeiss LSM software showing custom Hall pseudocolor palette. Note that the lowest intensity level is coded as black and the highest as white. Courtesy of Carl Zeiss, Germany; reprinted with permission of Zeiss UK.

4. For FLAP imaging, set the microscope to use 4 channels: CFP fluorescence, YFP fluorescence, phase contrast, and IRM (Fig. 21.2.5) with 512 × 512 pixels.

   Tile scan is used to identify expressing cells for FLAP imaging.

5. Set (typically) laser line 514 nm power to 1% and 548 nm power to 21%; pinhole diameters Ch1 to 408 μm; Ch2 to 409 μm; and Ch3 to 414 μm.

   These pinhole sizes give optical sections of 3 μm in all channels.

6. Set dichroic mirror HT to HTF 458/514; set dichoic mirror NT1 to NFT 635 VIS; set dichroic mirror NT2 to NFT 545; set dichroic mirror NT3 to Plate; set filter Ch1 to None for IRM; set filter Ch2 to BP 475-525 for CFP fluorescence; set filter Ch3 to LP 530 for YFP fluorescence; and set filter ChD for phase-contrast microscopy (Fig. 21.2.5).

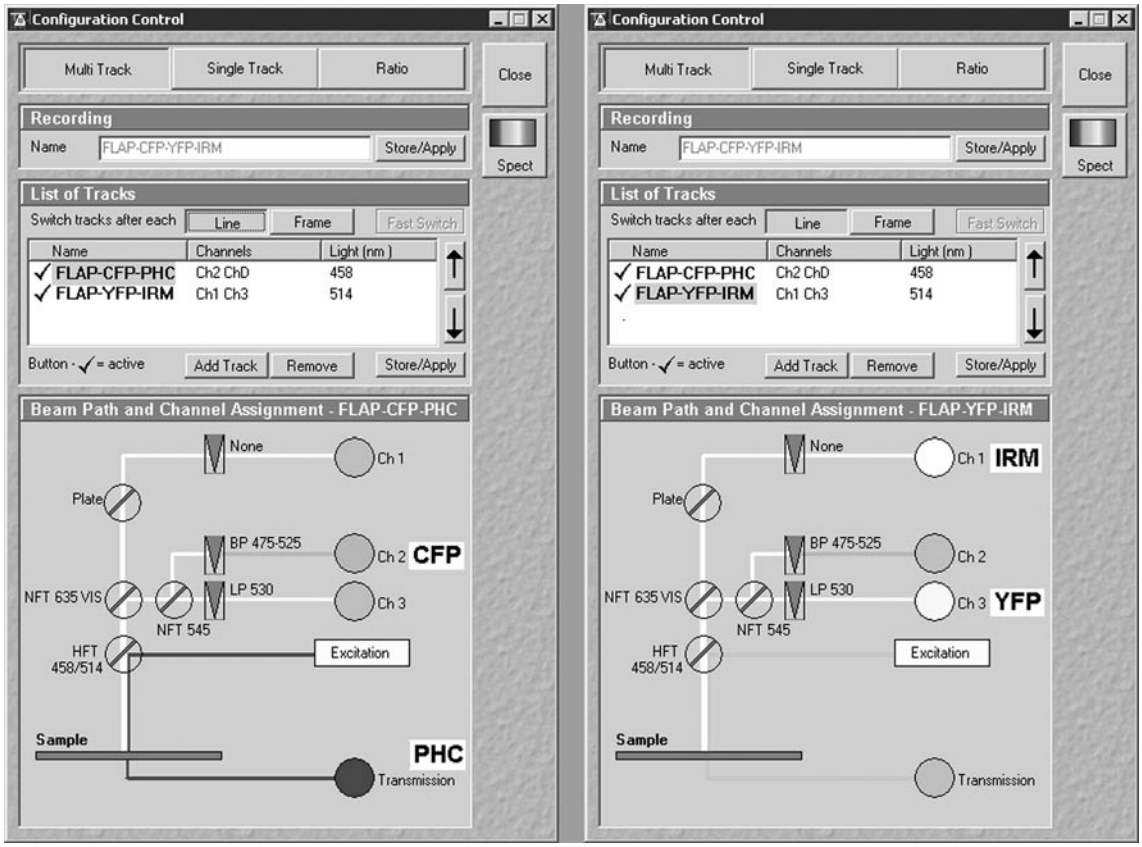

Figure 21.2.5 Window from Zeiss LSM software showing both tracks on the configuration panel. Courtesy˜of Carl Zeiss, Germany; reprinted with permission of Zeiss UK.

7. Set pixel size to 0.29 μm × 0.29 μm and pixel dwell time to 1.6 μsec.
8. Use laser line 514 nm under the bleach setup at maximum power measured as 1.32 mW.
9. Set palette of the CFP fluorescence channel to RGB = (0, 128, 255) and YFP fluorescence channel to RGB = (255, 128, 0) so that the cyan and yellow channels are easily identified and equal intensities combine to a white image when the phase contrast and IRM are switched off from the overlay panel.
10. Save settings by saving the trial run as a database for future Reuse. Do not check Re-use Objective in the Save Settings menu, to avoid unexpected movements of the objective revolver.

Further runs will be required to refine gain and laser power settings for fade matching of channels (Support Protocol 2).

SUPPORT PROTOCOL 2

IMAGE PROCESSING AND ANALYSIS

The authors perform the image processing in Mathematica (Wolfram Research). This has the advantage of immense flexibility over dedicated image-processing software and can be programmed to read the information in the `*.lsm` Zeiss file headers. A commercial image acquisition and processing program from Kinetic Imaging (*http://www.kineticimaging.com*) can also read these file headers as, of course, can the LSM Reader software distributed as a free download by Zeiss. The LSM Reader will also export the individual images of the four channels as 12-bit TIFF format files. The required

image processing is fairly basic, and it will be assumed that a package is available that can read and operate on the raw 12-bit TIFF files exported from LSM Reader.

Materials

Mathematica v 4.2 or 5 (Wolfram Research) or a dedicated image-processing package capable of processing 12-bit TIFF images

1. Subtract a constant from the intensity values of all the CFP and YFP images (it may be different for each image) so that the background regions outside the cell(s) have a mean intensity of zero. Set all negative intensity values to zero.

   The intensity values should now be proportional to the number of fluorescent molecules at each location if care was taken to avoid saturation in step 14 of the Basic Protocol.

2. Multiply the intensity values of the last pre-bleach YFP image by a factor so that the total image intensity matches that of the last pre-bleach CFP image.

   The two images should now look identical.

3. Multiply all the remaining YFP images by the factor obtained in step 2.

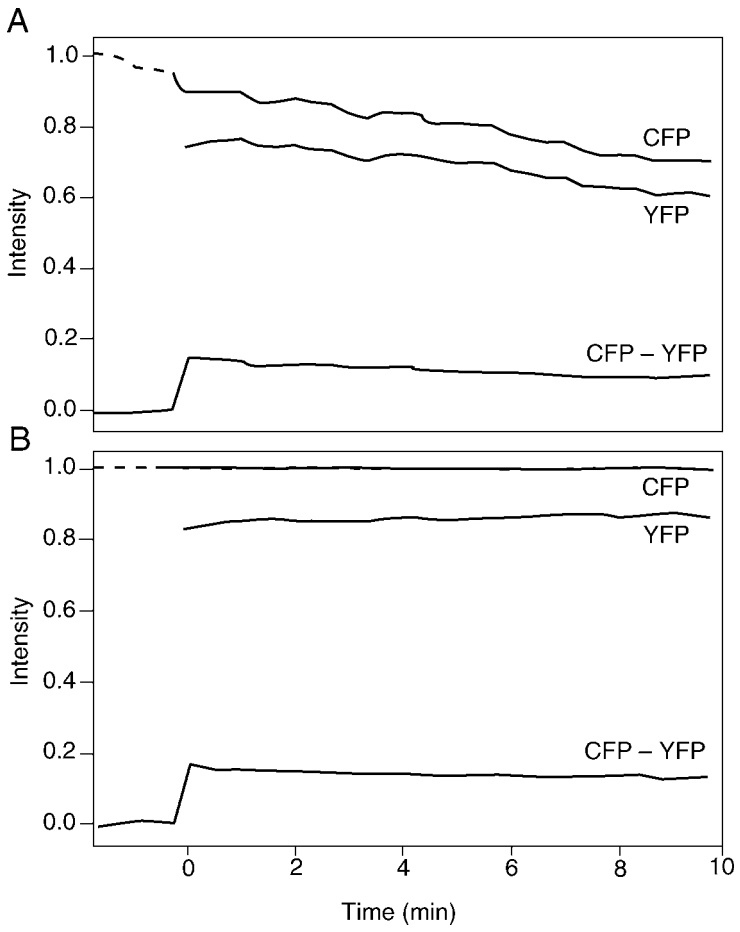

Figure 21.2.6 (**A**) The summed intensity values for a whole cell during a 10-min time series after step 3 in Support Protocol 2. These values have been normalized so that the total intensity of the first CFP image is 1. (**B**) The same intensity values after fade compensation as in step 4 of Support Protocol 2. This consists of dividing each CFP image by a factor so that the total intensity is 1 and then dividing the corresponding YFP image by the same factor. Note that fluctuations due to cyclical focus drift have also been compensated.

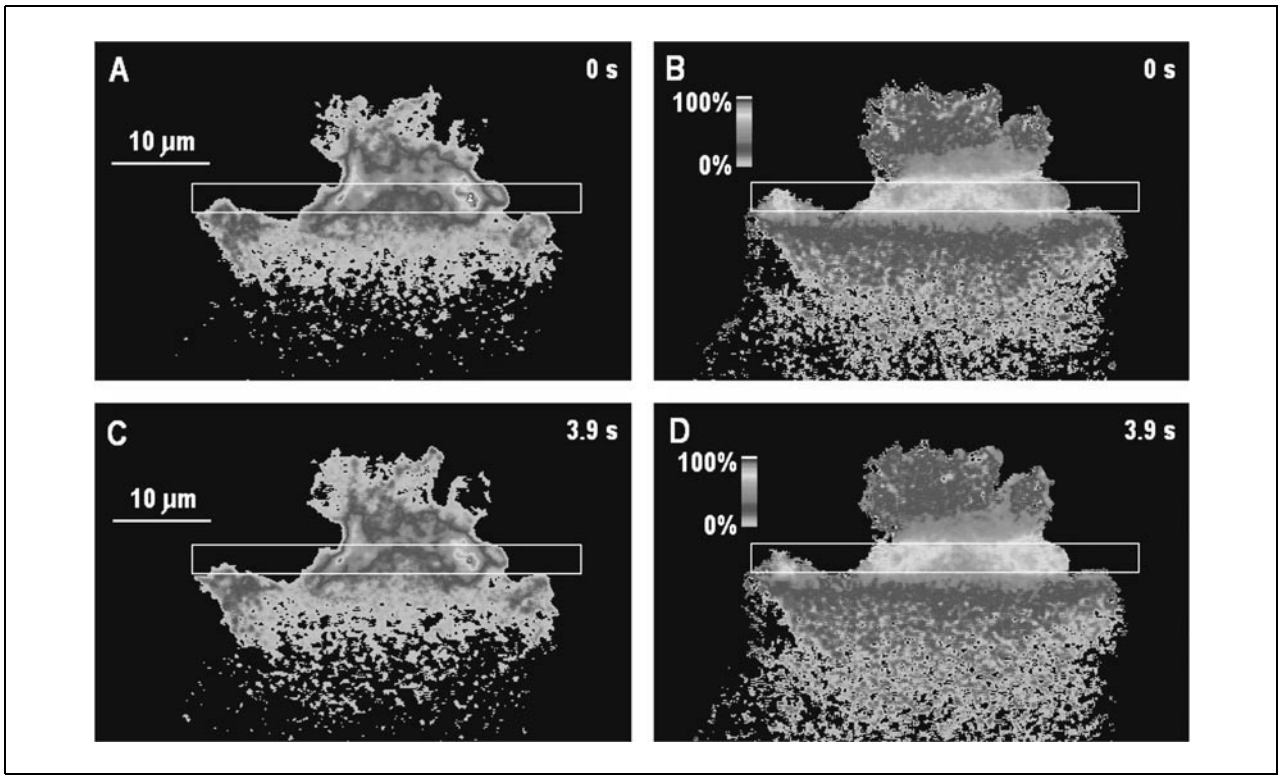

Figure 21.2.7 Absolute FLAP (**A, C**) and relative FLAP (**B, D**) images of the cell featured in Figures 21.2.2 and 21.2.3 recorded immediately after bleaching (**A, B**) and 3.9 sec later (**C, D**). Bleach box is shown as white rectangle. Hall palette. *This black and white facsimile of the figure is intended only as a placeholder; for full-color version of the figure go to http://www.currentprotocols.com/colorfigures.*

If the YFP and CFP channels do not fade at the same rate (see Support Protocol 1), it will be necessary to change this factor for each YFP image. This is best calculated if a whole cell is contained within the image. Plots of the total image intensity of each channel against time will then reveal the fade rates and any compensation that is necessary (Fig. 21.2.6A).

4. If planning to calculate absolute FLAP images, multiply all images after the first pair by a factor to compensate for fade.

   The fade rate is best calculated on whole cells as in step 3. After compensation, plots of the total image intensity of each channel against time should be horizontal lines with a step fall at bleaching in the YFP channel (Fig. 21.2.6B).

5. For each pair of simultaneous images, subtract the YFP image from the CFP image. Set all negative intensity values to zero.

   If fade compensation has been performed as in step 4, the resulting images are now absolute FLAP images.

6. Divide each image obtained in step 5 by the corresponding CFP image to obtain the relative FLAP images.

   Note that this operation has an infinite or undefined result for pixels in which the CFP intensity is zero and an unreliable result where intensity values are low. A threshold level of CFP intensity should be chosen (by trial and error) below which the result of this operation is set to zero.

7. View the final FLAP images, if desired, using a pseudocolor lookup table or palette.

   The authors often use the Hall palette (Support Protocols 1). The relative FLAP images (Fig. 21.2.7B) have intensity values in the range 0 to 1, and a scale bar showing the corresponding pseudocolors can be calibrated from 0% to 100%, showing the fraction

of bleached YFP molecules in each pixel. Absolute FLAP images (Fig. 21.2.7A) could in theory be calibrated for numbers of molecules, but this would require knowing numbers of expressed and native molecules for the whole cell. If the images are noisy and the noise levels in the raw images cannot be improved further (see Troubleshooting), there are two helpful image-processing procedures. A 3 × 3 or higher-order smoothing filter can be applied to the raw images before or after step 1, and/or a threshold can be used below which values are displayed as zero when viewing the FLAP images. Note that smoothing filters other than a block mean may change the intensity value total.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

cDNA constructs of eCFP-β-actin and eYFP-β-actin

Use a pEGFP-β-actin construct (Dunn et al., 2002; *daniel.zicha@cancer.org.uk*) as the basic starting vector. Use enhanced yellow and cyan fluorescent protein coding regions from pEYFP-C1 and pECFP-C1 (Clontech), respectively, to substitute the eGFP coding region using conserved restriction enzyme sites (James Monypenny and Daniel Zicha, Cancer Research UK; *daniel.zicha@cancer.org.uk*). Maintain the 45-bp linker (TCC GGA CTC AGA TCT CGA GCT CAA GCT TGC GGC CGC GCC GCG GCC) between eGFP and β-actin in the pEGFP-β-actin vector in the new fusions. Microinject the DNA in distilled water. The amino acid translation (SGLRSRAQACGRAAA) has net positive charge and 40% hydrophobic residues, ensuring linker flexibility in a cytosolic environment.

Hot wax mixture

Prepare a 1:1:1 (w/w/w) mixture of beeswax, soft yellow paraffin, and paraffin (melting point 46°C) maintained at 54°C in a wax bath.

All of the above materials are available from Fisher.

Optical chambers

Fabricate optical chambers from 76 × 26–mm (as cut) glass microscope slides (Chance Propper), No. 3, 76 × 26–mm glass coverslips, and No. $1\frac{1}{2}$, 18 × 18–mm glass coverslips (Chance Propper). Drill a ~10 mm hole centrally through the glass slide using a diamond-tipped drill (Proxon) under water. Fix a 76 × 26–mm coverslip to one face using Sylgard 184 silicone elastomer (Dow Corning) and allow it to set overnight at room temperature.

While in use, the other face of the medium-filled chamber is sealed with an 18 × 18–mm coverslip carrying the cell culture (see Basic Protocol).

COMMENTARY

Background Information

Fluorescence microscopy has long been the most important tool for revealing the changing distribution of specific proteins within living cells, but it is only recently that fluorescence methods have enabled the study of other aspects of molecular dynamics (see reviews by Lippincott-Schwartz et al., 2001; Holt et al., 2004). One serious limitation of conventional fluorescence localization is that it reveals little of the relocation of molecules during cyclical, steady-state dynamics. Thus critical activities such as the constant depolymerization, diffusive transport, repolymerization, and treadmilling of structural molecules of the cytoskeleton cannot be visualized by this means.

Two methods developed more recently for studying the relocation of molecules, fluorescence recovery after photobleaching (FRAP) and fluorescence loss in photobleaching (FLIP), can have a sufficiently high time resolution to enable diffusion rates of proteins

within the cytoplasm to be estimated (see review by Lippincott-Schwartz et al., 2001). Their chief disadvantage is that the bleached molecules themselves cannot be tracked. On the other hand, fluorescent speckle microscopy (FSM) permits the study of slow molecular movements such as treadmilling and translocation within polymerized structures (*UNIT 4.10*; Waterman-Storer and Salmon, 1997). It relies on a low percentage of tagged molecules (<1%) to produce a discontinuous pattern that can then be used to determine whether the labeled polymer is stationary or translocating. It cannot detect the much more rapid movements of freely diffusing molecules, but this is considered an advantage because it identifies which molecules are polymerized. A refinement of this technique detects the signals from single fluorophores and permits the sites of polymerization and depolymerization of the tagged molecule to be located and their rates to be estimated (Watanabe and Mitchison, 2002). Although complementary to some extent, FRAP, FLIP, and FSM cannot easily provide a full picture of the dynamics within a cyclical polymerization/depolymerization system because the depolymerized molecules cannot be tracked directly.

In contrast, photoactivation of fluorescence (PAF) allows specific molecules to be "flash" labeled at a chosen site and then tracked directly, regardless of whether or not they are polymerized. Earlier PAF methods relied on caged fluorophores and, although they yielded much significant information in the hands of skilled investigators (see review by Mitchison et al., 1998), results were generally disappointing. Uncaging the fluorophore requires exposure to intense UV light, and radiation damage cannot be ruled out. Moreover, molecules tagged with caged fluorophores have to be microinjected or otherwise introduced directly into the cell, and often clump or fail to distribute to their natural locations within the cell. This latter shortcoming led to the development of fluorescent proteins that could be expressed by the cells from cDNA constructs and photoactivated directly. Again, early results were disappointing, and it is only very recently that efficiently photoactivatable fluorescent proteins have been developed (Patterson and Lippincott-Schwartz, 2002; Chudakov et al., 2003). These promise to contribute a great deal to the knowledge of cellular dynamics in the future.

The FLAP method is an alternative approach to the problem of direct and localized photolabeling of a molecular species (Dunn et al., 2002). There is no need to use specialized fluorophores. The principle is simple and relies on photobleaching instead of photoactivation to label the targeted molecules. Suppose that, instead of a single fluorophore, each molecule carries two fluorophores that have differing spectral properties so that they can be imaged separately. If only one of the fluorophores is photobleached, then the resulting molecules are unambiguously labeled: they are the only molecules carrying just one active fluorophore. Although the bleached molecules cannot be imaged directly, one fluorescence image shows where all the molecules are, while the other shows only where the unbleached molecules are. If image intensities have been matched, simply subtracting the second image from the first generates an absolute FLAP image that shows where the bleach-labeled molecules are. Thus FLAP combines the best features of FRAP and PAF. In FRAP, the molecules can no longer be imaged after they have been targeted, whereas in PAF they cannot usually be imaged before they have been targeted. With FLAP, full information is retained on the distributions of both targeted and nontargeted molecules. It is therefore possible to construct other useful virtual images such as relative FLAP, which shows the percentage of bleach-labeled molecules at any given site (Zicha et al., 2003).

It is not an absolute requirement of the FLAP method that a single molecule carry both fluorophores. Indeed, there are some advantages when they are carried by different individual molecules of the same species. In this case, if each colocalizes with the corresponding native molecules as expected, they will still colocalize with each other. However, colocalization now depends on the statistical properties of molecular distribution and, in order to obtain noise-free FLAP images, it is important that both tagged molecules be present in large numbers. This is usually not a problem if the corresponding native molecules are abundant in the cell. It is hard to specify how many molecules need to be carrying fluorophores compared to the number of native molecules, since this depends on many other factors such as detection efficiency, pixel size, and post-processing. A general guideline is that results comparable to PAF or better will be obtained if the two fluorophores give well matched, noise-free images prior to photobleaching. The effect of having the fluorophores on different molecules is, roughly, that the error noise in the final FLAP image is doubled (see Critical Parameters).

The chief competitors to FLAP for flash labeling molecules at specific sites are PAF techniques. Each method has advantages and shortcomings. Although first in the field, the earliest PAF methods using caged fluorophores are probably now the ones with the most disadvantages. First, there are difficulties in conjugating and purifying the protein in sufficient quantity without impairing its activity, as well as in introducing it into cells so that it colocalizes with native protein. A serious limitation is that caged compounds cannot yet be incorporated into cDNA constructs and expressed by the cells. The photoactivatable fluorescent proteins are much more promising in this respect, and recent developments suggest that some will soon be able to be activated and deactivated repeatedly and efficiently (Chudakov et al., 2003), which will be a decided advantage over current FLAP methods.

On the other hand, an interesting feature of the FLAP method as described here is that there is much less need to worry about photodamage occuring to the photolabeled molecules. The method calculates where the virtual bleached molecules are located, i.e., where the bleached molecules would be assuming that they were not damaged, and it is not of much concern what happens to the real bleached molecules. While it is still possible that reactive intermediates generated by photobleaching might cause problems, the compact barrel-like structure of GFP and its variants is thought to shield the external environment from these (Lippincott-Schwartz et al., 2001). Coupled with this, FLAP has the advantages of not requiring specialized fluorophores, and the bleaching process is rapid and efficient using the 514-nm line of a standard argon laser on the LSM 510, whereas photoactivation may require an additional blue diode laser (the alternative two-photon photoactivation is very slow; *UNIT 4.11*). The main advantage of FLAP, however, is that all the tagged molecules are available for imaging throughout the experiment, whether or not they have been photobleached. In the authors' experiments (see Anticipated Results) it has been possible to see throughout where all the actin is, as well as where it has been FLAP-labeled. It may turn out to be possible to do this in conjunction with PAF, but it will require either a second reference fluorophore, as with FLAP, or a second way of exciting the molecules to fluoresce before photoactivating them.

A potential shortcoming of the FLAP method is that colocalization of the two fluorophores is not perfect, but relies on the statistical properties of large numbers of individual molecules. In practice, the authors have not found this to be a problem and have obtained results that compare very favorably with photoactivation methods (but see Critical Parameters). For the future, however, one way around this problem would be to achieve almost perfect colocalization by fusing both fluorophores to the same molecule. This has not been done in this unit because, besides the potential problems of creating a bulkier molecule that may no longer colocalize with corresponding native molecules, it would no longer be possible to ignore any photodamage that might occur to the bleached molecules. Moreover, there is an additional complication that the two fluorophores used in this unit are capable of fluorescence resonance energy transfer (FRET; *UNIT 17.1*) when very close together on the same molecule. Even so, there are early indications that the FRET complication may not be a serious disadvantage and may actually enhance the FLAP signal; however, there are still worries that the FRET efficiency may alter during configuration changes such as polymerization.

Critical Parameters

Expression levels are critical. At high expression levels, there is a danger that FRET may occur in regions of high fluorophore density even when the two fluorophores are carried on separate molecules as described in this unit (see Troubleshooting). On the other hand, the FLAP images would be unusably noisy if the density of fluorescent molecules were very low, as is required by the FSM method. This is especially true when the fluorophores are carried on separate molecules. The binomial theorem can be used to predict these statistical errors in the FLAP signals. Consider first the case in which there happen to be 1000 molecules of CFP-YFP-actin in a pixel and half of them are expected to have a photobleached YFP. Theory predicts that, in repeated experiments, the number of molecules found to be bleached by absolute FLAP would be 500 ± 16 (mean $\pm$ SEM). In the case of relative FLAP, the bleached fraction would be 0.5 ± 0.016. Now, consider the case in which the two fluorophores are not on the same molecule but there still happen to be 2000 fluorophores in the pixel: half are expected to be CFP-actin and half YFP-actin. Half of the latter are expected to have been photobleached. Theory now predicts that the number of molecules found to be bleached by absolute FLAP would be 500 ± 37, and the fraction of YFP-actin molecules

found to be bleached by relative FLAP would be 0.5 ± 0.027. Thus, one can conclude that having the fluorophores on different molecules approximately doubles the error of the FLAP estimates. This also holds true if there are only 200 fluorophores in the pixel, in which case the figures are: 50 ± 5; 0.5 ± 0.05; 50 ± 12; and 0.5 ± 0.09, respectively. The relative errors are proportional to the square of the number of molecules, so it is necessary to express four times as many fluorescent molecules in order to halve the relative error.

A further requirement, as with most fluorescence microscopy, is that the tagged molecules accurately colocalize with native molecules of the same species. There is evidence that GFP variants, fused to actin in the configuration used by the authors, do this well (Choidas et al., 1998). Ensuring that the two different variants are incorporated into otherwise identical cDNA constructs will give the best colocalization for FLAP even when colocalization with the native species is slightly impaired.

Even the best apochromatic objectives show a significant lateral and axial chromatic aberration. This means that the CFP and YFP images may not exactly coincide both laterally and vertically, and it is necessary for good results that the cell be close to the optical axis of the objective (see Troubleshooting) and that there be no drift in focus. Temperature stabilization is essential for maintaining a fixed focal plane. In the past, the authors have obtained satisfactory results using a fan and temperature-controlled heater within a spacious microscope dust cover placed over the entire microscope. However, a properly constructed air-flow chamber (Fig. 21.2.1) is essential for consistently good results. The thermocouple is placed very close to, but not touching, the optical chamber (see Troubleshooting). The temperature controller is

Table 21.2.1 Troubleshooting Guide to FLAP

Problem	Possible cause	Solution
Regions of cell edge show in FLAP images even before bleaching	Chromatic aberration	Minimize by using fluorescent beads to find best region of objective.
Rhythmic noise or parallel lines	Vibration from heater, thermocouple, table, or computer	Eliminate fan/computer vibration; make sure that table is properly isolated.
Focus drift	Temperature fluctuation	Check heater stability and presence of drafts.
Artifacts on top 1-2 lines of first image scanned after a frame interval	Software bug in acousto-optic driver	Avoid frame intervals if possible. Avoid placing critical part of cell near top of image.
Difference signal is not zero everywhere before bleach	Images not matched	See Basic Protocol, step 14 or match images during post-processing.
	Fluorophores not colocalized	Choose new fluorophore(s).
Striped or fluctuating phase image	Polarizing filter in the light path	Remove polarizing filter from the light path.
Lower (negative) FLAP signal in areas of dense expression before bleach	FRET	If unacceptable, use shorter expression times, compensate during post-processing, or choose new fluorophore(s).
Noisy fluorescence images on one or both channels.	Low expression	Wait longer for expression. Adjust cDNA injection ratio.
	Too much gain in photodetector amplifier	Increase laser power and reduce gain (but keep fade rates matched if possible).
	Too much magnification (pixels too small)	Use lower zoom factor or average more frames.

trained to maintain a temperature of 37°C, and should do so, ideally, within a range of ± 0.1°C.

Troubleshooting

See Table 21.2.1 for a troubleshooting guide.

Anticipated Results

FLAP has been used to estimate the diffusion rate of G-actin in cytoplasm (Zicha et al., 2003), and the result agrees well with previous estimates using FRAP (McGrath et al., 1998). Relative FLAP has proven particularly useful for detecting the rapid transport of actin to the cell's leading edge from regions up to 12 μm behind the edge (Zicha et al., 2003). Four FLAP images showing some of the results obtained from the cell featured in Figures 21.2.2 and 21.2.3 are shown in Figure 21.2.7. Note that the absolute FLAP images (Fig. 21.2.7A and C) show the highest intensity in parts of the bleach region where the density of actin is greatest (see Fig. 21.2.3), whereas relative FLAP (Figure 21.2.7B and D) gives a more uniform signal throughout the bleach region. In the later relative FLAP image which started 3.9 sec after bleaching (Figure 21.2.7D) highly labeled actin (∼60%) can be seen at small regions of the cell's leading edge. This phenomenon is not noticeable in the absolute FLAP image (Figure 21.2.7C) because these thin marginal regions have a relatively low density of actin. When interpreting the FLAP images, bear in mind that the top of the image has been scanned first and that there can be a time difference of several seconds between the top and bottom of the image. It is especially important to compensate for the scanning time when fitting mathematical models of fast molecular processes such as diffusion of monomer (see Internet Resources).

Time Considerations

Cell culture

Plan ahead by at least 72 hr to allow for sufficient cell density, depending on growth rate of cell type.

Microinjection

This should take no more than 15 min if injecting cells at room temperature without CO_2.

Expression of constructs

Allow at least $2\frac{1}{2}$ hr for expression and maturation of GFP and variants.

Filming chamber preparation

Chambers should be prepared well in advance (usually left overnight) and kept sterile in a sealed container until needed.

Visualization of Protein Interactions in Living Cells Using Bimolecular Fluorescence Complementation (BiFC) Analysis

Protein interactions control many cellular functions. The functional characteristics of many proteins are determined by the proteins that they interact with in each cell. Interactions with different partners and in response to different extracellular signals can occur in different subcellular locations. Determination of the locations of protein complexes and their regulation can provide insight into the functional roles of the protein interactions.

This unit describes the bimolecular fluorescence complementation (BiFC) assay for the visualization of protein interactions in living cells (Hu et al., 2002). This approach is based on complementation between nonfluorescent fragments of the yellow fluorescent protein (YFP) when they are brought together by an interaction between proteins fused to each fragment (Fig. 21.3.1). The BiFC assay allows direct visualization of the subcellular locations of protein interactions in living cells (see Basic Protocol). This approach can be used for the analysis of many protein interactions and does not require information about the structures of the interaction partners.

Most proteins have a large number of alternative interaction partners in each cell. Many of these interactions are mutually exclusive, resulting in competition for shared interaction partners in the cell. To study the competition for interactions between alternative interaction partners in living cells, the authors of this unit have developed a multicolor BiFC assay by fusing fragments of different fluorescent proteins to the interaction partners (see Alternate Protocol 1). The multicolor BiFC assay is based on the use of fragments of fluorescent proteins with distinct spectral characteristics. Bimolecular complexes formed between these fragments can be visualized using different excitation and emission wavelengths, enabling parallel visualization of multiple interactions in the same cell. The

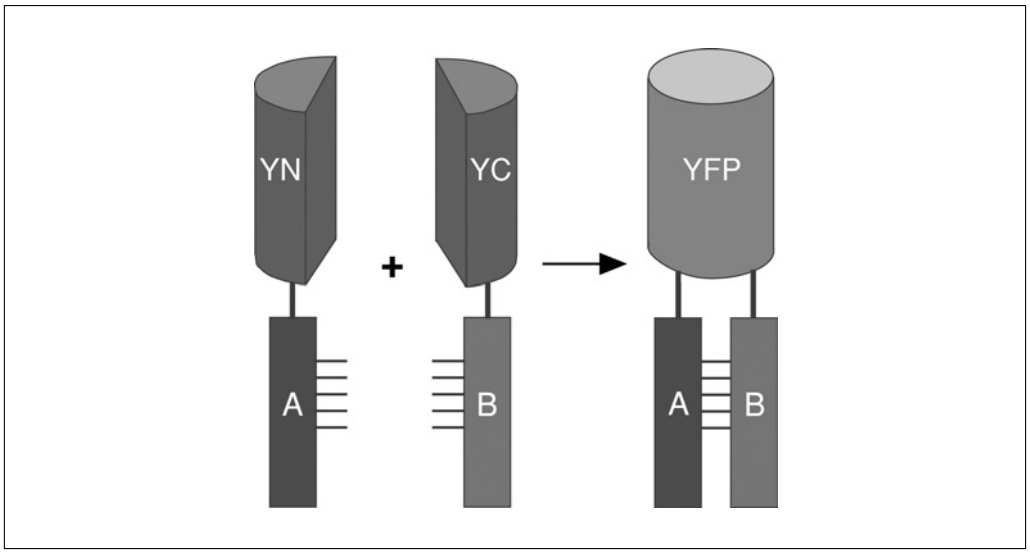

Figure 21.3.1 Schematic representation of the principle of the BiFC assay Two fragments (YN and YC) of the yellow fluorescent protein (YFP) are fused to putative interaction partners (A and B). The association of the interaction partners allows formation of a bimolecular fluorescent complex. For the color version of this figure, go to *http://www.currentprotocols.com.*

Current Protocols in Cell Biology (2005) 21.3.1-21.3.21

multicolor BiFC assay allows comparison of the subcellular locations of different protein interactions in the same cell, as well as analysis of the competition among mutually exclusive interaction partners for complex formation with a common partner (Alternate Protocol 2).

NOTE: Cells are cultured in a humidified 37°C, 5% CO_2 incubator. Cells can be incubated in a 30°C, 5% CO_2 incubator to promote maturation of the fluorophore and thereby increase the signal (see Commentary). Cells are maintained under conditions required for each line (*UNIT 1.1*).

BASIC PROTOCOL

VISUALIZATION OF PROTEIN INTERACTIONS IN LIVING CELLS

The BiFC assay allows direct visualization of protein interactions in living cells based on complementation between nonfluorescent fragments of YFP or other fluorescent proteins.

Materials

Plasmid vectors for expression of proteins of interest (also see Critical Parameters): e.g., pFlag-CMV2 (Sigma) or pHA-CMV (Clontech)
DNA encoding amino acid residues 1 to 154 of yellow fluorescent protein (YN fragment; also see Critical Parameters and Table 21.3.1)
DNA encoding amino acid residues 155 to 238 of yellow fluorescent protein (YC fragment; also see Critical Parameters and Table 21.3.1)
Linkers (see Critical Parameters)
DNA encoding proteins (interaction partners, wild-type) of interest
DNA encoding mutated, single amino acid–substitution variants of the protein of interest that do not interact with each other (controls)
Cells that can be transfected using plasmid DNA (preferably adherent, monolayer cell line)
Appropriate culture medium (*UNIT 1.2*)
FuGENE 6 (Roche Diagnostics) or other transfection reagent
Tissue culture vessels appropriate for experiment: e.g., cluster plates, slide chambers, or glass coverslips
Inverted fluorescence microscope (*UNIT 4.2*) equipped with:
  Sensitive CCD camera
  20× to 100× objectives
  Filters for visualization of YFP (excitation 500 ± 10 nm; emission 535 ± 15 nm)
  Software for instrument control and data analysis
Additional reagents and equipment for expressing proteins in mammalian cells (see *APPENDIX 3A* for cross-reference), mammalian cell culture (*UNIT 1.1*), and immunoblotting (see *UNIT 6.2*)

Table 21.3.1 Selection of Fluorescent Protein Fragments for BiFC and Multicolor BiFC Analyses

Fluorescent protein fragments	Applications	Filters
YN155+YC155	BiFC analysis	YFP
YN173+YC173	BiFC analysis	YFP
CN155+CC155	BiFC analysis	CFP
YN155+CN155+CC155	Multicolor BiFC analysis	CFP YFP

Construct plasmid vectors

1. Using the appropriate plasmid vectors, construct mammalian expression vectors by fusing the sequences encoding amino acid residues 1 to 154 (YN) and residues 155 to 238 (YC) of the yellow fluorescent protein to sequences encoding the proteins of interest. Whenever possible, include fusions to both the N- and C-terminal ends of the proteins to be investigated (Fig. 21.3.2). As controls, construct plasmids encoding mutated variants of the proteins that do not interact with each other.

   For additional information about the design of fusion constructs, see Critical Parameters; for cross-references to molecular biology techniques, see APPENDIX 3A. *The chimeric coding regions can be expressed in mammalian cells using vectors such as pFlag-CMV2 (Sigma) or pHA-CMV (Clontech).*

   As an alternative, fragments of the cyan fluorescent protein (CFP) may be used (see Table 21.3.1)

Prepare cells

2. Seed cells the day before transfection at a density that will allow for cell proliferation over the course of the experiment and, at the same time, allow for the effects of cell growth and density on the interaction under investigation.

   The BiFC assay can be used for the analysis of protein interactions in many mammalian cell lines. The authors have studied protein interactions using the BiFC assay in COS-1, HEK293, HeLa, Hep3B, αTN4, and NIH3T3 cells (Hu et al., 2002; Grinberg et al., 2004; Rajaram and Kerppola, 2004).

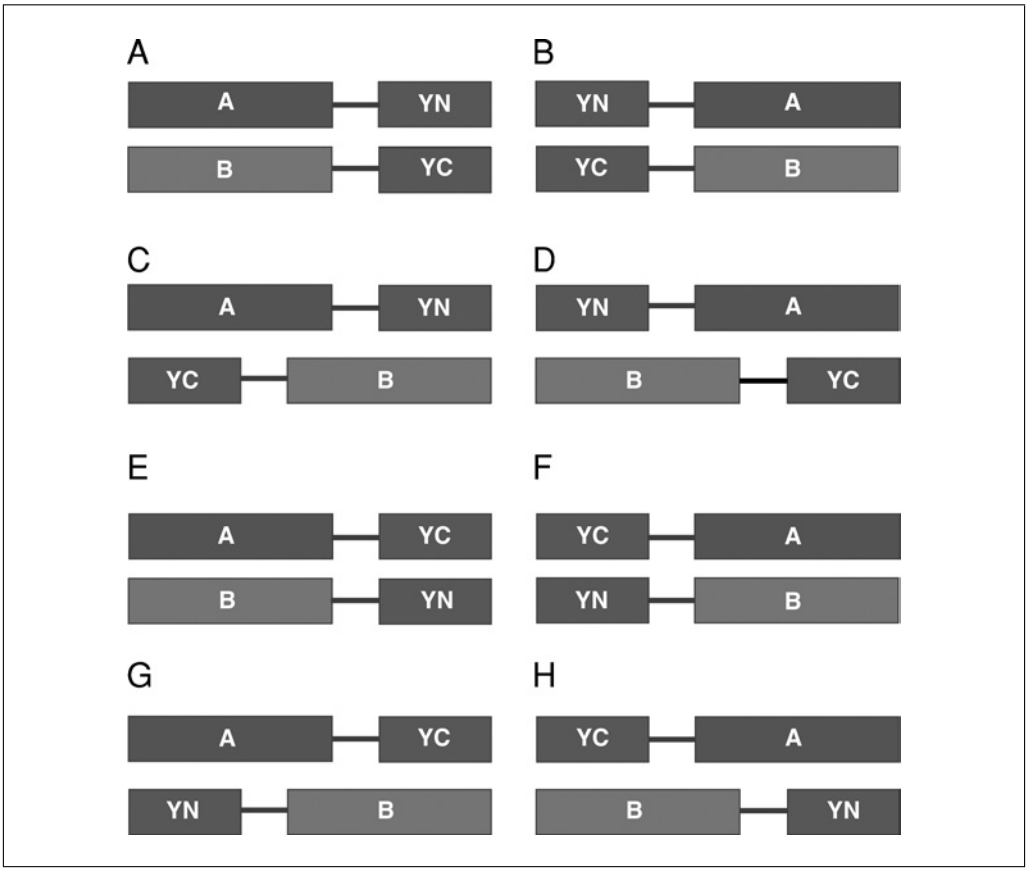

Figure 21.3.2 Multiple combinations of fusion proteins should be tested for bimolecular fluorescence complementation. Amino- and carboxyl-terminal fusions can be used to test eight distinct combinations in cells that are healthy and that have a morphology similar to nontransfected cells. For the color version of this figure, go to *http://www.currentprotocols.com*.

Cluster plates are convenient for processing multiple transfections in parallel. If short-working-distance objectives will be used to visualize the interaction, the cells should be grown in slide chambers or on glass coverslips.

UNIT 1.1 describes basic mammalian cell culture techniques.

3. When cells reach appropriate confluence (e.g., ~50%), transfect cells with appropriate amounts (e.g., 0.25 μg) of the BiFC plasmid (from step 1) encoding the fusion proteins. As controls, transfect cells in parallel with the plasmids encoding mutated variants of the proteins that do not interact with each other.

   FuGENE 6 from Roche Diagnostics is used according to the manufacturer's instructions to introduce plasmid DNA into cells, as it has low background fluorescence and requires minimal manipulation of the cells. Users need to follow specific protocols and optimize the conditions of transfection if other transfection reagents are used (UNITS 20.3-20.7).

4. Grow cells until fluorescence is detected (12 to 36 hr). If necessary, incubate the cells at 30°C with a 5% CO_2 atmosphere to promote maturation of the fluorophore and to increase the signal (however, interpret results obtained under such conditions with care, as incubation at a lower temperature could alter protein interactions). Compare the levels of fusion protein expression with those of the endogenous proteins by immunoblot analysis (see *UNIT 6.2*).

Examine cells

5. Wash the cells with PBS to remove dead cells and debris, then add fresh medium.

6. Image the cells using an inverted fluorescent microscope with a 20× long-working-distance objective and excitation at 500 ± 10 nm with emission detection at 535 ± 15 nm. Confirm that fluorescent cells are alive and exhibit normal morphology compared to nontransfected cells.

   Higher-numerical-aperture objectives may be necessary to visualize weak signals and higher magnification may be helpful to determine the subcellular localization.

   Cells grown on coverslips can be fixed and individual proteins can be visualized by indirect immunofluorescence analysis.

   If CFP is used as the reporter, the excitation wavelength is 436 ± 5 nm and the emission wavelength is 470 ± 15 nm.

Assess results

7. Compare results obtained with cells transfected with the wild-type interaction proteins and those transfected with the control, mutant constructs with single amino acid substitutions that prevent interactions. Compare the number of fluorescent cells observed in cultures expressing fluorescent protein fragment fusions with that observed in cultures expressing intact fluorescent proteins.

   Fluorescence in a small subpopulation of cells is difficult to interpret, since it may represent complementation due to nonspecific interactions, or it may reflect a regulated interaction that occurs only in response to signaling in a subset of cells.

   The following conclusions may be drawn:

   Specific interaction: If fluorescence is detected when wild-type proteins are expressed, and this signal is eliminated or significantly reduced by single amino acid substitutions that prevent the interaction, it is likely that the bimolecular fluorescence complementation represents a specific interaction between the proteins fused to the fragments of fluorescent proteins.

Nonspecific interaction: If mutations that are known to eliminate the interaction do not eliminate the fluorescence, then the bimolecular complementation is due to nonspecific interactions between the fusion proteins. If this is the case, the BiFC assay may not be an appropriate assay for the study of the two proteins. Alternatively, a different combination of fusion proteins or linkers should be tested.

No fluorescence complementation detected: The lack of fluorescence complementation in BiFC assay does not prove the absence of an interaction, even if coexpression of the same fusion proteins with other interaction partners results in bimolecular fluorescence complementation. Factors that may contribute to this are discussed in the Commentary. Different combinations of BiFC constructs or alternative approaches should be employed.

QUANTIFICATION OF FLUORESCENCE COMPLEMENTATION EFFICIENCY

SUPPORT PROTOCOL 1

Quantification of the efficiency of fluorescence complementation is useful for comparison of interactions involving closely related proteins. It is particularly important for determining whether fluorescence complementation represents a specific interaction by comparison of wild-type and mutated proteins. The relative efficiencies of bimolecular fluorescence complementation by structurally unrelated proteins cannot be used to determine the efficiencies of complex formation, since many factors unrelated to the efficiency of complex formation influence the efficiency of bimolecular fluorescence complementation.

Additional Materials *(also see Basic Protocol)*

Plasmid encoding full-length CFP (assuming YFP fragments are used in the Basic Protocol) or other spectrally distinguishable fluorescent protein

Filters for visualization of YFP (excitation 500 ± 10 nm; emission 535 ± 15 nm) and CFP (excitation 436 ± 5 nm; emission 470 ± 15 nm) fluorescence

1. Follow steps 1 to 5 of the Basic Protocol, but add 50 ng of a plasmid encoding full-length CFP or another spectrally distinguishable fluorescent protein into each transfection.
2. Image cells with a fluorescence microscope using filters optimized for separation of CFP and YFP signals. Collect images of at least 100 cells that show detectable fluorescence using both filter sets.
3. Quantify the fluorescence intensities using both YFP and CFP filters integrated over the area of each cell. Subtract the background in an area of the field containing no cells.
4. Calculate the ratio of YFP/CFP fluorescence for each cell.

   This represents the complementation efficiency for the combination of proteins expressed in individual cells.

5. Plot the data in a histogram by binning cells with similar ratios as shown in Fig. 21.3.3.
6. Assess result.

   If a mutation significantly reduces the YFP/CFP ratio compared to the wild-type protein (but the levels of expression and localization of the proteins are not altered), the observed fluorescence is likely to represent a specific interaction between the proteins. If the ratios for wild-type and mutated proteins are similar, the observed fluorescence signal may represent nonspecific fluorescence complementation, or the mutation may not affect the interaction between the proteins.

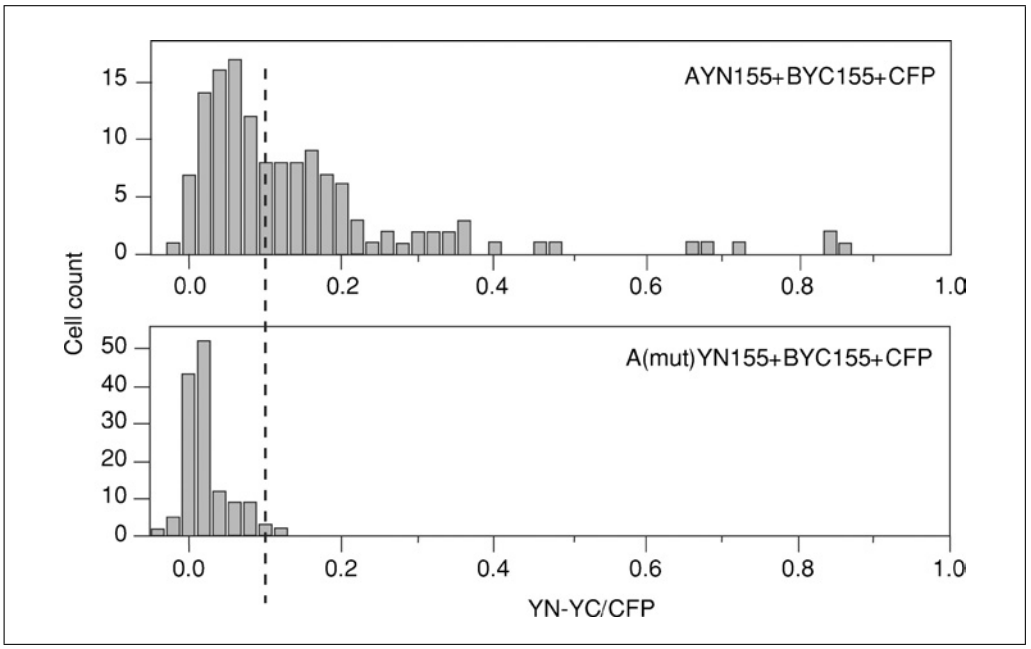

Figure 21.3.3 The effects of mutations that eliminate the interaction interface should be tested on the efficiency of bimolecular fluorescence complementation (data adapted from Hu et al., 2002). Plasmids encoding either wild-type (upper panel) or mutated (lower panel) interaction partners were transfected into cells together with an internal reference (CFP). The fluorescence intensities produced by bimolecular fluorescence complementation (YN-YC) and the internal reference (CFP) were measured in individual cells. The distribution of ratios between the fluorescence intensities in individual cells is plotted in each histogram. The dashed line indicates the maximal ratio produced by nonspecific interactions.

ALTERNATE PROTOCOL 1

SIMULTANEOUS VISUALIZATION OF MULTIPLE PROTEIN INTERACTIONS IN THE SAME CELL

Comparison of the subcellular localization of different protein-protein complexes can provide information about similarities and differences in their functions based on colocalization or nonoverlapping distributions of the complexes. The locations of different complexes can be compared in different cells by using markers for various cellular structures to define the localization of each complex separately. However, it is often difficult to find markers that precisely match the localization of a particular complex. It is therefore preferable to compare the locations of protein complexes in the same cell. This protocol describes a multicolor BiFC approach that enables simultaneous visualization of several interactions in the same cell (Hu and Kerppola, 2003; Grinberg et al., 2004).

The multicolor BiFC assay is based on complementation between fragments of different fluorescent proteins that produce bimolecular fluorescent complexes with distinct spectra. These fragments are fused to alternative interaction partners such that complexes formed with different partners can be visualized independently in the same cell using different excitation and emission wavelengths. This approach provides a unique method for comparison of the distributions of different protein complexes in the same cell and for analysis of the relative efficiencies of interactions with mutually exclusive interaction partners (Alternate Protocol 2).

Additional Materials *(also see Basic Protocol)*

DNA encoding amino acid residues 155 to 238 of cyan fluorescent protein (also see Critical Parameters and Table 21.3.1)
DNA encoding proteins of several alternative interaction partners

DNA encoding amino acid residues 1 to 154 of the cyan and yellow fluorescent proteins (also see Critical Parameters and Table 21.3.1)

Interference filters for fluorescence microscope designed to minimize cross-talk between the fluorescence signals from bimolecular fluorescent complexes formed by fragments of different fluorescent proteins (see below)

Construct plasmid vectors

1. Using the appropriate plasmid vectors, construct mammalian expression vectors by fusing the sequences encoding amino acid residues 155 to 238 of the cyan fluorescent protein (CFP) to the protein whose interactions are to be investigated (this protein is designated Z-CC155), and fuse sequences encoding amino acid residues 1 to 154 of YFP and residues 1 to 154 of CFP to two alternative interaction partners (these proteins are designated A-YN155 and B-CN155, respectively). As controls, construct plasmids encoding these fluorescent protein fragments fused to the same interaction partners.

   For additional information about the design of fusion constructs, see Critical Parameters; for cross-references to molecular biology techniques, see APPENDIX 3A.

   Other fluorescent proteins whose fragments produce bimolecular fluorescent complexes with distinct spectra may be used (Hu and Kerppola, 2003; also see Critical Parameters).

Prepare cells

2. Seed cells the day before transfection at a density that will allow for cell proliferation over the course of the experiment and, at the same time, allow for the effects of cell growth and density on the interaction under investigation.

   If short-working-distance objectives will be used to visualize the interaction, the cells should be grown in slide chambers or on glass coverslips.

3. When cells reach appropriate confluence (e.g., ~50%), transfect cells with an appropriate amount (e.g., 0.25 μg) of the plasmids encoding A-YN155, B-CN155, and Z-CC155. As a control, transfect each pair of expression vectors (A-YN155 and Z-CC155 as well as B-CN155 and Z-CC155) into separate cells.

4. Grow cells until fluorescence from both complexes (i.e., A-YN155—Z-CC155 and B-CN155—Z-CC155) is detected using filters optimized for the detection of YFP and CFP fluorescence, respectively. If necessary, incubate the cells at 30°C with 5% CO_2 to promote maturation of the fluorophores and to increase the signal (however, interpret results obtained under such conditions with care, as incubation at a lower temperature could alter protein interactions).

5. Compare the levels of expression of the proteins by western analysis (*UNIT 6.2*) and adjust the amounts of plasmids transfected if necessary.

Examine cells

6. Wash the cells with PBS to remove dead cells and debris, then add fresh medium.

7. Image the cells using an inverted fluorescence microscope with a 20× long-working-distance objective.

   To image the fluorescence emissions of A-YN155—Z-CC155 and B-CN155—Z-CC155 complexes use two filter sets with excitation at 500 ± 10 nm and emission at 535 ± 15 nm (to detect YN—CC complexes), and excitation at 436 ± 5 nm and emission at 470 ± 15 nm (to detect CN—CC complexes). The emission and excitation wavelengths are separated using a dichroic mirror with transmission windows at 450 to 490 nm and 520 to 590 nm.

   The fluorescence emissions of YN155—CC155 and CN155—CC155 bimolecular fluorescent complexes can be resolved with less than 2% cross-talk between the signals using the filters optimized for YFP and CFP detection.

ALTERNATE PROTOCOL 2

ANALYSIS OF THE COMPETITION BETWEEN ALTERNATIVE INTERACTION PARTNERS IN LIVING CELLS

The selectivity of protein interactions is determined by the relative binding affinities of alternative interaction partners and by the local concentrations of each protein. It is difficult to predict the selectivity of protein interaction in cells based on in vitro studies, since many factors, including covalent modifications, differences in subcellular distributions, interactions with additional proteins, and binding affinity, can influence the selectivity of interactions. The following protocol describes a quantitative multicolor BiFC assay that can provide information about the relative efficiencies of complex formation by mutually exclusive interaction partners in living cells (Hu and Kerppola, 2003; Grinberg et al., 2004).

Principles of competition experiment

To investigate the competition between two alternative interaction partners (i.e., A and B) for a shared partner (i.e., Z), the proteins are fused to fragments of different fluorescent proteins that can form spectrally distinct bimolecular fluorescent complexes (i.e., A-YN155, B-CN155, and Z-CC155). Equal concentrations of the two competing interaction partners (i.e., A-YN155 and B-CN155) are expressed with a limiting concentration of the shared partner (i.e., Z-CC155). The fluorescence intensities of bimolecular fluorescent complexes formed by the alternative interaction partners (i.e., A-YN155–Z-CC155 and B-CN155–Z-CC155) are measured in the same cells. For purposes of this protocol, the phrase "fluorescence intensities of complexes" and variations thereof will be used to refer to the fluorescence intensities of individual cells with specific spectral characteristics.

Additional Materials *(also see Basic Protocol)*

Constructs prepared in Alternate Protocol 1, step 1

Prepare cells

1. Seed cells the day before transfection at a density that will allow for cell proliferation over the course of the experiment and, at the same time, allow for the effects of cell growth and density on the interaction under investigation.
2. When cells reach appropriate confluence (e.g., ~50%), transfect cells with an appropriate amount (e.g., 0.05 μg) of the plasmid encoding Z-CC155 to produce a limiting concentration of the protein (established by immunoblot analysis) and appropriate amounts (i.e., 0.25 μg) of the plasmids encoding A-YN155 and B-CN155 to produce equal amounts of these proteins that are in molar excess relative to Z-CC155. For quantitation using absolute fluorescence intensities (see Support Protocol 2), also transfect each pair of expression vectors (A-YN155 and Z-CC155; as well as B-CN155 and Z-CC155) in separate cells. For quantitation using relative fluorescence intensities (see Support Protocol 3), also transfect expression vectors encoding fusions with the interaction partners fused to different combinations of fluorescent protein fragments (i.e. A-YN155 + A-CN155 + Z-CC155; as well as B-YN155 + A-CN155 + Z-CC155) into separate cells.
3. Grow cells until fluorescence from both complexes (i.e., A-YN155–Z-CC155 and B-CN155–Z-CC155) is detected. If necessary, incubate the cells at 30°C with a 5% CO_2 atmosphere to promote maturation of the fluorophore and to increase the signal (however, interpret results obtained under such conditions with care, as incubation at a lower temperature could alter protein interactions).
4. Compare the levels of expression of the proteins and adjust the amounts of plasmids transfected if necessary.

Examine cells

5. Wash the cells with PBS to remove dead cells and debris and add fresh medium.
6. Image the cells using an inverted fluorescence microscope with a 20× long working distance objective. Identify cells that are healthy and that have a morphology similar to nontransfected cells.

   Interactions between competing partners will result in the formation of two BiFC complexes, A-YN155–Z-CC155 and B-CN155–Z-CC155, with distinct spectral characteristics. To image the fluorescence emissions of A-YN155–Z-CC155 and B-CN155–Z-CC155 complexes, use filters with excitation at 500 ± 10 nm and emission at 535 ± 15 nm to detect YN–CC complexes and filters with excitation at 436 ± 5 nm and emission at 470 ± 15 nm to detect CN–CC complexes. The emission and excitation light are separated using a dichroic mirror with transmission windows at 450 to 490 nm and 520 to 590 nm.

QUANTITATION OF MULTICOLOR BiFC ANALYSIS

The authors of this unit have developed two methods for quantification of data from the multicolor BiFC assay that can provide information about the relative efficiencies of complex formation by mutually exclusive interaction partners in living cells (Hu and Kerppola, 2003; Grinberg et al., 2004). The first method, designated absolute competition (Support Protocol 2), is based on comparison of the absolute fluorescence intensities of bimolecular fluorescent complexes produced when a pair of interaction partners is expressed in the presence and absence of an alternative interaction partner in separate cells. The second method, designated relative competition (Support Protocol 3), is based on comparison of the relative fluorescence intensities of bimolecular fluorescent complexes produced when a protein is expressed together with two alternative interaction partners in the same cells. It is best to use both methods in combination to eliminate potential caveats inherent in each approach.

Comparison of the Absolute Fluorescence Intensities of Bimolecular Fluorescent Complexes Produced When a Pair of Interaction Partners Is Expressed in the Presence and Absence of a Competitor in Separate Cells

SUPPORT PROTOCOL 2

The absolute fluorescence intensities of bimolecular fluorescent complexes are compared when two fusion proteins are expressed alone (i.e. A-YN155+Z-CC155) and when they are expressed in the presence of a competitor (i.e. A-YN155+B-CN155+Z-CC155) in separate cells. This approach is designated absolute competition. This method is well suited for analysis of large differences in the efficiencies of complex formation between alternative interaction partners. Since it involves comparison of different cell populations, it is subject to error due to variations between the populations. Since the absolute fluorescence intensities vary between individual cells, this requires comparison of the fluorescence intensities of the populations or representative subsets of the populations. Using this approach, it is generally possible to detect only large differences in the efficiencies of complex formation. This approach compares the fluorescence intensities of bimolecular fluorescent complexes formed by the same interacting pair, in the absence and presence of competitor. This circumvents the effects of differences in the steric arrangement of the fluorescent protein fragments between different interaction partners that prevent comparison of the efficiencies of complex formation based on the absolute fluorescence intensities of different bimolecular fluorescent complexes.

Carry out Alternate Protocol 2, steps 1 to 6, then continue with the following steps.

1. Measure the fluorescence intensities of YN-CC complexes in 100 to 300 cells expressing A-YN155 + Z-CC155.
2. Measure the fluorescence intensities of YN-CC complexes in 100 to 300 cells expressing A-YN155 + B-CN155 + Z-CC155.
3. Measure the fluorescence intensities of CN-CC complexes in 100 to 300 cells expressing B-CN155 + Z-CC155.
4. Measure the fluorescence intensities of CN-CC complexes in 100 to 300 cells expressing A-YN155 + B-CN155 + Z-CC155.
5. Compare the fluorescence intensities of YN–CC complexes measured in steps 1 and 2 as well as the CN–CC complexes measured in steps 3 and 4.
6. Assess results.

   Case i: If the fluorescence intensities of the two bimolecular fluorescent complexes (i.e., A-YN155–Z-CC155 and B-CN155–Z-CC155) expressed in the same cells are ∼50% of the fluorescence intensities of the complexes when expressed separately, then the two complexes form with comparable efficiencies.

   Case ii: If the fluorescence intensity of one complex is similar whether it is expressed separately or in combination, whereas the fluorescence intensity of the other complex is reduced by >50% when expressed in combination, then the former complex forms with higher efficiency than the latter.

   Case iii: If the fluorescence intensities of both complexes expressed together are equal or higher than those observed when they are expressed separately, then the interaction partners do not compete for complex formation. The shared interaction partner may not be present at limiting concentration, and the relative efficiencies of complex formation cannot be determined based on the data.

   Case iv: If the fluorescence intensities of both complexes are reduced by significantly more than 50% when they are expressed together, or if the changes in fluorescence intensities are not reciprocal, then the interaction partners may affect the expression or functions of each other, and the relative efficiencies of complex formation cannot be determined based on the data.

SUPPORT PROTOCOL 3

Comparison of the Relative Fluorescence Intensities of Bimolecular Fluorescent Complexes Produced When a Protein Is Expressed with Two Alternative Interaction Partners in the Same Cells

The relative fluorescence intensities of bimolecular fluorescent complexes are compared when a fusion protein is expressed with two alternative interaction partners fused to fragments of different fluorescent proteins (i.e., A-YN155 + B-CN155 + Z-CC155). This approach is designated relative competition. This approach is suitable for detection of relatively modest differences in the efficiencies of complex formation between structurally related alternative interaction partners. Since this approach compares complexes in the same cells, it is less sensitive to variations between cells. However, since this approach compares the relative fluorescence intensitites of bimolecular fluorescent complexes produced by different interaction partners, it is subject to variations in the efficiency of association of the fluorescent protein fragments when they are fused to different interaction partners. Therefore, this approach can be used only when there are no large differences in the steric constraints to association of the fluorescent protein fragments between different complexes.

Carry out Alternate Protocol 2, steps 1 to 6, then continue with the following steps.

1. Measure the fluorescence intensities of 100 to 300 cells expressing A-YN155 + A-CN155 + Z-CC155 to use as a reference.
2. Measure the fluorescence intensities of 100 to 300 cells expressing A-YN155 + B-CN155 + Z-CC155.
3. Measure the fluorescence intensities of 100 to 300 cells expressing B-YN155 + A-CN155 + Z-CC155.
4. Plot the fluorescence intensities of YN–CC versus CN–CC complexes for each individual cell as a scatter plot as shown in Figure 21.3.4 (middle row).
5. Compare the slopes produced by different combinations of interaction partners. The relative slopes of these plots provide information about the relative efficiencies of complex formation between alternative interaction partners. Alternatively, calculate the ratio YN-CC/(YN-CC + CN-CC) and plot the data as a histogram as shown in Figure 21.3.4 (bottom row). The distribution of ratios in the population can provide information about the relative efficiencies of complex formation.
6. Assess results.

   Case i: If the relative fluorescence intensities of all combinations of complexes display a linear relationship, and the slopes of the relationships are not significantly different, then the two interaction partners compete with indistinguishable efficiencies for the shared partner.

   Case ii: If the fluorescence intensities of all combinations of complexes display a linear relationship, and the slopes of the relationships are significantly different, then the two interaction partners compete with different efficiencies for the shared partner.

   Case iii: If the fluorescence intensities of one or all combinations of complexes do not display a linear relationship, or if the slopes cannot be determined with sufficient confidence, then the relative efficiencies of competition cannot be determined based on the data.

Comparison of Results from the Absolute and Relative Competition Approaches

The relative competition approach (Support Protocol 3) is generally more accurate for complexes with similar structures. However, this approach can only be used when there are no differences in the steric constraints to association of the fluorescent protein fragments.

To confirm that the identities of the fluorescent protein fragments fused to the alternative interaction partners do not influence the relative efficiencies of complex formation, it is necessary to exchange the fragments between the interaction partners (i.e., compare A-YN155 + B-CN155 + Z-CC155 with B-YN155 + A-CN155 + Z-CC155). In the absolute competition approach, exchange of the fragments should not affect the difference in fluorescence intensity in the presence and absence of the competitor. In the relative competition approach, the slope of the plot of YN-CC versus CN-CC intensities should shift in the opposite direction relative to the slope observed for the reference complexes (A-YN155 + A-CN155 + Z-CC155 compare slopes of the plots on the right and the left of the middle row of Fig. 21.3.4 with that of the plot in the center). If exchange of the fluorescent protein fragments between the interaction partners does not produce the predicted results, it is possible that the fluorescent protein fragments influence the specificity of the interaction. In this case, the relative efficiencies of complex formation cannot be determined using multicolor bimolecular fluorescence complementation analysis.

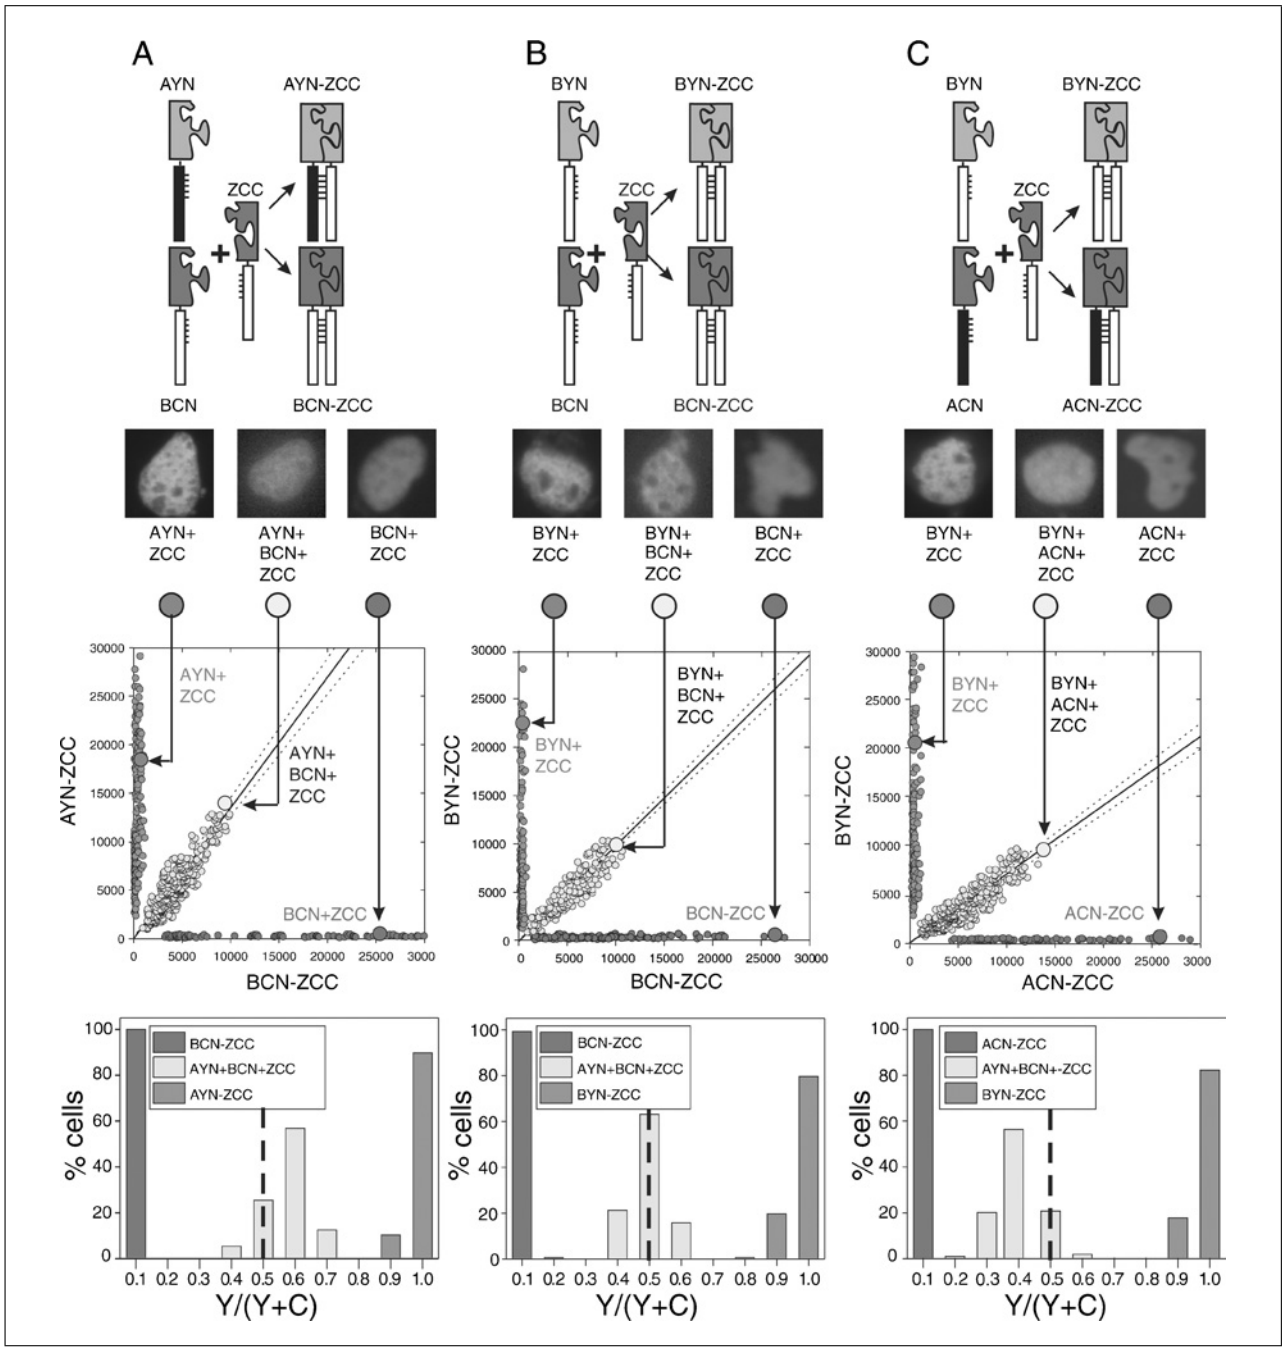

Figure 21.3.4 Legend at right.

Limitations of the Method

The multicolor BiFC assay for measurement of the efficiencies of protein interactions in cells enables determination of the relative efficiencies of competition between alternative interaction partners for a shared partner, but this does not necessarily reflect their relative binding affinities, since the complexes are not at equilibrium for the entire time of the experiment. The association of the fluorescent protein fragments is relatively slow ($t_{\frac{1}{2}} \approx 60$ sec) and essentially irreversible in vitro (Hu et al., 2002). The relative efficiencies of complex formation reflect the competition between alternative interaction partners during the time before association of the fluorescent protein fragments. This is predicted to give a valid estimate of the relative efficiencies of complex formation by proteins with rapid exchange rates. However, interaction partners with very slow rates of association may not compete efficiently for complex formation in the assay.

The multicolor BiFC approach is based on comparison of the relative amounts of bimolecular fluorescent complexes with different spectral characteristics. Differences between the rates of degradation of proteins in different complexes could alter the steady-state ratio between the complexes and thereby affect the apparent efficiencies of complex formation. The relative fluorescence intensities should therefore be measured at several time pointss, and the steady-state levels of proteins should be compared by western analysis. The rates of degradation of the complexes can be compared by monitoring the decrease in fluorescence in cells treated with protein-synthesis inhibitors (e.g. cycloheximide). The rates of degradation of the fusion proteins can also be measured directly using pulse-chase analysis.

Example of the Application of Quantitative Multicolor BiFC Analysis for Determination of the Relative Efficiencies of Complex Formation

To examine the relative efficiencies of complex formation by protein Z with two alternative interaction partners, A and B, the authors of this unit performed an experiment in which the proteins were fused to fluorescent protein fragments (A-YN, B-CN, and Z-CC) and were expressed separately and in combination (Grinberg et al., 2004). The fluorescence intensities of the alternative complexes (i.e., A-YN–Z-CC and B-CN–Z-CC) were measured when the complexes were expressed in separate cells and when they

Figure 21.3.4 *(at Left)* Multicolor fluorescence complementation analysis of the competition for dimerization between alternative interaction partners. The relative efficiencies of complex formation between protein Z and two alternative interaction partners, A and B, can be quantified by fusing them to fragments of different fluorescent proteins and expressing them in different combinations. (**A**) BiFC analysis of A-YN + Z-CC (green), B-CN + Z-CC (red) and A-YN + B-CN + Z-CC (yellow). (**B**) BiFC analysis of B-YN + Z-CC (green), B-CN + Z-CC (red) and B-YN + B-CN + Z-CC (yellow). (**C**) BiFC analysis of B-YN + Z-CC (green), A-CN + Z-CC (red) and B-YN + A-CN + Z-CC (yellow). The diagrams at the top indicate the combinations of proteins expressed either pairwise or in three-way competition in each experiment. The images show cells expressing the proteins indicated below each image. The cells were imaged using filters (described in the instrumentation section) that distinguish the fluorescence emissions of YN–CC (green) and CN–CC (red) complexes, and the images were superimposed. The fluorescence intensities of YN–CC complexes were plotted as a function of the fluorescence intensities of CN–CC complexes in individual cells (middle row of graphs). The fluorescence intensities are shown in green and red for cells that express the interaction partners pairwise, and in yellow for cells that express two alternative interaction partners in direct competition. The best fit of a linear function to the data from cells coexpressing three proteins is shown. The slope of this function reflects the relative efficiencies of complex formation between the alternative interaction partners. The ratio between the fluorescence emissions from each complex [Y/(Y + C) where Y represents YN–CC and C represents CN–CC] was determined in individual cells in each population, and was plotted in histograms (lower row of graphs) using the same colors as in the middle row. For the color version of this figure, go to *http://www.currentprotocols.com.*

were expressed together in the same cell (Fig. 21.3.4A). As a reference, the fluorescent proteins were fused to the same interaction partners (B-YN, B-CN and Z-CC), and their fluorescence intensities were analyzed in parallel (Fig. 21.3.4B). The fluorescence intensities of the complexes were plotted in scatter plots (middle panels) and histograms (lower panels) when the complexes were expressed separately (red and green) and when they were expressed together in the same cells (yellow). The ratio between the fluorescence intensities of the complexes reflects the relative efficiencies of complex formation between the alternative interaction partners.

When A-YN and B-CN were coexpressed with Z-CC, the fluorescence intensities produced by A-YN–Z-CC and B-CN–Z-CC exhibited a linear relationship with a slope of 1.3 and a 95% confidence interval of 0.08 (Fig. 21.3.4A, middle row). In comparison, when B-YN and B-CN were coexpressed with Z-CC, the fluorescence intensities produced by B-YN–Z-CC and B-CN–Z-CC exhibited a linear relationship with a slope of 0.98 and a 95% confidence interval of 0.05 (Fig. 21.3.4B, middle row). Likewise, the distribution of ratios between the fluorescence intensities [Y/(Y+C)] was shifted toward higher values for complexes formed by A-YN and B-CN with Z-CC compared to complexes formed by B-YN and B-CN with Z-CC (compare lower row of graphs for Fig. 21.3.4, panels A and B). These results are consistent with the interpretation that Z favors complex formation with A over complex formation with B. The absolute fluorescence intensities of A-YN–Z-CC and B-YN–Z-CC were comparable when expressed separately, suggesting that the efficiencies of association of the fluorescent protein fragments were comparable under conditions where no competitors for complex formation were present.

To confirm that the fluorescent protein fragments fused to the alternative interaction partners did not influence the relative efficiencies of complex formation, the authors exchanged the fragments between the interaction partners (i.e., B-YN, A-CN and Z-CC) and compared the fluorescence intensities of bimolecular fluorescent complexes formed by these proteins (Fig. 21.3.4C). The fluorescence intensities of these complexes exhibited a linear relationship with a slope of 0.7 and a 95% confidence interval of 0.04 (Fig. 21.3.4C, middle row). Likewise, the distribution of fluorescence intensity ratios was shifted in the opposite directions compared to the proteins in which the fragments were fused to the opposite interaction partners (see lower row of graphs for Fig. 21.3.4; compare panel C with panels A and B). These data are consistent with the interpretation that the difference between the efficiencies of bimolecular fluorescent complex formation by A and B fusions is not due to a difference between the fluorescent protein fragments fused to these proteins, but is caused by a difference between the efficiencies of complex formation between A and Z versus B and Z (Grinberg et al., 2004).

Controls for Quantitative Multicolor BiFC Analysis

The use of both absolute and relative competition methods for the quantification of relative efficiencies of complex formation is designed to correct for many of the factors that influence the fluorescence intensities of bimolecular fluorescent complexes formed by fragments of different fluorescent proteins. However, there are additional factors that need to be considered and examined as follows.

1. The relative levels of A-YN155 and B-CN155 expression affect the relative amounts of complexes formed. The alternative interaction partners must therefore be expressed at equal concentrations and the shared interaction partner must be expressed at a lower, limiting concentration. All protein concentrations should preferably be within the physiological range to observe the competition under normal cellular conditions. The levels of protein expression can be measured by immunoblot analysis using antibodies directed against the same epitope tag on the alternative interaction partners.

2. The efficiencies of association of different fluorescent protein fragments as well as the fluorescence intensities of the resulting bimolecular complexes can differ. It is therefore essential to determine the relative fluorescence intensities of the bimolecular fluorescent complexes when they are brought together by the same interaction partners (i.e., A-YN155, A-CN155, and Z-CC155). The relative fluorescence intensities of the two bimolecular fluorescent complexes (i.e., A-YN155–Z-CC155 and A-CN155–Z-CC155) reflect both differences between the efficiencies of association of the fluorescent protein fragments and differences between their fluorescence intensities when they are brought together by the same interaction partners.

3. The relative efficiencies of bimolecular fluorescence complementation can be affected by steric constraints imposed by the interaction partners on the association of the fluorescent protein fragments. To investigate this possibility, the fluorescent protein fragments can be fused to the interaction partners using several different extended linkers. If fusion proteins containing different linkers produce identical results, then the efficiencies of bimolecular complex formation are unlikely to be affected by steric constraints.

4. Different fluorescent protein fragments could have differential effects on the efficiencies of competition for the shared interaction partner. It is therefore essential to exchange the fluorescent protein fragments between the interaction partners (i.e., B-YN155, A-CN155, and Z-CC155) to determine if differences between the fluorescent protein fragments affect the relative efficiencies of competition. This can also be verified in vitro by measuring the relative amounts of bimolecular fluorescent complexes formed when different ratios of the fluorescent protein fragments fused to the same interaction partners are mixed (Hu and Kerppola, 2003). If the amounts of complexes formed are proportional to the relative concentrations of fusion proteins in the reaction, then differences between the fluorescent protein fragments do not influence the relative efficiencies of complex formation.

COMMENTARY

Background Information

The biological functions of proteins are determined in large part by their interactions with other proteins in the physiological environment. Numerous protein interactions have been identified using genetic screens and in vitro binding assays. It is important to develop experimental approaches that allow determination of the subcellular locations of these interactions.

The BiFC assay has been used to visualize interactions between many structurally unrelated proteins (Hu et al., 2002; Atmakuri et al., 2003; Deppmann et al., 2003; von der Lehr et al., 2003; Yu et al., 2003; Bracha-Drori et al., 2004; de Virgilio et al., 2004; Farina et al., 2004; Grinberg et al., 2004; Hynes et al., 2004a,b; Kanno et al., 2004; Rackham and Brown, 2004; Rajaram and Kerppola, 2004; Remy and Michnick 2004a,b; Remy et al., 2004; Tsuchisaka and Theologis, 2004a,b; Tzfira et al., 2004; Walter et al., 2004; Wei et al., 2004; Zal and Gascoigne, 2004; Zhang et al., 2004; Zhu et al., 2004). The authors of this unit and other investigators have determined the localization of complexes formed by Fos, Jun, and ATF-2 (Hu et al., 2002); c-Maf and Sox (Rajaram and Kerppola, 2004); BATF and Jun (Deppmann et al., 2003); p65, p50, and IkB (Hu et al., 2002); Myc, Max, Mxi1, Mad3, and Mad4 (Grinberg et al., 2004); Skp2 and c-Myc (von der Lehr et al., 2003); and Brd2 and histone H4 (Kanno et al., 2004).

Protein interactions are crucial for the control of most cellular functions. Several methods have been developed to study protein interactions in living cells. One of the most commonly employed methods is FRET (*UNIT 17.1*). The FRET assay is based on the use of two fluorophores either chemically linked or genetically fused to two proteins whose interaction is to be examined. Compared to the BiFC assay, FRET analysis generally requires higher levels of protein expression to detect energy transfer. Also, structural information or a great deal of luck is required to place the two fluorophores within 100 Å of each other, which is the maximal distance over which any significant energy transfer between fluorescent proteins can be detected. The fraction of proteins

that forms complexes must also be high to produce a sufficient change in the donor and acceptor fluorescence intensities. To exclude alternative interpretations of the results, numerous controls must be performed and the fluorescence intensities must be measured with high quantitative accuracy. Despite these limitations, FRET has been successfully used for the analysis of many protein interactions in living cells (Sorkin et al., 2000; Li et al., 2001; Majoul et al., 2002; Hink et al., 2003; Larson et al., 2003; Miyawaki, 2003; Tsien, 2003). A great advantage of FRET over BiFC analysis is the reversibility of complex formation, which potentially allows analysis of the interaction under equilibrium conditions. FRET is therefore superior for studies of the kinetics of protein association and dissociation.

Bimolecular complementation between fragments of a variety of proteins has been used to investigate protein interactions in cells (Johnsson and Varshavsky, 1994; Rossi et al., 1997; Pelletier et al., 1998; Rossi et al., 1998; Ghosh, 2000; Galarneau et al., 2002; Wehrman et al., 2002; Paulmurugan and Gambhir, 2003). The basic principle is to fuse fragments of a reporter protein to the interaction partners. Selected fragments of many proteins are able to associate with each other to produce a functional complex. This complex can be detected by the use of chromogenic or fluorogenic substrates or ligands. Reporter proteins that have been used to date include ubiquitin (Johnsson and Varshavsky, 1994), β-glactosidase (Rossi et al., 1997), dihydrofolate reductase (Pelletier et al., 1998), luciferase (Paulmurugan and Gambhir, 2003), and β-lactamase (Galarneau et al., 2002; Wehrman et al., 2002). BiFC employs the classical principle of complementation between protein fragments (Ullmann et al., 1967, 1968). The advantage of the BiFC approach over other complementation approaches is that the reconstituted fluorescent protein has strong intrinsic fluorescence that allows direct visualization of the protein complex. The complex can therefore be visualized with minimal perturbation of the cells. Using the BiFC approach, living cells can be observed over long periods, and the possibility of experimental manipulations altering the result is minimized. Potential problems with unequal distributions of the chromogenic or fluorogenic substrates or ligands are also avoided. Moreover, as described in Alternate Protocols 1 and 2, multiple protein interactions can be visualized in parallel using spectrally distinct bimolecular fluorescent complexes.

One limitation of the BiFC approach is the time required for fluorophore maturation. This prevents real-time detection of rapid changes in interactions using the BiFC assay. In addition, bimolecular fluorescent complex formation is irreversible in vitro. These characteristics prevent the use of the BiFC assay for studies of the dissociation and subunit exchange of protein complexes in cells.

Characteristics of the BiFC assay

The BiFC assay has several features that make it particularly useful for the study of protein interactions. First, it enables direct visualization of protein interactions and does not rely on their secondary effects. Second, the interactions can be visualized in living cells, eliminating potential artifacts associated with cell lysis or fixation. Third, the proteins are expressed in a relevant biological context, ideally at levels comparable to their endogenous counterparts. This increases the likelihood that they will reflect the properties of native proteins, including any post-translational modifications. Fourth, the BiFC assay does not require stoichiometric complex formation but can detect interactions between subpopulations of each protein. Fifth, multicolor BiFC analysis allows simultaneous visualization of multiple protein complexes in the same cell and enables analysis of the competition between alternative interaction partners for complex formation. Finally, BiFC does not require specialized equipment, apart from an inverted fluorescence microscope equipped with objectives that allow imaging of fluorescence in cells. The simple detection of bimolecular complex formation requires no post-acquisition image processing for interpretation of the data.

Critical Parameters

Design of BiFC fusion constructs

The fusion proteins for BiFC analysis must be designed with the specific proteins to be investigated as well as the purpose of the experiment in mind. Schematic diagrams of the different permutations of fusion proteins that can be used for BiFC analysis are shown in Figure 21.3.2. Some general guidelines for the design of fusion proteins for BiFC analysis are discussed below.

Fragments of fluorescent proteins

Several combinations of fluorescent protein fragments support bimolecular fluorescence complementation (Hu and Kerppola, 2003). The combinations of fluorescent protein fragments recommended for BiFC analysis are

listed in Table 21.3.1. For most purposes, fragments of YFP truncated at residue 155 (designated YN155, containing N-terminal residues 1 to 154, and YC155, containing of C-terminal residues 155 to 238) are recommended, as they exhibit a relatively high complementation efficiency when fused to many interaction partners, yet produce low fluorescence when fused to proteins that do not interact with each other. Fragments of YFP truncated at residue 173 (designated YN173 containing residues 1 to 172, and YC173, containing residues 172 to 238) can also be used. Other combinations of fluorescent protein fragments can be also used (Hu and Kerppola, 2003) as described in the multicolor BiFC assay (see Alternate Protocols 1 and 2).

Positions of fusions

The positions of the fusions must be determined empirically to fulfill three essential criteria:

1. The fusions must allow the fragments of the fluorescent proteins to associate with each other if the fusion proteins interact. Information about the structure and location of the interaction interface may be useful for this purpose. However, this information is not essential since BiFC vectors can be designed by screening multiple combinations of fusion proteins for fluorescence complementation. A simple strategy for the identification of fusion proteins that allow bimolecular fluorescence complementation is to fuse each of the fluorescent protein fragments to the N- and C-terminal end of each interaction partner, and to test the fusion proteins for complementation in all eight combinations that contain both fragments of the fluorescent protein (Fig. 21.3.2).

2. The fusions must not affect the localization or the stabilities of the proteins. This should be confirmed by comparing the localization and the level of expression of the fusion proteins with those of wild-type proteins lacking the fusions using indirect immunofluorescence (*UNIT 4.3*) and immunoblot (*UNIT 6.2*) analyses.

3. The fusions must not affect the functions of the proteins under investigation. Ideally, the protein functions should be validated using assays that evaluate all of the known functions of the endogenous proteins, and they should be performed under the conditions used to visualize the protein interactions.

Linkers

The linkers connect the fragments of the fluorescent proteins to the proteins of interest in the fusion proteins. The linkers must provide flexibility for independent motion of the fluorescent protein fragments and the interaction partners, allowing the fragments to associate when the proteins interact. The authors have used the RSIAT and RPACKIPNDLKQKVMNH linker sequences in many fusion constructs used for BiFC analysis (Hu et al., 2002; Hu and Kerppola, 2003). These linkers have been used for the visualization of interactions between many structurally unrelated proteins. The sequence AAANSSIDLISVPVDSR encoded by the multiple cloning sites of the pCMV-FLAG vector (Sigma) has also been successfully used as a linker in many BiFC experiments. Although these linker sequences worked well in the proteins examined, it is possible that the length or the sequence of the linker affects the complementation efficiency between other proteins.

Design of constructs for multicolor BiFC analysis

The basic principles for the design of BiFC constructs also apply to the design of multicolor BiFC constructs. The main difference is the use of fluorescent protein fragments that provide maximal spectral separation of the fluorescence signals from different bimolecular complexes. There are several combinations of fragments that can be used for multicolor BiFC analysis (Table 21.3.1). The use of CC155 (C-terminal fragment of CFP) paired with YN155 versus CN155 (N-terminal fragment of CFP) provides good spectral separation and high complementation efficiency. These combinations are therefore appropriate for the simultaneous analysis of two protein interactions. For the simultaneous analysis of more than two interactions, more selective interference filters and more complex spectral separation algorithms are required.

Expression system

The selection of an expression system should be based on the purpose of the experiment. To determine whether a pair of proteins can interact in cells and to determine the subcellular location of the complex, a transient overexpression system can be used. However, overexpression of proteins in cells can result in mislocalization of the proteins and formation of non-native complexes. To ensure that the observed fluorescence signal reflects native interactions, the fusion proteins should be expressed at levels comparable to the endogenous proteins. This can be done by the use

of plasmids with weak promoters and plasmid vectors that do not replicate in mammalian cells. Also, cells can be transfected using small amounts of plasmid DNA, and they can be observed soon after transfection.

More consistent results can be obtained by using inducible expression vectors integrated into the genomes of stable cell lines (e.g., pIND). This allows for the control of protein expression at relatively uniform levels in the entire cell population.

Controls

In order to determine if any fluorescence observed reflects a specific protein interaction, it is essential to include negative controls in each experiment. This is especially important because the fluorescent protein fragments are able to form fluorescent complexes with a low efficiency even in the absence of a specific interaction. This spontaneous complementation is generally reduced when the fragments are fused to proteins that do not interact with each other. The validity of bimolecular fluorescence complementation results must therefore be confirmed using fusions to proteins in which the interaction interface has been mutated (Hu et al., 2002; Grinberg et al., 2004). The mutant proteins must be fused to the fluorescent protein fragments in a manner identical to the wild-type protein. The mutation must not affect the stability or the subcellular location of the fusion protein. The level of expression and the localization of the mutant protein should be compared with the wild-type fusion protein by immunoblot (*UNIT 6.2*) and indirect immunofluorescence analyses (*UNIT 4.3*). The efficiencies of fluorescence complementation by the wild-type and mutant proteins should be quantified and compared. If the interaction interface has not been previously characterized, it is possible to screen for mutations that alter the efficiency of bimolecular fluorescence complementation, and thereby to determine if the complementation reflects a specific interaction. The BiFC assay can therefore be used to determine whether two proteins interact in cells without prior knowledge of the location or the structural nature of the interaction interface.

Protein concentrations

The levels of expression of fusion proteins used for BiFC analysis can have a profound influence on the experimental results and on interpretation of the data. A high level of expression may produce non-native protein interactions, and may result in bimolecular complementation independent of specific protein interactions. It may also alter the subcellular distributions of the fusion proteins and alter cell functions. These may lead to the misinterpretation of the observed interactions. It is therefore important to control the levels of expression of the fusion proteins and to compare them with those of the endogenous proteins. This can be accomplished by using regulated expression vectors and by making stably transfected cell lines. Differences between the levels of expression of the fusion proteins and their endogenous counterparts should also be considered when interpreting the results from competition studies using the multicolor BiFC assay.

Time and temperature

The time required for the detection of fluorescence varies depending on the complementation efficiency. For most productive interactions, transiently transfected cells exhibit fluorescence at 12 to 36 hr after transfection. In the case of some interactions, fluorescence can be detected as early as 8 hr after transfection (Hu et al., 2002; Grinberg et al., 2004). Long incubation times should be avoided since this may result in higher expression of fusion proteins and complementation due to nonspecific interaction. Since fluorophore maturation is sensitive to high temperature, incubation at 30°C for 30 min to several hours can increase the signal. Keep in mind that results obtained at 30°C should be carefully interpreted, as low-temperature incubation may alter protein localization and/or interactions.

Interpretation of lack of fluorescence complementation

The lack of fluorescence complementation does not prove the absence of an interaction because fusion of nonfluorescent fragments to the proteins of interest can alter their structures, which could interfere with an interaction between the proteins. Moreover, the spatial arrangement of the fragments of fluorescent proteins may not allow bimolecular complex formation. Only in cases where fluorescence complementation can be induced by an extracellular signal can the lack of fluorescence complementation in the absence of the signal be tentatively interpreted to reflect the absence of an interaction or a change in complex architecture. If there is strong evidence to indicate that the proteins interact in cells, fluorescence complementation could be examined in different cell types or in the presence of different extracellular stimuli. Alternatively, additional

fusion proteins containing different linker sequences could be tested.

Quantification of the efficiency of bimolecular fluorescence complementation

The efficiency of fluorescence complementation is defined as the fluorescence intensity produced by bimolecular fluorescent complex formation relative to the levels of fusion proteins present in the cell. The efficiencies of bimolecular fluorescence complementation by structurally unrelated proteins cannot be used to determine their efficiencies of complex formation, since many factors unrelated to the efficiency of complex formation influence the efficiency of bimolecular fluorescence complementation. However, in situations where all of these factors are expected to be identical, differences in the efficiency of bimolecular fluorescence complementation can provide information about the relative efficiencies of complex formation. Thus, the effects of single amino acid substitutions that do not alter the level of protein expression or its localization can be examined by quantifying the efficiencies of fluorescence complementation by the wild-type and mutated proteins (Hu et al., 2002; Hu and Kerppola, 2003). To quantify the efficiency of fluorescence complementation, it is necessary to include an internal control in the experiment to normalize for differences in the efficiencies of transfection and protein expression in individual cells. For this purpose, cells are cotransfected with plasmids encoding the two fusion proteins together with a plasmid encoding a full-length fluorescent protein with distinct spectral characteristics (e.g., CFP). The fluorescence intensities derived from both bimolecular fluorescence complementation (i.e., YFP) and the internal control (i.e., CFP) are measured in individual cells. The ratio of YFP to CFP emission is calculated after subtraction of background signal (Fig. 21.3.3). The ratio of YFP to CFP fluorescence is a measure of the efficiency of bimolecular fluorescence complementation. For structurally related proteins under carefully controlled conditions, the efficiency of complementation can provide information about the efficiency of the protein interaction.

Anticipated Results

If the fusion proteins under investigation support fluorescence complementation within 12 to 36 hr after transfection, it is likely that the complementation reflects a specific interaction. This possibility must be verified by the analysis of mutated proteins. For proteins that display complementation after longer times, it is increasingly probable that the complementation results from a nonspecific association. If eight different combinations of amino- and carboxy-terminal fusions are tested and no complementation is observed, it is unlikely that additional combinations will produce fluorescence complementation, although this does not exclude the possibility that the proteins may interact.

Time Considerations

The construction of plasmid vectors for BiFC and multicolor BiFC analysis can be accomplished in 1 to 2 weeks. For transfection, preparation of the cells takes 1 day and transfection takes 1 hr using FuGENE 6. Next, 1 to 2 days incubation at 37°C is required. To promote chromophore maturation, incubation at 30°C for 30 min to several hours or overnight may be necessary. Imaging of the cells may take a few hours depending on how the data will be analyzed. Quantitative analysis requires about half a day to 1 day for each experiment. If everything goes smoothly, 3 to 4 weeks should be enough to obtain preliminary results. However, it takes much longer to validate the results by performing all the necessary controls. Confirmation of the interaction using cells stably transfected with inducible expression vectors also takes longer, since it requires the establishment of stable cell lines expressing the fusion proteins.

Design and Use of Fluorescent Fusion Proteins in Cell Biology

The discovery that green fluorescent protein (GFP) variants and coral fluorescent proteins can be functionally expressed in heterogeneous systems has revolutionized cell biology (Lippincott-Schwartz et al., 2001; Miyawaki et al., 2003). Unmodified fluorescent proteins (FPs) can be visualized by fluorescence microscopy and can serve as probes of environments within living cells. The addition of targeting and retention sequences to FPs can be exploited to highlight specific cellular organelles and to follow their dynamics. The ability of FPs to fold, even when fused to cellular proteins, has made it possible to directly study the biology of proteins in vivo. A protein of interest can be monitored in cells or even in whole animals without having to purify, label, and deliver the protein into cells. Thus, it is now possible to label and observe proteins in previously inaccessible environments, such as organelle lumena. Fusion of FPs to proteins of interest can reveal a wealth of data, including information on a protein's steady-state distribution, dynamics, history, and association with other proteins (Lippincott-Schwartz et al., 2001; 2003). In this unit, strategies and background for designing and creating fluorescent fusion proteins (FFPs) are described.

To design an FFP, the investigator must consider what the FFP's intended use is, which fluorescent tag to add, whether the FP has complicating issues related to the protein of interest's environment (e.g., pH sensitivity, enhanced aggregation), and where to insert the FP. The actual construction of FFPs can be readily accomplished using standard molecular biology techniques and will only be described in general terms in the Basic Protocol. Investigators seeking specific advice on cloning techniques are referred to *Current Protocols in Molecular Biology* (Ausubel et al., 2005) or *Molecular Cloning: A Laboratory Manual* (Sambrook and Russell, 2001).

DESIGN OF A FLUORESCENT FUSION PROTEIN

BASIC PROTOCOL

Most fluorescent protein (FP) cDNAs are commercially available from BD Biosciences Clontech or from the laboratories that first described the FP. Often, FP coding regions are positioned adjacent to a multicloning site in the plasmid for ease of subcloning. The cDNA for the protein of interest can sometimes be directly cloned into the FP vector. However, in many cases, construction of a fluorescent fusion protein (FFP) will necessitate modification of the protein of interest and/or the FP. As described below, placement of an FP can affect the localization and functionality of the protein of interest. Because the required modifications will vary on a case-by-case basis, two different general cloning strategies are described below:

Strategy 1: When a protein's functional and targeting domains are unknown

Even if only minimal information on a protein is available, it is still possible to study the protein's environment and behavior in cells. However, the investigator should first assess the steady-state distribution of the unmodified protein of interest (e.g., by immunolocalization; *UNIT 4.3*). This is necessary to ensure that the corresponding FFPs localize properly. It is also useful to compare the distribution of the untagged protein in different cell types, as some proteins localize very differently in different types of cells. For example, procollagen only folds properly and exits from the ER in cell types expressing specific chaperones (Nagai et al., 2000).

Contributed by Erik Snapp
Current Protocols in Cell Biology (2005) 21.4.1-21.4.13

To maximize the likelihood of creating a functional and properly targeted FFP, the investigator should design two constructs. One construct should contain the FP at the NH_2-terminus of the protein of interest, and the other should have the FP at the COOH-terminus, as many proteins fold with their NH_2- and COOH-termini exposed on the protein surface, rather than buried in the protein core (Hovmöller and Zhou, 2004). It is often useful to include a small linker of two to ten amino acids, such as glycine interspersed with serine residues (to enhance the solubility of the linker), to provide flexibility between the FP and the protein of interest (Miyawaki et al., 2003). The linker can help promote proper folding and functioning of both the FP and the protein of interest. Note that the necessary size of a linker can only be determined empirically. The position of the FP can also affect the need for a linker. For example, the COOH-terminus of enhanced green fluorescent protein (EGFP) is floppy and rarely requires a linker when fused to the NH_2-terminus of the protein of interest (Miyawaki et al., 2003). A linker can be added by PCR to the cDNA encoding the protein of interest or to the FP cDNA.

The final FFP construct will contain an in-frame fusion between the FP and the protein of interest, an unambiguous initiating methionine within the appropriate Kozak sequence (for eukaryotes, this is 5′-ACCATGG-3′, where the internal ATG is the initiating methionine; Kozak, 1992), a linker between the FP and the protein of interest (if necessary), and appropriate regulatory elements (e.g., promoter, 5′ and 3′ untranslated regions). Appropriate regulatory elements are often included in commercially available FP subcloning vectors.

Once a cloning strategy and PCR primers have been designed, the investigator can generate the FFP construct. The final step of a cloning strategy is to place the FFP in an appropriate expression vector. For example, the cytomegalovirus promoter–containing EGFP-C1 vector (Clontech) can be used to express the FFP in mammalian cells, but not in bacteria or yeast. Insertion of the construct into an appropriate vector can be accomplished by ligation into a multicloning site.

In preparation for future experiments, it is often useful to make several color variants of the desired FFP. Because the GFP variant sequences are identical to each other at the NH_2- and COOH-termini, it is easy to use the same PCR primers to amplify multiple variants simultaneously.

Strategy 2: When a protein's function can be assayed and targeting domains have been identified

In this situation, the investigator can exploit the full potential of FFPs. The FP can be inserted at an optimal position (i.e., one at which the FP will not interfere with targeting domains or protein folding), and the resulting FFP can be assayed for function. As in strategy 1, it is important to be able to assess the steady-state distribution of the wild-type protein of interest. This will help the investigator distinguish whether the FP affects the spatial distribution of the protein being studied.

The example of a lumenal endoplasmic reticulum (ER) protein illustrates some of the considerations affecting FP placement (Fig. 21.4.1). A typical lumenal ER protein contains two critical sequences with targeting information—a signal sequence at the NH_2-terminus, and an ER-retention sequence at the COOH-terminus. The signal sequence is essential for the targeting and translocation of the nascent peptide into the lumen of the ER (Martogolio and Dobberstein, 1998). Thus, the FP must be placed after the signal sequence, but where?

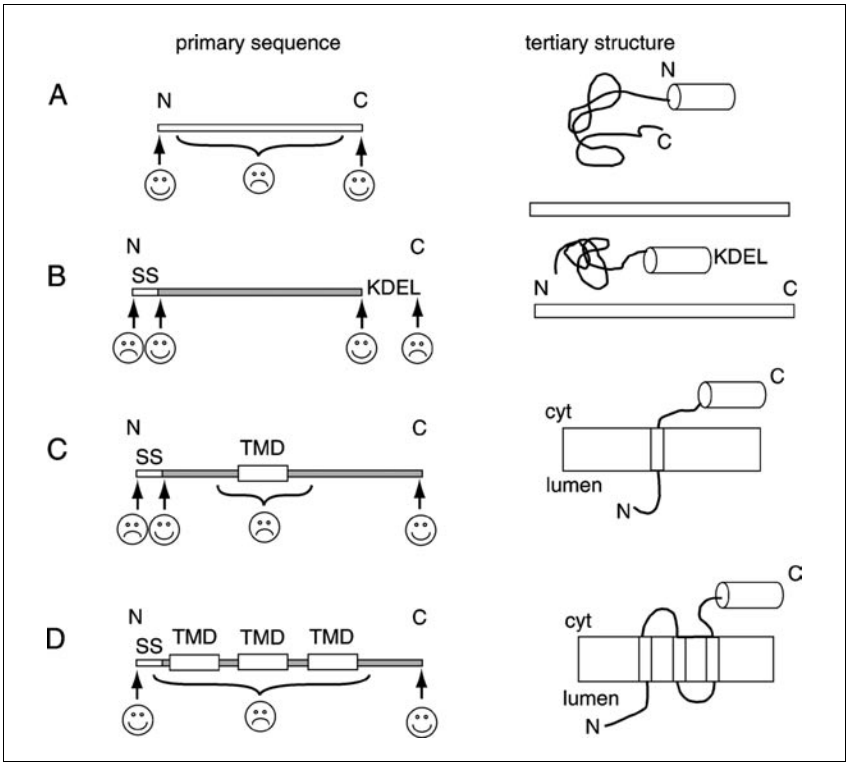

Figure 21.4.1 Appropriate positioning of a fluorescent protein (FP) in a fluorescent fusion protein construct. Preferred sites of FP fusion in the primary sequence of the protein of interest are indicated by happy face icons, and domains to be avoided are indicated by sad face icons. Each tertiary structure shows the folding of the sample construct with the FP (represented as a cylinder) fused at an optimal site. (**A**). A hypothetical globular protein expressed in the cytoplasm can have the FP fused at either the NH_2- or the COOH-terminus. Typically, one end of the protein of interest will contain a functional domain that may be sterically hindered by an FP, and so it is useful to make both of the possible constructs. (**B**) A hypothetical lumenal protein contains an NH_2-terminal signal sequence (SS), a mature domain, and a COOH-retention sequence (KDEL). An FP placed immediately after the SS or immediately before the retention sequence is less likely to interfere with the functioning of either sequence. (**C**) A single membrane–spanning protein has the additional constraint that the FP cannot be placed within or near the transmembrane domain (TMD), as this will disrupt the domain and cause problems with membrane integration. (**D**) A membrane multispanning protein has the same constraint as the example in panel C, but in multiple locations. The loops between the transmembrane domains are also poor choices, because the exact spacing between transmembrane domains is often important for protein folding, and because these loops often contain functional domains. Abbreviation: cyt, cytoplasm.

If the functional domain of the protein is near the COOH-terminus, then placing the FP after the signal sequence is a reasonable strategy. It is advantageous to place the FP two to ten amino acids downstream of the predicted signal-sequence cleavage site (R.S. Hegde, unpub. observ.). This will enhance the efficiency of signal-sequence cleavage and help promote the efficiency of translocation of the FFP into the ER.

If the functional domain of the protein is toward the NH_2-terminus, then the FP should be placed toward the COOH-terminus, but not necessarily at the absolute terminus. For example, in animal cells, the KDEL motif must account for the final four amino acids of the protein, as this motif functions as a lumenal ER retention sequence (Pelham, 1990). In such a case, the FP should be inserted just before the start of the KDEL motif.

Additional examples of appropriate and inappropriate FP placement sites are illustrated in Figure 21.4.1. Once the FP has been inserted, as in strategy 1, the last step is to place the FFP in an appropriate expression vector.

Finally, in both strategies, the investigator must confirm that the FFP construct has the correct DNA sequence and assess whether the expressed FFP is fluorescent, localizes in a pattern similar to that of the wild-type protein within the cell (e.g., by performing immunofluorescence and colocalization studies; *UNIT 4.3*), and retains the functionality of the native protein (as determined by the investigator's own assays). In the absence of functional characterization, the investigator should be vigilantly skeptical of inferring too much from studies of FFPs.

COMMENTARY

Background Information

Considerations for the design and application of FFPs

The various fluorescent proteins (FPs) have different advantages and limitations. Before designing and generating an FFP, the investigator needs to identify what questions the FFP will be used to address. It is worth spending some time asking whether the planned construct will be able to fulfill the stated purpose. Additional concerns include whether the FFP will be sufficiently bright, whether it will be appropriate for the time scale of the planned experiment, and whether the necessary equipment is available for the application.

The simplest fluorescent fusion proteins (FFPs) are FPs fused to targeting sequences (e.g., a nuclear localization sequence or a signal sequence) for the highlighting of an organelle or a cellular domain of interest. Such FFPs permit the investigator to colocalize a protein of interest with a specific organelle or to follow the dynamics of an organelle in a living cell (Lippincott-Schwartz et al., 2001; Miyawaki et al., 2003). In addition, these FFPs can be coupled with photobleaching methods (*UNIT 21.1*) to probe the viscosity or crowdedness of a cellular environment (Dayel et al., 2000; Nehls et al., 2000; Lippincott-Schwartz et al., 2001). FFPs containing a full-length protein fused to an FP are potentially valuable tools that can be exploited to illuminate a protein's function or behavior in its native environment.

How much of a fluorescent protein is enough?

The first issue to carefully consider is the normal expression levels of the protein of interest. Ranges of expression levels for a variety of proteins are provided in Table 21.4.1. Compare these values with the concentrations of FP that are required for visualization over background fluorescence in cells. For example, to achieve a twofold increase in fluorescence over background fluorescence, enhanced green fluorescent protein (EGFP) must be expressed at 200 nM (Patterson et al., 1997). Thus, to visualize a homogeneously distributed cytoplasmic FFP, the FFP must be expressed at levels two orders of magnitude higher than those for a kinase such as MAPKKK (Table 21.4.1). However, if all of the FFP will be concentrated in discrete compartments or domains, then low expression levels may be sufficient to visualize the protein or organelle of interest; in contrast, if a protein normally binds to a receptor present at low levels, the excess fluorescence of the unbound FFP could obscure the physiologically relevant population. More importantly, the potential biological consequences of the overexpressed protein should not be underestimated. Therefore, knowing the normal expression levels and localization of one's protein of interest can greatly assist in the planning and interpretation of experiments. To determine a protein's relative expression level, the investigator can compare immunoblots from lysates of cells that natively express the protein of interest and lysates of cells stably transfected with the FFP, using the same antibody for the native protein and the FFP (*UNIT 6.2*).

Rate of fluorophore maturation

FFPs are generally useful as markers for and probes of protein and organelle dynamics. However, the temporal aspects of FP maturation may place constraints on the utility of FFPs in certain experiments. For example, current FFPs are unlikely to be useful for following the behavior of nascent proteins within the first few minutes of translation. This is because EGFP takes up to 30 min to fold and fluoresce in solution (Heim et al., 1994). However, EGFP may become fluorescent more rapidly in cells (Prendergast, 1999).

The *Discosoma* red fluorescent protein (DsRed) is even slower, taking up to 48 hr

Table 21.4.1 Typical Protein Concentrations in Cells

Protein	Concentration[a,b] (μM)	Reference
Enzymes		
Ornithine decarboxylase	15 (rabbit liver)	Albe et al., 1990

[a] According to Niswender et al. (1995) and Patterson et al. (1997), a concentration of at least 200 nM enhanced green fluorescent protein (EGFP) is necessary to visualize a fluorescence increase over background autofluorescence in HeLa cells. Enhanced yellow fluorescent protein (EYFP) is 1.5× brighter than EGFP (Table 21.4.2), and so only 133 nM EYFP is necessary for a detectable fluorescence increase. See Table 21.4.2 for relative brightness data on other fluorophores.

[b] The volume of a BHK cell (3900 μm^3; Griffiths et al., 1984) was used to calculate concentration when only an absolute protein amount was provided in the literature.

to make 90% of all newly synthesized proteins fluoresce (Baird et al., 2000). However, new red FP variants are available that fold in <1 hr (Bevis and Glick, 2002; Campbell et al., 2002). The slow folding of one DsRed variant, DsRed-E5, has been exploited to visually distinguish between proteins younger and older than 9 hr (Terskikh et al., 2000).

Size matters

Unlike an epitope tag, FP fusions are not inherently small modifications to proteins (Fig. 21.4.2). An FP represents a significant addition to a protein and thus may have steric consequences for protein folding, function, or targeting. GFP variants and the coral FPs are 27 kDa in size. The crystal structures of all of the FPs show β-barrels that are 3 nm in diameter and 4 nm in length (Yang et al., 1996). In addition, many of the coral FPs exist as obligate tetramers of these β-barrels (Baird et al., 2000), which not only increases their size but also tends to induce formation of aggregates. For these reasons, investigators need to be alert to FP-related effects on a protein's behavior. Alternatives to FPs are briefly discussed in the following section.

Selecting a fluorescent protein

Once the investigator has determined that an FFP will meet the requirements of the experiment, he or she must choose an FP. In the past few years, the variety of available FPs has increased dramatically. In addition to GFP and its spectral variants, coral FPs that span the visible spectrum and FPs with new functionalities have become available (Miyawaki et al., 2003). Many of the currently available FPs are listed in Table 21.4.2. Generally, the investigator will want to select the brightest possible FPs to increase the signal-to-noise ratio. The relative brightness values of various FPs are indicated in Table 21.4.2. It is also important to confirm that the necessary equipment (e.g., filter sets, excitation lasers) for using the FP of interest is available. BD Biosciences provides a useful Web resource that profiles the excitation and emission spectra of several fluorescent dyes and proteins (*http://www.bdbiosciences.com/spectra/*).

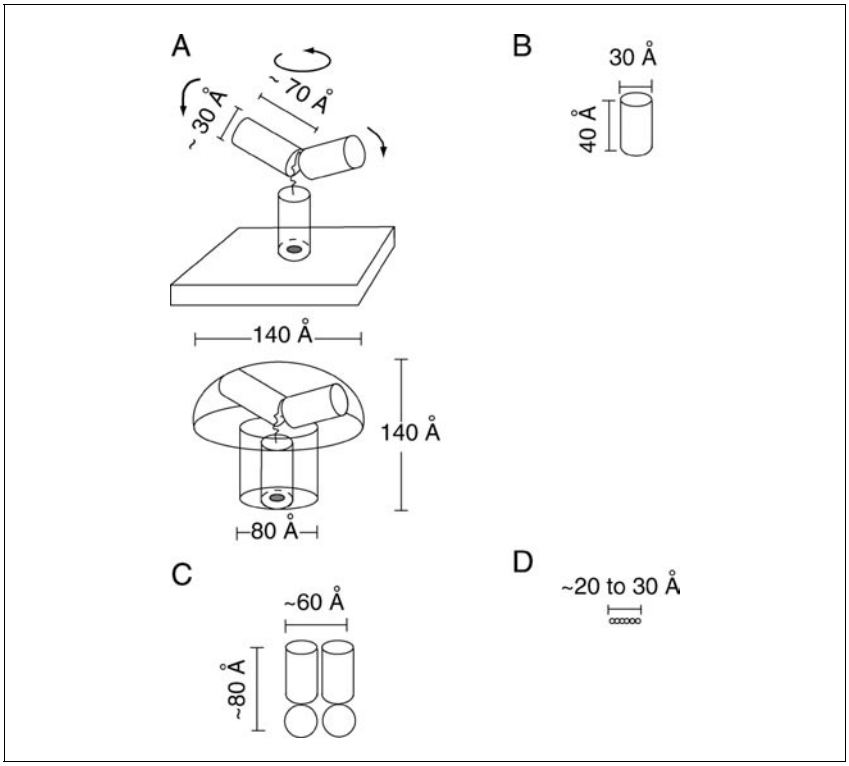

Figure 21.4.2 Relative sizes of (**A**) immunoglobulin G (IgG; reference for comparison with panels B to D), (**B**) green fluorescent protein (GFP), (**C**) the *Discosoma* red fluorescent protein (DsRed) tetramer, and (**D**) biarsenical tetracysteine.

Families of FPs that are currently available are described below. It is likely that improved variants will continue to become available, and so the investigator should regularly search the literature for the latest FPs.

Note that many of the FP cDNAs are either native sequences or have been codon-optimized for the intended host cell type. Codon-optimized variants are available for mammalian, fungal, and plant cells (Yang et al., 1996; Davis and Vierstra, 1998; Sheff and Thorn, 2004). If the FP expresses poorly in organisms such as bacteria or fungi, codon bias or Kozak sequence–related issues should be considered.

GFP and its spectral variants

The first FP to be cloned and characterized was green fluorescent protein (GFP) from the jellyfish species *Aequorea victoria* (Prasher et al., 1992). GFP folds to form a β-barrel bearing a triplet of internal amino acids (SYG) that autocatalytically form a fluorophore within the barrel (Heim et al., 1994). Wild-type GFP does not fold efficiently, is sensitive to pH, and can undergo reversible photobleaching (Patterson et al., 1997), which is a problem in FRAP (fluorescence recovery after photobleaching) and FLIP (fluorescence loss in photobleaching) experiments (*UNIT 21.1*). To improve the utility of GFP, the codon bias was modified to make the protein more suitable for expression in mammalian cells, and two amino acids were mutated to enhance brightness and protein folding (S65T and P64L). The resulting variant is termed EGFP and is available from Clontech (Yang et al., 1996).

Note that EGFP and its variants have a modified amino acid numbering system. When EGFP was first created, amino acid 2, a valine, was deleted. However, publications generally use the original wild-type GFP amino acid numbering scheme. Thus, the fourth amino acid (starting from the NH_2-terminus) in EGFP would be numbered as amino acid 5 in most publications. This can be important when sequencing or mutagenizing the EGFP variants.

Point mutations can alter the spectral properties of EGFP to create blue (ECFP) and yellow (EYFP) variants, also available from Clontech. These variants differ in other ways besides spectral excitation and emission.

Table 21.4.2 Properties of Commonly Used Fluorescent Proteins[a]

Fluorescent protein	Excitation maximum (nm)	Emission maximum (nm)	Relative brightness[b]	Reference
wtGFP	397	508	20,448 (0.6×)	Patterson and Lippincott-Schwartz, 2002
EGFP	490	509	33,000 (1×)	Rizzo et al., 2004
PAGFP (preactivation)	504	515	2691 (0.08×)	Patterson and Lippincott-Schwartz, 2002
PAGFP (postactivation)	400	517	13,746 (0.4×)	Patterson and Lippincott-Schwartz, 2002
EYFP	514	527	51,240 (1.5×)	Rizzo et al., 2004

KFP-1 (postactivation)	580	600	4130 (0.1×)	Chudakov et al., 2003
mAzami-Green	492	505	33,858 (1×)	Karasawa et al., 2003

[a]Abbreviation: na, not available.
[b]Quantum yield multiplied by extinction coefficient. Number in parentheses is the brightness of the fluorescent protein relative to EGFP.

For example, ECFP is substantially dimmer than EGFP, while EYFP is slightly brighter (Table 21.4.2). To calculate the brightness of an FP, multiply the protein's extinction coefficient (ε, the efficiency of photon absorption) by its quantum efficiency (ϕ, the ratio of photons emitted to photons absorbed; Table 21.4.2).

Recently, EGFP and its variants have been further improved. All EGFP variants can undergo weak transient dimerization in living cells (Zacharias et al., 2002). This dimerization can produce false-positive FRET results and lead to the reorganization of membrane structures when an enhanced FP is fused to a membrane protein (Fig. 21.4.3A; Zacharias et al., 2002; Snapp et al., 2003). Fortunately, dimerization can be disrupted by any one of three different point mutations (A206K, L221K, or F223R) without changing the fluorescent properties of EGFP (Zacharias et al., 2002). Such monomerized variants can be generated by mutagenesis or can be obtained from the author of this unit.

Another advance in EGFP variants has been the generation of brighter versions that fold more efficiently. Two YFP variants (called Venus and Citrine; Nagai et al., 2002; Griesbeck et al., 2001) that are more resistant to the effects of chloride ions and pH, as well as a CFP variant (called Cerulean Blue; Rizzo et al., 2004) that has improved fluorescence properties, have become available, and the reader is encouraged to use these improved versions.

Other groups have modified GFP to create environmental sensors. For example, the sensitivity of wild-type GFP to pH has been exploited by Miesenbock et al. (1998) to create mutants that can function as pH sensors.

Coral fluorescent proteins

GFP and its variants cover the visible spectrum from 400 to ~540 nm. Until recently, FPs were not generally available at the red

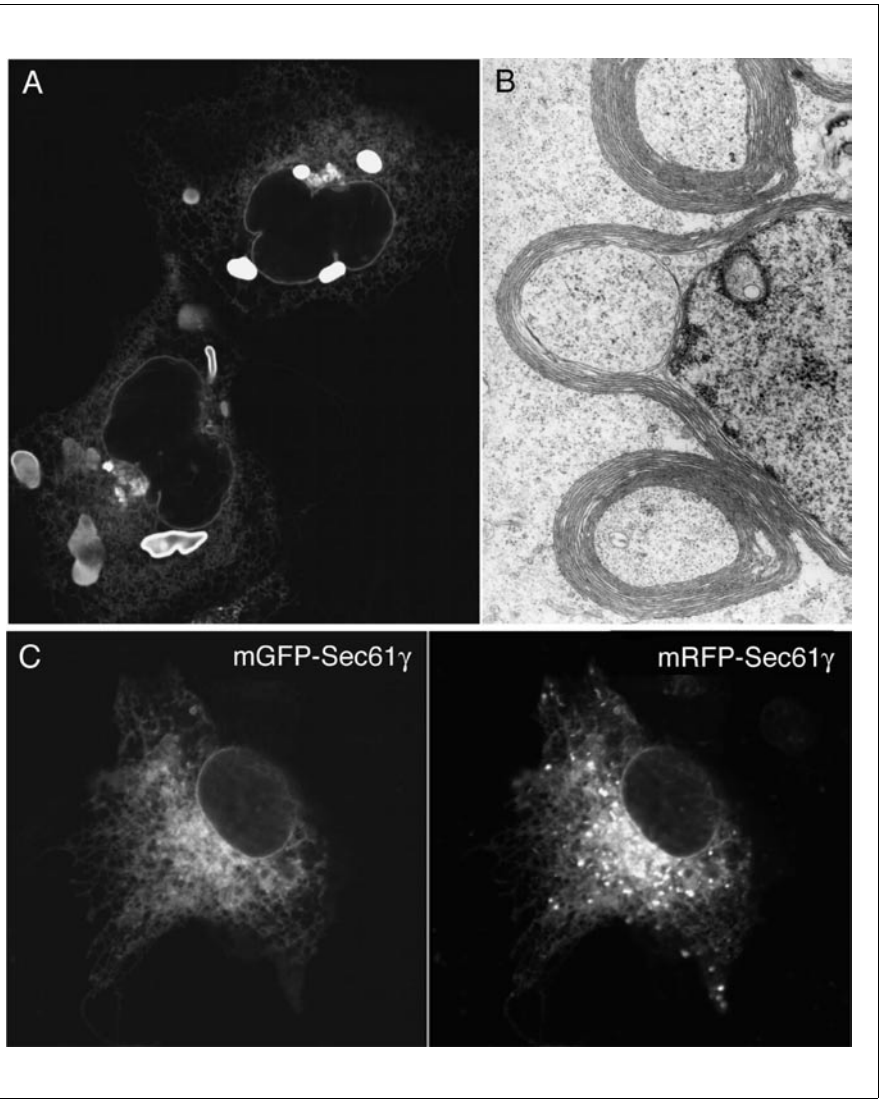

Figure 21.4.3 The fusion of a fluorescent protein (FP) to a native protein may change the protein's normal localization pattern or may lead to the formation of aggregates or oligomers. (**A**) The fusion of nonmonomerized enhanced green fluorescent protein (EGFP) to a resident endoplasmic reticulum (ER) membrane protein induces the formation of an organized smooth ER structure. (**B**) The fusion of monomerized EGFP to the same protein does not grossly alter the structure of the ER. (**C**) A Cos-7 cell expressing two fluorescent fusion proteins (FFPs), one containing monomerized green fluorescent protein (mGFP; left-hand image) and the other containing monomerized red fluorescent protein (mRFP; right-hand image). The mGFP-containing FFP localizes to the ER network, and similarly, the mRFP-containing FFP colocalizes to the ER membranes. The image yielded by the mRFP-tagged protein shows bright puncta, which are probably mRFP aggregates.

end of the spectrum. FPs that emit at longer wavelengths are highly desirable, because autofluorescence is reduced at these wavelengths (Miyawaki et al., 2003). The discovery of a series of red FPs and chromophores in coral species remedied this deficit. The first of the coral FPs, DsRed, has a spectral emission in the range of 583 nm (Table 21.4.2). This property offers the investigator an additional marker for imaging in the same cell with CFP and GFP/YFP fusion proteins. However, wild-type DsRed, like wild-type GFP, has significant drawbacks. It is an obligate tetramer, it matures slowly (48 hr), and its excitation and

emission profiles are in the same spectral range as EGFP during the first 6 hr of the maturation phase (Baird et al., 2000). Two enhanced versions of DsRed have become available—DsRed.T4 (Bevis and Glick, 2002) and mRFP (Campbell et al., 2002). DsRed.T4 matures much more quickly than DsRed (<1 hr) but is still a tetramer. The spectral properties of mRFP, a monomerized variant of DsRed created by Campbell et al. (2002), make it substantially dimmer than DsRed (Table 21.4.2). Yet, the rate of folding for this protein is ten times faster, which effectively results in similar levels of brightness compared with wild-type DsRed in cells (Campbell et al., 2002).

It should be noted that while mRFP is generally less prone to aggregation than previous variants of DsRed, researchers in the Lippincott-Schwartz laboratory have encountered difficulties with the fusion of mRFP to integral membrane proteins. Often, bright red puncta can be observed in cells expressing these FFPs (Fig. 21.4.3C), while GFP-based FFPs do not form these puncta. The most likely explanation is that attachment of mRFP to a membrane protein reduces that protein's rotational diffusion, increases its effective concentration (in the two dimensions of the membrane), and results in a tendency to form aggregates. In general, when using a new FP to make an FFP, it is useful to compare the FFP distribution with the distribution of the native protein fused to an EGFP variant or the immunofluorescence distribution of the native protein alone.

Additional coral FPs include a far red–emitting FP, HcRed (Gurskaya et al., 2001), as well as a green-emitting FP (Karasawa et al., 2003), among others (Table 21.4.2). Some of these proteins are also obligate oligomers, and the investigator should be familiar with the properties of these FPs before deciding to use them.

Photoactivatable proteins and timer proteins

Not all FPs are restricted to a single color. As noted in the preceding section, wild-type DsRed undergoes a slow maturation involving a phase as a green-emitting FP. A variant, DsRed-E5, has a more rapid transition from green to red (within 5 hr of protein synthesis) and permits investigators to follow both the steady-state distribution and the relative age of an FFP (Terskikh et al., 2000). The ratio of more mature (red) proteins to immature (green) proteins can be used to obtain information about the lifetime of the protein and whether proteins of different ages have different distributions.

To mark discrete populations of proteins, three FP options are currently available—PAGFP (Patterson and Lippincott-Schwartz, 2002), Kaede (Ando et al., 2002), and KFP-1 (Chudakov et al., 2003), which are all photoactivatable FPs. Because a particular population of protein molecules tagged with one of these FPs can be photoactivated (i.e., the fluorescent properties of the FP tag can be "turned on") at a discrete time, the new synthesis of fluorescent proteins during the time course of an experiment is eliminated as a potential problem. PAGFP is derived from GFP and is monomerized. Initially, it is excited by UV light (Patterson and Lippincott-Schwartz, 2002) and barely emits in the green range (505 to 530 nm). Upon brief stimulation with intense UV light (similar to a photobleaching experiment), however, it can be excited under the same conditions as EGFP and will fluoresce 100 times more brightly in the green range compared with the unstimulated protein. (Note that PAGFP is fluorescent in the blue range both before and after photoactivation.) UV photoactivation requires a 405- or 413-nm excitation laser or a mercury arc lamp with the proper filter set. For a more detailed description of working with this FP, see Patterson and Lippincott-Schwartz (2004). Once photoactivated, PAGFP can also be used for photobleaching applications, such as FRAP.

Kaede, a variant of DsRed, can be photoactivated with 350- to 415-nm excitation to increase its fluorescence intensity up to 1000-fold over background. Absorption shifts from 508 nm to 572 nm upon activation, and emission shifts from 518 nm to 582 nm (Ando et al., 2002). In contrast to PAGFP, Kaede undergoes a complete conversion in both its absorption and emission spectra, and this conversion readily permits the simultaneous spectral separation of activated and unactivated proteins. However, Kaede is an obligate tetramer and requires UV light for photoactivation. To avoid exposing cells to intense UV light, investigators can use the coral FP KFP-1, which can be excited with a less phototoxic, longer-wavelength laser (532 nm) to increase fluorescence 30-fold over background (Chudakov et al., 2003). In addition, KFP-1 differs from the other two photoactivatable FPs in that it is inherently nonfluorescent in its unactivated form. However, like Kaede, KFP-1 is an obligate tetramer.

In addition to having pulse-labeling applications, photoactivatable proteins can be used to mark organelles or whole cells and may be useful for following cell lineages in development experiments.

Alternatives

As noted above, none of the FPs are small, and some proteins do not fold or are nonfunctional following the attachment of a bulky FP (Andresen et al., 2004). If this is the case, a few alternative options are available.

Fluorescent dyes

Prior to the cloning of GFP, investigators studying proteins or compartments in living cells often used organelle-specific dyes (e.g., MitoTracker; Invitrogen) or microinjected purified proteins conjugated to dyes such as fluorescein or rhodamine into cells. These methods are still used and can be quite powerful by themselves or in combination with FFPs. Dye labeled proteins offer certain advantages over natural FPs, including (1) tight control over the amount of fluorescently labeled protein in the cell; (2) the elimination of concerns about new fluorescent protein synthesis; (3) the ability to acutely introduce otherwise cytotoxic proteins into the cell; (4) the wide variety of available dyes, compared with the relatively small selection of FPs; and (5) the much smaller size of dye molecules, making them less likely to cause steric hindrance. The primary concerns with dye-labeled proteins are that (1) dyes may render a protein nonfunctional; (2) many readily undergo photobleaching, which can cause significant photodamage to cells (although some of the newer dyes, such as Invitrogen's Alexa dyes, are more resistant to photobleaching); (3) a microinjector is often required to deliver dye-labeled proteins to the cytoplasm; and (4) the lumena of many organelles cannot be accessed or labeled.

Short fluorophore-binding epitopes

Some of the smallest available options for fluorescently labeling proteins include fluorescent biarsenical-linked dyes (namely, FlAsH and ReAsH). The addition of a tetracysteine amino acid sequence (CCPGCC) to a flexible exposed domain of a protein of interest (typically the COOH-terminus) makes the protein competent to bind these fluorescein- (FlAsH) or rhodamine-derived (ReAsH) arsenicals (Griffin et al., 1998; Gaietta et al., 2002). These modified dyes are membrane-permeable and relatively small. Thus, it is possible to fluorescently label both cytoplasmic and lumenal proteins in cells without resorting to microinjection or other protein delivery methods. An important advantage is the comparatively small size of the tetracysteine tag and the bound dyes. Andresen et al. (2004) recently demonstrated that specific yeast tubulin isoforms were functional when one or two tetracysteine motifs were added, whereas complementation in mutant cells was not possible when three tetracysteine motifs or a single GFP was added.

Another useful property of these two dyes is that they can be added sequentially to differentially label newly synthesized proteins, resulting in a kind of biochemical photoactivation (Gaietta et al., 2002). Furthermore, ReAsH can photoconvert diaminobenzidine (DAB) to produce an electron-dense reaction product, permitting tetracysteine-tagged proteins to be imaged in the same cells by fluorescence, bright-field, and electron microscopy (Gaietta et al., 2002).

The tetracysteine-binding dyes do have at least one limitation associated with their use. Stroffekova et al. (2001) observed a significant fluorescence background even in FlAsH-treated cells not expressing a tetracysteine-tagged protein, as mammalian cells were found to contain proteins that naturally bind FlAsH. Those authors concluded that FlAsH labeling was best suited to proteins that are expressed at especially high levels (Stroffekova et al., 2001). However, proteins that concentrate in discrete cellular domains, such as gap junctions (Gaietta et al., 2002), probably would not require substantial overexpression to be visualized over background. The biarsenical dyes are comparatively new and may have other limitations. Nonetheless, FlAsH and ReAsH represent viable alternatives to the more commonly used FPs and are worth considering.

Troubleshooting

See Table 21.4.3 for a guide to troubleshooting in FFP design and use.

Anticipated Results

The methods described in this unit should permit the investigator to generate a fluorescently labeled protein that is expressed at levels comparable to those for the native unlabeled protein, that targets to the correct compartment in the cell, and that exhibits behavior similar to that of the native protein (in terms of half-life, dynamics, and protein-protein interactions). The investigator may exploit the FFP in live cells, developing animals, or in solution.

Table 21.4.3 Troubleshooting Guide for the Design and Use of Fluorescent Fusion Proteins[a]

Problem	Cause	Solution
FFP is not fluorescent	FFP's environment may suppress fluorescence (e.g., pH is too low)	Try an FP that is more tolerant of different environments
	FFP may not be folded	Place a short linker (2 to 10 amino acids) between the protein of interest and the FP; this may help to ensure proper folding of both the protein and the FP
	FFP is not synthesized or is highly unstable	Determine whether the FFP is expressed by performing immunoblot analysis (*UNIT 6.2*) or pulse-labeling/immunoprecipitation analysis (*UNITS 7.1 & 7.2*) of transfected cells[b]
FFP does not localize correctly	FP interferes with native protein's targeting sequence	Construct the FFP with the FP at the opposite end of the protein of interest Place a short linker (2 to 10 amino acids) between the protein of interest and the FP; this may help to ensure proper folding of both the protein and the FP Targeting machinery may be saturated; determine whether mistargeting is seen specifically in cells with higher expression of the FFP; if so, limit observations to dimmer cells[c]
	FP oligomerizes	Use a monomeric FP
FFP is nonfunctional	FP may sterically hinder folding or obstruct functional domains	Try constructing the FFP with the FP placed elsewhere in the protein of interest Place a short linker (2 to 10 amino acids) between the protein of interest and the FP; this may help to ensure proper folding of both the protein and the FP Try using a fluorescent biarsenical-linked dye (FlAsH or ReAsH) in place of the FP Try using a dye-labeled protein instead of an FFP

[a] Abbreviations: FFP, fluorescent fusion protein; FP, fluorescent protein.

[b] If the protein is expressed but unstable, the FP must be placed in a different position. Try fusing the FP gene near the other terminus of the cDNA encoding the protein of interest. Alternatively, the FP may prevent incorporation of the FFP into a complex, thereby reducing FFP stability. If this is suspected, consider FlAsH or other smaller fluorescent labels. If the FFP is not expressed, check the sequence of the construct again. If the sequence is correct and contains an appropriate Kozak sequence, then the flanking sequences of the FFP gene may be interfering with transcription or translation. If this is the case, the FFP coding sequence (with Kozak sequence) should be excised and inserted in the multicloning site of an appropriate expression vector.

[c] Overall expression can be reduced by stably transfecting cells and/or by placing the FFP construct in a vector with an inducible promoter and modulating FFP gene expression.

Time Considerations

The time required for creation of an FFP will depend on the number of cloning steps required to generate the construct. If convenient restriction sites are present in the DNA sequence encoding the protein of interest and there are no concerns with targeting sequences, an FFP can be created in the time it takes to perform digestion, DNA purification, and ligation, followed by transformation and screening for the resulting DNA construct (1 to 3 days). More complex cloning strategies may require one or more PCR steps, the design of oligonucleotides, and more screening steps; in such cases, FFP creation can take up to 1 to 2 weeks. Characterization of the new construct with regard to proper localization will require the time necessary to transfect cells and perform immunocolocalization experiments (typically 4 hr to label cells and <1 hr to image them), and the time needed for functional assays will be application dependent.

The Fluorescent Protein Color Palette

INTRODUCTION

Although the first report of fluorescence emission in the bioluminescent hydrozoan jellyfish species *Aequorea victoria* was recorded in the mid-twentieth century (Davenport and Nichol, 1955), and a protein extract was independently demonstrated by two investigators to be responsible for this "green" fluorescence in the 1960s and 1970s (Shimomura et al., 1962; Morin and Hastings, 1971a), it took another 20 years and a number of significant advances in the technology of molecular and cellular biology to witness the elucidation of the primary amino acid structure (Prasher et al., 1992). Following shortly thereafter was the astonishing demonstration that the jellyfish green fluorescent protein (GFP) could be readily employed as a useful marker for gene expression (Chalfie et al., 1994) in cells evolutionarily far removed from the jellyfish. During the next several years, a number of "enhanced" genetic variants having fluorescence emission spectral profiles in the blue (Yang et al., 1998), cyan (Heim and Tsien, 1996), green (Heim et al., 1995), and yellow (Wachter et al., 1998) regions of the visible spectrum were developed by engineering specific mutations of the original GFP nucleotide sequence. One of the most significant advances following the initial cloning and early mutagenesis efforts on the *Aequorea victoria* green fluorescent protein was the discovery of similar proteins in nonbioluminescent reef corals and sea anemones (Matz et al., 1999; Shagin et al., 2004) that not only provided a large spectrum of new emission colors, but also demonstrated that these protein motifs occur in a wide range of organisms.

Over the past decade, fluorescent proteins have launched a new and unprecedented era in cell biology by enabling investigators to apply routine molecular cloning methods, fusing these optical probes to a wide variety of protein and enzyme targets, in order to monitor cellular processes in living systems using fluorescence microscopy and related methodology (for recent reviews, see: Chudakov et al., 2005; Miyawaki et al., 2005; Shaner et al., 2005; Dixit et al., 2006; Prescott et al., 2006). The spectrum of applications for fluorescent proteins ranges from reporters of transcriptional regulation and targeted markers for organelles and other subcellular structures to fusion proteins designed to monitor motility and dynamics. These fascinating probes have also opened the door to creating biosensors for numerous intracellular phenomena, including pH and ion concentration fluctuations, protein kinase activity, apoptosis, voltage, and cyclic nucleotide signaling (Zhang et al., 2002; Meyer and Teruel, 2003; Miyawaki, 2003; Zaccolo, 2004). By applying selected promoters and targeting signals, fluorescent protein biosensors can be introduced into an intact organism and directed to a host of specific tissues, cell types, as well as subcellular compartments, to enable an unprecedented focus on monitoring a variety of physiological processes.

When coupled to recent technical advances in widefield fluorescence and confocal microscopy, including ultra-fast low-light-level digital CCD cameras, spinning-disk and swept-field instruments, as well as multitracking laser control systems with acousto-optic tunable filter (AOTF) control, the green fluorescent protein and its color-shifted genetic derivatives have demonstrated invaluable service in many thousands of live-cell imaging experiments. Compared to many traditional synthetic fluorophores, which are often toxic or photoreactive, the use of fluorescent proteins is minimally invasive for living cells, enabling visualization and recording of time-lapse image sequences for extended periods of time (Lippincott-Schwartz and Patterson, 2003; Day, 2005). Furthermore, continued advances in genetically fine-tuning the properties of fluorescent protein variants have led to increased brightness levels, improved photostability, and significantly better expression in mammalian cells (Verkhusha and Lukyanov, 2004; Shaner et al., 2005). These functional enhancements have stimulated a wide variety of investigations into protein dynamics and function using fluorescent protein chimeras imaged at low-light intensities for many hours to extract valuable information about changes in the steady-state distribution.

Among the most noteworthy attributes of the original green fluorescent protein derived from the *Aequorea victoria* jellyfish, as well as the more recently developed palette of color-shifted genetic variants, is that a stable and highly-defined cylindrical polypeptide

Current Protocols in Cell Biology (2007) 21.5.1-21.5.34

structure is essential for the development and maintenance of fluorescence in this very remarkable family of proteins (Rizzo and Piston, 2005a). The principle fluorophore (often termed a chromophore) in GFP is a tripeptide consisting of the residues serine, tyrosine, and glycine at positions 65 to 67 in the sequence. Although this simple amino acid motif is commonly found throughout nature, it does not generally result in fluorescence. The chromophore forms spontaneously after translation without the requirement for cofactors or external enzyme components (other than molecular oxygen), through a self-catalyzed intramolecular rearrangement of the tripeptide sequence to produce the fluorescent species (as illustrated in Figure 21.5.1 for the enhanced GFP variant). The first step in maturation is thought to be a series of torsional peptide and side-chain bond adjustments that relocate the carboxyl carbon of the serine amino acid at position 65 (Ser65) in close proximity to the amino nitrogen atom of Gly67. Nucleophilic attack by this carbon atom on the amide nitrogen of glycine, followed by dehydration, results in the formation of an imidazolin-5-one heterocyclic ring system (Cody et al., 1993). Fluorescence occurs when oxidation of the tyrosine (Tyr66) α-β carbon bond by molecular oxygen extends electron conjugation of the imidazoline ring system to include the tyrosine phenyl ring and its para-oxygen substituent (Heim et al., 1994). The result is a highly conjugated π-electron resonance system that largely accounts for the spectroscopic properties of the protein. Extensive

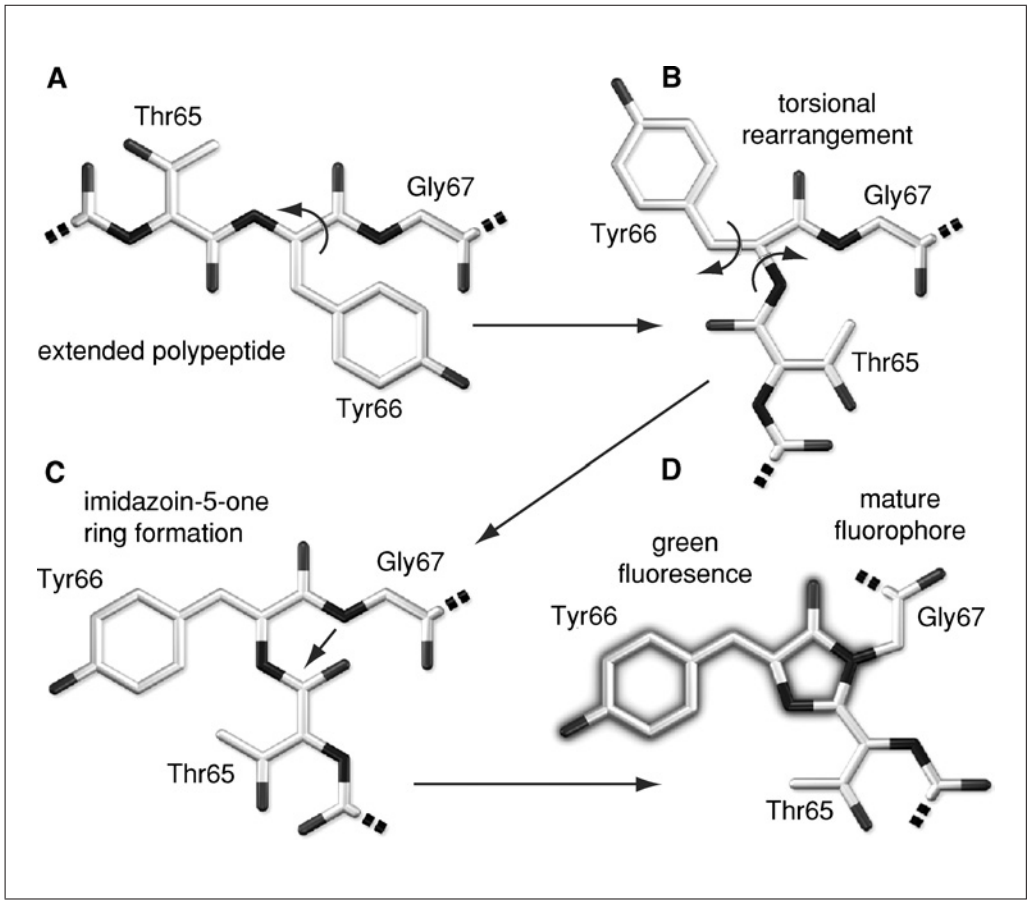

Figure 21.5.1 Schematic diagram of the chromophore formation in maturing enhanced green fluorescent protein (EGFP). (**A**) The prematuration EGFP fluorophore tripeptide amino acid sequence (Thr65-Tyr66-Gly67) stretched into a linear configuration so that the threonine residue is positioned in the upper left-hand corner of the diagram. The first step in maturation is a series of torsional adjustments (**B**) and (**C**) that relocate the carboxyl carbon of Thr65 so that it is in close proximity to the amino nitrogen of Gly67. Nucleophilic attack by this carbon atom on the amide nitrogen of glycine, followed by dehydration, results in formation of an imidazolin-5-one heterocyclic ring system. (**D**) Fluorescence occurs when oxidation of the tyrosine α-β carbon bond by molecular oxygen extends electron conjugation of the imidazoline ring system to include the tyrosine phenyl ring and its para-oxygen substituent.

mutagenesis studies suggest that the glycine residue at position 67 is critical in formation of the chromophore (Cubitt et al., 1995; Delagrave et al., 1995), and indeed, no fluorescent proteins have yet been discovered that lack this essential element.

Several fundamental physical and chemical aspects of the fluorescent protein chromophore have profound implications for the application of these biomolecules as intracellular probes. A striking aspect of the fluorescent protein chromophores is that although their presence to date has only been detected in sea creatures, they are able to form functional units in a wide variety of organisms ranging from bacteria to plants and mammals. The native *Aequorea victoria* GFP is composed of a single-domain protein with 238 amino acids and a molecular weight of ~27 kDa. Even though the photophysics of GFP are rather complex (Chattoraj et al., 1996; Jung et al., 2005), the molecular structure of the protein is quite robust and can accommodate a high degree of modification (executed through the amino acid sequence) without destroying the ability to emit fluorescence. A wide variety of amino acid substitutions to the original configuration have been successful in fine-tuning the fluorescence of native GFP to provide a broad range of derivative fluorophores that emit colors traversing the blue to the yellow regions of the visible spectrum (Tsien, 1998; Shaner et al., 2005). Site-directed and random mutagenesis investigations (Heim and Tsien, 1995; Tsien, 1998; Zacharias and Tsien, 2006) have revealed that fluorescence is very dependent on the three-dimensional structure of amino acid residues surrounding the chromophore. Denaturation of the protein, as might be expected, destroys fluorescence (Alkaabi et al., 2005; Ward, 2006), and mutations in residues immediately adjacent to the chromophore can significantly alter the fluorescent properties. Surprisingly, amino acid substitutions in regions of the polypeptide far removed from the chromophore can also affect the spectral characteristics of the protein (Zacharias and Tsien, 2006).

The remarkably well-conserved cylindrical geometry of all the fluorescent proteins discovered thus far appears to be ideally suited to the primary function of protecting the chromophore. Formed in the shape of a cylinder (Ormö et al., 1996) having dimensions of ~25 × 40 Å, the polypeptide backbone is wound into 11 strands of an extensively hydrogen bonded β sheet that surround a central α helix containing the chromophore with short helical segments protruding from the ends of the cylinder. Dubbed a "β can" because of the geometrical symmetry (Yang et al., 1998), the tight packing of amino acid residues bestows a high level of stability to the protein (Phillips, 2006), which often results in relatively large fluorescent quantum yields for GFP and its derivatives (up to 80%). A lack of clefts and gaps for access of small ligands (such as ions and oxygen), combined with the fact that the chromophore is located near the exact center of the protein, partially explains the extraordinary photostability and high quantum yields that are observed. In addition, both the N- and C- termini are "conveniently" exposed on the surface of the β can to readily participate in protein fusions that do not affect the structural integrity. This consolidated protein organizational motif also enhances resistance to changes in pH, temperature, fixation with paraformaldehyde, and the disruptive action of many common denaturing agents, such as urea and guanidine hydrochloride. Mutations in the amino acid sequence that affect the fluorescence profile generally also produce negative effects on overall stability, usually resulting in a reduction of quantum yield, increased rates of photobleaching, and enhanced environmental sensitivity.

FLUORESCENT PROTEIN BRIGHTNESS AND MATURATION

When designing experiments using fluorescent protein reporters, investigators should ensure that the highest possible signal levels are achieved, especially in cases where the targeted species is rapidly turned over or exhibits low overall population abundance. The apparent brightness of a fluorescent protein, a seemingly qualitative concept, is determined by a number of factors that include the efficiency and rate of maturation, the level of protein expression, the molar extinction coefficient values within the excitation wavelength range, and the quantum yield (Tsien, 1998; Shaner et al., 2005; Ward, 2006). In addition, the fluorescence filter combination, spectral distribution of the illumination source, and the digital camera parameters utilized for imaging of fluorescent proteins are of paramount importance in determining whether adequate contrast and signal-to-noise ratios can be achieved.

The intrinsic "brightness" of a fluorescent protein is determined by the product of the molar extinction coefficient at the peak of the absorption band and the integrated emission quantum yield (Rizzo and Piston, 2005a;

Shaner et al., 2005). As an example, if two proteins have identical quantum yields but one has twice the extinction coefficient at the wavelength of excitation, then the protein with the largest extinction coefficient would have double the brightness of the protein with the smaller extinction coefficient. Likewise, in fluorescent proteins with similar molar extinction coefficients, the one with the highest quantum yield will be the brightest. Quantitative assessment of extinction coefficients and quantum yields is a tedious process that requires a highly purified and correctly folded protein with >95% of the molecules having an active fluorescent chromophore (Ward, 2006). In addition, the total protein concentration must be accurately determined and the measurements of absorption and fluorescence emission performed in a reliable, calibrated spectrophotometer and fluorimeter. Quantum yield assessment requires the comparison of emission spectra between the unknown fluorescent protein and a reference standard having a similar wavelength profile. Investigators should be skeptical of purely qualitative fluorescent protein brightness evaluations (often made by commercial distributors) that lack quantitative information pertaining to the extinction coefficient and quantum yield. It is difficult, if not impossible, to accurately perform brightness comparisons between fluorescent proteins without knowledge of these critical parameters.

Fluorescent protein maturation efficiency is also determined by a number of variables, including the origin of the protein and the abundance of species-specific optimum codons in the organism chosen for expression. In general, fluorescent proteins that have been codon-optimized for expression in mammalian cells will be expressed with high efficiency and mature rapidly at 37°C, although a small percentage of the product may not fold correctly, resulting in poor targeting and high background fluorescence. Many of the protein variants derived from the original *Aequorea* jellyfish green fluorescent protein have been optimized (with regards to the wild-type GFP) through mutagenesis for expression in mammalian systems (Tsien, 1998; Nagai et al., 2002; Zapata-Hommer et al., 2003; Shaner et al., 2005) at high efficiency. Fluorescent proteins from reef corals and sea anemones generally express well at 37°C, presumably because the native species from which the proteins are obtained have evolved in warmer habitats (Salih et al., 2000). The presence of molecular oxygen is also a critical factor in fluorescent protein chromophore development during the maturation process. During the formation of chromophores in *Aequorea* protein variants, at least one oxygen molecule is required for dehydrogenation, while reef coral proteins that emit in the orange-red spectral regions usually require two molecules (Tsien, 1998; Gross et al., 2000; Zimmer, 2002). In mammalian cell cultures, fluorescent protein expression is rarely hampered by a lack of oxygen, but anoxia could become a limiting factor in other systems.

Regardless of the intrinsic brightness displayed by a particular fluorescent protein, the ability to achieve high signal levels is primarily determined by the configuration of the imaging equipment. The laser system or arc-discharge lamp coupled to fluorescence filters used to excite the chromophore should strongly overlap the chromophore absorption profile and the emission filters must have the widest possible bandpass region coinciding with the emission spectrum. In addition, the camera system must be capable of recording images with high quantum efficiency in the fluorescence emission region of interest (Patterson et al., 1997), and the optical system of the microscope should have high throughput in the wavelength regions necessary for producing excitation and gathering emission. Even with research-level instrumentation, it is often quite difficult to achieve the maximum potential fluorescent protein brightness levels in each spectral class unless the fluorescence filter sets are completely optimized for imaging the proteins. Many core imaging facilities have limited inventories of filter sets that are typically designed for traditional synthetic fluorophores rather than fluorescent proteins. For example, the standard DAPI, FITC, TRITC, and Texas Red fluorescence filter combinations, which are often marketed by default with widefield arc-discharge microscopes, are not suitable for many fluorescent proteins and are less than optimal for others.

The hazards of using incorrect filter sets for imaging fluorescent proteins are illustrated in Figure 21.5.2 for several of the more useful fluorescent proteins with standard widefield microscopy filter sets. The cyan fluorescent protein, Cerulean, is depicted in Figure 21.5.2A and 21.5.2B with the absorption and emission spectral profiles superimposed over a DAPI filter set (Fig. 21.5.2A), as well as a set designed specifically for cyan fluorescent proteins (Fig. 21.5.2B). Note the poor overlap of the DAPI filters with the Cerulean absorption and emission bands, which yields low signal when this combination is employed. Narrowing the

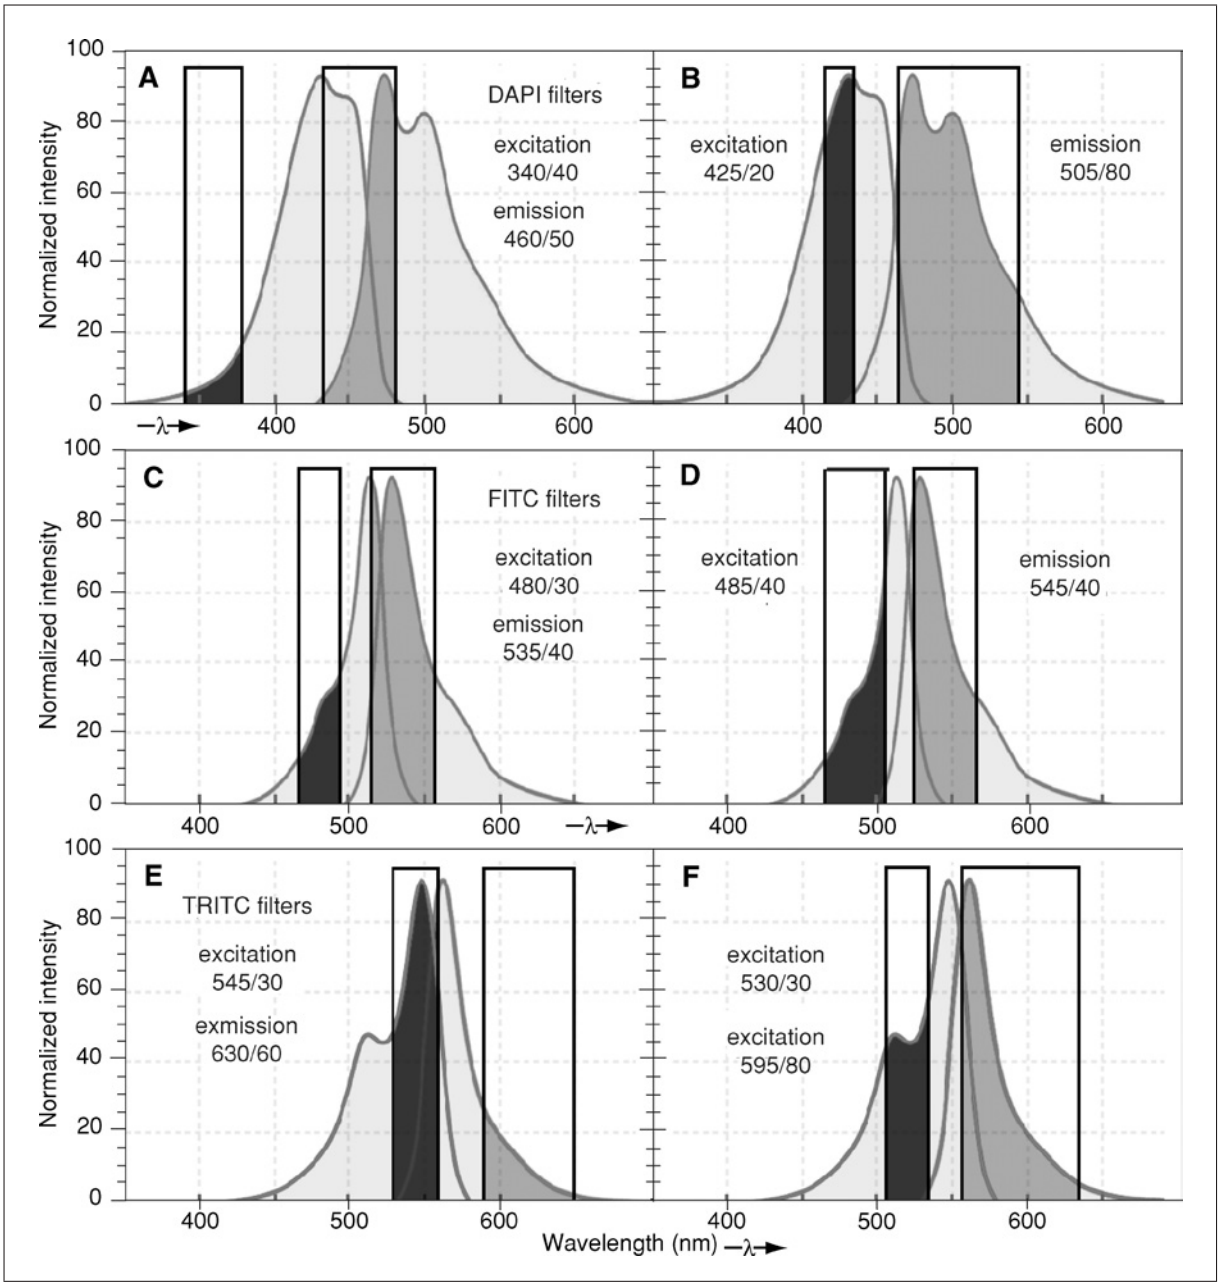

Figure 21.5.2 Spectral profiles of three common fluorescent proteins, Cerulean (**A**) and (**B**), Venus (**C**) and (**D**), and mKusabira Orange (**E**) and (**F**) superimposed over standard ultraviolet, blue, and green excitation filter combinations (**A**), (**C**), (**E**) and custom sets optimized to image the fluorescent proteins (**B**), (**D**), and (**F**). Filters are drawn as rectangles identifying the bandpass region and are described in terms of center wavelength and spectral bandpass.

excitation band to 20 nm and moving the center wavelength 85 nm to longer wavelengths significantly improves the excitation of Cerulean (Fig. 21.5.2B). Likewise, the emission filter effectively captures a majority of the fluorescence emission with a wideband (80-nm) filter having a center wavelength of 505 nm. In general, cyan fluorescent proteins are best imaged with custom filter sets specifically designed for their blue-violet excitation range. The standard FITC filter set is a much closer match for the absorption profile of the yellow fluorescent protein, Venus (Fig. 21.5.2C), but a better combination increases the excitation filter bandwidth to 40 nm and moves the center wavelength to 485 nm (red-shifted by 5 nm). The optimum emission filter bandwidth for Venus is similar to the FITC version with an increase of 10 nm for the center wavelength. Most of the green and yellow fluorescent proteins can be satisfactorily imaged with the FITC filter set, but quantitative imaging benefits from optimizing the central wavelengths and bandwidths for each protein. Orange fluorescent proteins have spectral profiles that fall between the FITC and TRITC filter

wavelength regions for optimal excitation and gathering of emission. Imaging mKusabira Orange with a TRITC filter combination (Fig. 21.5.2E,F) is a good example of the mismatch. The TRITC excitation filter covers an acceptable cross-section of the absorption spectrum, but it is shifted slightly too far towards the emission wavelengths (Fig. 21.5.2E). In addition, the emission filter for this set captures only a small portion of the fluorescent protein emission spectral tail, leading to a loss of signal. A more effective filter set for mKusabira Orange is illustrated in Figure 21.5.2F. Fortunately, a majority of the red fluorescent proteins (DsRed, mCherry, JRed, mPlum, etc.) can be imaged with good results using either the TRITC or Texas Red filter combinations.

PHOTOTOXICITY AND PHOTOSTABILITY

Aside from the toxicity that occurs due to excessive concentrations of synthetic fluorophores and the overexpression or aggregation of poorly localized fluorescent proteins, the health and longevity of optimally labeled mammalian cells in microscope imaging chambers can also suffer from a number of other deleterious factors. Foremost among these is the light-induced damage (phototoxicity) that occurs upon repeated exposure of fluorescently labeled cells to illumination from lasers and high-intensity arc-discharge lamps. In their excited state, fluorescent molecules tend to react with molecular oxygen to produce free radicals that can damage subcellular components and compromise the entire cell. In addition, several reports have suggested that particular constituents of standard culture media, including the vitamin riboflavin and the amino acid tryptophan, may also contribute to adverse light-induced effects on cultured cells (Spierenburg et al., 1984; Silva et al., 1991; Edwards et al., 1994; Lucius et al., 1998). Fluorescent proteins, due to the fact that their fluorophores are buried deep within a protective polypeptide envelope, are generally not phototoxic to cells (Shaner et al., 2005). In contrast, many of the common synthetic fluorophores, such as the MitoTracker and most nuclear stains (including Hoechst, SYTO cyanine dyes, and DRAQ5), can be highly toxic to cells when illuminated for even relatively short periods of time (Durand and Olive, 1982; Minamikawa et al., 1999). In designing experiments, synthetic fluorophores as well as fluorescent proteins that exhibit the longest excitation wavelengths possible should be chosen in order to minimize damage to cells by short wavelength illumination. Thus, rather than creating fusion products with blue or cyan fluorescent proteins (excited by ultraviolet and blue illumination, respectively), variants that emit in the yellow, orange, and red regions of the spectrum should, when possible, be used instead.

Investigators should take care to perform the necessary control experiments when using new fluorescent protein variants, chimeric fusion protein vectors, and cell lines to ensure that cytotoxicity and phototoxicity artifacts do not obscure important biological phenomena. In some cases, lipophilic reagents induce deleterious effects that may be confused with fluorescent protein toxicity during imaging in cell lines following transient transfections. Oligomeric fluorescent proteins (discussed below) from reef corals have a far greater tendency to form aggregates (combined with poor subcellular localization) than do the monomeric jellyfish proteins, but improperly folded fusion products can occur with any variant. Recently, a fluorescent protein capable of generating reactive oxygen species (ROS) upon illumination with green light has been reported (Bulina et al., 2006) as an effective agent for inactivation of specific proteins by chromophore-assisted light inactivation (CALI) and photodynamic therapy. Appropriately named KillerRed, this genetically encoded photosensitizer is capable of killing both bacteria and eukaryotic cells upon illumination in the microscope. Previous studies on GFP phototoxicity indicate that even though the chromophore is capable of generating singlet oxygen (Greenbaum et al., 2000), the probe is inefficient as a photosensitizer (Rajfur et al., 2002; Tour et al., 2003). However, prolonged illumination of cells expressing GFP and its variants can result in physiological alterations and eventual cell death (Dixit and Cyr, 2003), a definite signal of the potential for phototoxicity in long-term imaging experiments.

In live-cell experiments, fluorescent proteins are highly advantageous for extended imaging due to their reduced rate of photobleaching when compared to synthetic fluorophores (Zumbusch and Jung, 2000; Zhang et al., 2002; Rizzo and Piston, 2005a). Although there is a high degree of uncorrelated variability between fluorescent proteins in terms of photostability, most variants are useful for short-term imaging (from 1 to 25 captures), while several of the more photoresistant proteins can be employed in time-lapse sequences that span periods of 24 hr or longer

(in which hundreds to thousands of images are gathered). The long-term stability of any particular protein, however, must be investigated for every illumination scenario (e.g., widefield, confocal, multiphoton, swept-field) because differences in photostability are often observed with the same protein when illumination is produced by an arc-discharge lamp versus a laser system. Thus, in terms of photostability, the selection of fluorescent proteins is dictated by numerous parameters, including the illumination conditions, the expression system, and the effectiveness of the imaging setup.

OLIGOMERIZATION

All of the fluorescent proteins discovered to date display at least a limited degree of quaternary structure, exemplified by the weak tendency of native *Aequorea victoria* green fluorescent protein and its derivatives to dimerize when immobilized at high concentrations (Campbell et al., 2002; Zacharias et al., 2002). This tenant is also verified by the obligate dimerization necessary for solubility in fluorescent proteins isolated from *Renilla* sea pansies (Ward, 2006) and the strict tetramerization motif of the native yellow, orange, and red fluorescent proteins isolated in reef corals and anemones (Baird et al., 2000; Gross et al., 2000; Yarbrough et al., 2001; Verkhusha and Lukyanov, 2004). Oligomerization can be a significant problem for many applications in cell biology, particularly in cases where the fluorescent protein is fused to a host protein that is targeted at a specific subcellular location. Once expressed, the formation of dimers and higher order oligomers induced by the fluorescent protein portion of the chimera can produce atypical localization, disrupt normal function, interfere with signaling cascades, or restrict the fusion product to aggregation within a specific organelle or the cytoplasm. This effect is particularly marked when the fluorescent protein is fused to partners such as actin, tubulin, or histones, which themselves participate in natural oligomer formation. Fusion products with proteins that form only weak dimers (i.e., most *Aequorea victoria* variants) may not exhibit aggregation or improper targeting, provided the localized concentration remains low (see Fig. 21.5.3). However, when dimeric fluorescent proteins are targeted to specific cellular compartments, such as the plasma membrane (Zacharias et al., 2002), the localized protein concentration can, in some circumstances, become high enough to permit dimerization. This is a particular concern when conducting FRET experiments, which can yield complex data sets that are easily compromised by dimerization artifacts.

The basic strategy for overcoming oligomerization artifacts is to modify the fluorescent protein amino acid sequence to include residues that disrupt intermolecular binding, a procedure that varies in complexity depending upon the nature and origin of the protein. For many of the *Aequorea* protein variants, dimerization can be either significantly reduced or eliminated completely (Zhang et al., 2002) by replacing the hydrophobic amino acid side chains in the dimer interface with positively charged residues at several key sequence positions. The three most successful mutations, in decreasing order of effectiveness, are F223R, L221K, and A206K, where the nonpolar amino acids phenylalanine, leucine, and alanine are replaced by their hydrophilic relatives, arginine or lysine. In cases where close molecular associations are suspected involving a fusion protein and where quantitative FRET interactions are being investigated, it is highly recommended that *Aequorea* variants (CFP, GFP, YFP) should be converted into monomers using one of these point mutations (preferably A206K; Shaner et al., 2005; Zacharias and Tsien, 2006).

Creating fluorescent protein monomers from the tetrameric coral reef and sea anemone proteins is usually far more difficult. For example, even at exceedingly low concentrations, the DsRed fluorescent protein is an obligate tetramer (Baird et al., 2000; Vrzheshch et al., 2000; Wiehler et al., 2001) that cannot be dissociated without irreversible denaturation of the polypeptides (Mizuno et al., 2001). In the tetrameric unit, each DsRed protein interacts with two adjacent neighbors, one through a hydrophobic interface and the other through a hydrophilic interface resulting in a complex assembly (Baird et al., 2000; Campbell et al., 2002; Verkhusha and Lukyanov, 2004). Other Anthozoan proteins, such as the *Zoanthus* variants and eqFP611 (Zacharias, 2002; Wiedenmann et al., 2005), have simpler interfaces that may prove easier to disrupt into monomers. The most successful approaches (Campbell et al., 2002; Zacharias and Tsien, 2006) utilized so far to generate fluorescent protein monomers with Anthozoan species have involved repeated site-directed mutagenesis to disrupt the tetrameric interfaces, usually by substitution of hydrophilic or charged amino acids for hydrophobic and neutral moieties. Because a significant decrease in fluorescence emission quantum yield usually accompanies

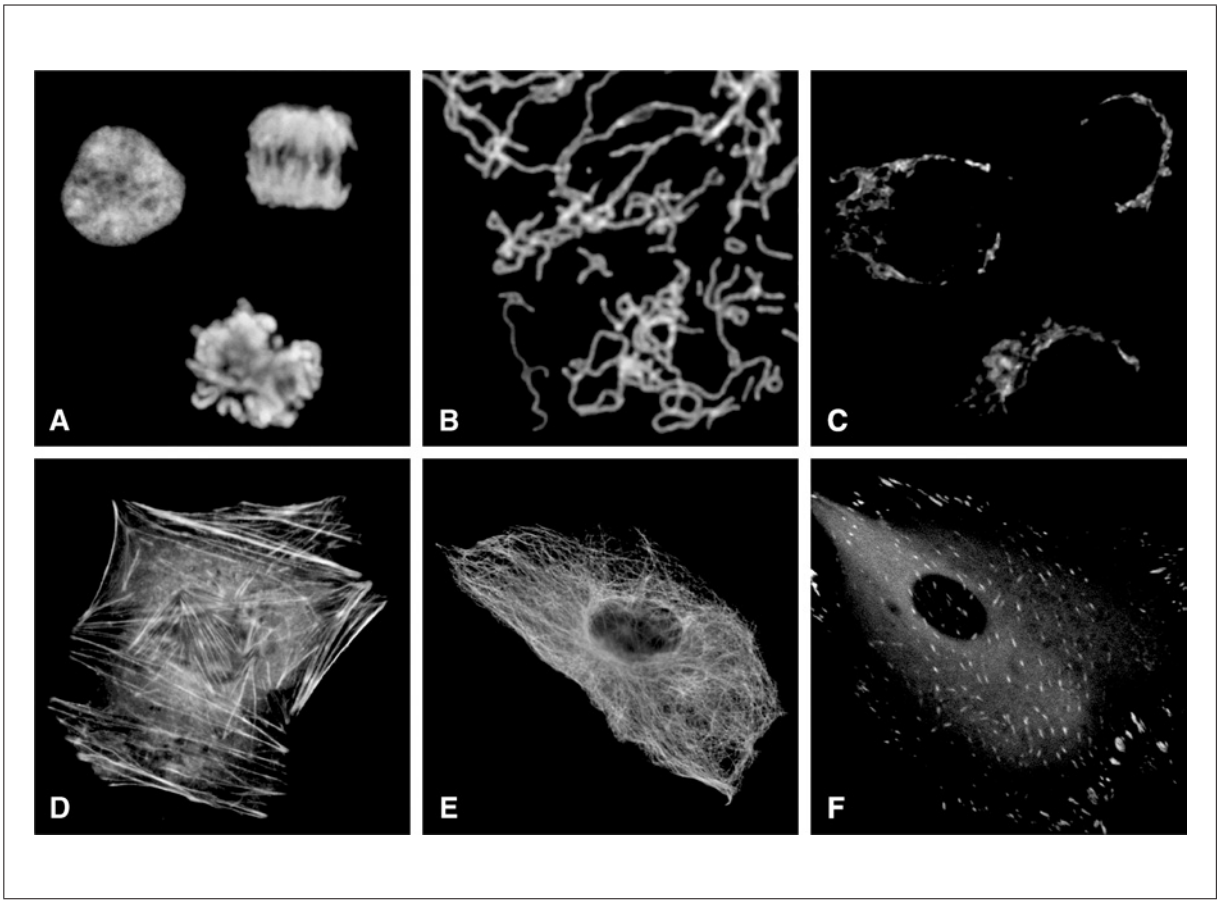

Figure 21.5.3 Localization of fluorescent protein fusion tags to specific subcellular compartments. (**A**) The chimera of mPlum and histone H2B localizes to the nucleus and can be utilized to observe chromosomes during cell division. (**B**) The monomeric red fluorescent protein mCherry highlights mitochondria when fused to the targeting sequence from subunit VIII of human cytochrome c oxidase. (**C**) A fusion between EYFP and the N-terminal 81 amino acids of human β-1,4-galactosyltransferase localizes the yellow fluorescent marker to the Golgi apparatus. (**D**) The actin cytoskeleton becomes fluorescent when Cerulean fluorescent protein is fused to the gene for human β-actin. (**E**) A EGFP-tubulin fusion vector marks the microtubule network in COS-7 cells. (**F**) Focal adhesions become fluorescent with a chimera of mKusabira Orange fluorescent protein and vinculin.

these genetic modifications, a second round of random mutagenesis is often necessary to rescue fluorescence (as discussed below). Another technique involves creating vectors containing two sequential coding regions separated by a short linker of nonspecific amino acids, known as tandem dimers, from proteins that exist naturally as dimeric and tetrameric complexes. Upon expression, the fused fluorescent proteins preferentially bind to each other to form an intramolecular dimeric unit that performs as a monomer, although at twice the molecular weight (and size). This method was successfully applied with HcRed by fusing two copies of the DNA sequence, separated by a short linker of four amino acids, to several subcellular localization proteins (Fradkov et al., 2002). Tandem dimer constructs have also been developed with DsRed (Campbell et al., 2002) and a photoconversion fluorescent protein known as Eos (Ivanchenko et al., 2005). Other mechanisms for reducing fluorescent protein oligomerization and aggregation effects include removing several basic residues from the N terminus (Yanushevich et al., 2002) and simultaneous co-expression of fluorescently tagged proteins with an excess of either fusion partner alone or with a nonfluorescent mutant of the marker protein (Lauf et al., 2001; Bulina et al., 2003). Regardless of the specific mechanism employed to overcome fluorescent protein oligomerization, the most important point is that experimental results are not compromised by artifacts induced by the existence of quaternary structures.

THE FLUORESCENT PROTEIN COLOR PALETTE

A broad range of fluorescent protein genetic variants have been developed (Verkhusha and Lukyanov, 2004; Chudakov et al., 2005; Shaner et al., 2005) over the past several years; these feature fluorescence emission spectral profiles spanning almost the entire visible light spectrum (see Table 21.5.1). Mutagenesis efforts in the original jellyfish green

[a]The excitation and emission peak values listed may vary in published reports due to the broad spectral profiles. In actual fluorescence microscopy investigations, spectral profiles and wavelength maxima are influenced by environmental effects, such as pH, ionic concentration, and solvent polarity, as well as fluctuations in localized probe concentration. Therefore, the listed extinction coefficients and quantum yields may differ from those actually observed under experimental conditions.

[b]The computed brightness values were derived from the product of the molar extinction coefficient and quantum yield, divided by the value for EGFP. This listing was created from scientific and commercial literature resources and is not intended to be comprehensive, but instead represents fluorescent protein derivatives that have received considerable attention in the literature and may prove valuable in research efforts.

[c]The protein actually exists in solution as a weak dimer, which can be converted to a true monomer with the A206K modification.

fluorescent protein have resulted in new fluorescent probes that range in color from blue to yellow (Tsien, 1998) and are some of the most widely used in vivo reporter molecules in biological research. Longer wavelength fluorescent proteins, emitting in the orange and red spectral regions, have been developed from the marine anemone *Discosoma striata* and reef corals belonging to the class Anthozoa (Matz et al., 1999). Still other species have been mined to produce similar proteins having cyan, green, yellow, orange, red, and far-red fluorescence emission (Chudakov et al., 2005; Shaner et al., 2005). Developmental research efforts are ongoing to improve the brightness and stability of fluorescent proteins, thus improving their overall usefulness.

Essential to the understanding of spectral diversity in the wide range of fluorescent proteins discovered thus far are structural investigations of the stereochemical nature of the fluorophore and the effects of its surrounding environment on fluorescent properties. Aside from the jellyfish proteins, there appears to be a high degree of variation in the fluorophores of red-shifted fluorescent proteins (Shkrob et al., 2005). Even though the DsRed fluorophore configuration, termed planar *cis*, appears to be the predominant structure in most proteins that emit in the orange and red regions, there are at least two additional motifs, planar *trans* and nonplanar *trans*, which have been elucidated through x-ray diffraction studies. A planar *trans* motif is found in the red fluorescent protein eqFP611, isolated from the sea anemone *Entacmaea quadricolor* (Peterson et al., 2003), which displays one of the largest Stokes shifts and red-shifted emission wavelength profiles of any naturally occurring Anthozoan fluorescent protein. In contrast, the nonplanar *trans* conformation is characteristic of the nonfluorescent chromoprotein Rtms5 from *Montipora efflorescens* (Beddoe et al., 2003). Several guiding motifs have emerged in recent years regarding the origins and manipulation of fluorescent protein emission color (Remington, 2006). The most important consideration appears to be the physical extent of π-orbital conjugation contained within the chromophore, which largely determines the general spectral class (i.e., cyan, green, yellow, or red). In addition, local environmental variables, such as the position of charged amino acid residues, hydrogen bonding network, and hydrophobic interactions within the protein matrix, are capable of producing either blue or red spectral shifts in the absorption and emission maxima by as much as 20 nm (Tsien, 1998; Remington, 2006; Shu et al., 2006). As further studies into the complex characteristics of fluorescent protein chromophores yield clues about the structure-function relationship with the polypeptide backbone, the task of genetically engineering more finely-tuned color variants and broadening the spectral range of useful proteins will undoubtedly become easier.

Blue Fluorescent Proteins

Fluorescent proteins emitting in the blue region of the visible light spectrum (~440 to 470 nm) were first obtained from site-directed mutagenesis efforts targeted at the tyrosine amino acid residue at position 66 in the GFP chromophore. Conversion of this residue to histidine (Y66H) produces a blue fluorescent protein (BFP) that exhibits a broad absorption band in the ultraviolet centered close to 380 nm and an emission maximum at 448 nm (Heim et al., 1994; Cubitt et al., 1999). The original protein exhibited only ~15% to 20% of the parent GFP brightness value due to a low quantum yield and required additional secondary mutations to increase its folding efficiency and expression levels. Subsequent investigations and several additional mutations led to an enhanced BFP version that is still only 25% as bright as the enhanced green variant (Patterson et al., 1997; Yang et al., 1998; Patterson et al., 2001;) and displays limited photostability compared to many other fluorescent proteins.

The primary motivation for developing blue fluorescent proteins in the mid-to-late 1990s was the keen interest in creating matched pairs for fluorescence resonance energy transfer (FRET) experiments and multicolor labeling (Tsien, 1998). Because the spectral characteristics (fluorescence emission profile) of BFP are readily distinguishable from EGFP, this protein combination was one of the first utilized for multicolor imaging (Heim and Tsien, 1996; Rizzuto et al., 1996). Blue fluorescent protein also has the distinction of being incorporated into the first genetically encoded biosensor along with an enhanced GFP variant to demonstrate FRET through linkage of the two fluorescent proteins via an intervening protease-sensitive spacer (Heim and Tsien, 1996; Mitra et al., 1996). The broad emission peak of BFP overlaps to a significant extent with the excitation spectrum of red-shifted GFP variants to yield a Förster distance of 4.1 (Patterson et al., 2000), a reasonable value for measuring FRET. Blue fluorescent protein has also been coupled with several GFP

derivatives into biosensors designed to monitor transcription factor dimerization (Periasamy and Day, 1998), calcium (Miyawaki et al., 1997; Romoser et al., 1997), and apoptosis (Rehm et al., 2002).

Aside from the limited brightness levels and rapid photobleaching, blue fluorescent proteins also suffer from the fact that they must be excited with ultraviolet light, which is phototoxic to mammalian cells, even in limited doses (Potter, 1996; Stephens and Allan, 2003; Khodjakov and Rieder, 2006). Furthermore, working in this spectral region is often hampered by autofluorescence and high absorption levels by cells and tissues, as well as light scattering. Microscopes operating in the ultraviolet also require specialized light sources, optics, and filter combinations that further complicate imaging (Rizzo and Piston, 2005a). For all of the reasons listed above, the quest for more efficient blue fluorescent proteins has only been pursued by a few research groups. Investigations of mutagenesis using nonnatural amino acids positioned in and around the chromophore have led to several blue-shifted "artificial" fluorescent protein variants that may find utility in several biological and photophysical applications (Kajihara et al., 2005).

Cyan Fluorescent Proteins

The first fluorescent protein emitting in the bluish-green cyan spectral region (CFP; ranging from ~470 to 500 nm) was discovered simultaneously with BFP during mutagenesis studies (Heim et al., 1994) that converted the tyrosine residue in the GFP chromophore to tryptophan (Y66W). This single mutation yielded a chromophore that displays an absorption maximum at 436 nm with a very broad fluorescence emission spectral profile centered at 485 nm. Subsequent refinements, including the F64L maturation improvement and S65T (discussed in Green Fluorescent Proteins), resulted in the production of an enhanced version (ECFP) with greater brightness and photostability (Cubitt et al., 1995; Patterson et al., 2001). Even these modifications failed, however, to increase the brightness level of ECFP beyond 40% of that shown by EGFP. Other than providing an additional hue for multicolor imaging, initially the most promising aspect of ECFP was the potential for utility as a biosensor FRET partner with yellow fluorescent proteins in widefield and confocal microscopy using blue-violet filter sets or the 457-nm spectral line of an argon-ion laser (Miyawaki et al., 1997; Tsien, 1998). Greater photostability compared to EBFP also positions ECFP as a more useful protein for time-lapse imaging in localization and dynamics studies.

By far the most successful applications using ECFP have taken advantage of the ability of this variant to be coupled with yellow fluorescent protein (YFP) and derivatives to generate FRET biosensors capable of monitoring a wide spectrum of intracellular processes (reviewed in Zhang et al., 2002; Miyawaki, 2003; Meyer and Teruel, 2003; Zaccolo, 2004). Although a host of FRET investigations have been performed using the ECFP-EYFP pair, the experimental results are often problematic due to limitations in the fluorophore properties that restrict measurements to a small dynamic range (Rizzo and Piston, 2005a). A majority of these biosensors exhibit a typical overall ratio change of 10% to 30% during FRET analysis, with a few exceptions (Ting et al., 2001; Zhang et al., 2001; Rizzo et al., 2002). Such a low level of contrast presents difficulties with modern digital microscopy due to a noise level that can approach 10% of the signal at low imaging intensities (Swedlow et al., 2002). These biosensors are further complicated by the potential to form dimers when constrained with tight two-dimensional spatial restrictions such as those that exist in membranes (Ward, 2006). To overcome the artifacts associated with dimerization, hydrophobic residues at the dimer interface were replaced with positively charged amino acids in both ECFP and EYFP to produce true monomeric variants (mCFP and mYFP), which achieve a far higher level of efficiency in FRET experiments (Zacharias et al., 2002). The critical mutation is the substitution of lysine for alanine at position 206 (A206K, as discussed above), which can be applied to virtually any *Aequorea victoria* variant in order to generate a true monomer capable of superior performance in applications such as localization, FRET, and protein dynamics.

Despite the host of improvements in CFP and the large database of experiments performed with this variant, continued investigation has produced additional useful fluorescent proteins in the cyan spectral class. Among the improved cyan fluorescent proteins that have recently been introduced, CyPet and an enhanced cyan variant termed Cerulean show the most promise (Rizzo et al., 2004; Nguyen and Daugherty, 2005) as fusion tags, FRET biosensors, and for multicolor imaging (see Figs. 21.5.3 and 21.5.4). The Cerulean fluorescent probe (named for the sky-blue color) was rationally engineered by site-directed mutagenesis

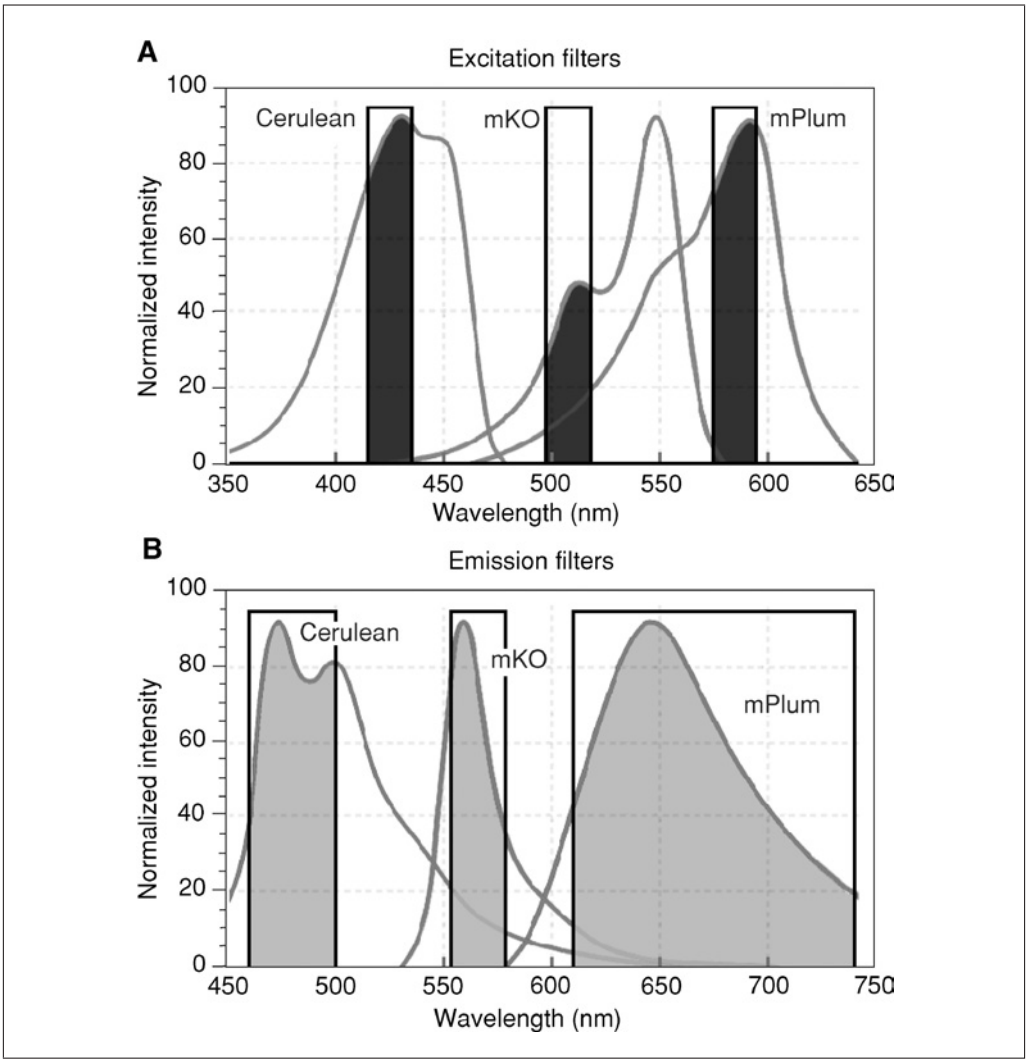

Figure 21.5.4 Optimized fluorescence filter combinations for multicolor imaging of three fluorescent proteins spanning the cyan through far-red wavelength regions. (**A**) Excitation filters optimized for Cerulean, mKO, and mPlum fluorescent proteins having center wavelengths of 425, 508, and 585 nm, respectively. The bandwidth of all excitation filters is 20 nm. (**B**) Emission filters optimized for the same probes having center wavelengths of 480, 564, and 675 nm with bandwidths of 40, 28, and 130 nm, respectively. The mKO excitation filter is designed to work off-peak to minimize simultaneous excitation of mPlum. Bleed-through of Cerulean fluorescence emission into the mKO filter is reduced by the fact that mKO is four times brighter at equimolar concentrations and requires much shorter exposure intervals for image capture.

of enhanced cyan fluorescent protein to yield a higher extinction coefficient, improved quantum yield, and a fluorescence lifetime decay having a single exponential component (useful in lifetime decay measurements of FRET; Wallrabe and Periasamy, 2005). Cerulean is at least 2-fold brighter than enhanced cyan fluorescent protein and has been demonstrated to significantly increase contrast, as well as the signal-to-noise ratio when coupled with yellow-emitting fluorescent proteins, such as Venus (see below), in FRET investigations. In addition to site-directed mutations designed to improve folding and brightness (Rizzo et al., 2004), random mutagenesis was conducted on preCerulean variants to further increase the molar extinction coefficient, and the optimized protein has been "monomerized" to enhance its utility in fusions (Rizzo and Piston, 2005b). The abundance of advantageous features afforded by Cerulean render this protein the most useful all-purpose cyan derivative.

The cyan fluorescent protein variant named CyPet (from the acronym: Cyan fluorescent Protein for energy transfer) was derived through a quantitative and unique strategy utilizing fluorescence-activated cell sorting (FACS; Boeck, 2001) to optimize the cyan and yellow pairing for FRET (Nguyen and Daugherty, 2005). Libraries were screened for

FRET efficiency and the best clones were subjected to several evolutionary cycles consisting of random mutagenesis and synthetic DNA shuffling. A total of seven mutations resulted in the production of the CyPet protein, which features absorption and emission maxima positioned at 435 and 477 nm, respectively. CyPet is about half as bright as EGFP and two-thirds as bright as Cerulean, but expresses relatively poorly at 37°C (Shaner et al., 2005). However, when paired with its FACS-optimized partner, YPet, in FRET biosensors, this cyan variant exhibits a dynamic range that is more than six times higher than CFP-YFP (Nguyen and Daugherty, 2005), dramatically improving contrast and potentially leading to far more sensitive detection of subtle intracellular processes. CyPet has a more blue-shifted and narrower fluorescence emission peak than mCFP, which greatly increases its utility in multicolor imaging, and is the most photostable cyan fluorescent protein of the weakly dimeric and monomeric versions currently available.

Several potentially useful cyan proteins have been isolated in Anthozoan species. Derived from the reef coral *Anemonia majano*, the AmCyan1 fluorescent protein (Matz et al., 1999), which is now commercially available (Clontech), has been optimized with human codons for enhanced expression in mammalian cell systems (Richards et al., 2002). Originally named amFP486 (am, *Anemonia majano*; FP, fluorescent protein; 486 emission maximum) in accordance with a nomenclature scheme (Matz et al., 1999) devised to simplify the discussion of myriad Anthozoan proteins, this variant exhibits a similar brightness level, but a significantly better resistance to photobleaching than CFP. The absorption maximum of AmCyan1 occurs at 458 nm while the fluorescence emission peak resides at 489 nm. Note that both peaks are shifted to longer wavelengths by 19 and 13 nm, respectively, compared to ECFP. On the downside, similar to most of the other reef coral proteins, the probe has a tendency to form tetramers, which will significantly complicate attempts to employ this protein as a fusion tag or a FRET biosensor.

First isolated by Miyawaki and associates from an *Acropara* stony coral species (Karasawa et al., 2004), the cyan-emitting Midoriishi-Cyan (abbreviated MiCy) probe was originally designed as the donor in a new FRET combination with the monomeric Kusabira Orange fluorescent protein to generate a biosensor probe with high spectral overlap (Förster distance of 5.3; mKO is discussed in the section on Orange Fluorescent Proteins). This protein features the longest absorption and emission wavelength profiles (472 and 495 nm, respectively) reported for any probe in the cyan spectral class. The high molar extinction coefficient and quantum yield exhibited by MiCy render the protein of equal brightness to Cerulean, although the spectra are far more sensitive to pH. Also similar to Cerulean, MiCy features a single exponential lifetime decay component with a time constant of 3.4 ns, which should be useful for measurements of FRET in combination with fluorescence lifetime imaging microscopy (FLIM). An unusual feature of MiCy is that it forms a homodimeric complex similar to the GFP variant isolated from the bioluminescent sea pansy, *Renilla reniformis* (Ward and Cormier, 1979), rather than the obligate tetramer observed in most coral reef species. Although the dimerization motif may be a problem in some fusion proteins, it should be far easier than a tetramer to mutate MiCy into a true monomer.

Recently, a new monomeric cyan fluorescent protein having excellent brightness, pH insensitivity, and photostability has been introduced for live-cell imaging of fusion partners, and as a FRET donor for yellow and orange acceptor fluorescent proteins in biosensors (Ai et al., 2006). Termed mTFP1 (monomeric teal fluorescent protein 1), the variant was produced from a synthetic gene library built around the tetrameric cyan protein, cFP484, originating from a *Clavularia* soft coral. Displaying red-shifted spectral profiles (excitation and emission maxima at 462 and 492 nm, respectively) when compared to other cyan members of this spectral class, mTFP1 has a total of 31 amino acid substitutions relative to the wild-type tetramer. The red-shifted spectra were considered when classifying the new color as teal rather than cyan. Unlike other members of the cyan fluorescent protein group, which generally feature the aromatic amino acid tryptophan at position 66 in the chromophore, mTFP1 contains the classical tyrosine residue at this location, characteristic of many GFP derivatives. Substituting tyrosine for tryptophan reduces the broad fluorescence emission spectral width from ~60 nm to a narrower and more manageable 30 nm, a factor that is useful for reducing bleed-through in multi-color experiments. The high quantum yield (0.85) of mTFP1 provides an excellent alternative to the cyan derivatives, mCFP and mCerulean, as a FRET donor having a Förster distance exceeding 5.0 when

combined with either yellow or orange fluorescent proteins.

Green Fluorescent Proteins

The original green fluorescent protein isolated from *Aequorea victoria* (termed wild-type) has been the principal subject of numerous investigations (Tsien, 1998), but it is not useful in a majority of the practical applications involving fluorescent proteins due to the bimodal absorption band (395 and 475 nm peaks), which is hampered by relatively low extinction coefficients and an absorption maximum in the ultraviolet part of the spectrum. Shortly after GFP was demonstrated to be a useful marker for gene expression (Chalfie et al., 1994), a point mutation altering the serine residue at position 65 in the chromophore to threonine (S65T) produced a new version of the protein having a well-defined absorption profile with a single peak at 484 nm (Heim et al., 1995). This mutation is featured in the most popular variant of green fluorescent protein, termed enhanced green fluorescent protein (EGFP), which can be imaged using commonly available filter sets designed for fluorescein (FITC); it is among the brightest and most photostable of the *Aequorea victoria* fluorescent proteins (Shaner et al., 2005). These features have rendered enhanced green fluorescent protein one of the most popular probes and the best choice for most single-label fluorescent protein experiments. As previously discussed, EGFP was coupled with blue fluorescent proteins as a FRET acceptor in early biosensor investigations, but it has subsequently been largely replaced by yellow, orange, and red variants. The only drawbacks to the use of EGFP as a fusion tag are a slight sensitivity to pH and a weak tendency to dimerize.

In addition to EGFP, several other green-emitting variants (in the range of ~500 to 525 nm) are currently being utilized in live-cell imaging (Rizzo and Piston, 2005a). Among the best of these in terms of photostability and brightness may be the Emerald variant (Cubitt et al., 1999), but lack of a commercial source (until recently) has limited its use. Emerald contains the S65T mutation featured in EGFP, but also has four additional point mutations that improve folding, expression at 37°C, and brightness. Although Emerald is far more efficient than EGFP in folding and developing fluorescence in mammalian cells, it has a fast photobleaching component that might affect quantitative imaging in some environments. One of the most interesting derivatives of wtGFP is Sapphire (Zapata-Hommer and Griesbeck, 2003), which contains a critical mutation of isoleucine for threonine at position 203 (T203I), abolishing the absorption peak at 475 nm. The result is a protein having an absorption maximum at 399 nm with emission in the green spectral region (511 nm) to yield a surprisingly large Stokes shift of over 100 nm. Several Sapphire variants have been developed to improve folding, including a probe known as T-Sapphire (for Turbo), and derivatives featuring circular permutations are available that might be useful for altering the orientation geometry with fusion partners. Due to the significant separation between absorption and emission peaks, the greatest potential for the Sapphire proteins is their pairing with orange and red derivatives as FRET donors.

A wide variety of additional fluorescent proteins emitting in the green spectral region have been isolated from other sources, including different *Aequorea* species, copepods, and coral reefs. One of the most promising of these probes, derived by random mutagenesis of a colorless protein isolated from *Aequorea coerulescens*, is known as aceGFP (Gurskaya et al., 2003). The conversion of glutamic acid into glycine at position 222 (E222G) transformed the wild-type protein into a highly fluorescent species with a relatively symmetrical pair of spectral profiles having an absorption maximum at 480 nm and an emission peak at 505 nm. The high molar extinction coefficient and quantum yield of aceGFP combine to produce a brightness level similar to that displayed by EGFP. Demonstrated to exist as a monomer by electrophoresis and gel filtration, this protein is commercially available from several sources (Clontech and Evrogen, as AcGFP1 and AceGFP) with human-optimized codon replacements. Proper localization of fusion products targeted at specific subcellular components and organelles (such as filamentous actin, the Golgi, nucleus, mitochondria, etc.; see Fig. 21.5.3) indicates that aceGFP is quite useful as a marker and could have potential for partnership with red-emitting proteins in a novel FRET combination. However, the photostability characteristics of aceGFP remain unknown, and there are no clear advantages to the use of this protein over the more common EGFP and Emerald variants.

Several closely related GFP-like proteins have been isolated from an assortment of copepod aquatic crustacean species. The brightest of these probes, originally referred to as ppluGFP2 (Shagin et al., 2004), have been

made commercially available (Evrogen) under the names CopGFP and TurboGFP (an enhanced variant). CopGFP is efficiently excited using an argon-ion laser or FITC filter set (absorption maximum at 482 nm) and produces green fluorescence at 502 nm with a brightness value ~30% higher than EGFP and a much greater resistance to changes in pH. Reported to be a monomer in dilute solution, CopGFP matures significantly faster than EGFP and is ideal for applications as a fusion partner targeted at expression in subcellular regions of low pH. Limitations of this probe include the inability to isolate stable cell lines and the formation of aggregates in long-term cultures. An improved version, TurboGFP, derived from site-directed and random mutagenesis, retains the fast maturation kinetics of the parent protein with a slight loss in brightness and substantially lower resistance to acidic environments. Despite the improved folding kinetics and excellent optical properties of these proteins, however, photostability data have not been reported and no compelling evidence exists to demonstrate a significant benefit over the application of the extensively studied original GFP derivatives.

Green fluorescent proteins have also been mined from reef corals and several of these are commercially available. A brightly fluorescent protein termed Azami Green (Karasawa et al., 2003), bearing only a surprisingly scant (<6%) sequence homology to EGFP, was isolated from the stony coral *Galaxeidae* and has been demonstrated to mature rapidly during expression in mammalian cell lines. Likewise, one of the original Anthozoan coral reef proteins from *Zoanthus* reported by Matz and coworkers (1999) has also been transformed into a commercial product (Clontech) under the trade name ZsGreen. The probes have absorption maxima at 492 and 496 nm and emission peaks at 505 and 506 nm, respectively, readily allowing visualization and imaging with standard lasers and filter combinations in confocal and widefield microscopy. However, similar to most of the other proteins isolated in corals, Azami Green and ZsGreen both exist as tetramers in the natural state, which significantly interferes with their use as fusion partners and as a FRET donor or acceptor in biosensors. To overcome the oligomerization problem, site-directed and random mutagenesis efforts were successful in creating a monomeric version of Azami Green, but this type of effort has not been reported for ZsGreen although the protein has been re-engineered with human codons to optimize expression (resulting in a variant termed ZsGreen1). Because reliable photostability data is lacking, it is unclear whether either of these proteins will outperform EGFP in long-term imaging experiments.

The sea pansy, an Anthozoan soft coral, is the source of several green fluorescent proteins that have been characterized in detail and are now commercially available (Cormier and Eckroade, 1962; Morin and Hastings, 1971b Miyawaki, 2002). A protein isolated from *Renilla reniformis* that exhibits properties similar to EGFP is the best characterized of the probes in this class. Having absorption and emission maxima at 485 and 508 nm, respectively, in addition to a similar sensitivity to pH, the *Renilla* protein would be an excellent substitute for EGFP were it not for the fact that it is an obligate dimer (Ward, 2006). Aside from the oligomerization problem, *Renilla* GFPs may be useful in many applications and have been expressed in a wide variety of organisms, including bacteria, fungi, and mammalian cells. Versions with human codon sequences are available from the manufacturers, as are derivatives optimized for expression in other species. There is a general lack of reliable data concerning extinction coefficients, quantum yields, and photostability for the commercial *Renilla* proteins, so valid comparisons to EGFP in terms of brightness and photobleaching are not possible.

Yellow Fluorescent Proteins

Yellow fluorescent proteins, as a spectral class, are among the most versatile genetically-encoded probes yet developed. Ranging in emission wavelength maxima from ~525 to 555 nm, those proteins residing in the shorter wavelength region actually appear green, rather than yellow, when viewed in a widefield fluorescence microscope. The first member in what has become a rather large family of probes was rationally engineered after the high-resolution crystal structure of green fluorescent protein revealed that threonine residue 203 (Thr203) was positioned near the chromophore and potentially able to alter the spectral characteristics upon substitution (Ormö et al., 1996; Rizzo and Piston, 2005a). Mutations of this aliphatic amino acid to several aromatic moieties were introduced in order to induce π-orbital stacking and attempt stabilization of the excited state dipole moment of the chromophore. The most successful mutant

proved to be tyrosine (T203Y; termed mutant 10C, the original YFP), which resulted in almost a 20-nm shift to longer wavelengths for both the excitation and emission spectra (Ormö et al., 1996; Tsien, 1998; Wachter et al., 1998). Several YFP variants were initially constructed in attempts to maximize brightness as well as to increase the speed of maturation and optimize expression at 37°C (Tsien, 1998; Cubitt et al., 1999). One of these variants, named Topaz, has been of service in fusion tag localization, intracellular signaling, and FRET investigations (Tavaré et al., 2001; Cornea and Conn, 2002; Sturman et al., 2006).

In an effort to improve the performance of FRET biosensors, further sequence refinements led to the development of the enhanced yellow fluorescent protein (EYFP), which is one of the brightest and most widely utilized fluorescent proteins (Miyawaki et al., 1999; Miyawaki, 2005; Shaner et al., 2005). EYFP was constructed from the original yellow variant by introduction of lysine to position 69 in place of glutamine (Q69K). The high brightness level and fluorescence emission spectrum wavelength profile of EYFP combine to make this probe an excellent candidate for multicolor imaging experiments in fluorescence microscopy, although maturation is slower, especially in organelles. Enhanced yellow fluorescent protein has also been widely employed as an acceptor for energy transfer experiments when paired with enhanced cyan fluorescent protein. However, all of the original yellow fluorescent protein variants present some problems in that they are very sensitive to acidic pH and lose ~50% of their fluorescence at pH 6.5. In addition, most of the *Aequorea*-derived proteins in this class have also been demonstrated to have significant sensitivity to chloride ions, undergo weak dimerization, exhibit relatively poor expression at 37°C, and photobleach much more readily than many of the green fluorescent proteins. Several investigations have taken advantage of the environmental sensitivity of YFP to measure cytosolic pH (Llopis et al., 1998), chloride ion concentrations (Jayaraman et al., 2000; Kuner and Augustine, 2000), and FRET efficiency (Llopis et al., 2000). The A206K mutation, substituting the charged amino acid lysine for alanine at the hydrophobic dimer interface, has been applied to YFP (Zacharias et al., 2002) in order to generate a true monomer.

Continued genetic development of the YFP family (Griesbeck et al., 2001) led to the discovery that a single point mutation near the chromophore, the substitution of methionine for glutamine at position 69 (Q69M), dramatically increases the acid stability of the protein and reduces the chloride sensitivity. Named Citrine in recognition of the yellow color and acid resistance, this variant also expresses at a much higher level in mammalian cell culture (especially when targeted to acidic organelles) and demonstrates almost twice the photostability of many previous yellow fluorescent proteins. Citrine features absorption and fluorescence emission maxima at 516 and 529 nm, respectively, and is 75% brighter than EGFP, although much less photostable. FRET biosensors constructed with Citrine demonstrate better performance than sister analogs containing EYFP, and the probe is a better choice for multicolor experiments in general. Although Citrine exists as a weak dimer in solution, the protein can be converted into a monomer with the A206K mutation (Shaner et al., 2005).

Introduction of yet another novel point mutation into *Aequorea*-derived YFP, the substitution of leucine for phenylalanine at position 46 (F46L), produced a variant that was named Venus in honor of the brightest star in the night sky (Nagai et al., 2002). This mutation, which was discovered during random mutagenesis experiments with circularly permuted GFP derivatives, dramatically accelerates oxidation of the chromophore, the rate-limiting step in fluorescent protein maturation. Additional mutations were also introduced in order to increase the tolerance of Venus to acidic environments and to reduce the sensitivity to chloride. The absorption and emission spectral peaks (515 and 528 nm, respectively) of Venus are shifted to longer wavelengths by a single nanometer compared to EYFP, but the brightness level is retained. Unfortunately, the photostability of Venus is only ~25% that of EYFP, a significant problem for long-term imaging experiments. Venus has been demonstrated to perform well in intracellular organelle fusion protein pH assays (Tsuboi and Rutter, 2003), for localization studies in yeast (Sheff and Thorn, 2004), in bimolecular fluorescence complementation analysis (Shyu et al., 2006), and holds significant potential as an acceptor in FRET biosensors (Nagai and Miyawaki, 2004; Sheridan and Hughes, 2004). Genetic conversion of the weakly dimeric Venus into a monomer using the A206K mutation will further expand the use of this probe in biological investigations (Rizzo and Piston, 2005b).

During the same fluorescence-activated cell sorting investigation that led to the generation

of the cyan fluorescent protein CyPet (Nguyen and Daugherty, 2005), the evolutionary optimized complementary FRET acceptor, termed YPet (YFP for energy transfer), was also obtained from Venus and YFP variants. Named after its proficiency in FRET, YPet is the brightest yellow fluorescent protein variant yet developed and demonstrates very good photostability. The resistance to acidic environments afforded by YPet is superior to Venus and other YFP derivatives, which will enhance the utility of this probe in biosensor combinations targeted at acidic organelles. However, although the optimized CyPet-YPet combination should be the preferred starting point in the development of new FRET biosensors, the utility of this pair has not yet been tested in widespread practice (Shaner et al., 2005). Likewise, the suitability of CyPet and YPet in fusion tags for localization experiments, bimolecular complementation analysis, and other routine fluorescent protein assays has yet to be established. Both proteins exist in solution as weak dimers, but presumably can be converted to true monomers using the A206K mutation that has worked so well with other *Aequorea* variants.

Although the potential for new discoveries of yellow and green fluorescent proteins in Hydrozoan species other than *Aequorea victoria* is significant, only one candidate has surfaced so far. Isolated from the *Phialidium* jellyfish, a protein termed phiYFP (Shagin et al., 2004) is reported to demonstrate very bright yellow fluorescence (absorption and emission at 525 and 537 nm, respectively) and to be useful for N-terminal fusion tags. An extraordinary feature of phiYFP is that the naturally occurring protein contains the same mutation at position 64 (leucine) that was introduced by Venus to increase the folding efficiency (Nagai et al., 2002). The probe also naturally contains tyrosine at position 203 (Ormö et al., 1996), another site-directed modification of the native GFP that resulted in yellow fluorescence. This remarkable discovery of a natural similarity between the structure of phiYFP and genetically modified *Aequorea* proteins is a testament to the efficacy of protein engineering efforts directed at GFP to adjust the spectral properties. The phiYFP protein has been optimized by random mutagenesis to produce a monomeric version without compromising the spectral properties.

Site-directed and random mutagenesis of a monomeric Anthozoan fluorescent protein (mRFP1) from *Discosoma* have resulted in the creation of two monomeric coral reef derivatives with spectral properties falling in the range of *Aequorea* yellow fluorescent proteins (Shaner et al., 2004). Named after similarly colored fruits, mHoneydew and mBanana both emit fluorescence in the yellow spectral region. The broad absorption band of mHoneydew (peaks at 487 and 504 nm) enables effective excitation with an argon-ion laser or standard FITC filter combination. However, the similarly broad emission spectrum (peaks at 537 and 562 nm) tails into the near-infrared, hampering the use of this protein in multicolor experiments. In addition, a low extinction coefficient and quantum yield render mHoneydew the dimmest member of the monomeric yellow fluorescent protein cadre. The mBanana variant is only twice as bright as mHoneydew, but features much narrower excitation and emission spectra (peaks at 540 and 553 nm, respectively). Because both proteins exhibit relatively poor photostability, and mBanana is highly pH-sensitive, neither will probably find great utility in imaging experiments. Perhaps the most promising aspect of these probes is that the mere existence of mHoneydew (a cyan-type Y67W mutant) demonstrates that the tryptophan-based chromophore of CFP can undergo a further maturation into a longer-wavelength emitting species (Shaner et al., 2004).

ZsYellow (originally referred to as zFP538) is a yellow fluorescent protein that was discovered in the Anthozoan button polyp *Zoanthus* during a search in reef corals for naturally occurring GFP analogs emitting fluorescence in longer wavelength regions (Matz et al., 1999; Gurskaya et al., 2001b Yanushevich et al., 2002). One of the most unique features of the ZsYellow fluorescence emission spectrum is that the peak (538 nm) occurs almost midway between those of EGFP (508 nm) and DsRed (583 nm), presenting an opportunity to investigate proteins emitting fluorescence in the yellow portion of the visible light spectrum. The ZsYellow fluorescent protein chromophore features a novel three-ring system and peptide backbone cleavage due to the substitution of lysine for serine as the first amino acid residue in the chromophore tripeptide sequence (Zagranichny et al., 2004; Remington et al., 2005;). As a result of the unique chromophore motif, the degree of conjugation observed in ZsYellow is intermediate between that observed with EGFP and DsRed (one double bond more than EGFP, and one less than DsRed), which accounts for the positioning

of emission wavelengths in the yellow region. ZsYellow exhibits a marked tendency to form tetramers when expressed in vivo, hampering the use of this protein as a fusion partner for localization investigations. Furthermore, the reduced brightness level of ZsYellow when compared to enhanced green fluorescent protein (25% of EGFP) also limits the utility of this reporter in fluorescence microscopy (the human codon-optimized version is commercially available as ZsYellow1). The unique emission spectral profile of ZsYellow, however, should encourage the search for genetic modifications that alleviate the tendency to form tetramers while simultaneously increasing the quantum yield and extinction coefficient, an effort that could ultimately yield a high-performance monomeric yellow fluorescent protein.

Orange Fluorescent Proteins

In contrast to the relatively large number of fluorescent proteins engineered in the cyan, green, and yellow spectral classes, only three probes have been developed so far in the orange portion of the spectrum (ranging from ~555 to 580 nm). Even so, all three of the existing orange fluorescent proteins, which were isolated from coral reef species, have the potential to be useful in a variety of imaging scenarios. Perhaps the most versatile of these is monomeric Kusabira Orange (Karasawa et al., 2004), a protein originally derived as a tetramer from the mushroom coral *Fungia concinna* (known in Japanese as Kusabira-Ishi). Kusabira Orange was engineered by site-specific mutagenesis from a cDNA clone of the coral by adding ten amino acids to the N terminus. The resulting protein has an absorption maximum at 548 nm (ideal for excitation with a 543-nm laser) and emits bright orange fluorescence at 561 nm. A monomeric version of Kusabira Orange (abbreviated mKO) was created using a strategy similar to that employed for DsRed to create mRFP1 (discussed in the section on red fluorescent proteins) by introducing over 20 mutations through site-directed and random mutagenesis. The monomer exhibits similar spectral properties to the tetramer and has a brightness value similar to EGFP, but is slightly more sensitive to acidic environments. The photostability of this probe, however, is the best of any fluorescent protein in all of the spectral classes, making mKO an excellent choice for long-term imaging experiments. Furthermore, the emission spectral profile is sufficiently well separated from cyan fluorescent proteins to increase the FRET efficiency in biosensors incorporating mKO, and the probe is useful in multicolor investigations (see Figure 21.5.4) with a combination of cyan, green, yellow, and red fluorescent proteins.

The mRFP1 derivative, mOrange (Shaner et al., 2004), was derived after four rounds of directed evolution to yield a probe absorbing at 548 nm and emitting orange fluorescence at 562 nm. The mOrange variant is slightly brighter than mKusabira Orange, but has <10% the photostability, thus severely compromising its application for experiments that require repeated imaging. However, mOrange remains the brightest protein in the orange spectral class and is still an excellent choice where intensity is more critical than long-term photostability. In addition, combined with the green-emitting T-Sapphire, mOrange is a suitable alternative to CFP-YFP proteins as a FRET pair to generate longer wavelength biosensors, and can be coupled with fluorescent proteins in other spectral regions for multicolor investigations. A novel orange fluorescent protein isolated from the *Cerianthus* tube anemone (Ip et al., 2004) is commercially available (trade name cOFP; Stratagene) and has spectral properties that are similar to mOrange and mKusabira Orange, but like the other anemone proteins isolated to date, exists in solution as a tetramer. The brightness and photostability of cOFP have not been reported so this protein cannot be directly compared to other orange fluorescent proteins, and its utility will be further limited until it can be converted into a monomer.

Red Fluorescent Proteins

The quest for a well-behaved red-emitting fluorescent protein has long been the holy grail of live-cell imaging. This is primarily due to the requirement for probes in this spectral region in multicolor imaging experiments, as well as the fact that longer excitation wavelengths generate less phototoxicity and can probe deeper into biological tissue. As an added convenience, most of the proteins in the red region of the visible spectrum can be imaged with the common TRITC and Texas Red widefield fluorescence filter sets, as well as cheap helium-neon (543, 561, 594, and 633 nm) lasers in confocal microscopy. After five years of unsuccessful mutagenesis efforts in the *Aequorea* GFP-derived proteins (Tsien, 1998), the first real breakthrough occurred with the discovery of potentially fluorescent chromoproteins in nonbioluminescent Anthozoa coral species (Matz et al., 1999). To

date, a wide spectrum of potentially useful red fluorescent proteins has been reported (spanning the emission wavelength range of 580 to 630 nm), many of which still suffer from some degree of the obligatory quaternary structure bestowed by their species of origin (Verkhusha and Lukyanov, 2004; Chudakov et al., 2005; Miyawaki, 2005; Shaner et al., 2005). Unlike the jellyfish proteins, most of the native and genetically engineered variants of coral reef proteins mature very efficiently at 37°C, presumably due to differing water temperatures of their respective habitats (Chudakov et al., 2005; Miyawaki et al., 2005).

The first Anthozoa-derived fluorescent protein to be extensively investigated was derived from the sea anemone *Discosoma striata* and originally referred to as drFP583, but is now commonly known as DsRed (Matz et al., 1999). Once the protein has fully matured, the fluorescence emission spectrum of DsRed features a peak at 583 nm, whereas the excitation spectrum has a major peak at 558 nm and a minor peak around 500 nm. Several problems are associated with DsRed in practice. Maturation of DsRed fluorescence occurs slowly and proceeds through an intermediate chromophore stage where a majority of the fluorescence emission is seen in the green region (Baird et al., 2000). Termed the "green state," this artifact has proven challenging for multiple labeling experiments in combination with other green fluorescent proteins because of the spectral overlap. In addition, DsRed is an obligate tetramer, an undesirable characteristic that interferes in fusion protein constructs, often leading to poor localization, and increases the tendency to form large protein aggregates in living cells. Although these side effects are not important when the probe is utilized simply as a reporter for gene expression, the utility of DsRed as an epitope tag is severely compromised (Rizzo and Piston, 2005a). In contrast to the large *Aequorea* family of proteins that have been employed to successfully tag hundreds of fusion proteins, DsRed fusion proteins have proven far less successful and often exhibit toxic effects.

Several of the major problems with DsRed fluorescent protein have been overcome through site-directed and random mutagenesis efforts. The second-generation version of DsRed, known as DsRed2, contains a series of silent nucleotide substitutions corresponding to human codon preferences and several internal sequence mutations that increase the maturation rate (Bevis and Glick, 2002). In addition, the elimination of basic amino acid residues (changed to acidic or neutral moieties) at the peptide amino terminus in DsRed2 reduces the tendency of the protein to form aggregates in fusion constructs (Yanushevich et al., 2002). The DsRed2 protein still forms a tetramer in solution, but it is more compatible with green fluorescent proteins in multiple labeling experiments due to the increased maturation rate (Rizzo and Piston 2005a). Further reductions in maturation time have been realized with the third generation of DsRed mutants, which also display an increased brightness level in terms of peak cellular fluorescence. Red fluorescence emission from DsRed-Express (a commercial vector from Clontech) can be observed within an hour after expression, as compared to ~6 hr for DsRed2 and 11 hr for DsRed (Bevis and Glick, 2002; Rizzo and Piston, 2005a). The presence of a green state in DsRed-Express is not apparent, rendering this fluorescent protein the best choice of tetrameric DsRed variants for multiple labeling experiments. Because these probes remain obligate tetramers, however, they have largely been replaced with dimeric and monomeric versions and are now only of historical interest. A commercially available monomeric version of DsRed (Clontech) has recently been introduced, but the intrinsic brightness and photostability of this probe are reported to be poor (Shaner et al., 2005).

Several additional red fluorescent proteins showing a considerable amount of promise have been isolated from the reef coral organisms. One of the first to be adapted for mammalian cell applications is HcRed1 (Gurskaya et al., 2001a), which was isolated from the anemone *Heteractis crispa* and is now commercially available (Clontech and Evrogen). HcRed1 was originally derived from a nonfluorescent chromoprotein that absorbs orange light through site-directed and random mutagenesis. A total of six amino acid substitutions were necessary to create a red fluorescent species that matured rapidly and efficiently at 37°C (absorption and emission at 588 and 618 nm, respectively). However, similar to many other reef coral proteins, the resulting red fluorescent HcRed displays a tendency to form obligate tetramers when expressed in bacteria. Additional mutagenesis efforts resulted in a brighter dimeric variant (Gurskaya et al., 2001a), but a monomeric version of the protein has not yet been discovered. In order to generate a species of the protein that is useful in creating fusion products for localization

studies, a tandem dimer expression vector of HcRed (two head-to-tail identical copies of the protein) has been constructed (Fradkov et al., 2002). When fused to a gene product that itself forms biopolymers (such as actin or tubulin), the HcRed tandem dimer forms an intramolecular self-association complex (mimicking a monomeric tag) that apparently does not interfere with the biological activity of the resulting chimera. However, because the overall brightness and photostability of this twinned protein combination has not yet been improved, it remains a secondary choice for routine applications in live-cell microscopy.

A far-red fluorescent protein, termed eqFP611, was isolated from the sea anemone *Entacmaea quadricolor* and displays one of the largest Stokes shifts and red-shifted fluorescence emission wavelength profiles (excitation and emission maxima at 559 and 611 nm, respectively) of any naturally occurring Anthozoan fluorescent protein (Wiedenmann et al., 2002). The quantum yield and extinction coefficient of eqFP611 combine to yield a probe approximately as bright as EGFP. During the in vivo fluorophore maturation process, which occurs in ~12 hr, the protein passes through a green intermediate state. After maturation, however, only a small fraction of this green species (<1 percent) can be detected. In contrast to other Anthozoan fluorescent proteins, eqFP611 has a reduced tendency to oligomerize at lower concentrations as evidenced through electrophoresis and single-molecule experiments (Schenk et al., 2004), although at high concentrations the protein does form tetramers. Site-directed mutagenesis efforts have yielded functional dimeric variants of eqFP611 (Wiedenmann et al., 2005), and continued efforts may finally lead to a monomeric far-red fluorescent protein from this species.

Two additional reef coral red fluorescent proteins, AsRed2 and JRed, are commercially available (Clontech and Evrogen), but these probes form tetrameric and dimeric complexes, respectively, and are less useful than the monomeric proteins described below. AsRed2 was originally isolated as a chromoprotein from *Anemonia sulcata* (Matz et al., 1999) and modified through mutagenesis to yield a protein having an absorption maximum at 576 nm and an emission peak at 595 nm (Lukyanov et al., 2000) with a very modest quantum yield (0.05). Although the protein has been optimized with human codons for expression in mammalian cell lines, it exhibits only ~10% the brightness level of EGFP and the photostability has not been reported. The dimeric protein, JRed, was derived through extensive mutagenesis of a jellyfish chromoprotein (Shagin et al., 2004) to produce a novel red fluorescent marker with peak absorption and emission wavelengths of 584 and 610 nm, respectively. The probe has been demonstrated to produce useful fusion tags, but is unsuitable for expression in prokaryotes due to folding problems. JRed is ~25% as bright as EGFP and exhibits limited photostability when illuminated in the 560 to 580 nm region, but it can be successfully employed for long-term imaging experiments when excited with a 543-nm laser.

The construction of true monomeric DsRed variants, as well as monomers from proteins in other Anthozoan species, has proven to be a difficult task (Rizzo and Piston, 2005a). A total of 33 amino acid alterations to the DsRed sequence were required for the creation of the first-generation monomeric red fluorescent protein (termed RFP1; Campbell et al., 2002). However, this derivative exhibits significantly reduced fluorescence emission compared to the native protein and photobleaches very quickly, rendering it much less useful than analogous monomeric green and yellow fluorescent proteins. Extensive mutagenesis research efforts (Shaner et al., 2004), including novel techniques such as iterative somatic hypermutation (Wang et al., 2004), have successfully been applied in the search for yellow, orange, red, and far-red fluorescent protein variants that further reduce the tendency of these potentially efficacious biological probes to self-associate while simultaneously pushing emission maxima towards longer wavelengths. The result has been improved monomeric fluorescent proteins that feature increased extinction coefficients, quantum yields, and photostability, although no single variant has yet been optimized by all criteria. In addition, the expression problems with obligate tetrameric red fluorescent proteins are being overcome by the efforts to generate true monomeric variants, which have yielded derivatives that are more compatible with biological function.

Perhaps the most spectacular development on this front has been the introduction of a new harvest of fluorescent proteins (Patterson, 2004) derived from monomeric red fluorescent protein (mRFP1) through directed mutagenesis targeting the Q66 and Y67 chromophore residues (Shaner et al., 2004), which have been

demonstrated to play key roles in determining the spectral characteristics in *Aequorea* proteins. The resulting cadre of monomeric fluorescent proteins exhibit maxima at wavelengths ranging from 560 to 610 nm and have been named in honor of common fruits that bear colors similar to their respective fluorescence emission spectral profiles. Among the potentially efficacious members in the fruit series of fluorescent proteins are mStrawberry, mCherry, and tdTomato (a tandem dimer), all of which have fluorescence emission profiles in the orange and red regions of the spectrum. Of these probes, tdTomato, which has an orange-red emission maximum at 581 nm, is the brightest and most photostable under widefield illumination (Shaner et al., 2005), although the dimer is twice the molecular weight of the monomers. The red proteins, mCherry and mStrawberry (emission peaks at 610 and 596 nm, respectively), have brightness levels of ~50% and 75% of EGFP, but mCherry is far more photostable than mStrawberry and is the best probe choice to replace mRFP1 for long-term imaging experiments. These new proteins essentially fill the gap between the most red-shifted jellyfish fluorescent proteins (such as Venus) and the multitude of oligomeric coral reef red fluorescent proteins that have been reported and are commercially available. Although several of these new fluorescent monomeric proteins lack the brightness and photostability necessary for many imaging experiments (Shaner et al., 2005; Tsien, 2005), their existence is encouraging as it suggests the eventuality of bright, stable, monomeric fluorescent proteins across the entire visible spectrum.

Far-Red Fluorescent Proteins

Further extension of the fruit protein spectral class through iterative somatic hypermutation (Wang et al., 2004) has yielded two new fluorescent proteins with emission wavelength maxima of 625 and 649 nm, representing the first true far-red (ranging from 630 to 700 nm) genetically engineered probes. The most potentially useful probe in this pair was named mPlum, which has a rather limited brightness value (10% of EGFP), but excellent photostability. This monomeric probe should be useful in combination with fluorescent proteins emitting in the cyan, green, yellow, and orange regions for multicolor imaging experiments (see Figure 21.5.4) and as a biosensor FRET partner with green and yellow proteins, such as mEmerald (Förster distance, 4.4) and mCitrine (Förster distance, 5.0). Another far-red fluorescent protein, termed AQ143, has been derived from mutagenesis efforts on a chromoprotein isolated from the anemone *Actinia equine* (Shkrob et al., 2005). The excitation and emission maxima of AQ143 are 595 and 655 nm, respectively, and the brightness is comparable to mPlum. On the downside, the photostability of this protein has not been reported and it forms an obligate tetramer.

OPTICAL HIGHLIGHTER FLUORESCENT PROTEINS

Protein chromophores that can be activated to initiate fluorescence emission from a quiescent state (a process known as photoactivation), or are capable of being optically converted from one fluorescence emission bandwidth to another (photoconversion), represent perhaps the most promising approach to the in vivo investigation of protein lifetimes, transport, and turnover rates. Appropriately termed molecular or optical highlighters, photoactivated fluorescent proteins generally display little or no initial fluorescence under excitation at the imaging wavelength, but dramatically increase their fluorescence intensity after activation by irradiation at a different (usually lower) wavelength (for reviews see: Lippincott-Schwartz et al., 2003; Miyawaki, 2004; Lukyanov et al., 2005). Photoconversion optical highlighters, on the other hand, undergo a change in the fluorescence emission bandwidth profile upon optically-induced changes to the chromophore. These effects result in the direct and controlled highlighting of distinct molecular pools within the cell (see Fig. 21.5.5). Because only the limited population of photoactivated molecules exhibit noticeable fluorescence, their lifetime and behavior can be followed independently of other proteins that are newly synthesized. In a similar manner, fluorescent proteins that are capable of being optically modulated through photoconversion to reversibly alter emission intensity and/or color are also potentially very useful for examining dynamic processes in living cells.

The ideal optical highlighter proteins should be readily photoconvertible (through the process of fluorescence activation and/or emission wavelength shifts) to produce a high level of contrast, as well as being monomeric for optimum expression in the target system. These probes will be especially useful in experiments paralleling results obtained with photobleaching techniques, such as recovery (FRAP) and loss (FLIP) of photobleaching,

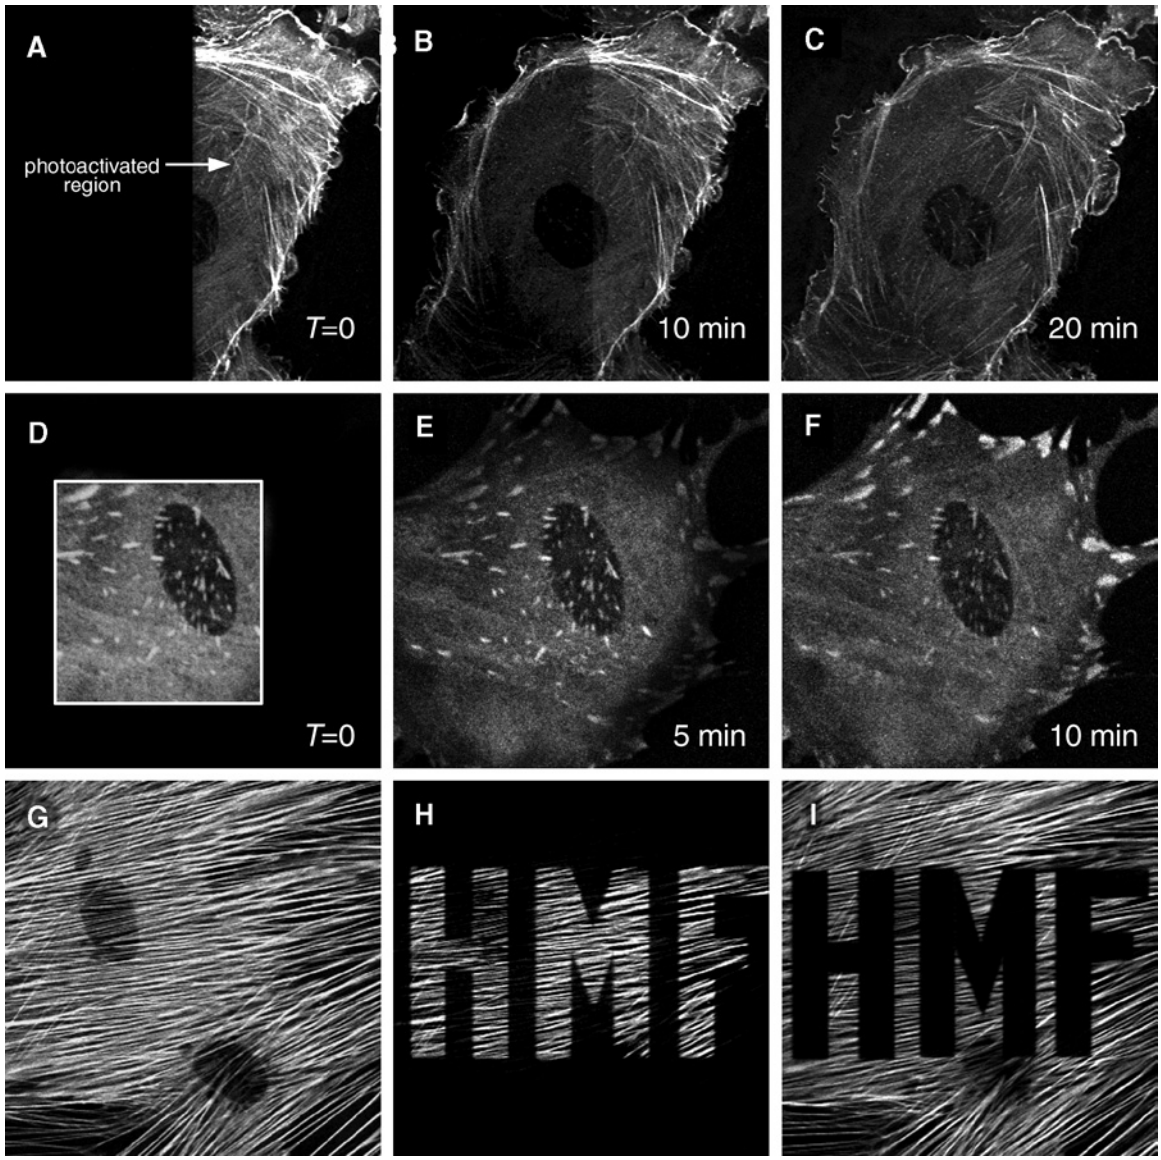

Figure 21.5.5 Photoactivation, photoconversion, and photoswitching with optical highlighter fluorescent proteins. (**A**) to (**C**) PA-GFP fused to human β-actin expressed in an epithelial cell is illuminated at high intensity with a 405-nm diode laser in the right-hand portion of (**A**) to photoactivate the protein, which is slowly distributed across the filamentous network (**B**) and (**C**) over a period of 20 min. (**D**) to (**F**) A fusion tag containing EosFP and vinculin is localized to the focal adhesion regions in a fibroblast cell. After photoconversion of fluorescence from green to red in a selected region (**D**); only the red channel is illustrated, the converted highlighter diffuses through the cytoplasmic pool slowly making its way to the focal adhesion areas over a period of 10 min (**E**) and (**F**). (**G**) to (**I**) Photoswitching of Dronpa fused to human β-actin in a fibroblast. (**G**) Image of the actin cytoskeletal network with a 488-nm laser. (**H**) An AOTF was used to spell the letters "HMF" and the labeled molecules within the letters were photoswitched to the "on" state using a 405-nm diode laser after photoswitching molecules outside to the "off" state with a 488-nm laser. (**I**) Molecules inside the letters were photobleached with the 405-nm laser while imaging exterior molecules with the 488-nm laser.

because they have the advantage that measurements are not influenced by newly synthesized or non-converted proteins, which either remain invisible or continue to emit the original wavelengths (Lippincott-Schwartz et al., 2003). Also, by repeated excitation in the region of interest, optical highlighters can be continuously photoconverted at a specific intracellular location. This technique is more efficient than FLIP because the translocation of activated proteins can be directly imaged. In addition, the time required for photoactivation (a few seconds) is often much less than the time required to completely photobleach a similar region. Investigations involving extremely rapid cellular processes will clearly benefit from such improvements in temporal resolution. Presented in Table 21.5.2 is a compilation of important data for optical highlighter fluorescent proteins that display significant potential in applications as in vivo probes targeting cellular structure and function. Included are the excitation (or absorption) and fluorescence emission maximum wavelengths for both the activated and nonactivated species, as well as the molar extinction coefficients, quantum yields, molecular structure (monomer, dimer, tetramer, etc.), and relative brightness level compared to enhanced green fluorescent protein (EGFP). Also listed are references to the original literature sources and review articles. This table should serve as a convenient guide for comparing the properties of optical highlighters.

The first useful optical highlighter designed specifically for photoactivation studies is a variant of the jellyfish (*Aequorea victoria*) green fluorescent protein, termed PA-GFP (an acronym for Photo Activatable Green Fluorescent Protein). This photoactivatable version of GFP was developed by improving on the photoconversion efficiency of the natural wild-type protein chromophore from a predominately neutral form to a species that is anionic in character (Patterson and Lippincott-Schwartz, 2002a,b; Lippincott-Schwartz and Patterson, 2003). Substitution of histidine for threonine at position 203 produced a variant with negligible absorbance in the region between 450 and 550 nm, thus dramatically enhancing the contrast between the nonactivated and activated species. After photoactivation with violet light, the absorption maximum at 504 nm in PA-GFP increases ~100-fold. This event evokes very high contrast differences between the converted and unconverted pools of PA-GFP, and is useful for tracking the dynamics of molecular subpopulations within a cell. Note that after photoactivation, both PA-GFP and the wild-type GFP exhibit comparable levels of fluorescence when illuminated with a 488-nm laser. On the downside, intracellular targets expressing PA-GFP are not readily distinguishable before photoconversion without the use of a low-intensity violet illumination source (such as a 405-nanometer blue diode laser), making it difficult to identify the proper regions to be selectively targeted in photoactivation experiments using microscopes having only blue and green lasers.

Several new photoactivatable proteins have been produced using site-directed mutagenesis of monomeric red-shifted reef coral fluorescent proteins. In particular, the monomeric derivative of DsRed fluorescent protein, mRFP1, has been converted into probes that are photoactivated by either green or violet irradiation (Verkhusha and Sorkin, 2005). These have been collectively termed PA-mRFP1s, the brightest of which exhibits a 70-fold increase of fluorescence intensity upon activation by wavelengths between 380 and 400 nm. The critical molecular determinant residues for producing photoactivatable proteins with coral reef variants appear to be the amino acids at positions 146, 161, and 197 (DsRed numbering scheme). These residues, which lay in close proximity to the chromophore, serve to stabilize the tyrosine residue at position 66 in either a *cis* (fluorescent) or *trans* (nonfluorescent) configuration to form a fluorescent protein (*cis*) or a chromoprotein (*trans*) that absorbs light but does not emit fluorescence. The monomeric red fluorescent protein optical highlighters have been demonstrated to be useful in some cases as a fusion tag in mammalian systems for investigation of intracellular dynamics. However, the relatively low level of fluorescence of PA-mRFP1s in the photoactivated form (3% of EGFP), along with a tendency to form nonspecific aggregates when fused to naturally oligomeric proteins (for example, actin and tubulin), render these probes less useful than PA-GFP for live-cell investigations (Verkhusha and Sorkin, 2005). Improved monomeric yellow, orange, and red fluorescent proteins (such as mCherry, mStrawberry, and mPlum) hold the potential to produce efficient photoactivatable optical highlighters with emission wavelengths extending into the deep red portion of the visible light spectrum.

A novel photoconversion optical highlighter, termed photoswitchable cyan fluorescent protein (PS-CFP), derived from the *Aequorea coerulescens* green fluorescent protein

Table 21.5.2 Fluorescent Proteins that Have Potential as In Vivo Probes[a]

Protein(Acronym)	Ex (nm)	Em (nm)	EC × 10^{-3}	QY	in vivo Structure	Relative Brightness (% of EGFP)	References
PA-GFP (G/NA)	400	515	20.7	0.13	Monomer	8	Patterson and Lippincott-Schwartz, 2002a

[a]A compilation of important data for fluorescent proteins that display significant potential in applications as in vivo probes targeting cellular structure and function.

variant, aceGFP, has been observed to transition from cyan (468 nm) to green fluorescence (511 nm) upon illumination at 405 nm. The PS-CFP highlighter was generated by site-directed mutagenesis of aceGFP (Chudakov et al., 2004). Expressed as a monomer in vivo, this probe should be useful in photobleaching, photoconversion, and photoactivation investigations because it can potentially be fused to a wide variety of proteins without altering their behavior. Another advantage of PS-CFP is the significant level of cyan fluorescence that is present before photoconversion, a factor that allows investigators to track and selectively illuminate specific intracellular regions or entire cells for study. However, the fluorescence emission intensity from PS-CFP is ~2.5-fold dimmer than PA-GFP, and the probe is inferior

to other highlighters in terms of photoconversion efficiency (the 40-nm wavelength shift in fluorescence emission upon photoconversion is less than that observed with similar optical highlighters). A high-contrast, brighter variant of PS-CFP, designated PS-CFP2, is commercially available (Evrogen) as a cloning vector.

Several interesting and potentially useful optical highlighters have been developed in fluorescent proteins cloned from reef coral and sea anemone species. One of the first and most important examples, a tetrameric fluorescent protein isolated from the stony Open Brain coral, *Trachyphyllia geoffroyi*, has been found to photoconvert from green to red fluorescence emission in the presence of ultraviolet light (Ando et al., 2002). It is interesting to note that the discovery of this highlighter occurred when researchers accidentally left a test tube containing the protein on a laboratory bench near a window, and then astutely observed the shift from green to red. The unusual color transition prompted investigators to name the protein Kaede, after the leaves of the Japanese maple tree, which turn from green to red in the fall months. Irradiation of the commercially available (MBL) Kaede optical highlighter with light between 380 and 400 nm results in a rapid spectral shift from principal maxima at 508 nm (absorption) and 518 nm (emission) to longer wavelength peaks at 572 and 582 nm, respectively. Upon photoconversion, Kaede exhibits a dramatic increase in the red-to-green fluorescence ratio (~2000-fold, considering both the decrease in green and the increase in red emission). The conversion is stable and irreversible under aerobic conditions. Neither exposure to dark for extended periods nor strong illumination at 570 nm is able to restore green fluorescence to the chromophore. The red fluorescent state of the Kaede chromophore is comparable to the green in terms of brightness and stability, and because the unconverted protein emits very little fluorescence above 550 nm, the appearance of strong red signal provides excellent contrast.

Similar proteins capable of being photoconverted by violet and ultraviolet illumination have been discovered in the Great Star coral (mcavRFP; derived from *Montastraea cavernosa*; Shagin et al., 2004), soft corals (DendFP; derived from members of the genus *Dendronephthya*; Pakhomov et al., 2004), and the mushroom coral (rfloRFP; derived from *Ricordea florida*; Shagin et al., 2004). All of these highlighters (including Kaede, Eos, and KikGR, discussed below) contain a chromophore derived from the tripeptide His-Tyr-Gly that initially emits green fluorescence until driven into a red state by light rather than chemical oxidation, as is the case with many red fluorescent proteins derived from reef corals. These amino acids form the imidazolinone chromophore (similar to the *Aequorea* proteins) that is transformed from green to red fluorescence emission under illumination at shorter visible and longer ultraviolet wavelengths. Irradiation induces cleavage between the amide nitrogen and α-carbon atoms in the histidine residue with subsequent formation of a highly conjugated dual imidazole ring system, a process requiring catalysis by the intact protein and resulting in the dramatic shift of fluorescence emission to red wavelengths (Mizuno et al., 2003; Nienhaus et al., 2005). The unconventional chemistry involved in this chromophore transition should serve fluorescent protein engineers with an excellent foundation upon which to develop more advanced highlighters.

The stony coral *Favia favus* has yielded a promising tetrameric derivative that exhibits efficient photoconversion from green to red fluorescence emission wavelengths (similar to Kaede) upon irradiation with near-ultraviolet or violet light (Tsutsui et al., 2005). Genetic engineering efforts based on structural analysis of this protein produced a variant, termed KikGR (named after Kikume-ishi, the Japanese term for *Favia*), which is several-fold brighter than Kaede in both the green and red states when expressed in mammalian cells. Commercially available (MBL) under the name Kikume Green-Red, the highlighter has been demonstrated to be successfully photoconverted using multiphoton excitation at 760 nm, which can be used for specific labeling of cells with high spatial resolution in thick tissues. Furthermore, the Kikume highlighter features a wider separation of green and red emission maxima (75 nm vs. 54 nm) than Kaede.

Another tetrameric stony coral (*Lobophyllia hemprichii*) fluorescent protein similar to Kaede, termed EosFP (named after the goddess of dawn in Greek mythology), emits bright green fluorescence at 516 nm that shifts to orange-red (581 nm) when illuminated with light at wavelengths in the near-ultraviolet region of 390 to 405 nm (Wiedenmann et al., 2004). Two single point mutations have been employed to split the wild-type tetramer into dimeric subunits, each of which is capable of being incorporated into functional fusion constructs with a variety of proteins that retain

normal biological activity. By introducing a combination of both single point mutations into the wild-type EosFP tetramer, a true monomeric protein has been created that is referred to as mEosFP. Similar to the dimer subunits, the monomer is able to be incorporated into functional biological chimeras to serve as a marker in live-cell imaging (Ivanchenko et al., 2005), although the monomer fusions are only efficiently expressed at temperatures below 30°C (limiting their applications in mammalian systems). Fluorescence spectroscopy of Eos indicates a pH dependence on photoconversion, suggesting that the protonated form of the chromophore is necessary for activation, which is consistent with an excited-state proton transfer mechanism.

Recently, an additional highlighter that undergoes green-to-red photoconversion has been isolated from the soft coral *Dendronephthya* and named Dendra (an acronym derived from the first four letters of the genus name, *Dend*, and *r*ed *a*ctivatable). Originally isolated as a tetramer, Dendra was converted into a true monomer through site-directed mutagenesis to yield a green fluorescent probe that can be photoconverted into a red species using either ultraviolet or blue light (Gurskaya et al., 2006). Upon photoconversion, Dendra exhibits up to a 4000-fold increase in red fluorescence and demonstrates remarkable photostability. Unlike many of the *Aequorea* protein variants, maturation of the Dendra green chromophore is very efficient over a wide temperature range, from 20°C to 37°C. A commercial version, Dendra 2 (see Table 21.5.2), contains the substitution of a single amino acid, valine for alanine, at position 224 (A224V), which leads to more complete maturation and brighter fluorescence both before and after photoconversion. The ability to photoconvert Dendra using a 488-nm laser at high intensity is distinctive in that other green-to-red optical highlighters require more phototoxic ultraviolet or violet (405-nm) light. However, caution should be used when adjusting the laser for imaging Dendra at 488 nm to avoid unwanted photoconversion.

The unique green-to-red optical highlighters discovered thus far in reef coral proteins certainly warrant an aggressive effort focused on solving the problems associated with aggregation, as well as fine-tuning photoactivation requirements and imaging spectral profiles. By engineering a variant that matures rapidly at 37°C, the monomeric Eos protein, which features optical properties very similar to Kaede and KikGR, should be far more useful as an epitope tag due to the dramatically reduced tendency to form intermolecular associations between fusion proteins in vivo. In the future, by engineering optical highlighter proteins that shift photoconversion illumination wavelengths to the blue and green spectral regions, which are significantly less toxic to living cells, coupled with shifts of fluorescence emission to the yellow through far-red wavelength bands, the potential applications for Kaede, KikGR, and Eos derivative probes can be greatly expanded.

A useful non-*Aequorea* optical highlighter, the Kindling fluorescent protein (KFP1) has been developed from a nonfluorescent chromoprotein isolated in *Anemonia sulcata* (Labas et al., 2002; Chudakov et al., 2003), and is now commercially available (Evrogen). Kindling fluorescent protein does not exhibit emission until illuminated with green or yellow light in the region between 525 and 580 nm. Low-intensity light results in transient red fluorescence (kindling) with excitation and emission maxima at 580 and 600 nm, respectively, which slowly decays upon cessation of illumination as the protein relaxes back to its initial non-fluorescent state (exhibiting a half-life of ~50 to 60 sec). Irradiation with intense blue light quenches the kindled fluorescence immediately and completely, allowing tight control over fluorescent labeling. Note that both kindling with low-intensity green light and quenching of fluorescence by blue light are reversible processes for the wild-type protein. In contrast, high-intensity illumination or continued irradiation at moderate levels results in irreversible kindling with a fluorescence intensity ~30-fold greater than that of the nonactivated protein. Irreversibly kindled molecules do not lose their fluorescence and are not quenched by illumination with blue light. This feature allows for stable long-term highlighting of cells, tissues, and organelles similar to PA-GFP and other highlighter proteins. The major drawback of kindling protein is its tendency to aggregate into tetramers, which seriously affects the potential for use as a protein fusion tag without some degree of disturbance to normal biological processes. However, the kindling protein is an excellent candidate for bulk photolabeling and tracking of individual organelles and cells within a large population.

A new generation of specialized optical highlighters with reversible on-off switching capabilities was heralded by the introduction of Dronpa, a monomeric fluorescent protein derived from Pectiniidae, a family of stony reef

corals featuring several members that naturally emit faint fluorescence upon irradiation with ultraviolet light (Ando et al., 2004). Named after a fusion of the ninja term for vanishing (dron) and photoactivation (pa), Dronpa exhibits unusual photochromic behavior due to its ability to toggle fluorescence on and off by illumination with two different excitation wavelengths. Dronpa was engineered using both directed and random mutagenesis to generate a monomeric version of the wild-type oligomeric fluorescent protein having a major absorption maximum at 503 nm and a minor peak at 390 nm at neutral pH. The absorption peak at 503 nm is due to the deprotonated species of the protein, while the smaller peak at 390 nm arises from the protonated form. When irradiated at 488 nm, the fluorescence emission spectral profile of the deprotonated species has a maximum at 518 nm with a relatively high quantum yield of 0.85. In contrast, the protonated form of the protein is almost nonfluorescent. Photoswitching of Dronpa occurs by interconversion between the deprotonated and protonated forms of the optical highlighter (Habuchi et al., 2005). Upon intense irradiation at 488 nm, the protein population is very efficiently driven to the protonated species with a commitment decrease in fluorescence to produce a dim (off) state in which the 390-nm absorption peak predominates. The dim state is readily converted back to the original fluorescent (on) deprotonated state with minimal illumination at 405 nm.

Although photochromism (the ability to switch fluorescence on and off) has been observed in the wild-type and several yellow fluorescent protein variants of *Aequorea victoria* GFP at the single molecule level (Cinelli et al., 2001; McAnaney et al., 2005; Tinnefeld and Sauer, 2005), none have demonstrated this phenomenon when measured in bulk. In these studies, during several minutes of illumination at 488 nm, the molecules produced fluorescence for several seconds, followed by an equally short time interval without emission, followed again by resumption of emission. Termed blinking behavior (Dickson et al., 1997), this on-and-off switching sequence can be repeated a number of times before each green fluorescent protein molecule ultimately reaches a final long-lived nonfluorescent state upon the emission of $\sim 10^6$ photons. The bright state can be recovered by irradiation with violet light (405 nm) for a period of 5 min before re-initiating the sequence by illumination with a 488-nm laser. In this manner, many native green fluorescent protein derivatives display an optically induced switching effect in which each molecule is individually addressable. However, the ability of large Dronpa-tagged molecular ensembles (including organelles and entire cells) to collectively act as an information storage medium with the ability to write, erase, and read information nondestructively, and with high efficiency, is truly unique in the field of fluorescent proteins.

THE FUTURE OF FLUORESCENT PROTEINS

The current thrust of fluorescent protein development is centered on fine-tuning the current palette of blue to yellow fluorescent proteins derived from the *Aequorea victoria* jellyfish, while simultaneously developing monomeric fluorescent proteins emitting in the orange to far-red regions of the visible light spectrum. Progress toward these goals has been substantial, and it is not inconceivable that near-infrared emitting fluorescent proteins loom on the horizon. The latest efforts in jellyfish variants have resulted in new and improved monomeric probes for the cyan, green, and yellow region, while the search for a bright monomeric and fast-maturing red fluorescent protein has yielded a host of excellent candidates spanning the longer wavelengths. Continuing protein engineering of the existing fluorescent proteins coupled with new technologies, such as the application of unnatural amino acids and circular permutation, should further expand the color palette.

The complex interplay of biological roles for an ever-increasing number of fluorescent proteins derived from a wide variety of marine species is only beginning to be understood. Light-induced changes to the autocatalytic chromophores, including photoactivation and photoconversion, may serve as a highly evolved photo-protection mechanism to assist these organisms in the useful dissipation of high-energy sunlight, especially the damaging shorter wavelengths, via the absorption and subsequent fluorescence re-emission of longer and safer wavelengths. In many cases, these remarkable fluorescent proteins display very high photostability and dynamic photo-induced transformation properties, including spectral fine-tuning of donor-acceptor pairs (and even cascades) for resonance energy transfer. The large number of spectral variants already discovered, featuring emission profiles covering the entire visible spectrum, suggests

that the diverse optical and biochemical properties of these proteins will generate a host of new candidates as probes for biological investigations and ensure the continued development of unique genetically engineered fluorescent proteins.

As the development of optical highlighters continues, fluorescent proteins useful for optical marking should evolve towards brighter, monomeric derivatives with high contrast that can be easily photoconverted and display a wide spectrum of emission colors. For example, proteins capable of reversible photoactivation, red-to-green photoconversion, improved expression at elevated temperatures, and derivatives emitting in the far-red or near-infrared regions of the spectrum would be especially useful. Coupled with these advances, microscopes equipped to smoothly transition between illumination modes for fluorescence observation and regional marking will become commonplace in most cell biology laboratories. The combination of photoactivation and photoconversion with advanced fluorescence techniques, such as resonance energy transfer and multiphoton excitation, will enable the study of protein dynamics with greater precision and spatial resolution. Ultimately, these innovations have the potential to achieve significant advancements in the understanding of spatial and temporal dynamics in signal transduction systems.

ABSTRACT

A major advance in the microscopic study of cells and tissues is the introduction of photoactivatable fluorescent proteins, which can specifically mark proteins of interest within a living cell. Fluorescent proteins are now available that allow a pool of molecules to be "turned on" by photoactivation. This unit discusses technical aspects for the general use of photoactivatable fluorescent proteins and introduces some specific applications in the concluding remarks. *Curr. Protoc. Cell Biol.* 38:21.6.1-21.6.10. © 2008 by John Wiley & Sons, Inc.

Keywords: photoactivatable • fluorescent protein • microscopy

INTRODUCTION

Cell biologists rely on the many advances in microscopy methods to study cells and tissues. A major advance is the introduction of photoactivatable fluorescent proteins (PA-FPs), which can specifically mark proteins of interest within a living cell. Fluorescent proteins are now available which allow a pool of molecules to be "turned on" by photoactivation. This unit discusses technical aspects for the general use of photoactivatable fluorescent proteins and introduces some specific applications in the concluding remarks.

BACKGROUND

Photoactivatable fluorescent proteins differ from normal fluorescent proteins in that they exhibit little or no fluorescence at certain excitation and emission wavelengths prior to photoactivation. However, they do retain many of the usual advantages associated with fluorescent proteins. The term "certain wavelengths" is used to avoid confusion about some PA-FPs that are highly fluorescent in their native inactivated states; this fluorescence arises from a different spectral region than that of the protein in its photoactivated state. Proteins from several marine species have been reported, along with several variants and approaches for their use as photoactivatable fluorescent proteins (Lukyanov et al., 2005; Table 21.6.1). For the purpose of a photoactivation protocol, these molecules are categorized in this unit on the basis of their spectral characteristics. Descriptions of their other characteristics that might be of interest for other types of experiments, as well as evidence for the mechanism for photoconversion, are discussed elsewhere (Lukyanov et al., 2005).

Photoactivatable Green Fluorescent Proteins

One of the first PA-FPs resulted from a photo-induced conversion (photoconversion) within the wild-type (wt) green fluorescent protein (GFP; Yokoe and Meyer, 1996). The wt GFP chromophore population exists as neutral phenols when Y66 within the chromophore is protonated and as anionic phenolates when Y66 is deprotonated, and these different populations produce a major absorbance peak at ~397 nm and a minor absorbance peak at 475 nm, respectively. After irradiation at ~400 nm, the absorbance at 475 nm increases, and this leads to an increase in the fluorescence upon excitation at 475 nm. This phenomenon was utilized in developing a GFP mutant with decreased absorbance at 488 nm (compared to wt GEP) that could also undergo photoconversion when irradiated at ~400 nm (Patterson and Lippincott-Schwartz, 2002). The first of these mutants was T203I, which has a mostly neutral phenol chromophore population giving a major absorbance peak at ~400 nm and little absorbance at the common 488-nm laser line used for excitation (Heim et al., 1994; Ehrig et al., 1995). Substitution of the threonine at position 203 on the protein lead to the T203H mutant, finally named PA-GFP (Fig. 21.6.1A), which gave the

[a]The wavelength range for activation can be broad for each protein. The wavelengths listed here are suggestions based on commonly available laser lines.

[b]The wavelengths to the right of Pre represent the major peaks prior to photoactivation; The wavelengths to the right of Post represent the major peaks after photoactivation; absence of Pre wavelengths indicates that the protein is not initially fluorescent (values not published).

[c]Dronpa displays green fluorescence with excitation at 503 nm and emission at 518 nm. Excitation at 490 nm results in loss of absorbance at 503 nm. Upon irradiation at 400 nm, green fluorescence is restored.

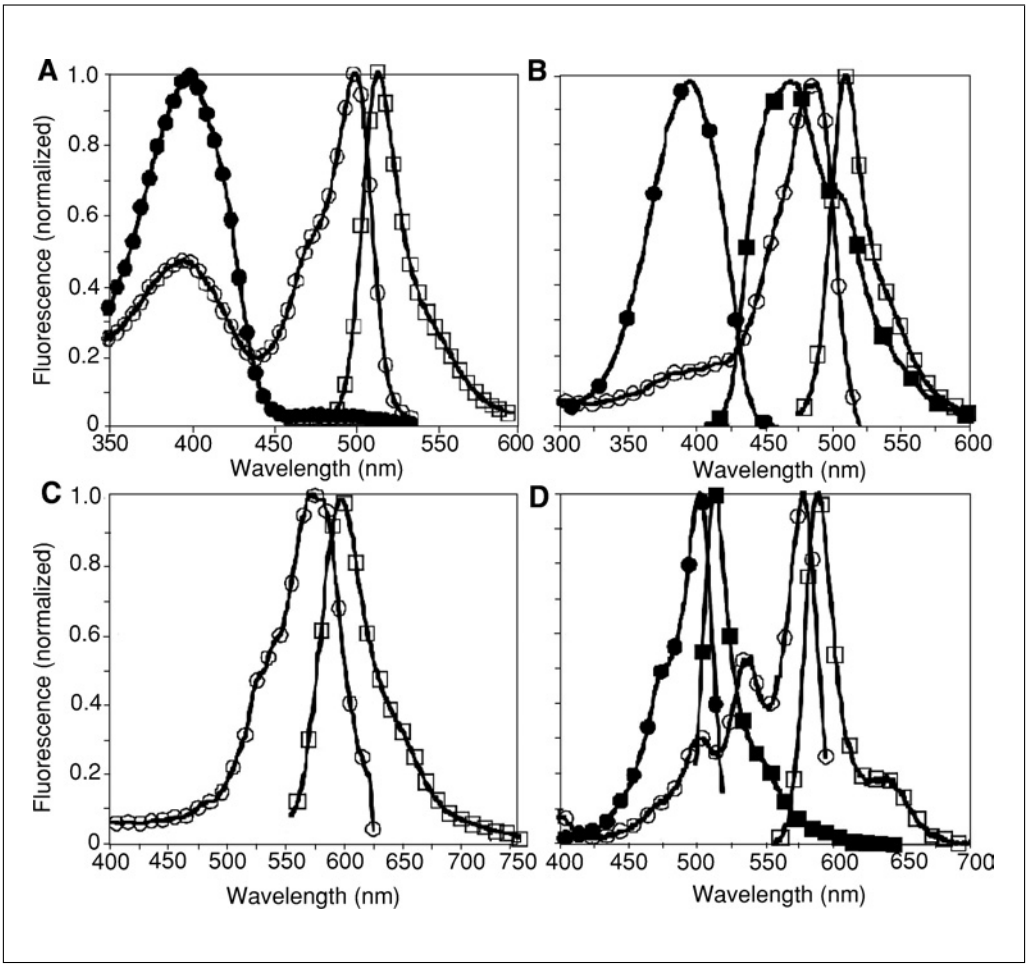

Figure 21.6.1 Fluorescence excitation and emission spectra of selected photoactivatable fluorescent proteins show the diversity that is now available from this class of fluorescent proteins. (**A**) The excitation spectra for PA-GFP are shown prior to (closed circles) and after (open circles) photoactivation. The emission spectrum after photoactivation is shown in open squares. (**B**) The excitation spectra for PS-CFP2 are shown prior to (closed circles) and after (open circles) photoactivation. The emission spectra for PS-CFP2 are shown prior (closed squares) to photoactivation and after (open squares) photoactivation. (**C**) The excitation spectra (open circles) and emission spectrum (open squares) are shown for photoactivated KFP1. (**D**) The excitation spectra for KikGR are shown prior to (closed circles) and after (open circles) photoactivation. The emission spectra for KikGR are shown prior to (closed squares) and after (open squares) photoactivation.

highest fluorescence emission contrast after photoactivation compared to nonphotoactivated protein (Patterson and Lippincott-Schwartz, 2002).

Dronpa is another green PA-FP; it is derived from *Pectimiidae* (Ando et al., 2004). Its spectra resemble those of PA-GFP (Fig. 21.6.1A), except that it has a much higher extinction coefficient and the photoactivation is reversible. Initially, Dronpa displays green fluorescence with excitation at 503 nm and emission at 518 nm. Excitation at 490 nm (0.4 W/cm^2) results in loss of the absorbance at 503 nm and an increase at ~390 nm. However, after irradiation at 400 nm (0.14 W/cm^2), 503-nm absorbance increases and the green fluorescence is restored.

Photoswitchable Green Fluorescent Proteins: Cyan-to-Green

Contrary to the previous examples, photoswitchable-cyan fluorescent protein (PS-CFP) displays a shift of both absorbance and emission from cyan to green fluorescent protein (Chudakov et al., 2004; Fig. 21.6.1B). It exhibits initial excitation at 402 nm and emission at 468 nm (Chudakov et al., 2004) which shift to 490 nm and 511 nm, respectively, and give ~1500-fold increase in the green-to-cyan

fluorescence ratio upon photoactivation at ~400 nm.

Photoactivatable Red Fluorescent Proteins

The monomeric red fluorescent protein, mRFP1 (Campbell et al., 2002), was converted into a series of photoactivatable fluorescent proteins, PAmRFP1-1, PAmRFP1-2, and PAmRFP1-3 by Verkhusha and Sorkin (2005). The brightest, PAmRFP1-1, has little fluorescence before activation and gives ~70-fold increase in red fluorescence upon ~400-nm irradiation (Verkhusha and Sorkin, 2005).

Less well known is asFP595 (emission λ_{max} = 595 nm), a protein isolated from the sea anemone, *Anemonia sulcata*. Its red fluorescence can be enhanced by exposure to green light and quenched by exposure to blue light (Lukyanov et al., 2000). Kindling fluorescent protein (KFP1) is an improved variant of asFP595 (Chudakov et al., 2003). Activation with 532-nm laser light increases its red fluorescence ~30-fold, and it can revert to the inactive state or be stabilized in the photoactivated state, depending on the intensity of the photoactivation light (see Fig. 21.6.1C).

Photoactivatable Green-to-Red Fluorescent Proteins

Many of the naturally occurring and engineered photoactivatable fluorescent proteins exhibit a spectral shift from a green fluorescent protein into a red fluorescent protein (see Fig. 21.6.1D). The first of these to be discovered is Kaede, from a stony coral, *Trachyphyllia geoffroyi* (Ando et al., 2002). Kaede absorbs maximally at 508 nm and emits at 518 nm, is photoactivated by irradiation at ~400 nm, and then exhibits absorbance at 572 nm and emission at 582 nm afterward. Since both the excitation and emission peaks are shifted, ratio imaging results in a >2000 fold increase in the red-to-green ratio. KiKGR is another fluorescent protein from coral that was engineered to undergo green-to-red photoactivation (Tsutsui et al., 2005). Its spectra are shown in Figure 21.6.1D as an example of this group of PA-FPs. EosFP, from another stony coral, *Lobophyllia hemprichii*, also exhibits a green-to-red fluorescence photoconversion after exposure to ultraviolet or near ultraviolet light (Wiedenmann et al., 2004). EosFP has a preactivated excitation maximum at 506 nm with emission at 516 nm, which shift to 571 nm and 581 nm, respectively, after photoactivation. The latest addition to this category is Dendra from *Dendronephthya sp*., which gives up to a 4500-fold increase in the red-to-green ratio after photoactivation (Gurskaya et al., 2006). Uniquely, Dendra can be activated with potentially less phototoxic wavelengths (~488 nm) in addition to the ~400-nm light required by the other green-to-red PA-FPs.

REQUIREMENTS FOR PHOTOACTIVATING FLUORESCENT PROTEINS

These general procedures can be applied to most photoactivatable fluorescent proteins, but the varied characteristics of each protein must be considered when addressing many of the points listed below.

Locating Positive Cells and Structures

Molecules that have little fluorescence prior to photoactivation produce the first obstacle, which is locating a cell and a specific region of a cell to activate. This is straightforward for the green-to red and cyan-to-green PA-FPs because the unactivated green or cyan emission wavelength can be used for targeting. Initially, the Dronpa protein has a 503-nm excitation peak and 518-nm fluorescence, but after irradiation with light in the 470- to 510-nm wavelength range, it is rendered nonfluorescent and develops absorbance at 390 nm. The PA-GFP emits green fluorescence when excited with low levels of ~400-nm light, and this may be sufficient to locate positive cells and structures. Alternatively, cotransfection with a second red or cyan fluorescent protein can usually be used to locate transfected cells.

Photoactivating the Fluorescent Protein

Photoactivation generally requires a separate excitation source (or at least a different filter set) than that used for imaging. For most of the molecules listed in Table 21.6.1, ~400-nm irradiation is required. Notable exceptions are the KFP1, which uses green (~532 nm) light and Dendra, which can be activated with ~400-nm light and ~490-nm light.

Imaging the Photoactivated Fluorescent Protein

Imaging of these molecules is similar to imaging any other molecule, with a few differences that can be advantageous or disadvantageous, depending on the experiment. Unlike conventional fluorescent proteins in which the starting level of fluorescence is usually the highest level that will be observed, the level of

fluorescence after photoactivation must be estimated to avoid detector saturation at a given imaging excitation power and detector gain. A simple procedure for estimation of post-photoactivation fluorescence involves taking a prephotoactivation image, measuring the mean fluorescence within the region to be photoactivated, background subtracting that mean and multiplying that number by the *x*-fold increase in fluorescence emission reported for the protein being used. This will give a rough estimation of the pixel values after photoactivation, but a little trial and error with various detector gain settings (contrast or voltage settings) will help the experimenter gain an appreciation of the levels of fluorescence to be expected with each experiment.

Optimizing Photoactivation

Regardless of the excitation source, some effort must be expended to obtain optimal photoactivation. Photoactivation is dependent on the duration of excitation power per unit area. In addition to photobleaching during the imaging after the photoactivation, photobleaching can also be encountered during the photoactivation event. Therefore, to maximize the contrast between pre- and post-photoactivation, power and duration of the photoactivation must be optimized such that the highest level of photoactivation is obtained with the least amount of photobleaching. The power and duration dependence are most easily demonstrated and optimized with cells expressing the PA-FP. A straightforward approach to optimization is to image a cell or field of cells between brief exposures to the activation light. This procedure is analogous to a fluorescence loss in photobleaching (FLIP; e.g., see *UNIT 21.1*) experiment, with the major difference being that fluorescence is increased instead of lost. As long as similar parameters (objective, zoom factor, photoactivation wavelength) are used, this optimization routine should suffice. However, fluctuations in laser power and alignment or changes in the parameters listed above will require additional optimizations. For a more detailed procedure, see below.

OPTIMIZATION PROCEDURES

1. Set the instrument light path configurations for imaging both the photoactivated PA-FP and inactive PA-FP, if desired. This will require proper mirrors and emission filters to detect the green and/or red fluorescence depending on the PA-FP in use. It is important to remember that a dichroic mirror capable of reflecting the photoactivation light source to the sample is also required. For most of the PA-FPs, this will be light of ~400 nm for one-photon excitation, with the notable exceptions of KFP1 and Dendra, discussed earlier. If two-photon excitation is to be used, be aware that the dichroic mirror should reflect the near-infrared wavelengths being used.

2. Set the imaging parameters (magnification or zoom factor, pixel dwell time or scan time, imaging excitation power, detector gain) required for the experiment. Some of these parameters may change for different experiments, but if the light path (mirrors, alignment etc.), magnification, and pixel dwell time remain similar, optimized photoactivation conditions should be similar for each experiment.

3. Locate a cell or cells expressing the PA-FP. As discussed earlier, this will depend on the PA-FP being used.

4. Set the photoactivation light power level to be used for the experiment. This parameter will have to be optimized depending on the requirements of the experiment and the light sensitivity of the cell type. Photoactivation light levels can affect both cell viability and the function of the protein of interest, but this depends on the protein as well as the cell type. It is the investigator's responsibility to test both possibilities. Regardless of the light level required, the procedure outlined here will be the same. To begin, use the maximum power available. This will lead to conditions for the most rapid photoactivation.

5. Set the photoactivation time. Depending on the instrument used, this may depend on the pixel dwell time or scan time used for imaging, or it may be set separately. Set this to a period of photoactivation as short as possible.

6. Set up an experiment with the following steps: (a) Image the PA-FP in the photoactivated spectrum before photoactivation, perform one photoactivation using the desired photoactivation power level, and image the PA-FP in the photoactivated spectrum again. (b) Repeat the photoactivation and imaging steps in sequence 10 to 100 times. Over the course of the experiment, the fluorescence should increase to a maximum and perhaps begin to decrease gradually. If the fluorescence is quantified within the photoactivated cells, the maximum level represents the optimal contrast that is obtainable over the inactivated PA-FPs. The number of photoactivation cycles required

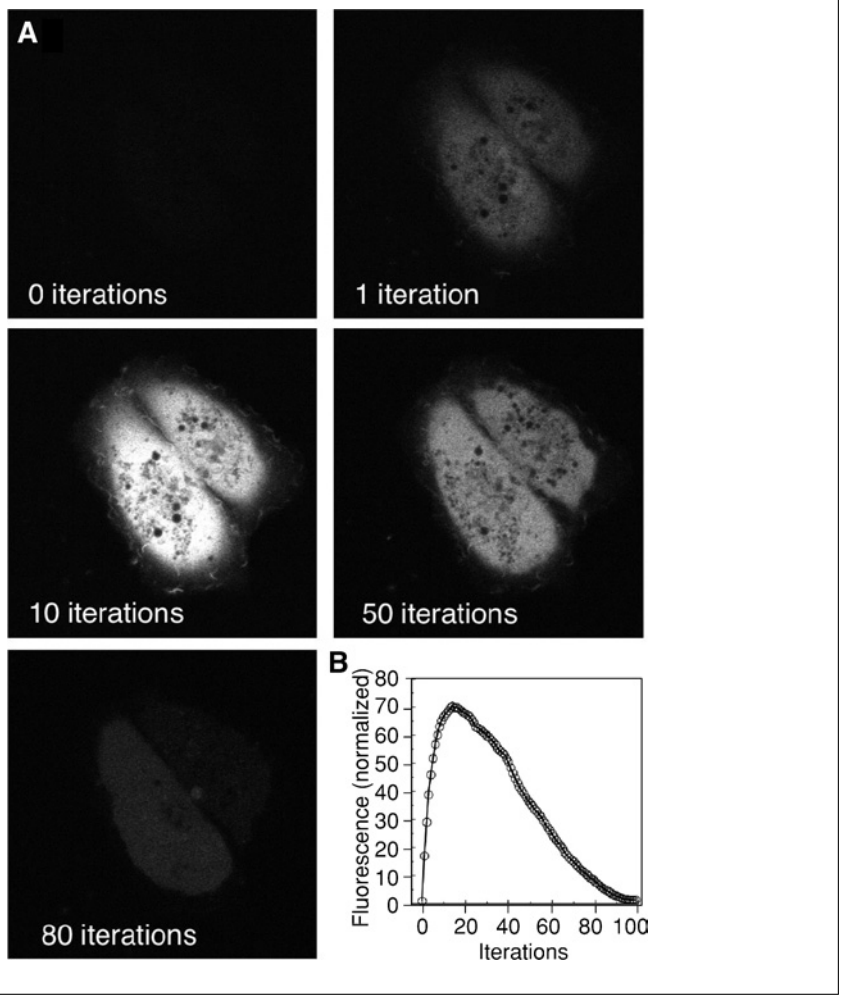

Figure 21.6.2 Photoactivation of PA-GFP. (**A**) COS-7 cells expressing PA-GFP were repeatedly imaged using 488-nm excitation. Between images, the entire field was briefly irradiated by two-photon excitation using 800-nm laser light. The total number of two-photon irradiations is shown in the lower left corner of the image. (**B**) The 488-nm excited fluorescence within the photoactivated region was normalized to the initial value and displayed as a function of the accumulated irradiations.

to reach the maximum fluorescent signal determines the optimal photoactivation time required for this photoactivation power level, magnification, and light path. An example of such an optimization is shown in Figure 21.6.2 using two-photon excitation for the photoactivation. A note of caution here is that if the photoactivation power level is too high for use with the PA-FP of choice, it may be photoactivated and photobleached during the same iteration. Thus, it may appear that no photoactivation is observed during the optimization. Performing the same protocol with lower photoactivation power levels will test for this possibility and help the experimenter find optimal photoactivation conditions.

GENERAL PHOTOACTIVATION EXPERIMENT

An example of a photoactivation experiment using the following procedure is shown in Figure 21.6.3. This protocol is written for PA-GFP using a laser scanning confocal microscope, but it should work for most of the PA-FPs in Table 21.6.1 and on other types of microscopes with appropriate alterations. Most commercial confocal systems have a software module devoted to performing photobleaching experiments. These can often be used for photoactivation experiments as well, as long as the laser wavelength used for the photoactivation event is close to ~400 nm rather than the normal imaging laser line.

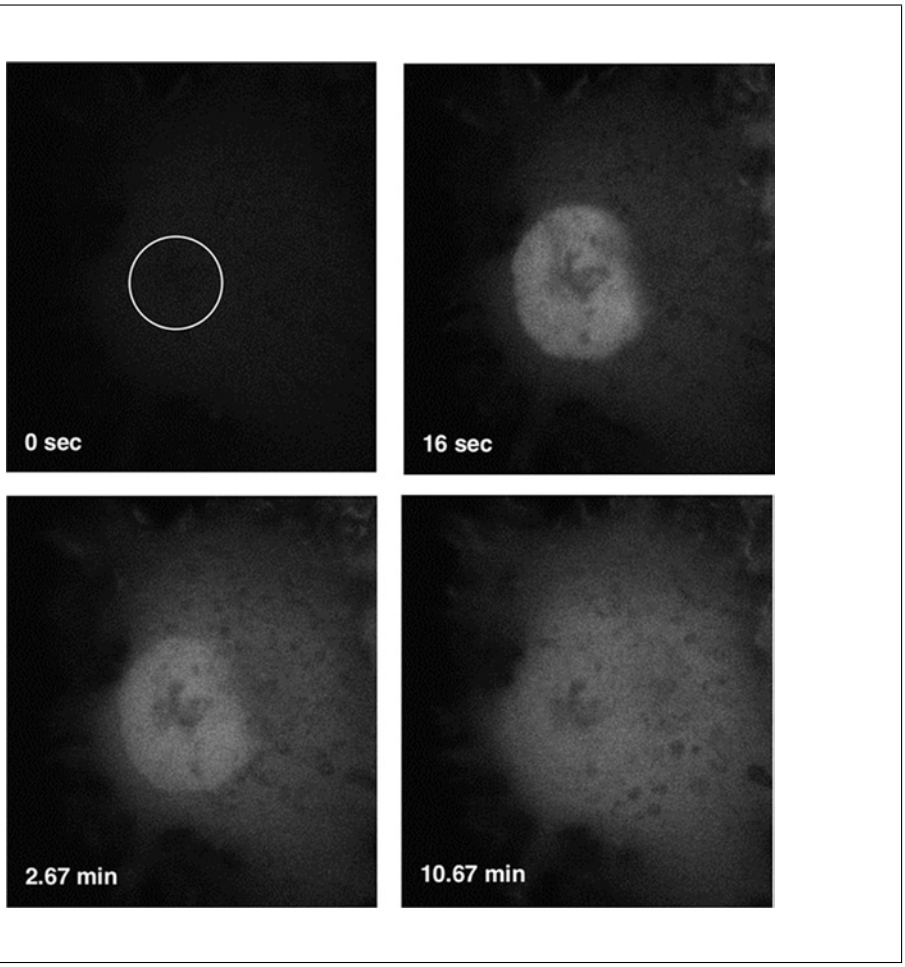

Figure 21.6.3 Selective photoactivation of PA-GFP. A COS-7 cell expressing PA-GFP was imaged using low levels of 488-nm light before and after photoactivation of the nuclear region (indicated by the white circle) with ~1 sec of 413-nm light. The images were acquired at 15.75-sec intervals.

1. Locate an expressing cell and the region of interest. The photobleaching or perhaps photoactivation software module generally has a feature for selecting the region to be photobleached or photoactivated. Select the region using the appropriate function.

2. Adjust the 488-nm laser power and detector gain for the expected fluorescence increase. This may require some of the trial and error indicated earlier.

3. Using the time series software module, program a time-lapse image experiment that will encompass the entirety of the process under study. This should collect images at the desired intervals, which will depend on the time scale of the process of interest.

4. Begin the time-lapse experiment by initially imaging the cell for one to ten frames with 488 nm to establish the baseline fluorescence.

5. Switch the irradiation wavelength to ~400 nm. For one photon, the increasingly common 405-nm diode lasers work well. A mercury lamp with a diaphragm can be used, but it is less efficient and has more limited temporal resolution. For two-photon excitation, published reports indicate 800 to 820 nm works well (Post et al., 2005; Schneider et al., 2005).

6. Irradiate the region of interest using the activation power levels and activation times determined in the optimization above.

7. Switch excitation back to ~488 nm and image the cell at the desired time intervals until the end of the experiment.

USES OF PHOTOACTIVATABLE FLUORESCENT PROTEINS

Some examples making use of PA-FPs are introduced here to convey the diverse applications of PA-FPs. With the exception of photoactivated localization microscopy (PALM; see below), where generally only a few molecules are activated at a time, the

procedures discussed earlier should assist or at least serve as an appropriate starting point for optimization of many PA-FP experiments.

Protein Dynamics

One of the most common uses of PA-FPs is complementary to the photobleaching technique, fluorescence photobleaching recovery (FPR) or fluorescence recovery after photobleaching (FRAP; *UNIT 21.1*). However, a distinct difference between FRAP and photoactivation is that in photoactivation, rather than monitoring the recovery of fluorescence within a region, a decrease in fluorescence can monitored when molecules are activated in one region and move to another. When monitoring rapid movement, this potentially provides two helpful characteristics compared to photobleaching. First, photoactivation can often rapidly and efficiently produce high contrast between highlighted and nonhighlighted molecules. Second, the highest signal-to-background ratio is found in the earliest points of the photoactivation experiment. Thus, the movement of proteins by diffusion or transport within a cell or organelle, movement of organelles within a cell, or even movement of a cell within an organism, can be readily monitored.

One disadvantage in photoactivation is that often the signal generated in one region dissipates as it moves throughout surrounding regions. To compensate for this signal dilution, it is possible to repeatedly photoactivate the same region, which is a variation similar to the photobleaching technique, fluorescence loss in photobleaching (FLIP; e.g., see *UNIT 21.1*). It relies on repeatedly photoactivating within the same region while monitoring the fluorescence increases in another region (Kim et al., 2006).

Fluorescence Pulse Labeling

New protein synthesis is often a concern when monitoring dynamics of fluorescent protein–tagged molecules of interest. This can often lead to artifacts in experiments unless synthesis is inhibited. However, photoactivation overcomes this problem because it affects only the protein that is already synthesized and properly folded at the time of photoactivation. Proteins synthesized before photoactivation fluoresce at the photoactivated wavelengths, while those that are synthesized after photoactivation do not. This characteristic of PA-FPs has been used to monitor the fate of cells during embryogenesis with KFP1 (Chudakov et al., 2003), the movements of chromatin loci in *Drosophila* embryos (Post et al., 2005), and the formation of new peroxisomes in cell culture (Kim et al., 2006).

This fluorescence pulse labeling ability also introduces an approach to monitoring protein turnover. A brief pulse with the activation wavelength of the tagged proteins of interest labels a population of molecules, and protein degradation is monitored by imaging the loss of fluorescence. It must be realized that the population of fluorescent molecules labeled under these conditions includes only those PA-FPs that are fully synthesized and properly folded, and the PA-FP must be degraded along with the protein of interest for proper read-out. Biochemical pulse-labeling thus should be carried out in parallel experiments to verify results. The temporal resolution of fluorescence pulse-labeling is essentially limited by the instrument parameters (usually milliseconds-seconds are required for activation), has subcellular spatial resolution (dependent on the optics used for imaging), and allows study of protein turnover in a single living cell.

Photoquenching Fluorescence Resonance Energy Transfer (PQ-FRET)

Fluorescent proteins have contributed to the study of protein-protein interactions within living cells by Förster resonance energy transfer (FRET; Day et al., 2001; *UNIT 17.1*). Since FRET requires that the distance between the donor and acceptor fluorophores be <10 nm, the energy transfer can be interpreted as an interaction of the tagged proteins of interest. An interesting approach to the study of protein-protein interactions in cells has been termed photoquenching FRET (PQ-FRET) and relies on the use of photoactivated PA-GFP as an acceptor to quench the fluorescence of a donor fluorophore, cyan fluorescent protein (CFP; Demarco et al., 2006). In the inactive state, the absorbance spectrum of PA-GFP has little overlap with the emission spectrum of CFP, but after photoactivation of PA-GFP it exhibits spectral overlap that makes FRET possible. Using PQ-FRET, the authors were able to monitor both the movement of the proteins and the interactions of the heterochromatin protein (HP1α) and the transcription factor CCAAT/enhancer binding protein alpha (C/EBPα) within distinct domains of the nuclei of living cells (Demarco et al., 2006). Thus, PQ-FRET offers the capability of monitoring the dynamic interactions of molecules

at steady state within different regions of the cell. Although the use of other PA-FPs in PQ-FRET has not been reported at the time of this writing, this technique should be expandable by using them in combination with the plethora of fluorescent proteins that are now available.

Photoactivated Localization Microscopy (PALM)

Unlike the applications mentioned above, the high-resolution imaging technique, photoactivated localization microscopy (PALM), does not benefit from optimizing PA-FP photoactivation and actually requires only a few molecules to be activated with each activation cycle. Fluorescent proteins tagged to a protein of interest offer spatial information that is accurate within a few nanometers. Yet, the limit of resolution for conventional optical techniques is $\sim$100$\times$ more than the size of the fluorescent proteins. PALM provides near molecular resolution of proteins (Betzig et al., 2006). PALM involves imaging of molecules individually and then localizing them to high precision by determining their centers of fluorescence emission. This is achieved by performing a statistical fit of their measured photon distributions with ideal point spread functions. When the background noise is negligible compared to the molecular signal, the error in the fitted position is $\sigma_{xy} \approx s/\sqrt{N}$, where s is the standard deviation of a Gaussian distribution approximating the point spread function of the objective, and N is the total number of detected photons (Cheezum et al., 2001; Thompson et al., 2002).

Determination of protein localization using PALM is usually limited to molecules that are separated by the distance required of conventional optics ($\sim$250 nm). However, within most fluorescent specimen, hundreds or thousands of molecules may be present within one point spread function. PALM approaches this problem using both spectral and temporal means to isolate individual molecules. It relies on the serial photoactivation (using low levels of photoactivation light) of a small population of PA-FPs and their subsequent imaging until photodestruction. The photoactivation of small populations ensures that the density of imaged molecules remains much less than one molecule per normal resolution limit, and their subsequent photodestruction allows a new subset of molecules to be imaged. By fitting the fluorescent signal from each molecule to a two-dimensional Gaussian distribution, the coordinates for the location of the molecule and its uncertainty are determined. Each molecule is then rendered in a new image as a two-dimensional Gaussian distribution of standard deviation based on its uncertainty centered at the determined coordinates.

Reversible Saturable Optical Fluorescence Transitions (RESOLFT)

Reversible saturable optical fluorescence transitions (RESOLFT; Hofmann et al., 2005), relies on the switching behavior of the reversible PA-FPs such as asFP495 (Lukyanov et al., 2000) or Dronpa (Ando et al., 2004) to increase obtainable resolutions to the 50- to 100-nm range. This technique relies on the photoactivation of the reversible PA-FP within the normal optical diffraction–limited spot in conjunction with photoswitching off of the PA-FP in the same diffraction limited spot with a zero node inactivation. This produces a region of inactivation that leaves a region of photoactivated PA-FP smaller than the diffraction limited spot.

FUTURE DIRECTIONS OF PA-FPS

A long-term goal in optical imaging is to monitor the behavior of individual molecules of interest within the living cells of an organism, and the developments using PA-FPs such the ones discussed above have certainly advanced this goal (see Hofmann et al., 2005; Betzig et al., 2006). If the trend in fluorescent protein development continues, molecules with more defined absorbance cross sections, narrower emission spectra, higher fluorescence quantum efficiencies, more photostability, and less blinking and/or flickering are likely to be introduced in the near future. These will undoubtedly serve to advance the techniques mentioned above and lead to new and clever optical approaches in studies of cell biology.

CHAPTER 22
Cell Biology of Chromosomes and Nuclei

INTRODUCTION

Organizing and expressing the information within the genome is an enormous challenge faced by all living organisms. Notably, the isolation of chromosomal DNA within the nucleus is one of the defining characteristics of eukaryotic cells. This isolation has important consequences for the organization of the genome, as well as for expression, trafficking, and interpretation of genetic information. This chapter is concerned with methods that address the expression, structure, and maintenance of chromosomes.

Chromosomes are highly dynamic structures, and the chromosomal DNA must undergo a complete, single round of duplication and packaging to allow accurate distribution of the genome to daughter cells. DNA replication is initiated at multiple sites along the chromosome (replication origins). There is considerable evidence that the timing of replication for different chromosomal sites is highly regulated with respect to expression patterns of genes within these domains and with respect to their distribution along the chromosome. Replication origins are organized into "replication factories" that can be visualized as punctate foci when sites of DNA synthesis are pulse-labeled within interphase mammalian nuclei. *UNIT 22.10* discusses the use of pulse-labeling strategies to characterize the organization of DNA replication within mammalian cells. Specifically, this unit includes bromodeoxyuridine (BrdU) labeling protocols for analysis of replication foci assembly, as well as for investigating their distribution with respect to chromosomal domains or subnuclear regions. This unit also discusses dual replication pulse labeling with chloro- and iododeoxyuridine, to examine the dynamics of DNA synthesis, and replication labeling of DNA fibers, to observe the distribution of replication sites on individual DNA fibers rather than on intertwined DNA strands within the nucleus. Units from other chapters that deal with DNA replication include *UNIT 11.5*, which describes systems for studying mammalian cell replication using the large T antigen-dependent replication of plasmids within mammalian cell extracts, and *UNIT 11.10*, which describes the assembly and analysis of replication-competent nuclei in *Xenopus laevis* egg extracts. *Xenopus* egg extracts provide a highly manipulable in vitro system (see *UNITS 11.10*, *11.11*, *& 11.13*), allowing the selective removal or addition of individual proteins.

UNITS 22.1 to *22.7* concern the cytogenetic analysis of vertebrate chromosomes. *UNIT 22.1* provides an overview of cytogenetic analysis techniques. These techniques are particularly important in analyzing subtle changes in chromosome structure that are associated with genomic instability in many contexts. *UNIT 22.2* describes culture methods and the preparation of mitotic and interphase samples for this analysis. *UNIT 22.3* describes traditional banding methods that permit the identification of chromosomes by number and allow the identifications of abnormalities. *UNIT 22.7* discusses the analysis of sister chromatid exchange using mitotic chromosomes from cells that have been labeled during DNA replication with 5′-bromodeoxyuridine (BrdU). Domains of exchange can be recognized through differential staining of the labeled strand by Hoechst dye and Giemsa, allowing direct monitoring of template switching during strand synthesis. Increased rates of sister chromatid exchange are diagnostic of a number of inherited diseases, and they are also observed in response to ionizing radiation or chemical insults.

Current Protocols in Cell Biology 22.0.1-22.0.3, March 2009
Published online March 2009 in Wiley Interscience (www.interscience.wiley.com).
DOI: 10.1002/0471143030.cb2200s42

UNIT 22.4 describes the use of fluorescence in situ hybridization (FISH) for the analysis of chromosomal structure. FISH analysis of mitotic chromosomes has provided a wealth of information about genetic changes in cancers and in genetic syndromes, such as chromosomal translocations and inversions. These methods have been extended with multicolor FISH applications to identify aberrations in genomic structure (*UNIT 22.5*). These techniques include M-FISH, wherein individual chromosomal paints are distinguished from one another during acquisition using distinct excitation filters. Alternatively, individual chromosomal paints within a mixture can be distinguished through spectral karyotyping (SKY) methods, which rely on Fourier transform methods for their analysis and separation. Moreover, fluorescence in situ hybridization analysis through comparative genomic hybridization (CGH; *UNIT 22.6*) provides sensitive determination of the net genomic gains and losses in test samples in comparison to normal reference genomic DNAs, giving a detailed picture of how genomes change during the progression of human disease.

Chromosomal instability is frequently associated with aberrations in spindle structure, and *UNIT 22.8* provides guidance for the examination of non-chromosomal spindle components by immunofluorescence, particularly microtubules and centrosomal proteins. *UNIT 22.9* provides protocols for assembling mitotic chromosomes in *Xenopus laevis* egg extracts and for the physical analysis of their structure. These methods should therefore be highly valuable in studying the construction and properties of mitotic chromosomes.

Among the most important aspects of nuclear biology is the regulation of messenger, transfer, and ribosomal RNA (mRNA, tRNA, and rRNA) synthesis. Closely related problems are involved in the post-transcriptional modification of RNAs, their assembly into ribonucleoprotein complexes (RNPs), and their trafficking between the nucleus and the cytoplasm. The expression of the RNA is controlled through a number of mechanisms, including modification of both chromatin components and DNA. One aspect of this modification is discussed in *UNIT 22.12*, which presents protocols for the analysis of DNA methyltransfereases at a single-cell level; these protocols utilize irreversible trapping of enzymatically active MTases to genomic DNA substituted with the nucleoside analog 5-aza-2-deoxycytidine (5-aza-dC).

Systems for analyzing transcription, processing, and export of mRNAs are described in a number of units: *UNIT 11.6* contains protocols for the preparation and use of mammalian and *Drosophila* extracts that accurately initiate basal and activated polymerase II transcription. *UNIT 11.17* describes protocols for in vitro analysis of post-transcriptional mRNA splicing, and *UNIT 11.14* describes protocols for RNA export assays, using microinjected *Xenopus* oocytes. Protocols for the analysis of mRNA export in both yeast cells and mammalian cells using oligo(dT) FISH are described in *UNIT 22.13*, along with methods to analyze mRNA export in live cells through microinjection of fluorescently labeled pre-mRNA within the nucleus. *UNIT 22.11* describes techniques for analysis of ribosomal (rRNA) maturation and ribosome assembly, using metabolic labeling and biochemical separation of preribosomal particles. Protocols for the analysis of nuclear trafficking in digitonin-treated cells are described in *UNIT 11.7*.

Other experimental approaches to nuclear processes are provided in Chapters 13, 17, and 18. *UNIT 13.5* describes the application of photobleaching techniques to proteins within the nucleus, providing temporally and spatially resolved data regarding the dynamics of nuclear structures. The measurement of protein-DNA interactions in the context of chromatin, through chromatin immunoprecipitation (ChIP) assays, is described in *UNIT 17.7*. Analysis of nuclear functions during apoptosis is provided in Chapter 18, particularly in *UNIT 18.4*, which discusses monitoring of telomeres through quantitative in situ hybridization, and *UNIT 18.6* which discussed other assays for telomere status and telomerase activity.

Together, these methods provide experimental avenues to address questions about the organization, maintenance, and expression of the genome—some of the most complex and fascinating problems in modern biology.

Mary Dasso

Overview of Cytogenetic Chromosome Analysis

This set of units describes the common techniques used in the preparation and analysis of mammalian chromosomes. Although the protocols mainly describe analysis of human chromosomes, the techniques are often applicable, with minor modifications, to the study of cytogenetics in other species. The amount of cytogenetic information that can be generated from a given piece of tissue or from a cell line is vast. Thus, the specific application of the techniques described depends on the type of question being asked by the researcher.

The first visualization of chromosomes in the late 1950s opened up the field of cytogenetics. Successful culturing of primary tissues or cell lines (*UNIT 22.2*) is paramount for obtaining a sufficient number of high-quality metaphase preparations for chromosome analysis. Once a culture has been established from a tissue or cell line, chromosome spreads need to be prepared (*UNIT 22.2*).

Banding techniques such as Giemsa banding (G-banding) have permitted the identification of chromosomes by number as well as the detection of chromosomal abnormalities (*UNIT 22.3*). For the past 40 years, these banding techniques have enabled the identification of chromosomal abnormalities in hematological malignancies, sarcomas, carcinomas, and genetic syndromes.

The 1990s brought about a second golden age for the field of cytogenetics with the advent of fluorescence in situ hybridization (FISH), where labeled DNA probes (*UNIT 22.4*), and, more recently, protein nucleic acid (PNA) probes, could now be hybridized to the chromosome target, detected, and analyzed using fluorescence microscopy (*UNIT 22.4*). This provided an important tool for gene mapping and for the identification of specific chromosomal aberrations associated with disease. Commercial diagnostic FISH tests could now routinely be included as an adjunct to classical banding analysis in the clinical hospital cytogenetics laboratory. In addition, with FISH, the drawback of having few metaphase spreads in specimens could be overcome by using gene/locus-specific probes and examining interphase nuclei. Tissues embedded in paraffin can also be examined by interphase FISH.

Multicolor FISH analysis of all human and mouse chromosomes can be carried out in one experiment. This recent development is a technological milestone and brings the field of cytogenetics full circle. Now, very subtle chromosomal aberrations such as small translocations or inversions can be readily identified without having to rely solely on the subjective interpretation of classical banding patterns. Chromosomes that were once dubbed as marker chromosomes, indicating that they provide insufficient banding information for chromosomal identification, can now easily be identified using advanced cytogenetics techniques. In conjunction with standard FISH experiments, small structural changes such as inversions, microdeletions, and amplifications can easily be assessed using locus-specific probes. Improvements in microscopy and fluorochromes make it possible to carry out many tests on one specimen.

Another FISH-based technology now routinely used is comparative genomic hybridization (CGH). This technique permits the determination of net genomic gains and losses in a given DNA sample. The test/tumor DNA is compared to a normal reference DNA sample and hybridized to normal metaphase slides. A two-color FISH detection experiment is performed, and image-analysis software calculates the change in the green/red ratio along the length of the chromosomes, corresponding to the tumor (green) DNA and normal reference (red) DNA that has hybridized, competitively, to the normal metaphase target. Increase in green/red ratios indicates a gain of genomic material at that chromosomal locus in the test/tumor, while a decrease in green/red ratio indicates a loss of genomic material at that chromosomal locus. CGH can provide important information from specimens where short-term culture has proven unsuccessful or impossible. DNA for CGH can readily be extracted from fresh or frozen tissue, paraffin-embedded tissue, or microdissected cells. More recently, CGH methods are being used to identify chromosomal imbalances using microarray target slides.

Sister chromatid exchange (SCE) refers to the interchange of DNA between replication

Contributed by Jane Bayani and Jeremy A. Squire

Current Protocols in Cell Biology (2004) 22.1.1-22.1.3

products. Each exchange represents a point of DNA template exchange during strand synthesis. SCEs are visualized as asymmetric chromatid staining or as harlequin chromosomes, because BrdU incorporation during strand synthesis causes differential staining with Hoechst dye and Giemsa. SCEs can be used to identify chromosomal anomalies and errors in the mitotic machinery.

Finally, improvements in antibody systems and identification of new proteins permit the study of the events that occur during DNA replication and the components involved in the mitotic machinery.

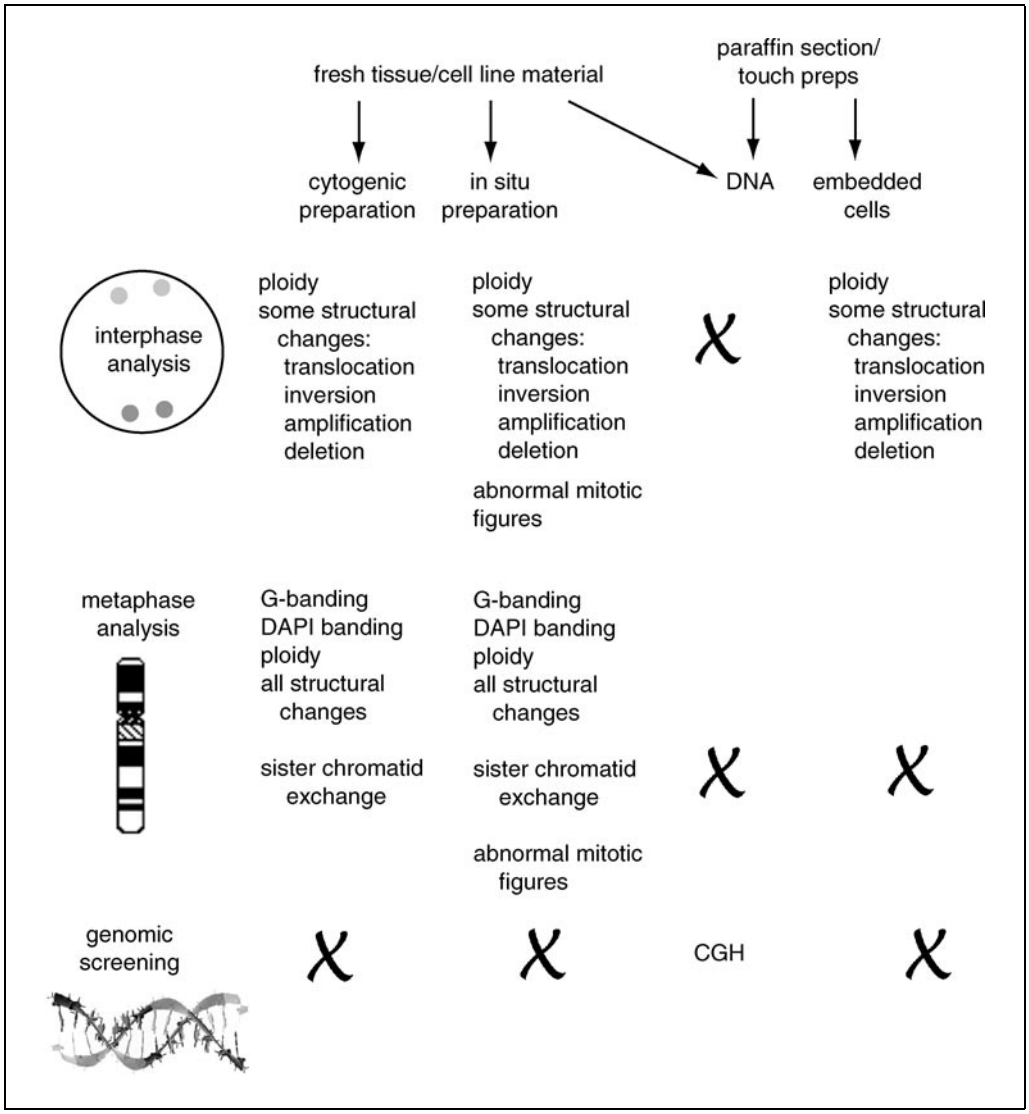

Figure 22.1.1 Overview of techniques for chromosomal analysis. Information regarding the status of whole chromosomes or specific chromosomal loci can be obtained from fresh material, such as fresh tissues and cultured cell lines, as well as from archival material including paraffin-embedded tissues, using FISH analysis. However, only cultured cells make it possible to perform specific chromosomal analysis using metaphase spreads as well as interphase cells. Tissues embedded in paraffin material can only provide information derived from interphase nuclei. Metaphase analysis provides information regarding ploidy, as well as the presence of structural changes such as balanced and unbalanced translocations, inversions, deletions, and additions. Complex extrachromosomal structures such as double-minute chromosomes (dmins), homogeneously staining regions (HSRs), ring chromosomes (r), and multicentric or acentric chromosomes can also be revealed by metaphase analysis; these features can only be indirectly inferred by interphase analysis. Both fresh and archival material will yield DNA that can be used for comparative genomic hybridization (CGH), a genome-screening technique. Other techniques that reveal chromosomal abnormalities and errors in the mitotic machinery include analysis of sister chromatid exchange and in situ hybridization using antibodies against proteins involved in the mitotic machinery, such as centrosomes.

Figure 22.1.1 describes the types of chromosomal analysis that can be performed on a given specimen and the information that can be generated from such analysis. Since each assay provides different information, it is important to determine which assay is most applicable for addressing a specific research question. Furthermore, the type, amount, and status of the tissue will greatly influence the type of analysis that can be carried out.

Preparation of Cytogenetic Specimens from Tissue Samples

This unit describes basic tissue culture techniques that enable the investigator to prepare metaphase or interphase cells suitable for cytogenetic analysis from short-term cultured cells derived from tissue or body fluids. Established cell lines from sources such as the American Type Cell Collection (ATCC) are well adapted to in vitro growth and can also be used. A comprehensive discussion of tissue culture techniques for long-term cell lines can be found in *UNIT 1.1* (also see Barch, 1991; Freshney, 1993). This unit will describe the general parameters for establishing a short-term culture from primary tissue for cytogenetic studies (see Basic Protocol 1 and Alternate Protocols 1 to 3).

Success in obtaining chromosomes for analysis depends on achieving a mitotically active cell population. Different tissues and cell types, depending on the nature of the experiment, may require specific growth factors and medium supplements (*UNIT 1.2*). In addition, some cell types may sustain mitotic activity for a few days in culture because of residual in vivo growth-promoting effects. It is suggested that the investigator refer to current literature sources for the most effective growth conditions and media required for specific tissue types to ensure successful in vitro mitotic activity. These factors may be essential when maintaining primary or cell line cultures for several days. Moreover, abnormal cells (e.g., tumors, xenografts, or transgenic tissues) will have different growth kinetics than normal cells, and optimal conditions to favor growth of the cell type of interest should be selected. The culture techniques described here are applicable to tissues acquired from human as well as murine and other rodent sources.

After the cultures are established, the viable cells must be harvested and fixed to make a cytogenetic suspension (see Basic Protocol 2 and Alternate Protocol 4). Growing cultures are treated with a microtubule stabilizer called Colcemid that arrests cells in metaphase. Following exposure to Colcemid, the cells are hypotonically treated to enhance chromosome morphology and to increase chromatin accessibility for appropriate fixation using methanol and acetic acid. Once fixed, the cytogenetic preparation can be stored as cell pellets, under fixative, at −20°C for several months or even longer. Metaphase slides are prepared by resuspending the cells and applying them to glass slides. Obtaining adequate-quality chromosome spreads is multifactorial, and is discussed in detail by Henegariu et al. (2001) and Barch (1991). Oftentimes there is insufficient material to establish a culture, and it may be necessary to harvest any remaining viable cells before the culture dies. Sometimes the cell type of interest will only grow adherently, so short-term cultures may have to be grown on a glass slide or coverslip and treated in situ. The techniques for obtaining metaphase spreads for these types of cultures are also described here and in the cited literature.

CULTURING CELLS DERIVED FROM SOLID TISSUES FOR CHROMOSOMAL ANALYSIS

BASIC PROTOCOL 1

This protocol describes the preparation and culture of cells from solid tissues; these cells may be fully or partially adherent. The tissue is subjected to enzymatic disaggregation (if required) of the solid tissue, and the cells are plated and maintained in vitro.

Materials

Solid tissue specimen maintained in transfer medium
Appropriate culture medium (*UNIT 1.2*)
10× collagenase IV stock (see recipe)

Contributed by Jane Bayani and Jeremy A. Squire
Current Protocols in Cell Biology (2004) 22.2.1-22.2.15

Sterile medium-sized petri dishes (e.g., 60-mm)
Tabletop centrifuge
Scalpel and scalpel blades
Vented 25-cm^2 tissue culture flasks or 10-cm diameter petri dishes
15-ml conical centrifuge tube

Additional reagents and equipment for cell culture (Chapter 1)

NOTE: All tissue culture incubations are performed in a humidified 37°C, 5% CO_2 incubator. Some media, e.g., DMEM, require increased levels of CO_2 to maintain the medium at pH 7.4.

NOTE: All solutions and equipment coming into contact with cells must be sterile, and proper aseptic technique must be used.

Dissociate solid specimen

1. Using aseptic techniques (see Chapter 1), remove solid tissue specimen from transfer medium/container and place in a sterile petri dish.

   If required, transfer transport medium and remaining cells to a sterile centrifuge tube, centrifuge 5 min at 200 to 300 × g in a tabletop centrifuge, room temperature, and transfer the cell pellet to a sterile tissue culture flask as in step 5. Transfer medium typically contains the same basal medium, growth factors, serum, and other ingredients as the medium for culture; it may contain higher concentrations of antibiotics or fungicide.

2. Mince tissue, using scalpels into a fine pulp.

3. Add a few milliliters of tissue culture medium to the minced tissue and gently draw into a 5-ml pipet. Transfer to a vented 25-cm^2 tissue culture flask (or 10-cm diameter petri dish) containing sufficient medium (~10 to 15 ml) to cover the surface of the flask.

   The culture should be densely seeded to promote growth.

4. Continue mincing the large tissue pieces (remaining in the original petri dish) until they are a fine pulp, and transfer to the flask.

5. Depending on the nature of the tissue, add sufficient 10× collagenase IV stock to the tissue culture flask containing the medium and minced tissue such that the final collagenase concentration is 1×.

   Tissues that are fibrous or contain bone may benefit from collagenase treatment. Other, softer tissues, such as brain, may not require collagenase treatment. Additionally, some tissues may be sensitive to collagenase treatment and die. Thus, if there is sufficient tissue, one flask should be prepared with collagenase IV and one without collagenase IV. For the culture without collagenase IV, proceed to step 12.

6. Cap the flask securely and place it on its side in the 37°C CO_2 incubator. Incubate overnight.

7. The following day, use a sterile pipet to gently pipet the treated tissue up and down to break up remaining solid masses and obtain a single-cell suspension.

8. Examine the culture using phase-contrast microscopy to assess the extent of digestion. Also assess the extent of cell adhesion and colony formation. Transfer the single-cell suspension to a 15-ml conical centrifuge tube. Add fresh medium to flask with the adherent cells

   Any adherent cells in the original flask should remain untouched.

9. Centrifuge the single-cell suspension 5 min at 200 to 300 × *g*, room temperature, in a tabletop centrifuge. Pour off the supernatant and resusupend the pellet in 5 ml of fresh medium.

   There may still be large fragments of tissue remaining. These tissues can be treated again with collagenase IV in a separate culture.

10. Add fresh medium and transfer the resuspended pellet back to the flask.

    If there is a very high density of cells, one or more other cultures can be established.

Establish culture

11. Place the cultures back into the incubator and leave undisturbed overnight.
12. Check cultures daily to obtain a general estimate of doubling time, and feed cultures as required (*UNIT 1.1*; also see Critical Parameters).
13. Once culture is ~80% confluent, proceed to Basic Protocol 2.

    If required, subculture cells as described in UNIT 1.1.

CULTURING TISSUES IN SITU

ALTERNATE PROTOCOL 1

This protocol is especially useful when a very small amount of tissue is available for analysis. The procedure is essentially the same as that in Basic Protocol 1.

Additional Materials *(also see Basic Protocol 1)*

Poly-L-lysine-coated glass coverslips *or* slides (see Support Protocol) *or* chambered glass tissue culture slides (Nunc)

Phase-contrast microscope

NOTE: All tissue culture incubations are performed in a humidified 37°C, 5% CO_2 incubator. Some media, e.g., DMEM, require increased levels of CO_2 to maintain the medium at pH 7.4.

NOTE: All solutions and equipment coming into contact with cells must be sterile, and proper aseptic technique must be used.

1. Proceed with transfer and mincing of the solid specimen (see Basic Protocol 1, steps 1 to 2), except transfer the minced tissue to a 15-ml conical centrifuge tube.
2. Mince remaining large tissue pieces again and transfer to the 15-ml conical centrifuge tube.
3. Depending on the nature of the tissue, add sufficient 10× collagenase IV to the 15-ml conical centrifuge tube for a final collagenase concentration of 1×.

   Tissues that are fibrous or contain bone may benefit from collagenase treatment. Other softer tissues, such as brain may not require collagenase treatment. Furthermore, some tissues may be sensitive to collagenase treatment and die. Thus, if there is sufficient tissue, prepare one culture with collagenase IV and one without collagenase IV. For the culture without collagenase IV, proceed to step 6.

4. Cap the tube loosely and place in the 37°C CO_2 incubator. Incubate overnight.
5. The following day, gently pipet the treated tissues up and down to further disaggregate to a single-cell suspension. Centrifuge 5 min at 200 to 300 × *g*, room temperature, in a tabletop centrifuge. Pour off the supernatant and resuspend the pellet in 3 to 4 ml fresh medium.
6. If using coverslips or nonchambered glass slides, carefully place each in a sterile petri dish and add a few drops of cell suspension, followed by a few drops of fresh

medium. If using chambered slides, add sufficient medium to cover the chambered area. Using a sterile plastic transfer pipet, add a few drops (~500 µl total) of cell suspension. View using a phase-contrast microscope and add more cell suspension if the cell density appears low.

Depending on preference, use glass coverslips or glass slides directly for in situ culturing or coat with an appropriate matrix (see Support Protocol). Commercially available chambered, coated tissue culture slides can also be used. The investigator should refer to the current literature to determine the ideal matrix for promoting attachment of the specific cell type.

Do not use plastic coverslips if subsequent fluorescent-based work will be carried out because plastics produce autofluorescence.

7. Place the slides or coverslips with the cells in the 37°C CO_2 incubator. Incubate overnight, undisturbed.
8. The following day, carefully examine the slides/coverslips with a phase-contrast microscope to determine the extent of adherence. Add fresh medium as required by carefully pipetting fluid from the slide or corverslip and replacing with new medium. Monitor growth daily until the cultures are 80% confluent, then proceed to Basic Protocol 2.

SUPPORT PROTOCOL

PREPARE GLASS COVERSLIPS OR GLASS SLIDES FOR IN SITU CULTURING

In many cases, cells will adhere to uncoated glass or plastic surfaces; however, the adherence process can be facilitated by the pretreatment of regular glass coverslips and slides. This protocol describes the steps to coat and store glass slides and coverslips for in situ culturing as in Alternate Protocol 1. Poly-L-lysine-coated slides can also be purchased commercially from many companies.

Materials

Glass coverslips *or* slides, autoclaved
1 mg/ml poly-L-lysine stock solution: mix 100 mg poly-L-lysine (Sigma) with 100 ml sterile H_2O
Sterile petri dishes or Coplin jar

1. Place autoclaved glass coverslips or slides in a petri dish or Coplin jar containing the 1 mg/ml poly-L-lysine stock solution. Incubate at least 1 hr at room temperature.
2. Carefully remove the coverslips and/or slides and allow to dry.
3. Store in a dry cool place up to 1 month at room temperature, in a sterile petri dish sealed with Parafilm.

ALTERNATE PROTOCOL 2

CULTURING NONADHERENT OR FLUID TISSUES FOR CHROMOSOMAL ANALYSIS

This protocol describes the culturing of fluid tissue sources and nonadherent cells for cytogenetic preparations.

Additional Materials (also see Basic Protocol 1)

Fluid specimen maintained in transfer medium

NOTE: All tissue culture incubations are performed in a humidified 37°C, 5% CO_2 incubator. Some media, e.g., DMEM, require increased levels of CO_2 to maintain the medium at pH 7.4.

NOTE: All solutions and equipment coming into contact with cells must be sterile, and proper aseptic technique must be used.

1. Using aseptic techniques, transfer fluid tissue-containing specimen to a sterile 15-ml conical centrifuge tube and centrifuge 10 min at 200 to 300 × *g*, room temperature, in a tabletop centrifuge.
2. Pour off supernatant and resuspend pellet in 5 ml fresh culture medium.
3. Transfer cells to a sterile 25-cm^2 vented tissue culture flask containing 10 ml of medium.

   Alternatively, if there is abundant material, the investigator may wish to establish a larger culture in a 75-cm^2 vented tissue culture flask. Keep in mind that high cell density tends to promote growth.

4. Place in a 37°C CO_2 incubator and incubate overnight.
5. Monitor growth daily by phase-contrast microscopy and pH changes as revealed by changes in medium color.
6. If required, subculture the cells (*UNIT 1.2*).

CULTURE OF PERIPHERAL BLOOD CELLS

ALTERNATE PROTOCOL 3

This is a standard protocol for obtaining metaphase spreads from blood. Depending on the nature of the specimen (e.g., specimens from hematological malignancies), most blood specimens will be processed in the same fashion. The blood is collected in heparin and processed for culturing as soon as possible. Although whole blood can simply be cultured with the medium, this protocol describes the separation of the white blood cells using a Ficoll-Hypaque density gradient and centrifugation. The isolated white blood cells are then cultured for 72 hr in medium containing phytohemagglutanin, a cell synchronizer. At a time point ~24 hr prior to harvesting, the cultures may be half-fed (see Critical Parameters).

Materials

Blood collected in heparin
Phosphate-buffered saline (PBS; *APPENDIX 2A*), sterile
Ficoll-Hypaque (density 1.077; Amersham Biosciences; store at 4°C protected from direct light)
Supplemented RPMI 1640 medium (see recipe)

50-ml conical tubes (e.g., Falcon)
15-ml conical centrifuge tubes (e.g., Falcon)
Refrigerated centrifuge
Sterile disposable plastic transfer pipets (Fisher)
25-cm^2 tissue culture flasks

NOTE: All tissue culture incubations are performed in a humidified 37°C, 5% CO_2 incubator. Some media, e.g., DMEM, require increased levels of CO_2 to maintain the medium at pH 7.4.

NOTE: All solutions and equipment coming into contact with cells must be sterile, and proper aseptic technique must be used.

Isolate white blood cells by Ficoll-Hypaque gradient

1. Transfer 12 ml of blood collected in heparin to a sterile 50-ml tube and add 20 ml sterile PBS. Cap tube and mix by inversion.

2. To each of four 15-ml conical centrifuge tubes, add 3 ml Ficoll-Hypaque.
3. Layer 8 ml of the blood/PBS mixture onto the top surface of the Ficoll-Hypaque.

   Add the blood/PBS mixture slowly, in such a way that it does not mix with the Ficoll.

4. Cap the tubes and carefully place them into a 4°C centrifuge. Centrifuge 20 min at 300 × *g*, 4°C, without the brake.

   If a refrigerated centrifuge is not available, a room temperature centrifuge can be used, but the investigator is cautioned to work quickly, as Ficoll can be toxic to cells.

5. At end of centrifugation, carefully remove the tubes from the centrifuge without disturbing the separated phases.
6. Using a sterile disposable plastic transfer pipet carefully remove the band of white blood cells located at the interface above the packed red cell pellet, and transfer into a new 15-ml conical tube.

   Cells from all four tubes may be combined into the same conical tube.

7. Fill the conical tube almost to the top with supplemented RPMI 1640 medium. Cap and mix by inversion. Centrifuge 5 min at 200 to 300 × *g*, room temperature.
8. Remove the supernatant and resuspend the pellet by gently tapping the tube. Add ~4 ml of fresh medium.

Establish cultures

9. Add 9 ml of supplemented RPMI 1640 medium to each of four 25-cm^2 tissue culture flasks. Add 1 ml of the resuspended cells to each flask for a total volume of 10 ml.
10. Place flasks on their sides in a 37°C CO_2 incubator and incubate 48 hr. At end of incubation, add 5 ml of medium to the flask and gently pipet the cells up and down to break up any clumps of cells. Return flasks to incubator.
11. After another 24 hr of incubation (total culture time of 72 hr), proceed to Basic Protocol 2.

    A normal peripheral blood culture usually requires a 1-hr Colcemid treatment at the standard concentration (see Basic Protocol 2).

BASIC PROTOCOL 2

PREPARATION OF METAPHASE SPREADS

The following protocol describes the steps required to obtain metaphase spreads from both adherent and nonadherent cultures as well as those from cells grown in situ. Briefly, the cultures are treated with Colcemid, pelleted by centrifugation, and hypotonically swollen. Finally the cells are fixed to maintain cellular architecture and to ensure that cellular proteins do not interfere with subsequent detection steps. The hypotonically swollen and fixed cytogenetic suspension is then applied to glass slides and air dried under controlled humidity. The slides are then ready for various analyses. The exposure time and concentration of Colcemid varies and depends on factors including tissue type and overall growth characteristics. The incubation times and concentrations listed below are typical starting points that will require modification. Barch (1991) provides a detailed summary of harvesting conditions for many of the hematopoietic malignancies and clinical samples such as amniocytes and chorionic villus cells. Harvesting solid tumors is far less predictable and requires experience borne from trial and error. Human, murine, and rodent cells are treated in the same fashion; however just as different cultures may respond differently to harvesting techniques within the same tissue type, there may also be some variability between species. An empirical approach to optimizing harvesting procedures is critical.

Materials

Adherent or nonadherent cell culture (Basic Protocol 1 or Alternate Protocol 2 or 3), 80% confluent
10 μg/ml Colcemid (Invitrogen) in H_2O (store up to 2 months at 4°C)
Appropriate tissue culture medium with serum
1× trypsin/citrate saline (see recipe)
0.075 M KCl (see recipe), prewarmed to 37°C in oven or water bath
3:1 (v/v) methanol/acetic acid fixative (see recipe)

15-ml conical centrifuge tubes
Tabletop centrifuge
Sterile disposable plastic transfer pipets (Fisher)
Coplin jars
Glass slides
Slide box

Additional reagents and equipment for cell culture (Chapter 1), including trypsinization (*UNIT 1.1*)

Treat cells with Colcemid

1. To 80% confluent adherent or nonadherent culture, add sufficient 10 μg/ml Colcemid stock to give a final concentration of 0.1 μg/ml.

2. Return the cultures to the 37°C CO_2 incubator and continue incubating for 1 hr.

See Troubleshooting for discussion of Colcemid sensitivity and incubation time.

Prepare single-cell suspension

3a. *For adherent and partially adherent cells*: At end of incubation, transfer the medium to a 15-ml conical centrifuge tube and centrifuge 5 min at 200 to 300 × *g* in a tabletop centrifuge, room temperature. Discard the supernatant. Trypsinize attached cells in the flask using 1× trypsin/citrate saline (also see *UNIT 1.1*) and transfer to the 15-ml tube containing the pellet of cells from the medium. When the cells have detached, add fresh medium, collect the cells, add to the tube, and centrifuge 5 min at 200 to 300 × *g*, room temperature. Discard supernatant.

3b. *For nonadherent cells*: Transfer cell suspension to a 15-ml conical centrifuge tube and centrifuge 5 min at 200 to 300 × *g*, room temperature. Discard supernatant.

4. Resuspend the cell pellet in the remaining solution by gently tapping the bottom of the conical tube. Resuspend as much of the pellet as possible into a uniform cell suspension.

Swell and fix cells

5. To the resuspended cells, add the first milliliter of prewarmed (37°C) 0.075 M KCl (hypotonic solution) in a dropwise fashion using a plastic disposable transfer pipet, gently tapping the bottom of the tube between drops. Once the first milliliter has been added, slowly fill the tube with the hypotonic solution. Gently mix by inversion and incubate 10 min at 37°C.

6. Again using a plastic disposable transfer pipet, add 5 to 10 drops of 3:1 methanol/acetic acid fixative. Cap tube and gently mix by inversion.

7. Centrifuge 5 min at 200 to 300× *g*, room temperature, in a tabletop centrifuge.

The pellet should look white and should have doubled in size.

8. Discard supernatant and resuspend the pellet thoroughly by flicking the bottom of the tube.
9. Using a plastic disposable transfer pipet, add 3:1 methanol/acetic acid fixative in a dropwise fashion for the first milliliter with gentle flicking between drops. Slowly fill the tube with 3:1 fixative after the addition of the first millliliter.
10. Centrifuge again as in step 7. Discard supernatant and resuspend pellet by gentle flicking of the bottom of the tube.
11. Repeat fixation by simply filling the conical tube with fixative, capping, and mixing by inversion.
12. Repeat steps 10 and 11 once more. If necessary, store the cytogenetic suspension as a pellet under fixative at −20°C.

Prepare cytogenetic slides

13. Discard fixative and resuspend pellet by gentle flicking of the bottom of the tube. Add sufficient fixative such that the suspension appears opaque.

    After preparing the first slide, the cell density may be adjusted as needed with fixative.

14. To a clean Coplin jar containing distilled water, add a clean glass slide.

    Different techniques for slide making exist. A comprehensive discussion can be found in Henegariu et al. (2001) and Barch, (1991).

15. Remove one slide and hold roughly at a 45° angle (Fig. 22.2.1).

    A thin layer of water will still remain.

16. Using a 1-ml plastic disposable transfer pipet, add 1 to 2 drops of the cytogenetic suspension. Allow the slide to dry.

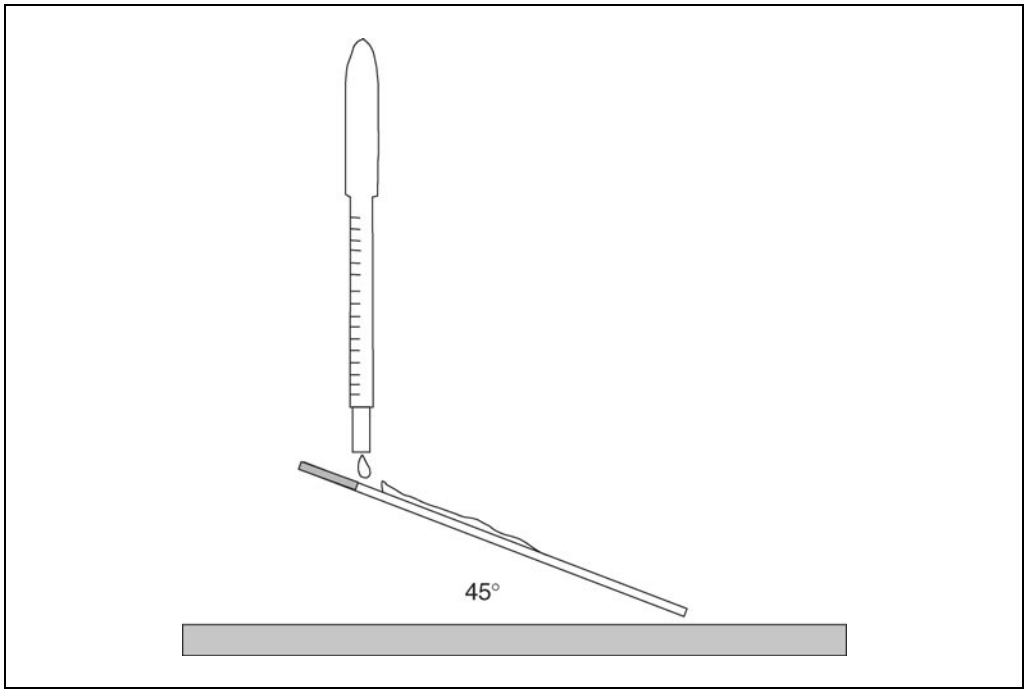

Figure 22.2.1 Schematic representation of "drop-method" of slide making. Shown in the figure is the general method for preparing slides for molecular cytogenetic analysis from a fixed suspension. Using a plastic disposable transfer pipet, add 1 or 2 drops (or 200 μl) to a clean slide held at ~45° angle. The slide may be pretreated with water or fixative. Allow the suspension to run down the slide. Expose the slide to humidity or heat as required to achieve the proper drying conditions.

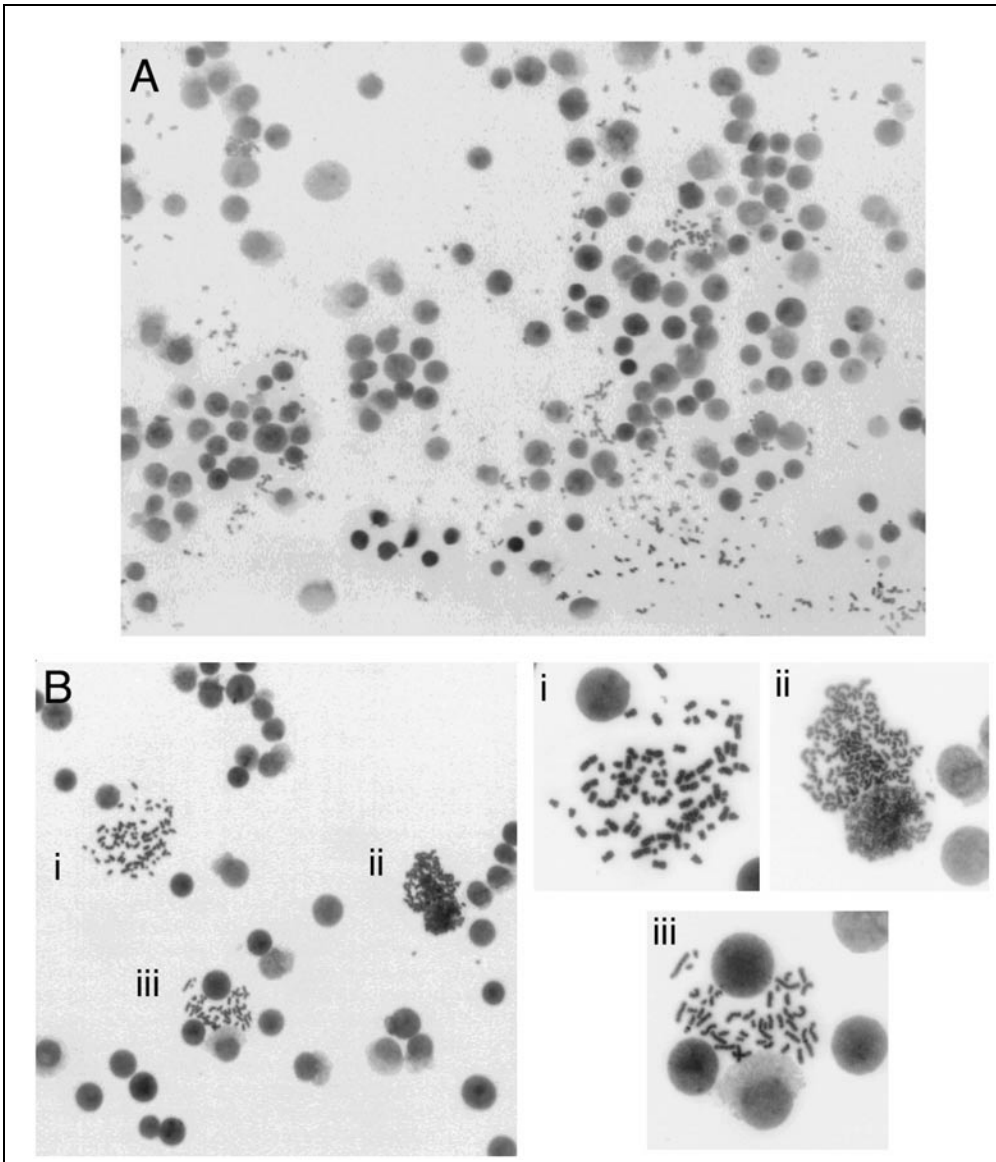

Figure 22.2.2 Phase-contrast images of slides that are appropriate and not appropriate for molecular cytogenetic analysis. (**A**) This panel is a 40× view of a prepared cytogenetic slide where the cell density is too high; thus, less suspension should be applied to the slide, or the main suspension should be diluted with fixative. This slide would be appropriate for interphase analysis, since the nuclei are intact and flattened, and chromosome analysis would not be accurate on this slide, since the metaphase spread is not intact. There is the appearance of "chromosome soup," making it difficult to discern the chromosomal content of one cell. The bursting of the cells may have occurred from rapid fixation following hypotonic treatment, or from excessive hypotonic treatment. If the entire slide has this appearance, a change in dropping technique could be used to prevent overspreading of chromosomes; however it is suggested that another suspension be made. (**B**) This panel shows a cell density that is manageable, with many intact metaphase spreads acceptable for analysis. Each metaphase spread in this field has been magnified. Metaphase "i" shows a well spread metaphase with few overlapping chromosomes that are at a reasonable length for banding analysis. Metaphase "ii" shows a tight spread with longer chromosomes. This metaphase is not appropriate for banding analysis. Metaphase "iii" shows a spread with good-length chromosomes and few overlaps. Its location between nuclei may make access to the spread difficult if there is residual cytoplasmic debris; however this is an analyzable metaphase.

17. Examine by phase-contrast microscopy. Change slide-making strategy as required based on visual assessment of slides (see Troubleshooting and Fig. 22.2.2).

18. Store slides in a slide box in a dry area until ready for use (see Troubleshooting).

ALTERNATE PROTOCOL 4

CYTOGENETIC PREPARATIONS FROM IN SITU CULTURES

This protocol describes the technique used for cells grown on slides or coverslips (Alternate Protocol 1). The principles of hypotonic treatment and fixation are similar to those of Basic Protocol 2.

Additional Materials *(also see Basic Protocol 2)*

In situ cultures (Alternate Protocol 1), 80% confluent
Cytoseal 60 mounting medium (Richard-Allan Scientific)

1. To 80% confluent cultures, add sufficient 10 μg/ml Colcemid stock to give a final concentration of 0.1 μg/ml.

   The amount of Colcemid used will depend on the amount of medium present (i.e., after adding fresh medium to the initial drops of cell suspension).

2. Return the cultures to the 37°C CO_2 incubator and continue incubating for 1 hr.

   See Troubleshooting for discussion of Colcemid sensitivity and incubation time.

3. Carefully remove medium and add fresh medium to wash the Colcemid from the cells.

4. Remove medium and carefully add prewarmed (37°C) 0.075 M KCl. Place in a 37°C incubator or dry oven for 10 min.

5. Add 5 to 10 drops of 3:1 methanol/acetic acid fixative and gently mix by rocking the petri dish or chambered slide.

6. Using a plastic disposable transfer pipet, remove solution. Slowly add fresh 3:1 methanol/acetic acid fixative and let stand at room temperature for 5 min.

7. Remove fixative and repeat fixation twice. Air dry slides

8. Mount coverslip on slide using mounting medium. Examine slides using phase-contrast microscopy. Change slide-making strategy as required based on visual assessment of slides (see Troubleshooting and Fig. 22.2.2).

9. Store slides in a slide box in a dry area until ready for use (see Troubleshooting).

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Citrate-saline, 10×

0.44 g sodium citrate (0.44% w/v)
1.0 g potassium chloride (1% w/v)
100 ml H_2O
Dilute to 1× using H_2O

Collagenase IV, 10×stock

153 mg of 260 U/mg Collagenase IV (Sigma)
20.0 ml sterile culture medium or H_2O
Filter sterilize
Store in 500-µl single-use aliquots indefinitely at −20°C

KCl, 0.075M

2.8 g KCl (Sigma; 0.075 M final)
500.0 ml H_2O
Store at room temperature or 37°C up to 1 month

Methanol/acetic acid fixative, 3:1

90.0 ml methanol (molecular biology grade)
30.0 ml glacial acetic acid (molecular biology grade)

Fixative should be made fresh, however it may be stored at −20°C for several days.

Supplemented RPMI 1640

415.0 ml RPMI 1640 medium with antibiotics (e.g., Life Technologies)
75.0 ml fetal bovine serum (15% v/v final)
5 ml 100× L-glutamine (Invitrogen; 1× final)
5 ml phytohemagglutinin (M Form, Invitrogen; reconsititute lyophilized powder per manufacturer's instructions)
Store up to 1 month at 4°C

Trypsin/citrate saline, 1×

10 ml 10× trypsin/EDTA (Invitrogen) (1× final)
90 ml 1× citrate-saline (see recipe)
Store indefinitely at 4°C
Place at room temperature or 37°C before use

COMMENTARY

Background Information

Cell cultures

Growing tissues in culture has given investigators the ability to analyze and control cellular events. However, it has become increasingly important to characterize the gross chromosomal changes and correlate them to abnormal cellular processes and phenotypes identified. A comprehensive discussion on tissue culture techniques can be found in Chapter 1 of this manual, as well as in Freshney (1993) and Barch (1991). The brief discussion in this unit covers basic tissue culture issues relevant for preparing cytogenetic preparations.

Slide preparation

The first karyotypes were made from peripheral lymphocytes by Hungerford et al. (1959), using a squash technique that is now considered primative. Later, Moorehead et al. (1960) published the method for air drying peripheral blood chromosomes, a modification of the method of Rothfels and Siminovitch (1958) using methanol/acetic acid. Prior to this, plant studies had revealed that mitotic-spindle disruptors such as colchicine made it possible to discern the beginning and end of distinct chromosomes, since the chromatin material was condensed and arrested at metaphase; this technique was later applied to mammalian cells. In the procedure used here, the hypotonic swelling of the cells causes a concentration gradient and stretches the cell membrane. Fixation helps to maintain this state until the cell is forced to flatten out when applied to the slide. It is evident from the many cytogenetic publications since those early reports that identifying the chromosomal content of a cell has significance in diagnosing, monitoring, and treating disease and genetic abnormalities. The success of fluorescence in situ hybridization (FISH)–based technologies lies largely in the meticulous principles of harvesting and slide making established by early cytogeneticists.

Finally, obtaining optimal chromosome spreads is an art in and of itself, and techniques

vary from laboratory to laboratory as well as between individuals in the same laboratory. It can be compared to a group of people who are given the same recipe and same ingredients and asked to prepare the same meal. Invariably some will prepare a better-tasting meal than others, based on their careful observations and years of culinary experience. This analogy is worth considering when preparing slides. The sections below (see Critical Parameters and see Troubleshooting) will discuss some of the more critical aspects of slide making, but the onus is on the individual to determine the best method of slide making from trial and error.

Critical Parameters

Cell cultures

Aceptic techniques and proper biohazard safety practices should always be implemented when handling tissue, especially human tissue. These precautions serve not only to protect the investigator and the laboratory but also to ensure that unwanted microbes or fungi in the cultures are minimized.

As mentioned, a search of the current literature will provide the requirements necessary for optimal short-term culture of the tissue of interest. Since not all tissues will have the same growth rate, the investigator should monitor the progress of the cultures daily to ensure that they are not becoming contaminated with normal cells and to estimate the likelihood that sufficient cells will grow. Investigators are urged to consult the current literature concerning the cells being used to determine the best way of limiting the growth of unlimited cell populations. Feeding should be carried out just as the medium starts to become more acidic, based on the change in color of the indicator present in most media. Cultures may be heterogeneous with respect to the types of cells present in the culture, ranging from fully adherent or nonadherent to partially adherent with floating viable cells. When feeding cultures, it is suggested that the cultures be half-fed. To do this, remove half of the tissue culture medium and centrifuge to bring down any floating cells. Discard the supernatant. Add fresh medium to the pellet, resuspend the pellet, and return the cells back to the culture. This ensures that the culture obtains fresh nutrients and at the same time retains critical growth factors or cytokines present in the original medium, which may have been produced by the cells themselves. Finally, some tissues may fail to thrive in culture after enzymatic treatment.

In this unit, collagenase IV is featured as the main enzyme for tissue disaggregation; however, there are several types of collagenase as well as other enzymes that may be used for tissue disaggregation. Caution should be exercised when treating with an enzyme, because some cells do not recover well from enzymatic treatment.

Preparing slides

Cell division may be stimulated by subculturing the cells 1 or 2 days before harvesting for cytogenetic suspension (Basic Protocol 2 or Alternate Protocol 4). Cultures do not necessarily need to be split into new flasks or dishes, but they can be passaged into a new flask simply to induce cell division by disaggregation while keeping cell density at a level just below confluence to avoid contact inhibition of proliferation.

The cultures to be harvested should be actively dividing. When using established cell lines, it is usually easy to identify and count rounded-up mitotic pairs of daughter cells at anaphase/telophase. However, cultures from primary tissues often do not have a uniform morphology, and it can be difficult to distinguish between proliferating and apoptotic or necrotic cells. Oftentimes there is not sufficient material to stain cells with trypan blue; thus the investigator should monitor primary cultures daily. Some tissues fail to thrive in vitro and may need to be harvested within 72 hr. Cellular heterogenetity with respect to cell cycle will also influence the mitotic index of the final cytogenetic suspension. Treatment with cell synchronizers is discussed in Barch (1991) and may help to increase the mitotic index.

Treatment with the drug Colcemid will also influence the mitotic index of a cytogenetic suspension. Since Colcemid arrests cells by disrupting the spindle, increasing treatment times will improve the mitotic index by accumulating cells arrested at metaphase. However, prolonged exposure or use of higher concentrations of the drug will cause increasing chromosome contraction, resulting in shorter chromosomes. As the chromatin within chromosomes becomes condensed, the ability to identify banding patterns continues to decrease.

Hypotonic swelling is generally carried out using KCl. However some have used a mixture of KCl with culture medium or water (Squire, 1983; Barch, 1991; Henegariu et al., 2001). These variations help to prevent the sudden rush of water into the cells. Should the hypotonic treatment occur too quickly, the cell

membranes may burst, yielding "chromosome soup" (Fig. 22.2.2A). Too little swelling will prevent the membranes from adequately releasing the chromosomes from the confines of the cell membrane, preventing them from spreading. Hypotonic treatment is typically carried out slowly, with gentle mixing. Vortexing is usually too harsh, although some individuals have used this method with success. A successful hypotonic treatment will yield a pellet that has doubled in size and that often looks translucent due to increased water content within cells.

The first fixation, termed the pre-fix, occurs after the hypotonic treatment. It involves the addition of a few drops of fixative to the swollen cells. This pre-fix serves to harden cell membranes to maintain cellular architecture and the swollen cell state. The first full fixation is carried out gradually. Once the first full fixation is complete, the subsequent fixations can be carried out in normal fashion. Repeated fixations help to remove cytoplasmic and other cellular debris as well as to preserve the cells.

Fixed cells can be stored for several years, provided that they are stored as pellets under fixative in tightly capped tubes at −20°C. The reasons why cytogenetic suspensions degrade over time are that the cells were not pelleted, they were stored at room temperature or 4°C, or that the methanol has evaporated, leaving an increased concentration of acetic acid, which will damage the cells.

The consensus of many experienced cytogeneticists is that the relative humidity in the room where slides are made is the most critical parameter for slide making. It is not uncommon to find laboratories hoping for a rainy or humid day so that their slide preparation will be optimal. In the authors' experience, a relative humidity of at least 30% to 35% is optimal for preparing well spread chromosome preparations. This can be achieved by having a boiling kettle, beaker of water, or water bath nearby, over which to pass the freshly prepared slide. Humidity in excess of 50% will require aided drying, usually with a warm-to-the-touch hot plate. Determining the best conditions for slide making requires frequent changes in test conditions and trips to a phase-contrast microscope to check the results. Fast drying can be controlled by applying the suspension to slides that are wet (with water). In more humid conditions, suspensions may be applied to dry slides. Others choose to wet their slides with fixative, but this may speed up the drying process. In many state-of-the-art cytogenetics laboratories, a humidity- and temperature-controlled unit (about the size of a fume hood) called a Thermotron (*http://www.thermotron.com/cryogen.html*) has been used to establish the correct humidity and temperature for slide making.

Storing of cytogenetic slides is also subjective. Some laboratories simply store slides at room temperature, while others store slides at −20°C (in or free of ethanol), and still others store in dessicators. Each laboratory will need to determine the best storage conditions. However, if there is left-over cytogenetic suspension, fresh slides can always be made as needed.

Troubleshooting

Cell cultures

Depending on the likelihood that tissues were handled aseptically before reaching the cell culture facility (i.e., from an operating room or pathology laboratory), it may be necessary to include antifungal agents in addition to the routine antibiotics supplementing both the culture and transport media. Once again, caution should be exercised because antifungal agents are often toxic to cells.

If bacterial or fungal contamination does occur, particularly in adherent cultures, and there are no backup cultures, the contaminants may be removed from the culture, the cultures washed with sterile PBS, and fresh medium added. The cultures must be harvested (Basic Protocol 2) within 24 hr so that the remaining contaminants do not have sufficient time to overgrow. The investigator should be warned that the presence of contaminating bacteria or fungi will cause subsequent background problems for banding analysis and FISH analysis because they contain DNA and antigens that bind the antibodies conjugated to a fluorochrome.

Slide preparation

See Table 22.2.1 for a troubleshooting guide to slide preparation for cytogenetic analysis.

Anticipated Results

Establishing short-term cultures from primary tissues requires careful and systematic monitoring to determine the optimal time to initiate harvesting. Longer-term cell lines will generally yield better quality cytogenetic preparations, as they have undergone adaptation to in vitro growth and usually exhibit high mitotic activity. The investigator should make

Table 22.2.1 Troubleshooting Guide for Cell Harvesting and Slide Preparation for Cytogenetics Analysis[a]

Problem	Possible cause	Solution
No metaphase spreads	Slowly dividing cell culture	No immediate solution to increasing cell growth; however growth can be stimulated by providing a half-feed of the culture the day before harvesting
	Insufficient Colcemid incubation	Treatment time with the standard Colcemid concentration of 0.1 μg/ml may need to be increased in increments from 60 to 90 min
	Insufficient Colecmid concentration	If the culture appears to be dividing (empirically determined), then increase the Colcemid concentration, but either maintain the same incubation time, or decrease it
Chromosomes too long	Short Colcemid incubation	Every cell type reacts differently to Colcemid treatment; if chromosomes are too long, this suggests that they can tolerate longer incubations or higher concentrations of Colcemid
	Insufficient Colecmid concentration	As described above, Colcemid incubation time and/or concentration can be increased to achieve shorter chromosomes
Chromosomes too short	Cells sensitive to Colcemid treatment	This is more of a problem than the situation above. Decrease amount of Colcemid but maintain the same incubation time, or maintain the same concentration of Colcemid, but decrease the incubation time.
	Colcemid incubation too long	Decrease the amount of Colcemid but maintain the same incubation time, or maintain the same concentration of Colcemid, but decrease the incubation time.
Metaphase spreads too tight	High cell density	If the concentration of cells in the working suspension is too high, it will not permit the chromosomes to spread. Either add less cell suspension to the slide, or dilute the suspension further while maintaining the amount applied to the slide.
	Insufficient hypotonic swelling	The chromosomes must burst out of the plasma membrane and spill onto the slide. If the hypotonic treatment is insufficient to build the necessary tension, then the chromosomes will fail to spread or burst from the plasma membrane. Increase the hypotonic treatment to by 5 to 10 min. However, too much swelling will cause the cells to be too fragile.
Presence of cytoplasm	High cell density	If the concentration of cells in the working suspension is too high, it will not permit the chromosomes to spread. Either add less cell suspension to the slide, or dilute the suspension further while maintaining the amount applied to the slide.
	Insufficient hypotonic swelling	The chromosomes must burst out of the plasma membrane and spill onto the slide. If the hypotonic treatment is insufficient to build the necessary tension, then the chromosomes will fail to spread or burst from the plasma membrane. Increase the hypotonic treatment to by 5 to 10 min. However, too much swelling will cause the cells to be too fragile
Refractile-looking chromosomes	Slides drying too quickly or too slowly	This is the "art" of slide making. Ambient temperatures in the lab and the time of year will greatly affect slide making and their appearance. During the dry months of the year, keep a beaker or kettle of water boiling, or have a water bath on in the lab to increase the relative humidity.
		For the humid days of the year, keep a "warm-to-the-touch" hotplate on to facilitate drying.

[a] A comprehensive discussion can be found in Barch (1991).

note of increasing debris from dead cells and the number of cells that appear to be inactive or senescent, and thus decide the best time to harvest the cells for optimal cytogenetic preparations.

Every harvest will be different, even when harvesting multiple cultures of the same cells. However, with experience, the investigator will learn when to change Colcemid concentration, alter hypotonic conditions, and vary slide-making techniques.

Under the perfect conditions, a slide will have a relatively high mitotic index, such that at least three metaphases can be seen under low power (Figure 22.2.2). Chromosomes should not be too long or too short. Cytoplasmic debris and other cellular debris should be minimal with nuclei and chromosomes appearing gray to dark gray.

Time Considerations

It takes several days to establish a primary culture from tissue and for the cells to reach 80% confluence, depending on the growth characteristics of the cells in question.

It takes 2 to 3 hr to prepare slides for cytogenetic analysis depending on the skill of the investigator and the number of slides to be prepared.

Traditional Banding of Chromosomes for Cytogenetic Analysis

This unit describes the two most commonly used methods for banding chromosomes, Giemsa banding (G-banding; see Basic Protocol) and DAPI banding (see Alternate Protocol). G-banding is the conventional means of staining chromosomes to reveal their banding patterns. It is a nonfluorescent technique requiring only a standard light microscope for visualization. DAPI banding utilizes a DNA stain that fluoresces. With appropriate pretreatment (if required), DAPI banding identifies the same major banding patterns revealed by G-banding. Imaging tools can convert the DAPI image into a black-and-white image, which can then be converted into a G-banding-like image, more familiar to cytogeneticists. Both techniques permit the identification of chromosomes and detection of the presence of grossly abnormal chromosomes and abnormal structures. G-banding requires sufficient chromosome aging, by enzymatic digestion, to remove cytoplasmic debris and allow access of the Giemsa stain to the DNA. The incubation times for each step may be variable depending on the type and quality of specimen. DAPI staining, on the other hand, is not as finicky; slides can be used as is and can normally be stained directly with minimal or no pretreatment.

GIEMSA BANDING (G-BANDING) OF METAPHASE CHROMOSOMES

BASIC PROTOCOL

This protocol describes the basic steps for G-banding metaphase spreads. The enzymatic treatment of the slides requires optimization, either with respect to duration or trypsin concentration. Similarly, the time for staining requires adjustments to suit the investigator's preference and the slide quality. The investigator must be able to recognize the morphology of overtrypsinized or undertrypsinized chromosomal banding patterns. It is suggested that a few practice slides be used first to determine the optimal conditions for digestion and staining. Practice slides should ideally be slides made from the same suspension at the same time and under the same aging conditions as the test slides.

Materials

Metaphase slide preparation made 1 to 2 days before banding (*UNIT 22.2*)
Trypsin working solution (see recipe)
1% (v/v) fetal bovine serum (FBS): mix 1 ml FBS with 99 ml H_2O
Gurr's buffer, pH 6.8: dissolve 1 Gurr's buffer table (Bio/medical Specialties) in 1 liter sterile H_2O
Giemsa stain working solution (see recipe)

55° to 60°C drying oven
Forceps
Coplin jars
Phase-contrast microscope

1. Age the air-dried slide overnight in a drying oven at 55° to 60°C. Remove and bring to room temperature just prior to banding.
2. Grasp the slide with forceps and immerse it in a Coplin jar containing the 0.025% trypsin working solution for 8 to 10 sec, moving the slide back and forth.

   The exposure to trypsin will need to be adjusted depending on the quality of the cytogenetic specimen and the resulting banding (see Troubleshooting and Fig. 22.3.1).

Contributed by Jane Bayani and Jeremy A. Squire
Current Protocols in Cell Biology (2004) 22.3.1-22.3.7

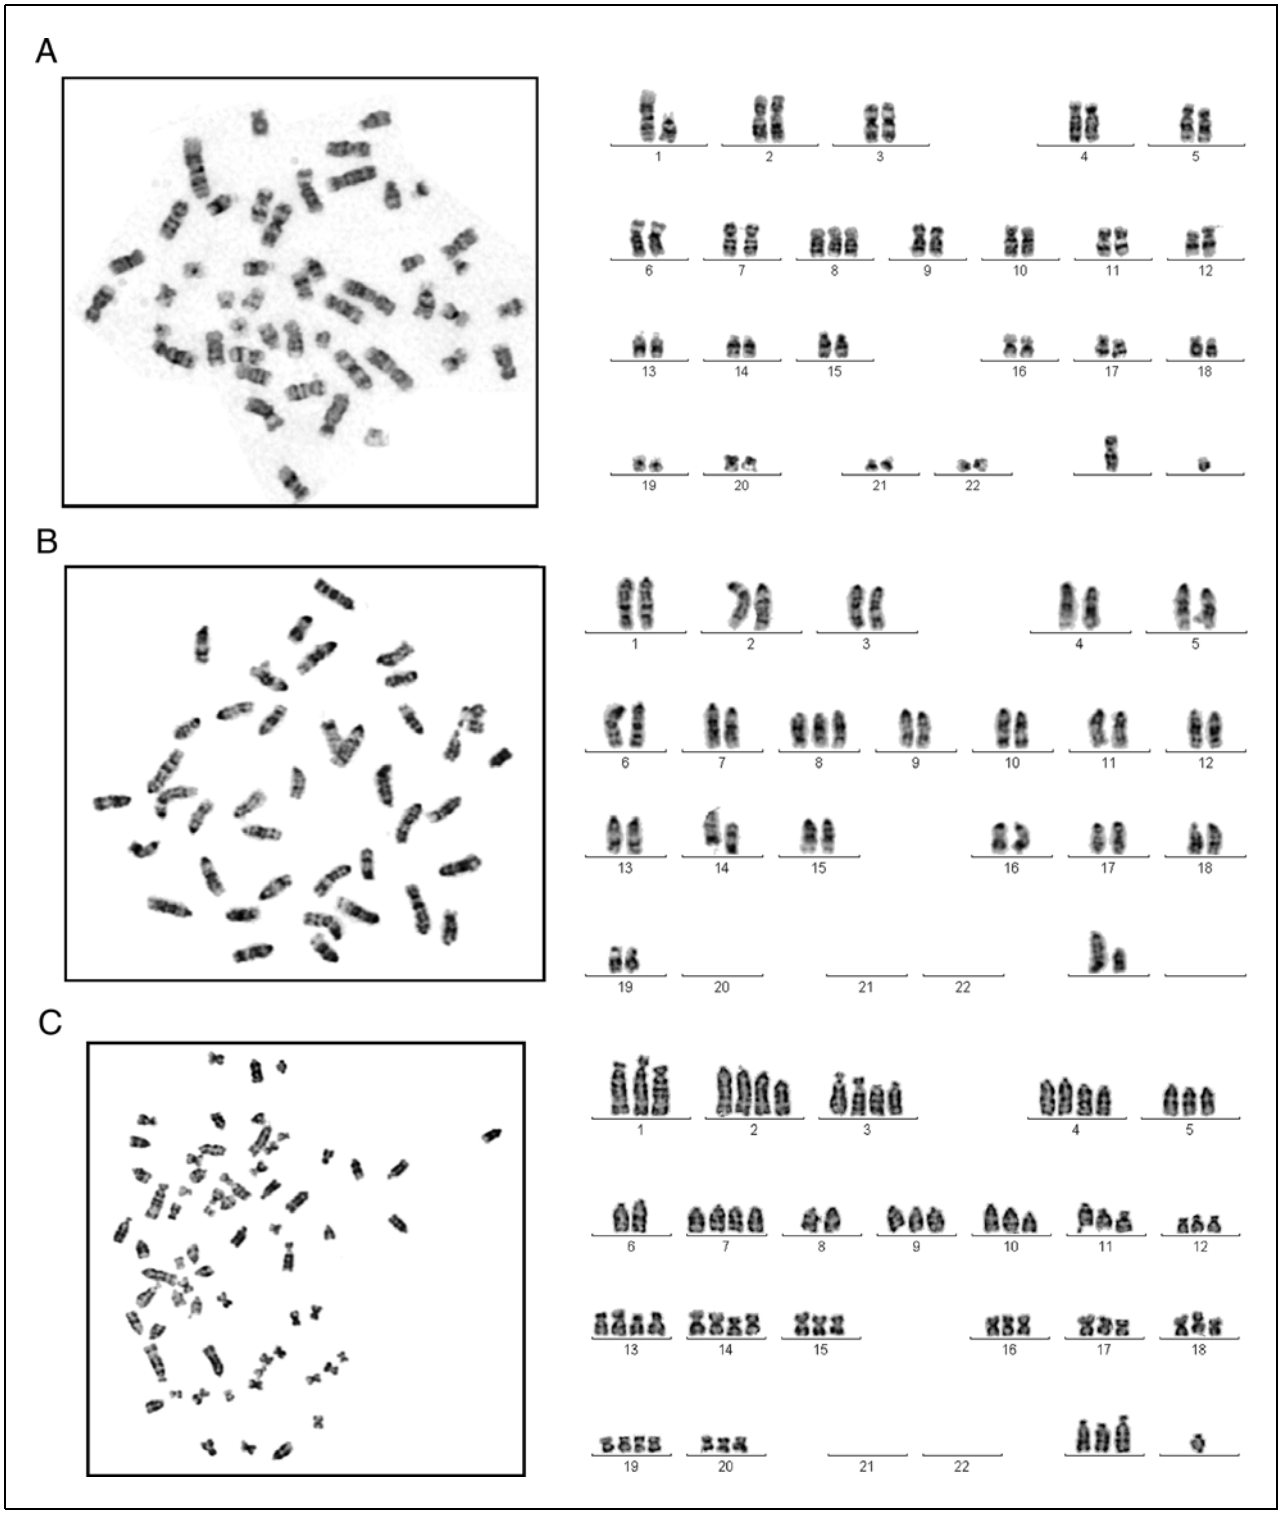

Figure 22.3.1 Images of G-banded metaphase spreads and karyotypes from human, mouse and rat tumors. For each panel, a G-banded metaphase spread and its karyotype has been shown for tumors derived from (**A**) human, (**B**) mouse, and (**C**) rat. All spreads show banding patterns that are well defined with few or no overlapping chromosomes.

3. Briefly rinse the slide in a Coplin jar containing 1% FBS to inactivate the trypsin.
4. Pre-rinse the slide by dipping in a Coplin jar containing Gurr's buffer, using the same agitation technique as in step 2.
5. Place slide in a Coplin jar containing Giemsa staining solution for 8 to 10 min.

The degree of staining will also require adjustment following visualization by phase-contrast microscopy.

6. Rinse slide in autoclaved distilled water until the stain no longer discolors the water, using the same agitation technique as in step 2.

   CAUTION: *Long exposure to water will result in destaining of the slide.*

7. Allow slide to air dry. Examine by light microscopy using a phase-contrast microscope to determine the quality of banding. Adjust trypsin exposure or duration of staining as required.

8. Once the optimal banding quality has been achieved, analyze the slides. Store the slides in a slide box free of dust and dirt at room temperature.

4′-6-DIAMIDINO-2-PHENYLINDOLE (DAPI) STAINING OF METAPHASE CHROMOSOMES

ALTERNATE PROTOCOL

In this protocol, cytogenetic specimens are stained with DAPI, which is typically mixed with an antifade mounting medium. Antifade mounting medium can be made in-house or bought commercially (e.g., Vectashield from Vector Laboratories). Unlike G-banding, DAPI staining requires no slide pretreatment and is fluorescently based.

Materials

Metaphase slide preparation (*UNIT 22.2*)
DAPI/antifade medium (see recipe)

Glass coverslips
Fluorescent microscope with DAPI filters

1. Add 50 μl of the DAPI/antifade medium to the metaphase slide preparation. Add a coverslip.

2. Visualize the chromosome banding pattern using fluorescence microscopy (Fig. 22.3.2). Store the slide at −20°C.

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

DAPI/antifade medium

DAPI stock solution: Dilute an entire container of DAPI (4′,6-diamidino-2-phenylindole, Sigma) powder with sufficient water to prepare a 100 μg/ml stock solution. Store in small aliquots up to several months at −20°C.

DAPI/antifade medium:

Combine in the following order:
5 ml PBS (*APPENDIX 2A*)
500.0 μl of 100 μg/ml DAPI stock (see above; 1 μg/ml final)
0.5 g *p*-phenylenediamine (Sigma; 10 mg/ml final)
Dissolve well, then add:
45 ml glycerol (90% final)
Total volume, 50.0 ml

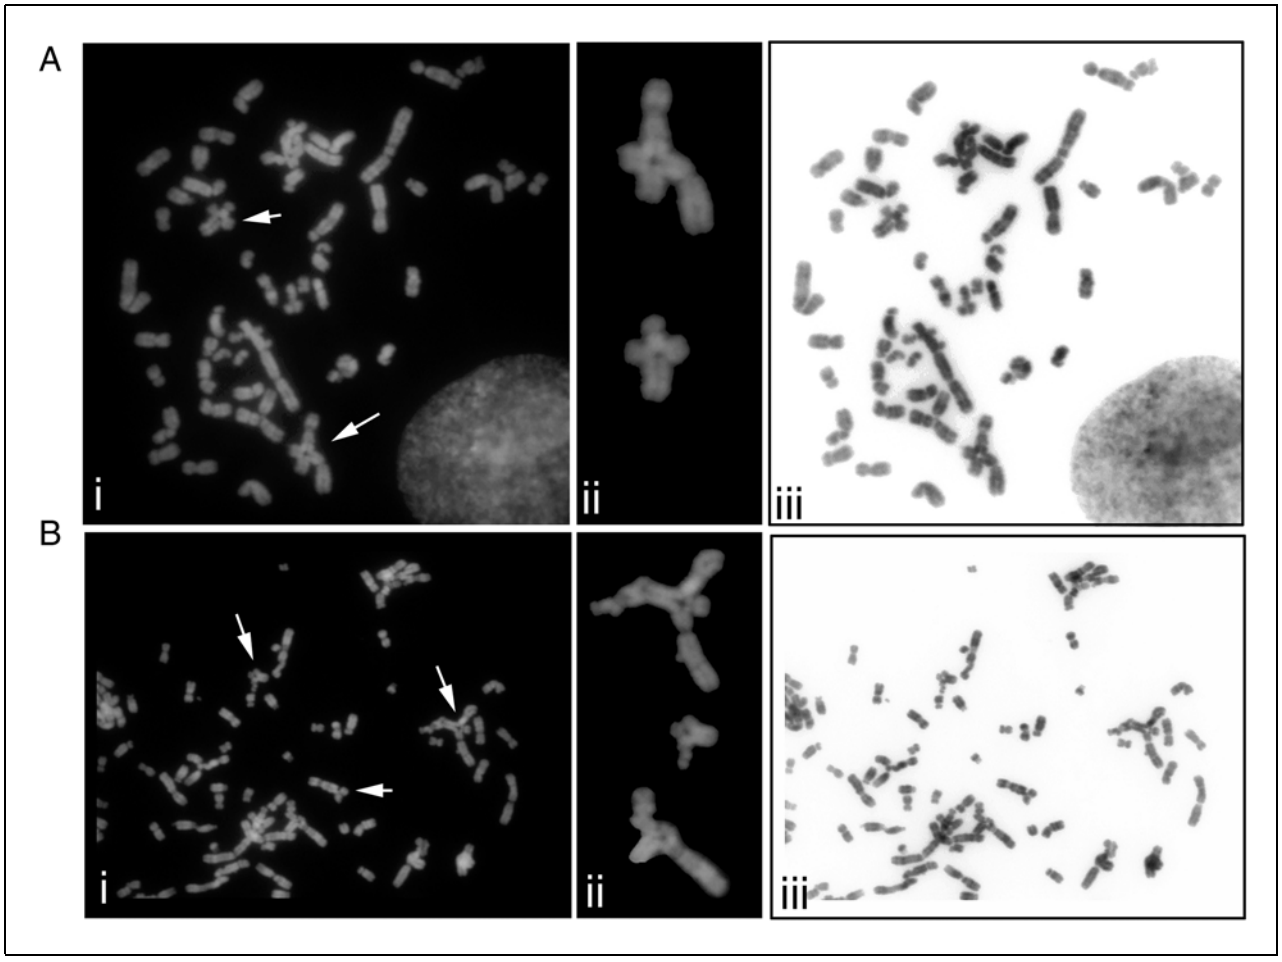

Figure 22.3.2 DAPI staining of a prostate cell line subjected to a chemotherapeutic agent and 4 Gy radiation. Shown in panel **A**, labeled "i," is a DAPI image of a prostate cell line subjected to mitomycin C treatment. Structural aberrations, e.g., radial structures, are labeled "ii.". Also in panel A is the inverted DAPI image (labeled "iii") demonstrating that DAPI banding provides similar banding patterns as G-banding, but at a lower resolution. Panel **B** illustrates the same prostate cell line subjected to 4 Gy of ionizing radiation, showing complex structural aberrations. Other aberrations, including DNA fragmentation, chromatid breaks, and dicentrics, can be identified. Arrows indicate multiradial chromosomal structures as shown enlarged in (ii).

The resulting medium is very viscous. Transfer to a 50-ml conical polypropylene centrifuge tube (e.g., Falcon), wrap tube in foil (product is light-sensitive), and place on an end-over-end rotator to ensure proper mixing (30 min). Store, protected from light, in 1-ml aliquots for several months at −20°C.

Giemsa stain working solution

1 ml Giemsa stain (Azure Blend, Harleco 620G/75, from EM Science; 2% v/v final)
50 ml Gurr's buffer solution, pH 6.8: dissolve 1 Gurr's buffer table (Bio/medical Specialties) in 1 liter sterile H_2O
Store up to 2 months at room temperature

Trypsin working solution 0.025%

0.5 g trypsin (Difco, 0.025% w/v final)
200.0 ml Earle's balanced salt solution (e.g., Life Technologies)
Store up to 1 day at room temperature

COMMENTARY

Background Information

Since chromosomes were first visualized in 1959, there has been an obvious need to determine ways of identifying individual chromosomes. Although size, shape, and the position of the centromere is clearly a means of identifying chromosomes, it became readily apparent that there were many chromosomes that were very similar in size and shape. Solid staining and chromosome measurement were used in the early 1960s; however, this still did not provide an adequate method for unequivocal chromosome identification. The Paris Conference of 1971 first systematically described chromosome bands that could be distinguished from adjacent segments on the basis of darker or lighter appearance by one or more techniques. Banded chromosomes were seen as appearing with a consistent series of dark and light bands. Human banding patterns and their nomenclature can be found in the International System of Cytogenetic Nomenclature (1995). Briefly, convention states that the short arm of a normal chromosome is called the p arm and the long arm is referred to as the q arm. A centromere is identified as a constriction along the length of the chromosome that defines the transition from the p to the q arm. Individual bands along each arm are designated numerically, with subdivisions of bands denoted as fractions of the main band. The resolution of bands is influenced by the length of the chromosome; hence, longer chromosomes produce more bands than shorter chromosomes.

There are several banding techniques that are described in Barch (1991). Today, G-banding is considered the gold standard for cytogenetics. Introduced in 1971 by Sumner et al. (1971), G-banding permits stable and effective banding of chromosomes without the need for fluorescence, which was used in an earlier technique called Q-banding (quinicrine banding). Through investigations by Sumner and colleagues, and others (reviewed in Barch, 1991), it was determined that the most effective means of revealing the banding pattern of human chromosomes was through digestion with a protease. Trypsin is used as the protease because it was found to effectively hydrolyze the proteins surrounding the chromatin. The differential protein composition along the length of the chromosome then reveals the variation of chromatin compaction associated with euchromatin and heterochromatin. These differences in chromatin condensation are easily revealed through the staining procedure.

Giemsa is a complex mixture of dyes including azure A, azure B, azure C, thionin, methylene blue, and eosin. Each dye component binds different protein moieties along the length of the chromosome, resulting the in typical banding patterns seen in Figure 22.3.1.

4′-6-diamidino-2phenylindole (DAPI) is a fluorescent dye that has an emission of 450 nm. It has AT specificity, which enables the elucidation of constitutive heterochromatin–containing regions. DAPI staining is typically used to detect centromeric regions, and it is useful in identifying pericentromeric breakpoints in chromosomal rearrangements. DAPI is also a good method for determining the quality of DNA on the slide and for identifying chromosomes when performing FISH. If the DNA fails to stain, it is often indicative of damaged DNA or slides that are too old to use.

Typical applications

Banding and staining of chromosomes permit the visualization of gross chromosomal abnormalities, including gains and losses of whole or partial chromosomes, the presence of extrachromosomal material, double-minute chromosomes, ring chromosomes, homogeneously staining regions (HSRs), chromosome fragments, and chromatid breaks (see Fig. 22.3.2). Banding and staining can also identify large structural abnormalities such as additions, deletions, inversions, and translocations. The technique has usefulness in xenograft studies, where the investigator can identify contaminating cells from the host (i.e., murine) and estimate the purity of the tissue. It is also useful for determining the extent of in vitro chromosomal (genetic) change that a given culture may have developed. Recently, investigations of genomic instability have used these simple methods for determining the rate of change of normal, tumor, or transfected cells using drug or radiation treatment (Gebhart et al., 1981; Ellis et al., 1999).

Critical Parameters

The most critical parameter in successful banding is a well spread metaphase with few overlapping chromosomes that are of good length. Generally there are spreads of varying chromosome lengths; thus the investigator is able to carry out effective analysis. Sometimes, particularly in abnormal cells, metaphase spreads will typically be too long or too short (see *UNIT 22.2*), a result of physiological responses to Colcemid treatment.

Table 22.3.1 Troubleshooting Guide to Banding Chromosomes

Problem	Cause	Solution
G-banding		
Solid staining	Insufficient trypsin treatment	Increase the trypsin incubation time in increments of 2-3 sec
	Excessive Giemsa staining time	Decrease the time in Giemsa. This will help to determine whether the trypsin time is sufficient.
No stain uptake	Excessive trypsin treatment	Decrease trypsin incubation time. Puffy chromosomes are also an indication of overtrypsinization.
	Insufficient Giemsa staining time	If the chromosomes do not appear overtrypsinized, increase the staining time in Giemsa. If the stain has been used for many specimens, the dye may be more dilute than before. If this is the case, prepare a fresh dye mixture.
Puffy chromosomes	Excessive trypsin treatment	Decrease trypsin incubation time. If the slides were not sufficiently aged prior to treatment, try more aggressive aging.
DAPI banding		
Solid staining	Insufficiently aged slides	Heat-treat the slides prior to DAPI staining or pass through an ethanol dehydration series.
	DAPI concentration too high	If the concentration of DAPI is too high (typically the case of in-house formulations), the bright signal intensity may obscure banding patterns. Remove coverslip and wash in 2 × SSC for 10 min at room temperature. Mount in a diluted DAPI/antifade medium (i.e., add more glycerol and PBS) and visualize again.
Puffy chromosomes	Insufficiently aged slides	Although no enzymatic treatment is required, very fresh chromosome preparations, and preparations made during high humidity (i.e., summer time), will produce puffy chromosomes with poor banding. Age slides artificially.

By phase-contrast microscopy, chromosomes should appear flat and range from pale gray to dark gray. The artificial aging of slides helps to sharpen the chromosome contours and increase band resolution. For G-banding, slides not aged sufficiently appear fuzzy after banding; this is due to the protease treatment. Very fat or puffy chromosomes, with little banding or stain uptake, are an indication of excessive trypsin treatment. Trypsin treatment (duration and concentration) must be optimized with each slide and for each batch of trypsin solution made. Duration adjustments will often be on the order of seconds. The brand of typsin and the supplier also influences trypsin digests markedly. Fetal bovine serum is used to inactivate the action of trysin; however, other rinses can be used such as 0.85% saline. Time spent in the Giemsa stain will also vary depending on the extent of trypsinization and the investigator's preference.

The criteria for DAPI banding are similar to those described above. Aged slides are preferred for DAPI banding, as discussed for Giemsa staining.

Careful consideration should be given to solution preparation and quality control. The trypsin solution may be used for the course of the day, although it loses its enzymatic activity as a function of use during this time period.

Be sure to take this into consideration, since a freshly prepared solution will digest more quickly than a solution that has been sitting for a few hours at room temperature or that has already been used to prepare several slides. Similarly, the concentration of Giemsa stain will become progressively more dilute, and the stain will start to precipitate as specimens are passed through it. As the day progresses, the stain requires an increase in incubation time to produce the same results. The stain is known for producing a slight film along the stain surface in the container. This can be removed by skimming the surface of the stain with some filter paper or a paper towel to prevent deposition of purple scum or precipitate on the slide as it is pulled out of the Coplin jar.

Troubleshooting

See Table 22.3.1 for troubleshooting chromosome banding techniques. The techniques are applicable to human and animal chromosomes.

Anticipated Results

Under the proper conditions, the resulting banding patterns should permit identification of the chromosomes and detection of gross anomalies or abnormal chromosomal DNA structures if present.

Time Considerations

Although the bench time is minimal, the most time-consuming portion of chromosomal banding is determining the correct trypsinization and staining times. Each specimen may require some minor adjustments.

Fluorescence In Situ Hybridization (FISH)

As early as 1988 (Lichter et al., 1988), FISH was used to visualize labeled DNA probes hybridized to chromosome and interphase nuclei preparations. The improvement of cloned DNA sources, antibodies, fluorochromes, microscopy and imaging equipment, and software has permitted a variety of scientific investigations.

This unit is divided into five parts—probe preparation, slide preparation, hybridization, post-hybridization washes, and interpretation. Probes are prepared by nick translation (see Basic Protocol 1) or degenerative oligonucleotide primer PCR (DOP-PCR; see Alternate Protocol 1) using hapten- or fluorochrome-labeled nucleotide. The amount of hapten label incorporated is quantified by dot blotting (see Support Protocol 1). Cytogenetic slide preparations are suitable for FISH (see Basic Protocol 2) if they are appropriately aged (see Support Protocol 2); these slides may be used even if they have previously been G-banded (see Alternate Protocol 2). In addition, slides made from paraffin-embedded tissues are suitable specimens for hybridization with DNA (see Alternate Protocol 3) or protein nucleic acid (PNA) probes (see Alternate Protocol 4). Hybridization conditions must be appropriate for both the sample and probe materials: cytogenetic slides can be hybridized with DNA (see Basic Protocol 3) and PNA (see Alternate Protocol 5) probes, as can paraffin sections (see Alternate Protocols 6 and 7). Post hybridization wash and detection conditions vary depending on the probe—indirectly labeled DNA probes (see Basic Protocol 4), directly labeled DNA probes (see Alternate Protocol 8 or 9), and peptide nucleic acid (PNA) probes (see Alternate Protocol 10).

NOTE: Coplin jars containing solutions at temperatures other than room temperature should be prewarmed and maintained in a water bath at the specified temperature.

LABELING DNA PROBES FOR FISH

This section describes methods for labeling probes for fluorescence in situ hybridization (FISH) analysis. The first protocol (see Basic Protocol 1) describes DNA labeling by nick translation either indirectly with a hapten (biotin or digoxigenin) or directly with a fluorochrome (*APPENDIX 1E*) conjugated to dUTP. This method is appropriate for most DNAs listed in Table 22.4.1; however, smaller DNAs, such as cDNAs, may require labeling by PCR methods, which are also described (see Alternate Protocol 1). The choice of label, whether direct or indirect, is based on the type of DNA probe, its size, and the application. Small probe inserts (such as cDNAs) should be labeled with a hapten, enabling the option of signal amplification. Larger inserts can be both directly or indirectly labeled (Table 22.4.1). The probe's signal strength can vary depending on the application and sequence specificity (Table 22.4.2). Furthermore, the choice of label or fluorochrome will also depend on the availability of conjugated antibodies, the nature of the experiment, and the availability of filters for the microscope utilized for visualization. A list of fluorochrome properties can be found in Table 22.4.3. For both labeling methods discussed here, assessment of probe labeling is determined by size, gel electrophoresis, and for indirectly labeled probes, dot blot analysis of incorporation (see Support Protocol 1). The labeled DNA is ethanol precipitated in the presence of excess unlabeled DNAs, which serve as carriers (sonicated salmon sperm DNA) and as suppressors of repetitive sequences (Cot-1 DNA). The final product is resuspended in a hybridization buffer and is then ready for use in FISH experiments (see Hybridization). The labeling procedures outlined can be applied to all species of DNA.

Contributed by Jane Bayani and Jeremy A. Squire
Current Protocols in Cell Biology (2004) 22.4.1-22.4.52

Table 22.4.1 Sources of DNA Probes for FISH Analysis[a]

Type	Application	Amplification of signal required	Labeling methods applicable	Indirect or direct labeling
Plasmids (10–20 kb insert)	Locus specific	Yes	Nick translation and PCR	Indirect
Cosmids (15–30 kb insert)	Locus specific	Yes	Nick translation and PCR	Indirect
PACs (~100 kb insert)	Locus specific	No	Nick translation and PCR	Both
BACs (~200 kb insert)	Locus specific	No	Nick translation and PCR	Both
YACs (300–1.5 Mb insert)	Locus specific	No	Nick translation and PCR	Direct
Genomic DNA from flow sorted chromosomes	Chromosome paints	No	PCR labeling	Both
Genomic DNA from microdissected DNA	Locus specific	Yes	PCR labeling	Both

[a]Shown are the most common types of DNAs used as probes for FISH analysis. Many of these DNAs can be labeled by nick translation (see Basic Protocol 1) or PCR (see Alternate Protocol 1). For probe inserts <2.0 kb, labeling by PCR is recommended.

Table 22.4.2 Different Classes of Commonly Used Probes for FISH Analysis[a]

Type	Fluorescence intensity	Typical applications
Centromere probes	Strong	Ideal probe for the beginner to learn basic FISH techniques. Commonly used to enumerate chromosomal monosomies and trisomies, and for sex determination in transplantation studies.
Subtelomere specific probes	Moderate/weak	Used for determining whether small terminal rearrangements near telomeres have taken place.
Chromosome paints	Strong/moderate	Useful for identifying small marker chromosomal aberrations where a specific chromosome is suspected. Also useful in confirming SKY or MFISH findings.
Translocation junction unique-sequence probes	Moderate	Used for detecting the presence of specific translocations in interphase cells or in metaphase spreads.
Microdeletion unique-sequence probes	Moderate	Identification of small submicroscopic deletions using metaphase preparations.
Probes detecting gene amplification	Strong	For detecting oncogene copy number increases (gene amplification) in interphase and metaphase cells

[a]Shown are the most common types of commercially available probes used in FISH experiments and their typical applications. Signal strength will vary depending on the size and application of the probe as well as the target DNA specimen.

Another choice for FISH analysis is a peptide nucleic acid (PNA) probe. These probes also bind DNA in a sequence-specific manner but are created by oligonucleotide synthesis. The fabrication of PNA probes is not easily accomplished in a typical molecular cytogenetic laboratory, so they are currently only available commercially (see Internet Resources).

BASIC PROTOCOL 1

Labeling FISH Probes by Nick Translation

This protocol, adapted from Beatty et al. (2002), outlines the basic steps for either directly or indirectly labeling DNA probes for FISH analysis. Once labeled probes are ethanol precipitated, they are ready for final preparation prior to hybridization to the target specimen.

Materials

DNA probe (i.e., cosmid, plasmid, PAC, BAC, or YAC; Table 22.4.1)
10× nick translation buffer (see recipe)

Table 22.4.3 Fluorescent Properties of Labels and DNA Stains Used for FISH[a]

Label	Excitation (nm)	Emission (nm)
Haptens[b]		
Digoxigenin	NA	NA
Biotin	NA	NA
Fluorochromes		
Alexa 488[c]	490	520
Alexa 532[c]	525	550
Alexa 546[c]	555	570
Alexa 594[c]	590	615
Amino-methyl coumarin	399	445
Cascade Blue	400	420
Cyanine 2[d]	489	506
Cyanine 3[d]	550	570
Cyanine 5[d]	649	670
Cyanine 7[d]	743	767
Fluorescein isothiocyanate (FITC)	495	523
Rhodamine B	560	580
Spectrum Aqua[e]	433	480
Spectrum FRed[e]	655	675
Spectrum Green[e]	497	524
Spectrum Gold[e]	530	555
Spectrum Orange[e]	559	588
Spectrum Red[e]	587	612
Tetramethylrhodamine isothiocyanate (TRITC)	550	570
Texas Red	595	610
DNA stains		
Chromomycin A3	430	570
4′,6-Diamindine-2-phenylindole (DAPI)	538	461
Ethidium bromide	518	615
Hoechst 33258 (bis-benzimide)	352	461
Propidium bromide	535	617

[a]Shown are the commonly used fluorochromes and DNA stains used in FISH analysis. Of these, DAPI is the most widely used.
[b]Haptens, such as digoxigenin and biotin are detected with antibodies conjugated to one of the fluorochromes listed.
[c]The Alexa family of fluorochromes can be purchased from Molecular Probes.
[d]The Cyanine family of fluorochromes can be purchased from Amersham Biosciences.
[e]The Spectrum family of fluorochromes can be purchased from Vysis.

DNase I dilution buffer (see recipe)
1 mM dNTP mixture (see recipe)
Fluorochrome/dTTP or hapten/dTTP mixture (see recipes)
3 mg/ml DNase I (see recipe)
10 U/μl *E. coli* DNA polymerase I (Roche)
5 × loading dye (see recipe)

2% (w/v) agarose gel (see recipe)
100-bp DNA ladder
Sonicated salmon sperm DNA standards (i.e., 12.5, 25.0, and 500 ng/μl; see recipe)
1× TBE buffer (see *APPENDIX 2A*)
300 mM EDTA (*APPENDIX 2A*)
10 mg/ml sonicated salmon sperm DNA (Invitrogen)
1 μg/μl human or mouse Cot-1 DNA (Invitrogen)
3 M sodium acetate (*APPENDIX 2A*)
100% ethanol
70% ethanol, cold
Hybridization buffer (see recipe)

Water bath or PCR machine
0.5-ml PCR tube (optional)

Additional reagents and equipment for agarose gel electrophoresis (*APPENDIX 3A*) and determination of hapten incorporation by dot blot analysis (see Support Protocol 1)

Prepare equipment and reagents

1. Set water bath or PCR machine to 15°C.
2. Put DNA probe and all labeling reagents (i.e., 10× nick translation buffer, DNase I dilution buffer, 1 mM dNTP mixture, and fluorochrome/dTTP or hapten/dTTP mixture) on ice.
3. Prepare 10× DNase I solution (1.0 ml total) by combining 1.0 μl of 3 mg/ml DNase I and 999.0 μl DNase I dilution buffer. Place on ice.

Perform labeling reaction

4. For each DNA to be labeled, prepare the following mixture in a 1.5-ml microcentrifuge or 0.5-ml PCR tube, adding the 10× DNase I solution and *E. coli* polymerase I last:

   2 μg DNA probe
   10.0 μl 10× nick translation buffer
   5.0 μl 1 mM dNTP mixture (i.e., dATP, dCTP, dGTP)
   4.0 μl fluorochrome/dTTP or hapten/dTTP mixture
   10.0 μl 10× DNase I solution
   2.5 μl *E. coli* DNA polymerase.
   Adjust the volume to 100 μl with water.

   The amount of DNase I solution added will vary (see Commentary).

   A probe prepared using hapten/dTTP is indirectly labeled, while one prepared with fluorochrome/dTTP is directly labeled.

5. Incubate 90 to 120 min at 15°C (see Table 22.4.22 and Critical Parameters).
6. After incubation, place tubes on ice.

Determine size of products from labeling reaction

7. Transfer 10 μl labeling reaction to a fresh tube and mix with 4 μl of 5× loading dye. Load onto a 2% agarose gel (*APPENDIX 3A*) along with a 100-bp DNA marker and 10 μl of each salmon sperm concentration standard.

   The salmon sperm standards are used to help determine the amount of labeled DNA probe, as well as to act as a molecular-size marker.

8. Electrophorese at 100 V for ~20 min or until the dye front is two thirds of the way through the gel.

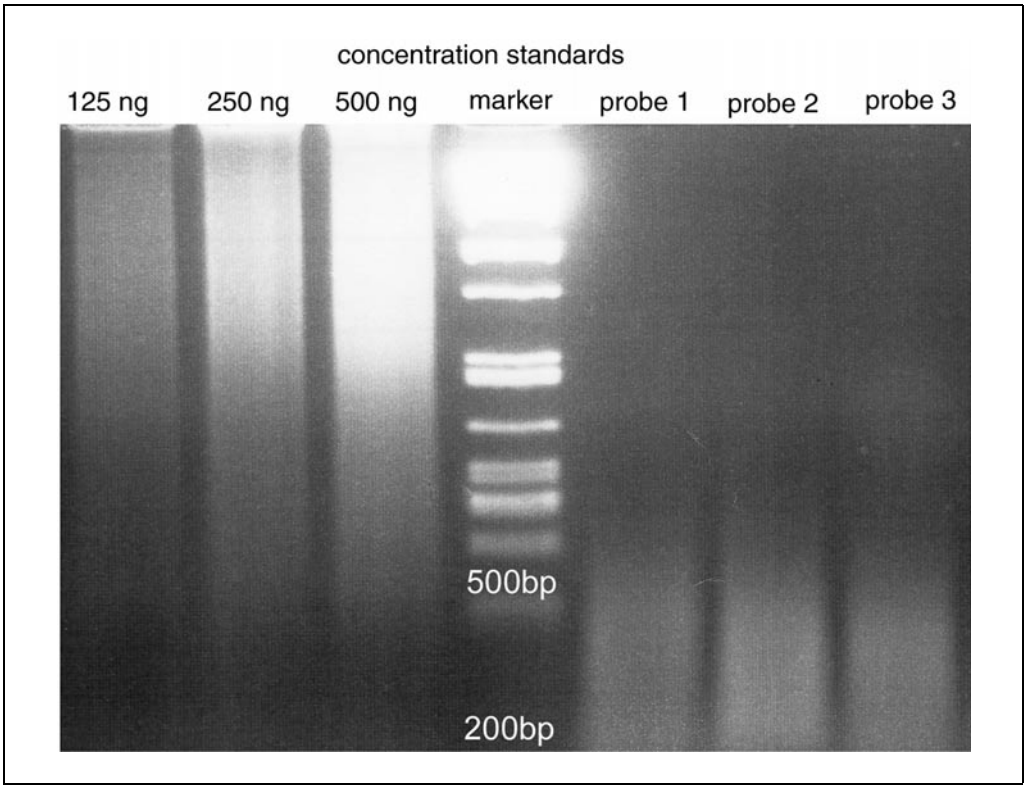

Figure 22.4.1 Nick translated DNA fragments electrophoresed on a 2% agarose gel. A volume of 10.0 μl labeled product was loaded. The fragment sizes range from 200 to 500 bp as determined from the molecular marker. The estimated concentration of the probe is 200 ng in 10 μl, yielding ~20 ng/μl.

The final fragment sizes should be between 200 and 500 bp, with ~200 ng labeled DNA present in the gel, assuming the original amount of labeled probe was 2 μg. This can be ascertained using the sonicated salmon sperm concentration standards (Figure 22.4.1).

9. If the fragment sizes are too large, return the labeling reaction to 15°C for 20 to 30 min (or time as required) and reassess the size of the fragments (i.e., repeat steps 5 to 8).

It may be necessary to spike the labeling reaction with additional DNase I solution and E. coli DNA polymerase I. If the fragments are too small, labeling (step 4) will need to be repeated with an adjustment in the amount of DNase I added to the labeling reaction. If there is no significant change in fragment size following further digestion, the investigator should start again and review Table 22.4.22 for possible reasons of insufficient digestion.

Determine amount of labeled probe

10. Once the proper labeling size has been achieved, add 10 μl of 300 mM EDTA to the labeling reaction to stop the action of the enzymes.

11. Estimate the amount of labeled probe on the gel using the salmon sperm standards as a guide. Calculate the amount of labeled DNA remaining in the tube.

Be sure to consider the volumes removed from the starting volume for loading onto the gel(s) when calculating the amount of labeled DNA left in the tube.

Based on the concentration standards, the labeled probe in Figure 22.4.1 appears to be somewhere between 125 ng/10 μl (1.25 ng/μl) and 250 ng/10 μl (25.0 ng/μl). A conservative estimate is 200 ng/10 μl (20 ng/μl). Thus, from an original 100 μl starting volume, 10 μl was removed for a gel, leaving 90 μl. If the estimated concentration is 20 ng/μl, the remaining labeled probe is 1800 ng (20 ng/μl × 90 μl = 1800 ng).

Add carrier and supressor of repetitive sequences

12. For each 1 μg labeled DNA in the tube, add 5 μl of 10 mg/ml sonicated salmon sperm DNA (50 μg).

    For example, for 1.8 μg DNA, add ~100 μg sonicated salmon sperm DNA.

13. For each microgram labeled DNA in the tube, add 5 to 10 μg human or mouse Cot-1 DNA.

    For the example given above (1.8 μg labeled DNA), ~20 μg Cot-1 DNA is required

    The amount of Cot-1 used is dependent on the number and extent of repeat elements in the DNA insert used as the probe. Generally, cDNA probes will have fewer repeats than genomic probes, so they will require relatively less Cot-1 suppression. BAC and YAC probes may need more suppression.

Determine incorporation

14. If the DNA probe has been labeled with hapten, check incorporation by dot blot analysis (see Support Protocol 1).

Ethanol precipitate DNA

15. Add 0.1 vol. of 3 M sodium acetate followed by 2.5 vol of 100% ethanol.

16. Incubate overnight at −20°C or 2 to 3 hr at −80°C.

    The recovery of DNA during the precipitation process can be increased by lengthening the time at −20°C or −80°C.

17. Microcentrifuge 20 min at 13,000 rpm, 4°C.

Resuspend DNA

18. Carefully remove the supernatant and wash the pellet with cold 70% ethanol.

19. Microcentrifuge 20 min at 13,000 rpm, 4°C.

20. Remove the ethanol and allow the pellet to air dry.

21. Resuspend the pellet in hybridization buffer to a final concentration of 10 ng/μl. Store labeled probe at −20°C up to several months (directly labeled probe) or several years (indirectly labeled probe).

    The final concentration should be based on the labeled DNA content, not the total DNA content, which includes the unlabeled Cot-1 and salmon sperm DNA. Thus, for a labeled DNA amount of 1.8 μg, 180 μl hybridization buffer should be added to reach a final concentration of 10 ng/μl.

    The labeled probe can now be used for FISH experiments.

    The amount of labeled probe used will depend on the area of the slide to be hybridized. For example, 10 μl is sufficient to cover a 22 × 22–mm coverslip, 20 μl is sufficient to cover a 22 × 30–mm coverslip, and 30 μl is sufficient to cover a 22 × 50–mm coverslip.

ALTERNATE PROTOCOL 1

Labeling Probes for FISH by Degenerative Oligonucleotide Primer Polymerase Chain Reaction (DOP-PCR)

This protocol describes direct and indirect labeling procedures using PCR labeling. The user has various choices in the primer sets. These may be specific primers for a region, specific primers for vector sequences, universal primers, or DOP primers.

Additional Materials *(also see Basic Protocol 1)*

DNA template (Table 22.4.1)
10× PCR buffer: 100 mM Tris·Cl, pH 8.3 (*APPENDIX 2A*)/500 mM KCl (store up to several months at −20°C)

2 mM dNTP mixture (i.e., dATP, dCTP, dGTP; see recipe)
5 μM each primers 1 and 2 (*APPENDIX 3F*)
50 mM $MgCl_2$
5 to 10 U/μl *Taq* DNA polymerase
Water, sterile
Mineral oil, sterile

1. For each labeling reaction, mix the following:

   1 to ng DNA template
   5.0 μl 10× PCR Buffer
   4.0 μl 2 mM dNTP
   2.0 μl 1 mM fluorochrome/dTTP or hapten/dTTP
   1.5 μl 5 μM primer 1
   1.5 μl 5 μM primer 2
   1.5 μl 50 mM $MgCl_2$
   0.5 μl 5–10 U/μl *Taq* DNA polymerase.

   Adjust final volume to 50.0 μl with sterile water. Overlay the mixture with sterile mineral oil and put on ice until ready to place in the thermocycler.

   The 10× PCR buffer is often supplied with the enzyme.

2. Place in a thermocycler and program the following steps:

Initial step:	5 min	93°C	(denaturation)
35 cycles:	30 sec	94°C	(denaturation)
	30 sec	55°C	(annealing)
	90 sec	72°C	(extension)
Final step:	5 min	72°C	(extension)
Hold:	indefinitely	4°C.	

3. Mix 5 μl labeled reaction with 1 μl of 5× loading dye and run on a 2% (w/v) agarose gel with molecular weight markers and sonicated salmon sperm DNA concentration standards as described (see Basic Protocol 1, steps 7 and 8).

   The final PCR product should fall between 200 and 500 bp.

4. Calculate the amount of labeled DNA remaining in the tube, add carrier and supressor DNA, precipitate, and resuspend in hybridization buffer as described (see Basic Protocol 1, steps 11 to 20).

5. If the DNA probe has been labeled with hapten, check incorporation by dot blot analysis (see Support Protocol 1).

Determination of Hapten Incorporation by Dot Blot Analysis

SUPPORT PROTOCOL 1

Gel electrophoresis of the labeled DNA FISH probe allows the investigator to determine whether the DNA has been nicked (see Basic Protocol 1) or amplified (see Alternate Protocol 1) to the appropriate sizes. It does not, however, allow determination of whether the hapten has been incorporated into the DNA. Using a dot blot assay, the degree of hapten incorporation can be assessed to determine the efficiency of the labeling protocol and the activity of the DNA polymerase I or *Taq* DNA polymerase. This method is useful in determining whether the lack of FISH signal is due to a poorly labeled probe or to hybridization or slide preparation factors. This method involves spotting labeled product onto a nylon filter along with a control. The labeled DNA is detected by immunolabeling and colorimetric visualization.

Materials

100 mM Tris·Cl (pH 7.5)/15 mM NaCl (*APPENDIX 2A*)
Indirectly labeled probe (i.e., with biotin or digoxigenin; Table 22.4.3)
Control DNA labeled with biotin or digoxigenin (i.e., labeled DNA probe known to produce good signal strength)
0.5% (w/v) BSA in 100 mM Tris·Cl, pH 7.5 (*APPENDIX 2A*)/15 mM NaCl (store up to 6 months at 4°C)
AP-labeled antibody mixture (see recipe)
100 mM Tris·Cl (pH 9.5)/100 mM NaCl/50 mM $MgCl_2$ (*APPENDIX 2A*)
NBT/BCIP (see recipe)

Charged nylon membrane (~5 × 5 cm per sample)
Filter paper
37°C dry oven
Rotating platform

Prepare and load nylon membrane

1. Cut a charged nylon membrane to a size appropriate for the number of samples.
2. Soak the membrane 5 min in 100 mM Tris·Cl (pH 7.5)/15 mM NaCl, room temperature. Blot the membrane with filter paper.
3. Pipet aliquots of indirectly labeled probe and control DNA labeled with biotin or digoxigenin in a dilution series (e.g., 200, 100, 50 ng) onto the membrane, leaving ample space between spots. Incubate 5 to 10 min, room temperature.

Block and label membrane

4. Incubate the membrane 1 min in 100 mM Tris·Cl (pH 7.5)/15 mM NaCl, making sure it is saturated.
5. Incubate the membrane 30 min in 0.5% (w/v) BSA in 100 mM Tris·Cl (pH 7.5)/15 mM NaCl at room temperature.
6. Transfer the membrane to an alkaline phosphatase–labeled antibody mixture in a plastic container and incubate 30 min in a 37°C dry oven on a rotating platform, making sure the membrane is completely saturated.

Develop dot blot

7. Remove the membrane and wash 15 min with 100 mM Tris·Cl (pH 7.5)/15 mM NaCl.
8. Remove the membrane and wash 2 min with 100 mM Tris·Cl (pH 9.5)/100 mM NaCl/50 mM $MgCl_2$, room temperature.
9. Remove the membrane and incubate 5 to 10 min in NBT/BCIP solution under dimmed lighting until the blot develops.
10. Wash the membrane with water and air dry.

The membrane can be stored at room temperature. Over time the intensity of the chemical stain will fade. Typical results are shown in Figure 22.4.2.

TARGET SLIDE PREPARATION

Slide quality can greatly influence the success of FISH assays. When slide preparations are less than optimal, treatment with a protease can decrease the risk of high background and increase access of the probe to the DNA target by removing protein barriers to allow efficient hybridization. FISH carried out on paraffin sections requires more aggressive

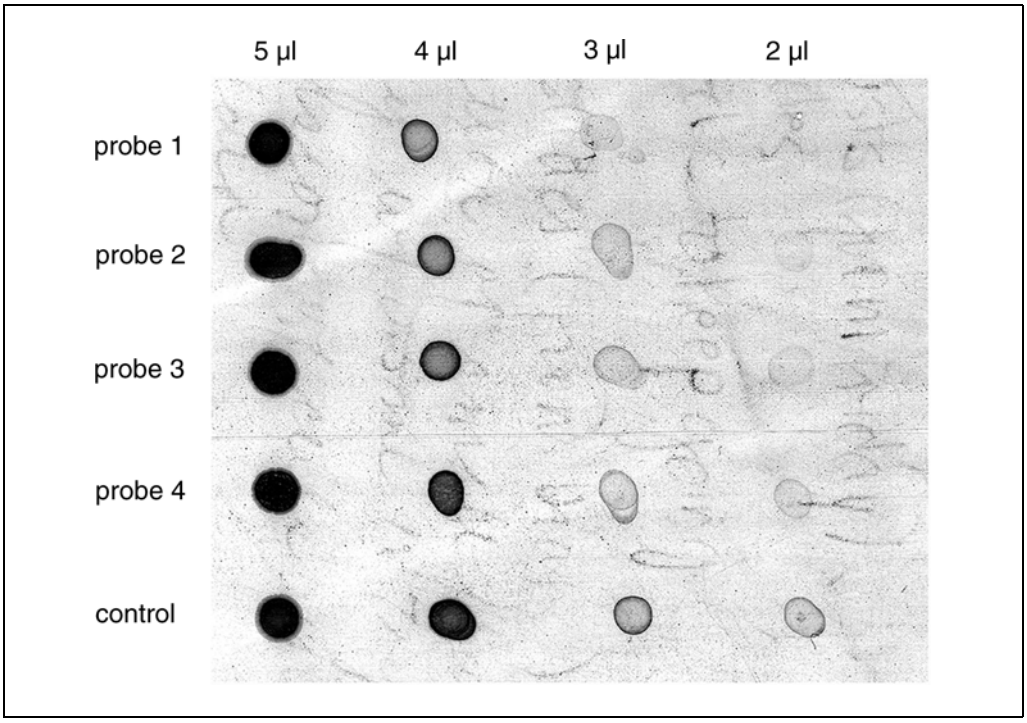

Figure 22.4.2 Dot-blot analysis of biotin incorporation in probes shown in Figure 21.4.1. Compared to control labeled DNA, the labeled probes appear to have incorporated biotin well, with probe 4 showing the greatest incorporation compared to probe 1. The concentration of each probe was estimated at 20 ng/µl; however, it is evident that the labeling efficiency was greater in some probes over others.

protease treatment and assessment. Following optimal slide pretreatment, the specimen is subjected to denaturation, causing double-stranded DNA to become single stranded. This will permit the efficient hybridization of the denatured probe to the DNA target on the slide.

Preparation of Cytogenetic Specimens for FISH

BASIC PROTOCOL 2

The following protocol describes the pretreatment of cytogenetic slides (*UNIT 22.2*) for FISH analysis with DNA probes (in-house or commercial) or commercially obtained PNA probes. In this protocol, pepsin is recommended for use as the protease; however, proteinase K is also often used. The concentration and conditions for proteinase K treatment are also noted in the protocol. The treatment with pepsin will vary depending on the extent of digestion required on the slide. In some cases, pepsin treatment is not needed.

Materials

Cytogenetic slide preparation (*UNIT 22.2*): age naturally at least 2 days at room temperature or artificially (see Support Protocol 2)

10% (w/v) pepsin—100 mg pepsin powder (Sigma) in 1.0 ml H_2O; store in 20-µl aliquots up to several months at −20°C—and 0.01 M HCl, 37°C *or*

14 mg/ml proteinase K (Roche Diagnostics) and proteinase K buffer—i.e., 20 mM Tris·Cl, pH 7 (*APPENDIX 2A*)/0.2 mM CaCl; store up to several months at room temperature

1× PBS (*APPENDIX 2A*)

70% formamide/2× SSC (pH 7.0), 72°C (see *UNIT 18.6* for SSC): prepare fresh

70% ethanol, ice-cold (for DNA probes)

Table 22.4.4 Coplin Jars Needed for Preparation of Cytogenic Specimens for FISH[a]

No. Coplin jars	Contents	Temperature
1	70% ethanol	Room temperature
1	70% ethanol[b]	4°C
1 or 2[b]	80% ethanol	Room temperature
1 or 2[b]	100% ethanol	Room temperature
1	70% formamide in 2× SSC[b]	72°C
1	1× PBS	Room temperature
1	Pepsin/0.01 HCl *or* proteinase K/buffer	37°C or room temperature (respectively)

[a]See Basic Protocol 2.
[b]For DNA probes only.

Phase contrast microscope (*UNIT 4.1*)
Coplin jars

Additional reagents and equipment for hybridization (see Basic Protocol 3 and Alternate Protocol 5)

CAUTION: Formamide is a carcinogen and should be handled with care. Discard according to biohazard rules of the institution.

NOTE: A list of all Coplin jars used in this protocol is given in Table 22.4.4.

Detect and remove cytoplasmic contamination by protease treatment

1. Using a phase-contrast microscope, determine the extent of cytoplasmic residue on the cytogenetic slide preparation. If there is no cytoplasm, proceed to step 6.

2a. *For pepsin digestion:* Add 10 to 15 µl of 10% (w/v) pepsin to 50 ml warm 0.01 M HCl in a Coplin jar. Incubate the slides in the protease 5 min at 37°C.

2b. *For proteinase K digestion:* Dilute 14 mg/ml proteinase K to a final concentration of 0.1 µg/ml in proteinase K buffer in a Coplin jar. Incubate the slides in the protease 6.5 min at room temperature.

Remove protease and determine efficacy

3. Wash the slide 5 min at room temperature in a Coplin jar containing 1× PBS.

4. Pass the slide through a dehydrating series of 70%, 80%, and 100% ethanol in Coplin jars for 5 min each. Allow to air dry after the final ethanol treatment (~5 min).

5. View the slide using phase-contrast microscopy to determine the extent of protein digestion. If necessary, repeat the protease step.

Prepare slides for hybridization

6a. *For PNA probes:* Proceed to hybridization (see Alternate Protocol 5).

6b. *For DNA probes:* Denature the slide for the recommended time (see Table 22.4.5) in 70% formamide/2× SSC (pH 7.0), 72°C.

The time will vary according to the age and quality of the slide.

7b. Promptly place the slide into a Coplin jar containing ice-cold 70% ethanol for 5 min. Pass the slides through a dehydration series of 80% and 100% ethanol for 5 min each.

Table 22.4.5 Formamide Denaturation Guide for Cytogenetic Specimens[a]

Slide criteria	Suggested denaturation time[b]
Fresh slide stored 1–2 days at room temperature	60–90 sec
Fresh slide artificially aged 1–2 days	60–90 sec
Aged slide stored 1–2 weeks at room temperature	1.5–2 min
Aged slide stored 2–4 weeks at room temperature	2 min
Aged slides stored 1–2 months	2–3 min
Previously G-banded slides >1-week old	30–40 sec
Previously G-banded slides <1-week old	20–30 sec

[a]Shown are general guidelines for denaturation of slides of varying ages and conditions. The investigator should pay attention to the slide quality and monitor the changes in denaturation conditions as the slides age or are processed. Each laboratory will possess different environmental conditions as well as slide making procedures, which will affect the denaturation procedures significantly.
[b]Denaturation conditions are 72°C in 70% formamide/2× SSC.

8b. Air-dry the slide after the final ethanol treatment and proceed to hybridization (see Basic Protocol 3).

Artificial Aging of Cytogenetic Slide Preparations for FISH

SUPPORT PROTOCOL 2

The chromosomes on freshly prepared slides are often too fragile for immediate use—i.e., the high temperatures used during the slide denaturation procedure can damage the DNA, making it less optimal for hybridization. Such slides require aging, which can be achieved by allowing them to naturally age a few days at ambient temperature; however, an experiment must occasionally be performed immediately. The protocol below outlines a method for artificially aging freshly prepared slides so that FISH results are available within 12 to 24 hr after preparation from the cytogenetic suspension. This method may also be used when the relative humidity in the laboratory is high due to local weather conditions.

To age, incubate a freshly prepared cytogenetic slide (*UNIT 22.2*) at least 1 hr (up to 3 hr) in a Coplin jar containing 2× SSC (*UNIT 18.6*), 37°C. Remove the slide and pass through a dehydration series of 70%, 80%, and 100% ethanol for 5 min each, and air dry (5 to 10 min). Proceed with enzyme digestion if required.

Note that a list of all Coplin jars used in this protocol is given in Table 22.4.6.

Preparation of Previously G-Banded Cytogenetic Specimens for FISH

ALTERNATE PROTOCOL 2

The following method outlines the steps involved in pretreating a previously Giemsa (G)-banded cytogenetic slide (*UNIT 22.3*) for subsequent use in FISH analysis. The slides must be completely free of any oils and must also be destained. Since the slide has already been treated with a protease, it will require no additional protease digestion; however, stripping the proteins, which are protective to the DNA, will cause it to become much more sensitive to degradation during the denaturation process. The ability to re-use a previously banded slide for FISH will be dependent on the age of the slide, the degree of trypsin digestion during the banding, and whether residual immersion oils or mounting buffers have degraded the DNA.

Materials

Banded cytogenetic slide specimen (*UNIT 22.3*)
Xylene

Table 22.4.6 Coplin Jars Needed for Artificial Aging of Cytogenetic Slide Preparations for FISH[a]

No. Coplin jars	Contents	Temperature
1	70% ethanol	Room temperature
1	80% ethanol	Room temperature
1	100% ethanol	Room temperature
1	2× SSC	37°C

[a]See Support Protocol 2.

Table 22.4.7 Coplin Jars Needed for Preparation of Previously G-Banded Cytogenetic Specimens for FISH[a]

No. Coplin jars	Contents	Temperature
1	70% ethanol	4°C
1	70% ethanol	Room temperature
2	80% ethanol	Room temperature
2	100% ethanol	Room temperature
1	70% formamide/2× SSC, pH 7.0	72°C
1	Methanol	Room temperature
1	Xylene[b]	Room temperature

[a]See Alternate Protocol 2.
[b]*CAUTION:* Maintain in a fume hood.

Methanol
70%, 80%, and 100% ethanol
70% formamide in 2× SSC (pH 7.0; *UNIT 18.6*), 72°C: prepare fresh
70% ethanol, ice-cold
Coplin jars

NOTE: A list of all Coplin jars used in this protocol is given in Table 22.4.7.

1. Remove residual oils from previously banded cytogenic slide specimen by incubating 5 min in a Coplin jar containing xylene under a vented chemical hood.
2. Destain by incubating the slide ~5 to 10 min in a Coplin jar containing room-temperature methanol.
3. Pass the slide through a dehydrating series of 70%, 80%, and 100% ethanol for 5 min each. Allow the slide to air dry (5 to 10 min) after the final ethanol treatment.
4. Denature slide 20 to 30 sec in 70% formamide/2× SSC (pH 7.0), 72°C.

   The time will vary according to the age and quality of the slide (Table 22.4.5).

5. Promptly place the slide into a Coplin jar containing ice-cold 70% ethanol for 5 min following denaturation.
6. Proceed through a dehydration series of 80% and 100% ethanol for 5 min each. Air-dry the slide after the final ethanol treatment and proceed with hybridization (see Hybridization).

Preparation of Paraffin-Embedded Specimens for Hybridization with DNA Probes

FISH analysis on paraffin sections is becoming increasingly important in both diagnostic and research laboratories. This protocol outlines the steps involved in pretreating paraffin sections for FISH. While the preparation of paraffin-embedded specimens can be modified, the most critical component is the quality of the starting section (see Commentary). Different histopathology laboratories will have various methods of tissue fixation which should be taken into consideration when assessing the success of an experiment.

Materials

5- to 10-μM paraffin sections on silanized slides
Xylene
100% ethanol
0.5% (w/v) pepsin in 0.85% (w/v) NaCl (pH 1.5), 45°C (see recipe)
2× SSC, pH 7.0 *(UNIT 18.6)*
Propidium iodide (PI) or DAPI in antifade (see recipes)
70%, 80% and 100% ethanol

Coplin jars
45°C water bath
Fluorescence microscope (*UNIT 4.2*) with a FITC, and PI or DAPI filter set

NOTE: A list of all Coplin jars used in this protocol is given in Table 22.4.8.

Remove wax

1. Add 5- to 10-μM paraffin sections on silanized slide to a Coplin jar containing xylene. Gently agitate 5 min at room temperature. Transfer slides to a second Coplin jar containing fresh xylene for an additional 5 min with gentle agitation.
2. Transfer the slide to a Coplin jar containing 100% ethanol. Soak 5 min, then transfer slides to fresh 100% ethanol and soak another 5 min. Agitate 2 to 3 times during each 5-min period.
3. Remove the slide from ethanol and allow to air dry (5 to 10 min).

Perform protease digestion and counterstain

4. Place slide in a Coplin jar containing 0.5% (w/v) pepsin in 0.85% NaCl, 45°C. Incubate 15 to 20 min in a 45°C water bath (see Table 22.4.5).
5. Rinse the slide 20 to 30 sec in a Coplin jar containing 2× SSC, pH 7.0.

Table 22.4.8 Coplin Jars Needed for Preparation of Paraffin-Embedded Specimens for Hybridization with DNA Probes[a]

No. Coplin jars	Contents	Temperature
1	70% ethanol	Room temperature
1	80% ethanol	Room temperature
3	100% ethanol	Room temperature
1	0.5% pepsin in 0.85% NaCl	45°C
4	2× SSC, pH 7.0	Room temperature
2	Xylene[b]	Room temperature

[a] See Alternate Protocol 3.
[b] *CAUTION:* Maintain in a fume hood.

Table 22.4.9 Troubleshooting Guide for Pretreatment of Paraffin-Embedded Sections

Problem	Cause	Solution
Green autofluorescence upon inspection/or poor uptake of counterstain	Under-digestion with pepsin solution	Remove coverslip and wash with 2× SSC as described (see Alternate Protocol 3, step 5). Return the slide to pepsin digestion buffer (see Alternate Protocol 3, step 4). The time required for subsequent protease treatment will be dependent on the existing degree of digestion.
		Should repeated attempts at digestion fail, consider another enzyme such as proteinase K (use at 10 mg/ml in 2× SSC for 20 min at 37°C) in place of the pepsin buffer (see Alternate Protocol 3, step 4) or in combination with the pepsin buffer.
Lifting of tissue from slide	Loosening by protease treatment	Occasionally the protease treatment will loosen the tissue from the slide. Try to work carefully such that the tissue is relatively undisturbed.
	Glass slides not coated with silane	Associated with this is the use of charged or silanated slides. Many pathology labs will use coated slides. Check if the sections were mounted onto such slides. If not, try to obtain sections on these slides.
Holes in tissue or "ghosty" appearance	Over-digestion	Over-digestion will be evident from the degradation of the tissue. Start again and decrease the tissue treatment.

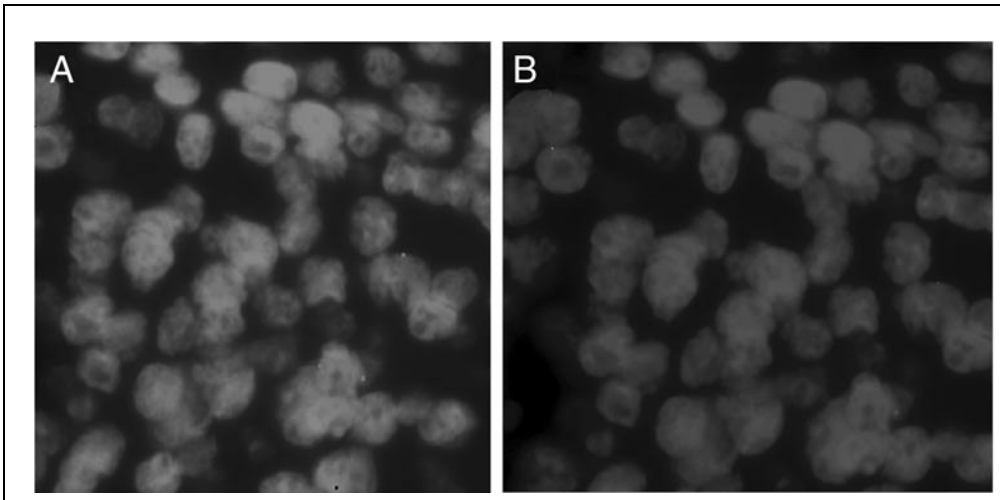

Figure 22.4.3 Digestion of paraffin-embedded specimen for FISH. (**A**) Under-digestion is indicated by weak uptake of the DAPI stain. (**B**) Increased digestion permits better access to the DNA and increase uptake of DAPI. *This black and white facsimile of the figure is intended only as a placeholder; for full-color version of figure, see color plates.*

6. Apply 10 μl PI or DAPI in antifade to counter stain and coverslip.

   The choice between PI or DAPI depends on the label color of the probe being analyzed.

7. View the slide using a fluorescence microscope with FITC, and PI or DAPI filter set. Evaluate the tissue sections for under-digestion, appropriate digestion, or over-digestion using the guidelines in Table 22.4.9 and Figure 22.4.3.

For certain types of tissue additional troubleshooting steps may also be necessary (see Troubleshooting).

8. Carefully remove the coverslip and rinse slide three times in separate Coplin jars containing 2× SSC, pH 7.0, for 5 min each, agitating 5 to 10 sec in each rinse.
9. Dehydrate slide in a series of 70%, 80%, and 100% ethanol washes for 1 min each.
10. Allow the slide to air dry. Proceed to hybridization with labeled DNA probes.

Preparation of Paraffin-Embedded Specimens for Hybridization with PNA Probes

ALTERNATE PROTOCOL 4

PNA probes are also applicable to paraffin sections. Like pretreatment for hybridization with DNA probes (see Alternate Protocol 3), pretreatment for hybridization with PNA probes requires some minor modifications as described below.

Materials

5- to 10-μM paraffin sections on silanized slides
Xylene
100% ethanol
100 μg/ml RNase I (see recipe)
2× SSC (*UNIT 18.6*)
1 M sodium thiocyanate, 80°C
5 mg/ml pepsin in 0.85% (w/v) NaCl, 45°C (see recipe)
0.1 M triethanolamine, pH 8.0
Acetic anhydride (Sigma)
1× PBS (*APPENDIX 2A*)
70%, 80%, and 100% ethanol
45°C hot plate or slide warmer
Coplin jars
37°C oven

NOTE: A list of all Coplin jars used in this protocol is given in Table 22.4.10.

Remove wax

1. Preheat 5- to 10-μm paraffin sections on silanized slide on a 45°C slide warmer or hot plate for ~30 min (i.e., until the wax melts).

Table 22.4.10 Coplin Jars Needed for Preparation of Paraffin-Embedded Specimens for Hybridization with PNA Probes[a]

No. Coplin jars	Contents	Temperature
1	70% ethanol	Room temperature
1	80% ethanol	Room temperature
4	100% ethanol	Room temperature
2	1× PBS	Room temperature
1	5 mg/ml pepsin in 0.85% NaCl	45°C
1	1 M sodium thiocyanate	80°C
5	2× SSC	Room temperature
1	Triethanolamine, pH 8.0	Room temperature
2	Water	Room temperature
3	Xylene[b]	Room temperature

[a] See Alternate Protocol 4.
[b] *CAUTION:* Maintain in a fume hood.

2. Dewax by transferring the slide to a Coplin jar containing 50 ml xylene and incubating 5 to 10 min at room temperature. Repeat twice with fresh xylene.

   Time for dewaxing is dependent on many factors (e.g., tissue section thickness, surface area, type of tissue).

3. Remove xylene by soaking slide 5 to 10 min in 100% ethanol. Repeat twice with fresh ethanol.

4. Allow slides to air dry (5 to 10 min).

   The tissue should turn white at this point.

Treat with RNase, SSC, and sodium thiocyanate

5. Add 40 µl of 100 µg/ml RNase I to the slide. Cover with a coverslip and incubate 1 hr at 37°C.

6. Wash twice in Coplin jars containing fresh 2× SSC for 5 min each time.

7. Incubate slide 8 min in a Coplin jar containing 1 M sodium thiocyanate, 80°C.

8. Rinse twice in Coplin jars containing fresh distilled water for 1 min each.

Digest with protease

9. Incubate 7 to 9 min at 45°C in a Coplin jar containing 5 mg/ml pepsin in 0.85% NaCl, pH 1.5.

10. Wash twice for 1 min each in Coplin jars containing fresh 2× SSC.

Acetylate

11. Start acetylation by placing slide in a Coplin jar containing 0.1 M triethanolamine, pH 8.0.

12. While stirring gently, slowly add 125 µl acetic anhydride to give a final concentration of 0.25% (v/v). Incubate 10 min at room temperature.

    The acetylation procedure is carried out to reduce the electrostatic binding of probe to positive charges on the tissue, thereby reducing the background.

Wash and dehydrate

13. Rinse 5 min in a Coplin jar containing 1× PBS. Repeat the rinse using a fresh Coplin jar of PBS.

    Washes from this point forward can be reduced in duration if adherence of tissue to the slide is poor.

14. Rinse 5 min in a fresh Coplin jar containing 2× SSC.

15. Dehydrate through a series of 70%, 80%, and 100% ethanol and allow to air dry.

16. Proceed to hybridization with PNA probes (see Alternate Protocol 7).

HYBRIDIZATION

In the following section, hybridization of the probe to the slide is described. The prepared DNA probe is denatured to a single-stranded state in the presence of denaturing buffer. Depending on the probe type, there may be a preannealing step. The denatured probe is applied to the denatured cytogenetic specimen and allowed to hybridize overnight. Additionally, this section also describes the hybridization conditions for paraffin sections, where the slide and probe are simultaneously denatured. If commercial DNA probes are being used, the manufacturer's instructions for probe denaturation are followed and the hybridization conditions are adjusted accordingly. If a PNA probe is utilized, the probe

is applied to the slide, and together the probe and target are denatured and permitted to hybridize for at least 1 hr.

Hybridization of Labeled DNA Probes to Cytogenetic Specimens

BASIC PROTOCOL 3

Hybridization of a cyotgenetic specimen with the probe requires heat-denaturation of the DNA probe in the hybridization buffer, and a pretreated and denatured slide specimen; together they are permitted to hybridize at 37°C. This protocol can be applied to cytogenetic specimens that are unstained or were previously G-banded (see Alternate Protocol 2).

Materials

DNA probe (see Basic Protocol 1 and Alternate Protocol 1)
Pretreated and denatured cytogenetic slide specimen (see Basic Protocol 2 and Support Protocol 2)
Rubber cement

75°C water bath or PCR machine
37°C dry oven
Glass coverslips
Hybridization box, slightly dampened (e.g., black plastic video tape box lined with slightly moistened gauze or paper towel)
Hybridization container (i.e., any plastic container with lid or a black video cassette box)

1. Heat-denature the required amount of labeled DNA probe 5 min in a 75°C water bath or PCR machine. Preanneal 1 hr in a 37°C dry oven (see Critical Parameters).
2. Add the appropriate amount of DNA probe to the pretreated and denatured cytogenetic slide specimen using guide given in Table 22.4.11. Coverslip and ring the perimeter with rubber cement to seal in place.

Table 22.4.11 Guide to Appropriate Probe Volume for a Given Coverslip Size

Probe volume	Coverslip size (mm)
10 µl	22 × 22
20 µl	22 × 30
30 µl	22 × 50

Table 22.4.12 Examples of Minimal Hybridization Times Required for Representative DNA Probes

Probe type (300–500 bp)	Minimal hybridization time (37°C)
Centromere Probes[a]	4 hr
Subtelomere chromosome-specific probes[a]	24 hr
Chromosome paints	4 hr
Translocation junction unique-sequence probes	24 hr
Microdeletion unique-sequence probes	24 hr
Probes detecting gene amplification	24 hr

[a]Protein nucleic acid (PNA) probes, which are commercially available, require a minimum of 60 min for hybridization.

3. Place slide in a slightly dampened hybridization box.
4. Transfer slide to a hybridization container and incubate overnight in a 37°C dry oven (see Table 22.4.12).
5. Proceed to post-hybridization washes and immunofluorescent detection of indirectly (see Basic Protocol 4) or directly labeled DNA probes (see Alternate Protocol 8)

ALTERNATE PROTOCOL 5

Hybridization of PNA Probes to Cytogenetic Specimens

PNA probes, as discussed below (see Critical Parameters), can be commercially obtained. Use of PNA probes requires minor modifications in the hybridization to both cytogenetic specimens and paraffin-embedded sections, as described below.

Additional Materials *(also see Basic Protocol 3)*

Labeled PNA probe (Applied Biosystems)
Pretreated cytogenetic specimen, not denatured (Basic Protocol 2)
80°C oven, hot plate, or HYBrite (Vysis)

1. Add the required amount of labeled PNA probe to the pretreated, undenatured, cytogenetic specimen.
2. Coverslip and seal with rubber cement. Allow the rubber cement to set and dry.
3. Place the slide in an 80°C oven or HYBrite, or on an 80°C hot plate for 90 sec.
4. Remove the slide and place it into a hybridization box. Hybridize at least 1 hr at room temperature.
5. Proceed to post-hybridization washes for specimens hybridized with PNA probes (see Alternate Protocol 10).

ALTERNATE PROTOCOL 6

Hybridization of Labeled DNA Probes to Sections from Paraffin-Embedded Material

Unlike cytogenetic specimens, tissue sections from paraffin-embedded material require higher denaturation temperatures and longer denaturation times. Hybridization to these sections requires co-denaturation of the probe and tissue section simultaneously. All experiments using previously paraffin-embedded material and a DNA probe should include a minimal 24-hr hybridization.

Additional Materials *(also see Basic Protocol 3)*

Deparaffinized and enzyme-digested specimen (see Alternate Protocol 3)
90°C oven, hot plate, or HYBrite (Vysis)

1. Apply DNA probe to the deparaffinized and enzyme-digested specimen using the guide given in Table 22.4.11. Add a glass coverslip and apply rubber cement along the perimeter of the coverslip. Allow the rubber cement to dry.
2. Denature the probe and target DNA simultaneously by placing the slide in a 90°C oven or HYBrite, or on a 90°C hot plate for 12 min.
3. *For slide denatured in an oven or on a hot plate:* Transfer the slide to a hybridization container lined with a wet paper towel or damp gauze, and incubate overnight in a 37°C dry oven.
4. *For slide denatured in a HYBrite:* Program the unit to hold at 37°C. Incubate overnight.

5. Proceed to post-hybridization washes and immunofluorescent detection of indirectly or directly labeled DNA probes (see Basic Protocol 4 or Alternate Protocols 8 or 9).

Hybridization of PNA Probes to Sections from Paraffin-Embedded Material

ALTERNATE PROTOCOL 7

The following protocol describes hybridization of commercially available PNA probes to pretreated sections from paraffin-embedded samples. Unlike DNA probes, PNA probes require a minimum of 60 min for hybridization.

Additional Materials *(also see Basic Protocol 3)*

PNA probes (Applied Biosystems)
Deparaffinized and enzyme-digested specimen (see Alternate Protocol 4)
80°C oven, hot plate or HYBrite (Vysis)

1. Apply the appropriate amount of PNA probe (as suggested by the manufacturer) to the deparaffinized and enzyme-digested paraffin section using the guidelines provided in Table 22.4.11. Coverslip and seal with rubber cement. Allow the rubber cement to dry.
2. Place in an 80°C oven or HYBrite, or on an 80°C hot plate for 3 min.
3. Place in a hybridization container and allow to hybridize at least 1 hr at room temperature.
4. Proceed to post-hybridization wash for slides hybridized with PNA probes (see Alternate Protocol 10).

POST-HYBRIDIZATION WASHES AND DETECTION

Following hybridization, unbound probes, whether DNA or PNA, must be removed from the specimen. This is accomplished through washes of appropriate stringency, using formamide and SSC in varying amounts. After immunodetection, final washes contain detergents to remove unbound antibodies. The slides are counterstained and mounted in an antifade medium for visualization. Variations on washing procedures reflect the nature of the probe, whether directly or indirectly labeled.

Post-Hybridization Washes and Immunofluorescent Detection of Indirectly Labeled DNA Probes

BASIC PROTOCOL 4

This protocol describes post-hybridization washes and detection of indirectly labeled DNA probes. Following overnight hybridization, the coverslip is removed and the slide is immersed in a solution of formamide to remove any unbound probe. The slide is then washed in stringent SSC washes and blocked with a solution of BSA. Depending on the type of DNA probe used, amplification of the signal may be required. This is achieved by the addition of primary and secondary antibodies that may or may not be conjugated with a fluorochrome. Detergent washes are carried out after each antibody incubation; it is critical that the slide not be permitted to dry out at any point of the assay. The slide is then counterstained and ready for visualization. In multicolor FISH experiments, the user may have both indirectly and directly labeled probes on the same specimen. If this is the case, it is important to keep the ambient light dim to prevent quenching of the signal; Coplin jars with lids are useful for this purpose. If using multiple indirectly labeled probes, be sure that the primary and secondary antibodies are raised in different animals such that there is no cross-reaction. This protocol is applicable to cytogenetic slides or sections from paraffin-embedded samples; however, more stringent or additional washes may be required for paraffin experiments.

Table 22.4.13 Coplin Jars Needed for Post-Hybridization Washes and Immunofluorescent Detection of Indirectly Labeled DNA Probes[a]

No. Coplin jars	Contents	Temperature
3	50% formamide in 2× SSC	45°C
3	1× SSC	45°C
9	0.1% Tween 20 in 4× SSC	45°C

[a]See Basic Protocol 4.

Materials

Hybridized slides in a hybridization box (see Basic Protocol 3 and Alternate Protocol 6)
50% formamide in 2× SSC, 45°C (prepare fresh)
1× SCC, 45°C (*UNIT 18.6*)
Blocking solution: 1% BSA (w/v)/0.1% (v/v) Tween 20 in 4× SSC (store indefinitely at −20°C or up to several months at 4°C)
Primary, secondary, and tertiary antibodies (see recipe for antibodies)
0.1% (v/v) Tween 20 in 4× SSC, 45°C
DAPI in antifade (see recipe)
Clear nail polish

Coplin jars
22 × 50–mm glass coverslips
37°C oven
Fluorescent microscope and appropriate filter sets (*UNIT 4.2*)

CAUTION: Formamide is a carcinogen and should be handled with care. Discard according to biohazard rules of the institution.

NOTE: A list of all Coplin jars used in this protocol is given in Table 22.4.13.

Remove coverslip

1. After 24 hr, remove hybridized slide from the hybridization box.
2. Carefully peel the rubber cement from the hybridized slide and immerse in a Coplin jar containing 50% formamide in 2× SSC, 45°C.
3. Allow the coverslip to fall off and let stand 5 min in solution with gentle agitation.

Wash and block

4. Remove slide and transfer to second Coplin jar containing formamide/SSC, 45°C, for 5 min. Agitate gently. Repeat with a third Coplin jar containing formamide/SSC, 45°C.
5. Wash the slide for 5 min each in three consecutive Coplin jars containing 1× SSC, 45°C, agitating gently between washes.
6. Drain excess solution but do not allow the slides to dry. Add 80 µl blocking solution, coverslip with 22 × 50–mm glass, and place back in hybridization box. Incubate 40 min at 37°C.

Label with primary antibody

7. Remove coverslip and add 80 µl primary antibody. Coverslip and place back into the hybridization box. Incubate 40 min at 37°C.

Table 22.4.14 Common Primary and Secondary Antibody Systems and Final Concentrations[a]

Hapten	Primary antibody	Secondary antibody	Tertiary antibody	Color	Probe Type
Biotin (no signal amplification)	5 μg/ml FITC-avidin	—	—	green	Centromere chromosome paints
Biotin	5 μg/ml FITC-avidin	5 μg/ml biotinylated goat anti-avidin	5 μg/ml FITC-avidin	Green	Locus-specific cDNAs
Biotin	5 μg/ml rhodamine-avidin	5 μg/ml biotinylated goat anti-avidin	5 μg/ml rhodamine-avidin	Red	Locus-specific cDNAs
Digoxigenin (no signal amplification)	2 μg/ml rhodamine anti-Dig	—	—	Red	Centromere chromosome paints
Digoxigenin (no signal amplification)	2 μg/ml FITC anti-Dig	—	—	Green	Centromere chromosome paints
Digoxigenin	0.5 μg/ml mouse anti-digoxigenin	2 μg/ml digoxigenin anti-mouse	2 μg/ml rhodamine anti-Dig	Red	Locus-specific cDNAs
Digoxigenin	0.5 μg/ml mouse anti-digoxigenin	2 μg/ml digoxigenin anti-mouse	2 μg/ml FITC anti-Dig	Green	Locus-specific cDNAs

[a]Shown in this table are the most common antibody systems for the detection of biotinylated and digoxigenin (Dig)-labeled DNA. Final concentrations for antibodies are also stated but may require adjustment. A variety of antibody systems are available from Molecular Probes and Roche Diagnostics. If a two–color FISH approach is being used, be sure that respective primary, secondary, and tertiary antibodies do not cross-react. This may require sequential hapten detection rather than concomitant hapten detection. The scheme above uses antibodies raised against mouse and goat, thus no cross-reaction will occur. Antibodies raised in rabbits will also offer more variety in hapten detection.

This antibody may or may not have a fluorescent moiety conjugated to it, depending on the nature of the probe (see Critical Parameters). Common primary antibody and secondary antibody systems are outlined in Table 22.4.14.

8. Remove coverslip and wash slide for 5 min each in three consecutive Coplin jars containing 0.1% Tween 20/4× SSC, 45°C, with gentle agitation. If proceeding with signal amplification (see Table 22.4.15) continue to step 9. Otherwise, proceed to step 14.

9. Drain excess wash solution, but do not allow slide to dry. Add 80 μl blocking solution, coverslip, and place back into the hybridization box. Incubate 10 min at 37°C.

Label with secondary antibody

10. Remove coverslip and add 80 μl secondary antibody (Table 22.4.14). Coverslip and place back into the hybridization box. Incubate 30 min at 37°C.

11. Remove coverslip and wash slide 5 min each in three consecutive Coplin jars containing 0.1% Tween 20 in 4× SSC, 45°C, with gentle agitation.

Label with tertiary antibody

12. Remove coverslip and add 80 μl tertiary antibody (conjugated to fluorochrome). Coverslip and place back into the hybridization box. Incubate 30 min at 37°C.

13. Remove coverslip and wash slide 5 min each in three consecutive Coplin jars containing 0.1% Tween 20 in 4× SSC, 45°C, with gentle agitation.

Counterstain and seal

14. Drain excess wash solution, but do not allow the slides to dry. Add 40 μl DAPI in antifade counterstain. Coverslip and seal with clear nail polish.

The slides are now ready for visualization. When not in use, store slides up to several weeks or months at −20°C, depending on the frequency of visualization.

15. Examine using a fluorescent microscope and appropriate filter sets.

Table 22.4.15 Interpretation of Parallel Positive Control Experiments

Problem	Slide hybridized with new probe	Slide hybridized with good known probe	Analysis
Background	Present	Not present	New probe may still contain unincorporated dNTPs or many small labeled fragments are present and did not hybridize. Slide quality is not the problem. Washing conditions also do not appear to be the cause.
Background	Present	Present	Problems likely related to washing conditions or slide quality rather than issues with the probe.
Weak Signal (indirect-labeled probe)	Yes	No	If using antibody detection system for indirectly labeled probes, this scenario indicates that the antibodies are in good working order. Look to problems with incorporation of the hapten into the DNA.
Weak signal (direct-labeled probe)	Yes	No	This indicates a problem with the labeling of the probe. Check that all enzymes and fluorochromes are within their shelf life. This also indicates that washing conditions are correct.
Weak signal (indirect labeled probe)	Yes	Yes	This indicates a problem with the antibody detection system. Ensure that the concentrations are correct and that the antibodies are fresh. It may also indicate a problem with hybridization, insufficient denaturation of the target DNA on the slide, or overall quality of the DNA specimen.
Weak signal (direct-labeled probe)	Yes	Yes	The problem may be in the post-hybridization washes: too stringent or temperatures too high.
Poor chromosome morphology with weak signal	Yes	Yes	Over denaturation if the chromosomes appear puffy.
Good chromosome morphology but no signal	Yes	Yes	Slides are likely too old and resistant to denaturation. Change to a more fresh preparation. Otherwise the experiment can be repeated but the denaturation of the slide should be increased.

ALTERNATE PROTOCOL 8

Post-Hybridization Washes and Detection of Directly Labeled DNA Probes

The protocol below outlines steps for washing slides hybridized with directly labeled probes. If using commercially produced probes, follow the manufacturer's instructions. This protocol is applicable to hybridized cytogenetic slides or paraffin sections. See Basic Protocol 4 for materials.

NOTE: A list of all Coplin jars used in this protocol is given in Table 22.4.16.

1. After 24 hr hybridization, carefully peel off rubber cement from slide and immerse in a Coplin jar containing 50% formamide in 2× SSC, 45°C. Allow the coverslip to fall off and let stand 5 min.
2. Remove slide and transfer to a fresh Coplin jar containing formamide/SSC, 45°C. Incubate 5 min. Repeat with a third Coplin jar containing formamide/SSC, 45°C.

Table 22.4.16 Coplin Jars Needed for Post-Hybridization Washes and Detection of Directly Labeled DNA Probes[a]

No. Coplin jars	Contents	Temperature
3	50% formamide in 2× SSC	45°C
3	1× SSC	45°C
3	0.1% Tween in 4× SSC	45°C

[a]See Alternate Protocol 8.

Table 22.4.17 Coplin Jars Needed for Rapid Wash of Directly Labeled Probes[a]

No. Coplin jars	Contents	Temperature
1	0.3% (v/v) NP-40 in 2× SSC	72°C
1	0.3% (v/v) NP-40 in 2× SSC	Room temperature
1	2× SSC	Room temperature

[a]See Alternate Protocol 9.

3. Wash slide 5 min each in three consecutive Coplin jars containing 1× SSC, 45°C.
4. Wash slide 5 min each in three consecutive Coplin jars containing 0.1% Tween 20 in 4× SSC, 45°C, with gentle agitation.
5. Drain excess wash solution, but do not allow the slide to dry. Add 40 µl DAPI in antifade counterstain. Coverslip with 22 × 50–mm glass and seal with clear nail polish. Store slide up to several months at −20°C.

   Fluorescence fading will depend upon the frequency of viewing.
6. Examine using a fluorescent microscope equipped with the appropriate filters.

ALTERNATE PROTOCOL 9

Rapid Wash of Directly Labeled Probes

This protocol describes the use of high temperatures and stringent SSC washes for the removal of unbound probe from target DNA. This protocol is generally effective for directly labeled DNA, particularly from commercial sources. It is important to consider the differing stringency requirements of each probe being used when planning this protocol since excessive temperature can strip bound probe from the target. This protocol is applicable to cytogenetic slides or paraffin sections.

Additional Materials *(also see Basic Protocol 4)*

2× SSC (*UNIT 18.6*)
0.3% (v/v) NP-40 in 2× SSC, room temperature and 72°C

NOTE: A list of all Coplin jars used in this protocol is given in Table 22.4.17.

1. Carefully remove rubber cement from the hybridized slide. Place the slide and coverslip in a Coplin jar containing 2× SSC to gently remove coverslip.
2. Once the coverslip has fallen off, incubate the slide 1 to 2 min in a Coplin jar containing 0.3% NP-40 in 2× SSC, 72°C.
3. Remove slide and wash 1 min in a Coplin jar containing 0.3% NP-40/2× SSC, room temperature.
4. Drain solution from slide and add DAPI in antifade counterstain. Add a 22 × 50–mm glass coverslip and seal with clear nail polish.
5. Examine the slide with a fluorescent microscope equipped with the appropriate filters.

ALTERNATE PROTOCOL 10

Post-Hybridization Washes for Specimens Hybridized with PNA Probes

This protocol describes a procedure for removing unbound PNA probe from cytogenetic specimens or from paraffin sections.

Materials

Slides hybridized with PNA probes (see Alternate Protocol 5 or 7)
70% (v/v) formamide/10 mM Tris·Cl (pH 7.0 to 7.5)/0.1% (w/v) BSA (see recipe)
0.1 M Tris·Cl (pH 7.0 to 7.5)/0.15 M NaCl/0.08% (v/v) Tween 20 (store up to several weeks at room temperature)
70%, 90%, and 100% ethanol
DAPI in antifade solution (see recipe)
Fluorescent microscope and appropriate filters

NOTE: A list of all Coplin jars used in this protocol is given in Table 22.4.18.

1. Remove coverslip from slide hybridized with PNA probes and wash 15 min in a Coplin jar containing 70% formamide/10 mM Tris·Cl (pH 7.0 to 7.5)/0.1% BSA. Repeat once.
2. Wash 5 min each in three consecutive Coplin jars containing 0.1 M Tris·Cl (pH 7.0 to 7.5)/0.15 M NaCl/0.08% Tween 20.
3. Dehydrate slide by incubating 5 min each in Coplin jars containing 70%, 90%, and 100% ethanol. Air dry (5 to 10 min).
4. Apply DAPI in antifade and coverslip.
5. Examine the slide using a fluorescent microscope and appropriate filters.
6. Store slides up to several months at −20°C

INTERPRETATION OF FISH FINDINGS

This section discusses interpretation of FISH experiments and relevant troubleshooting measures. Each laboratory may adopt a different means of assessing positive and negative results as is applicable to the experiment and the question being asked. The guidelines below can generally be applied to both interphase and metaphase analysis.

Evaluating FISH

FISH encompasses four main components: the slide and its preparation (see Target Slide Preparation), the DNA probe and its preparation (see Labeling DNA Probes for FISH),

Table 22.4.18 Coplin Jars Needed for Post-Hybridization Washes for Specimens Hybridized with PNA Probes[a]

No. Coplin jars	Contents	Temperature
2	70% formamide/10 mM Tris·Cl (pH 7.0–7.5)/0.1% BSA	Room temperature
3	0.1 M Tris·Cl (pH 7.0–7.5)/0.15 M NaCl/0.08% Tween 20	Room temperature
1	70% ethanol	Room temperature
1	90% ethanol	Room temperature
1	100% ethanol	Room temperature

[a]See Alternate Protocol 10.

denaturation and hybridization of the probe to the slide (see Hybridization), and finally, post-hybridization washes and detection (see Post-Hybridization Washes and Detection). Each of these components is, in itself, multistepped. The discussion below outlines many of the problems encountered in FISH experiments, including factors influencing signal strength, background, and preserving optimal chromosome morphology. Other sources for FISH optimization and parameters can be found in Beatty et al. (2002), Henegariu et al. (2001), Schwarzacher and Heslop-Harrison (2000), and van de Rijke et al. (1996).

Signal strength

Slide age. In the author's experience, optimal results have been obtained from slides not older than 2 months. As the slides age further (3 to 6 months), they become harder to denature. Conversely, very old preparations (>1 year) often have partially degraded DNA that may reduce or preclude effective FISH experiments. In such situations, preparations tend to become very sensitive to denaturation. Previously G-banded slides (*UNIT 22.3*) have an even shorter life span and should be processed within 2 weeks (refer to Table 22.4.5).

Cytoplasmic debris. The presence of cytoplasm on the slide may inhibit binding and contribute to overall background. A more aggressive protease pretreatment may be required to reduce cytoplasmic protreinacious noise. This can be accomplished by increasing the time of digestion or the amount of protease added (maintain the same digestion time). One must also consider whether the slide is made from a dropped suspension or FISHed to a slide made from an in situ culture, since the latter slides tend to possess more cytoplasmic and cellular debris. A high background obscures true signals. If there is minimal background but the signal is weak in different parts of the slide, then there may be a gradient or patchiness of cellular protein in areas of the slide with a higher density of fixed cells.

Excessive slide pretreatment. Excessive enzymatic treatment may damage the target DNA, making it less efficient for hybridization with the probe. This is usually indicated by weak uptake of the counterstain and the presence of bright centromeres.

Denaturation time. As the slide ages (see above), the chromosomes become harder to separate into single strands. Slides used within 1 to 2 weeks of preparation should be denatured for 1.5 to 2 min. Slides that are older may require times that range from 2 to 3 min. Under-denaturaton results in insufficient strand separation of the target DNA, decreasing the effective hybridization efficiency. Over-denaturation of the target DNA causes DNA damage and reduces the amount of target DNA that is able to hybridize with the probe; it also results in reduced hybridization efficiency. Over-denaturation usually also results in poor uptake and banding using the DNA counterstain and very bright centromeres.

Sealing of coverslip. It is critical that the coverslip be adequately sealed with rubber cement during incubations to prevent any moisture from entering the hybridized area, thus diluting the probe. Do not use contact cement or other ultra-adhesive glues.

Proper temperature for washes and incubations. Check that the temperature in the oven, hot plate unit, or water bath is correct for hybridization and other incubations. High temperatures during post-hybridization washes may remove bound probe with weak sequence homology (see Critical Parameters), thus decreasing the amount of DNA available for signal detection or antibody binding. Avoid taking shortcuts during incubation times with blocking reagents or antibody detection reagents. Also be sure that the reagents do not dry up on the slide; this makes washing more difficult.

Detergent type and concentration. Increasing the detergent content or choice of detergent may influence signal strength. Tween 20 is generally less harsh than NP-40. Increasing

the detergent concentration in combination with increasing temperature will remove more probe and/or bound antibodies. Be sure that the concentration and temperatures are correct.

SSC concentration. Decreasing SSC concentration increases stringency. Thus 0.1× SSC destabilizes double-stranded DNA more readily than 2× SSC. Double-stranded DNA stability is also affected by the extent of sequence homology between the probe and target DNAs. Ensure that the proper SSC concentrations are used during washes.

Proper filter sets. For fluorescence, make sure that the proper filter sets are used for image acquisition. The use of filters with incorrect spectral characteristics for the fluorochrome being used can severely impair the ability to detect the correct signals or they may increase the amount of autofluorescence. Also refer to *UNIT 4.2* and *APPENDIX 1E*.

Amplification of signal. When using an indirectly labeled DNA probe, signal amplification may be required. If the signal is amplified but still weak, check the concentrations and shelf lives of antibodies used. If the antibodies are in good order, relabel the probe and check the labeling efficiency (see Critical Parameters). For directly labeled probes, consider the labeling efficiency of the probe.

Probe characteristics

In-house probes. If probes are labeled in-house (see Labeling DNA Probes for FISH), strict controls must be undertaken to ensure that proper hapten or fluorochrome incorporation has been obtained to produce a high-quality DNA probe. Haptens may be assessed using the dot blot method of incorporation. Directly labeled probes can be assessed by removing a small aliquot of probe, placing it on a slide, and viewing it by fluorescence microscopy.

Cot-1 suppression. Excessive Cot-1 suppression may be the cause of reduced signal. Smaller DNA probes or cDNAs contain fewer repeat elements compared to larger inserts. Normally, 5 to 10 μg Cot-1 is sufficient per 100 ng labeled DNA; adjust as required.

Commercial probes. Usually commercial suppliers properly process the product with the necessary quality controls. Check that the probes were properly stored and used before the expiration date. For some experiments it is possible to optimize procedures using concentrations of commercial probes at levels slightly below those recommended by the supplier. This can prove very cost effective if a specific commercial probe is going to be used routinely.

Probe concentration. The probe is usually used in excess of the target DNA; however, make sure that sufficient probe volume has been added to adequately cover the area of interest on the slide (see Table 22.4.11).

Preannealing. Preannealing at 37°C is usually carried out for 1 hr following denaturation. This step is performed to permit the annealing of repetitive sequences in the DNA probe with unlabeled Cot-1 DNA to prevent cross-hybridization. If there are few repetitive elements in the probe, or the probe is a cDNA or small insert, this step may be omitted. The probe is simply denatured and applied to the denatured slide.

Background

Cytoplasmic debris. This is the most common cause of background. Increase the incubation time during protein digestion or maintain the same time but change the concentration of the enzyme.

Bacterial/yeast contamination. Microorganisms that contaminate cultures used to make the slide, or reagents used to prepare the slide or for hybridization are deposited onto the slide. If the contamination is minor, then it is only necessary to analyze the slide in areas that contain fewer deposits of fungi or bacteria. If the contamination is heavy, the slide or reagent must be prepared again.

Coverslips. Coverslips should be clean and dust free. If cells are to be grown in situ, use only glass coverslips as plastic coverslips autofluoresce.

Residual oils. Slides that have been previously visualized using immersion oil (e.g., G-banded slides) should be cleaned with xylene. Residual oils will prevent hybridization and cause background problems.

Dust and other particles. Particles may be deposited on the slide during various transfers into solutions. Be sure that solutions are well mixed and filtered as needed. Some solutions may form precipitates that may bind to the slide.

In-house probes. Ensure that nonincorporated conjugated nucleotides are removed from the final probe preparation.

Commercial probes. These probes are usually not the cause of background, especially when the same probe on another slide preparation has not produced background; however, note the lot number for future reference. It is also very helpful to introduce a new batch of a commercial probe into routine use before the previous lot is exhausted in case the supplier has had production difficulties

Unlabeled DNA: carrier and Cot-1. An excess of unlabeled DNA is added to the probe mixture. Although it is unlabeled, it can contribute to background by trapping antibodies. To reduce this problem, ensure that the resuspended probe pellet is fully dissolved in sufficient hybridization buffer. If the pellet does not completely dissolve, add more buffer. This will not significantly alter the reaction.

Denaturation time. The probe is usually heat denatured a minimum of 5 min. This should be sufficient time to denature the probe and dissolve any remaining DNA. The denaturation time may be increased to 10 min without any damage to the DNA probe.

Post-hybridization washes. Make sure that the correct temperature has been maintained for washes and incubations. Agitation during the washes can help to remove unbound probe and antibodies. Increasing the stringency of the washes by either increasing the temperature or altering the amount of SSC in the washes can also help considerably if background is encountered. Avoid drying the slide with any residual blocking or detection reagents.

Detergent concentration. Increasing the detergent concentration in post-hybridization washes in combination with increasing temperature removes more probe and/or bound antibodies. Be sure that the concentration and temperatures are correct.

Fading signals

In-house probes. Ensure that stocks of directly conjugated dNTPs are properly stored in the dark and used well before the expiration date. Unlike indirectly labeled probes, directly labeled DNAs have a much shorter shelf life.

Commercial probes. Although these probes are supposed to be quality controlled, these too are subject to the same concerns as in-house probes (see above). During denaturation

and hybridization, keep lights dimmed and hybridize in a light-proof container for directly labeled probes.

Directly-labeled DNA probes. When directly labeled probes are used, slides should be washed with the lights dimmed to prevent unnecessary exposure to extraneous light.

Mounting medium. Check that the DAPI/antifade mounting solution is used before its expiration date. Normally, the medium is clear with a slight pink tinge; medium that is degrading will turn increasingly amber. Expired antifade medium causes rapid signal degradation and displays a red glow when viewed under the microscope.

Image acquisition. Extended exposure of the hybridized slide to UV sources leads to signal quenching. When not in use, store slides at −20°C. During visualization, keep the light source off when not in use.

Poor chromosome morphology

Slide age. See Signal Strength (above) for information concerning this parameter.

Cytoplasmic debris. See Signal Strength (above) for information concerning this parameter.

Excessive slide pretreatment. Excessive enzymatic treatment may damage the target DNA, making it less efficient for hybridization with the probe

Previously G-banded slides. G-banding (*UNIT 22.3*) causes DNA to become sensitive to subsequent denaturation. For this reason, denaturation times are greatly reduced. This also has an effect on the quality of hybridization and signal strength.

Over-denaturation. The cause of poor chromosome morphology is usually over-denaturation, which causes the DNA to be destroyed. This can be sample specific and/or slide-age related.

Denaturation temperature. Check that the temperature for denaturation is accurate. The final internal temperature of the Coplin jar should be 72°C. Add 1°C for each slide that is denatured in the jar. Avoid denaturing more than five slides in one jar at one time. Note that plastic Coplin jars have a greater differential temperature between bath and internal temperatures as compared to glass.

Probe cross-hybridization

Clone identity. When using in-house FISH probes for research applications, ensure that the clone identity and the insert are correct for the experiment. Some genes have highly homologous sequences elsewhere in the genome and may cross-hybridize to other family members.

DNA contamination. Consider whether stock DNA was contaminated with DNA from another clone. Increase the hybridization temperature if contamination is suspected. Typically, the hybridization temperature is 37°C. If cross-hybridization occurs, try increasing the hybridization temperature to 42°C.

Stringency of washes. Some probes may cross-hybridize, particularly centromere probes. Usually cross-hybridization signals are significantly weaker than true signals. More stringent washes can be undertaken by decreasing the SSC concentration, increasing wash temperature, or adding additional washes.

Evaluation of a New DNA Probe

The most critical factor in optimizing a new FISH probe which was labeled in-house is first determining whether the probe of interest maps to the correct location. Many vectors (e.g., plasmids, cosmids, BACs) have traveled from laboratory to laboratory and have changed hands many times. These DNAs, as well as cloned DNA obtained from reputable repositories, can be mislabeled or misidentified. After a cloned DNA has been extracted and labeled, the first FISH experiment should be carried out on normal lymphocyte spreads and should address the following questions.

Is a signal visible on a pair of chromosomes?

If there is a weak signal, refer to the section above.

Does the DNA probe map to the right chromosomal location? Does it map to only one location?

It helps to have someone who can identify the chromosomes by DAPI banding. Most people are not as proficient as trained cytogeneticists, thus it may be useful to carry out a two-color experiment using a commercially available centromere probe for the chromosome of interest. Refer to *UNIT 22.3* for general conventions for identification of chromosomes according to ISCN nomenclature. Some DNA sequences/genes may belong to families with similar sequences. It is possible that hybridization to these similar regions may occur. Usually the true signals are stronger than the cross-hybridized ones. If this is the case, wash conditions can be adjusted or another clone should be obtained.

Does a positive control probe work properly?

It is useful to perform parallel experiments with a probe known to give good signals in the same experiment. This will help to identify any problems that are not related to the newly labeled probe (see Table 22.4.15 for interpretation of such control experiments).

For example, in panel iii of Figure 22.4.4A, two mouse BAC probes were labeled (one green and the other red) and assessed. A separate slide with a previously labeled BAC known to give good signal and no background was prepared as a control at the same time (not shown). The newly labeled BAC probes shown in panel iii of Figure 22.4.4A mapped to the proper location with weak signal intensity and high background. Analysis of this experiment is as follows.

The BAC probes map to the correct location. Because the signal intensity was weak consider (1) starting DNA quality and quantity, (2) labeling efficiency, (3) fidelity of DNA polymerase I and DNase I, (4) labeling time and temperature, (5) effective removal of nonincorporated nucleotides, and (6) insufficient Cot-1 suppression. Because the control probe displayed no background problems, one can assume that the hybridization and wash conditions were sufficient.

Evaluation of Hybridization Efficiency

The minimum number of cells or metaphase spreads required to obtain a given result reflects the clinical context of the finding, the limitations of the patient material available for study, and the question being asked. With tissues or cells that are hard to obtain, a single abnormal metaphase may be significant. For example, in some situations, limited FISH data may be supported by results obtained using PCR and/or Southern blot analysis.

Prior to enumerating or analyzing FISH results on a test sample, it is important to carefully assess the overall quality, uniformity, and effectiveness of hybridization as discussed

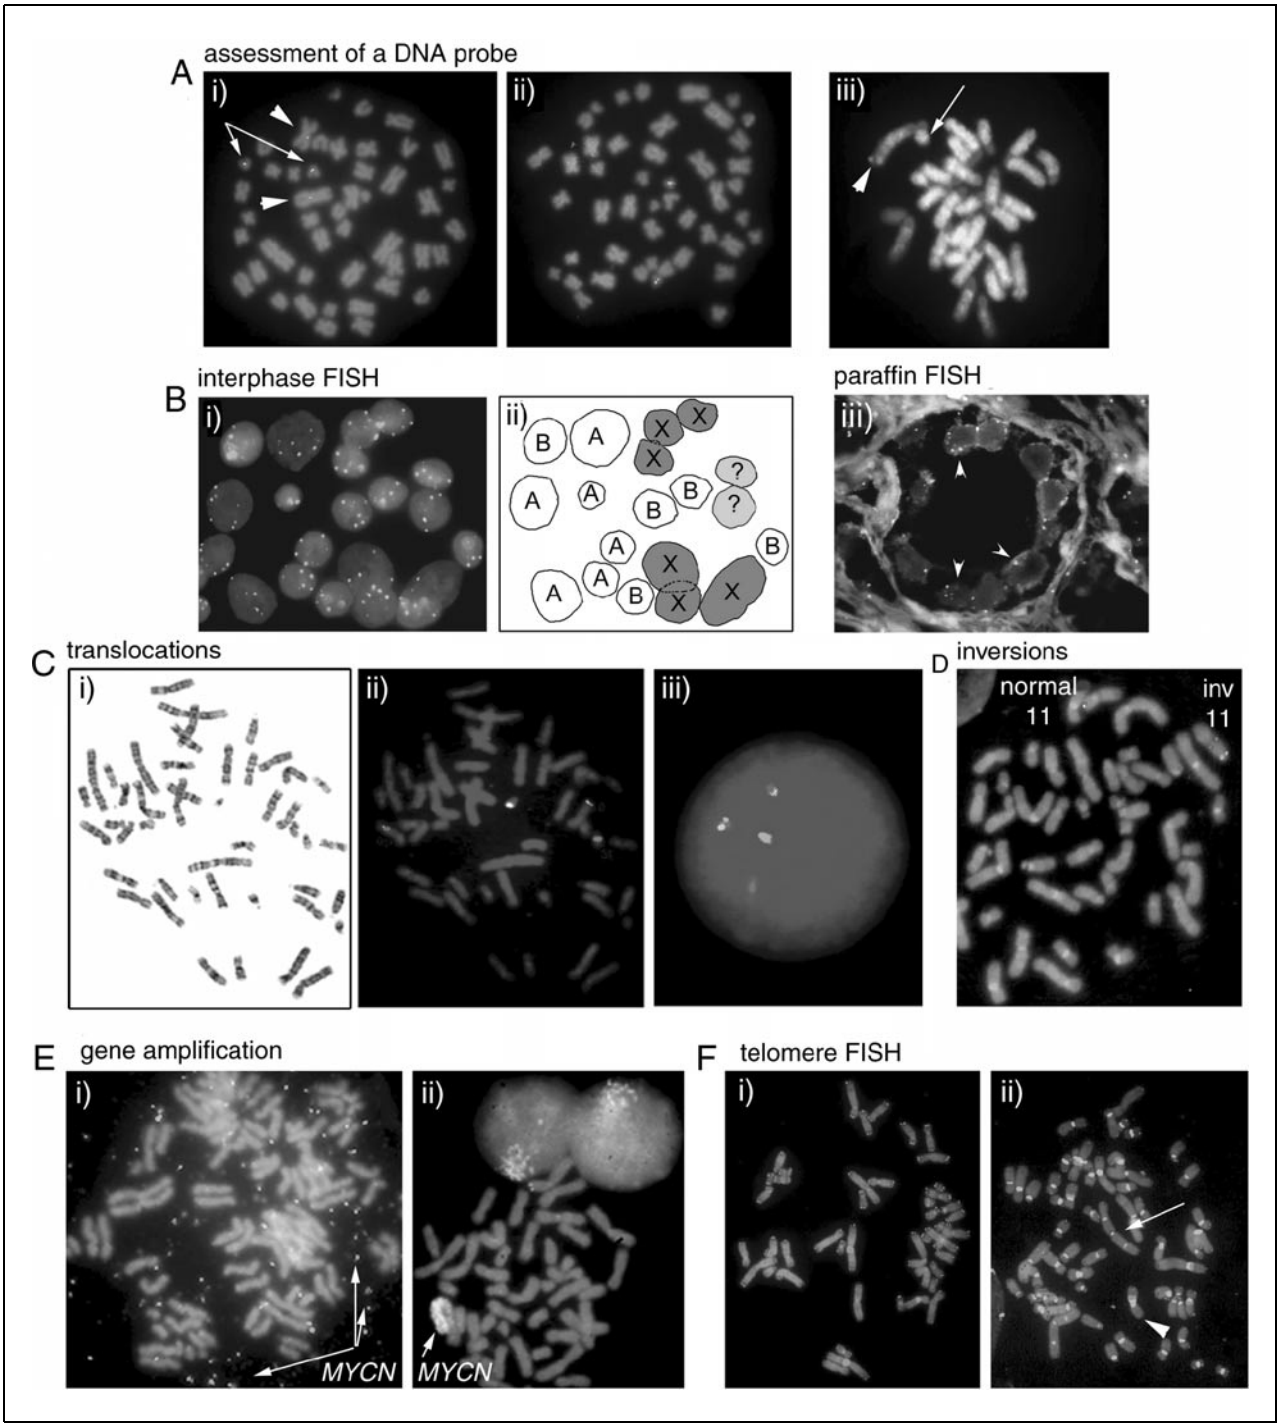

Figure 22.4.4 Legend at right.

above. Each hybridized slide should be evaluated for the specificity of the hybridization, the probe signal intensity, and the signal-to-background noise, to determine if the hybridization was optimum for the given analyses. There should be minimal background or nuclear fluorescent noise. At least 85% of all nuclei in the target area should be easily innumerable. For some applications (such as the detection of mosaicism or minimal residual disease), more rigorous analytical sensitivities and hybridization efficiencies are required.

1. Perform the FISH protocol appropriate for the type of patient and control slides in the experiment.
2. Prior to determining the hybridization efficiency, quickly scan the whole slide, noting the general signal-to-noise levels in different regions of the slide and any areas with high background or unusually weak signals. It may be useful to mark the underside surface of the slide in these areas with a diamond pen. If the signal intensity far exceeds background levels, proceed with estimating the hybridization efficiency.
3. Pick several representative areas of the slide and score at least 200 nuclei from the areas selected, following the selection criteria described below in Selecting Cells for FISH Microscopy. Keep a running log of the number of cells scored and the observed signal counts for the patient and control slides.
4. For all slides, add up the number of cells with no signal. In general, hybridization is considered to be adequate if $>85\%$ of the cells scored have one or more signals. Lower hybridization efficiencies may be encountered with smaller probes (generated

Figure 22.4.4 *(at Left)* Composite figure illustrating FISH hybridization. (**A**) Assessment of a DNA probe. (i) Cross-hybridization of probe (arrowhead) to chromosome 1. True signals are located on chromosome 22. (ii) Changes in stringency washes and post-hybridization removes cross-hybridization. (iii) High background associated with a insufficient repetitive sequence (Cot-1) suppression in this mouse metaphase spread. Weak signals (arrows) indicate poor labeling efficiency. (**B**) Interphase FISH analysis. (i) A cytogenetic specimen from a short-term ovarian primary culture hybridized with PNA probes for centromeres 7 (green) and 8 (red). When scoring interphase nuclei, it is especially important to focus through the cells since signals may be present at different *z* planes. (ii) Schematic indicating the nuclei that are acceptable for scoring: A, cell acceptable for scoring; B, cell is likely acceptable for scoring, but requires careful attention; ?, cell has qualities that make it questionable for scoring; X, cell is not acceptable for scoring. (iii) Interphase analysis using PNA probes specific for centromeres 7(green) and 8 (red) on a paraffin section from a prostate carcinoma. Arrowheads indicate cells containing changes in ploidy. (**C**) Analysis of translocation probes. (i) and (ii) Results of consecutive hybridization of a G-banded metaphase spread with the Vysis *BCR/ABL* translocation probe. Two fusion signals (yellow) are produced from the hybridization of *BCR/ABL* fusion on the Philadelphia chromosomes (Ph) on chromosome 22 and the reciprocal *ABL/BCR* on the derivative chromosome 9. Separate green and red signals from the normal chromosomes 9 and 22 are also seen. (iii) Interphase pattern from this specimen. (**D**) Example of a chromosomal inversion on chromosome 11. An inversion was identified involving the terminal portion of chromosome 11 by gross cytogenetic analysis. Clones 200 kb apart and in the 11p15.5 region, containing the *IGF2* gene (green) and *H19* (red) were hybridized to the patient specimen. The normal chromosome 11 shows the red and green signal hybridizing on top of each other at 11p15.5. The inverted 11 shows the clear spit of signal along the abnormal chromosome 11 indicating the breakpoint lies within the 200 kb between *IGF2* and *H19.* (**E**) Gene amplification of *MYCN* in neuroblastoma specimens. (i) Double minute chromosomes (dmns) containing hundreds of copies of the *MYCN* gene. This is in contrast to amplification of *MYCN* in (ii) as a large block of signal called a homogeneously staining region (HSR). Interphase nuclei nearby show the typical hybridization pattern for an HSR. (**F**) Use of subtelomeric and pan-centromeric PNA probes. (i) Hybridization of a prostate cell line with PNA subtelomeric probes. (ii) Hybridization of another prostate cell line with subtelomeric and pan-centromeric PNA probes. Loss of telomeric sequences are indicated by the arrow while the presence of multicentric chromosomes are indicated by arrow heads. *This black and white facsimile of the figure is intended only as a placeholder; for full-color version of figure, see color plates.*

for example in a research laboratory). Extreme caution must be exercised when using probes with lower hybridization efficiencies or elevated background signal to provide clinical information.

Selecting Cells for FISH Microscopy

Generally, look at all areas of the slide and analyze regions with uniformity in signal strength. Compare the intensity of the background signals to the intensity of the signals in the nuclei or metaphases of interest. The FISH signal intensity should consistently be greater than the background intensity in the regions of the slide chosen for analysis. If the background signals are equivalent to signals in the nuclei, then the counts will be skewed and the results biased. The following provides a guide to selecting targets for analysis.

1. Ideally analyze cells from all areas of the slide. Systematically select representative areas from different regions of the slide. Any regions that have unacceptable background or weak signals identified in prescreening evaluations should be excluded.
2. Select nuclei or metaphase cells that do not touch or overlap (Fig. 22.4.4B).
3. Select intact nuclei that have smooth well-rounded borders. Partially ruptured nuclear membranes may have lost informative chromatin. Similarly select metaphase spreads that have no evidence of preparation artifacts or breakage.
4. Select cells that are not surrounded by cytoplasmic material and that are without evidence of potential drying artifacts such as rings or clumped cells.
5. Do not evaluate interphase nuclei with signals located on the extreme periphery of the nucleus.
6. Do not score regions of the slide containing nuclei that have no signals. Absence of signals may represent uneven or patchy hybridization, resulting in some areas of the slide having very weak or absent signals.

Analysis of Interphase Nuclei

Interpretation of interphase FISH is very much dependent on statistical analyses and has inherent technical challenges. For instance, the presence of signal is dependent upon the probe and its fluorescent label successfully entering the cell and hybridizing to the target DNA. Detection of the correct number of signals can be complicated by signals overlapping or splitting. Any background hybridization whatsoever leads to major complications in interpretation. It is not uncommon to find monosomy or trisomy in nuclei that reflect technical artifact or false positive background signals. Therefore, the accuracy of interphase FISH analysis is dependent upon recognizing these technical issues, correcting for them, and standardizing the scoring criteria accordingly. Interphase analysis is typically used for enumeration of chromosomes using centromere probes, detection of gene amplification or deletion (see below), and detection of the presence of translocations, so that many cells should be scored. Metaphase FISH analysis, although more informative, is more difficult, especially when there are few metaphase spreads present.

1. Select nuclei in which signals generally have the same intensity.
2. Focus up and down in the *z* axis to accommodate spatial configurations of probe signals within the nucleus (Fig. 22.4.4B).
3. Signals that are more intense in some nuclei than the specific signal indicate the presence of regional background. Care must be taken when analyzing any sample with this type of background noise.

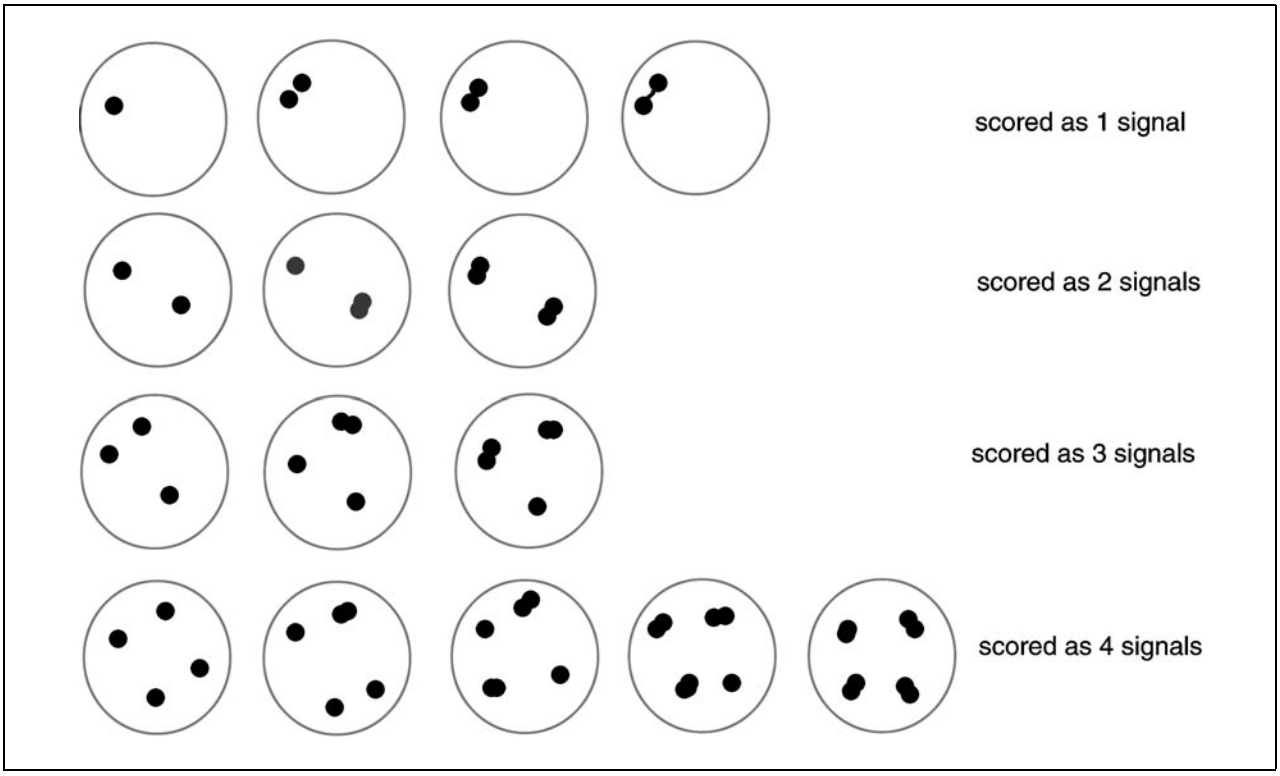

Figure 22.4.5 Schematic representation of scoring criteria. Shown in the illustration are typical hybridization signal configurations. These images pertain to a single probe, such as a centromere- or locus-specific probe. Signals must be more than one signal width apart to be considered one signal. Signals joined by a string of hybridization are also considered as one signal.

4. Do not count lower level nonspecific hybridization signals. These signals can usually be recognized by their lower intensity and different shape.
5. Some nuclei will have passed through the S phase of the cell cycle and may be present as G2-paired signals (i.e., two smaller signals in very close proximity). These paired signals represent a single chromosome already divided into chromatids and should be counted as one signal (Fig. 22.4.5).
6. Count two signals connected by a strand of fluorescence as one signal. Sometimes centromere or long genomic probes will generate signals that are not spherical. Typically, FISH signals appear as separate fluorescent dots on each chromatid of a metaphase chromosome when the target size is 100 to 250 kb. Similarly, in interphase nuclei, such probes will also generate discrete easy-to-interpret signals. Larger probes can appear as fused signals straddling both chromatids, and in interphase nuclei, these probes can generate signals that present more diffuse or dispersed hybridization spots in the chromatin of interphase nuclei. Knowledge of the probe size and anticipated configuration in both metaphase spreads, and interphase nuclei is essential. As long as the signal is continuous it should be scored as one signal.
7. Count only nuclei in which a definite enumeration can be made. Do not analyze or enumerate inconclusive cells.
8. Use two people to score 200 consecutive nuclei from each sample such that each person scoring will analyze ~100 nuclei from a given sample. The slides should be coded and scored independently by two analysts. Any discrepancies may mean the established scoring criteria for the FISH assay are not being adhered to rigidly.

Analytical sensitivity of interphase FISH assays

Once a particular probe set is made available as a routine FISH test for a clinical service, it is important that the laboratory perform assay validation and create a database establishing reportable range and general laboratory experience with each probe. The analytical sensitivity assay measures the success of a given FISH test in a particular laboratory environment and on a given tissue type. Since there are known differences in the cell populations and tissue types, it is important to use the appropriate positive control tissue for the assessment of analytical sensitivity and for the establishment of the database. Analytical sensitivity analyses are performed by scoring 200 interphase nuclei representing at least five normal, preferably male, individuals. (Pooling samples on one slide is acceptable.) The nuclei are scored for the percentage of nuclei exhibiting the appropriate number of distinct signals.

For constitutional studies using FISH, the recommended analytical sensitivity for probes intended for nonmosaic detection is 90%, while for probes intended to detect mosaicism, it is 95%. Similarly, for detection of minimal residual disease, sensitivities $\geq$95% are helpful. Databases for each probe should be established so that it will then possible to determine the mean and standard deviation of results from a series of normal samples processed and analyzed in the same manner as clinical samples. False positive rates can then be calculated and used for final scoring reports. More discussion on this issue is available from the following sources: VYSIS guidelines for single (*http://www.vysis.com/tech_sup_fishproto_quality_single.asp*) and dual probes (*http://www.vysis.com/tech_sup_fishproto_quality_dual.asp*), and scoring criteria for preimplantation genetic diagnosis of numerical abnormalities for chromosomes X, Y, 13, 16, 18, and 21 (Munne et al., 1998).

Statistical considerations concerning interphase FISH analysis of paraffin sections

Due to truncation of the nuclei during sectioning, loss of signal from areas of the nucleus excluded from the target slide will be encountered when enumerating signals after FISH has been performed on paraffin sections. The criteria for determining the significance of loss or gain of signals in interphase nuclei will depend on a number of parameters (e.g., nuclear diameter, age of patient, type of tissue). Readers are referred to some of the scientific literature where suggested cutoff values are adopted from the available literature (Qian et al., 1996). In the authors' experience with FISH analysis of prostate cancer, chromosomal gains can been identified when more than ~10% of the nuclei exhibit more than two signals. Panel iii of Figure 22.4.4B, shows an example of a prostate section hybridized with centromere probes for centromeres 7 (green) and 8 (red). Chromosomal losses have been identified when more than 50% of the nuclei exhibit a reduction of signal number, and tetraploidy has been assumed when all chromosomes investigated show signal gains up to four. For some classes of tumor, extreme polyploidy together with complex patterns of chromosomal rearrangement means that it is not realistic to select a suitable control chromosomal region in which two signals are expected. In such situations, it may be helpful to perform flow cytometric analysis of DNA content in parallel with interphase FISH analysis.

Analysis of Translocation and Inversion Probes

If the probes based on green and red fluorescence used for FISH are close to specific translocation breakpoints on different chromosomes, they will appear joined as a result of the translocation, generating a yellow color fusion signal. Commercial probes are now available for many of the common translocations in cancers (Table 22.4.19). One such probe from Vysis detects the Philadelphia chromosome (Ph) resulting from the

Table 22.4.19 Commonly Used Commercial Probes for Detection of Translocations in Sarcomas and Hematological Malignancies

Neoplasm	Chromosomal location	Probe	Scoring method
CML/pediatric ALL	9q34/22q	*BCR/ABL*	Color fusion observed in metaphase and interphase
Various leukemias	11q23	*MLL*	Split signal, metaphase
Various leukemias	5q31	*EGFR1*	Loss of signal, metaphase/interphase
Various leukemias	7q31	*DSS486*	Loss of signal, metaphase/interphase
AML M4 EO	Inv(16)	*CBFB*	Split signal, metaphase
Various leukemias	20q13.2	*ZNF217*, *D20S183*	Loss of signal, metaphase/interphase
Various hematologic malignancies	8q24 /14q32	*MYCC/IgH*	Color fusion observed in metaphase and interphase
AML-M1	12p13/21q22; 8q22/21q22	*TEL/AML1*; *AML1/ETO*	Color fusion observed in metaphase and interphase
AML-M3	15q22/17q21.1	*PML/RARA*	Color fusion observed in metaphase and interphase
Ewings sarcoma	t(11;22) (q24;q12)	*FLI1/EWS*	Color fusion observed in metaphase and interphase
Rhabdomyosarcoma	t(2;13)(q35;q14)	*PAX/FKR*	Color fusion observed in metaphase and interphase

translocation between ABL on chromosome 9 and BCR on chromosome 22. Shown in Figure 22.4.4C is an example of combined G-banding and FISH analysis using the Vysis *BCR/ABL* probe set. Panel i of Figure 22.4.4C shows the G-banded metaphase spread to which the *BCR/ABL* probe was subsequently hybridized. In panel iii of Figure 22.4.4C, detection of a Ph chromosome in interphase nuclei of leukemia cells is achieved by the presence of two double-fusion (D-FISH) signals. All nuclei positive for the translocation contain one red signal (*BCR* gene), one green signal (*ABL* gene), and two intermediate fusion yellow signals because the 9;22 chromosome translocation generates two fusions, one on the 9q+ and a second on the 22q−. The following general guidelines may be helpful for performing this type of assay.

1. Green and red signals that are juxtaposed but not overlapping should be scored as ambiguous.
2. Do not score nuclei that are missing a green or red signal. This assay is looking for the presence or absence of a fusion signal, not the absence of a green or red signal.
3. Atypical signal patterns have been reported and are now considered to be clinically important (Kolomietz et al., 2001).

Table 22.4.19 lists some of the commonly used FISH assays in hematological cancers as well as sarcomas. In addition to the scientific literature, readers are referred to the suppliers web sites (see Internet Resources and *SUPPLIERS APPENDIX*), which will provide the most up-to-date listing of currently available probes and the preferred scoring method.

Inversions are related to translocations such that a break and rejoining occurs within the resident chromosome. Probes are available to detect common inversions present in AMLs

(see Table 22.4.19). Mapping of breakpoints is common in many research cytogenetic laboratories and involves chromosome walking. To identify the locus containing the breakpoint, rough cytogenetic analysis locates the band region. Clones are then obtained spanning the putative breakpoint. These clones are then FISHed to the specimen of interest. Such is the case in Figure 22.4.4D. An inversion was identified involving the 11p15.5 region. Clones 200 kb apart, containing the *IGF2* gene (green) and *H19* (red) were hybridized to the patient specimen. The normal chromosome 11 shows the red and green signal hybridizing on top of each other at 11p15.5. The inverted 11 shows the clear split of signal along the abnormal chromosome 11 indicating the breakpoint lies within the 200-kb distance between *1GF2* and *H19.*

Use of FISH Probes in Assessing Solid Tumors and Gene Amplification

Gene amplification is one of the mechanisms by which cancer cells achieve over expression of some classes of oncogenes, which involves an increase in the relative number of copies of a gene per cell. This can range from one or two additional copies per cell to extreme examples where over a thousand copies per cell have been reported. Gene amplification can occur in association with the over-expression of oncogenes, thus conferring a selective growth advantage or mechanism of acquired resistance to chemotherapeutic agents leading to poor prognosis. Gene amplification is highly suited to FISH analytical approaches that have the added benefit of excellent sensitivity and the ability to address cellular heterogeneity.

Neuroblastoma is characterized by the frequent occurrence of a highly amplified oncogene, *MYCN*. It has been known for many years that the presence of this aberration is strongly associated with poor outcome. More aggressive management is usually required when *MYCN* is found to be amplified. Similarly, breast cancer can be accompanied by an amplified oncogene *HER2/Neu*, and presence or absence of this aberration may determine which of different treatment regimens are followed. Examples of metaphase and interphase FISH assays for gene amplification are shown in Figure 22.4.4E. In this figure, a DNA probe containing the *MYCN* gene was hybridized to a cytogenetic specimen from a neuroblastoma patient. Panel i of Figure 22.4.4E illustrates double minute (dmns) chromosomes containing hundreds of copies of the *MYCN* gene as extrachromosomal bodies. This is in contrast to another patient where amplification of the *MYCN* gene occurs as a homogeneously staining region (HSRs) inserted in a chromosome other than the resident site of *MYCN* (normally at 2p24). Interphase nuclei in this image show a large patch of hybridization signal characteristic of HSRs. Some of the commonly detected aberrations observed in solid tumors which are amenable to FISH analysis are presented in Table 22.4.20.

Analysis of Telomere Probes

Telomeres are located at the ends of chromosomes and are characterized as (T_2AG_3) repeat sequences and their associated proteins (Poon et al., 1999). Maintained by the ribonucleoprotein complex, telomerase, they function to protect chromosomes from end-to-end fusions. In most normal tissues, telomerase is expressed at very low levels. As such, each round of DNA replication results in the gradual shortening of the telomeres. The shortening of telomeres is associated with replicative cell senescence. The up-regulation of telomerase extends the proliferative lifespan of a normal cell. In abnormal cells, expression of telomerase is associated with the maintenance of telomere length or telomere lengthening. Conventional Southern blot analysis gives average telomere length but fails to yield information on individual chromosome ends. It also underestimates the size and number of short telomeres. Although DNA probes for these sequences are available commercially, the use of commercial PNA probes for such sequences, as well as for centromeric and pancentromeric sequences, has enabled researchers to determine the overall

Table 22.4.20 FISH Probes Used For Assessing Solid Tumors and Gene Amplification

Neoplasm	Chromosomal location	Probe	Scoring method
Neuroblastoma	2p24; 2p23-24	*MYCN*	Interphase, metaphase; amplification
Ewings sarcoma	t(11;22) (q24;q12)	*FLI1/EWS*	Color fusion observed in metaphase and interphase
Breast cancer	17q11.2-q12	*HER2/neu*	Interphase amplification
Glioblastoma	7p10-p21	*EGF-R*	Interphase amplification
Bladder cancer	Centromere regions of chromosomes 3, 7,17 and 9p21 region of chromosome 9	Centromere 7, 13, 9	Interphase enumeration

telomere lengths of individual cells (interphase nuclei) and chromosomes (metaphases) using quantitative digital imaging, as described by Poon (1999), with greater specificity and accuracy. Both fixed cytogenetic cells (Poon et al., 1999) and paraffin-embedded samples (Vukovic et al., 2003) have been used for telomere analysis. Panel i of Figure 22.4.4F illustrates subtelomeric PNA probes hybridized to a prostate cell line metaphase spread. Digital imaging and signal intensity ratios determine the relative telomere length. In some cases, loss of telomere signals can also be identified as in panel ii of Figure 22.4.4F (arrow). In this figure, a prostate cell line was hybridized with subtelomeric PNA probe as well as a PNA pan-centromeric probe. The pancentromeric probe confirmed the presence of multicentric chromosomal structures indicative of chromosomal instability.

For those who wish to engage in telomere studies, access to digital imaging and analysis software capable of determining telomere length is suggested. Like all other FISH experiments, the background should be minimal. Telomere signals are relatively small and located at the ends of chromosomes. Background, such as antibody speckling can greatly affect the sensitivity of the analysis. The proper controls must also be established. Since telomere length is dependent on the number of cell divisions, age- and sex-matched controls should be included in all experiments.

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Agarose gel, 2% (w/v)

Dissolve 2 g molecular biology–grade agarose in 1× TBE buffer (*APPENDIX 2A*) by either microwaving or placing on a hot plate, and allow to cool slightly. Add 5 μl of 10 mg/ml ethidium bromide in a well vented chemical hood. Pour into casting trays (*APPENDIX 3A*) and allow to solidify. Store up to 1 week at 4°C covered with foil.

AP-labeled antibody mixture

Dilute anti-biotin or anti-digoxigenin conjugated to alkaline phosphatase (AP; Invitrogen) to a final concentration of 0.75 U/ml in 100 mM Tris·Cl (pH 7.5)/15 mM NaCl (*APPENDIX 2A*). Prepare fresh for each experiment.

Antibodies

Prepare antibodies stocks according to the manufacturer's instructions. Tertiary antibodies are conjugated to fluorchromes. Store up to several months as frozen aliquots. Prepare working solutions of primary and secondary antibodies according to the manufacturer's instructions using the guidelines for final antibody listed in Table 22.4.14. Diluted antibodies should be kept at 4°C in light-proof containers for 2 to 3 months.

Minor adjustments in concentration will need to be made to account for background and signal intensity.

DAPI, 100 μg/ml

Dilute all of the powder from a 1-mg bottle of 4′,6-diamidino-2-phenylindole (DAPI; Sigma) in 10 ml buffer to produce a 100 μg/ml stock solution. Store in small aliquots up to 1 year at −20°C.

CAUTION: *DAPI is a potential carcinogen and should be handed with care.*

DAPI in antifade

Combine the following in order:
5.0 ml 1× PBS (*APPENDIX 2A*)
500.0 μl 100 μg/ml DAPI stock (see recipe; 1 μg/ml final)
0.5 g *p*-phenylenediaminie (Sigma; 10 mg/ml final; dissolve well)
45.0 ml glycerol (90% v/v final)

Transfer to a 50.0-ml conical tube, wrap with aluminum foil (product is light sensitive), and place on a rotator 30 min to ensure proper mixing. Store in 1-ml aliquots up to 1 year at −20°C.

The resulting solution is very viscous

This reagent is available commercially as Vectashield (Vector Laboratories).

DNase I, 3 mg/ml

3.0 mg DNase I powder
500.0 μl glycerol (50% v/v final)
50.0 μl 1 M Tris·Cl, pH 7.5 (50 mM final; *APPENDIX 2A*)
5.0 μl 1 M $MgCl_2$ (5 mM final)
1.0 μl 1 M 2-mercaptoethanol (1 mM final)
1.0 μl 10 mg/ml BSA (10 μg/ml final)
Adjust volume to 1.0 ml with H_2O
Store in 50-μl aliquots up to 1 year at −20°C.

DNase I dilution buffer

250.0 μl 1 M Tris·Cl, pH 7.0 (50 mM final; *APPENDIX 2A*)
25.0 μl 1 M $MgCl_2$ (5 mM final)
5.0 μl 1 M 2-mercaptoethanol (1 mM final)
20.0 μl 10 mg/ml BSA (4 μg/ml final)
4.7 ml H_2O
Store in 1-ml aliquots up to 6 months at −20°C *or*
In 1 ml aliquots up to 1 month at 4°C.

d*NTP mixture, 1 and 2 mM*

For a 1 mM mixture:
1.0 μl 100 mM dATP
1.0 μl 100 mM dCTP
1.0 μl 100 mM dGTP
97.0 μl H_2O, sterile
Store in 100-μl aliquots up to several months at −20°C

For a 2 mM mixture: Double the volume of each 100 mM dNTP added (i.e., use 2 μl of 100 mM dNTP) and reduce the amount of water to 94 μl. Store up to several months.

The total volume of either solution is 100 μl.

Fluorochrome/dTTP mixture

The amount of fluor-dUTP will vary. Thus, the recipes below are guidelines. Refer to the manufacturer's suggested final concentrations. All labeled nucleotides should be stored in 20 to 30-μl aliquots up to 6 months at −20°C in light-proof containers.

FITC-dUTP/dTTP:
3.5 μl 1 mM dTTP (0.6 mM final)
1.75μl 1 mM fluorescein (FITC)-dUTP (0.3 mM final; Roche)

The total volume, 5.25 μl, is appropriate for one labeling reaction and can be scaled up as needed.

Rhodamine-dUPT/dTTP mixture:
3.5 μl 1 mM dTTP (0.6 mM final)
1.75 μl 1 mM rhodamine-dUTP (0.3 mM final; Roche)

The total volume, 5.25 μl, is appropriate for one labeling reaction and can be scaled up as needed.

Texas Red-dUPT/dTTP mixture:
3.5 μl 1 mM dTTP (0.7 mM final)
1.0 μl 1 mM Texas Red-dUTP (0.2 mM final; Roche)

The total volume, 4.5 μl, is appropriate for one labeling reaction and can be scaled up as needed.

Cy3-dUPT/dTTP mixture:
3.5 μl 1 mM dTTP (0.7 mM final)
1.25 μl 1 mM Cy3-dUTP (0.2 mM final; Amersham Biosciences)

The total volume, 4.75 μl, is appropriate for one labeling reaction and can be scaled up as needed.

Cy5-dUPT/dTTP mixture:
3.5 μl 1 mM dTTP (0.7 mM final)
1.25 μl 1 mM Cy5-dUTP (0.2 mM final; Amersham Biosciences)

The total volume, 4.75 μl, is appropriate for one labeling reaction and can be scaled up as needed.

Formamide, 70%/Tris·Cl (pH 7.0 to 7.5), 10 mM/BSA, 0.1% (w/v)

Dissolve 100 mg BSA in 29 ml water. To this solution, add 70 ml formamide (Invitrogen) and 1 ml of 1 M Tris·Cl, pH 7.0 to 7.5 (*APPENDIX 2A*). Store up to several weeks.

CAUTION: *Formamide is a carcinogen and should be handled with care. Discard according to institution's biohazard rules*.

Total volume is 100.0 ml; however, the solution can be made in larger quantities and stored up to several weeks at 4°C.

Hapten/dTTP mixture

The amount of hapten-dUPT will vary. Thus, the recipes below are guidelines. Refer to the manufacturer's suggested final concentrations. Store up to several months or a year at −20°C.

Biotin-dTTP/dUTP mixture:
3.5 µl 1 mM dTTP (0.6 mM final)
1.75 µl 1 mM biotin-16dUTP (0.3 mM final; Invitrogen)

The total volume, 25 µl, is appropriate for one labeling reaction and can be scaled up as needed.

Digoxigenin-dTTP/dUTP mixture:
3.5 µl 1 mM dTTP (0.6 mM final)
1.75µl 1 mM dig-11dUTP (0.3 mM final; Roche)

The total volume, 5.25 µl, is appropriate for one labeling reaction and can be scaled up as needed.

Hybridization buffer

500.0 µl high grade formamide (50% v/v final; Invitrogen)
100.0 µl 20× SSC (2× final; *UNIT 18.6*)
100.0 µl dextran sulfate (10% final)
300.0 µl H_2O
Store in 100-µl aliquots up to several months at 4°C

Total volume is 1.0 ml.

Hybridization buffer can also be purchased from DAKO.

Loading dye, 5×

0.125 g bromphenol blue (0.25% final)
15.0 ml glycerol (30% final)
35.0 ml H_2O
Store in 1.0-ml aliquots up to several months at 4°C

Total volume is 50.0 ml.

NBT/BCIP

22.5 µl 75 mg/ml NBT (Invitrogen)
17.5µl 50 mg/ml BCIP (Invitrogen)
4.96 ml 100 mM Tris·Cl (pH 9.5; *APPENDIX 2A*)/100 mM NaCl/50 mM $MgCl_2$
Prepare fresh for each experiment.

Volumes can be scaled up or down as required.

Nick translation buffer, 10×

1.0 µl 10 mg/ml BSA (0.1 µg/µl final)
10.0 µl 1 M 2-mercaptoethanol (0.1 M final)
50.0 µl 1 M Tris·Cl (0.5 M final)
5.0 µl 1 M $MgCl_2$ (50 mM final)
34.0 µl H_2O
Store in 100-µl aliquots up to several months at 4°C

Total volume is 100.0 µl.

PBS, 1×/$MgCl_2$, 0.05 M

950.0 ml 1× PBS
50.0 ml 1 M $MgCl_2$
Store at room temperature until ready for use.

The total volume is 1 liter.

Pepsin, 0.5% (w/v) in NaCl, 0.85%

Dissolve 500 mg pepsin in 100.0 ml of 0.85% (w/v) sodium chloride. Adjust pH to 1.5 with 12 N HCl. Prepare fresh for each experiment.

PI, 100 µg/ml

Dissolve the powder from an entire 10-mg bottle of propidium iodide (PI; Sigma) in 10 ml water to a final concentration of 100 µg/ml. Store in small aliquots indefinitely at −20°C.

PI in antifade

Combine in the following order:
5.0 ml 1(PBS; *APPENDIX 2A*)
150.0 µl 100 µg/ml PI (0.3 µg/ml final; see recipe)
0.5 g *p*-phenylenediaminie (10 mg/ml final; Sigma; dissolve well)
45.0 ml glycerol (90% final)

Transfer to a 50.0-ml conical tube, wrap in aluminum foil (the product is light sensitive), and place on a rotator 30 min to ensure proper mixing. Store in 1-ml aliquots up to several months at −20°C.

The resulting solution (50 ml total) is very viscous.

This solution is available commercially available from Vectashield (Vector Laboratories).

RNase I, 100 µg/ml

Prepare a final 100 µg/ml solution of RNase I in 2× SSC (*UNIT 18.6*) fresh for each experiment using any molecular-grade RNase enzyme.

Sonicated salmon sperm DNA standards

Prepare 50.0 ng/µl salmon sperm DNA standard by combining 5.0 µl of a 10 µg/µl stock (Invitrogen), 300 µl of 5× loading dye (e.g., *UNIT 18.6*), and 695 µl water. Prepare a 25.0 ng/µl standard by combining 500 µl of the 50 ng/µl standard, 100 µl of 5× loading dye, and 400 µl water. Prepare a 12 ng/µl standard by combining 500 µl of the 25.0 ng/µl standard, 100 µl of 5× loading dye, and 400 µl water. Store all standards up to several months at 4°C or indefinitely at −20°C.

The average size of the commercial salmon sperm is ∼500 to 2.0 kb

Triethanolamine (pH 8.0), 0.1 M

660.0 μl triethanolamine (final 0.1 M; Sigma)
50.0 ml H_2O
Prepare fresh for each experiment.

Total volume is 50.0 ml.

COMMENTARY

Background Information

Applications of FISH

As early as 1988 (Lichter et al., 1988), FISH was used to visualize labeled DNA probes hybridized to chromosome and interphase nuclei preparations. The improvement of cloned DNA sources, antibodies, fluorochromes, microscopy and imaging equipment, and software has permitted a variety of scientific investigations. FISH analysis is routinely used in clinical cytogenetic laboratories for detection of syndromes in prenatal assessments, including Prader-Willi/Angelman Syndrome, DiGeorge Syndrome, and Cri-du-chat. Cancer cytogenetics laboratories use FISH to confirm and monitor hematological malignancies such as CML and AML (Table 22.4.19 and Table 22.4.20). Gene amplification studies for neuroblastoma (MYCN amplification), and breast cancer (HER2/NEU amplification) are also routinely carried out. Mapping of newly identified genes have relied heavily on FISH (Squire et al., 1993; Lichter et al., 1988) both in humans and other species (Boyle et al., 1990, Giguere et al., 1995). Metaphase spreads may not always be easy to obtain, thus interphase cells offer a means of obtaining information, albeit via an indirect method. This has been useful for gauging chromosome instability (Speicher et al., 1995; Ghadimi et al., 1999; Al-Romaih et al., 2003; Vukovic et al., 2003) and determining normal versus abnormal content, as well as gene amplification or deletion. FISH applied to paraffin-embedded sections appeared in the early 1990s (Thompson et al., 1994) and was applied to both thick (>5 μm) and thin (5 μm) paraffin sections. Application of FISH to paraffin-embedded sections provides a tremendous opportunity to correlate the histopathological classification to the genomic changes detected. Furthermore, it enables the investigator to study concepts of cellular heterogeneity, tumor focality, and metastasis (Squire et al., 1996). Paraffin FISH analysis requires patient and careful technical expertise. Proper controls must be used when interpreting final results. Depending on the type of information sought, paraffin FISH is an acceptable form of data collection when fresh tissues for cytogenetic suspensions are not available; however, paraffin FISH will not provide chromosome-based information.

Preparation of probes

The development of reliable cloning strategies in the 1980s facilitated the genomic analysis and sequencing of specific DNA fragments. Mapping of these genes to their chromosomal locations was previously laborious and infrequently reliable. The emergence of FISH in the early 1990s paved the way for an effective and direct means of mapping specific DNA fragments to their chromosomal locations.

Types of probes. The creation of comprehensive genomic libraries as a result of the human genome project provides renewable resources for FISH probes. At present, bacterial artificial chromosomes (BACs) are the most popular cloned forms of genomic DNA used for FISH probes. Although yields are generally considered low in comparison to plasmids and cosmids (predecessors of BACs), BAC inserts are larger (200 kb) and can produce a stronger FISH signal compared to cosmids and plasmids, which are considerably smaller in insert size (i.e., ranging from 2 to 30 kb). P1 artificial chromosomes (PACs) and yeast artificial chromosomes (YACs) have also been used in the past and are still used in many research laboratories. Other probes, such as RNA and oligonucleotide probes are options and are reviewed in Speel (1999), and Schwarzacher and Heslop-Harrison (2000). More recently, peptide nucleic acid (PNA) probes (Lansdorp, 1996), have been used for FISH experiments with great success (Martens et al., 1998; Vukovic et al., 2003.). Using the same nucleotide bases as DNA probes, PNA probes do not have a phosphate or deoxyribose sugar backbone. Specific fluorochromes, haptens, or enzymes can be chemically attached to the bases and used in the same fashion as DNA probes. PNA probes are sequence specific. Thus, sequence information must accompany a PNA custom probe

order to companies such as Applied Biosystems (*http://www.appliedbiosystems.com*). There are several advantages of PNA probes. For instance, PNA has a neutral backbone, which provides stronger binding and greater specificity of interaction. Also, the uncharged PNA structure creates stronger binding independent of salt concentration, allowing more robust hybridization applications. Finally, the fact that PNA oligomers have resistance to nucleases and proteases, permitting more robust in situ experiments, is also an advantage. The drawback of PNA probes are in the cost of their fabrication. The typical molecular (cytogenetic) laboratory cannot generate these probes in-house. The cost-effectiveness of PNA probes, therefore, can only be appreciated if the laboratory is carrying out a particular hybridization frequently, as in the case of a clinical cytogenetic laboratory.

Methods for preparing probes. By far the most commonly used strategy for labeling DNA probes is by nick translation. Nick translation involves the simultaneous actions of two enzymes: DNase I and DNA polymerase I. DNase I randomly nicks the DNA fragment in each strand of the double-stranded DNA molecule. DNA polymerase I (derived from *E. coli*), with its three activities—i.e., exonuclease function (removes bases in the 5′ to 3′ direction), polymerase function (adds nucleotides from the 3′ nick site), and the 3′ to 5′ proof reading function—incorporates the label, whether indirectly using a hapten (i.e., biotin or digoxigenin) or directly (i.e., fluorescein or rhodamine). Nick translation can be applied to all cloned DNA sources without the need to remove vector sequences. Polymerase chain reaction (PCR) is another commonly used method of labeling DNA probes from cloned sources, as well as from microdissected genomic DNA or flow-sorted chromosomes. PCR employs multiple rounds of template denaturation, primer annealing, and template replication, facilitated by *Taq* DNA polymerase. Primers are variable and may include sequence-specific primers to amplify those targeted fragments, vector sequence primers to amplify and label cloned DNA, and/or universal primers. Compared to nick translation, which requires micrograms of starting DNA, PCR requires only nanograms of template. Furthermore, nick translation is most efficient when the starting DNA is of high molecular weight with little or no degraded material. PCR labeling is a little more forgiving of DNA quality; thus, suboptimal DNA may still be used when not acceptable for nick translation. Depending on the template, several rounds of amplification may be required before labeling, as in the case of in-house production of chromosome painting probes. Other labeling strategies, including random priming and end-labeling, are also options and are described in Schwarzacher and Heslop-Harrison (2000).

For both nick translation and PCR labeling, commercial kits and enzyme mixes are readily available and optimized. Usually, commercial kits combine DNase I and DNA polymerase I as an enzyme mix. The drawback of combining them is the fact that one enzyme (usually the DNA polymerase I) will lose its enzymatic activity before the other. Commercial kits can also be costly. Making an in-house kit allows the investigator to alter enzyme concentrations as necessary to better optimize the reaction. This alleviates the combined-enzyme problem with commercial kits. In-house kits are also expensive and they do require rigorous internal quality control and troubleshooting from time to time.

See Critical Parameters for discussion of slide preparation, hybridization, post-hybridization washes and detection, and interpretation of FISH findings.

Critical Parameters

Preparation of probes

DNA quality. Ensure that the starting DNA to be labeled has a high molecular weight with no degraded DNA fragments or protein. Contaminating RNA will contribute slightly to the spectrophotometric quantification of the DNA and cause a miscalculation of the actual starting amount of DNA. DNA should be assessed using an accurate spectrophotometer and by gel electrophoresis. Compare the concentration of DNA as determined using a spectrophotometer and gel with a DNA of known concentration. The DNA used as a standard for concentration can be another undigested clone or genomic DNA.

The starting DNA should be dissolved in water rather than Tris/EDTA (TE) buffer. TE is normally used to inhibit any DNases that may be present in the water. By that reasoning, TE buffer has been known to inhibit the enzymatic activity of the DNase during the nick translation reaction. Furthermore, it may inhibit the polymerase activity for nick translation and PCR labeling.

Reagents. Ensure that reagents are used prior to their expiration dates. The most critical reagents in the labeling reactions are:

1. DNA polymerase I/*Taq* DNA polymerase. Failure of polymerase activity in the reaction will lead to inefficient incorporation of the labeled nucleotide into the DNA, resulting in a very weak FISH signal.

2. Conjugated nucleotides. Nucleotides conjugated to a fluorochrome are light sensitive. Repeated and prolonged exposure to direct light will quench the fluorescent signal. Store these reagents in small aliquots at −20°C in light-proof containers. Restrict exposure to light during the labeling procedure and store labeled DNA at −20°C in light-proof containers. Unlike nonfluorescently labeled probes, these directly-labeled DNAs will have a shorter shelf life. The concentration of nucleotides can vary from as much as 1 mM to as low as 0.2 mM in different nick translation protocols. The labeled nucleotide should always be in at least a 2- fold excess of the corresponding unlabeled nucleotide. Furthermore, the labeled nucleotide can be interchangeable between hapten-dUTP or hapten-dATP. If the investigator chooses to use Biotin 14-dATP rather than the dUPT form, the nucleotide mixture should be adjusted accordingly.

3. 2-Mercaptoethanol. Buffers containing 2-mercaptoethanol should be replaced every 3 to 4 months, particularly if not stored at −20°C.

4. DNase I. Although the activity of DNase I is usually potent enough that it may be used for up to a year when stored at −20°C, the specific activity may decrease over time. This is evident when the fragment sizes are larger than expected when the standard DNase I concentration and incubation times are used. Simply increase the amount of DNase I used in the reaction and keep the same period of incubation, or keep the same amount of DNase I used in the reaction and increase the time of incubation.

5. PCR factors. Treat PCR labeling like any other PCR experiment and consider the following factors: amount of template, pH, magnesium ion concentration, and primer sequence.

Equipment. Small volumes are used for both labeling strategies. Pipets should be calibrated and serviced often. Use an accurate spectrophotometer and water bath that can effectively maintain a constant temperature, if a thermocycler is not available for nick translation.

Preparation of slides

FISH involves the hybridization of the labeled and denatured DNA probe to its denatured DNA target located on the slide. Each component requires care to obtain the most effective results. Pretreatment of the slide with a protease before denaturation permits the removal of any cellular and cytoplasmic debris. In the case of paraffin-embedded sections, more aggressive treatment is required to remove residual wax as well as to allow sufficient protease treatment to permit access of the probe to the intended target DNA.

Protease treatment. Treatment with pepsin has been featured in this protocol because its action is relatively mild as compared to other proteases such as proteinase K; however, many laboratories use proteinase K alone or in combination with pepsin, particularly for the digestion of paraffin-embedded sections, to obtain the proper digestion conditions for FISH (see Table 22.4.9). The incubation times of any protease treatment will vary according to the type of tissue (e.g., paraffin-embedded), quality of the slide (i.e., quantity of cytoplasmic debris/cellular debris), as well as the lot or batch of pepsin used. It is suggested that incubation times be increased rather than the concentration of pepsin used in the digest. The temperature at which the incubations occur is also critical. Higher temperatures facilitate faster digestions as opposed to those at room temperature or below. While variations in the pretreatment protocol can be made, the starting quality of the fixed tissue is the most critical factor. Ideally, the tissue should be fixed shortly after removal from the host.

Paraffin-embedded samples. In the case of paraffin-embedded tissues, formalin is the fixative of choice for routine use in most clinical laboratories; however, superior results for most research needs may be obtained if tissue sections are fixed using ethanol or paraformaldehyde prior to embedding. Buffered formalin solutions have also been implemented to provide better recovery of DNA, RNA, and protein for future studies. The time spent in fixation is equally as important as the type of fixative. The longer the time spent in fixative, the more difficult it may be to denature the DNA to a single-stranded state. This is due to the cross-linking action of the fixative to proteins that enables the cells to maintain their morphology. Sections for FISH should be cut fresh from the original block, preferably a few sections from the exposed face. This will help to ensure that the DNA has not been exposed to DNases, or oxidative damage from the handling of the block or from the local environment. Several sections should be taken so that different pretreatment conditions can be tested. It is suggested that the investigator take the time to contact the

histology laboratory preparing the specimens to document the fixation procedure for troubleshooting later.

Denaturation. Denaturation is also a critical parameter for successful FISH. Too much denaturation of the target DNA causes excessive DNA damage, yielding poor banding and/or hybridization. Too little denaturation results in ineffective hybridization due to limited access to the target DNA. The extent of denaturation will depend on several factors.

1. Quality of the slide. Namely, the presence of cytoplasmic and/or cellular debris.
2. Age of the slide. Whether using a fresh slide, a fresh slide with artificial aging, a slide that is 1 week or 1 month old, and so forth.
3. Previous assays. Namely if banding has previously been performed on the slide.
4. Tissue type. Whether fibrous, bony, or muscle tissue, or the like, is being used.
5. Age and method of fixation. See above.
6. Section thickness. Normally 5-μm-thick sections are used.

Hybridization

Optimal hybridization is influenced by many factors that will affect the target DNA and the probe itself. These factors are sources for inefficiencies and should be carefully monitored and documented such that effective troubleshooting can be carried out.

Stringency. The hybridization of a DNA probe to its DNA target is dependent on the extent of sequence homology, the complexity of the DNA sequence, and the chemical factors that influence the success of maximal binding efficiency. Stringency refers to the percentage of matches and mismatches between the probe and target such that the hybridized double helix remains stable. FISH experiments are typically run at 70% to 90% stringency, with 70% representing a lower relative stringency than 90%. This is critical when determining the feasibility of carrying out cross-species FISH experiments (i.e., human probes on mouse targets or vice versa), where sequence homology may be considerably lower in parts of the probe. The reagents present in hybridization buffers, as well as the temperature significantly influence stringency.

Temperature. DNA strand melting and annealing are influenced by temperature. Since reagents such as formamide are present in the hybridization buffer, high temperatures (i.e., 80° to 90°C) are not required for DNA denaturation. This is the reason denaturation of the DNA can be accomplished at 72°C in the presence of formamide. Increasing temperatures also increases stringency, such that a 1°C alteration increases the stringency by 1%. Thus, increasing the hybridization temperature from 37° to 42°C will increase the stringency of the hybridization step, requiring the probe to possess higher sequence homology with its target. This may be particularly useful if there is a chance of cross-hybridization, which is typically the case with locus-specific probes of genes that belong to a class of genes/sequences that are very similar. Pseudogenes may also cross-hybridize. Lowering the hybridization temperature under 37°C will result in lower stringency conditions permitting the hybridization of the probe to targets with greater mismatch. This also has advantages and disadvantages. At low stringency, mismatched spurious hybridization events will be more common and contribute to more experimental noise at the detection step.

Probe size. The rate of hybridization is also influenced by probe size. Generally, longer fragments (>500 bp) will require a longer time to hybridize than shorter ones. Once again, the hybridization is affected by the extent of sequence homology.

PNA probes. In the case of PNA probes, the specificity of the probe, as a required function of their fabrication through oligosynthesis, eliminates some of the complexities experienced by DNA probes. Since the PNA probe has an uncharged backbone, there is no charge repulsion when the probe hybridizes to the DNA, thus creating a stronger bond. Furthermore, PNA/DNA bonds will melt 15°C above DNA/DNA bonds, almost independently of salt concentration. The specificity of the PNA/DNA bond lies in the increased destabilization of the PNA/DNA bond when a mismatch occurs.

Post-hybridization washes and detection

Stringency. The factors that affect hybridization also influence the conditions involved in post-hybridization washes and antibody incubations. Incubation at 37°C under a range of 50% to 60% formamide in 2× SSC sets a stringency of ~70% to 80%. This permits hybridization of sequences with a 20% to 30% mismatch and maintains duplex stabilization. Increasing hybridization temperatures raises the stringency, requiring greater sequence homology for effective hybridization. Conversely, decreasing temperatures permits hybridization with greater mismatch. Decreasing salt ion strength (i.e., SSC) also increases

Table 22.4.21 Stringency of DNA/DNA Hybridization and Post-Hybridization Washes[a]

SSC concentration	Temperature[b]	Stringency as a function of % formamide						
		60	55	50	45	40	35	30
5×	37°C	76	73	70	67	64	61	58
2×	37°C	83	80	77	74	71	68	65
1×	37°C	88	85	82	79	76	73	70
0.75×	37°C	90	87	84	81	78	75	72
0.5×	37°C	93	90	87	84	81	78	75
0.2×	37°C	100	96	93	90	87	84	81
0.1×	37°C	105	101	98	95	92	89	86
5×	42°C	81	78	75	72	69	66	63
2×	42°C	88	85	82	79	76	73	70
1×	42°C	93	90	87	84	81	78	75
0.75×	42°C	95	92	89	86	83	80	77
0.5×	42°C	98	95	92	89	86	83	80
0.2×	42°C	105	101	98	95	92	89	86
0.1×	42°C	110	106	103	100	97	94	91

[a]This Table describes the changes in stringency for probes with 43% GC content at 300 bp (modified from Schwarzacher and Heslop-Harrison, 2000). Increasing the formamide content or temperature, or decreasing the SSC strength will increase stringency. A combination of these three factors can be used to modulate the stringency.

[b]Hybridization of probe to DNA typically occurs under 50% formamide in 2× SSC at 37°C, giving a 77% stringency. Washing of unbound probe following hybridization typically occurs under 50% formamide in 2× SSC at 42°C, giving an 82% stringency.

stringency. The combination of temperature and salt concentration can affect hybridization kinetics considerably. The same holds true for removal of unbound probe.

Typically, post-hybridization washes are carried out at 42° to 45°C. This temperature, coupled with 50% formamide and 2× SSC, permits 90% stringency for probes with a 43% GC content, at a probe size of 300 bp (Schwarzacher and Heslop-Harrison, 2000). Table 22.4.21 describes the stringency conditions based on these parameters.

Detergents. Some suppliers of commercial probes may suggest higher temperature washes of 72°C in a low ion (high stringency) SSC wash containing a detergent. This too is based on high sequence homology and the relative GC sequence content of the probe. This rapid wash method eliminates the need for formamide. Caution should be exercised when using high temperatures, since there is the risk of partial denaturation of the hybridized probe and target. This will result in loss of signal. A rapid wash should only be used with probes that possess high sequence homology and high labeling efficiency. Commercial probes tend to fit these criteria.

The subsequent SSC washes and washes with detergents serve to remove any remaining unbound probe and antibodies. As before, decreasing the SSC content will create a more stringent wash. The choice of detergent is subjective, largely based on the preference and experience of the investigator. The most commonly used detergents include Tween 20, NP-40, IPEGAL, SDS, and Triton X-100 (reviewed in Speel, 1999). In general, the actions of these detergents are comparable when used at the standard 0.1% in 4× SSC; however, SDS, Triton X-100, and NP-40 are generally harsher than Tween 20. If high background persists, the number of washes with the detergent can be increased or the percentage of detergent and SSC strength can be altered.

Antibodies. The choice of antibody systems is also fairly standard. Many companies provide antibodies raised in different animals and conjugated to different fluorochromes so that a variety of probes may be used and detected at one time. Some antibodies may require a higher concentration; thus, it is important that the signal strength be monitored carefully for background and the antibody concentration adjusted as required. As discussed

above, caution should be exercised when using various antibody combinations for detecting more than one probe: ensure that there is no cross-reactivity between antibodies raised in different species.

Counterstains. Finally the use of a counterstain helps to visualize the cells or spreads. DAPI stains DNA blue upon fluorescence and is most commonly used. DAPI, however, may obscure a green signal if using a dual filter (i.e., FITC/DAPI), so a red counterstain, such as propidium iodide (PI), may be more appropriate. If the color of probe detected is red, do not use PI as a counterstain. The signals are protected from rapid quenching through the reagents used in the mounting medium. These counterstains in mounting (antifade) medium can be purchased commercially. If the counterstain is prepared in the laboratory, be sure to use high quality glycerol, since some lower quality glycerols can cause autofluorescence. The concentration of counterstain may require adjustment. Higher counterstain concentrations may obscure FISH signals. If this is the case, dilute the counterstain in antifade by adding more glycerol and PBS in amounts that will be consistent with the final concentrations.

Storage. All slides should be stored at −20°C for long-term storage (i.e., up to 1 year) and at 4°C for short-term storage (i.e., up to 6 months).

Troubleshooting

Preparation of probes

See Table 22.4.22 for a troubleshooting guide to labeling.

Preparation of slides

Cytogenetic specimens. The influence of pretreatment and denaturation cannot be readily assessed until the entire FISH protocol has been carried out and the slides are visualized by fluorescence microscopy (Henegariu et al., 2001). The slides, however, may be visualized by phase-contrast microscopy for cytogenetic preparations after the dehydration step following pepsin treatment to determine the extent of digestion. The slides may be returned for digestion if the cytoplasmic debris does not appear to have been removed. Similarly, for treatment of paraffin sections, following visualization for autofluorescence, the slides may be returned for digestion and reassessed.

If there are no cells remaining on the slide following pepsin treatment, then the treatment was too harsh. If many cells have lifted off, the treatment was too harsh. Adjust the time or pepsin concentration as required.

Paraffin sections. The diameter of nuclei in various tissue types will vary between 4 and 8 μm. The estimated diameter for the tissue of interest should be ascertained from the literature and sections of the same thickness or 2 to 4 μm greater should be cut, so that it is likely that the entire nucleas is included in the section.

Pepsin digestion works for most tissue types. Occasionally, the tissue will exhibit persistent green autofluorescence of nuclei and no signal (see Table 22.4.19). Variation in histology fixation procedures and quality control performed by the hospital pathology laboratory necessitates careful assessment of treatment times and/or concentration of pretreatment (also see Table 22.4.9). Certain tissue sections are more resistant to effects of protein digestion than others. This may be due to the tissue type or amount of protein cross-linking elicited by excessive formalin fixation. If surplus fresh tissue can be obtained, then ethanol or paraformaldehyde fixation will cause less cross-linking and provide better results for most research applications. It should also be noted that normal tissues are often more refractory to protein digestion than tumor material derived from the same tissue type. If there are a limited number of slides remaining from the patient sample of interest it is sometimes helpful to use a superfluous slide from another sample of the same age and cell type to derive the optimal digestion parameters with respect to aging and storage. More comprehensive guidelines for improved paraffin results are summarized by Hyytinen et al. (1994).

Anticipated Results

Preparation of probes

Successful labeling for FISH will yield fragment sizes between 200 and 500 bp. Fragments up to 1 kb are acceptable, but larger fragments will contribute to background. Investigators should expect that the actual amount of DNA aliquoted onto the gel for visualization should be fairly close to the expected amount loaded onto the gel. The labeling reaction is fairly tolerant to variations in concentration from half the actual amount to two-times greater than the actual amount.

Once the labeling conditions have been established and tested in control FISH experiments, the investigator can be confident that subsequent labeling experiments will proceed without incident. Minor adjustments must

Table 22.4.22 Troubleshooting Guide to FISH Probe Labeling[a]

Problem	Cause	Solution
DNA failed to digest	DNase I not present	Ensure that DNase I was added to the labeling reaction.
	Loss of DNase I activity	If DNase I was added, check the expiration date or change to a fresh aliquot.
	TE buffer used to dissolve DNA (EDTA inactivates DNase I)	If TE buffer was used to resuspend the DNA, reprecipitate the DNA, resuspend in water, quantify by spectrophotometry, and relabel.
Fragments too small	Too much DNase I added	Pipetting errors are the leading cause of many experimental problems. Use accurate pipettors.
	DNA starting concentration inaccurate	Refer back to spectrophotometer readings and gel images of undigested DNA to determine whether there were any discrepancies. Contaminating RNA and proteins may contribute to an inaccurate reading, such that the actual amount of starting DNA was less than expected, thus changing the labeling (digestion) kinetics for a specified amount of DNA over a specific time at a specific DNase I concentration. Relabel and increase the amount of starting DNA as required
	Starting DNA was degraded	If the starting DNA already contains degraded fragments, they will simply continue to degrade into relatively smaller fragments. Refer back to the gel of the undigested DNA and determine the percentage of degraded fragments present. Compensate for the fragments that will be digested away and increase the amount of DNA required to relabel. Consider PCR labeling strategies or obtain a better DNA sample.
	Labeling time too long	Be sure that the correct incubation time was used.
	Unstable water bath temperature	The labeling reaction has been optimized for a specific temperature. Increasing the temperature will facilitate faster nicking, while decreasing the temperature will slow it.
Fragments too long	Insufficient DNase I	Use accurate pipettors (see above).
	DNA starting concentration inaccurate	As described above, check the spectrophotometer reading and gel image. If too much DNA was added to the labeling reaction, the same amount of DNase I used to nick a given amount of DNA in a specific time will increase when there is more DNA present. The labeling of this DNA can be salvaged by continuing to incubate for 20 to 30 min (or as required). Be sure to spike the reaction with fresh enzymes.

continued

Table 22.4.22 Troubleshooting Guide to FISH Probe Labeling[a] , *continued*

Problem	Cause	Solution
	Starting DNA was dissolved in TE buffer	Check whether the starting DNA was dissolved in TE as this will inhibit the nicking of DNA. The labeling of this DNA can be salvaged by continuing to incubate as required. Be sure to spike the reaction with fresh enzyme.
	Decreasing activity of DNase I	Over time, the specific activity of DNase I will decrease. If this is the case, increase the amount of DNase I used in the reaction, while keeping the same incubation period. Otherwise, keep the same DNase I concentration and increase the labeling time.
No fragments present	Absence of DNA added to reaction	Make sure that DNA was added to the reaction
	Insufficient DNA added	As discussed above, check to see that the concentration of DNA is accurate and pipettors are accurate.
	Starting DNA degraded	If a significant portion of the starting DNA was degraded to begin with, as shown by gel electrophoresis, this will cause an increase in fragmentation speed, with the smaller fragments running off the gel. A new DNA specimen should be used, or the investigator should consider PCR methods.
	Too much DNase I added	Check that the proper DNase I concentration and/or volume was used in the labeling reaction.
Expected amount of DNA too low/too high (but fragmented to the right size)	DNA starting concentration inaccurate	Assess using a concentration standard. If the actual amount of DNA is less than expected, as determined by gel electrophoresis, then the starting amount of DNA was insufficient or caused by some of the factors described above. If the investigator chooses to relabel, increase the amount of starting DNA as required. If the actual amount of DNA is greater than expected, again as determined by gel electrophoresis, then the starting amount of DNA was incorrect. The investigator may choose to proceed and use this probe for FISH, but the overall incorporation of label into the DNA will be lower since the labeling reaction contains sufficient dNTPs for a specified DNA quantity. If the investigator chooses to relabel, decrease the amount of starting DNA material as required.
PCR failed	Amount of template, pH, or $MgCl_2$ concentration incorrect, or quality of template poor	Refer to *APPENDIX 3F* and *APPENDIX 2A*.

[a]The guide assumes that the labeling conditions have generally been optimized but occasionally anomalies occur.

be made when using new reagents. Once a probe has been FISHed, the signal should be clearly visible with little or no background or cross-hybridization. The investigator should be aware that other factors, such as hybridization efficiency, slide quality, antibody quality, stringency of post-hybridization washes can also affect the signal strength.

Preparation of slides

Optimal pretreatment of cytogenetic or paraffin-embedded slides should produce slides that are relatively free of cytoplasm/cellular debris, free of paraffin, and have adequately denatured DNA for FISH. The samples should not be autofluorescent.

Hybridization

Due to the multistepped nature of FISH, it is difficult to determine the success of hybridization until the entire assay is completed. Successful hybridization will depend on adequate denaturation of the target DNA on the slide, as well as adequate denaturation of the probe. Proper suppression of repetitive sequence elements with Cot-1 DNA can increase the specificity of hybridization. The specificity of hybridization is also regulated by stringency factors described above (see Background information; also see Critical Parameters). Successful hybridization will allow the identification of chromosomal location of the probe sequence.

Post-hybridization washes and detection

The protocols described provide a basic framework for adjusting post-hybridization washes and detections. Under ideal conditions, the stringency of the post-hybridization washes is sufficient to adequately remove any unbound/nonhybridized probe from the target DNA. The specificity of the probe and the suppression of repetitive elements during preannealing will also decrease the number of cross-hybridization signals. The concentration of detergent used in the washes is also optimized to remove any unbound antibodies, although minor modifications, as required, should be made when using a different brand, lot, or type of antibody. The result, upon visualization with a microscope, is a clean preparation showing minimal background and an easily visualized signal(s) on the DNA target.

Time Considerations

Preparation of probes

The most time consuming portion of labeling for FISH is in the optimization of the labeling procedure if using an in-house protocol. As discussed previously, commercial kits for labeling are available and give relatively consistent results.

Preparation of slides

The preparatory work for preparing cytogenetic slides requires minimal time and the protocol is fairly robust. Optimization for paraffin-embedded sections requires more careful time and trial-and-error. The preparation of cytogenic slides for FISH can be accomplished in ~1 hr. Once optimized conditions have been obtained for paraffin-embedded tissues, it too can be accomplished in 1 to 2 hr. However, initial optimization may require several experimental attempts.

Hybridization

The hybridization step of FISH typically occurs overnight (i.e.,. DNA probes), ~18 to 24 hr at 37°C. The time may be lengthened to 48 or 72 hr (as in the case with weekends), with no adverse affects. Hybridization with PNA probes require less time, at least 1 hr at room temperature. Caution, however should be taken that the slides are adequately sealed such that the probe in hybridization solution does not evaporate. Maintaining a slightly dampened slide container will help alleviate this problem.

Post-hybridization washes and detection

The time allotted for post-hybridization washes and detection will vary depending on the type of DNA probe used in the experiment. Directly labeled probes (DNA or PNA probes) require very little bench time since no antibody detection is required; typically they take up to 30 minutes. Probes are simply washed using high stringency washes as described in the methods. Indirectly labeled probes require incubations with antibodies (primary, secondary and/or tertiary), with the final incubation with a fluorochrome-conjugated antibody, as well as detergent washes and/or blocking steps between each antibody incubation. If the signal requires amplification, the bench time increases as each antibody incubation should last at least 30 minutes. A wash protocol using an indirectly labeled probe with signal amplification will range from 3.5 to 4 hours.

Multi-Color FISH Techniques

Small structural chromosomal aberrations are often difficult to determine with certainty using conventional cytogenetic banding methods alone (*UNIT 22.3*). The problems that can typically arise in both clinical and cancer cytogenetics are the presence of structural chromosome aberrations with unidentifiable chromosomal regions, or very complex chromosomes (sometimes called marker chromosomes) in which no recognizable region appears to be present. Confirmation of the cytogenetic origins of such chromosomal aberrations can sometimes be obtained by the judicious application of locus-specific FISH analysis (*UNIT 22.4*) if the investigator has some general impression regarding a possible identity. However, such an approach is very subjective and risky and requires some knowledge of the specific loci and available probes likely to be involved in the aberration. A more systematic approach is to use whole-chromosomal paints in succession, until the marker chromosome and its constituents can be identified. While this strategy will eventually identify each chromosomal region involved, it is both costly and time-consuming and may lead to the depletion of valuable patient samples. Recently, some generalized screening FISH techniques utilizing sensitive and differentially labeled chromosome-specific paints (also see *UNIT 22.4*) have been developed, and these allow the full chromosome complement to be analyzed to identify unknown aberrations. In this unit, the commonly available methods will be described with suggested protocols and approaches to troubleshooting.

There are currently two to three slightly different imaging systems available that utilize the mechanical rotation of fluorescence excitation filters to distinguish the distinct fluorescence of a mixture of chromosomal paints during image acquisition. Such filter-based systems are generically termed multicolor FISH (M-FISH; Speicher et al., 1996; each supplier has their own modified acronym for this technique). The second more frequently used system, called spectral karyotyping (SKY), utilizes image analysis based on Fourier transformation to spectrally analyze the differential fluorescence of each chromosomal paint (Schrock et al., 1996). Both the SKY and M-FISH methods require the use of human whole-chromosomal paints that are differentially labeled, so that each chromosome emits a unique combination of colors following hybridization, this color combination is used for identification purposes. Each method can be performed as a laboratory procedure and is capable of identifying the cytogenetic origins of all chromosomes in the complement in one image acquisition step (as in SKY) or through sequential imaging with specific filters (M-FISH).

The protocols in this unit employ the basic FISH techniques already discussed in *UNIT 22.4*. However, since multi-chromosome full-painting probe cocktails are different for specific assays, it is prudent to discuss the labeling strategy and denaturation, hybridization, and post-hybridization steps in detail. The probe labeling protocol is similar to those discussed in *UNIT 22.4*, where normally, genomic DNA from cloned sources serves as the template. However, the technique described for SKY and M-FISH requires multiple rounds of amplification. The in situ hybridization steps, whether for SKY or M-FISH, are very similar, differing only in the post-hybridization washes and specific reagents. The critical difference between the two assays is the method of image acquisition and analysis. All of the critical parameters of slide making, probe labeling, and washing stringency apply to SKY and M-FISH (see *UNIT 22.4*).

This unit includes protocols for labeling SKY and M-FISH probes (see Basic Protocol 1) and for multi-color FISH (see Basic Protocol 2 and Alternate Protocol 1), including

Contributed by Jane Bayani and Jeremy Squire
Current Protocols in Cell Biology (2004) 22.5.1-22.5.25

multi-color FISH of previously G-banded slides (see Alternate Protocol 2) and using locus-specific probes with previously SKY or M-FISH hybridized slides (see Alternate Protocol 3).

Multi-color FISH assays can be easily completed if the reagents are purchased commercially. If the investigator plans to produce the probes and antibody mixtures in-house, many more experiments and quality-control experiments will be required.

BASIC PROTOCOL 1

LABELING WHOLE-CHROMOSOME DNA PROBES FOR MULTI-COLOR FISH ASSAYS

This labeling protocol has been kindly provided by the laboratory of Dr. Thomas Ried; it outlines the general labeling strategy for in-house production of whole-chromosome paints to be used in SKY and M-FISH experiments. Some modifications may be required for optimization. The labeling protocol is divided into three parts: (1) primary amplification of flow-sorted chromosomes, (2) secondary amplification of the degenerate oligonucleotide primed (DOP) PCR-amplified primary product, and (3) labeling of the secondary amplification product with fluorochromes or haptens. Each labeling experiment involves the use of DOP primers as described by Telenius et al. (1992). The labeling protocol below includes tables of the human fluorochrome/hapten combinations currently used by Applied Spectral Imaging for use with the SKY system, the labeling combinations used by Vysis for use with the SpectraView System, and the combinations used by Applied Spectral Imaging for a Mouse SKYPaint (see Tables 22.5.3, 22.5.5, and 22.5.6). These labeling combinations can be used to custom produce probes for use with any standard FISH imaging system, provided that the proper filters are available on the microscope and there is a means of identifying and analyzing custom multi-color FISH experiments. Custom experiments may involve all the chromosomes, a subset of them, or specific bands along one chromosome (MBand). MBand, which differentially labels major chromosomal bands along the length of a chromosome is offered by Metasystems but is not covered in this unit.

Materials

Template DNA (flow-sorted chromosomes in a volume of 32.0 μl; Gray et al., 1986)
5× buffer D (accompanying 10 mM dNTP from Invitrogen)
10 mM dNTP nucleotide mix (see recipe)
5 μM 5′-CCGACTCGAGNNNNNNATGTGG-3′ primer
15 U/μl Super *Taq* polymerase (CPG)
5× loading buffer (see recipe)
2% (w/v) agarose gel with ethidium bromide (see recipe)
5 U/μl Ampli*Taq* polymerase (Perkin Elmer)
10× PCR buffer
25 mM $MgCl_2$
2 mM dNTP for secondary amplification (see recipe)
2 mM dNTP for labeling (see recipe)
100 μM Rhodamine 110 (Perkin Elmer)
1 mM FITC
1 mM Texas Red (see recipe for *x*-dUTPs)
50 mM biotin (Boehringer Mannheim)
50 mM digoxygenin (Boehringer Mannheim)
1 mM Spectrum green (see recipe for *x*-dUTPs)
1 mM Spectrum orange (see recipe for *x*-dUTPs)
1 mM Spectrum aqua (see recipe for *x*-dUTPs)
1 mM Spectrum gold (see recipe for *x*-dUTPs)

1 mM Spectrum far red (see recipe for *x*-dUTPs)
1 mg/ml human Cot-1 DNA (GIBCO)
10.0 mg/ml sonnicated salmon sperm DNA (Invitrogen)
3 M sodium acetate (*APPENDIX 2A*)
100% and 70% ethanol
Hybridization buffer (see recipe)

PCR tubes
PCR thermal cycler
Gel system and power source
0.5- and 2-ml microcentrifuge tubes
Refrigerated centrifuge

NOTE: Use aseptic technique throughout. Be sure to change pipet tips for each reagent and before addition to each tube.

DOP-PCR amplify flow-sorted chromosomes

1. Vortex flow-sorted chromosomes in PCR tubes well in order to detach chromosomes from the inner walls. Microcentrifuge for ≥3 min (~32.0 µl volume) at maximum speed, or 200 to 300 × *g*, room temperature.

   This will be the tube to which the PCR mix will be added. The total volume will be 50 µl.

2. Combine the following PCR mixture for each sample (make sure to change tips for each reagent):

   10.0 µl 5× buffer D
   4.0 µl 10 mM dNTP
   1.5 µl 5 µM 5′-CCGACTCGAGNNNNNNATGTGG-3′ primer
   2.0 µl ddH_2O
   0.25 µl 15 U/µl Super *Taq* polymerase.

3. Lightly vortex each tube and microcentrifuge 30 sec at maximum speed.

4. Immediately transfer tubes to PCR thermal cycler and run PCR with the following parameters:

1 cycle:	10 min	93°C
4 cycles:	1 min	94°C
	1.5 min	30°C
	3 min	30°–70°C
	3 min	72°C
34 cycles:	1 min	94°C
	1 min	62°C
	3 min, add 1 sec/cycle	72°C
1 cycle:	10 min	72°C (final extension)
		4°C (hold).

5. When the program is complete, mix a 2-µl aliquot with 1 µl 5× loading buffer from each reaction and run on a 2% agarose gel to determine the efficiency of the initial amplification reaction.

   The resulting smear migrates at ~500 bp. The efficiency of the amplification can be assessed by comparing the intensity of the resulting smear with concentration standards by gel electrophoresis or by standard spectrophotometry. The amplified product may be stored indefinitely at −20°C.

Table 22.5.1 Master Mix for Secondary Amplification

Reagent	Volume per reaction (μl)	Total for 13 reactions (μl)	Total for 12 reactions (μl)
Sterile ddH_2O	65	845	780
10× PCR buffer	10	130	120
25 mM $MgCl_2$	8	104	96
2 mM dNTP	10	130	120
5 μM primer (for 13 reactions)	4	52	48
Ampli*Taq* DNA polymerase	1	13	12

Perform secondary amplification of product

6. Label twenty-five 0.5-ml tubes with chromosome number and date (1 to Y and a control tube without DNA).

   Secondary amplification using DOP-PCR is used to amplify the primary product above. Future labeling experiments will start from this step.

7. Thaw template DNA at 37°C if previously frozen, vortex, and centrifuge briefly in a picofuge prior to dispensing the DNA into aliquots.

8. Pipet 2 μl of the amplified flow-sorted chromosomal DNA into each PCR tube and place closed PCR tubes temporarily at 4°C.

9. Since there are a total of 25 reactions (22 autosomes, 2 sex chromosomes, and a negative control), prepare the master mix in two 2-ml microcentrifuge tubes according to Table 22.5.1. Vortex the two tubes, centrifuge, and place on ice.

   One tube will contain enough master mix for 13 reactions and the other will contain enough for 12 reactions.

10. Take out the Ampli*Taq* polymerase, mix carefully (tap with finger), centrifuge, and then add an appropriate amount to each master mix. Vortex the master mix tubes, centrifuge, and put back on ice.

11. Place PCR tubes containing DNA in order and open each tube by handling only the outside of the tube. Pipet 96 μl of master mix into each tube (change tips with each tube) and place on ice.

12. Vortex each tube, centrifuge briefly, and place each into the thermal cycler. Amplify using the following amplification program:

29 cycles:	1 min	94°C
	1 min	56°C
	3 min, add 1 sec/cycle	72°C
1 cycle:	10 min	72°C (final extension)
		4°C (hold).

13. After completion, remove the tubes from the PCR machine, vortex, centrifuge, and place on ice.

14. Run a 2-μl aliquot with 1 μl 5× loading buffer from each reaction on a 2% agarose gel.

    The resulting smear migrates at ∼500 bp. The efficiency of the amplification can be assessed by comparing the intensity of the resulting smear with concentration standards by gel electrophoresis or by standard spectrophotometry. The amplified product may be stored indefinitely at −20°C.

Label amplified products

15. Label PCR tubes according to labeling scheme corresponding to the software/hardware system used (i.e., ASI or Vysis). Remember to include a zero control for each color (master mix with no DNA sample).

    Commercial probes for SKY and M-FISH are available from ASI and Vysis, however, some laboratories may prefer to produce their own probes to use with their system of choice. This labeling protocol can also be used to produce mutli-color custom probe cocktails, whether they be whole-chromosome paints, or band-, locus-, or centromere-specific probes, the investigator simply substitutes the template DNA as required.

    The critical difference between the two probe cocktails lies in the fact that SKY probes are both directly and indirectly labeled, thus requiring antibody detection, whereas the M-FISH probe cocktail is entirely directly labeled and does not require antibody detection.

    Contact ASI for any changes in probe cocktail combinations as this will affect the reference library, which has been integrated into the SKY software. Furthermore, should the investigator choose to alter the probe combination, the investigator should make sure that the reference library is concomitantly altered to reflect the changes made in the probe. Contact ASI or refer to the user manual for instructions on how to change the combinatorial table (referred to as a .ctb file).

16. Thaw template DNA at 37°C, vortex, and centrifuge briefly. Dispense a 4-μl aliquot of the appropriate DNA into each PCR tube, seal lid, and temporarily place at 4°C.

17a. *For SKY probes:* Label five 2-ml microcentrifuge tubes A through E and make the master mix for each fluorochrome according to Table 22.5.2 and in the following order: ddH_20, 10× PCR buffer, 25 mM $MgCl_2$, 2 mM dNTP, and 100 μM primer.

    Table 22.5.3 lists the fluorochrome combinations for specific chromosomes.

17b. *For M-FISH probes:* Label five 2-ml microcentrifuge tubes A through E and make the master mix for each fluorochrome according to Table 22.5.4 and in the following order: ddH_20, 10× PCR buffer, 25 mM $MgCl_2$, 2 mM dNTP, and 100 μM primer.

    Table 22.5.5 lists the fluorochrome combinations for specific chromosomes.

18. Dilute the Texas Red and spectrum-dUTPs 1:5 in sterile water immediately before use (1 mM final). Vortex the labeled fluor-dUTPs, centrifuge briefly, add each to the appropriate master mix, and place back on ice.

Table 22.5.2 SKY Master Mix

Reagent	Rhodamine (A)	Texas Red (B)	Biotin/Cy5 (C)	FITC (D)	Dig(Cy5.5) (E)
10× PCR buffer	120 μl	110 μl	130 μl	140 μl	120 μl
25 mM $MgCl_2$	96 μl	88 μl	104 μl	112 μl	96 μl

[a]Like the SKY probes, contact Vysis for the latest probe combinations. Ensure that in-house probe matches combinatorial libraries established by the SpectraView software.
[b]A, Spectrum Far Red; B, Spectrum Aqua; C, Spectrum Green; D, Spectrum Gold; E, Spectrum Red.

19. Mix the Ampli*Taq* enzyme carefully (tap with finger), centrifuge briefly, then add appropriate amounts to each master mix. Vortex the master mix tubes, centrifuge, and put back on ice.

20. Put labeled PCR tubes with aliquoted DNA in fluorochrome order (all As in one row, all Bs in the next, and so on).

21. Carefully open each tube in row A by handling only the outside of the tube. Vortex the master mix for spectrum-dUTPs, pipet 96 µl into each tube (change tips with each tube) and put on ice. Repeat the same procedure for each remaining *x*-dUTP. Vortex each tube, centrifuge briefly, and put on ice again.

22. Start the thermal cycler, arrange the tubes in the PCR machine, close lid, and start the program using the following parameters:

29 cycles:	1 min	94°C
	1 min	56°C
	3 min, add 1 sec/cycle	72°C
1 cycle:	10 min	72°C (final extension)
	hold	4°C.

Analyze labeling results

23. After completion, remove the tubes from the thermal cycler, vortex, centrifuge, and place on ice.

24. Analyze a 2-µl aliquot from each reaction on a 2% agarose gel.

The resulting smear migrates at ~500 bp.

At this point, the custom probe cocktail is generated according to the labeling scheme. The chromosome paint for each chromosome will be added together for each of the 22 autosomes and 2 sex chromosomes according to Table 22.5.3 or 22.5.5, or according to Table 22.5.6 for mouse chromosome probes.

The total number of differently labeled DNAs for the ASI labeling scheme is 57, while the total number of labeled DNAs for the Vysis labeling scheme is 52.

Purify probe

25. To produce the SKY cocktail, add 3 μl of labeled, amplified product according to the labeling scheme into a 1.5-ml microcentrifuge tube. Add 20 μl of 1 mg/ml Cot-1 DNA and 1 μl of 10.0 mg/ml salmon sperm DNA.

    This precipitation protocol outlines the amount of probe required for one slide to be hybridized. It is suggested that sufficient probe for five or ten assays should be precipitated together and stored as aliquots.

26. Add 1/10 vol of 3 M sodium acetate, 2.5 vol of 100% ethanol, mix well, and store overnight at −20°C or 1 hr at −80°C.

27. Centrifuge 20 min at 200–300 × *g* (13,000 to 14,000 rpm), 4°C. Wash the pellet with cold 70% ethanol and repeat centrifugation. Dry the pellet either by air drying or vacuum.

28. Dissolve pellet in 15 to 20 μl hybridization buffer at room temperature.

    If the probe does not readily dissolve back into solution, add more hybridization buffer.

29. Store the probe in aliquots sufficient for five to ten slide hybridizations at −20°C for long-term storage (>2 months), or at 4°C for short-term use (1 to 2 months).

IN SITU HYBRIDIZATION FOR SPECTRAL KARYOTYPING (SKY)

BASIC PROTOCOL 2

The following outlines the SKY protocol, which is simply FISH (*UNIT 22.4*) with different multi-color probes. The metaphase preparation is pre-treated with pepsin, formalin-fixed, and denatured. The prepared probe is denatured, allowed to pre-anneal and added to the denatured slide. After 48 hr, the slides are washed, detected with primary and secondary antibodies, counterstained, and visualized.

Materials

Metaphase slides (*UNIT 22.2*)
0.01 M HCl (see recipe), prewarmed to 37°C
10% (w/v) pepsin (see recipe)
1× PBS
1% formaldehyde/1× PBS/50 mM $MgCl_2$ (see recipe)
70% formamide/2× SSC (see recipe), prewarmed to 72°C
70%, 80%, and 100% ethanol
SKY kit (Applied Spectral Imaging) containing probe cocktail, block reagents, detection reagents, and counterstain *or* in-house custom-made probes in hybridization solution (see Basic Protocol 1)
Rubber cement
50% formamide/2× SSC, 45°C (3 Coplin jars)
1× SSC (see recipe), 45°C (3 Coplin jars)
0.1%Tween-20/4× SSC (see recipe), 45°C (7 Coplin jars)
Blocking solution (see recipe)
Avidin-Cy5 antibodies (see recipe for antibodies)
Mouse anti-digoxigenin (see recipe for antibodies)
Cy5.5 anti-mouse antibodies (see recipe for antibodies)
DAPI/antifade counterstain (see recipe)
Clear nail polish (do not use if planning to re-probe slide)

Phase-contrast microscope
37°C oven
Fume hood
22 × 22–mm coverslips

Hybridization container
Fluorescent microscope and associated Applied Spectral Imaging Acquisition hardware and software (Applied Spectral Imaging)

Prepare slide

1. Using a phase-contrast microscope, determine the extent of cytoplasmic residue on the metaphase slide preparation (*UNIT 22.2*).
2. To 50 ml of prewarmed 0.01 M HCl, add 10 to 15 μl of 10% pepsin. Allow the slide to incubate for 5 to 10 min at 37°C.
3. Wash the slide in 1× PBS for 5 min at room temperature. Then, wash in 1× PBS/50 mM $MgCl_2$ for 5 min at room temperature.
4. Incubate the slide in 1% formaldehyde/1× PBS/50 mM $MgCl_2$ for 10 min at room temperature in a well-ventilated area or fume hood.

Prepare the probe

5a. *For commercial probes:* From the commercially available SKY kit, pipet 10 μl of probe cocktail (vial 1) for each slide to be hybridized. Heat denature the probe for 10 min at 72°C, then place 1 hr at 37°C.

This is sufficient probe to cover a 22 × 22–mm area.

5b. *For in-house probes:* Heat denature prepared probe (labeled probe in hybridization buffer, see Basic Protocol 1) for 10 min at 72°C, then place 1 hr at 37°C.

6. Wash the slide in 1× PBS for 5 min at room temperature.
7. Pass slide through an ethanol dehydration series: 70%, 80%, and 100% ethanol for 5 min each. Allow slide to air dry after the final ethanol wash.
8. Denature the slide in 70% formamide/2× SSC for 1.5 to 2 min at 72°C.

The time required for denaturing will vary according to the age and quality of slide.

9. Promptly place the slide into 70% ethanol following denaturation and proceed through the dehydration series as in step 7.

Hybridize and wash slides

10. Add 10 μl of the preannealed probe to the denatured slide. Apply a 22 × 22–mm coverslip and seal with rubber cement.
11. Transfer the slides to a hybridization container that has been slightly dampened with a wet paper towel or gauze and place at 37°C.
12. After 48 hr, carefully peel rubber cement from slide and immerse in the first Coplin jar of 50% formamide/2× SSC at 45°C. Allow the coverslip to fall off and let stand for 5 min.
13. Remove slide and transfer to second Coplin jar of 50% formamide/2× SSC for 5 min. Repeat with third Coplin jar of 50% formamide/2× SSC.
14. Wash the slide three times in three separate Coplin jars of 1× SSC, 5 min each wash, at 45°C.
15. Briefly wash the slide in 0.1%Tween-20/4× SSC at 45°C.

Block and detect slides

16a. *For commercial probes:* Drain excess solution, but do not allow slide to dry. Add 80 μl of blocking reagent (vial 2 from the SKY kit) to the slide. Apply coverslip and place back in hybridization container for 40 min at 37°C.

17a. Remove coverslip and add 80 µl of detection reagent (vial 3 from SKY kit) to the slide. Apply coverslip and place back in hybridization container for 40 min at 37°C.

16b. *For in-house probes:* Drain excess solution, but do not allow slide to dry. Add 80 µl of blocking solution, apply coverslip, and place back in hybridization container for 40 min at 37°C.

17b. Add 40 µl each of Avidin-Cy5 antibodies and mouse anti-digoxigenin antibodies. Apply coverslip and place back in hybridization container for 40 min at 37°C.

18. Remove coverslip and wash slide in three times in three separate Coplin jars of 0.1% Tween-20/4× SSC, 5 min each wash, at 45°C with gentle agitation.

19a. *For commercial probes:* Drain excess solution, but do not allow slide to dry. Add 80 µl detection reagent (vial 4 from the SKY kit) to the slides. Apply coverslip and place back in hybridization container for 40 min at 37°C.

19b. *For in-house probes:* Drain excess solution, but do not allow slide to dry. Add 80 µl of diluted Cy5.5 anti-mouse antibodies. Apply coverslip and place back in hybridization container for 40 min at 37°C.

20. Remove coverslip and wash slide three times in three separate Coplin jars of 0.1% Tween-20/4× SSC, 5 min each wash, at 45°C with gentle agitation.

Counterstain and visualize

21. Drain excess solution, but do not allow slide to dry. Add 40 µl of DAPI/antifade counterstain (vial 5 from SKY kit or from another source). Apply coverslip and seal with clear nail polish. However, do not seal with nail polish if there are plans to re-probe the slide (see Alternate Protocols 1, 2, and 3).

    Slides may be stored at −20°C and visualized for up to 6 months with sustained signal strength.

22. Acquire and analyze metaphase preparation using SKY labeling scheme with the hardware and software provided by Applied Spectral Imaging (*http://www.spectral-imaging.com/*).

    See Figure 22.5.1 for a diagram of signal acquisition and Figure 22.5.2 for typical results.

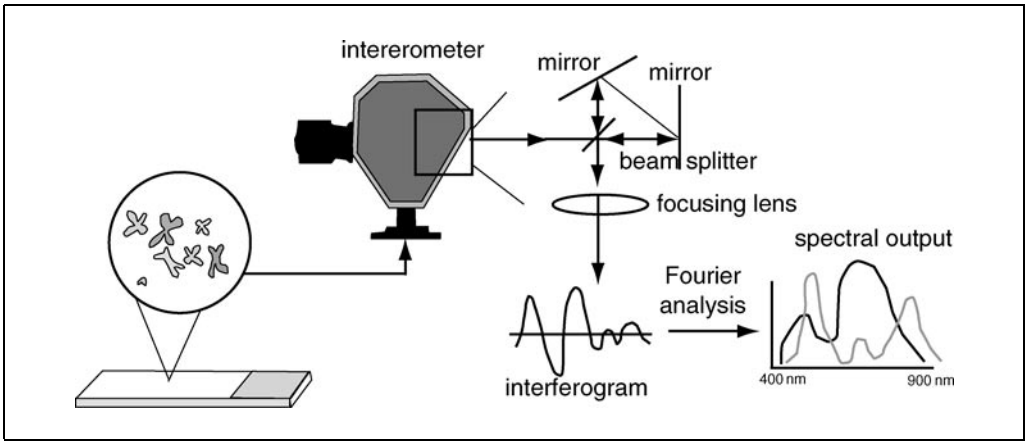

Figure 22.5.1 Schematic representation of spectral karyotyping image acquisition and image analysis. The metaphase, following hybridization with the SKYPaints is visualized by fluorescence microscopy. The light passes into the optical head containing the interferometer where 100 different images are taken. This information is Fourier transformed and processed using the SKYView software for analysis. (Adapted from the ASI manual.)

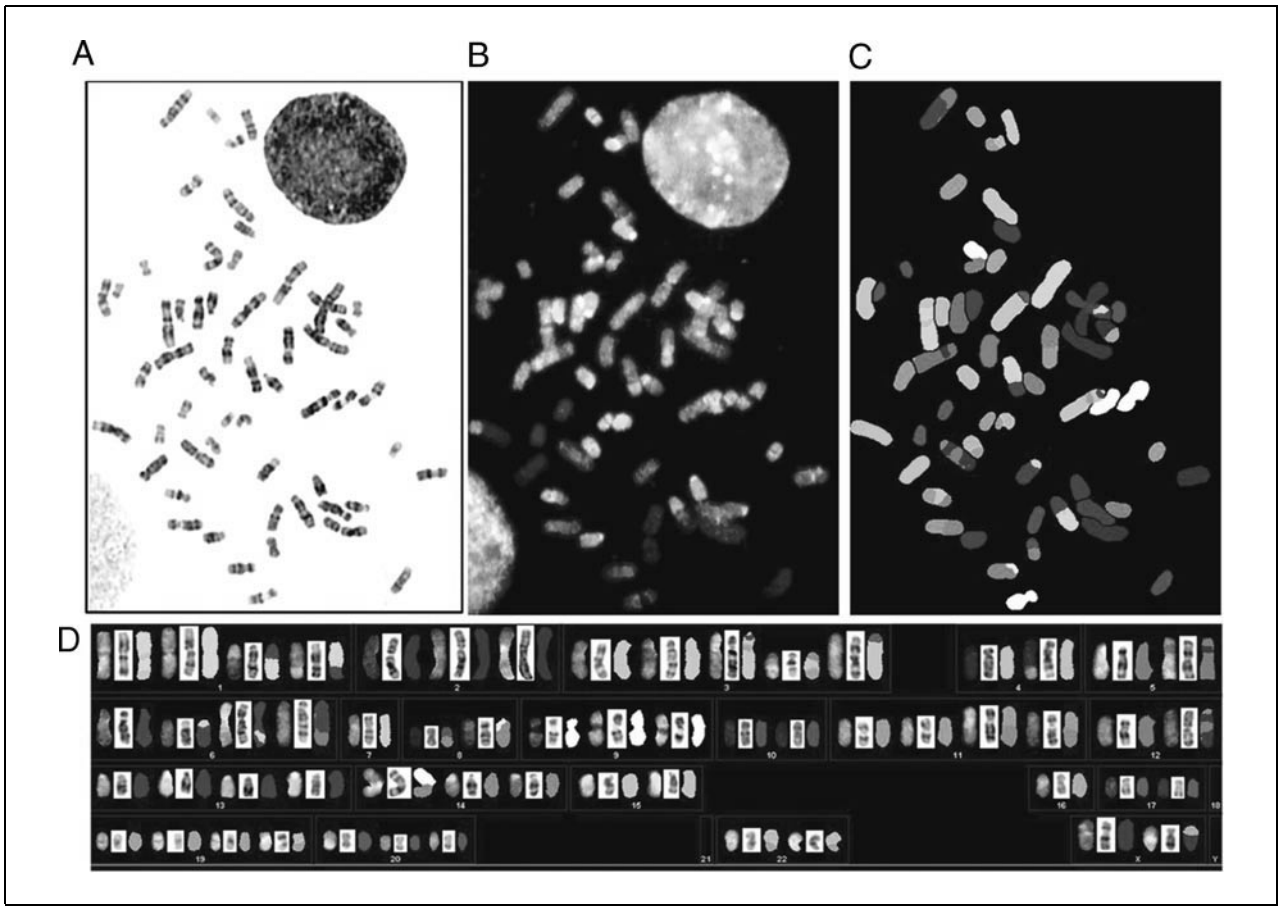

Figure 22.5.2 SKY analysis of a primary ovarian carcinoma. (**A**) Typical representations of SKY analysis. An inverted DAPI image reveals banding patterns similar to G-banding. (**B**) Red-Green-Blue (RGB) image of the hybridized spread as it would appear with the probe colors. (**C**) Classified or pseudo-colored image to help identify chromosomal aberrations not readily evident in the RGB image. Each chromosome is identified by a specific pseudo-color. A change in color along the length of a chromosome indicates a different chromosome. (**D**) SKY karyotype showing each representation of the chromosomes: RGB, inverted DAPI, and classified images. *This black and white facsimile of the figure is intended only as a placeholder; for full-color version of the figure go to http://www.currentprotocols.com/colorfigures.*

ALTERNATE PROTOCOL 1

IN SITU HYBRIDIZATION FOR M-FISH KARYOTYPING

The M-FISH protocol is very similar to the SKY protocol with one critical difference. Like SKY, the metaphase preparation is pretreated with pepsin, formalin-fixed, and denatured. The prepared probe is denatured, allowed to pre-anneal, and added to the denatured slide. After 48 hr, the slides are washed, counterstained, and ready for visualization. Because M-FISH probes are labeled using directly labeled dUTPs, there is no need for antibody detection.

Materials

Chromosome spreads (*UNIT 22.2*)
70%, 80%, and 100% ethanol
RNase A working solution (see recipe)
2× SSC (see recipe)
10% pepsin stock (see recipe)
0.01 M HCl (see recipe), 37°C
1× PBS (2 coplin jars)
1% formaldehyde/1× PBS/50 mM $MgCl_2$ (see recipe)
70% formamide/2× SSC (see recipe), 72°C
Commercially available M-FISH probes (Vysis) *or* in-house custom probes

0.4× SSC/0.3% NP-40 (see recipe), 73°C
2× SSC/0.1% NP-40 (see recipe)
DAPI/antifade counterstain (DAPI III, Vysis or see recipe)
50% formamide/2× SSC (see recipe), 45°C
1× SSC (see recipe), 45°C
0.1% Tween-20/4× SSC (see recipe), 45°C
Clear nail polish (do not use if planning to re-probe slide)

Phase-contrast microscope
Glass coverslips
37°C dry oven or incubator
Fume hood

Prepare slide

1. Prepare chromosome spreads as outlined in *UNIT 22.2*.
2. Under phase-contrast microscopy, determine the extent of cytoplasmic residue on the slide preparation.
3. Dehydrate the slide in a 70%, 80%, 100% ethanol series, 5 min each, and allow to air dry.
4. Apply 20 µl of the RNase A working solution to slide and coverslip. Incubate 30 min at 37°C.
5. Remove the coverslip and wash slide in 2× SSC for 5 min.

   This and the following incubations should use solutions in Coplin jars.

6. Add 10 to 15 µl of 10% pepsin to 50 ml prewarmed 0.01 M HCl and treat slide for 5 min. Then wash the slide in 1× PBS for 5 min.
7. Incubate the slide in 1% formaldehyde/1× PBS/50 mM $MgCl_2$ for 10 min at room temperature in a well-ventilated area or fume hood.
8. Wash the slide in 1× PBS for 5 min at room temperature.
9. Pass the slide through a 70%, 80%, and 100% ethanol series, 5 min each, and allow the slide to air dry.

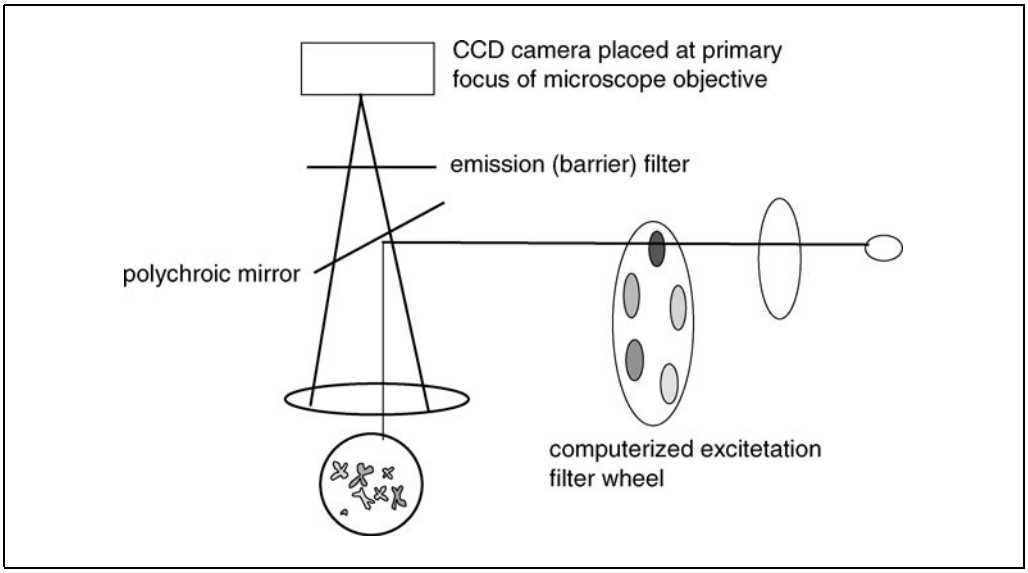

Figure 22.5.3 Schematic representation of M-FISH image acquisition and image analysis. M-FISH experiments involve the imaging of each dye or fluorochrome using a specific filter. The images are then stacked to produce the final merged image. (Adapted from the Vysis manual.)

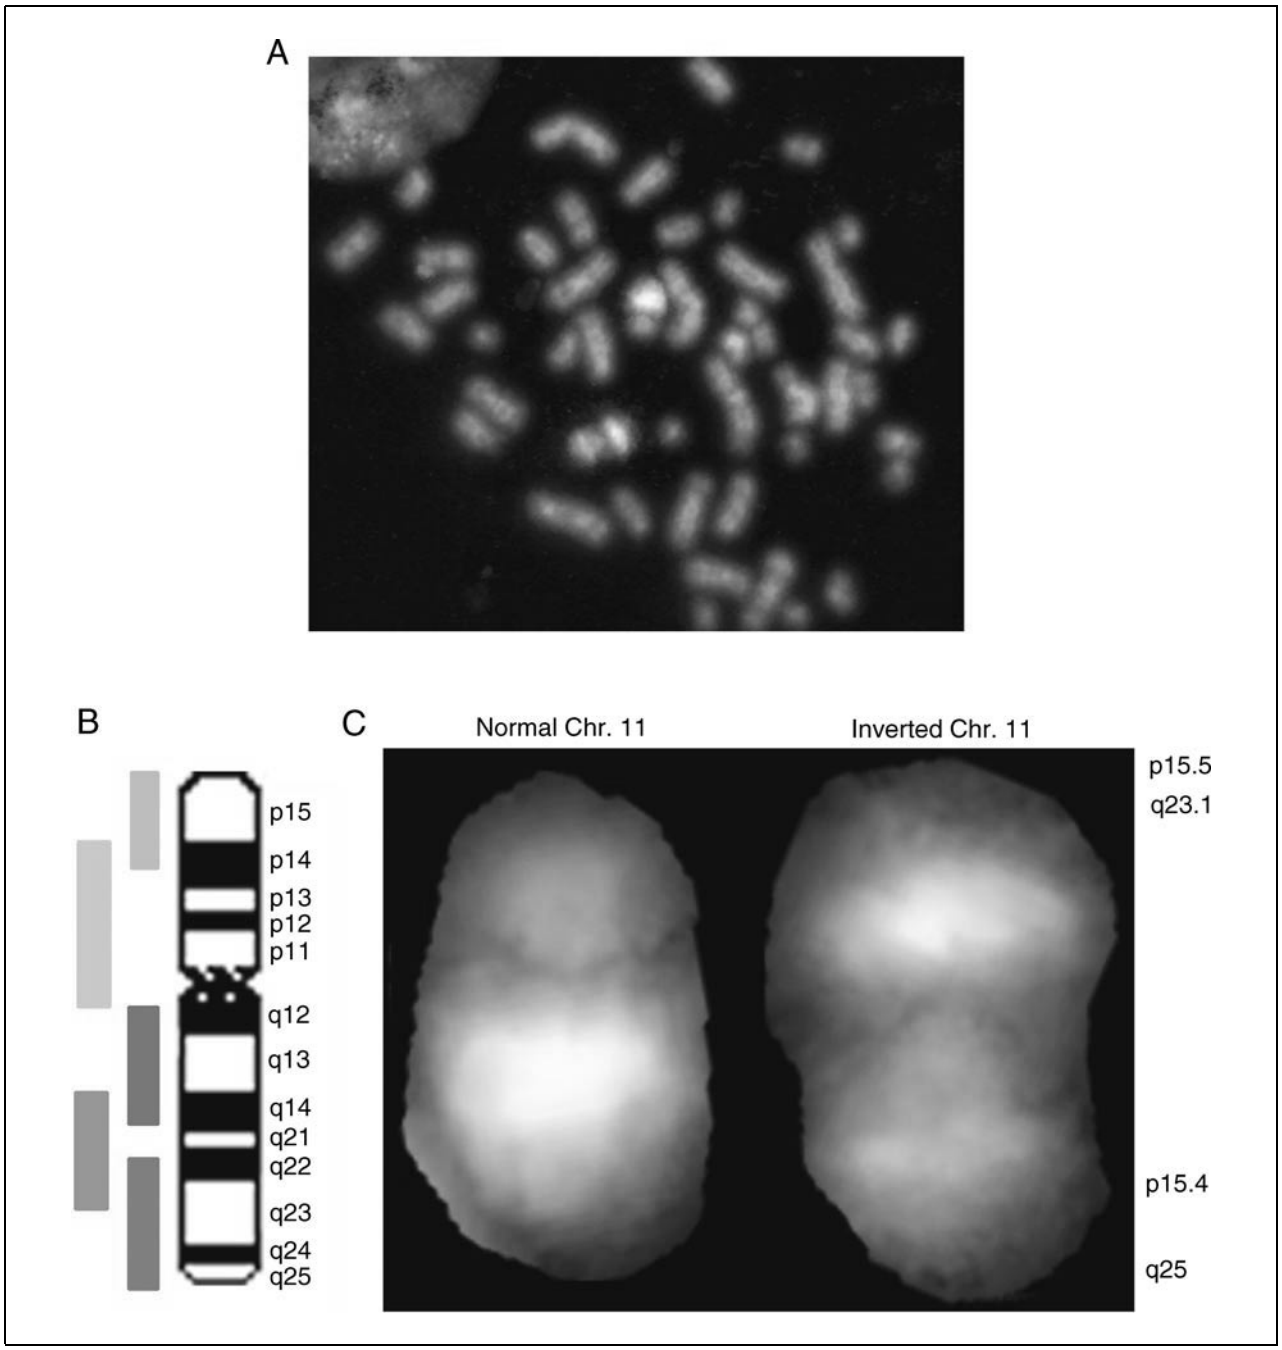

Figure 22.5.4 MBand using the 11Cyte probe and imaging system from Metasystems. (**A**) Metaphase spread from a patient possessing an inversion on chromosome 11, hybridized with the 11Cyte chromosome paint. Five different dyes are used to create the painting probe along the length of the chromosome in a specific order. (**B**) Ideogram of chromosome 11 showing the color order of the dyes along the length of the chromosome and the band regions they span. (**C**) The normal and inverted chromosome 11. *This black and white facsimile of the figure is intended only as a placeholder; for full-color version of the figure go to http://www.currentprotocols.com/colorfigures.*

10. Denature the slide for 1.5 to 2 min in 70% formamide/2× SSC at 72°C.
11. Promptly place the slide into 70% ethanol following denaturation and proceed through the dehydration series as in step 9.
12. Remove the slide from the ethanol, add the recommended amount of denatured and pre-annealed commercial probe or 15 to 20 µl of in-house probe and hybridize for 48 hr at 37°C.

Vysis rapid wash

13a. Carefully remove the coverslip from the slide and immerse in 0.4× SSC/0.3% NP-40 for 2 min at 73°C.

14a. Wash the slide in 2× SSC/0.1% NP-40 for 1 min at room temperature.

15a. Wash the slide in 1× PBS for 2 min at room temperature.

16a. Air dry the slide and stain with DAPI/antifade counterstain. Store slides at −20°C.

Slides can be stored for several months at −20°C.

17a. Visualize slide using a fluorescent microscope and the associated hardware and software provided by Vysis.

Traditional wash protocol (for in-house probes)

13b. After 48 hr, carefully peel off rubber cement from slide and immerse in the first Coplin jar of 50% formamide/2× SSC at 45°C. Allow the coverslip to fall off and let stand for 5 min. Remove slide and transfer to second Coplin jar for 5 min. Repeat with third solution.

14b. Wash the slide three times in three separate Coplin jars of 1× SSC, 5 min each wash, at 45°C.

15b. Remove coverslip and wash slide in three washes of 0.1% Tween-20/4× SSC, 5 min each wash, at 45°C with gentle agitation.

16b. Drain excess solution, but do not allow slide to dry and add 40 µl of DAPI antifade counterstain. Apply coverslip and seal with clear nail polish. However, do not seal with nail polish if there are plans to re-probe the slide (see Alternate Protocols 2, and 3).

The slides are now ready for visualization. When not in use, store slides at −20°C.

17b. Analyze the slide using fluorescence microscopy with the appropriate filters and imaging system capable of integrating multiple fluorochromes.

See Figure 22.5.3 for a diagram of signal acquisition and Figure 22.5.4 for typical results.

PRETREATMENT OF PREVIOUSLY G-BANDED SLIDES FOR SKY OR M-FISH

ALTERNATE PROTOCOL 2

This procedure can be used when a previously G-banded slide is needed for subsequent SKY or M-FISH analysis. The G-banded slide must be cleaned of residual oils using xylene. It is then destained using methanol. See Table 22.5.7 for guidelines for handling G-banded slides.

Materials

G-banded metaphase slides (*UNIT 22.3*)
Xylene
100% methanol
70%, 80%, and 100% ethanol
1× PBS
1× PBS/50 mM $MgCl_2$
1%formaldehyde/1× PBS/50 mM $MgCl_2$ (see recipe)
70% formamide/2× SSC (see recipe), 72°C
Fume hood

Table 22.5.7 General Guide for Processing Cytogenetic Preparations for G-Banding Analysis Followed by SKY or M-FISH

Banding steps	Slide 3 days to 1 month	Slide >1 month	In situ slide preparation 3 days to 1 month	In situ slide preparation >1 month
Trypsin (working solution)	10–20 sec with agitation	20–30 sec with agitation	40–60 sec with agitation	60–90 sec with agitation
Stain	50 sec	1+ min	50 sec	1+ min
Water	Brief rinse	Brief rinse	Brief rinse	Brief rinse
Water	Brief rinse	Brief rinse	Brief rinse	Brief rinse
Denaturing time	20–30 sec	45 sec–1 min	30–45 sec	1 min-?

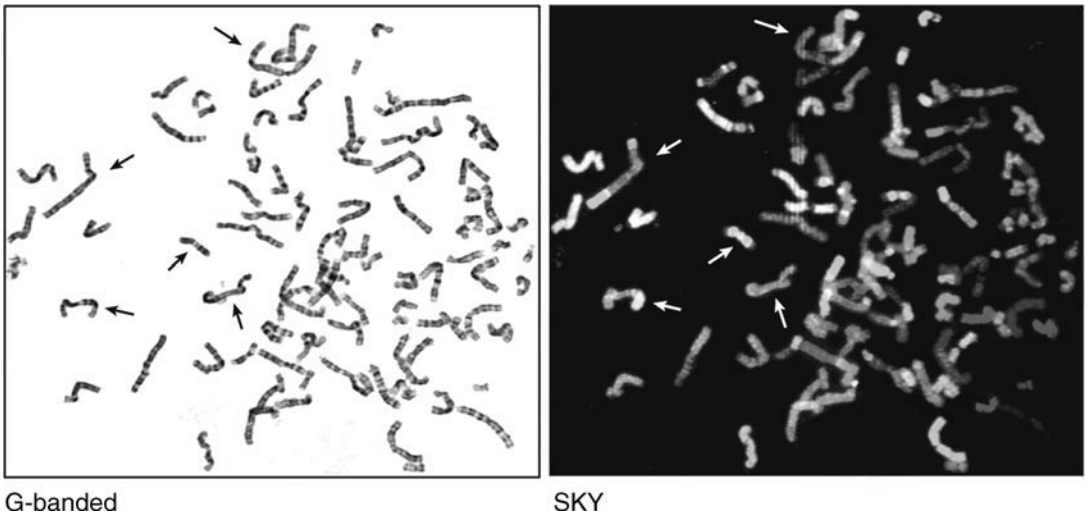

Figure 22.5.5 The results of sequential G-banding (**A**) and SKY (**B**) analysis of a rhabdomyoscaroma cell line. *This black and white facsimile of the figure is intended only as a placeholder; for full-color version of the figure go to http://www.currentprotocols.com/colorfigures.*

Destain slide

1. For previously G-banded slide, wash in xylene for 5 min.
2. Destain with 100% methanol for 10 min.
3. Pass the slide through a 70%, 80%, and 100% ethanol series, 5 min each wash, and allow the slide to air dry after the final ethanol wash.
4. Rehydrate in 1× PBS for 5 min.

Denature slide

5. Incubate the slide in 1% formaldehyde/1× PBS/50 mM $MgCl_2$ for 10 min at room temperature in a well-ventilated area or fume hood.
6. Wash the slide in 1× PBS for 5 min at room temperature.
7. Pass the slide through a 70%, 80%, 100% ethanol dehydration series, 5 min each wash, and allow the slide to air dry after the final ethanol wash.

8. Denature the slide in 70% formamide/2× SSC for 20 to 30 sec at 72°C.
9. Promptly place the slide into 70% ethanol following denaturation and proceed through the dehydration series as in step 6.

Hybridize slide

10. Proceed with probe denaturation and pre-annealing as outlined in the SKY (see Basic Protocol 2, step 6) and hybridization to slide (see Basic Protocol 2, step 11) or M-FISH protocols described above (see Alternate Protocol 1, step 12).
11. Proceed with the respective protocol (SKY or M-FISH) following the appropriate post-hybridization detection and washing procedures (see Basic Protocol 2 or Alternate Protocol 1).

See Figure 22.5.5 for an example of SKY hybridization of previously G-banded chromosomes.

FISH ANALYSIS USING LOCUS-SPECIFIC OR CHROMOSOME PAINTING PROBES FOLLOWING SKY/M-FISH HYBRIDIZATION

ALTERNATE PROTOCOL 3

This protocol can be used in conjunction with previously G-banded slides as well as SKY/M-FISH-hybridized slides. In some cases, investigators may wish to know the status of a specific DNA probe within the context of the SKY or M-FISH analysis that has been ascertained, thus it is particularly useful to be able to sequentially use locus-specific or chromosome paint probes on the same metaphase spread that was analyzed using SKY or M-FISH. The hybridized slides are washed free of mounting medium and dehydrated. The slides are redenatured and hybridized with the locus-specific or chromosome paint probe of interest. After hybridization, the slides are washed, the probe is detected with antibody (if needed), counterstained, and visualized.

Materials

Hybridized SKY or M-FISH slides (see Basic Protocol 2 or Alternate Protocol 1, respectively)
2× SSC (see recipe)
0.1% Tween-20/4× SSC (see recipe)
70%, 90%, and 100% ethanol
70% formamide/2× SSC (see recipe), 75°C
Labeled DNA probe (as prepared in *UNIT 22.4* or from a commercial supplier)
Rubber cement

Coverslips
Hybridization box
37°C dry oven or incubator

1. For SKY or M-FISH hybridized slide, record the microscope coordinates of the metaphase spreads of interest.
2. Carefully remove the coverslip and wash slide in 2× SSC for 5 to 10 min at room temperature. Gently agitate.
3. Transfer slide to 0.1% Tween-20/4× SSC and wash for 5 min at room temperature with gentle agitation.
4. Dehydrate the slide in a 70%, 90%, and 100% ethanol dehydration series, 5 min each wash. After the final ethanol (100%) wash, allow the slide to air dry.
5. Denature the probe at 75°C and pre-anneal as needed or follow the manufacturer's instructions.

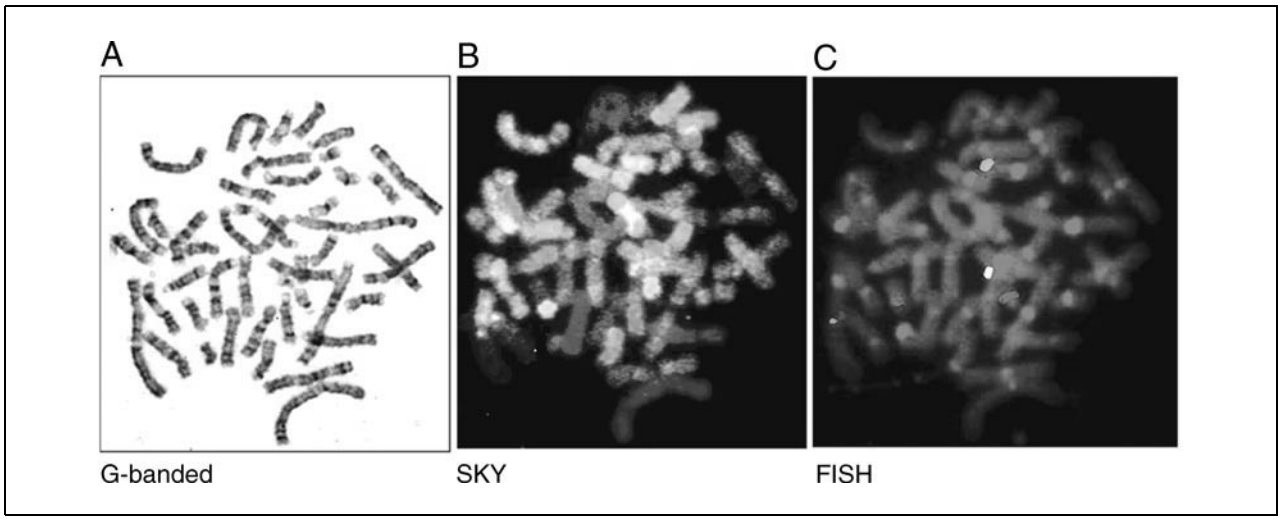

Figure 22.5.6 The results of sequential G-banding (**A**), SKY (**B**), and locus-specific FISH (**C**) for the BCR-ABL translocation in a CML sample. *This black and white facsimile of the figure is intended only as a placeholder; for full-color version of the figure go to http://www.currentprotocols.com/ colorfigures.*

6. Denature the slide in 70% formamide/2× SSC for 2 min at 75°C (for previously G-banded/SKY or M-FISH slides, denature for 1 min).
7. Immediately place the slide in 70% ethanol and continue with the dehydration series as in step 4.
8. Add the appropriate amount of the denatured probe to the denatured slide. Apply coverslip and ring with rubber cement. Hybridize at 37°C overnight.
9. Follow the necessary post-hybridization washes and detections as required (see *UNIT 22.4*)

See Figure 22.5.6 for typical results.

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protcol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Agarose gel, 2% (w/v)

Dissolve 2 g of agarose into 100 ml of 1× TBE buffer (*APPENDIX 2A*) by warming the solution, e.g., in a microwave oven. After the agarose has been dissolved, add 5 ml of ethidium bromide. Pour into electrophoresis tray with combs and allow to solidify at room temperature.

Antibodies

Avidin-Cy5 antibodies (Amersham Bioscience): Reconstitute antibodies using water according to the manufacturer's instructions. Dilute 1:200 in blocking solution (see recipe).

Mouse anti-digoxigenin (Sigma): Reconstitute antibodies using water according to the manufacturer's instructions. Dilute 1:500 in blocking solution (see recipe).

Cy5.5 anti-mouse antibodies (Amersham Bioscience): Reconstitute antibodies using water according to the manufacturer's instructions. Dilute 1:200 in blocking solution (see recipe).

Store antibodies in 100-μl aliquots up to 1 year at −20°C. Aliquots of working solutions may be stored for 2 to 3 months at 4°C protected from the light.

Blocking solution

1.0 g BSA (Sigma; final 1% w/v)
100.0 µl Tween-20 (Sigma; final 0.1% v/v)
20.0 µl 20× SSC (final 4×)
80.0 µl H_2O
Store indefinitely at −20°C

DAPI/antifade medium

Dissolve the entire powder of DAPI (4′,6-diamidino-2-phenylindole; Sigma) in water to a 100 µg/ml stock solution. Store in 500-µl aliquots up to 1 year at −20°C.

To combine DAPI in antifade medium, combine the following in order:
5.0 ml PBS
500.0 µl 100 µg/ml DAPI stock (final 1 µg/ml)
0.5 g *p*-phenylenediamine (Sigma; final 10 mg/ml)
Dissolve well then add
45.0 ml glycerol (final 90% v/v)

The resulting medium is very viscous. Transfer to a 50-ml Falcon tube and place on a rotator to ensure proper mixing (30 min). This product is light sensitive, so wrap the tube with foil. Store in 1-ml aliquots 1 year at −20°C. New medium must be made when an increasing amber tint appears.

This is also commercially available from Vectashield (Vector Laboratories).

CAUTION: *DAPI is a potential carcinogen and should be handled with caution.*

dNTP (dATP, dTTP, dGTP, dCTP) for secondary amplification, 2 mM

10.0 µl 100 mM dATP (final 2 mM)
10.0 µl 100 mM dCTP (final 2 mM)
10.0 µl 100 mM dTTP (final 2 mM)
10.0 µl 100 mM dGTP (final 2 mM)
460.0 µl sterile H_2O (final 2 mM)
Store up to 1 year at −20°C.

dNTP (dATP, dGTP, dCTP, 1.5 mM dTTP) for labeling, 2 mM

10.0 µl 100 mM dATP (final 2 mM)
10.0 µl 100 mM dCTP (final 2 mM)
10.0 µl 100 mM dGTP (final 2 mM)
7.5 µl 100 mM dTTP (final 1.5 mM)
460.0 µl sterile H_2O (final 2 mM)
Store up to 1 year at −20°C.

dNTP (dATP, dTTP, dGTP, dCTP), 10 mM

10.0 µl 100 mM dATP (final 10 mM)
10.0 µl 100 mM dCTP (final 10 mM)
10.0 µl 100 mM dTTP (final 10 mM)
10.0 µl 100 mM dGTP (final 10 mM)
60.0 µl sterile H_2O (final 10 mM)
Store up to 1 year at −20°C.

x-dUTPs

Dilute 1 mM Texas Red 1:5 in sterile H_2O (13 ml Texas Red + 52 ml H_2O)
Dilute 1 mM spectrum red 1:5 in sterile H_2O (14 ml spectrum red + 56 ml H_2O)
Dilute 1 mM spectrum far red 1:5 in sterile H_2O (14 ml spectrum far red + 56 ml H_2O)
Dilute 1 mM spectrum aqua 1:5 in sterile H_2O (14 ml spectrum aqua + 56 ml H_2O)
Dilute 1 mM spectrum green 1:5 in sterile H_2O (14 ml spectrum green + 56 ml H_2O)
Dilute 1 mM spectrum gold 1:5 in sterile H_2O (14 ml spectrum green + 56 ml H_2O)
Store up to 1 year at −20°C

1% formalin/PBS/$MgCl_2$

2.7 ml 37% formaldehyde (Sigma; final 1% v/v)
100.0 ml 1× PBS/$MgCl_2$ (see recipe)
Make fresh

Discard in accordance with the regulations of the institution.

70% formamide/2× SSC

35.0 ml formamide (Invitrogen; final 70% v/v)
5.0 ml 20× SSC (final 2×)
10.0 ml H_2O
Make fresh

CAUTION: *Formamide is a carcinogen and should be handled with caution. It should be discarded according to biohazard rules of the institution.*

HCl, 0.01 M

0.5 ml 1 M HCl (final 0.01 M)
49.5 ml H_2O
Store at room temperature until ready for use

Hybridization buffer

500.0 µl high-grade formamide (final 50% v/v)
100.0 µl 20× SSC (final 2×)
100.0 µl dextran sulfate (final 10% v/v)
300.0 µl H_2O

Alternatively, this solution may be purchased from DAKO.

Loading dye, 5×

0.125 g bromophenol blue (final 0.25% w/v)
15.0 ml glycerol (final 30% v/v)
35.0 ml H_2O
Store for several months to 1 year at room temperature or 4°C

1× PBS/$MgCl_2$

950.0 ml 1× PBS (*APPENDIX 2A*)
50.0 ml 1M $MgCl_2$ (final 50 mM)
Store at room temperature until ready for use

Pepsin stock, 10%

100 mg pepsin powder (Sigma; final 10% w/v)
1.0 ml H_2O
Store in 20-µl aliquots up to 1 year at −20°C

RNase A stock solution

10.0 mg RNase A (DNase-free; final 10 mg/ml)
1.0 ml 2× SSC
Dispense into 10-µl aliquots and store at −20°C
To make an RNase A working solution:
10.0 µl 10 mg/ml RNase A stock solution
990.0 µl 2× SSC
Vortex to mix. Do not freeze-thaw. Discard after use.

20× SSC

175.3 g NaCl
88.2 g sodium citrate
Adjust pH with 10 M NaOH to pH 7
Adjust volume to 1 liter with H_2O
Store for several months at room temperature

0.4× SSC/0.3% NP-40 solution

20.0 ml 20× SSC (final 0.4×)
950.0 ml H_2O
3.0 ml NP-40 (final 0.3% v/v)
Add up to 1 liter with H_2O
Store up to 6 months at room temperature

Discard stock solution after 6 months, or sooner if solution appears cloudy or contaminated.

2× SSC/0.1% NP-40 solution

100.0 ml 20× SSC (final 2×)
850.0 ml H_2O
1.0 ml NP-40 (final 0.1% v/v)
Add up to 1 liter with H_2O
Store up to 6 months at room temperature

Discard stock solution after 6 months, or sooner if solution appears cloudy or contaminated.

0.1%Tween-20/4× SSC

1.0 ml Tween-20 (Sigma; final 0.1% v/v)
200.0 ml 20× SSC (final 4×)
799.0 ml H_2O
Store at room temperature until ready for use

COMMENTARY

Background Information

Probe labeling

See Commentary on probe labeling in *UNIT 22.4*.

SKY

SKY is a combination of optical microscopy, high-resolution imaging, and the measurement of spectral emissions by Fourier spectroscopy (Malik et al., 1996; Fig. 22.5.1). It is an interferometer-based method of image acquisition and analysis and has specific requirements for its correct operation. The ability for SKY to properly identify chromosomal segments relies on the proper calibration of the spectral reference library. Upon installation, the optical head is carefully aligned with the digital camera. Slides hybridized with each pure dye are then imaged to create the spectral reference library for that particular system

and microscope. Since SKY analysis is based on the recognition of distinct spectral signatures, a less than optimal signal intensity can still generate a coherent chromosome classification, provided that there are no shifts in the spectra. Furthermore, should shifts in the spectra occur, it is possible to create a new spectral library based on the spectral signatures of hybridized slides. The advantage of SKY acquisition is the use of only the SKYCube to detect all the dyes and a short exposure using the DAPI filter for inverted banding images, rather than the lengthier exposure of the slide to five different filters as with M-FISH. The SKY software provides the capability to manually identify the spectral properties of each pixel along the length of a chromosomal region and compare this to the reference library. Such analyses can be very helpful in determining the identity of chromosomes where identity is inconclusive.

The commercial SKY probes are derived from flow-sorted chromosomes that are amplified and labeled using DOP-PCR (Telenus et al., 1992). A 24-chromosome probe cocktail is generated by the combinations of five pure dyes—rhodamine, FITC, Cy5, Cy5.5, and Texas Red. This allows 2^{n-1} or 31 combinations. Thus, each chromosome has a unique spectral signature generated by the specific combination of the five pure dyes. The generation of a spectral image is achieved by acquiring ~100 frames of the same image that differ from each other only by their optical path differences. Once a spectral image is acquired, the SKYVIEW software compares the acquired spectral image against the combinatorial library containing the fluorochrome combinations for each chromosome to generate a classified image. The classified image pseudocolors the chromosomes to aid in the delineation of specific structural aberrations where the RGB (red-green-blue) display images (Figure 22.5.2), which displays the fluorescent colors of the chromosomes, may appear quite similar. For every chromosomal region, identity is determined by measuring the spectral emission at that point. Regions where sites for rearrangement or translocation between different chromosomes occur, are visualized by a change in the display color at the point of transition.

M-FISH

All other M-FISH methods rely on the use of fluorochrome-specific filters moved sequentially during the image capturing process (Speicher et al., 1996; Fig. 22.5.3). The identity of each chromosome or chromosome region is based on which combination of the five fluorochromes hybridizes together in one location. As with SKY, the unique identification dye combinations are stored in a reference library within the software to which the test specimen is compared and aberrations are delineated in the same manner as described for SKY. Filter-based systems are more sensitive to the influences of high background and weak signal strength. Weak signal intensity or high background can misclassify a chromosome identity since the system may not consider the weak signal as true, thus choosing the next best chromosome filter pattern for identification. SKY, on the other hand, overcomes this obstacle since the fluorochrome spectral signature is the method of determining chromosome identity. Although a signal may be weak, its spectral output will remain the same. Nevertheless, both systems are widely used. Research laboratories are inclined to use SKY analysis, while clinical cytogenetic laboratories rely on M-FISH, since they already tend to have the filters and cytogenetic/FISH systems.

M-FISH probes are generated in the same manner as the SKY probes, differing only by their dye combinations. Commercial M-FISH probes can be purchased from Vysis as SpectraVision probes. The fluorochromes used for this probe set includes Spectrum Far Red, Spectrum Red, Spectrum Gold, Spectrum Green, and Spectrum Aqua used in a combinatorial fashion. Metasystems also provides M-FISH probes in their 24Xcyte kit. Metasystems has generated band-specific probes (M BAND) along the length of a given chromosome. Since each chromosome has a specific five-color FISH assay, each chromosome analysis must be performed individually (Fig. 22.5.4). Therefore, this assay is particularly useful when a specific rearrangement has been identified by banding, SKY, or MFISH, and the investigator wishes to further examine the rearranged region in detail to delineate the breakpoint or determine whether a more complex inversion or deletion is also present.

Locus- or band-specific M-FISH

Clearly the use of M-FISH-based techniques has increased the amount of cytogenetic data that can be derived from a given specimen. The integration of locus-specific or band-specific FISH permits further analysis regarding specific breakpoint locations and the status of specific genes or chromosomal loci. The ability to sequentially carry out traditional

banding analysis, SKY, or M-FISH, and locus-specific FISH on the same metaphase spread eliminates the question of clonality by identifying aberrations with increasing specificity, thereby identifying unique aberrations of common aberrations.

Critical Parameters and Troubleshooting

The investigator is referred to *UNIT 22.4* for general troubleshooting issues associated with FISH experiments. However, the investigator should also consider the following factors.

The use of commercially available probes significantly reduces the preparatory work and problems associated with quality control. If the laboratory chooses to produce custom probes, careful planning and control experiments should be carried out to ensure that each chromosome probe has been efficiently labeled.

Both SKY and M-FISH involve the hybridization of whole chromosome paints, thus the risk of background is high. Slide age and pre-treatment are critical to minimizing background. Similarly, if antibodies are being used, they should be diluted to the proper concentration and maintained according to the manufacturer's instructions. The microscope and imaging software should be well maintained, and the user should be fully trained. Although SKY and M-FISH reveal the same information, the methods by which these data are generated are quite different.

SKY

Criteria for successful image acquisition and analysis should be provided by the companies supplying the microscope, imaging equipment, and analytical software. As mentioned previously, all parameters that influence basic FISH analysis will apply to multi-color FISH assays, regardless of the analysis format.

The overall signal intensity along the length of the chromosome should be high with minimal background. The acquisition times, which are usually automatically set by the software, should be relatively short, as longer exposure times will amplify signals arising from background and increase the contribution of electronic noise associated with all forms of digital imaging. Similarly, bright spots that arise as a result of insufficient antibody or probe washing can skew automatic exposure times. This results in a low exposure of the metaphase of interest and increases the risk of ambiguous or erroneous chromosomal assignments.

Interpretation of the analysis relies both on the familiarity of the investigator with the basic technicalities of FISH assays, chromosomal identification by banding methods, and an understanding of fluorescence microscopy. One of the greatest concerns in the analysis is distinguishing between true translocation events and some of the preparation artifacts that may be misinterpreted during M-FISH and SKY. Regions of repetitive sequences such as centromeric areas and telomeric chromosomal ends can often give false classifications due to the differential suppression of those regions either with unlabeled Cot-1 DNA or by the labeled probe. Through careful analysis of normal metaphase spreads and confirmation by locus-specific FISH, real translocations can be distinguished from artifacts. Another phenomenon that contributes to misclassification is the sandwich effect where the junction between a true chromosomal translocation produces an intermediate color. This intermediate color could be identified by the software as another chromosomal segment giving the false impression of a tiny insertion at the site of translocation. Since 24-color painting analysis relies on the combination of up to five different fluorochromes, it is implicit that the fluorescence of two different chromosomal junction regions may in some circumstances be misclassified as a third chromosome undergoing insertion and bearing the spectra or dye combinations of the two partner chromosomes that are actually undergoing a simple rearrangement. This phenomenon can also be seen in chromosomes that are overlapping. The region of overlap will produce a color pattern contributed by both chromosomes, and the software will identify the fluorescence at the region of overlap as that which most closely matches the reference library. In trying to determine whether a translocation is real or not, it is advisable to look for longer chromosomes for analysis in another metaphase. If the insertion is no longer present, then the misclassification is likely to be due to suboptimal hybridization and/or the sandwich effect. Obviously, it is necessary to confirm any uncertain rearrangement of interest using single whole chromosome paint or locus-specific FISH assays on another slide from the same preparation or by re-hybridizing the slide after elution of chromosomal paints.

M-FISH

As discussed for SKY, criteria for successful image acquisition and analysis should be provided by the companies supplying

the microscope, imaging equipment, and analytical software. However, some general points should be considered regardless of which method of image acquisition and analysis is used. The overall signal intensity along the length of the chromosome should be high with minimal background. This is more critical for filter-based systems because the analysis is based on the presence or absence of that fluorochrome. Any background or bleed-over into another filter can influence the outcome of the analysis. The acquisition times, which are usually automatically set by the software, should be relatively short, as longer exposure times will amplify signals arising from background and increase the contribution of electronic noise associated with all forms of digital imaging. Similarly, bright spots that arise as a result of insufficient antibody or probe washing can skew automatic exposure times. This results in a low exposure of the metaphase of interest and increases the risk of ambiguous or erroneous chromosomal assignments.

M-FISH is also subject to the sandwich affect. Caution should be taken when analyzing small insertions. Be sure that the sandwiched chromosome is not simply the mixture of the flanking chromosomal fluorescence. Analyzing longer chromosomes will help to alleviate this problem.

M-FISH imaging relies on the sequential acquisition of images through specific filters and detecting the combination and the presence/absence of the reference dyes hybridized to the metaphase spreads. This entails the acquisition of five different images that are then merged to form the final image. One of the most critical factors is the use of the proper filter sets designed specifically for the M-FISH probe cocktail being used. Careful consideration must be taken with respect to pixel shifts from one image to the next. Careful attention must also be paid to the order in which the images are taken because it is known that some fluorochromes/dyes emit a different wavelength upon degradation or exposure to UV. Such interaction between two fluorochromes could cause misclassification should, for example, a red fluorescing dye that degrades to a yellow emission after exposure to UV, be imaged before the yellow probe is exposed. Because the slides are exposed to different filters, there will be varying exposure times for each dye, and this may also differentially quench the signals from the other fluorochromes/dyes later in the exposure sequence. Investigators are urged to refer to the manufacturer's instructions for both reagents and hardware/software for optimal results.

Like the SKY software, most M-FISH software packages allow the user to identify the fluorochromes that are present along the chromosome of interest and compare it to the combinatorial library. In the event of weak signals or small inconclusive regions of rearrangement, this function is very convenient.

Locus- or band-specific M-FISH

The use of SKY or M-FISH in combination with other cytogenetic or FISH methods provides more detailed information but also increases the damage to the DNA target. As with any FISH experiment, particularly with previously banded slides, the quality of the metaphase spreads, the age and pretreatment (for banding and SKY/M-FISH) influence the outcome for locus-specific FISH following these two assays. In many cases, the overall signal intensity of the locus-specific FISH probe will be weaker following banding and SKY/M-FISH. This is due to the fact that the target DNA has undergone a series of digestions and denaturations, thus compromising the quality of the DNA for hybridization. The overall background intensity will also increase since the slide was previously probed with a whole genome–painting probe. The denaturation of the slide prior to hybridization with the locus-specific probe should remove any bound probe and antibodies from the chromosomes, however, this is never complete. This is certainly the case if there is residual cytoplasm and a high density of cells on the slide. An indication that the DNA has been severely damaged is if it fails to take up the counterstain, such that the chromosomes appear a very faint blue and the centromeres are very bright.

Anticipated Results

In the best conditions, a given metaphase spread will classify perfectly.

If the DNA is not damaged, the resulting FISH should provide signals that can be clearly visualized by microscopy. These signals can be enhanced using imaging tools. For examples, see Figures 22.5.2, 22.5.4, 22.5.5, and 22.5.6.

Time Considerations

The time required to complete analysis depends on the complexity of the karyotype.

Comparative Genomic Hybridization

Comparative genomic hybridization (CGH; Kallioniemi et al., 1992) is a FISH-based technique that is conceptually different from the FISH experiments already discussed in this chapter (*UNITS 22.4 & 22.5*). The critical difference between CGH and standard FISH assays is that the target DNA for CGH, located on the slide, consists of metaphase chromosome preparations derived from cells of a karyotypically normal individual (Fig. 22.6.1). In standard FISH studies, the target cellular DNA is hybridized with a purified DNA probe, such as a specific gene or chromosomal locus or a chromosomal paint. In CGH, the labeled probe consists of differentially labeled genomic DNA. An equal amount of labeled normal reference DNA is mixed with a labeled tumor/test DNA. Together, these probes are allowed to hybridize to the normal metaphase slide and each labeled DNA is detected in a dual-color experiment. Many of the details of the steps required to perform CGH have already been reviewed in the previous units of Chapter 22, with minor changes. The investigator will be referred to these sections throughout the discussion. In this assay, DNA must be extracted from the test sample; this can be DNA extracted from cell lines or fresh/frozen bulk tissue (see Support Protocol 1 for extraction; see Support Protocol 3 for labeling) or DNA extracted from paraffin-embedded tissues (see Support Protocol 2; see Support Protocol 4 for labeling). DNA must also be extracted from any normal source, such as blood, tonsils, or placenta (see Support Protocol 5 and *UNIT 22.2*). If the experiment is based on DNA extracted from paraffin-embedded tissue, the normal control should also be extracted from paraffin-embedded material. Finally, the normal reference DNA should be derived from a male, as should the normal metaphase slide (see Critical Parameters). Typically, as described in the Basic Protocol (indirect labeling), the normal reference DNA is labeled with digoxigenin and the test/tumor DNA is labeled with biotin. The differentially labeled DNA samples are denatured and allowed to hybridize to the denatured normal metaphase spreads. Following a 72-hr hybridization, the slides are washed to remove any unbound probe and detected with FITC/avidin and rhodamine-conjugated to anti-digoxigenin, such that the tumor DNA is detected by a green signal and the normal DNA is detected by a red signal. Alternatively, as also described in the Basic Protocol, the two probes may be directly labeled with green and red fluorochromes, respectively; in this case, no antibody detection procedure is required. Imaging and CGH analysis software calculates the green/red ratio along the length of each chromosome and determines the net changes between the tumor and normal reference. CGH is useful when no sample is available for short-term culture or for archival material either frozen or embedded in paraffin.

STRATEGIC PLANNING

CGH is a lengthy process, requiring attention to each step both at the bench and at the microscope. A time-saving hint is to set up the hybridization just before a weekend and allow it to occur over the weekend, and then to carry out the post-hybridization washes and microscopy the following week.

An overview of the assay is as follows:

Preparatory work

1. Tissue/Cell acquisition.
2. DNA extraction.
3. DNA labeling (*UNIT 22.4*).
4. Metaphase slide preparation (culturing and slide making; *UNIT 22.2*).

Contributed by Jane Bayani and Jeremy A. Squire
Current Protocols in Cell Biology (2004) 22.6.1-22.6.15

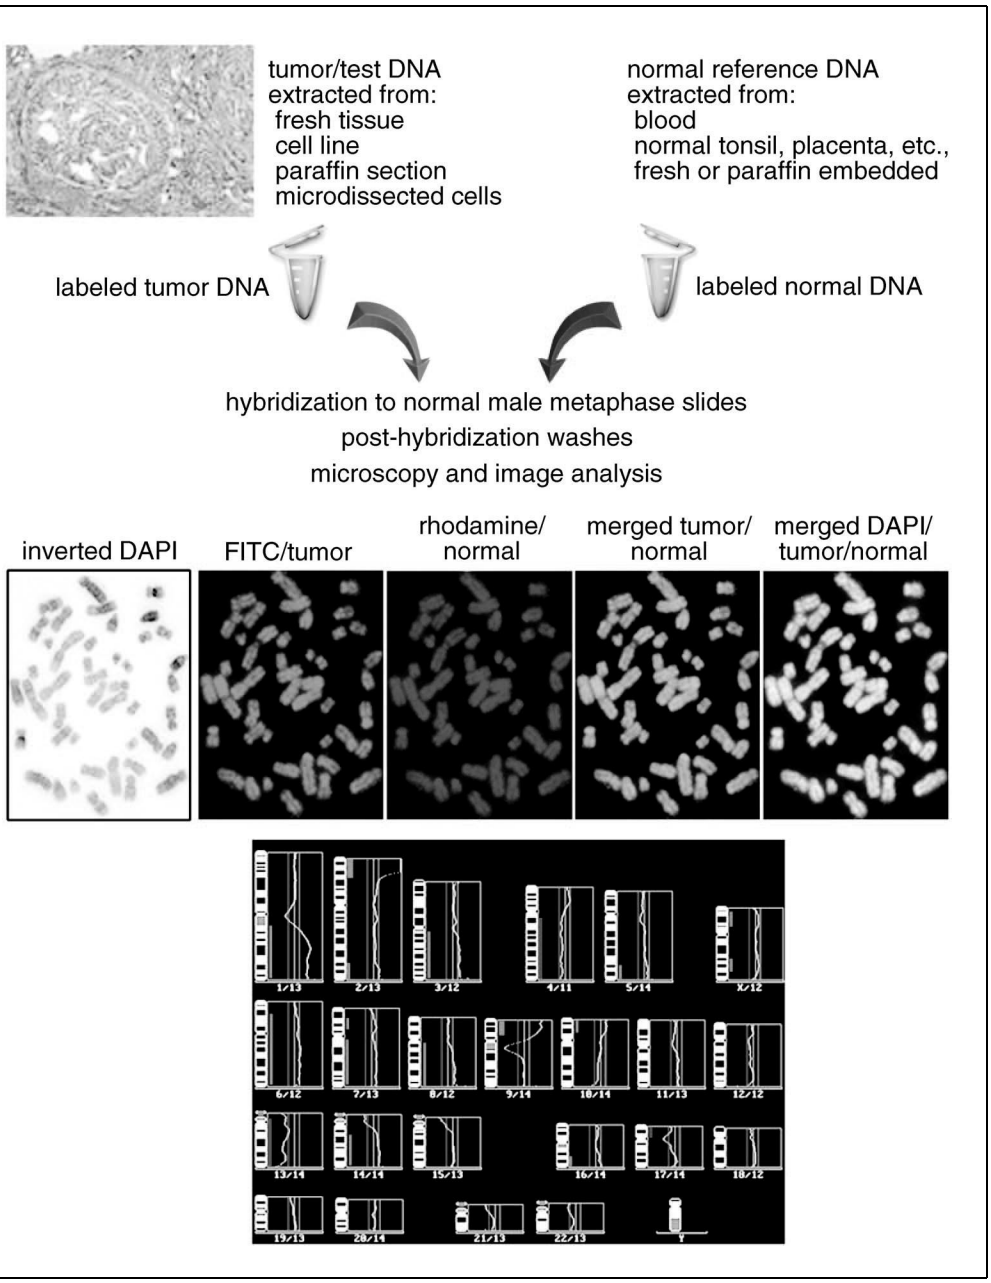

Figure 22.6.1 Schematic representation of CGH analysis. CGH analysis involves the labeling of normal reference DNA and the tumor/test DNA such that they can be identified by either green or red fluorescence (tumor and normal reference, respectively). Equal amounts of these labeled DNAs are hybridized and detected by standard in situ methods to normal metaphase spreads. The metaphase cells are then imaged and karyotyped. CGH analysis determines the change in green/red ratio along the length of each chromosome, corresponding to the net genomic change of DNA at a specific chromosomal locus in the tumor in comparison to the normal reference. The metaphase is imaged using three filters: a DAPI filter to identify chromosomes for karyotyping purposes (the blue image is converted into a pseudo G-banded image), a green filter (FITC/Spectrum Green) to detect the tumor DNA, and a red filter (rhodamine/Spectrum Orange) to detect the normal DNA hybridized to the normal chromosomes. These images can be overlayed as shown. Areas of genomic gain or amplification are seen as fluorescing green, while areas of loss are seen as fluorescing red. Regions of no genomic change are seen as yellow/orange. The three-color merged image (DAPI/FITC/rhodamine) is also displayed. Analysis of 7 to 10 metaphase spreads results in a CGH karyotype as shown at the bottom of the figure. The CGH karyotype of this tumor is as follows: +1q, amp 2p24-qter, +3q,−4q,+5q33-qter, +6p22-qter,+7p13-qter, +8q,amp9p,+10p,−13,+14q12-qter,+16q23-qter,−17p,+Xp11-14, +Xq221-22. *This black and white facsimile of the figure is intended only as a placeholder; for full-color version of figure go to http://www.interscience.wiley.com/c_p/colorfigures.htm.*

FISH (UNIT 22.4)

1. Slide pretreatment and denaturation.
2. Probe denaturation and preannealing.
3. Hybridization for 72 hr.
4. Post-hybridization washes.

Microscopy and analysis

1. Acquisition of images.
2. Karyotyping and CGH analysis.

COMPARATIVE GENOMIC HYBRIDIZATION

BASIC PROTOCOL

Slide pretreatment and denaturation should be carried out according to *UNIT 22.4*. There should be a high mitotic index, with chromosomes that are neither too short nor too long (preventing frequent overlapping chromosomes). Meanwhile, equal amounts of labeled normal DNA and tumor/test DNA should be mixed, denatured, and allowed to preaneal for 1 hr at 37°C. Next, the slides and probe are added together, coverslipped, sealed, and allowed to hybridize for at least 72 hr at 37°C. The slides are then washed of any unbound probes using the methods described in *UNIT 22.4*. Haptens are detected in a single round of antibody incubation; thus, the antibodies should be conjugated to their respective fluorochrome. In the case of directly labeled probes, no antibody detection is required.

Materials

10 ng/μl tumor DNA: indirectly labeled with biotin or directly labeled with Spectrum Green, FITC, or other green-fluorescing dye (see *UNIT 22.4* and Support Protocols in this unit) in hybridization buffer (see *UNIT 22.4* for buffer)

10 ng/μl normal reference DNA: indirectly labeled with digoxigenin or directly labeled with Spectrum Orange, rhodamine, or other red-fluorescing dye (see *UNIT 22.4* and Support Protocols in this unit) in hybridization buffer (see *UNIT 22.4* for buffer)

Pretreated and denatured male metaphase slides (*UNIT 22.4*)

Rubber cement

50% (v/v) formamide/2× SSC (see *UNIT 18.6* for 20× SSC), 45°C

2× SSC (*UNIT 18.6*), 45°C

Blocking solution: 1% BSA (w/v)/0.1% (v/v) Tween 20 in 4× SSC (store indefinitely at –20°C or up to several months at 4°C)

FITC-labeled avidin *and* rhodamine-labeled anti-digoxigenin antibody (*UNIT 22.4*; for detection of indirectly labeled probes only)

0.1% (v/v) Tween-20/4× SSC (see *UNIT 18.6* for 20× SSC), 45°C

DAPI in antifade (*UNIT 22.4*)

75°C water bath

37°C dry incubator or oven

Coverslips

Hybridization box: e.g., black videocassette box containing slightly dampened moist paper towel or gauze

Coplin jars

Fluorescent microscope with appropriate filter sets (*UNITS 4.2 & 22.4*)

Image acquisition software (*UNIT 4.2*)

CGH analysis software (e.g., Leica, Applied Imaging, Metasystems)

Additional reagents and equipment for FISH (*UNIT 22.4*)

Preanneal probe

1. In a 1.5-ml microcentrifuge tube, combine 200 ng of labeled normal DNA and 200 ng of labeled tumor/test DNA (as respective 10 ng/μl solutions). Mix well.

   Some protocols have used up to 1 μg each of labeled DNAs for one experiment. Since the DNAs are in great excess, there is no need to use such large amounts. In the event that the experiment fails (see Troubleshooting) due to factors other than the labeling, using the above amounts, the investigator will still have sufficient material to repeat the experiment without having to repeat the labeling procedure.

2. Denature the combined probes for 10 min at 75°C, then place in a 37°C oven for 1 hr.

Hybridize probe to metaphase slides

3. Add the preannealed probe to pretreated and denatured normal metaphase slides (also see *UNIT 22.4*).

4. Place a coverslip on top of the area of the slide containing the preparation, being careful to avoid bubbles. Seal with rubber cement and place in the dampened hybridization box at 37°C for 72 hr.

5. Carefully remove coverslip by peeling off the rubber cement and placing the slide in a Coplin jar containing 50% formamide/2× SSC at 45°C for 5 min; the coverslip may fall off unaided, but it might be necessary to gently ease it off of the slide surface. Repeat this procedure for a total of three washes, agitating gently between washes.

6. Wash slide three additional times as in step 5, except use 2× SSC at 45°C. For indirectly labeled probes proceed to step 7; for directly labeled probes, proceed to step 9.

Use antibody to detect indirectly labeled probes

7. Remove the slide from the last wash and allow excess solution to drain, but do not allow the slides to dry. Add 60 μl blocking solution to the slide. Add a coverslip and place in the hybridization box at 37°C for 30 min.

8. Remove coverslip and add FITC-labeled avidin and rhodamine-labeled anti-digoxigenin antibody in a total volume of 60 μl (also see *UNIT 22.4*). Apply a coverslip and place in the hybridization box at 37°C for 30 to 40 min.

9. Remove coverslip and wash slide three times with 0.1% Tween 20/4× SSC at 45°C using the technique described in step 5.

Perform imaging

10. Remove the slide from the last wash and allow the excess solution to drain, but do not let the slide to dry. Add 50 μl of DAPI in antifade (mounting medium) to the slide. Apply coverslip.

    The slides are now ready for visualization. When not in use, slides should be kept at −20°C.

11. Acquire the image using a fluorescent microscope equipped with the appropriate filters.

    CGH mapping is based on the average green/red ratio along the length of properly identified chromosomes. Approximately 7 to 10 well-hybridized spreads (see Troubleshooting) should be karyotyped, and the average green/red ratio from all the karyotyped chromosomes should be calculated, giving the final results. Metaphase spreads should have few to no overlapping chromosomes, since these will be excluded from analysis, and they should have strong signal strength across the metaphase spread with minimal to no background. It is crucial that the chromosomes be properly karyotyped; thus, if the DAPI banding is poor, so that identification of the chromosomes cannot be accomplished, the experiment should be repeated with changes in slide conditions.

    To ensure accurate calculation of ratios, there should be no pixel shifts when changing to different filters during image acquisition.

12. Analyze the image using CGH software.

Currently, there are several commercial CGH systems available from Leica (http://www.leica-microsystems.com), Applied Imaging (http://www.aicorp.com) and Metasystems (http://www.metasystems.de). As each system is different, consult with the company representative for the specification and training related to the system.

Standard metaphase CGH imaging systems have a mapping resolution of ~10 Mb. However Applied Imaging has recently introduced metaphase CGH imaging algorithms with improved mapping resolution (stated to be ~3 Mb) and improved sensitivity for dealing with normal-cell contamination (see Critical Parameters). Such improved resolution may be helpful for the detection and mapping of smaller deletions or focal amplifications.

EXTRACTION OF DNA FROM FRESH/FROZEN TISSUES OR CELL LINES

SUPPORT PROTOCOL 1

DNA extraction from fresh/frozen tissues or cell lines uses standard proteinase K treatment and phenol:chloroform extraction. Commercially available DNA extraction kits are available if the investigator prefers. Irrespective of the extraction method, the final DNA sample should be of high molecular weight with little or no degraded fragments and should be resuspended in water.

Materials

Tissue sample or cell pellet
TE buffer, pH 7.5 (*APPENDIX 2A*)
10% (w/v) SDS
14 mg/ml proteinase K
Molecular-biology-grade phenol, TE-saturated (*UNIT 18.3*)
1:1 (v/v) phenol/chloroform (see recipe)
Chloroform
3 M sodium acetate (*APPENDIX 2A*)
100% and 70% ethanol, cold
DNase-free H_2O

Scalpels and scalpel blades
15-ml polypropylene conical centrifuge tubes
Centrifuge
Platform rotator

Digest sample

1a. *For tissues:* Using sterile techniques, mince tissue into small pieces with a scalpel and place into 15-ml conical tube.

1b. *For cultured cells:* Place cells in a 15-ml tube and centrifuge 5 min at 200 × *g*, room temperature or 4°C. Discard supernatant and retain pellet.

2. Add 5 ml of TE buffer, 500 µl of 10% SDS (1% final), and 10 µl of 14 mg/ml proteinase K to the minced tissue or cell pellet. Cap tightly and place on a platform rotator at 37°C overnight.

If there is too much tissue or the resulting digest is too thick, add more TE buffer and SDS to the tube.

3. The following day, check digest. If there are still tissue pieces remaining, add more proteinase K and continue incubation at 37°C.

Extract DNA with phenol

4. When the tissue has completely digested, add an equal volume of TE-saturated phenol. Cap tightly and place on a platform rotator at room temperature for 10 min, or mix by manual inversion.
5. Centrifuge 10 min at 3000 × *g*, room temperature. Carefully remove the tube without disrupting the phases.
6. Using a sterile 1-ml plastic bulb pipet, carefully transfer the aqueous (upper) layer to a clean tube. Do not remove any solid matter that may be at the interface.
7. To the extracted aqueous layer, add an equal volume of TE-saturated phenol and repeat the extraction and centrifugation for a total of three extractions.

Extract DNA with phenol/chloroform

8. To the extracted aqueous layer removed from the third phenol extraction, add an equal volume of 1:1 (v/v) phenol/chloroform. Cap tightly and place on a platform rotator at room temperature for 10 min, or mix by inversion.
9. Centrifuge 10 min at 3000 × *g*, room temperature. Carefully remove the tube without disrupting the phases.
10. Using a sterile 1-ml plastic bulb pipet, carefully transfer the aqueous (upper) layer to a clean tube. Do not remove any solid matter that may be at the interface.
11. To the extracted aqueous layer, add an equal volume of 1:1 (v/v) phenol/chloroform and repeat the phenol/chloroform extraction and centrifugation for a total of three extractions.

Extract DNA with chloroform

12. To the extracted aqueous layer removed from the third 1:1 (v/v) phenol/chloroform extraction, add an equal volume of chloroform. Cap tightly and place on a platform rotator at room temperature for 10 min, or mix by inversion.
13. Centrifuge 10 min at 3000 × *g*, room temperature. Carefully remove the tube without disrupting the phases.
14. Using a sterile 1-ml plastic bulb pipet, carefully transfer the aqueous (upper) layer to a clean tube. Do not remove any solid matter that may be at the interface.
15. To the extracted aqueous layer, add an equal volume of chloroform and repeat the chloroform extraction and centrifugation for a total of three extractions.

Precipitate and resuspend DNA

16. To the extracted aqueous layer from the third chloroform extraction, add 1/10 volume of 3 M sodium acetate and 2.5 vol of cold 100% ethanol. Invert gently.

    The DNA will spool into a clump of thread-like wisps.

17. Collect the spooled DNA into a clean 1.5-ml tube using a pipet tip and rinse with 70% ethanol.
18. Microcentrifuge 5 min at maximum speed, room temperature, and remove the ethanol supernatant.
19. Resuspend the DNA in 100 µl DNase-free water. Tap or flick the tube to dissolve the DNA back into solution.

    If the solution is too thick, add more water.

20. Store the DNA at −20°C until ready for use.

The DNA is best stored at −20°C and can be kept for several years. DNA concentration can now be assessed by spectrophotometry (APPENDIX 3D) and DNA purity can be assessed by gel electrophoresis (see APPENDIX 3A for cross-references).

DNA EXTRACTION FROM PARAFFIN SECTION

SUPPORT PROTOCOL 2

DNA can also be extracted from paraffin-embedded tissue. The paraffin is removed and the tissue is digested under more harsh conditions than those described for fresh tissue in Support Protocol 1. The digest is then phenol/chloroform extracted as previously outlined in Support Protocol 1, steps 4 to 15. This method is typically used for the bulk extraction of large tissue sections. The DNA from small numbers of microdissected cells would be lost in this extraction method, so it is simply added to the labeling reaction following brief digestion (see Support Protocol 4).

Materials

Paraffin sections
Xylene
Methanol
1 M sodium thiocyanate, 55°C (prepare fresh)
DNA extraction buffer (see recipe), 55°C (prepare fresh)
Proteinase K

Microtome
Polypropylene tubes
Oven maintained at 55°C

1. Using a microtome, cut 30 to 50 slices from paraffin block, each 6 μm thick, and place the sections in a polypropylene tube.
2. Add 1 ml xylene and incubate 10 min. Remove xylene and repeat with 1 ml fresh xylene. Remove xylene, add 1 ml methanol, and incubate 10 min. Remove methanol.
3. Incubate overnight in 1 ml of 1 mM sodium thiocyanate at 55°C.
4. Digest for 3 days in 1 ml of extraction buffer at 55°C. Add 0.2 mg of proteinase K each day.
5. Perform extractions and precipitation of DNA (see Support Protocol 1, steps 4 to 20).

LABELING DNA EXTRACTED FROM FRESH TISSUES FOR CGH

SUPPORT PROTOCOL 3

UNIT 22.4 describes the basic method for labeling DNA for FISH analysis using nick translation. For CGH, the test/tumor DNA is typically labeled with biotin and detected with FITC/avidin; the normal reference DNA is labeled with digoxigenin and detected with rhodamine conjugated to anti-digoxigenin antibody. Direct labeling of each DNA sample can also be carried out using Spectrum Green or fluorescein for the tumor DNA and Spectrum Orange or rhodamine for the normal control DNA . Unlike conventional FISH experiments described previously, the final fragment sizes should be between 500 bp and 2 kbp. The final probe concentration should be determined by gel electrophoresis. The probes should be precipitated in a similar fashion using salmon sperm carrier and Cot-1 DNA and resuspended in hybridization buffer to a final concentration of 10 ng/μl, as outlined for FISH probes. It is always suggested that a normal control be carried out, particularly if the investigator is not familiar with the assay. In this case, normal DNA should be labeled with biotin (or directly labeled with a green-fluorescing fluorochrome), as well as labeled with digoxigenin (or directly labeled with a red-fluorescing fluorochrome), and included as another component of the experiment.

SUPPORT PROTOCOL 4

LABELING DNA EXTRACTED FROM PARAFFIN-EMBEDDED TISSUES FOR CGH

DNA extracted from paraffin-embedded tissues can range in both quantity and quality. If the DNA yield from bulk extracted tissue is sufficient and is of high molecular weight, labeling by nick translation can be employed. However, if the yield is significantly lower and it is not possible to obtain more material, then amplification by degenerate oligonucleotide primer (DOP)–PCR may be required, as described below. This amplification protocol is also applicable to microdissected cells. The DOP-amplified products may then be labeled by nick translation as described in *UNIT 22.4*, or may require labeling by DOP-PCR methods, also described in *UNIT 22.4*. As in the case of labeling for fresh tissue the test/tumor DNA is typically labeled with biotin and detected with FITC/avidin, while the normal reference DNA is labeled with digoxigenin and detected with rhodamine-conjugated anti-digoxigenin antibody. Direct labeling of the DNA can also be carried out using Spectrum Green or fluorescein for the tumor DNA and Spectrum Orange or rhodamine for the normal control DNA. In the case of DOP-PCR labeling strategies, the fragments tend to be generally smaller than those obtained with nick translation. The final probe concentration should be determined by gel electrophoresis. The probes should be precipitated in a similar fashion using the salmon sperm carrier and Cot-1 DNA, and resuspended in hybridization buffer to a final concentration of 10 ng/μl. Before proceeding with any method for genome amplification, the investigator should carry out the necessary control experiments (see Critical Parameters) to ensure that there is representative amplification across the entire genome, rather than any bias leading to over- or under-representation of the amplified product. As before, normal DNA should be labeled with biotin (or directly labeled with a green-fluorescing fluorochrome), as well as digoxigenin (or directly labeled with a red-fluorescing fluorochrome), and included as another component of the experiment. To optimize the PCR amplification and labeling, it is strongly suggested that the investigator label both normal DNA from the paraffin source and from fresh/frozen DNA (e.g., if using a paraffin-extracted test sample, the normal DNA should come from normal tissue embedded in paraffin). The protocol below is based on the techniques used by Stefan Joos, Carsten Schwänen, and Peter Lichter (Beatty et al., 2002), although other protocols can be performed (Speicher et al., 1993), including a recent method developed for whole-genome amplification termed "SCOMP" (single cell comparative genomic hybridization; Stoecklein et al., 2002). SCOMP has been assessed on archival tissues of different ages, and the method has been shown to be very well suited for formalin-fixed paraffin-embedded samples obtained by nuclei extraction or laser microdissection.

Materials

Isolated (microdissected) cells (20 to 200) or DNA extracted from paraffin section
1× DOP-PCR buffer (see recipe) containing 0.5 μg/μl proteinase K, freshly added
10× DOP-PCR buffer (see recipe)
2 mM dNTP mix (see recipe)
10× DOP primer (see recipe)
Taq DNA polymerase (Perkin-Elmer)
TBE buffer (*APPENDIX 2A*)

500 μl PCR reaction tube
50° and 95°C ovens
Thermal cycler

Additional reagents and equipment for agarose gel electrophoresis (*UNIT 6.7*) and labeling probes by nick translation (*UNIT 22.4*)

1. Collect 20 to 200 isolated cells in a 500-µl reaction tube containing 20 µl of 1× DOP-PCR buffer with 0.5 µg/µl freshly added proteinase K. Incubate at 50°C for at least 2 hr.

   If using extracted DNA, skip steps 1 and 2 and proceed directly to step 3.

2. Inactivate proteinse K by incubation at 95°C for 20 min.

3. Add the following reagents to the tube:

   Reaction from step 2 *or* 1 to 100 ng template DNA in 20-µl volume
   8.0 µl 10× DOP-PCR buffer
   10.0 µl 2 mM dNTP mix
   10.0 µl 10× DOP primer
   5 U *Taq* DNA polymerase
   H_2O to 100 µl.

   As a negative control combine the same solutions, but add water instead of any DNA.

4. For universal amplification of the genomic DNA, use the following program:

1 cycle:	10 min	94°C	(denaturation)
5 cycles:	1 min	94°C	
	1.5 min	30°C	
	3 min	30°-72°C transition	
	3 min	72°C	
35 cycles:	1 min	94°C	
	1 min	62°C	
	3 min (add 1 sec/cycle)	72°C	
1 cycle:	10 min	72°C	
1 cycle	indefinite	4°C	(hold).

5. Run 5 µl of the PCR reaction on a 1% agarose gel in TBE buffer.

   A smear of DNA ranging in size from about 200 to 2000 bp should be visible.

6. Compare reaction product to controls and concentration standards (*UNIT 22.4*) to calculate total amplified product.

7. Label the amplified DNA by nick translation as described in *UNIT 22.4*.

PREPARATION OF NORMAL METAPHASE SLIDES: PRETREATMENT AND DENATURATION

SUPPORT PROTOCOL 5

Cell culture, harvesting, and slide making are described in *UNIT 22.2*. The most commonly used source for normal metaphase spreads is a peripheral lymphocyte culture, ideally from a male. Once normal metaphase slides have been made, the slides can be pretreated with pepsin and denatured (*UNIT 22.4*). The criteria for metaphase slides for CGH analysis are discussed in the Commentary of this unit.

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

DNA extraction buffer

25.0 μl 1 M EDTA (25 mM final)
75.0 μl 1 M NaCl (75 mM final)
0.5 μl Tween 20 (0.5% v/v final)
28.0 μl 14.4 mg/ml proteinase K (0.4 mg/ml final)
H_2O to 1.0 ml
Prepare fresh for each experiment

dNTP mix (dATP, dCTP, dGTP), 2 mM

2 μl 100 mM dATP (2 mM final)
2 μl 100 mM dCTP (2 mM final)
2 μl 100 mM dGTP (2 mM final)
94 μl sterile water (total volume 100.0 μl)
Store up to several months at −20°C

DOP-PCR buffer, 10×

2.0 μl 1 M $MgCl_2$ (2 mM final)
50.0 μl 1 M KCl (50 mM final)
10 μl 1 M Tris hydrochloride (10 mM final)
0.1 mg gelatin
Sterile H_2O to 1 ml
Prepare using sterile technique and store in 100.0-μl aliquots up to several months at −20°C

DOP primer, 10×

Using sterile technique, prepare a 20 μM solution in sterile water of the following oligonucleotide:
5′-CCG ACT CGA GNN NNN NAT GTG G-3′, (N = A, C, G, or T).
Store in 100.0-μl aliquots up to several months at −20°C.

Phenol:chloroform, 1:1 (v/v)

50 ml molecular-biology-grade phenol, TE-saturated (*UNIT 18.3*)
50 ml chloroform
Total volume, 100.0 ml
Store up to 1 month at 4°C

Use appropriate eye and skin protection when using these chemicals and use in well ventilated areas or designated areas.

COMMENTARY

Background Information

Comparative genomic hybridization (CGH) was first introduced in 1992 (Kallioniemi et al., 1992). It is described as a FISH-based method by which information regarding the net gain or loss of genomic material in a given DNA can be assessed without the need for fresh material, as required for short-term culture and chromosome analysis. As shown in Figure 22.6.1, normal reference DNA and the tumor/test DNA are differentially labeled and hybridized to normal metaphase spreads. The normal DNA and tumor/test DNA are detected using different fluorochromes (green and red) and visualized by fluorescence microscopy. Metaphase spreads are karyotyped by inverted DAPI banding and the average green/red (tumor/test:normal) ratio is calculated. Regions of genomic gain in the tumor are expressed as an increase in green/red ratio,

whereas regions that are lost in the tumor are expressed as a decrease in green/red ratio. Regions that are normal maintain a 1:1 ratio. High-level amplifications can be readily seen as a spike at a specific chromosomal locus and are generally values that exceed 1.5. The major advantage of CGH as compared to other cytogenetic methods—chromosome banding (*UNIT 22.3*) and FISH (*UNIT 22.4*)—is the fact that, instead of metaphase chromosomes or interphase nuclei, only a few micrograms of genomic DNA are required from the cells or tissue to be studied. The best CGH results are obtained from DNA that is prepared from fresh or frozen tissue samples. However, it is also possible to analyze paraffin-embedded tissue samples, small populations of cells, or single tumor cells. Small samples require physical enrichment of tumor cells, e.g., by cell sorting or micromanipulation, in combination with a representative amplification of genomic DNA by universal PCR. However, CGH *only* provides the net genomic changes in a given DNA sample. Information regarding the specific karyotype of those cells that result in those genomic changes is lost; thus, it is not possible to determine whether gains of genomic regions are the result of duplications of whole or partial chromosomes, unbalanced translocations, or more complex cytogenetic changes such as the formation of double-minute chromosomes or homogeneously staining regions. Similarly, loss of genomic regions can result from whole or partial chromosome losses, from deletions that in turn result from translocations or inversions, or from small interstitial deletions. Furthermore, the determination as to karyotypic clonality is lost, since CGH will only provide a gross average of genomic imbalance present in the sample. Aberrations such as balanced translocations will not be detected, since in such cases there is no net genomic change, but rather a change of structure. Nevertheless, CGH has been an important tool for identifying genomic profiles for various human tumors (Zielenska et al., 2001; Bayani et al., 2002; Knutsen et al., 2003) as well as murine systems (Crabtree et al., 2003), and enabling investigators to identify novel regions of genomic loss and amplification that may contain putative tumor-suppressor genes and oncogenes.

Critical Parameters

Since CGH is a FISH-based strategy, those parameters discussed in *UNIT 22.4* are also applicable. However there are some additional critical factors, specific to CGH, that should be taken into consideration. An excellent guide for CGH parameters and troubleshooting can be found in the January 1995 issue of *Cytometry*.

Controls for CGH experiments

For an investigator just starting CGH, it helps to optimize the labeling, hybridization, washes, and analysis using a DNA that has been cytogenetically characterized. In these situations, an established cell line with full-chromosome gains and losses are useful, not only for standard nick-translation methods, but also as a positive copy-number control for universally amplified products and PCR labeling. The control cell line can also be pelleted and embedded in paraffin blocks, serving as a useful qualitative control for optimization of DNA extraction from paraffin-embedded cells. In addition, it is helpful for ensuring that amplification and labeling procedures are efficient. The control karyotype should be relatively simple and clonal—i.e., consistent from cell to cell. The presence of numerous structural aberrations and marker chromosomes can make analysis more difficult. By using a well characterized cell line, the investigator knows what to expect from the CGH analysis. Another method for determining accuracy is to use the sex chromosomes as a guide (Kirchhoff et al., 1998). It is for this reason that the target slides and reference DNA come from a male. Changes in the intensity of the X and Y chromosome can help to determine the success of an experiment. One caveat to this method is that it is quite common for established cell lines and tumors to gain or lose whole copies of the sex chromosomes. Thus, the investigator may know that the tumor/test DNA comes from a female or male, but due to tumor progression it loses a sex chromosome, and the CGH analysis may not reflect this. However, if the researcher is investigating breast or ovarian cancer and uses a male reference, one can be assured that no Y chromosome should be in excess or lost. Similarly, the normal reference DNA can be female if the investigator is studying prostate cancer, and this will allow determination of whether loss or gain of the Y (or X) has occurred.

Interpreting CGH results

Having established the technique and level of sensitivity on controls, the challenge of CGH is in determining the accuracy on a given DNA sample where no previous cytogenetic information is available. Generally, it is useful to include the labeled cell line control and normal reference pair (discussed above) with every experiment. Since the investigator already knows that the labeling produced good results,

it will help to determine whether any technical problems that arise are due to the slide, hybridization, or post-hybridization portions of the assay, and whether the new DNA/normal pair to be tested has labeling efficiency problems. Often CGH is performed because little or no cytogenetic analysis could be carried out, leaving only bulk frozen tissue, paraffin section, or extracted DNA as the source for analysis. When CGH analysis is not concordant with previous cytogenetic analysis, one must consider the following situations. First, the cytogenetic analysis only reflects the clonal changes, which is described by ISCN nomenclature as a case where a gain is seen in at least three metaphases, a loss is seen in at least two metaphases, or structural aberration is seen in at least two metaphases. Moreover, cytogenetic analysis only applies to the relatively few cells actively proliferating and producing metaphase spreads. The over-representation of cytogenetic information in resting interphase cells may contribute disproportionately to copy-number changes detected by CGH, either masking aberrations or leading to inconsistencies with metaphase findings. Nonclonal changes within the tumor can contribute to the relative normalization of copy number gains and losses. This leads to the complex issue of cytogenetic heterogeneity (or chromosomal instability) that can make CGH interpretation of tumors problematic. It is not uncommon for a given tissue to have different levels of chromosomal instability, i.e., gains of a chromosome in one cell population can be offset by an equivalent level of loss in other cells. Finally, the investigator should consider the level of normal contamination. Theoretically, there should be at least a 50% abnormal cell population to be detectable. The most recent Applied Imaging CGH system claims to detect copy number changes when 70% of the cell population consists of contaminating normal cells. In this context, the word "abnormal" refers to a cell that is not diploid. If the ploidy status of the abnormal cell is upwards of triploid or tetraploid, then the amount of normal contamination that the assay can withstand may be slightly higher. Confounding this issue is the fact that visual inspection of a tissue, whether this is simply gross inspection or carried out by histopathological means, may not be accurate in its estimation of the relative contribution of normal or tumor tissue. Some tumors tend to maintain a diploid status, (e.g., the hematological malignancies), whereas others show high levels of aneuploidy (e.g., ovarian and breast tumors and sarcomas). The possibility also arises that cells characterized as tumor cells may possess normal karyotypes. Nevertheless, the investigator can gain additional confidence in the CGH results by repeating the experiment with the labels for the normal and tumor reversed. The normal-versus-normal control and control cell line–versus–normal control should reveal the expected CGH profiles.

DNA quality

For any labeling reaction, the starting material, in this case total genomic DNA, should be of high molecular weight, with little degraded material. Depending on the sample, this may be difficult to achieve, particularly if the specimen contains necrotic or apoptotic tissue, as may be the case in many fresh tumor samples. DNA extracted from bony or cartilaginous tissues, as well as from tissues composed primarily of fat, will also produce low DNA yields of varying quality. The starting DNA should be assessed by gel electrophoresis. For DNA extracted from paraffin-embedded tissues, the criteria that influence paraffin FISH (see *UNIT 22.4*) will also influence DNA extraction. The age of the tissue block, its storage conditions, and quality of the fresh tissue before embedding will influence the subsequent quality of DNA extracted.

Labeling efficiency

Since the fluorescent intensities along the length of each chromosome will be calculated and averaged, it is important that the labeling efficiency be equal between the two samples (tumor and normal). It is suggested that the two be labeled as pairs during the labeling procedure, and that they also be labeled with reversed labels. Therefore, the normal DNA is detected with green fluorescence and the tumor detected with red fluorescence. If the profiles are consistent between both experiments, then the investigator can be sure that the results are accurate. All reagents should be used before their expiration dates.

Target metaphase slides

Since CGH is also dependent on identification of chromosomes, the banding quality of the metaphase spreads following hybridization is crucial. If the identification of a chromosome cannot be made based on the banding or by the cytogenetic skill of the investigator, there is a good chance that misclassification will occur giving inaccurate results. While a slide may produce good hybridization signals, failure to identify the chromosomes renders the experiment just as useless as if no signals were present.

Karyotyping

As already discussed above, the investigator will need to employ the help of a cytogeneticist or spend a good amount of time learning to karyotype chromosomes. With enough practice, the investigator should be able to easily identify and karyotype a metaphase spread.

Adequate Cot-1 suppression

Unlike FISH experiments, more Cot-1 suppression is needed, since the probes being used are derived from total genomic DNA. Hybridization is also targeted to the entire genome. Hybridization experiments can be severely impaired by insufficient suppression of repetitive sequences. This might manifest itself by a strong staining of the heterochromatin blocks on human chromosomes 1, 9, and 16. An increase in the amount of the Cot-1 DNA fraction and longer preannealing times (the latter being less effective) can be used to achieve adequate suppression of signals in these regions of the genome.

Low quality of equipment

The optical instrumentation, the camera system, and the image analysis software used can also contribute to insufficiencies. These are discussed elsewhere (du Manoir et al., 1995a,b; Lundsteen et al., 1995; Piper et al., 1995). Microscope lamps must be properly centered and the proper filter sets should be used. Image capture using a good-quality 63× fluorescence objective tends to produce the best results. See *UNIT 4.2* for general considerations in fluorescence microscopy.

Metaphase spreads for CGH analysis

CGH analysis can be carried out on 7 to 10 well hybridized metaphase spreads. The signal strengths should be high, with low background levels. Metaphase spreads should have no overlapping chromosomes; otherwise these must be excluded from analysis. Choose spreads where the chromosomes are long enough to produce a recognizable banding pattern. There should also be consistency with respect to chromosome length when choosing metaphases for analysis. If a chromosome cannot be readily identified, exclude it from the analysis. It is far better to exclude a questionable chromosome from the analysis than to karyotype it incorrectly. Analysis must be derived from one slide. Do not "mix-and-match" experiments. If a particular DNA is repeated, analyze it as its own experiment. Variables such as slide age, batch, and hybridization conditions can influence the quality of the hybridization and hence the results (see Troubleshooting below).

Troubleshooting

CGH, like other FISH assays is multifaceted, involving the preparation of many different components and bringing them together to achieve the final results. *UNIT 22.4* covers many of the typical problems encountered when carrying out FISH and FISH-based assays. The following discussion deals with common CGH difficulties and the strategies to pinpoint the cause of such difficulties.

Weak signal intensity of both normal and tumor DNAs

This can be caused by a number of factors at different points of the assay. Ensure that the labeling reaction was efficient. Check that all labeling reagents were maintained at the right storage conditions and used prior to their expiration dates, particularly the enzymes. If a dot-blot test was used to check the label incorporation (see *UNIT 22.4*) and the results were satisfactory, then the problem lies elsewhere. The quality of the DNA should also be investigated, making sure that it is resuspended in water rather than TE buffer and that it is of high molecular weight. If the labeling reaction can be ruled out, then consider the target slide. If the metaphases are puffy with poor banding, overdenaturation, which destroys the DNA, may be the problem. On the other hand, if the morphology of the chromosomes is very good, with sharp, crisp banding, there may have been insufficient denaturation as the result of over-aging of the slides or insufficient time for denaturation. If another CGH experiment using the same slides during the same hybridization experiments produces good results, it is likely not a slide problem. Weak signal intensity can also be a result of poor hybridization caused by the dilution of the probe and associated buffers if the coverslip was not adequately sealed. This will occur if there is so much moisture in the hybridization chamber that the moisture leaches under the poorly sealed coverslip, diluting the probe and/or causing the probe to leak out. The temperature for hybridization should be at 37°C with a minimum of 72 hr for hybridization. As discussed previously, longer fragments require more time to hybridize to their targets. Factors affecting signal intensity during the post-hybridization washes and detection are discussed in *UNIT 22.4*; these include stringency of washes, temperature, and quenching of the fluorescence of conjugated antibodies.

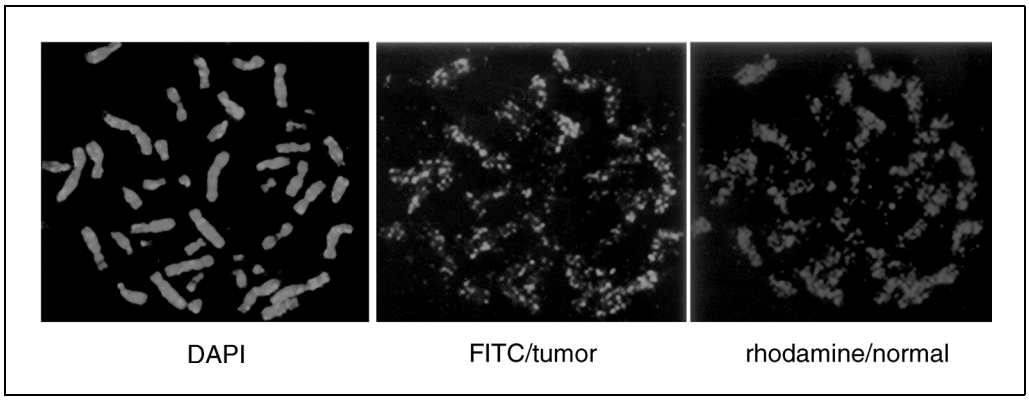

Figure 22.6.2 Examples of poor hybridization resulting in a speckled or patchy appearance of fluorescence across the metaphase. From left to right: DAPI-stained metaphase, FITC-detected tumor DNA, and rhodamine-detected normal reference DNA. *This black and white facsimile of the figure is intended only as a placeholder; for full-color version of figure go to http://www.interscience.wiley.com/c_p/colorfigures.htm.*

Weak signal intensity of one of the two DNAs

This is usually an issue with the labeling efficiency of the problem DNA. Check the quality of the starting DNA by examining gel photos of the undigested DNA. Contaminating proteins can inhibit labeling as can resuspension in TE buffer. Furthermore, check the antibody used to detect the labeled DNA, as this is the other factor causing weak signal intensity.

Granularity of hybridization

A good CGH experiment will have even hybridization across the metaphase spread with good signal intensity, as shown in Figure 22.6.1. Under these conditions, gross aberrations, e.g., gains or losses of a whole chromosome or distinct high-copy-number amplifications, can be detected visually without any equipment for digitized image acquisition or analysis, as seen in the three-color image (red-green-blue) in Figure 22.6.1. If the hybridization signals show a patchy or speckled appearance, this indicates that improper hybridization has occurred (Fig. 22.6.2). This can be caused by insufficient protease treatment, resulting in impaired access of the probe to the DNA target. Insufficient or overdenaturation of the metaphase slide can also cause this appearance, as can labeled DNA that is too long. High granularity is also indicated by large confidence intervals that indicate the variability of averaged ratio values when the analysis has been completed. The investigator should look to all these factors when analyzing a slide.

Poor DAPI banding

The ability to visualize the chromosomes and identify them using DAPI banding (which is normally converted into a pseudo-G-banding image by all CGH softwares) is critical to successful CGH. *UNIT 22.4* describes the possible causes for poor banding and methods for improvement.

Failure of control CGH experiments

The value of performing control experiments using a DNA with known gains and losses lies in its ability to establish the level of sensitivity. Having obtained good signal strength and banding in an experiment that has reached the analysis stage, the third critical aspect is whether the CGH assay has been able to detect the expected genomic changes.

None of the changes detected: If none of the expected changes were detected, the investigator must go back to the beginning of the procedure (i.e., starting from the DNA extraction and labeling through to hybridization). One of the biggest concerns would be the inequality of normal and tumor/test DNA used for the experiment. The investigator should review the labeling procedure, paying special attention to the quantity of DNA used in the initial labeling procedure and the quantitation using the gel images and standards. Hybridization problems can also contribute to lack of CGH findings (discussed above). Finally, poor karyotyping skills will significantly affect the CGH results.

Some of the changes detected: If some of the expected changes are detected, while others are not, this suggests either that karyotyping of those chromosomes may be suspect or that the hybridization of that particular experiment was not optimal; thus, some changes were detected while others were not. The investigator can analyze a few more metaphase spreads and increase the number of analyzed cells to the final profile. The drawback is that a poorly hybridized experiment will accentuate

false results, aggravated primarily by amplified background signals. It is suggested that the experiment be repeated with adjustments in slide pretreatment and/or denaturation, making sure that all hybridization and washing conditions are correct.

CGH results skewed in favor of gains or losses: Having carried out the analysis, if one finds that all the chromosomes have a tendency for gain or loss, this suggests that there was an unequal amount of one labeled DNA over the other in the experiment.

Anticipated Results

A good CGH experiment will have bright signal strength along the length of each chromosome and across the metaphase spread. The chromosome banding should be crisp and distinct. There should also be minimal background.

Time Considerations

The preparatory work may take several days, depending on the method of DNA extraction and the source of DNA being extracted. Hybridization is carried out for a minimum of 72 hr. Post-hybridization washes and detection will require ~2 hr. Image acquisition and image analysis will take several hours to several days, depending on the karyotyping skills of the investigator.

Sister Chromatid Exchange

Sister chromatid exchange (SCE) refers to the interchange of DNA between replication products. The technique takes advantage of the semiconservative nature of DNA synthesis. 5′-bromodeoxyuridine (BrdU) is incorporated into the newly synthesized DNA. Colcemid is added to the culture, and conventional cytogenetic preparations are made. Differential staining with Hoechst dye and Giemsa allows the newly synthesized DNA within a chromatid to be recognized because BrdU incorporation leads to much weaker staining. SCEs represent a point of DNA template exchange during strand synthesis, visualized as asymmetric chromatid staining or "harlequin" chromosomes. There are a number of minor variations in the basic SCE protocol, which are discussed in Barch (1991). The protocol below uses a nonfluorescent method of microscopy.

STRATEGIC PLANNING

To carry out SCE experiments, the investigator should be familiar with the growth kinetics of the cells being analyzed. Since SCE involves DNA replication, the cells should be actively dividing. Depending on the nature of the experiment, drug or radiation treatment should be carefully modulated. The researcher should refer to the current literature regarding growth medium and other relevant information. A quick guide to SCE analysis is as follows:

Cell culture

1. Growth of cells (culture medium should not contain thymidine).
2. Culture treatment.
3. BrdU treatment.
4. Cell recovery.

Cell harvesting

1. Colcemid treatment.
2. Preparation of cytogenetic suspensions and slide making.

Cell staining

Microscopy

HOECHST-GIEMSA STAINING FOR SCE AND REPLICATION BANDING

BASIC PROTOCOL

This technique is also known as the fluorescence plus Giemsa (FPG) technique for detection of SCE (Barch, 1991). The following protocol employs the basic technique of cell harvesting outlined in *UNIT 22.2*. BrdU is added to the culture and the cells are allowed to undergo replication. Colcemid is added to arrest the cells in metaphase, and the cells are harvested to make cytogenetic suspensions. Metaphase slides are prepared as described previously (*UNIT 22.2*), then stained with Giemsa.

NOTE: All solutions and equipment coming into contact with living cells must be sterile and aseptic technique should be used accordingly.

NOTE: All culture incubations are performed in a humidified 37°C, 5% CO_2 incubator unless otherwise specified.

Contributed by Jane Bayani and Jeremy A. Squire
Current Protocols in Cell Biology (2004) 22.7.1-22.7.4

Materials

Subconfluent cell culture
5′-bromodeoxyuridine (BrdU; Sigma): follow manufacturer's instructions and keep away from direct light
10 μg/ml Colcemid (Invitrogen) in H_2O
Phosphate-buffered saline (PBS; *APPENDIX 2A*)
Hoechst 33258 working solution (see recipe)
4% (v/v) Giemsa staining solution
2× SSC (see *UNIT 18.6* for 20×)
15-ml conical centrifuge tubes
Coplin jars
Large petri dish
UV light source, e.g., the UV light in a tissue culture hood
Additional reagents and equipment for harvesting cells and preparing metaphase spreads (*UNIT 22.2*)

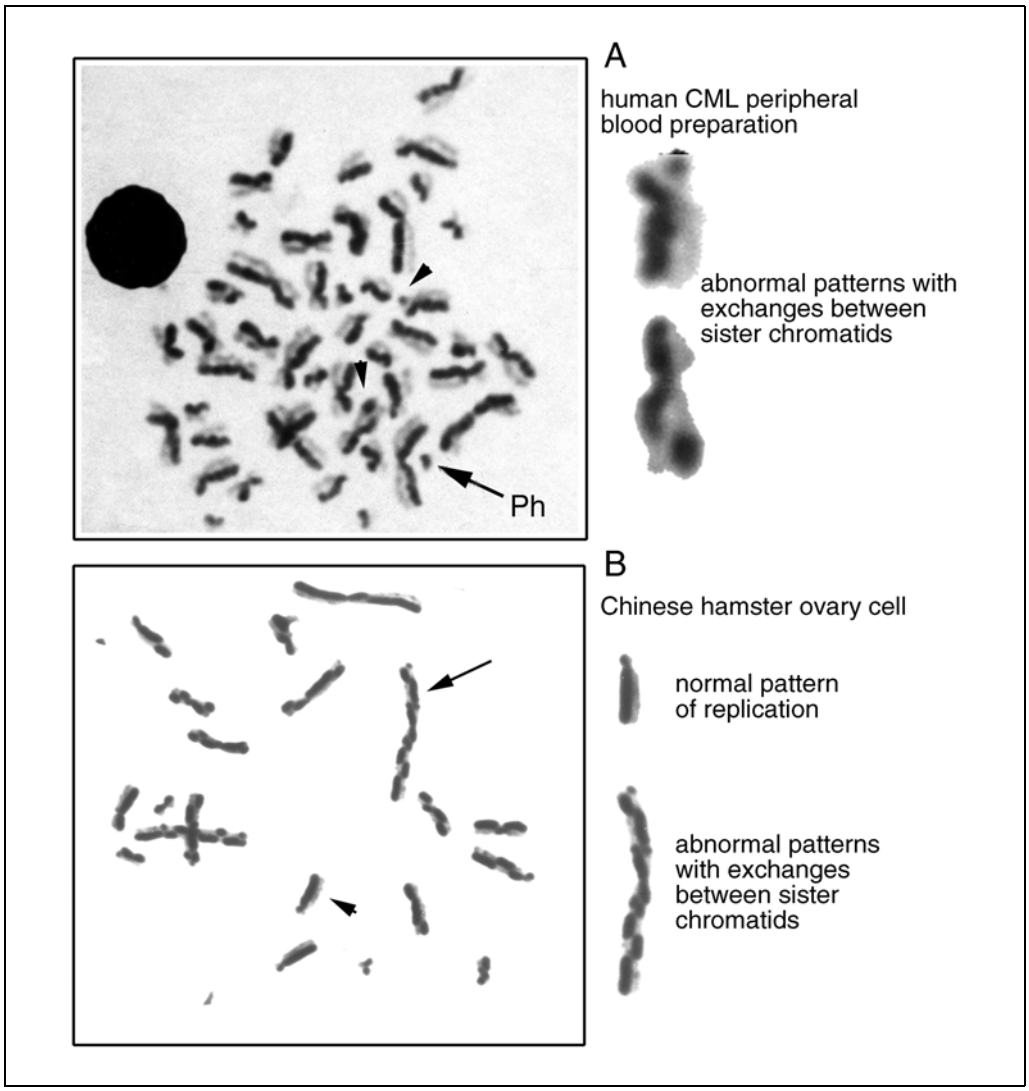

Figure 22.7.1 Sister chromatid exchange in a human CML spread and Chinese hamster ovary cells. Examples of sister chromatid exchange in a human CML spread (**A**) and in Chinese hamster ovary cells (**B**). Images kindly provided by Turid Knutsen, Hesed Padilla-Nash, and Thomas Ried, Genetics Branch, National Institute of Health, Bethesda, Maryland. *This black and white facsimile of the figure is intended only as a placeholder; for full-color version of figure go to http://www.interscience.wiley.com/c_p/colorfigures.htm.*

1. To a subconfluent cell culture, add BrdU to a final concentration of 5 μg/ml. Keep the cultures in the dark by wrapping flasks in foil. Return the flask to the incubator for 24 to 48 hr. Allow the cells to recover.

   Depending on the nature of the experiment, a period of cell recovery in medium without BrdU may be required. This period may range from one to several hours.

2. Add sufficient 10 μg/ml Colcemid stock to the culture to give a final concentration of 0.1 μg/ml. Return the flask to the incubator and continue incubating 1 hr.

3. Harvest the cells and prepare cytogenetic suspensions. Make metaphase spreads on clean glass slides (all techniques described in *UNIT 22.2*).

4. Incubate slides in Coplin jars containing PBS for 5 min at room temperature.

5. Incubate slides in Hoechst 33258 working solution for 5 min at room temperature, then rinse briefly in PBS.

6. In a large uncovered petri dish, place the slides face up in 2× SSC and expose to UV light for 10 min, then rinse in fresh 2× SSC.

7. Stain slides by immersing them in a Coplin jar containing 4% Giemsa stain for 3 to 5 min at room temperature.

8. Rinse slides in water, then visualize by light microscopy.

   The sister chromatid with BrdU incorporation will shown decreased staining with Giemsa.

9. Score the metaphases for sister chromatid exchange (see Fig. 22.7.1).

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Giemsa stain, 4% (v/v)

2 ml Giemsa stain (Azure Blend, Harleco 620G/75, from EM Science; 2% v/v final)
48 ml Gurr's buffer solution, pH 6.8: dissolve 1 Gurr's buffer table (Bio/medical Specialties) in 1 liter sterile H_2O
Store up to 2 months at room temperature

Hoechst 33258 working solution

Stock solution (75 μg/ml): Dissolve 7.5 mg Hoechst 33258 (e.g., Molecular Probes) in 100 ml water. Prepare fresh each time or store at room temperature up to 1 month. Protect from direct light.
Working solution: Combine 50.0 ml Hoechst stock solution with 25.0 ml PBS (*APPENDIX 2A*). Prepare fresh.

COMMENTARY

Background Information

Sister chromatid exchange (SCE) refers to the interchange of DNA between replication products. The mechanism of chromatid exchange is still not fully understood; however what occurs is the interchange of DNA at the same location in each chromatid. This requires fidelity in DNA repair. SCEs were first observed by Taylor et al. (1957), using autoradiography on cells that had undergone one cycle of tritiated thymidine incorporation followed by a replication cycle in non-radioactive medium (also see Barch, 1991). BrdU is now used in place of radiolabeled thymidine. SCEs have typically been studied for the detection of DNA damage (Gebhart et al., 1981). Exposure of cells to carcinogens, mutagens, or ionizing radiation has

been known to induce chromosomal aberrations. SCE has been used to diagnose inherited diseases such as Bloom's syndrome, Fanconi's anemia, and ataxia-telangiectasia (Ellis et al., 1999).

Critical Parameters

The use of BrdU is a quicker and much easier method than the use of radioactive thymidine for labeling newly synthesized DNA. BrdU is incorporated into DNA in the place of thymidine, but the BrdU concentration should be closely monitored because subtoxic levels may induce exchanges. To avoid these issues, it is necessary to have the appropriate controls. These controls will include establishing thresholds of toxicity by adjusting either the amount of BrdU or the time of BrdU exposure. Furthermore, cells treated with BrdU are light-sensitive; thus the cultures should be maintained in the dark.

BrdU incorporation complements the use of Hoechst 33258, since the Hoechst dye will fluoresce less efficiently when bound to poly (dA-dBrdU) than when bound to poly (dA-dT). Detecting exchanges relies on the semiconservative nature of DNA synthesis. 5′-bromodeoxyuridine (BrdU) is incorporated into the newly synthesized DNA. Differential staining with Hoechst dye and Giemsa allows the newly synthesized DNA within a chromatid to be recognized, since BrdU incorporation in only one DNA stand leads to much weaker staining than in the strand without any incorporation. Thus, SCEs represent a point of DNA template exchange during strand synthesis, visualized as asymmetric chromatid staining or "harlequin" chromosomes (see Fig. 22.7.1).

The modification of the basic SCE assay described in this unit employs Giemsa staining. The FPG technique is based on the theory that light energy absorbed, but not emitted, by the fluorescent dyes can promote selective degradation of BrdU-substituted DNA.

As with any assay involving chromosomes, the success of this assay requires mitotically active cells. The resulting cytogenetic suspension should have a high mitotic activity and good chromosome length, such that the exchanges can be easily identified. Refer to *UNIT 22.2* for culturing and harvesting conditions.

Troubleshooting

The detection of exchanges requires that the investigator be able to see subtle differences in staining intensities between the newly replicated strands. If the staining is too strong, it will obscure the subtle differences; in such cases, one should reduce the stain time or stain concentration. The investigator should also consider whether the concentration of BrdU was sufficient to label the new DNA. As mentioned above, caution should be taken when establishing BrdU quantities, since it can induce exchanges.

Anticipated Results

If sister chromatid exchanges are present they should be detectable at 40 × magnification. Exchanges should be reciprocal. The anticipated results will depend on the nature of the experiment. The frequency of exchanges can be determined and can be used in a correlative fashion (e.g., varying exposure to different drugs or to radiation).

Time Considerations

A SCE experiment should take 2 to 3 days depending on the duration of culture in BrdU.

Detection of Mitotic Figures and Components of the Mitotic Machinery

BASIC PROTOCOL

This unit describes the detection of proteins associated with the mitotic machinery. Mitotic figures can easily be identified by the condensation of chromatin into chromosomes as the cells undergo cell division. Staining of DNA and of the proteins associated with mitosis (e.g., tubulins and centromere-associated binding proteins) help to identify mitotic figures. Many different appropriate primary antibodies are available for this purpose, and they can be used with secondary antibodies conjugated to fluorochromes (indirect immunofluorescence, *UNIT 4.3*). Each assay requires a series of antibody incubations with intervening washes. The investigator should refer to the current literature to determine whether an antibody is available for the protein complex under study. The suppliers of each antibody will provide guidelines regarding optimal blocking and concentrations for the fixative that have been used. In the following protocol, γ-tubulin is used as a model. Table 22.8.1 outlines the other antibodies that can be used to detect mitotic figures and components of the mitotic machinery.

NOTE: All solutions and equipment coming into contact with living cells must be sterile and aseptic technique should be used accordingly.

NOTE: All culture incubations are performed in a humidified 37°C, 5% CO_2 incubator unless otherwise specified.

Materials

Cells growing on coated glass slides, coverslips, or chambered tissue culture slides (*UNIT 22.2*), 75% confluent
Phosphate-buffered saline (PBS; *APPENDIX 2A*), room temperature and cold
4% (w/v) paraformaldehyde in PBS (see recipe), cold
70% and 100% ethanol, cold
Permeabilizing solution (see recipe)
Blocking solution (see recipe)
Primary antibody: mouse anti γ-tubulin antibody (Sigma) at working concentration recommended by manufacturer
0.1% (v/v) NP-40 in PBS (prepare fresh)
Secondary antibody: rhodamine-conjugated anti-mouse IgG antibody (Sigma) at working concentration recommended by manufacturer
DAPI in antifade (see recipe in *UNIT 22.4* or purchase from Vector Laboratories)
Nail polish
Petri dishes
Coplin jars
37°C dry incubator or oven
Hybridization box: e.g., black videocassette box containing slightly dampened moist paper towel or gauze
Fluorescence microscope and appropriate filters (*UNIT 4.2* and *APPENDIX 1E*)

Grow and fix cells

1. Grow cells to 75% confluency on coated glass slides, coverslips, or chambered tissue culture slides (*UNIT 22.2*).

   If cells were grown on chambered slides, the chambers may be removed. If cells were grown on coverslips, petri dishes may be used for the incubations. Be sure to keep track of which side of the slide or coverslip the cells are were grown on.

Table 22.8.1 Components of the Mitotic Machinery Commonly Used for Analysis

Antibody	Structure(s) detected	Supplier(s)[a]
Aurora	Centrosomes	IHC World, Bethyl Laboratories, Abcam
CENPA	Kineticore, centromere	Abcam
CENPB	Kineticore, centromere	Bethyl Laboratories
Centrin	Centrosomes, spindle apparatus	Sigma
α-Tubulin	Centrosomes, spindle apparatus	Sigma
β-Tubulin	Centrosomes, spindle apparatus	Sigma
γ-Tubulin	Centrosomes, spindle apparatus	Sigma

[a]See Internet Resources.

2. Remove the medium and wash once with cold PBS, either by floating coverslips in a petri dish or by using a Coplin jar for slides.
3. Fix the cells using cold 4% paraformaldehyde in PBS for 10 min, either by floating coverslips in a petri dish or by using a Coplin jar for slides. Wash the cells with 1× PBS for 2 min using the same technique.
4. Fix with 100% ethanol for 10 min. Store slide in 70% ethanol at 4°C, or process immediately as in the following steps.
5. Hydrate the cells in PBS for 5 min at room temperature.

Prepare cells for staining

6. Permeabilize cells by immersing in permeabilizing solution for 15 min at room temperature.
7. Drain solution, but do not allow the slide or coverslip to dry. Apply blocking solution to the area with the cells. Place coverslip over this area and incubate at least 30 min at 37°C in a hybridization box.

Treat with primary antibody

8. Remove coverslip. Drain blocking solution, but do not allow slide or coverslip to dry. Add primary antibody to the area with the cells. Place coverslip over this area and incubate at least 1 hr 37°C.
9. Remove coverslip. Wash three times with 0.1% NP-40 in PBS, each time for 5 min at room temperature, either by floating coverslips in a petri dish or by using a Coplin jar for slides.
10. Drain solution, but do not allow the slide to dry. Apply blocking solution to the area with the cells. Place coverslip over this area and incubate at least 30 min at 37°C.

Treat with fluorochrome-conjugated secondary antibody

11. Remove coverslip. Drain blocking solution, but do not allow slide or coverslip to dry. Add rhodamine-conjugated secondary antibody to the area with the cells. Place coverslip over this area and incubate at least 1 hr 37°C.
12. Remove coverslip. Wash three times with 0.1% NP-40 in PBS, each time for 5 min at room temperature, using the washing technique described in the previous steps. Briefly rinse with PBS at room temperature.

Mount and visualize slides

13. Drain excess liquid but do not allow cells to dry. If cells were grown on coverslips, add 50 μl of DAPI in antifade solution (counterstain) to a clean glass slide and place the coverslip over it cell-side-down. If cells were grown on a slide, add the 50 μl of DAPI in antifade to the area on the slide with the cells, then apply the coverslip. Seal the coverslip to the slide using nail polish.

14. Visualize the slide preparation under a fluorescence microscope (*UNIT 4.2*). When slides are not in use, store at −20°C.

See Figure 22.8.1 for examples of mitotic figures.

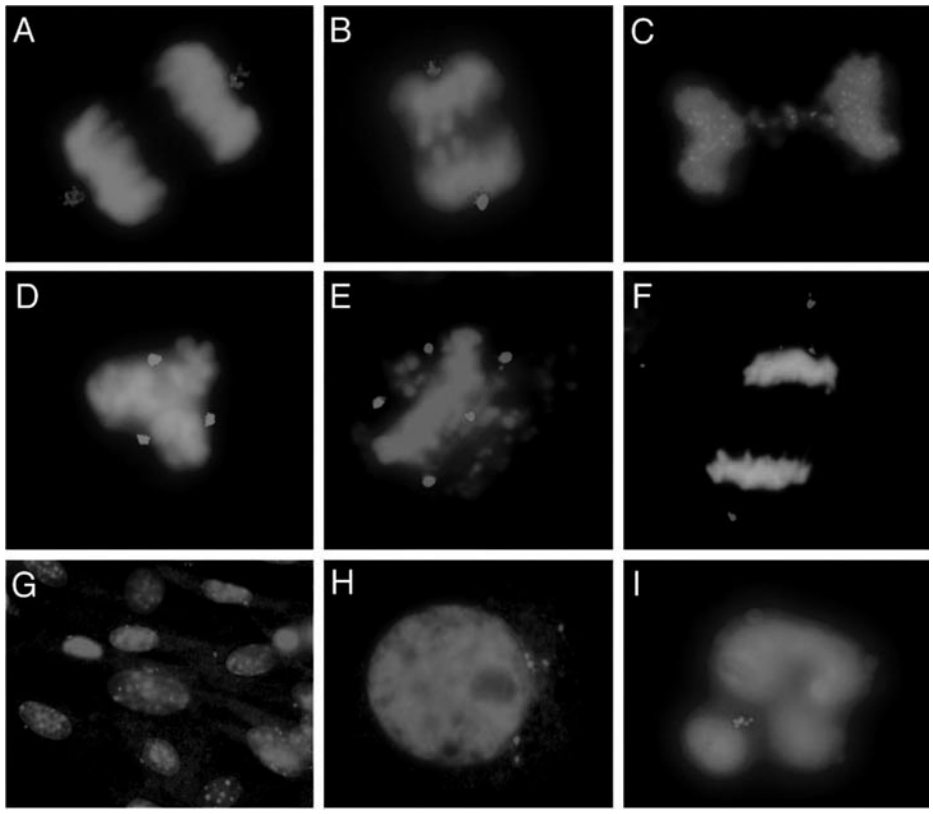

Figure 22.8.1 Examples of aberrant mitotic figures. Shown are examples of mitotic cells stained with γ-tubulin to detect centrosomes (red) and the spindle apparatus. Counterstaining with DAPI (blue) was used to visualize DNA. (**A**) and (**B**) show cells undergoing mitosis, where duplicated chromosomes are being pulled from the metaphase plate to their respective poles. (**C**) In this image, the cells were stained with antibodies against centromere/kinetichore proteins and illustrate the formation of an anaphase bridge. Abnormal mitotic figures are shown in (**D**), (**E**) and (**F**), where centrosome amplification has occurred, resulting in multipolar mitotic figures (D and E) and functional centrosomes. In (F), centrosome amplification has occurred, but the extra centrosome is apparently nonfunctional, and the cell maintains normal division. Amplification of centrosomes are also seen in interphase cells. (**G**) Mouse metastatic osteosarcoma cells derived from the lung show amplified centrosomes. (**H**) Amplified centrosomes are present in a clear cell ovarian cancer cell. (**I**) A multi-nucleated ovarian cancer cell shows amplified centrosomes. *This black and white facsimile of the figure is intended only as a placeholder; for full-color version of figure go to http://www.interscience.wiley.com/c_p/colorfigures.htm.*

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Blocking solution

3 g bovine serum albumin (BSA; 3% w/v final)
100 ml PBS (*APPENDIX 2A*)
Warm slightly to dissolve if necessary
Store up to 6 months at 4°C in small aliguots or up to 1 year at −20°C

Paraformaldehyde in PBS, 4% (v/v)

10.0 ml 16% paraformaldehyde (e.g., Electron Microscopy Sciences; 4% v/v final)
30.0 ml PBS (*APPENDIX 2A*)
Wrap bottle to protect from light
Store up to 1 month at 4°C

Permeabilizing solution

0.5 ml NP-40 (0.5% v/v final)
99.5 ml PBS (*APPENDIX 2A*)
Store at room temperature

COMMENTARY

Background Information

Chromosomal abnormalities are closely linked to errors in the mitotic machinery. Chromosomal instability (CIN) is thought to arise as a result of aberrations in mitotic checkpoints (Cahill et al., 1998) and pathways responsible for maintaining genomic integrity (Difilippantonio et al., 2000). There is controversy over whether aberrations in mitotic checkpoints are a prerequisite for chromosomal changes. Tetraploidy is a common feature in many carcinomas and sarcomas; it is believed to be an initial stage in the development of aneuploidy arising either through disruption of chromosome segregation during mitosis and/or through failure of cytokinesis (Andreassen et al., 2001). The failure to arrest in G1 following tetraploidization may be exacerbated by the abnormal function of genes including *p53*, *BRCA1/2*, *Bub1*, *BubR1*, and *Mad2* (Skoufias et al., 2001), such that the cell may not be able to stably maintain the arrest of the tetraploid in G1. When tetraploids fail to arrest in G1, the cell then re-enters G1 with a tetraploid content and double the number of centrosomes. Centrosomes maintain genomic stability through the establishment of bipolar spindles during cell division, ensuring equal segregation of replicated chromosomes into two daughter cells (Nigg, 2002). Centrosome duplication normally occurs during S phase through a cdk2-dependent mechanism and is under a system of constraint that ensures there is only one duplication event during interphase (Doxsey et al., 2001; Nigg, 2002; Pihan et al., 2003). As a result of fidelity in duplication, a nontransformed cell has two centrosomes at mitosis, which dictate the formation of two spindle poles. If more than one duplication event occurs in interphase, a multipolar spindle could result, in which case the genome would segregate in an aneuploid manner. The value of these experiments is in the identification of cell populations that possess characteristics of aberrant cell cycle function. They have been observed in breast carcinomas (Pihan et al., 2003), colorectal cancer (Ghadimi et al., 2000), prostate cancer (Pihan et al., 2003), and osteosarcomas (Al-Romaih et al., 2003).

Critical Parameters

Cell growth and division are the most critical factors when investigating errors in the mitotic machinery. Cells should be monitored daily such that contact inhibition does not occur. Careful preparation of fixatives such as the 4% paraformaldehyde should be monitored. The reagents are best used when freshly prepared. If the cells are not used immediately, they may be stored at 4°C in 70% ethanol. If the slides are kept in a petri dish under ethanol, be sure that the lid is well sealed to prevent evaporation. The slides may also be stored in plastic or glass Coplin jars. The alcohol will evaporate over time, leaving a higher water content, so it is strongly suggested that the fixed cells

be checked every few days to be sure there is enough ethanol.

When assessing the extent of mitotic errors, it is essential to select well matched normal, positive, and negative control cells. Subtle perturbations in the mitotic machinery may have significant implications for processes such as chromosomal instability.

Troubleshooting

The most common problem with immunostaining assays is the possibility of high background from the fluorochrome. If a high background is present and the signals are visible, it is possible to rewash the slide in the detergent solution. Increasing the percentage to 0.2% NP-40 may also help to remove background signals. If this does not decrease the background signal, the experiment should be repeated paying close attention to the following points.

1. Make sure the antibody used has high specificity for the protein of interest.

2. Ensure the cells are adequately fixed in the paraformaldehyde solution. Increase the fixation time by 5 min.

3. Ensure that the BSA powder used to make the blocking solution is adequately dissolved. A high percentage of BSA is used for this assay (3%), but some protocols use higher BSA content (4% to 6%). The solution should be stored at 4°C to discourage any unwanted microbial growth. The solution may be warmed in a water bath or incubator to make sure the BSA does not precipitate out.

4. Adjust antibody concentrations. Check the manufacturer's suggested working concentration. Be sure that the antibodies are thoroughly mixed. If the antibody concentration is suspected as being the culprit for background, decrease the concentration while maintaining the incubation time.

5. Washes using detergent should also include gentle agitation to facilitate the removal of any unbound antibody. The detergent concentration may also be increased.

Lack of signal is the next most common problem and is typically caused by the following.

1. Lack of antibody specificity or insufficient incubation time with the antibody.

2. Insufficient membrane permeation. Increase the incubation time using the permeablizing solution. The amount of detergent may also be increased.

3. Incorrect secondary antibody (conjugated to fluorochrome) concentration or incubation. The fluorochrome may also have quenched due to expired reagents.

4. Wash conditions are too stringent.

Anticipated Results

A successful experiment will yield signals specific to the structure/protein against which the antibody is directed, with low to no background.

Time Considerations

The greatest amount of time is expended in cell culture. Great care and time must be invested in determining the growth characteristics of the cells under study, so that the maximum number of cells at fixation will be in mitosis. The entire staining procedure can be accomplished during the course of a day.

Assembly and Micromanipulation of *Xenopus* In Vitro–Assembled Mitotic Chromosomes

During mitosis, chromatin undergoes dramatic changes resulting in the assembly of mitotic chromosomes. The mitotic chromosomes of a typical vertebrate cell exhibit a very high level of DNA compaction (~10,000 times). How this high level of compaction is achieved is largely unknown. Several generations of biologists have been involved in studying the structure of mitotic chromosomes, but these studies have not resulted in a generally accepted model for the structural organization of these objects. Numerous structures, including loop domains attached to a central protein scaffold (Paulson and Laemmli, 1977), hierarchical folding of chromatin (Manuelidis, 1990), or spaghetti-like disorder (DuPraw, 1966) were proposed. These models were derived mainly from microscopy studies. The use of microscopy techniques suffers, however, from several limitations. For example, the resolution of light microscopy is within the range of a few hundred nanometers and cannot be used for detailed characterization of the mitotic chromosome organization, while electron microscopy uses harsh treatment that may destroy chromosome structure.

Recently, a novel approach for studying the organization of mitotic chromosomes was developed that measures the elastic response of mitotic chromosomes to mechanical stress. Elasticity reflects the interactions that hold objects together and the capacity of the objects to reorganize their structure upon external stress, and these are strongly dependent on the structural organization of the object. Knowledge of the elastic properties is essential for building a proper model of an object, and, in the case of chromosomes, allows comparison with the different chromosome structures reported in the literature.

In vitro–assembled *Xenopus* chromosomes are very suitable for elasticity measurements since they can be easily manipulated (Houchmandzadeh and Dimitrov, 1999). Hard data for these in vitro–assembled chromosomes have been obtained, indicating that the structure of these chromosomes must be formed by one or a few thin rigid elastic axes surrounded by a soft chromatin envelope (Houchmandzadeh and Dimitrov, 1999). The diameter of these elastic axes is estimated from elasticity calculations to be <20 nm (Houchmandzadeh and Dimitrov, 1999). What are the components of these axes? Are the axes organized by proteins alone or by proteins along with and DNA and/or RNA? What is the structure of the axes? How is chromatin attached to the axes? These and many other questions remain unanswered and elasticity measurements should undoubtedly help achieve deeper insight into them.

A video illustrating the experimental approach for chromosome elasticity measurements may be viewed by going to *http://www.interscience.wiley.com/c_p/videos.htm*. Briefly, the chromosome is grabbed by its two ends and stretched, and its elastic response is measured. The procedure consists of the following steps. First, the chromosomes are assembled in mitotic extract isolated from *Xenopus* eggs. Next, one end of the chromosome is aspirated and fixed to a micropipet. The same operation is repeated with another micropipet and the other end of the chromosome. One of the micropipets is very flexible and immobilized, while the other one is relatively rigid and mobile. The chromosome is the material link between these two micropipets; any action of one micropipet on the chromosome will be felt by the other micropipet via the chromosome, and, consequently, when the rigid pipet moves, it exerts tension on the chromosome. The flexible, immobile micropipet

Contributed by Sébastien Almagro and Stefan Dimitrov
Current Protocols in Cell Biology (2005) 22.9.1-22.9.23

feels the tension applied on the chromosome, and a deflection of this micropipet is induced. By measuring this deflection, one can easily calculate the force applied to the chromosome. From the force applied to the chromosome, determined as a function of its relative extension, the stretch modulus, i.e., the force necessary to elongate the chromosome to twice its initial length, is measured. The stretch modulus is an important elasticity parameter that allows modeling of the chromosome structure (Poirier et al., 2000; Almagro et al., 2003a,b).

This unit describes in detail the procedures for measuring the elastic properties of mitotic chromosomes (see Basic Protocol). Support protocols describe preparing sperm nuclei (Support Protocol 1), assembling mitotic chromosomes (Support Protocol 2), assembling and setting up the equipment for elasticity measurements (Support Protocol 3), designing, producing, and testing micropipets (Support Protocol 4), calibrating pixel size (see Support Protocol 5), measuring the spring constant of micropipets (see Support Protocol 6), and preparing the force calibration reference (see Support Protocol 7).

BASIC PROTOCOL

STRETCHING A MITOTIC *XENOPUS* CHROMOSOME

The mitotic chromosome could be viewed as a spring: it is possible to stretch it, to measure the force applied on it, and to return it reversibly to its initial state, and thereby to determine its elasticity (Poirier, et al., 2000; Almagro, et al., 2003a,b). *Xenopus* in vitro–assembled mitotic chromosomes are about 10 μm long and 0.8 μm wide. They are relatively flexible and fluctuate at room temperature (Almagro, et al., 2003a,b). Since these chromosomes are assembled in the test tube and are free in solution, their elastic characteristics can be precisely measured. Below is a detailed protocol for stretching a *Xenopus* in vitro–assembled mitotic chromosome. The protocol is not complicated, but it requires some experience.

The analysis of stretch data comprises the determination of the force applied to the chromosome as a function of its relative extension at the moment where the force is applied. The analysis consists of the following steps. First, the video record is digitized to transform it into a stack of images. Second, the positions of the two pipets are determined for all images. Finally, since the spring constant of the flexible pipet (see Support Protocol 6) and the size of the pixels (see Support Protocol 5) are known, the force applied on the chromosome and its extension are calculated as a function of time.

Materials

Xenopus chromosome suspension (see Support Protocol 2)
Stain buffer: buffer to be used in experiment (usually EB buffer; see recipe), containing 1×10^{-5} Hoechst 33258
EB buffer (see recipe)
Experimental equipment setup, isolated from vibration (also see Support Protocol 3, Fig. 22.9.1, and Fig. 22.9.2) consisting of:
- 3 to 4 reservoirs (see Support Protocol 3)
- Inverted microscope equipped for phase-contrast and fluorescence microscopy using Hoechst 33258 excitation and emission filters (see Support Protocol 3 for greater detail)
- Objectives: Olympus LCPlanFl 20× (NA = 0.40; air; phase 1) and Olympus long-working-distance LCplanFl 40× (NA = 0.60; air; phase 2)
- Micromanipulators (see Support Protocol 3 for greater detail)
- Motor-driven injector, syringe pump, nitrogen source, connectors, and other necessary hardware (see Support Protocol 3 for greater detail)
- CCD camera (see Support Protocol 3 for greater detail)
- S-VHS videocasette recorder (AG-TL-700, Panasonic) with S-VHS tape and TV monitor

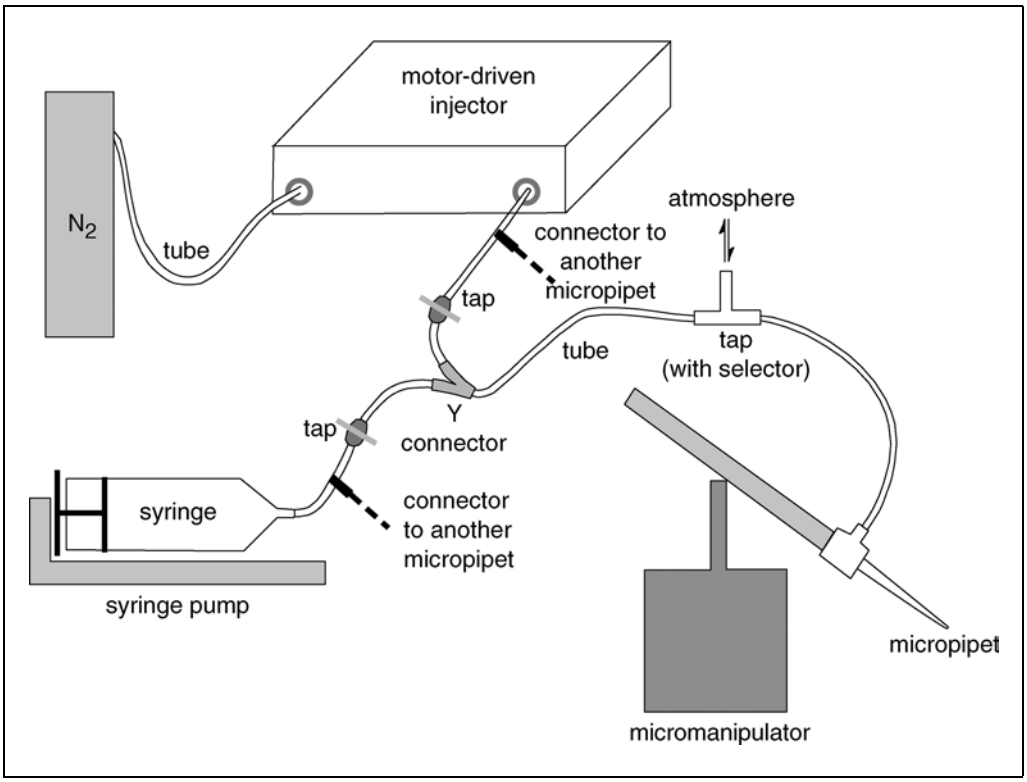

Figure 22.9.1 Schematic presentation of the pressurization/depressurization system. The pressurization system comprises an N_2 gas bottle linked to a motor-driven microinjector. A tap is present to isolate the pressurization system from the rest of the system. The depressurization system comprises a syringe mounted on a syringe pump along with another isolation tap. The two systems are linked together with a "Y" connector, and feed into a third tap (a three-way valve) that gives the user the ability either to isolate the global system from the atmosphere (under-pressure position, i.e., system closed, with the micropipet linked to the microinjector/syringe pump) or to vent it to the atmosphere (no pressure position, i.e., the system is opened to the outside and is not linked to the microinjector/syringe pump) This latter tap is the so-called pipet tap.

Computer (see Support Protocol 3 for greater detail) with PCI bus frame grabber (DT-3155, Datatranslation, Inc.)

UTHSCSA ImageTool image analysis software with plug-ins installed (see Internet Resources)

20 to 30 rigid micropipets and the same number of flexible micropipets (see Support Protocol 4)

Micropipet filling needles (MicroFil MF34G, World Precision Instruments)

10-ml syringes

24-mm × 24-mm × 170-μm glass coverslips

Additional reagents and equipment for pixel calibration (see Support Protocol 5) and measuring the spring constant of a micropipet (see Support Protocol 6)

Prepare the reservoir with the chromosomes

1. When the *Xenopus* chromosomes are completely formed (see Support Protocol 2, step 4), deposit a drop containing 10 μl of the chromosome suspension in a new reservoir. Immediately, add 7.5 μl of stain buffer and, to preserve from dust contamination, cover the reservoir with a 24-mm × 24-mm × 170-μm coverslip.

   Do not use fix/stain buffer for chromosome stretching; use stain buffer instead.

2. Wait 5 min. During this time, make sure that the 20× objective is attached to the microscope and positioned properly. Adjust the mode of the microscope to phase contrast.

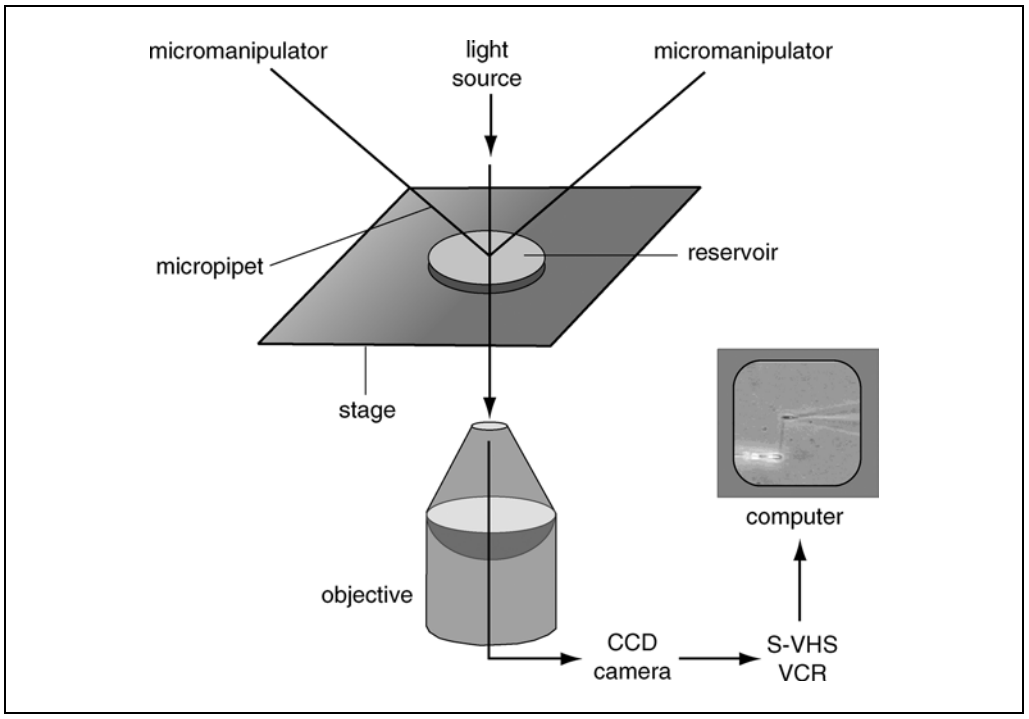

Figure 22.9.2 General scheme of the experimental set-up used for chromosome elasticity measurements. A reservoir containing the chromosome solution is placed on the motorized stage of an inverted microscope. The two micromanipulators holding the micropipets are located on each side of the microscope. The experiment is filmed with the help of a CCD camera and the video sequence is stored using an S-VHS VCR. A computer is linked to the VCR in order to analyze the results.

3. Remove the coverslip and add 300 μl of the buffer (usually EB buffer), then place the filled reservoir on the stage of the inverted microscope.

Prepare the micropipets

4. Using a micropipet-filling needle and syringe, fill either one of the two micropipets with EB buffer. Adjust the hold mode of the motor-driven injector on 10 psi and the clear mode on 25 psi (time = 10 sec). Mount the micropipet quickly on its respective micromanipulator, and activate the superpressure (hold mode) inside the pipet.

   Until the micropipet is out of the reservoir, it must be manipulated quickly (within 1 min) in order to prevent dust from sticking to the tip of the micropipet.

   To activate the superpressure mode, the motor-driven injector tap must be opened, the syringe tap must be closed, and the pipet tap must be in the under-pressure position (also see Fig. 22.9.1).

5. Center the micropipet quickly with the help of the 20× objective.

6. Activate the clear mode of the motor-driven injector by pressing the ”clear” button, and, within 10 sec of doing this, lower and place the micropipet in the reservoir liquid with the help of the micromanipulator. Check to make sure that the micropipet conducts fluid by applying a pressure on it and watching the end of the pipet; the particles neighboring the end of the pipet tip should move away from it.

   The tip of the micropipet must be situated approximately at at equal distances from the surface and the bottom of the reservoir. Do not touch the bottom of the reservoir.

7. Repeat steps 4 to 6 with the other micropipet on the other micromanipulator.

   If the first micropipet was the flexible one, the second will be the rigid one.

Stretch the chromosomes and record the video

8. Mount the 40× objective and change to fluorescence mode (adjust the excitation/emission filter wheel to see the chromosomes labeled with Hoechst). Find a chromosome.

   Because the chromosomes are all moving, concentrate on the ones that are at the bottom of the reservoir since they are less mobile. The atmosphere of the room agitates the surface of the reservoir and thus agitates the chromosomes that are close to the surface.

9. Change the microscope mode to phase contrast. Cut the pressure of one micropipet by turning the three-way valve to the "atmosphere" position (see Fig. 22.9.1). Lower this micropipet until it is near the chromosome, then turn the three-way valve to the "under-pressure" position.

10. With one end of the chromosome 2 to 5 μm from the tip of the micropipet, activate the syringe pump, using very low speed to create a very small suction.

11. Once a small part of one end of the chromosome has penetrated the pipet, cut off the suction by adjusting the tap to "atmosphere."

12. Repeat steps 9 to 11 with the other micropipet and the opposite end of the same chromosome such that the chromosome becomes attached between the two micropipets.

13. Coalign the tips of the micropipets on the long axis of the chromosome (see Fig. 22.9.3) without applying tension on the chromosome.

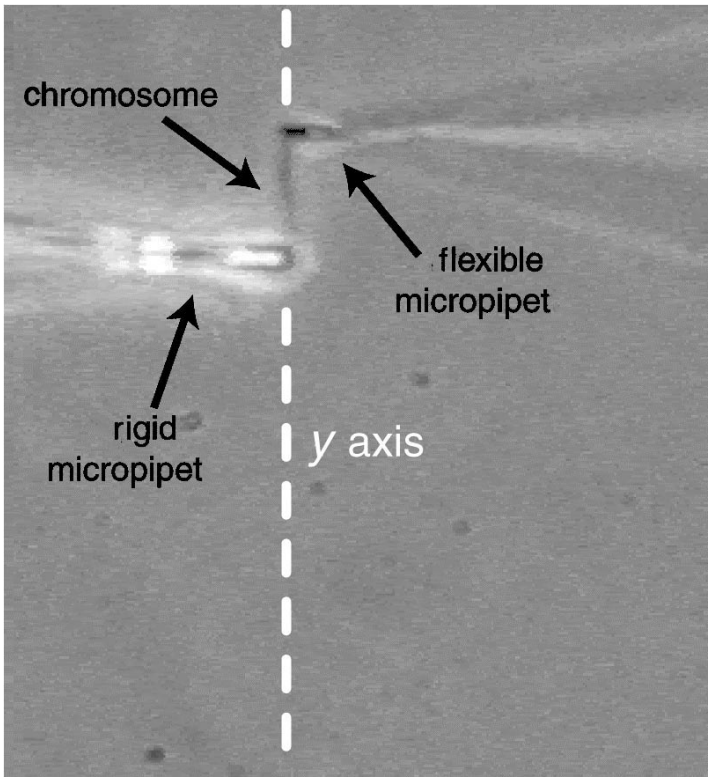

Figure 22.9.3 Positions of the two micropipets and the chromosome during a stretching experiment. The two micropipets are positioned upon on the *y*-axis, and each one has caught one end of the chromosome.

14. Program the MP–285 micromanipulator and activate the program to stretch the chromosome**.** Simultaneously, activate the CCD camera and VCR and record the experiment.

    The program for stretching consists of only two parameters: the distance at which the rigid pipet will be moved and the velocity at which the movement will take place. These parameters are entered directly in the keypad of the controller. To enter these two parameters in the program, first measure the length of the chromosome that is held between the two micropipets, then deduce the amplitude of movement to be applied to the chromosome and choose a velocity. Type the program on the keypad of the controller of the micromanipulator. For example, if the object is to stretch a chromosome of 10 μm length to twice its initial length at a velocity of 5% of its length per sec, type: "Distance = 10 μm; Velocity = 0.5 μm/sec."

    The chromosome stretching is stopped if the chromosome breaks or when the stretching program is over (indicated by a light switching off).

    Use the S–VHS VCR with S–VHS tape in PAL mode to obtain a resolution of 768 × 576 pixels. The recorded sequence will be later used for the computer analysis of the experiment.

15. Once the stretching is completed, prepare a new reservoir with some new chromosomes as in step 1 and repeat the experiment.

    The chromosomes can be used up to 8 hr after beginning the assembly reaction (see Support Protocol 2).

    Repeat the procedure a sufficient number of times to get statistically significant values (see Almagro, et al., 2003a,b for comparison values).

Digitize the video

16. Insert the videotape of the experiment in the VCR and note the time (t_0) at the beginning of the measurement and the time (t_1) corresponding to the end of the measurement. Calculate the length of the sequence (L_m) by subtracting the initial time from the final time ($L_m = t_1 - t_0$).

17. Choose a rate of images per sec (R_i). Calculate the total number of images (N_i) by multiplying the length of the sequence by the rate of image ($N_i = L_m \times R_i$).

    In most cases a collection of 100 to 2000 images is sufficient for the analysis. Acquiring large numbers of images will greatly increase the time of analysis and the amount of hard disk space consumed.

18. Open the video acquisition window in ImageTool and choose PCI frame grabber as a source. Acquire a stack of images.

    A typical picture stack is ~60 Mb and usually comprises from 100 to a few thousand images.

    ImageTool plug-ins must be installed.

19. Enter the delay between images (R_i) and the total number of images (N_i) to be taken.

20. Rewind the videotape to several seconds before t_0. Play the videotape and, when t_0 is reached, start the video acquisition process.

21. Save the image stack in a suitable image format. Store the image stack in a folder specially reserved for these images.

    Do not forget that some image formats decrease the resolution due to their lossy compression algorithms. This problem could be avoided by choosing, for example, a TIFF format without compression.

Extract the results from the images

22. With ImageTool running, open the image stack previously acquired.

23. Zoom in on the first image to enlarge it and place the mouse cursor on the extremity of each micropipet that is in contact with the chromosome (refer to Fig. 22.9.3), noting the *x*- and *y*-axis coordinates of the mouse cursor at each of these two points.

    The position of the mouse at the image appears in the bottom left part of the Image Tool window. Increase the size of the image when measuring the micropipet position.

24. Repeat the previous step for each image of the stack. Always refer to the same point on each micropipet all through the image stack.

25. Calculate the length (in pixels) of the chromosome on each image by subtracting the *y* coordinates of the two micropipets (the flexible and the rigid one).

26. Measure the deflection in pixels of the flexible micropipet relative to its initial position before stretching.

27. Calibrate pixel size (see Support Protocol 5). Convert all distances that are in pixels to meters by multiplying the value in pixels by the value obtained for the size calibration of the pixel.

28. Multiply the deflection values obtained in step 26 by the spring constant of the soft micropipet (see Support Protocol 6) in order to obtain the value of the force applied on the chromosome for each image recorded during the chromosome stretching experiment.

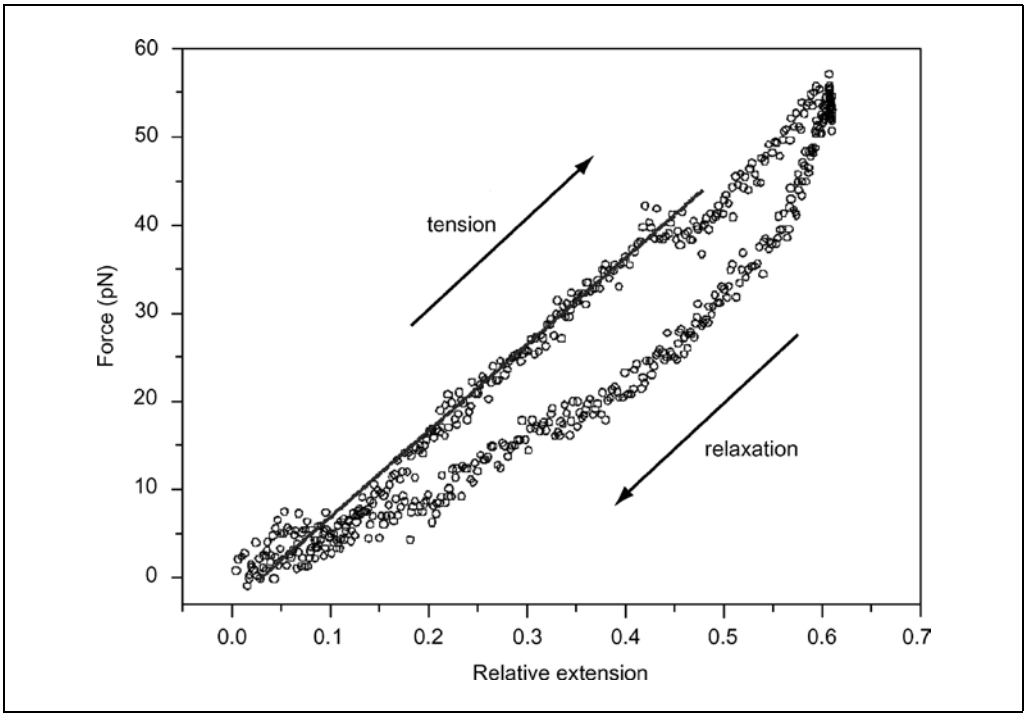

Figure 22.9.4 Graphic representation of the results of a chromosome-stretching experiment. The force applied on the chromosome during the stretching experiment is plotted as a function of its relative extension. Data points are represented as circles. The line represents the linear fit of the experimental data and its slope is the stretch modulus.

29. Calculate the relative extension (R_e) of the chromosome as $R_e = (L - L_0)/L_0$ where L_0 is the initial length of the chromosome and L the chromosome length on image number n.

    Note that the relative extension is dimensionless.

    Because the chromosome length varies from one chromosome to another, it is important to measure it each time in order to normalize the applied force.

30. Plot the measured force as a function of the relative extension [$F = f(R_e)$] (see Fig. 22.9.4, circles).

    The slope of the curve (Fig. 22.9.4, line) is the stretch modulus, i.e., the force needed to double the length of the chromosome.

    Figure 22.9.4 shows the two phases of the stretching experiment: the chromosome is first tensed by the moving the rigid pipet and then it is relaxed by returning the rigid pipet to its initial position.

    The stretch modulus may easily be calculated using a computer, but, for this, dedicated home-made software must be designed, since such software is not commercially available.

SUPPORT PROTOCOL 1

PREPARING *XENOPUS* SPERM NUCLEI

Incubation of sperm nuclei with the mitotic *Xenopus* egg extract allows the assembly of mitotic chromosomes. The use of sperm nuclei (not nuclei from somatic cells) is mandatory for the assembly of well-structured chromosomes. The assembly procedure is simple, straightforward, and reproducible. The assembled chromosomes are relatively large, and thus are easy to manipulate. They consist of one chromatid only and recapitulate the essential structural properties of somatic chromosomes (Housmandzadeh and Dimitrov, 1999; Almagro et al. 2003a,b).

In order to successfully carry out chromosome assembly, it is important to prepare sperm nuclei that are well demembranated and not aggregated. The following protocol for isolation of sperm nuclei, based on Lohka and Masui (1983), Smythe and Newport (1991), and de la Barre et al. (1999), satisfies these requirements.

Materials

Two or three male *Xenopus* frogs
Buffer T (see recipe), 4°C
Buffer S (see recipe), 4°C
Fix/stain solution (see recipe)
Buffer R (see recipe), 4°C

Instruments necessary for frog dissection: forceps, scalpel, scissors
Petri dishes
20-ml glass beaker
15-ml conical centrifuge tubes (e.g., Falcon)
Tabletop centrifuge (e.g., IEC Clinical)
Fluorescence microscope with excitation and emission filters for Hoechst 33258 fluorescent dye and oil-immersion objective (NA ~1.3) with 60×/100× magnification

Additional reagents and equipment for counting cells using a hemacytometer (*UNIT 1.1*)

1. Anesthetize two to three frogs by immersing them 10 min in a mix of ice and water.

   Better nuclear preparations are obtained when more than one animal is used.

2. Sacrifice a frog by decapitation and open its peritoneal cavity with a scalpel and scissors.

   A video showing the dissection of Xenopus is available (see Internet Resources).

3. Push the intestines carefully to one side of the frog in order to gain access to the testes.

   The testes are white, oval, hard to the touch, and ~1 cm long.

4. With scissors and forceps, remove the testes and deposit them in a petri dish containing buffer T.

5. Rinse the testes in the petri dish several times with buffer T.

6. Place the testes on a piece of absorbent paper and roll them gently several times in order to remove contaminating intestinal debris and blood.

7. Remove the fat body surrounding each testis with scissors, and place the testes in a 20-ml glass beaker containing 2 ml of buffer T.

8. With forceps, crush the testes forcefully. Place the crushed testes in a 15-ml conical centrifuge tube.

9. Centrifuge 10 to 20 sec at at 150 × *g*, room temperature, and, using a 1-ml pipet, transfer the supernatant, to a new 15-ml conical centrifuge tube.

10. Place the pellet (which now contains cell debris) back into the 20-ml beaker, add 2 ml of buffer T, and repeat step 9. Add the new supernatant to the original one in the tube from step 9.

11. Centrifuge 5 min at 1500 × *g*, room temperature, and discard the supernatant.

    The pellet consists of two parts: the upper one (white) is the sperm and the lower one (red) contains red blood cells.

12. Cut a 200-µl pipet tip so the internal diameter of the tip after cutting is ~2 or 3 mm. Using this tip carefully remove the upper part of the pellet containing the sperm and place it in an another 15-ml tube. Resuspend the sperm in 4 ml of buffer T.

    It is critical to avoid contamination of the sperm by red blood cells.

13. Repeat step 11 and step 12 once more, then repeat step 11.

14. Resuspend the sperm in 100 µl buffer T. Add 300 µl buffer S and let stand 5 min at room temperature.

15. Place the sperm suspension at 4°C and remove a 1-µl aliquot. Add 1 µl of fix/stain buffer to this aliquot and examinet with a fluorescence microscope.

    If the sperm nuclei are well demembranated, they should be uniformly labeled. If nonuniform labeling is observed, the demembranization has not gone to completion and an additional 5-min incubationof the sperm suspension at room temperature is necessary. After this additional incubation, check the sperm labeling again by fluorescence microscopy. Repeat all these manipulations until complete demembranation is achieved.

16. Block the reaction by adding 1.2 ml buffer R.

17. Centrifuge 5 min at 500 × *g*, room temperature, and resuspend the pellet in 1.5 ml of buffer R. Centrifuge again for 5 min at 500 × *g*, room temperature. Discard the supernatant and resuspend the pellet in 50 to 100 µl of buffer T.

18. Measure the sperm nuclei concentration with a hemacytometer (*UNIT 1.1*).

    A correct sperm concentration for in vitro Xenopus mitotic chromosome assembly in high-speed extract is between 0.8 to 1.2 μg/μl (about 4000 nuclei/μl). The sperm concentration is an important parameter for chromosome assembly (see Critical Parameters and Troubleshooting).

19. Divide the suspension of sperm nuclei into 5-μl aliquots and store up to several years at −80°C.

SUPPORT PROTOCOL 2

ASSEMBLING *XENOPUS* CHROMOSOMES

The assembly of mitotic chromosomes depends strongly on the quality of both the egg extract and the sperm nuclei. Different protocols for the preparation of the egg extract are available and some of them are described in this book (*UNIT 11.10*). The authors have been successfully using the the procedure of de la Barre, et al. (1999) for the isolation of a *Xenopus* mitotic egg extract.

Materials

Mitotic egg extract (de la Barre et al., 1999; *UNIT 11.10*)
EB buffer (see recipe)
10× ATP regenerating system (see recipe)

Coverslips
Fluorescence microscope with excitation and emission filters for Hoechst 33259 fluorescent dye

1. Dilute 20 μl mitotic egg extract with 20 μl of EB buffer.
2. Add 4 μl of 10× ATP regenerating system and mix gently.
3. Add 1 μl of sperm nuclei suspension to the extract, mix gently again, and incubate at a temperature between 20° and 24°C.

   Lower temperatures result in very slow chromosome assembly and higher temperatures lead to the formation of broken chromosomes.

4. Take 5-μl aliquots of the reaction mixture at different time points (e.g., 0, 10, 45, 90, 120, 150, and 180 min after sperm addition). Deposit each aliquot immediately on a coverslip and add an equal amount of fix/stain buffer. Follow the steps of chromosome assembly using a fluorescence microscope.

   Once the incubation time necessary for chromosome assembly is determined, in any further stretching experiments, simply check with a 2-μl aliquot that chromosomes are well formed at this time of incubation. If this is the case, use them directly for stretching. There is no need to make a time course before each stretching experiment. Frog chromosomes assembled in the egg extract are of different lengths and behave identically upon mechanical stress. The authors have stretched >100 chromosomes with lengths ranging from 5 to 20 μm, and no differences have been observed in their elasticity; no broken chromosomes were detected in these studies.

SUPPORT PROTOCOL 3

BUILDING THE EXPERIMENTAL SETUP FOR MEASUREMENT OF CHROMOSOME ELASTICITY

The experimental setup necessary for chromosome stretching is composed of relatively simple items; the quality of the technique used for assembling them is, however, critical. This protocol begins with design and construction of the reservoir used for single-chromosome stretching experiments and continues with a general description of the experimental setup and instructions on how to isolate it from mechanical vibrations.

Materials

50-mm × 26-mm × 170-μm glass coverslips
O-rings (rubber; internal diameter = 13 mm, external diameter = 19 mm)
Metal cylinders (height = 10 cm, diameter = 19 mm; weight = ~250 g; custom-prepared in machine shop)
Dow Corning 732 adhesive/sealant
24 × 24-mm × 170-μm glass coverslips
Table with pneumatic vibration isolators (TLC, Integrated Dynamics Engineering)
Inverted microscope (IX70, Olympus) with left-side connector tube for camera and 1.25× lens adapted to the connector tube, motorized stage (Newport, cat. no. 860–C2) and two filters for the Hoechst dye (excitation, 365 nm; emission, 465 nm)
Two micromanipulators: one (MP-285, Sutter Instrument Company) with a displacement precision of about 40 nm and a second (DC3 XYZ, World Precision Instrument) with a lower precision, and corresponding controllers
Motor–driven injector (IM–300, Narishige) connected to a N_2 gas bottle.
Syringe pump (World Precision Instruments, model no. SP100i), equipped with 50-ml syringe
Taps: two 2-way valves and one 3-way valve (available in aquarium supply stores)
Several meters (length depending on distance between components of setup) of plastic tubing (internal diameter, ~1 mm)
CCD camera (Micam VHR–2000 from Digital Vision Technologies, 512 × 512 pixels, 8 bits)
S–VHS VCR (AG–TL700, Panasonic)
Personal computer (PC), with Microsoft Windows 2000 or XP installed, sufficient RAM and hard drive space to work with stacks of pictures, and a free PCI bus
PCI bus frame grabber (DT3155 from Data Translation Inc.)
Spirit level
Strong bungee cords

Construct the reservoirs

The reservoir (see Fig. 22.9.5) must be prepared 4 to 6 hr before the experiment. It is recommended that several reservoirs be prepared because each reservoir is used only once (the O-rings may be reused, but only after incubation in 70% ethanol for several days).

1. Place a 50 × 26-mm × 170-μm glass coverslip on a clean piece of paper. Place an O-ring at the center of the coverslip.
2. Press the O-ring on the coverslip by placing the metal cylinder over it.
3. Using a thin object such as a micropipet tip or scalpel, apply Dow Corning 732 adhesive/sealant all around the O-ring in order to avoid leakage of liquid from the reservoir. Wait ≥3 hr for the glue to dry.

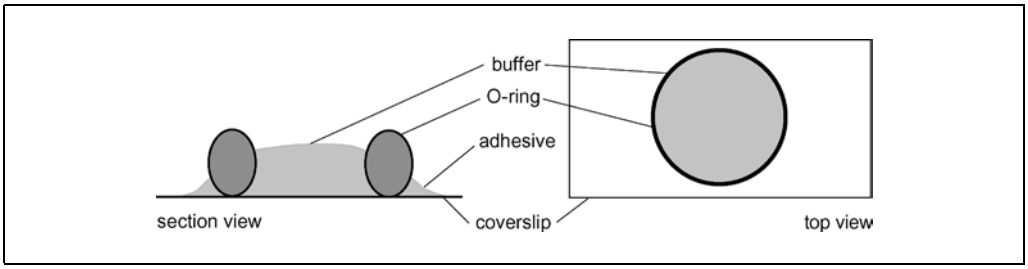

Figure 22.9.5 Diagram of the reservoir used for chromosome stretching experiments. An O-ring is attached to a coverslip with adhesive and the chromosome suspension is poured into the cavity formed by the O-ring.

The adhesive contains a solvent that can destroy the chromosomes and it is imperative to wait several hours for it to dry before addition of the chromosome suspension.

4. Remove the metal cylinder carefully and cover the reservoir with a 24 × 24-mm × 170-μm coverslip in order to prevent dust from entering in the reservoir.

   Sometimes the adhesive sticks the cylinder to the joint; if this happens, carefully remove the adhesive with a scalpel.

Set up the system and isolate it from vibrations

5. Locate a table equipped with pneumatic vibration isolators in an appropriate part of the laboratory and mount a wooden shelf ∼1 meter above the table to serve as a support for the power supply and the controllers of the micromanipulators and motor-driven injector. Drill a sufficient number of holes in the shelf to allow passage of all cables.

   The shelf will thus hold components of the system that do not need to be on the vibration-isolated table itself, thereby avoiding overloading of the table while still keeping the peripheral components close to the operator. Overloading of the table may lead to experimental problems.

6. Assemble the microscope, micromanipulators, motor-driven injector, and syringe pump on the pneumatic table, connecting these items with the appropriate taps and lengths of plastic tubing (see Fig. 22.9.1). Place a nitrogen tank with attached pressure reducer on the floor next to the table in proximity to the motor-driven injector (making sure to observe the safety precautions detailed below) and attach it to the corresponding port of the injector using plastic tubing. Connect the micromanipulators and motor-driven injector to their respective controllers on the wooden shelf with the appropriate cables according to the manufacturer's instructions. Situate the VCR and the computer on a separate table or bench near the rest of the apparatus.

   CAUTION: *Secure the nitrogen tank to avoid having it fall over. Bear in mind that pressurized nitrogen can be dangerous. Contact a qualified person to mount the pressure reducer, secure the bottle, ascertain that room ventilation is adequate, and inform laboratory personnel of the safety rules when using pressurized gas. Close the bottle when the experiment is finished; excessive nitrogen concentration in air can lead to asphyxiation.*

   The experimental setup (see Fig. 22.9.1) is very similar to the one used by Houchmandzadeh and Dimitrov (1999). The stage of the inverted microscope is motorized. The reservoir containing the chromosome suspension is placed on the stage with two micromanipulators positioned one on each side of the reservoir. A micropipet (Support Protocol 4) is attached to each one of the micromanipulators. The micropipet is connected with capillary tubes to a positive pressure system (a motor-driven injector), and a negative pressure system (syringe pump).

   The image obtained by the inverted microscope is redirected to the CCD camera (bottom of Fig. 22.9.2) attached to the microscope's left side port and recorded on the S-VHS VCR. A 1.25× lens adaptor is placed between the CCD camera and the left side port in order to obtain an optimal image size with the camera. The recorded sequences are then digitized using a PCI frame grabber.

7. Regulate the air pressure in each of the four pneumatic elements of the table such that it is high enough to raise the table and low enough to cut the vibrations.

   Vibrations are ubiquitous; the building where the experiment will be conducted vibrates continuously even if no one feels it, and the air in the laboratory continuously moves along with the hands of the laboratory personnel. These vibrations may lead to numerous problems and it is very important to isolate the microscope from them.

   With the model of pneumatic table recommended above, a distance of 5 mm between the base of the pneumatic element and the table seems to be the best compromise.

8. Test the isolation by mounting a micropipet with the smallest spring constant that will be used on the micromanipulator, then jumping on the floor near the table. If the micropipet has an amplitude of vibration >5 μm, reduce the pressure in the pneumatic elements. Acertain that the table is horizontal using a spirit level.

   The table must be placed as horizontally as possible (i.e., the slope of the table must not exceed 0.1%).

9. Firmly fix all the cables to the table with strong bungee cords.

   It is recommended that the frame of the table be fixed to the floor.

DESIGNING THE MICROPIPETS

SUPPORT PROTOCOL 4

Micropipets are the key elements of the experiment; they are used to catch the chromosome and to measure the force applied to it. Preparation of the micropipets is a delicate operation and requires both time and patience.

The micropipets must have a defined tip diameter, an ability to conduct fluids, and a specific spring constant falling within the range of forces used in the chromosome stretching experiments. Particular attention has to be paid to avoiding dust contamination during the preparation of the pipets and the manipulations (a 1-μm particle of dust can block the ability to conduct fluid). The micropipets and the capillaries are manipulated only with gloves.

Materials

Hellmanex II detergent (Helma; store in dust-free location)
Ultrapure H_2O (conductivity ~12 MΩ), filtered with a 0.22-μm filter immediately before use
EB buffer (see recipe)
Capillaries (GC100–T10; Harvard Apparatus Ltd; internal diameter= 0.78 mm; external diameter = 1 mm)
60°C water bath
Micropipet filling needles (MicroFil MF34G, World Precision Instruments)
10-ml syringes
Micropipet puller (P–97) with through filament (FT320B), both available from Sutter Instrument Company
Experimental setup for measuring chromosome elasticity (see Support Protocol 3; also see Basic Protocol)
UTHSCSA ImageTool image analysis software with plug-ins installed (see Internet Resources)
Additional reagents and equipment for calibrating pixel size (see Support Protocol 5) and measuring the spring constant of micropipets (see Support Protocol 6)

Clean the capillaries

1. Prepare 400 ml of 4% (v/v) solution of Hellmanex II in filtered ultrapure water in a 500-ml dust-free beaker.

   Hellmanex II is a detergent that is used to clean the capillaries and to make filling easier.

2. Place 20 to 30 capillaries in the beaker, then cover with Parafilm and shake vigorously.

   Two micropipets can be prepared from a single capillary.

3. Remove the Parafilm and cover the beaker with a sheet of aluminum foil. Incubate 45 min at 60°C, then let the beaker stand on the benchtop for 15 min.

4. Rinse capillaries vigorously 10 to 15 times, each time by swirling them in a beaker containing ~400 ml filtered ultrapure water. Cover the beaker with a new sheet of aluminum foil.

5. Attach a micropipet filling needle to a 10-ml syringe. Fill the syringe with filtered ultrapure water.

6. Place an absorbent paper on the bench. Rinse the interior of each capillary with the syringe, then completely remove the water from the capillary after the rinsing by placing one of its ends on the absorbent paper.

   Be careful to prevent dust from entering the capillaries. For this reason, cover them with a sheet of aluminium foil immediately after cleaning.

7. Place the clean capillaries in a beaker covered with a sheet of aluminium foil and incubate 45 min in a 120°C dry incubator. After incubation, let the capillaries cool down for about 20 min.

   Cleaned capillaries can be stored up to 36 hr in a covered beaker.

Pull the micropipets

As explained in the introduction to this protocol, the micropipets must have several specific properties. To obtain micropipets with these properties, the micropipets must be pulled with a specially designed pulling program. Unfortunately, it is impossible to create a general program for micropipet pulling, and the investigator must determine the pulling parameters for the micropipet puller being used.

8. Check to be sure that the crystals in the air-drying system of the micropipet puller have the right color (see the instrument manual).

   If the cartridge contains Drierite, crystals must be blue. Crystals of Drierite can be regenerated by heating 2 to 3 hr at 225°C.

9. Measure the ramp value of the micropipet puller according to the manufacturer's instructions.

10. Check to be sure that the filament of the micropipet puller has good geometry (see Fig. 22.9.6 and the instrument manual). If not, readjust it with tweezers, then measure the ramp value again. If it is different from that obtained in the previous step, note the new value.

    The geometry of the filament is extremely important for the reproducibility of the micropipet preparation and the fluid conduction.

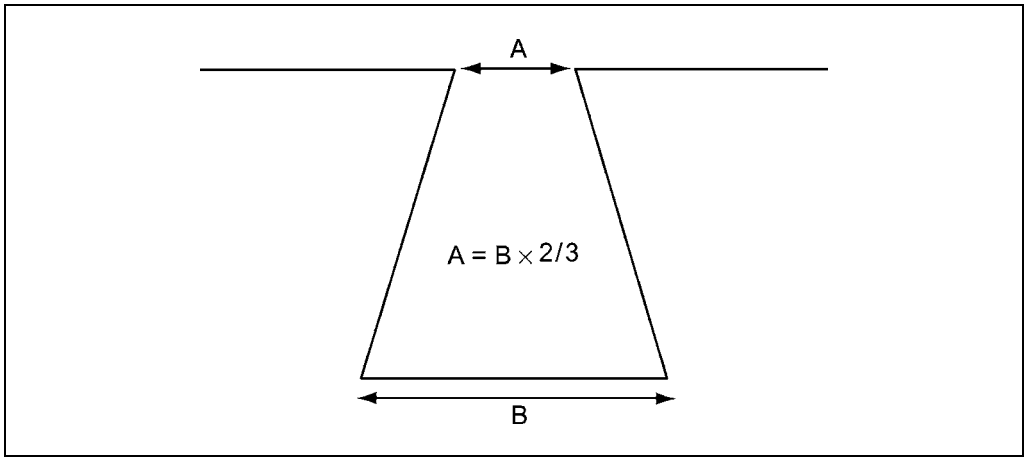

Figure 22.9.6 Correct geometry of the filament of the micropipet puller. The filament must have a trapezoidal shape with the length of the smallest base being 2/3 of the length of the largest base.

11. Check to make sure that the mounted capillary passes through the center of the micropipet puller filament. If not, center the filament, then measure the ramp value again. If it is different from that obtained in the previous step, note the new value.

12. Pull the capillary using, e.g., one of the following programs as a startup base for setting up the micropipet puller (ramp value = 225).

    To obtain a rigid micropipet with a spring constant (K) of ~2 nN/μm and an internal diameter of 1 μm:
    Pressure = 500
    Heat = 205
    Pull = 120
    Velocity = 90
    Time = 45.
    To obtain a flexible micropipet with spring constant (K) of ~100 pN/μm and an internal diameter of 1 μm:
    Pressure = 500
    Heat = 215
    Pull = 140
    Velocity = 150
    Time = 45.

    The filament is fragile and it should be touched as little as possible. The pulled micropipets must be stored in a covered container, e.g., a beaker with cover. They may only be used once.

Test the micropipets

Before conducting the real experiment, test the quality of micropipets as follows.

13. Place a reservoir on the stage of the microscope.

14. Using a syringe with a micropipet filling needle, fill a micropipet with EB buffer. Mount the filled micropipet on a micromanipulator, center it on the computer image, lower it into the reservoir, and measure its internal diameter using ImageTool software (see Support Protocol 5 for calibrating the size of the pixel.

    As explained in the Basic Protocol, two types of micropipets are used for chromosome stretching: flexible (K = 20 to 100 pN/μm) and rigid (K > 1 nN/μm). Both micropipets have internal diameters of ~1 μm and must conduct fluid.

15. Apply pressure inside the micropipet and observe if the micropipet is able to conduct fluid.

    Some 2-μm microbeads may be added to the reservoir to make it easier to visualize fluid conduction.

16. If the micropipet is able to conduct fluid, measure the spring constant of the micropipet (see Support Protocol 6).

17. If the desired spring constant has been obtained, repeat steps 14 to 16 for 10 different micropipets.

    Usually the variability in the measured micropipet spring constant value is from ~50 % to ~100 % (the older the filament, the higher the variability). If about half of the pipets exhibit the wanted spring constant, the pulling program used may be considered as appropriate.

    Note that using a micropipet puller with a laser instead of a filament reduces the variability of the prepared micropipets considerably. Such puller is, however, more expensive.

Prepare the remaining micropipets

18. Continue pulling micropipets. Each time use the same program parameters for the preparation of the micropipets

    See Critical Parameters and Troubleshooting for problems that may arise in micropipet pulling, and possible solutions.

SUPPORT PROTOCOL 5

CALIBRATING PIXEL SIZE

The following procedure is used to determine the effective size of the pixel. It is extremely important to know the size of the pixel, because without this knowledge it is impossible to analyze the results.

Additional Materials *(also see Basic Protocol and Support Protocol 3)*

Stage micrometer (graduated slide) with 100 divisions, 10 μm per division (Graticules Ltd., model PS 8)

1. Adjust the microscope at the magnification to be used for calibration.
2. Turn on the video system and the computer.
3. Place the stage micrometer on the stage and take an image of the stage micrometer.
4. Measure the number of pixels between the graduations of the stage micrometer on the image acquired with the computer (see Fig. 22.9.7), then calculate the size of the pixels in micrometers according to the following formula: number of pixels/distance = n pixels/μm.
5. Rotate the stage micrometer 90° and repeat step 4.

    It is necessary to calibrate on both the x and the y axes because some CCD cameras have different resolution on the x and y axes.

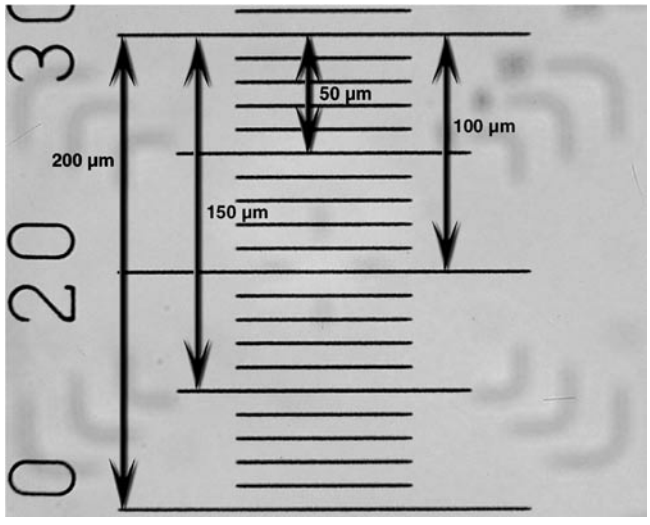

Figure 22.9.7 Size calibration of the pixel. The graduations of the stage micrometer are 10 μm apart. In order to calibrate the size of the pixel on the image it is necessary to measure the number of pixels between graduations.

MEASURING THE SPRING CONSTANT OF THE MICROPIPET

This method of pipet calibration requires that the ratio of spring constant between the two objects (the needle and the micropipet) be within a factor of 10. The protocol is illustrated in a video that may be viewed at *http://www.interscience.wiley.com/c_p/videos.htm* (a needle instead of a micropipet is used in the video).

Additional Materials *(also see Basic Protocol and Support Protocol 3)*

Experimental buffer (usually EB, see recipe) containing 50 to 100 mM NaCl
Calibrated needle (see Support Protocol 7)

1. Fill a reservoir with the experimental buffer (EB buffer, in general).

   Electrostatic interactions can sometimes provoke repulsion of the pipet from the needle; therefore, it is recommended that the buffer contain 50 to 100 mM NaCl to minimize such interactions.

2. Fix the previously calibrated needle (Support Protocol 7) on the lower-precision micromanipulator and adjust its position in order to visualize it on the computer screen.

3. Mount the micropipet on the higher-precision micromanipulator and adjust its position so that it is in the vicinity of the needle.

4. Use the micropipet to lift the needle up, moving the pipet on the *y* axis. Take a first image using ImageTool. Measure the respective *y*-axis positions (y_0) of the pipet ($y_{0\text{pipet}}$) and the needle ($y_{0\text{needle}}$) at their extremities on the image.

   Both the pipet and needle are deflected by the force they are applying to each other.

5. Quickly move the pipet along the *x* axis away from the needle without changing its *y* position, so that both the pipet and the needle reach a new position. Take another image with ImageTool. Measure the respective *y*-axis positions (y_1) of the pipet ($y_{1\text{pipet}}$) and the needle ($y_{1\text{needle}}$) at their extremities on the image (see video at *http://www.interscience.wiley.com/c_p/videos.htm*).

   Since there is no more contact between the pipet and the needle, they are no longer deflected.

6. Calculate the deflection of the pipet as $D_{\text{pipet}} = |y_{1\text{pipet}} - y_{0\text{pipet}}|$. Calculate the deflection of the needle as $D_{\text{needle}} = |y_{1\text{needle}} - y_{0\text{needle}})$.

7. Calculate the spring constant of the pipet (K_{pipet}) using the following equation.

   $K_{\text{pipet}} = (K_{\text{needle}} \times D_{\text{needle}})/D_{\text{pipet}}$

8. Repeat steps 4 to 7 several (n) times and measure $K_{1\rightarrow n}$. Determine the correct (average) value of the spring constant as:

$$K_{final} = \frac{K_1 + K_2 + \ldots + K_n}{n}$$

   Calculate the error on each measurement (E_i) as:

$$E_i = \frac{\left|K_i - K_{final}\right|}{K_{final}} \times 100$$

Calculate the final error (Err) on the spring constant as the average of all errors:

$$Err = \frac{E_1 + E_2 + \ldots + E_n}{n}$$

The error is typically within the range of 0.5% to 4%.

To calibrate micropipets with a much lower (e.g., 100×) spring constant than that of the needle, it is necessary to calibrate an intermediate micropipet. First, calibrate a micropipet against the needle. This intermediate pipet must be about 10× more flexible than the needle. Finally, use this intermediate micropipet to calibrate the pipet to be used in the stretching experiments.

SUPPORT PROTOCOL 7

PREPARATION OF THE FORCE CALIBRATION REFERENCE

The preparation of the force calibration reference is a key point of the experiment, so it has to be carried out very carefully. In this protocol, the investigator prepares a needle as the calibration reference for all the experiments, which is used to calibrate the spring constant of all the micropipets that will in turn be used to stretch the chromosomes. Therefore, an error at this point could lead to a systematic error in all force measurements.

Materials

Thin copper electric wire, 50 cm
Balance capable of precision within 1 mg
Mirror (at least 10 cm wide)
Transparent plastic ruler (graduated in millimeters)
Needle (MicroFil MF34G, World Precision Instruments)
Binocular microscope, preferably with zoom from 5× to 20×
Tweezers

1. Cut different lengths of thin copper electric wire and bend each of them into a U form.
2. Weigh them individually on high-precision balance (i.e., one capable of weighing <1 mg).

   Typically, fragments of copper wire must have a weight of 1 to 10 mg.

3. Using the mirror, needle, plastic ruler, and binocular microscope, construct the experimental setup shown in Figure 22.9.8.
4. Adjust the binocular microscope, the mirror, the needle, and the ruler to view the needle superimposed upon the ruler.

   A video illustrating the following two steps may be viewed at http://www.interscience.wiley.com/c_p/videos.htm.

5. Measure the initial position (x_0) of the needle on the ruler.
6. Using tweezers, put one copper wire fragment (with weight m_1) at the free extremity of the needle and note the new position (x_1) of the needle on the ruler. Calculate its deflection (D_1) using the equation $D_1 = |x_1 - x_0|$.
7. Repeat step 6 *n* times with at least five different copper wire fragments and calculate the deflection values.

   A reasonable value for n is when the investigator obtains an error on the calibration of <3 % with at least five independent measurements. If after 10 to 15 measurements this error range is not obtained, the investigator must take another needle and weigh all the thin copper wire filaments once again.

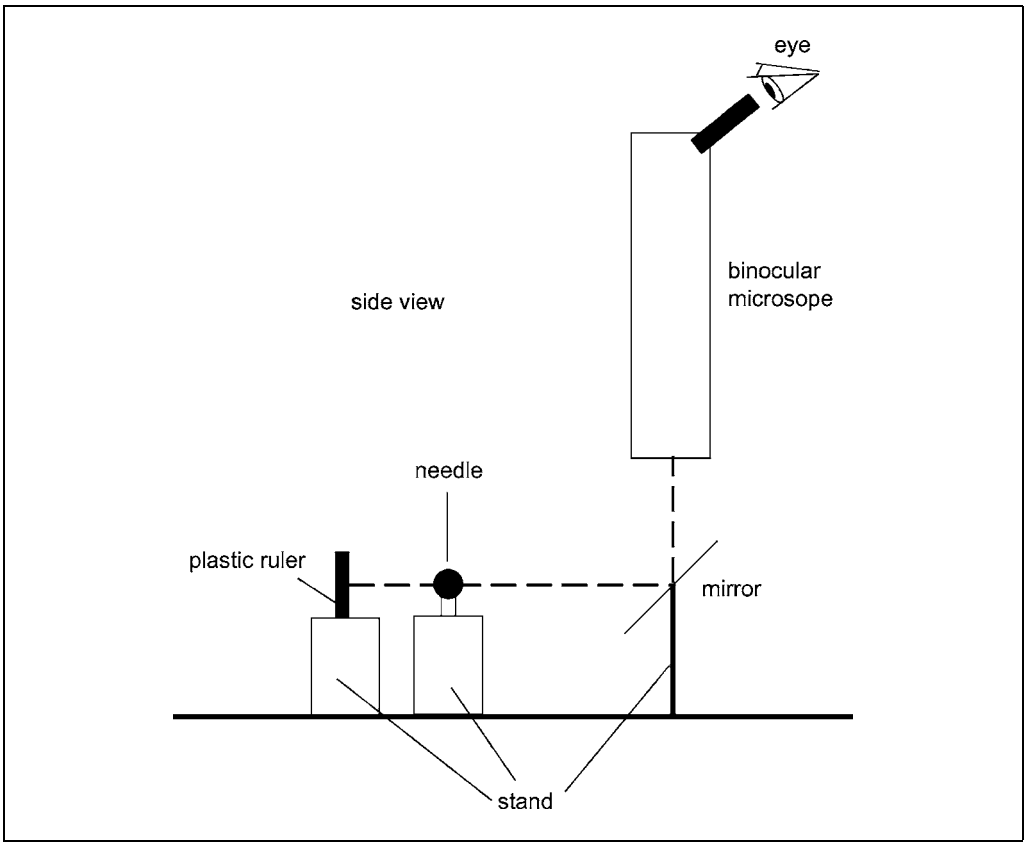

Figure 22.9.8 Schematic of the needle calibration apparatus. Three stands are aligned and a mirror, a needle, and a transparent plastic ruler are aligned on top of them. A binocular microscope is placed vertically above the mirror and adjusted to allow observation of both the needle and the plastic ruler.

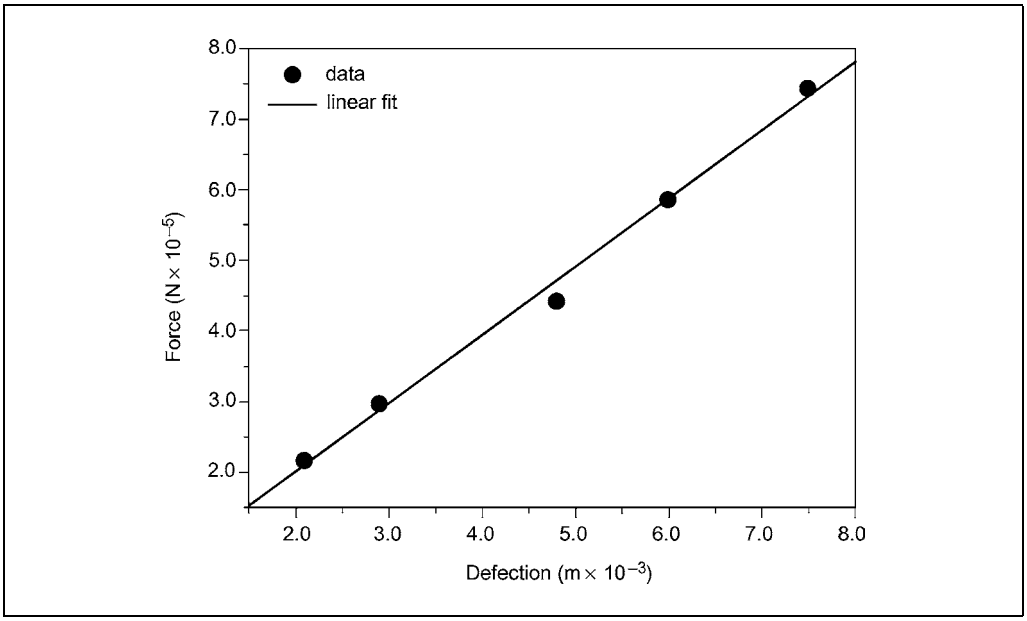

Figure 22.9.9 Graphic depiction of the spring constant of the needle. The force applied to the needle is plotted as a function of its deflection. The data points (circles) are fitted (gray line) to a line through zero. The slope of the gray line is the spring constant of the needle.

8. Calculate the force applied by the different copper wires (each one having a weight m) on the needle by the relation $F = mg$ where F is the force in newtons (N), m the weight in kg and g is the acceleration due to gravity (~ 9.8 meters/sec^2).

9. Plot the measured deflections (in meters) as a function of the force (in N) applied on the needle.

   For an example of graph, see Figure 22.9.9.

   The slope of the curve is the spring constant of the needle (K_{needle}).

10. Save the needle.

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

ATP regenerating system, 10×

Prepare the following 10× solutions fresh just before use:
200 mM phosphocreatine in 10 mM potassium phosphate buffer, pH 7.0 (*APPENDIX 2A*)
20 mM ATP, pH 7.0
50 μg/ml creatine kinase in 10 mM potassium HEPES, pH 7.5/50% (v/v) glycerol
Add each solution individually to reaction at final concentration of 1×

Buffer R

15 mM PIPES, pH 7.4
15 mM NaCl
7 mM $MgCl_2$
80 mM KCl
0.2 M sucrose
3% (w/v) bovine serum albumin
Prepare fresh and cool to 4°C before use

Buffer S

15 mM PIPES, pH 7.4
15 mM NaCl
7 mM $MgCl_2$
80 mM KCl
0.2 M sucrose
20 mM maltose
0.05% (w/v) lysolecithin
Prepare fresh and cool to 4°C before use

Buffer T

15 mM PIPES, pH 7.4
15 mM NaCl
7 mM $MgCl_2$
80 mM KCl
0.2 M sucrose
Prepare fresh and cool to 4°C before use

EB buffer

80 mM β-glycerophosphate (Sigma)
20 mM EGTA, pH 7.3
15 mM $MgCl_2$
1 mM DTT, pH 7.3
Store up to several months at −20°C

Fix/stain buffer

Prepare the following in filtered ultrapure H_2O:
1×10^{-5} M Hoechst 33258
200 mM sucrose
7.4% (w/v) formaldehyde
10 mM HEPES pH 7.5
Store up to 1 month at 4°C

This buffer must only be used for chromosome observation, not chromosome manipulation (because of the presence of formaldehyde).

COMMENTARY

Background Information

The first experiment where chromosomes were stretched (Nicklas, 1983) was performed using grasshopper somatic chromosomes. The goal of that experiment was to measure the force applied by the mitotic spindle on the chromosomes during anaphase. The first report on the elasticity of mitotic chromosomes assembled in *Xenopus* egg extract was published in 1999 (Houchmandzadeh and Dimitrov, 1999). In this work, an original combination of the measurements of both the bending rigidity and the longitudinal deformability of individual chromosomes was applied to the study of mitotic chromosome organization. Hard physical data were obtained indicating that the chromosome is formed by a few rigid elastic axes surrounded by a soft chromatin envelope. It was demonstrated that these axes are implicated in the maintenance of the overall chromosome structure. Recently, by coupling stretching experiments with microinjection of DNase I and proteases on an individual chromosome, Almagro et al. (2003a,b) showed that the intactness of DNA and proteins is important for the maintenance of chromosome integrity. Therefore, both the DNA and some specific proteins are involved in the organization of the chromosome axes. Almagro et al. (2003a,b) have shown that the axes exhibit a modular structure where the structural maintainance of chromosome (SMC) proteins are major players.

Critical Parameters and Troubleshooting

See Tables 22.9.1 and 22.9.2 for problems and possible solutions.

Anticipated Results

Sperm nuclei preparation

The demembranated sperm nuclei show a wormlike shape, and, if demembranation is complete, they are uniformly labeled by

Table 22.9.1 Troubleshooting Guide to Preparation of Sperm Nuclei

Problem	Possible cause	Solution
Few sperm nuclei visible when observed under the fluorescence microscope	Suspension of sperm nuclei is not concentrated enough	Repeat step 17 and step 18 to concentrate the sperm suspension
Sperm nuclei are aggregated	Sperm nuclei concentration is too high	Resuspend pellet with more buffer T during step 17
	Sperm nuclei are sensitive to repeated cycles of freezing/unfreezing	Use each aliquot only once and thaw just before use

Table 22.9.2 Troubleshooting Guide to Preparation of Micropipets

Problem	Possible cause	Solution
Micropipets are too rigid	Heat is too low	Increase the heat (be careful not to melt the filament).
	Velocity is too low	Increase the velocity (too high a value leads to bad reproducibility).
Micropipets are too flexible	Heat is too high	Decrease the heat.
	Velocity is too high	Decrease the velocity.
Micropipets are not reproducible	Heat is too high and/or Pressure is too low[a]	Adjust Heat and/or Pressure[a].
	Filament does not have the correct geometry	Reform the filament with the correct geometry (Fig. 22.9.6).
Some particles seem to be blocking the fluid in the micropipet.	Dust has penetrated into the micropipet	Be careful to not contaminate the capillaries with dust. Pull the micropipet just before use.
	Bad geometry of the filament	Reform the filament with the correct geometry (Fig. 22.9.6).

[a] See Support Protocol 3, step 12.

staining with Hoechst 33258. The expected yield per testis is the equivalent for 30 to 50 chromosome assemblies.

Chromosome assembly

If the chromosome assembly has gone to completion, the chromosomes are well separated from each other. This is a requirement for carrying out successful stretching experiments. It is difficult to quantify the chromosome concentration, but there are ~10,000 to 15,000 per μl of the chromosome assembly mix.

Chromosome elasticity

The in vitro–assembled mitotic chromosomes have a mean stretch modulus around 100 to 110 pN (standard deviation, ~60 pN and standard error, ~20 pN, see Almagro et al. 2003a,b, for details).

Time Considerations

Sperm nuclei preparation

Preparation of sperm nuclei can be completed in 1 day.

Chromosome assembly

The chromosome should be assembled in no more than 5 hr. If the assembly takes longer than that, use another mitotic extract.

Micropipet preparation

The preparation of the micropipets takes 2 days. During the first day the capillaries are cleaned and dried, and on the second day the micropipets are pulled.

Chromosome stretching experiment

The whole experiment must be completed within the same day. In the morning, start the assembly of the chromosome. During the assembly, prepare the reservoirs and verify that all parts of the apparatus work correctly. In the afternoon, stretch the chromosomes. The authors have found that chromosomes are stable for a period of 8 hr after the start of chromosome assembly.

Analyzing the results

The time required for analyzing the results of one chromosome stretching is variable. It depends on the duration of the chromosome stretching experiment, the number of images that were taken, and the availability of a homemade software that is able to automatically detect the position of the micropipets on the images. Thus, the time needed to extract the results from one chromosome stretching experiment varies from <1 hr to 1 day.

Replication Labeling with Halogenated Thymidine Analogs

DNA replication is essential for cell proliferation. Genetic information contained in the genome must be duplicated before each cell division (Gilbert, 2002; Goren and Cedar, 2003). Because the genome of eukaryotes consists of long, linear chromosomes, DNA replication must initiate at many positions along the length of the entire chromosome in order to complete replication in a timely fashion. DNA replication proceeds via the synchronous firing of clusters of about six replication origins that together form coordinately replicated domains of several hundred kilobases (Berezney et al., 2000). These coordinately replicated "replication domains" appear as punctuate foci when sites of DNA synthesis are pulse-labeled. Despite the fact that replication domains derive from many different chromosomal sites, the same cohort of replication foci replicate synchronously from cell cycle to cell cycle, implying a tight coordination of the temporal order of replication domains throughout S-phase (Ma et al., 1998; Dimitrova and Gilbert, 1999; Zink et al., 2004). Although the biological function of this temporal order is not understood, it has been shown that domains that replicate at particular times are localized to distinct regions of the nucleus, suggesting a relationship between replication domains and nuclear organization (McNairn and Gilbert, 2003). Mounting evidence suggests that replication domains form structural and functional units of chromosome organization (Bornfleth et al., 1999; Edelmann et al., 2001; Sadoni et al., 2004). Because replication is regulated at the level of large chromosomal domains, studies relating DNA replication to nuclear structure and function can be performed with the light microscope.

In higher eukaryotes, the molecular factors that dictate where and when replication will initiate are poorly understood. Replication origins do not appear to consist of any particular DNA sequence (Gilbert, 2001, 2004). Furthermore, replication origin activity is regulated both during development and in response to DNA damage or the metabolic state of cells (Anglana et al., 2003; Gilbert, 2005; Norio et al., 2005). Hence, studies of replication origins must be performed without any bias regarding where they may appear under different conditions. The distribution and spacing of origins throughout the genome, as well as the rate of elongation of replication forks, can reveal important information regarding the physiological state of cells without knowledge of the specific initiation sites. In addition, observing the positions of replication origins along the length of specific DNA fibers can reveal the positions of initiation sites to within a few kilobases.

In this unit, several conventional protocols to visualize replication foci in mammalian cells are described. Basic Protocol 1 describes visualizing DNA replication sites with bromodeoxyuridine (BrdU); this is the most basic procedure to visualize replication foci by identifying the sites of DNA synthesis. Newly synthesized DNA can be labeled with halogenated thymidine analogs such as BrdU. After immunostaining, replication foci containing BrdU-labeled replication forks can be observed using fluorescence microscopy. Basic Protocol 2, a combination of replication labeling and fluorescence in situ hybridization, is a typical application to examine the replication and subnuclear location of specific sequences, revealing the positional relationship between DNA synthesis and specific DNA regions. Basic Protocol 3, dual replication labeling with chloro- and iododeoxyuridine, provides an opportunity to examine the dynamics of DNA synthesis without the need for cumbersome cell-synchronization methods. This protocol distinguishes two different stages of S-phase by separating two different pulse labels with increasing chase times. Finally, Basic Protocol 4, replication labeling of DNA fibers, is

Contributed by Tomoki Yokochi and David M. Gilbert
Current Protocols in Cell Biology (2007) 22.10.1-22.10.14

a convenient method to observe replication sites on stretched DNA fibers, rather than on tangled DNA strands in the nucleus. Methods to examine the positional relationship between DNA synthesis and specific proteins or histone modifications have been described elsewhere (Wu et al., 2005b).

BASIC PROTOCOL 1

VISUALIZING DNA REPLICATION SITES WITH BROMODEOXYURIDINE (REPLICATION LABELING)

This protocol describes replication labeling. BrdU is added to culture medium to label replication sites (BrdU incorporation). Cells are treated with fixatives and detergents as necessary (fixation and permeabilization). BrdU incorporated in the genome is recognized by incubation with an appropriate antibody (immunostaining). Fluorophore-conjugated antibodies are observed by fluorescence microscopy (visualization). Anticipated images are shown in Figure 22.10.1.

Materials

Adherent tissue culture cells and appropriate medium
10 mg/ml bromodeoxyuridine (BrdU) stock in sterile tissue culture–grade water (store indefinitely at −20°C)
Phosphate-buffered saline (PBS; *APPENDIX 2A*)
2% (w/v) paraformaldehyde in PBS
0.4% (v/v) Triton X-100
1.5 N HCl
5% (w/v) BSA in PBST (0.5% v/v Tween 20 in PBS)
Primary antibody: monoclonal mouse anti-BrdU antibody (Becton Dickinson)

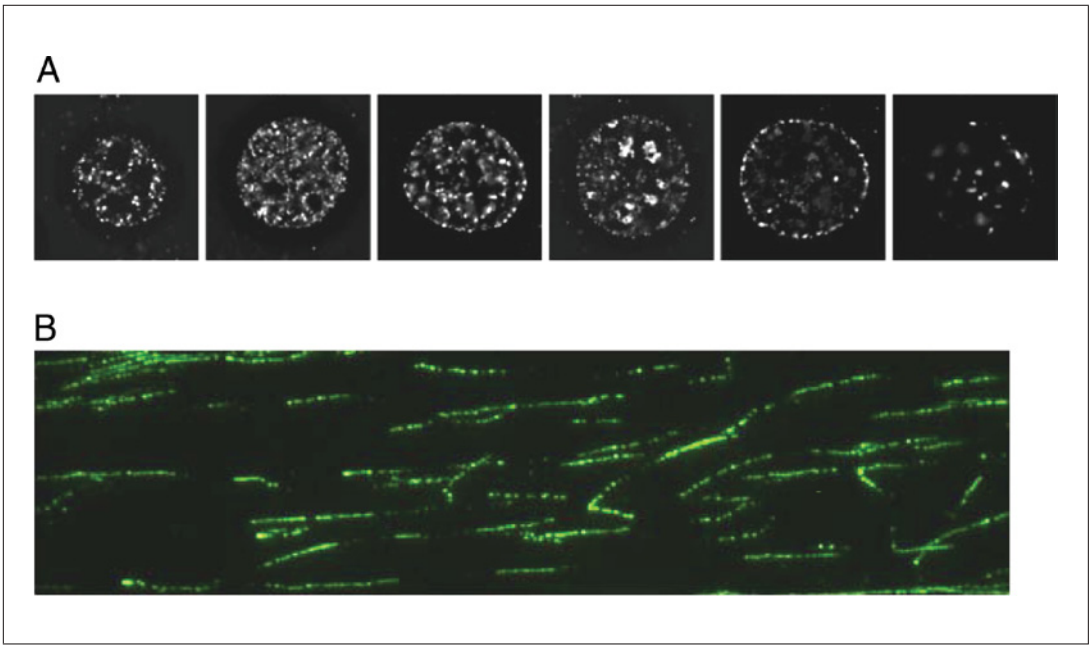

Figure 22.10.1 (**A**) Replication patterns visualized by BrdU incorporation during S-phase. Images are shown by courtesy of The American Society For Cell Biology. (Wu et al., 2005a). (**B**) DNA fibers visualized by CldU incorporation (F. Li and D.M. Gilbert, unpub. observ.). For the color version of this figure go to *http://www.currentprotocols.com*.

Secondary antibody: Alexa Fluor 495–conjugated goat anti-mouse antibody (Molecular Probes)
PBST: 0.5% (v/v) Tween 20 in PBS
1 μg/ml DAPI in Vectashield (Vector Labs) mounting medium

100-mm tissue culture dishes for plating cells on coverslips
12-mm-diameter round glass coverslips, sterilized by flaming after dipping in 70% ethanol or by autoclaving
24-well tissue culture plate
Glass microscope slides
Clear nail polish
Fluorescence microscope (*UNIT 4.2*) with appropriate color filters for fluorophores used, e.g., blue (DAPI), green (FITC, Alexa Fluor 488), and red (e.g., Texas Red, Alexa Fluor 594)

Additional reagents and equipment for cell culture (*UNIT 1.1*) and fluorescence microscopy (*UNIT 4.2*)

Prepare cells labeled with BrdU

1. Plate 5×10^6 adherent cells in a 100-mm tissue culture dish containing several round coverslips. Incubate overnight to allow cells to attach to coverslips.

   The authors use mammalian cells in their laboratory but believe that any tissue culture cells can be used in this protocol. The size of the dish and number of cells plated may vary depending upon the density desired. If cell density is too low, the yield in terms of cell number will be compromised; if density is too high, BrdU incorporation is decreased. Typically use 0.5–2 × 10^6 cells/ml.

   Basic cell culture techniques are described in UNIT 1.1.

2. Add sufficient 10 mg/ml BrdU stock solution for a final concentration of 10 μg/ml. Incubate the dish 30 min at 37°C.

3. Transfer the coverslips into a new container (24-well tissue culture plate recommended) containing prewarmed growth medium. Rinse the cells on the coverslip twice, each time with 1 ml PBS.

   Use of a 24-well culture dish as a container is convenient for handling many coverslips. Coverslips can be transferred to the 24-well dish one at a time prior to the BrdU labeling step to allow multiple time points with the same cell population.

4. Aspirate PBS. Add 0.5 ml/well of 2% paraformaldehyde solution and incubate for 10 min at room temperature. Wash twice with 1 ml/well PBS and remove the medium. Add 0.5 ml/well of 0.4% Triton X-100 and incubate for 10 minutes to permeabilize the cells. Wash twice with 1 ml/well PBS.

   If 3-D structure of the nucleus is not important, simply add 70% ethanol to fix the cells and incubate for 10 min at room temperature. The fixed cells on the coverslip can be stored in the 70% ethanol solution at 4°C for 1 week.

5. Aspirate PBS. Add 0.5 ml/well of 1.5 N HCl and incubate for 30 min to denature DNA.

6. Wash twice with 1 ml/well PBS and remove the medium.

7. Add 5 ml/well of 5% BSA and incubate for 10 min at room temperature. Remove the medium.

Immunostain cells

The antibody dilution factors below are those typically used in the authors' laboratory, but these should be determined empirically, and they depend on the cells and culture conditions used.

8. Dilute primary antibody (i.e., anti-BrdU mouse monoclonal antibody) 1:10 to 1:100 (depending on affinity of secondary antibody) in PBST. Add 30 µl of the diluted antibody to the cells on each coverslip. Incubate 30 min at room temperature.
9. Wash three times with 1 ml/well PBST. Aspirate PBST.
10. Dilute fluorophore-conjugated secondary antibody (i.e., Alexa Fluor 495–conjugated goat anti-mouse antibody) 1:100 in PBST. Add 30 µl of the diluted secondary antibody to the cells on each coverslip. Incubate 30 min at room temperature.
11. Wash three times with 1 ml/well PBST. Aspirate PBST.

Mount cells for imaging

12. Pipet 5 µl Vectashield containing 1 µg/ml DAPI on a glass microscope slide. Place the round coverslip with the labeled cells, cell-side-down, over the drop and seal with clear nail polish.

    Avoid air bubbles. If trapped air bubbles are a problem, Vectashield can be pipetted directly onto the coverslip first; the coverslip is then placed on the glass slide with the cell side facing down.

13. Observe the cells using fluorescence microscopy (*UNIT 4.2*) with appropriate filters for the fluorophore.

BASIC PROTOCOL 2

COMBINATION OF REPLICATION LABELING AND FLUORESCENCE IN SITU HYBRIDIZATION (FISH)

This protocol describes how to simultaneously visualize replication sites and specific sequences in the genome by fluorescence in situ hybridization (FISH). Cells are swollen in hypotonic buffer before being fixed using methanol/acetic acid (3:1). The DNA region of interest—gene locus, promotor region, or functional domain—is visualized by in situ hybridization with a specific DNA probe, while replication domains are visualized by BrdU labeling. Up to eight glass slides can be processed in one Coplin jar using this procedure.

Materials

Adherent tissue culture cells and appropriate medium
10 mg/ml bromodeoxyuridine (BrdU) stock (store indefinitely at −20°C)
Phosphate-buffered saline (PBS; *APPENDIX 2A*)
Trypsin solution (see recipe)
Fixative: 3:1 (v/v) methanol/acetic acid (prepare fresh and store on ice)
75 mM KCl
0.0625 µg/µl probe DNA sequence in TE buffer (see *APPENDIX 2A* for TE buffer)
Roche Nick Translation Mix (for digoxigenin or biotin, depending on desired labeling
0.5 mM disodium EDTA, pH 8.0
Hybridization mix (see recipe)
2× SSC (*APPENDIX 2A*) containing 0.1 mg/ml RNaseA
2× and 0.1× SSC (*APPENDIX 2A*)
70%, 90%, and 100% (v/v) ethanol
Clear nail polish
2× SSC (*APPENDIX 2A*)/70% (v/v) formamide
2× SSC (*APPENDIX 2A*)/50% (v/v) formamide
SSCT: 4× SSC (*APPENDIX 2A*)/0.1% (v/v) Tween 20
Blocking solution: SSCT (see above) containing 5% (w/v) nonfat dry milk

Primary antibody solution: cocktail in blocking solution of sheep anti-digoxigenin, FITC-conjugated (Molecular Probes) and mouse anti-BrdU (Becton Dickinson), each at a dilution of 1:10

Secondary antibody solution: cocktail in blocking solution of rabbit anti–sheep IgG, FITC-conjugated (Vector Labs), diluted 1:10, and goat anti–mouse IgG, Alexa Fluor 594–conjugated (Molecular Probes), diluted 1:500

Vectashield mounting medium (Vector Labs)

100-mm tissue culture dishes

15-ml conical centrifuge tubes

Centrifuge

Glass microscope slides

15°C water bath (kept in cold room)

45°, 65°, and 80°C water bath

Coplin jars

Vacuum desiccator with desiccant (e.g., silica gel)

18 × 18–mm square glass coverslips, sterile

Slide warmer (Precision Scientific)

Humidified chamber (e.g., covered Tupperware container with moistened paper towels on the bottom)

22 × 40–mm glass coverslips

Fluorescence microscope (*UNIT 4.2*) with appropriate color filters for fluorophores used, e.g., blue (DAPI), green (FITC, Alexa Fluor 488), and red (e.g., Texas Red, Alexa Fluor 594)

Additional reagents and equipment for cell culture technique including counting cells (*UNIT 1.1*) and fluorescence microscopy (*UNIT 4.2*)

Grow cells and treat with BrdU

1. Grow the cells in a 100-mm tissue culture dish to the appropriate cell density (*UNIT 1.1*).

   For overnight incubation seed 5 × 10^6 cells.

   If cell density is too low, the yield in terms of cell number will be compromised; if density is too high, BrdU incorporation is decreased. Typically, use 0.5–1 × 10^6 cells/ml.

2. Add 10 mg/ml BrdU to a final concentration of 10 μg/ml. Incubate the dish for 30 min at 37°C.

3. Rinse the cells twice with 10 ml PBS.

Permeabilize cells by hypotonic shock

4. Dissociate the cells into a single-cell suspension using 2 ml trypsin solution (also see *UNIT 1.1*), add 6 ml of serum-containing growth medium to stop the reaction, and collect them in a 15-ml conical tube. Determine cell number (*UNIT 1.1*).

5. Centrifuge cells 1 min at 200 × *g*, room temperature. Remove the supernatant. Resuspend the cells gently with 10 ml of 75 mM KCl at 1 × 10^6 cells/ml (total 1 × 10^7 cells) and incubate for 15 min at room temperature to swell the cell bodies.

   Cell concentration is critical for swelling.

   Prepare fresh fixative solution (3:1 methanol/acetic acid) during this time and keep it on ice.

Fix cells

6. Add 300 μl methanol/acetic acid fixative per 10 ml of KCl solution, dropwise, while gently vortexing the cell suspension. Leave the mixture 5 to 10 min at room temperature.

   During this incubation period, do not agitate the cell suspension, as this causes cells to aggregate.

7. Centrifuge the cells 1 min at 200 × *g*, room temperature. Remove the supernatant.
8. Add sufficient methanol/acetic acid fixative to adjust the cell density to 2×10^6 cells/ml. Incubate cells at −20°C for at least 1 hr or keep this cell suspension overnight in −20°C freezer.
9. Transfer 1×10^7 cells into a new 15-ml conical tube. Centrifuge the cells and resuspend the pellet with 5 ml methanol/acetic acid fixative.

   Note that the final cell density should be ~ 2×10^6 cells/ml.

   This step is essential to remove unnecessary salt that may interfere with clear imaging on the microscope. The cell suspension after this step can be stored at −20°C for up to 3 months.

Prepare mitotic spreads on glass slides

10. Dilute the fixed cell suspension 1/2 to 1/20 in methanol/acetic acid fixative.
11. Place or drop 10 µl of the diluted cell suspension on the glass microscope slide. Dry the specimen at room temperature for 10 min.

    At this stage, slides can be stored in the dark at room temperature indefinitely.

Prepare DNA probe labeled with digoxigenin or biotin and prepare probe mix

12. Mix 16 µl of 0.0625 µg/µl probe DNA solution (total amount 1 µg DNA) and 4 µl of Roche Nick Translation Mix (for digoxigenin or biotin, depending on desired labeling). Incubate for 90 min at 15°C in a water bath kept in a cold room.
13. Add 1 µl of 0.5 mM disodium EDTA pH 8.0, to stop the reaction. Heat the mixture at 65°C for 10 min. Combine 1 µl of this labeled probe DNA with 12 µl hybridization mix to prepare the probe mix. Mix well and denature 5 min at 95°C, then immediately place on ice and let stand 5 min.

Perform in situ hybridization

14. In Coplin jars, prewarm 40 ml 2× SSC containing 0.1 mg/ml RNase A at 37°C and 40 ml 2× SSC/70% formamide at 80°C.
15. Incubate the slides in 2× SSC containing 0.1 mg/ml RNase A in the first Coplin jar at 37°C for 30 min.
16. Transfer the slides to a second Coplin jar containing 2× SSC and wash briefly.
17. Dehydrate slides in Coplin jars containing 40 ml of each of the following ethanol solutions at room temperature for the times indicated:

    70% ethanol for 4 min
    90% ethanol for 4 min
    100% ethanol for 4 min.

18. Desiccate the slides under low pressure in a vacuum desiccator containing desiccant (e.g., silica gel) for at least 10 min.
19. Denature the slides in 40 ml 2× SSC/70% formamide at 80°C for 2 min.
20. Immediately dehydrate slides in Coplin jars containing 40 ml of each of the following ethanol solutions at room temperature for the times indicated:

    70% ethanol for 2 min
    90% ethanol for 2 min
    100% ethanol for 2 min.

21. Desiccate the slides in a vacuum desiccator for at least 10 min.

22. Warm the slides, probe mix (from step 13), and 18 × 18–mm coverslips on a slide warmer at 37°C. Place a humidified chamber in a 37°C incubator.

23. Pipet 12 μl probe mix on a prewarmed coverslip, then put it upside down on the slide. Seal with clear nail polish and place in the prewarmed humidified chamber. Incubate in 37°C incubator for 6 to 12 hr.

    Placing probe mix solutions on coverslips first before placing on the glass slides helps avoid trapping air bubbles under the coverslip.

24. Prewarm at least 120 ml of 2× SSC/50% formamide and at least 120 ml of 2× SSC at 45°C. Prewarm at least 120 ml of 0.1× SSC at 45°C to 80°C (optimal temperature determined empirically, see annotation to step 25).

25. Remove the nail polish from around the coverslip and wash the slides in Coplin jars for 5 min with 40 ml each of the washing solutions shown below:

    2× SSC/50% formamide at 45°C, three washes
    2× SSC at 45°C, three washes
    0.1× SSC at 45° to 80°C (optimized empirically), three washes.

    Every probe has unique hybridization properties. To achieve better signal-to-noise ratio, conditions for the final washing step (with 0.1× SSC) should be determined empirically. If background proves too high in a pilot experiment, use a higher temperature of 0.1 × SSC (i.e., more stringent washing conditions; 80°C); if background is low and signal is low, use a lower temperature of 0.1 × SSC (more relaxed washing conditions; 45°C).

26. Wash briefly in 40 ml SSCT in a Coplin jar at room temperature. Incubate the slides in a Coplin jar with 40 ml blocking solution at room temperature for >30 min.

Immunostain cells

27. Pipet 30 μl primary antibody solution onto the slide and cover with a 22 × 40–mm coverslip. Incubate the slide for 40 min at room temperature.

    It should be noted that the primary antibodies used here to detect the BrdU and FISH (digoxigenin) signals must be produced in different animal species in order to prevent cross-reaction of the secondary antibodies.

    Note that although the primary and secondary antibodies in this protocol are applied as a cocktail, in some cases this is not possible owing to the incompatibility of antibodies. For instance, if one of the secondary antibodies (e.g., rabbit anti–sheep IgG-FITC) were mouse anti-sheep IgG-FITC, it would not be possible to use the cocktail method because another secondary antibody (goat anti-mouse IgG-Alexa 594) could have a cross-reaction. In that case, the secondary antibodies would have to be applied sequentially, e.g., goat anti–mouse IgG–Alexa 594 first, then mouse anti–sheep IgG-FITC second.

    If biotin was used to label the probe (see step 12) only an anti-BrdU primary antibody is used, and the FISH signal is detected by fluorochrome-labeled avidin.

28. Wash the slides in Coplin jars three times, each time with 40 ml SSCT for 2 min.

29. Repeat steps 27 and 28 for the secondary antibodies.

    Signal intensity can be increased by sequential "sandwich" method if necessary (e.g., use avidin-Texas red as a first layer. Then use goat anti-avidin antibody conjugated to biotin as the second layer. Repeat this cycle to increase the signal).

Mount cells for imaging

30. Add 5 μl Vectashield mounting medium per slide and cover with 18 × 18–mm coverslip. Seal with clear nail polish and observe using a fluorescence microscope with appropriate filters for the fluorophores used (*UNIT 4.2*).

BASIC PROTOCOL 3

DUAL REPLICATION LABELING WITH CHLORO- AND IODODEOXYURIDINE

This section describes the procedure for visualizing replication sites using two halogenated thymidine analogs such as chlorodeoxyuridine (CldU) and iododeoxyuridine (IdU). It should be noted that the choice of primary antibodies is the key in this protocol. CldU is recognized by rat anti-BrdU antibody (Accurate Chemical), while IdU is recognized by mouse anti-BrdU antibody (Becton Dickinson). Anti-rat and anti-mouse IgG antibodies are used as secondary antibodies, respectively.

Materials

Cell culture on 12-mm round coverslips (Basic Protocol 1) in culture dish
10 mg/ml chlorodeoxyuridine (CldU) stock solution (store indefinitely at −20°C)
10 mg/ml iododeoxyuridine (IdU) stock solution (store indefinitely at −20°C)
Phosphate-buffered saline (PBS; *APPENDIX 2A*)
70% (v/v) ethanol
100% methanol
1.5 N HCl
PBST (0.5% v/v Tween 20 in PBS) containing 5% (w/v) BSA
PBST: 0.5% (v/v) Tween 20 in PBS
Primary antibody for CldU: rat anti-BrdU (Accurate Chemical)
Secondary antibody for CldU: FITC-conjugated goat anti-rat Ig (Molecular Probes)
Primary antibody for IdU: mouse anti-BrdU (Becton Dickinson)
Secondary antibody for IdU: Texas Red–conjugated donkey anti–mouse Ig (Jackson ImmunoResearch)
High-salt buffer (see recipe)
Vectashield mounting medium (Vector Labs)
Clear nail polish

12-mm-diameter round glass coverslips, sterilized by flaming after dipping in 70% ethanol or by autoclaving
100-mm petri dishes and 24-well plates
Humidified chamber (e.g., covered Tupperware container with moistened paper towels on the bottom)
Glass microscope slides
Fluorescence microscope (*UNIT 4.2*) with appropriate color filters for fluorophores used, e.g., blue (DAPI), green (FITC, Alexa Fluor 488), and red (e.g., Texas Red, Alexa Fluor 594)

Additional reagents and equipment for fluorescence microscopy (*UNIT 4.2*)

Pulse-chase-pulse label with CldU and IdU

1. Culture the cells on 12-mm round coverslips as in Basic Protocol 1.
2. Add the first halogenated thymidine analog (e.g., CldU) to the culture from 10 mg/ml stock solution for a final concentration of 10 μg/ml, to incorporate CldU in the genome. Incubate 30 min at 37°C.

   This is the first pulse step.
3. Change the medium to remove the analog and incubate the cells for the desired length of chase time.

   This is the chase step. The chase time depends on the objective of dual labeling and the properties of the cells (length of S-phase). To visualize the transition of replicating foci, the chase time can be omitted. To visualize the early and late replicating foci through the S-phase, the chase time should be 6 to 10 hr, depending on the length of the entire S-phase.

4. Add the second halogenated thymidine analog (e.g., IdU) to the culture from 10 mg/ml stock solution for a final concentration of 10 μg/ml. Incubate the dish for 30 min at 37°C.

   This is the second pulse step.

5. Rinse the cells on the coverslip twice with 10 ml PBS.

Prepare fixed cells on coverslips after double labeling

6. Immerse the coverslip in 10 ml of 70% ethanol in a 100-mm petri dish for 5 min at room temperature.

   Alternatively, transfer coverslips individually into wells of a 24-well plate at this step. In that case, use 1 ml/well of following reagents: 100% methanol (step 7), PBS (step 8), and 1.5 N HCl (step 9) per coverslip directly in the wells.

   The specimens can be stored indefinitely until use.

7. Incubate with 10 ml of 100% methanol for 5 min at room temperature.
8. Wash with 10 ml PBS twice.
9. Incubate with 10 ml 1.5 N HCl for 30 min at room temperature.
10. Wash with 10 ml PBS twice.

Stain with antibodies against CldU and IdU

Perform CldU staining

11. Block by incubating with 10 ml of 5% BSA in PBST for 20 min at room temperature. Transfer the coverslips to wells of a 24-well plate or a humidified chamber. Aspisate blocking solution.

    If the glass coverslips are kept inside a 24-well plate, the humidified chamber is not necessary; otherwise all staining steps should be done inside the humidified chamber.

12. Pipet 30 μl primary antibody (rat anti-BrdU antibody; diluted 1:10 in 5% BSA/PBST) onto the coverslip. Incubate 1 hr at room temperature.
13. Wash the coverslip three times, each time with 1 ml PBST for 5 min.
14. Pipet 30 μl secondary antibody (goat anti–rat IgG conjugated to FITC; diluted 1:10 in 5% BSA/PBST) onto the coverslip and incubate 1 hr at room temperature.
15. Wash three times with 1 ml PBST, each time for 5 min.

Perform IdU staining

16. Block by incubating with 10 ml of 5% BSA in PBST in a 100-mm petri dish for 20 min at room temperature. Transfer the coverslips to wells of a 24-well plate or a humidified chamber.

    If the glass coverslips are kept inside a 24-well plate, the humidified chamber is not necessary; otherwise all staining steps should be done inside the humidified chamber.

    When CldU and IdU staining are performed sequentially, this blocking step can be omitted, but be sure to prepare the antibody dilutions in blocking solution.

17. Pipet 30 μl primary antibody solution (mouse anti-BrdU antibody; diluted 1:10 in 5% BSA/PBST) onto the coverslip. Incubate for 1 hr at room temperature.
18. Wash the coverslip with 1 ml PBST three times, each time for 5 min at room temperature, then wash with 1 ml high-salt buffer for 15 min at room temperature.

    The wash with high-salt buffer is essential to avoid cross-reactivity of antibodies.

19. Pipet 30 µl secondary antibody (donkey anti–mouse IgG conjugated to Texas Red; diluted 1:10 in 5% BSA/PBST) onto the coverslip and incubate for 1 hr at room temperature.

20. Wash three times, each time with 1 ml PBST for 5 min.

Mount coverslips for imaging

21. Pipet 5 µl Vectashield mounting medium on a glass microscope slide. Place the coverslip with the labeled cells, cell-side-down, over the drop and seal with clear nail polish. Observe by fluorescence microscopy (*UNIT 4.2*) with appropriate filters for the fluorophores.

BASIC PROTOCOL 4

REPLICATION LABELING OF DNA FIBERS

This section describes the procedure to visualize replication sites on DNA fibers. BrdU-labeled cells are lysed in detergent-containing buffer on a glass slide. Tilting the glass slide extends DNA fibers along the surface of the slide. The fibers are fixed with methanol/acetic acid and are then immunostained.

Materials

Adherent tissue culture cells and appropriate medium
10 mg/ml bromodeoxyuridine (BrdU) stock (store indefinitely at −20°C)
Phosphate-buffered saline (PBS; *APPENDIX 2A*)
Lysis buffer (see recipe)
Fixative: 3:1 (v/v) methanol/acetic acid (prepare fresh and store on ice)
Blocking buffer: 1% (w/v) BSA in PBST (0.5% v/v Tween 20 in PBS)
PBST: 0.5% (v/v) Tween 20 in PBS
Primary antibody solution: mouse monoclonal anti-BrdU (Becton Dickinson), diluted 1:10 in blocking buffer (see above)
Secondary antibody solution: Alexa Fluor 594–conjugated goat anti–mouse IgG (Molecular Probes) diluted 1:500 in blocking buffer (see above)
Vectashield mounting medium (Vector Labs)

100-mm culture dishes
15-ml conical centrifuge tubes
Centrifuge
Glass microscope slides
Diamond pen (optional)
Coplin jars
Humidified chamber (e.g., covered Tupperware container with moistened paper towels on the bottom)
Fluorescence microscope (*UNIT 4.2*) with appropriate color filters for fluorophores used, e.g., blue (DAPI), green (FITC, Alexa Fluor 488), and red (e.g., Texas Red, Alexa Fluor 594)

Additional reagents and equipment for cell culture (including trypsinization and cell counting; *UNIT 1.1*) and fluorescence microscopy (*UNIT 4.2*).

Grow and label cells

1. Grow the cells in a 100-mm culture dish to the appropriate cell density (*UNIT 1.1*).

   For overnight incubation seed 5 × 10^6 cells.

   If cell density is too low, the yield in terms of cell number will be compromised; if density is too high, BrdU incorporation is decreased. Typically, use 0.5–1 × 10^6 cells/ml.

2. Add 10 mg/mlBrdU stock for a final concentration of 10 μg/ml. Incubate the dish 30 min at 37°C. Prepare cells without BrdU treatment under the same conditions at the same time.

   Alternatively, CldU and/or IdU can be used.

3. Trypsinize the cells (*UNIT 1.1*) and collect them in a 15-ml conical tube.

4. Centrifuge 1 min at 200 × *g*, room temperature, and remove supernatant. Add 10 ml PBS to the pellet, centrifuge again as before, and remove the supernatant.

5. Count the cells (*UNIT 1.1*). Prepare a single-cell suspension at 2×10^6 cells/ml in PBS.

   Mixing 20 μl labeled cells and 80 μl unlabeled cells can help to reduce the density of BrdU-incorporated DNA fibers on the slide, yielding clearer images. Unlabeled cells are also used as a negative control for immunostaining.

Prepare fibers

6. Place 2 μl of the cell suspension onto the edge of a glass slide.

7. Add 10 to 50 μl lysis buffer and mix briefly on the slide with a pipet tip. Incubate the slide for no more than 10 min at room temperature.

   The smaller the volume of lysis buffer, the better the result. However, it might be a bit difficult to handle a 10-μl volume of lysis buffer; therefore, beginners should try 20 to 50 μl.

8. Tilt the slide gradually to a 15° to 30° angle (e.g., by laying the slide on the edge of a test tube rack so that the one side of the slide is raised ∼2 cm).

   The cell lysate deposits DNA fibers as the cell suspension flows down the surface of the glass slide.

   It is useful to mark the extent of flow of the cell lysate on the opposite side of the slide with a diamond pen.

9. Pipet 400 μl freshly prepared fixation solution directly onto the slide. Incubate for 2 min, then remove the fixative and allow the slide to air dry.

   At this step, the glass slide can be stored in the dark at room temperature indefinitely.

Immunostain DNA fibers

10. Add sufficient blocking buffer (1% BSA in PBST) to cover the glass slide (∼1 ml) and incubate 20 min at room temperature.

    Large numbers of glass slides can be processed at the same time by using Coplin jars. Otherwise, pipet the solutions directly onto the glass slide.

11. Pipet 30 μl primary antibody solution onto the slide. Cover the slide with an 18 × 18–mm glass coverslip. Incubate the slide for 1 hr at room temperature in a humidified chamber.

12. Wash slides three times by immersion in 40 ml PBST in Coplin jars, each time for 3 min.

13. Add 30 μl secondary antibody and incubate for 1 hr at room temperature in a humidified chamber.

14. Wash slides three times by immersion in 40 ml PBST in Coplin jars, each time for 3 min.

Mount cells for imaging

15. Add 5 μl Vectashield mounting medium per slide and cover with 24 × 50–mm coverslip. Seal with clear nail polish and observe with a fluorescence microscope (*UNIT 4.2*) using the appropriate filters for the fluorochromes.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

High-salt buffer

Phosphate-buffered saline (PBS; APPENDIX 2A) containing:
0.5 % (v/v) Tween 20
0.4 M NaCl
0.2% (v/v) Nonidet P-40 (NP-40)
Prepare fresh

Hybridization mix

2 × SSC (APPENDIX 2A) containing:
50% (v/v) formamide
1% (v/v) Tween 20
10% (w/v) dextran sulfate
Prepare fresh

Lysis buffer

0.5% (w/v) sodium dodecyl sulfate (SDS; see *APPENDIX 2A* for 20% stock)
50 mM disodium EDTA
200 mM Tris·Cl, pH 7.4 (*APPENDIX 2A*)
Prepare fresh

Trypsin solution

Hanks' balanced salt solution (HBSS: APPENDIX 2A) without Ca, Mg, or bicarbonate, containing:
0.01% (w/v) trypsin
0.1 mM disodium EDTA

COMMENTARY

Background Information

Since the late 1960s, a variety of cytochemical methods have been developed to understand DNA metabolism in the nucleus. These techniques include autoradiography using tritium as well as dye staining using, e.g., Giemsa. Considering the sensitivity required to measure small amounts of newly synthesized DNA, the identification of proliferating cells has usually been accomplished by demonstrating [^{3}H]thymidine incorporation into DNA by autoradiography (Cleaver, 1967; Baserga and Malamud, 1969). The problem with tritium incorporation is that autoradiographic studies are time consuming. In addition, the radiation hazard posed by [^{3}H]thymidine has been a major barrier to its application in the field of clinical diagnostics and treatment, including cell kinetics and histopathology of human patients. Thus, investigators have been seeking a faster and less hazardous technique.

In the early 1970s, fluorescence quenching of DNA-specific fluorochromes by incorporated bromodeoxyuridine was developed (Latt, 1973; Stubblefield, 1975). Fluorescence quenching techniques using BrdU were first applied to flow cytometric studies of DNA replication (Dutrillaux et al., 1973). In the mid-1970s, antibodies raised against BrdU made possible an immunochemical method for detection of BrdU incorporated into DNA (Gratzner et al., 1975, 1976, 1978). In particular, the development of monoclonal anti-BrdU antibody significantly advanced microscopic methods, including image analysis, in the study of DNA synthesis (Gratzner, 1982). In combination with the use of fluorophore-conjugated secondary antibodies, immunochemical staining of incorporated BrdU and other halogenated thymidine analogs has been applied both to single cells and to tumor tissues, to estimate the labeling index of individual specimens (Raza et al., 1984; Nagashima and Hoshino, 1985).

Critical Parameters and Troubleshooting

Obviously, the most critical parameters common to all protocols described in this unit

are the concentration and incubation time for labeling with halogenated thymidine analog. Low concentrations result in lower signal-to-noise ratio, while high concentrations may affect cell viability because the thymidine analogs are toxic to cells. Short incubation periods yield low signal, whereas long incubation times result in larger regions being labeled, and, hence, lower resolution. In mammals, each replication focus takes 45 to 60 min to complete synthesis (Ma et al., 1998; Dimitrova and Gilbert, 1999), so periods longer than that will label several cohorts of foci. While the final concentration of 10 μg/ml and 30-min incubation time typically gives good results with most mammalian cells, the dose and period should be determined empirically. Different cell types may differ in their permeability or in the levels of endogenous thymidine pools, which affect the final intracellular concentration of labeled nucleoside. Thus, optimization may need to be performed if unexpected images are obtained.

It is feasible to employ a combination of the protocols in this unit to further analyze DNA replication. For example, it should be noted that the replication foci visualized by BrdU incorporation can be either replication origins or replication forks. To measure the density of active origins, IdU and CldU double labeling (Basic Protocol 3) should be employed in the DNA-fiber method (Basic Protocol 4). Cells are briefly labeled with IdU, followed by a longer CldU chase to allow forks to progress and to label the remainder of the long DNA fiber. DNA is then stretched on glass slides and stained with differentially labeled antibodies to highlight the sites of IdU and CldU incorporation. Short IdU stretches flanked on either side by long CldU stretches identify replication origins. The distances between these short IdU stretches can be measured under each experimental condition to evaluate the effects on the density of active replication origins (Pasero et al., 2002; Anglana et al., 2003; Norio et al., 2005).

Anticipated Results

Typical replication patterns visualized by BrdU incorporation are shown in Figure 22.10.1A. Cells were labeled with BrdU followed by anti-BrdU antibody immunofluorescence staining. Sites of BrdU incorporation (replication pattern) were shown in the order of appearance from early-S to late-S (left to right; Wu et al., 2005a). The results of dual replication labeling have been published (Dimitrova and Gilbert, 1999; Dimitrova et al., 1999; Li et al., 2003). DNA fibers labeled with CldU and visualized as per Basic Protocol 4 are shown in Figure 22.10.1B (F. Li and D.M. Gilbert, unpub. observ.). It should be noted that DNA fibers are not necessarily a single stretch of double-stranded DNA.

Time Considerations

Typically, replication labeling with one halogenated thymidine analog takes 30 min. After the labeling, an additional 1 hr is required to process the specimen. For immunostaining, typically 1 to 2 hr is required. Since FISH involves a hybridization step of 6 to 12 hr, 2 working days may be required. Preparation of DNA fibers usually takes <1 hr.

ABSTRACT

The synthesis of ribosomes is a major metabolic activity critical for cell growth and homeostasis. Understanding the mechanisms of ribosome biogenesis has important implications for studying both protein synthesis and cell cycle control. This unit describes several techniques for the analysis of rRNA maturation and ribosome assembly adapted for mammalian cells. Metabolic labeling of rRNA and hybridization analysis of precursors can be used to assess changes in rRNA processing that occur under experimental conditions of interest. Separation of preribosomal particles by sucrose gradient centrifugation is suitable for the analysis of proteins associated with preribosomes during their assembly and maturation in the cell nucleus. *Curr. Protoc. Cell Biol.* 39:22.11.1-22.11.16.

INTRODUCTION

During periods of rapid growth and high biosynthetic activity, transcription of ribosomal RNAs (rRNAs) accounts for the majority of RNA synthesis in the cell. One way to follow rRNA transcription and processing in cultured mammalian cells is to incubate the cells with a radioactive RNA precursor and analyze labeled RNA by gel electrophoresis. Basic Protocol 1 describes labeling of rRNA by using [5,6-^{3}H]uridine. Labeling with ^{32}P-orthophosphate ($^{32}P_i$; see Alternate Protocol 1) produces stronger signals and is preferred for the analysis of small rRNAs. Alternate Protocol 2 describes pulse-chase labeling of rRNA with the precursor of methyl groups L-[*methyl*-^{3}H]methionine to examine the kinetics of rRNA processing. The Support Protocol describes fluorographic detection of ^{3}H-labeled rRNA blotted on membranes.

A detailed picture of the steady-state levels of various pre-rRNA intermediates can be obtained by hybridization of cellular RNA with oligonucleotide probes specific to various regions of the rRNA or rRNA precursors (pre-rRNAs). This approach is detailed in Basic Protocol 2.

Processing of the rRNA transcript occurs in nuclear ribonucleoprotein complexes (preribosomes) that contain both ribosomal proteins and auxiliary factors necessary for the assembly and maturation of the ribosomal subunits. Basic Protocol 3 describes sucrose gradient centrifugation of preribosomal particles isolated from cell nuclei for the analysis of associated proteins.

CAUTION: Observe proper techniques for working with radioactivity and disposal of radioactive waste (*APPENDIX 1D*). To prevent accidental spillage of radioactive media inside a tissue culture incubator, place a plastic tray lined with an absorbent pad inside the incubator prior to adding the labeling plates.

DOI: 10.1002/0471143030.cb2211s39

NOTE: All culture incubations should be performed in a humidified 37°C incubator with the concentration of CO_2 appropriate for the cell culture medium used.

BASIC PROTOCOL 1

METABOLIC LABELING OF rRNA WITH [^{3}H]URIDINE

Labeling of the newly synthesized rRNA with tritiated uridine is a simple and inexpensive technique suitable for analysis of large rRNA precursors. In the following protocol, [5,6-^{3}H]uridine is added to a monolayer cell culture grown in a tissue culture plate. After a 2-hr incubation, cells are rinsed of excess label and total RNA is isolated using a phenol/guanidine thiocyanate reagent. The labeled RNA obtained in this way can then be analyzed by standard gel electrophoresis techniques, followed by nylon membrane blotting and fluorography.

The volumes in this protocol are for a 6-well plate. The procedure can be scaled in proportion to the surface area of the tissue culture vessel used.

Materials

Adherent cell cultures (e.g., NIH 3T3 cells)
Complete cell culture medium (e.g., DMEM supplemented with 10% FBS)
1 mCi/ml [5,6-^{3}H]uridine (specific activity ≥35 Ci/mmol)
Phenol/guanidine thiocyanate reagent (e.g., TRI Reagent, MRC or TRIzol, Invitrogen)
Deionized formamide
Scintillation fluid

6-well tissue culture plates
37°C, CO_2 humidified cell culture incubator
Flask for radioactive waste
Microcentrifuge tubes with screw-caps equipped with a rubber O-ring (tubes must withstand centrifugation forces of at least 12,000 × *g*)
55° to 65°C water bath
Liquid scintillation vials and counter

Additional reagents and equipment for RNA isolation (see manufacturer's protocol for the isolation reagent used) and RNA gel electrophoresis and nylon membrane transfer (Brown et al., 2004)

1. Set up cultures of adherent cells in a 6-well culture plate 1 to 2 days prior to labeling so that the cultures are subconfluent on the day of the experiment.

   For NIH 3T3 cells, plate ~2.5 × 10^5 cells per well of a 6-well plate in 2 ml DMEM containing 10% FBS 1 day before labeling. Confirm that cells look healthy prior to the experiment. rRNA synthesis will be significantly reduced if cell growth is inhibited by suboptimal conditions or contact inhibition.

2. Add [5,6-^{3}H]uridine to medium in each well to a final concentration of 3 μCi/ml. Immediately return cells to the 37°C, CO_2 humidified cell culture incubator and incubate for 2 hr.

3. Aspirate radioactive medium from each well into a flask for safe disposal. Rinse cell monolayers two times, each time adding 2 ml complete culture medium to a well and aspirating the medium into the same disposal flask.

4. Add 1 ml phenol/guanidine thiocyanate reagent directly to cells and lyse them by gentle mixing. Transfer lysates into screw-cap microcentrifuge tubes. Isolate total RNA following manufacturer's instructions for the RNA isolation reagent used.

   It is important to use screw-cap tubes that provide a tight seal to prevent leakage of radioactive samples during RNA purification.

5. Following isolation, dissolve RNA pellets in 15 µl deionized formamide. To ensure that RNA is completely dissolved, incubate 30 min on ice with occasional mixing followed by 10 min at 55° to 65°C.

^{3}H-labeled RNA dissolved in formamide can be stored for 1 to 2 months at −20°C or at least 1 year at −70°C.

Formamide protects RNA from degradation and simplifies handling of samples.

6. Measure [^{3}H] incorporation by liquid scintillation counting of 1 µl.

Incorporation observed in actively growing NIH 3T3 cells is typically 5–10 × 10^3 cpm/µg RNA, but may vary significantly depending on the cell line and growth conditions.

Optionally, determine RNA concentration either by measuring absorbance at 260 nm or fluorescent quantitation (APPENDIX 3D).

7. Separate RNA by agarose-formaldehyde gel electrophoresis and transfer to a nylon membrane.

Follow standard protocols for electrophoresis and blotting of RNA found in common molecular biology manuals (Brown et al., 2004). Detection of ^{3}H-labeled RNA blotted on nylon membranes by fluorography is described in the Support Protocol (also see UNIT 6.3). See Figure 22.11.1A for an example of results.

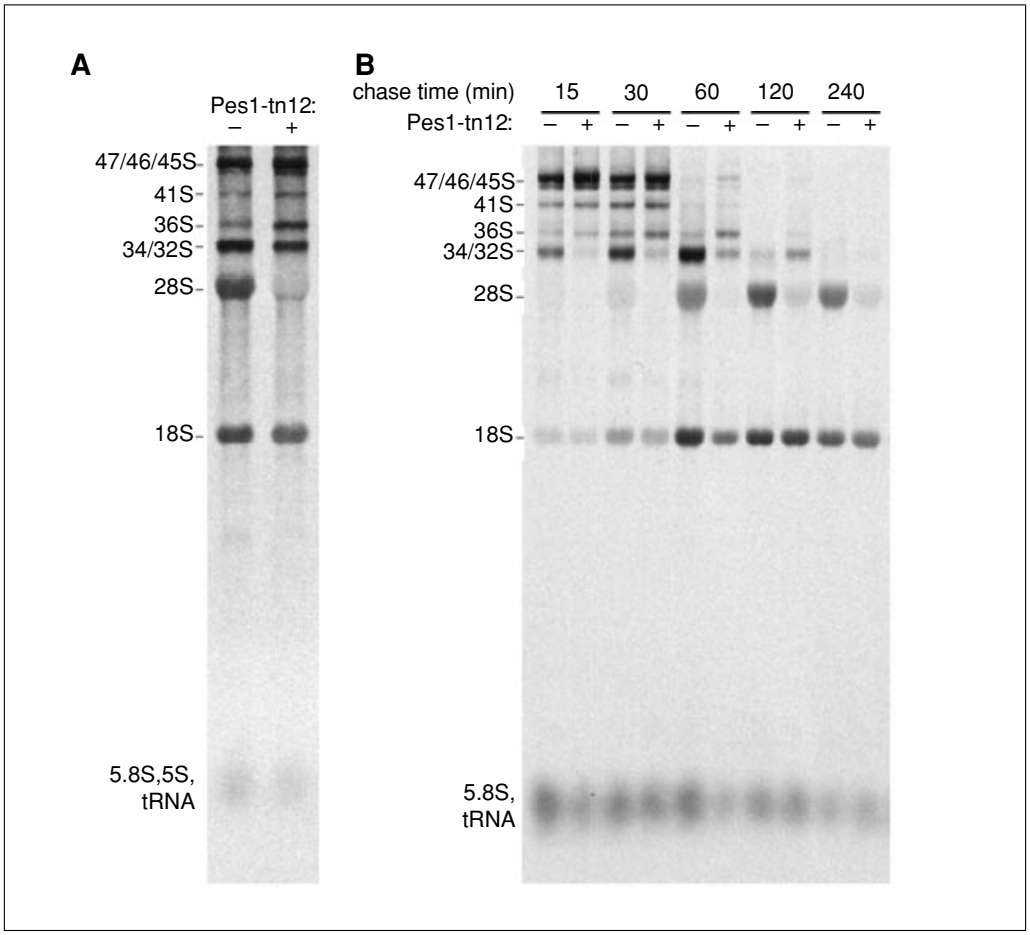

Figure 22.11.1 Gel analysis of labeled rRNA precursors from mouse cells. (**A**) An example of metabolic labeling with [^{3}H]uridine. (**B**) An example of pulse-chase labeling with L-[*methyl*-^{3}H]methionine. In the experiments shown, maturation of pre-rRNA in normal cells (– lanes) is compared with cells inducibly expressing Pes1-tn12 (+ lanes), a dominant-negative mutant of the processing factor Pes1 (Lapik et al., 2004). The positions of the major labeled RNA species are indicated on the left of each panel.

ALTERNATE PROTOCOL 1

METABOLIC LABELING OF rRNA WITH $^{32}P_i$

To improve detection of low-molecular-weight rRNA species (e.g., 5S, 5.8S) and their immediate precursors, it is more practical to use ^{32}P labeling, which significantly reduces exposure times necessary for detection. Cells are first pre-incubated in phosphate-free medium, followed by addition of $^{32}P_i$. After a 1-hr incubation, cells are briefly washed to remove the excess label and incubated for an additional 1.5 hr in complete medium. Total RNA is isolated using a phenol/guanidine thiocyanate reagent. ^{32}P-Labeled RNA separated on a gel can be detected using autoradiography or phosphorimaging (*UNIT 6.3*).

The volumes in this protocol are for a 6-well plate. The procedure can be scaled in proportion to the surface area of the tissue culture vessel used.

Additional Materials *(also see Basic Protocol 1)*

Phosphate-free cell culture medium (e.g., phosphate-free DMEM) supplemented with serum dialyzed against phosphate-free saline, prewarmed to 37°C
^{32}P-Labeled orthophosphate, carrier-free (10 mCi/ml $^{32}P_i$)
Aerosol-resistant tips
Plexiglas shields and other protective equipment for safe work with ^{32}P (*APPENDIX 1D*)

1. Grow cells as described in Basic Protocol 1, step 1.
2. One hr before labeling, replace cell growth medium with 1 ml prewarmed phosphate-free medium.
3. Add $^{32}P_i$ to the medium in wells containing cells to a final concentration of 20 μCi/ml.
4. Incubate cells 1 hr in a 37°C, CO_2 humidified cell culture incubator.
5. Discard $^{32}P_i$-containing medium into a radioactive waste container, and add 3 ml prewarmed complete growth medium to cells. Incubate for an additional 1.5 hr in a 37°C, CO_2 humidified cell culture incubator.

   It is recommended to use a pipettor equipped with aerosol-resistant tips to remove media containing high amounts of ^{32}P. Using a vacuum aspirator will spread radioactivity over large volumes, increasing exposure to the energetic radiation from ^{32}P.

6. Follow Basic Protocol 1, steps 3 to 6, to isolate RNA from cells.

   ^{32}P-Labeled RNA must be analyzed within a few days of labeling due to the short half-life of ^{32}P.

7. Carry out gel electrophoresis using either a denaturing polyacrylamide gel for analysis of small RNA species or an agarose-formaldehyde gel for large precursors (Brown et al., 2004).

   Follow standard procedures for electrophoresis of RNA found in common molecular biology manuals (see APPENDIX 3A). Since ^{32}P is a strong β-emitter, no transfer of RNA to membrane after electrophoresis is required; gels can be dried and analyzed directly by autoradiography or phosphorimaging (see UNIT 6.3).

ALTERNATE PROTOCOL 2

PULSE-CHASE LABELING OF rRNA WITH L-[*METHYL*-^{3}H]METHIONINE

L-[*methyl*-^{3}H]Methionine is a precursor for methyl groups that are abundant modifications in mature rRNAs. Because of the rapid turnover of the cellular methionine pool, this reagent can be used for pulse-chase labeling to study the kinetics of pre-rRNA processing. In addition, the overall background in this labeling is much lower compared to uridine or phosphate labeling because only methylated RNA is detected. However, any changes in rRNA methylation can affect labeling of precursors in this approach.

In this protocol, cells are briefly preincubated in methionine-free medium and then pulse-labeled for 30 min in medium containing L-[*methyl*-^{3}H]methionine. The chase is performed by incubating cells in medium containing an excess of methionine for various amounts of time. Total RNA is isolated using a phenol/guanidine thiocyanate reagent. The labeled RNA obtained this way can be analyzed by standard gel electrophoresis techniques, followed by nylon membrane blotting and fluorography (see Support Protocol).

The volumes in this protocol are for a 6-well plate (alternatively, 35-mm dishes can be used). The protocol can be scaled in proportion to the surface area of the tissue culture vessels used.

***Additional Materials** (also see Basic Protocol)*

Methionine-free cell culture medium (e.g., methionine-free DMEM) supplemented with dialyzed serum
1 mCi/ml L-[*methyl*-^{3}H]methionine (specific activity 70 to 85 Ci/mmol)
10× methionine medium: add methionine to culture medium at a final concentration of 0.3 mg/ml, prewarmed to 37°C

NOTE: L-[*methyl*-^{3}H]Methionine is prone to rapid decomposition if not properly stored. For storage conditions and shelf life, refer to the manufacturer's recommendations.

1. Grow cells as described in Basic Protocol 1, step 1.

   Prior to growing cells, determine the number of time points in the chase. Separate cell culture plates should be prepared for each time point.

2. For each plate, aspirate medium from wells and rinse cell monolayers once with 1 ml prewarmed methionine-free cell culture medium. Add 1 ml methionine-free cell culture medium and incubate 15 min in a 37°C, CO_2 humidified cell culture incubator.

3. Add L-[*methyl*-^{3}H]methionine to wells containing cells to a final concentration of 50 μCi/ml.

4. Incubate cells 30 min in a 37°C, CO_2 humidified cell culture incubator to label the RNA.

5. Aspirate L-[*methyl*-^{3}H]methionine-containing medium into a flask for safe disposal. Rinse wells with 2 ml prewarmed 10× methionine medium, aspirating it into the same disposal flask.

   Work fast to avoid temperature fluctuations.

6. Add 3 ml prewarmed 10× methionine medium to cells and return plate to the 37°C, CO_2 humidified cell culture incubator (note the time—this is the "zero" time point for the chase).

7. At appropriate times, remove corresponding cell culture plates from the incubator, isolate total RNA, and proceed with analysis as described in Basic Protocol 1, steps 3 to 7.

   Useful time points are 0, 15 min, 30 min, 1 hr, and 2 hr of chase. Depending on the cell type, a 4-hr time point may also be informative. Labeling efficiencies with methionine are usually lower than those obtained by using other techniques described in this unit, with specific activities in the range of 800 to 3500 cpm/μg RNA typically observed. See Figure 22.11.1B for an example of results using this method.

SUPPORT PROTOCOL

FLUOROGRAPHIC DETECTION OF ^{3}H-LABELED RNA ON NYLON MEMBRANES

Tritium (^{3}H) used for rRNA labeling in Basic Protocol 1 and Alternate Protocol 2 is a weak β-emitter that can be detected by coating RNA blots with a thin layer of a scintillant followed by exposure to a high-sensitivity photographic film. In this protocol, membranes containing blotted RNA are first sprayed with EN^{3}HANCE and then soaked in carbon tetrachloride, which acts as a solvent for the fluor and facilitates even coating of the membrane.

CAUTION: Work in a fume hood. Avoid breathing vapors.

NOTE: Nylon membranes used in the protocol are unaffected by carbon tetrachloride. Some plastic containers may dissolve in the fluor or carbon tetrachloride; if using other types than those recommended, check them first for solvent resistance.

Materials

Nylon membrane with transferred ^{3}H-labeled RNA (see Basic Protocol 1 or Alternate Protocol 2)
EN^{3}HANCE Spray (PerkinElmer Life)
Carbon tetrachloride (Sigma)

Glass or polypropylene tray (a size to fit the membrane)
Filter paper
High-sensitivity radiography film (e.g., Kodak BioMax MS or equivalent)

1. Before starting the procedure, make sure the RNA blot is completely dry.
2. Place the membrane in a suitable glass or polypropylene tray with the RNA side up.
3. Working in a fume hood, spray the membrane lightly with EN^{3}HANCE. Immediately add a small volume of carbon tetrachloride to completely cover the blot surface. Gently agitate the tray for several minutes to distribute the solution over the surface of the membrane.

   Carbon tetrachloride evaporates very rapidly creating a progressively more concentrated solution of the fluor, which will form a thin coating on the membrane once dried. Do not allow the solution to become too viscous, as it may lead to uneven coating.

4. Remove membrane when solvent has partially evaporated, but there is still enough free-flowing liquid to cover entire surface of membrane. Air dry membrane for 5 min on a piece of filter paper.
5. Expose membrane with direct contact to a radiography film in a light-proof cassette at −80°C. Develop film after a predetermined amount of time.

   Exposure length must be determined empirically. A good starting point is 1 to 2 days if labeling was performed with uridine and 2 to 5 days if labeled with methyl-methionine. Membranes can be repeatedly treated with carbon tetrachloride (with or without respraying, depending on the signal strength from the previous coating) and re-exposed until a satisfactory film is obtained.

BASIC PROTOCOL 2

HYBRIDIZATION OF rRNA PRECURSORS WITH OLIGONUCLEOTIDE PROBES

This protocol is designed to identify pre-rRNA species on a northern blot and examine changes in their steady-state levels. Oligonucleotide probes complementary to specific regions of the primary rRNA transcript are labeled at the 5′ termini with T4 polynucleotide kinase and [γ-^{32}P]ATP. The radiolabeled oligonucleotide probes are hybridized with RNA blotted onto a membrane.

Materials

Oligonucleotides (see Critical Parameters for details)
10× T4 polynucleotide kinase buffer (supplied with enzyme)
[γ-^{32}P]ATP (10 mCi/ml, specific activity ≥3000 Ci/mmol)
T4 polynucleotide kinase
0.5 M EDTA (*APPENDIX 2A*)
TE buffer (*APPENDIX 2A*)
Liquid scintillation fluid, optional
Nylon membranes containing total cellular RNA
2× and 5× SSC (see recipe)
Hybridization solution (see recipe)
2× SSC/0.1% SDS, room temperature and 70°C
0.1× SSC/0.1% SDS

1.5-ml microcentrifuge tubes
37°C and 60° to 75°C water baths or hybridization ovens
Spin columns (e.g., Micro Bio-Spin P-6 columns, BioRad) or equivalent
Liquid scintillation counter and vials, optional
Plastic boxes with tight-fitting lids or hybridization tubes suitable for the hybridization equipment used

Additional reagents and equipment for autoradiography or phosphorimaging (*UNIT 6.3*)

Radiolabel probes

1. Set up the labeling reaction by mixing the following components in a 1.5-ml microcentrifuge tube:

   10 pmol oligonucleotide
   2.5 μl 10× T4 polynucleotide kinase buffer
   16.5 pmol [γ-^{32}P]ATP (e.g., 5 μl of the 3000 Ci/mmol, 10 mCi/ml label)
   15 U T4 polynucleotide kinase
   water to 25 μl

2. Incubate 30 to 60 min in a 37°C water bath.
3. Stop the reaction by adding 0.5 μl of 0.5 M EDTA (final concentration of 10 mM) or by heating the reaction 10 min at 70°C.
4. Add 25 μl TE buffer to the labeling reaction and remove unincorporated [γ-^{32}P]ATP by centrifugation through a spin column according to the manufacturer's instructions.
5. Measure [γ-^{32}P]ATP incorporation by Cerenkov or scintillation counting.

   The typical specific activity of a probe determined by scintillation counting is 2–6 × 10^6 cpm/pmol. Alternatively, use a Geiger counter to quickly estimate the amount of radioactivity in the column eluate and the unincorporated label left in the column. Incorporation of the label should not be less than 50%.

   Probes can be stored at −20°C but they should be used within 2 to 3 days to avoid their degradation due to radiolysis.

Hybridize membrane

6. Prewet membrane to be hybridized in 5× SSC. Drain excess liquid.
7. Prehybridize membranes in hybridization solution (~0.2 ml/cm^2 membrane) 2 to 5 hr at 60°C.

8. Add the radiolabeled oligonucleotide directly to the hybridization solution in the container with the membrane to a final concentration of 100 to 200 pM.

   If using a probe directed against mature rRNAs, reduce oligonucleotide concentration to 20 pM to avoid an overly strong signal.

9. Hybridize overnight (12 to 18 hr) at 60°C.

10. Discard hybridization mixture and rinse membrane briefly in 2× SSC/0.1% SDS. Incubate with agitation in fresh changes of 2× SSC/0.1% SDS (0.6 to 0.7 ml/cm^2 membrane) as follows:

    a. 5 min at room temperature
    b. 10 min at room temperature
    c. 10 min at 70°C
    d. 5 min at room temperature.

    CAUTION: *Hybridization solution and all wash solutions should be treated as radioactive waste and disposed of appropriately.*

    If initial experiments show an excessive background or smear due to probe cross-hybridization, increase stringency of the high-temperature wash by 5° to 10°C.

11. Rinse the membrane in 2× SSC and wrap it securely in plastic wrap to prevent drying out. Use either autoradiography or phosphorimaging to detect hybridization signal.

    Keeping filters moist during exposure allows their subsequent reprobing after stripping. To strip filters, bring 0.1× SSC/0.1% SDS (0.6 to 0.7 ml/cm^2 membrane) to a boil and pour over the membrane. Incubate with agitation at room temperature until the solution cools down to 30° to 40°C. Repeat the procedure once, rinse the membrane with 2× SSC and check for the reduction of signal intensity by autoradiography or phosphorimaging.

BASIC PROTOCOL 3

SUCROSE GRADIENT ANALYSIS OF PRE-RIBOSOMAL RIBONUCLEOPROTEIN COMPLEXES

Preribosomes can be isolated from mammalian cell nuclei as heterogeneous particles with sedimentation coefficients ranging from ~50S to >100S. The first steps in the protocol describe isolation of nuclei and a sonication procedure for the extraction of preribosomes. The remaining steps describe separation of preribosomal particles by sucrose gradient centrifugation. A detailed discussion of the theory and methods for preparing and running sucrose density gradients can be found in *UNIT 5.3*. Proteins associated with preribosomal particles are recovered from gradient fractions by precipitation with TCA and can be further analyzed by SDS-PAGE and western blotting *(UNITS 6.1 & 6.2)*.

Materials

10% and 30% (w/w) sucrose solutions (see recipe)
Three 150-mm plates of subconfluent NIH 3T3 cells (~2 × 10^7 cells)
Phosphate buffered saline (PBS; *APPENDIX 2A*), ice cold
LSB (see recipe)
LSB$^+$ (see recipe)
10% (w/v) Igepal CA-630 (Sigma)
10% (w/v) sodium deoxycholate
Sonication buffer (see recipe)
0.1% (w/v) BSA (*APPENDIX 2A*)
100% TCA, 4°C
100% ethanol
Urea sample buffer (see recipe)
Polyallomer ultracentrifuge tubes for the SW41Ti rotor (9/16 × 3^1/$_2$– in., Beckman)

Plastic cell scraper
15-ml conical-bottom plastic centrifuge tubes
Refrigerated centrifuge with a swinging bucket rotor accommodating 15-ml conical-bottom tubes
1.5-ml microcentrifuge tubes
Ultrasonic processor equipped with a microtip
Refrigerated microcentrifuge
1-ml syringes and 20-G needles
Ultracentrifuge and SW41Ti rotor (Beckman)
50° and 95° to 100°C heating blocks

Additional reagents and equipment for gradient formation and fractionation (*UNIT 5.3*) and SDS-PAGE and immunoblotting (*UNITS 6.1 & 6.2*)

NOTE: This protocol was developed for NIH 3T3 cells. For other cell types, the amounts of detergents in steps 11 to 12 may require adjustment to isolate nuclei.

NOTE: Unless otherwise indicated, all steps in the protocol are performed at 4°C.

Prepare gradients

1. Prepare 10% to 30% (w/w) sucrose gradients in ultracentrifuge tubes (total volume 11.0 to 11.2 ml per tube) and store them at 4°C before use.

   Linear gradients can be prepared using any of the gradient makers available commercially (UNIT 5.3). Alternatively, a simple diffusion-based method can be used. Pipet 5.5 ml of 30% sucrose into a centrifuge tube, carefully overlay it with 5.5 ml of 10% sucrose solution, securely cap the tube with a silicone rubber stopper, and slowly lower the tube to a horizontal position. Keep the tube on its side for 3 hr at room temperature without moving, then carefully set it upright, and store overnight at 4°C. The resulting gradient will have an S-shaped rather than strictly linear concentration profile, but it is suitable for most types of work.

Isolate nuclei

2. Culture cells in three 150-mm tissue culture plates to obtain actively growing, sub-confluent cultures on the day of the experiment.
3. Discard growth medium from one plate and place plate on ice.
4. Rinse cell monolayer once with 10 ml ice-cold PBS.
5. Add 4 ml ice-cold PBS and scrape cells into the buffer. Pipet cell suspension into a 15-ml conical-bottom tube and store on ice.
6. Repeat with the remaining two plates combining cell suspensions into the same tube.
7. Pellet cells by centrifuging 5 min at 400–500 × *g*, 4°C, in a swinging bucket rotor.
8. Resuspend cell pellets in 2 ml ice-cold LSB by gently vortexing and incubate 10 min on ice.
9. Centrifuge as in step 7 to pellet swollen cells.
10. Resuspend cells in 2 ml LSB$^+$ by vortexing.
11. Add 66 µl of 10% Igepal CA-630 and briefly vortex tube to mix.
12. Add 44 µl of 10% sodium deoxycholate and vigorously vortex for 30 sec.

    The addition of detergents lyses the plasma membranes of swollen cells and facilitates removal of cytoplasmic material.

13. Centrifuge 5 min at 1000 × *g*, 4°C, to sediment crude nuclei.
14. Resuspend pellet in 2 ml LSB$^+$ by pipetting up and down with a 1-ml tip.

15. Repeat centrifugation as in step 13.

Phase-contrast microscopic examination of the pellet should show undamaged nuclei that may still have portions of the cytoplasmic membrane attached.

Sonicate nuclei and set up gradients

16. Resuspend nuclear pellets in 500 µl sonication buffer by gently pipetting up and down, and transfer to 1.5-ml microcentrifuge tubes.

17. Sonicate samples on ice using an ultrasonic processor equipped with a microtip to disrupt the nuclei.

When the procedure is performed for the first time, nuclear disruption should be monitored by phase-contrast microscopy. The intensity and duration of sonication should be adjusted so as to just break down nuclei in the sample; avoid oversonication. As a starting point, try ten 1-sec pulses at a low-to-medium output; briefly spin down samples in a microcentrifuge and repeat sonication once. Make sure to immerse the sonicator tip deep enough to avoid foaming. If working with several samples, keep tubes on ice between sonication cycles.

18. Incubate samples 5 min on ice with occasional mixing.

19. Microcentrifuge 15 min at 15,000 × *g*, 4°C. Transfer supernatant to a new microcentrifuge tube.

20. Remove and store a small (25-µl) aliquot at −80°C as a gradient 'input' sample.

21. Layer the nuclear extract (~450 µl total) onto a 10% to 30% (w/w) sucrose gradient (prepared in step 1) using a 1-ml syringe with a 20-G needle attached.

22. Carefully slide the tubes into pre-chilled buckets of the ultracentrifuge rotor, taking care not to disturb the gradients.

23. Ultracentrifuge gradients 3 hr at 160,000 × *g* (36,000 rpm), 5°C.

Fractionate gradients

24. Remove tubes from the rotor in a cold room or chromatography cabinet where the fractionation equipment is set up.

25. Fractionate gradients at 4°C and collect twelve 1-ml fractions. Monitor A_{254} to A_{260} of the gradient by using a flow cell connected between the tube and fraction collector (Fig. 22.11.2).

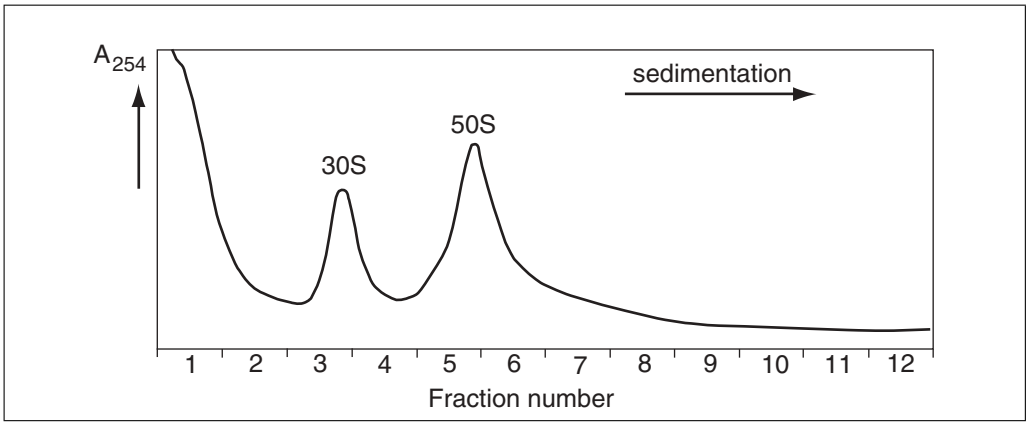

Figure 22.11.2 A typical profile of UV absorbance obtained upon fractionation of nuclear extracts on a sucrose gradient. The two major peaks sedimenting at ~30S and 50S contain small and large ribosomal subunits, respectively, and their precursors. Earlier preribosomal particles are found in fractions sedimenting ahead of 50S (fractions 6 through 9).

If possible, use upward displacement to fractionate gradients: pump 55% (w/w) sucrose through a needle inserted into the bottom of the tube at ~1 ml/min and collect fractions from the top using the funnel cap supplied by the separation system.

Analyze gradient fractions

26. To precipitate proteins, add 10 µl of 0.1% BSA and 100 µl cold 100% TCA to each 1-ml fraction, thoroughly mixing samples after each addition. Incubate 1 hr on ice.

    Because of the high viscosity of sucrose-containing samples, a combination of inverting the tube and vortexing may be necessary to achieve complete mixing. BSA serves as a carrier to ensure uniform protein recovery from different fractions.

27. Microcentrifuge tubes 15 min at ~12,000 × *g*, 4°C.

28. Wash protein pellets two times with 100% ethanol to remove residual TCA. Each time, incubate pellets at least 30 min at room temperature with occasional mixing and then microcentrifuge for 5 min at a maximum speed, 4°C.

    Samples can also be stored under ethanol overnight at −20°C—this is a convenient breakpoint in the procedure.

29. Air dry pellets for 5 to 10 min and dissolve in 50 µl freshly prepared urea sample buffer by incubating 5 min at 50°C followed by thorough mixing.

30. Briefly spin the samples in a centrifuge and store at −80°C.

    Urea in the sample buffer helps solubilize proteins.

31. Transfer an aliquot of each sample to be loaded onto a gel into a separate tube, heat 2 to 3 min at 95° to 100°C, and microcentrifuge 3 min at maximum speed, room temperature.

    A 15-µl aliquot is usually sufficient for one lane of a minigel. Avoid repeated heating of samples as it may lead to protein degradation.

32. Analyze samples by SDS-PAGE (*UNIT 6.1*) followed by immunoblotting *(UNIT 6.2)*.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Denhardt's solution, 50×

1% (w/v) Ficoll (type 400)
1% (w/v) polyvinylpyrrolidone
1% (w/v) BSA (fraction V; Sigma)
Filter sterilize through a 0.45-µm filter
Store in 25- to 50-ml aliquots up to 1 year at −20°C

Hybridization solution

5× SSC (see recipe)
5× Denhardt's solution (see recipe)
0.5% (w/v) SDS
25 µg/ml denatured salmon sperm DNA
Prepare fresh from stock solutions just before use

Low salt buffer (LSB)

10 mM HEPES-NaOH, pH 7.5
10 mM NaCl
2 mM $MgCl_2$

continued

1 mM EGTA
Filter sterilize through a 0.22-μm filter
Store up to 6 months at 4°C

LSB+

To LSB (see recipe), add 5 μl/ml protease inhibitor cocktail (Sigma) immediately before use.

Sonication buffer

25 mM Tris·Cl (*APPENDIX 2A*), pH 7.5, 25°C
100 mM KCl
1 mM NaF
2 mM EDTA
0.05% (v/v) Igepal CA-630 (Sigma)
Filter through a high protein-binding filter (nylon or nitrocellulose) to sterilize and remove any contaminating RNase traces
Store up to 6 months at 4°C
Add before use:
1 mM DTT (from 1 M stock solution stored at −20°C)
10 μl/ml protease inhibitor cocktail (Sigma)
50 to 100 U/ml RNase inhibitor (e.g., Promega or Fermentas)

SSC, 20×

3 M NaCl
0.3 M sodium citrate
Adjust pH to 7.0 with HCl
Sterilize by autoclaving
Store at room temperature

Sucrose solutions

To prepare 100-ml gradient solutions, start by weighing out 10.38 g sucrose for the 10% (w/w) solution, or 33.81 g sucrose for the 30% (w/w) solution. Add water and appropriate KCl and EDTA stock solutions to bring the final volume to 97.5 ml and 100 mM KCl and 2 mM EDTA final concentrations.

Filter the solution through a 0.22-μm filter and transfer to a glass bottle with a tight cap.

Add diethylpyrocarbonate (DEPC) to 0.05% (v/v), close cap securely, shake vigorously to mix, and incubate overnight at 60°C to decompose DEPC. Add 2.5 ml of 1 M Tris·Cl, pH 7.5 (*APPENDIX 2A*), at 25°C. Store up to 6 months at 4°C.

CAUTION: *Wear gloves and work in a fume hood when using DEPC, as it is toxic and a suspected carcinogen.*

Before making a gradient, add DTT to a final concentration of 1 mM to the working portion of solution.

Note that the percentage of sucrose used for making gradients is expressed as w/w. Use high-quality sucrose that is certified to have low A_{260}. DEPC treatment inactivates RNases that often contaminate commercial sucrose. Do not autoclave sucrose solutions because this will lead to caramelization and an increase of A_{260}.

Urea sample buffer

62.5 mM Tris·Cl, pH 6.8 (*APPENDIX 2A*)
3 M urea

continued

2% (w/v) SDS
0.01% (w/v) bromophenol blue
0.1 M DTT
Prepare fresh

Urea-containing solutions should be freshly prepared to minimize adverse effects of urea hydrolysis products.

COMMENTARY

Background Information

Ribosome biogenesis in eukaryotes occurs largely in the nucleolus, with final stages of subunit maturation taking place in the nucleoplasm and cytoplasm. In mammalian cells, the large primary 47S pre-rRNA transcript is synthesized by RNA polymerase I and then processed through a series of endo- and exonucleolytic processing steps and covalent nucleotide modifications to mature 18S, 5.8S, and 28S rRNAs (Bowman et al., 1981; Eichler and Craig 1994; Fig. 22.11.3). The small 5S rRNA is synthesized by RNA polymerase III.

rRNAs and their precursors (pre-rRNAs) are among the most abundant RNA species in the cell, and therefore can be detected simply by running metabolically labeled total RNA on a gel. Metabolic labeling of the newly synthesized rRNA can be accomplished with ^{3}H- or ^{32}P-labeled precursors. The use of ^{3}H for labeling offers a number of advantages including minimal exposure of the investigator to radiation and the excellent stability of radiolabeled samples. Coating membranes containing ^{3}H-labeled RNA with a thin layer of fluor is a sensitive method for detection of ^{3}H. Commercial intensifying screens for ^{3}H have been developed; however, they tend to produce artificially low signals from bands containing very large amounts of RNA (e.g., 28S), apparently due to inability of the weak β-emission to reach the screen in such areas. Labeling with $^{32}P_i$ results in stronger signals that can

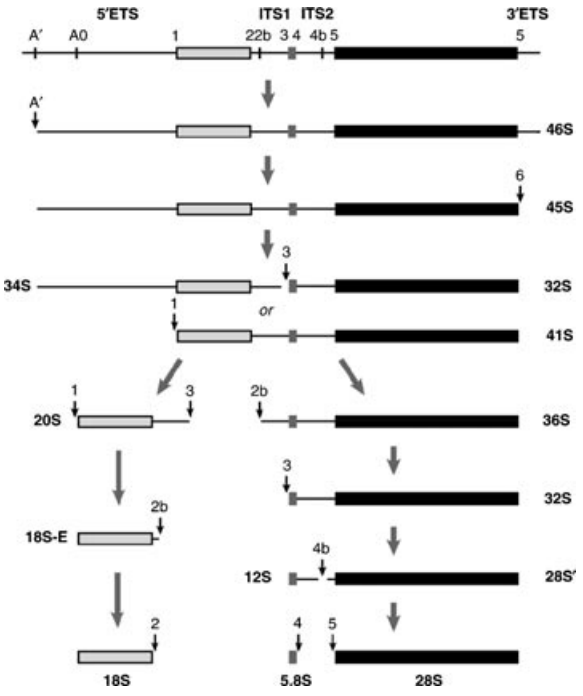

Figure 22.11.3 Structure of the primary transcript (47S) and major rRNA processing intermediates in mammals. The 47S pre-rRNA contains the sequences of mature 18S, 5.8S, and 28S rRNAs separated by the internal transcribed spacers (ITS1 and 2) and flanked by the external transcribed sequences (5'ETS, 3'ETS). Processing sites involved in the formation of each precursor are indicated. Adapted from Bowman et al. (1981) and Eichler and Craig (1994), with modifications.

be detected directly with autoradiography or using a phosphorimager.

[^{3}H]uridine labeling is the simplest type of rRNA labeling that does not require any special media or dialyzed serum, both of which are necessary for labeling with $^{32}P_i$ and [^{3}H]methyl-methionine (specialty media and sera are commercially available but could also be prepared in the laboratory). Pulse-chase labeling with [^{3}H]methyl-methionine is a highly sensitive technique that can often reveal more information about the temporal order and efficiency of different pre-rRNA processing events than other types of labeling.

For the isolation of radiolabeled RNA, commercial monophasic reagents containing phenol and guanidine thiocyanate are recommended because they require fewer manipulations than other methods, thus decreasing chances of accidental equipment contamination. Protocols for running RNA gels and northern blotting can be found in manuals such as *Current Protocols in Molecular Biology* (Brown et al., 2004).

Hybridization analysis of pre-rRNA allows unequivocal identification of precursor bands and is suitable for quantitative analysis of changes in steady-state levels of different processing intermediates. A readily detectable signal with rRNA precursors can be obtained on standard northern blots containing total cellular RNA using oligonucleotide probes ^{32}P-labeled at the 5′ termini with T4 polynucleotide kinase. A comprehensive analysis of pre-rRNA processing in a cell requires a series of hybridizations using probes that match different parts of spacer regions (5′ETS, 3′ETS, ITS1, ITS2) and mature rRNA sequences.

Processing of pre-rRNAs occurs within large ribonucleoprotein complexes that can be separated by centrifugation through sucrose gradients. The first studies that introduced this methodology date back to the 1960s (Warner and Soeiro, 1967). In addition to preribosomes, the gradients obtained from nuclear lysates contain other large complexes, including the abundant nuclear ribosomes, and may also contain contaminating ribosomal subunits from the cytoplasm. When gradient fractions are monitored for A_{254} to A_{260}, two prominent peaks of ~30S and ~50S are observed that are largely due to nuclear ribosomal subunits, whereas different preribosomal complexes are generally found in the faster sedimenting (55S to 100S) portion of the gradient.

The initial step in the isolation of preribosomal particles described in this unit involves preparation of nuclei by cell lysis using low concentrations of detergents in a hypotonic buffer. This method yields a relatively crude nuclear preparation, but is reliable and easy to perform. More complicated protocols may be needed if contamination with cytoplasmic material is of concern (*UNIT 3.10*). A number of techniques have been described to lyse the nuclei and release preribosomal particles. Many ribosome synthesis factors remain stably associated with preribosomal complexes under different conditions of isolation, but it is obvious that no single technique can preserve all interactions. The protocol in this unit uses sonication to disrupt nuclei in the presence of EDTA (Strezoska et al., 2000). A different approach in which nuclei are lysed in high salt buffer offers better protection of pre-rRNAs from endogenous ribonucleases but strips more proteins from preribosomes (Lapik et al., 2004).

Methods for preparing and running sucrose gradients and a discussion on the various types of equipment used for gradient fractionation can be found in *UNIT 5.3*. A typical setup for the analysis of preribosomes by upward displacement consists of a pump, an assembly for piercing the tube, a tube cap, a UV-monitoring cell, and a fraction collector. Fractionation of gradients by puncturing the tube and collecting drops from the bottom is not recommended as it leads to a considerable loss of resolution.

Critical Parameters and Troubleshooting

Metabolic labeling of rRNA

The rate of ribosome synthesis in mammalian cells strongly depends on the growth state of culture. A number of adverse conditions, such as contact inhibition, lack of growth factors or nutrients, or various chemical inhibitors including some transfection reagents, can inhibit ribosome biogenesis and greatly reduce incorporation of radioactive precursors into rRNA. Even under optimal conditions, kinetics of pre-rRNA processing may differ between cell lines. In particularly slow cell types, increasing the time of labeling to 2.5 to 3 hr may improve the signal detectable in mature rRNAs (especially 28S).

Gel analysis of large pre-rRNAs

Standard northern blotting procedures (Brown et al., 2004) apply to the analysis of rRNA and their precursors. Problems arising in the analysis of pre-rRNAs, such as smeared, poorly resolved bands, often result from gel overloading during electrophoresis. If samples are loaded based on their total cpm (e.g., to obtain similar intensities across the gel), it may

be useful to process one unlabeled RNA sample from an identical cell culture to estimate the total RNA amount obtained in the protocol. Loading 2 to 3 μg total RNA per lane is usually sufficient for a typical small- to medium-sized agarose gel. One should also keep in mind that rRNA precursors can be very large (the primary transcript in mammalian cells is >13 kb). Therefore, gels should be run for a sufficiently long time to ensure good separation.

Fluorography of ^{3}H-labeled rRNA

Exposure times necessary for detection of a weak ^{3}H signal after fluorography depend on multiple parameters, including type of labeling, total amount of radioactivity loaded, and the amount and uniformity of fluor coating. To obtain a high-quality picture, it is better to remove membranes from a relatively dilute fluor solution rather than try to evaporate the solvent almost to dryness. Excessive amounts of fluor residue left on the membrane may result in a spotty or blotchy signal after exposure to film. This can be corrected by repeating the solvent soaking procedure without additional spraying. Before re-exposing blots that have been already exposed for several days, recoating is recommended, as the fluor itself is volatile and tends to gradually disappear from a membrane starting from its edges. The sensitivity of film used for detection can also dramatically affect the exposure time.

Hybridization with pre-rRNA

Oligonucleotide probes used for hybridization must be reverse complementary to the regions of interest in the (pre)-rRNA. For optimal results with the protocol described in this unit, the oligonucleotide probes should be ~30 nucleotides in length and have a 50% to 70% GC content. Sequences that significantly deviate from these parameters may require an adjustment of the hybridization and/or wash temperatures. Sequences of probes designed for mouse pre-rRNA can be found in Strezoska et al. (2002) and Lapik et al. (2004). Synthetic oligonucleotides obtained from commercial sources can usually be used without additional purification. To allow for repeated reprobing of the same blot, it is recommended to use nylon membranes for blotting of the RNA. When a series of hybridizations is planned, one may wish to start with probes designed to detect those parts of pre-rRNA that are normally quickly degraded in the cell, such as 5′ETS or 3′ETS, because strong signals produced by mature rRNAs or highly abundant pre-rRNAs (e.g., 32S) can be difficult to eliminate completely by stripping the membrane.

Sucrose gradients

The efficient release of preribosomes from the sonicated nuclear material requires chelation of metal ions with EDTA and the presence of non-ionic detergents. Sonication conditions should be optimized for a particular instrument used. Insufficient sonication can result in inadequate nuclear breakage and reduced yield, while oversonication could lead to partial preribosome fragmentation. Although preribosomal complexes are relatively stable in sucrose gradient solutions, some degradation of pre-rRNAs due to endogenous RNase activity is commonly observed. To avoid introducing extraneous RNases, using RNase-free plasticware and reagents is strongly recommended. If a sonication probe is also used for processing bacterial cultures, it should be thoroughly cleaned before use.

Anticipated Results

Metabolic labeling of RNA in mammalian cells should yield a pattern of discrete bands corresponding to radiolabeled mature rRNAs and their precursors upon analysis by gel electrophoresis. Changes in pre-rRNA biosynthesis can manifest as (1) under- or over-accumulation of normal rRNA precursors, and/or (2) appearance of improperly processed (aberrant) rRNA intermediates. A series of hybridizations with oligonucleotide probes should provide the clues as to which processing steps are affected. Separation of nuclear extracts on sucrose gradients should yield two distinct major peaks corresponding to nuclear ribosomal subunits when the gradient is monitored for UV absorbance during fractionation. Many preribosome-associated proteins will co-sediment with large-molecular-weight complexes after separation; however, some factors may be detected in the top fractions of a gradient if they are loosely associated or require divalent cations for binding.

Time Considerations

Cells for rRNA analysis are typically plated 1 to 2 days in advance. Labeling with radioactive precursors and RNA isolation can be completed in 1 day. Detection of [^{3}H]-labeled RNA blotted onto a membrane by fluorography may take anywhere from 1 day to 1 to 2 weeks, depending on labeling efficiency, fluor coating, and film sensitivity. Hybridization of an RNA blot with one oligonucleotide probe requires

~3 days to complete if phosphorimaging is used for detection. Analysis of preribosomes by gradient centrifugation usually requires 3 to 5 days.

Visualization and Measurement of DNA Methyltransferase Activity in Living Cells

Lothar Schermelleh,[1] Fabio Spada,[1] and Heinrich Leonhardt[1]

[1]Ludwig Maximilians University Munich (LMU), Department of Biology II, Martinsried, Germany

ABSTRACT

In this unit, a live-cell assay to measure DNA (cytosine-5) methyltransferase (MTase) activity at the single-cell level is described. This method takes advantage of the irreversible binding of enzymatically active MTases to genomic DNA substituted with the mechanism-based inhibitor 5-aza-2′-deoxycytidine (5-aza-dC). The procedure comprises incorporation of this nucleoside analog into DNA during replication and quantification of the time-dependent MTase immobilization by fluorescence recovery after photobleaching (FRAP). This trapping assay monitors kinetic properties and activity-dependent immobilization of MTases in their native environment and enables direct comparison of mutations and inhibitors that affect MTase regulation and catalytic activity in single living cells. In addition, a simplified protocol to obtain qualitative information on the activity of either endogenously or exogenously expressed MTases is provided. *Curr. Protoc. Cell Biol.* 39:22.12.1-22.12.16. © 2008 by John Wiley & Sons, Inc.

Keywords: DNA methylation • DNA (cytosine-5) methyltransferase • Dnmt1 • trapping assay • fluorescence recovery after photobleaching • 5-aza-2′-deoxycytidine • mechanism-based inhibitor

INTRODUCTION

In this unit, a method to assay enzymatic activity of DNA (cytosine-5) methyltransferases (MTases) in living cells, which also provides information on protein kinetics and subcellular localization, is described. The method relies on incorporation of 5-aza-2′-deoxycytidine (5-aza-dC, also known as decitabine), an analog of 2′-deoxycytidine (dC) that acts as a mechanism-based inhibitor for all MTases. 5-aza-dC is added to the growth medium and is incorporated into the DNA during replication in place of dC. Under normal conditions, the catalytic mechanism of MTases involves the formation of a transient covalent bond with the base ring in dC that is released after methyl group transfer (Fig. 22.12.1). When an MTase is engaged in methylation of 5-aza-dC, this covalent bond cannot be resolved and the enzyme becomes irreversibly trapped at the site of action. As more 5-aza-dC gets incorporated in replicating cells, the enzyme becomes progressively immobilized at postreplicative CpG sites. Thus, the MTase immobilization rate directly reflects the efficiency of the methylation process. The enzyme activity can be quantified by expressing fluorescent MTase fusions and measuring their mobility by fluorescence recovery after photobleaching (FRAP; Schermelleh et al., 2005). Alternatively, both endogenous MTases and exogenously expressed MTase constructs can be assayed by fixing the cells at different time points after addition of 5-aza-dC and subsequent immunostaining (see Alternate Protocol).

STRATEGIC PLANNING

The trapping assay (see Basic Protocol) requires tissue culture experience (*UNIT 1.1*), knowledge in handling of cells for live-cell microscopy, and experience in advanced confocal live-cell microscopy techniques, in particular photokinetic applications and image analysis (*UNITS 13.5 & 21.1*). Generation of MTase constructs (fluorescent fusions and/or

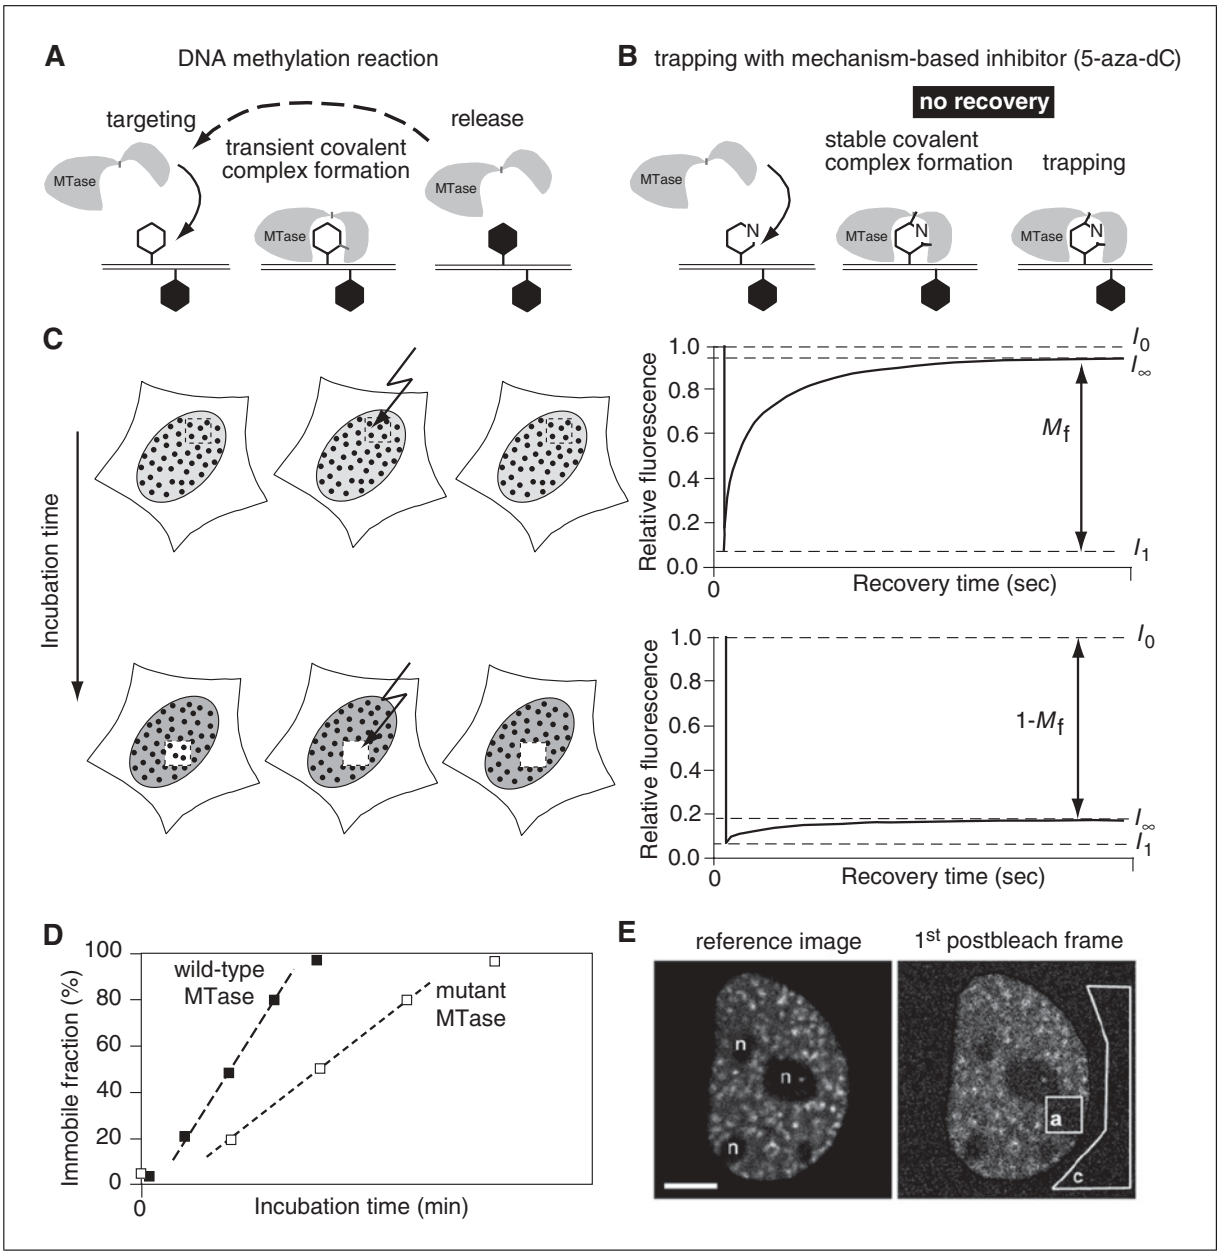

Figure 22.12.1 Principle of the trapping assay (shown here for the maintenance MTase Dnmt1 with hemimethylated CpG substrate sites). (**A**) Methylated and non-methylated cytosines are depicted as black and white hexagons, respectively. MTase binds to (hemimethylated) CpG sites produced during DNA replication and forms a transient covalent complex with the cytosine residue (gray line). After methyl group transfer, the enzyme is released and becomes available for another round of methylation (dotted arrow). (**B**) Mechanism-based inhibitors such as 5-aza-dC (hexagons with red N at position 5) are incorporated into DNA during S-phase. The MTase forms a stable covalent complex with 5-aza-dC (black line) and becomes trapped. (**C**) Dynamic exchange of MTases is visualized as fluorescence recovery after photobleaching of GFP-MTase in the outlined region (top row). Immobilization of GFP-MTase is detected as reduced recovery after photobleaching and decrease of mobile fraction (M_f) and increase of the immobile fraction, respectively (bottom row). Dots indicate MTase accumulation at replication foci (RF). Covalent trapping leads to an increase of the RF-associated fraction and a decrease of diffuse fraction. (**D**) To compare, e.g., specific mutant MTases with wild-type MTase, the immobile fractions (1 – M_f) are plotted as a function of incubation time. Such a comparison may also be performed simultaneously in single living cells when wild-type and mutant MTase tagged with spectrally distinct fluorescent proteins are co-expressed. (**E**) Example of ROI selection for quantitative FRAP evaluation. The left panel shows a high S/N reference image of an early S-phase mouse myoblast cell expressing GFP-Dnmt1 before bleaching (n, nucleoli). The right panel shows the corresponding first postbleach frame of the FRAP series. Bleach ROI (a), total ROI (b), and background ROI (c) are indicated. Bar = 5 μm. For color version of this figure, go to *http://www.currentprotocols.com*

specific mutants) and transfection in appropriate cell lines may be necessary (*UNITS 20.6, 20.7 & 21.4*). Establishment of stable cell lines may be considered as alternative to transient transfections (see Critical Parameters). Co-expression with a red fluorescent S-phase cell cycle marker (e.g., RFP-PCNA, RFP-DNA ligase I) is obligatory if the green fluorescent MTase fusion construct is not known to localize at replication sites during S-phase. The method described in the Alternate Protocol employs standard immunofluorescence detection techniques (*UNIT 4.3*) to yield qualitative data. It is technically less demanding and especially suited if only a standard epifluorescence microscope without FRAP capability is available.

FRAP-BASED QUANTITATIVE MEASUREMENT OF MTase ACTIVITY IN LIVING CELLS

BASIC PROTOCOL

The following protocol is based on routine procedures for the quantitative analysis of fluorescent Dnmt1 fusion constructs in mammalian cells and may require adaptation for different MTases, cell lines, and organisms.

The FRAP technique has been reviewed, e.g., in Lippincott-Schwartz et al. (2001). A detailed description of the FRAP method is given in *UNITS 13.5 & 21.1*.

Materials

Cultured cells
Expression vectors encoding MTase fusions with fluorescent proteins suitable for FRAP analysis (e.g., eGFP and RFP)
Transfection reagent (e.g., Transfectin, BioRad) or stably expressing cell line
5-Aza-2′-deoxycytidine (5-aza-dC; see recipe)

Live-cell chamber slides (e.g., Lab-Tek, Nunc or μ-Slides, Ibidi)
Confocal laser scanning microscope (CLSM) system (e.g., Leica TCS SP2/5 AOBS) suited for live-cell microscopy (inverted set up) equipped with the following:
High numerical aperture (1.2 to 1.4 NA) oil, glycerol, or water objectives (60×, 63×, or 100×)
High-power blue laser to provide a 488-nm line for bleaching and GFP excitation
Green laser (543-nm/561-nm) to excite red fluorescent protein
Temperature-controlled incubator box (recommended)
Motorized *xy*-stage (optional)

Prepare cells and carry out transient transfection

1. Seed cells in standard growth medium on live-cell chamber slides.

   In principle, any adherently growing cell line can be used. A normal to high proliferation rate and ease of transfection are advantageous.

   The seeding density depends on the cell line and should be chosen such that the culture reaches ~50% confluency at the desired time of transfection.

   Alternatively, perfusable live-cell chambers (e.g., FCS2 chamber, Bioptechs; POC-Chamber, LaCon) can be used.

2. Incubate cells until they have adhered on the slide surface and have reached ~50% confluence (from a few hours to overnight depending on the cell line).

3. Transiently transfect cells with expression vector (plasmid DNA) encoding a GFP-MTase fusion protein of choice.

   Optionally, co-transfect with RFP-PCNA or RFP-DNA ligase I if a reference marker of replication sites in S-phase cells is desired.

   The transfection method of choice must be determined and optimized for each cell line (see UNITS 20.6 & 20.7). Ideally, select transfection conditions that combine high transfection rates with moderate expression levels (see Critical Parameters).

4. Incubate cells for at least 16 hr, preferably 24 hr, to allow optimal expression of the fusion construct(s).

   Some transfection protocols require a medium exchange 2 to 4 hr after addition of the transfection mix. Depending on the following steps of the protocol, a change to the live-cell observation medium (without phenol red, with HEPES, see Critical Parameters) can be made at this stage.

Measure fluorescence recovery after photobleaching (FRAP)

5. For the confocal laser scanning microscope set up, set temperature of the incubator box (if available) to 37°C and allow the system to equilibrate for an appropriate time (~1 hr) to avoid thermal shifts during data acquisition. If an adjustable argon-ion laser is used to excite and bleach GFP, set it to maximum power.

6. Mount live cell chamber slide with transfected cells onto the microscope stage of the confocal laser scanning microscope.

   Alternatively, widefield or spinning disk confocal microscope systems equipped with a laser-based FRAP module may be employed.

7. Set CLSM parameters for FRAP measurements.

   For the Leica TCS SP2 AOBS (63×/1.4 oil objective, 75 mW argon-ion laser) and measurement of GFP-tagged Dnmt1 variants in mouse or human cells, the following settings are recommended (adaptation for other microscope systems and samples may be necessary; also see Critical Parameters). Scan size: 256 × 256 pixel; Zoom factor: 9.3 (resulting in a pixel size of 100 nm); Pinhole diameter: 3 Airy units; PMT settings should be kept constant with gain setting not exceeding 680 V; AOTF (transmission) setting of the 488-nm line may be varied from 2% to 5% depending on the brightness of the sample. Time intervals (minimum frame rate): 150 msec (using 1400-Hz scan speed and bidirectional scan) or 208 msec (1000-Hz, bidirectional scan); 10 to 20 prebleach frames, 1 to 2 bleach frames, 400 to 600 postbleach frames; for bleaching (using the FRAP-Wizard of the Leica software), select a 3 × 3–μm square ROI, set the 48-nm laser line to 100% transmission and activate "zoom in" option. Keep parameter settings constant for subsequent measurements.

   If the microscope is equipped with a motorized xy-stage, it can be useful to first search the sample for suitable S-phase cells and to store their positions before performing FRAP measurements. One cell may be FRAPed at several time points. Be aware, however, that photodamage induced by extensive bleaching and acquisition may slow down or even stall DNA replication. Consequently, 5-aza-dC incorporation and thus trapping can be negatively affected.

8. (Optional) Acquire a high-quality, high signal-to-noise ratio (S/N) reference image of all channels (GFP, RFP, transmission) using multiple averaging before recording the FRAP series.

9. Record reference FRAP series before 5-aza-dC treatment.

10. Add 5-aza-dC to the medium or, if a perfusable live-cell chamber is used, exchange with CO_2-adapted medium supplemented with the desired concentration of 5-aza-dC.

    Typically, a final concentration of 10 to 30 μM produces optimal results (see Critical Parameters).

    Note that 5-aza-dC is unstable in aqueous solution, thus effectiveness decreases when stored for more than a few days at 4°C. The 10 mM stock solution of 5-aza-dC should be dispensed into 0.2-ml aliquots and stored at least 1 year at −20°C.

11. Record FRAP series of ideally 10 or more cells during 5-aza-dC incubation.

    Take note of the exact incubation time after addition of 5-aza-dC for each series (see Critical Parameters).

Quantitatively evaluate data

FRAP may be evaluated using proprietary microscope software. Here, a procedure using the ImageJ image processing freeware (*http://rsb.info.nih.gov/ij/*) and a conventional spreadsheet program (e.g., Excel) is described.

12. Import FRAP data as image series into ImageJ (data may be converted to 8-bit grayscale).

13. Define the square evaluation region-of-interest (ROI) for the bleached region (bleach ROI) using the rectangular selection tool and measure mean gray values at all time points (Image → Stacks → Plot z-axis Profile) (Fig. 22.12.1E).

14. Define a correction ROI covering the total nucleus (total ROI) using the polygon selection tool and measure mean gray values.

    The nucleus must not shift laterally with respect to the ROI over the time course. Rather downsize the ROI so that it does not contain extra-nuclear (dark) pixels at any time point. Excessive lateral cell movement may be corrected with an image registration tool (e.g., StackReg Plug-in for ImageJ).

    Datasets of cells showing excessive z-drift should not be considered for evaluation.

15. Define background ROI covering a variable region outside of the cell. Measure mean gray values.

16. Transfer the numerical values to a spreadsheet program (e.g., Excel).

17. Within the spread sheet, create a column with the respective time stamp information (e.g., from the bleach series log-file). Set the first postbleach time point to 0 plus the time delay required to record the first frame.

18. For each time point subtract background value from the bleach ROI (B) and total ROI (T) values, respectively. Normalize postbleach ROI values by the mean of the last five prebleach values (B_0 and T_0) to compensate for gray level fluctuations.

    The first prebleach values of a FRAP series should not be considered, as the fluorescence typically drops and reaches a prebleach equilibrium after acquiring two to five image frames.

19. To correct for total loss of nuclear fluorescence over the time course (bleaching by image acquisition) and in some cases also for the gain of nuclear fluorescence due to import from the cytoplasm, multiply by the reciprocal of the total ROI values. The relative fluorescence intensity (normalized and corrected) at a given postbleach time point (I_t) is given by

$$I_t = \frac{B_t}{B_0} \times \frac{T_0}{T_t}$$

    where B_t and T_t represent the background subtracted values from the bleach ROI and the total ROI, respectively, at postbleach time point (t); B_0 and T_0 represent the mean of the last five prebleach values after background subtraction.

20. Determine the value I_∞, where the recovery curve reached its plateau (mean of the last values). Typically, the mobile fraction (M_f) is given by

$$M_f = \frac{I_\infty - I_1}{1 - I_1}$$

    where I_1 represents the first relative intensity value after bleaching (see Fig. 22.12.1C and Critical Parameters).

21. Plot the immobile fraction $1 - M_f$ of each FRAP series as a function of the 5-aza-dC incubation time.

Apply linear regression to the linear part of the plot (excluding initial ~5 min lag-phase and saturation effect near full immobilization) to compare different enzymes or mutants.

ALTERNATE PROTOCOL 1

QUALITATIVE MTase ACTIVITY ASSAY ON FIXED CELLS USING BrdU REPLICATION LABELING

For qualitative evaluation or if no FRAP equipment is available, cells co-expressing a GFP-MTase fusion and RFP-PCNA can be fixed at several time points after addition of 5-aza-dC. Alternatively, endogenous MTases can be detected by immunofluorescence in combination with BrdU replication labeling or PCNA immunostaining or combinations thereof (Fig. 22.12.2). The thymidine analog BrdU is incorporated into replicating DNA of S-phase cells. Thus, both PCNA and BrdU (when applied 15 to 30 min before fixation) mark sites of active DNA replication. Detection of incorporated BrdU requires denaturation of the genomic DNA. When combining BrdU labeling and visualization of GFP-tagged proteins, denaturation using DNase I is mandatory, as other protocols using HCl or NaOH destroy GFP fluorescence (also see *UNIT 4.3* for standard immunofluorescence staining and *UNIT 8.3* for DNA replication labeling with BrdU).

NOTE: All incubation steps and washes are carried out at room temperature unless stated otherwise.

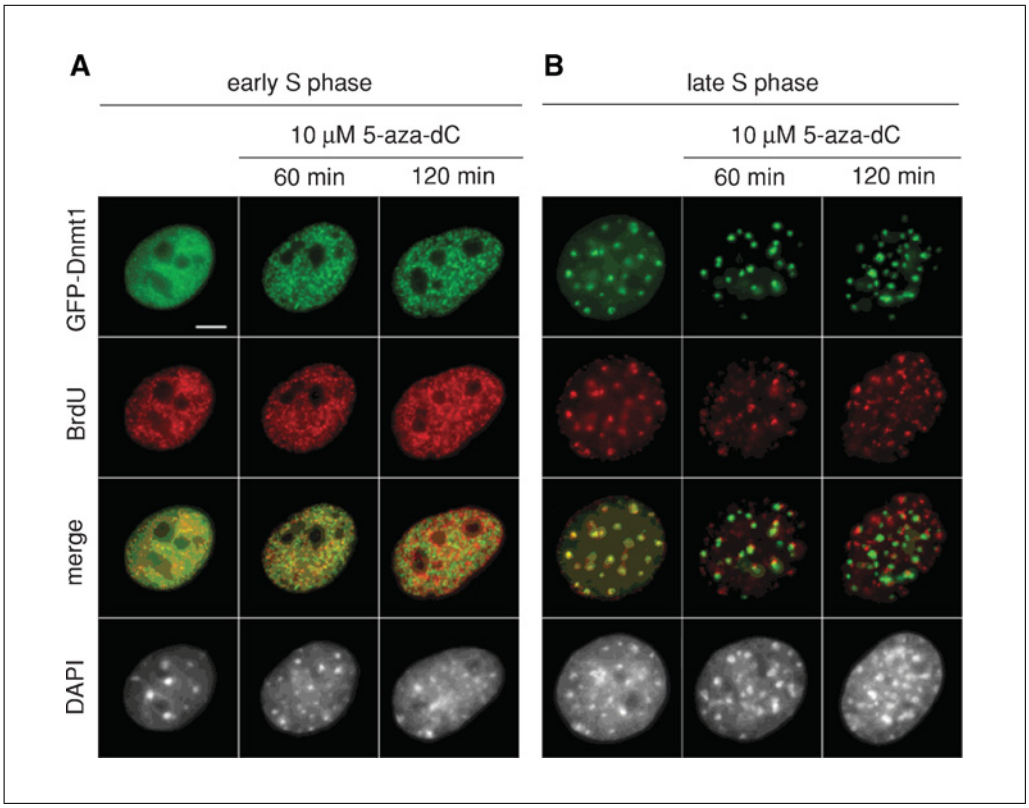

Figure 22.12.2 Fixed cell assay to visualize Dnmt1 immobilization after 5-aza-dC treatment. Typical early S-phase (**A**) and late S-phase nuclei (**B**) of mouse myoblast cells are shown. Cells were BrdU labeled and fixed without or after a 60- and 120-min treatment with 5-aza-dC. Replication foci were marked by BrdU immunostaining of nascent DNA. Note the stronger association of Dnmt1 at or near replication sites after 5-aza-dC treatment. At 120 min, a clear loss of co-localization is observed as the pool of initially mobile Dnmt1 is fully trapped at earlier replicated genomic DNA. The effect seems more pronounced in late S-phase, likely reflecting the higher density of methylated CpG sites in late replicating constitutive heterochromatin. Bar = 5 µm. For color version of this figure, go to *http://www.currentprotocols.com*

Materials

Cultured cells grown on coverslips of appropriate size (e.g., 15 × 15–mm) and thickness (e.g., 0.17 ± 0.01 mm) in small plastic petri dishes
5-Aza-2′-deoxycytidine (5-aza-dC; see recipe)
5-Bromo-2′-deoxyuridine (BrdU; Sigma-Aldrich)
Phosphate-buffered saline (PBS, *APPENDIX 2A*)
Fixation solution (see recipe)
PBST (see recipe)
10% (w/v) Triton X-100 (*APPENDIX 2A*)
Blocking solution (see recipe)
1 M $MgCl_2$ (*APPENDIX 2A*)
1:1000 mouse anti-BrdU antibodies (e.g., MAb IU-4, CALTAG Labs)
DNase I (see recipe)
PBSTE (see recipe)
Green and/or red fluorescent secondary antibodies (e.g., Alexa Fluor 488 and 555 conjugates, Invitrogen)
4′,6-diamidino-2-phenylindole (DAPI, see recipe)
Anti-fade mounting medium (e.g., Vectashield, Vector Laboratories)
Transparent nail polish (base coat)

6-well plates or 35-mm culture dishes
Fine-tip forceps
37°C incubator
Glass microscope slides
CLSM or epifluorescence microscope system appropriately equipped with CCD camera, fluorescence filter sets, and high-NA objectives

Label cells

1. Grow cells to ≥50% confluence on coverslips (cleaned in 80% ethanol and placed individually in suitably sized cell culture dishes (6-well plates or 35-mm culture dishes).

   If required, transfect cells with any desired MTase construct the day before or use a stable cell line.

2. Add 5-aza-dC to the cell culture medium to a final concentration of 10 to 30 μM and incubate for different time periods (e.g., 30 min, 1 hr, 2 hr) until fixation. Leave one sample untreated as control.

3. Add BrdU to a final concentration of 10 μM 15 min before fixation.

Fix cells

4. Transfer the coverslips briefly to PBS and then rapidly to fixation solution. Incubate for 10 min.

   Fixation and subsequent washing steps may be performed in 6-well plates or 35-mm culture dishes.

   Drying of cells must be avoided at any step of the protocol. Make sure that coverslips always remain covered by a film of liquid when changing solutions. The mild detergent Tween 20 in the washing solution (PBST) acts as a surfactant to lower the surface tension and thus helps to avoid drying artifacts.

   For transferring coverslips, use fine-tip forceps.

5. Exchange fixation solution with PBST.

   To avoid fixation artifacts, such as wrinkled nuclear morphology, first remove only ∼2/3 of the fixation solution and fill up with PBST before complete solution exchange with PBST.

   At this stage, cells may be stored overnight at 4°C.

Permeabilize cells and expose to antibodies

6. Permeabilize cells with 0.5% Triton X-100 in PBS for 5 min.
7. Incubate in blocking solution for 10 min.
8. Incubate with mouse anti-BrdU primary antibody solution (appropriate dilution in blocking solution containing 5 mM $MgCl_2$ and 10 U/ml DNase I) for 30 min at 37°C.

   There may be batch-to-batch variations of DNase I activity and the optimal concentration may vary according to the cell type/tissue. Optimal DNase I concentrations usually range from 5 to 20 U/ml and should be determined by titration in advance.

   Place drops of the antibody solution (typically 100 μl for 15 × 15–mm coverslips) onto a piece of Parafilm (flattened on a smooth plastic surface) and then place the coverslips cell-side down on the drops. Incubation should be performed in a dark humid chamber to prevent drying and fluorescence fading.
9. Wash three times, 5 min each time, with PBSTE.
10. Incubate with 1 μg/ml of secondary antibodies (typically 1:500 to 1:2000) in blocking solution for 1 hr at room temperature.
11. Wash thoroughly with PBST with several exchanges of the washing buffer.

    Extensive washing reduces background fluorescence of the sample and increases the signal-to-noise ratio.

Counterstain and mount

12. Counterstain nuclei with 50 ng/ml DAPI in PBST for 5 min and rinse briefly in PBST and then finally in water to remove salts.
13. Mount cells by adding a drop of antifade medium onto a glass microscope slide and quickly placing coverslip cell-side down onto the drop. Gently remove excess solution with soft tissue paper before sealing edges of coverslip with transparent nail polish.

ALTERNATE PROTOCOL 2

IMMUNODETECT PCNA

PCNA immunodetection may be performed as an alternative to BrdU labeling. Note, however, that with most if not all commercially available PCNA antibodies (e.g., MAb PC-10), a methanol treatment is required for epitope binding. In this case, replace Alternate Protocol 1, step 6, with a 5-min incubation with 100% ice-cold methanol followed by an exchange with PBST. In Alternate Protocol 1, step 8, prepare antibody solution without DNase I and $MgCl_2$ and incubate 1 hr at room temperature.

ALTERNATE PROTOCOL 3

IMMUNODETECT ENDOGENOUS MTases

Endogenous MTases may be detected by immunostaining as an alternative to exogenous expression of GFP fusion constructs. In this case, add a specific MTase antibody at an appropriate concentration to the primary antibody solution (see Alternate Protocol 1, step 8) and a matching green fluorescent secondary antibody to the secondary antibody solution (see Alternate Protocol 1, step 9). For this two-color immunostaining, care must be taken that the secondary antibodies do not show any cross-species reactivity. To avoid potential problems, use highly cross-adsorbed antibodies and/or perform cross-reactivity controls before using a specific antibody combination for the first time.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

5-aza-dC, 100 mM

10 mg 5-Aza-2′-deoxycytidine (5-aza-dC, dry chemical; Sigma-Aldrich)
438 μl DMSO

For 10 mM 5-aza-dC
100 mM stock solution diluted 1:10 in PBS

Store in 0.2-ml aliquots at least 1 year at −20°C

Blocking solution

2% (w/v) bovine serum albumin (BSA fraction V Sigma) in PBST (see recipe)
Store up to 1 month at 4°C

DAPI stock solution

5 μg/ml 4′,6-diamidino-2-phenylindole (DAPI; Sigma) in water

Store indefinitely at 4°C
To make up DAPI working solution:
50 ng/ml DAPI stock solution in PBST (see recipe)

Store up to 1 month at 4°C

DNase I stock solution

10,000 to 20,000 U/ml DNase I (code D; Worthington)
5 mM sodium acetate, adjusted to pH 4.5
1 mM $CaCl_2$
50% (v/v) glycerol
Mix gently, do not vortex
Store in 1-ml aliquots at least 1 year at −20°C

Fixation solution

37% reagent-grade formaldehyde solution 1:10 diluted in PBS
Prepare fresh
Alternatively, freshly prepare 4% para-formaldehyde (Sigma) in PBS.

PBST

0.05% Tween 20 in PBS
Store up to 6 months at room temperature

PBSTE

1 mM EDTA in PBST (see recipe)
Store up to 6 months at room temperature

COMMENTARY

Background Information

DNA methylation is essential for establishment and/or maintenance of cell lineage–specific expression patterns as part of an intricate network of epigenetic mechanisms. Thus, by affecting the transcriptional potential of genes, DNA methylation plays an important role in many fundamental processes such as cell differentiation, embryonic development, genome stability (silencing of transposable elements), neoplastic transformation, imprinting, and X chromosome inactivation (Bird, 2002). In metazoans, DNA (cytosine-5) methyltransferase (MTase) activity is the only detectable DNA methyltransferase activity and nearly all methylated cytosines occur as CpG dinucleotides. Four catalytically active DNA methyltransferases (Dnmts) have been

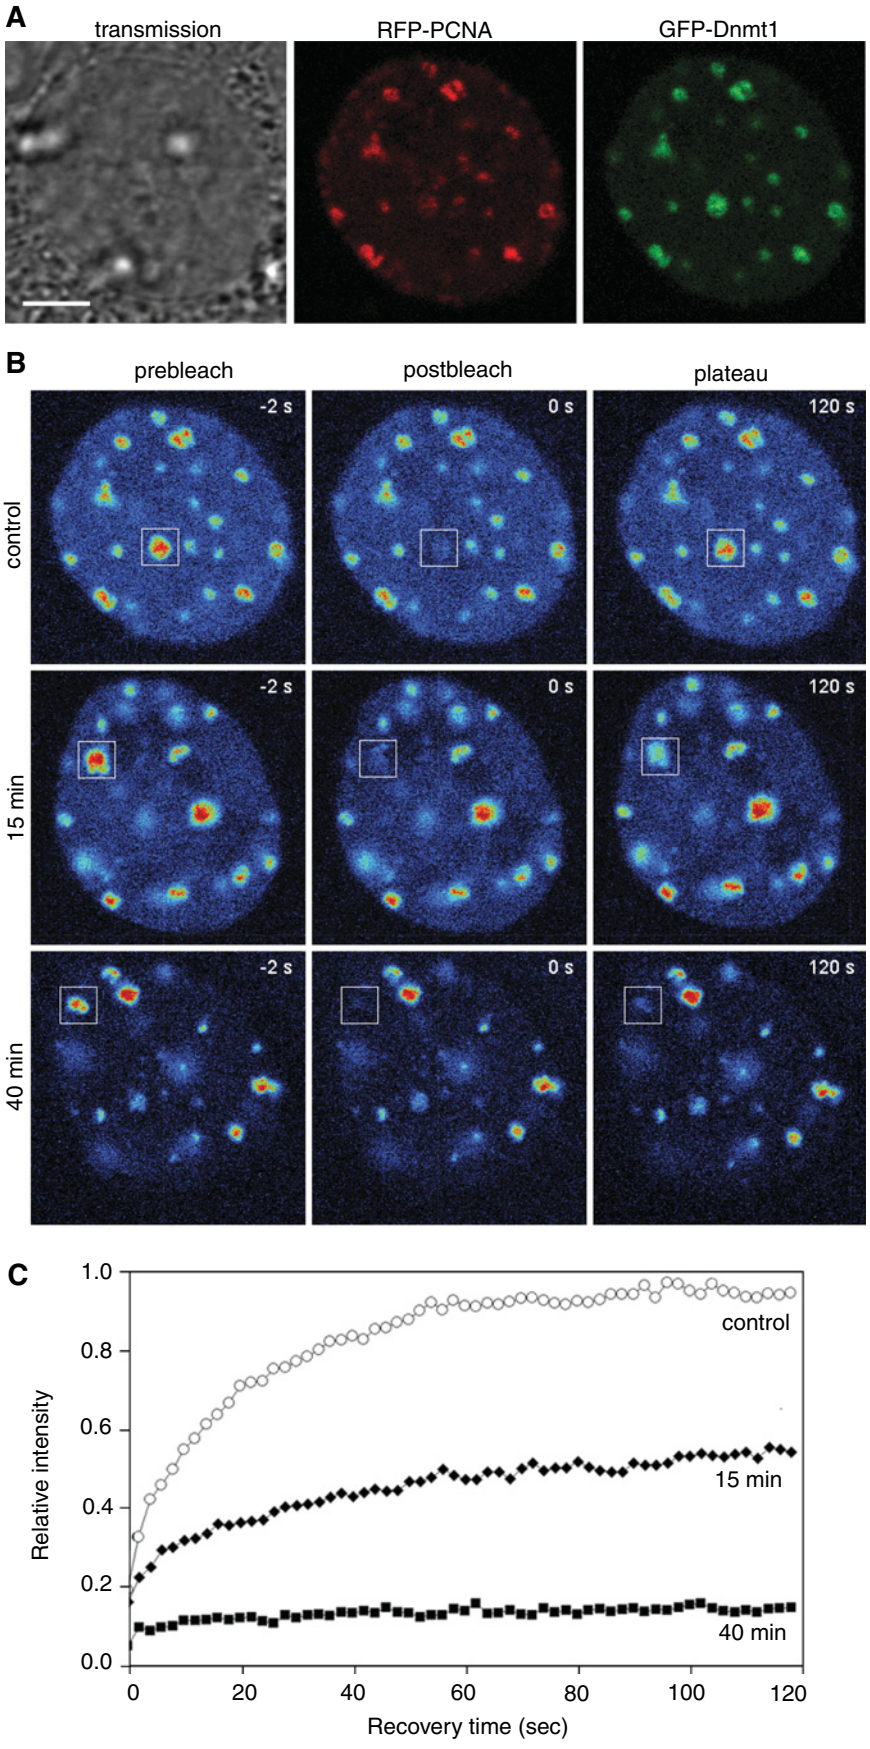

Figure 22.12.3 Legend at right.

described. Dnmt1 is the most abundant and ubiquitous enzyme and it is mainly responsible for maintaining genomic methylation patterns through successive DNA replication cycles. Dnmt2 shows very weak DNA methyltransferase activity, may be responsible for cytosine methylation in sequences other than CpG, and is involved in methylation of cytoplasmic $tRNA^{Asp}$. Dnmt3a and b are mainly responsible for de novo establishment of methylation patterns during embryonic development and maturation of germ cells (Hermann et al., 2004; Goll and Bestor, 2005).

Classically, MTase function is studied by knock-out experiments (Lei et al., 1996; Okano et al., 1998, 1999; Jackson-Grusby et al., 2001; Chen et al., 2007). Exogenous expression of the MTase and variants thereof in the respective knock-out cells (rescue/complementation) can also be used to gain further insight in the regulation of enzyme activity (Schermelleh et al., 2007). These studies are laborious and require extensive experimental set up for generation of knock-out and complemented cell lines or mouse models and analysis of genomic methylation patterns. In addition, these studies do not provide kinetic data. Enzyme kinetics is usually assayed in vitro under highly artificial conditions that cannot reproduce the complexity of the interactions occurring in vivo between MTases and their cofactors or their native chromatin substrate. The method presented here allows analysis of MTase activity in the native cellular environment and at the same time provides information on protein kinetics and subcellular localization of the enzyme with an experimental schedule of ~2 days (see Time Considerations).

The catalytic mechanism of MTases involves the formation of a transient covalent bond with position 6 of the cytosine ring, which is released by β-elimination after methyl group transfer. When an MTase is engaged in methylation of 5-aza-dC, the nitrogen atom at position 5 of the base lacks the hydrogen atom necessary for β-elimination and the enzyme is covalently trapped at the site of action. As more 5-aza-dC is incorporated into replicating cells, the initially free pool of enzyme becomes progressively immobilized at postreplicative CpG sites (Fig. 22.12.1).

Routinely, the procedure described in the Basic Protocol is used to assay postreplicative methyltransferase activity of wild-type and mutant DNA methyltransferase 1 (Dnmt1) constructs fused to GFP (GFP−Dnmt1), which are expressed either transiently or stably in different cultured cell lines (Schermelleh et al., 2005, 2007; Spada et al., 2007; Fig. 22.12.3). Co-expression of RFP-PCNA may serve as a marker of replication sites. Proliferating cell nuclear antigen (PCNA) is a core component of the replication machinery forming a trimeric ring around the DNA at the replication fork, which serves as a loading platform for various replication factors, such as DNA ligase I, pol δ, and others (Maga and Hubscher, 2003; Sporbert et al., 2005).

However, this method may be used to assay any MTase provided that is relatively mobile, as enzymes with very slow protein kinetics would not allow reliable measurement of trapping rates. This experimental strategy allows direct comparison of enzyme kinetics and subcellular localization before and after addition of 5-aza-dC within the same cell. Alternate Protocol 1 provides qualitative assessment of MTase activity and subcellular localization without the use of expensive and sophisticated equipment for imaging and photobleaching (Fig. 22.12.3).

The MTase trapping assay described here is set to be a useful tool not only for detailed studies on the properties of MTases but also for screening potential DNA methyltransferase inhibitors. When a functional MTase inhibitor (e.g., a small molecule inhibitor that blocks the catalytic center) is added to the cells along with 5-aza-dC it is expected to decrease or prevent

Figure 22.12.3 FRAP analysis of the Dnmt1 mobility before and during 5-aza-dC treatment in a single living cell. (**A**) Reference image (confocal mid section) of a mouse myoblast cell in late S-phase co-transfected with RFP-PCNA and GFP-Dnmt1 (wild-type). PCNA and Dnmt1 largely co-localize at replication foci. Bar = 5 μm. (**B**) FRAP of GFP-Dnmt1 (shown in false color) localized at a late replication focus is shown before treatment (control), as well as after a 15- and 40-min incubation of the same nucleus with 30 μM 5-aza-dC. The last prebleach, the postbleach and the final frame of each series is shown. Boxes indicate the bleach ROIs. FRAP series were recorded at different *z*-levels. Note the continuous loss of the diffuse fraction with longer incubation time. (**C**) Quantitative evaluation of the FRAP series shown in B demonstrating the decrease of the mobile fraction with 5-aza-dC incubation. For color version of this figure, go to *http://www.currentprotocol.com*

trapping of the enzyme at 5-aza-substituted CpG sites. As aberrant methylation patterns have been involved in the generation and/or progression of different tumor types, screening of potential DNA methyltransferase inhibitors would be helpful for drug development and evaluation as therapeutic agents.

Critical Parameters and Troubleshooting

Expression of fluorescent fusion proteins

For expression in mammalian cells, constructs where the cDNA coding for the MTase of interest is cloned into the pEGFP−C1 vector (Clontech) are routinely used. A clean plasmid DNA preparation is essential for good transfection rates. Transient transfection protocols are usually selected and optimized for a given cell line to provide high transfection rates, decent expression levels, and low toxicity. Unlike in biochemical assays, the optimal expression levels of GFP-fusion proteins for live-cell microscopy are rather moderate (ideally in the range of the respective endogenous proteins). Overexpressing cells showing typical artifacts like additional cytoplasmic signal or atypically large replication foci should not be considered for kinetic measurements. As the assay requires actively replicating cells, a high number of S-phase cells is desirable. Also, the relative number of transfected cells in S-phase should be in the range of untreated cells as an indication of their well-being. The use of stable cell lines should be considered to avoid problems arising from low or variable transfection rates and heterogeneous expression. Although the establishment of stable cell lines requires considerable time (2 to 4 weeks), it offers the advantage of nearly 100% expressing cells and the possibility of selecting for defined ratios of endogenous to exogenous protein levels.

Live cell imaging conditions

In principle, any standard culture medium can be used during live cell observation. However, using a medium without phenol red, to reduce autofluorescence, is recommended. If an "open" live-cell chamber system is used, medium containing 25 mM HEPES may be advantageous to avoid an increase in pH when imaging for extended time periods without a CO_2 supply (>2 hr). Experiments with mammalian cell lines should ideally be performed at a physiological temperature of 37°C; however, most cell lines will proliferate and replicate at room temperature, although at a reduced rate, which will likewise affect trapping rates. Thus, for direct comparability of experimental results, the temperature stability is maybe more important than the absolute temperature. This is important if no temperature-controlled incubator box or live-cell chamber is available.

Phototoxicity

Extensive illumination with an HBO mercury light source should be avoided (e.g., when searching for suitable cells using the epifluorescence light path of the confocal microscope). Epifluorescence filters are usually leaky in the range of the intense UV excitation peak of the HBO lamp, which likely induces unwanted photodamage even before recording of FRAP series. Thus, keeping the exposure with HBO light as short as possible or using the laser scanning mode of the microscope to select for suitable cells is recommended. Alternative light sources (e.g., standard halogen lamp) in combination with an additional UV filter(s) may also be considered (Chuang et al., 2006).

CLSM settings for FRAP experiments

Scan region size, scan speed, laser power, and gain settings should be selected to strike an optimal balance between resolution, frame rate, bleaching by image acquisition, and signal-to-noise (S/N) ratio. To increase frame rate, the image size should be reduced (e.g., 256 × 256 pixel). In this case, the zoom factor should be set to obtain a pixel size of 100 nm providing a scan region that usually covers typically sized mammalian cell nuclei while keeping the image resolution relatively high. To increase signal (at the cost of reduced *z*-sectioning), the pinhole may be opened to some extent (e.g., 3 Airy units instead of 1 as typical for standard imaging).

Generally, PMT gain and offset settings should be set so that the dynamic range (usually 8-bit, i.e., 0 to 255 gray values) is fully used, avoiding pixel saturation (use false color LUT to display pixels with values beyond the dynamic range). The PMT setting should be a reasonable compromise between signal strength and electronic noise and should be kept constant between individual measurements. To accommodate differences in sample brightness, the AOTF (transmission) setting of the 488-nm laser line should be varied rather than PMT gain setting. Here, the limit is set by the bleaching caused by image acquisition over the time course. As a rule of thumb, this "bleaching-by-acquisition" should not exceed 30%.

At least ten prebleach time points should be recorded to measure the prebleach equilibrium before disturbance by the actual bleaching pulse. Time intervals between postbleach time points are typically set between 100 and 500 msec, depending on the mobility of the MTase and limits of the imaging system. The number of postbleach time points should be chosen to allow the fluorescence to reach its plateau of recovery with the selected intervals/frame rates. When measuring fast kinetics, the time interval between the last bleach frame and the first postbleach frame should be as short as possible since fast diffusing molecules invading the bleached region during this short time period may, in extreme cases, affect the calculated mobile fraction. Intervals between subsequent postbleach time points may be extended if this option is available.

The bleach region of interest (ROI) should be set to a suitable size (e.g., 3 × 3 μm) covering a representative number of replication foci or binding sites (also see below). For bleaching, set the 488-nm laser line to 100% transmission (additional laser lines below 500 nm may also be set to 100% if available) and choose the "zoom in" option (Leica TCS SP2/5) or similar options, if available, to provide maximum bleaching efficiency. Bleaching efficiency and number of bleaching iterations should be determined in advance on a fixed sample (do not mount this sample in antifade medium). The first postbleach (mean gray) value of the bleach ROI should be as close as possible to the background level (i.e., I_1 should be near 0; see Fig. 22.12.1C) using the shortest and most intense bleach pulse possible (i.e., with a minimum number of iterations and total bleaching time not exceeding 1/10 of the half recovery time). This critically depends on the technical features of the CLSM system, in particular, maximal laser power to provide fast bleaching and scan speed to provide minimum delay between bleaching and first postbleach acquisition.

Factors affecting trapping rate

Time-dependent immobilization of a given MTase fusion construct measured with the trapping assay is related to the enzyme activity/efficiency, but also to the amount of (hemimethylated) 5-aza-substituted CpG sites produced during replication (Fig. 22.12.4). The number of "traps" set within a given time is itself a function of various parameters that include: (1) DNA-synthesis rate, which might be influenced by environmental conditions, the state of the culture, and of selected cells. (2) Density of (methylated) CpG sites that may vary considerably from early replicating euchromatin to late replicating constitutive heterochromatin and among cell types or species. The selection of the bleach-ROI indirectly also relates to this parameter, as the "traps" may not be homogeneously distributed, but locally concentrated at replication foci (RF) and hardly present in nucleoli. Thus, bleach-ROIs in different FRAP-measurements should contain a similar ratio of RF associated to diffuse enzyme. (3) The dose and incorporation efficiency of the mechanism-based inhibitor used (and possibly also the affinity of the MTase for the inhibitor). The 5-aza-dC inhibitor is likely the most potent mechanism-based inhibitor of MTases. Unlike the related (and widely used) inhibitor 5-aza-C, this precursor does not require reduction of the ribose and is also not incorporated into RNA explaining the approximately five-fold higher effectiveness of 5-aza-dC over 5-aza-C (Jones and Taylor, 1980; Schermelleh et al., 2005). Typically, when used as a demethylating agent, a much lower 5-aza-dC concentration (in the range of 0.1 to 0.3 μM) is applied and its effects are assayed after longer periods of time. For the trapping assay, typically, an ~100-fold higher concentration (10 to 30 μM) is applied to approach a maximum substitution rate in the newly synthesized DNA strand. Higher 5-aza-dC concentrations do not lead to a further (linear) increase in trapping rates, indicating a saturation effect (L. Schermelleh, F. Spada, and H. Leonhardt, unpub. observ.). This relatively high concentration ensures that an initially free pool of fluorescently labeled, enzymatically active MTase molecules becomes fully immobilized within a fraction of the S-phase. Nevertheless, one has to be aware that prolonged incubation with 5-aza-dC may result in cytotoxic effects likely due to the formation of bulky DNA-MTase adducts (Juttermann et al., 1994; L. Schermelleh, F. Spada, and H. Leonhardt, unpub. observ.). Therefore, experiments with cells that have been incubated in the presence of 5-aza-dC at high concentrations for several hours should be considered with caution.

Less clear is the effect of differences in expression levels and absolute numbers of exogenously and endogenously expressed MTase molecules. In the authors' experience, the assay is rather robust against variation of GFP-Dnmt1 fusion protein levels, which might be explained by an excess of traps over the absolute amount of MTase molecules.

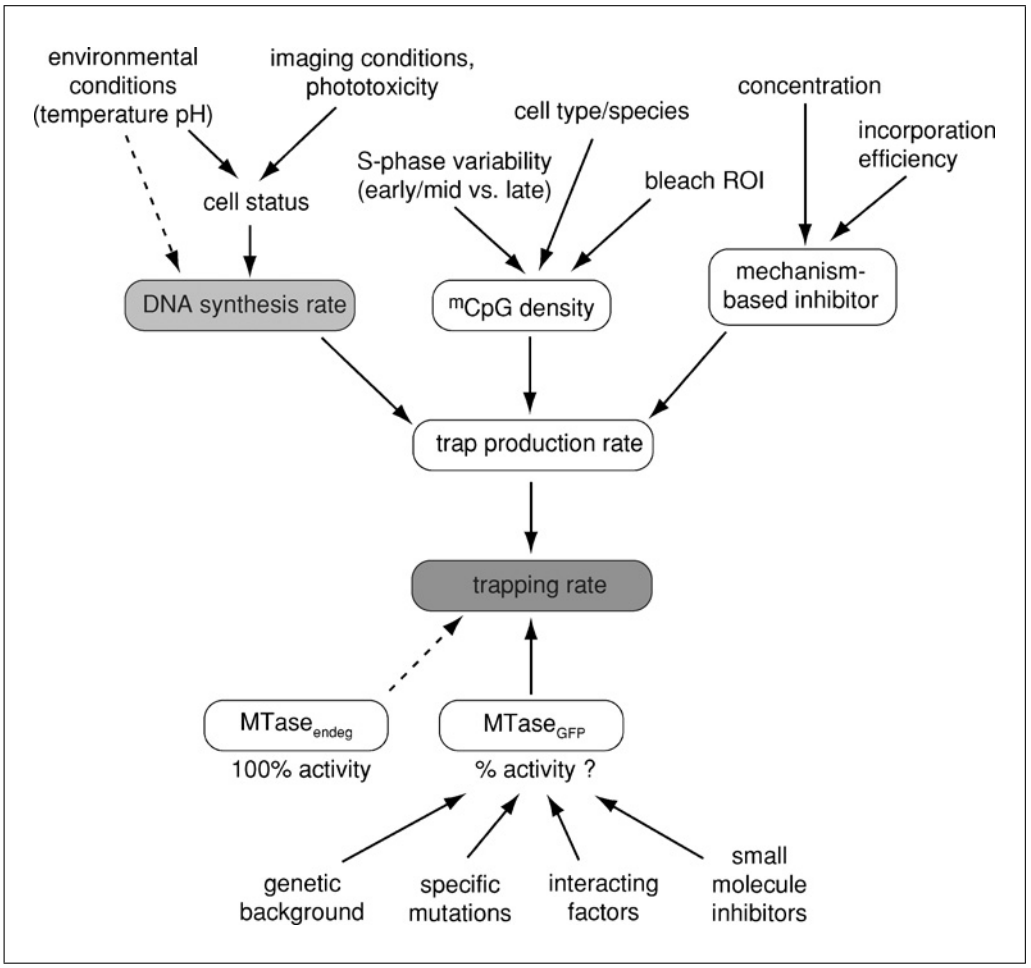

Figure 22.12.4 Summary of factors affecting the trapping rate of GFP-MTase fusion proteins. For comparability of results, experimental conditions that potentially affect the trap production rate should be kept constant. Two enzymes may also be directly compared side-by-side in single living cells using, e.g., red and green fluorescent fusions (see text for details).

When assaying MTase activity variations (e.g., as consequence of a specific mutation, catalytic inhibition by small molecules, or specific gene knock outs/downs), all other possible variables, such as cell type, cell cycle stage, bleach ROI, drug concentration, etc., should be kept as constant as possible to obtain meaningful and comparable results. On the other hand, the method also offers the possibility to assay other variables by using the same GFP construct, thus broadening the potential applicability of the trapping assay (Fig. 22.12.4).

Protocol variations and optimizations

The trapping assay also offers the possibility to test wild-type and mutant MTase simultaneously if one is labeled with GFP and the other with RFP. As an alternative to the classical FRAP approach, the trapping assay may be performed using a photoactivation approach with photoactivatible GFP (paGFP) fusions and a microscope system additionally equipped with a near-UV laser (405-nm diode laser; Schermelleh et al., 2005). Here, co-transfection with a red fluorescent cell cycle marker (e.g., RFP-PCNA) is mandatory for identifying S-phase cells and defining the photoactivation ROI.

The use of a motorized and programmable *xy*-stage, multi-well chamber slides (e.g., 6-well μ-slides, Ibidi), sophisticated software/macro programming (for semi-automation of different steps, such as target cell recognition, data acquisition and evaluation) are possible and should help raising the throughput, e.g., for screening of potential MTase inhibitors.

Anticipated Results

With regard to an anticipated outcome of a single FRAP experiment, most fluorescence MTase constructs that have been tested and that have shown reasonable mobility, reach the recovery plateau within <2 min. Plotting the

immobile fractions from all acquired FRAP curves against incubation time typically shows a short lag-phase of <5 min after adding the drug, until its incorporation into DNA. Also, a small saturation effect sometimes becomes obvious at late time points when the depletion of the mobile fraction is nearly completed.

Maintenance DNA methyltransferase 1 (Dnmt1) is likely the most efficient MTase on postreplicative DNA. Thus, trapping of GFP-tagged wild-type Dnmt1 (GFP-Dnmt1) can be considered a positive control. It has been previously shown that in various mouse and human cell lines (C2C12, SH-EP, HeLa), full immobilization of GFP-Dnmt1 is reached between 30 and 45 min when incubated with 30 μM of 5-aza-dC (Schermelleh et al., 2005, 2007; Spada et al., 2007). In contrast, a mutant Dnmt1 construct lacking the PCNA-binding domain (PBD), which targets the enzyme to the replication machinery, requires about a two times longer incubation for complete immobilization, reflecting the reduced methylation efficiency of these mutants in vivo (Schermelleh et al., 2007; Spada et al., 2007).

Time Considerations

The FRAP-based trapping requires seeding of cells on live-cell chamber slides, which is typically done the day before transient transfection (2 days before the actual trapping assay). Transient transfection typically requires ~1 hr hands-on work and an optional medium exchange 2 to 4 hr after adding the plasmid DNA-transfection reagent mix onto cells. The FRAP experiments should ideally be performed 24 hr after transient transfection. Several hours (depending on the number of experiments) should be scheduled for recording a FRAP series. A preparation lead time required to let the temperature of the microscope system stabilize, find the optimal CLSM settings, and (visually) screen the sample for suitable cells, should be taken into account. These steps may require up to 2 hr before recording the FRAP series of untreated cells. The length of a FRAP measurement depends on the mobility of the measured construct, i.e., how fast postbleach equilibration of fluorescence is reached. In the authors' experiments with human or mouse Dnmt1 fusion constructs, 2 min are usually sufficient. Progressive immobilization of MTase may be assayed over 0.5 to 2 hr depending on the construct, cell type, and cell cycle stage (early or late S).

Monitoring mRNA Export

Kazuaki Tokunaga[1] and Tokio Tani[1]

[1]Department of Biological Sciences, Graduate School of Science and Technology, Kumamoto University, Kurokami, Kumamoto, Japan

ABSTRACT

Transport of mRNA from the nucleus to the cytoplasm is an essential process for gene expression in eukaryotic cells. In this unit, methods for monitoring nuclear mRNA export are described. Visualization of cellular mRNAs by fluorescence in situ hybridization with oligo(dT) probes is effectively applied to monitoring mRNA export from the nucleus in yeast and mammalian cells. In addition to the protocols for fluorescence in situ hybridization, this unit includes an alternate method that the authors have been developing for visual analysis of nuclear mRNA export in living mammalian cells by microinjection of fluorescently labeled pre-mRNA into the nuclei. *Curr. Protoc. Cell Biol.* 41:22.13.1-22.13.20. © 2008 by John Wiley & Sons, Inc.

Keywords: mRNA • transport • in situ hybridization • microinjection • yeast • mammalian cells

INTRODUCTION

This unit contains protocols for monitoring transport of mRNA from the nucleus to the cytoplasm in yeast and mammalian cells. The first three protocols describe commonly used methods for monitoring mRNA export by fluorescence in situ hybridization with oligo(dT) probes that bind to the poly(A) tail of mRNA in the fission yeast *Schizosaccharomyces pombe* (Basic Protocol 1), the budding yeast *Saccharomyces cerevisiae* (Alternate Protocol 1), and mammalian cells (Alternate Protocol 2). The fourth protocol describes an alternate method for visual monitoring of mRNA export in a living mammalian cell by nuclear microinjection of fluorescently labeled pre-mRNAs that are synthesized in vitro (Basic Protocol 2).

NOTE: All steps in the following protocols must be performed using RNase-free, DEPC-treated water and all solutions must be prepared with RNase-free DEPC-treated water (see recipe in *APPENDIX 2A*). Also see *APPENDIX 2A* for general considerations when working with RNA.

MONITORING NUCLEAR mRNA EXPORT BY FLUORESCENCE IN SITU HYBRIDIZATION IN FISSION YEAST

BASIC PROTOCOL 1

Inhibition of mRNA export from the nucleus to the cytoplasm results in accumulation of mRNAs in the nucleus and concomitant decrease in cytoplasmic mRNAs. Based on such changes in cellular mRNA distribution, we can monitor nuclear mRNA export in eukaryotic cells. This protocol describes a procedure for fluorescence in situ hybridization using a biotin-labeled oligo(dT) probe to visualize the distribution of mRNAs in the fission yeast *Schizosaccharomyces pombe.* The oligo(dT) used as a probe hybridizes specifically to the poly(A) tail of mRNA.

The experiment can be divided into three stages. First, cells to be analyzed are fixed with paraformaldehyde and their cell walls are lysed with enzymes. The cells are then adhered onto a slide, followed by permeabilization with ethanol dehydration. In the second stage, after a short incubation with a prehybridization solution, cells are incubated with a hybridization solution, which allows the biotin-labeled oligo(dT) probe to bind to the

Current Protocols in Cell Biology 22.13.1-22.13.20, December 2008

DOI: 10.1002/0471143030.cb2213s41

poly(A) tails of mRNAs in the fixed cells. In the final stage of the experiment, the cells are washed with a series of sodium chloride/sodium citrate (SSC) solutions to remove unbound probe, then treated with avidin-FITC to visualize cellular mRNAs hybridized with the biotin-labeled probe.

Materials

S. pombe cells to be analyzed (e.g., wild-type strain *972* or temperature-sensitive export mutant strain *ptr8*; both strains available from Dr. Tokio Tani, Department of Biological Sciences, Graduate School of Science and Technology, Kumamoto University, Japan)
YE medium (see recipe)
4% paraformaldehyde solution (see recipe; freshly prepared)
0.1 M sodium phosphate buffer, pH 6.0 (*APPENDIX 2A*)
PEMS (see recipe), ice cold
Novozym (*http://www.novozymes.com*) or lysing enzyme from *Trichoderma harzanum* (Sigma, cat. no. L1412)
Zymolyase 100T (ICN Biomedicals)
70%, 90%, and 100% ethanol
Prehybridization solution for yeast (see recipe)
Hybridization solution for yeast: 1 ng/μl biotin-labeled oligo(dT) probe (Support Protocol 1) in prehybridization solution for yeast (see recipe); store at –20°C
4× SSC (see recipe for 20×)
2 μg/ml fluorescein isothiocyanate (FITC)–conjugated avidin (Roche, cat. no. 1975595) in 4× SSC/1% (w/v) RNase-free BSA (prepare fresh)
4× SSC/0.1% (v/v) Triton X-100 (prepare from 0.5% Triton stock, see recipe)
0.1 μg/ml DAPI solution (see recipe)
Phosphate-buffered saline (PBS; *APPENDIX 2A*)
Mounting medium (see recipe)
Clear nail polish

30° (for wild-type yeast) or 26°C (for temperature-sensitive mutants) shaking incubator
Refrigerated microcentrifuge with swinging-bucket rotor (e.g., Kubota model MF-2036)
Phase-contrast microscope
Coplin jars
Multi-well slide coated with poly-L-lysine (see recipe)
Glass coverslips
Moist chamber: place several sheets of filter paper soaked with distilled H_2O in a petri dish and put two toothpicks on the paper; slide on the toothpicks and seal the dish with tape or Parafilm
42°C air incubator
Epifluorescence microscope with FITC or DAPI filter set
Digital image acquisition system with a cooled CCD camera

Grow S. pombe cells

1. At a time point 2 days before the experiment, inoculate 5 ml of YE medium with a single colony of the *S. pombe* strain to be analyzed. Grow this preculture overnight with shaking to saturation at a temperature suitable for growth of the strain (in general, 30°C for the wild-type strain and 26°C for temperature-sensitive strains).

   When growing liquid cultures for in situ hybridization, gentle shaking is recommended to maintain uniform growth conditions.

2. The day before the experiment, inoculate 5 ml of YE medium with the appropriate amount of the saturated preculture. Grow overnight at the temperature used in step 1 to a mid-log phase—OD_{600} of 0.3 to 0.5 depending on the strain (1×10^7 cells/ml).

   Growth phase and cell density are very important for reproducible results of in situ hybridization. Saturated cultures cannot be used for the experiment. It is advisable to inoculate three independent culture tubes with varying amounts of the preculture (e.g., add 0.1, 0.2, or 0.5 ml preculture to 5 ml YE medium), then measure the OD_{600} of each culture the next day.

3. If the yeast strain to be analyzed is a temperature-sensitive mutant and its nuclear mRNA export at the nonpermissive temperature is being assessed, split the culture into two culture tubes and incubate one tube at a nonpermissive temperature (for example, at 37°C) using a water bath. Maintain the other tube at the permissive temperature during the temperature shift.

Harvest cells

4. Transfer 1.5 ml of each culture to a microcentrifuge tube. Harvest cells by centrifuging 2 min at 2000 × *g* (5000 rpm in Kubota microcentrifuge with swinging-bucket rotor MF-2036), 4°C. Discard supernatant by aspiration.

   We highly recommend a swinging-bucket rotor in centrifugation for collecting cells in this protocol. Centrifugation in a fixed-angle rotor causes loss of most cells during removal of supernatants, especially after digestion of cell walls, as spheroplast cells stick to the side walls of microcentrifuge tubes.

Fix cells

5. Resuspend the cells in 1 ml of 4% paraformaldehyde solution.

   The paraformaldehyde solution should be freshly prepared before the experiment.

6. Incubate at room temperature for 60 min to fix the cells.

7. Collect the cells by centrifugation for 2 min at 2000 × *g* (5000 rpm in Kubota MF-2036 swinging-bucket rotor), 4°C. Discard supernatant by aspiration.

8. Wash the cells three times, each time by resuspending them in 500 µl of 0.1 M sodium phosphate buffer, pH 6.0, and then collecting them by centrifuging 2 min at 2000 × *g* (5000 rpm in Kubota MF-2036 swinging-bucket rotor), 4°C, and discarding the supernatant by aspiration.

Digest cell walls

9. Resuspend the cells in 500 µl of PEMS containing 1 mg/ml Novozym (or 1mg/ml lysing enzyme from *Trichoderma harzianum*) and 1 mg/ml Zymolyase 100T.

10. Incubate at 37°C in a water bath for 15 to 20 min, then withdraw a drop of the cell suspension from the tube and check cells using a phase-contrast microscope.

    When cell walls are digested, cells look dark. If the percentage of dark cells is low, then continue incubation until the percentage of dark cells reaches 70% to 80%; do NOT continue incubation until the percentage of dark cells reaches 100%. Overdigestion of cells at this step will result in poor preservation of cell morphology and high background hybridization of the probe, and sometimes gives false positive signals in the nuclei.

11. Wash the cells three times with ice-cold PEMS (no enzymes), using the volumes and centrifugation conditions described in step 8.

    It is very important to use ice-cold PEMS for washing to prevent overdigestion of the cells during centrifugation and resuspension.

12. After washing, resuspend the cells in 300 µl ice-cold PEMS.

13. Put 50 μl of the cell suspension on a well of a multiwell slide coated with poly-L-lysine.
14. Leave the slide at room temperature for 30 min to allow the cells to settle to the surface of the well.
15. Aspirate the solution.

    An aspirator with a trapping jar is very convenient for quick removal of solutions from the wells of a slide. We connect a Pasteur pipet to the aspirator and attach a disposable pipet tip to the pipet when aspirating solutions.

Prepare cells for hybridization

16. Add 50 μl of 70% ethanol to each well.
17. Aspirate the ethanol solution to remove unattached cells.
18. Dehydrate the cells by incubating successively in 70%, 90%, and 100% ethanol in Coplin jars for 5 min each.
19. Air dry the slide at room temperature for 20 min.

    If desired, the dried slides can be stored in a plastic bag at −80°C after wrapping them with aluminum foil.

Prehybridize slides

20. Add 50 μl of prehybridization solution to each well.
21. Incubate the slide at room temperature for 30 min.
22. Discard the prehybridization solution by aspiration.

    Wells should not be allowed to dry during this and subsequent steps.

Hybridize slides

23. Add 10 μl of hybridization solution [prehybridization solution containing 1 ng/μl biotin-labeled oligo(dT) probe] to each well.
24. Put a glass coverslip on the multiwell slide to prevent evaporation of the hybridization solution.

    Usually, it is not necessary to seal the coverslip with rubber cement if the slide is incubated in a moist chamber.

25. Incubate the slide at 42°C overnight in a moist chamber.

Wash the slides

26. After incubation, remove the cover glass and wash the wells with 4× SSC (at 42°C) four times, each time for 10 min.

    To wash the wells, place the slide in 20 ml of 4× SSC in a petri dish or a small plastic container and change the 4× SSC every 10 min. After washing, wipe off the bottom of the multiwell slide carefully with paper towels to remove excess 4× SSC; otherwise deposition of salts on the glass surface will hinder microscopic observation.

27. Add 50 μl of 4× SSC/0.1 % Triton X-100 (at room temperature) to each well and aspirate the solution after 10-sec incubation at room temperature.
28. Add 50 μl 2 μg/ml FITC-avidin freshly diluted in 4× SSC/1% BSA to each well.
29. Incubate at room temperature for 30 min.

    Keep the slide in a dark box (or equivalent) to avoid fading of fluorescence.

Visualize hybridized probe

30. Aspirate the FITC-avidin and wash wells twice, each time for 10 min with 80 μl/well of 4× SSC.
31. Wash wells twice, each time for 10 min with 80 μl/well of 4× SSC/0.1% Triton X-100.
32. Wash each well twice, each time with 80 μl of 4× SSC.
33. Aspirate the 4× SSC, then add 50 μl of 0.1 μg/ml DAPI solution to each well and incubate for 2 min at room temperature.
34. Wash each well once with 50 μl PBS.
35. Apply 10 μl of mounting medium to each well, put a glass coverslip on the slide, and seal it with clear nail polish.

    Make sure not to trap air bubbles in the wells when placing the coverslip on the slide.

36. Inspect cells under an epifluorescence microscope equipped with a FITC or DAPI filter set and record images with a digital image acquisition system.

    If nuclear mRNA export takes place normally, fluorescent signals for mRNAs will be distributed throughout the cell, including the nucleus and the cytoplasm. If export of mRNA from the nucleus is blocked, strong nuclear signals will be observed, due to the accumulation of transcribed mRNAs in the nucleus, and the cytoplasmic signals will be concomitantly decreased.

MONITORING NUCLEAR mRNA EXPORT BY FLUORESCENCE IN SITU HYBRIDIZATION IN BUDDING YEAST

ALTERNATE PROTOCOL 1

These procedures are for fluorescence in situ hybridization in the budding yeast *Saccharomyces cerevisiae*. Reagents and steps for cell wall digestion are modified for *Saccharomyces cerevisiae*, as cell walls of *S. cerevisiae* are easily digested with Zymolyase 100T.

Additional Materials *(also see Basic Protocol 1)*

S. cerevisiae cells to be analyzed
YPD medium (see recipe)
Sorbitol buffer (see recipe), ice cold
2 mg/ml Zymolyase 100T
2-Mercaptoethanol

1. Perform steps 1 to 8 of Basic Protocol 1, except cultivate *S. cerevisiae* cells in YPD medium instead of YE medium.
2. Suspend fixed cells in 500 μl of sorbitol buffer. Add 2 μl of 2-mercaptoethanol and 20 μl of 2 mg/ml Zymolyase 100T dissolved in sorbitol buffer.
3. Incubate at 37°C in a water bath for 15 to 20 min.

   After incubation for 10 to 15 min at 37°C, withdraw a drop of the cell suspension from the tube and check cells using a phase-contrast microscope. If cell walls are digested, cells look dark under a phase-contrast microscope. Incubate until 70% to 80% of cells are digested.

4. Wash the cells three times, each time by resuspending them in 500 μl of sorbitol buffer, and then collecting them by centrifuging 2 min at 2000 × *g* (5000 rpm in Kubota MF-2036 swinging-bucket rotor), 4°C, and discarding the supernatant.
5. Resuspend the resulting spheroplast cells in 300 μl of sorbitol buffer and perform steps 13 to 36 of Basic Protocol 1 to label and visualize mRNA.

ALTERNATE PROTOCOL 2

MONITORING NUCLEAR mRNA EXPORT IN MAMMALIAN CELLS BY FLUORESCENCE IN SITU HYBRIDIZATION

Fluorescence in situ hybridization with an oligo(dT) probe can also be applied to the monitoring of nuclear mRNA export in mammalian cells. In the case of the fluorescence in situ hybridization of mammalian cells, an oligo(dT) probe labeled with digoxigenin is preferable to a biotin-labeled probe, as the biotin-labeled probe sometimes shows false-positive signals caused by an endogenous avidin-binding activity of mammalian cells. Detection of the digoxigenin-labeled probe hybridized to mRNAs is carried out by treatment with an anti-digoxin antibody followed by treatment with a fluorochrome-conjugated secondary antibody. The anti-digoxin antibody (Sigma) can recognize the digoxigenin specifically and yields low background staining.

Materials

HeLa cells (ATCC no. CCL-2) grown in a 100-mm tissue culture dish
Phosphate-buffered saline (PBS; *APPENDIX 2A*)
Trypsin/EDTA (see recipe)
DMEM with 10% FBS (see recipe)
3% paraformaldehyde (see recipe; freshly prepared)
0.5% (v/v) Triton X-100 (see recipe)
1× and 2× SSC (*APPENDIX 2A*)
Hybridization solution for mammalian cells (see recipe)
Rubber cement
PBS-BAG (see recipe)
Primary antibody: mouse anti-digoxin antibody (Sigma, cat. no. D8156)
Secondary antibody: anti–mouse IgG antibody conjugated with fluorescein isothiocyanate (FITC)
0.1 μg/μl DAPI solution (see recipe)
Mounting medium (see recipe)
Clear nail polish

Hemacytometer (*UNIT 1.1*)
12-mm glass coverslips, round or square
35-mm tissue culture dishes
Glass microscope slides
Moist chamber: place several sheets of filter paper soaked with distilled H_2O in a petri dish and put two toothpicks on the paper; slide on the toothpicks and seal the dish with tape or Parafilm
Forceps
Epifluorescence microscope with FITC or DAPI filter set
Digital image acquisition system with a cooled CCD camera

Additional reagents and equipment for counting cells using a hemacytometer (*UNIT 1.1*)

NOTE: All solutions and equipment coming into contact with living cells must be sterile, and aseptic technique should be used accordingly.

NOTE: All cell culture incubations should be carried out in a 37°C, 5% CO_2 humidified incubator.

Subculture cells for in situ hybridization

1. Aspirate medium from a confluent monolayer of HeLa cells in a tissue culture dish.
2. Add PBS (0.1 to 0.2 ml/cm^2 tissue culture surface), rinse the cells, and discard rinse.

   This step is necessary to remove traces of serum, which could inhibit the activity of trypsin.

3. Add trypsin/EDTA (0.1 ml/cm^2 tissue culture surface) to the dish.
4. Leave the trypsin/EDTA on the cells for 30 sec to 40 sec and aspirate the solution.
5. Incubate the dish at 37°C until the cells become round.
6. Add DMEM with 10% FBS to the dish (0.2 ml/cm^2 tissue culture surface) and disperse cells by repeated pipetting over the surface of the dish.

   Overtreatment of cells with trypsin/EDTA will reduce cell viability.

7. Count cells in an aliquot using a hemacytometer (*UNIT 1.1*) and dilute the cell suspension to 10^4 cells/ml with DMEM containing 10% FBS.
8. Put up to four sterilized 12-mm glass coverslips in a 35-mm tissue culture dish and then seed the dish with the diluted cell suspension (0.2 ml/cm^2).
9. Incubate the dish at 37°C in 5% CO_2 for 2 days.

Fix cells

10. Remove the medium and rinse cells once with PBS (0.1 to 0.2 ml/cm^2 tissue culture surface).
11. Add 3% paraformaldehyde (0.1 ml/cm^2 tissue culture surface) and incubate for 15 min at room temperature to fix the cells.

    The paraformaldehyde solution should be freshly made on the day of the experiment.

12. Wash the cells with PBS (0.2 ml/cm^2 tissue culture surface) three times, each time for 10 min.

Permeabilize cells

13. Add 0.5% Triton X-100 prepared in PBS (0.1 ml/cm^2 tissue culture surface) and incubate the dish for 5 min on ice to permeabilize the cells.
14. Rinse the cells with PBS (0.2 ml/cm^2) three times, each time for 10 min.
15. Rinse the cells with 2× SSC (0.2 ml/cm^2 tissue culture surface), each time for 10 min.
16. Remove coverslips from the dish using forceps and blot excess moisture on the coverslip with a paper towel.

Hybridize mRNA

17. Place 30 µl hybridization solution for mammalian cells onto the coverslip.
18. Invert the coverslip onto a glass slide and seal with rubber cement.
19. Place the slide/coverslip in a moist chamber and incubate overnight at 37°C.

    A moist chamber should be used to protect the coverslip from drying.

20. Peel rubber cement from the coverslip with forceps.

    Do not allow the coverslip to dry from this step on.

21. Place the coverslip with the cell culture side up in a 35-mm dish and wash cells three times, each time with 2 ml of 2× SSC for 10 min at 37°C.
22. Wash cells for 10 min with 2 ml of 1× SSC for 10 min at 37°C.
23. Add 2 ml of PBS-BAG and incubate for 30 min at room temperature.

Detect hybrids

24. Remove the coverslip from the dish. Place 30 μl of anti-digoxin primary antibody diluted 1:200 in PBS-BAG onto the coverslip and invert it onto a glass slide. Incubate the slide/coverslip in a moist chamber at room temperature for 60 min.

25. Wash the coverslip three times, each time with 2 ml PBS for 10 min in a 35-mm dish at room temperature.

26. After washing, place 30 μl of anti–mouse IgG secondary antibody conjugated with FITC, diluted 1:200 in PBS-BAG onto the coverslip and then invert it on a glass slide. Incubate the slide/coverslip in a moist chamber at room temperature for 60 min.

    Keep the coverslip in the dark during this and subsequent steps.

27. Wash the coverslip three times, each time with 2 ml PBS in a 35-mm dish for 10 min at room temperature.

28. Stain the cells on the coverslip with 100 μl of 0.1 μg/μl DAPI solution.

29. Wash the coverslip once for 10 min with 2 ml PBS in a 35-mm dish at room temperature.

Mount the coverslip

30. Remove the coverslip from the dish using forceps and blot excess moisture from the coverslip using a paper towel.

31. Apply 10 μl mounting medium to the coverslip and invert it onto the glass slide. Seal the coverslip with clear nail polish.

    Do not trap air bubbles in the mounting medium when placing the coverslip on the slide.

32. Observe cells under an epifluorescence microscope equipped with a FITC or DAPI filter set and record images with a digital image acquisition system.

    If nuclear mRNA transport is not impaired, fluorescent signals for mRNAs will be observed as a speckled pattern in the nucleus and a uniform distribution in the cytoplasm. If nuclear mRNA transport is inhibited, fluorescent signals in the nuclear speckles will be increased.

BASIC PROTOCOL 2

MONITORING NUCLEAR mRNA EXPORT IN A LIVING MAMMALIAN CELL BY MICROINJECTION OF FLUORESCENTLY LABELED PRE-mRNA INTO THE NUCLEUS

This protocol is designed to monitor mRNA export in a living mammalian cell by visualization of mRNAs injected into the nucleus. Pre-mRNAs transcribed in vitro are labeled with a fluorescent dye and microinjected into the nuclei. The injected pre-mRNAs have been shown to be spliced in the nucleus and exported to the cytoplasm via an energy-dependent process (Tokunaga et al., 2006). The process of mRNA transport from the nucleus to the cytoplasm in living mammalian cells can be analyzed visually under an epifluorescence microscope equipped with a cooled CCD camera.

Materials

HeLa cells (ATCC no. CCL-2)
DMEM supplemented with 10% FBS, penicillin, and streptomycin (see *APPENDIX 2A*)
Phenol red–free DMEM with 10% FBS (see recipe for DMEM with 10% FBS, but use phenol red–free DMEM)
3 M sodium acetate, pH 5.3 (*APPENDIX 2A*)
100% ethanol

Microinjection buffer (see recipe)
1.5 mg/ml FITC-dextran (see recipe)
Cy3-labeled *fushi tarazu* pre-mRNA (Support Protocol 2)
3% paraformaldehyde solution (see recipe)
Mounting medium (see recipe)
Clear nail polish

35-mm glass-bottom dishes
Humidified 5% CO_2 incubator
Refrigerated centrifuge with Kubota AF-2536A rotor (or equivalent)
Microloader pipet tip (Eppendorf or equivalent)
Inverted epifluorescence microscope
Digital image acquisition system with a cooled CCD camera
Microscope stage incubator, 37°C, 5% CO_2 (optional)
Microinjection needle (Eppendorf Femtotips II or equivalent)
Microinjector and manipulator (Eppendorf 5170 microinjector or equivalent)

Additional reagents and equipment for trypsinizing HeLa cells and preparing cell suspension (Alternate Protocol 2, steps 1 to 7)

NOTE: All solutions and equipment coming into contact with living cells must be sterile, and aseptic technique should be used accordingly.

NOTE: All cell culture incubations should be carried out in a 37°C, 5% CO_2 humidified incubator.

Subculture cells for microinjection

1. At a time point 2 days before mRNA injection, trypsinize HeLa cells and make a cell suspension of 10^4 cells/ml with DMEM supplemented with 10% FBS, penicillin, and streptomycin as described in steps 1 to 7 in Alternate Protocol 2.
2. Seed a 35-mm glass bottom dish with the cell suspension.
3. Incubate the dish at 37°C in a 5% CO_2 incubator.

   The cells should be ~80% confluent on the day of microinjection.

Prepare reagents for microinjection

4. Change the medium to fresh phenol red–free DMEM supplemented with 10% FBS.

   Phenol red in the medium generates red fluorescence that competes with the Cy3 fluorescence of the labeled mRNAs.

5. Ethanol-precipitate the labeled pre-mRNA by adding 1/10 vol of 3 M sodium acetate, pH 5.3, and 2.5 vol of cold 100% ethanol. After keeping the mixture at –80°C for 30 min, centrifuge 15 min at 20,000 × *g* (14,500 rpm in Kubota AF-2536A rotor), 4°C, and discard the supernatant. Dry the RNA pellet under vacuum and resuspend the RNA pellet in microinjection buffer to make a 1.5 μM labeled pre-mRNA working solution.
6. Mix equal volumes of 1.5 μM labeled pre-mRNA solution and 1.5 mg/ml FITC-dextran. To avoid clogging the injection needle, centrifuge the mixture 5 min at 2400 × *g* (5000 rpm in Kubota AF-2536A rotor), 4°C, and use the supernatant for microinjection.

   FITC-dextran (70 kDa), which cannot move to the cytoplasm through nuclear pores by passive diffusion, is used as an injection marker and coinjected into the nuclei to confirm the nuclear injection of the fluorescent pre-mRNA.

7. Load a microinjection needle with ~0.5 µl of the pre-mRNA/FITC-dextran mixture using a microloader pipet tip.

   Standard femtotip microinjection needles work well for the Eppendorf microinjection system and are convenient for obtaining reproducible results.

Microinject fluorescently labeled pre-mRNA into the nuclei

8. Place the dish on the stage of the inverted epifluorescence microscope and locate the cells to be injected using a 10× objective lens.
9. Attach the microinjection needle loaded with the pre-mRNA/FITC-dextran mixture to the manipulator.
10. Move the microinjection needle close to a cell and change the objective lens to 40×.
11. Microinject fluorescently labeled pre-mRNA into the nuclei of cells in the center of the glass-bottom dish. Inject at least 50 cells per experimental condition.

    In the case of the Eppendorf 5170 microinjector, we usually set the injection pressure to 50 hPa, the compensation pressure to 45 hPa, and the injection duration to 0.5 sec.

    It is necessary to maintain a constant flow from the needle to keep it from clogging. Injection of pre-mRNAs into cells in one dish should be finished within 20 min.

12. Place the dish in a 37°C, 5% CO_2 incubator. After 15, 30, and 60 min of incubation, inspect cells with an inverted epifluorescence microscope equipped with a cooled CCD camera.

Observe the cells

13. If a microscope stage incubator is available, set the dish in it after injection and observe migration of fluorescent mRNAs from the nucleus to the cytoplasm under the inverted epifluorescence microscope.
14. To obtain clear images of the injected mRNAs, fix the cells with 2 ml freshly prepared 3% paraformaldehyde for 15 min at room temperature.
15. Rinse the cells three times, each time with 2 ml PBS 10 min, then add the mounting medium to the glass-bottom dish and seal with a coverslip and clear nail polish.
16. Observe cells with an inverted epifluorescence microscope and record images with a digital image acquisition system.

SUPPORT PROTOCOL 1

PREPARATION OF A DIGOXIGENIN (OR BIOTIN)–LABELED OLIGO(dT) HYBRIDIZATION PROBE

In this protocol, a 50-mer oligo(dT) is enzymatically labeled with digoxigenin, biotin, or fluorochrome such as FITC or Texas red, at its 3′-end with terminal transferase. Digoxigenin is a steroid that occurs naturally only in digitalis plants.

Materials

DIG oligonucleotide 3′-end labeling kit (Roche Applied Science)
1 mM biotin-16-ddUTP (for preparation of biotin-labeled probe)
STOP solution (see recipe)
4 M LiCl
100% ethanol, cold
70% ethanol
TE buffer (*APPENDIX 2A*)

Microcentrifuge with, Kubota AF-2536A rotor (or equivalent), 4°C
Vacuum desiccator

1. Mix the following reagents from the Roche DIG oligonucleotide 3′-end labeling kit with oligo dT (50-mer) in a microcentrifuge tube:

   8 µl 5× reaction buffer (vial 1)
   8 µl $CoCl_2$ solution (vial 2)
   2 µl 1 mM DIG-11-ddUTP solution (vial 3)
   2 µl terminal transferase (vial 4)
   2 µl oligo(dT) (50-mer, 100 pmol/µl)
   18 µl distilled H_2O.

   For preparation of the biotin-labeled probe, add 2 µl of 1 mM biotin-16-ddUTP for the reaction in place of the digoxigenin-labeled dUTP.

2. Incubate at 37°C for 20 min in a water bath.
3. Add 4 µl of STOP solution, 5 µl of 4 M LiCl, and 150 µl of cold 100% ethanol.
4. Mix by vortexing and incubate at −80°C for 30 min.
5. Microcentrifuge 15 min at 20,000 × *g* (14,500 rpm in Kubota AF-2536A rotor), 4°C. Remove supernatant.
6. Add 300 µl of 70% ethanol and microcentrifuge 10 min at 20,000 × *g* (14,500 rpm in Kubota AF-2536A rotor), 4°C.
7. Remove supernatant carefully and dry pellet for 10 min under vacuum.
8. Resuspend the pellet in 50 µl of TE buffer. Store at −20°C.

PREPARATION OF FLUORESCENTLY LABELED PRE-mRNA

SUPPORT PROTOCOL 2

Materials

pSP64 (poly A)-ftz plasmid (available from Dr. Tokio Tani, Department of Biological Sciences, Graduate School of Science and Technology, Kumamoto University, Japan)
Restriction enzyme *Eco*RI and high-salt restriction buffer
25:24:1 (v/v/v) phenol/chloroform/isoamyl alcohol
3 M sodium acetate, pH 7.0
3 M sodium acetate, pH 5.2 (*APPENDIX 2A*)
100% ethanol, cold, and 70% ethanol
TE buffer (*APPENDIX 2A*)
5× transcription buffer (see recipe)
100 mM DTT
10 mM ATP, UTP, GTP, and CTP
m^7G cap analog (Promega, cat. no. P171B)
15 U/µl SP6 RNA polymerase
1 U/µl DNase I (RNase-free grade)
RNase-free H_2O (DEPC-treated; *APPENDIX 2A*)
RNA dye solution (see recipe)
8% polyacrylamide/7 M urea gel (also see Brown et al., 2004)
1 µg/ml ethidium bromide
10× labeling buffer (PanVera Corp.)
Label IT reagent (PanVera Corp.)
Microcentrifuge with Kubota AF2536A rotor (or equivalent), 4°C
Vacuum desiccator
MicroSpin G-50 spin columns (GE Healthcare)
Spectrophotometer capable of reading at 260 nm
90°C water bath or heat block

Additional reagents and equipment for agarose gel electrophoresis (Voytas, 2000), extraction of DNA from agarose gels (Moore et al., 2002), and denaturing polyacrylamide electrophoresis of RNA (Brown et al., 2004)

Linearize plasmid

1. To prepare a linearized substrate for in vitro transcription, digest 25 μg of the plasmid DNA in a 100-μl solution containing 50 U of *Eco*RI and 1× high-salt restriction buffer (supplied by the manufacturer of the restriction enzyme) at 37°C for at least 6 hr.

   pSP64 (poly A)-ftz was constructed as follows. pGEM-pre ftz (Rio, 1988) was digested with HindIII and SacI, and a fragment containing a part of the Drosophila fushi tarazu (ftz) genomic gene was inserted between HindIII and SacI sites of the pSP64-poly A vector (Promega), which contains SP6 promoter and a stretch of dA:dT residues for generation of a poly(A) tail.

2. Extract digested DNA with 100 μl 25:24:1 phenol/chloroform/isoamyl alcohol by vortexing for 1 min and centrifuging 10 min at 20,000 × *g* (14,500 rpm in Kubota AF2536A rotor), room temperature.

3. Take the upper phase and add 1/10 vol of 3 M sodium acetate, pH 7.0, and 2.5 vol of cold 100% ethanol. Mix and incubate at −80°C for at least 30 min.

4. Centrifuge 10 min at 20,000 × *g*, 4°C, and remove supernatant.

5. Add 500 μl of 70% ethanol and centrifuge 10 min at 20,000 × *g*, 4°C.

6. Remove supernatant and dry the pellet for 10 min under vacuum. Suspend the DNA pellet in TE buffer at a concentration of 0.5 μg/μl. Check the digested plasmid DNA by electrophoresis on an agarose gel (Voytas, 2000). If undigested plasmid DNA remains, purify the cleaved DNA fragment by electrophoresis on an agarose gel followed by extraction of DNA from a gel slice (Moore et al., 2002).

Transcribe to pre-mRNA

7. Mix the following and incubate at 37°C for 60 min:

   10 μl 5 μg/μl template DNA (from step 6)
   20 μl 5× transcription buffer
   10 μl 100 mM DTT
   10 μl 10 mM ATP
   10 μl 10 mM CTP
   10 μl 10 mM UTP
   2 μl 10 mM GTP
   8 μl 10 mM m^7G cap analog
   3 μl 15 U/μl SP6 RNA polymerase
   7 μl distilled H_2O.

   Transcription of pSP64 (poly A)-ftz linearized with EcoRI generates pre-ftz mRNA (497 nt) containing one intron (151 nt) and a poly(A) sequence (30 nt).

8. Add 5 μl of DNase I (1 U/μl, RNase-free grade) and incubate at 37°C for 60 min to digest the template DNA.

9. Add 100 μl of 25:24:1 phenol/chloroform/isoamyl alcohol and mix by vortexing for 1 min.

10. Centrifuge 10 min at 20,000 × *g*, room temperature.

11. Transfer the upper phase to a new microcentrifuge tube and add 1/10 vol of 3 M sodium acetate, pH 5.2, and 2.5 vol of cold 100% ethanol. Incubate for 30 min at −80°C.

12. Centrifuge 15 min at 20,000 × *g*, 4°C, and remove supernatant.
13. Add 500 µl of 70% ethanol and centrifuge 10 min at 20,000 × *g*, 4°C.
14. Remove supernatant and dry the RNA pellet under vacuum.

Purify pre-mRNA

15. Resuspend the RNA pellet in 50 µl of RNase-free (DEPC-treated) water.
16. Remove unincorporated ribonucleotides from the RNA sample using a MicroSpin G-50 column according to the manufacturer's instructions.
17. Measure the concentration of RNA using a spectrophotometer with absorbance at 260 nm.
18. To check integrity of the synthesized pre-mRNA, mix 1 µg of the RNA sample and 19 µl of RNA dye solution. After heating at 90°C for 3 min, electrophorese the mixture on an 8% polyacrylamide/7 M urea gel (also see Brown et al., 2004) followed by staining with 1 µg/ml of ethidium bromide solution for 10 min.

    It is also possible to run the RNA in the gel system with the ethidium bromide contained in the gel and running buffer, but the authors have found that post-staining results in more uniform staining of the gel, although it takes a little bit longer to perform the experiments.

Cy3-label pre-mRNA

19. To label RNA with a Cy3 fluorescent dye, set up the following reaction mixture in a final volume of 50 µl:

    10 µg pre-mRNA transcribed in vitro as described in the previous steps
    5 µl 10× labeling buffer
    5 µl Label IT reagent.

20. Incubate at 37°C for 1 hr.
21. Add 5 µl of 3 M sodium acetate, pH 5.2, and 125 µl of cold 100% ethanol. Mix by vortexing and incubate for 30 min at −80°C.
22. Centrifuge 15 min at 20,000 × *g*, 4°C.
23. Discard supernatant and rinse the RNA pellet with 70% cold ethanol as described in step 13.
24. Dry the RNA pellet under vacuum for 10 min.
25. Suspend the pellet in 50 µl of RNase-free water.

Purify the fluorescently labeled pre-mRNA

26. Purify the labeled pre-mRNA from unincorporated fluorescent dye using the MicroSpin G-50 column according to the manufacturer's instructions.

    The amount of Cy3 coupled with pre-mRNA can be measured spectrofluorometrically at an excitation wavelength of 550 nm. On the average, the pre-mRNA should be labeled with 18 molecules of Cy3 per molecule.

REAGENTS AND SOLUTIONS

Use RNase-free DEPC-treated (APPENDIX 2A) deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Carbonate-bicarbonate buffer

Mix 2 ml of 0.2 M anhydrous sodium carbonate (1.06 g/50 ml), 2 ml of 0.2 M sodium bicarbonate (1.84 g/50 ml), and 96 ml of distilled water. Store up to several months at 4°C.

DAPI solution

0.1 μg/ml 4′,6-diamidino-2-phenylindole (DAPI)
1× PBS (*APPENDIX 2A*)
Store up to several months at −20°C

Denhardt solution, 100×

10 g Ficoll 400
10 g polyvinylpyrrolidone
10 g bovine serum albumin (Pentax Fraction V)
H_2O to 500 ml
Filter sterilize
Store up to several months at –20°C in 25-ml aliquots

DMEM with 10% FBS

Dulbecco's Modified Eagle Medium (formulation containing L-glutamine; use phenol-red free formulation where specified in protocol) supplemented with:
10% fetal bovine serum (FBS)
100 U/ml penicillin
100 μg/ml streptomycin

FITC-Dextran

Prepare 3 mg/ml FITC-dextran (70 kDa) in microinjection buffer. Filter the solution with a 0.2-μm filter and store up to several weeks at 4°C protected from the light.

Hybridization solution for mammalian cells

20 μl formamide
10 μl 10 mg/ml tRNA
10 μl 20× SSC (see recipe)
20 μl 50% (w/v) dextran sulfate
3 μl oligo(dT) probe labeled with digoxigenin (Support Protocol 1)
37 μl distilled H_2O
Prepare fresh

Microinjection buffer

10 mM sodium phosphate buffer, pH 7.2 (*APPENDIX 2A*)
70 mM KCl
Store up to several months at 4°C

Mounting medium

8.5 ml glycerol (nonfluorescent grade)
750 μl 1× PBS (*APPENDIX 2A*)
10 mg *p*-phenylenediamine

Mix the above reagents in a small beaker wrapped with aluminum foil and stir ½ day to overnight to dissolve *p*-phenylenediamine, which is a chemical antibleaching agent that greatly retards the photobleaching of fluorophores. Then, add ∼20 drops of carbonate-bicarbonate buffer (see recipe) and check pH using pH paper. The pH of the solution should be 8.0. Store the mounting medium at −80°C in 200-μl aliquots for long-term storage. Working mounting medium can be stored up to several weeks at −20°C in the dark, although it will become dark brown with time, whereupon it should be discarded.

Multiwell slides, poly-L-lysine-coated

Place 50 µl of 1 mg/ml poly-L-lysine (mol. wt., 150,000 to 300,000) into each well of a multiwell slide (immunofluorescence slide from Polysciences, or equivalent). Leave at room temperature for 15 min, and then aspirate the solution, rinse each well once with 50 µl distilled water, and allow to air dry completely. Store slides up to several days at room temperature.

Paraformaldehyde solution, 3% or 4%

After suspending 0.4 g (for 4% solution) or 0.3 g (for 3%) of paraformaldehyde in 5 ml of distilled water, add 2 to 3 drops of 5 N NaOH, heat at 50° to 60°C in a water bath to dissolve paraformaldehyde completely, and then mix with 5 ml of 0.2 M phosphate buffer, pH 6.0 (see recipe). Prepare fresh.

CAUTION: *All operations involving paraformaldehyde should be performed in a fume hood, as formaldehyde (generated from the paraformaldehyde) is a carcinogen and may cause irritation to skin and mucous membranes.*

PBS-BAG

1× PBS (*APPENDIX 2A*)
1% (w/v) bovine serum albumin
0.1% (w/v) NaN_3
0.5% (w/v) cold water fish skin gelatin (Sigma)
Filter with a 0.45-µm filter.
Store up to several months at 4°C

PEMS

100 mM PIPES, pH 6.9
0.1 mM $MgCl_2$
1 mM EGTA
1.2 M sorbitol
Store up to several months at 4°C

Prehybridization solution for yeast

4× SSC (see recipe)
5× Denhardt solution (see recipe)
1 mg/ml baker's yeast tRNA (Sigma)
Store up to several months at −20°C

RNA dye solution

90% (v/v) formamide
50 mM Tris·Cl, pH 7.5 (*APPENDIX 2A*)
1 mM EDTA
0.1% (w/v) xylene cyanol
0.1% (w/v) bromphenol blue
Store up to several months at room temperature

Sodium phosphate buffer, pH 6.0, 0.2 M

Solution A: 13.9 g $NaH_2PO_4 \cdot H_2O$; make up to 500 ml with distilled H_2O
Solution B: 35.85 g $Na_2HPO_4 \cdot 12H_2O$; make up to 500 ml with distilled H_2O

Mix 87.7 ml of solution A and 12.3 ml of solution B to make a 0.2 M phosphate buffer (pH 6.0). Store up to several months at 4°C.

Sorbitol buffer

1.2 M sorbitol
0.1 M sodium phosphate buffer, pH 6.0 (see recipe)
Store up to several months at 4°C

SSC (sodium chloride/sodium citrate), 20×

3 M NaCl (175 g/liter)
0.3 M Na_3citrate·$2H_2O$ (88 g/liter)
Adjust pH to 7.0 with 1 M HCl
Store up to several months at room temperature

STOP solution

0.2 M EDTA, pH 8.0 (*APPENDIX 2A*)
100 μg/ml glycogen
Store up to several months at −20°C

Transcription buffer, 5×

250 mM Tris·Cl, pH 7.5 (*APPENDIX 2A*)
30 mM $MgCl_2$
10 mM spermidine
500 μg/ml bovine serum albumin (RNase free)
Store up to several months at −20°C

Triton X-100, 0.5% (v/v)

1× PBS (*APPENDIX 2A*)
0.5% (v/v) Triton X-100
Store up to several months at 4°C

Trypsin/EDTA

0.25% (w/v) trypsin
1 mM EDTA (*APPENDIX 2A*)
1× PBS (*APPENDIX 2A*)
Store up to several weeks at −20°C

YE medium

0.5% (w/v) yeast extract
3% (w/v) glucose
Store up to several weeks at room temperature

YPD medium

1% (w/v) yeast extract
2% (w/v) Bacto-peptone
2% (w/v) glucose
Store up to several weeks at room temperature

COMMENTARY

Background Information

In eukaryotic cells, domains for transcription and translation are spatially separated by the nuclear membrane. Therefore, transport of mRNAs from the nucleus to the cytoplasm is an essential step for gene expression in eukaryotic cells. Understanding of the mechanisms of mRNA transport from the nucleus to the cytoplasm has increased through the identification of genes involved in the export process. Genetic studies in the yeasts *Schizosaccharomyces pombe* and *Saccharomyces cerevisiae* have been an effective approach for identifying genes involved in nuclear mRNA export (for a

review see Strässer and Hurt, 1999). Dozens of yeast temperature-sensitive mutants defective in mRNA export were isolated by screening with fluorescence in situ hybridization using an oligo(dT) as a probe, and the genes responsible for the mutations have been cloned (e.g., Heath et al., 1995; Azad et al., 1997; Mizuki et al., 2007).

In yeast, the accumulation of mRNA in the nucleus by inhibition of mRNA export is easily visualized in the in situ hybridization assay, as most yeast mRNAs in the cytoplasm have relatively short half-lives and the accumulated nuclear mRNAs are considerably more stable. Average half-lives ranging from 16 to 23 min have been measured for mRNAs in the yeast *S. cerevisiae* (Herrick et al., 1990). In addition, yeast mRNAs have been shown to exit the nucleus within 2 min after synthesis under normal growth conditions (Groner and Phillips, 1975). Therefore, blockage of the mRNA transport pathway in yeast cells results in a drastic change in the steady-state distribution of mRNAs, which can be easily detected by fluorescence in situ hybridization with an oligo(dT) probe that binds to the poly(A) tail of mRNAs.

Fluorescence in situ hybridization with the oligo(dT) probe has been also used for monitoring nuclear mRNA export in mammalian cells (e.g., Shibata et al., 2002). However, the generally long half-lives of mammalian mRNAs and the presence of stable poly(A)$^+$ RNAs in specific nuclear compartments termed "speckles" or "splicing factor compartments" (Lamond and Spector, 2003) sometimes make it difficult to detect the inhibition of nuclear mRNA export using fluorescence in situ hybridization.

A *Xenopus* oocyte system has also been used for analyses of nuclear mRNA export (e.g., Jarmolowski et al., 1994). In that system, ^{32}P-labeled mRNAs are microinjected into the nuclei of *Xenopus* oocytes, followed by incubation for an appropriate time. The nucleus and the cytoplasm are then dissected, and RNAs are extracted from each fraction to be analyzed by electrophoresis on a gel with subsequent autoradiography. Compared to the *Xenopus* oocyte system, the microinjection assay for fluorescent pre-mRNA described in this unit has the advantage of analysis of mRNA export in a living mammalian cell in real time. It has been demonstrated that, like endogenous mRNAs, the injected fluorescent pre-mRNAs are exported to the cytoplasm after splicing by an energy-dependent process (Tokunaga et al., 2006).

Critical Parameters

In situ hybridization assay

To obtain strong hybridization signals with low background, it is important to use oligo(dT) probes efficiently labeled with biotin or digoxigenin. Labeling of the oligo(dT) with biotin or digoxigenin can be checked by spotting of 1 μl of the probe onto a nylon membrane and treating the membrane with avidin or anti-digoxigenin antibody conjugated with alkaline phosphatase or horseradish peroxidase, followed by appropriate detection reagents. Temperatures for hybridization and subsequent washing are also important. Hybridization at low temperatures (for example, at 37°C) sometimes causes high background hybridization.

One possible cause of weak or no hybridization signals in yeast cells is incomplete digestion of cell walls. Although removal of cell walls is essential for penetration of a probe into cells, overdigestion of cells damages cell morphology and gives background hybridization in the nuclei. As efficiencies of cell wall digestion by Novozym or Zymolyase 100T vary depending on the growth phase of the cells, inspection with a phase-contrast microscope at the digestion step is important for stopping the digestion reaction at the correct time for in situ hybridization (~80% of cells are spheroplasted). Washing cells with ice-cold PEMS or sorbitol buffer after treatment with the enzymes is also critical to prevent overdigestion of cells during the washing steps. Oligo(dT) labeled directly with fluorochrome, such as FITC, can be used as a probe for fluorescence in situ hybridization in yeast and mammalian cells. The signal intensity of the fluorochrome-labeled oligo(dT) probe, however, is generally weak compared to that of a biotin- or digoxigenin-labeled probe, which can amplify the signal intensities.

Microinjection assay

Labeling efficiency of pre-mRNAs with the Cy3 fluorescent dye is important for visualization of the export process in living mammalian cells. Too much labeling with the Cy3 fluorescent dye might inhibit the mRNA export process. The amount of Cy3 coupled with pre-mRNA can be measured spectrofluorometrically at an excitation wavelength of 550 nm. Pre-mRNAs labeled with ~18 molecules of Cy3 per molecule on average are suitable for the microinjection assay.

Table 22.13.1 Troubleshooting Guide for Fluorescence In Situ Hybridization for Monitoring mRNA Export

Problem	Possible cause	Solution
High background signal	Washing of the probe is insufficient	Increase washing steps and time. Increase volume of the washing buffer.
	Cells dried up during hybridization and subsequent washing steps	Make sure not to leave the sample without solution for a long time. Use an aspirator to quickly exchange solutions when removing supernatants.
	The probe is too concentrated	Decrease the amount of the oligo(dT) probe in the hybridization solution
	Antibodies or FITC-avidin are too concentrated	Dilute antibodies or FITC-avidin further
	Temperature of hybridization is low	Perform hybridization at 42°C or above
	Quality of ethanol used for the dehydration step is not suitable for in situ hybridization (for yeast cells only)	Some manufacturers' ethanols generate high fluorescent background. Change ethanol to an other manufacturer's absolute ethanol.
No or weak signal	Labeling efficiency of oligo(dT) with digoxigenin or biotin is low	Extend the incubation time for the labeling reaction and check the labeled probe by spotting on the nylon membrane as described in the protocol
	Cell walls are not sufficiently digested (for yeast cells only)	Extend the incubation time with the cell wall digestion enzymes. Make sure that the cells to be analyzed are in the mid-log phase. Cell walls of stationary-phase cells are hard to digest.
False hybridization in the nuclei (for yeast cells only)	Cells are overdigested by cell wall digestion enzymes	Shorten the incubation time with the enzymes. Cells should be checked frequently with a phase-contrast microscope to determine the best incubation time for cell wall digestion.
Poor morphological preservation (for yeast cells only)	Fixation of cells is not sufficient	Prepare fresh 4% paraformaldehyde on the day of the experiment
	Spheroplasted cells are centrifuged at inadequate speed	Make sure that centrifugation of spheroplasted cells in carried out at low speed (e.g., 3000 to 5000 rpm in a microcentrifuge)
	Cells are over-digested by cell wall digestion enzymes	Shorten the incubation time with the enzymes
Loss of cells during washing steps (for yeast cells only)	Poor packing of cells after centrifugation	Use a swinging-bucket rotor to collect cells

Table 22.13.2 Troubleshooting Guide for the Microinjection Assay

Problem	Possible cause	Solution
Microinjection needle clogs often	Pressure for constant flow from the needle is weak	Change the injection pressure, compensation pressure and injection time of the microinjector
	Insoluble particles are present in the microinjection mixture	Centrifuge and filter the microinjection mixture with a 0.2-μm filter
RNA samples are degraded	RNase contamination	Prepare all reagents with DEPC-treated RNase-free water

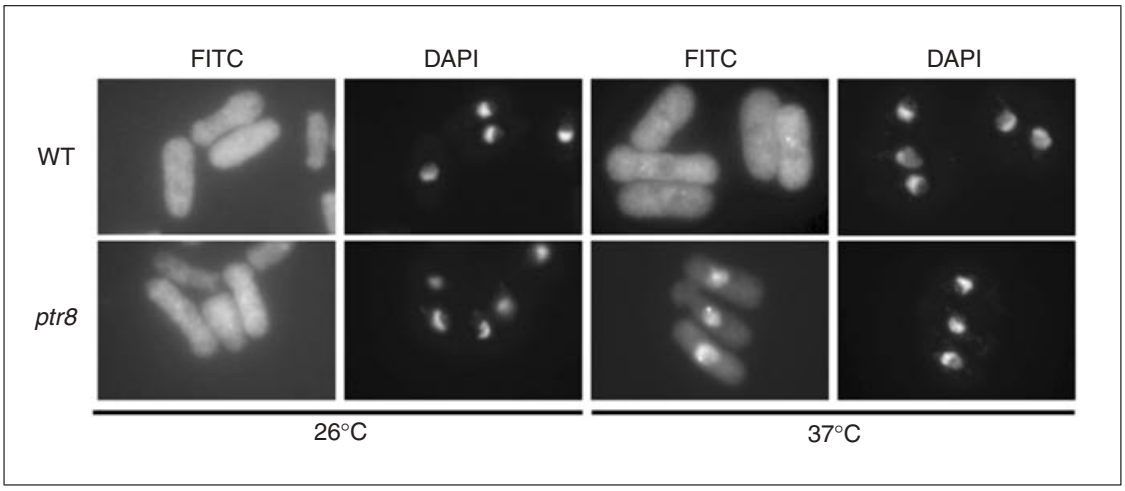

Figure 22.13.1 Fluorescence in situ hybridization with oligo(dT) probe in *S. pombe*. The wild-type strain *972* ("WT," upper panels) and the mRNA export mutant *ptr8* (lower panels, Mizuki et al., 2007) were grown at 26°C and either maintained at 26°C or shifted to 37°C for 60 min. The cells were fixed and analyzed by fluorescence in situ hybridization with the biotin-labeled oligo(dT)$_{50}$ probe. Hybridized signals were detected by FITC-conjugated avidin. The FITC columns show the distribution of mRNA in the respective cells. The DAPI columns show staining of DNA of the cells in the same field.

To monitor the mRNA export, fluorescent pre-mRNAs should be accurately injected into the nuclei. The injected pre-mRNAs are localized to the speckles in the nucleus, spliced, and then exported to the cytoplasm (Tokunaga et al., 2006). Intron-less mRNAs transcribed from cDNAs localize uniformly in the nucleus after injection and are not distributed to the speckles even after long incubation periods (Tokunaga et al., 2006). It is usually difficult to detect the nuclear export of intron-less mRNAs in the microinjection assay, as they degrade more rapidly than pre-mRNAs in cells. Pre-mRNA splicing might facilitate formation of export-competent RNP complexes and stabilize the injected mRNAs. We, therefore, recommend pre-mRNAs with high splicing efficiency, such as *fushi tarazu* pre-mRNA, as an injection substrate.

Troubleshooting

Tables 22.13.1 and 22.13.2 describe problems commonly encountered when performing the fluorescence in situ hybridization and the microinjection assays. Possible causes of these problems and how to solve them are also given.

Anticipated Results

In situ hybridization assay

In wild-type yeast cells, hybridization signals should be observed throughout the cells at all temperatures tested (Fig. 22.13.1, upper panels). In contrast, due to defects in mRNA export, temperature-sensitive mRNA export mutants will give strong nuclear signals and weak cytoplasmic signals in cells cultured at nonpermissive temperatures in the in situ hybridization assay with the oligo(dT) probe (Fig. 22.13.1, lower panels; Mizuki et al., 2007).

In the case of in situ hybridization of mammalian cells, hybridization signals will be detected as a speckle pattern in the nucleus and a uniform distribution in the cytoplasm under normal conditions. When nuclear mRNA export is inhibited in mammalian cells, intensities of hybridized signals in the speckles increase significantly (e.g., Shibata et al., 2002).

Microinjection assay

The fluorescent pre-mRNAs injected into the nuclei of HeLa cells are first distributed uniformly in the nucleus and then localized to the speckles within ∼15 min. After that, the cytoplasmic fluorescent signals will increase with incubation time, with concomitant decreases in nuclear fluorescence, suggesting that the injected mRNAs are exported to the cytoplasm from the nucleus.

Time Considerations

After culturing cells, the entire procedure for fluorescence in situ hybridization in yeast and mammalian cells will take 2 days, depending on the length of hybridization. If hybridization with the oligo(dT) probe is carried out within several hours, the procedures can be done in a single day. In the case of in situ hybridization in yeast cells, however, overnight hybridization is recommended

for reproducible results. After dehydration of yeast cells with ethanol (step 18 of Basic Protocol 1), the protocol can be interrupted. The slides can be stored at −80°C for more than several months.

For the microinjection assay, preparation of fluorescently labeled pre-mRNAs will require 1 day. Injection of the fluorescent pre-mRNAs into the nuclei of ∼50 cells will take 15 to 20 min, depending on the experimenter's skills for microinjection.

Analysis of DNA Replication in *Saccharomyces cerevisiae* by Two-Dimensional and Pulsed-Field Gel Electrophoresis

Satoru Ide[1] and Takehiko Kobayashi[1,2]

[1]National Institute of Genetics, Shizuoka, Japan
[2]The Graduate University for Advanced Studies, Sokendai, Mishima, Japan

ABSTRACT

Two methods to analyze DNA replication in budding yeast are described here. One is two-dimensional (2D) gel electrophoresis, which has been used to analyze replication intermediates in yeast. The other method is pulsed-field gel electrophoresis (PFGE) that monitors the replication status of a chromosome. These are convenient and easy, and they do not require specialized equipment. *Curr. Protoc. Cell Biol.* 49:22.14.1-22.14.12.

Keywords: two-dimensional gel electrophoresis • pulsed-field gel electrophoresis • DNA replication • agarose plug • replicative intermediate

INTRODUCTION

Two methods to analyze DNA replication in budding yeast are described in this unit. One is two-dimensional (2D) gel electrophoresis, which has been used to analyze replication intermediates in yeast. This method was developed by Brewer and Fangman (1987) to characterize the activity of autonomously replicating sequence elements (ARS) in yeast. In addition to mapping the replication origin, this method makes it possible to analyze the dynamics of replication forks, including blocking of replication forks (or slowing formation) and termination. Electron microscopy (EM) can also detect replication intermediates, but sample preparation is time-consuming and EM cannot recognize regions through which the detected replication fork has passed. The protocol described herein for two-dimensional gel electrophoresis is more convenient and does not require specialized equipment. Moreover, two-dimensional gel analysis can detect replication intermediates in a target locus using a specific probe and can follow temporal changes of replication intermediates.

The other method introduced here is pulsed-field gel electrophoresis (PFGE) that monitors replication status of a chromosome. PFGE was developed by Schwartz and Canter (1984) as a means of resolving very large DNA molecules (>20,000 bp). In the case of budding yeast, all of its linear chromosomes are resolvable by PFGE. However, replicating chromosomes cannot enter the gel and remain in the well because such chromosomes have a higher-order structure consisting of replication intermediates. Therefore, PFGE analysis can distinguish replication status by determining whether a chromosome can migrate in the gel or not. As a method to analyze the cell cycle, fluorescence-activated cell sorting (FACS) is known to be a powerful and convenient tool. For this application, FACS is used to measure cellular DNA content. While FACS can monitor the whole genome, it cannot determine the replication status of each chromosome. In contrast, PFGE can monitor replication status of each chromosome if chromosome-specific probes are used. In addition, when replication stalls, the DNA degradation products are detectable as a smear by Southern blotting.

Current Protocols in Cell Biology 22.14.1-22.14.12, December 2010

DOI: 10.1002/0471143030.cb2214s49

Two-dimensional gel analysis and PFGE share the same DNA preparation method. In both assays, DNA is eluted from yeast cells after being embedded in an agarose plug. This method of immobilizing the DNA prior to electrophoresis is crucial as it prevents unstable replication intermediates from forming secondary structures and minimizes random cleavage due to physical stress.

BASIC PROTOCOL 1

TWO-DIMENSIONAL AGAROSE GEL ELECTROPHORESIS TO ANALYZE DNA STRUCTURES

Two-dimensional gel electrophoresis distinguishes branched DNA structures from linear structures. In the first dimension of this analysis, digested DNA in an agarose plug is electrophoresed under conditions that separate DNA molecules on the basis of molecular mass (in a low-concentration agarose gel and relatively weak electric field). In the subsequent second dimension, electrophoresis is run under conditions that maximize the contribution of DNA shape to migration rate (in a higher concentration agarose gel and a stronger electric field, at lower temperature, and with the intercalating agent ethidium bromide to stiffen the DNA). Nonlinear DNA molecules (including replication intermediates) are more affected and migrate slowly; in comparison, linear DNA molecules migrate faster in a higher-concentration agarose gel. It is more difficult for nonlinear DNA to move through denser gel matrices because of their complicated structures (Bell and Byers, 1983).

Materials

Agarose solution no. 1 for the first dimensional (1D) gel electrophoresis (see recipe)
Agarose solution no. 2 for the second dimensional (2D) gel electrophoresis (see recipe)
Restriction enzyme–digested DNA in agarose plug (Support Protocol 2)
1× TBE (*APPENDIX 2A*)
Ethidium bromide
0.2 N HCl
Denaturation solution: 1.5 M NaCl/0.5 N NaOH
Neutralization buffer: 1 M Tris·Cl (pH 7.4)/1.5 M NaCl
20× SSC (*APPENDIX 2A*)
Phosphate-SDS hybridization buffer (see recipe)
Radiolabeled DNA probe made with Rediprime II DNA Labeling System (GE)
2% (w/v) SDS (*APPENDIX 2A*)

12 × 14–cm gel casting tray
Well combs
Electrophoresis apparatus
Power supply
Hybond N+ nylon membrane (GE)
UV light
Stratalinker (Stratagene)
200-ml roller bottle
65° and 68°C incubator
Plastic wrap
Imaging plate (Fuji film)

Prepare the agarose solutions

1. Melt the agarose solution by heating it in a microwave with frequent mixing (should take ~3 min at a 750-W microwave setting). Cool until it is comfortable to the touch (~45°C).

   For the second agarose solution, add the ethidium bromide after cooling.

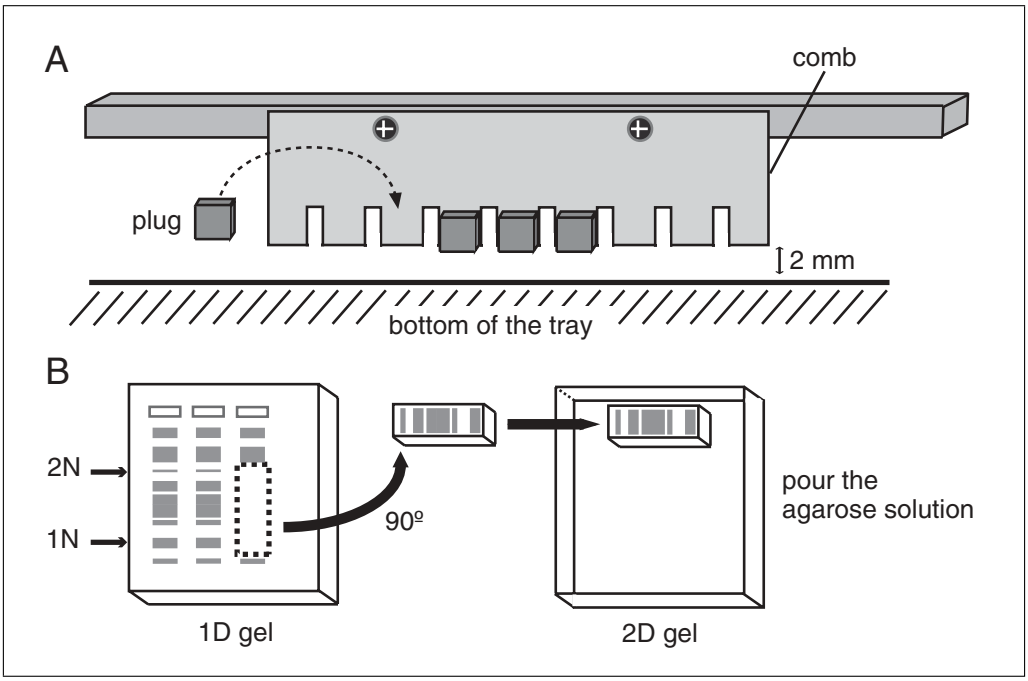

Figure 22.14.1 Tips for two-dimensional gel electrophoresis. (**A**) Embedding agarose plugs in agarose gel. (**B**) How to transfer a gel run in the first dimension for electrophoresis in the second dimension. Excise the portion of the gel containing DNA molecules ranging from 1N to 2N. Turn the excised gel piece 90° and re-position it at the top of the second gel. The agarose solution for the second dimension gel has been poured in the tray.

The second agarose solution should be prepared while the first dimension gel is stained with ethidium bromide.

Prepare and run the first dimension gel

2. Place the agarose plugs (tweleve plugs on one gel) from the restriction solution on the comb teeth (corresponding to wells), and remove buffer around the plug by blotting with tissue paper (Fig. 22.14.1A).

3. Place the comb with the agarose plugs into the casting tray leaving a 2-mm gap at the bottom (Fig. 22.14.1A).

4. Pour 100 ml agarose solution no. 1 (0.4% agarose) and allow to harden at 4°C.

5. Carefully remove the comb leaving the plugs in the gel.

6. Perform electrophoresis at 1.32 V/cm at room temperature for 14 hr.

Stain the gel

7. Stain the gel in 300 ml of 1× TBE containing 0.3 μg/ml ethidium bromide for 30 min at room temperature, and check the electrophoresis pattern.

   DNA fragments undergoing replication should be distributed between the non-replicating fragments of unit mass (1N) and ~2N (Fig. 22.14.1, one-dimensional gel). In the case of the yeast ribosomal gene that we are using, the fragment digested with BglII is 4.5 kb (1N, non-replicating fragment). Therefore, DNA fragments undergoing replication are distributed between 4.5 kb (1N) and 9.0 kb (2N), as assessed by the molecular size maker.

8. Excise the portion of the gel containing fragments ranging from 1N to 2N, turn it 90°, and re-position at the top of the second gel tray. Pour agarose solution no. 2 and allow it to harden at room temperature (Fig. 22.14.1B).

   It takes ~30 min for the agarose solution to harden.

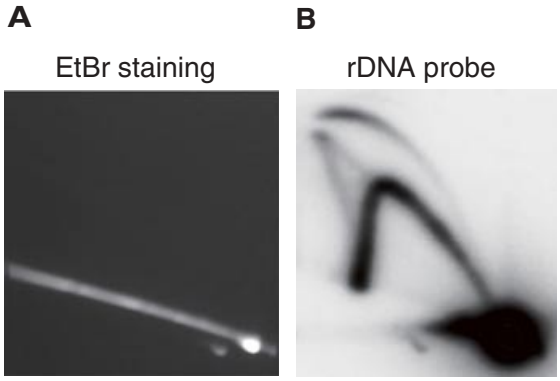

Figure 22.14.2 Migration pattern of replication intermediates separated by two-dimensional gel analysis. DNA is eluted from exponentially growing yeast cells, digested with *Nhe*I, and subjected to two-dimensional gel electrophoresis. (**A**) The gel was stained with ethidium bromide and photographed under UV illumination. Only linear DNA can be detected by ethidium bromide staining. (**B**) Hybridization pattern with an rRNA gene–specific probe is shown. Simple Y-shaped, replication bubble, and X-shaped molecules are observed.

9. Perform the electrophoresis in 750 ml of 1× TBE buffer containing 0.3 μg/ml ethidium bromide at 6.0 V/cm for 6 hr at 4°C.

   A representative example is shown in Figure 22.14.2A.

   This protocol is optimized for separation of ~4.5-kb fragments (1N). Separation of larger or smaller fragments will require adjustment of gel strength (percentage of agarose) and strength of the electric field.

Transfer the DNA to the membrane

10. Incubate the gel in 0.2 N HCl for 20 min at room temperature with agitation for depurination of DNA.
11. After depurination, denature the gel in denaturation solution (completely cover the gel) for 30 min at room temperature, with gentle agitation.
12. Following denaturation, neutralize the gel in neutralization buffer for 30 min at room temperature, with gentle agitation.
13. Proceed with standard capillary transfer using 20× SSC as a transfer buffer to transfer the DNA to a positively charged nylon membrane (Hybond N+), which is prewet with 6× SSC before blotting. Perform the transfer of DNA for 16 to 24 hr.
14. After the capillary transfer, rinse the membrane briefly with 6× SSC to remove any agarose and cross-link the DNA to the membrane with UV light at 254 nm (using a Stratalinker).

Hybridize the membrane-bound DNA

15. Place the membrane into a 200-ml roller bottle together with 40 ml of phosphate-SDS hybridization buffer.
16. Prehybridize 5 min at 65°C.
17. Add a radiolabeled probe (e.g., 3,000Ci/mmol dCTP with 32P for labeling) and incubate it overnight at 65°C.
18. Remove hybridization buffer and rinse the membrane once with 50 ml 2× SSC, 2% SDS at 68°C.
19. Wash the membrane once with 50 ml 2× SSC, 2% SDS at 68°C for 30 min.

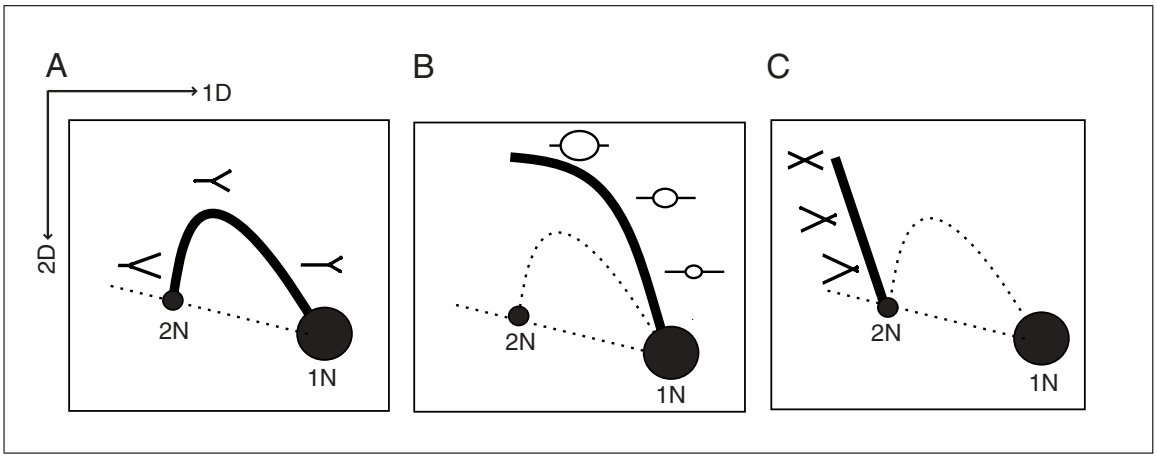

Figure 22.14.3 Behavior of replication intermediates and recombination intermediates in two-dimensional gel electrophoresis. The first dimension from left to right separates molecules in proportion to mass. The second dimension (top to bottom) mostly separates molecules as a function of their three-dimensional shape. The dashed lines mark the location of linear molecules of various sizes. Replication intermediates of the detected fragments vary in mass from 1N (large filled circle) to 2N linear fragments (small filled circle). (**A**) Fragments replicated passively from an outside origin correspond to Y-shaped simple replication fork signals. These consist of two branched daughter strands and one non-replicated stem strand. As a replication fork progresses, the branched strands increase in length and the stem strand shrinks. The migration pattern of a Y fork is determined by the ratio of branched strands to the stem strand. (**B**) Fragments containing a replication origin correspond to the bubble-shaped signal. The diameter of the bubble determines the mobility along a gently curved line. (**C**) Fragments containing a replication termination site corresponds to the X-shaped signal. Recombination intermediates undergoing repair due to broken replication forks also form X-shaped molecules. Fragments that have different termination sites or that undergo crossing-over migrate differentially along a linear line.

20. Wash once with 50 ml 0.2× SSC 0.2% SDS at 68°C for 30 min.
21. Rinse the membrane briefly five times, each time with 50 ml 0.2× SSC 0.2% SDS at room temperature.
22. Wrap the damp blot in plastic wrap, and expose it to the imaging plate (Fuji Film).

An example obtained with a probe specific for the rRNA gene cluster is shown in Figure 22.14.2B using bio-imaging analyzer system BAS2500 (Fuji Film). The fragment contains a replication origin. Figure 22.14.3 explains the behavior of various kinds of replication intermediates.

DNA PREPARATION IN LOW-MELTING-POINT AGAROSE

SUPPORT PROTOCOL 1

This protocol describes how to prepare DNA from yeast in low-melting-point agarose. Cells are treated with Zymolyase to hydrolyze the cell walls. The spheroplasts formed are subsequently embedded in a low-melting-point agarose plug, and are then incubated in detergent containing proteinase K to disrupt the plasma membrane and to hydrolyze proteins associated with DNA, respectively.

Materials

Cultures of yeast cells
10% (w/v) sodium azide solution
Sorbitol solution (see recipe)
Zymolyase solution (see recipe)
Agarose solution no. 3 (see recipe)
ES solution: 0.5 M EDTA (pH 9.0)/1% (v/v) sodium *N*-lauroyl sarcosinate
Proteinase K (Merck)
TE buffer, pH 9.0 (*APPENDIX 2A*)

50-ml tubes
37° and 50°C incubators
Mold for making agarose plugs, 10-mm (height) × 5-mm (width) × 1.5-mm (thickness; Bio-Rad)

Collect the cells

1. Harvest exponentially growing yeast cells (~8.0×10^7) in a 50-ml tubes, add 1/100 volume 10% azide solution, and mix gently.
2. Pellet the cells by centrifuging 5 min at 3000× *g*, 4°C, and wash twice with 1 ml cold sorbitol solution.
3. Resuspend the cell pellets in 47 µl sorbitol solution on ice.
4. Add 3 µl Zymolyase solution, mix gently by pipetting, and incubate at 37°C for 30 to 60 min until the solution becomes viscous.

Embed the cells

5. Add an equal volume of agarose solution no. 3 and mix gently by pipetting. Immediately, pour the mixture into molds for making plugs.
6. Hold the filled mold at 4°C for 20 min to allow the agarose to harden.
7. Transfer the agarose plugs from the mold into 1 ml ES solution and incubate for 10 min at room temperature.
8. Replace the ES solution with 1 ml fresh ES solution containing 1 mg/ml proteinase K.
9. Incubate at 50°C for 8 to 24 hr, until the color of plug become transparent from white.
10. Wash the agarose plug five times in 1 ml TE, pH 9.0, for 10 min.
11. Store the washed plugs in TE buffer at 4°C.

SUPPORT PROTOCOL 2

DIGESTION OF DNA IN LOW-MELTING AGAROSE

This protocol describes how to digest DNA embedded in agarose. It should be noted that the choice of appropriate restriction enzyme is critical for effective digestion. Some restriction enzymes are very sensitive to agarose. The agarose-sensitivity of restriction enzymes is generally described by the supplier.

Materials

Agarose plug (Support Protocol 1)
Restriction enzyme buffer (H buffer; Takara)
Restriction enzyme (e.g., *Bgl*II 30 U/µl to 60 U/µl; Takara)

NOTE: Restriction enzymes that digest the target region into small fragments (<10 kb) should be selected. Because the DNA fragment (<10kb) undergoing replication is shorter than 20 kb, it can be separated by the gel electrophoresis.

1. Cut the agarose plug in half (final dimensions of 5 mm × 5 mm × 1.5 mm).
2. Place half of the plug into 1 ml of restriction enzyme buffer.
3. Incubate for 30 min at room temperature.
4. Replace the solution with fresh 1 ml restriction enzyme buffer and incubate for an additional 30 min.

5. Remove the buffer and add 250 μl enzyme buffer containing 250 units of restriction enzyme.

6. Incubate the agarose plug–embedded DNA at an appropriate temperature for ~8 hr.

   To prevent DNA fragments from dispersing out of the plug, put the plugs on the comb right after the digestion with the restriction enzyme.

CONTOUR-CLAMPED HOMOGENEOUS ELECTRIC FIELD PULSED-FIELD GEL ELECTROPHORESIS TO MONITOR CHROMOSOME REPLICATION STATUS

BASIC PROTOCOL 2

Pulsed-field gel electrophoresis (PFGE) was developed as a means of separating large DNA molecules by periodically switching the direction and duration of the electric field. DNA molecules ranging from ~10 kbp to 10 Mbp are amenable to separation by PFGE, which can be used for a variety of purposes (e.g., direct visualization of chromosomes, RFLP analysis of large restriction fragments, and isolation of YACS and BACS). Here, we demonstrate an application for monitoring replication status of chromosomes isolated from the yeast *Saccharomyces cerevisiae*.

Contour-clamped homogeneous electric field (CHEF) electrophoresis, a popular form of PFGE, produces sharp reproducible DNA bands in a straight lane. Electrodes are set along a hexagonal array to make a homogeneous electric field using computer-controlled digital/analog converters at each electrode. This system can generate an unlimited variety of field strengths and angles.

Materials

Yeast DNA in agarose plugs (Support Protocol 3)
Agarose solution for CHEF (200 ml): 1.0% (w/v) pulsed-field certified agarose (Bio-Rad)/0.5× TBE
0.5× TBE (*APPENDIX 2A*)
Ethidium bromide

43°C water bath
Gel casting tray
Well combs
Electrophoresis apparatus
CHEF mapper (Bio-Rad)

Prepare the gel

1. Melt a fresh agarose solution for CHEF (1% w/v agarose in 0.5× TBE) by heating in a microwave with frequent mixing.

2. Cool the solution to 43°C in a water bath, but do not allow the agarose to gel.

3. Assemble casting tray to make the gel.

4. Place the agarose plug on the comb teeth (corresponding to wells), and remove buffer around the plug by blotting with tissue paper.

   The maximum number of plugs per gel is 44.

5. Place the comb with the agarose plug into the casting tray leaving a 2-mm gap at the bottom.

6. Pour the agarose solution (43°C) into the tray and allow the gel to harden completely for 20 min at 4°C.

7. Carefully remove the comb leaving the plugs in the gel, and seal each well with the remaining agarose solution (43°C) allowing the seals to harden for 5 min.

Sealing of the wells is required to prevent the plugs from breaking loose of the gel during the process of capillary transfer. The replication intermediates remain in the plugs.

Run the gel

8. Set the parameters for switching time, voltage, and duration of run, to separate the chromosomes. A typical program follows:

Initial switch time:	0.22 sec
Final switch time:	266 sec
Run time:	15.16 hr
Voltage:	6.0 V/cm
Included Angle:	120°.

9. Run the CHEF apparatus at 14°C by circulating 2.2 liters of 0.5× TBE buffer in the running tank.

Visualize the chromosomes bands

10. After the electrophoresis is complete, place the gel into 300 ml of 0.5 μg/ml ethidium bromide solution and incubate for 30 min at room temperature with gentle agitation.

11. Following the ethidium bromide staining, replace the solution with 400 ml deionized water and incubate for at least 20 min at room temperature. Check the migration pattern of each chromosome under UV illumination (Fig. 22.14.4A, left panel).

If necessary, destain the gel overnight in deionized water to further reduce background staining.

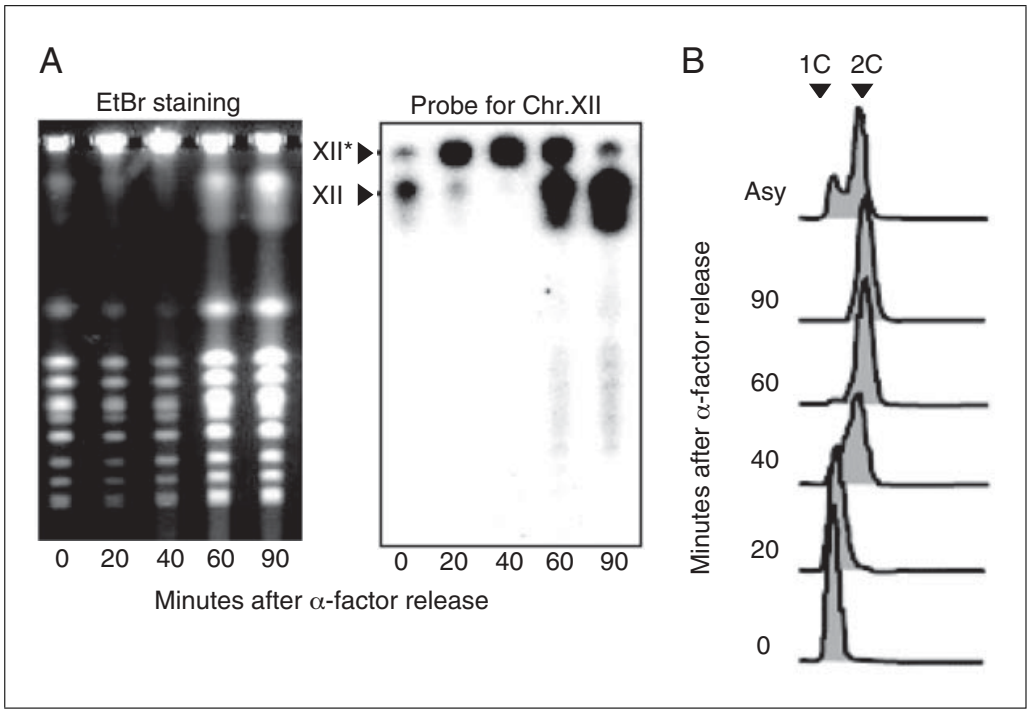

Figure 22.14.4 Migration of chromosomes from synchronously grown yeast. (**A**) Cells were released from G1 arrest by α-factor into YPD medium (see recipe) at 23°C. At the indicated times, DNA was prepared in agarose gel plugs and analyzed by CHEF. Chromosome patterns were detected by ethidium bromide staining (left) and by Southern blot hybridization using a chromosome XII specific probe (right). Triangles show the positions of chromosome XII in the well (with asterisk) and gel. (**B**) Flow cytometry analysis for cell cycle progression after release from G1-arrest by a-factor.

12. Because of the large size of the DNA fragments, it is necessary to nick them by acid treatment to achieve efficient transfer.

    A typical transfer protocol including acid treatment is shown in Basic Protocol 1 (steps 10 to 13).

    A typical migration pattern is shown in Figure 22.14.4A (right panel). At G1 (time 0 after released from the YPD medium containing α-factor), chromosomes enter the gel because they are linear. In S phase (time 20 to 40 min), most chromosomes get stuck in the well and fail to migrate because of the presence of replication intermediates. After completion of replication (60 to 90 min), chromosomes again are able to migrate into the gel. At the same time, the change in total DNA content can be followed by FACS analysis (Fig. 22.14.4B). FACS analysis confirms that total DNA content gradually increases with progression of replication.

DNA PREPARATION IN LOW-MELTING-POINT AGAROSE GEL FOR PFGE

SUPPORT PROTOCOL 3

This section describes an alternate protocol for preparing DNA from yeast in a low-melting-point agarose gel. While the DNA preparation protocol for two-dimensional gel analysis can be used for PFGE, it is not recommended, as it leads to chromosome degradation during Zymolyase treatment because spheroplasts are extremely fragile. Therefore, we highly recommend that yeast cells be embedded in low-melting-point agarose prior to Zymolyase treatment (even if this prolongs sample processing by a day), because this prevents chromosomes from being sheared, even if the spheroplast is burst.

***Additional Materials** (also see Basic Protocol 1)*

Agarose solution: 1.5% Sea plaque GTG agarose, 0.25 M EDTA (pH 8.0)
Synchronously grown yeast cells harvested from YPD medium (pH 4.0) containing 3.0 μM α-factor.
50 mM EDTA
LET buffer (see recipe)
ESP buffer (see recipe)
TE buffer, pH 9.0 (*APPENDIX 2A*)

Add cells to agarose

1. Heat agarose solution in a microwave until the agarose is melted and then equilibrate to 50°C.
2. Harvest ~8.0×10^7 cells, transfer the cells into a 50-ml tube, and pellet the cells by centrifuging 5 min at 3000 × *g*, 4°C.
3. Resuspend the cells with 1 ml ice-cold 50 mM EDTA and then centrifuge again.
4. Resuspend the cell pellets in 47 μl of 50 mM EDTA.
5. Warm the cells to 50°C.
6. Add 3 μl Zymolyase solution and 50 μl of agarose solution, and mix gently by pipetting.

Prepare the mold

7. Immediately pour the mixture into mold to form plugs.
8. Place the filled mold at 4°C for 20 min to allow the agarose to gel.
9. Transfer the agarose plug into 1 ml of LET buffer and incubate overnight at 37°C.

    LET buffer promotes degradation of the cell wall by Zymolyase

10. Replace the LET solution with 1 ml of ESP buffer containing 1 mg/ml proteinase K and incubate overnight at 50°C.

11. Wash the agarose plug with 1 ml TE buffer, repeat the wash at least five times, and store at 4°C.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Agarose solution no. 1, 100 ml

0.4% (w/v) Sea Kem agarose
1× TBE (*APPENDIX 2A*)

Agarose solution no. 2, 100 ml

1.2% (w/v) Sea Kem agarose
1× TBE (*APPENDIX 2A*)
0.3 μg/ml ethidium bromide

Agarose solution no. 3

1% (w/v) Sea plaque GTG agarose
0.1 M EDTA, pH 7.5 (*APPENDIX 2A*)
Heat in a microwave oven until the agarose melts and then equilibrate to 45°C

ESP buffer

100 mM Tris·Cl, pH 9.0 (*APPENDIX 2A*)
0.5 M EDTA, pH 8.0 (*APPENDIX 2A*)
1% (v/v) *N*-Lauroylsarcosine sodium
1 mg/ml proteinase K (Merck)
Prepare fresh

LET buffer

100 mM Tris·Cl, pH 7.5 (*APPENDIX 2A*)
0.5 M EDTA, pH 8.0 (*APPENDIX 2A*)
1 M 2-mercaptoethanol
Prepare fresh

Phosphate-SDS hybridization buffer

0.5 M Na_2HPO_4, pH 7.2
7% (w/v) SDS (*APPENDIX 2A*)
1% (w/v) bovine serum albumin (BSA)
1 mM EDTA (*APPENDIX 2A*)
Prepare fresh

Sorbitol solution

1 M sorbitol
0.1 M EDTA, pH 7.5
0.1% (w/v) sodium azide
Store up to 6 months at 4°C

YPD medium

Final concentration:
1% (w/v) Bacto yeast extract
2% (w/v) Bacto polypeptone
2% (w/v) glucose

Zymolyase solution

10 mg/ml Zymolyase (100T, Seikagaku BC)
20 mM Tris·Cl, pH 7.4 (*APPENDIX 2A*)
50% (v/v) glycerol
Store up to 3 months at −20°C

COMMENTARY

Background Information

Since the late 1980s, two-dimensional gel electrophoresis has been used as a sensitive physical mapping technique to identify chromosomal DNA replication origins. Two groups independently reported use of two-dimensional gel electrophoresis to localize replication origins and termination sites in *S. cerevisiae*. One used a neutral/neutral type of two-dimensional gel electrophoresis (Brewer and Fangman, 1987), while the other used a neutral/alkaline type of two-dimensional gel electrophoresis (Nawotka and Huberman, 1988). In the neutral/neutral type, it is possible to observe DNA molecules by electron microscopy, following excision of the gel band. This technique has also been applied to higher eukaryotic cells (Dijkwel and Hamlin, 1997). In the case of higher eukaryotic cells, enrichment for replicate intermediates is required. Enrichment involves: (1) synchronization of cell populations in the S phase, and (2) removal of nonreplicating DNA by chromatography using benzoylated naphthoylated DEAE (BND)-cellulose (Dijkwel and Hamlin, 1997). These enrichment techniques can also be applied to yeast as needed.

The CHEF pulsed-field gel system was first used to analyze DNA replication as an assay of chromosome damage in replication-deficient yeast mutants (Hennessy et al., 1991). It has since been shown that CHEF can monitor replication status in synchronized cells. Moreover, CHEF distinguishes chromosomes undergoing repair as the recombination intermediates formed during repair are unable to enter the gel because of their higher order structure (Ide et al., 2007; Ganley et al., 2009).

Critical Parameters and Troubleshooting

Condition of cells

The ratio of replication intermediates to nonreplicating DNA is the most critical parameter in two-dimensional gel electrophoresis. As described above, synchronization of the cell cycle is an effective means of increasing replication intermediates. In case of yeast, an exponentially growing population contains enough S phase cells for adequate detection. We recommend harvesting exponentially growing cells at a density of $<3.0 \times 10^6$ cells/ml.

Killing cells by azide solution

The first step in preparing the DNA is to kill yeast cells by exposure to azide solution. Treatment with azide stops DNA replication immediately and completely.

Efficiency of DNA digestion

Incomplete DNA digestion by restriction enzymes sometimes occurs because the DNA is embedded in an agarose plug. If another restriction enzyme cannot be used, we have two recommendations. One is extension of the reaction time from hours to overnight, for example. The other is to decrease cell density in the plug.

Detection of replication intermediates in single-copy loci

Two-dimensional gel electrophoresis can also be applied to single-copy loci. Although signals from single-copy loci are weaker than from repetitive sequences, e.g., ribosomal RNA genes, the protocol described here can detect a variety of replication intermediates. If the signal density of replication intermediates is found to be weak, we recommend using more cells.

Temperature of agarose solution

One critical parameter of CHEF electrophoresis to monitor the replication status is the temperature of the agarose solution when it is poured into the tray. Agarose solution at much higher temperatures may denature linear DNA in the plugs attached on the comb. As a result, the majority of the chromosome in the plugs stacks in the well and the migration pattern does not reflect the replication status. To avoid such artificial conformational change of DNA in the plugs, the temperature of the agarose solution should be lower than 45°C.

Anticipated Results

Typical DNA migration patterns resulting from two-dimensional gel analysis and

CHEF analysis are shown in Figure 22.14.2B and Figure 22.14.4A. In the case of two-dimensional gel analysis of rDNA, three kinds of nonlinear DNA, simple Y-shaped, replication bubble, and X-shaped molecules, are observed. They are detected by hybridization with the radiolabeled rDNA probes. Generally, as the signal intensity of nonlinear DNA is weaker than that of linear DNA, the blot is exposed to the imaging plate for longer time (~1 week). In CHEF analysis, linear chromosomes are separated from replicating chromosomes. Linear chromosomes are detected as bands in the gel and replicating chromosomes are detected as stacked bands in the well.

Time Considerations

For two-dimensional gel analysis, preparation of DNA in the plug takes 2 days. After preparation of DNA, first and second gel electrophoreses take 14 hr (overnight) and 6 hr, respectively. Capillary transfer and the subsequent hybridization require 2 days to complete, and the time to expose the blot to the imaging plate is 1 to 7 days, depending on the signal intensity of target DNA. In CHEF, analysis requires almost the same amount of time as two-dimensional gel analysis does, except the electrophoresis requires ~16 hr.

CHAPTER 23
Stem Cells

INTRODUCTION

Few issues in cell biology have garnered more public attention in recent years than stem cells. Research into stem cells holds the promise for novel therapeutic interventions that could revolutionize the treatment of a range of human diseases. On the other hand, objections to the use of human embryonic stem cells for research have been raised on religious, moral, and ethical grounds. While keeping in mind these two important aspects of the ongoing debate, scientists have steadily learned to exploit the potential of stem cells for unraveling the molecular mechanisms of cell differentiation and organismal development. This chapter presents a comprehensive collection of protocols describing the use of stem cells to study cell differentiation.

Stem cells have the dual ability to undergo self-renewal and to generate lineages of more differentiated or mature cells. *UNIT 23.1* is an overview of the current knowledge on stem cells and their pathways of differentiation. The overview describes the properties of stem cells, defines the meaning of totipotent, multipotent, pluripotent, and unipotent cells, and discusses the different cell lineages that can be derived from various stem cell types. The discussion deals with both embryonic and adult stem cells and gives examples of their use for tissue repair. The overview ends with two sections dealing with the genetic manipulation and potential therapeutic applications of stem cells.

UNIT 23.2 comprises a series of protocols for the production and handling of embryonic stem cells. The initial protocols describe procedures for the derivation, culture, and preservation of mouse embryonic stem cells. This is followed by a description of methods for the differentiation of mouse embryonic stem cells into "embryoid bodies," which are spherical masses of cells with regions of lineage-specific differentiation. This unit also includes protocols for the propagation of human stem cells and their differentiation into embryoid bodies, though not for their initial derivation.

UNIT 23.3 begins a series of units devoted to the differentiation of embryonic stem cells into various lineages. This unit deals specifically with the maintenance and differentiation of mouse embryonic stem cells to generate blood vessels. These vessels form early during embryonic development by two processes: vasculogenesis and angiogenesis. In vasculogenesis, mesodermally derived angioblasts differentiate to form primitive blood vessels. This is followed by angiogenesis, in which endothelial cells derived from the angioblasts proliferate and migrate, leading to vessel expansion and sprouting. Both of these processes can be studied by differentiation of embryoid bodies over a period of 8 days. Blood vessels can be identified by staining for various vascular markers (e.g., PECAM-1) or by performing the β-galactosidase reaction on differentiated cultures generated from mouse embryonic stem cells in which the *lacZ* gene is driven from a vascular-specific promoter.

UNIT 23.4 deals with the differentiation of mouse embryonic stem cells and human adult stem cells into adipocytes. Adipocytic differentiation of mouse embryonic stem cells also starts with the formation of embryoid bodies, which are first committed by the addition of retinoic acid and then terminally differentiated by the addition of adipogenic

Current Protocols in Cell Biology 23.0.1-23.0.2, September 2007
Published online September 2007 in Wiley Interscience (www.interscience.wiley.com).
DOI: 10.1002/0471143030.cb2300s36

factors (e.g., insulin, triiodothyronine, rosiglitazone). Adipocytes can also be derived from adult human multipotent adipose-derived stem (hMADS) cells or human mesenchymal stem (hMS) cells. For both of these adult stem cell types, differentiation does not require retinoic acid and is achieved in monolayer culture. hMADS are driven to adipogenic differentiation by addition of isobutylmethylxanthine (IBMX) and dexamethasone, whereas adipogenic differentiation of hMS occurs simply in the presence of fetal bovine serum. The resulting adipocytes can be easily identified through visualization of their lipid droplets by bright-field microscopy of unstained cells or of cells stained with the triglyceride-specific stain, Oil Red O. Adipocytic differentiation can also be monitored by northern analysis of the expression of adipose-specific genes.

UNIT 23.5 presents protocols for the differentiation of mouse embryonic stem cells to chondrocytes and osteocytes. The process also starts from embryoid bodies, which spontaneously differentiate into various cell types, including chondrogenic and osteogenic precursors. Mesenchymal condensations containing chondrogenic precursors and, at later stages of differentiation, cartilage nodules with mature chondrocytes and osteocytes, are isolated using either a microdissector or a microscalpel. Differentiated cells can be studied either in the aggregates or upon dissociation with collagenase followed by monolayer culture. Samples can be analyzed by histochemical staining, immunofluorescent staining, in situ hybridization, or RT-PCR, to test for the expression of various markers for cartilage or bone. The characteristic features of ES cell-derived mesenchymal condensations and cartilage nodules can also be visualized by light microscopy and further examined at the ultrastructural level by electron microscopy.

UNIT 23.6 features protocols to study the differentiation of human embryonic stem cells into hematopoietic progenitors and endothelial cells for coculture with bone marrow stromal cell lines. Cells belonging to both lineages can be derived simultaneously and characterized by immunostaining and flow cytometry. A colony-forming assay can be used to examine the potential of hematopoietic progenitors to differentiate into erythroid, granulocytic, macrophage, and megakaryocyte cells. The various cell lineages produced by differentiation of human embryonic stem cells can be isolated, as well as separated from the bone marrow stromal cells, by magnetically-activated cell sorting and preparative flow cytofluormetry.

UNIT 23.7 describes protocols for neural differentiation of human embryonic stem cells. Pure populations of neural precursors can be derived from human embryonic stem cells for differentiation in chemically defined serum-free culture medium containing noggin and fibroblast growth factor. Neural precursors derived in this way can be cultured for long periods or further induced to differentiate into mature neurons and glial cells. Other protocols describe methods for characterizing neural precursors and their derivatives by immunostaining for specific marker antigens followed by fluorescence microscopy or flow cytometric analysis of stained cells.

Juan S. Bonifacino

Stem Cells: An Overview

Stem cells are specialized cells that possess a capacity to undergo self-renewal while at the same time having the ability to give rise to at least one or more differentiated or mature cell type. They therefore represent a fundamental cornerstone during the life of all vertebrates, playing central roles in the production of new and replacement cells for tissues during development and homeostasis, including repair following disease or injury. Although all tissues during vertebrate development appear to possess cells with stem cell properties, whether this is the case in the adult remains to be clearly demonstrated. Certainly, the skin, muscle, intestine, hematopoietic system, and liver can be regenerated following acute trauma, but it is only now becoming accepted that similar properties may also be attributable to tissues of the brain, heart, and pancreas (Dor and Melton, 2004).

A diverse range of stem cells have been described according to their long-term ability to maintain stem cell–like properties in vitro and in vivo and the number and type of derivatives that they give rise to. The first category is the unipotential stem cell, which undergoes self-renewal and gives rise to only one mature cell type. One example is the keratinocyte stem cell of the dermis that divides to give rise to a population of closely related keratinocytes. The second category is the multipotent stem cell, characterized by an ability to undergo self-renewal and the capacity to yield at least two or more differentiated fetal or adult cell types. Examples of multipotential stem cells include a range of stem cells in the developing fetus and many of the adult stem cells so far described, e.g., neural stem cells (NSCs), neural crest stem cells (NCSCs) of the nervous system, and hematopoietic stem cells (HSCs) and mesenchymal stem cells (MSCs) of the bone marrow. A third category of stem cell is the pluripotent stem cell, which is also capable of self-renewal and gives rise to a vast array of mature cell types, but not every cell type characteristic of that species. Examples of pluripotent stem cells are the in vitro–generated embryonic germ (EG) cells of the gonads, embryonal carcinoma (EC) cells, which are derivatives of tumorigenic germinal tissue, and embryonic stem (ES) cells. ES cells are pluripotent in vitro derivatives of the blastocoel inner cell mass or epiblast (Mollard et al., 2002). They have a wide developmental potential and have been demonstrated to give rise to every cell type of the adult organism. However, they give rise only to a restricted subset of their respective extraembryonic lineages represented during development. A fourth type of stem cell is the totipotent stem cell, which includes the fertilized oocyte and premorula blastomeres. Totipotent stem cells replicate and generate all adult and extraembryonic tissues of their species, but undergo either no or only limited self-renewal. A relatively new fifth category is the cancer stem cell. These cells replicate and undergo self-renewal, yet their compromised self-renewal pathways result in neoplasia with accompanying undifferentiated, partially differentiated, and/or differentiated cell types.

Much attention has been focused on stem cells because of their wide potential for therapeutic applications and their potential for unraveling molecular mechanisms of development. They possess the potential to provide replacement tissue or a means to understand disease mechanisms, thus providing cures for numerous diseases and injuries, such as Parkinson's disease, spinal injury, cardiac failure, and diabetes. Before this is possible, however, and in addition to developing methods to determine how to differentiate stem cells into exactly the right lineage desired at a homogenous or near-homogenous frequency, a number of important factors need to be addressed. Firstly, the ethics of using ES cells need to be discussed widely in both the scientific and the general community. Secondly, issues related to the immune rejection of foreign stem cells need to be overcome. Thirdly, the issue of accessibility of stem cells to appropriate regions of the body must be determined.

THE STEM CELL NICHE

Maintenance of the stem cell phenotype in vivo is critically dependent upon its surrounding microenvironment or niche. This microenvironment is composed of a basement membrane, extracellular matrix, cell-cell interactions, cytokines, and other effector or maintenance proteins. Together, such factors regulate the stem cell's balance between self-renewal and differentiation. Functional genomic attempts to determine the genetic factors driving the balance between self-renewal

Contributed by Mark Denham, Brock Conley, Fredrik Olsson, Timothy J. Cole, and Richard Mollard

Current Protocols in Cell Biology (2005) 23.1.1-23.1.18

and differentiation in the stem cell niche have been recently undertaken (Hackney et al., 2002). The fetal liver, for example, provides the early microenvironment for expansion of its stem cell pool required for the liver in adult life. The cellular constituents of this hepatic stem cell niche were examined by cloning fetal stromal cell lines that support primitive hematopoietic cells in vitro (Hackney et al., 2002). Elucidating the genetic mechanisms that maintain stem cell populations in their stem cell state will aid in the production of large quantities of stem cells for therapeutic applications.

Stem Cell Division

The stem cell niche provides an environment that maintains cells in an undifferentiated stem cell state. Local injury in the surrounding tissue releases morphogenic signals to invoke proliferative and differentiation events within the niche, allowing tissue repair. This alters the balance within the stem cell niche, and through intrinsic mechanisms within the stem cell, a switch occurs from self-renewal (symmetric division) to a proliferative differentiation event (asymmetric division), leading to the production of more mature cellular derivatives.

Asymmetrical cell division produces both another stem cell and a more mature cell type known as a progenitor cell (in hematopoiesis) or transit-amplifying cell (in other tissues). Progenitor or transit-amplifying cells often undergo a more rapid expansion, producing fully differentiated cell types with specific characteristics appropriate to their function in the particular tissue. Stem cells generally display a slower rate of cell cycle progression. For example, stem cells of the epidermis cycle slowly, displaying a long-term retention of the nuclear label bromodeoxyuridine (Cotsarelis et al., 1990). Asymmetrical cell divisions thus maintain the local stem cell pool while contributing mature differentiated cells for tissue growth, turnover, or repair. Symmetrical cell division produces either two identical stem cells or two progenitor or transit-amplifying cells. Symmetrical cell divisions therefore maintain, increase, or deplete the stem cell pool.

IMMORTALITY: TELOMERASE AND STEM CELLS

The terminal ends, or telomeres, of eukaryotic chromosomes are protected from degradation, incomplete replication, or fusion by enzymes known as telomerases (Fig. 23.1.1). In the absence of telomerase activity, cells become subject to age-dependent mortality, with shortening of the chromosomes until a threshold senescence limit is reached. At this point, cells have a reduced replicative potential and therefore can no longer divide, an event characteristic of differentiated cell types. In order for stem cells to maintain their stem cell pool throughout the life of an organism and not reach replicative senescence, a higher telomerase activity is utilized by many stem cell populations (Morrison et al., 1996). Germ cells, cancer cells, and some stem cells, such as HSCs, express high levels of telomerase (Morrison et al., 1996). However, the amount of telomerase expressed in adult stem cells is not sufficient to keep the telomeres of chromosomes at the same length. Instead, enough is expressed to enable adult stem cells to divide and provide sufficient cells for an organism's life. ES cells, on the other hand, are theoretically immortal, and thus presumably produce enough telomerase such that their telomeres never shorten. However, depending upon the specific culture conditions used, it appears that karyotypic abnormalities can occur (Buzzard et al., 2004; Draper et al., 2004).

THE EMBRYONIC STEM CELL AS A PLURIPOTENT STEM CELL

ES cells can be maintained indefinitely in an undifferentiated pluripotent state in vitro. Their capacity to contribute to functional derivatives of all cells of the body is best exemplified by tetraploid embryo complementation studies in the mouse (Nagy et al., 1990, 1993). Mouse ES cells (mESCs) represent the best characterized ES cell lines, and in addition to their pluripotent properties described in vivo, have also been induced to differentiate into diverse cell lineages such as cardiac muscle, neural crest cells, neural stem cells, and hematopoietic cell lineages in vitro (Fig. 23.1.2). Human ES cells (hESCs), although less well characterized, are also known to possess similar properties to mESCs, but they also display some different characteristics. Inoculation of hESCs beneath the testicular capsule of severe combined immunodeficient (SCID) mice has produced solid teratomas containing representative cells from all three embryonic germ cell layers, including glandular and squamous epithelia, muscle, bone, and neuroectoderm. This represents a test for pluripotency in the human comparable to blastocyst injection of mESCs in mice (Reubinoff et al., 2000). In

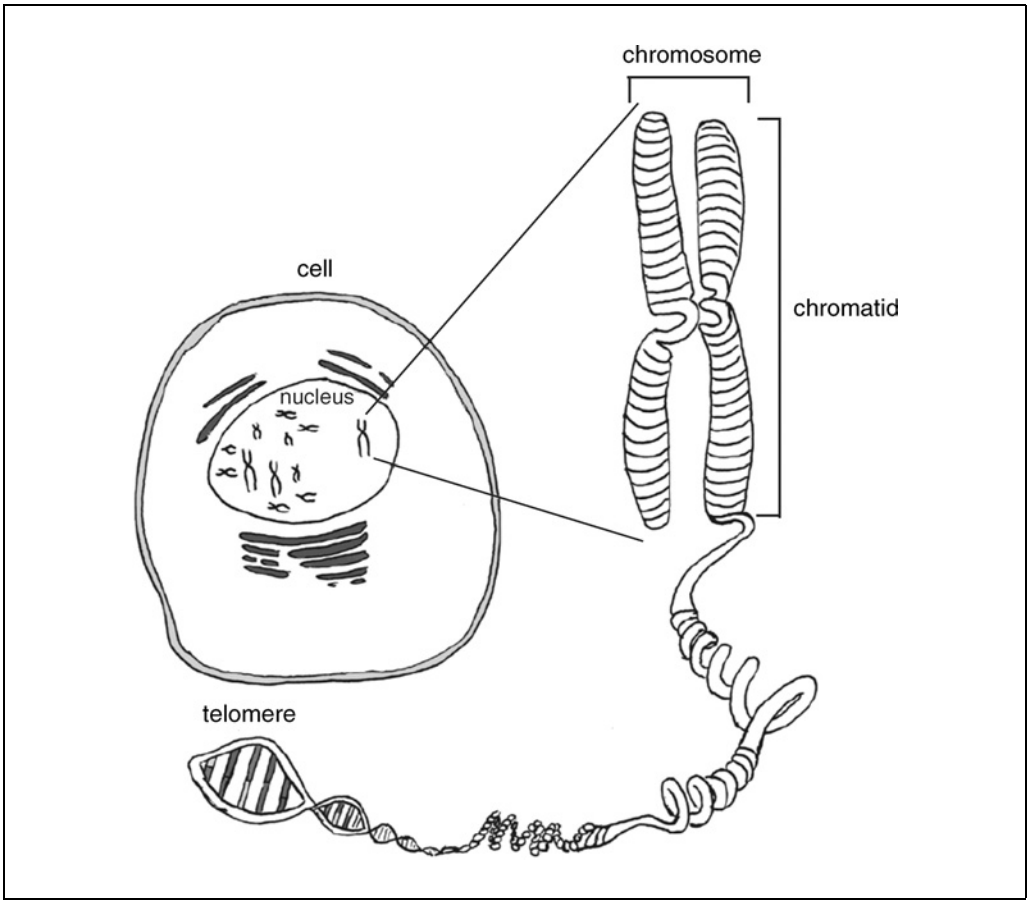

Figure 23.1.1 Eukaryotic cells express telomerase. Telomeres are located at the end of each chromosome in eukaryotic cells. Telomeres shorten with each cell division. Stem cells express telomerase, an enzyme that maintains telomere length during division. Maintenance of telomere length is crucial to the prevention of cell senescence.

addition to the blastocyst, isolation of hESCs has also been reported recently from the inner cell mass of human morula (Strelchenko et al., 2004). With the demonstrated pluripotency of mESCs in vivo and their amenability to manipulation in vitro, it is believed that hESCs may be induced in vitro to differentiate into any desired cell of the body for potential use therapeutically.

A common method for differentiating hESCs is embryoid body (EB) formation, which can be achieved through several different techniques such as suspension culture or culture in methylcellulose-containing media (Itskovitz-Eldor et al., 2000; Conley et al., 2004). ES cells cultured in these conditions form spherical structures which are called embryoid bodies (EBs), which refers to the appearance of lineage-specific regions of cell differentiation and a gene-expression profile similar to that found in the early embryo. These EBs contain cells representative of all three embryonic germ cell layers (ectoderm, mesoderm, and endoderm), and, under specific culture conditions, give rise to a number of distinct differentiated cell types. The isolation of relatively pure populations of several of these desired cell types has been subsequently achieved by culture with growth factors to enhance certain cell populations, by culture in selection media, or by fluorescence-activated cell sorting (FACS) for lineage-specific markers or lineage-specific reporter gene expression. In addition to EB formation, directed differentiation of ES cells into desired lineages has been achieved by coculture with selected tissues. For example, differentiation of hESCs into immature cardiomyocyte lineages has been reported following culture on a cell layer of a spontaneously differentiating visceral endoderm-like cell line derived from the P19 embryonal carcinoma cell line (Mummery et al., 2002). Similarly, culture of hESCs on a layer of γ-irradiated S17 murine bone marrow stromal cell line or the C166 yolk sac endothelial cell line has been reported to induce formation of hematopoietic colonies that give rise to erythroid, myeloid, and

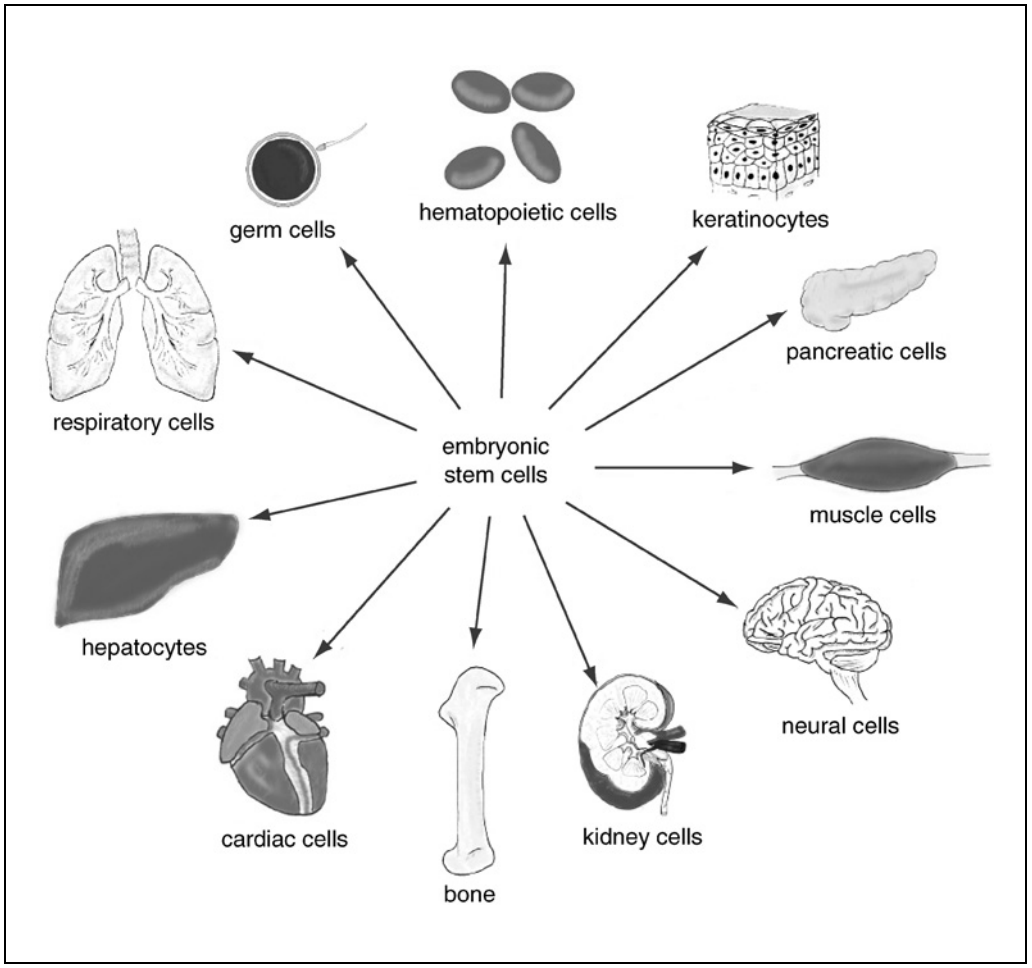

Figure 23.1.2 Pluripotency of embryonic stem cells. Embryonic stem cells have been reported to differentiate into a vast array of cells types in vitro. Differentiated cell types include: germ cells, respiratory cells, hepatocytes, cardiomyocytes, osteoblasts of the bone, neural cells, skeletal and smooth muscle, islet cells of the pancreas, keratinocytes, and hematopoietic cells.

megakaryocyte colonies following transfer to semisolid media in the presence of hematopoietic growth factors (Kaufman et al., 2001). Furthermore, prolonged cultivation of hESCs to a higher cell density has been shown to induce the formation of (1) contracting cells that stained positively for muscle-specific forms of actin and (2) cells possessing elongated processes that stain positively for neurofilament proteins and N-CAM, a neural cell adhesion molecule (Schuldiner et al., 2001). The differentiation of ES cells into motor neurons has been achieved by first producing EBs, then culturing them in the presence of retinoic acid (RA) to produce caudal neural cells, and finally adding an Shh signaling antagonist (Hh-Ag1.3) to induce the formation of ventral motor neurons. This procedure mimics the molecular signals known to promote normal development of motor neurons (Wichterle et al., 2002). Following implantation into the chick spinal cord, these cells were demonstrated to specifically innervate muscle. In another recent example, mESCs were treated with the phosphoinositide-3-kinase (PI3-K) inhibitor (LY294002) to induce differentiation of ES cells into islet-like cells, which could be transplanted into the pancreas of mice, thereby rescuing several effects associated with induced diabetes mellitus (Lumelsky et al., 2001; Hori et al., 2002).

MULTIPOTENT STEM CELLS

A potential source of cells for replacement therapeutics, apart from ES cells, is that of multipotent stem cells, in particular the hematopoietic and mesenchymal stem cells (HSCs and MSCs, respectively) of the bone marrow.

Hematopoietic Stem Cells

In terms of molecular properties, ease of isolation, developmental potential, and

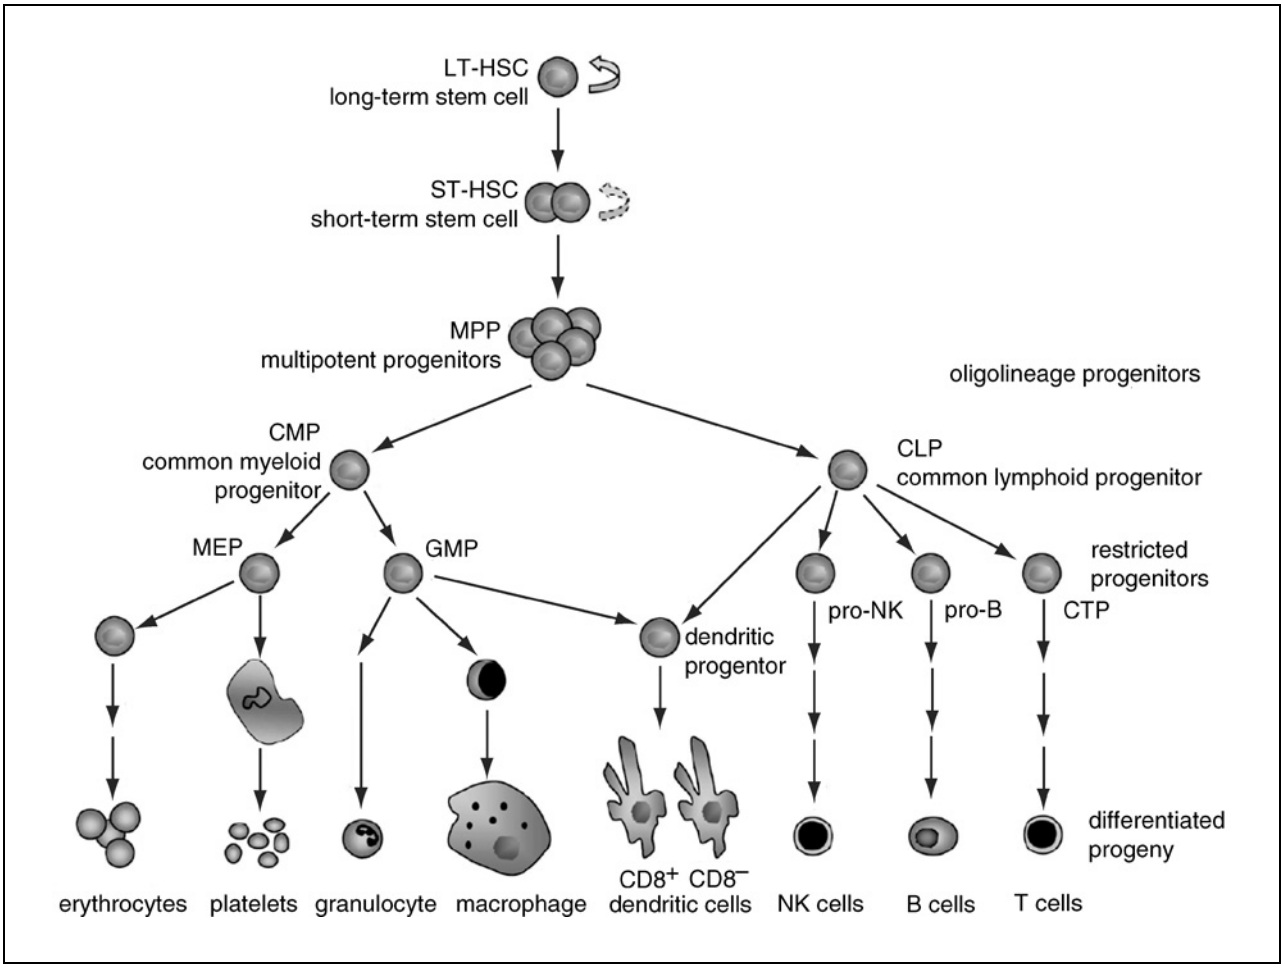

Figure 23.1.3 The hematopoietic hierarchy. Long-term hematopoietic stem cells (LT-HSCs) are located at the top of the hierarchy and give rise to short-term hematopoietic stem cells (ST-HSCs). In turn, ST-HSCs give rise to multipotent progenitors (MPPS) that generate the two distinct common myeloid and lymphoid progenitor populations (CMPs and CLPs, respectively). CMPs give rise to erythrocytes, platelets, granulocytes, and macrophages, whereas CLPs give rise to natural killer (NK), B cells, and T cells.

thrapeutic applications, HSCs represent the best characterized and understood of all stem cells (Orkin, 2000). HSCs found within adult bone marrow can give rise to all lymphoid and myeloid blood cell types and can be divided into two subtypes: long-term HSCs (LT-HSCs), which undergo extensive self-renewal, and their progeny, short-term repopulating HSCs (ST-HSCs), which undergo more limited self-renewal prior to becoming multipotential lymphoid or myeloid progenitors. At a single-cell level, LT-HSCs can be defined as being able to reconstitute all blood types of lethally irradiated mice (Osawa et al., 1996; Morrison et al., 1997). Although numerous definitions exist, LT-HSCs have also been defined within both the $CD34^+/lin^-$ population and Hoechst 33342/rhodamine 1223 effluxing ($Sca\text{-}1^+c\text{-}kit^+CD43^+CD45{+}lin^-$) side population (SP) of the bone marrow (Krause et al., 1994; Goodell et al., 1996, 1997; Christensen and Weissman, 2001; Scharenberg et al., 2002). Multipotential progenitors derived from ST-HSCs do not undergo self-renewal, but instead they provide both myeloid and lymphoid precursors that rapidly divide and give rise to all blood cell types (Kondo et al., 1997; Akashi et al., 1999a,b; Fig. 23.1.3). Although both LT-HSC and ST-HSC equivalents have been identified in both mouse and human, a number of cell surface markers have been shown to differ (Okuno et al., 2002).

With respect to therapies, both syngeneic (i.e., usually from twins) and allogeneic HSC transplantations can be used following systemic chemotherapy and chemoradiotherapy to replace the depleted hematopoietic systems and to induce immune tolerance of patients with severe aplastic anemias (80% of cases have neutropenia and megakaryocytic anemia), fatal leukemias and other

hematological malignancies (lymphomas and myelomas), clinically severe autoimmune disease, and thalassemias. Although success rates vary widely (between 15% and 20% for patients with acute leukemia and ~80% for patients with chronic myeloid leukemia) more than 20,000 transplants were performed worldwide in 2004 alone (see American Cancer Society, Cancer Facts and Figures, 2005; *http://www.cancer.org*).

Mesenchymal Stem Cells

MSCs were first identified as a mixed population of fibroblast-like plastic-adherent cells that separated from the nonadherent hematopoietic bone marrow fraction in culture (Friedenstein et al., 1966). Reports demonstrate that residual pre-B progenitor cells and granulocytic cells can best be removed on the basis of CD34/CD45/CD11b immunodepletion (Ortiz et al., 2002). MSCs provide a supportive role to HSCs during hematopoiesis, secreting growth factors and effecting direct cell-cell interactions, which play a role in HSC proliferation and differentiation. MSCs additionally possess the capacity to differentiate into a range of mature connective tissue cell types including chondrocytes, osteocytes, and adipose and smooth muscle cells. MSCs are also called bone marrow stromal cells, as they are most often isolated from the tibia, fibula, iliac crest, or the thoracic and lumbar spine. However, MSCs that possess the same multipotency have similarly been isolated from skeletal muscle, adipose tissue, deciduous teeth, and the synovium (Poulsom et al., 2002; Barry and Murphy, 2004). MSCs have therefore also been named mesenchymal progenitor cells because of the ability, for example, of MSCs isolated from adipose tissue to produce adipocytes and chondrocytes. The capacity to direct differentiation of MSCs preferentially into bone, cartilage, adipose tissue, or muscle has been demonstrated to be dependent upon the source tissue for extracting MSCs. Furthermore, different culture conditions can also prejudice the percentage or preference of differentiation into a specific lineage. For example, osteoblastic differentiation can be achieved by supplementing the medium with fetal bovine serum, dexamethasone, ascorbic acid, and β-glycerol phosphate in combination (Rodriguez et al., 2004). Preferential differentiation into chondroblastic lineages can be achieved by the addition of TGF-β, growth in a 3-D ultrastructure, and the removal of serum from the medium. However, differentiation of MSC into chondrocytes does not require all of these methods to be combined; chondrocyte differentiation can be achieved with the addition of TGF-β or by growth in 3-D culture, but if TGF-β is added to the 3-D culture, increased chondrocyte differentiation will result (Johnstone et al., 1998; Li et al., 2005). Differentiation of MSCs into adipocytes has been reported to be induced by monolayer culture of MSCs in the presence of isobutylmethylxanthine (Suzawa et al., 2003). Differentiation of MSCs into skeletal muscle induced by culture in the presence of amphotericin B has also been reported (Phinney et al., 1999). Therapeutically, MSCs have been reported to contribute to the repair of many tissues; this will be discussed below.

Neural Stem Cells

NSCs comprise the bulk of early fetal brain cells, and despite some conjecture, they have been reported to arise in the adult brain in the hippocampal dentate gyrus subgranular zone and the subventricular/subependymal zone of the lateral ventricles (Lois and Alvarez-Buylla, 1993; Doetsch et al., 1999; Johansson et al., 1999; Gage, 2000; Seaberg and van der Kooy, 2002). Linear differentiation of multipotent NSCs through more restricted progenitor populations provides all differentiated cells of the fetal neural system during development, as well as neurons and glia (oligodendrocytes and astrocytes) as required for learning and memory and following functional loss of established systems in the adult (Reynolds and Weiss, 1996; Shors et al., 2001; Carlen et al., 2002; Nakatomi et al., 2002). The regulation of NSCs and their progenitors into neuronal, astrocytic, or oligodendrocytic fates occurs according to the specificities of developmentally patterned transcriptional programming and the neural-specific microenvironmental niche (Song et al., 2002; Doetsch, 2003; Shen and Zhang, 2004). In addition to contributing to daily cellular turnover, neural cells possess a limited replacement potential following injury, but they are unable to restore function after damage.

Fetal neuronal transplantation has demonstrated some success in restoring motor function, memory, and spatial learning in rats following cortical grafting in focal ischemia–induced injury within the forebrain (Hodges et al., 1996). Furthermore, although some

patients display graft rejection and others develop severe dyskinesis, striatal grafting of fetal mesencephalic precursors or dopaminergic neurons can restore dopamine release to near-normal levels in patients with Parkinson's disease (Freed et al., 2001; Lindvall and Bjorklund, 2004). It is unlikely, however, that fetal neural tissue will become a routine source of material for treating neural disease, due to lack of availability and difficulties in standardizing functional outcome (Lindvall and Bjorklund, 2004). Several workers are therefore investigating the use of transplantable NSCs and their derivatives as a means to repair damage associated with diseases such as Parkinson's disease and multiple sclerosis.

NSCs isolated from fetal and adult brains of mice or humans can be expanded in culture from single cells in the presence of epidermal growth factor (EGF), fibroblast growth factor (FGF), or both EGF and FGF together, to form neurospheres (Reynolds and Weiss, 1992; Richards et al., 1992; Carpenter et al., 1999; Tropepe et al., 1999; Piper et al., 2001). Although some differences exist between NSCs isolated from humans and mice, expanded neurospheres from both species maintain a small percentage of multipotent NSCs and can be plated to give rise to neurons, oligodendrocytes, and astrocytes, or dissociated into single cells for serial neurosphere propagation. NSCs derived from fetal brain provide stable lines after extensive culture, and they maintain the capacity to engraft as neurons and glia following transplantation to the 6-hydroxydopamine-lesioned striata of cyclosporin-treated rats (Vescovi et al., 1999). Furthermore, multipotential cells isolated from the mouse optic nerve, hippocampus, and adult subventricular zone demonstrate remyelination of damaged axons, repopulation of the hippocampus, and rostral migration to the olfactory bulb where they produce two different types of olfactory neurons, respectively (Crang et al., 1992; Lois and Alvarez-Buylla, 1994; Ray and Rodrigues, 1995; Yandava et al., 1999). Perinatal intracallosal xenograft of more committed oligodendrocyte progenitor cells from both the late-gestation and adult human ventricular zone into myelin basic protein–deficient shiverer mice (*shi*$^{-/-}$), a model of perinatal leukodystrophy, generated myelinating oligodendrocytes (Windrem et al., 2004). Thus, several strategies aimed at developing transplantation therapies for correcting neurological disease and genetic deficits are underway.

ADULT STEM CELLS DISPLAYING UNEXPECTED MULTIPOTENTIALITY

In addition to the ability of NSCs to undergo linear differentiation into the three neural derivatives (neuron, astrocyte, and oligodendrocyte) and the ability of HSCs to differentiate into all known hematopoietic lineages, as well as the capacity of MSCs to give rise to a restricted subset of mesodermal-like derivatives, evidence has appeared in the literature suggesting an unexpected increased plasticity of these cell types (Bjornson et al., 1999; Clarke et al., 2000; Lagasse et al., 2000; Willenbring and Grompe, 2004). These reports indicate that both bone marrow (BM)–derived stem cells and NSCs may in fact also be capable of giving rise to a wider array of fully differentiated cell types, not previously expected.

Repair of Liver Tissue by Adult Stem Cells

Following liver damage, a subpopulation of hepatocytes with regenerative potential and oval cells recruited from the biliary duct epithelium were traditionally believed to potentiate hepatic regeneration and restore vital liver function (Overturf et al., 1997; Alison et al., 1998). With reports that BM-derived cells displayed greater multipotency than previously recognized, the contribution of specific bone marrow populations to liver regeneration was investigated. Informative studies have taken advantage of fumarylacetoacetate hydrolase (FAH)–deficient (*Fah*$^{-/-}$) mice, which normally display a lethal tyrosinemia manifested as progressive liver failure and chronic renal tubular damage unless maintained on 2-(2-nitro-4-trifluoro-methylbenzyol)-1,3-cyclohexanedione (NTBC) in their drinking water (Grompe et al., 1995). Lethally irradiated *Fah*$^{-/-}$ mice reconstituted intravenously with whole bone marrow or HSCs purified for c-kit^{high} Thy^{low} Lin^{-} Sca-1^{+} (Lin, lineage markers CD2, CD3, CD4, CD5, CD8, NK1.1, B220, Ter119, GR-1, and Mac-1) could survive after being withdrawn from NTBC (Lagasse et al., 2000).

Subsequent studies by the same group and others, aimed at understanding the underlying mechanisms of the apparent transdifferentiation events, demonstrated that appearance of hepatic phenotypes from the BM-derived cells could be best explained in terms of cell-cell

fusion events. Serial transplantation of HSCs along with karyotypic analysis and expression of donor versus host alleles in regenerating liver nodules confirmed that the apparent change in the HSC derivative phenotype and reinstated liver function was achieved by a mechanism associated with cell-cell fusion (Vassilopoulos et al., 2003; Wang et al., 2003).

Dissection of the HSC derivatives participating in the cell-cell fusion demonstrated that fusogenic macrophages are sufficient for the appearance of *Fah*$^{+/+}$ hepatocytes in the recipient mice. It was further demonstrated that mature hepatocytes did not fuse (Willenbring and Grompe, 2004). Conjecture, however, remains over the precise cell type and the extent of the role that a specific injury may play in the induction of fusion between donor HSC-derived cells and host liver. Two-dimensional homed Fr25lin$^-$ marrow cell lines, selected as both functionally and phenotypically representing HSCs, were reported to convert to a hepatocyte lineage in the absence of fusion following engraftment in carbon tetrachloride–induced hepatocyte injury in vivo (Jang et al., 2004). Similarly an independent study using Z/EG Cre-reporter BM donors to reconstitute lethally irradiated β-actin-Cre recipients reported transdifferentiation of BM-derived cells to hepatocytes in the absence of any apparent cell-cell fusion (Harris et al., 2004).

Repair of Cardiac Tissue by Adult Stem Cells

Myocardial infarction (MI) is an ischemic insult resulting in cardiomyocyte apoptosis and fibrous replacement. MI and its associated process of scarring is a leading cause of congestive heart failure (CHF) and morbidity in Western societies (Tang and Francis, 2003). Although cardiomyocytes or resident lin$^-$c-kit$^+$CD45$^-$ cells may regenerate the heart and improve function to some minor extent following injury, this process is largely insufficient. Therefore, heart transplantation, left-ventricular implantation devices, and pharmaceutical intervention remain as current clinical treatments. Novel strategies aimed at reducing heart failure after MI are warranted and greatly needed.

Investigations into the possibility that circulating myogenic precursors may contribute to cardiomyocyte regeneration demonstrated that cardiac and skeletal muscle of *mdx* mutant mice (a mouse model approximating Duchenne's muscular dystrophy) could be engrafted following total-body irradiation and hematopoietic reconstitution with donor whole BM (Bittner et al., 1999). BM engraftment of infarcted cardiac tissue was supported by several left coronary artery (LCA) ligation studies, including the intravenous injection of SP BM–derived cells (CD31$^{-/low}$/c-kit$^+$,Sca-1$^+$) following lethal irradiation and hematopoietic reconstitution, and the direct peri-infarct injection of lin$^-$c-kit$^+$ BM–derived cells (Jackson et al., 2001; Orlic et al., 2001). In both studies, transdifferentiation of BM-derived cells into cardiomyocytes and vascular endothelium was reported. In the latter, engraftment was reported to improve cardiac hemodynamics. In addition to providing a means of ameliorating the symptoms of heart disease, the delivery of BM cells to cardiac tissue was suggested as a viable means of delivering dystrophin to patients with Duchenne's muscular dystrophy.

Subsequent and more detailed studies of the mechanisms underlying engraftment using conditional transgenic mice revealed that BM–derived cells and cardiomyocytes can undergo cell-cell fusion (Alvarez-Dolado et al., 2003). Furthermore, c-kit$^+$, c-kit$^+$lin$^-$ and c$^-$kit$^+$lin$^-$Thy-1^{lo}Sca-1$^+$ BM–derived cells injected directly into ischemic hearts following LCA ligation, into c-kit$^+$Lin$^-$ BM-derived cells following freeze injury, or into α-myosin-GFP c-kit$^+$lin$^-$ BM–derived cells following LCA ligation or cauterization, although transiently present in the graft, did not express markers characteristic of cardiomyocyte differentiation (Murry et al., 2004; Nygren et al., 2004). Some benefit in limiting ventricular dilation and dysfunction in the long-term was observed; however, 30-day survival and infarct size did not differ significantly between control and treated groups, suggesting that recruitment of resident cardiomyocyte progenitors was minimal (Murry et al., 2004). Similarly, lethal irradiation followed by reconstitution with β-actin-GFP or α-actin-GFP c-kit$^+$lin$^-$Sca-1$^+$CD45$^+$ BM–derived cells, then LCA ligation and mobilization of stem cells with cytokines or reconstitution with α-myosin-GFP c-kit$^+$lin$^-$ BM–derived cells, followed by LCA ligation, did not show evidence for engraftment of donor cells displaying cardiac phenotype within the infarct (Murry et al., 2004; Nygren et al., 2004). Following lethal irradiation and reconstitution, however, a small number of donor cells were observed to take on characteristics of cardiomyocytes through a process of cell fusion with endogenous

cardiomyocytes within the peri-infarct zone. What effect these fused cells have on cardiac function is not known; however, it was suggested that the previously reported benefit in function is most likely attributable to left-ventricular remodeling and/or the potentiation of endogenous endothelial vascularization.

Despite this conjecture in the literature with animal models, several clinical trials have already been conducted, and mixed success in terms of functional benefit has been reported. Injection of BM-derived cells or cytokines has been reported to be safe and beneficial, yet it has also been associated with occlusion of microcoronary circulation, induction of myocardial infarction, increases in cardiac enzymes, and increased rates of restenosis (Lee et al., 2004).

Repair of Skeletal Muscle by Adult Stem Cells

Self-renewal, growth, and regeneration of skeletal muscle is effected by slowly dividing, self-renewing $CD45^-Sca1^-/CD34^+Sca1^-$ mononuclear satellite cells that lie between the muscle fiber plasmalemma and associated basement membrane (Campion et al., 1984; Zammit and Beauchamp, 2001; Asakura et al., 2002; Sherwood et al., 2004). Following injury, or in patients suffering degenerative myopathies, satellite cells divide and fuse to form multinucleated replacement myotubes. Satellite cells display a reduced self-renewal capacity with age, resulting in their gradual loss. In combination with chronic or severe injury, satellite cells are eventually depleted such that absent muscle tissue can be replaced only with scar tissue.

In addition to satellite cells, unfractionated, nonadherent and adherent BM-derived cells were reported to engraft cardiotoxin (CTX)–injured skeletal muscle fibers and SP cells were reported to engraft *mdx* null skeletal muscle fibers (Ferrari et al., 1998; Bittner et al., 1999; Gussoni et al., 1999; Ferrari et al., 2001). The production of mononuclear myoblasts and subsequent skeletal muscle engraftment by unfractionated whole BM following irradiation and/or exercise-induced injury were reported to occur after passage through a muscle satellite cell intermediary phenotype (LaBarge and Blau, 2002). Both $Sca\text{-}1^+CD45^+$ and $Sca\text{-}1^+CD45^-$ resident skeletal muscle cells were reported to harbor myogenic activity (Asakura et al., 2002; Polesskaya et al., 2003). With respect to $Sca\text{-}1^+CD45^+$ resident cells, myogenic recruitment into CTX-induced skeletal muscle injury was coupled to activation of Wnt signaling (Polesskaya et al., 2003). Although the precise identity of any single BM-derived cell type harboring myogenic activity is unknown, Camargo et al. (2003) showed that 0.03% to 0.08% of all skeletal muscle cells in the CTX-injured tibialis anterior muscle were derived from a single SP $Sca1^+$ $CD45^+$ HSC cell previously transplanted following irradiation and long-term hematopoietic chimerism. Furthermore, $CD45^+$ BM cells derived from SP $Sca1^+CD45^{+-}$ reconstituted mice, injected into lethally irradiated *mdx* mice, demonstrated a 0.13% TA myofibril contribution. No donor-derived cells were found in uninjured muscle or desmin-null muscle, and transplantation of $CD45^-$ BM-derived cells did not result in TA engraftment following injury. The presence of $\beta\text{-gal}^+$ cells in CTX-injured TA of bitransgenic *Lysozyme M-Cre recombinase* (*LysM-Cre*) × $ROSA^{flox/STOP}$ mice indicated that engraftment by BM derivatives was attributable to circulating myelomonocytic precursors, macrophages, and/or granulocytes. Furthermore, engraftment was attributable to fusion with myoblasts produced from resident satellite cells during muscle fiber regeneration and not transdifferentiation. Thus, it still remains unclear whether BM-derived stem cells may be exploited for myogenic therapeutics. However, it appears that fractionated cell types with myogenic potential (with or without fusion) can be isolated from both bone marrow and adult skeletal muscle, and can, to varying degrees, contribute to repair in an injury-specific fashion. Therefore, it remains uncertain whether the incidence of BM contribution will be high enough to offer therapy for muscle dystrophies and whether both subsets may eventually play equal roles in future therapeutics.

Neural Stem Cell Plasticity

In a similar fashion to BM-derived stem cells, mouse NSC differentiation pathways have been reported to be permissive to reprogramming, transdifferentiation, or transdetermination in response to ectopic stimuli (Frisen, 2002). Adult and fetal forebrain NSC derivatives were reported to reconstitute the hematopoietic system following intraportal injection of sublethally irradiated mice. Adult NSCs were reported to give rise to representatives of all three embryonic germ cell layers following injection into the amniotic cavity of chick embryos, and intrablastocoel injection and transfer to pseudopregnant mice (Bjornson et al., 1999; Clarke et al., 2000). Neurospheres derived from a human fetal brain

were injected into irradiated *scid-hu* mice and similarly displayed hematopoietic reconstituting activity (Shih et al., 2001). Coculture of adult mouse paraventricular NSCs and human embryonic NSCs with myoblasts and direct injection into CTX-injured tibialis anterior muscle were reported to result in transdifferentiation of NSCs into skeletal muscle cells (Galli et al., 2000). NSCs were thus suggested as an alternative source of cells for therapeutic strategies where caveats associated with therapeutic cloning or immune rejection of MHC-disparate donor cells limit the application of ES cells.

Theories concerning stem cell plasticity have not been unequivocally accepted (Anderson, 2001; Morshead et al., 2002). The ability of the blastocyst environment to alter NSC fate was considered an abnormal situation and repeat experiments using NSC/morula aggregation failed to demonstrate embryonic integration of NSC derivatives (Tropepe et al., 2001). Experiments aimed at repeating hematopoietic reconstitution of irradiated mice using NSCs similarly failed. It was suggested that this reported property was more likely due to a rare in vitro genetic or epigenetic alteration in long-term cultured NSCs or the presence of contaminating HSCs in the original NSC culture (Morshead et al., 2002; Magrassi et al., 2003). More recently, culture of mouse NSCs with human endothelium induced a type of transdifferentiation into endothelial lineages (Wurmser et al., 2004). No fusion was observed in vitro and injection of NSCs into the telencephalon of embryonic day 14 (E14) mice resulted in expression of endothelial markers by a fraction of the cells by E16. Although it is not known whether NSC conversion to endothelial cell phenotype represents a normal physiological process, the appearance of a small percentage of cells (1.6%) from all input cells opens up this possibility.

STEM CELLS STIMULATE ENDOGENOUS REPAIR

Despite debates over transdifferentiation and the capacity of transplanted adult stem cells to replace damaged tissue in a functionally relevant context, some studies suggest adult stem cell transplantation may stimulate endogenous repair mechanisms. These studies suggest direct consequences for treating diseases such as type I diabetes, multiple sclerosis, and idiopathic pulmonary fibrosis. For example, transplantation of c-kit$^+$ adult BM-derived stem cells was reported to reduce hyperglycemia in streptozotocin-induced damage of NOD-SCID mouse pancreas by contributing to neovasculogenesis, engrafting the pancreas, and stimulating endogenous islet cell proliferation and insulin secretion (Hess et al., 2003). Intraventricular or systemic injection of adult periventricular neural progenitors into myelin oligodendrocyte glycoprotein induced autoimmune encephalomyelitis, which resulted in decreases in astroglyosis, demyelination, axonal loss, and associated functional impairment (Pluchino et al., 2003). Neural progenitors were reported to home to the site of injury, remyelinate neurons, stimulate endogenous oligodendroglia, and attenuate reactive astrogliosis. Roughly a quarter of all mice in each group were reported to recover completely from the disease, whereas mice that were either sham-transplanted or transplanted with other cell types showed no recovery. Similarly, systemically administered plastic adherent and CD11bCD34CD45 immunodepleted whole BM MSCs were reported to home to bleomycin-induced respiratory injury. Notwithstanding issues of cell-cell fusion, MSCs adopted an epithelial-like morphology and were reported to graft as type II epithelial cells. Furthermore, MSC administration immediately following bleomycin-induced respiratory injury reduced inflammation and fibrosis with an associated decrease in collagen deposition and increase in metalloproteinase gene expression (Ortiz et al., 2003).

GENETIC MANIPULATION OF EMBRYONIC STEM CELLS

The ability to manipulate mESCs has proven to be a valuable tool in developing understanding of processes of differentiation, development, and disease. The generation of genetically altered cell lines is standard in many laboratories. The capacity to similarly genetically manipulate hESCs is fast becoming a reality. Several strategies have been developed that allow the successful transfection of hESCs. These have resulted in the generation of ES cell lines with ubiquitous or specific promoter-driven reporter genes for lineage tracing and gene-targeting events such as knock-in/up/out. The first major success came from liposome-based ExGen500 (Fermentas) technology, which produces a high transfection efficiency when compared to both standard electroporation conditions and other liposome-mediated systems (Eiges et al., 2001). This technique was used for the generation of stable hESCs with an EGFP reporter

gene driven by the Rex-1 promoter (Eiges et al., 2001). An alternative approach has been the use of both adenoviral and lentiviral vectors. Adenoviral vectors Ad5 containing the β-galactosidase reporter gene have proven the most successful, generating transient transfection efficiencies of 11.2% with no apparent effect on differentiation status (Smith-Arica et al., 2003). Self-inactivating lentiviral vectors have also been particularly successful in generating stable transgenic hESCs (Gropp et al., 2003; Ma et al., 2003). These viral vectors have been reported to generate stable transduction efficiencies of between 20% and 80% (Gropp et al., 2003; Ma et al., 2003). More importantly, electroporation of hESCs have resulted in both the *HPRT1* and *POU5F1* loci to be successfully targeted using homologous recombination (Zwaka and Thomson, 2003). Most recently, a novel transfection method has been reported that combines electroporation with a chemical-based technology. This method is termed nucleofection, as it enhances nuclear targeting of exogenous DNA to the nucleus, thus enhancing expression and genomic integration (Lakshmipathy et al., 2004).

The generation of defined lineage-restricted populations has also been explored through the use of genetic manipulation. The directed differentiation of mESCs has been successfully achieved through the manipulation of lineage-specific transcription factors. Ectopic expression of Nurr1 in transgenic mESCs directs their differentiation into a midbrain-type dopaminergic neuronal phenotype (Chung et al., 2002). Similarly, forced constitutive expression of GATA-6 and GATA-4 induces mESC differentiation into extraembryonic endoderm (Fujikura et al., 2002). The production of a more tightly regulated induction has recently been reported, whereby insulin-producing cells have been generated from mESCs via tetracycline-off regulated exogenous *Pdx-1* integrated into the *ROSA26* locus (Miyazaki et al., 2004). Alternatively, episomal constructs that are active as extrachromosomal vectors have also been shown to be effective in directing lineage-specific differentiation. In this study, the Wnt antagonist Sfrp2 was used to stimulate the production of neural progenitors (Aubert et al., 2002).

The development of new technologies such as RNA interference (RNAi)–based protocols may also efficiently result in lineage restriction of ES cells by modifying gene expression within the cell. RNAi technology has been applied to mESCs to suppress Oct4 expression, resulting in trophectodermal differentiation (Velkey and O'Shea, 2003). In the human context, Vallier et al. (2004) have shown that hairpin RNAi constructs can efficiently induce gene-specific knockdown of reporter gene expression in hESCs.

Advances in methods for high-efficiency transfection of hESCs, production of novel expression systems, and advances in the ability to direct specific activation and inactivation of gene expression provide powerful technologies for the future of human embryonic stem cell research. These, coupled with growing databases of genes implicated in pluripotency and lineage-specific differentiation, greatly enhance the ability to specifically regulate ES cell differentiation and thus fully harness the potential of ES cells.

THERAPEUTIC APPLICATIONS OF STEM CELLS

Mouse ES cells were first described some 17 years before hESCs, which were first isolated in 1998 (Martin, 1981; Thomson et al., 1998). Research using mESCs is currently more advanced, with several in vivo examples reporting appropriate physiological function of the transplanted cell types. Reports of mESC derivatives improving heart function (Min et al., 2002; Hodgson et al., 2004), curing blood disease (Rideout et al., 2002), normalizing weight, longevity, and insulin levels in diabetic mice (Hori et al., 2002), reducing symptoms of Parkinson's disease (Bjorklund et al., 2002; Kim et al., 2002), and partially repairing damaged spinal cords (McDonald et al., 1999; Liu et al., 2000) have already appeared in the literature. More sophisticated studies demonstrating similar physiological function of hESC derivatives in vivo, until now, have been lacking. Kehat et al. (2004) recently described the production of cardiac-like cells from hESCs, and, for the first time, meaningful in vivo physiological function of hESC derivatives. They successfully treated pigs with an atrioventricular block and restored a heart rhythm compatible with the survival of approximately half the animals tested. As acknowledged by the authors, this work was limited in part by the failure to test for cell fusion (between the transplanted cells and the cells already existing in the pig heart) and the inability to discriminate between direct electrical effects of the cells versus indirect instructive effects upon neighboring cells. This research provides important evidence to support the suggestion that hESCs

may represent suitable candidates for relieving heart conditions and disorders, and that hESCs may one day play an important role in cell-transplantation therapeutics.

The therapeutic application of ES cells is not only challenged by the ability to generate specific cell types capable of repairing various tissues, but it is also confronted with the additional hurdle of immune rejection. Currently, histocompatible donors and immune-suppression drugs are used to reduce these effects in organ-transplantation patients. However, alternatives in overcoming immune rejection will broaden the availability and success of organ transplantation and ES cell therapy. One approach is that of therapeutic cloning, whereby patient tissue is cloned into an oocyte for the generation of ES cells, which can then be differentiated into the desired cell type for tissue regeneration (Fig. 23.1.4). These cells, being genetically identical to the patient, will circumvent an immunological response. An alternative to therapeutic cloning may be in the form of ES cell banks. It is envisaged that, by generating large numbers of ES cells from a range of genetic backgrounds, a histocompatible hESC line will be available for any patient (Baharvand et al., 2004; Heins et al., 2004). Alternatively, reprogramming adult cells into the phenotype of an ES cell without the use of oocytes is also currently being investigated. ES cell extracts may be capable of de-differentiating/reprogramming adult patient cells to take on an ES-like phenotype, whereupon subsequent differentiation strategies can then be utilized (Tada et al., 2001).

A fourth approach has been that of manipulating immunological tolerance. Such methods include second-signal blockade (Rifle and Mousson, 2002), manipulation of recipient

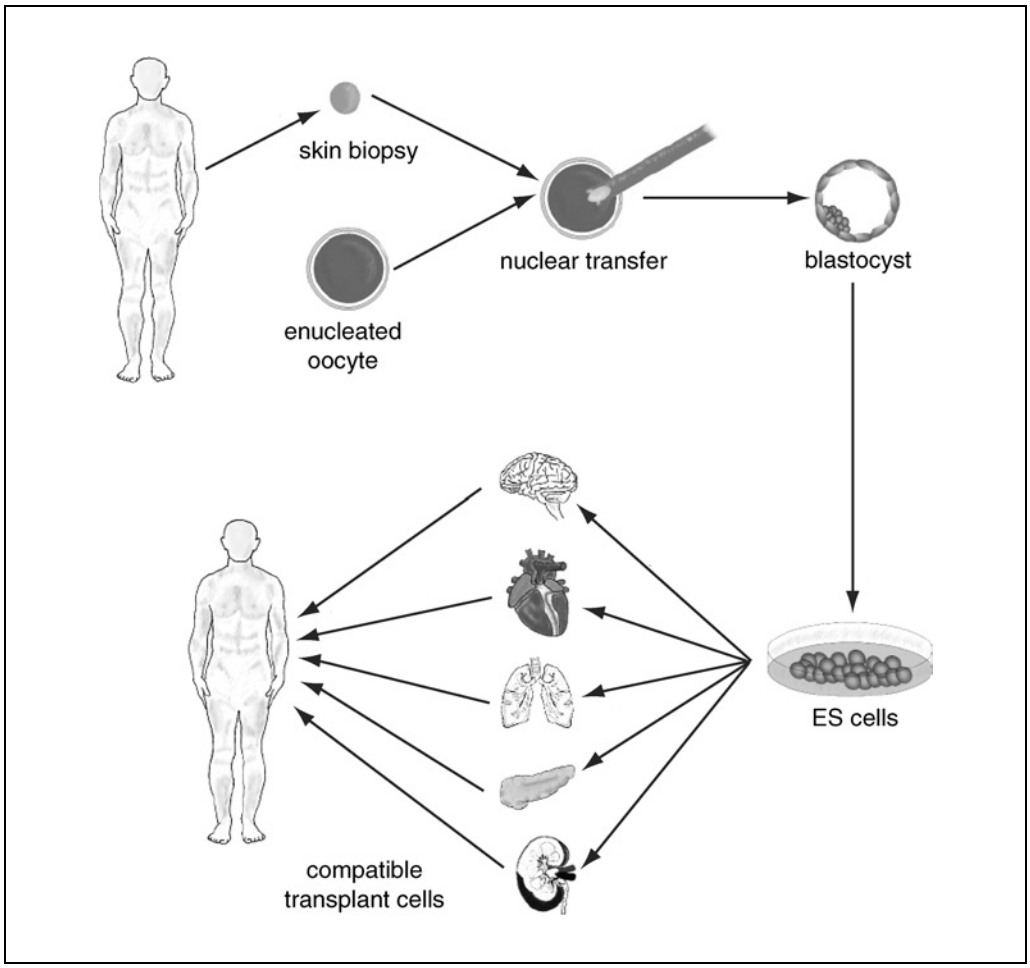

Figure 23.1.4 Therapeutic cloning. Therapeutic cloning involves the production of custom-designed embryonic stem (ES) cells by the transfer of a person's own DNA (nuclear transfer) into a donor oocyte. Following nuclear transfer, the oocyte is incubated to develop into a blastocyst, from which ES cells are derived. ES cells are then coaxed to become a desired cell type (e.g., neural, cardiac, respiratory, pancreatic, or renal) and made available for transplantation. Because the resulting tissue for transplant contains the same DNA as the donor, it should not be rejected.

antigen-presenting cells, and chimerism of the immune system. Chimerism involves the injection of donor bone marrow into the recipient in order to improve organ allograft survival (Monaco and Wood, 1970; Deng et al., 2004). It has been suggested that a combination of donor myeloid (immature) dendritic cells (Rifle and Mousson, 2002) and donor T cells aids in the induction of transplantation tolerance (Tian et al., 2004). This technique, combined with ES cell therapy, could aid in long-term survival for donor cells in patients and in overcoming the requirements for ES cell banks and therapeutic cloning.

CONCLUSION

Current research on the culture and differentiation of both adult and embryonic stem cells has allowed advances in unraveling the molecular mechanisms behind specific cellular differentiation events. In vitro expansion of stem cell populations, combined with differentiation protocols and genetic manipulation of ES cells, has enabled the tracing of various cell lineage differentiation events and the development of an understanding of several of the molecular pathways involved. Ethical issues surrounding the use of ES cells may be resolved by current research into adult stem cell plasticity, which offers a potential source of cells for replacement therapies in certain diseases and the ability to overcome immune-rejection issues. Overall, it is hoped that homogenous differentiation of stem cells into a desired precursor, or specific differentiated cell lineage, will facilitate the development of effective clinical methods for treating a wide range of diseases, and also increase understanding of the mechanisms leading to these diseases.

Mouse Embryonic Stem Cell Derivation, and Mouse and Human Embryonic Stem Cell Culture and Differentiation as Embryoid Bodies

Embryonic stem (ES) cells are pluripotent cells derived from developing mouse blastocysts in vitro that maintain long-term self renewal and the capacity to give rise to all cell types in the adult body (including some extraembryonic cell types) when subjected to the appropriate conditions. It is envisaged that the development of methods enabling controlled differentiation of mouse ES cell counterparts from human blastocysts would enable the provision of an unlimited supply of tissue for cell and tissue transplantation therapies for the repair and replacement of diseased, injured, and senescent tissue. Furthermore, derivation of mouse ES cells has allowed for the generation of thousands of gene-targeted mouse mutants. Culture of mouse ES cells as embryoid bodies (EBs) has provided a convenient system for studying early mouse developmental processes, including several aspects of extraembryonic lineage and axis formation associated with the pre- and peri-gastrulating mouse embryo. Relatively little is known regarding the corresponding development of the early human embryo due to limitations associated with the acquisition of relevant tissue material for study. The transfer of methods such as EB formation to human systems should, by association, facilitate a more advanced understanding of similar processes associated with early human development. This unit describes protocols for isolating mouse embryonic stem cells and methods for propagating, freezing, and producing EBs from both mouse and human embryonic stem cells.

The protocols in this unit are designed to provide a basis for the derivation of mouse ES cells (see Basic Protocol 1) and the successful propagation of both mouse (see Basic Protocol 1 and Alternate Protocol 1) and human ES cells (see Basic Protocol 3 and Alternate Protocol 2) in culture. In addition, protocols for the production of embryoid bodies (EBs) from both mouse (see Basic Protocol 2) and human (see Basic Protocol 4 and Alternate Protocol 4) ES cells are described. Descriptions of mouse embryonic fibroblast (MEF) feeder layer preparation (see Support Protocol 1), inactivation by mitomycin C (see Support Protocol 2) or γ-irradiation (see Support Protocol 3), mouse and human ES cell media preparation, methods for propagating ES cells on MEFs (see Basic Protocols 1 and 3), gelatin, and Matrigel (see Alternate Protocol 3), methods for passaging human ES cells by mechanical dissection (see Basic Protocol 4) and enzymatic digestion (see Alternate Protocol 3), conditioned medium preparation and storage (see Alternate Protocol 2), mouse blastocyst derivation, handling and cultivation techniques, vitrification, freezing and thawing protocols for human ES cells (see Basic Protocol 5), mouse ES cells and MEFs (see Support Protocol 4), and mouse (see Basic Protocol 2) and human EB (see Basic Protocol 3) formation using hanging drop and suspension culture are presented.

NOTE: For all procedures described in this unit, tissue culture, reagent preparation, and wash-up and sterilizing facilities are required. Experiments should be performed under sterile conditions in either Class II Biological Hazard Flow Hoods or laminar flow horizontal draft hoods. When working with human embryonic stem cells, Class II Biological Hazard Flow Hoods are recommended.

NOTE: Ethics approval for the described protocols is usually required from the appropriate institutional research office.

Contributed by Brock J. Conley, Mark Denham, Lerna Gulluyan, Fredrik Olsson, Timothy J. Cole, and Richard Mollard
Current Protocols in Cell Biology (2005) 23.2.1-23.2.22

NOTE: All incubations should be performed in a humidified 37°C, 5% CO_2 incubator unless otherwise specified. Some media (e.g., DMEM) may require altered levels of CO_2 to maintain pH 7.4.

BASIC PROTOCOL 1

DERIVING, CULTURING, AND FREEZING MOUSE EMBRYONIC STEM CELLS

Mouse embryonic stem cells (mES) are currently the best defined ES or ES-like cells. Due to the relative ease of working with mouse ES cells when compared to their human counterparts, it may be convenient for researchers working for the first time in this discipline to set up both systems in the laboratory. Basic culture techniques for working with mouse ES cells are outlined below. For further information, see Key References.

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) and must conform to governmental regulations for the care and use of laboratory animals.

Materials

3.5 days post coitum (dpc) pregnant strain 129sv mouse
M2 medium (Sigma), sterile
M16 medium (Sigma), sterile
Cell culture–grade distilled water (JRH Biosciences), sterile
Organ culture dishes treated with 0.1% (w/v) gelatin and coated with mitotically inactivated MEFs (see Support Protocol 2 or 3)
mES cell medium (see recipe), sterile
PBS, calcium- and magnesium-free (CMF-PBS; Invitrogen), sterile
0.025% trypsin/0.04% EDTA (see recipe), sterile
Cell culture–grade distilled water (JRH Biosciences), sterile
1-ml syringe and 26-G needle
Petri dishes
Organ culture dish (Becton Dickinson)
Finely drawn glass capillary pipets, 1 mm i.d.
Microscope
25-cm^2 tissue culture flask (Becton Dickinson), optional

Collect embryos

1. Sacrifice a 3.5-days dpc pregnant mouse by cervical dislocation. Fill a 1-ml syringe with M2 medium, attach a 26-G needle, then insert the needle into the oviduct of the mouse and gently flush out the embryos into a petri dish containing M2 medium.
2. Transfer embryos to 1 ml M16 medium in the central well of an organ culture dish and incubate at a 37°C until the embryos become expanded blastocysts. Add 5 ml cell culture–grade sterile distilled water to the outer compartment of organ culture dish to help maintain humidity during culture.

   Some freshly isolated embryos may already be expanded blastocysts, ~1 day in culture should be sufficient for all blastocysts to expand.

Isolate ICMs

3. Place four embryos in an organ culture dish treated with 0.1% (w/v) gelatin and mitotically inactivated MEFs in 1 ml mES cell medium (see Support Protocol 2 or 3).

   Embryos should attach within 2 days. The trophectoderm cells will be seen to migrate out onto the feeder cells and the inner cell mass (ICM) will be seen to expand.

4. Pick off each ICM with a finely drawn glass capillary and place in a microdrop (10 to 20 μl) of 0.025% trypsin/EDTA at room temperature.

5. Disaggregate the ICM with a finely drawn glass capillary into single cells, then replate onto a new organ culture dish coated with MEFs in 1 ml mES cell medium. Culture one dissociated ICM per MEF-coated organ culture dish.

   The ICM cells should proliferate in clumps as ES cells. Some non-ES cells may persist for a few days.

Grow ES cells

6. Change mES medium daily, removing and replacing 1 ml per central well.

7. After an additional 2 to 3 days, remove the medium from the plate, wash by adding 1 ml CMF-PBS and then removing the buffer, then add 200 μl of 0.025% trypsin/EDTA. Incubate 5 to 10 min at 37°C.

8. Observe cells detaching under a microscope and, prior to their disaggregation to single cells, add 600 μl mES cell medium while gently pipetting up and down with a finely drawn glass pipet.

9. Transfer cells to a fresh MEF-coated organ culture dish, incubate at 37°C, and change mES cell medium the following day.

10. Two days later, treat cells with 0.025% trypsin/EDTA as per previous steps 7 and 8.

11. After transferring the collected cells to a new MEF-coated organ culture dish, add 500 μl of 0.025% trypsin/EDTA to the old plate and incubate for an additional 5 to 10 min at 37°C.

12. Add 1 ml mES cell medium to stop reaction, transfer remaining cells to a second new MEF-coated organ culture dish and incubate overnight at 37°C.

13. Change medium the following day on both dishes and analyze under a microscope.

    The first plate should contain ES cell colonies, the second plate should not. If the second plate contains ES cell colonies, repeat previous steps 7 to 9.

Passage ES cells

14. When colonies have expanded (2 to 3 days), treat with 0.025% trypsin/EDTA as described in steps 7 and 8, and transfer to a fresh MEF-coated organ culture dish or a 25-cm^2 tissue culture flask coated with MEFs.

15. Trypsinize cells and transfer to a new dish or flask no longer than every 3 days for the first few passages. Observe cells each day and transfer when 80% to 90% confluent.

    For purposes of tracking passage number, begin counting passages the first time single cells are plated, i.e., step 5.

    To scale up the ES culture, cells can be split into two or more flasks or into larger flasks.

16. Freeze cells at regular intervals to prevent loss of cell line (see Support Protocol 4).

    It is recommended to freeze ES cells following the second or third passage at step 10.

17. Monitor ES cells at regular intervals via karyotypic analysis (G-banding; *UNIT 22.3*) and undifferentiated marker analysis.

    See Conley (2004a) for discussion of markers.

    The morphology of a typical mouse ES cell colony grown on MEFs can be seen in Figure 23.2.1C.

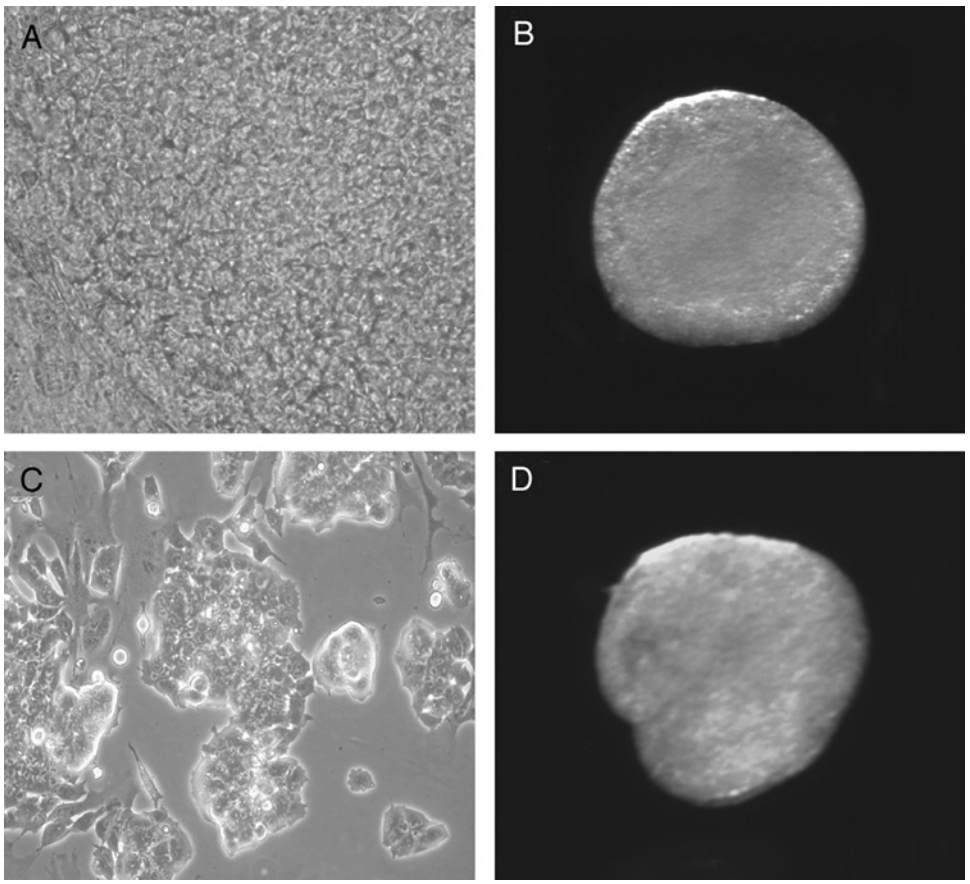

Figure 23.2.1 Photomicrographs of human ES cell and mouse ES cell propagation and growth as EBs. (**A**) Human ES cells (HES-2) propagated on MEFs (40× magnification). (**B**) An EB formed from human ES cells following mechanical dissection and culture in suspension for 7 days (2.5× magnification). (**C**) Zin40 mouse ES cells (see Munsie et al., 1998) propagated on gelatin in the presence of LIF (40× magnification). (**D**) An EB formed from Zin40 ES cells following 7 days of culture in a hanging drop (2.5× magnification).

ALTERNATE PROTOCOL 1

MOUSE ES CELL CULTURE IN THE ABSENCE OF FEEDER CELLS

Subsequent to their derivation, mES cells can be maintained in the absence of an MEF feeder layer in mES cell medium supplemented with 2000 U/ml leukemia inhibitory factor (LIF). Cells are grown in flasks and passaged when 75% to 85% confluent. Medium should be changed every 1 to 2 days.

SUPPORT PROTOCOL 1

PREPARATION OF MOUSE EMBRYONIC FIBROBLASTS

Mouse embryonic fibroblasts (MEFs) are used as a feeder support layer for the derivation of mouse ES cells and the propagation of both mouse and human ES cells. This protocol requires the investigator to possess basic animal handling, dissection, and tissue culture skills.

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) and must conform to governmental regulations for the care and use of laboratory animals.

Materials

12.5 to 13.5 days post coitum (dpc) pregnant strain 129sv females
PBS, calcium- and magnesium-free (CMF-PBS; Invitrogen), sterile
0.025% (w/v) trypsin/EDTA (see recipe), sterile
MEF medium (see recipe), sterile

90-mm bacteriological petri dish
Scalpel, sterile
20-G needle (Becton Dickinson)
75-cm^2 tissue culture flasks (Becton Dickinson/Falcon)
Platform shaker
15-ml tubes

Dissect and process embryos

1. Dissect the pregnant females at 12.5 to 13.5 days post coitus and remove the fetuses from the uterine horns into 90-mm bacteriological petri dishes containing sterile CMF-PBS.

2. Decapitate and eviscerate the fetuses to isolate the carcasses. Slice the carcasses into small, ~0.1-cm^2 fragments with a sterile scalpel.

3. Digest the carcass slices in 0.025% trypsin/EDTA for ~5 min at 37°C.

   In this and the following step, enough trypsin solution should be used to immerse the tissue.

4. Dissociate the tissue further by passing through a 20-G needle and then incubate the tissue in 0.025% trypsin/EDTA for an additional 10 min at 37°C.

5. Plate all of the cells from one carcass in a 75-cm^2 tissue culture flask containing 20 ml of MEF medium. Incubate at 37°C.

Passage MEFs

6. When the cells reach 80% to 90% confluency (~1 to 2 days), aspirate and discard the MEF medium, rinse with 2 ml CMF-PBS, replace with 1.5 ml of 0.025% trypsin/EDTA, and incubate 1 to 2 min at room temperature with agitation.

7. Inactivate trypsin by adding 1 ml MEF culture medium down the growing surface to dislodge all cells. Transfer cells to a 15-ml tube.

8. Centrifuge cells 2 min at ~700 × *g*, room temperature, to pellet. Remove and discard supernatant and resuspend the cells in 8 ml MEF medium.

9. Dispense cell suspension into 2-ml aliquots and add each aliquot to 18 ml of prewarmed MEF medium in 75-cm^2 tissue culture flasks. Incubate at 37°C (1:4 split).

10. Allow cells to reach 80% to 90% confluency (1 to 3 days) and passage again according to steps 6 to 9.

11. Passage cells four to five times to ensure minimal non-fibroblast contamination and to create a stockpile of genetically equivalent MEFs.

    For the purpose of counting passage number, begin counting following step 9.

    MEFs can be utilized following three or four passages, but for maximum efficiency, utilize them at passages five and six. After about seven passages, MEFs begin to lose their ability to support ES cells.

    MEFs can be frozen for storage at each passage number according to the freezing protocol (see Support Protocol 4).

Other strains of mice can be used to derive MEFs; however, these must be batch tested with ES cells to assess compatibility. Mouse ES cell derivation efficiency is severely reduced when not using the inbred 129sv mice. Mouse ES cells and MEFs need not be strain-matched. MEFs used for human ES cell culture provides a potential means for the xenobiotic transfer of pathogens from the mouse to human tissue, thus making these cells unsuitable for human therapeutic use. Human fetal fibroblasts have been utilized for propagation of human ES cells; however, currently, the use of MEFs in human ES cell culture is the most accessible and effective means for their propagation (Richards et al., 2002).

SUPPORT PROTOCOL 2

PASSAGING AND MITOTIC INACTIVATION OF MEFs BY MITOMYCIN C

Before MEFs can be used as a feeder layer for ES cells, they must be mitotically inactivated to prevent overgrowth or contamination of ES cells. They can be mitotically inactivated by treatment with mitomycin C or γ-irradiation (see Support Protocol 3). Mitomycin C treatment is an efficient and effective way to inactivate MEFs. Following treatment, ~90% to 95% of cells are seen to be inactivated.

Materials

MEF cultures in 75-cm^2 culture flasks (see Support Protocol 1)
MEF medium (see recipe)
Mitomycin C (see recipe)
0.1% (w/v) gelatin (see recipe)
PBS, calcium- and magnesium-free (CMF-PBS; Invitrogen)
0.025% (w/v) trypsin/EDTA (see recipe)
Cell culture–grade water (JRH Biosciences), sterile

Organ culture dishes
15-ml centrifuge tubes

Additional reagents and equipment for counting cells (*UNIT 1.1*)

Inactivate MEFs

1. Incubate all MEFs from one 75-cm^2 culture flask at passage 4 or 5 with 20 ml of MEF medium containing 10 μg/ml mitomycin C for a minimum of 2.5 hr (maximum 3 hr) at 37°C.
2. During incubation, pretreat the central compartment of organ culture dishes with 1 ml of 0.1% gelatin for 30 min at room temperature. After 30 min, aspirate the gelatin and allow the plates to dry at room temperature.
3. Aspirate MEF medium containing mitomycin C from MEFs and wash cells one time with 20 ml of prewarmed MEF medium at 37°C.

Collect cells

4. Wash three times each time by adding and then removing 20 ml of CMF-PBS at room temperature.
5. Detach cells from the flasks by incubating with 1.5 ml of 0.025% trypsin/EDTA for 1 to 2 min at room temperature with agitation.
6. Inactivate the trypsin by adding 6 ml of pre-warmed MEF medium at 37°C. Pipet up and down the growing surface of the flask to ensure all cells are dislodged.
7. Transfer cells to a 15-ml centrifuge tube and centrifuge 2 min at ~700 × *g*, room temperature, to pellet cells.

Set up organ culture dishes

8. Resuspend the cells in 8 ml of MEF or human ES culture medium. Pipet a 10-µl aliquot and count total cell number using a hemacytometer (*UNIT 1.1*).
9. Plate MEFs onto the pretreated, gelatin-coated central portions of organ culture dishes (from step 2) at a concentration of 1.75–1.8 × 10^5 cells/ml per dish.
10. Pipet 5 ml of tissue culture–grade distilled water into the outer section of the organ culture dish to maintain humidity. Place dishes at 37°C.

ES cells may be added 24 hr after the MEFs are plated (i.e., after the MEFs have attached).

PASSAGING AND MITOTIC INACTIVATION OF MEFs BY γ-IRRADIATION

SUPPORT PROTOCOL 3

γ-Irradiation can be used to mitotically inactivate MEFs. This method is as effective as mitomycin C inactivation provided that an appropriate level of radiation is utilized. A disadvantage to this method is that it requires additional equipment to irradiate MEFs, whereas mitomycin C is a reagent that can be directly applied in almost any laboratory.

Materials

MEF cultures (for fresh MEF, see Support Protocol 1 or for frozen MEF, see Support Protocol 4)
0.025% (w/v) trypsin/EDTA (see recipe)
MEF medium (see recipe)
Human ES (hES) cell culture medium (see recipe)
75-cm^2 culture flasks
50-ml centrifuge tube
γ irradiator (Gammacell 1000, Nordion)
150- and 100-mm gelatin-coated tissue culture dishes (optional)
Organ culture dishes

1. Grow MEFs at passage 4 to 5 or a thawed frozen vial of primary MEFs (from an earlier preparation, see Support Protocol 4) to confluence in 75-cm^2 culture flasks or on 150-mm gelatin-coated tissue culture dishes.
2. Detach cells using 0.025% trypsin/EDTA as described in Support Protocol 2, steps 4 to 6, and collect in a 50-ml centrifuge tube.
3. Centrifuge cells 2 min at ~700 × *g*, room temperature, to pellet and resuspend pellet in 25 ml MEF medium.
4. Irradiate each tube of cells with 3000 to 10,000 rads of γ-irradiation.

This varies with the cell line used, therefore, a titration should be performed to determine the effective dose.

5. Plate irradiated cells onto gelatin-coated plates at 3–4 × 10^6 cells per 100-mm gelatin-coated dish, or 1.8 × 10^5 cells per organ culture dish, in MEF or hES culture medium.

FREEZING MEFS

SUPPORT PROTOCOL 4

Early passaged MEFs can be frozen to provide cells for use at a later point.

Materials

Freezing solution (see recipe)
MEF cultures in 75-cm^2 tissue culture flasks (see Support Protocol 1)

PBS, calcium- and magnesium-free (CMF-PBS; Invitrogen)
0.05% (w/v) trypsin/EDTA (Invitrogen)
MEF medium (see recipe)
Liquid nitrogen
1-ml cryovial

1. Prior to freezing cells, store the freshly prepared freezing solution on ice. Label 1.0-ml cryovials with passage number and cell line and chill on ice (use two vials per 75-cm^2 tissue culture flask).
2. Aspirate medium from 80% to 90% confluent MEFs cultured in 75-cm^2 tissue culture flasks and wash gently with 2 ml CMF-PBS to remove all traces of medium.

   Freeze aliquots of MEFs from passage 1 to 5 for subsequent thawing and inactivation.
3. Add 1.5 ml of 0.05% trypsin/EDTA to cells and incubate for 1 to 2 min at room temperature. Tap flask/dish to gently dislodge the cells.
4. Add 6 ml MEF medium to inactivate the trypsin. Pellet cells by centrifuging 2 min at ~700 × *g*, room temperature.
5. Aspirate supernatant from the cell pellet and resuspend cells in 2 ml freezing solution.
6. Transfer 1 ml freezing solution and cells to each 1.0-ml cryovial and place at −80°C. After 24 hr, transfer the cryovials to liquid nitrogen.

   MEFs can be stored indefinitely in liquid nitrogen. Upon thawing, cells may take 1 to 3 days to recover to 80% to 90% confluency for subsequent use.

BASIC PROTOCOL 2

MOUSE EMBRYOID BODY FORMATION (HANGING DROP CULTURE)

Mouse embryoid body (EB) formation is routinely utilized as an initial differentiation method as it initiates differentiation into a variety of cell types that can be subsequently purified and analyzed. This method is for use with mES cells propagated in the absence of a feeder layer. It is important that the mES cell medium used in EB formation lacks LIF. A typical mouse EB can be seen in Figure 23.2.1D.

Materials

mES cell culture in the absence of a feeder layer (see Alternate Protocol 1) in a 25-cm^2 tissue culture flask
PBS, calcium- and magnesium-free (CMF-PBS; Invitrogen)
0.025% (w/v) trypsin/EDTA (see recipe)
mES medium (see recipe) without LIF
Cell culture–grade distilled water (JRH Biosciences), sterile
15-ml centrifuge tubes
90-mm bacterial culture plate
Additional reagents and equipment for counting cells (*UNIT 1.1*)

Collect cells

1. Aspirate the medium from a 25-cm^2 tissue culture flask of undifferentiated mES cells.
2. Rinse the growing surface with 2 ml CMF-PBS at room temperature.
3. Apply 1 ml of 0.025% trypsin/EDTA and incubate 3 to 7 min at room temperature or until cells have detached.
4. Inactivate trypsin by adding 6 ml mES medium without LIF down the growing surface to collect all cells.

5. Transfer cells and medium to a 15-ml centrifuge tube and centrifuge 2 min at ~700 × *g*, room temperature.

6. Aspirate supernatant and resuspend pellet in 3 ml mES medium without LIF. Count cells using a hemacytometer (*UNIT 1.1*).

7. Dilute cells in mES medium without LIF to obtain a concentration of 1×10^4 cells/ml.

Set up cultures for EB formation

8a. *For hanging drop cultures:* Apply 30- to 50-µl droplets (300 to 500 cells/droplet) onto the lid of a 90-mm bacterial culture plate (ensuring sufficient space is left between the droplets to avoid fusion of neighboring drops on lid—between 30 to 35 individual drops per lid) and flip lid in a smooth, steady manner to invert. Place the lid onto the bacterial dish, which has been half filled with cell culture–grade distilled water to maintain humidity.

8b. *For solution culture:* Alternatively, produce EBs by transfering dissociated ES cells to a bacteriological culture dish at a concentration of 2×10^6 cells in 10 ml mES cell medium without LIF.

EB formation is slower with this method and smaller spheres are observed after 2 to 3 days in culture.

9. Incubate at 37°C for desired time.

After 1 to 2 days of incubation, spheres can be observed; these increase in size.

Cell types observed in EBs may vary between cell lines used and between methods used.

HUMAN EMBRYONIC STEM CELL PROPAGATION

BASIC PROTOCOL 3

Human ES cell handling techniques are a little more challenging than mouse ES cell handling techniques. The following protocols are modifications of those described in Reubinoff et al. (2000) and those found at *http://www.geron.com/PDF/scprotocols.pdf*. The morphology of a typical human ES cell colony grown on MEFs can be seen in Figure 23.2.1A. The mechanical human ES cell propagation procedure is illustrated in Figure 23.2.2.

Materials

Mitomycin C–treated MEFs in organ culture dish (see Support Protocol 2)
Human ES cell medium (see recipe)
Cultures of human ES cells
Finely drawn glass capillaries, 1.0-mm o.d. (Clark Electromagnetic Industries)

1. On the day prior to human ES cell transfer, equilibrate mitomycin C–treated MEFs by incubating in human ES cell medium at 37°C.

2. At ~7 days of culture, mechanically dissect the human ES cell colonies into ~0.1-cm^2 morphologically designated undifferentiated fragments using a glass capillary finely drawn over a blue flame of a Bunsen burner. Gently lift the fragment from the plate with the end of a 20-µl micropipettor tip.

Morphologically undifferentiated fragments, visualized through a dissection microscope, appear as a uniform and consistent white color with distinct edges, whereas differentiated regions are more heterogenous and irregular in appearance often with cystic (fluid-filled) regions. Differentiated regions have indistinct edges and often display processes extending away from the colony. Often colonies of hES cells will contain a densely packed region in the center, from which the colony has initially arisen. This region also contains differentiated cells and thus is not transferred to a new dish.

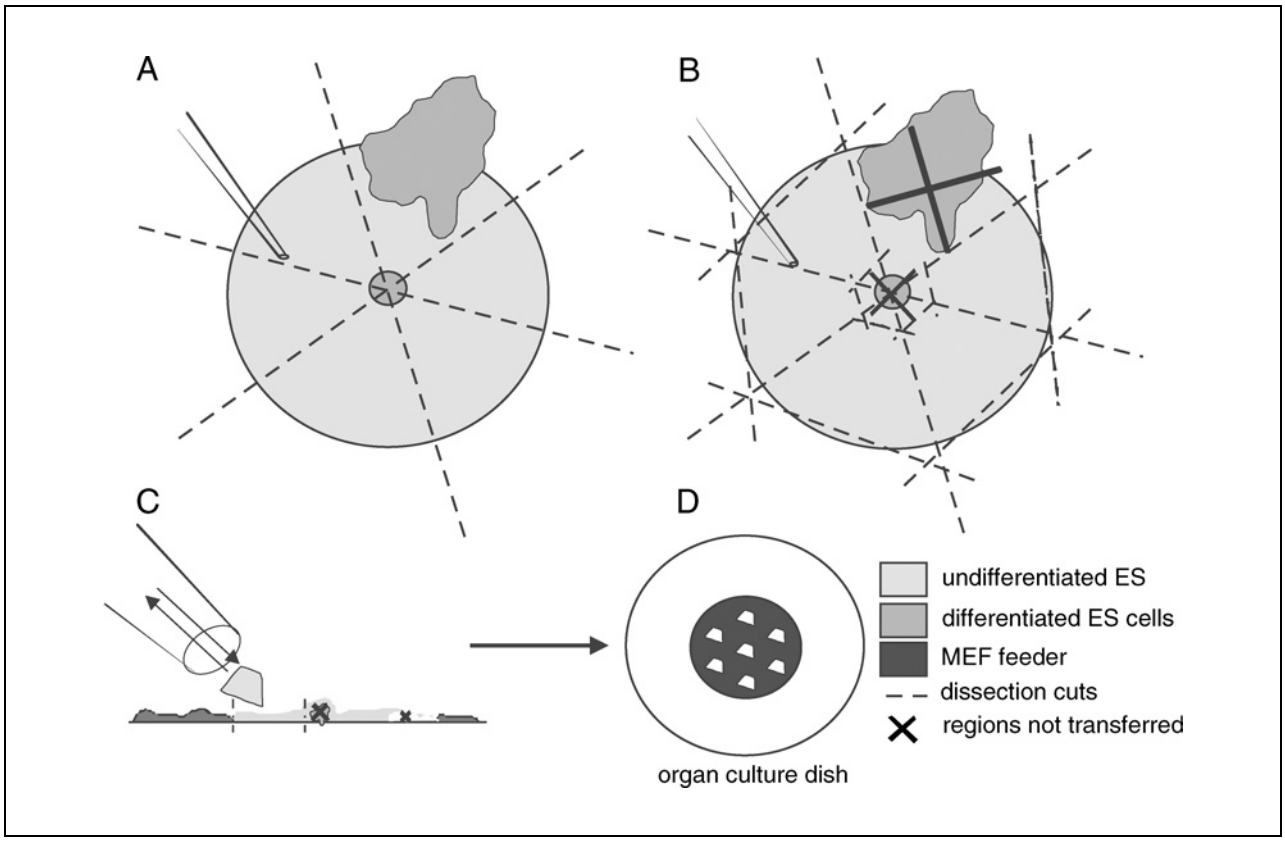

Figure 23.2.2 Schematic representation of the human ES cell mechanical dissociation culture procedure. (**A, B**, and **C**) Human ES cell colonies are dissected with a drawn glass micropipet according to the dotted lines. Isolated undifferentiated regions are gently lifted with a micropipettor to separate them from any differentiated cells. The undifferentiated regions are then transferred to wash plates. (**D**) Approximately six to nine regions of undifferentiated cells from the original colony are transferred to a new MEF layer for growth.

3. Transfer the undifferentiated fragments to a fresh organ culture dish containing 1 ml room temperature hES medium, then transfer to a second organ culture dish containing 1 ml medium for a second wash.
4. Transfer six to nine fragments to an equilibrated MEF-coated organ culture dish.
5. Change the medium daily (1 ml per dish) until the following transfer at ~7 days.

   Depending on the number of fragments seeded, one organ culture dish after 7 days should yield 25 to 35 colonies.

ALTERNATE PROTOCOL 2

PREPARATION OF CONDITIONED MEDIUM FEEDER-LAYER-FREE CULTURE OF HUMAN ES CELLS

Human ES (hES) cells can be cultured in the absence of a feeder layer using MEF cell conditioned medium supplemented with FGF-2 on an extracellular matrix (see Alternate Protocol 3). This method is efficient for larger cultures; however, prolonged culture in this manner (>23 passages) has been shown to produce chromosomal abnormalities (Mitalipova et al., 2005).

Materials

Mitotically inactivated MEFs (see Support Protocol 2 or 3)
MEF medium (see recipe)
Serum-free medium (see recipe)

0.1 mg/ml human recombinant basic fibroblast growth factor stock (hbFGF; Invitrogen): reconstitute 10 μg in 100 μl of 10 mM Tris·Cl, pH 7.6 (*APPENDIX 2A*), store at −20°C
hES cells
25-cm^2 tissue culture flasks
0.22-μm filter

1. Plate mitomycin C–treated or γ-irradiated MEFs at 5.6×10^4 cells/cm^2 in 5 ml MEF medium in 25-cm^2 tissue culture flasks. Incubate overnight at 37°C.
2. Replace the MEF medium the following day with 5 ml of serum-free medium. Incubate overnight at 37°C.
3. Collect medium from the flask, filter through a 0.22-μm filter, and add 8 ng/ml hbFGF. Transfer the new conditioned medium (CM) either to human ES cells (see Basic Protocol 3) or freeze for storage.

   CM can be stored for 1 month at −20°C.

4. Add 5 ml of fresh serum-free medium to the flask and incubate cells overnight at 37°C.
5. Repeat steps 3 and 4 for up to 7 days.

ENZYMATIC PASSAGE OF HUMAN ES CELLS FOR CULTURE ON FEEDER LAYERS AND ON MATRIGEL

ALTERNATE PROTOCOL 3

Human ES cells have also been propagated more recently using enzymatic methods as well as growth in the absence of feeders on the extracellular matrix substrate Matrigel. Some controversy remains with respect to the reliability of this culture method, however, especially in regard to human ES cell karyotype integrity following prolonged culture (see Mitalipova et al., 2005). Nevertheless, these protocols provide a more time-efficient method for regular maintenance of human ES cells in short-term cultures.

Materials

hES cell cultures in Matrigel-coated 4-well plates (see recipe for plates)
1 mg/ml collagenase IV (see recipe)
PBS, calcium- and magnesium-free (CMF-PBS; Invitrogen)
Serum-free medium (see recipe)
Conditioned medium (CM, see Alternate Protocol 2)
Matrigel-coated 4-well plates (see recipe)
15-ml centrifuge tubes

1. Replace the medium on human ES cells with 0.5 ml of 200 U/ml collagenase IV per well of a Matrigel-coated 4-well plate.
2. Incubate for 5 to 10 min at 37°C or until colonies just begin to detach from plate.
3. Gently remove collagenase IV and wash gently with 1 ml CMF-PBS.

4a. *For passage onto MEFs:* Replace CMF-PBS with 1 ml serum-free medium equilibrated at 37°C and proceed to Basic Protocol 3, step 4.

4b. *For passage onto Matrigel:* Remove CMF-PBS and add 1 ml CM to each well.

5. Gently pipet cells up and down, scraping with the pipet to dislodge cells, and transfer to a 15-ml centrifuge tube.

6. Dissociate cells with gentle pipetting to small clusters (50 to 400 cells), then transfer between 1/3 and 1/6 of the suspension to a Matrigel-coated well containing 1 ml of CM medium.

   Colonies should appear within days and should continue to expand.

7. Passage when human ES cells comprise 80% of the surface area of the well.

BASIC PROTOCOL 4

PRODUCING HUMAN ES CELL EMBRYOID BODIES BY MECHANICAL DISSOCIATION

Mechanical dissection is more laborious but more selective with the ability to select for morphologically undifferentiated regions whereby enzymatic dissociation obtains both differentiated and undifferentiated cells together. This results in a difference in cell potential and thus a difference in EBs produced.

Materials

Cultures of human ES cell colonies in organ culture dishes on MEF feeder layer, 6 to 9 colonies/dish
Human ES cell medium (see recipe)
Finely drawn glass capillary (1.0-mm o.d.)
90-mm bacteriological petri dish

1. Dissociate human ES cells colonies with a finely drawn glass capillary to obtain small undifferentiated regions of between 100 and 300 cells.
2. Transfer as many of these aggregates as required to 90-mm bacteriological petri dishes containing 10 ml human ES cell medium and culture as a suspension (see Conley et al., 2004b).
3. Incubate at 37°C.

   A typical 7-day-old EB formed from human ES cells can be seen in Figure 23.2.1B.

ALTERNATE PROTOCOL 4

PRODUCING HUMAN ES CELL EMBRYOID BODIES BY ENZYMATIC DIGESTION

Human EBs can also be produced following enzymatic digestion. EBs are produced this way from smaller digested fragments of ES cells and thus are generally smaller. Digestion additionally leads to more variability in ES cell fragment size as well as resultant EB size.

Materials

Human ES cell colonies
Serum-free medium (see recipe)
1 mg/ml collagenase/dispase stock (see recipe)
Certified fetal bovine serum (Invitrogen)
Human ES cell medium (see recipe)
Finely drawn glass capillary (1.0-mm o.d.)
15-ml centrifuge tube
90-mm bacteriological petri dish

1. Mechanically dissect each colony with a finely drawn glass capillary to obtain undifferentiated areas (see Basic Protocol 3).
2. Transfer fragments to a 15-ml centrifuge tube and centrifuge 2 min at ~700 × *g*, room temperature.

3. Aspirate as much medium as possible and resuspend pellet in 500 µl serum-free medium.
4. Add 500 µl of 1 mg/ml collagenase IV/dispase stock (final concentration 0.5 mg/ml for each enzyme) and mix gently with a pipet.
5. Incubate 3 min at 37°C and then agitate with a pipet ten times.
6. Add 5 ml certified fetal bovine serum and invert gently three to five times to mix.

   FBS should be batch tested for compatibility with ES cells.
7. Add 7 ml human ES cell medium, mix, and centrifuge 3 min at ~700 × *g*, room temperature.
8. Resuspend the pellet in 5 ml human ES cell medium and transfer to a 90-mm bacteriological petri dish containing 3 to 5 ml medium to allow aggregation as EBs in suspension.

   EBs can be seen to form after ~2 days.

VITRIFICATION/THAWING OF HUMAN ES CELLS

BASIC PROTOCOL 5

The vitrification protocol described is the one that can be found in Reubinoff et al. (2001). It is used to maintain frozen stocks of human ES cell lines.

Materials

Bench medium (BM; see recipe)
Vitrification solution 1 (VS1; see recipe)
Vitrification solution 2 (VS2; see recipe)
Liquid nitrogen
hES cell culture
Warming solution 1 (WS1; see recipe)
Warming solution 2 (WS2; see recipe)
Organ culture dish seeded with mitotically inactivated MEFs (see Support Protocol 2 or 3)
Human ES cell medium (see recipe)
4-well tissue culture plates (NUNC)
5-ml cryovials (NUNC)
18-G needle
Canes for liquid nitrogen tank
20-µl micropipettor
Vitrification straws (LEC Instruments)
Forceps

Prepare equipment for vitrification

1. Prior to freezing human ES cell fragments, prepare a vitrification plate. Pipet 1 ml of each of the solutions BM, VS1, and VS2, into separate wells of a 4-well tissue culture plate and pre-warm at 37°C.
2. Label a 5-ml cryovial with all details pertaining to cells being frozen. Using a flame-heated 18-G needle, punch holes in the upper section, base, and lid of the cryovial and attach the cryovial to a labeled cane. Submerge in a bucket of liquid nitrogen.

Prepare cells for freezing

3. Prepare human ES cell pieces for freezing by cutting fragments slightly larger than that required for usual transfer (0.1 cm^2). Transfer about eight fragments to the first well of the 4-well tissue culture plate containing BM using a 20-µl micropipettor.

4. With a fresh tip, transfer all fragments to the second well containing VS1 for 1 min, ensuring all pieces settle to the bottom of the viscous solution. During this minute, pipet a 20-µl drop of VS2 onto the inside of the 4-well tissue culture plate lid. Ensure a fresh drop is prepared for each straw to be frozen.
5. Transfer the human ES cell fragments to the last well containing VS2 for 25 sec and again ensure that all pieces settle to the bottom.
6. Transfer the fragments in the least possible volume to the 20-µl VS2 drop on the 4-well tissue culture plate lid.
7. Using a second pipet set at 3 µl, pick up the fragments and make a small, high droplet on the lid.

Collect cells in vitrification straws and freeze

8. Immediately after making the droplet, touch the narrow end of a vitrification straw to the side of the droplet at an angle of 30° to 45° to the plane of the lid and draw up the droplet and fragments into the straw by capillary action.
9. Plunge the straw into the bucket of liquid nitrogen at an angle of 45°. Without removing the straw from the liquid nitrogen, carefully transfer into the prepared cryovial. Repeat until all fragments have been collected (three to five straws per cryovial). Store the cryovial in liquid nitrogen.

Thaw and process ES cells

10. Prior to thawing the cryovial containing the human ES cell straws, prepare a 4-well tissue culture plate containing 1 ml of each of solutions WS2, WS1, and 2 wells of BM in separate wells and prewarm at 37°C.
11. Collect the cryovial containing the straws to be thawed in a bucket of liquid nitrogen. Remove a straw using forceps and hold it between the thumb and middle finger with the index finger blocking the larger end of the straw which is devoid of cells.
12. Immediately submerge the narrow end of the straw containing the fragments into the first well containing WS2 where, as the gas expands, the human ES cell fragments will expel from the straw and into the well.
13. After 1 min transfer the fragments to the next well containing WS1 for 5 min.
14. Transfer the fragments into the third well containing BM for an additional 5 min.
15. Transfer fragments to the last well containing BM for an additional 5 min.
16. Transfer the fragments onto a previously prepared organ culture dish containing mitotically inactivated MEFs (see Support Protocol 2 or 3) and 1 ml of human ES cell medium, and culture at 37°C.

REAGENTS AND SOLUTIONS

Use deionized or distilled tissue culture grade water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Bench medium (BM)

Add 800 µl DMEM/F12 (Invitrogen)
200 µl FBS (20% v/v; JRH Biosciences)
Store up to 2 weeks at 4°C

FBS purchased from JRH Biosciences has been traditionally used in the authors' laboratory for mouse ES cell and MEF cultures, while it has been observed that certain batches of FBS purchased from Invitrogen maintained human ES cells more effectively. It has been

hypothesized that may be due to a low endotoxin level in some of the batches from Invitrogen (however, this has not been proven definitively). Therefore, batch testing of all serum is imperative.

Collagenase IV, 1 mg/ml

Dilute 100 mg collagenase type IV (Invitrogen) in 100 ml knockout DMEM (Invitrogen). Dispense into aliquots and store up to 6 months at −20°C.

Collagenase IV/dispase stock, 1 mg/ml

Add 100 mg collagenase type IV (Invitrogen) and 100 mg dispase (Invitrogen) to 100 ml of filter-sterilized serum-free medium (see recipe). Store in aliquots at −20°C.

Gelatin, 0.1% (w/v)

Dilute 5 ml of 1% (w/v) gelatin stock (see recipe) in 50 ml distilled water. Store up to 4 weeks at 4°C.

Gelatin, 1% (w/v)

Dissolve 0.4 g of gelatin powder (Sigma) in 40 ml distilled water, autoclave, store in 30- to 50-ml aliquots up to 2 months at −20°C.

Freezing solution

Prepare a mixture of 90% (v/v) FBS and 10% (v/v) DMSO. Prepare fresh and store on ice.

FBS purchased from JRH Biosciences has been traditionally used in the authors' laboratory for mouse ES cell and MEF cultures, while it has been observed that certain batches of FBS purchased from Invitrogen maintained human ES cells more effectively. It has been hypothesized that may be due to a low endotoxin level in some of the batches from Invitrogen (however, this has not been proven definitively). Therefore, batch testing of all serum is imperative.

hbFGF stock, 0.1 mg/ml

Reconstitute 10 μg human basic FGF (Invitrogen) in 100 μl of 10 mM Tris·Cl, pH 7.6. Store up to 6 months in 20- to 50-μl aliquots at −20°C.

Human ES cell medium

High-glucose DMEM (Invitrogen) supplemented with:
20% (v/v) certified fetal bovine serum (FBS; Invitrogen)
1% (v/v) nonessential amino acids (Invitrogen)
2 mM L-glutamine (Invitrogen)
50 U/ml penicillin/50 mg/ml streptomycin (Invitrogen)
1× insulin-transferrin-selenium supplement (Invitrogen)
0.1 mM β-mercaptoethanol (Sigma)
Store up to 2 weeks at 4°C

FBS purchased from JRH Biosciences has been traditionally used in the authors' laboratory for mouse ES cell and MEF cultures, while it has been observed that certain batches of FBS purchased from Invitrogen maintained human ES cells more effectively. It has been hypothesized that may be due to a low endotoxin level in some of the batches from Invitrogen (however, this has not been proven definitively). Therefore, batch testing of all serum is imperative.

Matrigel-coated plates

Thaw an aliquot of Matrigel stock (see recipe) at 4°C. Dilute stock 1:10 in cold knockout DMEM (Invitrogen). Apply 500 μl of diluted Matrigel to each well of a 4-well tissue culture plate. Incubate 1 hr at 37°C and aspirate liquid immediately prior to use.

Matrigel stock

Thaw 10-ml bottle of Matrigel (Becton Dickinson) overnight at 4°C, add 10 ml cold knockout DMEM (Invitrogen), and mix well. Store in 10-ml aliquots up to 6 months at −20°C.

mES cell medium

High-glucose DMEM (Invitrogen) supplemented with:
10% (v/v) fetal bovine serum (FBS; JRH Biosciences)
2 mM L-glutamine (Invitrogen)
50 U/ml penicillin/50 mg/ml streptomycin (Invitrogen)
1% (v/v) nonessential amino acids (Invitrogen)
0.1 mM β-mercaptoethanol (Sigma)
1000 U/ml recombinant mouse leukemia inhibitory factor (LIF; Chemicon)
Store up to 2 weeks at 4°C

FBS purchased from JRH Biosciences has been traditionally used in the authors' laboratory for mouse ES cell and MEF cultures, while it has been observed that certain batches of FBS purchased from Invitrogen maintained human ES cells more effectively. It has been hypothesized that may be due to a low endotoxin level in some of the batches from Invitrogen (however, this has not been proven definitively). Therefore, batch testing of all serum is imperative.

MEF medium

High-glucose DMEM; (Invitrogen) supplemented with:
10% (v/v) fetal bovine serum (FBS; JRH Biosciences)
2 mM L-glutamine (Invitrogen)
50 U/ml penicillin/50 mg/ml streptomycin (Invitrogen)
Store up to 2 weeks at 4°C

FBS purchased from JRH Biosciences has been traditionally used in the authors' laboratory for mouse ES cell and MEF cultures, while it has been observed that certain batches of FBS purchased from Invitrogen maintained human ES cells more effectively. It has been hypothesized that may be due to a low endotoxin level in some of the batches from Invitrogen (however, this has not been proven definitively). Therefore, batch testing of all serum is imperative.

Mitomycin C

Reconstitute a 2-mg ampule of mitomycin C powder (Sigma) with 1 ml sterile PBS using a 21-G needle, with a 26-G needle in place to vent the ampule. Remove solution and filter through a 0.22-μm syringe filter. Store solution up to 2 weeks at 4°C protected from light.

CAUTION: *Mitomycin C is a toxic substance, refer to the product data sheet from the manufacturer for handling instructions.*

Serum-free medium (SFM)

High-glucose DMEM (Invitrogen) supplemented with:
1% (w/v) nonessential amino acids (Invitrogen)
2 mM L-glutamine (Invitrogen)
50 U/ml penicillin/50 mg/ml streptomycin (Invitrogen)
1× insulin-transferrin-selenium supplement (Invitrogen)
mM β-mercaptoethanol (Sigma)
Store up to 2 weeks at 4°C

Serum replacement medium

80% (v/v) knockout DMEM (Invitrogen)
20% (v/v) knockout serum replacement (Invitrogen)
1% (v/v) nonessential amino acids (Invitrogen)
2 mM L-glutamine (Invitrogen)
50 U/ml penicillin/50 mg/ml streptomycin (Invitrogen)
1× insulin-transferrin-selenium supplement (Invitrogen)
0.1 mM β-mercaptoethanol (Sigma)
Store up to 2 weeks at 4°C

Sucrose solution, 2 M

Dissolve 6.846 g sucrose (Sigma) in ~5 ml DMEM/F12 (Invitrogen). Add DMEM/F12 to a final volume of 10 ml. Prepare fresh.

Trypsin/EDTA, 0.025% (w/v)

Dilute 20 ml of 0.05% (w/v) trypsin/EDTA (Invitrogen) in 20 ml calcium- and magnesium-free PBS (CMF-PBS; e.g., Invitrogen) for a final concentration of 0.025%. Store in aliquots up to 2 weeks at 4°C or up to 6 months at −20°C.

Vitrification solution 1 (VS1)

600 µl DMEM/F12 (Invitrogen)
200 µl FBS (Invitrogen; 20% v/v final)
100 µl DMSO (10% v/v final)
100 µl ethylene glycol (Sigma; 10% v/v final)
Prepare fresh

FBS purchased from JRH Biosciences has been traditionally used in the authors' laboratory for mouse ES cell and MEF cultures, while it has been observed that certain batches of FBS purchased from Invitrogen maintained human ES cells more effectively. It has been hypothesized that may be due to a low endotoxin level in some of the batches from Invitrogen (however, this has not been proven definitively). Therefore, batch testing of all serum is imperative.

Vitrification solution 2 (VS2)

250 µl sucrose solution (0.5 M final; see recipe for 2 M sucrose)
150 µl DMEM/F12 (Invitrogen)
200 µl FBS (Invitrogen; 20% v/v final)
200 µl DMSO (20% v/v final)
200 µl ethylene glycol (20% v/v final)
Prepare fresh

FBS purchased from JRH Biosciences has been traditionally used in the authors' laboratory for mouse ES cell and MEF cultures, while it has been observed that certain batches of FBS purchased from Invitrogen maintained human ES cells more effectively. It has been hypothesized that may be due to a low endotoxin level in some of the batches from Invitrogen (however, this has not been proven definitively). Therefore, batch testing of all serum is imperative.

Warming solution 1 (WS1)

100 µl sucrose solution (0.2 M final; see recipe for 2 M sucrose)
700 µl DMEM/F12 (Invitrogen)
200 µl FBS (Invitrogen; 20% v/v final)
Prepare fresh

FBS purchased from JRH Biosciences has been traditionally used in the authors' laboratory for mouse ES cell and MEF cultures, while it has been observed that certain batches of FBS purchased from Invitrogen maintained human ES cells more effectively. It has been hypothesized that may be due to a low endotoxin level in some of the batches from Invitrogen (however, this has not been proven definitively). Therefore, batch testing of all serum is imperative.

Warming solution 2 (WS2)

50 µl sucrose solution (0.1 M final; see recipe for 2 M sucrose)
750 µl DMEM/F12 (Invitrogen)
200 µl FBS (Invitrogen; 20% v/v final)
Prepare fresh

FBS purchased from JRH Biosciences has been traditionally used in the authors' laboratory for mouse ES cell and MEF cultures, while it has been observed that certain batches of FBS purchased from Invitrogen maintained human ES cells more effectively. It has been hypothesized that may be due to a low endotoxin level in some of the batches from Invitrogen (however, this has not been proven definitively). Therefore, batch testing of all serum is imperative.

COMMENTARY

Background Information

Mouse embryonic stem (ES) cells are an in vitro–derived cell type isolated from the epiblast/inner cell mass (ICM) of mouse blastocysts (Evans and Kaufman, 1981; Martin, 1981). mES cells are said to possess properties consistent with an immortal phenotype: demonstrating continual self-renewal and maintaining a normal chromosomal content over extended periods in culture. mES cells further retain several properties of their in vivo predecessors, including a primitive pluripotent phenotype enabling differentiation into all functional cell types of the adult and some extraembryonic tissues given the appropriate stimuli (see Nagy et al., 1990, 1993).

The isolation of ES cells, or ES-like cells, has more recently been reported from other species including human and nonhuman primates (see Thomson et al., 1995, 1998). Functional studies, however, remain more advanced for mouse ES cell systems because of the relatively long time since their first description some 24 years ago and, when compared to human ES cell work, the relatively relaxed ethical regulations associated with their research (for a review, see Fischbach and Fischbach, 2004). For example, mouse ES cell protocols for culture and genetic manipulation at the single cell level, tetraploid complementation and blastocyst injection, and the transfer of mouse ES cell derivative structures to pseudopregnant females for full-term pregnancy are routine (but technically challenging) procedures in many laboratories (see Thomas and Capecchi, 1987; Zimmer and Gruss 1989; Nagy et al., 1993). Advances in these disciplines have led to a relatively sophisticated understanding of mouse ES cell definition, developmental molecular genetics and, in association, several techniques for controlling mouse ES cell fate reliably into predicted and functionally relevant phenotypes in vitro and in vivo (see Klug et al., 1996; Li et al., 1998; McDonald et al., 1999; Kim et al., 2002; Rideout et al., 2002; Wichterle et al., 2002). Failing such technological advances and due to the limitations that result from currently applied ethical regulations, the true pluripotential identity of human ES cell lines derived to date remains obscure and many researchers still refer to human ES cells as human ES-like cells (see Buehr and Smith, 2003).

The ability to manipulate mouse ES cell fate in vitro and in vivo, however, has driven the belief that ES-like cells derived from human blastocysts (human ES cells) may one day be similarly manipulated and thus used to produce sufficient tissue for replacement therapeutics aimed at treating a variety of human diseases and injuries. Technological advances supporting this notion include the development of strategies describing human ES cell differentiation into several desired lineages (for a review, see Pera and Trounson, 2004), clonal (albeit inefficient) derivation (Amit et al., 2000), cryopreservation (Reubinoff et al., 2001), knock-ins and knockouts using homologous recombination (Zwaka and Thomson, 2003), and biological interference using RNAi (Vallier et al., 2004a). With respect to reports describing differentiation into desired lineages, evidence has been restricted mostly to morphological and biochemical characterization of cells found, for example, within teratomas created form human embryonic stem cells following injection under the kidney capsule of NOD-SCID mice, or following the application of differentiation protocols designed to favor differentiation of particular cell types from an in vitro cultured cell colony (see Thomson et al., 1998; Reubinoff et al., 2000; Kaufman et al., 2001; Levenberg et al., 2002; Mummery et al., 2003; Rambhatla et al., 2003; Conley et al., 2004a). In the absence of relevant functional studies and in

agreement with arguments outlined above, absolute identification as the desired cell type is difficult to argue. Only recently has a study of human ES cell derived functionality appeared in the literature. According to this study, transplantation of cardiac-like cells derived from human ES cells to the heart of a pig model of atrioventriclular block reinstated heart rhythm in a manner compatible with survival in ~50% of the subject animals (Kehat et al., 2004).

In addition to the promise of providing tissue for therapeutic replacement strategies, ES cell culture facilitates a means to study several early developmental processes (see Doetschman et al., 1985). Reports in the literature suggest that human ES cells possess a capacity to produce representatives of both the trophoblast and the visceral endoderm in vitro when cultured in the presence of growth factors or as structures known as embryoid bodies (EBs; Xu et al., 2002; Conley et al., 2004b; Gerami-Naini et al., 2004; Vallier et al., 2004b). EB formation has additionally provided an integral first step in many in vitro differentiation protocols (see Zhang et al., 2001; Levenberg et al., 2002). It is believed that research on the differentiation of human ES cells into trophectoderm and visceral endoderm derivatives may provide important information regarding nutrient and gas exchange and patterning of the early human embryo.

Critical Parameters

All tissue culture is to be performed in Class 2 biohazard hoods and/or laminar flow hoods using sterile technique. All reagents and media must be sterilized either by autoclaving or filtering through a 0.22-μm filter. (Do not autoclave solutions containing proteins, such as media, FBS, amino acids.) Bottles used to store media should be washed thoroughly to avoid contamination by soaps or detergents, then placed for 4 hr in a 140°C sterilization oven prior to use.

Dissection of human ES cell colonies is to be performed using a dissecting microscope in a laminar flow hood. A microscope with a dark field function is useful in determining undifferentiated regions.

For human ES cell culture, the batch of FBS utilized is essential for maintenance of the undifferentiated state. FBS containing a low endotoxin level (<1.5 EU/ml) is proposed to be efficient for human ES cell culture. Batch testing is essential prior to culture with human ES cells. FBS should be aliquoted and stored at −20°C and thawed only once to make medium as repeated freeze/thaw cycles severely compromises its cell culture efficiency. Media should be discarded after 2 weeks as this can influence the differentiation of ES cells.

MEFs are an important and essential part of the human ES cell culture protocol; it is essential that the MEFs are not used beyond six passages, that they grow well, and that they look healthy. The strain of mouse used for MEF derivation can also influence the efficiency of human ES cell culture. It is advisable to utilize an inbred strain of mouse (e.g., 129sv) and to test each new batch of MEFs for their ability to support human ES cell culture. When testing MEFs, it is important to propagate human ES cells on the new MEFs for a minimum of three passages to determine their efficiency. Following the first week of culture on new MEFs, ES cell colonies may contain a proportion of differentiated cells; however, ES cells may subsequently equilibrate on the new MEFs following repeated transfer and propagate normally thereafter.

Human ES cell mechanical transfer must be delicately performed in the shortest possible time due to reduced cell viability and increased differentiation rates with increased dissection times. Additionally, for enzymatic digestion of human ES cells, it is important to stop the reaction prior to dissociation to single cells as cell viability is severely compromised otherwise.

For mouse ES cell derivation, efficiency can be dependent on the strain of mouse used.

Once derived, mouse and human ES cells are theoretically immortal and can be passaged extensively without loss of differentiation potential, although some karyotypic abnormalities may arise over time. It is therefore advisable to regularly karyotype ES cells and test them for appropriate pluripotent markers such as oct-4, nonog, stage specific embryonic antigen (SSEA) -3 and -4, Tra-1-60, Tra-1-81 and GCTM-2 for hES cells, and oct-4, nanog and SSEA-1 for mES cells. Freezing stocks of cells at regular passage numbers (e.g., passages 3, 5, 10, 15, 30, 50) is essential to prevent loss of the cell line. If proper culture conditions are maintained, the cells should not accumulate karyotypic changes; cells cultured over 150 passages in the authors' laboratory still maintain normal karyotype.

Troubleshooting

If human ES cells begin to spontaneously differentiate in culture, it is advisable to immediately transfer them regardless of the day following the last transfer. New medium should

be prepared and sterilized by filtration through a 0.22-μm filter. A new aliquot of MEFs should then be thawed and prepared for transfer of human ES cells.

Anticipated Results

MEF derivation is highly efficient and should be successful every time. Each batch of MEFs, however, may differ in their ability to support human ES cell culture and therefore must be tested for a minimum of three passages of human ES cells. Mouse ES cells are generally more tolerant of MEFs, especially when medium containing LIF is used.

Mouse ES cell derivation has an efficiency of 10% to 15% depending on the mouse strain used. Although inbred strains other than 129sv have been used, success rates for mouse ES cell derivation were significantly reduced. Mouse ES cell cultures tend to contain 5% to 10% differentiated cells, this increases upon confluency, thus passaging prior to confluence is important. When mouse ES cells are transferred to hanging drop cultures, ~90% to 95% of drops are seen to form EBs. At the meniscus of the drop, cells will aggregate and by 1 to 2 days will be seen to form spheres that continue to grow in the droplet until the desired time point. When mouse ES cells are transferred to suspension, EB formation is somewhat slower, with cells forming smaller spheres both with their progeny (clonal) and by aggregating with other cells. By 2 to 3 days, spheres should be present, and these spheres should continue to expand.

Human ES cell culture is efficient, provided that competent MEFs and sterile medium are used and care is taken when transferring them. Upon transfer of clumps of human ES cells, they attach forming colonies that expand in a regular manner. When freezing/thawing human ES cells, expect ~10% to 30% cell death. With human EB formation, ~70% to 80% of ES cell aggregates placed in suspension will form EBs, with some clumps attaching to the dish. Clumps should become spherical balls after 2 to 3 days in culture and continue to grow until ~8 to 12 days when fluid-filled cysts become obvious and EBs may begin to form attachments with the dish.

Time Considerations

MEFs

Dissection of fetuses will depend on the number of fetuses and competence of the operator. Approximately 1 to 1.5 hr should be spent dissecting and dissolving tissue into single cells. Subsequent to derivation, passaging of MEFs requires 20 to 40 min depending on number of flasks. Mitomycin C inactivation of MEFs requires ~3.5 hr (including a 2.5-hr incubation). Freezing of MEFs or mouse ES cells requires ~20 to 30 min. Thawing cells takes 20 to 30 min.

Media

Approximately 1 to 1.5 hr should be allowed for media preparation 2 weeks prior to culture.

Mouse ES cells

Mouse ES cell derivation is laborious and great care is required to ensure their subsequent growth, due primarily to the low efficiency of derivation. Maintenance of mouse ES cells is relatively time efficient when using LIF alone, with simple tissue culture passaging required; however, time requirements significantly increase when growing the cells on MEFs because of the time-consuming process of cell preparation and mitotic inactivation.

Mouse EB formation

The setup for EB formation requires 20 to 30 min depending on the number of drops needed for hanging drops; it takes 10 to 15 min to set up a suspension culture.

Human ES cells

Following MEF preparation, human ES cell mechanical dissection should take ~10 min or less per organ culture dish. Medium must be changed daily until the following transfer. With prewarmed medium, this can take 5 to 15 min depending on the number of plates. Medium must be made and MEFs prepared fresh each week for transfers or used to collect conditioned medium, this is quite a laborious undertaking and can take up to a full day.

Human EB formation

Human EB formation takes approximately the same time as required for transfers, with clumps cut smaller than those for transfers and then placed in suspension.

Maintenance and In Vitro Differentiation of Mouse Embryonic Stem Cells to Form Blood Vessels

Embryonic stem (ES) cells are pluripotent cells that have been derived from the inner cell mass of blastocyst-stage embryos. Early studies of the ES differentiation model demonstrated that vasculogenesis and hematopoiesis were among the earliest developmental processes to occur (Doetschman et al., 1988; Schmitt et al., 1991; Wiles and Keller, 1991; Wang et al., 1992). Furthermore, the endothelial cells that differentiate during this model coalesce to form primitive blood vessels that are analogous to the first vessels that form in the developing embryo and yolk sac (Wang et al., 1992). Vascular development during mouse ES cell differentiation in vitro occurs by two processes; vasculogenesis and angiogenesis, similar to embryonic vascular development in vivo (Poole and Coffin, 1989; Risau, 1997). In vasculogenesis, mesodermally derived precursor cells, known as angioblasts, differentiate and coalesce to form a primitive blood vessel. In angiogenesis, endothelial cells from preexisting vessels coordinate cell proliferation and sprouting migration as a basis for expansion of vessels. Primitive erythrocytes and embryonic macrophages mature alongside vascular endothelial cells during ES cell differentiation (Wiles and Keller, 1991; Inamdar et al., 1997; Kearney and Bautch, 2003). Thus this model is ideal for studying molecular and cellular aspects of early vascular and hematopoietic development. This unit describes protocols for maintaining and differentiating mouse embryonic stem cells and methods of analyzing the vasculature via immunohistochemistry and β-galactosidase staining.

A protocol for the formation of embryoid bodies (EBs) and subsequent in vitro differentiation of mouse ES cells is described (see Basic Protocol). In combination with the in vitro differentiation protocol, an explanation of how to test different lots of fetal bovine serum (FBS) for maintaining differentiated cultures has been described (see Support Protocol 8). Methods for analysis of differentiation are included: testing for optimum ES cell differentiation via benzidine staining (see Support Protocol 1) and PECAM/Mac-1 double immunostaining (see Support Protocol 2), antibody immunolocalization (see Support Protocol 3), and *lacZ* staining of in vitro differentiated ES cells (see Support Protocol 4). Other protocols in this unit are designed to provide a method for maintaining mouse ES cells (see Support Protocol 5). A protocol for harvesting 5637 cell–conditioned medium, which contains the LIF that prevents differentiation, is explained (see Support Protocol 6). In addition, a protocol used for testing FBS lots from different manufacturers for ES Medium for maintenance is described (see Support Protocol 7).

NOTE: The protocols in this unit should be conducted under aseptic conditions using sterile reagents and equipment. Experiments should be performed in a Class II Biological Flow Hood.

NOTE: All incubations should be performed in a humidified 37°C, 5% CO_2 incubator, unless otherwise indicated.

PROGRAMMED IN VITRO DIFFERENTIATION OF MOUSE EMBRYONIC STEM CELLS

BASIC PROTOCOL

Mouse embryonic stem cells have the distinctive ability to differentiate into numerous cell types. In vitro ES cell differentiation complements their ability to contribute many tissue types in vivo, thus providing a unique model system for aspects of early mammalian

Contributed by Nicholas C. Kappas and Victoria L. Bautch
Current Protocols in Cell Biology (2007) 23.3.1-23.3.20

development. The conditions that are used initiate a programmed differentiation that leads to the formation of many of the cell types typically found in the mouse embryo and yolk sac. The following utilizes an unmanipulated differentiation protocol that involves the removal of differentiation inhibitory factors, thus allowing the ES cells to undergo a programmed differentiation to form cells that will in turn provide developmental signals to each other. In this case, cultures are examined for vasculogenesis and angiogenesis.

Materials

5- to 6-day-old ES cell culture (Support Protocol 5)
1× CMF-PBS (Sigma)
2.4 U/ml dispase, grade II stock (Boehringer-Mannheim; see recipe)
Differentiation medium (see recipe)

50-ml centrifuge tubes (Sarstedt), sterile
10-cm bacteriological petri dishes (do not use TC-treated plates)
24-well tissue culture plates (Costar)
Medidroppers (Fisher Scientific), autoclaved

NOTE: All volumes are given assuming that one 6-cm dish of ES cell colonies is being used. Double all volumes if using 10-cm dishes.

Collect ES cells

1. Choose the dish that has the best ES cell clumps for differentiation.

   ES cell clumps should be round and differentiated on the very edge and tight, shiny, and undifferentiated in the middle (Figure 23.3.1). ES cell clumps are collected from dishes after incubation for 5 to 6 days at 37°C without feeding after normal passage.

2. Aspirate medium from the ES cell dish. Wash two times, each time with 5 ml of cold 1× CMF-PBS. Aspirate PBS.

3. Add 1 ml of cold 1.2 U/ml dispase (diluted 1:1 with cold CMF-PBS just before use), and let dish sit at room temperature for 1 to 2 min. Check to see if ES cell clumps have detached from dish bottom by shaking dish.

   If the majority of cells clumps have not detached, let the solution sit longer. Dispase produces small clumps of cells that are used to start the differentiation.

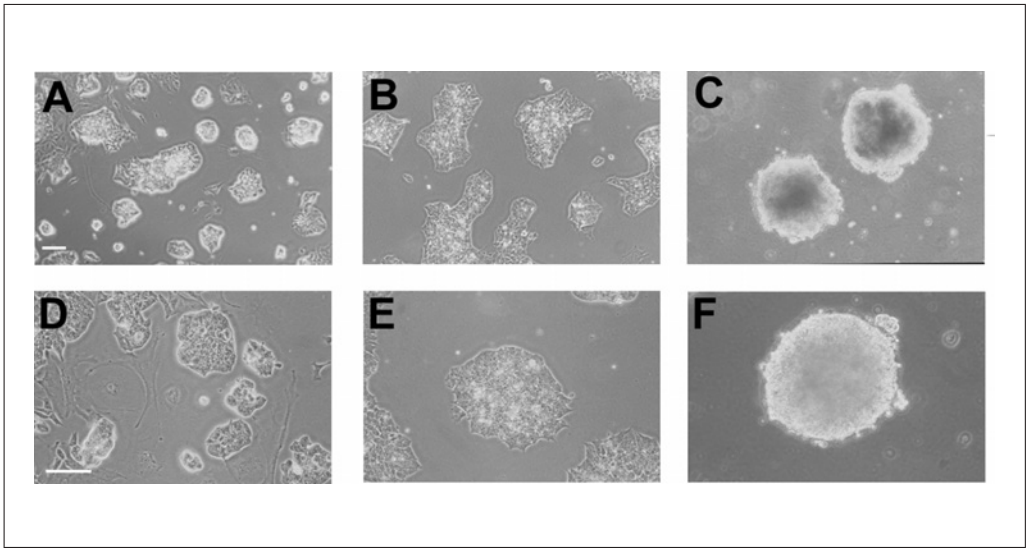

Figure 23.3.1 ES cells are typically processed for passage after 3 days of growth, when they are observed in tight, shiny clumps (**A, D**). ES cells undergo enzymatic disruption treatment for in vitro differentiation on day 5, when the ES clumps are large, but appear differentiated on the edges (**B, E**). Day 3 EBs (**C, F**) prior to plating (Bar = 100 μm).

4. When a majority of the cell clumps have detached from the dish, use a 5-ml pipet to gently transfer the cells into a 50-ml tube containing 35 ml of room temperature 1× CMF-PBS. Rinse the dish with 5 ml of 1× CMF-PBS and add the rinse to the 50-ml tube. Cap tube, and invert the tube once gently to mix.

5. Let the tube sit until the cell clumps have settled to the bottom of the tube.

Wash and plate the clumps

6. Aspirate all but 4 to 5 ml of CMF-PBS, carefully avoiding the ES cell clumps.

7. Add another 35 ml room temperature 1× CMF-PBS gently down the side of the 50-ml tube. Gently swirl the tube to redistribute the cell clumps. Cap tube, and invert gently to mix.

8. Let the tube sit until the cell clumps have settled to the bottom of the tube.

9. Aspirate the CMF-PBS (leaving 2 to 3 ml CMF-PBS/ES cell clump suspension at the bottom), and gently add 5 ml prewarmed (37°C) differentiation medium down the side of the tube.

10. Pipet 10 ml of prewarmed differentiation medium into a labeled 10-cm bacteriological petri dish. Using a 25-ml pipet, transfer the contents of the 50-ml tube (cell clumps/CMF-PBS/medium) to the 10-cm dish.

11. Check the density of cell clumps in each dish (~100 clumps). Incubate at 37°C in a humidified incubator with 5% CO_2.

    The authors attempt to achieve ~100 clumps/dish. Fewer clumps is not an efficient use of medium, while more clumps may allow for individual clumps to aggregate together.

Allow formation of embryoid bodies

12. Change the medium at least every other day after the dispase treatment (day 0). To feed the EBs, remove dish from incubator, place under hood, and gently swirl the dish in a circular manner so that the EBs migrate to the center of the dish.

13. Aspirate spent medium from the dish.

    This is easily done by aspirating along the inside edge of the dish (away from the EBs).

14. Add 10 ml of fresh prewarmed differentiation medium to the dish. Return dish to incubator.

Differentiate embryoid bodies

15. Set up reattachment cultures on day 3 after the dispase treatment (Fig. 23.3.1). Add 1.5 ml of prewarmed differentiation medium to each well of a 24-well tissue culture plate that is to be seeded with EBs.

16. Use a sterile medidropper to transfer EBs from the dish to the wells of a 24-well plate. Generally, dispense between 10 and 20 EBs per well.

    Holding the dish up and looking at it from underneath is helpful when determining the number of EBs in a well.

17. Ensure that the EBs are spread evenly in the well by gently shaking/moving the plate, or if necessary, use a pipettor with a sterile tip to gently pipet medium up and down in the well.

18. Place the plate in the incubator. Keep plate level when placed in incubator to ensure that the EBs do not settle to one side of the well. Incubate at 37°C in a humidified incubator with 5% CO_2.

    Attachment generally occurs within a few hours.

19. Feed the attached cultures every other day. To feed, aspirate medium, then slowly add 1.5 to 2 ml fresh prewarmed differentiation medium down the side wall of the well so as not to disturb the attached cultures.

20. Monitor the cultures for hematopoietic and vascular development (see Support Protocols 1 to 4).

    Using this protocol, the authors typically monitor vascular development in cultures that have been differentiated for 8 days (day of dispase treatment is day 0). Angioblast formation is generally observed at day 4 to 6, while vessel formation occurs at day 6 to 8.

    All volumes given are for staining cultures from a well of a 24-well plate. Gently add/remove all solutions from culture dishes, as harsh removal and addition of solutions may result in detachment of cultures.

SUPPORT PROTOCOL 1

BENZIDINE STAINING

Benzidine staining is performed on day-8 differentiated cultures to visualize the hemoglobin of red blood cells.

Materials

8-day differentiated ES cell cultures (Basic Protocol)
Benzidine solution (see recipe), 4°C
Differentiation medium (see recipe)
1× CMF-PBS (Sigma)

1. Remove 8-day differentiated cultures from incubator and add 0.2 ml of cold (4°C) benzidine solution per 2 ml (per well) of differentiation medium. Incubate at room temperature.

   Benzidine solution is added directly to the cultured cells while still in differentiation medium (i.e., do not rinse cells in CMF-PBS at this time).

   The benzidine reaction will occur immediately: upon addition of benzidine solution, the medium will turn a bluish/brown color, while positive cells will turn blue.

2. Observe/photograph cells within 1 hr, as the stain is not very stable.

   It is recommended that wells be rinsed once with 1× CMF-PBS before taking photographs of stained wells.

SUPPORT PROTOCOL 2

DOUBLE STAINING WITH PECAM AND Mac-1

PECAM/Mac-1 double staining is performed on day 10 differentiated cultures to visualize both blood vessels (PECAM) and embryonic macrophages (Mac-1).

Materials

Day-10 differentiated cultures (from Basic Protocol)
1× CMF-PBS (Sigma)
4% (w/v) paraformaldehyde fixative (see recipe)
1:500 trypsin solution (see recipe)
100% heat-inactivated fetal bovine serum
Staining medium (see recipe)
Primary and secondary antibodies (see recipe);
  Rat anti-mouse CD31 (PECAM-1; Mec 13.3; BD Pharmingen)
  FITC-AffinPure F(ab′)$_2$ fragment of donkey anti-rat IgG (Jackson Immunoresearch)
  Mac-1-BNHS (biotin coupled to Mac-1 antibody); clone M1/70; Rat anti-mouse Mac-1 (BD Pharmingen)
  Streptavidin-RPE (Southern Biotechnology Associates)
Rat serum staining medium (see recipe)

Treat cultures with trypsin

1. Remove day-10 differentiated cultures from incubator and bring plate to room temperature. Remove medium, wash cells twice with 1× CMF-PBS at room temperature, and fix cells in 4% paraformaldehyde (PFA). Use 1 ml of cold 4% PFA/well for 5 to 10 min at room temperature.
2. Aspirate PFA and add 2 ml room temperature 1× CMF-PBS/well. Allow dish to sit for 2 min before aspirating CMF-PBS. Repeat wash 1 more time. Either store at 4°C in CMF-PBS until ready to stain, or proceed with the staining protocol.
3. Add 0.2 ml room temperature 1:500 trypsin solution/well of a 24-well plate. Let 1:500 trypsin solution sit for no more than 60 to 75 sec at room temperature.

   Incubation times longer than 60 to 75 sec may result in complete detachment of differentiated cultures. This step slightly loosens cells and enhances Mac-1 staining.
4. Stop the trypsin reaction by adding 0.5 ml of room temperature 100% heat-inactivated FBS to the well. Immediately remove the solution from the well with gentle aspiration or pipetting.
5. Proceed with immunostaining or store in staining medium at 4°C.

Stain with PECAM

6. Gently add 1.5 to 2 ml (per well of a 24-well plate) of staining medium. Incubate for 1 hr at 37°C to block nonspecific sites.
7. Remove plate from incubator, aspirate staining medium, and add fresh staining medium containing Mec13.3 (PECAM antibody) at 1:1000 dilution. Incubate for 1 hr at 37°C.

   PECAM is expressed by mouse endothelial cells.

   Typically, 250 μl of staining medium/antibody is used per well of a 24-well plate.
8. Remove plate from incubator and aspirate PECAM antibody. Wash wells twice, each time with 2 ml room temperature staining medium.
9. Add fresh staining medium containing FITC-AffinPure F(ab')$_2$ donkey anti-rat antibody at 1:100 dilution. Incubate for 1 hr at 37°C in the dark.

   Typically, 250 μl of staining medium/secondary antibody is used per well of a 24-well plate.

Stain with Mac-1

10. Remove plate from incubator and aspirate FITC reagent. Wash wells twice, each time with 2 ml staining medium at room temperature.

    If desired, the plate can be stored at 4°C, in the dark, for later processing. Be sure to leave staining medium in wells.
11. Add 2 ml/well of rat serum staining medium. Incubate for 30 min at 37°C in the dark.

    If desired, the plate can be stored at 4°C, in the dark, for later processing. Be sure to leave rat serum staining medium in wells.
12. Remove rat serum staining medium. Add fresh rat serum staining medium containing Mac-1-BNHS at 1:800. Incubate for 1 hr at 37°C, in the dark.

    Mac-1 is expressed by embryonic macrophages.

    Typically, 250 μl of rat serum staining medium/ antibody is used per well of a 24-well plate.

13. Remove Mac-1-BNHS and wash well(s) twice with 2 ml staining medium at room temperature. Add fresh staining medium containing streptavidin-R-PE at 1:800. Incubate for 1 hr at 37°C in the dark.

    Typically, 250 μl of staining medium/secondary antibody is used per well of a 24-well plate.

14. Remove streptavidin-RPE and wash well(s) once with 2 ml staining medium at room temperature, then aspirate. Next, wash well(s) twice with 2 ml 1× CMF-PBS. Add 2 ml CMF-PBS and store plate at 4°C in the dark.

15. Examine the plate using fluorescence microscopy with the appropriate filter sets.

SUPPORT PROTOCOL 3

IMMUNOLOCALIZATION

An important aspect of a model system is that it recapitulates the expression of molecular markers seen in vivo. Much of the vascular development that is observed in this in vitro ES differentiation system is analogous to blood island and vascular development that is observed in the mouse embryo and yolk sac. Fortunately, it is with general ease that one can observe primitive ES cell–derived mouse blood vessels using several markers and protocols. There are a number of identified molecular markers for the early mouse vasculature. Platelet endothelial cell adhesion molecule-1 (PECAM-1, CD-31), VEGF (vascular endothelial growth factor) receptor 2 (Flk-1), VE-cadherin, and intercellular adhesion molecule 2 (ICAM-2) have proven particularly useful in visualizing primitive vessels. It has been shown that PECAM-1 and Flk-1 are expressed on mouse angioblasts and endothelial cells (Vittet et al., 1996; Redick and Bautch, 1999). Other vascular markers such as ICAM-2 and VE-cadherin are detectable later, when endothelial cells coalesce to form vessels. This is a protocol for visualizing expressed genes in the in vitro ES cell differentiation model system that utilizes antibodies specific for several vascular markers.

Materials

Differentiated ES cell culture (from Basic Protocol)
1× CMF-PBS (Sigma)
Methanol/actetone fixative (see recipe): 1:1 (v/v) methanol (Fisher Scientific)/acetone (Mallinckrodt) *or* 4% (w/v) paraformaldehyde (PFA; Polysciences; see recipe)
Staining medium (see recipe)
Primary and secondary antibodies (see recipe)
Fluorescent microscope, inverted (equipped with epifluorescence and camera)

NOTE: All volumes given are for staining cultures from a 24-well plate. Gently add and remove all solutions from culture plates, as harsh removal and addition of solutions may result in detachment of cultures.

Fix the cells

1. Remove differentiated cultures from incubator, and allow to slightly cool. Aspirate medium and wash twice with 2 ml/well of 1× CMF-PBS at room temperature.

2. Add 1 ml of cold methanol/acetone fixative/well and incubate for 5 min at room temperature.

    PECAM-1 and ICAM-2 antibodies work in both PFA and methanol/acetone fixatives. Both fixatives are listed here because some applications (not those described here) favor one fixative over another. The authors generally use methanol/acetone fixative because it is less harsh on the attached cultures.

3. Aspirate fixative and add 2 ml of room temperature 1× CMF-PBS/well. Allow plate to sit for 2 min before aspirating CMF-PBS. Repeat wash two more times. Either store at 4°C in CMF-PBS until ready to stain, or proceed with the staining protocol.

Stain the cells

4. If the plate has been stored at 4°C after fixation, allow the plate to come to room temperature.
5. Aspirate 1× CMF-PBS, and gently add 1.5 to 2 ml of staining medium. Incubate for 45 min to 1 hr at 37°C.
6. Remove plate from incubator, aspirate staining medium, and add fresh staining medium containing the properly diluted primary antibody. Incubate for 1 to 2 hr at 37°C.

   Typically, 250 μl of staining medium/primary antibody is used per well of a 24-well plate.

7. Remove plate from incubator, aspirate, and wash well(s) two times (2 to 3 min/wash) with 1.5 to 2 ml staining medium. Add fresh staining medium containing the properly diluted secondary antibody. Incubate for 1 hr at 37°C.

   Typically, 250 μl of staining medium/secondary antibody is used per well of a 24-well plate.

8. Remove plate from incubator, aspirate, and wash well(s) one time for 2 to 3 min with 1.5 to 2 ml staining medium. Aspirate wash, then wash one to two times (2 min/wash) using 1× CMF-PBS.
9. Aspirate last wash and add 1.5 to 2 ml of 1× CMF-PBS to each well, store in CMF-PBS at 4°C in the dark.
10. To visualize the vasculature, set up an inverted microscope equipped with epifluorescence and a camera.

β-GALACTOSIDASE STAINING

SUPPORT PROTOCOL 4

Another commonly used technique to visualize blood vessels in the in vitro ES cell differentiation model system relies on the β-galactosidase reporter system. The authors have mouse ES cells in which expression of the *lacZ* gene is under the control of a vascular promoter (Flk-1, Flt-1). The β-galactosidase protein is the gene product of *lacZ* and is easily assayed. β-galactosidase catalyzes the hydrolysis of the colorless substrate Xgal, to form a blue precipitate in β-galactosidase-expressing cells. This protocol describes the steps involved in β-galactosidase staining of ES cell–derived blood vessels.

Materials

Day-8 differentiated cultures in 24-well plate (Basic Protocol)
0.1 M phosphate buffer, pH 7.3 to 7.5 (see recipe)
Glutaraldehyde fixative solution (see recipe)
Xgal stain (see recipe)
Wash buffer (see recipe)

NOTE: All volumes given are for staining cultures from a 24-well plate. Gently add and remove all solutions from culture dishes, as harsh removal and addition of solutions may result in detachment of cultures.

1. Remove differentiated cultures from incubator, and allow to slightly cool. Aspirate medium and wash well(s) once with 1.5- to 2 ml 0.1 M phosphate buffer (pH 7.3 to 7.5) at room temperature.

2. Aspirate phosphate buffer and add 1 ml glutaraldehyde fixative solution to each well and fix for 5 min at room temperature.
3. Aspirate fixative. Wash cells three times (5 min/wash), each time with 1.5 to 2 ml 0.1 M phosphate buffer at room temperature.
4. Aspirate phosphate buffer. Add 200 µl Xgal stain to each well. Stain cells for 4 hr to overnight at 37°C depending on level of *lacZ* activity.
5. After staining, remove Xgal stain, add 1 ml wash buffer to each well, aspirate, then replace with 1 ml wash buffer to each well.
6. Examine plates for blue-staining structures indicating blood vessels (see Fig. 23.3.2C).

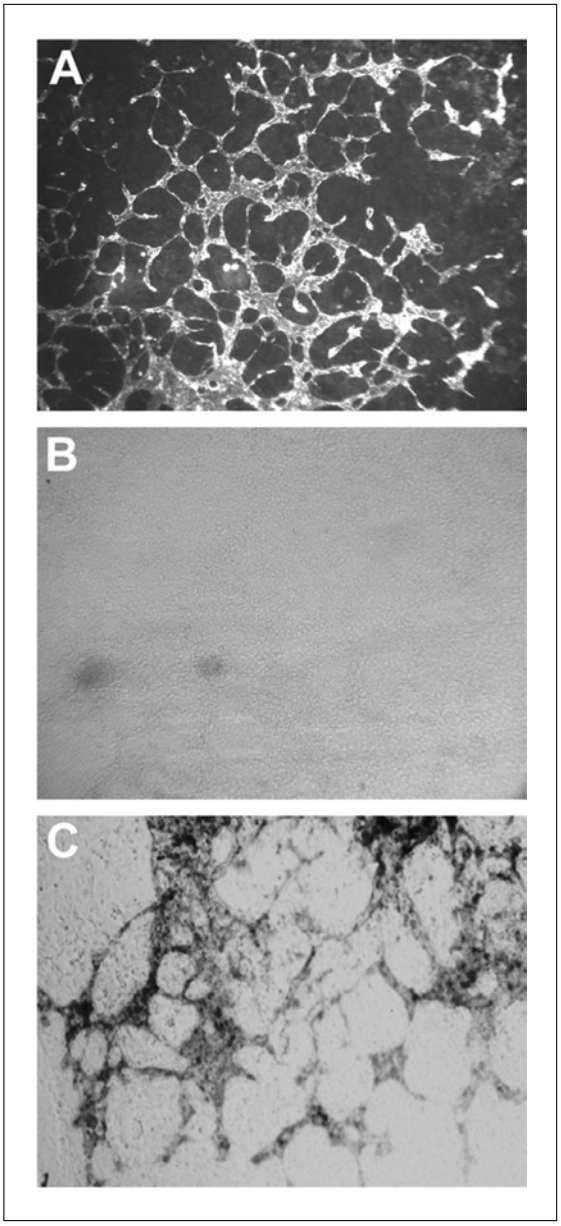

Figure 23.3.2 The vasculature of differentiated ES cell attached cultures can be visualized by both immunolocalization (PECAM stain) and enzymatic reaction (β-galactosidase stain). (**A, B**) ES cell culture differentiated to day 8, fixed and stained using the PECAM antibody, depicting a typical vascular pattern by immunofluorescence (**A**), and the corresponding phase image (**B**). (**C**) ES cell culture differentiated to day 8, fixed and stained for β-galactosidase, showing a vascular pattern (**C**) in phase.

CULTURING MOUSE EMBRYONIC STEM CELLS IN THE ABSENCE OF FEEDER CELLS

There are numerous published protocols describing mouse embryonic stem cell (ES) maintenance (Bautch, 2002; Kearney and Bautch, 2003). Here the authors describe the maintenance of mouse ES cells for in vitro differentiation. Leukemia Inhibitory Factor (LIF) is a leading component that contributes to stem cell maintenance and prevention of cell differentiation. Traditionally, ES cells are maintained on a layer of feeder cells (usually mouse embryo fibroblasts or STO cells), which provide LIF to the surrounding ES cells. Here the authors describe the maintenance of ES cells using medium that has been conditioned by the 5637 human bladder cancer cell line. This cell line produces LIF that is subsequently used for ES cell maintenance. The authors prefer the 5637 cell–conditioned medium to commercial LIF because they feel that it best preserves the undifferentiated morphology of the ES cells grown off of feeder layers.

Materials

3- to 4-day-old ES cell dishes (*UNIT 23.2*), without feeder layer, passage 3 to 45
1× CMF-PBS (Sigma)
0.25× trypsin/EDTA (see recipe)
Trypsin stop solution (see recipe)
ES cell culture medium (see recipe)

Gelatin-coated dishes (see recipe)
6-cm tissue culture (TC)–treated culture dishes (Corning)

NOTE: All volumes are given assuming that one 6-cm dish of ES cell colonies is being used. Double all volumes if using 10-cm dishes. Prewarm all solutions to 37°C prior to use.

1. Remove 3- to 4-day-old ES cell dish(es) from 37°C incubator. Aspirate medium. Wash two times, each time with 5 ml 1× CMF-PBS at room temperature and then remove.

   ES cells must be passed frequently to prevent differentiation. The authors typically pass ES cells every 3 to 4 days. On the day of passage, ES colonies are typically found in tight, shiny clumps (Fig. 23.3.1). If the colonies are large and flat, the optimal time for passage has passed.

2. Add 1 ml 0.25× trypsin/EDTA solution to dish. Place the dish in 37°C incubator until a majority of ES cell clumps disassociate upon gentle agitation (1 to 3 min).

   This 1-ml volume should just cover the bottom of the dish.

3. Stop trypsinization reaction by adding 4 ml trypsin stop solution to dish. Gently draw the ES cells/trypsin stop solution up and down with a pipet a few times to break up the cell clumps.

4. Remove a gelatin-coated 6-cm dish from incubator. Aspirate gelatin solution, and add 5 ml pre-warmed ES cell culture medium. Add 2 to 3 drops of the cell suspension into the dish. Observe the sizes of ES cell clumps under a microscope.

   ES cells should be in a single-cell suspension, or in clumps of no more than 4 to 6 cells/clump. If cell clumps are significantly larger, pipet solution to further break apart cell clumps.

5. Place dish in 37°C incubator with 5% CO_2 and gently move dish in a back-and-forth motion in order to evenly disperse ES cells throughout the dish.

SUPPORT PROTOCOL 6

PREPARATION OF 5637 CELL–CONDITIONED MEDIUM (CM)

The conditioned medium of confluent 5637 cells contains LIF (leukemia inhibitory factor/differentiation inhibiting activity), which is used as a medium component for the maintenance of ES cell cultures.

Materials

5637 human bladder carcinoma cell line (ATCC #HTB9)
5637 cell growth medium (recipe)
Collection medium (see recipe)

6- and 15-cm tissue culture (TC)–treated culture dishes (Corning)
15- and 50-ml centrifuge tubes (Sarstedt)
200-ml centrifuge tubes, if desired (NUNC)
1-, 3-, 10, and 25-ml disposable pipets
0.22-μm cellulose acetate filter units with bottle (Corning) *or* Nalgene SFCA 0.2-μm bottle top filter with 33-mm neck to fit standard 500-ml glass bottles
500-ml bottles, autoclaved

NOTE: The following protocol describes the collection of 5637 medium from one 15-cm plate, however, more plates are typically processed for collection. Adjust volumes as needed if more plates are to be processed for 5637 collection.

1. Thaw and grow 5637 cells in 5637 cell growth medium to 80% to 90% confluence (usually 2 to 3 days after thaw) in 15-cm tissue-culture dishes. Grow cells in 37°C incubator.

   The authors typically use 25- to 30 ml 5637 cell growth medium/15-cm dish.

2. At cell confluence (2 to 3 days), remove dishes from incubator, aspirate 5637 cell growth medium and feed cells using collection medium. Use 25 to 30 ml collection medium/15-cm dish.

3. After 48 hr, remove the dishes from the incubator and carefully transfer the 5637–conditioned medium from the 15-cm dishes of cells to 50-ml or 200-ml centrifuge tubes using a 25-ml pipet. Avoid scraping the monolayer of cells. Add 25 to 30 ml of fresh collection medium and return plate to incubator.

   The addition of fresh medium to the dish allows for subsequent collection of additional 5637–conditioned medium.

4. Balance the volumes in the 50-ml tubes and centrifuge 10 min at 770 × *g*, 4°C.

5. In the hood, remove the supernatant from each tube and sterile filter through a 0.22-μm cellulose acetate filter unit.

   The supernatant will take a long while to filter.

6. After filtration is complete, place 3 ml of the filtered 5637–conditioned medium in a 6-cm dish into the incubator and check for contamination after 24 hr.

7. Collect conditioned medium every 2 to 3 days for 5 or 6 collections (30 ml/collection/plate). Combine/pool the filtered collected media. Store 5637 cell–conditioned medium up to 1 month at 4°C. Freeze medium at −20°C for use at a later time (up to 6 months). Use the conditioned medium in ES cell culture medium.

   Collect conditioned medium until the cells look sub-optimal (usually after 5th collection). Suboptimal cells will typically detach from the dish or have a disrupted cell monolayer.

ES cell culture medium containing individual pooled collections of conditioned medium is subsequently used for maintenance of ES cell cultures. It is important for 5637 cell– conditioned medium to maintain ES cells in an undifferentiated state. Overly differentiated ES cells, as evidenced by large, flat cells in colonies and no shiny center, are an indication of sub-optimal 5637 cell–conditioned medium.

LOT TESTING OF FBS FOR PASSAGE OF ES CELLS

SUPPORT PROTOCOL 7

A number of different lots of FBS (in parallel with the current lot) are tested in ES medium to ensure the best maintenance and growth of undifferentiated ES cells. To test different lots of FBS, ES cells are maintained in ES medium containing one lot of FBS (one lot of FBS/batch ES cell culture medium), for three passages. During these three passages, ES cells are analyzed for their proper morphology (shiny, tight clumps of cells) and growth. After this point, ES cells are differentiated to day 8, then analyzed for a healthy and normal vasculature pattern via PECAM antibody staining. In this way, ES cells maintained in medium containing different FBS lots during cell passage can be compared. Typically, three to four lots of FBS are tested independently in batches of ES cell culture medium.

Materials

ES cell culture medium (see recipe), prepared with different lots of FBS
3- to 4-day-old ES cell culture dish (Support Protocol 5)
6-cm tissue culture–treated culture dishes (Corning)

Additional reagents and equipment on in vitro differentiation of ES cells (Basic Protocol), passaging of ES cells (Support Protocol 6), and fixing and staining differentiated cultures (Support Protocol 3)

1. Prepare different batches of ES cell culture medium, with each batch containing a different lot of FBS including the currently used lot. To test FBS lots, use the same ES clone to test all lots.
2. Remove 3- to 4-day-old ES cell culture dish from 37°C incubator. Passage ES cells (Support Protocol 6) setting up one to two 6-cm plates of ES cells per lot of FBS to be tested.
3. Passage ES cells for three passages using the same ES cell culture medium and FBS lot to be tested to maintain the same group of ES cells for the duration of the three passages.

   One parameter used to assess whether an FBS lot is of good quality is if ES cells maintain an undifferentiated morphology of tight, shiny clumps for the duration of the three passages.

4. After completion of the third passage, in vitro differentiate the groups of ES cells (Basic Protocol).
5. On day 8 of in vitro differentiation, remove cells from incubator. Fix and stain differentiated cultures with anti-mouse PECAM antibody (Support Protocol 3).

   By maintaining/differentiating ES cells and assessing the vasculature (via PECAM antibody staining) of ES cells maintained in different lots of FBS, it is possible to evaluate the ability of each lot of FBS to properly maintain ES cells to form blood vessels.

SUPPORT PROTOCOL 8

LOT TESTING OF FETAL BOVINE SERUM FOR IN VITRO DIFFERENTIATION OF MOUSE ES CELLS

A number of different lots of FBS are tested in differentiation medium to ensure the best in vitro differentiation of ES cells into blood vessels. To test different lots of FBS, differentiated ES cells are maintained in differentiation medium containing a unique test lot of FBS (one lot of FBS/batch of differentiation medium), until day 8 of differentiation. Day 8 differentiated cultures are then fixed and stained for vasculature (PECAM stain; Support Protocol 2), red blood cell differentiation (benzidine stain; Support Protocol 1), and embryonic macrophages (Mac1 stain; Support Protocol 2). This way, differentiated cells maintained in medium containing different FBS lots can be compared by the expression of markers that are observed in differentiated ES cultures.

Typically, three to four lots of FBS, including the lot currently in use, are tested independently in batches of differentiation medium.

Materials

Differentiation medium (see recipe), prepared with different lots of FBS
5-day-old to 6-day-old ES cell culture (Support Protocol 5)

Additional reagents and equipment for in vitro differentiation of ES cells (Basic Protocol)

1. Make up different batches of differentiation medium, with each batch containing a different lot of FBS. To test FBS lots, use the same differentiated clone for all test media.
2. Remove 5-day-old ES cell dishes from incubator. Ensure that there is one 6-cm dish per batch of differentiation medium (containing a unique FBS lot) to be processed for in vitro differentiation.
3. In vitro differentiate ES cells (see Basic Protocol).
4. For each group of differentiated ES cells (corresponding to each FBS lot to be tested), set up attached cultures as described in Basic Protocol (steps 15 to 20). Attach each group of differentiated cells in four wells in each of two 24-well plates.

   The four wells of one 24-well plate will be used for benzidine staining, while the four wells of the other 24-well plate will be used for double immunostaining with PECAM and Mac-1.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Antibodies, primary and secondary (and streptavidin-R-PE)

Dilute all antibodies in staining medium (see recipe).

Primary antibodies: Dilute rat anti-mouse PECAM-1 (CD31; Pharmingen) to 1:1000, rat anti-mouse ICAM-2 (3C4; Pharmingen) to 1:500, rat anti-mouse Mac-1-BNHS (Pharmingen, no. 01711D) to 1:800. Prepare just prior to use.

Secondary antibodies: Dilute reconstituted secondary antibody goat anti-rat Alexa Fluor 488 (Molecular Probes) to 1:250 (for detecting PECAM-1 and ICAM-2), FITC-AffinPure F(ab')$_2$ donkey anti-rat to 1:100 (Jackson Immunoresearch, no. 712-096.150), and streptavidin-R-PE (Southern Biotechnology, no. 7100-09) to 1:800. Store at 4°C after reconstitution (according to the manufacturer) for up to 6 months.

Do not freeze reconstituted antibodies.

Benzidine solution

Stock solution: Prepare a benzidine base stock solution that is 3% (w/v) benzidine base (Sigma) in 90% (v/v) acetic acid (Fisher Scientific)/10% water. Store up to 6 months at 4°C in the dark.

Working solution: To make benzidine solution, add 1 part benzidine base stock, 1 part 30% hydrogen peroxide, and 5 parts water. Prepare fresh for each use.

Cell growth medium, 5637

Heat inactivate FBS (lot tested for ES cell maintenance) at 55°C for 1 hr. Store up to 6 months at −20°C for future use.

Prepare growth medium:
DMEM-H containing:
10% (v/v) heat-inactivated FBS
50 μg/ml gentamicin (final concentration)
1× (75 μM) monothioglycerol (MTG; Sigma)
Freeze up to 6 months at −20°C. Avoid freeze thaws.
Once thawed, store at 4°C and use within 1 month.

Collection medium

Dulbecco's modified Eagle medium (DMEM-H; Invitrogen)
5% (v/v) heat-inactivated FBS
50 μg/ml gentamicin (final concentration)
1× (75 μM) monothioglycerol (MTG; Sigma)
Freeze up to 3 months at −20°C. Avoid freeze thaws.
Once thawed, store at 4°C and use within 1 month

Differentiation medium

Add gentamicin (Invitrogen) to a final concentration of 50 μg/ml per 500-ml bottle of DMEM-H (Invitrogen). Add lot-selected FBS (Support Protocol 8) to 20% (v/v) and MTG (Sigma) to 2× (150 μM final concentration). Store at 4°C. Use within 2 weeks.

Dispase

Dilute dispase, grade II stock (2.4 U/ml) 1:1 in 1× CMF-PBS (1.2 U/ml final). Use cold. Store at 4°C for up to 1 month.

ES cell culture medium

Stock solutions

DMEM-H/gentamicin: To a 500-ml bottle of DMEM-H add 0.5 ml of 50 mg/ml gentamicin (50 μg/ml final) and invert to mix.

100× MTG: Prepare a 7.5 mM solution of MTG in CMF-PBS. Store at 4°C.

FBS: Heat inactivate 100% lot-tested (Support Protocol 7) FBS at 55°C for 1 hr.

5637 cell–conditioned medium (Support Protocol 6)

Working solution:
100 ml 5637–conditioned medium (66% v/v final)
26 ml heat-inactivated, lot-tested FBS (17% v/v final)
1.5 ml 100× MTG [1× (75μm) final]
24 ml DMEM-H/gentamicin (16% v/v final)
Store at 4°C. Use within 2 weeks.

Gelatin-coated dishes

Add 2 ml of 0.1% (w/v) gelatin (Type A gelatin, porcine, Bloom Factor 200; Difco) in CMF-PBS (Sigma) per 6-cm dish or 4-ml per 10-cm dish. Ensure that bottom of dish is gelatin-coated by tilting dish back and forth. Incubate dish for at least 1 hr at 37°C.

Dishes can be prepared up to 1 week in advance, however, to ensure that there is no bacterial or fungal contamination, check the dish under a microscope.

Glutaraldehyde fixative solution

For 50 ml:
0.4 ml 25% (v/v) glutaraldehyde (Polysciences)
2.5 ml 100 mM EGTA, pH 7.3 (Sigma)
0.1 ml 1 M magnesium chloride (Mallinckrodt)
47 ml 0.1 M phosphate buffer (see recipe)
Prepare fresh for each use

Methanol/acetone fixative

Prepare a 1:1 (v/v) mixture of methanol/acetone fresh on the day of use.

Methanol and acetone can be stored separately at −20°C.

Monothioglycerol (MTG)

Prepare 100× MTG stock by adding 32.5 µl of monothioglycerol stock (Sigma no. M6145) to 50 ml CMF-PBS (7.5 mM final). Store at 4°C and use within 2 weeks.

Paraformaldehyde (PFA) fixative, 4% (w/v)

Add 2 g PFA (Polysciences) powder to 50 ml 1× CMF-PBS in a 50-ml conical centrifuge tube. Heat solution to 60°C, shaking occasionally until PFA is in solution. Cool to room temperature, then filter through a 0.45-µm filter fitted to a syringe. Divide into 3-ml aliquots and freeze up to 6 months at −20°C. Alternatively, store at 4°C in dark and use within 2 weeks.

Phosphate buffer, 0.1 M (pH 7.3 to 7.5)

Prepare 500 ml 0.1 M phosphate buffer solution by combining 115 ml 0.1 M sodium phosphate monobasic (Mallinckrodt) and 385 ml 0.1 M sodium phosphate dibasic (Mallinckrodt). The mixture should give a pH between 7.3 and 7.5. Store at room temperature and use until solution becomes cloudy.

Rat serum staining medium

5% (v/v) rat serum
3% (v/v) FBS, heat inactivated 1 hr at 55°C
0.1% (w/v) NaN_3 (Fisher Scientific)
1× CMF-PBS
Store up to 6 months at 4°C

Staining medium

3% (v/v) FBS, heat inactivated 1 hr at 55°C
0.1% (w/v) NaN_3 (Fisher Scientific)
1× CMF-PBS
Store up to 6 months at 4°C

Trypsin/EDTA, 0.25×

Add 1 ml 1× trypsin/EDTA stock solution (0.2% (w/v) trypsin/0.53 mM EDTA; Invitrogen) to 3 ml CMF-PBS. Store at 4°C. Use within 2 weeks.

Trypsin solution, 1:500

Dilute 2.5% (w/v) trypsin (no EDTA; Invitrogen) 1:500 using 1× CMF-PBS. Prepare fresh each time.

Trypsin stop solution

35% (v/v) FBS, heat inactivated 1 hr at 55°C
1× CMF-PBS
Store up to 1 month at 4°C

Wash buffer

For 200 ml:
0.4 ml 1 M magnesium chloride (Mallinckrodt)
2 ml 2% (v/v) Nonidet P-40 (Sigma)
197.6 ml 0.1 M phosphate buffer (see recipe)
Filter sterilize
Store at room temperature until solution becomes cloudy

Xgal stain

For 50 ml:
2 ml of 25 mg/ml Xgal stock (Bethesda Research Labs) in dimethyl formamide (Fisher Scientific)
0.106 g potassium ferrocyanide (Sigma)
0.082 g potassium ferricyanide (Sigma)
48 ml wash buffer (see recipe)
Store at 37°C for 2 weeks or until cloudy

COMMENTARY

Background Information

Embryonic stem (ES) cells are pluripotent cells that have been derived from the inner cell mass of developing blastocysts (Evans and Kaufman, 1981). ES cells maintained on embryonic fibroblasts in culture can repopulate all different cell lineages, including the germ line, after being injected into host blastocysts (Bradley et al., 1984). Furthermore, in vitro studies over the past twenty years have shown that ES cells can differentiate into a variety of cell lineages under appropriate conditions in culture (Keller, 2005). Many of the cell types that differentiate under theses conditions are those that are found in the developing embryo and yolk sac, such as hematopoietic cells, endoderm, and endothelial cells (Wiles and Keller, 1991; Schmitt et al., 1991; Wang et al., 1992; Keller et al., 1993). The vascular endothelial cells that arise during ES cell differentiation have the potential to form primitive blood vessels, comparable to the vessels that first form in the developing embryo and yolk sac.

An extensive discussion of nonmouse ES cell differentiation into endothelial cells and vascular structures is beyond the scope of this unit, but several excellent reviews have recently highlighted similarities and differences between mouse and human or nonhuman primate ES cells (reviews: Smith, 2001; Pera and Trounson, 2004; Hematti et al., 2005). Although human ES cells (hES) differ from mouse ES cells in requirements to maintain their undifferentiated status, hES can be induced to differentiate and form embryoid bodies similar to their mouse counterparts. Several reports have characterized endothelial progenitors, endothelial cells, and vascular structures derived from hES cells, although the development of hematopoietic cells and vascular structures takes longer than with mouse ES cell differentiation (Levenberg et al., 2002; Gerecht-Nir et al., 2003; Wang et al., 2004).

These recent findings suggest that the basic cell-cell interactions and differentiation programs are shared among the different species, but that the protocols must be modified when changing the species source of ES cells.

Mouse ES cells were initially cultured on embryonic fibroblast feeder cells (Evans and Kaufman, 1981; Martin, 1981), or with leukemia inhibitory factor (LIF) once it was identified as a factor to prevent differentiation (Smith et al., 1988; Williams et al., 1988). It was subsequently shown that LIF activates the transcription factor STAT3, and this activation is critical to ES cells (Matsuda et al., 1999). Sources of LIF include: recombinant LIF that is commercially available, transient transfection of COS cells with LIF-expressing plasmids, and harvesting medium conditioned by the 5637 human bladder cancer cell line (Kearney and Bautch, 2003). The authors prefer the 5637–conditioned medium because they feel it best preserves the undifferentiated ES cell morphology, perhaps because other factors in the medium co-operate with LIF to efficiently maintain undifferentiated ES cells. There are several methods used for initiating ES cell differentiation. ES cells are removed from medium containing LIF and cultured in differentiation medium in suspension where they aggregate to form a colony of partially differentiated cells known as an embryoid body (EB; Doetschman et al., 1985; Wang et al., 1992; review: Keller, 1995). Alternatively, ES cells are cultured directly onto stromal cells to provide an environment conducive to hematopoietic differentiation (Nakano et al., 1994). A commonly used stromal cell line for such differentiation is the OP9 cell line, isolated from CSF-1 deficient op/op mice (Yoshida et al., 1990). A third method utilizes the culture of ES cells in a monolayer on extracellular matrix proteins (Nishikawa et al., 1998). Also, EBs can be disaggregated into single ES cells and plated in methyl cellulose, and subsequent analysis of the colonies that form shows that EBs contain many of the hematopoietic progenitors found in bone marrow (Schmitt et al., 1991). More recent studies have shown that single cells disassociated from EBs and plated in methyl cellulose generate blast-cell colonies that indicate the existence of a common progenitor for hematopoietic and endothelial cells (Kennedy et al., 1997; Choi et al., 1998).

While this protocol discusses the formation of EBs by enzymatic disruption of ES cell clumps, an alternative method of creating EBs is by culturing ES cells in hanging drops for several days (Wobus et al., 1991; *UNIT 23.2*). Whether forming EBs by enzymatic disruption or by hanging drops, differentiation of the EBs can be performed in suspension rather than as attached cultures, as described here. EBs, which contain an inner and outer layer, can be expanded to form a large lumen and are called cystic embryoid bodies (CEBs; Wang et al., 1992). CEBs have hemoglobinized areas that are indicative of hematopoietic development, primitive blood vessels, and areas of beating that indicate differentiation of cardiac muscle (Doetschman, et al., 1985; Risau et al., 1988; Wang et al., 1992).

All methods of ES cell differentiation have both advantages and disadvantages. The formation of EBs (either enzymatic disruption or hanging drop) has the advantage of providing for a cellular structure that enhances cell-cell interactions. Cells within an EB provide critical developmental cues involved in differentiation of other cell types (review: Keller, 2005). However, EBs have the potential to generate unknown factors that can complicate analysis of developmental programs. The advantage of coculturing ES cells with stromal cells is that stromal cells can provide a beneficial growth environment for hematopoietic development. However, undefined factors produced by stromal cells may influence the differentiation of ES cells to one cell type over another (review: Keller, 2005). Separation of differentiated ES cells from the stromal cell layer has also been found to be a disadvantage of this method. The formation of EBs is sometimes preferred over the formation of CEBs, because reattachment of EBs lends itself to enhanced experimental manipulations such as in situ localization and image analysis (Kearney and Bautch, 2003).

The protocol of ES cell differentiation from EBs that is described here provides a tool for further understanding the process of vascular differentiation (vasculogenesis) and vascular expansion (angiogenesis) in an in vitro setting that is analogous to the in vivo setting. A number of markers for the early vasculature have been identified and are particularly useful, and protocols for immunolocalization and β-galactosidase staining described here are beneficial tools for analyzing vascular marker expression.

Critical Parameters

All tissue culture should be performed under sterile conditions in a class II biological flow hood. All reagents and media should be sterile. Pipet tips and medidroppers should be

sterilized by autoclaving. All bottles should be thoroughly washed and autoclaved before use. All incubations should be performed in a humidified 37°C, 5% CO_2 incubator, unless otherwise indicated.

ES cells should be passed on day 3 or 4 after the last passage. As the source of LIF is depleted over time, ES cells will become more differentiated, thus passage of ES cells on day 3 is preferred over day 4. Enzymatic dissociation of ES cells using trypsin should be carried out for no longer than 2 to 3 min as described. Longer incubations have the potential to cleave cell surface proteins important for cell viability. Once the trypsin reaction is stopped with trypsin stop solution, it is important to gently draw cells up and down with a pipet for further ES cell dissociation, as harsh handling of the ES cells at this step can result in decreased cell viability. The authors typically culture ES cells for 50 passages, after which, maintenance of cell viability declines and undifferentiated ES cells are not preserved.

For ES cell culture, 5637 cell–conditioned medium is a critical component for ensuring that ES cells are maintained in their undifferentiated state. Testing of pooled collections of 5637 cell–conditioned medium on ES cells for proper ES cell maintenance is essential. The lot of FBS that is utilized for proper maintenance of mouse ES cells is also a critical factor in ES cell maintenance. Thus, lot testing of FBS as described in Support Protocols 7 and 8 is essential. FBS and 5637 cell–conditioned medium aliquots should be stored at −20°C and repeated freeze-thaws should be avoided.

When choosing 5- to 6-day-old ES cells for in vitro differentiation, it is important to choose the dish containing ES clumps that are undifferentiated in the middle (tight and shiny appearance), but differentiated along the edges (Figure 23.3.1). This morphology indicates a partial differentiation that promotes further differentiation. After treating the ES cells with dispase to generate small clumps of cells, it is imperative to then transfer the cell clumps to bacteriological dishes to prevent them from sticking to the dish bottom. This will ensure that the cell clumps will form EBs in suspension culture. Some cell clumps will invariably attach to the dish, but are discarded upon EB transfer to attachment dishes. The authors have found that timely feeding of attached cultures with fresh differentiation medium is important for good differentiation. The pH of medium can be monitored with phenol red, and if the medium on the cultures is light orange or yellow after 24 hr, it should be changed every day. Daily feedings are sometimes necessary for densely seeded wells or for later days of a time course (past day 8) when there are a large number of cells in each well. The lot of FBS that is utilized for proper maintenance and differentiation of ES cells is also a critical parameter and it should be emphasized that often different lots are optimal for maintenance versus differentiation. Thus, lot testing of FBS as described in Support Protocol 8 is essential. When performing immunolocalization experiments, it is important to set up control conditions for the experiment. Set up attached cultures that do not receive primary antibody (staining medium alone), but do receive secondary antibody. This step should help determine if the secondary antibody exhibits nonspecific binding.

Troubleshooting

Maintaining undifferentiated ES cells during ES cell passage is a commonly encountered problem. There are a few potential causes for overly differentiated ES cells: (1) The 5637 cell–conditioned medium does not contain enough LIF. Thus, it is important to test the different pools of combined 5637 collections on ES cells to determine which pool is optimal at keeping ES cells undifferentiated. (2) The FBS lot is not efficient in maintaining ES cells. Testing lots of FBS from different manufacturers is critical for proper ES cell maintenance. (3) Cell passage number is too high. The authors typically stop maintaining ES cells once they reach passage 50.

If the ES cells begin to differentiate in culture after 1 or 2 days since passage, it is advisable to immediately feed cells with fresh ES medium. If ES cells do not adhere to the gelatin-coated dish, make sure that the gelatin-coated dishes are used within 1 week after preparation.

When feeding EBs on day 2 after enzymatic disruption of ES clumps for in vitro differentiation, many of the EBs stick to the dish bottom. If this occurs, it may be necessary to transfer the EBs to a fresh 10-cm bacteriological dish using a medidropper.

When setting up attached cultures for in vitro differentiation, it is best to select medium-sized EBs for attachment (Figure 23.3.1). Larger EBs do not adhere as well, and while smaller EBs do attach to the dish, they often do not spread out and differentiate as well. Another factor that can influence ES cell differentiation is the quality of FBS. Thus, testing lots of FBS from different manufacturers is critical for optimal ES cell differentiation.

A problem that is commonly encountered when fixing and staining differentiated ES cultures is detachment of cells from the dish. As mentioned in Support Protocol 4, the authors prefer to use methanol/acetone fixative over PFA when applicable, because methanol/acetone fixative is less harsh on the attached cultures. However, it is recommended that attention be given to treating the cultures as gently as possible during the fixing and staining procedures.

If background signal problems occur after β-galactosidase staining, try increasing the pH of the phosphate buffer. The β-galactosidase staining procedure works at a pH of 8.5.

Anticipated Results

Although maintenance and passage of mouse ES cells with 5637 cell–conditioned medium should result in cultures containing a population of only undifferentiated ES cells, the authors typically do not observe this. In general, they notice that ~80% of cultured cells appear to be undifferentiated ES cells on day 3. This percentage goes down significantly if the batch of 5637 cell–conditioned medium is sub-optimal.

Attached cultures of EBs are set up on day 3 following the dispase treatment. By day 4 of differentiation (1 day after attachment of EBs), most EBs have attached to the bottom of the plastic dishes, and the rest are removed by aspiration. This attachment is strengthened as the EBs spread out further on the dish bottom over time. Angioblasts are first observed between days 4 and 6 of differentiation. Vessels are routinely visualized between days 6 and 8, with some expansion of the vasculature after day 8. A typical time course to observe and analyze vascular development would begin on day 5 and conclude on day 8. While cultures are viable past day 8, they begin to deteriorate around day 10 of culture under differentiation conditions.

Time Considerations

Passaging mouse ES cells

Approximately 15 min should be allowed to prepare all solutions. Maintaining mouse ES cells is fairly time efficient. After allowing solutions to warm to appropriate temperatures (5 to 15 min depending on volumes), a beginner can anticipate about 20 to 30 min to process 1 to 2 6-cm dishes of ES cells.

Preparation of 5637 cell–conditioned medium (CM)

After 5637 cells are thawed and passed, cells are typically grown for 48 to 72 hr (or until 80% to 90% confluency in a 15-cm plate. At this point growth medium is replaced with collection medium, and the cells are cultured for a further 48 hr. Approximately 45 min should be allowed to process one 15-cm plate for 5637 cell–conditioned medium. More time should be added if more than one 15-cm plate is processed (typically about 5 min more for every plate added).

Enzymatic disruption of ES cells (dispase treatment)

Approximately 15 min should be allowed to prepare all solutions, and 25 to 30 min should be allowed to process one 6-cm dish of ES cells. More time should be added if more than one 6-cm dish is processed (typically about 2 to 3 min for every added dish).

In vitro differentiation

Medium must be changed on day 2 after the dispase treatment. After warming differentiation medium to 37°C, ~3 to 4 min should be allowed to aspirate and feed one dish of EBs. The time required to set up attached cultures varies depending on the number of samples that are to be processed and the number of wells to be plated. It typically takes only a couple of minutes to plate one sample into four wells of a 24-well plate. Differentiated samples must be fed every other day after plating. Generally, it takes 5 min or less to feed the wells of a 24-well plate.

Benzidine staining

Approximately 10 to 15 min should be allowed to prepare all of the solutions for the benzidine staining protocol. Including incubation times, ~5 min to 1 hr should be allowed for completion of protocol (benzidine stain does not typically last longer than 1 hr).

Double immunostaining with PECAM and Mac-1

Approximately 20 to 30 min should be allowed to prepare all of the solutions for this protocol. Including incubation times, ~7 to 7.5 hr should be allowed to double immunostain 24 wells of a 24-well plate.

Immunolocalization

Approximately 10 to 15 min should be allowed to prepare all of the solutions for the

immunolocalization protocol. Including incubation times, ~4 to 4.5 hr should be allowed to stain all 24 wells of a 24-well plate with antibody.

β-galactosidase staining

Approximately 30 to 40 min should be allowed to prepare all of the solutions for β-galactosidase staining protocol, and ~30 to 40 min should be allowed to complete all protocol steps leading up to the addition of Xgal stain. Cells are incubated with Xgal stain for 4 hr to overnight depending on the level of β-galactosidase activity.

Differentiation of Mouse Embryonic Stem Cells and of Human Adult Stem Cells into Adipocytes

Severe obesity is the result of increases in fat cell size and increased fat cell number. Mature adipocytes do not undergo cell division, and new fat cells arise from a pre-existing pool of adipose stem cells that are present irrespective of age. The development of established preadipose cell lines has facilitated the study of different steps leading to terminal differentiation of preadipocytes into adipocytes. The key events have been characterized by the identification of transcription factors that play a regulatory role in the differentiation process. The best characterized transcription factors shown to be important in the development of mature adipocytes are members of the CCAAT/enhancer binding proteins (C/EBPs) and peroxisome proliferative-activated receptors (PPARs) families (Tontonoz et al., 1995; Mandrup and Lane, 1997). However, established preadipose cell lines are limited for studying early events of differentiation as they represent cells that are already committed to the adipogenic lineage. Master genes that commit multipotent stem cells toward adipocytes remain to be identified. In vitro differentiation of multipotent stem cells to the adipogenic lineage provides an alternative source of adipocytes for study in tissue culture and offers the possibility to investigate regulation of the first steps of differentiation and to test effects of drugs on adipose cell development.

This unit includes a protocol for culture conditions in which mouse embryonic stem (mES) cells can be maintained at an undifferentiated state (Support Protocol 1) or committed to undergo adipocyte differentiation at a high rate and in a highly reproducible fashion (Basic Protocol 1). There are also protocols for maintaining (Support Protocol 2) and differentiating human adult stem cells, isolated form adipose tissue (hMADS cells) and from bone marrow (hMS cells), into adipocytes (Basic Protocol 2). These culture systems provide a powerful means for studying the first step of adipose cell development and the effects of drugs on the biology of adipocytes. There are also protocols for visualization of adipocytes (Support Protocol 3) and analysis of adipocyte gene expression (Support Protocol 4).

NOTE: All solutions and equipment coming into contact with living cells must be sterile, and aseptic technique should be used accordingly.

NOTE: All culture incubations should be performed in a humidified 37°C, 5% CO_2 incubator unless otherwise specified.

DIFFERENTIATION OF MOUSE ES CELLS TO ADIPOCYTES

BASIC PROTOCOL 1

Adipocyte differentiation of mES cells is initiated by aggregation of ES cells to form embryoid bodies (EBs). The authors routinely use the hanging drop method for the formation of EBs. Two phases can be distinguished in adipogenesis from ES cells. The first phase, between day 2 and 5 after EB formation, corresponds to the permissive period for the commitment of ES cells; this phase requires retinoic acid (RA). The second phase corresponds to the permissive period for terminal differentiation and is influenced by adipogenic factors (e.g., insulin, triiodothyronine, and rosiglitazone) as previously shown for the differentiation of cells from preadipose clonal lines. The treatment leads to 60% to 80% of outgrowths containing adipose cells compared to 2% to 5% in the absence of RA treatment.

Materials

ES cells
Growth medium for mES cells (see recipe)
Leukemia inhibitory factor (LIF)
CMF-PBS (phosphate-buffered saline, calcium and magnesium free; Cambrex)
Trypsin solution (see recipe)
Fetal bovine serum (FBS, see recipe)
Retinoic acid (RA, see recipe)
Differentiation medium for mES cells (see recipe)

60- and 100-mm bacteriological grade petri dishes (Greiner)
20-ml conical sterile tube
100-mm gelatinized-tissue culture dishes (see recipe)

Additional reagents and equipment for cell counting (*UNIT 1.1*)

Collect ES cells

ES cells are originally plated at 10^6 cells per 25-cm^2 flask and are grown for 2 or 3 days until they reach a confluency of 80%. At this point, cells are still maintained from the original plating in the presence of LIF, in order to keep ES cells in the undifferentiated state. ES cell cultures may contain a proportion of "differentiated" cells which have lost their pluripotency. It is crucial to minimize this proportion of differentiated cells. This is achieved by the addition of LIF in a high-quality culture medium, i.e., an adequate batch of serum. Identification of pluripotent stem cells is difficult unless one is familiar with the appropriate cellular morphology. Pluripotent stem cells: (1) are small, (2) have a large nucleus containing prominent nucleoli structures, and (3) have minimal cytoplasm. Pluripotent stem cells, in contrast to differentiated cells, grow rapidly.

1. Change medium on ES cells with complete growth medium supplemented with 1000 U/ml LIF 2 hr before subculture.
2. Aspirate medium and wash twice, each time with 5 ml of CMF-PBS.
3. Aspirate the CMF-PBS and add 1 ml of trypsin solution. Incubate 2 to 3 min.
4. Add 5 ml of growth medium to stop trypsinization and suspend the cells by vigorous pipetting. Transfer the cells to a sterile 20-ml tube and centrifuge 5 min at 250 × *g*, room temperature.
5. Aspirate the medium and resuspend the cell pellet in 10 ml of growth medium without LIF to prepare a single-cell suspension. Count the cells (*UNIT 1.1*). After cell counting, adjust the suspension to a concentration of 5×10^4 cells/ml.

Induce EB formation

6. Place aliquots of 20 µl of this suspension onto the lids of 10-cm bacteriological grade dishes.

   This is defined as day 0 of EB formation.

   Bacterial grade petri dishes are used to prevent cell attachment to the substrate. EBs have a tendency to attach to the bottom of the plastic dish. EBs that are firmly attached to the dish should be eliminated as these EBs seem to have no adipogenic capacity.

7. Invert the lid and place it over the bottom of a bacteriological petri dish filled with 8 ml CMF-PBS containing a few drops of FBS to decrease the surface tension of the liquid.

   It is essential to cover the bottom of the dish with the liquid to prevent the evaporation of the hanging drops. When the lid is inverted, each drop hangs and the cells fall to the bottom of the drop where they aggregate into a single clump (EB).

Attachment of EBs on petri dishes can be eliminated by coating the dish with poly (2-hydroxyethylmethylacrylate) supplied as Cellform polymer (ICN Biomedicals). Dishes are filled with a film of Cellform working solution (0.5 g of Cellform dissolved in 42 ml of 100% ethanol) and left in a culture hood, with the cover of the dish removed, to evaporate ethanol. Dishes are rinsed with CMF-PBS before use.

8. At a time point 2 days later, remove the lid, invert it and collect drops containing EBs in a 20-ml conical sterile tube. Let stand for 5 min at room temperature to allow the aggregates to sediment.

9. Aspirate the supernatant and resuspend the pellet in 4 ml of growth medium supplemented with 10^{-7} M retinoic acid (RA). Transfer the suspension to 60-mm bacteriological grade petri dishes.

   RA is light-sensitive.

10. Incubate for 3 days in the presence of RA changing the growth medium every day.

    Plate EBs on gelatin and differentiate.

Induce differentiation

11. At day 5 after EB formation, change the medium to growth medium without the addition of RA and plate 2 to 4 EBs per cm^2 in 100-mm gelatinized-tissue culture dishes.

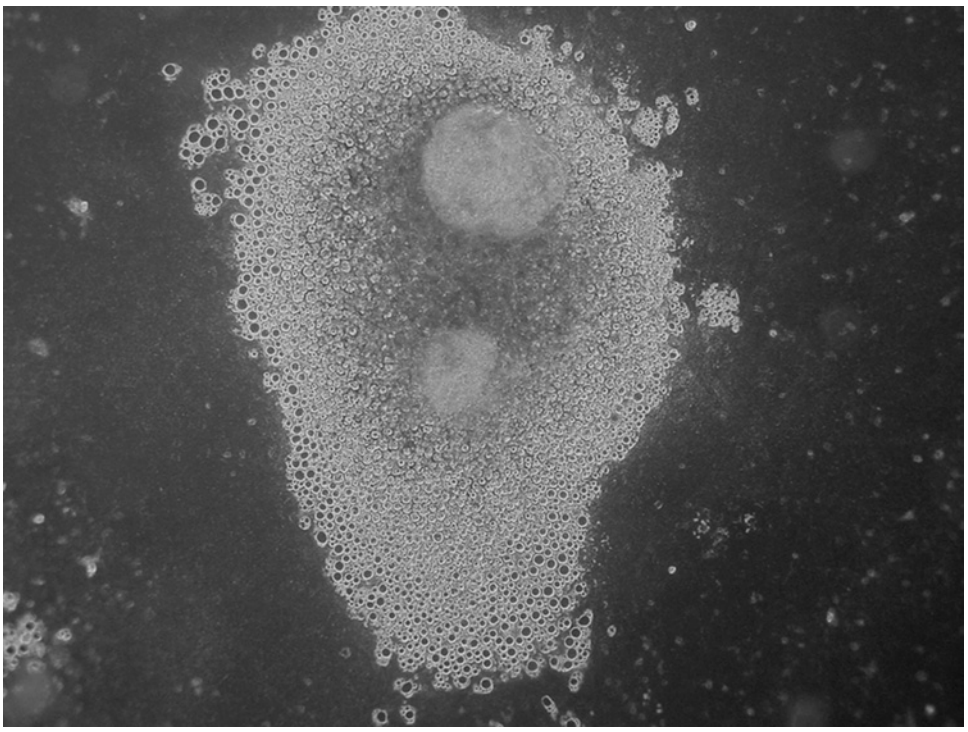

Figure 23.4.1 EB-derived adipocytes. ES cell–derived EBs were allowed to undergo adipocyte differentiation for 20 days. A large adipocyte colony around the dense center of an EB is visible under the microscope.

12. The day after plating, change the growth medium to differentiation medium. Change medium every other day.

    The addition of 0.5 μM rosiglitazone, which is a PPARγ activator (Lehmann et al., 1995), to the differentiation medium dramatically stimulates the terminal differentiation of RA-treated EBs into adipocytes (Phillips et al., 2003).

13. After 10 to 20 days in the differentiation medium, evaluate the cultures for adipocyte colonies (see Fig. 23.4.1).

    After 10 to 20 days at least 50% to 70% of EB outgrowths should contain adipocyte colonies.

SUPPORT PROTOCOL 1

MAINTENANCE OF MOUSE ES CELLS WITHOUT FEEDER LAYERS

The conditions outlined below are applicable for the maintenance of feeder layer–independent ES cell lines. Cells can be grown on gelatin-coated tissue culture flasks and maintained in a multipotent undifferentiated state by addition of leukemia inhibitory factor (LIF; Smith, 1992) to the growth medium.

Materials

ES cells in 25-cm^2 flasks (up to passage 25)
CMF-PBS (phosphate-buffered saline, calcium and magnesium free; Cambrex)
1× trypsin solution (see recipe)
Growth medium for mES cells (see recipe)
Leukemia inhibitory factor (Chemicon, Invitrogen)

20-ml conical centrifuge tubes, sterile
Gelatinized tissue culture 25-cm^2 flasks (see recipe)

Additional reagents and equipment for cell counting (*UNIT 1.1*)

1. For a 25-cm^2 flask containing ES cells, aspirate medium and wash twice each time with 5 ml CMF-PBS.
2. Aspirate the CMF-PBS and add 1 ml of 1× trypsin solution. Ensure the trypsin covers the cell monolayer and incubate for 2 to 3 min. Check that the cells are dissociated in single-cell suspension under an inverted microscope.

   It is critical to produce a single-cell suspension for subcultures. This is achieved by tapping the flask several times to ensure complete dissociation during the trypsin treatment.

3. Add 5 ml of growth medium to stop trypsinization and suspend the cells by vigorous pipetting.
4. Transfer the cells to a sterile 20-ml tube and centrifuge 5 min at 250 × *g*, room temperature.
5. Aspirate the medium and resuspend the cell pellet in 5 ml of growth medium by pipetting up and down two to three times. Count cells (*UNIT 1.1*).
6. Add 10^6 cells to 10 ml of prewarmed growth medium containing 1000 U/ml LIF then transfer to a freshly gelatinized 25-cm^2 flask.

   LIF is required to maintain pluripotent ES cells and is omitted to induce the commitment of ES cells towards the adipogenic lineage.

7. Change growth medium with LIF (1000 U/ml) every day.
8. Trypsinize the cultures 2 days later as in step 2.

   Cultures should be subcultured before cells have reached confluence.

DIFFERENTIATION OF HUMAN MULTIPOTENT ADIPOSE-DERIVED STEM (hMADS) CELLS TO ADIPOCYTES

Adipocyte differentiation of human multipotent adipose-derived stem (hMADS) cells and human mesenchymal stem (hMS) cells in vitro does not require pretreatment with RA. Induction of differentiation of hMADS cells and hMS cells is performed in monolayer culture. However, in contrast to hMADS cells, differentiation of hMS into adipocyte requires a differentiation medium supplemented with 10% fetal bovine serum (FBS).

Materials

Adult stem cells: hMADS (for isolation of hMADS cells see Rodriguez et al., 2005a; Zaragosi et al., 2006)
Growth medium for hMADS cells (see recipe)
Differentiation medium for hMADS cells (see recipe)
Tissue culture 100-mm dishes (Greiner, S.A. Dutscher) or 6-well plates or 12-well plates

1. Plate adult stem cells at a high density, e.g., 40,000 cells/cm^2 in 10 ml, 2 ml, or 1 ml growth medium, on tissue culture 100-mm dishes or 6- or 12-well plates, respectively.
2. When cells reach confluence (2 or 3 days after plating), change growth medium to differentiation medium containing 0.5 μM rosiglitazone.

   The addition of 0.5 μM rosiglitazone in the differentiation medium is required to differentiate cells into adipocytes.

3. Three days later, change cells to differentiation medium without IBMX and dexamethasone.

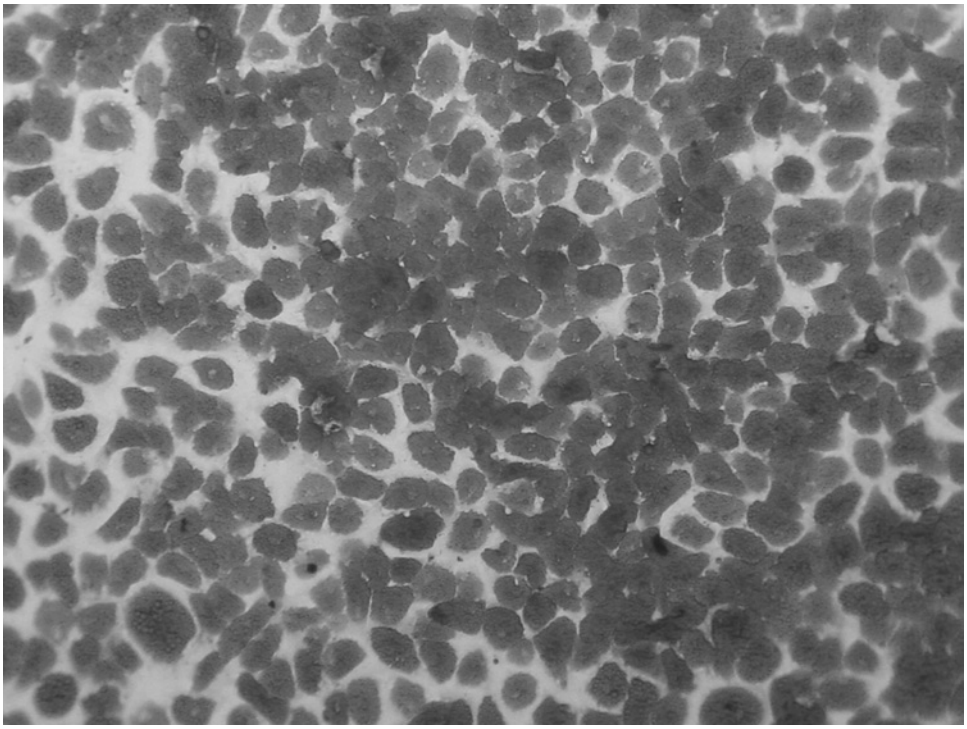

Figure 23.4.2 EB outgrowth fixed and stained with Oil-red O for fat droplets. For color version of this figure see *http://www.currentprotocols.com*.

4. Check the cultures for the appearance of adipocytes.

   Adipose cells contain lipid droplets which can be easily visualized microscopically, especially under bright-field illumination. Lipid droplets can also be visualized after staining with Oil-red O as indicated in Figure 23.4.2.

   Adipocytes should appear 5 to 7 days after induction of differentiation.

ALTERNATE PROTOCOL

DIFFERENTIATION OF HUMAN MS CELLS TO ADIPOCYTES

The same growth medium is used for hMADs cells and for hMS cells (see Reagents and Solutions). In contrast, the differentiation medium is different because hMS cells require 10% FBS to undergo differentiation into adipocytes, whereas adipocyte differentiation of hMADS cells occurs under a serum-free condition.

Materials

Adult stem cells: hMS cells (for isolation of adult stem cells from bone marrow see Pittenger et al., 1999)
Growth medium for hMS cells (see recipe)
Differentiation medium for hMS cells (see recipe)
Tissue culture 100-mm dishes or 6-well plates or 12-well plates (Greiner; S.A. Dutscher)

1. Plate cells at a high density, e.g. 40,000 cells/cm^2 in growth medium on tissue culture 100-mm dishes (or 6- or 12-well plates).
2. When cells reach confluence (2 or 3 days after plating), change growth medium to differentiation medium, containing 0.5 μM rosiglitazone.

   The addition of 0.5 μM rosiglitazone in the differentiation medium is required to differentiate cells into adipocytes

3. Three days later, change cells with differentiation medium without IBMX and dexamethasone.
4. Check the cultures for the appearance of adipocytes.

   Adipose cells contain lipid droplets which can be easily visualized microscopically, especially under bright-field illumination. Lipid droplets can also be visualized after stained with Oil-red O as indicated in Figure 23.4.2.

   Adipocytes should appear 5 or 7 days after induction of differentiation.

SUPPORT PROTOCOL 2

MAINTENANCE OF HUMAN MADS AND HUMAN MS CELLS WITHOUT FEEDER LAYER

No feeder layer and no gelatin-coated dishes are required to maintain the proliferation of hMADs cells and of hMS cells. The same growth medium is used to maintain both cell types.

Materials

hMADS or hMS cells (for isolation of hMADS see Rodriguez et al., 2005a; for isolation of hMS cells see Pittenger et al., 1999)
Phosphate-buffered saline, calcium and magnesium free (CMF-PBS, Cambrex)
1× trypsin -EDTA solution (Invitrogen no:25300-054)
Growth medium for hMADS and hMS cells (see recipe)
Tissue culture 100-mm dishes (Greiner; S.A. Dutscher)
20-ml conical centrifuge tubes, sterile
Additional reagents and equipment for cell counting (*UNIT 1.1*)

1. For a 100-mm dish of hMADS or hMS cells, aspirate medium and wash twice each time with 10 ml CMF-PBS.
2. Aspirate the CMF-PBS and add 1 ml of 1× trypsin solution. Ensure the trypsin covers the cell monolayer and incubate for 2 to 3 min. Check that cells are detached from the bottom of the dish by examining under an inverted microscope.
3. When the cells are detached, add 10 ml of growth medium to stop trypsinization and suspend the cells by pipetting.
4. Transfer the cells to a 20-ml sterile tube and centrifuge 5 min at 250 × *g*, room temperature.
5. Aspirate the medium and resuspend the cell pellet with 5 ml of growth medium by pipetting up and down 2 to 3 times. Count cells (*UNIT 1.1*).
6. Add 250 × 10^3 cells to 10 ml of prewarmed growth medium then transfer to a 100-mm dish.
7. Change medium every other day.
8. Trypsinize the cultures 3 to 4 days later as in step 1.

   Cultures should be subcultured before cells have reached confluence.

VISUALIZATION OF ADIPOCYTES

SUPPORT PROTOCOL 3

Adipose cells with lipid droplets are easily visualized microscopically, especially under bright-field illumination. Nonadipose cells containing structures resembling droplets are often detectable in untreated- and RA-treated ES cultures. Therefore, it is essential to identify droplet-like structures as triglyceride droplets. Staining of cultures with Oil-red O, a specific stain for triglycerides, gives a good indication of adipocyte differentiation.

Materials

Cultures to be examined
CMF-PBS (phosphate-buffered saline, calcium and magnesium free; Cambrex)
Fixation buffer (see recipe)
Oil-red O solution (see recipe)
Storage solution: 70% glycerol (v/v) in H_2O
Oil-red O elution buffer (see recipe)
Spectrophotometer

1. Aspirate medium from cultures and wash cells once with 10 ml CMF-PBS.
2. Fix cells for 15 min in 10, 2, or 1 ml fixation buffer in 100-mm dishes, 6- or 12-well plates, respectively, at room temperature.
3. Wash twice for 10 min each time with 10 ml Milli-Q water (for a 100-mm dish).
4. Stain with 10 ml Oil-red O solution for 15 min (for a 100-mm dish; stain with 2 ml or 1 ml Oil-red O for a 6- or 12-well dish, respectively).
5. Wash twice each time with 10 ml Milli-Q water. Cover cells with a film of storage solution (see Fig. 23.4.2) or elute the bound stain (step 6).

   Cells covered with storage solution can be kept at room temperature for several months.

6. Elute bound stain to quantify the formation of adipocytes. Incubate the 100-mm dish with 10 ml Oil-red O elution buffer (see reicpe) for 30 min at room temperature. Remove the solution.

7. After elution of the bound stain, measure the amount of bound Oil-red O spectrophotometrically at 490 nm.

SUPPORT PROTOCOL 4

ANALYSIS OF ADIPOCYTE GENE EXPRESSION

Finally, expression of a-FABP (adipocyte-fatty acid binding protein) an adipocyte-specific gene, in 20-day-old ES cell–derived EB or in 10-day-old differentiated human stem cells can be detected by northern blotting using 20 μg of total RNA. However, detection of the expression of these genes in early differentiating cells requires a more sensitive method such as RT-PCR. This protocol gives conditions to reveal mouse and human a-FABP gene expression.

Materials

TRI Reagent (Molecular Research Center, Euromedex, France)
Chloroform
Isopropanol
100% ethanol
5 M NaCl, sterile
TES buffer (see recipe)
RT-PCR kit (available from several companies)
Primers to reveal mouse a-FABP gene expression:
  forward: 5′-GATGCCTTTGTGGGAACCTGG-3′
  reverse: 5′-TTCATCGAATTCCACGCCCAG-3′
Mouse hypoxanthine phosphoribosyltransferase (HPRT, as a standard to balance the amount of RNA and cDNA used):
  forward: 5′-GCTGGTGAAAAGGACCTCT-3′
  reverse: 5′-CACAGGACTAGAACACCTGC-3′
Primers to reveal human a-FABP gene expression:
  forward: 5′-GCTTTGCCACCAGGAAAGTG-3′
  reverse: 5′-ATGACGCATTCCACCACCAG-3′
Human β-actin as a housekeeping gene standard:
  forward: 5′-AGCCATGTACGTTGCTA-3′
  reverse: 5′-AGTCCGCCTAGAAGCA-3′

RNAs are prepared using TRI Reagent according to the supplier's protocol.

Days of differentiation are indicated as 20 days for ES cells and 10 days for AS cells. The authors routinely obtain 100 to 200 μg RNA from one 100-mm tissue culture plate containing 20-day-old EB outgrowths or 10-day-old hMADS cells and hMS cells.

Using the abovementioned primers to reveal mouse a-FABP gene expression PCR is performed using an annealing temperature of 56°C and 25 cycles of PCR. The size of the expected cDNA is 213 bp. Mouse hypoxanthine phosphoribosyltransferase (HPRT) is used as a standard to balance the amount of RNA and cDNA used. With the abovementioned primers PCR is performed using an annealing temperature of 60°C and 25 cycles of PCR. The expected size of this cDNA is 249 bp.

Using the abovementioned primers to reveal human a-FABP gene expression PCR is performed using an annealing temperature of 55°C and 25 cycles of PCR. The size of the expected cDNA is 290 bp. Human β-actin is used as a standard. With the abovementioned primers PCR is performed using an annealing temperature of 55°C and 25 cycles of PCR. The expected size of this cDNA is 656 bp.

PCR products are separated and visualized by electrophoresis on a 2% (w/v) agarose gel containing ethidium bromide (see Voytas, 2000).

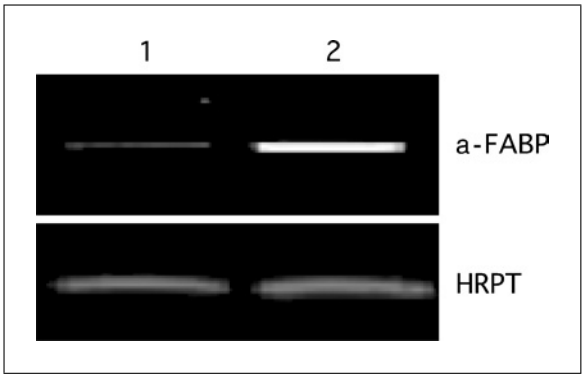

Figure 23.4.3 PCR analysis of expression of an adipocyte-specific gene. EBs were pretreated from day 2 to day 5 with 0.1% DMSO (1) or 10^{-7} RA (2). RNAs were prepared at day 20 after EB formation and transcripts for a-FABP. HPRT was used to monitor expression of a housekeeping gene.

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocols except as noted. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Dexamethasone, 1 mM

Dissolve 3.9 mg dexamethasone (powder; Sigma) in 10 ml ethanol. Store 0.5-ml aliquots up to 6 months at −20°C.

Differentiation medium for hMADS cells

To 25 ml of low-glucose DMEM (Invitrogen) add:
25 ml Ham's F12 (Cambrex)
0.5 ml 200 mM glutamine
0.5 ml 1 M HEPES-buffered saline (Cambrex)
0.5 ml 5000 IU/ml/5000 μg/ml penicillin/streptomycin (Cambrex)
0.5 ml 1 mg/ml transferrin
0.25 ml 1 mg/ml insulin (see recipe)
0.05 ml 100 mM IBMX (see recipe)
0.05 ml 1 mM dexamethasone (see recipe)
0.005 ml 2 μM T3 (see recipe)
Prepare fresh

The differentiation medium must be prepared just before use. Therefore, prepare only the volume of medium required for changing cells.

Differentiation medium for hMS cells

To 45 ml low-glucose DMEM (Invitrogen) add:
5 ml FBS
0.5 ml 200 mM glutamine
0.5 ml 1 M HEPES-buffered saline (Cambrex)
0.5 ml 5000 IU/ml/5000 μg/ml penicillin/streptomycin (Cambrex)
0.05 ml 100 mM IBMX (see recipe)
0.05 1 mM dexamethasone (see recipe)
0.25 1 mg/ml insulin (see recipe)
0.005 ml 2 μM T3 (see recipe)
Prepare fresh

The differentiation medium must be prepared just before use. Therefore, prepare only the volume of medium required for changing cells.

Differentiation medium for mES cells

Supplement growth medium for mES cells with:
0.5 μg/ml insulin (see recipe)
2 nM triiodothyronine (add from 2 μM T3 solution; see recipe)
0.5 μM rosiglitazone (provided by GlaxoSmthKline)
Prepare fresh

The differentiation medium must be prepared just before use. Therefore, prepare only the volume of medium required for changing cells.

Fetal bovine serum

Fetal bovine serum is tested for maintenance of the undifferentiated state. The authors select a batch of serum that is able to support the growth of stem cells. For that purpose, plate 10^6 ES cells/25-cm ^{2} flask in 10% of each set of FBS, supplemented with LIF, and subculture the cells every two days for 4 passages. For a high-quality serum, a flask should yield 5 to 10×10^6 cells at each passage. Furthermore, no toxicity of the selected serum should be observed at a 30% concentration.

The supplier used for this unit is Dutscher, France, but other suppliers can be used.

Fixation buffer

Dilute 2.5% glutaraldehyde (Sigma) to 0.25% (v/v) in CMF-PBS (Cambrex). Store up to 1 month at 4°C.

Gelatin 0.1% (w/v)

Dilute 2% (w/v) gelatin to 0.1% with CMF-PBS (Cambrex). Store up to 2 weeks at 4°C.

Gelatinized-tissue culture dishes/flasks

Add 5 or 10 ml of 0.1% gelatin (see recipe) per 25-cm^2 flask (Corning or Greiner) or 100-mm tissue culture dishes (Corning or Greiner Cell Star), respectively. Incubate for at least 10 min at room temperature and aspirate gelatin. Prepare fresh.

Growth medium for hMADS and hMS cells

To 500 ml low-glucose DMEM add:
5 ml 200 mM glutamine
5 ml 1 M HEPES -buffered saline (Cambrex)
5 ml 5000 IU/ml-/5000 μg/ml penicillin/streptomycin
50 ml FBS
Store up to 2 weeks at 4°C.

Growth medium for mES cell maintenance, 1×

To 440 ml Glasgow MEM/BHK21 medium (Invitrogen) add:
5 ml of 100× nonessential amino acids (stored at 4°C)
5 ml of 200 mM glutamine (stored at −20°C)
5 ml 100 mM sodium pyruvate (stored at −20°C)
0.5 ml 0.1 M 2 -mercaptoethanol (stored at 4°C; see recipe)
50 ml of FBS (stored at −20°C)
5 ml 5000 IU/ml/5000 μg/ml penicillin/streptomycin (Cambrex)
Store up to 2 weeks at 4°C

IBMX, 100 mM

Prepare IBMX (3-isobutyl-1methylxanthine; Sigma) at 100 mM in water. Dissolve 250 mg IBMX in 9 ml water and 5 to 10 µl of 10 N NaOH. Adjust volume to 11 ml with water and sterilize by filtration with a 0.22-µm filter. Store 0.1-ml aliquots up to 2 months at −20°C.

Insulin (for mES cells)

Dissolve lypholized insulin, —bovine for mouse cells; recombinant human (Sigma no. I-9278) for human cells—at 1 mg/ml in cold 0.01 N HCl. Mix gently and sterilize by filtration with a 0.22-µm filter. Store 0.1-ml aliquots up to 6 months at −20°C. Store thawed aliquots up to 2 weeks at 4°C.

2-mercaptoethanol, 0.1 M

100 µl 2-mercaptoethanol
14 ml sterile H_2O
Store up to 3 weeks at 4°C

Oil-red O elution buffer

4 M guanidinium thiocyanate (Sigma)
25 mM sodium citrate, pH 7
0.5% (v/v) sarcosyl
20% (v/v) isopropanol
Store up to 1 month at room temperature

Oil-red O solution

Oil-red O stock solution: Dissolve Oil red O (Sigma) at 0.5% (w/v) in isopropanol. Store up to several months at room temperature.

Oil red O working solution: Mix 6 vol of stock solution with 4 vol water. Mix and filter using a 0.45-µm filter. Store up to 1 month at room temperature.

Retinoic acid

Dilute all-*trans* retinoic acid (RA; Sigma) in the dark in dimethyl sulfoxide to prepare a 10 mM RA stock solution. Store 0.1-ml aliquots up to 1 year at −20°C, protected from the light.

Prepare subsequent dilutions of RA in ethanol and use for one experiment only.

After dilution into the culture medium, the concentration of ethanol should never exceed 0.1%.

TES buffer

10 mM Tris·Cl, pH 7.4 (*APPENDIX 2A*)
0.1 mM EDTA
0.1% (w/v) sodium dodecyl sulphate
Sterilize by autoclaving
Store up to several months at room temperature

Transferrin, 1 mg/ml

Dissolve apo-transferrin (human; Sigma) at 1 mg/ml in PBS (*APPENDIX 2A*) and sterilize by filtration with a 0.22-µm filter. Store 1-ml aliquots up to several months at −20°C. Store thawed aliquots up to 1 week at 4°C.

Triiodothyronine (T3), 2 μM

Dissolve 5 mg T3 (culture tested, powder; Sigma) into 7.43 ml ethanol to prepare a 1 mM T3 solution. Then, dilute 200 μl of 1 mM solution into 4 ml ethanol to prepare a 50 μM T3 solution. Finally, dilute 3.2 ml of 50 μM T3 solution into 80 ml ethanol to prepare a 2 μM T3 solution. Store up to 1 year at −20°C.

Trypsin solution, 1× for mES cells

1 ml 2.5% (w/v) trypsin (Invitrogen)
1 ml 100 mM EDTA
1 ml chicken serum
100 ml CMF-PBS (*APPENDIX 2A*)
Store 10-ml aliquots up to 2 months at −20°C
Store thawed aliquots up to 2 weeks at 4°C

COMMENTARY

Background Information

Mouse embryonic (ES) cells have been previously shown to differentiate spontaneously into various lineages in culture (Doetschman et al., 1985). The first morphological observation of adipocyte-like cells derived from ES cells was reported by Field et al. (1992). However, the number of ES cell–derived adipocytes was low because spontaneous commitment of ES cells to the adipogenic lineage is rare. In order to use ES cells to study adipocyte development it was essential to determine conditions of culture that committed ES cells to the adipogenic lineage at a high rate. This step has been achieved by showing that a prerequisite is to treat ES cell–derived embryoid bodies (EBs) at an early stage of their differentiation with all-*trans*-retinoic acid (RA) for a short period of time (Dani et al., 1997; Dani, 1999). Adipocytes derived from ES cells display both lipogenic and lipolytic activities in response to insulin and to β-adrenergic agonists respectively, indicating that mature and functional adipocytes are formed.

In regard to models of human cells presently available, for primary preadipocytes derived from stromal-vascular cells of human adipose tissue, with increasing passage number, the ability to differentiate into adipocytes under appropriate conditions undergoes a dramatic decrease before the cells become growth arrested and enter replicative senescence (Ailhaud, 2002). This limitation has been partly circumvented with cells that are immortalized either genetically or spontaneously while preserving their ability to undergo adipose conversion. Overexpression of SV40T and T antigens in human SV cells from infant brown adipose tissue (Zilberfarb et al., 1997) or coexpression of human telomerase reverse transcriptase and papilloma E7 oncoprotein in SV cells from adult white adipose tissue (Darimont et al., 2003) led to establishment of PAZ6 and Chub-S7 preadipocyte cell lines, respectively. Cells isolated from subcutaneous adipose tissue of an infant suffering from Simpson-Golabi-Behmed syndrome and from an adult suffering from liposarcoma were used to obtain SGBS preadipocyte cell strain and LiSa-2 preadipocyte cell line, respectively (Wabitsch et al., 2000, 2001). Upon differentiation, cells from these various lines expressed some of the characteristic markers of human adipocytes but the lipolytic responses specific of human adipocytes and the secretion of specific adipocytokines were not reported. Moreover, except for Chub-S7 cells which were diploid and showed no chromosomal alterations, cells from other lines exhibited chromosomal abnormalities. Recently, the establishment of multipotent stem cells from the stromal-vascular fraction of infant adipose tissue (Rodriguez et al., 2005a) has led the authors to examine, under serum-free adipogenic conditions, whether these human multipotent adipose-derived stem (hMADS) cells enter the adipose lineage and differentiate into cells that exhibit characteristics of human fat cells. The authors have shown that hMADS cells are a unique cell model in displaying the key features of human adipocytes after differentiation under adipogenic conditions (Rodriguez et al., 2004, 2005b). The human adult bone marrow also contains mesenchymal stem (hMS) cells that are able to undergo differentiation into adipocytes in vitro (Pittenger et al., 1999).

Critical Parameters and Troubleshooting

The first critical parameter for the commitment of mES cells into adipocytes is the formation of EBs. The authors use the hanging drop method for the formation of EBs. The formation of EBs in mass culture by maintaining ES cells in suspension at a high density in non-tissue culture grade plastic is rapid and gives rise to a high number of EBs formed. However in the hands of the authors, this method leads subsequently to a low number of outgrowths containing adipocyte colonies.

The, treatment of EBs with RA between day 2 and 5 after EB formation is prerequisite. The authors have observed that treatment of EBs with RA between days 2 and 5 after EB formation or between days 3 and 6 gives similar results. Owing to the high instability of RA, the concentration of RA able to commit ES cells into the adipogenic lineage at a high rate should be determined for each new preparation of RA (try 10^{-8} to 10^{-6} M). RA is light-sensitive.

Adipocyte differentiation of hMADS cells and hMS cells in vitro does not require pretreatment with RA. However, activators of PPARγ such as rosiglitazone, is required for the terminal differentiation of these stem cells into adipocytes.

hMS cells can be expanded for several passages in vitro. However, in the hands of the authors these cells lose their capacity to undergo differentiation after 15 passages. In contrast, hMADS cells can be maintained for 30 passages with no loss of their ability to undergo adipocyte differentiation.

Anticipated Results

The authors usually pool 2-day-old EBs from four lids of 100-mm bacteriological petri dishes into one 60-mm bacteriological grade petri dish. After RA treatment, EBs contained in one 60-mm dish are plated into one 100-mm tissue culture dish. Under these conditions development of more than 100 EBs can be observed. Twenty days after EB formation, 50% to 70% of EBs contain adipocyte colonies. Over 25 passages, adipocyte differentiation may decrease. In regard to the differentiation of adult stem cells, the authors usually perform differentiation in 24-well plates when monitoring differentiation by Oil-red O staining, and into 60-mm plates, or larger plates, for RNA preparation. Ten days after induction of differentiation, 50% to 90% of hMADS and hMS cells are differentiated into adipocytes. The level of differentiation may decrease over 25 passages of hMADs cells and over 10 passages of hMS cells.

Time Considerations

From mES, adipocytes can be observed 10 days after EB formation. However, 20 days in differentiation medium are required to complete adipocyte differentiation. Additions of PPARγ activator dramatically increase the kinetics and the level of adipocyte differentiation of ES cells. From human adult stem cells, adipogenesis is completed within 2 weeks. In that case PPARγ activator is required.

Induction of ES Cell–Derived Cartilage Formation

Embryonic stem (ES) cells are generated from the inner cell mass of the blastocyst (Evans and Kaufman, 1981; Martin, 1981). Therefore, these cells are pluripotent, and if they are cultivated in vitro as cellular aggregates—so called embryoid bodies (EBs)—they spontaneously differentiate into various cell types of all three germ layers (Rathjen et al., 1998). The ES cell model system of in vitro differentiation is useful to analyze cell differentiation from a pluripotent stem cell to progenitor cells, and, finally, to terminally differentiated cell types (for review, see Guan et al., 1999; Rohwedel et al., 2001). This unit contains protocols for ES cell differentiation to chondrocytes and osteocytes (Basic Protocol 1 and Alternate Protocol) and for characterization of the differentiated cell types (Kramer et al., 2000; Hegert et al., 2002).

The authors analyze chondrogenic and osteogenic differentiation in EBs by histochemical staining (Support Protocols 1 to 6), immunostaining (Support Protocol 7), mRNA in situ hybridization (Support Protocol 8), RT-PCR techniques (Support Protocol 9), and electron microscopy (Support Protocol 10; Kramer et al., 2000; 2005a,b). Chondrocytes are organized in cartilage nodules, which develop from aggregates of mesenchymal prechondrogenic cells (Basic Protocol 2). Later, chondrogenic cells within these nodules become hypertrophic and finally show characteristics of osteogenic differentiation (Hegert et al., 2002). In contrast to other mesodermal cell types, such as cardiac muscle cells, the amount of cartilage nodules is relatively low in EBs derived from ES cell line D3 (Kramer et al., 2005a). However, cartilage nodule formation can be induced, for example by growth factors of the TGF-β family (Kramer et al., 2000). Another important factor involved in modulating ES cell–derived cartilage formation is the basal medium and its basic supplementations (see Commentary).

For regenerative strategies, ES cell–derived chondrocytes have to be selected from EBs to enrich chondrogenic cells and to avoid teratoma formation by undifferentiated ES cells. For example, ES cells formed teratomas and destroyed the ambient tissue if they were injected in an undifferentiated stage into knee joints of mice (Wakitani et al., 2003). The authors of this unit isolated chondrocytes from cartilage nodules using microdissection (Basic Protocol 2) and collagenase treatment (Basic Protocol 3; Hegert et al., 2002) and analyzed their differentiation behavior in culture. These single ES cell–derived chondrocytes possess a high potential for regeneration, indicated by a rapid redifferentiation after an initial dedifferentiation. However, transdifferentiation into other mesodermal cell types was observed in the chondrocyte single-cell cultures (Hegert et al., 2002). Therefore, it may be necessary to improve the selection strategies to obtain defined cell populations before ES cell–derived chondrocytes can be used for therapeutic applications.

The model system of ES cell–derived chondrogenesis described in this unit can also be used to analyze the influence of different parameters—e.g., signaling molecules, growth factors, and extracellular matrix molecules—on cellular chondrogenic development. In particular, the authors have studied growth factor modulation of ES cell–derived chondrocyte differentiation in vitro (Kramer et al., 2000, 2003; Hegert et al., 2002).

In vivo, murine ES cells are used to generate knockout mice, which enable study of the phenotypic consequences of a gene mutation that has been established in vitro in ES cells via gene targeting. This is possible because genetically modified ES cells take

Current Protocols in Cell Biology (2007) 23.5.1-23.5.33

part in the development of all somatic tissues and most importantly, germ cells, after injection into blastocysts (Thomas and Capecchi, 1987). However, frequently, embryos carrying a homozygous knockout mutation die shortly after implantation. In this case, in vitro differentiation of homozygous knockout ES cells is an excellent alternative approach to analyze the consequences of a loss-of-function mutation at the cellular level. Therefore, the model system of ES cell–derived chondrogenesis in vitro can be used to characterize the function of specific genes during cartilage formation. For example, the authors investigated the consequence of a knockout mutation of the transcription factor Sox9 on ES cell–derived chondrogenesis in vitro (Hargus et al., submitted). In vivo studies have shown that Sox9 plays an important role during chondrogenesis (Bi et al., 1999; Akiyama et al., 2002). The authors tested EBs generated from homozygous Sox9-deficient ES cells for their cartilage differentiation in vitro and found that $Sox9^{-/-}$ cells failed to develop into cartilage nodules (Hargus et al., submitted). This result is in line with the previous in vivo studies.

Taken together, the ES cell in vitro model system is an alternative approach to in vivo studies with embryos and can be used to characterize cellular events of chondrogenic differentiation. In this unit, some basic techniques for ES cell cultivation and for differentiation into the chondrogenic direction in vitro are provided, along with protocols to characterize chondrogenic differentiation of ES cells by histochemical staining, immunofluorescence methods, mRNA-in situ hybridization, RT-PCR technique, and electron microscopy. Moreover, the authors of this unit review how ES cell–derived chondrogenic differentiation can be modulated by growth factors and discuss studies demonstrating chondrogenic differentiation of ES cells.

STRATEGIC PLANNING

Successful ES cell cultivation requires knowledge and experience with basic cell culture techniques like thawing, trypsinization, and freezing of cells. For isolation and ultrastructural analysis of chondrogenic aggregates from EBs, microdissection and electron microscopy techniques have to be established. For differentiation of ES cells, two principal methods can be used: (1) ES cells can simply be cultivated in bacteriological petri dishes where they form EBs spontaneously, or (2) ES cells can be cultivated via the hanging-drop method to obtain EBs. The advantage of the latter technique is that EBs of the same size are obtained, which enables a more reproducible differentiation process. Therefore, this unit provides detailed protocols for differentiation of ES cells via hanging drops (Basic Protocol 1). ES cell differentiation also requires advanced development of a time schedule (see Table 23.5.1) for the specific study and calculation of the number of EBs needed. The hanging-drop cultivation is performed for 2 days (days 0 to 2) to obtain the EBs, followed by cultivation of EBs in suspension for 3 days (days 2 to 5) and plating of EBs on the fifth day of differentiation (day 5). After plating, the EBs grow out and are subsequently cultivated for up to 35 days (day 5 plus 35 days). Initially, before plating of EBs (days 0 to 5), samples of 25 EBs are taken every day for RT-PCR analysis (a total of 125 EBs). Later, after plating of EBs, samples are analyzed every second to fifth day by RT-PCR, histochemical staining, immunostaining, or mRNA in situ hybridization (ten EBs per sample and per method). For isolation of chondrogenic cells from EBs, it is necessary to obtain sufficient amounts of chondrogenic aggregates in the EBs for microdissection. Ten 60-mm tissue culture plates, each with ten EBs, have to be prepared for every sample. Initially, every hanging drop contains 800 ES cells resulting in one single EB. These details have to be considered in advance to calculate the quantity of undifferentiated ES cells that have to be generated before the onset of the differentiation experiment. The standard ES cell protocol is based on the assumption that a 60-mm tissue culture plate with undifferentiated ES cells contains around 1×10^6 cells after 2 days of cultivation. However, to achieve this quantity of cells, the size and morphology of the ES

Table 23.5.1 A Time Schedule Useful for an ES Cell Differentiation Experiment[a]

	Monday	Tuesday	Wednesday	Thursday	Friday	Saturday	Sunday
1st week			Thaw feeder	Split feeder	Inactivate feeder		
2nd week	Thaw ES cells		0 days R	R	2 days R	R	R
3rd week	5 days R		5+2 days R,H	I	5+4 days R,H		
4th week	5+8 days R,I,H		5+10 days R,H	I	5+12 days R,H		
5th week	5+15 days R,I,H		5+17 days R,H	I	5+19 days R,H		
6th week	5+22 days R,I,H		5+24 days R,H	I	5+26 days R,H

8th week	5+36 days R,I,H						

[a]Hanging-drop cultivation of ES cells (Basic Protocol 1) is performed to generate embryoid bodies (EBs) in vitro. In general, 2 days after thawing, a sufficient number of ES cells for one differentiation experiment is obtained. The hanging-drop cultivation is performed for 2 days (days 0 to 2) to generate the EBs, followed by cultivation of EBs in suspension for 3 days (days 2 to 5) and plating of EBs on the fifth day of differentiation (day 5). After plating, the EBs grow out and are cultivated subsequently for up to 35 days (day 5 plus 35 days). Initially, RNA probes (R) for RT-PCR analysis are collected every day (days 0 to 5). Later, specimens for RT-PCR analysis and histochemical stainings (H) are taken approximately every second day. Indirect immunostaining and in situ hybridization (I) are performed twice a week, for example on Monday and Thursday. Samples for electron microscopy are collected at day 5 plus 10 days (mesenchymal condensations) and at day 5 plus 22 days (cartilage nodules), respectively.

cell colonies has to be controlled carefully by light microscopy (see Critical Parameters). A total of 1×10^6 ES cells can be used to generate 1250 EBs. The murine ES cell lines BLC6 (Wobus et al., 1988), D3 (Doetschman et al., 1985), E14 (Hooper et al., 1987), and R1 (Nagy et al., 1993) have been successfully used by the authors. Line BLC6 is most effective with respect to cartilage nodule formation (Kramer et al., 2005a). In general, all analyzed ES cell lines showed spontaneous chondrogenic differentiation. However, an important consideration with respect to the differentiation efficiency is the use of growth factors to enhance chondrogenic differentiation. For example, chondrogenic differentiation of murine ES cells can be enhanced by the addition of BMB-2 and/or BMP-4 to the differentiation medium (for details, see Commentary).

NOTE: All solutions and equipment coming into contact with cells must be sterile, and proper aseptic technique should be used accordingly.

NOTE: All culture incubations should be performed in a humidified 37°C, 5% CO_2 incubator unless otherwise specified.

IN VITRO DIFFERENTIATION OF EMBRYONIC STEM CELLS FROM EMBRYOID BODIES

BASIC PROTOCOL 1

Pluripotent ES cells differentiate spontaneously into cells of all three primary germ layers. ES cells can be differentiated into chondrogenic and osteogenic cell types by cultivation as cellular aggregates, so called embryoid bodies (EBs), generated by hanging drops. The major steps of ES cell differentiation are: (1) generation of EBs by hanging-drop cultivation of ES cells for 2 days (days 0 to 2); (2) cultivation of the EBs in suspension for 3 days (days 2 to 5); and (3) plating of the EBs at the fifth day of differentiation (day 5), followed by further cultivation up to 35 days (day 5 plus 35 days; Table 23.5.1).

Materials

ES cell lines BLC6 (Wobus et al., 1988), D3 (Doetschman et al., 1985), E14 (Hooper et al., 1987), and/or R1 (Nagy et al., 1993) growing (Support Protocol 12) on feeder layers (Support Protocol 11) in Medium 2 (see recipe) and Medium 4 (see recipe)

Phosphate-buffered saline (PBS; see recipe)
Trypsin/EDTA solution (see recipe)
Medium 2 (see recipe) and Medium 4 (see recipe)
Low-FBS medium (see recipe)

100-mm bacteriological petri dishes (Greiner), uncoated
100-µl sterile pipet tips with aerosol-filter barriers (Eppendorf)
5-ml glass pipets
Gelatin-coated (see recipe) 60-mm tissue culture dishes (Nunc), chamber slides (Falcon CultureSlides from BD Biosciences), and 24-well tissue culture plates

Additional reagents and equipment for basic cell culture techniques including counting cells (*UNIT 1.1*)

Cultivate ES cell in hanging drops

For the differentiation analysis described in Table 23.5.1, 475 EBs with 800 cells/EB must be prepared. In addition, ~40,000 ES cells are used for RNA isolation (at day 0). In total, 420,000 ES cells are necessary for the analysis. However, one should not use all cultivated ES cells for a single differentiation experiment, but should leave some that can be further cultivated in the undifferentiated state for freezing (see Support Protocol 12). A 60-mm dish contains $\sim 1 \times 10^6$ ES cells (if carefully cultivated), as mentioned in Strategic Planning. The authors thus suggest that two 60-mm dishes be prepared: one for the differentiation analysis and one for further cultivation.

1. Wash cells in dish once with 4 ml PBS. Trypsinize undifferentiated ES cells cultivated on MEF feeder layer in medium 2 in 60-mm dishes by adding 2 ml trypsin/EDTA solution. When the cells are dissociated pipet up and down and transfer the cells to a 15-ml centrifuge tube with 10 ml medium.

   The undifferentiated ES cells are grown, subcultivated, and cropreserved as in Support Protocol 12; feeder layers are produced as in Support Protocol 11.

2. Centrifuge 5 min at 180 × g, room temperature. Remove and discard supernatant.

3. Resuspend cells in 2 ml of Medium 4 and determine the cell number (*UNIT 1.1*).

   The authors use 800 ES cells per EB for differentiation into chondrogenic and osteogenic cells.

4. Dilute cells in Medium 4 to obtain a cell suspension with 4×10^4 cells/ml.

   For cell dilution, it is helpful to use a small sterile beaker with a diameter of 4 cm for preparing the cell suspension. The 20-µl drop samples are then transferred with a micropipettor under sterile conditions.

5. Place ~50 20-µl aliquots of the cell suspension on the inner side of the lid of a 100-mm uncoated bacteriological petri dish, using a micropipettor with sterile 100-µl tips containing aerosol-filter barriers (see Fig. 23.5.1).

   If using gloves for cell culture handling, the electrostatic charge of the petri dish lid can cause the drops to flow together. Therefore, avoid touching the lids outside on the top.

6. Place 10 ml PBS into the bottom of the petri dish (to avoid evaporation of the hanging-drop medium during cultivation). Carefully invert the lid containing the drops of ES suspension onto the bottom of the petri dish to create the hanging drops. Culture the hanging drops for 2 days at 37°C (day 0 to day 2).

Cultivate EBs in suspension (day 2 to day 5)

7. On the second day of hanging-drop culture, collect the drops containing the EBs from two petri dishes (containing ~50 drops per lid) by flooding the inverted lid

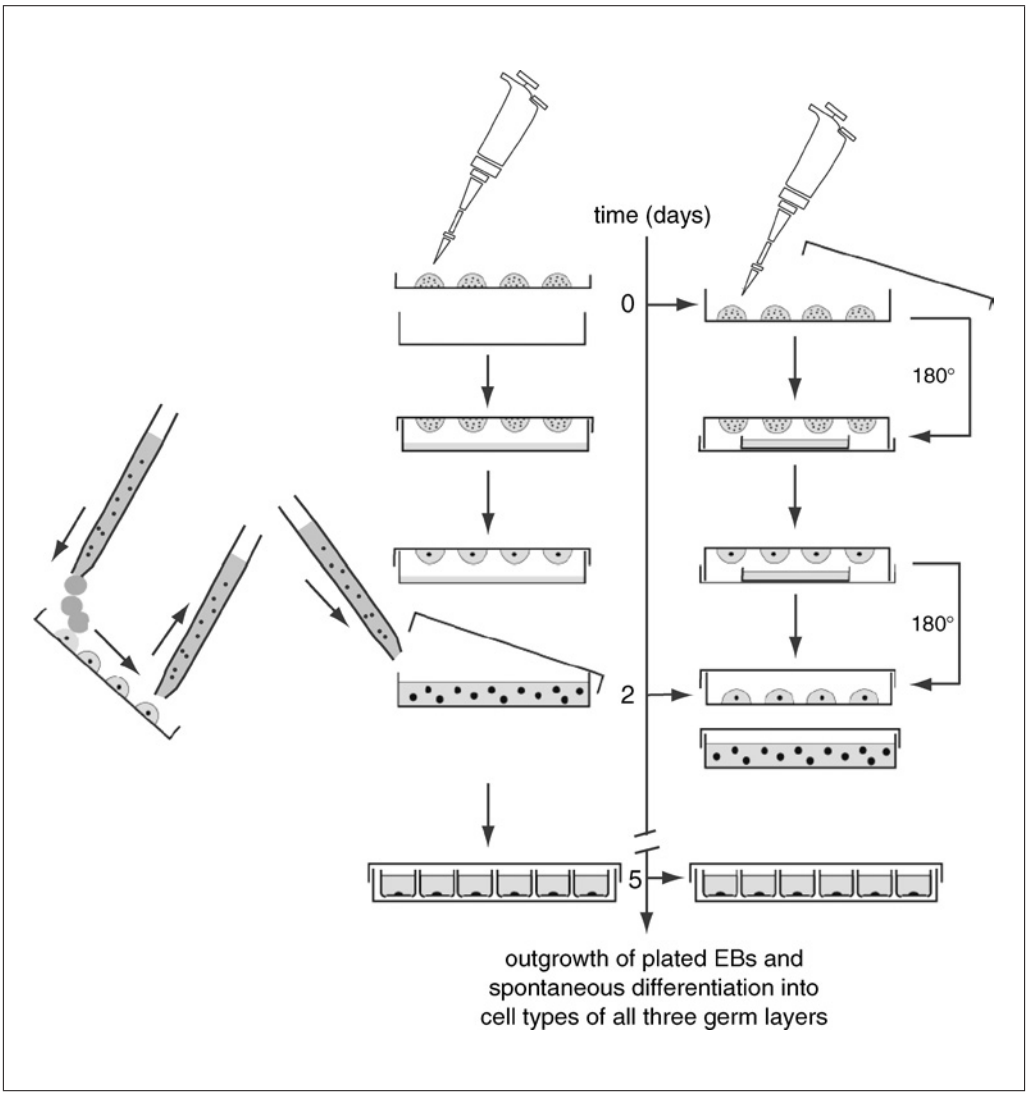

Figure 23.5.1 Schematic illustrating Basic Protocol 1 (left) and Alternate Protocol (right) for "hanging drop" cultivation of embryonic stem cells as embryoid bodies (EBs). The Alternate Protocol may provide the advantage of easier handling.

containing the drops with 2 ml of Medium 4 and then aspirating with a 5-ml glass pipet.

Do not do this if following the Alternate Protocol; also see Figure 23.5.1.

8. Place 8 ml of fresh Medium 4 into the bottom of an uncoated 100-mm bacteriological petri dish. Pool the EBs collected from the lids of the two dishes in step 7 in this dish.

   It is important to select a batch of bacteriological petri dishes that enable suspension culture. With some batches, the EBs attach, even if the dishes are not coated with gelatin. If this happens, it is sometimes possible to resuspend the EBs again by carefully rinsing the dishes with Medium 4.

9. Cultivate the EBs in suspension for 3 days (day 2 to day 5).

Plate EBs (day 5) and analyze

10. On the fifth day of differentiation (day 5), plate the appropriate number of EBs (see Table 23.5.2) onto gelatin-coated 60-mm tissue culture dishes (for Alcian blue staining, RT-PCR, microdissection, and electron microscopy), gelatin-coated chamber slides (for immunostaining, mRNA in situ hybridization, and most histochemical staining), and gelatin-coated 24-well plates (for morphological

Table 23.5.2 Conditions for Setting Up EB Cultures

Culture container	Number of EBs	Volume medium (ml)	Used for
60-mm petri dish	10	4	Alcian Blue staining, RT-PCR, microdissection, electron microscopy
2-chambered slide	5/chamber	2.5/chamber	Immunostaining, mRNA in situ hybridization, histochemistry
24-well plate	1/well	1/well	Morphological analysis

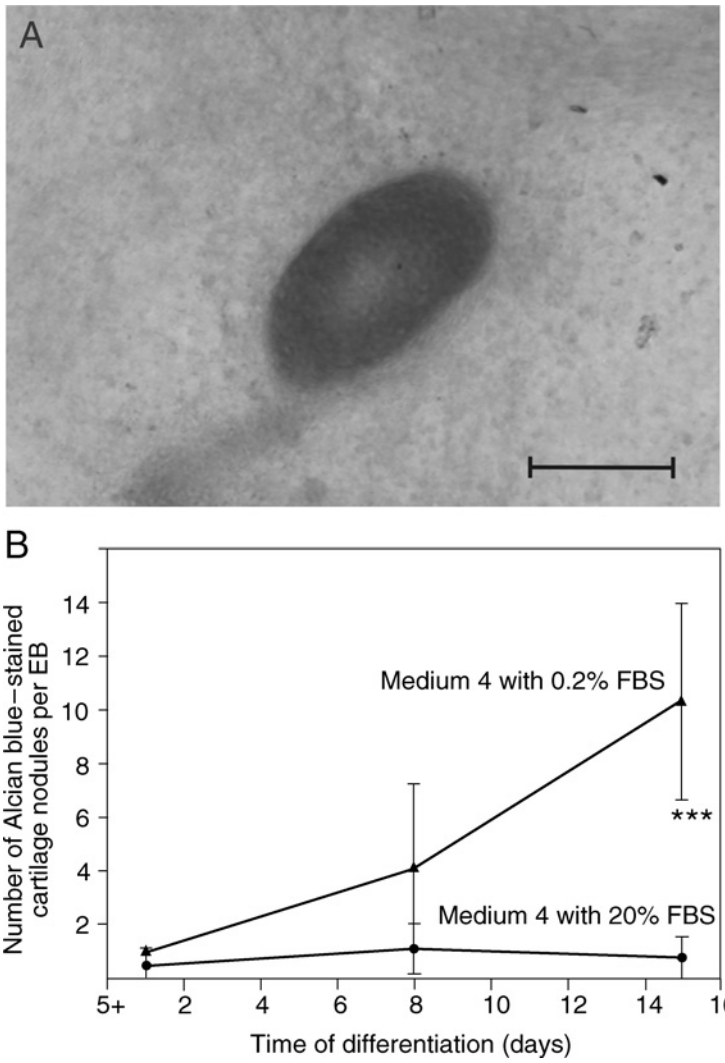

Figure 23.5.2 (**A**) Alcian blue staining demonstrates ES cell–derived cartilage nodule formation. (**B**) Cultivation of embryoid bodies (EBs) under low-serum conditions (0.2% FBS) after EB plating significantly enhanced the number of Alcian blue–positive cartilage nodules per EB. Bar = 100 μm. For the color version of this figure go to *http://www.currentprotocols.com*.

analysis) containing the appropriate volume of Medium 4 as listed in Table 23.5.2. Transfer EBs using a micropipettor with sterile 100-μl aerosol-filter barrier tips into the Medium 4 and handle the dishes very carefully during the first 2 days of culture to allow the EBs to attach.

11. Initially, change the medium after 4 and 8 days.

    In currently running studies the authors use Medium 4 with low FBS (0.2%) for chondrogenic differentiation of ES cells. This low-FBS medium (see recipe) is applied from 2 days after plating (day 5 plus 2 days) up to the end of EB cultivation. Medium is changed every 4 days. Up to the first 2 days after plating, Medium 4 (with 20% FBS) is used. Low-FBS conditions then induce cartilage nodule formation (see Fig. 23.5.2).

12. During further cultivation steps, up to 35 days after plating (day 5 plus 35 days) renew the medium about every second day.

13. To study the differentiation process, analyze samples every second to fifth day (see Table 23.5.1).

ALTERNATIVE PLATING METHOD FOR GENERATING EBs OF THE SAME SIZE

ALTERNATE PROTOCOL

This Alternate Protocol simplifies the "hanging drop" method (Basic Protocol 1), which is used as a standard protocol to obtain same-sized EBs. The Alternate Protocol is presented as an optional way to generate EBs of the same size.

For materials, see Basic Protocol 1.

1. Prepare cell suspension for hanging-drop-cultivation (see Basic Protocol 1, steps 1 to 4).

2. Place ~50 20-µl aliquots of the cell suspension on the inner side of the bottom of a 100-mm bacteriological petri dish (not the lid, in contrast to Basic Protocol 1), using a micropipettor with sterile 100-µl tips containing aerosol-filter barriers (see Fig. 23.5.1).

3. Place an open 60-mm culture dish filled with 4 ml PBS onto the lid of the bacteriological petri dish to avoid evaporation of the drops. Carefully invert the bottom of the petri dish containing the drops of ES onto the lid to create the hanging drops. Culture the hanging drops for 2 days at 37°C (day 0 to day 2).

4. Remove the PBS-filled 60-mm culture dish at the second day of hanging drop-culture, then turn the bacterial petri dish over to its normal configuration (see Fig. 23.5.1).

5. Add 8 ml Medium 4 to each 100-mm bacteriological petri dishes with the drops of EBs that are now at the bottom.

6. Cultivate EBs in suspension for 3 days (day 2 to day 5).

7. Follow Basic Protocol 1, steps 10 through 13, for plating of EBs.

MICRODISSECTION AND CHARACTERIZATION OF MESENCHYMAL CONDENSATIONS AND CARTILAGE NODULES FROM EBs

BASIC PROTOCOL 2

Mesenchymal condensations containing chondrogenic precursors are isolated around 10 days after EB plating (day 5 plus 10 days), and cartilage nodules with mature chondrocytes are isolated around 20 days after plating (day 5 plus 20 days) using either a microdissector or a microscalpel. Condensations and nodules can be easily detected by their specific morphology (Kramer et al., 2005b). EBs are cultivated as in Basic Protocol 1 (steps 1 through 11) or the Alternate Protocol (steps 1 through 7). To characterize the differentiation stage of the cells, samples of these isolated chondrogenic aggregates are investigated for expression of collagen marker proteins by immunostaining of cryosections (Hegert et al., 2002) and analyzed by ultrastructural analysis using electron microscopy.

Materials

EB cultures, (day 5 plus 10 days *or* day 5 plus 20 days; see Basic Protocol 1 or Alternate Protocol)
Tissue-Tek OCT compound (Sakura Finetek)
Acetone
Phosphate-buffered saline (PBS; see recipe)

Microscalpel or microdissector (Eppendorf)
Tissue-Tek Cryomold 10 × 10 × 5–mm (Sakura Finetek; *http://www.sakuraus.com/*)
Cryostat (Leica)
Vectabond-coated glass microscope slides (Vector)

Additional reagents and equipment for indirect immunostaining (Support Protocol 7)

1. Select nodules from EB cultures (day 5 plus 10 days or day 5 plus 20 days).
2. Microdissect the nodules and place them in ∼0.5 ml Tissue-Tek OCT compound in a Tissue-Tek Cryomold for embedding.

   Microdissection is performed using a commercially available microdissector (Eppendorf). The procedure to isolate cartilage nodules using this device is outlined in detail in Eppendorf Applications No. 48 (follow the "Applications" link at http://www.eppendorf.com).

3. Freeze the samples at −20°C.
4. Prepare 10-μm cryosections using a cryostat and plate onto Vectabond-coated slides.
5. Dry the sections in air.
6. Fix in acetone for 10 min at −20°C.
7. Perform indirect immunostaining (see Support Protocol 7, steps 3 to 10).

BASIC PROTOCOL 3

ISOLATION OF CELLS FROM SELECTED CARTILAGE NODULES BY COLLAGENASE TREATMENT

Chondrogenic cells can be isolated from cartilage nodules microdissected from EBs to analyze their behavior in single-cell cultures.

Materials

Microdissected nodules from EB cultures (Basic Protocol 2, steps 1 to 2)
0.1% (w/v) collagenase in Medium 4 (see recipe for Medium 4)
Medium 4 (see recipe)
Gelatin-coated (see recipe) or collagen II-coated 60-mm tissue culture dishes *or* chamber slides

Shaking water bath or incubator
15-ml centrifuge tubes
Centrifuge

Additional reagents and equipment for basic cell culture techniques including counting cells (*UNIT 1.1*)

1. Incubate ten microdissected nodules in 5 ml of 0.1% collagenase solution for 50 min at 37°C, with moderate shaking, to obtain a single-cell suspension.
2. Transfer the cells to a 15-ml centrifuge tube. Centrifuge the cells for 5 min at 180 × *g*, room temperature. Discard the supernatant.

3. Resuspend the cell pellet in 2 ml Medium 4 and count the cells (*UNIT 1.1*). Plate the cells at high density onto gelatin- or collagen II–coated 60-mm tissue culture dishes ($1–2 \times 10^5$ cells per 60-mm dish) or onto chamber slides (2.1×10^4 cells/well).

   Use 60-mm dishes for total RNA isolation or chamber slides for immunostaining and histochemical staining.

4. Culture cells at 37°C in Medium 4.

   The cellular processes of de-, re-, and transdifferentiation can be investigated using the isolated ES cell–derived chondrocytes (for details see Hegert et al., 2002).

HISTOCHEMICAL STAINING OF EB

Histochemical staining of EBs is performed after plating of EBs from day 5 plus 2 days up to about day 5 plus 35 days at regular intervals of about 2 days. Alcian blue staining (Support Protocol 2) is used as a fast screen for detection of cartilage nodules (see Figure 23.5.2A). Alcian blue selectively stains muco-substances, in particular cartilage-specific proteoglycans. Alizarin red (Support Protocol 3) forms chelate conjugates with bivalent cations (mainly with calcium), and is therefore used to detect bone nodule formation. In addition, von Kossa staining (Support Protocol 4) is performed to visualize bone nodule formation due to ion exchange (calcium ions are replaced by silver), which depends on the influence of daylight. ES cell–derived adipogenic differentiation can be demonstrated by cell staining with the vital dye Sudan III (Support Protocol 5), which can be tracked directly by light microscopy.

Fixation for Histochemical Staining

SUPPORT PROTOCOL 1

The specimens must be fixed before histochemical staining (except for Sudan III and AP staining).

Materials

Cultures with differentiating EBs (Basic Protocol 1), day 5 plus 2 days to day 5 plus 35 days, in chamber slides or tissue culture dishes depending on staining technique to be used (see Support Protocols below)
Phosphate-buffered saline (PBS; see recipe)
3.7% (v/v) formaldehyde in distilled H_2O

1. Remove medium from the culture and wash twice, each time for 30 sec with 1.5 ml PBS (for chamber slides) or 4 ml PBS (for 60-mm dishes).
2. Add 3.7% formaldehyde solution to the cultures (1.5 for chamber slides or 4 ml for 60-mm dishes) and incubate for 30 min at room temperature.
3. Remove formaldehyde and wash three times with PBS using the time and volume specified in step 1, then once with water using the time and volume specified in step 1.
4. Proceed to staining (Support Protocols 2 to 4).

Alcian Blue Staining

SUPPORT PROTOCOL 2

Alcian blue staining is a quick screen for cartilage nodules. The dye stains muco-molecules, especially cartilage proteoglycans.

Materials

Fixed EB cultures at the desired interval after plating on day 5 (Support Protocol 1) in 60-mm culture dishes
Alcian blue working solution (see recipe)

Phosphate-buffered saline (PBS; see recipe)
5% (v/v) acetic acid solution

1. To fixed EBs cultivated on 60-mm culture dishes, add 4 ml Alcian blue working solution.
2. Incubate the samples overnight at room temperature.
3. Remove the staining solution and wash for 30 sec once with 4 ml PBS and once with 4 ml 5% acetic acid.
4. Wash one more time with 4 ml PBS, then add ~5 ml PBS to avoid dehydration of the specimens.
5. View by light microscopy.

   Deeply blue stained nodules should be visible (see Fig. 23.5.2A).

SUPPORT PROTOCOL 3

Alizarin Red Staining

Alizarin red forms chelate-conjugates with bivalent cations (mainly with calcium) and is therefore used to detect bone nodule formation.

Materials

Fixed EB cultures at the desired interval after day 5 (Support Protocol 1) in chamber slides
100 mM Tris·Cl, pH 9 (*APPENDIX 2A*)
Alizarin red staining solution 1: 5% (w/v) Alizarin red S (Sigma) in H_2O; adjust to pH 9 with sodium hydroxide
Alizarin red staining solution 2: 0.5% (w/v) Alizarin red S (Sigma) in H_2O; adjust to pH 9 with sodium hydroxide
Vectashield mounting medium (Vector)
Clear nail polish
Coverslips

1. Incubate fixed EBs cultured on chamber slides in 100 mM Tris·Cl, pH 9, for 30 sec at room temperature.

   The reagents are added to the chambers on the slides.
2. Incubate the samples in 1.5 ml Alizarin red staining solution 1 for 1 hr.
3. Remove the staining solution and rinse two times with 1.5 ml PBS, each time for 30 sec.
4. Incubate the samples in 1.5 ml Alizarin red staining solution 2 per chamber for 5 min.
5. Remove the staining solution and rinse two times with 1.5 ml PBS, each time for 30 sec.
6. Remove chambers from slide and apply Vectashield mounting medium. Cover the slide with a coverslip and seal with clear nail polish.
7. View by light microscopy.

   Red-stained bone nodules should be visible.

Von Kossa Staining

SUPPORT PROTOCOL 4

Von Kossa staining allows visualization of bone nodule formation due to ion exchange (calcium ions are replaced by silver), which depends on the influence of daylight.

Materials

Fixed EB cultures at the desired interval after plating on day 5 (Support Protocol 1) in chamber slides
Von Kossa silver stain: 500 mg silver nitrate (Fluka) in 10 ml distilled water (5% w/v $AgNO_3$)
Von Kossa fixation solution: 1 g anhydrous sodium thiosulfate (Merck) in 20 ml distilled water (5% w/v sodium thiosulfate)
Phosphate-buffered saline (PBS; see recipe)
Vectashield mounting medium (Vector)
Clear nail polish
Coverslips

1. Treat EBs cultivated for the desired interval in chambers of chamber slides for 10 to 20 min with Von Kossa silver stain.
2. Wash carefully twice, each time with 1.5 ml distilled water for 15 sec.
3. Fix the resulting stained sample with Von Kossa fixation solution for 2 min.
4. Wash fixed EBs in chambers twice, each time with 1.5 ml PBS. Remove chambers from slide and immediately add Vectashield mounting medium, cover the slide with a coverslip, and seal with clear nail polish.
5. View by light microscopy.

Sudan III Staining

SUPPORT PROTOCOL 5

ES cell–derived adipogenic differentiation can be demonstrated by staining with the vital stain Sudan III (Support Protocol 5; also see *UNIT 23.4*), which can be tracked directly by light microscopy.

Materials

Unfixed EBs cultured in chamber slides for the desired interval after plating on day 5 (Basic Protocol 1 or Alternate Protocol)
Phosphate-buffered saline (PBS; see recipe)
Sudan III staining solution (see recipe)
Vectashield mounting medium (Vector)
Clear nail polish
Coverslips

1. Wash the EBs with PBS for 15 sec.

   The reagents are added to the chambers on the slides.

2. Add 1.5 ml Sudan III staining solution and incubate for 3 min at room temperature.
3. Wash three times, each time with 1.5 ml PBS.
4. Remove chambers from slide and immediately add Vectashield mounting medium, cover the slide with a coverslip, and seal with clear nail polish.
5. View by light microscopy.

   Lipid droplets in cells are stained red. Adipogenic cells contain large amounts of such droplets.

SUPPORT PROTOCOL 6

Alkaline Phosphatase (AP) Staining

Osteogenic cells show alkaline phosphatase activity.

Materials

Unfixed EBs cultured in chamber slides for the desired interval after plating on day 5 (Basic Protocol 1 or Alternate Protocol)
Phosphate-buffered saline (PBS; see recipe)
Leukocyte Alkaline Phosphatase staining kit (Sigma, cat. no. 86-R) containing:
  Citrate solution
  FRV-alkaline solution
  Hematoxylin solution, Gill No. 3
  Naphthol AS-BI alkaline solution
  Sodium nitrite solution
Acetone
37% (w/v) formaldehyde
Vectashield mounting medium (Vector)
Clear nail polish

15-ml conical polypropylene centrifuge tubes
Coverslips

1. Wash the EB cultures twice, each time with 1.5 ml PBS for 15 sec.

   The reagents are added to the chambers on the slides.

2. Combine 2.5 ml citrate solution (from the Sigma Leukocyte Alkaline Phosphatase staining kit) with 6.5 ml acetone and 0.8 ml of 37% formaldehyde to prepare the fixing solution. Add 1.5 ml fixing solution to the EBs and incubate 30 sec at room temperature to fix.

3. Remove the fixing solution and rinse the samples with 1.5 ml distilled water for 45 sec.

4. Prepare the AP staining solution by combining 125 µl FRV-alkaline solution and 125 µl sodium nitrate solution (both included in the staining kit) in a 15-ml tube. Mix and incubate 2 min at room temperature. Add 5.63 ml distilled water and 125 µl naphthol AS-BI alkaline solution (from kit), and mix. Add 1.5 ml of this solution to each chamber and incubate for 15 min at room temperature in the dark.

5. Wash once for 2 min in 1.5 ml distilled water. Counterstain with 1.5 ml hematoxylin solution (from kit) for 2 min according to the manufacturer's instructions. Again wash once for 2 min in 1.5 ml distilled water.

6. Remove the chambers and rinse slide thoroughly in tap water. Immediately add Vectashield mounting medium, cover slide with coverslip, and seal with clear nail polish.

7. View by light microscopy.

   Alkaline phosphatase–expressing cells are stained light red, whereas all other cells are stained a dark purple color.

SUPPORT PROTOCOL 7

INDIRECT IMMUNOSTAINING OF EBs

Whole EBs can be analyzed for specific specialized cell types by indirect immunostaining. EB cultures are set up and maintained on chamber slides. Immunostainings are performed at intervals of about 2 to 5 days starting 2 days after plating (day 5 plus 2 days) up to about 35 days after plating (day 5 plus 35 days; see Table 23.5.1). As an example, immunostaining for collagen II demonstrates ES cell-derived cartilage formation (Fig. 23.5.3).

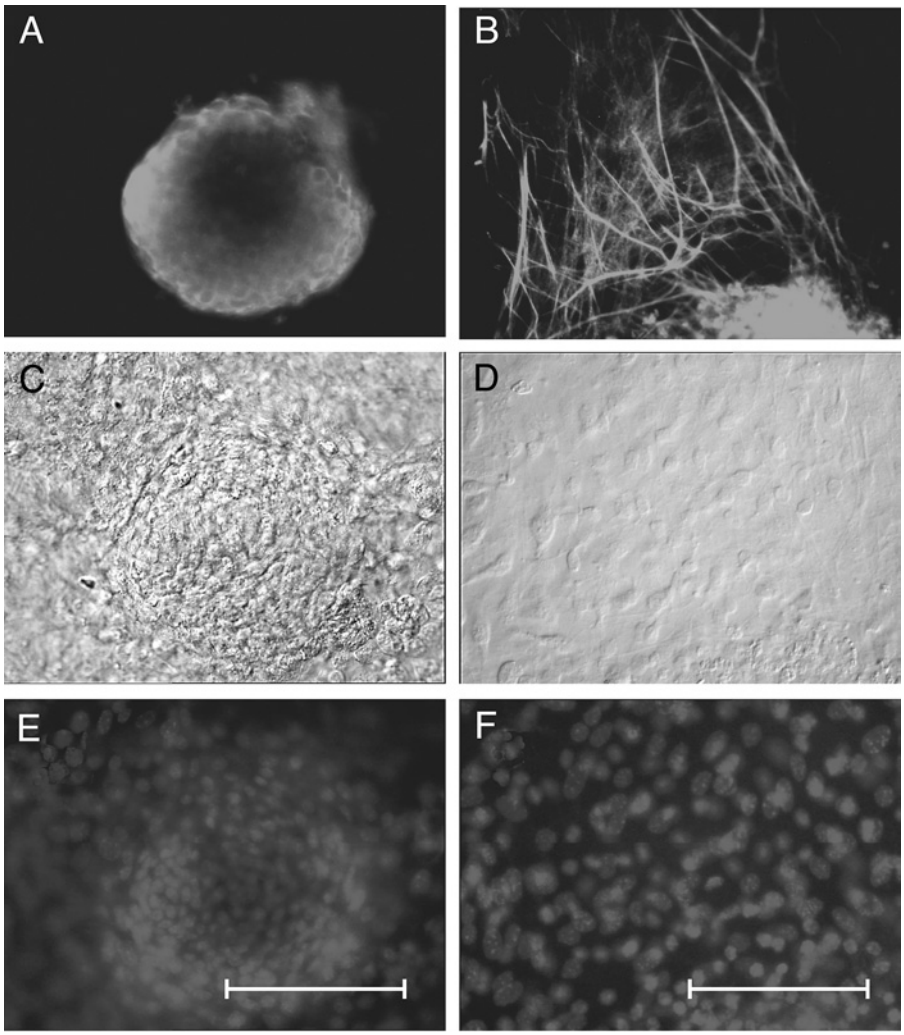

Figure 23.5.3 Immunostaining for collagen II demonstrates ES cell–derived cartilage formation. (**A**) The extracellular matrix of nodules consists of collagen II. (**B**) In addition, formation of collagen II fibrils could also be observed outside the nodules. (**C**) Chondrogenic cells within the cartilage nodules showed a typical round-shaped phenotype and the nodules were compact and clearly seperated from the surrounding tissue. (**D**) In comparison, the single cells expressing the network of collagen II fibrils outside the nodules do not form such distinct structures. (**E, F**) Cell nuclei are stained with DAPI. Bar = 100 μm. For the color version of this figure go to *http://www.currentprotocols.com*.

Materials

Unfixed EBs cultured on chamber slides for the desired interval after plating on day 5 (Basic Protocol 1 or Alternate Protocol)
Phosphate-buffered saline (PBS; *APPENDIX 2A*)
7:3 (v/v) methanol/acetone (e.g., 42 ml methanol/18 ml acetone), −20°C
10% (v/v) goat serum (Dianova, *http://www.dianova.de*) in PBS (see recipe)
Antibodies for immunostaining, primary and fluorophore-labeled secondary, appropriately diluted (see recipe)
Vectashield mounting medium (Vector)
Clear nail polish

Humidified chamber (15-cm covered glass dish with wet piece of filter paper)
Coverslips
Fluorescence microscope (e.g., AXIOSKOP; Zeiss)

Wash and fix EBs

1. Wash the cultures in the chamber slides twice, each time with 1.5 ml PBS for 30 sec.
2. Fix the cells for 5 min with 1.5 ml of 7:3 methanol/acetone at −20°C.
3. Rinse three times each time with 1.5 ml PBS for 30 sec.

Perform blocking and immunostaining

4. Move the sample in the chamber slide to a humidified chamber. Incubate the cells for 15 min in 10% goat serum at room temperature to block nonspecific antibody binding.
5. Incubate the specimens with 300 µl appropriately diluted primary antibodies for 1 hr at 37°C in the humidified chamber.
6. Rinse three times, each time with 1.5 ml PBS for 30 sec.
7. Incubate the slides for 45 min at 37°C in the humidified chamber with 300 µl of appropriately diluted fluorophore-labeled secondary antibody.

   Choice of species for the secondary antibody depends on the origin of the primary antibody (see Reagents and Solutions).

8. Wash the slides three times, each time in 1.5 ml PBS for 30 sec, then once in 1.5 ml distilled water for 30 sec.

Mount, coverslip, and examine slides

9. Remove the chambers, immediately add Vectashield mounting medium, cover the slides with a coverslip, and seal with clear nail polish. Store the slides up to 1 month in the dark at 4°C.
10. Examine slides with fluorescence microscope.

    Differentiated cell types are detected by fluorescence.

SUPPORT PROTOCOL 8

WHOLE-MOUNT FLUORESCENCE IN SITU HYBRIDIZATION FOR mRNA OF A GENE OF INTEREST COUPLED WITH IMMUNOSTAINING FOR COLLAGEN II

For a combination of fluorescence mRNA–in situ hybridization (ISH) and indirect immunofluorescence (IF) staining, a modified whole-mount procedure for EBs (Yamada et al., 1994) is used. This combination allows the simultaneous detection of a tissue-specific protein and mRNA expression. Samples of five EBs plated on chamber slides are analyzed at different developmental stages up to 35 days after plating (day 5 plus 35 days).

Materials

16-day post-coitum (p.c.) mouse embryo limb buds
TOPO II cloning kit (Invitrogen,)
pCR-BluntII-TOPO vector (Invitrogen)
DIG RNA labeling mix kit including Polymerases SP6 and T7 (Boehringer Mannheim; cat. no. 1175025).
EB cultures plated on chamber slides at day 5 (Basic Protocol 1 or Alternate Protocol)
Phosphate-buffered saline (PBS; see recipe)
4% (w/v) paraformaldehyde/4% (w/v) sucrose in PBS
2× SSC, 0.2× SSC, and 0.1× SSC (see recipe for 20× SSC)
50%, 70%, 95%, and 100% ethanol series
Prehybridization buffer (see recipe) with and without salmon sperm DNA

Monoclonal antibody II-II6B3 against collagen II (diluted 1:20 in PBS; see recipe for Antibodies for immunostaining)

FITC-conjugated sheep F(ab) fragments against digoxigenin (Roche, cat. no. 1207741).

Cy3-conjugated goat anti-mouse secondary antibodies (Dianova; cat. no. 115-165-062; *http://www.dianova.de*) for indirect detection of collagen II, both diluted 1:800 in PBS.

Vectashield mounting medium (Vector; cat. no. H-1000).

Clear nail polish

Humidified chamber (15-cm covered glass dish with wet piece of filter paper)

45° and 70°C incubators

Coverslips

Fluorescence microscope with FITC and Cy3 filters

Additional reagents and equipment for RNA isolation and cDNA synthesis via RT-PCR (Support Protocol 9), and DNA sequencing (Chapter 7 in Ausubel et al., 2007)

Generate hybridization probes

1. Isolate RNA from 16-day p.c. mouse embryo limb buds and synthesize cDNA following the RT-PCR protocol (Support Protocol 9) using the primers for the gene of interest listed in Table 23.5.3.

2. Blunt-end and clone the fragment into the plasmid vector pCR-BluntII-TOPO using the TOPO II cloning kit according to the manufacturer's protocol. Verify the sequences by sequencing (Chapter 7 in Ausubel et al., 2007).

3. Label RNA probes of sense and antisense orientation with digoxigenin using DIG RNA labeling mix kit. Synthesize the probes from linearized plasmids of the cloned cDNA fragments by in vitro transcription using the T7 or SP6 RNA polymerase and the DIG RNA labeling mix following the protocol supplied by the manufacturer.

   Final concentration of labeled probes should be 1 μg/ml.

Fix the cell-containing slides

4. Rinse EB cultures on chamber slides twice, each time with 1.5 ml PBS for 30 sec.

5. Fix the EBs with 4% (w/v) paraformaldehyde/4% (w/v) sucrose in PBS for 20 min at room temperature.

6. Wash the cells twice, each time in 1.5 ml PBS for 5 min.

7. Incubate the specimens with 1.5 ml of 2× SSC for 15 min in a humidified chamber inside a 70°C incubator.

8. Wash with 1.5 ml PBS followed by 1.5 ml 2× SSC, each time for 3 min.

9. Repeat steps 5 through 8.

Prepare the cell-containing slides for hybridization

10. Dehydrate the cells through an ethanol series at room temperature by adding 1.5 ml of the indicated concentration of ethanol directly to each chamber:

    2 min in 50% ethanol
    2 min in 70% ethanol
    2 min in 95% ethanol
    2 min in 100% ethanol
    2 min in 100% ethanol.

[a]Not given.
[b]Juvenile splice variant.
[c]Adult splice variant.
[d]Not published.

11. Prehybridize 3 hr in 1.5 ml prehybridization buffer in a humidified chamber in an incubator at 45°C.
12. Perform hybridization with 500 µl/well of 1 ng/µl digoxigenin-labeled sense and antisense probes (prepared in step 3) in prehybridization buffer without salmon sperm DNA at 45°C in a humidified chamber overnight.
13. The next day, wash the slide twice with 2× SSC for 15 min, once with 0.2× SSC for 15 min and twice with 0.1× SSC for 15 min, all at 45°C. Rinse in 1.5 ml PBS for 30 min.

Immunolabel the protein

14. Apply 300 µl monoclonal antibody II-II6B3 against collagen II (diluted 1:20 in PBS) to the cells and incubate in a humidified chamber for 1 hr at 37°C.
15. Wash the cells three times each time with 1.5 ml PBS at room temperature for 30 sec.
16. Add 300 µl FITC-conjugated sheep F(ab) fragments against digoxigenin to detect the RNA and 300 µl Cy3-conjugated goat anti-mouse secondary antibodies for indirect detection of collagen II, both diluted 1:800 in PBS as a cocktail. Incubate for 1 hr at 37°C.
17. Wash the slides three times, each time in 1.5 ml PBS for 30 sec, then once in 1.5 ml distilled water for 30 sec.
18. Mount in Vectashield mounting medium, cover the slides with coverslips, and seal with clear nail polish.
19. Analyze using a fluorescence microscope.

Differentiated cell types are detected by ISH and IF.

RT-PCR ANALYSIS TO DETECT CARTILAGE-SPECIFIC GENE EXPRESSION IN EBs

The expression of tissue-specific genes is analyzed during EB cultivation from days 1 to 5 days before plating, and up to 35 days after plating (day 5 plus 35 days). Total RNA is isolated from 25 EBs at the stages before plating (days 0 to day 5). After plating, samples of ten EBs are used (from one 60-mm tissue culture dish). Distilled water and no-RT reactions are always included as negative controls. RNA from limb buds or limbs of 10 and 16 day p.c. mouse embryos are used as positive controls.

Materials

Cultures of EBs at the desired time points (Basic Protocol 1 or Alternate Protocol)
Phosphate-buffered saline (PBS; see recipe)
RNeasy Mini Kit (Qiagen)
RNase-free DNase set (Qiagen)
Oligo-dT primer (Life Technologies)
Superscript II reverse transcriptase (Life Technologies)
Taq DNA polymerase (Roche)
Primer (see Table 23.5.3)
2% (w/v) agarose gel (Voytas, 2000)

Additional reagents and equipment for quantification of nucleic acids (*APPENDIX 3D*), isolation of total RNA (Ausubel et al. 2007, Chapter 4), RT-PCR (Beverley, 2001), agarose gel electrophoresis (Voytas, 2000), and densitometry (*UNIT 6.3*)

1. Wash EB cultures twice, each time with 4 ml PBS for 30 sec.
2. Isolate total RNA using the RNeasy Mini Kit along with the RNase-free DNase set (to avoid DNA contamination) according the manufacturers' protocols (also see Chapter 4 in Ausubel et al., 2007).
3. Determine the RNA concentrations by measuring the absorbance at 260 nm (*APPENDIX 3D*).
4. Reverse transcribe samples of 500 ng RNA using oligo-dT primer and Superscript II reverse transcriptase according to the manufacturer's protocols (also see Beverley, 2001).
5. Use 1-µl aliquots from the RT reactions for amplification of transcripts with primer (see Table 23.5.3) specific for the analyzed genes and *Taq* DNA polymerase according to the manufacturer's instructions. Use the following program:

1 cycle:	2 min	95°C	(initial denaturation)
35 to 45 cycles:	40 sec	95°C	(denaturation)
	40 sec	primer-specific temperature	(annealing)
	50 sec	72°C	(elongation).

Cycle numbers have to be determined using positive controls of RNA isolated from limb buds of 18-day-old embryos. The optimal cycle number depends upon the PCR machine used; further information may be found in the references listed in Table 23.5.3.

Primer-specific temperatures are listed in Table 23.5.3. For primer pairs established by other groups please also compare to the original reference given in Table 23.5.3.

For RT-PCR analysis of scleraxis, an established method (Wong et al., 1994; Wobus et al., 1997) including the oligonucleotide primer for HPRT and scleraxis in the same reaction, can be used.

6. Separate PCR products electrophoretically on 2% agarose gels (Voytas, 2000).

7. Analyze the fragments by computer-assisted densitometry (*UNIT 6.3*) in relation to GAPDH, HPRT, or β-tubulin gene expression.

   It has been suggested that GAPDH is a more suitable candidate to act as an internal RNA standard, while both HPRT and β-tubulin appear to be inappropriate (Murphy and Polak, 2002).

ULTRACTRUCTURAL ANALYSIS OF ES CELL-DERIVED MESENCHYMAL CONDENSATIONS AND CARTILAGE NODULES BY ELECTRON MICROSCOPY

SUPPORT PROTOCOL 10

ES cell–derived mesenchymal condensations and cartilage nodules exhibit a typical morphology and can be identified in EB outgrowths by light microscopy. The following protocol prepares such structures for further electron-microscopic analysis.

Materials

ES cell–derived mesenchymal condensations and cartilage nodules (see Basic Protocol 2)
5% (v/v) glutaraldehyde in 0.1 M sodium cacodylate, pH 7.4
1% (w/v) OsO_4
50%, 70%, 95% and 100% ethanol
Araldite embedding kit (e.g., Fluka)
Ultracut E (Leica Microsystems Nussloch, *http://www.leica-microsystems.com/*)
LKB Bromma Ultrostainer Carlsberg System for uranyl acetate and lead citrate staining

CAUTION: Glutaraldehyde and OsO_4 are potentially hazardous reagents. Work should be performed under a hood and protective clothing and gloves must be used during the procedure.

1. Fix the ES cell–derived outgrowths with 1 ml 5% glutaraldehyde in 0.1 M sodium cacodylate, pH 7.4, for ∼1 hr at 4°C.
2. Treat specimens with 1 ml 1% OsO_4 for 2 hr at room temperature.
3. Dehydrate the EB outgrowths in graded ethanol series:

   50% ethanol
   70% ethanol
   95% ethanol
   100% ethanol.

4. Embed the specimens in Araldite using kit according to manufacturer's instructions.
5. Cut ultrathin sections of the EBs on an Ultracut E.
6. Stain the sections with uranyl acetate and lead citrate using the LKB Bromma Ultrostainer Carlsberg System according to manufacturer's instructions.
7. Examine the sections for chondrogenic cell types with an electron microscope.

DERIVATION, CULTIVATION, AND INACTIVATION OF EMBRYONIC FIBROBLASTS

SUPPORT PROTOCOL 11

To grow them in an undifferentiated state, ES cells are cocultivated with a feeder layer of murine embryonic fibroblasts. Soluble factors produced by the feeder layer cells prevent the ES cells from differentiation (Evans and Kaufman, 1981). Embryonic fibroblasts used as feeder layers for ES cell cultivation are prepared and cultivated according to an established method (Wobus et al., 1984).

Materials

Day 14 p.c. pregnant mice
Phosphate-buffered saline (PBS; *APPENDIX 2A*)
Trypsin/EDTA solution (see recipe)
Medium 1 (see recipe) for cultivation of embryonic fibroblasts
1 μg/ml MMC working solution (see recipe)
Medium 3 (see recipe)

100 mm-bacteriological petri dishes (Greiner), uncoated
Sterile dissection instruments: scissors, forceps
100-ml Erlenmeyer flask with a stir bar, sterile
~4-mm-diameter glass beads
Sieve (e.g., autoclavable metal tea filter) with pore diameter of ~0.5 mm
15- and 50-ml conical polypropylene centrifuge tubes
Gelatin-coated (see recipe) 100-mm and 60-mm dishes
2 ml-cryopreservation vials (Nunc)
Dewar flasks with liquid nitrogen

Additional reagents and equipment for counting cells (*UNIT 1.1*)

Derive embryonic fibroblasts

1. Remove embryos at day 14 p.c. from uteri of pregnant mice and place under sterile conditions in PBS in a 100-mm bacteriological petri dish.

   Mouse embryos 14 days p.c. are optimal for isolation of embryonic fibroblasts used as a feeder layer. However, embryos up to 16 days p.c. can be used.

2. In a separate dish containing PBS, cut off the placenta and fetal membranes and remove head and liver using sharp sterile scissors.

3. Transfer the remaining carcasses first into a new petri dish with PBS for 30 sec and then into a dish with 5 ml trypsin/EDTA solution.

4. Mince the carcasses in the trypsin/EDTA solution at room temperature.

5. Transfer the 5 ml solution to a sterile 100-ml Erlenmeyer flask with fifty 4-mm glass beads and stir for 25 up to 45 min until most of the tissue pieces are dissociated, but not longer than 45 min.

6. Filter the resulting cell suspension through a sterile sieve and flush into a 15-ml conical centrifuge tube with 10 ml medium 1.

   The authors use a metal tea filter that can be autoclaved for a sieve.

7. Centrifuge the cells 5 min at 180 × *g*, room temperature. Remove the supernatant very carefully by aspiration and resuspend the pellet in 3 ml Medium 1.

8. Plate ~2 × 10^6 cells, isolated from about two embryos, onto a gelatin-coated 100-mm tissue culture dish filled with 10 ml Medium 1. Culture at 37°C in a humidified 5% CO_2 incubator overnight before freezing (at 1 × 10^6 cells/ml in Medium 3 in 2-ml cryovial) or MMC treatment (steps 9 to 12).

   These feeder layer cells can be cultivated for 1 to 2 days and either trypsinized and frozen in medium 3 (1 dish per freezing vial) or split 1:3 onto gelatin-coated 100-mm tissue culture dishes and cultivated for one more day in medium 1 for further use.

Inactivate embryonic fibroblasts

9. Incubate the cells with 6 ml MMC solution for ~2.5 hr at 37°C.

   CAUTION: *Mitomycin C (MMC) is a carcinogen, and for this reason at least in these steps disposable material/pipets are used.*

MMC is used for growth inactivation of the subcultured or frozen feeder cells before cocultivation with ES cells.

Frozen feeder layer cells are thawed rapidly, plated onto two gelatin-coated 100 mm-tissue culture dishes and cultivated overnight before MMC treatment as described in step 8.

10. Aspirate MMC solution. Wash the cells three times each time with 15 ml PBS for 30 sec.

11. Add 2 ml trypsin/EDTA solution to the cells and incubate 30 to 60 sec at room temperature, observing the detachment of the cells under the microscope. Suspend the cells in the trypsin/EDTA solution by pipetting up and down several times and immediately transfer them to a centrifuge tube with 10 ml Medium 1. Centrifuge 5 min at 180 × *g*. Determine the cell number (*UNIT 1.1*).

12. Plate ~1.5 × 10^5 cells onto gelatin-coated 60 mm-culture dishes with 4 ml Medium 1 to create a confluent monolayer. Use as feeder cells in Support Protocol 12.

Cells can be used immediately or stored up to 5 days in the incubator before use. They should not be frozen after MMC treatment.

PROLIFERATION AND SUBCULTIVATION OF ES CELLS

SUPPORT PROTOCOL 12

Murine ES cells are maintained in the undifferentiated state by cultivation on feeder layer cells (Support Protocol 11) and under the influence of leukemia inhibitory factor (LIF; Smith et al., 1988; Williams et al., 1988). LIF, also produced by feeder layer cells, binds to a heterodimer of the LIF receptor and gp130 that activates JAK/Stat3 signaling, and activated Stat3 is sufficient to sustain undifferentiated proliferation of mouse ES cells cultured in serum (Hocke, 1995). It is critical to subculture ES cells carefully for maintaining the undifferentiated ES cells in the pluripotent state. Therefore, ES cells should be subcultivated every 24 to a maximum of 48 hr.

Materials

Feeder layer cells: 60-mm dishes of MMC-treated embryo fibroblasts (Support Protocol 11)
Medium 2 (see recipe)
Frozen vial of ES cells
Phosphate-buffered saline (PBS; see recipe)
Trypsin/EDTA solution (see recipe)
Medium 3 for freezing the ES cells

15- and 50-ml conical polypropylene centrifuge tubes
2-ml glass pipet
2-ml cryopreservation vials (Nunc)
Dewar flasks with liquid nitrogen

Thaw undifferentiated ES cells

1. At a time point 2 hr before thawing ES cells, replace the Medium 1 in the dishes containing the MMC-treated feeder layer with 4 ml Medium 2. Return the cells to the incubator.

2. Thaw the vial with ES cells rapidly at 37°C.

3. Dilute the cold cell suspension 1:10 with Medium 2 in a 15-ml centrifuge tube and centrifuge 5 min at 180 × *g*, room temperature.

4. Resuspend the cell pellet in 2 ml Medium 2 and transfer to the prepared feeder layer. Incubate 1 to 2 days.

   The cell suspension is divided on to two 60-mm feeder layer dishes at 1 ml per plate. This corresponds to ~0.5 × 10^6 cells per plate.

Subcultivate undifferentiated ES cells

For cultivation of ES cells in the pluripotent state it is important that the cells grow in distinct colonies with a clear contour and a limited size.

5. Replace Medium 1 with 4 ml Medium 2 on fresh feeder layer cultures 1 to 2 hr before subcultivation.
6. At time of subcultivation, remove Medium 2 from the ES cells and wash the cells once with 4 ml PBS.
7. Add 2 ml trypsin/EDTA solution to the ES cells and incubate for 30 to 60 sec at room temperature. Monitor the detachment of the cells under the microscope, then suspend the cells in trypsin/EDTA solution by pipetting up and down several times.
8. Immediately transfer the cells to a 15-ml conical centrifuge tube with 10 ml Medium 2, then centrifuge 5 min at 180 × *g*, room temperature. Remove supernatant.
9. Resuspend the cell pellet thoroughly in 1.5 ml Medium 2 using a 2-ml glass pipet.
10. Check by microscopy that the suspension is a single-cell suspension, which is essential for efficient cultivation.
11. Transfer the single-cell suspension, splitting it 1:3 into 60 mm-tissue culture dishes with MMC-inactivated feeder layers.

Freeze undifferentiated ES cells

12. Trypsinize the cells and resuspend in 10 ml Medium 2.
13. Centrifuge for 5 min at 180 × *g*, room temperature. Resuspend the cells in 1.5 ml Medium 3.
14. Transfer the single-cell suspension to a 2-ml freezing vial.
15. Freeze the cells slowly at −80°C overnight.

    To avoid freezing the cells too rapidly, a simple styrofoam box or a freezing container (Cryo 1°C freezing container; Nalgene) can be used.

16. After 7 to 10 days, transfer the vials into liquid nitrogen.

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocols. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Alcian blue working solution, 0.05%, pH 1.5

Dissolve the following in 500 ml of 3% (v/v) acetic acid:
0.25 g Alcian blue (Sigma; cat. no. A-3157)
4.5 g sodium chloride
6.4 g magnesium chloride
Stir 2 to 3 hr
Clear by filtration through filter paper
Store up to 6 months at room temperature

Antibodies for immunostaining, primary and secondary

Primary antibodies: the following monoclonal antibodies (MAbs) can be obtained from the Developmental Studies Hybridoma Bank, Iowa City, U.S.A. (*http://www.uiowa.edu/~dshbwww/*). The designation of the MAb, the dilution (in PBS, see recipe) and a reference are given in brackets:

Collagen II [II-II6B3; 1:20; Linsenmayer and Hendrix (1980)]
Osteopontin [MPIIIB10_1; 1:10; Dorheim et al. (1993)]
Collagen X [X-AC9; 1:20; Schmid and Linsenmayer (1985)]
Bone sialoprotein I and II [WVID1(9C5); 1:10; Dorheim et al. (1993)]

Immunostaining for cartilage oligomeric matrix protein (COMP) and collagen I (CoI) are performed using polyclonal antisera. Again, designation of Ab, dilution in PBS and a reference are given in brackets:

[COMP; 1:20; Hedbom et al., (1992); a kind gift of M. Paulsson, Köln, Germany]
[CoI; 1:100; Chemicon cat. no. AB765P)]

In addition, the MAbs for cytokeratin (cytokeratin 1, 4, 5, 6, 8, 10, 13, 18, 19; 1:100; Sigma; cat. no. C-2562) and sarcomeric actinin (EA-53; 1:200; Sigma; cat. no. A-7811) are used to characterize transdifferentiation of isolated chondrocytes.

Secondary antibodies (dilution in PBS; see recipe): FITC (1:200)– or Cy3 (1:400)–labeled anti-mouse IgG (Dianova; *http://www.dianova.com*; cat. no. 111-015-144, 115-165-062)

2-Mercaptoethanol, 5 mM

Add 7 μl of 2-mercaptoethanol (2-ME; Serva) to 10 ml PBS (see recipe) to prepare the 5 mM 2-ME-stock solutio. Sterilize by filtration through a 0.2-μm filter.

2-ME is used in media at a concentration of 50 μM (1 ml 2-ME-stock solution per 100 ml medium).

Denhardt's solution, 50×

5 g Ficoll 400
5 g polyvinylpyrrolidone
5 g bovine serum albumin (BSA, Fraction V)
500 ml distilled H_2O
Store up to 1 year at −20°C

Fetal bovine serum (FBS)

Heat inactivation: Thaw FBS (Sigma) at room temperature and incubate at 54°C for 30 min for heat inactivation.

To select an appropriate FBS batch for supplementation of media (see individual recipes): ES cells (line BLC6 and D3) are differentiated via EBs using Medium 4 (see recipe; see Basic Protocol 1) supplemented with different FBS batches and analyzed for their chondrogenic differentiation efficiency by Alcian blue staining (see Support Protocol 2).

Gelatin-coated culture ware

Prepare a 1% (w/v) stock solution of gelatin (Fluka, cat. no. 48720) in PBS (see recipe) and autoclave. At a time point 1 day before cell or EB plating dilute the stock solution 1:10 with PBS for a final concentration of 0.1%, fill the dishes, multiwell

plates, or chamber slides with the 0.1% gelatin solution, and incubate overnight at 4°C. Aspirate the gelatin solution immediately before use.

Low-FBS medium

Dulbecco's Modified Eagle Medium (DMEM; Invitrogen) supplemented with:
0.2% (v/v) heat-inactivated FBS (see recipe)
100 U penicillin (add from 10,000 U/ml penicillin/10,000 μg/ml streptomycin stock; Invitrogen)
100 μg/ml streptomycin (add from 10,000 U/ml penicillin/10,000 μg/ml streptomycin stock; Invitrogen)
50 μM 2-mercaptoethanol (add from 5 mM 2-ME stock; see recipe)
20 μM L-glutamine (add from 2 mM stock; Invitrogen)
1× nonessential amino acids (add from 100× stock; Invitrogen)
Store up to 1 week at 4°C

Medium 1

Dulbecco's Modified Eagle Medium (DMEM; Invitrogen) supplemented with:
15% (v/v) heat-inactivated FBS (see recipe)
100 U penicillin (add from 10,000 U/ml penicillin/10,000 μg/ml streptomycin stock; Invitrogen)
100 μg/ml streptomycin (add from 10,000 U/ml penicillin/10,000 μg/ml streptomycin stock; Invitrogen)
50 μM 2-mercaptoethanol (add from 5 mM 2-ME stock; see recipe)
20 μM L-glutamine (add from 2 mM stock; Invitrogen)
1× nonessential amino acids (add from 100× stock; Invitrogen)
Store up to 1 week at 4°C

Medium 2

Dulbecco's Modified Eagle Medium (DMEM; Invitrogen) supplemented with:
15% (v/v) heat-inactivated FBS (see recipe)
100 U penicillin (add from 10,000 U/ml penicillin/10,000 μg/ml streptomycin stock; Invitrogen)
100 μg/ml streptomycin (add from 10,000 U/ml penicillin/10,000 μg/ml streptomycin stock; Invitrogen)
50 μM 2-mercaptoethanol (add from 5 mM 2-ME stock; see recipe)
20 μM L-glutamine (add from 2 mM stock; Invitrogen)
1× nonessential amino acids (add from 100× stock; Invitrogen)
5 ng/ml leukemia inhibitory factor (LIF; Chemicon, cat. no. LIF2005)
Store up to 1 week at 4°C

Medium 3

Dulbecco's Modified Eagle Medium (DMEM; Invitrogen) supplemented with:
20% (v/v) heat-inactivated FBS (see recipe)
100 U penicillin (add from 10,000 U/ml penicillin/10,000 μg/ml streptomycin stock; Invitrogen)
100 μg/ml streptomycin (add from 10,000 U/ml penicillin/10,000 μg/ml streptomycin stock; Invitrogen)
50 μM 2-mercaptoethanol (add from 5 mM 2-ME stock; see recipe)
20 μM L-glutamine (add from 2 mM stock; Invitrogen)
1× nonessential amino acids (add from 100× stock; Invitrogen)
8% (v/v) dimethylsulfoxide
Store up to 2 days at 4°C

Medium 4

Dulbecco's Modified Eagle Medium (DMEM; Invitrogen) supplemented with:
20% (v/v) heat-inactivated FBS (see recipe)
100 U penicillin (add from 10,000 U/ml penicillin/10,000 μg/ml streptomycin stock; Invitrogen)
100 μg/ml streptomycin (add from 10,000 U/ml penicillin/10,000 μg/ml streptomycin stock; Invitrogen)
50 μM 2-mercaptoethanol (add from 5 mM 2-ME stock; see recipe)
20 μM L-glutamine (add from 2 mM stock; Invitrogen)
1× nonessential amino acids (add from 100× stock; Invitrogen)
Store up to 1 week at 4°C

Mitomycin C (MMC) working solution, 10 μg/ml

Dissolve 2 mg mitomycin C (MMC; Serva) in 10 ml PBS (see recipe) to prepare the MMC stock solution. Sterilize by filtration through a 0.2-μm filter and store up to 6 months at −20°C. Dilute 300 μl of MMC stock solution in 6 ml of Medium 1 (see recipe) to obtain a 1 μg/ml MMC working solution.

Phosphate buffered saline (PBS)

10 g/liter NaCl
0.25 g/liter KCl
1.44 g/liter $Na_2HPO_4 \cdot H_2O$
0.25 g/liter KH_2PO_4
Adjust to pH 7.2 using 0.1 N NaOH
Sterilize by autoclaving
Store up to 6 months at room temperature

Prehybridization buffer

5× SSC (see recipe for 20×)
5× Denhardt's solution (see recipe)
50% (v/v) formamide
250 μg/ml yeast tRNA (Sigma; cat. no. R-8759)
250 μg/ml denatured salmon sperm DNA (Life Technologies; omit as indicated in protocol)
4 mM EDTA
Store up to 3 months at −20°C

SSC, 20×

175.3 g NaCl
88.2 g sodium citrate dihydrate
Adjust pH to 7.0
Add H_2O to 1000 ml
Store up to 6 months at room temperature

Sudan III staining solution

Prepare 0.2% to 0.3% (w/v) Sudan III (Sigma, cat. no. S-4136) in 70% ethanol. Heat the solution for 15 min at 60°C and filter through filter paper. Store up to 3 months at room temperature.

Trypsin/EDTA solution

Combine the following in a 1:1 ratio:
0.2 % (w/v) trypsin in PBS (see recipe for PBS)
0.02 % (w/v) disodium EDTA in PBS (see recipe for PBS)
Store the trypsin and EDTA stock solutions up to 1 year at −20°C

COMMENTARY

Background Information

Main stages of chondrogenesis are recapitulated during ES cell differentiation in vitro

Skeleton formation during embryogenesis is an orchestrated multistep process that is still incompletely understood (for review see Sandell and Adler, 1999; Cancedda et al., 2000; Provot and Schipani, 2005). Bones of the vertebral column, pelvis, and upper and lower limbs are formed on an initial cartilaginous template during vertebrate skeletal development. This process of endochondral ossification is represented by a complex cascade of cellular events including proliferation, hypertrophy, and apoptosis of chondrogenic cells. Initially, mesenchymal cells condense and form mesenchymal aggregations at the locations where later skeletal elements occur. These mesenchymal cells are chondrogenic progenitor cells differentiating into early chondroblasts, producing the extracellular matrix of the cartilage anlagen. Finally, the cartilage template is replaced by bone. However, in a few skeletal elements such as the lateral parts of the clavicle and parts of the skull, the mesenchymal cells bypass the chondrogenic stage and differentiate directly into osteoblast cells via intramembranous ossification. Moreover, different types of chondrocytes form the hyaline joint (Mitrovic, 1977), the tracheal and nasal cartilage (Pavlov et al., 2003), and elastic cartilage of the external ear (Moskalewski, 1976).

The specific patterns of marker-molecule expression can be used to define different stages of chondrogenesis and cellular subtypes of cartilage. Sox5 and Sox6 expression reveal the onset of differentiation into the chondrogenic lineage after the formation of condensations by mesenchymal cells (Lefebvre et al., 1998). These chondrogenic precursors differentiate into chondroblasts expressing cartilage marker molecules such as the proteoglycan aggrecan and the main protein of mature cartilage, collagen II. Collagen X expression indicates that the chondrocytes have become hypertrophic, and, finally, these cells undergo apoptosis (Zenmyo et al., 1996) or differentiate into osteoblasts (Bianco et al., 1998), depending on their microenvironment (Riminucci et al., 1998). To distinguish between elastic and hyaline cartilage, the expression analysis of elastic fibrils, e.g., elastin (Moskalewski, 1976), can be used. In contrast to elastic cartilage, hyaline cartilage lacks elastin.

The in vitro ES cell model system has been established to study cartilage cell differentiation. The authors have demonstrated that pluripotent mouse ES cells cultivated as cellular aggregates, so-called embryoid bodies (EBs), differentiate spontaneously into chondrogenic cell types in vitro (Kramer et al., 2000; Hegert et al., 2002). Cellular events during chondrogenesis can be recapitulated from the undifferentiated stem cell to mesenchymal and chondrogenic progenitor cells, through mature and hypertrophic chondrocytes resulting in osteogenic cells. In line with developmental processes in vivo, the mesenchymal cells form condensations in the EBs expressing mesenchymal marker molecules such as the transcription factors scleraxis (Kramer et al., 2000) and Sox5 and Sox6 (Kramer et al., 2005b), as well as the cell adhesion molecule N-cadherin (H.G. Hargus, unpub. observ.). Furthermore, these cells bind peanut agglutinin. Later on, these cellular condensations acquire a compacted phenotype, and collagen II expression can be detected at the stage of cartilage nodule formation (Fig. 23.5.3). Alcian blue staining (see Fig. 23.5.2A) demonstrates that cartilage-specific proteoglycans can be found in the ES cell–derived cartilage nodules. Indeed, large amounts of proteoglycans as well as collagen fibrils are detectable by electron microscopy within the nodules (Kramer et al., 2005b). Immunostaining against elastin reveals that this marker of elastic cartilage is not detectable within the nodules. However, some single collagen II positive cells within the EB-outgrowths outside the nodules express elastin. Moreover, groups of single cells express collagen II fibrils, as revealed by immunostaining (see Fig. 23.5.3). During later cultivation stages, collagen II expression in the ES cell–derived cartilage nodules is down-regulated, and increasing collagen X expression indicates that cells are becoming hypertrophic. At this stage, collagen II fibrils outside the nodules are still detectable. Finally, the nodules are no longer stainable with Alcian blue, and expression of bone marker molecules such as osteopontin, bone sialoprotein, and osteocalcin can be detected. Moreover, cells within these late nodules produce alkaline phosphatase, and the nodules can be stained by Von Kossa silver stain and Alizarin red due to osteomineralization. Furthermore, direct differentiation of precursors into osteoblasts has rarely been

detected in EB outgrowths independent of cartilage formation (Hegert et al., 2002).

Single-cell analysis of ES cell–derived chondrocytes demonstrates that these cells exhibit a plasticity of differentiation (Hegert et al., 2002). Chondrogenic cells expressing collagen II are isolated from cartilage nodules within the EBs. These nodules show a distinct phenotype and can easily be detected by light microscopy. After collagenase treatment, the cells are plated in low-density culture and initially show dedifferentiation during further single-cell cultivation, as indicated by a decreasing expression of collagen II and X and increasing expression of collagen I. Moreover, isolated cells cultivated in single-cell culture initially showed a fibroblastoid phenotype, but the cells later redifferentiated into chondrogenic cells expressing collagen II and X again, but not collagen I. Interestingly the redifferentiated mature chondrocytes aggregate again into cartilage nodules. Because TGF-β_3 promotes chondrogenic differentiation in cultures of mesenchymal stem cells (Mackay et al., 1998), an investigation was performed with application of TGF-β_3 (10 ng/ml) or (50 ng/ml) to the culture medium of chondrogenic cells isolated from EBs (Hegert et al., 2002). Analysis of the data showed that the process of redifferentiation was completely inhibited by TGF-β_3, independently of the concentration used. Moreover, mature chondrocytes isolated from ES cell–derived cartilage nodules exhibit a distinct plasticity with respect to transdifferentiation. Differentiation of other cell types, in addition to dedifferentiating and redifferentiating chondrocytes, was observed after prolonged cultivation of the isolated cells. Adipocytes were detected by Sudan III staining; muscle cell and epithelial cell differentiation was revealed by immunostaining for sarcomeric α-actinin and pan-cytokeratin, respectively. Analysis revealed that the additional cell types formed colonies. The numbers of these colonies and of additional cells were relatively low compared to the number of chondrogenic cells. The possibility that the observed additional cell types originated from contaminating precursor cells was excluded by repeated clonal analysis (Hegert et al., 2002).

Modulation of ES cell–derived cartilage formation

In general, different exogenous factors influence the differentiation of ES cells into the chondrogenic lineage (Fig. 23.5.4).

In general, cell density plays an important role in determining the degree of cell-to-cell contact mediating intercellular signals for cellular differentiation. In fact, the number of ES cells used for EB formation via hanging-drop cultivation was found to be decisive for the formation of cartilage nodules. EBs derived from the ES cell line D3 were prepared from 200, 500, and 800 cells, and the highest number of nodules was detected in EBs derived from 800 cells. Moreover, pellet culture and high-cell-density micromass culture, which allow

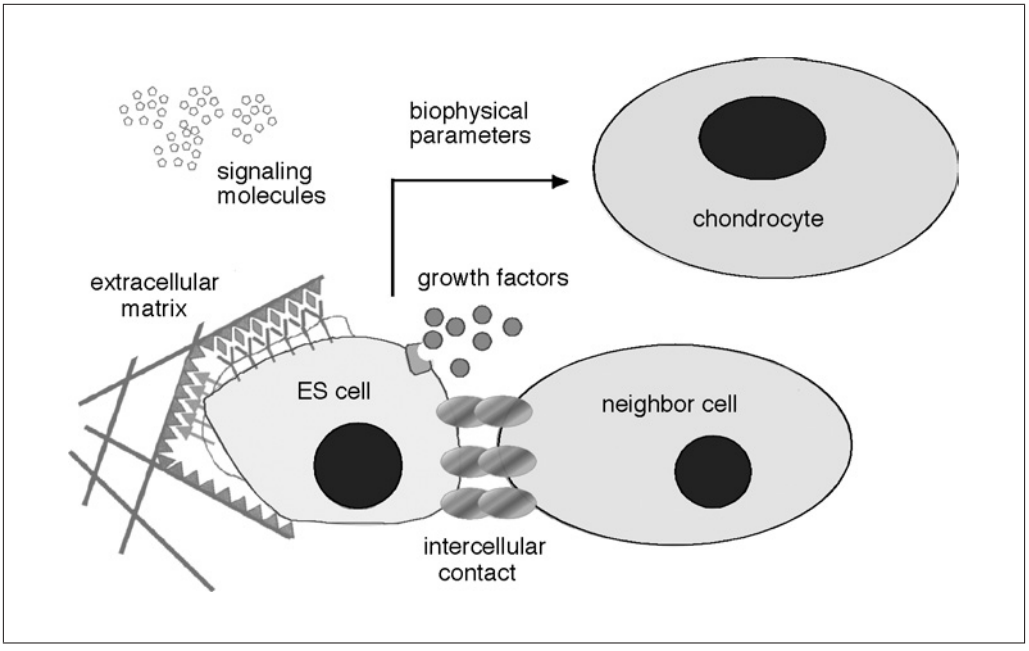

Figure 23.5.4 Different factors and signals influence chondrogenic differentiation of embryonic stem cells.

cell-cell interactions, are favorable for chondrogenic differentiation of ES cells, but alginate encapsulation of EBs does not increase cartilage formation in comparison to plating of EBs (Tanaka et al., 2004). Even the use of different ES cell lines for generation of EBs revealed differences regarding the efficiency of chondrogenic differentiation (Kramer et al., 2005a). For example, in EBs derived from ES cell line BLC6, the number of cartilage nodules was ~5-fold higher ~3 weeks after plating, compared to those derived from ES cell line D3. Other basic parameters playing an important role on the differentiation potential of ES cells are the basic cultivation medium, the batch of serum, the time of EB cultivation in suspension, and the day of EB plating (Kramer et al., 2003). For example, nodule formation was enhanced in outgrowths of EBs cultivated in DMEM compared to EBs cultivated in Iscove's modified Dulbecco's medium (J. Kramer, unpub. observ.). Previous studies showed that optimal differentiation in the mesenchymal direction could be obtained by cultivation in suspension for 3 days (days 2 to 5) and plating at the fifth day of differentiation (Rohwedel et al., 1994, 1998a,b). To establish a defined culture milieu, it is favorable to avoid the application of FBS. However, previous studies showed a reduced ES cell–derived mesodermal differentiation in the absence of FBS. It has been demonstrated that low FBS conditions do not significantly alter the differentiation efficiency of ES cells (Gissel et al., 2005). Actually, EB cultivation in low FBS induces ES cell–derived cartilage nodule formation (J. Kramer and J. Rohwedel, unpub. observ.; Fig. 23.5.2B). Another important factor for modulation of a specific differentiation process is the presence of other cell types in the cellular environment. For example, it has been demonstrated that pluripotent murine ES cells can be directed to differentiate into chondrocytes by coculture with progenitor cells from the limb buds of the developing embryo (Sui et al., 2003).

Growth factors and signaling molecules are useful to influence the efficiency of differentiation (Fig. 23.5.5). Different cytokines and growth factors have been described to promote stem cell–derived chondrogenesis (for review see Heng et al., 2004). ES cell–derived chondrogenesis is modulated by growth factors of the TGF-β-family (Kramer et al., 2000). For example, a slightly reduced ES cell–derived chondrogenic differentiation was detected after treatment of EBs with 2 ng/ml TGF-β_1 for the whole time of differentiation (from day 1 up to day 5 plus 35 days). Application of FGF-2 also resulted in a minor decrease of cartilage nodule formation in EBs (Kramer et al., 2003). However, if BMP-2 (at a concentration of 2 ng/ml) or BMP-4 (at a concentration of 10 ng/ml) was applied to the

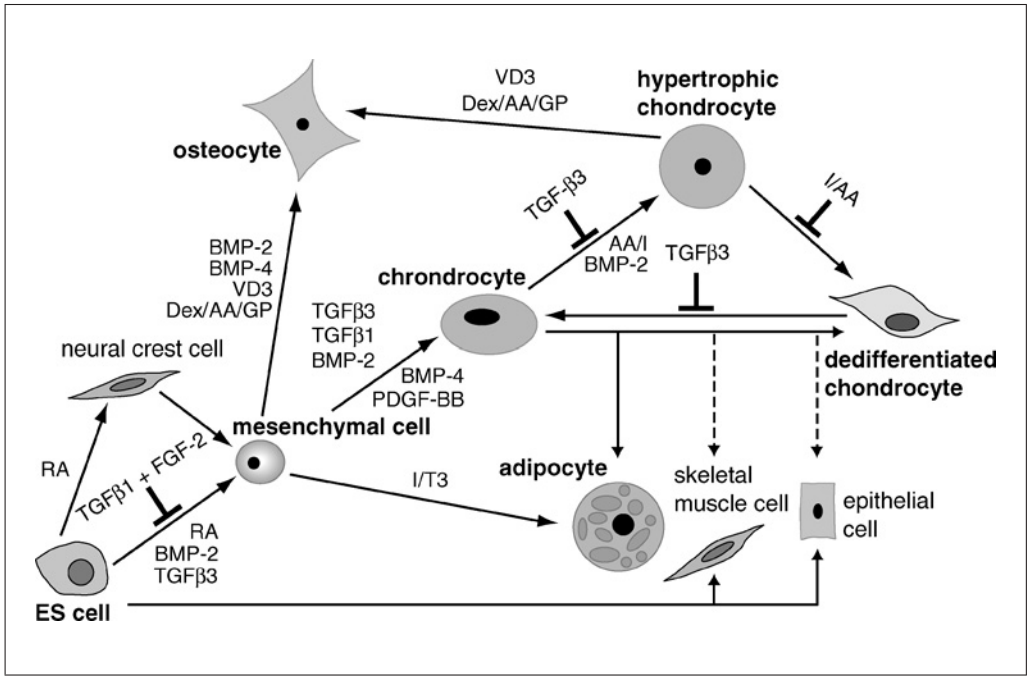

Figure 23.5.5 Overview on some growth factors and signaling molecules influencing mesenchymal ES cell differentiation in vitro.

EBs during the entire cultivation time (from day 1 up to day 5 plus 35 days) the development of chondrogenic cells organized in nodules increased ~2.5 fold (Kramer et al., 2000). No obvious differences in the size or growth rate of EBs cultivated in the presence or absence of growth factors were observed. Furthermore, the modulation of ES cell–derived cartilage formation by BMP-2 was found to depend on a specific stage of EB differentiation. The effect of BMP-2 to enhance chondrogenic differentiation was limited to a time window corresponding to the cultivation step of the EBs in suspension (days 2 to 5). In line with these findings, previous studies revealed the sensitivity of this period for the influence of signaling molecules, such as retinoic acid (RA), on other mesodermal cell types, e.g., cardiogenic, skeletal muscle, and adipogenic cells (Wobus et al., 1994; Dani et al., 1997). In addition, it is known that this early stage of ES cell differentiation is a decisive period of early mesodermal development (Yamada et al., 1994; Rohwedel et al., 1998a). RA treatment during EB cultivation in suspension seems to play a pivotal role in induction of the mesodermal pathway of ES cell differentiation (Dani et al., 1997; Kawaguchi et al., 2005). For example, Sox9 expression was found to be upregulated in RA-treated EBs (Kawaguchi et al., 2005). Sox9 is known to play an important role during development of pre-cartilage mesenchymal condensations. In fact, RA treatment of EBs followed by application of TGF-β3 is sufficient to induce cartilage nodule formation in EB outgrowths (Kawaguchi et al., 2005). Because RA treatment resulted in both an upregulation of the mesenchymal cell markers Runx2 and Ptprv and the appearance of neuroectodermal neural crest cells in EBs, either a mesodermal cell type or an ectomesenchymal cell type may be the source of the mesenchymal cartilage progenitor cells (Kawaguchi et al., 2005). Another two-step model for induction of cartilage formation in EBs was demonstrated by analysis of differentiation of ES cell–derived mesodermal progenitor cells into the chondrogenic direction (Nakayama et al., 2003). This study suggested that chondrogenesis of ES cell-derived mesodermal cells requires the influence of TGF-β3 followed by application of BMP-4. Moreover, a synergy of TGF-β with PDGF-BB regarding the induction of chondrogenesis was observed in a serum-free medium (Nakayama et al., 2003). In addition to induction of cartilage formation, BMP-2 can drive ES cells to the osteoblast or adipogenic fate depending on supplementary cofactors (zur Nieden et al., 2005). In contrast to findings obtained by the authors of this unit, in that study, TGF-β1 induced chondrogenic differentiation in ES cell line D3-derived EBs, and TGF-β1 and BMP-2 worked synergistically. Prolonged treatment of EB cultures with BMP-2 induced hypertrophy of ES cell-derived chondrocytes and resulted in alteration of the marker molecule expression towards a profile typical for osteoblasts, as well as an induced formation of bone nodules in EBs (Phillips et al., 2001; zur Nieden et al., 2005). Compactin, a member of the statin family of HMG-CoA reductase inhibitors, promoted an increase of BMP-2 expression that resulted in an induction of osteogenic differentiation in EB outgrowths (Phillips et al., 2001). Application of mineralization factors such as β-glycerophosphate and vitamin D3 to the culture medium has been found to enhance osteogenic differentiation (zur Nieden et al., 2003, 2005). It has also been shown that differentiation of murine ES cells towards the osteoblast lineage can be increased by supplementing media with ascorbic acid, β-glycerophosphate, and/or dexamethasone/retinoic acid, or by coculture with fetal murine osteoblasts (Buttery et al., 2001). However, dexamethasone alone, which is also known as an inducer of chondrogenic differentiation (Zimmermann and Cristea, 1993; Poliard et al., 1995), did not stimulate ES cell–derived chondrogenesis (Tanaka et al., 2004; zur Nieden et al., 2005).

Extracellular matrix (ECM) molecules, as well as soluble growth factors associated or connected to the matrix, modulate proliferation and differentiation of stem cells. The molecular composition of the ECM mediates cellular differentiation processes via cell matrix receptors, called integrins (Fässler et al., 1996; Rohwedel et al., 1998a; Czyz and Wobus, 2001). However, the role of the matrix material composition and structure in promoting ES cell growth and differentiation is only poorly understood (for example, Battista et al., 2005). Three-dimensional cultivation procedures such as EB encapsulation in polyethylene glycol–based hydrogels (Hwang et al., 2005) or alginate (Tanaka et al., 2004), as well as collagen matrices (Chen et al., 2003), influence ES cell differentiation.

Finally, biophysical parameters such as hydrostatic pressure, shear, oxygen tension, temperature, and electromagnetic forces have been found to influence chondrogenic differentiation (for review Malda et al., 2003; Smith et al., 2004; Fini et al., 2005). For example,

enhanced ES cell–derived bone nodule formation could recently be demonstrated after treatment of ES cell cultures with soluble ions released from bioactive glasses undergoing dissolution in vitro (Bielby et al., 2005).

Critical Parameters and Troubleshooting

1. Heat inactivation of FBS is performed at 54°C for 30 min after thawing the FBS at room temperature.

2. It is important to select a specific FBS batch for the chondrogenic differentiation experiments. Perform a differentiation experiment with different batches of FBS and compare chondrogenic differentiation between the variants by Alcian blue staining as described above.

3. For cultivation of ES cells in the pluripotent state it is important that the cells grow in distinct colonies with a clear contour and a limited size.

4. For ES cell cultivation in the undifferentiated stage the Medium 2 has to be changed daily.

5. During trypsinization of undifferentiated ES cells it is very important to obtain a single-cell suspension. This has to be checked by light microscopy. If cells are still clumped together after trypsinization and replating onto feeder layer, the cells have to be collected, centrifuged, washed twice with PBS, and trypsinized again.

6. For suspension culture of EBs, it is important to select a suitable batch of bacteriological petri dishes. In some batches, the EBs attach, even if the dishes are not coated with gelatin. If this happens, it is sometimes possible to resuspend the EBs again by carefully rinsing the dishes with Medium 4.

7. After plating, the EBs need some time to attach. Therefore, the dishes should not be moved for up to 2 days after plating.

Anticipated Results

For differentiation ES cells can simply be cultivated in bacteriological petri dishes where they spontaneously form EBs. But the size of these EBs varies enormously and the differentiation patterns observed under such conditions are sometimes not reproducible in detail. ES cell differentiation via the hanging-drop method results in EBs of the same size, leading to a more reproducible differentiation process. However, recently it has been found that culturing human ES cells without the EB step enhances osteogenesis in vitro (Karp et al., 2005).

Time Considerations

Table 23.5.3 provides a time schedule for an ES cell differentiation experiment.

Hematoendothelial Differentiation of Human Embryonic Stem Cells

Maxim A. Vodyanik[1] and Igor I. Slukvin[1,2]

[1]University of Wisconsin, Madison, Wisconsin
[2]WiCell Research Institute, Madison, Wisconsin

ABSTRACT

Human embryonic stem cells (hESCs) represent a unique population of cells capable of self-renewal and differentiation into all types of somatic cells, including hematopoietic and endothelial cells. Since the pattern of hematopoietic and endothelial development observed in the embryo can be reproduced using ESCs differentiated in culture, hESCs can be used as a model for studies of specification and diversification of hematoendothelial progenitors. In addition, hESCs can be seen as a scalable source of hematopoietic and endothelial cells for in vitro studies. This unit describes a method for efficient differentiation of hESCs into hematopoietic progenitors and endothelial cells through coculture with mouse OP9 bone marrow stromal cells, as well as an approach for their analysis and isolation. Support protocols are provided for culture of mouse embryonic fibroblasts, evaluation of hematopoietic and endothelial differentiation by flow cytometry and colony-forming assay, removal of OP9 cells, and propagation of hESC-derived endothelial cells. *Curr. Protoc. Cell Biol.* 36:23.6.1-23.6.28. © 2007 by John Wiley & Sons, Inc.

Keywords: human embryonic stem cells • hematopoietic development • in vitro differentiation • hematopoietic progenitors • endothelial cells

INTRODUCTION

Human embryonic stem cells (hESCs) are pluripotent cells capable of differentiating into all types of cells found in the body, including hematopoietic cells. Since the pattern of hematopoietic development observed in the embryo can be reproduced using ESCs differentiated in culture, hESCs provide a unique opportunity for elucidating mechanisms of early hematopoietic commitment, lineage specification, and maturation in humans (Keller et al., 1993; Nakano et al., 1996; Robertson et al., 1999; Lensch and Daley, 2004). Moreover, genetically modified hESCs provide an unprecedented opportunity for studying the role of human genes in hematopoietic development.

There are two major approaches for inducing hematopoietic differentiation of ESCs. One approach allows ESCs to form embryoid bodies after the withdrawal of factors that maintain ESCs in undifferentiated state. Various lineages of cells, including hematopoietic cells, develop inside embryoid bodies. Another approach is coculture of ESCs with bone marrow stromal cell lines, which provides an inductive environment for directed hESC differentiation to hematopoietic lineage.

This unit describes procedures for differentiating hESCs into hematopoietic cells by coculturing with mouse bone marrow stromal cell line OP9 (Basic Protocol 1), as well as methods for analyzing the efficiency of hematopoietic (and endothelial) differentiation by flow cytometry (Support Protocol 1) and a methylcellulose-based colony-forming assay (Support Protocol 2). Basic Protocol 2 describes isolation of hESC-derived hematopoietic progenitors. Since hematopoietic and endothelial lineages develop simultaneously in OP9 coculture, these protocols can also be used for generation and isolation of hESC-derived

DOI: 10.1002/0471143030.cb2306s36

endothelial cells. Additional supporting protocols describe the removal of OP9 cells from hESC/OP9 coculture (Support Protocol 3), maintenance of human embryonic stem cells on mouse embryonic fibroblasts (MEFs; Support Protocol 4), methods for culture of mouse embryonic fibroblasts (Support Protocol 5), techniques for OP9 culture (Support Protocol 6), and propagation of hESC-derived endothelial cells (Support Protocol 7).

NOTE: All procedures described in this unit—tissue culture, reagent preparation, and cell sorting—require sterilization facilities and a standard cell culture workplace, i.e., a laminar flow hood equipped with pipet-aids and an adjustable pipet set, sterile disposable items (tips, glass Pasteur pipets, serological pipets, polypropylene centrifuge tubes), and a vacuum-driven aspiration unit as well as a CO_2 incubator, 37°C water bath, temperature controlled swinging-bucket centrifuge, inverted phase-contrast microscope, and cell counting device. All experiments should be performed under sterile conditions in Class II biological safety cabinets.

NOTE: All incubations should be performed in a humidified 37°C, 5% CO_2 incubator unless otherwise indicated.

NOTE: All solutions and equipment coming into contact with cells must be sterile, and proper aseptic technique should be used accordingly.

BASIC PROTOCOL 1

HEMATOENDOTHELIAL DIFFERENTIATION OF hESCs IN OP9 COCULTURE

This protocol describes the optimal conditions for induction of hematoendothelial differentiation of hESCs through coculture with a mouse OP9 bone marrow stromal cell line. Hematopoietic differentiation of hESCs in coculture with OP9 cells proceeds very rapidly, and the first hematopoietic progenitors can already be detected after 4 to 5 days of coculture. Using this method, efficient hematopoietic differentiation can be achieved without the addition of cytokines or growth factors. The number of endothelial cells and hematopoietic progenitors peak on day 7 to 8 of hESC/OP9 coculture and decrease thereafter due to excessive cell density and overall decline in cell viability.

Materials

6-well plates with undifferentiated hESCs on day 5 to 6 of culture (Support Protocol 4)
1× phosphate-buffered saline, without calcium and magnesium (PBS; GIBCO)
Differentiation medium (see recipe), warmed to 37°C
10-cm dishes with OP9 cells on day 8 to 12 after plating (Support Protocol 6)
Collagenase IV solution (see recipe)
0.05% (w/v) trypsin/0.5 mM EDTA solution (1×; GIBCO)
Cell washing/MACS buffer (see recipe)

15- and 50-ml polypropylene centrifuge tubes
Temperature controlled centrifuge
70-μm nylon filters (cell strainers; Falcon)

Additional reagents and equipment for counting cells (*UNIT 1.1*)

Count hESCs

1. From one well of a 6-well hESC plate, aspirate growth medium and wash the well with 2 ml PBS. Add 1 ml trypsin/EDTA solution and incubate 5 min at 37°C.

   As for regular hESC passage, hESCs used for OP9 coculture must be in aggregates and therefore, cannot be counted directly. To determine the absolute number of hESCs within aggregates, a separate well of 6-well hESC plate should be treated with trypsin to obtain a single-cell suspension for counting.

2. Dissociate hESC colonies by pipetting. Transfer the single-cell suspension to a 15-ml tube containing 2 ml differentiation medium. Centrifuge 5 min at 300 × *g*, room temperature, and resuspend in 1 ml differentiation medium.

3. Count the number of cells in 1 ml (see *UNIT 1.1*).

   The total number of cells in 1 ml will be equal to the absolute number of hESCs in aggregates collected from single well.

Plate hESCs on OP9 dishes

4. Remove OP9 dishes prepared for differentiation (i.e., overgrown) from the CO_2 incubator. Aspirate growth medium completely and add 10 ml differentiation medium. Return the dishes to the CO_2 incubator.

   It is important to remove OP9 medium completely before hESC plating. Adding hESCs directly to an OP9 monolayer with conditioned medium suppresses hematopoietic differentiation.

5. Prepare undifferentiated hESCs as a suspension of small aggregates (described in Support Protocol 4), but perform the washing step using differentiation medium and resuspend the cell pellet in differentiation medium to a concentration of 1.5×10^6 cells/ml.

   The total resuspension volume can be calculated by formula $(n \times x)/1.5$, where n is the number of hESC wells collected for differentiation, and x is the absolute number of hESCs per single well determined by a counting of trypsin-dissociated cells (steps 1 to 3).

   Small clumps (not single hESCs) should be plated for differentiation. Single hESCs in suspension will not survive in the OP9 coculture.

   hESCs should be plated on OP9 cells at optimal density to ensure optimal growth and differentiation during 8 days of coculture. In the authors' experience, optimal plating density is 1–1.5 × 10^6 hESCs (lines H1 and H9) per one 10-cm dish. Since each well of a 6-well hESC plate contains 2–3 × 10^6 cells, hESCs collected from one well are routinely plated on two 10-cm OP9 dishes. However, before such routine plating, control cell counting should be performed in preliminary experiments.

6. Remove OP9 dishes (prefilled with 10 ml differentiation medium in step 4) from the CO_2 incubator. Add 1 ml hESC suspension to each OP9 dish. Place the dishes on the shelf in CO_2 incubator and move forth-and-back and side-to-side to distribute the hESC aggregates evenly throughout the dishes. Incubate overnight.

   Avoid rotating motions as this will lead to accumulation and attachment of hESC clumps in the middle of dish and in such instances the experiment can not be continued.

Feed hESC/OP9 cocultures

7. On day 1 after hESC plating, gently agitate the hESC/OP9 coculture dishes, aspirate the medium, and fill the dishes with 20 ml fresh, prewarmed differentiation medium.

   The 20-ml incubation volume and less frequent feeding are important for successful hematoendothelial differentiation. Conversely, a standard 10-ml incubation volume and more frequent feeding favor generation of mesenchymal-like cells.

8. On culture days 4 and 6, change half of the medium by removing 10 ml of medium from hESC/OP9 dishes by pipet and adding 10 ml of fresh, prewarmed differentiation medium.

   Optimized feeding is critical for efficient hematopoietic differentiation. Any changes in feeding may change differentiation significantly. The authors recommend a full change of medium on the first day after hESC plating (step 7) because it removes all nonattached (dead) cells and suppresses initial growth of undifferentiated colonies. As a result, a more synchronous differentiation can be achieved. In the following days, only half of the medium should be changed. The feeding regimen is one approach for manipulating differentiation, and variations can be tried to improve differentiation efficiency.

Collect cells

9. Warm the collagenase IV and trypsin/EDTA solutions in a 37°C water bath.
10. Remove hESC/OP9 dishes from CO_2 incubator. Aspirate the medium and wash the cell monolayer with 10 ml PBS.
11. Add 5 ml collagenase IV solution/dish and incubate 20 min in the CO_2 incubator.
12. Remove the collagenase solution using a pipet and transfer to a 15- or 50-ml collection tube. Reserve this tube for subsequent collection of trypsin-digested cells.
13. Add 5 ml trypsin/EDTA solution/dish and incubate for an additional 15 to 20 min in the CO_2 incubator.

    After 5 days of differentiation, hESC/OP9 cocultures form a collagen-rich matrix that cannot be efficiently digested by trypsin treatment. Therefore, a pretreatment of hESC/OP9 monolayers with collagenase is used to facilitate subsequent cell dissociation with trypsin. Successive collagenase-trypsin treatment is especially important to maximize cell recovery from day 7 to 9 hESC/OP9 cocultures.

14. Suspend the cells by pipetting and transfer the cell suspension to the collection tube. Close the tube, mix the cells gently by inverting tube, and centrifuge 5 min at 400 × *g*, 4°C.
15. Wash cells three times with cell washing/MACS buffer. Use at least a 10-ml wash volume for cells collected from one hESC/OP9 dish, and centrifuge the cell suspension 5 min at 400 × *g*, 4°C.
16. At the last washing step, resuspend the cells in 10 ml cell washing/MACS buffer, filter through a 70-μm nylon filter, and centrifuge as in step 15.
17. Resuspend the cells in 1 ml cell washing/MACS buffer or medium for each hESC/OP9 dish collected. Place the tube on ice.

    Cells are now ready to analysis (Support Protocols 1 and 2) and separations (Basic Protocol 2 and Support Protocol 3).

18. Count the cells (see *UNIT 1.1*).

    The cell yield from one 10-cm hESC/OP9 dish should be $>10^7$, typically in range of 1.5–2 × 10^7 cells.

SUPPORT PROTOCOL 1

ASSESSMENT OF HEMATOENDOTHELIAL DIFFERENTIATION BY FLOW CYTOMETRY

The hESC-derived endothelial cells and hematopoietic progenitors can be identified by the expression of a common hematoendothelial marker, CD31 (PECAM-1). Hematopoietic progenitors can be distinguished from endothelial cells by CD43 (leukosialin) expression; flow cytometric enumeration of $CD31^+CD43^-$ and $CD31^+CD43^+$ cells can be used to evaluate the efficiency of endothelial and hematopoietic differentiation in hESC/OP9 cocultures, respectively (Vodyanik et al., 2006). Based on expression of CD235a (glycophorin A), multipotent hematopoietic progenitors ($CD43^+CD235a^-$) can be separated from precommitted $CD43^+CD235a^+$ erythro-megakaryocytic progenitors, which also express CD41a (Vodyanik et al., 2006). The marker of the most primitive somatic hematopoietic stem cells/progenitors, CD34, is expressed on hESC-derived endothelial cells and a majority of hematopoietic progenitors. However, in contrast to bone marrow or cord blood, hESC-derived $CD34^+$ cells are more heterogeneous and include a significant proportion of mesenchymal cells (Vodyanik et al., 2006). Thus, the presence of $CD34^+$ cells does not necessarily reflect hematoendothelial differentiation in hESCs. Moreover, some erythroid progenitors are lacking CD34 expression, but express CD43

and CD31. The first $CD34^+$, $CD31^+$, and $CD43^+$ cells are detectable on day 3 to 4 of hESC/OP9 coculture. Cells collected on day 7 to 8 of hESC/OP9 coculture are optimal for assessment of hematoendothelial differentiation, because they contain a maximal number of endothelial cells and all types of hematopoietic progenitors. Total hESC-derived cells in OP9 coculture can be identified using TRA-1-85 monoclonal antibodies (mAb), which detect the OKa blood group antigen expressed by virtually all human cells (Williams et al., 1988). Absolute numbers of cell populations can be calculated by knowing the total number of cells harvested from one 10-cm hESC/OP9 dish, the percentage of total hESC-derived ($TRA\text{-}1\text{-}85^+$) cells, and the percentage of the cell population of interest.

Materials

Cells collected from hESC/OP9 coculture (Basic Protocol 1)
FACS buffer with and without fetal bovine serum (FBS; see recipe)
Mouse anti-human CD31-PE mAb (clone WM59; BD Pharmingen)
Mouse anti-human CD43-FITC mAb (clone 1G10; BD Pharmingen)
Mouse anti-human TRA-1-85-APC mAb (clone TRA-1-85; R&D Systems)
Mouse anti-human CD235a-PE mAb (clone CLB-ery-1; Caltag)
Mouse anti-human CD45-APC mAb (clone HI30; BD Pharmingen)
Mouse anti-human CD29-FITC/PE mAb (clone MEM-101A; Caltag)
Mouse anti-human CD34-APC mAb (clone 581; BD Pharmingen), optional
Mouse IgG1 FITC control mAb (clone MOPC-21; BD Pharmingen)
Mouse IgG1 PE control mAb (clone MOPC-21; BD Pharmingen)
Mouse IgG1 APC control mAb (clone MOPC-21; BD Pharmingen)
7-aminoactinomycin D (7AAD) staining solution (Via-Probe; BD Pharmingen)

5-ml polystyrene test tubes (Falcon)
Temperature-controlled centrifuge
Flow cytometer (FACSCalibur; BD Immunocytometry Systems)
FlowJo flow cytometry analysis software (Tree Star)

Stain cells

1. Suspend cells collected from hESC/OP9 coculture (Basic Protocol 1, step 17) in FACS buffer with FBS at 5×10^6 cells/ml (5×10^5 cells/100 µl per test).

2. Add monoclonal antibodies (mAbs) on the bottoms of 5-ml polystyrene test tubes according to the following plan (also see Table 23.6.1):

   Tubes S1 to S3 for setting up instrument compensation controls
   Tubes E1 to E2 for analysis of total hematopoietic ($CD31^+CD43^+$) and endothelial ($CD31^+CD43^-$) cells within $TRA\text{-}1\text{-}85^+$ human cell population
   Tubes E3 to E4 for analysis of multipotent ($CD43^+CD235a^-CD45^{\pm}$) and erythro-megakaryocytic ($CD43^+CD235a^+CD45^-$) progenitors within total $CD43^+$ hematopoietic population
   Tubes E5 to E6 (optional) for analysis of $CD34^+$ subpopulations of endothelial ($CD31^+CD43^-$), hematopoietic ($CD31^+CD43^+$), and mesenchymal ($CD31^-CD43^-$) cells.

3. Add 100 µl cell suspension to each tube. Incubate 30 to 40 min at 4°C, mixing the cells by agitation at least once during the incubation.

4. Add 4 ml FACS buffer with FBS to the tubes and centrifuge 5 min at $400 \times g$, 4°C.

5. Discard the supernatant by inverting the tubes and resuspend cells in 400 µl FACS buffer without FBS.

   Samples can be stored up to 4 hr at 4°C.

Table 23.6.1 Monoclonal Antibody Combinations for Flow Cytometric Analysis

Tube	FL1-FITC (488/519)[a]	FL2-PE (488/578)[a]	FL3-7AAD[b] (488/647)[a]	FL4-APC (633/660)[a]
Instrument setup samples				
S1	IgG1 control	IgG1 control	-	IgG1 control
S2	CD29[c]	IgG1 control	7AAD	IgG1 control
S3	IgG1 control	CD29[c]	-	TRA-1-85
Experimental samples				
E1	IgG1 control	IgG1 control	7AAD	TRA-1-85
E2	CD43	CD31	7AAD	TRA-1-85
E3	CD43	IgG1 control	7AAD	IgG1 control
E4	CD43	CD235a[c]	7AAD	CD45
E5 (optional)	IgG1 control	IgG1 control	7AAD	CD34
E6 (optional)	CD43	CD31	7AAD	CD34

[a]Fluorochrome excitation/emission wavelengths (nm).
[b]7AAD is a DNA staining dye (Via-Probe, BD) for dead cell exclusion. It should be added to mAb-stained cells immediately before analysis (10 μl/sample).
[c]These monoclonal antibodies (mAbs) are used at 2 μl/test; all other mAbs are used at 5 μl/test.

6. Before analysis, add 10 μl 7AAD staining solution to each tube.

   7AAD staining is used for dead cell exclusion. S1 negative sample and S2 and S3 samples stained with nonoverlapping fluorochromes (FITC/7AAD and PE/APC) are used for setting up instrument compensation.

Analyze samples

7. Perform analysis of cell samples on the flow cytometer and save a minimum of 50,000 (E1 to E2) and 100,000 (E3 to E4) acquisition events.

   Analysis of all samples begins from selection (gating) of 7AAD-negative viable cells. In E1 to E2 samples, total TRA-1-85$^+$ hESC-derived cells are gated for analysis of endothelial (CD31$^+$CD43$^-$) and total hematopoietic (CD31$^+$CD43$^+$) cells. In E3 to E4 samples, total CD43$^+$ cells are gated for analysis of multipotent (CD235a$^-$CD45$^-$ and CD235a$^-$CD45$^+$) and erythro-megakaryocytic (CD235a$^+$CD45$^-$) hematopoietic progenitors. See Figure 23.6.1 for examples.

8. Open listmode files in FlowJo analysis software.

9. Start analysis with E1 or E3 isotype control samples. Set a gate on all 7AAD-negative (viable) cells using FL3-7AAD/FCS dot plot.

10. Open the 7AAD$^-$ gate in FL4-TRA-1-85-APC/SSC (E1) or FL1-CD43-FITC/SSC (E3) dot-plots. Set a gate on all TRA-1-85$^+$ cells (E1) or all CD43$^+$ cells (E3).

11. Open the TRA-1-85$^+$ gate in FL1-IgG1-FITC/FL2-IgG1-PE (E1) or CD43$^+$ gate in FL2-IgG1-PE/FL4-IgG1-APC (E3) dot-plots. Set thresholds for positive staining using quadrant statistics.

12. Transfer (drag-and-drop) all gates to the samples stained with specific mAbs: E1 gates to E2 sample or E3 gates to E4 sample.

13. Determine percentage (%) values.

    E2 sample: % cell viability (7AAD$^-$), % hESC-derived cells (TRA-1-85$^+$), % CD31$^+$CD43$^-$ cells (endothelial), and % CD31$^+$CD43$^+$ (hematopoietic) cells (Fig. 23.6.1A).

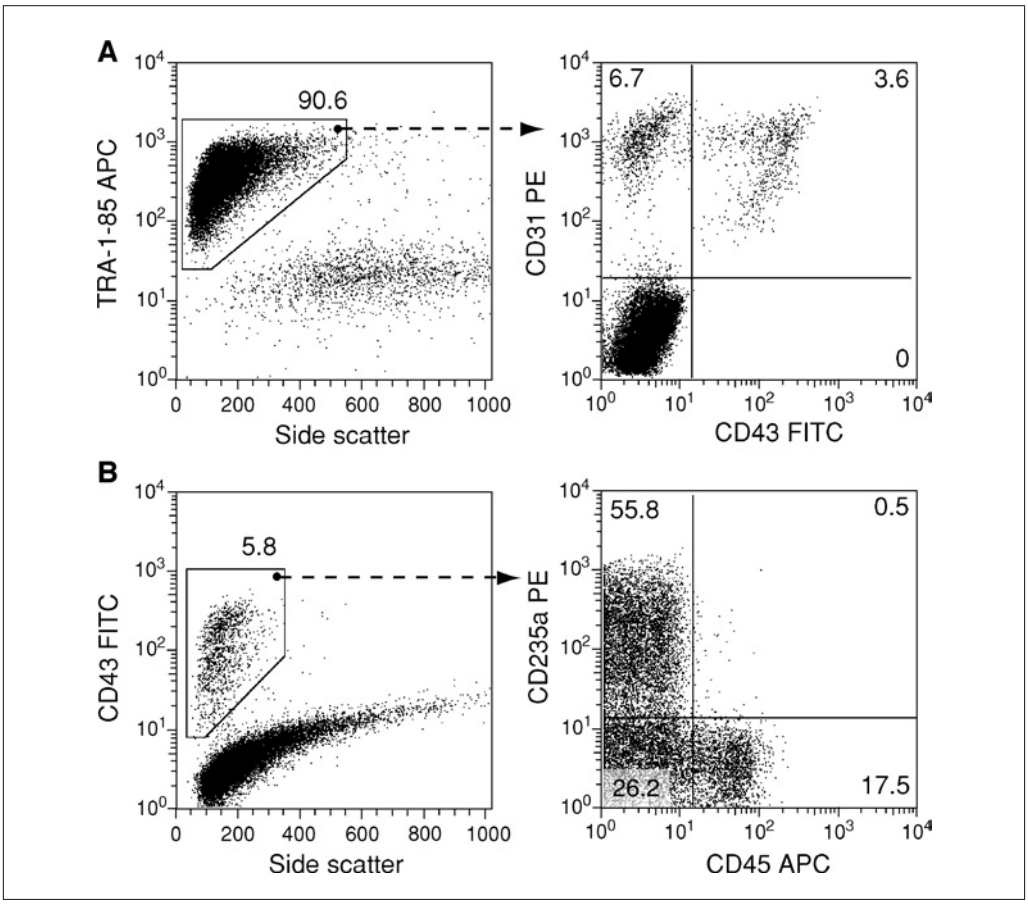

Figure 23.6.1 Flow cytometric analysis of hematopoietic progenitors and endothelial cells generated in hESC/OP9 coculture. (**A**) Representative flow cytometric analysis of hematopoietic ($CD31^+CD43^+$) and endothelial ($CD31^+CD43^-$ cells on day 7 of H1/OP9 coculture. Total H1-derived cells are brightly stained with TRA-1-85-APC mAb (left dot-plot). TRA-1-85^+ cells are selected (gated) for analysis of CD31 and CD43 expression (right dot-plot). (**B**) Representative flow cytometric analysis of $CD43^+$ hematopoietic progenitors on day 8 of H1/OP9 coculture. By low side scatter profile, total CD43-FITC-stained cells can be identified as compact cell population (left dot-plot). Selected (gated) total $CD43^+$ cells are then analyzed for CD235a and CD45 expression. In the right dot-plot, three distinct populations of $CD43^+$ hematopoietic progenitors can be defined: $CD235a^+CD45^-$, $CD235a^-CD45^-$ and $CD235a^-CD45^+$. Percentage values are shown for respective gates/quadrants.

E4 sample: % $CD43^+$ multipotent progenitors ($CD235a^-CD45^-$ and $CD235a^-CD45^+$), and % $CD43^+$ erythro-megakaryocytic progenitors ($CD235a^+$) (Fig. 23.6.1B).

$CD31^-CD43^+$ hematopoietic cells can be found in hESC/OP9 coculture after 8 days of differentiation. These cells represent erythroid cells, which down-regulate CD31 expression along with maturation.

14. Calculate absolute numbers of endothelial ($CD31^+CD43^-$) and hematopoietic ($CD31^+CD43^+$) cells recovered from hESC/OP9 coculture by the formula:

number of cells/$cm^2 = (N \times V \times H \times S)/78.56$

where

N is the number in millions of cells collected from one 10-cm dish
V is % cell viability
H is % human cells (TRA-1-85^+)
S is % cell subpopulation ($CD31^+CD43^-$ or $CD31^+CD43^+$)

78.56 is surface area (cm^2) of a standard 10-cm dish (use 9.62 for one well of 6-well plate).

For example, if 20×10^6 collected cells contain 95% 7AAD$^-$ viable cells, 90% TRA-1-85$^+$ human cells and 5% CD31$^+$CD43$^+$ hematopoietic progenitors, the number of CD31$^+$CD43$^+$ cells = $(20 \times 95 \times 90 \times 5)/78.56 = 10883$ cells per cm^2 of hESC/OP9 coculture.

SUPPORT PROTOCOL 2

HEMATOPOIETIC PRECURSOR COLONY-FORMING ASSAY

In addition to phenotypic analysis, hematopoietic progenitors can be identified using functional assays. A short-term test such as a colony forming assay is widely used to identify hematopoietic precursors at the intermediate stage between hematopoietic stem cells and cells with morphologically distinct features of differentiation. This assay is standardized and easy to perform. When grown in semisolid methylcellulose-based media in the presence of cytokines, hematopoietic progenitors form colonies with specific appearances and cell compositions. These colonies are formed by colony-forming units (CFUs) or colony-forming cells (CFCs) and can be morphologically discriminated into erythroid (E-CFC); granulocyte, erythroid, macrophage, megakaryocyte (GEMM-CFC); granulocyte-macrophage (GM-CFC); and macrophage (M-CFC) cells (Eaves and Lambie, 1995). Complete ready-to-use MethoCult H4435 GF$^+$ methylcellulose medium with added FBS and cytokines (SCF, G-CSF, GM-CSF, IL3, IL6) can be obtained from Stem Cell Technologies. This is a high-quality medium optimized for detection of very early hematopoietic progenitors, and it has minimal lot-to-lot variation. The cells prepared from day 7 to 8 hESC/OP9 cocultures are optimal for the colony-forming assay because they contain all CFC types. In the authors' experience, the presence of OP9 cells in the cell samples does not interfere with the CFC assay. However, if desired, the OP9 cells can be removed from the cell suspension by magnetic sorting (Support Protocol 3).

Materials

MethoCult H4435 GF$^+$ complete medium (Stem Cell Technologies): thaw, divide into 3-ml single-test aliquots (using a 10-ml syringe and blunt-end needle), and refreeze; store up to 6 months at −20°C
6×10^4 cells (Basic Protocol 1, step 17)/0.3 ml differentiation medium
Differentiation medium (see recipe)
Sterile distilled water

Blunt-end needles (Stem Cell Technologies) and 5- and 10-ml syringes, optional
37°C water bath
Disposable 5-ml serological pipet
3.5-cm low-adherence CFU assay dishes (Stem Cell Technologies)
3.5-cm regular plastic tissue culture dishes
10-cm regular plastic tissue culture dishes
Inverted microscope
Gridded scoring dishes (Stem Cell Technologies)

Prepare culture plates

1. Remove tubes with 3 ml MethoCult medium from the freezer and thaw in a 37°C water bath.

   If acquired in the bulk format (100 ml), MethoCult medium should be thawed and divided into single-test aliquots (3 ml per 15-ml polypropylene tubes) using a 10-ml syringe and blunt-end needles. Details on handling of methylcellulose medium can be found in the documentation accompanying the product.

2. Add 6×10^4 cells in 0.3 ml (or less) differentiation medium to a tube containing 3 ml MethoCult medium.

   The final concentration for plating is 2×10^4 cells/ml. The cell suspension should be prepared in differentiation medium and added in volume less than or equal to 0.3 ml.

3. Vortex the tube vigorously to thoroughly mix the cells and place in a 37°C water bath for 10 to 15 min, allowing bubbles to dissipate.

4. Slowly collect the suspended cells in a 5-ml pipet and dispense equal volumes (~1 ml/dish) to duplicate 3.5-cm CFU assay dishes. Rotate the dishes until semisolid medium covers entire plastic surface.

5. Place the two CFU assay dishes, along with an uncovered 3.5-cm dish filled with 4 ml sterile distilled water, into a 10-cm dish and cover.

6. Incubate 14 to 16 days in the CO_2 incubator.

Score colonies

7. Score different types of colonies (E, GEMM, GM, and M) according to their morphology (see Eaves and Lambie, 1995) using an inverted microscope and gridded scoring dishes.

8. Calculate the means for the different colony types from duplicate dishes and multiply by 5 (the dilution factor) to express CFC frequency per 10^5 plated cells.

REMOVAL OF OP9 CELLS FROM hESC/OP9 COCULTURE

SUPPORT PROTOCOL 3

As a xenogeneic system, hESC/OP9 coculture provides the advantage of easy discrimination between hESC-derived cells and feeder cells. Most monoclonal antibodies directed to human antigens do not cross-react with mouse homologs, and therefore, can be used for specific detection and isolation of hESC-derived cells. However, in several functional assays or gene expression studies, OP9 cells may interfere with results and should be removed. For such instances, this protocol describes removal of OP9 cells by magnet-activated cell sorting (MACS) using monoclonal antibodies (mAb) against mouse β1-integrin (CD29), which does not recognize human CD29. Depletion of OP9 cells using antibody-carrying magnetic microbeads results in 99.9% purity of human cells (TRA-1-85$^+$). This method can also be used for purification of human cells from other human-mouse cell coculture systems because CD29 is expressed in high density by virtually all adherent cell types. This protocol is optimized for one-column processing of up to 50×10^6 cells collected from day 7 to 8 hESC/OP9 cocultures. If using more cells or earlier days of coculture, the sample should be divided and processed through additional magnetic columns.

Materials

Cell suspension (Basic Protocol 1), hold on ice
Cell washing/MACS buffer (see recipe), degassed under vacuum and ice cold
Hamster anti-mouse CD29-PE mAb (clone HM beta 1-1; Serotec)
Anti-PE magnetic microbeads (Miltenyi Biotec)
Mouse anti-human TRA-1-85-APC mAb (clone TRA-1-85; R&D Systems)
7-aminoactinomycin D (7AAD) staining solution (Via-Probe; BD Pharmingen)

15-ml graduated polypropylene tubes
Temperature controlled centrifuge, 4°C
MACS rotation mixer (Miltenyi Biotec)
35-μm preseparation filters (Miltenyi Biotec)
Midi-MACS magnet/stand (Miltenyi Biotec)
LD (depletion) columns (Miltenyi Biotec)

Additional reagents and equipment for counting cells (*UNIT 1.1*) and analyzing cells by flow cytometry (Support Protocol 1)

NOTE: Cells and cell washing/MACS buffer must be kept on ice during the separation procedure.

Prepare cells

1. Add the suspension of cells (up to 5×10^7 cells) isolated from hESC/OP9 coculture (Basic Protocol 1) to a 15-ml graduated polypropylene tube.
2. Centrifuge 5 min at $400 \times g$, 4°C.
3. Aspirate the supernatant. Note the volume of the cell pellet and add an equal volume of cell washing/MACS buffer.

   The resulting total volume is referred to as the labeling volume.

Label mouse cells

4. Resuspend the cells thoroughly by gentle pipetting and add 1/10 vol hamster anti-mouse CD29-PE mAb.

   For example, if the cell pellet is ~0.2 ml, add 0.2 ml cell washing/MACS buffer (labeling volume is 0.4 ml), resuspend cells, and add 40 µl (1/10 vol) CD29-PE mAb.

5. Set up tube on the MACS mixer. Place the MACS mixer with the tube in the refrigerator (4°C). Incubate 15 min at the lowest rotation speed.

Add beads for separation

6. Wash cells once with 14 ml ice-cold cell washing/MACS buffer. Resuspend cells in cell washing/MACS buffer to the original labeling volume and add 1/10 vol anti-PE microbeads.
7. Incubate cells on MACS mixer 20 min at 4°C and lowest rotation speed.
8. Wash cells once with 14 ml ice-cold cell washing/MACS buffer. Resuspend cell pellet in 1 ml cell washing/MACS buffer.
9. Place a 35-µm preseparation filter on the top of an empty 15-ml tube. Apply the cell suspension on the filter and allow the cells to pass through filter completely. Wash the filter with 0.5 ml cell washing/MACS buffer.

   It is important to filter cells prior to application onto magnetic columns. Even very small cell aggregates may block the magnetic columns and adversely affect separation.

10. Place the tube with filtered cells on ice and reserve a 10- to 20-µl aliquot for FACS analysis of presort cells in step 16.

Separate mouse cells

11. Assemble the MACS-LD separation unit (midi-MACS magnet with LD column and 15-ml collection tube). Rinse the column with 2 ml MACS buffer and discard the tube with eluate. Place an empty collection tube under column.

    There are two types of magnetic columns optimized for positive (LS) and negative (LD) MACS separation, and they differ in flow-through rate. High flow rate LS columns provide a high purity of column-retained cell fractions (>95%), whereas low flow rate LD columns provide maximal recovery (depletion) of magnetically labeled cells (>99%).

12. Apply the cell suspension to the LD column and allow cells to pass through the column completely. Wash column with 2 ml cell washing/MACS buffer.
13. Remove collection tube with unlabeled (human) cell fraction. Centrifuge 5 min at $300 \times g$, 4°C.

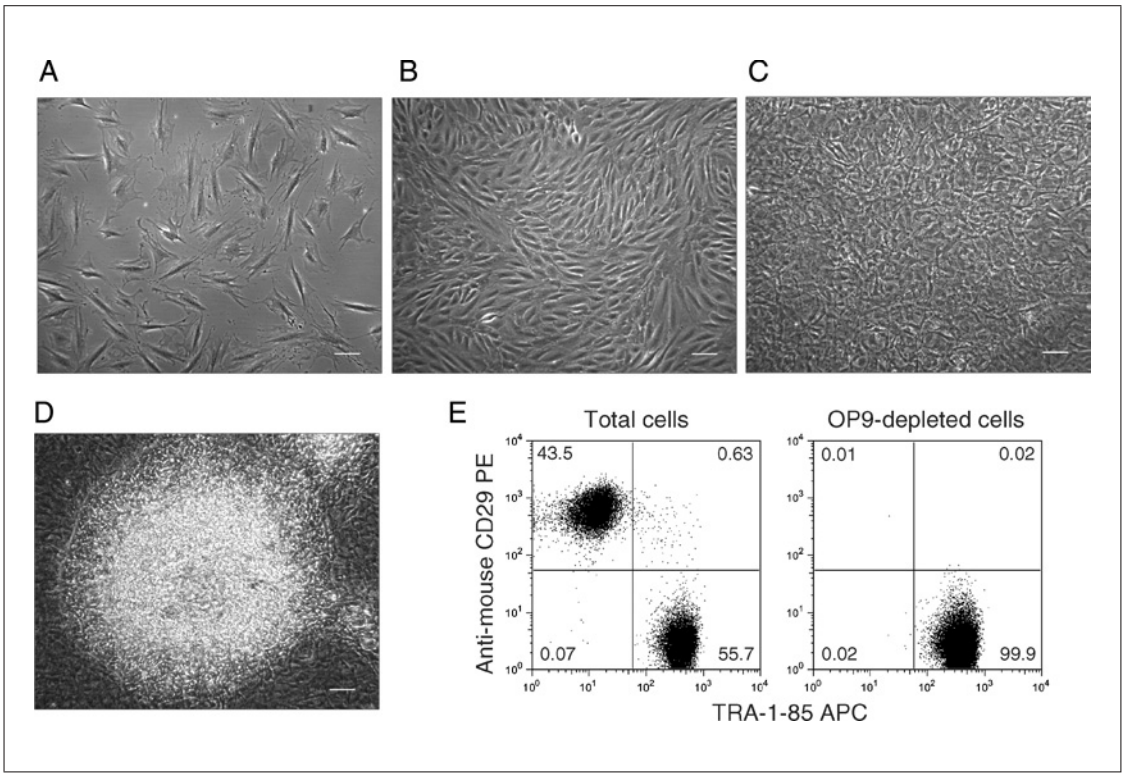

Figure 23.6.2 Major steps in establishing hESC differentiation cultures on OP9 cells and obtaining feeder-free differentiated human cells. (**A**) Morphology of OP9 cells on the day after plating. (**B**) Day 4 confluent OP9 cultures ready for passage. (**C**) Day 8 overgrown OP9 cultures prepared for hESC differentiation. (**D**) Differentiated "mesodermal" hESC colony on day 4 of H1/OP9 coculture. (**E**) Representative flow cytometric analysis of OP9 (mouse CD29-PE$^+$) and total hESC-derived (TRA-1-85-APC$^+$) cells on day 3 of H1/OP9 coculture before (left dot-plot) and after (right dot-plot) OP9 removal by magnetic sorting using depletion (LD) columns and anti-PE microbeads. Percentage values are shown in respective quadrants. Scale bar = 100 μm for all photographs.

14. Discard the supernatant and resuspend the cells in 1 ml cell washing/MACS buffer or medium. Reserve a 10- to 20-μl aliquot for FACS analysis.

15. Count the cells (see *UNIT 1.1*) and take an aliquot ($\sim 2 \times 10^4$ cells/test) for FACS analysis.

16. Analyze the cells by flow cytometry, labeling them with TRA-1-85-APC mAb and using 7AAD staining to exclude dead cells (see Support Protocol 1).

At analysis, mouse CD29-PE positive cells (OP9) should be negligible if detectable (<0.02%), whereas TRA-1-85$^+$ human cells should comprise >99.5% (Fig. 23.6.2E).

ISOLATION OF hESC-DERIVED HEMATOPOIETIC PROGENITORS AND ENDOTHELIAL CELLS

BASIC PROTOCOL 2

This protocol describes the isolation of hESC-derived hematopoietic progenitors and endothelial cells. As a first step, cells harvested on day 7 to 8 of hESC/OP9 coculture (Basic Protocol 1) are processed to isolate all hematopoietic progenitors by positive selection of CD43$^+$ cells using magnet-activated cell sorting (MACS) and depletion (LD) columns designed for efficient recovery of labeled cells. MACS-enriched CD43$^+$ cells labeled with CD235a (glycophorin A) and CD45 monoclonal antibodies (mAbs) are subsequently subjected to a FACS sorting procedure to isolate three types of hematopoietic progenitors: CD43$^+$CD235a$^+$CD45$^-$ erythro-megakaryocytic and multipotent CD43$^+$CD235a$^-$CD45$^-$ and CD43$^+$CD235a$^-$CD45$^+$ progenitors. Both CD43$^+$CD235a$^-$CD45$^-$ and CD43$^+$235a$^-$CD45$^+$ cells are negative

for lineage-specific markers and represent multipotent hematopoietic progenitors; however, $CD43^+CD235a^-CD45^+$ cells are enriched in myeloid progenitors and limited in lymphoid potential (Vodyanik et al., 2006). Endothelial cells can be subsequently isolated from the $CD43^-$ cell fraction by positive MACS selection of $CD31^+$ cells. $CD43^+$ subsets can be used for functional studies as well as a source of hematopoietic progenitors for directed differentiation towards specific hematopoietic lineages. Endothelial cells can be expanded in vitro for several passages in serum-free conditions (Support Protocol 7).

Materials

Cell suspension (Basic Protocol 1), hold on ice
Cell washing/MACS buffer (see recipe), degassed under vacuum and ice cold
Mouse anti-human CD43-FITC mAb (clone 1G10; BD Pharmingen)
Anti-FITC magnetic microbeads, (Miltenyi Biotec)
Basic (nonconjugated) microbeads (Miltenyi Biotec), optional
Mouse anti-human CD31-PE (clone WM59; BD Pharmingen)
Anti-PE magnetic microbeads, (Miltenyi Biotec)
FACS buffer without FBS (see recipe)
7-aminoactinomycin D (7AAD) solution (Via-Probe; BD Pharmingen)
Mouse IgG1-PE isotype control mAb (clone MOPC-21; BD Pharmingen)
Mouse IgG1-APC isotype control mAb (clone MOPC-21; BD Pharmingen)
Mouse anti-human CD235a-PE (clone CLB-ery-1; Caltag)
Mouse anti-human CD45-APC (clone HI30; BD Pharmingen)
FBS (GIBCO), heat inactivated

LD (depletion) columns, (Miltenyi Biotec)
15-ml graduated polypropylene tubes
Temperature-controlled centrifuge, 4°C
MACS rotation mixer, (Miltenyi Biotec)
35-μm preseparation filters (Miltenyi Biotec)
LS (positive selection) columns (Miltenyi Biotec)
Midi-MACS magnet/stand (Miltenyi Biotec)
Cell sorter (FACS Vantage SE; BD Immunocytometry Systems)
5-ml polypropylene tubes (Falcon)

Additional reagents and equipment for counting cells (*UNIT 1.1*) and performing FACS (Support Protocol 1)

NOTE: Cells and cell washing/MACS buffer must be kept on ice during the separation procedure.

Prepare cells

1. Add the suspension of cells (up to 10^8 cells) isolated from hESC/OP9 coculture (Basic Protocol 1) to a 15-ml graduated polypropylene tube.
2. Centrifuge 5 min at 400 × *g*, 4°C.
3. Aspirate the supernatant. Note the volume of cell pellet and add an equal volume of cell washing/MACS buffer.

   This resulting total volume is referred as labeling volume.

   Remember to keep cells and cell washing/MACS buffer on ice during separation procedure.

4. Resuspend cells thoroughly by gentle pipetting and add 1/10 vol CD43-FITC mAb.

   For example, if the cell pellet is ~0.2 ml, add 0.2 ml cell washing/MACS buffer (labeling volume is 0.4 ml), resuspend cells, and add 40 μl (1/10 vol) of CD43-FITC mAb.

5. Set up the tube on a MACS mixer. Place the MACS mixer with tube in refrigerator (4°C). Incubate 20 min at the lowest rotation speed.

Add magnetic beads

6. Wash the cells once by adding 14 ml ice-cold cell washing/MACS buffer and centrifuging 5 min at 400 × *g*, 4°C. Discard the supernatant and resuspend the cells in MACS buffer to original labeling volume and add 1/10 vol anti-FITC microbeads.

7. Incubate the cell suspension on MACS mixer 20 min at 4°C and low rotation speed.

8. Wash cell once by adding 14 ml ice-cold cell washing/MACS buffer and centrifuging 5 min at 400 × *g*, 4°C. Discard the supernatant and resuspend cell pellet in 1 ml cell washing/MACS buffer.

9. Place a 35-µm preseparation filter on an empty 15-ml tube. Apply the suspension to the filter and allow to completely pass through. Wash the filter with 0.5 ml cell washing/MACS buffer. Place tube with the filtered cells on ice.

Select CD43$^+$ cells

10. Assemble the MACS-LD separation unit (midi-MACS magnet with LD column and 15-ml collection tube). Rinse the column with 2 ml cell washing/MACS buffer and discard the tube with eluate. Place an empty collection tube under column.

11. Apply the suspension to the LD column and allow to completely pass through. Wash the column with 2 ml cell washing/MACS buffer.

12. Remove the collection tube containing the CD43$^-$ cell fraction and place on ice. Save the CD43$^-$ cells for endothelial cell isolation.

13. Remove the LD column from magnet and insert in an empty 15-ml tube. Add 5 ml cell washing/MACS buffer to the column funnel. Using a plunger (supplied with column), flush the CD43$^+$ cells out of the column. Discard the emptied column.

14. Centrifuge the tube containing the eluted CD43$^+$ cells 5 min at 300 × *g*, 4°C.

15. Discard the supernatant and resuspend the cells in 0.2 ml cell washing/MACS buffer and place tube on ice

    Typically, up to 10% of the cells are recovered in MACS-enriched CD43$^+$ cell fraction. For example, if the column were loaded with 10^8 cells, one should expect to recover 10^7 cells in CD43$^+$ fraction. This fraction usually contains 40% to 60% CD43$^+$ cells and can be used for subsequent sorting of CD43$^+$ subsets by FACS (step 23). If a higher purity of MACS-enriched CD43$^+$ cells is desired, all potential contaminants that bind nonspecifically to the magnetic beads and column can be removed prior to selection of CD43$^+$ cells. For this, cells (step 1) should be incubated with basic (unconjugated) microbeads (as in steps 6 to 9) and passed through an LD column.

    MACS magnetic microbeads are biodegradable microparticles (~50 nm) that do not interfere with subsequent FACS analysis, sorting, or functional assays. There is no need to release them from the cells after the separation procedure.

Select endothelial cells

16. Label the CD43$^-$ cell fraction (collected in step 12) with CD31-PE mAb and anti-PE microbeads as described in steps 2 to 9, but prepare the 35-µm filtered cell suspension (step 9) in 3 ml cell washing/MACS buffer.

    The cell filtrate should be prepared in 3 ml because this is the application volume for LS columns. This can be accomplished by doubling filtration volumes: resuspending the cells in 1 ml buffer, filtering, and washing the filter with 2 ml buffer to give a total volume of 3 ml or by adding 1.5 ml to the 1.5 ml cell filtrate obtained in step 9.

17. Assemble the MACS-LS separation unit (midi-MACS magnet with LS column and 15-ml collection tube). Rinse the column with 5 ml cell washing/MACS buffer and discard the tube with eluate. Place an empty collection tube under column.

    For a high purity (>98%) of isolated endothelial cells, positive selection (LS) columns must be used.

    There are two types of magnetic columns optimized for positive (LS) and negative (LD) MACS separation, and they differ in flow-through rate. High flow rate LS columns provide a high purity of column-retained cell fractions (>95%), whereas low flow rate LD columns provide maximal recovery (depletion) of magnetically labeled cells (>99%).

18. Apply the suspension to the LS column and allow to pass completely through. Wash the column three times with 3 ml cell washing/MACS buffer.

19. Discard the collection tube with the $CD31^-$ cell fraction.

Collect $CD31^+$ cells

20. Remove the LS column from the magnet and insert an empty 15-ml tube. Add 5 to 7 ml cell washing/MACS buffer to column funnel. Using a plunger (supplied with column), flush the $CD31^+$ cells out of column.

21. Discard emptied column. Centrifuge tube with eluted $CD31^+$ cells 5 min at 300 × *g*, 4°C.

22. Resuspend the cells in 1 ml cell washing/MACS buffer or medium for endothelial cell expansion (see Support Protocol 7). Count the cells (*UNIT 1.1*).

23. For FACS analysis, add 10 to 20 µl cell suspension to 0.4 ml FACS buffer (without FBS). Add 10 µl 7AAD solution for dead cell exclusion. Examine the cells by FACS (Support Protocol 1).

    CD43-FITC positive cells should not be detectable, whereas CD31-PE positive cells should comprise >98%.

Sort $CD43^+$ subsets by FACS

24. Add 5 µl mouse IgG1-PE and 5µl IgG1-APC isotype control mAbs to one 5-ml polypropylene tube, and add 10 µl CD235a-PE and 40 µl CD45-APC mAbs to another 5-ml tube.

25. Label MACS-enriched $CD43^+$ cells (from step 15, up to 10^7 cells in 0.2 ml) with isotype control and specific mAb combinations by adding 20 to 50 µl of the $CD43^+$ cells to the tube with isotype control mAbs and the rest of $CD43^+$ cells (150 to 180 µl) to the tube with CD235a-PE and CD45-APC mAbs.

26. Mix the cells gently and incubate samples 30 min at 4°C, with occasional agitation.

27. Wash cells twice with 5 ml cell washing/MACS buffer and resuspend in 0.5 ml cell washing/MACS buffer. Keep tubes on ice until sorting.

28. Before running on the cell sorter, pass cell samples through a 35-µm filter.

29. Using the control sample, setup the following gates:

    Live cells, using an FSC-A/SSC-A dot-plot (live $CD43^+$ cells form a compact population with low FSC/SSC profile)
    Single cells, using an SSC-A/FCS-W dot plot (exclude cell doublets)
    Total $CD43^+$ cells, using an FL1-CD43-FITC/SSC-A dot plot (verify instrument compensation).

    CD43-FITC-stained cells should not overlap the FL2 channel.

30. Open finally gated $CD43^+$ cells in an FL2-IgG1-PE/FL4-IgG1-APC dot plot. Set thresholds for positive staining.

31. Remove the control sample and insert a tube with $CD43^+$ cells stained with CD235a and CD45 mAbs. Identify three main $CD43^+$ subsets:

    $CD235a^+CD45^-$
    $CD235a^-CD45^-$
    $CD235a^-CD45^+$

    on an FL2-$CD235a^-$PE/FL4-$CD45^-$APC dot plot (Fig. 23.6.2B).

32. Set sorting gates on these populations and start sorting into 5-ml polypropylene tubes prefilled with 0.3 ml FBS. Sort at low pressure, using a wide 100-μm nozzle tip.

33. Remove tubes with sorted cells. Fill tubes with 4 ml cell washing/MACS buffer or medium and mix well by inverting tube several times. Centrifuge 5 min at 300 × *g*, 4°C.

34. Resuspend the cells in 0.5 ml medium and determine the number of sorted cells by manual counting (see *UNIT 1.1*).

    During the FACS sorting procedure, cells become electrically charged and may adhere to the tube walls. Therefore, the real number of sorted cells recovered after centrifugation is usually lower than known cell counts deposited by the sorter. For use in the following tests, sorted cells should be counted manually.

PROPAGATION OF hESCs ON MOUSE EMBRYONIC FIBROBLASTS

SUPPORT PROTOCOL 4

This protocol describes the maintenance of hESCs for in vitro hematopoietic differentiation based on the procedures described in Amit et al. (2000) and Thomson et al. (1998), with slight modifications. The hESCs are cultured on mouse embryonic fibroblasts (MEFs) and maintain pluripotency during an extended period of culture (Amit et al., 2000). They are less likely to produce chromosomal abnormalities, compared to methods that use feeder-free conditions (Draper et al., 2004). Undifferentiated hESCs grow in tight colonies attached to the MEF feeder. Passaging hESC cultures includes (1) detachment of hESC colonies by collagenase treatment, (2) fragmentation of hESC colonies into small clumps by pipetting, and (3) plating of hESC clumps to the newly prepared MEF feeder plate.

Materials

hESC cultures (H1 or H9 hESC lines; National Stem Cell Bank; see Internet Resources)
6-well plates with pre-plated irradiated MEFs (Support Protocol 5)
hESC growth medium (see recipe)
1× phosphate-buffered saline, without calcium and magnesium (PBS; GIBCO), room temperature
Collagenase IV solution (see recipe)

37°C water bath
5-ml glass pipet, sterile

Detach hESC colonies from plates

1. Warm the collagenase IV solution and hESC growth medium 15 to 20 min in a 37°C water bath.

2. Remove an MEF feeder plate from CO_2 incubator. Aspirate the MEF growth medium and wash wells quickly with 2 ml PBS at room temperature.

3. Add hESC growth medium at 1.5 ml/well and keep MEF feeder plates in the CO_2 incubator until the hESC are ready for plating.
4. Remove the hESC plate from the CO_2 incubator. Aspirate the growth medium. Wash wells quickly with 2 ml PBS at room temperature and add 2 ml/well collagenase IV solution.
5. Incubate the hESC plate 10 to 15 min in the CO_2 incubator until the edges of the hESC colonies detach from plate.
6. Using a 5-ml glass pipet, dislodge the hESC colonies by washing the plastic surface with the collagenase solution. Use gentle scraping to dislodge colonies that may still be attached.

   After collagenase treatment, hESC colonies should be dislodged easily by washing or gentle scraping. Forceful scraping should be avoided to prevent cell damage and collection of the firmly attached colonies, which may contain differentiated cells. Excessive mechanical damage of hESCs during passage may also provoke their spontaneous differentiation.
7. Transfer the suspension to a 15-ml tube and centrifuge 5 min at 200 × *g*, room temperature.

Disperse colonies and plate

8. Aspirate the medium and resuspend the cells in 4 ml hESC growth medium. Break up the hESC colonies into a fine suspension of small cell aggregates by pipetting cells up and down against the bottom of tube. Centrifuge 5 min at 200 × *g*, room temperature.
9. Aspirate the medium, resuspend the cells in 6 ml hESC growth medium, and dispense the suspension in a 6-well MEF feeder plate (1 ml/well), using a vertically positioned glass serological pipet.
10. Place the plate on the shelf in the CO_2 incubator and move it forth-to-back and side-to-side to distribute hESC clumps evenly throughout the plate.

    Avoid rotating motions because this will lead to accumulation of cell clumps in the center of wells.
11. Allow the hESC clumps to attach to the MEFs for 24 hr. Do not disturb the plate during this time.
12. Feed the hESC cultures daily by aspirating 2.5 to 3 ml medium/well and adding the same amount of fresh prewarmed hESC growth medium. Passage on day 6 to 7.

    It is imperative to avoid excessive density of hESC in maintenance cultures because it may lead to hESC growth retardation, long-lasting spontaneous differentiation, genetic abnormalities, and eventually poor differentiation efficiency in OP9 coculture. As a rule, hESC cultures must be split when evenly positioned single hESC colonies begin to reach confluence. The authors typically split H1 and H9 hESC cultures every 6 to 7 days at a 1:6 split ratio. The number of hESCs on the day of passage is ~3 × 10^6 cells/ well of a 6-well plate.

SUPPORT PROTOCOL 5

PREPARATION OF MEF FEEDER PLATES

MEF feeder cells support attachment and undifferentiated growth of hESC colonies. MEF derivation and propagation can be performed according to established protocols from the suppliers—the National Stem Cell Bank (see Internet Resources) or commercial sources (e.g., ATCC, GlobalStem). The authors use an MEF stock frozen at passage 3 for weekly preparation of MEF feeder plates. After thawing, MEFs are propagated during one adaptation passage, inactivated by irradiation, and plated to 6-well plates in semiconfluent density.

Materials

Gelatin-coated 10-cm dishes and 6-well plates (see recipe)
CF-1 strain MEFs (e.g., National Stem Cell Bank or ATCC: frozen stock at passage 3; 2–3 $\times$ 10^6 cells/vial)
MEF growth medium (see recipe)
1$\times$ phosphate-buffered saline, without calcium and magnesium (PBS; GIBCO)
0.05% (w/v) trypsin/0.5 mM EDTA solution (1$\times$; GIBCO)

15-ml polypropylene tubes
Gamma irradiator

Additional reagents and equipment for counting cells (*UNIT 1.1*)

Initiate MEF culture

1. Prepare one 15-ml tube and two gelatin-coated 10-cm dishes for each vial of MEFs to be thawed.
2. Thaw an MEF vial in a 37°C water bath and transfer the cells to a 15-ml tube.
3. Add 10 ml of cold (4°C) MEF growth medium to the cells in the tube and centrifuge 5 min at 300 $\times$ g, 4°C.
4. Aspirate the supernatant, resuspend the cells in 2 ml MEF growth medium, and add 1 ml to each gelatin-coated 10-cm dishes containing 10 ml MEF growth medium. Mix the cells by agitation and place the dishes in the CO_2 incubator.
5. Grow MEFs to confluence (3 to 4 days).

Collect MEFs

6. Remove the MEF dishes from the CO_2 incubator. Wash the cell monolayer once with 10 ml PBS and add 4 ml/dish prewarmed trypsin/EDTA solution. Incubate dishes 2 to 3 min in the CO_2 incubator.

   Do not incubate longer because the MEF monolayer disaggregates quickly.

7. Transfer the cell suspension to a 15-ml tube containing 5 ml MEF growth medium. Centrifuge tube 5 min at 300 $\times$ g, room temperature.
8. Aspirate and discard the supernatant and resuspend the cells in 2 ml MEF growth medium.

Inactivate MEFs

9. Irradiate tube with 5000 rads of gamma irradiation.
10. Centrifuge the cells 2 to 3 min at 300 $\times$ g, room temperature.
11. Resuspend the cells in 1 ml MEF growth medium.
12. Count the cells (*UNIT 1.1*) and adjust the MEF suspension to 2 $\times$ 10^5 cells/ml MEF growth medium.

Plate MEFs

13. Fill gelatin-coated 6-well plates with 2 ml/well MEF growth medium. Add 1 ml MEF suspension per well, mix, and incubate the plates in the CO_2 incubator at least 24 hr before hESC plating. Use MEF feeder plates within 1 week.

CULTURE OF OP9 CELLS

SUPPORT PROTOCOL 6

Originally isolated from macrophage colony–stimulating factor (M-CSF) deficient osteopetrotic (*op*/*op*) mice, OP9 cells have been identified as efficient inducers of hematoendothelial differentiation in mouse ESCs (Kodama et al., 1994; Nakano et al., 1994;

Zhang et al., 2005). While a direct application of mouse ESC/OP9 protocol for hESC resulted in relatively poor performance, modifications of OP9 culture have enabled efficient hematopoietic differentiation from hESCs (Vodyanik et al., 2005). These modifications include the use of overgrown OP9 cultures for hESC differentiation and the maintenance of OP9 cells on gelatin-coated dishes to minimize spontaneous adipogenesis and focal outgrowth during extended post-confluence culture.

After confluence, OP9 cells are prone to spontaneous adipogenic differentiation especially when cultured in adipogenic FBS. The supplier and particular lot of FBS should be selected by the ability of FBS to support efficient OP9 growth with minimal (if noticeable) adipogenesis during maintenance culture and after feeding (half medium change) and prolonged culture of confluent OP9 cells for 4 to 6 days. A high-quality FBS is mandatory. The authors use a "defined" type of FBS (a commercial description for high-quality, biochemically characterized FBS with minimal lot-to-lot variation) from HyClone without heat inactivation, which does not benefit culture but usually results in a higher adipogenic effect. Basal αMEM (standard formulation without nucleosides) must be prepared from powder. The authors split OP9 cultures on the next day after confluence, typically every 4th day at up to a 1:10 split ratio. On the day of passage, 2–3 × 10^6 OP9 cells can be recovered from one 10-cm dish.

Materials

OP9 growth medium (see recipe).
0.05% (w/v) trypsin/0.5 mM EDTA solution (1×; GIBCO)
OP9 cells (ATCC #CRL-2749)
1× phosphate-buffered saline, without calcium and magnesium (PBS; GIBCO)
Gelatin-coated 10-cm dishes (see recipe)

15-ml polypropylene tubes
Inverted microscope

Passage OP9 cells

1. Warm OP9 growth medium and trypsin/EDTA solution in a 37°C water bath.
2. Remove the OP9 dishes from the CO_2 incubator. Aspirate and discard the medium and wash the cell monolayer with 10 ml PBS.
3. Add 5 ml trypsin/EDTA solution and incubate 5 to 10 min in the CO_2 incubator.
4. Suspend the trypsinized OP9 cells by pipetting and add the cell suspension to a 15-ml tube containing 5 ml OP9 growth medium. Centrifuge 5 min at 300 × *g*, room temperature.
5. Discard the supernatant and resuspend the cell pellet in 1 ml OP9 growth medium.
6. Add 1/7 to 1/10 vol of the cell suspension to each gelatin-coated 10-cm dish containing 10 ml OP9 growth medium. Mix cells by agitation and place dishes in the CO_2 incubator.

   It is essential to use gelatin-coated dishes for OP9 propagation to prevent spontaneous adipogenesis. Because the intensity of OP9 growth is largely influenced by FBS, a split ratio should be adjusted with each new FBS lot to ensure formation of confluent OP9 cultures during 3 to 4 days. Feeding of OP9 cells between passages and splitting of semiconfluent cultures should be avoided.

7. Grow OP9 cells to confluence and on the day after reaching confluence (typically 4 days), split again as described above.

Prepare OP9 dishes for hESC differentiation

8. Plate OP9 cells on gelatin-coated 10-cm dishes as for a regular OP9 passage (steps 1 to 6).

9. On day 4, remove 5 ml of the medium using a pipet and add 5 ml fresh prewarmed OP9 medium. Incubate OP9 dishes for an additional 4 days.

   OP9 cultures used for hESC differentiation must be 8 to 10 days old, fed with fresh medium at confluence (day 4) and incubated for extra 4 to 6 days.

10. Observe cultures on day 8 under an inverted microscope.

    A typical overgrown OP9 monolayer should be formed (Fig. 23.6.2C) indicating that cells are ready for hESC plating.

    Overgrown OP9 cells do not appear as multilayered overcrowding cells, but form a regular dense monolayer embedded in extracellular matrix (Fig. 23.6.2C). Scattered adipocytes may appear in overgrown OP9 cultures, but no areas of extensive adipogenesis or focal outgrowth should be detectable.

    It is possible to incubate OP9 dishes for an additional 4 days without feeding until hESCs will be available for differentiation. However, the authors usually do not use OP9 dishes beyond total 12 days of culture.

PROPAGATION OF ENDOTHELIAL CELLS

SUPPORT PROTOCOL 7

Endothelial cells isolated on day 7 to 8 of hESC/OP9 coculture can be expanded for 4 to 5 passages in serum-free medium in the presence of fibroblast growth factor (FGF). Since a $>100\times$ cell expansion can be achieved, hESC/OP9 cocultures may be used as a source of hESC-derived endothelial cells for a variety of functional studies.

Materials

MACS-isolated endothelial ($CD31^+CD43^-$) cells on day 7 to 8 of hESC/OP9 coculture (Basic Protocol 2, step 22)
Fibronectin-coated 10-cm tissue culture dishes (see recipe)
Endothelial cell growth medium (ECGM; see recipe)
$1\times$ phosphate-buffered saline, without calcium and magnesium (PBS; GIBCO)
HyQ-Tase cell detachment solution (HyClone)
Endothelial serum-free medium (ESFM; GIBCO)
Temperature controlled centrifuge, 4°C

1. Plate 10^6 MACS-isolated endothelial ($CD31^+CD43^-$) cells on a fibronectin-coated 10-cm dishes containing 10 ml ECGM (10^6 cells/dish). Incubate in a CO_2 incubator 4 to 6 days until cells reach confluence.

   After a 1 to 2 day lag period, cells start proliferation and reach confluence in 3 to 4 days.

2. Aspirate the medium and wash the cell monolayer with 10 ml PBS.

3. Add 2 ml PBS and 2 ml HyQ-Tase solution. Mix the solutions by gently agitating and incubate 5 min in a CO_2 incubator.

4. Suspend the detached cells by pipetting and transfer the cell suspension to a 15-ml tube containing 5 ml ESFM. Centrifuge 5 min at $300 \times g$, room temperature.

5. Resuspend the cell pellet in 1 ml ESFM, add 1/5 vol to the freshly prepared fibronectin-coated 10-cm dish containing 10 ml ECGM. Mix the cells by agitation and place the dishes in the CO_2 incubator.

6. Grow the endothelial cells until they reach confluence (typically 4 days) and split as in steps 2 to 5.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Cell washing/MACS buffer

Phosphate-buffered saline, without calcium and magnesium (PBS; GIBCO) supplemented with 5% (v/v) heat-inactivated FBS (GIBCO) and 2 mM EDTA. Sterilize by passing through a 0.22-μm filter under vacuum. Allow the solution to remain under vacuum 15 to 20 min for degassing. Store up to 6 months at 4°C.

Keep the buffer on ice during a MACS procedure.

Collagenase IV solution

Dissolve 50 mg collagenase IV (GIBCO) in 50 ml DMEM/F12 basal medium (1 mg/ml final concentration). Sterilize by passing through a 0.22-μm filter. Store up to 2 weeks at 4°C.

Differentiation medium

Prepare the following components:

αMEM basal medium prepared from powder and sterilized by passing through a 0.22-μm filter. Store up to 2 months at 4°C.

50-ml aliquots of non-heat-inactivated defined FBS (HyClone). Store up to 1 year at −20°C.

1000× (100 mM) monothioglycerol (MTG) solution. Add 87 μl MTG (Sigma) to 10 ml water. Mix well and dispense into 0.5-ml aliquots. Store up to 6 months at −20°C.

1000× (50 mg/ml) ascorbic acid solution. Dissolve 500 mg ascorbic acid (Sigma) in 10 ml water. Dispense into 0.5-ml aliquots and store up to 6 months at −20°C.

To prepare differentiation medium:

Combine 450 ml αMEM basal medium (90%), 50 ml FBS (10%), 0.5 ml MTG (1×; 100 μM), and 0.5 ml ascorbic acid (1×; 50 μg/ml) in the upper chamber of a 500-ml bottle-top 0.22-μm filter unit (Nalgene). Sterilize by vacuum filtration and store up to 1 month at 4°C.

Endothelial cell growth medium

Supplement endothelial serum-free medium (ESFM; GIBCO) with 10 ng/ml basic fibroblast growth factor (bFGF; PeproTech) and 1/100 vol endothelial cell growth factor (acidic FGF and heparin; Sigma E9640). Prepare immediately before use.

Do not store medium with cytokines.

FACS buffer, with and without FBS

Phosphate-buffered saline, without calcium and magnesium (PBS; GIBCO) supplemented with 2% (v/v) heat-inactivated fetal bovine serum (FBS; GIBCO), if required; 2 mM EDTA; and 0.05% (w/v) sodium azide. Sterilize by passing through a 0.22- or 0.45-μm filter under vacuum. Store up to 6 months at 4°C.

Fibronectin-coated dishes

Dissolve 5 mg human fibronectin (GIBCO) in 5 ml sterile endotoxin-free water (Millipore). Store in 0.1-ml aliquots up to 6 months at −20°C. For plastic coating, dilute fibronectin solution 1/200 in phosphate-buffered saline (PBS; GIBCO; final

continued

concentration 5 μg/ml) and add 5 ml to each 10-cm tissue-culture dish (Falcon). Incubate dishes overnight at 4°C. Before use, aspirate the fibronectin solution and add the required amount of an appropriate growth medium.

Gelatin-coated dishes/plates

Prepare a 0.1% (w/v) gelatin solution: To a borosilicate glass bottle with autoclavable cap, add 500 mg Gelatin type A powder (Sigma) to 500 ml endotoxin-free reagent-grade water (Millipore). Mix well and autoclave the gelatin slurry 45 min at 121°C (gelatin will dissolve during autoclaving). Store up to 6 months at 4°C.

Add 6 to 7 ml gelatin solution to each 10-cm tissue-culture dish (Falcon) or 2 ml to each well of a 6-well tissue-culture plate (Falcon). Allow the gelatin solution to cover the entire plastic surface. Incubate dishes/plates in a CO_2 incubator at least overnight. Store up to 1 week in a CO_2 incubator. Before use, aspirate the gelatin solution and add the required amount of an appropriate medium.

hESC growth medium

Prepare the following components:

Prepare DMEM/F12 medium from powder (GIBCO). Sterilize by passing through a 0.22-μm filter. Store up to 2 months at 4°C.

100× L-glutamine/2-mercaptoethanol supplement. Dissolve 146 mg L-glutamine (GIBCO) in 10 ml phosphate-buffered saline, without calcium and magnesium (PBS; GIBCO) and add 7 μl of 2-mercaptoethanol (Sigma). Store up to 1 week at 4°C.

500× basic fibroblast growth factor (bFGF) solution. Dissolve 50 μg bFGF (PeproTech) in 25 ml PBS supplemented with 2 mg/ml bovine serum albumin V (GIBCO). Store up to 6 months at −80°C in 0.5-ml aliquots.

Dispense 50 ml aliquots of Knockout Serum Replacer (KSR; GIBCO). Store up to 1 year at −20°C.

To prepare complete hESC growth medium:

Combine 200 ml DMEM/F12 basal medium (80%), 50 ml Knockout Serum Replacer (20%), 2.5 ml 10 mM (100×) nonessential amino acid solution (GIBCO) (1×), 2.5 ml L-glutamine/2-mercapthoethanol (1×), and 0.5 ml bFGF (4 ng/ml) in the upper chamber of a 250-ml bottle-top 0.22-μm filter unit (Nalgene) and sterilize by passing through the filter under vacuum. Store up to 2 weeks at 4°C.

Final concentrations of components are given in parentheses.

MEF growth medium

Prepare the following components:

Sterile-filtered DMEM medium prepared from powder (GIBCO). Store up to 2 months at 4°C.

50-ml aliquots of heat-inactivated FBS (GIBCO). Store up to 1 year at −20°C.

To prepare MEF growth medium:

Combine 450 ml DMEM basal medium (90%), 50 ml FBS (10%), and 5 ml 10 mM (100×) nonessential amino acid solution (GIBCO) (1×) in upper chamber of 500-ml bottle-top 0.22-μm filter unit (Nalgene). Sterilize by passing through the filter under vacuum. Store up to 1 month at 4°C.

Final concentrations of components are given in parentheses.

OP9 growth medium

Prepare the following components:

Prepare αMEM medium from powder (GIBCO). Sterilize by passing through a 0.22-μm filter. Store up to 2 months at 4°C.

Dispense 50-ml aliquots of non-heat-inactivated defined FBS (HyClone). Store up to 1 year at −20°C.

To prepare OP9 growth medium:

Combine 400 ml αMEM basal medium (80%), and 100 ml FBS (20%) in upper chamber of 500-ml bottle-top 0.22-μm filter unit (Nalgene). Sterilize by passing through the filter under vacuum. Store up to 1 month at 4°C.

Final concentrations of components are given in parentheses.

COMMENTARY

Background Information

ESCs represent a unique population of cells capable of self-renewal and differentiation. hESCs give rise to tissues from all three germ layers upon injection into immunodeficient mice or when induced to form embryoid bodies in vitro (Thomson et al., 1998; Schuldiner et al., 2000). Systems for hematopoietic differentiation of hESCs provide a unique opportunity to study mechanisms regulating lineage commitment and maturation, identification of novel hematopoietic precursors, and evaluation of the function of genes critical for hematopoietic development. The ability of mouse ESCs to differentiate into hematopoietic cells was demonstrated in 1985 (Doetschman et al., 1985). In 2001, hematopoietic progenitors were obtained from hESCs cells (Kaufman et al., 2001). Since that time almost all blood lineages have been successfully generated from mouse and human ESCs, including red blood cells (Nakano et al., 1996; Qiu et al., 2005), neutrophils (Lieber et al., 2004; Vodyanik et al., 2005), megakaryocytes (Eto et al., 2002; Gaur et al., 2006), lymphocytes (Cho et al., 1999; Schmitt et al., 2004; Vodyanik et al., 2005; Woll et al., 2005; Galic et al., 2006), and dendritic cells (Fairchild et al., 2000; Senju et al., 2003; Slukvin et al., 2006).

Two major approaches are used to induce hematopoietic differentiation of ESCs. One approach allows ESCs to form embryoid bodies after withdrawal of factors that keep ESCs in an undifferentiated state. Various lineages of cells, including hematopoietic cells, develop inside embryoid bodies. The hematopoietic development within embryoid bodies is very similar to that found in the yolk sac (Burkert et al., 1991; Schmitt et al., 1991; Keller et al., 1993; Zambidis et al., 2005). The embryoid body method can be adapted to serum-free conditions (Ng et al., 2005), making it possible to exclude a variability related to different lots of the serum and identification of factors required for lineage-specific differentiation. However, it is difficult to induce lymphoid differentiation under normal culture conditions using an embryoid body method (Potocnik et al., 1994; Nakano, 2003).

Another approach to inducing hematopoietic differentiation is coculture of ESCs with bone marrow stromal cell lines. Several stromal cell lines, e.g., mouse bone marrow stromal cell lines S17, RP.0.10, and OP9 (Gutierrez-Ramos and Palacios, 1992; Nakano et al., 1994; Kaufman et al., 2001; Vodyanik et al., 2005), mouse yolk sac C166 cell line (Kaufman et al., 2001), and human fetal liver FH-B-hTERT cell line (Qiu et al., 2005), have been employed to induce hematopoietic differentiation of ESCs. The most commonly used stromal cell line for hematopoietic differentiation studies is OP9, which was derived from M-CSF-deficient *op*/*op* osteopetrotic mice (Yoshida et al., 1990; Kodama et al., 1994). The OP9 coculture was used to obtain multilineage hematopoietic progenitors as well as mature hematopoietic cells such as lymphocytes and megakaryocytes, which are difficult to obtain using the embryoid body method (Nakano et al., 1994; Eto et al., 2002; Vodyanik et al., 2005; Gaur et al., 2006). An important advantage of OP9 coculture is that efficient hematopoietic differentiation from hESCs can be achieved within a short period of time and without added cytokines. In addition, in contrast to the embryoid body

method, OP9 coculture allows one to obtain the earliest lymphohematopoietic progenitors without applying excessive mechanical disaggregation, which results in substantial viability loss. It should be noted, that differentiation of ESCs in a monolayer on extracellular matrix proteins has also been described (Nishikawa et al., 1998; Zhang et al., 2006), but it is not widely used.

The hematopoietic system comprises a hierarchy of cells at different stages of maturation, which can be identified using morphologic and phenotypic criteria as well as functional assays. The hematopoietic stem cell (HSC) is defined as a cell able to generate all types of hematopoietic cells and capable of self-renewal throughout the lifetime of an individual. While isolation of $CD34^+$ cells from bone marrow, unbilical cord, or peripheral blood highly enriches for HSCs, true HSCs can only be identified retrospectively using an in vivo repopulation assay. In this assay, HSCs are injected into immunocompromised mice (e.g., NOD/SCID), and the presence of hematopoietic progeny is evaluated 8 to 10 weeks after transplantation. While several investigators have reported successful engraftment of mouse and human ESC-derived hematopoietic progenitors (Hole et al., 1996; Potocnik et al., 1997; Burt et al., 2004; Wang et al., 2005a), these results have not been widely reproduced, and it is generally accepted that engraftment by ESC-derived hematopoietic progenitors is inefficient at the least (Daley, 2003; Nakano, 2003; Keller, 2005). This failure to engraft is at least partially due to an abnormal expression profile of *Hox* genes and could be corrected through forced expression of *HoxB4* and *Cdx4* genes (Kyba et al., 2002; Wang et al., 2005b).

Hematopoietic progenitors represent cells that may be multipotent, oligopotent, or unipotent, but they lack significant self-renewal capacity. Several types of in vitro assays have been developed to characterize hematopoietic progenitors at different stages of maturation. The colony-forming cell (CFC) assay in semisolid media is the most widely used and well-standardized assay for detection of progenitors at intermediate stages of development. This relatively simple assay requires a short period of time to perform and allows identification of several types of hematopoietic progenitors in one dish. The CFC assay remains an essential tool for characterizing hematopoietic progenitors generated from hESCs. Long-term in vitro assays are designed to identify less mature hematopoietic progenitors and usually require 3 to 5 weeks of culture in the presence of bone marrow-derived stromal cells. These assays identify cells that retain CFC potential after prolonged culture (long-term culture initiating cells; LTC-ICs) as well lymphoid progenitors (Coulombel, 2004). However, long-term in vitro assays are laborious and subject to great variability due to differences between laboratories in the use of media, growth factors, serum, and feeder cells for performing assays. It should also be noted that all in vitro assays do not reflect the presence of cells with stem cell potential in a sample.

Phenotypic analysis represents a valuable tool for the identification of different types of hematopoietic cells. The phenotype of adult hematopoietic progenitors is well characterized. However, it is important to emphasize that somatic and hESC-derived hematopoietic progenitors may demonstrate substantial phenotypic differences. While CD34 is present on most hESC-derived hematopoietic cells, it is also expressed on endothelial and mesenchymal cells. Flow cytometric analysis using CD34, CD43, and KDR (FLK1) or CD31 antibodies is useful for discriminating these subsets of CD34 cells in hESC/OP9 coculture (Vodyanik et al., 2006). The commonly used pan-hematopoietic marker CD45 is not expressed on the earliest hESC-derived multipotent hematopoietic progenitors. Another pan-hematopoietic marker (CD43) is present on all hematopoietic progeny from hESCs. This molecule is useful for evaluation of hESC hematopoietic differentiation as well as for isolation of hematopoietic progenitors from hESC/OP9 cocultures (Vodyanik et al., 2006). The first-appearing $CD43^+CD235a^+CD41a^{+/-}CD45^-$ hematopoietic progenitors in hESC/OP9 coculture represent precommitted erythro-megakaryocytic progenitors.

The primary hESC progeny with multilineage hematopoietic potential has $CD34^+CD43^+CD45^-Lin^-$ phenotype. These cells are capable of differentiation toward all blood lineages as well as B lymphoid cells. Acquisition of CD45 expression by $CD34^+CD43^+CD45^-Lin^-$ cells is associated with progressive myeloid commitment and a decrease of lymphoid potential (Vodyanik et al., 2006). Isolation of these progenitors and subsequent studies of their differentiation potential may provide important information regarding regulatory signals governing the development of specific hematopoietic lineages, and will eventually facilitate development of

bioreactor-based technology for large-scale production of blood cells for transfusion and cellular therapy.

Critical Parameters and Troubleshooting

It is essential to use semiconfluent monolayers of MEFs for hESC propagation. Overcrowded MEFs suppress growth of undifferentiated hESC colonies and may cause their spontaneous differentiation. Different batches of MEFs prepared using different lots of FBS and plastic may vary in cell size, and, therefore, MEF plating density should be adjusted accordingly to ensure a semiconfluent feeder layer for hESC culture.

A high-density overgrown OP9 monolayer is the most critical parameter for successful hematopoietic differentiation of hESCs. However, OP9 cells are prone to spontaneous adipogenic differentiation in postconfluence cultures. To minimize adipogenesis in high-density overgrown cultures, OP9 cells should be cultured on gelatin-coated dishes using preselected nonadipogenic lots of FBS. OP9 cells obtained from different sources (directly from Dr. Nakano or ATCC) efficiently support hematopoietic hESC differentiation. However, the authors recommend adaptation of OP9 cells for growth on gelatin-coated dishes for at least five passages before the cells are used for hESC differentiation.

A high-quality basal αMEM medium is essential for maintenance of OP9 cells as well as hematopoietic differentiation in hESC/OP9 cocultures. Freshly prepared αMEM from powder formulation is superior to commercial ready-to-use liquid medium. The αMEM formulation supplemented with nucleosides increases proliferation of OP9 cells in maintenance cultures, but has little effect on hematoendothelial differentiation in hESC/OP9 coculture. Addition of 100 μM (final concentration) SH-agent MTG to differentiation medium significantly increases the yield of total differentiated cells in hESC/OP9 cocultures including hematopoietic and endothelial cells, however at >200 μM concentration, hematoendothelial differentiation may be suppressed. While αMEM already contains a high concentration of ascorbate, the authors use additional supplementation of differentiation medium with 50 μg/ml ascorbic acid to specifically improve hematoendothelial differentiation.

Optimal hESC plating density in OP9 cocultures is important for efficient differentiation and may vary for different hESC lines. A plating density of 1.5×10^6 cells per 10-cm OP9 dish is acceptable for H1 or H9 hESC lines, although H9 cells differentiate more efficiently when plated at a lower density (10^6 cells/OP9 dish). Optimal plating density for other hESC lines should be determined in preliminary experiments using an initial range of $0.5–2.5 \times 10^6$ cells/OP9 dish with 0.5 intervals.

One problem that can be encountered is poor viability and cell loss following preparation of a single-cell suspension from hESC/OP9 cocultures, especially after 8 days of differentiation. This may happen because of excessive production of an extracellular matrix that withstands collagenase and trypsin treatment. As a result, many cells may be lost due to clumping and subsequent mechanical damage during pipetting. Longer incubation with collagenase and trypsin (up to 30 min each) should be used first to improve cell recovery. In addition, collagenase solution can be supplemented with 0.1 mg/ml hyaluronidase to further facilitate cell dissociation.

While the function of the CD43 molecule on early hematopoietic progenitors is largely unknown, it has been shown that cross-linking of CD43 on hematopoietic progenitors may induce apoptosis (Bazil et al., 1995). Therefore, it is critical to use antibodies that minimally affect the cell viability and function of isolated $CD43^+$ cells. Procedures in this unit use clone 1G10 anti-CD43 mAbs, which detect $CD43^+$ cells at maximal frequency compared to other anti-CD43 mAb clones (L10, 290111) and enable successful isolation of functional $CD43^+$ cells. It is important to note, that some anti-CD235a mAbs may cause cell agglutination, affecting flow cytometric detection and isolation of erythroid progenitors. Such cell clumping may be prevented by using a lower concentration of agglutinating mAb for cell labeling. Anti-CD235a mAb included in the present protocols are non-agglutinating.

Anticipated Results

On day 1 of hESC/OP9 coculture, only condensed hESC clumps attached to OP9 monolayer can be observed. Differentiation begins on day 2 when outgrowing hESCs immerse into OP9 monolayer. At this time, the first differentiating hESC colonies are readily detectable. On day 3, the number and size of differentiated colonies increase dramatically. Colonies acquire the characteristic appearance of "mesodermal" colonies with an elevated central portion composed of tightly packed rounded cells (Fig. 23.6.2D). On day 4, almost

all colonies have a typical "mesodermal" morphology and reach maximal size. On day 5, colonies begin the lateral growth that leads to their decomposition. Actively growing differentiated cells displace the OP9 cells and form confluent cultures on day 7. During 8 to 9 days, cultures do not change significantly, although ongoing differentiation can be observed by the emergence of proliferating cell clusters and vascular tubes. Due to high cell density, cultures begin to deteriorate after 10 to 12 days.

The efficiency of hematopoietic differentiation may vary for different hESC lines. Using H1 and H9 hESC lines, consistently higher differentiation efficiency in H1 cells is observed, especially regarding hematopoietic cell generation. Although H9 cells reproduce the kinetic profile of hematoendothelial differentiation observed in H1 cells, H9 differentiation is usually delayed for 1 day and results in 1.5 to 2× lower numbers of $CD43^+$ hematopoietic cells. A description of typical results for H1 cells (assuming that efficiency with other hESC lines may be different) follows: On day 7 to 8 of H1/OP9 coculture, H1-derived cells (TRA-1-85$^+$) constitute ~90% of total cells. Hematopoietic and endothelial cells ($CD31^+$) comprise 8% to 15% of total H1-derived cells. $CD34^+$ cells are always detectable in higher frequency (12% to 25%), due to the presence of $CD34^+$ mesenchymal cells. The $CD31^+$ population is typically composed of 60% to 70% endothelial cells ($CD31^+CD43^-$) and 30% to 40% hematopoietic progenitors ($CD31^+CD43^+$) that corresponds to 5% to 10% and 3% to 5% of total H1-derived cells, respectively. In the $CD43^+$ population, $CD43^+CD235a^+$ erythro-megakaryocytic progenitors comprise 50% to 70% of total $CD43^+$ cells or ~3% of total H1-derived cells. Multipotent progenitors found within the $CD43^+CD235a^-$ population (30% to 50% of total $CD43^+$ or ~2% of total H1-derived cells) undergo transition from $CD45^-$ to $CD45^+$ stage during 7 to 8 days of H1/OP9 coculture; on day 7, $CD45^-$ cells predominate (~80%), whereas on day 8, $CD45^-$ and $CD45^+$ cells comprise nearly equal populations.

The yield of endothelial and hematopoietic cells in isolation procedures is primarily dependent on the efficiency of hESC differentiation and the absolute number of cells generated in hESC/OP9 cocultures. The latter may vary from 15–30 × 10^6 cells per 10-cm dish and generally depends on variations in hESC growth during the first 2 to 3 days of coculture. For MACS isolation of 10^6 endothelial ($CD31^+CD43^-$) or hematopoietic ($CD31^+CD43^+$) cells, one to two H1/OP9 dishes is usually enough, but for FACS isolation of $CD43^+$ subsets, the number of H1/OP9 dishes should be scaled up as follows: for 10^6 $CD43^+CD235a^+$ erythro-megakaryocytic progenitors, three to four dishes; for 10^6 total $CD43^+CD235a^-CD45^{+/-}$ multipotent progenitors, eight to ten dishes. To isolate 10^6 FACS-sorted $CD45^-$ and $CD45^+$ multipotent progenitors on day 8, at least twenty H1/OP9 dishes should be processed.

Time Considerations

Setting up of hESC/OP9 cocultures requires coordinated maintenance of undifferentiated hESC, MEF, and OP9 cell cultures. One passage hESC culture takes 6 to 7 days. On the next day after hESC passage, new MEF culture should be initiated to ensure availability of MEF feeder plates for the next hESC passage. From 2–3 × 10^6 initially thawed MEFs, three to four feeder plates can be prepared. At splitting of a 6-well hESC plate, two wells will be used for hESC passage and counting, and four wells can be used for differentiation. Up to 8–12 × 10^6 hESCs can be collected from four wells, and that is sufficient for setting up six to eight hESC/OP9 dishes. At splitting of one 10-cm OP9 dish, 1/7 to 1/10 portions will be used for passage, and remaining cells can be plated on six to nine dishes for hESC differentiation. hESCs should be plated on OP9 dishes within 8 to 12 days after OP9 plating. During this time interval, actively growing undifferentiated hESCs (at 5 to 7 days of culture) should be available for differentiation.

All standard cell culture procedures with hESC, MEF, and OP9 maintenance cultures are time efficient and can be performed within 1 hr or less. One experiment for hESC differentiation can be completed within 15 to 20 days; it requires 8 to 12 days for OP9 preparation and 7 to 8 days for hESC/OP9 coculture. Depending on the volume of hESC differentiation cultures (typically up to ten hESC/OP9 dishes in one experiment) each of the following procedures may take 2 to 4 hr: harvesting of hESC/OP9 cocultures, analysis of differentiated cells by flow cytometry and cell plating for the methylcellulose CFC assay, single parameter MACS sorting, and FACS sorting.

ABSTRACT

Human embryonic stem cells (hESCs) may be converted into highly enriched cultures of neural precursors under defined culture conditions. The neural precursors can proliferate in culture for prolonged periods of time, and can differentiate in vitro into mature neurons, astrocytes, and oligodendrocytes. The neurons are functional and have normal electrophysiological properties. After transplantation to the developing rodent brain, the neural precursors migrate extensively into the host brain parenchyma, respond to host brain signals, and differentiate in a region-specific manner to progeny of the three neural lineages. The establishment of neuroectodermal precursors from hESCs allows the study of human neurogenesis in vitro and is an aid in drug discovery. In addition, the neural precursors may potentially serve as a platform for the development of specific functional neural cells for transplantation and gene therapy of neurological disorders. In this unit, we introduce methods for the derivation, propagation and characterization of hESC-derived neural precursors. *Curr. Protoc. INTRODUCTION

Embryonic stem (ES) cells can differentiate into all cell types of the body including neural cells, and thus offer an in vitro model for tracing early cell lineages in mammals. Derivation of neural precursors (NPs) from human ES cells (hESCs) may be invaluable for the study of early human neurogenesis and for the utilization of hESCs as an unlimited source of neural cells for transplantation in human neurodegenerative disorders. Neural cells may be generated from hESCs following spontaneous differentiation in vitro, either in high-density cultures or through embryoid body (EB) formation. However, the neural cells that are generated from these cultures are within a mixture of other types of differentiated cells. Protocols for the controlled derivation of cultures highly enriched for proliferating, developmentally competent NPs were recently reported.

Here, a protocol is described for the derivation of NPs from hESCs in chemically defined serum-free culture conditions (Basic Protocol). This protocol enables the controlled differentiation of hESCs into NPs by two major steps. In the first step, clusters of hESCs are enzymatically removed from the feeder cells to chemically defined serum-free suspension culture conditions. Contamination of the hESC-clusters by residual feeder cells is avoided. In the second step, controlled efficient differentiation of the hESCs to an NP fate is achieved by supplementation with the growth and differentiation–inducing factors noggin [bone morphogenic protein (BMP) antagonist] and basic fibroblast growth factor (bFGF), mimicking neural induction in vivo. Methods are also described for the characterization of the NPs by immunocytochemistry (Support Protocol 1) and flow cytometry (Support Protocol 2), and for induction of their spontaneous differentiation (Support Protocol 3). Finally, a protocol for culturing human embryonic stem cells is provided (Support Protocol 4).

Current Protocols in Cell Biology 23.7.1-23.7.20, September 2007
Published online September 2007 in Wiley Interscience (www.interscience.wiley.com).
DOI: 10.1002/0471143030.cb2307s36

NOTE: All incubations are performed in 5% CO_2, humidified 37°C incubators unless otherwise specified.

NOTE: All solutions and equipment coming into contact with living cells must be sterile, and aseptic technique should be used accordingly.

NOTE: All procedures describing the use of phosphate-buffered saline (PBS) in this unit refer to calcium- and magnesium-free PBS (e.g., Invitrogen, cat. no. 14190) unless PBS with calcium and magnesium (e.g., Invitrogen, cat. no. 14040) is specified.

BASIC PROTOCOL

CONTROLLED DERIVATION OF NEURAL PRECURSORS FROM hESCS

Controlled neural differentiation of hESCs enables the enrichment of NPs in the cell culture under serum-free suspension culture conditions. hESCs are cultured in a chemically defined medium supplemented with noggin and bFGF to promote neural differentiation, and then in a medium supplemented with bFGF to further propagate the hESC-derived NPs.

Materials

0.1% (w/v) low melting temperature (LMT) agarose (see recipe)
hESCs cultured on a feeder layer (see Support Protocol 4) in 6-well plates
1 mg/ml collagenase type IV (see recipe)
Neural precursor medium (NPM; see recipe)
20 μg/ml bFGF (see recipe)
100 μg/ml noggin (see recipe)
NPM (see recipe) containing 20 ng/ml bFGF (added from 20 μg/ml bFGF stock; see recipe) and 500 ng/ml noggin (add from 100 μg/ml noggin stock; see recipe)
NPM (see recipe) containing 20 ng/ml bFGF (added from 20 μg/ml bFGF stock; see recipe)

50-ml conical polypropylene centrifuge tubes
Centrifuge
24-well tissue culture plates
50-ml centrifuge tubes
20-G surgical blades

Additional reagents and equipment for culturing hESCs (Support Protocol 4)

Collect hESC clusters from culture

1. To prevent adhesion of hESC clusters to the culture dishes, cover the well bottoms of a 24-well plate with 0.5 ml of 0.1% low-melting temperature agarose for at least 30 min. Aspirate the agarose suspension and dry the plate at room temperature.

   Alternatively, one can use a low-cell-attachment plate.

2. Aspirate the medium from a 6-well plate containing hESC-colonies cultured on feeders, 6 to 7 days after their passage with EDTA as described in Support Protocol 4.

   Use the EDTA passage method (Support Protocol 4) for at least the last passage before hESC-cluster formation, to achieve hESC colonies homogenous in size (Fig. 23.7.1A).

3. Apply 1 ml of 1 mg/ml (~200 U) collagenase type IV to each well and incubate for 30 to 60 min.

   After this incubation, the edges of the hESC colonies should detach from the feeder layer (Fig. 23.7.1B).

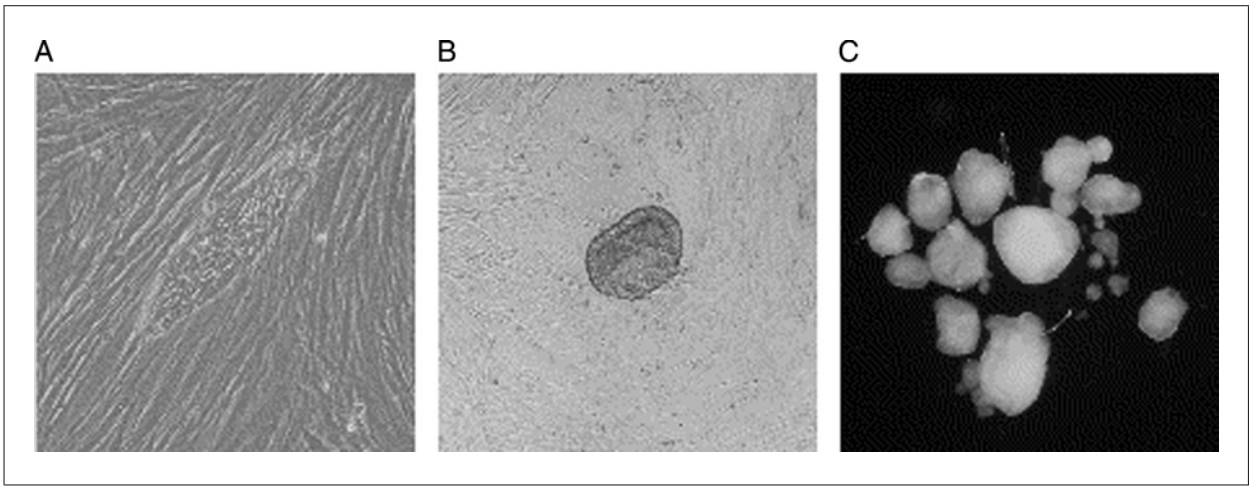

Figure 23.7.1 Derivation of NPs from undifferentiated hESCs. (**A**) An undifferentiated hESC colony cultured on human foreskin fibroblasts, 1 week after passaging with the aid of an EDTA dissociation solution (phase-contrast image; 40× magnification). (**B**) hESC colony after 30 min of collagenase treatment (phase-contrast image; 40× magnification). (**C**) hESC-derived neural spheres 3 weeks after derivation and culture in defined medium (NPM) supplemented with bFGF and noggin (dark-field stereomicroscopic image; 2× magnification).

4. Tap the plate to gently dislodge the clusters of hESCs from the feeder cells.

   The feeders should remain intact on the bottom of the well and the hESC clusters should be free of contaminating feeder cells.

5. Collect the supernatant medium with the hESC clusters from all wells and transfer to a 50-ml tube. Gently centrifuge 5 min at ~40 × *g*, room temperature.

Transfer hESC clusters to cultures with NPM

6. Aspirate the supernatant from the cell clusters and resuspend them in neural precursor medium (NPM) at a density of up to 80 × 10^3 cells/ml (~40 clumps/ml).

7. Add 1 μl of 20 μg/ml bFGF to each 1 ml of cluster suspension, to reach a final concentration of 20 ng/ml.

8. Add 5 μl of 100 μg/ml noggin to each 1 ml of cluster suspension, to reach a final concentration of 500 ng/ml.

9. Transfer the clusters at 1 ml per well to a 24-well culture dish pretreated with 0.1% LMT agarose (see step 1).

   Upon transfer of the hESC clusters into NPM, significant cell death should be observed during the first 2 to 3 days, which should be followed by a gradual increase in the sizes of the floating clusters, which acquire the form of spheres (Fig. 23.7.1C).

Propagate the neural cultures

10. Culture the clusters for the first 3 weeks in NPM containing 20 ng/ml bFGF and 500 ng/ml noggin.

11. Change the medium every 2 days as follows. Swirl the plate to centralize the spheres in the middle of the well, collect the spheres into a microcentrifuge tube, let the tube stand for 3 min to allow the spheres to sink, remove the supernatant, add 1 ml of fresh prewarmed NPM containing 20 ng/ml bFGF and 500 ng/ml noggin, and replate the sphere suspension in the well.

12. After 3 weeks of culture, change the medium to NPM supplemented with 20 ng/ml bFGF. Refresh the medium every 2 days, using the technique described in step 11.

13. Check the cultures weekly and dissect any spheres or aggregates of spheres whose diameters exceed 0.5 mm into small clusters with two 20-G surgical blades that are used like scissors, or by trituration. For trituration, use a pipettor with a 200-µl tip, and repeatedly draw the sphere suspension up and down to dissociate the spheres.

At a time point 4 weeks after transfer of the hESC clusters into NPM, the spheres are highly enriched for NPs that can be used for further differentiation protocols.

SUPPORT PROTOCOL 1

CHARACTERIZATION OF THE NEURAL PRECURSORS BY IMMUNOSTAINING

The phenotype of the pluripotent cells and the NPs derived from them may be analyzed by immunostaining. Staining of both pluripotent and NP markers and their analysis at sequential time points makes it possible to track the progression of neural differentiation over time.

Materials

10 µg/ml poly-D-lysine (see recipe)
Tissue culture–grade distilled H_2O
4 µg/ml laminin (see recipe)
NPs derived from hESCs (see Basic Protocol)
0.008% (w/v) trypsin/2.4 mM EDTA (see recipe)
Phosphate-buffered saline (PBS; containing calcium and magnesium; Invitrogen, cat. no. 14040)
2.35 mg/ml DNase (see recipe)
4% (w/v) paraformaldehyde (see recipe)
FACS buffer (see recipe)
0.2% (v/v) Triton X-100 (see recipe)
Blocking solution (see recipe)
Appropriate primary antibody (Table 23.7.1)
Secondary antibody: fluorophore-conjugated antibody against IgG of species from which primary antibody was derived
Mounting medium with 4′-6-diamidino-2-phenylindole (DAPI; e.g., Vectashield from Vector Laboratories)

16-mm-diameter round glass coverslips, sterile (Paul Marienfeld & Co.; *http://www.marienfeld-superior.com*)
Center-well organ culture dish (Falcon)
Glass microscope slides

Coat coverslips

1. Place a glass coverslip in the center of a center-well organ culture dish. Cover the glass coverslip with 500 µl of 10 µg/ml poly-D-lysine and incubate 1 hr at room temperature.

The staining procedure is done in organ culture dishes; coverslips must be maintained in the organ culture dishes until the fixation step (step 8) and can then be transferred to 12-well plates.

2. Aspirate the poly-D-lysine solution and wash the glass coverslip with 1 ml of tissue culture–grade distilled water for 1 min. Aspirate the water and cover the glass coverslip with 500 µl of 4 µg/ml laminin. Incubate overnight at 4°C or for 2 hr at room temperature.

Laminin-coated glass coverslips can be kept up to 1 month at 4°C in a sealed chamber.

Plate single-cell suspensions of NPs

The NPs can be plated on the glass coverslips as cell clusters or as single cells. Cell clusters should be plated on precoated glass coverslips with 1 ml of NPM for 24 hr. For single-cell plating, follow the steps described below.

3. Collect the clusters of NPs (Basic Protocol) into a microcentrifuge tube and microcentrifuge for a few seconds at 240 × *g*, room temperature.
4. Aspirate the supernatant and resuspend the clusters in 500 μl of 0.008% trypsin/2.4 mM EDTA. Incubate at 37°C for 15 min.
5. Pipet the clusters up and down to dissociate them into a single-cell suspension. Microcentrifuge the cells for a few seconds at 240 × *g*.

   A white cloudy pellet should appear.

6. Gently remove the supernatant and add 500 μl of PBS (with Ca and Mg) and 5 μl of 2.35 mg/m DNase, then incubate for an additional 10 min. Pipet the pellet gently up and down to obtain a single-cell suspension. Microcentrifuge the cells for a few seconds at 240 × *g*, room temperature. Remove the supernatant and resuspend the cells in 500 μl NPM.
7. Plate the cell suspension on glass coverslips pre-coated with poly-D-lysine and laminin (from step 2) at a density of 5–10 × 10^3 cells/ml, and incubate for 1 to 2 hr at 37°C to allow the cells to attach to the coverslips.

Fix the cells

8. Fix the cells by flooding them with 2 ml of 4% paraformaldehyde and incubating 20 min at room temperature.
9. Aspirate the supernatant from the coverslip and wash three times, each time for 1 min with 1 ml of FACS buffer.

   The cells can be kept under the FACS buffer for up to 1 week at 4°C.

10. For immunostaining of intracellular markers, permeabilize cell membranes by flooding the cells with 1 ml of 0.2% Triton X-100 and incubating 5 min at room temperature.
11. Incubate the cells with 500 μl blocking solution for 30 to 60 min at room temperature.

Immunostain the cells

12. Aspirate the supernatant from the coverslip and incubate the cells with the desired primary antibody (Table 23.7.1), diluted in FACS buffer as described in Table 23.7.1, for 1 to 2 hr at room temperature.

    Proper control staining for the primary and secondary antibodies should be conducted to rule out nonspecific staining or antibody cross-reactivity.

13. Aspirate the supernatant from the coverslip and wash three times, each time for 1 min with 1 ml of FACS buffer.
14. For primary antibody localization, incubate the cells with an appropriate fluorophore-conjugated secondary antibody, diluted in FACS buffer according to the manufacturer's recommendations, for 1 to 2 hr at room temperature.
15. Aspirate the supernatant from the coverslip and wash three times, each time for 1 min with 1 ml of FACS buffer.
16. Thoroughly aspirate the FACS buffer from the glass coverslip and mount it on a glass microscope slide using mounting medium with DAPI.

[a] Abbreviations: DSHB, Developmental Studies Hybridoma Bank, University of Iowa (*http://dshb.biology.uiowa.edu/*); GABA, γ-aminobutyric acid; GFAP, glial fibrillary acid protein; NCAM, neural cell adhesion molecule; PSA-NCAM, polysialylated form of NCAM; MAP2, microtubule-associated protein 2; NF, neurofilament; NeuN, neuronal nuclei.

CHARACTERIZATION OF NEURAL DIFFERENTIATION BY FLOW CYTOMETRIC ANALYSIS

The percentage of cells expressing markers of NPs or pluripotent cells and the intensity of expression of the markers should be analyzed by FACS. Analysis at sequential time points enables the characterization of the progression of neural differentiation over time. This protocol describes the characterization of both undifferentiated hESCs and NPs. The initial preparation of the two types of cells is described separately.

Materials

hESCs cultured on a feeder layer (see Support Protocol 4) *or* NPs derived from hESCs (see Basic Protocol)
0.05% (w/v) disodium EDTA
0.008% (w/v) trypsin/2.4 mM EDTA (see recipe)
Phosphate-buffered saline (PBS; Invitrogen) containing calcium and magnesium (Invitrogen, cat. no. 14040)
2.35 mg/ml DNase (see recipe)
FACS buffer (see recipe)
100% ethanol, –20°C
Permeabilization buffer (see recipe)
Appropriate primary antibody (Table 23.7.1)
Goat anti–mouse immunoglobulin conjugated with fluorescein isothiocyanate (FITC; Dako)
2 μg/ml propidium iodide (see recipe)

35-μm nylon mesh
15-ml centrifuge tubes
5-ml polystyrene round-bottom tubes (Falcon)
Refrigerated centrifuge
Flow cytometer (also see Robinson et al., 2007)

Additional reagents and equipment for counting cells (*UNIT 1.1*) and flow cytometry (Robinson et al., 2007)

Prepare cells

To prepare hESCs

1a. Dissociate the hESC colonies into a single-cell suspension by adding 2 ml of 0.05% EDTA per well and incubating 10 min at room temperature.

2a. With the aid of a pipettor, repeatedly blow 1 ml of the EDTA solution onto the hESCs to dislodge them from the feeders.

The feeders should remain intact and adherent to the culture dish.

3a. Filter the hESC suspension through a 35-μm nylon mesh to remove clusters.

4a. Transfer the cells to a 15-ml tube and centrifuge 5 min at ~240 × g, room temperature.

Prepare neural precursor clusters

1b. Collect the NP clusters into a 15-ml centrifuge tube and centrifuge 5 min at ~40 × g for 5 min, room temperature.

2b. Aspirate the supernatant and resuspend the NP clusters in 2 ml of 0.008% trypsin/2.4 mM EDTA. Incubate at 37°C for 15 min.

3b. Pipet the clusters up and down to dissociate them into a single-cell suspension. Centrifuge the NPs 5 min at ~40 × *g*, room temperature.

A white cloudy pellet should appear.

4b. Gently remove the supernatant and add 1 ml of PBS (with Ca and Mg) and 10 μl of 2.35 mg/ml DNase. Incubate an additional 10 min, and pipet the pellet gently up and down to obtain a single-cell suspension. Filter the cell suspension through a 35-μm nylon mesh and centrifuge 5 min at ~240 × *g*, room temperature.

Prepare cells for staining

The following steps should be done on ice. Centrifugation should be carried out in a refrigerated centrifuge appropriate for the centrifugation of 5-ml tubes.

5. Resuspend the cells in 1 ml cold FACS buffer. Count the cells and split them into aliquots of 100–150 × 10^3 cells in 5-ml round-bottom tubes.
6. *To detect nuclear proteins:* Fix the dissociated cells with 3 ml precooled 100% ethanol at –20°C for 15 min. Centrifuge the fixed cells 5 min at ~460 × *g*, 4°C, and remove the supernatant. Permeabilize the cells by adding 3 ml permeabilization buffer and incubating 15 min at 4°C.
7. Centrifuge cells (from step 5 or 6) 5 min at ~460 × *g*, 4°C.
8. Wash the cells by adding 2 ml of cold FACS buffer, then centrifuging 5 min at ~460 × *g*, 4°C.
9. Remove the supernatant by turning the tubes upside down.

   The cells should stay on the bottom of the tubes with ~100 μl of remaining fluid.

Immunostain cells

10. Incubate the cells 30 min on ice with the desired primary antibody (Table 23.7.1), diluted in FACS buffer as described in Table 23.7.1.
11. Wash the cells by adding 2 ml of cold FACS buffer and centrifuge for 5 min at ~460 × *g*, 4°C. Spill out the supernatant as described in step 9.
12. Detect primary antibodies by incubating the cells on ice for 30 min with goat anti-mouse FITC conjugated immunoglobulins diluted 1:100 with FACS buffer.
13. Wash the cells again by adding 2 ml of cold FACS buffer and centrifuging for 5 min at ~460 × *g* at 4°C. Spill out the supernatant as described in step 9.
14. Add 300 μl of 2 μg/ml propidium iodide solution for gating of viable cells.
15. Acquire 1–2 × 10^4 cells for each sample and analyze by flow cytometry with appropriate software.

    Robinson et al. (2007) provides detailed protocols for flow cytometry.

SUPPORT PROTOCOL 3

SPONTANEOUS DIFFERENTIATION OF hESC-DERIVED NPS

The characterization of the NPs should include an analysis of their potential to give rise to mature neurons and glia cells**.** Here, the methodologies for induction of differentiation in vitro and for the immunophenotyping of differentiated progeny are described**.**

Materials

10 μg/ml poly-D-lysine (see recipe)
Tissue culture–grade distilled H_2O
4 μg/ml laminin (see recipe)
NPs derived from hESCs (see Basic Protocol)
Neural precursor medium (NPM; see recipe)
16-mm-diameter round glass coverslips, sterile (Paul Marienfeld & Co.; *http://www.marienfeld-superior.com*)
Center-well organ culture dish (Falcon)

1. Place a glass coverslip in the center of a center-well organ culture dish. Cover the glass coverslip with 500 µl of 10 µg/ml poly-D-lysine and incubate 1 hr at room temperature.
2. Aspirate the poly-D-lysine solution and wash the glass coverslip with 1 ml of tissue culture–grade distilled water for 1 min. Aspirate the water and cover the glass coverslip with 500 µl of 4 µg/ml laminin. Incubate overnight at 4°C or for 2 hr at room temperature.

   Poly-D-lysine/laminin-coated glass coverslips can be kept up to 1 month at 4°C in a sealed chamber.
3. Collect the NP clusters (Basic Protocol) into a microcentrifuge tube and microcentrifuge for a few seconds at ~240 × *g*, room temperature. Aspirate the supernatant and add 1 ml NPM.
4. Partially dissociate the cluster by pipetting the clumps gently up and down several times.
5. Plate the cell suspension on a glass coverslip precoated with poly-D-lysine and laminin (from step 2), bring the volume to 1 ml with NPM (not supplemented with mitogens), and incubate the cells at 37°C for 7 to 21 days.
6. Replenish the culture medium (NPM) every 3 to 4 days.

   To evaluate the developmental potential of the NPs, their capability to differentiate into progeny representing the three major neural lineages should be characterized by immunostaining for neuronal, astrocytic, and oligodendrocytic markers. The methods for fixation and immunostaining are described in Support Protocol 1.

CULTURING HUMAN EMBRYONIC STEM CELLS

SUPPORT PROTOCOL 4

hESCs with a normal karyotype may be maintained on mouse embryonic fibroblasts, on the extracellular matrix substrate Matrigel (see *UNIT 23.2*) or on human foreskin fibroblasts. The authors' NP-derivation protocol is well established for hESCs maintained on mitomycin C–treated human foreskin fibroblasts.

Materials

Cultures of human foreskin fibroblasts (ATCC # SCRC-1041)
Phosphate-buffered saline (PBS; Invitrogen, cat. no. 14190), prewarmed to 37°C
0.04% (w/v) trypsin/0.16 mM EDTA (see recipe)
Feeder cell medium (see recipe)
2 mg/ml mitomycin C (see recipe)
0.1% (w/v) gelatin (see recipe)
Cultures of hESCs
0.05% (w/v) disodium EDTA
KnockOut (KO) medium (see recipe)
1 mg/ml collagenase type IV (see recipe)
175-cm^2 tissue culture flasks with 2-µm vent caps
Inverted microscope
15- and 50-ml conical polypropylene centrifuge
6-well tissue culture plates

Additional reagents and equipment for counting cells (*UNIT 1.1*)

Culture human foreskin fibroblasts

1. Culture human foreskin fibroblasts as a monolayer in a 175-cm^2 tissue culture flask in 40 ml feeder cell medium.

2. When the cells appear confluent, aspirate the medium. Rinse twice with 10 ml prewarmed PBS, each time for 1 min.
3. Add 2 ml of 0.04% trypsin/0.16 mM EDTA to the 175-cm^2 flask. Ensure that the entire cell surface is covered for 1 to 2 min.
4. Tap the flask to remove the cells. Observe the flask under an inverted microscope to ensure that trypsinization has been effective and the detachment of fibroblasts is complete.
5. Inactivate trypsin by adding 10 ml of prewarmed feeder cell medium and pipet the medium gently several times, blowing it onto the culture surface of the flask to remove remnants of attached fibroblasts and to disaggregate clusters of fibroblasts. Transfer the cells to a 50-ml tube.
6. Centrifuge the cells 5 min at ~240 × *g*, room temperature. Remove the supernatant and resuspend the cells in 10 ml feeder cell medium.
7. Count cells in a 10-µl aliquot using a hemacytometer (*UNIT 1.1*) and calculate the total cell number. Plate the cells in new 175-cm^2 flasks (3–3.4 × 10^6 cells per flask for a 3-day incubation period, or 2–2.6 × 10^6 cells per flask for a 4-day incubation period). Add prewarmed feeder cell medium to a total volume of 40 ml per flask.
8. Swirl the flasks gently. Incubate the flasks in a 37°C 5% CO_2 incubator for 3 to 4 days. When the cells are confluent, repeat the procedure.

Prepare feeder layers

9. Incubate a 175-cm^2 flask of confluent human foreskin fibroblasts with 20 ml of feeder cell medium supplemented with 125 µl of 2 mg/ml mitomycin C solution for 2.5 hr.
10. Meanwhile, cover the bottom of wells of a 6-well plate with 0.1% gelatin for a minimum time period of 30 min. Aspirate the gelatin solution and allow the bottom of the wells to dry.
11. Aspirate the mitomycin C–containing feeder cell medium from the 175-cm^2 flask of human foreskin fibroblasts and replace it with 20 ml prewarmed feeder cell medium without mitomycin C.
12. Trypsinize the fibroblasts as described in steps 1 to 5.
13. Count cells in a 10-µl aliquot using a hemacytometer (*UNIT 1.1*) and calculate the total cell number.
14. Plate 3 × 10^5 of the mitomycin C–treated fibroblasts in 2 ml of feeder cell medium per each gelatin-precoated well of the plates prepared in step 10. Incubate plate, without changing the medium, for at least 24 hr and up to 5 days before plating the hESCs.

Culture hESCs

Colonies of hESCs are cultured on feeders in KO medium and are passaged to a new feeder layer every 6 to 7 days. Passage is performed before the hESC colonies attach one to another and before the cells in their center start piling up, which may be associated with unwanted differentiation. Passage can be done using EDTA (Fig. 23.7.1A.) or using collagenase.

To passage cells using EDTA

15a. Dissociate the hESCs into a single-cell suspension by incubation with 2 ml per well of 0.05% EDTA for 10 min. With the aid of a pipettor, repeatedly blow 1 ml of the EDTA solution on the hESCs colonies to dislodge them from the feeders.

The feeders should remain intact and adherent to the culture dish.

16a. Transfer the cells to a 15-ml tube and centrifuge 5 min at ~240 × *g*, room temperature.

17a. Resuspend the cells in KO medium, count them (*UNIT 1.1*), and plate 4–6 × 10^4 cells per well of a 6-well plate on fresh mitomycin C–treated foreskin feeders generated as described above.

18a. Replenish the culture medium every day.

Note that, due to the high frequency of chromosomal abnormalities observed after extended passaging of hESCs as single cells, it is recommended that the number of passages performed with the aid of EDTA be limited (Mitalipova et al., 2005).

To passage cells using collagenase

15b. Dissociate the hESCs into small clusters by incubating for 1 to 2 hr with 1 ml per well of 1 mg/ml (~200 U/ mg) collagenase type IV.

16b. Tap the plate to gently dislodge the clusters or gently blow medium onto the hESC colonies to remove them from the feeders.

The feeders should remain intact on the bottom of the well and the hESC clusters should be free of contaminating feeder cells.

17b. Transfer the cell clusters to a 15-ml centrifuge tube and centrifuge the clusters 5 min at ~40 × *g*, room temperature.

18b. Resuspend the clusters in KO medium, pipet them gently up and down to disassemble the clumps, and plate the hESC-clusters on fresh, mitomycin C–treated foreskin feeder layers, splitting at 1:3 ratio (one well to three new wells).

19b. Continue incubation, replenishing culture medium every day.

REAGENTS AND SOLUTIONS

Use tissue culture–grade, distilled water in all recipes and protocol steps. All procedures describing the use of phosphate-buffered saline (PBS) in this unit refer to calcium- and magnesium-free PBS (e.g. Invitrogen, cat. no. 14190) unless PBS with calcium and magnesium is specified (e.g., Invitrogen, cat. no. 14040). For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

bFGF, 20 μg/ml

Dissolve 50 μg of recombinant human bFGF (R&D Systems) by adding 250 μl of 5 mM Tris·Cl, pH 7.6 (*APPENDIX 2A*) and 2250 μl of sterile 0.1% (w/v) BSA (Sigma) in PBS (Invitrogen, cat. no. 14190). Divide into aliquots and store up to 3 months at −20°C.

Blocking solution

Supplement FACS buffer (see recipe) with 5% (v/v) donkey or goat serum (Sigma). Prepare fresh.

Collagenase IV, 1 mg/ml

Add 6 mg (~1200 U) of collagenase IV (Invitrogen) to 6 ml of KO medium (see recipe) for each 6-well plate to be used. Filter through a 0.22-μm filter. Prepare fresh as needed.

DNase, 2.35 mg/ml

Dissolve 2.35 mg (~4700 U) of DNase (Sigma) in 1 ml of PBS (Invitrogen, cat. no. 14190), aliquot and store up to 2 months at −20°C.

FACS buffer

PBS (Invitrogen, cat. no. 14190) supplemented with:
0.1% (w/v) BSA (Sigma)
0.05% (w/v) sodium azide (N_aN_3)
Store up to 3 months at −20°C

Feeder cell medium

High-glucose DMEM (Invitrogen) supplemented with:
10% (v/v) fetal bovine serum (FBS; Hyclone)
2 mM L- glutamine (Invitrogen)
50 U/ml penicillin/50 μg/ml streptomycin (Invitrogen)
Store up to 2 weeks at 4°C

Gelatin, 0.1% (w/v)

Stock solution: (1% gelatin): Dissolve 0.25 g gelatin powder (Sigma) in 25 ml distilled water in a 50-ml tube (Falcon) to obtain a 1% (w/v) gelatin stock. Autoclave and store as 25-ml aliquots up to 1 year at 4°C.

Working solution (0.1% gelatin): Dilute 25 ml of 1% (w/v) gelatin in 225 ml distilled water. Store up to 4 weeks at 4°C.

KnockOut (KO) medium

KnockOut DMEM (Invitrogen) supplemented with:
14% (v/v) KnockOut Serum Replacement (Invitrogen)
2 mM L-glutamine (Invitrogen)
1% (v/v) nonessential amino acids (Invitrogen)
50 U/ml penicillin/50 μg/ml streptomycin (Invitrogen)
4 ng/ml bFGF: add 1 μl of 20 μg/ml bFGF (see recipe) per 5 ml KO medium to be prepared
Store up 2 weeks at 4°C

Batch testing of KnockOut serum replacement is imperative since there is variability, in the author's experience, with regard to the potential of different batches to support undifferentiated proliferation of hESCs.

Laminin, 4 μg/ml

Stock solution (1 mg/ml laminin): Prepare 1 mg/ml laminin (Sigma). Divide into 40-μl aliquots and store up to 1 year at −20°C.

Working solution (4 μg/ml laminin): Dilute 40 μl of 1 mg/ml laminin stock with 10 ml of PBS (Invitrogen, cat. no. 14190), for a final concentration of 4 μg/ml. Prepare fresh.

Low-melting-temperature (LMT) agarose, 0.1% (w/v)

Dissolve 0.2 g low-melting-temperature agarose (FMC BioProducts) in 200 ml distilled water. Store up to 3 months at room temperature. Boil the solution in a microwave oven for 1 to 2 min before each usage.

Culture dishes are pretreated with LMT agarose to prevent adhesion of cell clusters to their surfaces.

Mitomycin C, 2 mg/ml

Dissolve a 2 mg ampule of mitomycin C (Sigma) in 1 ml of PBS (Invitrogen, cat. no. 14190). Inject the PBS into the mitomycin C ampule using a syringe connected to a 23-G needle. Use a second needle to vent the ampule. Remove the solution and store in a 15-ml tube up to 1 week at 4°C protected from light.

CAUTION: *Mitomycin C is a toxic substance. See manufacturer's MSDS for handling instructions. Preparation of mitomycin C solutions should be conducted within an appropriate chemical fume hood, given the toxicity of this reagent.*

Neural precursor medium (NPM)

DMEM/F12 (1:1) (Invitrogen) supplemented with:
2% (v/v) B27 supplement (Invitrogen, cat. no. 17504)
2 mM L-glutamine (Invitrogen)
50 U/ml penicillin/50 μg/ml streptomycin (Invitrogen)
Store up to 2 weeks at 4°C

B27 supplement includes a low concentration of retinol. Since retinoic acid may restrict the developmental potential of NPs, B27 supplement that does not contain retinol (B27 supplement minus vitamin A; Invitrogen, cat. no., 12587) may be substituted.

Paraformaldehyde, 4% (w/v)

Dissolve 4 g of paraformaldehyde powder (Fluka) in 100 ml of PBS (Invitrogen, cat. no. 14190) at 60°C. Calibrate the pH to 7.4, filter, divide into aliquots, and store in a −20°C freezer for up to 6 months.

Permeabilization buffer

Supplement FACS buffer (see recipe) with 0.1% (v/v) Triton X-100 (Sigma). Prepare fresh.

Poly-D-lysine, 10 μg/ml

Stock solution (1 mg/ml poly-D-lysine): Dissolve 1 mg of poly-D-lysine (30 to 70 kDa; Sigma) in 1 ml of PBS (Invitrogen, cat. no. 14190), divide into 100-μl aliquots and store up to 2 months at −20°C.

Working solution (10 μg/ml poly-D-lysine) Dilute 100 μl of 1 mg/ml poly-D-lysine with 10 ml of PBS to a final concentration of 10 μg/ml. Prepare fresh.

Propidium iodide solution, 2 μg/ml

Dilute 1 volume of 1 mg/ml propidium iodide (Sigma) in 500 volumes of FACS buffer (see recipe) and store at 4°C up to 3 months.

Noggin stock, 100 μg/ml

Dissolve 50 μg of recombinant mouse noggin (R&D Systems) by adding 500 μl of sterile 0.1% (w/v) BSA (Sigma) in PBS (Invitrogen, cat. no. 14190). Divide into aliquots and store up to 3 months at −20°C.

Triton X-100, 0.2% (v/v)

Dilute 1 volume of Triton X-100 (Sigma) in 49 volumes of PBS (Invitrogen, cat. no. 14190) and store at room temperature up to 6 months.

Trypsin/EDTA solutions

0.04% (w/v) trypsin/0.16 mM EDTA: Dilute 1 volume of 0.25% (w/v) trypsin/EDTA (Invitrogen) in 5 volumes of PBS (Invitrogen, cat. no. 14190). Store at 4°C for up to 1 week.

0.008% (w/v) trypsin/2.4 mM EDTA: Dilute 1 volume of 0.04% (w/v) trypsin/0.16 mM EDTA (prepared as described above) in 4 volumes of 3 mM disodium EDTA in PBS. Keep at 4°C for up to 1 week.

COMMENTARY

Background Information

Controlled differentiation of ES cells into neural precursors (NPs) is required for the experimental dissection of the molecular events that occur during early development of the nervous system. Moreover, the generation of pure populations of hESC-derived neural progeny, rather than mixed populations of differentiated cells, is one of the major requirements for transplantation therapy (Li et al., 1998; Stavridis and Smith, 2003).

Derivation of NPs from mouse embryonic stem cells

During almost three decades of mouse ES cell research, several methods have been proposed for the conversion of ES cells into NPs. The most commonly used approach for induction of neural differentiation of mouse ES cells includes initial spontaneous differentiation within embryoid bodies (EBs) followed by treatment with retinoic acid (RA). EBs are formed when ES cells are cultured as free-floating clusters in the absence of feeder cells and anti-differentiation agents such as leukemia inhibitory factor (LIF). Under these conditions, spontaneous differentiation occurs, partially mimicking early processes of differentiation in the embryo, and therefore these clusters are termed EBs. Spontaneous differentiation of mouse ES cells within EBs yields a relatively small fraction of neural-lineage cells. To promote neural differentiation, ES cell aggregates are cultured first in the regular ES cell medium without LIF for 4 days and are then exposed to RA for another 4 days. Hence, this method is often regarded as a "4–/4+" protocol (Bain et al., 1995). While RA treatment of EBs promotes neural differentiation, the neural progeny that are formed are of a wide range of developmental stages and have a restricted developmental potential. This is supported by the study of Renoncourt et al. (1998), which showed that EBs treated with RA selectively differentiated into neuronal cell types characteristic of ventral CNS.

In addition to methods involving initial spontaneous differentiation within EBs, methods for directed differentiation of ES cells cultured as individual cells or in a monolayer have been developed by several investigators. These approaches use specific mesoderm-derived feeder cells or conditioned media to induce neural differentiation. The rationale behind coculturing with mesodermal cells is that signals from the mesoderm are required to induce neural specification of the ectoderm in vivo. Coculture of undifferentiated mouse ES cells with the bone marrow–derived stromal cell line PA6, under serum-free conditions or as a suspension culture in medium conditioned by the human hepatocellular carcinoma cell line HepG2, induces neural differentiation in a high percentage of the colonies (Kawasaki et al., 2000; Rathjen et al., 2002). However, the neuralizing agents exerted by PA6 or HepG2 lines remain unidentified as yet.

Given the limitations of most approaches for directing the differentiation of ES cells into a homogeneous population of NPs, complementary strategies to select neural cells from a heterogeneous population of differentiated cells have been developed. Enrichment for NPs may be accomplished in the mouse ES cell system by incorporating selective culture conditions. In this approach, ES cells are first cultured as aggregates to initiate spontaneous differentiation. They are then plated and cultured on an adhesive substrate in a serum-free medium. Under these selective conditions, the majority of cells die while NPs survive. The medium is then supplemented with bFGF to induce proliferation. After 6 to 8 days of selection and expansion, the NP cells are enriched to ~80% (Okabe et al., 1996; Brustle et al., 1997). Withdrawal of bFGF induces spontaneous differentiation into various subtypes of neurons and glia cells (Okabe et al., 1996; Brustle et al., 1999). The neurons are mature and electrophysiologically functional, and can generate both excitatory and inhibitory synaptic connections. In contrast to the RA

approach, NPs that are derived with the bFGF protocol are more synchronized with regard to their stage of differentiation, and their developmental potential is less restricted. In an alternative approach, neural cells have been sorted from heterogeneous populations of differentiated cells based on the expression of neural lineage-specific cell surface markers (Mujtaba et al., 1999), or by genetic selection. In the latter approach, a selectable marker was inserted into the open reading frame of genes encoding neural lineage-specific transcription factors, allowing genetic selection of NPs either by fluorescence-activated cell sorting (FACS) or drug selection (Li et al., 1998; Ying et al., 2003).

The inductive exocrine signals, such as those that are obtained from coculture or conditioned medium, are probably not required for mouse ES cells to commit themselves efficiently to the neural fate. Multicellular aggregates (Wiles and Johansson, 1999) or adherent monolayer cultures of ES cells (Ying et al., 2003) readily differentiated into neural cells when LIF and inductive signals for non-neural fates were eliminated. In the latter report, it was shown that the neural differentiation was not a simple default pathway but was dependent on autocrine fibroblast growth factor (FGF) signaling. This specific culture system could induce neural differentiation in ~60% of the ES cells, but could not give rise to a highly enriched preparation of NPs. A similar result was demonstrated when mouse ES cells were disaggregated into individual cells and were cultured at low density, under defined serum-free factor-free culture conditions. In the absence of non-neural inductive signals, the surviving individual cells acquired a neural identity, and gave rise to primitive neural stem cells (Tropepe et al., 2001; Smukler et al., 2006). Differentiation towards neural fate was more efficient in the presence of the BMP antagonist noggin. Neuralization in these reports was independent of FGF signaling, which is in line with a default mechanism of neural specification (Wilson and Edlund, 2001; Munoz-Sanjuan and Brivanlou, 2002). Nevertheless, the efficiency of this approach is relatively low (Tropepe et al., 2001) and in the presence of survival factors [*N*-acetyl-L-cysteine (NAC) and cAMP], ~20% of the starting population of undifferentiated ES cells will differentiate into neural stem cells (Smukler et al., 2006). These chemically defined neural differentiation systems facilitate the dissection of the molecular mechanisms of early neural differentiation.

Recently, pure expandable cultures of neural stem cells were derived from mouse ES cells. Adherent monolayer cultures of ES cells initially differentiated into the neural lineage under defined culture conditions, which lack inductive signals for non-neural fates (Ying et al., 2003). Basal culture medium supplemented with epidermal growth factor (EGF) and bFGF promoted the selection and prolonged propagation of pure adherent cultures of neural stem cells. This defined monoculture system can allow, for the first time, sustained robust expansion of neural stem cells, closely related to a radial glia lineage, liberated from any requirement for a specific cellular niche (Conti et al., 2005).

Derivation of NPs from human embryonic stem cells

While hESCs are similar to their mouse counterparts, they do differ in many aspects (Thomson and Odorico, 2000; Ginis et al., 2004). Therefore, the protocols for neural induction of hESCs share many of the principles that apply to mouse ES cells, though there are aspects that are specific to the human system. In the last 5 years, various approaches have been developed for the derivation of enriched cultures of proliferating developmentally competent NPs from hESCs. Due to the poor survival of hESCs in single-cell suspension culture conditions, direct neural differentiation procedures from disaggregated individual hESCs, similar to those described above for mouse ES cells, have not been reported thus far.

The initial protocols for the derivation of NPs from hESCs involved, as a first step, spontaneous disorganized differentiation that was induced by prolonged culture of hESC colonies at high density or by the formation of floating three-dimensional EB-like aggregates. This initial differentiation was followed by neural lineage selection by various approaches and culture under conditions that promoted the proliferation of NPs (Carpenter et al., 2001; Reubinoff et al., 2001; Zhang et al., 2001). Two research groups induced initial uncontrolled spontaneous differentiation of the hESCs through the formation of EBs, and subsequently plated the cells on appropriate substrates in defined medium containing mitogens (Carpenter et al., 2001; Zhang et al., 2001). Carpenter et al. (2001) used the traditional mouse ES cell differentiation protocol by RA treatment to derive NPs from hESC. The resulting hESC EBs were treated with RA in serum-containing

medium for 4 days to induce initial differentiation to NPs. NPs were then selected by immunosorting, based on the expression of neural-specific cell-surface markers. This method yielded heterogeneous neural cell populations similar to those observed in mouse ES cells. The neural cells generated by this approach displayed a wide range of developmental stages, from nestin-expressing and polysialylated neural cell adhesion molecule (PSA-NCAM)–expressing precursors to β-tubulin III$^+$ neurons. Zhang and colleagues used a process that initiated uncontrolled spontaneous differentiation of hESC within EBs cultured in serum-free medium for 4 days. The EBs were then plated onto an adhesive culture plate for 7 days' culture in a serum-free medium supplemented with bFGF, which supported the cultivation of NPs. Cells in the center of the plated EBs transformed initially into small columnar cells, whereas those in the periphery of the outgrowth gradually became flattened. The small columnar cell population expanded in the presence of FGF2 and organized into rosette formations by 7 to 10 days after plating the aggregates. The neural tube–like structures were isolated by selective enzymatic digestion followed by further purification on the basis of differential adhesion (Zhang et al., 2001; Li and Zhang, 2006). After transplantation into the neonatal mouse brain, the primitive neuroectodermal cells differentiated in a region-specific manner into neurons and glia cells. (Zhang et al., 2001; Guillaume et al., 2006). Recently, this group further demonstrated the potential to direct the differentiation of the NPs in vitro into dopaminergic neurons with midbrain properties and into motor neurons with spinal cord characteristics (Li et al., 2005; Yan et al., 2005).

The authors of this unit have reported an alternative approach where initial spontaneous differentiation was induced by prolonged culture of the hESC colonies to high density without replenishment of the feeders. Within the large colonies that were formed, there were a variety of differentiated cells, including distinct areas comprised of small, piled, tightly-packed early precursor cells that were destined to give rise to neural progenitors when transferred to serum-free media. Clusters of ~150 cells were mechanically dissected from these distinct areas and were plated in serum-free defined medium supplemented with mitogens (FGF2 and EGF). The aggregates gradually turned into round spheres that were highly enriched for proliferating, developmentally competent NPs. Upon transplantation into the brain ventricles of newborn mice, the NPs migrated extensively and differentiated in a region-specific manner to progeny representing the three major neural lineages (Reubinoff et al., 2001). In further studies, the authors have developed an alternative simple one-step approach for directed controlled differentiation of hESCs into NPs. In this protocol, small hESC colonies are removed from the feeder layer and cultured in defined serum-free medium supplemented with noggin and bFGF. The hESC clusters differentiate almost uniformly into NPs. The authors have shown that noggin, which inhibited BMP signaling, significantly enhanced the level of enrichment for NPs within the hESC clusters and suppressed the expression of transcripts of markers of non-neural lineages. Hence, it was suggested that noggin-mediated blockage of endogenous BMP signaling, within the hESC clusters, suppressed the differentiation into lineages other than the neural one (Itsykson et al., 2005). The potential of noggin to promote neural differentiation was also demonstrated by others with adherent cultures of hESCs rather than free-floating clusters (Gerrard et al., 2005).

In addition to noggin, the authors' protocol included the use of bFGF. FGF signaling is essential for neural specification in planarian (Cebria et al., 2002), frog (Launay et al., 1996), and avian embryos (Streit et al., 2000; Wilson et al., 2000). In the mouse ES cell system, autocrine FGF signaling was shown to have a role in neural l specification (Ying et al., 2003). However more recent data suggest that neural differentiation of mouse ES cells occurs in the absence of FGF signaling (Smukler et al., 2006). While FGF signaling induced the proliferation of the hESC-derived NPs (Itsykson et al., 2005), its role in neural induction of hESCs is unclear at present.

Similar to mouse ES cells, coculture of hESCs with mouse stromal cells can effectively induce neural differentiation (Muotri et al., 2005; Tabar et al., 2005). The factor or factors that exert the stromal cell–derived inducing activity (commonly termed SDIA) have not yet been identified. Recently, a similar effect was demonstrated when both mouse and human ES cells were cultured on the matrix components of the human amniotic membrane (amniotic membrane matrix-based ES cell differentiation; AMED; Ueno et al., 2006). In contrast to the SDIA method, which uses animal cells, the AMED culture uses a noncellular inductive material derived from an easily

available human tissue; therefore, AMED should provide a more suitable and versatile system for generating a variety of neural tissues for future clinical applications (Ueno et al., 2006). Lastly, the role of the Notch signaling system in promoting the entry into the neural lineage was recently demonstrated. Coculturing of mouse and human ES cells with genetically modified stromal cells expressing Notch ligand stimulated neural specification (Lowell et al., 2006).

The major advantages of the Basic Protocol in this unit are the use of a chemically defined culture system as opposed to serum-containing systems or coculture with unknown factors generated by stromal, amniotic, or feeder cells (Shin et al., 2006). Neural differentiation is obtained in one controlled step, which consistently gives rise to highly enriched populations of expandable, developmentally competent NPs within spheres. The authors' system, as well as those that induce neural differentiation of hESCs in monolayer cultures (Gerrard et al., 2005; Shin et al., 2006; Ueno et al., 2006), are invaluable for the dissection of the molecular mechanisms of early human neural specification and differentiation.

Potential applications of hESC-derived neural precursors

The establishment of neuroectodermal precursors from hESCs provides real advantages for basic and applied studies of human neural development and diseases. Directing hESCs to differentiate to the neural lineage and the establishment of NPs and their differentiated progeny enable a complete in vitro study of human neurogenesis. This approach allows access to hitherto unexplored territories of gene expression for modern genomics data mining, and will provide a platform for the discovery of polypeptide growth and differentiation factors which might find application in neural tissue regeneration. In vitro human models of neurodegenerative diseases may be created for basic research and drug discovery. New assays for toxicology and high-throughput screens for neuroprotective compounds may be developed.

Generation of NPs from hESCs in vitro may serve as a platform for further manipulations with growth and differentiating factors that may eventually enable the derivation of specific functional neural cells for transplantation therapy. The proof of principle of this potential application was demonstrated both with mouse (Brustle et al., 1999; Kim et al., 2002) and human (Roy et al., 2006) ES cell systems. These encouraging results suggest that hESC-derived NPs may eventually be applicable to cell and gene therapy of human neurological disorders. Long-term studies are required to determine the safety of hESC-derived neural progeny transplantation and to rule out potential hazards such as tumor formation (Roy et al., 2006) or the development of cells from other lineages. These pioneer transplantation studies highlight the potential of hESCs to serve in the future as an unlimited donor source of neural cells for transplantation.

Critical Parameters

The starting hESCs should be passaged two to three times on feeder cells after thawing, before being used for NP derivation. The hESC cultures should exhibit a minimal level of background differentiation. During those passages, assess the number of cells that should be plated per well at the last passage prior to the derivation of the NPs ($4–6 \times 10^5$ cells per well), so that the hESC colonies, after 6 to 7 days of culturing, would be of sufficient size to enable their survival as clusters, but not so large as to adhere to one another.

Troubleshooting

If differentiating hESC clusters attach to the plastic bottoms of the wells, it is advisable to transfer them to new wells precoated with 0.1% gelatin. Gently blow medium from a pipet on top of the hESC clusters to detach the clusters from the plastic surface, and transfer them to a fresh well precoated with gelatin.

If hESC clusters begin to aggregate one to the other, gently disperse them by gentle pipetting or dissect them with surgical blades.

Anticipated Results

The derivation of NPs from hESCs with the protocol described in this unit is very efficient and reproducible. A significant amount of cell death is expected during the first 2 to 3 days of culturing of the hESC clusters in suspension. However, after an additional few days, an increase in size of the clusters is observed due to cell proliferation.

After 4 weeks, 97% of the cells within the cultures should express NP markers such as Nestin and NCAM, and <2% of the cells should express markers of pluripotent cells such as Oct-4, Tra-1-81, and SSEA-3.

The NPs can differentiate into neurons and glial cells both in vitro under various culture conditions, as well as in vivo after transplantation.

While the NPs differentiate mainly into neurons at early culture stages, during prolonged propagation (25 weeks), a gradual shift in differentiation from a neuronal to a predominantly glial fate occurs (Itsykson et al., 2005). This finding is consistent with the concept of a gradual shift from predominantly neuronogenesis to gliogenesis during neural development in vivo (Nakai and Fujita, 1994; Encha-Razavi and Sonigo, 2003; Fujita, 2003).

Time Considerations

Approximately 0.5 to 1 hr should be allowed for the preparation of the media and various other factors and reagents. This may be performed up to 2 weeks before the protocol is initiated.

The time period for the whole process from the establishment of feeders through derivation of the NPs and their differentiation in vitro is 8 weeks.

Foreskin feeders are propagated 3 to 4 days before their inactivation by mitomycin C. About 30 min should be allowed for the human foreskin fibroblasts passaging procedure.

Preparation of mitomycin C inactivated feeder layers takes ~3 hr. The hESCs are plated on the feeders ~1 to 4 days after their preparation. About 0.5 to 2.5 hr should be allowed for hESC passaging.

The hESCs are cocultured with the feeders 6 to 7 days, until they are removed as clusters for induction of neural differentiation. During this week, medium must be changed every day. Changing the medium can take between 5 and 20 min, depending on the number of plates.

Removing the hESC colonies from the feeders should take ~1 to 3 hr.

Neural induction of the hESC clusters into neural spheres highly enriched for NPs takes 4 weeks. Spontaneous differentiation of the NPs into neurons and glial cells occurs within an additional 1 to 3 weeks. During this period, the medium must be changed every 3 to 4 days. Changing the medium can take between 5 and 20 min, depending on the number of wells needing refreshing.

CHAPTER 24
Lipids

INTRODUCTION

Lipids form the scaffold of biological membranes, store energy, anchor soluble proteins to membranes, and carry information as extracellular hormones or as intracellular second messengers. These different roles of lipids arise because of their diverse forms and characteristics within cells. The major lipid species comprising membrane bilayers are phosphoglycerides, which consist of a three-carbon backbone of glycerol, two long-chain fatty acids esterified to carbons 1 and 2 of glycerol, and phosphoric acid esterified to the carbon 3 of glycerol. Other lipid constituents of membrane bilayers include sphingolipids, sterols, and glycolipids. Because all these lipids have cylindrical shapes and an amphiphilic nature, they readily assemble into semipermeable membrane bilayers, in which the fatty acid chains of the lipids point inward toward each other and their polar head groups point outward and are exposed to water. Lipids not incorporated into membrane bilayers include triglycerides. They consist of glycerol with fatty acids esterified to all three carbons. They form large, oily droplets in the cytoplasm called lipid droplets that serve as storage sites for fatty acids.

Chapter 24 is devoted to biochemical and morphological assays used to study the function and intracellular pathways followed by lipids within cells. *UNIT 24.1* describes the use of fluorescent sphingolipid analogs to study the intracellular trafficking of sphingolipids. This class of lipids is characterized by sphingosine, a nitrogen-containing base that is the structural counterpart of glycerol, and one fatty acid of phosphoglycerides. Sphingolipids are an important class of lipid molecules that are enriched in the plasma membrane. There, they interact with cholesterol and other plasma membrane components to form membrane microdomains that are capable of sorting proteins and initiating plasma membrane internalization into endocytic structures. The unit highlights the use of fluorescent sphingolipid analogs to delineate the formation of sphingolipid microdomains at the plasma membrane, different mechanisms of sphingolipid internalization from the plasma membrane, and subsequent transport of sphingolipids to different subcellular compartments.

UNIT 24.2 describes the fluorescent detection of lipid droplets and associated proteins. Lipid droplets are triglyceride-enriched structures present in the cytosol of most eukaryotic cells. They participate in a variety of important cellular functions, including as storage sites of excess lipid and as sites for accumulation of potentially toxic lipid species. They consist of a core of neutral lipid, including triacylglycerol and cholesteryl ester, surrounded by a phospholipid monolayer. A number of proteins associate with the lipid droplet surface. The unit details several methods for detecting lipid droplets, as well as lipid droplet-associated proteins in live and fixed cells.

UNIT 24.3 describes protocols for generating giant unilamellar vesicles (GUVs), which are vesicles comprised of a single bilayer. These model membrane systems are useful for analyzing the impact of membrane and membrane-binding components on lipid bilayer stiffness and phase behavior. The main approach for making GUVs discussed in this unit uses rehydration of a lipid film. This produces vesicles having a large size (~30 μm), making them especially amenable to studies using fluorescence and light microscopy.

Current Protocols in Cell Biology 24.0.1-24.0.2, September 2008
Published online September 2008 in Wiley Interscience (www.interscience.wiley.com).
DOI: 10.1002/0471143030.cb2400s40

In these studies, mechanical measurements of membrane surfaces with optical traps or micropipets can be made. It is also possible to analyze membrane tubulation, fusion, and budding. Introduction of enzymes or proteins into GUVs is also possible, permitting the study of membrane reorganization in response to membrane binding of different molecules.

Jennifer Lippincott-Schwartz

Using Fluorescent Sphingolipid Analogs to Study Intracellular Lipid Trafficking

Sphingolipids (SLs) are an important class of lipid molecules that play roles in a wide variety of cell functions, including cell-cell interactions, cell growth, differentiation, and signal transduction (Chatterjee, 1998; Kolesnick et al., 2000). They are enriched at the plasma membrane (PM) where they interact with cholesterol and other PM components to form membrane microdomains (Parton, 2003; Simons and Vaz, 2004). The SL composition of the PM is thought to be tightly regulated and is controlled by a combination of processes, including SL synthesis and degradation and transport of SLs to and from the cell surface. Given the importance of SLs at the PM, studies have been performed to elucidate the routes of SL endocytosis and trafficking within the cells. This unit highlights the use of fluorescent SL analogs to delineate different mechanisms of SL internalization from the PM and the subsequent transport of SLs to different subcellular compartments.

Upon addition to cells, SL analogs are observed to undergo a series of processes (see Fig. 24.1.1). First, the probes are integrated into the plasma membrane. In some cases, the fluorescent probes may become concentrated in certain areas of the PM that are enriched in cholesterol and SLs (referred to here as microdomains). At temperatures above 10°C, endocytic processes are active, and fluorescent lipid analogs become internalized. The specific endocytic mechanism involved can be delineated by using different pharmacological inhibitors or by the expression of different dominant-negative (DN) proteins. After endocytosis into vesicles, the fluorescent probes are trafficked to intracellular organelles such as the Golgi apparatus or lysosomes. A portion of the endocytosed probe may also be recycled back to the PM. Transport between different cellular locations can be confirmed by expression of dominant-negative forms of rab proteins known to regulate these transport steps (e.g., rab9 regulates late endosome/Golgi apparatus transport; Mohrmann and Van der Sluis, 1999; Choudhury et al., 2002).

This unit focuses on techniques for three general areas of study: (1) SL-enriched microdomains at the PM, (2) mechanisms of endocytosis, and (3) steps in intracellular transport. Specific protocols are given for the study of each of these topics in Basic Protocols 1, 2, and 3, respectively. Alternative methods for trafficking studies are provided in Alternate Protocols 1 and 2. Specific biochemical and molecular techniques that have been useful in studying each of these processes are also discussed. Support Protocols 1 and 2 describe preparation of the C_8-LacCer/BSA complex and fluorescent sphingolipid analogs, respectively. The techniques presented in this unit utilize human skin fibroblasts (HSFs). Other cell types may be used; however, conditions for cell culture, loading of

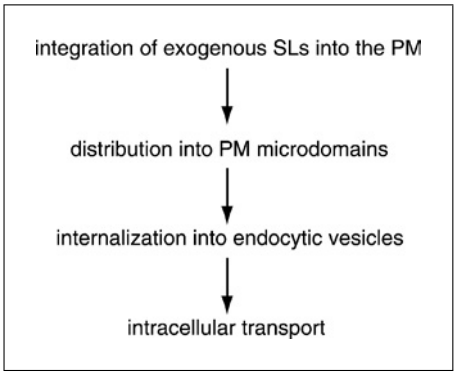

Figure 24.1.1 Schematic representation of steps involved in endocytosis and intracellular trafficking of sphingolipids. Abbreviations: SL, sphingolipid; PM, plasma membrane.

Current Protocols in Cell Biology (2007) 24.1.1-24.1.19

endocytic probes, and treatment with biochemical inhibitors may need to be optimized for each cell type.

NOTE: All solutions and equipment coming into contact with cells must be sterile, and proper aseptic technique should be used accordingly.

NOTE: All culture incubations should be performed in a humidified 37°C, 5% CO_2 incubator except for short-term (5 to 60 min) treatment incubations at 37°C, which may be performed by placing the dishes containing the cells on a rack in a water bath so that only the bottom of the dish touches the water. Because these short incubations are performed in ambient air, noncarbonate-based buffers (e.g., HMEM+G) are used.

NOTE: In general, solutions are added by gently pipetting them into culture dishes containing coverslips with attached cells. Solutions are typically removed by careful pipetting or vacuum aspiration. After removal of solutions, new solutions should be added quickly so that cells do not dry out.

BASIC PROTOCOL 1

VISUALIZATION OF SPHINGOLIPIDS AT PLASMA MEMBRANE MICRODOMAINS

Microdomains are very small in size and are normally beyond the detection limits of the fluorescence microscope; however, the clustering or coalescence of microdomains into larger, visualizable structures at the PM has been demonstrated using a number of different approaches (Thomas et al., 1994; Harder et al., 1998). These approaches include induction of microdomains by addition of nonfluorescent SLs or cholesterol or by treatment of cells with cross-linking antibodies for either the cholera toxin B subunit (CtxB) or β1-integrin (Mitchell et al., 2002; Upla et al., 2004; Sharma et al., 2005).

In this example, the spectral properties of the BODIPY fluorophore (see Support Protocol 2) are used to visualize microdomains at the PM of living cells. Such domains are detected by monitoring the red (excited dimer or excimer) versus green (monomer) fluorescence emission of the BODIPY group. Visualization of both the red and green signals can be achieved using multiple detectors for the different wavelengths or simultaneously using an image splitter attachment (e.g., Dual-View, Optical Insights, LLC) for fluorescence microscopes. Clusters of BODIPY-SLs are then detected as red patches on a sea of green fluorescence. This approach has been used for detecting microdomains at both the PM and early endosomes (Sharma et al., 2003, 2005). A typical protocol for visualization of microdomains at the PM is given below.

Materials

Human skin fibroblasts (HSFs; Coriell Institute for Medical Research)
EMEM containing 10% FBS (EMEM-10; see recipe)
HEPES-buffered minimal essential medium + glucose (HMEM+G; see recipe)
1 mM C_8-LacCer/BSA stock solution (Support Protocol 1)
1 mM BSA control stock solution (Support Protocol 1)
BODIPY-LacCer/BSA stock solution (Support Protocol 2)
25-mm acid-etched coverslips (Fisher), sterilized by immersing in 70% ethanol and flaming
35-mm tissue culture dishes
10°C cooling block (described in Marks et al., 2005)
Depression slides
Fluorescence microscope with high magnification (e.g., 1000×), image acquisition capability, and a stage maintained at 10°C
Additional reagents and equipment for culturing cells (*UNIT 1.1*)

Culture cells

1. Culture (see *UNIT 1.1*) HSFs on 25-mm sterile, acid-etched glass coverslips in 35-mm culture dishes (one coverslip per dish) with 2 ml EMEM-10 for 24 to 48 hr until a confluency of 50% to 70% is reached.

   Prepare enough coverslips for one to two cultures for each experimental condition to be tested and any controls.

2. Wash cells three times with 2 ml HMEM+G.

Incubate with C_8-LacCer

3. Prepare 5 to 20 μM C_8-LacCer/BSA (experimental) and BSA (control) solutions by diluting 1 mM stock solutions in HMEM+G. Prepare at least 1 ml of each solution for each culture dish to be tested.

4. Remove the HMEM+G solutions from the cells and add 1 ml of 5 to 20 μM C_8-LacCer/BSA or the BSA control solution (from step 3) to each dish.

5. Incubate cells 30 min at 10°C on a cooling block.

6. Rinse cells once with 2 ml HMEM+G to remove excess lipid.

Incubate cells with fluorescent SL

7a. *For samples previously treated with C_8-LacCer:* Prepare 2.5 μM BODIPY-LacCer/BSA solution by diluting BODIPY-LacCer stock solution in HMEM+G with the same concentration of C_8-LacCer used in step 3. Prepare at least 1 ml of each solution for each culture dish to be tested.

7b. *For samples previously treated with BSA control:* Prepare 2.5 μM BODIPY-LacCer/BSA solution by diluting BODIPY-LacCer stock solution in HMEM+G with the same concentration of BSA control used in step 3. Prepare at least 1 ml of each solution for each culture dish to be tested.

8. Remove HMEM+G solutions from the cells and add 1 ml 2.5 μM BODIPY-LacCer solutions with either C_8-LacCer or BSA (from step 7) to each dish. Incubate cells 30 min at 10°C.

   Low temperature is maintained to prevent the endocytosis of the fluorescent lipid.

9. Wash cells three times with 2 ml HMEM+G.

10. Invert the coverslips with the attached cells onto a drop of HMEM+G on a depression slide.

11. Remove liquid from the back of the coverslip with a Kimwipe.

Examine cells

12. View cells under a fluorescence microscope at high magnification (e.g., 1000×) on a microscope stage maintained at 10°C to inhibit endocytosis.

13. Acquire images with cells excited at 450 to 490 nm and emissions collected at green (520 to 560 nm) or red (≥590 nm) wavelengths.

    Discrete regions on the PM showing red/orange fluorescence demonstrate the organization of BODIPY-LacCer into microdomains in C_8-LacCer treated cells but not in control cells (Fig. 24.1.2).

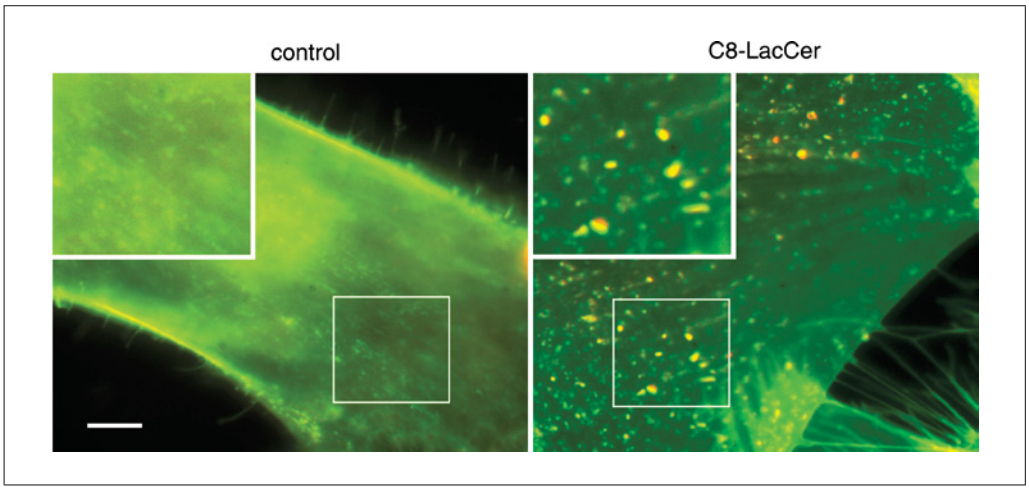

Figure 24.1.2 Human skin fibroblasts (HSFs) were incubated in buffer alone (control) or with 20 μM C_8-LacCer 30 min at 10°C. Cells were washed and incubated with 2.5 μM BODIPY-LacCer 30 min at 10°C. Samples were then washed and observed by fluorescence microscopy at green and red BODIPY emission wavelengths. Samples were maintained at 10°C at all times to prevent endocytosis. The punctate structures seen in the right panel exhibited both green and red fluorescence indicating enrichment of BODIPY-LacCer in these regions of the plasma membrane. Areas outlined with white rectangles are further magnified in insets. Bar = 10 μM. For the color version of this figure go to *http://www.currentprotocols.com*.

SUPPORT PROTOCOL 1

PREPARATION OF C_8-LacCer/BSA AND BSA CONTROL STOCK SOLUTIONS

The short-chain synthetic lactosylceramide D-lactosyl-β_1-1-*N*-octanoyl-D-*erythro*-sphingosine (C_8-LacCer) is used to stimulate the formation of plasma membrane microdomains (Sharma et al., 2005). The C_8-LacCer is complexed with fatty acid-free BSA to increase its solubility in water. After complex formation, DMSO and ethanol initially used to dissolve C_8-LacCer are removed by dialysis.

Materials

D-lactosyl-β_1-1′-*N*-octanoyl-D-*erythro*-sphingosine (C_8-LacCer) powder (mol. wt. 749.98; Avanti Polar Lipids)
2:1 (v/v) ethanol/DMSO
Fatty-acid-free bovine serum albumin (dfBSA; Sigma)
Phosphate-buffered saline (PBS; *APPENDIX 2A*)

5-ml glass tube
Dialysis tubing (12,000 to 14,000 MWCO)
Sonicator (optional)
Ultracentrifuge and appropriate tubes

1. Prepare a 20 mM C_8-LacCer stock solution by dissolving C_8-LacCer powder in 2:1 (v/v) ethanol/ DMSO (e.g., 15 mg powder in 1 ml).

   The solution may be briefly warmed to 37°C or sonicated to aid in dissolution.

2. Prepare 1 mM dfBSA in PBS (e.g., 66 mg dfBSA in 1 ml).

3. Dispense 950 μl of 1 mM dfBSA into a 5-ml glass tube. Warm to room temperature or 37°C.

4. Add 50 μl of 20 mM C_8-LacCer stock solution (step 1) dropwise into the BSA solution with vortexing between additions. Add the same amount of 2:1 (v/v) ethanol/DMSO to another 950-μl aliquot of BSA solution to create the BSA control.

5. Dialyze the solutions in 500 ml PBS overnight at 4°C with two to four changes of PBS to remove DMSO and ethanol.

6. Recover the C_8-LacCer/BSA and BSA control solutions from the dialysis tubing and centrifuge 20 min at 100,000 × *g*, 4°C, to remove aggregated lipid and protein. Save the supernatant and store up to 6 months at −20°C.

PREPARATION OF FLUORESCENT SPHINGOLIPID ANALOGS: BODIPY-LacCer/BSA COMPLEX

SUPPORT PROTOCOL 2

Various fluorescent sphingolipid SL analogs have been used in studies of intracellular transport. In most cases, the naturally occurring fatty acid moiety is replaced with a fluorescent fatty acid (see Fig. 24.1.3). Popular fluorophores include NBD, pyrene, BODIPY, rhodamine, and polyenes. Each analog has distinct advantages and disadvantages. For example, C6-NBD lipids are easily integrated into the PM outer leaflet because of their high rates of spontaneous transfer, and their topology in membranes can be readily assessed by several independent methods (Sleight and Pagano, 1985; McIntyre and Sleight, 1991), whereas the recently described polyene lipids are proposed to more closely mimic the behavior of natural lipids (Kuerschner et al., 2005).

Studies in the authors' lab have concentrated on SL analogs labeled with *N*-[5-(5,7-dimethyl boron dipyrromethene difluoride)-1-pentanoic acid (C_5-BODIPY-fatty acid; Pagano et al., 1991; Martin and Pagano, 1994; Fig. 24.1.3). The BODIPY-labeled lipids are especially useful because they exhibit a concentration-dependent shift in their

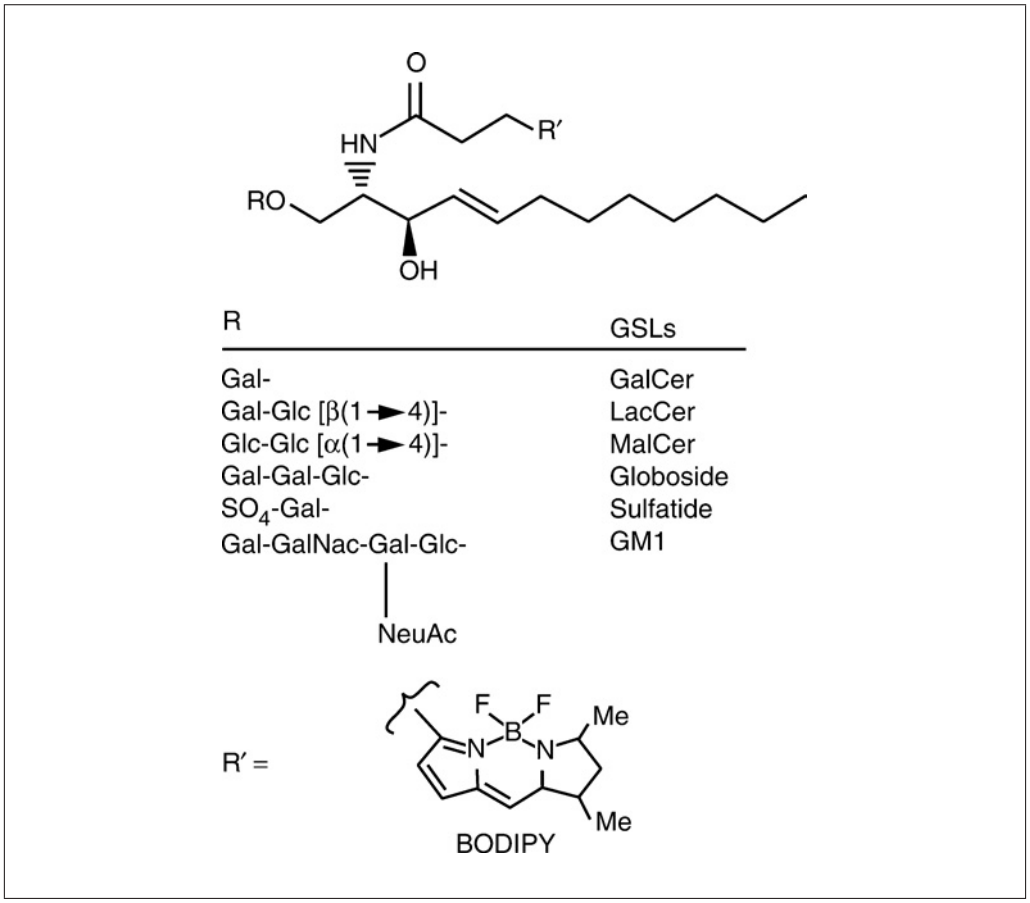

Figure 24.1.3 Structures of fluorescent SL analogs. Replacement of the natural acyl group at R′ with BODIPY yields BODIPY-SL. Addition of saccharide groups at R results in various BODIPY-glycosphingolipids (GSLs).

fluorescence emission from green to red wavelengths as a result of excimer formation at higher concentrations. This property allows an estimate of the molar density of the lipid analog within membranes of living cells based on measurements of the ratio of red to green fluorescence (Pagano et al., 1991; Chen et al., 1997). The authors have utilized these spectral properties of different BODIPY-lipids to study their distribution in microdomains, as well as their endocytosis and intracellular trafficking (Puri et al., 2001; Sharma et al., 2003, 2005). BODIPY-labeled lipids, as well as activated fluorophores for synthesis of other lipid analogs are available from Invitrogen.

To prepare for experiments, fluorescent lipid analogs are usually complexed (1:1 mol/mol) with fatty-acid-free bovine serum albumin (BSA; Martin and Pagano, 1994) as described below for BODIPY-lactosylceramide (BODIPY-LacCer). BSA/lipid complexes can be stored at 4°C for several weeks or at −20°C for longer time periods. For addition to cells, the BSA/lipid complexes are diluted in an appropriate aqueous buffer (e.g., HMEM; see below).

Materials

250 nmol BODIPY-LacCer (Invitrogen), dissolved in 19:1 (v/v) chloroform/ethanol
Nitrogen gas
HMEM−G (see recipe) or phosphate-buffered saline (PBS; *APPENDIX 2A*)
Absolute ethanol
1 mM (66 mg/ml) fatty-acid-free bovine serum albumin (dfBSA; mol. wt. 66,000; Sigma)
BODIPY standards (e.g., BODIPY-C_5-sphingomyelin; Invitrogen)

5-ml glass tubes
Dialysis tubing (12,000 to 14,000 MWCO)
1-ml ultracentrifuge tubes
Fluorometer

1. Dispense 250 nmole of BODIPY-LacCer (in organic solvent) into a 5-ml glass tube (e.g., take 0.5 ml from 0.5 mM stock of BODIPY-LacCer). Dry under nitrogen, and then under vacuum for 1 hr.

   BODIPY-LacCer is commercially available from Invitrogen. It can also be synthesized as in Martin and Pagano (1994).

2. Prepare 300 μl of an appropriate buffer (e.g., PBS or HMEM) containing 250 nmole of defatted bovine serum albumin in a 5-ml glass tube (e.g., mix 250 μl of 1 mM dfBSA in HMEM with 50 μl of HMEM).

3. Add 200 μl of absolute ethanol to the dry BODIPY-LacCer from step 1 and vortex until BODIPY-LacCer is completely dissolved.

4. Add the ethanolic solution of BODIPY-LacCer dropwise to the BSA solution from step 2 with vortexing between additions.

5. Dialyze against 500 ml PBS overnight at 4°C with two to four changes of PBS to remove chloroform and ethanol.

6. To remove aggregated material, centrifuge once or twice in an ultracentrifuge for 20 min at 100,000 × *g*, 4°C. Save the supernatant and store up to 2 months at 4°C. For long-term storage, dispense into 100-μl aliquots and store up to 12 months at −20° C.

7. Determine concentration of BODIPY-LacCer/BSA complex by measuring relative fluorescence intensity against known BODIPY standards using a fluorometer.

   The final concentration is usually 200 to 500 μM.

STUDYING ENDOCYTIC MECHANISMS WITH FLUORESCENT LIPID ANALOGS

To study the endocytosis of SLs, cells are incubated with suitable fluorescent lipid analogs at low temperature (usually 10°C) to label the PM and washed. The samples are then shifted to 37°C to allow endocytosis to proceed, followed by the removal of excess fluorescent lipid remaining at the outer leaflet of the PM, so that endocytic vesicles can be easily visualized. The latter is accomplished by a procedure termed "back exchange" (Martin and Pagano, 1994; Chen et al., 1997), in which cells are incubated multiple times at 10°C with 5% fatty-acid-free bovine serum albumin (dfBSA). Once fluorescence has been removed from the PM, lipid probes internalized by cells can be visualized by fluorescence microscopy or extracted from cells and analyzed by various chromatographic and/or fluorometric methods (Martin et al., 1993; Chen et al., 1998).

Although lipid analogs may be internalized into cells by a variety of mechanisms, including diffusion, active transport, and endocytosis, the authors have found that most SL analogs are internalized mainly via endocytosis in several cell types. The exception is BODIPY-glucosylceramide which is taken up by a combination of endocytic and nonendocytic mechanisms (Martin and Pagano, 1994; Puri et al., 2001; Singh et al., 2003). Various endocytic mechanisms have been reported, including clathrin-dependent endocytosis and several clathrin-independent endocytic routes (endocytosis via caveolae, and RhoA- or cdc42-dependent mechanisms; Marks et al., 2005; Cheng et al., 2006). To characterize the endocytic mechanisms involved in the uptake of SL analogs, a variety of biochemical inhibitors and expression of dominant-negative proteins that specifically inhibit certain endocytic pathways (Tables 24.1.1 and 24.1.2) are used. A typical example illustrating methods to study the mechanism of endocytosis of BODIPY-LacCer is described below.

Because cells are live at all stages in these experiments, care should be taken to prevent samples from drying out during washes, and cells should not be subjected to excessive force when washing or transferring coverslips. For viewing live cells on slides, sufficient time should be available to accurately view and photograph each sample (e.g., 15 to 20 min).

Materials

Human skin fibroblasts (HSFs; Coriell Institute for Medical Research)
EMEM containing 10% FBS (EMEM-10; see recipe)
HMEM+G and −G (see recipes)
BODIPY-LacCer/BSA stock solution (Support Protocol 2)
5% (w/v) fatty-acid-free bovine serum albumin (dfBSA) in HMEM−G (see recipe)

Inhibitors of endocytosis (Table 24.1.2)
25-mm glass coverslips, sterile
35-mm tissue culture dishes
Fluorescence microscope with image-acquisition capability
Image analysis software (e.g., Metamorph; Molecular Devices)

Additional reagents and equipment for culturing cells (*UNIT 1.1*)

Culture cells

1. Culture (see *UNIT 1.1*) HSFs on 25-mm sterile, acid-etched glass coverslips in 35-mm culture dishes (one coverslip per dish) with 2 ml EMEM-10 for 24 to 48 hr until a confluency of 50% to 70% is reached.

   Prepare enough coverslips for one to two replicates for each experimental condition to be tested and any controls.

2. Wash cells three times with 2 ml HMEM+G.

[g]Some studies showed an inhibition of clathrin-mediated uptake with methyl β-cyclodextrin (Rodal et al. 1999; Subtil et al., 1999).

Table 24.1.2 Biochemical Inhibition of Different Endocytic Pathways

Mechanisms[a]	Treatment	Conditions[b]	Dosage
Clathrin dependent	K+ depletion	Cells rinsed in K^+-free buffer[c], incubated 5 min in hypotonic K^+-free buffer[d], rinsed in K^+ buffer, and incubated 20 min in K^+ buffer at 37°C; K^+-free buffer for all subsequent steps; controls treated with buffers containing 10 mM KCl	NA[e]
	Chlorpromazine	Pretreatment for 30 min at 37°C	5–25 μg/ml
Caveolae	Filipin	Pretreatment for 30 min at 37°C	1–5 μg/ml
	Methyl-β-cyclodextrin	Pretreatment for 30 min at 37°C	5–10 mM
	Nystatin	Pretreatment for 30 min at 37°C	25–50 μg/ml
	Genistein	Pretreatment for 1-2 hrs at 37°C	200 μM
	PP2	Pretreatment for 1 hr at 37°C	10 nM
	Chelerythrine chloride	Pretreatment for 1 hr at 37°C	100 μM
Cdc42 and RhoA dependent	*Clostridium difficile* toxin B	Pretreatment for 1 hr at 37°C	100 μM

[a]Different endocytic mechanisms.
[b]In general, cells are pretreated in HMEM+G or other appropriate buffers. In addition to pretreatments, for all treatments except methyl-β-cyclodextrin, inhibitors are also present during subsequent incubations with the probe and during endocytosis. See Table 24.1.1 for references concerning these methods.
[c]K^+-free buffer: 140 mM NaCl, 20 mM HEPES, 1 mM $CaCl_2$, 1 mM $MgCl_2$, 1 mg/ml D-glucose (pH 7.4).
[d]Hypotonic buffer: K^+-free buffer diluted 1:1 with distilled water.
[e]NA, not applicable.

Label plasma membrane

3. Prepare 1 to 2.5 μM BODIPY-LacCer/BSA complex by diluting BODIPY-LacCer/BSA stock solution in HMEM+G.

4. Add 1 ml BODIPY-LacCer/BSA complex from step 3 to each dish of cells and incubate 30 min at 10°C.

5. Rinse the cells with 2 ml HMEM+G to remove excess lipid.

Initiate endocytosis

6. Add 1 ml HMEM+G and then warm samples to 37°C for 3 to 5 min (longer incubation may be required for some probes).

   This incubation initiates endocytosis. If cells are viewed at this time point, PM labeling predominates (Fig. 24.1.4, left panel).

7. Wash samples in 2 ml HMEM–G.

Remove surface label

8. Add 1 ml of 5% dfBSA in HMEM−G and incubate 10 min at 10°C. Remove the HMEM–G and repeat 5 more times to remove BODIPY-LacCer on the PM.

   At this point, fluorescently labeled intracellular vesicles can be visualized (Fig. 24.1.4, middle panel).

Identify specific pathways with inhibitor studies

9. To illustrate endocytosis via specific pathways, pretreat cells with various inhibitors (Table 24.1.2) diluted to appropriate concentrations with HMEM+G after step 2 (for pretreatment conditions see Table 24.1.2). Also include the same inhibitor concentration in the BODIPY-LacCer/BSA complex solution in step 4, and in HMEM+G in step 6.

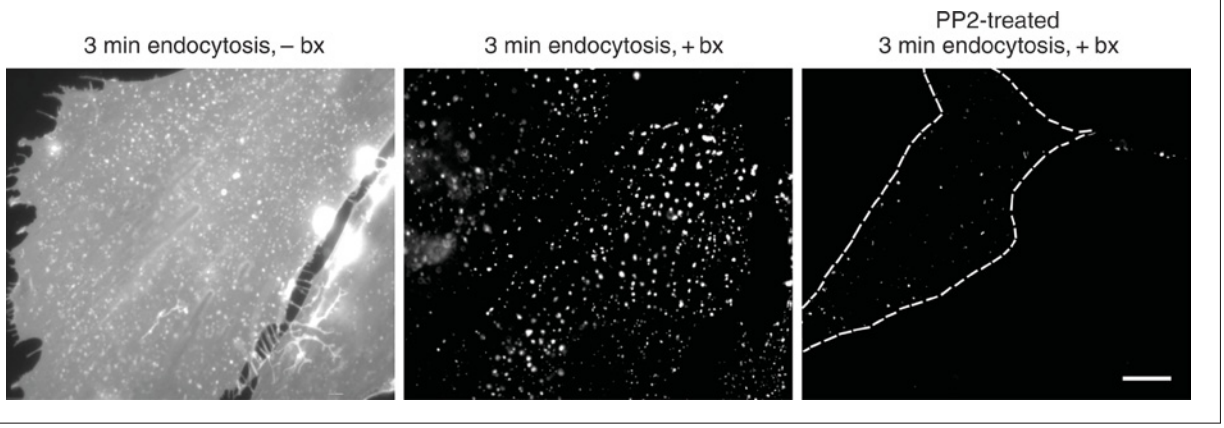

Figure 24.1.4 BODIPY-LacCer endocytosis assay. Human skin fibroblasts cultured on glass coverslips in 35-mm dishes were washed and then incubated with 2.5 μM BODIPY-LacCer for 30 min at 10°C. Cells were rinsed and warmed for 3 min at 37°C and viewed under the microscope. Cells in the left panel were not back exchanged (−bx) and show some punctate structures, but PM labeling predominates. Cells in the middle panel were back exchanged (bx) with defatted BSA at 10°C to remove PM labeling. Punctate labeling of endosomes is now clearly visible. In the right panel is a cell sample treated as in the middle panel, except that the cells were pretreated with the src kinase inhibitor PP2 (see Tables 24.1.1 and 24.1.2) before and during lipid incubations. Reduced intracellular labeling is observed in the right panel because endocytosis is inhibited. The dotted line indicates the perimeter of a cell in this field traced from a phase micrograph of the same field. Cell samples were viewed under the fluorescence microscope using a 100× objective. Bar = 10 μM.

In the present example, pretreatment with the src inhibitor PP2 decreased the intensity of internalized BODIPY-LacCer (Fig. 24.1.4, right panel), suggesting that uptake occurred via caveolae-mediated endocytosis.

10. Acquire images and then quantify by image analysis. Calculate the percent inhibition of uptake for each treatment, relative to untreated control cells (Puri et al., 2001; Singh et al., 2003; Sharma et al., 2005).

ALTERNATE PROTOCOL 1

DETECTION OF ENDOCYTOSIS IN ASSOCIATION WITH DOMINANT-NEGATIVE PROTEINS

Expression of dominant-negative (DN) proteins that block particular mechanism(s) of internalization or intracellular transport has been a useful technique to characterize SL transport. Since HSFs are difficult to transfect with high efficiency, DN protein expression experiments are performed in several ways. In some studies, green or DsRed fluorescent protein–tagged proteins are used so that transfected cells can be easily identified (Puri et al., 2001; Choudhury et al., 2002). This method is useful for qualitative studies, but DsRed and BODIPY fluorescence overlap, making quantitation of uptake difficult. Another approach is to cotransfect a cell with a nonfluorescent DN protein of interest and a DsRed-tagged protein plasmid, which targets to the nucleus (Choudhury et al., 2004). Co-expression of the two plasmids (DN protein and DsRed-Nuc) can be verified by the use of fluorescence microscopy for DsRed Nuc and immunostaining for the DN protein. The second approach ensures that all DsRed fluorescence is at the nucleus and it does not interfere with measurement of BODIPY-fluorescence in other parts of the cell. The authors use cationic lipid transfection reagents such as FuGENE 6 or Lipofectamine 2000 (Invitrogen) for transfection. In general, transfection of HSFs with FuGENE 6 has been relatively inefficient (<10%). Higher levels of transfection can be achieved using electroporation. A typical protocol for carrying out the DN protein transfection followed by inhibition of endocytosis is outlined below.

Additional Materials *(also see Basic Protocol 2)*

pDsRed-Nuc plasmid (0.3 μg/dish; Clontech)
Construct for dominant-negative inhibitor of endocytosis (e.g., AP180 DN; gift from H.T. MacMahon)
FuGENE 6 (Roche Applied Sciences)
10 μg/ml AF 488 labeled transferrin (Tfn; Invitrogen)
Serum-free medium (e.g., EMEM without serum)
HMEM−G (see recipe)
HMEM−G (see recipe), adjusted to pH 3.5 with acetic acid

1. Culture (see *UNIT 1.1*) HSFs on 25-mm sterile, acid-etched glass coverslips in 35-mm culture dishes (one coverslip per dish) with 2 ml EMEM-10 for 24 to 48 hr until a confluency of 50% to 70% is reached.

   Although many laboratories routinely use antibiotics in cell culture medium, culturing of cells without antibiotics is recommended because it can increase transfection efficiency.

2. After 12 to 24 hr, cotransfect cells with pDsRed-Nuc plasmid (0.3 μg DNA/dish) and AP180 DN construct (1 μg DNA/dish), using FuGENE 6 according to the manufacturer's instructions. As a control treat another sample of cells identically but exclude the AP180 DN construct DNA. Incubate 48 hr.

   The authors use transfection agents here rather than electroporation because it is more convenient and results in comparable levels of recombinant protein expression. In addition, the lower efficiency of transfection with the agents can be desirable because it often allows transfected and untransfected cells to be viewed in the same field under the microscope.

Measure endocytosis of probes

If using the BODIPY-LacCer probe

3a. Measure endocytosis of BODIPY-LacCer as described in Basic Protocol 2 steps 4 to 6. (e.g., preincubate cells with probe for 30 min at 10°C and then for 5 min at 37°C).

4a. Wash cells in 2 ml HMEM−G and back exchange for BODIPY-LacCer with 1 ml of 5% dfBSA as in Basic Protocol 2, step 8 to remove surface labeling.

If using the Tfn probe

3b. Serum starve cells by incubating 1 hr in 2 ml serum-free medium to up-regulate Tfn receptors and proceed as in Basic Protocol 2 steps 4 to 6. (e.g., preincubate cells with probe for 30 min at 10°C and then for 5 min at 37°C).

4b. Acid strip the surface labeling by incubating 10 to 30 sec with HMEM−G adjusted to pH <3.5.

Visualize endocytosed probe

5. View cells under the fluorescence microscope, with the cells excited at 450 to 490 nm and emissions collected at green (520 to 560 nm) wavelengths or excited at 520 to 560 nm with emissions collected at red (590 to 650 nm) wavelengths.

   The endocytosed probe (BODIPY-LacCer or AF 488 Tfn) is visualized at green wavelengths. For samples transfected with AP180 DN construct, cells exhibiting bright red fluorescence due to the DsRed protein within the nucleus are presumed to also express AP180 DN. Cells in the same dish without DsRed fluorescence are considered to be untransfected and can be used as controls. Separate dishes transfected with DsRed-nuc but not AP180 DN can be used as controls as well. In this case, cells with red nuclear fluorescence are considered controls and are compared to cells transfected with both DsRed-nuc and AP180 DN.

6. Acquire images of cell samples at standardized exposure conditions (i.e., the same exposure time and acquisition settings) and quantify by image analysis (e.g., Metamorph; Molecular Devices).

7. Calculate percent inhibition by comparing the fluorescence intensity of the endocytosed probe in transfected versus control cells (either nontransfected cells or cells transfected only with DsRed-nuc).

INTRACELLULAR LOCALIZATION AND TRANSPORT: CO-LOCALIZATION OF BODIPY-LacCer WITH ALBUMIN BUT NOT DEXTRAN

BASIC PROTOCOL 3

A number of techniques are available for determining the compartments (i.e., organelles) that an endocytosed probe traverses following its initial internalization from the PM. One widely used technique is co-localization of the internalized probe with other endocytic tracers. For example, BODIPY-LacCer may be endocytosed along with another fluorescently tagged cargo, (e.g., Tfn or dextran). The use of Alexa Fluor (AF) 594 or AF647 is preferred in such studies because there is no (or minimal) spectral overlap of these probes with BODIPY. AF probes are available from Molecular Probes. In the following example, BODIPY-LacCer is shown to co-localize with albumin (a caveolar marker in HSFs) but not with dextran (a fluid-phase marker).

When conducting co-localization studies using two endocytic probes, it is important to realize that each probe may move through a different series of compartments and that not all probes are transported at the same rate. For example, Tfn is visualized in early endosomes at 5 to 10 min after endocytosis begins but then becomes more concentrated in recycling endosomes by 15 to 20 min. BODIPY-LacCer, which is internalized via

caveolae in many cell types, is initially present (at 2 to 3 min) in Tfn-negative structures, but is transported to Tfn-positive early endosomes at 5 to 10 min after endocytosis (Sharma et al., 2003). It should also be recognized that markers may behave differently in different cell types (Torgersen et al., 2001; Singh et al., 2003). The concentration of probe may also be a consideration. For example, dextran used at 1 mg/ml is internalized via the fluid phase pathway, but may be taken up by additional pathways at higher concentrations (Sabharanjak et al., 2002).

In some cases, it is useful to evaluate the co-localization of an endocytic probe with a static compartment-specific marker, e.g., early endosomal antigen 1 (EEA1) for early endosomes, and lysosome-associated membrane protein-1 (LAMP-1) for late endosomes/lysosomes, using immunofluorescence (Sharma et al., 2003; Choudhury et al., 2004).

Materials

Human skin fibroblasts (HSFs; Coriell Institute for Medical Research)
EMEM containing 10% FBS (EMEM-10; see recipe)
HMEM+G and −G (see recipe)
1 μM BODIPY-LacCer/BSA complex (Support Protocol 2)
10 μg/ml Alexa-fluor 594 albumin (AF594-albumin) or 1 mg/ml Alexa-fluor 594 dextran (AF594-dextran)
5% fatty-acid-free bovine serum albumin (dfBSA) in HMEM−G (see recipe)

25-mm glass coverslips, sterile
35-mm tissue culture dishes
10°C cooling block (described in Marks et al., 2005)
Fluorescence microscope with image acquisition capability
Graphics program (e.g., Adobe Photoshop) or image analysis program (e.g., Metamorph; Molecular Devices)

Additional reagents and equipment for culturing cells (*UNIT 1.1*)

1. Culture (see *UNIT 1.1*) HSFs on 25-mm sterile, acid-etched glass coverslips in 35-mm culture dishes (one coverslip per dish) with 2 ml EMEM-10 for 24 to 48 hr until a confluency of 50% to 70% is reached.

   Prepare enough coverslips for one to two cultures for each experimental condition to be tested and any controls.

2. Wash cells three times with 2 ml HMEM+G.

3. Add 1 ml HMEM+G containing 1 μM BODIPY-LacCer/BSA complex and either 10 μg/ml AF594-albumin or 1 mg/ml AF594-dextran to the cells and incubate 30 min at 10°C.

4. Incubate cells without washing 3 to 5 min at 37°C.

   This incubation initiates endocytosis of BODIPY-LacCer along with the labeled albumin or dextran.

   Do not wash the cells prior to endocytosis because albumin and dextran do not bind to the PM.

5. Wash samples in 1 ml HMEM–G and back exchange five times in 1 ml of 5% dfBSA (see Basic Protocol 2, step 8).

   Carry out control experiments using cells labeled with each probe separately in order to optimize concentrations and exposure conditions for each channel so that no fluorescence is detected in the opposite channel. For example, for the BODIPY probe, no detectable

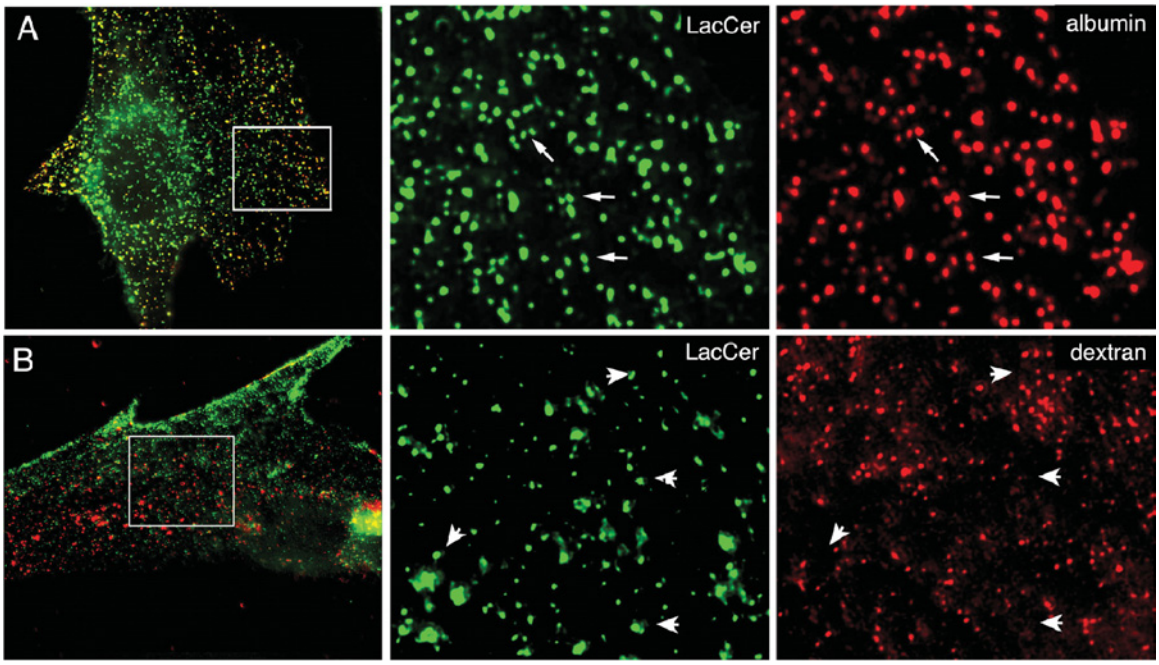

Figure 24.1.5 Co-localizatiion of BODIPY-LacCer with fluorescent albumin vs. dextran in rat fibroblasts (RF). RFs were incubated with BODIPY-LacCer along with either (**A**) AF594-albumin (30 μg/ml) for 30 min at 10°C, and further incubated for 3 min at 37°C, or (**B**) cascade blue dextran (1 mg/ml) for 30 min at 10°C, and further incubated for 5 min at 37°C. Cells were then back exchanged to remove PM labeling of BODIPY-LacCer and observed under the fluorescence microscope. Images were acquired of green (BODIPY-LacCer), and red (albumin or dextran) fluorescence. Panels to the right show regions within cells from images taken at 1000×. Arrows in the upper panels indicate points of co-localizatiion of BODIPY-LacCer and albumin. Arrowheads in the lower panels indicate LacCer-positive structures which do not co-localize with dextran. For the color version of this figure go to *http://www.currentprotocols.com*.

signal should be present in the AF594 channel and for an AF594 labeled probe, no signal should be present in the BODIPY channel.

6. View cells under the fluorescence microscope.

   Internalized BODIPY-lipid is then visualized in the green channel and the other cargo (albumin or dextran) are viewed at red (AF594) or far red (AF647) wavelengths.

7. Acquire separate images for each probe and then determine co-localization by image analysis or prepare merged color images using an appropriate graphics program (e.g., Adobe Photoshop) to obtain a qualitative view of the extent of colocalization.

   Co-localizatiion between red and green probes within the same endosomes will appear yellow whereas individual puncta labeled either with red or green in merged images indicate no co-localizatiion (see Fig. 24.1.5 for example).

USING DOMINANT-NEGATIVE rab PROTEINS TO IDENTIFY TRANSPORT STEPS

ALTERNATE PROTOCOL 2

Another method for characterizing the itinerary of endocytosed probes is to carry out transport studies in the presence of dominant-negative (DN) rab proteins. Rabs are small (21- to 25-kDa) GTPases which play important roles in the tethering and docking of vesicles to their target membranes; they are also involved in the regulation of vesicular transport between specific intracellular compartments (Mohrmann and van der Sluijs, 1999; Miaczynska and Zerial, 2002; Seabra et al., 2002). For example, rab5 is involved

in the homotypic fusion of clathrin-derived endocytic vesicles to form early endosomes (EEs) whereas rab9 regulates the transport of membranes from late endosomes to the Golgi apparatus (Riederer et al., 1994; Woodman, 2000). Transport between different compartments can be demonstrated by inhibiting such trafficking by expression of a particular DN rab protein. Using this technique, the authors have shown that BODIPY-LacCer transport to the Golgi apparatus is rab7- and rab9-dependent, whereas the recycling of BODIPY-LacCer from the EE back to the PM is largely dependent upon rab4 (Choudhury et al., 2002, 2004).

Studies of rab-dependent trafficking require the transfection of DN rab plasmids into cells and the identification of transfected cells by fluorescence microscopy. The authors have performed these studies by either using fluorescent protein–tagged rabs (e.g., DsRed-rab9) or by co-transfecting nonfluorescent rab proteins with the DsRed-nuc plasmid (Choudhury et al., 2002, 2004). The following is an example demonstrating the rab9-dependent transport of BODIPY-LacCer to the Golgi apparatus.

Additional Materials *(also see Basic Protocol 3)*

EMEM containing 1% and 10% FBS (EMEM-1 and EMEM-10; see recipe)
Wild-type rab9 plasmid and dominant-negative (DN) DsRed-rab9 plasmid (Addgene)
FuGENE 6 (Roche Applied Sciences)
BODIPY-LacCer/BSA (see Support Protocol 2)

1. Culture (see *UNIT 1.1*) HSFs on 25-mm sterile, acid-etched glass coverslips in 35-mm culture dishes (one coverslip per dish) with 2 ml EMEM-10 for 24 to 48 hr until a confluency of 50% to 70% is reached.

   Although many laboratories routinely use antibiotics in cell culture medium, culturing of cells without antibiotics is recommended because it can increase transfection efficiency.

2. Transfect cells with plasmids for wild type or DN DsRed-rab9 (1 μg DNA per dish) using FuGENE 6 according to the manufacturer's directions.

3. After 48 hr, wash the cells (now ~50% to 60% confluent) several times with 2 ml EMEM-1.

4. Add BODIPY-LacCer/BSA (3 to 5 μM final) in EMEM-1 to samples and incubate 45 min at 37°C in a CO_2 incubator.

5. Rinse cells with 2 ml EMEM-1 and incubate in 2 ml fresh EMEM-1 for an additional 60 min at 37°C in a CO_2 incubator.

6. Wash cells in 2 ml HMEM−G and then back exchange with 5% dfBSA as in Basic Protocol 2, step 8.

7. View cells under the fluorescence microscope.

   Transfected cells are identified by their bright red fluorescence. Wild-type rab9 shows a punctate distribution of fluorescence, whereas DN rab9 is diffusely distributed in the cytoplasm. In most cells expressing wild-type rab9, BODIPY-LacCer (visualized in the green channel) stains the Golgi apparatus, similar to the pattern seen in untransfected cells. In cells expressing DN rab9, BODIPY-LacCer is distributed in small punctuate structures, and Golgi targeting is blocked (Fig. 24.1.6).

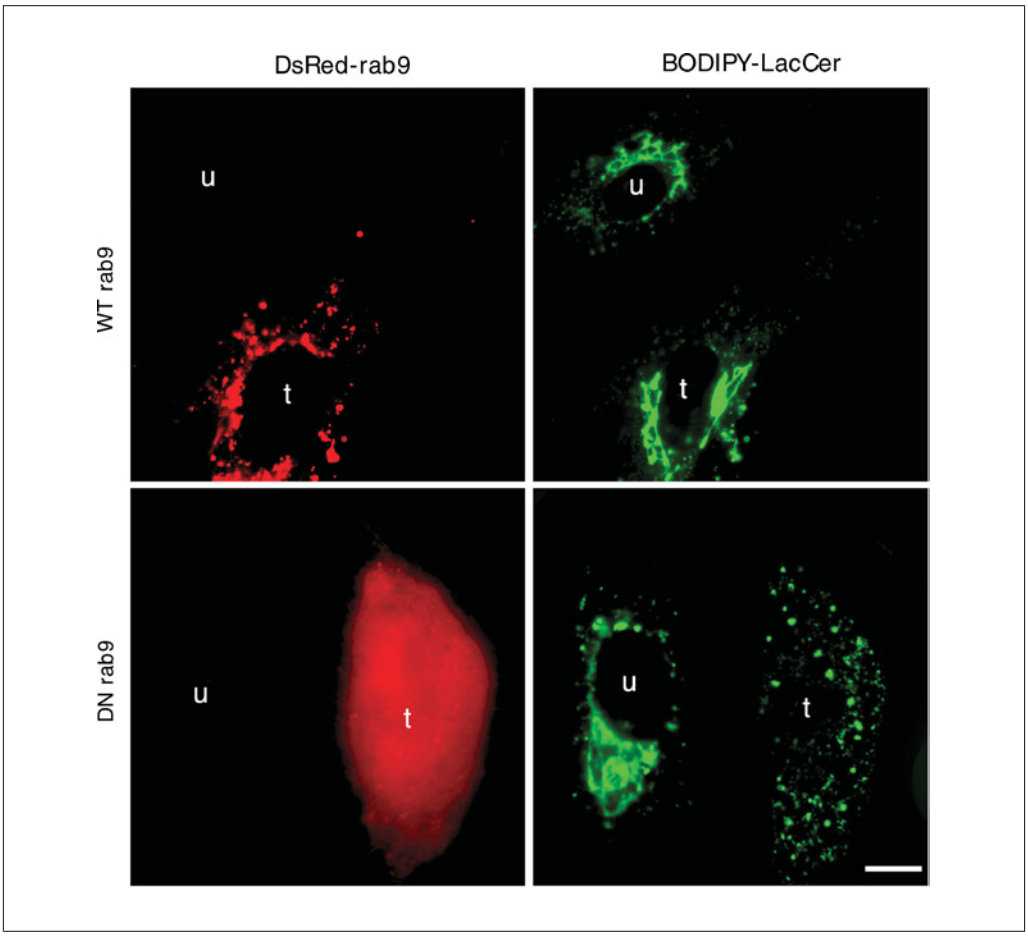

Figure 24.1.6 Overexpression of dominant-negative (DN) rab9 inhibits the Golgi targeting of BODIPY-LacCer. Cells were transfected with wild type (WT) or DN DsRed-labeled rab9 constructs. After 48 hrs, the cells were incubated with 5 μM BODIPY-LacCer for 45 min at 37°C, rinsed, and then chased in medium for 60 min at 37°C. The same cells were viewed in red (DsRed rab) and green (BODIPY-LacCer) channels (left and right images, respectively). Cells were either transfected (t) with rab9 or untransfected (u). The transfected cell in the lower left panel exhibits diffuse fluorescence because the dominant negative rab9 protein is diffusely distributed, unlike the wild type form (upper left panel). Note lack of perinuclear Golgi targeting of BODIPY-LacCer in the cell transfected with DN rab9 (lower right panel). Bar = 10 μM. For the color version of this figure go to *http://www.currentprotocols.com*.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

$CaCl_2$, 100×

Dissolve 1.85 g $CaCl_2 \cdot 2H_2O$ in 100 ml water. Store up to 3 months at 4°C.

EMEM containing 1% and 10% FBS (EMEM-1 and EMEM-10)

MEM with Earle's salts (Invitrogen) supplemented with:
0.1 mM MEM nonessential amino acids solution (10 mM; Invitrogen)
2 mM L-glutamine (200 mM; Invitrogen)
1% or 10% fetal bovine serum (FBS)

Also see Martin and Pagano (1994).

HEPES-buffered minimal essential medium with glucose (HMEM+G) and without glucose (HMEM–G)

10 ml 10× HMEM Stock (see recipe)
1 ml 100× $CaCl_2$ (1.25 mM final)

continued

1 ml 100× $MgSO_4$ (0.08 mM final)
Sterilize by passing through a 0.2-μm filter
Store up to 3 days at 4°C.

HMEM (+ G or – G) Stock, 10×

Combine the following in ~500 ml of distilled water:
32.84 g HEPES acid (138.0 mM final)
80 g NaCl (1370.0 mM final)
4 g KCl (54.0 mM final)
10 g glucose (55.0 mM final), for HMEM+G only
2.92 g glutamine (20.0 mM final)
0.6 g KH_2PO_4 (4.4 mM final)
0.254 g Na_2HPO_4 (1.8 mM final)
100 ml 100× MEM vitamins (Invitrogen)
200 ml 50× MEM amino acids (Invitrogen)
Adjust pH with NaOH to 7.4
Bring to 1 liter final volume
Sterilize by passing through a 0.2-μm filter
Divide into 25- to 50-ml aliquots and store up to 3 months at 4°C.

For 10× HMEM minus glucose (HMEM−G), exclude glucose from the medium.

$MgSO_4$, 100×

Dissolve 2.0 g $MgSO_4 \cdot 7H_2O$ in 100 ml water. Store up to 3 months at 4°C.

COMMENTARY

Background Information

Sphingolipid (SL) analogs may not represent the behavior of endogenous SLs in every aspect, and thus the utilization of additional approaches to study SL trafficking (e.g., SL-binding toxins or SL-specific antibodies) is important for validation of conclusions. However, while recognizing the limitations of fluorescent lipid probes, studies with lipid analogs have suggested new models for the transport of endogenous lipids that were not apparent prior to the use of the analogs.

SL-binding toxins have been used to follow the trafficking of endogenous plasma membrane (PM) SLs (Mallard et al., 1998; Orlandi and Fishman, 1998; Schapiro et al., 1998; Wolf et al., 1998; Puri et al., 2001). Moreover, trafficking of toxin binding to endogenous PM SLs can also be used to confirm the transport pathways demonstrated using fluorescent SL analogs (Choudhury et al., 2002). It should be kept in mind that in most cases, SL-binding toxin molecules possess multiple lipid binding sites (e.g., each molecule of CtxB is a pentamer that binds five molecules of GM1 ganglioside). Thus, the toxins may induce clustering of cell-surface SLs and in some cases may alter the transport of lipids at the PM (Singh et al., 2003).

Critical Parameters and Troubleshooting

To minimize experiment-to-experiment variations, it is important to use cells at the same degree of confluency. Some cell types exhibit changes in their levels of endocytosis depending upon their extent of confluence (R.D. Singh and R.E. Pagano, unpub. observ.). Moreover, passage number may also contribute to inconsistencies between different experiments.

The use of biochemical inhibitors has aided in the identification of endocytic pathways for many cargo molecules. However, such treatments have to be optimized for their use on different cell types. Inhibitor concentrations should be optimized to maximize the inhibition of specific pathways using a validated marker (e.g., Tfn for clathrin-mediated endocytosis) while minimizing any toxic effects on the cells. To minimize variation, control cells should also be treated identically to cells treated with inhibitors in terms of time and temperature during all incubations.

If a dominant-negative (DN) protein is transiently expressed after transfection, fairly high levels of transfection are usually desirable both to interfere with the function of normal protein and to unambiguously identify cells

transfected with fluorescent proteins. However, transient transfection always yields a range of protein expression levels, with the highest levels sometimes being toxic. Thus it is advisable to establish a suitable criterion for choosing transfected cells (e.g., a specific range of expression of fluorescent protein). Appropriate transfection controls (e.g., wild-type vs DN proteins, DsRed-nuc alone) are also important.

When using a fluorescent reporter protein (e.g., Ds-Red-nuc) to identify cells expected to be cotransfected with a nonfluorescent (e.g., DN) protein, it is important to verify the co-expression of the reporter protein and the non-flourescent protein by immunofluorescence. A useful alternative to transient transfection is adenoviral-mediated overexpression of DN proteins (Sharma et al., 2004). Adenoviral infection usually leads to similar levels of protein overexpression in all cells in a sample and thus avoids some of the problems associated with transient transfection.

Anticipated Results

The use of image analysis of digital micrographs to quantify endocytic uptake and its inhibition is limited in that absolute values (i.e., pmoles internalized) such as those achieved using biochemical analysis or radioactive tracers cannot be calculated from image analysis. However, image analysis provides useful relative values (e.g., percent uptake) that allow one to draw conclusions concerning mechanisms of endocytosis or intracellular transport. The efficiency of inhibitor treatment may vary between particular inhibitor, cell type or endocytic probe used. A reasonable guideline is that treatments are optimized when they inhibit uptake of a prototypical probe (e.g., transferrin inhibition by chlorpromazine) by 60% to 80%. Moreover, multiple inhibitors (or dominant-negative proteins) should be used to verify conclusions concerning any specific endocytic or transport mechanism. Because of the possibility of cell-cell variability, large samples sizes (e.g., greater than 30 cells for each condition) are also important to generate statistically significant data.

Time Considerations

Coordination of the different techniques described here requires planning and execution over several days. For example, cell samples must be grown to appropriate confluence on cover slips over 1 to 2 days. For transfection of dominant-negative proteins, an additional 1 to 2 days is required. Finally, each individual experiment using fluorescent probes may require 2 to 4 hr set up time, followed by sufficient time at the microscope (20 to 40 min per sample) to observe and photograph specimens.

Fluorescent Detection of Lipid Droplets and Associated Proteins

Lipid droplets are found in the cytosol of most eukaryotic cells, where they participate in a variety of cellular functions (Londos et al., 1999; Murphy and Vance, 1999; Zweytick et al., 2000). Adipocytes are highly specialized for the storage of excess lipid and contain giant, triacylglyceride-rich lipid droplets. Lipid droplets in adrenal cells store large amounts of cholesteryl esters for use in synthesis of steroid hormones. Smaller lipid droplets are found in cells of several other tissues including liver, kidney, heart, and skeletal muscle. These smaller droplets may serve as energy reservoirs, sources of lipid for membrane biosynthesis, or storage sites for potentially toxic lipid species. While the importance of lipid droplets in a variety of cell types has been established, very little is known about the mechanisms affecting lipid droplet structure and the targeting of lipid droplet–associated proteins. Visualization of lipid droplets and their associated proteins will be critical to understanding these processes.

This unit describes the detection of lipid droplets in cultured cells using fluorescence microscopy (see Basic Protocol 1). Fluorescent lipophilic dyes, which partition into the nonpolar lipid droplet core, are useful lipid droplet markers. Protocols are presented for lipid droplet visualization using two of these dyes, Nile Red and BODIPY 493/503. The differences in the spectral properties of these molecules and advantages of each are discussed (see Commentary). Lipid droplets in some cultured cells may be small or difficult to detect. Therefore, a protocol for supplementing growth media with excess lipid to enhance lipid droplet formation in cultured cells is included (see Support Protocol).

This unit also describes how visualization of intracellular lipid droplets can best be combined with indirect immunofluorescent detection of lipid droplet–associated proteins, using antibodies conjugated to standard red, green, or blue fluorophores (see Basic Protocol 2). Other investigators have demonstrated the localization of green fluorescent protein (GFP)-tagged lipid droplet–associated proteins in live cells (Imamura et al., 2002; Targett-Adams et al., 2003). Adipophilin, a broadly expressed protein that is widely used as a lipid droplet marker, is presented here as an example. Several recent reports suggest that lipid droplets are uniquely sensitive to fixation and permeabilization procedures (DiDonato and Brasaemle, 2003; Ohsaki et al., 2005). Some common fixation techniques severely affect lipid droplet morphology; thus, a protocol to examine the localization of lipid droplet–associated proteins while keeping lipid droplet structure intact is included (see Alternate Protocol).

DETECTION OF LIPID DROPLETS WITH LIPOPHILIC DYES

BASIC PROTOCOL 1

Two of the most widely utilized lipophilic dyes are Nile Red and BODIPY 493/503. In the procedure described here, cells are fixed with paraformaldehyde and then incubated with one of these dyes. However, fixation is not necessary, and lipophilic dyes can be used to detect lipid droplets in live cells. The hydrophobicity of these dye molecules promotes rapid partitioning into the nonpolar environment of lipid droplets. Nile Red and BODIPY 493/503 fluorescence is easily detected by confocal or wide-field fluorescent microscopy. See the Commentary for a discussion of differences between Nile Red and BODIPY 493/503.

Current Protocols in Cell Biology (2007) 24.2.1-24.2.11

Materials

Cultured cells

Poly-L-lysine, optional: prepare by dissolving 5 mg poly-L-lysine in 50 ml sterile H_2O; sterilize by passing through a 0.22-μm filter, and store up to 2 months at 4°C

Growth medium, optionally supplemented with 400 μM oleate (see Support Protocol)

Phosphate-buffered saline (PBS; *APPENDIX 2A*), without calcium and magnesium

3% (w/v) paraformaldehyde in PBS

1 mg/ml BODIPY 493/503 stock solution: prepare by dissolving 5 mg BODIPY 493/503 (4,4-difluoro-1,3,5,7,8-pentamethyl-4-bora-3a,4a-diaza-*s*-indacene; Molecular Probes) in 5 ml ethanol; divide into 500-μl aliquots, and store up to 1 month at −20°C *or*

1 mg/ml Nile Red stock solution: prepare by dissolving 5 mg Nile Red (Molecular Probes) in 5 ml DMSO; divide into 500-μl aliquots, and store up to 1 month at −20°C

150 mM NaCl: prepare by dissolving 4.38 g NaCl in 500 ml H_2O; store up to 1 year at room temperature

Mounting medium: e.g., Prolong Antifade Reagent (Invitrogen) or see Internet Resources

22-mm^2 square glass coverslips, sterile

35-mm tissue culture dishes or 6-well tissue culture plates

Glass slides

Fluorescence microscope with appropriate filters

Plate cells for staining

1. One or two days prior to staining, plate cells on sterile glass coverslips. Plate the cells at 50% to 70% confluency so that they remain semiconfluent at the time of staining.

   Whether this step is performed 1 or 2 days prior to staining depends on the length of time required for the chosen cell type to adequately adhere to the coverslip. For some cell types, coating the coverslip with 0.1 mg/ml poly-L-lysine prior to plating may facilitate adherence to the coverslip.

   It is easiest to place single coverslips (22-mm^2 square) in 35-mm tissue culture dishes or one per well in a 6-well plate. The coverslips are left in the dishes through the wash, fixation, and staining steps.

2. *Optional:* To enhance lipid droplet formation and facilitate detection, supplement the growth medium for cells with 400 μM oleate for 6 to 24 hr prior to fixation and lipid droplet staining.

   While the lipid present in serum may be sufficient to induce some lipid droplet formation, lipid droplet size and number is increased following supplementation with additional lipid.

   Preparation of fatty acid-supplemented medium is discussed in the Support Protocol.

Fix cells

3. Rinse the cells twice with 2 ml PBS.

   Extensive washes with rocking are not necessary for lipid droplet staining with these dyes.

4. Fix the cells by incubating with 2 ml 3% (w/v) paraformaldehyde 30 min at room temperature.

5. Wash the cells three times with 2 ml PBS.

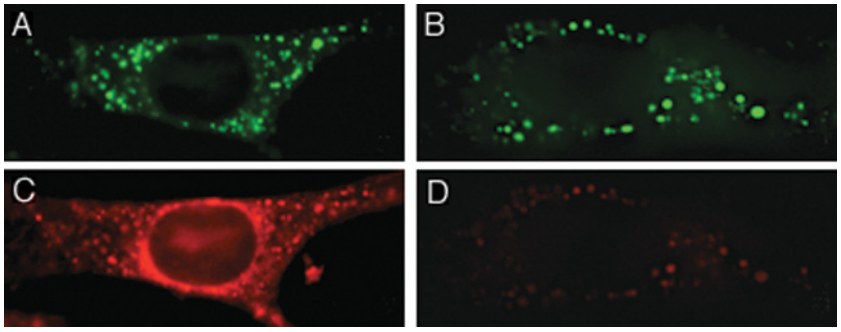

Figure 24.2.1 Detection of lipid droplets with Nile Red and BODIPY 493/503. BHK cells were fed medium supplemented with 400 μM oleate prior to staining with Nile Red (**A, C**) or BODIPY 493/503 (**B, D**). For each dye, fluorescent emission detected in the green (A, B) and red channels (C, D) are shown. Stained cells were visualized with a Zeiss Axiovision 200 fluorescent microscope. Out-of-focus fluorescence was removed with deconvolution software. Single sections of a *z*-stack are shown. For the color version of this figure go to *http://www.currentprotocols.com*.

Stain lipid droplets

6a. *If using BODIPY 493/503:* Add 10 μl of 1 mg/ml BODIPY 493/503 stock solution to 10 ml of 150 mM NaCl.

6b. *If using Nile Red:* Add 1 μl of 1 mg/ml Nile Red stock solution to 10 ml of 150 mM NaCl.

7. Cover the cells with 1 ml Nile Red or BODIPY 493/503 staining solution from the previous step and incubate 10 min at room temperature, protected from ambient light.

   Exposure of the fluorescent lipophilic dyes to ambient light should be minimized; therefore, cover the cells during this and all later steps.

8. Wash the cells three times with 2 ml PBS.

9. Mount the coverslips onto glass slides with 20 to 40 μl antifade mounting medium.

Analyze stained cells visually

10. Using a fluorescence microscope, detect BODIPY 493/503 staining of lipid droplets as green fluorescence. Detect Nile Red fluorescence in both the red and green channels.

    For Nile Red, green fluorescence is more specific for lipid droplets (Fig. 24.2.1; see Commentary for additional discussion).

IMMUNOFLUORESCENT DETECTION OF ADIPOPHILIN, A LIPID DROPLET–ASSOCIATED PROTEIN

BASIC PROTOCOL 2

Lipid droplets consist of a core of neutral lipid, including triacylglycerol and cholesteryl ester, surrounded by a phospholipid monolayer. A number of proteins that associate with the lipid droplet surface have recently been described (Brasaemle et al., 2004; Fujimoto et al., 2004; Liu et al., 2004; Umlauf et al., 2004). Many of the most abundant lipid droplet–associated proteins in mammalian cells share sequence similarity and have been termed PAT proteins. PAT proteins are named for the first members of this family to be identified—perilipin (P), adipophilin (also known as ADRP, A), and TIP47 (T). While perilipin expression is restricted to adipocytes and steroidogenic cells, adipophilin and TIP47 are widely expressed (Londos et al., 2005). Moreover, while TIP47 may exist in both cytosolic and lipid droplet–bound pools, adipophilin is exclusively lipid droplet associated (Londos et al., 2005). Largely because of these characteristics, adipophilin serves as a widely utilized marker for lipid droplet accumulation.

Localization of lipid droplet–associated proteins requires careful consideration of fixation and permeabilization techniques. Many common fixation methods (including solvents such as methanol or acetone) greatly alter lipid droplet morphology (DiDonato and Brasaemle, 2003). Moreover, recent work has shown that many lipid droplet proteins are poorly detected in cells after standard Triton X-100 permeabilization (Ohsaki et al., 2005). Thus, in this protocol for detecting adipophilin, cells are fixed with paraformaldehyde and permeabilized with saponin.

Materials

Cultured cells
Growth medium, optionally supplemented with 400 μM oleate (see Support Protocol)
0.1 mg/ml poly-L-lysine, optional: prepare by dissolving 5 mg poly-L-lysine in 50 ml sterile H_2O; sterilize by passing through a 0.22-μm filter, and store up to 1 month at 4°C
Phosphate-buffered saline (PBS; *APPENDIX 2A*), without calcium and magnesium
3% (w/v) paraformaldehyde in PBS
Blocking buffer: 0.2 M glycine /0.1 mg/ml saponin/30 mg/ml bovine serum albumin (BSA) in PBS (*APPENDIX 2A*)
Primary antibody: guinea pig anti-adipophilin polyclonal antibody (Research Diagnostics)
Antibody diluent: 0.1 mg/ml saponin /1 mg/ml BSA in PBS (*APPENDIX 2A*)
Secondary antibody: fluorescently-tagged anti-guinea pig IgG; e.g., Texas red dye–conjugated donkey anti-guinea pig IgG (Jackson Immunoresearch Laboratories)
Mounting medium: e.g., Prolong Antifade Reagent (Invitrogen) or see Internet Resources

22-mm^2 square glass coverslips, sterile
35-mm tissue culture dishes or 6-well tissue culture plates
Rocking platform
Glass slides
Confocal or widescreen fluorescence microscope with appropriate filters

Plate cells for staining

1. One or two days prior to staining, plate cells on sterile glass coverslips. Plate the cells at 50% to 70% confluency so that they remain semiconfluent at the time of staining.

   Whether this step is done 1 or 2 days prior to staining depends on the length of time required for the chosen cell type to adequately adhere to the coverslip. For some cell types, coating the coverslip with 0.1 mg/ml poly-L-lysine prior to plating may facilitate adherence.

   It is easiest to place single 2-mm square coverslips in 35-mm tissue culture dishes or one per well in a 6 -well plate. The coverslips are left in the dishes through the wash, fixation, and staining steps.

2. *Optional:* To enhance lipid droplet formation and facilitate detection of adipophilin, supplement growth medium for cells with 400 μM oleate for 6 to 24 hr prior to fixation of cells.

   Adipophilin expression is increased following supplementation with excess fatty acid (Gao et al., 2000). Moreover, adipophilin is quickly degraded when not bound to the surface of lipid droplets (Xu et al., 2005). Therefore, increasing the size and number of lipid droplets by supplementation with excess lipid will facilitate detection of adipophilin.

   Preparation of fatty acid–supplemented medium is discussed in the Support Protocol.

Fix cells

3. Wash the cells twice with 2 ml PBS.

   All washes are carried out at room temperature.

4. Fix the cells by incubating with 2 ml of 3% (w/v) paraformaldehyde for 20 min at room temperature.

5. Wash the cells four times with 2 ml PBS.

Immunostain the cells

6. Add 2 ml blocking buffer to the cells and incubate 45 min at room temperature to prevent nonspecific antibody binding.

7. Dilute the guinea pig anti-adipophilin polyclonal primary antibody 1:1000 (from whole antiserum) in antibody diluent. Incubate the cells with 1 ml diluted primary antibody overnight at 4°C.

   For primary antibodies other than anti-adipophilin, pilot experiments should be performed to optimize the antibody concentration.

8. Warm the cells at room temperature for 30 min before proceeding with step 9.

   The product literature accompanying this antibody states that it recognizes adipophilin in human, mouse, rat, dog, and bovine cells. The authors have also demonstrated its affinity for the Syrian gold hamster (BHK cell) protein (L.L. Listenberger and D.A. Brown, unpub. observ.).

9. Wash the cells four times (10 min each time) with 2 ml PBS on a gently rocking platform.

   Including 0.1 mg/ml saponin in this and all further wash and incubation solutions may enhance detection of some proteins.

10. Dilute the donkey anti-guinea pig secondary antibody to 5 μg/ml in antibody diluent. Add 1 ml diluted secondary antibody to the cells and incubate 1 hr at room temperature, protected from light.

    Excessive exposure of the fluorophore to ambient light should be avoided. Thus, cover the cells during the incubation with secondary antibody and subsequent wash steps.

    Secondary antibodies conjugated to red, green, or blue fluorophores may be used. Antibody concentration should be varied in pilot experiments to maximize signal while minimizing background.

11. Wash the cells four times (10 min each time) with 2 ml PBS on a gently rocking platform.

12. Mount the coverslips onto slides with 20 to 40 μl antifade mounting medium.

Analyze cells visually

13. Use confocal or wide-field fluorescence microscopy to detect adipophilin immunostaining.

SIMULTANEOUS DETECTION OF LIPID DROPLETS AND ADIPOPHILIN

ALTERNATE PROTOCOL

Simultaneous visualization of lipid droplet cores and intracellular proteins is possible by adding BODIPY 493/503 to the secondary antibody solution used to detect the protein. Using a secondary antibody conjugated to a red fluorophore allows detection of a lipid droplet–associated protein without interference from significant BODIPY 493/503 fluorescence (see Commentary). As a control for the absence of red fluorescence due to BODIPY 493/503 staining, include a sample in which the primary antibody incubation step includes antibody diluent alone.

Additional materials *(also see Basic Protocol 2)*

1 mg/ml BODIPY 493/503 stock solution: prepare by dissolving 5 mg BODIPY 493/503 (4,4-difluoro-1,3,5,7,8-pentamethyl-4-bora-3a,4a-diaza-*s*-indacene; Molecular Probes) in 5 ml ethanol; divide into 500-µl aliquots, and store up to 1 month at −20°C

Plate and fix cells

1. Follow steps 1 to 5 of Basic Protocol 2.

Immunostain for lipid and protein

2. Incubate the cells with 2 ml blocking buffer for 45 min at room temperature to prevent nonspecific antibody binding.
3. Dilute the guinea pig anti-adipophilin polyclonal antibody 1:1000 (from whole antiserum) in antibody diluent. Incubate the cells with 1 ml diluted primary antibody overnight at 4°C. Warm the cells at room temperature for 30 min before proceeding.
4. Wash the cells four times (10 min each) with 2 ml PBS on a gently rocking platform.
5. Prepare the secondary antibody solution as follows:
   a. Add 1 µl of 1 mg/ml BODIPY 493/503 stock solution to 1 ml of antibody diluent.
   b. Dilute the secondary antibody to 5 µg/ml in the antibody diluent containing the BODIPY dye.
6. Overlay each coverslip with 200 µl diluted secondary antibody. Incubate 1 hr at room temperature, protected from ambient light.

   Excessive exposure of the fluorophore to ambient light should be avoided. Thus, cover the cells during the incubation with secondary antibody and subsequent wash steps.
7. Wash the cells four times (10 min each) with 2 ml PBS on a gently rocking platform.
8. Mount the coverslips onto slides with 20 to 40 µl antifade mounting medium.

Analyze cells visually

9. Simultaneously detect adipophilin (red fluorescence) and neutral lipid droplets (green fluorescence).

   In large lipid droplets, adipophilin may be detected as a ring surrounding the BODIPY 493/503–positive lipid droplet core, while the two markers often appear to overlap in small lipid droplets (Fig. 24.2.2).

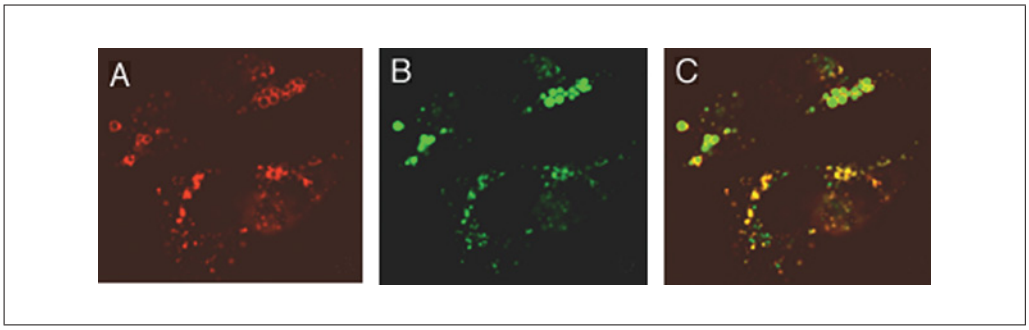

Figure 24.2.2 Simultaneous detection of lipid droplet cores and adipophilin. BHK cells were fed medium supplemented with 400 µM oleate prior to immunofluorescent detection of adipophilin (red, **A**) and BODIPY 493/503 staining of neutral lipid droplets (green, **B**). The merged image (**C**) shows adipophilin localized to the surface of neutral lipid droplets. Images shown are single sections of a *z*-stack visualized with a Zeiss Axiovision 200 fluorescent microscope and processed with deconvolution software. For the color version of this figure go to *http://www.currentprotocols.com.*

PREPARATION OF FATTY ACID–SUPPLEMENTED MEDIUM

SUPPORT PROTOCOL

Many cell types exhibit only a few, small lipid droplets when cultured under standard conditions. However, fatty acid supplementation of growth medium stimulates neutral lipid synthesis and can greatly enhance lipid droplet size and number. Elevated neutral lipid levels can increase cellular levels of adipophilin and possibly other lipid droplet proteins, both through induction of synthesis and stabilization, facilitating detection of these proteins. To enhance detection of lipid droplets, a simple protocol for preparing fatty acid–supplemented medium is included below.

Materials

1 M NaOH
Oleic acid
Phosphate-buffered saline (PBS; *APPENDIX 2A*), without calcium and magnesium
Bovine serum albumin (BSA), essentially fatty acid free
Growth medium for cultured cells of interest

50-ml conical tube
37°C and 70°C water bath
250- and 400-ml beakers, sterile
0.22-μm bottle-top filter and sterile, 200-ml glass bottle

Prepare 20 mM sodium oleate

1. Add 200 μl of 1M NaOH to 15.7 ml water in a 50-ml conical tube. Warm to 70°C in a water bath.
2. Add 100 μl oleic acid to the prewarmed solution. Incubate 30 min at 70°C. Invert the tube to mix several times throughout the incubation.
3. Add 50 μl of 1 M NaOH to the fatty acid solution. Invert to mix. Incubate 5 min at 70°C.
4. Repeat step 3 until micelles are no longer visible.

   The micelles may appear as small oil droplets floating near the surface of the solution.

   They are easiest to detect after swirling the tube. Typically, three to five aliquots of NaOH must be added before the oleate is adequately dispersed in solution and the micelles disappear.

Prepare 5% BSA solution

5. Add 80 ml PBS to a 400-ml beaker.
6. Weigh out 5 g BSA and add to the beaker on top of the PBS. When all of the BSA is in solution, swirl gently to mix.

   The BSA will gradually fall into solution.

   This method facilitates the addition of large amounts of BSA to solution. BSA added to the beaker before the PBS, or with stirring, will clump and be difficult to solubilize.

7. Adjust volume in the beaker to 100 ml with PBS. Sterilize by passing through a 0.22-μm filter and store up to several months at 4°C.

   A solution of 5% BSA in PBS may be made in advance and stored at 4°C for several months.

Form fatty acid/albumin complexes

8. Prewarm 11.6 ml of the 5% BSA in PBS at 37°C in a 50-ml conical tube.
9. Add 3.5 ml of the 20 mM sodium oleate solution dropwise to warmed BSA solution. Invert to mix several times during the addition.

Here, fatty acid is complexed to BSA at an approximate molar ratio of 8:1. Following addition to serum-containing culture media, the fatty acid to BSA ratio is ~6.6:1 (Listenberger et al., 2001). While this ratio enhances lipid droplet formation and may mimic some pathophysiologic conditions (Kleinfeld et al., 1996), physiological fatty acid to albumin ratios (and consequently, unbound fatty acid concentrations) are likely to be lower (Spector, 1975; Richieri and Kleinfeld, 1995).

10. In the sterile environment of a tissue culture hood, add the BSA/oleate mix to 160 ml cell culture medium (prewarmed to 37°C) in a sterile 250-ml beaker. Sterilize by passing though a 0.22-μm bottle-top filter placed on a sterile 200-ml glass bottle. Store up to 1 week at 4°C.

    The final concentration of oleate in the medium is 400 μM.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Antibody diluent

80 ml H_2O
10 ml 10× PBS (*APPENDIX 2A*)
100 mg bovine serum albumin (BSA)
2 ml 0.5% (w/v) saponin (see recipe)
H_2O to 100 ml
Store up to 1 week at 4°C

Blocking buffer

1.5 g glycine
3 g bovine serum albumin (BSA)
80 ml H_2O
10 ml 10× PBS (*APPENDIX 2A*)
2 ml 0.5% (w/v) saponin (see recipe)
H_2O to 100 ml
Sterilize by passing though a 0.22-μm filter
Store up to 1 month at 4°C

Paraformaldehyde, 3% (w/v)

3 g paraformaldehyde
Add 80 ml H_2O.
Adjust pH to 8.0 with 5 N NaOH
Warm to 50°C with stirring
Add 10 ml 10× PBS (*APPENDIX 2A*)
Add H_2O to 100 ml
Filter through standard filter paper to remove undissolved solids
Store up to 1 week at 4°C

Saponin, 0.5% (w/v)

50 mg saponin
Dissolve in 9 ml H_2O
Add 1 ml 10× PBS (*APPENDIX 2A*)
Store up to 1 week at 4°C

COMMENTARY

Background Information

The spectral properties of Nile Red and BODIPY 493/503 have important implications for their usefulness as lipid droplet markers. The emission maximum of Nile Red bound to phospholipid vesicles is ~636 nm, detected as red fluorescence (Molecular Probes). However, the emission spectrum is very broad, and in some environments (as detailed below) Nile Red also emits significant green fluorescence. For this reason, dual-localization studies using Nile Red and a protein detected with an antibody conjugated to either a red or green fluorophore is difficult. Because Nile Red bleaches faster than most antibody-linked fluorophores, dual localization may be possible by bleaching Nile Red fluorescence after capturing an image (Ostermeyer et al., 2001) or by detecting a protein using a blue fluorophore (Ostermeyer et al., 2004). By contrast, the relatively narrow emission spectrum of BODIPY 493/503 is largely restricted to wavelengths passed by typical green emission filters, facilitating simultaneous detection of another marker in red (Fig. 24.2.2). For this reason, BODIPY 493/503 is preferred over Nile Red for dual-localization studies.

Staining of hydrophobic structures other than lipid droplets by lipophilic dyes can also be a concern. For instance, Nile Red gives significant labeling of membranes when red fluorescence is examined. By contrast, green fluorescence of Nile Red is fairly specific for lipid droplets (Fig. 24.2.1). This results from the fact that Nile Red's fluorescence maximum shifts toward the red as the polarity of its environment increases (Greenspan et al., 1985; Deye et al., 1990). Green fluorescence of Nile Red in membranes is thus greatly reduced because they are more polar than lipid droplets. By contrast, BODIPY 493/503 fluorescence is fairly specific for lipid droplets.

Despite the advantages of BODIPY 493/503, Nile Red may sometimes be more useful. For example, with filters typically used to detect fluorescein fluorescence, BODIPY 493/503 fluorescence generally appears less intense than that of Nile Red and may photobleach more rapidly (L.L. Listenberger and D. A. Brown, unpub. observ.). Thus, green fluorescence of Nile Red remains a useful tool for single-color labeling of lipid droplets.

In addition to Nile Red and BODIPY 493/503, other classic dyes utilized for visualization of lipid droplets include Sudan III and Oil-red O. Both dyes allow detection of lipid droplets by either conventional light microscopy or fluorescence microscopy (Aoki et al., 1997; Koopman et al., 2001). The red fluorescence emitted by Sudan III and Oil-red O is particularly useful for codetection of lipid droplets and GFP-tagged proteins (Imamura et al., 2002). Importantly, some published protocols for staining with Sudan III and Oil-red O involve incubation with solvents (including isopropanol and ethanol) that cause fusion of small lipid droplets (Fukumoto and Fujimoto, 2002). Thus, these dyes should not be used to draw conclusions regarding lipid droplet size and morphology. (See Critical Parameters and Troubleshooting for additional discussion of treatments that alter lipid droplet morphology.)

Critical Parameters and Troubleshooting

Detection of lipid droplets using either Nile Red or BODIPY 493/503 staining is generally straightforward and uncomplicated. For cell types that have a tendency to detach from the coverslip during washes, it may be helpful to use acid-washed coverslips (incubate coverslips in 2:1 nitric acid: hydrochloric acid for 2 hr; rinse extensively with distilled H_2O and ethanol; autoclave) and to pretreat the coverslips with 0.1 mg/ml poly-L-lysine prior to plating. Moreover, detection of lipid droplets and lipid droplet–associated protein is greatly enhanced following supplementation with excess lipid. In addition to supplementation with oleate, others have observed similar increases in lipid storage following incubation with acetylated low-density lipoprotein (LDL; Larigauderie et al., 2004).

BODIPY 493/503–stained lipid droplets may be difficult to detect because of significant photobleaching. Samples should be mounted in medium that includes an antiquenching reagent and exposure to light should be minimized. If photobleaching of BODIPY 493/503–stained lipid droplets continues to be a problem, alternative labeling techniques may be pursued. One alternative method for the fluorescent detection of lipid droplets, Nile Red staining, is discussed in this unit. Another method is to supplement growth medium with a fluorescent fatty acid analog prior to fixation (Wolins et al., 2005). Because cells actively transport the fluorescent fatty acid to lipid droplets, staining is particularly intense and can be detected with reduced excitation, lessening photobleaching.

As highlighted in two recent reports, the hydrophobic nature of the lipid droplet requires careful consideration with respect permeabilization and fixation techniques. DiDonato and Brasaemle (2003) report that fixation with cold methanol or cold acetone disrupts lipid droplet morphology, causing lipid droplets to fuse or collapse in upon themselves. By contrast, paraformaldehyde fixation retains lipid droplet shape and is appropriate for visualization of lipid droplets and associated proteins. Furthermore, Ohsaki and colleagues (2005) have shown that fixation with a combination of glutaraldehyde and formaldehyde enhances detection of some lipid droplet proteins. The optimal concentration of glutaraldehyde was found to vary between markers and must be determined empirically. These authors also found that optimal detection of many lipid droplet–associated proteins required permeabilization with digitonin or saponin, rather than Triton X-100 (Ohsaki et al., 2005).

Adapting the procedure outlined in this unit to detection of lipid droplet–associated proteins other than adipophilin may require optimization in pilot experiments. Ideally, these should be performed in accordance with the guidelines determined by DiDonato and Brasaemle (2003) and Ohsaki et al. (2005). However, some antibodies work best only under conditions that do not preserve lipid droplet structure. For example, antigen detection by a mouse monoclonal anti-adipophilin antibody (Research Diagnostics Inc.) is markedly enhanced by fixation with cold methanol (Ostermeyer et al., 2004). Brief exposure to cold methanol does not completely extract lipids, and lipid droplets may still be detected with lipophilic dyes. Thus, if necessary, methanol fixation may be used in demonstrating targeting of a particular protein to lipid droplets, although no conclusions regarding lipid droplet size, structure, or distribution are possible.

Anticipated Results

Lipid droplets stained with Nile Red or BODIPY 493/503 are distinguished from most other organelles by their very round, smooth-surfaced appearance (Fig. 24.2.1). The number and size of lipid droplets vary between cell types and depend on whether medium has been supplemented with excess lipid prior to staining. Although lipid droplets are generally dispersed throughout the cell, extensive clustering of lipid droplets has been observed in some cell types.

Time Considerations

For both Basic Protocols 1 and 2, cells should be plated on coverslips 1 or 2 days prior to staining. The specific time depends on the cell type. In either case, cells must be fully adherent and well spread on the coverslip. The total time necessary for fixation and Nile Red or BODIPY 493/503 staining is minimal, requiring only ~1.5 hr. For immunostaining, ~1.5 hr is necessary on the first day for sample fixation and blocking. After overnight incubation in primary antibody, another 3.5 hr is needed to complete the washes and secondary antibody incubation. Once the coverslips are mounted on the slides, all samples may be stored at −80°C, protected from light, for several days prior to microscopy.

Making Giant Unilamellar Vesicles via Hydration of a Lipid Film

Suliana Manley[1] and Vernita D. Gordon[2]

[1]National Institutes of Health, Cell Biology and Metabolism Branch, Bethesda, Maryland
[2]University of Illinois Urbana-Champaign, Department of Materials Science and Engineering, Urbana, Illinois

ABSTRACT

This unit describes protocols for making giant unilamellar vesicles (GUVs) based on rehydration of dried lipid films. These model membranes are useful for determining the impact of membrane and membrane-binding components on lipid bilayer stiffness and phase behavior. Due to their large size, they are especially amenable to studies using fluorescence and light microscopy, and may also be manipulated for mechanical measurements with optical traps or micropipets. In addition to their use in encapsulation, GUVs have proven to be useful model systems for studying many cellular processes, including tubulation, budding, and fusion, as well as peptide insertion. The introduction of enzymes or proteins can result in reorganization, leading to such diverse behavior as vesicle aggregation, fusion, and fission. *Curr. Protoc. Keywords: liposomes • giant vesicles • electroformation • liposome swelling • model membranes

INTRODUCTION

This unit describes protocols for forming giant unilamellar vesicles (GUVs). The techniques described use hydration of dried lipid films, either by electroformation (Angelova et al., 1992) or by gentle hydration (Mueller et al., 1983). Swelling by electroformation (see Basic Protocol 1 and Alternate Protocol 1) produces a high yield of GUVs, typically 10 to 100 μm in diameter. Electroformation is not recommended for use with buffered solutions or charged lipids; instead, gentle hydration should be used (see Basic Protocol 2 and Alternate Protocols 2 and 3). An alternative technique that uses rapid evaporation is not described here (Moscho et al., 1996). Because nonfunctionalized vesicles are generally only weakly adhesive to many substrates, they may drift during imaging. Alternate Protocols 1 and 3 produce GUVs that are attached to wires or glass, thereby eliminating drift.

PREPARING GUVs BY ELECTROFORMATION ON INDIUM TIN OXIDE–COATED PLATES

BASIC PROTOCOL 1

This protocol is ideal for producing several milliliters of GUVs at $\sim 10^3$ to 10^4 per μl, which can then be submitted to a variety of different conditions. If desired, indium tin oxide (ITO) plates of coverslip thickness may be purchased, thus allowing observation of the growth of GUVs. For microscopy, lipids are generally rehydrated in aqueous sucrose solutions. Resuspension in equimolar glucose results in vesicles containing an interior solution that is denser than the suspending medium. This is commonly used in inverted microscopy to force vesicles to sink to the bottom of the sample chamber, next to the objective; switching solutions (glucose interior, sucrose exterior) causes vesicles to cream to the top for observation by upright microscopy. This also allows for application of osmotic stress and deflation using different molarities of sucrose and glucose. Furthermore, if fluorescent lipids are not incorporated, the difference in index of

refraction produced by the sugar solutions allows vesicles to be viewed using differential interference contrast or phase-contrast microscopy.

Materials

100 μl lipid in chloroform, at 5 to 10 mg/ml (see Support Protocol 1)
Up to 600 mM sucrose, or sterile deionized H_2O

25-cm^2 ITO-coated plates (e.g., Delta Technologies, Ltd., part no. CG-511IN-50x50/1.1; *http://www.delta-technologies.com/*)
Sealed chamber (e.g., vacuum desiccator) connected to dry nitrogen or vacuum source
Vacuum grease
Teflon holder and spacers for ITO-coated plates (see Support Protocol 2)
Oven with hole to introduce electrodes or heating bath (for lipid systems in which at least one component has a chain-melting transition temperature, T_m, above room temperature)
Electrodes ("Mini-Plunger to BNC Male" or equivalent; e.g., Radio Shack)
Function generator with readout for voltage and frequency (Stanford Research Systems, Ltd., *http://www.thinksrs.com/*)

Prepare dry lipid film on ITO plates

1. Prepare lipid mixtures (see Support Protocol 1).
2. Using a glass Pasteur pipet, deposit 2 to 3 drops of lipid mixture (~25 μl) onto the conductive side of a 25-cm^2 ITO-coated plate.

   Less lipid should be used for a smaller plate; maintain coverage of ~1 μl/cm^2.

3. Before the solution dries, use the side of the pipet to quickly spread the lipid over the surface of the plate using a single swipe. Repeat with second plate.

   Viewed in reflection, the lipid film should appear as colored interference fringes. The film should be as uniform as possible. Nonuniform films may result in a larger number of multilamellar or small vesicles. See Commentary for more information on the influence of film properties.

4. Place plates under vacuum at room temperature for at least 2 hr and up to overnight, until ready for use.

Carry out electroformation

5. Assemble plates into parallel assembly in the Teflon holder, separated by spacers.

   To prevent leakage, a small amount of vacuum grease may be spread around any seams in the Teflon holder. Parafilm or plastic wrap may be used to secure the assembly and render it leakproof.

6. Fill assembly with up to 600 mM sucrose solution or sterile deionized water.

   Choice of solvent and concentration is to be determined by the amount of osmotic stress, density, and index mismatch required for the experiment, and is a tunable parameter that is purely up to the experimenter.

7. *Optional:* For lipid mixtures or lipids with low T_m, place the assembly in an oven or heating bath set above T_m for the highest-melting component.

   For most unsaturated lipids and for many saturated lipids with tails up to 16 carbon atoms long, 50°C is sufficient.

8. Attach one electrode to each plate.

   Chamber should be covered to eliminate evaporation.

9. Set the function generator to output AC current (a sine wave), with amplitude 2 V, frequency 10 Hz. Incubate 1 to 2.5 hr.

Handle and store GUVs

10. Remove assembly from function generator and oven. Use a pipet or syringe needle to extract vesicles. Take care to minimize shear stresses by using a large pipet-tip opening or syringe needle and slow extraction to maximize the number of vesicles that survive this transfer.

    If using membrane dyes, unilamellar vesicles can be identified under the microscope as vesicles with the lowest fluorescence from the membrane.

11. Use GUVs within a few hours of formation (although a fraction will survive overnight).

12. Store GUVs at room temperature.

MAKING LIPID MIXTURES

SUPPORT PROTOCOL 1

This protocol describes the proper handling and storage of lipids, and gives some guidelines for selecting lipid mixtures.

Choice of lipids

Choosing a lipid composition is the first step in planning your experiments with GUVs. For testing your ability to make GUVs, a single, unsaturated lipid such as dioleoylphosphatidylcholine (DOPC) may be useful for troubleshooting. For model raft mixtures, a 1:1:1 molar composition of DOPC:sphingomyelin:cholesterol is typical, and is commonly referred to as the canonical raft mixture. However, this mixture produces GUVs that may not be phase-separated at room temperature. Therefore, if your microscope does not have the capability to be cooled, a mixture with a lower level of cholesterol that will readily phase-separate at room temperature may be preferable. For phase diagrams that provide the lipid phase melting temperatures of a range of ternary mixtures (Veatch and Keller, 2002), the influence of aliphatic chain length (Veatch and Keller, 2003) and sterol type (Bacia et al., 2005; Beattie et al., 2005) have also been investigated.

Lipid mixtures for peptide- and protein-binding experiments must be chosen carefully, since binding may depend strongly on lipid composition. In particular, it may be necessary to incorporate charged lipids in order to achieve binding (Bigay et al., 2003). A reasonable choice of lipids may be dictated by the natural lipid environment of the protein of interest. Biotinylated lipids are also available, and allow binding of vesicles to streptavidin or streptavidin-treated surfaces and objects.

Fluorescent lipid probes are useful for imaging vesicles and for determining phase behavior (Bagatolli, 2006). Headgroup-labeled phospholipids are typically used for these purposes, since the bulky fluorophore may interfere with lipid ordering if attached to an aliphatic chain. Several probes are available with readily accessible excitation wavelengths, including rhodamine-, Texas Red–, NBD- and fluorescein-conjugated lipids. These probes all partition preferentially into the liquid-disordered, non-raftlike phase, and are typically added at concentrations of ~0.1 mol%. Probes that partition into the liquid-ordered, raftlike phase can also be desirable for probing curvature and mobility; these include perylene (Baumgart et al., 2003) and cholera toxin B binding to GM1 gangliosides (Bacia et al., 2005). The lipid probe Laurdan is a particularly powerful tool for studying local membrane ordering; the spectrum of the Laurdan molecule is dependent on the polarity of its surroundings and therefore reflects the packing density of neighboring lipids (Bagatolli and Gratton, 2000). By measuring the spatially resolved spectra, a mapping of phases can be derived. However, Laurdan requires two-photon excitation, due to its low excitation wavelength and its rapid photobleaching.

Materials

Lipid (Avanti Polar Lipids; when received, store at –20°C or lower)
Chloroform
Methanol (optional)
Argon or nitrogen gas

Glass vials with Teflon closures
Microdispensers with glass bores (Drummond), or Hamilton syringes
Teflon tape

1. Rehydrate lipids supplied as powder in chloroform or a 2:1 (v/v) mixture of chloroform:methanol.

   See Commentary for more information on the influence of film properties.

2. Handle lipids in chloroform with glass, stainless steel, or Teflon labware. Store all solutions in glass vials with Teflon-lined caps.

3. Use microdispensers with glass bores or Hamilton syringes to measure volumes for making lipid mixtures.

   Typically, mixtures should be made in small volumes (~100 μl) or stored as aliquots to avoid contamination from handling.

4. Rinse all surfaces to come into contact with lipid solutions with chloroform.

   This includes microdispenser tips, glass bores, glass vials, ITO-coated plates, platinum wires, and Teflon plates.

5. After use, store solutions under argon or nitrogen gas at −20°C or lower to prevent hydrolysis or oxidation of lipids. After sealing, wrap caps in Teflon tape.

SUPPORT PROTOCOL 2

DESIGN OF A PTFE (TEFLON) HOLDER FOR ELECTROFORMATION ON ITO-COATED PLATES

This protocol describes the design of a Teflon holder for ITO-coated plates used in electroformation. The dimensions should be adjusted to accommodate the size of the plates. A polytetrafluoroethene (PTFE, or Teflon) block is machined to prepare the holder. The holder consists of two pieces of Teflon designed to fit together. The design considerations are that plates should be held 2 to 5 mm apart. The inner dimensions of each Teflon piece should slightly exceed (by ~1 mm) those of the ITO-coated plates. An example is shown in Figure 24.3.1, for plates with dimensions 50 × 50 mm.

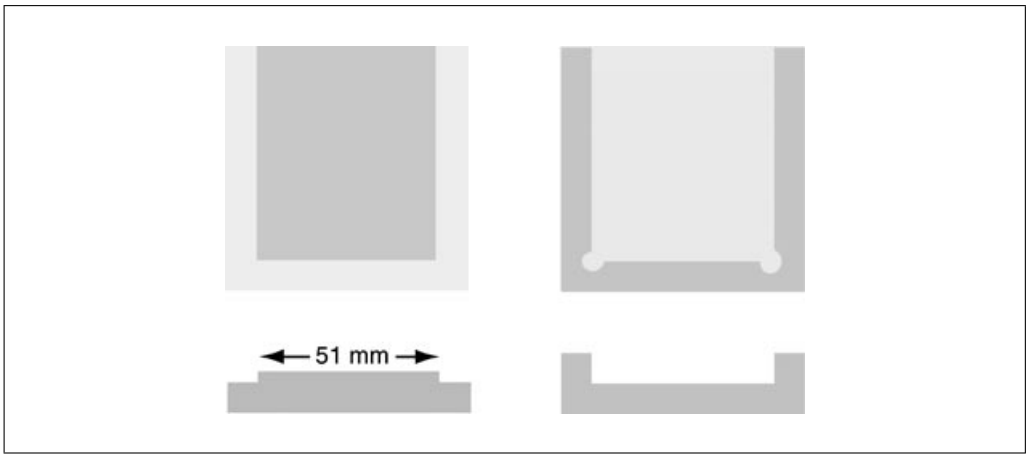

Figure 24.3.1 Teflon holder for ITO-coated plates, made from two pieces (shown left and right), front view and side view (shown top and bottom).

PREPARING GUVs BY ELECTROFORMATION ON PLATINUM WIRES

ALTERNATE PROTOCOL 1

This protocol produces a high yield of GUVs in a sample-chamber geometry that is well adapted for viewing under a microscope. Vesicles adhere to the platinum wire electrodes on which they form, so they remain largely stationary, without optically resolvable thermal fluctuations below ~45°C. If desired, the electroformation chamber can be adopted to allow harvesting of vesicles for experimentation on individual, isolated GUVs by using hydrodynamic flow along and across the electrodes.

Additional Materials *(also see Basic Protocol 1)*

5 to 10 μl of lipid solution in chloroform (Support Protocol 1) at concentration of 0.5 to 0.66 mM (~0.5 mg/ml)
Up to 600 mM sucrose, or sterile deionized H_2O

Platinum wires, 0.5- to 2.0-mm diameter
Microdispensers with glass bores (Drummond), or Hamilton syringes
Sealed chamber (e.g., vacuum desiccator) connected to dry nitrogen or vacuum source
Electroformation chamber (see Support Protocol 3), assembled with platinum wires

Prepare lipid-coated platinum wires

1. If using more than one species of lipid, mix in the desired ratio (see Support Protocol 1) and dilute in chloroform. Add membrane dye(s) and other components to be incorporated into the membrane, if desired, so that the total concentration of membrane components in chloroform solution remains ~0.5 to 0.66 mM, or ~0.5 mg/ml.

2. Using a glass microdispenser or Hamilton syringe, deposit solution onto platinum wires in drops of ~1 μl, so that drops are pendant from the wires.

   Drops can be closely spaced along the wires, but care should be taken that they do not coalesce; too high a concentration of lipid will result in multilamellar vesicles.

3. Dry lipid onto wires in nitrogen environment or under vacuum for 2 hr to overnight at room temperature.

Electroform GUVs

4. Add water (or other aqueous solution) to the chamber so that the wires are covered.

   Choice of solvent and concentration is to be determined by the amount of osmotic stress, density, and index mismatch required for the experiment, and is a tunable parameter that is purely up to the experimenter.

5. If necessary, heat chamber so that the temperature is above T_m for the highest-melting component in the system.

   For lipid systems in which T_m for one or more component is above room temperature, the electroformation chamber must be heated above T_m for the highest-melting component in the system. This may be done using a heating bath, by heating the chamber directly using resistive heating or Peltier plates, or by preheating the hydration solution, if the duration of electroformation is less than the time for the solution temperature to drop below T_m.

6. Apply a 2- to 10-V, 10-Hz AC electrical field across the electrodes for 30 to 120 min.

   During electroformation, care should be taken that the hydrating solution is in continuous contact with the electrode wires. If necessary, additional hydrating solution can be added to compensate for evaporation, but care should be taken to minimize hydrodynamic disturbances in the chamber, because these will wash vesicles off electrodes.

   Chambers can also be covered with a lid to reduce evaporation.

Time for electroformation varies with the lipids used, as does the yield. In general, increasing the percentage of phosphatidylcholine (PC) lipids increases yield and lowers electroformation time. Most vesicles formed using this technique will be unilamellar. Multilamellar vesicles can be identified, if membrane dyes are used, by higher levels of fluorescence.

SUPPORT PROTOCOL 3

DESIGN OF A CHAMBER FOR ELECTROFORMATION ON PLATINUM WIRES

This protocol describes the design and construction of a chamber for electroformation on platinum wires, intended for stringent temperature control and to allow for harvesting of GUVs. This design can be adapted depending on the need for viewing and manipulating GUVs.

Materials

Platinum wires, 0.5- to 2.0-mm diameter
Aluminum block (machined; typical dimensions, $10 \times 4 \times 1$ cm)
Electrical block fittings or terminal block fittings (McMaster-Carr, *http://www.mcmaster.com*)
Optional items:
  PTFE seals
  Cover glass for microscopy
  Norland optical adhesive
  Resistive heating wire
  Ceramic insulators and fittings for electrical attachment
  Thermocouple

Chamber construction

The essential elements of this electroformation chamber are provided by two platinum wires, which serve as the electrode substrates for formation of GUVs, and the aluminum block, machined to provide a water-tight chamber. If intended for viewing under an inverted microscope, this chamber may be created by machining a hole ~2 to 3 cm in diameter through the aluminum block and sealing a cover glass across the bottom using an epoxy that is nonreactive in water. Platinum-wire electrodes should be threaded through holes drilled in the side walls of this chamber so that they are parallel and spaced about 3 mm apart. These holes should be lined with PTFE or some other material so that the wires are electrically isolated from the aluminum block, and sealed so that the chamber is watertight using nonreactive adhesive and/or tightly packed PTFE tape. If viewing under an inverted microscope is intended, wire electrodes should be placed as close as possible to the bottom of the chamber, so that they are within the working distance of the microscope objective to be used. Electrical block fittings attached to the ends of the wires (which should protrude ~1 cm outside the aluminum block) allow these electrodes to be coupled to a function generator for electroformation. This design is illustrated by the central chamber of Figure 24.3.2.

If this chamber is to be used to electroform vesicles in which one or more lipid component(s) has T_m higher than room temperature, the chamber can be constructed so that it is resistively heated. This can be done by drilling two parallel holes in the aluminum block and threading heating wire through them so that the water chamber is approximately circumscribed. If this or another heating method is used, the chamber should be constructed with a thermocouple positioned as closely as possible to the wire electrodes, so that the temperature can be monitored.

Working at elevated temperatures will cause more rapid evaporation of the aqueous solution. If the solution level drops below the wire electrodes, vesicles will be destroyed by contact with air. Furthermore, if solutions other than pure water are used, evaporation

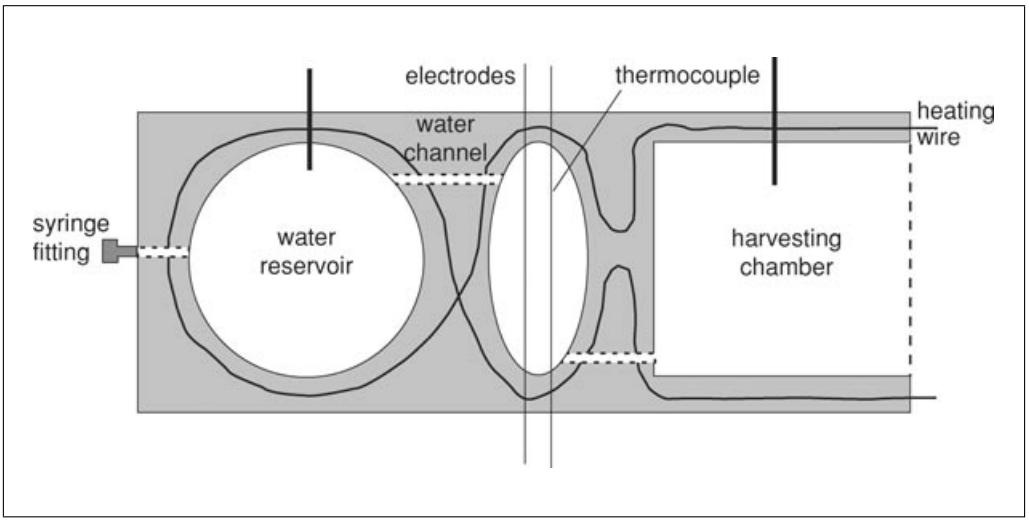

Figure 24.3.2 Electroformation assembly for platinum wires, showing optional water reservoir and harvesting chamber. The central chamber is essential, and contains the electrodes where the electroformation takes place.

will increase the concentration of solutes external to vesicle membranes (if any) and may cause membranes to become flaccid. If preventing this is desired, the chamber may be fitted with a sealed lid to reduce evaporation. However, such a lid may hinder application of some imaging techniques (if a lidded chamber is used under laser-scanning confocal microscopy, for example, reflection off the lid can significantly increase photobleaching throughout the sample). The effects of evaporation may also be mitigated by drilling the aluminum block to create a second water reservoir that is connected by a channel to the chamber in which electroformation and viewing are done. This is illustrated by the left chamber in Figure 24.3.2, marked "water reservoir." If this channel is higher (or lower) than the wire electrodes, water may be gently added to the reservoir to refill the electroformation chamber without significantly disrupting the lipids on the wires.

Alternatively, hydrodynamic flow can be deliberately used to flush GUVs off the wires so that isolated GUVs can be studied individually. Membranes should be fluid (above T_m) for this to be effective. To avoid temperature-shocking vesicles, it may be desirable to preheat the water used for flushing so that it is at approximately the same temperature as the solution surrounding the membranes. An electroformation chamber that has been used to form and harvest GUVs using this method is sketched below, in Figure 24.3.2. The chamber is lidded and sealed except for the harvesting chamber, which is open on one end to allow access to vesicles. Dimensions depicted are not necessarily to scale.

PREPARING GUVS BY SWELLING OFF OF PTFE (TEFLON)

BASIC PROTOCOL 2

While electroformation is the most successful protocol to date for producing a high yield of giant unilamellar vesicles, it works well only for a limited range of lipid compositions, notably those high in phosphatidylcholine (PC) lipids (>25% to 50 mol%) and low in charged lipids (<10 mol%), such as phosphatidylserine (PS) and phosphatidylglycerol (PG). Electroformation is also limited in the swelling solutions (buffers) to which it can be applied, because if salts are in the aqueous solution, the electric field can cause gas to be liberated by hydrolysis and form bubbles at the electrodes, where they destroy the vesicles. There is some evidence that electroformation can produce damaged membranes, and using a swelling technique to check the results seen for electroformed membranes allows the identification of artifacts (Gordon et al., in preparation).

This swelling technique requires at least ~10 mol% charged lipids to produce unilamellar vesicles (the threshold amount varies with the other lipids in the system and with the buffer used). This technique can produce GUVs in standard, salt-containing biological buffers.

Materials

20 mg/ml lipid in chloroform (Support Protocol 1)
Chloroform
Nitrogen gas
Swelling solution: 100 mM sucrose or glucose prepared using sterile deionized H_2O

Microdispensers with glass bores (Drummond), or Hamilton syringes
PTFE (Teflon) sheet, ~2 × 2–cm square, roughened with fine-grain sandpaper (McMaster-Carr, *http://www.mcmaster.com*)
Desiccator chamber, attached to vacuum pump
Glass beaker
Incubator or oven

Prepare dry lipid film

1. If using more than one species of lipid, mix in the desired ratio as in Support Protocol 1. Add membrane dye(s) and other components to be incorporated into the membrane, if desired, so that the total concentration of membrane components in chloroform solution remains approximately 20 mg/ml.

2. Using a glass microdispenser or Hamilton syringe, deposit 100 µl lipid(s) solution onto roughened PTFE. Spread the solution on the surface to distribute it as evenly as possible.

3. Dry under vacuum 3 hr to overnight at room temperature.

Hydrate lipid film

4. Prehydrate the resulting dry lipid film using moist nitrogen by bubbling nitrogen gas through sterile deionized water warmed on a hotplate and directing the resulting hydrated gas into a sealed chamber containing the lipid-coated PTFE sheet. Prehydrate film at least 30 min.

   If using light-sensitive membrane components, cover the chamber with aluminum foil.

5. Place PTFE sheet, lipid-side-up, on the bottom of the beaker. Fill with 5 ml swelling solution. Cover beaker with Parafilm.

   If using light-sensitive components, such as membrane dyes, wrap the beaker in aluminum foil.

6. Place beaker in incubator or oven and allow lipid film to swell into vesicles over 2 to 3 days.

   The temperature during swelling should be higher than the chain-melting transition temperature of the highest-melting membrane component. For many unsaturated lipids, 35° to 37°C gives satisfactory results.

   The resulting suspension will be dense in giant vesicles of a variety of sizes and lamellarities. These can be transferred to sample chambers for microscope viewing or other experimentation using a pipet or syringe. Taking care to minimize shear stresses by using a large pipet-tip opening or syringe needle and slow extraction will maximize the number of vesicles that survive this transfer. If using membrane dyes, unilamellar vesicles can be identified under the microscope as vesicles with the lowest fluorescence from the membrane.

PREPARING GUVs BY SWELLING OFF A UNIFORM FILM ON GLASS

ALTERNATE PROTOCOL 2

This method requires more preparation time and more specialized equipment than Basic Protocol 1, but it produces a higher percentage of unilamellar vesicles in the final, giant-vesicle suspension. This protocol also does not require charged lipids in the system to produce unilamellar vesicles if the swelling solution does not contain salt.

Materials

80 μl lipids in chloroform (Support Protocol 1) at 10 mM, (~10 mg/ml)
Chloroform
Nitrogen gas
Swelling solution: 100 mM sucrose in water (or other aqueous swelling solution), prepared using sterile deionized H_2O

Microdispensers with glass bores (Drummond), or Hamilton syringes
50- to 100-ml glass flask with pointed bottom
Rotary evaporator
Vacuum oven
Oven or incubator

Prepare dry lipid film in glass flask

1. If using more than one species of lipid, mix in the desired ratio as in Support Protocol 1. Add membrane dye(s) and other components to be incorporated into the membrane, if desired, so that the total concentration of membrane components in chloroform solution remains ~10 mM.
2. Using a glass microdispenser or Hamilton syringe, deposit 80 μl of this solution in a 50- to 100-ml pointed-bottom glass flask.
3. Attach flask to a rotary evaporator in a near-horizontal orientation.
4. Evaporate while rotating flask in a water bath that is at a temperature greater than the chain-melting temperature of the highest-melting component in the system (for most unsaturated lipids and for saturated lipids with tails up to 16 carbon atoms long, 50°C is sufficient).

   The resulting lipid film should be dry to the eye, with no remaining fluid discernible.

5. Dry this film for at least 2 hr in a vacuum oven at a temperature greater than the chain-melting temperature of the highest-melting component in the system.

Hydrate lipid film

6. Pre-hydrate the resulting dry lipid film using warm, moist nitrogen by bubbling nitrogen gas through sterile deionized water warmed on a hotplate and directing the resulting hydrated gas into a sealed chamber containing the lipid-coated glass flask. Prehydrate film at least 30 min.

   If using light-sensitive membrane components, cover the chamber with aluminum foil.

7. Fill flask with sufficient swelling solution to cover the lipid film. Seal top with Parafilm.

   If using light-sensitive components, cover flask with aluminum foil.

8. Incubate (in an oven or incubator, or in a water bath warmed on a hotplate) for 18 to 24 hr at a temperature greater than the chain-melting temperature of the highest-melting component in the system.

   Preventing vibrations and other mechanical disturbances during incubation is essential to a good yield of GUVs.

If using membrane dyes, a successful incubation will be identified by a "cloud" of color in the approximate center of the vial.

9. Harvest vesicles from the center of the vial using a pipet or syringe, taking care to minimize shear forces, and transfer to sample chambers for microscope viewing or other experimentation.

As in Basic Protocol 1, unilamellar vesicles can be identified by low fluorescence from membrane dyes.

ALTERNATE PROTOCOL 3

PREPARING GUVs BY DEHYDRATION AND REHYDRATION OF SUVs

This protocol uses dehydration and rehydration of small unilamellar vesicles (SUVs) to produce GUVs that adhere to a glass coverslip. This allows continuous microscopic observation of a single GUV or group of GUVs added as active agents directly to the system under study. At least 10 to 20 mol% PC lipid seems to be required to form vesicular structures using this protocol.

Materials

100 to 300 μl of lipid solution in chloroform at 20 mg/ml (Support Protocol 1)
100 mM NaCl (prepared using sterile deionized H_2O) containing 1 vol% glycerol
100 mM NaCl (prepared using sterile deionized H_2O), without glycerol

Hamilton syringe
Small glass vial
Desiccator chamber, attached to vacuum pump
Bath sonicator (43 kHz; L&R Ultrasonics Model T21, *http://www.lrultrasonics.com*)
Glass coverslips

Prepare dried lipid film in a glass vial

1. If using more than one species of lipid, mix in the desired ratio as in Support Protocol 1. Add membrane dye(s) and other components to be incorporated into the membrane, if desired, so that the total concentration of membrane components in chloroform solution remains ~20 mg/ml.

2. Deposit 100 to 300 μl of lipid solution in a small glass vial, place vial in vacuum desiccator, and dry under vacuum for 3 hr to overnight.

Hydrate lipid film and sonicate to form SUVs

3. Hydrate lipid film in vial with 100 mM NaCl containing 1 vol% glycerol. Add enough of this aqueous solution to produce a lipid concentration of 1 mg/ml.

If 300 μl of chloroform solution at 20 mg/ml is dried onto the vial, 6 ml of aqueous solution is added.

4. Cap the vial and seal with Parafilm. If using light-sensitive components, cover with aluminum foil. Refrigerate for 24 to 48 hr at 4°C.

The refrigeration step is necessary for vesicle formation.

5. Sonicate lipid suspension in vial for 5 to 10 min to make small unilamellar vesicles (SUVs).

Dry SUVs and rehydrate

6. Deposit 5 μl of SUV suspension onto glass cover slip, spreading as much as possible.

7. Let dry 30 to 60 min, long enough so that the droplet appears like a solid "gel," but not so long that it is visibly dry and cracked.

If using light-sensitive components, sample should be shielded from light while it is drying.

8. Rehydrate using 100 mM NaCl solution (without glycerol), adding at least enough to cover the initially-deposited droplet (10 μl).

Excess rehydrating solution (at least up to 500 μl) may be added if desired. Giant vesicles form within 10 min. As in Basic Protocol 1, unilamellar vesicles can be identified by low fluorescence from membrane dyes.

COMMENTARY

Background Information

Giant unilamellar vesicles (GUVs) are liposomes up to tens of microns in size, consisting of a single lipid bilayer membrane. Due to their large size, they are especially amenable to studies using fluorescence and light microscopy, and may also be manipulated for mechanical measurements with optical traps or micropipets. In addition to their use in encapsulation, GUVs have proven to be useful model systems for studying many cellular processes, including tubulation (Roux et al., 2002; Koster et al., 2003) and budding, and fusion (Holopainen et al., 2000; Staneva et al., 2004), as well as peptide insertion (Thoren et al., 2004). The introduction of enzymes or proteins can result in reorganization, leading to such diverse behavior as vesicle aggregation, fusion, and fission (Nurminen et al., 2001).

More recently, GUVs have gained prominence as a platform for studying lipid phase separation as a model for the lipid raft hypothesis (Korlach et al., 1999; Dietrich et al., 2001; Baumgart et al., 2003). According to the lipid raft hypothesis, in-plane heterogeneity within cell membranes, in the form of lipid rafts, may play a key role in protein sorting and cell signaling (Simons and Ikonen, 1997). GUVs composed of simple mixtures of lipids and cholesterol display a rich phase behavior similar to that of lipid mixtures extracted from cells (Dietrich et al., 2001). This phase separation yields coexisting lipid phases, which differ in composition, density, and local curvature. GUVs provide model systems for the controlled study of the effects of lipid composition and protein binding on lipid phase formation, bending, line tension, budding, and stability.

Critical Parameters

Lipid film thickness and uniformity

It is generally desirable to obtain unilamellar vesicles larger than 10 μm in size. To ensure a high yield of unilamellar vesicles free from small vesicles, it is important to begin with a thin lipid film without much roughness or too many defects. The protocols described here use rapid spreading to obtain this thin film. When viewed in reflection, the film should appear nearly uniform, with slight variations in color. Films that are too thick will appear dull, and nonuniform films will appear patchy.

A more controlled alternative to spreading is spin-coating; however, this requires access to a spin-coater. These are typically available in engineering facilities. The parameters for creating a film of optimal thickness are described by Estes and Mayer (2005); we have also used this technique with success.

Troubleshooting

The most common problem associated with making GUVs is contamination of lipid or sugar solutions. It is recommended that chloroform be divided into smaller bottles for use in solutions and in cleaning. Lipid solutions should be stored under nitrogen or argon gas at −20°C or lower. Small volumes of lipid should be used for mixtures, so that they may be discarded in case of contamination. Be attentive of changes in color or texture of lipid mixtures, as these are signs of contamination. Sugar solutions should be filter-sterilized, aliquotted, and frozen. Sugar solutions in use may be refrigerated, but should be brought to temperature before use in rehydration.

Anticipated Results

The protocols described should yield large vesicles, without many small vesicles or debris. By incorporating a small (0.1 to 1 mol%) amount of fluorescently labeled lipid, it is easy to check with microscopy that vesicles are unilamellar, since multilamellar vesicles appear brighter, as shown in Figure 24.3.3B. Vesicles can also be viewed either with phase contrast or DIC microscopy, as shown in Figure 24.3.3B.

Time Considerations

The time required depends on the protocol chosen. Forming GUVs using electroformation protocols requires a minimum of 2 hr. Gentle hydration protocols require 1 to 3 days. For all protocols, much of the time required is for drying or hydration of the lipid films.

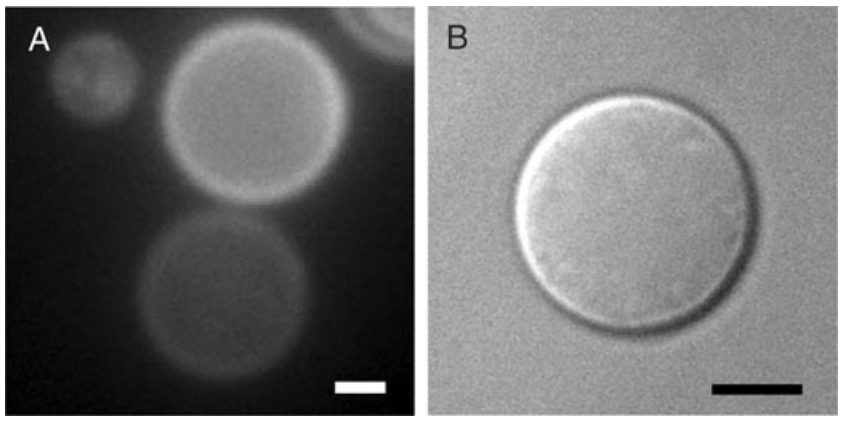

Figure 24.3.3 Giant vesicles, viewed with microscopy. (**A**) By incorporating 0.1 mol% of a fluorescently labeled lipid, vesicles are readily viewed with fluorescence microscopy. Multilamellar vesicles appear brighter, as demonstrated by the upper vesicle. (**B**) Vesicles may also be viewed using phase microscopy. Scale bars = 10 μm.

Visualization of Cellular Phosphoinositide Pools with GFP-Fused Protein-Domains

Tamas Balla[1] and Péter Várnai[2]

[1]National Institutes of Health, Bethesda, Maryland
[2]Semmelweis University of Medical School, Budapest, Hungary

ABSTRACT

This unit describes the method of following phosphoinositide dynamics in live cells. Inositol phospholipids have emerged as universal signaling molecules present in virtually every membrane of eukaryotic cells. Phosphoinositides are present in only tiny amounts as compared to structural lipids, but they are metabolically very active as they are produced and degraded by the numerous inositide kinase and phosphatase enzymes. Phosphoinositides control the membrane recruitment and activity of many membrane protein signaling complexes in specific membrane compartments, and they have been implicated in the regulation of a variety of signaling and trafficking pathways. It has been a challenge to develop methods that allow detection of phosphoinositides at the single-cell level. The only available technique in live cell applications is based on the use of the same protein domains selected by evolution to recognize cellular phosphoinositides. Some of these isolated protein modules, when fused to fluorescent proteins, can follow dynamic changes in phosphoinositides. While this technique can provide information on phosphoinositide dynamics in live cells with subcellular localization, and it has rapidly gained popularity, it also has several limitations that must be taken into account when interpreting the data. This unit summarizes the design and practical use of these constructs and also reviews important considerations for interpretation of the data obtained by this technique. *Curr. Protoc. INTRODUCTION

The first established role of phosphoinositides was recognized in the mid-80s as precursors for two important second messengers, the calcium mobilizing inositol 1,4,5-trisphosphate and the protein kinase C activator diacylglycerol (Berridge and Irvine, 1984). However, starting with the discovery of PI 3-kinases (Whitman et al., 1988), several new inositol lipid isomers have been identified and a much broader role of these lipids as organizers of membrane-associated signaling complexes were uncovered (Di Paolo and De Camilli, 2006). The highly compartmentalized nature of inositol lipid signaling processes demanded new methods that allow detection of the presence of the various inositide isomers with subcellular resolution. The idea of how this can be achieved was born out from discoveries that identified protein modules capable of inositol lipid recognition with reasonable specificity in proteins that are regulated by phosphoinositides (Lemmon et al., 1997).

Visualization of phosphoinositide changes in single living cells was then based on the premise that protein modules that possess high enough affinity and specificity to bind the inositide headgroup of specific phosphoinositides can find the lipids within the cell and visualize it when expressed in the form of a green fluorescent protein (GFP) fusion protein (Balla et al., 2000). As simple as it sounds, the short history of this method has

Current Protocols in Cell Biology 24.4.1-24.4.27, March 2009

DOI: 10.1002/0471143030.cb2404s42

already raised several important technical and theoretical questions that one needs to be aware of when attempting to use these methods. The protocols in this unit provide some practical guidance to users who are not experienced with live cell microscopy. Also included are sections that deal with theoretical considerations and interpretational issues highly relevant to these measurements (see Commentary). The protocols will not detail common laboratory practices but try to concentrate on aspects that are unique to these applications. The technical comments are intended for less experienced users and not intended for experts of this research field.

STRATEGIC PLANNING

Selecting Fusion Proteins for Detection of Selected Inositol Lipids

Table 24.4.1 summarizes protein domains that have been used for imaging purposes. Some of these are better established, while a consensus has yet to be reached for others. These protein domains are widely available and also can be easily duplicated. This section discusses the most important issues related to the individual lipid species for which the authors have accumulated experience.

PtdIns(4,5)P_2

Almost all imaging work for this lipid has used the pleckstrin homology (PH) domain of PLCδ_1 (PLCδ_1PH-GFP) construct developed independently in the Meyer laboratory and in the authors' laboratory (see references in Table 24.4.1). This construct expresses very well and decorates the plasma membrane and some vesicular structures but no other organelles. This has raised the question of whether PtdIns(4,5)P_2 is only present in detectable amounts in the plasma membrane, or is the probe biased against the plasma membrane pool of the lipid. Few reliable works have compared PLCδ_1PH-GFP distribution with staining with PtdIns(4,5)P_2 antibodies, and some have found the lipid in the Golgi with antibody staining but not with PLCδ_1PH-GFP (Matsuda et al., 2001), while others have seen no discrepancy and no Golgi staining with PtdIns(4,5)P_2 antibody either (Hammond et al., 2006). Also, EM studies showed some PtdIns(4,5)P_2 in the Golgi using GST-fused PLCδ_1PH-GFP post fixation (Watt et al., 2002). These data demonstrate one of the possible limitations of this method, namely, that not all pools of the lipids might be equally seen by the domain and this will be even more apparent when imaging other inositol lipid forms (see below).

In spite of this lingering question, the plasma membrane pool of PtdIns(4,5)P_2 can be monitored by PLCδ_1PH-GFP. This probe reports changes in this lipid either following phospholipase C (PLC) activation or after degradation by a phosphoinositide-sensitive 5-phosphatase (Stauffer et al., 1998; Várnai and Balla, 1998; Várnai et al., 2006). However, there is another question that complicates what these changes mean when following PLC-mediated hydrolysis of these lipids. Since PLCδ1PH-GFP recognizes the phosphorylated inositol headgroup within the lipid, the corresponding soluble inositol phosphate [in this case, Ins(1,4,5)P_3] can compete with the membrane PtdIns(4,5)P_2 for binding the PH-domain GFP fusion protein. Because of this competing effect, some research groups treat the changes in PLCδ_1PH-GFP membrane localization as a faithful index of InsP_3 elevations rather than lipid changes within the cell (Nash et al., 2001). A recent detailed review of the authors' opinion on this topic is available (Varnai and Balla, 2006). The bottom line is that inositol phosphates can compete with lipid binding of the PH-domain constructs and their effects on changing localization could be quite significant under certain conditions and cannot be ignored. At the same time, it would be just as misleading to treat the PLCδ_1PH-GFP translocation response as an index of InsP_3 change, and differences between the two have been recently demonstrated by simultaneous measurements of InsP_3 and PLCδ_1PH-GFP

[a]The usefulness of these domains for imaging purposes is questionable (see Michell et al., 2005).

[b]The OSH2-PH shows little discrimination between PtdIns4P and PtdIns(4,5)P_2 based on in vitro binding (Yu et al., 2004) and it is still uncertain whether it actually reports on both of these molecules in some proportions.

translocation (Matsu-ura et al., 2006). Another PtdIns(4,5)P_2 binding module called the Tubby domain was described from the Tubby protein (Santagata et al., 2001; Field et al., 2005; Yaradanakul and Hilgemann, 2007). Two recent studies using a full-length Tubby protein (Nelson et al., 2008) or a mutant form of the Tubby domain have shown that these domains are less sensitive to InsP_3 changes than the PLCδ_1PH-GFP (Nelson et al., 2008; Quinn et al., 2008).

The third complication to remember when using these methods is the inhibitory effect of the expressed domain on cellular responses regulated by the inositol lipids. Binding of the PH (or other) domain-GFP reporters to phosphoinositides should inhibit the lipid-mediated cellular process since it competes with the lipid binding of endogenous effectors. High expression of the PLCδ_1PH-GFP causes morphological changes that include rounding of the cells, loss of attachment, and development of intracellular vesicles (Fig. 24.4.1). These "toxic" effects are due to the inhibition by the construct of the connections between the cytoskeleton and the plasma membrane (Raucher et al., 2000). This problem can be minimized by choosing cells that express low levels of the protein and using a sensitive microscope that can resolve the weak signals that such cells will possess (Fig. 24.4.1A).

PtdIns4P

Several PH domains have been used to detect PtdIns4P in living cells. The two most popular ones are the PH domains of the oxysterol binding protein (OSBP) and four-phosphate-adaptor protein (FAPP1) that were first identified as specific binders to PtdIns4P by fat blots (Dowler et al., 2000). Based on lipid vesicle–binding assays, these domains not only bind PtdIns4P but also PtdIns(4,5)P_2 (Levine and Munro, 1998; Roy and Levine, 2004; Yu et al., 2004). These PH domains, as well as their close relative found in the ceramide transfer (CERT) protein, were indeed localized to the Golgi pool of PtdIns4P both in yeast and in mammalian cells (Levine and Munro, 2002), but not to the plasma membrane, where PtdIns(4,5)P_2 is abundant. These data suggest that within the cells these PH domains do not recognize PtdIns(4,5)P_2 efficiently. Moreover, it was also found that both the OSBP- and FAPP1-PH domains require active (GTP-bound) Arf1 for Golgi localization, and their Golgi targeting requires binding to both PtdIns4P and Arf1-GTP (Levine and Munro, 2002). Neither interaction alone is sufficient for efficient membrane recruitment. This also means that brefeldin A treatment that prevents the formation of Arf1-GTP in the Golgi causes release of these PH domains from these locations. The limited lipid-binding specificity and the need for additional protein interaction for membrane targeting make these probes less than optimal for lipid imaging in live cells. However, because of the lack of better probes, they have been used in many laboratories including the authors (see Table 24.4.1 for references).

Two additional PH domains, namely those of OSH1 and OSH2 (oxysterol binding protein homologs of *S. cerevisiae*) were found to show cellular localization consistent with binding to PtdIns4P in yeast (Roy and Levine, 2004; Yu et al., 2004). Remarkably, the OSH2-PH (used in tandem to increase its apparent affinity) showed both the plasma membrane and the Golgi pool of PtdIns4P in yeast, while the OSH1-PH domain only detected the pool in the Golgi (Roy and Levine, 2004; Yu et al., 2004). This spatial discrimination was the more surprising as these PH domains showed very little discrimination between PtdIns4P and several other inositides including PtdIns(4,5)P_2 in various in vitro lipid-binding assays (Yu et al., 2004). Studies in the authors' laboratory on mammalian cells with these two PH domains yielded somewhat different results: while the OSH1-PH is found as a very good marker for PtdIns4P in the Golgi (as it was in the yeast), the OSH2-2xPH (or the single PH domain) construct only localizes to the plasma membrane but does not show Golgi localization (Fig. 24.4.2C). In spite of its very limited in vitro lipid-binding specificity, the OSH2-2xPH appears to be biased towards PtdIns4P

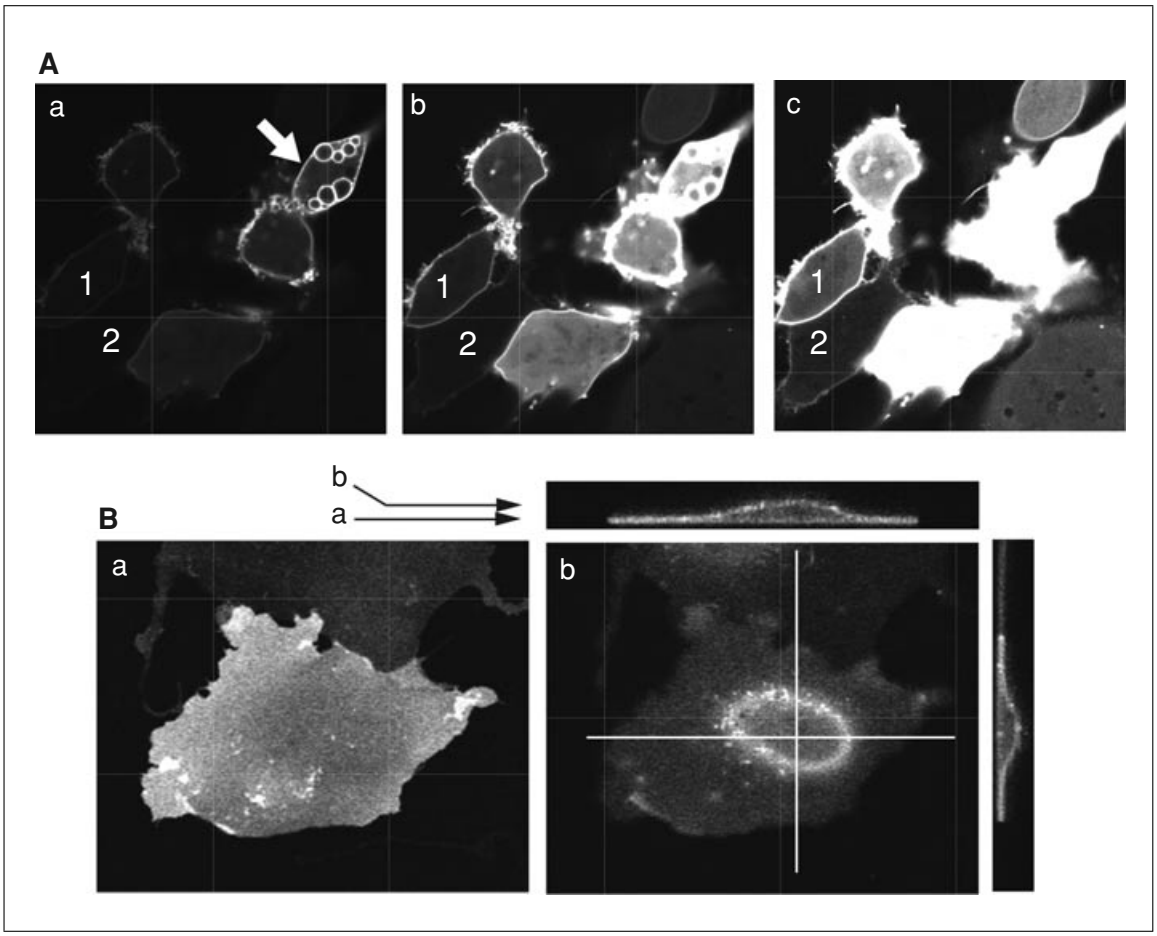

Figure 24.4.1 Cellular localization of the PLCδ_1PH-GFP. (**A**) Clusters of HEK293 cells transfected for 24 hr, and expressing the domain at various levels. Note the vesicular structures in the cell (arrow) that expresses a high level of the fusion protein. This is an example of toxic effects of the protein. Also note that with these illumination settings (panel a), cells 1 and 2 are not even visible, yet these are the cells that should be chosen for analysis as shown by higher illumination, which saturates the signal in other cells (b and c). (**B**) Confocal images of a COS-7 cell transfected with PLCδ_1PH-GFP for 24 hr and analyzed by z-sectioning. Panel a shows an image taken close to the bottom of the cell where it attaches to the coverslip. Note that there is no sharp outline of the cell and the signal covers the whole area of the cell. In panel b, the picture is taken at a z-plane higher up in the cell and again, there is no clear outline of the plasma membrane. Compare it with HEK293 cells that are not as flat and show a clear image of the plasma membrane (**A**). The side views of this COS-7 cell at the cross-sections (top and right side) show a better image of plasma membrane localization and the shape of the cell.

over PtdIns(4,5)P_2 in the plasma membrane, based on the resistance of its membrane localization to phosphoinositide 5-phosphatases that eliminate PtdIns(4,5)P_2 (Balla et al., 2008). The extent of this discrimination as well as the mechanism underlying its interaction with other proteins that would restrict access to PtdIns(4,5)P_2 but not PtdIns4P; however, requires further investigation.

It is clear that only specific pools of PtdIns4P can be monitored with these domains and there is not a single domain identified as yet that would detect all PtdIns4P pools within a cell. A domain that recognizes the PtdIns4P produced by type-II PI 4-kinases on endosomes has not been found. Even within the Golgi, PtdIns4P is produced by different PI 4-kinases (De Matteis et al., 2005), and it is possible that the different PH domains do not detect these pools equally. Moreover, there is an effect of the overexpression of the domains on the Golgi itself. For example, the FAPP1-PH localizes primarily in the trans-side of the Golgi (Godi et al., 2004), but its localization between the cis- and trans- side depends on the expression level (Weixel et al., 2005). In COS-7 cells, an increased level

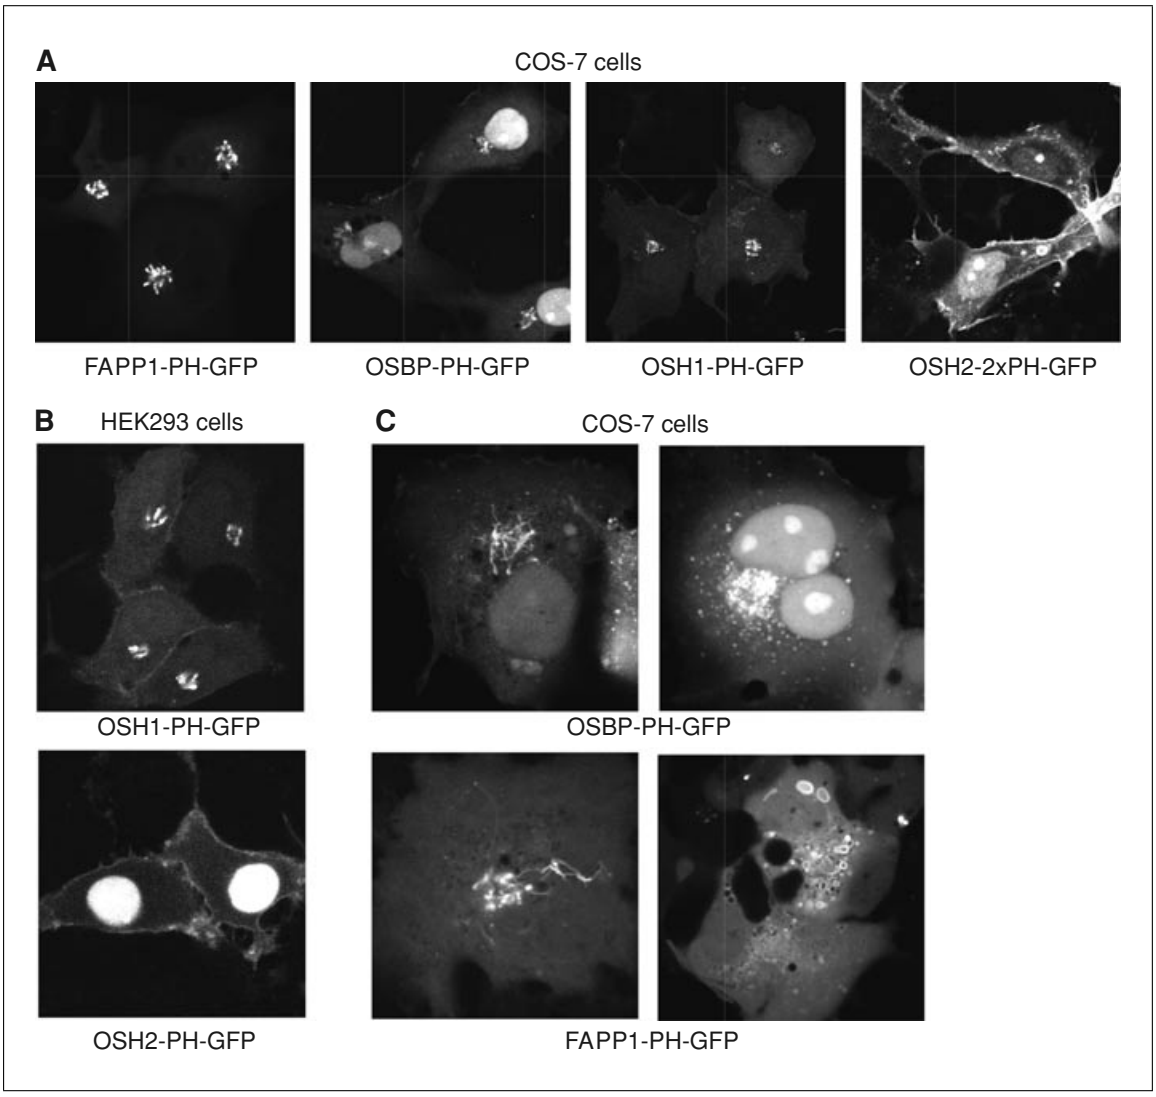

Figure 24.4.2 Localization of the various domains used for imaging PtdIns4P in COS-7 and HEK293 cells. (**A**) COS-7 cells transfected with the indicated domains for 24 hr. Note the sharp contrast and prominent recruitment of the FAPP1-PH domain and the higher nuclear staining of the OSBP-PH domain. The yeast OSH1-PH-GFP also shows the Golgi but is also localized to a small extent to the plasma membrane (better seen in **B**). The OSH2-2xPH-GFP prominently labels the plasma membrane but does not show Golgi localization. For this picture cells were selected that are not so flat, to demonstrate better plasma membrane localization. (**B**) Localization of the OSH1-PH-GFP and OSH2-PH-GFP constructs in HEK293 cells. Note the Golgi and moderate plasma membrane localization of the OSH1-PH and the lack of Golgi localization and high nuclear signal with the OSH2-PH domain. The nuclear localization is less prominent with the OSH2-2xPH-GFP construct. (**C**) Examples for interference of the domains with cellular functions. Both the OSBP- and FAPP1-PH domains cause tubulation of the Golgi. Remarkably, this always occurs at moderate levels of expression and never at high expression levels and only in a fraction of cells. This indicates that this effect is conditional and requires a certain functional state of the Golgi. At high expression levels, the two constructs have very different effects: the OSBP-PH breaks the Golgi into small vesicles that eventually cover the whole cytoplasm. These are completely resistant to brefeldin A, a treatment that rapidly eliminates the Golgi localization of the construct indicating the Arf1-GTP requirement of the localization (not shown). In contrast, the FAPP1-PH domain shows no Golgi localization at high expression levels and instead produces large vacuoles in the cell with FAPP1-PH domain attached to their limiting membranes.

of expression of FAPP1 and OSBP causes distinct morphological changes (Fig. 24.4.2B) suggesting that they interact with distinct proteins (in addition to PtdIns4P and Arf1) and indicating that even though they may appear in the same Golgi compartment at low expression levels, they still detect functionally distinct pools of the lipids. These are all important signs to indicate that not all PtdIns4P are created equal and cannot simply be imaged by a single probe.

PtdIns(3,4,5)P_3

There are a large number of studies imaging PtdIns(3,4,5)P_3 dynamics due to the high interest in phosphatidylinositol (PI) 3-kinase signaling and its role in polarized cell movements such as chemotaxis. In *Dictyostelium*, a widely used model for polarization migration, the PH domain of the CRAC protein (cytosolic regulator of adenyl cyclase, not to be mistaken with calcium release activated channels, as the same acronym is often used in mammalian cells) has been a very good reporter of PtdIns(3,4,5)P_3 distribution (Dormann et al., 2002; Huang et al., 2003). In mammalian cells, the Akt-PH domain has served best for following polarized PtdIns(3,4,5)P_3 production (Servant et al., 2000), even though this PH domain also recognizes PtdIns(3,4)P_2. The Btk-PH domain that is more specific for PtdIns(3,4,5)P_3 and detects lipid increases after PDGF or insulin stimulation in the plasma membrane (Varnai et al., 1999) has not seen similar popularity presumably because it does not show this polarization so effectively. This already suggests that in addition to PtdIns(3,4,5)P_3, protein-protein interactions probably also play a role in the effective recruitment of these PH domains to the plasma membrane. Because of its good in vitro specificity, the Grp1-PH domain (or its close relative, ARNO-PH) is considered to be the most specific probe to detect PtdIns(3,4,5)P_3. However, the authors' experiences have not been positive with this construct. In many cells it shows a relatively poor response, e.g., by showing high nuclear localization [independent of PtdIns(3,4,5)P_3] and membrane recruitment is largely dependent on active (GTP-bound) Arf6 (Cohen et al., 2007). Because membrane recruitment is largely dependent on active Arf6, the Grp-PH is also relatively toxic to the cells and inhibits several Arf6-dependent functions including attachment and spreading of cells (Varnai et al., 2005). A recent study compared several PtdIns(3,4,5)P_3-binding PH domains for their in vitro binding specificity and cellular localization response (Manna et al., 2007). This study found strikingly different membrane recruitment kinetics between the various domains in PDGF-stimulated NIH3T3 cells also suggesting that in addition to inositide lipid binding, membrane penetration and possibly protein-protein interactions have a role in membrane association of the domains. Based on all of the measurements presented, the Btk-PH appeared to be the best probe for the detection of PtdIns(3,4,5)P_3 in intact cells.

PtdIns3P

PtdIns3P was one of the first inositol lipids for which a recognition domain other than a PH domain was found. No PH domain that recognizes PtdIns3P specifically has been reported to date. It was the FYVE domain (the acronym originates from the first four proteins in which the domain was described: Fab1p, YOTB, Vac1p, and EEA1) that was found to be responsible for PtdIns3P recognition and shown to recognize this lipid in its isolated form fused to GFP (Burd and Emr, 1998). Since the strictly defined FYVE domain will recognize PtdIns3P very specifically in vitro, but poorly localizes without some adjacent residues that help its dimerization (and partially may also bind Rab5), the most widely used construct from the Stenmark laboratory is based on a tandem FYVE domain of the Hrs protein (Gillooly et al., 2000). The construct the authors have made from the EEA1 (early endosome-associated antigen) FYVE domain is the slightly longer version (Hunyady et al., 2002). Both of these constructs decorate an early endosomal compartment and will fall off from the vesicles upon inhibition of PI 3-kinases consistent with the view that the Class III PI 3-kinase (the mammalian Vps34p homolog) constitutively generates PtdIns3P on early endosomes.

The other domain that recognizes PtdIns3P is the PX domain of several proteins, but most prominently that of p40phox (Kanai et al., 2001). Expression of this PX domain as a GFP fusion protein also labels the early endosomes. However, in contrast to the FYVE domains, this construct leads to the accumulation of very brightly stained aggregated vesicles in many cells that express higher amounts of the protein. Moreover, these bright vesicles do not lose their signal after addition of PI 3-kinase inhibitors (while the solitary vesicles labeled in cells with low expression do), suggesting that the PX domain is part of a more stable protein complex that cannot disassemble and is probably responsible for the aggregation of vesicles. This again is an indication of protein-protein interactions that clearly differ between the FYVE and PX domains and a good example of why cells with low expression levels should be used in these studies.

PtdIns(3,4)P_2, PtdIns(3,5)P_2, and PtdIns5P

The authors have not had much experience with visualizing any of these lipids; therefore, a summary of what is known in the literature is presented. The only PH domains that showed in vitro specificity to binding PtdIns(3,4)P_2 were those of the TAPP1 and TAPP2 proteins (Dowler et al., 2000). The crystal structure of the TAPP1 PH domain clearly revealed the structural features responsible for this specificity (Thomas et al., 2001). The GFP-tagged TAPP1 PH domain has been shown to detect the lipid in live cells in the plasma membrane under conditions where PtdIns(3,4)P_2, but not PtdIns(3,4,5)P_3, was elevated (Kimber et al., 2002). In addition, a GST-fused TAPP1 PH domain labeled the membrane of internal vesicles and the multivesicular body in fixed cells processed for EM analysis (Watt et al., 2004). Moreover, this domain does not show membrane association when only PtdIns(3,4,5)P_3 is elevated, indicating that it can discriminate between these two otherwise closely related lipid products within the cell. Other studies also found this domain useful in detecting the formation of PtdIns(3,4)P_2 in phagocytic cups in macrophages (Horan et al., 2007). The PX domain of p47phox has also been claimed as a PtdIns(3,4)P_2-recognizing module (Zhan et al., 2002) and used to detect the lipid as a GFP fusion protein (Stahelin et al., 2003). However, in the authors' hands the p47phox PX domain-GFP chimera does not show any indication of binding to membranes in a lipid-dependent manner (T. Balla and P. Várnai, unpub. observ.) and its binding to other phospholipids such as phosphatidic acid (Karathanassis et al., 2002) and proteins (Zhan et al., 2002) may limit the usefulness of this PX domain as an imaging tool.

The formation of PtdIns(3,5)P_3 and its role in trafficking to the vacuole in yeast and to the multivesicular body in higher eukaryotes (Gary et al., 1998; Ikonomov et al., 2003; Jefferies et al., 2008) has made this lipid a highly interesting target for imaging studies. Unfortunately, in spite of several attempts and claims, there are no established tools to accomplish this task reliably. Two proteins, the yeast Ent3p (Friant et al., 2003) and Svp1p (Dove et al., 2004) have been found to be targets of PtdIns(3,5)P_2. The inositide binding site was located within the ENTH domain of Ent3p, while it was attributed to a cluster of basic residues on a beta propeller within Svp1p. To the authors' knowledge there has been no systematic analysis on the intracellular distribution of any isolated domains extracted from these molecules with the aim of localizing PtdIns(3,5)P_2 in live cells.

PtdIns5P is a lipid that was first identified as a substrate of the type II PIP kinases (PI5P 4-kinase; Rameh et al., 1997b). The main route(s) of its production in cells is highly debated, but most likely is the result of dephosphorylation of polyphosphoinositides (Coronas et al., 2007; Zou et al., 2007) rather than direct phosphorylation of PtdIns. The only domain that recognizes PtdIns5P has been identified in the nuclear protein ING2 within a domain (PHD as for plant homeodomain) that binds PtdIns5P, and to a lesser degree PtdIns3P, in vitro (Gozani et al., 2003). A GFP fusion protein made of the 3xPHD domain of ING2 detected PtdIns5P in the plasma membrane in response to overexpressed bacterial 4-phosphatase, IpgD (Gozani et al., 2003; Pendaries et al., 2006)

and did not show endosomal localization suggesting that it does not bind PtdIsn3P in the cells. Nevertheless, more experience is needed with this domain to determine where PtdIns5P is found in the cells and whether its role in the nucleus is associated with detectable changes in its nuclear level.

The common message from these examples is that none of these tools is useful as general lipid reporters without specific constraints that vary from probe to probe. However, if treated with caution and after performing proper controls, these reporters are very useful in answering questions that no other technique can provide.

Selecting the Fluorescent Protein to be Fused

Most of these fluorescent reporters have been originally created as fusion proteins with the enhanced green fluorescent protein (EGFP). However, over the past few years, a large number of fluorescent proteins were introduced now offering a wide variety of colors and other unique features (*UNIT 21.5*). In addition to the spectral variants that allow multicolor imaging of several probes in parallel, new features include photoactivation (*UNIT 21.6*), photoswitching, spectral change during maturation, pH stability, resistance to photobleaching or dimerization, etc. These have been summarized in several recent reviews and will not be detailed in this unit (Shaner et al., 2005; Giepmans et al., 2006; Wiedenmann and Nienhaus, 2006). These proteins are often very useful for a particular application but there is considerable confusion as to the source of these proteins. In addition to the GFP variants based on the pioneering work of the Tsien laboratory, many new proteins originate from the Miyawaki laboratory, and the company Evrogen. These proteins have been cloned from a variety of species and are not derivatives of the jellyfish *Aequorea victoria* GFP. A good summary of these proteins and their features are found in Muller-Taubenberger and Anderson (2007) and *UNIT 21.5*. However, these proteins do not only differ in their optical behavior and they cannot be replaced with one another without any problems. In the authors' experience, occasionally a probe behaves quite differently depending on whether an EGFP, an mRFP, or EosFP molecule is attached to it. Therefore, it is better to start with a few colors that are proven to work similarly with a particular lipid-binding domain than to generate a whole series of colors assuming that they will behave identically within the cells. As most studies were done with the pEGFP plasmids and their initial color versions, it is recommended to use these for initial experiments. Unfortunately, the original pEGFP-N and -C series plasmids are no longer available because Clontech has become part of Takara and these companies now offer their own fluorescent proteins that originate from a different species. The original EGFP and its color variants are now sold by Invitrogen in a different plasmid backbone. This often causes confusion among novices beginning their fluorescent protein collections that do not realize that a green fluorescent molecule now can mean different entities depending on the manufacturer.

EXPRESSION OF FLUORESCENT PROTEINS IN MAMMALIAN CELLS

BASIC PROTOCOL 1

The following procedure describes the general methods for analyzing cells expressing EGFP or GFP-fusion proteins by microscopic techniques.

Materials

98% ethanol
0.1% (w/v) poly-L-lysine in water (Sigma cat. no. P-8920)
Cultured cells of interest
Culture medium with serum and antibiotics (depending on the cells)
Plasmid DNA (usually a midiprep)
Transfection reagents (depending on the cells in use; *UNITS 20.3, 20.4, 20.5, 20.6, & 20.7*)
Phosphate buffered saline (PBS)

2% (w/v) paraformaldehyde (see recipe)
Blocking solution (10% FBS in PBS made fresh)
Primary antibody against fluorescent protein (available from several commercial sources)
0.2% saponin
Fluorophore-conjugated secondary antibody
Aqua-Poly/Mount (Polysciences)
Clear nail polish
25-mm coverslips (PGC Scientific cat. no. 60-4884-25 or Warner Instruments cat. no. 64-0705) for TIRF applications
6-well culture dishes
Glass microscope slides
Fluorescent microscope

Prepare poly-L-lysine-coated coverslips

1. Rinse 25-mm coverslips with 98% ethanol in a cell culture hood and air dry.
2. Place one coverslip in each well of a 6-well culture dish.
3. Add 2 ml of 1:50 or 1:100 dilution of poly-L-lysine in filter-sterilized deionized water to cover the entire surface of each coverslip and allow to stand 1 hr at room temperature.

   In a pilot study, plate cells on coverslips coated at each poly-L-lysine concentration to determine which is best for the cells being studied.

   Because most plastic-ware used for cell culture work has high autofluorescence, it is recommended that cells be cultured and transfected on poly-L-lysine-coated glass coverslips so that they can be viewed under the microscope after transfection without replating. For certain cell types and transfections, it is more advantageous to transfect the cells in culture dishes and re-plate the transfected cells on the poly-L-lysine-coated coverslips before microscopy. Some cells can be grown on coverslips without the coating (e.g., cost-7, CHO)

4. Aspirate the solution from the coverslip and air dry (~ 1hr) before plating cells.

Transfect cells with plasmid DNA

5. Plate ~50,000 cells directly onto the poly-L-lysine-coated coverslips in 2 ml of the appropriate culture medium and grow to the density best suited for transfection (usually 2 days).
6. Transfect the cells with the desired plasmid DNA construct using a method that is most appropriate for the cells.

   The authors usually use 2 μl Lipofectamine 2000 and 0.5 μg plasmid DNA per coverslip.

   Transfection protocols are available for different reagents (UNITS 20.3–20.6), and for each cell type, the reagent and the procedure that produce the best results can differ considerably (UNIT 20.7). Therefore, refer to the manufacturer's instructions as far as specifics for cell transfection are concerned. The optimal level of expression must be determined for each cell type and expression construct. It is important to remember that the expressed proteins often interfere with the functions of the lipids that they recognize, and in high concentrations, the lipid-binding fusion proteins are often toxic to the cells.

   Initial transfection of cells with a mutant version of the lipid-binding domain that does not bind lipids is recommended. For example, many constructs localize to the nucleus, but this localization is not dependent on lipid binding; thus, lipid-mediated localization can be confirmed by comparing the distribution of the native lipid-binding domain to that of the non-lipid binding mutant. Transfection of cells with the GFP protein alone without the lipid-binding domain is also recommended. These two controls help to track phenotypic changes and potential cellular toxicity associated with overexpression of the lipid-binding domain, as well as to serve as controls for monitoring localization that accurately reflects lipid binding.

7. Grow cells 24 hr to allow expression of the transfected protein.
8. Incubate cells in serum-free culture medium for 6 to 10 hr to render them quiescent before microscopy.

   Growing cells for >34 hr after transfection is not recommended because of the potential toxicity of the lipid-binding fusion protein and the ability of the expressed protein to interfere with the functions of the lipids that they bind. Not every experiment requires serum deprivation of cells.

Immunostain cells to detect expressed GFP fusion protein

9. Rinse the transfected cells with 2 ml of PBS.
10. Add 2 ml of 2% paraformaldehyde and incubate 10 min at room temperature.
11. Wash cells three times with 2 ml of PBS, 10 min each wash.
12. Cover cells with 2 ml of blocking solution to block nonspecific antibody binding. Incubate 10 min at room temperature.
13. Add primary antibody diluted appropriately in blocking solution supplemented with 0.2% saponin. Incubate 1 hr at room temperature.

    A volume of 100 μl of diluted antibody should be sufficient for a 25-mm circular or 22 × 2–mm square coverslip, if it is inverted on a glass slide and incubated in a humidified Petri dish.

    This step can be skipped when performing live cell microscopy (see below). However, it may be necessary to confirm expression of the fusion protein, especially if the GFP signal is not bright enough. This confirmation can be accomplished by immunocytochemistry with antibodies to the GFP portion of the fusion protein. Co-localization of the GFP-fused domain with other molecular markers may also require immunostaining.

14. Wash cells three times with 2 ml of blocking solution, 5 min each wash.
15. Add the fluorphore-conjugated secondary antibody diluted in blocking solution containing 0.2% saponin. Incubate 1 hr at room temperature protected from light.
16. Wash cells three times with 2 ml of PBS, 1 min each wash.
17. Air dry until coverslips are only damp.
18. Mount coverslips with cells down on a glass slide using Aqua-Poly/Mount.
19. Seal coverslips on the side with clear nail polish to prevent drying.
20. View the slides to detect expression of the GFP/fluorescent protein.

VERIFYING STRUCTURAL INTEGRITY OF THE FUSION CONSTRUCT

BASIC PROTOCOL 2

This protocol describes how to determine whether the fluorescent protein construct remains intact when expressed in the cells. This is an important control in addition to sequencing the DNA construct before performing any microscopy work. Often the fusion protein is cleaved within the cell so that the green fluorescence is not coming from the molecule that was designed. In the authors' experience, free EGFP is more often present when using pEGFP-N1 plasmids than with the pEGFP-C1-variant. (This can happen if an internal ribosomal entry site allows the translation of GFP itself, which can be prevented by removing the start codon of the original GFP.) In one case, a fusion protein expressed in COS-7 cells was proteolytically cleaved when placed COOH-terminal to EGFP. Analyzing cell lysates by sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) either using a phosphorimager equipped with a blue laser line (described below) or by conventional immunoblotting (*UNIT 6.2*) techniques using

antibodies against the GFP portion of the fusion protein is recommended. In many cases, samples that are boiled and analyzed by immunoblotting show more degraded product than those analyzed directly from the gel. The electrophoretic mobility of the EGFP molecule is clearly different when expressed from pEGFP-C1 versus pEGFP-N1. This may be due to altered migration of the non-denatured protein by extra amino acids encoded within the multiple cloning site of the pEGFP-C1 plasmid.

Materials

Cultured cells of interest
Culture medium with serum and antibiotics (depending on the cells)
Plasmid DNA (usually a midiprep)
Transfection reagents (depending on cells used)
Phosphate buffered saline (PBS)
Laemmli buffer
10-cm SDS-PAGE acrylamide gel
Gel running buffer

12-well culture plates
1.5-ml microcentrifuge tubes
Sonicator
SDS gel apparatus
Phosphorimager (or reagents and apparatus for immunoblotting)

1. Seed COS-7 (or other cells to be studied) at 2×10^5 cells/2 ml medium onto 12-well culture plates and incubate 24 hr.
2. Transfect cells with the method of choice and incubate 1 day (or equal to the time the experiments would be done).
3. Wash cells with 2 ml PBS and aspirate the PBS.
4. Dissolve cells in 100 µl Laemmli buffer and transfer to 1.5-ml microcentrifuge tubes. Do not boil, but briefly sonicate to disrupt DNA.
5. Load 40 µl of the sample per lane of a small (10-cm) SDS-PAGE gel with an acrylamide concentration that will resolve proteins in the size range of interest.
6. Run the gel at 100 V until the front reaches the bottom of the gel.
7. Remove gel from cassette and place in running buffer.
8. Place the wet gel directly onto a phosphorimager and scan using the appropriate laser line (blue for GFP and red for mRFP or similar colors)

Alternatively, if no phosphorimager is available, the fluorescent proteins can be detected with immunoblotting using an anti-GFP (or other appropriate) antibody. In this case, boil the samples before SDS gel analysis. It is also important to remember that the anti-GFP antibody does not recognize proteins that are derived from other species than Aequorea victoria.

BASIC PROTOCOL 3

OBSERVE GFP SIGNAL BY MICROSCOPY

Provided here are practical suggestions on what to pay attention to when observing cells by microscopy. This is not intended for experienced users but for researchers who have limited practical knowledge of microscopes and want to observe their proteins as GFP-fusion constructs in live cells. This protocol is not a substitute for training on any specific microscope system but rather an aid to help commonsense practices.

Wide field or confocal microscopy?

The first question to be answered is whether to view the cells with a conventional fluorescence microscope or with a confocal microscope. The authors suggest that the distribution of GFP fluorescence and other initial experiments such as assessing transfection efficiency should be performed with a conventional fluorescence microscope using filters suitable for fluorescein isothiocyanate (FITC) detection (excitation at 470 to 490 nm, emission at 500 to 550 nm). It is not necessary to examine the cells immediately with a confocal microscope, and it is more difficult to obtain a general impression of what the cells look like in a confocal microscope when expressing the construct. Individual cells, especially COS cells, show enormous variability in their shape, size, and general appearance, and often the level of expression changes their appearance. Conventional fluorescence microscopy is a significantly more efficient way to browse through many cells and notice trends in cellular morphology. In addition, many cells are flat in culture (especially COS cells), so there is little benefit from analyzing the cells in a confocal microscope. Confocal microscopy can be saved for recording cells and changes in fluorescence distribution once the conditions have been optimized with a fluorescence microscope. A further advantage of viewing cells in a fluorescence microscope is that autofluorescence often can be distinguished from the GFP signal because its color is different from the green color of GFP. It is important to remember that confocal microscopes detect light intensity without colors and the "color" given is artificial. Therefore, in each case, the autofluorescence has to be determined so that the GFP signal can be reliably used. For this, observation of untransfected cells is a useful control.

Fixed or live cells?

The next question is whether to analyze live or fixed cells. EGFP fluorescence can persist in fixed cells under proper fixation conditions (see Basic Protocol 1, steps 9 to 19). Fixed cells can be processed for immunostaining, which is often necessary to determine co-localization with organelle markers for which antibodies are available. Also, fixed cells can be stored and studied whenever convenient. On the other hand, changes cannot be followed as they happen in real time when using fixed cells. Moreover, fixation and permeabilization procedures may distort cellular morphology. For example, vesicular structures shrink during fixation, and long canaliculi can turn into small vesicles. The use of live cells is the most reliable way of assessing undistorted morphology, but it is also the most time-consuming and least efficient. For live-cell imaging, it is best to use an inverted microscope. New water-immersion objectives make it possible to look at cells under upright microscopes, but the objective has to be in culture medium. In addition, live-cell imaging would generally require some form of temperature control with all the complications associated with it while fixed cells do not.

When analyzing live cells, one major advantage is to record time-lapsed images sequentially after a stimulus is applied to the cells. In confocal microscopes, the speed of scanning determines how fast one can record an image, and generally the faster the scan, the poorer the quality of the individual pictures. Finally, one of the greatest difficulties is to keep the cell in focus after stimulation, because of shape changes that often occur in response to the stimulus (HEK 293 cells are especially lively). This change in position of the originally imaged plane can make the entire recorded process unsuitable. Software programs are being developed to compensate for "focal-drift" due to cell movements. These new developments may already be available for some confocal imaging systems.

BASIC PROTOCOL 4

LIVE-CELL IMAGING

This protocol describes steps to help guide a less-experienced user during the live-cell imaging process.

Materials

Coverslips holding transfected cells
Medium appropriate for cells (e.g., modified Krebs-Ringer solution; see recipe)
Immersion oil

Chambers to hold coverslips (e.g., metal Atto chambers, Invitrogen)
Kimwipes
Wide-field fluorescence microscope equipped with sensitive camera and appropriate software for data acquisition or confocal microscope
Lens cleaning paper
Objective heater and heated stage (Bioptechs, *http://www.bioptechs.com*) or a complete temperature control enclosure
Computer controlled valve-system and perifusion (optional)
Forceps

Mount transfected cells

1. Place coverslip with transfected cells face-up into metal chambers. Tighten the upper part with the O-ring in place gently but firmly so no leaks occur. Wash cells with medium and add 1 or 2 ml medium to the cells. Clean the bottom of coverslip with a clean Kimwipe.

   Ensure that the coverslip is in the grooved area of the chamber otherwise it will break during tightening. Test for leakage using a clean paper where the metal meets the glass coverslip. Leakage can worsen as the temperature changes on the stage. In any case, the use of a lens protector against leakage is advised when using live-cell imaging.

2. Dust off the objective and clean with a cleaning solution provided by the manufacturer (or isopropanol) using a lens cleaning paper.

   Cleaning the lens is important but it can do more damage than good if not done properly. Consult an expert before performing this task. Do not use Kimwipes or any other paper or cotton swab for this purpose. Never clean the lens with dry lens paper and do not use solutions containing ammonia (e.g., Windex) or organic solvents other than recommended.

3. Add one small drop of immersion oil to the lens without allowing it to flow down along the surface.

4. Place the metal chamber on the stage and slowly elevate the objective with eye control until it touches the coverslip.

Select cells

5. Observe the transfected cells and, if necessary, the control non-transfected cells using the fluorescence setting of the confocal microscope fitted with filters suitable for the chosen fluorophore (470 to 490 nm excitation and 500 to 550 nm emission for EGFP).

   Looking into the fluorescence microscope, one can usually see cells with a wide range of fluorescence intensities. Depending on the quality of the microscope and the intensity of the light source, sometimes only the cells with the highest expression levels are visible and these are the cells to avoid. It is recommended to study cells in which the GFP signal is as low as possible but clearly distinguishable from the autofluorescence of non-transfected control cells. Since microscopes are very different, there are no arbitrary rules.

   Often a separate non-transfected cell control is not necessary, because even in the transfected samples, not all cells express the fusion proteins. The non-transfected cells in the

population can usually be distinguished by their autofluorescence, allowing easy identification of transfected and non-transfected cells from the same sample when viewed using the fluorescent setting.

6. Choose cells in which expression levels are just high enough to be resolved above the background autofluorescence, and that are not obviously unhealthy.

   A good quality image should be obtained in confocal microscopy using 3% to 5% of the maximum laser power (assuming a 30-mW, 488-nm laser; see Fig. 24.4.1A).

   Analysis of cells that are unhealthy and suffer from toxicity induced by the expression of the fusion protein should be avoided. For example, cells that have rounded up and are about to detach—a common phenomenon with cells expressing high levels of a fusion protein consisting of the PH domain of PLC and GFP (PLCδ_1PH-GFP) are not likely to behave normally. Another indication of toxicity is the appearance of large intracellular vesicles.

Perform time-lapse analysis of live cells

7. Record and store an image before applying any stimulus.

   An important and often unappreciated problem in live-cell imaging is the proper temperature of the cells that are being observed. Even with a heated stage, an objective acts as a heat sink, keeping the cells in the observation field at a temperature near that of the objective. This temperature is closer to room temperature especially when rooms are kept on the cold side because of the lasers. Many trafficking processes in the cells slow down or do not work properly below 34°C. Therefore, use an objective heater. Unfortunately, the heater collar does not fit all objectives, and heating may be damaging to the objective if it is warmed very fast from a cold temperature. Alternative methods of maintaining the proper temperature include perfusion of cells with a high flow of warm medium or the use of a hair dryer to keep the objective at the proper temperature. Complete incubator enclosures are also available from various companies that can keep both the temperature and CO_2 concentration and humidity of cells on the stage at the desired levels. Unfortunately, they make manipulations of the cells often difficult.

8. Set the software to record time-lapsed images.

   The speed of recording must be decided based on the expected speed of the response and the scan speed that is required to generate an image. Phospholipase C activation by receptors is a fast event, but it can be followed by obtaining an image every 5 sec. Depending on the software, the scanning time (1.0 to 2.5 sec/image for one color) is taken into account when setting up the speed of image acquisition. It is important to remember that frequent scanning leads to fast photobleaching but including a break between scans helps to counter the bleaching problem.

9. Start data acquisition and add stimuli or inhibitors after a control period (five to ten images depending on the speed).

   Addition of a treatment is more complicated than it seems. The best method is to use a computer-controlled valve-system linked to constant perfusion of the cells with prewarmed medium. This ensures proper mixing, timing, and keeping the composition of the medium not affected by evaporation. However, the authors' experience is that many of the lipophylic compounds (ionomycin, thapsigargin, rapamycin, etc.) stick to the plastic tubing and to the valve components to such an extent that it is almost impossible to clean them even with organic solvents. This is also true for the metal chambers including the plastic O-ring seal. This may cause significant problems, especially in multi-user settings. Because of this potential problem, simply use a pipet to stimulate the cells. For this, remove 200 μl warm medium from the cells and add it to a microcentrifuge tube that contains the desired amount of drug in 1 to 5 μl, and after mixing, add the medium back to the cells. With practice, one can pipet the medium back at an angle that will yield proper mixing, which may be further mixed by pipetting up and down one time. This takes ~2 sec, which is acceptable for many applications but may be too slow for others. It is the investigator's choice whether to follow the manual pipetting procedure or to use the more sophisticated valve-controllers.

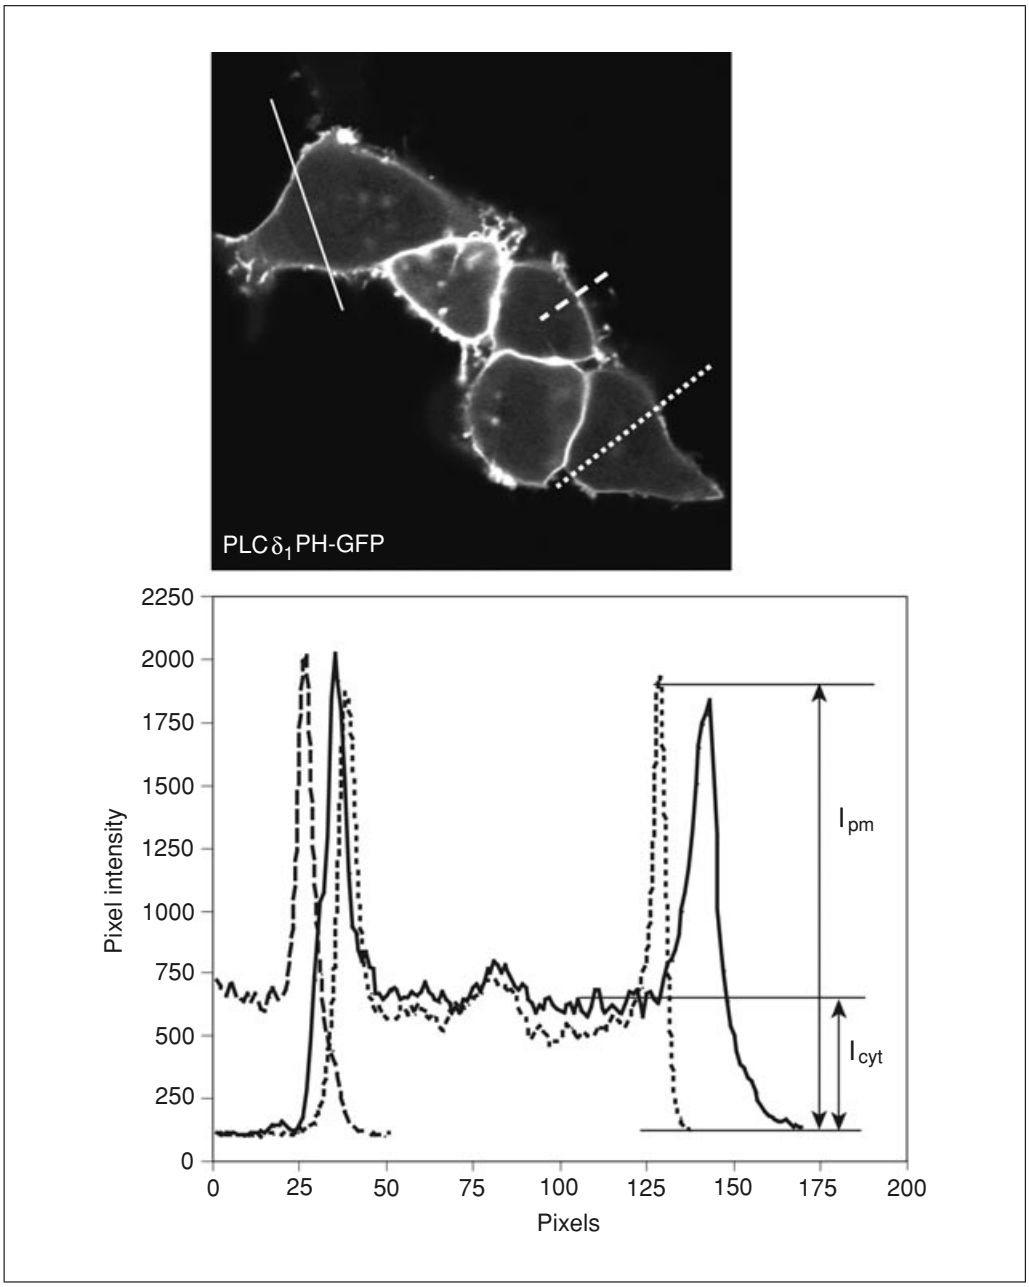

Figure 24.4.3 Quantification of the plasma membrane localization of an inositide binding domain. HEK293 cells are shown expressing the PLCδ_1PH-GFP. The pixel intensity histograms are calculated for the three lines placed on this recording. Note that the scale shows that this is a 12-bit image. An 8-bit image would only have 256 levels of intensities. Also note that the peak intensities are not at saturation. The lower panel shows how the intensity values from the membrane and the cytosol are calculated. Their ratio is then a good measurement of localization. Also note that no lines are placed over areas where two cells are joined. These calculations must be made for each picture from a sequence to obtain a full time-course of change. It is recommended that more than one line be placed on a cell to obtain a more accurate value as the intensities vary along the perimeter.

10. Once the scanning sequence is complete, save the results.

11. Quantify the data using appropriate software.

The most demanding part of the analysis of time-lapsed sequences is the quantification of data. Obvious changes can be documented in a series of pictures or movies that describe what is happening. However, as imaging tools are improving, some of the changes are not so obvious to the eye, especially when the number of vesicles, their movement patterns, or intensities all show some changes. Quantification is necessary when determining a dose-response relationship, comparing the relative effectiveness of two stimuli, or investigating the efficacy or potency of an inhibitor. It is difficult to provide recommendations that would cover all of these areas. In most of the applications dealing with plasma membrane phosphoinositides, it is necessary to assess the extent of plasma membrane recruitment; therefore, methods that determine plasma membrane association are focused upon. The simplest way is to monitor the cytosolic intensity since it will significantly increase as a domain translocates from the membrane to the cytosol. It is more demanding to calculate the ratio of membrane to cytosolic intensities. This can be done after creating a line-intensity histogram through a selected line across the cell. It is important that the highest intensities should not be in saturation, which requires a fine optimization of the dynamic range before recording in 8-bit systems (256 levels of gray intensity; Fig. 24.4.3). This is less of a problem with the newer 12-bit systems (4096 levels of intensity) or with a higher dynamic range. A more accurate but also more demanding way of quantification of the extent of membrane association of fluorescent proteins is to use fluorescence resonance energy transfer (FRET; UNITS 17.1 & 17.9) or total internal reflection fluorescence (TIRF; UNIT 4.12) microscopy as detailed in Varnai and Balla (2006) and Balla (2007). The latter is able to detect the radiationless energy transfer between two appropriate fluorophore pairs when they are within an optimal distance, while the former only detects fluorescence originating from the plane of the membrane attached to the coverslips. The variability of the cell population and the requirement for analysis of a large number of cells to obtain quantitative estimates of the fluorescence changes remains the most laborious parts of obtaining reliable, reproducible results.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Krebs-Ringers solution

120 mM NaCl
4.7 mM KCl
1.2 mM Na_2HPO_4
1.2 mM $CaCl_2$
0.7 mM $MgSO_4$
10 mM glucose
20 mM Na-HEPES, pH 7.4
0.1% bovine serum albumin (BSA; not added when lipofilic druqs are to be added)
Store up to 4 to 5 weeks at 4°C

Paraformaldehyde

Prepare paraformaldehyde fresh by dissolving the appropriate amount of EM-grade paraformaldehyde in PBS and heating (in a chemical hood) until the aldehyde goes into solution. Keep the bottle cap loosened so that pressure does not build up. Cool down to 20°C and pH to 7.4 with NaOH.

COMMENTARY

Background Information

The classical methods to study phosphoinositides relied upon metabolic labeling of phosphoinositides. Labeling cells with myo-[^{3}H]inositol or ^{32}P-phosphate followed by lipid extraction and separation by TLC (or other methods) has been widely used to measure phosphoinositide changes (e.g., Christy

et al., 1998). However, these techniques require millions of cells to obtain a sufficient signal. Moreover, depending on the labeling time and the turnover rate of the metabolically distinct inositide pools, it is not certain whether isotopic equilibrium is reached. Determination of the subcellular location of inositides requires even more cells and cell fractionation procedures, and by the end it is still questionable whether the distribution really reflects what was present in the intact cell. Total cellular mass of inositides have also been measured based on quantitation of the inositide headgroup that is liberated from the extracted lipid species (Pearson et al., 2000). Detection of phosphoinositides or inositol phosphate mass separated on HPLC has been done with metal dye-detection (Pittet et al., 1989) or suppressed conductivity detection (Nasuhoglu et al., 2002). Excellent collections of the conventional methods have been published (Irvine, 1990; Shears, 1997). In the meantime, newer methods have been introduced for mass measurement of inositides without extensive purification with the aid of protein domains that specifically recognize the inositide headgroup (Luo et al., 2003; Guillou et al., 2007). However, even in their most simple forms these methods are cumbersome and are unable to resolve the small changes that occur in subcellular compartments, especially against the higher background of non-responsive inositide pools. The realization that inositides are rapidly changing in restricted cellular compartments brought about the desire to detect them at the single-cell level preferably in live cells where the dynamics can be followed in real time.

Since the method employing protein domain fluorescent protein (FP) chimeras in live cells has certain limitations, there is a legitimate need for alternative methods in which the lipids are detected post-fixation without interfering with the biological process. Moreover, none of the live-cell imaging techniques can compete with the resolving power of electron microscopy. Post-fixation detection of the lipids has been achieved with anti-phosphoinositide antibodies or recombinant GST-fused inositol lipid–binding domains in immuno-cytochemical or -electron microscopy applications (Watt et al., 2002, 2004). The value of these techniques is clear; theoretically they would tell us where the lipids are in an intact cell without any distortion caused by the detection process and many cells can be analyzed with no time constraints. EM studies revealed the presence of lipids in compartments where in vivo PH domain imaging failed to do so, e.g., PtdIns(4,5)P2 in the Golgi (Watt et al., 2002). However, these techniques also have their drawbacks. First, the fixation process has a major influence on what inositide pools are visible to the antibodies or the GST-fused inositide-binding module. Second, the sensitivity of these methods is hard to evaluate. The fixation process is even more critical than in proteins in preserving the lipids and yet to make them accessible to the antibodies or protein modules. This technical difficulty explains the variability of the results obtained in different laboratories with the antibodies and their failure to work in some cases. The specificity of the antibodies should be a rigorous criterion and the data should be consistent with already existing knowledge on the distribution of phosphoinositides.

Assessing membrane localization by FRET

A quantitative assessment of the membrane localization of fluorescent probes is not always easy based on confocal images. An increase in the fluorescent intensity of the membrane can reflect a change in membrane volume or shape and not a real recruitment. Similarly, the cytosolic intensity of the probe can increase due to shrinkage instead of its release from the membranes. To overcome these problems, the FRET principle was used in several studies to obtain a signal that reflects true binding of the inositide binding domain to membranes. The method developed in the Jalink laboratory and also used in the authors' studies is based on co-expression of the CFP- and YFP-tagged versions of the same PH domain (e.g., PLCδ_1-PH). These fluorophores are the most widely used pairs for FRET studies although the more pH-resistant Venus replaces YFP and cerulean replaces CFP in newer applications. Newer fluorophore pairs are also available now for FRET studies but they are not as well established as the GFP derivatives. Nevertheless, the principle is the same; when the donor (CFP) and the acceptor (YFP) are within FRET distance (<8 nm) there will be energy transfer from CFP to YFP causing a decrease in CFP emission (475 nm) and an increase in YFP emission (525 nm) when using CFP excitation only (430 nm). In the so-called sensitized emission method, the efficiency of the energy transfer is numerically calculated after making all necessary corrections (such as bleed through of the CFP and YFP signals into the other pair's emission channels). However, for all practical purposes, the simple

fluorescence ratio of 525/475 can be used if the two wavelengths show opposite changes. This principle is applicable to the lipid binding PH domains when expressed both as a CFP or YFP fusion protein. The two fluorophores will show efficient energy transfer when their attached PH domains are bound to the lipids at the membrane. However, upon PLC activation, the PtdIns(4,5)P_2 molecules are hydrolyzed and the PH domains leave the membrane decreasing the FRET signal (van Der Wal et al., 2001). This method is quite sensitive and even small PLC activation can be detected and quantified. The method does not require a confocal microscope and can be used either in individual cells or in cell suspensions (Balla et al., 2005). A disadvantage of the method is that the FRET efficiency is not very high at low expression levels (which would be desirable to minimize the ill effects of the presence of the probes) and even at high probe concentrations there could be low FRET signal if the density of the lipids is below a certain level. Although the authors have not used this application, FRET can also be assessed by fluorescence life-time imaging microscopy (FLIM; *UNIT 4.14*) that calculates the half life of the excited state of the fluorophore that is very different when the energy is emitted in the form of photons or is transferred to an acceptor by FRET (Bastiaens and Squire, 1999). FLIM has many advantages over sensitized emission to evaluate FRET but it requires separate special instrumentation that is not as easily available as fluorescence microscopes.

In the above examples, two separate molecules are used to detect FRET between neighboring molecules (intermolecular FRET). A better solution would be to have inositol lipid probes based on intramolecular FRET in which case both fluorophores are attached to the same inositide-recognizing domain. Lipid binding then induces a molecular rearrangement that changes the distance (or more likely the dipole orientation) of the two fluorophores and, hence, the FRET signal. Such a probe based on the Grp1-PH domain was targeted to different membranes for PtdIns(3,4,5)P_3 detection (Sato et al., 2003) and a similar principle was utilized to generate FRET probes for monitoring InsP3 concentrations in the cytoplasm (Matsu-ura et al., 2006). The difficulty here is to ensure a large enough conformational change upon lipid binding to substantially change the FRET efficiency. Construction of a useful probe requires lots of experimentation with the domains themselves as well as with the linkers to connect the fluorophores. In a recent study, the AktPH domain was used to detect PtdIns(3,4,5)P_3/PtdIns(3,4)P_2 changes using a clever molecular design. The conformational change between the lipid-bound and unbound stages was achieved by inserting a negatively charged "pseudoligand" into the probe that binds to the PH domain (presumably to the lipid-binding site) when lipids are not present. Binding of the appropriate lipids abolishes this intramolecular interaction amplifying the conformational change and amplifying the change in the FRET signal (Ananthanarayanan et al., 2005). These single-molecule FRET probes do not require co-expression, their readout does not depend on their expression level (once above reliable detection limits) or on lipid density in the membrane. It is expected that more efforts will be made to generate similar probes for the detection of lipid production in the various cellular compartments.

More detailed technical and theoretical background on FRET measurements either with sensitized emission or with FLIM are covered in recent publications (Sekar and Periasamy, 2003; van Rheenen et al., 2004; Thaler et al., 2005).

Membrane localization based on TIRF analysis

Total internal reflection fluorescence (TIRF; *UNIT 4.12*) analysis has also been used to monitor plasma membrane association of inositol lipid binding domains (Tengholm et al., 2003). The basis of this technique is a special form of illumination where the light is shot at the sample at a shallow angle in a way that the photons do not illuminate the specimen beyond a ~200-nm thickness above the coverslip. This way the excitation is limited to the fluorescence molecules that are found close to the membrane of the cell attached to the coverslip, which makes this method suitable to detect membrane-associated events and also useful to study association and dissociation of molecules from the membrane. If the footprint of the cell changes, it could cause a change in fluorescence intensity unrelated to the actual amount of fluorescent molecules at the membrane. For this reason, use of a fluorescent membrane marker as a control and then evaluation of fluorescence changes against this reference signal are recommended.

Live-cell imaging of inositol lipids has become a standard approach in many laboratories. It has generated some controversy with examples for its uncritical use as well as for its complete dismissal as an unreliable method.

The truth is that this method—as every other—has its unique benefits as well as its limits. The authors emphasize that the phosphoinositides imaged with these molecular tools are only representative of a pool associated with certain processes and not necessarily representative of all of that particular inositide within the cell. This is especially true and obvious for PtdIns4P and may be less notable but still true for the other inositides. Also be cautious about high expression levels, which inhibit and distort cellular processes. Generating quantitative data with these methods is an added challenge but a very important necessity. As more domains that interact with inositides are identified in proteins it is important to remember that many of these will not work as reporters because their cellular localization is more dependent on protein-protein interaction than on lipid binding. However, some other probes should be compared for their imaging properties, especially for PtdIns(4,5)P_2 and PtdIns4P. Development of FRET-based probes relying on intramolecular rearrangements should also be facilitated. This research area will be in high demand for the near future. The high interest in phosphoinositides also demands constant improvement of the tools to further the knowledge on these molecules.

Troubleshooting

Described here are the most common problems that are encountered—starting from plasmid propagation to the final microscopy steps.

No bacterial colonies

The pEGFP plasmids have the kanamycin selection marker so transformed bacteria must be grown on kanamycin-containing plates and not on ampicillin-containing plates. However, companies are selling various forms of plasmids that one cannot assume that all GFP constructs are kanamycin selectable. Moreover, some laboratories add GFP to their chosen domain in ampicillin-resistance plasmids, and oftentimes researchers make wrong assumptions when selecting colonies of transformed bacteria. This should be the first consideration when no colonies are found after transformation of bacteria during subcloning or propagation of plasmids. Problems with subcloning, ligation reaction, or bacterial transformation can also result in no bacterial growth, but discussion of these variables is beyond the scope of this unit.

No green fluorescence

It may sound trivial but the most common reason for not seeing fluorescence is due to inappropriate microscope settings. Confocal microscopes used for fluorescence imaging can be intimidating for novices, with several filters and light directions that must be set properly to see the fluorescent signal. It is good practice to find the right focus of the cells with transmitted light. Switching to fluorescence, the blue (or other color) light coming through the objective must be visible to be sure that the illumination and the light path is properly set. It is very useful to have a slide of fixed GFP-expressing cells to use as a control. If the microscope settings are correct and there are still no GFP-positive cells (yet the autofluorescence is visible with a 40× or higher objective), then the problem lies with the transfection. Transfection problems can be caused by several factors, including inaccurate subcloning, impure plasmid for transfection, unsuitable transfection conditions for the cells. Even transfected primary cultured cells should have a few positive cells. Using cells transfected with the original pEGFP plasmid as control should help to determine whether the transfection procedure or the DNA construct is the source of the problem. If these cells are positive for GFP fluorescence, then the most likely source of the problem is the construct itself. The DNA construct could be defective by having an unwanted stop codon or a frame-shift either due to a flaw in the design or by a mutation. The plasmids should always be confirmed by DNA sequencing and the expression of the full-length protein should be confirmed by SDS-PAGE as described.

Weak fluorescence

If there are positive cells but their fluorescence is weak, the microscope may not be set up properly. Compare the cells with fixed cells transfected with EGFP alone to determine if the problem is with the microscope or the construct to be studied. If the EGFP-expressing cells are bright, but the fusion protein–expressing cells are weakly fluorescent, then the problem is inherent to the fusion protein. The authors' experience is that the larger the protein fused to GFP, the weaker its fluorescence. This could be because of the difficulty in the folding of GFP as part of a larger protein or that the translation of longer proteins is less efficient. Since the constructs listed in Table 24.4.1 express well, low levels of fluorescence usually indicates a transfection problem, which is also corroborated by few cells showing fluorescence. Many cells showing weak fluorescence indicates good transfection efficiency but low yield of the fluorescent protein.

Large aggregates present in cytoplasm
