1. Place 12-mm coverslips in wells of 24-well plate using forceps that have been sterilized by immersion in 70% ethanol and air dried. Add 1 ml of HeLa cells at 30,000 cells/ml in complete DMEM/10% FBS. Return plate to incubator and incubate 16 hr.

   The number of cells plated may have to be optimized to give ~50% confluence after 16 hr.

Permeabilize cells

2. Place plate on ice for 5 min. Aspirate medium and gently add 1 ml ice-cold TB.

   If using a repeating pipettor, designate one syringe for each solution (TB, digitonin, and fixative). Be gentle when adding solutions to the coverslips. Pipet slowly and do not spray directly onto the cells, but rather down the side of the well. From this point on, sterility is not required.

3. Aspirate TB and add 1 ml ice-cold digitonin solution. Incubate 5 min on ice.

   Digitonin preferentially solubilized cholesterol from membranes, which leaves large holes through which soluble material passes. Because the plasma membrane contains higher concentrations of cholesterol than the nuclear envelope, it is selectively permeabilized while the nuclear envelope is not.

4. Aspirate the digitonin solution and add 1 ml of ice-cold TB. Continue to hold plates on ice up to 30 min.

Perform import reaction

5. Tape Parafilm onto the benchtop, ensuring that it is flat on the surface, and mark with numbers in the same pattern as the plate (i.e., in rows of six). Place 40-µl drops of the import reaction mixture on the Parafilm so as to correspond to each well. Using forceps, remove coverslips from wells and wick off excess TB by touching the edge of the coverslip to filter paper. Gently invert each coverslip (cell-side-down) on its designated drop of import mixture.

   The coverslip will float on top of the drop of import mix.

   Controls for nuclear import include reaction mixes prepared with probes containing positive and negative NLS sequences (see Critical Parameters).

6. Cover the reactions with an opaque tray to prevent fading, and incubate 15 min at room temperature.

7. Gently pipet 250 µl of ice-cold TB underneath the coverslip to stop the import reaction and to float the coverslip up from the Parafilm. Gently remove coverslip and place back in the TB (cell-side-up) in the 24-well plate on ice.

Fix cells

8. Aspirate TB and add 1 ml of fresh ice-cold TB to each coverslip. Aspirate TB and add 1 ml of ice-cold 3% paraformaldehyde. Cover to protect from light, and incubate on ice for 15 min.

9. Remove coverslip, wick off excess fixative on filter paper, and gently invert on a small drop of mounting medium (cell-side-down). Allow top of coverslip to dry for 5 min before sealing the edges of the coverslips with clear nail polish.

Assess cells for nuclear import

10. Observe by fluorescence microscopy using 63× or 100× oil objective.

    The simplest way to record the results is photographically. To ensure that different panels of a given figure are comparable, the different samples should be photographed with the same exposure time and printed identically. The relative differences in fluorescence intensity between different samples is generally very reproducible. However, the overall fluorescence intensity of the assay does show some inter-assay variation from day to day. Therefore all the relevant samples for a given figure should be done in a single experiment. If desired, the prints from these photographs can be scanned and quantitated. However, if quantitation is to be used on a regular basis, it is strongly recommended that the investigator access or purchase a quantitation program and a system (such as a CCD camera or confocal microscope; UNIT 4.5) specifically designed for that purpose.

PREPARATION OF *XENOPUS* OVARIAN CYTOSOL

SUPPORT PROTOCOL 1

Cytosol from *Xenopus* ovaries is used to provide the cytosolic factors necessary for protein import.

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) or must conform to governmental regulations regarding the care and use of laboratory animals.

Materials

Eight female *Xenopus* frogs
PBS (see recipe), ice-cold
Protease inhibitor tablets (Boehringer Mannheim Complete, EDTA-free)
1× homogenization buffer (see recipe), ice cold
1× transport buffer (TB; see recipe), ice cold

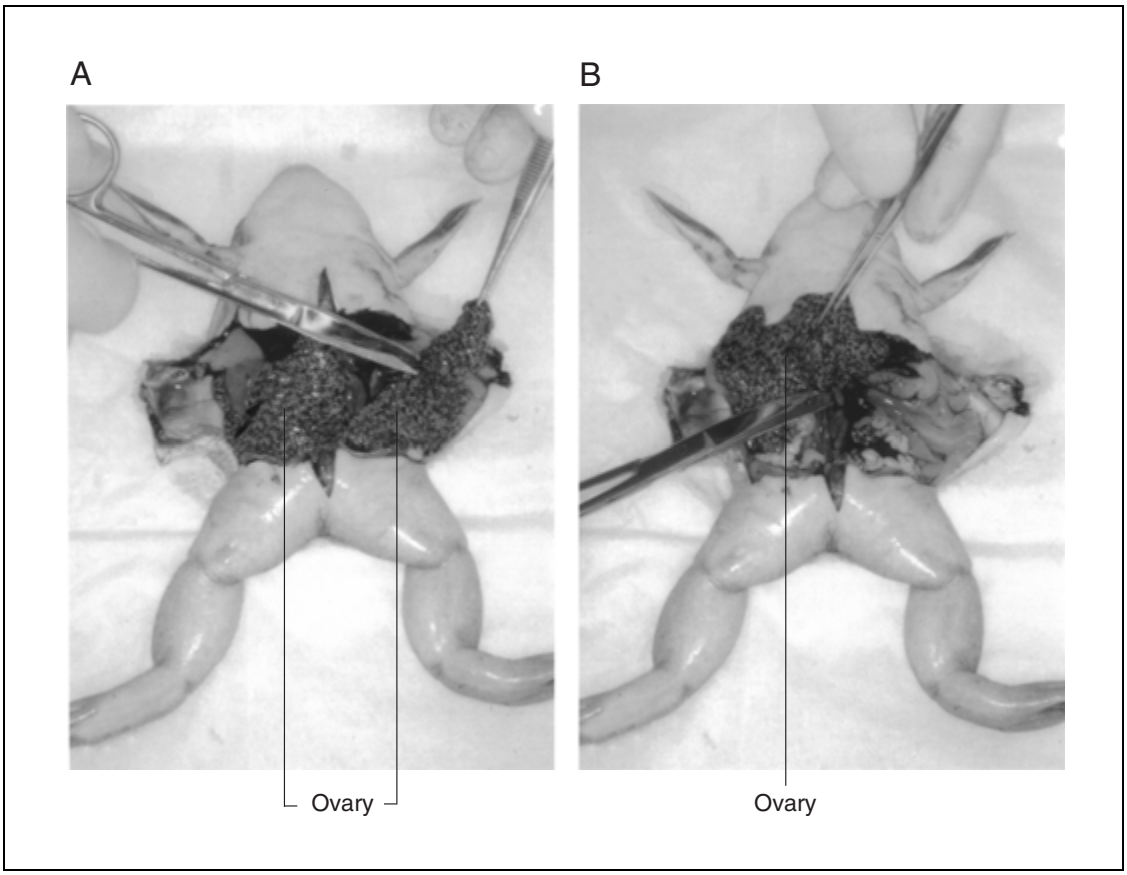

Figure 11.7.1 Frog ovary dissection. These panels show the exposed abdominal cavity of the female *Xenopus*. (**A**) Upon opening the abdominal cavity, the ovary is by far the most conspicuous organ. (**B**) To remove, gently lift the ovary with forceps and clip attachment points as near to the ovarian tissue as possible.

Carbon dioxide tank with attached tubing
Polytron homogenizer, PRO300D (PRO Scientific)
250-ml plastic centrifuge bottles
Sorvall centrifuge with GSA centrifuge rotor (or equivalent)
Cheesecloth
Beckman ultracentrifuge with Ti 70.1 rotor (or equivalent), and appropriate ultracentrifuge tubes
Plastic tubing, thin
20-ml syringe
Dialysis tubing (4000 to 6000 MWCO)
Centriplus-10 concentrators (Amicon)

Additional reagents and equipment for determining protein concentration (*APPENDIX 3B*)

Dissect ovaries

1. Place frogs and water into a covered bucket with two pipet-sized holes drilled in the top for gas exchange. Sacrifice frogs by bubbling carbon dioxide through the frog water for 20 min under a fume hood. Transfer dead frogs into ice to keep cold.

   Approximately 350 mg of cytosol can be prepared from eight frogs.

2. Remove ovaries (Fig. 11.7.1) and place in a beaker (kept on ice) containing 1 liter of cold PBS.

   Try to avoid harvesting connective tissue.

3. After all of the ovaries are collected, wash them several times with a total of 4 liters of ice-cold PBS. Let the ovaries settle between washes and decant the supernatant.
4. Place the ovaries in a large graduated cylinder containing cold PBS to measure the wet volume of the ovaries.
5. Using a large pair of forceps, remove ovaries from beaker and briefly blot on paper towel to remove excess liquid. Transfer to a plastic beaker.

Prepare homogenate

6. Add an equal volume of cold homogenization buffer containing dissolved protease tablets (1 tablet per 50 ml buffer).
7. Homogenize with a Polytron homogenizer using several short bursts (5 to 10 sec each).

   This tissue is very soft and homogenizes easily. Use a relatively low setting on the homogenizer. Do not operate at high enough speeds to foam the slurry.

8. Transfer homogenate to 250-ml plastic centrifuge bottles and centrifuge 20 min in a GSA rotor at 16,000 × *g*, 4°C.
9. Decant the supernatant, avoiding the floating fat layer as much as possible. Filter supernatant through several layers of cheesecloth. Discard pellet and fat layer.
10. Transfer the supernatant to ultracentrifuge tubes using homogenization buffer to top off the last tube. Centrifuge 2 hr in a Ti 70.1 rotor at 150,000 × *g*, 4°C.

Collect clarified cytosol

11. Attach thin tubing to a 20-ml syringe. Insert tubing approximately one-half of the distance into the tube, between the floating fat layer and the loose yellow precipitate near the bottom. Draw off this clear middle layer.

    It is better to leave a little cytosol behind than to draw up contaminants at this step.

12. Transfer this cytosol to dialysis tubing (4000 to 6000 MWCO). Dialyze into a total of 6 liters of TB at 4°C. Change buffer three times with the third change followed by overnight dialysis.

    Additional insoluble material will form during dialysis, making the cytosol appear cloudy.

13. Transfer dialysate to ultracentrifuge tubes and centrifuge 1 hr in a Ti 70.1 rotor at 100,000 × *g*, 4°C.
14. Perform a Bio-Rad protein assay on the resulting cytosol (*APPENDIX 3B*). Concentrate the cytosol to ~20 mg protein/ml using Centriplus-10 concentrators.

    The protein concentration at the end of the cytosol preparation is usually 4 to 6 mg/ml. Typically, the optimal final concentration required to support nuclear import is ~10 mg/ml. Because additional constituents will be added during the import assay, it is convenient to concentrate the cytosol to ~20 mg/ml. A concentration curve must be performed on each batch to determine the optimal concentration required to support nuclear import.

15. Divide the concentrated cytosol into aliquots, snap freeze, and store at −80°C up to 6 to 8 months.

    A 550-µl 10 mg/ml aliquot would be enough cytosol for 24 cover slips.

PRODUCTION OF FLUORESCENT IMPORT SUBSTRATE: TRITC-BSA-NLS

A nuclear localization substrate is prepared by coupling BSA to an NLS and conjugating the resulting protein to TRITC.

Materials

Sephadex G-25 and G-50 (Pharmacia Biotech)
0.1 M sodium phosphate, pH 7.0 and 8.0 (*APPENDIX 2A*), ice cold
Bovine serum albumin, fatty-acid free (Boehringer Mannheim)
0.1 M sodium carbonate, pH 9.0/50 mM NaCl (store indefinitely at room temperature)
Tetramethylrhodamine-5-(and 6)-isothiocyanate (TRITC; Molecular Probes)
DMSO
1.5 M hydroxylamine·HCl, pH 8.5 (see recipe)
Sulfo-SMCC (Pierce)
NLS or mutant NLS peptide (~1 mg)
20 mM HEPES (potassium salt), pH 7.3/110 mM potassium acetate (prepare fresh)
1× transport buffer (TB; see recipe)

Disposable 20-ml columns (Bio-Rad Laboratories, Cat # 732-1010)
Rocking platform
Centricon-30 concentrators (Amicon)

Additional reagents and equipment for dialysis (*APPENDIX 3C*), determining protein concentration (*APPENDIX 3B*), and SDS-PAGE (*UNIT 6.1*)

Prepare columns

1. Using disposable 20-ml columns, prepare three 15-ml bed volume desalting columns containing the following media.

   Sephadex G-25 equilibrated with 0.1 M sodium phosphate, pH 7.0
   Sephadex G-25 equilibrated with 0.1 M sodium phosphate, pH 8.0
   Sephadex G-50 equilibrated with 0.1 M sodium phosphate, pH 7.0

   Equilibrate each column at 4°C with at least 75 ml of the appropriate cold phosphate buffer.

Label BSA with TRITC

2. Dissolve 10 mg BSA in 1 ml of 0.1 M sodium carbonate, pH 9.0/50 mM NaCl. Save a 20-µl aliquot of this solution at 4°C as standard for SDS-PAGE analysis of conjugated products.

   This protocol will yield ~8 mg of TRITC-BSA-NLS import substrate.

   If more (or less) import substrate is required, scale entire procedure including BSA, TRITC, sulfo-SMCC, and peptide proportionally.

3. Dissolve 0.4 mg TRITC in 40 µl DMSO.

4. Add 12.5 µl of the TRITC/DMSO solution to dissolved BSA, 2.5 µl at a time, mixing after each addition. After all of the TRITC is added, wrap the tube in foil and incubate on a rocking platform 1 hr at room temperature.

   TRITC and its subsequent conjugates are sensitive to fading by ambient light, and prolonged exposure will result in noticeably dimmer import substrate. Protect from light whenever possible from this point onward.

5. Add 100 µl of 1.5 M hydroxylamine·HCl, pH 8.5, to the TRITC-BSA, wrap in foil, and mix for an additional 1 hr on the rocking platform at room temperature.

Hydroxylamine terminates the conjugation reaction and removes unstable conjugates from the BSA.

6. Microcentrifuge 10 min at 15,000 × *g*, 4°C, and save the supernatant.

Some insoluble complexes may form during steps 9 and 10.

Purify TRITC-BSA

7. Load the TRITC-BSA onto the 15-ml Sephadex G-25 column equilibrated with 0.1 M sodium phosphate, pH 8.0 (see step 1). Elute with 0.1 M sodium phosphate, pH 8.0, collecting 1-ml fractions. Pool the fractions containing the first red peak.

The separation of the TRITC-BSA (faster) and unconjugated TRITC (slower) should be obvious.

8. Concentrate eluate to ~0.5 ml in a Centricon-30. Remove a 10-µl aliquot and save at 4°C for SDS-PAGE analysis.

Note that if the separation of TRITC from TRITC-BSA on the Sephadex G-25 was effective, the filtrate from the Centricon should be colorless.

Activate TRITC-BSA

9. Dissolve 2 mg of sulfo-SMCC in 200 µl water (23 mM final). Add 166 µl of sulfo-SMCC to the TRITC-BSA. Wrap in foil and incubate 30 min at 37°C. Vortex lightly every ~5 min.

10. Microcentrifuge 10 min at 15,000 × *g*, 4°C, and collect the supernatant.

11. Load sample onto the 15-ml Sephadex G-25 column equilibrated with 0.1 M sodium phosphate, pH 7.0 (see step 1). Elute with 0.1 M sodium phosphate, pH 7.0, collecting 1-ml fractions. Pool the fractions containing the red eluate, which is the sulfo-SMCC activated TRITC-BSA. Remove 20 µl and save for SDS-PAGE analysis.

This column will separate unbound sulfo-SMCC (slower and colorless) from that bound to the TRITC-BSA (faster and red).

Conjugate NHS peptide to TRITC-BSA

12. Add a 5- to 20-fold molar excess of NLS peptide to TRITC-BSA-sulfo-SMCC. Cover with foil and incubate on a rocking platform overnight at 4°C.

13. Microcentrifuge 10 min at 15,000 × *g*, 4°C, to remove insoluble material.

14. Concentrate to 0.75 ml in Centricon-30.

15. Load the concentrated TRITC-BSA-NLS onto the 15-ml Sephadex G-50 column equilibrated with 0.1 M sodium phosphate, pH 7.0. Elute with 0.1 M sodium phosphate, pH 7.0, collecting 1-ml fractions Pool fractions containing the red eluate, which is the TRITC-BSA-NLS.

This column separates the final product, TRITC-BSA-NLS (faster and red) from the unconjugated NLS peptide (slower and colorless).

16. Dialyze (*APPENDIX 3C*) against a total of 3 liters of 20 mM HEPES (potassium salt), pH 7.3/110 mM potassium acetate at 4°C. Change the buffer three times, with the last change followed by overnight dialysis.

17. Centrifuge dialysate 10 min at 10,000 × *g*, 4°C. Save the supernatant. Remove 20 µl and save for SDS-PAGE analysis.

18. Determine protein concentration using the Bio-Rad assay (*APPENDIX 3B*).

19. Concentrate in Centricon-30 if necessary.

The concentration of the stock import substrate should be at least 40× the final concentration used in the import assay. The authors' TRITC-BSA-NLS conjugates typically exhibit maximal import at 5 to 10 μg/ml.

Analyze conjugates

20. Analyze aliquots collected at steps 2, 8, 11, and 17 by SDS-PAGE (*UNIT 6.1*).

Conjugation of sulfo-SMCC to BSA (without peptide) will result in an apparent increase in molecular weight on SDS-PAGE. Successful coupling of peptide to the sulfo-SMCC-BSA will cause a further decrease in mobility. The number of peptides conjugated can be roughly estimated by the change in molecular weight.

21. Divide the conjugate solutions into aliquots and snap freeze in liquid nitrogen. Store at −80°C (for up to a year).

22. When required, briefly thaw aliquot in 37°C water bath, dilute to 40× with TB, and microcentrifuge 20 min at 15,000 × *g*, 4°C. Transfer supernatant to a fresh tube. Store in a dark container at 4°C for up to 1 month.

SUPPORT PROTOCOL 3

PRODUCTION OF FLUORESCENT RECOMBINANT IMPORT SUBSTRATE: GFP-GST-NLS

As an alternative to coupling of BSA to the NLS and TRITC (see Support Protocol 2), the nuclear localization substrate can be a recombinant GFP-GST-NLS produced in *E.coli*.

Materials

LB medium (*APPENDIX 2A*) containing 100 μg/ml ampicillin
DH5α strain of *E. coli*
GST-GFP-NLS and GST-GFP-mutNLS constructs in *E. coli* (Dr. Manfred Lohka, Biological Sciences, University of Calgary, Calgary, Canada)
1 M IPTG in H_2O, sterile filtered
Phosphate-buffered saline (PBS; see recipe)
Protease inhibitors tablets (Boehringer Mannheim Complete, EDTA-free)
PBS/EDTA (see recipe)
10% (v/v) Triton X-100
Glutathione–Sepharose 4B (Pharmacia Biotech)
Glutathione/Tris (see recipe)
20 mM HEPES (potassium salt), pH 7.3/110 mM potassium acetate (prepare fresh)
Transport buffer (TB; see recipe)

Shaking incubator
Sorvall centrifuge with GSA and SS-34 rotors (or equivalents)
50-ml conical centrifuge tubes
French press or sonicator
Rocking platform
Disposable 2-ml column (Bio-Rad)
Centricon-30 (Amicon)

Additional reagents and equipment for dialysis (*APPENDIX 3B*), determining protein concentration (*APPENDIX 3B*), and SDS-PAGE (*UNIT 6.1*)

1. Inoculate a 250-ml culture of LB medium containing 100 μg/ml ampicillin with a single colony of *E. coli* DH5α containing GST-GFP-NLS. Grow overnight in a shaking incubator at 300 rpm, 37°C.

This 1-liter culture yields ~9 mg of GFP-GST-NLS.

2. Add the overnight culture to 750 ml of the LB medium. Mix and split into two flasks of 500 ml each. Add IPTG (from 1 M stock) to 0.4 mM, and continue shaking at 28°C for 24 hr.

3. Harvest cells by centrifuging 10 min in a GSA rotor at 4000 × *g*, 4°C. Discard the supernatant.

   Pellets can be frozen at –80°C at this time if desired.

4. Resuspend pellets in a total of 15 ml of 1× PBS and transfer suspension to a 50-ml conical tube. Rinse centrifuge bottles with an additional 3 ml PBS and pool the wash with the suspension. Vortex thoroughly to completely resuspend bacterial pellet.

5. Dissolve one protease inhibitor tablet in 1 ml of 1× PBS/EDTA and add to suspension. Add 3 ml of 10% Triton X-100 (1% final), and bring volume to to 30 ml with 1× PBS/EDTA. Vortex to mix.

   Dissolve tablet in room temperature PBS/EDTA. Crush tablet with a spatula to aid in dissolution and vortex until dissolved.

6. Disrupt cells by passage through a chilled French press at 16,000 psi.

   Chill the cylinder prior to use to minimize warming the sample. The authors find that lysis is most efficiently achieved with the French press. Alternately, cells can by lysed by sonication using three pulses of 1 min with a 1-min interval on ice after each pulse for cooling.

7. Clarify lysate by centrifuging 20 min at 16,000 × *g*, 4°C, in an SS-34 rotor or equivalent. Discard the pellet.

8. Gently resuspend glutathione-Sepharose 4B slurry in the stock bottle. Remove 2 ml (corresponding to ~1.5 ml of packed resin) and transfer to a 50-ml conical centrifuge tube. Centrifuge 2 min at 500 × *g* to sediment resin and remove supernatant. Resuspend the resin in 30 ml of 1× PBS/EDTA. Sediment resin by centrifuging 5 min at 500 × *g*. Discard supernatant.

9. Transfer clarified lysate from step 7 to the 50-ml conical centrifuge tube containing the glutathione–Sepharose 4B. Invert to mix and incubate with gentle rocking at 4°C for 2 hr.

   Brief exposure of GFP to ambient light does not noticeably affect its brightness, but protect the GFP from light during any prolonged step.

10. In the cold room, pour resin/homogenate from step 9 into a 2-ml disposable column and collect flowthrough for future analysis. Wash the column with 50 ml of cold PBS. Minimize disturbance of the column bed during addition of PBS. After the last wash, allow the meniscus of the buffer to approach the top of the column bed, then stopper the column.

    The presence of GFP should be particularly evident as the resin packs at the bottom of the column. The bedding will appear bright green.

11. Elute GFP-GST-NLS at room temperature with glutathione/Tris by adding 10 ml of glutathione/Tris to the top of the column bed. Unstopper column and collect 1-ml fractions of the eluate in 1.5-ml microcentrifuge tubes. Continue until the eluate is almost colorless and column bed appears nearly white. Place fractions on ice as they are collected and protect from light. Pool green fractions.

12. Dialyze (*APPENDIX 3C*) against a total of 3 liters of 20 mM HEPES (potassium salt), pH 7.3/110 mM potassium acetate at 4°C. Change buffer three times with the last change followed by overnight dialysis.

13. Centrifuge dialysate 20 min in an SS-34 at 10,000 × *g*. Save the supernatant.

    Some protein may precipitate during dialysis.

14. Determine protein concentration using the Bio-Rad assay (*APPENDIX 3B*). Concentrate using Centricon-30 if necessary. Determine purity by SDS-PAGE (*UNIT 6.1*).

    The authors typically find that the activity of this substrate in the nuclear import assay is maximal at 25 to 50 µg/ml. It is convenient to concentrate the substrate to at least 40× its estimated final concentration, corresponding to ~2 mg/ml.

15. Aliquot, snap freeze in liquid nitrogen, and store at −80°C.

    The GST-GFP-NLS can be stored at −80°C for long periods. The size of the aliquots depends on the size of the experiment.

16. Perform a preliminary import assay (see Basic Protocol) to determine the optimal concentration of import substrate.

    Test several concentrations between 0 and 100 µg/ml. Too little substrate gives a faint signal, while too much substrate increases background and also decreases signal.

17. When required, thaw aliquot briefly in 37°C water bath, then dilute with TB to 40× the optimal concentration determined in step 16. Microcentrifuge 10 min at 15,000 × *g*, 4°C, to remove any precipitated protein, and transfer the supernatant to a fresh tube. Store at 4°C in a dark container (for up to a few weeks).

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Digitonin solution

Stock solution (20 mg/ml):
40 mg digitonin (Calbiochem-Novabiochem)
Bring to 2 ml with DMSO
Store at room temperature for up to 1 month

Working solution: Dilute to 70 µg/ml in transport buffer (TB; see recipe) on day solution is to be used.

DMEM/10% FBS

Dulbecco's Modified Eagle Medium (e.g., Life Technologies, 1× liquid, high glucose) containing:
10% fetal bovine serum (*APPENDIX 2A*)
10 mM HEPES (pH 7.55)
100 U/ml penicillin G sodium
100 µg/ml streptomycin sulfate
Store up to 1 month at 4°C

Glutathione/Tris

2.5 ml 1 M Tris·Cl, pH 8.0 (*APPENDIX 2A*; 50 mM final)
H_2O to 45 ml
76.8 mg reduced glutathione (Sigma; 5 mM final)
Adjust pH to 8.0 at room temperature with NaOH
Bring to 50 ml with H_2O
Divide into aliquots
Store up to several months frozen at −20°C

Glutathione noticeably alters the pH of the Tris buffer, which strongly affects the elution of some proteins.

Homogenization buffer

Prepare 10 × stock by combining the following:
200 ml 1 M HEPES, pH 7.3 (use KOH to adjust the pH)
20 ml 1 M magnesium acetate, pH 7.3
Bring volume to 1 liter with H_2O
Filter sterilize using a 0.2-µm filter
Store up to several months at 4°C
Prepare 1× working solution on day of use:
Dilute 10× stock to to 1× with H_2O
Add 1 M dithiothreitol (DTT) stock (store frozen in aliquots at −20°C) to 2 mM final

Hydroxylamine·HCl, 1.5 M, pH 8.5

Dissolve 2.1 g hydroxylamine hydrochloride in 10 ml water. Adjust pH to 8.5 with 5 M NaOH and adjust volume to 20 ml with H_2O. Prepare fresh.

Import reaction mixture

~10 mg/ml *Xenopus* ovarian cytosol (see Support Protocol 1)
0.5 mM GTP: add from 20 mM GTP stock in transport buffer (TB; see recipe)
1 mM ATP: add from 20 mM ATP stock in transport buffer (TB; see recipe)
Import substrate (for approximate concentrations, see Support Protocols 2 and 3)
Transport buffer (TB; see recipe) to 40 µl
Mix and store on ice until immediately before use.

The 20 mM ATP and GTP stock solutions are stored frozen in aliquots at −80°C.

Paraformaldehyde solution

Stock solution (6%): Under a fume hood, heat 150 ml of water to 60°C. Remove from heat and add 9 g paraformaldehyde. While stirring, add 2 drops 5 N NaOH from a Pasteur pipet. Continue stirring until dissolved. Store at 4°C for up to 1 month.

Working solution (3%): Dilute to 3% with 10× transport buffer (TB; see recipe) and water on the day of use.

PBS/EDTA, 4×

46 ml 0.2 M sodium phosphate, monobasic (NaH_2PO_4)
154 ml 0.2 M sodium phosphate, dibasic (Na_2HPO_4)
35.1 g NaCl
Bring to 900 ml with H_2O
Add 8 ml of 0.5 M EDTA
Adjust pH to 7.4 with NaOH
Bring to 1 liter with H_2O
Store at 4°C

Phenylendiamine mounting medium

Dissolve 100 mg *p*-phenylenediamine (an antifading agent) in 10 ml of 1× PBS (see recipe). Add 90 ml of glycerol and stir until homogenous. Divide into aliquots and store at −80°C. Warm to room temperature before use.

Prolonged exposure to light causes the mounting medium to turn brown.

Phosphate-buffered saline (PBS), 10×

2.3 mM NaH_2PO_4
7.7 mM Na_2HPO_4
150 mM NaCl
Store up to several months at 4°C

Transport buffer (TB)

Prepare 10× stock by combining the following:

200 ml 1 M HEPES, pH 7.3 (use KOH to adjust the pH)
275 ml 4 M potassium acetate, pH 7.3
20 ml 0.1 M magnesium acetate
3.8 g EGTA
Bring to 900 ml with H_2O and adjust pH to 7.3 with KOH or acetic acid
Bring volume to to 1 liter with H_2O
Filter sterilize using a 0.2-µm filter
Store up to several months at 4°C (months)

Prepare 1× working solution on day of use:

Dilute 10× stock to 1× with H_2O (working concentration)
Add 1 M dithiothreitol (DTT) stock (store frozen in aliquots at −20°C) to 2 mM final

The 1× TB contains 20 mM HEPES, pH 7.3, 110 mM potassium acetate, 2 mM magnesium acetate, 2 mM DTT, and 1 mM EDTA.

COMMENTARY

Background Information

Development of the permeabilized cell assay permitted a biochemical dissection of nuclear import mechanisms (Adam et al., 1990). This assay depends on the specificity of the detergent digitonin for cholesterol, which is present at higher concentrations in the plasma membrane than in the nuclear envelope (Colbeau et al., 1971). During the permeabilization process, the soluble contents of the cytoplasm leak out into the surrounding solution and are washed away. Included in these soluble contents are proteins and nucleotides (ATP and/or GTP) required for nuclear import. These must be re-added to permeabilized cells, in this case in the form of crude cytosol, for nuclear import to occur (Fig. 11.7.2A). Energy, in the form of nucleoside triphosphate (NTP), must also be added for most types of nuclear import to occur. While GTP alone appears to be required, the authors have included both ATP and GTP in this protocol. This is a common practice within the field when energy requirements are not a specific focus of the experiment. NTP can be removed from the import assay by addition of apyrase in place of ATP and GTP. The absence of NTP in the reaction mixture results in docking of the substrate at the NPC, yielding a characteristic rim pattern (Fig. 11.7.2B). Many kinds of nuclear import can also be inhibited by the addition of wheat germ agglutinin (WGA; Finlay et al., 1987; Fig. 11.7.2C), which binds to certain glycosylated NPC proteins (Hanover et al., 1987). This demonstrates that transport occurs through the NPC and is not the result of nuclear envelope damage.

There are a number of variations on the basic nuclear import assay. Several cell types have been used, but to date no significant differences have been found in import mechanics (see for instance Adam et al., 1990; Moore and Blobel, 1992; Adam and Adam, 1994). Cells in suspension can also be permeabilized, divided into aliquots, and frozen for future use (Leno et al., 1992; Görlich et al., 1994). The optimal digitonin concentration required for permeabilizing can, however, differ between cell types. At the ideal concentration, treatment of cells with digitonin results in permeabilization of the plasma membranes in the vast majority of cells (>95%), and nuclear envelope damage in very few cells (<5%). The integrity of the plasma membrane can be tested with DAPI, which is membrane impermeable and strongly stains DNA only in cells in which the plasma membrane has been permeabilized. The DAPI molecule is below the diffusion size limit of the NPC, and can therefore diffuse through the NPC into nuclei with intact nuclear envelopes. The integrity of the nuclear envelope can be tested with antibodies against nuclear components—i.e., lamina proteins or DNA itself (Adam et al., 1990). These antibodies cannot diffuse through the NPC, and will therefore only yield nuclear signal when the nuclear envelope has been damaged. Both the plasma membrane and the nuclear envelope are permeabilized with 0.1% Triton X-100.

There are also several variations on the duration of the nuclear import reaction and the temperature at which the reaction is incubated, extending up to 1 hr at 37°C. These longer

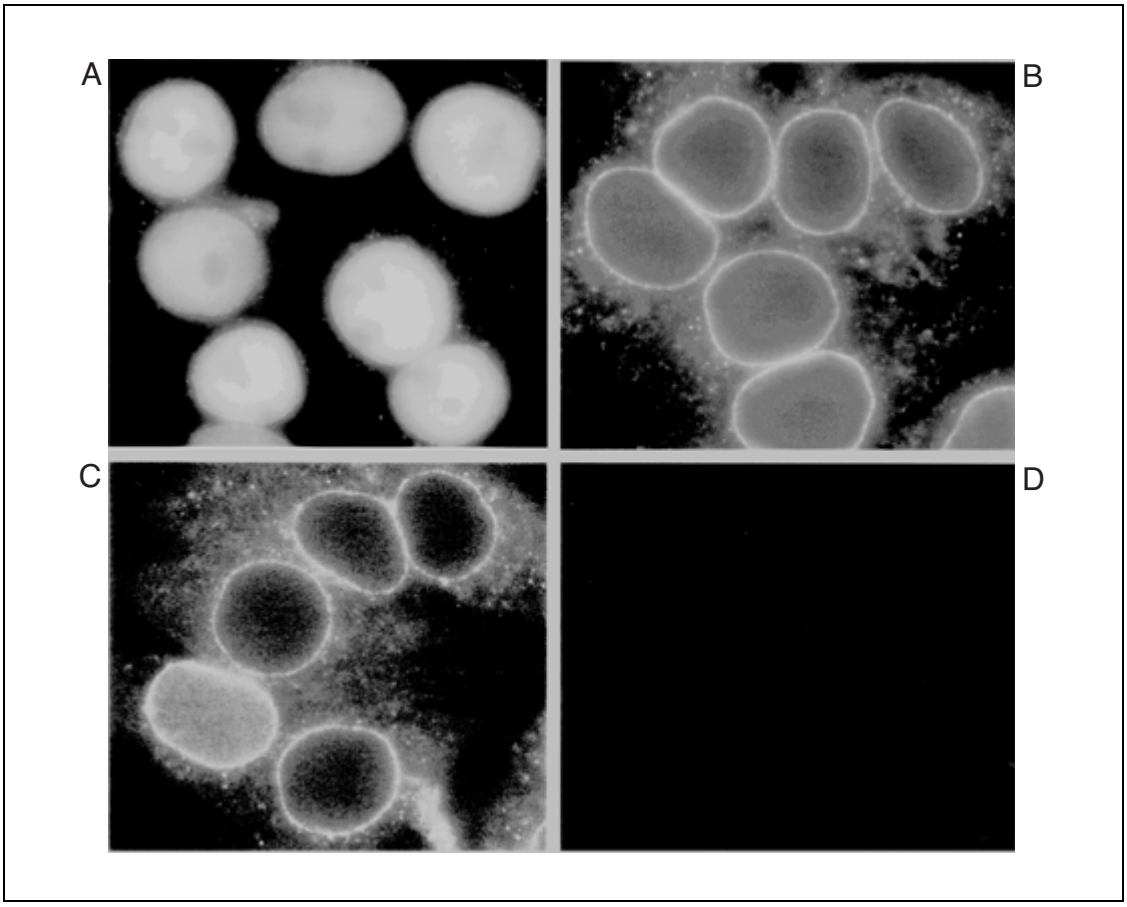

Figure 11.7.2 Fluorescence micrographs of the nuclear import assay performed under various conditions. All panels show representative nuclei from HeLa cells photographed and printed identically. (**A**) This positive control import reaction contained 10 mg/ml *Xenopus* cytosol, 0.5 mM GTP (0.5 mM), 1.6 mM ATP, and 50 μg/ml GFP-GST-NLS import substrate in TB, and was incubated for 15 min at room temperature prior to washing and fixation. (**B**) Same as (A) but GTP and ATP were replaced with 50 U/ml apyrase (50 U/ml), which at this concentration hydrolyzes any NTP. Note strong "rim" staining, reflecting the presence of substrate docked at the nuclear envelope. The punctate cytoplasmic signal may represent annulate lamellae (Davis and Blobel, 1986). (**C**) Same as (A), but in the presence of WGA (500 μg/ml), which binds to a subset of glycosylated NPC proteins and prevents import of NLS substrates. Note that the rim staining is still present but diminished. (**D**) Same as (A), but GFP-GST-NLS was replaced with GFP-GST-mutNLS. The mutant is neither imported into the nucleus nor bound to the nuclear envelope.

incubations should be performed in a humidified chamber to prevent the reaction mixture from evaporating. Long incubations may also require addition of an energy-regenerating system to maintain high NTP levels for the duration of the reaction. This regenerating system generally consists of 5 mM phosphocreatine and 20 U/ml creatine phosphokinase (final concentrations). The protocol given here is of relatively short duration by comparison, and addition of regenerating systems is not required.

Included is a support protocol describing the production of *Xenopus* ovarian cytosol (Moore and Blobel, 1992). While not as widely used as some other cytosols, it is simple and relatively inexpensive to produce. Alternatively, HeLa cytosol or reticulocyte lysate can either be produced (Adam, 1998) or be purchased from the NIH. Many people also use *Xenopus* egg extract produced from ovulated eggs (Görlich et al., 1994). Note that in ovulated eggs the nuclear envelope is broken down and the NPC is dissembled, so the constituents of this extract differ from those in ovarian cytosol.

Four proteins have been purified from cytosol on the basis of their ability to restore import in permeabilized cells. Karyopherin α/importin α (Adam and Gerace, 1991) binds to the NLS on nuclear proteins, and karyopherin β/importin β (Adam and Adam, 1994) in turn binds to the karyopherin α-NLS protein heterodimer and docks the complex at the NPC,

probably through karyopherin β interactions with a subclass of NPC proteins (Radu et al., 1995). Ran, a small GTPase (Moore and Blobel, 1993), and p10/NTF2 (Moore and Blobel, 1994), another protein known to interact with NPC proteins, are required for translocation of the NLS protein through the NPC and into the nuclear interior. Karyopherins α and β are sensitive to oxidation (Adam and Gerace, 1991; Adam and Adam, 1994), and the continuous presence of DTT in cytosol purification and during the import assay helps assure that these components are active (glutathione performs this role in vivo). Ran is in the GDP-bound form in the cytosol, but GTP is required for import, and it appears that Ran must be converted to the GTP-bound state to release substrate into the nuclear interior. Formation of stable nucleotide-Ran complexes requires Mg^{2+} (Bischoff and Ponstingl, 1991) which is present throughout the procedure. Potassium acetate is the preferred salt, as the buffer is designed to mimic the cellular interior, which is high in potassium. The total salt concentration is ~150 mM, similar to the situation in vivo.

The second common objective in nuclear import studies is to identify the NLS(s) within a given protein responsible for its localization. There are three cautions with this analysis (reviewed by Jans and Hübner, 1996). First, a protein may contain more than one NLS. Second, NLS activity may require a modification of the protein (e.g., phosphorylation/dephosphorylation or ligand binding) and that modification may not occur in the in vitro system. Along the same line, some proteins have both NLSs and NESs (nuclear export signals), and the steady-state localization of that protein can be a dynamic balance between these activities. The dynamics of these NLS and NES activities can also be modulated by secondary modifications. Third, some proteins are "piggy-backed" into the nucleus by binding to proteins that contain an NLS, so a protein above the diffusion limit may be exclusively nuclear and yet have no intrinsic NLS at all.

An active NLS is most accurately identified by a two-pronged approach (e.g., Kalderon et al., 1984a,b; Lanford and Butel, 1984). First, the protein is scanned for regions containing NLS activity. Cleavage products of the cDNA are joined to a reporter (e.g., GFP-GST), and the resultant fusion proteins are tested for import activity in nuclear import assays. Regions of the protein that confer nuclear localization on the reporter can be examined in more detail to specify the exact peptide sequence required for nuclear localization. There are no exact consensus sequences for NLSs, but there are some common themes that may be useful in their identification (Jans and Hübner, 1996). As mentioned above, this analysis may reveal more than one NLS. However, this analysis can also reveal NLSs that are not actually active in the native protein. There are portions of some proteins that act as NLSs in isolation, but which are not topologically exposed in the full-length protein and are, therefore, not active in vivo. For this reason, the putative NLS should also be mutated/deleted in the full-length protein to verify that inactivation of that putative NLS actually affects the localization of the protein.

This protocol is specifically designed to demonstrate nuclear import of test proteins and identify NLS(s) present in those proteins. Assays examining the intricacies of the nuclear import process itself require more specialized reagents, but are theoretically similar. In these studies, it is necessary to use more defined import reaction mixtures. This is most commonly achieved by depleting cytosol of certain import factors in order to determine their function, or, as is becoming more common, reconstituting nuclear import de novo using a complement of bacterially produced recombinant proteins.

Critical Parameters

The control import substrates are necessary to determine that the import assay is active. Typically, positive control substrates contain either an NLS like that of the SV40 T antigen (**PKKKRKV;** Kalderon et al., 1984a), or a bipartite NLS like that of nucleoplasmin (**KR**PAATKKAGQA**KKKK**L; Dingwall et al., 1988) in which two separate regions (shown here in bold) are required for activity. A longer peptide encoding the SV40 T antigen NLS is often used for coupling purposes (CYTP**PKKKRKV**). In addition to the NLS, the cysteine is required for the reaction with sulfo-SMCC cross-linker. The tyrosine residue allows for monitoring the peptide by A_{280} during chromatography to ensure that excess peptide is separated from the import substrate after cross-linking. It also allows the peptide to be iodinated if so desired. There are two common mutant NLS sequences used in negative controls. One contains a critical lysine mutation that abolishes NLS activity (PKTKRKV; Lanford and Butel, 1984). The second is simply the reverse amino acid sequence of the wild-type NLS, which also has no NLS activity (Adam et al., 1989). This reverse NLS may be a better

negative control because the charge of the peptide is conserved; both the wild-type and the mutant are highly basic. This high degree of positive charge confers high electrostatic binding properties, in particular a tendency to nonspecifically bind to DNA and proteins. Thus, the reverse sequence retains these nonspecific properties, unrelated to import activity, which may skew experimental results. These negative controls show neither rim staining (because they do not bind karyopherin α) nor nuclear import (Fig. 11.7.2D).

It is easiest to produce recombinant import substrates, such as GFP-GST-NLS, that encode both the fluorescent and targeting characteristics. The inclusion of GFP obviates the need to chemically attach fluorophores to the protein in order to detect nuclear import. The NLS directs the recombinant protein to the nucleus. The GST moiety serves a dual role. First, commercially available affinity resins greatly simplify the purification of this protein directly from bacterial lysates. Second, GST forms dimers under physiological conditions (reviewed in Mannervik and Danielson, 1988), raising the molecular weight of the import substrate to 106 kDa (2 × 53 kDa, the monomeric molecular weight of GST-GFP). This is well above the diffusion limit of the nuclear pore complex.

Alternatively, NLS peptides and fluorophores can be attached to BSA import substrate by chemical conjugation (Goldfarb et al., 1986). This method is a little more difficult. Both the sulfo-SMCC (which subsequently attaches to the peptide) and the TRITC react with lysines on the BSA, so it is important not to saturate the lysines with TRITC during the first reaction. Doing so will prevent subsequent binding of the sulfo-SMCC, and therefore prevent conjugation of the NLS (or mutant NLS) peptides. The terminal cysteine in the synthetic peptide is required for conjugation, because this residue reacts with the sulfo-SMCC on the BSA.

Many laboratories simplify this conjugation procedure by directly labeling nucleoplasmin (Newmeyer et al., 1986), which already encodes an NLS. In this manner a second reaction to attach NLS peptide is not required. The nucleoplasmin NLS is very protease sensitive, so negative control import substrate (lacking an NLS) can be produced by protease cleavage of the NLS from the nucleoplasmin, which is then referred to as nucleoplasmin core (Dingwall et al., 1982). In the authors' experience the nucleoplasmin-based import substrates have displayed higher background in the import assay, but this can be overcome by the addition of high concentrations of nucleoplasmin core as a blocking agent (Görlich et al., 1994).

The experimental protein must also, of course, be detectable to measure import, either by using an antibody against the protein or by fluorescently labeling the protein directly. Both of these approaches have potential drawbacks. TRITC reacts with lysines, which are often critical amino acids within the NLS. Thus, it is important not to utilize a high molar excess of TRITC, lest an endogenous NLS be inactivated. Indirect immunofluorescence microscopy avoids this detection problem, but the additional steps required to perform immunofluorescence microscopy after the import assay can have detrimental effects on cell morphology. Care must be taken to treat the cells gently, particularly when adding solutions to the coverslips.

If the protein has been cloned, it can be produced as a recombinant attached to GFP-GST and detected directly. Alternatively, a recombinant protein can be produced with an antigen site attached (such as FLAG, 6×His, or HA) and detected by indirect immunofluorescence microscopy. The nuclear pore complex can allow diffusion of substrates <50,000 Da (Bonner, 1975; Paine et al., 1975), so the molecular weight of the experimental substrate must be greater than that limit. If not, the possible nuclear accumulation demonstrated in the import assay could be the result of diffusion of the substrate through the nuclear pores and subsequent binding to sites within the nuclear compartment. This would not be considered active nuclear import. Note that GST forms a dimer under physiological salt conditions, so the GST-GFP-NLS positive control, with a monomeric molecular weight of 53 kDa, is actually a dimer of 106 kDa, well above the diffusion limit of the NPC.

Troubleshooting

The import assay itself is quite forgiving. It is important to titer the import substrate and cytosol relative to one another for every new batch. Incorrect concentrations (either too high or too low) will decrease the resulting signal. Poor morphology is generally due to rough handling of the cells. Be careful with all manipulations involving the coverslips, especially when adding solutions. Always pipet down the side of the well and not directly onto the cells. If no cells are present, check that the fixative was made according to the directions. Addition

of excess NaOH to the paraformaldehyde causes cells to detach from the coverslip.

Likewise, it is unusual for a batch of *Xenopus* cytosol to lack activity. Low activity generally correlates to long preparation time or extended storage. The entire prep should take ~1.5 days, including dialysis, concentration, and freezing. Be sure that DTT is added fresh to solutions where indicated to maintain the karyopherins α and β in their active forms, and likewise that Mg^{2+} is present to maintain Ran activity.

TRITC-NLS-BSA is a little more difficult to make. The resulting import substrate stock, at a few milligrams per milliliter, should appear bright red. At the recommended ratio of fluorophore to BSA (~1.5:1) most of the TRITC should conjugate to the BSA. This should be obvious during the subsequent chromatography. If the first peak (BSA-TRITC) is darker than the second peak (TRITC), there is enough label on the BSA. Monitor each step by SDS-PAGE to verify that peptide is actually conjugated. There should be a noticeable molecular weight increase with the addition of the sulfo-SMCC, and a further increase with the addition of peptide. TRITC-BSA or TRITC-BSA-NLS can also be visualized in the SDS-PAGE gel, prior to fixation and staining of the gel, by exposing the gel to UV light. Too many NLS peptides conjugated to the BSA may result in relatively bright rim staining and relatively low levels of import showing strong nucleolar staining. Too few NLS peptides may decrease the rate of import.

GFP-GST-NLS production and purification is relatively straightforward. The NLS may be susceptible to proteolysis, so maintain the protein at 4°C throughout the procedure (except for the elution).

Anticipated Results

The anticipated yield for each of the support protocols is ~350 mg *Xenopus* ovarian cytosol (see Support Protocol 1), 8 mg TRITC-BSA-NLS (see Support Protocol 2), and 9 mg GST-GFP-NLS (see Support Protocol 3). After optimization of these components, assays using 36 coverslips can be performed, viewed and photographed in one day. It is recommended that all experimental samples be performed in duplicate, with negative controls (WGA, apyrase, and/or mutant NLS) and NLS positive control performed on each experiment. This leaves room for testing ~14 experimental samples (in duplicate).

Time Considerations

A typical import assay requires 2.5 hr to perform, with an additional 3 hr to record the results photographically. It should take ~1.5 days to prepare the *Xenopus* ovarian extract. Production of the TRITC-BSA-NLS requires 2.5 days and GFP-GST-NLS 3 days.

In Vitro Translation Using HeLa Extract

This unit describes the production and use of HeLa extract as a cell-free translation system. HeLa extract provides a useful alternative to rabbit reticulocyte lysate (RRL), the most widely used eukaryotic translation system (*UNIT 11.2*). HeLa extract has advantages over RRL in that it can translate mRNAs that cannot be translated in RRL, is more cap-dependent, has a higher capacity for faithful initiation at the correct start codon, and is likely more representative of translation in intact human cells. HeLa extract has been used for routine translation of mRNAs to characterize viral infections, for de novo synthesis of viruses, and for high-throughput drug screening. The HeLa cell-free translation system described here has applications in protein production, biotechnology, and for answering fundamental questions in biochemistry.

The following protocol describes the preparation of HeLa extract and its use in in vitro translation reactions (see Basic Protocol). The Basic Protocol is based on methods published over the past 25 years, but contains modifications that simplify the procedure, save time, reduce cost, and most importantly, provide highly reproducible translation signals for independent replicates. There is also a protocol for producing and purifying mRNA (see Support Protocol).

CAUTION: When working with radioactivity, take appropriate precautions to avoid contamination of the experimenter and the surroundings. Carry out experiment and dispose of wastes in appropriately designated areas, following the guidelines provided by the local radiation safety officer (also see *APPENDIX 1D*).

PRODUCTION AND USE OF mRNA-DEPENDENT CELL-FREE TRANSLATION SYSTEM FROM HeLa EXTRACT

BASIC PROTOCOL

HeLa extract is produced by collecting HeLa cells grown in suspension, lysing the cells, removing cell debris, nuclei, and mitochondria, removing an inhibitory lipid layer, and exchanging the buffer by dialysis. Translation reactions are performed by adding an energy regeneration system, tRNAs, amino acids, and salts to the HeLa extract, Dounce homogenizing the mixture, removing the inhibitory lipid layer, adding purified mRNA, and incubating at 30°C for 3 hr. Translation signals are improved by removal of the lipid layer and treatment of the extract with calcium-dependent micrococcal nuclease to remove endogenous mRNAs. Dounce homogenizing the translation reaction prior to addition of mRNA provides a more homogenous mixture and greatly improves the reproducibility of the translation signal.

Materials

HeLa S3 cells (ATCC #CCL 2.2)
Joklik's modified Eagle medium for suspension cultures (SMEM)
Heat-inactivated iron-supplemented calf serum (Sigma)
200 mM L-glutamine
10,000 U/ml penicillin
10,000 µg/ml streptomycin
Hypotonic lysis buffer (see recipe)
Dialysis buffer (see recipe)
Diethylpyrocarbonate-treated H_2O (DEPCW; *APPENDIX 2A*)
1× phosphate-buffered saline (PBS; *APPENDIX 2A*)
0.4% (w/v) trypan blue stain
Bradford Reagent (Bio-Rad)

Contributed by Gary Witherell
Current Protocols in Cell Biology (2000) 11.8.1-11.8.10

1 mg/ml bovine serum albumin (BSA)
10× translation mix (see recipe)
0.1 M $CaCl_2$
1 mg/ml micrococcal nuclease (Pharmacia or Fluka)
0.2 M ethylenebis (oxyethylenenitrilo) tetraacetic acid (EGTA), pH 7.5
1 M and 2 M stocks of potassium acetate (KOAc), pH 7.5
10 mM magnesium acetate [$Mg(OAc)_2$]
1 mM amino acid mix minus methionine (Promega)
1 mm methionine or ^{35}S-labeled methionine (15 mCi/ml; >1000 Ci/mmole; e.g., NEN Life Sciences or Amersham)
150 nM purified mRNA (capped or uncapped; see Support Protocol)

0.5, 1, and 6-liter glass spinner flasks (autoclaved)
40-ml Wheaton Dounce homogenizer type A
8-ml collodion dialysis bags, MWCO 12 kDa (Sartorius)
50-ml plastic conical tubes
30-ml glass centrifuge tubes, one of known weight
500-ml or 1-liter centrifuge bottles
Preparative centrifuge and rotor (e.g., Beckman J6-HC centrifuge and JS-4.2 rotor or equivalent)
High-speed centrifuge and rotor (e.g., Beckman J2-21 centrifuge and JA-20 rotor or equivalent)
2-ml screw-cap cryogenic vials with O-ring seal
1-ml Wheaton Dounce homogenizer
96-well microtiter plates

Additional reagents and equipment for assessing cell disruption by trypan blue dye exclusion (*UNIT 1.1*) and measurement of [^{35}S]methionine incorporation (*UNIT 11.2*)

NOTE: All solutions and equipment coming in contact with the cells or extract during the preparation must be sterile and at 4°C and aseptic technique should be used accordingly.

NOTE: All tissue culture incubations should be performed in a humidified 37°C, 5% CO_2 incubator unless otherwise specified.

Grow HeLa cells

1. Grow 6 liters of HeLa S3 cells in suspension culture at 37°C with 5% CO_2 in SMEM supplemented with 10% (v/v) iron-supplemented calf serum, 2 mM L-glutamine, 100 U/ml penicillin, and 100 µg/ml streptomycin. Strictly maintain cell density between 2×10^5 and 8×10^5 cells/ml by passaging every other day. Transfer cells into larger spinner flasks as needed. Start initial 0.4-liter cultures with 2×10^7 cells from a frozen stock.

2. The day before preparation of the extract, prepare hypotonic lysis buffer and dialysis buffer. Place buffers and any apparatus that will come into contact with cells or extract at 4°C. Autoclave 40-ml Dounce homogenizer and place at 4°C.

3. Place two collodion bags in separate 50-ml conical tubes and wash with DEPCW twice to remove residual ethanol. Fill tubes to the top with DEPCW and store at 4°C until ready for use.

4. Weigh one 30-ml glass centrifuge tube and place at 4°C.

   The weight of the tube will be used to calculate the weight of the cell pellet.

5. Determine the cell density of the culture, and if necessary, dilute with fresh medium to give the desired density (4 to 5×10^5 cells/ml) the next day.

Collect cells for HeLa extract

6. Obtain 6 liters of HeLa S3 cells in log-phase (4 to 5×10^5 cells/ml). Centrifuge cells 10 min at $2800 \times g$.
7. Wash cells three times with ice-cold 1× PBS: 50 ml for first wash and 25 ml for second and third washes. After each wash, pellet the cells by centrifuging 8 min at $640 \times g$. Use a pre-weighed 30-ml glass centrifuge tube for the third centrifugation. Remove buffer and weigh tube and pellet. Calculate cell volume assuming a density of 1 mg/ml.

   The volume of the cell pellet should be ~10 ml.
8. Resuspend the cell pellet in 1.5 times its volume of hypotonic lysis buffer (~15 ml) and swell on ice for 10 min.
9. Homogenize cells with ~110 strokes of a 40-ml Wheaton Dounce homogenizer type A (tight). Check cell disruption visually or by dye exclusion using trypan blue (*UNIT 1.1*) after 40, 60, 70, 80, and 100 strokes.

   The goal is to lyse >95% of the cells.
10. Transfer extract to 30-ml glass centrifuge tube. Remove cell debris and nuclei by centrifuging 5 min at $640 \times g$ for 5 min and then increasing the speed to $10{,}400 \times g$ for an additional 20 min to remove mitochondria.

    The supernatant should be cloudy.
11. Carefully remove the upper white lipid layer if it is present.

    This lipid material inhibits translation.

Prepare extract

12. Dialyze the extract for 2 to 3 hr in two collodion dialysis bags (8 ml, MWCO 12 kDa) against 1 liter of dialysis buffer to clean and replace buffer.
13. Transfer extract into a 30-ml glass centrifuge tube and centrifuge 10 min at $12{,}100 \times g$. Carefully remove the upper white layer.
14. Remove 2 µl of extract and determine the protein concentration using the Bradford reagent (*APPENDIX 3B*). Use BSA to create a standard curve.

    Typical extracts have protein concentrations of 20 to 30 mg/ml.
15. Transfer 380-µl aliquots of extract to 2-ml screw-cap cryogenic tubes with O-rings and freeze and store in liquid nitrogen.

Prepare for translation reactions

16. Prepare translation mix, aliquot, and store at −80°C.
17. Autoclave 1-ml Dounce homogenizer and place at 4°C overnight.

Prepare extract for translation

18. Partially thaw vial containing 380 µl of HeLa extract in hand and place on ice.
19. (*Optional*) Treat extract with calcium-dependent micrococcal nuclease. Add 10 µl 0.1 M $CaCl_2$ and 2 µl of 1 mg/ml micrococcal nuclease to 380 µl of extract. Mix by pipeting gently up and down. Incubate 15 min at 25°C.

    Optimal micrococcal nuclease concentration may vary with different suppliers and different lots (see Critical Parameters).
20. Place extract on ice and add 15 µl of 0.2 M EGTA to chelate Ca^{2+} and inactivate the nuclease.

21. If micrococcal nuclease treatment is not performed, add 10 µl of 0.1 M $CaCl_2$, 15 µl of 0.2 M EGTA, and 2 µl of DEPCW in place of nuclease.

Perform in vitro translation

22. Add 70 µl of translation mix. For internal ribosome entry site (IRES)-dependent translation add 30 µl of 1 M KOAc (pH 7.5) and 60 µl of 10 mM $Mg(OAc)_2$. For non-IRES-dependent translation add 47 µl of 2 M KOAc (pH 7.5), 30 µl of 10 mM $Mg(OAc)_2$, and 13 µl of DEPCW.

    Optimal KOAc and $Mg(OAc)_2$ concentrations may vary for different mRNAs.

23. For non-radioactive assays add 7 µl of 1 mM methionine and 7 µl of DEPCW. For radioactive assays add 14 µl (15 mCi/µl) of [^{35}S]methionine.

24. Transfer extract to a 1-ml Wheaton Dounce homogenizer and homogenize with 15 strokes at 4°C.

25. Transfer the translation extract to a 1.5-ml microcentrifuge tube and microcentrifuge 10 min at 10,000 × *g* (e.g., 11,000 rpm in an Eppendorf model 5415C centrifuge), 4°C. Remove the upper white lipid layer.

26. Transfer extract to a clean 1.5-ml microcentrifuge tube and microcentrifuge again 10 min at 10,000 × *g* and remove the upper white lipid layer.

27. Transfer 22 µl of extract to a new 1.5-ml microcentrifuge tube or microtiter plate containing 3 µl of 150 nM mRNA and 3 µl of DEPCW. Incubate at 30°C for 3 hr.

    Optimal mRNA concentrations may vary for different mRNAs. DEPCW may be replaced with test compound.

    Microtiter plates should be covered to avoid evaporation.

28. Assay translation efficiency by reporter activity or [^{35}S]methionine incorporation (*UNIT 11.2*).

SUPPORT PROTOCOL

PRODUCTION AND PURIFICATION OF mRNA

mRNAs can be produced or purified from cells by a variety of methods. Purification of the mRNA results in higher translation signals and increased reproducibility for independent replicates. mRNA is purified by phenol/choloroform extraction, isopropanol precipitation, and desalting using a Microspin column. The integrity of the mRNA should be verified by agarose gel-electrophoresis prior to use.

Materials

Template: plasmid, synthetic, or PCR-amplified DNA
RNase-free DNase (optional)
0.5 M ammonium acetate
25:24:1 (v/v/v) phenol/chloroform/isoamyl alcohol (IAA)
24:1 (v/v) chloroform/IAA
Isopropanol
Diethylpyrocarbonate-treated H_2O (DEPCW; *APPENDIX 2A*)
10 mg/ml ethidium bromide or Stains-All (Kodak)
Microspin S-400 columns (Pharmacia)

Additional reagents and equipment for production of capped and uncapped mRNAs (*UNIT 11.2*) agarose gel-electrophoresis and spectrophotometric determination of RNA and DNA concentrations (*APPENDIX 3*)

1. Produce preparative amounts of both capped and uncapped mRNAs by transcription from plasmids, synthetic DNA templates, or PCR templates using bacteriophage RNA polymerases (*UNIT 11.2*).

   Large-scale RNA production systems using bacteriophage RNA polymerases are available from Promega and Ambion. mRNAs may also be isolated from cells (UNIT 11.2) or chemically synthesized to a limited degree (Stiege and Erdmann, 1995).

2. (*Optional*) Remove DNA template by treatment with RNase-free DNase (*UNIT 11.2*).

   The presence of template DNA does not affect the translation efficiency or mRNA quantitation.

3. Transfer mRNA to 1.5-ml microcentrifuge tube. Add ammonium acetate to the mRNA to a final concentration of 0.5 M. Remove protein by extraction with 1 vol 25:24:1 phenol/chloroform/IAA followed by extraction with 1 vol 24:1 chloroform/IAA.

4. Precipitate mRNA by adding an equal volume of isopropanol, incubating 15 min at –20°C, and microcentrifuging 15 min at 16,000 × *g* (e.g., 14,000 rpm in an Eppendorf model 5415C centrifuge), 4°C.

5. Remove as much supernatant from the pellet as possible but do not dry the pellet. Resuspend the pellet in 100 µl of DEPCW.

6. Remove salts and nucleotides with a Microspin S-400 column. Resuspend resin by vortexing and pre-spinning column 1 min at 735 × *g* (e.g., 3,000 rpm in an Eppendorf model 5415C centrifuge) to remove storage buffer. Place column in a clean 1.5-ml microcentrifuge tube and load 100 µl of mRNA sample to the top of the resin. Centrifuge 2 min at 735 × *g* to recover mRNA.

7. Quantitate mRNA concentration by absorbance at 260 nm (*APPENDIX 3*) using an extinction coefficient of 25 ml/mg-cm.

   The absorbance of template DNA is typically insignificant compared to the absorbance of mRNA.

8. Resuspend to 150 nM in DEPCW. Confirm integrity of mRNA by agarose gel-electrophoresis (*APPENDIX 3*) and staining with ethidium bromide or Stains-All. Store mRNA up to 1 month at –20°C.

REAGENTS AND SOLUTIONS

*Use DEPC-treated deionized or distilled water in all recipes and protocol steps. For common stock solutions, see **APPENDIX 2A**; for suppliers, see **SUPPLIERS APPENDIX**.*

Dialysis buffer

10 mM HEPES, pH 7.6, from a 1 M stock (see recipe)
90 mM potassium acetate (KOAc)
1.5 mM magnesium acetate [$Mg(OAc)_2$]
Adjust to pH 7.2 with KOH
Filter sterilize
Store overnight at 4°C
Add 1 mM DTT just before use

1 M HEPES, pH 7.6

Add 11.2 g HEPES to 38 ml DEPCW. Adjust solution to pH 7.6 with KOH and final volume to 50 ml with DEPCW.

Hypotonic lysis buffer

10 mM HEPES buffer, pH 7.6, from a 1 M stock (see recipe)
10 mM potassium acetate (KOAc)
1.5 mM magnesium acetate [$Mg(OAc)_2$]
Adjust to pH 7.6 with KOH
Filter sterilize
Store overnight at 4°C
Add 2 mM DTT just before use

Translation mix, 10×

152 mM HEPES, pH 7.6, from a 1 M stock (see recipe)
80 mM creatine phosphate (Boehringer Mannheim), from a 1 M stock
200 µg/ml creatine phosphokinase (Boehringer Mannheim), from a 10 mg/ml stock
8 mM ATP dipotassium salt
480 µM GTP disodium salt
200 µg/ml calf liver tRNA, from a 10 mg/ml stock
100 µM amino acid mix minus methionine, from a 1 mM stock (Promega)
2 mM spermidine
16 mM DTT
diethylpyrocarbonate-treated H_2O (DEPCW; *APPENDIX 2A*)
Aliquot and store for up to 1 year at −80°C

Creatine phosphate and creatine phosphokinase stocks are prepared in DEPCW and stored at −20°C for several months.

Calf liver tRNA is purified by 25:24:1 phenol/chloroform/IAA extraction, 24:1 chloroform/IAA extraction, ethanol precipitation using 0.3 M sodium acetate (NaOAc). Resuspend the pellet to 10 mg/ml in DEPCW and store for up to 1 year at −20°C.

COMMENTARY

Background Information

A variety of mammalian, yeast, plant, and bacterial cell-free extracts have been used to assay translation in vitro (*UNIT 11.1*; Villa-Komaroff et al., 1974; Iizuka and Sarnow, 1997; Jermutus et al., 1998). Cell-free extracts contain ribosomes, translation factors, aminoacyl tRNA synthetases, and other macromolecular components required for translation. Extracts are generally supplemented with amino acids, tRNAs, energy sources, salts, and energy regeneration systems. RRL and HeLa extract are the most commonly used mammalian translation systems. RRL has advantages in that it is simple to use, will translate both capped and uncapped mRNAs, and is commercially available in large amounts. The HeLa cell-free translation system has advantages in that it is more cap-dependent, will translate mRNAs that do not translate well in RRL, and is more likely to represent translation in intact human cells.

HeLa extract has been prepared and used for in vitro translation reactions for over 25 years, using a large variety of protocols (Villa-Komaroff et al., 1974; Celma and Ehrenfeld, 1975; Rose et al., 1978; Lee and Sonenberg, 1982; Molla et al., 1991; Carroll and Lucas-Lenard, 1993). The protocols used to prepare HeLa extract are similar in that they involve growing, collecting, and lysing cells, removing the cell debris, nuclei, and mitochondria, and storing the extract. The protocols differ in the type of serum used to grow the cells (horse, fetal bovine, calf), the cell lysis method (Dounce homogenization or detergent), lysis buffer composition and amount used, and the method used to exchange the buffer (dialysis, column chromatography, or none). In some protocols additional steps (freeze/thaw), treatments (micrococcal nuclease), or reagents (translation mix, buffer, or glycerol) are added before storage. In some cases these protocols fail to consistently produce useable extract, and the translation signals from in vitro translation reactions may vary 2- to 10-fold for independent replicates (Carroll and Lucas-Lenard, 1993; G. Witherell,

unpub. observ.). The method described here is a simplified protocol that saves time, lowers cost, and produces large amounts of HeLa extract. The quality of the HeLa extract produced is consistent from one preparation to another and the translation signals are highly reproducible.

The availability of a highly reproducible HeLa cell-free translation system has many applications in basic research, protein production, and biotechnology. Many of the applications performed with RRL and wheat germ extract (*UNIT 11.1*) have been or could be performed with HeLa extract. These applications include analysis and characterization of molecular interactions, functions, and structure of synthesized proteins. When studying biological processes, HeLa extract provides a translation system that is more cap-dependent, has a higher capacity for faithful initiation at the correct start codon, and is likely to be more predictive of results in intact human cells. HeLa extract has been used to translate mRNAs on a routine basis and is particularly useful for translation of mRNAs that do not translate well in RRL.

Human rhinovirus and enterovirus mRNAs are examples of mRNAs that translate poorly in RRL, producing low yields and a high degree of aberrant translation initiation (Belsham and Sonenberg, 1996; Hunt et al., 1999). Translation initiation of human rhinovirus and enterovirus mRNAs does not occur by a conventional 5′ cap-dependent translation mechanism. Cap-dependent translation, used by the vast majority of cellular mRNAs in eukaryotes, involves the interaction between components of the cell's translation machinery and the m^7G capped 5′ end of the mRNA (Dever, 1999). The m^7G cap, found on all nonorganellar mammalian mRNAs, is added post-transcriptionally. Translation initiation begins with the association of the 43S initiation complex (consisting of the 40S ribosomal subunit, charged initiator tRNA, and several initiation factors) with the m^7G cap structure. The "scanning model" describes the two-dimensional movement of the 43S initiation complex along the RNA, from the 5′ cap to the start codon of the protein coding region (Dever, 1999). To facilitate ribosome scanning, cellular 5′ untranslated regions (5′ UTRs) are typically <100 nucleotides in length, lack extensive secondary structure, and lack non-initiating AUG start codons.

In contrast, human rhinovirus and enterovirus 5′ UTRs lack a 5′ terminal m^7G cap structure, are several hundred nucleotides long, contain a high degree of secondary structure, and contain multiple noninitiating AUG codons preceding the authentic start codon of the polyprotein (Borman and Jackson, 1992). These features preclude ribosomes from binding the 5′ end of the viral RNA and scanning to the polyprotein start codon. Rather than by a scanning mechanism, translation initiation of human rhinovirus and enterovirus mRNAs occurs by a mechanism in which the 43S initiation complex locates the AUG start codon of the protein coding region by binding directly to a region of the viral 5′ UTR termed the internal ribosomal entry site, or IRES (Borman and Jackson, 1992). Human rhinovirus and enterovirus mRNAs can be translated under conditions in which cellular translation is inhibited. In fact, human rhinoviruses and enteroviruses encode a proteinase that is involved in the irreversible inactivation of 5′ end-dependent translation, resulting in shut-off of host cell translation. IRES-dependent translation in these viruses has been shown to require HeLa specific factors that stimulate translation and correct aberrant initiation (Svitkin et al., 1996; Hunt et al., 1999). HeLa extract supports all steps of enterovirus replication including translation, protein processing, RNA replication, and viral assembly and can therefore be used for de novo synthesis of infectious virus (Molla et al., 1991).

The high reproducibility of the HeLa cell-free translation system makes it suitable for high-throughput drug screening. RiboGene has used HeLa extract to identify defined chemical entities, natural product extracts, antisense oligonucleotides, antisense oligoribonucleotides, and RNA decoys that inhibit human rhinovirus and coxsackievirus IRES-dependent translation (G. Witherell, unpub. observ.). RiboGene has also used mRNA translation in HeLa extract as a selectivity assay to identify compounds that specifically inhibit viral, fungal, and bacterial translation systems (G. Witherell, unpub. observ.). Application of the HeLa translation system to screen for inhibitors or stimulators of other viral or cellular idiosyncratic translation mechanisms may lead to the discovery of new drugs for human diseases.

Critical Parameters

There are several critical parameters for the successful preparation of HeLa extract. The growth of the HeLa cells must be strictly maintained between 2×10^5 and 8×10^5 cells/ml. Allowing the cells to become more concentrated or more dilute typically results in less predictable growth cycles and a less efficient extract. Healthy cells should double every 24 to 36 hr.

Cells are grown in iron-supplemented calf serum, rather than fetal bovine serum, to reduce cost. Substitution of fetal bovine serum with iron-supplemented calf serum does not affect cell health or growth of the cells. The night before the preparation is to take place the cells are counted and a calculated amount of fresh medium is added to feed the cells and ensure that they will be at the correct concentration and volume the following morning. In addition, fresh medium is added to ensure that the cells are growing at optimal rates when harvested. Monitor the cell growth carefully and harvest between 4×10^5 and 5×10^5 cells/ml. Failure to adequately lyse the cells by Dounce homogenization, or resuspending the cell pellet in more than 1.5 times the packed-cell volume with hypotonic lysis buffer, results in a low protein concentration and a less active or inactive extract. Dialyzing the extract in collodion bags is preferred over dialysis tubing because they are firm bags that can be suspended in the dialysis beaker, saving significant time and greatly increasing the recovery of extract. Removing the inhibitory white lipid layer before and after dialysis is essential. The extract appears to maintain activity longer with storage in liquid nitrogen than at −80°C. Once the extract is thawed it is best not to reuse it. Each freeze/thaw cycle reduces the activity to approximately one-half the original activity. Extract may be stored as a cocktail with translation mix and salts at −80°C, for a few days or weeks, with little loss of activity.

Obtaining reproducible signals in the in vitro translation reaction requires Dounce homogenizing the translation cocktail and removing the upper white lipid layer in two subsequent centrifuge steps before addition of mRNA. Micrococcal nuclease treatment is not necessary for IRES-dependent translation but may stimulate scanning-dependent translation, depending on the mRNA. The pH of potassium acetate must be adjusted to 7.6 to maintain the pH of the reaction. Incubation temperature is optimal at 30°C, decreasing dramatically if the temperature is increased or decreased only a few degrees. Translation signals tend to be very low during the first hour of incubation, increase linearly over the next 2 hr, plateau at 3 hr, and then decrease after 4 hr. Addition of nuclease inhibitors has little effect on the translation signal, suggesting that the extract is largely nuclease free.

The purity and quality of reagents in the HeLa translation reaction is important. Micrococcal nuclease quality varies greatly between suppliers and even between lots, with some lots unusable due to contamination with other ribonucleases. Therefore, the optimal concentration of micrococcal nuclease must be determined for each supplier and each lot of micrococcal nuclease. Dipotassium ATP is used rather than disodium ATP to avoid high concentrations of sodium that could potentially reduce the translation efficiency of the HeLa extract. However, disodium ATP may be substituted for dipotassium ATP under most translation conditions. Purification of the mRNA and removal of salts with a Microspin column significantly improves the translation signal. Calf liver tRNA must be purified before use.

Suggested translation conditions for viral IRES-dependent translation are 50% (v/v) HeLa extract, 16 nM RNA, 40 mM potassium acetate, and 0.8 mM magnesium acetate for 3 hr at 30°C. Translation conditions for scanning-dependent translation are similar except that 126 mM potassium acetate and 0.4 mM magnesium acetate are suggested. Salts are added in addition to endogenous salts present in the extract. For radioactive assays, ^{35}S-labeled methionine may be substituted with a variety of commercially available labeled amino acids (e.g., Amersham).

During extract preparation, cells, extract, and all solutions and apparatus coming in contact with cells or extract, should be kept at 4°C unless otherwise specified. Latex or polyvinyl chloride gloves should be worn when handling extract, and only DEPCW used in buffers and reactions, to avoid contamination with ribonucleases.

Troubleshooting

A poor translation signal can typically be overcome by optimizing the translation conditions. Different mRNAs may require dramatically different translation conditions. The most critical factors for optimizing translation are Mg^{2+}, K^+, and mRNA concentrations.

The absence of a translation signal is typically due to degradation of the mRNA, an impaired energy regeneration system, or low protein concentration in the extract. Sources for ribonucleases include water, micrococcal nuclease stocks, and hands. An impaired energy regeneration system can typically be overcome with a new stock of creatine phosphokinase.

Anticipated Results

The yield of final extract should be ~10 to 15 ml per 6 liters of cells. Successful extracts contain between 20 and 30 mg/ml of protein. There is a positive correlation between protein concentration and translation efficiency.

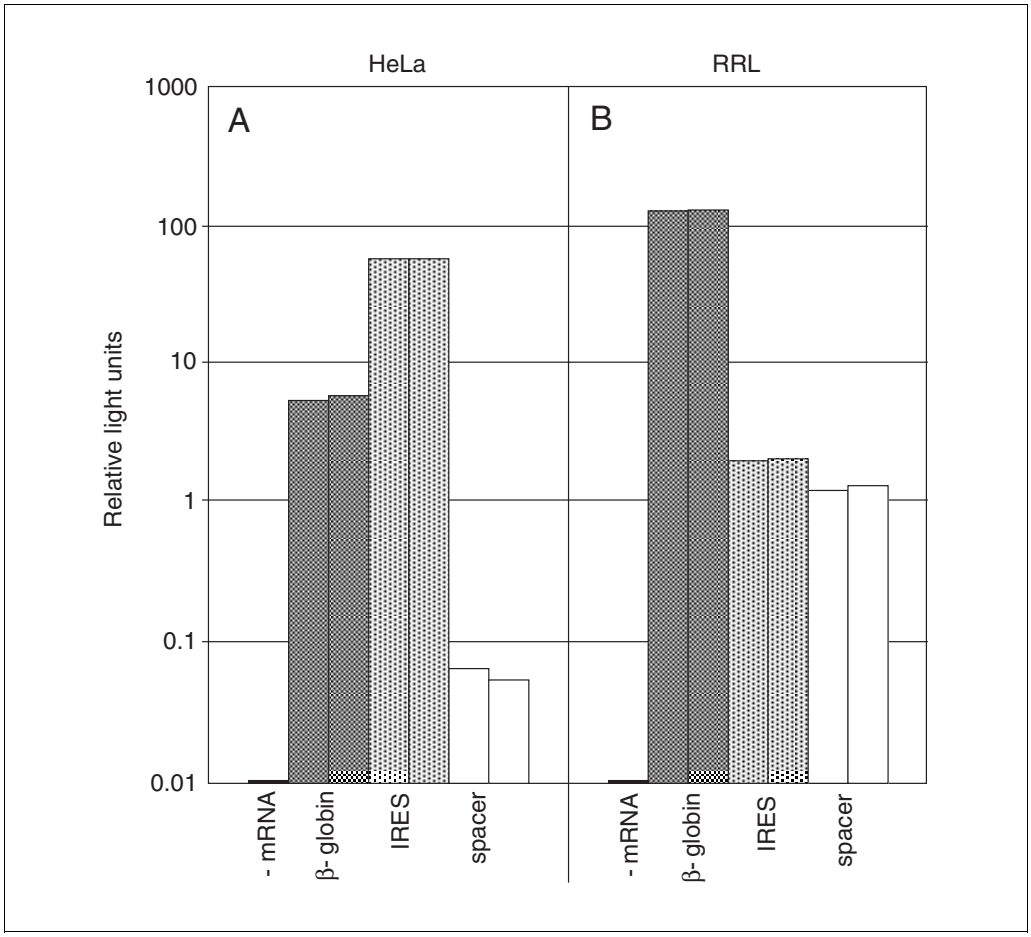

Figure 11.8.1 HeLa extract supports both viral IRES-dependent and human scanning-dependent translation. (**A**) HeLa in vitro translation reactions were performed as described in the Basic Protocol. (**B**) RRL translation reactions were performed as described previously (Witherell et al., 1995). Luciferase activity in relative light units (RLUs) was quantitated as a measure of translation. Translation reactions of luciferase driven by the β-globin 5′ UTR (β-globin), rhinovirus IRES (IRES), and a nonfunctional spacer sequence (spacer) are shown. A control reaction was performed in the absence of mRNA (–mRNA). RRL, rabbit reticulocyte lysate.

HeLa extract translates both scanning-dependent and IRES-dependent mRNAs (see Fig. 11.8.1). Translation of a monocistronic mRNA containing the human β-globin 5′ untranslated region (5′ UTR) driving translation of the luciferase reporter gene was used to represent human scanning-dependent translation. Translation of a dicistronic mRNA containing the human rhinovirus IRES (Borman and Jackson, 1992) driving translation of the luciferase reporter gene was used to represent viral IRES-dependent translation. A control dicistronic mRNA containing a non-functional spacer sequence in place of the rhinovirus IRES was used as a control mRNA. Uncapped mRNAs were prepared by in vitro transcription with T7 RNA polymerase using the MEGAscript kit (Promega) and purified as described in the Support Protocol. HeLa extract was prepared and in vitro translation reactions performed as described in the Basic Protocol. After incubation, luciferin reagent (Analytical Bioluminescence) was added and the relative light units (RLUs) quantitated using a Dynatech ML3000 luminometer. Luciferase activity was used as a direct measure of translation, and results were confirmed with a [^{35}S]-methionine incorporation assay (data not shown).

The HeLa cell-free translation system provides efficient and highly reproducible signals for both IRES- and scanning-dependent translation. Luciferase signals obtained from in vitro translation reactions were highly reproducible, with <5% variation for independent replicates (Fig. 11.8.1A). This degree of reproducibility is comparable to that of RRL (Fig. 11.8.1B). In vitro translation reactions using HeLa extract produced high luciferase activity from mRNAs containing the rhinovirus IRES and β-globin 5′ UTR (Fig. 11.8.1A). Translation driven by the

rhinovirus IRES was greater than 10,000-fold above background (Fig. 11.8.1A; compare IRES to −mRNA) and 1000-fold above translation driven by the nonfunctional spacer sequence (Fig. 11.8.1A; compare IRES to spacer) The low translation signal produced with the spacer sequence is likely due to a low level of aberrant initiation in the HeLa extract. These results demonstrate that the rhinovirus IRES is functional in HeLa extract. As expected, the rhinovirus IRES was not functional in RRL, producing a translation signal similar to that of the spacer sequence (Fig. 11.8.1B; compare IRES to spacer). RRL is known to lack certain factors required for rhinovirus IRES-dependent translation (Hunt et al., 1999). Translation driven by the spacer sequence was 20-fold higher in RRL than in HeLa extract (compare spacer in Fig. 11.8.1A to Fig. 11.8.1B), demonstrating that RRL initiates translation at incorrect start codons far more often in RRL than HeLa extract. Translation driven by the β-globin 5′ UTR in HeLa extract was greater than 1000-fold above background (Fig. 11.8.1A; compare β-globin to −mRNA), but 10-fold lower than rhinovirus IRES-dependent translation (Fig. 11.8.1A; compare β-globin to IRES). This was not surprising since the translation conditions were optimized for IRES-dependent translation rather than scanning-dependent translation. In addition, HeLa extract contains factors that limit translation of uncapped (non IRES-dependent) mRNAs (Svitkin et al., 1996). The translation signal produced by the β-globin 5′ UTR is far higher when capped mRNA and optimized conditions are used (data not shown). Translation of luciferase driven by the β-globin 5′ UTR was stimulated 26-fold in RRL compared to HeLa extract (compare β-globin in Fig. 11.8.1A to Fig. 11.8.1B). This result is consistent with the increased ability of uncapped mRNAs to translate in RRL (Svitkin et al., 1996).

Time Considerations

It takes ~4 days to grow the HeLa cells to 6 liters from a 400-ml starter culture. Preparation of the extract takes ~6 hr. Translation reactions take ~1 hr to set up followed by a 3-hr incubation.

Analysis of Eukaryotic Translation in Purified and Semipurified Systems

This unit describes analysis of eukaryotic translation in purified and semipurified systems. Sucrose gradients are used to separate ribosomal complexes to analyze eukaryotic translation by reconstituting the steps in initiation (see Basic Protocol 1 and Alternate Protocols 1 and 2). While gel-filtration chromatography is excellent for resolution of low-molecular-weight components (M_r <50,000 Da), sucrose gradients are most useful with high-molecular-weight complexes, often in excess of 1,000,000 Da. The large size of ribosomes has made sucrose gradients the method of choice for purification of ribosomes and ribosomal subunits. More importantly, this method has also proven highly useful for analyzing the formation of intermediates in translation initiation and identifying the protein translation factors associated with initiating ribosomes. Much of the current understanding of the sequential steps involved in translation initiation has been obtained by utilizing sucrose gradients in conjunction with purified translation factors to analyze translation in vitro.

Sucrose gradients are useful for other purposes as well. Because they provide an entirely liquid system, losses due to the sticking of material to a solid matrix are nonexistent. Thus, the gradients may be used in a preparative manner (see Support Protocol 1). Determining relative sedimentation coefficients can be accomplished by using analytical sucrose gradients (see Support Protocol 2).

Sucrose gradients have also been widely used to study translational regulation in intact cells. Interpretation rests on the assumption that the distribution of an mRNA in different complexes (e.g., polysomes versus free mRNP) is a reflection of the rate-limiting step for translation. For most situations, initiation is the affected step and the association of mRNA with polyribosomes is affected (Hershey, 1991; see Basic Protocol 2 and Alternate Protocol 3). Ribosomal complexes fron cultured cells can also be purified for biochemical studies (see Basic Protocol 2 and Alternate Protocol 4). Yeast cells can also be used as source material (see Support Protocol 3).

A term that is often associated with sucrose gradients is density (as in sucrose density gradients), which is misleading. For the experiments described in this unit, density is not a consideration. The materials to be separated are either proteins, RNA, or both, and as such will all pellet if the centrifugation is carried out long enough. Thus, an early consideration is the type of gradient (i.e., 5% to 20% versus 10% to 40% sucrose) and the length of time that centrifugation will be necessary (3 to 24 hr). The advantage of gradients that have a linear increase in sucrose concentration is that, due to the retarding effects of both the density and the viscosity of the solution, the distance a particle sediments is linear with time. Thus, if an 80S particle has traveled a third of the way down the gradient in time t, then in time $2t$ the particle will have traveled twice as far. This facilitates fine tuning of the time required for optimal resolution of components. However, the optimal time must be determined empirically for each rotor and bucket, even when identical g forces are considered, due to variability in length of centrifuge tubes.

The protocols in this unit are primarily focused on the sedimentation of large particles (>40S), although they could be adapted for smaller ones (4S to 25S; see Support Protocol 1). The two Basic Protocols focus on in vitro experiments with particles of 40S to 80S (see Basic Protocol 1) and on the analysis of particles from cultured cells, which range in size from 40S to 300S (see Basic Protocol 2). Basic Protocol 1 has been the primary method for analysis of intermediate steps in the formation of eukaryotic 80S initiation complexes, which contain 40S and 60S subunits, mRNA (or AUG codon), and Met-tRNA$_i$. Basic Protocol 2 has been used to study cell culture systems and ascertain under specific

Current Protocols in Cell Biology (2000) 11.9.1-11.9.26

conditions whether there has been a change in the initiation or elongation rate of protein synthesis. At the same time, this protocol also allows one to determine if there has been a selective change in the distribution of various mRNAs in polysomes.

CAUTION: When working with radioactivity, take appropriate precautions to avoid contamination of the experimenter and the surroundings. Carry out the experiment and dispose of wastes in appropriately designated areas, following the guidelines provided by the local radiation safety officer (also see *APPENDIX 1D*).

NOTE: Diethylpyrocarbonate (DEPC)-treated water (*APPENDIX 2A*) should be used for all protocols in this unit.

BASIC PROTOCOL 1

IDENTIFYING INTERMEDIATES IN THE FORMATION OF PROTEIN SYNTHESIS INITIATION COMPLEXES

Sucrose gradients have been a key methodology to analyze the binding of Met-tRNA$_i$, mRNA, and factors to 40S and 80S ribosomes because of the resolving power achieved. Free components are resolved from either of several 40S complexes (40S, 43S, and 48S; see Alternate Protocol 1), 60S, or 80S complexes (see Alternate Protocol 2). No other technique accomplishes this resolution. The procedure below describes an example of the methodology for isolation of a 43S complex (40S subunits bound to eIF2, eIF3, AUG, and Met-tRNA$_i$, but not mRNA); with some simple modifications, 48S or 80S complexes can be identified in a similar manner. For the preparation of [^{3}H]Met-tRNA$_i$, eukaryotic initiation factor 2 (eIF2), and eIF3, see Merrick (1979a,b) and Grifo et al. (1983) and references therein.

Materials

10% and 40% (w/v) sucrose gradient solutions (see recipe)
1 M Tris·Cl, pH 7.5 (*APPENDIX 2A*)
1 M KCl
100 mM $MgCl_2$ (see recipe)
100 mM dithiothreitol
100 A_{260} units/ml AUG
100 mM GTP (see recipe)
150 mM phosphoenolpyruvate
3000 IU/ml pyruvate kinase
10 µM [^{3}H]Met-tRNA$_i$ (15 Ci/mmol)
16 µM 40S subunits (see Support Protocol 1)
8 µM eucaryotic initiation factor 2 (eIF2)
15 µM eIF3
Aqueous scintillation solution (e.g., Ecoscint, National Diagnostics)
10% (w/v) trichloroacetic acid (TCA) solution, ice cold
Acetone
SDS sample buffer (see recipe)

Gradient maker
Refrigerated high-speed centrifuge (e.g., Beckman L7-55)
Swinging bucket rotor and appropriate tubes (e.g., Beckman SW56 rotor with 5-ml tubes)
UV absorbance detector and chart recorder
Syringe or peristaltic pump
Fraction collector (e.g., ISCO model 640 gradient fractionator)
90°C oven or heating block

Additional reagents and equipment for SDS-PAGE (*UNIT 6.1*)

1. Use a gradient maker to prepare linear 10% to 40% sucrose gradients in 5-ml SW56 centrifuge tubes. Use 2.5 ml each of 10% and 40% sucrose gradient solutions to prepare the gradient. Fill the tubes to within ¼ inch (6.4 mm) from the top (see Fig. 5.3.1). Keep gradients at 4°C.

   It is important to have the tube filled nearly to the top, as tubes that are only 80% filled tend to collapse. To determine the correct volumes for other tubes, fill a tube with water to within ¼ inch and measure the volume contained.

   The gradients may be stored overnight at 4°C prior to use. It is important that the gradients be cold at the beginning of the experiment.

2. Combine the following components in a reaction mixture (100 µl total):

   2 µl 1 M Tris·Cl, pH 7.5 (final 20 mM)
   10 µl 1 M KCl (final 100 mM)
   3 µl 100 mM $MgCl_2$ (final 3 mM)
   1 µl 100 mM dithiothreitol (final 1 mM)
   2 µl 100 A_{260} units/ml AUG (final 0.2 units)
   0.8 µl 100 mM GTP (final 0.8 mM)
   2.7 µl 150 mM phosphoenolpyruvate (final 4 mM)
   0.15 µl 3000 IU/ml pyruvate kinase (final 0.5 IU)
   3 µl 10 µM [^{3}H]Met-tRNA$_i$ (30 pmol)
   2 µl 16 µM 40S subunits (30 pmol)
   6 µl 8 µM eIF2 (50 pmol)
   7 µl 15 µM eIF3 (100 pmol).

   Incubate 15 min at 30°C and then chill on ice.

   While the inclusion of most of the above ingredients is standard, the inclusion of phosphoenolpyruvate and the enzyme pyruvate kinase are not. These two components make up an energy regenerating system that converts any GDP to GTP (i.e., phosphoenolpyruvate + GDP → pyruvate + GTP). This is important for translation initiation experiments, as eIF2 has a 100-fold higher affinity for GDP than GTP. Therefore, any GDP present in the original GTP stock solution or generated during the incubation is quite inhibitory.

   It was experimentally determined that the inclusion of 0.1 mM GDPNP in the gradients improved the yield of 43S complexes. The rationale is that GTP is lost from the ternary complex at a slow rate. This loss labilizes the Met-tRNA$_i$, and it dissociates from the 40S subunit. By having guanylyl-5′-imidodiphosphate (GDPNP; Calbiochem) or GTP in the gradient, the complex of eIF2·Met-tRNA$_i$ is able to bind GDPNP (or GTP) and reform the ternary complex, which is more stably bound to the 40S subunit.

3. Carefully layer the chilled reaction mixture onto the top of the 10% to 40% sucrose gradient and carefully place the tube in the rotor. Make sure the tubes are balanced in the rotor. Centrifuge gradients 150 min at 270,000 × *g* (55,000 rpm in SW56 rotor), 4°C.

   To avoid disturbing the gradients, great care should be taken when buckets are placed in and removed from the rotor, and when the rotor is placed in and removed from the centrifuge.

   If the number of samples is less than the number of positions in the rotor, all of the other positions must be occupied by similar gradients in buckets, but lacking a sample for analysis.

   Slow acceleration should be used if the centrifuge has that capability. Too fast of an acceleration causes mixing of the sample with the gradient or loss out of the tube. At the end of the run, normal braking is slow enough to not disturb the gradients (i.e., it is not necessary to coast to a stop).

If an SW56 swinging bucket rotor is not available, it is possible to calculate conditions for other rotors. For rotors with the same size bucket (4.4 to 5 ml; e.g., Beckman SW65L, SW50L, SW39L, SW60Ti, SW50.1), the relative k factor can be used to correct for time and speed (see Beckman Instruments, http://beckmancoulter.com; McEwen, 1967). The general formula is: (time × rpm of SW56)/SW56 k factor = (time × rpm of other rotor)/k factor of other rotor, where the k factor of the SW56 rotor is 55. Thus, to find the equivalent centrifugation using an SW39L rotor (k = 112), the calculation would be: (150 min × 55,000 rpm)/55 = (x min × 39,000 rpm)/112, giving x = 431 min. For centrifugation using alternate sucrose gradients, see McEwen (1967).

4. Carefully take the rotor out of the centrifuge, remove tubes, and place the tubes on ice.

   Warming causes thermal mixing and adversely affects the resolution of the gradients.

5. Unload samples from the tube by one of two alternative methods shown in Figure 11.9.1. In either case, use an in-line UV absorbance detector and chart recorder to monitor absorbance, and collect ~20 to 30 fractions (e.g., twenty-five 200-µl fractions) with a fraction collector.

   The tRNA and ribosomal RNAs will show up well by monitoring absorbance at 254 or 260 nm.

   At this point, the radioactivity in each fraction can be determined (step 6a). Alternatively, the location of eIF2 and eIF3 proteins can be determined by SDS-PAGE (steps 6b to 9b).

To measure radioactivity

6a. Mix 100 µl of each fraction with 5 ml of an aqueous scintillation solution and measure radioactivity by scintillation spectrometry (see Fig. 11.9.2).

   For the above example, two peaks of radioactivity should be observed, one of low molecular weight representing free [^{3}H]Met-tRNA$_i$ and a second, more rapidly sedimenting peak representing the labeled 43S complex (40S subunits, eIF2, GTP, Met-tRNA$_i$, eIF3, AUG).

To detect proteins

6b. Mix a 50- to 100-µl aliquot from each fraction with 1 ml ice-cold 10% TCA solution in a microcentrifuge tube and incubate 30 min on ice to precipitate the protein.

7b. Pellet protein by microcentrifuging 20 min at 10,000 × *g*, 4°C.

8b. Discard supernatant, wash pellet twice with 1 ml acetone to remove residual TCA, and allow to dry.

9b. Add 20 µl SDS sample buffer to the pellet, mix, heat 10 min at 90°C, and then analyze by SDS-PAGE (*UNIT 6.1*; Laemmli, 1970).

   If the sample is yellow in color, not all of the trichloroacetic acid was removed. Add 1 to 3 µl of 1 M Tris·Cl, pH 8, until the sample is blue.

   The peptide bands diagnostic for each factor can be visualized after the gel has been stained with Coomassie blue (UNIT 6.5). In general, only those peptide bands that are >40 kDa can be visualized in the 43S region of the gradient, as the 40S subunit has numerous subunits with molecular weights generally <40 kDa.

   An alternate approach to identify the proteins of interest is possible if antibodies are available. The proteins are transferred to a nitrocellulose or polyvinylidene difluoride (PVDF) membrane (immunoblotting; UNIT 6.2). The fractions containing the protein of interest are identified using standard methods for antibody binding and detection.

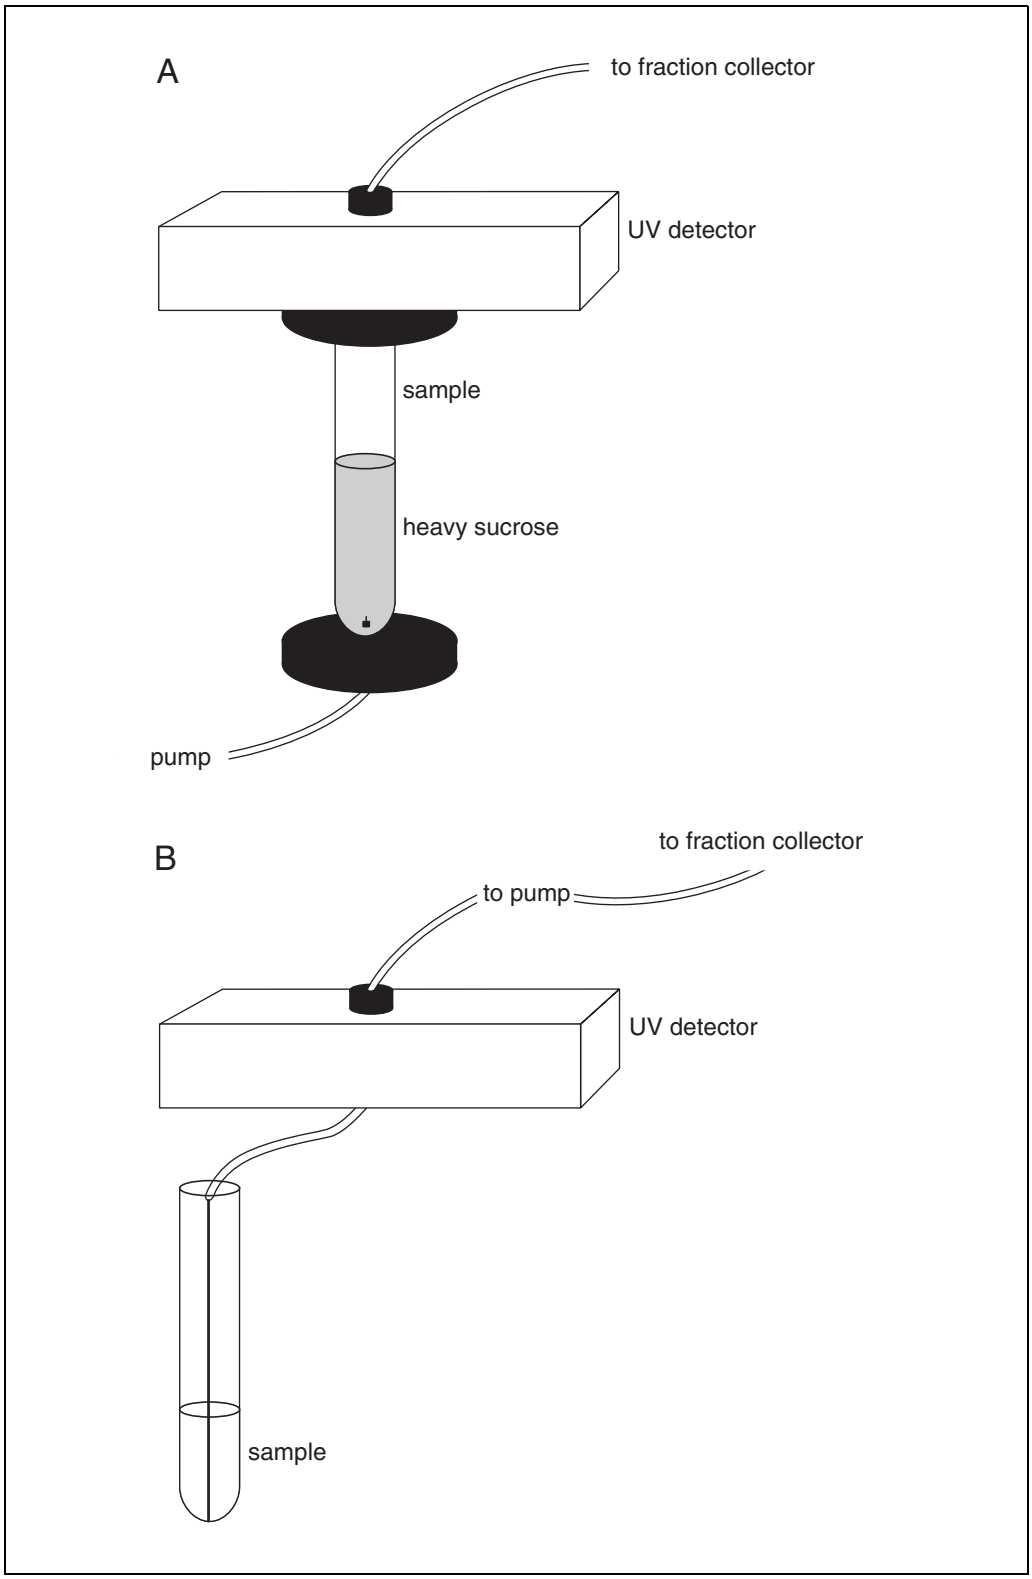

Figure 11.9.1 Methods for collecting sucrose gradients. In the example shown in (**A**), the top of the centrifuge tube is fitted into an adaptor that fits into the UV detector. A dense sucrose solution (i.e., >50% w/v) is introduced into the bottom of the centrifuge tube with the aid of a tube-piercing apparatus that seals the bottom of the tube. As the heavy sucrose is introduced, the gradient is displaced upwards through the UV detector and then to a fraction collector. In the example shown in (**B**), a thin metal tube is carefully inserted to the bottom of the centrifuge tube. The sample is pumped out of the bottom of the tube, through the UV detector, and then to the fraction collector.

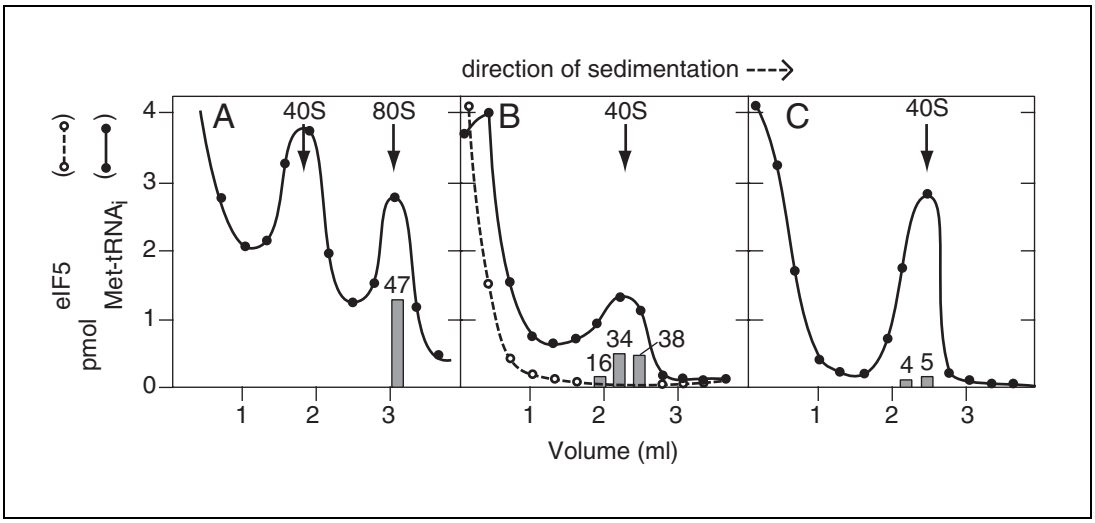

Figure 11.9.2 Reactivity of Met-tRNA$_i$ bound to 40S and 80S initiation complexes. In this experiment, eIF2, eIF3, AUG, GTP, [^{3}H]Met-tRNA$_i$, and 40S subunits were incubated 15 min at 30°C in a 100-µl volume. After incubation, the reaction was layered onto a 10% to 35% sucrose gradient (buffered in 20 mM Tris·Cl, pH 7.5, 100 mM KCl, and 5 mM $MgCl_2$). After centrifugation at 55,000 rpm at 4°C for 140 minutes, the gradients were fractionated (250-µl fractions) by displacement with 40% sucrose (Fig. 11.9.1A). Aliquots were sampled for radioactivity (closed circles) and for reactivity of Met-tRNA$_i$ with puromycin (expressed as a percentage of cpm bound Met-tRNA$_i$, shaded bars). (**A**) Also included in the incubation were eIF5 and 60S subunits. (**B**) [^{14}C]eIF5 (open circles) was present in the incubation; 60S subunits were added to test for reactivity with puromycin. (**C**) GDPNP replaced GTP in the incubation; eIF5 and 60S subunits were added to test for reactivity with puromycin. (Adapted from Peterson et al., 1979b.) This figure represents an experiment where different complexes are resolved by sucrose gradients. Met-tRNA$_i$, present in all experiments, was monitored by liquid scintillation spectrometry. The ability of bound Met-tRNA$_i$ to form methionyl-puromycin was determined separately. Previous studies had shown that formation of methionyl-puromycin required 40S and 60S subunits, AUG, eIF2, eIF3, eIF5, and Met-tRNA$_i$. eIF1A and eIF5A stimulate this process as well.

ALTERNATE PROTOCOL 1

FORMATION OF 48S PREINITIATION COMPLEXES

Using the same sucrose gradients, a variety of other components can be added to determine their influence on the binding of tRNA and mRNA to 40S subunits to form 48S preinitiation complexes (Benne and Hershey, 1978; Merrick, 1992). These include the substitution of globin mRNA (or an mRNA transcript of choice made with T7 polymerase) for AUG, the addition of ATP (required to obtain binding of mRNA to 40S subunits), or the addition of other translation initiation factors (most importantly eIF4A, eIF4B, eIF4F, and eIF4H to obtain maximal binding of mRNA to 40S subunits). As long as 60S subunits are not added, all of the products should be either free components or components bound to 40S subunits. Depending on additions, the 40S complexes could have the following characteristics: (1) 40S subunits: no factors, Met-tRNA$_i$, or mRNA are bound; (2) 43S complexes: eIF2, eIF3, AUG, and Met-tRNA$_i$ are bound, but not mRNA; (3) 48S complexes: eIF2, eIF3, mRNA, and Met-tRNA$_i$ are bound. The procedure is identical to that in Basic Protocol 1, except that the reaction in step 2 is replaced with the one in step 2a below.

Additional Materials *(also see Basic Protocol 1)*

1 M KCl
1 M Tris·Cl, pH 7.5 (*APPENDIX 2A*)
100 mM dithiothreitol

2a. Prepare a reaction for formation of 48S complexes (total 100 µl):

2 µl 16 µM 40S subunits (40 pmol)
3 µl 10 µM [^{3}H]Met-tRNA$_i$ (30 pmol)
7 µl 15 µM eIF3 (100 pmol)
6 µl 8 µM eIF2 (50 pmol)
3 µl 100 A_{260} units/ml of AUG (0.3 units)
10 µl 1 M KCl
2 µl 1 M Tris·Cl, pH 7.5
1 µl 100 mM dithiothreitol
4 µl 100 mM $MgCl_2$
1 µl 100 mM GTP
61 µl H_2O.

Incubate 15 min at 30°C and then chill on ice.

It has been the authors' experience that, when using purified translation factors and 40S subunits, factors other than eIF2 and eIF3 are not found associated with the above complexes. However, since their initial purification is based on their association with polysomes, it is likely that either the ribosomal subunits are damaged or that an unidentified factor that stabilizes the association of these other factors with the 40S subunit is lost during purification.

If the presence of mRNA in the 48S complexes is to be studied, 10 µl of a 100 µg/ml solution of mRNA and 1 µl of 100 mM ATP should be substituted for the AUG codon. In addition, translation factors eIF4A, eIF4B, and eIF4F should be added (Merrick, 1979a; Grifo et al., 1983).

FORMATION OF 80S INITIATION COMPLEXES

ALTERNATE PROTOCOL 2

When 60S subunits are also added, it is possible to obtain complexes that contain 40S subunits, 60S subunits, or 80S subunits. The gradient conditions described above should allow the separation of all of these complexes. Polysomes, if formed, will be found pelleted at the bottom of the tube. If the original reaction mixture contains GDPNP, then no 80S complexes will be seen, and usually more 40S complexes are seen than with GTP. In the presence of GTP, 43S (with AUG) or 48S (with mRNA) complexes may be converted to 80S complexes (40S and 60S subunits, mRNA, Met-tRNA$_i$) if eIF1A, eIF5, and eIF5A (Merrick, 1979a; Grifo et al., 1983) are present in the original reaction mixture. The isolated 80S complexes should be reactive with puromycin to form methionyl puromycin (see Fig. 11.9.2).

Additional Materials *(also see Basic Protocol 1)*

16 µM 60S subunits (see Support Protocol 1)
70 µM eucaryotic initiation factor 1A (eIF1A)
70 µM eIF5A
20 µM eIF5
1 M Tris·Cl, pH 7.5 (*APPENDIX 2A*)
1 M KCl
100 mM dithiothreitol
100 mM KPO_4, pH 8.0
Ethyl acetate
Scintillation solution (e.g., Econofluor)

13 × 100–mm test tubes
Scintillation vials

Separate and analyze complexes

1. Prepare 10% to 40% sucrose gradients in 5-ml SW56 tubes (see Basic Protocol 1, step 1).

2. Prepare a reaction for the formation of 80S complexes (total 100 µl):

   2 µl 16 µM 40S subunits (final 40 pmol)
   2 µl 16 µM 60S subunits (final 40 pmol)
   3 µl 10 µM [^{3}H]Met-tRNA$_i$ (final 30 pmol)
   7 µl 15 µM eIF3 (final 100 pmol)
   6 µl 8 µM eIF2 (final 50 pmol)
   0.7 µl 70 µM eIF1A (final 50 pmol)
   0.7 µl 70 µM eIF5A (final 50 pmol)
   0.5 µl 20 µM eIF5 (final 10 pmol)
   3 µl 100 A_{260} units/ml AUG (final 0.3 units)
   2 µl 1 M Tris·Cl, pH 7.5
   10 µl 1 M KCl
   1 µl 100 mM dithiothreitol
   4 µl 100 mM $MgCl_2$
   1 µl 100 mM GTP
   57 µl H_2O.

   Incubate 15 min at 30°C and then chill on ice.

3. Separate subunits and analyze radioactivity as described (see Basic Protocol 1, steps 3 to 6a).

   If desired, protein content may be determined for factions at this point.

Determine puromycin reactivity of peaks

4. Mix 100 µl of each fraction in a 13 × 100–mm test tube with 100 µl reaction buffer II (200 µl total). Incubate 15 min at 37°C.

5. Terminate reaction by sequential addition of 0.9 ml of 100 mM KPO_4, pH 8.0, and 3 ml of ethyl acetate. Vortex vigorously for 30 sec.

6. Separate aqueous and organic phases by centrifuging 10 min at 1000 × *g* (~2000 rpm), room temperature, in a tabletop centrifuge.

7. Carefully remove 2 ml of the organic phase (upper phase, containing the product methionylpuromycin) to a scintillation vial. Add 10 ml scintillation solution and measure radioactivity by scintillation spectrometry.

   The reactivity of the [^{3}H]Met-tRNA$_i$ in the 80S peak can be determined from the ratio of the amount of radioactivity obtained as methionylpuromycin relative to the radioactivity added to the reaction mixture in step 4 (equal to the radioactivity of the 100-µl aliquot measured in step 3).

SUPPORT PROTOCOL 1

ISOLATION OF RIBOSOMAL SUBUNITS USING PREPARATIVE SUCROSE GRADIENTS

The standard preparative use of sucrose gradients is for the isolation of 40S and 60S ribosomal subunits (Merrick, 1979b), although any macromolecular component with an S value of 10S or larger may be a candidate for purification by this method.

Materials

Rabbit reticulocyte lysate (Green Hectares)
Standard sucrose solution (see recipe)
KCl
Subunit buffer (see recipe)
5% and 20% (w/v) sucrose gradient solutions (see recipe)
0.25 M sucrose solution (see recipe)

Refrigerated high-speed centrifuge (e.g., Beckman L7-55)
Type 35 rotor and 70-ml polycarbonate centrifuge tubes (Beckman)
Ti60 or Ti70 rotor and 26-ml polycarbonate centrifuge tubes (Beckman)
Gradient maker
SW27 rotor and 32-ml polyallomer or cellulose nitrate centrifuge tubes (Beckman)

Prepare salt-washed ribosomes

1. In 70-ml polycarbonate centrifuge tubes for a Beckman type 35 rotor, centrifuge 420 ml rabbit reticulocyte lysate 4 hr at ~100,000 × *g* (35,000 rpm), 4°C.
2. Decant and discard supernatant. Rinse the surface of the polysomal pellets once with 3 ml standard sucrose solution.
3. Add 5 ml standard sucrose solution to each tube and tease the pellet using a glass stirring rod to give a solution of dissolved and partially dissolved polysomes.
4. Transfer contents of all tubes to a beaker in ice with a stir bar. Stir the polysome solution until all of the particles have dissolved (no more than 30 min).
5. Measure the volume of the polysome solution and add solid KCl to a final concentration of 0.5 M. Stir 30 min until KCl has dissolved completely.
6. Pour into 26-ml polycarbonate centrifuge tubes for a Ti60 or Ti70 rotor. Centrifuge 2 hr at 180,000 × *g* (50,000 rpm in Ti60 or Ti70 rotor), 4°C.
7. Decant supernatant and save as an enriched source of protein synthesis initiation factors (Merrick, 1979a). Store frozen at −120°C until needed (stable up to several years).
8. Dissolve pellet in a minimal amount of standard sucrose solution.

   This dissolved pellet is referred to as "salt-washed ribosomes." They may be stored frozen at −120°C.

Prepare ribosomal subunits

9. Dissolve salt-washed ribosomes in sufficient subunit buffer to achieve a concentration of 50 A_{260} units/ml.
10. Incubate 10 min on ice and then 10 min at 37°C.

    Puromycin causes release of the nascent peptide chains that stabilize ribosomal subunit interactions in translating polysomes during the initial high-salt wash. Release of the nascent chains followed by exposure to high salt causes the 80S ribosomes to dissociate into the 40S and 60S subunits.

11. Prepare 5% to 20% sucrose gradients in 32-ml SW27 polyallomer centrifuge tubes as described above (see Basic Protocol 1, step 1).
12. Layer 2- to 3-ml samples onto sucrose gradients and centrifuge 8 hr at 95,000 × *g* (27,000 rpm in SW27 rotor), 4°C.

13. Collect the gradients in sixty 0.5-ml fractions, monitoring A_{260} with a UV detector.

    The region used to obtain 40S subunits represents the front two-thirds of the 40S peak, while the region used for 60S subunits represents the middle half of the 60S peak. In this manner, 40S subunits are not contaminated with 60S subunits and 60S subunits are not contaminated with either 40S subunits or 80S subunits.

14. Concentrate individual subunits by centrifuging 18 hr at 170,000 × *g* (50,000 rpm in a Ti60 rotor), 4°C.

15. Dissolve pelleted subunits in a minimal amount of 0.25 M sucrose solution. Once the pellets are dissolved, determine the concentration of the subunits and adjust to 16 µM (135 A_{260} units/ml for 40S subunits and 270 A_{260} units/ml for 60S subunits). Store in 100-µl aliquots at the vapor temperature of liquid nitrogen for up to 2 years.

ALTERNATE PROTOCOL 3

MONITORING THE POSITION OF THE RIBOSOME ON GLOBIN mRNA

This protocol describes a method called "toeprinting" that is used for locating the position of the mRNA on the 40S subunit. For this assay (Anthony and Merrick, 1992), the mRNA of interest is hybridized to a radiolabeled oligonucleotide (≥20 nucleotides) that is complimentary to a region of the mRNA located ~50 nucleotides 3′ of the initiating AUG. In this case, the reaction is described for globin mRNA as an example.

Additional Materials *(also see Basic Protocol 1)*

mRNA for globin or other gene of interest
^{32}P-end-labeled oligonucleotide primer: e.g.,
5′-TCACCACCAACTTCTTCCAC-3′ for globin (5000 Ci/mmol), or primer appropriate to gene of interest
Micrococcal nuclease–treated rabbit reticulocyte lysate (Promega)
1 M HEPES·KOH, pH 7.5
100 and 500 mM $Mg(CH_3COOH)_2$
100 mM dithiothreitol
10 mM anisomycin
10% and 35% (w/v) sucrose gradient solutions (see recipe)
100 mM each dATP, dGTP, dCTP, dTTP
AMV reverse transcriptase
1:1 (v/v) phenol/chloroform (*APPENDIX 3*)
Ethanol
3 M potassium acetate, pH 5.0
SW56 rotor and 5-ml polyallomer centrifuge tubes (Beckman)

Additional reagents and equipment for DNA sequencing gels (*APPENDIX 3*)

Label message

1. For ten reactions, place 15 µCi of ^{32}P-labeled oligonucleotide primer and 10 µg globin mRNA in a microcentrifuge tube, place the tube in a small beaker of boiling water, and incubate 1 min.

   The probe should be a 20- to 30-oligonucleotide sequence complimentary to a portion of the mRNA of interest and located ~50 nucleotides 3′ of the initiating AUG.

2. Place the beaker on the bench top and allow to cool to room temperature (~30 min).

3. Prepare reaction mixtures (150 µl each):

50 µl micrococcal nuclease–treated rabbit reticulocyte lysate
2.25 µl 1 M HEPES·KOH, pH 7.5 (final 15 mM)
15 µl 1 M KCl (final 100 mM)
6.0 µl 100 mM $Mg(CH_3COOH)_2$ (final 24 mM)
1.5 µl 100 mM dithiothreitol (final 1 mM)
1.5 µl 10 mM anisomycin (final 0.1 mM)
$^1/_{10}$th volume of mRNA-oligonucleotide duplex (1 µg mRNA, 1.5 µCi oligonucleotide)
1 µl 100 mM dithiothreitol
2 µl 100 mM ATP
1 µl 100 mM GTP
55 µl H_20.

Incubate 15 min at 30°C and then chill 2 min on ice.

4. Prepare 10% to 35% sucrose gradients in 5-ml SW56 centrifuge tubes as described above (see Basic Protocol 1, step 1).

5. Layer the reaction on the sucrose gradients and centrifuge 150 min at 270,000 × *g*, 4°C.

6. Collect 0.2-ml fractions.

Reverse transcribe message

7. Combine the following:

200-µl aliquots of gradient fractions
0.2 mM each dATP, dGTP, dCTP, dTTP
4 U AMV reverse transcriptase.

Incubate 30 min at 37°C.

The concentrations of components in the sucrose gradient solution are designed to be compatible with the ionic and divalent ion requirements of the reverse transcriptase.

8. Extract reactions with an equal volume of 1:1 (v/v) phenol/chloroform. Separate phases by centrifuging 10 min at 1000 × *g*, 4°C. Remove the aqueous (upper) phase and add 0.1 vol 3 M potassium acetate, pH 5.0 and 2.5 vol ethanol. Let stand overnight at −20°C. Collect the precipitated nucleic acid by centrifuging 20 min at 10,000 × *g*, 4°C. Decant the aqueous/ethanol and allow tube to dry.

9. Resolve products on an 8% (w/v) acrylamide DNA sequencing gel (*APPENDIX 3*). Compare with a sequence ladder obtained by performing an extension reaction in the presence of dideoxynucleotides.

For the bottom sequencing gel, mix 10 ml of 8% acrylamide/urea bottom solution (see recipe), 40 µl of 10% ammonium persulfate, and 15 µl TEMED. For the top sequencing gel, mix 35 ml of 8% acrylamide/urea top solution (see recipe), 120 µl of 10% ammonium persulfate, and 50 µl TEMED.

10. Quantify the amount of mRNA in each complex (48S or 80S) based upon the radioactivity from the [^{32}P]primer.

DETERMINATION OF RELATIVE SEDIMENTATION COEFFICIENTS USING ANALYTICAL SUCROSE GRADIENTS

SUPPORT PROTOCOL 2

Sucrose gradients are a standard means for determining the relative sedimentation coefficient of proteins (for example see Merrick and Anderson, 1975) and to get a rough estimate of molecular mass. The advantage of this method over use of the analytical ultracentrifuge (which is much more accurate; see *UNIT 5.3*) is that either crude or pure

samples can be analyzed. The location of the desired protein can be determined by biological assay, by band pattern on SDS gels (*UNIT 6.1*), by antibody detection (immunoblotting; *UNIT 6.2*), or, in some instances, by ligand binding (far western blot; *UNIT 17.2*). For these determinations, 5% to 20% sucrose gradients are used. These lower concentrations of sucrose reflect the much smaller *S* values of proteins relative to ribosomal subunits. Buffer composition and ionic strength should be optimized for the protein in question, either for preservation of activity or for suitability in the subsequent assay. A variety of proteins can be used as markers, although a convenient set of proteins includes ovalbumin (3.55S), aldolase (7.8S), catalase (11.2S), and β-galactosidase (16.1S). As the shape of the protein will influence the *S* value (greater asymmetry will decrease the *S* value relative to a symmetric protein of the same molecular weight), this value is often used in conjunction with the Stokes radius, which can be determined by gel filtration (*UNIT 5.5*). The formula $M_r = 6\pi\eta Nsa/(1 - \bar{\nu}\rho)$ allows for the determination of the molecular weight, where η is viscosity, N is Avogadro's number, s is the sedimentation coefficient, a is the Stokes radius, $\bar{\nu}$ is the partial specific volume of the protein, and ρ is the solvent density. In this formula, the apparent increase in molecular weight that asymmetry causes in the determination of the Stokes radius is balanced by the decrease in *S* value that asymmetry induces.

Additional Materials *(also see Basic Protocol 1)*

5% and 20% (w/v) sucrose gradient solutions in suitable buffer (e.g., 20 mM Tris·Cl, pH 7.5/100 mM KCl/1 mM dithiothreitol)
Protein standards in same buffer:
10 mg/ml ovalbumin (3.55S)
10 mg/ml alddase (7.8S)
10 mg/ml catalase (11.2S)
10 mg/ml β-galactosidase (16.1S)
Unknown protein

1. Prepare 5% to 20% sucrose gradients in 5-ml SW56 centrifuge tubes as described above (see Basic Protocol 1, step 1).
2. Mix 50 to 100 µl of each protein standard together to yield 200 to 400 µl of standard mixture containing 10 mg/ml of each marker.

   Prepare 200 µl for SW rotors with small volumes (~5 ml/tube) or 400 µl for SW rotors with large volumes (~12 ml/tube).
3. Layer standard mixture on top of a 5% to 20% sucrose gradient.
4. Layer 100 to 300 µl unknown protein on top of a separate 5% to 20% sucrose gradient or mix with one or more of the standard proteins if an internal standard is desired.

   If an internal standard is used, it is best to choose a standard that is anticipated to have a significantly higher or lower S value, if possible.
5. Centrifuge 4.5 hr at 300,000 × *g* (65,000 rpm in SW56 rotor), 4°C.
6. Place the tubes on ice.
7. Collect twenty-five 0.2-ml fractions.
8. Analyze fractions by precipitating and electrophoresing the proteins (see Basic Protocol 1, steps 6b to 9b) or by assaying fractions directly for biological activity to determine the distance the protein has sedimented.
9. Determine the distance sedimented for each of the standard proteins by measuring UV absorbance at 280 nm as the gradient is removed from the tube or by analyzing aliquots of each fraction by SDS-PAGE (see Basic Protocol 1, steps 6b to 9b).

10. Construct a plot of $S_{20,w}$ of the standards versus the distance migrated (e.g., as milliliters or fraction tube number). Determine the S value for the unknown protein based upon its distance sedimented.

The plot should be a straight line.

The $S_{20,w}$ is the rate of sedimentation for a particle analyzed in distilled water at 20°C. Normally, one would have to correct for the usual centrifugation conditions, which would include both salt and temperature differences. However, as the protein standards are measured under the same conditions as the unknown, this correction is not necessary. For proteins that contain extensive sugar or lipid modifications, there will be a slight error as their partial specific volumes will not be 0.73 g/ml.

ANALYSIS OF TRANSLATION IN CULTURED CELLS

BASIC PROTOCOL 2

Initiation of translation is rate-limiting for translation of most mRNAs and is subject to regulation at multiple steps (Hershey, 1991). Thus, most changes in the translational efficiency of a given mRNA can be assessed by determining the percentage of that mRNA associated with actively translating polysomes. An approach to assess the relative amount of an individual mRNA in polysomes is outlined below.

The procedures described in this protocol have been broadly applied to analyze translation in adherent cells (BALB/c 3T3, Chinese hamster ovary, normal rat kidney, and C6 glioma cells), suspension cells (Friend erythroleukemia, Da3, and 32D hematopoietic cell lines), and in yeast (*Saccharomyces cerevisiae*). However, while broadly applicable, the necessity of lysing cells under conditions that do not denature ribosomes may preclude analysis of cells that have high concentrations of endogenous nucleases and that require strong denaturants (such as guanidinium or TriZol reagent) for preparation of intact RNA.

Materials

10% and 50% (w/v) sucrose gradient solutions (see recipe)
Cultured cells or yeast lysate (see Support Protocol 3)
PBS (*APPENDIX 2A*) or other neutral, buffered isotonic solution
TMK_{100} lysis buffer (see recipe), ice cold
Tris-buffered, water-saturated phenol: for buffering, use 1 M Tris·Cl, pH 7.5 (*APPENDIX 2A*)
Chloroform
Ethanol
RNA-loading buffer (see recipe)

Gradient maker
Refrigerated high-speed centrifuge (e.g., Beckman L7-55)
Swinging bucket rotor and appropriate tubes (e.g., Beckman SW28.1 rotor and 17-ml tubes)
15-ml polyethylene tubes with caps
UV absorbance detector and chart recorder
Syringe or peristaltic pump
Fraction collector (e.g., ISCO model 640 gradient fractionator)
Water bath or heating block at 65°C

Additional reagents and equipment for analyzing RNA on agarose or acrylamide gels and for northern blotting (*APPENDIX 3*)

NOTE: Experiments involving RNA require careful precautions to prevent contamination and RNA degradation (see *APPENDIX 2A*).

NOTE: All procedures are carried out on ice with solutions that have been precooled to 4°C.

Prepare gradients

1. Prepare a linear sucrose gradient in a 17-ml SW28.1 centrifuge tube using a gradient maker and 8.15 ml each of 10% (light) and 50% (heavy) sucrose gradient solutions. Store gradient on ice, or at 4°C, until lysate is ready for loading.

   The addition of nuclease inhibitors to the sucrose gradients is not necessary. Heparin has occasionally been added to gradients as a nonspecific inhibitor of nucleases. However, this practice is discouraged because heparin competes with RNA for nucleic acid–binding proteins, and 80S ribosomal/mRNA complexes are not stable in heparin (W.C. Merrick and J.O. Hensold, unpub. obser.).

   For analysis of interactions of mRNAs (or proteins) with individual ribosomal subunits, insufficient separation is obtained using 10% to 50% sucrose gradients. For analysis of these smaller complexes, 10% to 25% sucrose gradients should be used.

Prepare lysate

2a. *For suspension cultures:* Collect cells in a 15-ml sterile centrifuge tube. Rinse three times in 10 ml ice-cold PBS, centrifuging 10 min at 1500 × *g*, 4°C, each time. Proceed to step 3.

   For optimal results, it is best to empirically determine the number of cells necessary for analysis. While increasing the load can increase detection of proteins or RNAs of low abundance, there is a resultant loss of resolution. For practical purposes, 2 to 4 × 10^7 cells provides optimal resolution on 10% to 50% gradients, while still allowing for detection of most proteins or RNAs of interest by immunoblotting or northern blotting, respectively. For analysis of more slowly sedimenting complexes on 10% to 25% gradients, the number of cells is increased by 1.5 to 2 fold.

2b. *For adherent cultures:* Rinse adherent cells three times with 10 ml ice-cold PBS, detach cells with a rubber policeman, and transfer to a microcentrifuge tube. Pellet cells by microcentrifuging 10 min at 1500 × *g*, 4°C. Proceed to step 3.

   Trypsin should be avoided because it may affect cell signaling and its use is not practical at the low temperatures employed.

2c. *For yeast:* Grow and lyse yeast cells as described below (see Support Protocol 3). Proceed to step 5.

3. Discard supernatant and lyse cell pellet by repeated pipetting in 400 µl ice-cold TMK_{100} lysis buffer.

   RNase inhibitors may be added to the lysis buffer (see Critical Parameters).

4. Transfer lysed pellet to a microcentrifuge tube and pellet nuclei by microcentrifuging 5 min at 10,000 × *g*, 4°C.

Fractionate lysate

5. Remove supernatant and layer onto the 10% to 50% sucrose gradient. For yeast, load 10 A_{254} units lysate per gradient.

6. Centrifuge 4 hr at 100,000 × *g* (27,000 rpm in SW28.1 rotor), 4°C.

   The methods described have been optimized for use with the SW28 rotor and SW28.1 buckets. This rotor accommodates a centrifuge tube that is 15% longer than that accommodated by the SW41 rotor, and thus provides better resolution of ribosomal complexes. However, for most purposes the separations achieved with the SW41 rotor are adequate. Centrifugation conditions for the SW41 and other rotors can be found in a variety of references (Steel and Jacobson, 1987; Kaspar and Gehrke, 1994; Proweller and Butler, 1994).

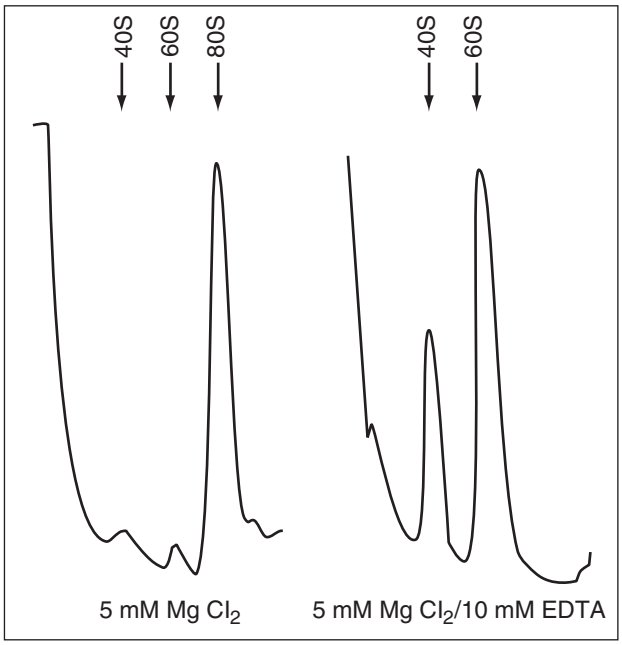

Figure 11.9.3 Sedimentation of ribosomes from erythroleukemic cells in 10% to 50% and 10% to 25% sucrose gradients. Erythroleukemic cells in log phase of growth were lysed as described in the text, and post-nuclear supernatants were loaded onto 10% to 25% sucrose gradients. The gradients were collected with an ISCO model 640 gradient fractionator by displacement from the bottom with 60% sucrose into a flow cell (Fig. 11.9.1A). UV absorbance was continuously monitored during the collection. The gradients contained 20 mM HEPES·KOH, pH 7.4, 5 mM $MgCl_2$, 100 mM KCl, and 2 mM dithiothreitol. In the experiment shown in the far right panel, 10 mM EDTA was added to the post-nuclear supernatants and to the gradients. The positions of sedimentation of the 40S, 60S, and 80S ribosomes are indicated by arrows above the figures. These assignments were confirmed by analysis of the rRNA content of the inclusive fractions. The direction of sedimentation is from right to left.

For analysis of 40S to 80S complexes in 10% to 25% sucrose gradients, centrifugation is 16 hr at 55,000 × g (20,000 rpm in SW28.1 rotor), 4°C. This completely pellets the polysomes while separating the 40S, 60S, and 80S complexes into distinct fractions (see Fig. 11.9.3). By increasing the sedimentation speed of these gradients to 23,000 rpm, 80S complexes are also pelleted, and separation of 43S from 48S (preinitiation) complexes is possible.

7. Collect gradients in 5-ml polyethylene tubes containing 1 ml Tris-buffered, water-saturated phenol using a fraction collector with continuous monitoring of absorbance at 254 nm (see Fig. 11.9.1).

   For most purposes, fractionation of the gradients into fourteen 1.2-ml fractions provides sufficient detail to determine the position of sedimentation of mRNAs in the gradient.

   To ensure that the amount of RNA in each fraction is representative of its relative distribution in the gradient, it is imperative that equal volumes of phenol and chloroform are added to the fractions. The amount of aqueous phase recovered following phase separation must also be constant.

Extract RNA

8. Immediately following collection, tightly cap the tubes, vortex to mix the phases, and place on ice until all fractions are collected.

9. Add 1 ml chloroform to each tube, mix phases by vortexing, and separate phases by centrifuging 15 min at 3000 × *g*, 4°C, in a tabletop centrifuge.

   The stepwise addition of phenol and then chloroform, rather than addition of a phenol/chloroform solution, facilitates mixing of the phenol with the viscous sucrose solution.

   Alternatively, the distribution of proteins in gradient fractions can be analyzed. In this case, the fractions are collected directly into microcentrifuge tubes containing 1/9 volume of 100% trichloroacetic acid (e.g., 133 µl for a 1.2-ml fraction). The pelleted proteins are recovered and analyzed by SDS-PAGE (UNIT 6.1).

10. To ensure equal recovery of extracted RNA from the fractions, transfer a constant volume of the aqueous phase (for example, separate the aqueous phase into two 500-µl fractions) to 1.5-ml microcentrifuge tubes and precipitate with 2 vol ethanol.

    The salt concentration in the buffer is sufficient for precipitation of RNA.

    The precipitated RNA can be stored for extended periods of time (3 to 6 months) in ethanol at −20°C prior to analysis.

11. Pellet RNA by microcentrifuging 20 min at 10,000 × *g*, 4°C.

Analyze RNA content

12. Carefully aspirate the ethanol-buffered sucrose solution, taking care not to disturb the RNA pellet. Resuspend pellet in 20 µl RNA-loading buffer.

    Excess sucrose remaining with the pellet can inhibit migration of the RNA out of the wells, particularly in the fractions that contain the highest concentration of sucrose. Complete removal of the sucrose can be facilitated by a second, brief (i.e., 30-sec) centrifugation in a microcentrifuge and aspiration of the residual supernatant.

13. Denature RNA by heating 15 min at 65°C.

14. Load the entire sample onto either an agarose or acrylamide gel prepared for electrophoresis (*APPENDIX 3*).

    Care must be taken to ensure that the entire RNA pellet is loaded onto the gel if the results are to be reflective of the actual distribution of RNA across the gradient fractions.

15. Blot the gel for northern blot hybridization and hybridize (*APPENDIX 3*).

ALTERNATE PROTOCOL 4

PURIFICATION OF RIBOSOMAL COMPLEXES FROM CULTURED CELLS FOR BIOCHEMICAL ASSAYS

When it is necessary to analyze ribosomal complexes in their native state, collection into either phenol or TCA is not possible. Collection of pooled polysomes is simplified by sedimentation in 10% to 25% sucrose gradients, since these conditions will pellet complexes that are larger than 80S.

Additional Materials *(also see Basic Protocol 2)*

Cultured cell lysate (Basic Protocol 2) or yeast lysate (Support Protocol 3)
25% sucrose gradient solution (buffered as for 10% and 50% solutions in Basic Protocol 2)
TMK_{100} lysis buffer (see recipe) without detergent
22% (w/v) sucrose solution (see recipe)
Swinging bucket rotor and tubes (e.g., Beckman SW50.1 rotor and 5-ml tubes)

1. Prepare and fractionate lysates as described (see Basic Protocol 2, steps 1 to 6), but use 10% and 25% sucrose gradient solutions and centrifuge 16 hr at 55,000 × g (20,000 rpm in SW28.1 rotor), 4°C.

2. Solubilize polysomal pellet in 0.4 ml TMK_{100} buffer without detergent.

   To obtain other complexes (such as individual subunits or monosomes), the relevant fractions from the 10% to 25% gradient are removed from the fractionator and placed on ice as soon as they are collected. The pooled fractions are then diluted in TMK_{100} lysis buffer.

3. Wash ribosomes and concentrate by centrifuging through 22% (w/v) sucrose solution in 5-ml tubes for 16 hr at 110,000 × *g* (34,000 rpm in an SW50.1 rotor), 4°C.

   This pellet contains all complexes larger than 40S.

4. Dissolve pelleted ribosomes and subunits in 0.25 M sucrose solution and store up to 2 years in liquid nitrogen.

PREPARATION OF YEAST LYSATES

SUPPORT PROTOCOL 3

Preparation of lysates from yeast follows general, previously described methods (Baim et al., 1985; Moritz et al., 1991).

Materials

Yeast culture
Breaking buffer (see recipe)
Dry acid-washed glass beads (425- to 600-µm; Sigma)
1 mg/ml cyclohexamide

Spectrophotometer

Additional reagents and equipment for growing yeast (*UNIT 1.6*)

1. Grow 100-ml yeast cultures to an OD_{600} of ~1 (log phase; *UNIT 1.6*).
2. Pellet cells by centrifuging 5 min at 1500 × *g*, 4°C.
3. Resuspend pellet in 5 ml sterile 4°C water containing 100 µg/ml cyclohexamide, incubate 1 min on ice, and pellet again.
4. Resuspend pellet in 500 µl breaking buffer and 400 µl acid-washed glass beads. Vortex eight times for 20 to 30 sec each, with 30-sec incubations on ice between vortexing steps.
5. Pellet beads and cellular debris in a refrigerated microcentrifuge 8 min at 10,000 × *g*, 4°C.
6. Transfer supernatant to a fresh tube and repeat centrifugation.
7. Measure the absorbance of an aliquot of the sample at 254 nm (nucleic acid).

REAGENTS AND SOLUTIONS

*Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see **APPENDIX 2A**; for suppliers, see **SUPPLIERS APPENDIX**.*

Acrylamide solution, 40% (w/v)

380 g acrylamide
20 g *N,N*-methlyenebisacrylamide
H_2O to 600 ml
Store up to 2 months at 4°C

Acrylamide/urea bottom solution, 8% (w/v)

40 ml 40% (w/v) acrylamide solution (see recipe)
90 ml 5× TBE electrophoresis buffer (*APPENDIX 2A*)
92 g urea
20 g sucrose
10 mg bromphenol blue
H_2O to 200 ml
Store up to 2 days at room temperature

Acrylamide/urea top solution, 8% (w/v)

100 ml 40% (w/v) acrylamide solution (see recipe)
50 ml 5× TBE electrophoresis buffer (*APPENDIX 2A*)
230 g urea
H_2O to 500 ml
Store up to 2 days at room temperature

ATP, 100 mM

Dissolve ATP to 100 mM in 20 mM Tris·Cl, pH 7.5 (*APPENDIX 2A*). Check the concentration by measuring A_{259}. Store 100-µl frozen aliquots, preferably at −80°C, for up to 6 months.

A 1:100 dilution of this solution (1 mM) should have an absorbance of 15.4 at 259 nm.

Breaking buffer

20 mM HEPES·KOH, pH 7.4
2 mM $MgCl_2$
100 mM KCl
14.4 mM 2-mercaptoethanol
100 µg/ml cyclohexamide
Store up to 2 weeks at −70°C

GTP, 100 mM

Dissolve GTP to 100 mM in 20 mM Tris·Cl, pH 7.5 (*APPENDIX 2A*). Check the concentration by measuring A_{252}. Store 100-µl aliquots frozen, preferably at −80°C, for up to 6 months.

A 1:100 dilution (1 mM) should have an absorbance of 13.7 at 252 nm.

$MgCl_2$, 100 mM

Since most bottles of $MgCl_2$ tend to contain visible H_2O (i.e., the crystals appear wet), assume that the original manufacturer's weight is correct and dissolve the entire contents of the bottle in H_2O to the desired concentration.

Recently, the authors have substituted magnesium acetate [$Mg(CH_3COO)_2$] for $MgCl_2$, as $Mg(CH_3COO)_2$ comes as a dry powder. However, since acetate is a great carbon source for bacteria or fungi, the solution should be autoclaved and stored cold.

RNA-loading buffer

20 mM MOPS, pH 7.0
8 mM sodium acetate
1 mM EDTA
50% (v/v) formamide
6.5% (v/v) formaldehyde
5% (v/v) glycerol
0.025% (w/v) bromphenol blue
0.025 (w/v) xylene cyanol
Store up to 2 months at 4°C

SDS sample buffer

1 mM dithiothreitol
80 mM Tris·Cl, pH 6.8 (*APPENDIX 2A*)
0.002% (w/v) bromphenol blue
2% (w/v) sodium dodecyl sulfate (SDS)
10% (v/v) glycerol
Store up to 6 months at −20°C

Standard sucrose solution

0.25 M sucrose
20 mM Tris·Cl, pH 7.5 (*APPENDIX 2A*)
0.1 mM EDTA
1 mM dithiothreitol
Store up to 6 months at −20°C

Subunit buffer

50 mM HEPES·KOH, pH 7.5
2 mM $Mg(CH_3COO)_2$
1 mM puromycin
500 mM KCl
Prepare fresh

If necessary, may be stored 1 day at 4°C

Sucrose gradient solutions, 5% and 20% (w/v)

5% or 20% (w/v) sucrose
50 mM HEPES·KOH, pH 7.5
5 mM $Mg(CH_3COO)_2$
2 mM dithiothreitol
500 mM KCl
0.1 mM EDTA
Prepare fresh immediately before use

These solutions are used to prepare gradients for isolating 40S and 60S ribosomal subunits (see Support Protocol 1).

Sucrose gradient solutions, 10% and 35% (w/v)

10% or 35% (w/v) sucrose
60 mM NaCl
6 mM $Mg(CH_3COOH)_2$
50 mM Tris·Cl, pH 8.4 (*APPENDIX 2A*)
10 mM dithiotreitol
Prepare fresh immediately before use

The solutions are used to prepare gradients for toeprinting (see Alternate Protocol 3).

Sucrose gradient solutions, 10% and 40% (w/v)

10% or 40% (w/v) sucrose
20 mM Tris·Cl, pH 7.5 (*APPENDIX 2A*)
100 mM KCl
5 mM $MgCl_2$
100 μM GDPNP
Prepare fresh immediately before use

These solutions are used to prepare gradients for isolating ribosomal complexes (see Basic Protocol 1 and Alternate Protocols 1 and 2). They may be stored overnight at 4°C, but GDPNP should be added just before use.

Sucrose gradient solutions, 10% and 50% (w/v)

10% or 50% (w/v) sucrose
100 mM KCl
5 mM $MgCl_2$
2 mM dithiothreitol
20 mM HEPES·KOH, pH 7.4
Prepare in diethylpyrocarbonate (DEPC)–treated water (*APPENDIX 2A*)
Store up to 3 months at 4°C

These solutions are used for analyzing translation in cultured cells (see Basic Protocol 2). General procedures to limit contamination with exogenous nucleases (use of gloves, buffer preparation with ultrapure reagents and DEPC-treated water; see APPENDIX 2A) should be employed at all times.

Sucrose solution, 22% (w/v)

22% (w/v) sucrose
100 mM KCl
5 mM $MgCl_2$
2 mM dithiothreitol
20 mM HEPES/KOH, pH 7.4
Prepare in diethylpyrocarbonate (DEPC)-treated water (*APPENDIX 2A*)
Prepare immediately before use

This solution is used for preparing ribosomal complexes for biochemical assays (see Alternate Protocol 4).

Sucrose solution, 0.25 M

0.25 M sucrose
1 mM dithiothreitol
0.2 mM EDTA
10 mM KCl
1 mM $Mg(CH_3COO)_2$
Store up to 6 months at −20°C

TMK_{100} ($Tris/Mg^{2+}/K^+$) lysis buffer

10 mM Tris·Cl, pH 7.4 (*APPENDIX 2A*)
5 mM $MgCl_2$
100 mM KCl
1% (v/v) Triton X-100
0.5% (w/v) deoxycholate
Prepare in diethylpyrocarbonate (DEPC)–treated water (*APPENDIX 2A*)
1 U/ml placental ribonuclease inhibitor, added fresh just before use
2 mM dithiothreitol, added fresh just before use
Store up to 3 to 6 months at 4°C

General procedures to limit contamination with exogenous nucleases (use of gloves, buffer preparation with ultrapure reagents and DEPC-treated water; see APPENDIX 2A) should be employed at all times.

COMMENTARY

Background Information

Translation of an mRNA can be conveniently separated into several discrete steps. Translation initiation is the sequential association of an mRNA with a 40S ribosomal subunit to form a 48S preinitiation complex, which is followed by joining of the 60S subunit to form an 80S ribosome. This complex can then initiate the repetitive cycle of tRNA binding, peptide bond formation, and translocation that defines elongation. Repeated episodes of initiation and elongation on an individual mRNA result in the formation of polysomes, which can include over fifteen translating ribosomes per

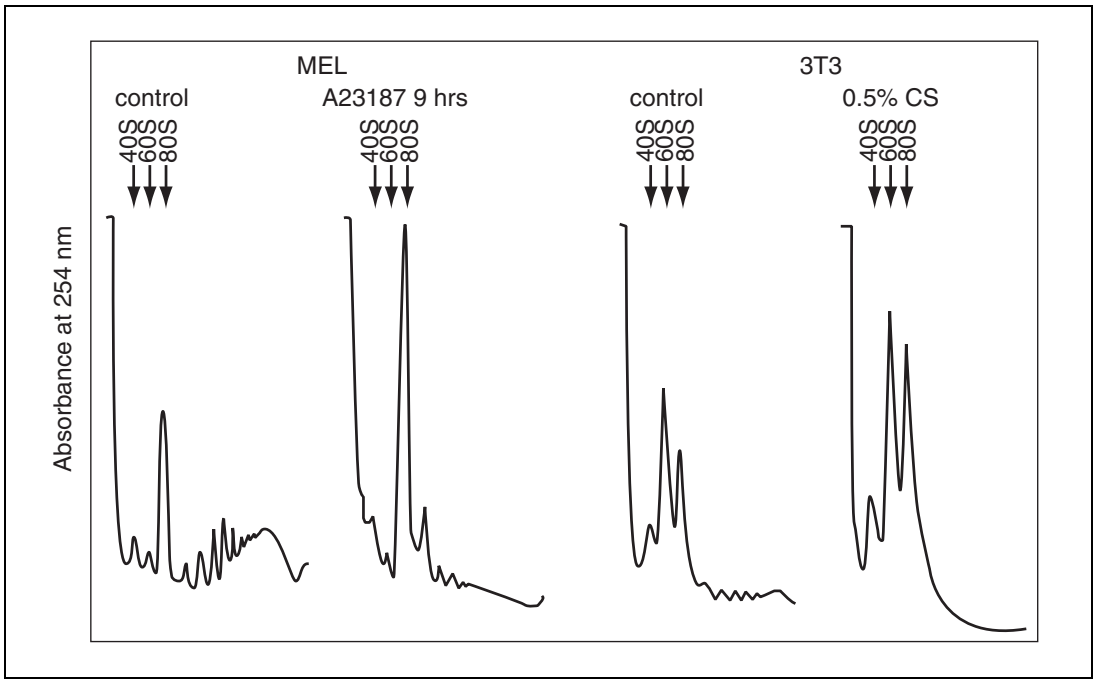

Figure 11.9.4 Serum-starved 3T3 cells and erythroleukemic cells exposed to inducers of differentiation demonstrate evidence of a decrease in the rate of translation initiation. Murine erythroleukemic (MEL) cells were grown for 9 hr in the presence or absence of the inducer of differentiation A23187 (0.75 μg/ml). BALB/c 3T3 cells were grown to confluence, and then either (1) replated in fresh medium containing 10% calf serum (control), or (2) washed with PBS, refed with medium containing 0.5% calf serum (0.5% CS), and incubated for an additional 18 hr. Cell lysates were prepared for analysis on 10% to 50% sucrose gradients as described in the text. Gradients were collected with an ISCO 640 gradient fractionator with continuous monitoring of the UV absorbance at 254 nm (Fig. 11.9.1A). Positions of 40S, 60S, and 80S ribosomal peaks are indicated by arrows above each tracing. The direction of sedimentation is from right to left.

mRNA. Due to the quantal increase in complex size as 40S and 60S subunits are added to an individual mRNA, it is possible to identify a number of different translational complexes by sucrose gradients. Using the techniques described here, it is possible to resolve a number of different complexes including uninitiated mRNAs (such as 7S globin mRNAs), 40S subunits (43S complexes), 48S preinitiation complexes, 60S subunits, 80S ribosomes, and polysomal complexes containing up to eight to ten ribosomes/mRNA.

Interpreting results of sucrose gradient separation of cell lysates

The distribution of ribosomes or mRNAs across a gradient ultimately reflects the combined rates of initiation, elongation, and termination of translation. Therefore, it is possible for different combinations of effects on these processes to produce similar changes in distribution. For example, a decrease in initiation rate would be expected to decrease the size of the average polysome as well as to decrease the total amount of polysomes (and polysomal mRNAs; e.g., Fig. 11.9.4). However, a similar result would be expected if initiation rate remained constant while elongation and termination rates were increased. Therefore, the results are best interpreted in the context of an independent determinant of translation, for example, as determined by the incorporation of radioactive amino acids into protein.

Suggested approaches for demonstrating physical association of mRNAs or proteins with ribosomes

To demonstrate that the proteins or RNAs found in individual fractions are in fact components of ribosomal complexes, several different approaches are commonly used. Digestion of extracts with RNase prior to their sedimentation can be used to confirm that the identified proteins are components of a ribonucleoprotein (RNP) complex. However, this approach does not distinguish between different types of RNPs and is not useful if the component of interest is itself an RNA. A more generally

useful approach takes advantage of the magnesium requirement for formation of higher-order ribosomal structures (Spirin, 1986). Addition of EDTA (5 mM in excess of $MgCl_2$) to the gradients results in complete dissociation of polyribosomes, 80S ribosomal complexes, and 40S ribosomal/mRNA preinitiation complexes (and also dissociates the 5S and 5.8S RNAs from the 60S ribosomal subunit). However, since most RNA/protein interactions are not dependent on magnesium, the presence of EDTA does not disrupt sedimentation of less complex RNPs. EDTA (10 mM) may be added to the postnuclear supernatant prior to loading on the gradient. (Its presence before separation of the nuclei results in nuclear dissolution.) An example of the effect of EDTA on ribosome sedimentation in 10% to 25% gradients is shown in Fig. 11.9.3.

A functional approach to demonstrate translation of an mRNA that cosediments with polysomes is to determine the sensitivity of the complex to puromycin. This inhibitor occupies the "A" site of the elongating ribosome, terminates translation, and causes release of the prematurely terminated peptide. Puromycin treatment therefore results in the "collapse" of polysomes, with an associated increase in monosomes and disomes, as determined by UV absorbance of the fractionated RNA. A similar effect should be evident for individual mRNAs in the fractions. For the purposes of these experiments, a 10-min incubation at 37°C in normal growth medium containing 100 µM puromycin is sufficient to observe the effects of this agent on translation.

As an alternative approach to determining translational activity, the stability of the ribosomal complexes in high concentrations of monovalent cations has occasionally been employed. This technique derived from the early observations that: (1) 80S fractions frequently contain a high content of ribosomal subunits, (2) radioactive amino acid incorporation does not occur in 80S fractions (Warner et al., 1963), and (3) 80S ribosomes can be dissociated into 40S and 60S complexes by sedimentation in 500 mM KCl (Martin and Hartwell, 1970; Zylber and Penman, 1970; Martin, 1973). On the basis of these observations, salt-labile subunits were considered to be "vacant couples" that did not contain bound mRNA. The addition of KCl at a concentration of 500 mM to the standard gradient conditions described in these protocols is sufficient to dissociate 80S ribosomal complexes in both mammalian cells and yeast, while polyribosomes remain intact (Martin and Hartwell, 1970; Zylber and Penman, 1970; Martin, 1973). However, while published data from this laboratory is consistent with the observations that salt-labile 80S complexes are translationally inactive, the authors have demonstrated that these complexes contain mRNA stably bound to the 40S ribosomal subunit (Hensold et al., 1996). Thus, while stability in 500 mM KCl can be used as a surrogate marker for translational activity, it cannot be assumed that these complexes do not contain mRNA, although the significance of these 80S complexes remains to be established.

When assessing the presence of a protein in a given ribosomal complex, it is important to keep in mind that the absence of a protein from a fraction does not exclude its existence in that complex. For example, elongation factors are not routinely found in polysomal fractions. Thus, loosely adherent proteins may be lost during sedimentation through sucrose or under the conditions used for lysis.

Critical Parameters

Cell translation is rapidly responsive to a variety of signals that are generated from both external and internal signaling pathways (Hershey, 1991; Merrick, 1992). Thus, care must be taken to ensure that extract preparation does not superimpose independent effects upon the cells to be assayed. For this reason, as a first step in the preparation of extracts, cells should be rapidly equilibrated in ice-cold PBS to cause a general arrest of cellular processes. This also serves to inhibit endogenous nucleases that may be released during extract preparation. Thus, it is critical that all steps in extract preparation are performed on ice or in refrigerated centrifuges. While some protocols for polysome analysis include cyclohexamide (50 to 100 µg/ml) to prevent "run-off translation" from polysomes, this is unnecessary if the extracts are maintained at 4°C during their preparation. Further, transient elevations in temperature that occur while the cells are exposed to cyclohexamide results in polysome profiles with characteristics of inhibited elongation. Thus, if cyclohexamide is included in buffers, precautions must be taken to avoid exposure to temperatures above 4°C.

The presence of ribonuclease inhibitors in the lysis buffer is also not absolutely necessary, since it is possible to fractionate intact RNA from MEL and 3T3 cells without added nuclease inhibitors as long as the extracts are prepared and fractionated at 4°C. For cell lines that have higher levels of endogenous RNases, lysis

buffer should be supplemented with placental ribonuclease inhibitor (1 U/μl) or RNase Block (Stratagene; Kaspar and Gehrke, 1994). The inclusion of deoxycholate in the lysis buffer increases the yield of polysomes, presumably due to the dissolution of the cytoskeleton that occurs in the ionic detergent. However, if ribosomal complexes are to be isolated for use in biochemical assays, it may be advisable to avoid this detergent, since it is more denaturing than nonionic detergents.

When assessing the distribution of mRNAs (or proteins) in gradient fractions, it is important that the amount of material recovered from each fraction be representative of the actual amount of material present in that fraction. As described here, this is ensured when care is taken to maintain equal volumes throughout all steps of the extractions. Further, it is equally important that the pellets be resuspended in a constant volume, and that either all of the material or a constant fraction of the volume be loaded onto gels, if the distribution of material is to be representative of its actual distribution across the gradient. Alternatively, a radiolabeled standard may be added to each fraction (such as an in vitro–transcribed RNA) prior to recovery of the RNA. Any variability in recovery of extracted RNA can then be corrected by loading equal amounts of the recovered radioactive RNA, as determined by scintillation counting of an aliquot of each fraction.

Troubleshooting

Translation in lysates

Translation in a system reconstituted from fractionated components is very inefficient and the molar yield of product is often on the same order of magnitude as the input level of ribosomes and factors. Reaction rates are also considerably reduced, especially for elongation. To circumvent this problem, unfractionated reticulocyte lysate can be used (see *UNIT 11.2*). However, in this case any added component must compete with the endogenous equivalent. Suggested approaches for the use of these lysates are discussed below.

The individual steps in initiation can be monitored by determining the binding of specific translation factors to either 40S, 60S, or 80S ribosomes. Purified factors can be radiolabeled by reductive methylation (Peterson et al., 1979a), or the factor may be translated in vitro in the presence of radioactive amino acids (Joshi et al., 1994). Alternatively, association of factors with specific translational complexes could be monitored by immunoblotting (*UNIT 6.2*), as previously described. Met-tRNA$_i$ may be monitored by addition of exogenously labeled [^{35}S]Met-tRNA$_i$. However, the aminoacyl linkage in Met-tRNA$_i$ is one of the least stable and generally has a half-life of ~8 to 10 min. Thus, under normal protein synthesis conditions, the percentage of radioactive Met-tRNA$_i$ falls quite rapidly. The stability of the initiator tRNA can be increased considerably by the addition of a formyl group (using *E. coli* transformylase) to yield fMet-tRNA$_i$, but this initiator tRNA is utilized about a third as well as the normal Met-tRNA$_i$.

For the analysis of mRNAs, radioactive mRNAs can be conveniently transcribed in vitro using bacterial polymerases (SP6, T7, or T4) in the presence of an mRNA cap analog, m^{7}GpppG. By setting the ratio of cap analog to GTP at 5:1 to 10:1, most of the transcripts emerge with an m^{7}G cap. The use of lysates that have been treated with micrococcal nuclease (Pelham and Jackson, 1976) reduces the level of endogenous mRNAs to the point where there is little competition for translation as long as the level of added transcript is <1 μg. The use of in vitro–transcribed RNAs allows one to systematically alter the RNA sequence/structure to determine the influence of either specific structural elements (stem-loops of specific sequences) or context (i.e., the nucleotides surrounding the AUG start codon) on the formation of 40S or 80S initiation complexes. If desired, the binding site of the ribosome/subunit to the mRNA can be mapped by toeprinting, as described previously (Anthony and Merrick, 1992). Both the 40S and 80S regions can be toeprinted. While it might appear ideal to perform toeprinting in the original translation mixture without gradient fractionation, it has been observed that it is not possible to reverse transcribe in the crude lysate. This may be due to the presence of phosphatases or other undefined inhibitors in the lysate.

Given that lysates contain all the ingredients necessary for complete polypeptide chain synthesis, normally most of the components end up in polysomes, and thus it is difficult to identify useful intermediate complexes. In this case, the use of inhibitors may facilitate their identification (Peterson et al., 1979a,b; Safer et al., 1979). To block the joining of the 40S and 60S subunits, the lysates can be supplemented with the drug edeine (which is increasingly difficult to obtain) or by the inclusion of GDPNP (as subunit joining requires the hydrolysis of the GTP in the ternary complex

eIF2-GTP-Met-tRNA$_i$). The presence of GDPNP also ensures that no elongation will take place. In the presence of these inhibitors, these experiments yield complexes that are either 40S, 43S, or 48S. Similarly, to monitor the flow of components (mRNA or Met-tRNA$_i$) into 80S complexes, anisomycin (an inhibitor of elongation) is used. It should be mentioned that in these studies with a specific inhibitor there will be a relative buildup of complexes at or before the point of the block. Inhibitors are therefore useful in magnifying the signal at individual steps.

Translation in intact cells

The most common problem in using gradients to analyze translation in cells is degradation of the RNA. If this occurs during extract preparation, the result will be a decrease in the amount of polysomal material, due to cleavage of the mRNA between translating ribosomes. If this is severe, it may be apparent on the UV absorbance tracing during collection of the gradient. Lesser degrees of degradation may only become apparent during subsequent gel electrophoresis of the RNA and be detected as widespread "nicking" of the rRNA by ethidium bromide staining of the gel. More subtle nicking may only be detected following northern blot hybridization and visualization of individual mRNAs. Suggestions to decrease nuclease activity during extract preparation are discussed. It is worth reemphasizing that keeping the cells and extracts on ice and precooling the gradients and centrifuge to 4°C before centrifugation provides an important safeguard against nuclease activity, even in the absence of exogenously added RNAse inhibitors.

If nicking is detectable in only one or two fractions, this is usually due to a nuclease that was inadequately removed following phenol and chloroform extraction of the gradient fractions. Ribonuclease can be recovered from polysome preparations (Caruccio and Ross, 1994), so the most likely cause of this problem is recovery of an incompletely (or reversibly) denatured nuclease from the interface during the phenol and chloroform extractions. In this case, greater care should be taken to avoid disturbing the interface, including removing a smaller volume of the aqueous fraction. In either case, if evidence of even partial RNA degradation is detected, the gradients should be repeated, since any conclusions obtained from even partially degraded complexes would be invalid.

When recovering proteins from TCA precipitates of gradient fractions, difficulty is sometimes encountered in solubilizing the proteins in the first one or two fractions. This is generally due to the high concentration of protein in these fractions. Complete solubilization may not be possible in the small volume of sample buffer necessary for loading the entire sample in a single well of a gel. In this case, it is best to increase the volume to ensure complete solubilization of the proteins and load a predetermined percentage of this volume in the well. This should then be taken into account when quantifying the results determined by immunoblotting.

During preparation of cell extracts, nuclear dissolution may occur due to the presence of the ionic detergent deoxycholate. This will be manifest as an increase in viscosity of the extract and the lack of a detectable nuclear pellet following centrifugation of the initial lysate. The concentration of deoxycholate used in Basic Protocol 2 was empirically determined for MEL cells, and cells differ in their sensitivity to this detergent. Thus, while 1% Triton X-100/0.5% deoxycholate is a useful starting point, the optimal concentration for other cells may need to be empirically determined. In addition, since mixed micelles of Triton X-100 and deoxycholate are formed in the extraction buffer, it is important that these detergents be well mixed in the lysis buffer before addition to the cells.

Anticipated Results

In analyzing the distribution of ribosomes or mRNA in cells, it is important to avoid preconceived notions of how the profile should appear. Most knowledge of translational mechanisms derives from insights gained from studies in reticulocyte lysates, and although these observations have been generally applicable to cells, it is likely that additional mechanisms of regulation have yet to be identified. For example, while phosphorylation of ribosomal protein S6 is one of the most highly conserved sequelae of mitogenic stimulation, the biochemical effect of this modification has yet to be conclusively established. Recent evidence suggests that this may influence translation of mRNAs that have a 5′-terminal oligopyrimidine tract (5′-TOP; Jefferies et al., 1994).

Changes in translation rate may also be due to changes in total ribosomal content (Rudland and de Asua, 1979). Recent studies in yeast suggest that ribosomal abundance may differentially affect mRNA translation (Proweller and Butler, 1997). However, unless care is taken

to standardize the amount of lysate loaded for total cell number, changes in cellular ribosomal abundance would not be detected by assessing the distribution of ribosomes across a gradient. In this case, it may be best to use alternative means to quantitate changes in ribosome content, such as blot hybridization with radiolabeled probes to rRNAs. In this case, RNA extractions and gel loading should be standardized for cell number.

Cell type differences in translational regulation are also likely to occur. The expression of the two isoforms of eIF4A demonstrate tissue-specific differences in their expression (Nielsen and Trachsel, 1988), and the mRNA levels of eIF4B and eIF4H are quite variable in different tissues (Richter et al., 1999). In addition, translational regulation may be abnormal in transformed cells (Rinker-Schaefer et al., 1992; Sonenberg, 1993) and thus in immortal cell lines. To emphasize these cell type differences in the distribution of ribosomes in sucrose gradients, Figure 11.9.4 illustrates differences between two murine cell lines. These differences are independent of cell growth conditions and cannot be attributed to differences in commonly identified means of translational regulation: phosphorylation of the initiation factors eIF2, eIF4E, or the 4E-binding protein PHAS I. Analysis of other cell types in this laboratory has identified at least two other distinct patterns of ribosomal distribution in mammalian cell lines. It is likely that the continued analysis of cellular growth and differentiation will provide insights into novel mechanisms of translational regulation.

Time Considerations

The time required for completion of these experiments will be largely dependent on the centrifugation time, since the 3 to 16 hr required for this step will be longer than any of the preceding or ensuing steps. For analyzing translation in cells, the preparation of the extracts should take 15 to 20 min, and a similar period of time should be allotted for pouring the gradients. Gradients can be poured the preceding day and stored at 4°C overnight without any ill effects. The time required for extraction of RNA or protein from the gradient fractions will depend on the number of gradients and the number of fractions collected from each gradient. In general, this should take 1 to 3 hr for most experiments.

Preparation and Use of Interphase *Xenopus* Egg Extracts

Xenopus interphase egg extracts (see Basic Protocol 1 and Alternate Protocol 1) are useful as sources of cytoplasmic and organelle material for in vitro reconstitution of cellular events such as nuclear assembly (see Basic Protocol 2) from demembranated sperm chromatin (see Support Protocol 2), nuclear protein import (see Basic Protocol 3), and nuclear DNA replication (see Basic Protocol 4 and Alternate Protocol 2). To characterize the molecular bases of these and other processes, the extracts can be modified by immunodepletion (see Support Protocol 3) or protein addition (see Support Protocol 4). Eggs are obtained from primed female frogs (see Support Protocol 1). These extracts can also be modified to support cycling (see *UNIT 11.11*) and apoptosis (see *UNIT 11.12*). To study meiotic maturation, extracts can be prepared from oocytes (see Basic Protocol 5).

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) or must conform to governmental regulations regarding the care and use of laboratory animals.

PREPARATION OF INTERPHASE EGG EXTRACTS

BASIC PROTOCOL 1

Prior to preparation of an interphase extract, the frog is injected and eggs are laid overnight in 100 mM NaCl (see Support Protocol 1). The mature *Xenopus* eggs are arrested in metaphase of meiosis II and therefore have high mitotic kinase or cyclin B/cdc2 activity. Egg lysis by centrifugation causes a transient release of Ca^{2+} from intracellular stores, resulting in proteolysis of cyclin B and subsequent loss of cdc2 kinase activity. After inactivation of cyclin B/cdc2, the extract moves from M phase to S phase. Addition of cycloheximide to the extract prevents synthesis of any new proteins, most notably cyclin B. Therefore, the extract remains in interphase of the cell cycle. Upon addition of sperm chromatin and an ATP regenerating system, membrane vesicles present in the extract fuse to the chromatin to form interphase nuclei (see Basic Protocol 2) which are capable of replicating their DNA (see Basic Protocol 4) and have intact nuclear pore complexes.

Materials

Eggs obtained from female frogs, in 100 mM NaCl (see Support Protocol 1)
2% (w/v) L-cysteine free base (Sigma) in H_2O
0.25× modified Ringer's solution (MMR), pH 7.7 (see recipe for 10×)
Egg lysis buffer, pH 7.7 (see recipe)
5 mg/ml cytochalasin B (Calbiochem) in DMSO
5 mg/ml aprotinin (Roche Diagnostics) in H_2O
5 mg/ml leupeptin (Roche Diagnostics) in H_2O
10 mg/ml cycloheximide in H_2O

200-ml beaker
100-mm glass petri dish
Pasteur pipets
Dissecting microscope
15-ml conical polypropylene centrifuge tubes
IEC Clinical centrifuge
Sorvall HB-4 swinging bucket rotor
18-G needle attached to 5-ml syringe

Contributed by Maureen Powers, Erica K. Evans, Jing Yang, and Sally Kornbluth
Current Protocols in Cell Biology (2001) 11.10.1-11.1.24

Wash and dejelly eggs

1. Collect eggs in a 200-ml glass beaker and pour off any excess solution.
2. Rinse eggs once in 2% L-cysteine, pH 8.0, then continue to incubate in 100 ml of 2% L-cysteine solution per frog for ~5 min at room temperature, gently swirling the eggs periodically.

   Before incubation with cysteine solution, a transparent jelly coat, which prevents the eggs from directly contacting each other, will surround each individual egg. Once eggs are dejellied, they will pack closely together

3. Pour the cysteine solution off of the dejellied eggs and wash eggs in 0.25× MMR by decantation to remove debris. Repeat 2 times. Pour eggs into a 100-mm glass petri dish.
4. Preferably working under a dissecting microscope, remove bad eggs from the petri dish with a Pasteur pipet.

   Mature Xenopus eggs have a darkly pigmented half on top and a light half on the bottom. The dark half of the egg should have a small white spot present in the middle created by breakdown of the oocyte nucleus (germinal vesicle breakdown) during the process of oocyte maturation. This spot can be seen by eye but is more easily seen using a dissecting microscope. Anything without this white spot is an oocyte and should be removed. Any eggs that are white, enlarged, or not uniformly pigmented should also be removed.

5. Wash eggs 2 to 3 times, each time by pouring egg lysis buffer on them and carefully pouring the buffer off, minimizing the number of eggs that are spilled out.

Lyse eggs

6. Transfer eggs with an inverted Pasteur pipet (with the bulb on the thin, pointed end) into a 15-ml polypropylene tube.

   The Pasteur pipets must be inverted because a wide-mouthed pipet is required to avoid lysing the eggs.

7. Centrifuge eggs 15 sec in a clinical centrifuge at 400 × *g*. Remove extra buffer from the top of the packed eggs by decantation.

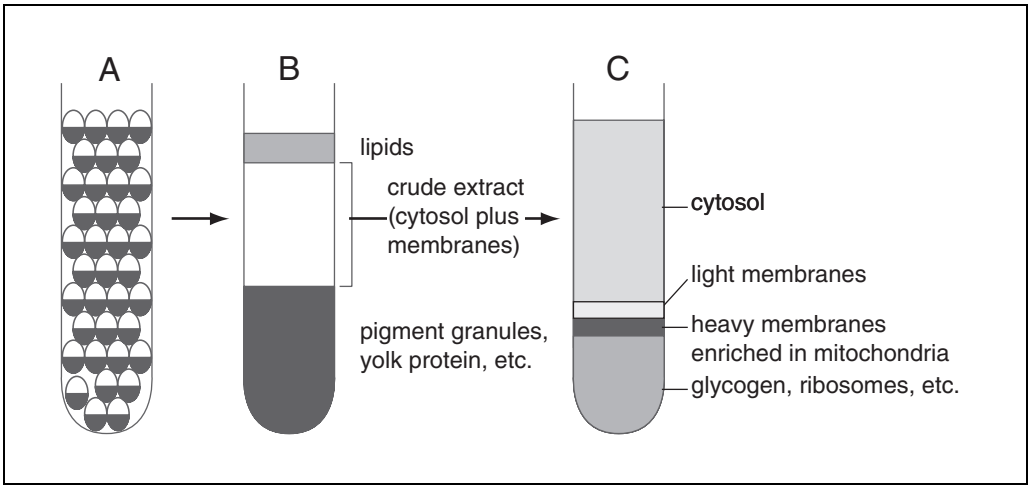

Figure 11.10.1 Preparation of the interphase egg extract. Eggs are packed in tubes by low-speed centrifugation (**A**) and then are centrifuged further at 12,000 × *g* to produce layers containing lipids, crude extract, and pigment granules (**B**). The crude extract can be further fractionated into cytosol, light membranes, and a heavy membrane fraction enriched in mitochondria (**C**).

8. On the basis of the volume of the packed eggs, add the following directly to the top of the packed eggs:

   5 µg/ml aprotinin (1:1000 dilution of 5 mg/ml stock)
   5 µg/ml leupeptin (1:1000 dilution of 5 mg/ml stock)
   5 µg/ml cytochalasin B (1:1000 dilution of 5 mg/ml stock)
   5 µl/ml of 10 mg/ml cycloheximide (50 µg/µl final)

   Aprotinin and leupeptin inhibit proteases, cytochalasin B inhibits actin polymerization, and cycloheximide inhibits protein synthesis.

9. Lyse eggs by centrifuging 15 min at 12,000 × *g*, 4°C, in Sorvall HB-4 swinging bucket rotor.

   The lysed eggs will be separated into three layers, a yellow lipid layer on top, the crude interphase extract in the middle, and a dark pellet (see Fig. 11.10.1B).

Collect extract

10. Remove the crude interphase extract by piercing the side of the polypropylene tube with an 18-G needle attached to a 5-ml syringe.

    The crude extract contains cytoplasm, light membrane from the ER and nuclear envelope, ribosomes, and heavy membrane organelles including mitochondria.

    When incubated at room temperature in the presence of sperm chromatin and an ATP-regenerating cocktail, the crude extract supports nuclear reconstitution (see Basic Protocol 2). However, this extract will not support nuclear assembly after freeze/thawing.

    The extract can be stored ~1 hr on ice.

PREPARING FRACTIONATED INTERPHASE EXTRACTS

ALTERNATE PROTOCOL 1

Using the following protocol, the crude interphase egg extract may be separated by high-speed centrifugation into discrete cytoplasmic, light-membrane, and heavy-membrane (mitochondrially-enriched) fractions. The cytosolic and light-membrane fractions can be snap-frozen in liquid nitrogen, stored at −80°C, and later reconstituted with sperm chromatin for nuclear assembly.

Additional Materials *(also see Basic Protocol 1)*

Crude interphase extract (see Basic Protocol 1)
2.5-ml Ultraclear centrifuge tubes
TLS centrifuge and TLS-55 rotor (Beckman) or equivalent

1. If this has not been done already (see Basic Protocol 1, step 8), supplement the isolated crude interphase extract with aprotinin and leupeptin (1:1000 dilution of 5 mg/ml stock) and cytochalasin B (1:1000 dilution of 5 mg/ml stock).

2. Transfer extract to a 2.5-ml Ultraclear centrifuge tube. Centrifuge the crude extract 70 min in a Beckman TLS-100 centrifuge at 250,000 × *g* (55,000 rpm in TLS-55 rotor), 4°C.

   The extract will separate into a clear cytoplasmic portion with a pale yellow membrane fraction below. A dark membrane fraction consisting of mitochondria and other organelles will lay below the light membranes (Fig. 11.10.1C).

3. Keeping extract on ice, remove clear cytoplasmic fraction with 200-µl pipet tip, taking care not to disrupt the light membrane layer. Retain both the cytoplasmic fraction and membrane layer and keep on ice.

4. Centrifuge cytoplasmic fraction again, in a new 2.5-ml Ultraclear centrifuge tube, 25 min at 250,000 × *g*, 4°C. Collect the top cytoplasmic fraction as in step 3, divide into aliquots (50 or 100 µl/microcentrifuge tube), freeze in liquid nitrogen, and store at −80°C until ready for use.

   Steps 5 and 6 should be performed while the above centrifugation is in progress.

5. Using a micropipettor with a cut-off or wide-bore pipet tip, carefully remove the light membrane fraction from the membrane layer (step 3), leaving dark membranes undisturbed. Dilute all of the light membrane in 1.5 ml egg lysis buffer and store on ice until ready to perform step 7.

6. Add 0.42 g sucrose to 5 ml egg lysis buffer to create 2× sucrose/egg lysis buffer. Chill to 4°C

7. When ready to centrifuge the membranes, place the diluted membranes (step 5) into 2.5-ml Ultraclear centrifuge tube. Underlay the membranes with 2× sucrose/egg lysis buffer by releasing it from a Pasteur pipet at the bottom of the membrane-containing tube. Add enough buffer to fill the tube.

   A clear layer will easily be seen below the membranes.

   The 2× sucrose/egg lysis buffer acts as a cushion to remove any proteins peripherally or nonspecifically associated with the membranes.

8. Centrifuge 20 min at 26,000 × *g* in the TLS-55 rotor, 4°C.

   After centrifugation, the membrane will be in a pellet at the bottom of the tube.

9. Pipet off the clear buffer until only the membrane fraction remains in the tube. With a wide-bore pipet tip, divide membranes into aliquots (5 to 10 µl per 0.5-ml microcentrifuge tube), flash freeze, and store at −80°C until ready for use.

   If there are any contaminating mitochondria/heavy membranes in the light membrane fraction, they will appear as a dark spot in the center of the light membrane pellet. By gently flicking the tube, the light membrane will dislodge, leaving an adherent mitochondrial pellet. It is important to avoid contaminating the light membrane with this fraction; therefore, should any dark spot be apparent, carefully use a wide-bore pipet tip to remove the light membranes to a separate tube before aliquoting.

SUPPORT PROTOCOL 1

INJECTION OF FROGS TO OBTAIN EGGS

Xenopus laevis mature females can be obtained from a number of commercial sources, including Nasco, Xenopus I, and Xenopus Express (see *SUPPLIERS APPENDIX*). Frogs should be kept in clean, dechlorinated tap water, at a maximal density of one frog per liter (though lower densities are desirable). Although dechlorination can be achieved by storing water in an open tank for 24 hr with aeration, it is faster to pass the water through a carbon filter. Optimal egg production is maintained by housing frogs at 18°C. Frogs can be fed a variety of foods, but the easiest is frog brittle from Nasco or Purina trout chow (1 g/frog, 3 to 4 days/week). Water should be changed on the days following feeding.

To produce eggs, frogs are primed with pregnant mare serum gonadotropin and are then induced to lay eggs at least 2 days later by injection of human chorionic gonadotropin.

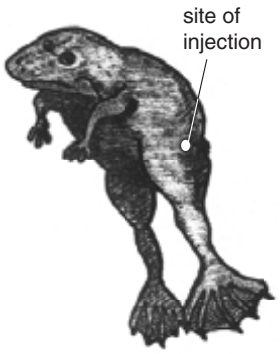

Figure 11.10.2 *Xenopus* injection site. The dorsal lymph sac, where the frog is injected, lies at the juncture of the torso and the upper portion of the leg. There is a loose fold of skin at this location under which the needle is slipped. Do not push the needle down into the muscle.

Materials

Female frogs, mature (e.g., Nasco, Xenopus I, or Xenopus Express)
100 mM NaCl (25 g NaCl/5 liters H_2O)
200 U/ml pregnant mare serum gonadotropin (PMSG; Calbiochem): reconstitute powder in sterile water to allow final injection volume of 0.5 ml (i.e., 200 U/ml final concentration); store in aliquots indefinitely at −20°C
1000 U/ml human chorionic gonadotropin (HCG; Sigma or Amersham/USB): reconstitute powder in sterile water to allow final injection volume of 0.5 ml (i.e., 1000 U/ml final concentration); store up to 1 month at 4°C
1× modified Ringer's solution (MMR; optional; see recipe)

Water tanks
1-ml syringes
25-G needles

1. For priming frogs, prepare a tank containing 100 mM NaCl to house frogs after injection.

   Primed frogs should be kept at a density of ~1 frog/liter.

2. Using a 25-G needle attached to a 1-ml syringe, inject frogs subcutaneously into the dorsal lymph sac (see Fig. 11.10.2) with 0.5 ml of 200 U/ml PMSG (total of 100 U). Return primed frogs to the tank prepared in step 1.
3. After a 2- to 3-day interval, induce egg laying by injecting frogs with 0.5 ml of 1000 U/ml HCG (total of 500 U), by the same route as PMSG injection (step 2). After injection, place each frog in 5 liters of 100 mM NaCl (or place the frog in 1× MMR if the eggs are to be used for preparation of cycling or CSF extracts; see *UNIT 11.11*).

   If more than one frog is injected, it is best to put each frog in its own container as the quality of eggs varies from frog to frog.

4. Approximately 16 to 22 hr after HCG injection (if frogs are kept at 18°C), remove the frog to a clean water tank and pour the eggs into a beaker.

   It is advisable to observe the frogs for 1 to 2 days for signs of infection at the site of injection.

5. Sort through the eggs and remove any bad eggs and oocytes.

   A "good egg" is one with even, unmottled pigmentation. A white pinpoint-sized spot, indicative of oocyte maturation, should be visible in the center of the darkly pigmented hemisphere of the mature egg. A particularly "bad" egg will appear as a white puffy ball, with the boundary between the hemispheres entirely obscured.

BASIC PROTOCOL 2

NUCLEAR ASSEMBLY IN THE INTERPHASE EGG EXTRACT

When sperm chromatin or other DNA templates (e.g., λ DNA) are added to interphase *Xenopus* egg extracts, membrane vesicles present in the extract bind to the surface of the chromatin, fuse, and incorporate nuclear pore components to form fully functional synthetic nuclei. These nuclei are competent to replicate their DNA (see Basic Protocol 4), transport macromolecules (see Basic Protocol 3), and undergo apoptotic nuclear fragmentation (see *UNIT 11.12*). This protocol describes the steps in setting up a nuclear assembly reaction using sperm chromatin as a template. This can be done using either crude interphase extract (Basic Protocol 1) or previously stored fractionated cytosol and light membranes (Alternate Protocol 1).

Materials

Interphase extract: crude (see Basic Protocol 1) or fractionated (see Alternate Protocol 1)
0.2 M phosphocreatine (store in small aliquots at −20°C)
5 mg/ml creatine kinase (store in small aliquots at −20°C)
0.2 M ATP (store in small aliquots at −20°C)
Sperm chromatin (see Support Protocol 2)
Fixative for visualizing nuclear assembly (see recipe)

Microscope slides
18-mm^2 glass coverslips
Fluorescence microscope

Prepare mix for nuclear assembly

1. To either crude extract or fractionated cytosol add phosphocreatine (from 0.2 M stock) to a final concentration of 20 mM, creatine kinase (from 5 mg/ml stock) to 50 µg/ml, and ATP (from 0.2 M stock) to 20 µM.

   Alternatively, It is also acceptable to use the 20× energy regenerating mix described in UNIT 11.11.

2. If fractionated extract is being used, add light membranes to the cytosol at a 1:10 dilution.

   This approximates the amount of membrane present in the original crude extract.

3. After vigorous mixing of the sperm chromatin preparation by repeated pipetting, add sperm chromatin to the crude or fractionated extract at the desired concentration and mix extract/sperm by up-and-down pipetting.

   Generally, these reactions are set up in 500-µl microcentrifuge tubes with a total volume <100 µl. Egg extracts will support the formation of up to 8000 to 9000 nuclei/µl. As more and more chromatin is used, the nuclei will become smaller in size due to depletion of nuclear-forming membranes. Below 50 nuclei/µl, it becomes increasingly difficult to locate nuclei by microscopy.

4. Incubate 60 min to 2 hr at room temperature.

   Nuclear formation in crude extracts is considerably faster than in the fractionated extract. In a robust extract, large nuclei can be seen in the crude extract within 60 min. Equivalently sized nuclei will form in the fractionated extract in ~2 hr.

Assess formation of nuclei

5. Mix the assembly reaction by gently pipetting up and down several times using a wide-bore or cut-off 200 µl pipet tip.

   This evenly suspends the nuclei which, especially as they grow larger, tend to settle out.

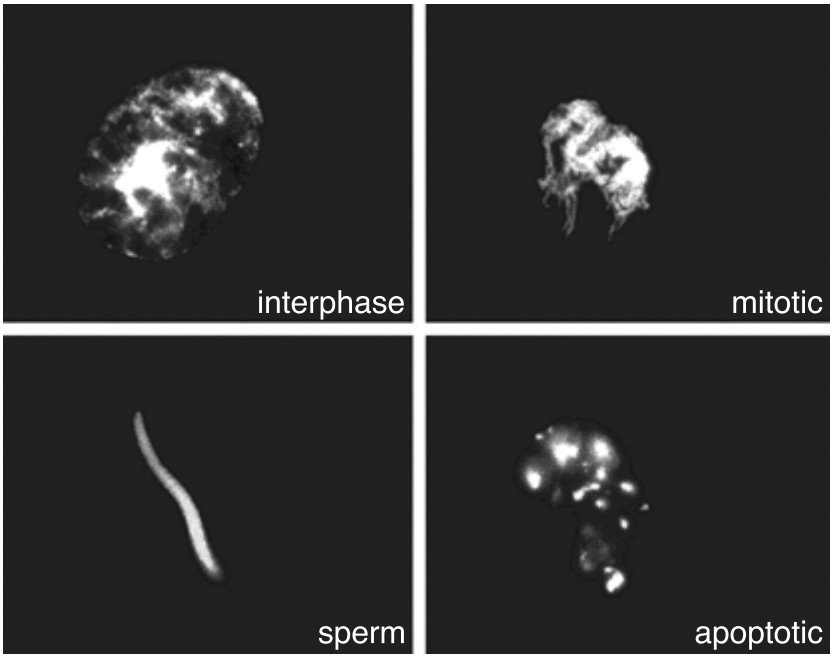

Figure 11.10.3 Nuclei in *Xenopus* egg extracts. Typical nuclei formed in *Xenopus* interphase extracts are shown as well as mitotic extracts (note condensed chromosomes) and apoptotic extracts (note fragmented nucleus). Also shown is a *Xenopus* sperm head prior to nuclear formation.

6. Remove a 4-µl aliquot of the assembly reaction mixture using a cut-off tip and spot it onto a glass microscope slide. Add 1 µl of fixative and gently swirl it into the sample by circling the pipet tip. Slowly and very gently lay a glass coverslip (18-mm^2) over the sample and examine the nuclei under the fluorescence microscope.

   The nuclei undergo a series of morphological changes as nuclear formation progresses. In a crude extract, after ~30 min, the newly formed nuclei will be small and oval in shape. The DNA is still quite condensed, and the nucleus should appear to be a solid light blue (from Hoechst binding) when observed in the UV channel. As the DNA decondenses further, the blue staining will be less homogeneous, with black "gaps" eventually appearing (e.g., Fig. 11.10.3). The formation of an intact nuclear envelope is evaluated by the ability of intact nuclei to exclude the high-molecular-weight FITC-dextran (which can be added to the fixative). Since the dextran does not contain a nuclear localization signal, once a fully closed nuclear membrane has formed, this large molecule will not enter the nucleus.

   As an alternative, the membrane can be visualized with 3,3′-dihexyloxacarboxyanine (DHCC; Kodak; 1 µg/ml included in the fix in place of FITC dextran). This is a fluorescent, lipophilic dye that is visualized in the fluorescein channel. In early stages of assembly, membrane vesicles are bound on the chromatin surface and begin to fuse in patches. This results in an uneven and discontinuous appearance of the forming membrane. Once the membrane is complete, it "smooths out" over the nuclear surface and will appear as an even, unbroken rim around the DNA (note that this can also be observed as a dark phase-dense line around the nucleus using phase-contrast microscopy). There will be a fair amount of background fluorescence in the surrounding cytosol due to membrane vesicles which have not been (or cannot be) incorporated into nuclei (see Fig. 11.10.3).

SUPPORT PROTOCOL 2

PREPARATION OF DEMEMBRANATED SPERM CHROMATIN TO USE AS TEMPLATES FOR NUCLEAR ASSEMBLY

Male *Xenopus* testes provide an abundant source of easily prepared chromatin to use as templates for nuclear assembly in the extract. Male frogs, which can be purchased from the same suppliers as the females (see Support Protocol 1), are most visibly distinguished from females by their relatively small size and by the presence of darkly pigmented patches on their forearms. Because frogs are external fertilizers, they produce large amounts of sperm. Consequently it is reasonable to expect to obtain 1 to 2×10^7 sperm heads per frog. These are generally used for nuclear formation in egg extracts at anywhere from 100 to 4000 per µl, depending upon the application. This protocol has been adapted from one developed by Drs. C. Macaulay and D. Forbes (University of California, San Diego).

Materials

4 to 5 male *Xenopus* (e.g., Nasco, Xenopus I, or Xenopus Express)
0.1% (w/v) Tricaine (see recipe)
Extraction buffer (see recipe), 4°C
Extraction buffer (see recipe) containing 200 mM, 2 M, 2.3 M, and 2.5 M sucrose
5 mg/ml aprotinin (Roche Diagnostics) in H_2O
5 mg/ml leupeptin (Roche Diagnostics) in H_2O
Dithiothreitol (DTT)
Triton X-100
Sucrose, ultrapure
Bovine serum albumin (BSA; fraction V)

Dissecting tools including scissors and 2 pairs of sharp forceps
60-mm glass petri dish
15-ml conical polypropylene tubes
Tabletop centrifuge
Refrigerated centrifuge with Sorvall HB-4 swinging-bucket rotor or equivalent
2.5 ml Beckman Ultraclear centrifuge tubes
TL-100 tabletop centrifuge and TLS-55 rotor (Beckman) or equivalent

Additional reagents and equipment for counting with a hemacytometer (*UNIT 1.1*)

Dissect testes

1. Anesthetize male frogs by immersion in 0.1% Tricaine (or immobilize in ice water) and sacrifice either by cervical dislocation or by pithing, followed by cutting through the spinal cord. Using dissection scissors, cut through the skin into the peritoneum along the midline of the frog.

   As indicated in the diagram (Fig. 11.10.4), the testes are located on either side of the midline in the center of the abdominal cavity. They are beige-colored 0.5-cm organs.

2. After pushing the liver aside, grasp the fatty material at mid-abdomen and pull gently until the testes emerge on either side of the midline. Gently cut them free of adherent tissue with either a forceps or scissors, and place in a 60-mm glass petri dish containing 4°C extraction buffer.

   To prepare a sizeable stock of sperm, testes should be isolated from 4 to 5 frogs and then placed in the petri dish containing extraction buffer.

3. Using 2 pairs of sharp forceps, mince the testes into small pieces and transfer them to a 15-ml conical polypropylene tube.

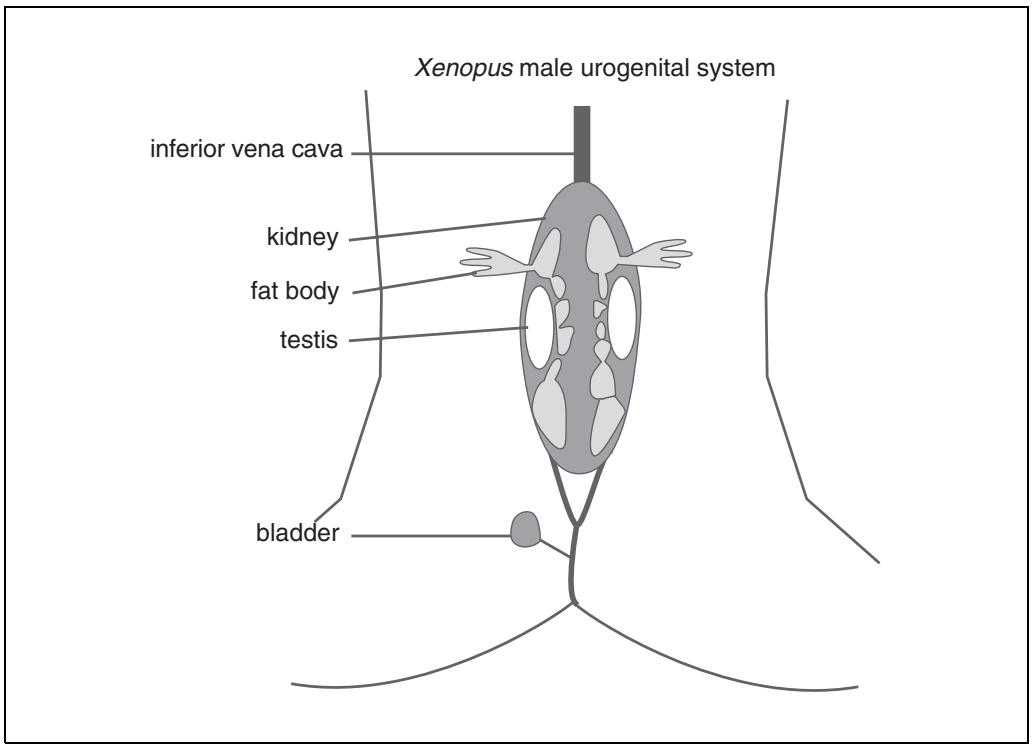

Figure 11.10.4 Schematic of the male *Xenopus* urogenital system. Testes are two white organs flanking the midline.

4. Vortex the minced testes vigorously and pellet the larger pieces by gentle centrifugation (10 sec at ~200 × *g*, room temperature in a clinical tabletop centrifuge).

Isolate sperm heads

5. Remove the supernatant to a new tube and add 3 ml extraction buffer supplemented with 200 mM sucrose to the pellet. Vortex 1 min, and briefly recentrifuge for 10 sec at 200 × *g*, room temperature. Combine the supernatants and repeat the extraction of the pellets 2 to 3 times until the supernatant is not very cloudy.
6. Centrifuge the combined supernatants 50 sec at 450 × *g*, room temperature, to pellet any remaining large pieces of tissue. Transfer the supernatants to a 15-ml tube and centrifuge 10 min at 2600 × *g* (4000 rpm in a Sorvall HB4 rotor), room temperature.
7. Prepare gradients by adding 0.2 ml extraction buffer containing 2.5 M sucrose to each of four 2.5-ml Beckman Ultraclear tubes and overlaying with 1.7 ml of extraction buffer containing 2.3 M sucrose.
8. Resuspend sperm in 0.8 ml extraction buffer containing 2 M sucrose and overlay gently onto the top of the sucrose gradients (0.2 ml per tube). After stirring the interface between the sperm and the 2.3 M sucrose with a pipet tip, centrifuge the sucrose gradients in a TL-100 tabletop ultracentrifuge, 25 min at 93,000 × *g* (33,000 rpm a TLS-55 rotor), 4°C.
9. Aspirate the top half of the gradient, which contains contaminating red blood cells. Transfer the lower half of the gradient to a new tube.

   Although the majority of the sperm bands on top of the 2.3 M sucrose cushion, the authors generally keep the entire lower half of the gradient.

10. Dilute sperm to 12 ml with extraction buffer containing 200 mM sucrose and pellet the sperm by centrifuging 10 min in a swinging-bucket rotor at 4100 × *g* (5000 rpm in a Sorvall HB4 or HB6 rotor or equivalent), 4°C.

Demembranate sperm

11. Supplement extraction buffer with additives at the following concentrations:

    200 mM sucrose
    5 µg/ml aprotinin (add from 5 mg/ml stock)
    5 µg/ml leupeptin (add from 5 mg/ml stock)
    1 mM DTT
    0.4% (v/v) Triton X-100.

    Resuspend the pellet in 1 ml of this supplemented extraction buffer/200 mM sucrose. Incubate 30 min on ice.

    This serves to demembranate the sperm.

12. Prepare sucrose cushions in two 1.5-ml microcentrifuge tubes by adding:

    0.5 ml extraction buffer
    0.5 M sucrose
    5 µg/ml leupeptin
    5 µg/ml aprotinin
    1 mM DTT
    3% (w/v) bovine serum albumin (BSA; fraction V).

    Overlay each sucrose cushion with one-half of the sperm preparation from step 11 and centrifuge 10 min in a clinical tabletop centrifuge at 870 × g, room temperature, to pellet the sperm.

13. Supplement extraction buffer with additives at the following concentrations:

    200 mM sucrose
    3% (w/v) bovine serum albumin (BSA; fraction V)
    5 µg/ml aprotinin (add from 5 mg/ml stock)
    5 µg/ml leupeptin (add from 5 mg/ml stock)
    1 mM DTT.

    Remove the supernatant from the pellets obtained in step 12 and resuspend the sperm pellet in 0.1 ml of the supplemented extraction buffer prepared in this step. Transfer the resuspended sperm to a clean microcentrifuge tube.

    At this point, it is important to avoid contaminating the preparation with residual Triton X-100 from the sides of the original tube.

Prepare final sperm suspension

14. Resuspend the sperm chromatin pellet in a total of ~0.25 ml of the supplemented extraction buffer/200 mM sucrose prepared in step 13.

15. Count the sperm using a hemocytometer and dilute the suspension to 50,000 to 100,000 sperm/µl. Snap freeze the sperm in small aliquots in liquid nitrogen and store at −70°C.

    The typical yield is 1–2 × 10^7 sperm per frog.

    At this point, the sperm are discrete masses of tightly condensed chromatin, unbounded by membranes.

NUCLEAR PROTEIN IMPORT IN VITRO

Once nuclei have been formed from interphase extracts, they can be assayed for the ability to import nuclear proteins by the addition to the extract of a fluorescently labeled import substrate (see *UNIT 11.7*). This provides a relatively rapid, visual assay that can be used to confirm that nuclei in the extract are intact and functional (see Basic Protocol 2). Nuclear transport can be monitored over time by quantitation of the amount of substrate that accumulates in the nucleus at various time points.

This following protocol can be used to quantitate nuclear import for comparison between different conditions or extracts, or simply to assess functional competence of nuclei in which another parameter is being altered.

Materials

Interphase egg extract: crude (see Basic Protocol 1) or fractionated (see Alternate Protocol 1)
ATP-regenerating system (see Basic Protocol 2)
Xenopus sperm chromatin (see Support Protocol 2)
Nuclear import substrate (*UNIT 11.7*)
Fix 1 (see recipe for fixatives for visualizing nuclear protein import)
16% (w/v) paraformaldehyde
Fix 2 (see recipe for fixatives for visualizing nuclear protein import)

Microscope slides
Coverslips
Fluorescence microscope equipped with:
64× objective (e.g., Zeiss 64× planapochromat, large aperture)
CCD camera
Frame grabber
Computer running image analysis software (e.g., NIH Image)

Additional reagents and equipment for assembling nuclei (see Basic Protocol 2)

1. Assemble nuclei using sperm chromatin and the interphase extract, along with the ATP-regenerating system (phosphocreatine, creatine kinase, and ATP; see Basic Protocol 2, step 1 and materials list), or add ~1000 nuclei per µl of extract from another source (e.g., rat liver nuclei) into the extract. Incubate 30 min, at room temperature.

2. After ~30 min incubation, check that nuclei have been formed (see Basic Protocol 2, step 5).

Where time course is not to be performed

3a. Once nuclei are formed, add the nuclear import substrate (*UNIT 11.7*) to the assembly reaction and mix by gently pipetting. Incubate 30 min, or longer, at room temperature.

> *The exact amount of substrate to add must be determined empirically, depending upon the particular batch of substrate and the purpose of the assay. For a simple determination of function, RITC import substrate should be added at a final concentration of ~5 µg/ml (1/200 dilution). For quantitation of a time course of import, the concentration should be somewhat lower in order to keep the signals within a linear response range over the time of the assay.*

4a. After the nuclei have been incubated with import substrate for 30 min or longer, remove and fix aliquots, using Fix 1, to detect uptake of the substrate. Store fixed samples in the dark at 4°C, if necessary.

> *Fixation is essentially immediate upon exposure to Fix 1.*

For quantitation of the time course of import

3b. Set up an assembly reaction (see above) of sufficient volume to allow for removal of at least 5-µl aliquots at each timepoint.

Quantitation of a import assay requires at least 15 to 20 min. For this reason, when performing a time course, it is best to fix each sample with 16% paraformaldehyde and then quantitate import after all samples have been collected.

4b. Immediately after the addition of import substrate, remove an aliquot from the reaction (5 µl) and transfer to a microcentrifuge tube on ice. Fix this sample (T_0) by adding 1.5 µl of 16% paraformaldehyde to bring the final concentration to 3.7% paraformaldehyde. Mix gently with a cut-off pipet tip. Store fixed samples in the dark at 4°C. At desired time points, continue to remove aliquots and fix as above.

5. Prepare samples for microscopy immediately before use. Place 4 µl of the fixed aliquot on a slide, and add 1 µl of Fix 2. Gently place a coverslip over the sample.

As the nuclei grow larger, they become increasingly susceptible to breakage when prepared for microscopy so the coverslip must be placed on the sample very gently and gradually. Breakage of a nucleus during processing can allow leakage of imported substrate. For this reason, the exclusion of FITC-dextran is used to identify intact nuclei.

6. Quantitate transport immediately after adding the coverslip and score only nuclei that exclude the FITC-dextran.

Because of the possibility of nuclear breakage, finding sufficient scorable nuclei can be a significant problem and thus, if possible, it is best to have large enough aliquots that more than one sample can be prepared if needed.

7. For quantitation, observe nuclei using a 64× objective on a microscope equipped with CCD camera, frame grabber, and computer running image analysis software.

The authors use a Zeiss 64× planapochromat large aperture objective which is very light sensitive.

NIH Image is available at no cost and is sufficient for this application, although more sophisticated and expensive software packages are available.

8. Once an appropriate nucleus is identified, capture the image and encircle the outline of the nucleus on the computer using the mouse. Determine the average fluorescence intensity within the nucleus, as well as the nuclear area using the software. Multiply average fluorescence by the area to yield the total nuclear fluorescence.

BASIC PROTOCOL 4

DNA REPLICATION WITH CONTINUOUS LABELING

DNA replication assays can be done using unfractionated interphase extracts (Basic Protocol 1), fractionated, reconstituted interphase extracts (Alternate Protocol 1), or cycling extracts (*UNIT 11.11*). While it takes ~1 hr to replicate 1000 synthetic nuclei/µl of crude extract, it can take 2 to 4 hr to fully replicate nuclei in a reconstituted extract. Although the protocol detailed below is useful for measuring replication of sperm chromatin nuclei in the extract, it can also be used to measure plasmid replication rates in the extract, and to examine replication of intact nuclei from other sources (e.g., nuclei prepared from tissue culture cells) added to extracts. It is worth bearing in mind the fact that these templates may replicate more slowly than sperm chromatin nuclei and that plasmid replication, in particular, will be slowed by inefficient nuclear formation (a prerequisite for replication in this system).

Two distinct replication assay protocols, continuous and pulse labeling (see Alternate Protocol 2) which depend upon the incorporation of radiolabeled nucleotides (e.g.,

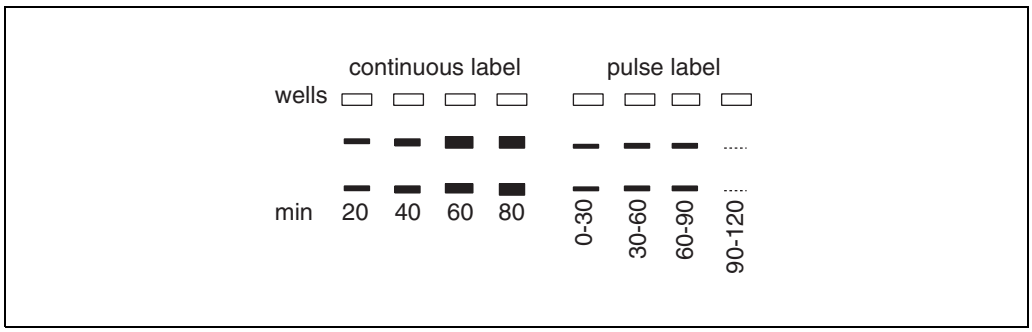

Figure 11.10.5 The banding pattern of labeled DNA following replication of DNA in egg extracts. When the products of a DNA replication reaction in *Xenopus* egg extract are resolved by agarose gel electrophoresis, two distinct bands are apparent (shown here schematically). In the case of continuous labeling, the intensity of these bands increases with time as increasingly more label is incorporated into DNA. In the case of pulse labeling, incorporation generally peaks and then diminishes as replication is completed (hence, as shown schematically here, no incorporation of label is seen at the later time point).

[α–^{32}P]dCTP) into replicating DNA, are routinely used. Direct inclusion of these nucleotides in extracts, withdrawal of aliquots, and resolution by agarose gel electrophoresis will give an estimate of total DNA replication, which will increase over time. Conversely, replication can be measured by inclusion of radiolabeled nucleotide in aliquots of extract over specific time intervals (e.g., 0 to 20 min, 20 to 40 min, 40 to 60 min, etc., after the start of nuclear formation) to compare, for instance, the replication that has occurred in one time interval with that which occurs in another. This "pulse replication" methodology is a more sensitive method than continuous labeling for comparing replication efficiency after different experimental treatments of the extract (e.g., depletion of particular components, addition of inhibitors; see Support Protocol 3 and Support Protocol 4, respectively).

When using sperm chromatin as the replication template, there should be two radiolabeled bands of replicated DNA. The pattern of incorporation differs when the two different replication protocols are used, as would be expected for continuous or pulsed incorporation of label (see schematic, Figure 11.10.5).

Materials

Interphase extract (see Basic Protocol 1)
0.2 M phosphocreatine (store in small aliquots at −20°C)
5 mg/ml creatine kinase (store in small aliquots at −20°C)
0.2 M ATP (store in small aliquots at −20°C)
Demembranated sperm chromatin (see Support Protocol 2)
10 μCi/μl [α–^{32}P]dCTP (3000 Ci/mmol)
Replication stop buffer (see recipe)
10 mg/ml proteinase K (Worthington)

Additional reagents and equipment for agarose gel electrophoresis (*APPENDIX 3A*) and autoradiography or phosphorimaging (*UNIT 6.3*)

1. To interphase extract add phosphocreatine (from 0.2 M stock) to a final concentration of 20 mM, creatine kinase (from 5 mg/ml stock) to 50 μg/ml, and ATP (from 0.2 M stock) to 2 mM.

2. For replication assays using sperm chromatin, pipet the demembranated sperm chromatin vigorously to eliminate clumping and add directly to extract at a final concentration of 100 to 4000 sperm heads/μl of extract.

3. Add [α–^{32}P]dCTP (or one of the other three deoxynucleotides in radiolabeled form) directly to the extract at 0.1 µCi/µl of extract and incubate at room temperature.
4. Withdraw 10-µl aliquots at 20-min intervals into an equal volume of replication stop buffer.
5. Add 3 µl of 10 mg/ml proteinase K stock to each aliquot and incubate 2 hr at 37°C.
6. Resolve samples on a 1% agarose gel.

   Any of the standard agarose gel running buffers will work fine.

   Loading the gel may be difficult if proteinase K treatment is not complete as the DNA will tend to adhere to the pipet tip.
7. Dry the gel and expose to film for autoradiography or develop by phosphorimager (*UNIT 6.3*).

ALTERNATE PROTOCOL 2

PULSE-LABELING DNA TO ASSESS REPLICATION

For this protocol, the replication reaction is initiated in the absence of labeled precursor. At defined time points (e.g., at 15- or 30-min intervals), samples of the reaction mixture are taken. Radiolabeled precursor is added to the sample for a defined period to measure replication during that time period.

Additional Materials *(also see Basic Protocol 4)*

XB buffer (see recipe)

1. Dilute 1 part [α–^{32}P]dCTP in 4 parts XB buffer and add 0.5 µl (1 µCi) of the resulting mix to an empty microcentrifuge tube for each time point to be taken. Do this for each condition to be tested (e.g., control extract, extract with added protein of interest, extract with depleted protein of interest, etc.). Let stand at room temperature.

   These are the assay tubes. To use fractionated extracts which have been reconstituted (the ultra S extract with added membrane), it should be suitable to set up assay tubes for the following intervals: 0 to 30 min, 30 to 60 min, 60 to 90 min. 90 to 120 min, and 120 to 150 min. For crude interphase extracts, it is better to have shorter time points; for example: 0 to 15 min. 15 to 30 min, 30 to 45 min, 45 to 60 min, 60 to 75 min, 75 to 80 min. Leave at room temperature.
2. Set up the reactions (Basic Protocol 4, steps 1 and 2). Place on ice.

   These are the master sample tubes.
3. To start the assay, move the master sample tubes to room temperature and remove 5 µl from each master sample tube to the first of each assay tube containing the [α–^{32}P]dCTP (e.g., the 0 to 30 min assay tube for fractionated extract or 0 to 15 min assay tube for unfractionated extract tube). Continue incubating the master sample and assay tubes at room temperature.
4. At the end of the specified time interval (e.g. 30 min or 15 min), add 5 µl of replication stop buffer and remove sample to ice. Withdraw 5 µl more from each of the master sample tubes and transfer to the next assay tube in the series (e.g., 30 to 60 min, 15 to 30 min). Again, stop the reaction by addition of replication stop buffer at the end of the specified time interval. Continue this until all time intervals have been done.

   This will give you "snapshots" of replication that occurred during each time interval.

   It is worthwhile to examine the morphology of nuclei in the samples at several time points during the experiment (see Basic Protocol 2) to make sure experimental treatments have not compromised nuclear architecture, which might in itself impair replication.
5. Digest samples with proteinase K and resolve by agarose gel electrophoresis as in Basic Protocol 4.

PREPARATION OF OOCYTE EXTRACT

Mature *Xenopus* Stage VI oocytes are physiologically arrested in prophase of the first meiotic division and therefore contain inactive cdc2/cyclin B complexes. Progesterone treatment of prophase I–arrested oocytes triggers meitotic maturation, concomitant with activation of the cdc2/cyclin B kinase. An additional Ser/Thr kinase, mos, is also required for meiotic maturation of oocytes. The oocyte extracts described below mimic several features of in vivo prophase I–arrested oocytes, including the ability of mos to evoke activation of MAP kinases.

Materials

Female frogs, mature (e.g., Nasco, Xenopus I, or Xenopus Express)
0.1% (w/v) Tricaine (see recipe)
Modified Barth's (MB) with and without calcium (see recipe)
1 mg/ml collagenase A (Roche Diagnostics) in MB (see recipe) without calcium
EB buffer (see recipe)
1000× CLAP protease inhibitor cocktail (see recipe)
1000× (5 mg/ml) cytochalasin B in DMSO

Dissecting microscope
Dissecting scalpel
Sharp forceps
50-ml plastic tubes
Tube rotator
Clinical centrifuge
Tabletop ultracentrifuge and swinging-bucket rotor
1-ml syringe
18-G needle

Dissect out ovary

1. Place female mature frog in 1 liter of 0.1% (w/v) tricaine until she is immobile, usually 30 to 60 min.

   Oocytes must first be dissected out of the anesthetized female frog

2. Place the frog on her back atop a bed of ice. Swab the abdomen first with deionized water and then with ethanol. Clean and sterilize all instruments with ethanol.

3. Make a small incision (~1 cm) in the abdomen, vertically and slightly off center. Cut through the skin and muscle layers.

   The oocytes, present in great abundance, should be readily apparent at this stage.

4. Gently tease oocytes out of the abdominal cavity and excise with a scalpel or scissors. Place oocytes in a petri dish containing MB without calcium.

   Precoating the dish with 6% (w/v) poly-HEMA in ethanol (dilute 12% poly-HEMA from Polysciences to 6% in ethanol) will prevent oocytes from sticking to the plastic dish. Simply pour the poly-HEMA solution onto the surface of the dish to coat, then pour off and allow to air dry in a hood. The dishes can be stored at room temperature (with lids).

5. Tear ovary (the mass of oocytes) into chunks of ~50 oocytes. Store oocytes that are not going to be used immediately in MB plus calcium at 18°C.

Free oocytes

6. Place ~10 ml oocytes in 50-ml tubes containing 30 ml collagenase A solution. Place on a tube rotator. Periodically check oocytes under the dissecting microscope until the majority have fallen away from the follicular cells.

Since prolonged treatment with collagenase can damage the oocytes, it is worthwhile to observe them carefully and remove them as soon as defolliculation is complete.

7. Remove and save the collagenase at −20°C.

   Collagenase A solution can be reused 3 to 4 times.

Wash and sort oocytes

8. Wash the oocytes extensively with MB minus calcium. Fill the 50-ml tube containing the oocytes with buffer, wait a few seconds for the larger, full-grown oocytes to settle and then, using a wide-bore pipet, aspirate the upper layer of buffer which contains the smaller, immature oocytes. Repeat this process five times to remove collagenase and to select for mature oocytes.

9. After washing, put oocytes in a petri dish for scanning with a dissecting microscope. Remove any oocytes that appear to be unhealthy (lysed or mottled), immature, or which have undergone germinal vesicle breakdown (GVBD).

   If oocytes have undergone GVBD, a while spot will appear at the top, center of the dark hemisphere of the oocyte.

   If oocytes are not to be used immediately to make an extract, store in MB plus calcium in a petri dish at 18°C for up to 2 days.

10. Carefully transfer oocytes to 50-ml conical tubes with the wide-end of a glass Pasteur pipet (place the bulb on the sharp end of the pipet, after snapping off most of the end). Wash twice with EB buffer using the method described in step 8.

11. Prepare 10 ml EB containing protease inhibitor cocktail CLAP (1:1000 dilution of stock solution). Wash oocytes with EB/CLAP using the method described in step 8.

12. Transfer oocytes to a thin-walled 2.5-ml polyallomer centrifuge tube for use in a tabletop ultracentrifuge rotor (e.g., for the Beckman TLS-55 rotor for the TL-100). Drop the filled small tube into a 15-ml centrifuge tube and pack the oocytes by gently spinning in a clinical centrifuge at 400 × *g* for 30 sec. Remove as much buffer as possible from the surface of the oocytes to prevent eventual dilution of the extracts.

Prepare oocyte extract

13. Lyse oocytes by centrifugation in a TL-100 ultracentrifuge (or equivalent), 15 min at 15,000 × *g* in a Beckman TLS-55 SW Ti rotor, 4°C.

    After centrifugation, three layers will be apparent: a black/green bottom layer (yolk platelets, mitochondria, etc.), a milky middle layer (oocyte extract), and a yellow top layer (lipids). The oocyte extract is a mixture of cytosolic and membranous components.

14. Using a 1-ml syringe with an 18-G needle, puncture the side of the tube at the base of the oocyte extract. Remove this layer and transfer to a second thin-wall centrifuge tube.

15. Add 1000× cytochalasin B to a final concentration in extract of 50 µg/ml (i.e., 1:1000 dilution of stock). Centrifuge as in step 13.

16. Transfer the large middle extract layer as in step 14 to a microcentrifuge tube and discard the pellet.

17. Divide the extract into 100-µl aliquots in mictocentrifuge tubes and snap freeze in liquid nitrogen. Store aliquots at −80°C.

IMMUNODEPLETION OF EXTRACTS

The ease with which components can be added to or depleted from in vitro reconstitution reactions is one of the chief advantages of using these systems to study biological processes. This protocol provides general guidelines for immunodepleting proteins from *Xenopus* egg extracts.

Complete immunodepletion of proteins from the egg extract often requires multiple rounds of depletion using a good, high-affinity antibody. One of the primary concerns is that depletion itself may cause artifactual perturbations in the process being studied. Therefore, it is critical to have a preimmune or IgG-depleted extract as a control. Moreover, it is important to avoid excessive dilution of the extract during the depletion procedure, since this may impair the proper functioning of the extract.

Materials

Antibody/antiserum
Preimmune serum or control IgG
Protein A–Sepharose
Phosphate-buffered saline (PBS; see recipe)
Bovine serum albumin (BSA), fraction V
XB buffer (see recipe)

1. Prepare antibody beads by incubating the affinity-purified antibody with protein A Sepharose in PBS containing 2 mg/ml BSA fraction V (also see *UNIT 7.2*). Prepare preimmune serum (control) beads in the same manner.

   If crude serum, rather than affinity-purified serum is being used, the protein A–Sepharose can be incubated directly with the serum without addition of BSA.

   Control protein A–Sepharose beads should be incubated with preimmune sera. If affinity-purified antibody is being used, the control can be pure IgG linked to protein A–Sepharose. While approximate volumes depend upon the antisera being used, ~15 µl of packed protein A–Sepharose can be incubated with ~10 µg of IgG in 200 µl of PBS containing 2 mg/ml BSA.

2. Pellet the beads in a microcentrifuge and remove all liquid.

3. *For crude or cycling extracts only:* Wash beads very rapidly with 100 µl or less of fresh extract that will be used for depletion experiments. Again, remove all liquid.

   Add extract to the beads, shake, centrifuge, and remove the extract; do this all in a cold room at 4°C. This allows the interstitial buffer of the beads to be replaced with extract and helps to avoid dilution of the extract to be depleted.

4. Add 100 µl of extract to be depleted to the 15 µl of packed antibody beads and rotate at 4°C for 40 min.

5. Pellet the beads by microcentrifuging and remove the supernatant to a new tube of antibody beads, washed as above.

6. Rotate at 4°C for 40 min and microcentrifuge. Remove the extract to a fresh tube.

   At this stage the supernatant contains a twice-depleted extract. A third (or even fourth) round of depletion may be necessary to completely deplete the protein of interest. The extent of depletion should be assessed by immunoblotting an aliquot of the depleted extract with the antibody used for the depletion or with an alternative antibody directed against the same protein. Occasionally, it is impossible to deplete a protein of interest, but addition of antibody directly to the extract has a "blocking" effect on the process being examined. If this effect can be reversed by adding an excess of the antigen, this can be an indication that the protein participates in the process under study.

ADDITION OF PROTEIN TO EXTRACTS

Addition of wild-type or mutant recombinant proteins to egg extracts often provides a relatively rapid assay of protein function. As with antibody addition, one of the most important considerations is adding a sufficient amount of protein to achieve an effect without excessively diluting the extract.

Materials

Recombinant protein of interest
XB buffer (see recipe)

Additional reagents and equipment for dialysis and microconcentration (*APPENDIX 3C*)

1. Dialyze or microconcentrate recombinant protein of interest into XB buffer.
2. Add proteins at more than a 1:5 dilution into the extract; if possible, a 1:10 or greater dilution is preferable.

   When using in vitro-translated proteins, the reticulocyte lysate will not grossly disrupt extract function if added directly to the extract at 1:10 or greater dilutions.

   This extract can be used for studying protein-protein interactions or for looking at biochemical reactions occurring in oocytes specifically. For example, MAPK can be activated in oocytes by addition of exogenous MOS protein.

REAGENTS AND SOLUTIONS

Use deionized distilled water in all recipes and protocol steps. For common stock solutions see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

CLAP protease inhibitor cocktail, 1000×

Prepare in DMSO:
10 mg/ml chymostatin
10 mg/ml leupeptin
10 mg/ml antipain
10 mg/ml pepstatin
Store in aliquots indefinitely at −70°C

EB buffer (for preparation of oocyte extract; Basic Protocol 5)

42.68 g sucrose (0.25 M final)
10 ml of 5 M NaCl (0.1 M final)
1.25 ml of 1 M $MgCl_2$ (2.5 mM final)
2.4 g HEPES (20 mM final)
Adjust pH to 7.2 with NaOH and bring the volume to 500 ml with water.
Store until cloudy at 4°C

Egg lysis buffer, pH 7.7

250 mM sucrose
2.5 mM $MgCl_2$
1 mM DTT
50 mM KCl
10 mM HEPES
Prepare fresh

Extraction buffer (for preparation of demembranated sperm chromatin; Support Protocol 2)

10 mM HEPES, pH 7.4
80 mM KCl
15 mM NaCl
5 mM $MgCl_2$
1 mM EDTA
Store until cloudy at 4°C

Fixative for visualizing nuclear assembly (Basic Protocol 2)

10 mM HEPES, pH 7.5
200 mM sucrose
1 µg/ml Hoechst 33258
1 mg/ml FITC-dextran
12% (w/v) paraformaldehyde
Store at −20°C wrapped in foil

Fixatives for visualizing nuclear protein import (Basic Protocol 3)

Fix 1:

1 µl of 1 M HEPES, pH 7.5 (10 mM final)
10 µl of 2 M sucrose (200 mM final)
1 µl of 1 mg/ml Hoechst 33258 (bisbenzimide; Calbiochem; 1 µg/ml final)
10 µl of 10 mg/ml fluorescein isothiocyanate–dextran (FITC-dextran, 150 kDa, Sigma; 1 mg/ml final)
77 µl of 16% paraformaldehyde (methanol-free, Polysciences; 12% final)

After opening 16% paraformaldehyde vial, divide solution into aliquots and store at –20°C.

Fix 2: (for use on previously fixed samples)

10 mM HEPES, pH 7.5
200 mM sucrose
1 µg/ml Hoechst 33258
1 mg/ml FITC-dextran
3.7% (w/v) paraformaldehyde
Store at −20°C wrapped in foil

Modified Barth's (MB) solutions

Prepare the following stock solutions:

Stock solution A:

64 g NaCl
1 g KCl
2.5 g $NaHCO_3$
44.5 g HEPES

Adjust pH to 7.6 with NaOH and bring the volume to 500 ml with water. Store in 20-ml aliquots at −20°C.

Stock solution B:

0.95 g $Ca(NO_3)_2 \cdot 4H_2O$
0.75 g $CaCl_2 \cdot 2H_2O$
1.23 g $MgSO_4$ anhydrous
Bring volume to 500 ml with water.
Store in 20-ml aliquots at −20°C

continued

Stock solution B without Ca:

Weigh out 1.23 g anhydrous $MgSO_4$ and bring volume to 500 ml with water. Store 20-ml aliquots at −20°C.

For Modified Barth's with calcium:

460 ml H_2O
20 ml stock solution A (see above)
20 ml stock solution B (see above)
2.5 ml 10 mg/ml gentamycin solution (Sigma)
Store at 4°C

For Modified Barth's without Ca:

460 ml H_2O
20 ml stock solution A (see above)
20 ml stock solution B without Ca (see above)
2.5 ml 10 mg/ml gentamycin solution (Sigma)
Store up to several months at 4°C

Modified Ringer's solution (MMR), pH 7.7, 10×

1 M NaCl
20 mM KCl
10 mM $MgSO_4$
25 mM $CaCl_2$
5 mM HEPES, pH 7.8
0.8 mM EDTA
Store indefinitely at room temperature
Dilute 10× MMR to 0.25× MMR in water (1:40) before extract is made

~200 ml of 0.25× MMR are required to make the interphase extract.

Phosphate buffered saline (PBS)

8 g NaCl
0.2 g KCl
0.1 g $CaCl_2$
0.1 g $MgCl_2 \cdot 6H_2O$
1.15 g $NaH_2PO_4 \cdot 2H_20$
0.2 g KH_2PO_4
Add water to 1 liter
Store indefinitely at room temperature

Replication stop buffer

80 mM Tris·Cl, pH 8.0 (*APPENDIX 2A*)
8 mM EDTA
0.13% phosphoric acid
10% Ficoll
5% (w/v) SDS
0.2% (w/v) bromphenol blue
Store at −20°C

Tricaine, 0.1% (w/v)

Dissolve 1 g 3-aminobenzoic acid ethyl ester (Tricaine; Sigma) in 1 liter water. Prepare fresh.

XB buffer

50 mM sucrose
100 mM KCl
0.1 mM $CaCl_2$
1 mM $MgCl_2$
10 mM potassium HEPES, pH 7.7
Prepare fresh

COMMENTARY

Background Information

The *Xenopus* egg is a very large cell (>0.5 mm in diameter) which, upon fertilization, gives rise to a 4000-cell embryo without any input from gene transcription and without any cell growth. In practical terms, this means that the egg contains a stockpile of cellular components poised for the assembly of cellular structures and for the execution of diverse cellular functions. While the normal somatic cell may contain the same range of cellular components as the egg, the vast excess of "uncommitted" components makes the egg an ideal source of material for in vitro reconstitutions.

There are multiple advantages to using the *Xenopus* egg cell-free system to study complex cellular processes such as cell cycle progression, DNA replication, apoptosis, nuclear envelope assembly and disassembly, and nuclear trafficking. In particular:

1. Because *Xenopus* are external fertilizers, each animal lays a large number of eggs, providing large amounts of homogeneous, cell cycle–synchronous material.

2. Pharmacological agents, recombinant proteins, and antibodies can be directly added to the in vitro extract, allowing direct manipulation and analysis of the biological process under examination.

3 Egg extracts are easily accessible to biochemical fractionation, facilitating immediate identification of factors involved in the process of interest.

4. Complex processes can be broken down into "partial reactions" that can be dissected individually (e.g., how does the first step in chromatin condensation occur?). Taken together, these features offer the opportunity to dissect even the most complex of cellular functions.

Extracts in interphase of the cell cycle

The key regulator of entry into mitosis in all eukaryotes studied to date is the Ser/Thr kinase cdc2/cyclin B (reviewed in Nurse 1990; Lew and Kornbluth 1996). This kinase complex is believed to catalyze mitotic cellular rearrangements either directly or indirectly through the phosphorylation of critical cellular substrates. Although cdc2 itself is inactive in its monomeric form, binding of the cyclin subunit activates cdc2 to promote mitosis. *Xenopus* eggs are physiologically arrested in metaphase of meiosis II with high cdc2/cyclin B kinase activity. Crushing these eggs by centrifugation releases Ca^{+2} from internal stores, leading to proteolysis of the cyclin subunit and loss of cdc2-associated kinase activity. Consequently, at the time of preparation, egg extracts transit from M phase to interphase of the cell cycle (S phase). Since cyclin B protein must be newly synthesized for each cell cycle, cycloheximide addition to extracts prevents reaccumulation of cyclin protein, and hence the extracts remain in interphase (Basic Protocol 1).

S phase extracts prepared from *Xenopus* eggs can spontaneously form nuclei upon addition of chromatin (Basic Protocol 2). While the most commonly used source of chromatin for these reconstitutions is demembranated sperm chromatin prepared from the testes of male *Xenopus* (see Support Protocol 2), even lambda phage DNA will suffice to provide a template for nuclear assembly, since it, too, will be packaged into chromatin by the extract (Forbes et al., 1983; Hartl et al., 1994). Although the precise molecular details of nuclear assembly have not yet been described in full, nuclear formation in the extract generally involves (1) swelling of the chromatin mediated, at least in part, by the nucleoplasmin protein, (2) binding of membrane vesicles to the surface of the chromatin, (3) fusion of bound membranes to form enclosed nuclear structures, and (4) further decondensation of the enclosed chromatin (Sheehan et al., 1988; Wilson and Newport, 1988; Philpott et al., 1991). At some point during this progression, functional nuclear pores are incorporated into the synthetic nuclei, allowing bidirectional nuclear transport of macromolecules. Indeed, it has been shown that nuclear pores can be incorporated de novo

into fully enclosed nuclear structures (Macaulay and Forbes, 1996).

Double-stranded DNA templates added to extracts will undergo a single round of semiconservative replication (see *UNIT 11.11*), provided they are assembled into nuclear structures (Blow and Laskey, 1986; 1988). In contrast, single-stranded templates will replicate even in the absence of nuclear structure, concurrently assembling into chromatin (Mechali and Harland, 1982).

Although primases in the extract will prime DNA synthesis from single-stranded templates, primers preannealed to the single-stranded DNA will be incorporated during replication. As is the case for nuclear assembly, the DNA sequence of templates to be replicated in the extract is not important, as highlighted by the ability of lambda DNA to replicate efficiently. This suggests that initiation at specific sequences may not be a feature of early embryonic DNA replication in *Xenopus*, though proteins critical for replication in all eukaryotes studied are of demonstrated importance in *Xenopus* (e.g., Orcs; Carpenter et al., 1996).

Nuclear transport and Xenopus egg extracts

Nuclei formed in egg extracts or added exogenously from another source are capable of supporting nuclear import of proteins. Nuclei can be assayed for the ability to import nuclear proteins by the addition to the extract of a fluorescently labeled nuclear import substrate (see Basic Protocol 3; Newmeyer et al., 1986; Finlay et al., 1989). This assay is often used as a relatively rapid and visual confirmation that nuclei are intact and functional (see Basic Protocol 2), and that they can be used to assess the rate of nuclear transport by quantitating the increase in nuclear fluorescence over time. Like nuclear transport in tissue culture cells, import into reconstituted nuclei is dependent upon temperature, energy in the form of ATP or GTP (which are readily interconverted in the extract), and a number of cytoplasmic protein factors. The specific functions of individual cytoplasmic factors have been most extensively studied using tissue culture cells which have been digitonin-treated to permeabilize their plasma membranes. This leaves the nuclear envelope intact, removes the cytoplasmic contents, and allows direct addition of proteins or cytosol to the environment outside the nucleus (see *UNIT 11.7*). Indeed, *Xenopus* extracts from eggs or oocytes have proven to be a convenient source of cytoplasmic material in such assays (e.g., Moore and Blobel, 1993; Gorlich et al., 1994). However, the unique advantage of the *Xenopus* extract in analysis of nuclear transport is the ability to manipulate the composition of the nuclear pore complex. Because the proteins that will make up the nuclear pore complex are found in the extract as soluble, individual components or small complexes, they are accessible for immunodepletion with specific antibodies (see Support Protocol 3; Finlay and Forbes, 1990; Powers et al., 1997). These depleted extracts are then used to form nuclei, and the effect of such "biochemical mutants" on nuclear transport can be monitored. In this manner, it is possible to address the function of individual proteins of the nuclear pore. Such depletion experiments can be performed on proteins involved in any process that is recapitulated in the extract and have proven invaluable in the study of cell cycle regulation and DNA replication.

Critical Parameters

The goal of extract preparation is to make a concentrated extract as close to the original composition of the cell as possible. Therefore, it is critical to remove as much of the buffer as possible after packing the eggs, even if it means loss of some of the eggs. During dejellying, it is important to wait just until the eggs settle against one another without a separation imposed by the jelly coat; however, dejellying the eggs for too long will result in damage to the egg, which can compromise extract function. It is also critical to handle the eggs gently until the time of centrifugation. Therefore, eggs should be transferred between containers either by direct pouring or by pipetting with a wide-bore cut-off and fire-polished (or upside-down) Pasteur pipet. If the eggs break prior to centrifugation, the extract will be sub-optimal.

Avoiding excessive dilution of the extract is also critical to the successful functioning of immunodepletion or protein addition experiments. For immunodepletions, this is accomplished by adding extract directly to packed beads (after washing and removal of all buffer) which have already been linked to antibody. It may require multiple immunodepletions to remove a protein of interest; therefore, it is important to examine the depleted extract by immunoblotting to confirm that the protein in question has actually been removed. It is also imperative that antibodies containing sodium azide not be used for the immunodepletions. This will disrupt extract function.

During preparation of light membranes, it is important to avoid contamination with the dark,

mitochondrial fraction. Since the light membranes are usually used after some time in frozen storage, contaminating mitochondria will lyse upon thawing, releasing cytochrome *c*. Any contaminating cytochrome *c* will induce activation of apoptotic proteases, or caspases (see *UNIT 11.12*), which will destroy nuclear function in the extract.

Many laboratories that prepare extracts also refrain from feeding any of the frogs once they have been primed. Any regurgitated food or stomach contents from the injected frogs may damage the eggs, compromising the extract.

To avoid damage to the sperm chromatin that will be used in the in vitro reconstitutions, it is important that they not be demembranated for longer than the allotted 30 min. In addition, it is best to avoid contamination with the red blood cells present in the gradient. These are much smaller than the sperm nuclei, and can produce confusion when examining samples under the microscope (e.g., it can be difficult to distinguish a nucleus with tightly condensed chromatin from a small red cell nucleus).

In examining nuclei, particularly in nuclear import experiments, it is important not to disrupt nuclear integrity. Therefore, when preparing slides, it is best to use a cut-off pipet tip and very gently lower the coverslip to the slide with a forceps.

Anticipated Results

These protocols can be used to produce extracts arrested in interphase. Upon addition of sperm chromatin, nuclei competent to transport macromolecules should be formed; these nuclei should replicate their DNA and undergo mitotic DNA condensation in response to addition of exogenous cyclin B.

Time Considerations

Interphase extracts require ~30 min to prepare and must be used within 2 hr of preparation if they are to preserve the ability to perform complex functions such as DNA replication and nuclear import. The fractionated egg extract requires an additional 2 hr of preparation time, but can be frozen indefinitely at −80°C.

Nuclear assembly in these extracts takes a variable amount of time. However, expect to see nice round nuclei in crude interphase extracts ~1 hr after the beginning of incubation at room temperature; similar nuclei can take up to 2 hr to form in a fractionated interphase extract. The kinetics of nuclear import in these two extracts are also different, with nuclear accumulation of a fluorescent import substrate to detectable levels requiring approximately twice as much time in a fractionated as in a crude extract.

Although preparation of the oocyte extract appears superficially as simple as the crude egg extract, sorting through the oocytes to remove mottled oocytes or oocytes that have undergone GVBD can be quite time-consuming. It is best to budget a full day to prepare an oocyte extract and perform a basic experiment using the extract.

Analysis of the Cell Cycle Using *Xenopus* Egg Extracts

This unit describes the preparation of cycling extracts that recapitulate, in vitro, the cell cycle of the intact fertilized egg. These extracts oscillate between interphase and mitosis, reproducing many of the in vivo events of the cell cycle including DNA replication, cyclin B synthesis and degradation, cdc2/cyclin B activation and inactivation, nuclear envelope breakdown and reformation, and chromosome condensation.

Preparation of a cycling extract requires activation of mature *Xenopus* eggs (see Basic Protocol 1). Extracts prepared in the presence of a calcium chelator are arrested in mitosis (see Basic Protocol 2), but these extracts can resume cycling upon addition of calcium (see Support Protocol 3). Extract stably arrested in mitosis requires not only a calcium chelator, but also a general phosphatase inhibitor (see Basic Protocol 3). It is also possible to drive interphase extracts into mitosis with the addition of recombinant cyclin. Changes in nuclear morphology (see Support Protocol 1) and in the extent of histone H1 phosphorylation (see Support Protocol 2) are used to follow cell cycle progression in these various extracts.

PREPARATION OF THE CYCLING EXTRACT

BASIC PROTOCOL 1

Mature *Xenopus* eggs are activated to provide an extract that cycles between interphase (S phase) and mitosis. Freshly collected eggs are activated in a specially constructed activation chamber and lysed for a crude cycling extract.

Materials

1× and 0.2× MMR (see recipe)
Unfertilized eggs laid in 1× MMR (see recipe)
Versilube F-50/silicone oil (see note in Basic Protocol 2)
XB buffer (see recipe)
CL protease inhibitor cocktail (see recipe)
2% (w/v) cysteine (see recipe)
5-ml polyallomer centrifuge tubes for Beckman SW 55 Ti rotor
Activation chamber (see Fig. 11.11.1)
12 V (AC) power supply with a toggle switch to rapidly control the delivery of current
Wide-bore Pasteur pipet
15-ml centrifuge tubes
Clinical centrifuge
Ice-water bath
Beckman floor model ultracentrifuge (with a SW 55 Ti rotor or equivalent)
18-G needle attached to a 5-ml syringe
1.5-ml microcentrifuge tubes and microcentrifuge at 4°C
Additional reagents and equipment for frog injection and egg collection (*UNIT 11.10*)

NOTE: Versilube F-50 silicon oil is the oil traditionally used in preparing cycling extracts. However, the company has recently replaced this with an M-20 oil, which purportedly has the same properties; this has not yet been tested extensively.

Contributed by Sally Kornbluth, Jing Yang, and Maureen Powers
Current Protocols in Cell Biology (2005) 11.11.1-11.11.14

Collect and wash eggs

1. Inject frogs (*UNIT 11.10*, Support Protocol 1), but place the frogs in 1× MMR after injection, so that the eggs will be laid in this solution.
2. The next morning, pour off the eggs into a beaker, rinse them once in room temperature distilled water, and then let them stand in water for 10 min.

   This facilitates the subsequent activation step.
3. Place 1 ml of Versilube F-50 oil into each of two 5-ml polyallomer centrifuge tubes for the Beckman SW 55 Ti rotor.

   It may be necessary to prepare more than two tubes to accommodate the eggs of one frog.
4. In a separate tube, mix 10 ml XB buffer with CL protease inhibitor cocktail to a final concentration of 10 μg/ml. Add 3 ml of this to each of the oil-containing tubes.

   This solution should sit on top of the oil layer.
5. Incubate the eggs in 2% cysteine for ~5 min until the jelly coat is removed and rinse three times with 0.2× MMR.

Activate eggs

6. Fill the activation chamber with 0.2× MMR so that the upper electrode will contact the solution. Pour in the eggs. For activation, deliver a 3-sec pulse (12 V AC), followed by a 5-sec pause and a subsequent 3-sec pulse. At the time of activation, start a timer (in the "counting up" mode) to keep the total time elapsed from activation until step 10 to <15 min.

   The activation chamber, made of Plexiglas, should be ~11 cm^2 on a side and 5 cm high (Fig. 11.11.1). The bottom of the chamber and the underside of the chamber lid

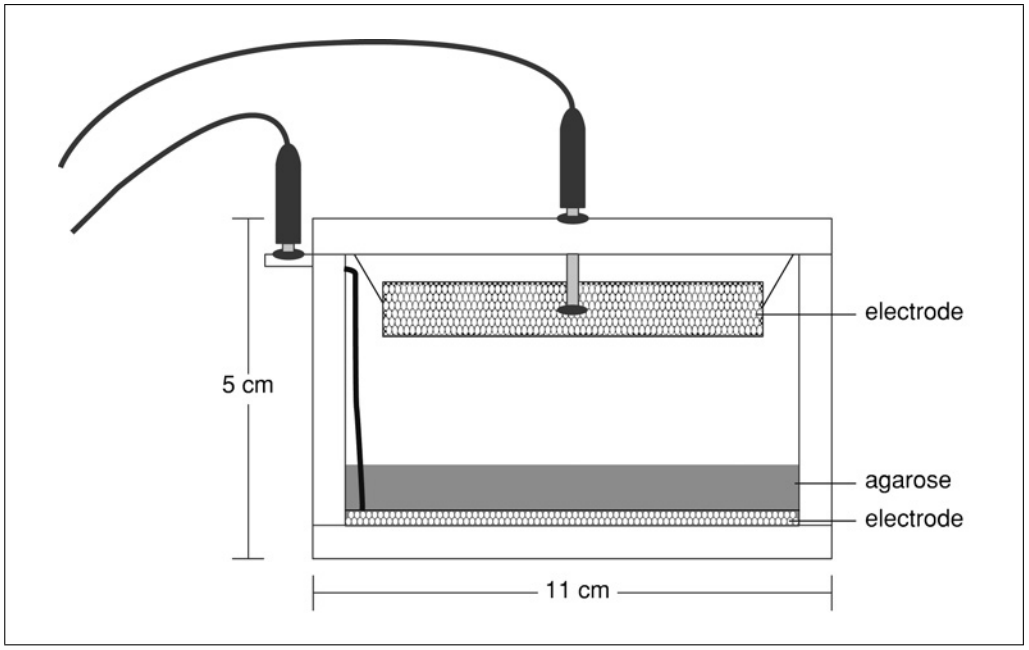

Figure 11.11.1 The activation chamber. The chamber is 11 cm on a side and 5 cm high and made of Plexiglas. The bottom of the chamber and the underside of the lid are covered with stainless steel plate electrodes. There is a pad of 0.2% (w/v) agarose in 0.2× MMR buffer covering the bottom of the chamber. Eggs and 0.2× MMR buffer are poured onto the agarose pad at the base of the chamber. The electrodes are attached via leads to a 12-V AC power supply. It is critical that the buffer make contact with the upper plate electrode in order for current to pass through the chamber, thereby activating the eggs.

are covered with stainless steel plate electrodes. A pad of 0.2% agarose prepared in 0.2× MMR is poured onto the bottom of the chamber.

Successful activation should induce the contraction of the pigment in the animal hemisphere. If the eggs are examined from above with the dark side up, a white rim (from the vegetal hemisphere) can be seen around the circumference of the egg after activation.

7. After activation, pour the eggs into a petri dish and rinse three times with XB buffer.
8. Using a wide-bore Pasteur pipet, drop the eggs gently into the centrifuge tubes containing oil and buffer, taking care to avoid dilution of the buffer in the tube with the buffer surrounding the eggs.
9. Place the tubes containing the eggs into 15-ml centrifuge tubes and centrifuge in a clinical centrifuge for 30 sec at 400 × *g*, followed by 20 sec at 1350 × *g*, room temperature.

   The eggs will have spun through the F-50 oil, resulting in elimination of excess buffer.

10. Remove all excess buffer and oil from above the eggs with a Pasteur pipet.

Lyse eggs

11. Continue incubation at room temperature until 15 min post-activation, then incubate a further 15 min in an ice-water bath.
12. Lyse the eggs by centrifuging them 10 min at 12,000 × *g*, 4°C (in a SW 55 Ti swinging-bucket rotor or equivalent).

    The extracts will now be fractionated into three layers: lipid, extract (cytoplasm plus membrane), and yolk, from top to bottom.

13. Collect the extract layer (cytosol plus membrane) by piercing through the side of the tube using a 18-G needle attached to a 5-ml syringe.
14. Place the extract into a 1.5-ml microcentrifuge tube and microcentrifuge 10 min at 12,000 × *g*, 4°C, to remove pigment granules and other particulate material.

    This extract should be used immediately for experiments requiring cycling extract; it should not be stored.

PREPARATION OF CSF-ARRESTED EXTRACTS

BASIC PROTOCOL 2

Xenopus eggs contain a cytoplasmic factor, termed cytostatic factor (CSF), that helps to stabilize the mitotic state, at least in part, through stabilization of the mitotic regulator cyclin B. Extracts prepared in the presence of a calcium chelator will maintain high levels of both CSF activity and cyclin B proteins. Extracts prepared in this manner are referred to as "CSF-arrested" extracts and are often used to study biochemical/morphological events of mitosis (but keep in mind that these are actually meiotically arrested extracts). While these extracts are in M phase at the time of preparation, they can be released into interphase by addition of calcium, leading to loss of CSF activity and destruction of cyclin B. Although these extracts will then behave like oscillating, or cycling extracts (see Basic Protocol 1), progressing to a subsequent mitosis as cyclins are synthesized, they tend to arrest at the next mitosis, rather than continuing to cycle, presumably because of residual, incompletely destroyed, CSF activity.

Materials

Xenopus eggs in 1× MMR (see recipe)
2% (w/v) cysteine (see recipe)
0.2× MMR (see recipe)

XB buffer (see recipe)
Versilube F-50/silicon oil (Andpak-EMA)
0.5 M EGTA stock solution, pH 8.0
1 M $MgCl_2$ stock solution
CL protease inhibitor cocktail (see recipe)
2% (w/v) cytochalasin B (Calbiochem)

5-ml polyallomer tubes for Beckman SW 55 Ti rotor (or equivalent)
Sawed-off and fire-polished Pasteur pipet
15-ml centrifuge tube
Clinical centrifuge
Floor model high-speed centrifuge (e.g., Sorvall, Beckman)
Beckman SW 55 Ti swinging-bucket rotor, or equivalent
5-ml syringe with an 18-G needle attached
Polycarbonate ultraclear microcentrifuge tubes (Beckman)
Microcentrifuge, 4°C

NOTE: Versilube F-50 silicon oil is the oil traditionally used in cycling extracts. However, the company has recently replaced this with an M-20 oil, which purportedly has the same properties; this has not yet been tested extensively.

Collect and wash eggs

1. Dejelly unfertilized eggs previously laid into 1× MMR in 2% cysteine and rinse with 0.2× MMR (see Basic Protocol 1).

   The amount of material to use depends on the amount of extract needed; 1 ml eggs yields ~0.5 ml packed eggs which yields ~0.25 ml extract.

2. Wash eggs three times in XB buffer.

3. Wash eggs three times in XB buffer containing 5 mM EGTA and an additional 1 mM $MgCl_2$.

4. Add 1 ml Versilube F-50 oil to each of two 5-ml polyallomer centrifuge tubes for an SW 55 Ti centrifuge (or equivalent).

5. In a clean tube, supplement a 10-ml aliquot of XB with EGTA to 5 mM, $MgCl_2$ to 1 mM, and add the CL protease inhibitor cocktail and cytochalasin B to a final concentration of 10 μg/ml each. Pipet 3 ml of this solution onto the top of the F-50 oil.

Isolate eggs

6. Using a sawed-off and fire-polished Pasteur pipet, drop the eggs into the centrifuge tubes containing oil and buffer until the tube is full.

   In lieu of a sawed-off pipet, use a short Pasteur pipet "backwards," with the sharp, long end inside the pipet bulb and the wide end to pick up the eggs. It is important that the eggs not be lysed at this step, so it is not advisable to use a narrow-bore pipet.

7. Place these egg-containing tubes inside 15-ml centrifuge tubes and centrifuge 40 sec in a clinical centrifuge at 400 × *g*, room temperature.

   This packs the eggs on the bottom of the tubes and the F-50 oil separates them from excess buffer.

8. Remove excess buffer and all of the oil with a Pasteur pipet.

Lyse eggs

9. Lyse the eggs by centrifuging 10 min at 12,000 × *g*, 4°C, in an SW 55 Ti (or equivalent) rotor.

   The extracts will now be fractionated into three layers, from top to bottom: a bright yellow lipid-containing layer, a brown extract layer (cytoplasm and membrane), and a dark greenish layer containing yolk and pigment granule.

10. Collect the extract layer (middle, brown layer) using an 18-G needle and a 5-ml syringe.

11. Place the extract into a microcentrifuge tube and microcentrifuge 10 min at 12,000 × *g*, 4°C. Using a needle, again withdraw the extract layer and place on ice.

    This extract can be used for mitotic reconstitutions or released into interphase by addition of $CaCl_2$ to a range of final concentrations between 0.1 and 0.4 mM (see Support Protocol 3).

PREPARING A MITOTIC EXTRACT

BASIC PROTOCOL 3

To make an extract more stably arrested in M phase than the CSF-arrested extract, it is necessary to include not only calcium chelators, but also a general phosphatase inhibitor. Together, these buffer components not only prevent the proteolytic destruction of cyclin B, but also maintain mitotic protein phosphorylation in the extract.

Materials

Xenopus eggs laid in 100 mM NaCl
2% (w/v) cysteine (see recipe)
Mitotic buffer (see recipe)
AL protease inhibitor cocktail (see recipe)
5 mg/ml cytochalasin B stock (see recipe)
Mitotic buffer (see recipe) supplemented with 250 mM sucrose (optional)

15-ml polycarbonate Ultraclear centrifuge tubes
Clinical centrifuge
High-speed floor model centrifuge (e.g. Sorvall or Beckman)
Large-capacity swinging-bucket rotor (e.g. Sorvall HB-4 or HB-6)
18-G needle attached to a 5-ml syringe

1. Collect eggs laid in 100 mM NaCl. Dejelly them in 2% cysteine, wash, and sort them (see *UNIT 11.10*).

2. After dejellying, rinse the eggs three times with mitotic buffer. Pour the eggs into a 15-ml polycarbonate Ultraclear centrifuge tube.

3. Pack the eggs by centrifuging 20 sec at 400 × *g*, room temperature, in a clinical centrifuge and remove all excess buffer with a Pasteur pipet.

   As in the interphase extract, it is better to lose a few eggs than to leave buffer behind.

4. Add the AL protease inhibitor cocktail to 5 μg/ml and the 5 mg/ml cytochalasin B stock to 5 μg/ml.

   Both reagents are diluted 1:1000 in the total egg volume.

5. Centrifuge the packed eggs 10 min at 12,000 × *g* (10,000 rpm in Sorvall HB-4 rotor), 4°C.

   As for the interphase extract, the mitotic extract will appear as a brownish layer sandwiched between a bright yellow lipid layer and a dark green layer.

6. Collect the brown extract layer, containing both cytoplasm and membrane, by inserting an 18-G needle attached to a 5-ml syringe through the wall of the centrifuge tube at the base of the extract layer.

7. *Optional:* Further separate the crude mitotic extract described above into cytoplasmic and membrane fractions using the method described for preparing fractionated interphase extracts (see *UNIT 11.10*, Alternate Protocol 1). In this case, use mitotic buffer supplemented with 250 mM sucrose to make a sucrose cushion for membrane fractionation.

   Note that this extract is an excellent source of mitotically vesiculated membranes.

BASIC PROTOCOL 4

DRIVING INTERPHASE EXTRACTS INTO MITOSIS

An interphase egg extract will not spontaneously enter mitosis because the added cycloheximide prevents synthesis of the cyclin proteins required for mitotic entry. To drive these extracts into mitosis, one can add recombinant forms of mitotic cyclins (e.g., cyclin B) that will associate with and activate the mitotic kinase, cdc2.

Since mitotic cyclins are degraded after cdc2 activation, mutant variants of cyclin lacking the signal for ubiquitination (the "destruction box") must be used if the extract is to be permanently arrested in mitosis (e.g., Murray et al., 1989). An alternative method to induce mitosis after nuclear assembly is to dilute the extract 1:1 with mitotic extract (see Basic Protocol 3). This provides active cdc2/cyclin complexes that will catalyze disassembly of the preformed nuclei.

Materials

Interphase extract (crude or fractionated) containing newly formed nuclei (see *UNIT 11.10*)

Recombinant cyclin protein (Desai et al., 1995)

Additional reagents and equipment for nuclear disassembly (*UNIT 11.10*)

1. After nuclear formation in either a crude or fractionated interphase extract, add recombinant cyclin protein (produced in either bacteria or baculovirus, e.g., Desai et al., 1995) to the extract and incubate at room temperature.

   It should take 30 to 60 min to observe nuclear envelope breakdown.

   It is best to titrate the added proteins over a range of concentrations since preparations vary in their potency.

   Typically, 15 to 20 nM recombinant cyclin B will drive extracts into mitosis.

2. To monitor nuclear disassembly, observe nuclei using the same methodologies described for nuclear assembly (see *UNIT 11.10*).

   In this case, the nuclear envelope will break down, as observed by loss of a dark ring by phase-contrast microscopy, loss of nuclear exclusion of the FITC-dextran, and loss of binding of the DHCC. More strikingly, the chromatin condenses into discrete packets (Fig. 11.10.3). Although prolonged incubation allows visualization of discrete chromosomes, in general, the mitotic DNA stained with Hoechst 33258 appears as a tangled, spaghetti-like mass.

   Although nuclear morphology is a good indicator of conversion into mitosis, the activity of added cyclin can be confirmed by assaying the kinase activity of the bound cdc2, using histone H1 as an exogenous substrate (see Support Protocol 2).

GENERATING A REPLICATION CHECKPOINT IN VITRO

ALTERNATE PROTOCOL

It is imperative that cells not enter mitosis prior to the completion of replication. To prevent this from occurring, cell-cycle checkpoints monitor the status of DNA replication and prevent onset of mitosis until DNA replication is finished. If DNA replication is artificially blocked using polymerase inhibitors, cells will arrest in G2, prior to mitotic entry. This form of cell cycle regulation can be recapitulated in vitro using cycling extracts and replicating sperm chromatin. While a permanent arrest prior to entry into mitosis can be achieved if extracts are supplemented with DNA replication inhibitors, the cell cycle can also be delayed by simple addition of large numbers of nuclei to the extract. Indeed, as increasing amounts of sperm chromatin are added, S phase and the time prior to entry into M phase lengthen concomitantly. Extracts will remain arrested prior to entry into mitosis until the DNA has been completely replicated.

Materials

Sperm chromatin (*UNIT 11.10*)
20× energy-regenerating mix (see recipe)
Cycling extract (see Basic Protocol 1)
5 mg/ml aphidicolin stock solution (Sigma) in high-quality DMSO (e.g., Pierce) (see recipe)

1. Supplement cycling extract with 20× energy-regenerating mix to a final concentration of 1×. Add sperm chromatin to a final concentration of 500 nuclei/μl extract. Supplement the reaction with 50 μg/ml aphidicolin and mix thoroughly. Incubate at room temperature and monitor the cell cycle state (see Support Protocol 1).

   Approximately 50 μl cycling extract is used per sample.

   Aphidicolin is a DNA polymerase inhibitor that will prevent replication of the sperm chromatin, thereby generating a cell cycle arrest prior to entry into mitosis. Note that the extract may not function well if the final DMSO concentration (the solvent base for the aphidicolin) in the extract exceeds 1% (v/v). To confirm that the failure to enter mitosis is due to the DNA replication checkpoint, extracts can be supplemented with 5 mM caffeine, which will override the checkpoint and drive the extracts into mitosis. Add the caffeine from a 0.5 M stock solution in water. It is necessary to boil the mixture to prepare the stock solution, since caffeine will only enter solution at this concentration if boiled.

MONITORING THE CELL CYCLE STATE OF EXTRACTS

SUPPORT PROTOCOL 1

As the cycling extract progresses through the cell cycle, nuclei form, DNA replication proceeds, and, after replication is complete, the extract enters mitosis. This series of events can be monitored by observation of nuclear morphology, by biochemical assessment of cdc2/cyclin kinase activity or phosphorylation state, and by direct measurements of DNA replication (see *UNIT 11.10*).

Materials

Cycling extract
Sperm chromatin (*UNIT 11.10*)
20× energy regenerating mix (see recipe)

1. To observe nuclear morphology through the cell cycle, supplement extracts with sperm chromatin (~500 nuclei/μl), and add a 1:20 dilution of the 20× energy regenerating mix. Mix the extract thoroughly by pipetting and incubate at room temperature. At 10-min intervals, withdraw samples for observation by fluorescence microscopy (see *UNIT 11.10*, Basic Protocol 2).

Since the extract is fairly viscous, it is best to gently invert the sample periodically to ensure uniform distribution of the nuclei. Initially, samples should appear identical to those described in UNIT 11.10 for interphase nuclei. These should then progress abruptly into mitosis, as described for nuclei in UNIT 11.10, Basic Protocol 4, and Figure 11.10.3. The transition from interphase into mitosis should occur between 60 and 120 min after the start of the room temperature incubation.

2. Use histone H1 as an exogenous substrate for cdc2/cyclin B (see Support Protocol 2). In general, withdraw aliquots of extract at 10-min intervals and snap freeze in liquid nitrogen for later histone H1 kinase assays.

The peak in histone H1-directed kinase activity typically appears ~10 min before observable chromatin condensation or nuclear envelope breakdown. Oscillations in histone H1 kinase activity occur even in extracts without sperm chromatin (or any other source of DNA).

As an alternative means of assessing the cell cycle status of the extract, one can measure the tyrosine phosphorylation state of cdc2. Phosphorylation of cdc2 at its two negative regulatory sites, Thr 14 and Tyr 15, is high in interphase and then drops precipitously as cdc25 dephosphorylates cdc2 at the time of mitotic entry. Therefore, aliquots of extract withdrawn at 10-min intervals can be resolved by SDS-PAGE (UNIT 6.1) and immunoblotted (UNIT 6.2) with anti-phosphotyrosine antisera.

SUPPORT PROTOCOL 2

ASSAYING HISTONE H1 KINASE ACTIVITY

Since entry into mitosis is regulated by the cyclin-dependent kinase, cdc2, progression into mitosis in the egg extract is often assayed by measuring cdc2 activity using histone H1 as an exogenous substrate. Aliquots of extracts are withdrawn at closely spaced time intervals (10 to 15 min) from either cycling extracts (see Basic Protocol 1) or interphase extracts converted to mitosis using recombinant cyclin protein (see Basic Protocol 4).

Materials

Extract: cycling (see Basic Protocol 1) or interphase driven into mitosis (see Basic Protocol 4)
EB buffer (see recipe)
Liquid nitrogen
10× kinase buffer (see recipe)
1 mg/ml histone H1 (Roche Diagnostics)
500 μM protein kinase inhibitor peptide (PKI; Sigma)
0.2 M ATP
5 mCi/ml [γ-^{32}P]-ATP (3000 Ci/mmol)
2× SDS sample loading buffer (*APPENDIX 2A*)

1. Dilute aliquots of extract to be assayed 1:1 with EB buffer (e.g., 2 μl of extract in 2 μl EB buffer will suffice) and place immediately into liquid nitrogen. Then transfer the frozen aliquots to a −80°C freezer without thawing.

2. Prepare the following kinase cocktail so there is sufficient amount for 10 μl per kinase reaction (i.e., for each aliquot of extract to be assayed). Prepare a master mix, multiplying the following amounts by the number of reactions plus 1 for pipetting error.

1 μl 10× kinase buffer
1 μl 1 mg/ml histone H1
0.4 μl 500 μM PKI
0.1 μl 0.2 M ATP
4-8 μCi γ-^{32}P]ATP
Water to 10 μl.

3. For each sample to be assayed, add 10 μl of kinase cocktail to a fresh microcentrifuge tube.

4. Transfer samples to be assayed from the −80°C freezer directly into a container containing finely crushed dry ice.

   The samples should be arrayed in the order in which they will be assayed.

5. To the first sample to be assayed (containing 2 μl extract and 2 μl EB buffer) add 240 μl EB buffer and pipet up and down rapidly. As soon as the sample is thawed, transfer 10 μl of the mixture to the corresponding tube containing 10 μl of kinase cocktail and start a timer counting upwards.

6. Stop the reaction after 10 min by adding 20 μl of standard 2× SDS sample loading buffer.

   Since reactions proceed for 10 min, for multiple aliquots start and stop reactions at staggered 1-min intervals.

7. Store samples by freezing or electrophorese directly on an 11% SDS-polyacrylamide gel (*UNIT 6.1*).

   Since most of the radioactive ATP runs below the dye front, it is best not to run the gel until the dye front reaches the bottom to avoid contamination of the SDS-running buffer. Indeed, it is best to cut the gel off at the dye front before drying and exposing the gel. After autoradiography, histone will be identifiable as a very closely spaced radiolabeled doublet.

RELEASE OF CSF-ARRESTED EXTRACTS AND THEIR PROGRESSION INTO INTERPHASE

SUPPORT PROTOCOL 3

To determine if removal or addition of particular components from an extract has a specific effect on exit from mitosis, it is easiest to use CSF extracts that can transit from mitosis to interphase in a controlled manner. Supplementation of CSF extracts with calcium drives them into interphase. If these extracts are supplemented with sperm chromatin, they will form nuclei and initiate DNA replication in the same manner as in cycling extracts described in Basic Protocol 1. However, the released CSF extracts have a tendency to arrest on re-entry into mitosis, unlike the cycling extracts that will continue through multiple cycles.

Materials

CSF-arrested extract (see Basic Protocol 2)
20× energy-regenerating mix (see recipe)
Sperm chromatin (*UNIT 11.10*)
1 M calcium chloride
Fixative for visualizing nuclear assembly (see recipe)
Cycloheximide (optional)

1. Supplement CSF extract with 20× energy-regenerating mix to a final concentration of 1×.

2. Add sperm chromatin to a final concentration of 100 to 500 nuclei/μl.

3. Determine the minimal concentration of calcium required to drive the extract into mitosis. Supplement small aliquots of extract containing energy-regenerating mix and sperm chromatin with 1 M $CaCl_2$ to 0.1 mM, 0.2 mM, or 0.4 mM and incubate at room temperature.

   While adding calcium to this extract will release it into interphase, the precise concentration of calcium required varies somewhat from extract to extract. Hence, to perform a large experiment it is probably worthwhile to first determine the minimal concentration of calcium required to drive a particular extract into interphase.

4. At 10-min intervals, remove a 4-µl sample and add 1 µl Hoechst 33258 to stain the DNA. Observe using fluorescence microscopy. Identify the lowest concentration of $CaCl_2$ that allows good release of CSF-arrested extract into interphase.

   Stain nuclei as described in UNIT 11.10, except FITC-dextran may be omitted here.

   In the absence of calcium addition, condensed mitotic chromosomes should be easily visible by fluorescence microscopy after 20 to 30 min of room-temperature incubation. For the calcium-released samples, find the lowest concentration allowing good release from CSF arrest into interphase. At the appropriate concentration, the sperm chromatin should decondense to form membrane-enclosed nuclei (see UNIT 11.10).

5. *Optional:* To arrest these extracts in interphase after calcium addition, add cycloheximide to a final concentration of 50 µg/ml at the time of calcium addition.

   The crude CSF-arrested extract can be further separated into cytoplasmic and membrane fractions (see UNIT 11.10, Alternate Protocol 1) and stored at −80°C. The freeze/thawed cytoplasmic fraction of CSF extracts can fully support chromosome condensation and spindle formation.

REAGENTS AND SOLUTIONS

*Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see **APPENDIX** 2A; for suppliers, see **SUPPLIERS APPENDIX**.*

AL protease inhibitor cocktail

Dissolve aprotinin to 10 mg/ml in water and leupeptin to 10 mg/ml in water. Mix these two solutions 1:1 to give a final 5 mg/ml solution. Store at −70°C.

Aphidicolin stock solution, 5 mg/ml

Dissolve aphidicolin to 5 mg/ml in high-quality DMSO (e.g., Pierce). Store several months at −70°C.

CL protease inhibitor cocktail

Dissolve leupeptin to 10 mg/ml in distilled water and chymostatin to 10 mg/ml in DMSO and mix them at a ratio of 1:1 to give a final concentration of 5 mg/ml. Store at −70°C.

Cysteine, 2% (w/v)

Prepare 2% (w/v) cysteine in water. Adjust pH to 8.0 with NaOH. Prepare fresh for each use.

Cytochalasin B stock solution, 5 mg/ml

Prepare a 5 mg/ml stock of cytochalasin B (Calbiochem) in DMSO. Store up to 1 year at −20°C.

EB buffer

42.68 g sucrose (0.25 M final)
10 ml of 5 M NaCl (0.1 M final)
1.25 ml of 1 M $MgCl_2$ (2.5 mM final)
2.4 g HEPES (20 mM final)
Adjust pH to 7.2 with NaOH and bring the volume to 500 ml with water.
Store until cloudy at 4°C

Energy-regenerating mix, 20×

150 mM creatine phosphate
20 mM ATP
2 mM EGTA, pH 7.7
20 mM $MgCl_2$
Store up to several months at −20°C, but avoid repeated freeze/thaw

Fixative for visualizing nuclear assembly

10 mM HEPES, pH 7.5
200 mM sucrose
1 μg/ml Hoechst 33258
1 mg/ml FITC-dextran
12% (w/v) paraformaldehyde
Store at −20°C wrapped in foil

Kinase buffer, 10×

200 mM HEPES, pH 7.3
5 mM EGTA
10 mM $MgCl_2$
Store indefinitely at 4°C, unless it becomes cloudy

Mitotic buffer

24 ml 1 M β-glycerophosphate, pH 7.3
12 ml 0.5 M EGTA, pH 8.0
4.5 ml 1 M $MgCl_2$
100 μl 1 M DTT
Add water to 100 ml
Adjust pH to 7.3 with NaOH
Store indefinitely at 4°C, unless a precipitate forms

Modified Ringer's solution (MMR), pH 7.7, 10×

1 M NaCl
20 mM KCl
10 mM $MgSO_4$
25 mM $CaCl_2$
5 mM HEPES, pH 7.8
0.8 mM EDTA
Store indefinitely at room temperature
Dilute 10× MMR to 0.25× MMR in water (1:40) before extract is made

~ 200 ml of 0.25× MMR are required to make the interphase extract.

XB buffer

50 mM sucrose
100 mM KCl
0.1 mM $CaCl_2$
1 mM $MgCl_2$
10 mM potassium HEPES, pH 7.7
Prepare fresh

COMMENTARY

Background Information

Eggs arrested in metaphase have not only high levels of cdc2/cyclin B activity but also a cytoplasmic component, CSF (cytostatic factor), which stabilizes this activity. During normal fertilization, sperm entry promotes the destruction of CSF, initiating the oscillation between S and M phases seen in early embryonic development. Destruction of CSF and cyclin B can be achieved synchronously in a large population of eggs by electrical stimulation of the eggs (see Basic Protocol 1). If cycloheximide is not added to these extracts (so that protein synthesis can occur), extracts made from these electrically activated eggs faithfully recapitulate the embryonic cell cycle oscillations with respect to nuclear envelope formation and breakdown, DNA replication, cyclin accumulation and destruction, and cdc2 kinase oscillations (Murray and Kirschner, 1989; Murray et al., 1989). Indeed, in these extracts, DNA replication occurs only once per cell cycle and multiple rounds of replication occur only because they are separated by intervening mitosis.

Although cycling extracts are useful for studying the basic cell cycle machinery, they can also be used to reconstitute more complex phenomena, such as the operation of cell cycle checkpoints. When cellular events regulated by the cell cycle machinery malfunction or do not occur on time, subsequent cell cycle events are delayed. For example, if DNA replication is inhibited or DNA is damaged, mitosis will not occur, preventing chromosome segregation and almost certain breakage of partially replicated or damaged chromosomes. In cycling extracts, if nuclei are formed in the presence of the DNA polymerase α inhibitor, aphidicolin, mitosis will not occur since replication cannot be completed. This cell cycle arrest can be overridden by caffeine, an agent known to override this cell cycle checkpoint in intact cells, reinforcing the idea that the extract uses the same biochemical pathways to implement the cell cycle arrest as are used in vivo (Dasso and Newport, 1990). Hence, this system can be used to unravel the biochemical pathways that underlie the operation of the DNA replication checkpoint.

Extracts in Mitosis

Although synthesis of cyclin will drive a cycling extract into mitosis, the extract will not remain in mitosis since cyclin is destroyed by regulated ubiquitination and proteasome-mediated degradation. To study mitotic functions in isolation (e.g., nuclear disassembly, chromosome condensation), inclusion of EGTA in the buffer used during egg lysis results in chelation of the Ca^{+2} normally released upon egg lysis, thereby preventing the loss of CSF and cdc2/cyclin B activity, and locking these extracts in M phase (Glotzer et al., 1991; Murray et al., 1989). If Ca^{+2} is then added to these "CSF-arrested extracts," they can be released into interphase. Because these extracts are competent to synthesize protein, cyclin will accumulate, driving this extract into a subsequent mitosis (see Support Protocol 3). These extracts are excellent for the study of mitotic enzyme activities and for microscopic and biochemical analysis of mitotic chromosome condensation and spindle assembly. In addition, they have recently been used to great effect in the purification of proteins interacting with mitotic chromosomes (Hirano and Mitchison, 1994). Ca^{+2} addition allows controlled release of CSF extracts into interphase, making this extract the preferred choice for examining the M to S phase transition. This feature has been exploited to study the biochemistry of the "spindle checkpoint" that prevents anaphase progression if chromosomes are not properly attached to the mitotic spindle (Minshull et al., 1994). The CSF extract is also particularly useful if removal and addition of cellular components is desired prior to commencement of DNA replication.

If β-glycerophosphate (as well as EGTA) is included in the egg lysis buffer, the mitotic state is stabilized indefinitely, not only by making CSF and cyclin impervious to degradation, but also by stabilizing mitotic phosphorylations. These "mitotic" extracts (see Basic Protocol 3) can be fractionated into cytosolic and membranous components, which can be stored indefinitely and retain the mitotic character of the original extract.

An alternative method to prepare extracts arrested in mitosis is to convert S phase extracts to the mitotic state by addition of a recombinant cyclin B whose "destruction box" (the region of the protein that renders it susceptible to proteolytic degradation) has been removed (see Basic Protocol 4; Solomon et al., 1990). This leads to constitutively high levels of cdc2/cyclin B activity with a consequent mitotic arrest.

Critical Parameters

Excessive dilution of the cycling extract will interfere with its ability to cycle. This is probably because protein synthesis in these extracts is sensitive to dilution, and cyclin synthesis is required to complete the various cell cycle transitions. When preparing the cycling extract, it is imperative that all of the eggs in the preparation have been properly activated. If a significant proportion of the eggs have not undergone activation after the electrical pulse, the extract probably will not cycle unless the unsuccessfully activated eggs are removed. Rarely, a batch of eggs will be contaminated with small numbers of immature oocytes; these lack the white spot characteristic of eggs (resulting from germinal vesicle breakdown and displacement of pigment granules) and should be removed before extract preparation.

When triggering a checkpoint in the extract, the aphidicolin should be prepared so as not to exceed 1% final DMSO concentration in the extracts. Higher amounts of DMSO will impair extract function. If caffeine is being used to override the replication checkpoint, make sure it is fully in solution and do not place on ice (to avoid precipitation of the caffeine).

To monitor progression of the cell cycle in the in vitro extract, it is convenient to assay kinase activity directed against histone H1 (catalyzed by cdc2/cyclin B complexes). Each time point should be assayed immediately after thawing. If the whole time course is thawed at once and then assayed, the peaks of H1-directed kinase activity will be lost.

After preparing the CSF extract, it is worthwhile to test that it can be successfully released from metaphase into interphase with the desired concentration of calcium. Occasionally, release does not occur, indicating a requirement for higher calcium levels or indicating that the extract is nonfunctional. The easiest way to determine if release can occur is to supplement the extract with sperm chromatin and examine samples by Hoechst staining and fluorescence microscopy.

When driving an extract into mitosis using exogenous cyclin, bear in mind that cyclin preparations vary in their potency to induce mitosis. All batches of cyclin should be titered with regard to mitosis-inducing activity. If a nondestructible cyclin B is used, the extract will remain arrested in mitosis. With native cyclin B, the extract will complete mitosis and return to interphase concomitant with cyclin destruction.

Anticipated Results

Cycling extracts should complete interphase, go into mitosis, and come out again two or three times. Histone H1 kinase activity should peak ~10 min before visual breakdown of added nuclei. In the CSF extract, added sperm chromatin should look like tangled threads. Upon addition of calcium, these should now form round nuclei similar to those formed either in interphase extracts or at the start of a cycling extract incubation.

Time Considerations

Once beginning a cycling extract, it is not possible to stop at any point. It is particularly important that the time from egg activation to incubation on ice not exceed 15 min. The cycling extract can remain on ice for 1 to 2 hr before use, but it cannot be frozen for later use.

For assaying progression of the cycling extracts using histone H1 kinase assays, it is critical that all of the time points be incubated for precisely the same amount of time; hence, the authors have recommended starting the sample incubations at 1-min intervals so that they can be subsequently stopped at 1-min intervals.

Entry into mitosis in interphase extracts supplemented with recombinant cyclin can take a variable amount of time, depending on the particular extract and preparation of cyclin. However, it is advisable to aim for an amount of cyclin that takes 30 to 45 min to promote mitotic entry. If, after 60 min, entry into mitosis is not observed, it is likely that the extract is not responsive, that suboptimal levels of cyclin have been used, or that the preparation is inactive.

Analysis of Apoptosis Using *Xenopus* Egg Extracts

Recapitulation of the apoptotic phenotype in the *Xenopus* egg extract system was first described by Newmeyer et al. (1994) where it was noted that prolonged incubation of the crude interphase extract resulted in extracts that were capable of undergoing apoptosis characterized by chromosome condensation and nuclear fragmentation. The presence of a subcellular fraction enriched in mitochondria is essential for the induction of apoptosis in the extracts. These extracts share many of the biochemical characteristics described in apoptotic cells from other systems, such as caspase activation and DNA fragmentation. In addition, apoptosis in these extracts can be inhibited by addition of caspase inhibitors as well as the anti-apoptotic protein Bcl-2.

PREPARATION OF APOPTOTIC EXTRACTS AND ASSESSING APOPTOSIS

BASIC PROTOCOL

This unit describes preparation of an apoptotic extract from a crude interphase extract (see Basic Protocol) and an extract fractionated into latent and execution phases (see Alternate Protocol). An apoptotic extract can also be reconstituted from a fractionated interphase extract (*UNIT 11.10*) and purified mitochondria (see Support Protocol 2). Protocols are also included for monitoring apoptotic progression in the extract either by following activation of apoptotic proteases (caspases; see Support Protocol 1) or by assessing translocation of cytochrome *c* from the mitochondria to the cytosol (see Support Protocols 3 and 4).

In essence, the apoptotic extract does not differ from the crude interphase extract described in *UNIT 11.10*. Prolonged incubation of the extract at room temperature will result in release of mitochondrial cytochrome *c*, activation of caspases, and if nuclei are present, nuclear fragmentation. Therefore most other applications using crude extract require that incubation times not exceed 3 to 4 hr or the extract may enter apoptosis confounding analysis of the process under study (e.g., nuclear transport, nuclear envelope assembly). However, extracts lacking mitochondria (e.g., the fractionated interphase extract; *UNIT 11.10*) will not enter apoptosis even after prolonged incubation.

Materials

Crude interphase extract (*UNIT 11.10*)
0.2 M phosphocreatine
0.5 mg/ml creatine kinase
0.2 M ATP
Hoechst 33258 (Bisbenzimide H 33258; Calbiochem)
Fluorescence microscope

Additional reagents and equipment for preparation of *Xenopus* crude interphase extract (*UNIT 11.10*)

1. To a crude interphase extract, add 0.2 M phosphocreatine to a concentration of 20 mM (1:10), 0.5 mg/ml creatine kinase to a concentration of 5 µg/ml (1:100 dilution), and 0.2 M ATP to a concentration of 2 mM (1:100) to create an ATP-regenerating system. Mix and incubate this extract 4 to 8 hr at room temperature.

   Since extracts undergo apoptotic nuclear fragmentation at slightly different times, it is a good idea to start observing the nuclei at 0.5-hr intervals starting at ~3 hr after beginning the room temperature incubation.

Contributed by Sally Kornbluth and Erica K. Evans
Current Protocols in Cell Biology (2001) 11.12.1-11.12.8

2. Determine the onset of apoptosis by observing synthetic nuclei stained with Hoechst 33258 and visualized using fluorescence microscopy.

Nuclei assembled around sperm chromatin in the extract can be used as morphological indicators of apoptosis. For assembly of nuclei in vitro and slide preparation, see UNIT 11.10.

At the time of apoptosis, condensation of the chromatin and nuclear fragmentation are clearly visible (see Figure 11.10.3).

For a more quantitative assessment of apoptosis, it is easiest to measure activation of the apoptotic proteases, or caspases in the extract. It is generally possible to detect caspase activity from 2 to 3 μl of apoptotic extract (see Support Protocol 1). It is not necessary to include nuclei in an extract when measuring apoptosis by caspase activation or cytochrome c release.

It is also possible to measure mitochondrial cytochrome c release in these extracts; this is tightly correlated with the onset of apoptosis (see Support Protocol 3).

ALTERNATE PROTOCOL

SEPARATING APOPTOSIS INTO LATENT AND EXECUTION PHASES

This protocol separates the apoptotic reaction into two steps. The first step is the latent phase where a reaction or series of reactions that prepare the extract for apoptosis takes place. The second step of the apoptotic reaction is the execution phase where the apoptotic phenotype characterized by caspase activation, DNA degradation, and nuclear fragmentation is manifested.

The latent phase requires only the cytosolic and light membrane fractions of an interphase extract. Because this extract lacks the mitochondrial fraction, it cannot support caspase activation or full-blown apoptosis. However, when the cytoplasmic and membrane components are combined and allowed to incubate at room temperature for 2.5 hr, a "latent" apoptotic activity develops that is able to accelerate apoptosis in an extract that contains mitochondria. It is likely that activities which trigger mitochondrial cytochrome *c* release develop during the latent incubation. After transfer to the execution extract containing mitochondria, the latent extract triggers release of mitochondrial cytochrome *c* to the cytosol, which then serves as a cofactor in caspase activation.

The execution phase of the apoptotic reaction requires the presence of mitochondria, which are provided by the crude extract. Once a latent extract has been incubated for the appropriate time, 1/10 vol is transferred into a crude extract (execution extract) containing nuclei and the apoptotic morphology of the nuclei is observed after 60 to 120 min. The advantage of setting up the apoptotic reaction in this manner is that signaling molecules operating during the latent phase of apoptosis (prior to detectable caspase activation) can be studied separately from those involved in the apoptotic dismantling of cellular components. The fractionated extract is also easier to immunodeplete (see *UNIT 11.10*), since the soluble extract can be depleted in the absence of membrane components and then later reconstituted with membrane.

Materials

Freshly obtained *Xenopus* eggs, washed with egg lysis buffer (*UNIT 11.10*)
0.2 M phosphocreatine
0.5 mg/ml creatine kinase
0.2 M ATP
20× energy-regenerating mix (*UNIT 11.11*)
Demembranated sperm chromatin (*UNIT 11.10*)
Hoechst 33258 (Bisbenzimide H 33258; Calbiochem)

15-ml polypropylene tubes
5-ml syringe and 18-G needle

Additional reagents and equipment for preparing crude and fractionated interphase extracts (*UNIT 11.10*)

Prepare a fractionated interphase extract

To create a latent extract, a fractionated interphase extract is made exactly as described in *UNIT 11.10*, Basic Protocol 1, and Alternate Protocol 1, with the following variations.

1. Once the eggs are washed with egg lysis buffer and transferred to 15-ml polypropylene tubes (see step 6 of Basic Protocol 1 in *UNIT 11.10*), keep them on ice until crushed (lysed) by centrifugation (step 9 in that protocol), and keep them on ice again at the completion of the lysis centrifugation, until high-speed centrifugation (performed in step 2 of Alternate Protocol 1, *UNIT 11.10*).
2. After removing the crude extract from the 15-ml polypropylene tube with a 5-ml syringe and 18-G needle, do not supplement the crude extract with additional protease inhibitors or cytochalasin B (i.e., skip step 1 of Alternate Protocol 1 in *UNIT 11.10*).
3. Proceed with the steps required for making a fractionated interphase extract (see *UNIT 11.10*, Alternate Protocol 1).

Prepare the latent extract

4. Thaw an aliquot of fractionated cytosol and membrane (*UNIT 11.10*). Recombine 10 µl of membrane with 100 µl of cytosol.
5. Add 0.2 M phosphocreatine to 20 mM (1:10), 0.5 mg/ml creatine kinase to 5 µg/ml (1:100), and 0.2 M ATP to 2 mM (1:100). Mix and incubate 2.5 hr at room temperature.

Prepare execution extract

6. Make fresh crude interphase extract (see *UNIT 11.10*, Basic Protocol 1).
7. Dilute 20× energy regenerating mix to 1× in fresh crude extract.

   This energy mix is used in the execution extract because it does not dilute the extract as much as separate addition of phosphocreatine, creatine kinase, and ATP.

8. Dilute demembranated sperm chromatin to 1000 nuclei/µl in the execution extract.

Mix extracts and assess for apoptosis

9. Transfer 1/10 vol latent extract into execution extract (e.g., 5 µl latent extract into 50 µl execution extract). Mix by flicking tube.
10. Incubate at room temperature. Withdraw samples at 10-min intervals and stain with Hoechst 33258 (as for visualizing nuclear protein import; see *UNIT 11.10*, Basic Protocol 3). Examine for apoptotic nuclei.

    Nuclei should form by 30 min. Nuclei usually undergo apoptosis between 60 and 120 min after transfer.

SUPPORT PROTOCOL 1

MEASURING CASPASE 3–LIKE ACTIVITY

When apoptosis is activated in the egg extracts, it is possible to detect a caspase activity with a substrate specificity very similar to that seen for mammalian caspase 3, one of the "effector" caspases. Measurement of this activity provides an easy way to quantitate apoptosis in the extract, particularly to compare apoptosis in extracts subjected to different experimental treatments.

In vitro caspase assays are based on the cleavage of synthetic peptide substrates of the caspases linked to either chromophores or fluorophores. Upon cleavage of the substrate by relevant caspases from the apoptotic extract, release of the chromophore or fluorophore can be detected by fluorimeter or spectrophotometer. In the case of caspase 3, the synthetic substrate, Ac-DEVD-pNA is used.

Materials

Assay buffer (see recipe), room temperature
Apoptotic egg extract (see Basic Protocol or Alternate Protocol)
Cleavage substrate: 2 mM Ac-DEVD-pNA (see recipe)
Cleavage inhibitor: 20× Ac-DEVD-CHO (see recipe)
96-well microtiter plate

1. For each sample/time point to be assayed, place 85 µl of room temperature assay buffer in a well of a 96-well microtiter plate. Keep at room temperature.

   Assays are done in a 96-well plate to facilitate reading of multiple samples.

2. Add 1 to 5 µl of the apoptotic egg extract to be assayed to the well.

3. Add 10 µl of caspase substrate, 2 mM Ac-DEVD-pNA. Mix by tapping the sides of the plate. Incubate 1 hr in a 37°C incubator.

4. Stop the assay by addition of 5 µl of caspase inhibitor, 20× Ac-DEVD-CHO. Read all samples at 405 nm at the very end of the experiment.

   Alternatively, read the samples immediately using a microtiter plate reader at 405 nm.

   Addition of the caspase inhibitor stops further development of the caspase assay, allowing samples to be read later. If the peptide inhibitor is not added, the caspase assay will continue to develop, making it impossible to compare samples from different time points.

SUPPORT PROTOCOL 2

PREPARATION OF MITOCHONDRIA FROM *XENOPUS* EGG EXTRACTS

As noted in the Basic Protocol, the mitochondrial fraction of *Xenopus* egg extracts is absolutely required for in vitro apoptosis. When the cytosol and light membrane fractions of the extract (*UNIT 11.10*) are combined, the reconstituted extract will not enter apoptosis. However, if a purified heavy membrane fraction enriched in mitochondria is added, the reconstituted extract becomes competent to support apoptosis. Indeed, it has been reported that adding twice the concentration of mitochondria found endogenously in the crude extract results in the production of a robust and reproducible apoptotic extract (Faure et al., 1997). This is almost certainly due to the fact that mitochondrial cytochrome *c* release, which triggers activation of apoptotic proteases, is the downstream target of many apoptotic signaling pathways. Therefore, increasing the mitochondrial concentration results in increased cytochrome *c* release and more rapid apoptosis. The following protocol describes a procedure, adapted from the laboratory of Dr. Don Newmeyer of La Jolla Institute of Allergy and Immunology, to prepare a heavy membrane fraction enriched in mitochondria.

Materials

Fractionated interphase extract (Alternate Protocol 1 in *UNIT 11.10*)
Percoll solutions (see recipe)
MIB buffer (see recipe)

2.5-ml ultracentrifuge tubes (e.g., Beckman)
Beckman TL-100 table-top ultracentrifuge and TLS-55 swinging-bucket rotor

Additional reagents and equipment for preparing fractionated *Xenopus* interphase extract (*UNIT 11.10*)

1. Harvest the cytosol and light membrane fractions of a fractionated interphase extract. After removing the light membranes, gently remove the heavy membrane fraction using a cut-off pipet tip and a P-200 micropipettor. Place the material on ice.

   The mitochondrial/heavy membrane fraction is the brown opaque layer that lies directly below the light membrane layer. The translucent layer directly below the heavy membranes consists largely of pigment granules and glycogen.

2. For each sample, prepare a Percoll step gradient by slowly adding successive 0.45 ml layers of each of the following Percoll solutions to a 2.5-ml tube for the TLS-55 swinging-bucket rotor: 42%, 37%, 30%, and 25%.

   These solutions must be layered on top of each other slowly to prevent mixing.

3. Add the entire mitochondrial layer from the extracts of eggs of one to two frogs on top of the gradient. Centrifuge 25 min at 53,500 × *g* (25,000 rpm in TLS-55 rotor), 4°C, without the brake.

   After centrifugation, any contaminating light membranes will be at the top of the Percoll gradient. Heavy membranes/mitochondria will form a discrete dark band between Percoll concentrations.

4. Withdraw the heavy membranes/mitochondria using a Pasteur pipet. Resuspend them in 50 vol MIB buffer. Mix by gently inverting the tube.

5. Pellet the mitochondria by centrifuging 10 min at 1700 × *g*, 4°C.

6. Discard the supernatant and resuspend the mitochondrial pellet in an equal volume of MIB buffer to give a 10× stock for addition to reconstituted extract.

   Although some laboratories use frozen stocks of mitochondria, freeze/thaw can result in puncturing of mitochondria. Should this occur, direct cytochrome c leakage from mitochondria may produce rapid, unregulated apoptosis upon addition to extracts. This is obviously not useful for studying regulation of the apoptotoic process. Consequently, the authors prefer to use the mitochondrial fraction on the day of preparation. The entire procedure takes ~2.5 hr.

CYTOCHROME *c* RELEASE ASSAYS

SUPPORT PROTOCOL 3

In many systems, execution of the apoptotic program depends upon release of cytochrome *c* from the mitochondria. Once released to the cytoplasm, cytochrome *c* serves as a cofactor in activation of the apoptotic proteases, or caspases. Indeed, addition of purified cytochrome *c* to *Xenopus* egg extracts results in rapid caspase activation and fragmentation of subcellular structures (e.g., nuclei, endoplasmic reticulum). Therefore, one way to assess apoptotic progression in the *Xenopus* egg extract is through measurement of mitochondrial cytochrome *c* release. This can be done in crude egg extracts or, alternatively, purified mitochondria (see Support Protocol 2) can be mixed with cytosol from the fractionated interphase extract (*UNIT 11.10*), which will also support mitochondrial cytochrome *c* release.

Materials

Crude extract for apoptotic reaction (see Basic Protocol)
0.1-µm ultrafree-MC filters (Millipore)
Anti-cytochrome *c* antibody (Pharmingen)

Additional reagents and equipment for SDS-PAGE (*UNIT 6.1*) and immunoblotting (*UNIT 6.2*)

1. At various time intervals (e.g., 0.5-hr to 1-hr intervals are generally sufficient), withdraw 25-µl aliquots of crude extract for apoptotic reaction and pass through a 0.1-µm ultrafree-MC filter.

   This removes both mitochondria and other particulate matter. The supernatant above the filter should contain any cytochrome c that has been released into the cytosol.

2. Separate 7 µl of the supernatant retained above the filter by SDS-PAGE (*UNIT 6.1*) and immunoblot (*UNIT 6.2*) with anti-cytochrome *c* antibody.

SUPPORT PROTOCOL 4

CYTOCHROME *c* RELEASE ASSAY USING PURIFIED MITOCHONDRIA AND CYTOSOL

Under some circumstances it is desirable to prepare cytosol and mitochondria separately for reconstitution of cytochrome *c* release. For example, separate preparations are used when immunodepleting the cytosol of a particular protein to determine whether the protein in question affects cytochrome *c* release. Moreover, using purified mitochondria it is possible to determine if a given recombinant protein can induce mitochondrial cytochrome *c* release in the absence of accessory cytosolic components. Under these circumstances, egg lysis buffer containing the protein of interest would be substituted for cytosol in this protocol.

Materials

Heavy membrane fraction containing mitochondria (see Support Protocol 2)
Cytosolic fraction containing energy regenerating mix (*UNIT 11.10*)

Additional reagents and equipment for SDS-PAGE (*UNIT 6.1*) and immunoblotting (*UNIT 6.2*)

1. Combine 14 µl of the heavy membrane fraction containing mitochondria with 170 µl cytosol containing an energy-regenerating mix. Incubate at room temperature.
2. At 0.5-hr intervals, withdraw 25-µl aliquots. Filter, electrophorese (*UNIT 6.1*), and immunoblot (*UNIT 6.2*) the supernatant for cytochrome *c*.

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Assay buffer

50 mM HEPES, pH 7.4
100 mM NaCl
0.1% (w/v) CHAPS
1 mM EDTA
10% (v/v) glycerol
10 mM dithiothreitol, added fresh before each use
Store indefinitely at 4°C

Table 11.12.1 Preparation of Percoll Solutions for Gradients

Ingredient	% Percoll			
	42%	37%	30%	25%
MIB buffer concentrate[a]	0.612 ml	0.612 ml	0.612 ml	0.612 ml
Percoll	1.05 ml	0.92 ml	0.75 ml	0.25 ml
Water	0.838 ml	0.968 ml	1.14 ml	1.263 ml

[a]See recipe for MIB buffer.

Cleavage inhibitor: Ac-DEVD-CHO, 20×

Prepare 0.1 mM or 0.05 mg/ml stock of Ac-DEVD-CHO (Biomol) in DMSO. Dilute stock 1:50 in assay buffer (see recipe). Store up to several months at −20°C.

Cleavage substrate: Ac-DEVD-pNA, 2 mM

Dissolve 1.3 mg/ml Ac-DEVD-pNA (Biomol) in assay buffer (see recipe) for a 2 mM final concentration. Store in light-proof tube at −20°C.

MIB buffer

Prepare MIB buffer concentrate:
50 mM sucrose
10 mM KCl
10 mM sodium succinate
10 mM HEPES adjusted to pH 7.5 with KOH
5 mM EGTA
210 mM mannitol
0.5 mM dithiothreitol, added fresh before each use
Store indefinitely at 4°C

To prepare MIB buffer: Dilute 2.45 ml MIB buffer concentrate to 10 ml final volume in water.

Discard MIB buffer concentrate if microbial growth is detected.

Percoll solutions

Prepare Percoll solutions according to Table 11.12.1.

COMMENTARY

Background Information

Recently, a cell-free extract of *Xenopus* eggs that can support apoptosis was described (Newmeyer et al., 1994). The preparation of these extracts and assays of apoptosis are described in this unit (see Basic Protocol and Alternate Protocol). The ability to use eggs as a source of material to reconstitute apoptotic processes in vitro most likely reflects the in vivo process of oocyte atresia, wherein oocytes that have matured but have not been laid due to a lack of appropriate hormonal stimuli, are systematically resorbed by apoptosis.

As is the case in vivo, the apoptotic nuclear fragmentation seen in the in vitro extract of *Xenopus* eggs is characterized by a series of stereotyped phenotypic changes in subcellular structures. The extract offers the opportunity to examine nuclear events of apoptosis and also to study biochemically the regulation and activation of proteases critical for apoptotic execution. In extracts, as in vivo, the onset of apoptosis is marked by the condensation of DNA, after which the condensed DNA is distributed into many small membrane-enclosed structures (see Figure 11.10.3). Gel electrophoresis reveals the characteristic "laddering" of DNA, indicative of internucleosomal cleavage. Nuclear fragmentation in these extracts is accompanied by the activation of apoptotic proteases, the caspases (Newmeyer et al., 1994; Cosulich et al., 1996), and this is completely inhibited by addition of the broad range apoptotic inhibitor, bcl-2 protein (Bellamy et al., 1995; Villa et

al., 1997; Chao and Korsmeyer, 1998). By these crititeria, the extract faithfully recapitulates a number of the biochemical events of in vivo apoptosis. Additionally, other known positive regulators of apoptosis (e.g., Drosophila reaper protein, activated caspases, and cytochrome *c*) and negative regulators of apoptosis (e.g., tetrapeptide caspase inhibitors) behave in the *Xenopus* extract as in other systems, again supporting the notion that the extract accurately reconstitutes the apoptotic process (Evans et al., 1997; Kuwana et al., 1998). Coupled with the fact that elements of the apoptotic machinery have proven to be well conserved from worms to man, these observations make it highly likely that the *Xenopus* system will provide an excellent model for understanding key events in the regulation of apoptosis, as has been the case for the study of cell cycle progression, DNA replication, nuclear transport, and nuclear architecture.

Critical Parameters

Although most extracts will eventually enter apoptosis, the time required varies a great deal from extract to extract. A CSF-arrested extract or an extract otherwise in mitosis is extremely refractory to apoptosis.

When handling mitochondria to be used for apoptotic or cytochrome *c* release assays, they must be treated gently to prevent breakage. Freeze-thawing the mitochondria can cause them to leak cytochrome *c*; therefore, fresh mitochondria are optimal for apoptosis experiments.

In extracts containing in excess of 1000 sperm nuclei/µl, the nuclei may fragment very slowly, despite relatively high levels of caspase activity. Therefore, to use nuclear fragmentation as an indicator of apoptosis, nuclei should be kept at concentrations <1000 sperm nuclei/µl.

When resolving samples by SDS-PAGE for anti-cytochrome *c* immunoblots, it is worth noting that many of the commercially available molecular weight markers include cytochrome *c* as one of the molecular weight standards. This band will also "light up" with the cytochrome *c* antibodies, providing a convenient size marker for the cytochrome *c* on immunoblots.

Anticipated Results

Extracts entering apoptosis should fragment added nuclei and activate DNases that can cleave the added DNA. Caspase activity should be detectable prior to visible chromatin fragmentation, and this activity should be preceded by observation of cytochrome *c* release from the mitochondria to the cytoplasm. Expect to obtain a volume of mitochondria ~1/20 the volume of the starting crude extract.

Time Considerations

The time for an extract to enter apoptosis varies enormously depending upon the extract. Although the typical extract takes 4 to 6 hr to enter apoptosis, extracts can enter apoptosis in as little as 1 hr or after as long as 12 hr. When doing an experiment dependent upon an extract having entered apoptosis, it is advisable to monitor apoptotic progression, either through examination of nuclei in the extract or through measurement of caspase activity. The authors have also observed that extract containing large numbers of nuclei may be slower to enter apoptosis than extracts lacking nuclei. Cytochrome *c* release from mitochondria will precede caspase activation slightly.

Mitotic Spindle Assembly In Vitro

This unit presents in vitro assays for studying the process of mitotic spindle assembly using *Xenopus laevis* egg extracts. These protocols all make use of cytostatic factor (CSF)–arrested extracts. CSF extracts arrested in metaphase are open to biochemical study and manipulation and allow for extensive cytological analysis of experiments. A detailed protocol for the preparation of CSF extracts can be found in *UNIT 11.11*, and the authors' modifications are given in Support Protocol 1.

The basic protocols in this unit can be used to assay the roles of different cellular factors in the many processes and events that must take place to properly assemble a mitotic spindle. All of these assays are performed in a test tube environment. The researcher combines CSF extract with factors that generate mitotic microtubule structures, such as centrosomes or dimethyl sulfoxide (DMSO), which give rise to mitotic asters (see Basic Protocol 1), sperm nuclei (see Basic Protocols 2 and 3), or DNA beads (see Basic Protocol 4), which lead to the formation of spindles. Rhodamine-labeled tubulin (see Support Protocol 2) is added to allow quick and easy visualization by fluorescence microscopy of microtubule growth and organization in samples taken at various time points. Experimental conditions are created by pretreating the extract to specifically inactivate or remove proteins of interest (see *UNIT 11.11* and Support Protocol 3). Finally, the results of individual experiments are preserved by transferring the extract reactions to coverslips for fixation and storage (see Support Protocol 4). This same fixation method also allows for immunofluorescence analysis of individual experiments (*UNIT 4.3*).

The first basic protocol (see Basic Protocol 1) describes a method for assembling microtubule asters in extracts using either DMSO or purified centrosomes. Although spindles are not formed in these reactions, they are useful, because of their simplicity of method and mechanism, for studying microtubule nucleation, dynamics, and organization. Subsequent protocols build on the same basic reaction, but substitute sperm nuclei (see Basic Protocols 2 and 3) or DNA beads (see Basic Protocol 4) to promote spindle formation. Purified *Xenopus* sperm nuclei added to the CSF extract support assembly of monopolar spindles ("half-spindles"), which eventually fuse to form bipolar spindles. This protocol is useful as a fast and simple assay of spindle assembly in the extract. A more physiological method for assembling spindles involves cycling the extract containing sperm nuclei through interphase and back into mitosis, allowing the chromosomes and centrosome to duplicate (see Basic Protocol 3). After reentry into a mitotic state, the extract assembles true bipolar spindles. This protocol allows the researcher to study the importance of interphase events in spindle assembly. The last basic protocol (see Basic Protocol 4) describes a method for assembling spindles in extract around DNA-coated beads (for preparation see Support Protocol 5). These beads are sufficient to support spindle assembly in the extract and yet lack centromeric DNA sequences and centrosomes. This protocol, therefore, allows study of the spindle assembly process in a more simplified system that depends on the microtubule-stabilizing and -organizing capacity of mitotic chromatin.

NOTE: Schematic diagrams illustrating the anticipated time course of extract reactions are shown in Figure 11.13.1, while actual micrographs of asters and spindles are shown in Figure 11.13.2.

(**B**) Spindle assembly reactions with sperm nuclei and chromatin beads.

BASIC PROTOCOL 1

ANALYZING DMSO AND CENTROSOME ASTER REACTIONS

Aster reactions provide a fast and simple method for determining the ability of an extract to support microtubule nucleation, polymerization, and organization. This protocol makes use of either purified centrosomes or DMSO to induce aster assembly. Centrosomes provide focal sites for microtubule nucleation and organization. A protocol for purifying centrosomes from human lymphocytes is given in Blomberg-Wirschell and Doxsey (1998). In contrast, DMSO acts as a microtubule-stabilizing agent that leads to the spontaneous nucleation of microtubules, which are then organized into focused asters by microtubule-based motor proteins. CSF extract is combined with either of the above and rhodamine-labeled tubulin (see Support Protocol 2). Asters begin to form within minutes after incubation at 20°C. Samples taken at various time points are squashed on slides with fixative. Reactions can be "spun down" onto coverslips for fixation, immunofluorescence analysis, and long-term storage (see Support Protocol 4).

Materials

20 to 30 mg/ml rhodamine-labeled tubulin (see Support Protocol 2)
CSF extract (*UNIT 11.11*; also see Support Protocol 1)
Dimethyl sulfoxide (DMSO), anhydrous *or* ~5×10^8 purified centrosomes/ml
Spindle fix (see recipe)
Nail polish

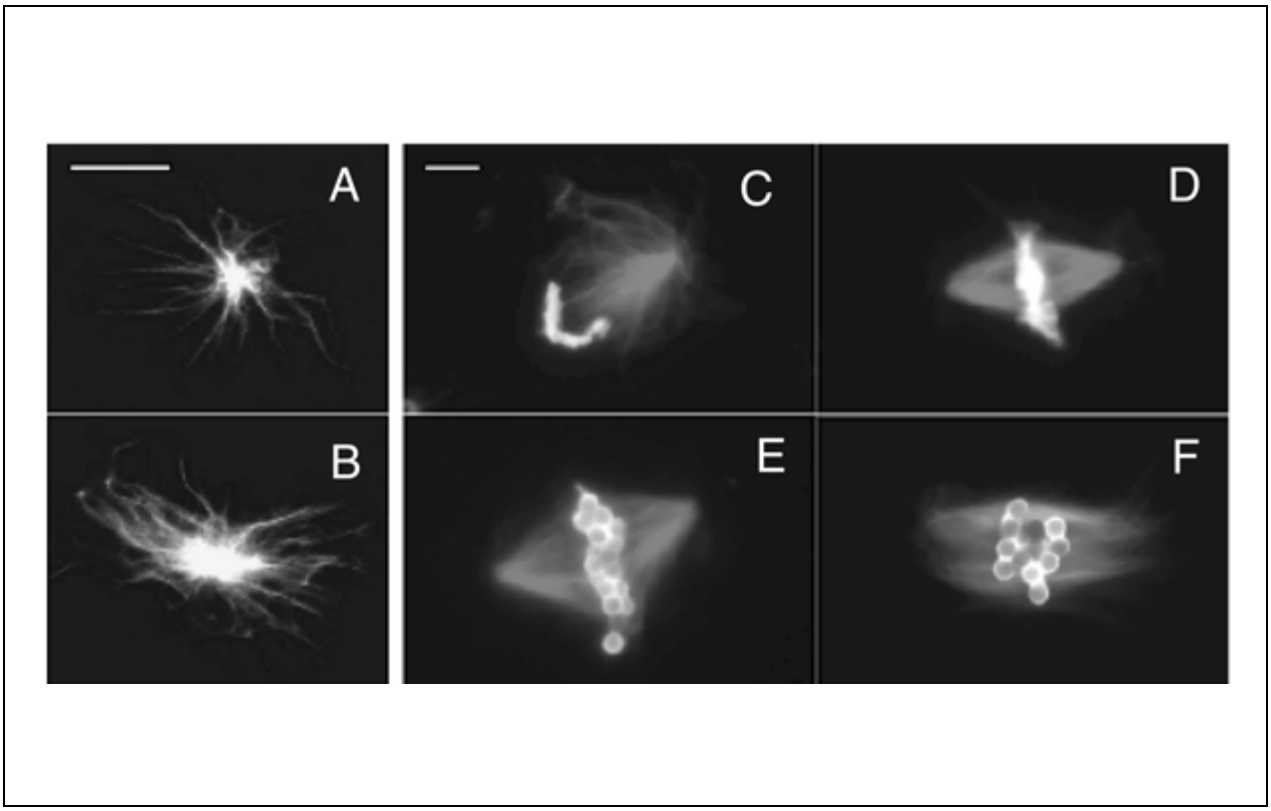

Figure 11.13.2 Examples of asters and spindles visualized by fluorescence microscopy. (**A**) Centrosome-nucleated aster. (**B**) DMSO aster. (**C**) Sperm half-spindle. (**D**) Sperm bipolar spindle. (**E**) DNA bead spindle. (**F**) DNA bead spindle assembled in the presence of antibody 70.1 that recognizes dynein intermediate chain. Microtubules are visualized by incorporation of rhodamine-labeled tubulin and appear gray. DNA is seen in the DAPI channel and appears white. Bar is equal to 5 μm.

1.5-ml microcentrifuge tubes
Wide-orifice 1- to 200-μl pipet tips
Water bath
Microscope slides and 18 × 18–mm square coverslips
Fluorescence microscope with 40× or 63× lens and rhodamine/Hoechst filter sets

1. On ice, prepare a 1:10 dilution of rhodamine tubulin stock by adding 1 μl stock to 10 μl CSF extract. Prepare the reaction tube on ice by adding 1.25 μl of the 1:10 dilution of rhodamine tubulin to 25 μl CSF extract (1:20) in a 1.5-ml microcentrifuge tube to give a final reaction mixture with a tubulin dilution of 1:200.

   IMPORTANT NOTE: *Always mix and transfer extract and extract reactions with wide-orifice (or cut-off) pipet tips, and avoid generating bubbles. It is important to use 1.5-ml tubes and not let reaction volumes exceed 100 μl, to permit better gas exchange.*

   For multiple reactions, dilute labeled tubulin stock, to a concentration of 0.10 to 0.15 mg/ml (1:200), into the total volume of extract needed, then aliquot into 25-μl reactions.

2. Add 1.25 μl of anhydrous DMSO or purified centrosomes.

   Centrosome stock should be ~5 × 10^8 centrosomes/ml.

3. Prepare a 20°C bath by adding sufficient ice to bring a room temperature bath to the appropriate temperature. Add additional ice, as needed, to maintain temperature.

   IMPORTANT NOTE: *Reactions are initiated by placing samples at 20°C. Do not place samples on ice before fixation, as this will cause the microtubules to depolymerize.*

4a. *For centrosome reactions:* Incubate for 5 to 15 min then take a "squash sample" by transferring 1 µl of the reaction to a microscope slide. Carefully place 5 µl of spindle fix on top of the drop of extract and squash by gently overlaying with an 18 × 18–mm coverslip.

Always mix reactions by pipetting gently before removing "squash samples" for mounting on slides.

For best results, lower the coverslip at an angle and let it touch the extract/fixative drop before releasing. Because preservation of microtubule structures is somewhat variable, take duplicate samples.

Two or three coverslips can be fit side-by-side on each slide.

Analysis using the rhodamine channel should reveal red asters of microtubules emanating from single focal points. Aster size will increase with increasing incubation time.

4b. *For DMSO reactions:* Incubate for 5 to 30 min then take a 1-µl sample of the reaction to fix and squash as described above.

At early time points extensive microtubule polymerization is apparent. By 20 min, asters have organized, and these contain many more microtubules than centrosome asters.

Analysis using the rhodamine channel should reveal red asters of microtubules emanating from single focal points. Aster size will increase with increasing incubation time.

5. Seal the edges of the coverslips with nail polish and store squash samples in the dark at 4°C.

Alternatively, reaction mixtures can be spun onto coverslips, fixed, and mounted (see Support Protocol 4).

Spin-downs and squash samples, if sealed, can be stored at 4°C for months to years after the experiment is performed.

6. Analyze on a fluorescence microscope with 40× or 63× lens and rhodamine/Hoechst filter sets.

Analysis using the rhodamine channel should reveal red asters of microtubules emanating from single focal points. Aster size will increase with increasing incubation time.

BASIC PROTOCOL 2

ANALYZING SPERM DNA "HALF-SPINDLE" REACTIONS

"Half-spindle" reactions provide a fast and easy assay for spindle assembly in an extract. This method of spindle assembly proceeds in a nonphysiological manner. The centrosome of a sperm nucleus nucleates a single microtubule aster that interacts with sperm chromosomes, forming a monopolar (half-) spindle. Half-spindles then fuse pairwise to form bipolar spindles; however, these reactions are still quite sensitive to perturbations in the extract, making them quite useful for studying the roles of specific proteins and factors in spindle assembly. CSF extract is combined with demembranated *Xenopus* sperm nuclei (for preparation, see *UNIT 11.10*) and rhodamine-labeled tubulin. Incubation at 20°C allows microtubule polymerization and spindle assembly. Fluorescence microscopy analysis of squash samples will reveal a few fully-formed bipolar spindles and many half-spindles as early as 15 to 30 min after the start of incubation; however, a reaction is not considered "complete" until at least 45 or 60 min. At this point, an unperturbed extract of good quality will have produced bipolar spindles around 75% to 95% of the sperm nuclei that it contains. Reactions can then be spun down onto coverslips for fixation, immunofluorescence analysis, and long-term storage (see Support Protocol 4).

Materials

20 to 30 mg/ml rhodamine tubulin stock (Murray, 1991)
CSF extract (*UNIT 11.11*; also see Support Protocol 1)
20× demembranated sperm nuclei (~100 sperm/µl extract; *UNIT 11.10*)

Spindle fix (see recipe)
Nail polish

1.5-ml microcentrifuge tubes
Water bath
Microscope slides and 18 × 18–mm square coverslips
Fluorescence microscope with 40× or 63× lens and rhodamine/Hoechst filter sets

1. On ice, prepare a 1:10 dilution of rhodamine tubulin stock by adding 1 µl stock to 10 µl CSF extract. Prepare the reaction tube on ice by adding 1.25 µl of the 1:10 dilution of rhodamine tubulin to 25 µl CSF extract (1:20) in a 1.5-ml microcentrifuge tube to give a final reaction mixture with a tubulin dilution of 1:200.

   IMPORTANT NOTE: *Always mix and transfer extract and extract reactions with wide-orifice (or cut-off) pipet tips, and avoid generating bubbles. It is important to use 1.5-ml tubes and not let reaction volumes exceed 100 µl, to permit better gas exchange.*

   For multiple reactions, dilute labeled tubulin stock, to a concentration of 0.10 to 0.15 mg/ml (1:200), into the total volume of extract needed, then aliquot into 25-µl reactions.

2. Add 2.5 µl of 20× demembranated sperm nuclei (~100 sperm/µl extract).

   More concentrated sperm stocks can be diluted to 20× in 100 mM KCl/150 mM sucrose/1 mM $MgCl_2$, flash frozen, and stored in aliquots at −80°C.

3. Incubate the reaction for 15 min in a 20°C water bath.

   The bath is prepared by adding sufficient ice to bring a room temperature bath to 20°C (see Basic Protocol 1, step 3) and adding additional ice as necessary to maintain temperature.

4. Prepare a squash sample by transferring 1 µl of the reaction to a microscope slide. Carefully place 5 µl of spindle fix on top of the drop of extract and squash by gently overlaying with an 18 × 18–mm coverslip. Analyze samples on a fluorescence microscope with 40× or 63× objective and rhodamine/Hoechst filter sets. Seal with nail polish.

   Always mix reactions by pipetting gently before removing "squash samples" for mounting on slides.

   For best results, lower the coverslip at an angle and let it touch the extract/fixative drop before releasing. Because preservation of microtubule structures is somewhat variable, take duplicate samples.

   Two or three coverslips can be fit side-by-side on each slide.

   Analysis of early time points on a fluorescence microscope should reveal condensed chromatin structures in the channel associated with microtubules in early stages of organization visible in the rhodamine channel.

5. Take additional squash samples at 30, 45, and 60 min to assess spindle assembly as described above. Analyze samples, seal with nail polish and store in the dark at 4°C.

   By 30 min, samples should contain condensed chromatin structures associated with astral arrays of microtubules focused into a single pole.

   At 45 to 60 min samples should also contain half-spindles that have fused to produce bipolar spindles that resemble those produced by the more physiological "cycling" reactions described in the next protocol (see Basic Protocol 3). At this point the reaction is complete. Continued incubation will lead to the formation of large aggregates of spindles.

   Alternatively, reaction mixtures can be spun onto coverslips, fixed, and mounted as described (see Support Protocol 4).

   Spin-downs and squash samples, if sealed, can be stored at 4°C for months to years after the experiment is performed.

BASIC PROTOCOL 3

ANALYZING SPERM DNA "CYCLING" REACTIONS

This protocol provides an assay for the importance of interphase events (i.e., DNA replication, centrosome duplication, and chromatin packaging) in the process of spindle assembly. Unlike half-spindle reactions, this protocol cycles the extract through interphase and back into mitosis. Any sperm nuclei present during the reaction undergo chromatin decondensation, DNA replication, and centrosome duplication. Returning the extract to mitosis promotes spindle assembly through the more physiological pathway of microtubule nucleation and growth from duplicated centrosomes around a replicated set of chromosomes containing duplicated kinetochores.

In this protocol, as in half-spindle reactions (see Basic Protocol 2), CSF extract is combined with rhodamine-labeled tubulin and demembranated *Xenopus* sperm nuclei. After a 10-min incubation at 20°C, calcium is added to the reaction to promote entry into interphase. After 80 min of further incubation at 20°C, nuclei will appear large and round, and microtubules should be long and abundant. Addition of fresh CSF extract to the reaction drives the reaction back into mitosis and spindle assembly begins. Spindles are formed 45 to 60 min after addition of fresh CSF extract, and, as with previous reactions, can be spun down onto coverslips (see Support Protocol 4).

Materials

20 to 30 mg/ml rhodamine tubulin stock (see Support Protocol 2)
CSF extract (*UNIT 11.11*; also see Support Protocol 1)
20× demembranated sperm nuclei (~100 sperm/µl extract; *UNIT 11.10*)
10× calcium solution (see recipe)
Spindle fix (see recipe)

20°C water bath
Microscope slides and 18 × 18–mm square coverslips
Fluorescence microscope with 40× or 63× lens and rhodamine/Hoechst filter sets

Prepare reaction

1. On ice, prepare a 1:10 dilution of rhodamine tubulin stock by adding 1 µl stock to 10 µl CSF extract. Prepare the reaction tube on ice by adding 1.25 µl of the 1:10 dilution of rhodamine tubulin to 25 µl CSF extract (1:20) in a 1.5-ml microcentrifuge tube to give a final reaction mixture with a tubulin dilution of 1:200.

   IMPORTANT NOTE: *Always mix and transfer extract and extract reactions with wide-orifice (or cut-off) pipet tips, and avoid generating bubbles. It is important to use 1.5-ml tubes and not let reaction volumes exceed 100 µl, to permit better gas exchange.*

   For multiple reactions, dilute labeled tubulin stock, to a concentration of 0.10 to 0.15 mg/ml (1:200), into the total volume of extract needed, then aliquot into 25-µl reactions.

2. Add 2.5 µl of 20× sperm nuclei (~100 sperm/µl extract).

3. Incubate the reaction 10 min in a 20°C water bath.

   The bath is prepared by adding sufficient ice to bring a room temperature bath to 20°C (see Basic Protocol 1, step 3) and adding additional ice as necessary to maintain temperature.

Release extract into interphase

4. Add 5 µl 10× calcium solution and mix well to release extract into interphase.

   Calcium leads to the degradation of the cell cycle regulatory proteins cyclin B and CSF, causing inactivation of the mitotic cdc2 kinase and exit from mitosis.

5. Incubate the reaction 80 min in a 20°C water bath.

6. Transfer 1 µl of the reaction to a microscope slide. Carefully place 5 µl of spindle fix on top of the drop of extract and squash by gently overlaying with an 18 × 18–mm coverslip. At 30 and 80 min after calcium addition, check that the extract is entering interphase. Analyze on a fluorescence microscope with 40× or 63× objective and rhodamine/Hoechst filter sets.

   If sperm nuclei do not appear to be decondensing at 30 min after calcium addition, add an additional 2.5 µl (1/20 dilution) of 10× calcium.

   By 80 min, nuclei are visible in the DAPI channel and should appear large, round, and uniform, while microtubules should be long and abundant.

Drive the reaction into mitosis

7. At 90 min post calcium addition, add 0.5 vol (25 µl) of fresh CSF extract to the reaction. Continue incubation at 20°C.

   Addition of fresh extract will send the reaction back into mitosis.

8. Take squash samples at 15, 30, 45, 60, and 90 min after addition of fresh CSF extract to assess the spindle assembly reaction. Examine the samples using a fluorescence microscope with 40× or 63× objective and rhodamine/Hoechst filter sets.

   Bipolar spindles should be visible by 45 min after addition of fresh CSF extract.

9. Seal the edges of the coverslips with nail polish and store squash samples in the dark at 4°C.

   Alternatively, entire reaction mixtures can be spun onto coverslips, fixed, and mounted (see Support Protocol 4).

ANALYZING DNA-BEAD REACTIONS

BASIC PROTOCOL 4

This protocol assays the ability of an extract to support spindle assembly around chromatin in the absence of centrosomes or special chromosomal sequences. This reduces the system even more towards a minimal set of necessary components and allows for detection of otherwise subtle phenotypes (such as those resulting from the disruption of motor proteins) in the absence of the strong structural cues normally provided by the centrosomes.

DNA-coupled Dynabeads are retrieved on a magnet, washed with CSF extract to remove the storage buffer, and resuspended in fresh CSF extract. After 10 min of incubation at 20°C, the reaction is sent into interphase by the addition of calcium. Incubation for 2 hr at 20°C allows for proper assembly of chromatin on the beads. Addition of fresh CSF extract and incubation at 20°C for 30 min brings the reaction back into mitosis. The beads are retrieved using a magnet, or flash frozen for later use. After removal of the extract, the beads are resuspended in fresh CSF extract. The reaction is again incubated at 20°C. Bipolar spindles should form after 30 to 90 min of incubation, and, as with previous protocols, reactions can then be spun down onto coverslips for fixation, immunofluorescence analysis, and long-term storage.

Materials

DNA beads (see Support Protocol 5)
CSF extract (*UNIT 11.11*; also see Support Protocol 1) with and without 1:200 rhodamine-labeled tubulin (Support Protocol 2)
10× calcium solution (see recipe)
Spindle fix (see recipe)

0.5-ml microcentrifuge tubes

Magnetic particle concentrator (MPC; Dynal)
20°C water bath
Microscope slides and 18 × 18–mm square coverslips
Fluorescence microscope with 40× or 63× lens and rhodamine/Hoechst filter sets

1. Transfer 3 µl of DNA beads (about 0.5 µg DNA) to a 0.5-ml microcentrifuge tube and place on a magnetic particle concentrator (MPC) on ice. Remove supernatant using a pipet. Be careful not to disturb the pellet. Wash beads by resuspending them in 20 µl of CSF extract.

2. Retrieve beads using the magnet, pipet off supernatant, and resuspend in 100 µl CSF extract. Transfer to a 1.5-ml microcentrifuge tube and incubate 10 min in a 20°C water bath.

   The bath is prepared by adding sufficient ice to bring a room temperature bath to 20°C (see Basic Protocol 1, step 3) and adding additional ice as necessary to maintain temperature.

3. Send CSF extract into interphase by adding 10 µl of 10× calcium solution. Incubate for 2 hr in a 20°C water bath, mixing periodically.

   Mixing the reactions periodically (every 20 to 30 min) is important to prevent aggregation of beads into large clumps.

4. Return the extract containing the beads to mitosis by adding 50 µl of fresh CSF extract. Incubate for 30 min at 20°C.

   At this point the entire reaction can be flash frozen in liquid nitrogen and stored at –80°C. This provides a stock of preformed chromatin beads thereby avoiding the lengthy chromatin-assembly steps.

5. Incubate the bead mixture on ice for several minutes. Retrieve the beads by incubating in the MPC (magnet) on ice for 10 to 15 min.

   Due to the high viscosity of the extract, bead retrieval is slow. To accelerate the process, mix by pipetting the mixture every few minutes, keeping the tube on the MPC.

6. Remove the supernatant with a pipet. Resuspend the beads in 100 µl of fresh CSF extract containing rhodamine-labeled tubulin at a 1:200 dilution. Incubate at 20°C.

7. Take squash samples to monitor the spindle assembly process by transferring 1 µl of the reaction to a microscope slide. Carefully place 5 µl of spindle fix on top of the drop of extract and squash by gently overlaying with an 18 × 18–mm coverslip. Analyze on a fluorescence microscope with 40× or 63× objective and rhodamine/Hoechst filter sets.

   Spindle assembly requires between 30 and 90 min, depending on the extract.

8. Seal the edges of the coverslips with nail polish and store squash samples in the dark at 4°C.

   Alternatively, entire reaction mixtures can be spun onto coverslips, fixed, and mounted (see Support Protocol 4).

PREPARATION OF CSF EXTRACT

The authors' method for extract preparation, presented here, is very similar to that presented in *UNIT 11.11*, but is somewhat more simple; i.e., oil is not used, eggs are crushed by centrifugation in a Sorvall HB-4 or HB-6 rotor, a second clarifying centrifugation is not performed, cytochalasin D is used instead of cytochalasin B, and a different mix of protease inhibitors is used. If the extract is to be cycled, EGTA should be omitted from the 20× energy mix.

Materials

Xenopus eggs, dejellied (*UNIT 11.10*)
Extract buffer (XB; see recipe)
CSF-XB (see recipe)
10 mg/ml LPC (see recipe)
10 mg/ml cytochalasin D in DMSO: store in aliquots at −20°C
20× energy mix (*UNIT 11.11*)

400-ml beaker
Polished, cut-off glass pipet
SW-50 tubes (Beckman)
13-ml adapter tubes (Sarstedt)
Clinical centrifuge
Sorvall centrifuge and HB-4 or HB-6 rotor with rubber adapters for 15-ml tubes
18-G needle and 1-ml syringe

Additional reagents and equipment for injecting frogs, and collecting and dejellying eggs (*UNIT 11.10*)

1. Inject frogs, collect eggs in 400-ml beaker, and dejelly (*UNIT 11.10*).
2. Wash dejellied eggs several times with 50 to 100 ml extract buffer (XB) and then twice with 50 to 100 ml CSF-XB (XB containing 5 mM EGTA and 1 mM $MgCl_2$). Swirl beaker gently and decant as much buffer as possible between washes.

   Preparation of a good extract is critical for the success of in vitro aster and spindle assembly reactions. Pay close attention to the protocols describing how to collect, handle, and dejelly eggs (UNIT 11.10).

3. Perform one final wash with 50 ml CSF-XB to which LPC has been added to a final concentration of 10 µg/ml.
4. Using a polished, cut-off glass pipet, rinsed with CSF-XB, load eggs into SW-50 tubes containing 1 ml CSF-XB with 10 µg/ml LPC, to which 10 µl of 10 mg/ml cytochalasin D has been added (100 µg/ml final).

   Immerse glass pipet into solution before expelling eggs, so that they do not contact air.

5. Transfer SW-50 tubes containing eggs to 13-ml Sarstedt adapter tubes containing 0.5 ml water to prevent tubes from collapsing.
6. Centrifuge in a room temperature clinical centrifuge at 150 × *g* for 1 min, then at 700 × *g* for 30 sec. Remove all buffer from the top of the packed eggs with a cut-off glass pipet.

   Removal of all the buffer is essential to obtain concentrated cytoplasm.

7. Place the tubes in an HB-4 or HB-6 rotor containing rubber adapters. Centrifuge 15 min at 16,460 × *g* (10,000 rpm), 16°C, to crush eggs.

8. Place tubes on ice. Pierce tube at the bottom of the yellow cytoplasmic layer with an 18-G needle attached to a 1-ml syringe, with the opening directed upwards. Collect cytoplasmic layer.

   Some of the grayish layer just below the cytoplasm should also be collected, but avoid the gray layer above the cytoplasm.

9. Dilute 10 mg/ml LPC to 1:1000, 10 mg/ml cytochalasin D to 1:500, and 20× energy mix to 1× in the cytoplasmic layer.

   If extract is to be cycled through interphase, omit EGTA from the 20× energy mix. The extract can be kept on ice for up to 6 hr before use.

SUPPORT PROTOCOL 2

PREPARATION OF RHODAMINE-LABELED TUBULIN

In the assays described in this unit, microtubules are visualized by incorporation of fluorescently-labeled tubulin subunits. This allows for easy analysis of the reaction without the need for immunostaining techniques. Combining a succinimidyl ester fluorochrome with pure bovine brain microtubules produces fluorescent tubulin derivatives (Hyman et al., 1991). The activated esters are thought to label random surface lysines and give good labeling stoichiometry and yield of functional tubulin. A variety of different fluorochromes can be used, including tetramethylrhodamine, X-rhodamine, Texas Red, and fluorescein. The following protocol requires 100 mg of purified tubulin for the eventual recovery of around 20 mg of labeled product.

Phosphocellulose column–purified tubulin is generally recovered and stored frozen in column buffer. After thawing the tubulin, 20× conversion buffer is added to convert this buffer to BRB80, a buffer that better promotes microtubule polymerization. Addition of GTP and glycerol, and incubation at 37°C, induces polymerization of the tubulin into microtubules. The microtubules are then pelleted, gently resuspended in labeling buffer, and incubated with the fluorochrome while still polymerized. After the addition of quenching buffer to end the reaction, the microtubules are again pelleted to remove unincorporated fluorochrome. The pellets are depolymerized and the resulting soluble tubulin subunits are separated from denatured protein by centrifugation. The recovered supernatants are incubated to again polymerize microtubules, which are then pelleted and depolymerized. After a final centrifugation, the tubulin-containing supernatants are frozen in small aliquots in liquid nitrogen and stored at −80°C until needed for use in extract reactions.

Materials

100 to 200 mg phosphocellulose column–purified tubulin, frozen (Ashford et al., 1998)
20× conversion buffer, ice-cold (see recipe)
200 mM GTP
Glycerol, 37°C
Labeling cushion (see recipe)
Labeling buffer, 37°C (see recipe)
Tetramethylrhodamine succinimidyl ester (Molecular Probes)
Dimethyl sulfoxide (DMSO), anhydrous (Sigma)
BRB80 cushion, 37°C (see recipe)
Quenching buffer, 37°C (see recipe)
IB, ice-cold (see recipe)
2× and 1× BRB80, ice-cold (see recipe for 5×)

37°C water bath
Ultracentrifuge with Ti50 rotor and polycarbonate screw-cap centrifuge tubes, prewarmed to 35°C (Beckman)
3-ml wide-orifice plastic transfer pipets
Wash bottle with H_2O
TLA100 table-top ultracentrifuge with TLA100.3 rotor, TL100 rotor, and polycarbonate centrifuge tubes, prewarmed to 35°C (Beckman)
Sonicator

Additional equipment and reagents for determining protein concentration by Bradford assay (*APPENDIX 3B*)

Prepare reaction mixture

1. Thaw phosphocellulose column–purified tubulin aliquots quickly in a 37°C water bath until mostly liquid. Transfer tubes to ice and measure the volume in a graduated cylinder.

   The starting tubulin amount should be at least 100 mg.

2. Add 1/20 vol ice-cold 20× conversion buffer to convert the column buffer to BRB80.

3. Add 200 mM GTP to 1 mM, and 0.5 vol glycerol, 37°C.

4. Mix well and cover with Parafilm. Immediately transfer to a 37°C water bath and incubate for 45 min to polymerize tubulin.

   Mix the tubulin periodically during this incubation. Bubbles should form and remain suspended in the viscous microtubule solution.

5. During the incubation, load polycarbonate screw-cap centrifuge tubes appropriate for a Ti50 rotor with 5 ml of labeling cushion. Prewarm along with Ti50 rotor to 37°C.

Perform first warm spin

6. Load polymerized tubulin on top of cushions with a 3-ml wide-orifice plastic transfer pipet. Ultracentrifuge 1 hr at 242,000 × *g* (50,000 rpm), 35°C.

   Keep polymerized tubulin warm at all times, for best results perform this step in a 37°C warm room. Fill each tube with 5 ml sample.

   Prewarm labeling buffer to 37°C at this step.

7. After centrifuging, keep tubes at 37°C. Aspirate down to the cushion. Wash the interface with water by filling each tube gently with water from wash bottle, then aspirate the wash and the cushion.

   This step removes inactive tubulin subunits.

8. Resuspend pellets in a minimal volume (50 µl each) of labeling buffer, 37°C, by drawing up and down into a cut-off pipet tip, and keep at 37°C. Wash tubes with 100 µl of labeling buffer, 37°C, to recover the remaining tubulin. Combine all resuspensions and the wash. Note the total volume, which should be around 1.5 ml.

   During this step, be sure to keep the microtubules at 37°C to maintain polymerization. The high pH of the labeling buffer is best for high-stoichiometry labeling, but it is not favorable for tubulin polymerization.

9. Prepare 100 mM tetramethylrhodamine succinimidyl ester in anhydrous DMSO. Add 1/10 volume 100 mM tetramethylrhodamine succinimidyl ester to the resuspended microtubules and vortex gently.

   As an alternative to 100 mM tetramethylrhodamine succinimidyl ester, a different succinimidyl ester fluorochrome can be used instead.

   Tetramethylrhodamine succinimidyl ester reacts with water and is not stable for storage.

10. Incubate 45 min at 37°C. Gently vortex the mixture every few minutes.

    Vortexing is especially important during the first few minutes of incubation. Do not vortex vigorously or the microtubules will depolymerize.

11. Add 1.5 ml BRB80 cushion to polycarbonate tubes appropriate for a TLA100.3 rotor.

    BRB80 cushion, rotor, and tubes should all be prewarmed to 37°C. During this step the quenching buffer can be prewarmed to 37°C as well.

12. Stop the labeling reaction (step 10) by adding 2 vol of quenching buffer, 37°C. Mix the reaction well and keep at 37°C.

Perform second warm spin

13. Load the mixture onto the prewarmed BRB80 cushions with a 3-ml wide-orifice plastic transfer pipet. Ultracentrifuge in a TLA 100.3 rotor for 30 min at 265,070 × *g* (70,000 rpm), 35°C. After the centrifugation, begin cooling the centrifuge to 4°C.

14. Aspirate the supernatants, washing the interface as before (step 8). Place both the rotor and the tubes on ice.

15. Resuspend each pellet in 100 µl ice-cold IB to depolymerize the microtubules. Pool the resuspensions. Draw up and down in a pipet to break up tubulin clumps. Incubate the mixture on ice for 15 min.

    Depolymerization can be accelerated by gentle sonication on ice for 1 to 2 sec pulses.

16. Add 1 vol of ice-cold 2× BRB80, and sonicate briefly. Check the tubulin concentration by Bradford analysis (*APPENDIX 3B*). If it exceeds 30 mg/ml, dilute tubulin with 1× BRB80 to 25 mg/ml before proceeding to the next step.

Perform first cold spin

17. Load depolymerized tubulin into a tube appropriate for the TLA100.3 rotor on ice. Centrifuge 15 min at 265,070 × *g* (70,000 rpm), 4°C. After the centrifugation, begin warming the centrifuge to 35°C.

18. Recover the supernatant and transfer to a 15-ml conical tube. Add 0.5 vol 37°C glycerol and GTP to 1 mM. After recovering the supernatants begin warming the rotor to 37°C.

19. Polymerize the microtubules by incubating 45 min at 37°C.

    Mix the reaction periodically during this step.

20. During the incubation add 1.5 ml of BRB80 cushion to tubes appropriate for a TLA100.3 rotor, and begin warming to 37°C.

Perform third warm spin

21. Load the polymerized microtubules onto the prewarmed cushions with a wide orifice (i.e., a cut 200- to 1000-µl pipet tip). Centrifuge 20 min at 265,070 × *g* (70,000 rpm), 35°C. After the centrifugation, begin cooling the centrifuge to 4°C. Also begin cooling a TLA100 rotor and polycarbonate tubes to 4°C.

22. Aspirate the supernatants and resuspend each pellet in 100 µl of ice-cold IB.

23. Add 1 vol cold 2× BRB80 and sonicate briefly. Check the concentration by Bradford assay (*APPENDIX 3B*). If necessary, dilute labeled tubulin to 30 mg/ml with cold 1× BRB80.

Perform final cold spin

24. Load mixture into TLA100 tubes on ice. Centrifuge 15 min at 265,070 × *g* (70,000 rpm), 4°C.

25. Recover the supernatant on ice and determine tubulin concentration by Bradford assay (*APPENDIX 3B*), and record.

26. Freeze in 1-µl and 50-µl aliquots in liquid nitrogen and store at −80°C.

    The 1-µl aliquots are for use with extract reactions. The 50-µl aliquots may be thawed when needed, split into 1-µl aliquots, flash frozen, and stored at −80°C.

MOTOR DISRUPTION

SUPPORT PROTOCOL 3

The following protocol illustrates a technique that can be used to assess the function of an individual protein in spindle assembly using the *Xenopus* egg extract system. The protocol describes how to disrupt the microtubule-based motor cytoplasmic dynein, which is required for organization of spindle poles. Disruption is achieved by adding inhibitory antibodies, which have been shown to inhibit association of dynein to microtubules in spindles (Heald et al., 1997). Antibodies dialyzed against extract buffer (XB) can be added to the CSF extract either before initiating the reaction, or after microtubule structures have formed. The effects of dynein disruption are monitored by squash or spin-down analysis.

Materials

Dynein intermediate chain antibody 70.1 (Sigma), as ascites
Unreactive antibody (e.g., mouse IgG or ascites; Sigma)
Extract buffer (XB; see recipe)

12,000 to 14,000 mol.-wt. cut-off dialysis tubing
4°C microcentrifuge
Low-volume concentrators with mol. wt. 50,000 cut-off (Microcon)

1. Dialyze 0.5 ml of 70.1 ascites against two changes of 1 liter XB, 4 hr each, using 12 to 14 kDa cut-off dialysis tubing at 4°C. Concentrate to 15 to 20 mg/ml using microconcentrator in a microcentrifuge at 4°C.

   Dynein inhibition requires a relatively high concentration of this antibody.

   Dialysis into XB removes any sodium azide, buffer, or salts that could disrupt the extract.

2. Add 1.25 µl diluted rhodamine tubulin and 2.5 µl dynein intermediate chain antibody 70.1 to 25 µl CSF extract (a dilution of 1:10). Mix well and incubate on ice for 10 to 20 min. Prepare a control sample containing a similar amount of control antibody such as mouse IgG in parallel.

3. Proceed with the aster or spindle assembly protocol (see Basic Protocols 1 to 4).

   Antibody can also be added to extract after reactions are complete. For dynein inhibition the same effects are observed.

4. Analyze squash or spin-down samples taken at different time points, and compare the phenotypes observed in the antibody-treated samples with the control samples.

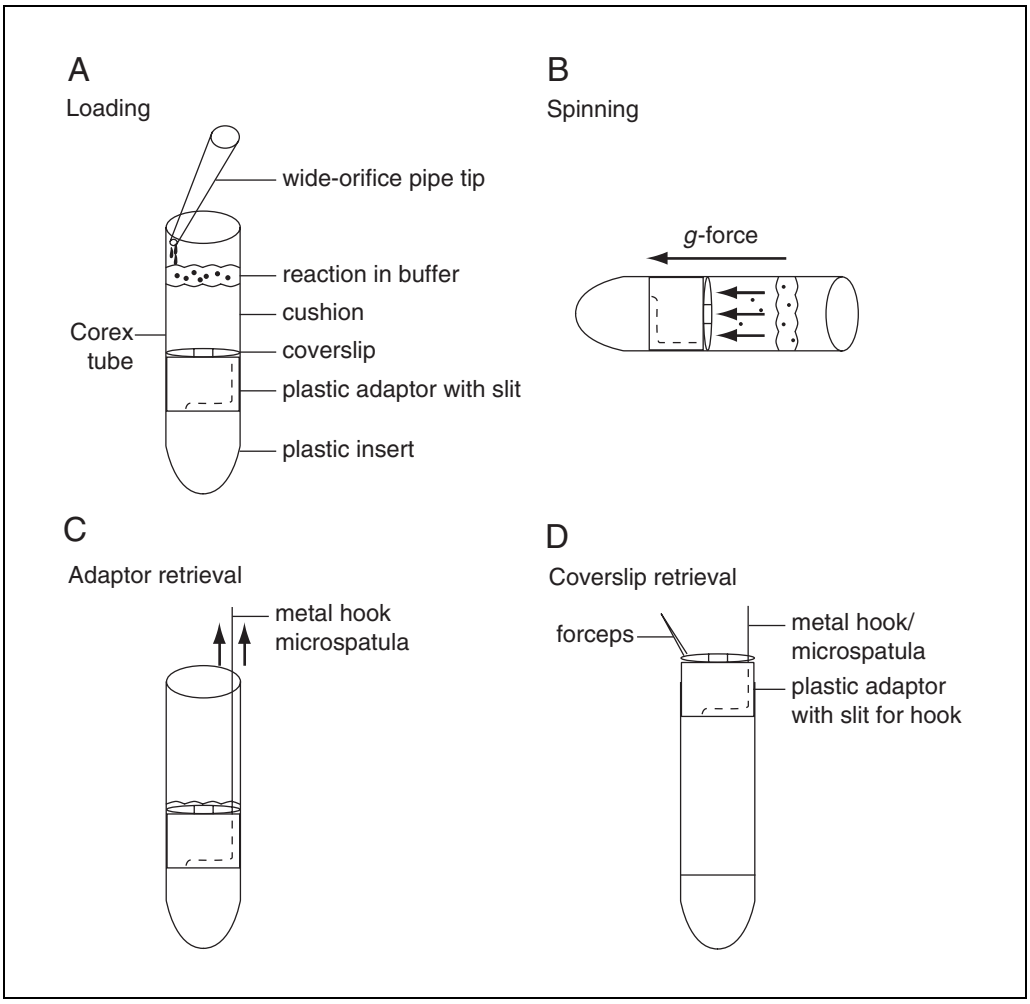

Figure 11.13.3 Schematic showing how spin-down tubes work to transfer spindles or asters from extract to coverslips for immunofluorescence and long-term storage. (**A**) Using a wide-orifice pipet tip, the extract reaction is layered on top of a glycerol cushion in a modified Corex tube containing a plastic insert and adapter with a coverslip on top. (**B**) Centrifugation in a swinging bucket rotor pellets asters and spindles through the cushion onto the coverslip. (**C**) After the cushion is aspirated, the adaptor is retrieved using a metal hook or spatula that fits into groove on one side of the adaptor. (**D**) The coverslip is retrieved from the top of the adaptor with forceps and transferred to –20°C methanol to fix.

SUPPORT PROTOCOL 4

REACTION SPIN-DOWNS

Spin-downs allow an entire reaction mixture to be transferred onto glass coverslips, fixed, and, if desired, subjected to immunostaining techniques. Because reactions are diluted into detergent and spun through a cushion, much of the soluble material is removed, including unincorporated fluorochrome-labeled tubulin subunits. This procedure dramatically reduces background fluorescence compared to squash samples.

Reactions to be processed are first diluted with the appropriate spin-down dilution buffer. The mixture is then gently layered over the appropriate spin-down cushion in a modified Corex centrifuge tube containing a 12-mm coverslip (Mitchison and Kirschner, 1984; Fig. 11.13.3). Centrifugation in a swinging-bucket rotor pellets spindles and other insoluble structures like asters, free nuclei, and DNA beads onto the coverslips. The coverslips are then fixed in methanol, washed in PBS/0.1% NP-40, immunostained if necessary, stained with Hoechst DNA dye, mounted onto slides, and sealed with nail polish. Slides are then observed on a fluorescence microscope and, over the long-term, stored in the dark at 4°C.

Additional Materials *(also see Basic Protocol 1)*

Extract reaction
30% or 15% spin-down dilution buffer (see recipe)
40% or 25% spin-down cushion (see recipe)
Methanol, −20°C
Wash buffer: PBS, sterile/0.1% (v/v) NP-40
PBS, sterile/3% (w/v) BSA
Primary and secondary antibodies in PBS, sterile/3% BSA (e.g., GTU88 anti γ-tubulin and FITC-conjugated goat anti-mouse; Sigma)
10 mg/ml Hoechst dye, in water
Mounting medium (see recipe)

1.5-ml microcentrifuge tube
Modified 15-ml Corex tube containing 12-mm round coverslip (Aladin Enterprises; see Fig. 11.13.3)
Wide-orifice 200- to 1000-µl pipet tips
Sorvall centrifuge, HB-4, HB-6, or HS-4 rotor and appropriate rubber adapters
Metal hook or microspatula
Watchmaker's forceps
Ceramic staining rack
Glass staining dish
Incubation chamber: parafilm cut to fit in bottom of 150-cm round plastic tissue culture dish with lid

NOTE: When using this protocol for either type of aster reaction (see Basic Protocol 1), substitute 15% spin-down dilution buffer and 25% spin-down cushion in place of those called for below.

1. Transfer up to 50 µl extract reaction to a 1.5-ml microcentrifuge tube and add 1 ml of 30% spin-down dilution buffer.

   Add the dilution buffer quickly and evenly to avoid clumping.

2. Layer the mixture over 5 ml of 40% spin-down cushion in a 15-ml modified Corex tube containing a 12-mm round coverslip using a wide-orifice 200- to 1000-µl pipet tip.

   Use care when layering. The mixture will form a distinct layer over the cushion.

3. Centrifuge tubes 15 min at 17,000 × *g* (10,000 rpm) in an HB-4 or HB-6 rotor, 16°C.

   If large numbers of samples are generated, an HS-4 rotor with 16-tube capacity can be used. Run the HS-4 centrifuge at 5930 × g (6,000 rpm) for 25 min, 16°C.

4. Aspirate supernatant and gently pull out plastic support with a metal hook or microspatula.

5. Pick up each coverslip off of support using watchmaker's forceps and place in ceramic staining rack in methanol, −20°C, in glass staining dish for 5 min.

   Take care to be aware which side of the coverslip is facing up. Once the proper orientation has been lost it can be very difficult to reestablish.

6. Transfer each coverslip right side up to Parafilm in an incubation chamber, placing it in a drop of wash buffer. Gently push each coverslip through the drop so that it adheres to the Parafilm.

7. Block coverslips to reduce background by aspirating wash buffer and adding 200 µl sterile PBS/3% BSA to each coverslip. Incubate 10 min at room temperature.

8. *Optional:* If desired, stain coverslips with primary and secondary antibodies in PBS/3% BSA for 15 min each. After each antibody incubation wash coverslips four times with copious amounts of wash buffer.

9. Stain DNA with 10 mg/ml Hoechst dye diluted 1:2000 in wash buffer (5 µg/ml final) for 1 min. After four washes in wash buffer, place coverslips upside down on a 3-µl drop of mounting medium on microscope slide. Aspirate excess mounting medium and seal coverslip edges with nail polish. Store slides in the dark at 4°C for up to one year.

SUPPORT PROTOCOL 5

DNA-COATED BEADS

The use of bead-bound plasmid DNA allows for assays of spindle assembly in a more minimal system. DNA beads are produced using the high-affinity interaction between biotin and streptavidin molecules to couple plasmid DNA to paramagnetic Dynabeads. Large batches of DNA beads can be produced and stored for long periods at 4°C until needed for use in extracts.

Purified plasmid DNA is cut with restriction enzymes to produce a linear DNA fragment containing two sticky ends. Klenow is used to fill in one end with biotin-conjugated nucleotides, while the other is filled in with thionucleotides to help prevent exonuclease digestion. After removing enzyme and unincorporated nucleotides, the biotin-labeled DNA is combined with streptavidin-coated Dynabeads in a specialized binding solution. Overnight incubation at 16°C on a rotator provides sufficient time for binding. After incubation, the beads are washed, resuspended, and stored in bead buffer. The amount of DNA bound is quantified by spectrophotometric analysis of the binding reaction supernatant before and after incubation with the beads.

Materials

50 µg plasmid DNA (<5 kb) purified by column (Qiagen) chromatography
Appropriate restriction enzymes (e.g., *Not*I, *Bam*HI)
TE buffer, pH 8, sterile (*APPENDIX 2A*)
Klenow DNA polymerase (exo$^-$) and buffer (New England Biolabs)
Nucleotides: biotin-dATP (Life Technologies), biotin-dUTP (Clontech), thio-dCTP, and thio-dGTP (Pharmacia)
G-50 Nick columns (Pharmacia)
Washing and binding solutions from Kilobase BINDER kit (Dynal)
Streptavidin Dynabeads from Kilobase BINDER kit (Dynal)
Bead buffer (see recipe)

Magnetic particle concentrator (MPC; Dynal)
Rotator at 16°C

Additional reagents and equipment for ethanol precipitation and restriction endonuclease digestion of plasmid DNA (see *APPENDIX 3A*), and quantification by absorption spectroscopy (*APPENDIX 3D*)

Prepare plasmid DNA

1. Prepare plasmid DNA by Qiagen-style column purification.

   While the sequence of the DNA is not important, the plasmid should be more than 5 kb to effectively induce chromatin assembly in extracts.

2. Cut 50 µg of the DNA with two restriction enzymes (see *APPENDIX 3A*) that have unique sites in the polylinker to produce one short and one long DNA fragment.

The choice of the enzyme should be such that one end of the long fragment terminates in an overhang containing guanines and cytosines, while the other contains only adenines and thymidines (e.g., NotI, BamHI).

3. Ethanol precipitate the linearized DNA (see *APPENDIX 3A*), and resuspend in 25 µl TE buffer, pH 8. Quantify recovery by A_{260} measurement (*APPENDIX 3D*).
4. Prepare fill-in reaction containing 1× Klenow buffer, 30 µg linearized DNA, 50 µM nucleotides (biotin-dATP, biotin-dUTP, thio-dCTP, and thio-dGTP), 20 U Klenow polymerase, and sufficient H_2O to make the final volume 70 µl. Incubate for 2 hr at 37°C.
5. Remove unincorporated nucleotides and small DNA fragments, using a Pharmacia G-50 Nick column, following manufacturer's instructions. Quantify recovery by A_{260} measurement (*APPENDIX 3D*).

   The DNA is eluted in a large volume (400 µl), but the recovery is better than with spin columns.

Couple DNA to beads

6. Prepare coupling mix by combining 400 µl biotinylated DNA (step 4) and 400 µl binding solution. Set aside 25 µl of the coupling mix for later evaluation of coupling efficiency.
7. Prepare 4 µl of streptavidin Dynabeads for each microgram of DNA to be coupled according to manufacturer's instructions.
8. Retrieve beads using the magnetic particle concentrator (MPC). Wash once with 5 vol binding solution (600 µl for 120 µl beads). Retrieve the beads and resuspend them in coupling mix containing DNA.
9. Incubate bead/coupling mixture for several hours (or overnight) on a rotator at 16°C.

Retrieve and wash beads

10. Retrieve the beads using the MPC. Save the supernatant. Compare the A_{260} of the supernatant to that of the sample taken before coupling (step 3) to determine the amount of DNA immobilized.

    Typically two-thirds of the DNA is coupled.

11. Wash beads twice with 500 µl washing solution, and then twice with 500 µl bead buffer. After the last wash, resuspend the beads in sufficient bead buffer such that the final concentration of immobilized DNA is 1 µg/5 µl of beads. Store at 4°C for up to one year.

    If beads are "clumpy," pass through a 12-G needle.

REAGENTS AND SOLUTIONS

*Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see **APPENDIX 2A**; for suppliers, see **SUPPLIERS APPENDIX**.*

Bead buffer

29.2 g NaCl (2 M final)
0.30 g Tris base (10 mM final)
73 mg EDTA, free acid (1 mM final))
200 ml H_2O
Adjust pH to 7.6 with 2 M HCl
H_2O to 250 ml
Store up to 1 year at room temperature

BRB80, 5×

30.24 g PIPES free acid (0.4 M final)
0.26 ml 4.9 M $MgCl_2$ (5 mM final; Sigma)
0.48 g EGTA (5 mM final)
200 ml H_2O

While stirring, add KOH pellets until the PIPES dissolves. Adjust to pH 6.8 with 10 M KOH. Add H_2O to 250 ml. Sterilize by filtration. Store up to 1 year at 4°C.

BRB80 cushion

60 ml glycerol (60% v/v final)
20 ml 5× BRB80 (1× final; see recipe)
20 ml H_2O
Sterilize by filtration
Store up to 1 year at 4°C

Calcium solution, 10×

1 ml 400 mM $CaCl_2$ (4 mM final)
20.4 µl 4.9 M $MgCl_2$ (1 mM final; Sigma)
0.75 g KCl (100 mM final)
H_2O to 100 ml
Store in aliquots indefinitely at −20°C

Conversion buffer, 20×

47.6 g PIPES free acid (630 mM final)
857 µl 4.9 M $MgCl_2$ (16.8 mM final; Sigma)
0.5 ml 0.5 M EGTA (1 mM final)
200 ml H_2O

While stirring, add KOH pellets until the PIPES dissolves. Adjust the pH to 6.8 with 10 M KOH, and bring the volume to 250 ml with water. Sterilize by filtration. Store up to 1 year at 4°C.

CSF-XB

198 ml extract buffer (XB; see recipe)
2 ml 0.5 M K·EGTA (5 mM final): store indefinitely in 2-ml aliquots at −20°C
40.8 µl 4.9 M $MgCl_2$ (1 mM final; Sigma)
Prepare fresh on day of use

The 0.5 M K·EGTA is made by dissolving 9.51 g EGTA in 40 ml water, pH is adjusted to 7.7 with 10 M KOH, and the volume is adjusted to 50 ml.

Extract buffer (XB)

25 ml 20× XB salts (see recipe)
12.5 ml 2 M sucrose (50 mM final); store in aliquots at −20°C
5 ml 1 M HEPES (0.1 M final), adjusted to pH 7.7 with 10 M KOH
H_2O to 500 ml
Make up fresh on day of use

IB

1.852 g monopotassium glutamate (50 mM final)
15 mg free glutamic acid (0.5 mM final)
20.4 µl 4.9 M $MgCl_2$ (Sigma; 0.5 mM final)
H_2O to 200 ml
Sterilize by filtration
Store in 50-ml aliquots indefinitely at −20°C

Labeling buffer

40 ml glycerol (40% v/v final)
2.38 g HEPES, free acid (0.1 M final)
20 µl 4.9 M $MgCl_2$ (1 mM final)
200 µl 0.5 M EGTA (1 mM final)
20 ml H_2O

Adjust the pH to 8.6 with 10 M NaOH. Add water to 100 ml. Sterilize by filtration. Store up to 6 months at 4°C.

Labeling cushion

60 ml glycerol (60% v/v final)
20 ml 0.5 M HEPES (0.1 M final)
20 µl 4.9 M $MgCl_2$ (1 mM final)
200 µl 0.5 M EGTA (1 mM final)
Adjust pH to 8.6 with 10 M NaOH
H_2O to 100 ml
Sterilize by filtration
Store up to 6 months at 4°C

LPC, 10 mg/ml

Combine leupeptin, pepstatin, and chymostatin to a concentration of 10 mg/ml each in DMSO. Store in aliquots at −20°C.

Mounting medium

9 ml glycerol (90% v/v final)
1 ml 0.2 M Tris·Cl, pH 8 (*APPENDIX 2A*; 10% v/v or 0.02 M final)
Store up to 1 year at room temperature

Quenching buffer

20 ml 5× BRB80 (2× final; see recipe)
20 ml glycerol (40% v/v final)
5 ml 1 M potassium glutamate (100 mM final)
H_2O to 50 ml
Make up fresh on day of use

Spin-down dilution buffer, 30%, 15%

30 ml glycerol (30% v/v final)
1 ml Triton X-100 (1% v/v final)
20 ml 5× BRB80 (1× final)
H_2O to 100 ml
Store up to 1 year at room temperature

For 15% spin-down dilution buffer, only add 15 ml glycerol.

Spin-down cushion, 40%, 25%

200 ml glycerol (40% v/v final)
100 ml 5× BRB80 (1× final)
H_2O to 500 ml
Sterilize by filtration
Store up to 1 year at 4°C

For 25% spin-down cushion, only add 125 ml glycerol.

Spindle fix

600 µl 80% glycerol (48% v/v final)
300 µl 37% formaldehyde (11% final)
100 µl 10× MMR (1× final; *UNIT 11.10*)
0.5 µl 10 mg/ml Hoechst dye (5 µg/ml final; Sigma)
Store up to 1 week at room temperature

Best prepared fresh on day of use.

XB salts, 20×

74.6 g KCl (2 M final)
2.04 ml 4.9 M $MgCl_2$ (Sigma; 20 mM final)
147 mg $CaCl_2$ (2 mM final)
H_2O to 500 ml
Sterilize by filtration
Store up to 1 year at 4°C

COMMENTARY

Background Information

The function of the mitotic spindle is essential for proper segregation of chromosomes during cell division. At the onset of mitosis, the radial interphase array of microtubules breaks down, and then forms a bipolar spindle around condensed chromosomes. Microtubules from each pole attach to sister chromatids and align them in the center of the spindle before segregating them to opposite poles during anaphase. Spindle assembly is a complex process, requiring intricate regulation of microtubule dynamics (Andersen, 1999; Walczak, 2000) and of microtubule and chromosome movements mediated by multiple different microtubule-based motor proteins (Heald and Walczak, 1999; Mountain and Compton, 2000).

Spindle assembly and function has been studied in a variety of model organisms, including genetic systems such as yeast, *C. elegans,* and *Drosophila*, and in cultured cells; however, *Xenopus* egg extracts provide the only system in which spindle assembly has been reconstituted in vitro. This is possible because eggs are synchronized in the cell cycle, and concentrated cytoplasm can be obtained without harsh disruption techniques. Pioneered by Lohka, Masui, and Maller (Lohka and Masui, 1983; Lohka and Maller, 1985), *Xenopus* egg extracts have been optimized to study cell cycle transitions (Murray and Kirschner, 1989), spindle assembly (Sawin and Mitchison, 1991), and anaphase (Shamu and Murray, 1992; Murray et al., 1996), as well as many other cellular processes (see *UNITS 11.10* to *11.12*).

Xenopus eggs are arrested in metaphase of meiosis II, a "mitotic-like" division, by cytostatic factor (CSF), which is thought to be the product of the *c-mos* protooncogene (Sagata et al., 1989). This calcium-sensitive activity is preserved if extracts are prepared in the presence of EGTA, a calcium chelator. CSF-arrested extracts allow experimentation in mitotic cytoplasm, without transiting through the cell cycle. CSF extracts can be induced to cycle by the addition of calcium, which causes the degradation of CSF and cyclin B, thereby inactivating the mitotic cdc2 kinase and promoting entry into interphase.

The power of egg extracts derives from the extensive structural and functional analyses, facilitated by the "open" nature of the system, which nevertheless maintains many properties of intact cytoplasm. Individual components can be manipulated in order to compromise their function by techniques such as immunodepletion (*UNIT 11.10*) or antibody addition (see Support Protocol 3). The excellent cytology of the system permits detailed analysis of the effects of the disruption on spindle assembly. In addition, the system has been ideal for dissecting subsets of processes required for spindle assembly, including microtubule nucleation, dynamics, chromosome condensation, and kinetochore assembly (Belmont et al., 1990; Verde et al., 1990; Hirano and Mitchison, 1991; Zheng et al., 1995; Desai et al., 1997).

The protocols in this unit highlight several of the reactions possible in *Xenopus* egg extracts, and serve to illustrate some of the mechanisms underlying spindle assembly. Microtubule nucleation and organization can be assayed using aster reactions (see Basic Protocol 1); however, there is an important distinction between the two agents used to induce aster formation. Centrosomes are found in most so-

matic cells and serve as focal microtubule nucleation sites that organize spindle poles. In contrast, DMSO, like the microtubule-stabilizing drug taxol, leads to random polymerization of microtubules, which are subsequently organized into focused asters in mitotic cytoplasm (Verde et al., 1991). This process is dependent on microtubule-based motors, including cytoplasmic dynein (Heald et al., 1997) and is thought to mimic the formation and organization of spindle poles (Gaglio et al., 1996, 1997).

Reactions containing *Xenopus* sperm nuclei (Basic Protocols 2 and 3) introduce another level of complexity to the reaction. The centrosome associated with each sperm nucleus nucleates microtubules that interact with sperm chromosomes. In a CSF extract, this leads directly to the formation of mitotic structures. If the reaction is cycled through interphase, the chromosomes and centrosomes duplicate and subsequent spindle assembly is more physiological. DNA bead spindle assembly reactions (see Basic Protocol 4) are similar to female meiosis in that both pathways occur in the absence of centrosomes and illustrate the microtubule-stabilizing force of mitotic chromatin (Heald et al., 1996). Such a mechanism of spindle assembly has been termed "self-organization," because obvious bipolar cues are absent. This system has been particularly useful in dissecting the roles of different microtubule-based motors in setting up the bipolar spindle structure (Walczak et al., 1998).

Therefore, CSF extracts provide a system to examine both centrosome-directed assembly and the self-organization mechanisms of spindle assembly. This system is also amenable to immunofluorescence techniques. Spindle assembly reactions can be easily transferred from reaction tubes onto coverslips, fixed, and stained for desired components.

Critical Parameters and Troubleshooting

The single most important factor in successful in vitro spindle assembly reactions is the quality of the extract; therefore, special attention should be paid to protocols outlining frog handling and extract preparation (*UNIT 11.10*). Once prepared, extract should always be transferred with wide-orifice pipet tips to minimize disruption. Vortexing or any violent agitation of extract or reactions should always be avoided. Flash-frozen extracts can be used in these assays, but generally give less reproducible results. Freeze/thawing can disrupt proteins and rupture vesicles, both of which lower the quality of the extract, and can result in poorly organized microtubule structures or loss of CSF arrest.

The authors find that the most common problem with these assays relates to the inconsistency of the extracts. Although the quality of eggs is by far the most important parameter for a good extract, it is nevertheless problematic to predict when an extract will be of sufficiently low quality to preclude use in these assays. When setting up an experiment involving manipulation of the extract, it is advisable to first run a standard half-spindle reaction to assess the quality of the extract. Running such a reaction will reveal the level of "mitotic" arrest, and the speed and quality of spindle assembly, before extensive time or scarce resources are invested. If assays that require cycling the extract through interphase are to be run, it is advisable to run a test "cycling" reaction with sperm nuclei. After the normal addition of calcium, squash samples can be taken to monitor the extract's ability to properly enter interphase, which is not always reproducible. In this case, a second addition of calcium may be made 10 to 30 min after the first addition. Non-extract-related problems frequently involve observations such as high background in spin-downs or squashes, absence of structures in squash samples, and the "stickiness" of DNA beads. High background in squash samples can be caused by a concentration of rhodamine-labeled tubulin in the reaction that is too high, the reagent should then be used at a higher dilution. High background in spin-down samples normally results from improper immunofluorescence techniques and can usually be remedied in subsequent reactions by titration of the antibodies used and more extensive washes or blocking incubations. A lack of observable structures in squash samples usually results from inadequate mixing of reactions before taking samples, as spindles tend to settle to the bottom of the tube. Problems with "stickiness" and aggregation of DNA beads can be avoided by occasional mixing of bead reactions during both the chromatin assembly and spindle assembly steps. Additionally, if a particular batch of DNA beads has proven to be quite "sticky," they should be passed through a 27-G needle immediately before being used for "bead spindle" reactions.

Anticipated Results

The consistency of results from these assays depends upon the quality of the CSF extracts, which is variable even under normal circum-

stances, as *Xenopus* have seasonal variations in egg yields. Extracts may exhibit differences in the amount of time necessary for spindle assembly, and microtubule and chromosome morphology can also vary from experiment to experiment; therefore, reactions should always be repeated several times to ensure interpretable results. With experience, a user of the system can run assays that show clear and reproducible differences between control and experimental reactions. With good extracts and effective disruption of target proteins, these assays can provide up to hundreds of scorable structures (spindle or aster) per coverslip.

Time Considerations

The assays described in this unit work best with freshly prepared extracts, which require ~2 hr of preparation. Once extracts are prepared, the assays generally take from 15 min for aster reactions, to 4 hr for bead-spindle reactions, to run to completion. Chromatin beads can also be prepared ahead of time and stored frozen in extract, reducing the time for this assay to that of a sperm spindle reaction. If reactions are spun down, an additional 30 to 60 min must be added depending upon whether immunofluorescence is also performed. Spindowns and squash samples, if sealed, can be stored in the dark at 4°C for months to years after the experiment is performed.

Preparation of DNA beads is generally a 2-day project only because of the need for long incubations for restriction digests and coupling. Once prepared, the beads can be kept for months to years at 4°C without significant loss of activity in extracts.

The rhodamine-labeled tubulin preparation requires considerable attention and a full day to complete, and, for best results, it should not be performed simultaneously with other experiments.

Analysis of RNA Export Using *Xenopus* Oocytes

Microinjection of *Xenopus* oocytes has long been a tremendously useful tool in the study of nucleocytoplasmic transport, as well as many other aspects of intracellular function. A mature *Xenopus* oocyte (stage V, VI) is an extremely large cell (~1 mm). Indeed, following maturation, the oocyte (now egg) will respond to fertilization by dividing into thousands of embryonic cells with no significant increase in total cellular volume. The large size of the *Xenopus* oocyte makes it possible to quantitatively address questions in cell biology on a single-cell basis. For instance, in the case of nucleocytoplasmic transport, it is uniquely possible to definitively monitor the nucleocytoplasmic distribution of a wide range of transport substrates simultaneously in individual cells. When studying RNA export, this panel typically includes transcripts that represent different classes of RNA, such as tRNA, snRNA, and mRNA. The experimental strategy is straightforward: transport cargos of choice are injected into either the nucleus or cytoplasm; then, at different points over time, each oocyte nucleus is dissected away from its respective cytoplasm. These physically divided pools of nuclear and cytoplasmic components are rapidly processed and analyzed for specific proteins or RNAs.

This unit will focus on the analysis of RNA export using oocyte microinjection. The procedure for the injection itself is described along with a method for recovering RNA from oocyte nuclear and cytoplasmic fractions (Basic Protocol). Obtaining the oocytes is a simple surgical procedure and is also presented (Support Protocol 1). Additional information is included to describe how RNA cargo can be synthesized and labeled in vitro prior to injection (Support Protocol 2).

CAUTION: When working with radioactivity, take appropriate precautions to avoid contamination of the experimenter and the surroundings. Carry out the experiment and dispose of wastes in an appropriately designated area, following the guidelines provided by the local radiation safety officer; also see *APPENDIX 1D*.

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) or must conform to governmental regulations regarding the care and use of laboratory animals.

NOTE: Experiments involving RNA require careful technique to prevent contamination (see *APPENDIX 2A*). All equipment should be RNase free and all solutions should be RNase free or made with DEPC-treated water.

ANALYSIS OF RNA EXPORT IN MICROINJECTED *XENOPUS* OOCYTES

BASIC PROTOCOL

Although the nucleus is not visible in an intact oocyte, material can be delivered specifically to this intracellular compartment because the position of the nucleus is relatively fixed within the cell (Fig. 11.14.1). Thus, by orienting the oocyte with respect to the needle and then pushing the needle a fixed distance into the oocyte, there is a high probability of hitting the nucleus. One procedure that can be used to ensure that the nucleus is in an obvious place is to centrifuge the oocytes. This causes the nucleus to rise to the top of the oocyte (just under the animal pole). It also can cause a slight clearing in the pigment granules at this central point, creating a bull's eye for the injection needle. This makes injections initially easier to master; however, with practice, this step is not necessary (it simply takes a little more effort to learn how far the needle must penetrate the oocyte when the nucleus has not been spun to the surface). In either case, it is important

Current Protocols in Cell Biology (2001) 11.14.1-11.14.13

to include markers that will confirm a nuclear hit. One marker is a visual tag, namely a high-molecular-weight dye. This allows the accuracy of the hit to be assessed at the time of dissection. Depending on the experimental design, more than one dye can be used in successive injections to create a color mix indicative of two nuclear hits. In the case of RNA export, the other useful marker is an RNA that is not an export (or import) cargo. Selective recovery of this marker with the nuclear fraction confirms that RNA was delivered to the nucleus and that the dissection was performed accurately.

Not only does the large size of the *Xenopus* oocyte facilitate the process of nuclear microinjection, but this feature is also key to the analysis of RNA export following microinjection. To analyze the localization of RNA, each oocyte is physically dissected into nuclear and cytoplasmic fractions, and RNA is prepared from these fractions. To begin this process, individual oocytes are retrieved, blotted dry, and then placed under oil prior to dissection. The nucleus is removed by puncturing a small hole in the middle of the animal hemisphere and then applying slight pressure to the oocyte with forceps. Due to the relatively light density of the nucleus compared to other contents of the cell, it will emerge first from this hole. A needle can then be used to guide the nucleus away from the cytoplasm. Performing this dissection under oil ensures that there will be no loss of material from the nucleus during the process (Lund and Paine, 1990). The nucleus and cytoplasm can then be pipetted out of the oil and into a microcentrifuge tube containing the appropriate buffer. Proteins are removed by a combination of proteinase K digestion and phenol extraction. The RNA is then precipitated and electrophoresed on a denaturing acrylamide gel.

Materials

RNA sample (see Support Protocol 2)
Xenopus oocytes (see Support Protocol 1)
Light mineral oil (e.g., Fisher Scientific)
RNA harvest buffer (see recipe)
4 mg/ml proteinase K solution: 1:4 (v/v) 20 mg/ml proteinase K (e.g., Ambion, Worthington) in RNA harvest buffer, prepared fresh
5:1 (v/v) acid phenol/chloroform, pH 4.5 (Ambion)
20 mg/ml glycogen or seeDNA (Amersham Pharmacia Biotech)
RNA sample buffer (see recipe)

Glass capillary tubes, 1-mm o.d., 0.75-mm i.d., 10-cm length (e.g., Sutter Instruments)
Needle-pulling apparatus (e.g., Sutter Instruments micropipet puller, model P-87)
Pico-injector, basic model (e.g., Model PL1-100, Medical Systems Corp.)
Nitrogen

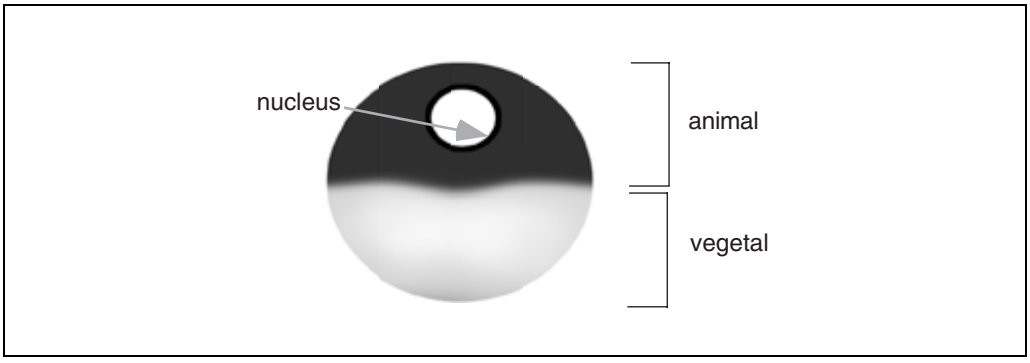

Figure 11.14.1 Stage VI oocyte with approximate location of nucleus and animal and vegetal hemispheres indicated.

Dumont no. 3 and Dumont SS forceps (Fine Science Tools), including one pair of no. 3 forceps set aside for use with oil

Disecting microscope (e.g., MZ7.5, Leica) with optional cold stage (e.g., Labworks # Equipment Service, Inc.; also requires circulating cold bath), 4°C

18°C incubator

Disposable transfer pipets (e.g., Fisher Scientific)

Whatman 3MM filter paper, cut into ~0.5-in × 3-in strips

Mid-sized polystyrene weighing dishes

1-ml syringes

27.5-G needles

100-µl glass capillary tubes with 25-µl microcaps (e.g., Drummond Scientific)

Additional reagents and equipment for phenol/chloroform extraction, ethanol precipitation (*APPENDIX 3A*), and polyacrylamide gel electrophoresis of RNA (*UNIT 6.1*)

Make injection needle

1. Wearing gloves to protect against RNase contamination, clamp a glass capillary tube into a needle-pulling apparatus. Adjust the apparatus and make needles with a 20-µm-diameter tip.

   This type of instrument automatically heats the capillary tube and pulls it in two. Each half is then considered a needle and has an extremely fine tapered point.

   There may be some variability in settings, depending on the instrument and the heating filament. With the Sutter Flaming/Brown micropipet puller, model P87, the authors have used the following parameters with success: P100, heat 340, velocity 120, time 150, and pressure 225.

   It is best to do this step ahead of time. Several needles can be pulled and then stored indefinitely in a large plastic petri dish. The needles should be anchored by embedding the center of the needle in a small piece of clay affixed to the dish. Depending on design (i.e.,whether successive injections, different cargo, etc), each experiment may take 4 to 10 needles. It is possible to reuse needles after extensive rinsing with DEPC-treated water. The needles do break easily, but with experience this becomes less of a problem.

2. Mount a needle into the injection arm of a pico-injector according to manufacturer's instructions. Place the threaded metal cuff over the back of the needle, followed by a freshly cut silicon gasket. Push the needle into the arm until gasket seals. Then slide the metal collar onto the injection-arm threads and screw firmly in place.

   These directions will vary with the specific type of injection apparatus.

3. Gently break the sealed tip of the needle by grasping the tip with a pair of Dumont no. 3 forceps and gently turning them perpendicular to the needle.

   The opening at this point should be <20 µm. The seal must be broken before the sample can be loaded.

4. Test the seal by pulling up some sterile water into the needle and then ejecting the water completely.

5. Spot ~3 µl RNA sample onto a piece of Parafilm and draw sample up into the needle using the load feature of the pico-injector. Avoid air bubbles.

   Alternatively, the needle can be backfilled using a gel-loading tip before it is mounted on the injection arm. If the needle is immobilized in an upright position for several minutes, the sample will slide into place at the tip through capillary action.

6. Adjust the size of the needle tip such that the ejected volume is 5 to 20 nl by successively breaking the tip with forceps and checking the ejected drop size under a microscope. Use the eye-piece reticule to compare the drop to a previously calculated conversion between drop diameter and volume.

The desired ejected volume depends on the particular injection. Although the cytoplasm can be injected with up to 50 nl, it is best to divide this total volume into more than one drop or injection.

Drop size is dependent on three main factors: the pressure of nitrogen (or air) in the output, the duration of the output, and the needle tip size. Generally, for an ~7-nl drop, the authors keep the pressure and time at ~15 psi and 100 msec, respectively, although these parameters can be used to make fine adjustments in volume.

Some pico-injectors also have a back-pressure feature that allows a constant low-level pressure to be continuously applied. This prevents dilution of the sample that can result from small amounts of buffer influx through the needle tip due to capillary action. Depending on the viscosity of the sample, back pressure is generally ~1 psi but should be adjusted empirically such that a minimal amount of sample flows out of the needle to counteract capillary flow into the needle.

There are alternative methods of perfecting the needle. One important technique is beveling the needle. This procedure can be found in Terns and Goldfarb (1998).

Inject oocytes

7. Chill *Xenopus* oocytes ~10 min on ice.

   Chilling the oocytes serves two purposes: (1) it stops active nucleocytoplasmic transport, allowing the transport experiment to be synchronized by the shift back to 18°C, and (2) it causes microtubules to depolymerize, allowing the nucleus to move towards the surface of the oocyte, which creates a more reproducible target.

   If not using a cold-stage, it is usually sufficient to work with ice-cold buffer and inject oocytes in small enough groups that they are returned to 4°C or 18°C without significant warming. Alternatively, an outer petri dish with ice-water can be used to keep the oocytes in chilled buffer if this is critical (for many experiments, the kinetics are slow enough that this is not a critical point).

   Oocytes can also be centrifuged (15 min, 1000 × g) to ensure that the nucleus is directly under the outer surface of the oocyte (Terns and Goldfarb, 1998). However, this will also cause the nucleus to flatten out, restricting the range of depth for an accurate nuclear injection.

8. Bring a petri dish with oocytes into the field of view of the microscope and push the oocytes into a group at one side of the dish using a pair of Dumont SS forceps.

   Alternatively, a mesh grid can be used to organize and orient the oocytes.

9. Hold one oocyte with forceps and orient the animal hemisphere (dark pigmented half) toward the needle such that the central axis of the oocyte is aligned with the path of the needle. For cytoplasmic injection, aim to hit the vegetal hemisphere, to assure avoiding the nucleus.

   The yield of RNA recovery per oocyte is quite efficient, so knowing the detectability of the input material should allow one to almost directly extrapolate to the number of oocytes needed in the harvest. One to two oocytes worth of material is typically sufficient for one lane of a gel. Since it is good to have duplicate samples and since not every injection will lead to a clean hit and a clean dissection, it is recommended to inject at least 10 to 12 oocytes per sample, more if multiple time points are being analyzed.

10. Lower the needle to the oocyte and advance the needle into the oocyte.

    This works best when a bit of pressure is applied to the oocyte with the forceps, creating a taut surface.

11. Deliver material by depressing the foot pedal of the pico-injector.

12. Retract needle and push oocyte to opposite side of the petri dish.

13. Repeat process on remaining oocytes. Return oocytes to an 18°C incubator until the desired time point (typically between 30 min and 18 hr).

    Some experiments require harvesting oocytes injected with the same material at different time points, in order to analyze kinetics.

    Intermittently between injections, a drop of sample should be ejected directly into the buffer to confirm that the needle has not become blocked. With experience, observing this drop also gives a rough idea of the ejection volume. If there is any concern that the volume has decreased, the drop size should be measured at high magnification.

Dissect oocytes

14. Using a disposable transfer pipet, place a few oocytes onto a strip of Whatman 3MM filter paper and allow buffer to absorb.

15. Gently nudge an oocyte with a second strip of filter paper until the oocyte sticks to the second strip. Using Dumont no. 3 forceps set aside for working with oil, immediately place oocyte into a mid-sized polystyrene weighing dish containing a layer of light mineral oil. Repeat until six or seven oocytes are in the oil.

    It is important to remove the right amount of liquid at this point, as any delay in transfer of the oocyte will result in dehydration, but premature transfer of the oocyte will result in a residual aqueous layer that is problematic during dissection. It may help to have a drop of oil on the forceps used to transfer oocytes from the filter paper to the oil.

16. To dissect the nucleus away from the cytoplasm, hold the oocyte with the same forceps and puncture the center of the animal hemisphere using a 27.5-G needle attached to a 1-ml syringe.

17. Gently squeeze the oocyte with the forceps until the nucleus emerges. Use the back side of the needle to brush the nucleus away from the cytoplasm.

    Some practice is required to know how much pressure to apply during dissection. The size of the hole punctured in the oocyte is important. It should be large enough to allow the nucleus to pass through intact and yet small enough to exclude cytoplasm while the nucleus is emerging.

18. Using a 100-µl glass capillary tube and 25-µl microcap, transfer nucleus and remaining cytoplasm (enucleated oocyte) to separate microcentrifuge tubes containing 165 µl RNA harvest buffer. Keep samples on ice (if processing within the hour or so) or frozen until ready for further processing.

    The samples are relatively stable once frozen, but for longer-term storage, proceed through RNA harvest step. Even then, analysis within a few days is optimal due to the radioactive nature of the sample.

    The cytoplasm can also be transferred with forceps.

Process RNA

19. Add 55 µl of 4 mg/ml proteinase K solution to each tube. Vortex and place at 37°C for 90 min. During the first 60 min, vortex periodically.

    Repeated vortexing is especially important for the cytoplasmic samples.

20. Extract samples with 5:1 acid phenol/chloroform, pH 4.5.

    To ensure that the interface is completely avoided, it is advisable to carry forward only 90% of the sample after extraction.

21. Ethanol precipitate RNA (*APPENDIX 3A*). Include a carrier such as 20 to 50 µg glycogen or seeDNA, especially in the nuclear fractions.

22. Air dry pellets and resuspend in RNA sample buffer (generally, 10 µl per oocyte).

    RNA in sample buffer can be stored for several weeks, but again since it is radioactive, it is advised to analyze it within a few days if possible or up to 2 weeks.

23. After heating the sample 5 min at 68°C and vortexing, analyze RNAs by electrophoresis on a denaturing polyacrylamide gel (*UNIT 6.1*).

    It is highly recommended to quantitate these results using a phosphorimager.

SUPPORT PROTOCOL 1

PREPARATION OF *XENOPUS* OOCYTES FOR MICROINJECTION

The ovary lies spread beneath the ventral surface of the female frog. The ovary consists of a mixed population of oocytes, representing various stages of maturation, that are held in loose proximity--much like a cluster of grapes. A small section, or lobe, of the ovary can easily be retrieved through a small incision towards the side of the abdomen. The desired amount of ovarian tissue is then clipped off the ovary and the incision sutured. The clump of oocytes is next teased apart and the immature oocytes are sorted away from the larger, mature oocytes.

Materials

Female *Xenopus laevis* (e.g., Nasco, Xenopus I, Xenopus Express)
0.05% (w/v) benzocaine (Sigma) in H_2O from 10% (w/v) stock in ethanol, stored at 4°C.
MBS (see recipe), 4°C

Toothed and Dumont no. 3 forceps (Fine Science Tools)
Surgical scissors
Sutures, Vicryl 4.0 (Ethicon) with attached needle
Hemostat
Recovery tank with lid
1-ml syringes
18-G needles bent into triangular loops
Disposable transfer pipets (e.g., Fisher)
18°C incubator

Make surgical incisions

1. Wearing gloves, place a female *Xenopus laevis* in a 4-liter beaker with 1 liter of 0.05% benzocaine for 10 min to anesthetize. Check efficacy of anesthetic by pinching the frog's toes.

   The frog should remain flaccid.

2. Place frog on its back on a paper towel soaked in 0.05% benzocaine and spread on top of ice chips.

3. Make a small (~1 cm) incision with the corner of a razor blade in the skin towards the lower side of the abdomen. To facilitate the incision, grip the skin with a pair of toothed forceps and then start the incision between the prongs of the forceps.

   A small amount of bleeding sometimes occurs and can simply be blotted with a tissue. At this point, it is usually possible to see the oocytes underlying the next layer of abdominal wall.

4. Using a pair of Dumont no. 3 forceps, grab the inner abdominal muscle wall, lift it up, and cut it with a pair of surgical scissors (so that this incision aligns with the initial one through the skin).

   Again, this can be a small incision (slightly <1 cm).

Harvest ovarian lobe

5. Reach through the incision with the forceps. Retrieve a lobe of the ovary by closing the forceps and gently pulling them out through the incision.

   Retrieving a lobe should be possible even if the view of the oocytes is somewhat obscured.

6. Clip off the desired amount of ovary with scissors and place in ice-cold MBS. Gently ease the remainder of the lobe back in through the incision.

   At this point, the benzocaine-soaked towel can be removed.

Suture incisions

7. To suture the inner incision, draw a needle and Vicryl 4.0 suture through the layers of the wall on each side of the incision using a hemostat. Pull until there is only a short (~2 cm) piece of thread remaining on the opposite side.

8. Using the hemostat, loosely wrap the long piece of thread twice around the pair of forceps. Grab the short end of the thread with the forceps. Pull on thread wrapped around the forceps and slip it off the forceps to make a knot. Cut the ends of the thread close to this knot.

9. Repeat steps 7 and 8 one to two more times to suture the inner incision. Then repeat the same steps to suture the incision in the skin.

   Alternatively, it is possible to suture both layers with the same stitches.

   Because the skin can be more difficult to push the needle through, it helps to brace against the force with forceps that are spread such that the needle pushes between the two arms of the forceps.

10. Rinse frog in frog tank water and move it to a recovery tank with a shallow layer of water. Initially prop its head up out of the water.

    Usually, the anesthetic wears off after 20 to 60 min and the frog can then be returned to a normal tank. It is advisable to monitor the frog an additional 12 hr or so before returning it to the colony.

    A lid with air holes should be kept on the recovery tank as some frogs will try to jump out as soon as they recover.

Collect and sort oocytes

11. Using two pairs of Dumont no. 3 forceps, grab two parts of the outer layer of tissue that encloses the ovary. Pull forceps apart to partially invert the ovary and expose the oocytes.

12. Using the forceps, pull the ovary apart into smaller pieces (~50 oocytes each). Rinse chunks of ovary by swishing through ice-cold MBS and place in a clean petri dish with ice-cold MBS.

    These clumps can be stored for a couple of days. In some cases they can be used for up to a week following the surgery; in this case, the buffer should be changed daily.

13. Using a 1-ml syringe attached to an 18-G needle bent into a triangular loop, press down on a section of stalk that attaches one oocyte to the rest of the ovary. Grab an adjacent piece of this connective tissue with no. 3 forceps and pull gently, detaching the oocyte from the ovary. Repeat until the desired number of oocytes are freed from the ovary.

14. Sort the oocytes, keeping only those that are large (stage V and VI) and in perfect condition. Use a disposable transfer pipet to place these in a new petri dish with fresh, ice-cold MBS and store overnight in an 18°C incubator.

Smith et al. (1991) provides illustrations of oocyte stages. Oocytes at earlier stages of maturation are also used in some types of experiments (Feldherr et al., 1998).

Oocytes with mottled pigmentation or any scarring where the stalk was detached should be discarded. Sometimes a small tear in the follicle layer will cause a slight bulge in the oocyte at this point. There is nothing wrong with these oocytes per se, but these bulges make the oocytes prone to breaking when they are blotted dry, so they are best discarded. Also, oocytes that appear to be softening (sometimes this is not obvious until dissection) should be discarded.

Some groups remove the layer of follicle cells that encase each oocyte. This can either be done manually or by collagenase treatment (Terns and Goldfarb, 1998). Removal of the follicle layer decreases resistance to the needle during injection. It is also useful for some procedures, such as when endogenous material is being examined. However, defolliculated oocytes tend to be more difficult to handle during the dissection.

SUPPORT PROTOCOL 2

PREPARATION OF RNA FOR INJECTION

RNA export cargo is most easily monitored by the injection of radioactively labeled RNA. Such RNA can be generated in vitro following standard procedures for in vitro transcription driven by bacteriophage polymerases (*UNIT 11.6*). In some cases, it is important to include a nucleotide cap analog in order to mimic the bona fide 5′ end of a typical polymerase II transcript. During the analysis, this structural feature will contribute to RNA stability as well as to transport. When choosing which RNAs to monitor for export, an important point to keep in mind is that some steps in RNA biogenesis--such as splicing and export--are coupled (Luo and Reed, 1999). This may impact the decision of how an RNA should be produced for a particular experiment (i.e., with or without an intron). It should also be noted that as an alternative to injecting RNA cargo directly, oocytes can be injected with plasmids in conjunction with radioactive nucleotide. In this case, the plasmid template should contain a gene under the control of a eukaryotic RNA polymerase promoter. It is also possible to monitor the export of endogenous RNAs labeled in the presence of radioactive nucleotide. This procedure has been done to monitor the export of ribosomal RNAs (Powers et al., 1997). Although there are specific circumstances when these alternatives would be desirable, they do involve the injection of more radioactive material than in the case of the labeled RNAs.

Table 11.14.1 Reaction Mixture for RNA Labeling[a]

Ingredient	Amount in one reaction	Stock concentration
ATP, CTP, UTP	0.5 µl	5 mM each
DEPC-treated H_2O	to 10 µl total	—
DNA template, linearized[b]	1-2 µl	250-500 ng/µl
GTP	0.5 µl	1 mM
m7GpppG[c]	1 µl	5 mM
[^{32}P]GTP	3 µl	3000 Ci/mmol
RNA polymerase buffer	1 µl	10×
RNase inhibitor	0.25 µl	40 U/µl
SP6 or T7 RNA polymerase[d]	0.5 µl	20 U/µl

[a]To transcribe multiple RNAs, make a mix of common components and distribute this pool to tubes containing reaction-specific ingredients, such as DNA template.

[b]Template DNA can be either a linearized plasmid or a PCR product (where the 5′ oligo used to generate the PCR product contains the appropriate promoter sequence).

[c]Include only for capped RNA.

[d]The choice of polymerase is dependent on the type of promoter in the particular construct being used.

Materials

5 mM each ATP, CTP, UTP
20 U/µl SP6 or T7 RNA polymerase and 10× buffer
DEPC-treated H_2O (*APPENDIX 2A*)
250 to 500 ng/µl DNA template, linearized (*APPENDIX 3A*)
1 mM GTP
5 mM m^7GpppG (for capped analogs only)
3000 Ci/mmol [^{32}P]GTP
40 U/µl RNase inhibitor (e.g., RNasin, Promega)
5 M ammonium acetate
20 mg/ml glycogen or seeDNA (Amersham Pharmacia Biotech)
70% and 100% (v/v) ethanol
Blue dextran (avg. mol. wt. 2,000 kDa; e.g., Sigma-Aldrich) or rhodamine B dextran (mol. wt. 70 kDa; e.g., Molecular Probes)

1. Set up reaction mixture in a microcentrifuge tube to include components listed in Table 11.14.1. Mix well and incubate 60 min at 37°C.

2. Add the following and mix well:

   16 µl 5 M ammonium acetate
   60 µl DEPC-treated H_2O
   1 µl 20 mg/ml glycogen or seeDNA
   240 µl 100% ethanol.

   Again, when processing multiple samples it is easiest to make a master mix of these reagents.

   Some protocols include DNase treatment and phenol/chloroform extraction (APPENDIX 3A) before precipitation.

3. Chill on ice ≥15 min. Pellet in a microcentrifuge ~30 min at maximum speed, 4°C.

4. Wash twice with 70% ethanol at room temperature.

5. Resuspend in 15 µl DEPC-treated water.

6. To analyze RNA, make a 1:15 (v/v) dilution in DEPC-treated water and quantitate the radioactivity in a 2-µl aliquot using a scintillation counter.

   It is also useful to electrophorese 2 µl of the dilution on a 6% denaturing gel (UNIT 6.1). After a quick exposure to film (~30 min), the RNA can be assessed for size and uniformity.

7. Prepare the mixture of RNAs and dyes to be injected. For nuclear injections, add blue dextran or rhodamine B dextran to a final concentration of ~6 mg/ml or ~4 mg/ml, respectively.

   Generally, 0.5 to 2 × 10^6 cpm/µl of an RNA is used for an injection. A quick phosphorimager scan of a gel with the newly-synthesized RNAs can be used to generate the desired ratio of RNAs when injecting a mixed population. This avoids the problem of counting residual free nucleotide, which can be variable. In terms of absolute levels of RNA, typically total levels of RNAs should be in the low femtomole range to prevent saturation of an export pathway.

   A high-molecular-weight dye can be mixed into the sample to monitor the injection accuracy (see Basic Protocol introduction). There are alternative markers for a nuclear hit, such as colloidal gold (Bataille et al., 1990).

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Modified Barth's solution (MBS; Sive et al., 2000)

88 mM NaCl
1 mM KCl
2.4 mM $NaHCO_3$
15 mM HEPES
0.74 mM $CaCl_2$
0.82 mM $MgSO_4$
Autoclave and store up to 6 months at room temperature or 4°C
Add penicillin/streptomycin (Life Technologies) to 100 U/ml before use

HEPES is not included in all MBS recipes. The original recipe had a mix of $CaCl_2$ and $Ca(NO_3)_2$.

RNA harvest buffer

100 mM Tris·Cl, pH 7.6 (*APPENDIX 2A*)
10 mM EDTA, pH 8.0
300 mM NaCl
2% (w/v) SDS
Store up to 6 months at room temperature

RNA sample buffer

1× TBE buffer (*APPENDIX 2A*) containing:
10 M urea
0.25% (w/v) bromphenol blue
0.25% (w/v) xylene cyanol
Store at room temperature

COMMENTARY

Background Information

Oocyte microinjection studies have laid much of the groundwork for our understanding of the nuclear pore complex. Among the many important functional parameters that have been elucidated by this approach are the size limits of both diffusion and active transport through the pore (Bonner, 1975; Feldherr et al., 1984) and the identification of steps in the transport of different cargo that are either unique or shared with other pathways through the pore (Jarmolowski et al., 1994; Pokrywka and Goldfarb, 1995). Injection experiments have also been extremely useful in delineating both the *cis* signals within RNA and the *trans*-acting factors that are required for efficient export (e.g., Guddat et al., 1990; Fischer et al., 1995). More recently, microinjection studies have been used to address the specific roles of particular pore proteins (Stutz et al., 1996; Powers et al., 1997; Ullman et al., 1999).

The experimental strategies made possible by oocyte microinjection take advantage of the ability to survey a wide variety of transport cargo simultaneously in an intact cell. The function of individual components of the transport machinery can be probed with reagents ranging from antibodies to dominant-negative recombinant proteins.

As both the nuclear pore and the soluble accessory factors involved in transport become understood at a molecular level, the oocyte will continue to be an indispensable tool in the field of nucleocytoplasmic transport. Of course, this method is most powerful when complemented with other approaches. For instance, examining a specific interaction biochemically in vitro provides critical substantiating evidence for a functional relationship that is identified through microinjection analysis. Similarly, structural and biochemical studies of the pore and the soluble factors involved in transport provide important clues to function that can then be tested in an in vivo setting. Thus, in combination with other techniques, further analysis of transport in the oocyte will be used to gain insight into how the transport machinery

coordinates the multitude of trafficking events that occur each minute through each pore.

Critical Parameters

One critical parameter for oocyte microinjection is simply the quality of the oocytes. There is a certain amount of variability from frog to frog and, however frustrating this may be, it is well worth demanding a high standard at the very first step of oocyte isolation. In other words, if the oocytes cannot be recovered from the ovary without damage or if they have any abnormalities in their pigment distribution in the first place, try a new frog! Once you find a frog that has good oocytes, this is usually a reproducible attribute, and the frog can be operated on several times (with a week or so of rest in between).

Some problems with the oocytes are not immediately evident. This is one reason why it is beneficial to store the oocytes overnight before use and cull those that do not remain stable during this time. Finally, it pays to inject more oocytes per experimental point than you actually want to harvest. Then, at harvest time, you can once again select only those oocytes that have remained stable through the treatment.

Another important parameter to consider is the amount of RNA that you inject. Export pathways are saturable. Thus, too much of any one RNA will result in a much slower apparent export rate. It is important to note that this problem can actually be used to an advantage. Saturation of a particular pathway with unlabeled RNA has been used to identify steps in transport that are shared by more than one substrate (Jarmolowski et al., 1994; Pokrywka and Goldfarb, 1995). This strategy has also been employed to purposefully create a situation where a particular factor is limiting, allowing an add-back experiment to be performed where a candidate factor is tested for its ability to overcome the saturation (Gruter et al., 1998; Kutay et al., 1998).

Finally, it is important to strictly control the drop size and needle tip size. Given that the volume of an oocyte nucleus is approximately equivalent to 40 nl, it is best if the volume of the injected material does not exceed 10 to 12 nl. This is a somewhat arbitrary cutoff, and some experiments have been done successfully with larger volumes; however, erring on the side of caution in terms of maintaining nuclear integrity is advisable. The same can be said for needle size. The authors have found that a 10-nl volume generated by a burst of ~100 msec with ~15 PSI pressure translates into a needle that is fine enough for these experiments. The question of whether both drop size and needle size are within acceptable parameters can be assessed empirically by including appropriate controls for injection and dissection.

Troubleshooting

The needle becomes clogged during the injection procedure. There could be particulate matter in the injection material. Clear the solution with a high-speed spin prior to loading the needle. Sometimes the needle clogs simply because the sample at the tip has dried. To circumvent this, minimize the amount of time that the tip of the needle is out of the buffer solution. When the needle has clogged due to a dry tip, it can often be cleared by advancing and retracting the needle in and out of the buffer system.

The needle won't penetrate into the oocyte. The layer of follicle cells can sometimes make the oocyte somewhat resistant to injection. In most cases, this is easily overcome simply by slightly squeezing the oocyte with forceps to counter the pressure of the needle. If this does not work, make a slightly larger needle tip. If this is still a general problem, either bevel the needle or defolliculate the oocytes (Terns and Goldfarb, 1998). The latter procedure may lead to more difficulty in handling the oocyte at later steps.

U6 snRNA (or U3 snRNA) is entirely or partially in the cytoplasmic fraction. These two RNAs do not get exported and therefore can serve to confirm that the nucleus was both selectively injected and cleanly dissected. If these RNAs do not appear exclusively in the nuclear fraction, either the injection or dissection was not clean. Looking at the distribution of pre-mRNA and the splice products can help narrow the problem. Whether due to injection or dissection, the solution is more practice!

Pre-mRNA is in the cytoplasmic fraction. These two RNAs do not get exported and therefore can serve to confirm that the nucleus was both selectively injected and cleanly dissected. If these RNAs do not appear exclusively in the nuclear fraction, RNA was injected into the cytoplasm. Practice making nuclear injections with blue dextran dye. It is possible to get some export of pre-mRNA when there is a large excess of RNA injected. Injecting less pre-mRNA (that has a greater specific activity) may help. Also note that pre-mRNA containing a specific *cis* element (such as the constitutive transport element from type D retroviruses) can in fact be actively exported. Make sure that

there has not been an error in the templates used for generating injection RNAs.

The intron is in the cytoplasmic fraction. This indicates that there was a problem in the dissection, because the intron is generated only in the nucleus and is not exported. Again, more practice is necessary. Watch carefully for the entire nucleus to extrude followed by a small amount of cytoplasm. Also see comment about *cis* elements above.

After the injections, the oocytes seem mushy. These oocytes may not have been of good enough quality from the beginning. Sorting the oocytes very carefully is important. Switching frogs might also overcome the problem. Alternatively, the needle tip used in the injection may have been too large. Try breaking needles closer to the tip to create a finer opening and adjusting the pressure and time of the pico-injector to compensate. It also might help to divide the injection volume into two drops (or more for cytoplasmic injections).

RNA harvested from oocytes has a smeary appearance on gels. If the injected RNA looks good (eliminating an early problem with degradation), then this indicates that the RNA is being degraded at some point in the procedure. If this seems specific to mRNA and U1 RNA, the cap analog may not have been incorporated. Double-check concentrations used; try fresh stock if nothing else looks incorrect. Otherwise, there may be a general problem with degradation during the procedure. Try making clean, fresh solutions.

An oocyte has protruding bulges. This indicates that there is a rupture in the follicle layer. Be extremely gentle when pulling each oocyte off of the stalk that holds it in the ovary. In some cases, the oocytes are particularly difficult to isolate without damage. If this is the case, the simplest solution is to try another frog.

Anticipated Results

Once this procedure is up and running, it should yield a very definitive answer to the question of where different RNA export cargos localize under conditions of interest. By harvesting the oocytes at multiple time points, it is also possible to assess the kinetics of export, which may prove to be an important parameter. By altering the sequence of the RNA itself, the *cis* signals that contribute to the export of an RNA can be readily assessed. Just as importantly, mutational analysis of the RNA can be used to delineate which features contribute to the retention of certain RNAs.

Time Considerations

The entire procedure typically takes a minimum of 3 days: (1) a day to synthesize and double-check the RNA cargo (surgery can be performed the same day); (2) a day to perform the microinjections and harvest the oocytes (time points will range from minutes to a few hours); (3) a day to prepare and analyze the RNA distribution. It often makes sense to do >1 day of injections in between day 1 and day 3, because ultimately this is more time efficient than having to do a second operation to get more oocytes for a second injection.

It is also important to consider the amount of time it takes to learn this technique. It will take a few to several weeks to develop the eye-hand coordination and the experience needed to reproducibly inject the nucleus (and note that when using oocytes that have not been spun, the hit rate can vary from 70% to 90% even with experience). It also takes some practice to dissect the oocytes--mostly this is the experience it takes to know how much to squeeze the oocytes to get the nucleus to extrude as well as how big a hole to puncture in the first place. It is advisable to start by injecting blue dextran as a way to practice both the injection and the dissection.

In Vitro Analysis of Peroxisomal Protein Import

This unit describes a quantitative in vitro assay for peroxisomal protein import. The assay (outlined in Fig. 11.15.1) is ELISA-based and employs semi-permeabilized human cells and a biotinylated import substrate (see Basic Protocol). In the Basic Protocol, import is assessed directly in cells; in the Alternate Protocol, import is quantitated after isolation of cellular organelles/peroxisomes. A method for preparing biotinylated luciferase is also described (see Support Protocol).

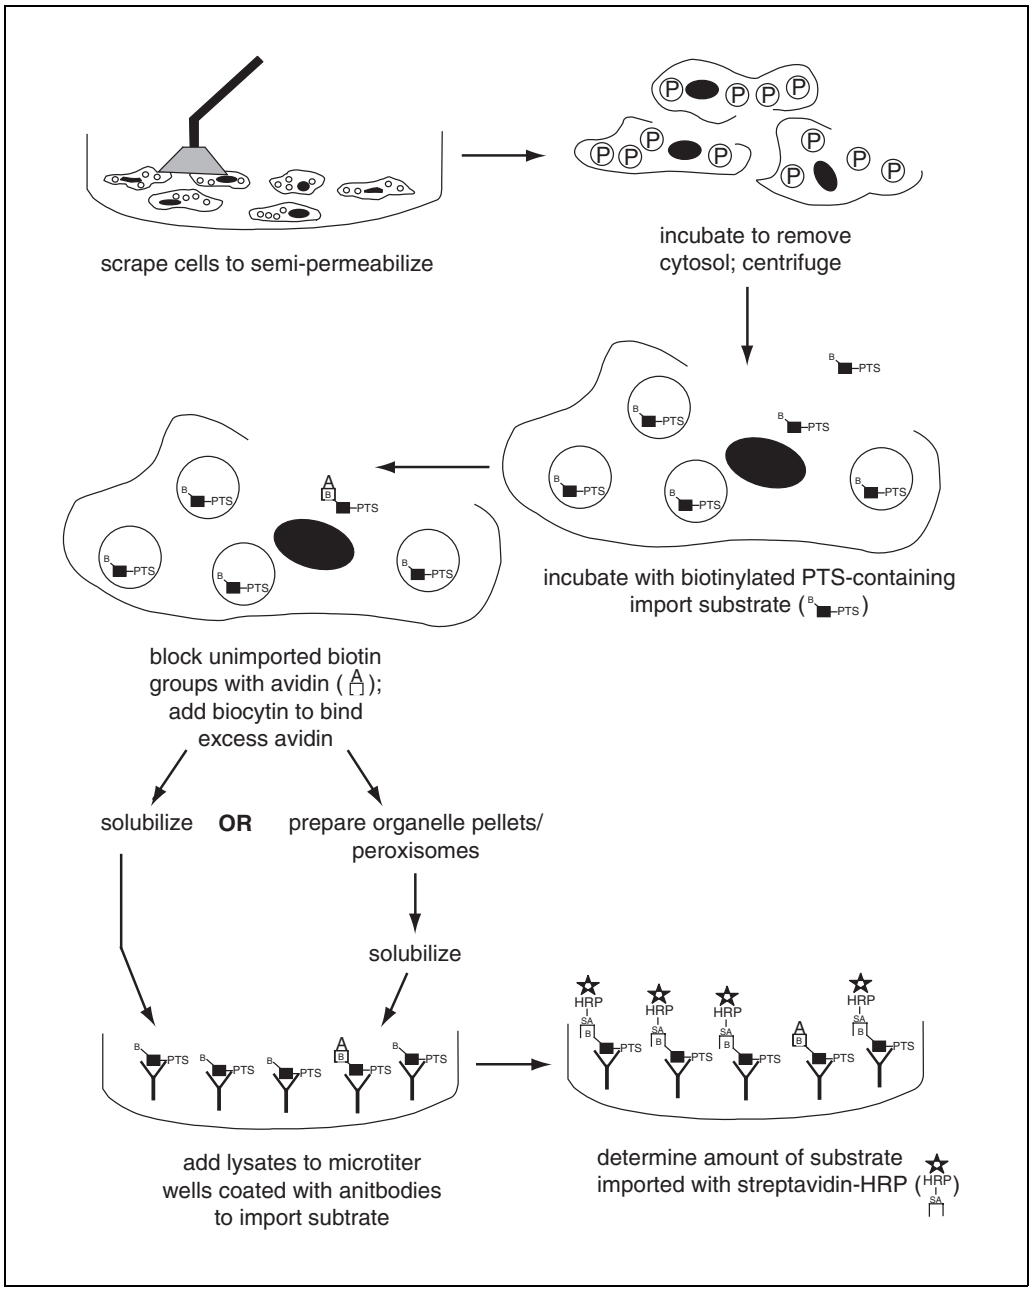

Figure 11.15.1 Quantitative in vitro assay for peroxisomal protein import. A, avidin; B, biotin; HRP, horseradish peroxidase: P, peroxisome; PTS, peroxisomal targeting signal; SA, streptavidin.

BASIC PROTOCOL

PEROXISOMAL PROTEIN IMPORT IN VITRO

Semi-permeabilized cells are incubated with import substrate, biotinylated luciferase. After the import reaction, cells are isolated and biotin groups on unimported substrate blocked. Cells are then lysed and import quantified by ELISA.

Semi-permeabilized cells are incubated with import substrate, biotinylated luciferase, and then unimported substrate is blocked. The extent of import is quantified by ELISA.

Materials

Rabbit polyclonal *APPENDIX 2A* anti-luciferase antibodies (*UNIT 16.2*)
ELISA coating solution: 50 mM sodium carbonate, pH 9.0
ELISA blocking solution (EBS; see recipe), pH 7.4
Human epidermoid carcinoma (A431; ATCC CRL-1555) cells or diploid lung (IMR90; ATCC CCL-186) fibroblasts growing in tissue culture
Hanks balanced salt solution (HBSS, Life Technologies; *APPENDIX 2A*)
Dulbecco's minimum essential medium containing 10% (defined) fetal bovine serum (FBS) (DMEM-10)
Import reaction buffer (IRB, see recipe), pH 7.4
ATP and regenerating system (ATP, see recipe)
800 µM ZnCl in IRB
Biotinylated luciferase (B-Luc, see Support Protocol)
IRB containing 1.25% or 0.2% (w/v) bovine serum albumin (IRB/1.25% BSA or IRB/0.2% BSA, respectively)
Avidin (Calbiochem)
Biocytin (Calbiochem-Novabiochem)
Phosphate-buffered saline (PBS; *APPENDIX 2A*), pH 7.4
Streptavidin horseradish peroxidase (Roche Diagnostics)
30% (v/v) hydrogen peroxide (H_2O_2)
o-Phenylenediamine
ELISA development buffer: 27 mM citric acid/51 mM sodium phosphate, pH 5.0
4 N sulfuric acid (H_2SO_4)

ELISA microtiter well strips (Maxisorp-Immunomodule, Nunc)
15-cm cell culture dishes (Corning)
Rubber policeman
50-ml conical centrifuge tubes (Corning)
Platform rocker
1.5-ml microcentrifuge tubes (Eppendorf)
37°C water bath
Microtiter plate washer (optional)
Microtiter plate reader

Prepare semi-permeabilized cells

1. Coat microtiter wells with antibody by adding 200 µl of a 1:500 dilution of rabbit polyclonal anti-luciferase antibodies in ELISA coating solution to ELISA microtiter well strips and incubating overnight at 4°C.

   Determine optimal concentration of coating antibody (and biotinylated ligand) added by serial dilution titration analysis. It is critically important that the amount of biotinylated ligand added to a given microtiter well not exceed the binding capacity of the coated antibody. Ideally, the amount of biotinylated ligand added should approach the upper range of where capture is still linear. This analysis must be performed for each ligand/antibody combination.

2. Wash ELISA microtiter well strips two times with 200 µl PBS and block residual binding capacity with 200 µl EBS. Incubate overnight at 4°C.

   Coated ELISA microtiter well strips may be stored in EBS until use—typically within 2 days of preparation.

3. Wash cells near, but not at, confluence, two times with 25 ml HBSS and add 25 ml fresh Dulbecco's minimum essential medium containing 10% FBS for 30 min prior to permeabilizing.

   Growing cells on 15-cm tissue culture plates works well for these procedures. These plates will contain ~5-6 × 10^6cells (sufficient for ~24 import reactions) when nearly confluent. The following steps describe procedures for treatment of each 15-cm plate.

   Pool cells from different plates at the end of the permeabilization procedure.

4. Wash cells three times with 25 ml IRB and harvest in a small residual volume (~5 ml) by scraping firmly with a stiff rubber policeman.

   Scraping in this manner removes portions of the plasma membrane and thus semi-permeabilizes cells.

5. Repeat scraping with an additional 5 to 10 ml IRB to harvest remaining cells.

6. Bring volume to 50 ml with IRB in a 50-ml conical centrifuge tube and rock 15 min at 4°C to remove cytosol.

7. After 15 min, centrifuge cells 5 min at 800 × *g*, 4°C. Aspirate supernatant.

   Properly semi-permeabilized cells will not exclude trypan blue or contain more than ~15% of their cytosolic contents. Lactate dehydrogenase and Hsc70 are convenient cytosolic marker proteins that may be examined by enzyme assay or immunoblotting, respectively.

8. Carefully resuspend cells in ~275 µl IRB and keep on ice until use.

   Once prepared, the cells should be used as quickly as possible. Therefore, step 7 should be initiated prior to completion of cell preparation.

Prepare and incubate import reactions

9. Add the following import reaction components, excluding cells, to labeled 1.5-ml microcentrifuge tubes on ice (final reaction volume is 40 µl, which includes 10 µl of cells):

   2 µl ATP
   5 µl zinc chloride
   5 µl 80 µg/ml B-Luc diluted in IRB/1.25% BSA
   18 µl IRB

   The 18 µl IRB addition may be reduced to accommodate such components as cytosol, (inhibitory) antibodies, chelators, and combinations or fractions thereof.

   Consolidating pipetting steps by pooling components improves reproducibility. Minimally, each condition should be performed in duplicate.

10. Initiate import reaction by adding 10 µl semi-permeabilized cells to microcentrifuge tubes containing import reaction mixture. Gently mix the contents and incubate 45 min at 37°C. Tap the microcentrifuge tubes gently every 5 min to ensure an even distribution.

    For zero-time incubations, add cells to import reaction components at the end of the incubation, i.e., at 45 min.

11. Terminate import reaction by microcentrifuging tubes for 1 min at 13,000 rpm, 4°C. Aspirate supernatant.

    The vast majority of unimported B-Luc is removed in this step. The small amount remaining in the pellet is "inactivated" in the following steps.

Block unimported B-Luc

12. Add 100 µl of 75 µg/ml avidin diluted in IRB/0.2% BSA and resuspend cell pellet. Incubate for 1 hr at 4°C on a platform rocker.

    Avidin blocks biotin groups on unimported B-Luc.

13. Add 10 µl of 750 µg/ml biocytin diluted in IRB/0.2% BSA and incubate for an additional 15 min at 4°C.

    Biocytin binds excess avidin.

14. Solubilize by adding 100 µl EBS and vortexing. Incubate 30 min at 4°C.

    Unmodified B-Luc, the hallmark of import, is now available for capture and detection in microtiter wells coated with anti-luciferase antibodies.

Capture B-Luc

15. Just prior to plating lysates, wash ELISA microtiter well strips two times with 200 µl PBS. Add 200 µl of cell (or organelle) lysates to appropriate microtiter wells and incubate overnight at 4°C.

Develop plates

16. Wash ELISA microtiter well strips three times with 200 µl PBS and add 200 µl EBS for 5 min. During this time, dilute the streptavidin horseradish peroxidase 1:5000 in EBS.

17. After 5 min, wash ELISA microtiter well strips three times with 200 µl PBS, and add 200 µl of the streptavidin horseradish peroxidase/EBS mixture. Incubate for 1 hr at room temperature.

18. After 1 hr, wash ELISA microtiter well strips three times with 200 µl PBS and add 200 µl EBS for 5 min. During this 5-min period, prepare the development solution by adding 10 µl of 30% H_2O_2 and 10 mg *o*-phenylenediamine to 25 ml ELISA development buffer.

    The development solution should not be prepared ahead of time.

    CAUTION: *o-Phenylenediamine is a carcinogen and contact should be avoided. All o-phenylenediamine-containing solutions should be discarded appropriately.*

19. After 5 min, wash ELISA microtiter well strips three times with 200 µl PBS, and add 200 µl of H_2O_2/*o*-phenylenediamine/ELISA development buffer mixture. Allow development to proceed for 1 to 2 min.

20. Stop development with 50 µl of 4 N H_2SO_4 and, in a microtiter plate reader, measure absorbance at 490 nm.

IMPORT INTO ORGANELLE PELLETS/PEROXISOMES

ALTERNATE PROTOCOL

In this protocol, import is carried out in semi-permeabilized cells. Then the cells are homogenized and fractionated, and import assessed in the resultant organelles.

Additional Materials *(also see Basic Protocol)*

Antibody-coated microtiter well strips (Basic Protocol, steps 1 and 2)
Homogenization buffer (see recipe), pH 7.8

15-ml conical centrifuge tubes (Corning)
27-G needle
1-ml syringe
2-ml glass Dounce tissue grinder, with loose- and tight-fitting pestles (Kontes)

Prepare semi-permeabilized cells

1. Wash cells near, but not at confluence, two times with 25 ml HBSS and add 25 ml fresh medium for 30 min prior to permeabilizing.

   For this protocol, two nearly confluent 15-cm tissue culture plates will provide sufficient cells for ~6 import reactions. The following steps describe procedures for treatment of two 15-cm plates.

2. Wash cells three times with 25 ml IRB and harvest in a small residual volume (~5 ml) by scraping firmly with a stiff rubber policeman.
3. Repeat scraping with an additional 5 to 10 ml IRB added to harvest remaining cells. Pool cells from two plates at this step.
4. Bring volume to 50 ml with IRB in a 50-ml conical centrifuge tube and centrifuge cells 5 min at 800 × *g*, 4°C. Carefully aspirate supernatant.

   Avoid touching cell pellet or it too may be aspirated. Leave a small amount of supernatant if necessary.

5. Carefully resuspend cells in ~12 ml IRB and dispense ~2-ml aliquots into each of six 15-ml conical centrifuge tubes on ice.

   Repeated gentle pipetting with a 5-ml pipet helps reduce clumping of the cells. It is critically important that each 15-ml conical centrifuge tube receive an equal volume/number of cells.

6. Centrifuge the cells 5 min at 800 × *g*, 4°C. Carefully aspirate supernatant.

   Once prepared, the cells should be used as quickly as possible. Therefore, the import reaction components should be prepared and pooled such that they may be added to cells in a one-step addition immediately after the supernatant is aspirated.

Prepare import reactions/incubations

7. Prepare a 187.5-µl import reaction mix with the following components:

   12.5 µl ATP
   31.3 µl zinc chloride
   31.3 µl 80 µg/ml B-Luc diluted in IRB/1.25% BSA
   112.4 µl IRB

   The 112.4 µl IRB addition may be reduced to accommodate such components as cytosol, (inhibitory) antibodies, chelators, and combinations or fractions thereof.

8. Gently resuspend the cells in the import reaction mix and immediately transfer the contents to a 1.5-ml microcentrifuge tube. Incubate for 45 min at 37°C. Tap the microcentrifuge tubes every 5 min to ensure an even distribution.

   The cell volume is ~60 µl, therefore the final reaction volume is ~250 µl. For zero-time incubations, add import reaction components to cells at the end of the incubation, i.e., at 45 min.

9. Terminate import reaction by microcentrifuging tubes 1 min at 13,000 rpm, 4°C. Aspirate supernatant.

Block unimported B-Luc

10. Add 250 µl of 187.5 µg/ml avidin diluted in homogenization buffer and resuspend cell pellet. Incubate for 1 hr at 4°C with rocking.

    Avidin blocks biotin groups on unimported B-Luc.

11. Add 25 µl of 1.875 mg/ml biocytin diluted in homogenization buffer and incubate for an additional 15 min at 4°C.

    Biocytin binds excess avidin.

Prepare organelle pellets/peroxisomes

12. Homogenize cells on ice by passing through 27-G needle attached to 1-ml syringe five times, followed by ten strokes with a loose-fitting pestle and ten strokes with a tight-fitting pestle in a 2-ml Dounce homogenizer.

13. Centrifuge 10 min at 1000 × *g* at 4°C to remove nuclei and unbroken cells.

14. Transfer supernatant to a fresh 1.5-ml microcentrifuge tube and microcentrifuge 20 min at 17,000 × *g*, 4°C, to prepare organelle pellet/peroxisomes. Aspirate supernatant.

15. Solubilize pellet by adding 200 µl EBS and vortexing. Incubate for 30 min at 4°C.

    Unmodified B-Luc, the hallmark of import, is now available for capture and detection in microtiter wells coated with anti-luciferase antibodies in the ELISA assay (see Basic Protocol, steps 1, 2 and 15 to 20). Alternatively, proteins in the organelle pellet are separated by SDS-PAGE (UNIT 6.1), transferred to nitrocellulose, and probed with streptavidin alkaline-phosphatase (see Terlecky et al., 2001; also see UNIT 6.2).

SUPPORT PROTOCOL

LUCIFERASE BIOTINLYATION

Biotinylated luciferase is used as the import substrate for the assays described in this unit. The protein contains a peroxisomal targeting signal and is readily available comercially

Materials

Firefly (*Photinus pyralis*) luciferase (Sigma-Aldrich)
Phosphate-buffered saline (PBS; *APPENDIX 2A*) pH 7.4
8.25 mM 6-((6-((biotinoyl)amino)hexanoyl)amino)hexanoic acid, succinimidylester (Molecular Probes) in dimethylsulfoxide (B-XX-SE)
PBS containing 0.2% (w/v) BSA (PBS/0.2% BSA)
Streptavidin alkaline-phosphatase (KPL)
Rabbit polyclonal anti-luciferase antibodies (*UNIT 16.2*)
Micro Bio-Spin P-6 chromatography column (spin column, Bio-Rad)

1. Dissolve 2 mg of firefly luciferase in 200 µl PBS.

2. Add 20 µl of 8.25 mM B-XX-SE (about five times molar excess over luciferase). Incubate 1 hr at room temperature.

3. During 1-hr incubation, wash four spin chromatography columns first three times with 500 µl PBS, then one time with 500 µl PBS/0.2% BSA, followed by a 500-µl PBS wash. Centrifuge each wash for 1 min at 1000 × *g*, room temperature.

4. After 1 hr, add 55 µl of biotinylation reaction (step 2) to each column and centrifuge for 4 min at 1000 × *g*. Collect and pool filtrates.

   This step effectively separates the modified protein from unincorporated labeling reagents.

5. Adjust volume of biotinylated luciferase (B-Luc) with PBS such that final protein concentration is ~2 mg/ml. Dispense into 10-µl aliquots and store at −80°C.
6. Confirm biotinylation by blotting with streptavidin alkaline-phosphatase and rabbit polyclonal anti-luciferase antibodies.

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

ATP and regenerating system (ATP)

20 mM adenosine 5′-triphosphate (disodium salt, Amersham Biosciences)
100 mM creatine phosphate (disodium salt, Calbiochem-Novabiochem)
8.0 IU creatine phosphokinase (Sigma-Aldrich)
Store up to 6 months at −80°C

ELISA blocking solution (EBS)

0.2% (w/v) BSA
1 mM EDTA (disodium salt)
50 mM sodium chloride
0.1% (w/v) sodium dodecylsulfate salt (SDS)
10 mM Tris·Cl
1.0% (v/v) Triton X-100
Adjust pH to 7.4 with HCl
Store up to 1 month at 4°C

Homogenization buffer

10 mM acetic acid
0.2% (w/v) BSA
1 mM EDTA (disodium salt)
0.1% (v/v) ethanol
0.25 M sucrose
10 mM triethanolamine
Adjust pH to 7.8 with NaOH
Store up to 1 month at 4°C

Import reaction buffer (IRB)

40 mM *N*-2-hydroxyethyl-piperazine-*N*′-2-ethane-sulfonic acid (HEPES)
2 mM magnesium acetate
100 mM potassium acetate
85 mM sucrose
Adjust pH to 7.4 with KOH
Store up to 1 month at 4°C

COMMENTARY

Background Information

Peroxisomes

Peroxisomes are critically important, ubiquitous subcellular organelles whose biology impacts human health, disease, and aging. In recent years, considerable efforts have been expended to try to understand how these single-membrane bounded multifunctional organelles arise. Powerful genetic approaches in a number of diverse organisms have identified 23 proteins, called peroxins, which participate in various aspects of peroxisome biogenesis. Biochemical approaches have also contributed significantly to an understanding of how peroxisomes are formed from a mechanistic standpoint.

Peroxisome biogenesis appears to involve three steps: (1) synthesis and assembly of membrane proteins and lipids, (2) signal-mediated

post-translational import of proteins from the cytosol, and (3) growth and division of the organelle (reviewed in Terlecky and Fransen, 2000). It is the processes associated with protein import into the organelle, i.e., step 2, that are reconstituted in the assay described here. An important question at this point is what sets this in vitro system apart from others currently available?

In vitro assays

Three other in vitro assays for peroxisomal protein import are in use. The first. involves isolating organelles from rat liver or yeast cells and incubating them with import substrates (Lazarow et al., 1991). Protease protection is used as the hallmark of import. The second involves microinjecting intact cells with import substrates and examining their redistribution to peroxisomes over time (Walton et al., 1992). Import is detected by immunofluorescence. The third involves bacterial cytolysin semi-permeabilizing cells and incubating them with import substrates (Wendland, 1994). Once again, import is detected by immunofluorescence. All three have contributed and will continue to contribute to the field. The assay described here is the most recently developed for peroxisomal protein import. Based on a cell-free system first designed to quantitate receptor-mediated endocytosis (Smythe et al., 1992), it employs mechanically disrupted cells and biotinylated import substrates. The hallmark of import is the accumulation of avidin-inaccessible biotin groups inside the peroxisome. The assay is a reliable and robust multisample system designed to permit examination of a number of parameters within a single experiment. It faithfully recapitulates the import process, is easy to use and reproducible, and it should greatly facilitate the search for novel biochemical factors and mechanisms fundamental to peroxisomal protein import.

Quantitative assay specifics/advantages

Nearly all peroxisomal proteins are directed to the organelle by virtue of a peroxisomal targeting signal (PTS); specifically, PTS1 or PTS2. Although the protocols described here employ the PTS1-containing protein luciferase, the assay may, in principle, be applied to other PTS1- and PTS2-containing substrates. Interestingly, PTSs exist as compositional motifs, and not as absolutely conserved sequences. The assay could be used to test the relative strength of signal variants; a powerful advantage over nonquantitative immunofluorescence-based assays that cannot discriminate between potentially subtle differences in import efficiencies.

The assay does not detect significant import in cells from patients who suffer from the fatal peroxisomal disorder Zellweger syndrome (Terlecky et al., 2001). In these particular cells, the basis of the import deficiency is known—they lack a functional PTS1 import receptor, called Pex5p. Perhaps in other patient cell lines, the system could be used as a "biochemical complementation assay" to identify missing or defective factors.

The assay is presented in two forms; as a Basic Protocol and as an Alternate Protocol. The two may be used interchangeably. The advantage of the ("cell") Basic Protocol is that it is easier to use and is less time-consuming. It is the approach of choice in most circumstances. The ("organelle pellet/peroxisome") Alternate Protocol is especially effective when trying to avoid problems associated with cell clumping in small volumes. Human fibroblasts, especially if over-confluent, can clump after being semi-permeabilized and concentrated. This can make dispensing equal (10 µl) volume aliquots problematic. In the Alternate Protocol, cells are (equally) divided while in a larger and more easily divided (12 ml) volume.

Critical Parameters and Troubleshooting

Biotinylation

A procedure is detailed for the biotinylation of luciferase (see Support Protocol). Clearly, there are other methods for the biotinylation of this enzyme—some involve isolation of the biotinylated-species on (monomeric) avidin columns. The latter is an effective approach but can be problematic if elution involves more stringent conditions (e.g., acid). Under such circumstances, care should be taken to ensure that the renaturation/refolding steps result in a protein that is still recognized by antibodies and captured in antibody-coated microtiter wells, and remains a substrate for the peroxisomal protein import pathway.

Import assays

Peroxisomal protein import is blocked at low temperatures (e.g., 4°C). Therefore, in addition to a zero-time incubation, (complete) import reactions should also be carried out at 4°C. Typically, import will be reduced to <10% of the 37°C value.

Factors that modulate import should be determined empirically for each ligand. For the PTS1-containing protein, B-Luc, import is stimulated some six-fold by zinc ions (100 µM) and an additional two- to three-fold by cytosol (10 µg/ml; Terlecky et al., 2001). For other substrates, the concentrations of these and other factors should be titrated to maximize the import signal. It should be noted that the cytosol effect on B-Luc import is variable, depending on the source, the concentration, the amount of endogenous cytosol removed from cells, and other factors (Terlecky et al., 2001). As such, it is recommended that each cytosol preparation be individually evaluated for activity with a given substrate.

Lastly, the assay described in the ("cell") Basic Protocol is performed in a final volume of 40 µl. It is, therefore, exquisitely sensitive to pipetting errors. Where possible, reduce or eliminate the potential for variance by pooling components.

ELISA quantitation

It is extremely important that the signal-to-noise ratio of the assay be high. Contributing to background noise (i.e., the absorbance detected in an import reaction at time-zero or at time 45 min at 4°C) is (1) impure or poor quality development reagents, (2) ineffective blocking of microtiter wells, and (3) incomplete washing of microtiter wells between steps. Contributing to reduced signals (i.e., the absorbance detected in an import reaction at 45 min at 37°C) is (1) using poorly permeabilized cells, (2) exceeding the binding capacity of the coated antibody, and (3) inactivation of the import substrate.

Suggested remedies for these problems are as follows. For high background noise: (1) use the reagents and sources suggested in the protocols, (2) modify the blocking buffer to include higher concentrations of BSA or switch to gelatin-, casein-, or non-fat milk-based blocking buffers (however, be sure not to interfere with antibody-capture of the biotinylated-import substrate), and (3) wash thoroughly (a plate washer helps increase reproducibility and simplifies the process). For low signals: (1) scrape the cells more vigorously, or consider growing the cells on fibronectin or other attachment factor, (2) reduce the amount of cell or organelle lysates loaded (from the Basic Protocol or Alternate Protocol, respectively), or, alternatively, reduce the amount of substrate added to the import reaction, and (3) biotinylate the import substrate in another way. With respect to the latter point, it is possible that biotinylation of the import substrate results in a

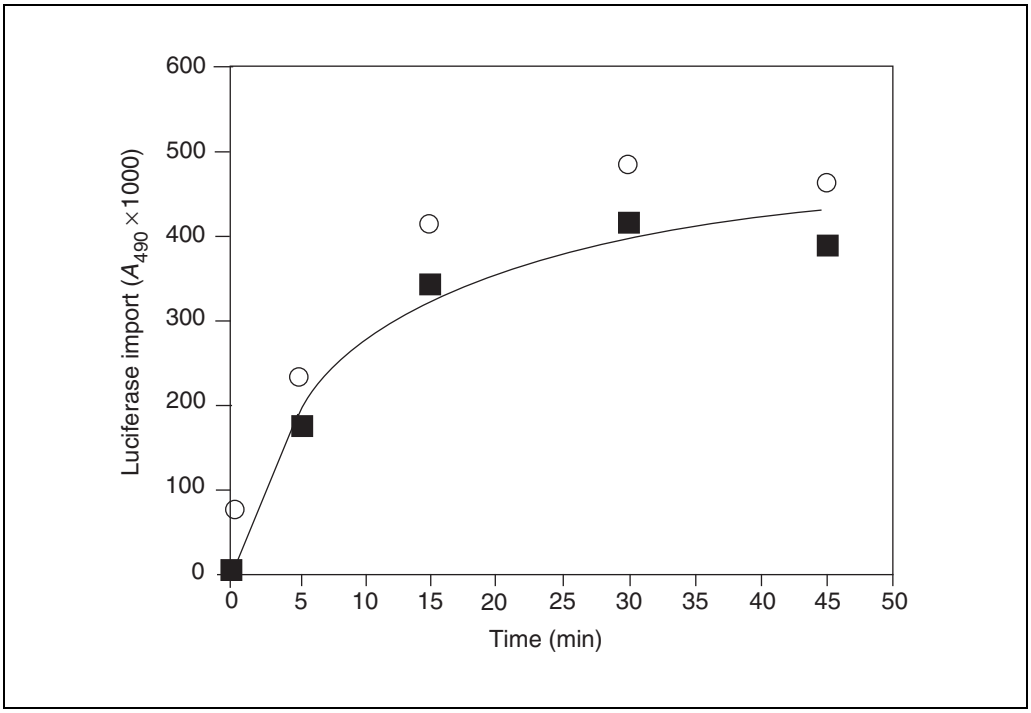

Figure 11.15.2 Peroxisomal import kinetics. Semi-permeabilized human A431 cells were incubated with biotinylated luciferase in the in vitro peroxisomal import reaction described in the Alternate Protocol. At the times indicated, the extent of import was quantified by ELISA. The raw absorbance units (×10^2) obtained at each time point (open circle); adjusted absorbance values reflecting subtraction of the time 0 value (filled square and solid line).

protein that is still recognized by antibodies and therefore captured in antibody-coated microtiter wells, but has had its PTS inactivated or shielded. Under such circumstances, consider using a different biotinylation method, or reducing the number of biotin groups coupled per protein molecule. If necessary, employ the immunofluorescence-based semi-permeabilized cell import assay (Wendland, 1994; Terlecky et al., 2001) to confirm import competence of the biotinylated substrate.

Anticipated Results

The protocols outlined here will result in a measurable absorbance at 490 nm. For example, Figure 11.15.2 illustrates results of an import time course. The challenge is to ensure that the signal is obtained under appropriate conditions (e.g., import conducted for 45 min at 37°C) and not inappropriate ones (e.g., import conducted at 4°C or for zero-time). Furthermore, to permit valid comparisons between experiments, every effort should be made to keep assay parameters as consistent as possible. This includes the number of cells and their treatment, the concentrations and preparations of assay components, and the conditions employed. Clearly, if the positive and negative controls are similar in experiments conducted on different days, then the results obtained for "experimental" conditions may be usefully and accurately compared.

Time Considerations

The biotinylation reaction described in the Support Protocol will require ~2 hr to complete. This excludes the time required for blotting the resultant biotinylated-species. Clearly, the Support Protocol must be completed before initiating import assays.

A typical import assay will require 30 min and an overnight incubation 2 days before the assay for coating microtiter wells with antibodies, and 30 min and an overnight incubation 1 day prior to the assay for blocking of wells. On the day of the import experiment, ~4.5 hr will be required for the "cell" Basic Protocol, and 6 hr for the "organelle pellet/peroxisome" Alternate Protocol. An overnight incubation is once again required, and on day 2 of the experiment, the assay is developed. This step requires ~2 hr to complete. Every effort should be made to design the experiment, prepare reagents, label tubes, and check on the availability of required equipment well in advance of beginning the assay. The only other time consideration is that of optimizing the ELISA assay by serial dilution titration analysis. Performed after biotinylation of the ligand, it will require the 2-day preparation of antibody-coated and blocked microtiter wells, and ~2 hr to add appropriate amounts of the biotinylated-ligand. After an overnight incubation, once again ~2 hr is required to develop the assay.

In Vitro Analysis of Chloroplast Protein Import

This unit describes methods for isolating intact chloroplasts from pea (*Pisum sativum;* see Support Protocol 1) and *Arabidopsis thaliana* (see Support Protocol 2) for the study of the import of nuclear-encoded plastid precursor proteins. Chloroplasts from both preparations are competent for the in vitro import of recombinant preproteins synthesized using in vitro translation systems derived from reticulocyte lysates or wheat germ lysates (see *UNIT 11.2* and Support Protocol 3). Preproteins expressed in *E. coli* also have been used for import studies using isolated pea chloroplasts (Pilon et al., 1990; Schnell and Blobel, 1993). These assays can be used to test whether a particular protein is targeted to chloroplasts, for analyzing the suborganellar location of newly imported preproteins, or to study the mechanism of import itself. The in vitro chloroplast protein import assay is described in the Basic Protocol, and methods for fractionating the chloroplasts and analyzing the results of import are provided in the Alternate Protocol.

IN VITRO CHLOROPLAST PROTEIN IMPORT ASSAY

BASIC PROTOCOL

Intact chloroplasts isolated from either pea or *Arabidopsis* using the methods described in Support Protocols 1 and 2 can be used for in vitro chloroplast protein import assays. These assays are often used to confirm the ability of proteins to be imported into chloroplasts, as chloroplast targeting prediction programs (Emanuelsson et al., 1999, 2000) are not 100% accurate, or to study the mechanism of import itself.

Generally, the intact chloroplasts are incubated with in vitro—translated, radiolabeled chloroplast preproteins in the presence of energy in the form of ATP (Pain and Blobel, 1987; Theg et al., 1989). The chloroplasts are re-isolated to remove any precursor not imported during the assay and analyzed using a PhosphorImager or by fluorography (*UNIT 6.3*) following SDS-PAGE (*UNIT 6.1*) to detect imported protein. The majority of chloroplast proteins are synthesized with a cleavable *N*-terminal transit peptide that is removed following import to the stroma (Bauer et al., 2001). This cleavage results in a shift in molecular weight, which provides a convenient indication that import has occurred. Chloroplasts are treated with exogenous protease (e.g., thermolysin), following the import assay, to digest any excluded preprotein and confirm that the processed preprotein has been imported, and thereby, protected from protease digestion (Cline et al., 1984). For proteins targeted to the outer envelope membrane, many of which do not have cleavable transit peptides, resistance to alkali extraction or the generation of a characteristic pattern of protease resistance can confirm integration into the membrane (Muckel and Soll, 1996; Froehlich et al., 2001).

Materials

Freshly isolated, intact chloroplasts (see Support Protocols 1 and 2)
HEPES-sorbitol buffer, pH 7.5 (if using pea chloroplasts, see recipe) or pH 8.0 (if using *Arabidopsis* chloroplasts, see recipe)
Chloroplast import master mix (see recipe)
0.1 M dithiothreitol (DTT)
0.1 M ATP
In vitro—translated [^{35}S]methionine-labeled chloroplast protein (see Support Protocol 3 or *UNIT 11.2*)
40% (v/v) Percoll (see recipe)
2 mg/ml thermolysin (see recipe)
0.5 M EDTA
SDS-PAGE sample buffer (see recipe)
Destain solution (see recipe)

Contributed by Matthew D. Smith, Lynda Fitzpatrick, Kenneth Keegstra, and Danny J. Schnell
Current Protocols in Cell Biology (2002) 11.16.1-11.16.21

26°C water bath
1.5-ml microcentrifuge tubes
Refrigerated microcentrifuge
Enlightening fluorography enhancer (NEN)
Additional reagents and equipment for SDS-PAGE (*UNIT 6.1*) and fluorography or phosphorimagery (*UNIT 6.3*)

Perform in vitro import assay

1. Adjust the chlorophyll concentration of freshly prepared chloroplasts (see Support Protocols 1 and 2) to 1 mg chlorophyll/ml using the appropriate HEPES-sorbitol buffer.

   Use the equivalent of 50 μg chlorophyll in a standard 100-μl assay.

   The amount of chlorophyll can be increased to 100 μg chlorophyll/100 μl assay if the sensitivity of import (i.e., the import efficiency of a particular substrate) is low.

2. Mix the following components on ice:

   50 μl 1 mg/ml chloroplasts (50 μg chlorophyll)
   10 μl chloroplast import master mix
   1 μl 0.1 M DTT
   2 μl 0.1 M ATP
   62 μl appropriate HEPES-sorbitol buffer

   Pre-incubate for 5 min at 26°C in the dark.

3. To begin import, add 1 to 5 μl [^{35}S]methionine-labeled in vitro translation product (equivalent to at least 10,000 cpm). Incubate 20 to 30 min at 26°C in the dark.

   The amount of in vitro–translated import substrate added to each reaction can vary considerably depending on the efficiency of import of the substrate. A model import substrate, such as the precursor to the small subunit of rubisco (preSSU), that is synthesized in a reticulocyte lysate system and radiolabeled with [^{35}S]methionine is imported with efficiencies of up to 65% of added substrate. However, the authors recommend that investigators assume an import efficiency of ~20% for previously untested preproteins. With this in mind, the amount (cpms) of substrate should be increased proportionately to ensure sensitivity of detection with film or a PhosphorImager. Also, be aware that transit peptide processing might remove [^{35}S]methionine residues, thereby, decreasing sensitivity.

4. Stop import by diluting the reaction into 0.5 ml of ice-cold HEPES-sorbitol buffer and hold on ice.

Re-isolate the chloroplasts

5. Layer the diluted chloroplasts over a 0.5- to 1-ml cushion of ice-cold 40% Percoll in a 1.5-ml microcentrifuge tube and microcentrifuge for 5 min at 2000 × *g*, 4°C.

6. Carefully aspirate the supernatant and 40% Percoll, containing any broken chloroplasts and nonimported translation product.

   It is important to remove all of the supernatant without disturbing the chloroplast pellet in order to minimize contamination of the chloroplasts with excess precursor.

Treat chloroplasts with thermolysin

7. Resuspend the chloroplasts in 100 μl of ice-cold HEPES-sorbitol buffer and transfer to a fresh 1.5-ml microcentrifuge tube. Add 5 μl of 2 mg/ml thermolysin, mix gently, and incubate for 30 min on ice.

   A concentration of 100 μg thermolysin/ml during the protease treatment is standard for the analysis of proteins imported to the inner envelope, stroma, or thylakoid. For integral outer

envelope proteins that will be susceptible to proteolysis, it may be desirable to titrate the level of thermolysin to generate a digestion pattern that is characteristic of the integrated protein (Muckel and Soll, 1996; Tu and Li, 2000; Froehlich et al., 2001). The final thermolysin concentration can be varied from 10 to 200 μg/ml depending on the substrate being studied and the susceptibility to degradation. The optimal concentration to be used for each substrate should be determined empirically.

8. Stop the reaction by adding 0.5 M EDTA to a final concentration of 10 mM. Re-isolate the chloroplasts by centrifugation through a 40% Percoll cushion, containing 5 mM EDTA, as described in step 5.

Analyze imported proteins

9. Resuspend the chloroplast pellet (step 6 or step 8) directly in 25 μl SDS-PAGE sample buffer and analyze by SDS-PAGE (*UNIT 6.1*) and fluorography or phosphorimagery (*UNIT 6.3*).

   As an alternative to analyzing the chloroplast pellet directly by SDS-PAGE, the chloroplasts may first be fractionated to determine the precise suborganellar location of the imported protein (see Alternate Protocol).

10. Analyze the results of import by SDS-PAGE using a 10% or 12% polyacrylamide gel (*UNIT 6.1*).

    Samples from each step of the import assay and subsequent treatments should be analyzed. For example, chloroplasts reisolated directly following the import assay (step 6) and following protease treatment (step 8) should be analyzed along with samples from alkaline extraction (see Alternate Protocol, steps 9 and 12) and each fraction from chloroplast subfractionation (Alternate Protocol, steps 18 and 23). A small aliquot of the in vitro translation product used in the import assay, usually equivalent to 1/10 of the amount added to the reaction, should be included on the gel. This will serve as a molecular weight reference, to confirm the transit peptide has been removed, and as a reference for the amount of radioactive substrate added to the reaction (keeping in mind that the processed protein might have fewer labeled methionine residues than the precursor protein with transit peptide). This will provide a complete and quantitative analysis of the import experiment.

11. Following electrophoresis, fix the gel in destain solution for 30 to 60 min. For exposure using a PhosphorImager, dry the gel under vacuum, wrap in plastic and expose to the phosphor storage screen overnight. For fluorography using film, soak the gel in Enlightening fluorography enhancer for 30 to 60 min, dry the gel under vacuum at 65°C for 1.5 to 2 hr, and expose to X-ray film overnight at −80°C.

FRACTIONATION OF RE-ISOLATED CHLOROPLASTS FOLLOWING IMPORT

ALTERNATE PROTOCOL

It may be desirable to subfractionate chloroplasts following an import reaction to determine the suborganellar localization of the newly imported preprotein. To assess stromal versus membrane localization, chloroplasts can simply be lysed and separated into stromal versus membrane fractions by differential centrifugation. To confirm that a suspected membrane protein is integrated, the membrane fraction can be subjected to alkaline extraction. Alternatively, the chloroplasts can be fractionated into outer and inner envelope membranes, thylakoids, and stroma if the precise suborganellar compartment must be determined (Keegstra and Yousif, 1986). Subfractionation into the three membrane components should not be attempted with chloroplast samples corresponding to <0.5 mg chlorophyll because of the low yield of envelope membrane. The inner and outer envelope membranes constitute ≤1% of the total chloroplast membrane fraction.

Materials

Chloroplast pellet from the import reaction (see Basic Protocol)
HEPES-sorbitol buffer (see recipe), ice cold
2 mM EDTA, ice cold
4 M NaCl
0.5% and 100% (w/v) trichloroacetic acid (TCA; see recipe)
SDS-PAGE sample buffer (see recipe)
0.1 M $NaCO_3$, pH 11.5, ice cold
TE/DTT buffer (see recipe) containing 0.6 M sucrose and buffer containing 0.2 M sucrose
TE/DTT buffer (see recipe)
1 M, 0.8 M, and 0.46 M sucrose

3-ml Beckman polyallomer thick-walled ultracentrifuge tubes
Ultracentrifuge and rotor (Beckman TL 100 and TLA 100.3 rotor, or equivalent)
Dounce homogenizer or Potter homogenizer and pestle
Swinging-bucket rotor (e.g., Beckman SW 50.1)
5-ml polyallomer tubes (e.g., for Beckman SW 50.1)
1-ml micropipettor
Gradient former (e.g., Buchler DensiFlow gradient former)
Gradient fractionater (e.g., ISCO gradient fractionater)

Additional reagents and equipment for SDS-PAGE (*UNIT 6.1*) and fluorography or phosphorimagery (*UNIT 6.3*)

Lyse chloroplasts for stromal versus membrane association

1. Resuspend the chloroplast pellet from the import reaction (see Basic Protocol, step 6 or 8) in 150 µl of ice-cold HEPES-sorbitol buffer.
2. Dilute the suspension with 800 µl of ice-cold 2 mM EDTA. Vortex vigorously and let stand for 10 min on ice to lyse the chloroplasts. Add 50 µl of 4 M NaCl, mix, and microcentrifuge the lysed chloroplasts for 30 min at 15,000 × *g*, 4°C, to pellet both the thylakoid and envelope membranes.
3. Carefully transfer the supernatant (stroma) to a fresh 3-ml polyallomer thick-walled tube and precipitate the protein by adding 100% TCA to a final concentration of 12%. Incubate for 1 hr on ice. Resuspend the membrane pellet directly in 25 µl SDS-PAGE sample buffer.
4. Collect the TCA precipitate by centrifugation for 30 min at 15,000 × *g*, 4°C. Remove and discard the supernatant.
5. Wash the pellet with 500 µl 0.5% TCA and resuspend the pellet of precipitated stromal proteins directly in 25 µl SDS-PAGE sample buffer.

Prepare chloroplasts for alkaline extraction

6. Resuspend and lyse the chloroplast pellet from the in vitro import assay (see Basic Protocol, step 6 or 8) in 100 µl of ice-cold 0.1 M $NaCO_3$, pH 11.5, by pipetting the pellet into solution. Transfer to a fresh microcentrifuge tube.
7. Add another 900 µl of ice-cold 0.1 M $NaCO_3$, pH 11.5, and transfer the solution to a 3-ml polyallomer thick-walled ultracentrifuge tube. Incubate for 10 min on ice.
8. Ultracentrifuge the lysed chloroplasts for 30 min at 40,000 × *g*, 4°C, to pellet the membranes.

9. Carefully collect the supernatant containing the stroma and transfer to a fresh 3-ml ultracentrifuge tube. Resuspend the membrane pellet in 25 µl SDS-PAGE sample buffer.

Precipitate the alkaline extract and chloroplast stroma

10. Precipitate the alkaline supernatant by adding 100% TCA to a final concentration of 12%. Incubate for 1 hr on ice.

11. Collect the TCA precipitate by centrifuging for 30 min at 15,000 × *g*, 4°C.

12. Wash the pellet with 500 µl of 0.5% TCA and resuspend the pellet directly in 25 µl SDS-PAGE sample buffer.

13. Analyze all fractions by SDS-PAGE (*UNIT 6.1*) and fluorography or phosphorimagery (*UNIT 6.3*).

Fractionate chloroplasts

14. Resuspend the chloroplast pellet from the in vitro import assay (see Basic Protocol, step 6 or 8) in TE/DTT buffer containing 0.6 M sucrose to a concentration of 1 to 2 mg/ml chlorophyll. Let stand for 10 min on ice.

    If the protein import assay was performed with <0.5 mg chlorophyll, the chloroplasts from the import assay should be mixed with a nonradioactive chloroplast fraction to bring the chlorophyll content >0.5 mg. Fractionation of samples containing 1 to 2 mg chlorophyll by this procedure is ideal.

15. Freeze the chloroplast suspension for 1 to 2 hr at −20°C.

    It is essential to lyse the chloroplasts under hypertonic conditions to ensure maximum separation of outer and inner envelope membranes in the subsequent sucrose gradient fractionation (Keegstra and Yousif, 1986). The sample may be transferred to −80°C at this stage and stored indefinitely.

16. Thaw the suspension and dilute with 3 vol of TE/DTT buffer. Homogenize with 20 strokes in a Dounce or Potter homogenizer with a tight pestle.

17. Ultracentrifuge the lysed chloroplasts in a swinging-bucket rotor for 1 hr at 40,000 × *g*, 4°C.

18. Remove the brownish supernatant containing the stromal contents using a pipet and store at −20°C.

    The supernatant also might appear yellowish. This color indicates the presence of high levels of plastoglobules in the stroma. These low-density stromal lipid bodies are high in carotenoids.

Fractionate the chloroplast membranes

19. Resuspend the membrane pellet in TE/DTT buffer containing 0.2 M sucrose to a concentration of 1 to 2 mg chlorophyll/ml with 20 strokes in a Dounce or Potter homogenizer.

    The total chloroplast membranes may be stored at −80°C for at least 6 months or separated into thylakoid and envelope fractions, as described in subsequent steps.

20. Set up a sucrose step gradient consisting of 2 ml of 1 M sucrose, 1 ml of 0.8 M sucrose, and 1 ml of 0.46 M sucrose in 5-ml polyallomer tubes. Layer the membrane suspension onto the top.

    The gradients can be made during the centrifugation at step 17.

21. Apply 1 ml of membrane suspension (not >2 mg chlorophyll content) on each gradient. Ultracentrifuge the samples for 1.5 hr at 270,000 × *g*, 4°C, in a Beckman SW 50.1 rotor using low acceleration and deceleration rates.

    Alternatively, the membranes can be separated using a TLS-55 rotor in a Beckman TL 100 or equivalent centrifuge. The volumes of the steps for this rotor are 0.75 ml of 1 M sucrose, 0.5 ml of 0.8 M sucrose, and 0.5 ml of 0.46 M sucrose. The membrane suspension should not exceed 0.5 ml in volume and 1 mg chlorophyll content. Centrifuge the samples for 1.5 hr at 55,000 rpm at low acceleration and deceleration rates.

22. Collect the interface from each step of the gradient (~0.6 ml from each interface) with a 1-ml micropipettor.

    The upper (0.2:0.46 M sucrose) interface contains residual stroma and plastoglobules. The middle (0.46:0.8 M sucrose) interface is highly enriched in outer envelope membranes. The lower (0.8:1 M sucrose) interface is enriched in inner envelope membranes. The thylakoid membranes form a tight pellet at the bottom of the tube.

23. To collect the membranes, dilute each fraction with 3 to 5 vol TE/DTT buffer and centrifuge in a swinging-bucket rotor (e.g., Beckman SW-40) for 1.5 hr at 270,000 × *g*, 4°C. Remove the supernatant with a pipet and discard. Resuspend the pellets in a small volume of SDS-PAGE sample buffer for analysis.

SUPPORT PROTOCOL 1

ISOLATION OF INTACT CHLOROPLASTS FROM PEA

Intact chloroplasts capable of importing nuclear-encoded plastid proteins can be isolated from pea seedlings grown on soil (Chua and Schmidt, 1978; Cline, 1986; Pain and Blobel, 1987; Bruce et al., 1994). Peas have been used as the model system for chloroplast protein import because large amounts of material can be grown quickly and easily. Plants are typically grown in standard potting trays, in either greenhouse conditions or in growth chambers under long-day (12 to 16 hr) conditions. However, peas are easily propagated without growth chambers or greenhouses and can be grown on a well-lit windowsill. Plants should be watered regularly, and 10- to 14-day-old seedlings will yield ample import-competent chloroplasts.

Prior to beginning the isolation procedure, all buffers should be prepared and chilled on ice. All procedures should be performed on ice or in a cold room, and all centrifuges and rotors should be precooled to 4°C. Maintaining the temperature of the extract at or below 4°C throughout the procedure is essential for preventing degradation of chloroplast proteins by proteases. Proceeding as quickly as possible will also limit proteolysis. To limit degradation of chloroplast components that are particularly susceptible to proteolysis, a protease inhibitor cocktail can be included in all buffers throughout the procedure.

This procedure can also be used for the isolation of intact chloroplasts from other species, most commonly spinach (Joyard et al., 1982). Fresh young spinach leaves can be obtained from a local grocer for use with the procedure. However, the yield and import capacity of chloroplasts obtained using this source is unpredictable.

Materials

Pea seeds (*Pisum sativum* Green Arrow, Jung Seed)
Potting soil (e.g., Premier Brand Pro-Mix BX or Scotts Brand Metro Mix)
85% and 40% (v/v) PBF-Percoll (see recipe)
Grinding buffer containing 0.25% (w/v) bovine serum albumin (BSA) and 0.1% (w/v) ascorbic acid (see recipe), ice cold
Protease inhibitor cocktail (optional, e.g., Sigma-Aldrich, *UNIT 3.4*)
HEPES-sorbitol, pH 7.5 buffer (see recipe)
80% acetone
40% (v/v) DMSO (see recipe), ice cold
Liquid nitrogen

Standard potting trays (21.5 × 11 × 2.5–in.)
30-ml glass centrifuge tubes (Corex)
Scissors
2-liter beakers
Rotary homogenizer (Polytron or comparable with a 30-mm saw-tooth generator)
50-cm Miracloth squares
Large funnel (180-mm diameter)
250-ml centrifuge bottles with screw-cap lids
Superspeed centrifuge (e.g., Sorvall RC-5B)
Large rotor capable of holding 250-ml bottles (e.g., Sorvall GSA)
Swinging-bucket rotor capable of holding 50-ml tubes (e.g., Sorvall HB-4)
Large-bore pipet
Cryotubes

Prepare seeds and grow plants

1. Weigh 120 to 150 g of dry pea seeds and imbibe by submerging the seeds in water for ≥5 hr or overnight at room temperature.

2. Fill two standard potting trays 2/3-full with potting soil, and spread the seeds evenly over the surface of the soil. Cover seeds with a thin layer of soil, and water thoroughly, until soil is saturated.

3. Transfer the tray to a greenhouse or growth chamber, and grow plants under 12- to 16-hr days for 10 to 14 days at 20° to 25°C.

   The light intensity is not critical. Plants can be grown on a sunlit windowsill if growth facilities are not available. Peas prefer a moderate growth temperature not exceeding 30°C.

Prepare pea tissue

4. Prepare three PBF-Percoll step gradients by gently overlaying 7 ml of 40% PBF-Percoll onto a 5 ml layer of 85% PBF Percoll in 30-ml glass centrifuge tubes. Hold tubes on ice until needed (see step 12).

5. Harvest the aerial portions of 10- to 14 day-old pea seedlings from two flats (~100 to 140 g of tissue) by clipping the seedlings at the base of the first leaves with sharp scissors. Place the tissue in a 2-liter beaker placed on ice and chill for 10 min. Avoid transferring soil with the seedlings.

   The amount of tissue harvested may be scaled up or down depending on requirements; however, the ratio of tissue to buffer (see step 6) should be kept constant.

6. Add 1 liter of ice-cold grinding buffer containing 0.25% BSA and 0.1% ascorbic acid to the harvested tissue.

   (Optional) Add a protease inhibitor cocktail to the grinding buffer to a final concentration of 0.05% (v/v) and mix well immediately prior to adding to the tissue (Chen et al., 2000).

Homogenize pea tissue

7. Grind the pea leaves for 30 sec to 1 min using a rotary homogenizer at 80 rpm.

   Take care not to over aerate the solution with the generator. Grind until all seedlings have been homogenized and continue for 15 sec to adequately disrupt the tissue.

8. Pass the homogenate through two layers of 50-cm Miracloth squares held in place by a 180-mm diameter funnel, into another 2-liter beaker that has been pre-chilled on ice. Use two filtration systems to facilitate rapid filtration of the homogenate, passing equal volumes of the homogenate through each filter.

9. Transfer the filtrate immediately into four pre-cooled 250-ml centrifuge bottles and centrifuge in a pre-cooled rotor for 2 min at 1500 × *g*, 4°C, with the brake on and stop immediately.

Isolate chloroplasts

10. Carefully decant and discard the majority of the supernatant, leaving ~5 ml in each bottle.

    The chloroplasts will be in the pellet, which is very loose. Therefore, use caution when decanting the supernatant, so as not to disturb and lose the pellet. Do not be alarmed if the supernatant remains dark green after the centrifugation step. These are broken chloroplasts. Do not leave >5 ml of supernatant on the chloroplast pellet. If too much supernatant is decanted, simply add back several ml of grinding buffer to aid in resuspending the chloroplast pellet.

11. Carefully resuspend the chloroplast pellets in the remaining 5 ml of grinding buffer by gently swirling the bottles and then combine all the pellets into a single bottle.

    Resuspend the pellet with a gentle rotary motion. This step might require 5 min. Do not shake vigorously or resuspend by pipetting.

12. Transfer the chloroplast suspension equally onto the top of three previously prepared PBF-Percoll step gradients (see step 4). Centrifuge in a pre-cooled swinging-bucket rotor for 10 min at 1500 × *g*, 4°C, with the brake off.

    The PBF-Percoll step gradients should be prepared prior to beginning the preparation (step 4) in order to proceed as quickly as possible and limit proteolysis. The protease inhibitor cocktail may also be added to the gradient to prevent degradation of particularly susceptible chloroplast components. Transfer the chloroplasts using a large-bore pipet and avoid rapid pipetting.

13. Following centrifugation, observe two green bands. The upper band at the 40% PBF-Percoll/grinding buffer interface contains broken chloroplasts and cellular debris. The lower band located at the interface between the 40% and 85% PBF-Percoll layers contains the intact chloroplasts. Aspirate the grinding buffer and most of the 40% PBF-Percoll layers, leaving the 40%:85% PBF Percoll interface and the band of intact chloroplasts.

    It might be difficult to distinguish the two bands at the interfaces of the PBF Percoll gradients if the yield of chloroplasts is high. Aspirate the upper layers within 1 cm of the 40% and 85% PBF-Percoll interface.

14. Carefully remove the bands of intact chloroplasts from the three gradients with a large-bore pipet and transfer equal volumes into two 30-ml glass centrifuge tubes that each contain 20 ml of HEPES-sorbitol buffer, pH 7.5. Centrifuge for 2 min at 4000 × *g*, 4°C, with the brake on.

    The band of intact chloroplasts forms a tight, viscous layer in the PBF-Percoll gradient. Remove the layer and the chloroplasts that adhere to the side of the tube, being careful to transfer as little PBF-Percoll as possible.

15. Carefully decant and discard the supernatant as the pellet is very loose. Gently resuspend the pellet of intact chloroplasts in a small volume (1 to 2 ml) of HEPES-sorbitol buffer, pH 7.5, by swirling.

Quantitate chloroplast yield

16. Measure chlorophyll content (Arnon, 1949). Dilute 5 µl of the chloroplast resuspension into 1 ml of 80% acetone. Mix vigorously and microcentrifuge the extract for 2 min at maximum speed to remove the protein precipitate. Remove the supernatant to a clean tube.

The supernatant should be bright green and the pellet completely white. If the pellet retains some pigment, the sample should be mixed and microcentrifuged again before proceeding.

17. Measure the A_{652} of the sample against an 80% acetone blank. Calculate the chlorophyll concentration (mg/ml) by:

    $(A_{652}/36) \times 200$

    to compensate for the dilution factor.

    The typical yield of chloroplasts from two trays of 10- to 14-day-old seedlings (100 to 140 g tissue) is 25 to 40 mg chlorophyll.

    The chloroplasts also can be inspected visually with a bright-field microscope to assess intactness. Intact chloroplasts appear as smooth spherical bodies with enclosed green thylakoids. Chloroplasts from this procedure should be ~90% intact. Counting the chloroplasts using a hemacytometer will allow the investigator to establish the conversion of chlorophyll content to chloroplast number (i.e., chloroplasts/mg chlorophyll). This unit can be used for absolute quantitation of molecules of substrate imported per chloroplast in the in vitro import assays.

    The yield of chloroplasts from two trays of peas is greater than typically needed for a protein import assay with controls. However, the larger-scale preparation is provided because the chloroplasts from pea can be cryopreserved (see below) and used for subsequent import assays. Chloroplasts corresponding to 2 mg chlorophyll will provide sufficient material for a standard import assay with controls. As a result, the pea chloroplast isolation procedure can be scaled down if desired.

Cryopreserve chloroplasts

Intact chloroplasts isolated from pea seedlings can be stored in liquid N_2 and can be subsequently used for in vitro import assays (Yuan et al, 1991). Cryopreservation will lead to the loss of some intact chloroplasts (typically 40% to 50% loss). It is preferable to use freshly prepared chloroplasts whenever possible.

18. Gently resuspend the chloroplast pellet (step 15) in HEPES-sorbitol buffer, pH 7.5, to a concentration of 5 mg chlorophyll/ml by swirling on ice.

19. Measure the volume with a pipet. Add an equal volume of ice-cold 40% DMSO buffer drop-wise to the chloroplast suspension while gently swirling to give a final concentration of 20% DMSO. Allow the chloroplast mixture to equilibrate for 5 min on ice. Immediately pipet 0.5-ml aliquots into cryotubes on ice and snap freeze in liquid nitrogen.

20. Store the tubes under liquid nitrogen.

    Chloroplasts can be stored under these conditions for up to 3 months.

21. When ready to use, thaw the chloroplast suspension on ice and quickly dilute with an equal volume of HEPES-sorbitol buffer, pH 7.5. Layer over a cushion of 40% Percoll and centrifuge for 10 min at $3000 \times g$, 4°C.

22. Remove the buffer and 40% Percoll layers by aspiration.

    The yield of chloroplasts from the 40% Percoll step following cryopreservation is ~50% to 60%.

23. Gently resuspend the chloroplast pellet in the appropriate volume of ice-cold HEPES-sorbitol buffer, pH 7.5.

    The chloroplasts are ready to be used for an import assay (see Basic Protocol).

SUPPORT PROTOCOL 2

ISOLATION OF INTACT CHLOROPLASTS FROM *ARABIDOPSIS THALIANA*

Intact chloroplasts can be produced from *Arabidopsis* plants grown either on soil or on agar plates (Fitzpatrick and Keegstra, 2001). The growth conditions required to produce intact chloroplasts from soil-grown plants are not critical. A 12- to 16-hr day, at 20° to 25°C with a light intensity of 80 to 200 $\mu Em^{-2}sec^{-1}$ will suffice. Plants can be grown on trays or in pots. However, for a high yield, it is important to prevent the plants from experiencing stress, particularly from watering too much or too little. Yields may be improved slightly by destarching these plants by incubating for 12 to 24 hr in the dark before harvesting. Soil-grown plants that are between 3- and 5-weeks-old typically give the best yield of intact chloroplasts. However, chloroplasts isolated from plants grown on soil do not import precursor proteins efficiently in vitro. Therefore, to obtain import-competent chloroplasts from *Arabidopsis*, plants should be grown on agar plates.

The following method is geared to produce chloroplasts from petri plate–grown plants that are capable of importing precursor proteins. However, if a capacity for importing proteins is not required, the method also works for soil-grown plants, observing the modifications noted in the text.

The aerial portions of the plants are incubated with cell-wall-degrading enzymes to release protoplasts. These are collected, washed, and then ruptured. The chloroplasts that are released are purified on a Percoll gradient. Harvesting of protoplasts and chloroplasts, should be done as quickly as possible to ensure a good yield of high-quality chloroplasts. In *Arabidopsis*, this method has the advantage over the traditional method described in Support Protocol 1, as it produces a higher yield of chloroplasts (up to ten times greater), which import precursor proteins well. This method uses two petri plates containing 4-week-old plants (~10 g total of tissue), and yields 0.5 to 1 mg chlorophyll of intact chloroplasts. This method can be scaled up if more chloroplasts are desired, but caution is advised as yields can suffer because of the longer time needed to harvest protoplasts and chloroplasts from large amounts of tissue.

Materials

Murashige and Skoog growth medium (see recipe)
Seed sterilizing solution (see recipe)
Arabidopsis thaliana seeds, 30 to 40 mg per plate
Sterile, autoclaved water
0.1% (w/v) agarose (autoclaved, sterile)
Digestion buffer (see recipe)
Digestion enzyme solution (see recipe)
40% and 85% (v/v) AT Percoll (see recipe)
Protoplast resuspension buffer (see recipe)
Protoplast breakage buffer (see recipe)
HEPES-sorbitol buffer, pH 8.0 (see recipe)

Plastic petri plates, 20-25 mm × 150–mm diameter, sterile
Sterile laminar-flow hood
1.5-ml microcentrifuge tubes or 15-ml tubes
Platform shaker
Parafilm
Growth room or chamber (16-hr day, 70 to 120 $\mu Em^{-2}sec^{-1}$, 20° to 25°C)
Single-edge razor blades
100-mm petri dishes
500-ml beakers (optional)

Plastic wrap (optional)
60 W light source (optional)
30-ml glass centrifuge tubes (e.g., Corex)
200-µm nylon mesh (e.g., Sefar America), 100- to 120-mm squares, fashioned into a cone and stapled to hold its shape
Small funnel
50-ml centrifuge tubes
Tabletop centrifuge with swinging-bucket rotor, capable of slow acceleration and deceleration
Protoplast rupturing device (see recipe)
Superspeed centrifuge capable of 39,000 × *g*, with a 50-ml tube swing-out rotor
23-cm Pasteur pipet

Prepare plates

1. After autoclaving, allow the Murashige and Skoog growth medium to cool before pouring into the 150-mm diameter plates. Pour 50 ml of growth medium per plate in a sterile laminar-flow hood and allow to set.

   Plates may be used immediately, or stored in a sealed, sterile environment for up to 6 weeks at 4°C.

   Plants from about two plates, yielding 0.5 to 1 mg chlorophyll intact chloroplasts, are used for each chloroplast isolation procedure.

Prepare seeds and grow plants

2. Add 1 or 12 ml of seed sterilizing solution to seeds in a microcentrifuge tube (if sowing two plates) or a sterile 15-ml tube (for sowing 3 to 12 plates), respectively. Rock for 20 min at room temperature on a platform shaker.

3. Wash seeds four times with sterile water.

   Seeds may be centrifuged for 15 sec at 100 × g to facilitate washing. The supernatant can be decanted in a laminar-flow hood to maintain sterility.

4. Resuspend seeds in 0.1% (w/v) sterile agarose and dispense ~1 ml per plate in the laminar-flow hood. Add 2 to 3 ml sterile water to each plate. Tip and shake the plates to evenly distribute the seeds. Allow the plates to dry with lids slightly askew in a laminar-flow hood.

   Excess water can be removed from the plates by pipetting to speed the drying process.

5. When the plates are dry, seal with Parafilm and vernalize the seeds by incubating the plates at 4°C for 24 to 48 hr.

6. Transfer to a growth room (16-hr day, 70 to 120 $\mu Em^{-2}sec^{-1}$, 20° to 25°C).

   After several days, condensation may accumulate on the lids. Plants remain small in these conditions, growing no larger than 15 mm in diameter. Import-competent chloroplasts can be obtained from plants between 2 and 6 weeks of age (assuming obvious senescence or death has not occurred by 6 weeks). Plants that are 4-weeks-old work well as they provide ample tissue without evidence of senescence. Destarching of plate-grown plants, by incubating them in the dark, is not necessary.

Harvest the tissue

7. Harvest the entire aerial portions of the plants with a razor blade, and place immediately in a 100-mm petri dish containing 15 ml digestion buffer on ice. When all the tissue has been harvested, place the petri dish on a firm surface and chop the tissue rapidly for up to 1 min using a fresh razor blade.

The tissue should separate from the agar easily, and be chopped such that it is no longer matted. If soil-grown tissue is used, leaves or the entire green portion of the plants may be harvested. The larger soil-grown leaves can be gently sliced such that each leaf is cut at least once.

8. Drain the tissue and wash with 10 to 20 ml digestion buffer. Allow the dish to sit on ice for several minutes and swirl to release cell contents released during the chopping. Pour off the digestion buffer and repeat the washing process until the discarded buffer is no longer, or only faintly, green.

   The petri dish, with the lid held firmly on, may be held vertically over a beaker and allowed to drain, to facilitate washing. Typically, two to three washes are required.

Digest the tissue

9. Add 10 ml digestion enzyme solution to the drained tissue, swirl to mix, and distribute the tissue uniformly with fingertips.

   The ratio of tissue to enzyme solution is high, but there should be sufficient liquid such that it is visible when the petri dish is tilted. A small amount of additional digestion buffer may be added if necessary, to achieve this.

   The amount of digestion enzymes should be halved for soil-grown plants, such that the final concentrations are 2% cellulase, 0.4% macerozyme.

10. Place the petri dish by a window that receives indirect sunlight at ~50 to 100 $\mu Em^{-2}sec^{-1}$ and a temperature of 21° to 25°C for 4 to 5 hr.

    Alternatively, the digestion may be carried out in a 500-ml beaker, covered with plastic wrap, placed in a water bath at 23°C, and illuminated with a 60 W bulb.

    The digestion time required for soil-grown tissue is ~3 to 3.5 hr.

11. When digestion nears completion, prepare a 40% (10 ml): 85% (7 ml) AT Percoll step gradient in a 30-ml glass centrifuge tube and hold on ice.

    Alternatively, a 50% continuous AT Percoll gradient may be used. Prepare by mixing well 15 ml Percoll and 15 ml gradient buffer in a 50-ml centrifuge tube. Centrifuge for 30 min at 39,000 × g, 4°C, with the brake off. A swinging-bucket rotor is not essential at this step. Hold on ice.

12. When the tissue is sufficiently digested, it becomes a darker green and the bathing medium becomes green when swirled gently. Transfer the petri dish to ice.

    Refrain from swirling the tissue until it is reasonably certain that digestion is complete. Protoplasts may be less stable once released into the medium and yields can suffer. In soil-grown tissue, tiny holes appear in the leaves when digestion nears completion.

Harvest protoplasts

13. Harvest the protoplasts by gently swirling the petri dish for 30 to 60 sec and filtering the medium through a 200-µm mesh cone, fitted inside a small funnel, into a 50-ml centrifuge tube on ice.

    Using a 5-ml Gilson pipetman, with ~15 mm cut from the end of the tip, facilitates harvesting. Avoid splashing and dripping of the protoplast suspension by allowing it to run down the inside of the tube.

14. Transfer any tissue from the nylon mesh back into the petri dish and wash the tissue with 10 to 15 ml of fresh digestion buffer, filtering it into the same 50-ml centrifuge tube. Wash the tissue one or two times more until little green is released from the tissue.

    Usually this coincides with the centrifuge tube becoming full.

15. Centrifuge the protoplasts for 5 min at 100 × *g*, 4°C, in a swinging-bucket rotor using a slow-accelerating tabletop centrifuge.

16. Remove and discard the green supernatant carefully with a pipet. Be careful not to disturb the protoplast pellet as it is very loose. Resuspend the pellet in 5 ml protoplast resuspension buffer by gently swirling the pellet while the buffer is dispensed down the side of the tube.

    A few drops of the protoplast suspension may be removed at this stage for inspection under a light microscope.

17. Centrifuge the protoplasts for 2 min at 100 × *g*, 4°C, in a tabletop centrifuge.

Break the protoplasts

18. Remove the supernatant and resuspend the pellet in 5 ml protoplast breakage buffer using the technique described in step 16.

    Before resuspending the pellet, ensure that the tools needed are at hand and the centrifuge is prepared. Once the protoplasts are broken, the goal is to load the released chloroplasts on the Percoll gradient as quickly as possible to minimize their exposure to proteases or other inhibitory compounds from either the digestion enzymes or from the ruptured protoplasts.

19. Immediately transfer the resuspended protoplast pellet into the barrel of the protoplast rupturing device (see recipe). Holding the end of the device over a 50-ml centrifuge tube on ice, carefully replace the plunger and gently and firmly force the suspension through the layers of mesh. Repeat this procedure.

    A few drops of the suspension may be removed at this stage for inspection under a light microscope to ensure that all of the protoplasts have been ruptured. If this cannot be done quickly, it is prudent to assume that this has occurred so as not to delay loading the gradient.

Isolate chloroplasts

20. Quickly and carefully layer the broken protoplasts onto the AT Percoll step gradient (step 11). Centrifuge in a swing-out rotor for 10 min at 2500 × *g*, 4°C, with the brake off.

    If using a continuous gradient, centrifuge in a swing-out rotor for 10 min at 8000 × g, 4°C, with the brake off.

21. Following centrifugation, visualize two green bands in the gradient: an upper band of broken chloroplasts at the protoplast breakage buffer/40% AT Percoll interface, and a lower band of intact chloroplasts at the 40%/85% AT Percoll interface. Remove the load zone and the upper band of broken chloroplasts by aspiration. Harvest the lower band using a 23-cm Pasteur pipet and transfer to a 50-ml centrifuge tube.

    About 5 ml is typically harvested from the gradient.

22. Dilute with 40 to 45 ml HEPES-sorbitol buffer, pH 8.0, and centrifuge for 5 min at 700 × *g*, 4°C.

    The authors routinely use an AT Percoll step gradient because of the ease of reproducibility of the gradient and the sharp resolution of chloroplasts at the step interfaces. The linear gradient also will yield two major bands: one containing broken chloroplasts near the top of the gradient, and a second band of intact chloroplasts near the bottom of the tube. Occasionally, a third band may be visible between the upper and lower bands towards the top of the Percoll gradient. It is composed of mostly broken chloroplasts and should be ignored.

23. Carefully decant the supernatant and, without righting the tube, blot away all excess buffer. Resuspend the pellet in a small volume (200 to 300 µl) of HEPES-sorbitol buffer, pH 8.0 and quantify the chlorophyll (see Support Protocol 1).

Occasionally, Arabidopsis chloroplasts have a tendency to clump together when being resuspended. To minimize this, swirl the pellet gently to loosen it, and continue to swirl while adding the HEPES-sorbitol buffer, pH 8.0, drop-wise. It may be necessary to gently pipet the suspension up and down to completely resuspend the pellet.

SUPPORT PROTOCOL 3

PRODUCTION OF [^{35}S]METHIONINE-LABELED IMPORT SUBSTRATE BY IN VITRO TRANSLATION

Typically, chloroplast-targeted proteins to be used as import substrates are synthesized as [^{35}S]methionine-labeled proteins using an in vitro translation system. These proteins can be made using the methods outlined in *UNIT 11.2* or using commercially available coupled transcription-translation systems (e.g., Promega). The coupled systems are relatively easy to use and generally produce enough substrate to be used in multiple import reactions. There has been some suggestion that wheat-germ extracts are preferable for producing import substrates to be used in chloroplast import assays, since they are plant-based. However, in practice, import substrates produced using rabbit reticulocyte lysates are efficiently imported into chloroplasts as well. Therefore, the method used to produce the import substrate will depend on which system is best suited for the individual protein being tested.

Materials

Expression vector harboring the gene that encodes protein to be used as import substrate
Plasmid isolation kit (e.g., Qiagen Plasmid Midi kit)
In vitro translation kit (e.g., TNT Coupled Reticulocyte Lysate system, Promega)
Destain solution (see recipe)
Image acquisition software (e.g., Molecular Dynamics)
Additional reagents and equipment for SDS-PAGE gel (*UNIT 6.1*)

In vitro translate [^{35}S]methionine-labeled import susbstrate using commercial reticulocyte lysate coupled transcription-translation system

1. Isolate the expression vector harboring the gene that encodes the protein to be used as an import substrate from an overnight culture of *E. coli*.

   Many commercial plasmid-isolation kits can be used for this purification. It is recommended that the isolated plasmid be extracted with phenol/chloroform prior to being used for in vitro transcription/translation. Novagen's pET series of vectors that use the T7 promoter work well for in vitro transcription/translation of proteins.

2. Follow the manufacturer's instructions for synthesizing [^{35}S]methionine-labeled protein.

   Promega's TNT Coupled Reticulocyte Lysate system produces ample, high-quality translation product that can be used for numerous import assays.

3. Run a small aliquot (0.5- to 1-µl) of the translation product on an SDS-PAGE gel (*UNIT 6.1*). Fix the gel in destain solution for 30 min and dry under a vacuum. Expose to a storage phosphor screen overnight (*UNIT 6.3*).

4. View an image of the gel and quantify the radioactivity for each of the translation products using commercial software.

   Adjust the amount of translation product used in the in vitro import assay to be at least 10,000 cpm (see Basic Protocol).

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

AT Percoll, 40% (v/v)

40% (v/v) Percoll (Sigma-Aldrich)
50% (v/v) gradient buffer (see recipe)
Store up to 1 month at −20°C and thaw before use

Optional, for isolating Arabidopsis chloroplasts using a Percoll step gradient.

AT Percoll, 85% (v/v)

For 50 ml:
42.5 ml Percoll (Sigma-Aldrich; final 85%)
2.5 ml 1 M HEPES-KOH, pH 7.3 (final 50 mM)
3.01 g sorbitol (final 330 mM)
H_2O to 50 ml
Store up to 1 month at −20°C and thaw before use

Optional, for isolating Arabidopsis chloroplasts using a Percoll step gradient.

Chloroplast import master mix, 50 ml

For 50 ml:
2.5 ml 1 M HEPES-KOH, pH 7.5 (final 50 mM)
3.01 g sorbitol (final 330 mM)
2.5 ml 1 M magnesium acetate (final 50 mM)
2.5 ml 5 M potassium acetate (final 250 mM)
H_2O to 50 ml
Store up to 4 weeks at 4°C

DMSO, 40% (v/v)

For 10 ml:
250 µl 1 M HEPES-KOH, pH 7.5 (final 25 mM)
0.0613 g sorbitol (final 330 mM)
4 ml DMSO (final 40% v/v)
H_2O to 10 ml
Store up to 2 weeks at 4°C

Destain solution

45% (v/v) methanol
10% (v/v) acetic acid
Store indefinitely at rom temperature

Digestion buffer

For 400 ml:
8 ml 1 M MES-KOH, pH 5.2 (final 20 mM)
29.13 g sorbitol (final 400 mM)
200 µl 1 M $CaCl_2$ (final 0.5 mM)
H_2O to 400 ml
Store up to 2 weeks at 4°C

Digestion enzyme solution

Dissolve 0.4 g cellulase "onozuka" R 10 (e.g., Yakult, Kanematsu) and 0.08 g macerozyme R 10 (e.g., Yakult, Kanematsu) in 10 ml digestion buffer (see recipe). Centrifuge for 5 min at 2000 × g to pellet insoluble materials. Use supernatant immediately.

The volume, 10 ml, is enough for two plates of Arabidopsis.

continued

Gradient buffer

For 100 ml:

10 ml 1 M HEPES-KOH, pH 7.3 (final 100 mM)
12.03 g sorbitol (final 660 mM)
100 µl 2 M $MgCl_2$ (final 2 mM)
200 µl 1 M $MnCl_2$ (final 2 mM)
800 µl 0.5 M EDTA (final 4 mM)
0.2 g BSA (final 0.2%)
H_2O to 100 ml
Store up to 2 weeks at 4°C

Grinding buffer

For 2 liters:

50 ml 1 M HEPES-KOH, pH 7.7 (final 25 mM)
120.25 g sorbitol (final 330 mM)
8 ml 0.5 M EDTA (final 2 mM)
1 ml 2 M $MgCl_2$ (final 1 mM)
2 ml 1 M $MnCl_2$ (final 1 mM)
H_2O to 2 liters
Store up to 2 weeks at 4°C

Just prior to use, add BSA to a final concentration of 0.25% (w/v) and sodium ascorbate to a final concentration of 5 mM (0.1% w/v).

HEPES-sorbitol buffer, pH 7.5

For 500 ml:

12.5 ml 1 M HEPES-KOH, pH 7.5 (final 25 mM)
30.06 g sorbitol (final 330 mM)
H_2O to 500 ml
Store up to 2 weeks at 4°C

HEPES-sorbitol buffer, pH 8.0

For 100 ml:

5 ml 1 M HEPES-KOH, pH 8.0 (final 50 mM)
6.01 g sorbitol (final 330 mM)
H_2O to 100 ml
Store up to 2 weeks at 4°C

Murashige and Skoog growth medium

1 liter for 20 plates:

4.4 g Murashige and Skoog salt and vitamin mix with buffer (e.g., Life Technologies)
10 g sucrose
H_2O to 800 ml
Adjust pH to 5.7 with 1 M KOH
H_2O to 1 liter
Add 8 g Phytagar (e.g., Life Technologies)
Autoclave
Allow to cool to touch
Pour into large, sterile petri dishes
Allow plates to set and dry
Store unused plates, sealed in a bag, up to 6 weeks at 4°C

If a Murashige and Skoog salt and vitamin mix without buffer is used, supplement with 50 mM MES-KOH, pH 5.7.

PBF-Percoll

For 170 ml:
5.1 g polyethylene glycol 4000
1.7 g BSA
1.7 g Ficoll
Percoll (Sigma-Aldrich) to 170 ml
Store up to 1 month at −20°C

PBF-Percoll, 40% (v/v)

For 50 ml:
20 ml PBF-Percoll (final 40%)
1.25 ml 1 M HEPES-KOH, pH 7.5 (final 25 mM)
3.01 g sorbitol (final 330 mM)
200 µl 0.5 M EDTA (final 2 mM)
25 µl 2 M $MgCl_2$ (final 1 mM)
0.0077 g glutathione (reduced; final 500 µM)
0.05 g sodium ascorbate (final 0.1%)
H_2O to 50 ml
Store up to 1 month at −20°C, thaw immediately before use

PBF-Percoll, 85% (v/v)

For 50 ml:
42.5 ml PBF-Percoll (final 85%)
1.25 ml 1 M HEPES-KOH, pH 7.5 (final 25 mM)
3.01 g sorbitol (final 330 mM)
200 µl 0.5 M EDTA (final 2 mM)
25 µl 2 M $MgCl_2$ (final 1 mM)
0.0077 g glutathione (reduced; final 500 µM)
0.05 g sodium ascorbate (final 0.1%)
H_2O up to 50 ml
Store up to 1 month at −20°C, thaw immediately before use

Percoll, 40% (v/v)

For 50 ml:
20 ml Percoll (Sigma-Aldrich; final 40%)
2.5 ml 1 M HEPES-KOH, pH 7.5 (final 50 mM)
3.01 g sorbitol (final 330 mM)
H_2O to 50 ml
Store up to 1 month at −20°C, and thaw before using

Protoplast breakage buffer

For 50 ml:
1 ml 1 M tricine-KOH, pH 8.4 (final 20 mM)
2.733 g sorbitol (final 300 mM)
0.5 ml 0.5 M EDTA (final 5 mM)
0.5 ml 0.5 M EGTA (final 5 mM)
0.042 g $NaHCO_3$ (final 10 mM)
H_2O to 50 ml
Store up to 2 weeks at 4°C
Immediately before use add 0.05 g BSA (final 0.1% w/v)

continued

Protoplast resuspension buffer

For 50 ml:
8 ml 1 M MES-KOH, pH 6.0 (final 20 mM)
29.13 g sorbitol (final 400 mM)
200 µl 1 M $CaCl_2$ (final 0.5 mM)
H_2O to 50 ml
Store up to 2 weeks at 4°C

Protoplast rupturing device

10-ml disposable syringe
10-µm nylon mesh, 30- to 35-mm square
20-µm nylon mesh, 30- to 35-mm square
Electrical tape, 15- to 20-mm wide

Cut off the end of the syringe barrel so that it resembles a hollow tube. Put the 10-µm mesh on top of the 20-µm mesh and place both over the cut end of the syringe such that the 10-µm mesh faces the outside and the 20-µm mesh is against the syringe barrel. Fix the mesh in place using the electrical tape to hold the two layers of mesh to the sides of the syringe leaving the mesh exposed at the end of the barrel.

This procedure is tricky. The meshes must be very firmly taped to the barrel or leaks will occur during use. Use a lot of electrical tape, wrapping it multiple times, overlapping the tape as far as half way down the syringe barrel and back up to the top. Constantly, and very firmly pull and stretch the tape to ensure a good seal. Both 20- and 10-µm meshes are used to more gently rupture large protoplasts (with 20-µm mesh), before more rigorously rupturing smaller protoplasts (with 10-µm mesh).

Seed sterilizing solution

1.5% (w/v) sodium hypochlorite (dilute commercially available bleach accordingly)
0.02% (v/v) Triton-X 100
Store at room temperature until used

SDS-PAGE sample buffer

For 1 ml:
350 µl 1 M Tris base (final 350 mM)
250 µl 20% (w/v) SDS (final 5% (w/v)
80 µl 1 M dithiothreitol (DTT; final 80 mM)
150 µl 50% (v/v) glycerol (final 7.5%)
10 µl saturated bromophenol blue
160 µl H_2O
Store at −20°C until used

TE/DTT buffer

For 50 ml:
2.5 ml 1 M tricine-KOH, pH 7.5 (final 50 mM)
200 µl 0.5 M EDTA (final 2 mM)
50 µl 1 M dithiothreitol (DTT; final 1 mM)
47.25 ml H_2O
Store up to 2 weeks at 4°C

Thermolysin, 2 mg/ml

Dissolve 2 mg thermolysin in 1 ml HEPES-sorbitol buffer (see recipe). Divide into 50-µl aliquots and store up to 6 months at −80°C. Do not freeze/thaw more than one time.

Trichloroacetic acid (TCA), 100% and 0.5%

To make 100% (w/v) TCA, add 227 ml of water directly to a bottle containing 500 g of solid TCA. Dissolve by shaking the closed container. Dilute part of the 100% solution to 0.5% (w/v) with an appropriate volume of water. Store indefinitely at room temperature.

COMMENTARY

Background Information

Traditionally, pea chloroplasts have been used as a model system for measuring chloroplast precursor protein import. The pea offers the advantages of the ability to obtain large amounts of material that can be grown quickly and easily, and rapid and simple isolation of intact import-competent chloroplasts. The basic mechanism of protein import into chloroplasts appears to be conserved across diverse plant species. In fact, isolated pea chloroplasts are capable of importing preproteins from species as far removed as the algae (Mishkind et al., 1985; Yu et al., 1988; Su and Boschetti, 1994). This makes the pea an ideal system for investigating protein targeting to chloroplasts, and in most cases, the demonstration of preprotein import and processing in pea chloroplasts is sufficient to establish chloroplast localization. However, the growing importance of *Arabidopsis thaliana* as a model system for the investigation of genetic, molecular, and cellular processes in plants makes it desirable to use a homologous biochemical system to analyze chloroplast targeting. In particular, the identification of gene families encoding components of the import apparatus in the complete *Arabidopsis* genome has focused considerable attention on *Arabidopsis* as a model for investigating the molecular mechanism of the import reaction (Jackson-Constan and Keegstra, 2001). The methods for isolating functional chloroplasts from *Arabidopsis* are less developed than those for pea, but experimental amounts of import-competent chloroplasts can now be isolated from *Arabidopsis* (Fitzpatrick and Keegstra, 2001).

Critical Parameters

The yield and import-competence of chloroplasts is directly related to the age and condition of the plant material. The plant material should be obtained from young seedlings. The protein import capacity of chloroplasts is developmentally regulated (Dahlin and Cline, 1991). The highest import capacities are observed in chloroplasts from young, rapidly growing tissues. Therefore, allowing plants to grow larger to obtain more material or isolating chloroplasts from mature plants will result in low import yields.

Temperature is one of the most important parameters that will determine the quality of chloroplasts isolated by these protocols. As stated above, it is essential that all reagents for the isolation of chloroplasts from both species be kept ice-cold and that all procedures be performed on ice or in a cold room to ensure that the extracts never warm up during isolation. The degradation of components of the import machinery during chloroplast isolation has been documented, and although protease inhibitor mixtures can aid in preventing degradation, they are only moderately effective (Bolter et al., 1998; Chen et al., 2000). The best approach to minimize degradation is to work quickly and in the cold. In addition, it is preferable to work in moderate to low light conditions during the isolation procedure. This will prevent photooxidation-induced damage to the chloroplasts.

Freshly isolated chloroplasts can be stored on ice for up to 30 min before initiating the import assay. However, as stated for the isolation procedure, it is best to have all reagents for the import assay assembled and ready to proceed directly to the import assay following the isolation procedure.

Troubleshooting

The potency of the cell wall–degrading enzymes used to generate the *Arabidopsis* protoplasts can vary. Therefore, if yields of protoplasts or chloroplasts from *Arabidopsis* (see Support Protocol 2) seem low, it may be necessary to adjust the digestion time accordingly. Since the enzyme preparations are rather crude and may contain many other degradative enzymes that could decrease yield, use caution when extending digestion times. In addition, it is important not to agitate the tissue during the digestion but to swirl the tissue thoroughly to release the protoplasts only when digestion is complete.

Import efficiency of precursor proteins (see Basic Protocol) varies widely. Should effi-

ciency be <20% of the added import substrate or if it is difficult to detect the imported product, it may be necessary to increase the amount of translation product or chloroplasts used in the assay.

Some proteins, particularly those targeted to the chloroplast envelope, may be susceptible to proteolysis by proteases that co-purify with chloroplasts. It may be possible to limit this proteolysis by performing the import reaction at 20°C, rather than 26°C (see Basic Protocol).

Anticipated Results

The expected results from an import assay will vary depending on the preprotein being studied. All proteins targeted to the internal compartments of the chloroplast contain a cleavable *N*-terminal transit peptide that is removed in the stroma after translocation across the envelope. Therefore, a protein imported into the stroma will have a lower molecular weight than its precursor form prior to import. While the length of transit peptides varies greatly (Chen and Schnell, 1999; Keegstra and Cline, 1999), in most cases the reduction in molecular weight (3000 to 10,000 Da) should be large enough to be easily detected by SDS-PAGE analysis. In order to confirm that the lower molecular weight protein has been imported, chloroplasts are treated with the protease thermolysin following the import reaction. At least 70% of the lower-molecular-weight protein should be protected from proteolysis to confirm that import to the stroma has taken place. Often, both processed and unprocessed forms of the import substrate will be detected in chloroplasts before treatment with exogenous protease. The unprocessed form of the precursor protein represents protein that is nonspecifically associated with the outer chloroplast envelope or bound to components of the import apparatus at the early, binding stages of import. The unprocessed form should therefore be removed by treatment with thermolysin. Thermolysin treatment can also be used to confirm that outer envelope membrane proteins have been integrated. In this case, the thermolysin will degrade only those portions of the protein exposed to the exterior of the chloroplast, leaving a predictable portion of the protein protected from proteolysis. In addition, resistance to alkaline extraction can be used to confirm the integration of membrane proteins.

Time Considerations

Chloroplast isolation from pea should not take >1 hr from the time of tissue homogenization to isolation of the intact chloroplasts. The entire time for the procedure, including gradient preparation and chlorophyll determination, may take ~2 hr. Isolation of chloroplasts from *Arabidopsis* takes considerably longer, as the tissue is digested with protoplast-forming enzymes for 4 to 5 hr. Isolation of intact chloroplasts from protoplasts takes an additional 45 to 60 min. The in vitro import assay requires 20 to 30 min of incubation time and additional time to re-isolate and process the chloroplasts following import. This time can vary from 2 to 8 hr depending on the method used to treat the chloroplasts and the degree of chloroplast subfractionation. A polyacrylamide gel takes 2 to 3 hr to run, 30 min to fix, and 30 to 60 min to dry. The gel is then exposed to a storage phosphorimaging screen or X-ray film overnight (16 hr) or longer, depending on the strength of signal and efficiency of import.

In Vitro RNA Splicing in Mammalian Cell Extracts

Almost every eukaryotic pre-mRNA generated by RNA polymerase II transcription requires the removal of introns to create mRNA. The correct splicing of constitutive exons is thus critical for normal protein expression and function. Moreover, the removal of many introns by the spliceosome is controlled in a tissue-specific or developmentally specific manner. The differential skipping or inclusion of exons in the final mRNA is called alternative splicing, and often leads to changes in the final protein product. By this mechanism, a finite number of genes in the genome can code for a more complex proteome. Aberrant splicing can lead to a disease state by altering the protein products of a gene. Thus, understanding the regulation of many genes requires a study of the splicing of their RNA products.

In order to study RNA splicing at a biochemical level, it is necessary to employ an in vitro, or cell-free, system. Cell-free splicing systems require two main components: (1) an extract made from mammalian cell nuclei and (2) the introns and exons of the eukaryotic gene of interest, cloned downstream from a prokaryotic phage promoter, such as T7 or SP6. This minigene construct allows the synthesis of sufficient quantities of pre-mRNA substrates in vitro, which are then incubated in the nuclear extract and analyzed for splicing. Nuclear extracts, first developed for studying transcription in vitro (*UNIT 11.6*), were subsequently modified for splicing (Support Protocol 1). Extracts are commonly generated from the HeLa cell line, but other cell lines and tissues can be used (Support Protocol 2). This is important when studying the regulation of an exon that is alternatively spliced in different cell types. These extracts can be used for functional studies of splicing and for isolation and characterization of splicing factors. This unit describes how to set up an in vitro splicing reaction (see Basic Protocol 1) using a mammalian nuclear extract derived from either cell line or tissue, and how to analyze the splicing reaction products (see Basic Protocol 2).

CREATING A MINIGENE CONSTRUCT FOR TESTING A NOVEL SUBSTRATE

To study the splicing of a gene of interest, its exons and introns must be cloned downstream of a bacteriophage promoter to create a minigene construct. Minigenes are subcloned from genomic DNA. It is difficult to analyze the splicing of introns larger than 1000 nucleotides in vitro. This is because lariat intermediates containing long introns cannot be resolved in a single denaturing acrylamide gel with smaller splicing intermediates and products (see Basic Protocols 1 and 2). Since mammalian introns can be very long (much longer than 1000 nucleotides), it is often not possible to test a full-length intron in an in vitro splicing reaction. This problem is overcome by deleting stretches of intron sequence that are not critical for splicing regulation.

Before testing the splicing of the original genomic clone and deletion mutants in vitro, it is necessary to test them in vivo. This will confirm that any shortened minigene version of the gene shows proper splicing and regulation. To test the splicing substrates in vivo, the equivalent minigene can be constructed in a mammalian expression vector and transfected into the appropriate cell line(s). After transfection and the appropriate incubation period, RNA is harvested from the cells and the percentage of inclusion or skipping of the exon in the mRNA is assayed by primer extension, RT-PCR, and ribonuclease protection assays. Further deletions can be made based on the initial in vivo results. One

Current Protocols in Cell Biology (2003) 11.17.1-11.17.20

way to guess which sequences are important in splicing regulation is through comparing the same intronic sequences of different species. Phylogenetically conserved intronic sequences are likely to be more important in splicing regulation than those sequences that are divergent. The goal is to create a minigene with short introns while maintaining the regulation of splicing of the exon. Once this has been achieved, the minigene can then be subcloned downstream of a bacteriophage promoter and used in the in vitro system.

NOTE: All reagents for these protocols should be high-quality, molecular-biology grade, and RNase- and DNase-free. All glass and plasticware should be RNase-free. Care should be taken to avoid RNase contamination (also see *APPENDIX 2A* for considerations when working with RNA).

BASIC PROTOCOL 1

IN VITRO SPLICING OF PRE-MESSENGER RNA

Methods for in vitro splicing of pre-mRNA in nuclear extract derived from animal cell lines or tissues have been described for many years (Hernandez and Keller, 1983; Padgett et al., 1983; Hardy et al., 1984; Krainer et al., 1984; Rio, 1988; Kramer and Keller, 1990; Black, 1992; and Eperon and Krainer, 1994). In these protocols, a uniformly radiolabeled pre-mRNA is incubated for several hours in nuclear extract supplemented with salts and other required cofactors. The RNA is then extracted from the nuclear extract, subjected to denaturing polyacrylamide gel electrophoresis, and visualized by autoradiography of the dried gel on film or a phosphor imager screen. The pre-mRNA and the reaction products and intermediates are identified as bands on the autoradiogram (see Basic Protocol 2).

Materials

Buffer DG (see recipe)
10 mM ATP
0.5 M creatine phosphate
55 mM $MgCl_2$
20% (w/v) polyethylene glycol 3350 (PEG; mol.wt. 3350; Sigma)
Nuclear extract (Support Protocols 1 and 2)
20 U/µl RNase inhibitor (RNA guard; Amersham Pharmacia Biotech; Ribonuclease Inhibitor, porcine)
5 to 20 fmol/µl uniformly radiolabeled pre-mRNA splicing substrate (Support Protocol 3)
20 mg/ml proteinase K (Amersham Pharmacia Biotech)
10% (w/v) sodium dodecyl sulfate (SDS; *APPENDIX 2A*)
1.1× PCA buffer (see recipe)
25:24:1 (v/v/v) phenol/chloroform/isoamyl alcohol (PCA)
20 mg/ml glycogen (Roche)
100% ethanol, ice-cold
RNA loading buffer (see recipe)

30°C and 80°C water baths or heating blocks
Whatman 3MM filter paper
Kodak XAR X-ray film (standard 14 × 17–in.) with intensifying screen, or phosphor imager screen and imager (e.g., PhosphorImager from Molecular Dynamics or equivalent; see *UNIT 6.3*)

Additional reagents and equipment for denaturing PAGE of nucleic acids (*APPENDIX 3A*) and autoradiography (*UNIT 6.3*)

Prepare splicing reaction

1. Place microcentrifuge tube(s) on ice and add in the order indicated:

≤15 µl buffer DG (for total of 15 µl buffer DG and nuclear extract)

1 µl 10 mM ATP

1 µl 0.5 M creatine phosphate

1 µl 55 mM $MgCl_2$ (2.2 mM final)

2.5 µl 20% PEG 3350

≤15 µl nuclear extract (for total of 15 µl buffer DG and nuclear extract)

H_2O to bring total volume of reaction to 24 µl

0.5 µl 20 U/µl RNase inhibitor.

The sum of the volumes of buffer DG and the nuclear extract should equal 15 µl, or 60% of the total reaction volume. The splicing activity of the nuclear extract will vary with each nuclear extract preparation. Also, different pre-mRNAs will splice with different efficiencies in each nuclear extract preparation; thus the amount of extract used in a splicing reaction should be titrated with respect to each pre-mRNA being tested. In addition, the splicing efficiencies of different pre-mRNAs can be affected by the concentration of $MgCl_2$ (see Critical Parameters). Therefore, the amount of $MgCl_2$ should also be titrated to optimize the splicing reaction. The use of PEG 3350 and RNase inhibitors is not always necessary. For notes on RNase contamination, see Critical Parameters in the Commentary section.

The total reaction volume can be scaled up if needed. Other protocols have been used in which the total reaction volume can vary from 10 to 50 µl.

2. Remove the reaction mixture(s) from the ice, mix by gently flicking the tube, and incubate in a 30°C water bath or heating block for 8 to 10 min.

3. Add 1 µl of a solution containing 5 to 20 fmol radiolabeled pre-mRNA to bring the total reaction volume to 25 µl. Mix the reagents by gently flicking the microcentrifuge tube. Centrifuge briefly to collect any droplets on the side of the tube and continue incubating at 30°C for 2 to 4 hr.

   The duration of the incubation is dependent on the rate of splicing for a particular pre-mRNA substrate, i.e., the percent conversion to intermediates and products as a function of time. The rate and overall splicing efficiency of a particular substrate is determined by doing a time-course experiment. Doing a time course can also help in identifying the splicing reaction products (see Basic Protocol 2). For some pre-mRNAs, splicing is readily detectable within 2 hr or less, but weaker substrates may take up to 4 hr to accumulate sufficient intermediates and products for analysis.

4. Terminate the splicing reaction by adding 3 µl of 20 mg/ml proteinase K and 2 µl of 10% SDS to the reaction. Continue to incubate at 30°C for 20 to 30 min.

Extract and separate RNA products

5. Add 370 µl 1.1× PCA buffer and 200 µl of 25:24:1 PCA. Vortex well. Microcentrifuge 1 min at maximum speed, room temperature.

   Adding 370 ml of 1.1× PCA buffer to the splicing reaction (25 µl) will bring the final concentration of PCA buffer to ~1×.

6. Transfer the upper, aqueous layer to a new microcentrifuge tube.

7. Add 1 µl of 20 mg/ml glycogen (to act as a carrier for the RNA) and 1.0 ml of ice-cold 100% ethanol. Mix well. Incubate on dry ice for 10 min or overnight at −20°C. Microcentrifuge 10 min at maximum speed, 4°C, to collect the pellet of RNA at the bottom. Carefully remove as much supernatant as possible, being careful not to disturb the pellet.

A drawn-out Pasteur pipet can aid in removing the last droplets.

8. Dry the pellet in a Speedvac evaporator for 1 min.

   If a Speedvac evaporator is not available, the pellet may be dried on the benchtop for 10 min.

9. Pour the appropriate percentage denaturing polyacrylamide gel (*APPENDIX 3A*).

   The gel should be poured using a large gel-running apparatus (30 × 40-cm gel or approximate equivalent), and it should contain 8 M urea, 0.5× or 1× TBE, 19:1 acrylamide:bisacrylamide, and 4% to 12% total acrylamide. The lariat intermediates formed during splicing will have anomalous electrophoretic mobility when run in a denaturing gel. This, and the sizes of the pre-mRNA and free exon, should be taken into account when deciding what percentage polyacrylamide gel to use and how far to run it. For pre-mRNAs between 350 nucleotides to 550 nucleotides, 6% to 8% polyacrylamide gels are standard. See Basic Protocol 2 for additional considerations regarding this denaturing PAGE step.

10. Resuspend the pellet in 8 to 10 µl RNA loading buffer by vortexing, heat to 80°C for 5 min, load on the denaturing polyacrylamide gel, and separate the RNA by denaturing PAGE (*APPENDIX 3A*).

11. Dry the gel on Whatman 3MM filter paper on a gel dryer. Visualize the RNA by autoradiography on 14 × 17–in. Kodak film or a large phosphor imager screen.

    Both of these visualization techniques are described in UNIT 6.3

BASIC PROTOCOL 2

ANALYSIS OF SPLICING REACTION RNA PRODUCTS

During the first step of splicing, the RNA is cleaved at the 5′ splice site between the first exon and the intron, and this intron 5′ end forms a 2′-5′ phosphodiester bond at the branch-site adenosine (Fig. 11.17.1). This generates a free 5′ exon and lariat-3′ exon intermediate. During the second step of splicing, the 3′ splice site is cleaved and the two

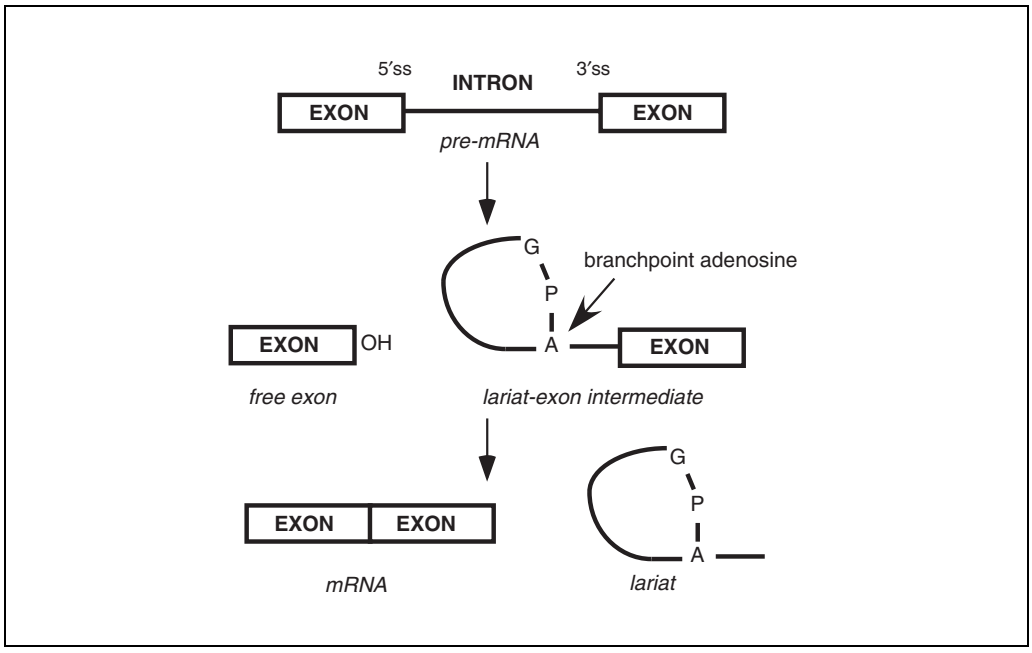

Figure 11.17.1 The splicing pathway of a two-exon, one-intron pre-mRNA. In the first step of splicing, the 2′ hydroxyl of the branchpoint adenosine attacks the 5′ end of the intron, creating a 2′-5′ phosphodiester bond. Two intermediates are generated, a free exon and a lariat-exon intermediate. In the second step, the 3′ hydroxyl of the free exon attacks the phosphate at the 3′ splice site. The lariat is released, and the two exons are ligated together, generating the final mRNA.

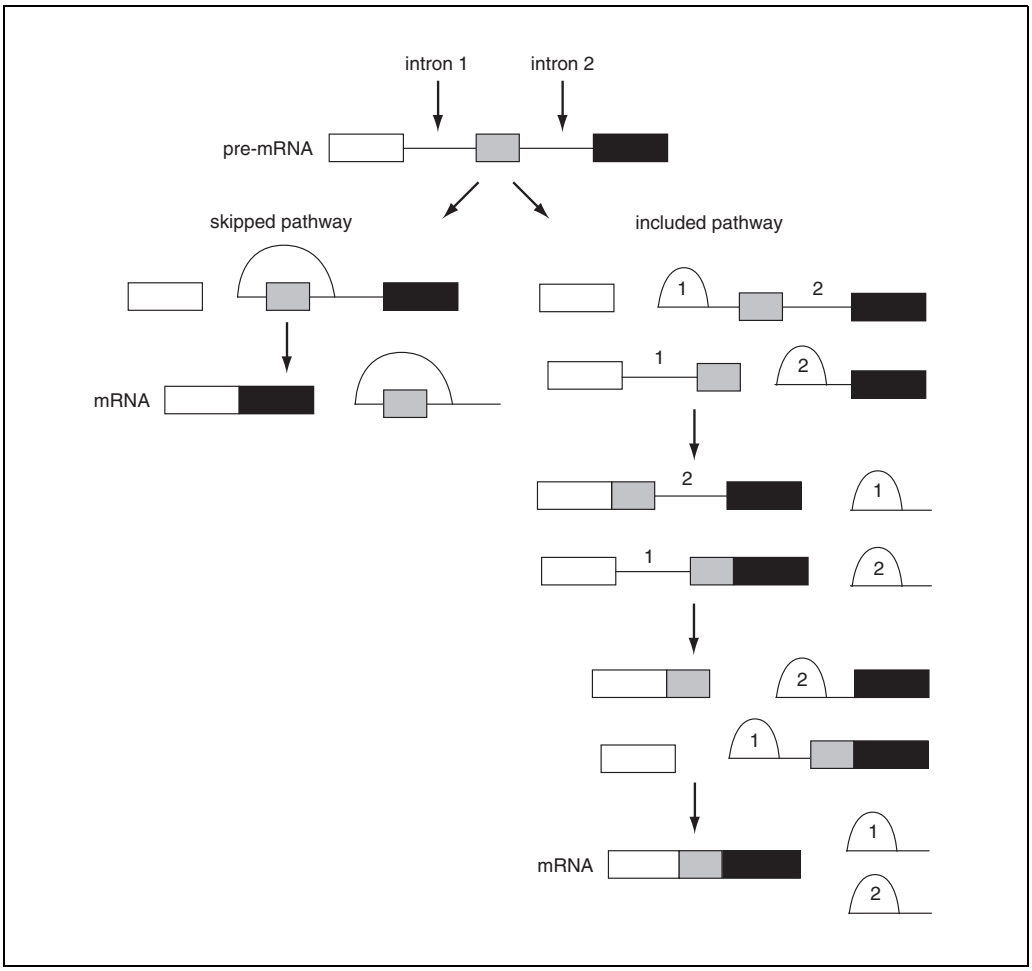

Figure 11.17.2 The splicing pathway of a three-exon, two-intron pre-mRNA. A pre-mRNA with three exons and two introns can proceed through two pathways, where the middle exon is either skipped or is included. In the included pathway, either the upstream or downstream intron can be spliced out first. Illustrated are the intermediates and products in both the skipped and included pathways.

exons are joined together, generating the final linear mRNA and the excised lariat intron. The pre-mRNA, lariat intermediate, free exon intermediate, lariat product, and final mRNA product will have distinct mobilities on a denaturing polyacrylamide gel, creating a pattern of bands. These bands will appear differentially over time. For example, the bands for the lariat intermediate and the 5′ exon intermediate will appear earlier than the final mRNA and lariat intron bands.

The splicing pattern of a two-exon, single-intron pre-mRNA is relatively simple. However, when studying regulated exons it may be useful to utilize a three-exon, two-intron pre-mRNA. The complexity of products resulting from pre-mRNAs that undergo multiple splicing patterns makes the identification of bands and the interpretation of the results more difficult. Figure 11.17.2 illustrates the intermediates and products expected in the splicing pathway of a three-exon, two-intron pre-mRNA. Figure 11.17.3 is a gel image for such a pre-mRNA, which was spliced in vitro in HeLa nuclear extract. The latter figure demonstrates the type of splicing pattern expected with a more complex substrate. Note that, in addition to the more prominent darker bands corresponding to splicing intermediates and products, a number of other bands may appear. These are most often caused by RNA degradation in the extract, as well as by radiolysis, and are often unavoidable.

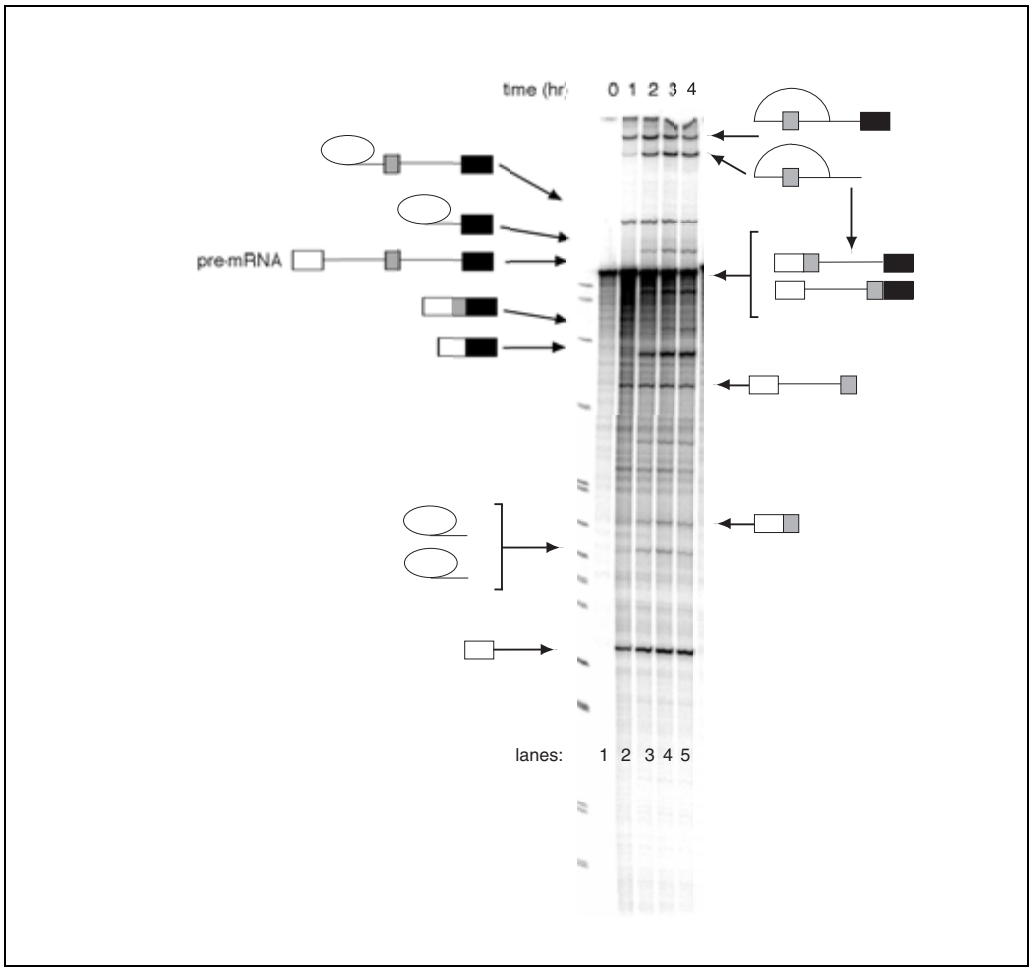

Figure 11.17.3 Autoradiogram of a splicing reaction with a three-exon, two-intron pre-mRNA. Splicing reactions containing the pre-mRNA were incubated in HeLa nuclear extract under the conditions described in Basic Protocol 1. A time course was conducted by terminating the reactions at 1-hr intervals after the initial start of incubation. The pre-mRNA used in this experiment has equal-sized introns, somewhat simplifying the pattern of splicing. It is possible to see the appearance of intermediates during the first hour of splicing, but the final products do not appear until the second hr or later (compare lanes 2 and 3).

Determining if an RNA Contains a Lariat

Determining which bands on the gel correspond to the different RNAs generated during the splicing reaction can be laborious. The linear pre-mRNA product and 5′ exon intermediate can be tentatively identified by their gel mobility. Their time of appearance in a time-course experiment is also diagnostic, in that the 5′ exon should appear earlier. Conclusive demonstration of the mRNA comes from RT/PCR amplification of the suspected band and sequencing of the product. This also confirms the position of the splice sites. Lariat molecules will also show diagnostic appearance times in the time course. The lariat intermediate should appear with the 5′ exon and the lariat product with the mRNA. The anomolous gel mobility of the looped RNA lariat molecules is also used to determine which bands correspond to the lariats. As the percentage of polyacrylamide increases, the mobility of lariat molecules decreases dramatically relative to linear molecules. A splicing reaction can be analyzed in two denaturing gels, one of low-percentage acrylamide (4% to 5%) and one of high-percentage acrylamide (8% to 10%), and the mobility of the different bands compared. RNA lariats will migrate with a marked difference between the two gels relative to linear markers. Often, in a high-percentage gel, the lariats will

shift above the precursor RNA and be the only bands in this region of the gel. This method is further described in Grabowski (1994).

Another approach to identifying a lariat is by debranching using the lariat debranching enzyme. RNA extracted from a band of interest is incubated with cytoplasmic S100 extract (see Support Protocol 1, step 8) or recombinant debranching enzyme (Ruskin and Green, 1990; Ooi et al., 2001). The S100 extract contains the lariat debranching enzyme, which specifically recognizes and cleaves the 2′-5′ phosphodiester bond. Samples of the RNA before and after debranching are separated on a denaturing acrylamide gel and their mobilities compared. The debranched lariat will migrate faster on a high-percentage gel than the intact lariat, at a position diagnostic of the linearized molecule.

Finally, it is possible to identify splicing intermediates and products by comparing related substrates. For example, increasing the length of the 3′ exon in a particular substrate will cause the intermediates containing this exon to migrate more slowly in a denaturing gel. Thus, comparison of the mobilities of the intermediates and products of the initial substrate versus the substrate with a longer 3′ exon can aid in the identification of bands.

Mapping the Branchpoint

Once an RNA is demonstrated to contain a lariat, it is possible to determine the site of the branchpoint. Primer extensions are used to map the site of the branchpoint. During the primer extension reaction, the 2′-5′ phosphodiester bond formed at the branchpoint partially blocks extension by reverse transcriptase at the base prior to the branch. The branchpoint location is determined by finding the primer extension stop. Primer extension on a debranched or linear RNA is used as a control to determine the positions of natural stops in the RNA. These reactions are run next to a sequencing ladder to identify the position of the stops. The most widely used protocol for debranching and primer extension to determine lariat intermediates and branchpoint location is that of Ruskin and Green (1990).

PREPARATION OF NUCLEAR EXTRACT FROM TISSUE CULTURE CELLS

SUPPORT PROTOCOL 1

HeLa cells are the standard source for a nuclear extract that is active in pre-mRNA splicing. This method was originally developed to prepare nuclear extracts competent for RNA polymerase II transcription, and was later adapted to study pre-mRNA splicing (Dignam et al., 1983 and *UNIT 11.6*). Subsequent revisions of this protocol have improved the splicing activity on some pre-mRNA substrates (Krainer et al., 1984; Reichert and Moore, 2000). Nuclear extracts from other tissue-culture cells have also been successfully prepared that reflect alternative splicing phenotypes present in vivo (Noble et al., 1987; Rio, 1988; Black, 1992; Guo and Kawamoto, 2000). Briefly, the cells are swelled in a hypotonic buffer and lysed by Dounce homogenization. After centrifugation of the lysed cells, the pelleted nuclei are recovered and resuspended in a high-salt buffer. During gentle mixing, this buffer extracts RNA processing factors, but does not lyse the nuclei. After extraction, the nuclei are pelleted by centifugation and the supernatant is the nuclear extract. After dialysis into a low-salt buffer, the extracts are ready for RNA processing reactions.

This extract protocol may be scaled down for smaller numbers of cells. Monolayer cell cultures may also be used, but should be grown on a scale that will produce at least 1 ml of packed cell volume and thus make the use of a small Dounce homogenizer feasible. Other extraction protocols have been described for preparing extracts from smaller cell numbers (Lee et al., 1988).

NOTE: This protocol uses HeLa cells, but the general technique can be used for other cell types.

Materials

~5–8 × 10^9 HeLa cells (~12 liters of suspension culture grown in spinner flasks; roller bottles are utilized for some cell types) *or* other mammalian cell of interest, in suspension or monolayer culture
Phosphate-buffered saline (PBS; *APPENDIX 2A*)
Phosphate-buffered saline (PBS; *APPENDIX 2A*) with 1 mM EDTA
Buffer A (see recipe)
Buffer C420 (see recipe)
Buffer DG (see recipe)

Beckman centrifuge with JS-4.2 and JA-20 rotors (or equivalents) and appropriate centrifuge tubes/bottles
50-ml (or other appropriate size) conical tubes, graduated
Rubber policeman or cell scraper
40-ml Dounce homogenizer with tight (type A) and loose (optional) pestle (Wheaton)
Dialysis tubing (10,000 to 14,000 MWCO), prepared as described in *APPENDIX 3C*
Conductivity meter (optional)
Liquid nitrogen

Additional reagents and equipment for trypan blue staining (*UNIT 1.1*), dialysis (*APPENDIX 3C*), and Bradford protein assays (*APPENDIX 3H*)

NOTE: Perform all steps of this procedure at 0° to 4°C. All buffers, vessels, and centrifuge rotors should be precooled to this temperature.

Isolate cell nuclei

For suspension cultures

1a. Grow cells to log phase. Transfer a quantity of suspension containing a total of ~5–8 × 10^9 log-phase cells to 1-liter centrifuge bottles and centrifuge for 20 min at 1800 × *g* in a Beckman JS-4.2 rotor, 4°C. Decant and discard the supernatants.

Overgrowth of cells can result in low splicing activity in the final extract.

2a. Resuspend the cells in 25 ml of PBS for each liter of suspension culture volume and transfer to graduated 50-ml graduated conical tubes. Consolidate the cells into one tube by recentrifuging, resuspending in a smaller volume of PBS, and transferring all pellets to on 50-ml tube.

For monolayer cultures

1b. Grow cells on ten 100- to 150-mm dishes to ~80% to 90% confluency. Remove the medium from the cells and wash the monolayer once with PBS. After washing, add fresh PBS containing 1 mM EDTA to cover the cells, then scrape the cells from the dish with a rubber policeman or cell scraper. Pool cells into conical tubes of the appropriate size for the volume of cells.

Overgrowth of cells can result in low splicing activity in the final extract.

2b. Centrifuge cells 10 min at 1800 × *g* in a JS-4.2 rotor, 4°C. Decant the supernatant and discard. If necessary, resuspend cells in a small volume of PBS, combine, and centrifuge again at 1800 × *g* to consolidate cells into a single conical tube.

3. Using the graduations on the conical tube, estimate the packed cell volume (pcv).

This starting pcv is utilized to estimate the volume of each buffer that is used in the preparation of the extract.

4. Gently resuspend the cells in a volume of buffer A that is ~5 times the pcv. Centrifuge cells 5 min at 1800 × *g* in a JS-4.2 rotor, 4°C,and discard the supernatant.

   This step washes residual PBS from the cells so that efficient osmostic swelling can occur in the subsequent step. Some swelling may occur during this first buffer A wash, so perform this step quickly.

5. Resuspend the cell pellet in a volume of buffer A that is ~3 times the starting pcv (from step 3). Incubate on ice for 10 min.

6. Transfer the cells to a precooled Dounce homogenizer. Homogenize using 5 to 15 slow strokes with a tight pestle.

   Homogenize slowly and use special care during the down stroke to avoid loss of the sample. Lysis can be monitored by staining a small aliquot of the cells with trypan blue (UNIT 1.1). Lysis should be ~90% before proceeding. Different cell types may require different amounts of homogenization to achieve cell lysis.

7. Transfer the lysed cells to appropriate centrifuge tubes and pellet the nuclei by centrifuging 15 min at 3300 × *g* in a JA-20 rotor, 4°C.

8. Discard supernatant or save it to prepare a cytoplasmic S100 extract. Estimate the packed nuclear volume (pnv) using the tube graduations.

   A cytoplasmic extract can be prepared by slow addition of 0.11 volumes of 10× cytoplasmic extract buffer (see recipe) to the above supernatant. After centrifugation for 1 hr at 100,000 × g, the supernatant is the S100 extract. This should be dialysed and subsequently cleared of precipitates in the same manner as a nuclear extract (see steps 11 to 15, below).

Preparation of nuclear extract

9. Resuspend the nuclear pellet in 1 pnv of buffer C420. If clumps of nuclei are difficult to resuspend, homogenize the sample in a Dounce with a loose pestle. Transfer to a small precooled glass beaker containing a small magnetic stir bar.

   The salt concentration in buffer C is one parameter that can be optimized during extract preparation. Active splicing extracts from HeLa cell nuclei are usually obtained by extraction in 0.4 to 0.6 M KCl. Lysis of the nuclei can sometimes be reduced by resuspending the cells in 0.5 pcv of buffer C100 and then adding 0.5 pcv of buffer C (high salt) dropwise to yield the appropriate final concentration.

10. Extract the nuclei by stirring very slowly for 30 min.

11. Transfer the extract to a centrifuge tube and centrifuge 30 min at 25,000 × *g* in a JA-20 rotor, 4°C.

    The supernatant after this spin is the nuclear extract.

12. If conductivity will be used to monitor the dialysis, save a small sample before transferring the extract into dialysis tubing.

13. Dialyze the nuclear extract against 2 liters of buffer DG for 2.5 hr using 10,000 to 14,000 MWCO dialysis tubing (*APPENDIX 3C*). Change the dialysis buffer to new buffer DG and dialyze for another 2 hr. If desired, check the conductivity to monitor the dialysis.

    Conductivity is checked by diluting 10 µl of the extract into 1 ml of distilled water. An equivalent dilution of the dialysis buffer (buffer DG) is used for comparison. Diluted buffer DG should read ~16 to 18 µS/cm. Dialysis is complete when the conductivity of the extract matches that of buffer DG. These dialysis times and volumes are based upon a large extract preparation. Smaller volumes can be dialyzed in less time. Overnight dialysis can result in a decrease in RNA splicing activity.

14. Remove the extract from the dialysis tubing and transfer to a centrifuge tube. Centrifuge 20 min at 12,000 × *g* in a JA-20 rotor, 4°C. Keep the supernatant, which is the completed nuclear extract, and discard the pellet.

    This step removes protein and nucleic acid precipitates that form during dialysis.The precipitates are normal and result from the drop in salt concentration.

15. Remove a small aliquot of the supernatant and use it to determine the protein concentration by the Bradford method (*APPENDIX 3H*). Divide the remaining nuclear extract into aliquots in separate tubes and quick-freeze in liquid nitrogen. Store the extracts at −80°C.

    Aliquots of 200 or 500 μl are convenient for in vitro splicing experiments.

    Nuclear extracts vary widely in final protein concentration (2 to 20 mg/ml), and the concentration does not always correlate with the splicing activity. All extracts should be tested for splicing on constitutive splicing substrates as a positive control, as well as any regulated splicing substrate that will be studied. The most common constitutive substrates are derived from the adenovirus major late first intron (Grabowski et al. 1984) and the β-globin first intron (Krainer et al. 1984).

SUPPORT PROTOCOL 2

PREPARATION OF NUCLEAR EXTRACT FROM PRIMARY TISSUE

In this protocol, the nuclear extract is prepared from a tissue that is isolated from an animal immediately after euthanasia. Like the extract protocol for cultured cells (Support Protocol 1; Dignam et al., 1983), this protocol was initially used to isolate extracts that display tissue-specific RNA polymerase II promoter activity (Sierra at al., 1993). The Grabowski laboratory adapted this protocol to study neuron-specific splicing and demonstrated that splicing-competent nuclear extracts could be generated from whole rat brain (Ashiya and Grabowski, 1997). They have further developed this procedure to produce rat cerebellum extracts that have higher activity for certain neuron-specific exons (Zhang et al., 1999). The protocol that follows is for rat brain and will require optimization for other tissues. Specifically, the salt concentration used for nuclear extraction is a critical parameter and may be changed to maximize the extraction of the nuclei and to minimize nuclear lysis. Note that some tissues (e.g., pancreas) have very high RNase content and may not generate usable extracts.

Briefly, the protocol involves homogenization of primary tissue to break open the cells. The nuclei are subsequently fractionated away from cellular debris by centrifugation through a sucrose cushion. The nuclei are then extracted and the resulting nuclear extract is processed in a manner similar to the standard Dignam extract (Support Protocol 1).

Materials

Sucrose cushion buffer (see recipe)
Dissected whole brains from six 28-day Sprague-Dawley rats
Phosphate-buffered saline (PBS; *APPENDIX 2A*)
Homogenization buffer (see recipe)
Buffer C230 (see recipe)
Buffer DG (see recipe)

Dissection tools
Small Petri dish or tissue-culture plate
Beckman SW 28 rotor (or equivalent) and polyallomer ultracentrifuge tubes
Motor-driven Teflon-glass homogenizer (e.g., Wheaton Overhead Stirrer; Wheaton Science Products)
Small dialysis cassette (0.1 to 0.5 ml Pierce "Slide-a-lyzer" or equivalent), 10,000 MWCO (also see *APPENDIX 3C*)

Additional reagents and equipment for dialysis (*APPENDIX 3C*), trypan blue staining (*UNIT 1.1*), and Bradford protein assays (*APPENDIX 3H*)

NOTE: Chill homogenization buffer and glass-Teflon homogenization apparatus overnight at −20°C before the procedure and perform all steps at 0° to 4°C. All other buffers, vessels and centrifuge rotors should be precooled. The volumes in this procedure assume a starting material of six whole brains from 28-day rats, ~15 grams of tissue. For other tissues, this protocol should be scaled according to the mass of starting material.

Isolate nuclei

1. Transfer 10 ml of sucrose cushion buffer into each of two ultracentrifuge tubes. Chill at −20°C.
2. Dissect the tissue and transfer the material of interest to a Petri dish on ice. Rinse tissue in cold PBS. Remove as much blood as possible by gently dabbing with a Kimwipe. Mince the washed tissue with a razor blade or sterile scissors.
3. Add 5 ml of homogenization buffer (containing DTT and protease inhibitors added immediately before use) to the homogenizer. Transfer the minced tissue to the homogenizer vessel and add another 25 ml of homogenization buffer with DTT and protease inhibitors.

   As a rule of thumb, the tissue should not constitute more than 10% to 15% of the total volume at the homogenization stage. However, the final homogenate must be less dense than the sucrose cushion on which it is layered.

4. Turn the homogenizer motor on at ~200 rpm. Begin homogenization by slowly raising the glass homogenizer over the rotating Teflon "pestle" to bring the pestle into contact with the homogenate. Set the motor to ~400 to 500 rpm. Raise the tube until the pestle reaches the bottom of the glass vessel. Slowly move it back out of the homogenate. Repeat this process one or two times until nuclei and not intact cells are observed when monitoring the homogenization by light microscopy and trypan blue staining (*UNIT 1.1*).

   It requires significant pressure to raise and lower the tube over the pestle. Glass homogenizers can break if the pestle does not seat properly, so safety glasses should be worn during this step. Plastic-coated homogenizer tubes reduce the shattering danger and are recommended. Keep the homogenizer dipped in an ice water bath to maintain maximum cooling during the procedure. Upon monitoring of the homogenate by light microscopy, the majority of the cells should be broken, but the nuclei should be intact.

5. Dilute the homogenate to 50 ml with homogenization buffer. Carefully layer 25 ml of the homogenate onto each 10-ml sucrose cushion.
6. Centrifuge 1 hr at 75,000 × *g* in SW 28 rotor, 0° to 4°C.
7. Remove any floating material and carefully aspirate and drain the solution without disturbing the nuclear pellet. Cut off the tube above the pellet with a clean razor blade or scissors.
8. Fill a 10-ml syringe with cold Milli-Q water and attach an 18-G needle. Holding the centrifuge tube upside down, rinse the tube walls with the syringe. Rinse the pellet twice with water and then twice with buffer C230 using a pipet. Dry the tube with a Kimwipe without touching the pellet.

Prepare nuclear extract

9. Resuspend the two pellets in a total volume of 600 µl of Buffer C230 using a micropipettor with a 1-ml tip that has had the end cut off to generate a 3-mm aperture. Transfer to a microcentrifuge tube and incubate on ice for 30 min.

   Brain nuclei are very sensitive to lysis and thus require the lower-salt (C230) buffer rather than the C420 buffer used for the tissue culture cells (Support Protocol 1). The salt concentration in buffer C is one parameter that can be optimized during extract preparation. Lysis of the nuclei can sometimes be reduced by resuspending the cells in 0.5 pcv of buffer C100 and then adding 0.5 pcv of buffer C (higher-salt) dropwise to yield the appropriate final concentration. Nuclei from different tissue types may require altered conditions. The buffer C100 suspension can be divided into several aliquots and various buffer Cs, differing in salt concentration, can be added to the aliquots in parallel to optimize the procedure.

10. Microcentrifuge 10 min at maximum speed, 0° to 4°C. Keep the resulting supernatant, which is the nuclear extract.

11. Load the supernatant into a small dialysis cassette ("Slide-a-lyzer") with a 1-ml syringe and 18-G needle (*APPENDIX 3C*).

12. Dialyze for 1 hr against 1 liter of buffer DG. Change to fresh buffer DG and dialyze for an additional 1 hr.

    The small volume of the extract and the high relative surface area of the Slide-a-lyzer assures that the dialysis is rapid. Monitoring the dialysis by conductivity is recommended for larger preparations (see Support Protocol 1).

13. Remove the extract from the dialysis cassette with a 1-ml syringe (18-G needle). Transfer to a microcentrifuge tube and microcentrifuge 15 min at 16,000 × *g*, to clear any precipitates. Retain the supernatant.

14. Determine the protein concentration by the Bradford assay (*APPENDIX 3H*). Divide the the extract into aliquots in microcentrifuge tubes and quick-freeze in liquid nitrogen. Store the nuclear extracts at −80°C.

    See the comments in Support Protocol 1 on testing nuclear extracts. Some tissue-derived nuclear extracts benefit from concentrating the extract (e.g., using Amicon centrifugal concentrators). This is a possible option if initial splicing assays are unsuccessful with a particular batch of extract.

SUPPORT PROTOCOL 3

IN VITRO TRANSCRIPTION OF CAPPED, RADIOLABELED RNA

The substrate for in vitro splicing reactions is usually produced by in vitro transcription of a DNA template by a bacteriophage RNA polymerase (e.g., T3, T7, SP6) in the presence of an [α-^{32}P]NTP. The resulting radiolabeled RNAs are of high specific activity and possess a 5′ mRNA cap structure (diguanosine 5′-5′ triphosphate). The cap structure stabilizes the RNA against exonuclease activity and may bind proteins that are important for RNA processing efficiency. The relative importance of the cap-binding complex to RNA splicing varies by substrate, but the cap is usually necessary to reduce nuclease digestion and thus produce cleaner results.

The DNA template can be derived by two methods. Commonly, the pre-mRNA sequence is cloned into a plasmid downstream of a bacteriophage promoter, and the resulting plasmid can be linearized after the pre-mRNA sequence with a restriction endonuclease to generate the template. Alternatively, the corresponding pre-mRNA sequence can be amplified by PCR with a special "tailed" sense primer. The primer (5′ to 3′) consists of the top strand sequence of a bacteriophage promoter followed by at least one guanosine

followed by the region that complements the pre-mRNA 5′ end. The antisense primer is designed at the 3′ end of the pre-mRNA sequence to specify the point where the polymerase "runs off." The resulting PCR product can be purified by agarose gel electrophoresis, cleaned up by standard methods (Beulsey et al., 1991; e.g., "freeze and squeeze" or kit), and used as transcription template. Any DNA used for transcription should be free of nuclease activity and thoroughly desalted.

NOTE: All water and microcentrifuge tubes used in this protocol should be RNase-free (see *APPENDIX 2A*).

CAUTION: All proper guidelines for radioisotopes should be followed. Use care when handling transcription reactions to avoid radioactive contamination. Monitor all work spaces, pipets, and the microcentrifuge for counts. Dispose of waste as specified by the local radiation safety officer (also see *APPENDIX 1D*).

Materials

RNase-free water (*APPENDIX 2A*)
10× transcription buffer (provided with polymerase, or see recipe)
0.1 M DTT
NTP mix (see recipe)
Cap analog solution (see recipe)
12.5 µM [α-^{32}P]UTP (800 Ci/mmol)
0.1 µg/µl DNA template (linearized plasmid or PCR product) in 10 mM Tris·Cl, pH 8.1 (see *APPENDIX 2A* for Tris buffer)
10 U/µl bacteriophage RNA polymerase (T3, T7, or SP6)
RNase-free DNase I (if PCR product is used as template)
Formamide loading buffer (see recipe)
RNA elution buffer (see recipe)
70% and 100% ethanol, –20°C
TE-acetate buffer (see recipe)

85°C heating block
Scintillation counter and vials appropriate for Cerenkov counting

Additional reagents and equipment for denaturing polyacrylamide gel electrophoresis (*APPENDIX 3A*) and autoradiography (*UNIT 6.3*)

1. Bring all solutions to room temperature. Assemble the 25-µl reaction in the following order:

   6.5 µl RNase-free water
   2.5 µl 10× transcription buffer
   2 µl 0.1 M DTT
   2 µl NTP mix
   3 µl cap analog solution
   5 µl 12.5 µM [α-^{32}P]UTP (800 Ci/mmol)
   2 µl DNA template
   2 µl 10 U/µl bacteriophage RNA polymerase.

   The final concentrations of the components are: 40 mM Tris·Cl, pH 7.9; 6 mM $MgCl_2$; 2 mM spermidine; 8 mM DTT; 1.2 mM cap analog; 0.2 mM each of GTP, ATP, and CTP; 0.01 mM cold UTP; 2.5 µM [α-^{32}P]UTP; ~20 µM DNA template; 0.8 U/µl bacteriophage RNA polymerase.

   The order of addition and the assembly at room temperature is critical. This order prevents precipitation of the DNA from contact with high concentrations of spermidine.

2. Incubate at 37°C for 1 to 2 hr. While the mix is incubating, prepare a 0.8-mm-thick analytical-size 4% 1× TBE urea-acylamide gel with wells capable of holding 50 µl. Pre-run the gel.

   APPENDIX 3A provides references for preparing and running denaturing PAGE gels.

3. If a plasmid serves as the template, proceed to step 4. If a PCR product is being used, add 2.5 U of RNase-free DNase I and incubate at 37°C for 10 min.

   PCR templates and the transcript RNA are so similar in size that they run in nearly the same position on a denaturing gel. Degrading the DNA after transcription resolves this problem.

4. Stop the reactions by addition of 25 µl of formamide loading buffer.

5. Incubate the stopped reactions at 85°C for 5 min.

6. Load 50 µl per well of each reaction directly onto the pre-run 4% 1× TBE urea-acylamide gel. Electrophorese at 25 V/cm for 10 min and then 40 V/cm until the bromphenol blue reaches the bottom of the gel.

7. Disassemble the gel so as to leave the radioactive gel slab on one of the glass plates. Cover in plastic wrap.

   CAUTION: *The bottom buffer chamber will be radioactive due to the unincorporated α-^{32}P-UTP. Dispose of the radioactive buffer appropriately (also see APPENDIX 1D).*

8. Visualize the transcript by brief autoradiography (*UNIT 6.3*).

   Exposure of the gel for 15 sec is usually adequate.

9. Align the film with the gel to locate the position of the radiolabeled RNA. Cut out the band using a razor blade and transfer to a microcentrifuge tube.

   Shredding the gel does not usually improve the RNA yield significantly and makes a clean transfer (step 11) more difficult.

10. Incubate overnight in 400 µl of RNA elution buffer.

    For large RNAs (> 600 nt), incubation at 37°C can generate more complete elution. For small RNAs (<300 nt), SDS can be omitted from the elution buffer and thus the second precipitation is not necessary.

11. Transfer the elution buffer to a new microcentrifuge tube.

    Elution efficiency can be monitored with a Geiger counter by comparing the elution buffer and gel slice counts.

12. Add 1 ml of 100% ethanol. Mix well and incubate on dry ice for 10 min.

13. Microcentrifuge 10 min at maximum speed, 0° to 4°C. Carefully dispose of supernatant as radioactive waste.

14. Rinse the pellet with 1 ml of cold 70% ethanol.

15. Resuspend pellet in 400 µl TE/acetate buffer and repeat the ethanol precipitation (steps 12 to 14).

    This step removes any residual SDS contamination from the first precipitation. Gel filtration over a disposable G-50 spin column (Amersham Pharmacia Biotech) can also be utilized.

16. Resuspend the pellet in 50 µl of RNase-free water and assay 1 µl by Cerenkov counting.

    Radiolysis occurs relatively rapidly with transcripts of high specific activity. The RNA should be used within 48 hr of completing this procedure, to assure the highest quality RNA.

REAGENTS AND SOLUTIONS

*Use RNase-free (**APPENDIX 2A**) high-purity deionized (Milli-Q or Nanopure) water in all recipes and protocol steps. For common stock solutions, see **APPENDIX 2A**; for suppliers, see **SUPPLIERS APPENDIX**.*

Buffer A

10 mM HEPES, pH adjusted to 7.9 with KOH (at 25°C)
1.5 mM $MgCl_2$
10 mM KCl
Store buffer with above components up to 3 months at 4°C
Add the following immediately before use, with rapid mixing:
0.2 mM PMSF (from 100 mM stock in ethanol)
1 mM DTT
1 µg/ml pepstatin A (from 1 mg/ml stock in ethanol)
1 µg/ml leupeptin (from 10 mg/ml stock in H_2O)
1 µg/ml aprotinin (from 10 mg/ml stock in 10 mM HEPES, pH 8.0)
Prepare fresh buffer with DTT and protease inhibitors for each extract preparation

Buffer C20

20 mM HEPES, pH adjusted to 7.9 with KOH (at 25°C)
25% (v/v) glycerol
1.5 mM $MgCl_2$
0.2 mM EDTA
20 mM KCl
Store buffer with above components up to 3 months at 4°C
Add the following immediately before use, with rapid mixing:
0.2 mM PMSF (from 100 mM stock in ethanol)
1 mM DTT
1 µg/ml pepstatin A (from 1 mg/ml stock in ethanol)
1 µg/ml leupeptin (from 10 mg/ml stock in H_2O)
1 µg/ml aprotinin (from 10 mg/ml stock in 10 mM HEPES, pH 8.0)
Prepare fresh buffer with DTT and protease inhibitors for each extract preparation

Buffers C230 and C420

Prepare as for Buffer C20 (see recipe) but use 230 mM and 420 mM KCl, respectively.

Buffer DG

20 mM HEPES, pH adjusted to 7.9 with KOH (at 25°C)
20% (v/v) glycerol
80 mM monopotassium glutamate
0.2 mM EDTA
Store buffer with above components up to 3 months at 4°C
Add the following immediately before use, with rapid mixing:
0.2 mM PMSF (from 100 mM stock in ethanol)
1 mM DTT
1 µg/ml pepstatin A (from 1 mg/ml stock in ethanol)
1 µg/ml leupeptin (from 10 mg/ml stock in H_2O)
1 µg/ml aprotinin (from 10 mg/ml stock in 10 mM HEPES, pH 8.0)
Prepare fresh buffer with DTT and protease inhibitors for each extract preparation.

Many in vitro splicing protocols use buffer D, which contains 100 mM KCl instead of potassium glutamate. These can sometimes work as well as the buffer DG used here. However, the use of glutamate as a potassium counterion instead of chloride improves in vitro splicing efficiency of some substrates and lowers RNA degradation (Black, 1992; Reichert and Moore, 2000; also see Commentary).

Cap analog solution

Dissolve 25 A_{260} units of dry diguanosine 5′-5′ triphosphate dinucleotide (New England Biolabs or Amersham Pharmacia-Biotech) in 130 µl of water to obtain a final concentration of 10 mM diguanosine 5′-5′ triphosphate. Store up to one year at −20°C.

Cytoplasmic extract buffer, 10×

0.3 M HEPES, pH adjusted to 7.9 with KOH (at 25°C)
1.4 M KCl
30 mM $MgCl_2$
Prepare fresh for each extract preparation

Formamide loading buffer

95% (v/v) formamide
15 mM EDTA pH 8.0 (*APPENDIX 2A*)
0.05% (w/v) bromphenol blue
Store in aliquots for up to 3 months at −20°C

Homogenization buffer

10 mM HEPES, pH adjusted to 7.9 with KOH (at 25°C)
15 mM KCl
1 mM EDTA
2.2 M sucrose
5% (v/v) glycerol
0.15 mM spermine
0.5 mM spermidine
Store buffer with above components up to 3 months at 4°C
Add the following immediately before use, with rapid mixing:
0.2 mM PMSF
1 mM DTT

Prepare fresh buffer with DTT and protease inhibitor for each extract preparation

NTP mix

2.5 mM GTP
2.5 mM ATP
2.5 mM CTP
0.125 mM UTP
Store up to one year at −20°C

Ribonucleotide triphosphates can be purchased as 100 mM stock solutions at neutral pH. Alternatively, the dry NTP salts can be dissolved in water and titrated to pH 8.0 with Tris base.

PCA Buffer, 1.1×

0.33 M sodium acetate
0.05 M Tris·Cl, pH 8.0 (*APPENDIX 2A*)
0.005 M EDTA, pH 8.0 (*APPENDIX 2A*)
0.2% (w/v) SDS
Store up to 1 year at room temperature

RNA elution buffer

20 mM Tris·Cl, pH 8.0 (*APPENDIX 2A*)
2 mM EDTA
0.5 M ammonium acetate
0.4% (w/v) SDS
Store for up to 1 year at room temperature

RNA gel loading buffer

0.1× TBE buffer (*APPENDIX 2A*)
8 M urea
0.025% (w/v) xylene cyanol
0.025% (w/v) bromphenol blue
Store up to one year at room temperature

Sucrose cushion buffer

10 mM HEPES, pH adjusted to 7.9 with KOH (at 25°C)
15 mM KCl
1 mM EDTA
2.0 M sucrose
10% (v/v) glycerol
0.15 mM spermine
0.5 mM spermidine
Store buffer with above components up to 3 months at 4°C
Add the following immediately before use, with rapid mixing:
0.2 mM PMSF
1 mM DTT
1 µg/ml pepstatin A
1 µg/ml leupeptin
1 µg/ml aprotinin
Prepare fresh solution with DTT and protease inhibitors for each extract preparation and filter sterilize

Transcription buffer, 10×

400 mM Tris·Cl, pH 7.9 (*APPENDIX 2A*)
60 mM $MgCl_2$
20 mM spermidine
Store for up to 1 year at–20°C

TE-acetate buffer

10 mM Tris·Cl pH 8.0 (*APPENDIX 2A*)
1 mM EDTA
0.5 M ammonium acetate
Store for up to 1 year at room temperature

COMMENTARY

Background information

Nuclear extracts from cultured mammalian cells were developed for analysis of transcription and were later adapted to the study of pre-mRNA splicing (Dignam et al., 1983; Krainer et al., 1984). Nuclear extracts that splice pre-mRNAs into mRNAs in vitro have become an indispensable tool for the analysis of splice site choice and splicing factors. In particular, the preparation of nuclear extract from various cell lines or tissues has enabled the study of regulated exons. Nuclear extracts produced by these methods are also used to study other RNA processing events such as 3′ cleavage and polyadenylation (Moore and Sharp, 1985; Takagaki et al., 1988; Christofori and Keller, 1988). Recently, nuclear extracts were shown to possess factors involved in mRNA export (Le Hir et al., 2000 and Zhou, et al. 2001). Laboratories are also now using nuclear extracts as a tool to investigate the coupling of the processes of transcription, splicing, 3′ end processing, and export.

Critical Parameters

The original splicing extract procedure and many subsequent adaptations utilized a final dialysis step into a buffer containing 100 mM KCl. Most laboratories still utilize these conditions. Several laboratories have reported an increase in splicing efficiency for some substrates by replacing potassium chloride (KCl)

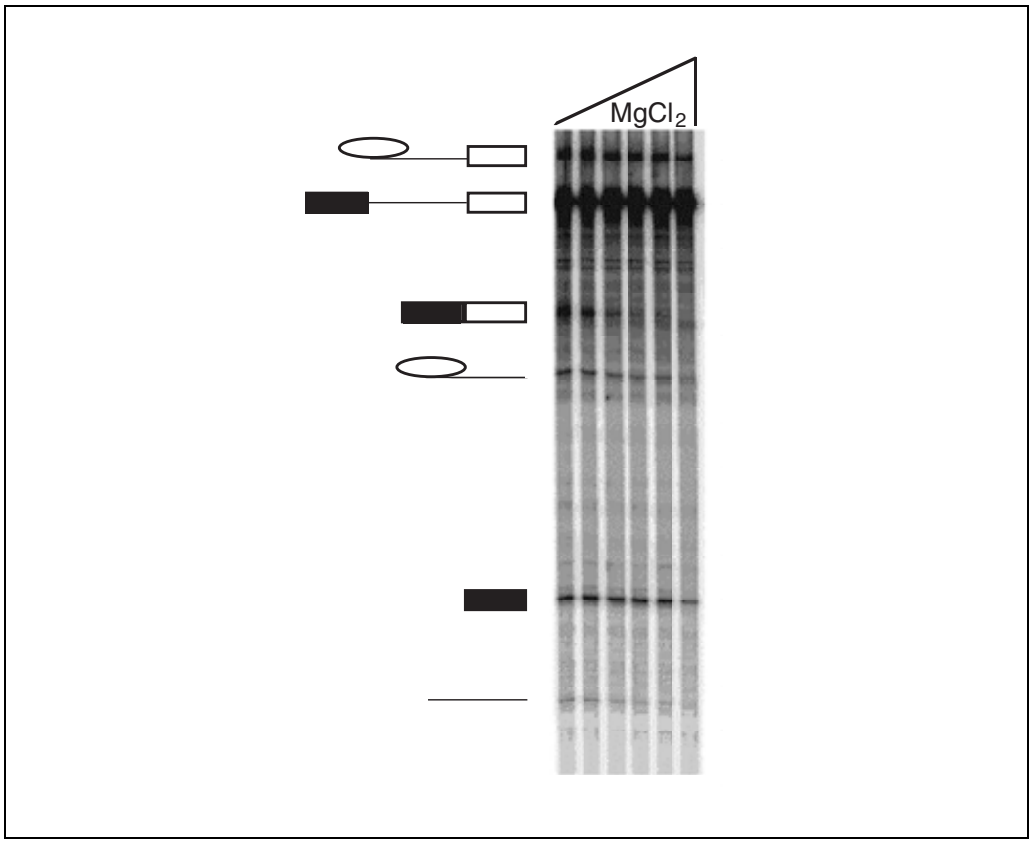

Figure 11.17.4 Magnesium titration on the β-globin first intron splicing substrate, HBΔ6 (Krainer et al., 1984). The final $MgCl_2$ concentration was titrated in 0.5 mM steps from 2.5 mM to 5 mM. Both the stability of the mRNA product and the efficiency of the second catalytic step of splicing are reduced as Mg is increased above 3 mM, while the efficiency of the first catalytic step is relatively constant over a wider Mg range.

with potassium acetate or potassium glutamate in the preparation of the nuclear extract (Black, 1992; Reichert and Moore, 2000). Moreover, some introns that are inactive in KCl are spliced in potassium glutamate. It is found that most constitutive and regulated substrates splice as well, if not better, in glutamate. This anion effect is seen in other processes involving nucleic acid binding proteins (Ha et al., 1992). The protocols presented in this unit all use glutamate.

Consistent preparation of the nuclear extract is also important to allow the technique to be optimized to yield the highest splicing activity. The condition of the starting material, whether cells or tissue, should be carefully monitored. Overgrowth of tissue culture cells will result in a loss of splicing activity in the prepared extract. The time that it takes to perform each step of the extract protocol, as well as any errors, should be noted so as to improve future preparations. For extracts made from tissues, it is important to minimize the time between isolation of the tissue from the animal and the homogenization stage.

Several parameters can be changed during optimization of the nuclear extraction. Extraction of the nuclear contents takes place in buffer C, and the KCl concentration of this extraction can affect the activity. Too low a salt concentration will result in a poor protein yield, while too high a salt concentration will result in lysis of the nuclei. This can be optimized by dividing the nuclei into several batches to be extracted under different salt conditions. Nuclei from various tissues or cell types are likely to require different conditions.

Extracts vary widely in concentration, and there is not always a direct corrolation between extract concentration and splicing activity. All new extracts should be tested on constitutive and regulated substrates. It is recommended that a simple two-exon/single-intron constitutive pre-mRNA be used when optimizing the reactions, because the splicing efficiency of these substrates is usually greater than a multiple intron substrate. As mentioned earlier, new extracts may require reoptimization of the splicing reaction (e.g., magnesium concentration). An extract that is dilute may show activity

on an efficiently spliced substrate (e.g., adenovirus first intron), but have no activity on a weaker splicing substrate.

Splicing conditions may need to be reoptimized for different pre-mRNA substrates. Pre-mRNA substrates have different optimal magnesium and monovalent salt concentrations, different requirements for macromolecular crowding reagents (e.g. PEG), and different optimal extract concentrations. For an example of a magnesium titration, see Figure 11.17.4.

As is standard when working with RNA, it is important to avoid contamination with RNases. Should contamination occur, the problem is usually most easily solved by discarding all solutions and preparing new ones. The bench area in which the experiment is being performed should be cleaned as well. This is true not only for the splicing reaction but also for the nuclear extract preparation. It is extremely important that all of the reagents used in the preparation be RNase-free and of the highest available purity. Filter sterilize all solutions and use only highly pure deionized (Milli-Q or Nanopure) water.

Anticipated Results

Using this protocol, it is possible to produce extracts between 4 to 20 mg protein/ml that will splice a uniformly labeled pre-mRNA generated by in vitro transcription

For most pre-mRNAs, the splicing reaction is more robust in vivo than in vitro. A standard in vitro splicing reaction does not usually convert all of the pre-mRNA to products during a standard reaction time of 1 to 4 hr. Much of the pre-mRNA input is still intact at the end of the incubation. With weak splicing substrates, the pre-mRNA is usually the most intense band on the splicing gel. Usually the linear molecules of the splicing reaction are identified by their migration relative to a radiolabelled DNA marker set (e.g., end labelled pBR322 *Msp1* digest). Linear RNA polynucleotides will migrate slightly slower through the urea-PAGE than the same length DNA. Branched products are identified by their retarded mobility in high percentage (8% to 12%) gels and by their susceptibility to debranching. Time course experiments run on the same splicing gel can often elucidate which products are from Steps 1 and 2 of the reaction. Normally, a splicing gel shows a number of radiolabeled RNA bands that are splicing-independent and splicing-dependent. Splicing-independent bands are often sites in the RNA with a high propensity for hydrolysis or radiolysis. Splicing-dependent bands will require the energy source ARP and creatine phosphate for their appearance, so this can be used as criteria for assigning band identities.

Time Considerations

Nuclear extract preparation takes 9 to 12 hr, including the final dialysis step. The extract preparation prior to dialysis requires 3 to 5 hr. Additional time for dissection is necessary for extracts from tissues and will depend upon the complexity of the tissue isolation. The entire procedure should be completed in 1 day. In vitro transcription and gel purification can be performed in ~4 hr, and the RNA is eluted overnight and used for splicing the next day. The in vitro splicing reaction requires ~3 to 5 hr. The preparation of the polyacrylamide gel and electrophoresis of the splicing reaction requires 4 to 5 hr.

Endocytosis Assays in Intact and Permeabilized Cells

Clathrin-coated pits and vesicles represent the major ports of entry into most eukaryotic cells. As well as performing housekeeping functions (e.g., allowing cells to take up essential nutrients), the endocytic pathway participates in a number of tissue-specific events such as synaptic-vesicle recycling, control of morphogen gradients during development, downregulation of receptor tyrosine kinases, and immune surveillance (Conner and Schmid, 2003). To understand the role played by clathrin-mediated uptake, it is therefore essential to have robust endocytosis assays in intact cells (Basic Protocol 1). The clathrin-coated vesicle cycle requires a complicated interplay of proteins and lipids that is regulated in space and time. Reconstitution assays in permeabilized cells (Basic Protocol 2 and Alternate Protocols 1 and 2) provide a powerful approach to understanding how this complex process is regulated. Support Protocols 1 to 9 describe the preparation of cells and reagents for the assays.

NOTE: All solutions and equipment coming into contact with live cells must be sterile, and aseptic technique should be used accordingly.

NOTE: All cell culture incubations should be carried out in a 37°C, 5% CO_2 humidified incubator unless otherwise indicated.

MEASUREMENT OF RECEPTOR-MEDIATED ENDOCYTOSIS IN INTACT CELLS

BASIC PROTOCOL 1

A number of methods have been described to measure the internalization of ligands such as transferrin (Hopkins and Trowbridge, 1983). In general, they rely on the ability to distinguish cell surface from intracellular pools of ligand. Routinely, the authors use transferrin that has been biotinylated via a cleavable disulfide linkage (B-SS-Tfn) as a reporter molecule to distinguish between intracellular and cell surface ligand by accessibility either to avidin or to the small membrane-impermeant thiol-reducing reagent, sodium 2-mercaptoethanesulfonate (MesNa). Transferrin is a ligand of choice to study the core machinery because the transferrin receptor is abundant on most cells, the route followed by transferrin when bound to its receptor is well characterized (Hopkins and Trowbridge, 1983), and transferrin is inexpensive and easy to modify by biotinylation or iodination. It is possible to use other ligands, however (see Background Information). Essential prerequisites are a reasonable number of receptor molecules on the cell surface and effective methods to label the receptor with either ligand or antibody or by cell surface labeling.

This protocol describes a method whereby avidin and the small membrane-impermeant reducing agent MesNa quench B-SS-Tfn at the cell surface so that the internalized B-SS-Tfn may be measured. Following addition of avidin or MesNa, these reagents are themselves functionally inactivated. Biocytin (a conjugate of biotin and lysine) is added to bind to remaining binding sites on avidin, which is tetrameric. Excess MesNa is removed by reaction with iodoacetamide (IAA). In each case, the cells are solubilized and all of the transferrin is captured on an ELISA plate coated with antibodies to transferrin. In the case of the avidin assay, cell surface B-SS-Tfn will be bound to avidin, whereas in the case of the MesNa assay, cell surface transferrin will no longer be biotinylated. In this case, internalized B-SS-Tfn may be detected using streptavidin conjugated with the enzyme horseradish peroxidase (HRP). The principles of the avidin and MesNa assays are outlined for permeabilized cells in Figure 11.18.1. For many experiments in intact cells, either the avidin or MesNa assays may be used, as under most conditions they give identical results

Contributed by Andrew Osborne, Alexander Flett, and Elizabeth Smythe
Current Protocols in Cell Biology (2005) 11.18.1-11.18.24

(Schmid and Smythe, 1991). There may be occasions, however, when a comparison of the results of these assays may provide valuable information. For example, under conditions where scission is inhibited in intact cells but invagination is not, the avidin assay will measure a larger amount of apparently internalized ligand as compared with the MesNa assay (Damke et al., 1994; Hill et al., 2001). The avidin and MesNa assays may be used with either adherent cells or cells growing in suspension.

Materials

35-mm tissue culture dishes of A431 cells (or other adherent cells; ~80% confluent) *or* cell suspension (~1 × 10^6 cells/200 μl)
Serum-free medium: DMEM containing 1 mg/ml BSA
PBS/BSA: CMF-DPBS (*APPENDIX 2A*) containing 0.2% (w/v) BSA, ice cold and 31°C
1 mg/ml biotinylated transferrin (B-SS-Tfn; see Support Protocol 1)
50 μg/ml avidin (Sigma) in PBS/BSA, for avidin assay only
1 mg/ml biocytin (Sigma), for avidin assay only
10 and 100 mM sodium 2-mercaptoethanesulfonate (MesNa; Sigma) in MesNa buffer (see recipe), prepare fresh (for MesNa assay only)
500 mM iodoacetamide (Sigma), prepare fresh (for MesNa assay only)
Blocking buffer (see recipe)
ELISA plates coated with anti-transferrin antibodies (see Support Protocol 2)
0.1 U/ml streptavidin–horseradish peroxidase (HRP; Pierce) in blocking buffer
Dulbecco's PBS (*APPENDIX 2A*)
o-Phenylenediamine tablets (Sigma)
H_2O_2 (Sigma)
HRP assay buffer: 51 mM phosphate/27 mM citrate, pH 5.0
2 M H_2SO_4 (see recipe)
31°C incubator or water bath with metal tray to support tissue culture dishes
Microscope suitable for examining cells in culture, for adherent cells only
ELISA plate reader with 492-nm filter

Incubate cells with B-SS-Tfn

1. Incubate a 35-mm dish of A431 cells in 2 ml serum-free medium for 30 min at 37°C. For cells in suspension, centrifuge 200 μl (~1 × 10^6 cells) cell suspension 5 min at 1000 × *g*, at room temperature. Remove supernatant and replace with 200 μl serum-free medium. Agitate gently for 30 min at 37°C.

   The purpose of this incubation is to remove bovine transferrin present in serum.

   A 35-mm dish of adherent cells or ~1 × 10^6 cells in suspension is used for each time point.

Figure 11.18.1 *(at right)* Principles of the avidin and sodium 2-mercaptoethanesulfonate (MesNa) assays. Permeabilized cells are incubated with transferrin (Tfn) that has been biotinylated via a cleavable disulfide linkage (B-SS-Tfn) under conditions where endocytosis can occur (1). Some of the B-SS-Tfn is sequestered into deeply invaginated coated pits or internalized into coated vesicles (2). The permeabilized cell mixes are then chilled and treated with avidin (3). Cell surface B-SS-Tfn is accessible to avidin, whereas sequestered B-SS-Tfn (either in deeply invaginated coated pits or internalized in coated vesicles) is inaccessible. Excess binding sites on avidin are quenched by the addition of biocytin (4). The cells are then lysed and applied to ELISA plates coated with anti-transferrin antibodies (anti-Tfn Ab). Sequestered and internalized B-SS-Tfn may be detected by binding of streptavidin–horseradish peroxidase (HRP; 5). Alternatively, following the endocytosis reaction, cell surface B-SS-Tfn is reduced using the small membrane-impermeant reducing agent MesNa. MesNa can access B-SS-Tfn sequestered in deeply invaginated coated pits, whereas B-SS-Tfn internalized in coated vesicles is resistant to MesNa reduction (6). Iodoacetamide (IAA) is used to quench excess MesNa (7). The cells are solubilized, and internalized B-SS-Tfn is detected using streptavidin-HRP (8).

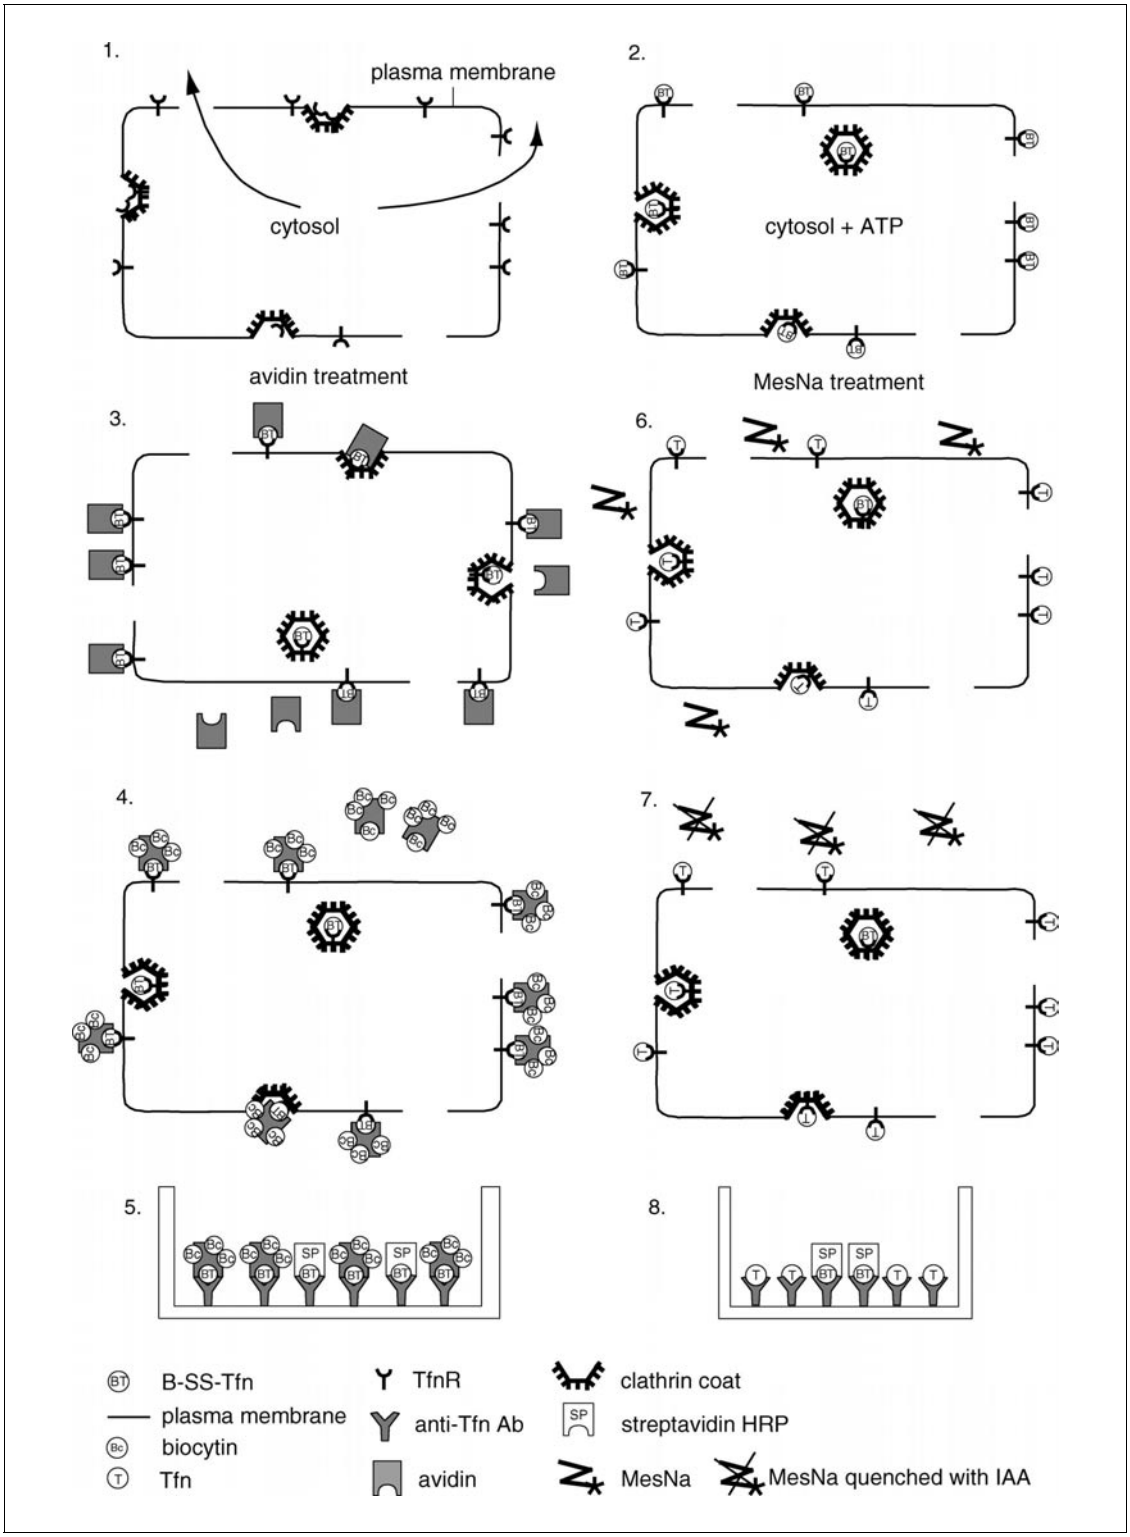

Figure 11.18.1 Legend at left.

2. Wash cells three times with ice-cold PBS/BSA. Use 2 ml for adherent cells and 1 ml for cells in suspension followed by centrifugation conditions given in step 1. Add 1 μg/ml B-SS-Tfn in PBS/BSA to sample (1 ml for adherent cells and 200 μl for cells in suspension) and incubate 30 to 60 min at 4°C.

   To minimize the amount of B-SS-Tfn to be used, dishes may be incubated with ligand in a volume of 0.6 ml with gentle rocking.

3. Wash cells three times with ice-cold PBS/BSA as in step 2. Warm cells at 31°C in 1 ml warm PBS/BSA for adherent cells or in 200 μl warm PBS/BSA for cells in suspension for various times.

   In general, to measure the internalization of a cell surface receptor, the incubation times that are chosen would range from 0 to 60 min, with a greater emphasis on early time points. Typical time points would include 0, 2, 5, 10, 15, 20, 30, and 60 min.

   The incubation is carried out at 31°C to slow down the rate of endocytosis. Ligands such as transferrin are endocytosed at a very fast rate at 37°C (∼15% of the surface pool per minute in many cell types; Watts and Marsh, 1991), making estimation of internalization difficult. Hence, the lower temperature facilitates data collection at early time points.

4. Return cells to 4°C and continue with either avidin (step 5a) or MesNa (step 5b) assay. For either assay, hold a set of duplicate cells (total B-SS-Tfn samples) at 4°C (i.e., do not treat with avidin or MesNa) and process with the other samples (step 8).

   The duplicate samples that are held at 4°C are processed with the other samples (step 8) to determine the total amount of B-SS-Tfn available to be internalized.

For avidin assay

5a. Wash cells two times with ice-cold PBS/BSA (2 ml for adherent cells and 1 ml for cells in suspension followed by 5 min centrifugation at 1000 × *g*). Incubate B-SS-Tfn-labeled cells with 50 μg/ml avidin in PBS/BSA (600 μl for adherent cells and 200 μl for cells in suspension) for 1 hr at 4°C with gentle agitation.

6a. Quench avidin with 30 μl of 1 mg/ml biocytin for adherent cells or 10 μl of 1 mg/ml biocytin for cell suspension at 4°C for 10 min. Continue with step 8.

For MesNa assay

5b. Incubate cells at 4°C with freshly prepared 10 mM MesNa in MesNa buffer (600 μl for adherent cells or 200 μl for cells in suspension) for 20 min with gentle agitation.

6b. Make two further additions of freshly prepared 100 mM MesNa (72 and 96 μl for adherent cells or 24 and 32 μl for cells in suspension) and incubate 20 min at 4°C after each addition.

   For effective reduction of B-SS-Tfn, it is critical that the MesNa solution is freshly prepared just prior to addition to the cells.

7b. Quench MesNa by addition of freshly prepared 500 mM IAA (150 μl for adherent cells or 50 μl for cells in suspension).

Solubilize cells

8. Remove avidin or MesNa mixture (use centrifugation for cells in suspension) and solubilize cells by adding blocking buffer. Add 600 μl to dish of adherent cells and pipet up and down; check under a microscope to ensure that all cells are removed. For cells in suspension, resuspend cell pellet in 200 μl blocking buffer. Treat total B-SS-Tfn samples (step 4) in parallel.

9. Add 100 μl blocking buffer to each well of an ELISA plate coated with anti-transferrin antibodies. Add 100 μl solubilized cells to duplicate wells of the ELISA plate. Plate a titration of different amounts of total B-SS-Tfn samples diluted in blocking buffer to maintain a final volume of 100 μl. Incubate plates overnight at 4°C or for 3 hr at 37°C.

   To ensure that color development falls within a linear range, different amounts of the total B-SS-Tfn samples should be plated.

   Incubation of the ELISA plate at 37°C does not require a humidified, 5% CO_2 incubator.

Develop assay

10. Wash plate three times with ~300 μl PBS per well.

    A plate washer can be used for the washes. In the absence of a plate washer, the washes may simply be removed by flicking into a sink or waste container, but all wells must be emptied on each wash.

11. Add 200 μl of 0.1 U/ml streptavidin-HRP in blocking buffer and incubate 1 hr at room temperature.

12. Wash three times with 300 μl PBS per well.

13. Prepare the following reaction mix:

    10 mg *o*-phenylenediamine
    10 μl H_2O_2
    25 ml HRP assay buffer.

    CAUTION: *During the development of the HRP reaction product, gloves should be worn at all times. o-Phenylenediamine is carcinogenic, but preweighed tablets are commercially available that can be added directly to assay buffer.*

14. Add 200 μl reaction mix to each well of the ELISA plate to develop the reaction.

15. Stop the reaction by adding 50 μl of 2 M H_2SO_4, which also enhances color development.

    CAUTION: *2 M H_2SO_4 is a strong and corrosive acid and should be treated with appropriate care. The ELISA plates containing the reaction product should be disposed of in accordance with local practices for the disposal of hazardous material.*

    The time taken for color to develop will be variable and will depend on the number of cells in a particular endocytosis assay. In general, when the darkest wells are a strong yellow color, it is time to add the acid. With experience, it becomes obvious when the reaction needs to be stopped so that the absorbance at 492 nm falls within the linear range.

16. Read absorbance on an ELISA plate reader at 492 nm. Check that the values obtained with the total B-SS-Tfn samples are within the linear range of absorbance.

    In general, there is a linear relationship up to an absorbance of ~0.8. Background values should have an absorbance <0.08.

Quantify results

17. Use total B-SS-Tfn samples (step 4) to estimate the total amount of B-SS-Tfn available for internalization.

18. Express the amount of avidin-inaccessible or MesNa-resistant B-SS-Tfn at each time point as a percentage of total B-SS-Tfn present in the samples held at 4°C.

BASIC PROTOCOL 2

MEASUREMENT OF RECEPTOR-MEDIATED ENDOCYTOSIS IN PERMEABILIZED CELLS

The avidin and sodium 2-mercaptoethanesulfonate (MesNa) assays are used extensively with permeabilized cells to reconstitute different stages in the clathrin coated–vesicle cycle (Schmid and Smythe, 1991; Smythe et al., 1992; Carter et al., 1993). The size difference between the two probes allows the difference between cargo sequestration into deeply invaginated coated pits and its internalization into coated vesicles to be distinguished (Fig. 11.18.1). Avidin is a tetramer composed of four subunits of 64 kDa and so is relatively bulky and is unable to access B-SS-Tfn that is sequestered in deeply invaginated coated pits or internalized in coated vesicles. MesNa is considerably smaller (165 Da) and so can access sequestered cargo but, because it is membrane impermeant, it fails to reduce B-SS-Tfn within coated vesicles. Reconstitution of the clathrin coated–vesicle cycle in permeabilized cells generates intermediates such as deeply invaginated coated pits that would be very transient and thus seldomly detected in vivo. This has the advantage of allowing the components required to generate these intermediates to be identified and characterized (Benmerah et al., 1998; Jost et al., 1998; McLauchlan, 1998; Hill et al., 2001; Olusanya et al., 2001; Jackson et al., 2003).

Materials

15-cm tissue culture dishes of A431 cells (~80% confluent)
Serum-free medium: DMEM containing 1 mg/ml BSA
KSHM buffer (see recipe), ice cold
4 μg/ml biotinylated transferrin (B-SS-Tfn; see Support Protocol 1) in KSHM containing 0.2% (w/v) BSA (KSHM/BSA)
ATP-regenerating system (see Support Protocol 6)
ATP-depleting system (see Support Protocol 7)
Cytosol (see Support Protocols 4 and 5)
50 μg/ml avidin (Sigma) in KSHM/BSA, for avidin assay only
1 mg/ml biocytin (Sigma), for avidin assay only
10 mM and 50 mM sodium 2-mercaptoethanesulfonate (MesNa; Sigma) in MesNa buffer (see recipe), prepare fresh (for MesNa assay only)
500 mM iodoacetamide (IAA; Sigma), prepare fresh (for MesNa assay only)
Blocking buffer (see recipe)
ELISA plates coated with anti-transferrin antibodies (see Support Protocol 2)
0.1 U/ml streptavidin–horseradish peroxidase (HRP; Pierce) in blocking buffer
Dulbecco's PBS (*APPENDIX 2A*)
o-Phenylenediamine tablets (Sigma)
H_2O_2 (Sigma)
HRP assay buffer: 51 mM phosphate/27 mM citrate, pH 5.0
2 M H_2SO_4 (see recipe)
Microcentrifuge, 4°C
ELISA plate reader with 492-nm filter
Additional reagents and equipment for permeabilizing cells (see Support Protocol 3)

Permeabilize cells

1. Incubate a 15-cm dish of A431 cells in 20 ml serum-free medium for 30 min at 37°C.
2. Wash cells four times with 20 ml each ice-cold KSHM.
3. Permeabilize cells (see Support Protocol 3).
4. Remove cytosol by dilution of cells into 50 ml KSHM and then collect permeabilized cell membranes by centrifugation at 1000 × *g* for 5 min at 4°C.

Set up reconstitution assay

5. Discard supernatant and resuspend permeabilized cell membranes (i.e., the pellet) in 500 μl of 4 μg/ml B-SS-Tfn in KSHM/BSA.

   For the number of A431 cells present in a confluent layer, 2×10^5 cells/cm^2 is a reasonable assumption. Therefore, a 15-cm dish at 80% confluency will yield 2.4×10^7 cells. Thus, each 15-cm plate should provide sufficient cells for ~50 to 70 assays. Each sample will therefore contain ~1×10^6 cells.

6. Add 10 μl membrane-B-SS-Tfn mixture to a microcentrifuge tube containing 4 μl of either an ATP-regenerating or an ATP-depleting mix, and/or cytosol, and/or purified components, and KSHM to give a final volume of 40 μl. Set up two sets of duplicates without cytosol and with an ATP-depleting system. Also set up two other sets of duplicates without cytosol and with an ATP-regenerating system. Incubate samples 30 min at 31°C except for one set of duplicates without cytosol and with an ATP-depleting system, which is held at 4°C.

   Information about purified components that might be added to the permeabilized cells is described elsewhere in more detail (see Alternate Protocols 1 and 2).

   The two sets of duplicate tubes without cytosol will be used as controls.

7. Incubate assay mixes 20 to 30 min at 37°C with gentle agitation every 5 min.

8. Pellet permeabilized cells by microcentrifugation for 20 sec at 22,000 × *g*, 4°C. Aspirate supernatant and continue with either avidin (step 9a) or MesNa (step 9b) assay. For either assay, hold a set of duplicate samples without cytosol but with an ATP-regenerating system at 4°C (i.e., do not treat with avidin or MesNa) and process with the other samples (step 13).

   The samples that are held at 4°C will be used to measure the total amount of B-SS-Tfn available for endocytosis.

For avidin assay

9a. Resuspend pelleted membranes in 100 μl KSHM containing 0.2% BSA and 50 μg/ml avidin. Incubate 60 min on ice.

10a. Quench remaining binding sites on avidin by the addition of 10 μl of 1 mg/ml biocytin. Leave for 10 min at 4°C. Continue with step 13.

For MesNa assay

9b. Resuspend pelleted membranes in 50 μl freshly prepared 10 mM MesNa in MesNa buffer and agitate gently for 30 min at 4°C.

10b. Add 12.5 μl freshly prepared 50 mM MesNa in MesNa buffer and incubate for a further 15 min at 4°C.

   For effective reduction of B-SS-Tfn, it is critical that the MesNa solution is freshly prepared just prior to addition to the cells.

11b. Add 16 μl freshly prepared 50 mM MesNa in MesNa buffer and incubate 15 min at 4°C.

12b. Quench unreacted MesNa by adding 30 μl of 500 mM freshly prepared IAA. Incubate 10 min at 4°C.

Solubilize cells

13. Add 100 µl blocking buffer to lyse the cells. Process total B-SS-Tfn samples (step 8) in parallel.

14. Add 100 µl blocking buffer to each well of an ELISA plate coated with anti-transferrin antibodies. Add 100 µl lysate to duplicate wells of the ELISA plate. Plate a titration of different amounts of the total B-SS-Tfn samples diluted in blocking buffer to maintain a final volume of 100 µl. Incubate 3 hr at 37°C or overnight at 4°C.

    To ensure that color development falls within a linear range, different amounts of the total B-SS-Tfn samples should be plated.

    Incubation of the ELISA plate at 37°C does not require a humidified, 5% CO_2 incubator.

Develop assay

15. Wash plate three times with 300 µl PBS per well.

16. Add 200 µl of 0.1 U/ml streptavidin-HRP in blocking buffer to each well and incubate 1 hr at room temperature.

17. Wash plate three times with 300 µl PBS per well.

18. Prepare the following reaction mix:

    10 mg *o*-phenylenediamine
    10 µl H_2O_2
    25 ml HRP assay buffer.

    CAUTION: *During the development of the HRP reaction product, gloves should be worn at all times. o-Phenylenediamine is carcinogenic, but preweighed tablets are commercially available that can be added directly to assay buffer.*

19. Add 200 µl reaction mix to each well of the ELISA plate to develop the reaction.

20. Stop the reaction by adding 50 µl of 2 M H_2SO_4, which also enhances color development.

    CAUTION: *2 M H_2SO_4 is a strong and corrosive acid and should be treated with appropriate care. The ELISA plates containing the reaction product should be disposed of in accordance with local practices for the disposal of hazardous material.*

21. Read absorbance on an ELISA plate reader at 492 nm. Check that the values obtained from titration of total samples (step 14) are within the linear range of absorbance.

    In general, there is a linear relationship up to an absorbance of ~0.8. Background values should have an absorbance <0.08.

Quantify results

22. Use the samples that were not treated with avidin or MesNa to estimate the total amount of B-SS-Tfn available for internalization.

23. Express the amount of avidin-inaccessible or MesNa-resistant B-SS-Tfn as a percentage of total B-SS-Tfn present in the samples held at 4°C.

    The signal (A_{492}) obtained from samples incubated on ice without cytosol and in the presence of ATP-regenerating system (step 6) indicates the background signal and is typically identical to that of an empty well. The signal from samples incubated without cytosol and in the presence of ATP-depleting system corresponds to that from any remaining intact cells in the preparation. This value should be subtracted from samples where B-SS-Tfn has been incubated with permeabilized cells under conditions where endocytosis occurs.

STAGE-SPECIFIC ASSAYS USING PERMEABILIZED CELLS

The clathrin coated–vesicle cycle can be divided into a series of steps with different biochemical requirements. These include the assembly of new coated pits onto the cell surface, cargo recruitment into these pits, invagination, and scission to form a coated vesicle.The permeabilized cell assay as described above distinguishes between the sequestration of cargo into deeply invaginated coated pits versus its internalization into coated vesicles (Schmid and Smythe, 1991). The assay system can be further refined, however, to select for particular intermediates. For example, although there are already coated pits present that are capable of cargo sequestration when the cells are permeabilized, addition of purified coat components can stimulate cargo sequestration into newly formed coated pits.

Coat Protein–Dependent Cargo Sequestration

ALTERNATE PROTOCOL 1

Addition of purified AP2 to assay mixes containing cytosol as described in Basic Protocol 2 results in enhanced B-SS-Tfn sequestration into newly formed clathrin-coated pits (Smythe et al., 1992; McLauchlan et al., 1998). The clathrin that participates in forming these new pits is recruited from the permeabilized cell membranes (McLauchlan et al., 1998). The permeabilized cell system can also be manipulated so that it is dependent on the addition of exogenously added clathrin (Jackson et al., 2003).

For AP2-dependent sequestration, perform the assay as described for the avidin inaccessibility assay in permeabilized cells (see Basic Protocol 2, steps 1 to 23), with the following changes. In step 6, add AP mix or purified AP2 (see Support Protocol 8) to the reaction mix, keeping the final volume at 40 μl. Also set up control incubations containing permeabilized cell membranes, ATP-regenerating system, and AP mix or AP2 only. The AP2 concentration that gives maximal AP2 dependence will vary with different cytosol preparations and needs to be determined empirically. The concentration of each batch of AP2 should also be titrated to optimize the signal. In general, 0.1 to 0.25 mg/ml AP2 gives maximum stimulation. AP2 is most stable in 10 mM Tris·Cl, pH 7.5, and no more than 10 μl of this solution should be added to the assay mixes to prevent buffer effects. The control reactions containing ATP-regenerating system and AP2 only give a signal that is generally equivalent to incubations in the presence of permeabilized cell membranes and ATP alone. If the signal is higher, then the difference should be subtracted from the AP2-dependent signal.

For clathrin- and AP2-dependent sequestration, perform the assay as described for the avidin inaccessibility assay in permeabilized cells (see Basic Protocol 2, steps 1 to 23), with the following changes. To generate a requirement for exogenous clathrin, add 0.4 μl of 100 μM stock (prepared in methanol) of the protein phosphatase inhibitor microcystin (1 μM final) to the reaction mixes in step 5 and incubate 10 min on ice and then 30 min at 37°C. Set up controls that include assay mixes containing coat components and ATP-regenerating system but omit cytosol. Coat proteins are added as described (see Basic Protocol 2, step 6). Typically, AP2 is added as described above. Microcystin is carcinogenic, so gloves should always be worn while carrying out these assays, and material must be disposed of in accordance with local practices. AP2-dependent cargo sequestration in permeabilized cells relies on recruitment of clathrin from the permeabilized cell membranes to participate in new coated-pit formation. There may, however, be occasions when it is necessary to add soluble clathrin. The amount of clathrin required (prepared as described, see Support Protocol 8, and dialyzed into KSHM) needs to be determined empirically but is generally in the range of 0.1 to 0.25 mg/ml. Microcystin is effective presumably because a dephosphorylation event(s) is required for the mobilization of clathrin from membranes (Jackson et al., 2003).

ALTERNATE PROTOCOL 2

Further Manipulation of Endocytosis in Permeabilized Cells

The list of components involved in coated-vesicle formation is expanding, and hence there is a need to further dissect the temporal and spatial requirements for coated-vesicle formation.

Manipulation of cytosolic components

Soluble components may be manipulated by addition of purified components directly to assay mixes or by supplementing cytosol with purified components. Alternatively, to test for a specific requirement for a particular protein, cytosol can be immunodepleted using antibodies specific for the protein before being added to the assay mix (McLauchlan et al., 1998). Controls should include cytosol that has been mock depleted with an irrelevant antibody.

Manipulation of membrane components

Permeabilized cell membranes may also be manipulated. For example, truncated proteins or particular domains of endocytic proteins can act as dominant-negative inhibitors of endocytosis by targeting interacting proteins and locking them into a dead-end nonfunctional complex. In particular, the SH3 domains of proteins that interact with the proline-rich domain of dynamin (e.g., amphiphysin and endophilin) have been utilized to inhibit ligand sequestration and internalization in permeabilized cells (Simpson et al., 1999; Hill et al., 2001). These protein modules bind to targets on the membrane and render them incapable of functioning in the coated-vesicle cycle.

Treatment of permeabilized cells with SH3 domains

The use of SH3 domains is one example of targeting a membrane-associated factor. Other possibilities are to use inhibitory antibodies or other protein modules. In each case, it is essential to include a negative control that mimics as closely as possible the inhibitory component. Care should be taken in the interpretation of experiments where membrane components are targeted with, for example, a specific antibody, in case there are issues of steric hindrance. The most meaningful results will be obtained if it is possible to rescue the inhibited membranes by addition of the target protein in a soluble form (e.g., Hill et al., 2001). The authors have found that the best working range for inhibition by the SH3 domains of amphiphysin and endophilin is 1 to 5 μM.

Many peripheral membrane proteins that cycle from the cytoplasm to the membrane during the coated-vesicle cycle remain associated with permeabilized cell membranes. If no specific inhibitor is available, it is sometimes possible to remove peripheral membrane proteins by stripping the membranes with high concentrations of NaCl and KCl or urea. The extent of removal of components may be assessed by immunoblotting (*UNIT 6.2*). The concentrations of chaotropic reagents required to remove peripheral proteins may, however, have detrimental effects on the ability of the membranes to support the reconstitution of clathrin-coated pit formation, and so it is important to titrate the concentration of stripping agent and test whether cargo sequestration and internalization may be reconstituted with a reasonable efficiency following the treatment.

Additional Materials *(also see Basic Protocol 2 and see Alternate Protocol 1)*

Purified GST fusion protein containing an SH3 domain of interest

1. Prepare permeabilized cell membranes and incubate with B-SS-Tfn as described (see Basic Protocol 2, steps 1 to 4).

2. Preincubate permeabilized cell membranes with GST fusion protein containing SH3 domain of choice for 5 min at 30°C.

   The minimum amount of GST fusion protein required to inhibit the membrane target needs to be determined empirically by titration of different amounts. A useful working range with which to start is 1 to 5 μM.

3. Pellet membranes by centrifugation for 5 sec at 22,000 × *g*, 4°C. Aspirate supernatant containing excess GST fusion protein.

4. Resuspend membranes and continue with assay as described (see Basic Protocol 2, steps 5 to 23).

   Controls should include membranes treated either with GST alone or with another similar SH3 domain that has no apparent role in endocytosis.

PREPARATION OF BIOTINYLATED TRANSFERRIN

SUPPORT PROTOCOL 1

Biotinylated transferrin (B-SS-Tfn) is used as a marker to follow endocytosis in intact and permeabilized cells. It binds to the transferrin receptor, which is internalized by receptor-mediated endocytosis.

Materials

Transferrin (Sigma)
Dulbecco's PBS (*APPENDIX 2A*)
NHS-SS-biotin: sulfosuccinimidyl 2-(biotinamido)-ethyl-1,3-dithiopropionate (EZ-Link Sulfo-NHS-SS-Biotin; Pierce)
Dimethyl sulfoxide (DMSO; Sigma)
500 mM Tris·Cl, pH 7.5 (*APPENDIX 2A*)
PBS/BSA: PBS containing 1 mg/ml BSA
Liquid nitrogen
Dialysis tubing (10,000 MWCO) or buffer exchangers (e.g., Vivaspins; Vivascience)
Quartz cuvettes
Spectrophotometer with UV source (280 nm)

1. Prepare a 10 mg/ml solution of transferrin in distilled water.

   Water is used rather than buffer because transferrin is usually sold as a desiccated solution and so already contains salt.

2. Dialyze or buffer-exchange the transferrin solution into PBS to ensure that any amines present in the buffer salts are removed.

   Amines could interfere with the biotinylation reaction.

3. Using a quartz cuvette, measure the absorbance at 280 nm to determine the exact concentration of transferrin.

   A solution of 1 mg/ml transferrin has an absorbance of 1.2 at 280 nm.

4. Use 1 mg transferrin for the biotinylation reaction. Incubate 30 min at 30°C with an ~20-fold molar excess of NHS-SS-biotin freshly prepared as a 100× stock in DMSO.

   This ratio of biotin to transferrin results in one or two molecules of biotin per transferrin molecule as determined with the HABA reagent (Green, 1970). This is optimal because too many biotin moieties per transferrin molecule could potentially interfere with binding to the transferrin receptor.

5. Stop the biotinylation reaction by adding 10 μl of 500 mM Tris·Cl, pH 7.5.

6. Exchange buffer by dialysis against PBS/BSA to remove free NHS-SS-biotin.

7. Prepare a 1 mg/ml solution of B-SS-Tfn. Divide into aliquots (usually 10 µl) in microcentrifuge tubes and snap freeze in liquid nitrogen before storing at −80°C.

   The B-SS-Tfn is stable for at least 1 year at −80°C. A fresh aliquot is used for each in vitro assay, and repeated freeze-thawing is avoided.

   CAUTION: *When dispensing and snap-freezing in liquid nitrogen, a face mask and protective gloves should always be worn.*

SUPPORT PROTOCOL 2

PREPARATION OF ELISA PLATES

This protocol describes the preparation of enzyme-linked immunosorbent assay (ELISA) plates for analysis of the samples.

Materials

Anti-transferrin antibodies (available as sheep serum from Alba Bioscience)
100 mM sodium bicarbonate, pH 8.3
Dulbecco's PBS (*APPENDIX 2A*)
Blocking buffer (see recipe)
Flat-bottomed ELISA microtiter plates

1. Coat flat-bottomed ELISA microtiter plates with 200 µl anti-transferrin antibody diluted to 1:5000 in 100 mM sodium bicarbonate, pH 8.3.
2. Incubate plates either at 37°C for 3 hr or overnight at 4°C.
3. Wash three times with 300 µl PBS followed by incubation with 250 µl blocking buffer for a minimum of 1 hr at room temperature.
4. Store plates in blocking buffer for up to 1 week at 4°C. Remove blocking buffer before using plates.

SUPPORT PROTOCOL 3

METHODS FOR PERMEABILIZATION OF CELLS

Freeze-Thaw Permeabilization

Freeze-thaw permeabilization is carried out by freezing the cells in liquid nitrogen and thawing them rapidly at 37°C. Further cycles of freeze-thawing may be required to efficiently permeabilize >90% of the cells, but it is important to assess the degree of cell breakage after each cycle to ensure that the cells have not been grossly damaged. The degree of cell breakage can be assessed either by measurement of release of lactate dehydrogenase (see Support Protocol 9) or by assessing accessibility to trypan blue using light microscopy (*UNIT 1.1*).

Streptolysin O Permeabilization

Bacterial toxin streptolysin O (SLO) has been used extensively to permeabilize various cell types (Bhakdi et al., 1985; Ullrich et al., 1995). As SLO makes relatively small holes in the plasma membrane, it is less likely to be physically disruptive to the cell as compared with, for example, scraping of the cells. SLO is sold in amounts measured in International Units, but these units do not necessarily correspond to the ability of the toxin to permeabilize cells (Ahnert-Hilger et al., 1985), and so each batch needs to be titrated and optimized accordingly for each particular cell type. A useful working range is 0.05 to 0.1 IU/ml diluted in PBS. SLO is perhaps more useful for cells grown in suspension rather than adherent cells as there may be problems with cell loss of adherent cells. A general procedure is to incubate the cells in the appropriate amount of SLO at 37°C followed by incubation at 4°C, although the lengths of these incubations need to be optimized.

Permeabilization by Mechanical Shear

Human carcinoma A431 cells can be effectively permeabilized (>90% of the cytosolic components are released) by simply scraping from the tissue culture dish.

PREPARATION OF CYTOSOL FROM TISSUE

SUPPORT PROTOCOL 4

Cytosol from bovine, porcine, and murine brain, tissue culture cells (e.g., A431 and K562), and even yeast cells supports endocytosis in permeabilized cells, although with varying efficiency. Brain cytosol is most often used because of the availability of relatively large amounts of tissue and the abundance of endocytic proteins in this tissue (Morris and Schmid, 1995). Cytosol prepared from liver may not be used to measure the sequestration and internalization of transferrin because of the high levels of blood found in liver. This may contain sufficient transferrin to compete for binding with biotinylated transferrin (B-SS-Tfn). See Support Protocol 5 for preparation of cytosol from tissue culture cells.

Materials

KSHM buffer (see recipe), ice cold
Tissue (brain or liver), freshly harvested or stored at −80°C
Liquid nitrogen

Motor-driven 50-ml Dounce homogenizer with Teflon restle
Medium-speed centrifuge and rotor (e.g., Beckman J2-21 with JA 25.5 rotor), 4°C, and centrifuge tubes
Ultracentrifuge (e.g., Beckman LE-80K with 45Ti rotor), 4°C, and ultracentrifuge tubes

1. Add an equal volume of KSHM buffer to brain or liver tissue that has been chopped into small pieces.

   Tissue can be used either fresh or frozen. If frozen tissue is used, it must be frozen as quickly as possible following slaughter, preferably in liquid nitrogen, and must be stored at −80°C.

   If mouse or rat brains are used, it is possible to pool several brains to make a larger batch of cytosol.

2. Homogenize in a motor-driven 50-ml Dounce homogenizer at 4°C. Homogenize until most material is in a smooth paste, but avoid foaming, which will lead to protein denaturation.

   CAUTION: *When using a motor-driven Dounce homogenizer, eye protection and protective gloves should always be worn.*

3. Centrifuge homogenate 20 min at 10,000 × *g*, 4°C, to remove large aggregates.

4. Transfer supernatant to an ultracentrifuge tube and centrifuge 1 hr at 100,000 × *g*, 4°C, to yield a cytosol supernatant and a microsomal pellet.

5. Transfer supernatant to microcentrifuge tubes in small aliquots (100 to 500 µl). Snap-freeze cytosol in liquid nitrogen before storage at −80°C for up to at least 1 year.

   For each experiment, a fresh aliquot is thawed rapidly at 37°C before being placed on ice for subsequent addition to the assay tubes.

   CAUTION: *When snap-freezing in liquid nitrogen, a face mask and protective gloves should always be worn.*

SUPPORT PROTOCOL 5

PREPARATION OF CYTOSOL FROM TISSUE CULTURE CELLS

Although adherent cells may be used for the preparation of cytosol, cells grown in suspension, (e.g., K562 or sHeLa cells) are generally used, as they can be conveniently grown in reasonable quantities.

Additional Materials *(also see Support Protocol 4)*

Cells grown in suspension
KSHM buffer (see recipe) containing protease inhibitors (e.g., Complete EDTA-Free Protease Inhibitor Cocktail; Roche), ice cold
10-ml Dounce homogenizer with Teflon pestle, optional

1. Maintain cells in suspension at a density between 0.2×10^5 and 1×10^6 cells per ml.

   The authors generally prepare cytosol from 1 to 2 liters of cells in suspension (or twenty 15-cm plates if adherent cells are used).

2. Collect cells by centrifugation at 1,000 × *g* for 5 min.

   Adherent cells should be collected by trypsinization (UNIT 1.1) before pelleting.

3. Resuspend cell pellet in 5 vol ice-cold KSHM buffer containing protease inhibitors.

4. Lyse cells either by homogenization using a 10-ml Dounce homogenizer (10 to 20 passes) or by one or two cycles of freeze-thawing. Maintain homogenate at 4°C at all times.

   Freeze-thawing is carried out by freezing the cell pellet in liquid nitrogen followed by thawing rapidly at 37°C before placing on ice. The degree of cell breakage can be assessed either by measurement of release of lactate dehydrogenase (see Support Protocol 9) or by assessing accessibility to trypan blue using light microscopy (UNIT 1.1). More than one cycle of freeze-thawing may be required to permeabilize the majority of the cells. In the case of both homogenization and freeze-thawing, however, care should be taken to avoid extensive damage to a limited number of cells, as this could result in the release of lysosomal enzymes with potential proteolytic activity.

5. Prepare cytosol by ultracentrifugation of the cell lysate for 1 hr at 100,000 × *g*, 4°C.

6. Transfer supernatant to cryovials in small aliquots (100 to 500 µl). Snap-freeze cytosol in liquid nitrogen before storage at −80°C for up to 1 year.

   For each experiment, a fresh aliquot is thawed rapidly at 37°C before being placed on ice for subsequent addition to the assay tubes.

   CAUTION: *When snap-freezing in liquid nitrogen, a face mask and protective gloves should always be worn.*

SUPPORT PROTOCOL 6

PREPARATION OF AN ATP-REGENERATING SYSTEM

ATP is required for endocytosis. To allow endocytosis to occur in permeabilized cells, it is thus necessary to provide ATP. A regenerating system ensures that the concentration of ATP is maintained at a constant level and hence never becomes limiting. The ATP-regenerating system is prepared as a 10× stock and consists of a mixture of ATP, creatine phosphokinase, and phosphocreatine. When ATP is hydrolyzed to ADP, creatine phosphokinase transfers phosphate from phosphocreatine to regenerate ATP, thus maintaining ATP at a constant level.

Materials

ATP (Sigma)
Phosphocreatine (Sigma)
Creatine phosphokinase (Sigma)
50% (v/v) glycerol in KSHM buffer (see recipe)

1. Prepare the following stock solutions:

   200 mM ATP
   200 mM phosphocreatine
   0.5 mg/ml creatine phosphokinase in 50% (v/v) glycerol in KSHM buffer.

   Stocks can be stored in aliquots at −20°C for up to 6 months.

   It is critical that stocks of ATP are maintained at neutral pH. Addition of ATP to many buffers at pH 7 will cause a substantial reduction in pH, and so the solution needs to be titrated to pH 7 or above before dividing into aliquots and freezing. The concentration of ATP should be determined by spectrophotometry using a molar extinction coefficient of 15.4×10^3 *at pH 7.0 and 260 nm.*

2. Prepare ATP-regenerating system just prior to use by making a solution of the following:

   10 μl 200 mM ATP
   200 μl 200 mM phosphocreatine
   10 μl 0.5 mg/ml creatine phosphokinase.

PREPARATION OF AN ATP-DEPLETING SYSTEM

SUPPORT PROTOCOL 7

Because endocytosis is dependent on ATP, certain control experiments in permeabilized cells require the use of an ATP-depleting system, which effectively removes all of the available ATP. Inclusion of an ATP-depleting system allows an estimate of the contribution made by any remaining intact cells to the endocytosis signal measured, because the ATP-depleting system is not cell permeable and so will only prevent endocytosis in permeabilized cells. The ATP-depleting system is prepared as a 10× stock and consists of a mixture of hexokinase and glucose. Hexokinase catalyzes the formation of glucose-6-phosphate from glucose, using ATP as a source of phosphate. Hexokinase is often supplied as an ammonium sulfate precipitate, which is stable for long periods at 4°C.

NOTE: Prepare ATP-depleting system just prior to use.

Materials

Ammonium sulfate suspension of hexokinase (Sigma)
500 mM glucose
KSHM buffer (see recipe)
Microcentrifuge, 4°C

1. Centrifuge 10 μl of an ammonium sulfate suspension of 10,000 U/ml hexokinase at 22,000 × *g* for 1 min at 4°C.
2. Discard supernatant and resuspend pellet in 10 μl of 500 mM glucose and 40 μl KSHM.

SUPPORT PROTOCOL 8

PREPARATION OF COAT PROTEINS

Coat proteins are prepared from either bovine or porcine brains according to modifications of the method of Campbell et al. (1984).

Materials

Bovine or porcine brains
Buffer A (see recipe)
12.5% (w/v) Ficoll/12.5% (w/v) sucrose in buffer A
Buffer B: 1 vol buffer A and 3 vol of 1 M Tris·Cl, pH 8 (*APPENDIX 2A*)
Ammonium sulfate
1 M DTT (*APPENDIX 2A*)
100 mM PMSF in 100% ethanol or isopropanol, store at −20°C
Staining solution: 40% (v/v) methanol/7% (v/v) acetic acid/25 g/liter Coomassie brilliant blue R250
Destaining solution: 15% (v/v) methanol/7% (v/v) acetic acid in water
10 mM Tris·Cl, pH 7.5 (*APPENDIX 2A*), for AP mix purification only
KSHM buffer (see recipe), for clathrin purification only
Liquid nitrogen
Kitchen blender
Medium-speed centrifuge and rotor (e.g., Beckman J2-21 with JLA 10.5 and JA 25.5 rotors), 4°C, and 500- and 50-ml centrifuge tubes
Ultracentrifuge (e.g., Beckman LE-80K with 45Ti rotor), 4°C, and 65-ml ultracentrifuge tubes
50-ml Dounce homogenizer with Teflon pestle
2-liter graduated cylinder
Sephacryl S-400 column (26 mm × 1 m)
Fraction collector and tubes
50-ml Vivaspin concentrators (Vivascience)
Dialysis membrane (10,000 MWCO)
Cryovials
Additional reagents and equipment for SDS–polyacrylamide gel electrophoresis (*UNIT 6.1*)

NOTE: All procedures are carried out at 4°C and all solutions should be ice cold.

Homogenize brains

1. Collect 1 kg bovine or porcine brains as soon as possible after animal sacrifice.

   Brains should be used as soon as possible after slaughter. If this is not possible, the tissue should be transported on dry ice from the slaughterhouse and stored frozen at −80°C. If frozen, the brains should be thawed overnight at 4°C or for 2 hr at room temperature.

2. Homogenize brains in an equal volume of buffer A with two 30-sec pulses in a kitchen blender.

Isolate coated vesicles

3. Centrifuge homogenate 30 min in a 500-ml tube at 12,000 × *g* in a JLA 10.5 rotor. Transfer supernatant to a clean 500-ml centrifuge tube.
4. Re-extract pellet in 600 ml buffer A and centrifuge at 12,000 × *g* for 30 min.
5. Combine supernatants, divide between 65-ml ultracentrifuge tubes, and ultra centrifuge 1 hr in a 45Ti rotor at 49,000 × *g*.

6. Discard supernatant and resuspend resulting microsomal pellet in 110 ml buffer A using a 50-ml Dounce homogenizer (10 to 20 strokes). Use a smaller volume of buffer A for initial resuspension and then mix thoroughly with the remaining volume. Add 110 ml of 12.5% Ficoll/12.5% sucrose in buffer A.
7. Divide mixture between 50-ml centrifuge tubes and centrifuge 40 min at 41,400 × *g* in a JA 25.5 rotor.
8. Transfer supernatant to a 2-liter graduated cylinder and dilute to 1 liter in buffer A. Divide between 65-ml ultracentrifuge tubes and ultracentrifuge 1 hr at 85,000 × *g* to pellet the coated vesicles.

Isolate coat proteins

9. To strip the coat proteins from the vesicles, resuspend pellet in ∼120 ml buffer B using the Dounce homogenizer (five to ten strokes) and incubate ≥15 min on ice.
10. To remove membranes, ultracentrifuge 1 hr at 158,000 × *g*. Re-extract membrane pellets by resuspension in buffer B and centrifugation as before.
11. Precipitate coat proteins from the combined supernatants by addition of solid ammonium sulfate to 50% saturation (e.g., 29.5 g per 100 ml supernatant).
12. To recover the precipitate, centrifuge 15 min at 12,000 × *g* and resuspend in ∼8 ml buffer B.

Purify clathrin and adaptor proteins

13. Apply this material to a 26-mm × 1-m Sephacryl S-400 column equilibrated in 800 ml (∼2 column vol) buffer B containing 0.1 mM DTT and 0.1 mM PMSF, added just before use. Elute with 600 ml buffer B. Collect 5-ml fractions with a fraction collector.
14. Identify fractions containing clathrin and the adaptor proteins by SDS-PAGE (*UNIT 6.1*) on an 8% SDS–polyacrylamide gel. Use staining and destaining solutions to visualize the proteins with Coomassie blue.

    Following gel filtration in Sephacryl S-400, the adaptor pool is a mixture of the plasma membrane adaptor AP2 and the trans-Golgi network adaptor AP1. Previous studies have compared the activity of this AP mix with AP2 that had been separated from AP1 and found that they exhibit the same activity, indicating that AP1 has no apparent competitive effect on AP2 for clathrin-coated pit and vesicle formation at the plasma membrane (Smythe et al., 1992). This means that for many experiments in the permeabilized cells, the mix of APs does not require further purification. In some cases, however, it may be important to prepare purified AP2. AP2 can be purified from AP1 according to the method of Matsui and Kirchhausen (1990) or alternatively according to the method of Pauloin and Thurieau (1993). Both methods rely on the differential binding of AP1 and AP2 to hydroxyapatite. The difference in the methods is that one yields AP2 that still has the μ2 kinase associated with it (Matsui and Kirchhausen, 1990) whereas the other yields AP2 free of μ2 kinase (Pauloin and Thurieau, 1993).

    For more information about staining protein gels, see UNIT 6.6.

15. Pool fractions containing clathrin (630 kDa) and adaptor proteins (∼320 kDa) separately.

    Clathrin can easily be identified by the presence of an ∼180-kDa heavy chain and two light chains of ∼30 kDa. The APs may be identified by several bands at ∼100 kDa and by the 50-kDa μ2 subunit.

16. Concentrate to ∼1 mg/ml using 50-ml vivaspin concentrators according to manufacture's instructions.

17. Dialyze against two changes of 1 liter of 10 mM Tris·Cl, pH 7.5 (for APs) or KSHM (for clathrin) for 2 to 3 hr or overnight at 4°C.

18. Using liquid nitrogen, snap-freeze in 100-µl aliquots in microcentrifuge tubes before storage at −80°C for up to at least 1 year.

    CAUTION: *When dispensing and snap-freezing in liquid nitrogen, a face mask and protective gloves should always be worn.*

    A fresh aliquot is thawed rapidly at 37°C for each assay.

SUPPORT PROTOCOL 9

LACTATE DEHYDROGENASE ASSAY

Lactate dehydrogenase (LDH) is a cytosolic enzyme, the release of which provides a good estimate of how well cells are permeabilized. LDH catalyzes the conversion of pyruvate to lactate coupled to the oxidation of NADH (Kornberg, 1955). The oxidation of nicotinamide adenine dinucleotide (NADH) is followed spectrophotometrically at 340 nm. A small aliquot of the total permeabilized cells is used to estimate the extent of cell breakage.

Materials

Cell suspension samples, unpermeabilized and permeabilized with method of choice (see Support Protocol 3)
KSHM buffer (see recipe)
0.5% (v/v) Triton X-100 in PBS (*APPENDIX 2A*)
LDH reaction buffer (see recipe)

Microcentrifuge, 4°C
Spectrophotometer with UV detector (340 nm) and quartz cuvettes

1. After initial permeabilization, dilute cells to 2×10^5 cells/ml with KSHM to promote the release of cytosol and then pellet by centrifugation at $1000 \times g$ for 5 min at 4°C. Analyze an equal number of unpermeabilized (intact) cells in parallel.

2. Resuspend cell pellet in 0.5% Triton X-100 in PBS. Leave on ice for 10 min.

3. Add a small volume of the cell suspension (1 to 5 µl) to a quartz cuvette and start the reaction by the addition of 1 ml LDH reaction buffer.

4. Follow the rate of oxidation of NADH by inserting the cuvette into a spectrophotometer and taking readings at 340 nm for 1 to 10 min, depending on the activity of the sample.

   The initial rate of enzyme activity is used to determine the amount of LDH remaining in the cells and is compared with that of an equal number of intact cells to assess the efficiency of permeabilization. Cell permeabilization should be >90% efficient (i.e., the LDH signal from permeabilized cells should be <10% of that from the intact cells).

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Blocking buffer

10 mM Tris·Cl, pH 7.4 (*APPENDIX 2A*)
0.2% (w/v) BSA
1% (w/v) Triton X-100
0.1% (w/v) SDS (*APPENDIX 2A*)
1 mM EDTA

continued

50 mM NaCl (*APPENDIX 2A*)
Store up to 1 week at room temperature

Blocking buffer can also be stored as a 5× stock without BSA for up to 2 months at room temperature.

Buffer A

100 mM 2-(*N*-morpholino)ethanesulfonic acid (MES), pH 6.5
0.5 mM $MgCl_2$ (*APPENDIX 2A*)
1 mM EDTA
1 mM DTT (*APPENDIX 2A*)
Store up to 1 week at 4°C (without PMSF)
Add 0.1 mM PMSF immediately before use

PMSF is a serine protease inhibitor that has a very short half-life in aqueous solution. A stock solution (100 mM) can be prepared in 100% ethanol or isopropanol. Immediately prior to use, this solution can be diluted into the relevant buffer, which should be vigorously stirred to enhance the solubility of PMSF in aqueous solution.

H_2SO_4, 2 M

Dilute 53.30 ml of 98% pure H_2SO_4 liquid (specific gravity, 1.84 g/ml; mol. wt., 98.07) into water to make 500 ml of a 2 M solution. Store up to 1 year at room temperature.

CAUTION: *Dilution of sulfuric acid is an exothermic reaction, and thus this solution should be prepared in a fume hood by the slow addition of the acid to distilled water with gentle stirring. Adequate eye protection should be worn.*

KSHM buffer

20 mM HEPES, pH 7.4
100 mM potassium acetate
85 mM sucrose
1 mM $MgCl_2$ (*APPENDIX 2A*)
Store up to 1 week at 4°C

The composition of this buffer has been chosen to mimic the intracellular environment as closely as possible.

Protease inhibitors should be included when preparing cytosol samples. Tablets containing a mixture of protease inhibitors with a broad substrate specificity are commercially available (e.g., Complete EDTA-Free Prolease Inhibitor Cocktail; Roche)

LDH reaction buffer

0.33 mM pyruvate (Sigma)
0.132 mM reduced NADH (Sigma; diluted from a 1.32 mM stock made fresh in 1 mM $NaHCO_3$)
250 mM sucrose (Sigma)
6.6 mM HEPES, pH 7.2 (Merck)
Prepare fresh

MesNa buffer

50 mM Tris·Cl, pH 8.6 (*APPENDIX 2A*)
100 mM NaCl (*APPENDIX 2A*)
1 mM EDTA
0.2% (v/v) BSA
Store up to 2 weeks at 4°C

COMMENTARY

Background Information

Clathrin-mediated endocytosis is responsible for the cellular uptake of a variety of biologically important macromolecules, including nutrients, growth factors, and hormones (Mellman, 1996). Material destined for internalization is packaged into specialized regions of the membrane called coated pits. The coated pits invaginate and pinch off forming coated vesicles. Following uncoating and fusion with the early endosomal compartment, internalized material is sorted to a variety of destinations within the cell. It may be recycled to the cell surface, delivered to late endosomes and ultimately lysosomes, or transported across the cell in the process of transcytosis. Material can be internalized either bound to specific transmembrane receptors (receptor-mediated endocytosis) or by being present in the soluble material captured by coated pits as they become coated vesicles (fluid-phase endocytosis). Bulk membrane is similarly internalized if included in clathrin-coated vesicles (absorptive endocytosis).

As well as being a fundamental process in almost all eukaryotic cells, coated-vesicle formation plays a critical role in a number of tissue-specific events such as synaptic-vesicle recycling, the control of morphogen gradients during development, immune surveillance, and downregulation of receptor tyrosine kinases that have mitogenic effects (Conner and Schmid, 2003). Furthermore, the endocytic pathway is often hijacked by pathogens in order to infect cells (Marsh and Pelchen-Matthews, 2000). For these reasons, it is important to have robust assays that allow the measurement of clathrin-mediated endocytosis in intact cells.

Coated pits form from the assembly of clathrin, the AP2 adaptor complex, and other accessory proteins from the cytosol onto the membrane. Clathrin polymerizes onto the membrane to form the characteristic lattice diagnostic of coated pits. The heterotetrameric AP2 complex is the other major protein component of isolated coated vesicles. Within the clathrin lattice, it links clathrin to transmembrane cargo such as the transferrin receptor (Ohno et al., 1995). AP2 is composed of two 100-kDa subunits (α- and β2-adaptin), a 50-kDa subunit (μ2), and a 17- to 19-kDa subunit (σ2). AP2 interacts with clathrin via the hinge of β2-adaptin (Shih et al., 1995) and with cargo via the μ2 subunit (Ohno et al., 1995; Owen and Evans, 1998). The large-molecular-weight GTPase dynamin functions in the invagination and scission of clathrin-coated pits, although its precise mechanism of action remains controversial (Song and Schmid, 2003). In addition to clathrin, AP2, and dynamin, a host of other proteins (including eps15, epsin, β-arrestin, Dab2, numb, ARH, AP180, amphiphysin, endophilin, and rab5) are involved in coated-vesicle formation, and their functions are beginning to be defined (Brodsky et al., 2001; Traub, 2003). Some of these proteins, such as epsin, Dab2, ARH, and β-arrestin, may act as adaptors for specific cargo (Bonifacino and Traub, 2003). Many of these proteins are involved in a complex series of interactions with each other and with AP2 and clathrin. Furthermore, there is increasing evidence for links between coated-vesicle formation and the actin cytoskeleton with such proteins as intersection, syndapin, and mAbp1 being important in mediating these interactions (Schafer, 2002; Smythe and Ayscough, 2003). This implies that coated-vesicle formation results from a complex series of interactions between different components that is regulated in space and time. The real challenge for the future lies in deciphering how these interactions are regulated.

One approach to understanding the complexity of these interactions is through the use of cell-free assays that reconstitute individual stages in the coated-vesicle cycle. These assays allow the manipulation of endocytic components so that their temporal and spatial interactions can be determined. These assay systems are not only applicable to understanding the regulation of the core endocytic machinery but might also be used to investigate how specific cargo (e.g., receptor tyrosine kinases) modulate the core machinery to facilitate their internalization (Lamaze and Schmid, 1995; Lanzetti et al., 2000; Haglund et al., 2002).

Other ligands

The uptake of transferrin bound to its receptor is used extensively to study receptor-mediated endocytosis because the pathway followed by transferrin has been extensively characterized (*UNIT 15.3*). It is known that the kinetics of the internalization of the receptor alone are identical to those of the ligand-bound receptor (Watts, 1985). Although transferrin is a valuable reporter molecule that allows examination of the core endocytic machinery, the uptake of other ligands and

receptors may also be measured in permeabilized cells. The assay systems may, for example, be modified to measure the uptake of other transmembrane proteins. A ligand may be biotinylated as described for transferrin. If no ligand is readily available, specific antibodies that can be biotinylated may also be used as ligands. Care needs to be taken using this approach because antibodies are divalent and can potentially cross-link receptors and induce their internalization via other endocytic routes (e.g., phagocytosis; *UNIT 15.7*). Therefore, it is advisable either to confirm that antibody cross-linking is not occurring using intact cells (e.g., by potassium depletion of cells, which is a reasonably specific inhibitor of clathrin-mediated endocytosis; Larkin et al., 1983) or, perhaps more cleanly, to use antibody Fab fragments (Harlow and Lane, 1988).

If no suitable ligands are available, it is still possible to measure internalization of particular transmembrane proteins by biotinylation of the entire cell surface using NHS-SS-biotin. Biotinylated cargo protected from avidin or MesNa may then be collected following immunoprecipitation (*UNIT 7.2*) or by immunoblotting (*UNIT 6.2*) of material captured on avidin agarose (Schmidt et al., 1997; Palacios et al., 2002).

When examining the stimulated uptake of cell surface receptors such as growth factor receptors in vitro, it should be borne in mind that there is a significant uptake of membrane simply by inclusion into clathrin-coated pits as they invaginate and pinch off. This must be taken into account when designing a permeabilized cell assay for this type of receptor, and the amount of sequestration or internalization by bulk flow must be subtracted from the total signal. This has been demonstrated for epidermal growth factor (EGF) receptor uptake (Lamaze et al., 1993; Lamaze and Schmid, 1995). In this case, an antagonistic antibody to the receptor was used to assess bulk internalization in the absence of EGF under conditions where this antibody had been shown not to induce internalization in intact cells. Analysis showed that bulk uptake of material accounted for ~50% of the signal seen, demonstrating the importance of this measurement in accurately assessing the role of individual components in stimulated uptake.

Critical Parameters

Cell maintenance and permeabilization

The permeabilized assays may be performed in a variety of different cell types. The major criteria are that the cells are in good condition and that permeabilization of the cells occurs efficiently, as the success of the assay depends on this.

Cell maintenance. For optimal efficiency of reconstitution of the coated-vesicle cycle in permeabilized cells, care should be taken to maintain cells in logarithmic phase. It is worth screening a variety of conditions of serum and growth and degrees of confluency to establish the optimum conditions of permeabilization for particular cell types. In the authors' experience, for example, they reconstitute different stages of the coated-vesicle cycle in A431 cells most efficiently when cells are grown in defined fetal bovine serum (HyClone) and seeded <24 hr prior to permeabilization, with a final confluency of 70% to 90%.

Cell permeabilization. The optimal method used to permeabilize the cells also needs to be determined empirically. The biochemical assays described in this unit for cargo sequestration and internalization are reliant on efficiencies of permeabilization of >90% (measured by LDH release; see Support Protocol 9). Cell preparations where ≤90% of the cells are permeabilized are unsuitable because endocytosis by the remaining intact cells in the preparation will make a significant contribution to the background signal measured in incubations containing an ATP-depleting system only. Different cell lines show different degrees of permeabilization, however, and it is beneficial to screen several different conditions of permeabilization to ensure maximum efficiency of reconstitution of the clathrin coated–vesicle cycle. Several possible methods are listed in Support Protocol 3. One criterion by which to judge the effectiveness of the permeabilization procedure is visualization of the cells by light microscopy following staining with trypan blue (*UNIT 1.1*). Analysis of the permeabilized cell preparation by electron microscopy will provide further confidence that the overall morphology of the cells is maintained. Ultimately, however, the best measure of a good permeabilization protocol is efficient ligand sequestration and internalization.

Ligand detection

Transferrin receptors are abundant on most cell types, but for other transmembrane proteins, it is important to ensure that the method of detection will be sufficiently sensitive to allow detection of small amounts of endocytosed protein. For example, if surface biotinylation is used to label a transmembrane protein, it is essential that enough biotin moieties are

attached so that between 1% and 5% of the total biotinylated transmembrane protein can still be detected, as this will be the amount internalized at early time points. Another important parameter that should be determined is the linearity of the ELISA plate signal by optimizing the amount of cell lysate that is plated.

Anticipated Results

In intact cells (Basic Protocol 1), the avidin and MesNa assays will measure the same amount of internalized B-SS-Tfn in control cells. This will peak to a maximum of 40% to 60% of the total cell-associated B-SS-Tfn after 5 to 10 min. There is then a drop in the amount of B-SS-Tfn that is apparently cell associated as a result of recycling of B-SS-Tfn back to the cell surface and discharge into the medium (Hopkins and Trowbridge, 1983). Differences in the extent of internalization measured by these assays will be detected under conditions where, for example, scission is inhibited but invagination is not. This could result from transfection of a dominant-negative mutant form of a protein required specifically for scission. Under these conditions, the avidin assay will measure increased apparent internalization as compared with the MesNa assay, although the difference in signals will actually be due to increased sequestration in deeply invaginated coated pits.

In Basic Protocol 2, where endocytosis is being measured in permeabilized cells, the avidin assay measures B-SS-Tfn sequestration into deeply invaginated coated pits and internalization into coated vesicles, whereas the MesNa assay will measure internalization into coated vesicles only. This difference is reflected in the signal obtained with the two assays. Routinely, 25% to 50% of total B-SS-Tfn becomes avidin inaccessible, whereas 10% to 30% becomes MesNa resistant. Coat protein–dependent sequestration results in 10% to 20% of total B-SS-Tfn becoming avidin inaccessible. If results lower than these values are obtained, care should be taken in the interpretation of results, as this will indicate that the reconstitution of a particular step in the coated-vesicle cycle is suboptimal.

Time Considerations

Following preincubation with serum-free medium (0.5 hr), endocytic assays in intact cells (see Basic Protocol 1) require binding of B-SS-Tfn (0.5 to 1 hr); washing and internalization (0.5 to 1 hr); and incubation with avidin and biocytin, solubilization in blocking buffer, and plating on ELISA plates (2.5 to 3 hr). The ELISA plates may be incubated at 37°C for 3 hr or overnight at 4°C. Because the ELISA plates need to be incubated with streptavidin coupled to horseradish peroxidase (HRP; 1 hr) and the HRP reaction product is then developed and detected at 492 nm (0.5 to 0.75 hr), the overnight incubation at 4°C is usually the preferred option. It is also possible to interrupt the procedure following solubilization of the samples by freezing them, storing them at –20°C for up to 1 month, and applying them to ELISA plates at a later stage.

For endocytic assays in permeabilized cells (see Basic Protocol 2), following preincubation in serum-free medium, preparation of the permeabilized cells (which may include specific treatments of the membranes), incubation at 37°C to allow endocytosis to proceed, treatment with avidin and biocytin, solubilization, and plating onto ELISA plates requires 4 to 5 hr. Thus, incubation of the ELISA plates overnight at 4°C is usually most convenient, with addition of streptavidin-HRP and development of the HRP reaction product taking place the next day (1 to 2 hr).

Preparation of B-SS-Tfn (Support Protocol 1) will take between 1.5 and 2.5 hr. Preparation of ELISA plates (Support Protocol 2) involves ~30 min to plate the antibodies and ~15 min (either 3 hr later or on the next day) to wash the plates and prepare for storage. If streptolysin O permeabilization is the method of choice (Support Protocol 3), this could increase the time taken to permeabilize the cells to 40 min depending on the optimal incubation times at 37° and 4°C. Preparation of cytosol from brain (Support Protocol 4) will take ~15 min for the homogenization followed by 1.5 to 2 hr for centrifugation and freezing. Preparation of cytosol from cells in culture (Support Protocol 5) will take ~45 min for washes and homogenization followed by 1.5 to 2 hr for centrifugation and freezing. The preparation of coat proteins (Support Protocol 8) takes 2 to 3 days in total. In general, steps 1 to 12 are carried out on day 1 and steps 13 to 18 take a further 1 to 2 days. The lactate dehydrogenase assay (Support Protocol 9) requires 1 to 2 hr.

In Vitro Analysis of Yeast Mitochondrial Protein Import

Mitochondrial targeting prediction programs (e.g., Mitoprot, *http://ihg.gsf.de/mitoprot.html*) are often used to predict whether a protein contains a mitochondrial targeting sequence, (usually at the N-terminus) or if the protein resides in the mitochondrion. However, these programs can give inaccurate results. For example, they can predict that known mitochondrial resident proteins localize to other organelles, or they can fail to recognize a mitochondrial protein due to lack of an N-terminal targeting sequence (Guda et al., 2004). Intact mitochondria isolated from *Saccharomyces cerevisiae* using the methods described in *UNIT 3.8* (Glick and Pon, 1995) can be used for in vitro mitochondrial protein import assays to confirm or reject the predicted ability of proteins to be imported into mitochondria. In addition, because protein import is highly conserved among metazoans, yeast mitochondria can be used to model mitochondrial protein import in higher eukaryotes such as plants and animals, which are not always amenable to genetic and biochemical manipulation. Alternatively, these protocols can be adapted to assays for import of proteins into plant and mammalian mitochondria. Finally, the import assay, when used in combination with genetic and biochemical strategies, can be used to study the mechanism of mitochondrial biogenesis.

Isolated *S. cerevisiae* mitochondria can also be used for in organello translation assays for studying export of mitochondrial proteins translated in the yeast matrix into the inner mitochondrial membrane. These assays are performed by incubating isolated mitochondria in a buffer containing high concentrations of ATP, GTP, and amino acids. One of the amino acids added, usually methionine, is radiolabeled, and new synthesis of proteins in the isolated mitochondria is monitored by the incorporation of the radiolabeled amino acid into the newly synthesized polypeptide chains. Following translation, the mitochondria are re-isolated by centrifugation and lysed in an SDS-containing buffer. The mitochondrial proteins are resolved by SDS-PAGE and the newly synthesized proteins detected through fluorography or by using a PhosphorImager.

This unit describes methods for importing in vitro–translated (see *UNIT 11.2*) or recombinant (e.g., see Ausubel et al., 2007 or Coligan et al., 2007) proteins into isolated yeast mitochondria (*UNIT 3.8*) and exporting mitochondrial proteins translated in the yeast mitochondrial matrix into the inner mitochondrial membrane. Yeast cells are generally grown in a nonfermentable carbon source (e.g., lactate, ethanol, or glycerol) to promote respiration and hence increase mitochondrial proliferation and improve bioenergetic fitness and yield. Mitochondria isolated from yeast (*UNIT 3.8*) can be quickly frozen in liquid nitrogen and stored at −80°C for extended periods of time before use in import assays.

Mitochondrial precursor proteins (proteins not yet imported into mitochondria) can be derived from an in vitro transcription/translation reaction in reticulocyte lysate or purified from an *E. coli* recombinant protein expression system. The translocation (import and export) assays described in this unit can be used to test whether a protein is targeted to mitochondria, determine its location within the mitochondrion, and study its import mechanism. In addition, translation in the mitochondrial matrix and export of the translated proteins can also be investigated. The in vitro mitochondrial import and export methods are described in the Basic Protocols 1 and 2. Methods for fractionating mitochondria and analyzing the results of import and export assays are provided in Alternate Protocols 1 and 2.

BASIC PROTOCOL 1

IN VITRO MITOCHONDRIAL PROTEIN IMPORT ASSAY: IMPORT OF LABELED PROTEINS

Generally, intact mitochondria are incubated with in vitro–translated, radiolabeled mitochondrial precursor protein in the presence of an energy form (ATP) and metabolites (e.g., NADH) to generate a membrane potential. The mitochondria, often treated with protease (e.g., trypsin or proteinase K) to remove any nonimported precursor, are re-isolated, and their proteins are analyzed to detect the imported protein by SDS-PAGE (*UNIT 6.1*) followed by fluorography (*UNIT 6.3*) or use of a PhosphorImager. The mitochondrion contains four compartments—the outer and inner membranes, intermembrane space, and matrix—to which the precursor can be imported (Koehler, 2004). Many proteins are synthesized with a cleavable N-terminal targeting sequence that is removed following import. As an example, this protocol describes the import of a typical precursor, the targeting sequence from *Neurospora crassa* ATPase subunit 9 fused to the reporter dihydrofolate reductase (Su9-DHFR; Pfanner et al., 1987), which is cleaved when imported into the matrix. This cleavage results in a shift in molecular weight and provides a convenient indication that import has occurred. However, many proteins (e.g., those of the inner and outer membrane and intermembrane space) may not be proteolytically processed during import. To confirm import of this category of proteins, other techniques are used: (1) In the case of an inner membrane–targeted protein, the membrane potential can be dissipated with uncouplers that generally prevent the import of a precursor. (2) For membrane proteins, resistance to alkali extraction or generation of a characteristic pattern of protease-resistant fragments can confirm integration into the membrane. Basic Protocol 1 should serve as a starting point for performing basic import assays.

CAUTION: When working with radioactivity, take appropriate precautions to avoid contamination of the experimenter and the surroundings. Carry out the experiment and dispose of wastes in appropriately designated areas, following guidelines provided by the local radiation safety officer (also see *APPENDIX 1A*).

Materials

Freshly isolated or frozen, intact mitochondria (*UNIT 3.8*)
Buffer C (see recipe)
2× import buffer (see recipe)
0.1 M ATP (see recipe)
0.5 M NADH (see recipe)
1 mg/ml valinomycin in ethanol: store in 50-µl aliquots up to 6 months at −20°C
In vitro–translated [^{35}S]methionine-labeled mitochondrial precursor protein (Support Protocol 1) (e.g., *Neurospora crassa* Su9-DHFR)
10 mg/ml trypsin in 20 mM potassium HEPES, pH 7.4 (see recipe): prepare 0.5 ml fresh
20 mM potassium HEPES, pH 7.4 (see recipe)
20 mg/ml trypsin inhibitor (see recipe), freshly prepared
SDS sample buffer (*APPENDIX 2A*)

15-ml centrifuge tubes
25°C water bath
Refrigerated microcentrifuge

Prepare mitochondria

1. Thaw the mitochondrial aliquot quickly by hand and then place on ice. Dilute the mitochondria to 10 mg protein/ml with buffer C, if necessary.

2. To remove BSA (if used in the storage medium), wash the mitochondria by adding 0.5 ml buffer C, centrifuging 5 min at 14,000 × *g*, 4°C, and resuspending the pellet in buffer C to 10 mg protein/ml.

   The mitochondria are typically frozen in 25 mg/ml aliquots supplemented with 10 mg/ml BSA (see UNIT 3.8). If not maintained in an osmotically stabilized buffer, mitochondria can rupture or shrink, becoming import incompetent.

   Removal of excess BSA facilitates the protease treatment to remove nonimported precursors in subsequent steps.

Perform import assay

3a. *To perform the import reaction in the presence of a membrane potential* ($\Delta\Psi$): Add the reagents in the order presented to a 15-ml centrifuge tube (500 µl total reaction volume). Mix well after each addition by gentle vortexing.

   250 µl 2× import buffer
   10 µl 0.1 M ATP
   2 µl 0.5 M NADH
   207 µl H_2O
   10 µl mitochondria (10 mg/ml)
   1 µl ethanol

3b. *To perform the import reaction in the absence of a membrane potential (control):* Add the reagents in the order presented to a 15-ml centrifuge tube (500 µl total reaction volume). Mix well after each addition by gentle vortexing.

   250 µl 2× import buffer
   10 µl 0.1 M ATP
   2 µl 0.5 M NADH
   207 µl H_2O
   10 µl mitochondria (10 mg/ml)
   1 µl 1 mg/ml valinomycin

   This is a general import reaction; volume, mitochondria amount, and temperature can be varied. Because protein import generally requires a membrane potential, it is important to include a control import reaction in which mitochondria are dissipated of $\Delta\Psi$ by uncoupling, i.e., dissipating aspects of the proton motive force across the energized inner mitochondrial membrane. The uncoupler valinomycin has limited solubility in water and therefore should be added to the tube after the mitochondria. An alternative uncoupler is FCCP.

4. Incubate the reaction 1 to 2 min at 25°C.

5. Add 20 µl in vitro–translated radioactive precursor protein (e.g., Su9-DHFR), either directly from the reticulocyte lysate (Support Protocol 1, step 2) or denatured with urea (Support Protocol 1 step 6) while gently vortexing the import reaction to ensure adequate mixing.

   Intact mitochondria should be handled gently.

   Some proteins such as those that reside in the inner membrane and lack an N-terminal cleavable targeting sequence (e.g., Tim22 or the adenine nucleotide translocator) must be imported directly from the reticulocyte lysate. The chaperone proteins in the reticulocyte lysate are bound to the precursors and maintain them in an import competent state. However, most precursors that contain an N-terminal targeting sequence can be imported either directly from the reticulocyte lysate or in a urea denatured form.

The amount of in vitro–translated precursor protein added to each reaction can vary considerably depending on the efficiency of labeling and import. A model import precursor Su9-DHFR (Neurospora crassa subunit 9 fused to dihydrofolate reductase) is imported with efficiencies of up to 50% of the added precursor. However, the recommended import efficiency is estimated at 5% to 20% for previously untested precursors. With this in mind, the amount of a precursor should be increased proportionately to ensure sensitivity in detection with film or a PhosphorImager. In addition, processing of the targeting sequence may result in the removal of [^{35}S]methionine residues, thereby, decreasing sensitivity. For urea-denatured precursors, the dilution into the import assay should be at least 1:13.3 because the final urea concentration cannot exceed 0.6 M to ensure that mitochondria integrity is unaffected.

6. Incubate 10 min at 25°C. Agitate gently every other minute to facilitate gas exchange.

   The import time can be varied depending upon the robustness of import. In addition, the reaction can be expanded into an import time course by removing aliquots at particular time points.

7. Stop the import reaction by adding 1 µl of 1 mg/ml valinomycin to each tube.

Characterize import results

8. Remove two aliquots of 200 µl each from each reaction and transfer to separate 1.5-ml microcentrifuge tubes.

9. Treat mitochondria in one tube with protease to remove nonimported precursor. Treat mitochondria in the other tube (the control) in the same manner, but add buffer instead of trypsin solution.

   a. Add 2.5 µl 10 mg/ml trypsin or 20 mM potassium HEPES, pH 7.4 (control) to the aliquot from the import assay and incubate on ice for 30 min.

   b. Add 2.5 µl 20 mg/ml trypsin inhibitor to inhibit the trypsin and incubate on ice for 15 min.

   A concentration of 50 µg protease/ml during the protease treatment is standard for the analysis of imported proteins across the outer membrane. As an alternative protease, 10 µg/ml proteinase K can be used followed by 200 mM PMSF to inactivate the protease, but trypsin is generally used. A precursor that is imported into the outer membrane facing the cytosol will be protease sensitive; carbonate extraction (Alternate Protocol 2) can be used to evaluate import insertion into the outer membrane.

10. Microcentrifuge 5 min at 20,000 × *g*, 4°C.

11a. *To fractionate mitochondria and analyze the reaction for localization:* Discard the supernatant and resuspend the pellet as described in Alternate Protocol 1.

11b. *To prepare samples for SDS-PAGE:* Discard the supernatant and resuspend the protein pellet in 20 µl SDS sample buffer and proceed to Support Protocol 2 or store up to 3 days at −20°C before proceeding with SDS-PAGE.

   Steps 11a and 11b may be used as alternate or parallel steps, depending on the information desired. Step 11a is used when proceeding to Alternate Protocol 1 to determine where in the mitochondria (matrix, membranes, or intermembrane space) the imported proteins were incorporated. Step 11b can be used alone when characterizing the overall import and calculating the efficiency of import for a given precursor.

IN VITRO MITOCHONDRIAL IMPORT ASSAY: MITOCHONDRIAL FRACTIONATION AND PROTEIN LOCALIZATION

It may be desirable to fractionate mitochondria following an import reaction to determine the suborganellar localization of the newly imported protein. To assess matrix versus intermembrane space localization of the imported protein, mitochondria can be treated by osmotic shock to rupture the outer membrane, followed by centrifugation to separate the matrix, along with the inner and outer membranes, from the soluble intermembrane space components. Protection from added protease during osmotic shock confirms localization of the protein in the matrix, whereas protease sensitivity confirms localization in the intermembrane space or association with the mitochondrial membranes facing the intermembrane space. To confirm that a protein is integrated into the membrane, mitochondria can be subjected to alkali extraction (Fujiki et al., 1982); integral membrane proteins remain in the pellet and peripheral membrane proteins are released to the supernatant. Protease treatment that results in a protected fragment supports the idea of membrane integration for a protein that contains both membrane and soluble domains and can be used to confirm localization within the mitochondrion. For membrane proteins, the authors suggest using the procedures for both mitochondrial fractionation and alkali extraction. If the protein of interest is soluble, the alkali extraction can be eliminated. It is important to use controls when performing mitochondrial fractionation, and immunoblotting with antibodies for mitochondrial markers for the various compartments is suggested. Increasing the reaction volume or running replicate reactions of the import assays will provide the additional material required for immunoblot analysis (see Support Protocol 2).

Materials

Mitochondrial pellet from the import reaction (Basic Protocol 1, step 10)
1× import buffer + ATP + NADH (see recipe)
20 mM potassium HEPES, pH 7.4 (see recipe), cold
100% trichloroacetic acid (TCA): add 227 ml H_2O directly to bottle containing 500 g solid TCA and shake to dissolve; store up to 2 months at 25°C.
SDS sample buffer (*APPENDIX 2A*)
10 mg/ml proteinase K/20 mM potassium HEPES, pH 7.4 (see recipe): prepare 0.5 ml fresh using 5 mg proteinase K (Sigma)
0.2 M phenylmethylsulfonyl fluoride (PMSF) in ethanol: prepare 1 ml fresh using 34.8 mg PMSF in 1 ml ethanol
10% (v/v) Triton X-100
Acetone
0.1 M Na_2CO_3: store up to several weeks at 4°C
Refrigerated microcentrifuge

Fractionate mitochondria

1a. Resuspend the mitochondrial pellet from the import reaction (Basic Protocol 1, step 11a) in 50 µl of 1× import buffer + ATP + NADH with a pipet, gently pipetting up and down to displace the pellet. Do not introduce air bubbles.

The samples should be kept in ice during subsequent manipulations.

2a. Dilute the mitochondria with 450 µl of 20 mM potassium HEPES, pH 7.4. Vortex briefly and incubate on ice for 15 to 30 min to rupture the outer membrane.

Dilution with 20 mM potassium HEPES, pH 7.4 causes hypotonicity of the solution which results in the rupture of the mitochondrial outer membrane while the inner membrane should remain intact, securing the matrix from protease. Mitochondria hypotonically swollen in this manner are referred to as mitoplasts.

3a. Microcentrifuge the lysed mitochondria 10 min at 20,000 × *g*, 4°C. Save the pellets of mitoplasts (intact inner membrane and matrix) and lysed outer membrane fragments for processing in step 8a, and proceed to step 4a with the supernatant.

4a. Carefully transfer the supernatant (soluble intermembrane space fraction) to a 1.5-ml microcentrifuge tube and precipitate the protein by adding 100% TCA to a final concentration of 10%.

5a. Keep the supernatant samples on ice until they have all been acid denatured, and then heat the TCA-precipitated samples 5 min at 65°C to inactivate proteases.

6a. Incubate the samples 10 min on ice.

7a. Microcentrifuge 10 min at 20,000 × *g*, 4°C.

8a. Resuspend the protein pellet from step 7a and the mitoplast membrane pellet from step 3a in 20 µl SDS sample buffer. Use immediately or hold up to 3 days at −20°C until ready to analyze by SDS-PAGE (Support Protocol 2).

The radioactive signal may be reduced upon prolonged storage.

If the protein of interest is recovered in the pellet after centrifugation, it may be localized in the matrix, inner or outer membrane, or intermembrane space tightly associated with a membrane. If the protein is released to the supernatant, it is a soluble intermembrane space protein.

Confirm suborganellar localization with protease treatment

1b. Resuspend the mitochondrial pellet from the import reaction (Basic Protocol 1, step 10) in 50 µl of 1× import buffer + ATP + NADH by gentle pipetting. In a parallel control reaction resuspend a second mitochondrial pellet from the import reaction in 50 µl of 1× import buffer + ATP + NADH containing 1% Triton X-100 (5 µl of 10% Triton X-100).

The inclusion of Triton X-100 in the fractionation protocol will solubilize the mitochondrial membranes thus giving the endogenously added proteases full access to the imported radiolabeled protein. This control is often added because it is important to confirm that the imported protein can, in principle, be degraded by the protease when the barrier of the membranes is removed. Once this has been controlled, the recovery of radiolabeled imported proteins following protease treatment of mitochondria/mitoplasts can be safely interpreted as an "inaccessibility" (i.e. import across the membrane) of the imported protein, rather than merely due to an inherent stability of the protein towards the exogenously added protease.

2b. Dilute the mitochondria in both reactions with 450 µl of cold 20 mM potassium HEPES, pH 7.4. Vortex briefly.

3b. Add 2.5 µl of 10 mg/ml proteinase K and incubate 15 to 30 min on ice. Add 2.5 µl of 0.2 M PMSF, incubate for an additional 5 min.

4b. Microcentrifuge the lysed mitochondria 10 min at 20,000 × *g*, 4°C, to separate the mitoplast pellet from the intermembrane space. In the case of the Triton X-100–containing control samples, do not centrifuge, but proceed directly to the TCA precipitation in step 5b. Save the pellets of the mitoplasts following centrifugation for processing in step 9b and proceed to step 5b with the supernatant.

Centrifuging the Triton X-100–treated controls is not necessary because there will be no mitoplast pellet.

5b. Carefully transfer the supernatants (soluble intermembrane space fractions) to 1.5-ml microcentrifuge tubes and precipitate the protein by adding 100% TCA to a final

concentration of 10%. Also add 125 µl acetone to the parallel reaction tube that originally included Triton X-100.

Because Triton X-100 precipitates in TCA, the addition of acetone until the mixture is hazy resolubilizes the Triton X-100.

6b. Keep the samples on ice until they have all been acid denatured, and then heat the TCA-precipitated samples at 5 min 65°C to inactivate proteases.

7b. Incubate the samples 10 min on ice.

8b. Microcentrifuge 10 min at 20,000 × *g*, 4°C.

9b. Resuspend the protein pellet and the mitoplast pellet from step 4b in 20 µl SDS sample buffer. Use immediately or hold up to 3 days at −20°C until ready to analyze by SDS-PAGE (Support Protocol 2).

The radioactive signal may be reduced upon prolonged storage.

Precipitate integral membrane proteins with alkaline extraction

1c. Resuspend the mitochondrial pellet from the import reaction (Basic Protocol 1, step 10) in 100 µl of 0.1 M Na_2CO_3, pH 11.0 by gentle pipetting.

2c. Incubate 10 min on ice.

Treatment of mitochondria with carbonate releases the soluble proteins from the mitochondria, whereas integral membrane proteins are retained and are pelleted with the membranes following centrifugation.

3c. Microcentrifuge the mitochondrial extract 30 min at 20,000 × *g*, 4°C.

4c. Carefully transfer the supernatant containing the soluble proteins to a new microcentrifuge tube and precipitate the soluble protein by adding 100% TCA to a final concentration of 10% and proceed with steps 5c to 8c. Save the pellet from step 3c and process further as in step 8c.

5c. Keep the samples on ice until they have all been acid denatured, and then heat the TCA-precipitated samples 5 min at 65°C to inactivate proteases.

6c. Incubate the samples 10 min on ice.

7c. Microcentrifuge 10 min at 20,000 × *g*, 4°C.

8c. Resuspend the membrane pellet from step 4c and the precipitated proteins from step 7c in 20 µl SDS sample buffer. Use immediately or hold up to 3 days at −20°C until ready to analyze by SDS-PAGE (Support Protocol 2).

The radioactive signal may be reduced upon prolonged storage.

IN ORGANELLO TRANSLATION OF MITOCHONDRIALLY ENCODED PROTEINS

The vast majority of mitochondrial proteins are encoded by the cell's nucleus, synthesized in the cytosol, and imported into mitochondria. Understanding of the process of protein import into mitochondria over the years has been greatly advanced through the use of in vitro protein import assays, such as those described in Basic Protocol 1. A small percentage of mitochondrial proteins are encoded by the mitochondrial DNA and are synthesized on ribosomes located in the mitochondrial matrix (Stuart, 2002). In the yeast *S. cerevisiae*, eight proteins are translated within the mitochondria: cytochrome oxidase subunits 1, 2 and 3 (Cox1, Cox2, and Cox3); cytochrome *b* (cyt *b*) of the cytochrome bc_1 complex; subunits 6, 8 and 9 of the F_1F_o-ATP synthase complex (Atp6, Atp8, and Atp9); and the Var1 protein of the small ribosomal subunit.

One can monitor the synthesis and membrane association of these proteins in vitro, using isolated yeast mitochondria; this process is termed in organello translation of mitochondrially encoded proteins. With the exception of Var1, which is soluble in the mitochondrial matrix, the other seven proteins synthesized within the mitochondria are integral inner membrane proteins. These proteins become inserted into the inner membrane during their synthesis on matrix-localized ribosomes, and post-translational insertion can be monitored in the isolated mitochondria largely through proteolytic accessibility assays.

In organello assays can address the bioenergetics of the translation and membrane insertion steps by performing them in the presence of uncouplers, which dissipate aspects of the proton motive force across the energized inner mitochondrial membrane. In addition, the in organello translation assay, followed by protease (e.g., proteinase K) accessibility studies, can be used to study the roles of certain proteins (e.g., Oxa1) in the membrane insertion steps (Stuart, 2002), using mitochondria isolated from null mutants or from conditional mutants proposed to be defective in the membrane insertion process. The translation pattern and protease accessibility profile of the radiolabeled translation products can be compared between wild-type and mutant mitochondria. For example, Cox2 is synthesized as a precursor form (pCox2), containing a cleavable N-terminal targeting sequence (Rojo et al., 1999). The presequence is removed following insertion of the protein into the inner membrane by a peptidase (Imp1), located on the intermembrane space side of the inner membrane. pCox2 is approximately 1 kDa larger than the processed mature form; thus these two forms of Cox2 can be resolved by SDS-PAGE. It should be noted that in wild-type mitochondria, and in the presence of a fully energized membrane, the processing of pCox2 occurs very efficiently, and under these optimal insertion conditions the pCox2 species is not normally observed. Failure to undergo efficient insertion (i.e., in absence of energized inner membrane, or following translation in mitochondria with a defective insertion machinery, e.g., in *oxa1* mutants) may result in the accumulation of pCox2 species.

The in organello translation assay is described in Basic Protocol 2, and methods for fractionating mitochondria and analyzing membrane insertion of the newly synthesized proteins are provided in Alternate Protocol 2.

BASIC PROTOCOL 2

IN ORGANELLO MITOCHONDRIAL PROTEIN ASSAY: TRANSLATION AND TRANSLOCATION OF MITOCHONDRIALLY ENCODED PROTEINS

Mitochondria isolated from *S. cerevisiae* according to methods described in *UNIT 3.8* and Glick and Pon, (1995) can be used for the in organello translation assays. Generally, the intact mitochondria are incubated with [^{35}S]methionine, translation buffer, which contains the other nonlabeled amino acids, in the presence of energy in the form of ATP, GTP, and metabolites (e.g., NADH) to generate a membrane potential. After an incubation period, further incorporation of radiolabeled methionine into the newly synthesized proteins is prevented by the addition of excess cold (unlabeled) methionine, followed by the addition of puromycin, a drug that results in the release of nascent chains from the ribosomes. The mitochondria are then re-isolated and, following SDS-PAGE (*UNIT 6.1*), analyzed using fluorography or a PhosphorImager E (*UNIT 6.3*) to detect the newly synthesized, radiolabeled proteins.

For protease accessibility studies (Alternate Protocol 2), the authors have found that it is better to pre-swell the mitochondria, i.e., convert them to mitoplasts, prior to the in organello translation procedure, rather than afterwards. The efficiency of both the mitoplast formation and the protease accessibility of exported segments of the newly synthesized radiolabeled proteins are greater if the hypotonic swelling procedure precedes the translation step, rather than vice versa. For other types of investigations (e.g., translation pattern studies) unswollen mitochondria may be used.

CAUTION: When working with radioactivity, take appropriate precautions to avoid contamination of the experimenter and the surroundings. Carry out the experiment and dispose of wastes in appropriately designated areas, following guidelines provided by the local radiation safety officer (also see *APPENDIX 1A*).

Materials

Frozen, intact mitochondria (see *UNIT 3.8*)
Buffer C (see recipe)
20 mM potassium HEPES, pH 7.4 (see recipe)
0.2 M ATP (see recipe)
1.5× translation buffer (see recipe), freshly prepared
0.5 mg/ml pyruvate kinase: prepare fresh using 2.5 mg pyruvate kinase (Roche) and 5 ml sterile H_2O
0.2 M NADH: prepare fresh using 14.2 mg NADH and 100 µl sterile H_2O
[^{35}S]methionine (15 mCi/ml >1000 Ci/mmol in vitro–translation grade; GE Healthcare)
0.2 M methionine: prepare using 30 mg methionine and 1 ml sterile H_2O; store up to 1 year at −20°C
1 mg/ml puromycin: prepare 1 ml fresh using sterile H_2O
SDS sample buffer (*APPENDIX 2A*)

Heating block set at 25°C
Refrigerated microcentrifuge
Rotary shaker

Additional reagents and equipment for hypotonic swelling of mitochondria (Alternate Protocol 2; optional), SDS-PAGE (*UNIT 6.1*)

Prepare mitochondria or mitoplasts

1. Preheat the microcentrifuge tube heating block to 25°C.
2. Thaw the mitochondria quickly by warming in the hand immediately before beginning the experiment. If necessary, dilute the mitochondrial concentration to 10 mg protein/ml with buffer C. Store on ice until needed.

3a. *For studies using mitochondria:* Proceed with step 4.

3b. *For studies using mitoplasts*: Perform the hypotonic swelling procedure as follows.

i. Add the following to a 1.5-ml microcentrifuge tube:
440 µl cold 20 mM potassium HEPES, pH 7.4
10 µl 0.2 M ATP.

The hypotonic swelling reaction should contain ATP to ensure that ATP levels are not depleted from the mitochondrial matrix. Incubation of mitochondria in an ATP-free buffer would result in the release of ATP via the ADP/ATP carrier protein from the mitochondrial matrix to the external medium.

ii. Mix well and add 50 µl of isolated mitochondria (10 mg protein/ml) in buffer C.
iii. Mix gently and leave on ice for 30 min.
iv. Collect the swollen mitochondria (mitoplasts) by microcentrifuging 10 min at 20,000 × *g*, 4°C.
v. Remove the supernatant and resuspend the mitoplasts in 50 µl cold buffer C.

The mitoplasts should be handled gently. If the preparation does not perform well in the in organello translation, the inner membranes may have been ruptured. If necessary, the presence of matrix proteins can be investigated by immunoblot analysis (see Support Protocol 2 and UNIT 6.2) with the supernatant. Should a significant proportion of the matrix-localized proteins be present in the supernatant, the membrane may have lysed during osmotic shock.

Perform in organello translation

4. Mix the following in a 1.5-ml microcentrifuge tube:

   40 µl 1.5× translation buffer, freshly prepared
   1.5 µl 0.5 mg/ml pyruvate kinase
   6.5 µl H_2O.

5. Premix the tube by vortexing lightly and then add:

   5 µl 10 mg/ml mitochondria (from step 2) or mitoplasts (from step 3b)
   6 µl of 0.2 M NADH.

   Mix well by vortexing gently. Incubate the sample for 5 min at 25°C.

   It is important to maintain the mitochondria in an osmotically buffered solution so that they remain intact. The translation buffer should be made fresh.

6. Add 1 µl [^{35}S]methionine, mix well and incubate at 25°C, typically for 20 min.

   The incubation time may need to be varied with mitochondria from different strains or mutants.

Perform chase

7. Add 30 µl 0.2 M methionine and incubate for an additional 5 min at 25°C.

8. Add 15 µl 1 mg/ml puromycin, mix, and incubate 10 min at 25°C.

   The addition of cold methionine serves as a chase to ensure that translation is completed, whereas the addition of puromycin induces release of translating polypeptides from the ribosomes. Failure to add methionine and puromycin can result in the observation of a high level of partially synthesized radiolabeled proteins.

Analyze mitoplasts or mitochondria

9a. *To localize in organello–translated proteins in mitoplasts:* Proceed with protease accessibility analysis as in Alternate Protocol 2.

9b. *To re-isolate mitoplasts and mitochondria:* Microcentrifuge 12 min at 20,000 × *g*, 4°C. Carefully remove the supernatant with a pipet tip and add 500 µl cold buffer C. Vortex lightly, to wash tube walls and microcentrifuge 12 min at 20,000 × *g*, 4°C.

   If not proceeding with Alternate Protocol 2 (step 9a), step 9b would be used to isolate mitochondria and mitoplast samples directly for SDS-PAGE in step 10 (e.g., for translation pattern studies).

10. *To prepare mitoplasts and mitochondria directly for SDS-PAGE:* Remove the supernatant from the mitoplast or mitochondrial pellet and add 35 µl SDS sample buffer to the pellet. Shake 30 min at 4°C to achieve full solubilization of the mitochondrial proteins. Use immediately or hold up to 3 days at −20°C until ready to analyze by SDS-PAGE (Support Protocol 2).

    *The mitochondrial and mitoplast samples should **not** be heated to 95°C prior to SDS-PAGE, as is customary for sample preparation. Exposure of the samples to these elevated temperatures can lead to aggregation of the mitochondrially encoded proteins because of their high hydrophobicity.*

IN ORGANELLO MITOCHONDRIAL PROTEIN ASSAY: PROTEIN LOCALIZATION BY PROTEASE TREATMENT

The insertion of translation products into the mitochondrial inner membrane results in the translocation of hydrophilic segments of these proteins into the intermembrane space. Insertion of these integral membrane proteins can be assessed by analyzing the protease accessibility of their intermembrane space–exposed segments to exogenously added proteases (e.g., proteinase K). Because the mitochondria are double-membrane organelles, exogenously added proteases only gain access to the outer surface of the inner membrane when the integrity of the outer membrane is compromised. The outer membrane can be disrupted by hypotonic swelling, which when carefully performed results in rupture of the outer membrane while leaving the inner membrane intact. The resulting hypotonically swollen mitochondria are termed mitoplasts. The soluble intermembrane space components will be released from mitoplasts and exogenously added protease can access the outer surface of the inner membrane, but not the matrix space, because the integrity of the inner membrane should not have been compromised using this procedure. It is important to include controls for the integrity of the inner membrane to ensure that the hypotonic swelling procedure does not also result in rupture of the inner membrane.

CAUTION: When working with radioactivity, take appropriate precautions to avoid contamination of the experimenter and the surroundings. Carry out the experiment and dispose of wastes in appropriately designated areas, following guidelines provided by the local radiation safety officer (also see *APPENDIX 1A*).

Materials

Labeled mitoplasts (Basic Protocol 2 step 8)
20 mM potassium HEPES, pH 7.4 (see recipe)
0.2 M ATP (see recipe)
Buffer C (see recipe)
0.5 mg/ml pyruvate kinase: prepare fresh using 2.5 mg pyruvate kinase (Roche) and 5 ml sterile H_2O
1 mg/ml proteinase K in 20 mM potassium HEPES, pH 7.4 (see recipe), cold: prepare 0.5 ml fresh using 0.5 mg proteinase K (Sigma)
0.2 M phenylmethylsulfonyl fluoride (PMSF): prepare fresh using 34.8 mg PMSF and 1 ml alcohol
SDS sample buffer (*APPENDIX 2A*)

Refrigerated microcentrifuge
Rotary shaker

Treat mitoplasts with protease

1. Divide the labeled mitoplasts into two equal aliquots of 50 µl and keep on ice.

   One sample will be treated with protease and the second sample will be included as a control.

2. Add 2.5 µl 1 mg/ml proteinase K to one sample and add 2.5 µl H_2O to the second sample, which will serve as the mock-treated control.

3. Incubate the samples for 20 min on ice and then add 0.5 µl of 0.2 M PMSF to each sample and vortex gently.

4. Re-isolate the mitoplasts by microcentrifuging 15 min at 20,000 × *g*, 4°C.

5. Remove the supernatant and add 500 µl buffer C containing freshly added PMSF (2 mM final concentration).

   The addition of PMSF to buffer C ensures that the proteinase K remains inactive.

6. Vortex gently and centrifuge again 15 min at 20,000 × *g*, 4°C.

Prepare samples for SDS-PAGE

7. Remove all supernatant and add 35 µl SDS sample buffer to the pellet. Resuspend the pellet by shaking 30 min at 4°C, to achieve full solubilization of the mitochondrial proteins.

   The samples should not be heated to 95°C prior to SDS-PAGE, as is customary for sample preparation. Exposure of the samples to these elevated temperatures can lead to aggregation of the mitochondrially encoded proteins because of their high hydrophobicity.

8. Electrophorese the samples as in Support Protocol 2.

SUPPORT PROTOCOL 1

PREPARATION OF PRECURSOR PROTEINS

Typically, mitochondrial-targeted proteins used as import precursors (e.g., *Neurospora crassa* Su9-DHFR) are synthesized as [^{35}S]methionine-labeled proteins using an in vitro translation system. These proteins can be made using the methods outlined in *UNIT 11.2* or using commercially available coupled transcription/translation systems (e.g., Promega). The coupled systems are relatively easy to use and generally produce enough precursor to be used in multiple import reactions. In general, imported substrates are produced using a rabbit reticulocyte lysate as opposed to a wheat germ lysate because rabbit reticulocyte lysate contains necessary chaperone proteins and allows the high mitochondrial import efficiency of precursors proteins required for import experiments. Alternatively, precursors can be purified as recombinant proteins from *E. coli*. These proteins can be rendered detectable by radiolabeling during *E. coli* expression or by immunoblotting after import. Precursors can be presented to mitochondria from the reticulocyte lysate directly or from a urea solution that is diluted to a final concentration of 0.6 M urea or less upon addition to the import reaction.

Materials

Expression vector (e.g., pET vector using the SP6 or T7 promoter; Novagen) carrying the gene encoding the protein of interest
Plasmid isolation kit (e.g., Qiagen or Promega)
In vitro translation kit (e.g., TNT coupled reticulocyte lysate system; Promega)
[^{35}S]methionine (10 mCi/ml; >1000 Ci/mmol in vitro translation grade; GE Healthcare)
Ammonium sulfate solution, saturated (see recipe)
8 M urea solution (see recipe)
Refrigerated microcentrifuge

Addition reagents and equipment for performing SDS-PAGE (*UNIT 6.1*)

1. Isolate the expression vector containing the gene encoding the protein of interest using a commercial plasmid isolation kit.

   Many commercial plasmid isolation kits can be used for this purification. It is recommended that the isolated plasmid be extracted with phenol/chloroform prior to being used for in vitro transcription/translation.

2. Using an in vitro translation kit, follow the manufacturer's instructions for synthesizing [^{35}S]methionine–labeled protein.

   The TNT coupled reticulocyte lysate system from Promega produces an abundant, high-quality translation product that can be used for numerous import assays.

3. Electrophorese a small aliquot (0.5 to 1 μl) of the translation product in 20 μl SDS sample buffer using SDS-PAGE (see *UNIT 6.1*) to confirm successful translation.

   Adjust the amount of translation product used in the in vitro import assay to be at least 10,000 cpm or to an amount that can be detected after 1 to 2 days on film. The ability of the reticulocyte lysate to translate the precursor should be tested before assaying import. Translation should generate a major radiolabeled band of the predicted size upon SDS-PAGE. Prestained molecular weight markers can be used on the gel for size comparison.

4. Add two volumes of saturated ammonium sulfate solution to the translation reaction. Mix well and incubate 30 min on ice to allow precipitation.

5. Microcentrifuge 10 min at 20,000 × *g*, 4°C.

6. Remove the supernatant and resuspend the pellet (precursor protein) in the same volume of 8 M urea as the original volume before precipitation. Keep the precursor at room temperature.

FINAL PROCESSING OF SAMPLES AND ANALYSIS BY SDS-PAGE

SUPPORT PROTOCOL 2

Samples should be loaded in the gel in a logical order, including a standard for the translation reaction. For example, mitochondria re-isolated directly following the import assay (Basic Protocol 1, step 8) and the protease treatment (Basic Protocol 1, step 10) can be analyzed with the samples from mitochondrial subfractionation and alkaline extraction. A sample of the translation product used in the in vitro import assay, usually equivalent to 1/10 to 1/20 of the amount added to the reaction, should be included on the gel. This will serve as a molecular weight reference, to confirm that the presequence has been removed, and as a reference for the amount of radioactive precursor imported into the mitochondrion. Note that the processed protein may contain fewer radioactive methionine residues than the precursor with the presequence. This will provide a complete and quantitative analysis of the import experiment. If additional manipulations, such as an import time course have been included, those samples should be loaded in a logical order.

Materials

Labeled protein samples (from Basic Protocol 1, Alternate Protocol 1, Basic Protocol 2, or Alternate Protocol 2)
25% (w/v) ammonium hydroxide solution
Labeled precursor proteins (Support Protocol 1)
10 mg/ml heat-denatured mitochondria: heat mitochondria (see *UNIT 3.8* and Basic Protocol 1) 5 min at 95°C
SDS sample buffer (*APPENDIX 2A*)
Antibodies against endogenous mitochondrial markers (e.g., Hsp60, ADP/ATP carrier, and cytochrome b_2), optional (not commercially available; contact authors at *rosemary.stuart@marquette.edu* or *koehler@chem.ucla.edu* for more information)
5% (w/v) trichloroacetic acid (TCA) solution
1 M Tris base (store up to 2 months at 4°C)
1 M sodium salicylate (store up to 6 months at 25°C)

65°C water bath
Rotary shaker
Nitrocellulose membrane, optional
Gel vacuum, optional
Storage phosphor screen and image acquisition software and instrumentation (e.g., PhosphorImager; GE Healthcare) *or*
X-ray film and cassette and densitometer

Additional reagents and equipment for performing SDS-PAGE (*UNIT 6.1*), immunoblotting (*UNIT 6.2*), and detecting and quantitating radiolabeled proteins (*UNIT 6.3*)

Prepare samples

1. If the labeled protein samples sample turns bright yellow, use a disposable Pasteur pipet to overlay the sample with NH_3 gas obtained from the vapors of a 25% (w/v) ammonium hydroxide solution (**do not** aspirate liquid). Agitate to mix the gaseous NH_3 into the sample buffer until the mixture turns blue.

   A yellow color indicates that the sample pH is acidic and that the proteins may still be precipitated. A blue color indicates that the sample pH is basic and the proteins are in solution.

2. Incubate the samples 5 min at 65°C. If the sample turns yellow, treat with NH_3 vapors again.

Obtain a 10% translation standard

To estimate the efficiency of the import of radiolabeled precursor proteins in the import assay, the amount of precursor added to the import reaction has to be determined.

3. To obtain a 10% translation standard based on the basic import assay (20 µl of precursor from the translation reaction; see Basic Protocol 1, step 5), mix 2 µl of the translation reaction (Support Protocol 1) with 10 µl of heat-denatured mitochondria and add an equal volume of 2× SDS sample buffer.

   Mitochondria are first denatured in sample buffer at 95°C for 5 min to prevent any reaction with the precursor. Including denatured mitochondria in the translation standard is important because a precursor may migrate differently when mixed with mitochondrial proteins in comparison to the translation reaction.

Analyze proteins by SDS-PAGE

4. Electrophorese the labeled protein samples and the import assay 10% standard (if appropriate) as described in *UNIT 6.1*.

   The authors use a gel system with 0.2% bisacrylamide and 16% acrylamide to separate 10- to 80-kDa proteins.

5. *Optional, but recommended:* Transfer proteins following SDS-PAGE to a nitrocellulose membrane for immunoblotting (*UNIT 6.2*) with antibodies against endogenous mitochondrial markers (e.g., Hsp60 for matrix, ADP/ATP carrier for inner membrane, and cytochrome b_2 for intermembrane space) to confirm successful mitochondrial swelling, extraction, or lysis.

6. To reduce radioactive background in the gel after electrophoresis, incubate the gel 30 min in 5% TCA in a beaker in a fume hood. Alternatively, heat the 5% TCA to 65°C to hasten the process.

   The proteins in the gel will precipitate and turn an opaque white color.

7. Remove the gel to a tray and wash briefly with water. Neutralize the gel by incubating it 5 min in 1 M Tris base at room temperature, with gentle shaking.

8. Wash the gel briefly with water. Add 1 M sodium salicylate and incubate 20 min at room temperature, with gentle shaking.

9. Dry the gel under vacuum and expose to a storage phosphor screen or X-ray film at −70°C overnight (see *UNIT 6.3*).

   Alternatively, the gel can be prepared as described in UNIT 6.3 with commercial enhancers.

Estimate import efficiency

10. Estimate the efficiency of the import reaction by quantifying the intensity of the imported precursor's radioactive signal and the intensity of the 10% translation standard's signal using a PhosphorImager or densitometer (see *UNIT 6.3*). Compare the intensity of the imported precursor signal to the intensity of the 10% translation standard.

    If the intensity is similar, the import efficiency is 10%. The import efficiency is typically between 5% and 50%.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Amino acid stock solution

For 10 ml:

20 mg each of the amino acids: alanine, arginine, aspartic acid, asparagine, glutamic acid, glutamine, glycine, histidine, isoleucine, leucine, lysine, phenylalanine, proline, serine, threonine, tryptophan, and valine
Dispense in 100-µl aliquots and store at −20°C

Ammonium sulfate solution, saturated

For 25 ml:

25 g $(NH_4)_2SO_4$ (ammonium sulfate)
H_2O to 25 ml
Stir for 30 min at room temperature. Remove the supernatant and keep at room temperature.

The $(NH_4)_2SO_4$ will not dissolve entirely.

ATP, 0.1 M

For 10 ml:

551 mg ATP
20 mM potassium HEPES, pH 7.4 (see recipe)
H_2O to 10 ml
Adjust pH to 7.4 using 10 M KOH and pH indicator paper
Store in 1-ml aliquots at −20°C

ATP, 0.2 M

For 1 ml:

130 mg ATP
Sterile H_2O to 1 ml
Adjust pH to 7.4 using 10 M KOH and pH indicator paper.
Store in 100-µl aliquots at −20°C

Buffer C, pH 7.4

For 100 ml:

25 ml 2.4 M sorbitol stock (0.6 M final), sterile
2 ml 1 M potassium HEPES, pH 7.4 (see recipe; 20 mM final), sterile
Sterile H_2O to 100 ml
Store up to several weeks at 4°C

Import buffer, 2×

For 100 ml:

2.38 g HEPES
150 mg L-methionine
200 mg BSA, fatty acid free
50 ml 2.4 M sorbitol
0.4 ml 1 M KH_2PO_4, pH 7.4
4 ml 2.5 M KCl
2 ml 1 M Mg_2Cl
1 ml 0.5 M EDTA, pH 7.4
Sterile H_2O to 100 ml
Adjust pH to 7.4 with 10 M KOH, if necessary
Store in 15-ml aliquots at −20°C

Import buffer, 1× + ATP + NADH

For 1 ml:

0.5 ml 2× import buffer (see recipe)
20 µl 0.1 M ATP (see recipe)
4 µl 0.5 M NADH (see recipe)
Sterile H_2O to 1 ml
Prepare fresh.

NADH, 0.5 M

For 1 ml:

355 mg NADH
20 mM potassium HEPES, pH 7.4 (see recipe) to 1 ml
Store in 20-µl aliquots at −80°C

Potassium HEPES, pH 7.4

For 100 ml:
2 ml 1 M potassium HEPES, pH 7.4 (20 mM final)
H_2O to 100 ml
Adjust pH to 7.4 with 10 M KOH
Autoclave and store up to several weeks at 4°C

Translation buffer, 1.5×

For 1 ml:

1.7 mg α-ketoglutarate
3.5 mg phosphoenolpyruvate
375 µl 2.4 M sorbitol
225 µl 1 M KCl
22.5 µl 1 M potassium phosphate buffer, pH 7.4
30 µl 1 M Tris·Cl, pH 7.4
19 µl 1 M $MgSO_4$
45 µl 100 mg/ml BSA (fatty acid free; Sigma)
30 µl 0.2 M ATP (see recipe)
15 µl 50 mM GTP
9 µl amino acid stock solution (see recipe)
10 µl 10 mM cysteine
18.5 µl 1 mg/ml tyrosine (see recipe)
Sterile H_2O to 1 ml

continued

Store on ice until ready to use
Prepare fresh

The individual components of this buffer can be made in advance, sterilized by passing through a 0.22-μm filter, and stored up to 1 year at −20°C.

Trypsin inhibitor, 20 mg/ml

For 0.5 ml:

10 mg soybean trypsin inhibitor
0.5 ml 20 mM potassium HEPES, pH 7.4 (see recipe)
Prepare fresh

Tyrosine, 1 mg/ml

For 1 ml:

1 mg tyrosine
Sterile H_2O to 900 μl
Adjust pH to 7.2 with 5 N KOH
Sterile H_2O to 1 ml
Store in 100-μl aliquots at −20°C

Urea, 8 M

For 10 ml:

4.85 g urea
0.039 g dithiothreitol
0.25 ml 1 M Tris·Cl, pH 7.5
H_2O to 10 ml
Store up to 4 weeks at −20°C

COMMENTARY

Background Information

Yeast mitochondria have been typically used as a model system for studying import of mitochondrial precursor proteins because it is easy to purify large quantities and store them frozen at −80°C for extended periods of time without affecting import performance. In addition, because yeast can be manipulated genetically, the system is amenable to the development of mutant mitochondria. The basic mechanism of protein import into mitochondria is conserved across metazoan species. Mammalian mitochondria for import assays can be purified from mouse and rat organs such as liver, heart, and brain as well as from cultured cells. Mitochondria for import studies can also be purified from plants and lower eukaryotes (e.g., *C. elegans* and *Xenopus*; Curran et al., 2004). Most researchers use fresh rather than frozen mitochondria from mouse and rat organs, purifying them immediately before use.

Precursors from a wide array of organisms, including mammals and plants, can be imported into mitochondria using the import assay in Basic Protocol 1. For example, the ADP/ATP carrier that resides in the *Trichomonas vaginalis* hydrogenosome can be imported into yeast mitochondria (Dyall et al., 2000), indicating that protein translocation pathways are highly conserved. Because of the possibility of inappropriate import into yeast mitochondria, import studies of heterologous precursors into yeast mitochondria should be confirmed by localization studies in the organism from which the precursor originates.

In organello methods (Basic Protocol 2 and Alternate Protocol 2) can easily be adapted to mitochondria from organisms other than yeast, particularly plants and mammals. This assay can be particularly useful for studying cell lines derived from patients with mitochondrial diseases, which are often characterized by defects in mitochondrial translation (Boulet et al., 1992). Isolation of mitochondria is not required for in organello translation, the process can be studied in intact cells treated with cycloheximide to inhibit translation from cytosolic ribosomes (Barrientos et al., 2004).

Critical Parameters

In vitro import assay

The quality of the mitochondria preparation influences the success of the import assay. The yield of mitochondria from a yeast culture and their ability to import proteins are directly related to the cell density at harvest. If the cells have reached stationary phase, purification of mitochondria may be difficult because the cell wall is resistant to zymolyase treatment, reducing the yield.

The carbon source influences the quality of the mitochondrial preparation. Cells grown in a nonfermentable carbon source, such as lactate, ethanol, and glycerol, have more respiratory-active mitochondria than cells grown in glucose, making them bioenergetically more robust for import.

Mitochondria should be kept cold during isolation to minimize proteolysis of the proteinaceous surface receptors, which are required for efficient precursor import. Purification of mitochondria also should be performed on ice once the cells are being homogenized. Buffers should be kept ice cold and rotor and homogenizers should be prechilled. Mitochondria should be prepared quickly. After isolation, mitochondria should be frozen quickly in liquid nitrogen in small aliquots and then transferred to a −80°C freezer.

Several parameters affect the robustness of the import reaction itself. Precursors vary in their ability to be imported and each one must be evaluated empirically. For example, membrane proteins such as those of the mitochondrial carrier family, Tim22 and Tim23, lose import competence when treated with urea, which most likely reduces the ability of chaperone proteins in the reticulocyte lysate to help maintain the mitochondrial protein import competency.

In contrast, precursors with a typical N-terminal targeting sequence usually import equally well whether used directly from the reticulocyte lysate or treated with urea. Urea denaturation is the typical method for preparing recombinant precursors from *E. coli* for import assays.

In steps where proteases have been added, subsequent inactivation of the proteases is important to maintain the stability of the products. PMSF addition to the sample buffer ensures protease inactivation before separation by electrophoresis.

TCA precipitation is necessary when the volume of the sample is too large to load on a gel for SDS-PAGE, e.g., supernatants from osmotic shock or carbonate extraction.

In organello assays

For in organello assays, the quality of the mitochondrial preparation is also important for the same reasons as in the in vitro assays.

During the translation reaction, inclusion of the methionine chase and subsequent puromycin treatment are important for release of the mature polypeptide from the ribosome. Failure to do so can result in a high level of partially synthesized radiolabeled proteins.

Because the mitochondrial proteins are especially hydrophobic, samples should not be heated to 95°C prior to SDS-PAGE, as is customary for sample preparation. Exposure of the samples to these elevated temperatures can result in aggregation of the mitochondrially encoded proteins due to their high hydrophobicity.

The inclusion of high ATP levels is important for solutions used in hypotonic swelling of mitochondria. Hypotonic treatment of mitochondria may result in leaking of the inner membrane, causing depletion of ATP from the mitochondrial matrix. Limiting the ATP levels in the mitoplasts will severely hinder the efficiency of the translation reaction and also possibly inhibit protein insertion into the inner membrane. Including ATP during osmotic lysis ensures that the mitochondria are not energetically compromised during the translation reaction.

Troubleshooting

Import efficiency of precursors varies widely. If efficiency is less than 5% of the added import substrate, or if it is difficult to detect the imported product, it may be necessary to increase the amount of translation product or mitochondria used in the assay. The in vitro transcription/translation reaction can be altered to increase the yield of the radiolabeled precurson. Alternatively, the protein may lack numerous methionine residues. In this case a template can be generated to add methionine residues at the C-terminus or in another position that does not alter targeting.

Controls to verify that manipulations to the mitochondria (e.g., osmotic swelling and carbonate extraction) are successful should be included. For example, when a membrane protein is extracted using carbonate, additional reactions should be included so that the samples can be immunoblotted with antibodies against endogenous marker proteins, (e.g., Hsp60 for matrix, ADP/ATP carrier for inner membrane, and cytochrome b_2 for intermembrane space). These proteins serve as excellent controls for verifying that hypotonic lysis is successful.

For the in organello translation assays, it is especially important to control the efficiency of the hypotonic swelling procedure and ensure integrity of the inner membrane. Failure to efficiently form mitoplasts will prevent protease accessibility to the intermembrane space. The translation products will not be degraded by the protease, despite being correctly inserted into the membrane. Immunoblot analysis should be included with antisera against inner membrane control proteins, known to have protease-accessible domains in the intermembrane space (e.g., ADP/ATP carrier protein, Tim23 of the Tim23 translocase, and D-lactate dehydrogenase protein).

On the other hand, the Var1 protein is a soluble protein in the mitochondrial matrix and hence should not be accessible to proteases exogenously added to the mitoplasts. Degradation of Var1 by the added proteases would indicate that the integrity of the inner membrane has been compromised during the mitoplast preparation procedures or in subsequent steps. Therefore, it is important to include the mock-protease treated sample in parallel, so the Var1 levels can be directly compared with the protease-treated sample. Immunoblot analysis of the samples with known matrix-localized proteins (e.g., Mge1, Hsp70, Hsp60) is also advised for this reason.

Anticipated Results

The results from an import assay will vary depending on the precursor being studied. All proteins targeted to mitochondria that at least partially cross the mitochondrial inner membrane require a membrane potential for import. Most precursors with an N-terminal targeting sequence are processed by mitochondrial proteases in the matrix and intermembrane space to remove the targeting sequence; these precursors will have a lower molecular weight than the precursor prior to import. The length of the targeting sequence can vary greatly, but in most cases the reduction of molecular weight (2000 to 10,000 Da) should be large enough to be easily detected by SDS-PAGE analysis. To confirm that the lower-molecular-weight protein has been imported, mitochondria are treated with an uncoupler such as valinomycin that renders the mitochondria defective in import because the membrane potential across the inner membrane has been dissipated.

Often the unprocessed and processed forms of the import substrate will be detected by comparing mitochondria before treatment with exogenous protease (trypsin or proteinase K). The unprocessed form of the precursor represents protein that is nonspecifically associated with the outer membrane or potentially bound to components of the import apparatus at the early, binding stages of import. The unprocessed form should be removed by treatment with exogenous protease; the processed form that has completely crossed the outer membrane should be protected. In addition, resistance to alkaline extraction in combination with protease treatment can be used to confirm integration into the membrane.

For SDS-PAGE analysis of the in organello import reaction, a gel with final concentrations of acrylamide and bisacrylamide of 16% and 0.2% (w/v), respectively, is recommended. The relative mobilities of the translation products using this gel system correspond to proteins with molecular masses as follows: Var1 (~45 to 47 kDa, depending on the genetic background of the strain used for mitochondrial isolation), Cox1 (36 kDa), Cox2 (34 kDa), cyt *b* (30 kDa), Cox3 (23 kDa), Atp6 (21 kDa), Atp8 (9 kDa), and Atp9 (8 kDa).

In analysis of the insertion of exported proteins into the mitochondrial inner membrane, correctly inserted Cox1, Cox2, Cox3, cyt *b*, and Atp6 proteins are accessible to exogenously added proteases from the intermembrane space side of the inner membrane. Thus, proteinase K treatment of mitoplasts, following the translation reaction, should result in the degradation of these proteins, if they became correctly inserted into the membrane during the translation reaction. The protease treatment results in the generation of proteolytic fragments of these proteins with SDS-PAGE mobilities that are ~10 kDa and smaller. These fragments are membrane associated and, therefore, are re-isolated with the mitoplast fraction. Due to their abundance and also the fact that the sizes of these proteolytic fragments are similar to those of the full length Atp8 and Atp9 proteins, it is not possible to distinguish these fragments from the Atp8 and Atp9 proteins. For this reason it is not possible to ascertain whether the Atp8 and Atp9 proteins are accessible to the protease, i.e., have been correctly inserted into the membrane, using this assay.

Time Considerations

Isolation of mitochondria from yeast takes ~4 to 8 hr after the cells have reached the correct density. Mitochondria are then frozen in small aliquots of ~1 mg at a concentration of 10 to 25 mg/ml in an osmotically stabilized buffer (see *UNIT* 3.8). The transcription-translation assay to generate radiolabeled

precursor proteins requires ~1 to 2 hr (Support Protocol 1).

The import assay takes ~1 hr (Basic Protocol 1), whereas additional manipulation requires another 1 to 2 hr (Alternate Protocol 1), depending upon the assays that will be done. A polyacrylamide gel takes 2 to 3 hr to run, 30 min to fix, and 30 to 60 min to dry. The gel is then exposed to a storage phosphorimaging screen or X-ray film overnight (16 hr or longer), depending upon the strength of the signal and efficiency of import (see Support Protocol 2 and *UNIT 6.3*). If gels are used for immunoblotting (see *UNIT 6.2*), an additional 1 to 2 hr is required.

The in organello assay (including buffer preparation time) takes ~2 hr (Basic Protocol 2), and additional manipulations (e.g., mitoplast formation and protease accessibility studies) require an additional 1 to 2 hr (Alternate Protocol 1). A polyacrylamide gel takes 2 to 3 hr to run (Support Protocol 2), with an additional 2 hr to transfer the proteins (using a semidry blotting chamber) to a nitrocellulose membrane if the gels are used for immunoblotting (see *UNIT 6.2*). Drying the gels under a heating lamp takes 10 to 15 min and exposing them to a storage phosphorimaging screen or X-ray film takes 5 hr or longer, depending upon the strength of the efficiency of the translation reaction and the age of the [^{35}S]methionine used (see *UNIT 6.3*).

CHAPTER 12
Cell Motility

INTRODUCTION

The ability of eukaryotic cells to move and respond to their environment is critical for morphogenesis, and underlies the invasiveness of tumor cells. The majority of cells have the capacity to actively migrate toward a chemoattractant. For a cell to move in this manner, it must be able to detect the direction of a chemical gradient, orient toward the gradient, and move directionally toward it. The cellular processes that mediate this response are numerous, including extension of a pseudopod, attachment of the cell to the substratum, and breakage of existing attachments. Chapter 12 describes methods for analyzing these processes.

UNIT 12.1 describes basic assays for studying directed cell movement along a chemical gradient. These are useful for identifying new chemoattractants and studying the cellular processes required for such movement. Among the assays described are those that monitor a population of cells after exposure to a chemoattractant in a steep gradient across a thin porous filter or over short distances through a gel of extracellular matrix or agarose. In these assays, the gradient is applied gradually or suddenly depending on the purpose of the experiment. The latter approach is useful for biochemical analysis of chemoattractant signal transduction, where a rapid change in chemoattractant concentration is required to generate a signal. Cell migration in these assays is detected using radioactive, fluorescent, or enzymatic cell markers, or cytochemistry. Direct observation of an individual cell's behavior in response to a chemoattractant is an alternative visual approach described in several assays in this unit. These assays can be used to dissect the complex processes involved in the chemotatic response; the questions of how a cell detects a chemical gradient and determines its direction, orients its movement toward the signal, and moves along the gradient are emphasized in this unit. Selection of an appropriate assay is important because cells move at vastly different rates in response to a chemotactic signal (e.g., neutrophils and *Dictyostelium* amoebae move about ten times faster than fibroblasts and neurons) and require different time scales and conditions for monitoring their movements.

UNIT 12.2 describes a protocol for assessing the invasiveness of cells through a basement-membrane matrix. Cells are placed in the upper well of a Boyden migration chamber that is coated with basement-membrane matrix, and a chemoattractant is applied in the lower well. After a short incubation period, cells that have migrated through the matrix-coated filter are counted and can be recovered for further analysis. This type of assay can be used to identify compounds that either promote or inhibit invasion of cells across the matrix-coated filter, and is easily adapted for large-scale screening of compounds. In addition, because cells that have moved to the lower chamber can be recovered, subpopulations that have increased invasiveness can be isolated and studied. A useful application of the assay is for analysis of metastatic tumor cells that invade somatic tissues through blood vessel basement membrane and underlying connective tissue.

UNIT 12.3 describes protocols for monitoring the traction forces exerted by migrating cells as they move along a substratum. These assays provide important information relevant to understanding subcellular events occurring during migration, including breakage of adhesive contacts with the extracellular matrix, cytoskeletal rearrangements involved

Contributed by Jennifer Lippincott-Schwartz
Current Protocols in Cell Biology (2005) 12.0.1-12.0.3

in forward motion, and the formation of new contacts. The least expensive and easiest method described for studying cell traction uses a silicone sheet to measure traction forces under the entire cell. The orientation of wrinkles generated in the substrate by locomoting cells is used to describe the global orientation of the forces under the cell. A newer, more expensive technique that is also included measures subcellular traction forces by employing a system of deformable levers with variable stiffnesses to measure forces directly under regions of the cell as small as 4 μm^2.

Many cells reside in environments where they frequently experience disruptions in membrane integrity. When such tearing or wounding of the cell surface occurs, an active and complex resealing mechanism rapidly repairs the membrane disruptions. *UNIT 12.4* describes methods for studying the processes of cell wounding and resealing. The methods are based on the finding that wounded cells will take up tracer macromolecules to which they are normally impermeable; upon resealing, the tracers are trapped in the cell. Because dead cells do not reseal, they do not trap the tracers and are thereby distinguishable from live wounded cells. Protocols in this unit describe how to detect wounded cells using fluorescent dextrans or immunostaining for rat serum albumin added to the medium. Also covered are electron microscopic analysis of wounded cells and quantification of wounded cells by image analysis and flow cytofluorometry. Because plasma membrane disruptions provide a route of entry for otherwise impermeable macromolecules that an experimentalist might want to introduce into the cytosol of cells (including enzymes, antibodies, and expression vectors), understanding how plasma membrane disruptions arise and reseal is of considerable practical utility.

A powerful system for studying cell dynamics is *Dictyostelium discoideum* amoebae, which grow as separate independent cells, but upon starvation actively cluster together to form multicellular structures. During this process the amoebae undergo a range of different behaviors, including chemotaxis, signal transduction, plasma membrane ruffling, phagocytosis, and cytokinesis. *UNIT 12.5* describes how to grow and image *D. discoideum* amoebae in order to study motile and chemotactic behavior in wild-type and genetically modified strains. Protocols are described for growing and maintaining the cells and how to transform them with GFP fusion plasmids. Methods are also provided for characterizing the functionality of GFP fusion proteins expressed in the amoebae. The unit also includes methods for imaging GFP fusion proteins in chemotaxing cells, aggregates, mounds, and slugs.

UNIT 12.6 describes a microscopy-based assay for analyzing the migration of human neutrophils. Neutrophils play an important role in initiating the inflammatory response in higher organisms. They accomplish this by migrating into an area of infection in response to a chemotactic signal. The protocol in this unit describes how to perform time-lapse confocal imaging of neutrophils migrating in two-dimensions and techniques for analyzing the speed and directional persistence of such movement. This type of analysis, in which migration parameters are quantified, is important for understanding potential causes of cell migration defects. A protocol for the isolation of human neutrophils from blood is also detailed in this unit, as is a method for preparing microscope chambers for imaging.

UNIT 12.7 presents assays relevant for studying actin-based motility within cells. The assays are based on the propulsion of the *Listeria* and *Shigella* or functionalized microspheres reconstituted from five proteins, including profilin, actin-depolymerizing factor, gelsolin, neural Wiskott-Aldrich syndrome protein (N-WASP) and the actin-related protein, Arp2/3 complex (all of whose purification protocols are described). By quantifying the dependence of motility parameters on the concentration and/or combination of these

components, these assays provide an approach for characterizing the molecular processes underlying actin-based motile behavior of cells.

UNIT 12.8 presents a novel technique—photoactivation—for marking cells deep within an embryo so that these cells can be followed using confocal microscopy techniques over time. In this approach, standard electroporation techniques are used to deliver photoactivatable GFP attached to a protein of interest into cells in an embryo. The expressing cells are then excited with ~400 nm light. This causes the chromophore population to undergo photoconversion to a form whose baseline fluorescence at 488 nm excitation increases 100-fold, resulting in the cells becoming optically highlighted. By using photoactivation to selectively highlight cells in this manner, it becomes possible to follow individual cells over time in an embryo. This method provides a way to trace cell lineages and to study cell migration patterns, noninvasively.

Jennifer Lippincott-Schwartz

Chemotaxis Assays for Eukaryotic Cells

Chemotaxis is defined as a bias in the direction of cell movement along a chemical gradient. Chemotaxis contributes to morphogenetic movements and to cell accumulation at sites of inflammation. In recent years, interest in the field of chemotaxis has focused on identifying new chemoattractants, especially the chemokines, which attract various leukocytes (Baggiolini et al., 1997; Baggiolini, 1998), and the netrins and semiphorins/collapsins, which attract or repel neuronal growth cones (McKenna and Raper, 1988; Tessier-Lavigne and Goodman, 1996; Song et al., 1997). Much attention is also focused on the cellular and molecular basis of chemotaxis (Devreotes, 1994; Schleicher et al., 1995; Van Haastert, 1995). Assays appropriate for identifying new chemoattractants often differ from those appropriate for investigating the mechanisms of chemotaxis. This unit describes both types of assays in general terms, provides detailed instructions for performing various assays, and considers issues specific to neutrophils, lymphocytes, fibroblasts, and *Dictyostelium discoideum* amoebae.

Chemotaxis is most clearly documented by observing individual cells moving up a gradient, e.g., toward a pipet or a well containing a chemoattractant. However, to assay a number of test materials in this manner can be time-consuming. Thus, assays have been developed that, although less definitively detecting chemotaxis, allow an efficient search for potential chemoattractants. Most of these assays monitor the redistribution of a population of cells after exposure to a test material established in a steep gradient (change in concentration ≥2% per 10 μm) across a thin porous filter (filter assay; see Basic Protocol 1), or over short distances (several mm) through a gel of extracellular matrix or agarose (under-agarose and small population assays; see Basic Protocols 2 and 3, respectively). The rigid matrix allows a gradient to form by diffusion, while protected from disruption due to fluid flow. Cell migration toward the test material, detected microscopically or through radioactive, fluorescent, or enzymatic cell markers, is quantified after a set incubation time. Such assays allow a large number of materials and concentrations to be tested in parallel. Increased migration toward a test material in these assays suggests that the material might be a chemoattractant. However, increased migration might also be seen if the material merely enhances the number of cells migrating and/or their rate of migration (chemokinesis; see Background Information). A protocol is also included for distinguishing enhanced migration from chemotaxis (see Support Protocol 1).

For a cell to exhibit chemotaxis, it must detect the direction of a chemical gradient, orient its translocation in that direction, and then move along the gradient. The signaling pathways that mediate this complex response are being investigated. Often it is helpful to consider different aspects of the response. For example, a particular cellular component (i.e., a mutated gene or a pharmacologically altered enzyme) might be required for a cell to extend a pseudopod, direct the pseudopod up the gradient, limit pseudopods from extending in other directions, stimulate an attachment to the substratum, or break attachments. To investigate the responsible mechanism, assays are used that give detailed information about an individual cell's behavior through direct observation of the cell during the response. Such assays include observation of cells in established gradients (under-agarose, bridge assays; see Basic Protocols 2 and 4, respectively), video recording of cells presented with a pipet containing attractant (pipet assay; see Basic Protocol 5), and observation of cells exposed to a sudden increase or decrease in concentration of chemoattractant (upshift assay; see Basic Protocol 6). These methods can be modified to allow monitoring by fluorescence microscopy to follow the time course of redistribution of GFP-tagged proteins (Maniak et al., 1995; Moores et al., 1996; Westphal et al., 1997). Image analysis systems may also be used to analyze results (see Support Protocol 2).

Current Protocols in Cell Biology (1998) 12.1.1-12.1.29

STRATEGIC PLANNING

In all assays, the accuracy of cell orientation in a gradient of chemoattractant (Fig. 12.1.1) depends on both the steepness of the gradient and the mean concentration of the chemoattractant. To exhibit chemotaxis, a cell must detect a change in the concentration of chemoattractant over time and/or distance. A cell detects the change in concentration by a change in the occupancy of its chemoattractant receptors. The change in occupancy is greatest when the gradient is steepest and when the concentration of the attractant is well below that which saturates the receptors. In linear gradients of a constant steepness (e.g., a 10-fold increase in concentration over 1 mm), a concentration of chemoattractant somewhat less than the K_d of the receptor (i.e., the concentration that results in occupancy of half of the receptors) gives optimal cell orientation. Because the geometry of the gradient varies between assays, the concentration needed to achieve a steep gradient in the appropriate concentration range also varies. The gradient needs to have an appropriate concentration and steepness throughout the time the cells are migrating.

Selection of an appropriate assay is influenced by four principal factors. (1) The choice of assay depends on the rate of locomotion of the cell under study. Neutrophils and *Dictyostelium* amoebae move about ten times faster than fibroblasts and neurons (~10 μm/min versus ~1 μm/min). Since the gradient in most assays is both established and then dissipated by diffusion, assays of slower moving cells may require a special means of renewing or maintaining a gradient (Fisher et al., 1989). Filter assays are useful for most cell types because the filter is so thin, a steep gradient is established, and even slowly moving cells can move across a thin filter before the gradient is lost. For specific information about different cell types and media considerations, see Critical Parameters.

The choice of assay also depends upon (2) the purpose of the assay (i.e., whether to determine if a factor is chemotactic or to assess the mechanism of chemotaxis) and (3)

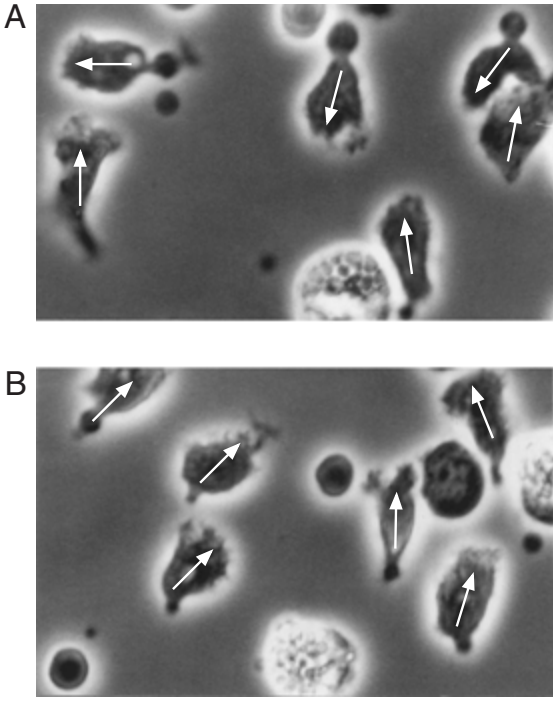

Figure 12.1.1 Cell orientation in (**A**) random migration (chemokinesis) versus (**B**) chemotaxis. Arrows indicate direction of individual cell movement; direction of chemotaxis in (B) is to the top.

Table 12.1.1 Appropriate Chemotaxis Assays for Desired Information

Cell type	Assay to detect a response	Assay to determine mechanism of response
Leukocyte	Filter, under-agarose	Under-agarose, bridge, pipet, upshift
Dictyostelium	Small population, pipet, aggregation[a]	Bridge, pipet, upshift
MTLn3/fibroblast	Filter	Filter, pipet, upshift

[a]Normal aggregation of *Dictyostelium* is mediated in part by chemotaxis. For assay details see Soll (1987).

Table 12.1.2 Experimental Requirements for Chemotaxis Assays

Assay type	Cells per assay	Chemoattractant		Replicates
		Concentration ($\times K_d$)	Minimum volume (µl)	No. of simultaneous assays
Multiwell filter	10^4-10^5	0.1-10	25[a]	12-48 per chamber
Culture insert	$0.5–5 \times 10^6$	0.1-10	10	24 per chamber
Under-agarose	10^5	10-1000	10	10-20 per chamber
Small population	10^3	0.1-10	0.3[b]	~8 per chamber
Bridge	10^3	0.1-10	50[a]	5
Pipet	1-50	10^3-10^4	5	1

[a]Volumes indicated for 48-well multiwell chambers and for glass bridge chambers. Other multiwell chambers and Plexiglas bridge chambers require more chemoattractant.
[b]From three sequential 0.1-µl applications.

the time available to perform the assay. Assays vary in their time commitment and in the type of information that they can provide (Table 12.1.1 and Table 12.1.2). "Survey assays" are those that can be performed on many samples simultaneously and scored at a later time, either automatically or at least at one's leisure. These are useful for screening for potential chemoattractants. These assays would need to be modified to examine directional neurite extension from neurons. Information about how a particular agent affects cell behavior is often best obtained from "visual assays," which allow direct monitoring of cell movement and behavior. However, direct visualization (and video recording) must usually be performed by altering one parameter at a time. Finally, the choice of assay is dependent upon (4) the availability of cells and chemoattractants, because assays vary in the number of cells and the total amount of chemoattractant required (Table 12.1.2).

FILTER ASSAY FOR CHEMOTAXIS

BASIC PROTOCOL 1

In this protocol, cells suspended in buffer are placed on top of a porous filter while chemoattractant is placed below the filter. After incubation, cell migration into or through the filter is measured (Boyden, 1962). Prior to performing the assay, it is necessary to select the appropriate (1) chamber (e.g., blind-well or multiwell chambers from Neuro Probe, Fig. 12.1.2, or 24-well tissue culture plates with filter inserts), (2) filter type (thick cellulose nitrate or thin polycarbonate), (3) filter pore size, and (4) filter coating for the cell type being assayed (see Critical Parameters). Migration is quantified by measuring (1) the distance cells have migrated into the filter, (2) the number of cells attached to the bottom of the filter, and/or (3) the number of cells that have migrated through the filter and fallen into the lower chamber. It is surprising that both of the latter measures have been used, because they would be expected to shift in opposite directions if the test factor

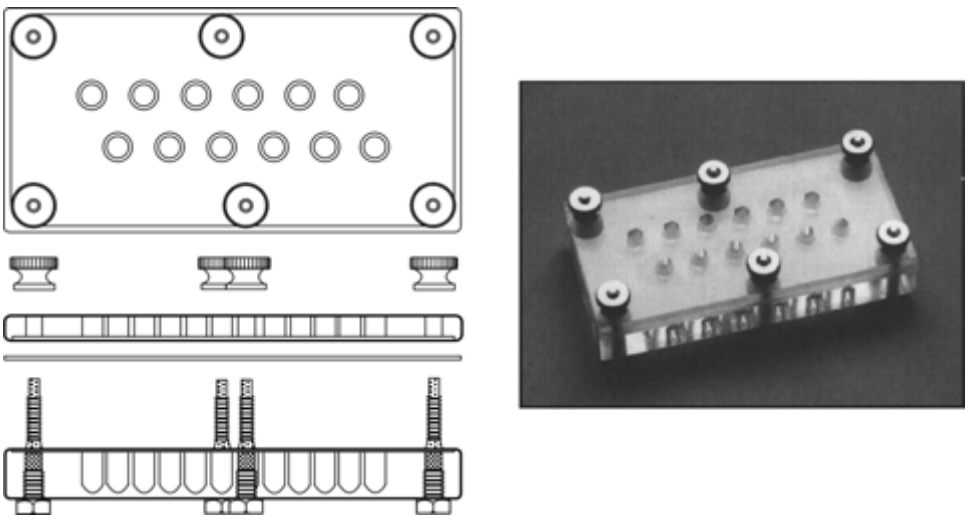

Figure 12.1.2 A standard 12-well multiwell chemotaxis chamber from Neuro Probe is made of acrylic and has 4.75-mm-diameter wells that expose 18 mm^2 of filter. Volumes of upper and lower wells are 100 and 150 μl, respectively. A 48-well multiwell chamber is also available (upper and lower well volumes 50 and 25 μl, respectively). A blind-well chamber, which is a nonstandard special-order chamber, is also available with upper and lower well volumes of 200 and 75 μl, respectively. Figure redrawn with permission from Neuro Probe.

alters all adhesivity. However, each measure has been used successfully with particular cell types. In general, fibroblasts have been quantified on the lower surface while lymphocytes, which are less adhesive, have been quantified in the lower chamber. Neutrophils are frequently in both places (Jungi, 1975); thus, it is advisable to initially monitor the number of cells both on the filter bottom and in the lower chamber.

If a factor induces an increase in cell migration, additional tests are required to determine whether this is due to an increase in the rate of random migration (chemokinesis) or in a directional movement (chemotaxis) toward the test material, or both (Zigmond and Hirsch, 1973). One can examine the effects on chemokinesis by measuring migration in a series of homogeneous (isotropic) concentrations of test material placed both above and below the filter. The results from these assays are compared to those from cells migrating in a gradient, to determine whether migration in a gradient exceeds that expected from random locomotion alone. Alternatively one can use a different assay in which directional migration is assayed directly (e.g., small population assay, see Basic Protocol 3; bridge assay, see Basic Protocol 4; pipet assay, see Basic Protocol 5). For thick filter assays, the migration distance expected in the absence of chemotaxis (see Support Protocol 1) can be used to determine if chemotaxis is present.

This assay is described for neutrophils; adaptations for other cell types are indicated in annotations.

Materials

Buffer for upper and lower wells (see Critical Parameters discussion on media)
Chemoattractant in buffer
Cells of interest
3.7% (w/v) formaldehyde in PBS (*APPENDIX 2A*)
Giemsa stain (see recipe) or Diff-Quick (EM Science) for neutrophils; hematoxylin for lymphocytes

70% and 100% isopropanol
1:1 (v/v) isopropanol/Americlear
Americlear (Baxter Biotech)
Permount (EM Science)
15-µm polystyrene beads (Polysciences)

Chemotaxis chamber: blind-well or multiwell chamber (Fig. 12.1.2; Neuro Probe) with appropriate filters, or 24-well tissue culture plate with filter inserts (see Critical Parameters)
Filter scraper (Neuro Probe; optional)
Microscope with 40× objective and micrometer (16× objective optional)

Additional reagents and equipment for counting cells using a hemacytometer (*UNIT 1.1*) or cell sorter

Perform assay

1. Fill the lower wells of a chemotaxis chamber with buffer or with chemoattractant in buffer. Use sufficient volume to slightly overfill the well, to prevent air bubbles from being trapped when the filter is lowered (see Table 12.1.3).

   The cells in the middle of the filter will be exposed to the mean of the concentrations of chemoattractant present above and below the filter. Thus, when the upper well contains no chemoattractant, the optimal chemoattractant concentration in the lower well is approximately that of the dissociation constant, K_d, of the receptor. Initially, if the K_d is known, one might test concentrations from one tenth to ten times K_d (Table 12.1.2). If K_d is not known, one could test 10-fold dilutions between 0.1 nM and 10 µM. Most leukocyte chemokines are active at nM concentrations.

2. Lower a filter smoothly onto the chamber, checking that the liquid in each well makes full contact with the filter (i.e., that there are no air bubbles). Assemble rest of chamber and tighten screws. Before adding cells, aspirate off any fluid from the lower well that came through the filter.

   When using multiwell chambers, prewetting the filter with buffer helps prevent wicking of fluid out of wells. Avoid moving the filter after it is lowered so that chemoattractant concentrations in different wells are not mixed.

   When using a 24-well tissue culture plate, place a tissue culture insert containing the appropriate pore size into each well, just prior to adding the cells.

3. Dilute cells into the upper-well buffer such that the correct number of cells is added when the chamber is filled (Table 12.1.3).

   The number of cells is based on the exposed filter area. The cells will rapidly settle by gravity onto the upper surface of the filter.

4. Incubate chamber in a humid environment at 37°C.

   The duration of incubation depends of the cell type, filter, and parameter assayed (see Table 12.1.4).

Table 12.1.3 Characteristics of Assay Chambers Used for Filter Assay

Assay chamber	Lower well volume (µl)[b]	Filter surface area	Upper well volume (µl)	Number of cells
Blind-well[a]	200	18 mm^2	200	50,000
12-well multiwell[a]	150[b]	18 mm^2	100	48,000
48-well multiwell[a]	25	3.2 mm^2	50	15,000
24-well tissue culture plate	600	0.3 cm^2	100	1,000,000

[a]Available from Neuro Probe.
[b]It is best to load a small excess to prevent air bubbles.

Fix and stain cells

5. Drain off top wells with a pipet. Disassemble chamber and remove filter carefully. Immediately put empty chambers in water to soak. If a thin filter is used, scrape the upper side with a filter scraper.

   It is easier to clean chambers if they are not allowed to dry.

   It is difficult to separate the focal planes at the top and bottom of thin filters. Most investigators, therefore, wipe the cells off the upper surface before attempting to count those on the lower surface (Harvath et al., 1980). As an alternative to a filter scraper, a clip can be attached to either end of the filter, and a moist Q tip can be used to scrape the cells from the top side of the filter while the filter hangs from one clip. It is important to work quickly before the filter dries.

6. Place the filter in 10 ml of 3.7% formaldehyde in a small Coplin jar and incubate 30 min to overnight at room temperature.

   Alternatively, a thin filter can be fixed in methanol and air dried for staining with Diff-Quick (Harvath et al., 1980).

7. Stain the cells on the filter ≥1 hr at room temperature (see Table 12.1.4). Make sure multiple filters are separated from one another so that stain readily penetrates each filter.

   For Diff-Quick and hematoxylin, follow manufacturer's instructions.

8. Destain and clear the filter by incubating 5 min each as follows: twice in water, once in 70% isopropanol, twice in 100% isopropanol, once in 1:1 isopropanol/Americlear, and three times in Americlear. Incubate the filter 30 min in Permount and mount on a microscope slide.

   Large slides (e.g., 75 × 50–mm) are convenient for mounting and viewing the larger filters (e.g., 48-well filter).

Score cell migration

9a. *To score distance moved in a thick filter:* Under a 40× objective, use the micrometer on the fine focus knob of the microscope to measure the distance from the top of the filter to the furthest two cells in a single focal plane (or some other convenient measure). Repeat in 5 separate fields across the filter.

   In some instances, investigators have measured the population distribution in the filter (Zigmond and Hirsch, 1973; Buettner et al., 1989; Table 12.1.5).

Table 12.1.4 Incubation Times and Staining Procedures for Filter Assays

Cell type	Filter type	Pore size (μm)	Duration of incubation	Stain
Neutrophils	Thick	3.0	0.5-2.0 hr for migration into filter; 3-4 hr for migration through filter	Formaldehyde fixed: freshly prepared Giemsa, 1 hr to overnight
Neutrophils	Thin	3.0	20 min	Methanol-fixed, air dried: Diff-Quick
Lymphocytes	Thin	3.0-5.0	4 hr	Hematoxylin, overnight
Fibroblasts	Thin	8.0	3-4 hr	Hematoxylin, 1 hr to overnight

Table 12.1.5 Response of Neutrophils to *f*-Met-Met-Met: Mean Distance From the Top of the Filter to the Front PMNs[a]

Concentration above the filter (M)	Distance to front PMNs (μm) at concentration below the filter (M)			
	10^{-9}	10^{-8}	10^{-7}	10^{-6}
10^{-9}	27	30 [27]	57 [30]	69 [35]
10^{-8}	27 [30]	30	47 [30]	62 [35]
10^{-7}	34 [33]	36 [34]	34	60 [38]
10^{-6}	38 [52]	34 [52]	48 [52]	56

[a]Numbers in brackets are the distances to the front two PMNs calculated for a hypothetical population undergoing random migration (see Support Protocol 1), based on PMN migration observed in a uniform concentration gradient (numbers along the diagonal of the table). Data from Showell et al. (1976); reproduced with permission from Rockefeller University Press. *f*-Met-Met-Met, *N*-formyl-methionyl-methionyl-methionine; PMN, polymorphonuclear leukocyte.

9b. *To score number of cells on lower surface of a thin filter:* Using a 16× or 40× objective, count the number of cells per field that are on the under side of the filter for each well. Repeat for at least 5 fields.

When using a new cell type, it is important to check that cells are not falling off the filter into the bottom well.

9c. *To count cells recovered from lower chamber:* Collect fluid from the lower well, pipetting fluid up and down to remove cells stuck to bottom and sides of the well. Use a hemacytometer or cell sorter to count the number of cells in the cell suspension. To quantify by cell sorting, mix half of the cell suspension with a known number of 15-μm polystyrene beads. Run the suspension through the sorter and acquire a plot of forward scatter versus side scatter. Determine the ratio of beads to cells, and thereby calculate the number of cells in the cell suspension.

Since they have different light-scattering properties, beads and cells will appear as two discrete populations, allowing quantitation of cells from the known number of beads (Campbell et al., 1997b).

Differentiate chemotaxis from chemokinesis

10. If enhanced migration is observed at a particular concentration in the lower well, test the effects of that concentration on migration (both rate and number of migrating cells) when it is present both above and below the filter. Also test ½, ¼, and ⅛ of that concentration.

This approach allows a rough evaluation of whether the results observed under gradient conditions are due to chemotaxis or to effects on the rate of migration or on the number of migrating cells (Wilkinson, 1982). It makes the reasonable assumptions that the gradient through the filter is linear, and that cells moving from one concentration to another rapidly adjust their rate of locomotion to that observed when cells are incubated exclusively at that concentration. Simple mathematical analysis of chemokinesis versus chemotaxis can also be applied (see Support Protocol 1).

CALCULATING THE DISTANCE CELLS ARE EXPECTED TO MOVE IN THICK FILTERS IN THE ABSENCE OF CHEMOTAXIS

This calculation, which comes from Zigmond and Hirsch (1973), can be used to roughly estimate the contribution of unstimulated migration and chemokinesis to the extent of migration into a thick filter (see Basic Protocol 1). More sophisticated calculations are found in Buettner et al. (1989). Migration beyond this value can be considered a chemotactic response. Calculation of migration in the absence of chemotaxis is based on a number of assumptions: (1) a linear gradient exists across the filter, (2) acceleration of the cells between two known velocities is constant, and (3) movement of the leading two cells of the population is equal to that of a single particle moving with a velocity that is a function of the concentration of stimulatory material.

For this sample calculation, migration of cells was initially examined in a gradient of 10% to 50% serum across a 130-µm-thick filter. To test migration in the absence of chemotaxis, the velocity of migration was determined at three homogeneous concentrations (i.e., same above and below the filter): 10%, 30%, and 50%. The duration of the assay (30 min, or 1 time unit) is the same in both gradient and homogeneous assays. The following assay parameters/results are used. (1) The velocity (V) in a given concentration (both above and below the filter) is the distance from the top of the filter to the front two cells after an incubation of 1 time unit. In this example, velocities were determined to be: V_o = 84 µm/unit time (10% serum), V_1 = 73 µm/unit time (30% serum), and V_2 = 60 µm/unit time (50% serum). (2) The distance from the top of the filter to the first concentration for which a velocity is determined is d_1, the distance from the first concentration to the second is d_2, and so on. Since this example calculated velocities for three evenly distributed concentrations over a linear gradient, d_1 is the distance from the top of the filter (10%) to the middle of the filter (30%), and d_2 is the distance from the middle to the bottom of the filter (50%). Thus, $d_1 = d_2$ = 65 µm.

Since acceleration is constant, the mean velocity over distance d_1 is $\overline{V}_1 = (V_0 + V_1)/2$ = 78.5 µm/unit time. Thus, the time required to move from the top of the filter over distance d_1 is $T_1 = (d_1)/(\overline{V}_1)$ = 0.828 unit time. Similarly, the mean velocity over distance d_2 is $\overline{V}_2 = (V_1 + V_2)/2$ = 66.5 µm/unit time, and the time to move over d_2 is $T_2 = (d_2)/(\overline{V}_2)$ = 0.977 unit time.

Since $T_1 + T_2 > 1$ unit time, the front two cells will not get all the way across $d_1 + d_2$ in 1 unit time. To calculate the distance the cells will move into d_2 in one unit time, acceleration over d_2 is used, where $a_2 = (V_2 - V_1)/T_2 = -13.3$ µm/(unit time)^2. The time remaining after the cells have crossed d_1 (i.e., the time they migrate through d_2) is $T_f = 1 - T_1$ = 0.172 unit time. The distance migrated into d_2 is

$$V_1(T_f) + \frac{a_2(T_f)^2}{2}$$

Thus, the total distance the front cells would be expected to move is

$$d_t = d_1 + V_1(T_f) + \frac{a_2(T_f)^2}{2}$$

$$d_t = 65\,\mu\text{m} + (73\,\mu\text{m / unit time} \times 0.172\text{ unit time}) +$$

$$\frac{[-13.3\,\mu\text{m / (unit time)}^2] \times (0.172\text{ unit time})^2}{2} = 77\,\mu\text{m}$$

Table 12.1.6 Sample Data for Cell Response to Serum[a]

Concentration above the filter (%)	Distance migrated (μm) at concentration below the filter (%)		
	10	30	50
10	84		[77]
30		73	
50			60

[a]Unbracketed numbers are measured values at homogenous concentrations. Bracketed number is the calculated value for the 10% to 50% gradient.

The measured distances at homogeneous concentrations and the calculated distance for this gradient are presented as for a checkerboard assay in Table 12.1.6. To determine whether chemotaxis occurs with these cells in a 10% to 50% serum gradient, the measured distance for migration in the gradient is then compared to this calculated value. Movement greater than 77 μm would suggest that chemotaxis occurs.

UNDER-AGAROSE CHEMOTAXIS ASSAY

BASIC PROTOCOL 2

In this assay (Nelson et al., 1975), a tissue culture dish is filled with a mixture of agarose and cell culture medium. Wells are cut in the hardened agarose, and chemoattractant added to one well forms an approximately exponential gradient as it diffuses into the agarose (Foxman et al., 1997). Cells are placed in a nearby well, from which they migrate in the small space between the agarose layer and the culture dish. The cell distribution, in the presence and absence of chemoattractant, is determined after an incubation period (Fig. 12.1.3). The assay is useful for monitoring migration of neutrophils, monocytes, and possibly lymphocytes (Nelson et al., 1975; Laroche et al., 1983), as well as more adherent cells (Orredson et al., 1983; Stokes et al., 1990).

This protocol describes the analysis of cells fixed after a set migration time. Alternatively, the behavior of migrating cells can be monitored under the agarose by video microscopy using an inverted microscope fitted with a charge-coupled device (CCD) camera. It is important to determine the best parameters (e.g., magnification, contrast) to observe the behavior of interest. To maintain the proper environment, a stage warmer should be used to keep the cells at 37°C, a humidified chamber should be used to prevent drying, and HEPES-buffered agarose and migration medium should be used to maintain pH.

Materials

Agarose plate mixture (see recipe)
Migration medium (see recipe)
Cell suspension (10^7/ml) in migration medium
Chemoattractant solution in migration medium
Absolute methanol
37% (w/v) formaldehyde
0.5% (w/v) Fields stain B (Gallard-Schlesinger)
2.5% (w/v) Fields stain A (Gallard-Schlesinger)

35-mm tissue culture dishes
3-mm hole cutter (e.g., steel punch or plastic pipet tip), sterile, with a vacuum line and a catch flask
Template for cutting 3-mm wells separated by 2 mm in a single line
Counting grid (optional)

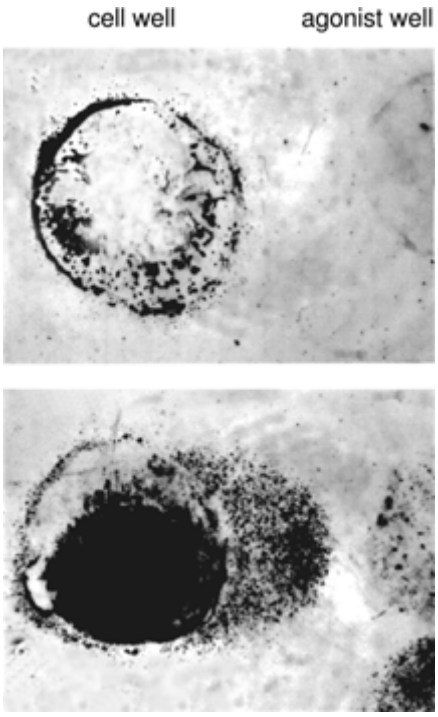

Figure 12.1.3 Under-agarose assay: response of neutrophils to interleukin 8 (IL-8). (**A**) Neutrophils exposed to a well containing no IL-8. (**B**) Neutrophils exposed to a well containing 1 pmole IL-8. Reproduced from Foxman et al. (1997) with permission from Rockefeller University Press.

NOTE: All culture incubations should be performed in a humidified 37°C, 5% CO_2 incubator unless otherwise specified. Some media (e.g., DMEM) may require altered levels of CO_2 to maintain pH 7.4.

Prepare plates

1. Add 3 ml agarose/plate mixture to each 35-mm tissue culture dish and allow to cool and solidify at room temperature. Transfer plates to a humidified 37°C, 5% (v/v) CO_2 incubator, and incubate several hours to overnight.

2. Attach a sterile 3-mm hole cutter to a vacuum line with a catch flask. Use a template to make five 3-mm wells in a straight line, separated by 2 mm. Push the implement through the agarose layer until it reaches the plastic plate, using the vacuum to remove the agarose plug.

   If using a steel punch, avoid scratching the plastic; scratches become barriers to cell migration.

   The agarose plugs collect in the catch flask. To prevent the tubing from clogging, flush with water after cutting holes.

   Cut wells no more than several hours before the assay. If a well is cut too long before it is filled with fluid, the agarose around the well dries and sticks to the plastic, preventing the cells from crawling underneath.

   A good template is a piece of metal containing precisely positioned holes (Nelson et al., 1975) and constructed to fit over a 35-mm dish. Alternatively, an actual-size diagram of the desired well pattern can be placed underneath the dish and used as a guide for cutting wells.

   The pattern of wells can be varied. Linear and parallel cell and attractant wells can be cut, yielding a steeper gradient of attractant, with a linear rather than radial distribution (Tranquillo et al., 1988). A triangular placement of wells allows analysis of migration in the presence of two chemoattractant sources (Foxman et al., 1997).

Prepare cells and chemoattractants

3. Suspend chemoattractants at the desired upper concentrations in migration medium. Suspend cells at 10^7 cells/ml in migration medium.

   To form an effective gradient, the chemoattractant concentration should be ~10 to 1000 times the chemoattractant receptor K_d (Table 12.1.2).

Perform assay

4. At the start of the assay, fill the two most peripheral wells with 10 µl migration medium. Next, place 10 µl cell suspension (10^5 cells) in each of the two intermediate wells. Finally, place 10 µl chemoattractant in the central well.

5. Return the plate to the 37°C, 5% CO_2 incubator for 2 hr (neutrophils) or longer (other cell types).

Fix and stain cells

6. Flood each plate with 1 ml absolute methanol. Allow cells to fix 30 min at room temperature, or overnight at 4°C.

7. Pour off methanol and flood each plate with 1 ml of 37% formaldehyde. Allow cells to fix 30 min at room temperature (longer if cold).

8. Remove agarose, using a Pasteur pipet to pry the edge loose, if necessary.

   The cells should now be fixed to the plastic and thus remain on the dish.

9. Add 1 ml of 0.5% Fields stain B followed by 1 ml of 2.5% Fields stain A, and allow to stain for 1 to 2 min. Rinse plates with water and allow to dry.

Measure cell migration

10a. *Measure leading edge distance:* Along a line running through the center of the five wells, measure the distance from the edge of the cell well to the edge of the migrating cell front. Compare the distance cells have migrated toward the chemoattractant well to the distance they have migrated toward a well containing only medium (i.e., the peripheral wells).

   A magnifier with reticles (Fisher Scientific) is a useful tool for performing these measurements.

10b. *Determine number of migrating cells:* Use a counting grid to count the number of cells that have migrated into squares at different distances from the cell well.

   This method allows comparison between the number of cells migrating in one assay versus another. A plot of cell density at different distances from the starting well provides more information about cell migratory behavior than an estimate of the leading front distance alone (Lauffenburger et al., 1983).

11. Evaluate chemokinesis and chemotaxis coefficients.

   Because most chemoattractants stimulate cell motility in a dose-dependent manner, a careful analysis is required to distinguish chemoattractant-stimulated motility (chemokinesis) from directional migration (chemotaxis). One approach is to measure chemoattractant-stimulated motility by observing the effect of a uniform field of chemoattractant (i.e., incorporated into the agarose) on cell migration, at a variety of different concentrations. Using these measurements, a chemokinesis coefficient can be determined, which can be used to calculate the relative contribution of chemokinesis and chemotaxis to the cell migration pattern in a chemoattractant gradient (Tranquillo et al., 1988).

   The orientation and directionality of migration of individual cells can be observed by viewing migrating cells using video microscopy. In fixed cells, some investigators have used nuclear orientation to determine if cells are oriented toward the chemoattractant source (Palmblad et al., 1982; Krauss et al., 1994).

BASIC PROTOCOL 3

SMALL POPULATION CHEMOTAXIS ASSAY

This assay utilizes a hydrophobic agar surface to allow the placement of two small drops of liquid extremely close to each other (Konijn, 1970; Konijn and Van Haastert, 1987; Fig. 12.1.4). Diffusion through the agar generates a transient gradient, which allows a qualitative (yes or no) judgment as to whether there is a chemotactic response. This assay has not been used for any cell types other than *Dictyostelium*.

Materials

Purified agar (e.g., Noble agar, Difco)
Bonner's salts (see recipe)
Dictyostelium cells at $\leq 5 \times 10^6$ cells/ml
17 mM Sorensen's phosphate buffer, pH 6.2 (see recipe)
Chemoattractant solution in Sorensen's phosphate buffer
10-cm petri dishes

1. Prepare 0.5% to 1% (w/v) purified agar in Bonner's salts.

   Purified agar can be replaced by less-expensive bacterial agar (e.g., Bacto agar, Difco) if it is extensively washed. A 20-g aliquot should be washed five times with 1 liter distilled water, followed by ten to fifteen times with an equal volume of deionized water, using no. 1 Whatman filter paper and a funnel to remove each wash (Konijn and Raper, 1961).

   The correct hydrophobicity and agar density is reached when 0.1-µl drops of cell suspension form half spheres and do not spread out from their original deposition site, and when the cells are unable to move out of the area covered by the original drop.

2. Pour 10 ml agar/salt solution in 10-cm petri dishes and allow to solidify.

   Plates can be stored 1 day at room temperature followed by up to one week at 4°C.

3. Wash *Dictyostelium* cells twice in ice-cold 17 mM Sorensen's phosphate buffer, pH 6.2, and resuspend at 10^7 cells/ml. Shake suspension 1 hr (for measuring responses to folate) or 6 to 8 hr (for cAMP) at 150 rpm, 21° to 23°C.

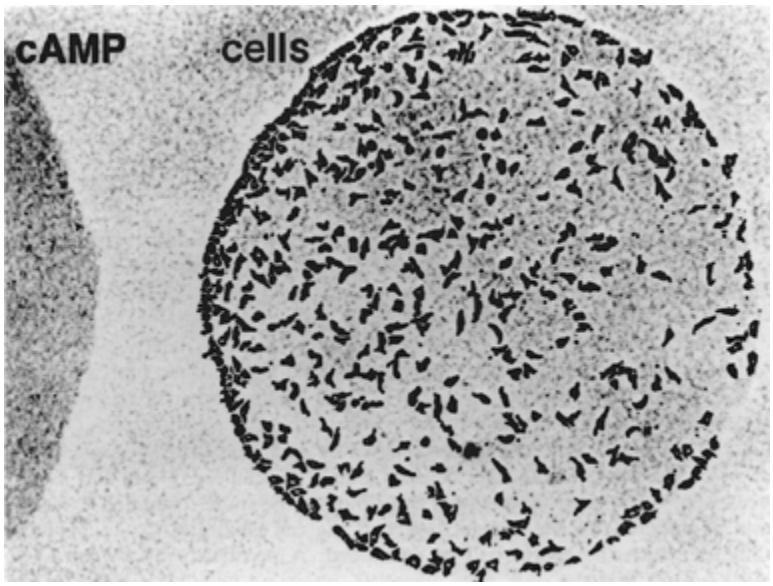

Figure 12.1.4 Small population assay. A single drop containing 500 to 1000 cells was exposed to cAMP (applied on the left in three 0.1-µl drops containing 10 nM cAMP) and was photographed 5 min after stimulus. Note the higher denisty of cells on the side nearest the stimulus. Reproduced from Konijn (1970) with permission from Birkhauser Verlag AG.

It is important that starting cells be grown at or below 5×10^6 cells/ml so that they are in log growth phase. For information on preparing Dictyostelium, consult Devreotes et al. (1987). Grow axenic strains in axenic media such as HL5 (Watts and Ashworth, 1970). Grow nonaxenic strains in association with bacteria (Sussman, 1987).

4. Wash cells once more and resuspend at 10^7/ml in 17 mM Sorensen's phosphate buffer. Place 0.1-µl drops (10^3 cells) at regular intervals on the agar surface.

   The small drops can be generated by using a Pasteur pipet with the tip drawn out by hand over a flame, and broken off (once cooled) to provide a small bore (40- to 70-µm inside diameter). Fine pressure control can be achieved by using rubber tubing and either mouth pipetting or using a pipet bulb. Uniform speed of deposition of the drops is important to minimize variation in cell density. The pipet should be refilled after every ten to twenty drops to prevent cells from settling in the pipet and ensure uniformity of cell density. It is useful to set up rows of 10 replicate drops, with each row stimulated by a different concentration of chemoattractant.

5. Add 0.1-µl drops of chemoattractant ~100 µm away from the cell drops. Repeat at 5-min intervals for a total of three applications.

   The concentration of chemoattractant should span a range between one tenth and ten times K_d (Table 12.1.2).

6. Incubate ~30 min at 21° to 23°C.

   The plates should be checked every 10 min, since the precise details of when the gradient forms and cells respond will vary slightly from assay to assay, and the gradient may be relatively transient.

7. Examine the distribution of cells within each drop to determine whether more cells are pressing against the side of the drop that is next to the stimulus (Fig. 12.1.4). Quantify the response by calculating the percent of responding drops, with 100% showing a strong response.

   See Konijn and Van Haastert (1987) for images of responding populations.

BRIDGE CHEMOTAXIS ASSAY

BASIC PROTOCOL 4

Cells are prepared on coverslips and are then inverted and observed on a 1-mm-wide bridge that connects two wells via a thin layer of fluid (Fig. 12.1.5). When different concentrations of chemoattractant are placed in the two wells, an approximately linear gradient develops across the bridge. The orientation or movement of cells toward one or the other well is monitored.

Materials

Cells: whole blood, neutrophils in suspension, or *Dictyostelium discoideum*
0.9% (w/v) NaCl
HEPES-buffered HBSS (prepare as for HBSS in *APPENDIX 2A*, but replace bicarbonate with 10 mM HEPES acid) containing 0.2% (w/v) BSA (for neutrophils in suspension)
17 mM Sorensen's phosphate buffer, pH 6.2 (for *Dictyostelium*; see recipe)
Chemoattractant in HEPES-buffered HBSS/1% (w/v) gelatin
HEPES-buffered HBSS/1% (w/v) gelatin

20 × 40–mm coverslips, unwashed (neutrophils) or acid-washed (*Dictyostelium*; see recipe)
Glass (Neuro Probe) or Plexiglas bridge chamber (Fig. 12.1.5; see Critical Parameters)
Microscope with 40× phase objective

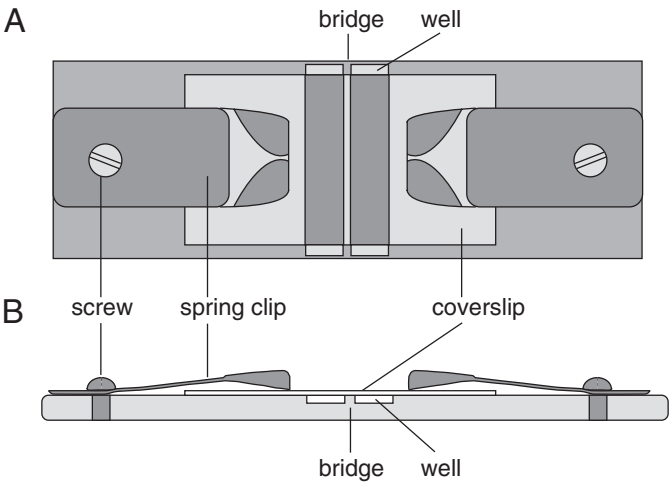

Figure 12.1.5 Apparatus for bridge assay. (**A**) Top view; (**B**) side view. A Plexiglas (or glass) base (3 mm high × 2.5 cm wide) contains two wells (4 to 5 mm wide × 1 mm deep) separated by a 1-mm-wide bridge. A 20 × 40–mm coverslip is placed across the wells and secured by two spring clips, so that a thin gap (e.g., 5 μm) is made between the coverslip and the bridge. Cells on the underside of the coverslip are flattened between the coverslip and bridge, and the direction of migration (to one or the other wells) is monitored.

Prepare cells on coverslips

For neutrophils from whole blood:

1a. Place ~0.1 ml human blood (e.g., from finger prick) across the center of a 20 × 40–mm coverslip.

Enough blood must be placed on each coverslip to allow it to clot and partially retract without drying.

2a. Place the coverslip in a moist chamber (e.g., a petri dish containing a wet piece of filter paper) at 37°C (with or without 5% to 10% CO_2, depending on whether the medium is buffered with bicarbonate). Incubate ~45 min, until the blood has clotted and is beginning to retract so that fluid is visible around the edges.

3a. Gently rinse the clot and red blood cells off with 0.9% NaCl.

A monolayer of cells, mostly neutrophils, remains on the coverslip. Care must be taken not to let the cells dry.

For neutrophils in suspension:

1b. Prepare a suspension of human or rabbit cells at 3×10^5 cells/ml in HEPES-buffered HBSS containing 0.2% BSA.

Neutrophils do not stick well in gelatin, which is used during the assay.

2b. Apply 0.1 ml cell suspension in a ~200-mm^2 strip across the center of a 20 × 40–mm coverslip. Allow to settle for ~5 min at room temperature.

3b. Rinse the cell layer with a few drops of incubation medium immediately before placing coverslip on bridge chamber (step 4).

For Dictyostelium:

1c. Prepare a single-cell suspension of *Dictyostelium* at 5×10^4 cells/ml in 17 mM Sorensen's phosphate buffer, pH 6.2.

2c. Place 50 µl cell suspension in a thin strip across the center of an acid-washed 20 × 40–mm coverslip.

Dictyostelium adhere best to acid-washed coverslips (Soll, 1988; Segall, 1992). The coverslips can also be coated with 2 mg/ml BSA.

3c. Allow cells to settle and attach for 5 to 10 min at room temperature.

Assemble bridge chamber

4. Quickly remove most of the fluid over the cells by tipping the coverslip and allowing fluid to flow onto a Kimwipe.

5. Invert the coverslip onto a clean chamber so that cells lie over the bridge. Lower the coverslip slowly, allowing one edge to touch first.

A clean chamber is essential to successful chemoattractant-induced orientation of cells (see Critical Parameters). Touching one side of the coverslip to the bridge and then lowering the other side helps eliminate air bubbles.

6. Secure the clips on each side without moving the coverslip.

Any movement of the coverslip will cause enough sheer force to lyse the cells on the bridge.

Chamber assembly requires practice, as short distances between the coverslip and the bridge are required for optimal cell orientation (see Critical Parameters). The chamber thickness can be measured by the difference in focal plane between the top of the bridge and the bottom of the coverslip, using the micrometer on the fine focus knob of the microscope.

Perform assay

7. Fill the two wells by capillary action with ~0.1 ml HEPES-buffered HBSS or chemoattractant both containing 1% gelatin.

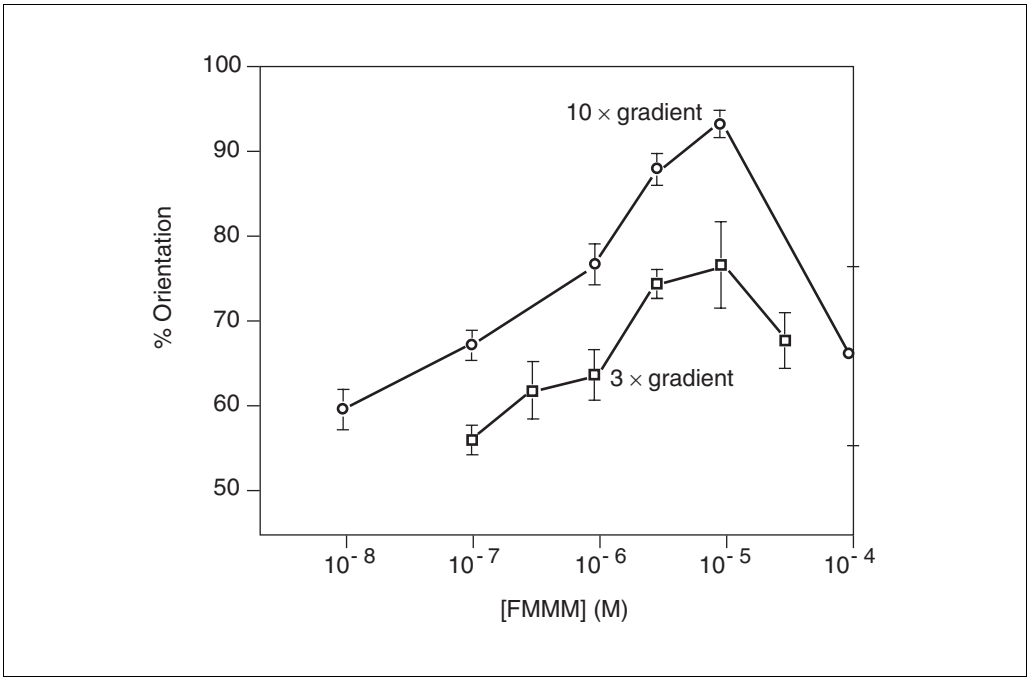

Figure 12.1.6 Results from bridge assay expressed as percent oriented cells versus chemoattractant concentration. The two curves represent different gradient steepnesses. The *x* axis corresponds to the high-concentration well. The other well contained one-tenth (circles) or one-third (squares) this value. *f*MMM, *N*-formyl-methionyl-methionyl-methionine. Reproduced from Zigmond (1977) with permission from Rockefeller University Press.

The chemoattractant concentration in the middle of the bridge will be approximately the mean of the two concentrations in the wells. Thus, the concentration of chemoattractant should range from one tenth to ten times the K_d of the receptor (Table 12.1.2).

A gradient of formyl peptide is ~90% established within 10 min and is roughly stable for 1 hr (Lauffenburger and Zigmond, 1981).

8. Incubate chambers 10 to 20 min at 37°C (or room temperature for *Dictyostelium*) to allow the cells to respond.

9. View cells at the middle of the bridge with a 40× phase objective. Determine the direction of cell migration for 100 cells based on morphological criteria, and plot percent cells oriented toward chemoattractant versus chemoattractant concentration (Fig. 12.1.6).

The front of a locomoting cell has a broad lamellipodium, while the tail is thinner and can be knob-like or drawn out into retraction fibers. The polarized morphology is clearest when the cells are moving well. When cooled, even to room temperature, neutrophils can round up and are difficult to score. The direction of movement can also be evaluated by video recording.

BASIC PROTOCOL 5

PIPET CHEMOTAXIS ASSAY

A pipet containing chemoattractant is brought up to a cell or group of cells, and the behavior of the cells is observed directly or by video microscopy.

Materials

Chemoattractant solution in assay buffer

Assay buffer: 17 mM Sorensen's phosphate buffer, pH 6.2 (see recipe), with or without $CaCl_2$ and $MgCl_2$ (for *Dictyostelium*), or DPBS (*APPENDIX 2*); JRH Biosciences; for MTLn3 cells)

Cells of interest

Omega dot tubing (4-in. glass capillary tubing, 1-mm o.d. × 0.58-mm i.d.; A-M Stevens)

Pipet puller for microinjection or neurobiology, capable of producing ~0.1-μm tip diameters (e.g., David Kopf Instruments, Narishige, Sutter Instruments)

Syringe with fine-bore needle (e.g., 3-in., 30-G)

Micromanipulator that can be attached to a microscope stage (e.g., Leitz, Narishige)

1. Prepare pipets (~0.1-μm tip diameter) using omega dot tubing and a pipet puller.

The thin tip allows a steep concentration gradient to be set up outside the pipet by diffusion, rather than by bulk flow. Omega dot tubing is used because it provides an internal filament to allow backfilling via surface tension (capillary action).

Alternatively, microloader micropipet tips are available from Eppendorf. To evaluate the suitability of the pipet, trial pipets can be filled with a high concentration (0.1 to 1 mM) of fluorescein or other fluorescent dye, and then viewed with a fluorescence microscope. If the tip is too large, a polarized stream of fluorescent material will be seen coming out of the tip. With the correct size tip, a spherically symmetric ball of fluorescence will be seen, brightest near the pipet tip, and getting dimmer with distance from the pipet, reflecting the spatial gradient generated by diffusion. Appropriate tips will be too small to resolve well with a 40× long–working distance objective.

2. Backfill the pipet by inverting and placing a drop of chemoattractant solution on the base. When the tip is full, fill the shank using a syringe with a fine-bore needle.

For expensive protein chemoattractants, load 5 μl directly to the tip with a microloader (Eppendorf).

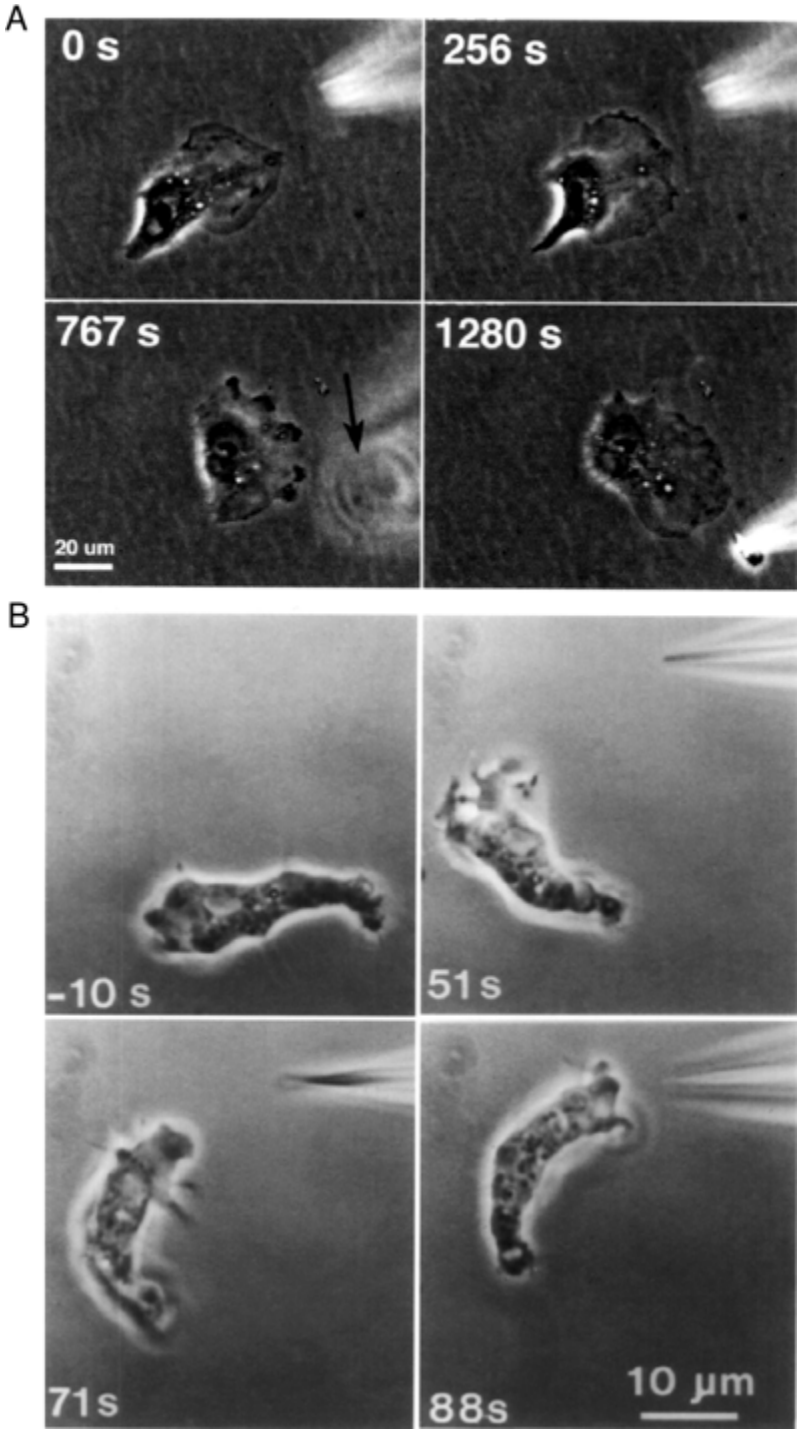

Figure 12.1.7 Pipet assay. (**A**) Response of mammary adenocarcinoma cell to a micropipet filled with 50 µM epidermal growth factor. The cell moved toward the micropipet (0 and 256 sec) and then reoriented when the pipet was moved (767 and 1280 sec). Arrow indicates movement of pipet. Reproduced from Bailly et al. (1998) with permission from Academic Press. (**B**) Response of *Dictyostelium discoideum* cell to a micropipet containing 0.1 mM cAMP. At −10 sec, the cell is moving to the left. At 0 sec, the pipet was placed in the upper right corner of the image field and the cell reoriented rapidly, moving toward the pipet. Reproduced from Segall and Gerisch (1989) with permission from Current Biology Limited.

A high concentration of chemoattractant (10^3 to 10^4 times K_d of the receptor; Table 12.1.2) is required inside the pipet. For example, in Dictyostelium, with a receptor K_d of 20 to 100 nM, 0.1 to 1 mM cAMP in the pipet provides a strong stimulus (>1000 times K_d). For MTLn3 tumor cells, with receptor K_d of 1 to 10 nM, 50 μM EGF in the pipet is necessary.

3. Place cells in a petri dish and cover with a thin layer of assay buffer.

   If temperature control is important, the buffer can be covered by mineral oil to minimize evaporation.

4. Place the micropipet in the micromanipulator and carefully bring the tip of the pipet to within 2 to 5 μm of the surface of the dish. If necessary, use positive pressure to increase the ejection rate.

   Note, however, that fluid flow generated by positive pressure may perturb a gradient that is generated purely by diffusion.

   Depending on the concentration of chemoattractant in the pipet and the chemotactic abilities of the cells, the tip may need to be within 10 μm of the cell, or it may be better at 50 μm away (for pipets containing high concentrations of chemoattractant). However, it is important to note that the gradient becomes shallower as the pipet is moved away from the cell, so that the steepest gradients are produced by pipets near the cell but perhaps utilizing a lower chemoattractant concentration so as to avoid saturating the receptors.

5. Incubate for the appropriate time.

   For Dictyostelium, responses can occur within seconds to minutes, while for slower-moving cells (e.g., MTLn3 cells), reorientation and movement may take 10 to 20 min.

6. Score the response of the cells (Fig.12.1.7) by measuring (1) the percent of cells that move toward the pipet, (2) the accuracy of redirection (cosine of the angle between the direction of cell movement and the direction of the pipet), or (3) the speed of cell movement toward the pipet.

   Typically, a 40× long–working distance objective provides adequate resolution. Lower magnification objectives may be useful in order to visualize the responses of multiple cells.

BASIC PROTOCOL 6

UPSHIFT CHEMOTAXIS ASSAY

In this assay, cell behavior is observed after a sudden homogeneous increase (or decrease) in concentration of chemoattractant. This assay is useful for biochemical analysis of chemotactic signal transduction, which almost always relies upon bath application of chemoattractant to cells followed by lysis and biochemical assays. In such studies, there is little or no significant spatial gradient. Rather, a sudden temporal change in chemoattractant concentration is the stimulus.

Although this is different from the stimulus experienced by cells in a spatial gradient, it provides useful information about the kinetics of various biochemical responses. A similar evaluation of behavioral responses to such a stimulus is also possible, allowing the correlation of biochemical changes with specific behaviors. In its simplest form, the upshift assay can be performed by microscopic evaluation of cells moving in a petri dish. By adding an equal volume of chemoattractant solution, a relatively efficient concentration increase is effected and cell behavior can be observed. An example of this approach is shown in Figure 12.1.8, and a detailed protocol is provided in Cammer et al. (1997). Alternatively, a number of specialized chambers or procedures can be utilized to allow a more precise control of the concentration (Varnum-Finney et al., 1988; Segall, 1992) or of the rate of increase in concentration (Omann and Sklar, 1988).

USING IMAGE ANALYSIS PROGRAMS TO ASSESS CHEMOTAXIS

In many chemotaxis assays (e.g., under-agarose, bridge, micropipet, and upshift assays), the area, shape, speed, and direction of movement of individual cells must be measured. Although it is possible to trace video or still images on the monitor screen, a number of image processing programs that aid in subsequent quantification are available. DIAS (Dynamic Image Analysis System) is specifically designed for such analysis (Soll, 1995). Depending on the image itself, the program can directly determine cell borders (for slightly defocused bright-field images). Alternatively, it allows a user to trace high-resolution differential-interference-contrast (DIC) or phase-contrast images. The program then calculates the center of mass, area, roundness, speed, and direction of movement of each cell in the field. A number of other parameters can be calculated as well. Other programs, such as NIH Image (Cammer et al., 1997) and Metamorph (Universal Imaging), can also be adapted to provide a limited subset of similar measurements.

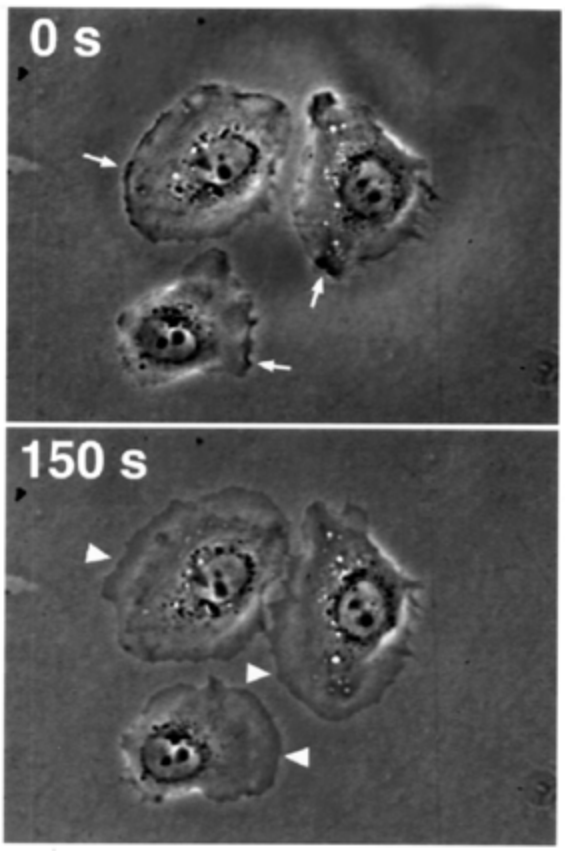

Figure 12.1.8 Upshift assay. MTLn3 cells were grown 24 hr on tissue culture plastic in growth medium in a 37°C CO_2 incubator. They were transferred to a microscope with a 37°C incubator box. The lid of the dish was removed and the medium was covered with a layer of prewarmed mineral oil (Sigma). After tracking for 5 to 10 min, an equal volume of 10 nM epidermal grown factor (EGF) in 37°C growth medium was added under oil using a sterile pipet (final 5 nM stimulus). The top panel shows cell morphology immediately after addition of EGF. The phase-dark areas at the edges of the cells are vertical ruffles (arrows). The bottom panel shows cell morphology 150 sec after addition of EGF. The ruffles have disappeared and flat hyaline lamellipodia have extended (arrowheads), increasing the total area of the cells. Reproduced from Segall et al. (1996) with permission from Kluwer Academic Publishers.

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Acid-washed coverslips

Soak coverslips 10 min in 2.7% HCl. Rinse extensively in water and dry in a clean area or a laminar-flow hood. Store several days to a week at room temperature in a clean, sealed container to reduce the rate at which the surfaces become hydrophobic.

Agarose plate mixture

For bicarbonate-buffered under-agarose plates:

Boil agarose in HBSS (*APPENDIX 2A*) at a final concentration of 2.4% (w/v). Make a separate solution of 20% (v/v) heat-inactivated bovine calf serum (BCS) in bicarbonate-buffered RPMI 1640. When agarose solution is cooled to 50°C, mix solutions 1:1 (final 1.2% agarose, 10% BCS, 0.5× RPMI, 0.5× HBSS) and use immediately.

For HEPES-buffered under-agarose plates:

Boil 2.4% (w/v) agarose in sterile water. In a separate container, dilute 1 M HEPES (Life Technologies) to 20 mM in 2× RPMI 1640 without bicarbonate (from low-endotoxin 10× RPMI 1640 stock; Sigma). Add 20% (v/v) heat-inactivated BCS to RPMI/HEPES and adjust to pH 7.2. When agarose solution is cooled to 50°C, mix solutions 1:1 (final 1.2% agarose, 10% BCS, 1× RPMI) and use immediately.

For both types of plates, the agarose must be boiled and cooled before addition of protein solution, to avoid denaturing the protein. For serum-free assays, replace 20% BCS with 1% (w/v) BSA or 0.25% gelatin (see Critical Parameters).

Media with serum/protein (but no agarose) can be filter sterilized and stored up to 6 months at 4°C.

Bonner's salts

10 mM NaCl
10 mM KCl
2.7 mM $CaCl_2$
Store at 4°C (stable at least 1 month)

Giemsa stain

4 ml 95% (v/v) ethanol
3 ml Giemsa stock (Ricca Chemical)
43 ml 15 mM sodium or potassium phosphate buffer, pH 6.8
Prepare fresh before use

Migration medium

For bicarbonate-buffered under-agarose plates (see agarose plate mixture above), use 1× bicarbonate-buffered RPMI 1640 with 10% (v/v) heat-inactivated BCS. For HEPES-buffered under-agarose plates, use 1× RPMI without bicarbonate (from low-endotoxin 10× RPMI 1640 stock; Sigma) containing 10 mM HEPES and 10% (v/v) heat-inactivated BCS. Filter sterilize and store up to 6 months at 4°C.

For either medium, 10% BCS can be replaced with 0.5% (w/v) BSA (see Critical Parameters).

Sorensen's phosphate buffer, 17 mM, pH 6.2

For 10× stock solution:
20.6 g/liter KH_2PO_4
5.05 g/liter $Na_2HPO_4 \cdot 7H_2O$
Store at room temperature or 4°C (stable at least 1 month)
Before use, dilute to 1× and supplement with 1 mM $MgCl_2$ and 0.2 mM $CaCl_2$

COMMENTARY

Background Information

Distinguishing chemotaxis from chemokinesis

Chemotaxis assays are designed to determine if a biological compound has the ability to induce directed migration of cells. To demonstrate that a factor elicits chemotaxis, it is important to show that a gradient of the factor biases the direction of locomotion rather than simply stimulating locomotion in random directions (chemokinesis). Unfortunately, merely demonstrating that cell migration is not stimulated when the gradient is reversed does not prove that the test substance is a chemoattractant. This is because many factors, including many chemoattractants, stimulate the rate of migration in a concentration-dependent manner, and because very high concentrations of some substances can be less stimulatory than lower concentrations (Harvath et al., 1980; Tranquillo et al., 1988).

To determine if chemotaxis is present in a spatial gradient, one must show that the enhanced migration cannot be accounted for quantitatively by enhanced rates of random migration. To do this one needs to first define the effects on random migration, by quantifying migration in a series of homogeneous concentrations of the test material (a checkerboard assay as in Tables 12.1.5 and 12.1.6). Once the effects of different concentrations on random migration are known, it is possible to determine if they account fully for the migration observed in a gradient. Migration in a positive gradient that exceeds that expected from random migration is evidence for chemotaxis. This analysis does not correct for the possibility that migration is stimulated as cells are exposed to higher concentrations of attractant and inhibited as the concentrations decrease (Rhodes, 1982). Such effects on migration rates have been observed, but their magnitude is probably too small to appreciably alter the results. It is also possible to determine if a factor testing positive in an initial assay is truly chemotactic by testing it in an assay that directly monitors the movement of individual cells.

When and why should one determine if a factor is really a chemoattractant?

In some cases the investigator may not care if the response is due to enhanced migration or chemotaxis. If documentation of chemotaxis is not shown, a valid way to report the results is that the factor "stimulated (or enhanced) cell migration." However, understanding the cellular basis for the increased migration is important for predicting how the factor will function in a given situation. Consider a test factor that merely enhances migration in a concentration-dependent manner. A purely chemokinetic factor can appear to attract cells in one assay but repel them in a different assay. If, in one assay, cells are placed in a well and exposed to a gradient of this factor emanating from an adjacent well, cells exposed to the higher concentration will move faster and spread further toward the well than cells exposed to the lower concentration. However if, in a second assay, the cells are distributed evenly throughout a gradient, again emanating from an adjacent well, the cells exposed to the higher concentration will again move the fastest, but now the movement results in net dispersion of cells away from the well containing the factor. Thus, the factor could appear to be a chemoattractant in one assay and a repellent in a second. In reality, it simply stimulates migration in a concentration-dependent manner.

Chemotaxis when the gradient is attached to the substratum

There are many situations in which the chemoattractant is not in solution but rather is attached to the substratum. Cells can respond to a chemoattractant gradient even when the chemoattractant is attached in a fixed gradient (Wilkinson and Allan, 1978). In vivo, it is likely that binding of chemoattractant to the extracellular matrix allows a gradient to be maintained in the midst of water flux through the extracellular space (McCormick et al., 1993, 1995; Webb et al., 1995). In other cases, the chemoattractant acts directly through adhesive receptors that signal to the cell interior to stimulate spreading and process outgrowth (Aznavoorian et al., 1996; Condic and Letourneau, 1997). Finally, adhesivity itself can result in cell accumulation in regions of high adhesivity, a phenomenon initially termed haptotaxis (Carter, 1965). This cell accumulation can result merely from the trapping of cells in regions of very high adhesivity, not from directed movement (Harris, 1973).

Variations in the basic assays

The assays presented in this unit represent basic starting procedures. They can be modified

for a variety of specific purposes. Some examples of such modifications are described here.

Filter assays. Cell migration assays performed with filters can be automated through the use of radiolabeled or fluorescently tagged cells. In addition, instead of filters, cell migration can be assayed across epithelial cell monolayers (Nash et al., 1987), endothelial cell monolayers (Huang et al., 1988), or gels of extracellular matrix components (Loike et al., 1995).

Under-agarose assays. An interesting variation has been developed by Tranquillo and collegues (Moghe et al., 1995). These investigators initiate the assay with neutrophils evenly distributed throughout a fibrin gel rather than concentrated in a well. This geometry allows analysis of cell movements that are uncomplicated by the effects of high cell concentration and gradients of cell concentration.

Bridge assays. The chemoattractant can be added after the cells have had time to equilibrate in the chamber. With *Dictyostelium* amoebae, where the thickness of the fluid layer does not appear to be so critical, it is possible to first fill the wells with buffer and incubate the bridge chamber in a humidified chamber for 20 min at room temperature to allow the cells to equilibrate. Unstimulated cell behavior can be measured under these conditions. One well can then be flushed with 10 nM to 2 μM cAMP, while the other is flushed with just buffer. After allowing 10 min for gradient formation, cell behavior over the next 20 to 30 min will demonstrate the chemotactic response. Cells move at ~10 μm/min with a strong bias toward the well filled with cAMP (cosine of direction of movement relative to the direction of the gradient is typically 0.3 to 0.6). With neutrophils, also, it is possible to remove the fluid from a well and replace it with a different solution. However, care must be taken not to move the coverslip, which will shear the cells on the bridge.

For slower moving cells such as fibroblasts or epithelial cells, a chamber that may have a more stable, longer-lasting gradient has been designed (Zicha et al., 1997) and is available from Weber Scientific. An alternate approach to generating a stable spatial gradient utilizes hollow fibers embedded in an agarose gel that is continuously supplied with new medium. This method provides the longest-lasting gradients, but is quite delicate and is not commercially available. Details on construction of the chamber are described in Fisher et al. (1989).

Pipet assay. A two-pipet assay has been used to analyze the dynamics of leukocyte pseudopod extension (Zhelev et al., 1996).

Critical Parameters

Equipment options for filter assays

For filter assays (see Basic Protocol 1), there are a number of chamber and filter options to select from (see Tables 12.1.3. and 12.1.4).

Chamber design. Filter assays can be performed in individual, blind-well chambers (Fig. 12.2.1), or in multiwell chambers (Fig. 12.1.2) containing 12 or 48 wells. These are available from Neuro Probe. Alternatively, cells can be induced to migrate through porous tissue culture inserts (Collaborative Biomedical Products, Corning Costar) that fit in standard 24-well tissue culture dishes.

Filters. The original Boyden filter assay used thick cellulose acetate or nitrate filters (Boyden, 1962). They are ~100 μm thick, and have torturous pores (Millipore or Neuro Probe). Because these filters are thick, measurable parameters include: the distance of migration into the filter (Zigmond and Hirsch, 1973; see Support Protocol 1), the number of cells that have moved a given distance into the filter, and the number of cells that have migrated all the way through the filter. These filters may be used with blind-well or multiwell Neuro Probe chambers.

Thin polycarbonate filters (Nucleopore) are only ~10 μm thick and have pores that are straight channels through the filter. These filters can be used to count the number (or fraction) of cells that have migrated through the filter to the lower surface (Harvath et al., 1980) and to count the number of cells that have fallen off into the lower chamber. Since the filters are only one cell diameter thick, it is impossible to further define the distance migrated. Polycarbonate membranes are available for blind-well and multiwell Neuro Probe chambers. In addition, two types of thin filters are available as tissue culture inserts for standard 24-well tissue culture plates, including polyethylene terephthalate (PET) BIOCOAT control inserts (Collaborative Biomedical Products) and polycarbonate Transwell inserts (Corning Costar). It appears that chemokinetic effects are less pronounced in thin polycarbonate filters than in thick cellulose nitrate filters (Bignold, 1988).

Pore size. Both filter types come in different mean pore sizes. The appropriate pore size depends on the cell type being studied (see

Table 12.1.4). Monocytes can be assayed using filters with 5.0- to 8.0-μm pores, and mesenchymal cells using filters with 8.0-μm pores. Neutrophils are usually assayed with 3.0-μm pores. They can migrate into very small pores (1 μm) when induced by a gradient of chemoattractant, but not when exposed to a homogeneous concentration of attractant (Campbell et al., 1997a). Thus, a small pore size can be chosen to minimize the contribution of chemokinesis.

Filter coating. Usually the clean filters are toxic and some protein coat must be included. Albumin can be added to the assay medium, or the filter can be precoated with an extracellular matrix protein. For example, for MTLn3 cells or fibroblasts it is helpful to coat the filter 2 hr with type I collagen (27 μg/ml rat tail collagen) in Dulbecco's phosphate-buffered saline (DPBS) without calcium or magnesium (JRH Biosciences; also see DPBS and CMF-DPBS in *APPENDIX 2A*). The filter is then rinsed in DPBS before use. Depending on the cell type, better responses may be obtained by drying the matrix molecules onto the filter.

Equipment considerations for bridge assays

Glass chambers are available from Neuro Probe. The glass chamber is thin and provides excellent optics. Plexiglas chambers can usually be cut locally. The shop should be advised that the Plexiglas must be completely flat (i.e., not warped). After cutting the wells, the burrs on the edge of the wells must be removed, but the top of the chamber should not be polished, as this lowers the height of the bridge.

The distance between the bridge and coverslip must be precise for proper cell orientation. For instance, optimal neutrophil orientation occurs when the distance between the coverslip and bridge is ~5 μm. Improved orientation when the fluid layer is thin probably reflects the fact that the gradient across the bridge is formed by diffusion. The thin space creates resistance to fluid flow between compartments, which disturbs the gradient. The thin space, and resultant high cell concentration, probably allows the cells to steepen the gradient by removing/degrading the chemoattractant.

The chamber thickness can be measured by the difference in focal plane between the top of the bridge and the bottom of the coverslip, using the micrometer on the fine focus knob of the microscope. When the distance is 5 μm, the cells are somewhat flattened. To obtain a fluid layer in the 5- to 10-μm range requires a clean chamber and sufficient force applied by the clips. Chambers exposed to room air rapidly absorb "junk." Therefore, chambers should be washed just before use in warm water with tissue culture detergent, rinsed well with distilled water, and wiped dry. The bridge can also be wiped with 70% or 95% ethanol. To obtain the proper fluid layer, it also helps to use a minimal amount of fluid when making the cell preparation. It is usually necessary to prepare extra chambers and then incubate and score only those of appropriate thickness.

Cell-specific issues

Neutrophils like to be squeezed and move rapidly through filters, under agarose, and when compressed between two surfaces as in the bridge assay. When merely placed on a surface, neutrophils show a variable ability to translocate, and are frequently described as being "stuck by their tails". These "stuck" cells extend processes into the medium but appear unable to form effective new attachments. This behavior is remedied by altering the extracellular matrix protein present (Marks et al., 1991; Maxfield, 1993), and is rarely seen when cells are in contact with (squeezed between) two or more surfaces, such as in a filter, bridge, or under-agarose assay.

Neutrophils respond to various chemoattractants, including bacterial-derived peptides (*N*-formyl peptides), a cleavage product of complement factor 5 (C5a), lipids such as leukotriene B_4 (LTB_4), proteolytic fragments of the extracellular matrix (Senior et al., 1980), and many of the C-X-C family of chemokines (Baggiolini et al., 1997).

With neutrophils, the method of cell isolation and the time between drawing the blood and starting the assay can have important effects. Different labs use different protocols. Endotoxin-free neutrophils can be stored at room temperature for several hours without activity. Note that some investigators have demonstrated that neutrophils change phenotype when assayed >2 hr after cell preparation (>5 hr after blood drawing; Seligmann et al., 1981). Rabbit peritoneal neutrophils can be stored overnight at 4°C, as long as they are kept in the peritoneal fluid.

Monocytes move more slowly than neutrophils but are readily assayed in filter assays. They respond to many of the CC family of chemokines as well as to *N*-formyl peptides.

Lymphocytes (T and B cells) respond chemotactically to a variety of chemokines. Lymphocytes migrate well through thin poly-

carbonate or polyethylene terephthalate membranes.

Dictyostelium amoebae respond well in filter, under-agarose, small population, bridge, and micropipet assays. *Dictyostelium* amoebae do not typically show tight attachment to surfaces and do not require surfaces coated with specific adhesion molecules. The sensitivity of *Dictyostelium* cells to specific chemoattractants can vary with cell state. Cells taken directly from growth medium are chemotactic to folate. As cells are starved, they undergo a developmental program that involves formation of aggregates of cells by chemotaxis to extracellular cAMP. During morphogenesis in aggregates to form pseudoplasmodia or fruiting bodies, responsiveness to cAMP may be reduced and responses to monapterin derivatives develop. Thus far, the best characterized chemotactic responses have been those to extracellular cAMP by cells starved for 6 to 8 hr.

Mammalian fibroblasts and epithelial cells (including many tumor cell types) typically move slowly (0.2 to 2 μm/min). This may reflect the slow detachment of focal contacts to surfaces coated with typical extracellular matrix molecules such as collagen, laminin, vitronectin, or fibronectin. Chemotactic responses of such cells have been characterized using filter assays. Identified chemoattractants for these cells include ligands for G protein–coupled receptors—such as autocrine motility factor (AMF)—and growth factors that bind to receptor tyrosine kinases—such as fibroblast growth factor (FGF), epidermal growth factor (EGF), insulin, platelet-derived growth factor (PDGF), and hepatocyte growth factor/scatter factor (HGF/SF). The methods described in this unit have been developed for a chemotactic tumor cell line (termed MTLn3 cells), but similar conditions should work for most fibroblast and epithelial cells. Extracellular matrix molecules can be used instead of chemoattractants to evaluate haptotactic responses.

Neurons have shown a variety of motile responses. One distinctive feature of neurons is the formation of a growth cone, which shows polarized movement while the main cell body may remain stationary. Growth factors, neurotransmitters, and adhesion molecules have been shown to attract or repel neuronal growth cones. The assays typically utilized for growth cone responses are micropipet or tissue fragment assays. Thus far, the focus has mainly been on identifying chemoattractants for various neuronal types. Future studies will begin to focus on mechanistic questions, given the recent advances in characterizing chemoattractants for neurons.

Media

Since most neutrophil assays are short, the cells can be assayed in Hanks' balanced salt solution (HBSS). Alternatively, a full medium such as RPMI can be used. Neutrophils move best in slightly acidic (pH 7.1 to 7.2) and slightly hypotonic conditions. Bicarbonate-buffered tissue culture medium can be used when assays are incubated in 5% to 10% CO_2. For incubations in room air, both RPMI and HBSS can be purchased without bicarbonate, and then supplemented with 10 to 20 mM HEPES. All solutions should be kept sterile and as endotoxin-free as possible, since endotoxin activates neutrophils.

All assays require some protein to allow migration and prevent toxicity from glass, filters, and agarose. The protein can be albumin, gelatin, or serum proteins. Most commonly, bovine serum albumin is added to a final concentration of 0.1% to 1% (w/v). Although albumin itself can stimulate migration, this effect is diminished through use of fatty acid–free albumin. Gelatin is dissolved fully in boiling water as a 10% (w/v) stock, which is then warmed to remelt the gelatin and diluted tenfold (final 1%) into medium. Gelatin is nonstimulatory (Chenoweth et al., 1979) and minimizes neutrophil adhesion to various surfaces. Gelatin enhances migration in the bridge assay but does not provide enough traction to allow cells to enter pores of the Millipore filter. However, once cells have entered the pores, substitution of gelatin for BSA stimulates subsequent migration (Zigmond, unpub. observ.). Heat-inactivated serum (≤10%) may also be used as a protein source. Serum is heat-inactivated by warming to 56°C for 25 min. However, even after heat inactivation, serum contains chemoattractants.

The optimal medium for studies with *Dictyostelium* is 17 mM Sorensen's phosphate buffer, pH 6.2, with 1 mM $MgCl_2$ and 0.2 mM $CaCl_2$.

For MTLn3 cells/fibroblasts, α-MEM with 12 mM HEPES, pH 7.4, can be used. BSA can be included at 0.35% (w/v) to provide an osmotic strength similar to 5% BCS. Optimal responses to EGF are obtained by always growing and passing cells at <80% confluency, and by serum starving the cells in HEPES-buffered MEM with 0.35% BSA for 3 to 24 hr just before stimulation.

Decreased orientation in the bridge assay

The level of orientation in the bridge assay is reduced when competing chemoattractants are present. Neutrophils adjacent to air bubbles or cell clumps produce chemoattractants, and thus become foci for attracting adjacent cells. These foci reduce the level of orientation induced by the chemoattractant gradient across the bridge. When chemoattractant is present in both wells, cells near the edge of the well containing the lower concentration are sometimes observed to orient toward this edge. This "edge effect" appears to be due to a high concentration of cells on the bridge degrading chemoattractant until there is a lower concentration at the center of the bridge than in the well containing the lower concentration.

Controls

Under all conditions, the most important control is using medium without chemoattractant. Cell responses under these conditions provide a baseline for comparison with medium containing chemoattractant. Distinguishing between chemokinesis and chemotaxis can then be done, if desired, by evaluating cell responses when the same concentration of chemoattractant is present in all solutions.

Anticipated Results

Filter assay

With a thick cellulose nitrate filter, unstimulated cells typically move 10 to 15 μm into the filter and stimulated cells move 80 to 90 μm into the filter. When measuring the distance to the cell front, it is important to stop the incubation before cells have moved all the way through the filter (~100 μm after staining and clearing; Zigmond and Hirsch, 1973). When measuring the number of cells on the bottom of the filter, between 20% and 50% of the cells move to the bottom following stimulation (Harvath et al., 1980).

For thin-filter assays, with neutrophils migrating through tissue culture inserts with 1-μm pores, typically 5% to 20% of the cells added to the top well traverse the filter and can be counted in the bottom well in response to an optimal gradient. Without stimulation, <1% of cells appear in the bottom well (Campbell et al., 1997a).

The percentage of lymphocytes/lymphoid cells that migrate through 3- or 5-μm pores varies widely (from 1% to 50%) with cell type and chemoattractant used. However, when the optimal pore size is used, the background migration without chemoattractant is typically very low (<1% of cells added).

Under-agarose assay

Neutrophils migrating in response to an optimal chemoattractant source can migrate up to 1.6 mm toward the attractant during the 2-hr migration period. Neutrophils in this assay tend to migrate farther toward some chemoattractants than others, e.g., migrating more toward interleukin 8 or *N*-formyl-methionyl-leucyl-phenylalanine (*f*MLP) than C5a or LTB_4 (Foxman et al., 1997). The differences in migration may reflect differences in gradient formation, difference in cellular responsiveness to chemoattractants, or both. Neutrophils in the migrating cell population are densely packed. In the absence of stimulation, individual neutrophils can be observed to migrate as far as 0.5 mm away from the starting well, but the cells are much more sparsely distributed (Fig. 12.1.3).

Small population assay

This assay is designed to score rapid movement of *Dictyostelium* cells toward a chemoattractant. As the chemoattractant concentration is increased, the fraction of responding cells will go from 0% to a maximum of near 100%, followed by a decrease when the concentration becomes too high. The optimal concentration range may be very narrow.

Bridge assay

Random migration results in ~50% of the cells moving toward each well. In an optimal gradient of a potent chemoattractant, it is possible to observe 100% of the cells with polarized morphology, all oriented toward the attractant. Often, only between 50% and 80% have clear enough polarity to be scored, and of these, between 80% and 90% are oriented toward the chemoattractant (Zigmond, 1977). In video studies, up to 100% of the cells are observed to move toward the chemoattractant, although the accuracy of the orientation toward the attractant varies.

Pipet assay

For *Dictyostelium* or neutrophils, changes in cell shape and extensions are seen within seconds after placement of the pipet, with net movement toward the pipet observed within 1 min. For epithelial or mesenchymal cells, such as MTLn3 cells or fibroblasts, a slow response involves extension of projections followed by net cell movement, which may take up to 20 to

30 min. In the most extreme cases, such as orientation of *Sacchyromyces cerevisiae* cells in a gradient of mating factor, responses may take hours (Segall, 1993). In all cases, too high of a concentration of chemoattractant in the pipet will result in responses similar to those seen in the upshift assay (see below), with no oriented movement toward the pipet.

Upshift assay

Within 20 min a series of shape changes should occur. The specific changes and their kinetics vary with cell type. For *Dictyostelium,* cells stop and round up within 30 sec, and extend lamellipodia at 1 to 2 min, followed by at least a partial restoration of motility (Varnum-Finney et al., 1988; Segall, 1992). Restoration can be observed within 10 min, especially at low chemoattractant concentrations. For neutrophils, dramatic lamellipodial extension occurs 1 min after stimulation, followed by motility at 3 to 5 min (Zigmond and Sullivan, 1979). For MTLn3 cells, maximal lamellipodial extension is seen at 3 to 5 min (Segall et al., 1996). For mammalian cells, restoration may take 30 min, or a permanent change (either increase or decrease) in rate of movement may be seen.

Time Considerations

Filter assay

Isolating cells from blood or a peritoneal exudate takes 3 to 6 hr, respectively. It takes 30 min to prepare medium and 10 min to prepare a 12-well multiwell chamber. The assay itself requires 30 min to 3 hr for incubation (depending on cell and filter type), 2 to 3 hr for staining and clearing the filter (staining can be performed overnight), and 5 to 15 min per filter for mounting and scoring.

When the filter assay is performed using a 24-well plate with inserts, ~30 min are required to prepare the medium, but it may be prepared the night before and equilibrated overnight in a tissue culture incubator. It takes ~30 min to set up the chamber with filter and medium. The amount of time required to prepare the cells for the assay depends on the cells, on average from a few minutes to 2 to 3 hr or more. Incubation time for the assay is 1.5 hr for neutrophils and 3 to 4 hr for lymphocytes or lymphoid cell lines. Scoring the assay requires 5 min per well.

Under-agarose assay

It takes ~1 hr to prepare the medium and pour the plates, and this can be done the night before the assay. On the day of the assay, it takes ~1 min per plate to cut the wells. The time required to prepare cells for the assay ranges from a few minutes for cultured cells to 2 to 3 hr for cells isolated from blood. It takes ~1 min to set up each plate, 2 hr to incubate neutrophils (longer for other cells), 1.5 hr to fix and stain cells, and ~2 min per plate to score migration distance.

Small population assay

It takes 1 to 2 days to prepare the agar dishes for this assay. Practice is required to prepare Pasteur pipets of the appropriate tip diameter. Cell preparation time will vary depending on the cell type. For example, for optimal chemotactic response to cAMP, *Dictyostelium* requires starvation for 4 to 8 hr. Performance of the assay itself requires 15 to 20 min to place the various drops, and 30 min to record the responses.

Bridge assay

The time to perform an individual assay includes 3 to 6 hr to obtain the cells from blood or peritoneal exudate, or 45 min from a finger prick sample; ~30 min to prepare the medium, which can be done during cell preparation; 1 to 3 min to prepare each chamber; 20 min to incubate; and 5 to 10 min to score orientation or migration on a video recording.

Pipet assay

For rapidly moving cells such as *Dictyostelium* or neutrophils, the responses of individual cells can be determined within 2 to 4 min. For slowly moving cells such as fibroblasts or epithelial cells, responses occur after 10 to 20 min. The time required to quantitate the results depends upon the number of cells and images analyzed. On average, using NIH Image or DIAS, 10 to 30 min per cell are required to quantitate area, speed, and direction of motion (Cammer et al., 1997; Bailly et al., 1998; Fig. 12.1.7).

Upshift assay

Preparing and warming solutions requires 20 to 30 min. Recording of cell responses in a microscope requires 20 min per upshift compartment. Quantitation of results depends on the method used. For NIH Image or DIAS, roughly 10 min are required to trace out the perimeter and calculate the area for one cell if one image per min is recorded.

Invasion Assays

The basement membrane is a thin extracellular matrix that underlies epithelial and endothelial cells and separates these tissues from stroma. Tumor cells must cross the vessel basement membrane and penetrate the underlying stroma in order to invade tissue and form distant metastases. They do this by producing proteases that degrade the extracellular matrix. Several in vitro invasion assays have been developed using various extracellular matrix barriers including amnion, type I collagen gels, and a reconstituted basement membrane termed Matrigel (see *UNITS 10.2 & 10.3*). Matrigel-based invasion assays (see Basic Protocol) are the most reliable, reproducible, and representative of in vivo events, and they are the assays most frequently used. Porous filters are coated with a thin layer of Matrigel and placed in a Boyden migration chamber with a chemoattractant in the lower well and tumor cells in the upper well (Fig. 12.2.1). The entire chamber is then incubated for ~3 to 10 hr, depending on the tumor cells used. After incubation, the filter is removed, fixed, and stained, and the cells on the lower surface of the filter are quantitated. This assay is advantageous because it is quick, reliable, quantitative, and in most cases does not require sterility. Compounds that either promote or inhibit invasion can be assayed. In addition, at the end of the assay, the invasive cells can be recovered and used for further study. The invasion assay can be used to screen for a large variety of compounds in 48-well chambers, with the advantages that smaller amounts of test material and fewer cells are needed. Commercial kits are also available. This protocol is provided for those investigators who seek to test a large number of samples or to modify the basic protocol (for example, by increasing or decreasing the amount of Matrigel coated on to accommodate cells with high or low invasive activity, respectively).

MEASURING INVASION THROUGH A MATRIX

BASIC PROTOCOL

This protocol describes a method for assessing tumor cell invasion through a basement membrane matrix in vitro. Tumor cells are placed in the upper well of a Boyden migration chamber, which is separated from the lower well by a porous filter coated with basement membrane matrix (Matrigel). A chemoattractant is placed in the lower well to facilitate cell migration. After a short incubation, invasive cells are counted or recovered from the lower surface of the filter.

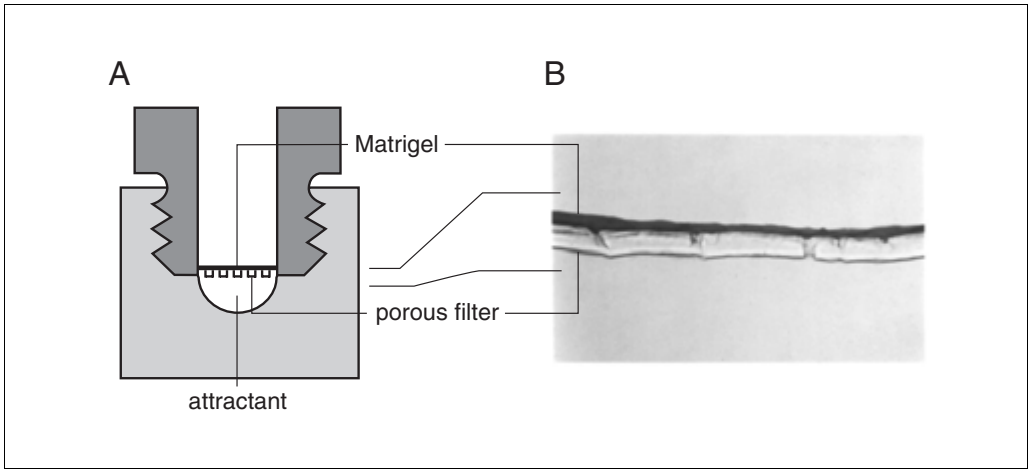

Figure 12.2.1 Configuration of chamber used for invasion assay. (**A**) Schematic representation of the Boyden chamber assembly. (**B**) Photomicrograph of matrix barrier cross-section, consisting of a porous polycarbonate filter coated with Matrigel. Reproduced with permission from the American Association for Cancer Research (Albini et al., 1987).

Materials

3T3-conditioned medium (see recipe) or selected chemoattractant or inhibitor
Tumor cells in culture
0.5 M EDTA, pH 8.0 (*APPENDIX 2A*)
Culture medium containing 0.1% (w/v) BSA (varies by cell type)
Diff-Quik fixative and stains (Baxter)

Boyden chambers (Neuro Probe; available as single or 48-well chambers)
Polyvinylpyrrolidone (PVP)-free polycarbonate membranes, 8- or 12-μm pore size (e.g., Nucleopore filters, Neuro Probe), sized to fit Boyden chambers (13-mm for single chambers and 25 × 80–mm for 48-well chambers) coated with Matrigel (see Support Protocol)

1. Add 3T3-conditioned medium or other chemoattractant to be tested to lower wells of Boyden chambers until a small meniscus appears.

   Each assay data point is generally based on triplicate filters/wells. Always include three negative control wells that lack the migration factor in the lower well. If using 48-well chambers, each filter should include three positive- and three negative-control wells (i.e., medium alone). Generally nano- or microgram amounts of chemoattractants are used. It is best to test several different concentrations.

2. Place a Matrigel-coated filter over the lower well of each Boyden chamber and secure the filter with a gasket.

   For 48-well chambers, start putting the filter down from the middle of the chamber to the edges to avoid bubbles. Never move the filter after it has been placed or there will be a possibility of cross-contamination of the wells. Do not screw the gasket too tight.

3. Release tumor cells from their culture vessel by first removing the culture medium and then adding enough 0.5 M EDTA to fully cover the cell layer in the culture dish. Centrifuge the cell suspension 5 min at 170 × *g* in a tabletop centrifuge, room temperature. Decant the supernatant and resuspend the pellet in serum-free medium at 5×10^5 cells/ml (1×10^6 cells/ml for 48-well chambers).

   The cells should not be confluent. Best results are obtained when the cells are split 24 hr before the assay and always seeded at the same density. It is very important to use EDTA rather than trypsin to release the cells from the plate, as trypsin will degrade the Matrigel.

4. Add cells to the upper wells of the chambers.

   Generally 100,000 to 200,000 cells per 0.3-ml well are placed in the upper chamber. When using the smaller 48-well chambers, 50,000 cells per 0.05-ml well are placed in each upper chamber well.

5. Incubate 3 to 6 hr in a humidified 5% CO_2, 37°C incubator.

   The time of incubation is dependent on the tumor cells used; 3 to 6 hr is the most frequently used range of incubation times. The optimal time can be determined in an initial test assay with and without attractant in the lower well, looking for the greatest difference between the two conditions. Usually <2% of the added cells migrate in the presence of the attractant.

   NOTE: *All culture incubations should be performed in a humidified 37°C, 5% CO_2 incubator unless otherwise specified. Some media (e.g., DMEM) may require altered levels of CO_2 to maintain pH 7.4.*

6. Stop the incubation by removing and fixing the filters using the Diff-Quik system. Remove the filters, dip in fixative for 10 sec, and place in solutions I and II for 2 min each. Wash in water for a few seconds.

   Small weigh boats or Coplin jars may be used for these steps and the solutions can be reused. The cells will appear dark blue with a pale blue to white background.

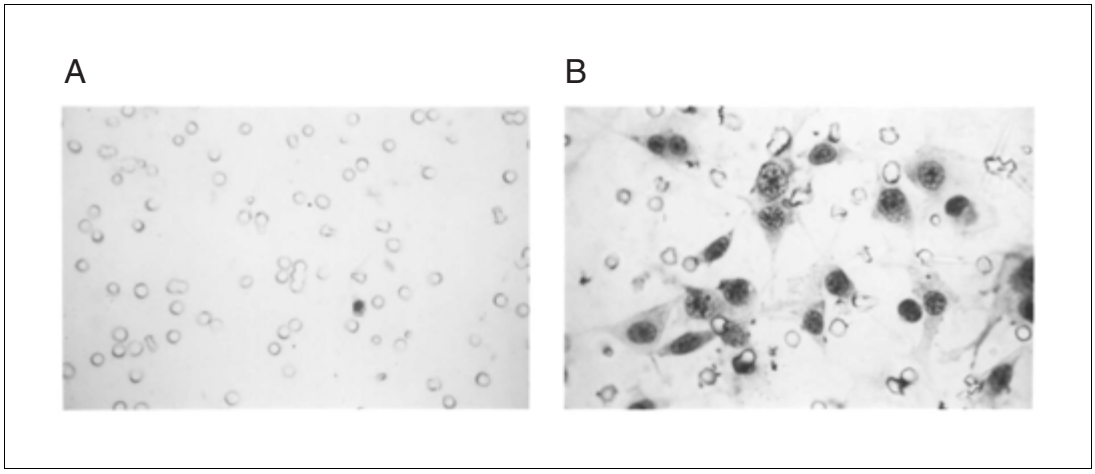

Figure 12.2.2 Photomicrographs showing results of an invasion assay: filter underside (attractant side) after incubation with (**A**) noninvasive and (**B**) invasive cells. Reproduced with permission from the American Association for Cancer Research (Albini et al., 1987).

7. Wipe cells from the upper surface with a cotton-tipped swab and mount filter on a slide with the lower side down.

   This step removes the cells that have attached to the upper surface of the filter and makes counting easier. The migrated cells will be on the underside of the filter facing the glass slide.

8. Count the cells.

   This can be done with a computer system or by eye (see Fig. 12.2.2). Be sure to survey the entire filter, as the distribution of migrated cells may be uneven. Count the most representative areas. Counting with a 10× magnification using a grid has proven to be reliable and reproducible.

PREPARATION OF MATRIGEL-COATED FILTERS

SUPPORT PROTOCOL

Coating the filter with Matrigel provides a surface similar to that encountered by cells migrating in vivo.

Materials

PVP-free polycarbonate membranes, 8- or 12-µm pore size (e.g., Nucleopore filters, Neuro Probe), sized to fit Boyden chambers (13-mm for single chambers; 25 × 80–mm for 48-well chambers)

Matrigel (*UNIT 10.2*; Matrigel can also be obtained commercially from Becton Dickinson Labware or Sigma)

1. Number the filters on the dull side with a permanent ink pen.

2a. *If using single chambers:* Dilute Matrigel to 1 µg/µl and pipet 25 µl as a center spot on the dull side of the 13-mm-diameter filter. Air dry overnight.

2b. *If using 48-well chambers:* Dilute Matrigel to 0.5 µg/µl in cold water. Place the filter shiny side down and cover the top with 1 ml of the diluted Matrigel. Incubate 15 to 20 min, then hang the filter to air dry for 5 to 10 min (a pin or needle stuck in one corner through the filter and into a board is convenient for drying). Cut the corner so that the orientation of the filter can be determined at the end of the assay.

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

3T3-conditioned medium

Grow 3T3 cells to confluence and replace medium with serum-free medium containing freshly prepared 50 μg/ml ascorbic acid. DMEM or RPMI 1640 can be used, but it is generally best to use the medium in which the invasive cells to be tested are normally cultured. Collect the conditioned medium after 24 hr and store in 1-ml aliquots at −20°C for up to 2 years.

COMMENTARY

Background Information

To metastasize, tumor cells invade through vessel basement membrane and the underlying connective tissue by attaching to, degrading, and migrating across the basement membrane matrix (Liotta, 1989). The in vitro assay described in this unit is performed to determine the invasive character of tumor cells, to test for factors that promote or inhibit invasion, and to select for malignant subpopulations, which are invasive (Kramer et al., 1986; Albini et al., 1987). The assay is rapid, quantitative, and proven to be highly reliable in a number of research laboratories.

Matrigel is a better barrier than amnion or other natural substrates, because it shows high reproducibility in its activity, and the assay time is much shorter (Hendrix et al., 1989). Many known inhibitors of tumor metastases, such as protease inhibitors, block invasion in this assay (Reich et al., 1988; Stahl and Meuller, 1994; Kobayashi et al., 1995). Likewise certain growth factors, such as basic fibroblast growth factor (bFGF), epidermal growth factor (EGF), transforming growth factor α (TGFα), hepatocyte growth factor (HGF), and thyroid-stimulating hormone (TSH), have all been found to promote invasion (Nicolson et al., 1993; Hoelting et al., 1994; Rong et al., 1994; Sunitha et al., 1994; Chambers et al., 1995). Having an assay that is quick, reliable, and accurate can facilitate diagnosis and aid in the development of therapeutics. The assay can be used as a prescreen for a large number of test compounds.

Critical Parameters and Troubleshooting

The exact time of incubation varies depending on the cells used and the amount of coated Matrigel. Trials using different incubation time in the presence and absence of a chemoattractant such as 3T3-conditioned medium should be performed initially to determine the optimum time of incubation. The optimum is the time at which there is the largest difference in the number of infiltrating cells between the control and positive attractant. In some cases, it may also be desirable to vary the number of cells added. For example, if the cells are highly invasive and too numerous to count, fewer cells can be used. In addition, because of the assay's sensitivity, if possible stimulators or inhibitors are being assessed, several different concentrations of the test substance should be tested.

Choosing an appropriate attractant is important. Many studies employ conditioned medium from 3T3 cells, which is collected for 24 hr with serum-free medium containing 50 μg/ml ascorbic acid. The conditioned medium is generally used directly without preconcentration. With cells that have not been previously tested, it may be desirable to test a range of concentrations. Several other chemoattractants have also been identified and include various growth factors, such as EGF (Hoelting et al., 1995), bFGF (Hasegawa et al., 1994), and HGF (Rong et al., 1994). Tissue extracts have been found to act as chemoattractants with some cell types (Hujanen and Terranova, 1985), and laminin as well as other matrix molecules can also promote invasion when placed in the lower well of the chamber (Koochepour et al., 1995). To determine the best chemoattractant, it is advisable to test 3T3-conditioned medium first and then various growth factors and matrix molecules if needed. Cells generally respond by migrating toward growth factors for which they have receptors. The attractant needs to be in the lower well of the chamber and should be present during the entire assay. It may be necessary to test various concentrations as cells usually migrate to factors at concentrations approximately one-tenth of that needed for growth, and many chemoattractants are inhibitory for migration when used at high concen-

trations. Preincubation with the chemoattractant is not required.

It is important to include controls in each assay. Generally the negative control is medium alone (lacking attractant), whereas the positive control is either 3T3-conditioned medium or a medium containing a substance already identified as a chemoattractant for the cells being tested. The assay should be performed in triplicate for the best results.

Anticipated Results

Results are assessed quantitatively by comparing the cell counts for experimental and control wells or plates: for example, when testing an attractant, very few cells invade in its absence, whereas more cells (usually at least twice background) should be observed in its presence.

Time Considerations

The assay should be completed in 1 day. Filters can be coated the night before the assay. Once fixed, the filters are stable for months and can be easily stored in slide boxes.

Cell Traction

Traction forces are exerted by cells against their substrates during migration and can be measured under the entire cell or under subcellular regions. This unit describes several protocols for making silicone sheets to measure traction forces under the entire cell, as well as a protocol for developing a micromachined device to measure forces under subcellular regions.

The original technique used to measure tractions, which examined the orientation of wrinkles generated in the substrate by locomoting cells, is described first (see Basic Protocol 1). The technique is useful for providing a global orientation of the forces under cells such as fibroblasts, which typically exert large traction forces (10 nN/μm of leading cell edge; Harris et al., 1980). Calibrated microneedles (see Support Protocol 1) are used to calibrate all of the substratum (see Basic Protocols 1 and 2 and Support Protocols 1 and 2).

Also described (see Alternate Protocol 1) is a modification of the original protocol that provides increased optical resolution as well as a simple method for quantitatively decreasing the stiffness of the substrate. This second substratum can be made with stiffnesses ranging from 0.26 to 50 nN/μm (Burton and Taylor, 1997).

Another modification is described in Alternate Protocol 2. This method measures forces with enhanced spatial resolution by determining the displacement of fiduciary markers embedded within the substrate. This protocol can also produce substrates of varying stiffness, ranging from 5 to 20 nN/μm (Lee et al., 1994; Oliver et al., 1995); however, the time constant for the beads to recover to their original position increases from ~1 to 15 sec (Lee et al., 1994; Oliver et al., 1995) between these two levels of stiffness. A modified airbrush apparatus (see Support Protocol 2) is used to coat the substrate with the fiduciary markers (Oliver et al., 1995).

Finally, a new technique is described for measuring subcellular traction forces using a micromachined substrate (see Basic Protocol 2). This substrate is based on a system of deformable levers that have stiffnesses ranging from 0.09 to 89 nN/μm. It can measure forces under regions of the cell as small as 4 μm^2 in real time, but cannot measure forces under multiple regions of the cell simultaneously (Galbraith and Sheetz, 1997). A procedure for creating silanized coverslips is presented in Support Protocol 3. The assay requires polarized reflection microscopy for visualization (see Support Protocol 4).

The protocols are presented in order of increasing cost and complexity. All three of the silicone-substrate protocols can be implemented in a reasonable amount of time, are not particularly expensive, and can measure forces under the entire cell. The protocol using micromachined substrates is more costly, but it has the advantage of measuring forces under subcellular regions. The appropriate protocol should be selected according to the magnitude of the forces that a particular cell exerts, the time constant of the events to be measured, and the resources available for development of the substrate.

MEASURING CELL TRACTION ON WRINKLING SUBSTRATES

BASIC PROTOCOL 1

This protocol outlines the construction and calibration of wrinkling silicone sheets and the use of these sheets in measuring cell traction. The fabrication of the sheets follows the procedure developed by Harris et al. (1980), and the calibration follows the procedure developed by Burton and Taylor (1997). Sheets that monitor forces by observing the displacement of fiduciary markers are discussed in Alternate Protocol 2. For a given

Contributed by Catherine G. Galbraith and Michael P. Sheetz
Current Protocols in Cell Biology (1998) 12.3.1-12.3.16

experiment, sheets should be chosen so that their stiffness matches the forces expected to be be generated by the cell type of interest (see Table 12.3.1).

Materials

Cells of interest
Culture medium specific for cells being used, phenol red–free and supplemented with 20 to 50 mM HEPES
Dimethylpolysiloxane (60,000 or 30,000 centistokes; Sigma)
Phenol red–free culture medium degassed using house vacuum

Temperature-control system for microscope stage (or hair dryer and controller)
Glass coverslips, acid washed
Petri dishes slightly larger than the coverslips used
Inverted microscope with long-working distance-objective *or* upright microscope with a multi-immersion-medium objective, equipped with video system
Micromanipulator (adjustable in three dimensions; e.g., Nanishige) with needle holder (World Precision Instruments)
Calibrated microneedles (see Support Protocol 1)
Computer with a video-frame capture card and image-analysis software (optional; e.g., NIH Image, available by anonymous FTP from *zippy.nimh.nih.gov*)
Macintosh computer with Scion frame grabber running

Additional reagents and equipment for trypsinization of cells (*UNIT 1.1*)

Construct the wrinkling substrate

1. Spread a thin layer, 20 to 50 μm deep, of dimethylpolysiloxane fluid over the surface of a clean glass coverslip.

Table 12.3.1 Traction Forces Exerted by Various Cell Types

Traction assay	Cell type and method	Force	Reference
Microneedle (Basic Protocol 1)	Chick heart fibroblast, force exerted against particle attached to dorsal surface	50 pN/μm^2	Felder and Elson, 1990
	Chick sensory neuron growth cone, force pulling neurite during growth cone advance	2 nN	Lamoureux et al., 1989
	Chick heart fibroblast, force required to stall cell per micron of cell leading edge	10 nN/μm	Harris et al., 1980
	Fish keratocyte, force required to stall cell	60 nN	Oliver et al., 1995
Silicone substrates with fiduciary markers (Alternate Protocol 2)	Fish keratocyte, forces from local markers under cell pincer region	~45 nN	Dembo et al., 1996; Lee et al., 1994; Oliver et al., 1995
Wrinkling silicone substrates (Alternate Protocol 1)	3T3 fibroblast, forces at cleavage furrow during division	~75 nN	Burton and Taylor, 1997
	3T3 fibroblast, force of respreading after division	300-1200 nN	Burton and Taylor, 1997
Micromachined substrates (Basic Protocol 2)	Chick embryo fibroblast, forces under subcellular regions	0.9-4.0 nN/μm^2	Galbraith and Sheetz, 1997

2. Set the gas on a Bunsen burner to its minimal level. Invert the coverslip and use forceps to pass it over the upper part of the flame for ~1.5 sec.

This method typically cross-links only the topmost layer (1 μm) of fluid. The silicone sheet will spontaneously wrinkle into many folds, making it opaque, but the sheets become transparent again within 5 to 20 sec as they cool. If the sheets are exposed to the flame for too long, permanently roughened surfaces which are less flexible will be made. These sheets contain an appreciable number of "prestress" wrinkles that will not diminish with time.

Prepare cells for traction assays

3. Set up a temperature-controlled environment for the cells on the stage of the microscope that will be used for making the measurements (if they are normally not cultured at room temperature).

This usually takes the form of a 37°C incubator that surrounds the microscope stage. Incubators can be purchased from most microscope manufacturers; alternatively, inexpensive incubators can be constructed by building a plastic enclosure around the microscope and then heating it with a hair dryer. The temperature can be regulated manually by adjusting a Variac rheostat connected to the hair dryer or by purchasing an independent controller. Controllers are available from a variety of sources (e.g., Fisher). It is important to pick a controller that is capable of supplying the current needed to run a hair dryer (a 1500-W hair dryer requires ~13 A).

4. Grow cells or isolate primary cultures in the phenol red–free formulation of the regular medium supplemented with 20 to 50 mM HEPES.

5. If cells can be passaged, remove cells from the culture vessel using a mild trypsin/EDTA treatment (*UNIT 1.1*), then inactivate the trypsin by adding an excess of degassed phenol red–free culture medium supplemented with HEPES. Resuspend cells in the same medium.

Cells to be used in traction assays should be removed from the culture vessel using as gentle a procedure as possible. The normal method of passaging any cell line or isolating any primary cell culture can be used.

The medium used to inactivate trypsin should contain serum or BSA.

Plate cells on substrate and measure wrinkling

6. Place the coverslip, fluid side up, into a petri dish just slightly larger than the coverslip. Flood the petri dish with degassed tissue culture medium to a depth of ≥0.5 cm. Incubate for 1 to 3 hr at normal culture temperature or until the cells resume their normal shape and migration speed.

Plate the cells onto the traction-assay substratum at densities that do not allow cells to contact each other but provide a sufficient number of cells on the surface for measurement. This number must be determined empirically for all of the assays. The density of cells will depend upon the stiffness of the substrate, since the wrinkles (Basic Protocol 1 and Alternate Protocol 1) and bead displacements (Alternate Protocol 2) generated by cells on very compliant substratum can interfere with each other. The density of cells will also depend upon the density of the measuring devices (see Basic Protocol 2).

There are a number of difficulties wetting the membrane that are due to the hydrophobic nature of the silicone surface. If there is insufficient medium in the petri dish, then the coverslip will float to the surface and the silicone sheet will "unwet," killing the cells and possibly rupturing the surface. A rapid wetting from one end of the dish to the other usually works well, but expect to rupture a number of membranes while practicing.

Normal migration speed typically refers to the migration speed on glass coverslips that are coated with the same extracellular matrix (ECM) as the traction assay substrate.

7. Place cells on the temperature-controlled microscope stage and record the length of the wrinkles produced by the cells. Record a calibration scale for the video field and use this field to measure the length of the wrinkles either directly or with a computer equipped with a frame grabber and image-analysis software.

Calibrate the substrate

8. Mount the substrate in a petri dish containing cell culture medium on the stage of a microscope equipped with a video system. Position a micromanipulator equipped with a needle holder so that the tip of the needle can reach the center of the optical field.

   Do not coat the membrane with cells if you are going to calibrate the membrane. Note that it is difficult to do the calibration under sterile conditions, so several duplicate membranes that will never be plated with cells should be calibrated instead of the actual "experimental" membrane.

   The calibration technique described in Alternate Protocol 2 for nonwrinkling substrates is more accurate, but it requires that the substrate be larger (>10-fold) than the diameter of the needle and that the substrate be approximately parallel to the coverslip. However, the substrate is often concave with respect to the coverslip in this assay.

9. Mount a calibrated microneedle in the micromanipulator and use it to push laterally on the surface of the sheet until it produces wrinkles that are shorter and longer than those produced by cells.

   An alternative method (Burton and Taylor, 1997) is to plate cells on the sheet and then fix the cells and sheets in 1% glutaraldehyde for 10 min. The fixed cells now act as "handles" that can be pushed by the microneedles.

10. Determine the displacement of the tip of the needle that is needed to produce each wrinkle length from a video recording of the calibration experiment. Record a calibration scale for the video field, and then use this field to calculate the displacement of the needle tip from its position before and after producing the wrinkle as described in step 7.

11. For each wrinkle length, calculate the force needed to generate the wrinkle as the product of the needle stiffness (see Support Protocol 1) and the needle deflection. This produces a curve of force versus wrinkle length.

Calculate traction force

12. Use the force versus wrinkle length curve generated in step 11 to calculate the force needed to produce the wrinkles measured in step 7.

SUPPORT PROTOCOL 1

CALIBRATING MICRONEEDLES

Calibrated microneedles can be used to measure the force of a locomoting cell by determining the amount of force required to stall the forward movement. The microneedles are also a necessary tool for measuring the stiffness of any of the devices whose construction is described in this unit.

Materials

25-µm-diameter Chromel thermocouple wire (Omega Engineering)
Pipet puller (David Kopf Instruments)
Pyrex capillary glass of various diameters and wall thicknesses (Drummond Scientific)

Small microscope mounted with its optical axis parallel to the bench
Eyepiece reticule (i.e., a calibration scale that fits into the eyepiece of the microscope; Edmund Scientific)

1. Cut a long (~30-cm) piece of 25-μm-diameter Chromel wire, weigh it, and carefully determine the length. Use the mass/length ratio to determine the mass of smaller pieces of Chromel wire that will be used in step 3.

2. Pull glass needles using a pipet puller.

   As a guide, 0.86-mm-o.d., 0.51-mm-i.d. Pyrex glass pulled on a vertical puller (David Kopf Instruments) at heat 27 and pull 10 should produce a microneedle in a useful starting range. Make sure that the diameter of the needle is less than the width of the wrinkles and that it can fit within the micromachined substrate (Basic Protocol 2).

3. Calibrate the needle by mounting it on the stage of the horizontal microscope (microscope turned onto its back so that its optical axis is parallel to the bench) and hanging a series of different-mass pieces of Chromel wire off the end of the needles. Measure the deflection of the tip by each mass using the eyepiece reticule. Pieces of wire ranging from 0.02 to 1.0 mg should provide a useful starting range.

   It is important to place the weights consistently on the very tip of the needle so that the deflection is consistent throughout the calibration.

   If needles that are too flexible to be calibrated by hanging weights are desired, then calibrate the needles by measuring the relative stiffness of the more flexible needles against stiffer needles that are calibrated as described above (Nicklas, 1983).

   As an alternative to the stiffer calibrated reference needles, 8- and 16-mm lengths of the Chromel wire can be used to make the "reference needles" (Dennerll et al., 1988). These lengths of wire can be glued into the center of capillary glass and tested with the same techniques as the needles. This should yield a stiffness (see Basic Protocol 2 for mathematical definition) of 2.43×10^{-2} N/m for the 8-mm length of wire. Note that the moment of inertia (I) for a circular beam is $1/4\pi r^4$.

4. Calculate the slope of the curve for force (mass of wire in g × 980 cm/sec^2) versus tip deflection to obtain the stiffness of the needle.

MEASURING CELL TRACTION ON WRINKLING SUBSTRATES WITH AN ALTERNATIVE POLYMER

ALTERNATE PROTOCOL 1

Deformable substrates can be formed with an alternative silicone polymer that has been described by Burton and Taylor (1997). Substrates formed with this polymer (phenylmethylpolysiloxane) have several advantages over those formed with the polymer described in Basic Protocol 1 (dimethylpolysiloxane)—i.e., they are suitable for differential interference microscopy and their stiffnesses can be decreased by exposure to ultraviolet light. This polymer can be cross-linked with the Bunsen burner technique described in Basic Protocol 1, the sputter-coater technique described in Alternate Protocol 2, or the tungsten-wire technique described by Burton and Taylor (1997). An example showing fibroblasts wrinkling a sheet that was made with this polymer cross-linked in a sputter coater is shown in Figure 12.3.1.

Additional Materials *(also see Basic Protocol 1 or Alternate Protocol 2)*

Phenylmethylpolysiloxane, trimethyl terminated (Dow Corning 710 fluid)
Ultraviolet lamp (UVGL-58 from UVP)

1. Prepare coated coverslips, replacing the dimethylpolysiloxane with trimethyl-terminated phenylmethylpolysiloxane. Perform the measurements in Basic Protocol 1 or Alternate Protocol 2.

   The advantage of this silicone is that it has a high index of refraction (1.536), which is suitable for polarized (differential interference) and interference reflection microscopy. Additionally, the silicone absorbs ultraviolet light (peak absorbance λ = 254 nm),which

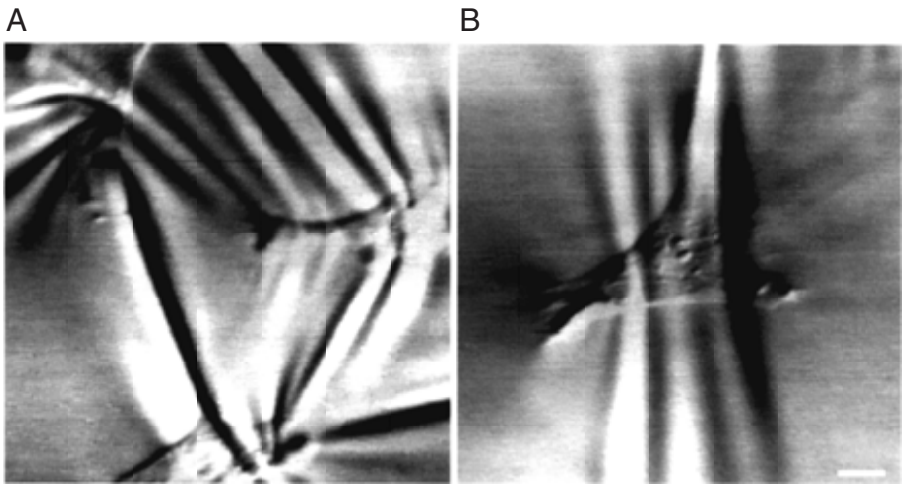

Figure 12.3.1 Chick embryo fibroblasts plated on a membrane made from phenylmethylpolysiloxane (J.A. Galbraith, unpub. observ.). The membrane was cross-linked in a sputter coater according to Alternate Protocol 2. Cells were plated in phenol red–free DMEM that was supplemented with 10% fetal bovine serum and antibiotics. Substrates were visualized with differential interference microscopy on a Zeiss inverted microscope using a 40 × 0.75–NA long-working-distance objective. (**A**) A group of three fibroblasts generates wrinkles that are perpendicular to their long axis. (**B**) A single fibroblast that is moving from left to right also generates wrinkles perpendicular to its long axis and the direction of migration. Bar is 10 μm.

weakens the sheet, making it more distensible. The disadvantage of this polymer is that it is considerably more expensive than dimethylpolysiloxane.

2. If calibration experiments indicate that the sheets are too stiff, make the sheets more distensible by exposing them to ultraviolet irradiation (6 W at 15 to 20 mm above the sheet, λ = 254 nm, 300 μWcm^2 at 15 cm for the surface) using a UVGL-58 lamp. Repeat the measurements.

   The curve for stiffness versus time of irradiation needs to be determined for each method of curing the silicone fluid. The curve given by Burton and Taylor (1997) for creating a sheet of any stiffness should be used as a starting point, but the actual time of exposure may depend upon the method of cross-linking.

ALTERNATE PROTOCOL 2

MEASURING CELL TRACTION ON NONWRINKLING SUBSTRATES

This protocol describes the use of nonwrinkling silicone sheets containing 1-μm diameter beads that act as fiduciary markers for measuring displacements and calculating force (Lee et al., 1994; Oliver et al., 1995).

Additional Materials *(also see Basic Protocol 1)*

Vacuum grease or Valap (*UNIT 13.1*)
Dimethylpolysiloxane (12,500 centipoise; Sigma)
1-μm liquid bead suspension (Polysciences)
Phenol red–free formulation of culture medium
Culture medium degassed using house vacuum

22 × 8–mm Pyrex cylinders (Bellco Glass)
Glass coverslips, acid washed
Airbrush apparatus (see Support Protocol 2)
Vacuum source
Sputter coater (e.g., Electron Microscopy Sciences)

Construct nonwrinkling substrate

1. Make Rappaport chambers by sealing the Pyrex cylinders to acid-washed coverslips with vacuum grease or Valap.
2. Pour 60 mg dimethylpolysiloxane into each chamber and allow it to spread evenly.
3. Disperse 1-μm beads on the surface of the dimethylpolysiloxane at a density of ~3×10^4 beads/mm^2, using a modified airbrush apparatus as described in Support Protocol 2.

   Although this can be done with a bristle brush using freeze-dried beads, a modified airbrush apparatus (see Support Protocol 2) using a liquid suspension of beads produces fewer aggregates.

4. Allow air bubbles from the dimethylpolysiloxane to escape or outgas under vacuum.
5. Cross-link the top layer of gel using a sputter coater at a vacuum of 0.15 torr and a target height of 60 mm. Apply the voltage to maintain a constant current of ~2 mA for 2 sec.

   The time, vacuum, and target height may need to be adjusted between different sputter coater models.

6. Add degassed culture medium to each cross-linked chamber (see Basic Protocol 1, step 6).

   Degassing the medium prevents the nucleation of small air bubbles on the silicone surface which can pull and distort the membrane. The presence of serum seems to stabilize the surface (Oliver et al., 1995).

Calibrate the substrate

7. Place the chamber on the microscope stage. Mount two calibrated microneedles of the same stiffness in the micromanipulators and position them toward the center of the sheet.

   A more accurate method of calibrating silicone sheets was introduced by Dembo et al. (1996). This method is similar to the one described in Basic Protocol 1, except that two identical calibrated needles and two manipulators are needed. The revised technique has the advantages of eliminating boundary effects due to the size of the Rappaport chamber and of satisfying global force balance during the calibration. See Oliver et al. (1998) for a more complete discussion.

8. Simultaneously move the needles toward each other, pinching the sheet between them.
9. Determine the stiffness of the sheet (force versus bead displacement curve) from the bending of the needles (see Oliver et al., 1998).

Measure cell traction

10. Add a suspension of cells to another cross-linked chamber, incubate for 1 to 3 hr, and measure the displacement of the beads (see Basic Protocol 1, steps 6 and 7).
11. Use the stiffness of the sheet determined in step 9 and the displacement of the beads by the cells determined in step 10 to calculate the force exerted by the cells.

SUPPORT PROTOCOL 2

PREPARING A MODIFIED AIRBRUSH APPARATUS

The airbrush is used to evenly disperse beads on the surface of polymer-coated coverslips (see Alternate Protocol 2). This device is illustrated in Oliver et al. (1995) and Figure 12.3.2. The details of this protocol were kindly supplied by Tim Oliver.

Materials

Nebulizer (DeVilbiss model 646)
Drying reservoir (16-liter container; Nalgene)
T-connector
Connecting tubing
Glass transfer pipet with tip drawn to 1-mm-i.d. opening
Impactors (37-mm Air Sampling Cassettes; model 4339, Gelman)

Assemble the apparatus

1. Connect one end of the nebulizer to a supply of filtered air.
2. Connect the other end of the nebulizer to the drying reservoir (16-liter Nalgene container).

   This is the input side of the drying reservoir.

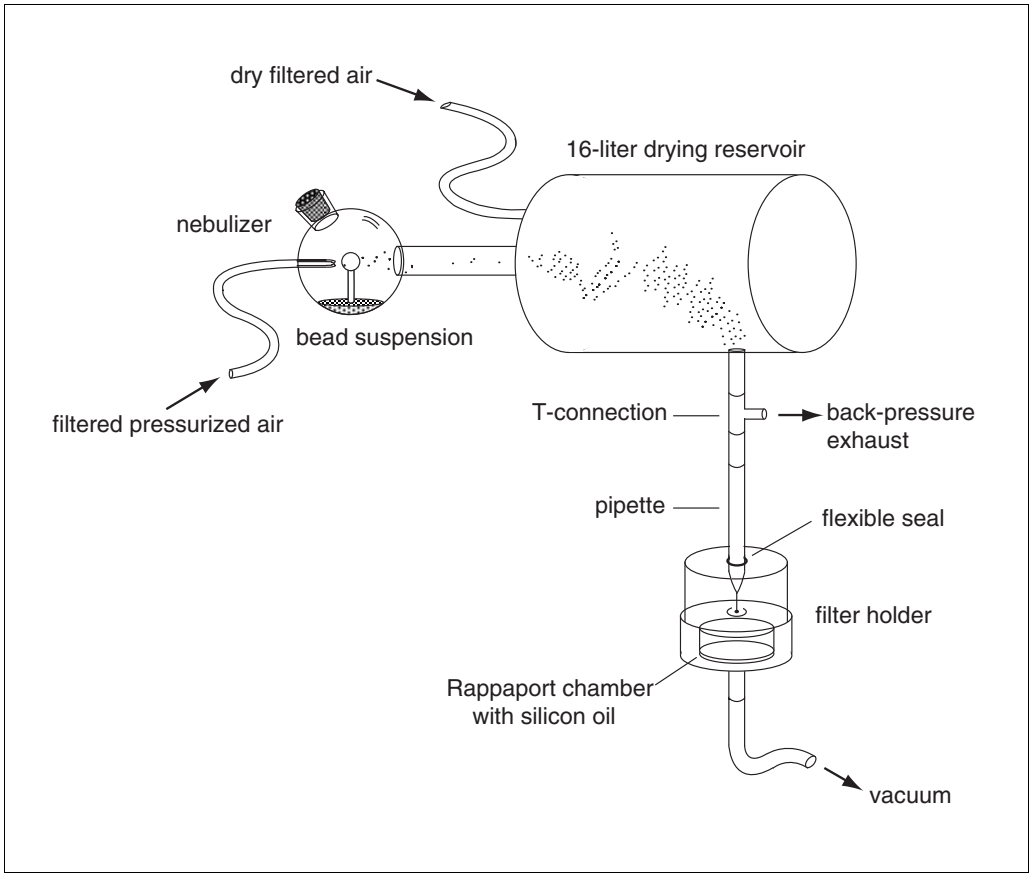

Figure 12.3.2 Illustration of a modified airbrush apparatus based on that of Oliver et al. (1995). This device separates a solution of beads into single dried particles. One end of the nebulizer is connected to a supply of filtered air. The other end of the nebulizer is connected to the input side of the drying reservoir. Another, independent filtered air supply is also connected to the input side of the reservoir. The output side of the reservoir is connected to a pipet with a 1-mm-i.d. tip. The pipet tip enters a modified impactor that contains the Rappaport chamber filled with silicone oil. The tip can be moved around to disperse the beads.

3. Supply the input side of the reservoir with dry filtered air, independent of the supply of air to the nebulizer.

   A pressure of 5 psi is recommended, but the air flow should be adjusted so that beads remain in the reservoir for several seconds.

4. Attach a T-connector to the output side of the reservoir.

   The perpendicular end of the T will be used as an exhaust.

5. Use a piece of tubing to connect the other end of the T to the drawn glass pipet.

6. Create an impactor thick enough to accommodate the Rappaport chambers by stacking the middle inserts of several cassettes between the top and bottom of one of them. Place a Rappaport chamber containing degassed silicone inside this thicker impactor.

7. Place the drawn pipet into the top of the impactor, and connect the two with a piece of flexible tubing.

8. Connect the bottom of the impactor to a vacuum.

Use airbrush apparatus to disperse beads (also see Alternate Protocol 2, step 3)

9. Add a suspension of the beads in ethanol to the nebulizer, then turn on the air and vacuum.

10. Move the pipet to disperse the beads over the top of the silicone.

    A recommended concentration is 3×10^4 beads/mm^2.

MEASURING CELL TRACTION ON MICROMACHINED SUBSTRATES

BASIC PROTOCOL 2

This protocol describes a method for developing micromachined substrates to measure traction forces under subcellular regions. An example of this is shown in Figure 12.3.3 (Galbraith and Sheetz, 1997). This device is based on a system of 5904 cantilevers of different lengths and therefore different stiffnesses. The levers are buried beneath the surface of the device, but on the free end of the lever there is a small pad that is planar with the surface of the device. The pads range in area from 4 to 25 μm^2 and are surrounded by a square hole that provides a 2-μm space on each side of the pad to allow the lever to move when a cell pulls on the pad. The forces that the cells exert on the pads can be determined by measuring the displacement of the pads and calculating the product of the pad displacement and the stiffness of the cantilevered lever. This approach is conceptually similar to the use of calibrated microneedles to measure forces.

Materials

50% (v/v) hydrofluoric acid
Appropriate extracellular matrix (ECM; e.g., 40 μg/ml laminin)
25% (w/v) $MgSO_4$
Phenol red–free culture medium

Nanofabrication facility
Computer-aided drawing (CAD) software package
Polarized reflection cube (see Support Protocol 3)
Fluorescence illumination for microscope
Red filter (645 nm long-pass)
Cloning cylinders
Silanized coverslips (see Support Protocol 3)
Sylgard 184 (Dow Corning)

1. Contact a nanofabrication facility that can perform the actual fabrication of the device.

   MCNC (Web site, http://www.mcnc.org; email, pr@mcnc.org) is one facility that can design and fabricate devices.

Design cantilever-beam force-measuring device

2. Estimate the traction forces that will be generated by the cells (see Oliver et al., 1994, and Table 12.3.1). Be certain to provide over- and underestimates of force in addition to the best guess.

3. Determine the maximum deflection allowable for beam displacement.

   A general guideline is several microns, but the actual number will depend upon the precision of the micromachining.

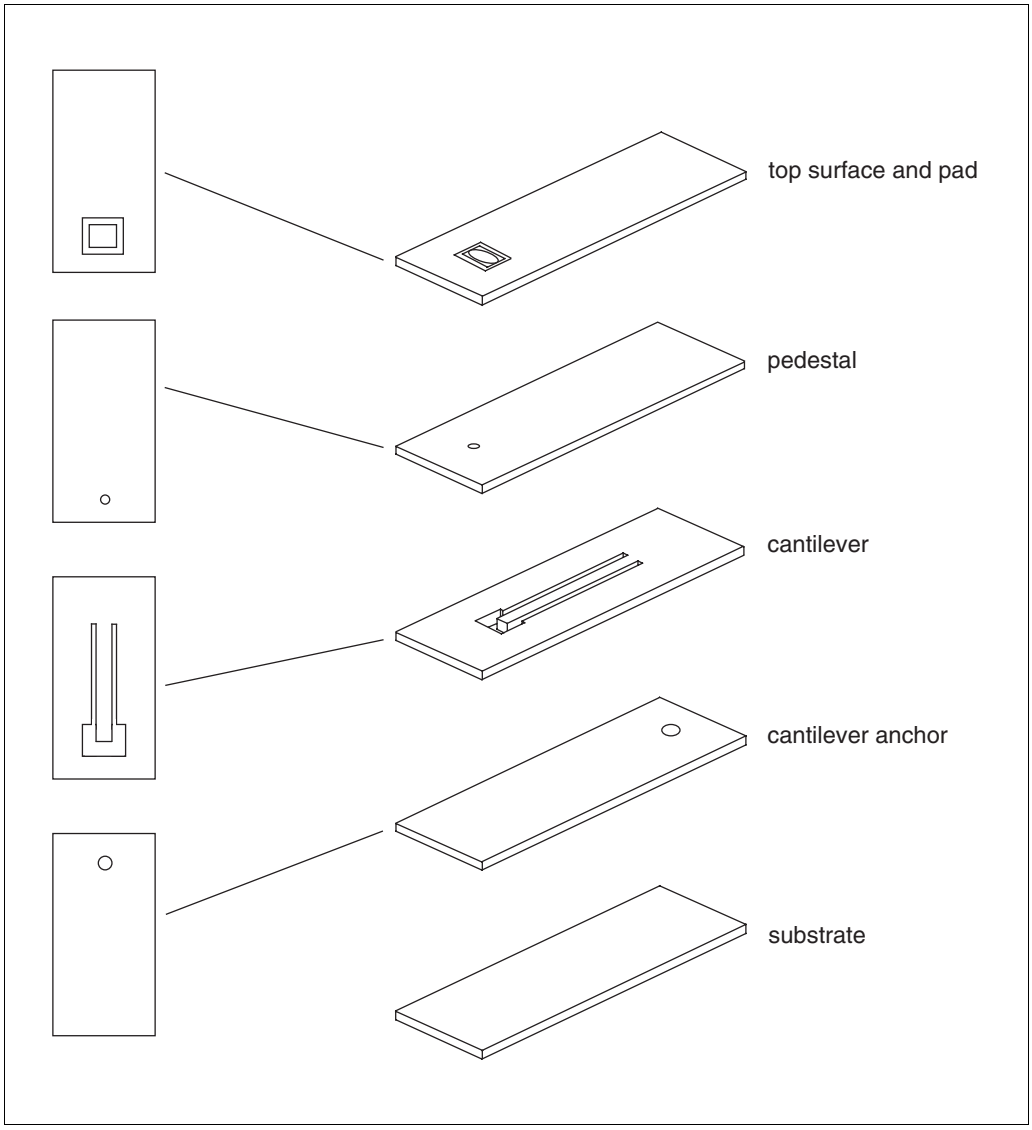

Figure 12.3.3 Masks and layers that are involved in making a single cantilever. A silicon wafer is used as substrate. Phosphosilicate glass (PSG) is placed on the silicon wafer, and a mask with holes is used to lithographically pattern the PSG to form anchors for the beams. Polycrystalline silicon is deposited over the PSG, and the mask with the beams and surrounding wells is used to pattern these structures. A layer of spin-on glass is added, and another mask is used to place a small hole at what will be the free end of the beam. The surface is then coated with a plasma-deposited amorphous silicon that fills the holes and forms a pedestal that anchors the pad to the beam. A final mask is used to etch the pad and square hole in the top layer.

4. Determine the appropriate beam stiffness by using the following equation:

$$\text{stiffness} = \frac{\text{traction force}}{\text{beam displacement}}$$

5. Calculate the appropriate geometric factors that will provide beams of this stiffness, using the following formulas, which give the relationship between the pertinent parameters for a square beam.

$$\text{stiffness} = \frac{3EI}{l}$$

$$I = \frac{h^4}{12}$$

In these equations, E is the Young's modulus of the silicone substrate, l is the length of the beam, I is the moment of inertia, and h is the height of the beam, which is equal to the width. Note that the height and width of the beam may be limited by constraints imposed by the fabrication facility. In the case of the authors' device, E is between 145 and 160 GPa, the width and height of the beams are 2 μm, and the lengths vary from 0.86 to 0.086 mm. These geometric parameters yield beams with stiffnesses ranging from 89 to 0.09 nN/μm. Additionally, very long beams may have "stiction" problems that will cause them to adhere to the walls of the channels in which they reside. The authors believe that they have encountered this with the longest beams used, which often appear immovable.

6. Determine the spacing and orientation of the measurement sensors (beams).

This will determine the layout for each unit, which will be repeated to make up the device or chip. Numerous chips can then be fabricated from one wafer of silicon. A typical layout has 9 repeating units, and ~40 chips are fabricated on one wafer.

Fabricate the device

7. Using a CAD package, generate mechanical drawings of each mask that is needed to create the layers of the repeating unit.

This step can be done by the fabrication facility. Micromachining is similar to a multiple-step photolithography: silicon layers are grown, exposed, and etched, and the process is repeated. For each layer a separate mask must be generated to create the appropriate pattern for etching. Figure 12.3.4 illustrates the types of masks and layers that are involved in making a single cantilever.

8. Use the CAD drawings to generate the actual masks that will be used for machining each layer.

9. Have the nanofabrication facility manufacture wafers containing numerous chips, then cut the wafer into individual pieces and perform the final etch (using 50% hydrofluoric acid, HF) that frees the assembly.

Initial releases that are performed by the facility can cause many of the pads to be dissociated from the ends of the beams. Titrate the time of exposure to HF to obtain free beams that still have pads on their ends.

CAUTION: *HF is an aggressive reagent requiring appropriate protective clothing and appropriate tools such as Teflon containers and forceps.*

Different reagents are needed to release other substrates.

Prepare the device for cells

10. Remove any residual HF from the chip to ensure the biocompatibility of the chip. After release, soak the chips in deionized water for 1 hr and then 25% $MgSO_4$ for 2 hr.

    This procedure seems to effectively sequester any free fluoride left trapped beneath the surface of the chip.

11. Prepare chambers for chips by attaching cloning cylinders to silanized coverslips with Sylgard gel.

    Follow manufacturer's instructions for curing. Note that large batches of the 2-part gel can be mixed and frozen in aliquots at −80°C until use.

12. Place the chips in chambers and coat the chip with an appropriate extracellular matrix (ECM) in the same way that you would coat a glass coverslip. However, take care

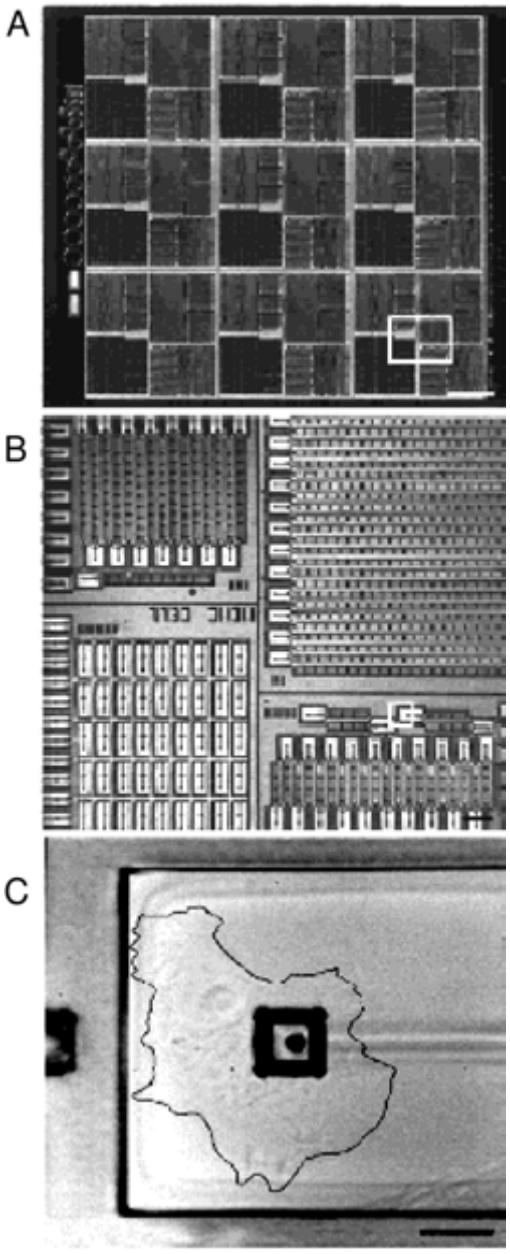

Figure 12.3.4 Micrographs of micromachined substrate. (**A**) Entire surface of a device that has nine repeats of a basic pattern containing four different lever lengths. Box indicates area shown in the next panel. Bar is 1 mm. (**B**) The four different lengths of beams. Box indicates area shown in the next panel. Bar is 0.1 mm. (**C**) A chick embryo fibroblast crossing a 25-μm^2 pad. Bar is 10 μm.

never to let the chip completely dry out, since changes in surface tension can remove the pads from the ends of the chips.

13. Plate cells on the chips by placing a suspension of cells in the cloning cylander chambers. Follow step 6 of Basic Protocol 1 to determine concentration and incubation time. View the chips by polarized reflection microscopy, using a polarized reflection cube (see Support Protocol 3) and a microscope with fluorescence illumination, a 645-nm long-pass filter, and temperature control if needed.

    Reflection microscopy must be used since the chips are opaque and do not transmit light. This viewing method produces high-contrast images of the chip, but low-contrast images of the cell.

14. Calibrate the movable pieces of the device with calibrated microneedles (see Basic Protocol 1, steps 8 to 11).

    For this procedure, a long working distance water-immersion objective on an upright microscope is convenient.

15. Compare the calibrated stiffness with the theoretical calculations.

SILANIZING COVERSLIPS

SUPPORT PROTOCOL 3

Silanized coverslips are used as a base for assays of cell traction using micromachined substrates (see Basic Protocol 2). This protocol describes a simple procedure for coating glass coverslips.

Materials

20% HNO_3
Acetone, reagent grade
1,1,1,3,3,3-Hexamethyldisilazane (HMDS; Aldrich)
70% ethanol

Glass coverslips and coverslip racks (Thomas Scientific)
Pyrex dish large enough to hold coverslip racks
Drying oven
Nitrogen gas cylinder with regulator
3-cc syringe with needle

1. Place coverslips on coverslip racks and soak in 20% HNO_3 for 1 hr.
2. Rinse coverslips in Milli-Q-purified water for 1 hr.
3. Soak in reagent-grade acetone for a few minutes. Pour off acetone and allow excess fluid to air dry.
4. Place coverslip racks in Pyrex dish and cover with aluminum foil. Bake 1 hr in 140°C oven.
5. Collect a plastic bag full of nitrogen gas. Puncture the bag with a needle attached to a 3-cc syringe. Withdraw 2.5 cc of nitrogen gas, insert the needle into the top of the HMDS container, and withdraw 2.5 cc HMDS.

    The gas is used to equalize the pressure in the container without oxidizing the HMDS.

6. Dispense HMDS into the Pyrex dish through the aluminum foil, coating the coverslips.
7. Bake 20 min at 140°C.

8. Evacuate the oven for 5 min, then lift foil cover off the Pyrex dish and continue to evacuate for a further 15 min.
9. Continue baking for 1 hr at 140°C.
10. Cool coverslips and store in 70% ethanol.
11. Drain excess ethanol and allow coverslips to air dry before use.

SUPPORT PROTOCOL 4

PREPARING A POLARIZED REFLECTION CUBE

Reflection microscopy must be used with micromachined substrates (see Basic Protocol 2), because the chips are opaque. While commercial polarization microscopes may be used, this method provides a convenient way to modify existing laboratory microscopes for use in this technique.

Materials

Fluorescence slider or cube (available from microscope manufacturers)
50-50 mirror (Chroma)
Polarizers (Chroma)

1. Place a 50-50 mirror in the position of the fluorescent slider or cube that normally holds the dichroic mirror.
2. Place polarizers where the excitation and emission filters normally reside, and orient the polarizers to be perpendicular each other.

Chroma will provide polarizers backed with glass in the appropriate sizes and mounts.

COMMENTARY

Background Information

Migrating cells exert traction forces against their substrates. These tractions result from the interactions between the force-generating cytoskeleton, the focal adhesion complex, and the extracellular matrix (ECM). The interaction of the intracellular forces results in a net forward movement of the cell. However, the majority of the force acts to break the adhesive contacts with the ECM, since traction forces are several orders of magnitude larger than the force required to move a cell swimming in solution. Traction forces measured on the ventral surface of the cell are also much larger (Galbraith and Sheetz, 1997) than forces generated on the dorsal surface (Felder and Elson, 1990), and this may be due to differences in the cytoskeletal organization between the ventral and dorsal surfaces (Cramer et al., 1997). Given this difference between tractions on the two surfaces, it has been important to develop techniques and technologies that can measure many of the subcellular events of cell migration on the dorsal surface of the cell.

Most of the techniques for measuring traction forces have been developed around sheets of cross-linked silicone polymer (see Basic Protocol 1). The original technique used to measure tractions examined the orientation of wrinkles generated in the sheets by locomoting cells. This technique has been useful for providing a global orientation of the forces under cells (Harris et al., 1980) and for comparing the relative forces of different cell types (Harris et al., 1981). These original experiments did not determine the magnitude of the forces generated underneath a cell, but they did establish the force required to stop a locomoting chicken heart fibroblast (~200 nN if the cell has a 20-μm-long leading edge). These sheets also demonstrated that cells that migrated at the highest velocities generated the smallest traction forces, since fast-moving cells such as leukocytes and nerve growth cones were unable to wrinkle the sheets (Harris et al., 1981).

This assay was modified to produce nonwrinkling substrates that measure traction forces by examining the displacement of beads embedded within the sheet (Lee et al., 1994; see Alternate Protocol 2). These sheets were able to determine the small traction forces generated under different regions of rapidly moving keratocytes. The forces measured by these sheets were limited in temporal resolution,

since the half time for recovery was ~0.5 sec for the stiffest membranes. However, the forces were easier to quantitate than those measured by wrinkles, and the bead displacements have been used to provide detailed information about the orientation and location of traction forces (Oliver et al., 1995; Dembo et al., 1996).

A more recent modification of the original traction assay used a different polymer to generate another wrinkling sheet whose stiffness can be easily modified by exposure to ultraviolet light (Burton and Taylor, 1997; see Alternate Protocol 1). These less stiff sheets can be wrinkled by cells undergoing cytokinesis (Burton and Taylor, 1997) and can measure forces as small as 10 to 20 nN. All three of these silicone substrates are useful for measuring forces under the entire cell.

Another technique for measuring traction forces is based on micromachining technology (Galbraith and Sheetz, 1997; see Basic Protocol 2). The device is constructed with a system of movable levers that have stiffnesses ranging from 0.09 to 89 nN/μm. This device can measure forces under regions of the cell as small as 4 μm^2 in real time, but it cannot measure forces under multiple regions of the cell simultaneously. Therefore, the protocols presented in this unit either provide detailed real-time subcellular information from a small number of adhesive contacts or extensive spatial information of slower events under the entire cell.

Critical Parameters

The time of cross-linking for the silicone sheets will critically affect their stiffness. It may be necessary to manufacture a number of sheets using an array of different conditions. This will provide a number of specimens, some of which will be suitable.

The other critical parameter in using the membranes is how they are wetted with the cell-containing medium. Rapid coating, starting from one side and moving to the other, produces the fewest membrane ruptures, but any coating method requires practice.

Troubleshooting

The traction forces generated by several different cell types have been reported in the literature. It is therefore important to compare the measurements obtained with values presented in the literature (Table 12.3.1; Oliver et al., 1994). If the measurements obtained are vastly different, recheck the calibration. Begin by recalibrating the 8-mm length of Chromel wire and comparing its stiffness with the value obtained by Dennerll et al. (1988). If this is accurate, then check the calibration of the needles. Finally, recalibrate the film or micromachined device.

Anticipated Results

Typical traction forces generated by various cell types are listed in Table 12.3.1.

Time Considerations

The time required to manufacture any of the sheets is not extensive, however finding the conditions under which the sheets are produced with suitable stiffness may require some experimentation. In contrast, the time required to manufacture the micromachined devices may be considerable. Depending upon the schedule of the microfabrication facility and the number of process iterations required, the time from concept inception to product can easily consume 6 months to 1 year.

Additionally, the time required to collect data will vary greatly, depending upon the migration speed of the cells of interest. It should also be noted that the time required to analyze the video data is severalfold greater than the amount of time required to collect the data.

Cell Wound Assays

It is often assumed that plasma membrane continuity is a constant feature of the life of the normal, healthy cell, and that when there is evidence of a disruption in continuity, one can conclude that cell death has occurred. Neither of these assumptions is correct. The plasma membrane, like other moving parts, is vulnerable to mechanically induced wear and tear. Many animal cells that reside in mechanically active tissue environments normally and frequently experience disruptions in plasma membrane integrity (McNeil, 1993; McNeil and Steinhardt, 1997; McNeil et al., 1981). Cells locomoting in culture periodically tear off small pieces of cytoplasm as their trailing end is drawn out into long retraction fibers that eventually break (Chen, 1981). Pathological levels of mechanical stress can, of course, exacerbate these constitutive levels of cell "wounding." An active and complex Ca^{2+}-regulated resealing mechanism rapidly repairs disruptions, preventing influx of potential toxins and loss of vital cytosolic constituents (Steinhardt et al., 1994). Indeed, many cells survive surprisingly large membrane disruptions. Skeletal muscle cells and certain free-living amoebae, for example, recover after being cut in half, and sea urchin eggs can be fertilized and undergo cleavage after a 20×40–μm^2 patch of plasma membrane and underlying cortex is ripped from their surface (Terasaki et al., 1997).

The study of cell wounding, whether it has biological or practical aims (see Commentary), requires methods for identifying wounded cells, often present as a small minority in a culture or tissue. This unit describes such methods, which can also yield quantitative data concerning the frequency and magnitude of wounding. Wounding can be detected microscopically in cultures of adherent cells and in tissues using fluoresceinated dextrans (see Basic Protocol and Alternate Protocol 1, respectively) or using an animal's endogenous serum albumin and enzyme immunohistochemistry (see Alternate Protocol 2). Electron microscopy of wounded cells or tissues (see Alternate Protocol 3) can be used to verify the cytoplasmic location of the tracer molecule. Wounding can be quantified by image analysis (see Support Protocol 1) or flow cytofluorometry (see Support Protocol 2).

STRATEGIC PLANNING

The wounded cell is identified by virtue of cytosolic labeling with a normally impermeant tracer macromolecule (Fig. 12.4.1). An open plasma membrane disruption allows the tracer to enter the cytosol, and resealing traps it there. Dead cells, which do not reseal, are not labeled as long as all exogenous tracer is washed away after the disruption. There are several wound tracers to choose from. Fluoresceinated dextrans are relatively inexpensive and are available in a range of sizes (mol. wt. 5,000 to 2,000,000). If aldehyde-fixed specimens will be employed, dextrans containing conjugated lysine residues must be used. The advantage of an exogenously added tracer, such as fluoresceinated dextran, is that its time of addition and removal are known, and thus it can be used in pulse-chase labeling protocols to determine the timing of wound events. Albumin is an excellent endogenous wound tracer. For whole-animal studies it has the prominent advantage of normally bathing the cells of many tissues at high concentration.

Detection of a wound tracer by microscopy provides useful structural detail. For example, one can identify wounded cells on a cell-by-cell basis in a background of nonwounded cells, and determine which cell types in a tissue are vulnerable and at what location. Microscopy also allows one to determine whether the labeling pattern is cytosolic, the pattern expected of a wound tracer. Endocytosed tracer is recognizable as a punctate staining of the cytoplasm only. In contrast, tracer entering through a disruption results in

Contributed by Paul L. McNeil, Mark F.S. Clarke, and Katsuya Miyake
Current Protocols in Cell Biology (1999) 12.4.1-12.4.15

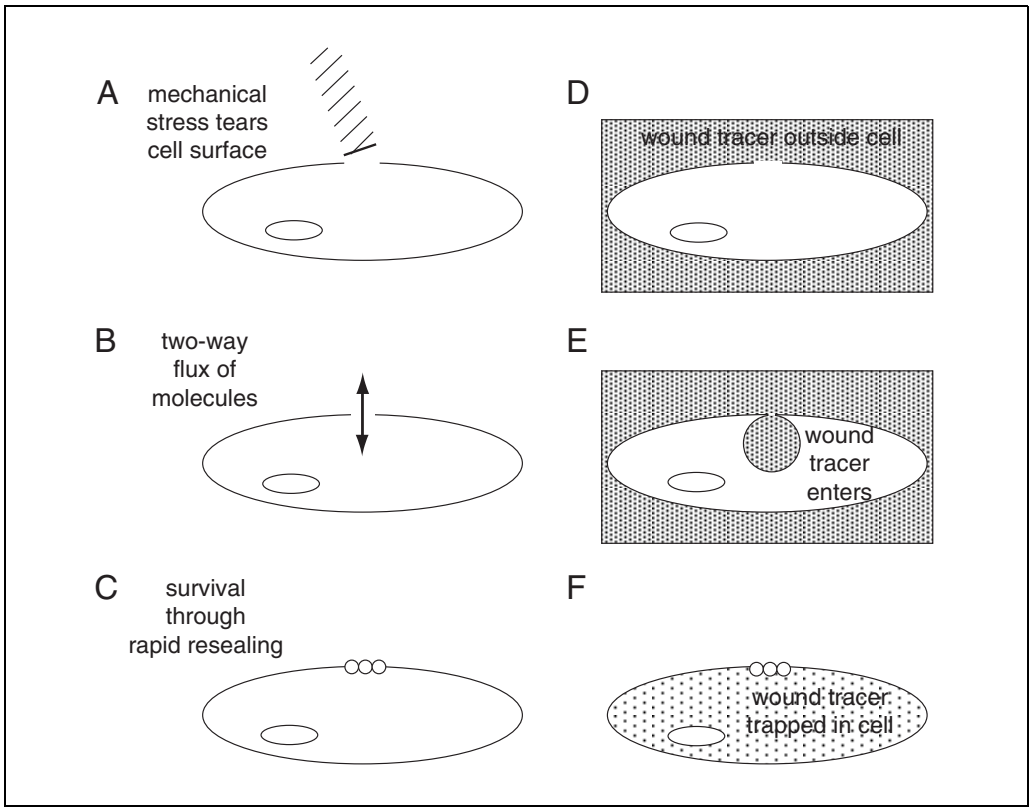

Figure 12.4.1 Cell wounding defined and identified. Mechanical stress creates a plasma membrane disruption (**A**) through which normally impermeant molecules may enter and leave the cell (**B**). Rapid resealing (<5 sec, mediated by Ca^{2+}-induced membrane mobilization and fusion events) allows the cell to survive the wound (**C**). When the disruption occurs in the presence of a normally impermeant wound tracer molecule (**D**), it can enter the cell (**E**), and become trapped there upon successful resealing (**F**). If the wound tracer is visible microscopically or fluorometrically, the cell can be identified as having been wounded.

a diffuse, even labeling of cytoplasm and nucleoplasm (if a probe <40,000 mol. wt. is employed). Often such patterns are discernible by fluorescence microscopy, but electron microscopic localization provides a more definitive indication of tracer location, especially in tissues.

BASIC PROTOCOL

WOUND DETECTION IN CULTURED MONOLAYERS USING FLUORESCEIN DEXTRAN

A procedure for microscopical detection of wounded cells growing in adherent culture is described in this protocol, along with a useful positive control (mechanical injury of the monolayer; Swanson and McNeil, 1987). This procedure is written for human umbilical vein endothelial cells, but is applicable to many and perhaps most cell types commonly grown in the laboratory. The authors have applied it to HeLa, COS, fibroblast (NIH and Swiss 3T3), various endothelial, and smooth muscle cells.

Materials

Adherent cells of interest (e.g., human umbilical vein endothelial cells; HUVEC; *UNIT 2.3*)

Cell culture medium (e.g., DMEM/10% FBS for HUVEC; Life Technologies)

Dulbecco's phosphate-buffered saline (DPBS), sterile (Life Technologies; *APPENDIX 2A*)

continued

5 mg/ml FDxLys solution: lysine-fixable fluorescein dextran, 10,000 mol. wt. (Molecular Probes) in DPBS
3.7% (w/v) formaldehyde (Fisher) in DPBS
Antibleaching microscopic mounting medium (e.g., ProLong, Molecular Probes)
22 × 22 × 1–mm glass coverslips (Fisher), sterilized by flaming with ethanol (*UNIT 1.3*)
Sterile petri dishes (Falcon; e.g., 100 × 15–mm with four compartments)

1. Plate cells of interest onto flame-sterilized coverslips and culture in an appropriate cell culture medium until the desired degree of confluency is reached.

   The wound protocol will work at any cell density, although higher densities induce a greater number of wounding events per coverslip.

2. Remove coverslip from its culture dish or well with tweezers and wash two times by dipping in two 50-ml beakers containing sterile DPBS. Touch the coverslip edge to a paper towel to wick off excess DPBS after each wash, but do not allow cells to dry out.

   In this and all following manipulations, be sure to keep track of which side of the coverslip the cells are plated on.

3. Place the coverslip cell-side up in the bottom of a plastic petri dish that is large enough to comfortably accommodate the coverslip. Pipet 100 µl of 5 mg/ml FDxLys solution onto and off of the coverslip several times.

   This ensures that the cells, which reside in an "unstirred" layer, are thoroughly and uniformly exposed to the tracer solution.

4. Initiate experimental conditions suspected of causing wounding. Leave negative controls undisturbed.

   Examples of mechanical stress that might be suspected of causing wounding are shear stress due to medium flow over or around cells and tensile stresses due to compression or stretching of the cell or its substratum. Negative controls receive FDxLys but are not mechanically disturbed.

   Time in the dye should be minimized after wounding has been completed.

5. As a positive control, scratch the coverslip approximately ten times using a single-edge razor blade. View under phase-contrast optics to ensure that zones of cells (2 to 4 cells wide) have been denuded from the substratum by this maneuver.

6. Wash all coverslips as in step 2 and return to normal culturing conditions (add culture medium, return to incubator) for the desired interval.

7. Wash each coverslip three times in DPBS and then immerse in 3.7% formaldehyde for 10 to 30 min.

   The investigator may need to determine the appropriate fixative for other fluorescent wound tracers.

8. Wash the coverslip twice in distilled water and then mount in an antibleaching microscopic mounting medium according to manufacturer's instructions. View microscopically using a standard fluorescein filter set.

   An example of FDxLys-labeled cells is shown in Figure 12.4.2.

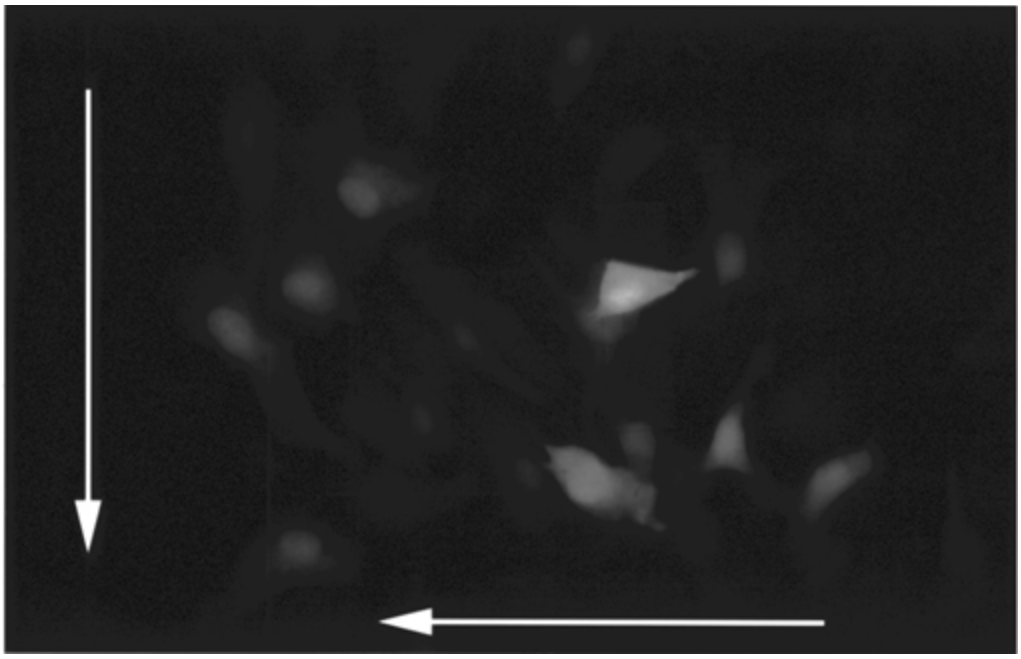

Figure 12.4.2 Example of detection of mechanically induced cell wounding in vitro. A monolayer of bovine aortic endothelial cells growing on a glass coverslip was scratched with a syringe needle in two directions (arrows indicate scratch tracks) in the presence of the wound tracer FDxLys (1 mg/ml). The culture was fixed in 4% formaldehyde 3 hr later. Cells that incurred plasma membrane disruptions that were successfully resealed are labeled with FDxLys (green). Cells that were not labeled are present in the upper right-hand corner of the micrograph. In the absence of this wound tracer, it would have been impossible to tell which of the cells in this field had been wounded, since morphologically they are indistinguishable from undisturbed neighbors. **See color figure.**

ALTERNATE PROTOCOL 1

WOUND DETECTION IN MAMMALIAN TISSUES USING FLUORESCEIN DEXTRAN

This procedure describes detection of wounded cells when the wound is induced in an intact animal by physiological or pathological mechanical stress. As with the in vitro procedure (Basic Protocol), wounded cells are detected by virtue of labeling with an impermeant marker. However, experimental access to the extracellular environment of cells in tissues is severely restricted compared to that available in the monolayer tissue culture situation. In vivo, tracer addition and removal and cell fixation are most efficiently accomplished with minimal tissue perturbation by delivering reagents (tracer, wash solution, fixative) through the blood vascular system (Clarke et al., 1995; McNeil and Khakee, 1992). Hence, the technique of vascular perfusion is described in detail in this protocol. The technique presented here focuses on the triceps skeletal muscle of the rat front leg. It should provide adequate perfusion for detecting cell wounding in most other mammalian tissues/organs, but may not be adequate for all. For example, it is not suitable for the heart, because the heart is purposefully injured in gaining access to the blood vascular system and its circulation is then bypassed during the perfusion.

In this procedure, as in the Basic Protocol, wounded cells are labeled by virtue of uptake of fluorescein dextran. Alternatively, tissue sections can be immunostained for rat serum albumin (see Alternate Protocol 2).

CAUTION: Due to the highly reactive and volatile nature of freshly prepared formaldehyde solution, the perfusion apparatus and the animal being perfused should be contained in a fume hood.

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) or must conform to governmental regulations regarding the care and use of laboratory animals.

Materials

Male Sprague-Dawley rats (250 g)
Lysine-fixable fluorescein dextran (FDxLys; Molecular Probes; 10,000 mol. wt.)
Dulbecco's phosphate-buffered saline (DPBS), sterile (Life Technologies; *APPENDIX 2A*)
1% (w/v) procaine solution in DPBS, 37°C
4% and 8% (w/v) freshly prepared formaldehyde solution in DPBS
10%, 20%, and 30% (w/v) sucrose solutions in DPBS
Tissue-Tek OCT compound (Fisher)
OCT/sucrose solution: DPBS containing 50% (v/v) OCT compound and 30% (w/v) sucrose
Isopentane
Liquid nitrogen
100 mM Tris·Cl (*APPENDIX 2A*; but adjust to pH 7.0)
Antibleaching microscope mounting medium (e.g., ProLong; Molecular Probes)

500-ml reservoirs
0.3-meter lengths of 0.2-mm-i.d. plastic tubing
1.5-meter length of 0.1-mm-i.d. plastic tubing
Three-way valve
5-cm-long, 1- to 2-mm-o.d. blunt cannula
18-G needles
1-ml syringes
Cryostat microtome
Superfrost plus microscope slides (Fisher) coated with the appropriate adhesion factor (*UNITS 2.3 & 4.3*)

Set up perfusion apparatus

1. In a fume hood, set up two 500-ml reservoirs connected by two separate 0.3-meter lengths of 0.2-mm-i.d. plastic tubing to a three-way valve. At the third end of the valve, connect a single 1.5-meter length of 0.1-mm-i.d plastic tubing to a 5-cm-long, 1- to 2-mm-o.d. blunt cannula. Elevate the solution reservoirs ≥1 meter above the animal to produce an adequate perfusion pressure.

   This setup, illustrated in Figure 12.4.3, allows perfusion of the animal first with procaine solution and then with formaldehyde solution.

Introduce tracer into blood vascular system

2. Grasp a male Sprague-Dawley rat firmly by the skin over its neck/shoulder region. With the free hand,administer 0.25 ml sterile DPBS containing ~400 mg FDxLys/kg body weight by i.p. injection with an 18-G needle and 1-ml syringe.

   FDxLys is rapidly distributed throughout the vascular system and extracellular spaces within 2 min of successful injection into the peritoneal cavity. This can be confirmed by illuminating the animal's ear with a hand-held UV lamp; it should rapidly become fluorescent.

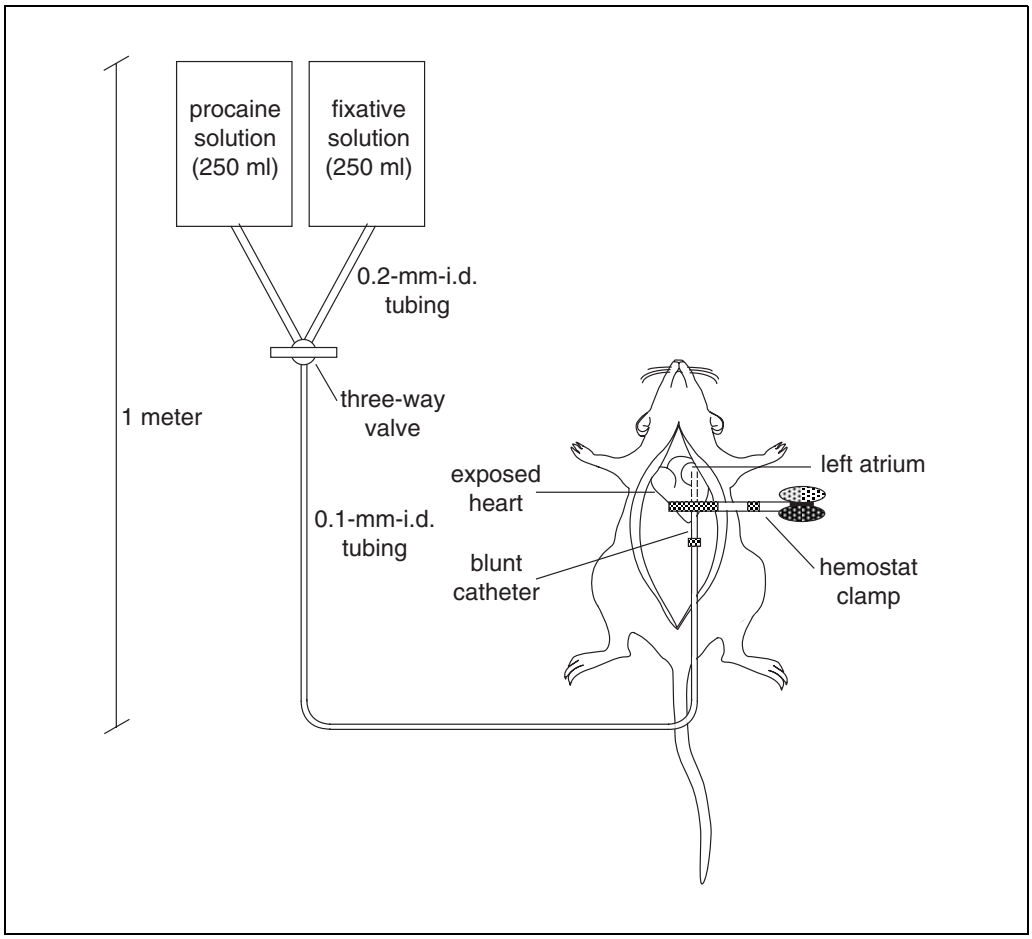

Figure 12.4.3 Perfusion setup for use after wounding in situ. Procaine and fixative solutions are elevated ≥1 meter above the subject and are administered sequentially to the left atrium via a three-way valve and a 5-cm-long cannula.

Initiate experimental conditions suspected of causing wounding

3. Expose the rat to the experimental condition of interest (e.g., exercise or administration of positively inotropic agents).

   Negative controls are not exposed to these conditions; positive controls are exposed to pathological levels of mechanical stress (e.g., a needle-puncture injury; Fig. 12.4.4).

Perfuse blood vascular system to remove exogenous tracer

4. Deeply anesthetize rat by administering an i.p.. injection of 200 mg/kg pentobarbital.
5. Place the animal on a dissection board and immobilize the front limbs with surgical tape so that the triceps muscles are in an unstretched, uncontracted state (Fig. 12.4.3).
6. With the three-way valve in the closed position, fill one reservoir of the perfusion apparatus with 250 ml warm (37°C) 1% procaine solution and the other with 250 ml of 8% formaldehyde solution. Displace any air bubbles trapped in the plastic tubing.
7. Make a small horizontal incision through the abdominal wall of the rat. Using this incision to gain access to the abdominal cavity, expose the abdominal organs by making a longitudinal incision in the abdominal wall along the full length of the animal. Expose the ribcage, puncture the diaphragm using a small pair of surgical scissors, and, working quickly, dissect out the diaphragm to expose the heart.

   Be careful not to damage any of the major blood vessels, heart, or lungs within the chest cavity.

8. Make a small incision (0.2 mm) in the apex of the left ventricle. Turn the three-way valve of the perfusion apparatus so that procaine solution is flowing, and insert the blunt cannula through the small incision, positioning the end of the cannula so that it rests in the left atrium close to the aortic arch. Clamp the cannula in place with a hemostat so that the perfusion solutions cannot exit the heart except through the aorta.
9. Begin perfusing the animal with procaine solution.
10. A few seconds after initiating perfusion with procaine, make an incision in the right atrium to allow the perfusion solution to exit the vasculature. Perfuse all 250 ml procaine.

    Adequate whole-body perfusion (with the exception of the heart) has been achieved if the liver is clear of blood (i.e., has changed from a deep red to a light brown color).

11. Without allowing air to enter the three-way valve, switch to the formaldehyde perfusion solution and perfuse the animal with 250 ml formaldehyde.

    Fixation is rapid and can be checked by gently pressing on the liver, which should become hard to the touch.

12. Fill the body cavity with absorbent pads to contain the fixative solution and leave the animal for 1 hr in the fume hood.

Prepare tissue for microscopy

13. Carefully dissect out the tissue or organ of interest and place it in fresh 8% formaldehyde solution overnight.
14. Wash tissue once quickly with DPBS and cut into pieces of a suitable size for mounting for frozen sectioning.
15. Infiltrate tissue sequentially with 10%, 20%, and 30% sucrose solutions and with OCT/sucrose solution for a minimum of 24 hr per solution.
16. Immerse infiltrated tissue in OCT compound for 3 hr and slowly freeze the tissue onto a sectioning stub using liquid nitrogen–cooled isopentane.
17. Cut 10-µm-thick frozen sections on a cryostat microtome and collect onto adhesion factor–coated Superfrost plus microscope slides.
18. Postfix sections in 4% formaldehyde solution for 10 min at room temperature.
19. Wash sections in 100 mM Tris·Cl, pH 7.0, for 5 min. Mount in antibleaching microscope mounting medium and coverslip.
20. View sections directly using a fluorescence microscope equipped with a standard fluorescein filter set.

    Cells that have suffered a membrane wound during the exercise period will contain the green FDxLys fluorescence signal (Fig. 12.4.4A).

WOUND DETECTION USING ALBUMIN AS A WOUND TRACER

ALTERNATE PROTOCOL 2

Albumin, a prominent protein constituent of blood (~10 mg/ml; ~60,000 mol. wt.), is present in most mammalian extracellular fluids. Hence, it can be used as an endogenous wound tracer in whole animal experiments (Clarke et al., 1995; McNeil and Khakee, 1992). Cultured cells can be labeled with albumin as described in the Basic Protocol. Wounded cells are labeled with an anti–rat serum albumin antibody directly conjugated with horseradish peroxidase, and are then detected enzymatically. The protocol can be

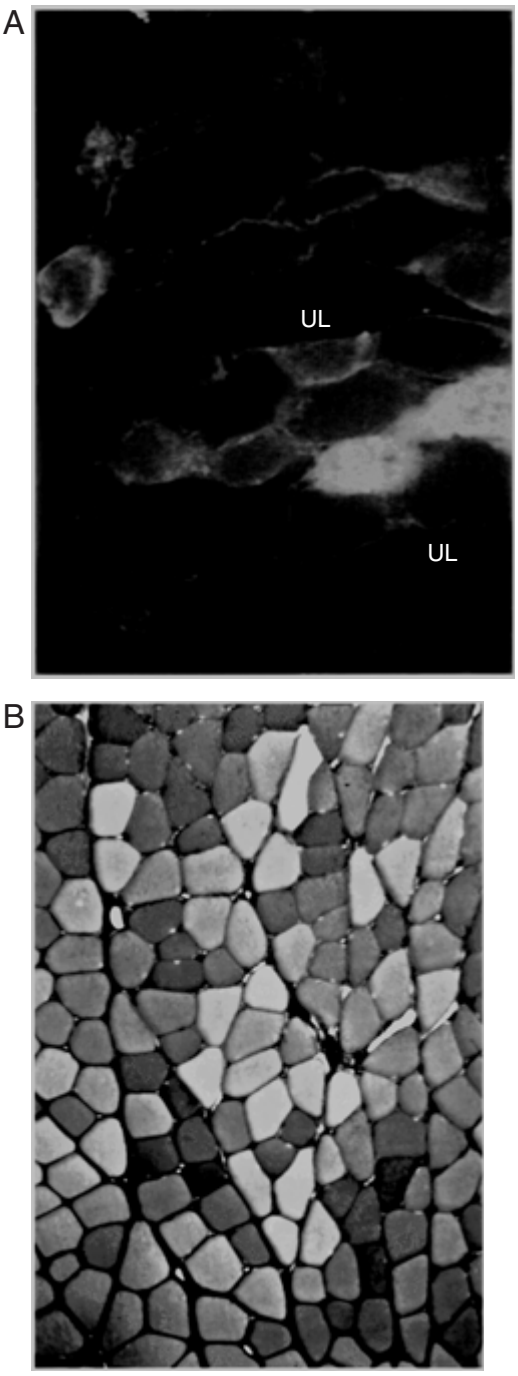

Figure 12.4.4 Example of wounded cells in skeletal muscle detected using FDxLys (**A**) or albumin (**B**) as the wound tracer. Mouse quadriceps muscles were injured by penetration with a narrow-gauge needle. Wounded cells (myofibers) are labeled with FDxLys as described in Alternate Protocol 1 (UL, unlabeled cells) or with rat serum albumin as described in Alternate Protocol 2. **See color figure.**

modified for use with alkaline phosphatase–conjugated antibodies or for secondary antibody amplification of the albumin signal.

CAUTION: Diaminobenzidine (DAB) is carcinogenic. Wear gloves and work in a fume hood when handling. Treat all DAB-containing solutions and contaminated supplies with bleach, and dispose according to institutional guidelines for hazardous chemicals.

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) or must conform to governmental regulations regarding the care and use of laboratory animals.

Additional Materials *(also see Basic Protocol and Alternate Protocol 1)*

10 mM ammonium chloride solution in DPBS
0.1% (v/v) Triton X-100 solution in DPBS
Wash buffer: 0.05% (v/v) Triton X-100 in DPBS
H_2O_2/NaN_3/DPBS: 0.3% (v/v) hydrogen peroxide and 2% (w/v) sodium azide in DPBS (add stock H_2O_2 to azide buffer immediately before use)
Heat-inactivated sheep serum (Life Technologies)
Horseradish peroxidase (HRP)–conjugated sheep anti–rat serum albumin (RSA) polyclonal antibody (Organon Teknika Cappel)
100 mM Tris·Cl, pH 7.0 (*APPENDIX 2A*; but adjust pH to 7.0)
HRP substrate kit (Vector Laboratories) with 3,3′-diaminobenzidine (DAB)
50%, 75%, 90%, 95%, 99%, and 100% (v/v) EM-grade ethanol
EM-grade xylene
Permanent mounting medium (e.g., Cytoseal 60, Stephen's Scientific)

NOTE: All staining procedures are carried out at room temperature unless otherwise specified.

1a. *For cultured monolayers:* Prepare experimental and control cultured cells as described (see Basic Protocol, steps 1 to 7), but replace 5 mg/ml FDxLys with 5 mg/ml rat serum albumin (step 3).

1b. *For tissues:* Prepare experimental and control tissue sections as described (see Alternate Protocol 1, steps 1 to 18), but omit the FDxLys injection.

2. Wash the specimen twice with DPBS and incubate in 10 mM ammonium chloride solution for 30 min to inactivate reactive aldehyde groups.

3. To permeabilize tissue sections, incubate 5 min in 0.1% Triton X-100 solution, followed by 5 min in wash buffer.

   Use gentle agitation for these and all subsequent incubations and washes.

4. To block endogenous peroxidase activity, incubate 30 min in H_2O_2/NaN_3/DPBS followed by 5 min in wash buffer.

5. To block nonspecific protein binding, incubate tissue section 1 hr in wash buffer containing 4% (v/v) heat-inactivated sheep serum, followed by 5 min in wash buffer alone.

6. Incubate overnight at 4°C with HRP-conjugated sheep anti-RSA polyclonal antibody made up in wash buffer/1% sheep serum.

   Due to batch-to-batch variations, titration of primary antibody concentration will be required to achieve optimal staining intensity of wounded cells; a range of 1:100 to 1:1000 is recommended as a starting point.

7. Wash five times with wash buffer and two times with 100 mM Tris buffer.
8. Prepare fresh HRP substrate buffer per manufacturer's instructions and incubate tissue section in substrate buffer for 30 min in the dark.
9. Wash section in distilled water for 5 min and dehydrate in a graded ethanol series: 10 min each in 50%, 75%, 90%, 95%, 99%, and 100% ethanol.
10. Incubate in fresh xylene with two to three changes over a total of 10 min. Mount in permanent mounting medium and view by light microscopy.

Cells that have suffered a membrane wound within the 24 to 48 hr prior to animal sacrifice will be positively stained for serum albumin in their cytoplasm (Fig. 12.4.4B).

ALTERNATE PROTOCOL 3

ELECTRON MICROSCOPE VISUALIZATION OF WOUND TRACERS

It is often desirable to use electron microscopical (EM) localization techniques to demonstrate that the wound tracer is present in cytosol and not in a membrane-bounded cytoplasmic compartment. This resolves the issue of whether the tracer has entered directly into the cytosol after crossing the plasma membrane boundary (the localization predicted if entry occurred through a disruption) or gained access to the cell interior by an endocytotic process. In this procedure, cells that have wounded in tissues in the presence of albumin are prepared for EM as well as preliminary light microscopy. The procedure requires expertise in preparing and handling ultrathin sections.

CAUTION: Osmium tetroxide and uranyl acetate are hazardous. Wear gloves when handling. Perform steps in a fume hood to avoid vapors. Dispose of used osmium and uranyl acetate according to institutional guidelines for hazardous chemicals.

Additional Materials *(also see Alternate Protocols 1 and 2)*

70% (v/v) EM-grade ethanol
LR-White acrylic resin, hard (EM Science)
Goat anti–rat serum albumin (RSA) primary antibody (Oregon Teknika Cappel)
Biotinylated rabbit anti–goat IgG secondary antibody (Oregon Teknika Cappel)
Streptavidin-gold (10-µm particles; Auroprobe EM kit; Amersham)
Intense Silver Enhancement kit (Amersham) containing silver salt (solution A), initiator (solution B), and sodium thiosulfate solution
Immersion oil
100 mM sodium cacodylate, pH 7.4/1% (w/v) osmium tetroxide

60°C oven
Formvar-coated nickel grids (Monsanto)

Additional reagents and equipment for preparing and handling ultrathin sections and for uranyl acetate/lead citrate staining (e.g., Glauert, 1975)

Prepare sample

1. Wound tissues in the presence of albumin and perfuse/dissect tissues as described (see Alternate Protocol 1, steps 1 to 13).
2. Wash tissue in DPBS and cut into 5-mm^3 or smaller pieces.
3. Dehydrate in 70% ethanol with constant agitation for 2 hr.

Prepare thin sections

4. Transfer samples from ethanol directly into LR-White acrylic resin and incubate overnight with constant specimen agitation.

5. Polymerize at 60°C for 2 hr according to manufacturer's instructions.
6. Prepare 1-µm-thick sections according to standard ultramicrotomy methods.

Stain sections for preliminary light microscopy

7. Perform immunostaining for RSA as described (see Alternate Protocol 2, steps 5 to 7) but use an unlabeled goat anti–RSA primary antibody.

   These and all subsequent incubations and washes should be done with gentle agitation.

8. Wash thoroughly (5 min) with wash buffer and incubate 2 hr in biotinylated rabbit anti–goat IgG secondary antibody at 1:200 in wash buffer/1% sheep serum.
9. Wash thoroughly (5 min) with wash buffer and incubate 2 hr in streptavidin-gold according to manufacturer's instructions.
10. Mix silver salt (solution A) and initiator (solution B) 1:1 (v/v) immediately before use and float a gold-labeled section on a drop of this solution. Monitor the intensity of staining to determine the optimal staining time (typically 5 to 10 min). Rinse the stained section with distilled water.
11. Incubate section for 2 to 3 min in sodium thiosulfate solution to stop the reaction, and rinse again with water.
12. Dry section thoroughly, mount in immersion oil, and view by transmitted-light microscopy (see example in Fig. 12.4.5A).

Prepare and stain ultrathin sections

13. Prepare 70-nm ultrathin sections from the same block according to standard ultramicrotomy techniques and collect on a formvar-coated nickel grid.
14. Perform immunostaining as described above (steps 7 to 9). Do not use silver enhancement (step 10).
15. Incubate overnight in 100 mM sodium cacodylate, pH 7.4/1% osmium tetroxide at room temperature.
16. Stain with uranyl acetate and lead citrate and view by standard transmission EM (for example see Fig. 12.4.5B).

QUANTIFICATION OF WOUNDING FREQUENCY AND INTENSITY: IMAGE ANALYSIS

SUPPORT PROTOCOL 1

Because the details of the following procedure (Clarke et al., 1995; McNeil and Khakee, 1992; McNeil et al., 1981) are computer and software dependent, the following protocol is written in generic form and refers to common image analysis software capabilities. Universal Imaging (*http://www.image1.com*) sells appropriate software for Windows-based PCs. For Macintosh, NIH Image software can be downloaded free of charge at *http://www.rsb.info.nih.gov*.

1. Acquire a digitized 256–grey scale image of the specimen in a blinded fashion or using a predetermined pattern of image acquisition from the microscopic specimen. Acquire all images that are to be compared with one another under identical conditions with regard to magnification, specimen illumination, camera sensitivity and gain settings, and image acquisition time.
2. Import the digitized images into an image analysis program.

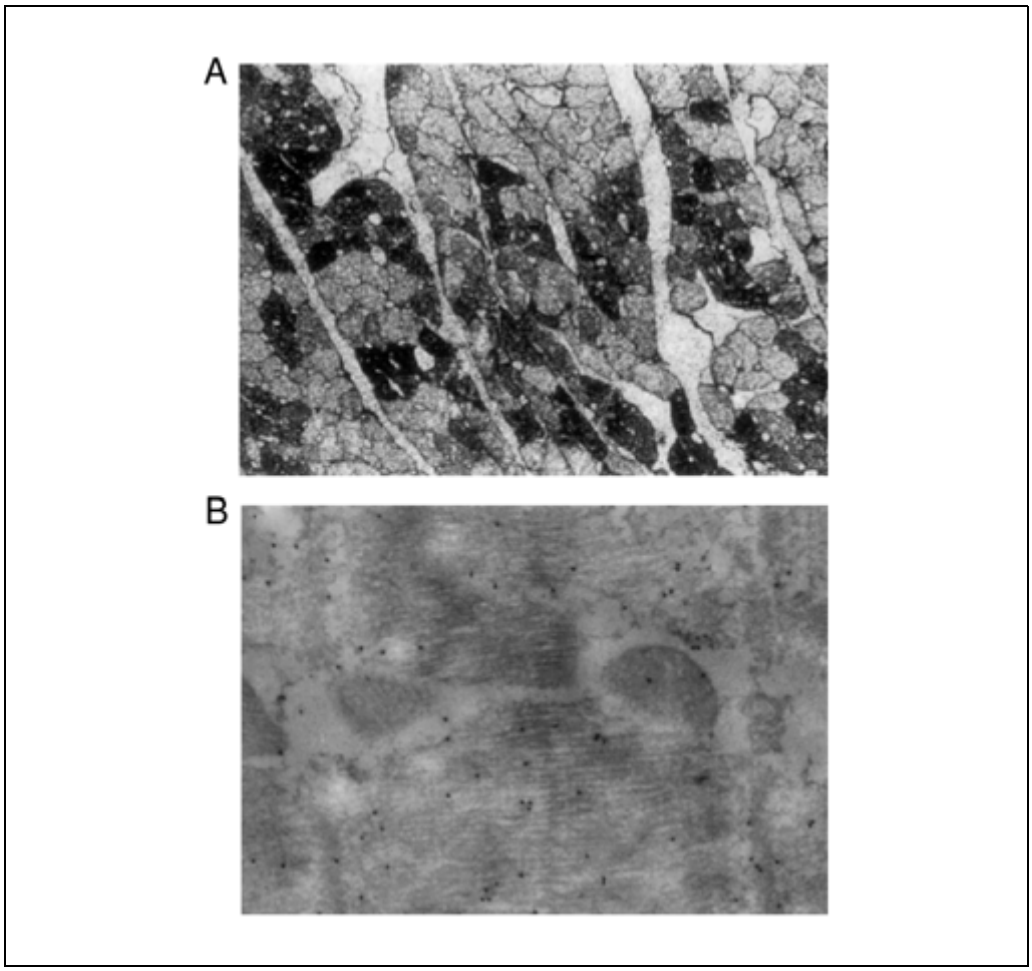

Figure 12.4.5 An example of EM localization of a wound tracer (albumin). (**A**) Light microscope image of an ~1-µm-thick plastic section of rat cardiac muscle stained with an antibody to rat serum albumin, a biotinylated secondary antibody, and streptavidin-gold according to Alternate Protocol 3. The gold is visualized by intensification with silver, resulting in dark labeling of the albumin-positive (wounded) cells. (**B**) Electron microscope image of the same specimen showing that the gold label, and therefore the wound tracer, is present in the cytosol, not in an organellar compartment. This rules out uptake of the rat serum albumin by endocytosis or through this cell's T-tubule system.

3. Utilizing the densitometry option of the software (or functional equivalent), create a measurement "window" that comfortably fits within the on-screen image of the cell or portion of a cell from which a measurement will be made.

   This can be repeated for as many cells/areas as are present on the screen. By varying the size of the measurement window to suit the cell type being studied, membrane wounding in a variety of different tissues/in vitro specimens can be analyzed using this protocol.

4. Instruct the image analysis software to measure the average pixel intensity in each measurement window, and to record the data in a file for later analysis.

5. Export these values to a spreadsheet software package.

6. Determine a control, nonwounded level of labeling by measuring the average pixel intensities of cells that clearly contain no wound tracer.

7. Calculate an average threshold value for designating wounded cells by calculating the average pixel value of the control data pool obtained in step 6.

8. Using this threshold value, calculate the percentage of wounded cells with the spread sheet.
9. To compare two different experimental conditions, plot data as a population histogram or calculate mean population intensities.

QUANTIFICATION OF WOUNDING FREQUENCY AND INTENSITY: FLOW CYTOFLUOROMETRY

SUPPORT PROTOCOL 2

This protocol is written with the assumption that the flow cytofluorometer will be operated by a skilled technician, and that the goal is to assess the degree of wounding in a cell population (Clarke and McNeil, 1994; McNeil et al., 1984). The compatibility of potential wound tracers with the available flow apparatus should be determined in advance by consultation with its operator or other local expert. This procedure requires additional reagents and equipment for trypsinization (*UNIT 1.1*) and flow cytometry (Shapiro, 1995; Robinson et al., 1999).

Prepare single-cell suspensions

1. Wound and label adherent cells (see Basic Protocol, steps 1 to 6). For controls, include cells that were exposed to the wound tracer but not to wound-inducing conditions (pinocytosis control) and wounded cells that were not exposed to the tracer (autofluorescence control).
2. Wash twice with DPBS.
3. Trypsinize adherent cells from substratum (*UNIT 1.1*) or otherwise manipulate cells or tissues to obtain a single-cell suspension.
4. Resuspend in 0.25 to 1 ml DPBS or similar saline suitable for flow equipment.

   If the cells tend to form clumps, filter through a nylon mesh (20-mm mesh Nitex, Tetko) before use.

   For most efficient flow analysis (important when paying per unit time of instrument usage), the density of the suspension should be 10^6 cells/ml or higher. Discuss this, and the exact method employed locally for filtering out cell clumps, in advance with the flow operator.

Perform flow analysis

5. Acquire 20,000 events from the autofluorescence control, measuring both forward scatter and fluorescence.

   Excitation and emission settings, filters, and so on will depend on the instrument and wound tracer used.

6. Use this data to set a low threshold for the fluorescence channel acquisition.

   Living cell and dead cell populations, as well as cell doublets, should be discernible from the forward scatter data. If not, adjust instrument accordingly.

7. Acquire 20,000 events from the experimental population. Use this data to adjust the high end of parameters such as gain and laser intensities so that the entire range of fluorescence intensities in the population is captured.

   Fluorescence intensities may range over several log values.

8. Acquire 20,000 events from the pinocytosis control population. Use the fluorescence profile of this population to set a threshold allowing discrimination between this population and that subset of the experimental population whose fluorescence intensities fall above this threshold.

9. Calculate the percentage of cells in the experimental population that are above the level derived from the pinocytosis control and display the distribution of fluorescent cells within this population.

This displays wound-induced uptake of the tracer.

COMMENTARY

Background Information

Why is survivable plasma membrane disruption, referred to here as cell wounding, of interest to the cell and molecular biologist? There are number of reasons. First, such disruptions provide a route out of cytosol for numerous impermeant molecules that are not capable of being exported by the classical secretory pathway but nevertheless are present outside cells and/or have an extracellular function that can only be understood in terms of a release mechanism (Smallheiser, 1996). An example is basic fibroblast growth factor (bFGF). This polypeptide lacks a classical signal sequence for import into the endoplasmic reticulum, but is a potent extracellular cell growth–promoting signal. One route of release of bFGF is through disruptions. Characterization of cell wounding using the methods described here has demonstrated how this mode of release may have both physiological and pathological relevance in vivo (McNeil, 1993; McNeil and Steinhardt, 1997).

Second, disruptions provide a route into the cytosol for potentially potent second messengers, such as Ca^{2+}. When a cell suffers a plasma membrane disruption, Ca^{2+} can enter down a 10,000-fold concentration gradient until resealing intervenes. This entry of a potent, broadly acting intracellular second messenger might have profound consequences on subsequent cell functioning, both in the short term through the activation of Ca^{2+}-sensitive proteins and in the long-term through changes in gene expression. For example, Ca^{2+} entry is now known to evoke massive intracellular vesicle-vesicle fusion (Terasaki et al., 1997) and vesicle transport to and docking and fusion with the plasma membrane (Bi et al., 1995; Miyake and McNeil, 1995; Steinhardt et al., 1994). Ca^{2+} entry also may evoke *cfos* and other gene expression events (Grembowicz et al., 1999).

Third, plasma membrane disruptions can be of considerable practical utility to the cell and molecular biologist. They provide a route of entry for otherwise impermeant macromolecules that an experimenter might wish to introduce into cytosol. Enzymes, antibodies, oligonucleotides, and expression vectors are all examples of macromolecules that can be loaded into living cells through disruptions (McNeil, 1989; McNeil et al., 1981). Skeletal muscle cells can be transfected with naked DNA simply by injecting it through a syringe needle into a muscle (Wolff et al., 1990). It is clear from studies using the methods described in this unit that the injected DNA enters muscle cells through plasma membrane disruptions, which are prominently induced by the needle puncture.

Critical Parameters

Certain artifacts must be avoided. First, artifactual membrane wounding induced by animal handling must be kept to a minimum prior to removal of wound tracers and fixation. For example, early studies indicated that relatively low levels of mechanical force applied to skin caused significant membrane wounding of the epithelial cells (McNeil and Ito, 1990). Second, as membrane wound quantification relies on densitometry, section thickness is extremely important. The authors routinely mount two or more specimens for quantitative comparisons on the same stub to ensure equivalency of section thickness. However, any such potential problems associated with differing section thickness can be avoided if the experimenter has access to a confocal microscope, which allows the volumetric quantification of fluorescent wound tracer within the specimen in optical sections of identical thickness.

For additional critical parameters related to immunofluorescence and immunoperoxidase staining procedures, see *UNITS 4.3 & 4.6*, respectively.

Troubleshooting

Poor staining of wounded cells in positive control experiments could be due to insufficient wound tracer. A higher concentration of the wound tracer should be used, and its access to the extracellular environment of interest verified. Artificially high labeling in negative control experiments not subject to mechanical stress prior to fixation is most likely due to probe entry during and/or after cell fixation. The cells/tissue must be more thoroughly

washed to remove all exogenous tracer prior to fixation.

Anticipated Results

In all mechanically active tissues/culture environments tested by the authors, evidence of plasma membrane disruption events has been obtained. However, the percentage of cells affected and the range of labeling intensities varies tremendously (<1% up to 80%). It is therefore impossible to generalize as to expected results.

Time Considerations

Most of these protocols can be completed in a day or less. Exceptions are the EM immunostaining and image analysis quantitation protocols, which may take several days to complete.

Dictyostelium Cell Dynamics

Dictyostelium discoideum is a powerful, genetically accessible system that can be used to study fundamental cellular processes, including cytokinesis, motility, phagocytosis, chemotaxis, signal transduction, and aspects of development such as cell sorting, pattern formation, and cell-type determination (Maeda et al., 1997; Daunderer et al., 1999; Kay and Williams, 1999). *D. discoideum* amoebae grow as separate, independent cells but, upon starvation, interact to form multicellular structures (see Commentary). Among the great strengths of this model system is the capacity to track the dynamic behaviors of individual cells. Most importantly, phenotypic complementation of null mutants with green fluorescent protein (GFP) fusion proteins is providing an extremely useful tool for cell biology.

This unit describes how to grow and image *D. discoideum* amoebae and focuses primarily on cell motility and chemotaxis processes. Specific step-by-step procedures are described for imaging GFP-labeled proteins in live amoebae (see Basic Protocol 1), aggregation stream and mound preparations (see Basic Protocol 2), and slug preparations (see Basic Protocol 3). Alternate Protocols 1 and 2 describe the imaging of GFP-labeled proteins in the presence of a chemoattractant. Support Protocols 1 and 2 give an in-depth description of how the cells are cultured and maintained. Support Protocol 3 describes the transformation of *D. discoideum* with a GFP fusion plasmid. Support Protocols 4 and 5 describe two different ways to characterize the functionality of the fusion protein generated by the complementation of null mutants or by overexpression in wild-type backgrounds.

IMAGING GFP-LABELED PROTEINS IN LIVE SINGLE CELLS

BASIC PROTOCOL 1

Once the functionality of a GFP fusion protein expressed in *Dictyostelium* amoebae is established (see Support Protocols 4 and 5), studying its cellular localization can be performed by examining single cells (as described here) or by analyzing the behavior of cells as they come together to form aggregates or mounds (see Basic Protocol 2) and slugs (see Basic Protocol 3). The methods described in this protocol are divided in two sections. First, a brief overview of the imaging arrangement is presented. Second, a detailed step-by-step description of how samples are prepared for live microscopy is provided.

Materials

Transformed *D. discoideum* cells (see Support Protocol 3) expressing desired green fluorescent protein (GFP) fusion protein
Phosphate buffer (PB; see recipe)
Developmental buffer (DB; see recipe)
Stock solution of adenosine 3′,5′-cyclic monophosphate (cAMP, sodium salt) to give appropriate final concentration, for developed cells only

Inverted microscope equipped with a charge-coupled device (CCD) camera, mercury light source, and appropriate filter sets for GFP imaging
Computer with either IPLab-Spectrum (Scanalytics) or Openlab (Improvision) acquisition software
Chambered coverglass (e.g., Lab-Tek II, Nalge Nunc International)
Brass holder designed to fit in a standard mechanical stage holder
Peristaltic pump connected to timer (for developed cells only)

Additional materials and reagents for growing *D. discoideum* cells (see Support Protocols 1 and 2) and for counting cells (*UNIT 1.1*)

Current Protocols in Cell Biology (2001) 12.5.1-12.5.19

Set up imaging hardware

1. Set up an inverted microscope and its associated hardware.

   The CCD camera must be capable of acquiring images rapidly and with high sensitivity. Good examples of this type are the Photometrics PXL (Roper Scientific) and the Hamamatsu Orca (Hamamatsu Photonic Systems) cameras.

   For double-labeling experiments, a filter wheel is required to ensure rapid changes in the filters while the cells are moving.

2. Set up a computer with IPLab-Spectrum or Openlab acquisition software to control image acquisition.

   These software programs handle image acquisition, processing, measurement, and analysis for a variety of applications. Since the amoebae are light sensitive, the exposure time and the intensity of the fluorescence excitation light should be kept at a minimum using neutral-density and UV filters and shutters. Of course, the exposure time will be highly dependent on the level of expression of the GFP fusion protein, and will therefore have to be empirically determined.

3. Mount the chambered coverglass on a standard stage holder.

   Alternatively, a 35-mm coverslip can be positioned on an Attofluor cell chamber (Molecular Probes) and directly mounted in a standard 35-mm-diameter stage holder.

Visualize cells

For growing cells:

4a. Grow transformed *D. discoideum* cells to log phase in liquid medium (see Support Protocol 1) or on bacterial lawns (see Support Protocol 2).

5a. Count cells (*UNIT 1.1*), dilute in PB to ~1×10^6 cells/ml, and deposit 4 µl (4000 cells) onto a mounted chambered coverglass.

6a. Let cells adhere 5 min.

7a. Gently add PB to cover the surface of the coverglass, and examine for GFP.

For developed cells:

4b. Grow transformed *D. discoideum* cells to log phase in liquid medium (see Support Protocol 1) and dispense 50-ml aliquots into conical tubes.

5b. Centrifuge 4 min at 1500 × *g*, 22°C, and wash cells in DB.

6b. Centrifuge again as in step 5b. Pool and count cells (*UNIT 1.1*), and resuspend in a flask at 2×10^7 cells/ml in DB.

7b. Shake 1 hr at 100 rpm at 22°C.

8b. To optimize development, while shaking at 100 rpm for 4 to 5 hr add cAMP stock solution at a final concentration of 75 nM to the cells every 6 min using a peristaltic pump connected to a timer (see Commentary).

9b. Remove 1 ml cells, centrifuge 4 min at 1500 × *g*, 22°C, and resuspend in 1 ml PB.

10b. Vortex to break up cell aggregates.

11b. Dilute 20 fold in PB and deposit 4 µl onto a mounted chambered coverglass.

12b. Let cells adhere 5 min.

13b. Gently add PB to cover the surface of the coverglass, and examine for GFP.

IMAGING GFP-LABELED PROTEINS FOLLOWING A UNIFORM INCREASE IN CHEMOATTRACTANT

ALTERNATE PROTOCOL 1

The distribution of the GFP fusion protein can be studied under basal, nonstimulated conditions where processes such as cytokinesis and phagocytosis (for growth stage cells) as well as random motility can be measured. In addition, the effect of receptor stimulation on the localization of the labeled protein can be easily assessed on developed cells. This can be performed in two ways: in the presence of a uniform concentration of chemoattractant (Figure 12.5.1A) or a chemoattractant gradient (Figure 12.5.1B,C; see Alternate Protocol 2).

Materials

Transformed *D. discoideum* cells (see Support Protocol 3) expressing desired green fluorescent protein (GFP) fusion protein
Developmental buffer (DB; see recipe)
Adenosine 3′,5′-cyclic monophosphate (cAMP, sodium salt) to give appropriate final concentration
Phosphate buffer (PB; see recipe)

Inverted microscope equipped with a charge-coupled device (CCD) camera, mercury light source, and appropriate filter sets for GFP imaging
Computer with either IPLab-Spectrum (Scanalytics) or Openlab (Improvision) acquisition software
Eight-chambered coverglass (Lab-Tek II, Nalge Nunc International)
Peristaltic pump connected to timer

Additional materials and reagents for growing *D. discoideum* cells to log phase in liquid medium (see Support Protocol 1) and for counting cells (*UNIT 1.1*)

Set up imaging hardware

1. Set up an inverted microscope and its associated hardware.

   The CCD camera must be capable of acquiring images rapidly and with high sensitivity. Good examples of this type are the Photometrics PXL (Roper Scientific) and the Hamamatsu Orca (Hamamatsu Photonic Systems) cameras.

   For double-labeling experiments, a filter wheel is required to ensure rapid changes in the filters while the cells are moving.

2. Set up a computer with IPLab-Spectrum or Openlab acquisition software to control image acquisition.

   These software programs handle image acquisition, processing, measurement, and analysis for a variety of applications. Since the amoebae are light sensitive, the exposure time and the intensity of the fluorescence excitation light should be kept at a minimum using neutral-density and UV filters and shutters. Of course, the exposure time will be highly dependent on the level of expression of the GFP fusion protein, and will therefore have to be empiricallly determined.

3. Mount an eight-chambered coverglass on a standard stage holder.

Prepare developed D. discoideum cells

4. Grow transformed *D. discoideum* cells to log phase in liquid medium (see Support Protocol 1) and dispense 50-ml aliquots into conical tubes.

5. Centrifuge 4 min at 1500 × *g*, 22°C, and wash cells in DB.

6. Centrifuge again, pool and count cells (*UNIT 1.1*), and resuspend in a flask at 2×10^7 cells/ml in DB.

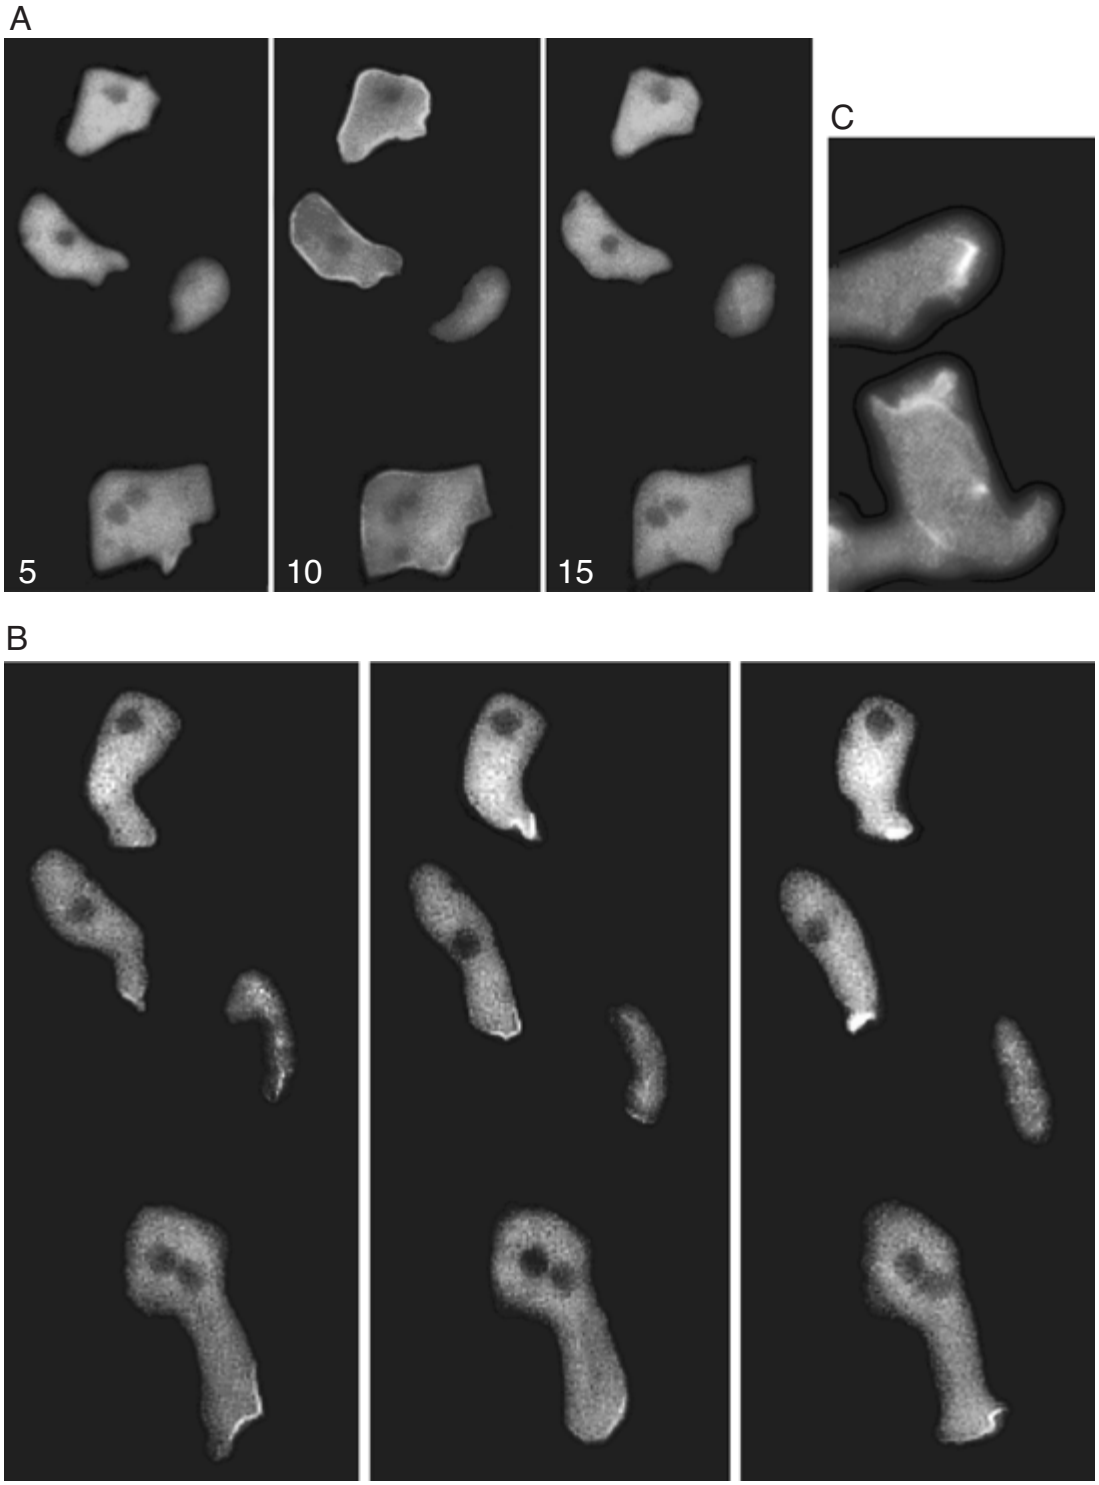

Figure 12.5.1 Translocation of pleckstrin homology (PH) domain–containing proteins to the plasma membrane at the leading edge of chemotaxing *D. discoideum* cells. Endogenous cytosolic regulator of adenylyl cyclase (CRAC), a PH domain–containing protein of *D. discoideum* amoebae, was replaced with a CRAC-GFP fusion protein. Transformants were grown, starved in the presence of pulses of cAMP, and processed for microscopy analysis. (**A**) Chemoattractant was applied uniformly by increasing the pressure on the microinjector (this can also be done by adding a bolus of attractant to the chamber). The cells respond with uniform translocation of CRAC to the plasma membrane. The colors were obtained by merging the 5-sec frame (in blue) with the 10- and 15-sec frames (in yellow). The association of CRAC-GFP appears in yellow. (*Legend continues on next page.*)

7. Shake 1 hr at 100 rpm.
8. To optimize development, while shaking at 100 rpm for 4 to 5 hr, add cAMP to a final concentration of 75 nM to the cells every 6 min using a peristaltic pump connected to a timer (see Commentary).
9. Remove 1 ml cells, centrifuge 4 min at 1500 × *g*, 22°C, and resuspend in 1 ml PB.
10. Vortex to break up cell aggregates.
11. Dilute 20 fold in PB and deposit 4 µl into each chamber of the eight-chambered coverglass.
12. Let cells adhere 5 min and gently add 300 µl PB to each well.

Acquire GFP images

13. Mount coverglass on the inverted microscope and set the acquisition software to time-lapse mode.

    D. discoideum amoebae have a diameter of ~10 to 20 µm. Using 63× or 100× oil-immersion objectives will give the best results, increasing both spatial resolution and brightness. The exact time frame to be chosen will depend on the protein of interest.

14. Start the acquisition process and record baseline images from a chamber for about 4 to 5 frames.
15. Between two frames, delicately add 30 µl of cAMP stock solution to the chamber.

    This will give a 10× dilution factor. Prepare stock solutions of cAMP to give final concentrations ranging from 10^{-9} to 10^{-5} M.

16. Finish data acquisition.

    The length of the acquisition process will depend on the protein studied.

17. Move to a different chamber and repeat steps 14 to 16, using a different concentration of cAMP.

    A dose-response curve with cAMP concentrations ranging from 10^{-9} to 10^{-5} M should be performed.

IMAGING GFP-LABELED PROTEINS IN A CHEMOATTRACTANT GRADIENT

ALTERNATE PROTOCOL 2

The spatial localization of the GFP fusion protein in chemotaxing cells can be assessed by observing cells exposed to a chemoattractant gradient (Parent and Devreotes, 1999). This is achieved using a micropipet to deliver a constant amount of attractant on the coverglass (Figure 12.5.1B,C).

Figure 12.5.1 *(continued from previous page)* (**B**) These three images are from the same series as in (A). The gradient of cAMP was restored, and a polarized CRAC-GFP signal was observed as the cells moved up the gradient (from low concentrations at the top of the frame to high concentrations at the bottom). The micropipet was located just outside the bottom of the frames. In both (A) and (B), the numbers in the bottom left corner are seconds after the start of the experiment. (**C**) Wild-type amoebae expressing the PH domain of PKB (protein kinase B or Akt) linked to GFP were placed in a gradient of chemoattractant. As the cells were moving up the gradient, the fluorescent signal was observed at the front of the cells. The micropipet was located at the top right corner of the frame. Reprinted from Parent and Devreotes (1999) with permission from the American Association for the Advancement of Science. **See color plate.**

Additional Materials *(see Basic Protocol 1 and Alternate Protocol 1)*

10^{-5} to 10^{-6} M adenosine 3′,5′-cyclic monophosphate (cAMP, sodium salt)
One-chambered coverglass (Lab-Tek II, Nalge Nunc International) or Attofluor cell chamber (Molecular Probes) fitted with a 35-mm coverslip
Micropipet consisting of pulled glass capillary with an opening of ~0.5 µm (e.g., Femtotips, Eppendorf Scientific)
Microinjector (e.g., Eppendorf Scientific)
Additional reagents and equipment for imaging GFP-labeled proteins following a uniform increase in chemoattractant (see Alternate Protocol 1)

NOTE: A Microloader (Eppendorf Scientific) can be used to load the micropipet.

1. Set up an inverted microscope and prepare developed transformed *D. discoideum* cells as described (see Alternate Protocol 1, steps 1 to 10).
2. Dilute cells 20 fold in PB and deposit 4 µl onto a one-chambered coverglass or on an Attofluor cell chamber fitted with a 35-mm coverslip.
3. Let cells adhere 5 min and gently add ~2 ml PB.
4. Mount coverglass or cell chamber on the inverted microscope.
5. Load a micropipet with 10^{-5} to 10^{-6} M cAMP and secure it in a microinjector.

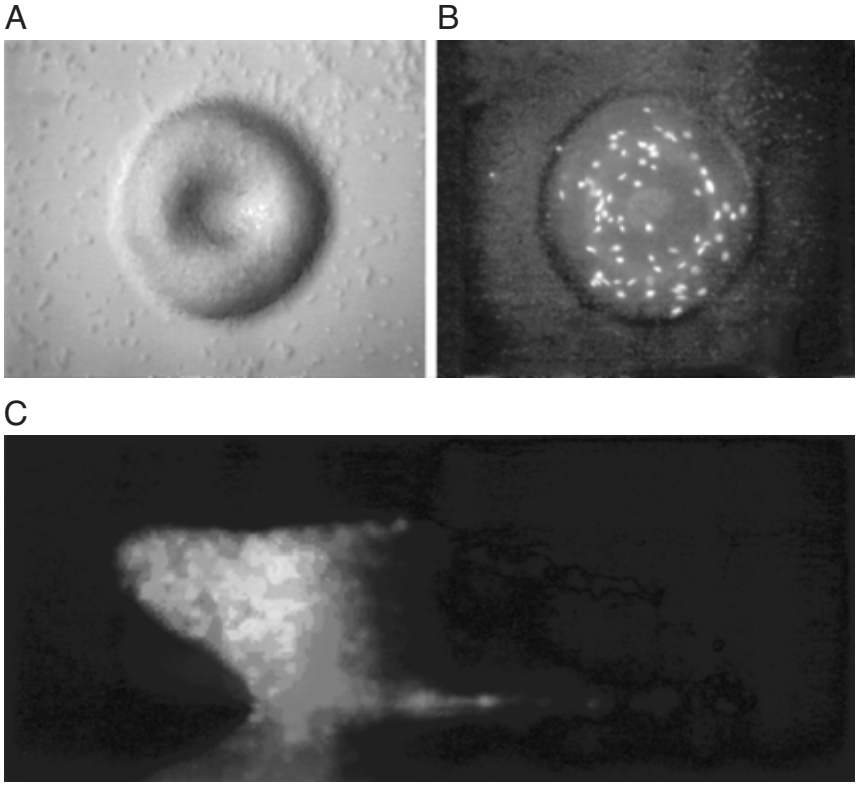

Figure 12.5.2 Visualizing GFP-labeled cells in *D. discoideum* mounds and slugs. (**A**) Bright field and (**B**) fluorescence images of a mound containing 0.1% cells expressing GFP under the actin 15 promoter, viewed at 10× magnification. (**C**) Merged image of a slug co-expressing wild-type GFP under the ecmA promoter and the red-shifted S65T GFP mutant under the ecmO promoter. The slug is viewed from the side at 10× magnification as described (see Alternate Protocol 2). Separate images were taken <0.5 sec apart using excitation at 400 and 485 nm, respectively, to show the wild-type (in green) and red-shifted (in red) GFP. These images were then merged to give the image shown. Regions that express both forms of GFP appear in yellow. Figure and methods generously provided by D. Dormann and C.J. Weijer (Dormann et al., 1996). **See color plate.**

6. Using phase optics and a 40× oil-immersion objective, carefully position the micropipet in the vicinity of a group of cells.

   A 40× objective is used to view larger field of cells.

   Because the cells move rapidly towards cAMP (~15 ìm/min), the micropipet should be positioned far enough from them so the cells do not aggregate on the micropipet and clog it.

7. Adjust the microinjector to manual mode with a compensation pressure of ~20 hPa.

   The gradient generated can be assessed by placing a diluted solution of rhodamine (which has a molecular weight similar to cAMP) in the micropipet and observing the fluorescence signal after the gradient reaches steady state (Parent et al., 1998).

8. Set the acquisition software to time-lapse mode at one frame every 15 sec and begin data acquisition.

   Acquisition can be performed for as long as desired.

   The distribution of the fusion protein can be observed while the gradient is re-established if the micropipet is repositioned while the cells are chemotaxing.

IMAGING GFP-LABELED PROTEINS IN AGGREGATION STREAM AND MOUND PREPARATIONS

BASIC PROTOCOL 2

GFP-labeled cells can be used to study the patterns of cell movement during multicellular development in *D. discoideum*. This is achieved by mixing nonexpressing cells with cells expressing GFP under a constitutive promoter. Alternatively, GFP (and/or a color variant of GFP) can be fused to cell-specific promoters, thereby allowing the visualization of different cell types in a live organism. This technique not only allows the observation of wild-type organisms, but it can also be used to precisely study the developmental defects of mutants.

This protocol describes the procedures used to visualize aggregation streams and mounds. The aggregation streams are formed in early development as the cells are chemotaxing toward centers. Visualization of these streams is best observed at higher magnification. For the visualization of mounds and later structures, lower magnification is preferred (Fig. 12.5.2, panels A and B; also see Rietdorf et al., 1996).

Materials

Transformed *D. discoideum* cells (see Support Protocol 3) grown on non-nutrient agar (see Support Protocol 5)
Silicone oil (e.g., Dow Corning 200/20cs, BDH Chemicals)

Incubator, 22°C
Attofluor cell chamber (Molecular Probes) fitted with a 35-mm coverslip (optional)
Additional reagents and equipment for imaging GFP-labeled proteins (see Basic Protocol 1)

1. Set up an inverted microscope and its associated hardware as described (see Basic Protocol 1, steps 1 to 2).

2. Place transformed *D. discoideum* cells grown on non-nutrient agar in an incubator at 22°C until aggregation streams or mounds have formed (~6 to 9 hr).

3. Directly mount the 35-mm petri dish containing the *D. discoideum* cells on the inverted microscope and observe with a 10× objective.

   The agar layer is thin enough to allow imaging through the agar with a 10× objective.

4. *For observation at higher magnifications (20×, 40×, and 63×):* Excise a small piece of agar containing aggregation streams or mounds with a scalpel and deposit the agar piece on its side onto a one-chambered coverglass or an Attofluor cell chamber fitted with a 35-mm coverslip.
5. Carefully pick up the agar piece, invert it, and lower it with the cells facing down onto the surface of the coverglass such that the mounds will be squashed against the glass.
6. Fill the chamber with silicone oil to prevent the agar from drying.
7. Mount the chamber on the microscope and start data acquisition.

BASIC PROTOCOL 3

GFP-LABELED PROTEINS IN SLUG PREPARATIONS

This protocol includes methods used to visualize structures appearing in later development such as slugs. Here again, optimal visualization will be obtained under lower magnification conditions.

Materials

Transformed *D. discoideum* cells (see Support Protocol 3) grown to log phase in liquid medium (see Support Protocol 1)
35-mm petri dish containing 0.5 ml of 1% (w/v) aqueous Bacto Agar (Difco)
Silicone oil (e.g., Dow Corning 200/20cs, BDH Chemicals)

Incubator, 22°C
Small rubber ring (1 mm high and 5 mm in diameter)

Additional reagents and equipment for imaging GFP-labeled proteins (see Basic Protocol 1)

Prepare D. discoideum slugs

1. Set up an inverted microscope and its associated hardware as described (see Basic Protocol 1, steps 1 to 2).
2. Dispense transformed *D. discoideum* cells, grown to log phase in liquid medium, in 50-ml aliquots into sterile conical tubes.
3. Centrifuge 4 min at 1500 × *g*, 22°C, and wash cells in DB.
4. Centrifuge as in step 3 and wash cells in water.
5. Centrifuge again, count cells (*UNIT 1.1*), and resuspend at 10^8 cells/ml in water.
6. Spot 10 µl cells on a 35-mm petri dish containing 0.5 ml of 1% aqueous Bacto Agar.
7. After 30 min, tilt the plate and blot excess fluid.

   The 30-min period will allow cells to adhere.
8. Place plate in the dark in an incubator at 22°C until slugs are formed (~16 to 36 hr).
9. Place a small rubber ring around a slug and carefully push the ring against the agar surface.

   This eliminates light scattering at the slug's surface.
10. Fill ring with a few drops of silicone oil to cover the slug.

View D. discoideum slugs

11. Directly mount the 35-mm petri dish on the inverted microscope and observe with a 10× objective.

    The slug can be viewed through the agar.

12a. *To view the slug from its side:* Carefully cut an agar piece with a slug on it, turn agar 90° around its long axis (relative to the long axis of the slug), and place it on a one-chambered coverglass. Immediately fill chamber with silicone oil and mount on the microscope.

12b. *To view at higher magnification:* Carefully cut an agar piece with a slug on it, invert agar 180°, and deposit it on a one-chambered coverglass, slug-side down. Fill chamber partly with silicone oil and mount on the microscope.

The agar should be cut right next to the slug tip. If the tip protrudes between the edge of the agar and coverglass, the slug usually continues to migrate.

13. Start data acquisition.

GROWING *D. DISCOIDEUM* AXENICALLY

SUPPORT PROTOCOL 1

The availability of axenic strains (i.e., strains that can grow in liquid cultures) renders growth of *D. discoideum* amoebae in the laboratory very simple (Sussman, 1987). The most common wild-type strains used are Ax2 and Ax3. The standard growth medium, HL5, is easily made in the laboratory. Over 10^{11} clonal amoebae can be grown and harvested in a few days without sophisticated equipment. The optimal growth temperature for the amoebae is 22°C; the cells will die at temperatures above 29°C. Amoebae are handled aseptically and grown in temperature-controlled incubators. Cells can be harvested at growth stage or at any developmental stage. In the early stages of development, the genetically identical cells differentiate synchronously and the population remains homogenous (Sussman, 1987). This allows biochemical analyses to be performed using a variety of physiologically relevant conditions. Amoebae can also easily and rapidly be grown on a lawn of bacteria (see Support Protocol 2). *D. discoideum* amoebae can readily be stored under liquid nitrogen as amoebae in the presence of glycerol or dimethyl sulfoxide. Alternatively, spores can be stored virtually indefinitely with silica gel at 4°C (Sussman, 1987).

Materials

D. discoideum cells (ATCC)
HL5 medium (see recipe)
Phosphate buffer (PB, see recipe)

100-mm tissue culture plate
250-ml tissue culture flask
Incubator, 22°C, with shaker

1. Aseptically grow *D. discoideum* cells to confluence in 12 ml HL5 medium in a 100-mm tissue culture plate in an incubator at 22°C.

The procedure can be scaled up as needed by increasing the number of plates used.

2. Using a 10-ml sterile pipet, transfer cells from the plate to a 250 ml tissue culture flask containing 100 ml HL5 medium.

This procedure can be scaled up or down depending on the need. A flask/medium volume ratio of ~2.5 is preferred for good aeration.

3. Shake at 200 rpm in the incubator at 22°C until log phase is reached.

Under these conditions, cells double every 10 to 12 hr and reach log-phase densities of 5 × 10^6 cells/ml in ~2 days.

4. Collect log-phase cells as needed by centrifuging 4 min at 1500 × *g*, 22°C.

5. Passage the mass culture plates every 3 to 5 days (split ratio of ~1:5) in HL5 medium (*UNIT 1.1*).

   These cultures can usually be kept for ~2 months.

SUPPORT PROTOCOL 2

GROWING *D. DISCOIDEUM* ON BACTERIAL LAWNS

Alternatively, *D. discoideum* can be grown on bacterial lawns (Sussman, 1987). This type of growth is used when studying phagocytosis.

Materials

Klebsiella aerogenes (ATCC)
HL5 medium (see recipe) without dihydrostreptomycin
D. discoideum amoebae (ATCC)
100-mm SM plates (see recipe)
Phosphate buffer (PB; see recipe)
Incubator, 22°C

1. Grow a dense culture of *Klebsiella aerogenes* in HL5 medium without dihydrostreptomycin overnight at room temperature with shaking at 250 rpm.

   Start cells from a single colony.

2. Mix ~10^6 *D. discoideum* amoebae with 200 µl grown bacterial culture and plate on a 100-mm SM plate.

   Use log-phase-grown amoebae.

   The procedure can be scaled up as needed by increasing the number of plates used.

3. Store plate in a humidified environment in an incubator at 22°C.

   Placing the plates in a closed plastic box in the incubator will provide an appropriately humid environment. Within 36 to 48 hr, the bacterial lawn will be cleared by the growing cells and ~10^9 amoebae can be recovered per 100-mm plate. It is important to recover the amoebae before they eat up the bacteria and enter the development program.

4. Add ~6 ml PB to the plate, scrape the layer of cells from the plate, and transfer to a 50-ml conical tube.

5. Repeat step 4 three times.

6. Centrifuge 1 min at 1000 × *g*, 22°C. Discard supernatant.

   This supernatant should remain turbid from the remaining bacteria.

7. Resuspend pellet in 50 ml PB.

8. Repeat steps 6 to 7 until supernatant is clear (usually three times).

9. Resuspend pellet as required for subsequent analysis.

SUPPORT PROTOCOL 3

PLASMID CONSTRUCTION AND TRANSFORMATION

Transformed lines of *D. discoideum* amoebae can be established using either integrating or episomal vectors (Nellen and Firtel, 1985; Manstein et al., 1995). Several selectable markers and promoters active during the developmental program have been well characterized (Egelhoff et al., 1991; Kay and Williams, 1999; Pang et al., 1999). Episomal vectors carrying Ddp1 sequence, which can amplify up to 100 copies per cell, and the actin 15 promoter/2H3 terminator expression cassette are used to establish cell lines expressing GFP fusion proteins (Hughes et al., 1994; Parent and Devreotes, 1996a,b).

This cassette gives rise to high constitutive levels of protein expression, and the extrachromosomal vector leads to little or no variation in protein expression between clones. Since the *D. discoideum* genome is ~70% A+T, a *recA* bacterial stain should be used to propagate the plasmid. In order for the gene to be translated, a ribosome binding site (RBS) must precede the ATG of the gene to be expressed. The 9-nucleotide RBS sequence, TTATAAAAA, has been routinely used for the constitutive expression of a variety of genes. The position of the GFP label within the protein will vary depending on the protein of interest. For information on plasmid construction, see *APPENDIX 3A*.

The enhanced version of GFP (eGFP; Clontech Laboratories), which harbors the F64L and S65T mutations and fluoresces about 35 times more intensely than wild-type GFP, has been used successfully in *D. discoideum*. This is the so-called red-shifted GFP because its maximal excitation peak is 490 nm compared to 395 nm for the wild-type GFP. Moreover, with the availability of eGFP variants in different colors (blue, cyan, green, and yellow; Clontech Laboratories), it is easy to perform double-and triple-labeling experiments.

When studying the distribution of a *D. discoideum* protein whose deletion by homologous recombination gives rise to a phenotype, gene replacement becomes a powerful tool to assess the functionality of the GFP fusion protein (see Commentary). Transformation of *D. discoideum* amoebae is accomplished by electroporation using supercoiled DNA preparations (Howard et al., 1988). The plasmid is introduced in both the wild-type and the appropriate null cells. Typically, transformants will appear 2 weeks after addition of G418. The cells should be kept under selection at all times during growth when episomal vectors are being used.

Materials

D. discoideum cells grown to log phase in liquid medium (see Support Protocol 1)
Electroporation buffer (EB; see recipe), ice cold
Supercoiled DNA vector encoding a GFP fusion protein
100-mm SM plate (see recipe)
Healing solution (see recipe)
HL5 medium (see recipe)
20 mg/ml (w/v) G418 solution (see recipe)
Klebsiella aerogenes prepared for bacterial lawns (see Support Protocol 2)

Electroporation cuvettes (0.2-cm electrode gap; e.g., Bio-Rad), ice cold
Electroporator (e.g., Gene Pulser II, Bio-Rad)
Incubator, 22°C, with shaker
24-well plates

Additional reagents and equipment for counting cells (*UNIT 1.1*), immunoblotting (see Support Protocol 4 and *UNIT 6.2*), and microscopic visualization (see Basic Protocols 1, 2, and 3; see Alternate Protocols 1 and 2)

NOTE: Unless otherwise mentioned, all manipulations are performed aseptically on ice.

Prepare cells

1. Dispense *D. discoideum* cells, grown to log phase in liquid medium, in 50-ml aliquots into sterile 50-ml conical tubes.
2. Centrifuge 4 min at 1500 × *g*, 22°C, count cells (*UNIT 1.1*), and resuspend at 4×10^7 cells/ml in ice-cold EB.
3. Remove 400 µl cells and mix in a sterile microcentrifuge tube with 5 to 10 µg supercoiled DNA vector encoding a GFP fusion protein.

   A vector containing GFP alone should be used as a control.

4. Incubate tube 4 min on ice.

Transform cells

5. Transfer cells to ice-cold electroporation cuvettes.
6. Place cuvettes in an electroporator and electroporate at 1.1 to 1.2 kV and 3 µF using a 5-Ω resistor in series with the chamber.

   A τ value of 0.5 to 0.7 msec should be obtained.

7. Move cuvette to ice and incubate 10 min.
8. Transfer electroporated cells to a 100-mm tissue culture plate using a sterile Pasteur pipet.
9. Add 2 µl healing solution and gently mix.
10. Incubate 15 min at room temperature.
11. Add 12 ml HL5 medium and incubate overnight in an incubator at 22°C.
12. Add G418 to 20 µg/ml.

Clone cells

13. When the plate is confluent, isolate clones by clonally plating cells on *Klebsiella aerogenes* bacterial lawns at ~100 amoebae per plate (see Support Protocol 2, steps 1 to 3).
14. Grow cells 4 to 5 days at 22°C (Fig. 12.5.3).
15. Select individual clones by scraping the feeding edge of the plaques and transferring into 24-well plates containing 20 µg/ml G418 in HL5 medium.
16. Move plate to 22°C incubator and allow growth.

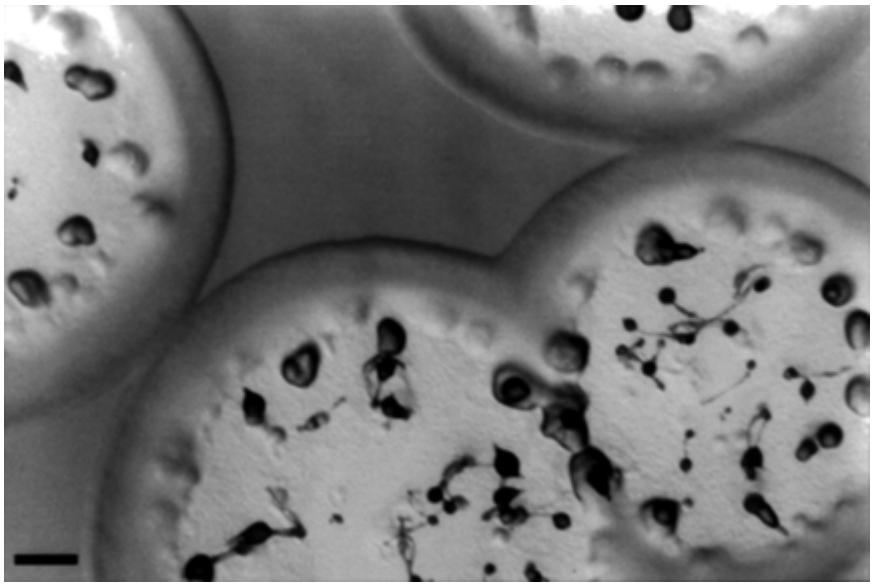

Figure 12.5.3 Cloning *D. discoideum* transformants on bacterial lawns. *D. discoideum* cells were mixed with *Klebsiella aerogenes* bacteria, plated on SM plates, and incubated at 22°C. This picture was taken 5 days after plating. Four cleared plaque regions are partially visible. Each plaque arose from a unique clone. Bar is 1.5 mm.

17. Analyze individual clones for GFP expression by immunoblotting (see Support Protocol 4 and *UNIT 6.2*) or microscopic visualization (see Basic Protocols 1, 2 and 3 and Alternate Protocols 1 and 2).

PHENOTYPIC SCREENING BY IMMUNOBLOTTING

SUPPORT PROTOCOL 4

The level of expression of the fusion protein is assessed by performing immunoblot analysis using commercially available antibodies directed against GFP (also see *UNIT 6.2*). This is especially important because it will confirm that the full-length GFP fusion is expressed and will provide information on the level of expression. In addition, probing with an antibody directed against the protein of interest allows one to compare the level of expression of the endogenous protein to that of the fusion protein. This is sometimes difficult as the epitope recognized by the antibody can be masked by the presence of the GFP.

Materials

Transformed *D. discoideum* cells (see Support Protocol 3) grown to log phase in liquid medium (see Support Protocol 1)
Developmental buffer (DB; see recipe)
4× SDS sample buffer (*APPENDIX 2A*)
Anti-GFP antibody (e.g., Clontech Laboratories)
Antibody directed against protein of interest (optional)

Additional reagents and equipment for SDS-PAGE (*UNIT 6.1*) and immunoblotting (*UNIT 6.2*)

1. Dispense transformed *D. discoideum* cells, grown to log phase in liquid medium, into 50-ml tubes.

   A cell line that does not express GFP should be used as a control.

2. Centrifuge 4 min at 1500 × *g*, 22°C, and wash cells in DB.
3. Centrifuge as in step 2 and resuspend at 2×10^7 cells/ml in DB.
4. Transfer cells to a flask and shake 2 hr at 100 rpm.

   This starvation period will downregulate the expression of proteases and therefore limit protein degradation.

5. Mix 200 µl cells with 67 µl of 4× SDS sample buffer in a microcentrifuge tube.
6. Boil 2 min.
7. Carry out SDS-PAGE (*UNIT 6.1*), loading ~53 µl sample (8×10^5 cellS) per lane.
8. Transfer gel to nitrocellulose membrane.
9. Perform immunoblot analysis (*UNIT 6.2*) using an anti-GFP antibody and an antibody directed against the protein of interest (optional).

PHENOTYPIC SCREENING BY DEVELOPMENT ON NON-NUTRIENT AGAR

SUPPORT PROTOCOL 5

The functionality of the GFP fusion protein is assessed by determining if it behaves as its wild-type counterpart when expressed in the null background. In order to assess the effect (or noneffect) of the GFP fusion protein on normal development, this characterization is also performed when the fusion protein is expressed in wild-type cells. The procedure is simple and fast—wild-type cells will differentiate and form fruiting bodies 24 hr after the

initiation of the starvation period (Fig. 12.5.4). Moreover, the whole developmental program can be readily recorded using time-lapse video. Alternatively, development can be assessed by clonally plating amoebae on bacterial lawns (see Support Protocol 2).

Materials

Transformed *D. discoideum* cells (see Support Protocol 3) grown to log phase in liquid medium (see Support Protocol 1)
Developmental buffer (DB; see recipe)
Developmental buffer agar (DB agar; see recipe)
35-mm petri dish
Incubator, 22°C

1. Dispense transformed *D. discoideum* cells, grown to log phase in liquid medium, in 50-ml aliquots into sterile conical tubes.

   Wild-type cells should be used as controls.

2. Centrifuge 4 min at 1500 × *g*, 2°C, and wash cells in DB.
3. Centrifuge again, count cells (*UNIT 1.1*), and resuspend at 1×10^7 cells/ml in DB.
4. Transfer 1 ml cells to a 35-mm petri dish containing 0.5 ml DB agar.
5. Let cells adhere 5 min.
6. Tilt plate, wait 5 min, and aspirate excess buffer.
7. Let air dry 2 min.
8. Replace lid and store plate in a humidified environment in an incubator at 22°C.

   Placing the plates in a closed plastic box in the incubator will provide an appropriately humid environment.

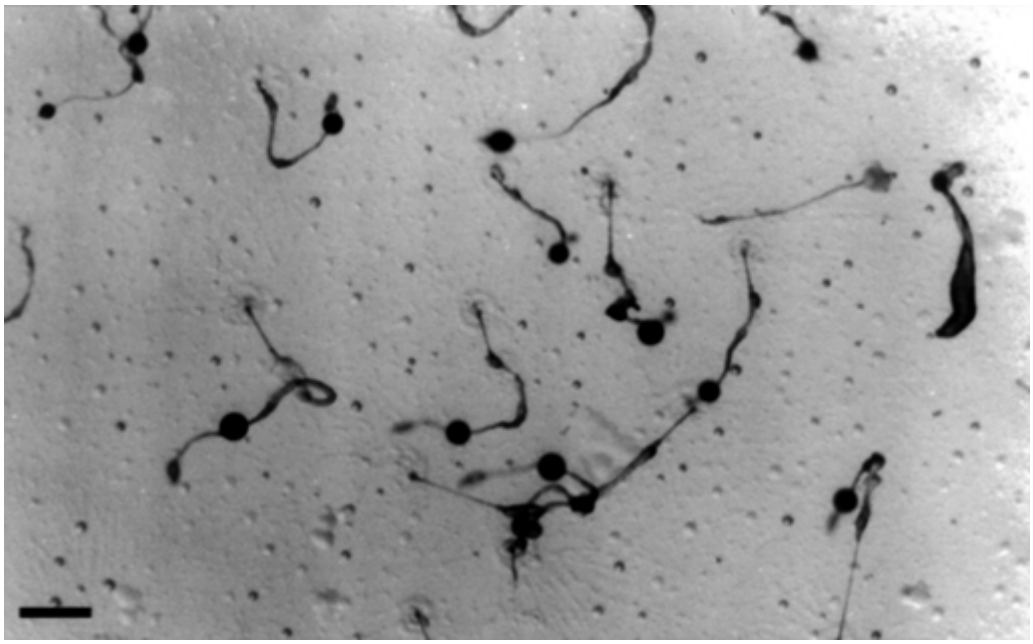

Figure 12.5.4 Development of *D. discoideum* on non-nutrient agar. Wild-type *D. discoideum* cells were grown axenically (see Support Protocol 1), plated on non-nutrient agar (see Support Protocol 5), and incubated at 22°C. This picture was taken 24 hr after plating. Bar is 1.5 mm. Note the characteristic spore heads on top of the stalks that form the fruiting bodies. Mutants can give rise to a wide variety of developmental phenotypes.

9. Assess development as appropriate.

The developmental program of the cells can be recorded so that the 24-hr period is compressed into a few minutes. This is easily accomplished by connecting a video camera to the microscope and using a time-lapse video recorder to capture images. For best results, a low-magnification objective should be used (2.5× to 5×). Since the cells are sensitive to high temperature, care should be taken to use a very dim light source. The functionality of the GFP fusion protein is then easily assessed by comparing the phenotype of the transformed cell line with that of wild-type cells. A comprehensive analysis of the developmental program of wild-type cells can be found in Kessin (2000) and references within.

REAGENTS AND SOLUTIONS

Use deionized distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Developmental buffer (DB)

5 mM $Na_2HPO_4 \cdot 7H_2O$
5 mM KH_2PO_4
2 mM $MgSO_4$
200 µM $CaCl_2$
Final pH 6.2
Store up to 6 months at 4°C

Developmental buffer agar (DB agar)

Add 1% (w/v) Difco Bacto Agar to 50 ml DB (see recipe) in 100-ml bottles and autoclave on liquid cycle for 20 min. Store up to 6 months at room temperature. When ready for use, unscrew the cap and microwave until the agar is melted.

Electroporation buffer (EB)

10 mM sodium phosphate buffer, pH 6.1 (*APPENDIX 2A*)
50 mM sucrose
Final pH 6.1
Filter sterilize using 0.22-µm filters
Store up to 6 months at −20°C

G418 solution, 20 mg/ml

Prepare a 20 mg/ml solution in 10 mM HEPES, pH 7.2. Filter sterilize using 0.22-µm filters, dispense into 0.5-ml aliquots, and store at −20°C.

Healing solution

100 mM $CaCl_2$
100 mM $MgCl_2$
Filter sterilize using 0.22-µm filters
Store up to 6 month at 4°C

HL5 medium

10 g glucose (55 mM final)
10 g Difco Peptone (1% w/v final)
5 g yeast extract (0.5% w/v final)
0.95 g $Na_2HPO_4 \cdot 7H_2O$ (3.5 mM final)
0.5 g KH_2PO_4 (3.7 mM final)
0.03 g dihydrostreptomycin (41 µM final)
H_2O to 1 liter
Final pH 6.5

continued

Mix all components and divide into aliquots in bottles and flasks. Cover flasks with a stopper made of cotton cheesecloth. Autoclave 20 min on liquid cycle. Store up to 1 month at 22°C.

Autoclaving for longer periods will cause the glucose to caramelize (making the medium appear darker) and serious growth problems to occur.

Phosphate buffer (PB)

5 mM $Na_2HPO_4 \cdot 7H_2O$
5 mM KH_2PO_4
Final pH 6.2
Store up to 6 months at 4°C

SM plates

10 g dextrose (55 mM final)
10 g Difco Bacto Peptone (1% w/v final)
1 g yeast extract (0.1% w/v final)
1.9 g KH_2PO_4 (13.9 mM final)
0.9 g K_2HPO_4 (5.2 mM final)
20 g Difco Bacto Agar (2% w/v final)
H_2O to 1 liter
Final pH 6.4
Autoclave 20 min on liquid cycle
Pour 25 ml per 100-mm petri dish
Let solidify at room temperature
Store up to 6 months at 4°C

COMMENTARY

Background Information

D. discoideum amoebae live in two distinct phases (Bonner, 1982). Vegetative or growth-stage cells function independently and use phagocytosis or pinocytosis to ingest bacteria or liquid medium. Similar to mammalian cells, amoebae grown in liquid medium divide using binary fission. Upon starvation, the amoebae acquire the capacity to communicate with one another and enter a developmental program that leads to the formation of a multicellular organism. In the early stages of development, ~10^5 amoebae use chemotaxis to come together and form a tight aggregate. This aggregate then differentiates into stalk and spore cells and, through a series of morphological changes, forms a spore head atop a stalk of vacuolated cells—the so-called fruiting body. Once environmental conditions are favorable again, the spores germinate and repeat the life cycle. The unique feature of *D. discoideum*'s life cycle allows one to study in great detail the dynamic behavior of individual cells. Moreover, the advent of the GFP technology now allows one to readily assess the dynamic behavior of individual proteins within living, migrating cells.

The growth and developmental programs of *D. discoideum* are mediated via the evolutionarily conserved G protein–coupled signaling cascade (Parent and Devreotes, 1996a; Aubry and Firtel, 1999). Four hours after the initiation of starvation, cells maximally synthesize and secrete cAMP. Through the action of an extracellular phosphodiesterase, cAMP is produced at 6-min intervals. These oscillations in the levels of cAMP produce propagating waves that generate gradients directing the cells toward the aggregating centers. At the same time, G protein–coupled receptors that specifically bind cAMP are expressed on the cell surface, and binding of the nucleotide to its receptor leads to a variety of biochemical responses. As is observed when leukocytes are stimulated with chemoattractants, rapid and transient increases in polymerized actin, Ca^{2+} influx, intracellular messengers such as IP_3, cAMP, and guanosine 3′,5′-cyclic monophosphate (cGMP), and in the phosphorylation of myosins I and II have all been measured following cAMP addition to amoebae.

In the early aggregation period, these biochemical changes give rise to chemotactic movement and changes in gene expression, both of which are essential components of normal development. Genetic and biochemical analyses have established that, throughout

growth and development, four cAMP receptors (cAR1 to 4) coupled to eleven G proteins (composed of eleven distinct α subunits associated with a unique βγ-complex) are expressed. Similarly, various conserved signaling effectors are expressed at specific times in the course of the *D. discoideum* life cycle. A number of these effectors have been identified by cloning and through information emerging from the genome and cDNA sequencing projects. These effectors include: adenylyl and guanylyl cyclases, phosphodiesterases, phospholipase C, protein kinase A, glycogen synthase 3, small guanosine trisphosphatases and their regulators, actin and a plethora of actin binding proteins, conventional and unconventional myosins, MAP kinases, two-component histidine kinases, and STATs, which are not present in yeast (Harwood et al., 1995; Parent and Devreotes, 1996a; Kawata et al., 1997; Maeda et al., 1997; Brown and Firtel, 1998; Loomis, 1998; Loomis et al., 1998; Aubry and Firtel, 1999; Eichinger et al., 1999; Thomason et al., 1999; Williams, 1999).

D. discoideum's highly accessible genetics renders it a unique model system to study fundamental cellular processes including cell motility and directed migration (Eichinger et al., 1999). Most of the molecular genetic techniques typically associated with *S. cerevisiae* are available in *D. discoideum*. Random mutagenesis can be performed using high-efficiency extrachromosomal vectors (Parent and Devreotes, 1996a). Because the genome is haploid, novel genes can be identified using insertional mutagenesis or restriction-enzyme-mediated integration (REMI; Kuspa and Loomis, 1992). Nonessential genes can be easily disrupted by homologous recombination (De Lozanne and Spudich, 1987). So far, over 400 genes involved in cell motility, signal transduction, and cell differentiation have been targeted, and important generalizations for eukaryotic cells have been derived using these cell lines. Strains with multiple gene deletions can be constructed by consecutive transformations using different selectable markers. Since the cells are free living, gene deletions that might be lethal in other organisms can often be productively studied in *D. discoideum* (Kay and Williams, 1999).

Using phenotypic complementation of null mutants with GFP fusion proteins is extremely useful for cell biology. Because heterologous expression of yeast and mammalian genes is possible in *D. discoideum*, this technique can be used to assess the functionality of endogenous as well as heterologous genes (Manstein et al., 1995; Slade et al., 1997; Pang et al., 1999; Parent and Devreotes, unpub. observ.). Moreover, studying the phenotypic behavior of wild-type cells overexpressing wild-type or mutated genes is very useful in assessing the function of a given protein. Consequently, the high degree of conservation between amoebae and higher eukaryotes at the cellular and molecular levels coupled to the accessible genetics of this model system renders the study of fundamental biological processes observed in *D. discoideum* indispensable for deciphering complex biological responses.

Critical Parameters and Troubleshooting

Using *D. discoideum* to study cell motility has many advantages. Compared to mammalian cells, amoebae are easy to grow and manipulate. The medium is readily made in the laboratory and is inexpensive. As amoebae eat bacteria, the risk of bacterial contamination is small, and the optimal growth temperature of 22°C is very convenient. The cells adhere well to plastic and glass but do not require trypsinization procedures. Stable transformants are easily obtained and maintained, and phenotypic characterization is rapid. Nonetheless, there are some aspects of *D. discoideum* research that require special attention.

1. The quality of the peptone used to make the HL5 medium is critical for proper growth. It has been observed that the Difco brand gives by far the best results. Suboptimal medium will result in slow or no growth.

2. When growing cells on bacterial lawns, the author has found that using overgrown cultures of *Klebsiella aerogenes* results in serious growth problems. Growing the bacterial cultures overnight at room temperature gives rise to the best results.

3. A transformation efficiency of ~1/1000 is expected when using extrachromosomal vectors. Good quality DNA preparations free of contaminants and salt will give the best results. Also, because the heat generated by the electrical shock can kill the cells, prechilling the cuvette and using ice-cold buffer is critical. Looking at the cells 24 hr after electroporation, before the selection antibiotic is added, is a good way to see if the cells were harmed by the electrical burst. At that time, most of the cells should be adhering to the bottom of the plate.

4. Performing a dose-response curve analysis for the effectiveness of G418 on the survival of wild-type cells is preferable. This is

achieved by simply adding various concentrations of G418 to wild-type cells and monitoring cell survival. The optimal concentration should be close to 20 μg/ml.

5. Development on non-nutrient agar is influenced by environmental conditions, and most of the abnormal developmental problems are caused by an inadequate level of humidity on the plate. This can be fixed by not air drying the plate after aspirating the excess buffer and simply leaving it slightly tilted with the lid on.

6. When assessing the effect of receptor stimulation on the cellular distribution of the GFP fusion protein, it is essential to make sure that the cells are expressing cAMP receptors (a key point when studying cells that display a developmental phenotype). This is accomplished by performing immunoblot analysis using a specific polyclonal antibody directed against cAR1 (a receptor expressed in early development) on samples taken from developed cells.

Time Considerations

The limiting step in these procedures is obtaining the transformants, which under normal conditions will require ~2 to 3 weeks. Once the phenotypic characterization is completed (~1 week), the live-cell imaging is fast and rewarding.

Optical Microscopy–Based Migration Assay for Human Neutrophils

This unit describes an in vitro microscopy assay for examining the migration of human neutrophils in two dimensions. The method is particularly useful for identifying the underlying cause of a migration defect, and it can be used to evaluate a variety of migration parameters (e.g., speed and directional persistence) that cannot be easily discerned from assays based on migration through a porous barrier (e.g., Boyden chamber assays; *UNIT 12.4*). For this assay, freshly isolated human neutrophils are added to microscopy chambers and then stimulated to migrate with a chemotactic agent. Images of fields of cells are acquired at multiple time points after stimulus addition. The images are used to create time-lapse movies that can be analyzed to determine the effects of specific pharmacological treatments on migration of individual cells.

The Basic Protocol describes the method for acquiring time-lapse images of migrating neutrophils, while support protocols describe isolation of human neutrophils from blood (see Support Protocol 1) and preparation of microscopy chambers (see Support Protocol 2).

NOTE: There are special ethical and safety considerations for working with human cells.

NOTE: All solutions and materials used with living neutrophils should be sterile and free of lipopolysaccharide (LPS, endotoxin) contamination, which will activate the neutrophils (see Critical Parameters).

ACQUIRING TIME-LAPSE IMAGES OF MIGRATING NEUTROPHILS

BASIC PROTOCOL

A crucial initial step in an inflammatory response is the migration of neutrophils and other immune cells toward chemotactic stimuli. Cell migration requires a highly orchestrated series of attachment and detachment events, which occur in concert with protrusive and contractile forces. Importantly, each step in the process must be regulated in both space and time, and so investigations of migration mechanisms often warrant assays that provide both types of information. The assay described here measures the extent to which neutrophils translocate (i.e., migrate in two dimensions) in response to an isotropic bath of chemoattractant. This assay is based on the observation of cells by optical microscopy, which provides intracellular and extracellular spatial information. Temporal information is available because the cells are imaged at various times after stimulation, rather than at a single fixed timepoint.

Materials

HBS, pH 7.4 (see recipe)
50× (0.5 M) glucose stock solution (filter sterilize and store at 4°C)
Human neutrophils, freshly isolated (see Support Protocol 1)
Formyl-Met-Leu-Phe (fMLF)

1.5-ml polypropylene microcentrifuge tubes
End-over-end rotator or platform rocker
Air-curtain heater (Arenberg Sage)
35-mm fibronectin-coated coverslip dishes (see Support Protocol 2)
Humidified slide warmer (LabLine Instruments)
Inverted microscope equipped for digital imaging with 20×, 40×, or 63× objective

Contributed by Lynda M. Pierini and Frederick R. Maxfield
Current Protocols in Cell Biology (2003) 12.6.1-12.6.15

NOTE: Neutrophils are readily activated by shear forces or by contact with certain surfaces. Cells should be handled gently, transferred using wide-bore pipet tips, and kept in polypropylene (as opposed to glass or polystyrene) vessels.

Prepare cells, coverslip dishes, and microscope

1. On the day of the experiment, prepare ~25 ml of HBS, pH 7.4, with 10 mM glucose (added from 50× glucose stock) for every ten coverslip dishes to be used. Prewarm the HBS/glucose to 37°C and maintain at that temperature.

2. For every coverslip dish to be used, prepare 50 µl of neutrophil suspension at 1–2 × 10^6 cells/ml in HBS/glucose. Prepare in bulk (up to 1.5 ml per 1.5-ml conical tube) and place on a slow-moving rotator or rocker at room temperature.

   If testing the effects of a particular pretreatment (e.g., pharmacological agent) on the migration of neutrophils, split the cells into the appropriate number of aliquots and treat the test samples at this time.

3. Prewarm the microscope stage to 32° to 35°C with an air-curtain heater for 30 to 60 min before the start of the experiment.

   Neutrophil migration is completely abrogated at temperatures above ~39°C, so it is essential that the temperature of the microscope stage and objective be carefully monitored throughout the experiment.

   Typically, the air-curtain heater should be placed 4 to 6 in. (10 to 15 cm) away from the microscope stage and aimed so that warm air is blown across both the stage and the objective. As an alternative, a microscope objective heater may be used (e.g., Bioptechs; http://www.bioptechs.com).

   If using an oil-immersion objective, prewarm the immersion oil to the same temperature as the stage and objective. This will minimize focus drift caused by temperature-dependent changes in oil viscosity.

4. When ready to begin, remove excess PBS from a 35-mm fibronectin-coated coverslip dish and add 50 µl of cell suspension to the well in the center of the dish. Place the coverslip dish onto a humidified slide warmer maintained at 37°C, and let cells settle onto the coverslip for 5 min.

5. Gently add 1 ml of warm HBS/glucose to the coverslip dish, adding the buffer off to the side of the dish so that cells do not become dislodged.

   Neutrophils will not become tightly adherent until after they are stimulated. For this reason, it is easy to accidentally wash them away.

6. Transfer the coverslip dish to the microscope stage and look at the cells using transmitted light illumination and any contrast method available (e.g., phase contrast or differential interference contrast) to confirm by morphology that the cells are healthy and resting.

   Neutrophils are relatively thick cells that are best imaged with differential interference contrast optics, which allows detailed observation of morphological changes. Phase-contrast imaging is usually less informative because the cells become extremely refractile at some points during migration.

   This is a good time to evaluate the activation state of the neutrophils. As noted above, resting neutrophils should not be tightly adherent and they should not spread on the coverslip. Usually <10% of the cells will attach, spread, and become spontaneously polarized; the remainder of the cells will be rounded with smooth plasma membranes (see Fig. 12.6.1). If much greater than 10% of the neutrophils appear to be activated in the absence of exogenously added chemoattractant, subtle effects of experimental treatments may be difficult to detect. In this case, the investigator may wish to discard the samples and

begin again with a fresh blood draw from a different donor. If >40% of the neutrophils appear to be activated, neutrophils should be re-isolated from a new donor. If the basal level of activation of the neutrophils from various donors is consistently high, all solutions used in the isolation procedure should be discarded and prepared anew. LPS contamination should be considered (see Critical Parameters). Mechanical stimulation (e.g., from an unbalanced centrifuge) can also cause activation.

Add chemoattractant and begin image acquisition

7. Prepare a 20 nM solution of fMLF in HBS/10 mM glucose (see step 1) and maintain at 37°C in a water bath. Gently add 1 ml of the warm 20 nM fMLF solution to the periphery of the coverslip dish on the microscope stage and let stand for 2 min.

   Because the cells are in an isotropic bath of chemoattractant (i.e., there is no gradient), they will become oriented in random directions.

8. Begin image acquisition. Acquire a transmitted-light image of the same field of cells every 10 to 20 sec for 4 min. Save this series of images, then acquire a second and third series of images of different fields from the same dish.

   Alternatively, a single, longer time series can be acquired if detailed analyses of cell paths and behaviors are to be performed.

   After data acquisition is complete, the sample can be discarded or used for immunofluorescence staining (see UNIT 4.3).

9. Repeat steps 4 to 8 with fresh cells and a new coverslip dish.

Analyze cell behavior

10a. *To determine the migration capacity of neutrophils:* Draw a circle of a fixed diameter around each cell within the first image of the time series. For each cell in the field, step through the images in the sequence and note whether the cell has moved out of its circle (i.e., for each cell, determine if the cell's centroid has translocated beyond the perimeter of the circle).

   It is not sufficient just to compare the first and last images in a time series because cells may have moved out and then back into their circles and would thus be scored as nonmigratory. Alternatively, cells may become detached during the course of the assay and so may no longer reside within their starting circles; these cells would mistakenly be scored as migratory.

   Some cells become very elongated. Depending on the intent of the experiment, a cell whose front, but not rear, moves outside the circle can be counted or not, as long as the criterion is specified and consistent throughout the analysis.

   There are sophisticated image-analysis programs that can perform this sort of analysis in an automated fashion. A description of these programs and their use in analyzing time-lapse movies is beyond the scope of this unit. It should be noted that automated analysis of migration is most easily accomplished using fluorescence images of labeled cells rather than transmitted-light images in which object identification is more difficult.

   Choosing the diameter of the circle to draw around the cells in the initial images is somewhat arbitrary. For historical reasons, the authors ordinarily use a 14-μm-diameter circle, so a migrating neutrophil is defined as one that has translocated >7 μm in 4 min. With this definition, 60% to 90% of control cells are migratory. All samples on a given day should be evaluated using circles with the same diameter.

   The neutrophil preparation used for these studies will contain a small percentage (1% to 5%, depending on the donor) of eosinophils. Eosinophils are relatively easy to identify because their cytoplasm is full of distinct spherical granules that are generally larger and more refractile than the granules in neutrophils (see Fig. 12.6.3). Cells that are clearly identifiable as eosinophils should not be considered in the data analysis.

   To compare data from experiments performed on different days, results should be normalized relative to the migratory level of the control cells.

10b. *To determine displacement, persistence, and turning behavior of individual cells:* Track and analyze each cell manually or by computer. To track cell paths manually, mark and record the positions of every cell's center in each field, then enter these positions into a graphing program for further analysis (Mandeville et al., 1995).

SUPPORT PROTOCOL 1

ISOLATING HUMAN NEUTROPHILS

Primary human neutrophils cannot be maintained in culture, making it necessary to isolate neutrophils from volunteers each day of an experiment. The first step of the isolation procedure is based on a centrifugal technique that separates neutrophils from red blood cells (RBCs) and most other leukocytes. The neutrophil-containing layer of cells isolated in this way will contain a small percentage of contaminating RBCs and eosinophils. RBCs are nearly completely removed from the preparation by using hypoosmotic shock to preferentially lyse the RBCs, leaving the neutrophils and eosinophils unharmed. Contaminating eosinophils typically comprise only 1% to 5% of the remaining cells and can be easily identified and disregarded during image analysis.

This separation technique is based on the density of human neutrophils and the osmolality of the separation medium. It is likely that the density of neutrophils from other animals will differ slightly from that of human neutrophils, so the density of the separation medium (i.e., Polymorphprep) will have to be adjusted if the protocol is to be used for isolation of neutrophils from animals other than humans. Suggestions for adjustments can be obtained from the manufacturer.

CAUTION: Only qualified and experienced personnel, following governmental and institutional guidelines for working with human subjects, should draw blood from donors.

NOTE: It is important to verify that the donor is healthy and not taking any medications because neutrophil function may be altered under these circumstances.

Materials

Sodium heparin
Healthy volunteer blood donor
Polymorphprep density gradient medium (Accurate Chemical & Scientific Corp.)
5× PBS (see recipe)
HBS/glucose: HBS, pH 7.4 (see recipe), containing 10 mM glucose added from 0.5 M stock (see Basic Protocol)

15- and 50-ml conical polypropylene centrifuge tubes
Tourniquet
Alcohol wipes
21-G needles
10-ml disposable syringes
Tabletop centrifuge with swinging-bucket rotor

Additional reagents and equipment for counting cells with a hemacytometer (*UNIT 1.1*)

NOTE: Use PBS without calcium or magnesium throughout the isolation procedure until the final resuspension step. Divalent cations in HBS will cause cells to aggregate.

Obtain donor blood sample

1. Place 200 U sodium heparin in a 15-ml conical tube.

   The authors have avoided using Vacutainers because they tend to stimulate the neutrophils. Newer plastic Vacutainers have not been evaluated for this assay.

2. Place tourniquet on a healthy donor's arm, swab arm with alcohol wipe, and then draw 10 ml blood using a 21-G needle and a 10-ml syringe.

   The health of the blood donor is essential to the success of the assay. For further details, see Critical Parameters.

3. Immediately transfer blood into the heparin-containing conical tube. Mix the heparin and blood by gently inverting the capped tube several times, and then let stand 10 min to allow blood to cool to room temperature.

   The blood should be used within 2 hr of being drawn from the donor.

Isolate neutrophils

4. Place 5 ml Polymorphprep into each of two 15-ml conical tubes. Carefully layer 5 ml of the heparinized blood onto the top of the Polymorphprep in each tube using a sterile polypropylene transfer pipet. Cap the tubes and centrifuge 30 min at 450 × *g*, room temperature (18° to 22°C), in a swinging-bucket rotor.

   At the end of the centrifugation step, several layers can be discerned within each tube, including (from bottom to top) a dark red layer consisting largely of RBCs, a clear layer containing Polymorphprep with some RBCs and some neutrophils, a fuzzy white band containing neutrophils and eosinophils, a tight white band of mononuclear cells (T cells, B cells, and monocytes) at the sample/medium interface, and a yellow layer of plasma. The two white bands of leukocytes are typically separated by 0.5 to 1.0 cm. If RBCs are clumped at the top of the clear Polymorphprep layer such that the band of neutrophils is not clearly defined, centrifuge the samples for an additional 5 to 10 min.

5. From each tube, carefully aspirate the yellow plasma layer and top tight white band (mononuclear cells), leaving the fuzzy white band (containing neutrophils and eosinophils). Remove the neutrophil-containing band from each tube with a sterile polypropylene transfer pipet and combine in a single 50-ml conical tube. Collect the clear Polymorphprep layer from each tube and add to the neutrophils.

   When removing the tight white band of mononuclear cells (i.e., the upper band), it is best to err on the side of losing some neutrophils so that purity is optimized over yield. The number of neutrophils obtained from this procedure is far greater than needed for the migration assay.

6. Fill the 50-ml conical tube with 1× PBS and sediment cells by centrifuging 10 min at 400 × *g*, room temperature (18° to 22°C).

7. Aspirate the PBS. Resuspend neutrophil pellet in 1 ml of 1× PBS and transfer to a 1.5-ml microcentrifuge tube.

   The cell suspension appears reddish because it contains contaminating RBCs in addition to neutrophils and eosinophils.

Remove contaminating RBCs

8. Microcentrifuge 6 to 8 sec at 10,000 rpm (7,500 × *g*). Aspirate supernatant, leaving reddish pellet.

9. Using a wide-bore pipet tip, carefully resuspend pellet in 800 µl water.

10. Allow RBCs to lyse for 30 sec and then add 200 µl of 5× PBS. Rapidly mix the contents of the tube by capping the tube and inverting several times. Immediately sediment cells in microcentrifuge as in step 8, then aspirate the supernatant.

    Keeping the cells in water for <30 sec will result in incomplete lysis of RBCs, while waiting significantly longer than 30 sec may damage the neutrophils.

11. Resuspend the pellet from step 10 in 1 ml of 1× PBS. Microcentrifuge as in step 8 and aspirate the supernatant. Repeat wash and resuspend final pellet in 1 ml HBS/glucose.

12. Determine concentration of cells using a hemocytometer (see *UNIT 1.1*).

Neutrophils can be kept on ice or at room temperature for several hours before use. In general, neutrophils should be used within 4 to 6 hr of isolation.

SUPPORT PROTOCOL 2

PREPARING COVERSLIPS AND MICROSCOPY CHAMBERS

Long-term observation of live cells often requires specialized chambers to maintain cell viability. Neutrophil migration assays are typically completed within 30 min, so environmentally controlled perfusion chambers are unnecessary. Instead, the open-air chambers described below are adequate, and they are less expensive and easier to use than most perfusion setups. Prefabricated chambers with poly-D-lysine-coated coverslips can be purchased from commercial sources (e.g., MatTek) for approximately twice the cost of making them.

NOTE: These chambers are open to the air, so bicarbonate-buffered media cannot be used.

NOTE: Chemotaxis chambers can be constructed from these sample chambers by covalently attaching opsonized erythrocytes to the coverslip surface (Pytowski et al., 1990).

Materials

Nochromix glass cleaning reagent (Godax Laboratories) mixed with H_2SO_4 per manufacturer's instructions
Paraffin
Petroleum jelly
1× PBS (see recipe)
0.1 mg/ml fibronectin (see recipe)

Glass coverslips (thickness should be matched with recommendation of microscope manufacturer)
35-mm tissue culture dishes
Sheet metal hole punch
Cotton-tipped applicator or fine-tipped paint brush

Prepare coverslips

1. Clean glass coverslips by immersing in Nochromix/H_2SO_4 solution for 1 hr. Make sure that coverslips are well separated so that the surfaces of all of the coverslips are exposed to the cleaning solution.

   CAUTION: *Nochromix cleaning solution is extremely caustic. Use appropriate safety gear and procedures.*

2. Remove the Nochromix/H_2SO_4 solution, rinse the coverslips with water three times, then soak for 1 hr in water. Repeat this water rinse and soaking process two more times.
3. Remove clean coverslips from the last wash one at a time using a pair of tweezers. Place coverslips in a single layer onto filter paper and let dry. Store clean, dry coverslips in a covered receptacle.

Prepare coverslip dishes

4. Prepare a mixture of paraffin/petroleum jelly at a ratio of 3:1 (v/v) by first melting enough paraffin over low-medium heat to yield 75 ml. Bring the volume of the liquefied paraffin up to 100 ml by adding petroleum jelly. Stir the mixture well.

   This mixture can be stored for up to 6 months and remelted over low-medium heat when needed. The mixture should be stirred before each use, and the last ~25 ml of the mixture should be discarded because the composition changes with repeated heatings.

5. Punch a 1.2-cm-diameter hole in the bottom center of a 35-mm tissue culture dish using a sheet metal punch.
6. Keeping the dish in an inverted orientation, use a cotton-tipped applicator or a fine-tipped paint brush to spread a thin layer of melted paraffin/petroleum jelly around the perimeter of the hole on the outside surface of the dish. Allow paraffin/petroleum jelly to resolidify on the dish.
7. Place a single clean, dry coverslip atop the solid ring of paraffin/petroleum jelly on the underside of the dish.
8. To affix the coverslip to the dish, warm the inverted dish (with coverslip on top) briefly to liquify the paraffin/petroleum jelly, and then let cool to room temperature.

   To warm the inverted dish, an inverted hot plate or an infrared lamp can be positioned such that heat from the hot plate or infrared lamp will warm items underneath. The heating rate should be set so that the paraffin/petroleum jelly mixture melts in ~5 sec when the inverted dish (with its coverslip on top) is warmed. Immediately after the paraffin/petroleum jelly melts, remove the dish from the heat and let it cool to room temperature.

   The result will be a well in the center of the right-side-up dish. The coverslip forms the bottom of the well, and the sides of the hole in the dish form the sides of the well. The thin solidified ring of paraffin/petroleum jelly, which seals the coverslip to the dish, does not contribute significantly to the depth of the well.
9. Store coverslip dishes for up to 6 months at room temperature. Dishes should be stored in an inverted position to prevent scratching of the coverslips and to keep debris from collecting in the wells.

Coat coverslip dishes with fibronectin (perform on day of assay)

10. Rinse the well of each coverslip dish three times with 1× PBS. Apply 50 µl of 0.1 mg/ml fibronectin to the well of each coverslip dish and allow to stand at room temperature for 30 to 60 min. Carefully wash the coverslip dishes three times with 1× PBS, and then leave covered with PBS until use.

REAGENTS AND SOLUTIONS

Use enodotoxin-free deionized water in all recipes and protocol steps. For common solutions see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Fibronectin, 0.1 mg/ml

Purchase lyophilized human fibronection (1.0 mg per vial) from BD Biosciences. To rehydrate lyophilized fibronectin, add 1 ml of distilled water and let stand at room temperature for 1 hr, gently swirling the solution periodically to completely dissolve the fibronectin (do not vortex). Store fibronectin at 4°C and use within one month of rehydration. Dilute fibronectin 1:10 (v/v) with 1× PBS (see recipe) on day of use.

HEPES-buffered saline (HBS), pH 7.4

200 µl 5 M $MgCl_2$ (1 mM final)
0.147 g $CaCl_2$ (1 mM final)
0.37 g KCl (5 mM final)
8.8 g NaCl (150 mM final)
4.8 g HEPES (20 mM final)
H_2O to 1 liter
Adjust to pH 7.4 with 1 M NaOH or 1 M HCl
Filter sterilize and store up to 4 months at 4°C

The authors prefer to use a commercial $MgCl_2$ stock solution (e.g., 49 M $MgCl_2$ from Sigma) because $MgCl_2$ is very hygroscopic and difficult to weigh accurately.

Phosphate-buffered saline (PBS), 5×

1.0 g KH_2PO_4 (7.5 mM final)
40.0 g NaCl (685 mM)
1.0 g KCl (13.5 mM)
5.8 g Na_2HPO_4 (40.5 mM)
H_2O to 1 liter
Adjust to pH 7.4 with 1 M NaOH or 1 M HCl
Filter sterilize and store up to 4 months at 4°C

COMMENTARY

Background Information

Neutrophils, with their capacity to migrate in response to a variety of stimuli, are essential for maintaining human health. In the absence of functional neutrophils people would rapidly succumb to infection. It has been over a century since Metchnikoff suggested that neutrophils serve as active defenders against invaders (Metchnikoff, 1893), yet there are still many questions about neutrophil locomotion that remain to be answered. How do neutrophils polarize in an isotropic bath of stimuli? How can they migrate in persistent paths when there is no gradient of stimulus? What are the molecular components of the migration machinery? How are these components regulated? To address these sorts of questions, visual assays have been used for over fifty years and have provided detailed descriptions and quantification of cell locomotion (Dixon and McCutcheon, 1936; McCutcheon, 1946). Microscopy-based assays are still one of the most powerful means of gaining insight into the mechanics of cell migration.

Precise terminology has been developed to describe migration phenomena (Keller et al., 1977a,b,c), and brief definitions of the relevant terms (shown in italics) are given here. Cells may possess or lack an *intrinsic capacity* to migrate. For example, promyelocytic cells are nonmotile, and it is only after they differentiate into monocytes or neutrophils that they acquire the capacity for migration. Once migration has been induced, the cells' behavior can be described as *random* or *directed*. Cells that are migrating randomly move along a path with no particular orientation relative to the environment. Neutrophils and other cells have been shown to exhibit a "persistent random walk" as opposed to "Brownian" random movement (Dunn, 1981). The direction of persistence is completely random with no correlation between individual cells or between cells and environmental factors. In contrast, cells that migrate directionally move with a preference for (or avoidance of) a particular direction, usually dictated by an environmental cue such as a *chemoattractant*, a soluble factor that activates cells to migrate (e.g., bacterially generated formyl-peptides and inflammatory chemokines). Cells within a gradient of a chemotactic chemoattractant will be oriented nonrandomly with their front-to-rear axis aligned parallel to the gradient (Zigmond, 1977). Chemoattractants can affect the speed or frequency of migration (*chemokinesis*) and/or the direction of migration (*chemotaxis*). Chemokinesis and chemotaxis are *not* synonymous with random and directed migration, respectively. Directed migration can result from either chemotaxis or chemokinesis coupled with *contact guidance*, where the physical properties of the environment dictate the direction of migration—e.g., aligned fibrils within tissue matrices (Mandeville et al., 1997; Wilkinson and Lackie, 1983). Refer to Keller et al. (1977a,b,c) for more in-depth definitions of the abovementioned italicized terms.

The assay described in this unit can only determine if an agent is chemokinetic; it cannot establish the chemotactic potential of a chemoattractant. To directly show that a chemoattractant is chemotactic, an orientation chamber, such as the one introduced by Zigmond (1977) and modified by others (Zicha et al., 1991, 1997) should be used. Alternatively, the assay chamber described here can be converted into a chemotaxis chamber by attaching bacterial spores (Allan and Wilkinson, 1978) or opsonized erythrocytes (Pytowski et al., 1990) to the surface of the coverslip. Addition of fresh serum to the chambers activates complement and generates radial gradients around the spores or erythrocytes when these particles are widely separated on the coverslip (~20 to 100 μm apart). Time-lapse imaging of neutrophils migrating towards these point sources provides a direct measure of chemotaxis. To address chemotactic potential, researchers have also used assays based on migration through micropore filters—e.g., Boyden chamber as-

says (Boyden, 1962). These are indirect assays that determine the end-point distribution of a cell population after exposure to chemoattractant. Although much larger numbers of cells are analyzed, filter assays can only provide information on cell populations as opposed to individual cells and/or subsets of cells. With a visual assay, the direction and speed of migration can be measured to directly demonstrate chemotaxis or chemokinesis, and displacement, persistence, and turning behavior of individual cells can be extracted from detailed analyses of cell paths (Haston and Wilkinson, 1987, 1988; Mandeville et al., 1995). Excellent discussions on the benefits and limitations of various filter assays can be found elsewhere (Wilkinson, 1996, 1998).

It should also be noted that the assay described here is a two-dimensional one. Thus, the analogous in vivo situation is likely to be cells migrating along the luminal surface of vascular endothelium rather than through the three-dimensional environment of connective tissues. Cells use somewhat different mechanisms for migration through three-dimensional matrices as compared to migration across two-dimensional surfaces, but there are enough similarities that a simple two-dimensional migration assay is an excellent starting point for dissecting the complexities of locomotion.

Clearly, no single type of migration assay is suitable for answering every question, so a variety of complementary assays should be used. See *UNITS 12.1, 12.2 & 12.4* for descriptions of other types of migration assays, and reviews by Wilkinson for an overview and critique of popular methods for studying cell migration (Wilkinson, 1996, 1998).

Critical Parameters

The success of neutrophil migration assays hinges on just two main parameters, the neutrophils and their environment. In vivo, the role of the neutrophil is to sense and respond to environmental signals that may indicate the presence of pathogens. The exquisite sensitivity of neutrophils to the presence of microbes is one of the main obstacles to performing an in vitro migration assay. Cells that are slightly prestimulated (or "primed") often respond differently to chemoattractants than naïve cells, so it is important to start with truly unstimulated neutrophils. The neutrophils from a donor who is coming down with or just getting over a cold may be slightly activated and should not be used. Similarly, many medications are known to affect cell migration, and for that reason

Table 12.6.1 Troubleshooting Guide for Optical Microscopy–Based Neutrophil Migration Assays

Problem	Possible cause	Solution
Cells appear jagged prior to stimulation and migrate poorly or not at all in response to chemoattractant	Endotoxin contamination	Test H_2O supply for endotoxin contamination; decontaminate H_2O and remake all solutions
	Cells were activated during isolation	Isolate neutrophils from a different donor taking extra care not to activate cells by rough handling
Cells appear round and nonadherent	Chemoattractant not added	Remake solution of chemoattractant
	No divalent cations in assay buffer	Remake assay buffers; verify that HBS (not PBS) has been used as the assay buffer
Cells appear very spread and tightly adherent after stimulation, and they do not migrate	Temperature too high	Adjust temperature
	Substrate too adhesive	Prepare coverslip dishes with varying amounts of substrate to optimize conditions
	Chemoattractant concentration too high	Perform dose-response analysis with chemoattractant to optimize concentration
Cells are slow to polarize and migrate only a short distance after stimulation	Temperature too low	Adjust temperature

neutrophils should not be isolated from donors taking medication. Donor health needs to be carefully assessed prior to drawing blood, and all results ought to be confirmed with neutrophils from various donors.

Neutrophils are fragile cells that are readily activated by rough handling. Extreme care is required during the isolation procedure to minimize shear stress and to avoid cell contact with activating surfaces, such as glass. An unbalanced centrifuge, overzealous resuspension technique, or excessive handling of cells can all contribute to cell activation. Isolated neutrophils are still adept at sensing microorganisms in the environment, and they will become activated in the presence of even very low levels of bacterial lipopolysaccharides (LPS, endotoxin). It is crucial that the water supply be tested for the presence of LPSs prior to making isolation and assay buffers, and that all stock buffers be prepared and maintained under sterile conditions. Recirculating reverse osmosis (RO) water systems can become contaminated with algae or other microorganisms. It is important to check for LPSs because contamination anywhere in a closed-loop system can release LPSs, which then spread throughout the loop. Filtration or UV light at the tap will not remove LPSs. The water supply can be tested for LPS contamination using a commercially available kit (e.g., Chromogenic Limulus Amebocyte Lysate Assay Kit from BioWhittaker).

After cells with a low basal level of activation have been isolated, they will be added to the assay chamber and stimulated to migrate. At this point, the ability of the cells to migrate and the extent of migration will depend upon the agent used to stimulate the cells, the matrix on which they will migrate, and the temperature during the assay. The absolute concentration of chemoattractant, even in the absence of a gradient, is an important determinant of migration. Neutrophils exhibit dose-dependent migration that varies between chemoattractants, making it necessary to generate dose-response curves to determine the optimal concentration of a

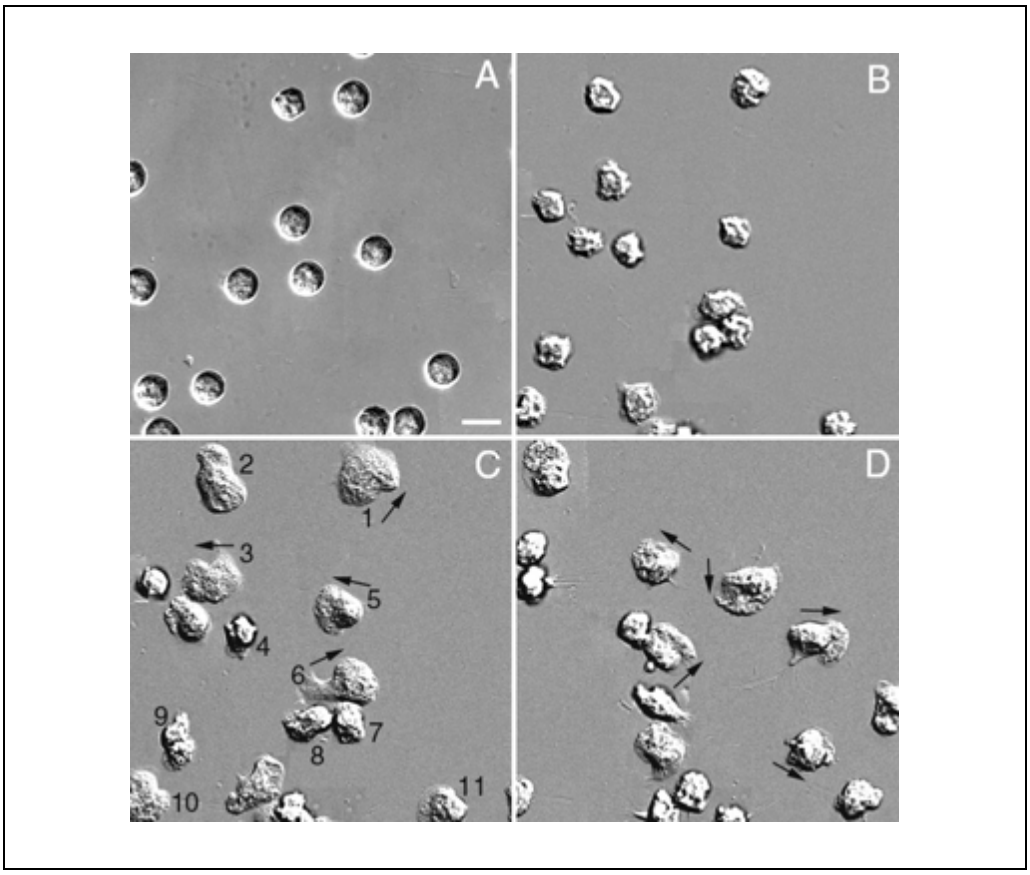

Figure 12.6.1 Morphological changes induced in human neutrophils by stimulation with the chemoattractant fMLF. Neutrophils were plated onto a fibronectin-coated coverslip dish for 5 min at 37°C and then left unstimulated (**A**) or stimulated with fMLF for 15 sec (**B**), 1 min (**C**), or 6 min (**D**). The images shown in panels A, B, and C are each from different fields of cells, whereas the image shown in panel D is the same field of cells shown in C, but imaged 5 min later. Numbers in C correspond to cell paths traced in Figure 12.6.2. Arrows indicate direction of neutrophil migration. Bar is equal to

particular chemoattractant. Because migration is dependent upon the precise regulation of cell attachments in space and time, the adhesive nature of the substratum is another critical parameter that can be varied. Substrata of differing adhesiveness can yield very different migration data in response to a given chemoattractant at a fixed concentration. If the substratum is too adhesive, cells will be unable to detach from the surface and therefore they will be unable to translocate. On the other hand, if the substratum is not adhesive enough, cells will not be able to form tight enough attachments to generate the tractional forces necessary for locomotion. Thus, the ability of cells to migrate, and their speed of migration, depend upon the tightness of the attachments that the cell forms with the substratum. This in turn depends upon the concentration of the ligand (e.g., the density of the matrix element deposited on the coverslip), the concentration of the ligand receptor (e.g., integrin expression levels), and the ligand receptor binding affinity (Palecek et al., 1997). Optimal migration conditions for substrates can be determined empirically by measuring migration of cells plated onto coverslips coated with varying concentrations of substrate. When using a range of substrate concentrations, one should add an appropriate amount of albumin to keep the concentration of total protein constant, otherwise there may be areas of exposed glass at the low end of the substrate concentration range. Because contact guidance or exposed glass surfaces can bias cell migration, it is wise to verify that substrates have been deposited evenly. This can be accomplished by fluorescently labeling the substrate directly or indirectly via immunofluorescence (Marks et al., 1991) and evaluating the fluorescence intensity profile across the coverslips.

Finally, neutrophil migration is sensitive to temperature, with the complete abrogation of migration occurring at temperatures not much above 37°C. Neutrophils migrate well, though more slowly, even at room temperature, so it is sensible to perform migration assays slightly below 37°C (~35°C) to avoid deleterious effects of higher temperatures.

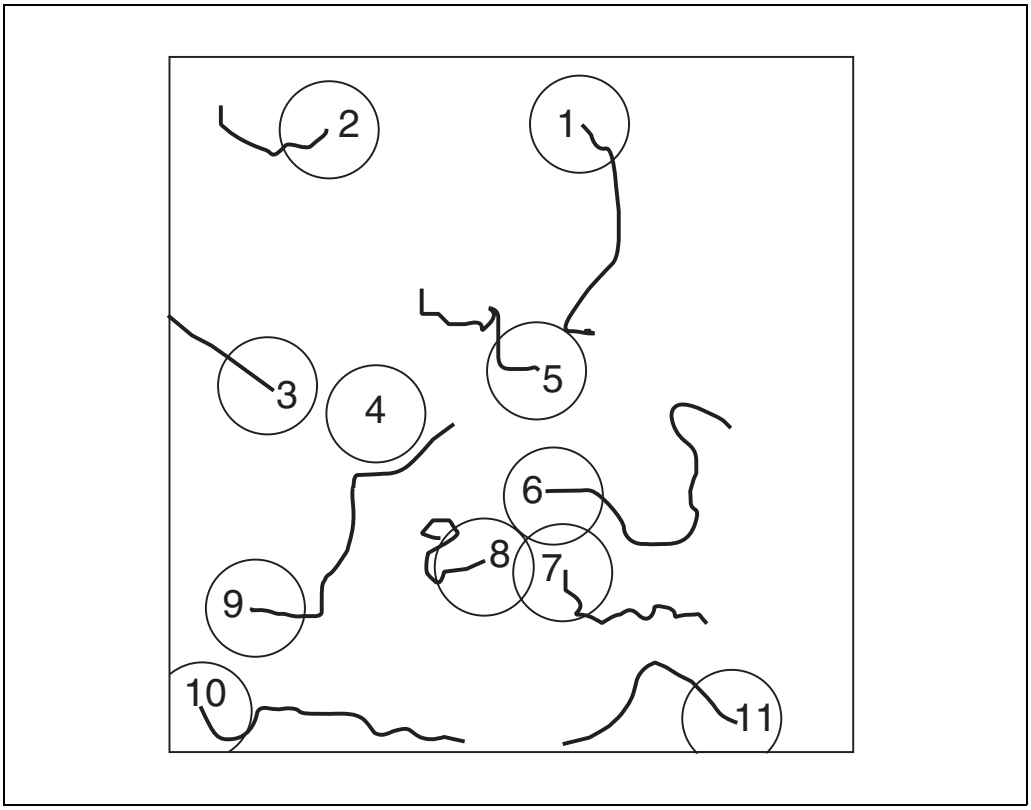

Figure 12.6.2 Tracings of cell paths. An image of a field of fMLF-stimulated neutrophils was acquired every 12 sec for 5 min (see Fig. 12.6.1C and D for initial and final images, respectively). 14-μm-diameter circles were drawn around the cells in the first image (Fig. 12.6.1C), and the positions of cell centroids were marked for each image in the sequence. Centroid positions were then connected to indicate the paths traveled by each cell.

Table 12.6.2 Possible Phenotypes of Neutrophils Observed in Optical Microscopy–Based Migration Assays

Phenotype	Potential cause	Reference
Prominent, elongated uropod (Fig. 12.6.4B)	Inability to detach from substratum. Cells with this defect will make attempts to move forward, but will usually "snap back" to their starting positions because their rears are tightly attached to the substratum. Inability to retract tail. Cells with this defect will move forward slowly, dragging along their elongated tails.	Hendey and Maxfield (1993); Marks et al. (1991); Pierini et al. (2000)
Few or no cells on dish, but remaining cells are still polarized	Adhesion inhibited. Neutrophils do not require adhesive interactions to polarize. Separate polarization and adhesion assays can be performed to verify conclusions.	Graham and Brown (1991); Wilkinson (1998)
Cells remain symmetrical in shape, without a discernible front or rear (Fig. 12.6.4D,F)	Inhibition of cell contraction. Cells with this defect can send out membrane protrusions, but cannot undergo the contractions required to form a polarized morphology. Inhibition of membrane extension. Cells with this defect may look as if they are unstimulated.	Eddy et al. (2000)

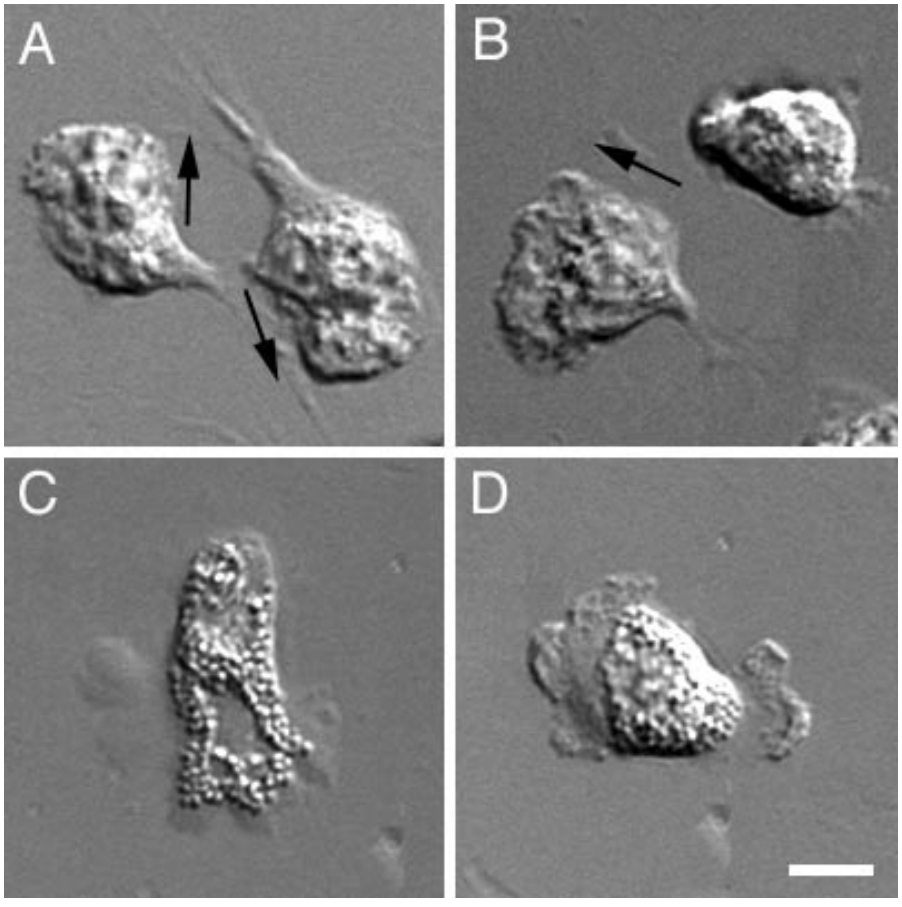

Figure 12.6.3 Comparison of eosinophil and neutrophil morphology. Differential interference contrast images of neutrophils (**A**, **B**) and eosinophils (**C**, **D**) are shown. Note the large refractile granules in the eosinophils. Arrows indicate direction of neutrophil migration. Bar is equal to 10 μm.

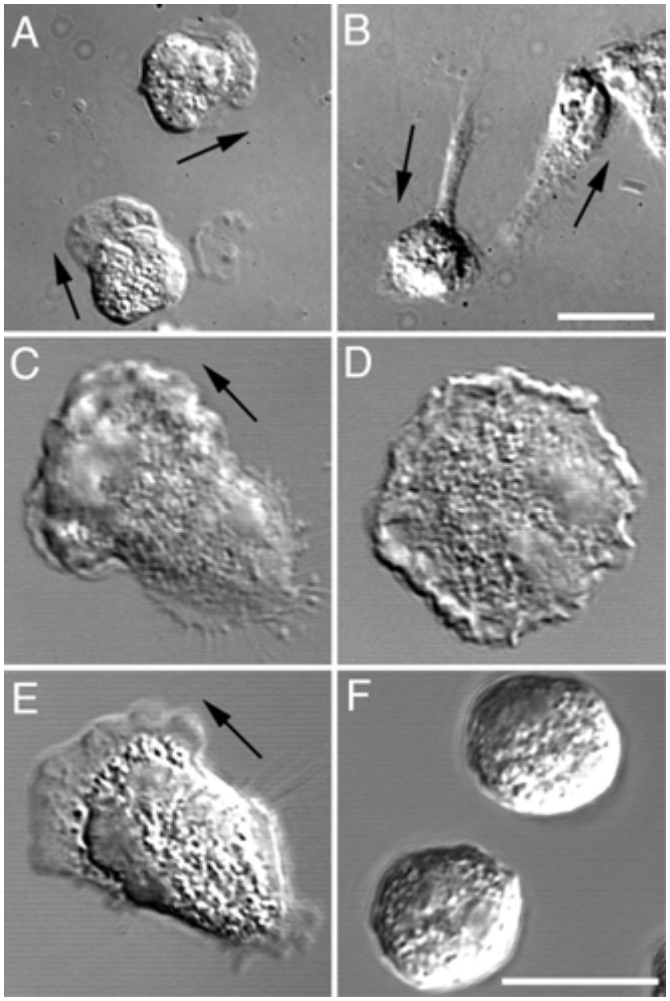

Figure 12.6.4 Examples of phenotypes resulting from various treatments of neutrophils. Images of control (**A**, **C**, **E**) and treated (**B**, **D**, **F**) neutrophils are shown after 2 min stimulation with fMLF. When intracellular calcium is buffered, neutrophils can polarize, but they cannot migrate because they are unable to detach from the substratum (Hendey and Maxfield, 1993; Marks et al., 1991; Pierini et al., 2000). Note the prominent elongated tails in panel B. In contrast, when either myosin light chain kinase is inhibited (Eddy et al., 2000; panel D) or cholesterol is depleted (Pierini and Maxfield, unpub. observ.; panel F), neutrophils can neither polarize nor migrate. These images make it evident that the underlying cause for each of these migration defects is different (see Table 12.6.2). Arrows indicate direction of neutrophil migration. Bars are equal to 10 μm. Images in panels C and D courtesy of Dr. Robert J. Eddy.

Troubleshooting

Table 12.6.1 provides a list of problems that can arise in the neutrophil migration assay, along with their possible causes and solutions.

Anticipated Results

Neutrophils go through a sequence of morphological changes following activation (Seveau et al., 2001; Zigmond and Sullivan, 1979; Fig. 12.6.1). When neutrophils are unstimulated, they are very nearly spherical in shape (Fig. 12.6.1A) and do not adhere tightly to the coverslip. Within 15 to 30 sec after the addition of chemoattractant, the cell periphery becomes irregular, with small membrane protrusions and retractions occurring in every direction (Fig. 12.6.1B). By 2 min, the cells take on a polarized morphology with a distinct front (lamellipod) and rear (uropod) that will orient randomly in the field when chemoattractant is present isotropically (Fig. 12.6.1C).

Less than 10% of the neutrophils should polarize and migrate spontaneously (that is, in the absence of chemoattractant), compared to 60% to 90% of the cells polarizing and migrating after addition of chemoattractant (compare

panels A and C in Fig. 12.6.1). The numbers for spontaneous and stimulated migration will vary somewhat from day to day and will depend on the donor, the basal level of activation of the isolated neutrophils, the temperature of the microscope and buffers during the assay, and other parameters such as the migration matrix and chemoattractant used.

Representative of a typical data set, panels C and D in Figure 12.6.1 show images of a field of neutrophils at 1 min and 6 min after stimulation with fMLF, respectively. Figure 12.6.2 shows the paths traveled by the cells as they moved from their starting positions in panel C to their final positions in panel D. Note that most of the cells have moved several cell lengths during the 5-min course of the assay. Though not readily apparent from this relatively short migration assay, neutrophils normally exhibit a "persistent random walk," with long stretches of approximately straight-line runs between infrequent turns (Fig. 12.6.2; see cells 1, 3, 9, and 10).

Up to 5% of the cells in the field may be eosinophils, as opposed to neutrophils, and it is important to be able to distinguish these cells from neutrophils so that they can be removed from the analysis. Eosinophils (Fig. 12.6.3C,D) tend to have more prominent granules than neutrophils (Fig. 12.6.3A,B).

Often it is informative to evaluate the effects of a pharmacological agent or other treatment on cell migration, using visual analysis to discern the likely basis for any effects on migration. Some phenotypes that can result, along with their possible causes, are listed in Table 12.6.2 and illustrated in Figure 12.6.4. This table is not meant to be comprehensive, only illustrative of how observation of cell morphology and/or behavior can lead to a mechanistic understanding. A particular treatment may have significantly subtler effects on cell migration that may only become apparent after careful analysis of cell paths and behavior.

Time Considerations

The entire procedure, from isolation of cells (~1.25 hr) and preparation of coverslip dishes (~1 hr) to acquisition of three 4-min image series from each of ten dishes can be accomplished in ~4 hr. Coverslips and coverslip dishes can be prepared and assembled ahead of time, with the exception of coating the coverslips with extracellular matrix component, which should be done on the day of the experiment. The time required for image analysis will depend on the exact nature of the analysis and whether automation is employed.

Actin-Based Motility Assay

This unit describes an in vitro assay to study actin-based motility in which the propulsion of the bacteria *Listeria* and *Shigella* or functionalized microspheres is reconstituted from five pure proteins (see Basic Protocol). The pathogens *Listeria* and *Shigella* are acknowledged models of the leading edge of motile cells. By quantitating the dependence of motility parameters on the concentrations of components of the assay, the molecular processes that support the motile behavior of living cells can be understood, predictions of different theoretical models can be evaluated, and insight into the role of newly discovered proteins in motility can be obtained. Data analysis for the assay is described in Support Protocol 1.

This unit includes support protocols for biochemical purification of profilin (see Support Protocol 2), actin-depolymerizing factor (ADF; see Support Protocol 3), gelsolin (see Support Protocol 4), neural Wiskott-Aldrich syndrome protein (N-WASP; see Support Protocol 5), and Arp2/3 complex (actin-related protein; see Support Protocol 6), and for the preparation of N-WASP-coated microspheres (see Support Protocol 7).

STRATEGIC PLANNING

Performing a successful motility assay requires 1 month of preparatory biochemistry. Preparation of the main biochemical components for the motility assay is detailed in Support Protocols 2 to 6. These components must be prepared in advance, dispensed into aliquots of appropriate size, and stored at −80°C. Two different types of animal tissue must be obtained for the various preparations: bovine brain and bovine spleen. The tissues must be obtained from a freshly slaughtered cow in a slaughterhouse and used immediately or flash-frozen. Actin purification from rabbit muscle is also required for the motility assay (see *UNIT 13.2*).

The biochemical purifications represent a challenging task. The reader should also note that several proteins used in the assay (actin, rhodamine-labeled actin, and Arp2/3) are now commercially available (Cytoskeleton, Inc).

Motility assays are performed under optimal conditions using functionalized microspheres. Such particles can indeed be coated with N-WASP (see Support Protocol 7) or ActA in a chemically controlled and reproducible fashion. Use of bacteria (*Listeria* or *Shigella*) is recommended in restricted cases where *Listeria* strains mutated in ActA or *Shigella* strains mutated in IcsA (the bacterial activator of N-WASP) are to be examined.

ACTIN-BASED MOTILITY ASSAY

BASIC PROTOCOL

This protocol describes the execution of an assay that reconstitutes the propulsion of *Listeria*, *E. coli* expressing the *Shigella* protein IcsA, or N-WASP-functionalized microspheres in a minimum motility medium containing Arp2/3 complex, ADF, gelsolin, profilin, and actin (Loisel et al., 1999).

Materials

Profilin (see Support Protocol 2)
ADF (see Support Protocol 3)
Gelsolin (see Support Protocol 4) or other capping protein
VASP (for use with *Listeria* or ActA-functionalized microspheres only; prepare as for N-WASP, see Support Protocol 5)

Contributed by Christophe Le Clainche and Marie-France Carlier
Current Protocols in Cell Biology (2004) 12.7.1-12.7.20

Arp2/3 complex *or* Alexa488-Arp2/3 complex (see Support Protocol 6)
Assay buffer (see recipe) containing 1% (w/v) bovine serum albumin (BSA)
10% (w/v) bovine serum albumin (BSA) in distilled water
5 μM α-actinin (Sigma) in distilled H_2O
48 μM Mg-F-actin (see recipe)
1% (w/v) methylcellulose (see recipe)
ATP/DABCO/DTT mix (see recipe)
40 μM rhodamine-G-actin (Cytoskeleton, Inc.) in assay buffer/1% BSA (store up to 1 month at −80°C)
4×10^9 microspheres/ml suspension of N-WASP-functionalized microspheres (see Support Protocol 7) *or* 4×10^9 bacteria/ml suspension of *Listeria* or *E. coli* IcsA in assay buffer/1% BSA
Valap (*UNIT 13.1*)

Glass slides (Superfrost Plus, Fisher, or Menzel-Gläser; 25 × 75 × /mm)
Glass coverslips (22 × 22 mm)
Microscope, phase-contrast or fluorescence (with appropriate filters; *UNIT 4.2*)

1. Rapidly thaw ADF, profilin, Arp2/3 complex, gelsolin, and VASP, and dilute to the appropriate stock concentrations (see Table 12.7.1) with assay buffer/1% BSA.
2. Combine the components of the actin-based motility assay in a 0.5 ml tube in the (top-to-bottom) order indicated in Table 12.7.1.

Table 12.7.1 Components of Actin-Based Motility Assay

Ingredient[a]	Stock concentration	Volume added	Final concentration
BSA	10% (w/v)	1.2 μl	0.5%
ADF	55 μM	1.6 μl	3.7 μM
Profilin	50 μM	1.2 μl	2.5 μM
Gelsolin[b]	0.5 μM	2.4 μl	50 nM
α-Actinin	5 μM	1.2 μl	0.25 μM
Arp2/3[c]	1 μM	1.8 μl	75 nM
VASP[d]	8 μM	1.4 μl	0.47 μM
Mg-F-actin	48 μM	3.8 μl	7.6 μM
Methylcellulose	1% (w/v)	5.4 μl	0.23%
ATP/DABCO/DTT mix	see Reagents and Solutions	3.0 μl	—
Rhodamin-G-actin	40 μM	0.6 μl	1 μM
N-WASP functionalized microspheres or *Listeria* or *E. coli* IcsA	4×10^9 microspheres or bacteria per ml	0.6 μl	2×10^8 microspheres or bacteria/ per ml
Final volume		24 μl	

[a]Abbreviations: Arp2/3, actin-related protein; ADF, actin-depolymerizing factor; ATP, adenosine triphosphate; BSA, bovine serum albumin; DABCO, 1.4.-diazobicyclo[2,2,2]octane; DTT, dithiothreitol; N-WASP, neural Wiskott-Aldrich syndrome protein; VASP, vasodilator-stimulated phosphoprotein.
[b]Other capping proteins may be used.
[c]Alexa488-Arp2/3 (also prepared as in Support Protocol 6) may be used.
[d]Add only for assays using *Listeria* or ActA-functionalized microspheres in place of the N-WASP functionalized microspheres (see Strategic Planning).

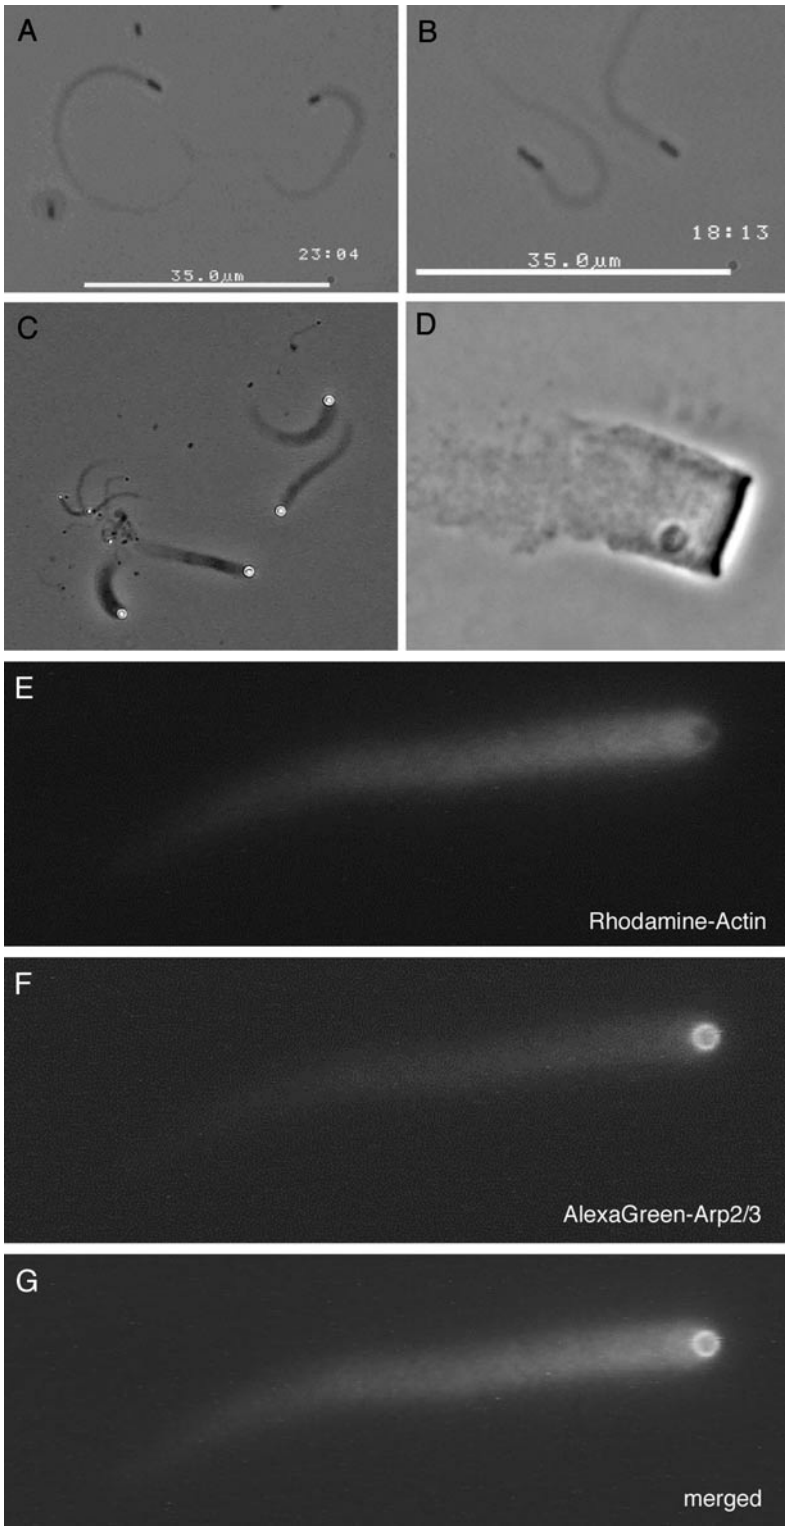

Figure 12.7.1 Examples of actin-based motility of bacteria or functionalized particles in the reconstituted motility assay. Synchronous films of up to four selected fields per chamber were recorded with a CCD camera on an Olympus AX70 microscope equipped with a motorized stage (Märzhäuser) using MetaMorph 4.6 for microscope control and image acquisition. (**A**) *Listeria monocytogenes*; (**B**) *E. coli* IcsA (substitute for *Shigella flexneri*); (**C**) N-WASP-coated polystyrene beads of different diameters; (**D**) N-WASP-coated glass rod (1 µm in diameter); (**E, F, G**) double-label experiment using N-WASP-coated beads in motility assay containing rhodamine-labeled actin and Alexa488-labeled Arp2/3 (from Wiesner et al., 2003). Both the surface of the bead and the tail are labeled by Arp2/3.

Because high concentrations of methylcellulose can cause excessive filament bundling, all components excluding methyl cellulose and F-actin must be mixed first.

Although α-actinin cross-links actin filaments and increases the density of the actin tail, this protein is not essential and can be omitted.

If the pipetting scheme given in Table 12.7.1 is modified (e.g., to vary the concentration of some component), the resulting change in volume of the assay should be such that all concentrations of other protein, BSA, and nonprotein components remain unchanged. To make up the final volume use assay buffer/1% BSA.

3. Pipet 3 μl of the mixture on a glass slide and cover with a coverslip. Seal the preparation with Valap.

   Be careful to avoid introducing bubbles between the slide and the coverslip.

   For microspheres of diameter >5 μm, do not compress the coverslip onto the slide; rather, use a larger sample volume and chamber slide to avoid sticking of the bead to the glass surfaces of the slide and coverslip.

4. Observe under a phase-contrast or fluorescence microscope at room temperature (see Anticipated Results and Figure 12.7.1). Record up to four selected fields per chamber with a CCD camera, using MetaMorph 4.6 for microscope control and image acquisitiion. Analyze data (Support Protocol 1).

   When optimal conditions are used, the actin tails can be observed in phase contrast using a 20× phase-contrast objective (NA 0.5). Fluorescence is useful to colocalize a fluorescent protein like Alexa488-labeled Arp2/3 with the fluorescent rhodamine-actin tail.

   If the rhodamine-labeled actin and/or Alexa488-labeled Arp2/3 photobleach rapidly, the concentrations of DABCO, an oxygen-scavenging component, and DTT, a reducing agent, should be checked (see Reagents and Solutions, recipe for ATP/DABCO/DTT mix).

SUPPORT PROTOCOL 1

DATA ANALYSIS

The reconstituted motility assay can be used as an analytical tool. Parameters that have been exploited are speed, percentage of motile particles, length of the actin tail, and density of actin and Arp2/3 in the actin tail.

Average rates of movement are determined by selecting freely moving microspheres from several different fields in the motility assay recordings. For microspheres of 0.5-μm diameter and larger, the template recognition–based tracking tool of MetaMorph (Universal Imaging) is used to measure mean velocities. In this assay, 100% of the beads move. Generally, when bacteria are used (see Strategic Planning), less than 100% of the bacteria move. The fraction of motile bacteria, in this case, is an additional parameter that should be considered in characterizing the motile behavior.

To determine F-actin and Arp2/3 densities in the actin tails, first, rhodamine-labeled actin and Alexa488-labeled Arp2/3 are used in the motility assays, and their respective fluorescence intensities are recorded with a LHESA 72LL CCD camera using appropriate filters and a 100 objective (NA 1.35). The extent of Arp2/3 labeling (100%) and of actin labeling (10%) is chosen to yield intensities in the linear response range of the camera for both fluorophores. Control experiments are performed to make sure that no emission overlap exists between the two fluorophores. Images of comets are recorded at steady state, and average emission intensities of rhodamine (IR) and Alexa488 (IA) are measured as mean gray values in a square section of the actin tail at least one bead diameter behind the bead. An average IR/IA ratio is determined from sets of at least five microspheres. To estimate the absolute stoichiometry of actin and Arp2/3 from these values, a calibration

is performed using solutions of the two fluorescent proteins at different concentrations (Wiesner et al., 2003).

The percentage of motile microspheres is determined manually by counting the ratio of motile particles to total particles. Only central regions are used because the edge of the preparation displays significant differences in the percentage of motile microspheres.

PROFILIN PURIFICATION

SUPPORT PROTOCOL 2

Recombinant profilin from different sources or profilin purified from bovine spleen can be used. Here, the purification of profilin from bovine spleen (Perelroizen et al., 1996) is described.

Materials

Bovine spleen (see Strategic Planning)
Profilin buffer A (see recipe) containing 0.5% (v/v) Triton X-100
200 mM PMSF stock in absolute ethanol
4 M and 7 M urea in profilin buffer A (see recipe for buffer)
Profilin buffer B (see recipe)
Liquid nitrogen
Centrifuge with Sorvall SLA 1500 rotor (or equivalent)
Cheescloth
Ultracentrifuge with Sorvall A641 rotor (or equivalent)
15-cm length × 2.5-cm inner diameter poly-L-proline-Sepharose column (see recipe)
10,000-kDa MWCO dialysis membrane
Centriprep 10 centrifugal concentrator (Millipore; also see *APPENDIX 3C*)
Ultracentrifuge with Beckman TLA 100.3 rotor (or equivalent)
Additional reagents and equipment for dialysis and concentration of protein solutions (*APPENDIX 3C*) and determination of protein concentration (*APPENDIX 3B*)

Prepare tissue homogenate

1. Homogenize 240 g of frozen spleen in 350 ml of profilin buffer A/0.5 % Triton X-100. Add PMSF (from 200 mM stock) to 1 mM final and homogenize 45 sec.
2. Centrifuge 45 min at 22,000 × *g* (12,000 rpm in a Sorvall SLA 1500 rotor), 4°C. Filter the supernatant through eight layers of cheesecloth.
3. Centrifuge the filtered supernatant for 1 hr and 45 min at 200,000 × *g* (39,000 rpm in a Sorvall A641 rotor), 4°C. Filter again through eight layers of cheesecloth.

Purify by affinity chromatography

4. Add the sample to a 15-cm length × 2.5-cm inner diameter poly-L-proline-Sepharose column equilibrated with profilin buffer A. Wash the column with 400 ml profilin buffer A.
5. Elute actin with 250 ml 4 M urea in profilin buffer A, monitoring absorbance at 280 nm.
6. Elute profilin with 250 ml 7 M urea in profilin buffer A, monitoring absorbance at 280 nm.
7. Wash the column with 500 ml water.

Purify by dialysis

8. Combine fractions containing protein eluted by 7 M urea and dialyze 18 hr against two changes of 1000 ml profilin buffer B, using a 10,000-kDa MWCO dialysis membrane (*APPENDIX 3C*).

9. Concentrate dialyzed protein on Centripep 10 centrifugal concentrator according to the manufacturer's instructions.

10. Dialyze again once for 18 hr against 1000 ml profilin buffer B, using a 10,000-kDa MWCO dialysis membrane (*APPENDIX 3C*).

11. Ultracentrifuge 15 min at 334,000 × *g* (90,000 rpm in a Beckman TLA 100.3 rotor), 4°C. Retain supernatant.

12. Measure the protein concentration of the supernatant using UV absorbance (*APPENDIX 3B*). Freeze in liquid nitrogen in 0.1-ml aliquots and store at −80°C.

Profilin can be stored for months at −80°C. Thawed aliquots can be stored on ice for a few weeks without loss of activity.

SUPPORT PROTOCOL 3

ADF PURIFICATION

Bacterial recombinants of ADFs from different sources (plant, amoeba, and vertebrate) have been used successfully in the motility medium. Here the purification of recombinant human ADF expressed in *E. coli* (Carlier et al., 1997) is described.

Materials

E. coli BL21 DE3 strain transformed with pET16-ADF (see *APPENDIX 3A* for transformation of *E. coli* with plasmid)
LB medium (*APPENDIX 2A*) containing 0.2 mg/ml ampicillin
ADF buffers A, B, C, D, and E (see recipes)
10 mg/ml lysozyme
250 mM EDTA
200 mM PMSF in absolute ethanol
1 M $MgCl_2$
2 mg/ml DNase I
Liquid nitrogen

Centrifuge with Sorvall GSA rotor (or equivalent)
Probe sonicator (Fisher)
Centrifuge with Sorvall SS-34 rotor (or equivalent)
10,000-kDa MWCO dialysis membrane
Ultracentrifuge with Beckman TL-100 rotor (or equivalent)
DEAE (DE-52; Whatman) column (20 × 2.5 cm; *UNIT 10.11*)
Stirred cell with Diaflo PM 10 ultrafiltration membrane (Amicon)
SP trisacryl column (15 × 1.5 cm; BioSepra)

Additional reagents and equipment for transforming and growing bacteria and induction of protein expression with IPTG (*APPENDIX 3A*), dialysis (*APPENDIX 3C*), and determination of protein concentration (*APPENDIX 3B*)

Express the protein and lyse the cells

1. Grow *E. coli* BL21 DE3 strain transformed with pET16-ADF in LB medium containing 0.2 mg/ml ampicillin at 37°C. At OD = 1, add 0.5 mM IPTG to induce ADF expression. Incubate 2 hr and 30 min at 37°C.

APPENDIX 3A provides cross-references for the molecular biology techniques used in this step.

2. Centrifuge 10 min at 4000 × *g* (5000 rpm in a Sorvall GSA rotor), 4°C. Resuspend pellet in 100 ml ADF buffer A. Rapidly freeze-thaw the homogenate.
3. Add 1 ml of 10 mg/ml lysozyme. Incubate 5 min, then add 1 ml of 250 mM EDTA and incubate an additional 5 min.
4. Add 250 µl of 200 mM PMSF. Sonicate three times, each time for 1 min at 150 W power in a probe sonicator on ice.
5. Add 500 µl of 1 M $MgCl_2$ and 1 ml of 2 mg/ml DNase I. Incubate 5 min at room temperature.

Purify the protein

6. Centrifuge 30 min at 17,000 × *g* (12,000 rpm in a Sorvall SS-34 rotor), 4°C.
7. Dialyze supernatant overnight at 4°C against 1000 ml of ADF buffer B using a 10,000-kDa MWCO dialysis membrane (*APPENDIX 3C*).
8. Ultracentrifuge 45 min at 100,000 × *g*, 4°C.
9. Load the sample onto a 20 × 2.5–cm size DEAE column. Elute with ADF buffer B Collect fractions at 2 ml/min and 2 min/fraction.
10. Concentrate the flowthrough to 10 ml by ultrafiltration in a stirred cell with a Diaflo PM 10 membrane.
11. Dialyze overnight at 4°C against 1000 ml ADF buffer C using a 10,000-kDa MWCO dialysis membrane (*APPENDIX 3C*).
12. Load the sample onto a 1.5 × 15 size SP trisacryl column. Elute with 100 ml ADF buffer D. Collect fractions at 1 ml/min and 2 min/fraction.
13. Concentrate to 3 ml and dialyze overnight at 4°C against 1000 ml ADF buffer E using a 10,000-kDa MWCO dialysis membrane (*APPENDIX 3C*).
14. Ultracentrifuge the dialysate 15 min at 313,000 × *g* (90,000 rpm in a Beckman TL-100 rotor), 4°C.
15. Measure the concentration using UV absorbance (*APPENDIX 3B*). Freeze 0.1-ml aliquots in liquid nitrogen and store at −80°C.

ADF can be store for months at −80°C. Thawed aliquots can be stored on ice for a few weeks without loss of activity.

GELSOLIN PURIFICATION

SUPPORT PROTOCOL 4

Although in the original protocol published by Loisel et al. (1999) Capping Protein was used, further assays showed that any other capping protein can work as well as Capping Protein, i.e., the general barbed-end capping function is required for motility. In particular, gelsolin, which can easily be obtained as a bacterially expressed recombinant protein, supports motility.

Materials

E. coli BL21 DE3 strain expressing gelsolin (see *APPENDIX 3A* for transformation of *E. coli*)
Gelsolin buffers A, B, C, and D (see recipes)
1 M $MgCl_2$
2 mg/ml DNase I
500 mM NaCl in gelsolin buffer B (see recipe for buffer)
Anti-gelsolin antibody (Sigma)

500 mM NaCl in gelsolin buffer C (see recipe for buffer)
Liquid nitrogen

Probe sonicator (Fisher)
Refrigerated centrifuge
Centriprep 30 centrifugal concentrator
30,000-kDa MWCO dialysis membrane
2.5 × 20–cm DEAE-cellulose (DE-52; Whatman) column (*UNIT 10.11*)
Gradient maker
11 × 1.25–cm SP trisacryl column (BioSepra)

Additional reagents and equipment for transforming and growing bacteria and induction of protein expression with IPTG (*APPENDIX 3A*), dialysis (*APPENDIX 3C*), and determination of protein concentration (*APPENDIX 3B*), and immunodetection (*UNIT 6.2*)

1. Grow *E. coli* BL21 DE3 expressing gelsolin (see *APPENDIX 3A* for molecular biology techniques).
2. Add 100 ml gelsolin buffer A per liter of bacteria grown. Incubate 10 min at 4°C, then sonicate five times, each time for 1 min at 150 W power.
3. Add $MgCl_2$ from 1 M stock to a final concentration of 5 mM and 2 mg/ml DNase I to a final concentration of 0.02 mg/ml. Incubate 10 min at 4°C.
4. Centrifuge 30 min at 18,000 × *g*, 4°C.
5. Dialyze overnight at 4°C against 1000 ml gelsolin buffer B using a 30,000-kDa MWCO dialysis membrane (*APPENDIX 3C*).
6. Add the sample to a DEAE column equlibrated in gelsolin buffer B. Prepare a 1-liter, 0 to 500 mM linear NaCl gradient by placing 500 ml gelsolin buffer B in one compartment of a gradient maker and 500 ml of 500 mM NaCl (in gelsolin buffer B) in the other compartment. Apply the gradient to elute.
7. Identify the gelsolin-containing fractions by immunodetection (*UNIT 6.2*) using anti-gelsolin antibody. Combine desired fractions, then concentrate using a Centriprep 30 centrifugal concentrator and dialyze overnight at 4°C against 1000 ml gelsolin buffer C using a 30,000-kDa MWCO dialysis membrane (*APPENDIX 3C*).
8. Add the sample to an 11 × 1.25–cm SP trisacryl column equilibrated in gelsolin buffer C. Prepare a 300-ml, 0 to 500 mM linear NaCl gradient by placing 150 ml gelsolin buffer C in one compartment of the gradient maker and 150 ml of 500 mM NaCl (in gelsolin buffer C) in the other compartment. Apply the gradient to elute.
9. Identify the gelsolin-containing fractions by immunodetection (*UNIT 6.2*) using anti-gelsolin antibody. Combine desired fractions and dialyze overnight at 4°C against 1000 ml gelsolin buffer D. Freeze in liquid nitrogen and store at −80°C.

SUPPORT PROTOCOL 5

N-WASP PURIFICATION

His-tagged human N-WASP is expressed in *Sf*9 cells using the baculovirus system (Egile et al., 1999). His-tagged human VASP (see Basic Protocol and Table 12.7.1 for applications) is purified using the same protocol (Laurent et al., 1999).

Materials

Insect (*Sf*9) cells expressing N-WASP (see *APPENDIX 3A* for transformation of insect cells)
Phosphate-buffered saline (PBS; *APPENDIX 2A*)

PBS (*APPENDIX 2A*) containing 0.5 mM PMSF (add from 200 mM PMSF stock in absolute ethanol)
N-WASP buffers A, B, C, D, E, and F (see recipes)
NaCl
Imidazole
50% (w/v) suspension of Ni-NTA resin (Qiagen)
Liquid nitrogen

Cell scraper
Clinical (tabletop) centrifuge
Dounce homogenizer
Probe sonicator (Fisher)
Ultracentrifuge with Beckman TL-100 rotor (or equivalent)
2.5 × 20–cm DEAE-cellulose (DE-52; Whatman) column (*UNIT 10.11*)
1 × 5 cm, 10-ml chromatography column
30,000-kDa MWCO SpectraPor 2 dialysis membrane (Spectrum)

Additional reagents and equipment for protein expression in insect cells (*APPENDIX 3A*) and dialysis (*APPENDIX 3C*)

1. Collect 5×10^8 insect cells with a cell scraper in PBS. Centrifuge 5 min at 500 × *g* (2000 rpm in a clinical centrifuge), room temperature.
2. Wash by adding 100 ml PBS containing 0.5 mM PMSF and centrifuging again as described above. Remove supernatant.
3. Resuspend cells in 10 ml N-WASP buffer A. Homogenize in a Dounce homogenizer, then sonicate three times, each time for 1 min at lowest power.
4. Ultracentrifuge 40 min at 334,000 × *g* (90,000 rpm in a Beckman TL-100 rotor), 4°C.
5. Dilute the supernatant to obtain 0.1 M NaCl. Add the sample to a DEAE column equilibrated in N-WASP buffer B.
6. Save the flowthrough, adjust the NaCl concentration up to 0.3 M, and add imidazole to a final concentration of 10 mM.
7. Equilibrate 4 ml of a 50% suspension of agarose Ni-NTA resin with 30 ml N-WASP buffer C.
8. Mix the DEAE flowthrough and the Ni-NTA resin for 1 hr at 4°C on an end-over-end rotator. Load the sample/resin onto a 10-ml column and wash twice, each time with 4 ml N-WASP buffer D. Elute by adding ten 0.4-ml aliquots of N-WASP buffer E.
9. Dialyze eluate twice, each time for 30 min at 4°C in 500 ml N-WASP buffer F using a 30,000-kDa MWCO SpectraPor2 dialysis membrane (*APPENDIX 3C*). Freeze in liquid nitrogen and store at −80°C.

N-WASP can be stored for months at −80°C. Thawed aliquots kept on ice can be used for motility for a week.

ARP2/3 PURIFICATION

SUPPORT PROTOCOL 6

Arp2/3 can be purified from a variety of sources, including amoeba (Mullins et al., 1998) and vertebrate tissues like thymus (Higgs et al., 1999) or brain (Egile et al., 1999). It is also possible to purify recombinant Arp2/3 expressed in insect cells. Here, the purification of Arp2/3 from bovine brain (Egile et al., 1999) is described.

Materials

Bovine brain (see Strategic Planning)
Arp2/3 buffers A, B, C, D, E, F, G, and H (see recipes)
2 M sucrose
100 μM Alexa488-C5-maleimide (Molecular Probes) in Arp2/3 buffer H (see recipe for buffer)
DTT

Hammer
Waring blender
Refrigerated centrifuge
30,000-kDa MWCO dialysis membrane
SP trisacryl column (4 × 30 cm; BioSepra)
Sepharose GSH-GST-VCA as described by Egile et al. (1999) 2-ml column containing
Disposable NAP-10 column (Amersham Biosciences)

Additional reagents and equipment for dialysis (*APPENDIX 3C*) and determination of protein concentration (*APPENDIX 3B*)

Purify Arp2/3 complex

1. Break 300 g frozen bovine brain in small pieces using a hammer and mix with 600 ml Arp2/3 buffer A at 4°C. Homogenize in a Waring blender three times at high speed, each time for 20 sec.
2. Centrifuge the homogenate 1 hr at 100,000 × *g*, 4°C.
3. Dialyze the supernatant overnight at 4°C in 4 liters Arp2/3 buffer B using a 30,000-kDa MWCO dialysis membrane.
4. Centrifuge the supernatant 30 min at 100,000 × *g*, 4°C.
5. Load the supernatant onto a 4 × 30–cm SP trisacryl column equilibrated with Arp2/3 buffer B. Wash the resin with 5 volumes of Arp2/3 buffer B, wash again with 150 ml Arp2/3 buffer C, then elute with 150 ml Arp2/3 buffer D.
6. Dialyze the peak fractions 18 hr against 500 ml of Arp2/3 buffer E using a 30,000-kDa MWCO dialysis membrane (*APPENDIX 3C*).
7. Load the dialysate on a 2-ml column containing 1 ml of Sepharose-GSH-GST-VCA equilibrated in Arp2/3 buffer E.
8. Wash with 10 ml Arp2/3 buffer F, then elute with 10 ml Arp2/3 buffer G.
9. Combine the fractions showing absorbance at 290 nm and dialyze 18 hr against 1000 ml of Arp2/3 buffer F using a 30,000-kDa dialysis membrane.
10. Adjust the concentration of the solution to 200 mM sucrose using a 2 M sucrose stock solution. Measure protein concentration. Freeze in liquid nitrogen and store at −80°C.

Arp2/3 can be stored for months at −80°C. Thawed aliquots kept on ice can be used for 2 days.

The activity of Arp2/3 can be monitored during the purification by measuring the stimulation of actin assembly using pyrene fluorescence as a probe. In such an assay, the cuvette contains 2.5 μM G-actin (10% pyrenyl-labeled), 0.5 μM VCA, and an aliquot of the fraction to be tested, in polymerization buffer (see recipe).

Fluorescently label Arp2/3 complex (optional)

11. Filter Arp2/3 complex through a NAP-10 column equilibrated with Arp2/3 buffer H, to remove DTT.
12. Incubate Arp2/3 complex with 100 μM Alexa488-C5-maleimide in Arp2/3 buffer H for 1 hr on ice, then add DTT to 1 mM to stop the labeling.
13. Add the sample to a NAP-10 column to separate the labeled protein from the free unreacted fluorophore. Elute with Arp2/3 buffer F. Keep Alexa488-Arp2/3 on ice and use within 3 days.

    Determine the labeling stoichiometry from the UV-visible spectrum of the labeled protein.

PREPARATION OF N-WASP-FUNCTIONALIZED MICROSPHERES

SUPPORT PROTOCOL 7

The successful reconstitution of actin-based motility of *Listeria* and *Shigella* opened the way for the design of a biomimetic system using carboxylated polystyrene microspheres functionalized with an activator of the Arp2/3 complex (N-WASP or ActA) and placed in the minimum motility medium. This protocol describes the procedure to functionalize the beads with N-WASP (Wiesner et al., 2003). The same procedure can be used to make ActA-coated beads (Samarin et al., 2003).

Materials

Polystyrene carboxylated microspheres of diameters from 0.2 to 3 μm (Polysciences)
N-WASP buffers A and C (see recipes)
4 μM N-WASP (see Support Protocol 5)
10 mg/ml BSA
Refrigerated centrifuge

1. Incubate polystyrene carboxylated microspheres of diameters from 0.2 to 3 μm in N-WASP buffer A containing 400 nM N-WASP (added from 4 μM stock) for 1 hr on ice.

   To prepare ActA-functionalized microspheres, use the same protocol but incubate the microspheres with 0.7 μM full-length ActA.

   The quantity of microspheres in a 50-μl suspension is adjusted so that the total surface of solid per unit volume of solution was 7.5 × 10^9 μm^2/ml, independent of the diameter of the microspheres.

2. Add 5 μl of 10 mg/ml BSA to block free adsorption sites and incubate 15 min on ice.
3. Centrifuge the microspheres 5 min at 10,000 × *g*, 4°C, then wash twice, each time by adding 250 μl N-WASP buffer A and centrifuging 5 min at 10,000 × *g*, 4°C. Resuspend final pellet in 50 μl N-WASP buffer C containing 1 mg/ml BSA.

   Functionalized microspheres have been stored on ice and used for up to 1 week without any change in their motile properties.

REAGENTS AND SOLUTIONS

Use deionized distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

ADF buffer A

10 mM Tris·Cl, pH 7.5 (*APPENDIX 2A*)
1 mM EDTA
Store up to 1 week at 4°C

ADF buffer B

10 mM Tris·Cl, pH 7.8 (*APPENDIX 2A*)
50 mM NaCl
5 mM DTT
0.2 mM EGTA
0.01% (w/v) NaN_3
Store up to 1 week at 4°C

ADF buffer C

10 mM PIPES, pH 6.5
25 mM NaCl
5 mM DTT
0.2 mM EGTA
0.01% (w/v) NaN_3
Store up to 1 week at 4°C

ADF buffer D

10 mM PIPES, pH 6.5
50 mM NaCl
5 mM DTT
0.2 mM EGTA
0.01% (w/v) NaN_3
Store up to 1 week at 4°C

ADF buffer E

5 mM Tris·Cl, pH 7.5 (*APPENDIX 2A*)
1 mM DTT
0.01% (w/v) NaN_3
Store up to 1 week at 4°C

Arp2/3 buffer A

10 mM PIPES, pH 6.8
5 mM EGTA
1 mM DTT
0.1 mM PMSF added just before use
Store up to 1 week at 4°C

Arp2/3 buffer B

20 mM PIPES pH 6.8
1 mM DTT
Store up to 1 week at 4°C

Arp2/3 buffer C

20 mM PIPES, pH 6.8
30 mM KCl
1 mM DTT
Store up to 1 week at 4°C

Arp2/3 buffer D

20 mM PIPES, pH 6.8
100 mM KCl
1 mM DTT
Store up to 1 week at 4°C

Arp2/3 buffer E

20 mM Tris·Cl, pH 7.4 (*APPENDIX 2A*)
25 mM KCl
0.25 mM DTT
0.1 mM ATP
1 mM $MgCl_2$
0.5 mM EDTA
Store up to 1 week at 4°C

Arp2/3 buffer F

20 mM Tris·Cl, pH 7.4 (*APPENDIX 2A*)
25 mM KCl
0.25 mM DTT
10 μM ATP
1 mM $MgCl_2$
0.5 mM EDTA
Store up to 1 week at 4°C

Arp2/3 buffer G

20 mM Tris·Cl, pH 7.4 (*APPENDIX 2A*)
25 mM KCl
0.25 mM DTT
10 μM ATP
200 mM $MgCl_2$
0.5 mM EDTA
Store up to 1 week at 4°C

Arp2/3 buffer H

20 mM HEPES, pH 7.2
0.2 mM $MgCl_2$
0.2 mM ATP
Store up to 1 week at 4°C

Assay buffer

10 mM HEPES pH 7.5
0.1 M KCl
1 mM $MgCl_2$
0.1 mM $CaCl_2$
1 mM ATP
Store up to 1 week at 4°C

ATP/DABCO/DTT mix

Add 15 μl of 0.2 M ATP, pH 7.0, and 6 μl 1 M $MgCl_2$ to 79 μl of distilled water to prepare a 30 mM ATP/60 mM $MgCl_2$ stock solution. Next, prepare the

continued

ATP/DABCO/DTT mix by mixing 40 µl of the 30 mM ATP/60 mM $MgCl_2$ stock solution with 20 µl of 2.2 mM 1,4-diazabicyclo[2.2.2]octane (DABCO; Molecular Probes) and 10 µl 0.2 M DTT. Store on ice and use within 3 days.

Gelsolin buffer A

50 mM Tris·Cl, pH 8.0 (*APPENDIX 2A*)
1 mM EDTA
100 mM NaCl
Store up to 1 week at 4°C
Just before use, add:
0.1 mg/ml lysozyme
0.5 mM PMSF (added just before use from 200 mM stock in absolute ethanol)
10 µg/ml benzamidine

Gelsolin buffer B

20 mM Tris·Cl, pH 7.8 (*APPENDIX 2A*)
1 mM EGTA
0.01% (w/v) NaN_3
Store up to 1 week at 4°C

Gelsolin buffer C

10 mM MES pH 6.5
1 mM EGTA
Store up to 1 week at 4°C

Gelsolin buffer D

20 mM Tris·Cl, pH 7.5 (*APPENDIX 2A*)
1 mM EGTA
0.15 M NaCl
0.01% (w/v) NaN_3
Store up to 1 week at 4°C

Methylcellulose, 1%

Prepare 1% (w/v) methylcellulose in distilled water, heat to 60°C, and stir until the solution clears. Store up to 1 week at 4°C.

Mg-F-actin

Prepare KME:
2 M KCl
20 mM $MgCl_2$
4 mM EGTA

Prepare low-ionic-strength buffer:
5 mM Tris·Cl, pH 7.8 (*APPENDIX 2A*)
0.1 mM $CaCl_2$
0.2 mM ATP
1 mM DTT
0.01% (w/v) NaN_3

Prepare 100 µl of Mg-F-actin by adding 5 µl of KME (see above) to 95 µl Ca-G-actin (prepare as in *UNIT 13.2*) in low-ionic-strength buffer (see above). Store up to 1 week at 4°C.

N-WASP buffer A

20 mM sodium phosphate buffer, pH 7.8 (*APPENDIX 2A*)
5% (v/v) glycerol
0.3 M NaCl
0.1% (v/v) Tween 20
Store up to 1 week at 4°C
Just before use, add:
1 mM PMSF
5 μg/ml leupeptin
5 μg/ml chemostatin
5 μg/ml pepstatin
10 μg/ml benzamidine

N-WASP buffer B

20 mM sodium phosphate buffer, pH 7.8 (*APPENDIX 2A*)
5% (v/v) glycerol
0.1 M NaCl
Store up to 1 week at 4°C

N-WASP buffer C

20 mM sodium phosphate buffer, pH 7.8 (*APPENDIX 2A*)
5% (v/v) glycerol
0.3 M NaCl
10 mM imidazole
Store up to 1 week at 4°C

N-WASP buffer D

20 mM sodium phosphate buffer, pH 7.8 (*APPENDIX 2A*)
5% (v/v) glycerol
0.3 M NaCl
30 mM imidazole
Store up to 1 week at 4°C

N-WASP buffer E

20 mM sodium phosphate buffer, pH 7.8 (*APPENDIX 2A*)
5% (v/v) glycerol
0.3 M NaCl
100 mM imidazole
Store up to 1 week at 4°C

N-WASP buffer F

10 mM sodium phosphate buffer, pH 7.8 (*APPENDIX 2A*)
5% (v/v) glycerol
0.1 M NaCl
1 mM DTT
Store up to 1 week at 4°C

Poly-L-proline-Sepharose column

Conjugate poly-L-proline (Sigma) to Sepharose-CNBr (Amersham Biosciences) according to the coupling instructions supplied by the manufacturer of the Sepharose-CNBr. Pack the poly-L-proline-Sepharose in a 15-cm length × 2.5-cm inner diameter chromatography column.

Polymerization buffer

5 mM Tris·Cl, pH 7.8 (*APPENDIX 2A*)
0.2 mM ATP
1 mM DTT
0.1 mM $CaCl_2$
1 mM $MgCl_2$
0.2 mM EGTA
0.1 M KCl
Store up to 1 week at 4°C

Profilin buffer A

10 mM Tris·Cl, pH 7.8 (*APPENDIX 2A*)
0.1 M KCl
0.1 M glycine
1mM DTT
Store up to 1 week at 4°C

Profilin buffer B

5 mM Tris·Cl, pH 7.5 (*APPENDIX 2A*)
1mM DTT
Store up to 1 week at 4°C

COMMENTARY

Background Information

Early studies of the movement of motile cells and associated dynamics of actin filaments revealed that the polarized array of actin filaments turns over rapidly in the lamellipodium. Filament barbed ends (dynamic ends) facing the plasma membrane grow, while filament pointed ends depolymerize at the rear of the lamellipodium in a treadmilling process. In the lamellipodium, actin filaments turn over 100 times faster than pure actin. To account for the rapid movement of eukaryotic cells, actin treadmilling is enhanced by several factors. ADF enhances the rate of pointed-end depolymerization and increases the concentration of actin monomers at steady state. Profilin specifically binds monomeric actin in a complex that has the property of associating exclusively at the barbed ends. The flux of actin monomer provided by ADF-mediated depolymerization is converted into the profilin-actin complex, which polymerizes at the barbed ends only. Hence, the processivity of treadmilling is enhanced by profilin in the presence of ADF. In addition to ADF and profilin, a capping protein is required for efficient motility in the reconstituted medium. By blocking a large fraction of the barbed ends, capping proteins funnel the flux of pointed-end depolymerization to feed the growth of a few noncapped filaments, which individually grow faster than if the other filaments were not capped. In conclusion, ADF, profilin and capping proteins act synergistically in enhancing pointed-end depolymerization and barbed-end polymerization, resulting in an increase in treadmilling (Pantaloni et al., 2001).

In the treadmilling process, capping proteins are recycled after depolymerization of capped filaments and eventually cap the growing barbed ends. Maintenance of a steady number of transiently growing barbed ends requires the constant generation of barbed ends. The cellular factor that generates new filaments in a site-directed, signaling-controlled fashion is the Arp2/3 complex. The Arp2/3 complex, a conserved ubiquitous complex of seven subunits including the two actin-related proteins Arp2 and Arp3, stimulates the formation of actin filaments by branching pre-existing filaments. In higher eukaryotic cells, Arp2/3 alone is inactive and needs to be activated by a variety of activators like WASP family proteins (Rohatgi et al., 1999; Egile et al., 1999) and cortactin. (Weaver et al., 2001; Uruno et al., 2001). The multimodular proteins WASP interact with the Arp2/3 complex and G-actin via its C-terminal WA domain to stimulate branching of actin filaments. The activity of N-WASP is enhanced by the binding of effectors like Cdc42 (Egile et al., 1999; Rohatgi et al.,

1999), phosphatidylinositol bisphosphate (Rohatgi et al., 1999), Grb2 (Carlier et al., 2000), and Nck (Rohatgi et al., 2001).

The propulsive movement of the pathogens *Listeria* and *Shigella* involves the same molecular mechanism as the protrusive behavior of the leading edge of motile cells. The *Listeria* protein ActA directly activates Arp2/3 complex (Welch et al., 1998). The protein VASP interacts with the *Listeria* protein ActA and increases actin-based movement of *Listeria* 10-fold, but has no effect on *Shigella* (Laurent et al., 1999). The *Shigella* protein IcsA does not activate Arp2/3 complex but recruits and activates the host protein N-WASP, which in turn activates Arp2/3 complex (Egile et al., 1999).

In view of the abovementioned information, a number of biochemical assays have been developed to study actin-based propulsion of the bacteria *Listeria* and *Shigella*. First, the reconstitution of *Listeria* movement in cell extracts has converted the complex cell biology problem of motility into a simpler biochemistry problem (Theriot et al., 1994). This assay has been instrumental in identifying the Arp2/3 complex as the cellular factor responsible for stimulating actin assembly at a bacterial surface (Welch et al., 1997). This assay was also useful in understanding the function of the key players of actin-based motility, like VASP (Laurent et al., 1999) and ADF (Carlier et al., 1997). The design of a minimal motility medium using pure proteins (Loisel et al., 1999), presented in this unit, comes as a logical conclusion from discoveries of the factors involved in the reorganization of actin cytoskeleton at the surface of *Listeria* and *Shigella* and at the leading edge of motile cells.

The assay is based on two essential biochemical functions: (1) local nucleation of actin filaments by the Arp2/3 complex at the surface of a solid particle (bacteria or microsphere) coated with an activator of Arp2/3 and (2) constant renewal of the Arp2/3-induced actin array by treadmilling regulating proteins (ADF, gelsolin, profilin; Loisel et al., 1999).

This chemically controlled medium offers advantages in analyzing the mechanism at work, because the dependence of velocity on the concentration of different factors and their interplay with the surface density of Arp2/3 activator can be addressed.

The minimum motility medium has the potential to test the function of proteins involved in signaling pathways or actin dynamics. For instance, the function of Grb2, a protein that links N-WASP to receptor tyrosine kinase, has been tested in the motility medium. Grb2 shortens the delay preceding actin comet, supporting the biochemical demonstration that Grb2 is an activator of N-WASP (Carlier et al., 2000). Similarly, potential inhibitors or drugs can be tested as well. Another application is the study of the effect on motility of actin-binding proteins like thymosin β4, actobindin, and ciboulot. Ciboulot and actobindin enhance motility and substitute for profilin in the minimum motility medium. In contrast, thymosin β4 has no effect on motility and cannot replace profilin. These results and in-depth biochemical studies support the view that ciboulot-actin and actobindin-actin complexes assemble exclusively at the barbed end. Table 12.7.2 recapitulates examples of applications of the motility assay.

The physical mechanism of force protrusion can be addressed using the minimum motility medium. This biomimetic motility assay has been used to address the force-velocity relationship, by varying the size of the bead and the viscous drag (see Fig. 12.7.1C). Movement was not slowed down by increasing the diameter of the microspheres (0.2 to 3 μm) or by increasing the viscosity of the medium by several thousand-fold. This result shows that forces due to actin polymerization are balanced by internal forces resulting from transient attachment of filament ends at the surface. These forces are greater than the viscous drag (Wiesner et al., 2003).

Critical Parameters and Troubleshooting

The actin-based motility assays described in this unit involve the purification of seven different proteins. The major source of problem is the loss of activity of one or more components of the motility medium. Several experiments that are commonly used to verify the activity of the proteins are listed below, but a detailed description of the protocols is outside the scope of this unit.

To verify actin assembly, measure the pyrenyl-labeled actin polymerization by the increase of pyrenyl fluorescence.

To verify the activity of Arp2/3 complex and N-WASP, measure the increase of pyrenyl-actin assembly in the presence of Arp2/3 activated by N-WASP.

The activity of gelsolin can be tested by its ability to bind NBD-labeled actin in a 1:2 complex. Add increasing concentrations of NBD-labeled actin in the presence of a fixed

Table 12.7.2 Applications of Actin-Based Motility Assay

Protein	Experiment	Result	Interpretation
Ciboulot	Substitution of profilin by ciboulot	Ciboulot functionally replaces profilin	The complex ciboulot-G-actin participates in barbed-end assembly in a profilin-like fashion (Boquet et al., 2000).
Actobindin	Substitution of profilin by actobindin	Actobindin functionally replaces profilin	The complex actobindin-G-actin participates in barbed-end assembly in a profilin-like fashion (Boquet et al., 2000).
Thymosin β4	Substitution of profilin by thymosin β4	Thymosin β4 does not replace profilin	The complex actin-thymosin β4 does not participate in barbed end (Boquet et al., 2000).
Grb2	Addition of Grb2	Grb2 shortens the delay preceding actin comet tail formation	The protein Grb2 is an activator of N-WASP (Carlier et al., 2000).
VASP	Addition of VASP in the motility medium containing *Listeria* or ActA- or WASP-coated microspheres	VASP enhances actin-based propulsion of *Listeria* (Laurent et al., 1998), of ActA-coated beads (Boujemaa-Paterski et al., 2001), and WASP-coated beads (Castellano et al., 2001)	VASP enhances the dissociation of the newly formed branch junction from the immobilized branching enzyme ActA (Samarin et al., 2003).

concentration of gelsolin. Monitor the formation of this complex by the increase of NBD-labeled actin fluorescence. At saturation, the ratio of gelsolin to actin is 1:2. Capping activity of gelsolin is highly dependent on the presence of Ca^{2+} at concentrations of the order of 10^{-4} M, at least. If one protein is added to the medium, be sure that the buffer in which it is equilibrated does not contain EDTA in amounts sufficient to chelate all Mg^{2+} and/or Ca^{2+} ions in the medium. ATP-Mg is the ligand of actin; the affinity of ATP decreases by six orders of magnitude upon removal of Mg^{2+} ions. Subsequent dissociation of ATP leads to irreversible denaturation of actin. EDTA can be removed by dialysis or gel filtration (on a G-25 column) in the appropriate buffer.

ADF binds to filaments and destabilizes them, causing partial depolymerization. The effect of ADF on the treadmilling is a suitable probe of its active state. In the presence of etheno-ATP-F-actin and a large excess of ATP, the decrease of etheno-ATP fluorescence reflects the rate of pointed-end depolymerization. ADF increases the rate of depolymerization. ADF activity is highly dependent on the pH, which should be >7.8.

To verify the labeling of Alexa488-labeled Arp2/3, first resolve the different subunits of Arp2/3 complex on SDS-PAGE and identify subunits by UV illumination of the gel. Typically 80% of the label is bound to the ARCp41 subunit, which contains five cysteines and 20% is bound to the Arp3 subunit (Wiesner et al., 2003).

To verify the branching activity of Alexa488-labeled Arp2/3 complex, polymerize actin (2.5 μM, 10% pyrenyl-labeled) in the presence of 0.5 μM VCA, in the absence or presence of 30 nM Arp2/3 before addition and after a 1-hr incubation with Alexa488-C5-maleimide. The authors find that the activity of Arp2/3 complex is not affected by Alexa488 labeling (Wiesner et al., 2003).

The reader will also find helpful information regarding the dependence of bacterial velocity on the concentration of essential components (Arp2/3, ADF, and gelsolin) and nonessential components (α-actinin, profilin, and VASP) in Figure 12.7.2.

Anticipated Results

A successfully completed assay is defined by the following criteria. Typically, the actin tails appear 5 to 15 min following addition to the motility medium. Typical examples of actin tails are shown in Figure 12.7.1. The percentage of motile bacteria/microspheres

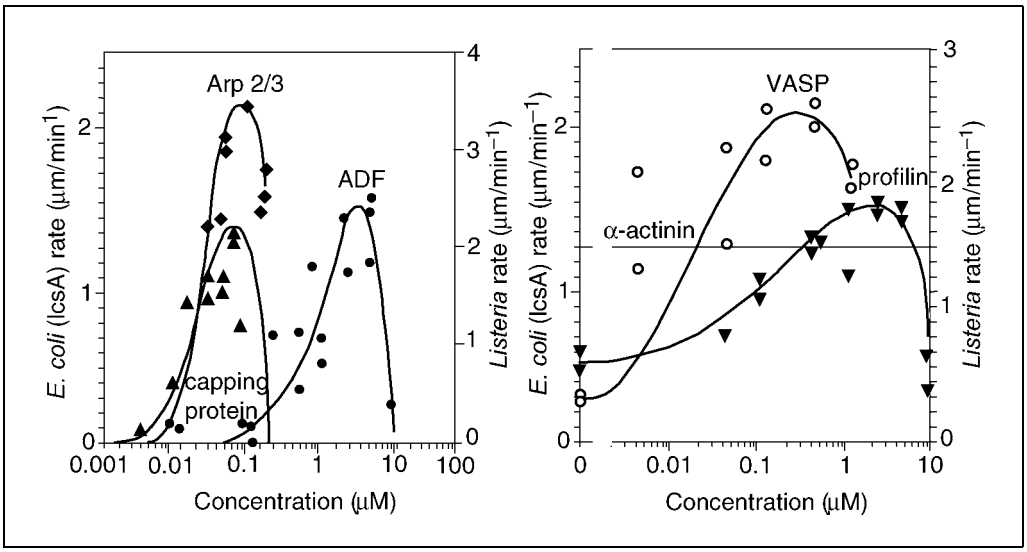

Figure 12.7.2 Dependence of bacterial rate on the concentration of essential components (left) and nonessential components (right). Filled symbols, *E. coli* (IcsA); open symbols, *Listeria*. Note the logarithmic abscissa scale. Duplicate data points represent independent measurements made by two experimentalists. Each data point is the average of 10 measurements. The standard deviation was generally 20%. From Loisel et al. (1999).

under optimal conditions falls between 70% and 80% for *Listeria* or *E. coli* IcsA and near 100% for N-WASP-coated polystyrene microspheres. At all surface densities of N-WASP, the steady-state velocity of microspheres was reached after 10 to 15 min incubation in the medium and remained constant for 1 hr. Average rates of movement at steady state are 1 to 2 μm/min for N-WASP or ActA-coated microspheres, 2 μm/min for *E. coli* IcsA and *Listeria*.

Time Considerations

Actin preparation requires 1 day to prepare an acetone powder from rabbit muscle and 6 days to purify actin extracted from acetone powder. Purifications of the proteins takes 3 days for Arp2/3 complex, 2 days for N-WASP, 2 days for gelsolin, 2 days for ADF, and 2 days for profilin. The motility assay only takes 1 hr.

In Vivo Marking of Single Cells in Chick Embryos Using Photoactivation of GFP

This unit describes a technique that uses a photoactivatable variant of GFP (PAGFP) and confocal laser scanning microscopy to selectively mark single cells within living embryos (see Basic Protocol). This method can be used to trace short-term cell lineage and study cell migratory behaviors. Initially, a region of interest within an embryo is microinjected with a glass needle containing the PAGFP construct. Electroporation opens pores in the cells through which the PAGFP construct enters. Individual cells that incorporate PAGFP are selected, focused in on, and made visually distinct from the host population by photoactivation with 405-nm laser light. Migratory behaviors of cells with photoactivated GFP are captured and analyzed using previously developed chick embryo culture and confocal time-lapse imaging techniques. Alternatively, embryos can be reincubated until a desired stage to survey the lineage of photoactivated cells. In addition, this unit includes a protocol for in ovo and whole chick embryo explant culture and time-lapse imaging (see Alternate Protocol).

PHOTOACTIVATION OF GFP IN SINGLE CELLS IN CHICK EMBRYOS

BASIC PROTOCOL

Early stage chick embryos are microinjected with photoactivatable GFP (PAGFP) and control constructs that are electroporated into the cells. Cells are imaged and the GFP is photoactivated to label individual or small groups of cells. These cells can be followed to analyze migratory behavior or cell lineage (see Fig. 12.8.1).

Materials

Fertilized white Leghorn chick eggs incubated at 37°C
India ink (drawing ink, Pelikan)
Howard Ringer's solution (J.A. Webster), sterile
10 mg/ml Fast Green FCF (Fisher) in Howard Ringer's solution, optional
PAGFP construct (available from J. Lippincott-Schwartz; *jlippin@helix.nih.gov*)
H2B-mRFP construct (optional; available from P. Kulesa; *pmk@stowers-institute.org*)
70% ethanol
High-vacuum silicone grease (Dow Corning)
B27 supplement (Invitrogen)
Neural basal medium (Invitrogen)
L-glutamine (Sigma-Aldrich)
H_2O, sterile
Human fibronectin (Invitrogen), diluted to 20 μg/ml in phosphate butter

Egg incubator (G.Q.F. Manufacturing Co., Model 1550)
15-ml tubes
Glass capillary tubes; borosilicate with filament (Sutter Instrument)
Glass needle puller (Sutter Instrument, Model P-87)
Micropipet loader
20-μl pipettor
Picospritzer (Picospritzer III, Parker Hannifin Corporation)
Dumont no. 5 forceps and iris scissors (Fine Science Tools)
Electroporator (BTX)
Platinum electrodes (A.M. Systems)

Contributed by D. A. Stark and P. M. Kulesa
Current Protocols in Cell Biology (2005) 12.8.1-12.8.11

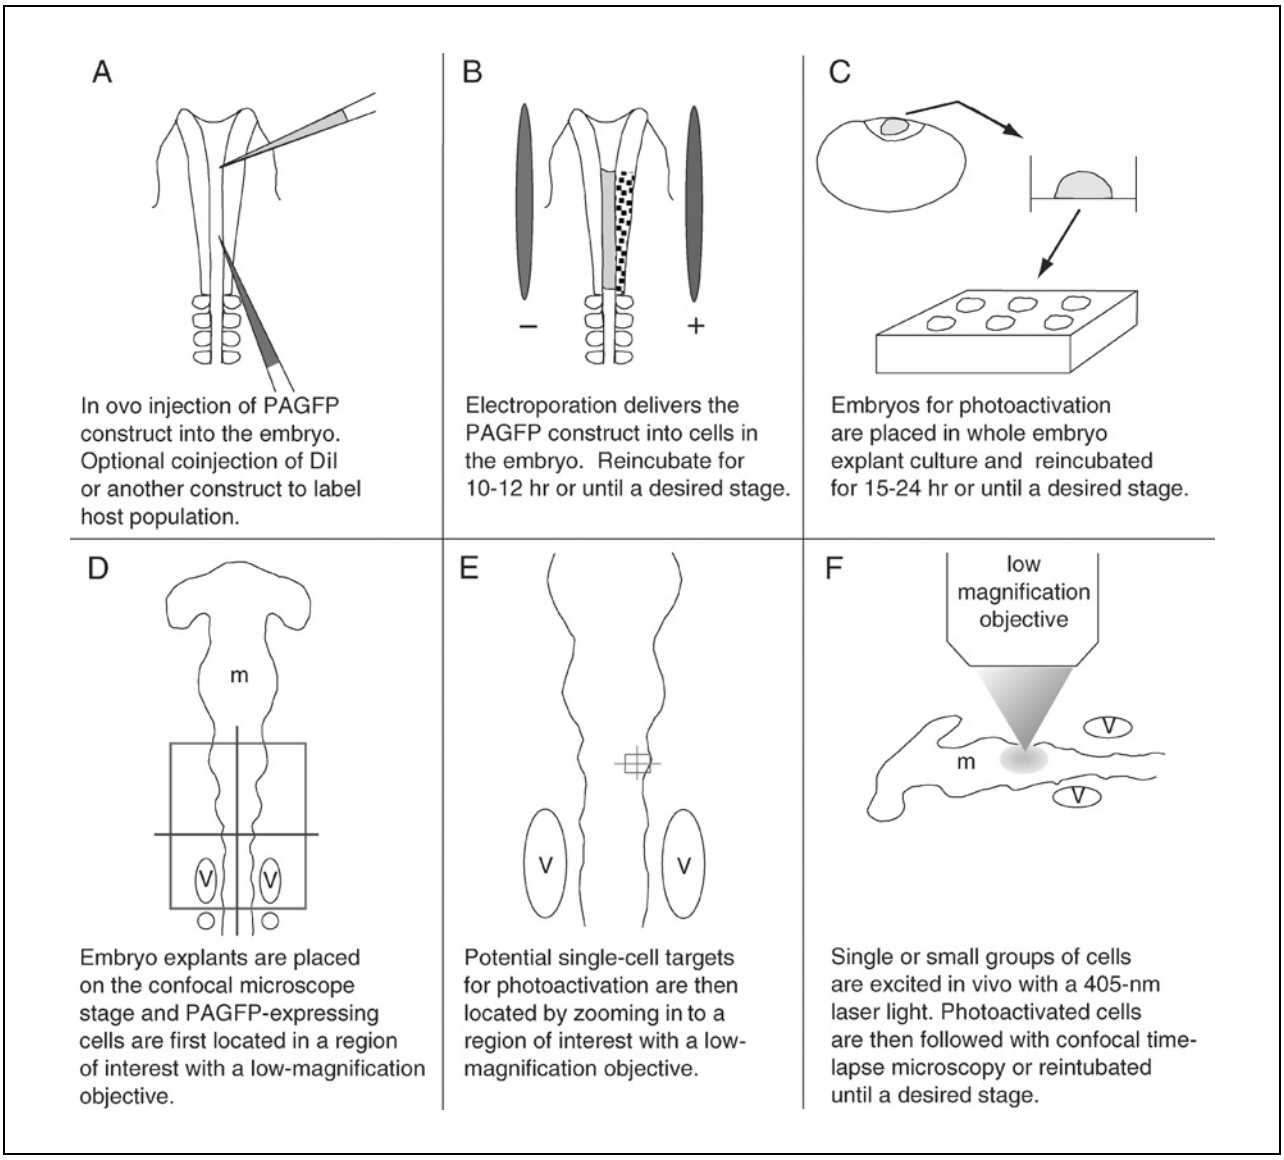

Figure 12.8.1 A diagram of the photoactivation process in a chick embryo. A summary outline of the photoactivation technique starting with the injection of PAGFP and H2B-mRFP constructs and ending with the photoactivation in the whole chick embryo. From left to right this figure shows a flowchart of the photoactivation process in a chick embryo, including: (**A**) injection, (**B**) electroporation, (**C**) mounting, (**D**) region of interest targeting, (**E**) selection of an individual cell for photoactivation, and (**F**) the photoactivation process.

18- and 25-G needles (Becton Dickinson)
1- and 5-ml syringes (VWR)
Tape (e.g., Scotch)
Plastic transfer pipet, sterile
Tungsten needle (A.M. Systems)
Micromanipulator (World Precision Instruments)
6-well culture plates
Soldering tool (Weller)
Sandpaper, medium grade (3M)
Glass cover slips, 22-mm round (VWR)
Culture insert (Millipore)
Petri dishes (Falcon)
Fluorescence stereo microscope with halogen light source and appropriate filters (LP-DAPI, TRITC; Leica)

Whatman no.1 filter paper
Dissecting scissors
Stereo dissecting microscope
Confocal inverted laser scanning microscope with 488- and 405-nm laser lines (Zeiss LSM5 PASCAL) and cell tracking software (optional)
Parafilm
Cardboard (1/4-in. thick)
Velcro (sticky back tape)
Insulation for cardboard box (5/16-in. thick; Reflectix)
Clear plastic packaging tape
Chick incubator heater (Model 115-20, Lyon)

Prepare reagents and equipment for injection

1. Incubate fertilized chick eggs at 37°C until the desired stage in an egg incubator.

   Incubate eggs for 40 to 43 hr for HH (Hamburger and Hamilton, 1951) stage 8 to 9 embryos.

2. Mix 1 ml of India ink in 9 ml of Howard Ringer's solution in a 15-ml tube.

3. Prepare a glass needle from a glass capillary tube using a needle puller with the following settings: heat, 400; pull, 50; velocity, 50; and time, 100.

4. (Optional) Prepare a very small amount of 10 mg/ml Fast Green to aid in visualizing the amount of injected dye.

5. Load the glass needle with a 1:1 mixture of the PAGFP construct (concentration of 1 to 2 μM/μl) and H2B-mRFP using a micropipet loader and a 20-μl pipettor.

   Both constructs should incorporate into the cells in a stochastic manner. Some cells will have one or the other of the constructs, and some will have both. Figure 12.8.2 (see Commentary) illustrates only the photoactivated cells (green) and not all of the cells that took up the PAGFP construct.

   H2B-mRFP is another fusion protein construct (H2B-mRFP) with a different emission spectrum such that the host population is fluorescently labeled. DiI (Molecular Probes) may also be used.

6. Trim the tip of the glass needle such that the construct is able to pass through the tip of the glass needle at small quantities with the application of the picospritzer. To do this, bring the tip of the glass needle to make gentle contact with the tip of a pair of Dumont no. 5 forceps. Tap the picospritzer foot pedal to visualize the amount of dye exuding from the tip of the needle.

   The picospritzer settings need to be adjusted with the size of the capillary needle; however, the recommended settings are: duration, 10 msec; and pressure, 10 psi.

7. Set the electroporator to a desired value.

   For an HH stage 10 embryo and platinum electrodes, the recommended settings are: 20 V, 55 pulse-length, and 5 pulses.

8. Attach an 18-G needle to a 5-ml syringe and a 25-G needle to a 1-ml syringe.

9. Bend the 25-G needle near the tip at a 90° angle in the direction of the pivot end and fill the syringe with the India ink solution from step 2.

Prepare embryo

10. Remove eggs from the incubator and lightly rinse the tops of the eggs with 70% ethanol.

11. With an 18-G needle, remove 3 ml of albumin from the caudal part of each egg.

12. Place a strip of tape over the top portion of the egg and use iris scissors to carefully cut a window in the egg without penetrating the yolk.

13. Locate the embryo within the window and angle the 1-ml syringe with the attached 25-G needle to inject India ink solution directly under the embryo. Try to use only enough ink to make the embryo visible (e.g., ~100 μl).

14. Place a few drops of Howard Ringer's solution around the embryo with a transfer pipet to prevent drying.

15. With a sharpened tungsten needle, carefully penetrate the vitelline membrane and pull it away from the desired injection site.

Inject and deliver constructs to embryos

16. Position the micromanipulator next to the egg and direct the injection needle to the injection site. Inject the PAGFP and control constructs into a selected region (Fig. 12.8.1).

    For example, PAGFP is injected into the lumen of the neural tube of HH stage 9 to 10 embryos to label cells in the neural tube and premigratory neural crest cells. The timing of the injection and the electroporation depends on the cells or tissue to be labeled.

17. After injection of the PAGFP construct, quickly retract the injection needle and place electroporator electrodes at the edge of the blastoderm (Fig. 12.8.1). Place the positive electrode on the right side of the embryo (as viewed from above the egg) and the negative electrode on the left side of the embryo.

18. Start the electroporation process using the parameters suggested in step 7.

    As the embryo develops, it will roll on its left side and this will expose the right side as the construct is attracted to the positive electrode.

19. Add a few more drops of Howard Ringer's solution around the embryo with the transfer pipet.

Incubate egg

20. Tape over the eggshell window and place the egg back into the 37°C incubator for 10 to 12 hr.

Prepare for embryo culture

21. Prepare a 6-well culture plate. In one well, cut a hole in the plastic bottom by melting a coin through the plastic with a soldering tool. Use sandpaper to smooth over the hole.

22. Secure a 22-mm glass coverslip to the bottom of the hole with a thin ring of silicone grease.

23. Mix 0.5 ml of B27 supplement with 25 ml of neural basal medium and add 0.0025 g of L-glutamine. Place 1 ml of culture medium into the well with the coverslip and fill the other wells half full with sterile water.

24. Pipet 200 μl of 20 μg/ml fibronectin onto a culture insert and swirl the insert such that the fibronectin covers the entire surface. Place the culture insert into a covered petri dish for 20 min at room temperature.

Dissect embryo

25. Remove the tape from the eggshell window and observe the health of the embryo and fluorescence labeling (construct expression) using a fluorescence stereo microscope.

    If the PAGFP is not highly expressed, then the construct will not be seen under a GFP filter cube; however, the construct can be seen under a long-pass DAPI filter cube at the

risk of photoactivation and UV exposure to the embryo. If under low expression, it would be most suitable to observe the control construct (H2B-mRFP) with a TRITC filter cube and assume the PAGFP cells have the equivalent (approximately) level of expression in the cells.

26. Cut a piece of Whatman no. 1 filter paper into a donut-shaped ring with an inner diameter large enough to encompass the whole embryo and blastoderm. Dip filter paper ring into Howard Ringer's solution, and place over the embryo.

    The embryo should be taken out of the egg and cultured prior to the photoactivation process.

27. Use dissecting scissors to cut around the outside edge of the filter paper.

28. Take the Dumont no. 5 forceps and pull out the paper ring with the embryo attached. Place the embryo into a petri dish containing Howard Ringer's solution.

29. Place the dish under a stereo microscope and use the forceps to tease off the vitelline membrane and filter paper. Rinse away any yolk or ink that may have accumulated around the embryo.

Establish embryo culture

30. Remove all excess fibronectin from the culture insert.

31. Cut the end off of a plastic transfer pipet so that the embryo can be easily picked up. Place the embryo onto the culture insert. Orient the embryo such that it is dorsal-side down (for photoactivation of PAGFP with an inverted confocal microscope).

    If the embryo is difficult to manipulate, place a few extra drops of Howard Ringer's solution onto the culture insert. After the embryo is positioned, gently pipet excess Howard Ringer's solution from the culture insert surface and let the embryo continue to spread out onto the culture insert surface.

32. Position the embryo in the center of the culture insert such that the edges of the embryo do not come in contact with the culture insert edges.

    If contact occurs, the embryo will be drawn to the point of contact with the culture insert.

33. Carefully place the culture insert inside the well of a 6-well dish containing medium. Position the culture insert directly over the center of the coverslip bottom. Cover the 6-well plate with the lid.

    The culture is now prepared for imaging. If not imaging immediately, place the dish into the 37°C incubator. Incubate 15 to 24 hr or until the desired stage.

Visualize embryo

34. Place the culture dish onto the microscope stage and bring the sample into focus using a low-magnification objective, e.g., using a 10× or 20× objective lens. Use a mercury lamp source and the filter cube needed to locate the population of cells expressing the control construct.

    A long-pass DAPI filter can be used to view PAGFP; however, avoid prolonged exposure of the embryo to UV light. The expression may be very dim depending on how many hours it is post injection.

35. If there is an option for multi-track excitation scanning available with the confocal imaging software, choose a multi-track configuration to include GFP and any excitation that is required for highlighting the host cell population, if necessary.

    If multi-tracking is not an option, select the single-track configuration. The multi-track configuration will create an image without any bleed through from the two constructs.

36. Create an image of the PAGFP-expressing cells, as if it were very low-expressing GFP, by turning up the detector gain, pinhole diameter, and applying four to eight averages before smoothing out the noise. If the expression is still too low to visualize, then increase the laser power past 10% on an argon laser.

37. Locate a region where the cells are expressing PAGFP.

Photoactivate GFP

38. To target an individual cell for photoactivation of PAGFP, continue to zoom in on a particular region. To focus on an individual cell, crop the region of excitation and scan around the area of the cell.

    The PAGFP construct is located in the cytoplasm and will diffuse rapidly during and post photoactivation. The selected cell does not have to be completely located inside the cropped box before photoactivation can occur.

39. To photoactivate PAGFP within a cell, use a 405-nm laser with a power setting between 2% and 5%. Then, scan a single image to photoactivate the PAGFP within the cell.

    A single scan may not be enough to optimize the photoactivation.

40. Evaluate the increase in mean GFP fluorescence in the cell by following the 405-nm excitation scan with a 488-nm excitation scan.

    A second or third scan at 405 nm may be necessary. Repeat as needed for other cells in the embryo.

    As the image is zoomed in, the power from the laser increases by:

    $$\textit{laser dosage} = (\textit{laser intensity} \times \textit{scan time})/\textit{scan area}.$$

    The higher the zoom, the less percent laser power is required. It is recommended to have 2% to 3% laser power if $\geq$35$\times$ zoom and 3% to 5% laser power if <34$\times$ zoom.

    If immediate photobleaching occurs, the 405-nm power is too high and must be lowered accordingly for the subsequent cell(s). The current cell is no longer suitable for photoactivation.

    Often, photoactivated cells become so bright that they are over exposed. At this point, the detector gain and pinhole can be reduced to create a more acceptable confocal image. If laser power levels were increased, then begin by reducing the power level.

41. Once photoactivation is complete in a single or number of cells in an embryo, begin collecting time-lapsed images or reincubate the embryo.

    Cell-lineage and cell-migratory behavioral studies use time-lapse imaging or reincubation of embryos.

42. To reincubate the embryo, add 0.5 ml of culture medium to the well.

    If the culture insert begins to float, remove some medium so that the culture insert sits on the bottom of the dish.

43. Wrap the dish in Parafilm and place in a 37°C incubator for the designated amount of time for post-photoactivation.

Construct a heater box for the microscope

44. Construct a 1/4-in. thick cardboard box around the microscope stage. Use Velcro strips to attach the box sides together.

    The box should fit around the stage but not enclose any lamp sources.

45. Cut holes in the box to allow for access to the microscope.

46. Wrap insulation around the outside of the box and attach it with clear packaging tape.

47. Near the back of the box, place the chick incubator heater within the box.

Perform time-lapse visualization

48. Configure the confocal imaging software to collect images at a desired time-interval.

    A minimum of a 2-min interval setting between time points is recommended.

IN OVO PHOTOACTIVATION

ALTERNATE PROTOCOL

In ovo photoactivation is an easier protocol that requires less time and allows the chick embryo to develop more naturally. Unfortunately, the technique requires more specialized equipment. An upright Zeiss LSM 5 Pascal was specifically ordered to provide the working distance needed to place a chicken egg under the objective for imaging. Another limitation to this protocol is that cells targeted for photoactivation must be accessible to confocal laser excitation. Once the embryo starts to turn, it becomes more difficult to target a cell for photoactivation. An advantage of this technique is that it allows a longer incubation period post photoactivation versus that for the cultured embryos.

Additional Materials *(also see Basic Protocol)*

Beeswax (Eastman Kodak)
Microinjected and electroporated eggs (see Basic Protocol)
3.8-cm × 7.5-cm × 15-μm Teflon membrane, high-sensitivity, oxygen permeable (Fisher)
~2.2-cm i.d. × 2.6-cm o.d. × 0.5-cm high acrylic ring (constructed in machine shop)
2.4-cm i.d. × 2.1-cm o.d. rubber O ring (constructed in machine shop)
Upright, laser scanning confocal microscope with 488-nm and 405-nm laser excitation, equipped with a long working distance 10× Plan Neofluar objective (NA = 0.3)

Prepare equipment

1. Prepare the Teflon membrane to mount over the embryo in ovo to allow oxygen transfer to the embryo without drying the contents of the egg.

   a. Warm beeswax enough to melt it (~37°C). Dip one edge of the acrylic ring in the heated beeswax. Quickly place the ring in the center of the Teflon membrane and use the rubber O ring to pull the membrane taught around the acrylic ring. Hold the O ring in place until the beeswax has completely dried.

   b. Cut away the extra Teflon and roll the edges of the ring over a hot plate to adhere the membrane to the ring.

2. Prepare the upright LSM 5 Pascal microscope by turning it on, removing any unnecessary objectives, dropping the removable scanning stage and focus drive to the lowest position, and placing a protective cover of plastic wrap over the stage to prevent any egg accidents.

3. Ten to 12 hr post injection, remove microinjected and electroporated eggs from the incubator and observe for fluorescence.

4. Cut out a window of an egg so it is large enough to place the membrane directly over the embryo.

5. Place a 1 ml of Howard Ringer's solution over the embryo to prevent any drying that may occur and drop the membrane so that the center is directly over the embryo.

Photoactivate GFP

6. Carefully place the egg under the long-working distance objective and settle it in a low platform holder.
7. Photoactivate as described in Basic Protocol, steps 38 to 40.
8. Remove the egg from the microscope and gently pull the membrane and acrylic ring off of the embryo. Retape the egg and place it back into the 37°C egg incubator.
9. Rinse the membrane in Howard Ringer's solution before preparing it for the next embryo.

SUPPORT PROTOCOL

IMAGING USING HIGH-MAGNIFICATION ACQUISITION

To image post photoactivation, use a high-magnification acquisition protocol because once the embryo grows older, the tissue becomes too thick and deep to collect quality images. To acquire images at a higher magnification, the embryo must be removed from the culture disk and placed on a slide and coverslipped.

Additional Materials *(also see Basic Protocol)*

Embryos on culture inserts (see Basic Protocol)
Glass-bottomed petri dishes (Mat Tek)
Glass microscope slides (VWR)
Coverslips, 22-mm

1. Remove the embryo on a culture insert from a 6-well plate and place into a larger glass-bottomed petri dish filled with Howard Ringer's solution. Gently rinse the disk until the embryo detaches and floats off of the membrane.

   If the embryo remains attached, then forceps may be used to pull away the edges of the blastoderm from the membrane.

2. On a glass microscope slide, use silicone grease to create a circle large enough to place the whole embryo inside.
3. Cut the tip off of a plastic transfer pipet so that the embryo may be freely picked up from the petri dish. Place the embryo inside of the ring of grease on the glass microscope slide.
4. Position the embryo so that the dorsal side will contact the coverslip. Using a small-tip transfer pipet, remove excess Howard Ringer's solution from the grease ring.
5. Place a 22-mm round coverslip over the embryo and gently seal the glass against the grease. Continue to image as described above.

COMMENTARY

Background Information

The photoactivatable GFP (PAGFP) was developed at the National Institutes of Health (Patterson and Lippincott-Schwartz, 2002). The technique takes advantage of the inherent brightness of the green fluorescent protein (Chalfie et al., 1994) and previously developed photoactivation methods (Yokoe and Meyer, 1996; Sawin and Nurse, 1997). The mechanism of PAGFP is not completely understood; however, when it is excited with ultraviolet or an ~400-nm light, the chromophore population undergoes photoconversion and shifts predominantly to the anionic form. This results in an increase in minor peak absorbance. PAGFP is designed with a lower initial minor peak absorbance that greatly increases after photoconversion, giving a more noticeable optical contrast with 488-nm excitation. Upon intense illumination with ultraviolet or an ~400-nm light, the baseline fluorescence in a PAGFP-labeled cell increases ~100-fold under 488-nm excitation (Patterson and Lippincott-Schwartz, 2002).

Other groups have taken advantage of these types of protein characteristics to create fluorescent reporters such as Kaede (Ando et al., 2002) and photoswitchable CFP (PS-CFP; Chudakov et al., 2004). Kaede takes advantage of a photoconversion technique that changes the green emission, excited at 488 nm, to red when exposed to 405-nm light. A 2000-fold increase can be seen as the green expression decreases and the red expression increases. Both the green and the converted red forms have the same excitation wavelength of 488 nm. Kaede serves as an excellent marker to selectively distiguish a single cell while maintaining the ability to observe other neighboring cells. PS-CFP is similar to of Kaede with a UV-induced ability to convert from cyan-to-green emission. However, both excitation and emission spectra are affected during the switch when exposed to 405-nm laser light creating a 1500-fold increase in fluorescence. The PS-CFP construct has been used to study protein trafficking and fluorescence resonance energy transfer (FRET) analysis.

The PAGFP technique has distinct advantages over existing techniques, including the ability to mark a cell deep within an embryo and sustain individual cell health with minimal invasiveness. PAGFP can be re-excited with 405-nm light to extend the duration of the increased fluorescent signal in a cell versus non-photoactivated cells. Previous cell labeling techniques, for the most part, rely on the ability to inject a fluorescent dye into a cell(s) using a glass needle. A brief history of cell tracing methods is found in Stern and Fraser (2001). Iontophoretic labeling is described in Fraser (1996). A comparison of optical techniques is found in Patterson and Lippincott-Schwartz (2003). Standard electroporation techniques are used to deliver the PAGFP construct into cells in an embryo (Itasaki et al., 1999).

Critical Parameters and Troubleshooting

During the photoactivation process, photobleaching may be observed during high magnification or zoom using the 405-nm laser. Once cells start to photobleach, they are no longer suitable for photoactivation. This can be prevented by starting the experiment with a low-power laser or using an objective with a low magnification such as the 10× 0.3 NA Plan Neofluar objective.

An increase of intensity from non-photoactivated cells can be seen over time. Eventually, the photoactivated cells may be lost among the host population, usually after 24 hr. This is an effect that appears to depend on the embryo reincubation time and the efficiency of the photoactivation. The longer an embryo has to reincubate post injection, the more effective is the photoactivation of the cells.

Photoactivated cells can be reactivated. Follow the same procedure as photoactivation, zooming in on cells and irradiate with a 405-nm light. There may not be another 100-fold intensity increase; however, a strong discrimination will be seen in comparison to the non-photoactivated cells. There are several reasons why a cell may not be visually distinguishable when it is followed over time. These include: cell death, migration deep into the embryo, or simply poor photoactivation. When final images are taken and some or all of the photoactivated cells are missing, then the image histogram must be used to determine which cells have the highest fluorescence intensity. PAGFP proves to be stable in 488-nm light, which makes it a good candidate for z-stack and time-lapse usage; however, under 405-nm light, the cell can start to rapidly bleach if scanning persists after photoactivation.

Anticipated Results

A cell with good expression of PAGFP can be photoactivated such that there is a 100-fold increase in mean fluorescence intensity (Fig. 12.8.2, panel B). The photoactivated cell will be visually distinguishable when compared to other cells that have not been irradiated with 405-nm light (Fig. 12.8.2, panels A, C, and D). By using confocal microscopy, three-dimensional renderings of the photoactivated cell(s) can be created to visualize the morphology during active migration or post migration. This data is best collected under the conditions of a healthy embryo, strong PAGFP photoactivation in the target cell, and active cellular activity.

Time Considerations

The total protocol as written will take up to 3 days to complete with a 12-hr post-photoactivation incubation period. The majority of this time is taken up with culture and egg incubation times. For example, to photoactivate cells in the neural tube and premigratory neural crest cells, eggs were incubated for 36 to 40 hr to bring them to an HH 9 to 10 somite stage before injecting PAGFP.

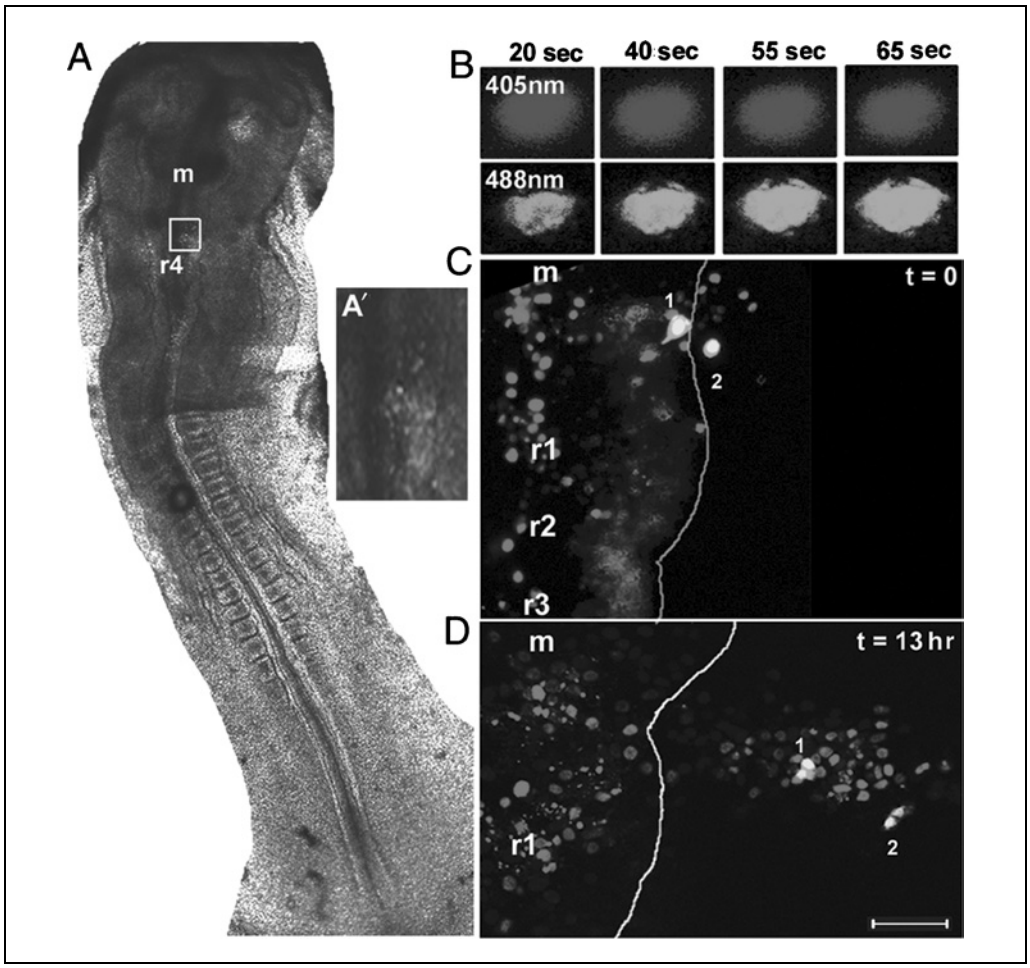

Figure 12.8.2 Photoactivation of PAGFP in a single cell in a living chick embryo. (**A**) A global view of a 16-somite chick embryo (5× magnification) showing post-photoactivation of PAGFP in a single cell (green-colored cell, within the box region) surrounded by a subpopulation of host cells (red). (**A′**) A magnified view of the box region in **A** shows the photoactivated cell (green-colored). (**B**) The photoactivation process in a single cell within the chick embryo is shown as a sequential series of confocal excitation scans. The top row represents the 405-nm excitation scans of the cell (blue) at various time points of a typical sequence. The second row shows the resulting increase in GFP-fluorescence after each 405-nm excitation scan is followed by a 488-nm excitation scan. (**C,D**) As an example of the ability to observe individual cells within the chick embryo, two individual migrating cells (labeled as 1 and 2) were photoactivated separately at a time when the cells were just starting to emerge and migrate into the surrounding unlabeled tissue. The subpopulation of cells (red) within the chick neural tube provide a background view of other adjacent migrating and non-migrating cells. After a 13-hr reincubation of the whole embryo explant in culture, the final image (**D**) shows the location of the original cells that have migrated further laterally away from the neural tube. The cells (1 and 2) appear to have divided. The scale bar is 50 μm. The embryo in (**A**) is ∼2 mm in length. The individual cell in **B** has a diameter of ∼15 μm. The labels refer to the midbrain (m) and rhombomeres 1 to 4 (r1, r2, r3, r4). This black and white facsimile of the figure is intended only as a placeholder; for full-color version of figure go to *http://www.interscience.wiley.com/c_p/colorfigures.htm*.

Culture and photoactivation can be done within 2 to 3 hr after a minimum 10- to 12-hr incubation period. The length of the time-lapse imaging session or reincubation can vary depending on the desired stage and morphological event that is to be probed.

CHAPTER 13
Organelle Motility

INTRODUCTION

The cytoplasm of eukaryotic cells is comprised of a complex network of filaments, including microtubules and actin, that extend throughout the cytoplasm. These filaments are highly dynamic and continuously remodel as the cell changes shape, divides, and interacts with the environment. They play a key role in organizing the cytoplasm by connecting protein compartments and organelles in different regions of the cell. Microtubules, for example, are known to provide communication paths between organelles, controlling the spatial location of these structures. Actin filaments, on the other hand, form contractile bundles with myosin and mediate muscle contraction and contractile-ring formation during cytokinesis. In this chapter, assays are described for examining the characteristics and functions of the microtubule and actinomyosin filament systems. These assays are useful for identifying accessory proteins that attach microtubules to organelles and/or modulate sliding of myosin molecules across actin fibers.

UNIT 13.1 describes an in vitro assay for examining interactions between microtubules and isolated organelles. Microtubules are polar structures with their plus (i.e., rapidly growing) ends extending out to the cell periphery, and their minus ends associated with the centrosome adjacent to the nucleus. They emanate as a star-like network out from the centrosome, with new microtubules constantly extending out to replace old ones that have depolymerized. The endoplasmic reticulum (ER) uses microtubules to move out to the cell periphery, while membranes of the Golgi complex cluster inwards toward the centrosome along microtubules. These organelle movements are mediated by microtubule-associated motor proteins, including kinesin and cytoplasmic dynein. The in vitro motility assay described in this unit provides a useful system for studying organelle transport along microtubules. It can be used for dissecting the molecular machinery involved in such movement, including proteins that regulate microtubule motors or that cross-link motors to membranes. Effects of pharmacological or biochemical perturbations on microtubule structure and dynamics can also be investigated. In the assay described in *UNIT 13.1*, microtubules are nucleated from a stationary point (i.e., the flagellar axoneme), allowing their plus ends to grow and shorten in a way analogous to what happens in normal cells. Both motor-driven motility of organelles and microtubule polymerization–driven movement of organelles can be studied. The unit also provides detailed methods for preparation of purified tubulin, cytosol enriched in motor proteins, and axonemes from sea urchin sperm, as well as for isolation of membrane-bound organelles. The assay is performed in a simple perfusion chamber and the results are visualized using video-enhanced DIC microscopy.

UNIT 13.2 provides a motility assay for transport of actin by myosin. F-actin filaments labeled with rhodamine-phalloidin are imaged in an in vitro system that contains purified myosin, an ATP-activated motor protein that hydrolyzes ATP to ADP and P_i when stimulated by binding to actin filaments. This assay uses two purified proteins, actin and myosin, to study the contractile forces produced by the sliding of actin filaments along the myosin filaments. During muscle contraction, the head regions of myosin molecules engage in an ATP-driven cycle in which they attach to adjacent actin filaments, undergo a conformational change that pulls the myosin filament, and then detach. This results in

Contributed by Jennifer Lippincott-Schwartz
Current Protocols in Cell Biology (2005) 13.0.1-13.0.2

the sliding of actin filaments against the myosin, which can be directly visualized and quantified in this assay.

The use of GFP fusion proteins has revolutionized the study of organelle motility by providing a method to visualize diverse organelles directly under the microscope. Virtually any protein can be tagged with GFP, expressed in cells, then visualized by applying blue light. *UNIT 13.3* describes how to express and image GFP fusion proteins in plants in order to study organelle dynamics in these cell types. Both transient and viral-mediated expression methods are described for expressing GFP fusion proteins. Tips are given for imaging GFP proteins targeted to the endoplasmic reticulum and Golgi complex, two organelles that function in secretory transport. Solutions to common problems with expression and imaging GFP fusion proteins–e.g., misfolding and autofluorescence–are also discussed.

Nuclear migration (*UNIT 13.4*) occurs in a wide variety of cell types, including newly fertilized eggs, muscle, nerves, and dividing cells. It is vital for the cell to properly locate its nucleus and surrounding endomembrane system. This unit describes an in vitro assay for monitoring nuclear motility of the pronucleus from frog eggs. This motility is, as are other examples of nuclear motility, driven by microtubule-dependent motility. Purified nuclei are added to a motility extract that includes *Xenopus* cytosol, centrosomes, purified microtubules, dynein, and regulatory factors. The system is then visualized using video enhanced-differential interference contrast microscopy. Once they associate with microtubules, the nuclei normally move toward the centrosomes in microtubule minus end-directed (due the dynein in the extract) motility. There they accumulate over time. Regulators or inhibitors of this movement can be assayed, and the effects on motility can be quantified using this system.

UNIT 13.5 describes dynamic live cell imaging approaches employing photobleaching to measure the kinetics of nuclear proteins. Three major methods of photobleaching microscopy are described fluorescence recovery after photobleaching (FRAP), fluorescence loss in photobleaching (FLIP), and inverse fluorescence recovery after photobleaching (iFRAP). The unit highlights how each technique differs in permitting the determination of distinct particular parameters of protein behavior in vivo. In addition to describing the photobleaching techniques, this unit details transfection methods for introducing GFP-expression vectors into mammalian cells by electroporation or by lipofection. Moreover, it provides a method for the determination of the number of GFP molecules in a single, living cell, which is critical for the quantification of GFP-fusion proteins.

UNIT 13.6 describes a number of in vitro assays for characterizing the function of putative actin-binding proteins. One assay described uses a change in fluorescence of pyrenyl-labeled actin to assess a protein's actin capping activity. The read-out of this assay includes kinetic measurements of filament growth or depolymerization at one or the other end of the actin filament. Another assay describes assays of filament growth from actin seeds. This allows proteins that interact with G-actin to be analyzed, and permits the determination of whether the actin association rate constant for filament assembly is the same or different from that of free G-actin. The unit also provides protocols for measuring the turnover of a population of filaments in vitro using a fluorescent analog of ATP whose fluorescence changes when bound to actin. It further describes mathematical modeling approaches for understanding the mechanism by which the basic features of actin spontaneous assembly (nucleation-growth process) are modified by the severing or branching agents. Finally, the unit highlights light microscopy approaches that can be used to observe the dynamics of individual actin filaments, including total internal reflection fluorescence microscopy (TIRF).

Jennifer Lippincott-Schwartz

Microtubule/Organelle Motility Assays

This unit describes an in vitro assay that uses video-enhanced differential interference contrast (VE-DIC) microscopy to examine the motile interactions between isolated organelle fractions and microtubules (MTs; see Basic Protocol). The method can be used to dissect the molecular requirements for organelle movement and membrane trafficking. A field of axoneme-nucleated MTs, growing and shortening as they would in a living cell (dynamic MTs), is generated in a simple microscope perfusion chamber. Various combinations of isolated endoplasmic reticulum (ER) and Golgi apparatus organelles, cytosol containing motor proteins and other soluble factors, nucleotides, and specific pharmacological reagents are then added to the dynamic MT, and the motile interactions between the organelles and MTs are observed by VE-DIC microscopy.

In addition, this unit includes protocols for biochemical preparation of phosphocellulose-purified tubulin from porcine brain (see Support Protocol 3), axonemes from sea urchin sperm (see Support Protocol 2), rat liver cytosol (see Support Protocol 4), and rat liver organelle fractions (see Support Protocol 5). To ensure more reproducible results, a protocol for preparing thoroughly cleaned ("squeaky clean") coverslips and simple microscope perfusion chambers is also included (see Support Protocol 1).

STRATEGIC PLANNING

Performing a successful motility assay requires ~2 weeks of preparatory biochemistry and considerable skill in obtaining VE-DIC images. Detailed description of how to set up the sophisticated optical system required for imaging single MTs by VE-DIC is outside the scope of this unit and is not included here. Instead, the reader should consult the unit on microscopy by E.D. Salmon (*UNIT 4.1*) and other more comprehensive descriptions of the techniques required for achieving such images (Walker et al., 1988; Salmon and Tran, 1998).

Preparation of the principal biochemical components for the motility assay is detailed in Support Protocols 2 to 5. These components must be prepared in bulk in advance, dispensed into appropriately sized aliquots, and stored at −70°C. Unopened samples can be stored for >2 years. Three different types of animal tissue must be obtained for the various preparations. The animals that are most difficult to acquire are the sea urchins, *Strongylocentrotus purpuratus*, used for the preparation of axonemes. Sea urchins can be obtained from early winter through mid spring from Marinus, Inc., but their availability depends on the seasonal catch. Porcine brains for the tubulin preparation must be obtained from freshly slaughtered pigs, and the tubulin preparation should begin within 3 to 4 hr after the tissue is harvested. A local butcher can supply information regarding the location of the closest slaughterhouse. Fresh rat livers are fairly easy to obtain; alternatively, flash-frozen livers can be purchased from Pel-Freez.

In contrast to the biochemistry and microscopy, setting up the motility assay in the Basic Protocol is relatively simple. Note, however, that specific brands of microscope coverslips and slides are required for the preparation of the microscope perfusion chambers (see Support Protocol 1), and the coverslips should be cleaned according to the steps outlined. Rigorous attention to the detailed instructions presented in Support Protocol 1 is crucial to the success of the assay. Inexpensive microscopy supplies are often coated with oils and dirt that can lead to spurious and inconsistent results.

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) and must follow officially approved procedures for care and use of laboratory animals.

Current Protocols in Cell Biology (1998) 13.1.1-13.1.21

MT/ORGANELLE MOTILITY ASSAYS

This protocol describes the set-up and execution of an assay that combines dynamic MTs with cellular organelle fractions and cytosolic proteins to reconstitute organelle motility in vitro (see Fig. 13.1.1).

Materials

Axoneme fragments (see Support Protocol 2)
Golgi or ER membranes (see Support Protocol 5)
45 μM purified brain tubulin (see Support Protocol 3)
Rat liver cytosol (see Support Protocol 4)
PM buffer (see recipe)
PM buffer containing 1 mM GTP
20× energy regeneration system (see recipe)
15 mM MgGTP, prepared by diluting 100 mM MgGTP stock (see recipe) in PM buffer
Valap (see recipe)

Simple perfusion chambers (see Support Protocol 1)
Filter paper cut into 2-cm squares

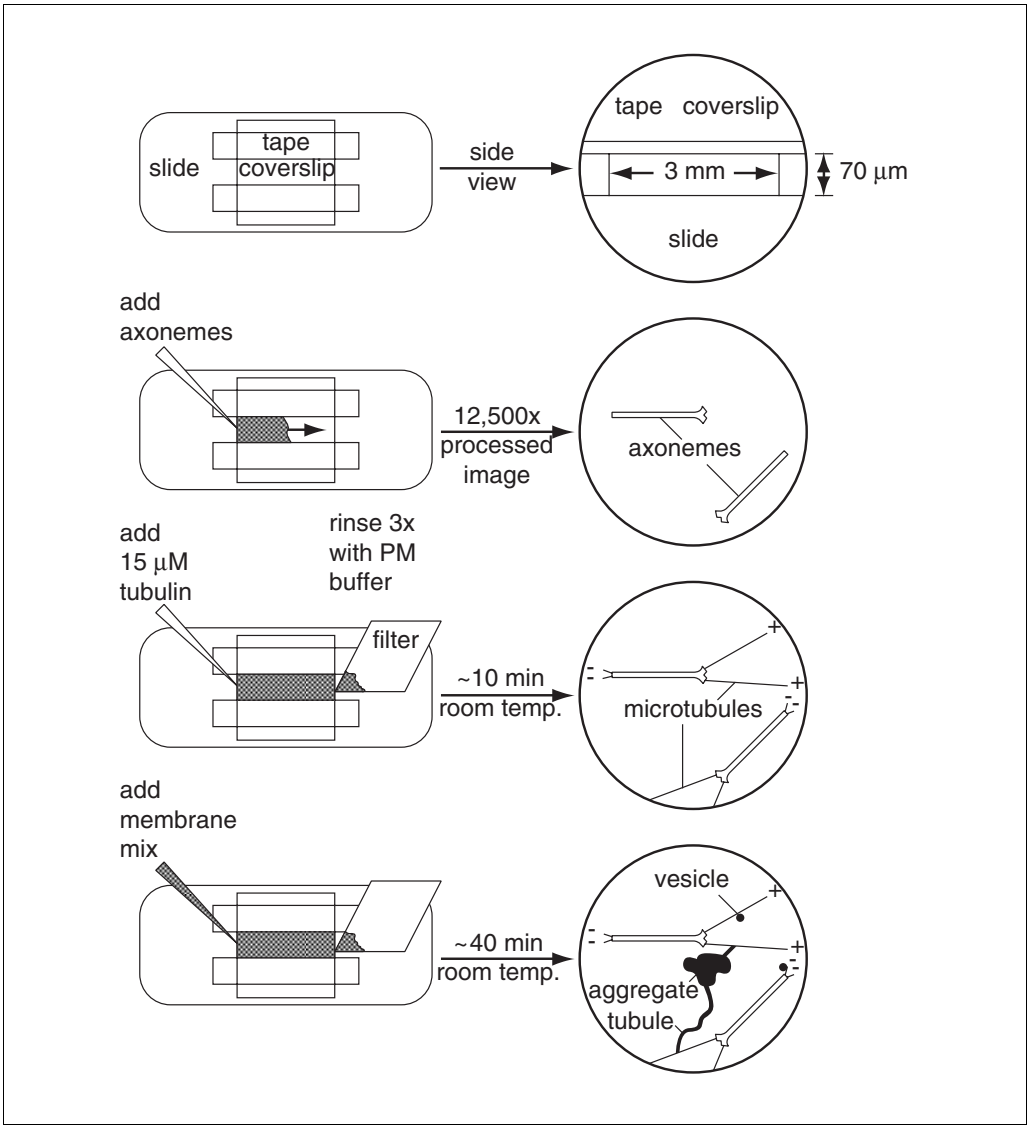

Figure 13.1.1 Flow chart for performing MT/organelle motility assay.

Humid chamber made of a 90-mm glass petri dish containing moist paper towels
High-resolution VE-DIC microscope system (as described in Salmon and Tran, 1998 or equivalent)

1. Rapidly thaw and immediately place on ice one aliquot each of axonemes, Golgi or ER membranes, 45 μM purified brain tubulin, rat liver cytosol, and 20× energy regeneration system.
2. Dilute axonemes with PM buffer to the proper concentration as determined in Support Protocol 2. Prepare 6× Golgi or ER membranes by diluting organelles with PM buffer/1 mM GTP (see Support Protocol 5, step 10).
3. Prepare and place on ice a 30-μl membrane mix:

   5 μl 6× Golgi or ER membranes
   1.5 μl 20× energy regeneration system
   10 μl 45 μM tubulin
   1 μl 15 mM MgGTP
   12.5 μl cytosol.

4. Add axonemes to a simple perfusion chamber by slowly pipetting ~10 μl of diluted axonemes against one open end of the chamber and allowing the chamber to fill.

   Be careful to avoid introducing large bubbles into the chamber.

5. Place the perfusion chamber into the humid chamber and incubate 10 min at room temperature to allow the axonemes to adhere to the glass.
6. Wash out unadhered axonemes by slowly pipetting 10 μl PM buffer against one end of the perfusion chamber while simultaneously wicking excess buffer from the opposite side of the chamber with the tip of a square of filter paper. Repeat wash two more times.
7. Dilute 5 μl of 45 μM tubulin with 10 μl PM buffer/1 mM MgGTP. Perfuse the diluted tubulin into the chamber containing the washed axonemes. Place a drop of immersion oil on the top and bottom of the slide, and transfer it to the VE-DIC microscope stage.

   Briefly, the microscope system consists of illumination from an HBO100-W mercury arc lamp introduced into an upright microscope stand (equipped with optical components for DIC image formation) via a fiber-optic scrambler. Illumination is passed through IR reflecting and 546-nm narrow band-pass filters before being focused for Köhler illumination onto the specimen via a 1.4-NA oil-immersion condenser. The light is collected by a 100 × 1.3- or 1.4-NA objective and magnified 12.5× before being collected by a scientific-grade Newvicon tube type video camera (equivalent of Hamammatsu C2400). The video signal is processed by frame averaging, background subtraction, and contrast enhancement by a real-time image processor (equivalent to the Hamammatsu Argus 10), and then recorded in real time onto high-resolution S-VHS video tape.

8. Focus on the axonemes with the 100× objective lens. Align the slide on the stage so that one edge of the double-stick tape that forms the perfusion chamber perfectly bisects the area illuminated by the microscope condenser lens. Immerse the 100× objective lens in oil and focus on the edge of the tape. With the edge of the tape in view, back off fine focus until the very edge of the tape begins to go out of focus. Move the slide so the lens is within the area coated with axonemes, which should now be quite close to focus.

   It can be difficult to focus on axonemes on the surface of the coverslip because of their very small size and the very bright illumination needed for VE-DIC. This procedure should make focusing on the axonemes easier.

Table 13.1.1 Pharmacologic Agents for Addition to Membrane Mix[a]

Pharmacologic agent	Final concentration	Function	Stock solution	Amount added to 30-µl membrane mix
Brefeldin A	60 µM	Removes Golgi coat proteins	Dilute 1.5 µl of a 3.6 mM Brefeldin A stock in ethanol[b] 1:1 into PM buffer[b] prior to use	3 µl
Aluminum fluoride		Activates hetero-trimeric G proteins		Add 1 µl of 30× NaF[b] and 1 µl of 30× $AlCl_3$[b]
MgGTP-γ-S	1 mM	Activates hetero-trimeric G proteins	30 mM MgGTP-γ-S[b]	1 µl
MgAMP-PNP	1 mM	Inhibits kinesin-like proteins[c]	150 mM MgAMP-PNP[b]	1 µl
Sodium ortho-vanadate	25 µM	Inhibits cytoplasmic dynein[d]	Dilute 1 µl of 100 mM stock into PM buffer[b]	1 µl

[a]Also see *APPENDIX 1B*.

[b]See recipes for instructions on solution preparation. Abbreviations: MgAMP-PNP, 5′ adenylylimidodiphosphate magnesium salt.

[c]Vale et al., 1985.

[d]Shpetner et al., 1988.

9. Optimize the image for visualization of individual MTs by aligning the microscope for Köhler illumination. Use the real-time image processor to perform background subtraction, contrast enhancement, and frame averaging. Observe and record onto S-VHS video tape images of polymerization dynamics of individual MTs as they are nucleated off the axonemes.

   Note the difference between the plus (longer, faster-growing MTs) and minus (shorter, slower-growing MTs) ends of the axonemes. For details on microscopy techniques, refer to UNIT 4.1 or Salmon and Tran (1998).

10. During the observation of MT dynamics, allow the membrane mix to warm to room temperature.

11. Perfuse 12 µl of membrane mix into the simple perfusion chamber on the microscope stage. Seal the chamber edges on both sides with a drop of melted valap. Observe and record the dynamic interactions between the organelles and MTs.

    Note that often it takes up to 45 min for motility to develop. This time period is proportional to room temperature.

    Pharmacological agents (see Table 13.1.1) may be added to the membrane mix prepared in step 3 to test the involvement of Golgi coat proteins and MT motor proteins in organelle movement in vitro. For review of the effects of these pharmacological agents on membrane trafficking, see Klausner et al. (1992). These agents should be added to the mix, correcting all components for concentration, and incubated 15 min at 37°C prior to being introduced into the flow chamber.

    Organelles may also be pretreated to strip them of specific subsets of peripheral proteins prior to addition to the mix. This will allow examination of the involvement of these proteins in organelle movement (see Support Protocol 5, steps 12 to 14).

PREPARATION OF SIMPLE PERFUSION CHAMBERS AND COVERSLIPS

SUPPORT PROTOCOL 1

For the MT/organelle motility assay to be reproducible, the perfusion chambers and coverslips must be "squeaky clean."

Materials

Versa Clean dish detergent (Fisher)
1 mM EDTA
70% and 100% ethanol

22 × 22–mm no. 1.5 coverslips (Corning)
Water-bath sonicator
Double-stick tape
Clay-Adams precleaned Goldseal 3 × 1–in. microscope slides (Becton Dickinson)
Dumont no. 5 forceps

Prepare "squeaky clean" coverslips

1. Place coverslips, one at a time, into a 500-ml glass beaker filled halfway with hot tap water containing ~5 ml Versa Clean detergent. Take care to separate coverslips that are stuck together. Sonicate 45 min in a water-bath sonicator.

   Prepare three packages of coverslips at one time.

2. Rinse coverslips ten times by swirling with hot tap water. Sonicate 30 min in hot tap water.
3. Rinse coverslips ten times by swirling with double distilled water. Sonicate 30 min in double distilled water.
4. Rinse coverslips three times by swirling with 1 mM EDTA. Sonicate 30 min in 1 mM EDTA.
5. Rinse coverslips three times by swirling with 70% ethanol. Sonicate 30 min in 70% ethanol.
6. Rinse coverslips three times by swirling with 100% ethanol. Sonicate 30 min in 100% ethanol.
7. Rinse coverslips once with 100% ethanol. Transfer clean coverslips to a 500-ml screw cap jar, cover with 100% ethanol, and store at room temperature until use.

Prepare simple perfusion chambers

8. Cut pieces of double-stick tape into 25 × 5–mm strips. Apply two strips of tape to the center of a slide, side by side, 3 mm apart, and parallel to the long axis of the slide.
9. Using Dumont no. 5 forceps, retrieve a single squeaky clean coverslip from the storage jar. Dab the edge of the coverslip with a Kimwipe to remove any large drops of ethanol and quickly pass it through the flame of a Bunsen burner. Allow ethanol to burn off.
10. Center the coverslip over the tape strips on the slide and apply the coverslip to the strips of tape, pressing firmly with the back of the forceps to make a good seal.
11. Repeat until ~20 perfusion chambers have been prepared and store them in a slide storage box until use.

SUPPORT PROTOCOL 2

PREPARATION OF SEA URCHIN SPERM AXONEMES

This protocol (as adapted from Bell et al., 1982) should yield enough axoneme fragments to perform thousands of motility assays.

Materials

4 male *S. purpuratus* sea urchins (Marinus)
0.55 M KCl
Artificial sea water (mixes available from aquarium supply stores; prepare per manufacturer's instructions)
20% (w/v) sucrose in distilled water
Isolation buffer (see recipe)
High-salt buffer (see recipe)
Isolation buffer (see recipe) containing 50% glycerol

60-ml syringe with 18-G needle
Tabletop clinical centrifuge
Refrigerated superspeed centrifuge (Sorvall RC-5B) with Sorvall SS-34 rotor (or equivalent)
50-ml polycarbonate centrifuge tubes (e.g., Sorvall)
50-ml Dounce glass homogenizer with type A and B pestles

NOTE: Because it is impossible to tell what sex a sea urchin is until it sheds gametes from the pores located on its dorsal surface, order at least twice as many animals as needed.

Collect sperm

1. Sacrifice the sea urchins. Fill a 60-ml syringe with 0.55 M KCl and attach an 18-G needle. Pierce the urchin from the bottom center of the animal, insert the needle ~1 in., and inject body cavity with fluid until resistance is felt. Place the animal upright on paper toweling. Allow several minutes for gametes to begin to exude from the five pores located on top of the urchin.

   The urchins must be injected and sacrificed to induce their gametes to shed. Upon arrival from shipment, some urchins may have shed a small amount of gamete. In this case, identifying the sex of the animal should be simple: sperm is white and eggs are peach or orange colored.

2. Using a glass Pasteur pipet with a rubber bulb, collect white sperm dropwise as it is exuded. Pool sperm from all four animals into a single test tube on ice.

   Expect to get 3 to 4 ml of sperm per animal over a ~20-min collection period. Do not collect orange- or peach-colored eggs.

3. Dilute the sperm with 3 vol artificial sea water. Let stand 20 min on ice.

4. Centrifuge 5 min at 500 rpm in a tabletop clinical centrifuge to pellet debris.

5. Transfer supernatant to 50-ml polycarbonate centrifuge tubes. Pellet sperm by centrifuging 5 min at 3000 × *g* (5000 rpm in SS-34 rotor), 4°C.

Isolate sperm tails

6. Remove and discard supernatant. Resuspend pellet by trituration in 5 vol of 20% sucrose to osmotically remove the plasma membranes.

7. Transfer the demembranated sperm to a Dounce glass homogenizer partially immersed in slushy ice. Homogenize with fifteen rapid passes of a type B pestle to break the sperm heads from the tails.

   The pestle should be moved from the top of the liquid to the very bottom of the homogenizer, and upon return to the top, the pestle should not break the surface of the liquid.

8. Transfer the homogenate to 50-ml centrifuge tubes, pellet sperm heads by centrifuging 10 min at 12,000 × *g* (10,000 rpm in SS-34 rotor), 4°C.

9. Collect the supernatant containing the demembranated tails into new 50-ml tubes and pellet the tails by centrifuging 15 min at 20,000 × *g* (13,000 rpm in SS-34 rotor), 4°C.

10. Discard the supernatant. Using a metal weighing spatula and a Pasteur pipet, collect only the top white layer that contains the demembranated tails. Resuspend pelleted tails by trituration in 4 vol isolation buffer.

    The bottom yellow layer of the pellet contains sperm heads and debris.

Disrupt tails and extract axonemes

11. Transfer resuspended tails to Dounce glass homogenizer on ice. Homogenize with five rapid passes of a type A pestle to break the tails into fragments. Transfer fragment suspension into 50-ml centrifuge tubes.

12. Pellet the tail fragments in 50-ml tubes by centrifuging 10 min at 12,000 × *g,* 4°C.

    This step will also result in a two-layer pellet.

13. Discard the supernantant and collect only the top white layer. Resuspend this white pellet by trituration in 4 vol isolation buffer. Transfer to new tubes and centrifuge as in step 12. Repeat this cycle of resuspension and centrifugation one or two more times to completely separate the tail fragments from heads and debris. Continue until the pellet is a single layer of pure white.

14. Discard the supernatant and resuspend the white pellet in 4 vol high-salt buffer.

15. Transfer to Dounce glass homogenizer on ice. Homogenize with five passes of a type A pestle. Incubate 45 min on ice to extract dyneins and central pair MTs from the tail fragments.

Isolate axonemes

16. Transfer extraction suspension to 50-ml centrifuge tubes and separate the extracted axonemes from soluble proteins by centrifuging 15 min at 20,000 × *g,* 4°C.

17. Discard the supernatant and resuspend the axoneme pellet by trituration in 4 vol high-salt buffer. Transfer to a new 50-ml centrifuge tube and reextract the axoneme fragments by incubating 15 min on ice.

18. Pellet the extracted axonemes by centrifuging 15 min at 20,000 × *g,* 4°C.

19. Discard supernatant and resuspend extracted axoneme pellet by trituration in ⅓ the original volume of sperm (in step 2) in isolation buffer/50% glycerol.

20. Distribute the axonemes into 20-µl aliquots in 0.5-ml microcentrifuge tubes and freeze by immersing tubes in liquid nitrogen.

21. Store frozen axonemes at −70°C until use.

22. Determine the proper axoneme dilution for use in the MT/organelle motility assay. Thaw an aliquot of axonemes and observe various dilutions by VE-DIC (at the same magnification as will be used in the assay) in a simple perfusion chamber (see Support Protocol 1). Note the dilution required such that two to three axonemes are visible per ~30-μm^2 microscopic field.

SUPPORT PROTOCOL 3

PREPARATION OF PORCINE BRAIN TUBULIN

Although many protocols for tubulin preparation are available, this procedure (as adapted from Walker et al., 1988) is the simplest and, in the author's experience, provides the highest yields of tubulin. Three pig brains should yield ~60 mg of purified tubulin.

Materials

100-g P-11 cellulose phosphate fibrous cation exchanger (Whatman)
0.1 M HCl
0.1 M and 10 M NaOH
0.1 M $MgSO_4$
10× and 1× column buffer (see recipe)
3 fresh pig brains (use <3 hr after slaughter)
Homogenization buffer (see recipe; freshly prepared)
PM buffer (see recipe)
100 mM MgATP (see recipe)
PMG buffer (see recipe)
100 mM MgGTP (see recipe)
1 M dithiothreitol (DTT; *APPENDIX 2A*)
Glutamic acid, sodium salt

2-liter sintered-glass filter funnel and 2-liter sidearm Erlenmeyer flask
Waring blender
Temperature-controlled ultracentrifuge (Beckman L7-55) with Beckman 50.2Ti rotor (or equivalent)
31.5-ml thick-walled polycarbonate ultracentrifuge tubes (e.g., Beckman) with screw caps
30-ml Dounce type A glass homogenizer
44 × 250–mm adjustable volume column for low-pressure liquid chromatography (e.g., Amicon model #95240 or equivalent)

Additional reagents and equipment for determining protein concentration (*APPENDIX 3*)

DAY 1: Prepare phosphocellulose column

1. Add 90 g of Whatman P-11 phosphocellulose to 2 liters of 0.1 M NaOH in a 4-liter beaker while mixing very gently with a glass rod. Mix suspension gently 5 min, then allow the solids to settle 20 min. Aspirate and discard excess solution. Transfer remaining phosphocellulose slurry to a 2-liter sintered-glass funnel on a 2-liter sidearm Erlenmeyer flask connected to a vacuum line. Carefully vacuum filter the remaining 0.1 M NaOH from the phosphocellulose, but do not allow the resin to run dry.

2. Gently scrape the phosphocellulose from the funnel and return it to the 4-liter beaker. Add 2 liters of 0.1 M NaOH, mix gently 5 min, and check the pH with pH paper. If the pH of the slurry is not >12, repeat the settling, aspiration, and filtering treatment and resuspend phosphocellulose in 2 liters of 0.1 M NaOH. Repeat until pH >12.

3. Rinse phosphocellulose with 4 liters of distilled water by vacuum filtration, again being careful never to let the resin run dry.

4. Transfer phosphocellulose from the funnel to the 4-liter beaker and add 2 liters 0.1 M HCl. Mix gently, allow the resin to settle, aspirate excess solution, and vacuum filter the resin (as in step 1). Repeat the 0.1 M HCl treatment cycle until the pH of the phosphocellulose slurry is <3.

5. Rinse the phosphocellulose with 4 liters of distilled water by vacuum filtration.

6. Transfer the phosphocellulose resin to the 4-liter beaker and add 2 liters of 0.1 M $MgSO_4$. Mix, settle, aspirate, and vacuum filter.

7. Transfer the phosphocellulose resin to the 4-liter beaker and add 2 liters of 10× column buffer. Mix gently 10 to 15 min, allow the resin to settle, aspirate excess column buffer, and vacuum filter.

8. Transfer resin to the 4-liter beaker, add 2 liters of 1× column buffer, and mix gently for 5 min. Check the pH of the slurry with a pH meter and adjust to 6.6 with 10 M NaOH. Allow resin to settle, aspirate excess buffer, and vacuum filter. Repeat the 1× column buffer treatment cycle, using 10 M NaOH to adjust the pH of the slurry to 6.6, until the pH of the slurry is 6.6 without adjustment after resuspension and mixing. Allow resin to settle 20 min and aspirate buffer until the settled resin:buffer ratio is 3:1 (v/v).

Pour column

9. Mix the resin gently until evenly suspended in the buffer, then rapidly pour the slurry into an empty 44 × 250–mm liquid chromatography column (clamped to a support in the cold room). Fill column to the top. Cover with Parafilm and allow the resin to settle for several hours.

10. Fill the column adjuster plunger with column buffer, and very slowly insert it into the column, being very careful not to disturb the phosphocellulose resin. Insert the adjuster plunger until all air bubbles are expelled from column through the column inlet tubing which is immersed in a 4-liter reservoir of column buffer. Tighten and seal the adjuster plunger fittings, leaving the inlet tube in the buffer reservoir.

11. Attach the outlet tubing to a peristaltic pump and set the pump to run at 0.25 ml/min to allow the column to pack for ~48 hr.

    A well-packed phosphocellulose column should be perfectly even in color with no evidence of cracks in the resin. The better the phosphocellulose column is packed, the more concentrated the peak of elution of tubulin protein.

DAY 2: Prepare MT protein

12. Transport brains from slaughterhouse to laboratory in an evacuated plastic ziplock bag buried in ice.

    Brains must be kept on ice from the time the animals are slaughtered.

13. Working in a 4°C cold room, carefully and thoroughly remove the meninges and any blood-red tissue from the surface, stem, and within the folds of each brain. Pick tissue away by hand and use Kimwipes to peel membranes from surface of brain.

    The dry wipe will stick to the meninges; as it is drawn gently across the surface of the brain, it will peel away the deep red membrane from the pinkish-gray nervous tissue underneath.

14. Cut cleaned brains into 2- to 3-cm^2 cubes and weigh the tissue. Transfer the tissue to a Waring blender and add 0.5 ml/g freshly prepared homogenization buffer containing 1 mM MgATP.

Homogenize brain tissue

15. Homogenize the tissue by blending 5 sec on high speed and then 45 sec on low speed.

    This should result in a suspension with the color and consistency of a strawberry milkshake.

16. Using a 50-ml serological pipet with one-third of the tip cut off and a pipet bulb with strong suction, transfer the brain homogenate to several 31.5-ml polycarbonate

ultracentrifuge tubes. Note the homogenate volume and pair the tubes by weight (to 0.01 g). Discard any extra homogenate that does not fit into a full rotor-full of centrifuge tubes.

Tubulin is sensitive to proteases and easily denatured; keeping extra homogenate that must be left for 1 hr unprocessed while the first set of tubes is centrifuged does not significantly increase the final yield.

17. To remove undisrupted tissue from cell cytosol, centrifuge homogenate 60 min at 100,000 × *g* (29,000 rpm in 50.2Ti rotor), 4°C.

18. Working at room temperature, carefully collect the cytosolic supernatants from the tubes with a pipet. Pool supernatants in a graduated cylinder and add an equal volume of PMG. To promote MT polymerization, add MgGTP to 0.2 mM. Distribute into 31.5-ml ultracentrifuge tubes and pair tubes by weight.

Isolate MT protein

19. Immerse the portion of the tubes containing the cytosol in a 37°C water bath and incubate 45 min to allow MT proteins to polymerize into MTs. During this incubation, warm the ultracentrifuge and 50.2Ti rotor to 25°C.

20. Pellet MTs from the cytosol by centrifuging 45 min at 100,000 × *g,* 25°C.

21. In the cold room, discard the supernatant and resuspend the MT pellet in a volume of PM buffer containing 0.2 mM GTP equal to one-fifth the volume of homogenate.

To resuspend the pellet, add a few milliliters of resuspension buffer to each centrifuge tube and to a small glass Dounce homogenizer (on ice).

22. Using a round-ended weighing spatula, scrape out the sticky pellets and transfer them to the Dounce homogenizer. Resuspend any pellet remaining in the ultracentrifuge tubes by trituration and transfer to the homogenizer.

23. Homogenize the pellets with five to ten passes of a type A pestle. Dispense the resuspended MTs into 31.5 ml-ultracentrifuge tubes and pair tubes by weight.

24. Incubate the resuspended MTs on ice for 30 min with gentle mixing every 5 min to allow for MT depolymerization. During this incubation, chill the ultracentrifuge and rotor to 4°C.

25. Clarify the MT protein by centrifuging 45 min at 100,000 × *g,* 4°C.

26. At room temperature, collect the supernatant containing the MT protein, add an equal volume of PMG, and add GTP to a concentration of 0.2 mM. Dispense into 31.5-ml centrifuge tubes and pair tubes by weight.

27. Immerse the portion of the tubes containing the MT protein solution in a 37°C water bath and incubate 45 min to allow MTs to polymerize. During the incubation, warm the ultracentrifuge and rotor to 25°C.

28. Pellet the MTs from polymerization-incompetent tubulin by centrifuging 45 min at 100,000 × *g,* 25°C.

29. In the cold room, discard the supernatant. Add 1 ml of column buffer containing 0.5 mM GTP to each tube. Making sure that the buffer is covering the pellet, immerse tube in liquid nitrogen to freeze pellet.

Store the tubes at −70°C until the next day or whenever phosphocellulose column purification of tubulin is to be carried out.

DAY 3: Purify tubulin from MT protein on phosphocellulose column

30. Chill ultracentrifuge and 50.2Ti rotor to 4°C.

31. Prepare and equilibrate phosphocellulose column with column buffer containing 0.5 mM GTP and 1 mM DTT. Turn off peristaltic pump, and if resin bed has settled, carefully loosen the seals on adjuster plunger. Slowly insert adjuster plunger further into column until it barely touches the top of the resin and retighten the seals. Switch the inlet tube from the reservoir of 1× column buffer to a 1-liter reservoir of 1× column buffer containing 0.5 mM MgGTP and 1 mM DTT. Be careful not to introduce bubbles into the inlet tube. Turn the peristaltic pump on and adjust speed to 1.8 ml/min. Allow ≥300 ml of buffer to be drawn through the column before loading the MT protein.

32. While column equilibrates, thaw MT pellets (from step 29) by immersing ultracentrifuge tubes in a 37°C water bath until pellets turn from chalky white to completely translucent white. When pellets are thawed, place tubes immediately on ice and put them in the cold room.

33. Add a volume of 1× column buffer containing 0.2 mM GTP equal to ~3× vol of pellets. Resuspend pellets on ice with a Dounce glass homogenizer and type A pestle (as in step 21). Transfer resuspended MTs to a 31.5-ml ultracentrifuge tube. Allow MTs to depolymerize by incubating on ice for 30 min with gentle mixing every 5 min.

34. Clarify the MT protein by centrifuging 45 min at 100,000 × *g,* 4°C.

35. In the cold room, collect the clarified MT protein supernatant and add MgGTP to a final concentration of 0.5 mM (an additional 0.3 mM) and DTT to 1 mM.

Load MT protein

36. When column has equilibrated, switch the inlet tube from the buffer reservoir to the clarified MT protein. Load the MT protein onto the column at 1.8 ml/min. When all of the protein is loaded, switch the inlet back to the buffer reservoir and begin to collect 10-ml fractions. As each aliquot comes off, add MgGTP to a final concentration of 1 mM (an additional 0.5 mM).

    Tubulin will pass through the column and come off after ~100 ml. MT binding proteins will remain bound to the phosphocellulose resin.

37. Monitor the elution of tubulin by using a UV monitor to measure absorption at 280 nm. Pool fractions containing tubulin (usually ~100 ml).

    Alternatively, the protein concentration of a 100-µl aliquot of each fraction can be determined by colorimetric assay (APPENDIX 3).

Separate MTs from denatured tubulin

38. Working at room temperature, add 0.186 g/ml glutamic acid (sodium salt) to the tubulin solution and stir slowly until dissolved. Dispense the solution into 31.5-ml ultracentrifuge tubes and pair tubes by weight.

39. Immerse the centrifuge tubes to the level of the liquid in a 37°C water bath and incubate 30 min to allow MTs to polymerize. During this time, warm the ultracentrifuge and rotor to 25°C.

40. Separate MTs from polymerization-incompetent tubulin by centrifuging 30 min at 100,000 × *g,* 25°C.

41. In the cold room, resuspend MT pellets on ice in 3 vol of PM buffer containing 0.5 mM MgGTP using a glass Dounce homogenizer. Incubate resuspended MTs on ice 30 min to allow MT depolymerization.

42. During this time, determine the tubulin concentration by measuring the absorbance at 280 nm (using PM buffer containing 0.5 mM MgGTP as a blank). Calculate the tubulin concentration using the formula: [tubulin] = (A_{280} × dilution factor)/extinction coefficient), where the extinction coefficient of tubulin = 115,000 mol/cm. Add PM buffer containing 0.5 mM MgGTP to adjust the final protein concentration to 45 µM.

43. Dispense into several 1-ml aliquots (stock aliquots) and several 50-µl aliquots (to be used directly in the MT/organelle motility assays). Freeze by immersing in liquid nitrogen and store at −70°C until needed.

SUPPORT PROTOCOL 4

PREPARATION OF RAT LIVER CELL CYTOSOL

This protocol (modified from Donaldson et al., 1991) should yield enough cytosol for up to 200 MT/organelle motility assays.

Materials

Fresh or flash-frozen (Pel-Freez) rat livers
PBS (*APPENDIX 2A*)
Homogenization buffer (see recipe)
Homogenization buffer containing 0.5 mM MgGTP (from 100 mM MgGTP stock; see recipe)
PM buffer (see recipe) containing 0.25 M sucrose

Superspeed centrifuge (Sorvall RC-5B) with Sorvall SS-34 rotor (or equivalent)
Ultracentrifuge (Beckman L7-55) with Beckman 50.2Ti and SW-28 rotors (or equivalents)
20-ml glass homogenizer with Teflon pestle
Homogenizer or drill press
50-ml polycarbonate centrifuge tubes (e.g., Sorvall)
31.5-ml thick-walled polycarbonate ultracentrifuge tubes (e.g., Beckman) with screw caps

Additional reagents and equipment for determination of protein concentration (*APPENDIX 3*)

1. Chill the superspeed centrifuge, ultracentrifuge, and rotors to 4°C.
2. In the cold room, rinse liver well in PBS, then rinse in freshly prepared homogenization buffer.
3. Weigh liver, return to the cold room, and mince tissue finely with scissors. Transfer minced tissue to 20-ml glass homogenizer and add 1 vol homogenization buffer containing 0.5 mM MgGTP. Keeping the homogenizer immersed in slushy ice, homogenize tissue with a Teflon pestle attached to a homogenizer or drill press using six slow passes at 3000 rpm.
4. Transfer homogenate to 50-ml centrifuge tubes, pair tubes by weight, and remove cellular debris by centrifuging 10 min at 10,000 × *g* (9000 rpm in SS-34 rotor), 4°C.
5. In the cold room, collect supernatant, transfer to 31.5-ml ultracentrifuge tubes, and pair tubes by weight. Clarify cytosol by centrifuging 60 min at 100,000 × *g* (29,000 rpm in 50.2Ti rotor), 4°C.
6. Collect clarified cytosolic supernatant, dispense into 50-µl aliquots, and freeze by immersion in liquid nitrogen. Store at −70°C until use.

PREPARATION OF RAT LIVER ORGANELLE FRACTIONS

This protocol should yield enough organelles for up to 200 MT/organelle motility assays.

Additional Materials *(also see Support Protocol 4)*

Homogenization buffer (see recipe) containing 0.5 mM MgGTP (from 100 mM stock; see recipe) and 0.25 M sucrose
Homogenization buffer containing 0.5 mM MgGTP
2.3 M sucrose
PM buffer (see recipe) containing 0.25 M sucrose and 0.5 mM GTP
3 M KI stock (optional)
0.5 M EDTA stock (optional; *APPENDIX 2A*)
0.5 M Na_2CO_3 stock, pH 11.5 (optional)
PM buffer containing 0.25 M sucrose (optional)

25-ml Ultraclear ultracentrifuge tubes (e.g., Beckman)
Beckman SW-28 and 50.2Ti rotors or equivalents
31.5-ml thick-walled polycarbonate ultracentrifuge tubes (e.g., Beckman) with screw caps
TLA tabletop ultracentrifuge (Beckman) with TLS-55 swinging bucket rotor or equivalent and mini-ultracentrifuge tubes (e.g., Beckman)

Additional reagents and equipment for determining protein concentration (*APPENDIX 3*)

Clarify rat liver homogenate

1. Rinse liver, mince, and perform initial centrifugation as in the preparation of rat liver cytosol (see Support Protocol 4, steps 1 to 4), except in step 2, homogenize minced liver in homogenization buffer containing 0.5 mM MgGTP and 0.25 M sucrose.

2. In the cold room, collect the supernatant from the clarified homogenate and add 2.3 M sucrose to a final concentration of 1.25 M sucrose.

Isolate Golgi and ER

3. Set up a sucrose density step gradient in a 25-ml Ultraclear ultracentrifuge tube as follows, using 2.0, 1.25, 1.1, and 0.25 M sucrose solutions prepared by diluting the 2.3 M sucrose stock solution with homogenization buffer containing 0.5 mM MgGTP, chilled to 4°C. Add a 2-ml 2.0 M sucrose cushion to the bottom of the tube. Being careful to avoid disturbing the sucrose cushion, layer 12 ml of clarified homogenate containing 1.25 M sucrose on the 2.0 M sucrose by using a pipet and allowing the solution to slowly run in a steady stream down the side of the centrifuge tube. Add a 12-ml layer of 1.1 M sucrose and then an 8-ml layer of 0.25 M sucrose. Discard any excess homogenate. Pair the gradient with a balance tube of equal weight.

4. Separate the organelles on the basis of density by centrifuging the gradient 3 hr at 100,000 × *g* (28,000 rpm in SW-28 rotor), 4°C.

5. Working in the cold room, use a Pasteur pipet to carefully harvest the off-white band of Golgi membrane at the interface between the 0.25 M and 1.1 M sucrose layers and the off-white band of ER membrane at the interface between the 1.1 M and 1.25 M sucrose layers. Place each in separate 31.5-ml ultracentrifuge tubes on ice.

6. Determine protein concentration of the Golgi and ER membrane fractions (*APPENDIX 3*).

7. Dilute both membrane fractions with 3 vol of 0.25 M sucrose in homogenization buffer containing 0.5 mM GTP. Pellet membranes by centrifuging 60 min at 100,000 × *g* (29,000 rpm in 50.2Ti rotor), 4°C.
8. In the cold room, discard the supernatants and resuspend the dense, sticky ER and Golgi membrane pellets separately by extensive trituration in PM buffer containing 0.25 M sucrose and 0.5 mM GTP to achieve a protein concentration of 5 mg/ml.
9. Dispense into 20-µl aliquots and freeze by immersion in liquid nitrogen. Store at −70°C until use.
10. To determine the proper dilution of ER of Golgi membranes for use in the motility assay, view various dilutions of membranes in PM buffer in simple perfusion chambers by VE-DIC microscopy. Note the dilution required such that ~20% of the area of the microscopic field is covered with organelles.
11. When preparing membranes prior to the MT motility assay, thaw one of the aliquots frozen in step 9 and make a stock membrane preparation 6× the dilution determined in step 10.

Prepare stripped membranes (optional)

12. To strip the membranes, incubate a small aliquot (~50 to 100 µl) of isolated organelles with one of the following solutions for 30 min on ice:

    Salt-washed organelles: 0.6 M KI (from 3 M KI stock);

    EDTA-stripped organelles: 10 mM EDTA (from 0.5 M EDTA stock);

    Carbonate-washed organelles: 150 mM Na_2CO_3 (from 0.5 M Na_2CO_3 stock, pH 11.5).

13. Transfer to a mini-ultracentrifuge tube and pellet membranes by centrifuging 1 hr at 110,000 × *g* (50,000 rpm in TLS-55 rotor) at 4°C in a Beckman TLA tabletop ultracentrifuge.
14. Carefully remove supernatant and resuspend membrane pellet by gentle trituration in the original volume of PM buffer containing 0.25 M sucrose.

Treat membranes with pharmacological agents

15. Incubate membranes, cytosol, and energy mix with brefeldin A, aluminum fluoride, or GTP-γ-S (30 min at 37°C) prior to adding them to the mix (see Table 13.1.1). Isolate treated membranes by centrifugation as in step 13. Resuspend and use as described for stripped membranes.

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

$AlCl_3$, 30× (1.5 mM)

20 mg $AlCl_3$
Distilled water to 100 ml
Store <1 year at room temperature

Brefeldin A, 3.6 mM

10 mg brefeldin A (Epicenter Technologies)
100% ethanol to 12 µl
Store <1 year at −20°C

Column buffer, 10×

500 ml 1 M PIPES (see recipe; 250 mM final)
40 ml 0.5 M EGTA (see recipe; 10 mM final)
40 ml 1 M $MgSO_4$ (5 mM final)
Distilled H_2O to 1800 ml
Adjust pH to 6.7
Add distilled H_2O to 2 liters
Store <1 month at 4°C

EGTA, 0.5 M

19.02 g EGTA sodium salt
Distilled H_2O to 90 ml
Adjust pH to 7.0
Distilled H_2O to 100 ml
Store <1 year at room temperature

Energy regeneration system, 20× (see Murray, 1991)

150 mM creatine phosphate (Boehringer Mannheim)
2 ml 100 mM MgATP (see recipe; 20 mM ATP/20 mM $MgSO_4$ final)
40 ml 0.5 M EGTA (see recipe; 2 mM final)
Distilled H_2O to 10 ml
Dispense into 100-µl aliquots and store indefinitely at −20°C

HEPES, 1 M, pH 7.0

119.15 g *N*-2-hydroxyethylpiperazine-*N*′-2-ethanesulfonic acid (free acid)
Distilled H_2O to 400 ml
Add solid NaOH, a few pellets at a time while mixing, until the pH is ~6.8
Add concentrated NaOH dropwise to pH 7.0
Add distilled H_2O to 500 ml
Filter sterilize and store <6 months at 4°C

High-salt buffer

120 ml 5 M NaCl (0.6 M final)
4 ml 1 M $MgSO_4$ (4 mM final)
2 ml 0.5 M EDTA (*APPENDIX 2A*; 1 mM final)
10 ml 1 M HEPES (see recipe; 10 mM final)
Distilled water to 900 ml
Adjust pH to 7.0
Add H_2O to 1 liter
Store <1 year at 4°C
Add 2-mercaptoethanol (2-ME) to 7 mM final and DTT (*APPENDIX 2A*) to 1 mM final just before use

Homogenization buffer

300 ml PM buffer (see recipe)
52.3 mg PMSF (1 mM final)
3 g leupeptin (10 mg/ml final)
300 µg pepstatin A (1 µg/ml final)
3 mg *N*-α-*p*-tosyl-L-arginine methyl ester (TAME, 10 µg/ml final)
Mix well to dissolve; use immediately

Isolation buffer

20 ml 5 M NaCl (0.1 M final)
4 ml 1 M $MgSO_4$ (4 mM final)
2 ml 0.5 M EDTA (*APPENDIX 2A*; 1 mM final)
10 ml 1 M HEPES (see recipe; 10 mM final)
Distilled H_2O to 900 ml
Adjust pH to 7.0
Add distilled H_2O to 1 liter
Store <1 year at 4°C
Add 2-mercaptoethanol (2-ME) to 7 mM final just before use

MgAMP-PNP, 150 mM

25 mg AMP-PNP (Boehringer Mannheim)
90 µl 1 M $MgSO_4$ (150 mM final)
Add 225 µl distilled H_2O (to 315 µl)
Store <2 years at −20°C

MgATP, 100 mM

Check formula weight of the lot of ATP and determine the amount required for 10 ml of 100 mM solution. Add 8.5 ml distilled H_2O to the determined amount of ATP. Add 1 ml 1 M $MgSO_4$ stock and adjust pH to 7.0 using NaOH. Add H_2O to 10 ml. Dispense into 200-µl aliquots and store <2 years at −20°C.

MgGTP, 100 mM

Check formula weight of the lot of GTP and determine the amount required for 10 ml of 100 mM solution. Add 8.5 ml distilled H_2O to the determined amount of GTP. Add 1 ml 1M $MgSO_4$ stock and adjust pH to 7.0. Add H_2O to 10 ml. Dispense into 200-µl aliquots and store <2 years at −20°C.

MgGTP-γ-S, 30 mM

10 mg GTP-γ-S tetralithium salt (Boehringer Mannheim)
18 µl 1 M $MgSO_4$ stock (30 mM final)
Add 572 µl distilled H_2O
Store <2 years at −20°C

NaF, 30×

378 mg NaF (0.9 M final)
Distilled H_2O to 10 ml
Store indefinitely at −20°C

Na_2CO_3, 0.5 M

531 mg Na_2CO_3
Distilled H_2O to 10 ml
Store <1 year at room temperature

PIPES, 1 M, pH 6.9

151.2 g piperazine-*N,N′*-bis(2-hydroxypropanesulfonic acid), free acid
Distilled H_2O to 400 ml
Add solid NaOH a few pellets at a time while mixing until the pH is ~6.7
Add concentrated NaOH dropwise to pH 6.9
Add distilled H_2O to 500 ml
Filter sterilize and store <1 year at 4°C

PM buffer, pH 6.9

100 ml 1 M PIPES (see recipe; 100 mM final)
2 ml 1 M $MgSO_4$, (2 mM final)
2 ml 0.5 M EGTA (see recipe; 1 mM final)
Add distilled H_2O to 900 ml
Adjust pH to 6.9
Add distilled H_2O to 1 liter
Store <2 months at 4°C

PMG buffer

80 ml 1 M PIPES (see recipe; 80 mM final)
2 ml 1 M $MgSO_4$, (2 mM final)
2 ml 0.5 M EGTA (see recipe; 1 mM final)
600 ml glycerol
Distilled H_2O to 900 ml
Mix well
Adjust pH to 6.9
Add distilled H_2O to 1 liter
Store <1 month at 4°C

Sodium orthovanadate, 100 mM

1.839 g sodium orthovanadate
Distilled H_2O to 8 ml in a screw-cap tube
Adjust pH to 10 with NaOH or HCl
If solution is yellow, place in boiling water until clear, then recheck pH (repeat as necessary)
Adjust to final concentration by checking A_{265} and adding distilled water as needed
Store indefinitely at −20°C

The extinction coefficient for sodium orthovanadate is 2925 $M^{-1}cm^{-1}$.

Valap

50 g Vaseline (Fisher)
50 g lanolin (Fisher)
50 g paraffin (Fisher)

Place vaseline, lanolin, and paraffin in a 1-liter Pyrex beaker. Heat on low setting on a hot plate, stirring occasionally, until all components are melted and well mixed. Pour into several small screw-cap jars (~50 ml capacity). Store indefinitely at room temperature.

COMMENTARY

Background Information

As proteins mature and are processed and secreted, they move continuously between the membranous network compartments of the endoplasmic reticulum (ER) and Golgi apparatus, and from the Golgi apparatus to the cell surface. In living cells, this dynamic membranous organelle traffic occurs through a process in which membrane tubules or vesicles bud from one membrane compartment and fuse with another to deliver their contents. Membrane tubulation, budding, and fusion is believed to be controlled by G proteins and specific "coat" proteins that reversibly associate with the organelle surface (Klausner et al., 1992; Pfeffer, 1994; Bennett, 1995; Schmid and Damke, 1995). In addition, in living cells, ER and Golgi membrane tubules extend and branch in a microtubule (MT)-dependent fashion (Terasaki et al., 1986; Dailey and Bridgman, 1989; Lee et al., 1989; Cooper et al., 1990; Terasaki and Reese, 1994). MT-dependent membrane trafficking is believed to involve the MT-based motor proteins kinesin and cytoplasmic dynein (Lippincott-Schwartz et al., 1995; Presley et al., 1997; reviewed in Cole and Lippincott-

Schwartz, 1995; Sheetz, 1996). The MT/organelle motility assay provides an in vitro system in which MT-based membrane tubule movement and fusion can be observed and the effects of pharmacological, immunochemical, or biochemical treatments can be tested. As mentioned in the Basic Protocol, manipulations of the system may include: the addition of known effectors of coat proteins, G proteins, or MT-based motors to the membrane mix; the removal of subsets of peripheral proteins from the isolated organelles; and fractionation or immunoprecipitation of specific proteins from the cytosol prior to addition to the membrane mix.

ER-like membrane tubules have been shown to form in vitro in a MT-dependent fashion by two mechanisms. The first involves motor proteins and occurs when crude organelle fractions are mixed with cytosolic extracts and taxol-stabilized MTs in the presence of ATP. Here, membranes make gliding attachments to MTs or stable attachments to gliding MTs (Dabora and Sheetz, 1988; Vale and Hotani, 1988; Allan and Vale, 1991, 1994; Gill et al., 1991; Schroer and Sheetz, 1991; Allan, 1995). The second mechanism is independent of motor ATPase activity and occurs in extracts of *Xenopus laevis* eggs. In this case, membranes attach to the growing ends of MTs, and membrane tubules extend by a MT polymerization-dependent mechanism (Waterman-Storer et al., 1995). Similar MT polymerization-dependent movements of chromosomes have also been demonstrated in vitro (Coue et al., 1991; Lombillo et al., 1995a,b). The assay described in the Basic Protocol improves on previously published membrane motility assays in that the MTs are nucleated from a stationary point (a fragment of a flagellar axoneme), allowing their free ends to grow and shorten similar to the way they would behave in a living cell. This assay permits observation of both motor-driven motility of organelles and MT polymerization–driven mechanisms of organelle movement. Nucleation of MTs from stationary axonemes also provides a good marker for determining the polarity of organelle movement, as MTs grow more robustly from the plus ends of axonemes than from their minus ends. Thus axoneme-nucleated MTs with free plus ends are much longer than those with free minus ends (Walker et al., 1988).

Critical Parameters and Troubleshooting

The success of the membrane MT motility assay depends on two basic parameters: the cleanliness of the slides, coverslips, and perfusion chamber, and the quality of the biochemical components used in the assay. Adherence to the recommended choice of brand names and proper cleaning of coverslips is tantamount to making a good perfusion chamber for the motility assay.

Motile interactions between membranes and MTs take 30 to 45 min to develop. If no motility occurs after this period of time, try raising the room temperature. Be aware that many of the manipulations of membrane mixes suggested in the Basic Protocol have not yet been described in published work. Thus they may not yield any results, much less interesting results.

For all biochemical preparations, pay attention to the cleanliness of the glassware. Use double glass-distilled water for the preparation of solutions. Plan manipulations carefully in advance and follow the protocols with expedience.

The most important step for getting pure axonemes (Support Protocol 2) with very little debris is the careful collection of only the top, white layer of the pellet (containing sperm tails) without collecting any of the yellowish bottom layer of the pellet (containing heads and debris). The pellet must be washed until it is pure white and free of debris before completing the protocol. When determining the proper axoneme dilution, it is possible to check the purity of the preparation. If excess non-axoneme material appears to be present, dilute the axonemes 1:4 with isolation buffer (final glycerol concentration is 12.5%), centrifuge, and resuspend pellet in isolation buffer plus 50% glycerol. Check the purity of the axonemes by microscopy. If the preparation still appears "dirty," repeat the wash step until the axonemes appear "clean."

Several steps are critical for the preparation of tubulin (Support Protocol 3). First, proper packing of the phosphocellulose column is necessary to obtain a good concentrated peak of tubulin. If the resin has a cracked appearance after packing, it should be emptied, resuspended in column buffer, and repoured. If this procedure requires an extra day, keep the pellets of MT protein frozen until the column is packed properly. Never use phosphocellulose resin that is >1 week old. Tubulin is susceptible to proteolysis and easily denatured; therefore time is critical throughout the preparation of MT protein. Thorough removal of brain meninges, which contain high levels of blood proteases, and addition of protease inhibitors to the homogenization buffer just prior to use is very

important. Improper resuspension of microtubule pellets in a Dounce homogenizer can greatly reduce tubulin yields; be very careful not to cause bubbling in the solution and always keep the homogenizer on ice when moving the pestle. Be sure that rotor temperatures are equilibrated prior to use and that enough centrifuge tubes are clean. Fortunately, even if timing is drastically off or slightly careless technique is used, the preparation should yield some usable protein.

When preparing rat liver organelles (Support Protocol 4), pour the step gradients so that there is as little mixing between steps as possible. This is the most critical step to clean separation of the different fractions of organelles. To avoid diluting organelles at the interface between the gradient steps, avoid collecting solution above and below the interface; it is better to leave some membrane behind than to collect too much from adjacent fractions that may contain soluble protein complexes. Finally, some labs insist that interactions between motor proteins and organelles are better preserved when organelle fractions are isolated on Nycodenz gradients. If active motor proteins are present in the MT/organelle motility assay (i.e., microtubules or whole axonemes glide on the coverslip surface), but organelles do not form motile interactions with microtubules, consider isolating organelles on Nycodenz gradients (McIlvain et al., 1993; Kumar et al., 1995).

Anticipated Results

The membrane MT motility assay should generate the formation of moving membrane tubules and vesicles similar to those seen in Figure 13.1.2. Key observations may include the following: (1) What form do the membranes take on: tubular, vesicular, or both? (2) Are both static and dynamic interactions between membranes and MTs observed in the same preparation? (3) How are the membranes attached to the MT: along the shaft or at the end? (4) What direction do the membranes move on the MT? (5) Do axonemes or free MTs glide on the coverslip surface, and in what direction do they glide? (6) Does the motility change direction? Comparison of different assays, using differently treated membrane mixes, may yield interesting differences in these behaviors.

Sperm axonemes prepared from four sea urchins (Support Protocol 2) should yield enough fragments for thousands of motility assays. Isolation of tubulin from three pig brains (Support Protocol 3) should yield ~60 mg of purified tubulin. One rat liver should yield enough cytosol (Support Protocol 4) or organelles (Support Protocol 5) for up to 200 assays.

Time Considerations

Once all biochemical components are prepared, their proper dilutions determined, and a supply of perfusion chambers is made, the MT/organelle motility assay should take 2 hr to perform, allowing 30 to 45 min to record the motility on video tape. Thus, several different membrane mixes or treatment conditions can be tested in a single day. New aliquots of membrane and cytosol should be thawed for each new assay done in a single day.

Axonemes, rat liver organelles, and rat liver cytosol are all relatively easy to prepare; each requires two 3- to 6-hr days. Reagents and

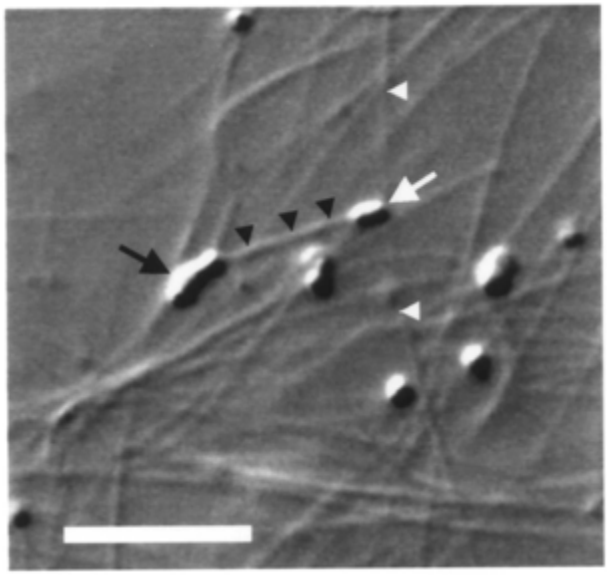

Figure 13.1.2 VE-DIC micrograph of a membrane/microtubule motility assay. Membrane associated with an axoneme fragment (black arrow) has extended a thin membrane tubule (black arrowheads) via a motile attachment (white arrow) to a single microtubule (white arrowheads). Many single microtubules and membrane vesicles can be seen in this field. Bar = 5 μm.

buffers are prepared on the first day and the components are purified the second day. Tubulin purification is much more difficult, and requires 4 long (8- to 12-hr) days of work. Buffers and reagents are prepared on the first day. The phosphocellulose column is prepared during the second day. The pig brains should be acquired fresh on the third day for the preparation of MT protein, and on the fourth day tubulin is purified from the MT protein on the phosphocellulose column. The first tubulin preparation attempted will probably not give the best results. The organization, timing, and motor skills required for the preparation must be practiced and developed over time, and the preparation must often be adapted to the constraints of the particular laboratory in which it is performed (types of rotors available, cold room space available) before this purification results in high protein yields.

In Vitro Motility Assay to Study Translocation of Actin by Myosin

A most basic property of myosin is its ability to interact with and translocate actin. This unit describes an in vitro motility assay that can be used to study the translocation, or sliding, of actin filaments by myosin bound to a coverslip. The assay makes use of the ability to image single F-actin filaments labeled with rhodamine phalloidin, a high-affinity fluorescent ligand using fluorescence microscopy. The system is fast, easy to set up and maintain, uses only small amounts of protein, and yields quantitative results.

Several preliminary steps are required before the in vitro motility assay can be conducted. Special flow cells that are used in the assay must be prepared (see Support Protocol 1). The assay also requires purified myosin and actin. Other proteins, such as the regulatory proteins tropomyosin and troponin must be prepared if needed for assay variations. The method for preparing myosin varies greatly depending on the type of myosin being studied (see Table 13.2.1). Actin can be purified by the method in Support Protocol 2, and then it must be labeled with rhodamine phalloidin (see Support Protocol 3). When the in vitro motility assay is conducted (see Basic Protocol), the flow cell is placed under the objective of a fluorescent microscope, and the image is recorded on videotape. Afterward, the data from the videotape can be quantified.

ANALYZING ACTIN TRANSLOCATION BY MYOSIN

BASIC PROTOCOL

Translocation of actin by myosin is followed using rhodamine phalloidin–labeled actin exposed to immobilized myosin in a flow cell. The assay can be modified for specific purposes. For example, myosin can be applied to the coverslip surface either as filaments or as monomers. The enzymatically active fragments of myosin, heavy meromyosin (HMM) or subfragment-1 (S1), can also be used. The ionic strength can be varied over a range extending up to physiological levels and the temperature can be varied over a wide range. The movement of pure actin, or of actin complexed with regulatory proteins, can be measured.

The assay is best conducted with freshly prepared myosin, although it is possible to use myosin that has been flash frozen and stored in liquid nitrogen. The presence of damaged myosin heads (dead heads) that bind actin, but do not hydrolyze ATP, contributes to poor quality of movement. Two procedures can minimize this problem. The myosin-coated coverslip can be washed with a solution containing unlabeled actin in the presence of ATP before the rhodamine phalloidin–labeled actin is introduced, as is done in this protocol. This has the effect of complexing the dead heads with the unlabeled actin. If this simple treatment does not prove sufficient, a stoichiometric amount of F actin can be added to myosin in the presence of ATP at high ionic strength and sedimented at 480,000 × *g* for 15 min in a Beckman TL100 ultracentrifuge. This removes dead heads before the myosin sample is applied to the coverslip.

Quantification of the images can be done in several ways. The most thorough method makes use of a dedicated automatic tracking system such as the Cell Trak system from Motion Analysis (Homsher et al., 1992). Another alternative involves the use of frame grabbers to digitize images coupled with the use of tracking software run on a desktop computer (Work and Warshaw, 1992; Marston et al., 1996).

Current Protocols in Cell Biology (1998) 13.2.1-13.2.10

Table 13.2.1 Purification Protocols for Myosins

Myosin type	Purification protocol
Rabbit skeletal muscle myosin	Margossian and Lowey, 1982
Invertebrate striated muscle myosin	Sellers, 1981
Chicken smooth muscle	Sellers et al., 1981
Nonmuscle myosin II	Daniel and Sellers, 1992
Native thick filaments	Sellers and Kachar, 1990
Myosin I	Collins et al., 1990
Myosin V	Nascimento et al., 1996
Baculovirus/*Sf* 9-expressed recombinant myosins	Trybus, 1994[a]

[a]If the recombinant myosin is HIS or FLAG tagged, specific affinity columns can be used to aid in purification.

Materials

0.2 mg/ml myosin monomers (see Table 13.2.1)
1 mg/ml BSA in G-actin buffer (see recipe)
Wash buffer (see recipe)
Wash buffer containing 1 mM ATP and 5 μM actin (see Support Protocol 2)
Wash buffer containing 20 nM rhodamine phalloidin–labeled actin (see Support Protocol 3)
Assay buffer (see recipe)

Flow cell (see Support Protocol 1)
Fluorescent microscope, with high-numerical-aperture objective (60× to 100×, 1.3 to 1.4 NA) and 100-W mercury lamp
SIT camera or an intensified CCD
VHS or sVHS video recorder
Image processor
Cell Trak image analysis system (Motion Analysis)

1. Fill the flow cell with myosin monomers (or the soluble fragments HMM and S1) at a concentration of 0.2 mg/ml. Allow the solution to remain in the cell for 1 to 2 min to allow myosin to bind.

   Myosin monomers are applied in a high-ionic-strength buffer (e.g., 0.5 M NaCl/10 mM MOPS [pH 7.0]/0.1 mM EGTA/1 mM DTT), whereas HMM or S1 can be applied at a low ionic strength (e.g., 10 mM MOPS [pH 7.0]/0.1 mM EGTA/1 mM DTT). Myosin filaments must be applied at low ionic strength in a buffer where myosin filaments are stable such as 50 mM KCl/10 mM MOPS (pH 7.0)/1 mM $MgCl_2$/0.1 mM EGTA/1 mM DTT.

2. Wash the flow cell with 2 to 3 volumes of 1 mg/ml BSA in actin buffer. Allow the last volume of buffer to remain in the cell for 1 to 2 min to block non-specific binding.

   This serves to wash unbound myosin from the flow cell and block the surface. Note that if myosin filaments are being applied to the surface, it is necessary to wash the flow cell with BSA in a low-ionic-strength buffer that will not depolymerize myosin filaments.

3. Wash the flow cell with 2 to 3 vol wash buffer containing 1 mM ATP and 5 μM actin. Allow the last volume of solution to remain in the flow cell for 1 to 2 min.

   Note that prior to use this actin/ATP–containing solution is vortexed intensely or passed through a narrow-gauge syringe in order to sheer the unlabeled actin. The actin added in this step binds to damaged, noncycling myosins and dramatically improves the quality of measurements. The actin is sheared to increase the accessibility to the surface.

4. Wash the flow cell with 2 to 3 vol wash buffer to remove ATP, followed by 2 vol wash buffer containing 20 nM of rhodamine phalloidin–labeled actin. Allow to bind for 0.5 to 1 min.

5. Begin the motility assay by adding assay buffer.

   Note that this buffer is viscous due to the methylcellulose and it may be necessary to use a piece of filter paper placed at the outflow of the flow cell as a wick to pull the solution into the cell.

6. Place the flow cell on the microscope stage and observe the motion of the rhodamine phalloidin–labeled actin using a filter cube for detecting rhodamine fluorescence and a high-NA 60× to 100× objective.

   Movement of actin by myosin is dependent on temperature, and thus it is necessary to regulate the temperature of the slide. Most investigators use 25° or 30°C as standard. This can be accomplished in several ways. The least expensive way is to place a blow dryer at an appropriate distance to yield the desired temperature. It is also possible to regulate the temperature of the assay by jacketing the objective using either a water jacket or a Peltier-type device. Simply regulating the temperature of the stage is usually not sufficient to control the temperature because the objective constitutes a large heat source. The temperature of the sample in the flow cell can be estimated using a fine wire thermister mounted between a coverslip and a slide. This "dummy" flow cell is mounted on the stage, and the objective is brought to the same position as the one used when imaging a flow cell.

   It is useful to have several neutral density filaments that can be placed in the light path to attenuate the light intensity to avoid bleaching of rhodamine fluoresence.

7. Process the results with either an intensified CCD (charge-coupled device), a neuvicon camera, or a SIT (silicon-intensified target) camera to detect the image and an sVHS video recorder to record the image movements, which can be displayed on a standard black-and-white video monitor.

   It is useful to have an image processor to conduct frame averaging and background subtraction. This is especially helpful if the myosin being studied moves actin filaments slowly. This can be accomplished using either a dedicated image processor such as the Argus-20 (Hamamatsu) or image-processing software running on a desktop computer. If an image processor is used, it is useful to have two monitors, one for the processed image and one for the raw image.

8. Quantify results by measuring the position of an actin filament over time, measuring five to ten time points for each actin filament. Calculate and record the mean velocity for the measurements.

   Quantification of the rate of movement is most easily accomplished using an automated tracking system such as the Cell Track System by Motion Analysis. This system digitizes the image of all actin filaments in a video sequence, determines the centroid position, determines the path, and calculates the main velocity of each actin filament. In the absence of such an automated system, some investigators have written their own software using commercially available frame grabbers (Work and Warshaw, 1992; Winkleman et al., 1995).

SUPPORT PROTOCOL 1

PREPARATION OF FLOW CELLS

The actin translocation assay requires nitrocellulose-coated coverslips applied to a simple flow cell.

Materials

1% (w/v) nitrocellulose (Ernest F. Fullham) in amyl acetate
Apiezon M grease (Thomas; optional)

Double-sided tape
18-mm^2 no. 1 coverslips
Glass microscope slides
24 × 60–mm no. 0 coverslips (optional)

1. Place a 2-µl drop of 1% nitrocellulose in amyl acetate onto a no. 1 coverslip and spread the drop over the surface using the long axis of the pipet as a swab. Allow the surface to dry (5 min).

   Alternatively, to create a thin film of nitrocellulose, apply 1 drop of 1% nitrocellulose from a Pasteur pipet to the surface of deionized water in a 10-cm round dish and allow the amyl acetate to evaporate. Place no. 1 coverslips onto the dried film. Tear excess film away from the area surrounding the coverslips using forceps. Remove the coated coverslips by submersing and inverting them while lifting them from the water. Air dry the coated coverslip with the film side up. Coverslips and microscope slides are typically used as they come from the box.

2. Apply two parallel strips of double-sided tape ~10 mm apart on a glass microscope slide. Place a nitrocellulose-coated coverslip with the coated side down on top of the tape strips to create a quick and simple flow cell.

   Alternatively, cut spacers (24 × 3 to 4 mm) from a no. 0 coverslip using a diamond scribe. Place parallel tracks of Apiezon M grease ~10 mm apart and 25 mm long on the long axis of a glass microscope slide. Place the thin coverslip spacers on the outside of the grease tracks and cover them with a nitrocellulose-coated coverslip with the coated side down. It is also possible to glue the spacers and coverslip to the slide with fingernail polish.

SUPPORT PROTOCOL 2

PURIFICATION OF ACTIN

Rabbit muscle actin used for the translocation assay is most often purified by this method (Spudich and Watt, 1971). After it is prepared, a portion is labeled with rhodamine phalloidin (see Support Protocol 3).

Materials

Back and leg muscles of freshly sacrificed 350-g rabbit
0.1 M KCl/0.15 M potassium phosphate, pH 6.5
0.05 M $NaHCO_3$
1 mM EDTA, pH 7.0
Acetone
G-actin buffer (see recipe)
2 M KCl (stock solution)
1 M $MgCl_2$ (stock solution)

Meat grinder, prechilled
Cheesecloth
Filter paper
Sorvall centrifuge and SS-34 rotor (or equivalent)
Beckman ultracentrifuge and 55 Ti rotor (or equivalent)
Potter-Elvehjem tissue grinder

Additional reagents and equipment for dialysis (*APPENDIX 3*)

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) or must conform to governmental regulations regarding the care and use of laboratory animals.

NOTE: All procedures are performed at 4°C unless otherwise specified and all buffers should be prechilled to this temperature.

Prepare actin powder

1. Excise the back and leg muscles of a freshly sacrificed rabbit, wash them free of blood with distilled water, and chill on ice.

   Steps 2 to 6 should be carried out in a cold room at 4°C.

2. Grind the muscle in a meat grinder that has been prechilled.

3. Extract the mince with 1 liter of 0.1 M KCl/0.15 M potassium phosphate, pH 6.5, for 10 min with stirring. Filter the mince by squeezing it through several layers of cheesecloth.

   Stirring in steps 3 to 7 is done by hand using a glass rod or spatula or by using an overhead motorized stirrer. The suspension is too viscous to use a magnetic stirrer.

   Filtration is most easily accomplished by spreading several layers of cheesecloth over a large funnel which is supported by a ring stand. This method of filtering is also used in steps 4 to 7.

4. Extract the retained mince with 2 liters of 0.05 M $NaHCO_3$ for exactly 10 min with stirring, and filter as in step 3.

5. Extract the filtered mince with 1 liter of 1 mM EDTA, pH 7.0, for 10 min with stirring.

6. Extract the mince twice with 2 liters distilled water for 5 min each time.

7. Extract the mince five times at room temperature with chilled acetone for 10 min each time. Stir to break up residue clumps and filter the extract.

8. Spread out the acetone-washed, filtered residue on a large piece of filter paper and dry overnight in a hood.

   The resulting acetone powder can be stored for months at −20°C.

Extract the acetone powder

9. Extract the acetone powder (typically 5 g) in 20 ml of G-actin buffer per gram of powder on ice, 30 min with stirring.

10. Filter the extract through cheesecloth (see step 3 annotation) and retain the filtrate. Reextract the residue using 20 ml of the same buffer per gram of original dried acetone powder, 10 min with stirring.

11. Filter through cheesecloth again, retaining the filtrate, and combine the filtrates.

12. Centrifuge 1 hr at 40,000 × *g*, 4°C. Carefully decant the supernatant and discard the pellet.

Polymerize the actin

13. Add KCl to 50 mM and $MgCl_2$ to 2 mM to polymerize actin. Allow polymerization to continue for 2 hr on ice.

14. Slowly add solid KCl to a final concentration of 0.8 M and stir gently 30 min.

    This step helps to remove tropomyosin and α-actinin contaminants.

15. Centrifuge 1.5 hr at 150,000 × *g*, 4°C, to sediment the polymerized actin.
16. Resuspend the F-actin pellets by homogenization in a Teflon-lined homogenizer using 3 ml G-actin buffer per gram of acetone powder. Dialyze for 2 days in G-actin buffer with repeated changes to depolymerize the actin.
17. Centrifuge the depolymerized actin 1.5 hr at 150,000 × *g*, 4°C. Retain the supernatant.
18. Add KCl and $MgCl_2$ to concentrations of 50 mM and 2 mM, respectively, to polymerize the actin. Dialyze in the buffer of choice containing 1 to 2 mM $MgCl_2$ to maintain the polymerized state. Store on ice at a concentration of 100 to 200 µM for ~1 month.

If the actin is stored longer than 1 month, it should be put through a new depolymerization/polymerization cycle by repeating steps 16 to 18.

SUPPORT PROTOCOL 3

PREPARATION OF RHODAMINE PHALLOIDIN–LABELED ACTIN

Actin is labeled with rhodamine phalloidin so that its translocation can be followed in the assay described in the Basic Protocol. Rhodamine phalloidin serves two purposes: the phalloidin moiety binds to actin and stabilizes the filaments against depolymerization; and the rhodamine moiety is a common flurophore that is excitable by green light.

Materials

Rhodamine phalloidin (Molecular Probes)
Methanol
Labeling buffer (see recipe)
Actin (see Support Protocol 2, step 18)
Wash buffer (see recipe)
Speed-Vac evaporator (Savant) or equivalent

1. Place 60 µl of rhodamine phalloidin in a microcentrifuge tube and dry in an evaporator.
2. Redissolve the dried powder in 5 µl methanol.
3. Add 85 µl labeling buffer.
4. Dilute actin to 20 µM in labeling buffer. Add 10 µl of 20 µM actin and incubate overnight. Store on ice up to 1 month.
5. Dilute an aliquot to 20 nM actin with wash buffer the day of use.

REAGENTS AND SOLUTIONS

*Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see **APPENDIX 2A**; for suppliers, see **SUPPLIERS APPENDIX**.*

Assay buffer

Wash buffer (see recipe) containing:
0.7% (w/v) methylcellulose (see recipe)
1 mM ATP
50 mM DTT
2.5 mg/ml glucose
0.1 mg/ml glucose oxidase
0.02 mg/ml catalase
Prepare fresh daily

continued

Assay buffer should be prepared fresh daily from stocks of ATP (0.1 M ATP, pH 7.0, stored at −20°C), DTT (1 M, prepared fresh daily), glucose (2.5 mg/ml, stored at −20°C), glucose oxidase (Sigma), and catalase (Sigma).

The ionic conditions of this buffer (KCl, $MgCl_2$, $CaCl_2$ concentrations) and the pH and temperature can be varied according to the experimental protocol.

G-actin buffer

2 mM Tris base
0.2 mM Na_2ATP
0.5 mM DTT
0.2 mM $CaCl_2$
3 mM NaN_3
Adjust pH to 8.5 with HCl
Store at 4°C

Labeling buffer

10 mM MOPS [3-(*N*-morpholino) propane sulfonic acid], pH 7.0
0.1 mM EGTA
3 mM NaN_3
Store at 4°C

Methylcellulose, 14% (w/v)

Prepare a 1.4% (w/v) solution of methylcellulose (Sigma). Dialyze the solution against deionized water for 24 hr. Store at −20°C until used.

Methylcellulose should have a viscosity of 4000 centipoise for a 2% solution at 20°C.

Wash buffer

80 mM KCl
5 mM $MgCl_2$
20 mM MOPS, pH 7.4
0.1 mM EGTA
Store at 4°C

COMMENTARY

Background Information

Myosin is an ATP-dependent molecular motor that interacts with actin (Sellers and Goodson, 1995). In muscle fibers actin and myosin are arranged in interdigitating filaments that slide past each other during contraction. There is a superfamily of myosins that also perform mechanical functions such as cytokinesis and vesicle transport in nonmuscle cells. The in vitro motility assay to study actomyosin interactions fills a void between biochemical measurements of the actin-activated Mg-ATPase activity of myosin and mechanical measurements of skinned muscle fibers. In this assay, myosin molecules bound to a nitrocellulose-coated surface interact with actin filaments in solution and translocate them in an ATP-dependent process. This is a simple assay that reconstitutes the essence of a muscle fiber using only two purified proteins, actin and myosin. It requires only small quantities of these proteins (e.g., 1 to 2 μg myosin per assay) and is quick to perform. Thin filament regulatory proteins can be added to examine actin-linked regulatory systems (Shirinsky et al., 1992; Fraser and Marston, 1995; Lin et al., 1996). The ionic conditions can be easily varied as needed. The assay is much simpler than a previous in vitro motility assay that followed the movement of myosin-coated microbeads over actin cables exposed by dissection of the long cells of *Nitella axillaris*, a green alga (Sheetz and Spudich, 1983).

Many novel techniques for the study of actomyosin interaction have evolved from the in vitro motility assay, including assays that allow for the imaging of both the myosin and actin filaments (Sellers and Kachar, 1990), assays in which the force generation of myosin is measured, and assays in which single molecules of myosin can be imaged as they interact with actin. Force measurement is accomplished by two methods. In the first case, actin filaments

attached to flexible microneedles are lowered onto a myosin-coated surface (Kishino and Yanagida, 1988; VanBuren et al., 1995). Force per unit length of actin is monitored by imaging the bending of the needle. In the other mechanical assay, beads are attached to the opposite ends of an actin filament, and optical trapping techniques are used in which the position of each bead is controlled by dual optical traps. The filament is lowered to a surface coated with low-density myosin, and force-producing events are measured by monitoring the position of the beads at the end of the actin filament (Finer et al., 1994; Molloy et al., 1995). The use of single-molecule fluorescence methods allows one to image individual myosin molecules or observe their interactions with fluorescently labeled nucleotides (Funatsu et al., 1995; Vale et al., 1996).

Critical Parameters

Myosin can be attached to the coverslip surface by a variety of methods. It can be bound as filaments or as monomers (Toyoshima et al., 1987; Umemoto and Sellers, 1990). Fragments of myosin such as HMM or S1 can also be used (Toyoshima et al., 1987). A more specific attachment of myosin to the surface is accomplished using site-specific antibodies, usually directed against the carboxyl terminus of the myosin or subfragment (Winkelmann et al., 1995). Isoform-specific antibodies can also be used to select a specific myosin isoform from a mixture of myosins or from a crude cell or tissue extract (Cuda et al., 1993; Kelley et al., 1996). In these cases, the affinity-purified antibody (0.2 mg/ml) is first bound to the nitrocellulose surface; this is followed by washing and blocking with BSA. Myosin (or an extract) is then added and allowed to complex with the antibody for 10 to 30 min. Subsequent steps are performed as described in the Basic Protocol.

The rate of actin-filament sliding generated by myosin varies greatly among myosin isoforms (Sellers and Goodson, 1995). In addition, assay conditions such as ionic strength, temperature, and pH can modulate the rate of sliding. Various parameters of the assay must therefore be varied. With slowly moving myosins (<0.2 μm/sec), longer imaging intervals are required, necessitating lower illumination levels, and as a consequence, it is very useful to average 16 to 64 frames to improve the signal-to-noise ratio. With more rapidly moving myosins (4 to 10 μm/sec), short imaging intervals can be used along with higher illumination levels. Under these conditions, it is preferable to have an intensified CCD camera as opposed to a SIT camera, which has a slower temporal response that may result in the appearance of comet-tail-like images of the actin filaments.

There are many high-quality manufacturers of the required equipment. It is advisable to have representatives demonstrate the various pieces of equipment before purchase. A detailed treatise on video microscopy is available (Inoue and Spring, 1997).

In general, the assay does not work well at pH 6.5 or below, and the rate of actin filament sliding by myosin slows dramatically as the temperature falls below 20°C.

Troubleshooting

There are several common problems in the assay that are usually easily remedied.

1. *The actin filaments are too dim.* Increase the light intensity or the number of frames that are averaged. Remove any unnecessary glass surfaces between the actin filaments and the camera. If necessary, prepare fresh actin. It is important that the dried rhodamine phalloidin powder be predissolved in methanol to ensure complete solubilization.

2. *Rhodamine label attached to actin filaments photobleaches rapidly.* The light intensity should be reduced by means of neutral density filters, and frame averaging should be used to increase signal-to-noise ratio. The oxygen-scavenging components of the in vitro motility assay (glucose oxidase and catalase) should be checked to ensure they are active. Use 50 mM DTT, if not already doing so.

3. *The actin filaments move intermittently or rapidly shear into small pieces.* This is typical in myosin preparations containing rigorlike, noncycling "dead heads" (see Basic Protocol). Reducing the surface density of myosin also leads to less shearing. If necessary, prepare fresh myosin.

4. *Actin filaments detach from the surface or exhibit wobbly motions.* Increase the density of myosin attached to the surface or decrease the ionic strength. Use of methylcellulose generally allows for movement over lower myosin surface densities by decreasing the lateral Brownian movement of actin filaments. In the presence of methylcellulose, Brownian movement occurs only in the long dimension of the actin filament.

Anticipated Results

A successfully completed assay should allow measurement of translocation of actin by myosin and dissection of the biochemistry of

the process. Typically, translocation rates range from <0.2 μm/sec to 10 μm/sec depending upon the source of myosin and the assay conditions.

Time Considerations

Actin preparation requires ~1 day to prepare an acetone powder and 3 to 4 days to prepare polymerized filaments. Myosin preparation takes from 1 day to 5 days, depending on the myosin isoform. Performing the translocation assay requires 30 min to set up. Data acquisition is in real time. Data analysis can be very slow and laborious unless an automated tracking system is used. The time required for data analysis is a function of how many filaments are being followed and the system being used for analysis.

Organelle Motility in Plant Cells: Imaging Golgi and ER Dynamics with GFP

This unit describes the use of green fluorescent protein (GFP) from the jellyfish *Aequoria victoria* as a vital marker for endoplasmic reticulum (ER) and Golgi apparatus (GA) in higher plant cells. GFP is expressed as a chimeric protein either with selected peptide targeting sequences or with complete proteins that are resident in the ER or GA. Expression of GFP constructs can be observed in living material using conventional, or preferably, confocal laser–scanning epifluorescence microscopes. GFP has a number of intrinsic properties that make it attractive as a marker for cell biological studies. For instance, it is highly fluorescent, yet requires no cofactors or substrates. In addition, it is relatively stable, is pH insensitive, shows no detectable level of cytotoxicity (when expressed in organelles), and in many instances, does not interfere with the functioning of native proteins when expressed as chimeric constructs. Moreover, there are genetically modified variants of GFP with altered spectral and other properties, such as folding rate (Cubitt et al., 1995).

This unit describes two protocols for rapid transient expression of GFP in the plant endomembrane system using *Agrobacterium* and virus vectors. These protocols can be used for the expression of GFP targeted to most organelles. Besides *Agrobacterium*-mediated transformation (see Basic Protocol), virus transformation (see Alternate Protocol), has been optimized for GFP expression in some *Nicotiana* species.

TRANSIENT EXPRESSION FOR VISUALIZATION OF ER AND GOLGI PROBES IN LEAVES

BASIC PROTOCOL

This protocol describes the production of GFP-transcripts in *Nicotiana* using an *Agrobacterium tumefaciens*–mediated transient expression system. There are a number of techniques for transient expression of reporter constructs in plant cells, such as electroporation and PEG-mediated transformation of protoplasts, and microprojectile bombardment and virus-mediated expression in tissues; however, transient expression mediated by *Agrobacterium* containing a reporter construct in a suitable binary vector (e.g., pVKH18En6) is one of the easiest, quickest, and more reliable methods. It requires minimum laboratory equipment, and it allows the study of intact cells and tissues from leaves still attached to the plant with minimal tissue disruption, although it is not clear to what extent the bacterial infection alters cell physiology. Moreover, transformed leaf tissue may be used to generate stable transformants.

The basic principle of the transformation is infiltration of the intracellular spaces of *Nicotiana* leaves with a suspension of *A. tumefaciens*, which is injected into the leaf tissue by pressure though the stomata of the abaxial leaf epidermis. The infectious *Agrobacterium* cells then transfer the T-DNA carrying the genes to be transferred to the host cell resulting in a transient build-up of reporter transcripts in the cell. With GFP-based reporters, fluorescence can be detected in the infected area from abaxial and adaxial epidermis, guard cells, and palisade and spongy mesophylls, but rarely trichomes and vascular tissue. The technique gives high expression levels of GFP constructs, which may fade in a week to ten days after inoculation of the leaves due to progressive depletion of the foreign DNA.

This method offers a number of advantages including speed and relatively little variability between cells within the infected area in which most, if not all cells, appear to express the construct. Moreover, Rossi et al. (1993) have shown that expression from T-DNA

Contributed by Chris Hawes, Federica Brandizzil, Henri Batoko, and Ian Moore
Current Protocols in Cell Biology (2001) 13.3.1-13.3.10

varies linearly with bacterial concentration over three orders of magnitude offering the opportunity to control GFP expression levels. Finally, the geometry of epidermal cells, which have large vacuoles and a thin layer of cytoplasm immediately below the cuticular wall, greatly facilitates observation by both conventional epifluorescence microscopy (*UNIT 4.2*) and confocal imaging (*UNIT 4.5*). For example, the authors have been able to distinguish the distribution of ER- and Golgi-targeted GFP in these cells using a conventional epifluorescence microscope.

Materials

Suitable *Agrobacterium* vector (e.g., pVKH18En6) with multiple cloning site and appropriate selectable marker
Agrobacterium tumefaciens (e.g., GV3101::pMP90)
YEB medium containing appropriate selective antibiotic (see recipe)
5% (v/v) sodium hypochlorite or 1% (w/v) Virkon (Amtec Int. Ltd.)
Infiltration medium (INM; see recipe)
Four-week-old greenhouse plants of *Nicotiana tabacum*, *N. clevelandii*, and *N. benthamiana*

Shaking incubator, 28°C
1.5-ml microcentrifuge tubes, sterile
Spectrophotometer
1-ml disposable plastic syringe, without needle
22° to 25°C greenhouse for growing plants
Permanent marker pen
Fine scissors
Slides and coverslips (use thickness 0 for confocal microscopes)
Electrical or waterproof tape
Conventional epifluorescence microscope, laser-scanning confocal microscope (preferred), or equivalent, with appropriate filters (e.g., standard FITC filter block)
Confocal-imaging time-lapse software (Zeiss, Leica, Biorad)

Additional reagents and equipment for vector construction, transformation, and cell culture (see *APPENDIX 3*) adapted for plants

CAUTION: All solutions used to culture and wash bacteria should be treated with a suitable disinfectant before discarding in an autoclavable waste container. Resulting plant material should be treated as biological hazard and handled accordingly.

NOTE: Sterile conditions are required for culture and handling of *Agrobacterium*, but not during tobacco leaf infiltration and subsequent incubation of the plant. All equipment coming into contact with bacteria should be autoclaved.

Clone GFP into bacteria and grow Agrobacterium

1. Using standard molecular biology techniques (see *APPENDIX 3*), clone GFP chimera into a suitable vector with an appropriate selectable marker (e.g., kan^r, amp^r) and transform into a suitable *Agrobacterium* strain.

   A number of binary Agrobacterium vectors can be used for the cloning of GFP (Bevan, 1984). In the authors' laboratories a vector with an enhanced 35S promoter, pVKH18En6, is used to drive high levels of GFP expression (Hawes et al., 2000).

2. Pick a single colony of *Agrobacterium* from a selection plate and inoculate 2 to 5 ml YEB medium containing appropriate selectable antibiotic.

3. Culture *Agrobacterium* at 28°C in a shaking incubator to stationary phase (24 to 48 hr).
4. Transfer 1.0 ml of culture to a 1.5-ml sterile microcentrifuge tube and pellet bacteria by microcentrifuging for 5 min at 4000 rpm.
5. Discard the supernatant in a disinfecting solution of either 5% (v/v) sodium hypochlorite ($NaOCl_3$) or 1% (w/v) Virkon.
6. Wash the bacterial pellet twice with 1.0 ml INM each.
7. Microcentrifuge for 5 min at 4000 rpm.
8. Resuspend in INM to OD_{600} 0.5 to 0.6 or higher to increase the level of expression.

Inoculate plants

9. Inject bacterial suspension into the abaxial epidermis of plant leaves from a 1-ml disposable plastic syringe by simply pressing the nozzle against the leaf surface (do not use a needle), holding the leaf on the other side with a gloved finger at the point of contact to support the pressure.

   The infiltration is easier when the leaf stomata are open. Illuminating the plants from underneath with a bright light prior to infiltration is recommended.

   The spread of liquid entering the leaf via stomata is visualized by a darkening of the leaf tissue. The boundaries of the infiltrated area should be outlined with a permanent marker pen.

   Expression can also be achieved in whole Arabidopsis plants by immersing plantlets in bacterial suspension under vacuum (Rakousky et al., 1998).

10. Incubate plants for 2 to 3 days under normal growing conditions in a greenhouse, except at 20° to 22°C to optimize infection.

11a. *For observation with a UV lamp:* Check for GFP fluorescence in leaves with a hand-held long-wavelength UV lamp after 2 days (assuming a GFP variant with a UV-excitation peak).

   The time required for the fluorescence to appear may depend on the construct. It is wise to check a piece of leaf tissue 2 days after the inoculation of Agrobacterium cells into the leaf, and every 4 to 6 hr thereafter, to establish the optimal time for expression of each construct used.

11b. *For observation using a microscope:* After 2 days, cut out a segment of leaf tissue with fine scissors, mount in a drop of water on a microscope slide, and cover with a long coverslip held in position with strips of electrical or waterproof tape at either end.

   It is important to remember that GFP fluorochrome cyclization will not occur in an anoxic environment so it is preferable that microscope preparations are not sealed.

Visualize expression

12. Observe the specimen with a conventional epifluorescence microscope or laser-scanning confocal microscope (preferred) and appropriate filters.

   Most forms of GFP can be observed with a standard FITC filter block; however, the exact filter configuration will depend upon the excitation and emission wavelengths of the GFP (or its spectral variant) used.

   Depending on the levels of expression, for ER- or GA-targeted constructs, image capture by confocal microscopy may require high laser power. This is possible with GFP as it is relatively resistant to photobleaching. Moreover, a wide pinhole aperture may be required

to obtain a satisfactory signal-to-noise ratio. Although, this strategy reduces confocality, and the ultimate resolution of the image, it can help overcome problems of image blurring due to organelle movement during the image capture process.

13. (Optional) To make a confocal video of endomembrane dynamics, select a region of interest, increase the laser power to the maximum available, select a wide pinhole aperture, and collect images as fast as possible using confocal-imaging time-lapse software.

    If cytoplasmic movement is not dramatic then line (not sequential) image averaging can be used to improve the signal-to-noise ratio.

ALTERNATE PROTOCOL

VIRUS MEDIATED EXPRESSION OF GFP CONSTRUCTS

Viruses are often used as vectors for transient expression of DNA in foreign organisms, due to the high level of replication of the virus and the high level of protein synthesis (results may be obtained 4 to 10 days after inoculation of leaves of the host plants). In general the level of protein expression is high because of the activity of the strong viral promoter. The limitation associated with the virus expression technique resides in the fact that not all cells in plants expressing the viral genome become infected. This may in turn limit the reproducibility of biochemical assays. Moreover, the high levels of expression of the desired protein may be a reason for their mistargeting in the cell. Some inserts may be unstable in the vector, and the likelihood of instability increases with the size of the insert, such that 3 kb may be close to the practical limit. Finally, the pathogenic effects of the viral infection must be taken into account.

For plants, potato virus X (PVX) has been used successfully to express the marker proteins GFP and β-glucuronidase (GUS; Chapman et al., 1992; Baulcombe et al., 1995), and numerous other foreign proteins, often as fusions with GFP (Blackman et al., 1998; Boevink et al., 1998, 1999). The foreign genes inserted into the multiple cloning site are under the transcriptional control of the subgenomic promoter. A site at the 3′ end of the PVX sequence is used to linearize the plasmid before infectious run-off transcripts are made with T7 RNA polymerase (the T7 promoter is present immediately upstream of the PVX sequence).

Additional Materials *(also see Basic Protocol)*

GFP chimera construct
PVX vector (pTXS.P3C2) with multiple cloning site and T7 promoter (available from various laboratories)
Midiprep kit, without RNase (Qiagen)
T7 RNA polymerase transcription kit (e.g., Ambion T7 message in machine kit)
*Spe*I or *Sph*I restriction enzymes (see *APPENDIX 3*)

Aluminum oxide
Aluminum oxide dispenser: small glass flask containing abrasive, sealed with miracloth

Additional equipment and reagents for restriction digestion, phenol/chloroform extraction, and ethanol precipitation (see *APPENDIX 3*), and quantification of DNA concentration by spectroscopy (see *APPENDIX 3D*)

IMPORTANT NOTE: In some countries in order to handle plant viruses as vectors, a license must be obtained from the appropriate authorities.

IMPORTANT NOTE: All solutions used for virus work must be RNase-free.

1. Insert the GFP chimera in the multiple cloning site of the PVX vector in the correct orientation with respect to the T7 promoter (see *APPENDIX 3*).

2 Prepare a high-quality, medium-scale, RNase-free DNA preparation using a midiprep kit. Avoid using RNase in preparation of the DNA (i.e., do not add RNases to solution P1 and increase the volume of the wash buffer as recommended by the manufacturer).

3. Linearize the vector with *Spe*I or *Sph*I restriction enzymes to make infectious RNA.

4. (Optional) Clean the DNA by phenol/chloroform extraction and ethanol precipitation (see *APPENDIX 3*).

5. Synthesize capped transcripts using 0.2 to 1.0 µg linearized DNA for a single infection, as template for the T7 RNA polymerase transcription kit, following the manufacturer's instructions.

   The transcripts are generally not phenol/chloroform extracted or precipitated before inoculating.

6. Dust host plants *lightly* with abrasive aluminum oxide using an aluminum oxide dispenser.

7. Drop 5 µl of transcripts (1 to 5 µg/µl) onto four leaves and spread lightly with a glove-protected fingertip.

8. After inoculation wash the abrasive off the leaves. Keep plants at ~23°C in a culture room or sealed greenhouse.

9. Four to seven days post inoculation with PVX-GFP virus, screen plants for small fluorescent lesions on inoculated leaves with a hand-held long-wavelength UV-light or an epifluorescence microscope.

10. Analyze as described elsewhere (see Basic Protocol, steps 11 to 13).

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Infiltration medium (INM)

In a 10-ml measuring cylinder, add 50 mg glucose, 1 ml 0.5 M MES, pH 5.6 (see recipe), 1 ml 20 mM Na_3PO_4 (see recipe), and 5 µl 200 mM acetosyringone (Aldrich) in dimethyl sulfoxide (DMSO; final concentration 100 µM). Bring volume to 10 ml with water, seal the cylinder with 1 cm^2 Parafilm, and mix thoroughly by inversion. Make fresh prior to use.

200 mM acetosyringone in DMSO and 20 mM Na_3PO_4 can be stored at 4°C up to two weeks, or aliquoted and kept at –20°C for longer (i.e., 6 months) storage.

NOTE: *No antibiotic must be added to this medium.*

MES, 0.5 M, pH 5.6

In a 20-ml beaker add 1.95 g MES and 18 ml water. Adjust the pH to 5.6 with KOH and bring the volume to 20 ml with water.

Store up to 2 weeks at 4°C, or for longer storage (i.e., 6 months), aliquot and store at –20°C.

Na_3PO_4, 20 mM

Dissolve 0.152 g $Na_3PO_4 \cdot 12H_2O$ in 20 ml water. Store up to 2 weeks at 4°C, or for longer storage (i.e., 6 months) aliquot and store at –20°C.

YEB medium

In a 1-liter beaker, dissolve 5 g beef extract (Difco), 1 g yeast extract (Merck), 5 g peptone (Difco), 5 g sucrose (BDH Laboratory), and 0.5 g $MgSO_4 \cdot 7H_2O$, in 0.8 liters of water. Add water to 1 liter, stirring continuously. Autoclave and store up to 6 months at room temperature.

It may take some time to dissolve completely.

COMMENTARY

Background Information

While many experimental programs may ultimately require the production of stable transformants, much useful information can be obtained through the use of transient expression systems. The production of transgenic plants and culture cell lines expressing GFP can be achieved using standard transformation and gene expression technologies. One of the major advantages of GFP and its wavelength-shifted derivatives, when used to tag proteins of interest, is that cellular events can be studied in vivo in planta and monitored by conventional epifluorescence microscopy. However, with tissue samples it may be necessary to use either confocal microscopy or conventional fluorescence microscopy combined with low-light-level cameras and deconvolution software.

The introduction of jellyfish fluorescent protein has provided cell biologists with a powerful new tool with which to study cell structure and function in vivo.

GFP chimeras were first used in plant cell biology to investigate the movement of viruses by the construction of both fluorescent viruses and fluorescent viral proteins, such as the movement proteins (Baulcombe et al., 1995; Oparka et al., 1995; Itaya et al., 1997). Subsequently, most major organelles have been successfully labeled with GFP chimeras, including the nucleus (Grebenok et al., 1997), vacuole (Di Sansebastiano et al., 1998), mitochondria (Köhler et al., 1997), plastids (Köhler and Hanson, 2000), cell plate (Gu and Verma, 1997), GA and ER (Boevink et al.,1998, 1999), and cytoskeleton (Köst et al., 1998; Marc et al., 1998).

In plant cells, GFP can be expressed on its own, fused to targeting peptides, or as a chimera with a complete protein of interest. Targeting the protein into the ER can be achieved by the addition of an appropriate N-terminal signal peptide (such as sporamin, patatin, or chitinase signal; Boevink et al., 1999; Haseloff et al., 1997) to translocate the protein into the ER lumen, and a C-terminal His/Lys, Asp, Glu, Leu (H/KDEL) retrieval sequence to maintain the protein in the ER (see *APPENDIX 1C*). For GA visualization, targeting (signal-anchor) sequences from plant or mammalian transferases can be spliced onto the C terminus of GFP to locate the Golgi (Boevink et al., 1998), as can complete Golgi enzyme–coding sequences (Nebenführ et al., 1999). For instance the signal-anchor sequence of a rat sialyl transferase, incorporating the transmembrane and cytoplasmic amino acid domains, targets GFP to the *trans*-Golgi, while a soybean mannosidase I-GFP fusion locates towards the *cis*-face (Nebenführ et al., 1999). Both ER and Golgi can be targeted with the *Arabidopsis* homolog of the yeast H/KDEL receptor, *aERD2* (Boevink et al., 1998).

The transient expression protocol described in this unit can be used for species other than *Nicotiana*. The authors have been able to transiently express ER-targeted GFP in *Arabidopsis*, *Petunia*, and cucumber.

Critical Parameters

There are now a number of variants of GFP, obtained by genetic modification of the wild-type gene, which have been optimized to change various characteristics of the protein. This reengineering has been aimed at changing the spectral properties of the protein and improving the speed of maturation of the chromophore, including photoisomerisation and reduction in photobleaching of the protein (Cubitt et al., 1995, 1999); therefore, it is advisable to make a careful choice of the GFP to be used before embarking on extensive transformation procedures. For instance, mutations with enhanced blue excitation peaks may have reduced UV excitation, making rapid screening of plants with UV lamps impossible.

In order to avoid possible artifacts, it is important to ensure that the detected GFP fluorescence in transiently expressing plant cells is not derived from *Agrobacteria* synthesizing the protein. With other reporter systems this problem has been overcome by insertion of a plant intron into the reporter gene. Unfortunately such intron-containing GFPs have yet to be

constructed. Furthermore, as high expression levels may result in mistargeting, it is advisable that serial dilutions of bacteria be used to optimize expression levels.

Due to the availability of the spectral variants of GFP, including yellow (YFP), cyan (CFP) and the newly released red fluorescent proteins (dsRed), co-expression of constructs is possible. Care must then be taken with the choice of filter sets to prevent bleed through of signal when excitation and emission spectra are close. This of course is not the case for specific techniques, such as fluorescence resonance energy transfer (FRET; *UNIT 17.1*), in which the overlapping spectra are essential parameters (Gadella et al., 1999).

GFP will remain fluorescent after both paraformaldehyde and light glutaraldehyde fixation, thus permitting the use of other fluorescent probes, such as rhodamine conjugated phalloidin (Boevink et al., 1998), or standard immunofluorescence protocols, with red or far-red emitting fluorochromes. GFP will also retain antigenicity after fixation and preparation for immunogold labeling using the progressive-lowering-of-temperature technique and embedding in acrylic resins (Vanden-Bosch, 1991; Boevink et al., 1998; *UNIT 4.7*). Thus, it is possible to confirm the location of GFP fusion proteins at the ultrastructural level. This is important when proteins are targeted to some of the smaller organelles, such as mitochondria, plastids, and Golgi. One may encounter difficulties in obtaining GFP antibodies that are suitable for immunogold labeling of plant tissue. Consequently, it may be advisable to incorporate one of the widely used epitope tags into the GFP fusion if at some stage in the future immunogold labeling is envisaged.

Finally, with the observation of living plant material, specific problems, such as autofluorescence of chlorophyll and rapid cytoplasmic streaming, or organelle movements, are often encountered; these problems can be overcome by selective use of filter sets and optimization of microscope settings.

Troubleshooting

Sometimes a GFP chimera does not fluoresce, which can be due to several reasons. For example, frame shifts when GFP-fusions are used. If the resulting cDNAs have been checked and confirmed by sequencing, it is advisable to check that the binary plasmid carrying the construct is stable in *Agrobacterium*. Another possible explanation for lack of fluorescence may be that the GFP chimera is misfolded. Levels of expression can be checked by conventional immunoblot assay of protein extract (*UNIT 6.2*). This is also useful when with a particular construct, one encounters a relatively low-fluorescence level, which may result from protein instability or reduced folding kinetics.

On occasion a mislocalization of the fusion protein can be observed. If the quality of the targeting signals is trusted, then the phenome-

Table 13.3.1 Optimization of Images of GFP Targeted to GA and ER at the Confocal Microscope

Problem	Solution	Result
Autofluorescence of chlorophylls	Use a narrow-band emission filter set (e.g., 515–525 nm) in combination with optimum brightness and contrast settings	Reduction of fluorescence from chloroplasts
Blurred image due to the dynamics of the ER and GA	Increase laser intensity and/or increase pinhole aperture in combination with single-line scan or collect data from a defined region of interest (ROI)	Reduction in resolution and confocality may be experienced. A collection of time-resolved data sets for presentation as movies can be obtained
Low signal from GFP that is not compensated by change of brightness/contrast settings	Increase the laser intensity and/or increase the pinhole aperture	Increase of signal from GFP and reduction of confocality and resolution
Photobleaching of GFP fluorescence	Reduce the laser intensity, the number of image scans for averaging, and the number of sections per Z-series	Reduction of resolution and photobleaching damage

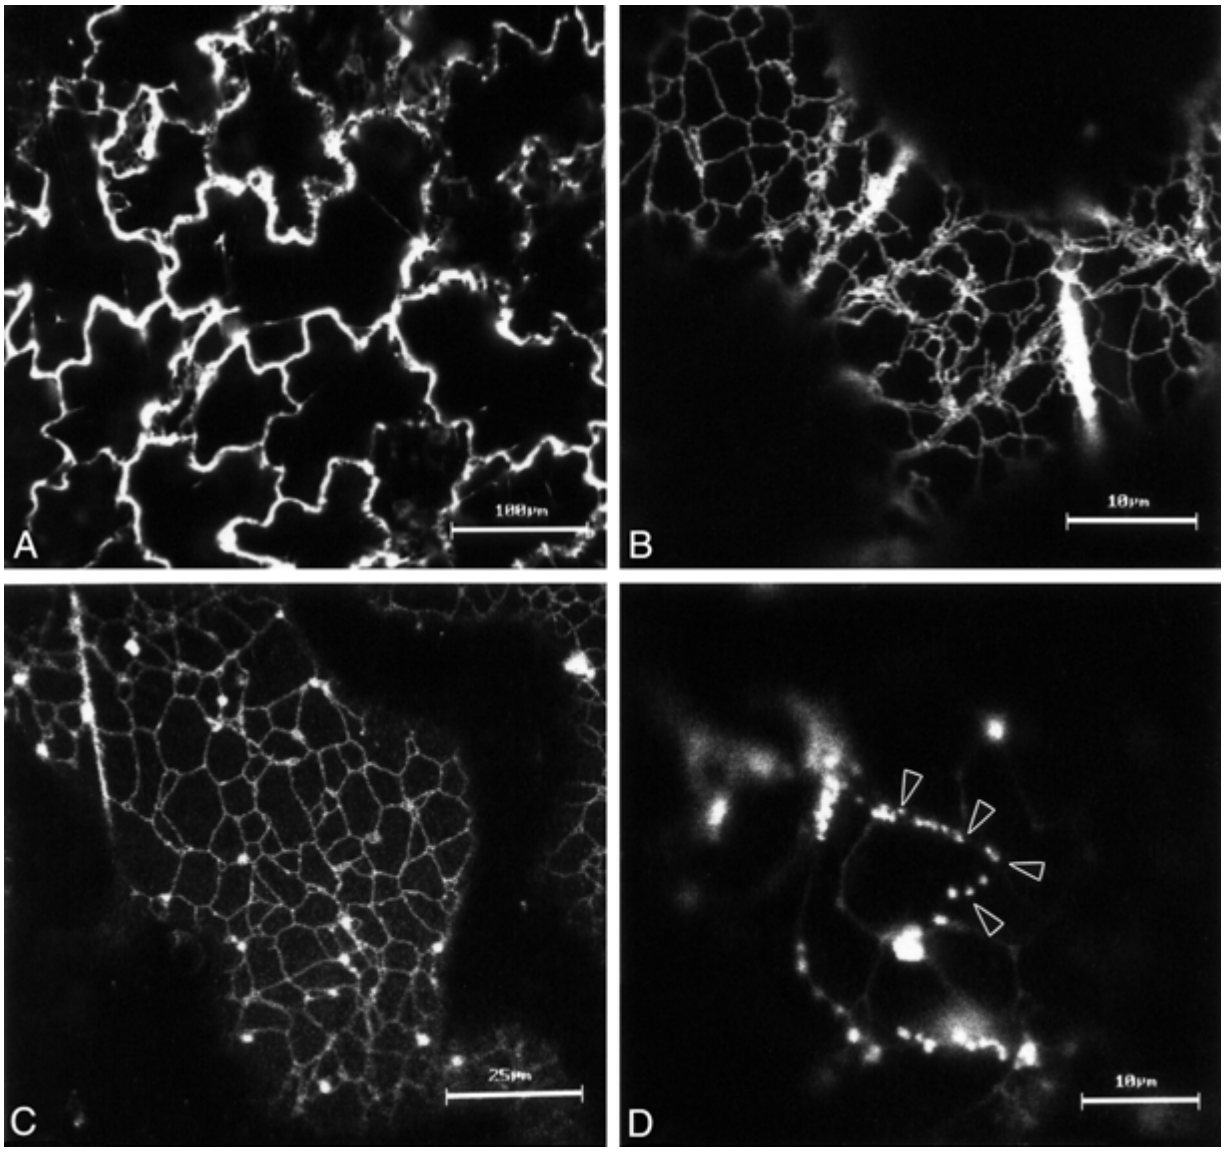

Figure 13.3.1 (**A**) *Agrobacterium*-mediated expression of a signal peptide-GFP-HDEL construct in leaf epidermal cells of *Nicotiana clevelandii*. The low magnification micrograph shows high levels of expression in the endoplasmic reticulum at the cortex of the cells. (**B**) Potato virus X–mediated expression of a signal peptide-GFP-calreticulin construct in a leaf epidermal cell of *N. clevelandii*. (**C**) Virus-mediated expression of an ER/Golgi–targeted construct (aERD2-GFP) in a leaf epidermal cell. Note the bright Golgi bodies are associated with the cortical ER tubules. (**D**) Golgi dynamics. Sequential frame capture of Golgi (arrows) moving over static cortical ER tubules. All micrographs taken with a Zeiss LSM 410 laser scanning confocal microscope.

non may be due to overexpression of the construct. Optimization of the bacterial concentration (as measured by optical density) is then suggested. Mislocalization can be also due to instability of the targeting signal within the fusion protein.

During observation of leaf tissue, the autofluorescence of the chlorophylls can mask low levels of GFP fluorescence. The use of a narrow-band emission filter set (e.g., 515 to 525 nm) in combination with optimum brightness and contrast settings will reduce the autofluorescence from chloroplasts. Increasing the laser power and/or altering brightness and contrast settings can usually compensate for the overall reduction in signal that may result. Movement of labeled organelles in plant cells may result in a blurred image. Modifying laser and/or pinhole settings in combination with single-line scanning can help limit this problem. If necessary, the authors recommend collecting data from a defined region of interest (ROI). A reduction in resolution and confocality will occur, but quick collection of time-resolved

data sets for presentation as movies can be obtained. GFP is an ideal marker for time-lapse studies because of its relative resistance to photobleaching; however, if a reduction of signal from GFP and its variants due to photobleaching is observed, the laser intensity, the number of scans for image averaging, and the number of sections per Z-series should be reduced. Recommendations for the optimization of the ER and GA image at the confocal microscope are summarized in Table 13.3.1.

Anticipated Results

Typical results can be seen in Figure 13.3.1. The results illustrated in the figure are typical for those organelles to which GFP has been deliberately targeted. The percentage of transformed cells can vary with the time and with the concentration of bacteria. With the experimental conditions suggested in the Basic Protocol usually, 3 to 4 days after inoculation of plants, 20% to 40% of the cells are transformed within the area of initial bacterial penetration. Similarly, the virus transformation may produce approximately the same yield of transformed cells (after 4 to 5 days), and this number of cells may increase with time due to the virus spread which is not a feature of *Agrobacterium* transformation.

Time Consideration

As mentioned above, fluorescence may be detected 2 days after plant transformation. In the authors' experience, this depends on the particular construct, but in general, a detectable expression is obtained from 2 to 4 days and may last about 7 to 10 days.

Movement of Nuclei

This unit presents an in vitro assay for nuclear motility along microtubules (see Basic Protocol). This assay system mimics the movement of the female pronucleus of the fertilized frog egg. Dynamic microtubule asters are assembled from purified centrosomes in *Xenopus* cytosol. Purified nuclei are then added and the motility is observed using video-enhanced differential interference contrast (VE-DIC) microscopy. This assay has been used to demonstrate that cytoplasmic dynein drives the motility of nuclei along microtubules in this system. Dynein activity causes nuclei to move to microtubule minus-ends. Therefore, the nuclei move to and accumulate at centrosomes. Other components of the nuclear motility apparatus can be defined by this assay including regulatory factors present in the cytosol, or binding partners for dynein on the nuclear membrane. Pharmacological and biological inhibitors of nuclear motility can be assayed and the effects on motility can be quantitated.

The assay system requires the following components: purified nuclei assembled in *Xeno*pus egg extracts (see Support Protocol 5); purified centrosomes (see Support Protocols 1 and 2); and *Xenopus* cytosol that has been clarified by high-speed centrifugation (see Support Protocol 4) from fractionated interphase extracts (see Support Protocol 3). The clarified extract provides the subunits for microtubule assembly, the dynein motor complex that drives motility, and regulatory factors that have not yet been defined.

STRATEGIC PLANNING

These experiments require familiarity with handling *Xenopus laevis* for obtaining eggs used in this protocol. Protocols for handling *Xenopus* for egg production and preparation of active cytoplasmic extracts are described elsewhere and should be reviewed (Murray, 1991; *UNIT 11.10*). Included here are those procedures specifically required for nuclear motility experiments. These experiments require significant microscopy expertise, especially using VE-DIC. VE-DIC theory and techniques are not presented here. Refer to *UNIT 4.1* for basic microscopy theory and techniques. Specific techniques for imaging microtubules and organelles using VE-DIC are presented elsewhere (Walker et al., 1988; Salmon and Tran, 1998; *UNIT 13.1*). The support protocols describe the procedures to prepare the different components used in the Basic Protocol.

NUCLEAR MOTILITY ASSAY

BASIC PROTOCOL

This protocol describes the set-up and execution of an assay that combines dynamic microtubules with synthetic nuclei assembled in *Xenopus* egg extracts (see Fig. 13.4.1 for a schematic of the assay). All assay components are stored separately in small aliquots at –70°C and recombined during the assay. (Assay components have been stored as long as 6 months without any loss of activity. Longer storage is conceivable, but has not been tested.) The use of aliquotted, frozen components allows reproducibility between assays as well as the possibility to inactivate or modify individual components to study the function of individual proteins in microtubule-mediated nuclear motility.

Current Protocols in Cell Biology (2001) 13.4.1-13.4.28

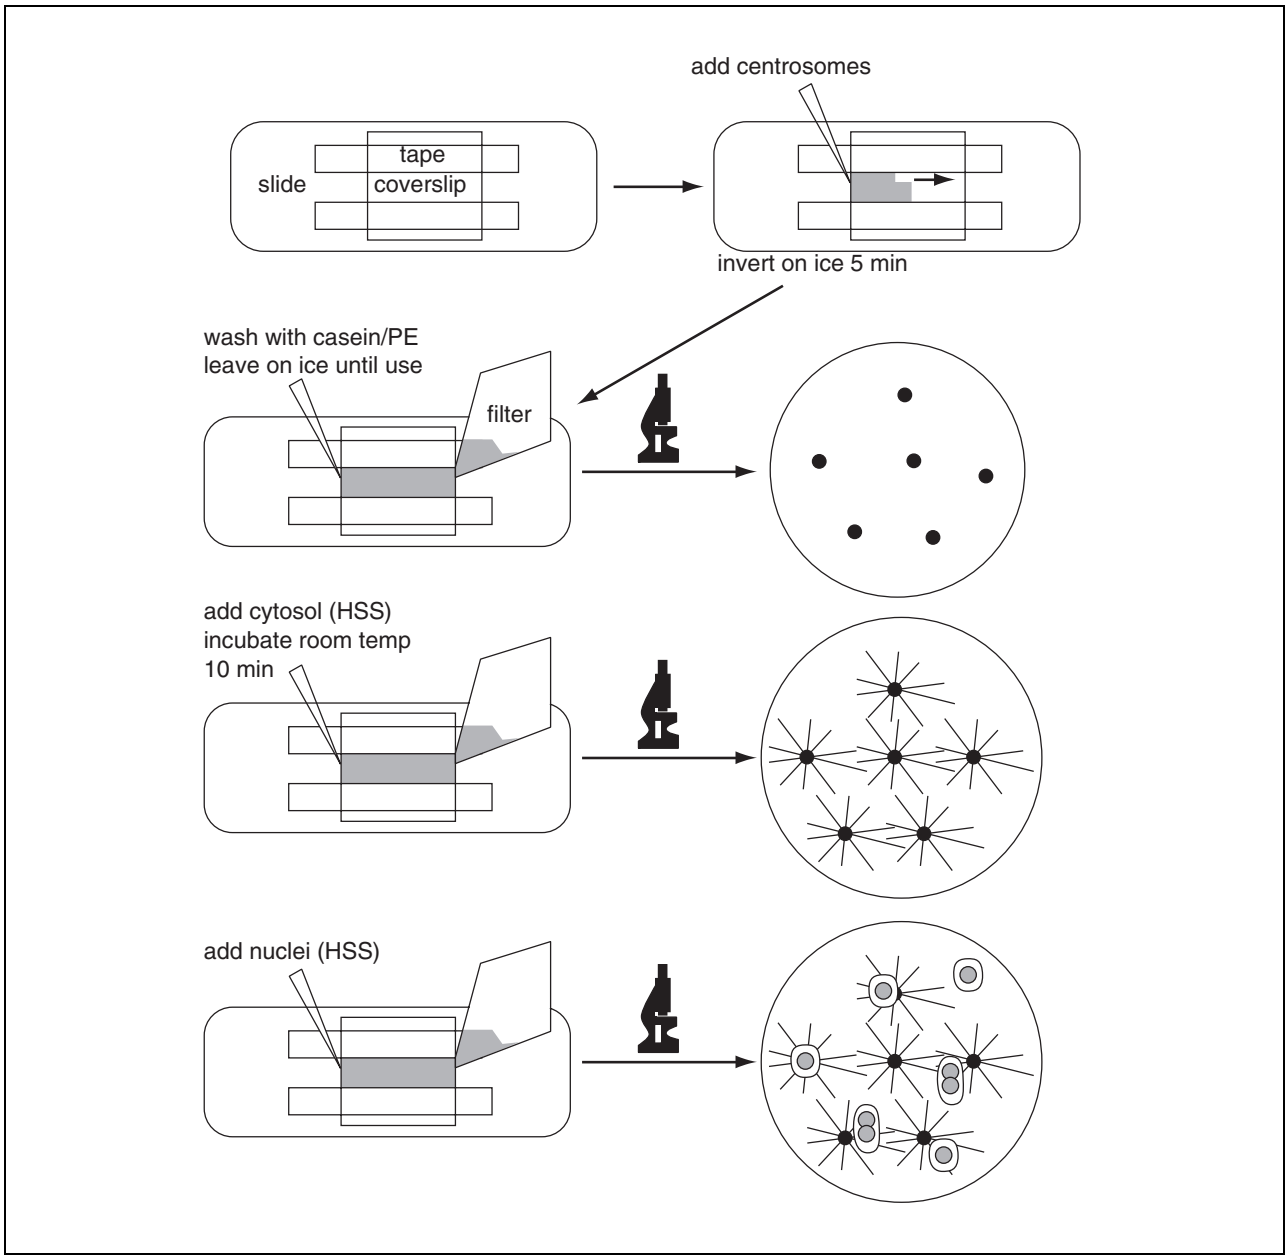

Figure 13.4.1 Flow chart of nuclear motility assay. Schematic showing the slide/coverslip chamber assembly used in this assay, and the flow-through technique. The individual steps are shown on the left panels and a representative microscope field is shown on the right panels. Centrosomes appear as round dots scattered on the field, microtubules are the lines emanating from the centrosomes in the second step, and nuclei moving on the asters are shown in the third step.

Materials

Centrosomes (see Support Protocol 1)
PE buffer (see recipe)
5 mg/ml casein in PE buffer (see recipe)
ABC buffer (see recipe)
HSS cytosol (see Support Protocol 4)
DNA-bead nuclei (see Support Protocol 5)
Valap (*UNIT 13.1*) at 37°C
Immersion oil
Assay reagent (e.g., drug, antibody, expressed protein)
Antibodies bound to beads (for immunodepletion experiments)

Inverted microscope equipped for high-resolution DIC optics
Simple perfusion chambers made from: clean slide, double-stick tape, and clean 18 × 18–mm coverslips (for preparation see *UNIT 13.1*, Support Protocol 1)
Humid chamber: a covered 10- or 15-cm glass petri dish with strip of moist filter paper around perimeter
Magnetic particle concentrator (Dynal)
Inverted microscope
Camera (e.g., Hamamatsu CCD C307, Hamamatsu)
Image processor (e.g., Argus 10, Hamamatsu or equivalent)

Assay nuclear motility

1. Prior to the experiment, optimize inverted microscope for DIC imaging of microtubules.

2. Assemble perfusion chambers according to the instructions in *UNIT 13.1*, Support Protocol 1. Assemble by placing two pieces of double-sided tape 2 mm apart on a microscope slide and attach an 18 × 18–mm coverslip.

   The chambers should have an approximate volume of 7 µl.

3. Thaw an aliquot of centrosomes. Dilute with PE buffer to the optimal concentration determined in Support Protocol 2. Flow 7 µl of diluted centrosomes into each chamber to be used in the day's set of experiments. Be careful not to introduce bubbles into the chamber. Invert perfusion chambers onto ice and allow the centrosomes to settle onto the coverslip and attach for 5 min.

   For all perfusion steps, samples are pipetted at one opening of the perfusion chamber and wicked on the opposite side with a small piece of filter paper.

4. Flow 30 µl of 5 mg/ml casein in PE through perfusion chamber to block binding sites on the glass and rinse out unattached centrosomes. Incubate on ice until use (up to 4 hr maximum).

   From this point, only one chamber will be used at a time because each must be viewed individually on the microscope.

5. Ten minutes before the start of the assay, rinse chamber with 30 µl of ABC buffer. Flow 10 µl of HSS cytosol into chamber and incubate for 10 min at room temperature in the humid chamber.

   This allows recruitment of pericentriolar material from the cytosol, nucleation of microtubules, and aster formation.

6. During the 10-min incubation, quickly thaw an aliquot of DNA-bead nuclei (see Support Protocol 5) and immediately place on ice. Resuspend in 150 µl ABC buffer. Retrieve on a magnetic particle concentrator, carefully remove the ABC buffer, and resuspend in 10 ml HSS cytosol.

7. Flow the nuclear suspension into the chamber to start the assay. Seal the chamber with Valap, oil top and bottom of chamber with immersion oil, and observe at 20° to 22°C. Use DIC optics, a 100× objective, and a high-resolution condenser.

   If appropriate, use additional magnification to obtain an optimal on-screen field size ~50 µm. Use image background subtraction to enhance the microtubules (Walker et al., 1988; Salmon and Tran, 1998).

   Simultaneous imaging of nuclei and microtubules is a bit trickier than imaging only microtubules or other organelles due to the high refringence of the nuclei (especially magnetic-bead nuclei). Nuclei move rapidly on the microtubules. By 20 min, most nuclei have stopped moving and reached the centrosomes.

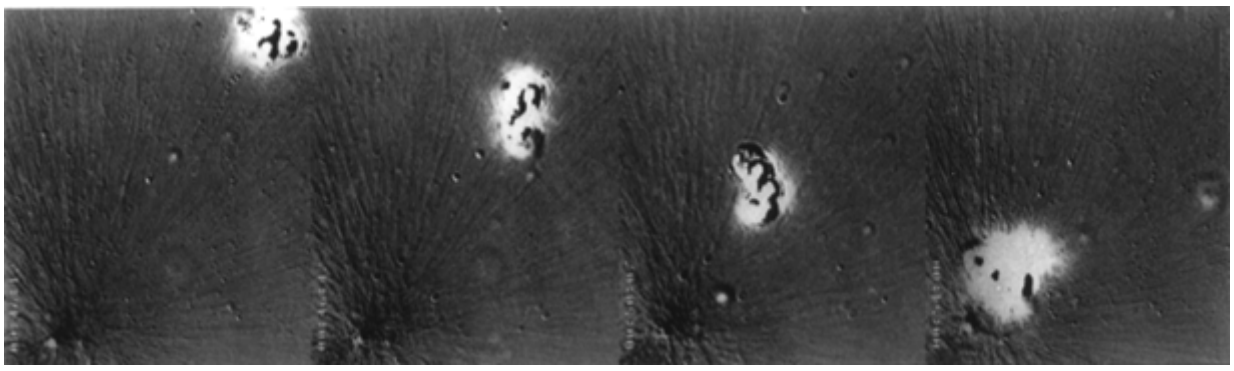

Figure 13.4.2 DIC images of a nucleus moving on a microtubule aster. A sequence of four stills are shown from a motility assay over a period of 10 min. The centrosome is in the lower left corner of each panel, and a robust microtubule aster emanates from this focus. A synthetic nucleus containing several paramagnetic beads starts in the upper right corner and moves to the centrosome during the course of the experiment. The nucleus appears refractory under AVEC-DIC imaging conditions. Image processing, including background subtraction and frame averaging, enhances the microtubules for clearer visualization. The time points are not indicated, but would occur during the first 20 min following assembly of the assay. By the 20-min time-point where quantitation is performed, 90% of nuclei will have reached the centrosome.

Collect images

8. To film nuclear movements, collect shuttered images with a camera. Perform rolling image averaging and background subtraction with an Argus 10 image processor, or equivalent image processing program.

   An appropriate interval between shuttered images is 5 sec. Figure 13.4.2 shows several sequential frames of a movie of a nucleus migrating on a microtubule aster.

Quantitate nuclear motility

9. To perform a quantitative assay for accumulation at centrosomes, repeat steps 1 through 8. Starting at 20 min after adding DNA-bead nuclei, for an additional 10 min, count as many fields as possible to determine percentage of nuclei present at centrosomes versus those at a distance (>5 μm) from centrosomes.

   One should be able to count 50 to 100 nuclei in the 10-min interval. Typical values are 90% to 95% of the nuclei present at centrosomes. Because many nuclei contain multiple DNA beads, each centrosome containing beads/nuclei should be counted as "1". Therefore numbers for accumulation are minimal values. Values <90% to 95% indicate difficulties with the assay that must be addressed before continuing (see Troubleshooting). If the assay looks optimized, then proceed to the next step.

Perform addition experiments

To assess pharmacological or biological reagents for effect

10a. Perform steps 1 through 4.

11a. Add 2 μl of drug, antibody, or expressed protein to 18 μl of HSS cytosol.

12a. Resuspend an aliquot of DNA-bead nuclei in 150 μl of ABC buffer. Retrieve on a magnet particle concentrator and discard supernatant.

13a. Resuspend DNA-bead nuclei in 10 μl of HSS/test compound mixture (step 11a). Use the remaining 10 μl to flow through perfusion chamber after the nucleation step (step 4) to replace the normal HSS cytosol with that containing the test compound.

14a. Flow in the nuclei/HSS/test compound mixture, incubate 20 min at 20° to 22°C and count as in step 9.

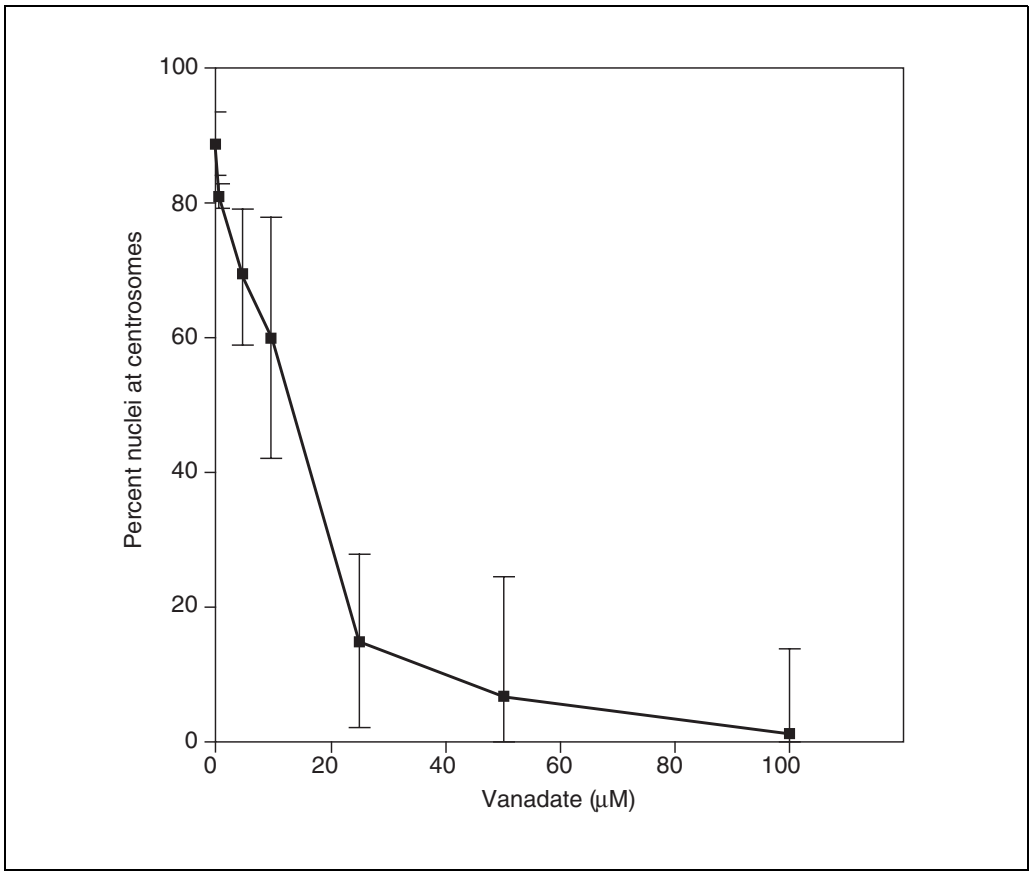

Figure 13.4.3 Effect of vanadate on accumulation of nuclei at centrosomes is an example of how this assay is used to derive quantitative data. Accumulation of nuclei at centrosomes was compared in HSS containing varying amounts of sodium orthovanadate, a general ATPase inhibitor. Assays were performed in triplicate for each vanadate concentration to generate a dose-response curve. The experiment indicates that vanadate significantly inhibits nuclear accumulation at centrosomes at a concentration of 20 mM. This concentration has been shown to be effective in inhibiting the motility of cytoplasmic dynein, while inhibition of kinesins requires concentrations of vanadate in the 100 mM range.

Perform each assay three to four times to obtain statistically significant data. The control mixture should contain 2 μl of appropriate buffer. Figure 13.4.3 shows a titration curve for the effects of different concentrations of vanadate on the accumulation of nuclei at centrosomes.

For some reagents, it is important to incubate the cytosol with the reagent for 30 to 60 min before the assay. This is especially true for proteins expressed in bacteria, which may need to undergo refolding, or other post-translational modification in the extract to be effective (S. Reinsch, unpub. observ.).

To perform depletion experiments

10b. Immunodeplete specific components from HSS cytosol using antibodies bound to beads. Use depleted HSS cytosol for motility cytosol in the assay.

For examples of successful depletion experiments using Xenopus extracts see Merdes et al. (1996); Walczak et al. (1996); or Tournebize et al. (2000).

These experiments are technically more challenging.

SUPPORT PROTOCOL 1

CENTROSOME ISOLATION FROM LYMPHOCYTES

Centrosomes in fibroblastic and lymphoid cells are anchored in the cytoplasm by microtubules and interact with the nucleus in an unknown way. The centrosome-nucleus association is dynamic in vivo but becomes irreversible in vitro if cells are lysed at physiological ionic strength. Most procedures for making nuclei lead to the preparation of nucleus-centrosome complexes that are almost impossible to dissociate. Therefore, in this protocol, the nucleus-centrosome interaction in vivo is first disrupted, then cells are lysed under conditions where centrosomes can be purified away from the nucleus.

Human lymphoid cells in culture are used here because they grow in suspension and have a low cytoplasm/nucleus ratio. Evidence indicates that both the microtubule cytoskeleton and the actin network are involved in centrosome anchoring in the cytoplasm (Euteneuer and Schliwa, 1985; Buendia et al., 1990; Mack and Rattner, 1993). To purify centrosomes, cells are first preincubated with cytochalasin and nocodazole to disrupt connections between centrosomes and nucleus (Bornens et al., 1987). Extremely fast lysis of cells at very low ionic strength in the presence of Triton X-100 leads to chromatin dispersion and release of centrosomes in suspension. The addition of a low concentration of magnesium ions to the lysis buffer leads to partial chromatin stabilization and still allows centrosome release. This reduces contamination of centrosomes by chromatin components. Centrosomes are rapidly sedimenting particles. Their purification is therefore achieved by separation on sucrose gradients.

It takes ~1 week to grow enough cells for the preparation. The preparation itself takes 1 day. One or two people can do the preparation, and a minimum of two people are needed to perform steps 6 to 7, which need to be done very rapidly. It is important to have highly concentrated centrosomes (~2×10^8/ml) for this assay. The yield is typically 30% to 50%, with several fractions containing centrosomes at the optimal concentration.

Materials

KE37 human lymphoblastic cells (ACC46; DSMZ German Collection of Microorganisms and Cell Cultures)
RPMI-10: RPMI 1640 medium with 10% (w/v) FBS
10 mM nocodozole stock solution in DMSO (see recipe)
10 mg/ml cytochalasin D stock solution in DMSO (see recipe)
PBS (see recipe), ice cold
PBS/10 with 8% sucrose (see recipe)
Lysis buffer (see recipe)
4 ml 0.5 M K-PIPES (pH 7.2)/1 mM EDTA (see recipe)
1 mg/ml DNase I (see recipe)
40%, 50%, and 70% sucrose in gradient buffer (see recipe)
Liquid nitrogen
PE buffer (see recipe)
Methanol, −20°C
PBS/0.1% Triton X-100
Monoclonal anti-tubulin antibody (Amersham)
Secondary antibodies
Hoechst
Polyclonal anti-pericentriolar antibody (e.g., γ-tubulin, pericentrin; optional)

250-ml plastic flask
2-liter spinner culture flask
500-ml centrifuge bottles
Clinical centrifuge or equivalent with swinging bucket rotor for 50-ml tubes

Super-speed centrifuge (e.g., Sorvall RC-26 or equivalent)
Large volume rotor (GSA or equivalent)
50-ml capped conical tubes
10-ml plastic pipet
125-µm nylon mesh (Millipore)
Beckman SW28 and SW28.1 centrifuge tubes
Ultracentrifuge
Ultracentrifuge SW28 rotor with SW28 and SW28.1 buckets
18-G needles
Refractometer
Modified Corex tubes (Evans et al., 1985; *UNIT 11.13*)
11- to 12-mm diameter coverslips (acid-washed)
HB-4 or HB-6 rotor
Forceps
Fixing jar with coverslip holder

Additional reagents and equipment for immunofluorescence staining (*UNIT 4.3*) and analyzing centrosomes by spinning onto coverslips (*UNIT 11.13*)

Grow KE37 cells

1. Grow 1 liter of KE37 cells in four 250-ml plastic flasks in RPMI 1640-10.
2. One day before the centrosome preparation, transfer 1-liter cells to a 2-liter spinner culture bottle and add 1 liter RPMI 1640-10.
3. On the day of purification have 2 liters of cells at a density close to 1.5×10^6 cells/ml (3×10^9 cells total).

   It is important that the cells are maintained in exponential phase at densities between 1 and 4×10^6 cells/ml.

4. Add 60 µl of 10 mM nocodazole to a final concentration of 33 µM and 200 µl of 10 mg/ml cytochalasin D to 1 µg/ml final. Incubate 1 hr at 37°C with continuous stirring.
5. Transfer to 500-ml centrifuge bottles and centrifuge for 15 min at 650 × g (2000 rpm in GSA rotor), 4°C.

   During all subsequent centrifugations, do not decant supernatant, but rather aspirate supernatant.

6. Resuspend cells in ice-cold PBS to a maximum total volume of 160 ml.
7. Transfer to four 50-ml capped conical tubes. Centrifuge for 5 min at 500 × *g* (in a clinical centrifuge), 4°C. Repeat PBS wash and centrifugation once.
8. Resuspend cells in ≥25 ml/tube PBS/10 with 8% sucrose. Centrifuge for 5 min at 250 × g (1000 rpm in a clinical centrifuge), 4°C.

   Do this step and step 9 as quickly and gently as possible.

9. Lyse cells in each tube by adding 10 ml of lysis buffer to pellet. Disperse pellet by pipetting up and down with a 10-ml plastic pipet without generating bubbles. Bring volume in each tube up to 20 ml with lysis buffer. Invert 2 to 3 times slowly. Incubate 5 min on ice.

   Cells should not form an aggregate. They should lyse immediately. The maximum total volume for the preparation should not exceed 90 ml at this point.

10. Centrifuge 10 min at 2000 × *g* (3000 rpm in a clinical centrifuge), 4°C.

11. Filter supernatant through 125-µm nylon mesh. Remove a 300-µl sample for counting.

12. To the pooled 90 ml supernatants add 1.8 ml of 0.5 M K-PIPES (pH 7.2)/1 mM EDTA and 90 µl DNase I stock solution.

Purify centrosomes on sucrose gradients

13. Load 30 ml of lysate into three Beckman SW28 ultracentrifuge tubes and using a 10-ml plastic pipet underlay with 5 ml of 50% sucrose in gradient buffer.

14. Ultracentrifuge 20 min at 20,000 × *g* (11,100 rpm in SW28 rotor), 4°C.

15. Aspirate supernatant leaving ~2 ml of lysate above the cushion in each tube.

    To estimate the 2-ml volume above the cushion, prepare a blank tube containing the cushion volume and 2 ml above this volume. Mark tube at the appropriate height to compare with the tubes containing the centrosome samples.

16. Take the 2 ml of remaining supernatant and 2 ml of 50% sucrose cushion. Pool 12-ml total volume from the three step gradients. Keep a 100-µl aliquot for counting.

17. Mix well and layer over a discontinuous sucrose gradient in a SW28.1 ultracentrifuge tube.

    2.0 ml 70% sucrose
    1.5 ml 50% sucrose
    1.5 ml 40% sucrose
    12.0 ml of centriole suspension (~25% sucrose: pooled volume from the three-step gradients).

18. Ultracentrifuge 75 min at 110,000 × *g* (25,000 rpm in SW28.1 rotor), 4°C.

19. Eliminate top of the gradient to the 40% solution. Pierce bottom of tube with an 18-G needle and collect 0.4-ml fractions manually.

Analyze gradient fractions and count centrosomes

20. Read the fractions with a refractometer. Take 5-µl aliquots from fractions between 40% and 70% sucrose to count centrosomes by immunofluorescence. Snap freeze the remaining volume of these fractions in liquid nitrogen without further aliquotting. Store at −70°C. Discard fractions at <40% and >70% sucrose.

21. Prepare one modified Corex tube for each 5-µl aliquot and one each for the samples from steps 11 and 16. Place the removable chuck on top of the bottom spacer. Place a clean 11-mm diameter coverslip on top of the chuck.

22. Mix the 5-µl aliquots each with 5 ml of PE buffer by inverting several times in a 15-ml capped tube. Pipet into the prepared Corex tube. Centrifuge 10 min at 23,600 × g (12,000 rpm in HB4 rotor), 4°C.

23. Carefully remove coverslips from the tube: use a thin spatula with a bent tip to lift the chuck out of the tube, then use forceps to transfer coverslip into cold methanol. Fix coverslips 5 min in methanol at −20°C.

    It is important to remember which side of the coverslip the centrosomes are on; maintain all of the coverslips in the same orientation.

24. Remove coverslips from fix and place in PBS/ 0.1% Triton X-100.

    For a more detailed description of the proecdure in steps 21 through 25, see UNIT 11.13, Support Protcol 4.

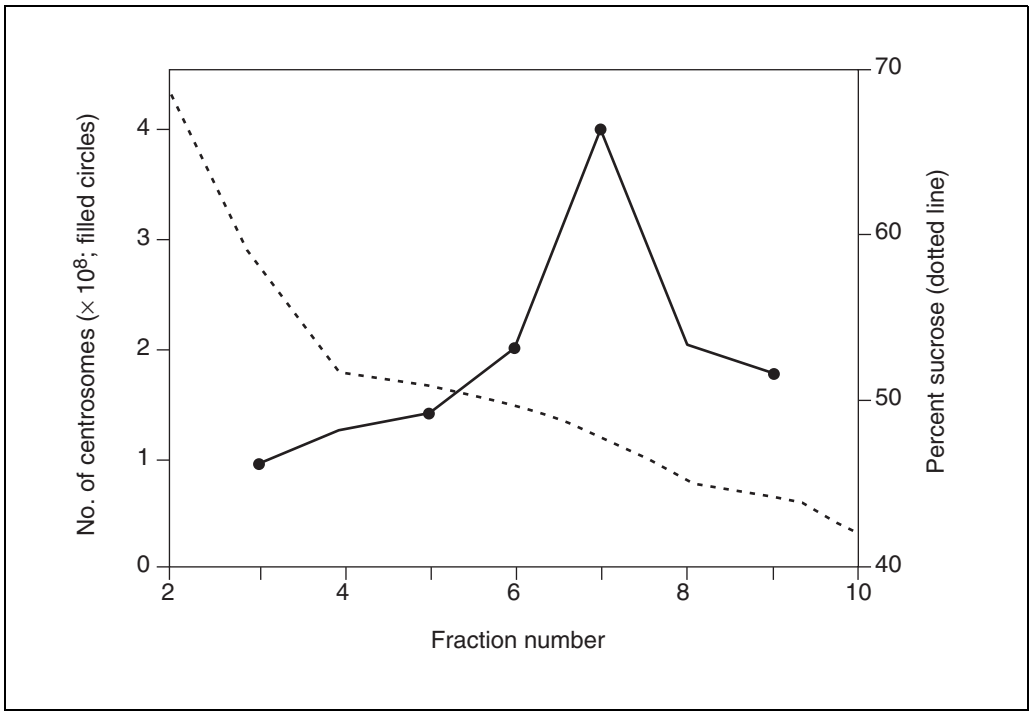

Figure 13.4.4 Fractionation of centrosomes in sucrose step gradient. A typical graph obtained after fractionation of centrosomes on a sucrose step gradient. The sucrose concentration (dotted line) of each fraction was determined using a refractometer, while the centrosome concentration (solid line) was determined as in Support Protocol 1. The peak fractions, containing centrosomes sufficiently concentrated for use in this assay, typically sediment between 45% and 50% sucrose.

25. Perform immunofluorescence using a monoclonal anti-tubulin antibody, followed by appropriate secondary antibodies (*UNIT 4.3*). Add Hoechst to secondary antibodies to check for DNA contamination.

    If possible, also use a polyclonal antibody against pericentriolar material (anti-γ-tubulin). This helps to confirm that the dots are centrosomes. Santa Cruz Biotechnology offers polyclonal anti-γ-tubulin antibody, but it has not been tested in this protocol.

26. Observe samples at a magnification where centrosomes are easily visualized (usually as pairs of dots, with some single dots). Count the total number of centrosomes in several microscope fields to get an average number. Use a stage micrometer to measure the size of the field. Extrapolate to the total cross-sectional area of the Corex tube to get the total number of centrosomes in a particular 5-µl aliquot or from intermediate steps 11 and 16 (see Fig. 13.4.4 for a typical determination of centrosome concentration from a sucrose gradient).

27. Maintain the sucrose gradient fractions of centrosomes frozen at −80°C.

    Centrosomes can be stored this way for ≥1 year. See Support Protocol 2 for subaliquotting the centrosomes and for titration in the motility assay.

TITRATION OF CONCENTRATED CENTROSOMES

SUPPORT PROTOCOL 2

The assay presented in the Basic Protocol requires standardized components so that assays performed on different days can be compared. In particular, the same concentration of centrosomes must be used from one assay to the next as the plating density of centrosomes affects assay results.

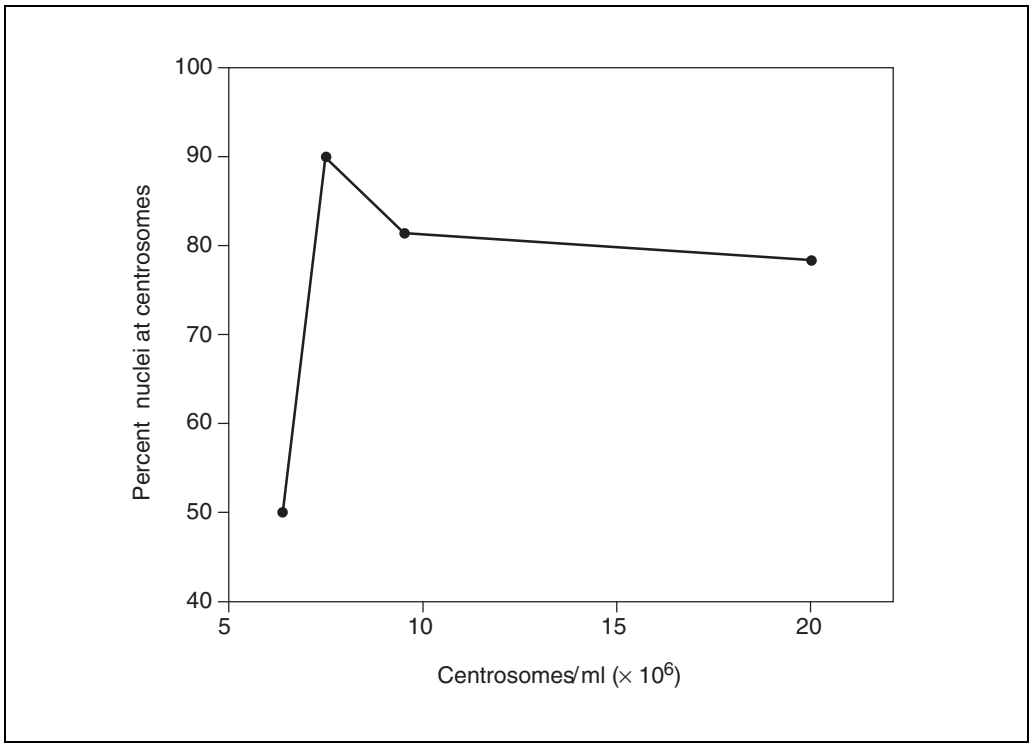

Figure 13.4.5 Titration of centrosomes in motility assay. An assay showing how centrosome concentration affects the accumulation of nuclei at centrosomes. If centrosomes are plated to sparsely, microtubules form spontaneously rather than at centrosomes preferentially, and nuclei will move in a random fashion on these microtubules rather than accumulating at centrosomes. At high centrosome concentrations, elevated concentrations beyond a certain value do not enhance accumulation of nuclei at centrosomes. Steps for titrating centrosomes for this assay are described for Support Protocol 2.

Additional Materials *(also see Basic Protocol)*

Large aliquot of centrosomes (see Support Protocol 1)
Liquid nitrogen
0.5-ml microcentrifuge tubes for aliquotting

Prepare centrosome aliquots

1. Prepare about one hundred 0.5-ml microcentrifuge tubes on ice.
2. Rapidly thaw one large 400- to 500-µl aliquot of centrosomes. Mix the aliquot well by inverting tube several times or pipetting up and down without introducing bubbles. Make 5-µl aliquots. Snap freeze in liquid nitrogen.

   It is important that the large aliquot is well mixed before dividing into smaller aliquots so that the concentration of centrosomes is the same in each tube. Since centrosomes are large particles they will sediment in the tube over time.

Titrate centrosomes

3. Prepare 8 perfusion chambers according to *UNIT 13.1*, Support Protocol 1.
4. Thaw four 5-µl aliquots of centrosomes. Resuspend each in a different volume to bracket the range of final concentrations of 5-20 $\times$ 10^6 centrosomes/ml.
5. Flow each centrosome sample into two perfusion chambers to serve as duplicates.
6. Perform Basic Protocol, steps 2 through 7 on each sample to determine which centrosome concentration yields the highest value for number of nuclei that accumulate at the centrosomes.

A typical plot is shown in Figure 13.4.5.

Empirically, a final concentration in the range of 7.5×10^6 centrosomes/ml gives consistently good values. This corresponds to a plating density of 2 to 3 centrosomes/50 μm^2 microscope field. The optimum value is a result of the competition between free nucleation of microtubules and that nucleated by centrosomes. If there are too few centrosomes, there is a lot of spontaneous nucleation of microtubules that generates random arrays. With too many centrosomes, there is little or no spontaneous microtubule assembly, but microtubules will have a shorter overall length at the 20-min time point.

PREPARING FRACTIONATED INTERPHASE EXTRACTS FOR NUCLEAR ASSEMBLY

SUPPORT PROTOCOL 3

Functional nuclei can be assembled in vitro using *Xenopus* extracts (for review see Newmeyer and Wilson, 1991; Gant and Wilson, 1997; *UNIT 11.10*). Freshly made 16,000 × *g* interphase extracts generally give the best results for nuclear assembly and can be used with the DNA-magnetic beads (stop at step 11). However, extracts that have been fractionated into membraneous and cytosolic components are useful for many types of functional studies and are therefore presented here. The cytosolic and membrane fractions are stored frozen and are recombined with template DNA to assemble chromatin and nuclei. Many published protocols for nuclear assembly use sperm nuclei. These are not appropriate for studies of nuclear motility that mimic movement of the female pronucleus along microtubules. Sperm nuclei have an associated centrosome, and microtubules nucleated from this centrosome will generate motility events in their own right (reviewed in Reinsch and Gonczy, 1998). For motility assays one can use nuclei assembled with magnetic beads coupled with plasmid DNA, or nuclei assembled around larger purified DNA such as lambda DNA. The use of magnetic beads as substrates for nuclear assembly allows rapid and gentle purification of the nuclei.

For handling of frogs and general methodologies for preparing *Xenopus* egg extracts see Murray (1991) and Newmeyer and Wilson (1991); also see *UNIT 11.10*. The following protocol uses eggs that have been collected after overnight stimulation of the frogs with human chorionic gonadotropin (HCG), and is based on a published protocol (Hartl et al., 1994; also see *UNIT 11.10*).

The general principles of this procedure are illustrated in Figure 13.4.6.

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) or must conform to governmental regualtions regarding the care and use of laboratory animals.

Materials

5 to 7 frogs
100 U pregnant mare serum gonadotropin (PMSG; see recipe)
500 U HCG (see recipe)
MMR (see recipe)
Dejellying solution (see recipe)
S-lysis buffer (see recipe)
S-lysis-plus buffer (see recipe)
10 mg/ml cytochalasin D stock solution in DMSO (see recipe)
1 M DTT (see recipe)
Protease inhibitors (LPC; see recipe)
2.5 M sucrose (see recipe)
Glycerol
Liquid nitrogen for freezing aliquots
S-lysis-plus/500 mM sucrose solution (see recipe)

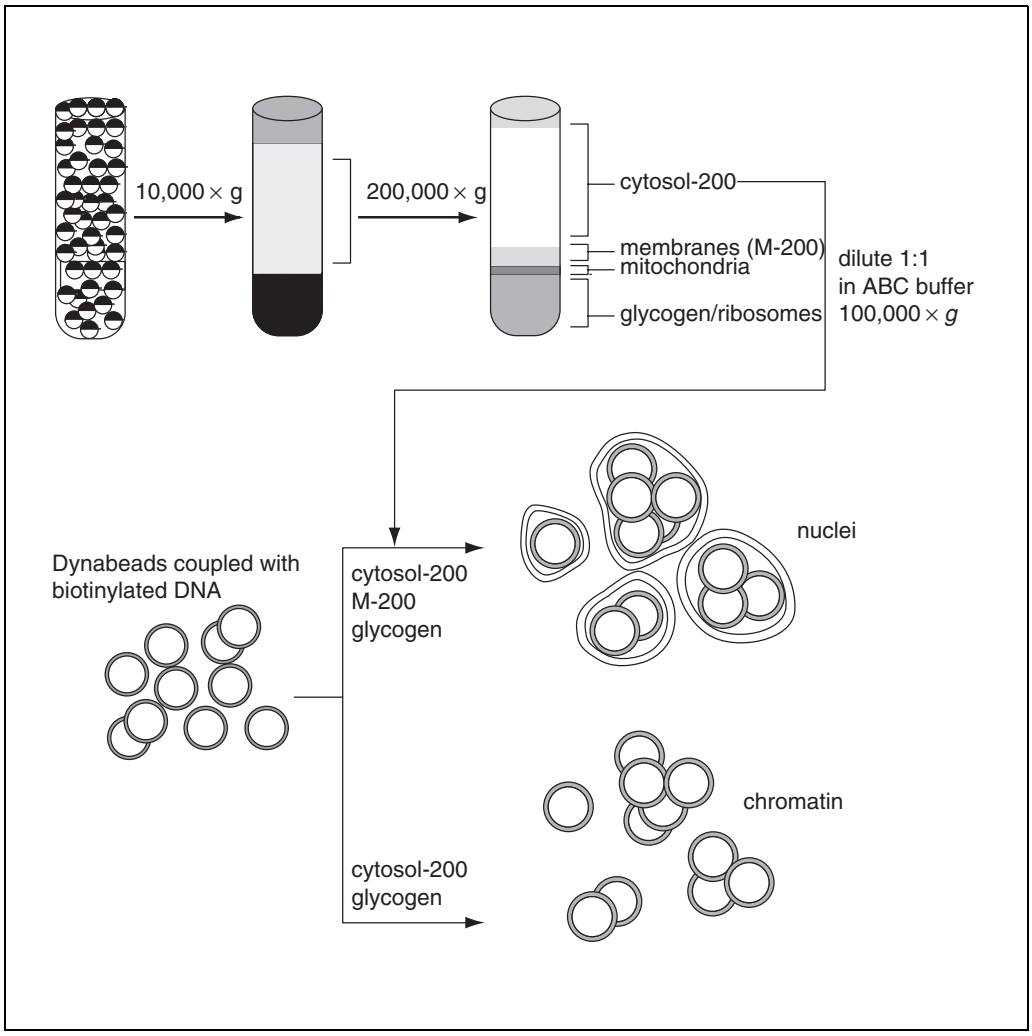

Figure 13.4.6 Nuclear assembly from fractionated extracts. Schematic showing the basic steps required to assemble synthetic nuclei using fractionated extracts. In the protocol presented here, generation of the cytosol-200 and M200 fractions are described in Support Protocol 3. These are frozen separately and then recombined with DNA-coupled Dynabeads as described in Support Protocol 5. Preparation of DNA-coupled Dynabeads is described in *UNIT 11.13* (Heald et al., 1998). If the M200 membranes are omitted during the assembly process, interphase chromatin assembles on the DNA, but full nuclear assembly requires the M200 fraction. Synthetic nuclei often contain multiple Dynabeads which behave very similarly in the assays presented here.

1-ml syringes and 27-G needles
400-ml beakers
SW50 ultraclear centrifuge tubes (Beckman)
Pasteur pipet cut to a wide-mouth bore with a file, fire polished
Sarstedt 13-ml adaptor tubes
2-ml syringe and 18-G needle
Clinical centrifuge
Sorvall RC5 centrifuge
HB-4 rotor with rubber adapters (Sorvall)
5-ml polyproponate tubes with caps
Ultracentrifuge
SW55 rotor
500-ml microcentrifuge tubes for aliquotting cytosol and membranes

NOTE: Make sure that all glassware is clean and rinsed with distilled water before use. Additionally, wet all glassware with buffer before contact with the eggs as they will stick to the glassware and activate or lyse.

Collect the eggs

1. Inject 5 to 7 frogs subcutaneously into the dorsal lymph sac with 0.5 ml of 100 U PMSG, using a 1-ml syringe and 27-G needle. Perform the injection ≥4 days (and ≤10 days) before the extract is to be prepared. Do not feed frogs after PMSG injection.
2. Twelve to 18 hr before use, inject each frog subcutaneously with 0.5 ml of 500 U HCG. Place frogs in individual containers with 500 ml MMR and maintain the frogs overnight at 16°C.
3. Collect eggs into 400-ml beakers using a separate beaker for each frog. Discard batches of eggs containing >5% of lysed, mottled, or stringy eggs.

   Keep batches of eggs separate through dejellying and even through the 16,000 × g centrifugation, if possible. Note that there is no need to activate the eggs to send them into interphase. They will spontaneously enter interphase due to lysis in the presence of Ca^{2+} ions. Cycloheximide added to the buffers will maintain the interphasic state of the extract. Any batches of eggs that lyse during dejellying, loading into tubes, or packing in the low-speed centrifuge should be discarded.

Dejelly the eggs

4. Pour off MMR and add 50 to 100 ml dejellying solution to each beaker. Swirl beaker gently and change the solution several times until the eggs start to pack (usually ~5 min).

   The eggs should be left in dejellying solution for the minimal amount of time required to completely remove the jelly coat. Further incubation seriously compromises egg quality.

5. Rinse three times with 50 to 100 ml MMR. Work quickly through the next steps, until lysis/centrifugation, as the eggs are quite fragile once the jelly coat is removed. Ensure that the eggs are always covered with buffer. Remove bad eggs (white and puffy, or dark pigment retracted or mottled).

Lyse the eggs

6. Pour off as much MMR as possible while keeping eggs immersed in a minimal quantity. Rinse two times with S-lysis buffer in the same manner.
7. Rinse once with S-lysis-plus buffer. Use a wide-bore Pasteur piper to load eggs into SW50 ultraclear centrifuge tubes containing 1 ml S-lysis-plus buffer and 10 µl of 10 mg/ml cytochalasin D stock (to 100 µg/ml final concentration). Fill tubes as full as possible and remove any buffer on top of eggs.

   Always place the tip of the pipet containing the eggs into the buffer in the tube before expelling the eggs. This ensures that the eggs do not contact air which would cause lysis.

8. Place each filled SW50 tube into a Sarstedt 13-ml adapter tube containing ~0.5 ml water in the bottom. Pack eggs by centrifuging 30 sec at low speed, 150 × *g*, room temperature, in a clinical centrifuge, then 30 sec at 700 × *g*. Remove all the buffer above the eggs and discard any tubes with significant lysis.
9. Lyse eggs by centrifuging 15 min at ~16,000 × *g* (10,000 rpm in HB-4 rotor containing rubber adapters), 4°C. Remove tubes from adapters and place upright on ice.

Collect cytoplasm

10. Attach an 18-G needle to a 2-ml syringe. Move syringe plunger back and forth once to loosen before piercing tube. Wipe sides of tube with a tissue and then pierce the tube just above the bottom of the clear cytoplasmic layer. Make sure the opening of the needle faces upwards. Withdraw the clear straw-colored cytoplasm avoiding the yellow lipid layer above and the heavier layers containing yolk, mitochondria, and cortex fragments below. Remove the needle from the syringe and expel the cytosol from the syringe into an appropriate sized polyproponate tube with a cap.

    Bracing the centrifuge tube against the inside of an ice bucket will help avoid accidents during piercing.

    One 5-ml tube of eggs will yield 1 to 2 ml of cytosol.

11. Pool cytosols that look good. Add 1/1000 volume each of cytochalasin D (final 10 µg/ml), DTT (to 1 mM) and protease inhibitors.

12. If there is any contamination of the cytosol, then repeat the 16,000 × g centrifugation to clarify cytosol of any residual yolk or heavy cortex fragments. Remove clear cytosol as above and add 2.5 M sucrose to 125 mM to the cytosol.

    This helps separate the membranes out of the cytosol in the following centrifugation.

Isolate membrane and cytosol fractions

13. Ultracentrifuge cytosol for 60 min at 200,000 × *g* (555,000 rpm in SW55 rotor), 4°C.

    There will be the following fractions from top to bottom: lipid, clear cytosol, golden membranes, grayish mitochondrial membranes, then translucent pellet consisting of glycogen and ribosomes.

14. Carefully aspirate clear lipid layer and discard. Remove the clear cytosol to a separate tube using a 200-µl tip (do not use a 1000-µl tip).

    From a 5-ml tube one should collect ~2.5 ml. It is difficult to remove the clear cytosol without pulling up some of the golden membranes. Go slowly when near the membrane layer.

15. Remove and save golden membrane fractions (they are the nuclear assembly membranes) and follow with them at step 17. Carefully avoid the gray mitochondrial layer.

16. Recentrifuge cytosol 30 min at 200,000 × *g* (55,000 rpm in TLS55 rotor), 4°C, to remove residual membranes and lipid. Remove cytosol as in step 14. To cytosol, add glycerol to a final concentration of 3%. Snap freeze in liquid nitrogen in 50-µl aliquots. Store aliquots at −70°C.

    This cytosol fraction is called cytosol-200.

17. Resuspend the golden membranes in excess S-lysis-plus (≥10 vol) and centrifuge over a 0.5-ml cushion of S-lysis-plus/500 mM sucrose for 20 min at 26,000 × *g* (14,000 rpm in SW55 rotor), 4°C. Resuspend as a 10× stock in S-lysis-plus/500mM sucrose solution and freeze in 10-µl aliquots (10× stock means 1/10th the volume of cytosol).

    This membrane stock is called M-200.

PREPARATION OF HIGH-SPEED SUPERNATANT (HSS)

SUPPORT PROTOCOL 4

The cytosol used for the motility assay is clarified of all membranes by dilution of concentrated 16,000 × *g* cytosol followed by centrifugation. The concentrated cytosol is prepared, dispensed into aliquots, and stored frozen until the day of the experiment, when the dilution and centrifugation steps are performed.

Additional Materials (see Support Protocol 3)

ABC buffer (see recipe)
Table top ultracentrifuge and TLA-100 rotor or Airfuge (Beckman) and rotor

1. Perform Support Protocol 3, steps 1 through 11. However, in step 11 lower the sucrose concentration to 100 mM rather than 125 mM.
2. Pipet the cytosol into 50-µl aliquots and snap freeze in liquid nitrogen. Store aliquots at −80°C until use.
3. On the day of the assay, thaw an aliquot of cytosol and dilute with 2 vol ABC buffer. Centrifuge for 20 min at 100,000 × *g* (15 min, 30 psi in Beckman Airfuge or 550,000 rpm in TLA-100 rotor,), 4°C, to pellet membranes.
4. Pipet the cytosol to a fresh tube and maintain on ice until use (~4 hr max).

NUCLEAR ASSEMBLY USING DNA-COATED MAGNETIC BEADS AS TEMPLATE

SUPPORT PROTOCOL 5

This protocol describes the assembly of nuclei around DNA-coated magnetic beads. The protocol for binding of DNA to the beads is presented in *UNIT 11.13* (Heald et al., 1998). The nuclei can be assembled by simply adding DNA beads to fresh 16,000 × *g* cytosol (see Support Protocol 2, step 11). However, to perform manipulations of the nuclei to test specific components of the nucleus for a role in nuclear motility, use this alternate approach. Each batch of fractionated cytosol has to be titrated for nuclear assembly using DNA-magnetic beads. Given below is a starting protocol. One may have to vary the glycogen, amount of membranes, and/or dilution of cytosol with ABC buffer to get better assembly. Assembly using beads is much trickier than assembly with either sperm nuclei or lambda DNA. The beads must have a high concentration of DNA. Only one end of the DNA should be attached to the beads (i.e., fill in only one end of the DNA with biotinylated nucleotides), and the plasmid cannot be too short. (The MCP plasmid is ~8 kb and assembles nuclei much better than a 6-kb plasmid. Much shorter plasmids do not assemble at all.) Once the parameters for assembly with the extract preparation has been optimized, then scale up to make a nuclear prep for dispensing aliquots and freezing.

Materials

Cytosol-200 (see Support Protocol 2)
ABC buffer (see recipe)
DNA-Dynabeads (for preparation see *UNIT 11.13*, Heald et al., 1998)
PBS/1% (w/v) BSA (see recipe)
150 mg/ml glycogen stock (see recipe)
M-200 (see Support Protocol 2)
50 mM Mg-ATP (see recipe)
0.5 M creatine phosphate (see recipe)
8 mg/ml creatine kinase (see recipe)
1.4 mg/ml TRITC-BSA-NLS (transport substrate; *UNIT 11.7*, Support Protocol 2)
Fix solution (see recipe)

Beckman table top ultracentrifuge and TL100 rotor (or Beckman airfuge and rotor)
Magnetic particle concentrator

Microscope slides and clean coverslips
Nail polish
Microscope equipped with epifluorescence optics

1. Thaw one 50-µl aliquot of cytosol-200.
2. Add 50 µl ABC buffer and centrifuge for 30 min at 100,000 × *g* (55,000 rpm inTL100 rotor or 15 min, 30 psi in airfuge), 4°C.
3. During spin, prepare DNA beads. Use 10 µl beads (70 µg/ml) for a 100-µl reaction. Resuspend the DNA-bead stock well before pipetting. Pipet 10 µl beads to a clean tube. Add 200 µl PBS/1% BSA and pipet beads up and down several times. Retrieve beads on the magnetic particle concentrator, carefully remove the buffer and repeat washing step.
4. Resuspend washed beads in the diluted and centrifuged ceptosol (step 2, ~100 µl). Pipet thoroughly but carefully to disrupt any aggregates. Do not introduce air bubbles into the cytosol.

   Failure to disrupt aggregates results in large masses of beads that do not properly assemble into nuclei.

5. Add and mix by pipetting:

   10 µl 150 mg/ml glycogen
   10 µl membranes (M-200)
   2 µl 50 mM Mg-ATP
   2 µl 0.5 M creatine phosphate
   1 µl 8 mg/ml creatine kinase.

   Incubate 2 to 3 hr at 20°C.

   Fully formed nuclei are first apparent at 40 min and increase progressively until 3 hr.

6. To assay for functional nuclei, remove a 10-µl aliquot and add 0.5 µl of 1.4 mg/ml TRITC-BSA-NLS. Incubate 30 min at 4°C. Pipet 2 µl of this reaction onto a clean slide. Add 5 µl of fix solution and apply a clean coverslip. Seal the edges with nail polish if retention of the sample is desired. Observe nuclei with a microscope equipped with epifluorescence optics to detect nuclei that have accumulated the transport substrate (see Fig. 13.4.7 for images of nuclear uptake).

   Since Dynabeads are autofluorescent with emissions in the red wavelengths, a nuclear uptake substrate that will emit in the green wavelengths is often preferable, such as GFP or fluorescein-labeled. If desired, prepare FITC-BSA-NLS as in UNIT 11.7, Support Protocol 2, by substituting fluorescein-5-EX succinimidyl ester (Molecular Probes) for TRITC in steps 2 to 6 of the protocol. Follow manufacturer's recommendations for coupling buffer and pH conditions. The rest of the protocol remains the same. Alternatively, prepare GFP-GST-NLS (UNIT 11.7, Support Protocol 3). Use both as indicated here for TRITC-BSA-NLS.

7. When functional nuclei are observed, then scale up the reaction 10- to 20-fold and repeat all steps including the assay step. To freeze, add glycerol to 10% (v/v), dispense 10-µl aliquots, and freeze in liquid nitrogen. Store at −70°C.

   Nuclei can be stored for several years in this state. Frozen nuclei can be thawed on ice and washed in ABC buffer, retrieved on a magnet for several minutes (on ice) and resuspended in cytosol, or other buffers. Typically, they retain ~90% activity or higher after freezing. One 10-µl aliquot of nuclei is used for each motility assay.

   If the membranes are omitted from the reaction, interphase chromatin assembles onto the DNA, but no nuclear envelope forms. The motility of the chromatin can be compared with that of bona fide nuclei (Reinsch and Karsenti, 1997).

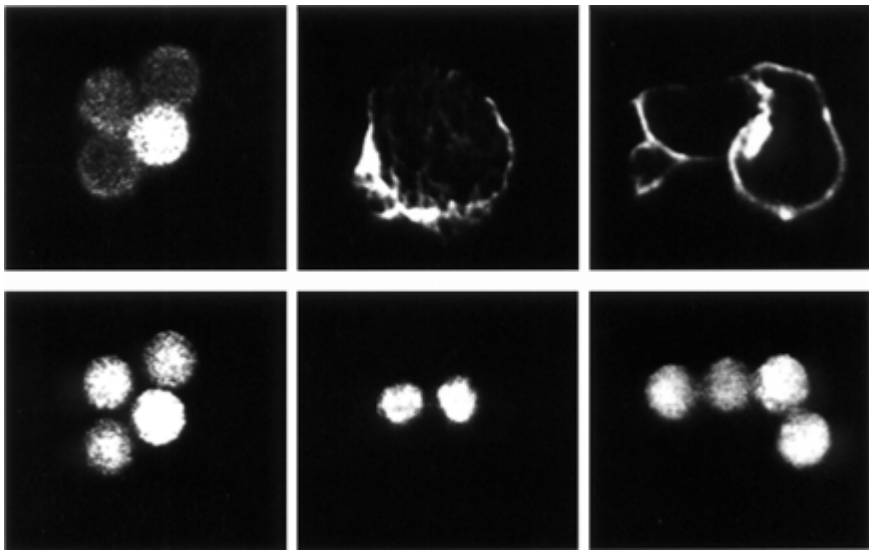

Figure 13.4.7 Nuclei assembled around magnetic DNA-beads are functional for nuclear transport and contain nuclear antigens. Confocal fluorescence images of synthetic nuclei assembled using the protocols described here. Autofluorescence of the beads is shown below (rhodamine filter), while the upper panels show the same beads in the fluorescein channel. FITC-BSA-NLS: typical fluorescence following uptake of the nuclear transport substrate FITC-BSA NLS in an unfixed sample. Staining for lamins and nuclear pores gives the typical peripheral staining pattern for these antigens.

REAGENTS AND SOLUTIONS

*Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see **APPENDIX 2A**; for suppliers, see **SUPPLIERS APPENDIX**.*

ABC (complete acetate buffer)

Acetate buffer (see recipe) supplemented with:
7.5 mM creatine phosphate (see recipe for 0.5 M)
1 mM MgATP
80 µg/ml creatine kinase (see recipe for 8 mg/ml)
10 mg/ml protease inhibitors
Store as 1- to 2-ml aliquots 1 year at −20°C
Thaw once and discard

Acetate buffer

To prepare 1 liter:
9.8 g potassium-acetate (100 mM final)
0.64 g magnesium-acetate (3 mM final)
1.9 g EGTA (5 mM final)
2.38 g HEPES (10 mM final, pH 7.4)
51.34 g sucrose (150 mM final)
H_2O to 950 ml
Adjust the pH to 7.4
H_2O to 1 liter
Aliquot in 50-ml tubes
Store 1 year at −20°C

Casein in PE

100 mg casein
Add 20 ml PE (see recipe)
Vortex vigorously
Incubate at 37°C with intermittent vortexing to aid solubilization of casein
Aliquot and store 1 year at −20°C

Creatine kinase, 8 mg/ml

8 mg creatine kinase
Add 475 µl distilled water
Add 20 µl 1 M HEPES-KOH, pH 7.5
Add 5 µl 1 M DTT
Add 500 µl glycerol
Snap freeze in 10-µl aliquots in liquid nitrogen
Store 1 year at −70°C

Creatine phosphate, 0.5 M

127.55 mg creatine phosphate
1 ml H_2O
Store 1 year at −20°C in 50-µl aliquots

This solution can be thawed and refrozen

Cytochalasin D, 10 mg/ml

10 mg of cytochalasin
1 ml DMSO
Store 1 year at −20°C in 50-µl aliquots

Dejellying solution (2% L-cysteine, pH 7.8)

20 g cysteine
H_2O to 970 ml
Adjust pH to 7.8 with 6 M NaOH
Prepare fresh just before use

DNaseI, 1 mg/ml

10 mg DNase I
10 ml H_2O
Store 1 week at 4°C

DTT, 1 M

0.77 g of DTT
5 ml H_2O
Keep on ice. Dissolve the DTT precipitate by moderate heating just before use.
Prepare fresh.

Fix solution

600 µl 80% glycerol
300 µl 37% formaldehyde
100 µl 10× MMR (see recipe)
0.5 µl 10 mg/ml Hoechst dye
Always prepare fresh on day of use

Glycogen, 150 mg/ml

750 mg glycogen
Dissolve in 5 ml acetate buffer (see recipe)
Aliquot and store 1 year at −20°C

Aliquots can be repeatedly thawed and refrozen

Gradient buffer

3.02 g PIPES (10 mM final)
H_2O to 950 ml
Add:
2 ml 0.5 M EDTA stock solution (1 mM final)
1 ml pure 2-β-mercaptoethanol (1% final)
10 ml of 10% Triton X-100 stock solution (0.1% final)
Bring to pH 7.2 with KOH
H_2O to 1 liter
Use immediately to prepare sucrose gradient solutions
Store remainder 1 year at −20°C

HCG, 500 U/ml

10,000 U human chorionic gonadotropin (Sigma)
Add 10 ml sterile distilled water
Keep sterile
Store at 4°C
Use within 10 days

HEPES/KOH, pH 7.5 (1 M)

59.6 g HEPES
200 ml H_2O
Adjust pH to 7.5 with concentrated KOH
H_2O to 250 ml
Filter sterilize
Store 1 year at −20°C in 5-ml aliquots

K-PIPES, pH 7.2, 0.5 M, 1 mM EDTA

7.55 g PIPES
40-ml H_2O
Add 0.1 ml 0.5 M EDTA stock solution
Bring pH to 7.2 with KOH
H_2O to 50 ml
Store 1 year at −20°C in 2-ml aliquots

Lysis buffer

0.5 ml Tris·HCl, pH 8.0, 1 M stock (*APPENDIX 2A*; 1 mM final)
490 ml H_2O
0.5 ml pure β-mercaptoethanol (0.1% v/v final)
2.5 ml pure NP-40 (0.5% v/v final)
51 µl 4.9 M $MgCl_2$ (Sigma; 0.5 mM final)
87.1 g PMSF
0.5 ml 10 mg/ml stock aprotinin
50 µl 10 mg/ml stock leupeptin
50 µl 10 mg/ml stock pepstatin
H_2O to 500 ml

This buffer can be freshly prepared or stored in aliquots at −20°C.

NOTE: *NP40 is chemically identical to IGEPAL CA-630 (Sigma).*

Mg-ATP, 50 mM

0.275 mg ATP
9 ml H_2O
0.1 g $MgCl_2$
Adjust pH to 7.5 with NaOH
H_2O to 10 ml
Store 1 year at −20°C as 500-µl aliquots

MMR, 10×

58.4 g NaCl (100 mM final)
1.49 g KCl (20 mM final)
2.04 ml of 4.9 M $MgCl_2$ stock solution (Sigma) (10 mM final)
2.94 g $CaCl_2$ (20 mM final)
372 mg EDTA (0.1 mM final)
11.9 g HEPES (50 mM final, pH 7.8)
900 ml H_2O
Adjust pH to 7.8 with 6 M NaOH
H_2O to 1 liter
Autoclave and store 6 months at room temperature

For MMR, dilute 10× stock 1:10 with water.

Nocodazole, 10 mM

To prepare 1 ml:
3 mg nocodazole
1 ml DMSO
Store 1 year at −20°C in 50-µl aliquots

PBS, 10×

14.2 g Na_2HPO_4 dissolved in 500 ml H_2O
2.67 g NaH_2PO_4 dissolved in 100 ml H_2O
Mix the 2 solutions
Add 90 g NaCl
H_2O to 1 liter
Check that solution is at pH 7.4
Store 1 year at −20°C

For PBS: Dilute 10× PBS 1:10 with water.

PBS/10 with 8% sucrose

10 ml 10× PBS (see recipe) diluted to 1 liter with H_2O (PBS/10)
80 g sucrose
Bring weight to 1 kg with PBS/10
Store 1 year at −20°C

PBS/1% (v/v) BSA

Weigh 500 mg BSA
Dissolve in 50 ml PBS (see recipe)
Filter and store 1 week at 4°C or aliquot and store 1 year at −20°C

PE buffer

To prepare 500 ml:
1.51 g K-PIPES (10 mM final; see recipe)
480 ml H_2O
Add 1 ml 0.5 M EDTA stock solution (final 1 mM)
Bring to pH 7.2 with KOH
H_2O to 500 ml
Filter
Store 3 months at 4°C

PMSG, 200 U/ml

Add 5 ml sterile water to vial containing 1000 U pregnant mare serum gonadotropin
Store 2 weeks at 4°C

Protease inhibitor stock (LPC, 10 mg/ml)

10 mg each of leupeptin, pepstatin, and chymostatin
Dissolve in 1 ml DMSO
Store 1 year at −20°C in 50-µl aliquots

S-lysis buffer

50 ml 2.5 M sucrose (250 mM final)
255 µl 4.9 M $MgCl_2$ (Sigma; 2.5 mM final)
12.5 ml 2M KCl (50 mM final)
5 ml 1 M HEPES-KOH, pH 7.5 (10 mM final)
H_2O to 500 ml
Adjust pH to 7.5 with KOH
Prepare fresh

S-lysis-plus buffer

150 ml S-lysis buffer (see recipe)
150 µl protease inhibitor stock (LPC; see recipe)
150 µl 1 M DTT (see recipe)
15 mg cycloheximide (final 100 µg/ml)
Stir until dissolved and store on ice until use

Wear gloves when handling cycloheximide.

S-lysis-plus/500 mM sucrose

3.4 g sucrose
S-lysis buffer (see recipe) to 20 ml
Incubate 37°C with intermittent vortexing until dissolved
20 µl protease inhibitor stock (LPC; see recipe)
20 µl 1 M DTT (see recipe)
20 mg cycloheximide
Store on ice until use

Wear gloves when handling cycloheximide.

Sucrose, 2.5 M (85% w/v)

85 g sucrose
Adjust to a total volume of 100 ml with H_2O
Allow overnight for dissolving (at 60°C)
Filter
Store 6 months at 4°C

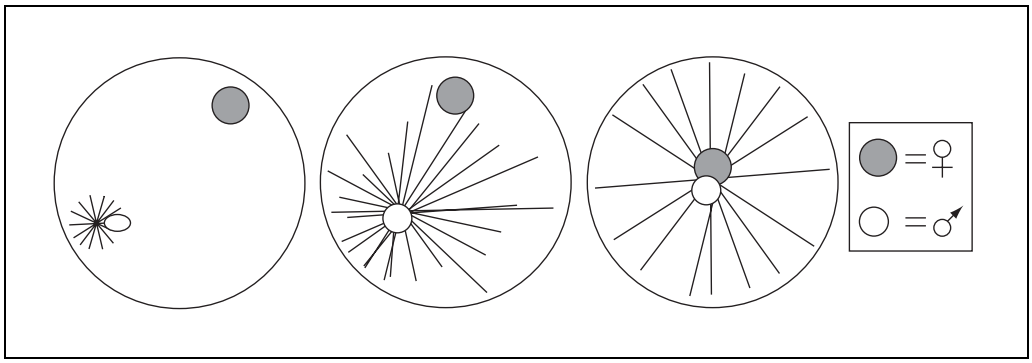

Figure 13.4.8 Movements of the male and female pronuclei in newly fertilized eggs. Schematic showing the microtubule-mediated positioning events of the male and female pronuclei in a typical metazoan early embryo. See text for details. Microtubules are represented by lines, and the male and female pronuclei by open and shaded circles respectively.

Sucrose in gradient buffer, 40% (w/w)

40 g sucrose
Gradient buffer (see recipe) to 100 g
Prepare fresh or store 6 months at −20°C

Sucrose in gradient buffer, 50% (w/w)

50 g sucrose
Gradient buffer (see recipe) to 100 g
Prepare fresh or store 6 months at −20°C

Sucrose in gradient buffer, 70% (w/w)

70 g sucrose
Gradient buffer (see recipe) to 100 g
Prepare fresh or store 6 months at −20°C

COMMENTARY

Background Information

The microtubule cytoskeleton plays a crucial role in positioning of the nucleus (reviewed in Reinsch and Gonczy, 1998). Nuclear migration processes occur in numerous cell types such as muscle, nerve, and somatic dividing cells. In newly fertilized eggs, long-range microtubule-dependent movements of the male and female pronuclei are essential for the two nuclei to meet and form the zygotic nucleus (Schatten, 1994).

During oogenesis in metazoan organisms, including *Xenopus*, the centrosome of the egg degenerates (Schatten, 1994). At fertilization, the basal body of the sperm flagellum converts to the centrosome by recruiting pericentriolar material from the egg cytosol, and nucleates a large microtubule aster. The male pronucleus (Fig. 13.4.8, open circle) remains at the center of the aster, which grows to fill the egg, thus transporting the male pronucleus to the center of the egg. The female pronucleus (Fig. 13.4.8, shaded circle) has no associated centrosome or microtubule-nucleating activity. Instead, the female pronucleus translocates along the microtubules of the sperm aster from the cell cortex to the centrosome located in the center of the aster. Thus, the two nuclei meet at the center of the aster prior to the first cleavage. Pronuclei of some species traverse hundreds of microns in a fraction of the first cell cycle (Stewart-Savage and Grey, 1982). The motility of the two nuclei differs in that the female pronucleus translocates along microtubules towards the microtubule minus-end while the movement of the entire sperm aster drives the movement of the male pronucleus.

The assay presented here recapitulates the movement of the female pronucleus in vivo and is the first system to demonstrate the translocation of nuclei along microtubules in vitro. Using this extract-based assay, it has been determined that cytoplasmic dynein is required for nuclear movements along microtubules (Reinsch and Karsenti, 1997). This system can be further used to determine how cytoplasmic

dynein is targeted to the nuclear membrane to mediate the organelle-like movement along microtubules.

Until the development of this assay, microtubule-dependent nuclear motility had only been studied in vivo because of the complexity of the process. Perturbation studies in vivo have used pharmacological agents to demonstrate the role of the microtubule cytoskeleton in pronuclear movement (Aronson, 1971; Schatten, 1982; Rouviere et al., 1994). Genetic studies in *C. elegans* have only very recently begun to address this process (Gonczy et al., 1999b). Recent experiments using RNA-mediated inhibition of expression in *C. elegans* embryos have confirmed the role of dynein and associated proteins in pronuclear migration (Gonczy et al., 1999a). These genetic experiments, thus, validate the biochemical approach presented here to demonstrate that dynein is required for the motility of synthetic nuclei along microtubules (Reinsch and Karsenti, 1997), and indicate that this approach is a valid means to identify candidate molecules involved in complex processes in the early embryo.

There were two important constraints on the choice of nuclei for the motility assay. First, it is important to use nuclei lacking an associated centrosome to resemble the female pronucleus. Nuclei purified from many tissues and from cells in culture generally have an associated centrosome whose activity could potentially generate motility events resembling those of the male rather than the female pronucleus (Reinsch and Gonczy, 1998). Second, it is important to choose a source of nuclei that would be competent for motility. Nuclei from many tissue sources may not be functional for motility if nuclear migration events are not occurring in the selected tissue at the time of purification.

Interphase *Xenopus* egg extracts spontaneously assemble nuclei from soluble and membrane components stored in the egg (Forbes et al., 1983; Newport, 1987; Newmeyer and Wilson, 1991). Upon the addition of DNA or chromatin to a lysed extract, nuclei containing double nuclear membranes, a nuclear lamina, and nuclear pores are quickly assembled (*UNIT 11.10*). These nuclei are capable of nuclear import, DNA replication, and normal mitotic disassembly. The most commonly used and convenient substrate for nuclear assembly studies is demembranated sperm nuclei. However, the sperm has an associated basal body that converts into a centrosome in the egg (or extract). Sperm nuclei are therefore not appropriate substrates for this assay. Recently, magnetic beads coupled to plasmid DNA have been demonstrated to function as artificial chromosomes capable of inducing nuclear assembly in interphase extracts and bipolar spindles in mitotic extracts (Heald et al., 1996; Reinsch and Karsenti, 1997; *UNIT 11.13*). Since DNA beads are paramagnetic, they can be simply retrieved from the extract. Centrosomes do not spontaneously assemble in these extracts and eggs contain no centrosomes. Therefore, the nuclei assembled around magnetic beads in this extract lack an associated centrosome. These synthetic nuclei provide a novel approach to studying nuclear motility since they allow rapid and gentle isolation of large numbers of nuclei in a motility competent state.

An alternative to magnetic bead nuclei, is to use DNA purified from phage lambda as a substrate for nuclear assembly. The DNA is simply added to a $16{,}000 \times g$ fresh extract and allowed to assemble (see Support Protocol 3, steps 1 through 11). However, the nuclei must then be purified over sucrose gradients (S. Reinsch, unpub. observ.). The advantage of the lambda DNA–nuclei is that they are much smaller than the DNA-bead nuclei used here and more suitable for certain analyses such as electron microscopy.

The benefits of using this extract-based assay system are numerous. This is an ideal system for the identification of the molecular components involved in nuclear motility as it is amenable to biochemical dissection of both nuclear and cytoplasmic components and allows high-resolution microscopic observation of nuclear motility.

This assay allows pronuclear migration to be studied in isolation of other simultaneous or upstream processes. Both microtubules and cytoplasmic dynein function in numerous processes that occur both prior to and after fertilization. By using this assay, the molecular components that are specific to this process as well as those which are shared with other processes can be identified. The ease of biochemical manipulation of these extracts allows experiments that are impossible in intact cells or organisms.

Nuclear motility can be observed using much cruder preparations from *Xenopus* eggs than those described here (S. Reinsch, unpub. observ.; Murray et al., 1996). However, this assay provides a means to define the minimal essential components required for nuclear motility along microtubules.

Critical Parameters and Troubleshooting

The system presented here uses largely homologous components. Only the centrosomes are purified from humans rather than frog. In theory, purified centrosomes from any source can be used. The use of homologous cytosol and nuclei is critical. Cytosol from other sources (e.g., bovine brain, HeLa cells, rat liver) does not support the movement of nuclei assembled *Xenopus* egg extracts (S. Reinsch, unpub. observ.). The use of heterologous nuclei has not been rigorously tested to determine whether heterologous nuclei will move on microtubules in *Xenopus* egg extracts. However, nuclei purified from other sources may undergo "repair" when incubated in *Xenopus* egg extracts and acquire components from the cytosol (Leno and Munshi, 1994) that may enable them to use the *Xenopus* cytosolic machinery for motility. It is conceivable then, that they will demonstrate motility events in this system. However, it is important to realize that nuclei purified from tissues or cultured cells may have associated centrosomes. Microtubules nucleated from these associated centrosomes may generate motility events in their own right that are independent of the translocation of nuclei along microtubules (reviewed in Reinsch and Gonczy, 1998).

As stated previously, nuclear motility per se can be visualized using less purified extract-based components. Freshly prepared low-speed (10,000 × *g*) extracts support both nuclear assembly and motility. Visualization of nuclear motility in this simpler system is a bit more challenging and requires the use of fluorescent components to label microtubules and nuclei. The assay presented here has been developed to allow for biochemical manipulations of both the cytosol and the nuclei to dissect the motility apparatus while simultaneously allowing visualization of motility events. It has also been optimized so that only frozen aliquotted components are used. This allows reproducibility from one assay to the next so that the effects of drugs or other added components can be determined.

For the motility assay, each component can present specific difficulties as outlined below. Once the assay has been optimized and is working well, then it is quite reproducible. To minimize difficulties, prepare larger stocks with aliquots that are the appropriate size for individual experiments. Never refreeze aliquots. Prepare a new stock (centrosomes, nuclei, HSS) well before the last aliquots are used. Try to switch out only one component at a time. Test the new batch of the component alongside the old batch to ensure that it functions properly.

Careful biochemical preparation of the individual components of the Basic Protocol is absolutely critical for the success of the quantitative motility assay. Several steps are critical in preparing extracts of *Xenopus* eggs. Please read the general references for handling *Xenopus* and extract preparation (Murray, 1991; Newmeyer and Wilson, 1991; *UNIT 11.10*). It is also worthwhile to understand the scientific literature on using *Xenopus* extracts for nuclear assembly (for review see Lohka, 1998 and *UNIT 11.10*). Eggs for preparation of nuclear assembly extracts and for HSS must be of top quality. Carefully read each support protocol and have all materials on hand before starting the preparations. Do not let the preparations sit on ice for long periods. Proceed immediately through the steps to the finished frozen product.

One of the most critical parameters in preparing fractionated extracts for nuclear assembly is to avoid contaminating the nuclear membranes with mitochondria. The mitochondria contribute to apoptotic events (Newmeyer et al., 1994; *UNIT 11.12*). The mitochondrial layer appears as grayish as opposed to the nuclear membranes, which have a golden tint. During the 200,000 × *g* centrifugation, sometimes the membranes do not band optimally and multiple bands are visible. Recentrifuge for a longer time to allow better separation. Too low a sucrose concentration in the extract can also contribute to this. The prep can be done on a smaller scale using a TLS-55 rotor instead of an SW-55 rotor.

For nuclear assembly using magnetic beads, the quality of DNA-beads is very important. Be sure to precisely follow the instructions in *UNIT 11.13* for bead preparation. By Hoechst staining, the DNA should make a uniform bright rim around the bead. There should not be a punctate pattern around the bead. Make sure to use long DNA fragments. An 8-kb fragment works very well. Shorter fragments do not assemble well into nuclei. The DNA must be filled in with biotin at only one end so that only one end attaches to the bead. This assures good chromatin assembly on the DNA bead. DNA-beads can be stored for months at 4°C. Do not freeze.

When assembling the bead-nuclei from fractionated extracts make sure that DNA-beads are well suspended in extract so that they don't clump too much. Otherwise all the nuclei will contain many beads. An average of 1 to 3 beads per nucleus is optimal for the motility assay. Glycogen is essential for assembly of

chromatin onto naked DNA (Hartl et al., 1994). The source of the glycogen is not important. Commercial oyster glycogen works quite well. The length of time for the nuclear assembly reaction is not critical and can be from 1 to 3 hr. The longer the nuclei are left in the assembly reaction, the larger they tend to get. They do not acquire more beads, but they will import proteins from the extract and become more swollen. This is not really a problem and often is helpful for visualizing uptake of the transport substrate TRITC-BSA-NLS. When performing the transport reaction, one should be able to clearly see uptake of nuclear transport substrate into 90% to 95% of nuclei. After assembly, nuclei can be stored overnight at 4°C without loss of function. Longer storage at this temperature is not advised. If one encounters difficulties in assembling nuclei from fractionated components, then try a different substrate, such as sperm nuclei (see *UNIT 11.13* for preparation) or lambda DNA to be convinced that the problem is not the DNA-bead substrate.

The centrosome preparation presented here has been optimized for high yield and high concentration of centrosomes. It is a variation of a published method (Moudjou and Bornens, 1998). Other preparations of centrosomes have not been tested for use in this assay, but would be interesting to compare (e.g., Blomberg-Wirschell and Doxsey, 1998). In theory, any centrosome preparation should be acceptable for use in this assay as long as robust microtubule asters are generated upon addition of HSS. For this particular preparation, it is essential that the lymphocytes be grown in exponential phase. The treatments with the cytoskeletal inhibitors, nocodozole and cytochalasin, separate the centrosome from the nuclear membrane so that centrosome and nucleus do not copurify. The incubation time for this treatment allows depolymerization of microtubules and actin filaments without causing cells to accumulate in mitosis. The washes with high osmotic strength buffers cause the cells to be very fragile. These steps should be done as rapidly as possible to minimize cell lysis. However, do not pipet so vigorously that bubbles are produced. The centrifugation steps are straightforward and can be adapted for other rotors and volumes. Do not leave the centrosomes unfrozen for long periods. Freeze the large aliquots as quickly as possible. Thaw only once to re-aliquot and freeze again. The size for the small aliquots should be dictated by experiment design. Do not refreeze the small aliquots.

Preparations of HSS can vary in activity largely due to egg quality. Cycloheximide is added to ensure that the extract stays in interphase. It is important to add sucrose as a cryoprotectant to the 16,000 × *g* extract before freezing. The prep is frozen as a 16,000 × *g* extract for several reasons. First, this takes up less freezer space, and the subsequent dilution and centrifugation steps to be done on the day of preparation are very reproducible. Second, preps that were carried through the subsequent dilution and centrifugation and then frozen as aliquots did not function as well in the motility assay. On the day of the motility assay, the dilution before high-speed centrifugation ensures that all of the membranes are sedimented. This allows optimal DIC imaging of nuclei without extraneous membranes. The dilution recommended here has been optimized for microtubule aster assembly. Too low a dilution causes a lot of spontaneous microtubule assembly. Sometimes asters generated in HSS become fragmented before the 20-min time point. Throw these batches of cytosol away since they will consistently give the same result, and prepare a new batch of 16,000 × *g* extract. These poor-quality batches often also show high apoptotic activity. Try keeping egg batches from different frogs separate all the way through the preparation if poor quality cytosol is a problem.

The quantitative assay for nuclear motility requires nuclei to accumulate at centrosomes. Therefore, robust aster morphology with nice spacing between the asters is crucial. Human lymphocytes assemble asters with only a few microtubules in the presence of pure tubulin. Incubating centrosomes in HSS allows pericentriolar material to be recruited to the centrosomes. After incubation in *Xenopus* egg extract, their nucleation capacity increases significantly (Buendia et al., 1992) so that robust microtubule asters are generated. Plating density of the centrosomes can affect the outcome of the assay. Steps for optimizing this parameter are outlined in Support Protocol 3. The asters should be spaced so that there are not more than 1 to 3 centrosomes/50-μm field. This allows nuclei to reach centrosomes so that quantitation is possible. If asters are too widely spaced, then there will be a lot of free microtubule nucleation and random movement of the nuclei rather than nuclei moving to and accumulating at centrosomes. Make sure the incubation to allow centrosomes to attach to the glass coverslip is consistently 5 min. Several blocking agents have been tested; casein gives satisfactory re-

sults to prevent nuclei from sticking. The casein also inhibits dynein present in HSS from binding to the coverslip. This decreases the amount of microtubule gliding that occurs.

If robust, well-spaced asters are not obtained, the problems can either be in the density of the centrosomes or more likely in the preparation of HSS as described above. Adding agents such as drugs and antibodies can also seriously affect the ability of asters to be nucleated and should only be added after the nucleation step. For example, addition of agents that inhibit dynein activity cause random microtubules to assemble, rather than preferential assembly off centrosomes (S. Reinsch, unpub. observ.). If one does not plan to use the motility assay as a quantitative assay, but only for visualizing nuclear movements without perturbing agents, then the nucleation step can be completely omitted. Many agents also compromise microtubule assembly. For example, BAPTA, a calcium chelator, completely inhibits microtubule assembly in this assay (S. Reinsch, unpub. observ.). Since the microtubules are dynamic in this assay, any factor that affects microtubule dynamics may compromise the success of the assay.

Anticipated Results

The nuclear motility assay allows clear documentation of nuclear motility events. When bead-nuclei are purified on the magnet, they do come with a considerable amount of associated endoplasmic reticulum (ER). Therefore, both nuclear movements and ER tubule elongation will be visible. In HSS, the nuclei move exclusively towards the minus-ends of the microtubules, that is, towards the centrosome. The average rate of movement of nuclei assembled in *Xenopus* extracts is 1 μm/sec with a range from 0.2 to 1.8 μm/sec. Neither DNA-beads (unassembled) nor chromatin-beads (assembled in cytosol without adding membranes) will move to the microtubule minus-ends. In the presence of inhibitors of dynein (e.g., >15 μM vanadate) minus-end directed movements are blocked. The nuclei then are moved to the aster periphery due to the action of growing microtubules. This is not plus-end directed movement. Instead nuclei appear to be pulled out by growing microtubules due to ER tubule attachment to the tips of growing microtubules (Waterman-Storer et al., 1995; Reinsch and Karsenti, 1997).

For the quantitative assay, 90% to 95% of the nuclei should accumulate at centrosomes by the 20-min time point under control conditions. One should be able to easily count between 50 and 100 nuclei in the 10-min counting interval. Dynein inhibitors significantly inhibit accumulation at centrosomes (see Fig. 13.4.3; Reinsch and Karsenti, 1997). An antibody against the intermediate chain of cytoplasmic dynein (mAb 70.1, Sigma) also inhibits nuclear motility and accumulation of nuclei at centrosomes when directly added to HSS (Reinsch and Karsenti, 1997). Not all antibodies against cytoplasmic dynein successfully inhibit nuclear motility (S. Reinsch, unpub. observ.).

Each assay should be performed at least three times to generate statistically significant data. Once a control reaction has been performed on a given batch of centrosomes/nuclei/HSS, the control reaction should be consistent from day to day and should always give 90% to 95% accumulation. This includes adding buffer to account for added experimental agents. Therefore, on a given experimental day, the control reaction can be performed once or possibly twice, to confirm that the system looks the same as on the previous experimental day, rather than having to perform multiple control experiments on each day an experiment is performed. This gives more time for experimental manipulation (see below).

The HSS should contain no membraneous materials. When incubated at room temperature, microtubule assembly should be visible within several minutes using VE-DIC optics. In the absence of centrosomes, only random microtubule assembly occurs. In the presence of centrosomes, microtubules first assemble randomly, but over the 10-min nucleation period, the centrosomes acquire pericentriolar material and nucleate more microtubules. By 10 min almost all microtubules are nucleated by centrosomes. Microtubule dynamics do occur and by VE-DIC both growing and shrinking microtubules should be visible.

The typical yield for this centrosome preparation is 30% to 50%. Therefore, a 2-liter preparation of lymphocytes (3×10^9 cells) generally yields ~10^9 centrosomes with several fractions containing centrosomes at or above the optimal concentration (~2×10^8/ml). A single centrosome preparation generates enough centrosomes for at least 1000 motility assays.

Eggs from one frog (5 ml dejellied eggs) generally yields 1 ml of 16,000 × *g* cytosol. Each milliliter of cytosol generates ~3 ml of HSS. Each assay uses 20 μl of HSS. Therefore, one frog yields enough HSS for ~150 assays.

Eggs from one frog (5 ml dejellied eggs) will generally yield ~300 μl of cytosol-200 (and

membranes). This will make a ~700-µl nuclear assembly reaction, which is aliquotted by 10 µl at the end. Each 10-µl aliquot contains nuclei for one motility assay. Therefore, eggs from one frog generate nuclei for ~70 motility assays.

Time Considerations

Once all of the support protocols have been followed to generate the components of the motility assay and the learning period has been overcome, then each motility assay takes ~40 min to perform. One to 2 hr of preparation time is required before each assay period. Therefore, only a few experimental samples can be compared on 1 day if assays are performed in triplicate with appropriate buffer controls.

The centrosome preparation requires minimal time for 10 to 14 days to grow the lymphocytes, 1 day to prepare the buffers, and 1 day to do the actual preparation. Titration of the centrosomes in the motility assay requires another full day, but should only be done once all the other components have been prepared.

Preparation of fractionated extracts for nuclear assembly requires 1 full day. Frogs must be primed 4 to 10 days in advance with PMSG and the night before the prep with HCG.

For time considerations in preparing magnetic DNA-beads, see *UNIT 11.13*. Working out the conditions for optimal nuclear assembly using DNA beads and fractionated extracts can optimistically be done in an afternoon, but often can take several tries. Actual preparative scale nuclear assembly takes half a day.

Preparation of 16,000 × *g* extracts for generation of HSS takes half a day once frogs are primed as above.

Preparation of slide chambers for motility assays takes parts of a day, during which many other activities can be undertaken simultaneously.

Time considerations for familiarization with VE-DIC and optimization for visualization of microtubules are beyond the scope of this protocol. Please refer to *UNITS 4.1 & 13.1* and to Salmon and Tran (1998) and Walker et al. (1988).

Measuring Dynamics of Nuclear Proteins by Photobleaching

Photobleaching techniques offer the possibility of obtaining information on molecular motion and interactions in a specific part of a cell (McNally and Smith, 2002). The three main advantages of photobleaching techniques are fast experimental turn around, good spatial and temporal resolution, and the ability to measure kinetics inside of living cells. The main disadvantage of these techniques is the requirement for fluorescently tagged proteins (in this case by creating a gene fusion with GFP). Alternatively, other genetically engineered fluorescent tags may be used for a fusion with the protein of interest—e.g., cyan fluorescent protein (CFP) or yellow fluorescent protein (YFP). Also, in some cases, addition of this moiety can functionally alter the protein. Thus, prior to proceeding with photobleaching studies, the fusion protein must be rigorously tested to ensure it has the same properties and function as its native counterpart.

Ideally, a fusion protein is tested in a functional in vivo assay. The best is a functional complementation assay, for example, in a knock-out cell line or yeast. However, for many mammalian proteins such assays are not readily available. A minimal requirement for testing GFP-fusion proteins is their stability and proper localization in cells. The stability of a GFP-fusion protein can be tested by immunoblot (*UNIT 6.2*), using either a specific antibody against the endogenous protein of interest or an antibody against GFP. An immunoblot ensures that the protein is of the expected molecular weight and that it is not degraded upon expression. Furthermore, the GFP-fusion protein must also colocalize with its endogenous counterpart. If the immunoblot shows degradation products of the protein chimera or the protein is mislocalized, the GFP-fusion protein is likely not fully functional. In this case, it is worth trying to introduce the GFP tag at the opposite end of the protein molecule. In some cases, the introduction of a longer linker between the protein and GFP is also helpful.

Three major methods of photobleaching microscopy are commonly used: fluorescence recovery after photobleaching (FRAP; see Basic Protocol), fluorescence loss in photobleaching (FLIP; see Alternate Protocol 1), and inverse fluorescence recovery after photobleaching (iFRAP; see Alternate Protocol 2). As summarized in Table 13.5.1, each of these techniques has specific characteristics permitting the determination of distinct particular parameters of protein behavior in vivo. In addition, transfection methods are given for introducing GFP-expression vectors into mammalian cells by electroporation (see Support Protocol 1) or by lipofection (see Support Protocol 2). Finally, since quantification of GFP-fusion proteins is critical, a method for the determination of the number of GFP molecules in a single, living cell is also described (see Support Protocol 3).

NOTE: The reader is referred to *UNIT 4.5* for a general discussion of confocal microscopy.

Table 13.5.1 Comparison of Photobleaching Methods for Detecting Movement of Nuclear Proteins[a]

	Mobility	Diffusion constant	Immobile fraction	Distinct pools	Compartment continuity
FRAP	+++	+++	+++	+	+
FLIP	+++	+	+	+++	+++
iFRAP	−	−	+	+++	−

FLUORESCENCE RECOVERY AFTER PHOTOBLEACHING (FRAP)

In a FRAP experiment, an intense focused laser beam of the appropriate wavelength bleaches a relatively small region of interest. The laser light irreversibly bleaches the fluorescent signal of molecules in the region of interest and, immediately following bleaching, the recovery of the fluorescence signal in the bleached area is monitored using an attenuated laser beam. The signal in the region of interest is measured and a fluorescence recovery curve $F_{rec}(t)$ (fluorescence intensity as a function of time after photobleaching) is generated (Fig. 13.5.1). Acquisition of a FRAP data set involves three phases: prebleach images, bleach pulse, and postbleach monitoring of fluorescence recovery.

FRAP experiments are most easily performed on any modern confocal microscope (e.g., Zeiss 510 and newer, Leica SP and newer), as these microscopes have integrated FRAP routines. Alternatively, it is possible to custom write macros for many older microscopes that will automatically perform FRAP routines (Ellenberg et al., 1998). This protocol, as well as its alternatives (see Alternate Protocols 1 and 2), are designed for the Zeiss LSM

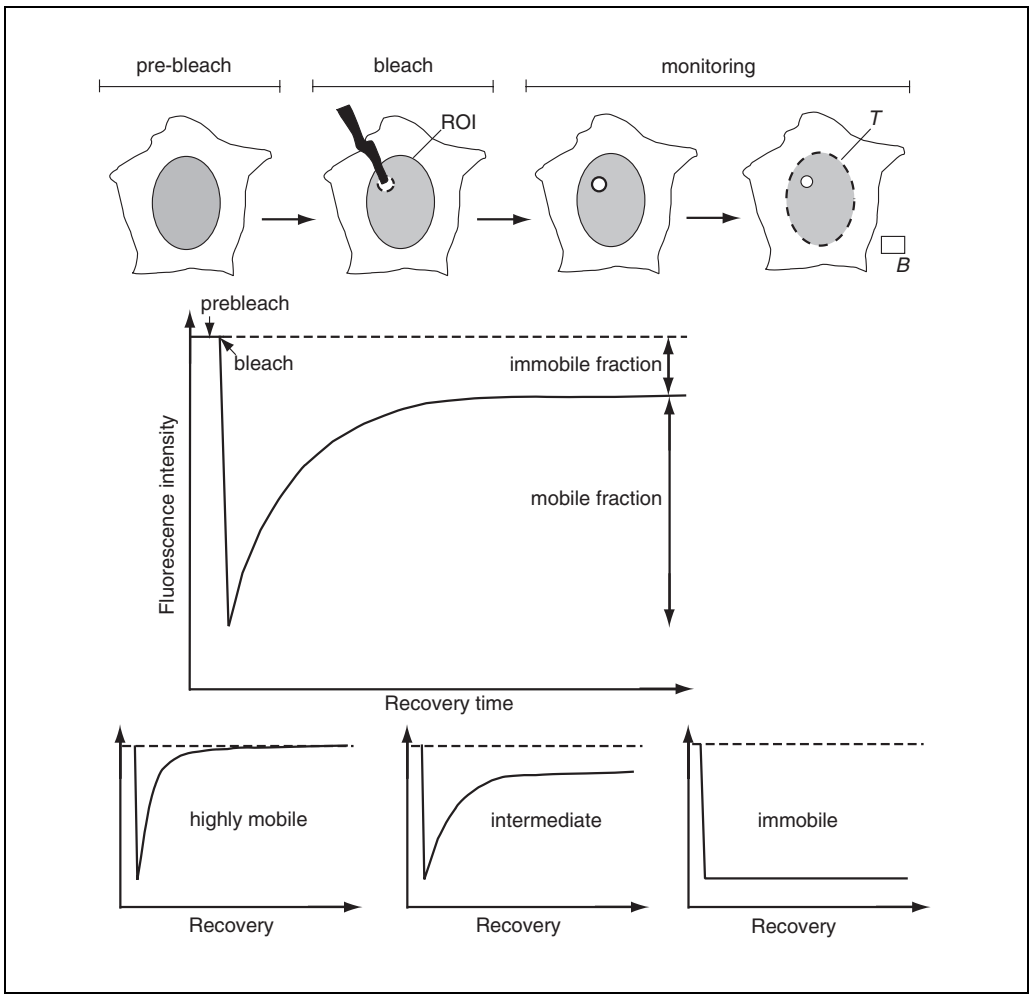

Figure 13.5.1 General scheme of a FRAP experiment. A cell is imaged before a short bleach pulse is applied to a defined region of interest (ROI). The recovery of the average fluorescence signal in the ROI is then monitored. To quantify and normalize FRAP data, the average fluorescence signal in the ROI, average total nuclear signal (*T*), and average signal in a random area outside of the cell for background correction (*B*) are measured during the entire experiment. The FRAP curve shows the prebleach intensity, depth of bleach, and recovery of the signal. The immobile fraction is determined as the difference between the prebleach signal and the signal after complete recovery. Based on different profiles of recovery curves, proteins can be considered highly mobile with virtually no immobile fraction, intermediately mobility with an immobile fraction, or immobile.

510 confocal microscope, but similar protocols can be applied to other confocal microscopes.

When FRAP experiments are carried out on confocal microscopes, the fluorescence recovery in the region of interest can be considered largely the result of two-dimensional exchange of fluorescent protein molecules within the same focal plane as the bleached area. This condition is approximately valid when objectives with high-numerical-aperture (N.A. of 1.2-1.45) lenses are used; a large cone of out-of-focus light bleaches the fluorescent molecules above and below the focal plane so that only nonbleached molecules from the focal plane participate in the recovery in the region of interest (Ellenberg et al., 1998).

There are several essential conditions that must be fulfilled for a successful FRAP experiment. (1) The fluorescent signal to be bleached must be clearly detectable over any background signal. (2) The photobleaching must be fast relative to the period of recovery to provide sufficient temporal resolution for analysis of the recovery curve and to allow measurement of the half-time of recovery. (3) The monitoring beam must be of low intensity to minimize photobleaching. To obtain a sufficiently high signal during the recovery period, the sensitivity of the photomultiplier tube may be increased.

Materials

2- or 4-chambered Lab-Tek II coverglass (Nalgene Nunc) containing cells, 50% to 70% confluent

Complete normal growth medium with 25 mM HEPES, but without phenol red (*UNIT 1.2*)

Confocal microscope

Air stream incubator (Nevtek)

1. On the stage of a confocal microscope, place a 2- or 4-chambered Lab-Tek II coverglass containing cells in complete normal growth medium with 25 mM HEPES, but without phenol red. Maintain growth temperature with a Nevtek air incubator. Examine the cells with fluorescent light of the appropriate wavelength.

2. Choose the appropriate lens (at least 63× magnification) and zoom setting to clearly observe the region of interest.

   If the same zoom is used for all observed cells, one can easily compare individual data sets without correction for bleach-area size.

3. Image a cell of interest using a low level of laser power to prevent photobleaching.

   On the Zeiss LSM 510 microscope, 20% to 50% output from a 40-mW laser with the beam attenuated to 0.1% is routinely used for the image acquisition.

4. Choose a small pinhole diameter.

   The authors recommend using a pinhole diameter in the range of 1 Airy unit (minimal resolvable distance which corresponds to the diameter of the peak of the bright spot of the point source of light; UNIT 4.1). A larger pinhole diameter improves the signal intensity, but increases the optical thickness of the collected section. This could affect monitoring of the signal in the region of interest by collecting data from a thicker optical section including unbleached fluorescent molecules. When a smaller pinhole diameter is used, the monitoring of signal recovery is restricted to the optical section most completely bleached. Therefore, it is advisable to use the smallest pinhole diameter which gives a sufficient signal-to-noise ratio.

Setup imaging sequence

5. Adjust the intensity of fluorescence signal to slightly below the saturation level by adjusting the gain on the photomultiplier tube.

   Use at least 8- but preferably 12-bit imaging. It is important to ensure that no pixels are saturated since the change in fluorescence intensity in these pixels cannot be measured accurately.

6. Adjust laser power to 100% for bleaching.

   The bleach time should be minimized. The efficiency of the bleach should be tested on a fixed sample. The average intensity in a bleached spot in a fixed sample should be reduced by at least 70% compared to its surroundings. If the bleach depth is insufficient, use several, rapid, consecutive bleach pulses. If the bleach spot in a living cell is distinct from the bleach spot in a fixed cell, do not increase the bleach time or intensity. The discrepancy is an important indication that the observed protein contains a very rapidly moving fraction. These highly mobile molecules enter the bleached spot between the time the bleach pulse is terminated and the acquisition of the first image. Recovery of freely mobile proteins in the nucleus can occur on the time scale of ≤50 msec.

7. Adjust the number of prebleach images for five to ten images and acquire five to ten prebleach images.

   It is important to acquire more than one prebleach image, as many fluorescent molecules are disproportionately bleached when first excited.

8. Adjust the number of postbleach intervals and the time between images.

   The number of intervals is determined by the resolution needed. The length of intervals should cover the curve until it reaches a plateau. Be careful not to collect an unnecessarily high number of images as this will bleach the sample.

9. Define the region to be bleached.

   The size of the bleach region is critical for quantitative analysis of FRAP recovery. The authors recommend using a small circular spot as the bleach region over the desired region of interest in the nucleus. The size of the bleach region should be small compared to the size of the nucleus. The advantage of a circular bleach spot is its symmetry, which permits finding it even when the cell moves. To check the dimensions of the bleach region, it is necessary to fix the sample, bleach the region of interest, and collect a series of optical sections through the cell. When the bleached region is monitored for signal recovery, the same size area or slightly smaller can be used for measurement of signal recovery. Using a larger monitoring area allows one to obtain the recovery data even if the bleached area moved slightly during monitoring; however, the relatively unchanged fluorescence intensity in the neighborhood of the bleached region reduces the sensitivity of the measurement.

10. Initiate data collection (i.e., prebleach images, bleach, postbleach images) and monitor the recovery of the fluorescence signal. Check the position of the cell and the focal plane to ensure that the region of interest is not moving from its original position due to focal-plane movement.

    It is essential to determine that recovery is complete—i.e., the curve should reach a clear plateau. The shape of a recovery curve should resemble the one in Figure 13.5.1. If the recovery is not complete, it is essential to increase the monitoring time of recovery by increasing the number of acquired images during monitoring or the time between images (step 8).

Perform quantitative analysis of FRAP

11. Measure the average intensity of the region of interest at each time point (I_t).

    Most confocal microscope software packages allow the researcher to perform this measurement on a whole stack of time-lapse data.

12. To correct for signal bleaching during monitoring, measure the average intensity of the entire nucleus at each time point (T_t).

13. Measure the background intensity (B_t) in a randomly selected region outside of the cell at each time point.

14. Calculate the relative intensity for each time point:

$$I_{rel} = (T_0 - B_0) \times (I_{(t)} - B_{(t)}) / (T_{(t)} - B_{(t)}) \times (I_0 - B_0)$$

where T_0 is the average intensity of the entire nucleus during prebleach and I_0 is the average intensity of the region of interest during prebleach (step 6).

This formula is derived in three steps. First, background is subtracted from all measured values, then the fluorescence loss due to monitor bleaching is normalized, and finally fluorescence intensity is normalized to one.

15. Plot I_{rel} as function of time.

For convenient calculation, it is useful to import FRAP data sheets from the microscope software to a spread sheet program such as Microsoft Excel.

16. Evaluate the individual curves and determine the average and standard deviations for each time point.

It is advisable to plot all acquired curves before determining the average. Jumps in the recovery curves or declining curves are frequently caused by cell or focal plane movement. These curves can either be discarded from analysis, or if possible, they should be manually remeasured. For many applications, it is sufficient to collect data for 10 to 20 individual cells. Typical error bars are on the order of 5% to 10% of the measured value.

Alternative normalization procedures have been published. For example, some investigators assign the value 1 to the prebleach intensity and the value 0 to the postbleach image in the bleached spot. (Kruhlak et al., 2000). This method is only appropriate for relatively slow-moving molecules where the signal in the bleached region is reduced by ≥75%. For fast moving molecules where the reduction of signal might only be ≤50%, this normalization method overestimates the recovery kinetics.

In the case of FRAP analyses of proteins which are enriched in small nuclear compartments such as the nucleolus or dot-like nuclear bodies and present at only low concentrations in the surrounding nucleoplasm, the relative fluorescent intensity in the bleached nuclear compartment can be normalized against the nonbleached nuclear compartment in the same nucleus (Chen and Huang, 2001). For each time point, the relative intensity is determined by the formula $I_{rel} = (Ne_tN1_0)/(Ne_0N1_t)$, where Ne_t and Nl_t are the average intensities of the bleached compartment and control nonbleached compartment at each time point, respectively, and Ne_0 and Nl_0 are the average intensities of the bleached compartment and control nonbleached compartment in the same nucleus during prebleach, respectively.

Determine the immobile fraction and diffusion constant

17. Calculate the immobile fraction of fluorescent molecules as the difference between the relative fluorescence intensity in the region of interest after the recovery curve has reached plateau, and the prebleach fluorescence signal intensity (normalized as 100%; Fig. 13.5.1).

Failure to recover to 100% prebleach fluorescence signal intensity even for a protein without immobile fraction such as GFP alone may represent the loss of total nuclear fluorescence due to bleaching during monitoring.

18. Determine the diffusion constant.

The mobility of a protein is characterized by its diffusion constant (D). FRAP experiments allow the determination of D assuming lateral diffusion in the focal plane (Axelrod et al.,

1976); however, it is essential to understand that the measured diffusion constant is only an apparent diffusion constant. The overall mobility of a protein is not only determined by its diffusional properties, but more significantly, by its functional properties such as incorporation into multiprotein complexes and binding to relatively immobile structures such as chromatin or a karyoskeleton (Misteli, 2001). Therefore, although a diffusion constant is a convenient method to compare the recovery kinetics of various proteins, one must be cautious in interpreting diffusion constants as a true indicator of the translational mobility of a protein. For discussion of diffusion constants see Lippincott-Schwartz et al. (2001). For determination of diffusion constants using a bleached strip of defined size see Ellenberg et al. (1998) Alternatively, diffusion constants can be determined directly from fitting the experimental data to the theoretical curve by computer simulation (Phair and Misteli, 2000; Houtsmuller and Vermeulen, 2001; Reits and Neefjes, 2001).

ALTERNATE PROTOCOL 1

FLUORESCENCE LOSS IN PHOTOBLEACHING (FLIP)

In FLIP, a region in the nucleus is repeatedly bleached and the loss of fluorescence in a monitoring region of interest some distance away from bleached region is recorded (Fig. 13.5.2). The basis of FLIP is the bleaching of mobile molecules as they pass through a bleached region. If all or a fraction of the fluorescently-tagged molecules in the nucleus are immobile, they will never enter or exit the repeatedly bleached region; therefore, they will not be bleached and cannot distribute the bleached signal elsewhere. As a consequence, the fluorescence signal in the regions surrounding the bleached spot will remain constant. In contrast, if molecules are highly mobile, they will eventually pass through the bleached region. The fluorescence signal in the nucleus will decrease. If all fluorescently-tagged molecules inside of the monitoring region of interest move freely into the bleached region, repeated bleaching will reduce the fluorescent signal in the monitoring region of interest at a constant rate. On the other hand, if multiple, kinetically distinct fractions of molecules exist, the loss curve will contain multiple distinct slopes. FLIP is also a particularly effective technique for testing continuity between nuclear compartments such as nucleoli, splicing factor compartments, Cajal bodies, or PML bodies.

FLIP is complementary to FRAP. Since in FLIP the signal in an unbleached region is measured, the technique is often used to ensure that the mobility of a protein of interest observed in FRAP experiments is not due to photodamage of the protein at the bleached spot.

See Basic Protocol for materials.

1. Set up the cells on the confocal microscope as described (see Basic Protocol, steps 1 and 2).
2. Image two cells of interest close to each other using a low level of laser power to prevent photobleaching.

   On the Zeiss LSM 510 microscope, 20% to 50% output from a 40-mW laser with the beam attenuated to 0.1% is routinely used for the image acquisition.
3. Adjust settings as described for FRAP (see Basic Protocol, steps 4 to 9).

   A successful FLIP experiment depends on the successful loss of fluorescence in regions outside the bleached region. It is therefore more practical to use bleach areas that are larger in size than the ones used in the FRAP experiments.
4. Initiate data collection (i.e., prebleach images, bleach, postbleach images) and monitor fluorescence loss. Check the position of the cell and the focal plane to be sure that the monitoring spot is not moving from the original position.

   The acquisition routine should run in a loop between bleach pulse and single image acquisition separated by the predetermined time interval.

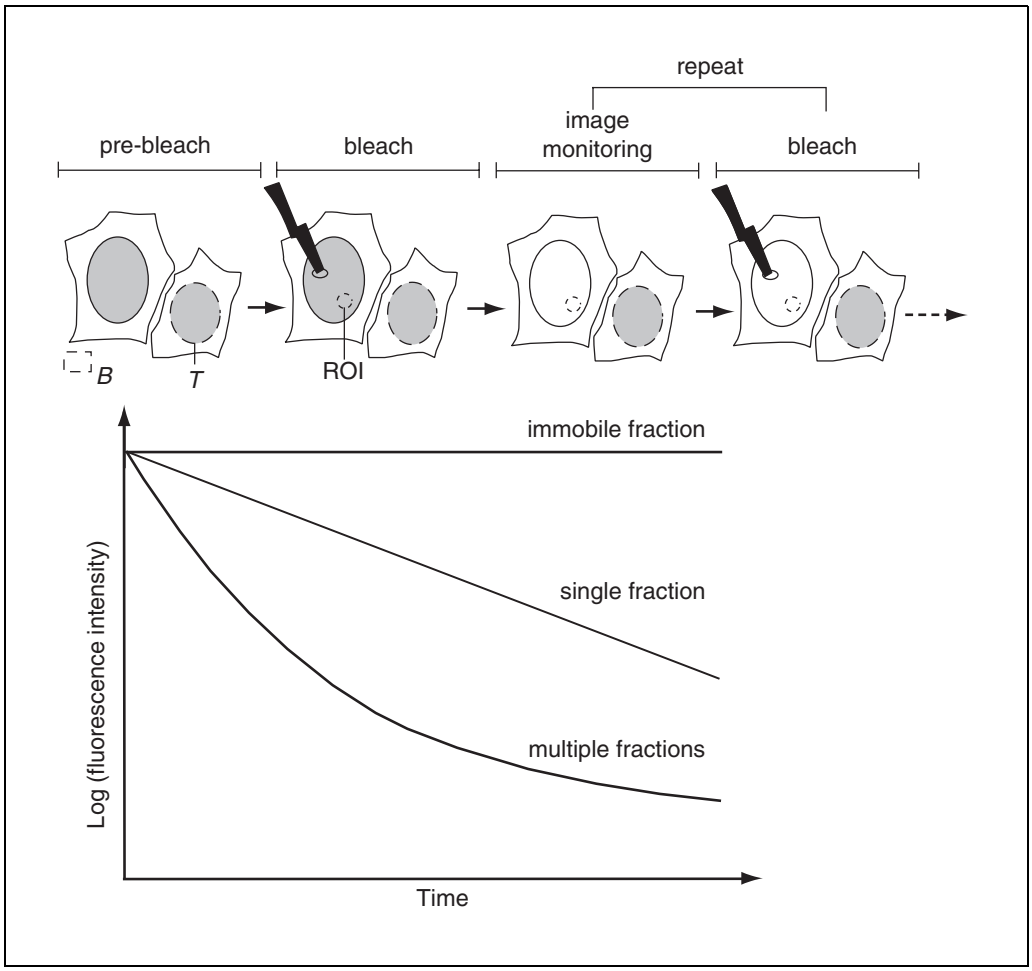

Figure 13.5.2 General scheme of a FLIP experiment. A cell is imaged before a short bleach pulse is applied to a defined bleach region. The image-bleach routine is repeated with the two steps separated by a predetermined time interval. To quantify and normalize FLIP data, measure the average fluorescence signal in a region of interest (ROI) distinct from the bleached region, measure the average total nuclear fluorescence signal (*T*) in a neighboring cell, and the average signal in a random region outside of the cell for background correction (*B*), for the duration of the experiment. When the FLIP data are plotted on a semilog scale, the shape of the curve indicates whether the GFP-fusion protein exists in the cell in a single fraction, in multiple fractions or whether it is immobile.

It is essential that the level of fluorescence signal at the end of the experiment be below 15% of the prebleach level. The fluorescence loss curve should resemble the FLIP curve in Figure 13.5.2. If the loss of fluorescence is not below 15%, it is essential to increase the monitoring time. Note that the slope of the loss curve depends on the size, intensity, and duration of the bleach pulse.

Perform quantitative analysis of FLIP

5. Measure the average intensity of the monitoring region of interest as a function of time I_t.
6. Measure the average intensity of the total nuclear area of a neighbor cell at each time point (T_t).
7. Measure the background intensity in a random region outside of the cells at each time point (B_t).
8. For each time point, calculate the relative intensity:

$$I_{rel} = (I_t - B_t)/[(I_0 - B_0) \times (T_t - B_t)]$$

where I_0 is the average intensity of the region of interest during prebleach.

This formula is derived in three steps. First, background is subtracted from all measured values, then fluorescence loss due to monitor bleaching is normalized, and finally fluorescence intensity is normalized to one.

9. Plot I_{rel} as a function of time and determine average and standard deviations as described for FRAP (see Basic Protocol, steps 16 and 17).

If all fluorescently tagged proteins in the compartment are kinetically identical, the region of interest will lose its fluorescence linearly. If the nuclear compartment contains kinetically distinct pools of proteins (e.g., due to binding of one fraction of the protein to chromatin or incorporation of a fraction into a large complex), the loss of fluorescence will be multiphasic. The number of distinct fractions can be determined by plotting the loss curve as a function of time in a semilog plot. Each kink in the semilog plot corresponds to a kinetically distinct fraction of molecules (Fig. 13.5.2).

As a negative control, fixed cells should be used. No significant loss of signal should be observed outside of the bleached region. The amount of loss that is observed corresponds to bleaching due to imaging.

ALTERNATE PROTOCOL 2

INVERSE FLUORESCENCE RECOVERY AFTER PHOTOBLEACHING (iFRAP)

iFRAP is a hybrid method between FRAP and FLIP. In iFRAP, the entire nucleus except a small region of interest is bleached using a single bleach pulse. The loss of fluorescence signal from the unbleached region of interest is then monitored over time (Fig. 13.5.3). Because the number of unbleached molecules in the region of interest is small compared to the number of bleached molecules outside the region of interest, the unbleached molecules do not contribute to new binding events because their pool is proportionally too small in comparison to the large pool of bleached molecules. Thus, iFRAP is ideally suited to provide information about off-rates of proteins from binding sites (e.g., those on chromatin) or from nuclear compartments. iFRAP is particularly well suited for proteins which are enriched in relatively small structures (e.g., replication sites, intranuclear compartments) and for proteins which are bound to a substrate for relatively long periods of time.

See Basic Protocol for materials.

1. Set up cells on the confocal microscope and image as described for FLIP (see Alternate Protocol 1, steps 1 to 2). Adjust the microscope settings as described for FRAP (see Basic Protocol, steps 4 to 6).
2. Adjust laser power to 100% for bleaching.

The bleach time should be minimized and the efficiency of the bleach should be tested on a fixed sample. The average intensity in a bleached region in a fixed sample should be reduced by at least 70% compared to the same region of the neighboring cell. If the bleach depth is insufficient, use several, rapid, consecutive bleach pulses.

3. Adjust the number of prebleach images for five to ten images.
4. Adjust the number of postbleach intervals and the time intervals.

The number of intervals is determined by the resolution needed and the length of intervals should cover the curve until it reaches a plateau. Be careful not to collect an unnecessarily high number of images as this will bleach the sample.

5. Define the region to be bleached excluding the region of interest.

This must be performed quickly as the region of interest can move while the bleached region is being outlined. The bleach has to be as fast as possible to obtain information about rapidly moving molecules in the unbleached region of interest.

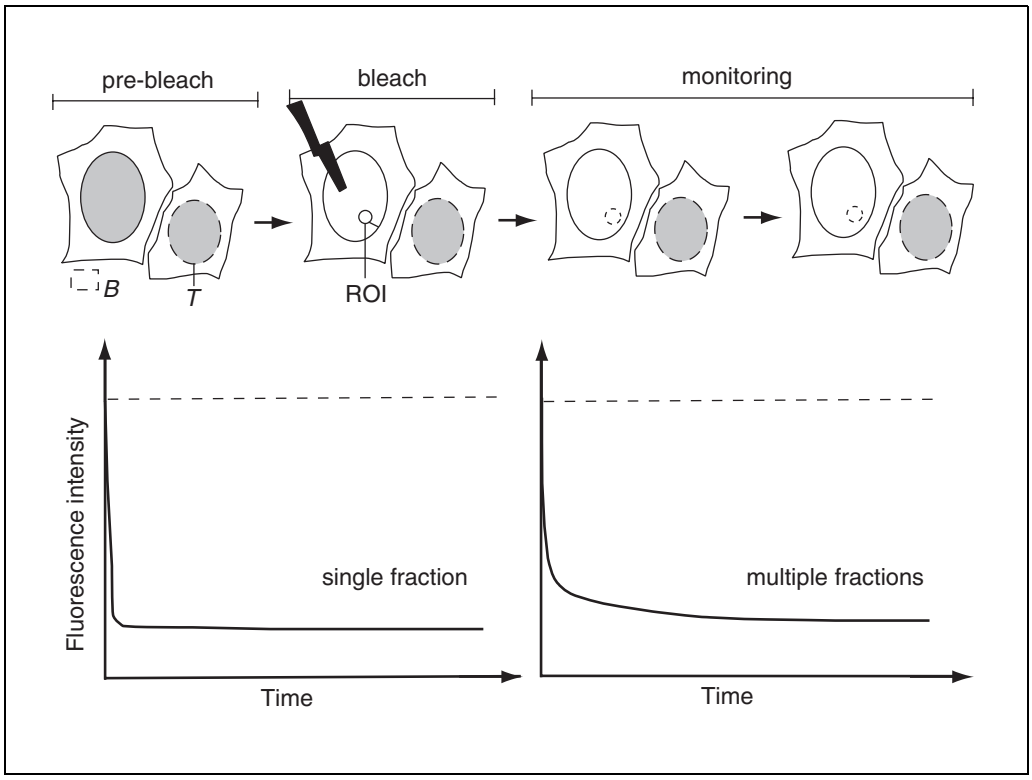

Figure 13.5.3 General scheme of an iFRAP experiment. A cell is imaged before a short bleach pulse is applied to the whole area of the nucleus except a small region of interest (ROI). The loss of fluorescence signal in the ROI is then monitored. To quantify and normalize iFRAP data, measure the average fluorescence signal in the ROI, the average total nuclear fluorescence signal (*T*) in a neighboring cell, and the average signal in random place outside of the cell for background correction (*B*), for the duration of the experiment. If the GFP-fusion protein in the ROI exists as a single population, the iFRAP curve should resemble the iFRAP curve on the left. If the GFP-fusion protein exists in the region of interest in multiple populations, the iFRAP curve should resemble the curve on right.

6. Initiate data collection (i.e., prebleach images, bleach, postbleach images) and monitor fluorescence loss in the region of interest. Check the position of the cell and the focal plane to be sure that the region of interest is not moving from the original position.

   The shape of the fluorescence loss curve should resemble the iFRAP curve in Figure 13.5.3. The region of interest has to be monitored until the loss of fluorescence signal reaches a plateau.

Perform quantitative analysis of iFRAP

7. Measure the average intensity of the region of interest at each time point (I_t).
8. To correct for the photobleaching effect due to monitoring, measure the average intensity of the entire nucleus of a neighboring cell at each time point (T_t).
9. Measure the background intensity in a randomly selected region outside of the cell at each time point (B_t).
10. Calculate the relative intensity (I_{rel}) each time point:

$$I_{rel} = \frac{(I_t - B_t) \times (T_0 - B_0)}{(I_0 - B_0) \times (T_t - B_{t)}}$$

where I_0 is the average intensity of the region of interest during prebleach (step 1) and T_0 is the average intensity of the total nuclear area of a neighbor cell during prebleach.

This formula is derived in three steps: first background is subtracted from all measured values, then fluorescence loss due to monitor bleaching is normalized, and finally fluorescence intensity is normalized to one.

11. Plot I_{rel} as a function of time and determine average and standard deviations as described for FRAP (see Basic Protocol).

It is advisable to plot all acquired curves before determining the average. Jumps in the recovery curves or declining curves are frequently caused by cell or focal plane movement. These curves can either be discarded for analysis or, if possible, they should be manually remeasured. For many applications it is sufficient to collect data for 10 to 20 individual cells. Typical error bars are on the order of 5% to 10% of the measured value.

If all GFP-fusion proteins in the compartment are fast moving components from the same pool, the fluorescent signal in the region of interest after the bleach will drop dramatically and then reach a plateau immediately (Fig. 13.5.3). If the nuclear compartment contains kinetically distinct pools of proteins (due to binding of one fraction of the protein to chromatin or substrate for longer time or incorporation of a fraction into a large complex), the curve of loss of fluorescence in the region of interest will drop dramatically and then show a linear decline until it finally reaches a plateau (Fig. 13.5.3).

As a control, fixed cells should be used. In this case the loss of fluorescence in the region of interest should show no significant loss of signal after the bleach over the monitoring.

SUPPORT PROTOCOL 1

TRANSIENT TRANSFECTION OF MAMMALIAN CELLS BY ELECTROPORATION

To study the dynamics of nuclear proteins in living cells, the specific protein-GFP chimera needs to be expressed. Ideally, a cell line stably expressing the GFP fusion protein from an integrated transgene is generated. The use of stable cell lines and inducible promoters such as the tetracycline- or ecdysone-inducible expression systems (No et al., 1996) are recommended when the overexpression of a fusion protein might be toxic or interfere with essential biological functions (Freundlieb et al., 1998). Detailed protocols for establishing stable cell lines are presented elsewhere (e.g., Stenmark and Zerial, 1998).

A quicker and often sufficient option for expression of GFP-fusion proteins in living cells is the introduction of a GFP-fusion protein by transient transfection encoded on a vector which does not integrate into the cell's genome. These vectors result in short-term, high-level expression of the fusion protein, but they will eventually be eliminated from the cell and expression will cease. Regardless of whether GFP fusion proteins are stably or transiently expressed, a vector containing the GFP-fusion protein cDNA must be introduced into cells by transfection. Two of the most effective and reliable methods of transfection are transfer of DNA via electrical current (presented here) or through one of the commercially available lipid-mediated delivery protocols (see Support Protocol 2). These protocols are for transfection of adherent cells, but both methods can also be used for transfection of suspension cells.

This protocol has been tested for the following adherent cell lines: HeLa, COS, CMT3, NIH 3T3, BHK, and CHO cells. The protocol must be optimized for other cell types. The important parameters for optimal results are the strength of applied electric field, duration of the electrical pulse, number of pulses applied, and concentrations of cells and plasmid DNA.

Materials

Cells
Complete growth medium (e.g., *UNIT 1.2*)
Plasmid DNA
Carrier DNA: sheared salmon sperm DNA
1× PBS (*APPENDIX 2A*)
0.25% (w/v) trypsin/1 mM EDTA, 37°C
Complete growth medium with 25 mM HEPES, but without phenol red

10-cm Petri dish
37°C warming tray
15-ml test tubes
Electroporation cuvettes with 2-mm gap
BTX ECM830 electroporator (BTX, a division of Genetronics, Inc.) or equivalent
Culture dish or incubation chamber (e.g., 2- or 4-chambered Lab-Tek II coverglass; Nalgene Nunc)

Additional reagents and equipment for mammalian cell culture (*UNIT 1.1*)

NOTE: All solutions and materials coming into contact with cells must be sterile, and proper aseptic technique must be used.

NOTE: All cell culture incubations should be performed in a humidified 37°C, 5% CO_2 incubator unless otherwise indicated.

NOTE: Avoid repeated freezing and defrosting of plasmid DNA stock solution. It may cause nicks in the plasmid DNA which leads to linearization of supercoiled DNA. Prepare aliquots of plasmid DNA and store them at −20°C.

1. Prepare an ~70% confluent monolayer of cells in a 10-cm Petri-dish (*UNIT 1.1*) in complete growth medium.
2. Add 3 to 7 µg plasmid DNA to a 1.5-ml test tube. Add sufficient carrier DNA to bring the total amount of DNA to 20 µg. Adjust the volume to 30 µl with water.
3. Wash cells once with 1× PBS.
4. Add enough 0.25% (w/v) trypsin/1 mM EDTA, 37°C to the culture to cover the adhering cell layer. Place the plate on a 37°C warming tray 1 to 2 min.
5. When cells round up, but before they detach from the substratum, add 7 ml complete growth medium. Harvest by collecting the cells and transferring them to a 15-ml centrifuge tube. Pellet cells by centrifuging 2 min at 1000 rpm in a benchtop centrifuge, room temperature.
6. Decant the aqueous layer and resuspend cells in 200 µl fresh complete medium. Pipet the cell suspension into the 1.5-ml test tube containing the prepared DNA solution (step 2). Mix well by pipetting up and down three times, let stand 2 min, and transfer to an electroporation cuvette with 2-mm gap.
7. For HeLa, COS, CMT3, NIH 3T3, BHK, or CHO cells, electroporate on a BTX ECM830 electroporator using the following settings: 150 V, 1-msec pulse, 4 pulses, and 0.5-sec interval.

   For BTX electroporator settings for other cell types refer to http://www.btxonline.com/btx and the manufacturer's lab manual at http://www.btxonline.com/products/pdfs/ECM_830/ECM_830_Manual.pdf. For electroporators from other manufacturers see the appropriate company's web pages.

8. Using a Pasteur pipet, transfer the cells from the cuvette to a well in a culture dish or to an incubation chamber.

   For HeLa, COS, CMT3, NIH 3T3, BHK, or CHO cells, one drop of cell suspension in a 35-mm well gives a confluent layer after overnight incubation. For other cell types, the amount of cells must be optimized.

9. Change the medium 8 to 10 hr after transfection.

10. Before imaging living cells (see Basic Protocol and Alternate Protocols 1 and 2), replace the medium with complete medium containing 25 mM HEPES, but no phenol red.

    Phenol red increases background fluorescence.

SUPPORT PROTOCOL 2

TRANSIENT TRANSFECTION OF MAMMALIAN CELLS USING FuGENE 6

FuGENE 6 is a transfection reagent that highly efficiently transfects a wide variety of cells including primary cultures and hard-to-transfect cell lines. The advantage of FuGENE 6 is that it demonstrates virtually no cytotoxicity even with primary cell cultures. The authors have successfully tested several adherent transformed cell lines—HeLa, COS, CMT3, NIH 3T3, CHO—and mouse primary fibroblasts. The FuGENE 6 reagent web page—*http://biochem.roche.com/techserv/fugene.htm*—has a current list of 250 successfully transfected cell lines.

Materials

Cells
Serum-containing and serum-free medium (*UNIT 1.2*)
FuGENE 6 reagent (Roche)
Plasmid DNA solution
Serum-containing medium (*UNIT 1.2*)
Serum (optional)
Glass coverslips or Lab Tek II incubation chambers (Nalgene Nunc)

Additional reagents and equipment for mammalian cell culture (*UNIT 1.1*)

NOTE: All solutions and materials coming into contact with cells must be sterile, and proper aseptic technique must be used.

NOTE: All cell culture incubations should be performed in a humidified 37°C, 5% CO_2 incubator unless otherwise indicated.

NOTE: Avoid repeated freezing and defrosting of plasmid DNA stock solution. It may cause nicks in the plasmid DNA which leads to linearization of supercoiled DNA. Prepare aliquots of plasmid DNA and store them at −20°C.

1. Prepare ~50% to 70% confluent monolayers on glass coverslips or in Nalgene Lab Tek II incubation chambers (*UNIT 1.1*) in serum-containing medium.

2. In a 1.5-ml sterile test tube, add 97 µl serum-free medium, then add 3 µl FuGENE6 reagent directly into this medium.

   The order of addition is critical. The serum-free medium must be aliquoted into the test tube first to avoid adversely affecting transfection efficiency by contact of the undiluted FuGENE with plastic surfaces.

3. Add 1 to 2 µg plasmid DNA solution in a volume of 0.5 to 50 µl to the diluted FuGENE 6 reagent.

   The total volume of DNA solution has to be in this range.

4. Gently tap the test tube to mix the contents, but do not vortex. Incubate a minimum of 15 min at room temperature.

   Continued incubation for up to 45 min will not affeect the transfection efficiency in most cell types.

5. Dissolve the mixture into 2 ml serum-containing medium. Add to the cells dropwise, distributing it around the well or incubation chamber. Swirl the wells or incubation chamber to ensure even dispersal.

6. Return the cells to the incubator. After 3 to 8 hr, replace the medium with serum-containing medium or add serum directly to wells. Continue incubating (12 to 20 hr) until imaging is performed (see Basic Protocol and Alternate Protocols 1 and 2).

QUANTIFICATION OF FLUORESCENTLY TAGGED PROTEIN MOLECULES IN NUCLEAR COMPARTMENTS OF SINGLE LIVING CELLS

SUPPORT PROTOCOL 3

The number of fluorescently tagged molecules in nuclear compartments in single living cells can be determined using individual fluorescently labeled virus-like particles (VLP) as a standard for the observed signals. VLPs contain a precise number of GFP molecules and the number of GFP molecules in a test volume can therefore be determined by comparing the total fluorescent intensity of VLP and the total fluorescent intensity of a nuclear volume. Since VLPs are small spherical particles, this technique is especially useful for the determination of the GFP content of small spherical cellular compartments and organelles such as Cajal bodies, PML bodies, fibrillar centers within the nucleoli, mitochondria, or vesicles.

VLPs are in vitro–assembled rotavirus particles (Charpilienne et al., 2001). Rotaviruses are large icosahedral particles, which contain three concentric capsid layers. While the outermost layer is composed of the VP4 and VP7 proteins, the intermediate capsid layer is composed of trimers of VP6. The innermost layer contains exactly 120 molecules of VP2. When VP2 fused to GFP is coexpressed with the intermediate capsid protein VP6 in a baculovirus-insect cell system, double-layered icosahedral VLP are completely assembled. Each such VLP measures ~100 nm in diameter and contains exactly 120 VP2-GFP molecules (Charpilienne et al., 2001).

Materials

Cells expressing GFP-tagged protein of interest (see Support Protocols 1 and 2)
Complete growth medium (*UNIT 1.2*)
1× PBS (*APPENDIX 2A*)
GFP-labeled VLP particles (Charpilienne et al., 2001; Dundr et al., 2002)

22 × 22–mm glass coverslips
Confocal microscope with 100× objective

Additional reagents and materials for mammalian cell culture (*UNIT 1.1*)

1. Culture cells expressing the GFP-tagged protein of interest on 22 × 22–mm glass coverslips for 16 to 20 hr (*UNIT 1.1*) in complete growth medium.

2. Wash cells twice with 1× PBS for 5 min each time.

3. Dilute purified GFP-labeled VLP particles to a concentration of 1 to 10 µg/ml in PBS.

4. Place ~30 to 40 µl diluted VLP onto the coverslip (step 1).

   It is advisable to perform a pilot experiment in which VLP particles are imaged in solution without cells. This allows for their easy detection later when they are mixed with the cells.

5. Examine cells using a confocal microscope with 100× objective.

   The powerful objective is needed because VLPs are difficult to see at low magnifications.

   Alternatively, a conventional wide-field microscope fitted with a cooled CCD camera can be used.

6. Adjust the photomultiplier tube intensity such that the fluorescence signal of the GFP fusion protein is slightly below the saturation level.

   Use at least 8- but preferably 12-bit imaging. It is important to ensure that no pixels are saturated since the fluorescence intensity in these pixels cannot be measured accurately.

7. Collect a series of 50 single images of the cells expressing the GFP-fusion protein.

8. Using identical settings, collect 50 single images of the VLP-GFP particles in a different field of view in the same specimen.

9. Measure the average area and the average intensity of at least fifty compartments of interest containing the GFP-fusion protein and at least fifty VLPs.

10. Measure the background intensity in a randomly selected area that does not contain cells or VLPs.

11. Subtract the background intensity from the average intensity value of compartments and VLPs.

12. Multiply the average area with the background-corrected average intensity to obtain average fluorescence intensities for the compartment and VLPs.

13. Calculate the number of GFP molecules per compartment:

    $$\text{no. GFP molecules/compartment} = (TI_C \times 120)/(TI_{VLP})$$

    where TI_C is the average intensity of the compartments and TI_{VLP} is the average intensity of the VLPs.

    When using a confocal microscope, not all of the imaged VLP particles will fall within the focal plane and a range of signals will be observed. To determine the average intensity of a single VLP particle, it is helpful to perform three-dimensional reconstruction of VLPs with a distance of 100 nm between optical sections. Collect the maximum number of sections possible and observe them for quantification as a maximum projection. In this case, the total intensities of VLPs should fall within a 10% range of intensities.

COMMENTARY

Background Information

It has been established that the eukaryotic cell nucleus is not a homogeneous organelle but contains several specific membrane-less compartments. Recent observations using photobleaching methods have demonstrated that many nuclear proteins are highly mobile and do not permanently reside in any specific nuclear compartment but are continuously exchanged between the compartment and the surrounding nucleoplasm (Kruhlak et al., 2000; Phair and Misteli, 2000; Chen and Huang, 2001). In this view, nuclear compartments are the consequence of the steady-state dynamic behavior of their components. Nuclear proteins are not primarily targeted to the nuclear compartments by specific targeting signals but rather retained there as a result of binding or collision with other nuclear components (i.e., protein-protein interactions; DNA-protein interactions: engagement in replication, DNA repair or RNA-protein interactions, and engagement in transcription etc.). The exchange rate of the nuclear proteins is strongly determined by the roles they play in nuclear function.

The localization of proteins within cells has traditionally been studied by indirect immunofluorescence microscopy using fluorescently labeled antibodies. This method is limited by the requirement for chemical fixation

of cells and yields only static snapshots of a protein's distribution. The development of the green fluorescent protein (GFP) as a genetically encoded fluorescent protein reporter has revolutionized the study of protein localization in living cells.

Apart from the use of GFP as a convenient and rapid method to determine where a known protein or one encoded by a newly cloned cDNA is localized, GFP has also been extensively used to visualize proteins in living cells by time-lapse microscopy. These latter approaches allow the study of dynamic aspects of protein function. GFP fusion proteins have been particularly insightful in the study of the cell nucleus. Using time-lapse-microscopy approaches, it has become clear that many nuclear compartments are highly dynamic both in interphase and during mitosis, and that many proteins continuously shuttle between the nucleus and the cytoplasm. (Ellenberg et al., 1997; Misteli et al., 1997; Boudonck et al., 1999; Dundr et al., 2000; Platani et al., 2000; Tsukamoto et al., 2000; Kamath et al., 2001). More recently, nuclear GFP fusion proteins have also been used in combination with photobleaching techniques to study the dynamic organization of nuclear compartments in vivo.

Fluorescence photobleaching techniques were originally developed in the 1970s to study the mobility of lipids and proteins in the lipid bilayer of the plasma membrane (Axelrod et al., 1976). They have now become a standard method for studying the dynamics of nuclear proteins in living cells (Ellenberg et al., 1997; Houtsmuller et al., 1999; Kruhlak et al., 2000; Phair and Misteli, 2000; Snaar et al., 2000; Misteli, 2001; Chen and Huang, 2001; Boisvert et al., 2001). The noninvasive nature of the photobleaching approach allows one to label nuclear compartments in living cells with high specificity, but often without functional interference. The GFP-protein marker is particularly useful for photobleaching experiments, because the signal is stable and does not bleach significantly at the low-intensity levels used to monitor bleach recovery. In addition, the bleaching of GFP in living cells can be considered irreversible and does not cause any detectable damage to the cell (but see Verkman, 2002).

What are the advantages of using photobleaching techniques for studying the dynamics of nuclear proteins in living cells? Recent observations using photobleaching techniques have demonstrated that many nuclear proteins are highly mobile and do not permanently reside in any specific domain of the nucleus (Kruhlak et al., 2000; Phair and Misteli, 2000; Chen and Huang, 2001). The various available photobleaching techniques can provide information about the in vivo kinetics of the protein of interest and since the kinetic behavior of a protein is often directly related to its functional status, information about a protein's biological role may also be obtained (Phair and Misteli, 2001). Furthermore, photobleaching methods can be used to determine how many different pools of a protein are present in a cell and whether an immobile statically bound fraction exists.

Critical Parameters

Transfection efficiency

Transfection efficiency plays an important role in photobleaching experiments. Very low numbers of transfected cells can affect the evaluation of the pattern of GFP-fusion protein localization and selection of optimal cells for bleaching. In the case of FLIP or iFRAP experiments, high transfection efficiency is essential so that images of two neighboring cells expressing the GFP protein can be obtained, which is required for correction of the signal due to photobleaching. Therefore special attention should be paid to optimization of transfection efficiency.

Cell type

A cell type that tolerates introduction of plasmid DNA should be selected. If there is an option, select preferentially transformed cells over primary cells, which are usually more difficult to optimize for transfection. Cells should be in logarithmic growth when used for transfection.

Quality of plasmid DNA

One critical parameter of good transfection efficiency is the quality of plasmid DNA. It should be pure and the stock DNA solution should not be repeatedly frozen and defrosted. When transfection efficiency is low, a higher concentration of plasmid DNA can be used.

Electroporation

When electroporation is used, three parameters should be varied for optimization: electrical field, duration, and number of pulses. When the electrical field is too high, the survival rate of the cells is lowered. When it is too low, the efficiency of transfection is usually poor. When

a low electric field is used, longer pulses should be applied and vice versa.

Expression levels

For photobleaching experiments, it is advisable to select only cells expressing low or moderate levels of GFP fusion protein. Overexpression of a protein of interest can dramatically affect its localization and may change its behavior as well as influence the overall metabolism of the cell.

Critical elements

Special attention must be paid to the viability of the cells during photobleaching measurements. Cells in a chambered coverglass should not be on the microscope stage for more than 1 hr. Longer exposure of cells can affect cell metabolism and can cause changes in protein mobility. After 1 hr cells should be replaced with another sample or put back in the incubator for at least 30 min.

Controls

Fixed cells should be used as a control for all photobleaching experiments. The fixed sample permits determination of the *x*, *y*, and *z* dimensions of the bleach region and depth of bleach, if the series of optical sections through the sample is collected. The size of the bleach spot should be small relative to the size of the nucleus. Typically a bleach spot 1 μm in diameter works for most applications. Bleaching a region that is larger than the compartment of interest will affect the accuracy of measurement by mixing the populations of GFP-molecules outside and inside of the compartment. Therefore, it is advisable to adjust the size of compartment relative to the size of the bleach spot by using the appropriate zoom.

Each individual recovery curve should be evaluated. Any dramatic change in the shape of the curve may indicate that the monitoring region of interest changed position or focal plane due to cell movement. These data should be discarded.

Anticipated Results

In a typical transient transfection, a fluorescent signal should be detected 12 to 20 hr after transfection, but weak signals can often be observed as early as 4 to 6 hr. The differences in expression level can vary depending on the purity of DNA, the vector and promoter used, and the cell type used in the study.

The recovery curve of the GFP fusion protein of interest contains information about the degree of mobility of a protein of interest within the nucleus. Generally, qualitative analysis of any photobleaching curves allows one to conclude whether a protein is completely mobile, mobile with a fraction of immobile molecules, or almost completely immobile. In many cases this basic information has significant ramifications for protein function. Note that coincidence of recovery curves for multiple proteins does not necessarily mean that these proteins are found in a complex and move together. Conversely, however, distinct curves of several proteins are generally a good indication that the

Table 13.5.2 Comparison of the Mobility of Nuclear Proteins

GFP-fusion protein	FRAP recovery (sec)	Diffusion coefficient ($\mu m^2/s$)	Reference
EGFP	~0.5	27	Swaminathan et al., 1997
580 kDa dextran	7	0.95	Calapez et al., 2002

ERCC1-GFP/XPF	8	15 (absence of DNA damage)	Houtsmuller et al., 1999
	—	(immobile with DNA damage)	

majority of the proteins of interest are not present in a complex in vivo.

Examples of recovery times and diffusion coefficients are given in Table 13.5.2.

As a positive control for the evaluation of the mobility of GFP protein of interest, GFP alone can be used as a standard for relatively freely mobile protein. The recovery of the fluorescent signal of the GFP alone is very fast (within 1 sec) and complete recovery with virtually no immobile fraction should be observed. Convenient negative controls are GFP fusions with the core histones (H2A-GFP, H3-GFP, H4-GFP; Kimura and Cook, 2001). In this case, there should be no recovery over the monitoring period. If recovery of fluorescence is observed using either fixed cells or core histone fusion proteins, it should be ensured that the correct excitation wavelength of the laser (488 nm for GFP) is used. Similarly, if no bleaching is observed, the laser settings should be checked.

In FLIP experiments, the kinetic status of specific nuclear compartments is evaluated. Specifically it is tested whether a GFP-fusion protein resides statically or moves rapidly in and out of a compartment. If two or more compartments are in physical continuity, bleaching one will result in loss of fluorescence in the other(s).

In iFRAP experiments, loss of fluorescence in region of interest reflects predominantly how the GFP-fusion protein is lost from its binding site.

Most photobleaching experiments should be completely reproducible with a typical error among cells in a population on the order of 5% to 10% of measured values. To achieve this goal, each acquired curve has to be evaluated independently, and every curve with jumps due to cell or focal plane movement should be discarded before final averaging. Since these are single-cell experiments, variations in cell populations might be observed as relatively large errors in a population measurement. For many proteins the position of the cell in the cell cycle can affect their behavior and mobility. If large fluctuation in measurements is observed, it is recommended to use cell-cycle-synchronized cells.

Special care must be applied to minimize photobleaching due to imaging during monitoring. The number of images collected during monitoring should be a compromise between the resolution of measurements needed and the length of the interval. The decline of the signal intensity due to photobleaching during monitoring should generally not exceed ~5% to 10% of the prebleach value. If bleaching is a problem, the laser power or the interval between images can be reduced.

GFP levels can be quantified with VLPs by comparing total fluorescent intensities of VLPs with a defined number of GFP molecules and fluorescently labeled specific small nuclear compartments of interest (see Support Protocol 3). This measurement provides the average number of GFP-fusion protein molecules in the compartments in single living cells. Since in 12-bit imaging, 4096 gray levels can be distinguished and the typical background intensity is ~100 to 200 units, the observable ratio of VLP to compartment signal is ~20-fold. Given that each virus particle contains 120 GFP molecules, only compartments which contain ~2500 molecules of interest can be measured using this method. The level of GFP molecules found in many nuclear compartments is well within this range.

Time Considerations

A transient transfection can be done in 30 to 45 min and the cells can be used for microscopy 12 to 20 hr after transfection. The time for a FRAP and iFRAD experiment depends on the mobility of the GFP fusion-protein, but is typically on the order of seconds to <10 min. A FLIP experiment takes on the order of minutes up to 1 hr. Each GFP fusion protein should be tested on 15 to 20 cells. The normalization of one sheet of FRAP data using Microsoft Excel takes several minutes. Electroporation takes ~20 min and the transfection procedure using FuGENE 6 takes 25 min to 1 hr. Acquiring a sufficient number of images of cells expressing protein-GFP and VLPs requires 0.5 to 1.0 hr. Measuring the average area and the average intensity of at least fifty compartments of interest and fifty VLPs using microscope or Metamorph software requires ~2 to 3 hr.

Functional Characterization of Proteins Regulating Actin Assembly

The actin cytoskeleton is a dynamic array of polar helical filaments that allows a eukaryotic cell to organize its intracellular space and the traffic of organelles, as well as to react to signals from the outside world by changing shape or migrating. Directed assembly of actin filaments is at the heart of motile processes involved in cell migration, oogenesis, tissue morphogenesis and repair, embryonic development, and the immune response.

A very large repertoire of actin-binding proteins regulates the assembly dynamics and the spatial organization of actin filaments, thus orchestrating the motile behavior of the cell (Small et al., 2002). At least 50 to 60 regulatory proteins have been identified so far, yet regulatory factors endowed with new specific properties continue to be discovered. The goal of this unit is to describe a logical method and derived in vitro assays for the characterization of the function of a putative actin-binding protein. The classical basic regulatory activities are presented here as dogma, or basic themes, on which variations are played by nature to generate the full complexity of the actin response in physiological situations.

In the physiological context, actin is in a dynamic steady state between the monomeric (G, for globular; see Support Protocol 1) and polymeric (F, for filamentous) forms. A filament has two ends that differ both structurally and dynamically: a barbed end (the fast end) and a pointed end (the slow end). Actin is an ATPase: it binds MgATP, and hydrolysis of ATP is associated with incorporation of ATP-G-actin in the filament. Actin assembly at steady state is described by an ATPase cycle featuring the energetic imbalance between the two ends, which is linked to the irreversible hydrolysis of ATP. This cycle comprises three elementary steps: net depolymerization from the pointed end releases ADP-G-actin, exchange of ATP for bound ADP restores ATP-G-actin, which then undergoes net assembly at the barbed end (Fig. 13.6.1). The rate constants of all these steps determine both the concentrations of each species at steady state and the turnover of actin filaments. It is noteworthy that the concentration of unpolymerized ATP-G-actin that is maintained in this cycle is intermediate between the critical concentrations at the barbed and pointed ends.

Individual actin regulatory proteins affect the kinetic and thermodynamic parameters of actin assembly at one or the other end of the filament in various fashions. Actin exposes many functionally relevant sites for regulating assembly: side binding or end binding to the F-actin filament and binding to G-actin in ways that allow, favor, or inhibit incorporation of actin in filaments or that favor or inhibit nucleation of filaments.

A primordial question is whether a given actin-binding protein binds with a higher specificity to G-actin or F-actin. A protein that binds F-actin better than G-actin stabilizes the filaments (i.e., shifts the monomer-polymer equilibrium toward the polymer form), thus causing a decrease in G-actin concentration at steady state. Conversely, a protein that binds G-actin preferentially, also called a G-actin-sequestering factor, shifts the equilibrium toward the monomer, thus causing depolymerization of F-actin. Sedimentation assays (see Basic Protocol 1), which allow separation of F-actin (in the pellet) from free and liganded G-actin (in the supernatant) are useful to address this issue and may provide quantitative information on the protein's affinity for and molar binding ratio to actin. Changes in fluorescence of pyrenyl-labeled actin or other fluorescently labeled forms of actin (see Support Protocols 2 and 3) also provide accurate measurements of the concentration of F-actin and G-actin at the steady state of assembly.

Contributed by Maud Hertzog and Marie-France Carlier
Current Protocols in Cell Biology (2005) 13.6.1-13.6.23

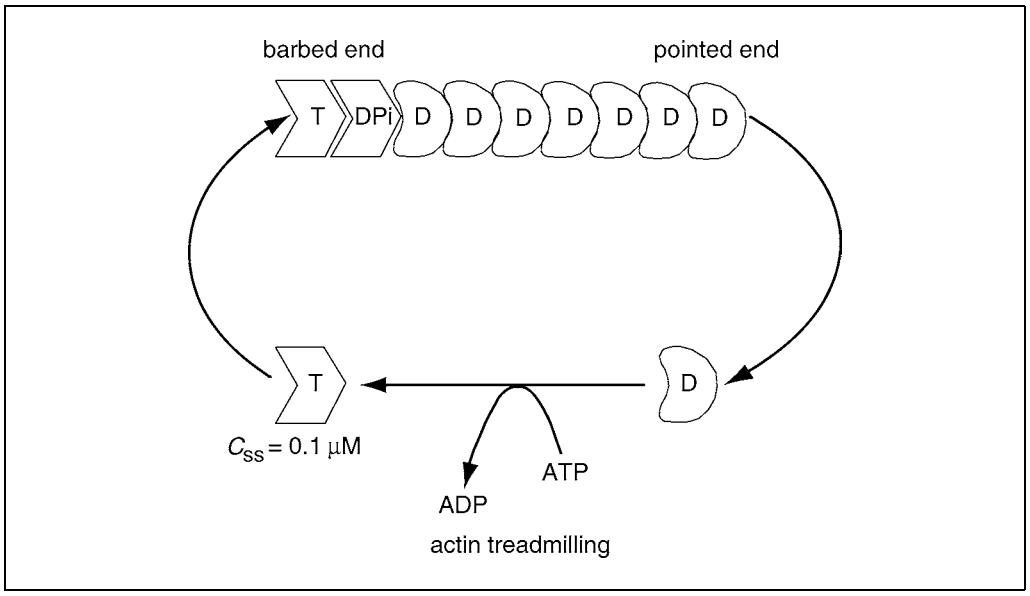

Figure 13.6.1 Treadmilling of the actin filament. This diagram emphasizes that the actin filament has a polar structure, with a barbed end and a pointed end. Under physiological ionic conditions, F-actin is at a steady state with ATP-G-actin monomers. An energetic imbalance occurs between the two ends, because of ATP hydrolysis linked to F-actin assembly. Monomer-polymer exchanges at the two ends do not sum up to zero at each end; instead the barbed ends undergo net growth, balanced by equal depolymerization at the pointed end. This flux of subunits through the filament is called treadmilling. C_{ss}, steady-state (critical) concentration; D, ADP-actin; DPi, ADP-P_i-actin; T, ATP-actin.

Because ATP hydrolysis accompanies filament assembly, a relevant question is whether an actin-binding protein shows specificity for ATP-actin or ADP-actin (in either the G or F form). Direct binding assays (solid phase or fluorometric assays; see Basic Protocols 2 and 3) are recommended. The change in tryptophan fluorescence (actin has four tryptophans) may be used as a probe of the binding of a protein to ATP- or ADP-G-actin. Alternatively, actin can be labeled on specific residues (e.g., Cys374) with a variety of fluorophores that may react to ligand binding, thus providing information on binding affinity and the mechanism of interaction through the use of rapid kinetics. Labeling may alter the affinity of the protein for actin, but this can easily be checked by competition studies with unlabeled actin. Similarly, the interaction with an actin filament can be studied in the standard ADP-F-actin state and also using the nonhydrolyzable analogs BeF_3^- and AlF_4^- in the ATP- or ADP-P_i-F-actin state (Combeau and Carlier, 1988, 1989).

Regulation of filament turnover is crucial in motility and is elicited by changing the kinetic parameters for actin association-dissociation at the two ends of the filament. A large class of actin regulatory proteins, called capping proteins, binds tightly to the barbed end of the actin filament, thus blocking all association-dissociation processes at this end. Appropriate kinetic measurements of filament growth or depolymerization at one end or the other using the change in fluorescence of pyrenyl-labeled actin is described to test the capping activity (see Basic Protocols 5 and 6). Blockage of barbed ends also results in a shift in the steady state critical concentration (C_{ss}) for assembly, increasing it up to the critical concentration at the pointed end (C_c) (see Basic Protocol 4). Most capping proteins simply block barbed ends, but leaky cappers that alter the association or dissociation of actin without blocking the end may exist.

Another way to affect the rate of filament elongation is provided by proteins that interact with G-actin to form a complex that has an association rate constant for filament ends that differs from that of free G-actin. Appropriate assays of filament growth from seeds help to evaluate this possibility. Seeds are preformed filaments with a few subunits, which are used to initiate actin elongation from the barbed or pointed end of the actin filament.

The turnover of a population of filaments in vitro is monitored using a fluorescent analog of ATP whose fluorescence changes when bound to actin. The rate at which F-actin becomes nonfluorescent following an ATP chase is an indication of the filament turnover rate (see Basic Protocol 7).

CO-SEDIMENTATION ASSAY FOR MEASURING BINDING OF A PROTEIN TO F-ACTIN (OR G-ACTIN)

BASIC PROTOCOL 1

F-actin is easily sedimented by centrifuging 20 min at 400,000 × *g* (20°C). G-actin and small complexes of G-actin with a G-actin-binding protein remain in the supernatant.

Materials

50 μM G-actin in G-buffer (see Support Protocol 1), store on ice
2 M KCl
20 mM $MgCl_2$ (*APPENDIX 2A*)
100 μM protein of interest in 10 mM Tris·Cl (pH 7.5)/1 mM dithiothreitol (DTT)
10 mM Tris·Cl (pH 7.5)/1 mM DTT
F-buffer (see recipe)
G-buffer (see recipe)

0.5-ml polycarbonate centrifuge tubes
Beckman TL100 tabletop ultracentrifuge (or equivalent)
Densitometer

Additional reagents and equipment for SDS-polyacrylamide gel electrophoresis (*UNIT 6.1*)

1. To 1 ml of 50 μM G-actin, add 100 μl of 2 M KCl (0.2 M final) and 100 μl of 20 mM $MgCl_2$ (2 mM final). Allow to polymerize 15 min at room temperature.
2. Dilute 360 μl polymerized G-actin (i.e., F-actin) to 1.5 ml with F-buffer. Mix thoroughly and prepare ten samples of 100 μl F-actin (10 μM final) in 0.5-ml polycarbonate centrifuge tubes.
3. Centrifuge 200 μl of 100 μM protein of interest at 400,000 × *g*, 20°C, for 20 min. Prepare ten dilutions of the protein of interest ranging from 0 to 100 μM final concentration in a final volume of 100 μl using 10 mM Tris·Cl/1 mM DTT.
4. Add 100 μl protein of interest dilutions (0 to 50 μM final) to each of ten 100-μl F-actin samples (step 2; 5 μM final) and incubate 15 min at room temperature. Divide each sample between two tubes (100 μl each). Process one sample from each pair immediately (step 5). Incubate the other sample from each pair for 18 hr at room temperature before processing.

   With the longer incubation, one can monitor possible shifts in the steady state of actin assembly (changes in C_{SS}) that are induced by the protein.

5. Centrifuge 20 min at 400,000 × *g*, 20°C, using a tabletop ultracentrifuge. Remove and save supernatant, wash pellets and tube walls three times with 150 μl F-buffer, and resuspend pellets in 150 μl G-buffer.

6. Perform SDS-PAGE of the pellets and supernatants on a 12% gel to visualize full-size actin. Run samples in parallel with appropriate molecular mass standards for actin and the protein of interest (15,000 to 100,000 Da). Identify actin by its molecular weight (42 kDa).

   Under denaturing conditions, F- and G-actin migrate at the same level, but F-actin will be found in the pellet and G-actin will be in the supernatant.

7. Scan the gel and use a densitometer to evaluate the amount of protein bound to F-actin.

   If the protein binds to G-actin, it should cause depolymerization; the amount of G-actin will be greater in the supernatant after overnight incubation of the samples.

BASIC PROTOCOL 2

DIRECT BINDING TO G-ACTIN: FLUORESCENCE MEASUREMENTS

Actin can be fluorescently labeled using a variety of probes, such as 7-chloro-4-nitrobenzofurazane (NBD-Cl), pyrene, BODIPY, and *N*-iodoacetyl-*N*′-5sulfo-1-naphtyl-ethylenediamine (IAEDANS), that are differentially sensitive to local environments. Thus, binding of an actin-binding protein to the fluorescently labeled actin can lead to a change in fluorescence. The change in fluorescence (ΔF) reflects the fraction of actin in complex with the protein (Y) as follows:

$$Y = \Delta F/\Delta F_{max} = [\mathrm{PA}]/[A]_0$$

Equation 13.6.1

where ΔF_{max} is the maximal extent of change in fluorescence that is caused by the protein at a saturating actin concentration, [PA] is the concentration of the protein-actin complex, and $[A]_0$ is the total actin concentration.

Several fluorescent labels should be tried (see Support Protocols 2 and 3 for two examples), to determine which is best suited to the purpose (see Troubleshooting). This assay may be performed with ATP-G-actin or ADP-G-actin to determine which actin species is preferentially bound by the protein. For example, β-thymosins and profilin prefer ATP-actin, whereas ADF/cofilin and twinfilin prefer ADP-actin.

Materials

1.5 μM 100% fluorescently labeled G-actin in G-buffer (see Support Protocols 2 and 3)
Actin-binding protein of interest in G-buffer (see recipe)
Spectrofluorometer (time base mode) at wavelengths appropriate for label.

1. Using a spectrofluorometer, record emission and excitation spectra of 1.5 μM fluorescently labeled G-actin in the absence and in the presence of a saturating amount of an actin-binding protein of interest in G-buffer. Choose the set of excitation and emission wavelengths at which the largest change is observed upon association of actin with the protein.

   A protein is at a saturating amount when its concentration is about ten times its K_d.

   For NBD-labeled actin, $\lambda_{ex} = 475$ nm and $\lambda_{em} = 530$ nm; for IDEDANS-labeled actin, $\lambda_{ex} = 340$ nm and $\lambda_{em} = 410$ nm; and for prenyl-labeled actin, $\lambda_{ex} = 366$-nm and $\lambda_{em} = 407$.

   This protocol can also be carried out in F-buffer (see recipe) to determine the effect of ionic strength on binding.

2. Measure the fluorescence of 1.5 μM fluorescently labeled G-actin alone and in the presence of increasing amounts of the actin-binding protein across a range of 0 to 100 μM.

This protocol is suitable if the K_d is in the 0.5- to 10-μM range. If the K_d is much lower, the experiment should be carried out at a lower actin concentration (~0.1 μM) and with a lower range of protein concentrations (0 to 1 μM). For proteins with an unknown K_d, the entire range should be tested at first, with a subsequent finer resolution of solution concentrations tested once an approximate K_d is known.

3. Plot the change in fluorescence versus the protein concentration and perform data analysis.

If a simple 1:1 complex (PA) is formed between actin (A) and the protein (P), then the value of the equilibrium dissociation constant for the PA complex, K_p, can be derived from analysis of the fluorescence curve:

$$\Delta F/\Delta F_{max} = \left\{ \begin{array}{l} [A]_0 + [P]_0 + K_P \pm \\ \left(\{[A]_0 + [P]_0 + K_P\}^2 - 4[P]_0 \times [A]_0\right)^{1/2} \end{array} \right\} / 2[A]_0$$

Equation 13.6.2

where $[P]_0$ is the total protein concentration.

This method is useful to measure K_p in the range of 0.1 to 10 μM. To obtain a reliable value of K_p, the concentration of G-actin in the assay should be as close as possible to the value of K_p. A few preliminary trials at different actin concentrations are advisable.

BINDING TO ACTIN DERIVED FROM A CHANGE IN THE RATE OF NUCLEOTIDE DISSOCIATION FROM G-ACTIN

BASIC PROTOCOL 3

Many G-actin-binding proteins affect the rate of nucleotide exchange on G-actin. For instance, profilin increases the rate of nucleotide dissociation from G-actin, whereas β-thymosins and cofilin slow it down. On the condition that the protein (P) shuttles more rapidly between actin molecules (A) than nucleotide dissociates from either actin or the PA complex, the change in the observed first-order rate constant for nucleotide dissociation upon increasing the concentration of protein reflects the saturation of actin by the protein.

Dissociation of G-actin-bound ATP can be monitored by the increase in etheno-ATP (ε-ATP) fluorescence that takes place upon addition of a 10-fold molar excess of ε-ATP to the ATP-G-actin 1:1 complex. The fluorescence of ε-ATP increases 6-fold upon binding to G-actin. Because ATP dissociation from G-actin is rate limited by dissociation of the bound metal ion (the Ca^{2+} ion in G_0-buffer, which is G-buffer without ATP) and is affected by ionic strength, all measurements performed in the absence and presence of the actin-binding protein should be carried out under identical ionic conditions (i.e., the protein to be tested must be equilibrated in the G_0-buffer used for the assays).

Materials

50% suspension of Dowex-1-X8 (Sigma) *or* AG-1-X8 (Bio-Rad) strong anion exchange resin in G_0-buffer
50 μM G-actin in G-buffer (see Support Protocol 1)
G_0-buffer: G-buffer (see recipe) without ATP
1 mM etheno-ATP (ε-ATP), pH adjusted to 7.2 with NaOH, stock solution (Sigma)
100 μM protein of interest in 10 mM Tris·Cl (pH 7.5)/1 mM dithiothreitol (DTT)
Microcentrifuge, 4°C
Spectrophotometer and quartz cuvettes
Spectrofluorometer (time base mode): $\lambda_{ex} = 350$ nm, $\lambda_{em} = 410$ nm, slits = 5- to 10-nm band width

1. Add 150 µl of a 50% Dowex-1-X8 suspension in G_0-buffer to 1 ml of 50 µM G-actin in a 1.5-ml microcentrifuge tube. Incubate 30 sec on ice while rotating the tube to mix actin and Dowex-1-X8. Microcentrifuge 1 min at 10,000 × *g*, 4°C, and transfer supernatant to a clean tube.

2. Repeat step 1 with 150 µl fresh Dowex-1-X8.

   The supernatant should contain ATP-G-actin in a 1:1 complex.

3. Measure the UV spectrum in a spectrophotometer to determine whether free ATP has been removed.

   The maximum of the UV spectrum should shift from 260 nm (typical of ATP) to 280 nm (typical of protein) and should show a minimum at 250 nm.

   Most generally no dilution is required, even when using a 1-cm path cuvette. If the absorbance of the sample is larger than 3.0 at the peak, the authors generally use a smaller path cuvette (e.g. 0.2 cm) rather than diluting, and thus losing, an aliquot of the sample.

   If ATP has not been totally removed, the Dowex treatment should be repeated.

4. Use the absorbance at 290 nm to measure the concentration of ATP-G-actin 1:1 complex ($\varepsilon = 0.617$ cm^2/mg at 290 nm).

   The absorbance at 278 nm is 1.97-fold higher.

5. Dilute ATP-G-actin (1:1 complex) to 2 µM in G_0-buffer. Mix together 50 µl of 2 µM ATP-G-actin and 49 µl G_0-buffer in a 1.5-ml microcentrifuge tube. Transfer solution to a microcuvette. At time zero, add 1 µl of 1 mM ε-ATP (10 µM final) to start the exchange reaction. Monitor and record the increase in fluorescence (~50% increase) at 410 nm (excitation wavelength, 350 nm) in a spectrofluorometer.

   For G-actin in Ca^{2+}-containing buffer at a low ionic strength, dissociation of ATP follows the rate-limiting dissociation of bound metal ion. The rate of dissociation therefore varies with the concentration of free Ca^{2+} (Nowak et al., 1988; Valentin-Ranc and Carlier, 1989), and the measurement period will need to be adjusted accordingly.

6. Prepare 10 dilutions of the protein of interest using G_0-buffer to final concentrations of 0 to 50 µM in a final volume of 50 µl.

7. Repeat step 5, replacing G_0-buffer with the protein of interest diluted in G_0-buffer.

   An actin-binding protein that binds ATP-G-actin would be expected to cause an increase or a decrease in the rate of ATP association.

8. To measure the change in rate of ATP dissociation, derive the first-order rate constant (k_{obs}) at different concentrations of the protein.

   The time course of ATP dissociation is a monoexponential process. The change in k_{obs} versus the total concentration of the protein reflects the formation of the PA complex.

9. Determine *Y*, the fraction of actin in complex with the protein, as follows:

$$Y = \left(k_{obs} - k_{obs}^{0}\right) / \left(k_{obs}^{\infty} - k_{obs}^{0}\right)$$

Equation 13.6.3

where k_{obs}^{0} and k_{obs}^{∞} are the rate constants measured in the absence of protein and in the presence of a saturating amount of protein, respectively, and $[P]_0$ is the total concentration of protein. To derive K_P, plot *Y* versus $[P]_0$ as described in Equation 13.6.2 (Perelroizen et al., 1995).

STEADY-STATE MEASUREMENTS OF ACTIN ASSEMBLY: CRITICAL CONCENTRATION PLOTS

The 25-fold increase in fluorescence of pyrenyl-labeled actin linked to the G-to-F transition is the most accurate and convenient tool for measuring the critical concentration (C_{ss}) for actin polymerization at the barbed and pointed ends.

Materials

50 μM pyrenyl-labeled G-actin (see Support Protocol 2), 10% labeled
G-buffer (see recipe)
Gelsolin solution: 100 μM gelsolin (Sigma) in 10 mM Tris·Cl (pH 7.5)/1 mM dithiothreitol (DTT), for assaying actin with capped barbed ends only
Protein of interest
KM solution: 500 μl of 4 M KCl/20 μl of 1 M $MgCl_2$ (*APPENDIX 2A*)
Spectrofluorometer (time base mode): $\lambda_{ex} = 360$ nm, $\lambda_{em} = 407$ nm, slits = 5- to 10-nm band width

1a. *To assay actin with free barbed ends:* Dilute 200 μl of 50 μM pyrenyl-labeled G-actin to 1 ml with G-buffer (continue with step 2).

1b. *To assay actin with capped barbed ends:* To pretreat a 50 μM pyrenyl-labeled G-actin solution, mix together the following:

200 μl of 50 μM pyrenyl-labeled G-actin (10 μM final)
800 μl G-buffer
0.4 μl gelsolin solution (0.4 μM final).

Gelsolin needs calcium; EGTA must not be present in any solutions used for this assay.

2. To polymerize actin, add 50 μl KM solution (5%, v/v) to 1 ml untreated or gelsolin-pretreated G-actin (step 1a or 1b).

Two complementary types of assays will be carried out. In the first (step 3), the total actin concentration is varied in the presence of a constant amount of the protein of interest. In the second (step 4), actin is maintained at a given concentration, whereas the concentration of the protein of interest is varied.

3. Prepare fifteen dilutions of F-actin from 0 to 2 μM in F-buffer along with a single concentration of the protein of interest. The final volume should be 100 μl. Be sure to include control samples that do not contain the protein.

4. Prepare twelve dilutions of the protein of interest (e.g., from 0 to 10 or 20 μM) in F-buffer along with a single concentration of F-actin. The final volume should be 100 μl.

5. Incubate all samples overnight in the dark either at room temperature or at 4°C, depending on the stability of the protein of interest.

6. Add 10 μl of each protein dilution to a sample tube (step 2). Add 5 μl KM solution to all 20 tubes and incubate overnight at room temperature.

7. Read fluorescence of pyrenyl-actin from control and sample tubes in a spectrofluorometer.

8. Plot fluorescence intensity versus either total actin concentration (samples from step 3) or concentration of the protein of interest (samples from step 4) and determine C_{ss}.

The increase in pyrenyl-actin fluorescence is proportional to the amount of F-actin assembled. Fluorescence increases linearly with actin concentration. The slope is very low when actin is monomeric and 25-fold higher when actin is polymerized. C_{ss} is defined as the total actin concentration at which a large change in slope takes place (i.e., above which actin polymerizes).

Under physiological ionic conditions, a value of 0.1 μM is measured for C_{ss} when barbed ends are free, and 0.6 μM when barbed ends are capped. The value of 0.6 μM is the critical concentration (C_c) at the pointed ends. The value of 0.1 μM is slightly above the C_{ss} at the barbed ends, because pointed ends also contribute to assembly. Because the contribution of barbed ends is largely predominant, however, it is routinely considered that 0.1 μM is very close (within 15%) to the C_{ss} at the barbed ends.

BASIC PROTOCOL 5

INITIAL RATE OF FILAMENT GROWTH AT BARBED OR POINTED ENDS

Initial rates of filament growth at barbed ends are measured spectrofluorometrically using spectrin-actin seeds or F-actin filaments. Growth at pointed ends is measured using gelsolin-actin seeds [i.e., the gelsolin(actin)$_2$ (GA_2) tight complex] or gelsolin-capped filaments.

Materials

Actin seeds (choose one):
- 100 nM gelsolin-actin (for pointed-end growth): add 2.5 molar equiv G-actin to gelsolin in G-buffer
- 5 nM spectrin-actin isolated from human blood (Casella et al., 1986; for barbed-end growth) in G-buffer
- 5 μM F-actin (with or without 20 nM gelsolin)

KME solution (see recipe)

5 μM pyrenyl-labeled (10%) G-actin (see Support Protocol 2)

G-buffer (see recipe)

100 μM protein of interest in 10 mM Tris·Cl (pH 7.5)/1 mM dithiothreitol (DTT)

Microcuvettes suitable for spectrofluorometer

Spectrofluorometer (time base mode): $\lambda_{ex} = 366$ nm, $\lambda_{em} = 407$ nm, slits = 5- to 10-nm band width

Additional reagents and equipment to generate a calibration curve (see Basic Protocol 4)

1. Mix the following in a microcuvette:
   - 51 μl G-buffer
   - 4 μl actin seeds (final 4 nM for gelsolin-actin, 0.2 nM for spectrin-actin, or 0.2 μM for F-actin)
   - 5 μl KME solution
   - 40 μl 5 μM pyrenyl-labeled G-actin.
2. Immediately place the cuvette in a spectrofluorometer (time zero) and read the increase in fluorescence at 407 nm versus time for a few minutes.
3. Repeat the assay (steps 1 and 2) in the presence of the protein of interest at various concentrations (about twelve to fifteen different concentrations in a final range of 0 to 100 nM for a K_d in the nanomolar range and 0 to 100 μM for a K_d in the micromolar range), diluted from a 100 μM solution. Adjust the amount of G-buffer added to the assay to keep a final volume of 100 μl.

   For proteins with an unknown K_d, the entire range should be tested at first, with a subsequent finer resolution of solution concentrations tested once an approximate K_d is known.

4. Determine the initial rate of fluorescence increase in absorbance units (arbitrary unit of fluorescence intensity) per second (AU/sec) and convert to molar amount of F-actin assembled per second using a calibration curve (see Basic Protocol 4).

The initial rate of actin assembly or velocity (V) measured when filaments or seeds at a concentration [F] are placed in a solution of G-actin at concentration C is

$$V = k_+[F] \times \left(C - k_-\right)$$

Equation 13.6.4

$$V = k_+[F] \times \left(C - C_C\right)$$

Equation 13.6.5

Where k_+ and k_- are the rate constants for G-actin association to and dissociation from, respectively, the filament end, and C_c is the critical concentration (k_-/k_+). The effect of the protein on V provides insight into its function. Barbed-end capping and G-actin sequestering functions give different results (see Anticipated Results).

MEASUREMENT OF DILUTION-INDUCED DEPOLYMERIZATION OF FILAMENTS

BASIC PROTOCOL 6

The depolymerization rate of actin filaments is monitored by the decrease in pyrenyl fluorescence upon dilution of the solution of pyrenyl-labeled F-actin in F-buffer to a final actin concentration that is lower than the critical concentration (C_{ss}). When depolymerization from the pointed end is to be measured, gelsolin-capped filaments are used.

Materials

G-buffer (see recipe)
4 M KCl
100 mM $MgCl_2$ (*APPENDIX 2A*)
50 μM G-actin in G-buffer (see Support Protocol 1)
50 μM G-actin, 50% to 100% pyrenyl labeled in G-buffer (see Support Protocol 2)
Gelsolin solution: 100 μM gelsolin in 10 mM Tris·Cl (pH 7.5)/1 mM dithiothreitol (DTT), for assaying depolymerization from pointed ends only
100 μM protein of interest in 10 mM Tris·Cl (pH 7.5)/1 mM DTT
F-buffer (see recipe)

Microcuvettes, suitable for spectrofluorometer
Spectrofluorometer (time base mode): $\lambda_{ex} = 366$ nm, $\lambda_{em} = 407$ nm, slits = 5- to 10-nm band width

1a. *To measure total depolymerization from the actin filament:* Mix together the following in a 1.5-ml microcentrifuge tube:

865 μl G-buffer
25 μl 4 M KCl (0.1 M final)
10 μl 100 mM $MgCl_2$ (1 mM final)
50 μl 50 μM G-actin (5 μM final)
50 μl 50 μM pyrenyl-labeled G-actin (5 μM final).

Incubate 30 min at room temperature.

1b. *To measure depolymerization from the pointed end of the actin filament:* Mix together the same reagents as in step 1a but add 0.2 μl gelsolin solution (20 nM final gelsolin concentration). Incubate 1 hr at room temperature.

Gelsolin needs calcium; EGTA must not be present in any solutions used for this assay. A longer incubation allows a more complete exchange of calcium and magnesium.

Steps 1a and 1b yield 50% pyrenyl-labeled F-actin at 5 μM.

2. Dilute a 100 μM solution of the protein of interest in F-buffer as needed to generate stock solutions to add to the assay. Generate stocks that will give twelve to fifteen different concentrations in a final range of 1 to 100 nM for a K_d in the nanomolar range and 0 to 100 μM for a K_d in the micromolar range.

   For proteins with an unknown K_d, the entire range should be tested at first, with a subsequent finer resolution of solution concentrations tested once an approximate K_d is known.

3. At time zero, dilute 2 μl of the 5 μM actin solution (step 1a or 1b) 100-fold in F-buffer in a spectrofluorometer microcuvette and measure the decrease of pyrenyl fluorescence in a spectrofluorometer in the absence or in the presence of the protein of interest at various concentrations. Record the change in fluorescence for a few minutes.

   Total depolymerization occurs because the final actin concentration (50 nM) is lower than the critical concentration (0.1 μM).

4. Plot the change in fluorescence versus time. Calculate the initial rate of depolymerization from the slope of the time-dependent decrease in pyrenyl fluorescence.

5. Plot a calibration curve of the fluorescence of pyrenyl-labeled F-actin versus total actin concentration. Convert fluorescence units into micromolar F-actin and then express the initial rate of depolymerization in micromolar per second.

BASIC PROTOCOL 7

MEASUREMENTS OF THE TREADMILLING OF ACTIN FILAMENTS

The turnover of filaments is evaluated by measuring the rate at which fluorescently labeled etheno (ε)-ADP-F-actin filaments assemble from ε-ATP-G-actin subunits and become nonfluorescent ADP-F-actin filaments after addition of ATP to the medium. Turnover occurs via the consecutive steps of dissociation of ε-ADP-actin from the pointed end, exchange of ATP for bound ε-ADP on G-actin in the medium, and association of ATP-G-actin to barbed ends. The fluorescence of ε-ADP is 6-fold lower in the free state than it is in the actin-bound state.

Materials

50% (w/v) suspension of Dowex-1-X8 (Sigma) *or* AG-1-X8 (Bio-Rad) strong anion exchange resin in G_0-buffer
50 μM G-actin in G- buffer (see Support Protocol 1), store on ice
5 mM etheno-ATP (ε-ATP), pH adjusted to 7.2 with NaOH, stock solution (Sigma)
KME solution (see recipe)
G-buffer (see recipe)
100 μM protein of interest in 10 mM Tris·Cl (pH 7.5)/1 mM dithiothreitol (DTT)
200 mM ATP, pH adjusted to 7.2 with NaOH, stock solution (Sigma)

Microcentrifuge, 4°C
Spectrophotometer microcuvette, suitable for spectrofluorometer
Spectrofluorometer (time base mode; PM voltage adequate): $\lambda_{ex} = 350$ nm, $\lambda_{em} = 410$ nm, slits = 5- to 10-nm band width

1. Add 150 μl of a 50% Dowex-1-X8 suspension in G_0-buffer to 1 ml of 50 μM G-actin in a 1.5-ml microcentrifuge tube. Incubate 30 sec at 0°C. Microcentrifuge 1 min at 10,000 × *g*, 4°C, and transfer supernatant to a clean tube.

2. Repeat step 1 with 150 μl fresh Dowex-1-X8.

   The supernatant should contain ATP-G-actin in a 1:1 complex.

3. Add 50 μl of 5 mM ε-ATP (0.25 mM final). Let the solution sit overnight on ice to allow exchange of ε-ATP for bound ATP.

4. Repeat steps 1 and 2 to obtain ε-ATP-G-actin in a 1:1 complex. Measure concentration of G-actin spectrophotometrically (see Basic Protocol 3, steps 3 and 4).
5. Add 5 mM ε-ATP to make a final concentration of 50 μM free ε-ATP.
6. In a 1.5-ml microcentrifuge tube, mix together ε-ATP-G-actin (5 μM final) and 5% (v/v) KME buffer along with G-buffer as needed.

   Adding 5% (v/v) KME buffer will lead to polymerization, yielding ε-ATP-F-actin.
7. Divide the sample in 100-μl aliquots among several tubes. Add 100 μM protein of interest to individual tubes to cover a final range of 0 to 50 μM. Adjust volumes as needed with G-buffer.

   This step is used to test the effects of actin depolymerizing factor (ADF), profilin, or other proteins.
8. Transfer each sample to a spectrofluorometer microcuvette and measure its ε-ATP fluorescence intensity in a spectrofluorometer at 410 nm. At time zero, add 0.25 μl of 200 mM ATP (500 μM final).
9. Record the decrease in ε-ATP fluorescence using a time-based scan over at least 2 hr. Determine the rate of fluorescence decrease, which provides an indication of filament turnover.

ACTIN PURIFICATION FROM RABBIT MUSCLE

SUPPORT PROTOCOL 1

Actin for these protocols is purified from an acetone powder of rabbit muscle. Actin is also available commercially (Cytoskeleton). To prepare commercially purchased actin for the other protocols in this unit, follow the manufacturer's instructions.

Materials

Acetone powder of rabbit muscle (Cytoskeleton)
Extraction buffer (see recipe), 4°C
Solid KCl and 4 M KCl
Buffer D1 (see recipe)
1 M $MgCl_2$ (*APPENDIX 2A*)
G-buffer (see recipe)

500-ml beaker
Sorvall centrifuge and A641 rotor (or equivalent), 4°C
Glass wool
20°C water bath
Large (3-cm wide) dialysis bags (MWCO 14,000)
Dounce homogenizer (glass-Teflon; 20-ml working volume)
Sonicator with microtip (e.g., Vibra-cell; Sonics & Materials)
10-ml ultracentrifuge tubes
Beckman ultracentrifuge and 70.1 Ti rotor (or equivalent), 4°C
2.5 × 100–cm gel filtration column (Superdex-200 prep grade; Amersham Biosciences)
Spectrophotometer (290 nm) and quartz cuvettes

Extract actin

1. Place 9 g acetone powder in a 500 ml beaker on ice and slowly add 270 ml cold extraction buffer while gently stirring with a glass rod to thoroughly wet powder. Let sit on ice for 30 min, stirring gently once every 10 min.

   Gentle stirring minimizes α-actinin extraction.

2. Centrifuge 45 min at 25,000 × *g*, 4°C, in a Sorvall A641 rotor. Filter supernatant through glass wool into a graduated cylinder and measure volume.

3. Transfer filtrate to a beaker. Add solid KCl to 3.3 M while stirring (add KCl all at once).

   The KCl adds ~10% to the volume, which must be figured in when deciding how much KCl to add (usually 55 to 57 g for ~220 ml).

4. Place in a 20°C water bath and stir until temperature reaches 15°C. Place on ice without stirring until temperature returns to 5°C. Centrifuge 30 min at 25,000 × *g*, 4°C.

   A tight white pellet indicates the presence of actin-α-actinin networks.

5. Filter supernatant through glass wool, transfer to a large dialysis bag, and dialyze overnight at 4°C against 32 vol (usually 6 to 8 liters) buffer D1.

Release tropomyosin from F-actin

6. Add 4 M KCl to a final concentration of 0.8 M (0.22 vol of 4 M KCl) and stir for 1.5 hr at 4°C.

7. Centrifuge 3.5 hr at 100,000 × *g*, 4°C, in the Sorvall A641 rotor. Decant and discard supernatant. Dislodge pellet and transfer to a Dounce homogenizer, using 25 ml (total) extraction buffer to transfer pellet and clean centrifuge tube.

8. Homogenize pellet with 20 strokes while keeping homogenizer on ice.

9. Add 75 µl of 1 M $MgCl_2$ and 375 µl of 4 M KCl and adjust the volume to 38.6 ml with extraction buffer. Leave at 4°C overnight without stirring.

10. Add 9 ml of 4 M KCl and 2.37 ml extraction buffer and stir for 1.5 hr at 4°C. Centrifuge 3.5 hr at 100,000 × *g*, 4°C.

11. Resuspend pellets with 20 to 30 ml extraction buffer and homogenize as described (step 8).

12. Dialyze against 2 liters G-buffer for 2 days at 4°C with one change of buffer.

13. Insert microtip of a sonicator into dialysis bag, sonicate twice for 30 sec each on low-power setting. Reclose bag, change dialysis buffer, and continue dialysis one additional day.

Purify actin

14. To clarify actin, transfer to 10-ml ultracentrifuge tubes and centrifuge 2 hr at 400,000 × *g*, 4°C, in a Beckman 70.1 Ti rotor.

15. Load supernatant onto a 2.5 × 100–cm gel filtration column. Run 2 liters G-buffer through column at 1 ml/min 4°C. Collect 5-ml fractions.

16. Read A_{290} of each fraction in a spectrophotometer and pool the fractions showing an absorbance at 290 nm.

17. Determine the concentration of G-actin in the pooled fractions using A_{290} as follows:

$$C = \left(A_{290} / .0617\right) / 42$$

Equation 13.6.6

where *C* is the actin concentration in milligrams per milliliter.

18. Store actin on ice for up to 3 weeks

The typical yield of this preparation is 40 ml of 50 μM (2.1 mg/ml) G-actin (mol. wt. = 42 kDa).

PREPARATION OF PYRENYL-LABELED ACTIN

SUPPORT PROTOCOL 2

N-pyrenyliodoacetamide (NPI) is a fluorescent compound that can be used to label actin specifically on Cys374. Its fluorescence changes in response to the local environment; in particular, it increases 25-fold upon polymerization of G-actin into F-actin. Pyrenyl-labeled actin can also be used to monitor binding of proteins to actin.

Additional Materials *(also see Support Protocol 1)*

4 mg/ml (~95 μM) G-actin in G-buffer (see Support Protocol 1)
Buffer A (see recipe)
N-pyrenyliodoacetamide (NPI; Sigma)
Dimethylformamide
0.2 M dithiothreitol (DTT; *APPENDIX 2A*)
Rotating wheel, 4°C

1. Mix 10 ml of 4 mg/ml G-actin and 10 ml buffer A. Incubate 1 hr at 25°C (room temperature) to polymerize actin.
2. Transfer polymerized actin (F-actin) to a large dialysis bag and dialyze overnight against 2 liters buffer A at 4°C.

   As NPI is destroyed by the light, all labeling steps must be carried out in the dark.

3. Prepare 1 ml solution of 14 mg/ml NPI in dimethylformamide in a 1.5-ml microcentrifuge tube. Add 0.2 ml NPI solution to 20 ml F-actin (step 2) in a 50-ml conical centrifuge tube wrapped with aluminum foil. Mix by inverting the tube several times. Incubate overnight on a rotating wheel in the dark at room temperature.

   The solution becomes white after mixing because of insoluble NPI.

4. Add 50 μl of 0.2 M DTT to stop the reaction. Centrifuge 15 min at 1,000 × *g*, 4°C, to remove excess insoluble NPI.
5. Centrifuge supernatant 3.5 hr at 100,000 × *g*, 4°C in a Sorvall A641 rotor.
6. Dislodge the actin pellet and resuspend with 5 ml G-buffer. Homogenize with 20 strokes of a Dounce homogenizer on ice.
7. Continue with actin purification as described (see Support Protocol 1, steps 12 to 18), except dialyze against 1 liter G-buffer in steps 12 and 13 and perform all steps in the dark.

   G-actin thus prepared is 100% labeled. For a 10% labeled G-actin solution, 0.9× moles of regular unlabeled actin (see Support Protocol 1) is mixed with 0.1× moles of 100% pyrenyl-labeled G-actin in G-buffer.

PREPARATION OF 7-CHLORO-4-NITROBENZENO-2-OXA-1,3-DIAZOLE-LABELED ACTIN

SUPPORT PROTOCOL 3

7-Chloro-4-nitrobenzeno-2-oxa-1,3-diazole (NBD-Cl) is a fluorescent compound that can be used to label actin specifically on Lys373. Its fluorescence changes in response to the local environment. Thus, NBD-labeled actin can be used to monitor binding of proteins to actin. The fluorescence of NBD-labeled actin also increases 2.6-fold upon polymerization of G-actin into F-actin.

Additional Materials *(also see Support Protocol 1)*

0.1 M KCl (*APPENDIX 2A*)
50 μM G-actin in G-buffer (see Support Protocol 1)
100 mM *N*-ethylmaleimide (NEM), prepare fresh
20 mM dithiothreitol (DTT; *APPENDIX 2A*)
G-buffer (see recipe) with and without DTT and NaN_3
F-buffer (see recipe) without DTT and NaN_3
10 mM 7-chloro-4-nitrobenzeno-2-oxa-1,3-diazole (NBD-Cl) in dimethylformamide
15°C water bath

Label actin with NEM

1. Add 750 μl of 0.1 M KCl to 15 ml of 50 μM G-actin in G-buffer in a tube. Add 375 μl of 100 mM NEM (2.5 mM final), mix, and incubate as follows:

   15 min at room temperature
   15 min at 15°C
   3 hr at 0°C (on ice).

2. Stop the reaction by adding 375 μl of 20 mM DTT (5 mM final). Centrifuge 2 hr at 200,000 × *g*, 4°C a Beckman ultracentrifuge.

3. Discard supernatant and use 20 ml G-buffer with DTT and NaN_3 to resuspend pellet and transfer to a Dounce homogenizer. Homogenize pellet with 20 strokes on ice.

   The pellet contains NEM-F-actin.

Label NEM-actin with NBD

4. Transfer homogenized actin to a large dialysis bag and dialyze 2 days against 1 liter G-buffer without DTT and NaN_3 at 4°C.

5. Centrifuge 2 hr at 400,000 × *g*, 4°C, in the Beckman 70.1 Ti rotor.

   NEM-G-actin is in the supernatant.

6. Dilute supernatant 2-fold to a total volume of 30 ml with F-buffer without DTT and NaN_3. Let polymerize overnight at 4°C in the dark.

   The actin concentration should be at 1 to 2 mg/ml to optimize NBD labeling.

7. Add 1.2 ml of 10 mM NBD-Cl (0.4 mM final). Incubate 5 hr at 15°C.

Purify labeled actin

8. Centrifuge NBD-labeled F-actin 2 hr at 400,000 × *g*, 4°C. Homogenize pellet and dialyze as described (steps 3 and 4).

9. Centrifuge 2 hr at 20,000 × *g*, 4°C, in the Sorvall A641 rotor to eliminate aggregates.

   NBD-labeled G-actin is in the supernatant.

10. Purify actin as described (see Support Protocol 1, steps 14 to 18) except perform all steps in the dark.

    G-actin thus prepared is 100% labeled. For a 10% labeled G-actin solution, 0.9× moles of regular unlabeled actin (see Support Protocol 1) is mixed with 0.1× moles of 100% NBD-labeled G-actin in G-buffer.

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. Prepare all buffers 1 day in advance. Store at 4°C for up to 1 week. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Buffer A

20 ml 0.5 M Tris·Cl, pH 8 (5 mM final; *APPENDIX 2A*)
50 ml 4 M KCl (0.1 M final)
4 ml 1 M $MgCl_2$ (2 mM final; *APPENDIX 2A*)
1 ml 0.2 M $CaCl_2$ (0.1 mM final; *APPENDIX 2A*)
5 ml 0.2 M ATP (0.5 mM final)
1 ml 0.2 M dithiothreitol (DTT; 0.1 mM final; *APPENDIX 2A*)
H_2O to 2 liters

Buffer D1

2 mM Tris·Cl, pH 7.8 (*APPENDIX 2A*)
1 mM $MgCl_2$ (*APPENDIX 2A*)
1 mM dithiothreitol (DTT; *APPENDIX 2A*)

Extraction buffer

2 mM Tris·Cl, pH 7.8 (*APPENDIX 2A*)
0.5 mM ATP
0.1 mM $CaCl_2$ (*APPENDIX 2A*)
0.01% (w/v) NaN_3
1 mM dithiothreitol (DTT; *APPENDIX 2A*)

CAUTION: *Sodium azide is poisonous. Follow appropriate precautions for handling, storage, and disposal.*

F-buffer

G-buffer (see recipe) supplemented with 0.1 M KCl (*APPENDIX 2A*) and 1 mM $MgCl_2$ (*APPENDIX 2A*).

G-buffer

5 mM Tris·Cl, pH 7.8 (*APPENDIX 2A*)
0.2 mM ATP
0.1 mM $CaCl_2$ (*APPENDIX 2A*)
1 mM dithiothreitol (DTT; *APPENDIX 2A*)
0.01% (w/v) NaN_3

CAUTION: *Sodium azide is poisonous. Follow appropriate precautions for handling, storage, and disposal.*

G_0-buffer is G-buffer without ATP.

KME solution

500 µl 4 M KCl (2 M final)
20 µl 1 M $MgCl_2$ (20 mM final; *APPENDIX 2A*)
16 µl 250 mM EGTA (4 mM final)
464 µl H_2O

To polymerize actin, 0.5% (v/v) KME solution is added to G-actin (final 0.1 M KCl, 1 mM $MgCl_2$, 0.2 mM EGTA).

COMMENTARY

Background Information

G-actin-sequestering proteins

G-actin sequesterers bind G-actin in a non-polymerizable complex. β-Thymosins are the most abundant typical G-actin-sequestering proteins (Cassimeris et al., 1992; Safer and Nachmias, 1994). The β-thymosin-actin complex associates with neither the barbed nor the pointed end of the filament, and thus β-thymosins do not affect filament assembly dynamics or motility. It is often thought that these proteins buffer the free ATP-G-actin concentration in cells. On the contrary, both in vitro and in vivo evidence shows that β-thymosins react passively to changes in the steady-state concentration of free G-actin (Carlier et al., 1993; Safer and Nachmias, 1994).

Profilin and profilin-like proteins

Profilin also binds G-actin but acts differently from sequestering proteins. The profilin-actin complex associates productively with the barbed end (the dynamic end of the actin filament) but not with the pointed ends of the filaments (Pantaloni and Carlier, 1993). Thus, profilin merely sequesters actin when all barbed ends are capped but enhances barbed-end growth as soon as a few of them are not capped. Recently, other proteins like the β-thymosin repeat proteins and, more generally, the actin-binding WH2 (WASP-homology 2) domains, which are inserted in a number of proteins involved in motility, have been found to behave functionally like profilin (Egile et al., 1999; Boquet et al., 2000). As a result, profilin and its functional homologs improve the processivity of treadmilling in synergy with actin depolymerizing factor (ADF) and so enhance actin-based motility (Loisel et al., 1999; Paunola et al., 2002).

Capping proteins

Capping proteins bind tightly to the barbed end and block actin association and dissociation (Hug et al., 1995; Sun et al., 1995). Capping proteins are required for efficient motility of many cells. By blocking a large fraction of the barbed ends at the steady state of actin assembly, capping proteins funnel the treadmilling process: pointed-end depolymerization of many capped filaments feeds the growth of a few noncapped filaments, which individually grow faster than if the other filaments were not capped. Capping proteins cooperate with ADF to accelerate actin-based motility.

ADF/cofilin proteins

ADF/cofilin proteins are essential proteins in morphogenetic and motile processes. ADF/cofilin increases the turnover of actin filaments, which powers actin-based motility (Didry et al., 1998; Carlier et al., 1999). The

Figure 13.6.2 *(at right)* Functional assays of a G-actin-sequestering protein. (**A**) Steady state measurements of F-actin in the presence of increasing amounts of the sequestering protein (see Basic Protocol 4). F-actin (1.5 μM, 10% pyrenyl labeled) with free barbed ends (solid line) or gelsolin-capped barbed ends (dashed line) was supplemented by the protein as indicated. Linear depolymerization was consistent with a K_d of 2 μM. (**B**) Steady-state measurements of F-actin in the presence of the sequestering protein. Experiments were conducted as in A at 2, 1.5, and 1 μM F-actin with free barbed ends. The parallel straight lines are consistent with a K_d of 2 μM. (**C**) Critical-concentration (C_{ss}) measurements for actin alone or in the presence of 2 μM sequestering protein. The sequestering protein shifts C_{ss} for both free and capped barbed ends, in agreement with the K_d obtained in B. Solid line, free barbed ends alone; short-dashed line, capped barbed ends alone; dotted line, free barbed ends with sequestering protein; long-dashed line, capped barbed ends with sequestering protein. (**D**) Depolymerization rate measurements (see Basic Protocol 6). The solution of 2.5 μM F-actin (50% pyrenyl labeled) with free barbed ends was diluted 20-fold in F-buffer at time zero in the absence (solid line) and presence (dotted line) of 10 μM sequestering protein. The sequestering protein has no effect on actin depolymerization. (**E**) The sequestering protein inhibits pointed-end growth of actin filaments (see Basic Protocol 5). The rate of pointed-end growth was measured in the presence of 2.5 μM Mg-ATP-G-actin, 2 nM gelsolin-actin seeds, and the sequestering protein at the indicated concentration. The inhibition observed is consistent with a K_d of 2 μM. (**F**) The sequestering protein inhibits barbed-end growth of actin filaments. The rate of barbed-end growth was measured in the presence of 2.5 μM Mg-ATP-G-actin and 0.16 nM spectrin-actin seeds. The inhibition observed is consistent with a K_d of 2 μM, as in E. (**G**) Co-sedimentation assay (see Basic Protocol 1). F-actin (10 μM) was sedimented alone or in the presence of increasing amounts of the sequestering protein. The sequestering protein depolymerizes F-actin, leading to an increasing amount of G-actin in the supernatant (S) and less G-actin in the pellet (P). Lines shown in A-F represent typical experimental curves, derived from known proteins (e.g., thymosin β_4).

function of ADF/cofilin proteins is complex because under physiological ionic conditions, ADF/cofilin recognizes the ADP-bound form of both F- and G-actin with a 100-fold higher affinity than ATP-bound actin. ADF/cofilin modifies both the structure and the assembly dynamics of filaments. (1) The rate of dissociation of ADF-F-actin from the pointed ends (the rate-limiting step in treadmilling) is 30-fold higher than the rate of dissociation of F-actin. (2) The dissociation of ADP from ADF-G-actin is 10- to 20-fold slower than the dissociation of ADP from G-actin. The combination of these two properties affects actin dynamics at steady state. The physiologically relevant effect of ADF in actin-based motility is to enhance treadmilling by increasing the rate-limiting step in the ATPase cycle of actin.

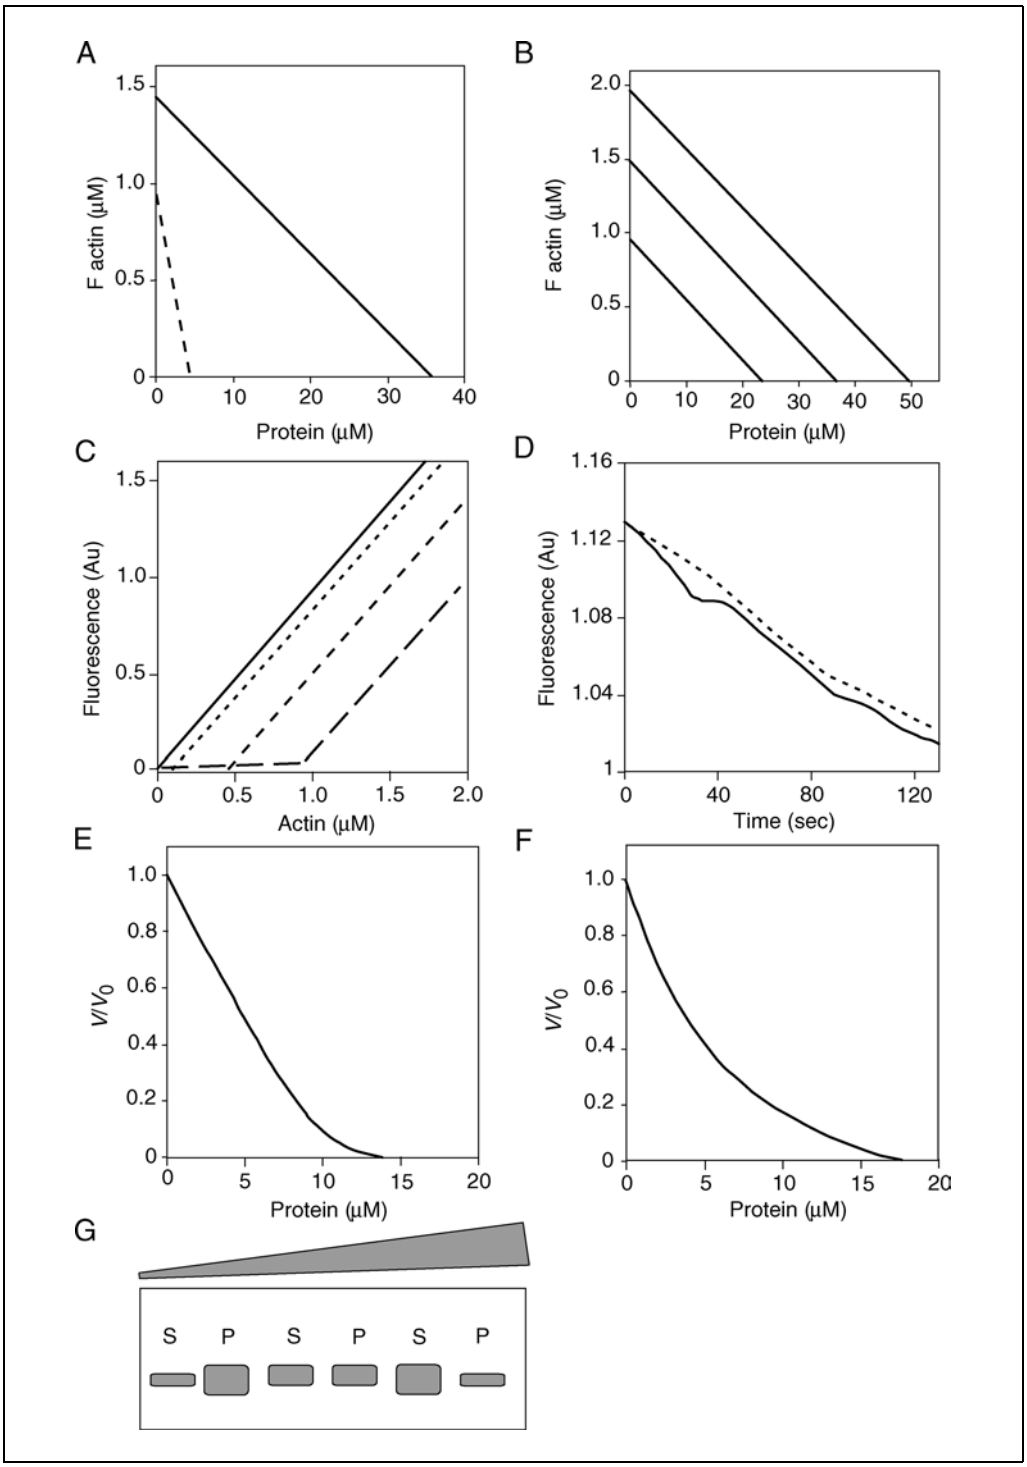

Figure 13.6.2 Legend at left.

Troubleshooting

Because in many protocols pyrenyl-labeled or NBD-labeled actin is used, it is important to check that measurements of F-actin concentrations using these probes are not biased by possible changes in fluorescence of labeled actin upon binding by the protein of interest. For instance, ADF quenches the fluorescence of NBD- and pyrenyl-F-actin, hence alternative measurements (e.g., using light scattering or sedimentation) are required to elucidate the function of this protein. Some components, such as glycerol in a buffer, could also modify the fluorescence of labeled actin.

Labeling of actin may also affect its affinity for the protein to be tested (Uyemura et al., 1978). It is recommended to carry out tests at different percentages of labeled actin and to verify that the result is independent of the percentage of labeled actin in the mix. It is also appropriate to use competition assays to determine the affinity of labeled and unlabeled actin for the protein.

The solution of F-actin should be manipulated carefully to avoid breaking of filaments.

Anticipated Results

G-actin-sequestering proteins

In the presence of β-thymosin, both β-thymosin (T) and actin filaments (A) are at equilibrium with free G-actin at the steady state (critical) concentration, C_{ss}. The double equilibrium implies that the amount of TA complex formed at equilibrium in the presence of F-actin is determined by the value of C_{ss} and the total β-thymosin concentration, $[T]_0$, as follows (Fig. 13.6.2A):

$$[\mathrm{TA}] = \left([T]_0 \times C_{SS}\right) / \left(C_{SS} + K_T\right)$$

Equation 13.6.7

where K_T is the equilibrium dissociation constant of the TA complex.

According to this equation, sequestering proteins shift the critical concentration plots to a higher apparent value. The apparent critical concentration is the sum of C_{ss} and [TA] given by Equation 13.6.7. Parallel C_{ss} plots are obtained at different values of $[T]_0$ (Fig. 13.6.2C).

Changes in C_{ss} are elicited by proteins that affect the dynamics of assembly; these changes are amplified by sequestering proteins. For instance, capping proteins increase the value of C_{ss} up to the critical concentration at pointed ends (C_c). It is easy to see (Equation 13.6.7) that when more filaments are capped, more actin is sequestered at a given concentration $[T]_0$ (i.e., F-actin depolymerizes in the cell). In contrast, when the proportion of capped filaments is lowered by creation of new barbed ends, C_{ss} becomes lower; hence the pool of sequestered actin decreases and F-actin increases (e.g., upon platelet stimulation).

The ability of sequestering proteins to depolymerize F-actin in a manner that depends on the value of C_{ss} is used to determine the value of K_T. Addition of increasing amounts of β-thymosin to a given amount of F-actin causes depolymerization because of formation of TA with a linear dependence on $[T]_0$. The (negative) slope of the plot of F-actin versus $[T]_0$ is $C_{ss}/(C_{ss} + K_T)$, which is independent of the amount of actin. Hence at different concentrations of actin, the decreases in F-actin are parallel straight lines (Fig. 13.6.2B). The

Figure 13.6.3 *(at right)* Functional assays of profilin-like proteins (barbed-end assembly-promoting factors). (**A**) Steady-state measurements of F-actin in the presence of increasing amounts of profilin-like protein. The experiment was conducted as in Figure 13.6.1A. When barbed ends are capped (dashed line), the profilin-like protein depolymerizes F-actin. Linear depolymerization was consistent with a K_d of 2 μM. When the barbed ends are free (solid line), the profilin-like protein fails to depolymerize F-actin. (**B**) Critical-concentration (C_{ss}) measurements for actin alone and in the presence of 2 μM profilin-like protein. The experiment was conducted as in Figure 13.6.2C. Solid line, free barbed ends alone; short-dashed line, capped barbed ends alone; dotted line, free barbed ends with sequestering protein; long-dashed line, capped barbed ends with sequestering protein. (**C**) Profilin-like protein inhibits pointed growth of actin filaments. The inhibition is consistent with a K_d of 2 μM. The experiment was conducted as in Figure 13.6.2E. (**D**) The profilin-like protein fails to inhibit barbed-end growth of actin filaments. The experiment was conducted as in Figure 13.6.2F. (**E**) Co-sedimentation assay in the absence or presence of profilin-like protein. The experiment was conducted as in Figure 13.6.2G. (**F**) Depolymerization rate measurements in the absence (solid line) and presence (dotted line) of 10 μM profilin-like protein. The experiment was conducted as in Figure 13.6.2D. The profilin-like proteins have no effect on actin depolymerization. Lines shown in A-D and F represent typical experimental curves derived from known proteins (e.g., profilin).

slope is steeper when filaments are capped because the value of C_{ss} is higher. Analysis of the slopes of F-actin versus $[T]_0$ yields the same value of K_T, however, when barbed ends are free or capped. This property identifies a sequestering function.

In a co-sedimentation assay, sequestering proteins cause an accumulation of actin in the supernatant, which is dependent on the value of C_{ss} (i.e., it is greater when barbed ends are capped; Fig. 13.6.2G). The sequestering proteins are always present in the supernatants.

Sequestering proteins, in forming a non-polymerizable complex with actin, cause a decrease in the rate of filament growth when tested at a given G-actin concentration (Fig. 13.6.2D,F). The equilibrium dissociation constant for the TA complex is derived from the dependence of the elongation rate at barbed ends on $[T]_0$ using the following equation,

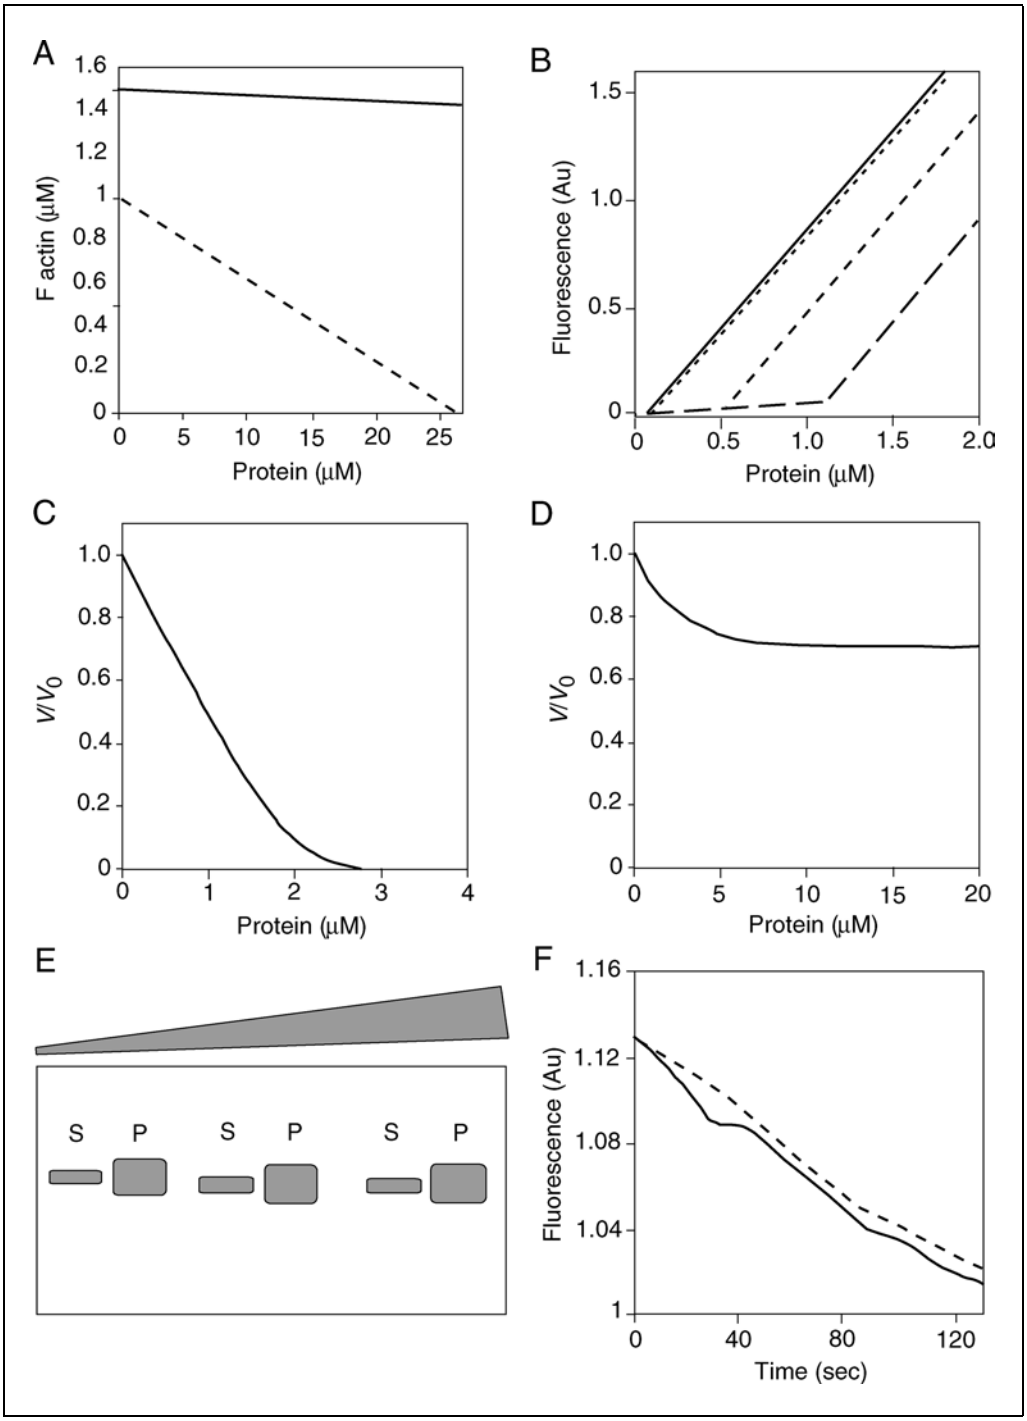

Figure 13.6.3 Legend at left.

which describes saturation of G-actin in the growth assay by the sequestering protein:

$$(V_0 - V)/V_0 = [TA]/[A]_0 = (/2[A]_0) \times \left\{ [A]_0 + [T]_0 + K_T \pm \left(\{[A]_0 + [T]_0 + K_T\}^2 - 4[A]_0[T]_0 \right)^{1/2} \right\}$$

Equation 13.6.8

where V is the initial rate of elongation measured at concentration $[T]_0$ of the sequestering protein, V_0 is the initial rate of elongation in the absence of the sequestering protein, $[A]_0$ is the total G-actin concentration (assumed for simplicity to be much higher than the critical concentration at the barbed end), and K_T is the equilibrium dissociation constant for the sequestering protein-actin complex. G-actin-sequestering proteins display no effect on the rate of depolymerization at either end of the filament (Fig. 13.6.2D).

Profilin and profilin-like proteins

At the steady state of assembly, when the barbed ends of filaments are capped, profilin-like proteins cause depolymerization of F-actin (Fig. 13.6.3). The amount of depolymerized actin increases linearly with the concentration of the protein, which is consistent with sequestration of Mg-ATP-G-actin by protein in a 1:1 complex and with an equilibrium constant as calculated with Equation 13.6.7; this behavior is typical of a sequestering protein. In contrast with sequestering proteins, however, profilin-like proteins fail to depolymerize F-actin when barbed ends are free, because the protein-actin (PA) complex participates in monomer-polymer exchanges at the barbed ends. Because both actin (A) and the PA complex contribute to stabilization of filament barbed ends, the presence of PA lowers the contribution of A (i.e., the partial critical concentration of A is lowered by profilin-like proteins; Fig. 13.6.3A,B).

Co-sedimentation assays confirm these conclusions. When barbed ends are free, profilin-like proteins fail to depolymerize F-actin, but depolymerization is readily observed if barbed ends are capped. Profilin-like proteins are present in the supernatant fraction (Fig. 13.6.3E). Finally, these proteins display no effect on the initial rate of depolymerization at either end of the filament (Fig. 13.6.3F).

In seeded growth assays, profilin-like proteins prevent association of actin to the pointed end of the filament (Fig. 13.6.3C). The equilibrium dissociation constant (0.2 μM for profilin) for the profilin-like PA complex was derived from the dependence of the elongation rate inhibition on the protein concentration with the same equation used for the sequestering protein (Equation 13.6.8).

Profilin-like proteins fail to prevent fully elongation at the barbed end of the filament because the PA complex productively associates with the barbed end. When the G-actin that is present in the growth assay is saturated by the protein, the rate constant for association of PA to the barbed end is derived from the growth rate measurements. For profilin, the value of k_+ is 30% lower than that for G-actin (Fig. 13.6.3D).

Capping proteins

In measurements of F-actin assembly at steady state, when capping protein is added

Figure 13.6.4 *(at right)* Functional assays of capping proteins. (**A**) Steady state measurements of F-actin in the presence of increasing amounts of capping protein. The experiment was conducted as in Figure 13.6.2A. When barbed ends are free (solid line), capping proteins depolymerize F-actin, partially blocking all barbed ends; the maximum amount of unpolymerized actin equals the critical concentration of the pointed end (C_c = 0.6 μM, under physiological conditions). When barbed ends are capped (dashed line), addition of another capping protein has no effect on the steady-state amount of F-actin; all barbed ends remain capped and C_{ss} remains equal to the C_c at the pointed ends. (**B**) C_{ss} measurements for actin alone or in the presence of capping proteins. The experiment was conducted as in Figure 13.6.2C. When barbed ends are capped, capping proteins have no effect on C_c. When barbed ends are free, capping proteins shift C_c to 0.6 μM, in physiological conditions. Solid line, free barbed ends alone; dotted line, free barbed ends with capping protein; dashed line, capped barbed ends alone or with capping protein. (**C**) Capping proteins do not inhibit pointed-end growth of actin filaments. The experiment was conducted as in Figure 13.6.2E. (**D**) Capping proteins inhibit barbed-end growth of actin filaments. The experiment was conducted as in Figure 13.6.2F. (**E**) Depolymerization rate measurements. The experiment was conducted as in Figure 13.6.2D. Capping proteins block depolymerization at the barbed end. Dotted line, no capping protein; solid lines, capping protein present at indicated concentrations. (**F**) Co-sedimentation assay. The experiment was conducted as in Figure 13.6.2G. At a saturating amount of capping protein, the amount of G-actin in the supernatant corresponds to the C_c at the pointed end. Lines shown in A-E represent theoretical lines in each case.

to a solution of F-actin with free barbed ends, partial depolymerization occurs until the critical concentration of the pointed ends (C_c^P) is reached. The amount of F-actin that disassembles therefore equals the difference $C_c^P - C_c^B$, at any F-actin concentration. Under physiological ionic conditions, this amount is 0.6 μM − 0.1 μM = 0.5 μM (Fig. 13.6.4A,B). When barbed ends are capped by a standard capping protein like gelsolin, addition of another capping protein does not cause further depolymerization of F-actin. The same conclusions are derived from C_c plots (Fig. 13.6.4B).

In co-sedimentation assays, capping proteins cause limited depolymerization of 0.5 μM F-actin because of the establishment of C_c^P. Capping proteins co-sediment with F-actin in a largely substoichiometric molar ratio with F-actin, but they are detectable by western blotting (Fig. 13.6.4F).

In seeded growth assays, capping proteins inhibit elongation at the barbed end, generally

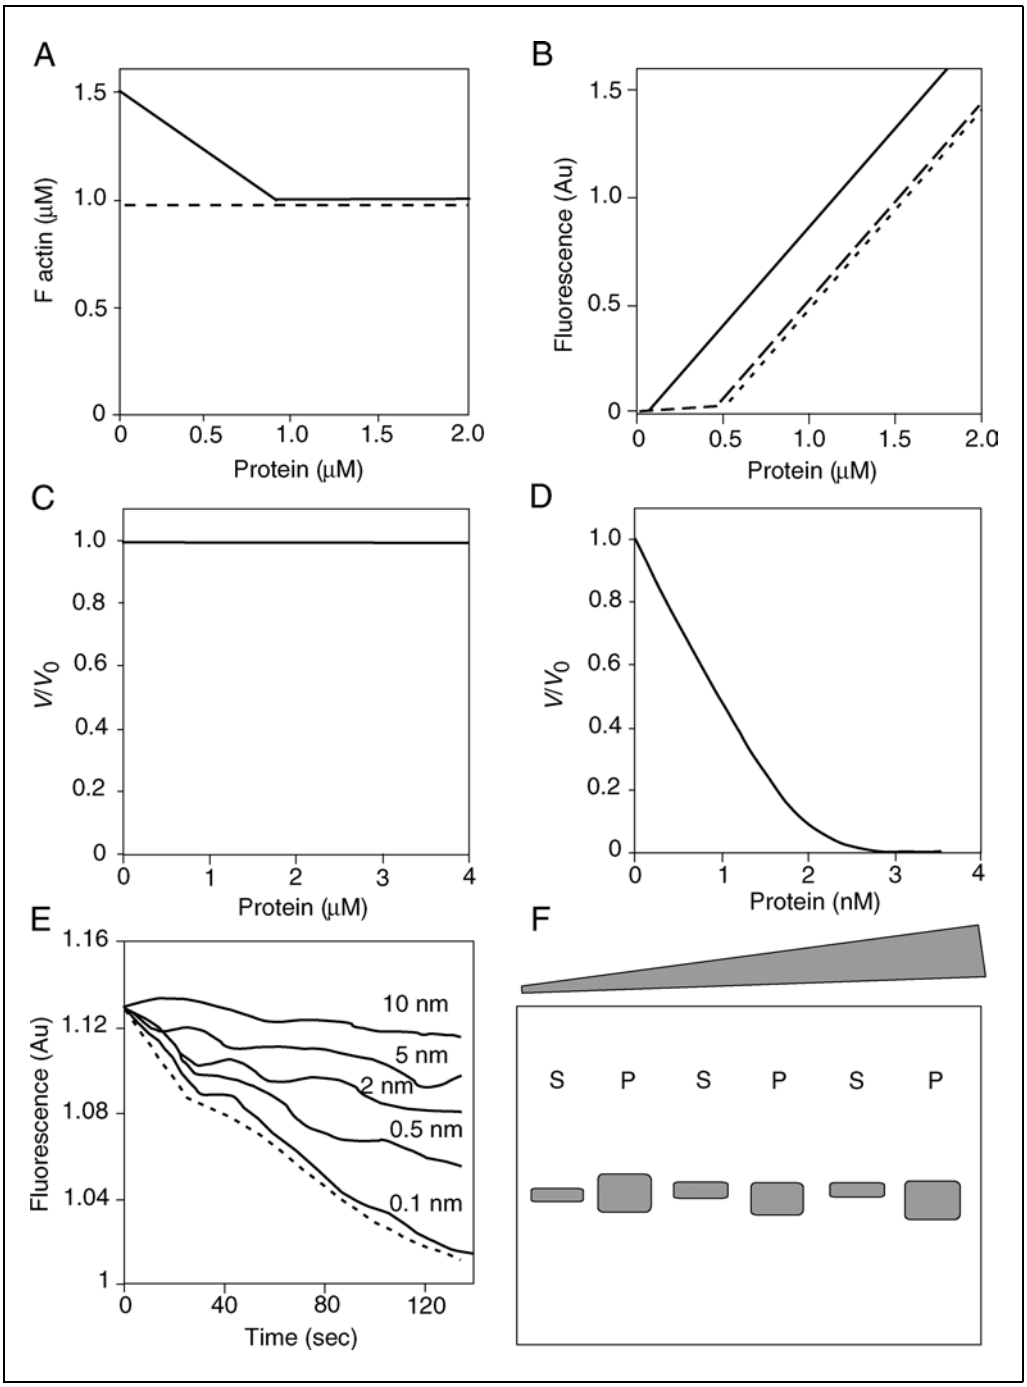

Figure 13.6.4 Legend at left.

with high affinity (nanomolar range) but not at the pointed end (Fig. 13.6.4C,D). Barbed-end growth inhibition can be described by the following equation:

$$\left(V_0 - V_\infty\right) / \left(V_0 - V\right) = 1 + K_c / C$$

Equation 13.6.9

where V_0 is the rate of elongation in the absence of the capping protein, V_∞ is the rate of elongation in the presence of a saturating amount of capping protein (corresponding to the rate of elongation of the pointed end), K_c is the equilibrium constant between the capping protein and actin, and C is the concentration of capping protein.

These proteins block dilution-induced depolymerization at the barbed end (Fig. 13.6.4E). The depolymerization rates are inhibited when the barbed ends are free. The equilibrium dissociation constant (20 nM for gelsolin) for the capping protein–actin complex can be derived from the dependence of the rate of dilution-induced depolymerization on the protein concentration using Equation 13.6.9.

Particular class of leaky cappers

The above properties characterize strong cappers that completely block reactions of both actin association to and dissociation from the barbed ends. Proteins that bind to barbed ends may still allow either growth only or depolymerization only, or may allow both reactions while remaining bound to the end, with altered kinetic parameters. Recent evidence for these activities has been reported for a new class of actin-binding proteins called formins (Pruyne et al., 2002; Wallar and Alberts, 2003). These proteins nucleate barbed-end actin assembly and can remain bound to the barbed end as it grows, thus mediating insertional polymerization under certain conditions. The steady state measurements and kinetic measurements described above allow the quantification of effects of formins on actin dynamics.

ADF/cofilin proteins

In steady-state measurements of actin assembly, ADF causes partial (limited) depolymerization; however, its behavior is different from a capper because partial depolymerization is observed in the presence as well as in the absence of capping proteins. Co-sedimentation assays show evidence for binding of ADF to F-actin, but the partial depolymerization implies that ADF also binds to G-actin. Binding studies show that ADF binds preferentially to ADP-actin and kinetic data indicate that ADF slows down nucleotide exchange, implying that at steady state a large fraction of G-actin consists of ADF-ADP-G-actin. Kinetic measurements of dilution-induced depolymerization provide evidence for faster depolymerization from the pointed ends, which is confirmed by measurements of filament turnover. Taken together, these observations help to explain the function of ADF/cofilin proteins. (for a review, Carlier et al., 1999)

Time Considerations

Purification of G-actin requires 6 days (Support Protocol 1). Labeling actin with either pyrenyl or 7-chloro-4-nitrobenzeno-2-oxa-1,3-diazole (NBD-Cl) requires 3 days (Support Protocols 2 and 3). Basic Protocols 1, 2, 3, 5, and 6 each take half of a day. Basic Protocols 4 and 7 take 2 days each.

CHAPTER 14
Signal Transduction: Protein Phosphorylation

INTRODUCTION

Cells use selective phosphorylation of proteins to regulate a vast number of intracellular processes. Enzymes termed protein kinases couple phosphate groups to tyrosine, serine, or threonine residues in specific amino acid sequence motifs of target proteins. The process can be reversed by protein phosphatases. Specificity is determined by the ability of each of the many different types of protein kinases and phosphatases to recognize specific motifs and proteins. By such site-specific regulation of phosphorylation, which affects 10% or more of all proteins, cells can switch on or modulate many major signaling and metabolic pathways, as well as regulate cell behavior in biological events such as migration and embryonic development. The importance of phosphorylation to cell biological regulation is underscored by the fact that cells have over a thousand different protein kinases.

One class of protein phosphorylations regulates enzymes, and the addition or removal of a key phosphate activates or suppresses activity of the enzyme. Other protein phosphorylations enable a protein to bind to another to form a complex—e.g., via the binding of an SH2 domain to a specific tyrosine-phosphorylated site in a target protein. Another general cellular strategy is to activate cascades of protein phosphorylation in signal-transduction pathways. For example, complex linear and interconnecting pathways of sequential phosphorylation of proteins leading to the various types of MAP kinases are important regulators of cell growth, differentiation, and gene expression. A current overview of this large field of protein phosphorylation is presented in *UNIT 14.1*, and a more specific review of MAP kinase pathways is presented in *UNIT 14.3*; both provide a number of relevant literature references.

Although phosphorylation has classically been characterized by the incorporation of ^{32}P using radioactive inorganic phosphate, a recent methodological breakthrough of particular value to cell biologists involves powerful nonradioactive approaches to the study of protein phosphorylation. Studies of complex signaling pathways in cells and tissues are now possible even for nonexperts by using immunoblotting and immunofluorescence or immunohistochemical methods. These new approaches are based on specific antibodies that recognize a phosphate group on one or more amino acids selectively—e.g., phosphotyrosine residues on any protein, or the presence of a certain type of phosphate linkage on a specific protein such as an activated MAP kinase. A wide selection of these immunological tools is now available commercially. *UNIT 14.2* provides methods for rapid direct characterization of phosphorylated proteins using a specific antibody. If antibodies of sufficiently high specificity with respect to a single protein are not available, this unit also provides a more indirect approach using immunoprecipitation by antibodies against the protein of interest, followed by anti-phosphotyrosine immunodetection. It also describes methods for antibody localization of key phosphorylated regulatory molecules. This approach permits an investigator to follow the expression patterns or intracellular movements of key phosphorylated proteins in cells, or even in various tissues of intact organisms.

Current Protocols in Cell Biology 14.0.1-14.0.3, September 2010
Published online September 2010 in Wiley Online Library (wileyonlinelibrary.com).
DOI: 10.1002/0471143030.cb1400s48

MAP kinase signaling is central to many critical cell biological regulatory events, and *UNIT 14.3* provides methods for quantitative characterization of this important signaling process. Because of the daunting complexity of signaling via MAP kinases, specific antibodies are needed. This unit starts by providing a general protocol for detecting MAP kinase activation by immunoblot analysis using specific anti-phospho-MAP kinase antibodies. It then provides an alternative approach that uses specific antibodies to isolate phosphoprotein, and then phosphorylation of a MAP kinase substrate is measured by determining amounts of incorporated ^{32}P. Because novel kinases may be involved in a specific cell biological regulatory event, *UNIT 14.3* also presents methods for detecting unknown kinases using an in-gel kinase assay. A test substrate is incorporated into an SDS-polyacrylamide gel, and electrophoretically separated crude protein extracts are evaluated for enzyme bands with ability to produce phosphorylation in vitro.

Although the recent proliferation of immunological methods for detecting specific types of protein phosphorylation has made the analysis of phosphorylation much easier, the "gold standard" for characterizing phosphorylation of individual proteins continues to be radioactive labeling with ^{32}P followed by biochemical analysis of the radiolabeled phosphoproteins. *UNIT 14.4* provides cell culture and biochemical protocols for incorporating ^{32}P-labeled inorganic phosphate and for characterizing radiolabeled phosphoproteins. *UNIT 14.5* presents current methods for unambigously identifying the specific phosporylated amino acids in individual phosphoproteins. Appropriate combinations of radioactive and immunological approaches should permit full characterization of the protein phosphorylation cascades and pathways that regulate many important cell biological functions.

Akt (protein kinase B) is another important kinase, which is regulated by phosphoinositide 3-kinase downstream of signaling cascades induced by a number of different growth factors and integrin ligands. Akt in turn regulates critical cellular functions including cell survival, growth, and proliferation, and it can play roles in cancer and other diseases. *UNIT 14.6* provides protocols for assaying the phosphorylation state of Akt that regulates its activity, as well as its dephosphorylation. It also provides a protocol for quantifying the translocation of activated Akt to the plasma membrane.

Cells generally interact with extracellular matrix molecules using integrin receptors, which trigger complex signaling cascades that regulate cell survival, growth, migration, and differentiation. These cascades involve integrin-associated kinases that include focal adhesion kinase (FAK) and c-Src. These and related kinases are both the mediators and the targets of specific tyrosine phosphorylation events that play important regulatory roles. *UNIT 14.7* provides a comprehensive series of protocols for analyzing signal transduction involving FAK and the structurally related kinase Pyk2, as well as the master regulatory kinase c-Src. Procedures are described for inducing signaling, performing immunoprecipitation analysis, measuring kinase activity, and characterizing changes in phosphorylation and activity with phospho-specific antibodies. Protocols are also provided for visualizing activated FAK, Pyk2, and Src, and there are cell biological assays for cell migration regulated by these types of kinase signaling.

Many cell biological processes are regulated by small GTPases. Cell adhesion, migration, and proliferation are strongly regulated by the Rho family of GTPases. Although this family consists of a number of members with both distinct and overlapping functions, RhoA, Rac, and Cdc42 are particularly important and implicated in a wide range of functions. *UNIT 14.8* provides methods for determining the activation of each of these key Rho GTPases using proteins that bind specifically to the activated form. Specificity of these assays is then provided by immunodetection of the specific Rho GTPase isoforms bound to these activation-detecting reagents.

The precise regulation of the activities of small GTPases is important during many biological processes. *UNIT 14.9* describes detailed protocols for assaying their key regulators, the GEFs (guanine nucleotide exchange factors) and the GAPs (GTPase activating proteins). These enzyme regulators respectively stimulate or inactivate GTPase activities. Quantification of the activities of each of these two types of regulators using these methods can provide valuable mechanistic insight into GTPase functions in cell and developmental biology.

Recent advances in biosensors and microscopy now permit researchers to image the subcellular sites of enzymatically activated Ras and Rho GTPases in living cells. These methods often use FRET (fluorescence/Förster resonance energy transfer) probes that emit fluorescence at a different wavelength when the enzyme of interest is activated and can then bind to a target molecule. In FRET, binding brings two fluorescent molecules into sufficiently close proximity that one can activate fluorescence of the other. *UNIT 14.10* describes the principles and methods for using genetically encoded, single-chain FRET biosensors for activation of Ras family GTPases. It describes strategies for developing and characterizing such FRET probes, as well as detailed information about the acquisition and processing of FRET information from living cells. *UNIT 14.11* provides detailed information about multiple different approaches to designing and using different types of biosensors. One approach uses a single fluorescent dye that detects when an enzyme changes conformation after activation, another uses FRET occurring intramolecularly, and the third functions by detecting FRET between separate proteins. Each approach requires its own type of imaging and image analysis. These two units provide a wide range of powerful tools to detect enzyme activity at specific sites within a living cell.

Another important class of GTPases besides the Rho family is the intriguing group of Arf (ADP-ribosylation factor) GTPases and Arf-like proteins. *UNIT 14.12* provides methods for determining the localization and functions of these multifunctional regulatory proteins. It also describes procedures for measuring the activation state of specific Arfs, as well as providing information on assessing functions of their regulators, the GEFs (guanine nucleotide exchange factors) and GAPs (GTPase-activating proteins).

Kenneth M. Yamada

Overview of Protein Phosphorylation

HISTORY

Phosphorylation is the most common and important mechanism of acute and reversible regulation of protein function. Studies of mammalian cells metabolically labeled with [^{32}P]orthophosphate suggest that as many as one-third of all cellular proteins are covalently modified by protein phosphorylation. Protein phosphorylation has an important role in essentially all aspects of cell biology. Most polypeptide growth factors (platelet-derived growth factor and epidermal growth factor are among the best studied; Heldin, 1995) and cytokines (e.g., interleukin 2, colony stimulating factor 1, and γ-interferon; Ihle et al., 1994) stimulate phosphorylation upon binding to their receptors. Induced phosphorylation in turn activates cytoplasmic protein kinases, such as Raf, the activators of the mitogen-activated protein (MAP) kinases SEK and MEK, the MAP kinases ERK, JNK, and p38 (Marshall, 1995; see also *UNIT 14.3*), the Janus/JAK kinases (Ihle et al., 1994), the p21 activated kinases (PAKs) (Lim et al., 1996), and the phosphatidylinsoitil 3′-kinase-activated kinase, protein kinase B/Akt (Alessi and Cohen, 1998). Additionally, in all nucleated organisms, cell cycle progression is regulated at both the G1/S and the G2/M transitions by cyclin-dependent protein kinases (Doree and Galas, 1994; also see Chapter 8). These kinases regulate the G1/S transition by the phosphorylation of cell cycle regulators such as Rb protein (Reed, 1997) and the G2/M transition through the phosphorylation of nuclear lamins (Peter et al., 1990) and histones (Arion et al., 1988).

Differentiation and development are also controlled by phosphorylation. Development of the R7 cell in the *Drosophila* retina (Simon, 1994) and of the vulva in *Caenorhabditis elegans* (Eisenmann and Kim, 1994) are both dependent on the function of receptor and cytoplasmic protein kinases, such as the sevenless and LET-23 receptors and the RAK kinase (Perrimon et al., 1995). Additionally, adhesion is regulated by the FAK kinase (Hanks and Polte, 1997) and motility is regulated, in part, by Met, the hepatocyte growth factor/scatter factor receptor (Furlong, 1992). Finally, metabolism—in particular, the interconversion of glucose and glycogen and the transport of glucose—is regulated by phosphorylation (Cohen, 1985). Cell biologists of all stripes therefore find, often unexpectedly and occasionally reluctantly, that they must study protein phosphorylation in order to understand the regulation and function of their favorite gene and its product.

LABELING STUDIES

Protein phosphorylation is usually studied by biosynthetic labeling with ^{32}P-labeled inorganic phosphate ($^{32}P_i$). This is intrinsically quite simple—the label is just added to growth medium. It is this step of an experiment, however, that makes many investigators the most nervous, given the perceived danger of radioactive exposure and the real danger of contamination of laboratory equipment with radioactivity. Neither problem is insurmountable. With proper shielding and technique, exposure of the investigator can be limited to the hands and contamination of the laboratory can be avoided. A general protocol for biosynthetic labeling with $^{32}P_i$ that maximizes incorporation and minimizes radioactive exposure of workers in the lab and contamination of lab equipment will be provided. (For a general discussion of radiation safety consult Safe Use of Radioisotopes, *APPENDIX 1D*.)

SITES OF PHOSPHORYLATION

Most proteins are found to be phosphorylated at serine or threonine residues, and many proteins involved in signal transduction are also phosphorylated at tyrosine residues. These three hydroxyphosphoamino acids exhibit sufficient chemical stability at acidic pH that they can be recovered after acid hydrolysis and identified in a straightforward manner. Proteins that contain covalently bound phosphate at histidine, cysteine, and aspartic acid residues, either as phosphoenzyme intermediates or as stable modifications, have also been described. Each of these phosphoamino acids is chemically labile and impossible to study with the standard techniques used for the acid-stable phosphoamino acids. Indeed, they are often identified by inference or elimination. A technique for identifying phosphoserine, phosphothreonine, and phosphotyrosine by acid hydrolysis and two-dimensional thin-layer electrophoresis will be presented. Techniques for analyzing acid-labile forms of protein phosphorylation are described in Ringer, 1991; Kamps, 1991; and Duclos et al., 1991.

Contributed by Bartholomew M. Sefton

Current Protocols in Cell Biology (1998) 14.1.1-14.1.3

Phosphotyrosine is not an abundant phosphoamino acid. Its detection in samples labeled with $^{32}P_i$ is often difficult, therefore, especially if the samples contain large quantities of proteins phosphorylated at serine residues or if they are contaminated with RNA. Detection of phosphotyrosine, as well as of phosphothreonine, can be enhanced considerably by incubation of gel-fractionated samples in alkali. This hydrolyzes RNA and dephosphorylates phosphoserine, allowing visualization of minor tyrosine- and threonine-phosphorylated proteins. A simple procedure for alkaline treatment will be described.

DETECTION OF UNLABELED PHOSPHOAMINO ACIDS

If a protein is modified by phosphorylation, identification of the phosphoamino acid can often be accomplished without resorting to biosynthetic labeling. For example, tyrosine phosphorylation can be studied because proteins containing this rare phosphoamino acid can be detected with great specificity and sensitivity by antibodies to phosphotyrosine (Kamps and Sefton, 1988). Attempts to generate antibodies that recognize phosphoserine or phosphothreonine have failed to produce reagents with the required specificity and/or sufficient sensitivity to be useful. Once the primary sequence around a phosphorylation site containing phosphoserine or phosphothreonine has been determined, however, it is possible to make antibodies against synthetic phosphopeptides modeled on these phosphorylation sites (Czernik et al., 1991). Such anti-phosphopeptide antibodies have been very useful tools for monitoring phosphorylation of the parent protein at specific sites (also see *UNIT 14.2*).

More generally, because phosphorylation often alters the mobility of a protein during SDS–polyacrylamide gel electrophoresis and almost always alters its isoelectric point, the presence of phosphorylated residues in an unlabeled protein can be deduced from altered gel mobility after incubation of the protein with a phosphatase.

PROTEIN KINASES

Most protein kinases exhibit a strict specificity for phosphorylation of either serine/threonine or tyrosine residues. Protein kinases comprising a third group more closely resemble the serine/threonine kinases in their primary sequence but phosphorylate both serine/threonine and tyrosine residues. MEK, a MAP kinase activator (Crews and Erickson, 1992), and wee1, an inhibitor of cdc2 kinase (Parker et al., 1992), are examples of such dual-specificity protein kinases that phosphorylate threonine and tyrosine residues that are closely located in substrate proteins.

PROTEIN PHOSPHATASES

Many protein phosphatases also show a strict specificity for either phosphoserine/phosphothreonine or phosphotyrosine residues. Unlike kinases, however, the serine/threonine and tyrosine phosphatases are not evolutionarily related and exhibit no primary sequence homology (Shenolikar and Nairn, 1991; Charbonneau and Tonks, 1992). Acid and alkali phosphatases can also dephosphorylate phosphoproteins in vitro but share no structural homology with protein phosphatases. A new family of phosphatases, such as cdc25, CL100, and VH-1, are distantly related to the tyrosine phosphatases but dephosphorylate both phosphotyrosine and phosphothreonine in their target substrates (Fauman and Saper, 1996).

A number of potent phosphatase inhibitors have been identified in recent years. Okadaic acid and several other toxins inhibit protein (serine/threonine) phosphatase 1 and 2A, and vanadate and phenylarsenoxide inhibit tyrosine phosphatase. These compounds have implicated reversible phosphorylation as a regulatory mechanism in many physiological processes (Cohen, 1989; Hardie et al., 1991; Shenolikar and Nairn, 1991; Shenolikar, 1994); under certain conditions, they may be the dominant regulators of these cellular processes. These phosphatase inhibitors can also be used to distinguish protein dephosphorylation from proteolysis in crude tissue extracts (Cohen, 1991). By far the most important contribution of these reagents has been that they have allowed assessment of the role played by phosphorylation in cellular processes where neither the identity of the phosphoprotein involved nor that of the kinase(s) that regulates its function are known.

The units in this chapter will describe techniques that detect protein phosphorylation and identify amino acids that have been covalently modified.

Immunological Detection of Phosphorylation

Incorporation of phosphates into serine, threonine, and tyrosine acceptors in proteins is a common mechanism for regulating protein function. This unit presents protocols that use specific anti–phosphoamino acid (PAA) and anti-phosphoprotein antibodies to detect protein phosphorylation and protein kinase activity. The first protocol describes the use of protein blots (immunoblotting; see Basic Protocol 1) to detect protein phosphorylation using either anti-PAA or anti-phosphoprotein antibodies. This is a convenient method that usually yields impressive results. Phosphorylation can also be detected by immunoprecipitation followed by immunoblot analysis (see Basic Protocol 2) or by immunofluorescent staining (see Basic Protocol 3); these methods are typically more complicated and time consuming. All three methods have been successfully used to detect protein phosphorylation with a wide variety of antibodies and most phosphorylated proteins.

IMMUNODETECTION OF PROTEIN PHOSPHORYLATION BY IMMUNOBLOTTING

BASIC PROTOCOL 1

This method describes the immunodetection of phosphoproteins using detergent extraction of proteins followed by immunoblot analysis (also see *UNIT 6.2*). Phosphorylation of mitogen-activated protein kinase (MAP kinase, MAPK) is used here as an example; however, this immunodetection protocol can be used with most specific anti-PAA or anti-phosphoprotein antibodies. This protocol minimizes the time phosphorylated proteins are exposed to phosphatases, allowing reliable and quantitative detection of the phosphorylated proteins, and can be completed within 7 to 10 hr. This protocol describes EGF stimulation of Rat1 cells, but with minor changes can be used with almost all tissue culture cell lines, homogenized animal organs, and even whole lower organisms.

Materials

Rat1 cells
Dulbecco's modified Eagle medium containing 10% heat-inactivated fetal bovine serum (DMEM/10% FBS; *APPENDIX 2A*)
Starvation medium: DMEM/0.1% FBS
Epidermal growth factor (EGF) buffer: phosphate-buffered saline (PBS)/0.5 mg/ml bovine serum albumin (BSA, crystalline)
50 µg/ml EGF in EGF buffer
PBS (*APPENDIX 2A*), ice cold
Homogenization buffer (see recipe), ice cold
Lysis buffer: homogenization buffer/1% Triton X-100, ice cold
Kinase buffer (see recipe), ice cold
Coomassie protein assay reagent (Pierce)
Protein standards: 5, 10, 20, 50, 100, and 200 µg/ml BSA in homogenization buffer/0.03% Triton X-100
4× SDS-polyacrylamide gel electrophoresis (PAGE) sample buffer (see recipe)
Prestained protein markers (16 to 200 kDa)
12% SDS-polyacrylamide gel (12% polyacrylamide/0.32% bisacrylamide; *UNIT 6.1*)
Transfer buffer: 50 mM Tris·Cl (pH ~8.8)/50 mM glycine
Tris-buffered saline/Tween 20 (TBST; see recipe)
Blocking solution: TBST/2% BSA
Primary antibodies: monoclonal anti–active MAP kinase *and* polyclonal anti–general MAP kinase
Secondary antibodies: horseradish peroxidase (HRP)–conjugated goat anti–rabbit *and* alkaline phosphatase (AP)–conjugated goat anti-mouse

Contributed by Zhong Yao and Rony Seger
Current Protocols in Cell Biology (1998) 14.2.1-14.2.15

AP detection system (e.g., Promega)
Enhanced chemiluminescence (ECL) detection system (see recipe)

6-cm tissue culture plates
1.5-ml microcentrifuge tubes, prechilled to 4°C (four sets of six, each set labeled 1 to 6)
Stopwatch
1-ml pipet tips, prechilled to 4°C
Microcentrifuge, 4°C
96-well flat-bottomed microtiter plate
Microtiter plate reader, 595-nm wavelength
Nitrocellulose membrane cut to size of gel
Whatman 3MM filter paper, two pieces, cut to size of gel
Transfer apparatus for electroblots (e.g., Bio-Rad)
Flat container for washing nitrocellulose membrane

Additional reagents and equipment for tissue culture (*UNIT 1.1*), chromogenic and luminescent visualization (*UNIT 6.2*), and SDS-PAGE (*UNIT 6.1*)

NOTE: All solutions and equipment coming into contact with cells must be sterile, and proper aseptic technique should be used accordingly.

NOTE: All tissue culture incubations should be performed in a humidified 37°C, 5% to 10% CO_2 incubator unless otherwise specified.

Prepare cellular extracts

1. Grow six 6-cm tissue culture plates of Rat1 cells in DMEM/10% FBS to subconfluency (~0.5×10^6 cells/plate).

2. Remove culture medium, add 2 ml starvation medium to each plate, and culture a further 18 hr.

   Make sure that the plates remain flat and that the medium covers the entire plate. Serum starvation makes the cells quiescent, which can be achieved under these conditions within 14 to 24 hr. Starvation for too long or any change in temperature or pH may be stressful to the cells and may induce activation of one or more signaling pathways.

3. Add 2.5 µl of 50 µg/ml EGF to three plates (stimulated) and 2.5 µl EGF buffer to three plates (control). Return the plates to the incubator for 5, 15, and 45 min.

   Add EGF or EGF buffer first to the plates with the longest incubation, then at appropriate intervals to the plates with the next longest incubation. It is useful to make and use a time chart to ensure that stimuli will be given at the appropriate times and the cells harvested within a short period of time (5 to 10 min).

   If the influence of the stimulating agent on the particular cells being used is not yet known, a positive control should be included—for example, peroxovanadate (0.1 mM vanadate/0.2 mM hydrogen peroxide), which nonspecifically activates many signaling events in most tissue culture cells.

4. After 5, 15, or 45 min, remove medium from plates. Rinse plates twice with 5 ml ice-cold PBS and once with 5 ml ice-cold homogenization buffer.

   Since slowing and arresting of biological processes is desired at this stage, the plates should be placed on ice. Washing and harvesting each plate takes 0.5 to 1.5 min; all six plates should be harvested within 5 to 10 min.

5. Add 350 µl ice-cold lysis buffer to each plate, tilt the plate gently (on ice), and scrape the cells into the buffer using a plastic scraper or rubber policeman. Using prechilled

1-ml pipet tips, transfer the cells and buffer to prelabeled, prechilled 1.5-ml microcentrifuge tubes.

The sample being harvested may become slightly viscous; the 1-ml pipet tips can be cut to make the tip opening wider, allowing easy collection of these samples.

Detergents other than Triton X-100, such as 0.5% Nonidet P-40 (NP-40; Igepal), can also be used.

6. Continue the cell lysis for an additional 10 min on ice.

   A nonionic detergent is used for membrane disruption because it extracts proteins from membranal, cytosolic, and some nuclear fractions of the cell, and because the determination of protein concentration in such extracts is relatively easy (steps 9 to 12). Alternatively, a more stringent mix of detergents (RadioImmunoPrecipitation Assay [RIPA] buffer, see Reagents and Solutions), which causes complete extraction of proteins from most cell compartments, can be used for membrane disruption, although it might interfere with the protein determination. Cells can also be disrupted by sonication (two 7-sec, 50-W pulses for a 0.5-ml sample) on ice, which extracts proteins from the cytosolic and nuclear fractions, but not from membranes. The extraction by sonication is performed in homogenization buffer without detergents, and allows easy determination of protein concentration.

7. Microcentrifuge the cellular extracts 15 min at 15,000 × *g*, 4°C. Transfer supernatants to fresh, prechilled, and prelabeled microcentrifuge tubes.

   The supernatants contain the protein extracts to be examined for phosphorylation.

8. Transfer 5- to 10-µl aliquots of each extract to labeled microcentrifuge tubes for determination of protein concentration, and store the remainder of the extracts on ice until needed.

   The protein concentration is determined at this stage so that identical amounts of proteins from the different samples can be compared and the relative amount of phosphoproteins can be determined accurately. Comparing samples based on cell number, rather than protein concentration, can result in differences of up to 20% in the amount of protein; such large differences can cause even larger ones when phosphorylation is assessed immunologically.

Determine protein concentration

9. Add 145 µl kinase buffer to each 5-µl aliquot of cellular extract.

   High concentrations of Triton X-100 can interfere with colorimetric measurements of the Coomassie brilliant blue; therefore, dilutions of ≥1:20 are necessary. Similar or higher dilutions are required for sonicated and RIPA extracts as well, because of high detergent or protein concentrations. The Lowry method of protein determination cannot be used because of the dithiothreitol used to prevent degradative oxidation in the extraction buffer.

10. Transfer 10 µl of each of the protein standards into two wells of a 96-well flat-bottomed microtiter plate.

    Protein standards should be prepared in the same buffer as was used for cell extraction.

11. Transfer 10 µl of each of the diluted cellular extracts into two wells of the same microtiter plate. Add 200 µl Coomassie protein assay reagent to all wells.

12. Place the microtiter plate in a microtiter plate reader and measure the absorbance of the standards and samples at 595 nm (A_{595}). Use the absorbance of the standards to construct a standard curve (absorbance versus concentration). Calculate the protein concentrations of the samples by comparing the absorbance of the sample with the standard curve.

Analyze samples by SDS-PAGE

13. Based on the calculated protein concentrations, transfer a volume of each cellular extract containing 40 μg protein to a fresh 1.5-ml microcentrifuge tube.

14. Add $\frac{1}{3}$ vol of 4× SDS-PAGE sample buffer to each tube, mix the contents, and boil 3 min.

15. Load samples and prestained protein markers on 12% SDS-polyacrylamide gel.

    Load prestained markers into the first or second lane of the gel so the molecular weights of the detected proteins can be determined. These markers will also indicate whether the proteins were completely transferred from the gel onto the nitrocellulose paper during blotting.

16. Place the gel in an electrophoresis apparatus filled with appropriate buffer and run the gel at 150 V (see *UNIT 6.1*).

Immunoblot protein

17. Soak nitrocellulose membrane in transfer buffer until completely wet.

18. Once the dye front has reached the end of the gel, remove the gel from the electrophoresis apparatus, cut off the stacking (upper) gel, and carefully place the gel in a flat container with transfer buffer.

19. Fill transfer apparatus with transfer buffer. Open the inner transfer apparatus and remove air bubbles from the pads. Make a sandwich of the gel, nitrocellulose membrane, and pads by putting one piece of Whatman 3MM filter paper (wetted with transfer buffer) on the wet pad, the gel on top of the filter paper, the wet nitrocellulose membrane on top of the gel, and the second piece of wet Whatman 3MM paper on top of the nitrocellulose membrane (Fig. 6.2.1).

20. Remove any air bubbles from between the different layers of the transfer sandwich by gently rolling a 10-ml pipet over the sandwich. Place the other wet pad on top of the transfer sandwich.

    Make sure air bubbles are not trapped between the gel and the other components.

21. Place the transfer sandwich containing the gel and nitrocellulose membrane into the buffer-filled transfer apparatus, with the nitrocellulose membrane facing the side with the cathode and the gel facing the side with the anode. Connect the apparatus to a power supply and start the current (200-mA constant current, preferably with a cooling device). Run for 2 hr.

    The voltage will drop as the transfer progresses and the conductivity increases.

    To shorten the time and improve the yield of transfer, methanol or 0.05% SDS is sometimes included in the transfer buffer; their inclusion will allow higher current but will necessitate the use of a cooling device.

22. At the end of the transfer period, turn off the power supply and remove the nitrocellulose membrane from the transfer sandwich. Rinse the nitrocellulose membrane with transfer buffer to remove any adhering pieces of gel and place the membrane in a flat container.

    At this stage, the efficiency of protein transfer can be visually monitored by assessing the transfer of prestained protein markers from the gel to the nitrocellulose membrane. The total amount of protein transferred can also be detected by staining the nitrocellulose membrane with Ponceau S (Salinovich and Montelaro, 1986). The total amount of unphosphorylated protein is determined by staining with general antibodies as described later, however, and staining with Ponceau S is not essential.

23. Place nitrocellulose membrane into flat container and incubate in 30 to 50 ml blocking solution for 60 min at room temperature.

This ensures that any free nonspecific protein-binding sites on the membrane are blocked, and will not nonspecifically bind the antibodies used in this protocol.

Incubate nitrocellulose membrane with antibody

24. Dilute primary antibody (e.g., monoclonal anti–active MAP kinase antibody) in TBST according to manufacturer's instructions. Incubate nitrocellulose membrane in a flat container with 15 ml primary antibody overnight at 4°C, 30 min at 37°C, or 1 to 2 hr at room temperature.

Although anti-MAP kinase antibodies are used as an example, other anti-phosphoprotein or anti-PAA antibodies (from, e.g., Transduction Laboratories, Sigma, Santa Cruz Biotechnology, Upstate Biotechnology, New England BioLabs, or Zymed Laboratories) can be used as well, in combination with antibodies directed to the same nonphosphorylated proteins.

25. Wash nitrocellulose membrane with TBST in flat container at least three times, 15 min each time, at room temperature.

26. Dilute secondary antibody in TBST according to manufacturer's instructions. Incubate nitrocellulose membrane with secondary antibody for 45 min at room temperature.

For detection of anti–active MAP kinase antibody; the AP detection system is recommended, because it has a broader linear range than does ECL (see Commentary). Alternatively, HRP-conjugated antibodies can be used as secondary antibodies and can be detected by ECL (see below). If HRP- rather than AP-conjugated antibodies are used at this stage, then AP-conjugated antibodies should be used in step 30.

27. Wash nitrocellulose membrane with TBST at least three times, 10 min each time, at room temperature.

28. Use an AP detection protocol (*UNIT 6.2*) to detect active MAP kinase.

After detecting active (phosophorylated) MAP kinase, determine whether there is an equal amount of MAP kinase in all lanes by exposing the same nitrocellulose membrane to anti–general MAP kinase antibody and redeveloping it (steps 29 to 31).

29. Incubate the stained nitrocellulose membrane in blocking solution for 30 min at room temperature.

If there is no steric hindrance between the two antibodies, it is not necessary to strip away the antibodies used in steps 24 to 26 because two different types of antibodies are used (mouse and rabbit). To perform the second blotting add the different type of antibody and follow steps 29 to 31. Antibodies from the same species of origin (mouse or rabbit) or antibodies that interfere with each other can be used for both steps, but in that case the membrane must be stripped (UNIT 6.2) before step 29 is performed.

30. Remove blocking solution and incubate nitrocellulose membrane with the new primary antibody (e.g., polyclonal anti–general MAP kinase antibody) as in steps 24 to 25, and use HRP-conjugated goat anti–rabbit antibody as the secondary antibody (step 26).

31. Use an ECL detection protocol (*UNIT 6.2*) to visualize general MAP kinase staining. Incubate nitrocellulose membrane with ECL solution for 1 min, dry the blot with Whatman 3MM filter paper, wrap the blot in plastic wrap, and expose to X-ray film.

BASIC PROTOCOL 2

IMMUNODETECTION OF PROTEIN PHOSPHORYLATION BY IMMUNOPRECIPITATION FOLLOWED BY IMMUNOBLOTTING

This protocol, for which reagents are readily available, can be used instead of Basic Protocol 1 when antibodies against phosphorylated sequences (anti-phosphoprotein antibodies) are not available. This protocol involves immunoprecipitation (also see *UNIT 7.2*) using antibodies to the whole protein, followed by immunoblot detection with anti-PAA antibodies, which have been used effectively to detect many tyrosine-phosphorylated adapter molecules in growth factor signaling pathways.

Materials

Protein A–Sepharose beads
PBS (*APPENDIX 2A*), room temperature and ice cold
Antibodies for immunoprecipitation of the desired protein (1 to 5 µg per reaction)
Homogenization buffer (see recipe), ice cold
Cellular extract in lysis buffer (see Basic Protocol 1, step 7)
RIPA buffer (see recipe), ice cold
0.5 M LiCl solution, ice cold
0.1 M Tris·Cl, pH 8.0 (*APPENDIX 2A*)
4× SDS-PAGE sample buffer (see recipe)
12% SDS-polyacrylamide gel (12% polyacrylamide/0.32% bisacrylamide; *UNIT 6.1*)

End-over-end rotator
Microcentrifuge, 4°C

Additional reagents and equipment for analysis by SDS-PAGE and immunoblotting (see Basic Protocol 1 and *UNIT 6.1*)

Prepare antibody-conjugated protein A beads

1. Place protein A–Sepharose beads (~150 µl) in a 1.5-ml microcentrifuge tube, add 1 ml PBS, and let the beads swell for 10 min at room temperature.

   Although protein A–Sepharose is recommended for this method, other commercially available protein A–conjugated resins (e.g., agarose, HiTrap) can be used. Protein G–coupled resins are required to immunoprecipitate certain types of monoclonal antibodies (Table 7.2.1).

   Some resins are supplied as ready-to-use solutions and will not require this swelling step.

2. Add 1 ml PBS to swollen beads and microcentrifuge 1 min at 15,000 × *g*, room temperature. Discard the supernatant. Repeat for a total of three washes.

3. Add 300 µl PBS and 25 µl of the antibody to be conjugated to 250 µl swollen packed beads. Rotate the mixture on an end-over-end rotator for 1 hr at 10 to 30 rounds/min, room temperature to allow antibody to bind to protein A.

   These volumes are calculated for ten reactions (usually 10 to 20 µl beads is used per reaction), but because of the density of the beads, this amount will probably only be sufficient for eight reactions. The amounts can be scaled up as long as the proportions are maintained.

   For easy handling of the resin, cut the ends of the pipet tips to make the openings larger.

4. Resuspend beads in 1 ml ice-cold PBS, then microcentrifuge 1 min at 15,000 × *g*, room temperature. Remove supernatant and add 1 ml ice-cold homogenization buffer, then repeat centrifugation two more times with homogenization buffer ending with a final addition of an equal volume of buffer.

   Antibody-conjugated beads can be stored in homogenization buffer for ≤2 days at 4°C.

Immunoprecipitate

5. Add 40 µl antibody-conjugated bead suspension (20 µl beads and 20 µl homogenization buffer) to a 300-µl sample of cellular extract containing 100 to 500 µg total protein in prechilled 1.5-ml plastic microcentrifuge tubes. Rotate on end-over-end rotator for 2 hr at 10 to 30 rounds/min, 4°C.

   See Critical Parameters for the rationale behind this particular method.

6. Microcentrifuge antibody-conjugated beads 1 min at 15,000 × *g*, 4°C. Discard supernatant, add 1 ml ice-cold RIPA buffer, and centrifuge again as before. Repeat twice with 1 ml ice-cold 0.5 M LiCl and once with 1 ml ice-cold 0.1 M Tris·Cl, pH 8.0.

   These stringent washes will remove most of the phosphorylated proteins that can nonspecifically interact with the protein A beads.

7. Add 30 µl of 4× SDS-PAGE sample buffer to each sample of washed beads, boil 5 min, and centrifuge 1 min at 15,000 × *g*, room temperature. Load supernatant and prestained markers on 12% SDS-polyacrylamide gel (see *UNIT 6.1*).

8. Perform SDS-PAGE and immunoblot analysis (see Basic Protocol 1, steps 16 to 31).

   At this stage the immunoprecipitate can also be subjected to a protein kinase assay (see UNIT 14.3).

FLUORESCENT IMMUNOSTAINING OF TISSUE CULTURE CELLS

BASIC PROTOCOL 3

This protocol uses similar antibody reagents as described in Basic Protocol 1 to allow staining of tissue culture cells, blood cells, thin tissue sections, or lower organisms. It involves fixation of the cells or tissues to be examined, brief permeabilization of the plasma membranes to allow immunological recognition of intracellular components, and fluorescent detection. This method is especially useful to determine localization of signaling events, but is less accurate in determining the level of activations. Recently, Gabay et al. (1997) used this method to identify the MAP kinase pattern of activation in the developing *Drosophila* enbryo.

Materials

Rat1 cells
DMEM/10% FBS (*APPENDIX 2A*)
Starvation medium: DMEM/0.1% FBS
PBS (*APPENDIX 2A*)
3% (w/v) paraformaldehyde in PBS
Permeabilization buffer: PBS/0.2% (v/v) Triton X-100
Primary antibody
Secondary antibodies: fluorescein isothiocyanate (FITC)–conjugated goat anti-rabbit *and* rhodamine-conjugated goat anti–mouse

6-well tissue culture plates
22-mm-square coverslips, sterile
Parafilm, two 10 × 20–cm pieces
Slide mounting medium (e.g., Polymount, Polyscience)
Confocal or fluorescent microscope

Additional reagents and equipment for tissue culture (*UNIT 1.1*)

NOTE: All solutions and equipment coming into contact with cells must be aseptic, and proper aseptic technique should be used accordingly.

NOTE: All tissue culture incubations should be performed in a humidified 37°C, 5% to 10% CO_2 incubator unless otherwise specified. Some media (e.g., DMEM) may require altered levels of CO_2 to maintain pH 7.4.

1. Place one 22-mm-square coverslip in each well of a 6-well tissue culture plate. Seed ~30,000 Rat1 cells in 2 ml DMEM/10% FBS in each well. Incubate 24 hr. Remove medium, replace with starvation medium, and incubate a further 14 hr (see Basic Protocol 1, steps 1 to 2).

   Seeding a small number of cells per well allows the cells to be well dispersed as they grow, which usually facilitates good cell staining.

   Many cell types other than Rat1 can be used with this protocol.

2. Remove starvation medium and add 2 ml DMEM/10% FBS to each well. Incubate 30 min in incubator.

   Serum-induced translocation of MAP kinases into the nucleus is much more pronounced and prolonged than the translocation induced by EGF.

3. Wash wells twice with 5 ml PBS at room temperature. Add 2.5 ml of 3% paraformaldehyde in PBS to each well for 20 min. Remove paraformaldehyde solution and wash three times with 5 ml PBS each time.

   Once the samples are fixed by the paraformaldehyde, protein degradation and dephosphorylation are minimized; therefore, the subsequent stages can be performed at room temperature. Leave coverslips in the wells for all washes.

4. Add 2 ml permeabilization buffer to each well for 5 min. Remove permeabilization buffer, add 5 ml PBS to each well, allow to sit for 2 min, then remove. Repeat PBS wash twice.

   Other methods of fixation can be used, but paraformaldehyde fixation followed by permeabilization with 0.2% Triton X-100 is a very effective method when antibodies directed against signaling components are used.

5. Stretch one 10 × 20–cm piece of Parafilm on a clean, straight, and stable surface, such as a work bench; fasten it to the surface.

6. Centrifuge primary antibody 5 min at 15,000 × *g*, room temperature. Dilute primary antibody in PBS as per manufacturer's instructions. Place six 40-µl drops of diluted primary antibody on the stretched piece of Parafilm ~5 cm apart from each other. Remove the fixed and permeabilized coverslips from the wells with fine forceps and place each, cell side down, on top of one of the drops. Incubate 45 min at room temperature.

   An antibody dilution of 1:20 to 1:500 is usually used for staining by this method. For costaining with monoclonal and polyclonal antibodies, the 40-µl drops can contain both antibodies. It is important to know which coverslip was exposed to which antibody.

   Centrifuging the antibody solution 5 min at 15,000 × g, room temperature, will remove particulate contaminants and antibody aggregates.

7. Remove each coverslip from the drop of primary antibody solution with fine forceps. Holding each coverslip with forceps, tilt it and gently touch its edge to a Kimwipe to remove all antibody solution. Place the coverslips back in the wells of the 6-well plate, cell side up. Wash the wells three times with 2 ml PBS for 10 min each.

8. Centrifuge rhodamine-conjugated secondary antibody 1 min at 15,000 × *g*, room temperature. Dilute secondary antibody 1:100 to 1:500 in PBS. Prepare a new 10 × 20–cm piece of Parafilm as in step 5 and place 40-µl drops of centrifuged secondary antibody on the Parafilm. Place coverslips on top of the drops, cell side down. Incubate 45 min at room temperature.

The type of secondary antibody will depend on the species in which the primary antibody was generated.

9. Remove coverslips from the drops of antibody and remove any remaining antibody solution with a Kimwipe as in step 7. Place coverslips back in the 6-well plate, cell side up, and wash three times with 2 ml PBS, 10 min each time.

10. Place one drop of mounting medium on each slide. Remove each coverslip from the well with fine forceps and remove remaining PBS by touching its side with a Kimwipe. Place each coverslip on the drop of mounting medium with the cell side facing the mounting medium. Store slides in the dark at least overnight.

    Keep stained slides in the dark to minimize decay of the fluorescent dye.

11. Monitor the fluorescent staining by examining the slides with either a normal or confocal fluorescent microscope. Note the amount of staining per cell and the percentage of stained cells per sample.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Enhanced chemiluminescence (ECL) system

Solution A:
2.5 mM luminol (Sigma)
400 mM *p*-coumarin (Sigma)
100 mM Tris·Cl, pH 8.5 (*APPENDIX 2A*)

Solution B:
5.4 mM H_2O_2
100 mM Tris·Cl, pH 8.5 (*APPENDIX 2A*)

Store solutions A and B up to 3 months at 4°C
Mix equal amounts of solution A and solution B just before use

The ECL system is also commercially available.

Homogenization buffer

50 mM β-glycerophosphate, pH 7.3
1.5 mM EGTA
1.0 mM EDTA
0.1 mM sodium vanadate
1.0 mM benzamidine
10 µg/ml aprotinin
10 µg/ml leupeptin
2.0 µg/ml pepstatin A
1.0 mM DTT (*APPENDIX 2A*)
Store up to 3 months at 4°C without DTT
Add DTT just before use

This buffer is derived from the work of Ahn et al. (1990) and Seger et al. (1994).

Kinase buffer

50 mM β-glycerophosphate, pH 7.3
1.5 mM EGTA
1.0 mM EDTA
0.1 mM sodium vanadate
1.0 mM dithiothreitol (DTT; *APPENDIX 2A*)
Store up to 3 months at 4°C without DTT
Add DTT just before use

This buffer is derived from the work of Ahn et al. (1990).

RadioImmunoPrecipitation Assay (RIPA) buffer

20 mM Tris·Cl, pH 7.4 (*APPENDIX 2A*)
137 mM NaCl
10% (v/v) glycerol
0.1% (w/v) SDS (*APPENDIX 2A*)
0.5% (w/v) deoxycholate
1% (v/v) Triton X-100
2.0 mM EDTA
1.0 mM PMSF (*APPENDIX 2A*; add fresh)
20 μM leupeptin
Store up to 3 months at 4°C

200 mM Tris·Cl, pH 6.8 (*APPENDIX 2A*)
40% (v/v) glycerol
8% (w/v) SDS (*APPENDIX 2A*)
0.2% (w/v) bromphenol blue
8% (v/v) 2-mercaptoethanol
Store up to 12 months at –20°C

TBST (Tris-buffered saline/Tween 20)

20 mM Tris·Cl, pH 8.0 (*APPENDIX 2A*)
150 mM NaCl
0.05% (v/v) Tween 20
Store up to 3 months at 4°C

COMMENTARY

Background Information

Protein phosphorylation, the incorporation of phosphates into serine, threonine, and tyrosine acceptors in proteins, is a common means of regulating protein function and hence many cellular processes (Krebs, 1994; Campbell et al., 1995) that has been extensively studied in recent years. More than 30% of cellular proteins are believed to be either constitutively or transiently phosphorylated by ~2000 distinct protein kinases (Hunter, 1994), and the large number of protein kinases and phosphoproteins makes detection of specific phosphorylation sites challenging. Over the years, several methods have been developed to single out and characterize particular phosphoproteins, including the traditional methods of metabolic labeling with inorganic ^{32}P and in vitro protein phosphorylation (*UNIT 14.1*). Some of these techniques, such as metabolic labeling, phosphorylation by known protein kinases, and purification of phosphorylated proteins, are covered in other units in this chapter.

Another approach is immunological (*UNIT 14.3*); a number of immunological reagents have now been developed that can be used to study many aspects of phosphorylation. Two classes of antibodies have historically been used to monitor phosphorylation. One class consists of anti–phosphoamino acid (PAA) antibodies, such as anti-phosphotyrosine (PY), -phosphothreonine (PT), and -phosphoserine (PS; see Fig. 14.2.1). The anti-PAA antibodies nonspecifically recognize many of the phosphorylated amino acids in most proteins (Fig. 14.2.2). The second class is composed of anti-phosphoprotein antibodies, i.e., antibodies against specific phosphate-containing sequences.

Of the anti-PAA antibodies, the anti-PY antibodies, which can detect membranal signaling in response to extracellular agents, are the most commonly used. Immunoblot analysis with anti-PY antibodies usually detects a dramatic increase in the amount of PY in proteins from stimulated cells, such as epidermal growth factor (EGF)–stimulated A431 cells (Frackelton et al., 1983), and insulin-stimulated Fao hepatoma cells (Pang et al., 1985). A similar growth factor–induced increase in other PAAs is also detected with anti-PT and anti-PS antibodies, but the increases detected with these antibodies are usually less dramatic. Anti-PAA antibodies are, therefore, good probes to detect bulk changes in phosphorylation that accompany signaling processes in a variety of cell types. Changes in the phosphorylation of specific pro-

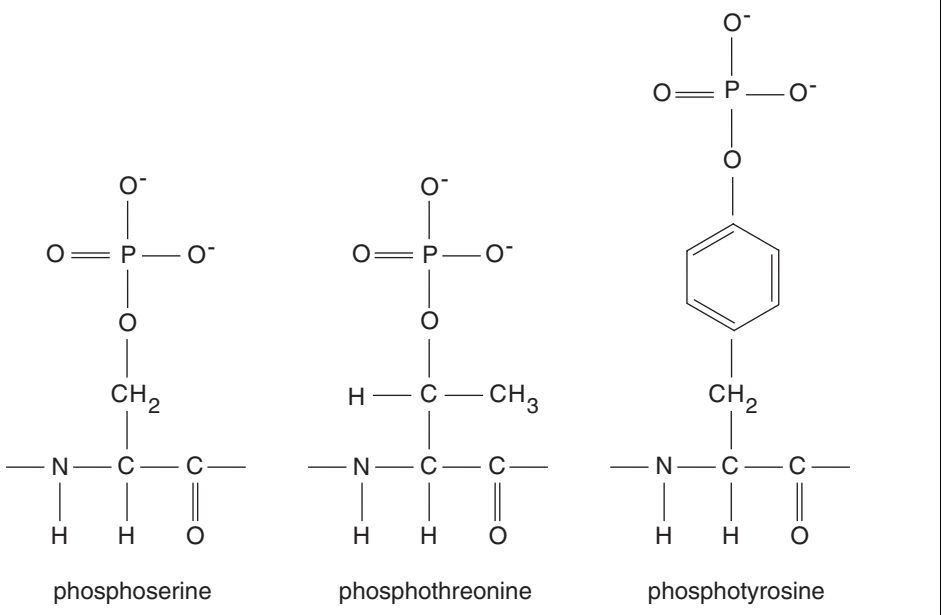

Figure 14.2.1 Schematic representation of phosphoserine (PS), phosphothreonine (PT), and phosphotyrosine (PY).

teins can also be detected by these anti-PAA antibodies if isolated (usually immunoprecipitated) proteins are used (Fig. 14.2.2).

Anti-PAA antibodies are widely used, but they usually do not interact with all the PAAs in a given extract; the anti-PS and anti-PT antibodies appear to recognize only a small percentage of the phosphorylated residues on some proteins. Another disadvantage of using anti-PAA antibodies to monitor phosphorylation is their inability to distinguish between several similar PAAs that may appear simultaneously on a particular protein, which can sometimes preclude detection of activity-modulating site-specific phosphorylation.

Anti-PAA antibodies provide a general and nonspecific tool for monitoring phosphorylation. Anti-phosphoprotein antibodies, those with unique specificity to a certain phosphorylated sequence in a given protein, provide a specific monitoring probe. Probably the best known examples are the anti–active mitogen-activated protein kinase (MAP kinase; Seger and Krebs, 1995) antibodies called anti-diphospho-ERKs (Gabay et al., 1997; Yung et al., 1997), which are now commercially available (Sigma).

In response to mitogen stimulation, the MAP kinases (ERK1 and ERK2) are rapidly phosphorylated at up to six sites (Robbins and Cobb, 1992). Phosphorylation at two of these sites (Thr 183 and Tyr 185 in ERK2; Payne et al., 1991) can lead to full activation of the enzyme; the effects of phosphorylation at the other sites are not yet known. Antibodies directed towards the activation motif of ERK (PT–glutamic acid–PY) serve as good tools to detect the enzymatic activity of ERK. Anti-PAA antibodies, on the other hand, can detect total phosphorylation, which does not fully correlate with ERK's enzymatic activity.

An important advantage to using anti-phosphoprotein antibodies is that the procedure for their detection is shorter and simpler than that for anti-PAA antibodies, and can be achieved in a single step (immunoblotting or cell staining). Because of the specificity of anti-phosphoprotein antibodies, however, these antibodies do not always provide an overall indication of signaling events, as do anti-PAA antibodies.

Immunological reagents have been extensively used to study the involvement of phosphorylation in growth factor signaling. When growth factors bind to their receptors, the receptor-associated tyrosine kinases are activated to initiate intracellular signaling events (Krebs, 1994). These signals are then transmitted through a series of interacting proteins (Grb2, SOS, and Ras; see *UNIT 14.3*) that in turn sequentially stimulate the several groups of cytoplasmic protein serine/threonine kinases known as MAP kinase signaling cascades (Seger and

Krebs, 1995; Marshall, 1996; Robinson and Cobb, 1997). Thus, the initial burst of tyrosyl phosphorylation associated with growth factor binding is translated into serine/threonine phosphorylation, which alters the properties and activities of the target proteins (Karin and Hunter, 1995). These phosphorylation cascades eventually activate regulatory molecules and initiate cellular proliferation (Seger and Krebs, 1995).

The first antibodies that were used to study growth factor and oncogene signaling were specific anti-PY antibodies. These antibodies, which were first prepared by immunizing rabbits with azobenzyl phosphate (Ross et al., 1981), were successfully used to monitor signaling events in many cellular systems. Thousands of studies using anti-PY antibodies and various immunological techniques have been published since then. For example, affinity chromatography with anti-PY antibodies was used to isolate PY-containing proteins (Frackelton et al., 1983); immunoblot analysis and immunoprecipitation were used to detect the huge increase in protein tyrosine phosphorylation that occurs in response to cellular transformation (Comoglio et al., 1984); and immunofluorescence techniques were used to localize tyrosine kinases to adherens-type junctions and other intracellular locations (Volberg et al., 1992). The successful use of anti-PY antibodies encouraged the preparation of anti-PT and anti-PS antibodies (Heffetz et al., 1989). These antibodies are usually not as reliable tools as the anti-PY ones, however, because they are less specific.

Anti–active kinase antibodies, which are specific anti-phosphoprotein antibodies, are

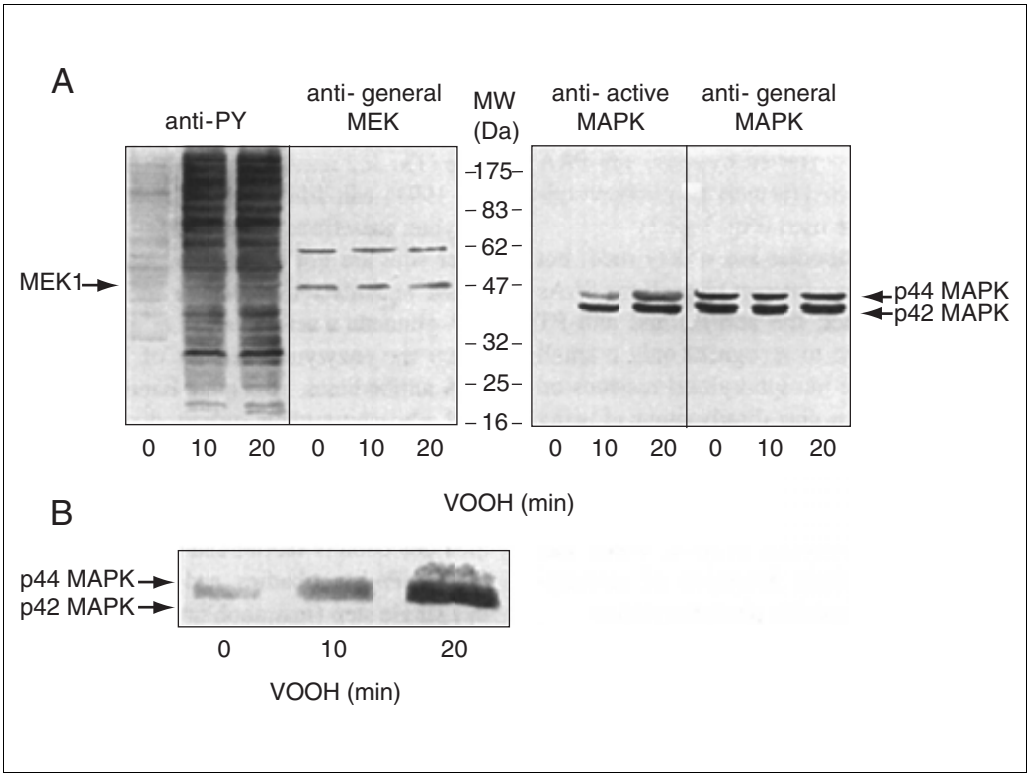

Figure 14.2.2 Immunoblotting of phosphorylated proteins. (**A**) NIH 3T3 cells were grown in 6-cm plates until subconfluency and then serum starved for 18 hr in 2 ml starvation medium. After stimulation with peroxovanadate (VOOH) for different times (0, 10, and 20 min), the cells were harvested and lysed. Aliquots (30 μg) from each sample were run on 10% SDS-polyacrylamide gels and subjected to immunoblotting. Blots were first reacted with polyclonal anti-phosphotyrosine (PY; Zymed) antibody or monoclonal anti–active mitogen-activated protein kinase (MAP kinase; Sigma) antibody and detected using an alkaline phosphatase detection system. The same membranes were blocked and reacted with monoclonal anti–general MAP kinase kinase (MEK) antibody (Transduction Laboratories) or polyclonal anti–general MAP kinase antibody (Sigma). Enhanced chemiluminescence (ECL) was used for detection. (**B**) Aliquots (200 μg) from each sample in A were immunoprecipitated with polyclonal anti-MAP kinase antibody (Santa Cruz Biotechnology). The samples were subjected to SDS-PAGE and immunoblotted with anti-PY antibody followed by detection with ECL.

also useful tools for studying cellular signaling. Many of these antibodies are directed against protein kinases that belong to the MAP kinase signaling cascades, and are activated by phosphorylation of distinct amino acids in the kinase domains. For example, antibodies specific for the doubly phosphorylated, activated form of MAP kinases are now extensively used to determine kinase activity, in place of traditional chemical methods (Fig. 14.2.2). As with anti-PY antibodies, anti–MAP kinase antibodies have been used in a variety of methods, including immunoblotting and fluorescence staining of tissue culture cells, tissue sections, and whole tissues. The latter enables the detection of MAP kinase activation in whole or sectioned organisms (see *UNIT 14.3* for more details).

Anti-phosphoprotein antibodies have also been used to efficiently detect the phosphorylation and activation of the transcription factor CREB (Ginty et al., 1993) and the phosphorylation of the brain-specific, microtubule-associated protein Tau (Biernat et al., 1992). The multitude of studies using anti-phosphoprotein antibodies indicate that these reagents are simple and reliable tools to study phosphorylation and that their use will be invaluable for studying a variety of cellular processes that involve phosphorylation and dephosphorylation.

Critical Parameters

The elements most critical to the success of the methods for immunological monitoring of phosphorylation described here are the quality and specificity of the antibodies used. Antibodies should (1) recognize the phosphorylated protein but not its unphosphorylated counterpart and (2) recognize only the desired PAA, not additional phosphorylated sites in either the same or different proteins. In addition, the amount of protein in the different samples subjected to immunoblot analysis and the dilution of antibodies should be optimized to avoid nonspecific recognition of excess proteins.

Successful detection of phosphorylation by immunological or other means also depends in large part on the efficiency of cellular extraction. Since most phosphorylated proteins are localized within cells, cellular membranes must be disrupted to physically access the desired targets. During disruption of these membranes (cellular extraction), most cellular organelles break, exposing phosphoproteins to phosphatases and proteinases (see *UNIT 14.1*), which have detrimental effects on the detection of phosphorylation (Hunter, 1995). The effect of these enzymes can be minimized by adding specific enzyme inhibitors to extraction buffers and extracting at low temperatures. Phosphatases are usually efficient enzymes, however, and extractions should be performed as fast as possible; if necessary, additional means should be used to secure phosphorylation sites.

Other considerations for the extraction of phosphoproteins are: (1) to ensure that the proteins of interest are indeed presented in the examined fraction and (2) to reduce the number of irrelevant proteins in this fraction. For example, the presence of PY-containing cytosolic proteins might be masked by an excess of activated membranal proteins, and detection of cytoskeletal-associated phosphoproteins might be difficult unless extraction is performed using RadioImmunoPrecipitation Assay (RIPA) buffer. One good cellular extraction method, which can be used for detection of phosphoproteins by either immunoprecipitation or immunoblotting, is described in Basic Protocol 1. In this method, detergent is used to disrupt the cellular membranes, and the resulting extracts should contain membranal, cytosolic, and some nuclear fractions.

Depending on the subcellular localization of the proteins of interest, however, other extraction methods can be used. For example, extracts obtained by sonication usually contain cytosolic and nuclear components, but not membranal ones; those obtained with RIPA buffer should contain most cellular components. Cellular extraction by the addition of hot SDS-PAGE sample buffer to cells is not recommended, because it frees chromatin and results in a gel that is difficult to handle. Extraction by freeze-thawing is also not recommended because molecular degradation can occur during thawing.

Several immunoprecipitation methods have been developed and used over the years (see *UNIT 7.2*). These methods vary in the order in which the antibodies and protein A are added to the cell extracts. In Basic Protocol 2, the antibodies are first conjugated to protein A beads and then added to the cellular extracts. This procedure minimizes the time the samples are incubated with the antibodies, minimizing exposure of the phosphoproteins to phosphatases and proteinases in the extracts. Furthermore, this procedure ensures that only antibodies recognized by protein A will be used for the immunoprecipitation. If the antibodies are added to the lysate prior to precipitation with the beads, antibodies that are not recognized by protein A can bind to the desired antigen, but will not be precipitated when pro-

tein A beads are added, reducing the efficiency of the immunoprecipitation.

The successful use of sequence-specific anti-phosphoprotein antibodies relies on their specificity for the phosphorylated form of the examined protein (see anti-MAP kinase antibodies below). Monoclonal antibodies, which are generally more specific than polyclonal ones, are reliable tools for distinguishing phosphorylated from unphosphorylated forms of proteins; affinity-purified polyclonal antibodies can be used as well. Both monoclonal and polyclonal antibodies can be generated by immunization with whole phosphorylated proteins or with keyhole limpet hemagglutinin (KLH)– or BSA–coupled peptides, followed by standard procedures for the isolation of the monoclonal and polyclonal antibodies. For example, immunization with whole phosphorylated protein was used to prepare monoclonal antibodies against several of the phosphorylated sites of Tau (Biernat et al., 1992). Immunization with KLH-conjugated phosphorylated peptides was used to prepare anti–active MAP kinases (Yung et al., 1997), anti–phosphorylated CREB (Ginty et al., 1993), and other anti–phosphorylated protein antibodies.

Immunofluorescent staining, another immunodetection method, can be performed with intact cells, such as those obtained from blood or tissue cultures, and on thin sections of various tissues. With immunofluorescence, degradation and dephosphorylation is less problematic because of the rapid fixation of the tissues. Although this method is very useful for detecting changes in phosphorylation in intact tissues and for localization studies, it requires highly specific antibodies, which are not always available. When appropriate highly specific antibodies are available, however, this method should be seriously considered.

For accurate comparison of the amounts of phosphoproteins, detection must be performed in the linear range of the detection system. Thus, the amount of protein loaded on the gel, the concentrations of primary and secondary antibodies, and the enhanced chemiluminescence (ECL) exposure time should be optimized in order to attain linearity. Alternatively, a standard curve can be prepared using a range of concentrations of the proteins of interest, and serial dilutions of the cellular extracts of each treatment can be loaded on the SDS-polyacrylamide gel. The blotting detection systems—e.g., ECL–^{125}I-, alkaline phosphatase (AP)–, or biotin-conjugated antibody—should be chosen carefully. ECL generally has the narrowest linear range of these systems, whereas ^{125}I-labeled antibodies have a relatively broad range. The AP detection system is convenient to use, has a moderate linear range, and is usually used for the types of experiments described here.

Anticipated Results

The desired phosphoprotein can be selectively detected with immunoblotting. For example, when anti–active MAP kinase antibodies are used (Basic Protocol 1; Yung et al., 1997), two faint bands at molecular weights of 42 and 44 kDa can be detected in the basal, nonstimulated fractions of Rat1 cells (Fig. 14.2.2). These two bands represent the small amount of active MAP kinase (ERK1 and ERK2) present in resting cells. Upon addition of EGF to these cells, the staining intensity of those bands should increase, peak at 30 min after stimulation, and decline thereafter. At later time points after EGF stimulation, a third band, at 46 kDa, usually appears; this may represent another isoform of MAP kinase. The kinetics of detection of the phosphoprotein represents the transient activation of MAP kinase by EGF in these cells. Staining the same blots with anti–general MAP kinase antibodies should result in equal staining of the 42-, 44-, and 46-kDa bands in all lanes of the blot.

Time Considerations

After cell harvesting, Basic Protocol 1 requires extraction (0.5 hr), determination of protein concentration (0.5 hr), SDS-PAGE (2.5 hr), and immunoblot analysis (6 to 8 hr). Since this procedure may take more than a working day, it can be stopped after boiling the samples in sample buffer. Alternatively, the transfer onto the nitrocellulose membrane can be performed at 40 to 50 mA overnight (instead of at 200 mA for 2 hr). Immunoprecipitation and washes (Basic Protocol 2) add ~4 to 5 hr to Basic Protocol 1. Fluorescent staining (Basic Protocol 3) takes ~3 to 4 hr, and up to 24 hr may be required to mount the stained coverslips onto the slides, depending on the mounting medium used.

The Detection of MAPK Signaling

The transmission of extracellular signals to their intracellular targets is mediated by a network of interacting proteins that relays biochemical messages and thus controls cellular processes. Several related intracellular signaling pathways (Seger and Krebs, 1995; Chen et al., 2001; Morrison and Davis, 2003; Raman and Cobb, 2003; Rubinfeld and Seger, 2004), collectively known as mitogen-activated protein kinase (MAPK) signaling cascades, have been demonstrated to play a role in many systems. Transmission of signals via these cascades is usually initiated by activation of a small G protein (e.g., Ras) and followed by a sequential stimulation of several sets of cytosolic protein kinases. Four distinct MAPK cascades (ERK, JNK, p38 and BMK; Fig. 14.3.1) have been elucidated so far. Each is named after the subgroup of its MAPK component and is composed of from three to five tiers (MAP4K, MAP3K, MAPKK, MAPK and MAPKAPK; Fig.14.3.1), where the three tiers MAP3K, MAPKK, and MAPK are considered the core cascade. One or more components in each of these tiers phosphorylates and activates components in the next level, until a downstream component phosphorylates a target regulatory molecule. These cascades can cooperate in transmitting signals from most extracellular stimuli, and thus can determine a cell's fate in response to the ever-changing environment. For detailed description see Background Information.

Because many of the MAPK cascade components are activated by phosphorylation, a convenient method to detect their activation is the use of phosphorylation-site-specific (anti-phospho) antibodies. Indeed, Basic Protocol 1 describes the use of protein blots (immunoblotting; also see *UNIT 6.2*) to detect protein phosphorylation with anti-phospho antibodies (see, e.g., Fig. 14.3.2). This method involves only three steps and usually yields impressive results. Unfortunately, the available, reliable anti-phospho antibodies are limited to some of the MAPK cascade components, and the use of these antibodies does not always reflect the kinetic parameters of the kinase activation. To overcome this problem, the unit also includes protocols that utilize the kinase activity of the MAPK components to determine their activation (Basic Protocols 2 and 3). Basic Protocol 2 describes an immunoprecipitation of desired protein kinases followed by phosphorylation of specific substrates. Basic Protocol 3 describes an in-gel kinase assay, which is mainly used when the identity of the kinase is not known, or when there are no reagents available for its determination.

STRATEGIC PLANNING

The relative intensity and duration of signals transmitted in each MAPK cascade are thought to be major determinants of signaling specificity (Marshall, 1995). Therefore, an accurate detection of the amount of signals transmitted via various MAPK cascades toward target molecules is important for studying intracellular signaling. Usually, the activity of one component of the MAPK level of each cascade (ERK, JNK, p38 and BMK) is a sufficient indicator of the transmitted signal. However, sometimes the activity of additional components at upstream or downstream levels must be determined because of a cross-talk between various cascades. For example, p38 can be activated by as many as three distinct MAPKKs (MKK 3, 4, or 6; Ono and Han, 2000), and, therefore, it is important to check which one of these MAPKKs is the immediate activator in different systems.

Most components of MAPK cascades belong to the large family of protein kinases, which in humans consists of about 520 members (Manning et al., 2002). To study protein kinases in general, and MAPK components in particular, specific detection of the activity

of the desired protein kinase is essential. Singling out the activity of a particular protein kinase from a multitude of related activities that might mask its activity can be achieved in two main ways. One of them requires the use of a specific substrate that is recognized only by the desired protein kinase. This method is good for detecting kinases like MEK, which seems to specifically and selectively phosphorylate its downstream component, ERK. The other, and more common method is to isolate the protein kinase and then use a general substrate as an indicator of its activity. This unit will concentrate on the latter method of kinase activity determination, which has successfully been used in studies of MAPK cascades.

In one of the first methods used for the systematic detection of protein kinases involved in growth factor signaling, protein kinases were isolated using MonoQ fast protein liquid chromatography (FPLC; Ahn et al., 1990). This method involves stimulation of tissue culture cells, fractionating the cytosolic extracts of these cells on a MonoQ column, and examining the resulting fractions for protein kinase activity. Since fractionation with the MonoQ column is extremely reproducible, kinases that are activated upon stimulation can be detected by comparing the elution profiles of kinases from activated and nonactivated cells. The advantages of this method are: (1) the ability to identify novel protein kinases and measure their activity, (2) the ability to detect the overall activity of many protein kinases, and (3) the method's good linear range, which allows the determination of

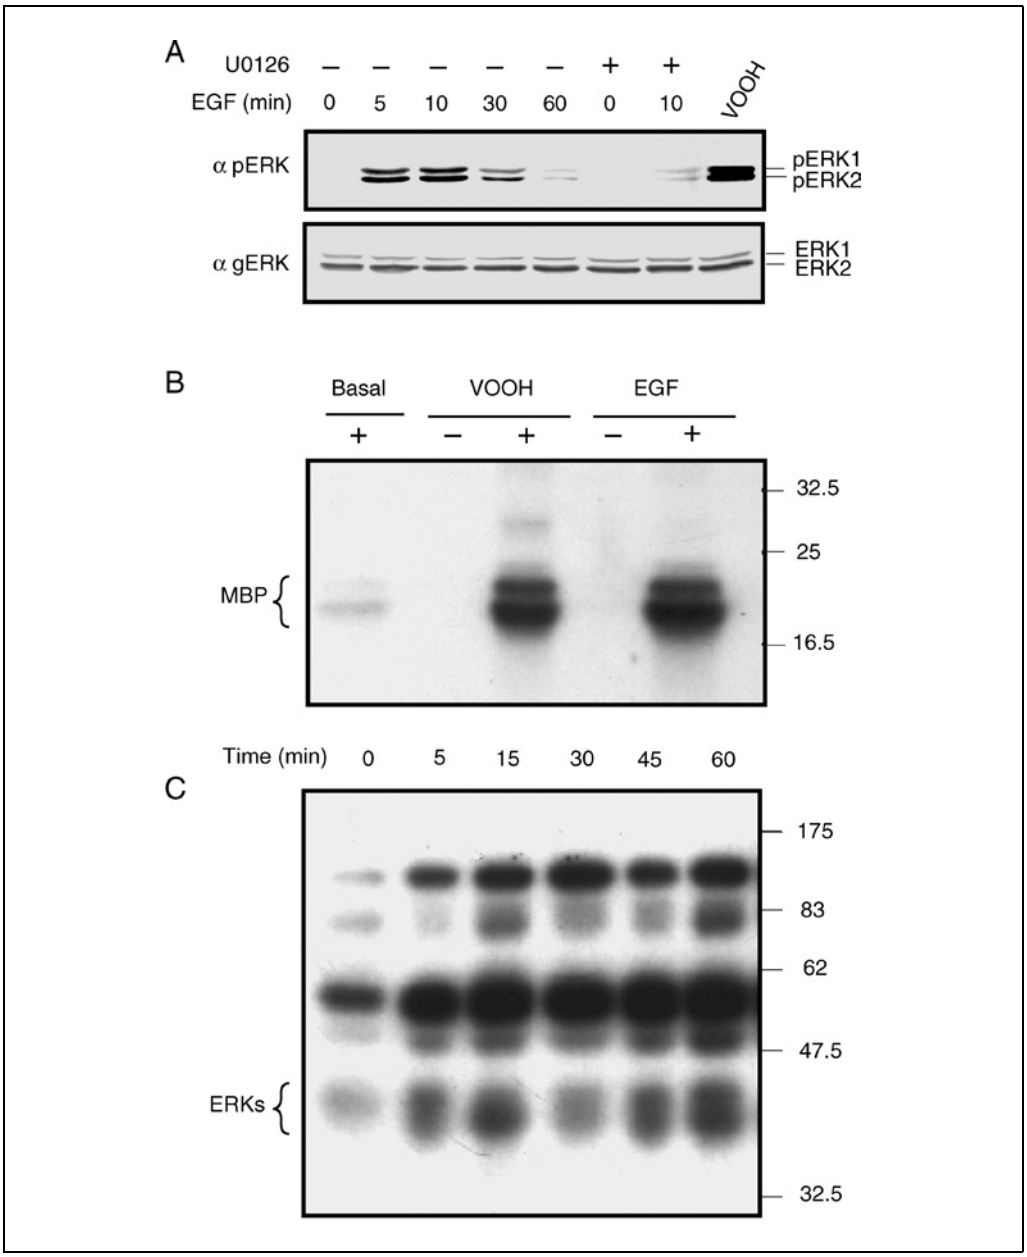

Figure 14.3.2 Detection of MAPK activity by the methods described in this unit. (**A**) Detection of ERK phosphorylation (activity) with anti–phospho ERK antibody. HeLa cells were grown in 6-cm plates until subconfluency and then starved for 18 hr in 2 ml/plate of starvation medium. Two plates (indicated) were then pretreated with the MEK inhibitor U0126 (10 μM) for 20 min while the other plates were left untreated. The cells were then either stimulated for the indicated times with EGF, peroxovanadate (0.1 mM vanadate, 0.2 mM H_2O_2), or with vehiecle control. Aliquots (30 μg) from each sample were separated by a 10% SDS-PAGE and subjected to immunoblotting with anti-pERK antibody and anti-gERK antibody (C-16; Santa Cruz Biotechnology), and detected using an AP detection system (Sigma). (**B**) Detection of ERK activity by immunoprecipitation and MBP phosphorylation. NIH-3T3 cells were grown in 6-cm plates until subconfluency and then starved as described as above. Cells were then stimulated either with VOOH (100 μM sodium orthovanadate/200 μM H_2O_2) for 15 min, with EGF (50 ng/ml) for 5 min, or left untreated (basal). Cytosolic extracts were prepared by sonication and the resulting proteins (300 μg) were incubated either with 30 μl of protein A beads conjugated with anti-ERK C-terminus antibody (C-16; Santa Cruz Biotechnology), represented by (+) or with protein A beads only, represented by (–). The phosphorylation reaction on MBP was performed as described in Basic Protocol 2. (**C**) Detection of protein kinase activities by in-gel kinase assay. MCF7 cells overexpressing ErbB-2 receptor were stimulated with EGF (50 ng/ml) for the indicated times. The in-gel kinase assay was performed as described in Basic Protocol 3. ERK1 and ERK2 bands are indicated. The identity of other bands was not determined.

the ratio between the activities of distinct protein kinases at a given time. Although this method has been good for some protein kinases, its main disadvantages are that separation of various proteins kinases is not always complete, and that it is a very laborious method.

Another method that is useful in detecting novel protein kinases is the in-gel kinase assay (Basic Protocol 3). This technique involves copolymerization of a given substrate on a sodium dodecyl sulfate (SDS)–polyacrylamide gel, electrophoresis of the samples of interest on the copolymerized gel, and in-gel phosphorylation in the presence of [γ-^{32}P]ATP. The advantage of this method is that it reveals the molecular weight of the kinases with the desired specificity, assisting in the identification of the enzymes of interest. Also, several samples can be examined simultaneously. The main disadvantages of this procedure are: (1) not all protein kinases can be renatured in the SDS gel, (2) each in-gel assay takes 2 or 3 days, and (3) there is a narrow linear range of protein kinase activities that can interfere with the detection of the fold induction of protein kinases upon stimulation.

The MonoQ fractionation and in-gel kinase assay methods are mainly used to identify or characterize novel protein kinases. However, since the resolutions of these two methods are not always adequate and they are very labor-intensive, more specific and convenient methods are recommended for the characterization of given protein kinases. Such specific methods often require the isolation of the protein kinase of interest, although a specific activator or substrate can sometimes be used (as is the case with PKA or MEK). The separation is often done by specific antibodies, which can be either directed against the phosphorylated sequence (anti-phospho antibodies) or against the whole molecule (anti-general antibodies), as described in this unit. The anti-phospho antibody becomes useful when the examined protein kinase is activated by phosphorylation and the activating phosphorylation site is known. Indeed, this seems to be the case for most MAPKs, MAPKAPKs, and MAPKKs known today, but it does not seem to be applicable for MAP3Ks and MAP4Ks, as described below. Probably the best known examples are the anti–active mitogen-activated protein kinase (MAPK; Seger and Krebs, 1995) antibodies (anti-diphospho ERK; Gabay et al., 1997; Yung et al., 1997), which are commercially available (Table 14.3.1). In response to stimulation, ERK1 and ERK2 are rapidly phosphorylated at up to six sites (Robbins and Cobb, 1992). Phosphorylation of two of these sites (threonine 183 and tyrosine 185 in ERK2; Payne et al., 1991) can lead to full activation of the enzyme, whereas the effects of phosphorylation of the other sites are not yet known. Antibodies directed towards the activation motif of ERK, which is PT-E-PY, serve as good tools for detecting its enzymatic activity, whereas anti-PAA antibodies can detect the total phosphorylation, which does not fully correlate with ERK's enzymatic activity. An important advantage of using anti-phospho antibodies is that they shorten and simplify the procedure of detection, which can be achieved in only one step (immunoblotting or cell staining). However, the antibodies do not usually serve as reliable tools to determine the exact kinetic parameters of the MAPK, as their dynamic range of detection is limited.

The successful use of sequence-specific anti-phospho antibodies relies on their specificity for the phosphorylated form of the examined protein. Monoclonal antibodies, which usually confer better specificity than polyclonal ones, are considered a reliable tool for distinguishing phosphorylated from nonphosphorylated forms of proteins, although affinity-purified polyclonal antibodies can be used as well. Both monoclonal and polyclonal antibodies can be generated by immunization with whole phosphorylated proteins or with KLH- or BSA-coupled peptides (see *UNIT 16.6*). Standard procedures for the isolation of the monoclonal and polyclonal antibodies are then employed. In this unit, the use of anti-phospho antibodies in immunoblot analysis is described. However, most of these antibodies can be used also for cell staining, which is described in *UNITS 4.3 & 14.2*.

Table 14.3.1 Antibodies Available Against MAPKs

Tier	Name	MAPK activated	Mol. wt. (kDa)	Commercially available antibodies	Supplier[a]	Reference

Because not all MAPK components are activated by phosphorylation, and because the availability of commercial anti-phospho antibodies might be limited, the activity of the desired protein kinases may be determined by immunoprecipitation with specific antibodies directed to the C-terminal domain of the kinase (as described in Basic Protocol 2). Another use for anti-general antibodies is detection of slower migration on SDS-PAGE that occurs upon phosphorylation of regulatory residues of some MAPKs. However, this gel shift does not always correlate with enzymatic activity, as was shown for ERK and Raf1. Methods for affinity purification that do not involve antibodies can sometime be used to isolate given protein kinases (e.g., JNKs; Hibi et al., 1993). Although affinity techniques (including immunoprecipitation) are often used, it should be noted that the attachment to a solid support that occurs in this method may interfere with the accurate detection of the kinase activity. However, affinity reagents are not available for all MAPK components, and the identity of the desired protein kinase might be obscured. Therefore, the method that can be used in this case is the in-gel kinase assay as described in Basic Protocol 3. Although other methods are available, the combination of the methods described here should allow determination of the activity of most MAPK components and identification of the components that are activated by various extracellular stimuli.

IMMUNODETECTION OF MAPK ACTIVATION USING ANTI-PHOSPHO MAPK ANTIBODIES

BASIC PROTOCOL 1

This method describes the immunodetection of phosphoproteins using extraction of proteins by sonication followed by immunoblot analysis. Although phosphorylation of ERK1/2 is used here as an example, this immunodetection protocol can be used with most specific anti-phospho antibodies available for many components of the MAPK cascades (Table 14.3.1). This protocol minimizes the time phosphorylated proteins are exposed to phosphatases, which allows reliable and quantitative detection of the phosphorylated proteins, and it can be completed within 7 to 10 hr. Furthermore, this method can be used with almost all tissue culture cell lines, homogenized animal organs, and even whole lower organisms.

Materials

Rat1 cells (ATCC #CRL-2210)
DMEM containing 10% heat-inactivated FBS (see *APPENDIX 2A* and *UNIT 1.2*)
Starvation medium: DMEM containing 0.1% (v/v) heat-inactivated FBS (see *APPENDIX 2A* and *UNIT 1.2*)
50 μg/ml epidermal growth factor (EGF) in EGF buffer (0.5 mg/ml BSA in PBS)
EGF buffer: 0.5 mg/ml bovine serum albumin (BSA) in phosphate-buffered saline (PBS; *APPENDIX 2A*)
Phosphate-buffered saline (PBS; *APPENDIX 2A*), ice-cold
Buffer A (see recipe), ice-cold
Buffer H (see recipe), ice-cold
Protein standards: 5, 10, 20, 50, 100, and 200 μg/ml BSA in Buffer H (see recipe for buffer H)
Bradford protein assay reagent (Pierce or Bio-Rad; also see recipe for Coomassie dye reagent in *APPENDIX 3H*)
4× sample buffer for SDS-PAGE (see recipe)
1.5 M Tris·Cl, pH 8.8 (*APPENDIX 2A*)
30% acrylamide/0.8% bisacrylamide (Table 6.1.1)
10% (w/v) ammonium persulfate (prepare fresh)
Tetramethylethelendiamine (TEMED)
0.5 M Tris·Cl, pH 6.8 (*APPENDIX 2A*)
Running buffer (see recipe)
Prestained protein markers

Transfer buffer (see recipe)

Blocking solution: 2% (w/v) bovine serum albumin (BSA) in TBST (see recipe for TBST)

Primary antibodies: monoclonal mouse anti-phospho ERK antibody (Table 14.3.1) and polyclonal rabbit anti-general ERK antibody (C-terminus)

Tris-buffered saline with Tween 20 (TBST; see recipe)

Secondary antibodies: alkaline phosphatase (AP)–coupled goat anti-mouse antibody and horseradish peroxidase (HRP)–conjugated goat anti-rabbit antibody

6-cm tissue culture dishes

1-ml pipet tips, precooled

1.5-ml microcentrifuge tubes precooled; four sets of six (each labeled 1 to 6)

Plastic (or rubber) policeman

Probe sonicator (e.g., Branson)

96-well flat-bottom microtiter plate

Microtiter plate reader capable of reading at 595 nm

95°C or boiling water bath

Gel-casting apparatus: 7 × 10–cm glass plates, 1.5-mm spacers, and 1.5-mm comb with 10 teeth (also see *UNIT 6.1*)

Gel electrophoresis apparatus and power supply (also see *UNIT 6.1*)

0.45-μm nitrocellulose membrane (e.g., Schleicher & Schuell or Millipore), cut to gel size

Whatman 3MM paper (two sheets cut to gel size)

Transfer apparatus and power supply (also see *UNIT 6.2*)

Additional reagents and equipment for cell culture (*UNIT 1.1*), SDS-PAGE (*UNIT 6.1*), and visualization of immunoblotted proteins (*UNIT 6.2 & 14.2*)

NOTE: All reagents and equipment coming into contact with living cells must be sterile, and aseptic technique should be used accordingly.

NOTE: All culture incubations should be performed in a humidified 37°, 5% CO_2 incubator unless otherwise specified. Some media (e.g., DMEM) require altered levels of CO_2 to maintain pH 7.4.

Prepare cellular extracts

1. Grow Rat1 cells in six 6-cm tissue culture dishes in 4 ml DMEM containing 10% FBS to subconfluency (~0.5×10^6 cells/dish).

   UNIT 1.1 describes basic cell culture techniques.

2. Serum-starve the Rat1 cells by removing the culture medium from each dish, replacing it with 2 ml starvation medium, and incubating 18 hr.

   During serum starvation, place the dishes in the tissue culture incubator, making sure that the dishes remain flat and that the medium covers the entire dish evenly. The aim of this starvation is to make the cells quiescent, and thereby reduce the amount of the inducible MAPK phosphatases (MKPs). Under these conditions, this can be achieved within 14 to 24 hr. Starvation for too long or any change in temperature or pH may be stressful to the cells, thereby inducing activation of one or more signaling pathways. Although this protocol describes EGF stimulation of Rat1 cells, this procedure, with minor changes, can be used for most extracellularly stimulated cells.

3. To each of three of the dishes, add 2.0 μl of 50 μg/ml EGF (stimulated samples). To each of the other three dishes, add 2.0 μl EGF buffer (control samples). Incubate one sample and control for 5 min, another sample and control for 15 min, and the third sample and control for 45 min.

Usually, the stimulus is given first to the dishes with the longest incubation, then, at appropriate intervals, to the dishes with the second longest and the shortest incubation periods. It is useful to make and use a time chart so that stimuli will be given at the appropriate times and the cells harvested within a short period of time (within 5 to 10 min for all dishes). If the influence of the stimulating agent on the particular cells is not yet known, a positive control should be included, such as a dish treated with 50 μl peroxovanadate (VOOH) solution (see recipe), for a final concentration of 100 μM sodium orthovanadate and 200 μM H_2O_2, which nonspecifically activates many signaling events in most tissue culture cells.

4. At the end of the assay, remove the medium from the dishes containing the Rat1 cells. Rinse dishes twice with 5 ml ice-cold PBS and once with 5 ml ice-cold buffer A. Be sure to remove all of the PBS after the last wash. Place dishes on ice.

   Because the objective at this stage is to arrest or slow down biological processes, the dishes should be placed on ice. Washing and harvesting of each dish should take 0.5 to 1.5 min. so that all six dishes are harvested within 5 to 10 min.

5. Add 250 μl of ice-cold buffer H to each dish, tilt the dish gently (preferably on ice), and scrape the cells into the buffer using a plastic (or rubber) policeman. Using precooled pipet tips, transfer the cells and buffer to prelabeled, precooled 1.5-ml plastic test tubes.

   Special consideration should be given to the composition of the buffer H (see Reagents and Solutions). The authors recommend using β-glycerophosphate, which serves both as a buffer and a general phosphatase inhibitor, rather than Tris or HEPES. Sodium orthovanadate is used to inhibit tyrosine phosphatases, and the mixture of pepstatin A, aprotinin, leupeptin, and benzamidine is used to inhibit proteinases. This buffer, when cold, blocks most of the phosphatase and proteinase activities in cell extracts.

6. Disrupt the cells by sonication using two 7-sec, 50-W pulses with a 20-sec interval per ~0.5-ml sample on ice.

   Over the years, several methods of protein extraction from cells have been successfully used in the study of protein kinases. In this protocol, which utilizes sonication, proteins are extracted from the cytosolic and nuclear fractions, but not from the membrane fraction, and therefore can be considered as cytosolic extract. Cellular extraction with nonionic detergents, which extract proteins from membranal, cytosolic, and some nuclear fractions of the cell, makes determination of the protein concentration somewhat difficult, but it is often used. Extraction with RIPA buffer or by freezing-thawing can also be used for some kinases.

7. Microcentrifuge the cellular extracts 15 min at 14,000 × *g*, 4°C. Transfer the resulting supernatants (cytosolic extracts), which contain the protein to be examined for phosphorylation, to fresh, precooled microcentrifuge tubes. Take a 5- to 20-μl aliquot of each extract and determine protein concentration (steps 8 to 11). Store the remainder of each cytosolic extract on ice until needed for the electrophoresis, transfer, and detection steps (steps 12 to 36).

   The protein concentration of each sample should be determined so that the amounts of proteins from the different samples can be compared, making it possible to determine the relative amounts of protein kinases in all samples accurately. If samples are compared based on cell number, differences of up to 20% in the amount of protein may result. Such differences may cause even larger ones in the following steps.

Determine protein concentration and prepare extracts for electrophoresis

8. Dilute 10 μl of each cytosolic extract sample in 190 μl buffer A (a final dilution of 1:20) in labeled tubes.

   Usually, dilutions of at least 1:20 are necessary to ensure that the samples will be in the linear range of the protein determination assay. For some Coomassie blue reagents with extended ranges, this dilution is not always necessary.

9. Put 10 μl of each of the protein standards (10, 25, 50, 75, 100, 150, and 200 μg/ml BSA in buffer H) into duplicate or triplicate wells of a flat-bottom 96-well microtiter plate.

   Protein standards should be prepared in the same buffer used for the cell extraction (in this case, buffer H).

10. Put 10 μl of each of the sample dilutions from step 8 into duplicate or triplicate wells of the same microtiter plate. Add 200 μl of Bradford protein assay reagent to all wells.

11. Place the microtiter plate in a microtiter plate reader and measure the optical density at 595 nM.

Perform electrophoresis

12. From the optical densities, calculate the protein concentrations of the samples. Take an aliquot of each extract corresponding to 40 μg of protein and place in a new 1.5-ml microcentrifuge tube.

    30 to 50 μg protein should be loaded in each lane of the gel. The authors strongly recommend using equal protein amounts for each sample to avoid inaccuracies.

13. Add 1/3 vol of 4× sample buffer to each tube, mix the contents, and place in 95°C or boiling water bath for 5 min.

14. Assemble 7 × 10–cm glass plates and 1.5-mm spacers for casting the polyacrylamide gel.

15. Prepare a 12% separating gel by mixing the following (total volume, 10.0 ml):

    3.4 ml H_2O
    2.5 ml 1.5 M Tris·Cl, pH 8.8
    4.0 ml 30% acrylamide/0.8% bisacrylamide
    100 μl 10% ammonium persulfate
    6 μl TEMED.

16. Pour the separating gel (*UNIT 6.1*). Overlay the top of the gel with water and allow it to polymerize ~30 to 45 min.

17. Prepare 3% polyacrylamide stacking gel by mixing the following (5 ml total):

    550 μl 30% acrylamide/0.8% bisacrylaimde solution
    625 μl 0.5 M Tris·Cl, pH 6.8
    3.7 ml H_2O
    120 μl ammonium persulfate
    5 μl TEMED.

18. Remove the water from the top of the polymerized separating gel. Using a Pasteur pipet, layer 2 ml of the stacking gel on top of the separating gel (*UNIT 6.1*) to fill up the apparatus. Insert comb into the stacking gel and allow it to polymerize for ~10 to 20 min.

19. Place the polymerized gel in the electrophoresis apparatus, add running buffer, and check for leaks.

20. Load 30 μl of the samples (from step 13) and 10 μl of the prestained protein markers into each well of the gel.

    Usually, prestained markers are loaded into the first or second lane of the gel so that the first lane can be located in the immunoblot and the molecular weights of the detected proteins determined. These markers will also indicate whether the proteins were completely transferred from the gel onto the nitrocellulose paper during blotting.

21. Connect the wire leads of the gel apparatus to the power supply. Turn on the power supply and run the gel at 150 V (constant voltage) until the bromphenol blue dye reaches a point 0.5 cm from the bottom of the gel (which usually takes ~1 hr).

Transfer the proteins to a membrane

22. Prewet (soak) the nitrocellulose membrane and 3MM Whatman paper in transfer buffer.

23. Once the dye front of the SDS-PAGE has reached the end of the gel, remove the gel from the apparatus, cut off the stacking gel, and place the separating gel in a container with transfer buffer.

24. Fill the transfer apparatus with transfer buffer. Open the inner transfer apparatus and remove air bubbles from the pads. Make a sandwich by putting a wet 3MM Whatman paper on the wet pad, the gel on top of the 3MM Whatman paper, the wet nitrocellulose membrane on top of the gel, and the other wet 3MM Whatman paper on top of the nitrocellulose membrane.

    Basic immunoblotting techniques are described in detail in UNIT 6.2.

25. Remove any air bubbles from between the different layers of the transfer sandwich by gently rolling a 10-ml pipet over the sandwich. Place the other wet pad on top of the transfer sandwich.

    Make sure that no air bubbles are trapped between the gel and the other components.

26. Place the sandwich containing the gel and nitrocellulose membrane into the buffer-filled transfer apparatus with the nitrocellulose membrane facing the side with the cathode and the gel facing the side with the anode. Connect the apparatus to a power supply and start the current. Transfer the proteins at 200 mA constant current for 120 min, preferably with a cooling device.

    The voltage will drop as the transfer progresses due to an increase in the conductivity. Methanol or 0.05% SDS are sometimes included in the transfer buffer; their inclusion will require different transfer conditions (see UNIT 6.2).

27. At the end of the transfer period, turn off the power supply and remove the nitrocellulose membrane from the transfer sandwich. Rinse the nitrocellulose membrane with transfer buffer to remove any adhering pieces of gel, and place the membrane in a flat container.

    At this stage, the efficiency of protein transfer can be monitored visually by the transfer of prestained protein markers to the membrane. The total amount of protein transferred can also be detected by staining the membrane with Ponceau S solution (UNIT 6.2). However, since the total amount of nonphosphorylated proteins is determined by general antibodies, as described later, staining with Ponceau S is probably not essential for this particular protocol.

Expose the membrane to antibodies

28. Incubate the nitrocellulose membrane in ~25 ml blocking solution for 60 min at room temperature.

    This will ensure that nonspecific protein binding sites on the membrane are blocked. The use of milk for blocking is not recommended because it causes nonspecific binding of some of the antibodies.

29. Incubate the blot with 10 to 20 ml of the primary antibody (e.g., monoclonal anti-phospho ERK antibody, diluted according to the supplier's recommendations in TBST) either overnight at 4°C, 30 min at 37°C, or 1 to 2 hr at room temperature.

30. Wash the blot in the flat container at least three times, each time for 15 min with 50 ml TBST at room temperature.

31. Incubate the blot with 10 to 20 ml of the secondary antibody (e.g., AP-conjugated goat anti-mouse IgG, diluted according to the supplier's instructions in TBST) for 45 min at room temperature.

For detection of the anti-phospho ERK antibody, the AP detection system is recommended because of its broader linear range compared to ECL (see Commentary). Alternatively, HRP-conjugated goat anti-rabbit antibodies can be used as secondary antibodies with detection by ECL. If HRP-rather than AP-conjugated antibodies are used at this stage, then AP-conjugated antibodies should be used in step 35.

32. Wash the blot at least three times, each time for 10 min, with 50 ml TBST.

33. Use an AP detection protocol (*UNIT 6.2*) to detect phospho ERK.

After detecting the phosophorylated (active) ERK, it is recommended that it be determined whether there is an equal amount of ERK in all lanes by exposing the same blot to polyclonal anti-general ERK antibody and redeveloping it (see steps 34 to 36).

Expose the membrane to general antibody

34. Incubate the stained nitrocellulose in blocking solution for 30 min at room temperature.

Since two different types of antibodies are used (mouse and rabbit), stripping away the antibodies used in steps 29 to 30 is not necessary, and the second blotting can be performed by simply adding the different type of antibody and following steps 35 and 36. Antibodies from the same species of origin (mouse or rabbit) can be used for both steps; however this requires a stripping step, which must be performed before continuing with step 35. Note that some of the antibodies can hinder recognition by other antibodies directed against different epitopes, and therefore also require stripping before the second type of antibody is applied.

35. Incubate the blot with 10 to 20 ml of the polyclonal rabbit anti-general ERK primary antibody, wash as described in step 30, then incubate with 10 to 20 ml of HRP-conjugated goat anti-rabbit secondary antibody.

36. Use a luminescent detection protocol for HRP (*UNIT 6.2*) to observe general ERK.

The ECL protocol involves mixing solution A (2.5 mM Luminol, 400 mM p-coumarin, 100 mM Tris·Cl, pH 8.5) with an equal amount of solution B (5.4 mM H_2O_2, 100 mM Tris·Cl, pH 8.5), incubation of the blot with the substrate solution for 1 min, drying the blot with 3MM Whatman paper, wrapping the blot in transparent plastic wrap and exposing it to X-ray film. See UNITS 6.2 & 14.2 for additional details.

BASIC PROTOCOL 2

DETERMINATION OF MAPK (ERK) ACTIVITY BY IMMUNOPRECIPITATION

This method describes determination of ERK activity by isolating the enzyme using immunoprecipitation with specific antibodies and then performing a phosphorylation reaction in vitro. Although this protocol uses ERK with its appropriate reagents, it can be performed with other components of the MAPK cascade, as antibodies are available for most components of these cascades (Table 14.3.1). This protocol allows a fast and efficient isolation of the desired protein kinase and its reliable quantitation by a phosphorylation reaction. It involves standard biochemical procedures and can be completed in 7 to 10 hr. Furthermore, this method can be used with almost all tissue culture cell lines, homogenized animal organs, and even lower organisms.

CAUTION: When working with radioactive materials, take appropriate precautions to avoid contamination of the experimenter and the surroundings. Carry out the experiment and dispose of wastes in an appropriately designated area, following guidelines provided by the institutional Radiation Safety Officer (also see *UNIT 7.1* and *APPENDIX 1D*).

Materials

Rat1 cells (ATCC #CRL-2210)
DMEM containing 10% heat-inactivated FBS (see *APPENDIX 2A* and *UNIT 1.2*)
Starvation medium: DMEM containing 0.1% (v/v) heat-inactivated FBS (see *APPENDIX 2A* and *UNIT 1.2*)
50 μg/ml epidermal growth factor (EGF) in EGF buffer
EGF buffer: 0.5 mg/ml bovine serum albumin (BSA) in phosphate buffered saline (PBS; *APPENDIX 2A*)
Phosphate-buffered saline (PBS; *APPENDIX 2A*), ice-cold
Buffer A (see recipe), ice-cold
Buffer H (see recipe), ice-cold
Protein standards: 5, 10, 20, 50, 100 and 200 μg/ml BSA in Buffer H
Bradford protein assay reagent (Pierce or Bio-Rad; also see recipe for Coomassie dye reagent in *APPENDIX 3H*)
Protein A–Sepharose beads (Amersham Biosciences; 10 to 20 μl of packed beads per reaction)
Antibody for immunoprecipitation (e.g., anti-ERK C-terminus antibody, 1 to 5 μg per reaction according to the supplier's instructions)
RIPA buffer (see recipe), ice-cold
Lithium chloride solution: 0.5 M LiCl/0.1 M Tris·Cl, pH 8.0 (see *APPENDIX 2A* for Tris·Cl), ice-cold
RM×3 (see recipe)
2 mg/ml myelin basic protein (MBP), or other appropriate phosphorylation substrate at appropriate (usually lower) concentration
4× sample buffer for SDS-PAGE (see recipe)
7 × 10–cm 15% SDS-PAGE gel with stacking gel (*UNIT 6.1*; also see Basic Protocol 1)
Prestained protein markers
Staining solution (see recipe)
Destaining solution (see recipe)
6-cm tissue culture dishes
1-ml pipet tips, precooled
1.5-ml microcentrifuge tubes precooled; four sets of six (each labeled 1 to 6)
Plastic (or rubber) policeman
Probe sonicator (e.g., Branson)
96-well flat-bottom microtiter plate
Microtiter plate reader capable of reading at 595 nm
End-over-end rotator
30°C Thermomixer (Eppendorf) or water bath
Boiling water bath
Flat container for staining/destaining gel
Additional reagents and equipment for cell culture (*UNIT 1.1*), SDS-PAGE (*UNIT 6.1*), and autoradiography or phosphor imaging (*UNIT 6.3*)

NOTE: All reagents and equipment coming into contact with living cells must be sterile, and aseptic technique should be used accordingly.

NOTE: All culture incubations should be performed in a humidified 37°, 5% CO_2 incubator unless otherwise specified. Some media (e.g., DMEM) require altered levels of CO_2 to maintain pH 7.4.

Prepare cellular extracts

1. Grow Rat1 cells in six 6-cm tissue culture dishes in 4 ml DMEM containing 10% FBS to subconfluency ($\sim 0.5 \times 10^6$ cells/dish).

   UNIT 1.1 describes basic cell culture techniques.

2. Serum-starve the Rat1 cells by removing the culture medium from each dish, replacing it with 2 ml starvation medium, and incubating 18 hr.

   During serum starvation, place the dishes in the tissue culture incubator, making sure that the dishes remain flat and that the medium covers the entire dish evenly. The aim of this starvation is to make the cells quiescent, and thereby reduce the amount of the inducible MAPK phosphatases (MKPs). Under these conditions, this can be achieved within 14 to 24 hr. Starvation for too long or any change in temperature or pH may be stressful to the cells, thereby inducing activation of one or more signaling pathways. Although this protocol describes EGF stimulation of Rat1 cells, this procedure, with minor changes, can be used for most extracellularly stimulated cells.

3. To each of three of the dishes, add 2.0 μl of 50 μg/ml EGF (stimulated samples). To each of the other three dishes, add 2.0 μl EGF buffer (control samples). Incubate one sample and control for 5 min, another sample and control for 15 min, and the third sample and control for 45 min.

   Usually, the stimulus is given first to the dishes with the longest incubation, then, at appropriate intervals, to the dishes with the second longest and the shortest incubation periods. It is useful to make and use a time chart so that stimuli will be given at the appropriate times and the cells harvested within a short period of time (within 5 to 10 min for all dishes). If the influence of the stimulating agent on the particular cells is not yet known, a positive control should be included, such as a dish treated with 50 μl peroxovanadate (VOOH) solution (see recipe), for a final concentration of 100 μM sodium orthovanadate and 200 μM H_2O_2, which nonspecifically activates many signaling events in most tissue culture cells.

4. At the end of the assay, remove the medium from the dishes containing the Rat1 cells. Rinse the dishes twice with 5 ml ice-cold PBS and once with 5 ml ice-cold buffer A. Be sure to remove all of the PBS after the last wash. Place dishes on ice.

   Because the objective at this stage is to arrest or slow down biological processes, the dishes should be placed on ice. Washing and harvesting of each dish should take 0.5 to 1.5 min. so that all six dishes are harvested within 5 to 10 min.

5. Add 250 μl of ice-cold buffer H to each dish, tilt the dish gently (preferably on ice), and scrape the cells into the buffer using a plastic (or rubber) policeman. Using precooled pipet tips, transfer the cells and buffer to prelabeled, precooled 1.5-ml plastic test tubes.

   Special consideration should be given to the composition of the buffer H (see Reagents and Solutions). The authors recommend using β-glycerophosphate, which serves both as a buffer and a general phosphatase inhibitor, rather than Tris or HEPES. Sodium orthovanadate is used to inhibit tyrosine phosphatases, and the mixture of pepstatin A, aprotinin, leupeptin, and benzamidine is used to inhibit proteinases. This buffer, when cold, blocks most of the phosphatase and proteinase activities in cell extracts.

6. Disrupt the cells by sonication using two 7-sec 50-W pulses with a 20-sec interval per ~0.5-ml sample on ice.

   Over the years, several methods of protein extraction from cells have been successfully used in the study of protein kinases. In this protocol, which utilizes sonication, proteins are extracted from the cytosolic and nuclear fractions, but not from the membrane fraction, and therefore can be considered as cytosolic extract. Cellular extraction with nonionic detergents, which extract proteins from membranal, cytosolic, and some nuclear fractions of the cell, makes determination of the protein concentration somewhat difficult, but is often used. Extraction with RIPA buffer or by freezing-thawing can also be used for some kinases.

7. Microcentrifuge the cellular extracts 15 min at 14,000 × *g*, 4°C. Transfer the resulting supernatants (cytosolic extracts), which contain the protein to be examined for phosphorylation, to fresh precooled microcentrifuge tubes. Take a 5- to 20-µl aliquot of each extract and determine protein concentration (steps 8 to 12). Store the remainder of each cytosolic extract on ice until needed for the immunoprecipitation and phosphorylation steps (steps 13 to 27).

   The protein concentration of each sample should be determined so that the amounts of proteins from the different samples can be compared, making it possible to determine the relative amounts of protein kinases in all samples accurately. If samples are compared based on cell number, differences of up to 20% in the amount of protein may result. Such differences may cause even larger ones in the following steps.

Determine protein concentration

8. Dilute 10 µl of each cytosolic extract sample in 190 µl buffer A (a final dilution of 1:20) in labeled tubes.

   Usually, dilutions of at least 1:20 are necessary to ensure that the samples will be in the linear range of the protein determination assay. For some Coomassie blue reagents with extended ranges, this dilution is not always necessary.

9. Put 10 µl of each of the protein standards (10, 25, 50, 75, 100, 150, and 200 µg/ml BSA in buffer H) into duplicate or triplicate wells of a flat-bottom 96-well microtiter plate.

   Protein standards should be prepared in the same buffer used for the cell extraction (in this case, buffer H).

10. Put 10 µl of each of the sample dilutions from step 8 into duplicate or triplicate wells of the same microtiter plate. Add 200 µl of the Bradford protein assay reagent to all wells.

11. Place the microtiter plate in a microtiter plate reader and measure the optical density at 595 nM.

12. From the optical densities, calculate the protein concentrations of the samples.

Prepare antibody-conjugated protein A–Sepharose beads

13. Place ~150 µl protein A–Sepharose beads in a 1.5-ml microcentrifuge tube and add 1 ml of PBS. Let the beads swell for 10 min at room temperature.

    Although protein A–conjugated Sepharose is recommended for this method, other commercially available protein A–conjugated resins, such as agarose, HiTrap, etc., may be used. Protein G–coupled resins are sometimes required to immunoprecipitate certain types of monoclonal antibodies (Table 7.2.1). If resins are supplied as ready-to-use suspensions, this swelling step is not necessary.

14. Microcentrifuge the swollen beads 1 min at 14,000 × *g*, room temperature, and remove the supernatant. Wash the swollen beads three times, each time by adding 1 ml PBS, centrifuging again as before, and discarding the supernatant.

15. Combine 180 µl of the swollen packed beads with 320 µl PBS. Add the recommended amount of the antibody for immunoprecipitation (e.g., ~10 µg anti-ERK C terminus). Rotate the mixture 1 hr at room temperature on an end-over-end rotator to allow the antibodies to bind to the protein A.

    Alternatively, this step can be done at 4°C for 16 hr.

    Usually, anti-C-terminal antibodies are used for the determination of kinase activity because their binding to the kinase does not interfere with the kinase activity. Ideally, the volumes listed here should be sufficient for ten reactions, but, because of the density of the beads, they will probably only be sufficient for eight reactions. Depending on the

number of reactions to be performed, the amounts given here can be scaled up as long as the proportions are maintained.

For easy handling of the resin, the ends of the pipet tips can be cut to enlarge their openings.

16. Microcentrifuge the antibody-conjugated beads 1 min at 14,000 × *g*, room temperature. Resuspend the beads in 1 ml PBS, then centrifuge again as before and remove the supernatant. Wash three times, each time by adding 1 ml ice-cold PBS, centrifuging again as before, and removing the supenatant. Resuspend the washed beads in an equal volume of ice-cold buffer A (~250 µl for ~250 µl of beads).

    Either use the antibody-conjugated beads immediately, or store at 4°C until used. It is best to use the conjugated beads within 3 days of preparation.

17. In precooled 1.5-ml microcentrifuge tubes, add 30 µl of the antibody-conjugated bead suspension from step 16 (equivalent to 15 µl packed beads) to 300 µl of cytosolic extract (from step 7) containing 50 to 500 µg total protein (determined as in steps 8 to 12) in buffer H. Rotate on an end-over-end rotator for 2 hr at 4°C.

    Several immunoprecipitation methods have been developed. These methods usually vary with respect to the order in which the antibodies and protein A are added to the cell extracts. In the protocol described here, the antibodies are conjugated to protein A beads and only then added to the cytosolic extracts. This procedure minimizes the time the samples are incubated with the antibodies, and thereby minimizes exposure of the desired kinases to phosphatases and proteinases in the extracts. Furthermore, this procedure ensures that only antibodies recognized by protein A will be used for the immunoprecipitation. Antibodies that are not recognized by protein A can bind to the desired antigen, but they will not be precipitated when protein A beads are added; therefore, such antibodies will reduce the efficiency of immunoprecipitation.

18. Centrifuge the incubation mixture 1 min at 14,000 × *g*, 4°C. Remove and discard the incubation supernatant from the antibody-conjugated beads. Add 1 ml ice-cold RIPA buffer, centrifuge again as before, and discard the supernatant. Wash the pellet twice, each time by adding 1 ml ice-cold 0.5 M lithium chloride solution, centrifuging again as before, and removing the supernatant, then wash twice, each time by adding 1 ml ice-cold buffer A, centrifuging again, and discarding the supernatant.

    These stringent washes are important because they will remove most sticky protein kinases that might nonspecifically interact with the protein A beads.

Perform phosphorylation reaction

19. After the last wash step in 18, completely remove buffer A from the conjugated beads by microcentrifuging again after the buffer has been aspirated from above the pellet (without resuspension), then gently removing the residual buffer above the beads.

20. Resuspend the bead pellet in 15 µl water.

    At this stage, prepare the bench for working with small amounts of radioactivity (see APPENDIX 1D).

21. Add 10 µl of RM×3 to each tube.

    See Reagents and Solutions for a discussion of the components of RM×3.

22. Start the phosphorylation reaction by adding 5 µl of the phosphorylation substrate (e.g., 2 mg/ml MBP) to the tube and placing the mixture in an Eppendorf Thermomixer (or water bath) at 30°C. Incubate 20 min at 30°C with either constant or frequent shaking.

    Although MBP is probably not a physiological substrate for any MAPK, it is a good general substrate for many kinases, including ERKs, in vitro. Substrates should be well phosphorylated by the desired kinases to allow accurate detection of the phosphorylation

kinetics. Therefore known substrates of the MAPK can be used as good substrates instead of MBP, but those are usually used at lower concentrations in the phosphorylation reaction.

23. End the phosphorylation reaction by adding 10 µl of 4× sample buffer to each tube.

24. Place samples in a boiling water bath for 5 min. Microcentrifuge 1 min at 14,000 × *g*, room temperature. Load the resulting supernatants on a 7 × 10–cm, 15% SDS-PAGE gel with stacking gel (*UNIT 6.1*). Load prestained markers on gel as well. Run the gel at 150 V (constant voltage) for ~1 hr or until the dye front is 0.5 cm from the bottom (*UNIT 6.1*).

    Usually, prestained markers are loaded into the first or second lane of the gel so that the first lane can be located on the dried gel and the molecular weight of the detected proteins determined.

    Since determination of enzymatic activity is not always accurate when enzymes (in this case protein kinases) are bound to beads, the kinase(s) of interest can be released from the beads at step 19 or 20 by using excess immunizing peptide. The phosphorylation reaction (steps 21 to 23) can thus be performed without the interference of the beads. Then the activity can be detected as described (step 27) or by a paper assay. For the paper assay, the phosphorylation reaction is terminated by spotting 20 µl of each sample on phosphocellulose paper squares (Whatman P81), which are immediately washed with 150 mM phosphoric acid. Phosphate incorporation is then measured using a scintillation cocktail. Gel quantitation can also be carried out by densitometry after imaging the gel as in step 27.

25. Turn the power supply off and disconnect the leads. Remove the glass plates containing the gel and remove the gel from the plate.

26. Place the gel in a flat container and stain the gel with 50 ml staining solution for 20 min at room temperature. Destain with four 30-min changes of 50 ml destaining solution.

    This extensive destaining removes excess free [γ-^{32}P]ATP, which would affect the background. In some cases, the extensive destaining is not necessary, or the proteins can be transferred to a nitrocellulose membrane and then be imaged as described below.

27. Place the gel on a sheet of Whatman 3MM paper, cover the gel with a clear plastic wrap, and dry the gel in a gel dryer (usually 1.5 hr at 80°C is sufficient). Expose the gel in a phosphor imager or autoradiograph on X-ray film (*UNIT 6.3*).

    Bands should appear at 16 to 21 kDa, corresponding to the molecular weight of the four MBP isoforms.

IN-GEL KINASE ASSAY

BASIC PROTOCOL 3

If the identity of the kinase is not known or there are no specific antibodies available for the kinase, the in-gel kinase assay may be used instead of the immunoprecipitation protocol (Basic Protocol 2). This in-gel protocol involves copolymerization of a substrate with the polyacrylamide gel followed by electrophoresis of the protein sample(s) on the gel. After several rounds of denaturation and renaturation, a phosphorylation reaction is performed with the gel, and the phosphorylated bands are visualized by autoradiography or phosphor imaging. With this method, the molecular weight of the protein kinase is revealed and unknown protein kinases can be identified (the molecular weight of most MAPK components is shown in Table 14.3.1). However, not all protein kinases can be renatured under the conditions of this protocol, and the linear range of this assay is usually limited. Therefore, this method should not be routinely used to monitor and characterize known protein kinases.

CAUTION: When working with radioactive materials, take appropriate precautions to avoid contamination of the experimenter and the surroundings. Carry out the experiment and dispose of wastes in an appropriately designated area, following guidelines provided by the institutional Radiation Safety Officer (also see *UNIT 7.1* and *APPENDIX 1D*).

Materials

Rat1 cells (ATCC #CRL-2210)
DMEM containing 10% heat-inactivated FBS (see *APPENDIX 2A* and *UNIT 1.2*)
Starvation medium: DMEM containing 0.1% (v/v) heat-inactivated FBS (see *APPENDIX 2A* and *UNIT 1.2*)
50 μg/ml epidermal growth factor (EGF) in EGF buffer
EGF buffer: 0.5 mg/ml bovine serum albumin (BSA) in phosphate buffered saline (PBS; *APPENDIX 2A*)
Phosphate-buffered saline (PBS; *APPENDIX 2A*), ice-cold
Buffer A (see recipe), ice-cold
Buffer H (see recipe) containing 1% (v/v) Triton X-100, ice-cold
Buffer H (see recipe), ice-cold
Protein standards: 5, 10, 20, 50, 100 and 200 μg/ml BSA in Buffer H (see recipe for buffer H)
Bradford protein assay reagent (Pierce or Bio-Rad; also see recipe for Coomassie dye reagent in *APPENDIX 3H*)
4× sample buffer for SDS-PAGE (see recipe)
1.5 M Tris·Cl, pH 8.8 (*APPENDIX 2A*)
30% acrylamide/0.8% bisacrylamide (Table 14.3.1)
10% (w/v) ammonium persulfate (prepare fresh)
Tetramethylethelendiamine (TEMED)
2 mg/ml myelin basic protein (MBP)
0.5 M Tris·Cl, pH 6.8 (*APPENDIX 2A*)
Running buffer (see recipe)
20% (v/v) isopropanol/50 mM HEPES, pH 7.6
Renaturation buffer**:** 50 mM HEPES, pH 7.6 containing 5 mM 2-mercaptoethanol
Renaturation buffer containing 6 M urea
Renaturation buffer containing 0.05% (v/v) Tween 20
In-gel kinase buffer (see recipe)
In-gel kinase reaction solution (see recipe)
5% (w/v) trichloroacetic acid (TCA)/1% (w/v) sodium pyrophosphate

6-cm tissue culture dishes
1-ml pipet tips, precooled
1.5-ml microcentrifuge tubes precooled; four sets of six (each labeled 1 to 6)
Plastic (or rubber) policeman
96-well flat-bottom microtiter plate
Microtiter plate reader capable of reading at 595 nm
Gel-casting apparatus: 7 × 10–cm glass plates, 1.5-mm spacers, and 1.5-mm comb with 10 teeth (also see *UNIT 6.1*)
Gel electrophoresis apparatus and power supply (also see *UNIT 6.1*)
Flat containers for washing gel
30°C water bath with proper shielding for radioactive work

Additional reagents and equipment for cell culture (*UNIT 1.1*), SDS-PAGE (*UNIT 6.1*), and autoradiography (*UNIT 6.3*)

NOTE: All reagents and equipment coming into contact with living cells must be sterile, and aseptic technique should be used accordingly.

NOTE: All culture incubations should be performed in a humidified 37°, 5% CO_2 incubator unless otherwise specified. Some media (e.g., DMEM) require altered levels of CO_2 to maintain pH 7.4.

Prepare cellular extracts

1. Grow Rat1 cells in six 6-cm tissue culture dishes in DMEM containing 10% FBS to subconfluency ($\sim 0.5 \times 10^6$ cells/dish).

   UNIT 1.1 describes basic cell culture techniques.

2. Serum-starve the Rat1 cells by removing the culture medium from each dish, replacing it with 2 ml starvation medium, and incubating 18 hr.

   During serum starvation, place the dishes in the tissue culture incubator, making sure that the dishes remain flat and that the medium covers the entire dish evenly. The aim of this starvation is to make the cells quiescent, and thereby reduce the amount of the inducible MAPK phosphatases (MKPs). Under these conditions, this can be achieved within 14 to 24 hr. Starvation for too long or any change in temperature or pH may be stressful to the cells, thereby inducing activation of one or more signaling pathways. Although this protocol describes EGF stimulation of Rat1 cells, this procedure, with minor changes, can be used for most extracellularly stimulated cells.

3. To each of three of the dishes, add 2.0 µl of 50 µg/ml EGF (stimulated samples). To each of the other three dishes, add 2.0 µl EGF buffer (control samples). Incubate one sample and control for 5 min, another sample and control for 15 min, and the third sample and control for 45 min.

   Usually, the stimulus is given first to the dishes with the longest incubation, then, at appropriate intervals, to the dishes with the second longest and the shortest incubation periods. It is useful to make and use a time chart so that stimuli will be given at the appropriate times and the cells harvested within a short period of time (within 5 to 10 min for all dishes). If the influence of the stimulating agent on the particular cells is not yet known, a positive control should be included, such as a dish treated with 50 µl peroxovanadate (VOOH) solution (see recipe), for a final concentration of 100 µM sodium orthovanadate and 200 µM H_2O_2, which nonspecifically activates many signaling events in most tissue culture cells.

4. At the end of the assay, remove the medium from the dishes containing the Rat1 cells. Rinse the dishes twice with 5 ml ice-cold PBS and once with 5 ml ice-cold buffer A. Be sure to remove all of the PBS after the last wash. Place dishes on ice.

   Because the objective at this stage is to arrest or slow down biological processes, the dishes should be placed on ice. Washing and harvesting of each dish should take 0.5 to 1.5 min, so that all six dishes are harvested within 5 to 10 min.

5. Harvest cells in 250 µl buffer H containing 1% Triton X-100 on ice, scraping the dishes with a plastic or rubber policeman and transferring the homogenate to a 1.5-ml microcentrifuge tube. Microcentrifuge 15 min at 14,000 × g, 4°C. Collect the supernatant and transfer to a new 1.5-ml tube.

   For this protocol, extraction with detergent is usually better than sonication.

Determine protein concentration

6. Dilute 10 µl of each extract from step 5 in 190 µl buffer A (a final dilution of 1:20) in labeled tubes.

   Usually, dilutions of at least 1:20 are necessary to ensure that the samples will be in the linear range of the protein determination assay. For some Coomassie blue reagents with extended ranges, this dilution is not always necessary.

7. Put 10 μl of each of the protein standards (10, 25, 50, 75, 100, 150, and 200 μg/ml BSA in buffer H) into duplicate or triplicate wells of a flat-bottom 96-well microtiter plate.

   Protein standards should be prepared in the same buffer used for the cell extraction (in this case, buffer H).

8. Put 10 μl of each of the sample dilutions from step 6 into duplicate or triplicate wells of the same microtiter plate. Add 200 μl of Bradford protein assay reagent to all wells.

9. Place the microtiter plate in a microtiter plate reader and measure the optical density at 595 nM.

10. From the optical densities, calculate the protein concentrations of the samples. Take an aliquot of each extract corresponding to 50 to 100 μg of protein and place in a new 1.5-ml microcentrifuge tube.

11. Add 1/3 vol of 4× sample buffer to each tube. Keep at 4°C, without boiling.

Electrophorese the sample

12. Assemble 7 × 10–cm glass plates and 1.5-mm spacers for casting the polyacrylamide gel.

13. Prepare a 12% separating gel containing MBP by mixing the following (total volume, 8 ml):

    0.7 ml H_2O
    2.0 ml 2 mg/ml MBP
    2.0 ml 1.5 M Tris·Cl, pH 8.8
    3.2 ml 30% acrylamide/0.8% bisacrylamide
    100 μl 10% ammonium persulfate
    6 μl TEMED.

14. Pour the separating gel (*UNIT 6.1*). Overlay the top of the separating gel with water. Allow the gel to polymerize ~30 to 45 min.

15. Prepare 3% polyacrylamide stacking gel by mixing the following (5 ml total):

    550 μl 30% acrylamide/0.8% bisacrylaimde solution
    625 μl 0.5 M Tris·Cl, pH 6.8
    3.7 ml H_2O
    120 μl ammonium persulfate
    5 μl TEMED
    5 ml total.

16. Remove the water from the top of the polymerized separating gel. Using a Pasteur pipet, layer ~2 ml of the stacking gel on top of the separating gel (*UNIT 6.1*) to fill up the apparatus. Insert comb into the stacking gel and allow it to polymerize 10 to 20 min.

17. Place the polymerized gel in the electrophoresis apparatus, add running buffer, and check for leaks.

18. Load ~40 μl of the samples (from step 13; containing ~70 μg protein per lane) and 10 μl of the prestained protein markers (according to the manufacturer's instructions) onto the gel. Electrophorese at 100 V for ~1 hr or until the dye front is ~0.5 cm from the bottom (*UNIT 6.1*).

    The gel should not be heated above 30°C, therefore, the voltage used for electrophoresis should not be higher than 100 V.

19. When electrophoresis is completed, turn the power supply off, remove the glass plates from the electrophoresis apparatus, and remove the gel from the plates.

Wash the gel and renature the proteins

20. Cut off the stacking gel. Place the separating gel in a flat container and wash twice, each time with 100 ml of 20% isopropanol/50 mM HEPES, pH 7.6, for 30 min at room temperature with shaking on a platform shaker. Wash the gel twice more, each time with 100 ml renaturation buffer for 30 min at room temperature with shaking, then wash the gel twice more, each time with 100 ml of 6 M urea (in renaturation buffer) for 15 min with shaking at room temperature. Leave the last urea wash on the gel and proceed to step 21.

    If necessary, the second wash with 20% isopropanol/50 mM HEPES can be done overnight at 4°C.

21. Place the gel in a 4°C cold room, remove 50 ml of the 6 M urea, add 50 ml renaturation buffer containing 0.05% Tween 20, and shake for 15 min on a platform shaker.

    The washing solution is now 3 M urea in renaturation buffer containing Tween 20.

22. Remove 50 ml of the washing solution, add 50 ml of renaturation buffer containing 0.05% Tween 20, and shake for additional 15 min

    This reduces the urea to 1.5 M.

23. Remove 50 ml of the washing solution once more and replace with renaturation buffer/0.05% Tween 20, so that the washing solution contains 0.75 M urea. Shake for 15 min.

24. Wash the gel twice, each time with 100 ml renaturation buffer containing 0.05% Tween 20 for 15 min with shaking at 4°C. Wash a third time with the same solution with shaking overnight in the cold room.

Detect kinase activity

25. Remove the washing buffer and incubate the gel in 30 ml in-gel kinase buffer for 30 min at 30°C. Remove the buffer and add 20 ml of in-gel kinase reaction solution.

    At this stage, the amount of radioactive material is very high, and therefore the reaction should be performed with a proper shielding. Make sure that the gel is straight in the flat container. Unequal distribution of the phosphorylation buffer may lead to wrong concentrations of the ingredients and thereby interfere with the phosphorylation reaction.

26. Wash gel carefully four times, each time with 3 ml 5% TCA/1% sodium pyrophosphate for 15 min at room temperature.

    If the gel is still very radioactive, continue washing overnight.

27. Dry the gel and subject to autoradiography (*UNIT 6.3*).

    Bands should appear where kinases are present and cause phosphorylation of the MBP copolymerized in the gel (see Fig. 14.3.2).

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Buffer A

50 mM β-glycerophosphate, pH 7.3
1.5 mM EGTA
1.0 mM EDTA
1.0 mM dithiothreitol (DTT)
0.1 mM sodium orthovanadate
Store up to 2 weeks at 4°C

Recipe from Ahn et al. (1990).

Buffer H

50 mM β-glycerophosphate, pH 7.3
1.5 mM EGTA
1.0 mM EDTA
0.1 mM sodium orthovanadate
Store solution with above components up to 3 months at 4°C
Immediately before use, add:
1.0 mM DTT
1.0 mM benzamidine
10 μg/ml aprotinin
10 μg/ml leupeptin
2.0 μg/ml pepstatin A

Recipe from Seger et al. (1992). "H" refers to homogenization buffer.

Destaining solution

15% (v/v) isopropanol
7% (v/v) acetic acid
Store up to 1 month at room temperature

In-gel kinase buffer

20 mM HEPES, pH 7.6
20 mM $MgCl_2$
Store up to 1 month at 4°C

In-gel kinase reaction solution

20 mM HEPES, pH 7.6
20 mM $MgCl_2$
2 mM DTT
20 μM ATP (unlabeled)
100 μCi [γ-^{32}P]ATP
Store up to 2 weeks at −20°C

Peroxovanadate (VOOH) solution

Mix 200 μl of 20 mM sodium orthovanadate with 800 μl of 10 mM H_2O_2 in PBS (see *APPENDIX 2A* for PBS). Allow mixture to incubate 15 min at room temperature before use. Prepare fresh.

RIPA buffer

137 mM NaCl
20 mM Tris·Cl, pH 7.4 (*APPENDIX 2A*)
10% (v/v) glycerol
1% (v/v) Triton X-100
0.5% (w/v) sodium deoxycholate
0.1% (w/v) SDS
2.0 mM EDTA
Store with above components up to 1 month at −20°C
1.0 mM phenylmethylsulfonyl fluoride (PMSF, add fresh)
20 μM leupeptin

RM×3

75 mM β-glycerophosphate, pH 7.3
30 mM $MgCl_2$
100 μM [γ-^{32}P]ATP (~4000 cpm/pmol)
0.9% (w/v) bovine serum albumin (BSA)

continued

3 mM DTT
3 mM EGTA
0.3 mM sodium orthovanadate
Store up to 3 month at −20°C

The most important components of the reaction mixture (also see Basic Protocol 2, step 21) are the Mg^{2+} and [γ-^{32}P]ATP, which are essential for the phosphorylation reaction. The authors recommend the use of 100 μM ATP with ~4000 cpm/pmol of the labeled ATP, which provides an extended linear range and reproducible results. When the enzymatic activity of the kinases is very low, which makes detection of phosphorylation difficult, the concentration of cold ATP should be reduced to 10 to 20 μM and the amount of radioactive material elevated. Addition of labeled ATP alone is not recommended because this will result in a nanomolar concentration of ATP, which is much below the K_m for ATP and may lead to nonspecific phosphorylation. The β-glycerophosphate in the reaction mixture serves as a buffer, but it can also inhibit residual phosphatases that may have nonspecifically bound to the beads. The BSA serves as a carrier protein, but when purity is required, it can be eliminated. The EGTA chelates Ca^{2+}, which may interfere with some kinase activities, DTT keeps the proteins reduced, and sodium orthovanadate inhibits tyrosine phosphatases.

Running buffer

25 mM Tris·Cl, pH 8.3 (*APPENDIX 2A*)
188 mM glycine
0.1% (w/v) SDS
Store up to 1 month at room temperature

Sample buffer, 4×

200 mM Tris·Cl, pH 6.8 (*APPENDIX 2A*)
40% (v/v) glycerol
8% (w/v) SDS
8% (v/v) β-mercaptoethanol
0.2% (w/v) bromphenol blue
Store up to 3 months at −20°C

Staining solution

40% (v/v) methanol
7% (v/v) acetic acid
0.005% (w/v) bromphenol blue
Store up to 3 months at room temperature

Transfer buffer

50 mM Tris·Cl, pH 8.8 (*APPENDIX 2A*)
50 mM glycine
Store up to 1 month at room temperature

Tris-buffered saline with Tween 20 (TBST)

20 mM Tris·Cl, pH 7.5 (*APPENDIX 2A*)
150 mM NaCl
0.05% (v/v) Tween 20
Store up to 1 month at room temperature

COMMENTARY

Background Information

Sequential activation of kinases (protein kinase cascades) is a common mechanism of signal transduction in many cellular processes (Seger and Krebs, 1995). The best studied protein kinase cascades known today are mitogen-activated protein kinase (MAPK) signaling cascades, which are the topic of this unit (Seger

and Krebs, 1995; Chen et al., 2001; Morrison and Davis, 2003; Raman and Cobb, 2003; Rubinfeld and Seger, 2004). Each of these signaling cascades consists of up to five tiers of protein kinases that sequentially activate each other by phosphorylation. The similarity among the enzymes that comprise each tier in the various cascades categorizes them into a superfamily of kinases with similar structure and function.

The activation of each of these cascades is initiated either by small GTP-binding proteins or by adaptor proteins that transmit the signal to protein kinases, commonly referred to as MAPK kinase kinases (MAP3Ks). In some cases, the activation is mediated by upstream, Ste20-like kinases, which are termed MAP4Ks, although in many cases the MAP3Ks can be activated directly by the GTP binding proteins, or the MAP4Ks bypass the MAP3Ks (Fig. 14.3.1, Table 14.3.1). The signal is then transmitted downstream in the cascade by the sequential activation of MAPK kinase (MAPKK), MAPK and MAPK-activated protein kinases (MAPKAPKs), and, in a few cases, also kinases downstream of this tier. The existence of as many as three to six tiers in each of the MAPK cascades is probably essential for signal amplification, specificity determination, and tight regulation of the transmitted signal.

The four distinct MAPK cascades that are currently known are named according to the subgroup of their MAPK components. These are (1) the extracellular signal-regulated kinase (ERK) cascade; (2) the c-Jun N-terminal kinase [JNK; or stress activated protein kinase 1 (SAPK1) cascade]; (3) the p38 cascade (Freshney et al., 1994; Han et al., 1994; Lee et al., 1994); and (4) the BMK1 (ERK5) cascade (see Seger and Krebs, 1995 and Chuderland and Seger, 2005, for reviews). The identification of ERK7/8 (Abe et al., 1999) indicates that additional full MAPK cascades can emerge. The ERK cascade seems to participate mainly in the transmission of mitogenic signals, whereas the p38 and JNK cascades transmit mainly stress signals. BMK seems to be activated equally by mitogens and stress stimuli. These MAPK cascades cooperate to transmit signals to their intracellular targets, and thus to initiate cellular processes such as proliferation, differentiation, development, stress response, and apoptosis. In this section, the various MAPK cascades will be briefly reviewed.

The ERK cascade, also known as the p42, p44 MAPK cascade, was the first MAPK cascade elucidated (Seger and Krebs, 1995). This cascade is initiated in many cases by the small G-protein Ras, which, upon stimulation, causes membranal translocation and activation of the protein serine/threonine kinase, Raf1 (reviewed in Hagemann and Rapp, 1999). Once activated, Raf1 continues the transmission of the signal by phosphorylating two regulatory serine residues located in the activation loop of MEK, thus causing its full activation (Kyriakis et al., 1992). Interestingly, Raf-1 activation can be facilitated by PKC, and this can implicate the PKC as a MAP4K of the ERK cascade. Other kinases that act in the MAP3K level of the cascade under various conditions are—(1) B-Raf (Peraldi et al., 1995), which is usually activated by the small G-protein Rap1 (Hagemann and Rapp, 1999) in combination with phosphorylation by MLK3 (Chadee and Kyriakis, 2004); (2) A-Raf (Hagemann and Rapp, 1999); (3) Mos, which acts specifically in the reproductive system (Gotoh and Nishida, 1995); (4) the protooncogene TPL2 (Salmeron et al., 1996); (5) under stress conditions, possibly also MEKK1 (Lange-Carter et al., 1993) and other MAP3Ks such as MLK2 (Hirai et al., 1997), MLTK, (Gotoh et al., 2001), MLK3 (Chadee and Kyriakis, 2004), and even IRAK (MacGillivray et al., 2000), although the direct effect of these kinases is still controversial. Another kinase on this level is kinase suppressor of Ras (KSR), which seems to act mainly as a scaffold protein for some of the MAP3K and MAPKK components of the cascade (Morrison and Davis, 2003); but the role of its catalytic activity is still controversial (Kolesnick and Xing, 2004). In any case, all the indicated MAP3Ks seem to phosphorylate the same regulatory residues of MEK, which are required for its full activation (Ahn et al., 1991; Seger et al., 1992). Activated MEK is a dual-specificity protein kinase, which appears to be the only kinase capable of specifically phosphorylating and activating the next kinase in this cascade, i.e., ERK (Boulton et al., 1990, 1991). ERK activation requires phosphorylation of two regulatory residues, threonine and tyrosine, which reside in a TEY phosphorylation motif (Payne et al., 1991; Canagarajah et al., 1997). Although phosphorylation of threonine and tyrosine residues is essential for the activation of all MAPKs, in the other cascades, the identity of the middle amino acid in the TXY motif of the MAPK is different,

and this determines the specificity of the signal (Seger and Krebs, 1995).

ERK appears to be an important regulatory molecule, which, by itself, can phosphorylate regulatory targets in the cytosol such as phospholipase A_2 (PLA_2; Lin et al., 1993). It can translocate into and phosphorylate nuclear substrates such as the transcription factors Elk1 (Gille et al., 1992), cFos (Murphy et al., 2002), p53 (Milne et al., 1994), ERF (Sgouras et al., 1995), PEA-3 (O'Hagan et al., 1996), ERM (Janknecht et al., 1996), ER81 (Janknecht et al., 1996), Ets1/2 (Yang et al., 1996), SAP-1a (Strahl et al., 1996), and cJun (Morton et al., 2003), or it can transmit the signal to the MAPKAPK level. The main MAPKAPK of the ERK cascade is RSK (Sturgill et al., 1988), which can also translocate to the nucleus upon activation and phosphorylate a set of nuclear substrates different from those phosphorylated by ERK. Additional MAPKAPKs are the mitogen- and stress-activated kinase (MSK; Deak et al., 1998) and the MAPK-interacting kinases (MNKs; Fukunaga and Hunter, 1997; Waskiewicz et al., 1997), which are activated equally by the related p38 cascade. Finally, the MAPKAPK3 (McLaughlin et al., 1996) and MK5 (Ni et al., 1998) cascades are only slightly related to the ERK cascade and are mainly activated by the p38 cascade (for review see Roux and Blenis, 2004). MAPKAPKs can regulate the activity of additional kinases (e.g., Myt1; Palmer et al., 1998), but those are usually not considered to be genuine members of the MAPK cascade.

ERKs are activated primarily by mitogenic signals, whereas other MAPK cascades (p38, JNK) are activated mainly by cellular stresses such as heat shock, ischemia, UV irradiation, and cytokines (Davis, 2000); therefore they are referred to as stress-activated protein kinase (SAPK) cascades (Kyriakis and Avruch, 1996). The p38 cascade consists of MAPKs that contain a glycine residue in their activation, TXY motif (TGY; Han et al., 1994). Many kinases on the MAP3K and MAP4K levels have been implicated in the p38 cascade (Fig. 14.3.1, Table 14.3.1); however, their individual roles are not yet fully elucidated. Moreover, in spite of their sequence similarity to the Ste20 and Ste11 kinases (the MAP4K and MAP3K in *Saccharomyces cerevisiae* that operate in a sequential order; Herskowitz, 1995), the mammalian kinases do not always act in a sequential order, and may use different mechanisms to activate the rest of the cascade (Dan et al., 2001; Hagemann and Blank, 2001).

Independent of the particular MAP3K or MAP4K, the signals of the p38 cascade are funneled into two main MAPKKs: MKK3 (also known as MEK3 or p38MAPKK; Derijard et al., 1995) and MKK6 (also known as MEK6, or SAPKK3; Han et al., 1996). Similarly to MEK1/2, these are dual-specificity protein kinases that phosphorylate the regulatory threonine and tyrosine residues of the p38s to fully activate them. Although these two MKKs are unique in their ability to activate p38s and no other MAPKs, the p38s seem to be activated by MKK4 (Derijard et al., 1995) and to some extent also by MKK7 (Dashti et al., 2001), which are the main activators of the JNK cascade (as indicated below). The MAPK-level components of this cascade are the four p38s (p38α to δ, also known as SAPK2a SAPK2b, SAPK3, and SAPK4; Han et al., 1994; Goedert et al., 1997), which are normally expressed as four main proteins of 41, 43, 47, and 51 kDa, and at least six additional alternatively spliced forms with molecular masses that range between 32 and 65 kDa. Once these p38s are activated, they phosphorylate and modulate the activity of a large number of substrates in various compartments in the cells (Davis, 2000). Thus, the p38s can phosphorylate and activate various MAPKAPK-level components including MAPKAPK2 and 3 (Stokoe et al., 1992; McLaughlin et al., 1996), MSK (Deak et al., 1998), MNK (Fukunaga and Hunter, 1997; Waskiewicz et al., 1997), and MK5 (Ni et al., 1998). Except for MAPKAPK2, all MAPKAPKs can also be activated by the ERK cascade (see above) and therefore present a point of cross-talk between the two cascades (for review see Roux and Blenis, 2004). Another important group of p38 substrates are various transcription factors that are usually activated under stress conditions, including ATF2, Elk1 (Raingeaud et al., 1996), CHOP (Wang and Ron, 1996), MEF2C (Han et al., 1997), SAP-1 (Cuenda et al., 1997), and p53 (Huang et al., 1999).

Other stress-activated MAPKs are the c-Jun amino-terminal kinases (JNKs; also named SAPK1), which comprise a third MAPK subgroup (Derijard et al., 1994; Kyriakis et al., 1994). These enzymes are distinct from the p38s mainly because they contain a TPY rather than a TGY motif in their activation loop. As the other MAPK cascades, the JNK cascade is triggered by small GTPases (Crespo et al., 1997), i.e., Rac and CDC42, or it can be activated by various adaptor molecules (Davis,

2000). Next, the signals are transmitted via MAP4K and MAP3K components that are mostly shared with the p38 cascades (Table 14.3.1). Since the p38 and JNK cascades are not always simultaneously activated, the signals must be separately regulated to allow separate cascades, and this is mostly executed by a physical segragation between the components by specialized scaffold proteins (Morrison and Davis, 2003). At the MAPKK level, the JNKs can be activated by MKK4 (MEK4, SEK1, JNKK1; Sanchez et al., 1994; Yan et al., 1994), and MKK7 (MEK7, JNKK2; Tournier et al., 1997). These MKKs are able to phosphorylate and activate the components in the MAPK level, which are JNK1-3 (SAPKs) of molecular weights 46, 54, and 52 kDa, respectively (Derijard et al., 1994; Kyriakis et al., 1994). No enzymes in the MAPKAPK level have been identified for JNKs, which appear to be major regulators of nuclear processes, in particular, transcription. Shortly after activation, JNKs translocate to the nucleus where they physically associate with and activate their targets, mostly transcription factors such as c-Jun (Hibi et al., 1993), ATF2 (Gupta et al., 1995), Elk1 (Whitmarsh et al., 1995), p53 (Milne et al., 1995), JUN-D (Kallunki et al., 1996), PEA3 (O'Hagan et al., 1996), NFAT4 (Chow et al., 1997), c-Myc (Noguchi et al., 1999), and SAP-2/Net (Ducret et al., 2000). Interestingly, the JNKs also participate in the induction of apoptosis by several proapoptotic drugs, and this is mediated by the phosphorylation of various death-related components in various cellular compartments (for review see Varfolomeev and Ashkenazi, 2004).

Another MAPK subgroup is the BMK (also known as ERK5; Zhou et al., 1995; Abe et al., 1996), with a molecular weight of 110 kDa. Like ERK1/2, BMK contains a TEY phosphorylation motif in its activation loop, but because it is not activated at all by MEK1 and 2, it forms a separate signaling cascade. BMK seems to be activated equally by stress (Zhou et al., 1995; Abe et al., 1996) and by mitogenic signals (Kato et al., 1998), and thereby participates in the regulation of a variety of cellular processes including oncogenic transformation (English et al., 1999). The cascade is thought to be activated by the adaptor protein Lad, which operates downstream of c-Src, at least in the pathway that leads to BMK activation by growth factors (Sun et al., 2003). In turn, Lad transmits the signal to protein kinases on the MAP3K level of the cascade, MEKK2 and MEKK3, which are implicated also in the activation of the p38 and JNK cascade (Chao et al., 1999; Chayama et al., 2001). The signal is then transmitted downstream the cascade to the MAPKK, MEK5 (Zhou et al., 1995), which specifically phosphorylates and activates the kinase on the MAPK level, BMK. Interestingly, MEK5 and BMK are often localized in the cell nucleus (Raviv et al., 2004), where BMK associates with several transcription factors substrates including c-Myc (English et al., 1998), MEF2 family members (Kato et al., 1997; Yang et al., 1998), c-Fos (Kamakura et al., 1999), SAP1a (Kamakura et al., 1999), Fra-1 (Terasawa et al., 2003), and possibly also NFκB (Pearson et al., 2001). Importantly, BMK also influences transcription through a direct transcriptional activity, as shown in the activation of the Nur77 gene upon calcium signals in T cells (Kasler et al., 2000). In addition to its nuclear activity, BMK mediates several cytosolic functions including phosphorylation of connexin-43 (Cameron et al., 2003) and of the serum- and glucocorticoid-inducible kinase SGK (Hayashi et al., 2001), implicating the latter as a MAPKAPK in the ERK5 cascade.

Besides these four MAPK cascades, which are composed of similar components in each level, other protein kinases and kinase cascades are activated in response to mitogenic stimulation. First, two MAPKs termed ERK7 and ERK8, which are similar to each other (Abe et al., 2001), have been identified. Although their mode of activation is not clear, they are likely to operate within an independent, fifth MAPK cascade. Another cascade is that of ERK3, which, in spite of its 50% identity to ERK1/2, is not considered a MAPK because of the absence of the TEY motif in its activation loop (Boulton et al., 1991). ERK3 is activated by an ERK3K with an unknown identity (Cheng et al., 1996), and it seems to function mainly in muscles. In addition, the NIK-IKK (Malinin et al., 1997), PI3K-PDK-AKT-GSK3 (Cohen et al., 1997), Rho-dependent pathways (Leung et al., 1995), and the PKA-phosphorylase kinase pathway (Brushia and Walsh, 1999) operate in a kinase cascade. However, because of their distinct characteristics, these pathways are not considered MAPK cascades, although they are involved in transmission of mitogenic signals. The inactivation of many components of the MAPK cascade is mediated by a large number of distinct phosphatases, including MKP, PTPs, and PPs (for review see Yao and Seger, 2004).

All the pathways mentioned are apparently activated to some extent by distinct extracellular agents, and as a result of their action in an elaborate network, determine the outcome of each stimulation. The full dimensions of this network, the mode of regulation of its components, and the mechanism by which these cascades determine cell fates in response to various stimuli, have yet to be fully elucidated.

Critical Parameters

Several points should be considered when using Basic Protocol 2 (immunoprecipitation followed by phosphorylation). One of the most important parameters for the success of this protocol depends on the method of protein extraction used. Since the MAPKs are localized within cells, the cellular membranes must be disrupted to access the desired targets. The protein kinases of interest must then be obtained and preserved in their active form, while decreasing the amount of nonrelevant kinases. For example, activated Raf-1 can be present in Golgi membranes, which might not be disrupted by some extraction procedures, but are disrupted if RIPA buffer is used for extraction. The method for cellular extraction described in Basic Protocol 1 can be effectively used for detection of most MAPKs by immunoprecipitation or other methods. Sonication disrupts the plasma membrane but does not solubilize it, and therefore the resulting extracts (referred to as cytosolic extracts) should contain both cytosolic and some nuclear fractions. Depending on the subcellular localization of the proteins of interest, other extraction methods can be applied. For example, cellular extracts obtained with Triton X-100 usually contain membrane, cytosolic, and some nuclear components, whereas cellular extracts obtained with RIPA buffer should contain solubilized proteins from most cellular compartment. Cellular extraction by addition of hot SDS-PAGE sample buffer to cells is not recommended because it frees chromatin, which causes formation of a gel that is hard to handle. Extraction by freeze-thawing is not recommended either, because of molecular degradations that might occur during the thawing phases.

Another consideration for successful detection of phosphoproteins is minimization of protein degradation and dephosphorylation. During extraction, most cellular organelles break, and thus expose phosphoproteins to phosphatases and proteinases. Addition of specific inhibitors of phosphatases and proteinases to the extraction buffers, and extraction at low temperatures, minimizes the effect of these enzymes. However, since phosphatases are usually efficient enzymes, even if these precautions are taken extractions should be performed as quickly as possible.

One of the most critical elements for the success of the basic methods for immunological monitoring of phosphorylation is the quality and specificity of the antibodies used. The antibodies employed should (1) recognize the phosphorylated protein but not its nonphosphorylated counterpart, and (2) recognize only the desired phosphorylated amino acid, not additional phosphorylated sites in either the same or different proteins. In addition, the amount of proteins in the different samples subjected to immunoblot analysis and the dilution of the antibodies should be optimized to avoid nonspecific recognition of excess proteins. The antibodies used for immunoprecipitation (Basic Protocol 2) should not interfere with the enzymatic activity of the enzymes tested. In addition, it is necessary to avoid nonspecific precipitation of contaminant kinases. However, sometimes the washings may not prevent coimmunoprecipitation of protein kinases other than those desired, and these might interfere with the phosphorylation reaction. This difficulty can be overcome by using a specific substrate or direct assay methods (i.e., in-gel kinase assay, Basic Protocol 3).

For accurate comparison of the amounts of phosphoproteins, detection should be performed in the linear range of the detection system. Thus, the amount of protein loaded on the gel, the concentration of primary and secondary antibodies, and the time of ECL exposure should be optimized in order to reach linearity. Alternatively, a standard curve with the proteins of interest can be made and serial dilutions of the cellular extracts of each treatment can be loaded onto the SDS-PAGE gel. The blot detection system, e.g., ECL-^{125}I-, AP-, or biotin-conjugated antibodies, should be chosen carefully. Usually, ECL has the narrowest linear range of these systems, whereas ^{125}I-antibodies have a relatively broad range. The AP detection system, which has moderate linear range, is usually used for the types of experiments described here, because it is a reliable method that does not necessitate the use of radioactive materials.

Other parameters that should be considered for accurate comparison of protein kinases are as follows.

1. Starvation of the cells before activation, which may interfere with the activation of the desired protein kinase or cause activation of some stress-activated protein kinases.

2. The optimal length of stimulation may vary from cell type to cell type and from one protein kinase to the other; thus, appropriate time points for each kinase should be determined.

3. For accurate comparison of protein kinase activities, detection should be performed in the linear range of the phosphorylation reaction. Thus, the amount of protein used for immunoprecipitation, the concentration of antibodies, the length of the phosphorylation reaction, and the exposure to X-ray film or to the phosphor imager should be optimized in order to reach linearity. If necessary, a standard curve with the protein kinases of interest can be made, and serial dilutions of the cytosolic extracts or a time course of the phosphorylation can be used to ensure one is working in a linear range.

Anticipated Results

With immunoblotting, the desired phosphoprotein should be selectively detected by both anti-phospho and anti-general antibodies. For example, when anti-active ERK antibodies are used (Basic Protocol 1), two faint bands at molecular weights of 42 and 44 kDa should be detected in the basal, nonstimulated fractions of the cells (Fig. 14.3.2). These two bands represent the small amount of active ERK (ERK1 and ERK2) present in resting cells. Upon addition of EGF to these cells, the intensity of staining of the same bands should increase with time, peak at 30 min after stimulation, and decline thereafter. Usually a third band at 46 kDa (ERK1b) appears at the longer time points of EGF stimulation. The kinetics of detection of the phosphoprotein result from the transient activation of ERK by EGF in these cells. Staining the same blots with anti-general ERK antibodies should result in equal staining of the 42-, 44-, and 46-kDa bands in all lanes of the blot.

In Basic Protocol 2, extracts from nonstimulated Rat-1 cells should yield very little MBP phosphorylation (Fig. 14.3.2), which represents the activity of both ERK1 and ERK2 in these cells. Upon addition of EGF to the cells, the amount of phosphate incorporated should increase with time, peaking at 30 min after stimulation and declining thereafter. The kinetics of phosphorylation represent the transient activation of ERK by EGF in these cells. When the in-gel assay is used (Basic Protocol 3), both ERK1 and ERK2 should be detected at molecular weights of 44 and 42 kDa, and the kinetics of activation of both of them should be similar to those of the MBP phosphorylation obtained with Basic Protocol 1. Typical results of Basic Protocol 3 are shown in Figure 14.3.2.

Time Considerations

After cell harvesting, Basic Protocol 1 requires extraction (0.5 hr), determination of protein concentration (0.5 hr), SDS-PAGE (2.5 hr), and immunoblot analysis (6 to 8 hr). Because this procedure may take more than 1 working day, it can be stopped after boiling the samples in sample buffer, or the transfer onto the nitrocellulose membrane can be performed overnight at 40 to 50 mA (instead of 200 to 300 mA). Immunoprecipitation and washes (Basic Protocol 2) add about 4 to 5 hr to Basic Protocol 1.

After cell harvesting, Basic Protocol 2 requires extraction (0.5 hr), immunoprecipitation and washings (3 to 4 hr), the phosphorylation reaction (0.5 to 1.0 hour), SDS-PAGE (2.5 hr), and processing of the gel (6 to 16 hr). Because this procedure usually takes more than 1 working day, it can be interrupted after boiling the samples in sample buffer or at any time during the destaining period.

The in-gel kinase assay (Basic Protocol 3) may take 2 to 3 days.

Labeling Cultured Cells with $^{32}P_i$ and Preparing Cell Lysates for Immunoprecipitation

This unit describes $^{32}P_i$ labeling and lysis of cultured cells to be used for subsequent immunoprecipitation of proteins. The approach is appropriate, however, for labeling any cellular constituent with ^{32}P. This procedure is suitable for insect, avian, and mammalian cells and can be used with both adherent and nonadherent cultures. The same general approach—biosynthetic labeling with $^{32}P_i$ in medium containing a reduced concentration of phosphate—can also be applied to bacteria and yeast; however, specific techniques to accomplish this are not presented here. If this approach is used to label cellular constituents other than proteins, it will probably be necessary to modify the Basic Protocol beginning with step 9 (cell lysis).

The first procedure described (see Basic Protocol) is $^{32}P_i$ labeling of adherent or nonadherent (e.g., hematopoietic) cells with subsequent lysis in a detergent buffer containing either Nonidet P-40 (NP-40), 3[(3-cholamidopropyl)-dimethylammonio]-1-propane-sulfonate (CHAPS), or a combination of NP-40, sodium deoxycholate and SDS (RadioImmunoPrecipitation Assay or RIPA buffer). More rigorous lysis conditions to be used for working with proteins that are difficult to solubilize are also described (see Alternate Protocol).

CAUTION: Unshielded ^{32}P will penetrate ~1 cm into flesh. Exposure to the skin and eyes is, therefore, of concern. Gloves and protective eyeware should always be worn when handling significant amounts of ^{32}P. A 1-in.-thick (2.5-cm) Plexiglas shield, tall enough to look through when seated or standing comfortably, should be used when handling samples containing ^{32}P. For more specific precautions, refer to the section on Safe Use of Radioisotopes (*APPENDIX 1D*).

LABELING CULTURED CELLS WITH $^{32}P_i$ AND LYSIS USING MILD DETERGENT

BASIC PROTOCOL

The first six steps of this protocol describe culturing and labeling procedures for cultures of adherent cells; modifications appropriate for nonadherent cells are described in alternate steps. The remaining steps describe lysis of cells in detergent buffer to prepare the sample for immunoprecipitation. For a more detailed discussion of mammalian cell culture conditions and reagents see *UNITS 1.1* and *1.2*.

Materials

Cell culture to be labeled
Labeling medium: phosphate-free tissue culture medium (e.g., DMEM, *APPENDIX 2A*) supplemented with the usual concentration of serum or serum dialyzed against phosphate-free saline, 37°C
500 mCi/ml to 1 Ci/ml $H_3{}^{32}PO_4$ in HCl (carrier free ICN)
Tris-buffered (TBS; see recipe) or Dulbecco's phosphate-buffered saline (DPBS; *APPENDIX 2A*), cold
Mild lysis buffer or RIPA lysis buffer (see recipes)

1-in.-thick Plexiglas shield (*APPENDIX 1D*)
Plugged, aerosol-resistant pipet tips
Plexiglas box (*APPENDIX 1D*), warmed to 37°C
Screw-cap microcentrifuge tubes
Plugged disposable pipet or disposable one-piece transfer pipet

Contributed by Bartholomew M. Sefton
Current Protocols in Cell Biology (1999) 14.4.1-14.4.7

Rubber policeman

Sorvall refrigerated centrifuge with SM 24 rotor and rubber adaptors, refrigerated microcentrifuge, or equivalent, 4°C

Plexiglas sheet (10 × 10 × ¼–in.) or Plexiglas tube holder, 4°C (*APPENDIX 1D*)

Additional reagents and equipment for cell culture (*UNIT 1.1*) and gel electrophoresis (*UNIT 6.1*) or immunoprecipitation (*UNIT 6.2*)

NOTE: All solutions and equipment coming into contact with living cells must be sterile and appropriate aseptic techniques should be used accordingly.

NOTE: All culture incubations should be performed in a humidified 37°C, 5% CO_2 incubator unless otherwise specified. Some media (e.g., DMEM) may require altered levels of CO_2 to maintain pH 7.4.

Label the cell culture

1. Culture the cells to be labeled to an appropriate stage of growth.

   Phosphate transport is maximal in rapidly growing cells. Therefore, except in those cases where phosphorylation of a protein in quiescent cells is to be examined, cells to be labeled should be subconfluent (adherent cells) or at less than maximal density (nonadherent cells). It is useful to change the medium to fresh growth medium 3 to 18 hr prior to labeling.

   Brief cultivation of cells in low-phosphate medium (to reduce the phosphate pool by starvation prior to labeling) is of minimal value.

For adherent cells

2a. Remove growth medium by aspiration. Wash away any residual phosphate-containing medium by adding 37°C labeling medium supplemented with serum, but lacking the label, and removing the wash medium by aspiration.

   Phosphate-free DMEM is routinely used for labeling medium because RPMI has a very high concentration of phosphates.

3a. Add prewarmed labeling medium to cultures, using 0.5 to 1 ml per 35-mm dish, 1 to 2 ml per 50-mm dish, or 2 to 4 ml per 100-mm dish of adherent cells.

For nonadherent cells

2b. Gently centrifuge the culture 1 min at 1800 × *g*, room temperature, and aspirate the medium away from the cell pellet. Resuspend the cells in labeling medium supplemented with serum, but lacking the label. Centrifuge and remove the medium.

3b. Add 2 ml medium per 10^7 cells and transfer to an appropriate size petri dish.

4. Working behind a Plexiglas shield, use a micropipettor with plugged, aerosol-resistant pipet tips to add $^{32}P_i$ to a final concentration of 0.1 to 2 mCi/ml.

   Use of plugged, aerosol-resistant pipet tips will minimize contamination of the micropipettor. $^{32}P_i$ is usually shipped in HCl and is generally sterile, so it is not necessary to sterilize the labeling medium after adding the radioisotope. Additionally, except in the rare cases when steady-state labeling with ^{32}P is desired, the labeling interval is usually so short (<6 hr) that microbial growth resulting from added isotope is undetectable. Therefore, addition of ^{32}P to cells can be performed on the lab bench rather than in a tissue culture hood.

5. Place dishes in a warmed Plexiglas box, and put box in the incubator.

   Labeling for 1 to 2 hr is usually sufficient, but cells will tolerate as much as 2 mCi/ml for 6 hr and lower concentrations (0.1 to 0.5 mCi/ml) for 18 hr.

Wash and lyse the cells

6. At the end of the labeling period, carry the labeled cells, still in the Plexiglas box, into the cold room. Place the cells behind a Plexiglas shield.

For adherent cells

7a. Take the dish out of the box and remove the labeling medium manually, using either a plugged disposable pipet or a disposable one-piece plastic Pasteur transfer pipet. Discard the medium and pipet as radioactive wastes.

Labeling medium should be removed without using a vacuum aspirator. Vacuum aspiration generates radioactive aerosols and leaves a radioactive film on the equipment.

8a. Wash cells once with 2 to 10 ml cold TBS. Remove the wash buffer manually, as in step 7, and discard as radioactive waste.

The uptake of phosphate is efficient and often a majority of the added $^{32}P_i$ is found within the labeled cells. This necessitates continued shielding of the labeled cells following removal of the labeling medium.

9a. Add lysis buffer to cells, using 0.3 ml per 35-mm dish, 0.6 ml per 50-mm dish, or 1.0 ml per 100-mm dish of adherent cells. Dislodge adherent cells by scraping with a rubber policeman, but leave the lysate in the dish. Incubate 20 min at 4°C. With a rubber policeman, scrape the lysate of adherent cells to the side of the dish and transfer lysate to a screw-cap microcentrifuge tube.

If a low background of nonspecific contaminants is critical, use RIPA lysis buffer. If maintenance of enzymatic activity or the structure of protein complexes is critical, use a milder lysis buffer containing either 3[(3-cholamidopropyl)-dimethylammonio]-1-propane-sulfonate (CHAPS) or Nonidet P-40 (NP-40) as the only detergent. If complete solubilization of the cells and denaturation of the protein is desired, use SDS for lysis (see Alternate Protocol).

For nonadherent cells

7b. Take the dish out of the box, transfer the cells to a screw-cap centrifuge tube, pellet them by centrifugation (1 min at 1800 × *g*), and remove the medium.

Do not use a vacuum aspirator to remove medium.

8b. Resuspend pelleted cells gently in a small volume of cold TBS, transfer to a screw-cap microcentrifuge tube, and pellet the cells by microcentrifuging 1 min at 1800 × *g*.

Continue to use shielding with cells and lysate.

9b. Add 0.5 to 1 ml lysis buffer per 10^7 cells and resuspend the pellet by gentle agitation with a disposable plastic Pasteur pipet. Incubate 20 min at 4°C.

Choose the lysis buffer as in annotation to step 9a.

10. Cap the tube, and clarify the lysate by centrifuging 30 min at 26,000 × *g* (17,000 rpm in Sorvall SM24 rotor), 4°C.

Use an ice bucket with a sheet of Plexiglas over it, a chilled Plexiglas tube holder, or a prechilled centrifuge rotor to transport the tube of lysate.

It is best to half-fill the tube to prevent spilling. A Sorvall SM24 rotor with rubber adaptors for microcentrifuge tubes is ideal for clarifying lysates. Alternatively, a refrigerated microcentrifuge can be used for 30 min at maximum speed. Do not use a nonrefrigerated microcentrifuge in the cold room because the centrifuge will warm to 20°C during a 30-min spin.

Lysates prepared with RIPA buffer often become viscous due to lysis of nuclei. If this occurs, increase the time of centrifugation to 90 min, or add 50 µl of fixed Staphylococcus aureus bacteria (Pansorbin, Calbiochem) in RIPA buffer to the lysate prior to centrifugation. Either modification will cause the solubilized DNA to pellet.

11. After centrifugation, transfer the supernatant (lysate) to a new tube and discard the tube and pellet in radioactive waste.

If the pellet is very viscous, so that it is impossible to remove the supernatant cleanly, suck part of the pellet into a micropipet tip, lift the viscous material out of the tube, and discard it in the radioactive waste. The residual liquid in the tube is the supernatant and can be used for immunoprecipitation.

12. Analyze the labeled lysate using gel electrophoresis, immunoprecipitation, or protein purification. Carry out all analytical procedures at 4°C using adequate shielding.

ALTERNATE PROTOCOL

LYSIS OF CELLS BY BOILING IN SDS

Some proteins, such as eukaryotic RNA polymerase II, are difficult to solubilize with mild lysis buffer or RIPA lysis buffer, and some analytical procedures use antibodies that recognize epitopes exposed only in denatured proteins. In these cases, it is useful to solubilize labeled cells completely in SDS and then adjust the composition of the lysate solution to match that of RIPA buffer for immunoprecipitation. To avoid the formation of spurious disulfide bonds, lysis and washing during immunoprecipitation are carried out in the presence of fresh 1 mM dithiothreitol (DTT). The protocol describes the procedure for adherent cells; modifications for working with nonadherent cells are described as alternate steps.

Additional Materials *(also see Basic Protocol)*

SDS lysis buffer (see recipe)
RIPA correction buffer (see recipe)
Immunoprecipitate wash buffer (see recipe)
Fixed *Staphylococcus aureus* bacteria (Pansorbin, Calbiochem; optional)
Boiling water bath

1. Label and wash cells (see Basic Protocol steps 1 to 7).

2a. *For adherent cells:* Add SDS lysis buffer using 0.1 ml for a 35-mm dish, 0.25 ml for a 50-mm dish, or 0.5 ml for an 100-mm dish. Immediately scrape off the dish with a rubber policeman and transfer the cell lysate to a screw-cap microcentrifuge tube.

2b. *For nonadherent cells:* Vortex briefly to loosen the cell pellet, add 1 ml SDS lysis buffer per 5×10^7 cells and vortex again.

3. Boil the samples 2 to 5 min, then add 4 vol RIPA correction buffer and mix well.

4. Clarify the cell lysate by centrifuging 90 min at 26,000 × *g* (17,000 rpm in Sorvall SM24), 4°C or at maximum speed, 4°C in a refrigerated microcentrifuge.

   Lysate may also be clarified by adding 50 µl fixed Staphylococcus aureus and centrifuging 30 min at 26,000 × g, 4°C.

5. Carry out immunoprecipitation as usual using immunoprecipitate wash buffer for washes.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Immunoprecipitate wash buffer for boiled sample

RIPA lysis buffer (see recipe)
1 mM DTT, added fresh

DTT is added from a 1 M stock solution stored at −20°C.

Mild lysis buffer

10 mM 3[(3-cholamidopropyl)-dimethylammonio]-1-propane-sulfonate (CHAPS) or 1% (w/w) Nonidet P-40 (NP-40)

0.15 M NaCl
0.01 M sodium phosphate, pH 7.2 (*APPENDIX 2A*)
2 mM EDTA
50 mM sodium fluoride
0.2 mM sodium vanadate added fresh from 0.2 M stock solution
100 U/ml aprotinin (Trasylol, Pentex/Miles)
Store buffer without vanadate at 4°C up to 1 year

CHAPS is a milder detergent than NP-40, but yields precipitates with a higher background and may solubilize some proteins less efficiently.

Sodium vanadate stock solution can be stored in plastic at room temperature.

RIPA (RadioImmunoPrecipitation Assay) correction buffer for boiled sample

1.25% (w/w) Nonidet P-40 (NP-40)
1.25% (w/v) sodium deoxycholate
0.0125 M sodium phosphate, pH 7.2 (*APPENDIX 2A*)
2 mM EDTA
0.2 mM sodium vanadate added fresh from 0.2 M stock solution
50 mM sodium fluoride
100 U/ml aprotinin (Trasylol, Pentex/Miles)
Store buffer without vanadate at 4°C up to 1 year

Sodium vanadate stock solution can be stored in plastic at room temperature.

RIPA (RadioImmunoPrecipitation Assay) lysis buffer

1% (w/w) Nonidet P-40 (NP-40)
1% (w/v) sodium deoxycholate
0.1% (w/v) SDS
0.15 M NaCl
0.01 M sodium phosphate, pH 7.2 (*APPENDIX 2A*)
2 mM EDTA
50 mM sodium fluoride
0.2 mM sodium vanadate added fresh from 0.2 M stock solution
100 U/ml aprotinin (Trasylol, Pentex/Miles)
Store buffer without vanadate at 4°C up to 1 year

Sodium vanadate stock solution can be stored in plastic at room temperature.

SDS lysis buffer

0.5% (w/v) SDS
0.05 M Tris·Cl, pH 8.0 (*APPENDIX 2A*)
1 mM DTT, added fresh

SDS and Tris·Cl solutions can be made in advance and stored at room temperature. DTT is added from a 1 M stock solutions stored at −20°C.

Tris-buffered saline (TBS)

Dissolve the following salts in 800 to 900 ml H_2O:
8 g sodium chloride (136.8 mM final)
0.38 g potassium chloride (5.0 mM final)
0.1 g calcium chloride (anhydrous; 0.9 mM final)
0.1 g magnesium chloride hexahydrate (0.5 mM final)
0.1 g dibasic sodium phosphate (anhydrous; 0.7 mM final)
Add 25 ml 1 M Tris·Cl, pH 7.4 (*APPENDIX 2A*)
Add H_2O to 1 liter
Dispense 50- or 100-ml aliquots into glass bottles
Autoclave and store indefinitely at room temperature

COMMENTARY

Background Information

The extent to which a protein becomes radiolabeled via biosynthetic labeling with $^{32}P_i$ depends on the rate of transport of phosphate into the cells being labeled, abundance of the protein, stoichiometry of phosphorylation of the protein, and rate of phosphate turnover in the protein. The rate of turnover of the protein itself is less important because phosphate in protein usually turns over at a much faster rate than does the protein. Most of the phosphate incorporated into cells is not incorporated into phosphoproteins—the vast majority is incorporated into phospholipid, RNA, and DNA. The efficiency of incorporation of $^{32}P_i$ into proteins is therefore low—only ~1% of incorporated radioactivity is found in phosphoproteins.

An obvious and immediate question is how many cells and how much isotope should be used. The answer is that it depends on the protein being studied. If the protein is abundant (i.e., it constitutes 0.5% to 1% of total cellular protein) and highly phosphorylated (i.e., it contains 1 mole of phosphate per mole of protein), it can be labeled by incubating 10^6 cells with 0.2 to 0.5 mCi $^{32}P_i$ in 2 ml labeling medium for 1 hr. In contrast, if the protein is rare or nonabundant, it may be necessary to label 10^7 cells with 5 to 10 mCi of $^{32}P_i$ in 3 to 5 ml labeling medium for 4 to 6 hr. A pilot experiment can be useful: if 50 cpm are recovered in the protein of interest, use more cells and more isotope; if 200,000 cpm are recovered in the protein of interest, use fewer cells with less isotope.

Critical Parameters

Incorporation of $^{32}P_i$ during biosynthetic labeling is greatest if labeling is done in medium lacking any phosphate except the added radioisotope. Labeling can also be accomplished at a somewhat reduced efficiency in complete growth medium. Phosphate-free medium is commercially available but can also be easily formulated in-house by omitting sodium and potassium phosphate from a recipe and replacing them with either sodium chloride or potassium chloride or both. Serum dialyzed against phosphate-free saline can be used instead of complete serum to further reduce the level of phosphate in labeling medium. Dialysis of serum against phosphate-free saline reduces but never entirely eliminates the phosphate in serum. Washing or rinsing cells in reduced-phosphate medium just prior to labeling significantly increases labeling efficiency, but starvation of cells by incubation in reduced-phosphate medium prior to labeling is of very limited value.

Labeling cells with ^{32}P almost certainly induces radiation damage in the labeled cells and will affect or arrest cell-cycle progression. If phosphorylation of the protein under study varies during the cell cycle, labeling with ^{32}P may alter its phosphorylation.

At the end of the labeling interval, the radioactive medium should be discarded, except in experiments where labeled virions or labeled secreted proteins are being studied. Labeling medium should be removed *without* using a vacuum aspirator. Vacuum aspiration generates radioactive aerosols and leaves a radioactive film inside the aspirator hose. As a result the hose can become an intense source of radiation exposure. It is best to use a plugged disposable pipet or disposable plastic Pasteur pipet for removing labeling medium. The medium and pipet should be discarded immediately as radioactive wastes.

In general, labeled cells are lysed and subjected to gel electrophoresis, immunoprecipitation, or protein purification. If the labeled cells are to be centrifuged, they should be transferred to capped, disposable centrifuge tubes. Tubes should be no more than half full if they are to be spun in a fixed-angle rotor; tubes that are too full may leak radioactive lysate and contaminate the centrifuge. Screw-cap microcentrifuge tubes are ideal for centrifuging lysates. If large volumes are being handled, multiple partially filled tubes are preferable to tubes filled to the top.

An ice bucket can be used for storage and transport of samples to keep the samples cold and provide considerable shielding. Radiation exposure from the tops of the tubes can be minimized by covering the ice bucket with a ¼-in. Plexiglas sheet.

RadioImmunoPrecipitation Assay (RIPA) buffer (Brugge and Erikson, 1977) is the lysis buffer of choice because it solubilizes proteins well, gives a low background of nonspecific proteins, and is tolerated by most antigens and antibodies. It does however denature some antigens and disrupt some protein:protein complexes. If 1% (w/w) Nonidet P-40 (NP-40) is used as the only detergent, most of these problems are solved without increasing background unacceptably (Sefton et al., 1980). Some workers like to use digitonin as an extremely mild detergent for cell lysis. Digitonin sometimes is

tricky and idiosyncratic, giving erratic results and high backgrounds during immunoprecipitation. 3[(3-cholamidopropyl)-dimethylammonio]-1-propane-sulfonate (CHAPS; Chen et al., 1990) and Brij 96 (Osman et al., 1992) are mild detergents that appear to give more reproducible results.

Besides the usual concern about proteolysis following cell lysis, the cells must be handled carefully to prevent protein phosphorylation and dephosphorylation following lysis of the cells. Both problems can be minimized by proper formulation of the lysis buffer and by keeping the sample at 4°C. Inclusion of 2 mM EDTA in the lysis buffer will minimize phosphorylation in the lysate by chelating both Mg^{2+} and Mn^{2+}, which are essential for protein kinase activity. Addition of phosphatase inhibitors to the lysis buffer will reduce dephosphorylation significantly. For example, 50 mM sodium fluoride is used to inhibit serine and threonine phosphatases, and 0.2 mM sodium vanadate is used to inhibit all known tyrosine phosphatases. Sodium vanadate appears to lose its effectiveness if it is stored diluted in lysis buffer, so it should be added fresh each time. The concentrated stock solution should be stored in plastic at room temperature.

Anticipated Results

This protocol can be used to label phosphoproteins or other phosphorylated cellular constituents. Phosphoproteins will contain ~1% of incorporated label.

Time Considerations

Proteins can and should be labeled biosynthetically with $^{32}P_i$ and isolated by immunoprecipitation in a single day. As is the case with all ^{32}P-labeled samples, it is important to work quickly because the specific activity of the sample declines 5% per day. If it is absolutely necessary to stop during the immunoprecipitation, it is best to leave the samples as precipitated pellets after aspiration of the wash buffer. Such samples can be stored at 4°C or −20°C overnight. Freezing the cell lysate tends to increase the background. Frozen lysates should be reclarified by centrifugation prior to immunoprecipitation.

Phosphoamino Acid Analysis

It is often valuable to identify the phosphorylated residue in a protein. In the case of proteins phosphorylated at serine, threonine, or tyrosine, this is readily accomplished by partial acid hydrolysis in HCl followed by two-dimensional thin-layer electrophoresis of the labeled phosphoamino acid (see Basic Protocol). Phosphothreonine and phosphotyrosine are more stable to hydrolysis in alkali than are RNA and phosphoserine. Therefore, mild alkaline hydrolysis of protein samples can be used to enhance the detection of phosphothreonine and phosphotyrosine (see Alternate Protocol).

Although this procedure can be carried out with a protein eluted from a preparative gel and concentrated by trichloroacetic acid (TCA) or acetone precipitation, it is most easily accomplished by transfer of the protein of interest to a PVDF membrane. This technique is obviously not ideal if the protein being studied does not transfer efficiently.

NOTE: Wear gloves and use blunt-end forceps to handle membranes.

CAUTION: When working with radioactivity, take appropriate precautions to avoid contamination of the experimenter and the surroundings. Carry out the experiment and dispose of wastes in an appropriately designated area, following the guidelines provided by the local radiation safety department (also see *APPENDIX 1D*).

ACID HYDROLYSIS AND TWO-DIMENSIONAL ELECTROPHORETIC ANALYSIS OF PHOSPHOAMINO ACIDS

BASIC PROTOCOL

The protein to be acid hydrolyzed is transferred to a PVDF membrane using the same technique used for immunoblotting (*UNIT 6.2*) or for microsequencing. It is valuable, but not absolutely essential, to keep the filter wet following transfer. Following acid hydrolysis, phosphoamino acids are separated by two-dimensional thin-layer electrophoresis. Because electrophoresis equipment differs considerably in design, the details of the assembly and placement of the plate are not discussed here. It is assumed that a suitable apparatus is available for use by an experienced operator. Electrophoresis conditions are described for using the HTLE 7000 (CBS Scientific). They are almost certainly not correct for other equipment and will need to be altered according to the equipment manufacturer's directions.

Materials

^{32}P-labeled phosphoprotein (*UNIT 14.4*)
India ink solution: 1 µl/ml India ink in TBS (*UNIT 14.4*)/0.02% (v/v) Tween 20, pH 6.5 (prepare fresh or store indefinitely at room temperature); *or* radioactive or phosphorescent alignment markers
6 M HCl
Phosphoamino acid standards mixture (see recipe)
pH 1.9 electrophoresis buffer (see recipe)
pH 3.5 electrophoresis buffer (see recipe)
0.25% (w/v) ninhydrin in acetone in a freon (aerosol, gas-driven) atomizer/sprayer
PVDF membrane (Immobilon-P, Millipore)
110° oven
Screw-cap microcentrifuge tubes
20 cm × 20 cm × 100 µm glass-backed cellulose thin-layer chromatography plate (EM Sciences)
Large blotter: two 25 × 25–cm layers of Whatman 3MM paper sewn together at the edges, with four 2-cm holes that align with the origins on the TLC plate

Contributed by Bartholomew M. Sefton
Current Protocols in Cell Biology (1999) 14.5.1-14.5.8

Glass tray or plastic box
Whatman 3MM paper
Thin-layer electrophoresis apparatus (e.g., HTLE 7000, CBS Scientific)
Fan
Small blotters: 4 × 25–cm, 5 × 25–cm, and 10 × 25–cm pieces of Whatman 3MM paper
50° to 80°C drying oven
Sheets of transparency film for overhead projector

Additional reagents and equipment for SDS-PAGE (*UNIT 6.1*), immunoblotting (*UNIT 6.2*), and autoradiography (*UNIT 6.3*)

Prepare sample

1. Run radiolabeled phosphoprotein on a preparative SDS-polyacrylamide gel (*UNIT 6.1*).

   It is difficult to obtain good results with <100 cpm of labeled protein.

2. Transfer proteins electrophoretically to a PVDF membrane (*UNIT 6.2*). Wash the membrane several times with water. Do not let the membrane dry.

   These washes remove buffer and detergent.

3. Locate the band of interest by staining the filter 5 to 10 min in 30 to 50 ml India ink solution with shaking until bands are detectable, *or* by wrapping the filter in plastic wrap, applying radioactive or phosphorescent alignment markers, and performing autoradiography (*UNIT 6.3*).

4. Excise the piece of filter containing the band of interest with a clean razor blade. Rewet the piece of filter with methanol for 1 min and then rewet it in >0.5 ml water. Place the piece of filter paper in a screw-cap microcentrifuge tube.

   Keep the excised piece as small as possible.

Hydrolyze sample

5. Add enough 6 M HCl to submerge the piece of filter. Screw the cap on the tube tightly and incubate 60 min in 110°C oven.

6. Let cool. Microcentrifuge 2 min at maximum speed, room temperature. Transfer the liquid hydrolysate to a fresh microcentrifuge tube and dry with a Speedvac evaporator.

   Drying takes ~2 hr. Simultaneous drying of the hydrolysate and deblocked oligonucleotides in NH_4OH must be avoided, as this will generate a cloud of ammonium chloride that will collect in the centrifuge tube and render the hydrolysate unsuitable for thin-layer electrophoresis.

7. Dissolve the sample in 6 to 10 µl water by vortexing vigorously. Microcentrifuge 5 min at maximum speed.

Prepare plate for first-dimension electrophoresis

8. Spot 25% to 50% of the sample, in 0.25- to 0.50-µl aliquots, on one origin of a 20 cm × 20 cm × 100 µm glass-backed cellulose thin-layer chromatography plate (see Fig. 14.5.1 for arrangement of samples). Between each application, dry the sample spot with compressed air delivered through a Pasteur pipet plugged with cotton.

   Use long, thin plastic micropipet loading tips for loading, and do not let the tip touch the plate.

   Four samples can be analyzed simultaneously. The complete hydrolysate can be spotted on a single origin, but some streaking in the first dimension may be observed due to overloading. This problem can be avoided by using a fraction of the sample.

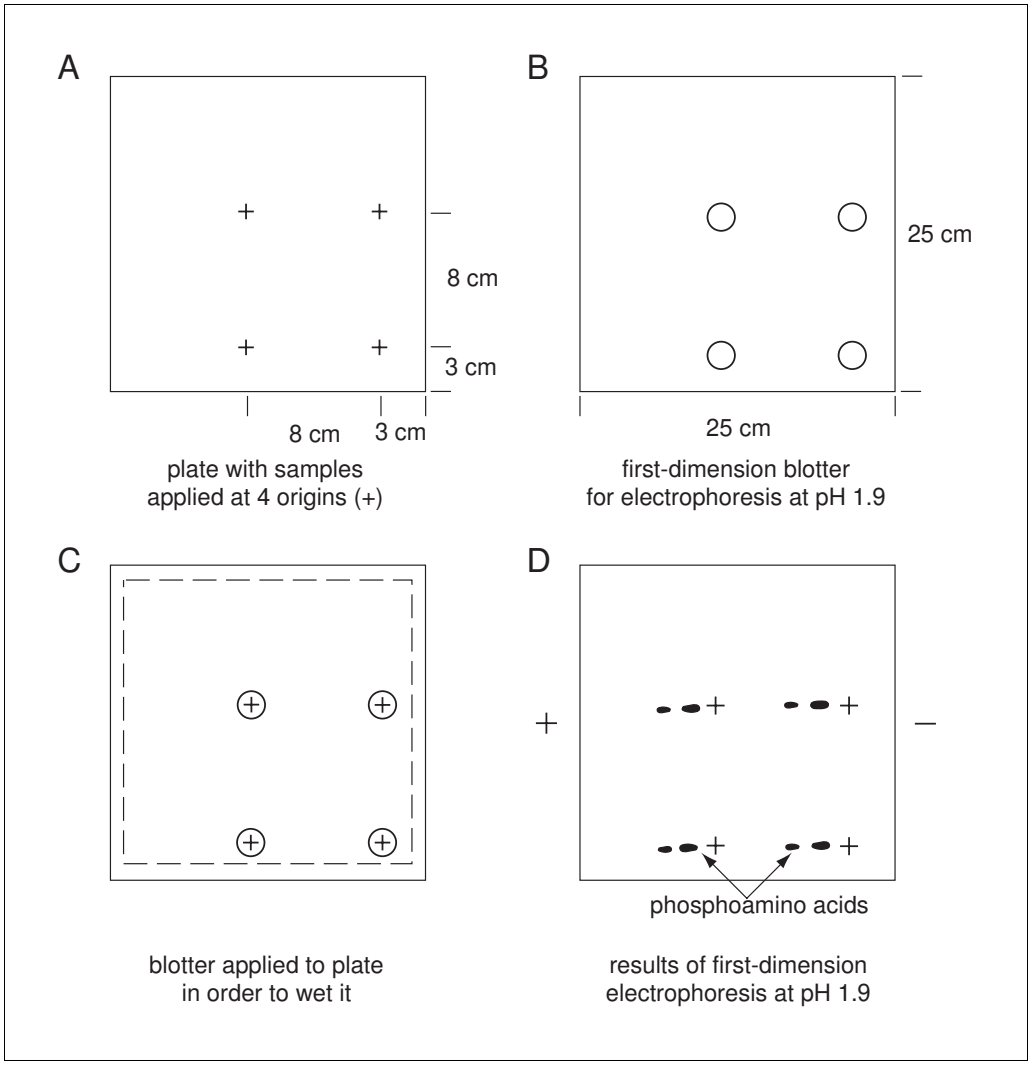

Figure 14.5.1 First-dimension electrophoretic separation of phosphoamino acids at pH 1.9. (**A**) Positions of the four origins on a single 20 × 20–cm plate; (**B**) blotter used for wetting the plate with pH 1.9 electrophoresis buffer; (**C**) placement of the blotter on the plate (underneath; indicated by dashed outline); and (**D**) orientation of the plate between the + and – electrodes with the positions of the phosphoamino acids after electrophoresis.

9. Spot 1 µl nonradioactive phosphoamino acid standards mixture (containing phosphoserine, phosphothreonine, and phosphotyrosine) on top of each sample in 0.25- to 0.50-µl aliquots as above.

10. Wet the large blotter (with four holes) by submerging it in pH 1.9 electrophoresis buffer in a large glass tray or plastic box. Briefly allow the excess buffer to drain off. Lower the wet blotter onto the prespotted plate with the origins on the plate in the centers of the four holes in the blotter (Fig. 14.5.1). Press on the blotter gently to achieve even wetting of the cellulose and concentration of the samples. When the plate is uniformly wet, remove the blotter.

    The blotter should be quite damp but not sopping wet. Excess buffer can be wicked off onto filter paper.

    Areas of the plate that are too dry can be seen through the blotter and will appear to be whiter than the rest of the plate. If this happens, dab the blotter with a Kimwipe wetted with pH 1.9 electrophoresis buffer. If there are puddles of buffer on the plate, let them dry before carrying out electrophoresis.

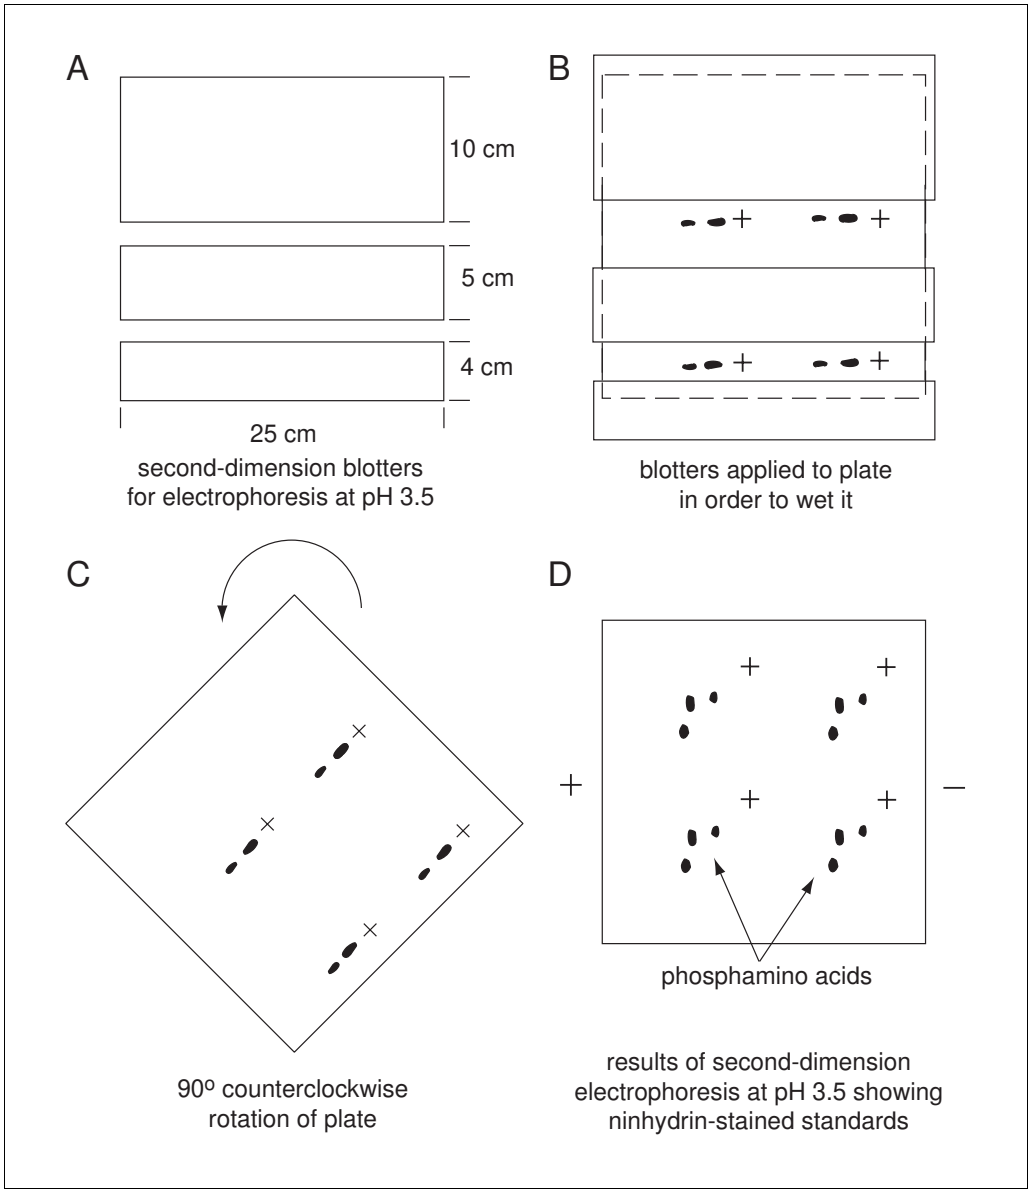

Figure 14.5.2 Second-dimension electrophoretic separation of phosphoamino acids at pH 3.5. (**A**) The three pieces of Whatman 3MM paper used for wetting the plate with pH 3.5 electrophoresis buffer; (**B**) proper placement of the blotters on the plate (underneath; indicated by dashed outline); (**C**) reorientation of the plate for electrophoresis in the second dimension; and (**D**) orientation of the plate between the + and - electrodes with the position of the phosphoamino acids after electrophoresis.

11. Place the thin-layer plate in the electrophoresis apparatus and overlap 0.5 cm of the right and left sides of the plate with wicks made of Whatman 3MM paper. If the apparatus has an air bag, be sure to inflate it. Close the cover and start electrophoresis. With an HTLE 7000, double-thickness Whatman 3MM wicks, and a plate with four samples, electrophorese 20 min at 1.5 kV.

    For the HTLE 7000 apparatus, use folded-over Whatman 3MM wicks that are 20 cm wide (the same as the plate) and not overly wet. Overly wet wicks will flood the plate and cause sample diffusion.

    For other electrophoresis apparatuses the appropriate duration of electrophoresis can be determined empirically by examining the rate of migration of the phosphoamino acid standards.

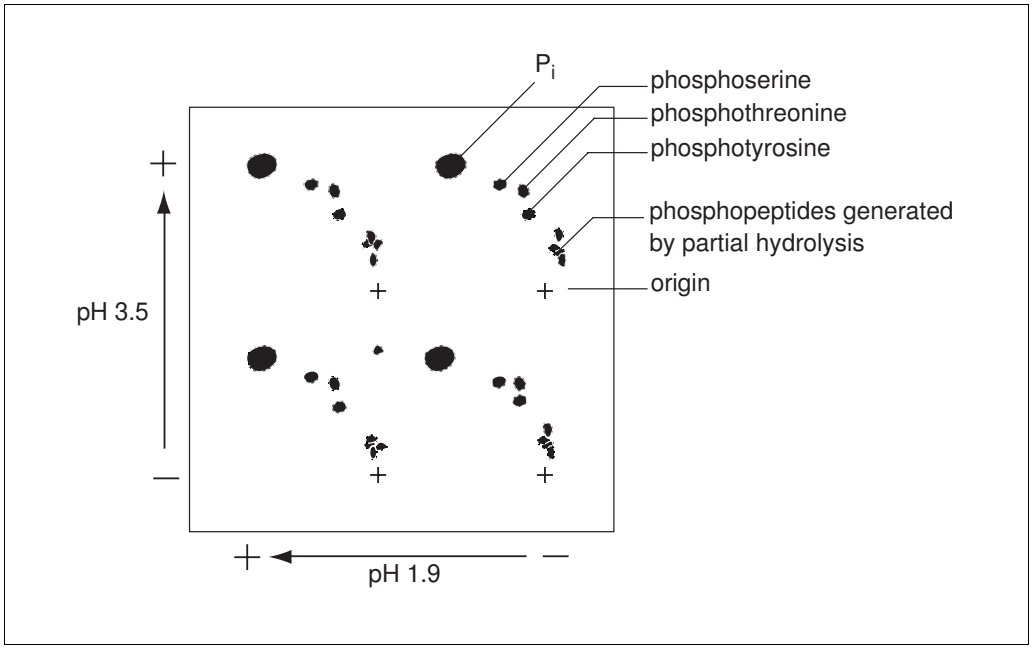

Figure 14.5.3 Hypothetical autoradiogram of a two-dimensional separation. Four samples of acid-hydrolyzed, ^{32}P-labeled proteins are applied at the origins, one in each of the four quandrants. This diagram shows the origins, the directions of electrophoresis, the positions of phosphoserine, phosphothreonine, and phosphotyrosine, the position of P_i, and the position of partially hydrolyzed fragments of the proteins for the upper right-hand sample. Every protein generates different partial hydrolysis peptide fragments.

12. Following electrophoresis, remove the plate and quickly air dry with a fan without heating.

    It takes ~20 min to dry the plate.

Perform second-dimension electrophoresis

13. Wet the small blotters in pH 3.5 electrophoresis buffer and use them to wet the plate using the method described in step 10 to achieve even wetting without puddling (Fig. 14.5.2).

    After electrophoresis at pH 1.9, phosphoamino acids are present as a streak extending from the origin towards the + electrode. Blotters are not applied directly over the phosphoamino acids to prevent sample blurring or smearing.

14. Remove the blotters, rotate the plate 90° counterclockwise, and electrophorese 16 min at 1.3 kV in pH 3.5 electrophoresis buffer if using the HTLE 7000 apparatus.

15. At the end of the electrophoresis run, remove the plate and dry 20 to 30 min in an oven at 50° to 80°C. When dry, spray with 0.25% ninhydrin in acetone, then reheat in the oven 5 to 10 min to visualize the phosphoamino acid standards.

16. Place radioactive or phosphorescent alignment marks on the plate and autoradiograph with an intensifying screen overnight to 10 days at −70°C.

17. Following autoradiography, trace the alignment markers and the stained phosphoamino acid markers onto a transparent sheet used for overhead projectors. Save this template. Align the film with the plate and identify radioactive phosphoamino acids (Fig. 14.5.3).

    Use of fluorography or autoradiography to detect the labeled phosphoamino acids is preferable to use of a phosphorimager. The image on film is precisely the same size as the thin-layer plate, which allows the transparent film to be overlaid on the plate for an unambiguous spot identification. A phosphorimager can subsequently be used for quantification.

ALTERNATE PROTOCOL

ALKALI TREATMENT TO ENHANCE DETECTION OF TYR- AND THR-PHOSPHORYLATED PROTEINS BLOTTED ONTO FILTERS

Phosphothreonine and phosphotyrosine are much more stable to hydrolysis in alkali than RNA or phosphoserine. Detection of proteins containing phosphothreonine and phosphotyrosine in impure samples containing ^{32}P-labeled RNA and serine-phosphorylated proteins can often be enhanced by mild alkaline hydrolysis of gel-fractionated samples. Although this technique was first developed for the treatment of fixed polyacrylamide gels, it is much more easily performed with proteins that have been first transferred to a PVDF membrane.

Alkaline hydrolysis does not preclude subsequent phosphoamino acid analysis. A band from a blot that has been treated with alkali can be excised and subjected to acid hydrolysis as described in the Basic Protocol.

Additional Materials *(also see Basic Protocol)*

1 M KOH
TN buffer: 10 mM Tris·Cl (pH 7.4 at room temperature)/0.15 M NaCl
1 M Tris·Cl, pH 7.0 at room temperature

Covered plastic container (e.g., Tupperware box)
55°C oven or water bath

1. Run radiolabeled sample on a preparative SDS–polyacrylamide gel and transfer proteins electrophoretically to a PVDF membrane (see Basic Protocol steps 1 and 2).

   A band containing as few as 10 cpm is detectable under optimal conditions with this technique.

   A nylon membrane may be used in place of a PVDF membrane, but in that case, the bands cannot subsequently be analyzed by acid hydrolysis, as nylon membrane will dissolve in 6 M HCl.

2. Wash membrane thoroughly with water: three 2-min incubations in 1 liter water are sufficient.

   These washes remove buffer and detergent.

3. Incubate membrane 120 min at 55°C in an oven or water bath in sufficient 1 M KOH to cover the filter in a covered Tupperware container.

4. Discard KOH. Wash membrane and neutralize remaining KOH by rinsing once for 5 min in 500 ml TN buffer, once for 5 min in 500 ml of 1 M Tris·Cl (pH 7.0), and twice for 5 min in 500 ml water. Wrap the membrane in plastic wrap and autoradiograph (*UNIT 6.3*) overnight with flashed film and an intensifying screen at −70°C.

   Identification of the band of interest is most easily accomplished by coelectrophoresis of a radioactive marker protein of known identity.

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

pH 1.9 electrophoresis buffer

50 ml 88% formic acid (0.58 M final)
156 ml glacial acetic acid (1.36 M final)
1794 ml H_2O
Store indefinitely in a sealed bottle at room temperature

pH 3.5 electrophoresis buffer

100 ml glacial acetic acid (0.87 M final)
10 ml pyridine [0.5% (v/v) final]
10 ml 100 mM EDTA (0.5 mM final)
1880 ml H_2O
Store indefinitely in a sealed bottle at room temperature

Phosphoamino acid standards mixture

Prepare a solution of phosphoserine, phosphothreonine, and phosphotyrosine (Sigma) in water at a final concentration of 0.3 mg/ml each. Store in 1-ml aliquots indefinitely at −20°C.

COMMENTARY

Background Information

Phosphoamino acid analysis by the two-dimensional electrophoretic technique described in the basic protocol was first carried out with proteins isolated by elution from unfixed SDS-polyacrylamide gels (Hunter and Sefton, 1980). However, this technique is laborious, especially if it involves grinding up pieces of high-percentage acrylamide gels, and the yields can be disappointing. Additionally, because the eluted protein must be precipitated in the presence of a carrier protein, spotting the whole sample on a single origin usually yields a badly smeared pattern. The grind-and-elute technique is, however, advantageous with proteins that are very refractory to electrophoretic transfer to PVDF membranes.

The alkaline treatment of protein described in the alternate protocol was first developed by Jon Cooper and Tony Hunter, who treated fixed gels with KOH (Cooper and Hunter, 1981). The original technique is tricky because the gel becomes extremely sticky during incubation with KOH and swells. Additionally, the manipulations needed to recover proteins from the gel following treatment are very involved because the proteins are contaminated with products of the hydrolysis of polyacrylamide.

Critical Parameters and Troubleshooting

It is essential to use PVDF membranes to immobilize proteins for acid hydrolysis rather than nylon or nitrocellulose membranes, both of which dissolve in 6 M HCl. Proteins immobilized on either PVDF or nylon membranes may be subjected to alkaline hydrolysis with KOH (Contor et al., 1987), but nitrocellulose membranes are not suitable. Proteins immobilized on nylon cannot subsequently be analyzed by acid hydrolysis because nylon is dissolved by 6 M HCl.

Two-dimensional thin-layer electrophoresis is required for unambiguous identification of phosphorylated residues, as some spots after one-dimensional electrophoresis do not represent pure species. For example, uridine monophosphate, which is generated during acid hydrolysis of RNA (a frequent contaminant of phosphoproteins), comigrates with phosphotyrosine during one-dimensional electrophoresis at pH 3.5.

Streaking of the sample in the first dimension is a symptom of overloading, either with the phosphoprotein itself or with contaminants in the sample. This problem can be corrected by loading less sample. Streaking in the second dimension is usually the result of problems with wetting or running the plate and cannot be corrected by loading less sample.

Some batches of blotting paper contain calcium, which interferes with electrophoresis of phosphoamino acids (probably by precipitating them). In the author's experience Whatman 3MM paper is quite reliable; other blotting papers are probably suitable as well. Inclusion of EDTA in the pH 3.5 buffer alleviates this problem.

This unit calls for glass-backed cellulose thin-layer plates rather than the plastic-backed variety, which are lighter and less expensive. This is because plastic-backed plates can under some circumstances cause sample streaking. They are, however, probably satisfactory for most experiments. If use of plastic-backed plates results in streaking, try glass-backed plates to see if that corrects the problem.

Anticipated Results

To detect a phosphoamino acid by autoradiography, a minimum of 10 cpm must be spotted and the plate exposed for a week with flashed film and an intensifying screen. Only 15% to 20% of the radioactivity in a phospho-

protein is recovered as phosphoamino acids. The majority is present as $^{32}P_i$, which is released by dephosphorylation of phosphoamino acids, with the remainder being peptide products resulting from partial acid hydrolysis. As a result, the thin-layer plates will contain a number of radioactive spots that are not phosphoamino acids (see Fig. 14.5.3). Partial hydrolysis products remain near the origin during electrophoresis at pH 1.9, but exhibit some mobility at pH 3.5 (see Fig. 14.5.3). After two-dimensional electrophoresis, they are found above the origin and below the phosphoamino acids. $^{32}P_i$ has a high mobility at both pH 1.9 and pH 3.5 and is found in the upper left-hand corner of each quadrant of the plate (see Fig. 14.5.3). Because of these additional radioactive spots, it is essential to localize internal phosphoamino acid standards by staining with ninhydrin.

Time Considerations

After the preparative gel has been run and the protein transferred to the membrane, isolation of the membrane fragment containing the protein, followed by acid hydrolysis, takes <2 hr. Two to three hours are required for drying the sample with a Speedvac evaporator. First- and second-dimension electrophoresis and staining the internal phosphoamino acid standards takes no more than ~2 hr. Overnight autoradiographic exposure with flashed film and an intensifying screen is usually sufficient; however, exposures can be carried out for up to 10 days before the background from the screen becomes objectionable.

Detection of phosphorylated protein after alkali treatment, as described in the alternate protocol, is a very quick procedure requiring little more time than it takes to carry out the alkaline hydrolysis. In general, samples of this sort can be detected after overnight exposure with flashed film and an intensifying screen at –70°C.

Determination of Akt/PKB Signaling

Akt—also known as protein kinase B (PKB)—is a central regulator of cell survival (Franke et al., 1997; Hemmings, 1997; Marte and Downward, 1997), and its activity is often used to assess the apoptotic effect of different experimental conditions. This Ser/Thr protein kinase is activated downstream of phosphoinositide 3-kinase (PI3K) in response to a wide variety of growth factors (Fig. 14.6.1). The activated form of the kinase targets a specific set of effector proteins involved in cell-survival signaling. The activation involves membrane translocation and dual phosphorylation on threonine at position 308 and serine at position 473. Because the activation of Akt depends on this phosphorylation, it is possible to assess Akt activity not only with a kinase assay but also by determining its level of phosphorylation.

This unit provides a protocol for assaying the phosphorylation and the dynamics of dephosphorylation of Akt/PKB in cultured cells (see Basic Protocol). A protocol is also provided for assaying membrane translocation in response to Akt activation (see Support Protocol).

DETERMINATION OF Akt/PKB SIGNALING IN CULTURED CELLS

BASIC PROTOCOL

This protocol can be applied to nearly all cultured cell lines with few or no modifications. In this particular example, the chosen cell system involves cells expressing or deficient in the β1 integrin because of the links between integrin signaling, Akt activation, and cell survival. This protocol describes PDGF stimulation of GD25 β1 integrin–null cells (Fassler et al., 1995) expressing wild-type β1 integrin or its mutant variant W/A, which is deficient in Akt signaling (Pankov et al., 2003). Specific treatments and time-course sampling of cultured cells are described; these allow determination of the phosphorylation level of Akt, its sensitivity to growth factor stimulation, and the mode of its inactivation by dephosphorylation. All these results can be obtained in a single nonradioactive experiment by using standard techniques such as immunoblotting (*UNIT 6.2*) and immunodetection with phosphospecific antibodies (*UNIT 14.2*). Cell cultures are serum-starved, stimulated with growth factor, and maintained for 2 hr after the stimulation for assessing the dynamics of Akt dephosphorylation. Samples are taken after each treatment, and Akt activity is determined with phosphospecific antibodies.

Materials

GD25 cells obtained from R. Fassler, Max Planck Institute of Biochemistry, Martinsried, Germany, and expressing wild-type β1 integrin (β1 cells) or integrin mutant W/A (mutant cells)

Dulbecco's modified Eagle medium supplemented with 10% fetal bovine serum (DMEM/10% FBS; *APPENDIX 2A*)

Starvation medium: DMEM containing 1% bovine serum albumin (DMEM/1% BSA)

0.5 μM okadaic acid (OA; 1 mM stock solution in DMSO, *APPENDIX 1B*) in DMEM/1% BSA

Platelet-derived growth factor-BB (PDGF-BB), freshly prepared at 10 μg/ml in 10 mM acetic acid

AG 1433 (e.g., Calbiochem) PDGF kinase inhibitor, 10 mM stock solution in dimethyl sulfoxide (DMSO)

PBS (*APPENDIX 2A*), ice cold

Modified radioimmunoprecipitation assay (mRIPA) buffer (see recipe), ice cold

2× SDS sample buffer (*APPENDIX 2A*)

10% separating gels with 4% stacking gels (*UNIT 6.1*)

Current Protocols in Cell Biology (2004) 14.6.1-14.6.12

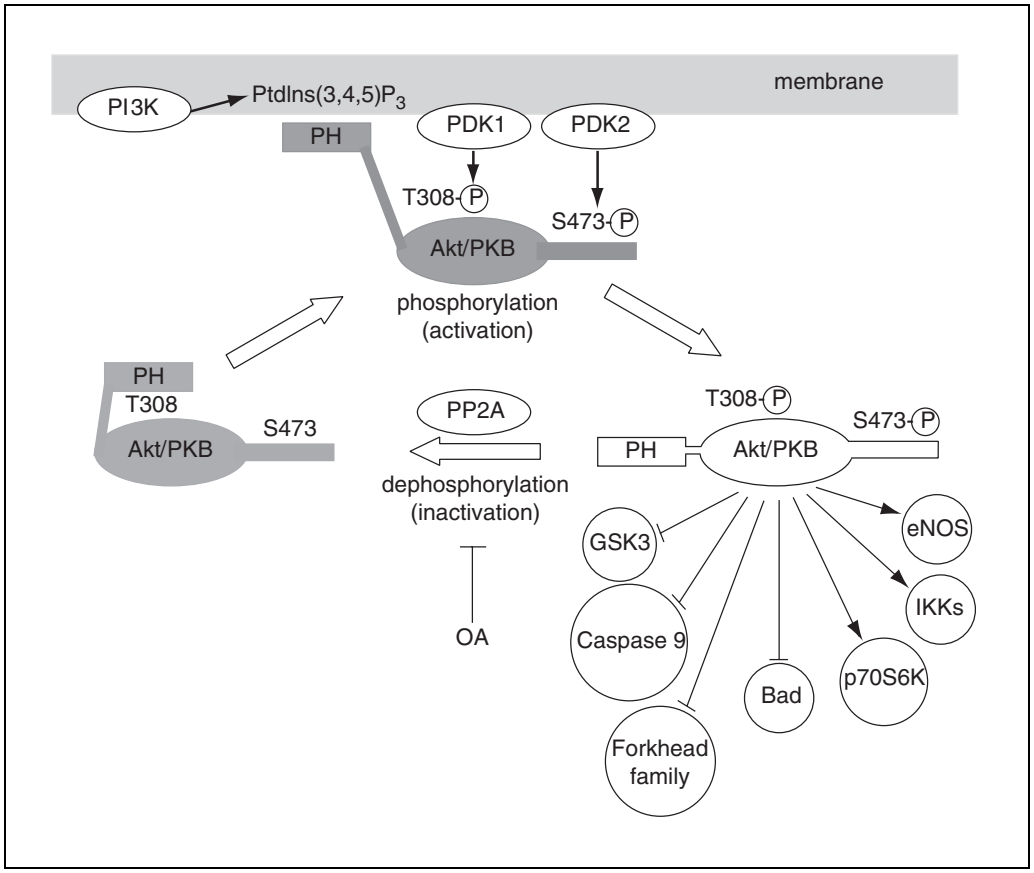

Figure 14.6.1 Activation of Akt/PKB and its effectors. Akt is activated by phosphatidylinositol 3-kinase (PI3K) products PtdIns(3,4,5)P_3 and PtdIns(3,4,)P_2. These phosphoinositides target inactive Akt to the plasma membrane via its pleckstrin homology (PH) domain. At the membrane, Akt is phosphorylated on two residues: threonine 308 (T308) by phosphoinositide-dependent kinase 1 (PDK1) and serine 473 (S473) by an unidentified PDK2. The dual phosphorylation is necessary for full activation of Akt. Activated Akt in turn phosphorylates its targets, thus modulating their function. Akt effectors include glycogen synthase kinase-3 (GSK3), caspase 9, Forkhead family of transcription factors, Bad, p70 ribosomal S6 kinase (p70S6K), IκB kinases (IKKs), and endothelial nitric oxide synthase (eNOS). Akt is inactivated through dephosphorylation by protein phosphatase 2A (PP2A), and this process can be blocked by okadaic acid (OA).

Pre-stained protein standards (e.g., Novex)
Transfer buffer (*UNIT 6.2*)
Ponceau S solution (*UNIT 6.2*)
Tris-buffered saline with 0.1% Tween 20 (TTBS, *APPENDIX 2A*)

Primary antibodies: polyclonal anti-phospho Akt (Ser 473) (e.g., Cell Signaling, Biosource), monoclonal anti-actin (e.g., Sigma)
Dry nonfat milk
Secondary horseradish peroxidase (HRP)–conjugated anti-rabbit or anti-mouse antibodies (e.g., Amersham Biosciences)
Enhanced chemiluminescence (ECL) detection reagent (*UNIT 14.2*)

35-mm tissue culture dishes
Plastic cell scraper (rubber policeman)
1.5-ml microcentrifuge tubes, prechilled
Sonicator/ultrasonic processor
Boiling water bath
Two nitrocellulose membranes cut to gel size

Four Whatman 3MM filter papers cut to gel size
SDS-PAGE/transfer apparatus (e.g., Bio-Rad, Novex)
Constant-voltage/current power supply (e.g., Bio-Rad)
Flat containers for washing gels and membranes
Shaker
Heat-sealable plastic bags
Heat sealer
X-ray film (e.g., Hyperfilm; Amersham Biosciences)
Film cassette for X-ray film
X-ray film developer

Additional reagents and equipment for tissue culture (*UNIT 1.1*), SDS-PAGE (*UNIT 6.1*), and immunoblotting (*UNIT 6.2*)

NOTE: All tissue culture incubations should be performed in a humidified 37°C, 10% CO_2 incubator. Use pre-warmed cell culture medium for all treatments.

Treat cells

1. Plate twelve 35-mm tissue culture dishes each of GD25 cells expressing wild-type β1 integrin and mutant cells (1.0×10^6 cells/dish) in 2 ml DMEM/10% FBS and allow them to attach and spread for 3 to 4 hr.

2. Wash dishes with 2 ml starvation medium two times, then add 2 ml/dish of the starvation medium and serum-starve the cells overnight.

   At this point the dishes should be ~80% confluent. Depending on the cell type being used, adjustment of the initial number of plated cells may be necessary.

3. Treat half of the dishes (six dishes of β1 cells and six dishes of mutant cells) with 0.5 μM okadaic acid (OA) (protein phosphatase inhibitor) in DMEM/1% BSA for 15 min. Label the dishes "OA". Maintain the same concentration of OA in the medium to be used to treat these dishes throughout the entire experiment. To ensure similar treatment, dispense 25 ml of pre-warmed DMEM/1% BSA and add 12.5 μl of 1 mM okadaic acid stock solution to the 25 ml of medium to be used for the "OA" sets of dishes. Add 12.5 μl of DMSO to the other 25 ml medium for the untreated sets.

   After this treatment, four sets of six samples are formed (two for each cell line). These are untreated cells of each β1 cells (β1) and W/A mutant cells (mutant), and okadaic acid–treated β1 cells (β1/OA) and mutant cells (mutant/OA).

4. Aspirate the starvation medium and stimulate cells on five dishes of each set with 20 ng/ml PDGF-BB in 2 ml DMEM/1% BSA for 15 min. Leave four dishes, one from each set (β1, β1/OA, W/A, and W/A/OA) without stimulation in fresh DMEM/1% BSA and label them as controls. To ensure similar treatment, dispense 40 ml of pre-warmed DMEM/1% BSA and add 80 μl of 10 μg/ml stock solution of PDGF-BB, mix well, divide into two 20-ml aliquots, and add 10 μl of 1 mM okadaic acid stock solution to the 20 ml of medium to be used for the "OA" sets of dishes. Add 10 μl of DMSO to the other 20 ml of PDGF-containing medium.

5. Rinse all dishes one time with DMEM/1% BSA. Put aside the control dishes and one of each PDGF-stimulated dishes (β1, β1/OA, W/A, and W/A/OA) for lysis. To the remaining four dishes of each set, add 2 ml/dish of the same medium containing 30 μM AG 1433 PDGF kinase inhibitor (four of the β1 and four of the mutant PDGF-stimulated dishes). Treat the "OA" set of dishes (four of the β1/OA and four of the W/A/OA PDGF-stimulated dishes) with the same AG 1433–containing medium supplemented with 0.5 μM okadaic acid. Incubate the AG 1433–containing dishes for 30, 60, 90, and 120 min at 37°C. Specifically, dispense 40 ml of pre-warmed

DMEM/1% BSA and add 120 µl of 10 mM stock solution of AG 1433, mix well, and divide into 20-ml aliquots and add 10 µl of 1 mM okadaic acid stock solution to the 20 ml of medium to be used for the "OA" sets of dishes. Add 10 µl of DMSO to the other 20 ml of AG 1433-containing medium.

AG 1433 is used to eliminate residual receptor kinase activity after the PDGF stimulation and to identify the rate of dephosphorylation.

Prepare cellular lysates

6. Rinse the dishes that were put aside for lysis (control and PDGF-stimulated β1, β1/OA, W/A, and W/A/OA) with 2 ml ice-cold PBS two times. Keep the dishes on ice, and use ice-cold buffers to slow down biological processes and prevent protein degradation.

7. Add 100 µl/dish of ice-cold mRIPA buffer plus inhibitors, scrape the cells with a plastic scraper or rubber policeman, and transfer the lysate into prechilled and prelabeled 1.5-ml microcentrifuge tubes. Incubate the lysates for an additional 10 min on ice.

Prepare gel samples

8. Add 100 µl/sample of 2× SDS sample buffer, sonicate (two 5-sec, 50-W pulses) on ice.

   The samples will become quite viscous after the addition of the SDS sample buffer. It is necessary to shear the released DNA by sonication to eliminate the viscosity and to allow correct loading of the samples on SDS-PAGE gels.

9. Boil samples in a water bath for 3 min or heat at 95°C for 5 min on a heating block.

10. Remove the PDGF-stimulated and AG 1433–treated β1, β1/OA, W/A, and W/A/OA dishes after 30, 60, 90, and 120 min.

11. Rinse with 2 ml ice-cold PBS two times and repeat steps 7, 8, and 9 for the samples at each timepoint.

    The samples can be stored sealed and frozen at least 1 month at −20°C.

Separate samples by SDS-PAGE

12. Cast two 10% separating gels with 4% stacking gels (*UNIT 6.1*).

    Use 15-well combs so that all 24 samples can be loaded on two gels.

13. Load 20 µl of each sample/gel lane and a separate sample containing prestained protein standards on the gel.

    Load each set of samples starting with the control sample, followed by the PDGF-stimulated sample, taken immediately after the stimulation, followed by the samples that have been kept in AG 1433–containing medium for 30, 60, 90, and 120 min for each sample set. Load the prestained protein standards into the first or the last lane so that the orientation of the gel can be identified after it is removed from the apparatus. Fill the empty lanes of the gels with 1× SDS sample buffer to prevent distortion of the separation in the adjacent lanes.

14. Run the gels at 150 V until the bromophenol blue dye reaches the bottom of the gel (see *UNIT 6.1*).

Transfer separated proteins from gel to membrane

15. When the electrophoresis is complete, remove the gels from the gel plates, cut off the stacking gels and incubate the separating portion of the gels in 50 ml transfer buffer for 15 min.

    Use gloves to handle the gels and membranes since oils from hands can block the transfer.

16. Assemble the transfer sandwich consisting of pad, Whatman 3MM filter paper, nitrocellulose membrane, equilibrated acrylamide gel, second Whatman 3MM filter paper, and second pad (Fig. 6.2.1).

    All pads, filter papers, and nitrocellulose membranes should be handled using gloves and prewetted with transfer buffer. The transfer cassette should be assembled underneath the transfer buffer to avoid trapping air bubbles. Ensure the orientation of the gel (judged by the position of the prestained protein standards) such that the correct order of the samples after transfer onto the nitrocellulose membrane is maintained.

17. Place the transfer sandwich into the electroblotting apparatus filled with transfer buffer with the nitrocellulose membrane on the cathode side of the gel. Connect the apparatus to the power supply and transfer proteins for 1 hr at 100V (constant voltage) with cooling (*UNIT 6.2*).

    Transfer time depends on the size of the proteins, acrylamide percentage, and the thickness of the gel. The completeness of the transfer can be easily judged by the transfer of the prestained protein standards.

18. At the end of the transfer, turn off the power supply and disassemble the apparatus and transfer cassette. Remove the nitrocellulose membranes and stain with 50 ml Ponceau S solution in a flat container for 5 min. Destain the membranes by rinsing several times with distilled water.

    Two membranes can be incubated in the same container by orienting them back to back.

    Staining with Ponceau S does not interfere with the subsequent antibody reactions and provides a good estimation of the protein loading, separation, and quality of the transfer. The Ponceau S solution can be reused several times.

Probe the membranes with antibodies

19. Rinse the membranes once with TTBS and incubate in 50 ml blocking solution for 30 min at room temperature with gentle shaking.

    Milk proteins in the blocking buffer are used to saturate free protein-binding sites and to prevent the nonspecific binding of the antibody. Do not incubate the membrane longer than 1 hr in this buffer since blocking buffer also has a slight stripping effect and may cause detachment of the transferred sample proteins.

20. Dilute primary anti-phospho Akt antibody according to the supplier's instructions in 10 ml TTBS containing 3% dry nonfat milk. Place the membranes in heat-sealable plastic bags, add diluted antibody, and seal the bag with a heat sealer. Incubate the membranes overnight at 4°C with gentle shaking.

    Two membranes can be incubated in the same bag by orienting them back to back. Remove all air bubbles from the bag before sealing it.

21. Remove the membranes from the bag and wash them three times, 15 min each with 50 ml TTBS in flat container with vigorous shaking.

    Do not allow the membranes to dry out after the incubation with primary antibody.

22. Dilute the secondary antibody in 10 ml TTBS, 3% dry nonfat milk according to the supplier's instructions. Place the membranes in a new heat-sealable bag, add diluted antibody and seal the bag. Incubate for 30 to 45 min at room temperature with gentle shaking.

    Either HRP- or AP-conjugated secondary antibodies can be used. HRP-conjugated secondary antibodies can be combined with the high-sensitivity ECL detection system. This system allows detection of signals from weak antibodies although attention should be paid if accurate quantification of the signal is necessary (see Commentary).

23. Repeat step 21.

24. Use the ECL immunodetection protocol (*UNIT 6.2*) to detect phosphorylated Akt. Incubate the membranes with ECL solution for 1 min, dry the excess fluid by touching the edge of the membrane to a piece of filter paper, wrap the membranes in plastic wrap, and expose to X-ray film for 1 min.

25. Incubate the membranes in 50 ml blocking buffer for 15 min at room temperature with shaking.

26. Repeat steps 20 to 24 with new primary antibody (e.g., anti-actin).

    This second reaction is used as an internal control for loading.

    If both primary antibodies are generated in the same species (e.g., both are mouse or both are rabbit) and the molecular weights of the antigens are different (e.g., 60 kDa for Akt and 45 kDa for actin) the membranes can be incubated with a mixture of the primary antibodies, and the two signals can be detected simultaneously on the same X-ray film.

SUPPORT PROTOCOL

DETERMINATION OF Akt/PKB TRANSLOCATION TO THE PLASMA MEMBRANE

An important step in Akt activation involves its targeting to the plasma membrane. This translocation is dependent on the pleckstrin homology (PH) domain localized at the N-terminus of the Akt molecule and the presence of phosphatidylinositol 3-kinase products PtdIns(3,4,5)P_3 and PtdIns(3,4,)P_2.

This protocol describes the preparation of membrane and cytosolic fractions from starved and PDGF-stimulated GD25 β1 integrin-null cells expressing wild-type β1 integrin or its mutant variant W/A that is deficient in Akt signaling. The distribution of Akt is determined in each fraction by immunoblotting and immunodetection with antibodies. The same protocol can be applied to almost all cultured cell lines with little or no modifications.

Additional Materials *(also see Basic Protocol)*

Cytosolic buffer (see recipe)
Membrane buffer (see recipe)
Dry ice
60-mm dishes

Treat cells

1. Plate two 60-mm dishes each of β1 and mutant cells (2.5×10^6 cells/dish) in DMEM/10% FBS and allow them to attach and spread for 3 to 4 hr.

2. Wash dishes with 5 ml DMEM/1% BSA (starvation medium) two times, then add 5 ml/dish of DMEM/1% BSA and serum-starve the cells overnight.

    At this point the dishes should be ~80% confluent. Depending on the cell type being used, adjustment of the initial number of plated cells may be necessary.

3. Aspirate the starvation medium and stimulate one dish from each cell line with 20 ng/ml PDGF-BB in 5 ml DMEM/1% BSA for 15 min. Leave one β1 and one mutant dish without stimulation in fresh DMEM/1% BSA and label them as controls. To ensure similar treatment, dispense 10 ml of pre-warmed DMEM/1% BSA and add 20 µl of 10 µg/ml stock solution of PDGF-BB, mix well, and add to the dishes to be stimulated.

Prepare cytosol fractions

4. Rinse the control and PDGF-stimulated dishes with 5 ml cytosolic buffer two times. Keep the dishes on ice and use ice-cold buffers to slow down the biological processes and prevent protein degradation.
5. Add 350 µl/dish of ice-cold cytosolic buffer, scrape the cells with a plastic scraper or rubber policeman, and transfer the lysate into prelabeled 1.5-ml microcentrifuge tubes.
6. Place the tubes on dry ice until frozen. Thaw the cells in a 37°C water bath. Repeat freeze-thaw cycle two additional times.

   Freeze-thaw cycles will break plasma membranes and liberate most of the cytosolic proteins.

7. Centrifuge 15 min at 19,000 × *g*, 4°C. Transfer the supernatant into prelabeled 1.5-ml microcentrifuge tubes, mix with equal volume of 2× SDS sample buffer, and leave on ice.

   This supernatant represents the cytosolic fraction.

Prepare membrane fraction

8. Resuspend the pellet in fresh 350 µl cytosolic buffer, centrifuge as in step 7, and discard the supernatant.

   This washing step clears most of the remaining cytosolic proteins from the pellet.

9. Suspend the pellet in 50 µl membrane buffer and centrifuge 15 min at 10,000 × *g*, 4°C.

   This step solubilizes cellular membranes. Pipet the pellet up and down through a micropipet tip several times, but avoid excessive foaming.

10. Transfer the supernatant into prelabeled 1.5-ml microcentrifuge tubes and mix with an equal volume of 2× SDS sample buffer.

Analyze fractions

11. Boil all the samples (supernatants from steps 7 and 10) in a boiling water bath for 3 min or heat at 95°C for 5 min on a heating block.

    The samples can be stored sealed and frozen at least 1 month at −20°C.

12. Proceed with SDS-PAGE and immunoblotting (see Basic Protocol 1, steps 12 through 24). Use anti-Akt antibody to probe the distribution of the total Akt between the cytosolic and membrane fractions.

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Cytosolic buffer

20 mM Tris·Cl, pH 7.5 (*APPENDIX 2A*)
150 mM NaCl
50 µM leupeptin (*APPENDIX 1B*), add fresh
50 µM pepstatin (*APPENDIX 1B*), add fresh
1 mM PMSF (*APPENDIX 1B*), add fresh
1 mM sodium vanadate (*APPENDIX 1B*), add fresh
50 mM NaF, add fresh
Store up to 3 months at 4°C

The cystolic buffer is derived from Kobayashi et al. (2001).

Membrane buffer

20 mM Tris·Cl, pH 7.5 (*APPENDIX 2A*)
150 mM NaCl
1% (v/v) Triton X-100
50 µM leupeptin (*APPENDIX 1B*), add fresh
50 µM pepstatin (*APPENDIX 1B*), add fresh
1 mM PMSF (*APPENDIX 1B*), add fresh
1 mM sodium vanadate (*APPENDIX 1B*), add fresh
50 mM NaF, add fresh
Store up to 3 months at 4°C

The membrane buffer is derived from Kobayashi et al. (2001).

Modified radioimmunoprecipitation assay (mRIPA) buffer

50 mM HEPES, pH.5
150 mM NaCl
10% (v/v) glycerol
0.1% (w/v) SDS (*APPENDIX 2A*)
1% (w/v) sodium deoxycholate
1% (v/v) Triton X-100
1.5 mM $MgCl_2$
1 mM EGTA
50 µM leupeptin (*APPENDIX 1B*), add fresh
50 µM pepstatin (*APPENDIX 1B*), add fresh
1 mM PMSF (*APPENDIX 1B*), add fresh
1 mM sodium vanadate (*APPENDIX 1B*), add fresh
50 mM NaF, add fresh
Store up to 3 months at 4°C

COMMENTARY

Background Information

Akt (c-Akt) is the cellular homolog of the viral oncoprotein v-Akt. It was first identified as a protein kinase with high homology to protein kinases A and C and was therefore termed PKB (protein kinase B) or RAC (related to A and C). Mammals have three closely related Akt genes that are expressed differentially at both mRNA and protein levels (Datta et al., 1999; Brazil and Hemmings, 2001). The family of Akt proteins contains a central kinase domain with specificity for serine or threonine residues in substrate proteins and a carboxyl terminus containing a hydrophobic motif (HM) and a proline-rich domain. The N-terminal region of the molecule includes a pleckstrin homology (PH) domain, which together with the HM play important roles in the Akt activation process (Scheid and Woodgett, 2003). The activation mechanism involves direct binding of PI3K

products phosphatidylinositol 3,4,5-trisphosphate and phosphatidylinositol 3,4-bisphosphate to the PH domain of Akt (Chan et al., 1999). As a consequence, Akt is localized to the plasma membrane where PI3K-generated 3′-phosphorylated phospholipids reside (Fig. 14.6.1). This translocation is now known to be an important step in Akt activation (Testa and Bellacosa, 1997). Myristylated c-Akt, which is specifically targeted to the plasma membrane, is constitutively active similarly to the oncogenic v-Akt, which is permanently targeted to the plasma membrane by the viral gag sequence, and exhibits constant kinase activity. Membrane-localized Akt undergoes conformational changes leading to the exposure and phosphorylation of two residues—Thr308 in the activation loop, proximal to the catalytic core, and Ser473 in the HM. This dual phosphorylation is necessary for the full activation of Akt. The kinase that phosphorylates Thr308 has been named 3-phosphoinositide-dependent kinase 1 (PDK1) because it also requires lipids for its activity (Vanhaesebroeck and Alessi, 2000). Phosphorylation of Akt on Thr308 causes a charge-induced change in conformation allowing substrate binding and an elevated rate of catalysis. The second important phosphorylation event associated with Akt activation occurs at Ser473. The mechanism of this phosphorylation is not completely understood and may involve autophosphorylation or distinct serine kinases like integrin-linked kinase (ILK; Persad and Dedhar, 2003). The function of phosphorylation at this site is also not fully clarified, though the necessity of this modification for Akt activity is well documented. For example, kinase activity is significantly reduced by mutations of this residue, and a similar effect is observed after ceramide-promoted dephosphorylation at this site. It has been proposed that phosphorylation at Ser473 may change the properties of the hydrophobic motif, shifting it to a docking site for PDK1 (Scheid and Woodgett, 2003). After activation, Akt appears to detach from the inner leaflet of the plasma membrane and to translocate through the cytosol to the nucleus (Andjelkovic et al., 1997; Meier and Hemmings, 1999).

Cells can inhibit or reverse the activation of Akt by several mechanisms (Hill and Hemmings, 2002). One of them includes the lipid phosphatase PTEN (phosphatase and tensin homolog deleted on chromosome 10; Yamada and Araki, 2001), which decreases the levels of phosphatidylinositol 3,4,5-trisphosphate and phosphatidylinositol 3,4-bisphosphate within cells, thus preventing membrane translocation of Akt. Direct inactivation of Akt occurs by dephosphorylation of Thr308 and Ser473. This process is mediated by the ubiquitous Ser/Thr protein phosphatase 2A (PP2A; see Millward et al., 1999) and can be blocked by the phosphatase inhibitor okadaic acid. A negative regulator termed CTMP (carboxy-terminal modulator protein), which attenuates the activation of Akt at plasma membrane, has also been identified (Maira et al., 2001). Thus, the level of Akt activity in steady state is the result of an equilibrium between activation and inhibition events.

Extensive research has clarified the intracellular mechanisms of Akt activation by upstream PI3K and PDK1. Less is known about the means through which Akt regulates cell growth, proliferation, and survival, even though a number of downstream Akt substrates have been identified (Fig. 14.6.1; Chan et al., 1999; Datta et al., 1999; Vanhaesebroeck and Alessi, 2000). While the Akt phosphorylation consensus sequence is defined (RXRXXS/THydrophobic), to date only a small number of Akt substrates have been positively or tentatively identified.

Ongoing studies on Akt signaling and the possibility of using this kinase as a drug target for cancer, diabetes, and stroke, make probing for Akt activity a frequently used task. This can be achieved by measuring Akt kinase activity directly or by assaying the level of phosphorylation as described in this unit. Determination of Akt kinase activity follows the general scheme applicable for most kinases (e.g., see *UNIT 14.3*) and involves immunoprecipitation of the enzyme with antibodies and then performing a phosphorylation reaction in vitro. While this approach offers a direct and relatively accurate determination of Akt activity, the method is laborious and often involves use of radioactivity. Determination of Akt activation state by assaying the level of phosphorylation after specific treatments is quicker and employs basic non-radioactive laboratory techniques. Moreover, the same samples (in some cases the same membrane used for immunoblotting with anti-Akt antibodies) can be used for determination of the activity of upstream Akt regulators and the phosphorylation level of downstream Akt substrates, making this method more versatile than the classical kinase assay.

Critical Parameters and Troubleshooting

Several parameters play critical roles for success in determination of Akt activation and

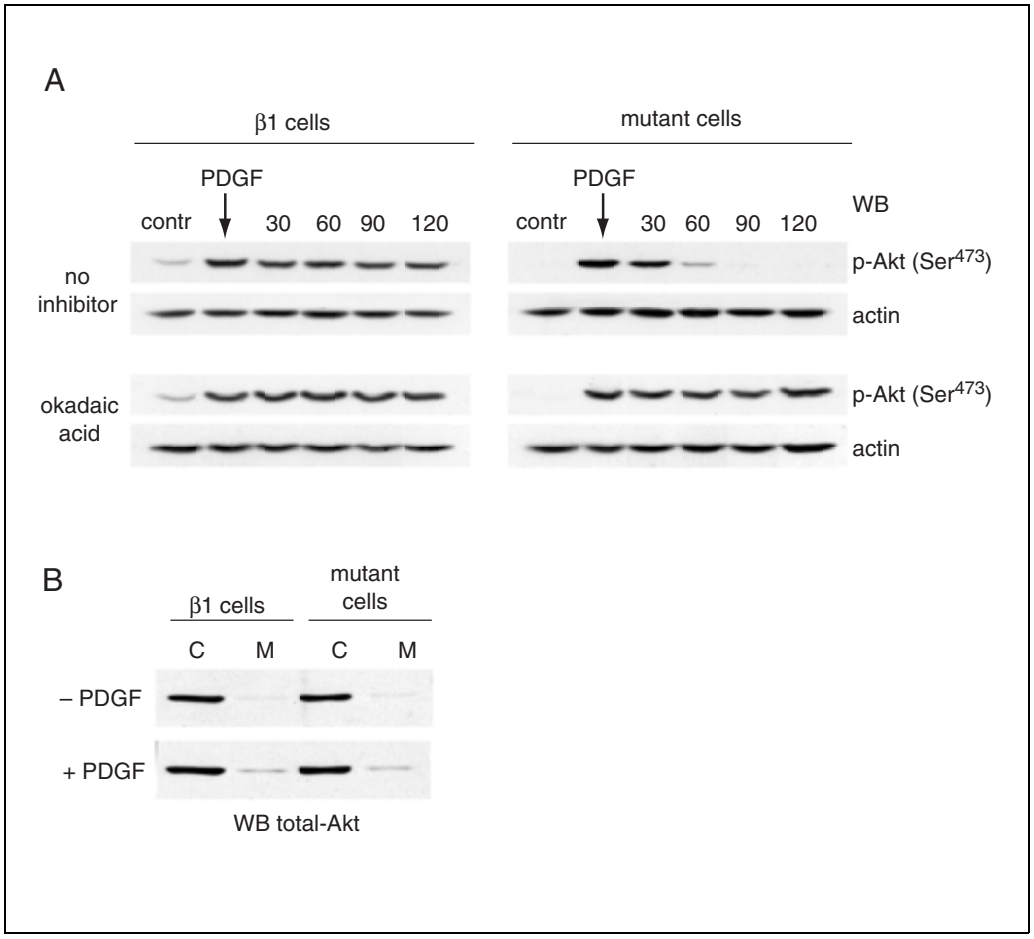

Figure 14.6.2 Probing of Akt signaling by the methods described in this unit. (**A**) Determination of Akt signaling in cultured cells. GD25 cells expressing either wild-type (β1 cells) or tryptophan mutant (mutant cells) integrins were cultured overnight in the absence of serum. Cells were then stimulated with 20 ng/ml PDGF-BB for 15 min, the growth factor was washed away, and the cells were maintained in medium without serum supplemented with 30 μM PDGF kinase inhibitor AG 1433. Samples were taken after starvation (contr), immediately after stimulation (PDGF, ↓), and at the indicated time points. The experiment was performed in the absence (no inhibitor) or presence of 0.5 μM okadaic acid. Lysates from the samples were analyzed by immunoblotting (WB) with anti-phospho Ser^{473} Akt [p-Akt (Ser^{473})] or anti-actin (actin) antibodies. Actin was used as an internal control for loading. (**B**) Determination of Akt translocation to the plasma membrane. Cells were starved overnight and stimulated with 20 ng/ml PDGF (+ PDGF) or left without stimulation (–PDGF) and used to prepare cytoplasmic (C) and membrane (M) fractions. Samples from these fractions were analyzed by immunoblotting with anti-total Akt (WB total-Akt) antibodies. Increased amount of Akt is detected in the membrane fraction of the PDGF stimulated cells.

inhibition. Initial reduction of the phosphorylation level of Akt is achieved by a period of starvation, which varies depending on the type of cells and should be determined experimentally. For some cell lines like primary human fibroblasts, withdrawal from serum for 4 hr is sufficient, while for most immortalized cell lines, longer periods of starvation work better. The length of serum starvation of the chosen cell line needs to be such that it will ensure a five-fold or higher increase of Akt phosphorylation after stimulation with growth factor.

The response to PDGF by different cell lines varies significantly. If the increase of Akt phosphorylation after stimulation is not sufficient, activation with another growth factor, e.g., EGF, may be used. If a different growth factor is applied, the corresponding growth factor receptor (GFR) kinase inhibitor should be added to the medium instead of AG 1433 (e.g., AG 1478 if EGF is utilized). Addition of a growth factor kinase inhibitor is necessary to block residual activity of the receptor after withdrawal of the growth factor. This treatment is critical, since residual GFR activity may

mask the Akt inactivation pattern by prolonging the dephosphorylation time. Experimental blocking of dephosphorylation is achieved by treatment with okadaic acid. Incubations with this potent protein phosphatase inhibitor, especially for prolonged times, may cause cell rounding and even detachment from the substrate. Okadaic acid sensitivity should be determined experimentally for each cell type to be used.

Obtaining a high signal-to-noise ratio after immunoblotting is essential for the successful determination of Akt signaling. This can be ensured by: (1) use of specific antibodies that recognize the phosphorylated Akt but not its unphosphorylated form (now offered by several companies like Cell Signaling, Biosource); (2) use of freshly added phosphatase and protease inhibitors added to the lysis buffers to prevent Akt dephosphorylation and degradation after cell disruption; (3) loading sufficient amount of proteins from the cellular lysate that will ensure trouble-free detection of the Akt by the antibodies (this is easily achieved by keeping the samples for SDS-PAGE concentrated—e.g., $>5 \times 10^5$ cells/minigel lane); (4) following the proper techniques for SDS-PAGE and immunoblotting (see *UNITS 6.1 & 6.2*).

Accurate comparison and quantification by densitometry of the amounts of phosphorylated Akt in different samples can be achieved if the detection system is kept in a linear range. The enhanced chemiluminescence (ECL) system should be optimized to obtain linearity by adjustments of the amount of the protein loaded on the gel, concentrations of primary and secondary antibody, and the X-ray film exposure time. If the weakest signal is detectable and the strongest signal is still within the linear range of the film (e.g., not saturated), then the rest of the samples are also in the linear range of the system, which can be used for quantification.

Anticipated Results

Typical results expected after probing for Akt activity (see Basic Protocol) or Akt membrane translocation (see Support Protocol) are presented in Figure 14.6.2A and B, respectively. Comparison between the starved cells (contr) and cells after PDGF stimulation (PDGF) should demonstrate a several-fold increase in the amount of phosphorylated Akt. Attenuation of this response after experimental manipulations of the cell cultures may indicate effects on the upstream pathways leading to Akt activation. Evaluation of the amount of phosphorylated Akt in the samples taken after PDGF stimulation at different time points provides information about the rate of Akt dephosphorylation (inhibition). While in the samples from β1 cells, this decrease is modest, the Akt in the samples from mutant cells is rapidly dephosphorylated. Such a result indicates activation of some of the systems for Akt inhibition (see Background Information). Performing the same experiment in the presence of a PP2A inhibitor, okadaic acid completely reverses this effect, indicating that activation of this phosphatase is involved in the observed increased dephosphorylation rate in W/A mutant cells. If OA is ineffective, additional experiments should be designed to test the role of other Akt inhibitors (see Background Information). Activation of Akt is dependent on its membrane translocation. A typical increase in membrane-bound Akt after growth factor stimulation is presented in Figure 14.6.2B. A modest but detectable increase in total Akt in the membrane fraction is observed in both cell lines after PDGF stimulation. Failure to detect such translocation may indicate defects in the function of the PH domain of Akt or insufficient phosphatidylinositol 3,4,5-trisphosphate and phosphatidylinositol 3,4-bisphosphate (see Background Information).

Time Considerations

The entire procedure described in the Basic Protocol can be completed in 3 days. This period includes the time for cell attachment after plating (4 hr); starvation (12 hr); PDGF stimulation and the necessary incubations up to preparation of the SDS-PAGE samples (3 hr); SDS-PAGE and electrotransfer (6.5 hr for mini gels or 9.5 hr for normal size gels); overnight incubation with the primary antibody; and completion of the immunoreactions with ECL processing (4 hr). Since this procedure takes >1 day, it is helpful to use one night for starvation of the cells and the next night for incubation with the primary phosphospecific antibody. There are a number of points where the procedure can be interrupted: (1) after the preparation of the SDS-PAGE samples; (2) after the electrotransfer (membranes can be stored wet or dry in resealable plastic bags at 4°C); and (3) after the completion of the first immunoreaction (membranes can be stored wet in resealable plastic bags at 4°C). A similar timeframe applies for the procedure described in the Support Protocol.

Analyzing FAK and Pyk2 in Early Integrin Signaling Events

Integrins are a family of heterodimeric α/β transmembrane receptors that bind to extracellular matrix proteins (ECM) proteins, and the signals generated by activated integrins regulate cell motility (Schwartz, 2001; Hynes, 2002). As integrins do not possess intrinsic signaling activity, integrin-stimulated signaling events promoting cell motility are initiated by integrin-associated kinases, e.g., focal adhesion kinase (FAK). FAK is one of several intracellular protein-tyrosine kinases (including the Src family, Pyk2, c-Abl, and Syk) that are activated by cell adhesion to ECM proteins such as fibronectin, collagen, or vitronectin. Integrin activation of FAK promotes increased FAK tyrosine phosphorylation and leads to the formation of an FAK-Src signaling complex (Schlaepfer et al., 1999; Schlaepfer and Mitra, 2004). Fibroblasts lacking FAK spread poorly and display migration defects in response to integrin stimuli (Ilic et al., 1995). Although the FAK-related kinase Pyk2 is expressed in FAK-null fibroblasts (FAK−/−), Pyk2 is not as effective in promoting FAK−/− cell motility as the FAK-Src signaling complex (Sieg et al., 1998). This unit describes methods for culturing FAK+/+ and FAK−/− mouse embryo fibroblasts (MEFs; see Support Protocol 1) and stimulating these cells by replating onto fibronectin-coated dishes (see Basic Protocol 1). It also contains support protocols for cell starvation (see Support Protocol 2), preparation of protein cell lysates (see Support Protocol 3), and conditions and antibodies available for immunoprecipitation of FAK, Pyk2, and c-Src (see Support Protocol 4).

Cell replating onto fibronectin activates FAK, and procedures are described for analyzing FAK-associated autophosphorylation activity (see Basic Protocol 2) with alternate protocols describing assays for measuring FAK-Pyk2 phosphorylation of a peptide substrate (see Alternate Protocol 1) and changes in c-Src-associated in vitro kinase activity (see Alternate Protocol 2). These catalytic measurement assays are complemented by methods using antibodies available for evaluating activity changes in FAK, Pyk2, or c-Src using immunoblotting techniques with phospho-specific antibodies (see Basic Protocol 3). In addition, the biochemical analyses are complemented by cell biological methods to evaluate integrin-stimulated haptotaxis migration (see Basic Protocol 4) and time-lapse imaging to monitor wound closure motility in culture (see Basic Protocol 5). In these cell motility assays, transient plasmid expression vector transfection can be used to overexpress various proteins to test their effects on cell motility (Alternate Protocol 3). Finally, protocols are provided for visualizing activated FAK, Pyk2, and c-Src in cells plated onto extracellular matrix proteins (see Basic Protocol 6) with support methods for staining filamentous actin in cells (see Alternate Protocol 4), an easy means to visualize changes in cell shape and indirectly localize integrin-containing focal adhesions that are found at the ends of actin stress fibers.

NOTE: All culture incubations should be performed in a humidified 37°C, 10% CO_2 incubator unless otherwise specified. Some media, e.g., DMEM, require higher levels of CO_2 to maintain pH 7.4.

NOTE: All solutions and equipment coming into contact with cells must be sterile, and proper aseptic technique should be used accordingly.

BASIC PROTOCOL 1

REPLATING ASSAYS FOR SIGNALING STUDIES

Although anti-integrin antibodies can be used to facilitate integrin clustering, one of the strongest activators of integrin signaling is replating or passaging cells onto ECM-coated culture dishes. In the span of 1 hr, cells will rapidly bind to the ECM protein provided and will undergo cell spreading and morphology changes. Fibronectin binds to variety of α/β integrin pairs expressed on cells and is the strongest activator of FAK. Other ECM proteins can be used in replating assays, although the effective concentrations needed to stimulate integrin signaling are varied and dependent on cell type. This protocol describes the optimal conditions for replating FAK+/+ and FAK−/− cells on fibronectin to achieve maximal FAK or Pyk2-Src activation, respectively. It also provides a method for collecting protein lysates from these cells for further signaling studies. For comparative purposes, cell lysates are collected from adherent serum-starved cells, cells that have been held in suspension, cells replated onto fibronectin, and cells that have been replated onto a positively-charged ligand such as poly-L-lysine where rapid cell adhesion does not depend on integrin engagement.

Materials

Fibronectin (from bovine plasma; Sigma-Aldrich)
Poly-L-lysine (mol. wt. 70,000 to 150,000 or 150,000 to 300,000; Sigma-Aldrich)
Replating and migration medium (see recipe)
FAK+/+ and FAK−/− MEFs, serum-starved (Support Protocol 2)
Phosphate buffered saline (PBS; *APPENDIX 2A*)
Trypsin/EDTA: 0.25% (w/v) trypsin/1 mM EDTA (Invitrogen)
Trypsin inhibitor solution (see recipe)

10-cm plastic tissue culture plates (Falcon)
4°C incubator
15-ml centrifuge tubes (Corning)
Tabletop centrifuge
10-ml transfer pipets, sterile
50-ml conical centrifuge tubes (Corning)
Light microscope

Coat plates and prepare cells

1a. *To prepare fibronectin plates:* Dilute fibronectin to 10 μg/ml in PBS and distribute 5 ml per 10-cm plastic tissue culture plate. Incubate at 4°C overnight.

1b. *To prepare poly-L-lysine plates:* Dilute poly-L-lysine to 50 μg/ml in PBS and distribute 5 ml per 10-cm plastic tissue culture plate. Incubate at 4°C overnight.

2. Prior to preparing cells, aspirate fibronectin or poly-L-lysine solutions, add 3 ml of replating and migration medium, aspirate, and place dishes at 37°C.

   The number of cell plates prepared depends on the number of experimental points to be evaluated. For example, to perform a time course of FAK activation, it is recommended that fibronectin and poly-L-lysine replating time points of 20, 40, 60, and 180 min be performed (see Support Protocol 3).

3. Reserve one plate of serum-starved cells for a control. Wash serum-starved cells with PBS by adding 10 ml PBS and aspirating it off with a transfer pipet. Add 2.5 ml trypsin/EDTA per dish. Tap side of plates to facilitate cell release.

4. Add 5 ml trypsin inhibitor solution warmed to 37°C. Transfer cells to a 15-ml centrifuge tube. Centrifuge 3 min at 750 × *g*, 21°C, in a tabletop centrifuge and aspirate supernatant.

Replate cells

5. Resuspend cells in 37°C replating and migration medium to 2×10^5 cells/ml. Keep cells in suspension at least 30 min and rotate tube gently at least every 5 min to keep cells from clumping, settling, and sticking to the plastic.

   It is convenient to pool all suspended cells into 50-ml conical centrifuge tubes such that subsequent cell distribution in replating assays is consistent. FAK−/− cells will sometimes clump together in suspension and forced pipetting to break apart clumps is recommended prior to replating. Keep additional cells in suspension during replating.

6. Add 5 ml cell suspension to a 10-cm plate pre-coated with fibronectin or poly-L-lysine (from step 3) and incubate at 37°C.

7. Periodically visualize replated cells under a microscope for changes in cell attachment and spreading.

   Maximal FAK activation occurs when cells have bound to fibronectin and are undergoing rapid cell spreading (between 20 and 60 min). Cells on poly-L-lysine will adhere, but will be very slow to spread.

8. Proceed with Support Protocol 3 to prepare cell lysates of control cells (adherent serum-starved cells), experimental cells (replated on fibronectin or poly-L-lysine), and unplated serum-starved cells in suspension (45 min post replating).

   The unplated serum-starved cells in suspension and serum-starved experimental cells will be very important in correctly evaluating changes in FAK activation in immunoblotting (Basic Protocol 3) and in vitro kinase assays (Basic Protocol 2).

GROWTH OF FAK+/+ AND FAK−/− FIBROBLASTS

SUPPORT PROTOCOL 1

FAK-null MEFs were derived from an E8.0-day-old mouse embryo that had null mutations in genes for FAK and p53 (Ilic et al., 1995). Therefore, the cells are genetically FAK−/− p53−/−. Control FAK+/+ cells were derived in 1995 from an E8.0-day-old mouse embryo that had null mutations in p53 but not in FAK. Therefore, the cells are genetically FAK+/+ p53−/−. Both cell lines were derived from embryos of littermates obtained by crossing FAK+/− p53−/− female and FAK+/− p53−/− male mice.

FAK+/+ and FAK−/− MEFs are grown on gelatin precoated plates because this was used during cell outgrowth from embryos. Although the fibroblasts are p53-null, the cells will become senescent (exhibited by an increase in cell size and the lack of cell proliferation) at high passage numbers.

Materials

Gelatin
Phosphate buffered saline (PBS; *APPENDIX 2A*)
FAK+/+ mouse embryo fibroblasts (ATCC CRL-2645) FAK−/− mouse embryo fibroblasts (ATCC CRL-2644): grown on plates as per ATCC product sheet
Trypsin/EDTA: 0.25% (w/v) trypsin/1 mM EDTA (Invitrogen), 37°C
Cell growth medium (see recipe), warmed to 37°C
42°C water bath
0.22-μm GP Express Plus filter membrane (Millipore)
10-cm plastic tissue culture plates (Falcon)
10-ml transfer pipets, sterile
Light microscope
15-ml conical centrifuge tubes (Corning)

Prepare gelatin-coated plates

1. Dissolve 0.5 g gelatin in 500 ml PBS to make 0.1% (w/v) solution.
2. Heat in 42°C water bath to dissolve gelatin.
3. Sterilize by passing through a Millipore 0.22-μm GP Express Plus filter membrane. Store up to 2 weeks at 4°C.
4. Coat 10-cm plastic tissue culture plates with 5 ml sterile 0.1% gelatin solution and incubate 1 hr at 37°C
5. Aspirate gelatin solution. Do not wash plates.

Trypsinize cells

6. Aspirate growth medium from a 10-cm plate of FAK−/− or FAK+/+ mouse embryo fibroblasts.
7. Wash cells with 5 ml PBS.
8. Add 2.5 ml warm trypsin/EDTA per plate. Tap side of plates to facilitate cell release.
9. Incubate 2 to 3 min. Verify cell detachment under a microscope.

   FAK−/− cells adhere to the culture plates more firmly than FAK+/+ cells and will take longer to be released by trypsin/EDTA treatment. Senescent FAK−/− cells exhibit very strong adhesion to gelatin-coated dishes.

10. Inactivate trypsin/EDTA by adding 5 ml cell growth medium.

Replate cells

11. Wash cells off plates by pipetting, and transfer them into 15-ml conical centrifuge tubes.
12. Centrifuge cells in a tabletop centrifuge 3 min at 750 × *g*, 21°C.
13. Aspirate supernatant and discard, retaining the pellet.
14. Resuspend cells in fresh growth medium, count (see *UNIT 1.1*), and add growth medium to obtain the desired density. Add to gelatin-coated plates containing cell growth medium.

    Total volume is 8 to 10 ml medium per 10-cm plate.

    Consistent subcultivation is very important as cells that remain confluent for more than 24 hr exhibit alterations in cell morphology and motility properties. In routine passage, FAK−/− cells may proliferate faster than FAK+/+ cells, so cell counting and normalization of cell numbers is required for equivalent experimental analyses.

    Both FAK−/− and FAK+/+ cells contain neomycin resistance genes and G418 (neomycin) selection can be applied (500 μg/ml), although this is not absolutely required.

15. Passage the cells when they are confluent.

    Split cells 1:10 to 1:15 every 3 days. Do not allow cells to become overly confluent, as this can result in a premature senescent phenotype.

SUPPORT PROTOCOL 2

SERUM STARVATION OF CELLS

For the stimulation and analysis of FAK activity and phosphorylation (Basic Protocols 1, 2, and 3) and assays that involve cell replating onto extracellular matrix (ECM) proteins (Basic Protocols 4, 5, and 6), it is important to start with cells that are adherent and in a quiescent or nonproliferative state. This is accomplished by lowering the percent of serum to 0.5% in the growth medium.

Additional Materials *(also see Support Protocol 1)*

Starvation medium: prepared by making cell growth medium (see recipe) with FBS reduced to 0.5%.

1. Passage cells (see Support Protocol 1) by plating 1×10^6 cells onto gelatin-coated 10-cm dishes in growth medium.

   This is a subconfluent density, and it is important that cells do not reach confluency prior to initiation of cell motility analyses.

2. After 24 hr, wash cells with PBS.

3. Add 8 ml of starvation medium and incubate 16 to 24 hr at 37°C. Use cells immediately after starvation.

   Greater than 95% of FAK−/− and FAK+/+ cells should remain adherent under serum-starvation conditions.

PREPARATION OF CELL LYSATES

SUPPORT PROTOCOL 3

Activated FAK is associated with the cytoskeleton-rich fraction of cells that is not easily solubilized with low-detergent-containing buffers. The following lysate preclearing steps are used as the first step for immunoprecipitation, blotting, and in vitro kinase assays. All procedures are to be performed at 4°C.

Materials

Experimentally treated, control adherent, and control suspended cells (Basic Protocol 1)
Phosphate-buffered saline (PBS; *APPENDIX 2A*), 4°C
RIPA cell lysis buffer (see recipe), 4°C
50% (w/v) Sephadex G-100 (Sigma G100-120) slurry in PBS (*APPENDIX 2A*)
Cell scraper (Corning)
Refrigerated centrifuge
1.5-ml microcentrifuge tubes
1-ml disposable syringes
21-G Luer-Lok needles
Tube rotation device (e.g., Labquake, Barnstadt-Thermolyne)
Microcentrifuge
−80°C freezer (optional)

1. Wash experimentally treated and adherent control cells with 10 ml cold PBS.

2. At 45 min after replating the experimental cells (see Basic Protocol 1), centrifuge control suspended cells 3 min at 750 × *g*, 21°C. Resuspend cells in PBS and repeat centrifugation.

3. Add 750 µl cold RIPA cell lysis buffer to each 10-cm plate (or 1×10^6 suspended cells).

4. Scrape adherent cells using cell scraper and transfer to a 1.5-ml microcentrifuge tube.

5. Using a 1-ml disposable syringe and 21-G Luer-Lok needle, pull cell lysate into syringe and shear cellular DNA by extrusion. Repeat at least five times.

   Be careful using the sharp needle and do not use too much force as this will result in excessive bubbling of the lysate.

6. Add 100 µl 50% Sephadex G-100 slurry in PBS to each tube. Rotate tubes 10 min at 4°C.

   Sephadex G-100 beads will reduce DNA contamination and non-specific protein binding for subsequent immunoprecipitation analyses.

7. Centrifuge 10 min at 16,000 × *g*, 4°C.

8. Transfer supernatant (cleared total cell lysate) into new 1.5-ml microcentrifuge tubes.

   If the bead pellet is distributed along the sidewall of the microcentrifuge tubes, rotate tube direction 180° in centrifuge rotor and centrifuge an additional 5 min.

9. Store cleared lysate indefinitely at −80°C or proceed with subsequent analyses.

SUPPORT PROTOCOL 4

IMMUNOPRECIPITATION OF FAK, Pyk2, AND c-Src

FAK is expressed at high levels in FAK+/+ fibroblasts. The FAK-related kinase, Pyk2, is expressed at low levels in FAK+/+ fibroblasts and at high levels in FAK−/− fibroblasts. Upon replating on fibronectin, both FAK and Pyk2 will form transient signaling complexes with the c-Src protein-tyrosine kinase. Replating of cells on fibronectin can also lead to the activation of c-Src through dephosphorylation of Tyr-527 located in the C-terminal domain of the regulatory region. This protocol describes standard immunoprecipitation methods used to isolate FAK, Pyk2, or multi-protein complexes with c-Src.

Materials

Primary antibody (see Table 14.7.1 and Table 14.7.2)
Lysate of treated or control cells (Support Protocol 3)
50% (w/v) protein A-agarose beads (fast flow immobilized protein A; Repligen, *http://www.repligen.com*) in PBS (*APPENDIX 2A*)
50% (w/v) protein G-Plus-agarose beads (Calbiochem) in PBS (*APPENDIX 2A*)
Triton lysis buffer (see recipe), 4°C
HNTG buffer (see recipe), 4°C
1.5-ml microcentrifuge tubes
Tube rotation device (e.g., Labquake, Barnstadt-Thermolyne)
Centrifuge
Transfer pipets

1. Add 1 to 2 µg of primary antibody to 0.75 ml lysate of treated or control cells in a microcentrifuge tube.

   If using cells from a frozen lysate, thaw at 37°C then maintain at 4°C.

   Use a FAK or Pyk2 antibody for subsequent analysis of FAK/Pyk2 kinase activity or phosphorylation. (Basic Protocol 2 or Alternate Protocol 1).

   Use an Src antibody for subsequent Src-associated analysis (Alternate Protocol 2).

2. Rotate from 3 to 14 hr at 4°C.

3. Add 30 µl of protein A– or protein G–bead slurry and rotate 60 min at 4°C.

   Protein A beads are used to capture rabbit polyclonal antibodies and protein G beads are used to bind goat polyclonal and mouse monoclonal antibodies (Table 14.7.1 and Table 7.2.1).

4. Centrifuge beads 1 min at 1000 × g, 4°C. Remove supernatant with a transfer pipet.

5. Add 800 µl Triton lysis buffer to beads, invert tube to suspend the bead pellet, and centrifuge 1 min at 1000 × *g*, 4°C. Remove supernatant with a transfer pipet and repeat step two more times.

6. Add 800 µl of HNTG buffer, invert the tube to suspend the bead pellet, and centrifuge 1 min at 1000 × *g*, 4°C. Remove supernatant with a transfer pipet and repeat step two more times.

From this point, the immunoprecipitated samples can be analyzed in either the in vitro kinase assay (Basic Protocol 2) or resolved by SDS-PAGE (UNIT 6.1) and processed by immunoblotting (UNIT 6.2 and Basic Protocol 3).

IN VITRO KINASE ASSAY

BASIC PROTOCOL 2

Integrin binding to fibronectin leads to rapid cell spreading, and FAK, Pyk2, and c-Src tyrosine kinases become activated. The process can be characterized through changes associated with in vitro kinase activity. Assays are designed to detect auto-phosphorylation or the intramolecular phosphorylation of an added substrate such as a synthetic poly (Glu:Tyr) peptide for FAK and Pyk2, or the phosphorylation of a recombinant fragment of the FAK C-terminal domain by c-Src.

Materials

Immunoprecipitated samples (Support Protocol 4, step 6)
FAK-Pyk2 kinase buffer (see recipe), 4°C
Src kinase buffer (see recipe), 4°C
10 µCi/µl [γ^{32}P]ATP (>3,000 Ci/mmol; PerkinElmer)
Magnesium/ATP cocktail (Upstate Biotechnology or see recipe)
2× Laemmli SDS buffer (see recipe)
Coomassie blue stain (see recipe)
Molecular weight marker (Precision Plus, Bio-Rad)
Destaining solution (see recipe)

Microcentrifuge
1.5-ml microcentrifuge tubes
32°C water bath
Plexiglas shielding
Gloves
Geiger counter
Plexiglas box
Micro tube cap locks (RPI 145063; *http://www.rpicorp.com*)
Whatman 3MM filter paper
Gel dryer
Immobilon PVDF membrane (Millipore IPFL 000-10)

Additional reagents and equipment for SDS-PAGE (*UNIT 6.1*), autoradiography (*UNIT 6.3*), and transfer of proteins to membranes for immunoblotting (*UNIT 6.2*)

CAUTION: When working with radioactivity, take appropriate precautions to avoid contamination of the experimenter and the surroundings. Carry out the experiment and dispose of wastes in appropriately designated areas, following guidelines provided by the local radiation safety officer (also see *APPENDIX 1A*).

1. Wash the immunoprecipitated samples (Support Protocol 4, step 6) with 800 µl cold FAK-Pyk2 kinase buffer two times, centrifuging 2 min at 16,000 × *g*, 4°C, each time.
2. Aspirate supernatant, but leave a small amount above pellet (~20 to 30 µl).
3. For FAK-Pyk2 autophosphorylation assays, add 2.5 µl of 10 µCi/µl [γ^{32}P] ATP and 5 µl magnesium/ATP cocktail to the immune complexes. Slightly flick tubes to mix and place in 32°C water bath for 15 min.

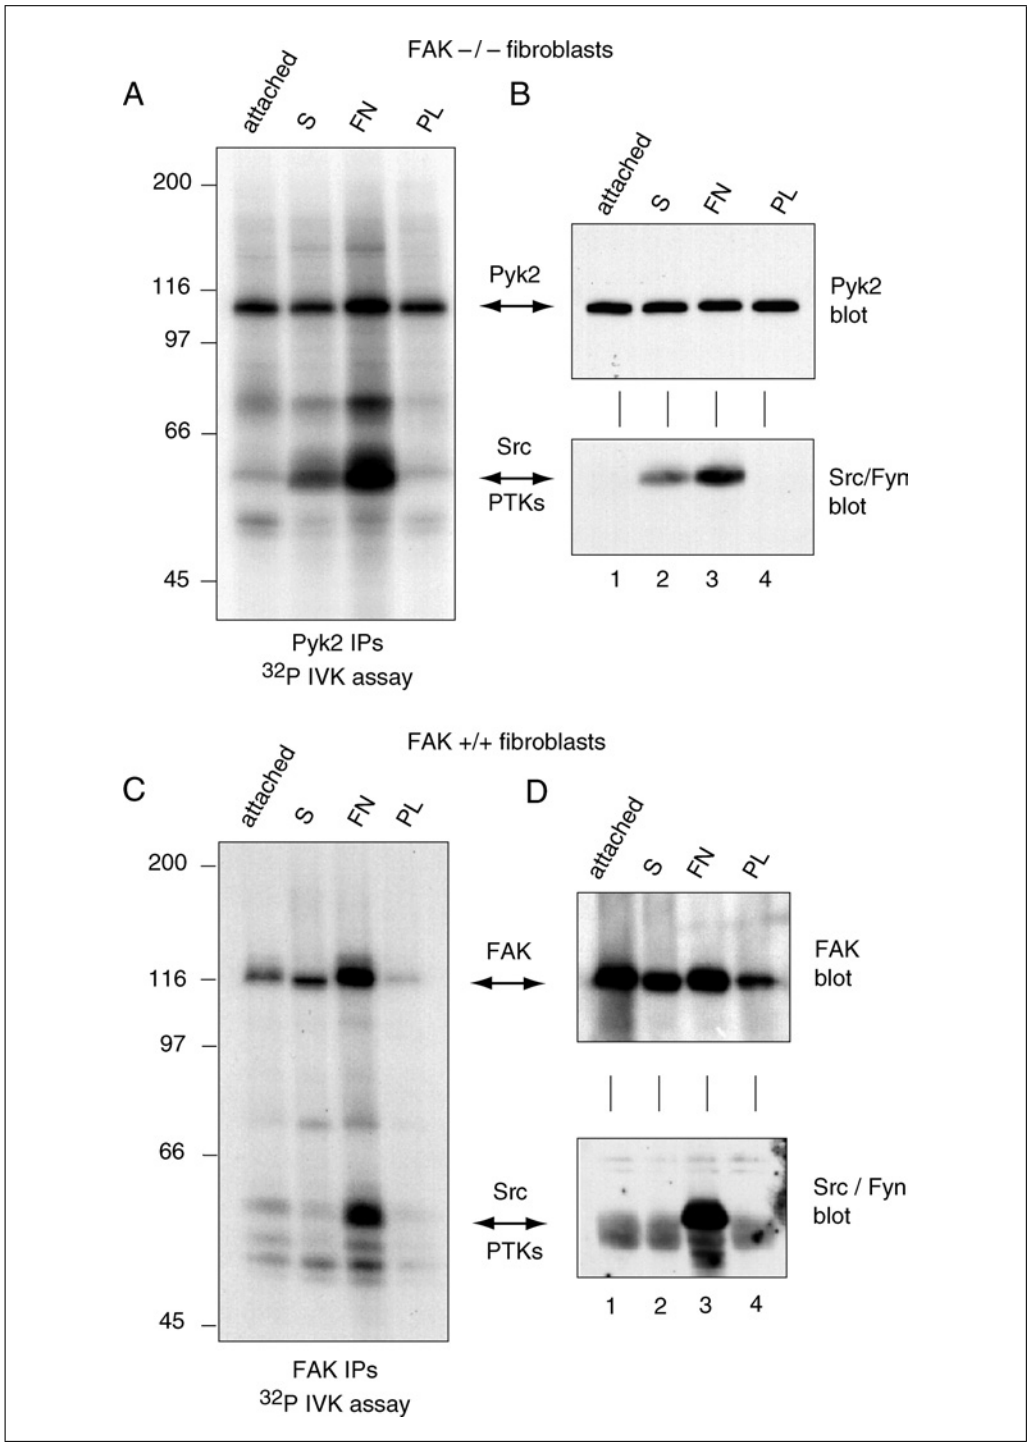

Figure 14.7.1 Measurements of Pyk2 of FAK-associated in vitro kinase activity. Lysates from serum-starved (attached), suspended (S) fibronectin-plated (FN), and poly-L-lysine-plated (PL) FAK$-/-$ cells (A and B) or FAK$+/+$ cells (C and D) were prepared and divided into equal aliquots for either Pyk2 immunoprecipitates (IPs) or FAK IPs, respectively. (**A**) Pyk2 IPs were labeled by the addition of [γ-^{32}P]ATP in an in vitro kinase (IVK) assay. ^{32}P-labeled proteins were transferred to membranes and visualized by autoradiography. (**B**) The same membrane shown in (A) was cut and analyzed by either anti-Pyk2 or anti-Src family PTK blotting. (**C**) FAK IPs were labeled by the addition of [γ-^{32}P]ATP in an IVK assay and the same membrane (**D**) was cut and analyzed by either anti-FAK or anti-Src family protein-tyrosine kinase (PTK) immunoblotting. Molecular weight standards are indicated in kDa to the left. (previously published in the *EMBO Journal*; Sieg et al., 1998)

CAUTION: *Place Plexiglas shielding around gel area to prevent radiation exposure. Remember to check gloves and work areas with a Geiger counter after the kinase assay is done. Use a Plexiglas box for moving radioactive materials within the laboratory and dispose of radioactive waste into designated storage according to institutional requirements.*

4. Add 50 µl 2× Laemmli SDS buffer to stop kinase reactions. Secure 1.5-ml tubes with micro tube cap locks.
5. Boil samples for 3 min at 100°C.
6. Microcentrifuge agarose beads 2 min at 16,000 × *g*, 21°C. Load supernatants and molecular weight marker onto a 7.5% SDS-PAGE gel (see *UNIT 6.1*).

For autoradiography

7a. After gel is run (~4 hr), cut one top corner to mark orientation. Place gel in Coomassie blue stain for 1 hr and then destain gel for 6 to 12 hr in multiple changes of destaining solution on a shaking platform. Wash a final time in water.

8a. Place gel onto Whatman 3MM filter paper and dry using a gel dryer.

9a. Expose gel to film or phosphor-imager screen (*UNIT 6.3*) to quantify ^{32}P incorporated into FAK (~116 kDa), Pyk2 (~110 kDa) or associated c-Src (~60 kDa).

See Fig. 14.7.1 A and C.

For autoradiography and subsequent immunoblotting

7b. Transfer the gel to a PVDF membrane via semidry electrophoretic transfer (see *UNIT 6.2*).

8b. Stain min with Coomassie blue stain. Destain 10 min in destaining solution and wash a final time in water.

9b. Place membrane between protective plastic sheets and expose gel to film or phosphor-imager screen to quantify ^{32}P incorporated into FAK (~116 kDa), Pyk2 (~110 kDa) or associated c-Src (~60 kDa). See *UNIT 6.3* for more information.

In this manner, subsequent immunoblotting (see Basic Protocol 3) can be performed on the kinase reactions to verify the amount of FAK or Pyk2 in the immune complex or the amount of c-Src associated with the activated FAK and/or Pyk2 complex reaction (see Fig. 14.7.1B and D).

FAK-PYK2 POLY GLU:TYR PHOSPHORYLATION

ALTERNATE PROTOCOL 1

This procedure is used to measure the autophosphorylation of FAK/Pyk2 (as in Basic Protocol 2) combined with the transphosphorylation of an added generic substrate peptide.

Additional Materials *(also see Basic Protocol 2)*

Immunoprecipitated samples (see Support Protocol 4, step 6)
10 mg/ml poly(Glu:Tyr; 4:1) mol. wt. 20,000 to 50,000: sodium salt (Sigma-Aldrich) prepared in PBS and stored up to 2 years at −20°C in 1-ml aliquots
Magnesium/ATP cocktail (Upstate Biotechnology or see recipe)
10 µCi/µl [$\gamma^{32}P$]ATP (>3,000 Ci/mmol; PerkinElmer)
FAK-Pyk2 kinase buffer
0.75% phosphoric acid
100% acetone
Scintillation fluid (Sigma)
2 × 2–cm Whatman 3MM filter paper squares

Conical 50-ml centrifuge tube
Scintillation vials
Scintillation counter

Additional reagents and equipment for preparing immunoprecipitated samples (Support Protocol 4)

CAUTION: When working with radioactivity, take appropriate precautions to avoid contamination of the experimenter and the surroundings. Carry out the experiment and dispose of wastes in appropriately designated areas, following guidelines provided by the local radiation safety officer (also see *APPENDIX 1A*).

1. Wash the immunoprecipitated samples (from Support Protocol 4, step 6) with 800 µl cold FAK-Pyk2 kinase buffer two times, centrifuging 2 min at 16,000 × g, 4°C, each time.
2. Remove supernatant, but leave a small amount above pellet (~20 to 30 µl).
3. Add 5 µl 10 mg/ml poly(Glu:Tyr), 5 µl magnesium/ATP cocktail, and 2.5 µl of 10 µCi/µl [γ^{32}P]ATP (25 µCi) to the immunoprecipitated samples. Slightly flick tubes to mix and place in 32°C water bath for 15 min. Include a negative control for the phosphorylation assay, substituting 35 µl kinase buffer for the immunoprecipitated samples.

   CAUTION: *Place Plexiglas shielding around gel area to prevent radiation exposure. Remember to check gloves and work areas with a Geiger counter after the kinase assay is done. Use a Plexiglas box for moving radioactive materials within the laboratory and dispose of radioactive waste into designated storage according to institutional requirements.*

   The negative control will measure the level of background binding of [^{32}P ATP] to the assay squares.

   The total volume of immune complex reaction is ~50 µl yielding a final concentration of 50 µM ATP from the magnesium/ATP cocktail and 1 mg/ml poly Glu:Tyr.

4. Transfer a 10-µl aliquot onto the center of a labeled (with a #2 pencil) 2 × 2–cm Whatman filter paper square.

   There should be enough volume for triplicates for each immune complex reaction.

5. Allow the radiolabeled substrate to bind to filter paper for at least 1 min. Transfer filter papers to a 50-ml conical tube containing 40 ml 0.75% phosphoric acid. Gently invert tube to wash the assay squares for 5 min. Repeat three times and discard liquid as radioactive waste.

   Ten or more assays squares can be washed per 50-ml tube.

6. Wash assay squares once with 40 ml of 100% acetone for 5 min. Discard liquid waste and transfer assay squares to scintillation vial. Add scintillation fluid and evaluate using a scintillation counter.

   For information on creating a standard curve, see http://www. perkinelmer.com.

ALTERNATE PROTOCOL 2

MEASUREMENTS OF Src-ASSOCIATED KINASE ACTIVITY

As c-Src contains both stimulatory (Tyr-416) and inhibitory (Tyr-527) phosphorylation sites that act to regulate catalytic activity, measurements to analyze changes in c-Src-associated kinase activity are performed by c-Src immune complex phosphorylation of an FAK C-terminal domain fragment that contains the known c-Src phosphorylation sites, FAK Tyr-861 and FAK Tyr-925.

Additional Materials *(also see Basic Protocol 2)*

10 mg/ml GST-FAK 853-1052 (Schlaepfer lab)
Enolase (Sigma-Aldrich E-0379), optional
50 mM HCl, optional
1 M PIPES, pH 7, optional
30°C water bath, optional

CAUTION: When working with radioactivity, take appropriate precautions to avoid contamination of the experimenter and the surroundings. Carry out the experiment and dispose of wastes in appropriately designated areas, following guidelines provided by the local radiation safety officer (also see *APPENDIX 1A*).

1. Wash the immunoprecipitated samples (from step 6 in Support Protocol 4) with 800 µl cold FAK-Pyk2 kinase buffer two times, centrifuging 2 min at 16,000 × *g*, 4°C, each time.
2. Remove supernatant, but leave a small amount above pellet (~20 to 30 µl)
3. Add 5 µl of 10 mg/ml GST-FAK 853-1052, 5 µl magnesium/ATP cocktail, and 2.5 µl of 10 µCi/µl [γ^{32}P]ATP (25 µCi) to the immunoprecipitated samples. Slightly flick tubes to mix and place in 32°C water bath for 15 min.

   CAUTION: *Place Plexiglas shielding around gel area to prevent radiation exposure. Remember to check gloves and work areas with a Geiger counter after the kinase assay is done. Use a Plexiglas box for moving radioactive materials within the laboratory and dispose of radioactive waste into designated storage according to institutional requirements.*

   The total volume of immune complex reaction is ~50 µl yielding a final concentration of 50 µM ATP from the magnesium/ATP cocktail and 1 mg/ml GST-FAK 853-1052.

   Alternatively, acid-denatured enolase may be used as a substrate. Enolase must be freshly prepared: Add 10 µl of enolase (1 mg/ml) to 2 µl of 50 mM HCl and incubate 10 min at 30°C. Neutralize with 2 µl 1 M PIPES, pH 7.0, and use 2 µl acid-denatured enolase per kinase reaction.
4. Proceed with Basic Protocol 2, steps 4 through 9 to perform SDS-PAGE and autoradiography or autoradiography and immunoblotting.

IMMUNOBLOTTING WITH FAK/PYK2 PHOSPHO-SPECIFIC ANTIBODIES

BASIC PROTOCOL 3

While in vitro kinase assays will reflect changes in catalytic activity, immunoblotting with FAK/PYK2 phospho-specific antibodies can be used to assess specific phosphorylation site modification(s) within the kinases. For example, FAK and Pyk2 first become phosphorylated at their autophosphorylation sites Y397 and Y402 respectively. Upon phosphorylation and binding of c-Src in an active signaling complex, c-Src can phosphorylate other sites on FAK and Pyk2. Additionally, there are several serine-threonine sites on FAK that can be phosphorylated by other cellular kinases. Finally, phospho-specific antibodies have been developed to indirectly measure the activation state of c-Src.

Materials

2× Laemmli SDS buffer (see recipe)
Immunoprecipitated samples (Support Protocol 4, step 6)
100% and 20% methanol
Transfer buffer (see *UNIT 6.2*)
EZBlue gel staining reagent (Sigma)
BSA blocking buffer (see recipe)
Primary antibody (see Tables 14.7.1 and 14.7.2)

Tris-buffered saline with Tween (TBST, see recipe)

Secondary antibody: Horseradish peroxidase (HRP)-conjugated appropriate species (Pierce)

Enhanced chemiluminescence (ECL) western detection solution (Amersham RPN 2132)

Western blot stripping buffer (see recipe)

Immobilon PVDF membrane (Millipore)

Rotating shaker

Additional reagents and equipment for gel electrophoresis (*UNIT 6.1*) and electrophoretic transfer (*UNIT 6.2*)

Perform gel electrophoresis

1. Add 50 µl of 2× Laemmli SDS buffer to the immunoprecipitated samples from Support Protocol 4, step 6 and boil samples 3 min at 100°C.
2. Centrifuge 2 min at 16,000 × *g*, 21°C. Using the supernatants perform SDS-PAGE (*UNIT 6.1*), including molecular size markers.

Transfer proteins to PVDF membrane

3. Transfer proteins to a PVDF membrane using an electrophoretic transfer unit (*UNIT 6.2*).

   PVDF membrane should be prepared by soaking in 100% methanol followed by the appropriate transfer buffer before use.

4. After transfer is complete, stain protein bands with EZBlue gel staining reagent. Rinse membrane in water and destain in 20% methanol until background staining disappears.
5. Photocopy membrane for record keeping purposes and to note positions of protein size markers.

Probe membrane

6. Place membrane in BSA blocking buffer for 1 hr at room temperature.
7. Remove blocking buffer and incubate membranes with primary antibodies 3 hr at room temperature or overnight at 4°C.

   A 1:1000 dilution (~0.5 µg/ml in BSA blocking buffer) is a good starting point for using an antibody for the first time.

8. Wash membranes by rotational shaking with TBST for 10 min. Repeat three times using fresh TBST.
9. Dilute secondary antibody 1:5000 to 1:10,000 in TBST (e.g., 5 µl in 15 ml) and incubate membranes with the antibody 1 hr at room temperature.

   HRP-conjugated secondary antibodies commonly used are: goat anti-mouse IgG, Protein A, donkey anti-rabbit IgG, and mouse anti-goat IgG.

10. Wash membranes by rotational shaking with TBST for 10 min. Repeat three times using fresh TBST.
11. Incubate in 5 ml ECL solution for 5 min at 21°C. Expose to film 30 sec to 10 min to achieve optimal exposure.

    Although many phospho-specific antibodies can be used to probe FAK, Pyk2, or c-Src activation states in whole cell lysates, multiple immunoreactive bands detected can complicate the interpretation of results. This is not a problem when analyzing FAK, Pyk2, or c-Src by immunoprecipitation.

Table 14.7.1 Commercially Available Antibodies to FAK, Pyk2, and c-Src[a]

Antibody	Company	Source	Application	Catalog number
FAK, clone 4.47	Upstate	mouse (mAb)	WB, IP, IC, IH	05-537
FAK clone 2A7	Upstate	mouse (mAb)	IP, IC	05-182
FAK	Upstate	rabbit	WB, IP, IH	06-543
FAK, BC3	Upstate	rabbit	IP, IC	06-446
FAK	BioSource	rabbit	IP, WB	AHO0502
FAK	BD PharMingen	rabbit	WB, IP	556368
FAK	BD Transduction	mouse (mAb)	WB, IP, IC, IH	610087
FAK	Cell Signaling	rabbit	WB, IH	3285
FAK	BioSource	rabbit	WB, IP, IC	AH0502
FAK	BioSource	rabbit	WB, IP, IC	AMO0672
FAK	Chemicon	rabbit	IP	AB1605
FAK	Chemicon	mouse (mAb)	WB, IP, IC	MAB2156

[a]Abbreviations: mAb, monoclonal antibody; WB, western (immuno)blot; IP Immunoprecipitation; IC, immunocytochemistry; IH, immunohistochemistry.

Reprobe membranes

12. For sequential probing of membranes with different antibodies, strip bound antibodies from membranes by incubating 15 min in western blot stripping buffer at 65°C. Wash membrane thoroughly with water.

13. Repeat immunoblotting procedure from step 4 to step 9.

Blots can be stripped two to three times to analyze FAK and Pyk2 immune complexes with various phospho-specific antibodies. It is recommended that a different species of primary antibody be used (rabbit, mouse, or goat) in the subsequent blotting analyses to ensure that signals detected are not from the first set of antibodies used to probe the membrane.

HAPTOTAXIS MOTILITY ASSAY: MATRIX-STIMULATED MIGRATION

BASIC PROTOCOL 4

FAK is rapidly activated via tyrosine phosphorylation and binds directly to c-Src, resulting in the formation of a FAK-Src signaling complex that leads to the activation of various downstream signaling cascades. In the preceding protocols, emphasis was placed on biochemical evaluations of FAK, Pyk2, or Src activation or phosphorylation after cell binding to extracellular matrix proteins. In addition to biochemical signaling changes

inside cells, cell binding to matrix proteins such as fibronectin can result in enhanced cell spreading and the initiation of cell migration. Notably, FAK−/− cells spread poorly and exhibit refractory motility responses in response to a fibronectin stimulus. Although it has been shown that FAK reexpression within FAK−/− cells can reverse the motility defects, the molecular pathways through which FAK promotes cell motility and the inability of Pyk2 in FAK−/− cells to function as a replacement for FAK remain active areas of research. There are various assays whereby cell motility can be measured. To specifically evaluate the contribution of integrin signaling, haptotaxis (a directed response of cells in a gradient of adhesion) motility assays are performed in the absence of serum where FAK signaling plays important roles in promoting efficient cell movement towards the extracellular matrix.

Materials

FAK−/− and FAK+/+ cells, subconfluent (see Support Protocol 1)
Human plasma fibronectin (Sigma-Aldrich F2006): 2 to 10 μg/ml in replating and migration medium (see recipe), 37°C
BSA-coating control: 10 μg BSA/ml in replating and migration medium (see recipe)
Trypsin/EDTA: 0.25% (w/v) trypsin/1 mM EDTA (Invitrogen)
Trypsin inhibitor solution (see recipe)
PBS^{++}: phosphate-buffered saline (PBS; *APPENDIX 2A*) with 0.1 g/liter $CaCl_2$ and 0.5 mM $MgCl_2$
Cell fixative: PBS with 1.85% (v/v) formaldehyde and 0.05% (v/v) glutaraldehyde
10% (w/v) crystal violet stain (Sigma) in ethanol
0.1 M sodium borate, pH 9.0
Parafilm
Millicell PCF chamber inserts, 8-μm pore (Millipore PITP01250)
Flat-tipped forceps
15-ml centrifuge tube
Tabletop centrifuge
Hemacytometer
24 well-tissue culture dishes (Costar)
Cotton swabs
Inverted light microscope
Spectrophotometer with A_{600} capability, optional
Additional reagents and equipment for serum-starving cells (Support Protocol 2) and counting cells (*UNIT 1.1*)

Starve cells

1. Twenty-four hr before the motility assay, serum starve subconfluent FAK−/− and FAK+/+ cells (see Support Protocol 2).

   Cells should be subconfluent during starvation. High-density or contact-inhibited cells do not respond well to motility stimuli during the short time period of the assay.

Prepare assay chamber

2. Pipet 100 μl of human plasma fibronectin onto Parafilm. Carefully place Millicell PCF chamber inserts one at a time on top the fibronectin-containing droplets. Prepare three chambers per experimental point and include a BSA-coating control.

   The use of flat tipped forceps is best for the handling of individual chambers.

   Be sure to cover the entire membrane and to avoid bubbles as this will result in poor ligand coverage. This method is designed to coat just the under surface of the Millicell chamber with fibronectin.

3. Incubate chambers 2 hr at room temperature. Cover the Parafilm and chambers on the bench top with a plastic container to avoid evaporation.

4. Rinse each chamber gently in PBS and let dry for at least 10 min at room temperature.

Prepare cells

5. Wash serum-starved cells with 10 ml PBS and aspirate off. Add 2.5 ml trypsin/EDTA per dish. Tap side of plates to facilitate cell release.

6. Add 5 ml trypsin inhibitor solution warmed to 37°C. Transfer cells to 15-ml centrifuge tube. Centrifuge 3 min at 750 × *g*, 21°C, in a tabletop centrifuge and aspirate supernatant.

7. Resuspend cells to ~2×10^5 cells/ml in 37°C replating and migration medium. Keep in suspension at least 30 min and rotate tube at least every 5 min to keep cells from clumping, settling, and sticking to the plastic.

8. During incubation period, count cells using a hemacytometer (*UNIT 1.1*) and dilute a suspension of cells to a density of 33×10^4 cells/ml in replating and migration medium

Perform migration assay

9. Add 400 µl replating and migration medium to each experimental well of a 24-well tissue culture dish. Carefully place chambers into wells making sure there are no bubbles.

10. Add 300 µl cell suspension to each chamber (total of 1×10^5 cells).

11. Incubate 3 to 4 hr at 37°C with 10% CO_2.

    Fibroblasts will show maximal migration within this period.

    Variations of this assay can be used to examine different types of motility. For example, chambers can be coated on the top and bottom to study random motility. Additionally, growth factors can be added to the lower chamber to investigate cell chemotaxis responses.

Fix, stain, and count cells

12. Fill two 24-well tissue culture plates with 0.5 ml PBS^{++} and one with 0.5 ml cell fixative. Transfer chambers to PBS^{++} and incubate 2 min to wash. Move chambers to fixative for 5 min then into fresh PBS^{++} for 2 min.

13. Dilute 10% crystal violet stain stock 1:100 in 0.1 M sodium borate, pH 9.0. Place chambers into 0.5 ml of 0.1% crystal violet for 30 min.

14. Remove chambers from stain and wash repeatedly in a large volume of water (e.g., in a 500 ml beaker).

15. Use a cotton swab to wipe excess cells and stain from the top side of the chamber membrane while taking care not to touch the bottom side of the chamber membrane. Let chambers dry overnight.

    Chambers are now ready for analysis. Cells that migrate to the bottom of the chamber towards the ligand will be stained purple with crystal violet while nonmigrating cells on the upper surface have been removed.

16. Count cells using a standard 10× objective on an inverted microscope. Use the lid of the 24-well plate to support the chamber. Count fields at 2, 4, 6, 8, 10, and 12 o'clock positions and in the center of the membrane.

    If there are too many cells per field to be accurately counted, the crystal violet stain can be eluted from the membrane in 10% acetic acid and values can be obtained by measuring light absorption in a spectrophotometer at 600 nm (A_{600}).

Motility values are determined by the average number of cells per field when counting three chambers per experimental point. The BSA-coated chambers should contain less than 1% of the total as migratory cells.

ALTERNATE PROTOCOL 3

ANALYZING CELL MOTILITY USING PLASMID-TRANSFECTED CELLS

The haptotaxis protocol is a good way to evaluate integrin-stimulated signaling events affecting cell migration. In many instances, there is a need to test the role of particular signaling proteins in altering cell motility responses. This is best accomplished through the transient transfection of cells with plasmid expression vectors combined with the cotransfection of a marker such as β-galactosidase (*lac Z*) to identify the plasmid-transfected cells, the assumption being that the cells that have been transfected with the *lac Z* plasmid and show β-galactosidase activity have also taken up the cotransfected FAK plasmid. This protocol is used to show that FAK re-expression can rescue the motility defects of FAK−/− cells.

Additional Materials *(also see Basic Protocol 4)*

pcDNA3.1 FAK (contact Schlaepfer lab)
FAK−/− cells (see Support Protocol 1)
pcDNA3.1 LacZ (Invitrogen)
Phosphate-buffered saline (PBS; *APPENDIX 2A*)
PBS^{++}: phosphate-buffered saline (*APPENDIX 2A*) with 0.1 g/liter $CaCl_2$ and 0.5 mM $MgCl_2$
Opti-MEM I reduced-serum medium (Invitrogen)
PLUS reagent (Invitrogen)
Lipofectamine (Invitrogen)
Cell growth medium (see recipe) containing 20% (v/v) FBS (instead of 10%)
Starvation medium: Cell growth medium (see recipe) with FBS reduced to 0.5%
Lac Z staining solution (see recipe)
Additional reagents and equipment for bacterial transformation (Seidman et al., 1997), plasmid miniprep (Engebrecht et al., 1991), and DNA quantification (*APPENDIX 3D*)

Prepare plasmids

1. Prepare high purity supercoiled plasmid DNA from bacteria (see Seidman et al., 1997; Engebrecht et al., 1991; and *APPENDIX 3D*). Combine 5 μg of pCDNA3.1 FAK with 3 μg pcDNA3.1 LacZ for each 10-cm plate.

   Make sure the DNA is sterile by using alcohol precipitation.

   Maximum amount of DNA per 10-cm plate transfection is 8.0 μg.

Prepare cells

2. Plate 7.5×10^5 FAK−/− cells onto gelatin-coated 10-cm plates (see Support Protocol 1) and let grow overnight at 37°C.
3. Aspirate medium and wash once with PBS to remove serum.
4. Add 4 ml of Opti-MEM I reduced-serum medium and place cells in the 37°C incubator for 30 to 45 min.

Prepare transfection mix

5. Aliquot 0.5 ml Opti-MEM I reduced-serum medium into two 1.5-ml microcentrifuge tubes (label tubes A and B).
6. Add 8 μg plasmid DNA (FAK plus LacZ) to tube A and resuspend by tapping with your fingers.

7. Add 48 µl PLUS reagent to the DNA in tube A and mix by tapping.
8. Add 32 µl Lipofectamine reagent to tube B. Mix by tapping and incubate for 15 min.
9. Add contents of tube B to tube A and mix by tapping. Incubate for 30 min at 21°C.

   IMPORTANT NOTE: *Do not mix by pipetting at this step.*

Transfect cells

10. Add the DNA/lipid complexes from step 9 to the cells from step 4 and allow cell transfection to proceed for 5 hr at 37°C in the 10% CO_2 incubator.
11. Add 5 ml cell growth medium containing 20% FBS to stop transfection. Continue incubation to 24 hr without changing the medium.

Prepare cells for motility assays

12. To set up cells for motility assays, wash with 10 ml PBS and place in 10 ml serum starvation medium and incubate overnight at 37°C in 10% CO_2.
13. Use cells for motility experiments 48 hr after transfection to ensure good protein expression from plasmids.
14. Proceed with the motility assay (Basic Protocol 4, steps 2 to 11).
15. Save excess cells not used in the motility assay to make protein lysates (Support Protocol 3) and to analyze by SDS-PAGE (*UNIT 6.1*) followed by immunoblotting (Basic Protocol 3 and *UNIT 6.2*).

    This is required in order to verify transient protein overexpression (i.e., FAK and Lac Z) in the population of cells used for the motility assay.

Fix and count cells

16. After haptotaxis assays have proceeded for 3 to 4 hr, fill two 24-well tissue culture plates with 0.5 ml PBS^{++} and one with 0.5 ml cell fixative. Transfer chambers to PBS^{++} and incubate for 2 min (wash). Move chambers to fixative for 5 min then into fresh PBS^{++} for 2 min. Repeat final PBS wash.

    It is important to not leave cells in fixative for too long as this will result in less β-galactosidase activity.

17. Use a cotton swab to wipe excess cells from the top side of the chamber membrane while taking care not to touch the bottom side of the chamber membrane. Do not let chambers get too dry.
18. Add 0.5 ml Lac Z staining solution to wells of a 24-well tissue culture plate and incubate chambers 2 to 12 hr at 37°C or until blue-green color is observed.
19. Rinse chambers by gently immersing them in PBS and enumerate the blue β-gal positive cells under light microscopy.
20. To store plates fix chambers 10 min with 1 ml 10% formalin in PBS at room temperature, rinse with PBS, and store in PBS up to 1 week at 4°C.

    It is assumed that the cells that have been transfected with the Lac Z plasmid and show β-galactosidase activity have also taken up the cotransfected FAK plasmid. If the protein of interest is tagged with a fluorescent marker such as green fluorescent protein, then the direct identification of transfected cells is facilitated, making it possible to observe the behavior of such cells in time-lapse imaging studies (see Basic Protocol 5).

BASIC PROTOCOL 5

SCRATCH-WOUND HEALING ASSAY WITH TIME-LAPSE IMAGING

Wound healing assays (*UNIT 12.4*) are ideal for visualizing cellular dynamics during stimulated migration. In particular, time-lapse imaging allows for analysis of lamellipodia extension and membrane ruffling into the wounded area. Wound healing assays do not, however, address directional motility because the cells are plated at high density and movement is limited into the wound. Random migration assays can be preformed to address directional motility by plating cells at low density and following the imaging protocol outlined below.

Materials

Extracellular matrix molecule (ECM) of interest (e.g., 2 μg fibronectin/ml PBS)
70% confluent 24-hr serum-starved cells (see Support Protocol 2)
DMEM with and without 0.5 μg/ml mitomycin-C
Phosphate-buffered saline (PBS; *APPENDIX 2A*)
Serum, optional
Mitomycin-C (Sigma)
Medium 199 (Invitrogen) with 0.5 μg/ml mitomycin-C
Mineral oil (Sigma)
25-mm glass coverslips (1 oz., Fisher) and 6-well tissue culture plates *or* 35-mm Bioptechs delta-T dishes (Fisher)
Forceps
1- to 10-μl micropipet tips
Transfer pipets, sterile
Inverted microscope with 20× objective, 37°C heated stage, and acquisition/analysis software (e.g., Improvision Openlab; *https://www.improvision.com*)
Etched-grid coverslips (Bellco), optional

Coat coverslips

1. Place 25-mm round glass coverslips into wells of a 6-well tissue culture plate. Precoat glass coverslip or delta-T dishes with matrix molecule of interest (e.g., 2 μg fibronectin/ml PBS) for 2 hr at 37°C.

   Other ECM molecules may be prepared in the same concentrations in PBS as fibronectin.

   Too high a ligand concentration will inhibit cell motility. If migration is slow or nonexistent, try decreasing the ligand concentration.

Add cells

2. Prepare a cell suspension of 1×10^6 70% confluent 24 hr serum-starved cells/ml in DMEM (see Basic Protocol 1, steps 4 to 5).

   Serum starve cells for 24 hr before initiating wound healing assay.

   Cells should be ~70% confluent during starvation.

3. Wash coverslips or delta-T dishes with PBS and plate 2×10^6 cells onto coverslips in a 6-well tissue culture plate or directly onto the delta-T dish.

   Coverslips in 6-well tissue culture plates are used if subsequent procedures include an imaging chamber. Bioptechs delta-T dishes are self-contained.

4. Incubate at 37°C with 10% CO_2 for 2 hr.

   The incubation time can be adjusted to accommodate other cells types if needed. This step is to facilitate equal cell adhesion and spreading on the matrix-coated glass surface.

Wound the cultures

5. Remove plates with coverslips from incubator. Using forceps to stabilize the coverslip in the well, carefully scratch the confluent monolayer of cells down the center using a micropipet tip.

   If using a delta-T dish, use a similar technique to scratch the center of the glass insert while holding the dish steady.

   This step is critical and will require practice in order to achieve consistent wounds. In order to reliably compare results from experiment to experiment, the wound distance must be equivalent each time.

6. Rinse the coverslip/delta-T dish three times with 2 ml PBS to remove loose cells.

   If the cell monolayer is not washed effectively after scratching, loose cells can settle into the wounded area and result in an inaccurate interpretation of wound healing ability.

7. Place coverslip in fresh DMEM medium with 0.5 μg/ml mitomycin-C and incubate at 37°C with 10% CO_2 for 1 hr.

   Add 0.5 μg/ml mitomycin-C to all medium changes from this point. This will inhibit cell mitogenesis and, therefore, control for wound closure due to cell proliferation.

   Serum can be added (1% to 5% v/v, depending on cell type and required stimulation) at this point to stimulate cell motility if needed.

Assess motility

8. Aspirate medium and move coverslip into imaging chamber (if using the delta-T dishes, the imaging chamber is the unit itself). Add 1 ml of medium 199 with 0.5 μg/ml mitomycin-C (with serum addition as needed).

9. Carefully layer 0.5 ml mineral oil on top of the medium to prevent evaporation during imaging and place imaging chamber/delta-T dish in heated stage on the microscope and set to 37°C.

10. Using a 10× or 20× objective, center the wound such that the image captured will show both sides of the cell monolayer flanking the wounded region. Using Improvision Openlab or comparable acquisition software, begin the time-lapse sequence and collect one image every 2 to 5 min for 12 to 15 hr or until the wound is closed.

    Alternatively, if time-lapse software is not available, etched-grid coverslips can be used (Bellco). These coverslips have a grid system that allows tracking and measuring wound closure over time with a light microscope while leaving the coverslips in the incubator in between phase-image collection.

IMMUNOLOCALIZATION OF FOCAL ADHESION PROTEINS

BASIC PROTOCOL 6

Immunostaining is the best approach to determining whether a protein of interest is localized to integrin-enriched focal adhesions. For valid interpretation of the staining results, two controls are essential: (1) immunoblot evaluation of the antibody against the protein before immunostaining and (2) cells costained with markers for focal adhesion proteins. The antibody to be used is suitable for cell staining analyses if it yields one band by immunoblotting analyses of whole cell lysates. The presence of multiple bands, even though the main one is the strongest, easily leads to misinterpretation of results. The most commonly used focal adhesion markers are vinculin and paxillin. Some of the best markers for activated focal adhesions are antibodies that recognize tyrosine-397-phosphorylated FAK or active Src-family members.

Materials

Matrix-coating substrates: prepared according to manufacturer's directions and diluted (commonly to 10 μg/ml) in PBS (*APPENDIX 2A*)
  Fibronectin, human plasma (Roche)
  Laminin, human placenta (Sigma)
  Vitronectin, human plama (Sigma)
  Poly-L-lysine (70,000–150,000 or 150,000–300,000; Sigma)
  Collagen, Type I, human placenta (Calbiochem)
  Collagen, Type II, bovine (Calbiochem)
  Collagen, Type IV, human placenta (Calbiochem)
  Collagen, Type V, human (Calbiochem)
FAK−/− and FAK+/+ cells (see Support Protocol 1)
Replating and migration medium (see recipe), warm *or* growth medium (see recipe), 37°C
Phosphate-buffered saline (PBS; *APPENDIX 2A*)
3.8% (w/v) paraformaldehyde fixative (see recipe)
Acetone, cold (stored at −20°C) *or*
0.5% (v/v) Triton X-100/0.05% (v/v) Tween 20/PBS *or*
0.2% Triton X-100/PBS *or*
0.2% (v/v) Triton X-100/3.8% (w/v) paraformaldehyde/PBS *or*
0.1% (v/v) Triton X-100/0.1% (w/v) sodium citrate *or*
Methanol, cold
Blocking antibody (e.g., ChromPure donkey IgG, unconjugated; Jackson Immunoresearch) *or*
2% (w/v) BSA in PBS
1 to 10 μg/ml PBS (*APPENDIX 2A*) primary antibodies for focal adhesion markers
  anti-paxillin (ZO35; Zymed/Invitrogen)
  anti-vinculin (VIN-11-5; Sigma)
  anti-FAK (clone #77; BD-Transduction)
  anti-FAK (Ab-1; LabVision)
  anti-phospho Y397FAK (BioSource)
  anti-active Src family members (clone #28; BioSource)
Secondary antibodies: e.g., fluorescein (FITC)-conjugated donkey antibodies (excitation/emission maxima 492/520 nm; Jackson Immunoresearch) *or* FITC-conjugate
  anti-mouse IgG
  anti-mouse IgM
  anti-rabbit IgG
  anti-goat IgG
  anti-rat IgG
Rhodamine X (RRX)-conjugated donkey antibodies (excitation/emission maxima 570/590 nm; Jackson Immunoresearch) *or* Rhodamine X (RRX)-conjugated
  anti-mouse IgG
  anti-mouse IgM
  anti-rabbit IgG
  anti-goat IgG
  anti-rat IgG
Hoechst 33342 (excitation/emission maxima 350/460; Molecular Probes)
Vectashield mounting medium (Vector)
Nail polish, clear

12-mm round coverslips, German glass (Bellco Glass)
4-well tissue culture plates (Nunc)
12-well tissue culture plates (Costar)
18- to 22-G needle with a slightly bent tip
Flat-ended forceps with beveled, unserrated tips, stainless steel (Millipore)

6-well tissue culture plates
Rotating platform shaker
Vacuum source
Porcelain spot plates with 12 cavities (CoorsTek)
Light microscope with fluorescence excitation and detecting capability

1. Coat 12-mm round coverslips with matrix-coating substrate (e.g., by incubating with 10 μg/ml fibronectin 45 min at room temperature).

   The most commonly used adhesion molecule to induce formation of focal contacts is fibronectin, but the same volumes and concentrations are recommended for laminin, vitronectin, poly-L-lysine, and collagen. The coating time should be extended to 2 hr for collagen, and the coverslips should be washed with PBS to neutralize the acidity of the collagen solutions.

Plate cells

2. Prepare FAK−/− and FAK+/+ cell suspension of 2×10^4 cells/ml in 37°C replating and migration medium or growth medium (see Basic Protocol 1, steps 5 to 6), and add 0.5 ml cell suspension per well of a 4-well tissue culture plate containing a coated coverslip.

   Blocking with BSA is not required because cells will not attach to the uncoated glass surface.

   At this concentration the adherent cells will be spread apart.

   If the purpose is to determine activation or localization of the protein by adhesion molecule of interest, replating and migration medium should be used, otherwise growth medium is appropriate.

   The well size of 4-well tissue culture plates is the same as in 24-well plates. However, the wells are not so deep, and it is easier to take coverslips out.

3. Incubate at 37°C for desired time.

   Activation (phosphorylation) of the focal adhesion proteins is the highest during cell spreading. For fibroblasts, the best time to capture localization of the activated proteins in focal adhesions is ∼1 hr after plating. At that time most of cells will be spread. Some cells will still be spreading and often both types can be visualized within a single field.

   Activated focal adhesion proteins at the leading edge of migrating cell are best visualized 5 to 6 hr after wounding a cell monolayer with a micropipet tip. Activation is higher in the presence of serum. The most commonly used serum concentration is 10%, but one could also see activation at much lower serum concentrations.

Fix and permeabilize cells

4. Aspirate medium and rinse briefly 2 to 3 times in ∼1 ml PBS by adding ∼1 ml PBS and aspirating or decanting it.

For most cells

5a. Add ∼1 ml 3.8% paraformaldehyde/PBS, pH 7.4 to fix cells. Incubate 20 min at room temperature and rinse with PBS as above.

6a. Transfer coverslips into a porcelain spot plate filled with cold acetone (stored at −20°C) to permeabilize the cells. Keep on ice for 10 min. Remove acetone and add ∼1 ml PBS to rehydrate for 3 to 5 min.

   Transfer of coverslips to a porcelain plate is necessary only when using acetone, which will dissolve plastic tissue culture dishes.

Fixation and permeabilization are the most critical steps for successful immunostaining. Even for the same protein, this step can differ from cell type to cell type and from antibody to antibody. Most focal adhesion proteins are detectable when cells are fixed in paraformaldehyde and permeabilized in acetone. If the staining is weak or negative, changing fixation and permeabilization should be the first step to troubleshoot.

For weakly staining cells (alternative 1)

5b. Add ~1 ml 3.8% (w/v) paraformaldehyde/PBS, pH 7.4 to fix cells. Incubate 20 min at room temperature.

6b. Remove paraformaldehyde and add ~1 ml 0.5% (v/v) Triton X-100 + 0.05% (v/v) Tween 20/PBS for 2 min to permeabilize the cells.

For weakly staining cells (alternative 2)

5c. Add ~1 ml 3.8% (w/v) paraformaldehyde/PBS, pH 7.4 to fix cells. Incubate 20 min at room temperature.

6c. Remove paraformaldehyde and add ~1 ml to 0.2% (v/v) Triton X-100/PBS for 2 min to permeabilize the cells.

For weakly staining cells (alternative 3)

5d. Add ~1 ml 0.2% (v/v) Triton X-100/3.8% (w/v) paraformaldehyde/PBS and incubate 2 min at room temperature to fix and permeabilize cells. Rinse several times with 3.8% paraformaldehyde/PBS as in step 4.

6d. Add ~1 ml 3.8% paraformaldehyde/PBS and continue fixing for 20 min at room temperature.

For weakly staining cells (alternative 4)

5e. Add ~1 ml 3.8% (w/v) paraformaldehyde/PBS, pH 7.4 to fix cells. Incubate 20 min at room temperature.

6e. Add ~1 ml 0.1% (v/v) Triton X-100/0.1% (w/v) sodium citrate and keep 2 to 5 min on ice to permeabilize the cells.

For weakly staining cells (alternative 5)

5f. Transfer coverslips into a porcelain spot plate filled with cold acetone (stored at −20°C) to fix and permeabilize cells. Keep on ice for 10 min.

In some cases in the more common protocol described in step 5a, paraformaldehyde fixation can interfere with staining. In these cases coverslips are directly exposed to acetone, which can also act as a fixative.

6f. Remove acetone and add ~1 ml PBS to rehydrate for 3 to 5 min.

Staining of actin stress fibers is impossible when fixation/permeabilization is done with ONLY acetone or methanol (alternatives 5 and 6).

For weakly staining cells (alternative 6)

5g. Add ice-cold methanol (stored at −20°C) to fix and permeabilize cells. Keep on ice for 10 min.

6g. Aspirate methanol, rinse briefly in ~1 ml PBS and leave in PBS for 3 to 5 min to rehydrate.

Staining of actin stress fibers is impossible when fixation/permeabilization is done with ONLY acetone or methanol (alternatives 5 and 6).

Block and immunostain cells

7. Pace a 30-µl drop of PBS containing blocking antibodies and primary antibodies for focal adhesion markers on the inner side of 12-well plate lid (facing up), and place the coverslip with fixed and permeabilized cells on top, with the attached cells facing the drop of antibody solution. Cover with the bottom of the plate and incubate 1 hr at room temperature or as long as overnight at 4°C, depending on convenience and the effectiveness of staining with various samples and procedures.

   Using a 30-µl drop of PBS containing blocking antibodies and primary antibodies for focal adhesion markers on the inner side of a 12-well plate lid helps prevent evaporation, ensure equal exposure, and use less antibody solution.

   Flip coverslip over the 30-µl drop of PBS containing blocking and primary antibodies using an 18- to 22-G needle with a slightly bent tip to lift and flat-ended forceps to hold and transfer the coverslip. Sharp-ended forceps tend to crack the coverslip. Alternatively, if the cell type is sensitive to flipping the coverslips for incubations and cells detach, utilize a humidified chamber (to avoid evaporation) and add 50 µl of antibody directly on top of the coverslips.

   Blocking is done with whole IgG of the host animal for the secondary antibody. For example, the primary antibody is made in mouse. If the secondary antibody is fluorescein-conjugated donkey anti-mouse, donkey whole IgG should be used for blocking. If the secondary antibody is fluorescein-conjugated goat anti-mouse, goat whole IgG should be used for blocking, etc. Blocking antibodies are sold in concentrations ~10 mg/ml. Recommended dilution for blocking purposes is 1:100 (~100 µg/ml). To keep costs low, the authors use secondary antibodies that are all made in donkey, requiring only one reagent (ChromPure donkey whole IgG) for blocking purposes.

   Alternatively, blocking can be performed with 2% (w/v) BSA in PBS. In this case, blocking is done at the same time as sample incubation with the primary antibody, saving time. BSA blocking is less specific than IgG, and in rare cases BSA might be too strong a blocking agent.

   Dilution of primary antibodies can vary and should be optimized for each antibody. Generally a range of 1 to 10 µg/ml is effective. A starting point for optimization would be a 1:100 dilution of a commercial antibody, which is usually sold in concentrations 0.1 to 1 mg/ml.

   For co-immunostaining, incubate samples with both primary antibodies and with blocking antibodies at the same time. If incubations are for several hours, samples can be left at room temperature. If incubation is performed overnight, the incubation should be at 4°C.

8. Lift the coverslip by injecting 150 µl PBS under it, and place it in a well of a 6-well tissue culture plate, attached cells facing up. Wash in three changes of ~3 ml PBS 5 min each time at ~50 rpm on rotating platform shaker.

   Smaller size wells (e.g., wells of 12- or 24-well plates) do not allow sufficient movement of PBS to wash unbound antibodies from the samples.

9. Pace a 30-µl drop of PBS containing secondary antibodies and 10 µg/ml Hoechst 33342 on the inner side of a 12-well plate lid (facing up), and place the coverslip with fixed and permeabilized cells on top with the attached cells facing the drop of antibody solution. Cover with plate bottom and incubate 40 min at room temperature.

   Hoechst 33342 binds DNA, and it is an excellent bright nuclear marker visible at UV excitation wavelengths. It does not leak to green or red channels. It is of immense help for orientation and focusing of samples during microscopy.

   For visualization of actin stress fibers, fluorescent phalloidin conjugate is added together with secondary antibody for costaining of two antigens: one is detected by the primary antibody, and the other (actin stress fibers) is detected directly by fluorophore-conjugated phalloidin.

10. Wash in three changes of ~3 ml PBS three times 5 min each time at ~50 rpm on a rotating platform shaker.

11. Mount on microscope slides in Vectashield mounting medium. Aspirate excess mounting medium under the coverslip using a Pasteur pipet attached to vacuum. To prevent sliding, fix the edge of the coverslip with clear nail polish. Wait 15 to 20 min for the nail polish to dry, then analyze samples under the microscope.

    Samples can be preserved at 4°C in the dark for varying lengths of time, depending on the strength of the staining. For example, actin staining can be preserved for a month or longer. Weak staining will fade beyond recognition within several days. The authors recommend analysis within 2 to 3 days after staining.

ALTERNATE PROTOCOL 4

IMMUNOLOCALIZATION OF ACTIN STRESS FIBERS

Visualization of actin stress fibers with fluorescent phalloidin, a toxin with high binding affinity for actin filaments, is easy and almost certainly yields dazzling results. Unlike indirect immunostaining with antibodies, phalloidin staining is strong, and the contrast between stained and unstained areas is high. Because focal adhesions are located at the end of actin stress fibers, phalloidin staining is also used as a localization marker and as a quick assay to assess cell shape. Costaining actin stress fibers with fluorescent phalloidin–conjugate and DNA-binding Hoechst dye can be a rewarding experience for a new investigator who is performing immunofluorescence cell staining for the first time.

Additional Materials *(also see Basic Protocol 6)*

0.4 to 1 U/ml (10 to 30 nM) fluorescein-conjugated phalloidin (Molecular Probes) or rhodamine-conjugated phalloidin (Molecular Probes) in PBS

Rotating platform shaker
Vacuum source

Prepare cells

1. Coat coverslips, prepare FAK−/− and FAK+/+ cell suspension, and plate the cells (Basic Protocol 6, steps 1 to 3).

2. Incubate at 37°C for desired time.

Fix and permeabilize cells

3. Aspirate medium and rinse briefly 2 to 3 times in ~1 ml PBS by adding ~1 ml PBS and aspirating or decanting it.

4. Add ~1 ml 3.8% paraformaldehyde/PBS, pH 7.4, to fix cells. Incubate 20 min at room temperature and rinse with PBS as above.

5. Transfer coverslips into a porcelain spot plate filled with cold acetone (stored at −20°C) to permeabilize the cells. Keep on ice for 10 min. Remove acetone and add ~1 ml PBS to rehydrate for 3 to 5 min.

6. Place a 30-µl drop containing 0.4 to 1 U/ml (10 to 30 nM) fluorescein-conjugated phalloidin with 10 µg/ml Hoechst 33342 in PBS on the inner side of a 12-well tissue culture plate lid (facing up), and place the coverslip with fixed and permeabilized cells on top with the attached cells facing the drop of solution. Cover with the plate bottom and incubate 30 min at room temperature.

    If dissolved as recommended by the manufacturer (Molecular Probes), 0.4 to 1 U/ml (10 to 30 nM) phalloidin is 1:200 to 1:500.

Rhodamine-conjugated phalloidin is an alternative to fluorescein-conjugated phalloidin.

If costaining with some other protein, phalloidin should be added together with the secondary antibody (see Basic Protocol 6).

7. Wash in three changes of ~3 ml PBS 5 min each time at ~50 rpm on a rotating platform shaker.

8. Mount on microscope slides in Vectashield mounting medium. Aspirate excess mounting medium under the coverslip using a Pasteur pipet attached to vacuum. To prevent sliding, fix the edge of the coverslip with nail polish. Wait 15 to 20 min for the nail polish to dry, then analyze samples under the microscope.

Samples can be preserved at 4°C in the dark for varying lengths of time depending on the strength of the staining. For example, actin staining can be preserved for a month or longer. Weak staining will fade beyond recognition within several days. The authors recommend analysis within 2 to 3 days after staining.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

BSA blocking buffer

20 mM Tris·Cl, pH 7.4
150 mM NaCl
2% (w/v) BSA (Fraction V)
0.05% (v/v) Tween 20
0.05% (w/v) sodium azide
Store up to 3 months at 4°C

Cell growth medium

DMEM high-glucose with L-glutamine (Invitrogen)
10% (v/v) FBS
1 mM sodium pyruvate (Invitrogen)
0.1 mM MEM nonessential amino acids (Invitrogen)
10 U/ml penicillin and 10 μg/ml streptomycin (Invitrogen; 100× stock)
Sterilize by passing through a 0.22-μm filter
Store up to 2 weeks at 4°C

Coomassie blue stain

25% (v/v) isopropanol (2-propanol)
10% (v/v) glacial acetic acid
0.03% (w/v) Coomassie G-250 (BioRad)
Store up to 1 year at 21°C

Destaining solution

10% (v/v) isopropanol (2-propanol)
10% (v/v) glacial acetic acid
Store up to 1 year at 21°C

FAK-Pyk2 kinase buffer

20 mM HEPES, pH 7.4
10% (v/v) glycerol
10 mM $MgCl_2$
10 mM $MnCl_2$
150 mM NaCl
Store up to 6 months at 4°C

HNTG buffer

50 mM HEPES, pH 7.4
0.1% (v/v) Triton X-100
150 mM NaCl
10% (v/v) glycerol
Store up to 6 months at 4°C

Lac Z staining solution

70 ml H_2O
10 ml of 10× PBS (1× final)
10 ml of 50 mM potassium ferricyanide (5 mM final)
10 ml of 50 mM potassium ferrocyanide (5 mM final)
0.2 ml of 1 ml $MgCl_2$ (2 mM final)
Store up to 2 weeks at 4°C
Just before use, add 1 ml of 20 mg/ml Xgal per 20 ml of staining solution (1 mg/ml final). Make a stock solution of 20 mg/ml X-gal in dimethylformamide (DMF). Store at −20°C in the dark.
NOTE: *Use a glass pipet to measure DMF solutions as it will dissolve plastics.*

Laemmli SDS sample buffer (2×)

125 mM Tris·Cl, pH 6.8
20% (v/v) glycerol
4% (w/v) SDS
0.006% (w/v) bromophenol blue (Fisher Biotech)
3.5% (v/v) 2-mercaptoethanol
Store up to 1 week at 4°C or 6 months at −20°C

Magnesium/ATP cocktail

75 mM $MgCl_2$
500 μM ATP
20 mM MOPS, pH 7.2
25 mM β-glycerol phosphate
5 mM EGTA
1 mM sodium orthovanadate
1 mM dithiothreitol
Store up to 1 week at 4°C

Paraformaldehyde fixative, 3.8% (w/v)

Add 3.8 g paraformaldehyde (Sigma) to 100 ml PBS (*APPENDIX 2A*), heat, and stir to dissolve. When temperature reaches 50°C, add ~100 μl 1 N NaOH, and continue stirring until temperature reaches 60°C. Remove from the heating plate, continue stirring until it reaches room temperature and filter to remove fine precipitate. Store up to 10 days at 21°C.

Once made, paraformaldehyde fixative is ready to use for up to 10 days. The exact percentage of paraformaldehyde is not crucial; it is sufficient to be somewhere between 3.8% and 4.0%. Similarly, the exact pH does not matter, if it is somewhere in a physiological range (7.2 to 7.6). Paraformaldehyde from different manufacturers or of different purity might require different amount of NaOH to adjust the pH.

Replating and migration medium

500 ml DMEM
0.5% (w/v) BSA (add 20 ml 12.5% BSA solution)
1 mM sodium pyruvate (Invitrogen)

continued

0.1 mM MEM nonessential amino acids (Invitrogen)
Sterilize by passing through a 0.22-μm filter
Store up to 1 month at 4°C

RIPA cell lysis buffer

1% (v/v) Triton X-100
1% (v/v) sodium deoxycholate
0.1% (w/v) SDS
50 mM HEPES, pH 7.4
150 mM NaCl
10% (v/v) glycerol
1.5 mM $MgCl_2$
1 mM EGTA
10 mM sodium pyrophosphate
100 mM sodium fluoride
1 mM sodium orthovanadate (add dropwise)
10 μg/ml aprotinin
10 μg/ml leupeptin
Sterilize by passing through a 0.22-μm filter
Store up to 1 week at 4°C
Add ingredients slowly to water. Start over if buffer becomes brown after sodium orthovanadate addition.
Alternatively, a protease inhibitor cocktail (e.g. Sigma P2714) may be used instead of aprotinin and leupeptin.

Src kinase buffer

20 mM PIPES, pH 7.0
10 mM $MnCl_2$
1 mM DTT
Store up to 6 months at 4°C

Tris-buffered saline with Tween (TBST)

50 mM Tris·Cl, pH 7.5
150 mM NaCl
0.05% (v/v) Tween 20
Store up to 6 months at 4°C

Triton lysis buffer

RIPA cell lysis buffer (see recipe) without sodium deoxycholate and SDS addition. Store up to 1 week at 4°C

Trypsin inhibitor solution

500 ml DMEM
125 mg soybean trypsin inhibitor (Worthington)
Dissolve by stirring
0.25% (w/v) BSA (add 10 ml of 12.5% w/v BSA solution)
Sterilize by passing through a 0.22 μm filter
Prepare fresh

Western blot stripping buffer

100 mM Tris·Cl, pH 6.8
2% (w/v) SDS
100 mM 2-mercaptoethanol
Store up to 3 months at 21°C

COMMENTARY

Background Information

FAK was first identified in 1992 as a highly tyrosine-phosphorylated protein associated with cellular focal adhesions, i.e., the integrin-associated cell attachment points with the extracellular matrix (Parsons, 2003). At that time, it was shown that changes in cell adhesion or integrin clustering could result in the increased phosphorylation of tyrosine in FAK (Guan and Shalloway, 1992; Hanks et al., 1992; Kornberg et al., 1992; Schaller et al., 1992). Today we know that this activation event is much more complicated than the simple binding of FAK to integrins leading to intermolecular FAK phosphorylation after clustering (Schlaepfer and Mitra, 2004). For instance, evidence to date does not strongly support direct binding of FAK to integrins. Instead, FAK is associated with integrin cytoplasmic tails through binding to integrin-associated proteins such as paxillin and talin. Additionally, integrins can activate Src-family protein-tyrosine kinases in a manner that is independent of FAK. It is known that cell binding to fibronectin promotes FAK and c-Src activation and the formation of a FAK-Src signaling complex, and these facts support the conclusion that the events are related. Current research is focused on deciphering the molecular mechanisms through which FAK and c-Src are activated by integrins, and the methods outlined in this unit comprise the foundation for these studies.

Additional complexity in this integrin signaling linkage comes from the studies of the FAK-related kinase, Pyk2, which is highly expressed in FAK−/− cells (Sieg et al., 1998). Stimulation of FAK−/− cells by replating on fibronectin promotes the activation of Src-family tyrosine kinases and the enhanced tyrosine phosphorylation of Pyk2. However, neither Pyk2 nor c-Src strongly colocalize with FAK−/− cell focal adhesions, and these cells do not correctly spread and migrate like wild-type FAK+/+ fibroblasts (Sieg et al., 1999; Klingbeil et al., 2001). The localization of FAK to particular integrin signaling sites is important for fibronectin-stimulated cell motility, the molecular mechanisms of which are still under investigation.

What the authors have tried to accomplish in this unit is to consolidate related protocols on how to measure changes in FAK, c-Src, and Pyk2 activity after fibronectin-mediated integrin stimulation through the use of in vitro kinase assays, phospho-specific blotting, or immunolocalization techniques. These assays involve using FAK−/− and FAK+/+ cells. The handling or preparation of these cells prior to performing biochemical activation assays is the same as the procedures used in evaluating the properties of these cells in cell migration assays. In this manner, cause and effect relationships can be established between integrin-stimulated signaling events and the modulation of a complex biological process such as cell motility. Alternate protocols that have been successfully used by other investigators include the use of antibodies or recombinant ligands for particular integrin subunits to facilitate binding or clustering and intracellular signaling (Giancotti and Ruoslahti, 1999). As cells usually contain multiple integrin α/β pairs that can bind fibronectin, and current research has shown that sequence-specific differences between integrin cytoplasmic domains facilitates the binding or activation of distinct intracellular signaling proteins (Liu et al., 1999; de Virgilio et al., 2004), antibody/ligand activation of integrins is a powerful means to study integrin signaling. However, antibody-mediated clustering of integrins is usually a weaker stimulus compared to cell binding and spreading on matrix proteins. Therefore, if a recombinant ligand can be purified and immobilized to facilitate specific integrin engagement and cell binding, this can be effectively used to study the signaling linkage between particular integrins, the actin cytoskeleton, and cell motility.

Critical Parameters and Troubleshooting

Maintenance of FAK+/+ AND FAK−/− fibroblasts and replating assays for signaling studies

It is critical to use well maintained FAK+/+ and FAK−/− cells for all experiments in this unit. Because the fibroblasts may exhibit altered morphology and premature senescence when overly confluent or at high passage number, cells need to be subcultured consistently and used within the first 15 passages from the cells available from American Type Culture Collection (ATCC). To prevent poor attachment to the extracellular matrices when cells are replated, avoid overtrypsinization and always make fresh trypsin inhibitor solution. Further, serum starvation is an important step in allowing maximal cell response and activation of focal adhesion molecules to stimuli (e.g., fibronectin). This

is also critical for successful motility assays (Basic Protocol 4) and scratch-wound healing assays (Basic Protocol 5).

In vitro kinase assay

It is important that a control antibody is included with immunoprecipitation experiments to accurately interpret in vitro kinase assay results. For example, preimmune serum can serve as the control for a rabbit antiserum. Further, the species (e.g., rabbit, mouse, goat, rat, or sheep) of antibody used in immunoprecipitation should be carefully considered if the immunoprecipitates will be analyzed by subsequent immunoblotting. HRP-conjugated secondary antibodies will recognize the immunoprecipitating antibody as well as the primary immunoblotting antibody of the same species, resulting in very high background around the 60-kDa protein region. As this is region where c-Src is present on gels, nonspecific antibody cross-reactivity can complicate co-immunoprecipitation experiments and c-Src immunodetection.

Immunoblotting with FAK/Pyk2 phospho-specific antibodies

For the detection of FAK and Pyk2 phosphorylation with phospho-specific antibodies, the most critical issue is the specificity and quality of the antibody. Ideally, the phospho-specific antibody should recognize only the phosphorylated form of the target protein on a specific site. However, in the experience of the authors, some phospho-specific antibodies for FAK can cross-react with corresponding sites on Pyk2 and may even react with other phosphorylation sites on the target protein. It is for this reason that results should be double-checked using complementary means such as phospho-specific antibodies from various manufacturers and alternate procedures (e.g., in vitro kinase assays). When reprobing with different phospho-specific antibodies, it is critical to ensure that stripping or removal of previous antibodies is complete. This can be done by performing the ECL reaction and exposing film after every blot stripping to confirm that no residual signal remains.

Haptotaxis motility assays

As confluent cells do not respond to extracellular matrix stimuli, it is essential to maintain a low cell confluency when performing the haptotaxis assay. Additionally, chamber coating is key to a successful and interpretable motility assay. Uneven or improper chamber coating will result in experimental variability within single chambers as well as throughout the experiment. Potential causes of uneven coating include denatured or sticky extracellular proteins and the presence of bubbles underneath the chambers during coating.

Scratch-wound healing assays

After generating the wound, it is important to ensure that no residual cells settle in the scratch area. This would severely complicate interpretation of the assay and can be avoided by thorough washing after creating the scratch wound. Additionally, wound-closure measurements must be compared to the original wound distance for each individual coverslip due to experimental scratch variations.

Immunostaining

The most important issues for visualization of focal adhesion molecules with immunofluorescent staining are (1) fixation and permeabilization of cells and (2) specificity of the staining antibody. Optimized fixation allows the preservation and localization of the antigen as well as cell morphology, while proper permeabilization allows access to the antigen. To achieve specificity for the immunostaining, the primary antibody should recognize only its target antigen, and proper controls (e.g., preimmune serum or secondary antibody only) should be included to optimize the staining conditions and to reduce background. See Table 14.7.3 for troubleshooting the experiments described in this unit.

The authors do not recommend use of preimmune serum as a control for staining specificity. The more appropriate control is a Western blot of whole cell lysate made from the same cells treated in the same matter. If multiple bands are visible, the antibody is not reliable for immunostaining. A control for secondary antibody is not necessary if whole IgG of the same species in which the secondary antibody was generated is used as a blocking agent together with the primary antibody.

Anticipated Results

In attached and serum-starved FAK+/+ and FAK−/− cells, FAK and Pyk2, respectively, display high basal levels of tyrosine phosphorylation and moderate level of kinase activity. In suspended cells, phosphorylation of tyrosine in both FAK and Pyk2 is greatly reduced. Replating cells on fibronectin, but not poly-L-lysine, increases tyrosine phosphorylation on both FAK and Pyk2 in FAK+/+ and FAK−/− cells. Immunoblotting with phospho-specific antibodies reveals that FAK and Pyk2 can be phosphorylated on

Table 14.7.3 Troubleshooting Guide for Common Problems Encountered in These Assays

Problem	Possible cause	Solution
Cell replating		
Cells slow to adhere and spread on matrix	Too much trypsin used to prepare cell suspension	Use limited trypsin/EDTA treatment at 37°C and tap plates to remove cells
		Make fresh trypsin inhibitor solution
In vitro kinase assay		
No or low levels of substrate labeling	Old [γ-^{32}P]ATP	Order fresh [γ-^{32}P]ATP
	Kinase denatured or degraded	Add fresh protease inhibitor to lysis buffer. Use freshly prepared lysates for immunoprecipitation
		Avoid repeated freeze-thaw of samples
		Use polyclonal antibodies to target protein for immunoprecipitation
High background	Carryover of cell debris following preclearance	Avoid disturbing cell debris when transferring supernatant during lysate preparation
	Incomplete washing	Completely resuspend beads at each wash
Phospho-specific immunoblotting		
Phospho-specific antibody recognizing nonphosphorylated form of protein in immunoblotting	Too much antigen or antibody present	Optimize the amount of lysates and concentration of antibody used. Reduce antibody incubation time and increase washing
Haptotaxis motility assay		
Migratory cells too dense to quantify	Assay went too long	Decrease assay time
	Too many cells were plated	Plate fewer cells
Inconsistent cell migration	Improper chamber coating	Avoid bubbles underneath chamber
	Matrix protein precipitated out of solution	Confirm the pH of medium used to resuspend matrix protein
Scratch-wound healing		
Cells do not close the wound	Matrix protein concentration is too high	Decrease matrix protein concentration
	Cells are not plated as a confluent monolayer	Increase cell density
	Cells require serum stimulation	Add 1% to 5% serum during assay
Cells close the wound too quickly	Too many cells	Decrease cell density
	Elevated cell proliferation	Add mitomycin C to block cell division

continued

Table 14.7.3 Troubleshooting Guide for Common Problems Encountered in These Assays, *continued*

Problem	Possible cause	Solution
Immunolocalization		
No staining	Primary antibody is not binding to epitope	Use different primary antibody
		Try another fixation procedure
		Try a different secondary antibody
Staining looks non-specific or high background	Complications due to fixation procedure	Try another fixation procedure
	Primary antibody does not cross-react across species	Change primary antibody
	Antigen target is expressed at low levels	Increase primary antibody incubation from 1 hr to overnight.
		Increase concentration of primary antibody
		Use biotin-avidin enhancement
Identical pattern observed for multiple proteins	Primary antibodies are from same species	Change one primary antibody to a different species
Signal "leaking" through microscope filters	Too high concentration of primary or secondary antibody	Decrease antibody concentrations or increase number of washes

multiple tyrosine residues following replating onto fibronectin matrix, and, following integrin activation, Src-associated in vitro kinase assays demonstrate that FAK and Pyk2 can transiently form signaling complexes with Src.

In haptotaxis and scratch-wound healing assays, FAK−/− cells display impaired migration compared to FAK+/+ cells. The defective cell motility of FAK−/− cells cannot be compensated by the presence of high levels of Pyk2, but it can be rescued by transiently re-expressing FAK. Furthermore, FAK can be detected via immunofluorescence staining that prominently and specifically localize to focal adhesions. In fact, some of the best markers of activated focal adhesions are antibodies that recognize FAK phosphorylated on tyrosine 397. Finally, strong activation of FAK can be detected in focal adhesions about 1 hr after replating fibroblasts onto extracellular matrix as well as at the leading edge of migration 5 to 6 hr following a scratch wound.

Time Considerations

Cells need to be serum starved (Support Protocol 2) for 16 to 24 hr before replating (Basic Protocol 1), haptotaxis motility (Basic Protocol 4), and scratch-wound healing (Basic Protocol 5) assays. Cells are kept in suspension for at least 45 min or replated for 1 to 3 hr before whole-cell lysates are collected, which takes 1 hr to complete (Support Protocol 3).

FAK, Pyk2, and c-Src can be captured from whole cell lysates by immunoprecipitation in 4 to 5 hr (Support Protocol 4), and can be further analyzed through in vitro kinase assay (Basic Protocol 2) or processed by immunoblotting for their phosphorylation and activation status (Basic Protocol 3). In these protocols SDS-PAGE gel electrophoresis takes 1 to 1.5 hr, gel transfer onto membrane takes 1.5 to 2 hr, and immunoblotting is best when membranes are incubated in primary antibodies overnight. Therefore, these biochemical assays will take a total of 3 days.

Following serum starvation (16 to 24 hr), the haptotaxis assay (Basic Protocol 4) takes ~8 hr to complete. It takes 2.5 to 3 hr to prepare the chambers and 1 to 1.5 hr to prepare cells (depending on how many different experimental groups are being analyzed), but these two items can be done concurrently. Cells migrate for 3 hr followed by an additional 1 to 2 hr

to fix and stain chambers. Microscopic quantification of migratory cells can take several hours.

To transfect FAK+/+ and FAK−/− cells (Alternate Protocol 3), cells need to be plated the previous day; preparation of transfection mix requires 45 min to 1 hr, and the transfection takes 5 hr. Cells are grown for an additional 48 hr to allow maximal protein expression and need to be serum starved for 24 hr before haptotaxis assay.

For the scratch-wound healing assay (Basic Protocol 5), cells are serum starved for 16 to 24 hr, plated on a cover slip for 2 hr, scratch wounded, and incubated for 1 hr after wounding. Live images are collected for 12 to 15 hr. The scratch-wound healing assay spans 32 to 45 hrs, but requires only 2 to 3 hr of hands-on time. For immunolocalization of focal adhesion proteins (Basic Protocol 6), immunofluorescence staining can be performed in ~7 hr.

Rho GTPase Activation Assays

Stéphanie Pellegrin[1] and Harry Mellor[1]

[1]Mammalian Cell Biology Laboratory, Department of Biochemistry, School of Medical Sciences, University of Bristol, United Kingdom

ABSTRACT

The Rho GTPase family of signaling proteins controls a wide range of highly dynamic cellular processes. Activation of Rho GTPases can be investigated and quantified in cell extracts using so-called pull-down assays. Proteins that bind specifically to the activated form of the Rho GTPase are used to capture it onto a bead support. Western blotting of the captured samples with specific antibodies then allows for quantification of the level of Rho GTPase activation in the sample. This unit describes the techniques for preparing the reagents required for assays of RhoA, Rac, and Cdc42 and gives practical tips for the successful application of the assay in a range of situations. *Curr. INTRODUCTION

Most Rho GTPases cycle between an active GTP-bound and an inactive GDP-bound state. When bound to GTP, Rho GTPases can interact with their effector proteins, and this nucleotide-dependent interaction forms the basis of the activation assays described below. The Rho GTPase-binding domain (RBD) of Rho GTPase effectors can be made

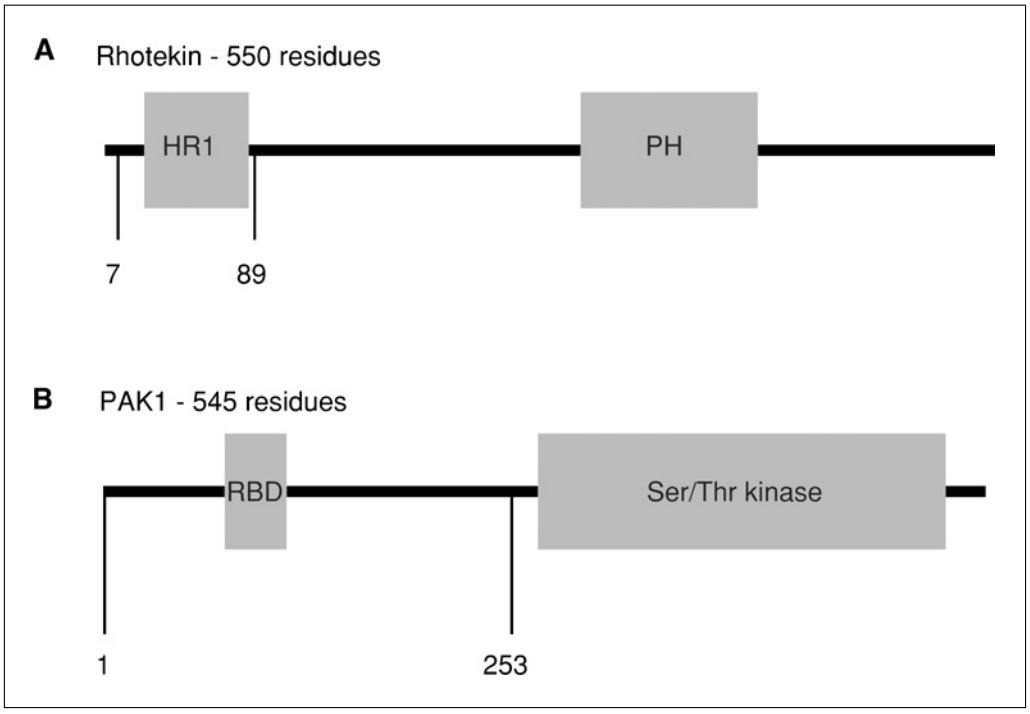

Figure 14.8.1 Diagram of Rho-binding domains used for GST pull-down assays: (**A**) Rhotekin-RBD and (**B**) PAK-CRIB. The GST-RBD constructs we have used span residues 7 to 89 of Rhotekin variant 2 (accession number NM_033046) and residues 1 to 253 of PAK1 (accession number NM_002576). When made as GST-fusion proteins, these are 35.7-kDa and 55.7-kDa respectively. Abbreviations: HR1, protein kinase C-related kinase homology region 1; PH, pleckstrin homology domain; RBD, Rho binding domain.

Current Protocols in Cell Biology 14.8.1-14.8.19, March 2008

as a glutathione-*S*-transferase (GST) fusion protein, coupled to beads, and added to cell lysates to pull down the active, GTP-bound form of the Rho GTPase (see *UNIT 17.5*). The RhoA binding domain from Rhotekin has been widely used to pull down active RhoA (Ren et al., 1999; Ren and Schwartz, 2000), whereas the PAK-CRIB domain of PAK1 is favored for Rac1 and Cdc42 activation assays (Sander et al., 1998; Benard et al., 1999; Benard and Bokoch, 2002). These constructs are shown in Figure 14.8.1. The CRIB motif of WASP has also been used for Cdc42 activation assays (Haddad et al., 2001).

This unit describes how to make recombinant GST-PAK-CRIB beads for Rac1 or Cdc42 activation assays and recombinant GST-Rhotekin-RBD beads for RhoA activation assays (Support Protocol). We use the same protocol to prepare both types of GST-RBD beads; the only difference is the construct used. The activation assay itself is detailed in the Basic Protocol and Alternate Protocol 1. Additional protocols describe how to load Rho GTPases with GDP, GTP, or GTPγS (Alternate Protocol 2) and how to perform activation assays on nonadherent cells (Alternate Protocol 3). Finally, suggestions on how to design activation assays for Rho GTPases other than RhoA, Rac1, and Cdc42 are given in the Commentary.

STRATEGIC PLANNING

The first step consists of making the recombinant GST-RBD fusion proteins. These are loaded onto glutathione-coupled beads and stored with the beads at −80°C in a buffer containing 10% glycerol. Following this, a small aliquot of the GST-RBD beads is run on an SDS-PAGE gel to estimate the amount of fusion protein made and purified. All of these steps are described in the Support Protocol.

The GST-RBD beads then need to be tested to verify that they only interact with the active, GTP-bound form of the Rho GTPase of interest. Good controls for Rac1 and RhoA activation assays are described in the Basic Protocol. These include treatment of serum-starved HeLa cells (70% confluent) with 100 ng/ml epidermal growth factor (EGF) for 3 min, which induces robust Rac1 (e.g., see Figure 14.8.2) and RhoA activation. A clear increase in active Rac1 or RhoA should be seen when comparing the amount of active GTPase in starved and agonist-treated cells. In order to test GST-RBD beads before use in Cdc42 activation assays, it is easier to load Cdc42 with GTP than to use agonist stimulation because few agonists give marked activation of this small GTPase. This method is described in Alternate Protocol 2, and expected results are shown in Figure 14.8.4. Since the GST-RBD beads can be stored at −80°C for long periods of time, it is important to test them regularly to ensure they have not lost their specificity for active Rho GTPase over time.

BASIC PROTOCOL

Rac1 ACTIVATION ASSAYS ON HeLa CELLS

This protocol describes how to prepare the cell lysates to carry out Rac1 and RhoA (also see Alternate Protocol 1) activation assays on agonist-treated cells. The conditions described in this protocol (see step 2) are used as a quality control or positive control for Rac1 or RhoA activation (see Fig. 14.8.2 for an example of a Rac1 activation assay). This protocol forms the basis for activation assays that can be carried out on cells treated with other agonists or over-expressing Rho GTPase mutants (active, GTP-bound or inactive, GDP-bound mutants), inhibitory GTPase activating proteins (GAPs), or activating guanine nucleotide exchange factors (GEFs) of interest. This protocol is also valid for Cdc42 activation assays although it is unclear which agonist can be used to obtain good Cdc42 activation. In this case, the alternative control is to load endogenous Cdc42 with GDP, GTP, or GTPγS (see Alternate Protocol 2 and Figure 14.8.4).

Preparation of cell lysates for Rac1 and RhoA activation assays are identical except for the lysis buffers used—lysis buffer B and lysis buffer C (see Alternate Protocol 1),

respectively. In all cases, it is important to avoid phosphate-based buffers for washing or lysing the cells because phosphate forms a precipitate with magnesium (Ren and Schwartz, 2000). $MgCl_2$ is present in the lysis buffer to stabilize GTP-bound GTPases and to prevent nucleotide exchange.

In an experimental setting, the level of activation obtained should be quantified by normalizing the amount of GST-RBD bound GTPase (i.e., active GTPase) to the amount of total GTPase. Care must be taken when quantifying scanned images of X-ray films because they have a narrow linear range of exposure (Ren and Schwartz, 2000); it is very important to make sure that the films are not overexposed. Activation assays are usually performed at least three times so that the mean (± standard deviation) of the ratio of active over total GTPase signal can be shown.

Materials

HeLa cells: 70% confluent 10-cm plates (two plates per experiment)
Phosphate-buffered saline (PBS; *APPENDIX 2A*)
100 μg/ml epidermal growth factor (EGF; Calbiochem); store aliquots at −80°C
DMEM/0.1% (w/v) fatty-acid-free bovine serum albumin (BSA)
Tris-buffered saline (TBS): 50 mM Tris·Cl (pH 7.6; see *APPENDIX 2A*)/140 mM NaCl, ice cold
Lysis buffer B, ice cold (see recipe)
4× SDS-PAGE sample buffer (see recipe)
GST-PAK-CRIB beads in Tris wash buffer A/10% (v/v) glycerol (Support Protocol)
Tris wash buffer B (see recipe), ice cold
2× SDS-PAGE sample buffer (see recipe)
SDS-PAGE gel (see *UNIT 6.1*)

Refrigerated centrifuge, 4°C
Heating block, 95°C
0.5- to 20-μl GELoader tips (Eppendorf)

Additional reagents and equipment for performing SDS-PAGE (*UNIT 6.1*) and immunoblotting (*UNIT 6.2*)

1. Wash two 10-cm plates of 70% confluent HeLa cells twice with 10 ml PBS and serum starve overnight in DMEM/0.1% (w/v) fatty-acid-free BSA.
2. Incubate one of the plates of HeLa cells 3 min with 10 ml of 100 ng EGF/ml of DMEM/0.1% fatty-acid-free BSA (prepared by diluting the 100 μg/ml EGF in the medium).

   The second plate in each experiment is a control. It is serum-starved but not treated with agonist. It is incubated overnight in DMEM/0.1% (w/v) fatty-acid-free BSA and remains in the cell incubator while treating the other plate with agonist.

3. On ice, quickly wash the cells twice in 10 ml ice-cold TBS and drain.
4. Still on ice, extract each plate in 800 μl ice-cold lysis buffer B.

   It is important to keep the samples cold and to work quickly throughout the protocol. Over time, the GAP activity in the cell lysates can drastically reduce the amount of active GTPase (Ren and Schwartz, 2000).

5. Centrifuge the cell lysates 10 min at 25,000 × *g*, 4°C. Carefully collect the supernatant and transfer to a new tube on ice.
6. Meanwhile, thaw 400 μl GST-PAK-CRIB beads on ice.
7. Remove 30 μl from each cleared cell lysate for total Rac1 protein control and add to 10 μl of 4× SDS-PAGE sample buffer. Heat 10 min at 95°C.

Taking samples from each lysate for each time point is important because these will be used to determine the amount of total GTPase, which is used to normalize the amount of active, GTP-bound GTPase.

8. Transfer 650 µl of each cell lysate into a microcentrifuge tube with 200 µl (or the equivalent of 30 µg) of GST-PAK-CRIB beads in Tris wash buffer A/10% glycerol.
9. Rotate 45 min at 4°C.
10. Wash the beads four times with 600 µl ice-cold Tris wash buffer B: resuspend the beads gently by inversion, centrifuge 20 sec at 500 × *g*, 4°C, and remove the supernatant.
11. After the last wash, use the thin GELoader pipet tip to remove all of the remaining buffer from the beads.

    This can be done by attaching the GELoader tips to a vacuum aspirator. These tips have a smaller diameter than the beads and the beads will not be aspirated. As the buffer is removed, the beads should become whiter.

12. Elute the proteins from the beads by adding 50 µl hot 2× SDS-PAGE sample buffer/40 mM DTT and heating 10 min at 95°C.
13. Load both the samples for total (obtained in step 7) and active Rac1 (obtained in step 12) onto an SDS-PAGE gel to resolve the ~21 kDa GTPase (*UNIT 6.1*) and process for western blotting (*UNIT 6.2*).

    The amount of total and active Rac1 will vary with the conditions and cell type used, so the volume of cell lysate to load in each well should be determined accordingly. As a starting point, 20 µl of total and 10 µl of active Rac1 can be loaded for each time point (Fig. 14.8.2).

    We have used 15% Tris·Cl gels but have found that 12% Bis-Tris gels run with MES buffer give much better resolution and allow for better detection.

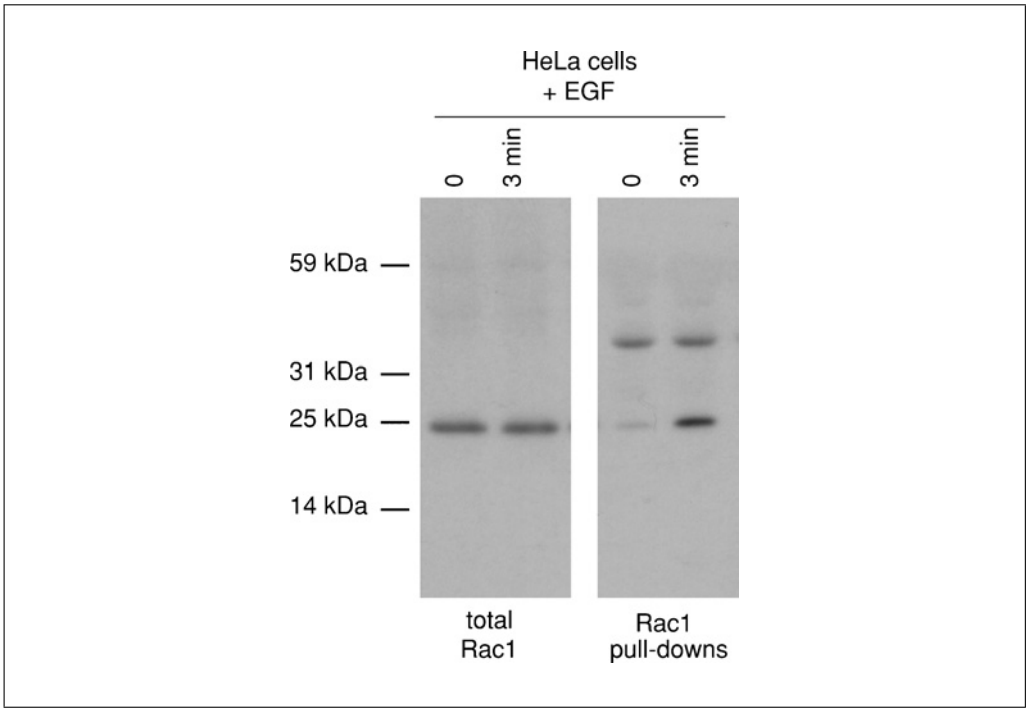

Figure 14.8.2 Rac1 activation assays carried out on HeLa cells. Total Rac1 is shown in the left panel and the activation assay in the right panel. After 3 min of EGF treatment (100 ng/ml), Rac1 is activated as seen by the appearance of Rac1 in the right-hand panel. The upper bands are nonspecific signal from the GST-RBD protein.

MAKING GST-RBD BEADS FOR ACTIVATION ASSAYS

SUPPORT PROTOCOL

The CRIB motif of PAK1 interacts with active (i.e., GTP-bound) Rac1 and Cdc42 (Burbelo et al., 1995) and has thus been used extensively to pull down active Rac1 and Cdc42 from cell lysates (Sander et al., 1998; Benard et al., 1999; Benard and Bokoch, 2002). The WASP CRIB motif has also been used to pull down active Cdc42, but this construct does not interact with Rac1 (Haddad et al., 2001). It is still unclear which of the CRIB motifs gives a more robust assay for Cdc42 activation. For RhoA, the Rho-binding domain of Rhotekin is used (Reid et al., 1996; Ren et al., 1999; Ren and Schwartz, 2000).

This protocol assumes that the construct of interest is available and already transformed into *Escherichia coli* to make recombinant protein. For activation assays on RhoA, the construct used consists of the cDNA sequence for amino acids 7 to 89 of Rhotekin cloned into a pGEX2T vector (Amersham; Fig. 14.8.1A). For Rac1 and Cdc42 activation assays, we use a construct which consists of the cDNA sequence for amino acids 1 to 253 of PAK1 cloned into the same expression vector (Ren and Schwartz, 2000; Fig. 14.8.1B). In pGEX vectors the GST-fusion protein is expressed from the tac promoter after induction with IPTG. Because these vectors also carry the *lacI^q* gene, they can be used in any *E. coli* host. We have used BL21(DE3)pLysS *E. coli*, but other hosts such as simple BL21 *E. coli* should work as well.

This protocol describes how to make beads from 4 liters of *E. coli* culture, which will yield enough GST-RBD beads for at least 40 activation assays. The method can theoretically be scaled down, but this is not recommended because using smaller volumes may cause the solutions to undergo greater temperature fluctuations during the procedure.

Materials

LB broth (*UNIT 20.2*)
100 mg/ml ampicillin stock solution in water; store small aliquots at −20°C
34 mg/ml chloramphenicol stock solution in ethanol; store small aliquots at −20°C, protected from light
E. coli: e. g., BL21(DE3)pLysS (Stratagene)
GST-RBD construct (obtained from the authors or self-constructed; see Figure 14.8.1)
1 M isopropyl-β-D-thiogalactopyranoside (IPTG); store small aliquots at −20°C
Glutathione-Sepharose 4B beads (Amersham)
Lysis buffer A (see recipe), ice cold
Tris wash buffer A (see recipe), ice cold
Tris wash buffer A (see recipe)/10% (v/v) glycerol, ice cold
4× SDS-PAGE sample buffer (see recipe)
12% SDS-PAGE gel (see *UNIT 6.1*)
Bovine serum albumin (BSA)
Coomassie blue staining solution (*UNIT 6.1*)

Shaking incubator, 37°C
2-liter flasks
Refrigerated centrifuge, 4°C
30-ml centrifuge tubes, capable of withstanding 17000 × *g* for 30 min (e. g., Oak Ridge), prechilled
Sonicator
15- and 50-ml polypropylene tubes (e. g., Falcon), prechilled
End-over-end rotator, 4°C
Heating block, 95°C
Microcentrifuge tubes, prechilled

Additional reagents and equipment for performing SDS-PAGE (*UNIT 6.1*)

Grow plasmid-bearing bacteria

1. Inoculate 5 ml LB broth containing 100 μg/ml ampicillin and 34 μg/ml chloramphenicol with a single colony of *E. coli* containing the GST-RBD construct.

   Instead of keeping glycerol stocks, it is preferred to keep the DNA at −20°C and to transform E. coli when needed. The plates can be kept for a month in the refrigerator.

   Chloramphenicol is required for maintenance of the pLysS plasmid of the BL21(DE3)pLysS E. Coli. It is not needed if other hosts are used.

2. Incubate overnight at 37°C, with shaking.
3. Inoculate 400 ml LB broth containing 100 μg/ml ampicillin and 34 μg/ml chloramphenicol with the 5-ml overnight culture.
4. Incubate overnight at 37°C, with shaking.
5. Prewarm 4 liters LB broth overnight at 37°C.

   LB broth is kept in a 37°C incubator overnight to save time the next day.

6. Dilute the overnight culture 1:10 into prewarmed 3.6 liters LB broth containing 100 μg/ml ampicillin and 34 μg/ml chloramphenicol (typically, 100 ml culture in 900 ml broth in a 2-liter flask).
7. Grow to $OD_{600} = 0.8$.

   This usually takes ∼1 hr, but the OD should be checked after 45 min.

Induce protein synthesis

8. Add IPTG to a final concentration of 0.5 mM IPTG using the 1M IPTG stock. Incubate 2 hr at 37°C.
9. Harvest by centrifuging 25 min at 2500 × *g*, 4°C.

   The culture does not have to be precooled.

10. Carefully remove the supernatant
11. Keep the bacterial pellets on ice and resuspend them completely in a total of 40 ml ice-cold lysis buffer A (i.e., 10 ml lysis buffer A per liter of bacteria culture)

    It is important to keep the solutions cold at all times. Everything should be kept on ice, and, if possible, working in a cold room is recommended.

    The bacteria should be completely resuspended before sonication (step 13). This is best achieved by first resuspending the pellet into only a small volume of lysis buffer, before adding the entire 40 ml. The suspension should be homogenous and devoid of clumps.

Sonicate bacteria

12. Transfer the suspension into two prechilled 30-ml centrifuge tubes.

    A volume of ∼20 ml is dispensed equally into each tube. These centrifuge tubes should be able to withstand centrifugation at 17,000 × g for 30 min (see step 14).

13. Sonicate on ice six to eight times for 15 sec each. Cool 2 min on ice between sonication bursts to prevent the lysates from overheating.

    It is important that the samples do not overheat and do not foam. The settings for sonication will vary from sonicator to sonicator. The samples should be checked regularly.

    Expect the lysate to first become a little viscous as the cells release their DNA—you may see a trail from the sonicator probe when you remove it from the lysate. This viscosity should disappear with further sonication as the DNA is sheared. It is important that all traces of viscous material are removed by sonication, or the lysate will not form a proper pellet of debris in the next step.

14. Centrifuge 30 min at 17,000 × *g*, 4°C.

Prepare beads

15. In the meantime, equilibrate 0.6 ml (packed bead volume) of glutathione-Sepharose 4B beads in lysis buffer A by washing them three times in lysis buffer A: add 0.8 ml lysis buffer A, resuspend the beads by inverting the tube gently, collect the beads by brief centrifugation (1 min at 500 × *g*, 4°C), and remove the supernatant without disturbing the bead pellet.

    The beads are sold as a suspension in ethanol. To obtain a reasonably accurate volume of packed beads, it is useful to first pipet 0.6 ml of lysis buffer A into a tube (e.g., a 1.5-ml microcentrifuge tube) and to draw a line at the level of the meniscus. Remove the buffer and add bead suspension until the level of packed beads meets the line on tube.

Bind GST-RBD to beads

16. Remove the clarified bacteria lysate supernatant and transfer the ~40 ml of lysate to a prechilled 50-ml polypropylene tube.

17. Add the equilibrated glutathione-Sepharose 4B beads (prepared in step 15) to the lysate.

    To make sure all the beads are transferred, resuspending the beads in a small volume of lysate is recommended. The tube that contained the beads can also be washed several times with lysate.

18. Rotate 60 min at 4°C.

19. Centrifuge 1 min at 500 × *g*, 4°C.

Recover bound beads

20. Carefully discard the supernatant without disturbing the bead pellet and add 12 ml ice-cold Tris wash buffer A.

21. Resuspend the beads by gentle inversions and transfer everything into a prechilled 15-ml polypropylene tube. Centrifuge 1 min at 500 × *g*, 4°C.

22. Wash the bead pellet another five times by discarding the supernatant, resuspending the beads in 12 ml ice-cold Tris wash buffer A by gentle inversions, and centrifuging 1 min at 500 × *g*, 4°C.

23. Wash once with 12 ml Tris wash buffer A/10% glycerol as in step 22.

24. Resuspend the beads in 8 ml Tris wash buffer A/10% glycerol.

25. Remove a 30-µl aliquot of beads in Tris wash buffer A/10% glycerol and add to 10 µl of 4× SDS-PAGE sample buffer. Heat at 95°C for 10 min and store at −70°C.

    This sample will be used to check the protein preparation on an SDS-PAGE by Coomassie blue staining (see steps 27 to 29).

26. Divide the beads into small aliquots in prechilled microcentrifuge tubes and store at −70°C.

    200 µl of beads in Tris wash buffer A/10% glycerol are generally used for each activation assay; make aliquots of 400 µl and 800 µl for two or four activation assays, respectively.

Quantify GST-RBD bound to beads

27. On a 12% SDS-PAGE gel, load 21 µl, 14 µl, and 7 µl of beads in 4× SDS-PAGE sample buffer prepared in step 25.

    This is equivalent to loading 15 µl, 10 µl, and 5 µl of beads in Tris wash buffer A/10% glycerol.

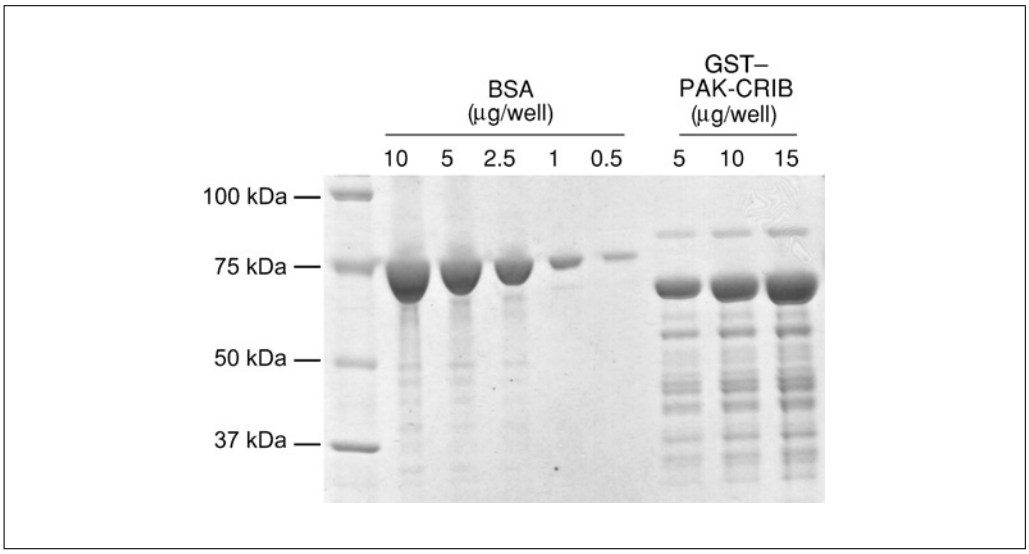

Figure 14.8.3 GST-PAK-CRIB preparation visualized on an SDS-PAGE gel stained with Coomassie blue. 45 μl of bead suspension in glycerol buffer was added to 15 μl of 4× SDS-PAGE sample buffer to give a final volume of 60 μl. Aliquots of 7 μl, 14 μl, and 21 μl (corresponding to 5, 10, and 15 μl of bead suspension respectively) were added to each well and compared to a dilution range of BSA (10, 5, 2.5, 1, and 0.5 μg per well). In this preparation 5 μl of bead suspension is equivalent to ~2.5 μg of protein, so the 200 μl of bead suspension used per assay is equivalent to ~100 μg of protein (30 μg would be fine).

28. Also load different amounts of BSA (e.g., 0.5 μg, 1 μg, 2.5 μg, 5 μg, and 10 μg of BSA per well).

29. Perform electrophoresis, staining with Coomassie blue (see *UNIT 6.1*).

30. Estimate the amount of GST-RBD protein bound to the beads by comparing band intensities to that of the known amounts of BSA.

    Usually, there is at least ~2.5 μg of GST-PAK-CRIB for 5 μl of beads in Tris wash buffer A/10% glycerol (Fig. 14.8.3). We use 30 to 100 μg of fusion protein per assay. This is considerably more than supplied by commercial assay kits, and the assay is consequently more sensitive.

    The presence of breakdown products is typical in these preparations, and they do not affect the assay (Benard and Bokoch, 2002).

ALTERNATE PROTOCOL 1

RhoA ACTIVATION ASSAYS

The only difference between preparing cell lysates for Rac1/Cdc42 activation assays and RhoA activation assays lies in the constituents of the lysis buffer. The lysis buffer used for RhoA activation assays (lysis buffer C) contains 0.1% SDS (Ren and Schwartz, 2000). This prevents nonspecific interactions in this assay but would affect Rac1 or Cdc42 binding to GST-PAK-CRIB if used in the Basic Protocol (Benard and Bokoch, 2002). As in the Basic Protocol, it is important to avoid phosphate-based buffers for washing or lysing the cells because phosphate forms a precipitate with magnesium (Ren and Schwartz, 2000). $MgCl_2$ is present in the lysis buffer to stabilize GTP-bound GTPases and to prevent nucleotide exchange. The high salt concentration has been shown to help minimize GAP activity that might otherwise lead to inactivation of Rho GTPases in the lysate (Ren and Schwartz, 2000).

***Additional Materials** (also see the Basic Protocol)*

Swiss 3T3 cells: e.g., 70% confluent 10-cm plates (two plates per experiment)
Lysis buffer C, ice cold
GST-Rhotekin-RBD beads in wash buffer A/10% (v/v) glycerol (Support Protocol)

Proceed as in the Basic Protocol with changes in the following steps:

2. Treat HeLa cells as described in the Basic Protocol, or, alternatively, treat serum-starved Swiss 3T3 cells with 10 ml of 1 μg/ml lysophosphatidic acid (LPA) for 1 min (Ren et al., 1999) or with 10% (v/v) serum for 2 to 3 min (Ren and Schwartz, 2000).

4. Still on ice, extract each plate in 800 μl ice-cold lysis buffer C.

   Lysis buffer C contains 0.1% SDS (Ren and Schwartz, 2000). This prevents nonspecific interactions, but if used for Rac1 activation assays (see Basic Protocol) would affect Rac1 or Cdc42 binding to GST-PAK-CRIB (Benard and Bokoch, 2002).

8. Transfer 650 μl of each cell lysate into a microcentrifuge tube with 200 μl (or the equivalent of 30 μg) of GST-Rhotekin-RBD beads in wash buffer A/10% glycerol.

LOADING Rac1 OR Cdc42 WITH NUCLEOTIDE

ALTERNATE PROTOCOL 2

This protocol provides an alternative control to the ones described above and is useful when no strong agonist is known (e.g., for Cdc42). The cells are lysed in a buffer devoid of magnesium. To load the endogenous GTPases with nucleotide, the cleared lysates are spiked with a magnesium-chelating agent (EDTA) and a high concentration of GDP, GTP, or GTPγS. Under these conditions, the GTPases will bind the most abundant nucleotide. Loading of endogenous GTPases with GTP rather than GTPγS gives a more realistic view of the level of activation one can expect in the cell. The exchange is stopped by adding magnesium chloride, and GST-RBD beads are added to carry out a pull-down assay.

An example of a Rac1 and Cdc42 activation assay carried out after nucleotide exchange is shown in Figure 14.8.4. An aliquot of the lysate is taken to show basal levels of the GTPase of interest before nucleotide exchange. Also recommended is taking an aliquot after nucleotide loading (but before adding the beads) to check that the GTPase has not been degraded during the incubation at 30°C. The only difference between the protocols for RhoA or Rac1/Cdc42 is the time of incubation at 30°C, during which nucleotide loading takes place. This protocol is theoretically applicable to other Rho GTPases but the conditions for nucleotide loading might have to be optimized (e.g., time and temperature of incubation).

Materials

10-cm plates of cells (two plates for each experiment)
Tris-buffered saline (TBS): 50 mM Tris·Cl (pH 7.6; see *APPENDIX 2A*)/140 mM NaCl, ice cold
Lysis buffer D (see recipe), ice cold
4× SDS-PAGE sample buffer (see recipe)
10 mM GTPγS (Calbiochem)/20 mM HEPES, pH 7.4; store aliquots at −20°C
100 mM GDP (Sigma)/20 mM HEPES, pH 7.4; store aliquots at −20°C
0.5 M EDTA, pH 8.0 (see *APPENDIX 2A*)
1 M $MgCl_2$
GST-RBD beads in Tris wash buffer A/10% glycerol (Support Protocol)
Tris wash buffer C (see recipe), ice cold
2× SDS-PAGE sample buffer (see recipe), 95°C
SDS-PAGE gel (see *UNIT 6.1*)

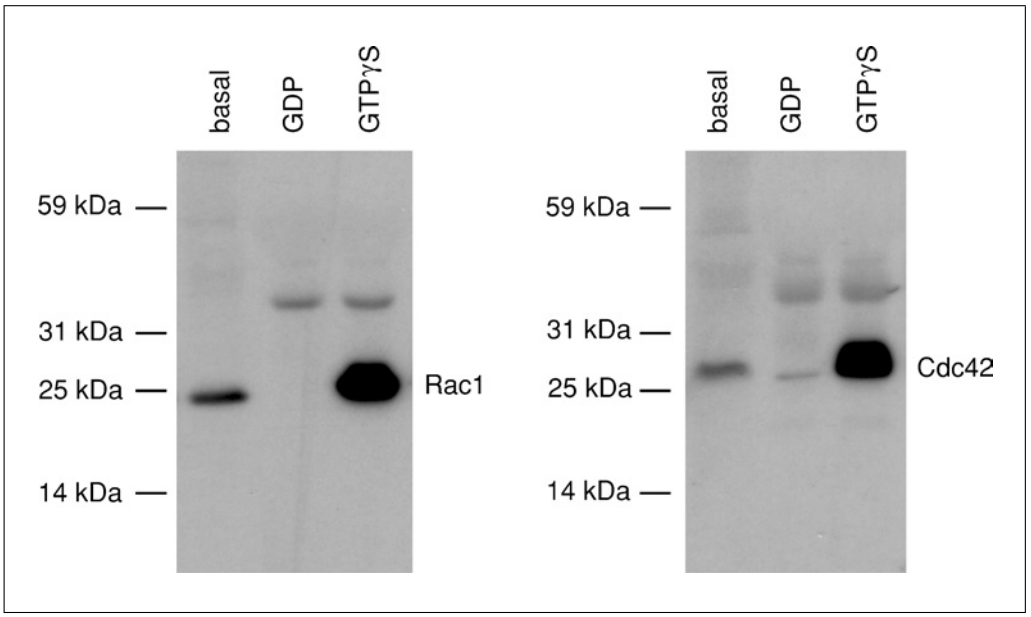

Figure 14.8.4 GDP and GTPγS loading of Rac1 and Cdc42. HeLa cells were lysed and loaded with GDP or GTPγS as described in Alternate Protocol 2, and Rac1 or Cdc42 activation assays were carried out. The amount of GTPase in lysates to which no nucleotide was added is referred to as basal.

Refrigerated centrifuge, 4°C
Shaking incubator, 30°C
Heating block, 95°C
End-over-end rotator, 4°C
0.5- to 20-µl GELoader tips (Eppendorf)

Additional reagents and equipment for determining protein concentration (*APPENDIX 3B* or *3H*) and performing SDS-PAGE (*UNIT 6.1*) and immunoblotting (*UNIT 6.2*)

1. Wash two 10-cm plates of cells twice with 10 ml cold TBS.
2. Extract each plate in 600 µl lysis buffer D.
3. Clear the lysate by centrifuging 10 min at 25,000 × *g*, 4°C.
4. Remove 60 µl of supernatant (to determine total protein; e.g., see *APPENDIX 3B or 3H*) and add 20 µl of 4× SDS-PAGE sample buffer.
5. Transfer 500 µl of each lysate to a new tube.

6a. *To load GTPγS:* Add

6 µl of 10 mM GTPγS (≥100 µM final concentration)
12 µl of 0.5 M EDTA pH 8.0 (≥10 mM final concentration).

Pipet gently to mix, using a pipet volume of ≥200 µl.

6b. *To load GDP:* Add

6 µl of 100 mM GDP (≥1 mM final concentration)
12 µl of 0.5 M EDTA pH 8.0 (≥10 mM final concentration).
Pipet gently to mix, using a pipet volume of ≥200 µl.

7. Incubate 15 min at 30°C, with gentle shaking (for Cdc42 and Rac1), or 30 min for RhoA.

8. Terminate the exchange by adding 38 µl of 1 M $MgCl_2$ to each tube (≥60 mM final concentration).
9. Add 200 µl (or 30 µg) GST-RBD beads in Tris wash buffer A/10% glycerol to each of the tubes.
10. Rotate 45 min at 4°C.
11. Centrifuge 20 sec at 500 × *g*, 4°C, and discard the supernatant.
12. Wash the beads four times in 600 µl cold Tris wash buffer C: add 600 µl cold Tris wash buffer C, invert the tube to gently resuspend the beads, and centrifuge 20 sec at 500 × *g*, 4°C, for each wash.
13. After the last wash, use the GELoader tips to remove all of the remaining buffer from the beads.
14. Elute with 50 µl of hot (95°C) 2× SDS-PAGE sample buffer.
15. Heat 10 min at 95°C.
16. Dilute again two-fold in 2× SDS-PAGE sample buffer and load 10 µl per well of an SDS-PAGE gel (*UNIT 6.1*) for immunoblotting (*UNIT 6.2*).

    The exact amount to load may vary and should be determined accordingly.

Rac1 ACTIVATION ASSAY ON NONADHERENT CELLS

ALTERNATE PROTOCOL 3

Preparing lysates from nonadherent cells to carry out an activation assay consists of spiking the cell culture medium with a concentrated solution of agonist and stopping the activation by adding an equal volume of 2× lysis buffer. This allows for rapid lysis just after agonist treatment. The protocol below is based on that described by Takesono et al. (2004). The activation assay for Rac1 is carried out on a lymphocyte cell line treated with 100 ng/ml of SDF1α for 0 sec, 30 sec, 2, 5, and 10 min. The results are shown in Figure 14.8.5.

Materials

Cultures of cells in suspension
RPMI/0.1% (w/v) fatty-acid-free BSA
RPMI/0.1% (w/v) fatty-acid-free BSA/20 mM HEPES, pH 7.4
SDF1α (R&D #350-NS)
2× lysis buffer (see recipe), ice cold
GST-PAK-CRIB beads in Tris wash buffer A/10% (v/v) glycerol (Support Protocol)
4× SDS-PAGE sample buffer (see recipe)
2× SDS-PAGE sample buffer (see recipe)
SDS-PAGE gel (see *UNIT 6.1*)

Refrigerated centrifuge, 8°C
0.5- to 20-µl GELoader tips (Eppendorf)
Heating block, 95°C

Additional reagents and equipment for performing SDS-PAGE (*UNIT 6.1*) and immunoblotting (*UNIT 6.2*)

Prepare cells for assay

1. Starve the suspension cells for 4 hr in RPMI/0.1% (w/v) fatty-acid-free BSA.

   It might be possible to starve certain cell lines overnight and this could help reduce the basal level of active GTPase. The protocol can be adapted accordingly.

2. Prewarm the RPMI/ 0.1% (w/v) fatty-acid-free BSA/20 mM HEPES.

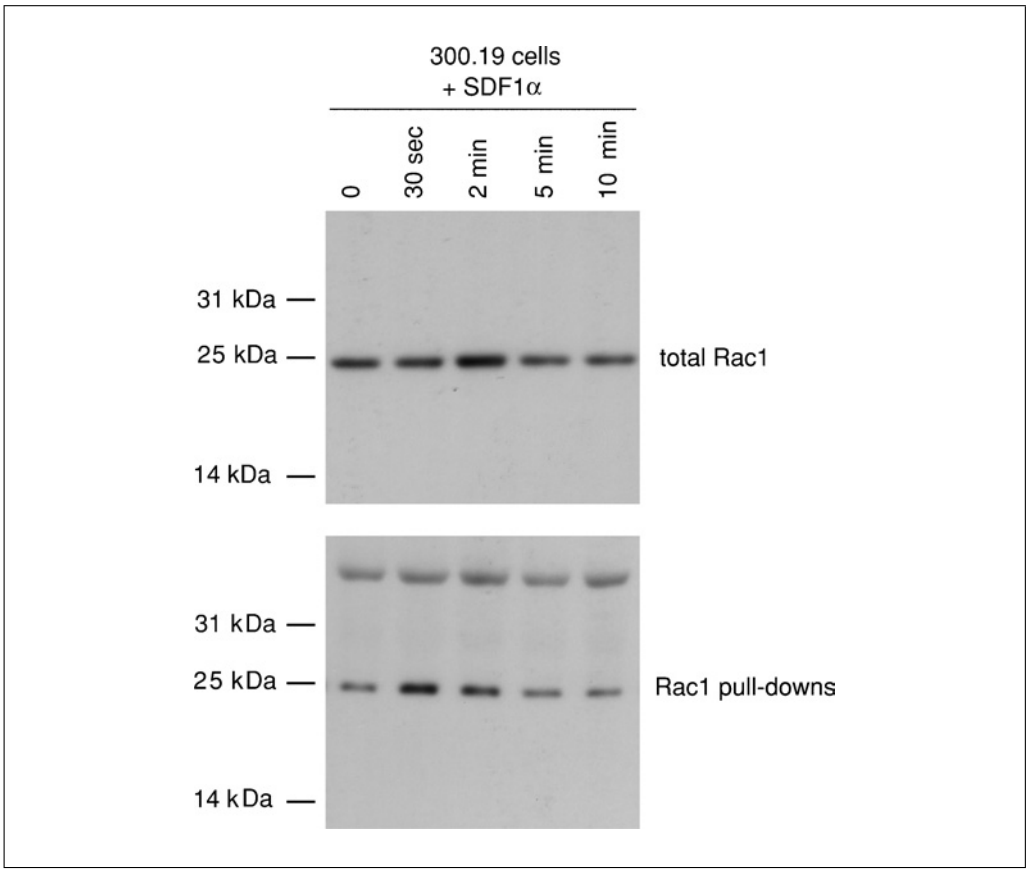

Figure 14.8.5 Rac1 activation assay carried out on nonadherent cells. Nonadherent 300.19 cells, a mouse pre-B lymphocyte cell line, were treated with SDF1α for different time points and Rac1 activation assays were carried out. The levels of total Rac1 are shown in the top panel (exposure of time 30 sec), and the bottom panel shows the levels of active Rac1 (exposure time of 1 min 30 sec). Rac1 is activated after 30 sec but the activation is lost by 5 min.

3. Resuspend the cells at 4.4×10^7 cells/ml in RPMI/0.1% (w/v) fatty-acid-free BSA/20 mM HEPES. For five time points, prepare 6.6×10^7 cells in 1.5 ml.
4. Transfer 225 µl of cells (10^7 cells) for each of the five time points into microcentrifuge tubes.
5. Prepare at least 120 µl of 1 µg/ml SDF1α in RPMI/0.1% (w/v) fatty-acid-free BSA/20 mM HEPES.

   SDF1α at 1 µg/ml is ten times more concentrated than the final SDF1α concentration to which the cells will be exposed. When added to the cells, the concentrated solution of SDF1α will be diluted 1:10 by the cell culture medium, and the final concentration of SDF1α will be 100 ng/ml.

6. To the cells corresponding to the 0 sec time point, add 25 µl of RPMI/0.1% (w/v) fatty-acid-free BSA/20 mM HEPES.

Perform assay

7. To each of the tubes for the other four time points, add 25 µl of the 1 µg/ml SDF1α to the 225-µl cell suspension prepared in step 4.

   Each tube will contain 10^7 cells in 250 µl and a final concentration of 100 ng/ml of SDF1α.

8. Stop the reaction by adding 250 µl ice-cold 2× lysis buffer. Keep the lysates on ice.

Analyze lysates

9. Clear the lysates by centrifuging 10 min at 25,000 × *g*, 4°C.
10. Meanwhile, thaw 1 ml (or the equivalent of 150 μg) of GST-PAK-CRIB beads in Tris wash buffer A/10% glycerol on ice.
11. Transfer the cleared lysates to new tubes.
12. For each time point, transfer 30 μl of cleared cell lysate to a new tube and add 10 μl of 4× SDS-PAGE sample buffer. Heat 10 min at 95°C.

    These will be the "total" Rac1 samples.

13. Add 200 μl of beads in Tris wash buffer A/10% glycerol (or the equivalent of 30 μg) to 450 μl of cleared lysate (the rest of the cleared lysate).
14. Rotate end-over-end 45 min at 4°C.
15. Wash the beads four times with 0.5 ml ice-cold 1× lysis buffer (dilute 2× lysis buffer): add 0.5 ml cold 1× lysis buffer, invert the tube to gently resuspend the beads, and centrifuge 20 sec at 500 × *g*, 4°C, for each wash.
16. After the last wash, use the thin GELoader pipet tip to remove all of the remaining buffer from the beads.
17. Elute the proteins from the beads by adding 50 μl of 2× SDS-PAGE sample buffer and heat for 10 min at 95°C.
18. Load both the samples for total (obtained on step 12) and active Rac1 (obtained in step 17) onto an SDS-PAGE gel to resolve the ~21-kDa GTPase (*UNIT 6.1*), and process for immunoblotting (*UNIT 6.2*).

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Lysis buffer, 2× (for nonadherent cells)

100 mM HEPES, pH 7.4
300 mM NaCl
2% (w/v) Triton X-100
20 mM $MgCl_2$
20 μg/ml aprotinin
20 μg/ml leupeptin
Prepare fresh and keep on ice
Add 0.4 mM PMSF (use 200 mM stock; see recipe) just before use

For nonadherent cells, the lysis buffer has to be twice as concentrated (2× lysis buffer) because it will be diluted in half by the cell culture medium.

Lysis buffer A

50 mM Tris·Cl, pH 7.5 (see *APPENDIX 2 A*)
1% (w/v) Triton X-100
150 mM NaCl
5 mM $MgCl_2$
1 mM DTT
Prepare fresh and keep on ice
Add 0.2 mM PMSF (use 200 mM stock; see recipe) just before use

Lysis buffer B (for Rac1 & Cdc42 activation)

50 mM Tris·Cl, pH 7.2 (see *APPENDIX 2A*)
1% (w/v) Triton X-100
500 mM NaCl
10 mM $MgCl_2$
10 μg/ml aprotinin
10 μg/ml leupeptin
Prepare fresh and keep on ice
Add 0.2 mM PMSF (use 200 mM stock; see recipe) just before use

Lysis buffer C (for RhoA activation)

50 mM Tris·Cl, pH 7.2 (see *APPENDIX 2A*)
1% (w/v) Triton X-100
0.1% (w/v) SDS
500 mM NaCl
10 mM $MgCl_2$
10 μg/ml aprotinin
10 μg/ml leupeptin
Prepare fresh and keep on ice
Add 0.2 mM PMSF (use 200 mM stock; see recipe) just before use

Lysis buffer D

50 mM Tris·Cl, pH 7.2 (see *APPENDIX 2A*)
1% (w/v) Triton X-100
500 mM NaCl
10 μg/ml aprotinin
10 μg/ml leupeptin
Prepare fresh and keep on ice
Add 0.2 mM PMSF (use 200 mM stock; see recipe) just before use

PMSF, 200 mM

200 mM phenylmethylsulfonyl fluoride in ethanol
Store protected from light

SDS-PAGE sample buffer, 4×

0.5 M Tris·Cl, pH 6.8 (see *APPENDIX 2A*)
4% (w/v) SDS
20% (w/v) glycerol
40 mM DTT
0.02% (w/v) bromphenol blue

SDS-PAGE sample buffer, 2×

250 mM Tris·Cl, pH 6.8 (see *APPENDIX 2A*)
2% (w/v) SDS
10% (w/v) glycerol
40 mM DTT
0.01% (w/v) bromphenol blue

Note that this sample buffer also contains 40 mM DTT.

Tris wash buffer A

50 mM Tris·Cl, pH 7.5 (see *APPENDIX 2A*)
0.5% (w/v) Triton X-100
150 mM NaCl

continued

5 mM $MgCl_2$
1 mM DTT
Prepare fresh and keep on ice
Add 20 μM mM PMSF (use 200 mM stock; see recipe) just before use

Tris wash buffer B

50 mM Tris·Cl, pH 7.2 (see *APPENDIX 2A*)
1% (w/v) Triton X-100
150 mM NaCl
10 mM $MgCl_2$
10 μg/ml aprotinin
10 μg/ml leupeptin
Prepare fresh and keep on ice
Add 0.2 mM PMSF (use 200 mM stock; see recipe) just before use

Tris wash buffer C

50 mM Tris·Cl, pH 7.2 (see *APPENDIX 2A*)
1% (w/v) Triton X-100
150 mM NaCl
30 mM $MgCl_2$
10 μg/ml aprotinin
10 μg/ml leupeptin
Prepare fresh and keep on ice
Add 0.2 mM PMSF (use 200 mM stock; see recipe) just before use

COMMENTARY

Background Information

The Rho proteins belong to the Ras superfamily of low-molecular-weight GTPases (Wennerberg et al., 2005). They were first identified in 1985 (Madaule and Axel, 1985) and have now been shown to regulate a wide range of cellular processes (Jaffe and Hall, 2005). Most Rho GTPases cycle between an active GTP-bound form and an inactive GDP-bound form. When bound to GTP, the active Rho proteins exert their biological functions by interacting with target or effector proteins (Bishop and Hall, 2000). In the cell, the GTPases are themselves regulated by three different classes of proteins. The guanine nucleotide exchange factors (GEFs) catalyze the exchange of GDP for GTP, thereby activating the GTPase (Rossman et al., 2005). The GTPase activating proteins (GAPs) stimulate the intrinsic GTPase activity of Rho proteins, leading to inactivation (Moon and Zheng, 2003). Finally, the guanine nucleotide dissociation inhibitors (GDIs) affect membrane targeting and nucleotide exchange (DerMardirossian and Bokoch, 2005; Dovas and Couchman, 2005).

Activation assays have become fundamental to the study of small GTPase function. Originally, GTPase activity was measured by immunoprecipitating the GTPase of interest from lysates of cells that had been metabolically labeled with [^{32}P]phosphate and by identifying the associated radioactive nucleotide using thin layer chromatography (Downward et al., 1990). The first nonradioactive activation assay was developed for the small GTPase Ras. In 1996, Taylor and Shalloway used the amino acids 1 to 149 of Raf1 to pull down active Ras (Taylor and Shalloway, 1996; Taylor et al., 2001). Very soon after, De Rooij and Bos (1997) described the same approach using a smaller domain of Raf1 (amino acids 51 to 131). After RhoA was shown to interact with Rhotekin in a nucleotide dependent fashion (Reid et al., 1996), Martin Schwartz and colleagues used the Rho-binding domain of Rhotekin to pull down active RhoA from cell lysates (Ren et al., 1999; Ren and Schwartz, 2000). The CRIB motif of PAK1 interacts with active (i.e., GTP-bound) Rac1 and Cdc42 (Burbelo et al., 1995) and has thus been used extensively to pull down active Rac1 and Cdc42 from cell lysates (Sander et al., 1998; Benard et al., 1999; Benard and Bokoch, 2002). The WASP CRIB motif has also been used to pull down active Cdc42, but this construct does not interact with Rac1 (Haddad et al., 2001). It is still unclear which of the CRIB motifs gives a more robust assay for Cdc42 activation.

As shown in Figure 14.8.1A, the Rhotekin construct used to pull down RhoA usually consists of amino acids 7 to 89 (Ren and Schwartz, 2000). On the other hand, a range of PAK-CRIB constructs have been used successfully for Rac1 and Cdc42 activation assays. Collard and colleagues used amino acids 56 to 272 of PAK1B (Sander et al., 1998), whereas Bokoch's group prefers using amino acids 67 to 150 of PAK1 (Benard and Bokoch, 2002). We have used a larger portion of PAK1, namely amino acids 1 to 253 (Fig. 14.8.1B). Although the CRIB motif is only 16 amino acids long, the minimal domain for Rac1/Cdc42 binding to PAK consists of residues 75 to 105 (Thompson et al., 1998).

Activation assays for small GTPases have led to the identification of a wide range of extracellular stimuli that result in GTPase activation and initiate downstream signaling. They are also a good tool for assessing basal activation states, especially in tumor biology where they can be used to compare normal and tumor samples or cell lines. GST-RBD pull-down assays are also useful for measuring GEF-mediated activation and GAP inhibition, but it has been suggested that they will not reflect GDI-mediated inhibition (Ellerbroek et al., 2003).

Designing and testing activation assays for Rho GTPases other than RhoA, Rac1, and Cdc42

The best characterized Rho GTPases are RhoA, Rac1, and Cdc42, but over 20 human Rho GTPases have now been identified (Wherlock and Mellor, 2002; Wennerberg and Der, 2004; Boureux et al., 2007). Developing activation assays for the other Rho GTPases could prove an important tool for studying their function, assuming that a specific antibody is available for the GTPase of interest.

Certain Rho GTPases, however, do not cycle between an inactive, GDP-bound and an active, GTP-bound form. These include Rnd1/RhoE, Rnd2, and Rnd3 which are thought to be GTPase deficient and constitutively GTP-bound (Foster et al., 1996; Nobes et al., 1998; Chardin, 2006). Like the Rnd proteins, RhoH/TTF, RhoBTB1, and RhoBTB2 lack the conserved residues corresponding to G12 and Q61 (Rac1 numbering) found in other Rho GTPases; they are therefore likely to be GTPase deficient and not regulated by GDP/GTP cycling (Wennerberg and Der, 2004; Li et al., 2002). Such noncycling Rho GTPases are not amenable to activation assays. So far, their activity is thought to be regulated by their level of expression and/or by phosphorylation and could, therefore, be monitored by assessing the amount of protein present and/or the level of phosphorylation.

Among the cycling RhoGTPases, RhoB and RhoC both bind Rhotekin, and the GST-Rhotekin-RBD construct used for RhoA activation assays has also been used successfully for RhoB and RhoC (Arthur et al., 2002; Gampel and Mellor, 2002; Bellovin et al., 2006; Pan et al., 2006). In this case, it is important to ensure that the antibodies used are specific and can distinguish between the different Rho proteins (Table 14.8.1). The GST-PAK-CRIB construct has been used successfully to pull down Rac1 and Cdc42-like Rho GTPases such as active Rac2 (Benard et al., 1999) and TC10 (Tong et al., 2007). TCL has been shown to bind GST-PAK-CRIB, suggesting that this construct could be used to pull down active TCL from cell lysates (Vignal et al., 2000). Thus, the first step in designing an activation assay would be to test whether the GST-Rhotekin-RBD, GST-PAK-CRIB, or GST-WASP-CRIB constructs can be used (see Figure 14.8.1). If this is not the case, one needs to identify a protein domain which can be made as a GST fusion protein and which only interacts with the GTP-bound form of the GTPase of interest.

In order to test whether the GST-fusion protein only interacts with the active GTPase, pull-downs can be carried out on cells overexpressing the inactive, GDP-bound T17N mutant or the active, GTP-bound G12V and Q61L mutants (Rac1 numbering; Benard et al., 1999). Alternatively, endogenous GTPases can be loaded with nucleotides (Alternate Protocol 2). In our experience, not all Rho GTPases can be loaded following Alternate Protocol 2 because incubation at 30°C for 15 or 30 min can lead to degradation of the protein of interest. It might be possible to overcome this by optimizing the protocol.

Rho GTPases generally have multiple binding partners, with a range of different binding parameters. The general sense is that successful pull-down assay probes will have high affinities for the active Rho GTPase, high specificity for the active form, and a low rate of dissociation. The last parameter is important in preventing loss of the complex during the assay procedure.

Critical Parameters and Troubleshooting

When studying agonist-induced activation, it is sometimes difficult to obtain low levels of active GTPase in the control, untreated cells. Not all cell types can be starved and the length of serum starvation needed can vary from cell type to cell type; this has to be determined empirically. The level of active GTPase should be as low as possible, and this is usually achieved by long periods of serum starvation (e.g., 16 hr). However, the cells should still look healthy after serum starvation. Also, the cells should not be too confluent; 60% to 70% confluency is usually ideal. Finally, carrying out regular quality control activation assays on the GST-RBD beads is important. Beads do lose their specificity over time and can then interact with the inactive form of the GTPase. The only way to resolve this is by making new GST-RBD beads.

The major obstacle to activation assays is the residual GAP activity found in cell lysates (Ren and Schwartz, 2000). The high salt content of lysis buffers should help minimize GAP activity, but it is also important to work quickly and to keep all solutions and samples at low temperature (Ren and Schwartz, 2000). If possible, it is advisable to carry out the procedure in a cold room. Buffers should be made fresh and kept on ice. The PMSF is added just before use.

Rho GTPases are not very abundant and they can be difficult to detect by immunoblotting. Good antibodies are available commercially, and these are described in Table 14.8.1. The GTPases are only 21 kDa and the SDS-PAGE gels used should be chosen accordingly. We have used 15% Tris·Cl gels but have found that 12% Bis-Tris gels run with MES buffer give much better resolution and allow for better detection.

The kinetics of GTPase activation are not always predictable. These depend on the cell type, the agonist used, and the GTPase studied. A typical assay involves a time course of 0, 30 sec, 1, 3, 5, and 10 min. If no activation is seen over this period, it is advisable to use a wider range of time points. Activation can occur very quickly and be very short lived; alternatively, it can occur a very long time after treatment with agonist. Indeed, treatment of Schwann cells with sphingosine-1-phosphate (S1P) leads to maximal RhoA and Rac1 activation after only 15 sec (Barber et al., 2004). This activation is very rapidly downregulated; it is barely noticeable after 1 min and disappears completely after 3 min of S1P treatment (Barber et al., 2004). On the other hand, treatment of HeLa cells with EGF leads to a biphasic activation of RhoB, with an early peak in activity at 3 min, followed by a second peak that appears as late as 60 min after stimulation (Gampel and Mellor, 2002).

In an experimental setting, the level of activation obtained should be quantified by normalizing the amount of GST-RBD bound GTPase (i.e., active GTPase) to the amount of total GTPase. Care has to be taken when quantifying scanned images of X-ray films because they have a narrow linear range of exposure (Ren and Schwartz, 2000); it is very important to make sure that the films are not overexposed. Activation assays are usually performed at least three times so that the mean ($\pm$ standard deviation) of the ratio of active over total GTPase signal can be shown.

Anticipated Results

Examples of anticipated results are shown in Figures 14.8.2 to 14.8.5. The level of sensitivity of the activation assay has not been determined. It would vary hugely among cell types. Concentrations of agonists used would

Table 14.8.1 Commercially Available Antibodies for RhoA, RhoB, Rac1, Rac2, and Cdc42

GTPase	Company	Catalogue number	Species
RhoA[a]	Santa Cruz	RhoA (26C4) sc418	Mouse monoclonal
RhoB[a]	Santa Cruz	RhoB (C5) sc8048	Mouse monoclonal

saturate the receptors, based on their known affinities.

Time Considerations

The most time consuming task is making the GST-RBD beads (Support Protocol). The whole procedure is carried out on the same day, starting with the inoculation of 4 liters of medium with 400 ml overnight culture and finishing with the aliquoting and freezing of the GST-RBD beads. The beads then need to be checked on an SDS-PAGE gel and tested in a quality control activation assay using known agonists or Rho GTPases loaded with nucleotide. Once a batch of beads has been made and tested, individual aliquots can be thawed on ice just before being added to cell lysates.

A specific timeline for this process follows: After the GST-RBD construct has been made or obtained, it needs to be transfected into bacteria which are left to grow overnight (day 1). A single colony can be picked the next day and grown overnight in a 5-ml culture (day 2). The 5-ml culture is used to inoculate a 400-ml culture, which is grown overnight (day 3). The GST-RBD beads (see Support Protocol) can then be made in 1 day (day 5) and frozen in small aliquots. Checking that the GST-RBD is bound to the beads can be done the next day (day 6). The beads can be tested as described in the Basic Protocol on control cell lysates to check that the beads bind the active but not the inactive form of the GTPase either on that same day (day 6) or the next (day 7).

In Vitro GEF and GAP Assays

Alexander Eberth[1] and Mohammad Reza Ahmadian[1]

[1]Institut für Biochemie und Molekularbiologie II, Klinikum der Heinrich-Heine-Universität, Düsseldorf, Germany

ABSTRACT

Small GTPases act as tightly regulated molecular switches governing a large variety of critical cellular functions. Their activity is controlled by two different biochemical reactions, GDP/GTP exchange and GTP hydrolysis. These very slow reactions require catalysis in cells by two kinds of regulatory proteins. While the guanine nucleotide exchange factors (GEFs) activate small GTPases by stimulating the slow exchange of bound GDP for the cellularly abundant GTP, GTPase-activating proteins (GAPs) accelerate the slow intrinsic rate of GTP hydrolysis by several orders of magnitude, leading to inactivation. There are a number of methods that can be used to characterize the specificity and activity of such regulators, to understand the effect of binding on the protein structure, and, ultimately, to obtain insights into their biological functions. This unit describes (1) detailed protocols for the expression and the purification of small GTPases and the catalytic domains of GEFs and GAPs; (2) preparation of nucleotide-free and fluorescent nucleotide-bound small GTPases; and (3) methods for monitoring of the intrinsic and GEF-catalyzed nucleotide exchange as well as intrinsic and GAP-stimulated GTP hydrolysis. *Curr. Protoc. Cell Biol.* 43:14.9.1-14.9.25. © 2009 by John Wiley & Sons, Inc.

Keywords: fluorescence spectroscopy • guanine nucleotide • mant • tamra

INTRODUCTION

A great variety of small GTPases are known, and each of these in turn interacts with a variety of regulatory proteins, including guanine nucleotide exchange factors (GEFs) and GTPase-activating proteins (GAPs). Analysis of the human genome sequence predicts 69 GEFs and up to 80 GAPs for Rho family GTPases, which may possibly regulate the activity of 19 Rho GTPases. To understand the biological relevance of this molecular diversity, it is important to measure the activity and to determine the specificity of these regulators in vitro. Only a sparse number of such intermolecular interactions have been investigated, primarily using radioactive ligand overlay, filter binding, or pull-down assays. These methods are often not sufficient to determine the specificity of regulation and quantify the activity of recombinant proteins. However, many of the potential interactions defined by these methods require a more detailed analysis of their kinetics by appropriate real-time methods. Fluorescent guanine nucleotides are often ideally suited to fulfill these criteria, as it is known that they do not grossly disturb the biochemical properties of the GTPase and that the fluorescence reporter group is sensitive enough to changes in the local environment to produce a sufficiently large fluorescence change (Ahmadian et al., 2002; Hemsath and Ahmadian, 2005). Furthermore, it is often sensitive to the interaction with partner proteins that happen to bind in its neighborhood. This unit describes the role of two different fluorescently labeled guanine nucleotides in the biochemical analysis of Rho GTPases (Fig.14.9.1), which can be used to evaluate the GEF-catalyzed nucleotide exchange and the GAP-stimulated GTP-hydrolysis activities, respectively. Table 14.9.1 describes the protocols presented in this unit.

BASIC PROTOCOL 1

MEASUREMENT OF INTRINSIC AND SLOW GUANINE NUCLEOTIDE EXCHANGE FACTOR (GEF)–CATALYZED NUCLEOTIDE EXCHANGE REACTIONS

To obtain a detailed picture of the molecular switch function of small GTPases and their interaction with regulators and effectors, we have established fluorescence-based methods for the time-resolved monitoring and quantification of small GTPase functions and interactions with their binding partners (Ahmadian et al., 2002; Hemsath and Ahmadian, 2005).

Different procedures are available for investigating the guanine nucleotide exchange on small GTPases. The dissociation of a protein-bound nucleotide can easily be determined in real time by fluorescence spectroscopy using a fluorescent GDP. Usually, *N*-methylanthraniloyl (mant) derivatives of guanosine nucleotides, coupled at the 2′(3′) hydroxyl group of the ribose, are used.

In principle, each nucleotide-binding protein has a defined intrinsic rate of GDP release, which is often too low to be physiologically relevant. Thus, GEFs operate on these small GTPases and catalyze the generation of the active GTP-bound state from the inactive GDP-bound form. This process is often a result of the GEFs themselves being activated or recruited to the vicinity of the corresponding GTPase in response to extracellular signaling events.

Specificity and activity of GEFs can be analyzed qualitatively by comparison of intrinsic and GEF-stimulated fluorescence measurements. Usually, this is performed in a fluorescence spectrometer, since these reactions are slow (>1000 sec). Here, the bacterially expressed recombinant proteins, purified to >90% homogeneity, as well as the chemically

synthesized pure nucleotide solution, are prepared in a cuvette. The mant-fluorescence signal in a fluorescence spectrometer is recorded using an excitation wavelength of 366 nm and an emission wavelength of 450 nm, an integration time of at least 2 sec, and a recording time for each data point of 20 sec.

GEF and also GAP assays do not need post-translationally modified GTPases. Thus, all proteins and protein domains produced in *Escherichia coli* can be used. Cleared cell lysate is not suitable in this assay for several reasons: (1) protein concentration may not be sufficient; (2) the protein of interest may exist in a complex with other proteins and may thus not be freely available; (3) the activity of other regulators may falsify the assay.

Materials

>5 μM mantGDP-bound GTPase (Support Protocol 1)
GEF buffer (see recipe), store at 25°C
>50 μM GEF protein including the catalytic domains (recombinant protein, expressed and purified as described in Support Protocols 4 to 13)
10 mM GDP (Pharma Waldhof, *http://www.pharmawaldhof.de/*), pH 7.5
0.5 M EDTA, pH 8.0 (*APPENDIX 2A*)

Fluorescence cuvettes (Suprasil quartz glass; Hellma, cat. no. 108.002F-QS)
Fluorescence spectrometer (Perkin-Elmer, Spex Instruments)
Grafit program (Erithacus Software) or alternative program packages for evaluation of the data

1. Preincubate a solution of 0.1 μM mantGDP-bound GTPase (see Support Protocol 1) in a fluorescence cuvette in GEF buffer with the GEF protein at a final volume

of 600 µl and at 25°C for at least 5 min, while measuring the fluorescence signal at 366 nm excitation and 450 nm emission.

Always use 366 nm for excitation and 450 nm for emission with mant-labeled nucleotides.

2. If the fluorescence signal is stable, add 1.2 µl of 10 mM nonfluorescent GDP solution (20 µM final GDP concentration) and mix rapidly with a pipet to start the reaction.

   With this setup, the intrinsic dissociation reaction in the absence of GEF is monitored, which, depending on the GTPase, lasts between 2 and 72 hr. This slow reaction is accelerated in the presence of GEF proteins. To determine the activity and specificity of the exchange factors in a fluorimeter, usually concentrations of 0.1 to 2 µM (depending on the specific activity of the GEF) should be used (for faster kinetics, see Alternate Protocol 1).

   For slow nucleotide dissociation reactions (>5 hr), the cuvettes should be closed with a lid and can additionally be sealed by a thin layer of silicone grease between cuvette and lid to prevent evaporation of the sample, which usually results in an artifactual increase in fluorescence.

   Alternatively, four parallel measurements can be performed simultaneously using an instrument equipped with an automated four-position turret.

   Using cleared cell lysates may disturb the proper fluorescence signal in this assay because they are often very opaque solutions and, due to the very low GEF concentrations, useless if greatly diluted.

3. Monitor the exponential decrease in fluorescence over the time course of the reaction (2 to 72 hr).

   The decrease in fluorescence is due to the mantGDP release into the aqueous solution.

4. When no further change in fluorescence can be observed, add 24 µl of 0.5 M EDTA solution (for final concentration of 20 mM) and monitor the reaction for an additional 10 min.

   This will reveal whether the nucleotide dissociation reaction is entirely complete.

   EDTA will deplete the magnesium ion, which is an essential cofactor for nucleotide binding, from the nucleotide binding site of the GTPase. This reduces the nucleotide affinity by several orders of magnitude and thus leads to a complete dissociation of the bound mant-nucleotide. However, the fluorescence baseline will not change if mantGDP dissociation is already complete.

5. Fit the data single exponentially with, e.g., the Grafit program to provide the dissociation (off) rates.

   In the case of small GTPases, the dissociation rate is usually $\sim 10^{-3}$ to 10^{-5} sec^{-1}.

SUPPORT PROTOCOL 1

PREPARATION OF mantGDP-BOUND GTPases

Loading of nucleotide-free forms of GTPases with fluorescently labeled nucleotides can be achieved by simply mixing both components and subsequently performing small-scale size-exclusion chromatography with a desalting column. The protocol described below is usually necessary for the preparation of GTPases bound to fluorescent GDP analogs. For nonhydrolyzable GTP analogs like Gpp(NH)p, the method described in Support Protocol 2 is sufficient and, additionally, steps 4 to 5 of Support Protocol 2 could be omitted (addition of phosphodiesterase is dispensable).

Materials

Standard buffer (see recipe)
Nucleotide-free GTPase (see Support Protocol 2)
mantGDP (synthesized as described in Hemsath and Ahmadian, 2005, or purchased from Jena Bioscience, *http://www.jenabioscience.com/*)

Ponceau S (*UNIT 6.2*)
HPLC buffer (see recipe) containing 20% to 25% (v/v) acetonitrile

NAP-5 column (GE Healthcare)
Nitrocellulose membrane (*UNIT 6.2*)

Additional reagents and equipment for Ponceau S staining of proteins on nitrocellulose membrane (*UNIT 6.2*) and HPLC (Support Protocol 3)

1. Equilibrate the NAP-5 column with 2 to 3 column volumes of standard buffer.
2. Mix 0.5 mg of a nucleotide-free GTPase (e.g., 50 µl from a 0.5 mM solution) with a 1.5-fold molar excess of mantGDP (e.g., 3.75 µl from a 10 mM stock solution).
3. Apply complete sample volume to the NAP-5 column and let it sink into the medium.
4. Add sufficient standard buffer for a 500-µl total buffer/sample volume and let it sink into the medium again (e.g., for the example here, add 446.25 µl).
5. Add 1 ml of standard buffer and collect fractions at 2 drops per fraction.

   Usually the protein elutes in fractions 3 to 5, which corresponds to an elution volume between 0.2 and 0.5 ml.

6. Analyze the fractions for their protein content by dotting 2 µl from each fraction on a nitrocellulose membrane and subsequently staining with Ponceau S (*UNIT 6.2*).

   This is just to determine which fractions contain the protein of interest.

   We do not use any protein standard here since this is not a quantitative analysis. It is just qualitative and should answer in which fractions the protein is localized and identify which fractions to pool.

7. Pool protein-containing fractions and determine the mantGDP-bound protein concentration by HPLC (Support Protocol 3) using an HPLC buffer containing 20% to 25% acetonitrile.
8. Store the protein aliquots at −80°C.

   It is important to note that the resulting concentration needs to be multiplied by the factor 0.6 to filter out absorption portions, which trace back to the mant-group absorption at 254 nm.

PREPARATION OF NUCLEOTIDE-FREE FORMS OF SMALL GTPases

SUPPORT PROTOCOL 2

Preparation of nucleotide-free GTPase is carried out in two steps according to John et al. (1990). In the first step, the bound GDP is degraded by alkaline phosphatase and replaced by Gpp(CH_2)p (a nonhydrolysable GTP analog, which is resistant to alkaline phosphatase but sensitive to phosphodiesterase). In the second step, after GDP is completely degraded, snake venom phosphodiesterase is added to the solution of the Gpp(CH_2)p-bound GTPase to cleave this nucleotide to GMP, G, and P_i.

Materials

Alkaline phosphatase, agarose bead-coupled (Sigma-Aldrich)
Nonhydrolyzable GTP analog Gpp(CH_2)p (Sigma-Aldrich)
GDP-bound GTPase (expressed and purified from *E. coli*; as described in Support Protocols 4 to 13)
10× exchange buffer (see recipe)
HPLC buffer (see recipe) containing 7.5% (v/v) acetonitrile
Snake venom phosphodiesterase (Sigma-Aldrich, cat. no. P3134)
Liquid nitrogen

Additional reagents and equipment for HPLC (Support Protocol 3 and Basic Protocol 2)

1. Add 0.1 to 1 U of agarose bead–coupled alkaline phosphatase and a 1.5 molar excess of Gpp(CH_2)p to 1 mg GDP-bound GTPase.

   Use a highly concentrated protein solution of 0.5 to 1 mM in order to obtain highly concentrated nucleotide-free GTPases.

2. Start the reaction by diluting the 10× exchange buffer to 1× in the prepared reaction mixture from step 1. Mix exchange buffer and protein/nucleotide-solution rapidly.

   Fast mixing of the exchange buffer should be carried out to prevent local protein precipitation due to a high ammonium sulfate concentration. Ammonium sulfate destabilizes the nucleotide binding of the GTPase and zinc chloride, and is an essential cofactor of the alkaline phosphatase.

3. Incubate the protein solution at 4°C for 2 to 16 hr (depending on the GTPase used) and analyze the GDP content by HPLC (Support Protocol 3) using an HPLC buffer containing 7.5% acetonitrile.

   The GDP peak declines in the course of the degradation progress. It disappears and GMP or G peaks appear instead. The amount of Gpp(CH_2)p remains unchanged, as it is resistant to alkaline phosphatase.

   This protocol can also be used to prepare Gpp(NH)p-bound or mantGp(NH)p-bound GTPases as described by Hemsath and Ahmadian (2005).

4. After GDP is degraded completely, add 0.002 U snake venom phosphodiesterase per mg GTPase to cleave Gpp(CH_2)p to GMP, G, and P_i. Incubate 2 to 24 hr at 4°C (depending on the GTPase and activity of the phosphodiesterase).

   This is the critical step in the procedure, since here the nucleotide is degraded and generation of a low-affinity product can lead to partial denaturation of the protein. In some cases, it might be helpful to reduce the amount of exchange buffer used or to do repeated cycles of room temperature incubation (e.g., for 20 min) followed by recooling on ice (e.g., for 10 to 15 min), which might accelerate the process. The latter method might be employed in cases where denaturation of the protein occurs due to a long incubation time (>2 days).

5. Analyze the degradation process by HPLC (Basic Protocol 2).

   Progress of the reaction can be followed by observing reduction and finally elimination of the Gpp(CH2)p peak and an increase in the guanosine peak.

6. After the degradation of Gpp(CH_2)p is complete, centrifuge the solution 2 min at 1500 × *g*, 4°C, to remove bead-coupled alkaline phosphatase and insoluble guanosine. Repeat this process two to three times to quantitatively remove all traces of alkaline phosphatase-coupled beads, since this enzyme might interfere with subsequent biochemical assays performed with the nucleotide-free GTPase.

   Depending on the GTPase, Gpp(CH_2)p degradation continues 6 to 18 hr at 4°C.

7. Inactivate the phosphodiesterase by snap freezing in liquid nitrogen and quickly defrosting at 37°C, and then repeating the process. Store the protein solution at −80°C.

   Nucleotide-free GTPases are actually in a GMP- and G-bound form that can be stored at −80°C for several months. GMP and G, which are the products of the enzymatic degradation of GDP and Gpp(CH_2)p, usually exhibit a 6– to 7–orders of magnitude lower affinity for the GTPases as shown previously for H-Ras (John et al., 1990). Nonetheless, the presence of G and GMP, which can be rapidly exchanged by GDP- and GTP-derivatives, provides for stability of the so-called nucleotide-free GTPases.

DETERMINING NUCLEOTIDE CONCENTRATION USING HPLC

SUPPORT PROTOCOL 3

HPLC allows determination of the concentration of nucleotides (nonlabeled- or mant- or tamra-labeled nucleotide) using a reversed-phase C18 column (ODS-Hypersil, 5 μM, Bischoff Chromatography) and a precolumn (Nucleosil 100 C18, Bischoff Chromatography), which separates protein–nucleotide complexes by adsorbing the denatured protein. Due to the 1:1 ratio of GTPase and nucleotide complex, this method can be used to accurately determine the concentration of a nucleotide-bound protein population.

Materials

HPLC buffer (see recipe)
50 to 100 μM GTPase (recombinant protein, expressed and purified as described in Support Protocols 4 to 13)
Nucleotide standard solutions: e.g., 20 to 400 μM GDP

Beckman Gold HPLC instrument (Beckman Coulter)
Reversed-phase C18 HPLC column: Ultrasphere ODS, 5-μM; 250 × 4, 6-mm (Beckman Coulter)
Guard column: Nucleosil 100-5-C18, 5 μM (Bischoff Chromatography; *http://www.bischoff-chrom.de/*)
20- or 50-μl sample loop (Bischoff Chromatography; *http://www.bischoff-chrom.de/*)

1. Equilibrate the pump and column of the HPLC system with HPLC buffer until a stable baseline at 254 nm is reached.

   For the separation of nonlabeled nucleotides, HPLC buffer (see Reagents and Solutions) containing 7.5% acetonitrile is used; 20% to 25% acetonitrile is used for mant- or tamra-labeled nucleotides.

2. Wash the sample loop (20- or 50-μl) with ≥1 ml deionized water.

3. Prepare ~30 or 60 μl (depending on the loop size used) of a 50 to 100 μM GTPase solution (1 to 2 mg/ml in the case of 21-kDa proteins such as Ras or Rho GTPases) in water or standard buffer, and load the entire 20- or 50-μl sample loop with it.

4. Inject the protein sample prepared in step 3 and monitor eluting nucleotides for 5 to 10 min (depending on the performance of the reversed-phase column and the flow rate; here 1.8 ml/min is used) by absorption at the appropriate wavelength.

   The absorption is detected at 254 nm for nonlabeled as well as mant-labeled nucleotides (for the latter, a factor of 0.6 is multiplied by the result, which is based upon the ratio of the extinction coefficient of nonlabeled and mant-labeled nucleotides). Molar extinction coefficients (at 254 nm) of 13,700 M^{-1} cm^{-1} for nonlabeled, 22,000 for mant-labeled, and 78,000 for tamra-labeled guanine nucleotides (measured at 546 nm) are employed. Due to ion–pair formation between the bulky hydrophobic tetrabutylammonium bromide and phosphate groups, the elution of the nucleotides is retarded with increasing phosphates. Concentrations of tamra-labeled GTPases are not determined by HPLC but spectrophotometrically at 546 nm.

5. Evaluate the nucleotide concentration using a linear absorbance profile of a nucleotide standard, e.g., 20 to 400 μM GDP. Calculate the area below a peak in the chromatogram using the HPLC integrator and correlate with the absorption of the respective probe. Use this value to determine the nucleotide concentration of the applied sample by comparison with a linear absorption profile that is generated with a nucleotide standard.

   Analogous to the calibration of the Bradford dye solution, the reversed-phase column can be calibrated using different GDP nucleotide samples of known concentration. In order to calibrate a column, GDP solutions in the range of 20 μM to 400 μM should be prepared,

and their concentrations should be verified spectrophotometrically. These samples can be then be applied to the column and their respective peak areas can be plotted versus the nucleotide concentration. Linear fitting of the data gives a regression line, and the slope represents a correlation factor between concentration and peak area.

ALTERNATE PROTOCOL 1

MEASUREMENT OF FAST GEF-CATALYZED NUCLEOTIDE EXCHANGE REACTIONS

For fast GEF-catalyzed nucleotide dissociation reactions, the time resolution of a fluorescence spectrometer is insufficient for a reliable data analysis. Instead, a stopped-flow instrument is routinely used for analysis of rapid kinetics as obtained by quantitative GEF-stimulated nucleotide exchange reactions. Here, equal volumes of two different 2× samples are automatically injected into a mixing chamber (in a single mixing mode), where the fluorescence can be detected directly after the rapid mixing (dead time ~2 to 5 msec). Five to eight identical measurements are recorded and averaged in order to obtain a higher degree of accuracy. The excitation wavelength for the mant-nucleotides is 366 nm and the fluorescence is detected with a cut-off filter mounted in front of a photomultiplier (408 nm for mant-nucleotides).

This is a fast and easy assay to obtain nucleotide exchange activities of GEFs toward the respective GTPases. Also, GEFs can be compared in respect to their specificity with different GTPases either by simply comparing nucleotide dissociation rates at given GEF and GTPase concentrations or by quantitative determination of Michaelis–Menten constant (K_m) and maximal dissociation rate (k_{max}). Such kinetic parameters can be obtained by using the above condition and increasing concentrations of the GEF proteins as described (Guo et al., 2005; Hemsath and Ahmadian, 2005).

***Additional Materials** (also see Basic Protocol 1)*

Stopped-flow instrument (Applied Photophysics SX18MV or Hi-Tech SF-61 DX2; *http://www.photophysics.com*)

NOTE: Because the samples are mixed 1:1, all stock solutions for components of the samples should be 2×.

1. Wash the drive syringes of the stopped-flow instrument several times with 5 to 10 ml GEF buffer and adjust the temperature to 25°C.
2. Prepare 2× samples in 1× GEF buffer at room temperature (~25°C) and a final volume of 1000 µl:
   a. One sample contains 0.2 µM of mantGDP-bound GTPase.

      Example: Dilute 2 µl from a 100 µM mantGDP-bound GTPase solution in 998 µl of GEF buffer to obtain a 0.2 µM solution of the respective mantGDP-bound protein.

   b. The other sample contains the GEF protein (at a concentrations ranging from 2 to 1000 µM, depending on the activity and affinity of the GEF for the respective GTPase), and 40 µM GDP (200-fold excess above mantGDP).

      A 10-fold excess of the GEF protein usually is a first choice to determine the activity of the GEF protein. Therefore, mix 20 µl from a 100 µM GEF solution (20 µM final concentration) and 4 µl from a 10 mM GDP solution (40 µM final concentration) in 976 µl with GEF buffer.
3. Load each sample into one of the two drive syringes of the stopped-flow instrument. Set the excitation wavelength for the mant-nucleotides to 366 nm and detect the fluorescence with a cut-off-filter mounted in front of a photomultiplier (408 nm for mant-nucleotides).

Signal-to-noise ratio can be considerably improved if all samples are centrifuged (>20 min, 20,000 × g, 4°C) and if the buffer is filtered and degassed.

The photomultiplier current should be adjusted manually to a value with a well balanced signal-to-noise ratio. More modern instruments are also able to set an optimal value automatically.

4. Start the measurement with the supplied stopped-flow software, which initiates pushing the contents of the two syringes containing the samples into the sample cell so that both samples join together and rapidly mix at a final volume of about 50 to 75 µl. Record the fluorescence using excitation at 366 nm and detection with a cut-off filter mounted in front of a photomultiplier at 408 nm for mant-nucleotides, for a defined time period (depending on the kinetics).

5. Repeat the mixing and fluorescence recording event up to 10 times until all volume in the drive syringe reservoir is consumed.

   Using 1000-µl samples, up to 11 identical measurements can be performed, from which the first three are required to equilibrate the sample cell. The fourth measurement can be used to reset the photomultiplier current and to determine the timescale for recording the complete reaction. Between 400 and 1000 data points should be recorded per measurement. Thus, about seven identical measurements can be repeatedly performed and averaged to obtain a mean value of all comparable curves. The single exponential data obtained corresponds to one averaged experiment at a defined GEF concentration.

6. Fit all data according to Hemsath and Ahmadian (2005) to obtain the observed rate constant (k_{obs}) for the respective concentration of the GEF protein.

MEASUREMENT OF GTPase-ACTIVATING PROTEIN (GAP)-STIMULATED GTP HYDROLYSIS BY HPLC

BASIC PROTOCOL 2

All small GTP-binding proteins, with a few exceptions, e.g., Rnd proteins, have a defined rate of GTP hydrolysis, which is often too low to be physiologically relevant. Thus, GAPs stimulate the very slow intrinsic reaction rate of GTP hydrolysis by several orders of magnitude, which is a critical step in signal transduction.

For the measurement of intrinsic and GAP-stimulated GTP-hydrolysis reaction of small GTPases, several assays have been developed so far. There are filter-binding and HPLC-based assays as well as spectrophotometric and spectrofluorometric methods available. A generally useful and accurate method is HPLC, by which concentrations of GDP and GTP can be determined to describe the reaction progress as described for Ras (Ahmadian et al., 1999) and Rho-proteins (Hemsath and Ahmadian, 2005).

HPLC needs large amounts of proteins and is not suitable for quantitative analysis of the GAP activity. In another approach, which is less material- and time-consuming, the GTPase reaction rates can be conveniently measured in real time using tryptophan fluorescence with an excitation wavelength of 295 nm and an emission wavelength of 350 nm. For example, the Ras(Y32W) mutant provides a large increase in fluorescence signal upon hydrolysis of GTP to GDP and inorganic phosphate, which has been used to study the mechanism of the intrinsic GTPase reaction (Ahmadian et al., 1999).

Stopped-flow experiments using mantGTP and mantGpp(NH)p (see Alternate Protocol 2) have provided key insights into the mechanism of the GAP-stimulated GTPase reaction of Ras in several studies (Ahmadian et al., 1997a,b, 2003). However, it should be noted that mantGTP does not work for most GTPase/GAP systems. A case in point is the interaction between Rho and RhoGAP, which, although similar in the type of enzymatic catalysis to the Ras–RasGAP interaction (Scheffzek and Ahmadian, 2005), does not show any fluorescence change upon interaction or hydrolysis.

Most recently, we have demonstrated that tetramethylrhodamine (tamra; see Alternate Protocol 4) is a powerful fluorescence reporter group to study the GTP-hydrolysis in the presence and in the absence of GAPs (Eberth et al., 2005). The intrinsic GTP-hydrolysis reaction of Ras and Rho GTPases can be detected in a fluorescence spectrometer or a stopped-flow instrument, showing a significant decrease in the fluorescence signal.

The HPLC method is an accurate way of determining the intrinsic hydrolysis rate of a GTPase and is also useful for determining a GAP protein's specific activity. The advantage is the lack of any artificial reporter group or necessity to use a GTPase mutant in this assay. Here wild-type proteins and unlabeled nucleotides can be used.

Materials

500 μM nucleotide-free GTPase (Support Protocol 2)
GAP buffer (see recipe)
10 mM GTP (Pharma Waldhof; *http://www.pharmawaldhof.de/*), pH 7.5
>50 μM GAP protein including the catalytic domains (recombinant protein, expressed and purified as described in Support Protocols 4 to 13)
Liquid nitrogen
HPLC buffer (see recipe) containing 7.5% (v/v) acetonitrile

Thermomixer/thermoblock
Beckman Gold HPLC instrument (Beckman Coulter)
Reversed-phase C18 HPLC column: Ultrasphere ODS, 5-μM; 250 × 4.6–mm (Beckman Coulter)
Guard column: Nucleosil 100-5-C18, 5-μM (Bischoff Chromatography)

1. Dilute 40 μl of 500 μM nucleotide-free GTPase with 60 μl GAP buffer and the GAP protein and preincubate it at 25°C in a thermomixer/thermoblock (the final concentration of the nucleotide-free GTPase should be 80 μM in a volume of 250 μl after addition of the GTP).

   The GAP protein can be used in a ratio of 1:100 to 1:1000 with respect to the GTPase concentration (0.8 to 0.008 μM in this example) and should be added in step 1 to the nucleotide-free GTPase before starting the reaction by addition of GTP.

2. Dilute 10 μl of 10 mM GTP stock solution with 990 μl GAP buffer (1:100 dilution) to obtain a 100 μM GTP solution, and preincubate this solution at 25°C in a thermomixer/thermoblock.

3. Add 150 μl of the 100 μM GTP solution (60 μM final concentration) and mix it with the 80 μM nucleotide-free GTPase solution by pipetting up and down.

   The total volume (in this case calculated for 8 time points) should be 250 μl, but depending on the number of data points to be taken, can be increased or even decreased.

   The timescale for the intrinsic GTP hydrolysis reaction varies from 0.5 to 6 hr, which depends on the GTPase variant used. Alternatively, a protein comprising a catalytic active GAP domain can be added before starting the reaction, which allows the determination of the activity and specificity of the GAP protein.

   Note that in the presence of the GAP, the reactions are much faster and the time scale (e.g., 1 to 5 min instead of 30 to 60 min for RhoGTPases) is much shorter. Using the conditions described here, the reaction is usually accelerated by a factor of 5 to 20 (depending on the dilution ratio of GAP with respect to GTPase and the activity of the GAP protein). In order to obtain reliable results, parameters including GAP concentration and the time points need to be optimized for the respective GTPase/GAP system.

   In the case of slow GTP-hydrolyzing GTPases (e.g., Ras or Rap) or GTP-hydrolysis, deficient Rho or Ras proteins GTP-bound proteins can be prepared and stored at −80°C for several weeks.

Depending on the sensitivity of the HPLC, the concentrations of GTPase and GTP can be reduced to 25 μM and 20 μM, respectively.

4. At defined time points, collect and immediately snap-freeze 30-μl samples in liquid nitrogen.

   Proper time points and intervals are important for an appropriate evaluation of the data to determine the rate constant of the hydrolysis reaction. These need to be adjusted to the activity of the respective GTPases. In principle, 7 to 8 time points are enough to cover a complete reaction. The intervals increase in the course of the reaction. For example 0, 1, 2, 5, 10, 15, 20, and 30 min have been used to determine the GTP hydrolysis reaction of the Rac proteins (Haeusler et al., 2003) and 0, 5, 10, 15, 20, 30, 40, 80, 150, and 200 min to determine that of H-Ras wild-type (Ahmadian et al., 1999).

5. Defrost each sample of the defined incubation interval at 95°C (using a thermoblock for about 10 sec) such that they are freshly thawed just before injecting on a reversed-phase analytical HPLC system.

   The HPLC system should be equipped with a guard column in between the injector valve and the analytical C18 reversed phase column. The buffer condition used for the separation of non-fluorescently-labeled nucleotides is HPLC buffer (see Reagents and Solutions) containing 7.5% acetonitrile. The retention time of guanine nucleotides on such an HPLC system and under the described isocratic conditions correlates with the number of phosphate groups of the nucleotide (retention order: GMP, GDP, and then GTP).

6. Determine the amount of each nucleotide immediately, using the HPLC integrator, from the area integration of the GTP- and GDP-peaks, respectively.

   These values are used to calculate the relative content of the GTP-bound GTPase species from the ratio (GTP)/(GTP) + (GDP).

   GTP content (y-axis) can be plotted versus the incubation time of the respective sample (x-axis) and fitted with a single exponential. Intrinsic GTP-hydrolysis rates of small GTPases usually are in the region of 0.0005 to 0.5 min^{-1}.

MEASUREMENT OF SLOW GAP-STIMULATED GTP HYDROLYSIS USING mantGTP

ALTERNATE PROTOCOL 2

Since there is almost no difference in the fluorescence signal between mantGTP and mantGDP, mantGTP-hydrolysis by the GTPase cannot be monitored directly. However, association of GAPs with the mantGTP-bound GTPase provides a tool to measure GAP-stimulated GTP-hydrolysis reaction, as shown for the Ras and RasGAP proteins (Ahmadian et al., 1997a). The GAP-stimulated GTP hydrolysis can be recorded with a stopped-flow instrument as a consequence of rapid association and dissociation of the GAP protein. Since this assay accounts only for the Ras/RasGAP system, here, the specific proteins Ras and the catalytic domain of p120RasGAP are mentioned as an example.

Additional Materials *(also see Basic Protocol 2 and Alternate Protocol 1)*

10 mM mantGTP (synthesized as described in Hemsath and Ahmadian, 2005 or purchased from Jena Biosciences) bound to Ras, pH 7.5
20 μM catalytic domains of RasGAP protein (e.g., $p120^{RasGAP}$) or any other GAP protein specific for Ras (expressed and purified as in Support Protocols 4 to 13)
Stopped-flow instrument (Applied Photophysics SX18MV or Hi-Tech SF-61 DX2)

NOTE: Because the samples are mixed 1:1, all stock solutions for components of the samples should be 2×.

1. Wash the drive syringes of the stopped-flow instrument several times with 5 to 10 ml GAP buffer and adjust the temperature to 25°C.

2. Charge one drive syringe with 2 μM mantGTP-bound Ras and fill the other syringe with 20 μM catalytic domains of the RasGAP protein (e. g., $p120^{RasGAP}$) in GAP buffer at 25°C.

3. Set the excitation wavelength to 366 nm (as for all mant-nucleotides) and restrict the emission light to >408 nm by a corresponding cut-off-filter.

   The same rules concerning volumes to prepare and photmultiplier settings described in Alternate Protocol 1 also apply to this assay.

4. After the initial injections to prepare the system for reliable data recording, carry out individual measurements, which usually show a rapid decrease of fluorescence.

   Change in fluorescence is, in this case, due to the GAP dissociation from the GDP-bound Ras after GTP hydrolysis. This implies a preceding fluorescence increase upon GAP association with the GTP-bound Ras, which cannot be resolved temporally by the stopped-flow machine due to the large rate constant of the association process. Depending on the rate constant of the association it is possible to observe (by a stopped-flow system with a short dead time) both association and GTP hydrolysis in one experiment, following subsequent dissociation of the Ras-RasGAP complex, which allows mechanistic studies (Ahmadian et al., 1997a,b).

   These measurements are in principle performed using the same procedure and conditions described in Alternate Protocol 1.

ALTERNATE PROTOCOL 3

MEASUREMENT OF SLOW GAP-STIMULATED GTP HYDROLYSIS USING tamraGTP

In contrast to other fluorescent nucleotide derivatives, including the mant-nucleotides, tamraGTP (a ribose hydroxyl-substituted tetramethylrhodamine derivative of GTP) enables us to measure the intrinsic and GAP-stimulated GTPase reactions of Rho and Ras proteins using fluorescence spectroscopy (Eberth et al., 2005). Besides much lower consumption of proteins and nucleotides as compared to the HPLC-based assay, the tamraGTP hydrolysis assay allows monitoring the real-time kinetics of the hydrolysis reaction of the Ras and Rho families. Intrinsic and GAP-stimulated hydrolysis reactions are recorded by a fluorescence spectrometer at an excitation wavelength of 546 nm and an emission wavelength of 583 nm, with an integration time of at least 2 sec and a recording time for each data point of 20 sec.

Additional Materials *(also see Basic Protocol 2)*

2 mM tamraGTP (synthesized as described in Eberth et al., 2005), pH 7.5
50 μM nucleotide-free GTPase (Support Protocol 2) in GAP buffer (see recipe for buffer)

Fluorescence cuvettes, Suprasil quartz glass; Hellma, cat. no. 108.002F-QS
Fluorescence spectrometer (Perkin Elmer, Spex Instruments)
Grafit program (Erithacus Software) or alternative program packages for evaluation of the data

1. Preincubate a solution of 0.1 μM tamraGTP (prepared from 2 mM stock solution) in a fluorescence cuvette in GAP buffer (stored at 25°C) with the GAP protein, at a final volume of 600 μl at 25°C for at least 5 min.

   The GAP protein would be added in step 1 to the tamraGTP before the reaction is started by addition of nucleotide-free GTPase in step 2.

2. Add 1.8 μl of 50 μM stock solution of nucleotide-free GTPase (0.15 μM final concentration), to observe complex formation with the nucleotide through a strong increase in fluorescence.

   Alternatively, four parallel measurements can be performed simultaneously using an instrument equipped with an automated four-position turret.

3. After this initial phase of nucleotide association, monitor the significant fluorescence decay as a result of GTP hydrolysis, which lasts between 0.5 and 6 hr, depending on the GTPase variant used (Eberth et al., 2005).

   Such an intrinsic reaction is significantly faster in the presence of a catalytic amount of a GAP protein (0.001 μM to 1 μM, depending on the specific activity of the GAP protein).

   TamraGTP fluorescence cannot be used for Rab, Ran, alpha-subunits of the heterotrimeric G-proteins, and elongation factors (Eberth et al., 2005).

4. Continue the measurement until no further decrease in fluorescence can be observed.

5. Evaluate data obtained by single-exponential fitting with a scientific software, e.g., the Grafit program.

MEASUREMENT OF FAST GAP-CATALYZED GTP HYDROLYSIS WITH tamraGTP

ALTERNATE PROTOCOL 4

The following protocol measures GAP-stimulated tamraGTP hydrolysis by a stopped-flow instrument as described in Alternate Protocol 1, except that an excitation wavelength of 546 nm is employed and a cut-off-filter of 570 nm in front of a photomultiplier is used to detect the fluorescence.

Additional Materials *(also see Basic Protocol 2 and Alternate Protocol 1)*

tamraGTP (synthesized as described in Eberth et al., 2005; 2 mM in deionized H_2O, pH 7.5)
Stopped-flow instrument (Applied Photophysics SX18MV or Hi-Tech SF-61 DX2)

NOTE: Because the samples are mixed 1:1, all stock solutions for components of the samples should be 2×.

1. Wash the drive syringes of the stopped-flow instrument several times with 5 to 10 ml GAP buffer and adjust the temperature to 25°C.

2. Prepare 2× samples in GAP buffer at room temperature (~25°C) and a final volume of 1000 μl:

   a. One sample contains 0.3 μM nucleotide-free GTPase and 0.2 μM tamraGTP.

   b. The other sample contains the GAP protein (at a concentration ranging from 0.2 to 200 μM, depending on the activity and affinity of the GAP for the respective GTPase).

      Example: (1) prepare the GAP solution by diluting the concentrated GAP protein to a defined concentration between 0.2 to 200 μM in GAP buffer. (2) Dilute 6 μl from a 50 μM solution of nucleotide-free GTPase (0.3 μM final concentration) in 984 μl GAP buffer and add 10 μl from a 20 μM tamraGTP solution (0.2 μM final concentration) just prior to loading the drive syringes of the stopped-flow instrument with your sample. The latter sample is prepared immediately before starting the measurement in order to avoid intrinsic tamraGTP-hydrolysis, particularly in the case of rapidly GTP-hydrolyzing proteins such as Rho GTPases.

      In the case of slow GTP-hydrolyzing GTPases (e.g., Ras or Rap) or GTP-hydrolysis-deficient Rho or Ras proteins, tamraGTP-bound proteins can be prepared and stored at −80°C for several weeks.

      Using 1000-μl samples, up to 11 identical measurements can be sequentially performed, from which the first three are required equilibrate the sample cell. The fourth measurement can be used to reset of the photomultiplier current and to determine the timescale for recording the complete reaction.

The photomultiplier current should be adjusted manually to a value with a well-balanced signal-to-noise ratio. Alternatively, modern instruments are also able to set an optimal value automatically.

The single-exponential data obtained corresponds to one experiment at a defined GAP concentration.

To obtain k_{cat} and K_d values, increase GAP concentrations as described (Eberth et al., 2005).

3. Continue as described in steps 3 to 6 of Alternate Protocol 1, except use 546 nm as excitation wavelength and a 570 nm cutoff filter mounted in front of the photomultiplier.

SUPPORT PROTOCOL 4

GENE EXPRESSION AND BACTERIAL CULTURE CONDITIONS

For the optimization of synthesis of a protein of interest in *E. coli*, various culture conditions should be examined including concentration of isopropyl-D-thiogalactopyranoside (IPTG; the inducer of lac-promoter-controlled gene expression), optical density of culture at IPTG induction, and, particularly, the temperature and culturing time. These culture-condition tests should be performed in small-scale (20 to 50 ml) pilot studies prior to scaling up to large-scale cultures for preparative protein expression. To improve the maximal recovery, we alternatively used, besides *E. coli* strain BL21 (DE3), strains containing additional plasmids such as BL21 pLys S (to improve bacterial lysis and for the expression of toxic proteins), and BL21 Codon Plus RIL or Rosetta (DE3) (to improve the codon usage).

All recombinant proteins described in this unit, including GTPases, GEFs, GAPs, and their catalytically active fragments are expressed in *E. coli* and purified using the methods described in this and the following support protocols.

Materials

Escherichia coli strain: BL21(DE3), BL21(DE3) Codon plus RIL, BL21(DE3) pLysS, or Rosetta (DE3) (Novagen) containing prokaryotic expression plasmid carrying gene for protein of interest
Terrific broth medium (TB medium; see recipe)
Appropriate selection antibiotics
Isopropyl-β-D-thiogalactopyranoside (IPTG; Gerbu Biochemicals, *http://www.gerbu.de*)
Wash buffer (see recipe)

150- to 1000-ml and 5-liter sterilized Erlenmeyer flasks
Horizontal environmental shaker incubator (Infors HT, *http://www.infors-ht.com/*)
1000-ml and 30- to 250-ml centrifuge bottles
Centrifuge: Avanti J-20 XP (Beckman Coulter) or equivalent
6-liter rotor: JLA-8.1000 (Beckman Coulter) or equivalent
50-ml plastic tubes

1. Grow 30 to 250-ml precultures of the desired *E. coli* strain in TB medium in a 150- to 1000-ml flask overnight at 37°C.

   Remember to add the required antibiotics to the TB medium to maintain transformed plasmids. If using BL21 (DE3) Codon plus RIL, BL21 (DE3) pLysS, or Rosetta (DE3) strains, chloramphenicol (25 mg/liter) needs to be added.

2. Fill each 5-liter Erlenmeyer flask to be used with 2.5 liter TB medium. Inoculate each flask with 25 ml of an overnight preculture.

   Cultivations usually are carried out in 2.5- to 20-liter scale, depending on the expression level and yield of the particular protein.

3. Place the inoculated culture flasks in a horizontal environmental shaker and let them grow at 37°C and 160 rpm.
4. When the logarithmic growth phase is reached (OD_{600} = 0.4 to 0.8), lower the temperature to the previously determined optimal expression condition (usually 18° to 30°C), and add IPTG (usually 0.05 mM to 0.5 mM; depending on pilot tests of expression conditions) to induce gene expression.

   The small GTPases as well as GEF and GAP proteins including their catalytic domains are usually expressed at an optical density of OD_{600} = 0.6 to 0.8, with 0.1 mM IPTG, and at 18° to 25°C overnight.
5. Perform the incubation either overnight, or for only 2 to 4 hr in difficult cases, depending on the results from the optimization of expression tests.
6. Transfer the cells to 1000-ml centrifuge bottles and harvest the cells by centrifugation for 15 min at 6000 × *g*, 4°C, using a 6-liter rotor if available. Repeat this step several times if the culture volume exceeds the capacity of the available rotor.
7. Wash the bacterial pellet in each rotor bottle with 20 ml wash buffer. Combine the resuspended cell pellets into a smaller (30- to 250-ml) rotor bottle (tared) and centrifuge again for 20 min at 6000 × *g*, 4°C.

   This step is carried out in order to remove residual medium.
8. Discard the supernatant and weigh the bacterial pellet–containing bottle. Determine the weight of the bacterial pellet and resuspend it in wash buffer (3 ml/g bacterial pellet) or any other proper buffer that is suitable for solubilizing and stabilizing the desired protein. Prepare aliquots in 50-ml plastic tubes.
9. Store aliquots at −20°C.

   In addition to cryopreserving the sample, freezing will also help to improve the efficiency of bacterial lysis.

BACTERIAL LYSIS BY SONICATION

SUPPORT PROTOCOL 5

An efficient bacterial lysis is an important prerequisite for the complete recovery of expressed recombinant protein. Cell walls of bacteria which have produced proteins of interest must be disrupted in order to allow access to intracellular components. Different methods have been developed to achieve this goal; they vary considerably in the severity of the disruption process, reagents needed, and the equipment available. Besides enzymatic methods using lysozyme treatment, which is suitable for analytical scale and not always reproducible, there are several mechanical methods—including glass bead, cell bomb, French press, sonication, and microfluidizer—to gently disrupt bacterial cell walls. We commonly use the latter two methods, both of which are efficient and fairly quick. This protocol describes sonication, which permits cell disruption in smaller samples (≥200 µl and ≤200 ml).

Materials

70% ethanol
Bacterial sample (Support Protocol 4)
Pefabloc (ICN Biochemicals)
Lysozyme (Sigma-Aldrich)
DNase I (Sigma-Aldrich)
Sonicator: Branson Sonifier S-450A and 3- to 19-mm titanium probe

NOTE: The protease inhibitor Pefabloc (0.02% w/v) and lysozyme (2 µg/ml suspension), as well as DNase I (10 µg/ml suspension) are added to the bacterial suspension before lysis.

1. Equip the cell sonicator with a titanium probe of 3- to 19-mm diameter (depending on the culture volume to be disrupted) and clean it before use with 70% ethanol.

   Use a 3-mm sonifier probe for volumes of 2 to 50 ml and a 19-mm probe for volumes of 50 to 500 ml.

2. Transfer the thawed bacterial suspension from all aliquots to a beaker of suitable size and place it on ice.

3. Place the sonicator probe about 0.5 to 1 cm beneath the surface into the suspension.

4. Start the sonication procedure by increasing the output control (add 5 to 10 W each time) at 10-sec intervals starting with 30 W and ending with ~95 W. Repeat this procedure eight to twelve times, and always wait 30 sec in between to prevent overheating of the sample. Keep the beaker with the bacterial solution on ice during the entire procedure.

   Optionally, the wave duty cycle function of the ultrasonic instrument can be used to reduce heat production and free radical formation.

   A color change from very milky to slightly more translucent should be observed and can act as an indicator for cell disruption.

SUPPORT PROTOCOL 6

BACTERIAL LYSIS USING A MICROFLUIDIZER

The microfluidizer is an instrument that uses high pressure to squeeze the bacterial solution through a flux cell containing a narrow channel, thereby generating high shear forces that pull the cells apart. The system permits controlled cell breakage and does not require addition of detergent or higher ionic strength. Since heat is generated during this process, the flux cell needs to be cooled. The microfluidizer system provides a convenient and efficient method for cell lysis of larger cell suspensions (≥20 ml to several liters).

Materials

Bacterial sample (Support Protocol 4)
Buffer to be used for protein purification
Pefabloc (ICN Biochemicals)
Lysozyme (Sigma-Aldrich)
DNase I (Sigma-Aldrich)
100% 2-propanol
Microfluidizer (Microfluidics Corp., *http://www.microfluidicscorp.com*)

NOTE: The protease inhibitor Pefabloc (0.02% w/v) and lysozyme (2 μg/ml suspension) as well as DNase I (10 μg/ml suspension) are added to the bacterial suspension before lysis.

1. Wash the instrument extensively with water. For a final wash step, use the standard buffer for the protein purification.

   This will remove all traces of alcohol in which the instrument is usually stored to prevent microbial growth.

2. Pour the thawed bacterial suspension into the instrument's reservoir and turn on the instrument

   Direct the flow of the instrument's outlet toward the wall of a beaker to prevent foam formation.

3. Prevent intake of air on the inlet, as this will also produce foam and lead to protein denaturation. For this, turn off the instrument before air enters the instrument's inlet.

Wash with a small volume of standard buffer and switch the instrument on again. Stop again before air enters the inlet of the instrument.

By repeating this step two to three times, nearly all of the bacterial suspension will be processed.

4. If necessary, flush the bacterial solution two to three times through the instrument, until a color change from milky to slightly more translucent is observed.

5. Wash the instrument extensively with water and finally with 2-propanol, and store it in this solution.

PROTEIN PURIFICATION FOR GST FUSION PROTEINS

SUPPORT PROTOCOL 7

The use of proteins with high purity (>95%) is a mandatory prerequisite for investigation of protein structure-functional relationships. The use of recombinant protein expression systems and the development of a variety of fusion tags has facilitated the preparation of high-purity proteins dramatically. Nevertheless, choosing the right purification strategy is still a matter of trial and error and has to be discovered for each individual protein. The GST-fusion affinity purification system is a well established technique and works successfully for purification of GTPases and their regulatory proteins.

Materials

Bacterial lysate with an overexpressed GST-fusion protein
Glutathione-Sepharose 4B FF (GE Healthcare)
Standard buffer (see recipe)
Standard buffer (see recipe) containing 500 mM KCl and 1 mM ATP
Standard buffer containing 20 mM glutathione (adjusted to pH 7.5 with NaOH again after addition of glutathione)
0.01% (w/v) sodium azide *or* 20% (v/v) ethanol

Centrifuge: Avanti J-30I (Beckman Coulter) or equivalent
Rotor: JA-30.50 or JA-17 (Beckman Coulter) or equivalent
Äkta Sytem, e.g. Äkta Prime (GE Healthcare)
XK 26/20 chromatography column chassis (GE Healthcare)

Additional reagents and equipment for SDS-PAGE (*UNIT 6.1*) and Coomassie staining (*UNIT 6.6*)

Centrifuge lysate

1. Separate insoluble constituents from the bacterial lysate by centrifuging 40 min at 35,000 to 100,000 × *g*, 4°C.

If possible, centrifuge at 100,000 × g to remove as much insoluble cell debris as possible. If such a high-speed rotor/centrifuge is not available, a minimal force of 35,000 × g might also be sufficient.

Prepare glutathione-Sepharose column

2. Equilibrate an XK 26/20 column packed with Glutathione-Sepharose (≥25-ml bed volume) with ~3 to 4 column volumes of standard buffer until a stable baseline is reached. Monitor absorption at 280 nm using the Äkta System.

3. After centrifugation apply the cleared bacterial lysate onto the Glutathione-Sepharose column (at 4 ml/min, if using fast-flow material).

4. After all lysate is applied, wash with standard buffer until the baseline at 280 nm is reached again.

5. Wash with 2 to 4 column volumes standard buffer containing 500 mM KCl and 1 mM ATP in order to elute nonspecific proteins, especially chaperones that might

be associated with the desired protein. Afterwards, wash again with standard buffer until the baseline at 280 nm is reached.

High amounts of chaperones indicate folding difficulties with the protein of interest.

Note that the baseline increases due to 1 mM ATP and drops down after changing to the standard buffer with no ATP.

6. Elute GST-fusion proteins from the column with 100 to 150 ml standard buffer containing 20 mM glutathione. Collect fractions of 2- to 5-ml volume using the fraction collector provided with the Äkta system.

   The pH value of the standard buffer needs to be readjusted to 7.5 with NaOH after addition of glutathione.

7. Analyze peak fractions by SDS-polyacrylamide gel electrophoresis (SDS-PAGE; *UNIT 6.1*) and Coomassie staining (*UNIT 6.6*).

8. Regenerate the column with 50 ml 5 M guanidine hydrochloride and wash with 100 to 150 ml standard buffer afterwards.

   If the column will not be used for a long period, it should be stored in a buffer containing 0.01% sodium azide, or, alternatively, in 20% ethanol solution.

SUPPORT PROTOCOL 8

DETERMINING PROTEIN CONCENTRATION USING THE BRADFORD ASSAY

There are different colorimetric and spectrophotometric methods to determine the concentration of proteins in a solution including the Lowry, the Smith copper/bicinchoninic assay, or the Bradford dye assay. We use both the Bradford dye assay and the Ehresmann UV method (Support Protocol 9) for determination of the concentration of a protein in solution as well as HPLC in the case of nucleotide binding proteins (also see *APPENDIX 3B* and *APPENDIX 3H*).

Materials

Protein solutions: standards (e.g., BSA or γ-globulin) and test sample
Bradford reagent (Coomassie dye reagent; Sigma, Pierce, Bio-Rad, or see *APPENDIX 3H*)
Spectrophotometer

1. Mix 0.5 ml of Bradford reagent with 1 to 20 μl of a protein solution. For the standard curve, mix 0.5 ml of Bradford reagent with 1 to 2 μl of different concentrations of a standard protein (e.g., BSA or γ-globulin) covering the range of 0.25 to 2 mg/ml.

   The reagent/protein solution should shift color to blue.

2. Incubate for 5 min at room temperature.

3. Measure the absorption of the sample at 595 nm.

   The absorption should be between 0.2 and 0.8 to guarantee correlation between absorption and concentration according to the Lambert-Beer law. If the absorption is too low or too high, concentrate or dilute the protein solution and reassay.

4. Determine the protein concentration using the linear absorbance profile of the protein standard.

   The Bradford dye solution can be calibrated using different concentrations of a standard protein like BSA or γ-globulin. The absorption values of the standards at 595 nm can be plotted versus the standard protein concentrations and fit by a linear equation. The slope of this regression line will represent a correlation factor between absorbance and protein concentration and can in principle be used for the determination of protein concentrations.

DETERMINING PROTEIN CONCENTRATION USING THE EHRESMANN ASSAY

SUPPORT PROTOCOL 9

This method is rather useful for small proteins or peptides, since their staining by the Bradford dye solution does not lead to a shift of the absorption maxima from 465 nm to 595 nm comparable to that of BSA or γ-globulin used as standard protein for calibration. This method cannot be used for nucleotide binding proteins, since the bound nucleotides also absorb at the wavelengths used.

Materials

Protein solution
Quartz cuvettes
UV/VIS spectrophotometer

1. Dilute the protein sample to ~50 μg/ml in deionized water.
2. Measure the absorption (using a quartz cuvette) of the dilution at 228.5 nm and 234.5 nm, and use deionized water as a reference.
3. Calculate the concentration by the following equation: $A_{228.5} - A_{234.5}/3.154 =$ mg/ml.

No protein standard is used here since the correlation between concentration and absorption is due to light absorption of the peptide backbone and not to reactive side chains of the proteins.

CONCENTRATING A DILUTE PROTEIN SOLUTION

SUPPORT PROTOCOL 10

There are a large variety of methods that can be used for concentrating a protein solution, including dialysis, ammonium sulfate precipitation (salting out), ion exchange followed by desalting chromatography, ultrafiltration or spin-filters, and trichloroacetic acid/deoxycholate precipitation.

We often use the ultrafiltration method by employing spin filters, which accumulate the protein at a membrane with a defined molecular weight cutoff (MWCO 5 to 100 kDa) while the solvent passes through.

Materials

Protein solution
Refrigerated centrifuge
Amicon filter, MWCO 5 to 100 kDa

1. Fill the Amicon device with the diluted protein solution and centrifuge at 2900 × *g*, 4°C.
2. Continue centrifuging either until a desired concentration is reached (10 to 20 mg/ml is a proper concentration for storage) or the volume is sufficient for further purification via gel filtration ($\leq$1% of the column volume).

It is important not to centrifuge to the point where all liquid in the reservoir passes through the membrane; this would lead to drying of the protein and consequently to denaturation.

THROMBIN PROTEOLYTIC CLEAVAGE OF GST FUSION PROTEINS

SUPPORT PROTOCOL 11

The fusion tag that helps to purify a recombinant protein from crude cell extracts should be removed when the protein is intended for use in structural or biochemical analysis. There are a variety of expression vectors available which have protease-specific cleavage sites inserted between the coding sequence for the fusion tag and the multiple cloning site.

The corresponding fusion protein can thus be processed with the appropriate protease and, finally, the fusion tag can be removed by further chromatographic purification steps. While this protocol is for thrombin cleavage of GST fusion proteins, it can be adapted for other enzyme/linker combinations.

Materials

GST-fusion protein
Thrombin (Serva)
End-over-end rotator

Additional reagents and equipment for SDS-PAGE (*UNIT 6.1*) and Coomassie staining (*UNIT 6.6*)

1. Cleave fusion proteins (at a concentration of ≥1 mg/ml) in batch by incubation with 1 U thrombin per mg GST-fusion protein for 4 to 16 hr at 4°C with end-over-end rotation.

   Other vectors containing PreScission, factor Xa, TEV, enterokinase, or IgA protease cleavage sites can alternatively be used if thrombin does not cleave (masked cleavage site) or additional thrombin cleavage sites are within the fusion protein.

2. Take 10 µl from the reaction mix after 4 hr and after the overnight incubation and analyze the cleavage progress by SDS-PAGE (*UNIT 6.1*) and Coomassie blue staining (*UNIT 6.6*).

   Usually, an overnight incubation at 4°C is sufficient for a quantitative cleavage of the fusion protein. In the SDS-PAGE gel, a band of 26 kDa for GST and a band of the size of the fusion partner will appear, whereas the band of the fusion protein at higher molecular size will disappear.

SUPPORT PROTOCOL 12

GEL-FILTRATION CHROMATOGRAPHY

Further purification and removal of protein impurities or small components including glutathione are achieved by size-exclusion chromatography (also called gel filtration) on the scale of 16/600 or 26/600 columns (meaning columns of 16- or 26-mm diameter and 600-mm length, respectively) using Superdex 75 or Superdex 200 medium.

Materials

Concentrated protein sample (after digestion of the fusion protein with the respective protease; see Support Protocol 10 for concentration and Support Protocol 11 for digestion)
Standard buffer (see recipe)

16/600 or 26/600 columns prepacked with Superdex 75 or Superdex 200 (GE Healthcare)
Äkta System, e.g. Äkta Prime (GE Healthcare)
Prepacked 16/600 or 26/600 columns with Superdex 75 or Superdex 200 resin (GE Healthcare)
1- to 5-ml sample loop (GE Healthcare)

Additional reagents and equipment for SDS-PAGE (*UNIT 6.1*), Coomassie staining (*UNIT 6.6*), and concentration of protein samples (Support Protocol 10)

1. Equilibrate the column with one column volume (120 ml for 16/600 Superdex or 320 ml for 26/600 Superdex) of standard buffer using the Äkta System.

   Use a 16/600 column for protein amounts of ≤40 mg or 26/600 column for ≥40 mg but ≤100 mg; when the protein amount to be purified exceeds 100 mg, divide the sample into several portions ≤100 mg and do several consecutive column runs. Use 120 ml of buffer for the 16/600 column and 320 ml buffer for the 26/600 column.

2. Mount a 1- to 5-ml loop (GE Healthcare) on to the Äkta System, flush it with standard buffer, and load with the concentrated protein (≥10 mg/ml).

   The volume of the concentrated protein sample to be injected should not exceed 1% of the column volume to guarantee efficient separation. In case of a 16/600 column this means that no more than 1.2 ml, and in case of a 26/600 no more than 3.6 ml of protein solution should be injected.

3. Collect 1- to 3-ml fractions with the Äkta fraction collector and analyze 10-µl samples by SDS-PAGE (*UNIT 6.1*) and Coomassie staining (*UNIT 6.6*).

4. Pool and concentrate the fractions containing the desired protein to 10 to 20 mg/ml (Support Protocol 10).

   If the gel filtration does not separate the GST fractions from the desired protein, a second affinity chromatography with glutathione-Sepharose is necessary to remove the GST completely.

FREEZING AND THAWING PROTEINS

SUPPORT PROTOCOL 13

Freezing and thawing of protein solutions is a very critical step and has a large impact on protein stability. It is absolutely mandatory to freeze a protein solution in liquid nitrogen and to store it afterwards at −20°C or even −80°C for storage. For longer storage periods, the latter is recommended. Before freezing a protein, try a small-scale test to verify that the protein can be frozen in a standard buffer and to test if addition of supplements like glycerol or sucrose might help to prevent protein denaturation during freezing. Thawing of protein solutions can either be performed rapidly at 37°C or slowly on ice. For each protein, the recommended strategy has to be elucidated in trials.

Materials

50- to 500-µl aliquots of purified protein (10 to 20 mg/ml)
Liquid nitrogen

1. Snap freeze 50- to 500-µl aliquots of purified proteins in liquid nitrogen, then store in −80°C freezer.

2. Thaw all proteins except nucleotide-free GTPases on ice. Thaw nucleotide-free GTPases at 37°C and immediately store on ice when defrosted.

   It is recommended to freeze and thaw an aliquot only once; otherwise, activity of the protein might be reduced due to repeated freezing/thawing cycles. Adjust the volume of the aliquots to the volume needed for the respective application. However, we have observed that most proteins described in this unit (GTPases and GTPase-regulators like GEF- and GAP-proteins) can in fact be frozen and thawed at least five times without any detectable loss of activity.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Exchange buffer, 10×

2 M $(NH_4)_2SO_4$
10 mM $ZnCl_2$
Filter and degas
Store up to several weeks at room temperature

GAP buffer

30 mM Tris·Cl, pH 7.5 (*APPENDIX 2A*)
10 mM $MgCl_2$
3 mM dithiothreitol (DTT)
10 mM potassium phosphate buffer,, pH 7.4 (*APPENDIX 2A*)
Filter and degas
Store up to several weeks at room temperature

GEF buffer

30 mM Tris·Cl, pH 7.5 (*APPENDIX 2A*)
5 mM $MgCl_2$
3 mM dithiothreitol (DTT)
10 mM potassium phosphate buffer, pH 7.4 (*APPENDIX 2A*)
Filter and degas
Store up to several weeks at room temperature

HPLC buffer

100 mM potassium phosphate buffer, pH 6.5 (*APPENDIX 2A*)
10 mM tetrabutylammonium bromide (e.g., Merck)
7.5% to 25% (v/v) acetonitrile as specified in protocol
Filter and degas
Store up to several weeks at room temperature

Standard buffer

30 mM Tris·Cl, pH 7.5 (*APPENDIX 2A*)
5 mM $MgCl_2$
3 mM dithiothreitol (DTT)
50 mM NaCl
Filter and degas
Store up to several weeks at room temperature

Terrific broth (TB) medium

12 g/liter Bacto-tryptone (BD Difco)
24 g/liter yeast extract (BD Difco)
0.4% (v/v) glycerol
2.31 g/liter KH_2PO_4
12.54 g/liter K_2HPO_4
Sterilize by autoclaving
Store up to 2 weeks at 4°C

Wash buffer

30 mM Tris·Cl, pH 7.5 (*APPENDIX 2A*)
5 mM $MgCl_2$
3 mM dithiothreitol (DTT)
100 mM NaCl
Filter and degas
Store up to several weeks at room temperature

COMMENTARY

Background Information

Fluorescence techniques to study the intrinsic properties of GTPase-like nucleotide binding, nucleotide exchange, or GTP hydrolysis have been evolving over more than two decades. They were pioneered by Toshiaki

Hiratsuka and Roger S. Goody (Alexandrov et al., 2001; Hiratsuka, 2003). Since that time, further development has been going on, with the design of new fluorescent molecules, enhanced technical instrumentation, and new applications to study biochemical reactions and processes.

Fluorescence-based GEF and GAP assays described in Basic Protocols 1 and 2 and Alternate Protocols 1 through 4 are convenient methods to study the process of nucleotide release or hydrolysis. It has been shown that the extrinsic fluorophore usually does not influence these reactions. Fluorescence-based assays allow real-time monitoring of ligand- and protein-protein interactions at submicromolar concentrations, as well as quantification of the kinetic and equilibrium constants.

Critical Parameters and Troubleshooting

Spectroscopic measurements like the fluorescence assays described in this unit require the use of very clean quartz cuvettes, filtered and degassed buffers, and protein solutions without precipitate or any other solid material. Otherwise, light dispersion will take place and the signal-to-noise ratio will deteriorate. It is, therefore, very important to centrifuge the protein solution immediately before using it in assays.

To obtain reliable and reproducible kinetic data, the protein and nucleotide quality need to be high. Thus, nucleotides with >90% purity should be used and, if necessary, additional purification steps should be carried out to obtain nucleotides and proteins of a high purity. For HPLC measurements, the performance of the guard and main columns are essential for an optimal separation of the nucleotides. Washing the system with filtered and degassed deionized water should be carried out daily to prevent valve blockage by buffer salts. Regeneration of the columns should be accomplished periodically according to the column manufacturer's instructions to maintain separation performance.

When purifying guanine nucleotide–binding proteins, it is mandatory to add both GDP and magnesium ions to the buffer; they are essential especially in the case of low-affinity GDP/GTP-binding proteins, and will increase the protein stability.

Releasing the GTPase from GDP (or GTP in the case of the constitutive mutants) and loading with fluorescent nucleotides, as described above, are prerequisites to perform fluorescence measurements. The incubation time for preparing the nucleotide-free proteins varies among GDP/GTP-binding proteins, and has to be established for every GTPase.

The amounts of proteins and (fluorescent) nucleotides required are rather dependent on the assay used. For the determination of intrinsic nucleotide dissociation or intrinsic GTP hydrolysis in a cuvette (at a final volume of 600 μl), ~10 to 20 μg of nucleotide-bound GTPase is required for three identical experiments. At least 60 μg of catalytic domains of GEF or GAP proteins (250 to 300 amino acids) is needed for one experiment to measure the specificity and activity of these regulatory proteins. A stopped-flow experiment requires 3 to 5 μg GTPase, but provides an averaged value obtained from five to seven identical measurements. A stopped-flow analysis of the specificity of GEFs or GAPs requires about 15 to 50 μg of these proteins. However, between 2 and 10 mg of the catalytic domains will be required to quantitatively analyze the GEF or GAP activities.

It is recommended to perform each experiment using a negative and a positive control sample. The negative sample, necessary in order to have correct instrument settings, is assessed by measuring free fluorescent nucleotide in the absence of GTPase. The positive sample, necessary in order to make sure that the method works, is assessed by using known proteins, for example Ras, to measure intrinsic nucleotide dissociation and GTP-hydrolysis as well as GTPases in combination with their specific GEFs (e.g., Ras/Sos1, Rac1/Tiam1, Cdc42/Asef or RhoA/p115) or GAPs (Ras/p120, Rho GTPases/p50).

Anticipated Results

The elucidation of the molecular switch mechanism of the GTPases and particularly their specificities and affinities for regulators require the dissection of such interactions at the molecular level by utilizing a sensitive biochemical assay. Fluorescence spectroscopic methods provide researchers with a number of tools for studying the intercommunication of a GTPase with nucleotides and binding partners. Compared to other qualitative assays (e.g., filter-binding assay or thin-layer chromatography, which contain between three and six time points), fluorescence methods described in this unit allow monitoring of the activity of the GEFs and GAPs in real time, where every single measurement consists of at least 400 data points per reaction trace. These assays are highly sensitive and, in principle, reproducible presuming: (1) that the proteins of

interest do not reveal the expected activity; and (2) that the proteins and reagents are carefully prepared from high-purity materials and tested for quality. Thus, optimal gene expression and protein purification as well as sufficient quality of fluorescent nucleotide-bound GTPases and other components including GEF and GAP proteins and nucleotide derivatives are prerequisites for reliable and reproducible measurements. In all assays described in this unit, a decrease in fluorescence should be monitored in a time-dependent manner. However, another important aspect to be considered is the fluorescence offset, which represents the actual fluorescence signal value before the fluorescence decay is initiated by starting the reaction. This should be relatively similar for all experiments (1) when using the same instrument settings (e.g. the same monochromator slit with in a fluorescence spectrometer and photomultiplier tension in case of the stopped-flow instrument); (2) under the same concentrations of the fluorescent nucleotides in the complex with the GTPase; and (3) independent of the GEF or GAP concentrations.

The fluorescence-based assays described in this unit are quite sensitive methods which give proper results even if using submicromolar protein and nucleotide concentrations. The fluorescence decay followed over time is usually in the range of 40% to 60% in the case of nucleotide exchange experiments (GEF assay) and 10% to 15% in the case of the fluorescence GTP hydrolysis assay using tamra-GTP.

Time Considerations

The expression of a protein in *E. coli* takes about 2 days, including inoculation of the culture and induction of gene expression. On the second day, the culture is harvested, washed, resuspended, and stored in a buffer solution. When the expression is carried out for only 2 to 4 hr, all steps should be performed in 1 day. The purification of a protein usually involves several steps. It takes about 1 day to do the affinity chromatography, to elute, to analyze by SDS-PAGE, and to concentrate the fusion protein before the overnight protease digestion. On the next day, the protein can be applied to the size-exclusion chromatography (gel filtration) and subsequently analyzed by SDS-PAGE. Optionally, a second affinity chromatography may need to be carried out to completely remove the tag; it can be performed immediately after gel filtration. Finally the protein needs to be concentrated, which may take several hours, before it can be frozen in small aliquots and stored at –80°C.

The preparation of Gpp(NH)p-bound and mantGpp(NH)p-bound GTPases takes 2 to 48 hr, and usually can be carried out overnight. The generation of a nucleotide-free GTPase involves the same step followed by the phosphodiesterase reaction for another 2 to 30 hr until $Gpp(CH_2)p$ is completely degraded. The loading of a nucleotide-free GTPase with mant-GDP can be performed in 1 to 2 hr.

GEF measurements in a fluorescence spectrometer usually take at least 16 hr before the intrinsic nucleotide dissociation in the absence of the GEF protein is recorded. GEF-accelerated processes usually take less than 1 hr. Stopped-flow experiments are performed at higher concentrations of the GEF protein and are, thus, quite fast reactions on the order of seconds or even milliseconds. For quantitative measurements and evaluation of the data, 2 to 3 hr should be allowed.

Intrinsic GTP-hydrolysis measurements for small GTPases take 0.5 to 6 hr (depending on the GTPase), whereas the presence of catalytic amounts of a GAP protein advances the reaction to a 0.5- to 30-min process. Quantitative measurements using increasing GAP concentrations are also very fast and complete after a few seconds or even milliseconds.

In Vivo Imaging of Signal Transduction Cascades with Probes Based on Förster Resonance Energy Transfer (FRET)

Takeshi Nakamura[1] and Michiyuki Matsuda[1]

[1]Laboratory of Bioimaging and Cell Signaling, Graduate School of Biostudies, Kyoto University, Kyoto, Japan

ABSTRACT

Genetically encoded FRET probes enable us to visualize a variety of signaling events such as protein phosphorylation and G-protein activation in living cells. This unit focuses on FRET probes wherein both the donor and acceptor are fluorescence proteins and incorporated into a single molecule, i.e., a unimolecular probe. Advantages of these probes lie in their easy loading into cells, simple acquisition of FRET images, and clear evaluation of data. We have developed FRET probes for Ras-superfamily GTPases, designated Ras and interacting protein chimeric unit (Raichu) probes. We hereby describe strategies to develop Raichu-type FRET probes, procedures for their characterization, and acquisition and processing of images. Although improvements upon FRET probes are still based on trial-and-error, we provide practical tips for their optimization and briefly discuss the theory and applications of unimolecular FRET probes. *Curr. Protoc. Cell Biol.* 45:14.10.1-14.10.12. © 2009 by John Wiley & Sons, Inc.

INTRODUCTION

Signal transduction is an organized ensemble of dynamic state changes in signaling molecules, which is often caused by phosphorylation and guanine nucleotide exchange reactions. Needless to say, the timing and localization of these events critically influence the outcomes. To visualize such spatio-temporal changes in the activity of signaling molecules, several research groups have been developing probes based on the principle of Förster resonance energy transfer (FRET; Miyawaki, 2003; Kiyokawa et al., 2006). FRET is a radiation-less transfer of excited-state energy from a donor fluorophore to an acceptor fluorophore (Lakowicz, 2006). This unit focuses on FRET probes wherein both the donor and acceptor fluorophores are proteins and incorporated into a single molecule, i.e., genetically encoded unimolecular probes. The advantages of these probes lie in their easy loading into cells, simple acquisition of FRET images, and clear evaluation of the data (Kurokawa et al., 2004). Another type of FRET probe, namely, the bimolecular probe, is preferably used for monitoring protein-protein interactions (*UNIT 21.3*; also see *UNITS 17.1 & 17.9*).

A major application of unimolecular FRET probes is the monitoring of protein kinase activities. The activities of EGF receptor, Src, PKA, and PKC have been successfully monitored by FRET probes containing the specific substrate peptides for each kinase (Kurokawa et al., 2001; Ting et al., 2001; Zhang et al., 2001; Violin et al., 2003; Wang et al., 2005). Furthermore, FRET probes that monitor the activation-related conformational change have also been developed for PKC, Raf, Erk, and CaMKII (Braun et al., 2005; Takao et al., 2005; Terai and Matsuda, 2005; Fujioka et al., 2006). Visualization of the "on" and "off" states of Ras-superfamily GTPases is another valuable application of unimolecular FRET probes; such FRET probes developed in the authors' laboratory

Current Protocols in Cell Biology 14.10.1-14.10.12, December 2009
Published online December 2009 in Wiley Interscience (www.interscience.wiley.com).
DOI: 10.1002/0471143030.cb1410s45

are collectively designated Ras and interacting protein chimeric unit (Raichu) probes (Mochizuki et al., 2001).

The following procedure describes the development of Raichu-type FRET probes and the use of these probes to visualize the activation state of GTPases.

BASIC PROTOCOL 1

DEVELOPMENT OF RAICHU FRET PROBES

Raichu probes are composed of four modules: donor (CFP), acceptor (YFP), a GTPase, and the GTPase-binding domain of its binding partner (Fig. 14.10.1). In the Raichu probes for Ras-family GTPases, YFP, GTPase, GTPase-binding domain, and CFP are sequentially connected from the N-terminus by spacer peptides (Mochizuki et al., 2001). A typical mode of action of Raichu is as follows. In the inactive GDP-bound conformation, CFP and YFP are located at a distance from each other. Therefore, excitation of CFP results in emission mostly from CFP. Upon stimulation, GDP on the GTPase is exchanged for GTP, which induces an interaction between the GTP-bound GTPase and the GTPase-binding domain. This intramolecular binding brings CFP within close proximity to YFP, thereby permitting energy transfer from CFP to YFP. FRET is manifested by a quenching of CFP fluorescence and an increase in sensitized emission of YFP; therefore the fluorescence intensity ratio of YFP versus CFP can be conveniently used as a representation of FRET efficiency. This YFP/CFP value of the Raichu-expressing cells correlates with the molecular ratio of GTP-bound probes versus GDP-bound probes, which reflects the balance between guanine nucleotide exchange factors (GEFs) and GTPase-activating domains (GAPs) for the GTPase within the probe (Mochizuki et al., 2001; Yoshizaki et al., 2003). Therefore, the activities of endogenous GTPases, which are under the control of the same set of GEFs and GAPs, can be estimated by measuring the YFP/CFP ratio of Raichu-expressing cells.

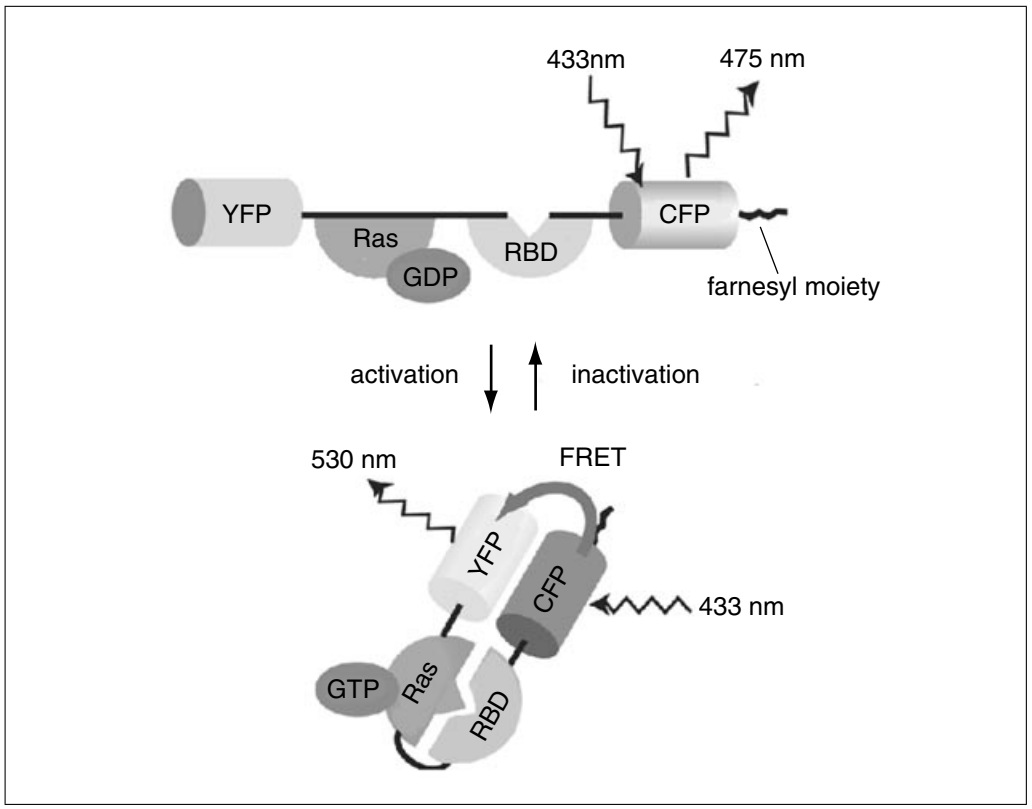

Figure 14.10.1 Basic structure of the GFP-based FRET probe for Ras GTPases (Raichu-Ras). The FRET probe for Ras activation comprises H-Ras and the Ras-binding domain (RBD) of Raf sandwiched between YFP and CFP. For plasma-membrane localization, this probe is fused to the carboxyl-terminal region of K-Ras4B. Upon stimulation, GDP on Ras is exchanged for GTP, and FRET occurs.

Materials

Needed DNA constructs:

- Plasmid for the Raichu probe (available from Matsuda Lab, *http://www.path1.med.kyoto-u.ac.jp/mm/e-phogemon/index.htm*)
- cDNA of the GTPase of interest (can either be purchased from a public depository or cloned by PCR from cDNA libraries)
- cDNA of GTPase-binding domains of effector proteins (can either be purchased from a public depository or cloned by PCR from cDNA libraries; try at least a few known effectors for initial experiments)

Ion-exchange resin for DNA purification (e.g., Qiagen; also see Ausubel et al., 2009)

Transfection reagent for calcium phosphate coprecipitation (*UNIT 20.3*)

293T cells (ATCC cat. no. CRL-11268), cultured in 100-mm-diameter collagen-coated dishes, 80% confluent

MEM (Invitrogen, cat. no. 10370) containing 10% fetal bovine serum (FBS)

Phenol-red-free MEM (Invitrogen, cat. no. 11054) containing 10% FBS

Lysis buffer (see recipe)

Fluorescence spectrophotometer (for example, JASCO FP-750) and 3-ml cuvettes

Additional reagents and equipment for basic molecular biology techniques including restriction digestion, PCR, plasmid preparation, cloning of DNA, and purification of DNA (Ausubel et al., 2009), and calcium phosphate transfection of DNA (*UNIT 20.3*)

Make candidate probes

1. Design a candidate Raichu probe.

   To achieve a wide dynamic range, it is desirable to search for a GTPase-binding domain having a moderate affinity for the GTPase (Yoshizaki et al., 2003). One explanation for this is that the GTPase-binding domain competes with GTPase-activating proteins (GAPs) in cells (Kurokawa et al., 2004). This inhibition of GAPs leads to a relatively high GTP level in the probe, even in the unstimulated state, and may therefore cause a narrowing of the dynamic range.

   Crystallographic data for the GTPase and GTPase-binding domain can help to determine the minimum regions to be incorporated into the probe. Unfortunately, crystallographic data for optimal design of a Raichu probe cannot currently be obtained in most cases. Therefore, various lengths of the GTPase and GTPase-binding domain should be tried until a satisfactory result is obtained. In addition, various combinations of the four modules, namely, YFP, CFP, GTPase, and the GTPase-binding domain, should be tested. YFP is usually placed before CFP because an excess of acceptor (YFP) does not decrease the signal-to-noise ratio by much, even when the translation of the probe is prematurely terminated.

   Eleven amino acids at the carboxyl terminus of GFP can be truncated without affecting its fluorescence profile. In most Raichu probes, we have removed the 11 carboxyl-terminal residues of YFP, hoping to reduce the flexibility between YFP and the subsequent module.

   The length and sequence of the spacers are also critical. If the FRET efficiency of a prototype probe varies to some extent upon activation, the possibility of further improvement by changing the spacer should be considered. As spacers, we usually use 1 to 6 repeats of the pentapeptide Gly-Gly-Ser-Gly-Gly. It is believed that Gly provides flexibility while Ser prevents aggregation of peptide chains. Misfolding of CFP occasionally occurs, and this can sometimes be rectified by modifying the spacer before the CFP. The ideal location for a probe in a cell has been a matter of debate. The most persuasive idea is that the probe should be colocalized with the endogenous protein; for this purpose, the GTPase's own authentic CAAX-box should be added to the C-terminus of the probe. Alternatively, the addition of the CAAX-box of K-Ras4B to the C-terminus enables the probe to be located mostly at the plasma membrane; this approach yields a high signal-to-noise ratio, especially when only a limited fraction of the GTPase is activated upon stimulation.

2. Construct a plasmid for a candidate probe.

   If you use the basic Raichu probe structure (Fig. 14.10.1), you should first perform PCR cloning of the trimmed GTPase and GTPase-binding domain with restriction enzyme recognition sites. Thereafter, insert the PCR fragments into the basic FRET vector.

   The 5′ and 3′ primers for the GTPase should have XhoI and Aor13HI restriction sites, respectively. The 5′ and 3′ primers for the GTPase-binding domain should have KpnI and NotI restriction sites, respectively. Any restriction enzymes that generate compatible ends can also be used. The primers must be designed so that the inserted cDNA is in the correct reading frame of the Raichu (http://www.path1.med.kyoto-u.ac.jp/mm/e-phogemon/index.htm). The amplified cDNAs of the GTPase and GTPase-binding domain are cleaved with the aforementioned restriction enzymes and subcloned into XhoI/Aor13HI and KpnI/NotI restriction sites, respectively. The order of the GTPase and GTPase-binding domain can be reversed by changing the restriction sites in the primers accordingly.

3. Prepare transfection-quality plasmid DNA.

   DNA purified using Qiagen ion-exchange resin (or equivalents from other manufacturers) performs well. Also see Ausubel et al. (2009).

Characterize candidate probes

4. Grow 293T cells to 80% confluence in MEM containing 10% FBS (may contain phenol red). Transfect 10 μg of a probe-encoding plasmid into 293T cells using calcium phosphate coprecipitation (*UNIT 20.3*).

   Candidate probes without lipid modification at the C-terminus are often preferable for spectral analysis, because this lipid modification generally reduces the level of probe expression.

5. At 6 hr after transfection, change the culture medium to phenol red–free MEM/10% FBS.

6. At 48 hr after transfection, harvest the cells in 1 ml lysis buffer. Microcentrifuge the lysates at 15 min at 10,000 × *g*, 4°C.

   The centrifugation serves to clear the lysate. If necessary, the cell lysates may be cleared by ultracentrifugation for 15 min at 100,000 × g, 4°C, to reduce the autofluorescence from cell debris.

7. Transfer the cleared lysates into 3-ml cuvettes and place the cuvettes in a fluorescence spectrophotometer. Next, illuminate lysates with an excitation wavelength of 433 nm, and obtain a fluorescence spectrum from 450 nm to 550 nm. Subtract the background using the spectra of cell lysates prepared without transfection.

   Fluorescence spectral analysis becomes even easier when the FreeStyle 293-F cell line (Invitrogen), a variant of the 293 cell line adapted for suspension growth, is used. This cell line is very easy to culture, transfect, and harvest, and only 1.5 ml of cell suspension is required to obtain a fluorescence spectrum.

8. Evaluate a candidate probe using the fluorescence spectrum (Fig. 14.10.2).

   For the characterization of a candidate probe, we introduce a constitutively active or inactive mutation into the GTPase in the probe for comparison with the same probe containing the wild-type GTPase. Alternatively, we cotransfect the candidate probe with guanine nucleotide exchange factor (GEF) and GAP toward the GTPase, and compare the new spectrum with those of samples transfected with the probe alone. Under our criteria, Raichu-type probes can be applicable for imaging analysis when the maximum increase (%) in the YFP/CFP ratio exceeds 30%.

   Practically, further evaluation of a probe is recommended before use in a wide range of applications: i.e., (1) whether the probe shows a near-linear correlation between its GTP loading and FRET efficiency upon cotransfection with various quantities of GEF or GAP and (2) whether the probe and its endogenous counterpart show comparable responses to physiological stimulations when examined by biochemical methods.

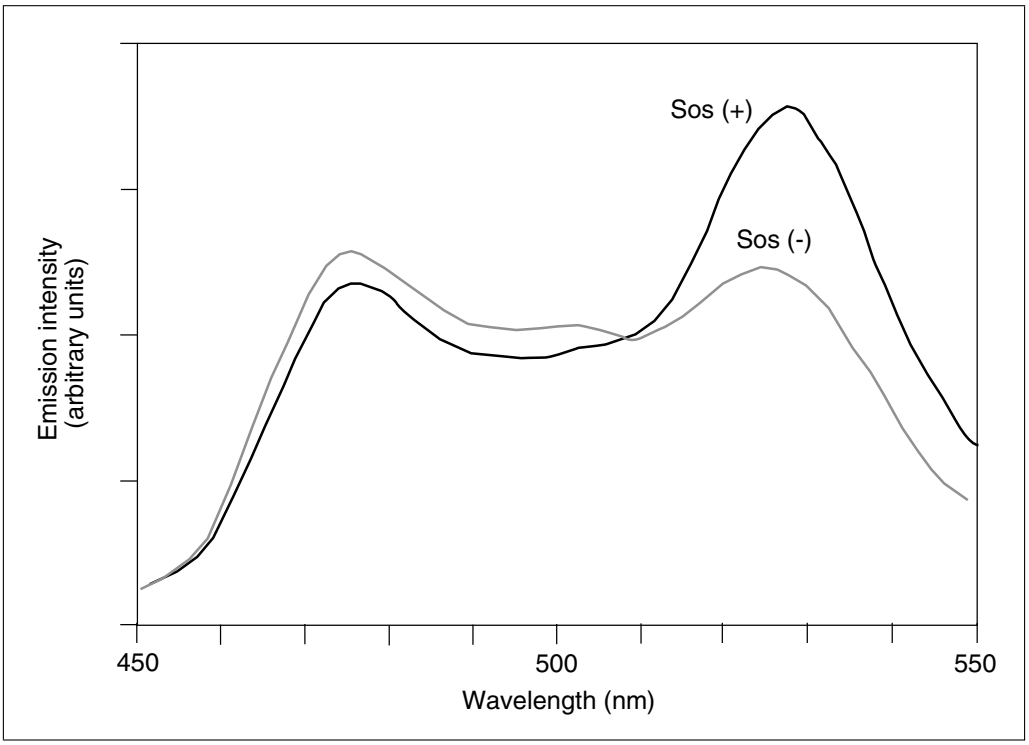

Figure 14.10.2 Fluorescence spectral analysis using 293T cells. Shown are emission spectra of Raichu-Ras expressed with the guanidine nucleotide factor Sos (black line, Sos +) or without Sos (gray line, Sos −) in 293T cells at an excitation wavelength of 433 nm.

IMAGING WITH FRET PROBES

BASIC PROTOCOL 2

Imaging with FRET probes must be performed with general live-cell imaging precautions, and should be modified depending on the specific cell type; these modifications are beyond the scope of this unit. Furthermore, the technical details differ among optical imaging systems and image analysis software. The following is only a typical example of such an analysis.

Materials

Cells for experiment [e.g., HeLa cells (ATCC cat. no. CRL-2) or COS7 cells (ATCC cat. no. CRK-1651)] and appropriate medium
Expression plasmid for FRET probe (Basic Protocol 1)
Transfection reagent
Phenol red-free medium
Mineral oil (Sigma)

35-mm glass-base dish (Asahi Techno Glass; *http://www.agc.co.jp/*) with a 10-mm-diameter glass coverslip mounted on the bottom
Temperature-controlled chamber with thermostat and/or a CO_2 controller
A fluorescence microscope with a CCD camera including:
IX81 inverted microscope
75-W xenon arc lamp
60× oil immersion objective lens, PlanApo 60×/1.4 (Olympus)
Cool SNAP-HQ cooled CCD camera (Roper Scientific)
Laser-based auto-focusing system, IX2-ZDC (Olympus)
Automatically programmable XY stage, MD-XY30100T-Meta (SIGMA KOKI).
Excitation and emission filter wheels: Filter wheel 99A354 and MAC5000 shutter controller (Ludl Electronic Products)

Filters:
XF1071 (Omega Optical; cat. no. 440AF21) excitation filter
XF2034 (Omega Optical; cat. no. 455DRLP) dichroic mirror
XF3075 (Omega Optical; cat. no. 480AF30) emission filter for CFP
XF3079 (Omega Optical; cat. no. 535AF26) emission filter for FRET
Neutral-density (ND) filters

Software for operation of the microscope and analysis of acquired images; e.g., MetaMorph software (Universal Imaging)

Additional reagents and equipment for construction of the FRET probe (Basic Protocol 1)

Prepare cells

1. Seed the cells onto a glass-base dish with a glass coverslip at the bottom.

   The coverslip at the bottom may be coated with collagen, fibronectin etc., depending on the cell types used. The cell density can be varied depending on the purpose of experiments and the transfection protocol.

2. Transfect cells with the plasmid for a FRET probe using any protocol suitable for the cells of interest.

   The transfection efficiency need not be high, because fewer than 10 cells can be time-lapse imaged in most experiments. Rather, the transfection method should be chosen to minimize cell toxicity.

3. Grow the cells, typically for 1 to 3 days, depending on the probe and cell type.

   In most cases, within 2 days the amount of probe reaches a level sufficient for imaging. In cases where the overexpression of the probes is toxic to the cells, the cells should be used 1 day after transfection.

4. On the day of the experiments, change the medium to phenol red-free medium and overlay the medium in the cell-containing dish with mineral oil.

   A reduction in the amount of serum is preferable to reduce the background fluorescence. Bovine serum albumin may be included when serum is not included. HEPES should be included in the medium unless CO_2 is supplied during imaging. In some cases, phosphate or HEPES-buffered saline may be preferable to minimize the background fluorescence. Note that some media, such as Opti-MEM, give off high fluorescence.

Acquire images of a single field of view

5. Warm the temperature control chamber to 37°C and set up fluorescence microscope.

   A large chamber that covers most of the microscope is preferable to minimize defocusing during image acquisition. However, if the microscope is equipped with an autofocusing system, the chamber may be as small as needed to keep the cells warm. Always use a neutral density (ND) filter to minimize the photobleaching of the probe during observation.

6. View the specimen on the microscope using a 60× oil-immersion objective and a filter set for CFP, and find a cell for time-lapse imaging.

   Cells to be observed should look healthy and represent the cell population. The optimal expression level varies depending on each FRET probe. Repeated experiments are required to determine the conditions suitable for the imaging.

7. Set up the image-acquisition software, with the following being a typical setup for the FRET imaging of growth factor-induced activation of signaling molecules:

   ND filter, 10%
   Camera binning, 4
   Digitizer, 10 MHz
   Gain 2 (4×)

Shutter speed for phase contrast image or differential interference contrast image, 50 msec
Shutter speed for CFP and FRET, 200 msec
Time-lapse interval, 1 min
Number of images, 60.

The conditions should be optimized for the probes and cells to be analyzed.

What should be most considered in this process is the photobleaching of YFP and phototoxicity to the cells. For an unknown reason, images obtained with shorter exposure time and brighter excitation light, which can be easily achieved by removing the ND filter, usually result in lower FRET efficiency. This is a principal reason why we prefer the conventional epifluorescence microscope to the scanning laser confocal microscope.

8. Start time-lapse imaging.

   When cells of interest become defocused, stop the image acquisition and focus the cells again. Minimize the time to focus, or YFP intensity will be decreased (YFP bleaches faster than CFP), resulting in apparent decrease in FRET.

Acquire images of multiple fields of view with autofocusing system

9. Set up the microscope as described above. Find the first cell to be monitored and focus on it. Set the offset value by using the laser-based auto-focusing system.

   Offset value is the distance from the top of the objective lens to the top of the coverslip. With a "find focus" command, the autofocusing system remembers the distance between the top of the objective lens to the top of the coverslip, and thereby corrects the z-axis coordinate prior to image acquisition. Usually, this correction is required only for the first cells at each time point.

10. Find cells to be monitored and record the coordinates.

    The number of cells to be imaged can be reduced afterwards; therefore, a large number of cells should be recorded at this stage. When the interval of time lapse is 1 min, 10 to 15 view fields can be imaged.

11. By moving the motor-driven stage with the obtained coordinates, confirm the cells to be monitored and correct the focus, if necessary.

    The order of the image acquisition can be changed to minimize the movement of the stage.

12. Start image acquisition and confirm whether a series of image acquisitions finishes within the interval time. If it goes well, continue image acquisition.

    If not, interrupt image acquisition and reduce the number of cells to be monitored, or extend the interval time. It is also strongly recommended to ensure that the hard disc contains sufficient space for the image.

Analyze the images

13. Create stack files for the acquired images and overview.

    Carefully examine for defocusing, floating bright debris, photobleaching, and phototoxic change in the cells.

14. Create background-subtracted images for CFP and FRET. First, choose region(s) for background, where no cells or debris are observed during the entire time-lapse imaging. Second, subtract the averaged value of the background region from the image. Third, repeat this background subtraction for all planes and make a background-subtracted stack file.

    The background value should be obtained for each plane. A macro should be prepared to repeat this process. Other corrections such as shading can be applied at this stage, if necessary.

15. Create ratio images either in simple pseudocolor or intensity-modulated display mode.

    The FRET/CFP value is usually used for showing the level of FRET.

    In the intensity-modulated display mode, the brightness and color of each pixel indicates the concentration of the probe and the FRET level, respectively.

16. Create video files. From the stacked ratio image, create video files either in `.avi`, `.mov`, or `.mpg` format.

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Lysis buffer

20 mM Tris·Cl, pH 7.5 (*APPENDIX 2A*)
100 mM NaCl
5 mM $MgCl_2$
0.5% (v/v) Triton X-100
Store indefinitely at 4°C

COMMENTARY

Background Information

FRET is a process by which a donor fluorophore in an excited state transfers its excitation energy to an acceptor nonradiatively through dipole-dipole interactions if the emission spectrum of the donor overlaps the excitation spectrum of the acceptor (Lakowicz, 2006; *UNIT 17.1*). This energy transfer manifests itself by a quenching of donor fluorescence intensity and lifetime, as well as the simultaneous increase in the emission of acceptor fluorescence. Because the efficiency of FRET decreases in proportion to the inverse sixth power of the distance between the donor and acceptor, FRET has been utilized as a spectroscopic ruler to measure the distance (<10 nm) between two sites on macromolecules. Additionally, when GFP and its derivatives are used for FRET probes, the relative orientation between the donor emission dipole and the acceptor absorption dipole has a significant impact on FRET efficiency. Based on these two properties, GFP-based FRET probes should be able to monitor protein-protein interactions and protein conformational changes in living cells (Miyawaki, 2003).

In general, GFP-based FRET probes are classified into two types, bimolecular and unimolecular probes (Miyawaki, 2003; Kurokawa et al., 2004). In the bimolecular probe, donor (CFP) and acceptor (YFP) are fused to the sensor domain and detector domain, respectively. The sensor domain changes its conformation upon modification. The detector domain binds to the sensor domain upon this conformational change. In the unimolecular probes, all four modules are combined into a single chain. In the authors' opinion, if good probes are available, using a unimolecular probe is a better way to start; in fact, the most significant hurdle of a unimolecular probe is the labor-intensive process needed to optimize its design. The reasons we chose a unimolecular probe as the basic design for detecting conformational changes are as follows. First, in the unimolecular probe, the sensor domain and the detector domain are placed within close proximity, and thus the detector domain is primed to bind the sensor domain upon stimulation. This increases the percentage of real FRET signal versus undesired signals that result from donor emission bleedthrough and direct acceptor excitation (Hailey et al., 2002; Kurokawa et al., 2004). Concurrently, the perturbation of endogenous signaling will be reduced (Miyawaki, 2003). Second, the molar ratio of CFP and YFP is a fixed constant at every pixel in the unimolecular probe; therefore, a simple ratio between the intensity of CFP fluorescence and that of YFP fluorescence suffices to represent FRET efficiency.

It should be noted that, from a general point of view, suitable applications for bimolecular and unimolecular probes are different. Thus, in practice, the type of probe is chosen depending on the aim of the experiment. In the case of monitoring an interaction

between two proteins, it is natural to select a bimolecular probe (*UNIT 17.1 & 21.3*). Correction of FRET signals obtained with a bimolecular probe is elaborate, but executable (Kraynov et al., 2000; Sekar and Periasamy, 2003). If one wishes to visualize the change of the activity of a protein, pH, Ca^{2+} concentration, etc., a unimolecular probe is preferable; in this case, one might take advantage of the merits described above.

Unimolecular FRET probes now cover a wide range of signal transduction cascades. The archetype is the Ca^{2+} sensor, cameleon (Miyawaki et al., 1997). The unimolecular cameleon has been expressed in specific cell types of genetically tractable animals, aiming at in vivo Ca^{2+} imaging (Kerr et al., 2000; Fiala et al., 2002). Concentration of other second-messenger molecules such as cyclic nucleotides and phosphoinositides can be visualized using unimolecular FRET probes (Sato et al., 2000, 2003; Zhang et al., 2001).

Indicators for the on and off states of small GTPases such as Ras, Rap1, Ral, R-Ras, RhoA, Rac1, and Cdc42 have been developed (Mochizuki et al., 2001; Itoh et al., 2002; Yoshizaki et al., 2003; Takaya et al., 2004; Pertz et al., 2006; Takaya et al., 2007). These FRET probes have been used for the investigation of ligand-induced morphological change, cell migration, cell division, neurite outgrowth, and membrane trafficking. FRET imaging of Raichu-TC10 by total internal reflection microscopy uncovered that the activity of TC10 on the exocytic vesicles drops immediately before the vesicular fusion (Kawase et al., 2006).

The largest number of unimolecular FRET probes are used to monitor protein kinase activities. In archetypical probes, an appropriate phosphorylation substrate peptide or domain and a phosphoamino acid binding domain have been linked to produce a hybrid protein, which was then flanked by CFP and YFP. This approach has yielded indicators for the activities of PKA, PKC, Src, and EGF receptor (Kurokawa et al., 2001; Ting et al., 2001; Zhang et al., 2001; Violin et al., 2003). In a simpler form, the substrate peptide is sandwiched between CFP and YFP; conformational changes induced by the phosphorylation of substrate lead to the change in FRET efficiency (Nagai et al., 2000; Yamada et al., 2005; Brumbaugh et al., 2006). Alternatively, entire protein kinases are flanked by YFP and CFP to produce a kinase-type probe. Protein kinases generally consist of the catalytic and regulatory domains, the latter of which associates with the former to hold the enzyme in a closed, inactive state. Upon stimulation, the regulatory domain dissociates from the catalytic domain to drive the enzyme into an open, active state. This conformational change has been successfully monitored as a change in FRET efficiency in the probes for PKC, Raf, Erk, and CaMKII (Braun et al., 2005; Terai and Matsuda, 2005; Takao et al., 2005; Fujioka et al., 2006).

Critical Parameters

For the development of a FRET probe, the signal gain, i.e., the difference in the FRET ratio (the lowest versus the highest value of [YFP fluorescence]/[CFP fluorescence] of the probe excited for CFP) should exceed 30%. If one uses probes in which the gain is less than 30%, it is typically difficult to observe a significant change in FRET efficiency upon stimulation.

As for image acquisition, we strongly recommend starting with the easiest experiment, using established probes, to become familiar with the imaging technique. For example, we recommend monitoring agonist-induced calcium oscillation with a recently developed calcium sensor, cameleon YC3.60, which has an extraordinarily wide dynamic range (Nagai et al., 2004). Imaging of Ras activation in EGF-stimulated COS cells with Raichu-Ras probe (Mochizuki et al., 2001) is another fairly easy example (Fig. 14.10.3).

Recently, the quantitative analysis of acquired images has become a necessary skill in live cell imaging. Therefore, it is desirable to have a good knowledge of image-processing software. For that purpose, expert training in image processing is helpful.

Troubleshooting

Table 14.10.1 provides troubleshooting information for these protocols.

Anticipated Results

Figure 14.10.3 shows the FRET images of COS-1 cells expressing Raichu-Ras following EGF stimulation. The FRET images are presented in an intensity-modulated display mode. EGF-induced Ras activation was detected at the periphery of the cell, where membrane ruffling was prominent. The increase in the YFP/CFP ratio of Raichu-Ras upon EGF stimulation is usually 30% to 50%.

Table 14.10.1 Troubleshooting Guide to In Vivo Imaging of Signaling Cascades

Problem	Possible cause	Solution
Gradual decrease in YFP/CFP ratio without stimulation	Photobleaching during imaging	Lengthen time-lapse interval or shorten exposure time
Gradual increase in YFP/CFP ratio without stimulation	1. Photobleaching during searching for the target cell. 2. Progress of folding of fluorescence proteins. In this case, both YFP and CFP intensities should increase.	Wait for 5-10 min and restart the imaging. Prolong the incubation time after probe transfection.
Defocus during imaging	Distortion of warmed microscope	Warm up microscope and chambers in advance. To avoid defocus completely, a focus-drift compensation system (e.g., Olympus IX2-ZDC) is very useful.
Higher (or lower) YFP/CFP ratio in specific side of the image	Uneven illumination to samples	Align an arc lamp precisely
Appearance of paired high and low areas of YFP/CFP ratio at the edge of cells	Misregistration (subtle displacement between CFP and YFP images)	Correct misregistration using imaging software
Cells expressing FRET probes look unhealthy	Cell toxicity due to the overexpression of probes	Choose the healthy cells expressing low levels of probes or retry the transfection with less DNA

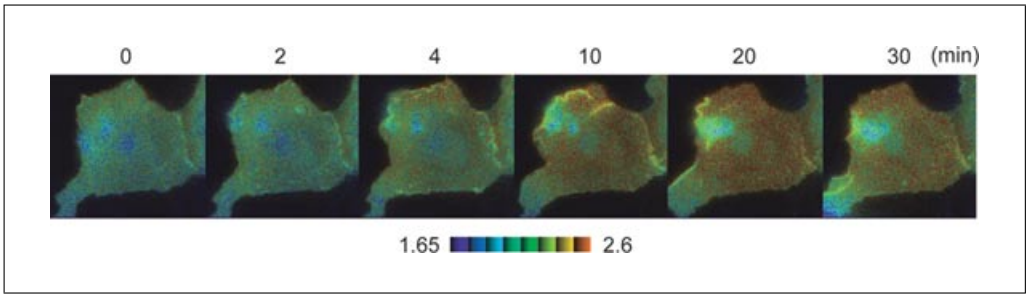

Figure 14.10.3 Time-lapse experiment of Ras activation upon EGF stimulation in COS-1 cells. Serum-starved COS-1 cells expressing Raichu-Ras were treated with 50 ng/ml of EGF and imaged every 2 min. FRET images are shown at the indicated time points. For color figure go to *http://www.currentprotocols.com/protocol/cb1410*.

Time Considerations

In some cases, more than one hundred candidate probes should be designed, constructed, and checked for FRET efficiency to obtain an ideal probe. Thus, the term needed to develop a good probe is ~3 months. This time frame significantly varies, depending on the knowledge of the target for probe development.

The entire cell-imaging procedure can be performed in 3 to 4 days from cell seeding. This period includes 1 day for expression of FRET probe after transfection, 1 day for data acquisition, and 1 day for data analysis.

ABSTRACT

The biosensors developed in the authors' laboratory have been based on different designs, each imparting specific strengths and weaknesses. Here we describe detailed protocols for the application of three biosensors exemplifying different designs—first, a design in which an environmentally sensitive dye is used to report the activation of endogenous Cdc42, followed by two biosensors based on FRET, one using intramolecular and the other intermolecular FRET. The design differences lead to the need for different approaches in imaging and image analysis. *Curr. Protoc. Cell Biol.* 46:14.11.1-14.11.26.

Keywords: biosensors • Rho family GTPases • FRET • live cell imaging

INTRODUCTION

In this unit, we describe detailed protocols for the application of three biosensors developed in our laboratory, exemplifying different designs with specific strengths and weaknesses. The first biosensor described represents a design in which an environmentally sensitive dye is used to report the activation of endogenous Cdc42. Also described are two biosensors based on fluorescence resonance energy transfer (FRET; also see *UNIT 17.1*), one using intramolecular and the other intermolecular FRET. The design differences lead to the need for different approaches in imaging and image analysis.

Figure 14.11.1 shows the design of the three biosensors. MeroCBD (Fig. 14.11.1A) is a sensor for Cdc42 activation in which a fragment of Wiskott-Aldrich Syndrome protein that binds only to active Cdc42 is derivatized with an environmentally sensitive dye (Nalbant et al., 2004). In living cells, the dye undergoes a fluorescence change when the biosensor binds to endogenous, untagged Cdc42. This design is advantageous for several reasons: Cdc42 is not tagged with a fluorophore or other biosensor component, expression of exogenous Cdc42 is not needed, and the signal is substantially brighter than FRET because a bright dye is directly excited, rather than indirectly as in FRET. The major disadvantage is that the biosensor is not genetically encoded, so must be loaded in the cells, e.g., via microinjection or electroporation.

The FRET biosensor for RhoA (Pertz et al., 2006) is shown in Figure 14.11.1B. A fragment of Rhotekin is attached directly to RhoA, and fluorescent proteins undergoing FRET are built into the chain connecting the RhoA and Rhotekin fragment. The C terminus of the RhoA is purposely left free of fluorescent protein or other modifications, to maintain intact the regulation of RhoA by GDI. Unlike the Cdc42 biosensor, this biosensor is completely genetically encoded, greatly simplifying loading into cells.

Finally, the biosensor for Rac1 is shown in Figure 14.11.1C. Named Rac1 FLAIR, it is a modification of a design originally published using a covalently attached fluorescent dye

Current Protocols in Cell Biology 14.11.1-14.11.26, March 2010

DOI: 10.1002/0471143030.cb1411s46

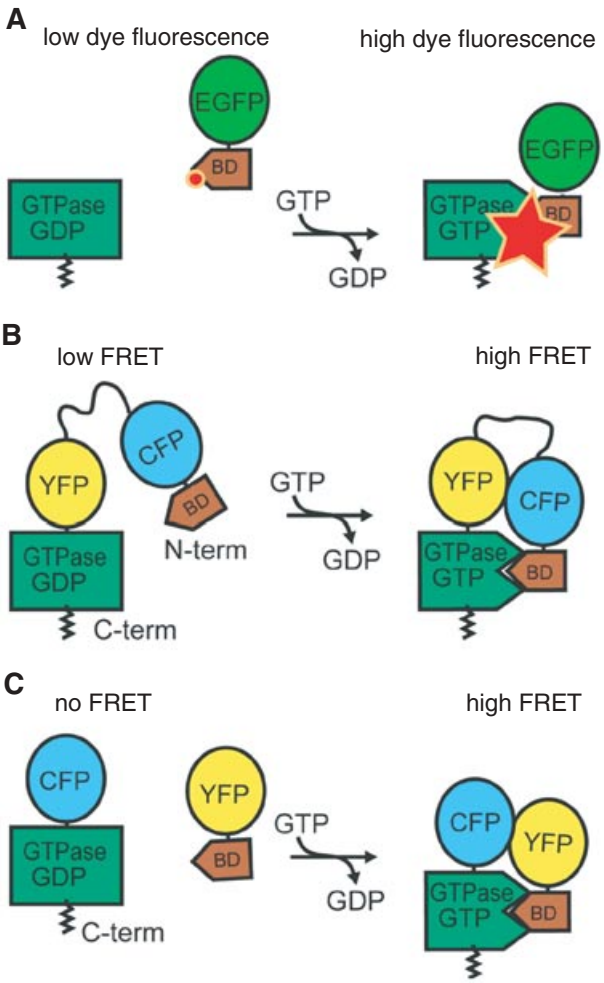

Figure 14.11.1 Fluorescent biosensor designs. (**A**) MeroCBD, biosensor of endogenous Cdc42 activation. Here, a fragment of Wiskott-Aldrich syndrome protein (WASP) that binds only to activated Cdc42 is covalently derivatized with an environmentally sensitive dye. When the WASP fragment encounters and binds to activated Cdc42, the solvation of the dye by water is reduced, leading to a fluorescence change. Advantages of this design include the ability to study endogenous protein, and enhanced sensitivity due to direct excitation of a bright, long-wavelength dye (as opposed to indirect excitation via FRET). The disadvantage is the need for microinjection, electroporation, or some other means to load the covalently tagged protein biosensor into cells. (**B**) RhoA biosensor. Here a fragment of Rhotekin that binds only to activated RhoA is attached to RhoA as part of the same protein chain. Two different fluorescent proteins undergoing FRET are in the chain between RhoA and the Rhotekin fragment, such that binding of the fragment to activated RhoA alters the distance and/or orientation between the fluorescent proteins, affecting FRET. This biosensor is fully genetically encoded, greatly simplifying loading into the cell. Because the Rhotekin fragment is attached to the RhoA, image processing is simplified relative to the dual-chain sensor shown in (C) (see text). (**C**) Rac1 FLAIR, biosensor of Rac1 activation. This design is similar to that of the RhoA biosensor, but here the PAK fragment used to bind activated Rac1 is not part of the same chain as the Rac1. The use of a dual-chain, intermolecular FRET design enhances sensitivity because, unlike the single-chain design, there is no FRET when the biosensor is in the off state. Additional image processing (bleed-through correction) is required because the biosensor components can distribute differently throughout the cell. For color figure go to *http://www.currentprotocols.com/protocol/cb1411*.

for FRET (Kraynov et al., 2000). In the modification described here, the dye has been replaced with a fluorescent protein, rendering the biosensor fully genetically encoded (Machacek et al., 2009). A fragment of p21-activated kinase (PAK) is used to bind specifically to activated Rac1. The main difference between this design and that of the RhoA biosensor is that the PAK fragment is not attached to Rac1. Rac1 FLAIR is an intermolecular FRET biosensor, frequently referred to as a dual-chain sensor.

NOTE: All solutions and equipment coming into contact with cells must be sterile, and proper aseptic technique should be used accordingly.

NOTE: All culture incubations should be performed in a humidified 37°C, 5% CO_2 incubator unless otherwise specified.

PRODUCTION AND USE OF meroCBD, DYE-BASED BIOSENSOR FOR CDC42

BASIC PROTOCOL 1

As discussed above, the meroCBD biosensor for Cdc42 activation is based on a fragment of WASP (the Cdc42 binding domain, CBD) that binds only to activated Cdc42. This fragment is covalently coupled to a solvent-sensitive dye that increases in fluorescence intensity when the CBD interacts with endogenous, activated Cdc42 (Toutchkine et al., 2003, 2007a,b). Because the dye responds to Cdc42 binding with an intensity change, rather than with a shift in λ_{max}, it is useful to attach a second fluorophore to the biosensor for ratio imaging.

CBD-EGFP is expressed in the form of a C-terminal 6× His fusion from the prokaryotic expression vector pET23. This vector has a strong T7 promoter, and is designed to work with BL21(DE3) strains of *E.coli* (Stratagene). It was determined experimentally that the highest levels of expression are observed when a plain T7 promoter (not T7*lac*) is used in combination with a BL21(DE3) strain, and not BL21(DE3)pLysS. The BL21(DE3) strain is more leaky, but this is not of great consequence, as CBD-EGFP shows no appreciable toxicity. The protein is best induced and expressed at room temperature (26°C), which increases the proportion of correctly folded, soluble CBD-EGFP.

Materials

Transformation-competent BL21(DE3) *E. coli* (e.g., Stratagene)
pET23-CBD-EGFP (Addgene)
LB medium and plates (*APPENDIX 2A*) containing 100 μg/ml carbenicillin
1 M IPTG (in water), store at −20°C
Lysis buffer (see recipe)
Talon resin (Co^{2+} affinity, Clontech)
Lysis buffer (see recipe but omit 2-ME and PMSF) containing 5 mM and 150 mM imidazole
50 mM Tris·Cl, pH 7.5 to 8.0 (*APPENDIX 2A*)
50 mM sodium phosphate buffer, pH 7.5 (*APPENDIX 2A*)
Storage buffer (see recipe)

2000-ml Erlenmeyer flask
Incubator with shaker
250-ml centrifuge bottles
Beckman centrifuge with JA-10 and JA-20 rotors (or equivalent)
50-ml conical polypropylene centrifuge tubes (Falcon)
Centrifuge with swinging-bucket rotor
End-over-end rotator
Ultrafree Centrifugal Filtration Device (MWCO, 5000; Fisher Scientific, cat. no. UFV5BCC25)
Slide-A-Lyzer cassettes (MWCO 3500; Pierce)

Additional reagents and equipment for transformation of bacteria and other basic molecular biological techniques (e.g., Sambrook et al., 1989; Ausubel et al., 2009), SDS-PAGE (*UNIT 6.1*), and dialysis (*APPENDIX 3H*)

NOTE: Use the buffers suggested in this unit. Apparently small changes have proven to greatly reduce yield.

Day 1: Transform the bacteria

1. Transform competent BL21(DE3) *E. coli* cells with pET23-CBD-EGFP according to standard protocols (Sambrook et al., 1989; Ausubel et al., 2009), and plate on LB plates containing 100 μg/ml carbenicillin.

   The 200-μl transformation volume should be split over two plates.

   The bacterial strain is critical. BL21(DE3) are recommended. Do not use BL21(DE3)pLysS.

2. Incubate plates at 37°C overnight.

Day 2: Grow and induce the transformed bacteria

3. Inoculate 500 ml of LB liquid medium containing 100 μg/ml carbenicillin with the colonies from the plates by adding 5 ml of medium to each plate and resuspending the cells into the medium, then transferring the cell suspension into 500 ml LB medium/carbenicillin (in a separate 2000-ml Erlenmeyer flask for each plate) and growing at 37°C with shaking at 225 rpm, to an OD_{600} of 0.8 to 0.9.

4. Briefly chill the culture on ice to 26°C and put back in the shaking incubator, with temperature reduced to 26°C.

5. Add IPTG (1 M stock in water, kept at –20°C) to a final concentration of 0.2 mM, and allow the cultures to grow for another 6 hr at 26°C at 225 rpm.

   IPTG concentrations of 0.2 to 0.5 mM have been used successfully.

6. Transfer cells to 250-ml centrifuge bottles. Collect cells by centrifuging 10 min at 6000 × *g*, 4°C, and store as a pellet at –20°C until use.

   Approximately 2.5 to 3 g of cells is usually obtained from each liter of culture.

Day 3: Prepare the lysate

7. Resuspend cells (~3 g) in 35 ml of lysis buffer in a 50-ml conical tube and lyse by sonication with a probe sonicator (four pulses, 30 sec each, on ice with 1-min intervals).

8. Centrifuge the lysates 30 min at 20,000 × *g* (13,000 rpm in a JA-20 rotor), 4°C, and carefully transfer the supernatant containing CBD-EGFP into a 50-ml conical polypropylene centrifuge tube.

Day 3: Prepare the resin

9. While the lysates are being centrifuged, transfer 2 ml of Talon resin (dry volume) into a 50-ml conical polypropylene centrifuge tube and centrifuge 3 min at 700 × *g*, 24°C, in a centrifuge with a swinging-bucket rotor. Remove supernatant.

   Do not use Ni-NTA resin.

   A ratio of 2 ml resin per 3 g cell pellet is recommended.

10. Wash Talon resin twice, each time by adding 10 volumes of lysis buffer without 2-mercaptoethanol or PMSF centrifuging 3 min at 700 × *g*, 24°C, and removing the supernatant.

Day 3: Bind the CBD-EGFP to the resin

11. Add the cell lysate to the washed Talon resin in the 50-ml tube, wrap in foil, and invert gently using an end-over-end rotator at room temperature for 40 min to 1 hr.

    The tube is wrapped in foil to avoid unnecessary exposure of EGFP to light.

12. Separate the unbound material by centrifuging 3 min at 700 × *g*, 24°C, in a centrifuge with a swinging-bucket rotor.

13. Remove and save the supernatant (unbound fraction) for SDS-PAGE analysis (*UNIT 6.1*).

    If a large portion of unbound material is present in this fraction, consider increasing the Talon resin volume by preparing two tubes of 2 ml resin and splitting the lysates into two tubes during the binding reaction.

14. Wash the resin twice, each time by adding 20 ml fresh lysis buffer without PMSF or 2-mercaptoethanol, rotating for 5 min at room temperature on an end-over-end rotator, then centrifuging as in step 12 and removing the supernatant.

15. Perform the final resin wash with 10 volumes of lysis buffer containing 5 mM imidazole (no PMSF or 2-ME).

    It is important to prepare a fresh 5 ml of 1 M imidazole stock solution in the same buffer. Always prepare the stock imidazole solution fresh.

Day 3: Elute the resin

16. Perform the elution by adding 5 ml of lysis buffer (no PMSF or 2-ME) containing 150 mM imidazole to the resin and then rotating using an end-over-end rotator for 5 min. Pellet the resin again by centrifugation for 3 min at 700 × *g*, 24°C.

17. Remove the supernatant and save (eluted fraction).

18. Concentrate the resulting 5-ml eluate with a centrifugal concentrator by centrifugation at 4°C according to the manufacturer's instructions. Check the concentration process every 20 min to ensure proper filtration.

    Do not over-concentrate; optimal final concentration should be ∼120 μM.

19. Measure the concentration of CBD-EGFP by taking a small aliquot (5 to 10 μl) and diluting 1:10 into 50 mM Tris·Cl, pH 7.5 to 8.0.

20. Determine protein concentration using the absorption at 280 with an extinction coefficient of 28,260 (cm^{-1} M^{-1}), and Equation 14.11.1:

$$[\text{CBD}-\text{EGFP}](\text{in mol/liter}) = \frac{\text{OD}_{280} \times \text{dilution factor}}{28,260}$$

Equation 14.11.1

    On average, 10 to 20 mg of CBD-EGFP is obtained per liter culture.

21a. *If dye-labeling is to be performed the following day:* Dialyze a part of the concentrated protein overnight against 2 liters of 50 mM sodium phosphate buffer, pH 7.5, at 4°C (*APPENDIX 3H*).

    Slide-A-Lyzer cassettes (Pierce) with a molecular weight cut-off of 3,500 Da can be conveniently used.

21b. *For long-term storage:* Dialyze the protein overnight against 2 liters of storage buffer at 4°C (*APPENDIX 3H*), and freeze at −80°C.

    Freezing at −80°C appears to be better than flash freezing for this protein.

SUPPORT PROTOCOL

LABELING CBD-EGFP WITH REACTIVE FLUOROPHORE

Dyes are available from the Hahn lab and should be commercially available soon. Solvent-sensitive dyes other than those that have been used to date should also respond to Cdc42 binding.

Materials

Dye: ISO-IAA (Toutchkine et al., 2003, 2007a,b)
Dimethylsulfoxide (DMSO)
CBD-EGFP (Basic Protocol 1)
2-mercaptoethanol (2-ME)
50 mM sodium phosphate buffer, pH 7.5 (*APPENDIX 2A*)
12% SDS-PAGE gel (*UNIT 6.1*)
50 mM Tris·Cl, pH 8.0 (*APPENDIX 2A*)

Spectrophotometer
2-ml microcentrifuge tubes
End-over-end rotator
0.5 cm × 6 to 8 cm column packed with Sephadex G15 gel-filtration resin (GE Healthcare)

Additional reagents and equipment for SDS-PAGE (*UNIT 6.1*) and spectrophotometric determination of protein concentration (*APPENDIX 3B*)

Prepare dye stock solution

1. Prepare a fresh solution of dye, ISO-IAA, in pure DMSO by adding ~1 mg of dye into 30 to 40 µl DMSO.

   Once dissolved in DMSO, the dye should be used immediately.

2. Determine the exact concentration of the dye spectrophotometrically at 593 nm by diluting a small aliquot of the DMSO solution 1:5,000 to 1:10,000 in additional DMSO. For ISO-IAA, assume an extinction coefficient in DMSO at maximum absorption (593 nm) of 135,000 (cm^{-1} M^{-1}):

$$[\text{ISO}-\text{IAA}](\text{in mol/liter}) = \frac{\text{OD}_{593} \times \text{dilution factor}}{135,000}$$

Equation 14.11.2

   The authors routinely obtain concentrations of 30 to 40 mM for the DMSO stock solution.

Label the protein

3. Transfer a 300-µl aliquot of fresh CBD-EGFP protein into a 2-ml microcentrifuge tube wrapped in foil to protect from light.

   For attachment of the dyes to cysteine, CBD-EGFP needs to be in 50 mM sodium phosphate buffer, pH 7.5 (APPENDIX 2A), at a protein concentration of 200 µM.

4. Add the dye to the CBD-EGFP solution in two to three aliquots to bring the final dye-to-protein molar ratio in the reaction to 6:1.

   The molecular weight of the ISO-IAA is ~1300 Da, and the molecular weight of the CBD-EGFP is ~36.5 kDa.

   This ratio can be further optimized depending on the reactivity of the dye if different dyes are used. We suggest 6:1 as a useful starting point.

Using higher dye-to-CBD-EGFP ratios (e. g. 10:1 or 15:1) in the reaction mixture can produce excessive amounts of precipitated material and "over-labeling" (dye to protein ratio in the purified covalent adduct >1.0 due to labeling of the exposed cysteine in EGFP). EGFP mutants lacking surface cysteines can be used to ameliorate this problem. The optimal dye-to-protein ratio to use in the reaction mixture depends on the reactivity of the dye, so it can vary for different dyes, or dyes from different sources/batches.

5. Vortex the protein/dye mix once briefly at the highest setting, immediately after addition of the dye stock solution.

   Avoid excess mixing as this may denature the protein.

6. Wrap the tube containing the reaction mixture in foil and gently rotate on an end-over-end rotator at room temperature for exactly 1 hr.

   Here, the time is critical; longer reaction times result in over-labeling of the protein.

7. After the reaction is complete, add 1 to 5 μl of 2–ME to stop the reaction, and incubate the tube 5 to 10 min at room temperature on the end-over-end rotator.

8. Microcentrifuge the tube 2 min at 13,000 × *g*, room temperature, to pellet insoluble material.

9. Load the supernatant on a 0.5 cm × 6 to 8 cm G15 gel-filtration column to separate the conjugate from free dye. Equilibrate and run this column in 50 mM NaH_2PO_4 buffer at pH 7.5. Collect fractions of ∼200 μl each.

   The first colored band to elute contains the dye-labeled CBD-EGFP (meroCBD).

Analyze the labeled protein

10. Analyze an aliquot (3 to 5 μl) of each fraction on a 12% SDS-PAGE gel (*UNIT 6.1*) to confirm the presence and purity of the meroCBD. Visualize the gel with fluorescent illumination using a UV transilluminator or a hand-held UV lamp.

    Fluorescence visualization of the gel ensures labeling with the dye, and can reveal a band of free dye running at much lower molecular weight, often near marker dyes used in the electrophoresis sample.

11. To evaluate the success of the procedure, and generation of an optimal biosensor, determine the dye/protein ratio once the biosensor has been freed from unattached dye.

Determine protein concentration

It is also important to know the protein concentration to optimize later microinjection in living cells.

12. Determine an approximate protein concentration rapidly by taking an absorbance spectrum of the conjugate solution. Dilute a small aliquot (5 to 10 μl) in 50 mM Tris·Cl, pH 7.5 to 8.0, and use OD_{280} and Equation 14.11.1 above (also see *APPENDIX 3B*).

    Importantly, the protein absorbance at 280 overlaps dye absorbance.

13. Correct this overlapping absorbance by subtracting, from the OD_{280}, a fraction of the dye's absorbance at its maximum (∼593 nm); however, this is variable due to the solvent sensitivity of the dye. For a more accurate measure, compare a sample of the meroCBD (dye-labeled CBD-EGFP) to unlabeled CBD-EGFP by running them on the same gel, using different known concentrations of the unlabeled protein.

    Colorimetric assays, limited to those whose readouts do not overlap dye absorbance, have proven less reliable in our hands.

Determine the dye concentration

14. Determine the dye concentration by taking an absorbance spectrum of meroCBD. Dilute 5 to 10 μl of meroCBD in 100 μl DMSO.

    DMSO as a solvent will denature and overwhelm the effect of the protein or buffer on the dye's absorbance, resulting in a consistent dye extinction coefficient.

15. Use the OD at the dye absorbance maximum of 593 nm to calculate the dye concentration, using Equation 14.11.2 above.

BASIC PROTOCOL 2

IMAGING meroCBD IN LIVING CELLS

The authors of this unit routinely microinject cells on coverslips and image meroCBD following 30 min of recovery time in a tissue culture incubator. MeroCBD can produce puncta (possibly autophagy) after 2 to 3 hr in some cells, in which case the timing between microinjection and observation must be carefully controlled.

Cells are observed in a live-cell chamber atop an inverted epifluorescence microscope outfitted with an Hg arc-lamp light source. When imaging with a single camera, excitation and emission filter wheels can be used to alternately illuminate the dye and EGFP to obtain a ratiometric image set at every time point during the time-lapse experiment. If two cameras are available, two-camera modules such as those available from Olympus (U-DPCAD module), Technical Video (Technical Video Inc.), or Optical Insights (Dual-Cam) can be used to acquire two images simultaneously using a dual band-pass excitation filter. Since the dye and EGFP will have different brightnesses, band-pass filters can be designed to pass different amounts of excitation light at each wavelength through the dual band-pass filter.

When meroCBD is made using I-SO type fluorophores (Toutchkine et al., 2003, 2007a,b), including the new dyes we currently employ (Dyes 53 and 87; manuscript in preparation), EGFP bleed-through into the dye channel is practically zero. This is made possible by using relatively narrow excitation and emission band-pass filters. We use a customized multiband-pass dichroic mirror (Fig. 14.11.2) and the following excitation and emission filters: HQ470/40 and HQ525/50 for EGFP; HQ580/30 and HQ630/40 for dye (Chroma Technology).

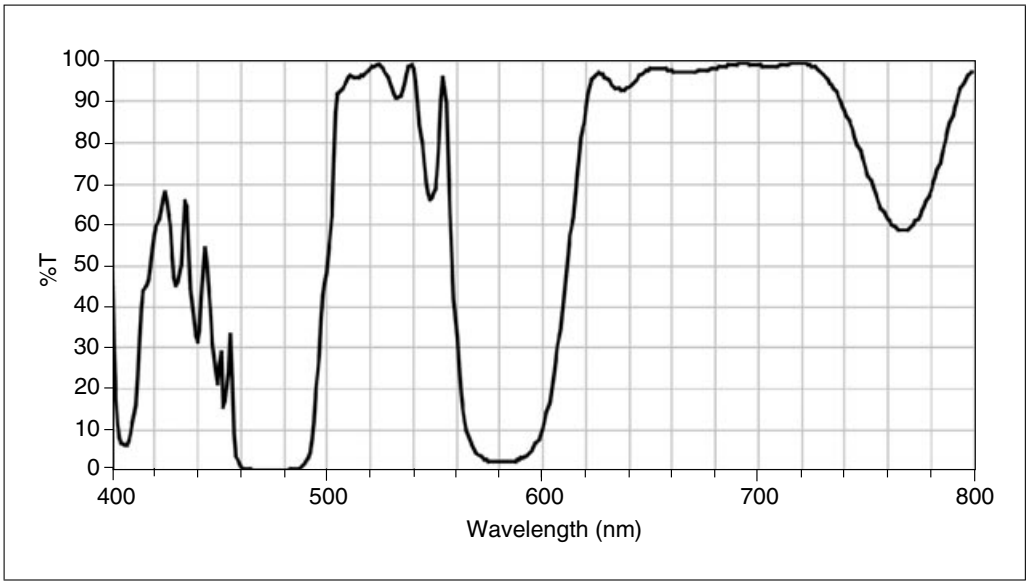

Figure 14.11.2 Transmittance spectra for the "Scripps Custom" dichroic mirror (Chroma Technology, lot no. 511111886).

The interval between images will vary depending on the images. We routinely acquire images at 10-sec to 1-min time intervals using 2 × 2 binning on a full-field 1.3k-by-1.0k cooled CCD camera. Importantly, the excitation light from the 100 W Hg arc lamp source is too bright, so it is routinely reduced using neutral-density filters for 4% to 10% transmittance (ND 1.4 to 1.0). The integration (exposure) time on a CCD camera depends on the quantum efficiency of the CCD and the noise characteristics of the camera. The dye exposure is usually 0.5× to 0.3× as long as the EGFP exposure. Dye exposure times may be reduced with some cameras; many current cameras, including those we use, are less efficient at the red wavelengths of the dyes. Users should fine-tune the exposure times depending on their optics and camera setup. Ideally, the integrated average intensity from both fluorescence channels should be similar, to maximize the dynamic range of the data. Cameras with 12-bit depth have an intensity range from 0 to 4096; we routinely fill ∼3000 of this dynamic range in a single field of view. We carefully monitor the pixel intensities near the cell periphery where the signals are usually low, aiming for approximately 100 to 200 over the background values. This translates to 2 to 3 in signal-to-noise ratio at the darkest regions.

Because different wavelengths are used to image EGFP and dye, many objectives (even apochromatic objectives) will focus on slightly different planes within the specimen. The *z*-axis difference between these two focal planes needs to be calibrated, and the objective slightly offset between the two images. We use a *z*-axis position control on our microscope to accomplish this. Typically, the *z*-distance offset is determined by focusing on the same small object at different wavelengths, using image-based autofocus (Shen et al., 2006, 2008) followed by manual fine adjustment. A script is written to execute the shifts in *z* for each color acquired during an automated time-lapse sequence. Moving the objective turret back and forth in different directions to account for these *z* offsets will not give reproducible results, due to hysteresis in the focus drive mechanism. Therefore, it is better to acquire different colors so that the objective always changes *z* position in one direction. Alternatively, a linear-encoder feedback or piezo-stage system can be installed for precise *z* positioning, to eliminate the hysteresis problem. It is important to always set the search range for autofocus to be more than twice as large as the total motions programmed in for *z* focus offset.

EXPRESSING THE RhoA SINGLE-CHAIN BIOSENSOR

BASIC PROTOCOL 3

The genetically encoded biosensor for RhoA consists of (N-terminus to the C-terminus) a small RhoA-binding domain (RBD) derived from the RhoA effector Rhotekin, ECFP, an unstructured linker of optimized length, pH-insensitive Citrine-YFP, and a full-length RhoA (Fig. 14.11.1B). Three different expression constructs for this single-chain biosensor have been developed, all available from the nonprofit distributor Addgene (*http://www.addgene.org*):

1. pTriEX mammalian expression and cloning vector (pTriEX-RhoA/amp resistance).

2. pBabe retroviral expression vector (pBabe-RhoA/amp resistance).

3. pBabe-sin-tet-CMV-puro retroviral vector for Tet-On/Off system (pBabe-sin-tet-CMV-puro-RhoA/amp resistance).
