Generally, tests 1 and 2 are the most reliable. They also lead to experimental techniques that can be utilized to reduce or eliminate mass transport artifacts. The most effective way for reducing mass transport influence is lowering the surface density of the immobilized ligand. Higher flow rates give only comparatively very small improvements, but are connected with strongly increased sample volume requirements. If the surface density of the ligand cannot be reduced further without leading to an insufficient signal-to-noise ratio, then switching from kinetic experiments to steady-state or competition steady-state experiments is the best solution. This will give information on the equilibrium constant. The kinetic rate constants can then be estimated best from a saturation experiment (approaching complete saturation of all surface sites), followed by a dissociation phase during which soluble ligand is coinjected. The soluble ligand will minimize rebinding and allow the estimation of the chemical off-rate constant, from which the chemical on-rate constant can be determined via Equation 17.6.3.

Analyte Aggregates

Oligomeric aggregates of analyte can be troublesome in biosensor experiments in two different ways. First, if trace amounts of higher oligomers are present in the analyte sample, this will lead, in the association phase, to a slow accumulation at the sensor surface, which can be visible as a slower second phase of binding. As depicted in Figure 17.6.2, these multimeric analyte aggregates can have multiple interactions with immobilized ligand molecules, and therefore they will dissociate much more slowly than the monomeric analyte. Consequently, they will appear in the dissociation phase as a submoiety with a very low off-rate constant (Davis et al., 1998). The troublesome trace amounts of oligomers can be eliminated by careful chromatographic purification, or their influence can be minimized by exchanging the role of analyte and ligand (Davis et al., 1998; Andersen et al., 1999). This is illustrated in the example of Figure 17.6.6, which demonstrates the importance of both the sample preparation and the choice of ligand and analyte.

The second potentially problematic form of aggregation is a surface-induced multimerization of the analyte. Because the local macromolecular concentrations at the sensor surface are very high (e.g., in the order of 10 mg/ml at a signal of 1000 RU in Biacore instruments), local crowding effects combined with non-specific interactions of the analyte can promote oligomer formation at the sensor surface (Fig. 17.6.7A; Minton, 1995, 1998). As with the influence of preformed aggregates, this process will lead to biphasic association and dissociation profiles, with the slower phase resulting from oligomer accumulation and dissociation, respectively. This process will be favored by

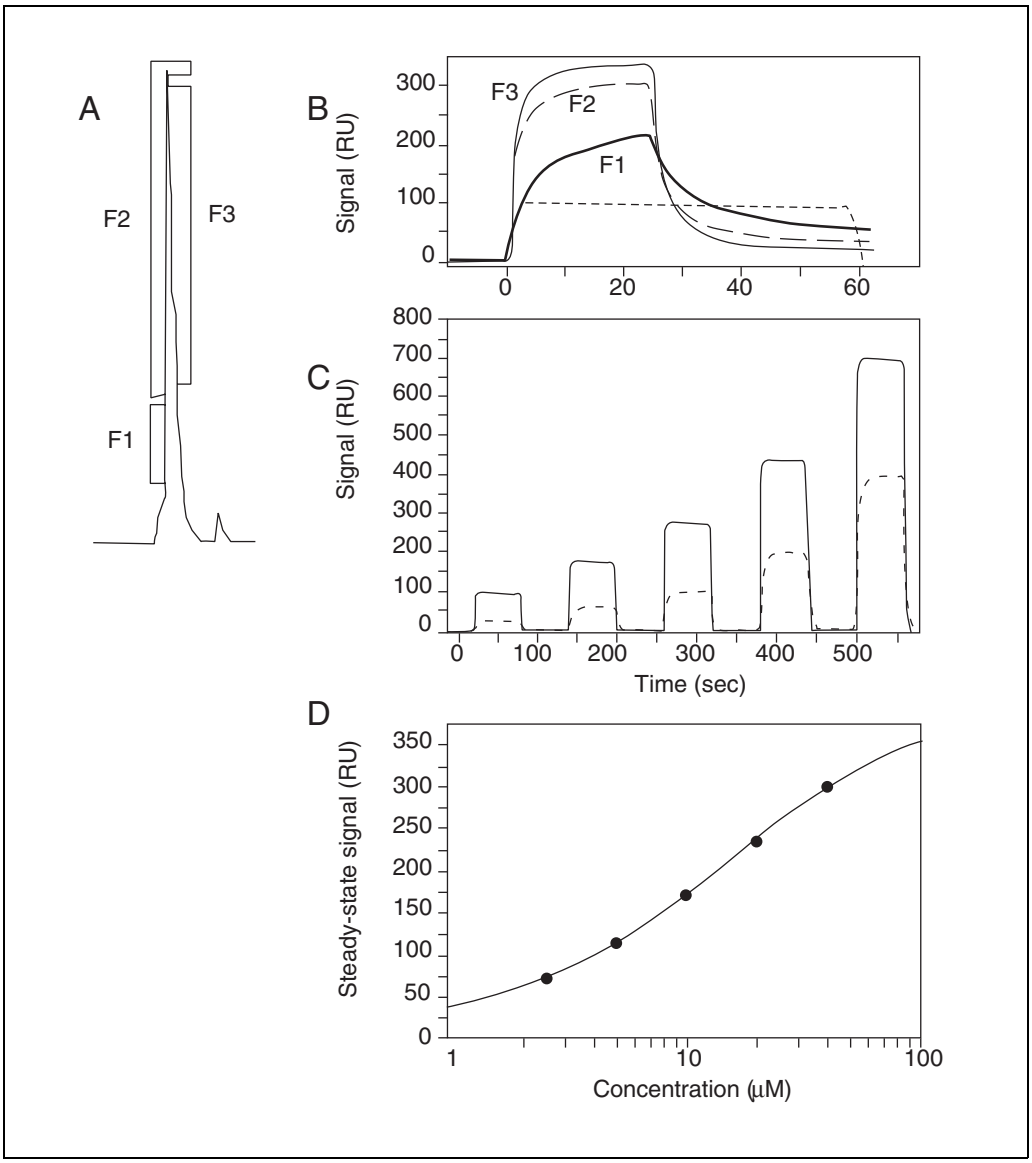

Figure 17.6.6 Exemplary data of the interaction of TCR with superantigen (for details of this interaction see Andersen et al., 1999). (**A**) Elution profile of the TCR from size-exclusion chromatography, indicating the fractions used for kinetic analysis of the interaction with immobilized superantigen, as shown in (**B**). It should be noted that fraction 1 (bold solid line), fraction 2 (dashed line), and fraction 3 (solid line) all exhibit multiphasic binding, with different relative magnitudes of the slower component. It should also be noted that despite the lower concentration of fraction 1, which results in the lowest response in the association phase, the signal in the dissociation phase is highest. This slower kinetic component in the binding progress curve reflects different amounts of aggregates bound to the sensor surface. The aggregates have a slower dissociation because of their multivalent attachment. For comparison, the same interaction is shown in the reverse orientation, with immobilized TCR and soluble superantigen (dotted line). (**C**) Sequence of association-dissociation curves at different superantigen concentrations, binding to immobilized TCR. In this orientation, the association and the dissociation is much faster, virtually monophasic, and the binding is completely reversible, which provides further evidence that the slow kinetic components introduced in the different fractions of the soluble TCR sample in Panel B are artifacts. For quantitative analysis, the signal measured at a nonfunctionalized surface (dotted line) is subtracted in order to remove the bulk refractive index contribution of the analyte. (**D**) A plot of the net steady-state binding signal versus superantigen concentration allows the measurement of the affinity of the interaction free from artifacts due to TCR aggregation that would be introduced in the configuration of Panel B.

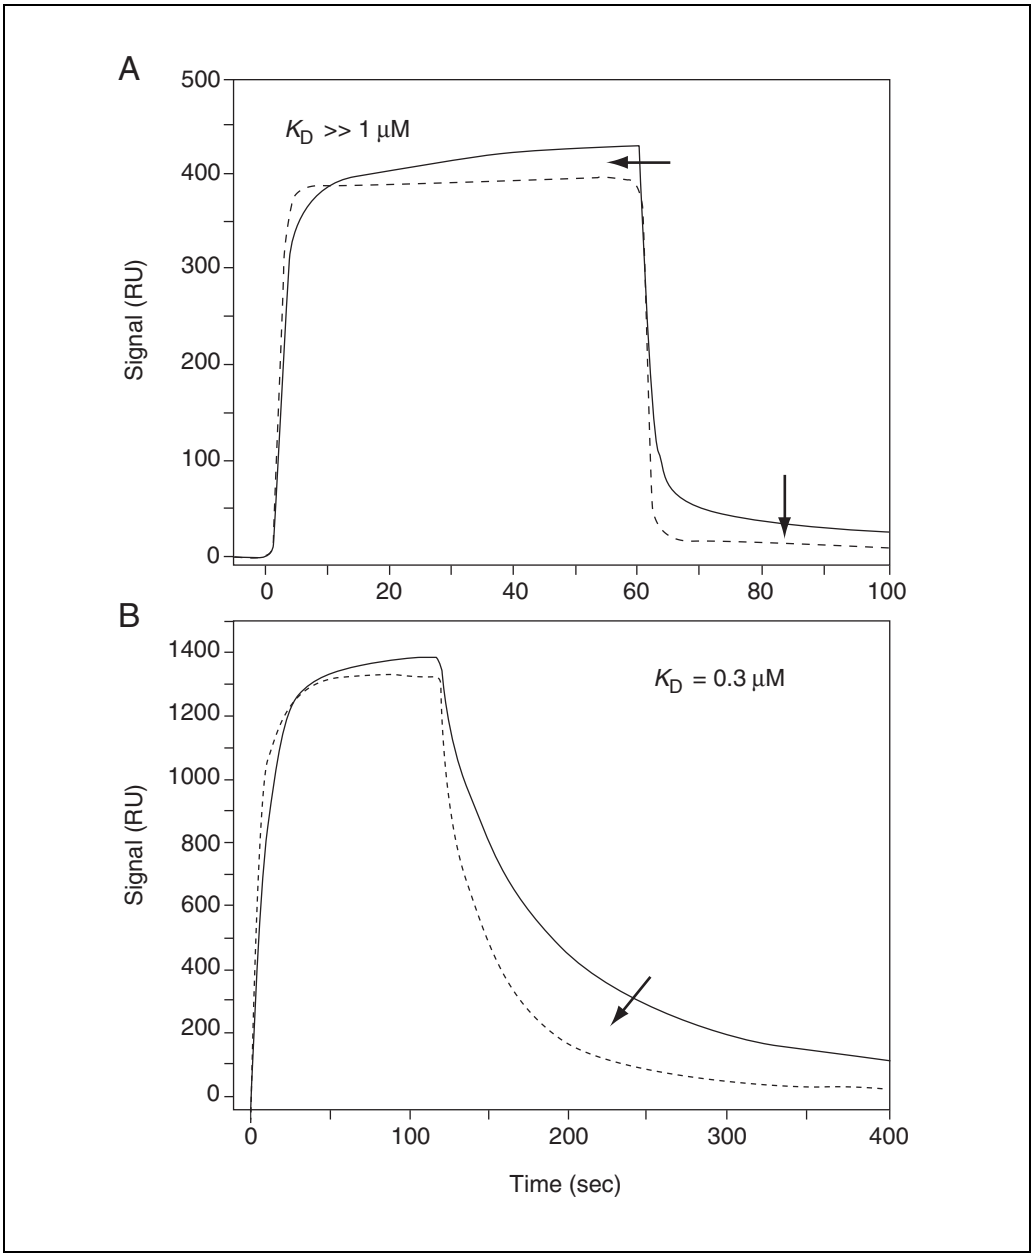

Figure 17.6.7 Effects of the ligand density on the binding kinetics for interactions with relative low affinity (**A**) and medium affinity (**B**). Each panel shows the interaction of immobilized superantigen with single-chain TCR, observed at high ligand surface density (1700 RU, solid lines) and low ligand surface density (700 RU, dashed lines). For easier comparison, the signal obtained at the lower density surface was scaled proportionally. In panel A, a slow phase of binding in the association phase and a residual binding (possible slow dissociation of multivalently bound aggregates) is introduced at high ligand density, under otherwise identical conditions. For the interaction in panel B, the chemical off-rate constant is smaller than for the low-affinity interaction shown above. Nevertheless, from comparison of the binding curves at different ligand surface densities (under otherwise identical conditions) it is obvious that an increased ligand density has significant effects on the surface binding kinetics. This observation could be due to aggregation or to mass transport limitations, both of which are more likely at higher ligand densities.

Table 17.6.1 Troubleshooting Guide for Measuring Protein Interactions by Optical Biosensors

Problem	Solution
No electrostatic preconcentration achieved; poor immobilization	Desalt protein (e.g., using spin column or microdialysis); decrease pH of buffer used for immobilization (should be below pI of protein).
Nonspecific binding is high	Analyte may be too hydrophobic, or there may be electrostatic interaction with surface. Increase salt or detergent concentration in running buffer.[a]
High signal from buffer; refractive index changes	If this does not result from high analyte concentrations, dialyze the analyte against running buffer, or use a spin column for buffer exchange.
Analyte does not come off after regeneration	Use increasingly harsher conditions for regeneration; test procedures used in affinity chromatography; check for strong nonspecific binding of the analyte; check for possible incomplete blocking of activated surface sites after immobilization.
No binding of biotinylated sample to streptavidin surface	Check for presence of free biotin in sample. Biotin on the analyte may not be accessible by surface-immobilized streptavidin; in this case try biotinylated linker.
Kinetics does not follow 1:1 binding	Check for mass-transport artifacts; check for possible traces of aggregates and for formation of aggregates at the surface; change immobilization method (avoid random coupling, avoid large surface densities). If this is not successful, go to steady-state analysis methods.
No steady-state binding is reached in a flow system	Use longer injections by increasing injection volume and/or decreasing flow rate. If sample volume is limiting, try an equilibrium titration.
Mass transport limitation	Decrease immobilization density.[b] If immobilization density cannot be lowered further, go to steady-state analysis, combined with establishment of lower limit of k_{dis} from dissociation after saturation.
Increasing slope in the association phase	Potential signature of mass transport; lower the immobilization density.
Increasing signal in the dissociation phase	Signature of mass transport limitation; lower the immobilization density.

[a]Be aware of effects of nonspecific binding on the binding kinetics, which substantially decreases the diffusivity of the analyte across the sensor surface, potentially leading to mass transport artifacts that cannot be detected through change of the ligand density.

[b]Increasing the flow rate affects transport much less, but consumes much more sample.

higher surface concentrations—i.e., higher density of immobilized ligand, and by higher ligand affinity (Fig. 17.6.7). As with mass transport limitations, they can be detected by variation of the surface density of the ligand. They also can be reduced by lowering the surface density of the immobilized ligand, by size-exclusion chromatography immediately prior to the experiment, or by exchanging the role of ligand and analyte.

Troubleshooting

As with other complex biophysical techniques and all investigations involving biological samples, it is impossible to give guidelines which are even nearly complete or generally helpful for troubleshooting. Nevertheless, Table 17.6.1 presents a small list of possible solutions to potential problems, given in the hope that some readers may find them helpful.

SUMMARY

Binding studies with optical biosensors can be very powerful and versatile. Among the most important virtues are their high sensitivity and utility for a broad range of affinities, real-time detection allowing studies of binding kinetics, and relatively low requirements of sample volume. We have outlined some general strategies and described some of the most commonly used techniques. The work with protein interactions at a surface can introduce additional experimental difficulties as compared to solution methods. As a general rule in experiments with optical biosensors, it is highly recommended that analyses be performed in different ways so that the consistency of the results can be tested. Biosensors can be an excellent tool in the study of protein interactions, and become particularly powerful if combined with other methods.

ACKNOWLEDGMENT

The authors are grateful for helpful comments by D. Margulies in the preparation of the manuscript. They acknowledge D. Kranz and K. Karjalainen for providing the samples used for some of the experiments shown. Peter Andersen acknowledges grant support by the Danish Natural Sciences Research Council.

Chromatin Immunoprecipitation for Determining the Association of Proteins with Specific Genomic Sequences In Vivo

Chromatin immunoprecipitation (ChIP) is a powerful and widely applied technique for detecting the association of individual proteins with specific genomic regions in vivo. In this technique, live cells are treated with formaldehyde to generate protein-protein and protein-DNA cross-links between molecules in close proximity on the chromatin template in vivo. A whole-cell extract is prepared, and the cross-linked chromatin is sheared by sonication to reduce average DNA fragment size to ~500 bp. The resulting material is immunoprecipitated with an antibody against a desired protein, modified (e.g., acetylated, phosphorylated, methylated) peptide, or epitope (in situations where the protein of interest is epitope-tagged). DNA sequences that directly or indirectly cross-link with a given protein (or modified variant) are selectively enriched in the immunoprecipitated sample. Thus, the method is not restricted to sequence-specific DNA-binding proteins. Reversal of the formaldehyde cross-linking by heating permits the recovery and quantitative analysis of the immunoprecipitated DNA. The amounts of specific genomic regions in control and immunoprecipitated samples are determined individually by quantitative PCR. The fold enrichment of certain chromosomal sequences (e.g., presumed binding sites) relative to other chromosomal sequences (e.g., presumed nonbinding sites) provides quantitative information about the relative level of association of a given protein with different genomic regions. Protein association with specific genomic regions can be performed under a variety of conditions (e.g., environmental change, cell-cycle status) and/or in wild-type versus mutant strains. Furthermore, as formaldehyde inactivates cellular enzymes essentially immediately upon addition to cells, ChIP provides snapshots of protein-protein and protein-DNA interactions at a particular time point, and hence is useful for kinetic analysis of events occurring on chromosomal sequences in vivo. In addition, ChIP can be combined with microarray technology to identify the location of specific proteins on a genome-wide basis (see Commentary). This unit describes the ChIP protocol for cells of the baker's yeast *Saccharomyces cerevisiae* (see Basic Protocol); however, it is also applicable to other organisms, although some organism-specific modifications related to cell lysis and sonication are necessary. A protocol for eluting immunoprecipitated protein-DNA complexes is also provided (see Alternate Protocol 1). As an alternative to gel electrophoretic analysis of the PCR products, a quantitative PCR analysis in real time with SYBR Green is also provided (see Alternate Protocol 2).

CHROMATIN IMMUNOPRECIPITATION

BASIC PROTOCOL

Materials

Saccharomyces cerevisiae cells to be studied
37% formaldehyde: store up to 1 year at room temperature
2.5 M glycine, heat sterilized
TBS (*APPENDIX 2A*), ice cold
FA lysis buffer with and without 2 mM PMSF (see recipe), ice cold
ChIP elution buffer (see recipe)
20 mg/ml Pronase (Roche) in TBS; store up to 1 year at −20°C
TE buffer, pH 7.5 (*APPENDIX 2A*)
20 mg/ml DNase-free RNase A (see recipe)
10× loading buffer (see recipe)

Contributed by Oscar Aparicio, Joseph V. Geisberg, and Kevin Struhl
Current Protocols in Cell Biology (2004) 17.7.1-17.7.23

Primary antibody against protein or epitope of interest
50% (v/v) protein A-Sepharose beads (Amersham Pharmacia Biotech) or equivalent in TBS
FA lysis buffer (see recipe), room temperature
FA lysis buffer (see recipe)/0.5 M NaCl
ChIP wash buffer (see recipe)
Primers (see Critical Parameters and Troubleshooting)
3000 Ci/mmol [^{32}P]dATP (optional; see annotation to step 30)

2-ml screw-cap microcentrifuge tubes with (relatively) flat bottoms
~0.5-mm-diameter silica-zirconia (BioSpec; preferred) or glass beads
Mini bead beater (BioSpec; preferred) or individual or multivortexer
5-ml syringe
15-ml conical tubes, disposable
25-G needles
Sonicator with microtip probe (e.g., Branson Sonifier 250)
End-over-end rotator
0.5-ml PCR tube
Spin-X centrifuge-tube filter (e.g., Corning)
65°C water bath
PCR-purification spin column (Qiagen)
Software for analyzing PCR primers and products

Additional reagents and equipment for growth of *Saccharomyces cerevisiae* cultures (*APPENDIX 3A*), phenol/chloroform extraction and ethanol precipitation (*APPENDIX 3A*), PCR (*APPENDIX 3F*), agarose gel electrophoresis (*APPENDIX 3A*), and nondenaturing acrylamide gel electrophoresis (*UNIT 6.5*)

CAUTION: When working with radioactive materials, take appropriate precautions to avoid contamination of the experimenter and the surroundings. Carry out the experiment and dispose of wastes in an appropriately designated area, following guidelines provided by the local radiation safety officer (also see *APPENDIX 1D*).

Cross-link protein-DNA complexes in vivo

1. For each sample, grow 200 ml *Saccharomyces cerevisiae* to $OD_{600} = 0.6$ to 0.8.

   CAUTION: *Keep cultures covered or work in a fume hood to avoid noxious formaldehyde fumes.*

   The volumes of culture can be reduced (20 ml is a reasonable minimum) or increased depending on need. Typically, 20 to 40 ml yeast is used for an individual immunoprecipitation, so the 200-ml volume permits multiple immunoprecipitations from the same cells. This is particularly useful for experiments involving the analysis of multiple factors or for carrying out independent immunoprecipitations involving the same factor for data reproducibility.

2. Add 5.5 ml of 37% formaldehyde (1% final). Cross-link 15 to 20 min at room temperature by occasionally swirling flask or shaking slowly on a platform.

3. Add 30 ml heat-sterilized 2.5 M glycine and incubate an additional 5 min at room temperature.

   Glycine stops the cross-linking by reacting with formaldehyde.

Harvest cells

4. Centrifuge cells 5 min at 2500 × *g*, 4°C. Discard supernatant into a chemical waste container and resuspend pellet in 50 to 200 ml ice-cold TBS. Repeat once.

5. Centrifuge cells for a third time 5 min at 2500 × g, 4°C. Discard supernatant and resuspend cells in 10 ml ice-cold FA lysis buffer.

6. Pellet cells by centrifuging in a benchtop centrifuge 5 min at 3000 rpm, 4°C. Discard supernatant.

   The cells can remain on ice for a few hours while other samples are being collected so that all samples may be processed as a group from this point onward. Alternatively, the cells may be frozen in liquid nitrogen or a dry ice/ethanol bath and stored up to several months at −80°C. This is particularly helpful if multiple samples are being generated during a time-course experiment. If cells are frozen, they must be thawed on ice before continuing with the procedure.

Lyse cells and isolate chromatin

For lysis using a mini bead beater (preferred)

7a. Resuspend the cell pellet in 1 ml ice-cold FA lysis buffer/2 mM PMSF. Fill three-quarters of a 2-ml flat-bottomed screw-cap microcentrifuge tube with ∼0.5-mm-diameter silica-zirconia or glass beads. Add cells, taking care to avoid introduction of bubbles, and screw the cap on tightly. Make sure there are no leaks.

   The mini bead beater is recommended because it is more efficient at breaking cells (multiple samples can be broken simultaneously). Silica-zirconia beads are more efficient at breaking cells than glass beads and are also recommended. To facilitate cell breakage with the mini bead beater, it is important that the final suspension nearly fill the tube. Do not break >160 OD_{600} units of cells (i.e., <5 × 10^9 cells) in a single 2-ml tube; for larger cultures, split the cells into multiple tubes.

8a. Lyse cells 3 min with a mini bead beater at maximum speed. Remove sample and incubate 1 min in an ice-water bath. Repeat five times for a total breakage time of 18 min.

   This step assumes breakage with silica-zirconia beads. The cell breakage time with glass beads may be longer.

For lysis using an individual or multivortexer

7b. Resuspend in 250 µl FA lysis buffer/2 mM PMSF. Add 350 µl silica-zirconia or glass beads to a 2-ml microcentrifuge tube with relatively flat bottom. Add cells.

   When using a multivortexer (or standard vortexer), it is important to keep the volume small as this improves cell breakage. Do not break >160 OD_{600} units of cells (i.e., <5 × 10^9 cells) in a single 2-ml tube; for larger cultures, split the cells into multiple tubes.

8b. Vortex continuously on an individual or multivortexer 30 min at full speed, 4°C.

   Success and reproducibility of the ChIP procedure is aided by complete (or near-complete) breakage of cells. In this regard, formaldehyde-cross-linked cells are considerably harder to break than untreated cells. The use of 1.5-ml microcentrifuge tubes with conical bottoms should be avoided because the narrow shape constricts bead movement, resulting in unequal lysis among samples. The 2-ml microcentrifuge tubes have a nearly flat bottom that allows the beads to vortex vigorously. The indicated vortexing or bead-beating conditions should be tested if a different device is used.

Isolate lysate

9. Cut a 5-ml syringe ∼1 cm below the flared opening (i.e., where the plunger is inserted) with a razor. Insert the smaller portion into a 15-ml disposable conical tube so that the flared portion of the truncated syringe rests on top of the conical tube opening, forming a microcentrifuge-tube holder.

10. Invert the sample tube and punch a hole in the bottom with a 25-G needle. Place the sample tube into the syringe/conical tube and punch a hole in the top cover with the same needle.

11. Spin the assembly in a benchtop centrifuge 1 min at 1000 rpm, 4°C. Place the conical tube on ice. Discard the 2-ml centrifuge tube containing the dry beads after confirming the sample has been transferred to the 15-ml tube.

    Occasionally, beads will clog the pierced hole and prevent complete transfer of the sample. If this occurs, pierce the tube one or two more times and repeat the step in the same 15-ml tube. No additional buffer should be added.

Shear DNA

12. Transfer the sample to a standard 1.5-ml microcentrifuge tube. Microcentrifuge 15 min at maximum speed, 4°C. Discard the supernatant and add 1 ml ice-cold FA lysis buffer to the pellet.

    The pellet contains the cross-linked chromatin, cell debris, and unbroken cells. The purpose of this centrifugation step is to remove soluble protein, most of which is not cross-linked to DNA, as it might contribute to nonspecific background in the subsequent immunoprecipitations step. There is no need to resuspend the pellet at this point.

13. Holding the microtip probe near the bottom of the tube to prevent foaming, sonicate the sample 30 sec at 4°C using a continuous pulse at a power output of 20%. Cool in an ice-water bath >1 min. Repeat two more times.

    Take great care that the sample does not get too hot.

    If a different sonication device is used, empirically determine the conditions necessary to achieve the desired level of DNA shearing. The shear size is determined as described below (see Critical Parameters and Troubleshooting).

14. Microcentrifuge 30 min at maximum speed, 4°C. Transfer the supernatant to a fresh 15-ml disposable conical tube, add 4 ml ice-cold FA lysis buffer, and gently mix by inversion. Remove 250 µl for checking DNA fragment size and freeze the remaining chromatin solution in 800-µl aliquots in liquid nitrogen.

    Upon sonication, the cross-linked chromatin is solubilized and purified away from the pelleted material which contains cell debris and unbroken cells. The resulting chromatin solution constitutes the input sample for the subsequent immunoprecipitation. The frozen aliquots are stable for many months when stored at −70°C and are suitable for immunoprecipitations.

Check chromatin-fragment size

15. Add 250 µl ChIP elution buffer and 20 µl of 20 mg/ml Pronase in TBS to the 250-µl chromatin aliquot. Incubate 2 hr at 42°C, followed by 6 hr at 65°C. Phenol extract and ethanol precipitate sample (*APPENDIX 3A*).

    While it is convenient to perform the reaction in a PCR machine overnight, it could just as easily be done in heat blocks or water baths. The same is true of the incubation described in step 26.

16. Resuspend in 30 µl TE buffer, pH 7.5, add 1 µl of 20 mg/ml DNase-free RNase A, and incubate 15 min at 37°C. Add 3 µl of 10× loading buffer and electrophoretically separate the material on a 1.5% agarose gel (*APPENDIX 3A*).

    Fragments should be between 100 to 1000 bp, with an average length of 400 to 500 bp.

    It is important to shear DNA fragments down to an average length of 400 to 500 bp. Longer fragments will increase the background and will decrease the resolution of the region to which the protein associates (see Commentary).

Immunoprecipitate

17. Incubate 800 µl chromatin solution with 10 µl primary antibody against the protein or epitope of interest and 20 µl of 50% (v/v) protein A–Sepharose beads in TBS on an end-over-end rotator 90 min at room temperature.

The actual amount of antibody needed has to be empirically determined and can vary considerably. The idea is to have an excess of antibody to efficiently precipitate at least 50% of the antigen in question. One way to assess the efficiency of antigen immunoprecipitation is to determine the amount of antigen present in the sample before and after the immunoprecipitation. An aliquot of 30 µl chromatin solution, taken before and after immunoprecipitation, is usually sufficient to visualize the protein of interest via immunoblotting (UNIT 6.2) and standard chemiluminescent detection; however, the samples have to be boiled in SDS/PAGE sample buffer for 30 min prior to loading in order to reverse the formaldehyde cross-links. The immunoprecipitation conditions can be varied (e.g., time, temperature, salt concentration, presence of detergents) if necessary.

Protein A–Sepharose beads are used here because they work well with most monoclonal and polyclonal sera derived from mouse and rabbit, respectively. In some cases, the use of other beads (e.g., protein G–Sepharose) may improve binding of some antibodies, including rat IgG (see Table 7.2.1).

18. Microcentrifuge beads 1 min at 3000 rpm, room temperature. Transfer 300 µl supernatant into a 0.5-ml PCR tube labeled "INPUT." Discard the rest of the liquid.

Wash beads

19. Resuspend beads in 700 µl FA lysis buffer, room temperature, and transfer mixture into a Spin-X centrifuge-tube filter.

The use of Spin-X filters aids in the recovery of the beads after washes and results in better uniformity between different samples. The procedure is also substantially faster with the filters, particularly when multiple samples are processed simultaneously. Alternatively, one could use conventional microcentrifuge tubes for the washes and aspirate the supernatant with a narrow-bore pipet tip after each spin.

20. Place the filter into a 1.5-ml microcentrifuge tube and mix sample 3 min on an end-over end rotator. Microcentrifuge 2 min at 3000 rpm, room temperature. Discard the flow-through liquid at the bottom of the tube.

21. Add 700 µl FA lysis buffer, room temperature, to the beads and repeat step 20.

Elute protein from beads

22. Wash beads for 3 min each with 700 µl FA lysis buffer/0.5 M NaCl, 700 µl ChIP wash buffer, and finally 700 µl TE.

For many polyclonal antibodies, the more stringent washes in this step result in a cleaner signal, while gentle washes frequently lead to an unacceptably high background. For some antibodies (e.g., monoclonal against peptide epitopes; see Alternate Protocol 1), repeated washes with FA lysis buffer, which are gentler, might be more appropriate.

23. Place filter unit containing the beads into a new 1.5-ml microcentrifuge tube and add 100 µl of ChIP elution buffer. Gently pipet up and down two or three times in order to dislodge beads from the filter. Incubate 10 min in a 65°C water bath.

A water bath is used instead of other heating apparatuses in order to improve heat transfer.

24. Microcentrifuge beads 2 min at 3000 rpm, room temperature. Discard filter with beads. Transfer the eluate into a 0.5-ml PCR tube labeled "IP."

Reverse cross-links and purify DNA

25. Add 80 µl TE and 20 µl Pronase in TBS to the IP tube. Combine 20 µl INPUT material (step 18), 100 µl ChIP elution buffer, 60 µl TE, and 20 µl TBS into a new 0.5-ml PCR tube.

26. To reverse cross-links, place tubes into a PCR machine. Incubate 2 hr at 42°C, followed by 6 hr at 65°C. Store samples at 4°C until use.

The incubation at 42°C allows for Pronase digestion of cross-linked polypeptides, while the 65°C incubation results in a reversal of the formaldehyde cross-links.

27. Purify DNA using a Qiagen PCR-purification spin column as per manufacturer's instructions.

    This will require double loading of the spin column (i.e., 600 μl spin through and then repeat).

    Alternatively, add 20 μl of 4 M LiCl and purify by extracting with 25:24:1 phenol/chloroform/isoamyl alcohol, followed by extraction with chloroform and ethanol precipitation (APPENDIX 3A). It is useful to add 2 μl of Pellet Paint (Novagen) prior to the addition of ethanol, as this aids both the ethanol precipitation and visualization of the very small pellet.

28. Resuspend in 300 μl TE and store at −20°C.

    DNA pellets stored in this fashion should be stable for years.

Perform quantitative PCR

29. Design primer pairs for the desired genomic regions to be examined.

    Success in obtaining high-quality data is critically dependent on good primer design (see Critical Parameters and Troubleshooting). In general, primers should be 20 to 30 bases long with a T_m of 55° to 60°C. The design of good primers is greatly facilitated by commercially available software packages such as Oligo 6.6 (see http://www.oligo.net) or Primer Express 1.5 (see http://www.appliedbiosystems.com). Most primers require no purification or special treatment prior to PCR. Amplification products should be 75 to 350 bp; longer products should be avoided, as the amplification efficiency is substantially lower. A final primer concentration of 1 μM works well for most primers, but in some instances, improved product specificity may be obtained by lowering the final primer concentration 5 to 10 fold. Refer to APPENDIX 3F for more information.

30. Dilute INPUT DNA (obtained from step 18) in three separate tubes by a factor of 5, 10, and 20. Set up standard PCR reactions (*APPENDIX 3F*) with 2 μl DNA sample, primers at 1 pmol/μl, and total reaction volumes of 10 to 50 μl. If PCR products will be detected by radioactivity, add 1 μCi of 3000 Ci/mmol [^{32}P]dATP.

    For a typical measurement, the three dilutions of input DNA are tested along with duplicate immunoprecipitated samples (or undiluted and 5-fold diluted immunoprecipitated samples). This permits an assessment of whether the assay is being performed in the linear range as well as of the reproducibility of the PCR reaction. The immunoprecipitated DNA is typically used without dilution, although it is useful to analyze different amounts to ensure that it is also in the linear range.

    There are several key parameters for achieving an optimum PCR reaction. For example, it is very important to have a quality repeat pipettor that can reproducibly dispense 2 μl DNA. Pipetting inaccuracies at this stage will lead to greater well-to-well variability and poorer reproducibility among identical samples. Additionally, multiple primer pairs (up to 4 to 5) can be included in the same reaction, provided that the PCR products can be unambiguously resolved from each other by gel electrophoresis. This permits simultaneous and internally controlled analysis of multiple genomic regions in a single reaction. However, it is critical to ensure that there is no competition between the different primer pairs and PCR products. Also, comparable results are obtained when PCR reactions are performed in volumes between 10 to 50 μl; using smaller volumes reduces the cost and facilitates loading of the reaction products on gels. See Critical Parameters and Troubleshooting for a discussion of primer choice.

    Detection of PCR products by [^{32}P]label is recommended over detection by ethidium bromide or SYBR Green (see Alternate Protocol 2) staining as it improves the sensitivity and extends the linear range of detection; however, it necessitates using the usual precautions in working with radioactivity.

31. Carry out hot-start PCR using the following thermal cycling parameters.

Initial step:	10 min	95°C	(denaturation)
26 cycles:	30 sec	95°C	(denaturation)
	30 sec	55°C	(annealing)
	1 min	72°C	(extension)
Final step:	4 min	72°C	(final extension).

These conditions are generally appropriate for most situations. The annealing temperature may have to be adjusted if the melting temperatures of the primers is substantially above or below 55°C. The number of cycles might also have to be adjusted in some cases if reactions are not in the linear range. See Critical Parameters and Troubleshooting for more details.

Analyze PCR products

32. Add the appropriate loading buffer to the PCR products, and analyze by electrophoresis on nondenaturing polyacrylamide (*UNIT 6.5*) or agarose gels (*APPENDIX 3A*).

The gels should be stained either with ethidium bromide or SYBR Green dyes, or analyzed by autoradiography or PhosphorImager.

33. Quantitate the relative amount of PCR products using appropriate software for the accompanying instrument.

34. Calculate the apparent immunoprecipitation efficiency for a specific fragment by dividing the amount of PCR product obtained with the immunoprecipitated DNA by the amount obtained with the input DNA.

A volume of 2 μl immunoprecipitated DNA sample (1/150 total immunoprecipitated material) contains ~200 times the number of cell equivalents as 2 μl INPUT sample that has been diluted 5-fold (1/30,000 of the original aliquot that was immunoprecipitated). Thus, if the amount of PCR product in the immunoprecipitated sample is equal to the amount of PCR product in the 5-fold diluted INPUT sample, the apparent immunoprecipitation efficiency is 0.5%. The apparent immunoprecipitation efficiency for the background signal is typically ~0.025% to 0.05%, and it should not be higher than 0.1%.

SPECIFIC PEPTIDE ELUTION OF PROTEIN-DNA COMPLEXES IMMUNOPRECIPITATED FROM CROSS-LINKED CHROMATIN

ALTERNATE PROTOCOL 1

Peptide elution represents an alternative method for removal of immunoprecipitated protein-DNA complexes from beads. In this procedure, beads containing the immunoprecipitated complexes are incubated with high concentrations of a peptide recognized by the antibody used in the immunoprecipitation. The added peptide competes with the protein antigen of interest for binding to the antibody, and specifically liberates the protein-DNA complexes from the beads. The high specificity of peptide elution reduces the nonspecific background (typically by a factor of 2 to 4), which makes it the method of choice, particularly for applications where the expected immunoprecipitation signal is low. Peptide elution is especially useful for chromatin immunoprecipitation experiments involving proteins that are tagged with the HA or myc epitopes (in single or multiple copies); however, it would also be appropriate in cases where the antibody used for the immunoprecipitation was generated against a defined peptide sequence. Peptide elution is slightly more expensive than conventional elution, due to the cost of the peptide. In general, peptide elution should be used in conjunction with gentle washes during the immunoprecipitation procedure described below, which minimizes antigen leaching. Stringent washes, such as those employed in the main method (see Basic Protocol), will often result in signals that are several-fold lower, with little or no improvement in background. Finally, peptide elution may vary in quality depending on factors such as the number of epitopes in the antigen and the relative stability of the antibody-antigen interaction.

Additional Materials *(also see Basic Protocol)*

1 mg/ml peptide (e.g., myc, HA) in TBS (see *APPENDIX 2A* for buffer)

For this protocol, follow steps 1 to 21 of the main method (see Basic Protocol), replace steps 22 to 25 with the following, and continue with step 26 onwards.

22. Repeat FA lysis buffer wash (see Basic Protocol, steps 20 and 21) three additional times for a total of five washes.

    Repeated washes with FA lysis buffer are much more gentle than the single washes with FA lysis buffer/0.5 M NaCl, ChIP wash buffer, and TE used in the Basic Protocol and result in higher signal-to-background ratios.

23. Place the Spin-X centrifuge-tube filter unit containing the beads into a new 1.5-ml microcentrifuge tube and add 100 µl of 1 mg/ml peptide (typically myc or HA) in TBS. Gently pipet up and down two or three times in order to dislodge beads from the filter. Incubate 30 min at 30°C.

24. Microcentrifuge beads 2 min at 3000, room temperature. Discard filter with beads. Transfer the eluate into a 0.5-ml PCR tube suitable for PCR labeled "IP."

25. Add 150 µl TE, pH 7.5, 250 µl of ChIP elution buffer, and 20 µl of 20 mg/ml Pronase in TBS.

ALTERNATE PROTOCOL 2

ANALYSIS OF CHROMATIN IMMUNOPRECIPITATION EXPERIMENTS BY REAL-TIME QUANTITATIVE PCR WITH SYBR GREEN

Quantitative PCR (QPCR) analysis in real time with SYBR Green has several advantages over the analysis of PCR reactions by gel electrophoresis (see Basic Protocol, step 32). First, the method saves considerable time because no gels are involved and because quantitative values are obtained directly from the data curves and do not require densitometry or phosphor imager analysis. As a consequence, this approach permits very rapid analysis of much larger numbers of chromatin immunoprecipitation samples than can be performed with the Basic Protocol. Using standard 96-well instruments, it is a straightforward procedure to analyze 100 to 200 samples/day (in replicates of three) with only 1 to 2 hr of total setup time. With newer 384-well instruments and automated robotics equipment, sample throughput can be further increased to thousands per week. Second, the data generated by this procedure are more accurate and reproducible, because quantitative values are determined from continuous sampling throughout the PCR reaction rather than a single end-point determination. Furthermore, the quality and "linear range" of every PCR reaction are directly visualized. Third, the procedure is significantly safer for the researcher, as no radioactive materials or toxic acrylamide are used. The major disadvantage of this procedure is that the measurements are performed individually and hence are not internally controlled, whereas the Basic Protocol permits the simultaneous analysis of multiple genomic regions in a single PCR reaction (provided the individual primer pairs function independently). As such, the Basic Protocol is more useful for analyzing the same small set of genomic regions under multiple experimental conditions and for simultaneous analysis of electrophoretically distinguishable alleles of a given genomic region.

SYBR Green is a sensitive and highly selective double-stranded DNA (dsDNA)–binding dye that remains associated even at the high temperatures normally used for PCR template extension. Real-time PCR reactions involving SYBR Green are performed with standard oligonucleotide primers, and hence are much less expensive than real-time PCR reactions using fluorophore-conjugated oligonucleotides (e.g., TaqMan or Lux probes). Measurements of SYBR Green fluorescence at the polymerase extension step of PCR, when

plotted against PCR cycle number, provide both a qualitative assessment of the progress of the PCR and a way to quantitate the relative amount of DNA template initially present in the reaction. Typical real-time QPCR graphs feature the plot of the $\log_{10}$(Net fluorescence) on the *y* axis versus the PCR cycle number on the *x* axis, and usually contain three well-defined stages: (1) baseline, (2) linear, and (3) plateau. In the baseline stage, the amount of DNA product formed is still below the sensitivity threshold of SYBR Green, so product formation is undetectable. This part of the curve is typically used as a baseline for SYBR Green signal drift. The linear part of the curve is the most important from the analytical standpoint, because it is at this stage that the rate of PCR product accumulation is both constant on a per-cycle basis and readily detectable by increased SYBR Green fluorescence. Finally, as all of the SYBR Green in the reaction becomes bound to the recently synthesized PCR products, the amount of fluorescence stays constant from cycle to cycle and the reaction reaches a plateau.

In the protocol described below, PCR is performed under special conditions that minimize the inhibitory effects of SYBR Green on *Taq* activity and maximize the linear range of product detection. After amplification is complete, raw data are stripped of outliers and exported in a format readable by a spreadsheet program such as Microsoft Excel. Finally, data points from replicate samples are averaged, and mean values are further manipulated and ultimately compared to some internal reference or control.

Additional Materials *(also see Basic Protocol)*

Input DNA (see Basic Protocol, step 28)
Immunoprecipitated fragments ("IP" sample; see Basic Protocol, step 23)
2× SYBR Green *Taq* mix (see recipe)

Real-time PCR machine and corresponding software (e.g., ABI)
96-well PCR plates (ABI, cat. no. 4306737) and optical adhesive covers
Centrifuge with swinging-bucket rotor and microtiter plate adapter
Spreadsheet program (e.g., Microsoft Excel)

Set up PCR reactions

1. Dilute input DNA to an approximate equivalent of 1×10^6 cells/ml in TE buffer, pH 7.5.

   If immunoprecipitations were performed as described in the Basic Protocol, then a 1:25 dilution of the input sample from step 28 will result in 1:1000 overall dilution and will correspond to ~5×10^8 to 1×10^9 cell equivalents.

2. If necessary, resuspend immunoprecipitated fragments in TE buffer, pH 7.5, so that the approximate cell equivalent is 1×10^9 cells/ml.

   Immunoprecipitated DNA derived from the IP sample obtained by the Basic Protocol (step 23) is appropriately diluted and needs no further treatment.

3. Prepare PCR primer stocks by mixing each primer pair at a final concentration of 3.3 μM in TE buffer, pH 7.5.

   It is critical to test newly obtained primer pairs for amplification specificity and performance under conditions that will be used for real-time PCR with SYBR Green (see Critical Parameters and Troubleshooting). SYBR Green can inhibit PCR reactions, and primer pairs that are appropriate for quantitative PCR analysis in the absence of SYBR Green may not work well in the presence of SYBR Green. High-quality primer pairs should result in ~1.9-fold amplification/cycle (this can be determined from quantitative analysis of raw fluorescence data for each cycle, which is generally available on commercial instruments). Amplified material at the completion of the PCR should contain only one band

(as assayed on high-percentage agarose or polyacrylamide gels). Specificity information may also be obtained by running dissociation curves on reactions following the conclusion of the PCR run. Typically, samples are melted for 15 min at 95°C, cooled to 60°C, and then slowly heated back up to 95°C over a period of 20 min. Plotting the first derivative of the fluorescence against the temperature allows for simple visual identification of sample heterogeneity. Some instrument-specific software packages have built-in modules for dissociation curve analysis.

4. Select and label the wells to be used in the run.

   In general, individual samples should be run in triplicate. Obvious outliers occur with some frequency, generally at <5%. Triplicate analysis of samples permits removal of those outliers while still allowing for inclusion of two accurate measurements for each sample. While this reduces the number of different samples that can be run at any given time, the resulting data is much more reliable and accurate.

   For each primer pair examined, the input DNA samples should be run alongside the immunoprecipitated samples. Amplification efficiencies among different primer pairs vary slightly on a per-cycle basis, but those slight variations in efficiency translate into substantially different amounts of amplified material in the cycle range used for analysis. Precise quantitation of relative binding cannot be accurately performed without primer pair–specific input signal.

   Detailed instructions on the use of the real-time PCR machine and general issues, e.g., calibration and camera exposure settings, are addressed in the documentation that accompanies the instruments.

5. Program the real-time PCR machine as follows:

1 cycle:	10 min	95°C	(initial denaturation)
40 cycles:	30 sec	95°C	(denaturation)
	30 sec	53°C	(annealing)
	30 sec	72°C	(extension).

   Collect the data only at 72°C.

   The annealing temperature may have to be adjusted if the melting temperatures of the primers are substantially above or below 53°C. If the desired amplification product is >500 bp (this is not recommended), the extension time at 72°C should be increased to 1 min. See Critical Parameters and Troubleshooting for more details.

6. Using a small-volume automatic pipettor (20-µl capacity), place a 2-µl aliquot of each DNA template into the appropriate wells of a 96-well PCR plate. Gently tap the plate to allow the sample droplets to fall to the bottoms of the wells.

   It is very important to have a quality repeating pipettor that can reproducibly dispense small volumes of sample into the wells. Pipetting inaccuracies at this stage will lead to greater well-to-well variability and poorer reproducibility among identical samples.

7. Using a small-volume automatic pipettor (20-µl capacity), place a 3-µl aliquot of primer mix (see step 3) into the relevant wells and tap the plate a few times to settle the contents.

   On many real-time PCR machines, results from 10-µl reactions are virtually indistinguishable from those of 25- and 50-µl reactions in their accuracy and reproducibility. The use of 10-µl reactions provides substantial savings in reagent costs. On some machines, the minimal reaction volume needed for accurate and reproducible results may be greater.

8. With a larger automatic pipettor (100-µl capacity), add 5 µl of 2× SYBR Green *Taq* Mix to every assayed well. Place microtiter plate into appropriate microtiter plate adapter and centrifuge 1 min at 200 × *g*, room temperature, in a swinging-bucket rotor.

The 2× SYBR Green Taq Mix contains a variety of components that considerably reduce the inhibitory effect of SYBR Green, thereby resulting in more reproducible signals that require fewer amplification cycles. Comparable mixes containing proprietary buffers can be obtained commercially. It is critical that quantitative PCR reactions containing SYBR Green be performed under conditions of efficient amplification (e.g., 1.9-fold amplification/cycle).

9. Seal plate with clear optical adhesive covers, overlay foam compression pad with gold side facing up, and place into the real-time PCR machine. Secure lid.

   The details of this step may differ, depending on the machine.

10. Start the PCR protocol (see step 5). After completion, save the run for future analysis.

DATA analysis

11. Open the file containing the real-time data according to the manufacturer's instructions for the instrument.

    Although the specific protocol will depend on the software and instrument, the overall logic and approach to the analysis of real-time data is generally applicable.

12. Look at the different curves and set the baseline as needed.

    Generally, the baseline should be set from cycle 3 to the cycle just prior to where the curves start increasing in a linear fashion. It is desirable to have at least 10 cycles for the calculation of the baseline, as this results in increased accuracy in the subsequent calculations of the threshold cycle.

13. Change the value in the Threshold box to be about halfway up in the linear range, and apply changes to the data set.

    The threshold cycle is defined to be the PCR cycle at which the fluorescence is 10 times (10 is the default multiplier) the standard deviation obtained in the baseline calculation. When the multiplier is set to 10, the fluorescence at the threshold cycle is considered the lowest fluorescence value that is significantly above the background. In practice, this number frequently lies in the nonlinear range of many of the curves. For later calculations, it is easier to manually set the fluorescence value used to calculate the threshold cycles to 0.04. At this value, all the curves should be in the linear range and well above the baseline, allowing for far more accurate comparisons of the threshold cycles. On occasion, however, it will be necessary to adjust this value either up or down to better reflect the linear range of net fluorescence for most of the curves.

14. Manually select one group of triplicates and visually inspect their amplification plots. If curves are essentially superimposable and the threshold cycle (C_T) values are close to each other (maximal and minimal replicates within 1 cycle, preferably within 0.5 cycles), proceed to the next triplicate sample. Otherwise, remove the outlier and continue to the next triplicate.

    Decisions regarding the removal of some outliers could either be straightforward or judgment calls, depending on the circumstances. In cases where two out of three curves are superimposable while the third is clearly off by more than a cycle, it is a fairly easy decision to consider the third replicate an outlier. If the curves are closer, the decision on which one to eliminate, if any, becomes much more difficult. As a general guide only, if the spread between the lowest and highest C_T values is less than 0.5, it is probably safe to average all the C_T values (see step 12). If the C_T range is <1 but >0.5, the data are less reliable and the decision to remove any data points should probably be made on a case-by-case basis. It is highly recommended that the PCR be repeated for samples where the C_T ranges are >1 with no two curves superimposable.

15. Proceed to analyze the data for all triplicates in the manner described above. Save the results in a different file.

16. Export the data to a spreadsheet program such as Microsoft Excel by using built-in filters. The file should not contain omitted wells (see step 14) and should be in a column format containing well positions, descriptors, and C_T values for each selected well.

    Final calculations are most easily handled in a spreadsheet but could also be performed with a scientific calculator.

17. Open the exported file. Proceed to average triplicate measurements for each sample in a new column ($^{AVERAGE}C_T$).

    For some samples, there may be only two measurements left as a result of the removal of outliers in step 14.

18. For each primer pair, subtract the $^{AVERAGE}C_T$ (INPUT) from $^{AVERAGE}C_T$ (IP) in a new column. This number is the $^{NET}C_T$.

    This value represents the difference in cycles between the immunoprecipitated sample and the input DNA.

19. Subtract $^{NET}C_T$ for one primer pair (experimental; EXPT) from the $^{NET}C_T$ of another primer pair that serves as a reference or a control (CTRL) in a new column. The resulting value is $^{NET}C_T{}^{EXPT} - CTRL$. Repeat $^{NET}C_T$ subtraction of control primer for all other experimental primers.

    It is very desirable to have a control primer pair that can be used to assess the relative cross-linking efficiency at promoters of interest. Frequently, the control primer pair could be specific for a DNA region that does not bind to the immunoprecipitated protein of interest. The signal from the control primer pair could then be considered the background, and the binding efficiency of the protein to different promoter regions could be expressed as fold over background binding.

20. Evaluate the expression POWER ([mean primer slope], $[- {}^{NET}C_T{}^{EXPT} - CTRL]$), where the [mean primer slope] is the base and $[- {}^{NET}C_T{}^{EXPT} - CTRL]$ is the exponent. Repeat the process with other primers by using the different $^{NET}C_T{}^{EXPT} -$ CTRL values calculated in step 19.

    The actual value calculated in the POWER expression above is the degree of occupancy of the immunoprecipitated protein at the sequence of interest relative to that of a control (or background) DNA region.

    Perfectly efficient PCR, in which the number of amplified molecules doubles every cycle, has a primer slope of 2. As defined, this value is independent of primer pair sequence, target sequence length, and other variables that under normal circumstances may adversely affect the efficiency of amplification. In practice, however, the mean primer slope is almost always <2 and is slightly variable from primer pair to primer pair, mostly due to differences in primer sequence and other parameters (e.g. GC content and length of amplified sequence). For the majority of primers designed to amplify S. cerevisiae promoter sequences, the mean slope is 1.9 ± 0.06, and this value can be safely used in the calculations above. However, it is still good practice to calculate representative slopes for every newly synthesized primer pair; any substantial deviation from 1.9 (± 0.06), especially to the downside, should be viewed suspiciously. Frequently, a slope that substantially deviates from the normal range is indicative of problems in the amplification.

    The mean primer slope for a given primer pair is most easily calculated by performing linear regression on the linear portion of the amplification plot (log net fluorescence versus PCR cycle). In order to perform this calculation, it is first necessary (if possible) to export a file containing the fluorescence values for all the wells in use at every PCR cycle (see software manuals for more information). It is then possible to use linear regression to estimate the slope within the linear range (i.e., by using the MS Excel function LINEST). Since it is rather time-consuming to calculate slopes for an entire 96-well plate one-by-one, it may well be worthwhile to write a macro (or a stand-alone program) to automate this process.

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

ChIP elution buffer

50 mM Tris·Cl, pH 7.5 (*APPENDIX 2A*)
10 mM EDTA (*APPENDIX 2A*)
1% (w/v) SDS (*APPENDIX 2A*)
Store up to 1 year at room temperature

ChIP wash buffer

10 mM Tris·Cl pH 8.0 (*APPENDIX 2A*)
0.25 M LiCl
1 mM EDTA (*APPENDIX 2A*)
0.5% (v/v) Nonidet P-40
0.5% (w/v) sodium deoxycholate
Store up to 1 year at room temperature

FA lysis buffer with and without 2 mM PMSF or 0.5 M NaCl

For FA lysis buffer:
50 mM HEPES: adjust pH to 7.5 with KOH
150 mM NaCl
1 mM EDTA (*APPENDIX 2A*)
1% (v/v) Triton X-100
0.1% (w/v) sodium deoxycholate
0.1% (w/v) SDS
Store up to 1 year at room temperature

For FA lysis buffer/2 mM PMSF add 100 mM phenylmethylsulfonyl fluoride (PMSF) in ethanol (store up to 1 year at −80°C) to a final concentration of 2 mM just before use. For FA lysis buffer/0.5 M NaCl, change the amount of NaCl added to 0.5 M. Store up to 1 year at room temperature

Loading buffer, 10×

20% (w/v) Ficoll 400
0.1 M disodium EDTA, pH 8 (*APPENDIX 2A*)
1.0% (w/v) sodium dodecyl sulfate
0.25% (w/v) bromphenol blue
0.25% (w/v) xylene cyanol (optional; runs ∼50% as fast as bromphenol blue and can interfere with visualization of bands of moderate molecular weight, but can be helpful for monitoring very long runs)

RNase A stock solution (DNase-free), 2 mg/ml

Dissolve RNase A (e.g., Sigma) in DEPC-treated H_2O (*APPENDIX 2A*) to 2 mg/ml. Boil 10 min in a 100°C water bath. Store ≤1 year at 4°C.

SYBR Green Taq mix, 2×

12 mM Tris·Cl, pH 8.3 (*APPENDIX 2A*)
50 mM KCl
5 mM $MgCl_2$

continued

150 mM trehalose (Sigma)
100 mM betaine (Aldrich)
0.2% (v/v) Surfact-Amps 20 (Pierce; active ingredient, Tween 20)
0.2 mg/ml nonacetylated BSA (Sigma, B8667)
1 μM 5(6)-carboxy-X-rhodamine (ROX; Helix Research)
0.133× SYBR Green (Molecular Probes; final dilution 1:75,000)
Store solution with above components indefinitely at −80°C or up to several months at 4°C in the dark
Add the following immediately prior to use
0.5 mM each dATP, dTTP, dCTP, dGTP
0.2 U/μl hot-start *Taq* DNA polymerase

The amount of Taq DNA polymerase may need to be slightly adjusted to account for batch/activity variations among different manufacturers.

COMMENTARY

Background Information

Direct protein-DNA contacts and indirect protein-DNA interactions regulate fundamental chromosomal functions such as DNA replication, gene expression, and chromosome segregation. Thus, knowledge about the distribution of particular proteins on specific chromosomal DNA sequences can provide important insights into the mechanisms that govern chromosomal functions, structure, and organization. In vivo footprinting methods provide high-resolution mapping of protein-DNA interactions but cannot directly identify the chromatin-associated protein(s) responsible for the footprint. Chromatin immunoprecipitation, by contrast, is ideally suited for determining the identity of proteins associated with specific DNA sequences in vivo, albeit with lower resolution (≤1 kbp).

Two groups, Gilmour and Lis and Solomon and Varshavsky, independently pioneered cross-linking and immunoprecipitation methods for in vivo chromatin analysis (Gilmour and Lis, 1984; Solomon and Varshavsky, 1985; Solomon et al., 1988; Gilmour et al., 1991). These methods exploited cross-linking to conserve in vivo chromatin structures and permit their isolation under the stringent conditions necessary to isolate soluble chromatin. Cross-linked protein-DNA complexes were purified by cesium chloride centrifugation (a time-consuming step) and subjected to immunoprecipitation. Their methods were distinguished primarily by the cross-linking agent: Gilmour and Lis employed UV irradiation, while Solomon and Varshavsky used formaldehyde. The biochemical characteristics of each method have been discussed extensively (Gilmour and Lis, 1984; Solomon and Varshavsky, 1985; Orlando et al., 1997, and references therein). In short, UV irradiation cross-links only protein-DNA complexes in direct contact, which limits its use. Formaldehyde reacts with primary amines on amino acids and DNA and RNA bases, reversibly forming a covalent adduct between two primary amines in close proximity to each other (≤2 Å). Because protein-protein adducts are formed in addition to protein-DNA adducts, chromatin-associated proteins not directly bound to DNA can be cross-linked to DNA via other proteins such as histones, significantly broadening the applicability of this procedure. Cross-linking with formaldehyde is also more easily accomplished than UV irradiation, especially with larger culture volumes.

Formaldehyde-based chromatin immunoprecipitation was simplified and adapted for use in other experimental systems, including budding yeast, where it was first used to assess the association of differentially acetylated histones with the silent mating-type loci (Dedon et al., 1991; Braunstein et al., 1993). This method involved fractionation of cell extracts to isolate a chromatin fraction before immunoprecipitation. A closely related method was used to assess the composition of the budding yeast centromere (Meluh and Koshland, 1997). The protocol presented here (see Basic Protocol; Fig. 17.7.1) is for a simpler procedure derived by Hecht and Grunstein in which immunoprecipitations were performed with whole-cell extracts to assess the spatial distribution of SIR proteins on telomere-proximal DNA regions (Hecht et al., 1996; Strahl-Bolsinger et al., 1997). The Basic Protocol has also been applied to characterize the spatial and temporal associations of DNA replication proteins with chromatin at replication origins (Aparicio et al., 1997; Tanaka et al., 1997), the

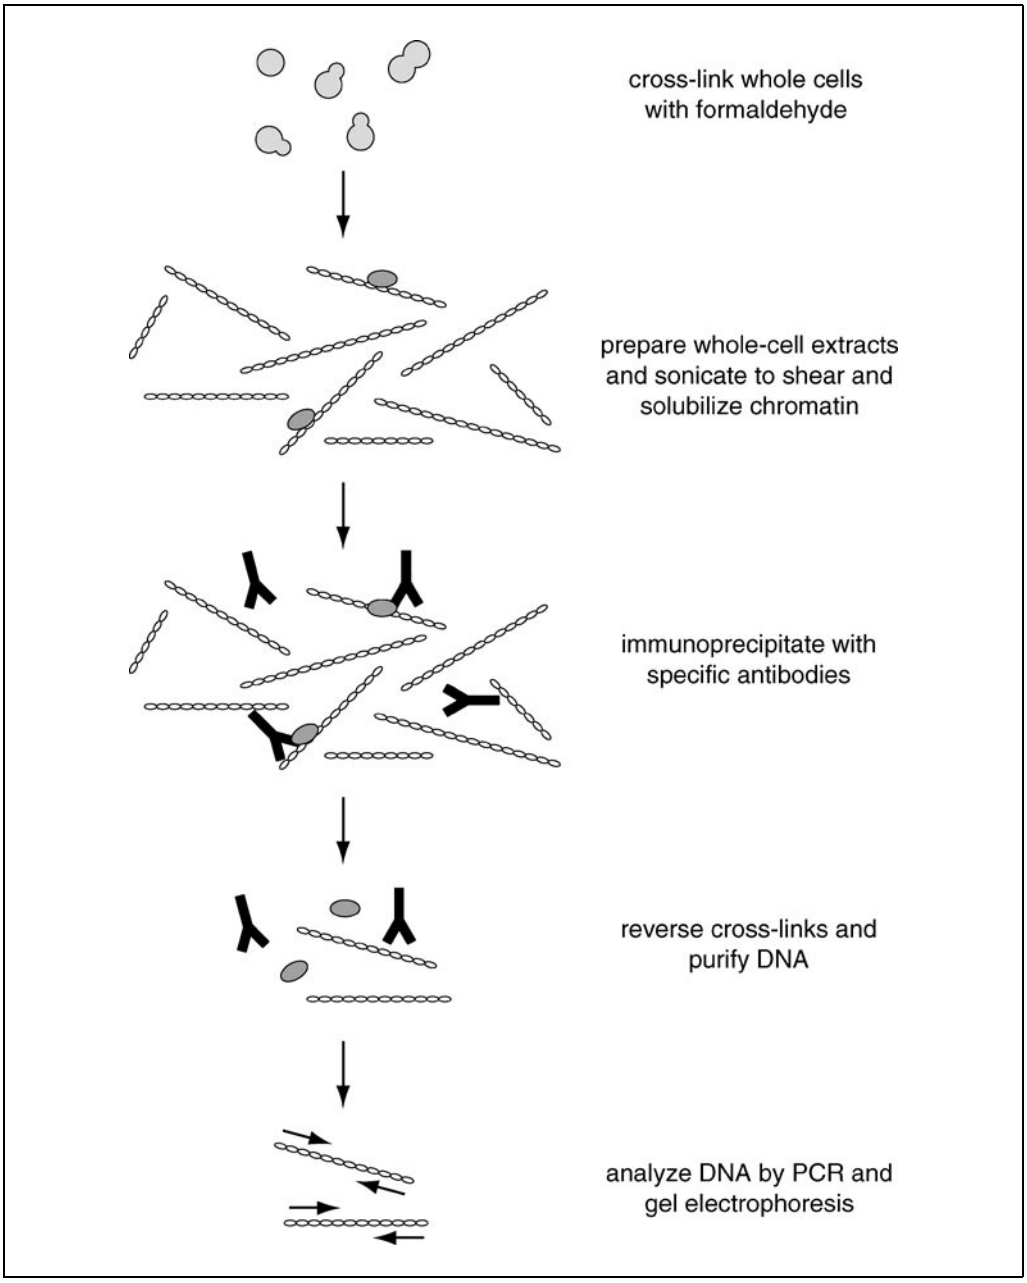

Figure 17.7.1 Scheme for chromatin immunoprecipitation from yeast whole-cell extracts.

association of general transcription factors at promoters (Kuras and Struhl, 1999; Li et al., 1999), and the dynamics of DNA-binding proteins and chromatin-modifying activities associated with a cell-cycle and developmentally regulated promoter (Cosma et al., 1999). In each of these latter studies, protein association with relevant DNA sequences was examined using PCR amplification.

ChIP can also be used to specifically follow the genomic association of mutant proteins that are unable to support cell growth (Mencia and Struhl, 2001). This involves a strain containing both an epitope-tagged version of the mutant protein and an untagged version of the wild-type protein, which supports cell growth; ChIP is performed with an antibody against the epitope. Lastly, ChIP can be combined with microarray technology to identify the location of specific proteins on a genome-wide basis (Ren et al., 2000; Iyer et al., 2001). The immunoprecipitated DNA is PCR amplified with linkers, and the resulting material hybridized to microarrays containing the complete set of intergenic regions in *Saccharomyces cerevisiae*. Such "genome-wide location" or "ChIP-chip" is particularly powerful, because it allows one to identify novel regions of protein association, without any previous knowledge.

Critical Parameters and Troubleshooting

Controls

There are two basic types of controls for a standard ChIP experiment. One control is mock immunoprecipitation to determine the specificity of an observed signal. This is accomplished by performing parallel immunoprecipitations of a given cross-linked chromatin sample with the antibody of interest and with an irrelevant antibody (or simply not providing any antibody). Alternatively, when antibodies against epitope-tagged proteins are employed (e.g., anti-HA, anti-myc), a similar comparison can be made with parallel immunoprecipitations (primary antibody included) of chromatin samples from strains expressing epitope-tagged or untagged versions of the protein of interest. However, in such experiments, it is often observed that the apparent immunoprecipitation efficiency for any irrelevant genomic region is about 2- to 3-fold higher in the experimental sample than in the control sample. This probably reflects nonspecific, and perhaps artifactual, association of the protein of interest with chromatin; hence it is not indicative of specific protein association with the genomic region. For proteins that generally and strongly associate with the entire genome (e.g., histones), the apparent immunoprecipitation efficiency in the experimental sample will be much higher than the control sample.

The second control, which is usually more meaningful, is to examine a given pair of input and immunoprecipitated samples for multiple genomic regions. Control genomic regions (i.e., those not interacting with the protein) should all give the same background level of apparent immunoprecipitation efficiency (typically ~0.025% to 0.05%). Fragments bound by the protein of interest will give higher apparent immunoprecipitation efficiencies, and the difference can be expressed as fold enrichment over the background level. In the best cases, enrichments can be >100-fold, but even a factor of two can be meaningful if the experiment is repeated enough times and the experimentally determined error is sufficiently low. The advantage of this approach is that the identical samples are used to directly determine relative protein association to different genomic regions. Furthermore, differences in fold enrichments for different genomic regions represent relative quantitative measurements of protein association in vivo.

Additional controls may be used depending on the specific application. For example, where binding to a putative binding site is being tested, a mutation in the binding site is a critical control (especially if such a mutation previously was shown to eliminate binding in vitro). In a related manner, it might be useful to determine the protein association in mutant strains or under particular environmental conditions that are suspected to be important for the protein of interest.

Cross-linking

The extent of formaldehyde cross-linking is an important variable that in principle may be modified by changing the duration of cross-linking, the concentration of formaldehyde, or the temperature at which the cross-linking is performed. The use of 1% (final concentration) formaldehyde for 15 min at temperatures ranging from 12°C to 37°C usually works well; however, at temperatures above 30°C, background sometimes increases. Therefore, when fixation at a higher temperature is required, reducing the duration of cross-linking or the formaldehyde concentration may be helpful. Excessive cross-linking can interfere with cell breakage by bead beating and effective fragmentation and solubilization of the DNA by sonication (see below). For some applications where protein cross-linking is particularly efficient (e.g., histones), it might be useful to decrease the cross-linking time or formaldehyde concentration. In particular, histone tails have a number of lysine residues that are likely to be modified by formaldehyde, and such modified lysines may interfere with the binding of antibodies against specific peptides corresponding to modified histones (e.g., by acetylation, phosphorylation, methylation).

Cell lysis

Although complete lysis of all cells is not absolutely necessary (and may be difficult to achieve), it is very important that lysis be as efficient as possible. Efficient lysis is important to obtain a reproducible degree of cell breakage among a group of samples to reliably compare results. Significant differences in cell lysis efficiency will result in immunoprecipitations with different ratios of antibody to chromatin, which will possibly alter immunoprecipitation efficiency. Cell breakage by a mini bead beater is generally more efficient than breakage by a multi-vortexing apparatus, although both methods work. In both cases, it is important to use flat-bottomed 2-ml microcentrifuge tubes. When using the mini bead beater, the sample and beads should nearly fill the tube, whereas for vortexing it is important

to maintain a small volume. The extent of cell breakage may be monitored microscopically by comparing the number of intact cells (determined by counting on a hemacytometer) in small, diluted aliquots of the sample taken before and after vortexing. In addition, the size of the remaining pellet (unbroken cells and debris) obtained in the first centrifugation following sonication (see Basic Protocol, step 14) is a good general indicator of the extent of lysis. The size of this pellet should be routinely checked (by rapid visual inspection) to compare the extent of lysis among samples.

The final yield of genomic DNA in the extract is also an important indicator of the extent of cell breakage, although the DNA yield is also dependent on the solubilization of chromatin by sonication (see below). Poor or variable cell breakage may result from excessive cross-linking that toughens the yeast cell wall and other structures. The procedure for lysis of *Saccharomyces cerevisiae* is appropriate for other yeast species. However, modified procedures are necessary for breaking mammalian cells.

Sonication

Shearing DNA to a small size (~500 bp average) by sonication is the critical factor in achieving resolution between a DNA sequence where a particular protein is bound and a nearby (*cis*-)DNA sequence that does not bind that protein. In addition, fragmentation of the chromatin is essential for its solubilization from the ruptured cells. As indicated above, the ability to fragment and solubilize the chromatin depends on the extent of chromatin cross-linking. In general, more cross-linking results in larger fragment size and lower solubility, resulting in lower yield (Orlando et al., 1997). Because of the importance of this variable, the shear size of the DNA should be assessed to confirm that the desired degree of fragmentation has been achieved, and it should be reassessed if fixation conditions are altered. The shear size is determined by electrophoresing DNA from step 16 of the Basic Protocol on a 1.5% to 2.0% agarose gel and visualizing with ethidium bromide. A smear of DNA should be apparent with an average size of 500 bp and most of the DNA (>90%) should be in the size range of 100 to 1000 bp.

As an alternative to sonication, DNA fragment size can be reduced by treatment of the cross-linked chromatin with micrococcal nuclease. Micrococcal nuclease preferentially cleaves DNA located in the linker regions between nucleosomes. By varying the concentration of micrococcal nuclease, it is possible to generate samples in which average DNA size varies. The minimal useful size is about 150 bp, which corresponds to a mononucleosome. However, cleavage to mononucleosome-sized fragments may also result in a preferential loss of certain genomic regions due to the sequence-specificity of micrococcal nuclease.

Immunoprecipitation

The success of this procedure relies on the use of an antibody that will specifically and tightly bind its target protein in the buffer and wash conditions used. In addition, antibody should be present in excess with respect to its target protein so that differences in the amounts of the protein-DNA complexes of interest will be accurately measured. Perform preliminary experiments to confirm avid immunoprecipitation and determine an approximate amount of antibody to use. Chromatin extracts should be prepared without prior cross-linking of the cells and subjected to immunoprecipitation with varying concentrations of antibody (20 μg/ml antibody may be a good starting point). The amount of the protein of interest in the extracts before and after immunoprecipitation should be analyzed by immunoblotting (*UNIT 6.2*) to determine the lowest antibody concentration that depletes >90% of the protein of interest from the extract. This antibody concentration is a good starting point for the full protocol and may later be modified to maximize the signal-to-noise ratio (see Anticipated Results). With cross-linked chromatin, immunodepletion of the target protein is less efficient (~50%), presumably due to masking or modification of the epitopes, and a significant amount of the protein remains refractory to immunoprecipitation even with higher antibody concentrations. Thus, the ideal antibody concentration is ultimately determined empirically to maximize the yield of specific coprecipitated DNA while minimizing precipitation of nonspecific DNA.

Both monoclonal and polyclonal antibodies have been used in this procedure. The monoclonal antibodies 12CA5 (anti-HA), 17D09 (anti-HA), and 9E10 (anti-myc) have been used successfully in different laboratories. In general, triple-HA epitope tags work well (Hecht et al., 1996; Aparicio et al., 1997; Tanaka et al., 1997), and larger multi-myc epitope tags have also been successful (e.g., myc-9, myc-18; Tanaka et al., 1997). Protein G–Sepharose, Protein A–Sepharose, and

anti-mouse immunoglobulin-coupled magnetic beads have all been used to precipitate the immune complexes, although it should be noted that certain classes of mouse and rat immunoglobulins are not strongly bound by protein A (Harlow and Lane, 1988; see Table 7.2.1).

For optimal results, it is critical to minimize the background level of material that inevitably comes down during the immunoprecipitation. The procedures described here work well with a diverse set of antibodies, but it might be necessary to modify the binding and elution conditions in specific cases. Peptide elution is clearly preferred over heat elution, as it is more specific and results in lower experimental backgrounds and hence higher-fold inductions. However, peptide elution is only possible for experiments using antibodies against peptides (typically for analyzing epitope-tagged proteins, but analysis of native proteins should also be possible). In performing peptide elution, it is important to add enough peptide such that the protein-DNA complexes are efficiently eluted from the beads.

Another consideration is that the epitope of interest in the chromatin-bound protein might be inaccessible to the antibody due to associated proteins or DNA structures. In such a case, one might obtain a false-negative result. Whereas the majority of a given protein may be efficiently immunoprecipitated from the cross-linked cells, the fraction that is actually cross-linked might be undetectable. The use of polyclonal antibodies (which often recognize multiple determinants within a protein) or epitope-tagged proteins (the epitope is unlikely to have a specific interaction with other proteins or DNA sequences, particularly if the epitope does not affect the biological function as determined by genetic complementation) minimizes, but does not eliminate this concern. Because of this caveat, negative results should be interpreted cautiously and alternative methods (e.g., in vitro DNA binding or association of the protein with bulk chromatin) should be tried. This concern is particularly relevant when a protein of interest does not appear to interact with any genomic sequence. However, if a protein selectively associates with some genomic sequences, this concern is significantly reduced—i.e., it is unlikely that epitope masking will occur at some loci, but not others.

PCR strategy

The choice of primers depends on the experimental goals. If binding to a specific site is being tested, a primer pair that flanks the site and at least one control primer pair recognizing a DNA sequence not expected to bind the protein of interest are the minimal requirements (see Fig. 17.7.2). When choosing primers, it is important to remember that resolution between adjacent sequences is limited by the shear size of the DNA. For an average DNA size of 500 bp, a significant fraction of the DNA molecules will be in the 500 to 1000 bp

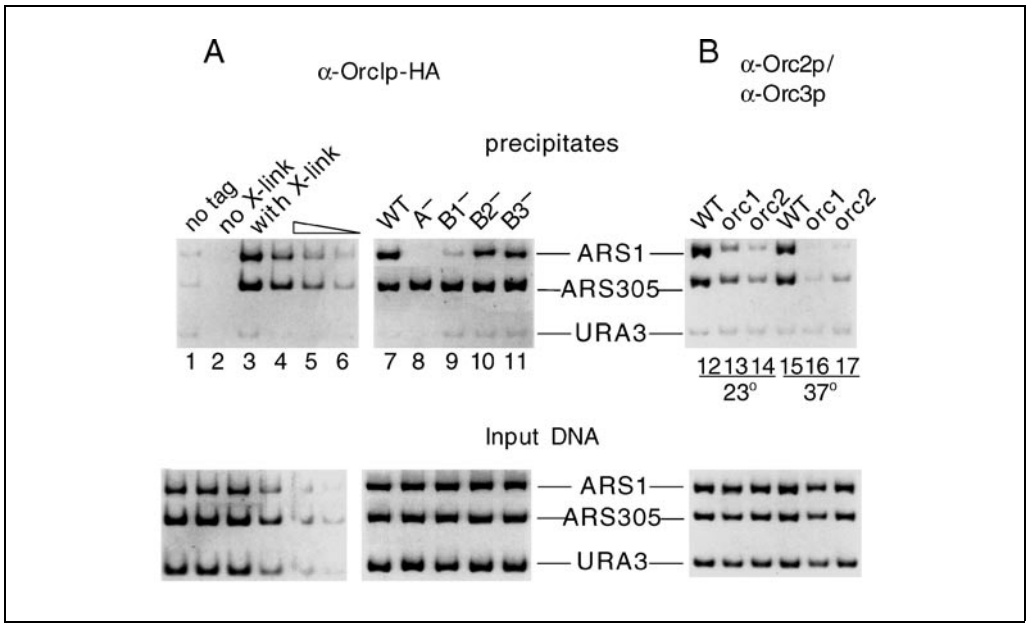

Figure 17.7.2 Anticipated results from chromatin immunoprecipitation analysis of origin recognition complex (ORC) with replication origin and nonorigin DNA sequences.

range, and hence DNA sequences 1000 bp distal from the actual protein binding site may be coprecipitated. Therefore, primer pairs used as controls should amplify a region of DNA that is far enough away from the expected binding site (e.g., >1 kbp) that coprecipitation of adjacent DNA is not detected. A good strategy is to design multiple sets of primers at increasing distances from a suspected binding site. Such a strategy has also been used to probe the "spreading" and "movement" of proteins on chromatin (Hecht et al., 1996; Aparicio et al., 1997; Strahl-Bolsinger et al., 1997).

Success in obtaining high-quality quantitative data is critically dependent on good primer design! In general, primers should be 20 to 30 bases long with a T_m of 55° to 60°C. Most primers require no purification or special treatment prior to PCR. Amplification products should be 75 to 300 bp. Longer PCR products should be avoided, because the amplification efficiency is substantially lower, and DNA fragments that do not bind to both primers will not be amplified (this can be a significant problem since the size of DNA fragments in the samples averages ~500 bp and ranges between 100 to 1000 bp). A final primer concentration of 1 μM works well for most primers, but in some instances, improved product specificity may be obtained by lowering the final primer concentration 5 to 10 fold.

The design of good primers is greatly facilitated by commercially available software packages such as Oligo 6.6 or Primer Express 1.5. These packages allow for extensive customization of many different parameters, including T_m, oligonucleotide length, GC content, and more. While the success of each individual primer pair in the specific amplification of its target sequence is dependent on many variables, special care must be taken to minimize primer-dimers and hairpins. Finally, it is a good idea to check primers for hybridization to other genomic sequences through the use of a web-based program such as BLAST.

Newly obtained primer pairs must be tested for amplification specificity and performance under the conditions that will be used in quantitative PCR. Primer pairs that are suitable for reactions performed by the Basic Protocol might not be suitable for real-time PCR reactions using SYBR Green, because SYBR Green can inhibit *Taq* polymerase. It is particularly informative to analyze input DNA amplification by the primers in question on high-percentage agarose or polyacrylamide gels after completion of the PCR. The presence of multiple product bands indicates poor specificity and will invariably lead to unreliable results.

For the Basic Protocol, the best test for quality of a given primer pair is to carry out a standard curve using different dilutions of DNA. For a high-quality primer pair, the amount of PCR product should be directly proportional to the amount of DNA, with an error of less than ±20%. The number of PCR cycles is determined empirically. Usually, 25 to 28 cycles is appropriate. More than 28 cycles can result in detection of nonspecifically precipitated sequences and/or lead to variable results due to inactivation of *Taq* polymerase. Multiple primer pairs can be used in combination if the PCR products are separable by gel electrophoresis (as many as five have been used), but some combinations interfere with efficient amplification of one or more products. It is essential to test primer pairs singly and in combination, with titrations of template DNA, to determine if this is a problem. The advantage of using multiple primer pairs is that individual reactions can generate data for multiple genomic regions in an internally controlled manner. In addition, the Basic Protocol can be used to simultaneously analyze two alleles of a given locus in an internally controlled manner, provided the individual alleles result in different-sized PCR products.

When quantitative PCR will be performed in real time using SYBR Green (see Alternate Protocol 2), high-quality primer pairs should result in ~1.9-fold amplification/cycle. Such amplification efficiency can be determined from quantitative analysis of raw fluorescence data for each cycle. Amplification efficiencies <1.8 are likely to cause problems, particularly if detection of the PCR product requires 30 cycles or more. Specificity information may also be obtained by running dissociation curves on reactions following the conclusion of the PCR run.

Quantitation

For the Basic Protocol, PCR products are analyzed by gel electrophoresis and detected by staining with ethidium bromide or SYBR Green or by radioactivity (typically by including a small amount of [^{32}P]dATP in the reactions). DNA staining has the advantage of not requiring radioactivity, but the linear detection range is relatively limited. In this regard, SYBR Green is more sensitive than ethidium bromide and is preferred. Radioactive detection is more sensitive and has a larger linear range than detection by DNA staining. Whatever detection method is employed, it is

essential to use a high-quality imager to accurately quantitate the amounts of PCR product in the various reactions.

When quantitative PCR is performed in real time using SYBR Green (Alternate Protocol 2), the linear range is directly visualized and the quality of the reactions can be directly assessed. For reactions involving a given primer, the curves should be superimposable with respect to shape, and they should differ only in the number of cycles needed to reach the threshold (C_T). Amplification efficiencies should be ~1.9-fold/cycle. If the curves have different shapes and/or amplification efficiencies are <1.8, the reactions are not equivalent and accurate quantitation is impossible.

Data interpretation

In most experiments, it is presumed that the protein of interest associates specifically with certain genomic regions and associates only nonspecifically with other genomic regions. In general, it is very difficult to distinguish true nonspecific association from experimental background of the cross-linking procedure. In this regard, immunoprecipitations with the antibody of interest generally give 2- to 3-fold higher immunoprecipitation efficiencies than immunoprecipitations with control (or no) antibodies, but it is unclear whether this effect is physiologically meaningful or an experimental artifact.

For this reason, the best way to interpret the data for most experiments is to compare the immunoprecipitation efficiencies for different genomic regions from the same INPUT and IP samples. The immunoprecipitation efficiency is calculated by the amount of PCR product in the IP sample divided by the amount of PCR product in the INPUT sample. A typical background level for DNA fragments that do not associate with the protein of interest is 0.025% to 0.05%. However, background levels can vary, depending on the antibody used and the elution method. In general, monoclonal antibodies give lower background signals than polyclonal antibodies. Peptide elution is preferred over heat elution for the same reason, although this can only be employed for ChIP experiments involving antibodies against defined peptide epitopes. By definition, the background level should be the same for all DNA fragments that do not specifically associate with the protein of interest. In many cases, the choice of suitable negative control regions is based on expectation from other lines of evidence (e.g., the middle of protein-coding regions are unlikely to bind general transcriptional initiation factors). In cases where there is no previous knowledge, the background level can only be based on multiple regions having similar immunoprecipitation efficiencies that are roughly at the level of a typical background immunoprecipitation efficiency. In this regard, it is particularly useful to use proteins tagged with a standard epitope (e.g., HA or myc), as there is considerable information on background levels in such cases.

DNA fragments that display immunoprecipitation efficiencies significantly above the background are indicative of protein association to those genomic regions in vivo. Moreover, for a given pair of INPUT and IP samples, the fold enrichment of a given genomic region over the background is directly related to the level of protein association in vivo. It is useful to define "relative protein occupancies" for different regions by subtracting the background from the observed immunoprecipitation efficiencies. For example, if the background level is arbitrarily defined as 1 occupancy unit, fragment A that shows 6-fold enrichment over background will have 5 occupancy units, whereas fragment B that shows 21-fold enrichment over background will have 20 occupancy units. Thus, one can conclude that the protein association with fragment B is 4-fold greater than with fragment A. Without further considerations (see below), this conclusion is only relevant for the particular pair of INPUT and IP samples because absolute immunoprecipitation efficiencies and fold enrichments can vary among repeated trials of the same experiment.

Absolute immunoprecipitation efficiencies and fold enrichments depend on multiple factors. First, the number and physical location of amino acid and nucleotide residues within the interacting protein surfaces that react with formaldehyde vary considerably among protein-protein and protein-DNA interactions. Second, proteins directly interacting with DNA can be cross-linked by a single event, whereas proteins that indirectly associate with DNA need multiple cross-linking events. In this regard, proteins directly binding DNA (e.g., specific DNA binding proteins and general transcription factors) typically give higher fold enrichments than other proteins (e.g., components of chromatin-modifying complexes). Third, some proteins might stably associate with genomic DNA sequences (maximally 100% occupancy), whereas association of other proteins might be transient. Fourth, the absolute immunoprecipitation efficiency depends on the quality of the specific

antibody-antigen interaction as well as the antibody concentrations, and the fold enrichment depends on both the absolute immunoprecipitation efficiency and on the background. Thus, absolute immunoprecipitation efficiencies and fold enrichments cannot be used to compare binding characteristics of different proteins. Furthermore, ChIP experiments do not provide absolute measurements of protein occupancy on specific genomic regions or relative stoichiometry of factors on a given sequence. Despite these limitations, ChIP experiments do provide direct quantitative information on the relative levels of protein association on different genomic sequences.

As mentioned above, absolute immunoprecipitation efficiencies and fold enrichments can vary among repeated trials of the same experiment due to potential differences in overall immunoprecipitation efficiency and experimental background. To account for these experimental variations, it is useful to arbitrarily define occupancy units for a specific protein-DNA association. In the example above, one might arbitrarily define fragment A to have 4 occupancy units. In independent experiments, association with fragment A will always be defined as having 4 occupancy units, and association with other fragments will be defined relative to that of fragment A in the same pair of INPUT and IP samples. In this manner, it is possible to accurately determine the relative level of protein association to multiple genomic regions even though the absolute immunoprecipitation efficiencies and fold enrichments might vary in different repeats of the same experiment. However, in actual practice, differences in absolute immunoprecipitation efficiencies and fold enrichments should not show significant sample-to-sample variation.

A related issue occurs when comparing the level of protein association under different physiological conditions (e.g., different growth conditions or strains). The ideal way to handle this situation is to analyze a "positive control" region that is predicted to be unaffected by the growth condition or genetic constitution. For example, in analyzing association of general transcription factors under a particular environmental condition, it would be useful to examine promoters that are regulated and promoters that are not. In some cases, such a control genomic region is not available, in which case one must rely on simple sample-to-sample reproducibility from independent trials of the same experiment.

ChIP can be used to determine the relative occupancy levels of different proteins at genomic regions (Kuras et al., 2000). Ideally, this is accomplished by performing parallel immunoprecipitations with different antibodies on the same cross-linked chromatin sample. Alternatively, immunoprecipitations can be performed on different samples (this often occurs when using epitope-tagged strains or when multiple proteins are examined). To determine occupancy ratios for two different factors (e.g., X and Y), occupancy units for X and Y are calculated independently as described above. The X:Y occupancy ratios are then calculated for all genomic regions examined. The resulting occupancy ratios are defined in arbitrary units, but the relative occupancy ratios for the different genomic regions are valid. To account for potential sample-to-sample variations among repeats of the same experiment, a given X:Y occupancy ratio should be defined for a specific genomic region and ratios at all other genomic regions calculated in relative terms. Using this rationale, it has been shown that the relative associations of TBP and the general transcription factors TFIIA and TFIIB are essentially constant at all promoters, whereas the TAF:TBP occupancy ratios vary considerably (Kuras et al., 2000). Importantly, however, occupancy ratios determined from such experiments cannot address whether two proteins co-occupy a given genomic region or mutually compete for the same genomic region.

For some experiments, particularly those involving histone modifications, it is inappropriate to analyze the data in terms of occupancy units and specific versus nonspecific binding sites. Histones associate with essentially all genomic regions, and the level of a particular chromatin modification typically occurs in a continuum. Thus, it is very difficult to determine whether a given region is devoid of a particular modification, although information in this regard can be obtained in control immunoprecipitations using an irrelevant antibody. For these reasons, quantitative analysis of the relative level of a given histone modification is best presented using simple immunoprecipitation efficiencies. Again, to account for sample-to-sample variations, a specific genomic region should be given an arbitrarily defined value, which is used to determine the relative levels of all other genomic regions.

Anticipated Results

Figure 17.7.2 shows the results of chromatin immunoprecipitation of protein subunits of the origin recognition complex (ORC)

and relevant controls (Aparicio et al., 1997). In panel A, immunoprecipitation of Orc1p-HA was shown to specifically coprecipitate the replication origin sequences *ARS1* and *ARS305* but not the nonorigin DNA sequence *URA3*. Enrichment of *ARS1* and *ARS305* (~0.4% precipitated relative to total) compared to *URA3* (~0.01% precipitated) was ~40-fold and depended on formaldehyde cross-linking and on the epitope-tagged Orc1p (lanes 1 to 3). Mutation of DNA sequences (A and B1) in the *ARS1* replication origin (required in vivo for origin activity and in vitro for binding of ORC to origin DNA) greatly reduced or eliminated association of Orc1p-HA with *ARS1*. The continued association with the wild-type *ARS305* origin served as an additional control (lanes 7 to 9). Analysis of the totals demonstrated that the origin and nonorigin DNA sequences were equally represented in the whole-cell extract (lower panel, "input DNA"). In panel B, origin association of ORC was tested in strains with temperature-sensitive alleles of *ORC1* or *ORC2* demonstrating loss of ORC-origin DNA binding under nonpermissive conditions (lanes 15 to 17). Nevertheless, it should not be assumed that a mutation in a protein of interest would necessarily result in loss of its chromatin association.

Time Considerations

The Basic Protocol may be completed in a 2- or 3-day period. On the first day, cells are fixed with formaldehyde and harvested (1 hr). For convenience, or if preparation of the cells for cross-linking will require an extended period of time beforehand (e.g., induction of expression, cell cycle synchronization), the cells may be frozen and stored at −80°C as described (see Basic Protocol, step 6). Preparation of chromatin extracts (2 hr) and immunoprecipitations (primary antibody incubation, ~2 hr; incubation with secondary-coupled beads, ~1 hr; washing and elution, 2 hr) may be carried out in 1 day, after which the samples are placed at 65°C overnight to reverse the cross-links. If necessary, immunoprecipitation with the primary antibody or bead-coupled secondary antibody may be extended overnight; however, it is most efficient to perform the ≥6 hr cross-link reversal step overnight. On the final day, the DNA is purified (<4 hr, including a 2-hr incubation with proteinase K), PCR amplified (<3 hr, including 2 hr for the PCR program), and analyzed by gel electrophoresis (<2 hr, including 1 hr of gel running time).

For Alternate Protocol 2, setup time is <30 min, thermal cycling takes ~2 hr, and data analysis takes <30 min.

Isothermal Titration Calorimetry

Isothermal titration calorimetry (ITC) is the only technique that can directly measure the binding energetics of biological processes, including protein-ligand binding, protein-protein binding, DNA-protein binding, protein-carbohydrate binding, protein-lipid binding, and antigen-antibody binding. ITC has the ability to precisely determine the Gibbs energy, enthalpy, entropy, and heat capacity changes associated with binding.

In this unit several protocols are presented, from the basic ones that are aimed at characterizing binding of moderate affinity (see Basic Protocols 2 and 3) to the advanced ones that are for determining very high or very low affinity (see Alternate Protocols 1 and 2). Also, alternate protocols for special cases (homodimeric proteins and unstable proteins; see Alternate Protocols 3 and 4) and additional information obtainable by ITC (heat capacity and proton transfer coupled to binding; see Alternate Protocols 5 and 6) are presented.

PRINCIPLES OF THE TECHNIQUE

The ITC instrument is a heat-flux calorimeter operating according to the dynamic power compensation principle, i.e., it measures the amount of power (μcal/sec) required to maintain a constant temperature difference (close to zero) between the sample and the reference cell (see Basic Protocol 1). Initially, the feedback system continuously applies a small power to the sample cell, which determines the baseline level. Each injection of the syringe solution (usually termed as ligand) triggers the binding reaction and, depending on the binding affinity and the concentration of reactants (macromolecule, M, and ligand, L) in the cell, a certain amount of macromolecule/ligand (ML) complex is formed. The formation of complex is accompanied by the release (exothermic reaction) or the absorption (endothermic reaction) of heat that causes a difference in temperature between the two cells. Then, the feedback system either lowers or raises the thermal power applied to compensate such temperature unbalance. After each injection, the system reaches equilibrium and the temperature balance is restored. Therefore, the recorded signal shows a typical deflection pattern in the form of a peak (Fig. 17.8.1). Integrating the area under the peak, assuming the baseline as reference, provides the amount of heat associated with the injection. As the reactant in the cell becomes saturated, the heat signal diminishes until only the background heat, due to an unspecific phenomena (e.g., ligand dilution, liquid friction), is observed.

INSTRUMENTATION

Two identical coin-shaped cells, sample and reference, are enclosed in an adiabatic shield (jacket) as illustrated in Figure 17.8.1. The temperature difference between the reference cell and the jacket is continuously monitored to maintain a constant temperature. A feedback control system monitors the difference in temperature between the two cells through a semiconductor Peltier sensor device sandwiched between them. This temperature difference is kept constant and as close to zero as possible at any time. The feedback signal is the measured signal.

One of the reactants is placed in the sample cell and the other one in the injection syringe. During the course of an experiment, the syringe is used to add the titrant reactant to the sample cell in a stepwise fashion and, at the same time, stir the solution in the sample cell to achieve fast mixing. The reference cell serves only as a temperature reference.

Current Protocols in Cell Biology (2004) 17.8.1-17.8.24

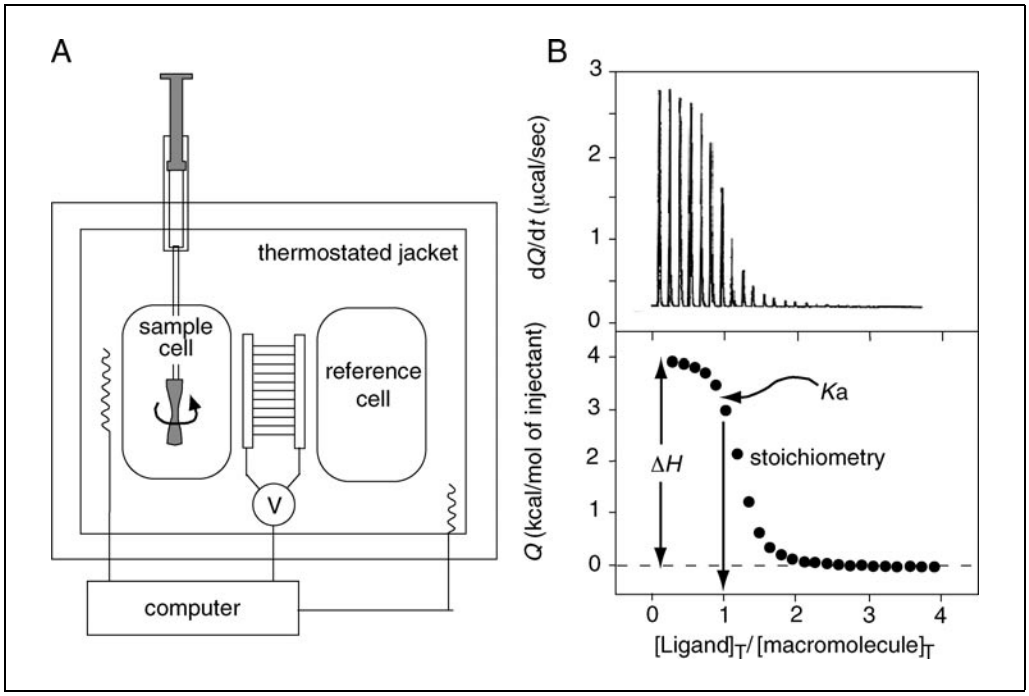

Figure 17.8.1 (**A**) Basic schematic illustration of the ITC instrument, showing the two cells (sample and reference) surrounded by the thermostated jacket, the injection syringe that also works as stirring device, and the computer-controlled thermostatic and feedback systems (using Peltier and resistor devices as sensor and actuator subsystems). (**B**) Example of a typical ITC experiment. The top panel shows the sequence of peaks, each one corresponding to each injection of the solution in the syringe. The monitored signal is the additional thermal power needed to be supplied or removed at anytime to keep a constant temperature in the sample cell and as close as possible to the reference cell temperature. This example corresponds to an endothermic binding. The bottom panel shows the integrated heat plot. The areas under each peak, calculated and normalized per mole of ligand injected in each injection, are plotted against the molar ratio (quotient of the total concentrations of ligand and macromolecule in the sample cell). From this plot, and applying the appropriate model, the thermodynamic parameters of the binding can be obtained: binding affinity, binding enthalpy, and stoichiometry.

BASIC PROTOCOL 1

ISOTHERMAL TITRATION CALORIMETRY

The protocols differ only in the way the experiment is planned and not in the procedure for using the instrument. This protocol consists of a detailed description of setting up and using the ITC instrument. The time required for performing a complete ITC experiment (setting up the instrument, running the experiment, and analyzing the results) is ~2 hr.

This protocol should not be considered a substitute for the instrument manual, where more detailed and specific explanations are provided. This protocol is written based on the VP-ITC MicroCalorimeter (Microcal LLC) and it can serve as a guide for other models.

Materials

Reactant solutions: macromolecule and ligand
Methanol

VP-ITC calorimeter (e.g., Microcal LLC or equivalent)
Vacuum pump
2.5-ml long-needle syringe (e.g., Hamilton)
12 × 75–mm and 6 × 50–mm glass tubes

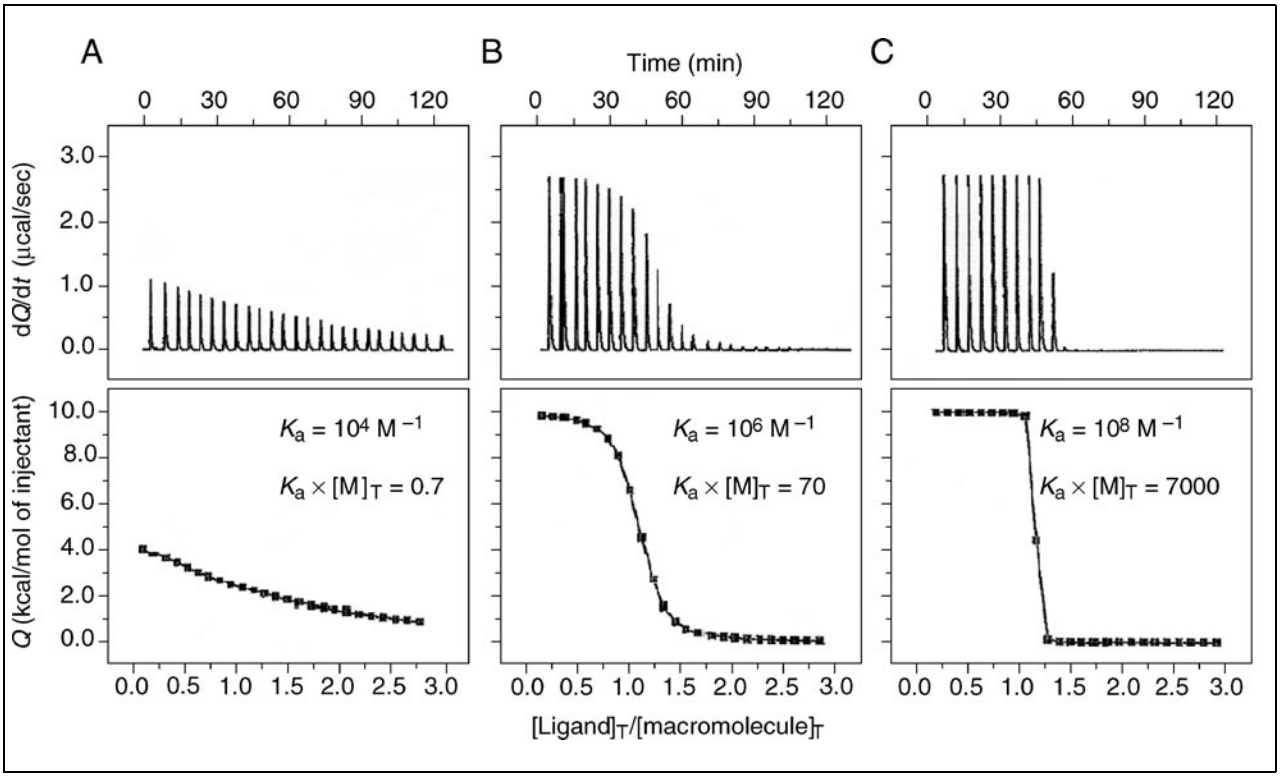

Figure 17.8.2 Illustration of the effect of the association constant value on the shape of a titration curve. The plots represent three titrations simulated using the same parameters (concentrations of reactants and binding enthalpy), but different binding affinities. Low (**A**), moderate (**B**), and high affinity (**C**) binding processes are shown. To obtain accurate estimates of the binding affinity an intermediate case is desirable (**B**, $1 < c = K_a \times [M]_T < 1000$). When the parameter c is large enough, a good estimate of the enthalpy can be determined from the *y*-axis intercept of the curve (if the heat effect associated with dilution is used as a reference). Such an intercept value is given by $(c/c+1) \times \Delta H_a$ (Indyk and Fisher, 1998).

Select concentration of reactants

1. Determine the appropriate concentrations of reactants.

   Typically, the concentrations of reactants are in the micromolar range; if the heat associated with the reaction is significant, however, the concentrations can be lowered.

   An important requirement for an ITC experiment is having appropriate concentrations of interacting molecules such that the heat associated with a given binding reaction is within the calorimetric determination range. Sensitivity of the instrument varies depending on brand and model. The Microcal VP-ITC instrument used in all the experiments described in this unit has a limiting sensitivity of 0.1 μcal. Therefore, to accurately determine the change of heat involved in the interaction between molecules, each injection should have a minimum of 1 μcal of associated heat.

   The affinity of the interaction should also be considered in choosing the required concentrations of the interaction components. A dimensionless constant, c, describes the practical window of the instrument to accurately determine the binding constants (Wiseman et al., 1989) in Equation 17.8.1:

$$c = nK_a[M]_T$$

Equation 17.8.1

   where, K_a is the binding constant, $[M]_T$ the total macromolecular concentration in the cell, and n is the stoichiometry of interaction. As illustrated in Figure 17.8.2, a large c value corresponds to very tight binding, resulting in an isotherm that is rectangular in shape and is devoid of data points in the transition region of binding, therefore, making the estimation of the binding affinity unreliable, although the binding enthalpy can still be obtained accurately. Conversely, a very low c value corresponds to weak binding and

the resultant isotherm is featureless, making the determination of both the binding affinity and enthalpy unreliable. Keeping other parameters constant (K_a, ΔH, etc), the c value could be reduced or increased by changing the $[M]_T$. ITC data with c values between 1 and 1000 can be used for determination of binding constants.

To obtain a complete binding isotherm within the specified number of injections, the ligand solution in the syringe should be more concentrated than the macromolecule in the cell, so that at the end of the experiment, the molar ratio of ligand to macromolecule inside the cell is 2 to 3 (for 1:1 stoichiometry). Considering the volume of the sample cell (1.4 ml), the typical injection volume (10 μl), and the typical number of injections (~30), it is advisable to use a concentration of ligand in the syringe 10 to 20 times higher than the solution in the cell. This will guarantee that the reaction reaches the neutralization point after 7 to 13 injections.

Prepare samples

2. Choose experimental conditions, taking into account the stability and the solubility of the reactants and the biological considerations of the system under study. Prepare reactant solutions for the cell and the syringe under identical conditions and with the same composition.

   For the reactant solutions, buffer type, buffer concentration, pH, ionic strength, and co-solvents must be the same. In an ITC assay, consistency between the exact composition of the buffer in the cell and the syringe is of crucial importance to prevent dominance of unspecific heat effects. The composition, concentration, pH, and ionic strength of the buffer all affect the thermodynamic parameters, and the quality of the experiment depends on maintaining a perfect match of the buffer in the cell and syringe samples. One effective way of achieving this goal is to dialyze the macromolecule against the desired buffer and then using the filtered dialysis buffer to prepare the ligand solution. Certain additives such as DMSO, which increases the solubility of hydrophobic ligands, have an enormous effect on the ITC signal, therefore, utmost care should be taken to keep the concentration of DMSO in the cell and syringe nearly the same.

3. Prepare the reactant solutions in the appropriate volumes.

   Although the apparent volume of the sample cell is 1.4 ml, the volume of solution required for proper filling of the cell is 2.2 ml. The volume required for the syringe is 0.5 ml.

4. Degas all solutions (reactants and buffer solution used for rinsing the cell) for 10 to 20 min (stirring and temperature control are optional) to avoid formation of bubbles in the sample cell during the experiment.

5. To prevent long equilibration delays, lower the calorimeter thermostat setting slightly below the running temperature (with a difference of 0.5° to 2°C).

Load solutions

6. Place degassed, distilled water or buffer solution in the reference cell using a 2.5-ml, long-needle syringe.

7. Rinse the sample cell several times with buffer solution, then remove all liquid.

8. Fill the cell with macromolecule solution, taking care to prevent the appearance of bubbles in the cell.

   The most common configuration is one in which a macromolecule is placed in the reaction cell and a low-molecular-weight ligand is placed in the injecting syringe. For convenience, the injected reactant located in the syringe is referred to as "ligand" and the one in the reaction cell is referred to as "macromolecule," throughout this unit. The reader should be aware that other configurations are possible.

9. Fill the calorimeter syringe with ligand solution according to the maufacturer's instructions. Rinse off excess ligand solution on the surface of the needle with water and then carefully blot the surface of the needle with a paper towel.

A special plastic syringe is used to fill the calorimeter injecting syringe. A purge-refill cycle may be performed to ensure the absence of air bubbles inside the syringe.

Set instrument settings

10. Set the total number of injections to 30.
11. Set measurement temperature to °C.
12. Set reference power to 10 μcal/sec.

    The reference power can be modified if a large exothermic or endothermic reaction is expected.

13. Set the initial delay (time between the start and the first injection) to 200 sec.
14. Set the syringe ligand concentration to millimolar (mM).
15. Set the cell macromolecule concentration to millimolar (mM).

    During the experiment and analysis, the concentrations are always expressed as millimolar.

16. Set the stirring speed ~500 rpm.

    This speed is selected to ensure good mixing, but it can be modified depending on the sample (e.g., high viscosity, tendency to generate foam, etc.).

17. Set feedback mode/gain to high (high sensitivity and small response time).
18. Set injection volume to 10 μl.

    A different injection volume can be set, for example, if the heat of reaction is expected to be very large or very small. However, if the ligand concentration can be varied, then it is preferable to adjust its concentration in the injecting syringe rather than the injection volume.

19. Set duration for injection to 20 sec.

    This setting is automatically assigned according to the injection volume.

20. Set spacing between injections to 400 sec (usually).

    The spacing might be increased depending on peak size or the reaction kinetics.

    The user should allow enough time between peaks in order to keep the next injection from starting before the signal from the previous injection returns to baseline. Typically, there should be ~200 sec between the end of an injection and the beginning of the next one.

21. Set filter period (the signal-average time period) to 2 sec.
22. Set the volume of the first injection to ≤3 μl. Do not include the heat associated with the first injection in the data analysis.

    Due to inter-diffusion of the solutions during the insertion of the syringe or the equilibration stage, the first injection is not useful in the analysis, therefore, the volume of the first injection should be set to ≤3 μl to minimize the amount of ligand wasted.

Start measurement and troubleshoot the baseline (noise, drift, level)

23. After gently setting the injection syringe in place, initiate the experiment. If fast equilibration is initially selected, both thermal and mechanical equilibration will proceed simultaneously.

    The equilibration level will be slightly less than the reference power value entered in the parameter setting due to the power generated by stirring.

24. Check the quality of the baseline in a full scale of 1 μcal/sec. When the baseline becomes flat, with no significant drift or noise, start the injection sequence.

If the baseline is of poor quality, several possibilities should be considered. (1) Small irregular noise is probably due to air bubbles in reference or sample cell. In the case of bubbles in the sample cell, stop measurement, remove syringe, and check cell content. In the case of bubbles in the reference cell, replace the content of the cell. (2) Strong regular noise and/or drift indicates that the injection syringe is bent. Stop measurement and check the needle of the syringe by rolling it on a flat surface. (3) A high baseline level indicates low liquid level or air bubbles in the reference cell. (4) A low baseline level indicates that the viscosity of the cell solution is high or the cell is dirty.

25. Collect data.

    Once the sequence of injections is initiated, the titration should be continued until saturation is observed.

Clean the ITC

26. Wash the injection syringe with ≥150 ml water. Frequently, and especially for low solubility reactants, wash the syringe with 50 ml methanol (or water-organic co-solvent) and 300 ml water. Dry syringe for ≥10 min.

27. Wash the plunger tip of the syringe injector with water and dry it.

28. Wash the sample cell with water (ten times or more) using the long-needle syringe.

    For periodic deep cleansing or when using a different macromolecule or in cases where the sample precipitated or aggregated in the sample cell, the sample cell should be washed with a cleaning solution (compatible with the material the cells are made of) according to the manufacturer's instructions.

    CAUTION: *Do not leave any methanol or organic solvent in the injection syringe or the cells.*

SUPPORT PROTOCOL

DATA ANALYSIS FOR ITC EXPERIMENTS

The following section is an outline of the foundations for data analysis, including the basic equations describing the binding equilibrium and its implementation. Data analysis is usually performed by non-linear regression using fitting functions defined in the control and analysis software provided by the manufacturer.

Adjust baseline and integrate peaks

1. Carefully check the quality of the automatic baseline and, if applicable, manually modify the baseline and the integration interval.

    The application automatically creates a baseline and integrates each peak when reading the data file. The baseline should follow a smooth path, clearly define a peak signal that relaxes and asymptotically merges with the baseline, and go through the noise when the reaction is finished. The appropriate integration interval should cover the entire peak, taking care to include all the area corresponding to the relaxation stage.

Enter concentration values

2. Enter the values of the ligand and macromolecule concentrations, as well as the sample cell volume to ensure the accuracy of the calculations.

Estimate heat of dilution

3. Note the heat observed after saturation; it reflects different unspecific phenomena, and it is referred to as "heat of dilution." If the fitting procedure does not account for the heat of dilution through an adjustable parameter, make an estimation of such value, e.g., by averaging the values of the last injections or by performing a blank experiment injecting reactant into a buffer solution (see below). If estimated, subtract the heat of dilution from the heat associated with each injection.

Select fitting function

4. Determine the model for binding to be used.

   Although traditional data analysis methods based on linearization of the binding equations have been commonly used, a non-linear regression is a more appropriate methodology for analyzing ITC data. A suitable model, according to the system under study, needs to be considered when selecting a fitting function to use in the non-linear least square regression analysis. The description for different models can be found in the literature (Cantor and Schimmel, 1980; Freire et al., 1990; Wyman and Gill, 1990; Van Holde et al., 1998; Jelesarov and Bosshard, 1999; Sigurskjold, 2000).

5. Express the binding equations in terms of total concentrations. The total concentration of each reactant inside the calorimetric cell is known and after each consecutive injection, *i*, is given by Equation 17.8.2:

$$[\mathrm{M}]_{\mathrm{T},i} = [\mathrm{M}]_o\left(1-\frac{v}{V}\right)^i$$

$$[\mathrm{L}]_{\mathrm{T},i} = [\mathrm{L}]_0\left(1-\left[1-\frac{v}{V}\right]^i\right)$$

Equation 17.8.2

   where $[\mathrm{M}]_0$ is the initial concentration of macromolecule in the cell, $[\mathrm{L}]_0$ is the concentration of ligand in the syringe, V is the cell volume, v is the injection volume and $1-(v/V)$ is the factor that accounts for the change in the concentration of reactants due to the dilution that takes place upon each injection.

   Since the concentration of each chemical species (free reactants and complex) is not known, the binding equations must be expressed in terms of total concentrations.

6. Determine the heat released or absorbed due to each ligand injection, q_i, i.e., the heat associated with the formation of complex in injection *i* according to Equation 17.8.3:

$$q_\mathrm{i} = V\Delta H_\mathrm{a}\left([\mathrm{ML}]_i - [\mathrm{ML}]_{i-1}\left[1-\frac{v}{V}\right]\right)$$

Equation 17.8.3

   where ΔH_a is the binding or association enthalpy. Again, the dilution factor indicates that the heat change in each injection corresponds to different reactant concentrations.

7. Using the mass action law and the conservation of mass for each species, the expression for the concentration of complex after each injection becomes Equation 17.8.4:

$$[\mathrm{ML}]_i = \frac{1+[\mathrm{M}]_{\mathrm{T},i}K_\mathrm{a} + K_\mathrm{a}[\mathrm{L}]_{\mathrm{T},i} - \sqrt{(1+[\mathrm{M}]_{\mathrm{T},i}K_\mathrm{a} + K_\mathrm{a}[\mathrm{L}]_{\mathrm{T},i})^2 - 4[\mathrm{M}]_{\mathrm{T},i}K_\mathrm{a}^2[\mathrm{L}]_{\mathrm{T},i}}}{2K_\mathrm{a}}$$

Equation 17.8.4

8. It is customary to include in this equation a factor *n*, the stoichiometry, which can be interpreted in two ways: (1) as the generalization for a macromolecule with *n*

equivalent and independent binding sites or (2) to account for the possibility of having a percentage of the macromolecule in a non-competent binding conformation:

$$[\mathrm{ML}]_i = \frac{1 + n[\mathrm{M}]_{\mathrm{T},i} K_\mathrm{a} + K_\mathrm{a}[\mathrm{L}]_{\mathrm{T},i} - \sqrt{(1 + n[\mathrm{M}]_{\mathrm{T},i} K_\mathrm{a} + K_\mathrm{a}[\mathrm{L}]_{\mathrm{T},i})^2 - 4n[\mathrm{M}]_{\mathrm{T},i} K_\mathrm{a}^2 [\mathrm{L}]_{\mathrm{T},i}}}{2K_\mathrm{a}}$$

Equation 17.8.5

Equations 17.8.4 and 17.8.5 constitute the formalism to analyze binding experiments in which a ligand binds a macromolecule with n equivalent and independent binding sites. Given the initial concentrations of reactants, $[M]_0$ and $[L]_0$, the binding affinity, K_a, the binding enthalpy, ΔH_a, and the stoichiometry, n, it is possible to estimate the heat involved in each injection, which will be the dependent variable used in the analysis, and incorporate that calculation in a fitting function. The thermodynamic parameters (K_a, ΔH_a, and n) will be estimated as adjustable parameters in the fitting procedure.

All examples presented in this unit can be analyzed with built-in functions embedded in Origin version 5.0 or 7.0.

The previous formalism can be applied to other cases (see Basic Protocol 2) by appropriately modifying Equations 17.8.3 and 17.8.4.

BASIC PROTOCOL 2

MACROMOLECULE/LIGAND INTERACTION WITH MODERATE AFFINITY

Ligands with moderate binding affinities to their target macromolecule constitute the majority of the cases in biological systems. However, ligands with very low or very high affinities are also encountered. Conducting ITC assays for a complete thermodynamic characterization of the binding of such ligands requires modified versions of the basic ITC protocol and will be explained later. When the affinity between the macromolecule and the ligand is moderate ($10^4 < K_\mathrm{a} < 10^8\ \mathrm{M}^{-1}$), it is possible to determine the affinity and the enthalpy of binding simultaneously in a single experiment.

This protocol uses commercially available ribonuclease A (RNase A), a well-studied endonuclease of 13.7 kDa, and its commercially available inhibitor 2′-cytidine-monophosphate (2′CMP) of 323 Da, to familiarize first-time users with the setup, procedure, and data analysis of isothermal titration calorimetry. The binding of 2′CMP to RNase A is an example of an exothermic binding reaction, and the binding constant for this reaction is within the range measurable by conventional ITC (Wiseman et al., 1989; Straume and Freire, 1992). It is highly recommended that every attempt at ITC begin with this simple protocol and that conducting experiments with other samples only take place after mastering the technique and analysis explained in this protocol. This protocol presents an efficient way of keeping the conditions in the ITC cell and syringe as close to each other as possible.

Materials

RNase A, lyophilized powder (Sigma)
15 mM potassium acetate buffer, pH 5.5
2′CMP, lyophilized powder (Sigma)

12 × 75–mm and 6 × 50–mm glass tubes
6-kDa MWCO dialysis membrane
0.22-μm filter

Prepare samples

1. Prepare RNase A stock solution in a 12 × 75–mm glass tube. Dissolve the protein in 15 mM potassium acetate buffer, pH 5.5, to a final concentration of 200 to 300 μM.

   RNase A is commercially available as a lyophilized powder. A final volume of 5 ml of this stock solution should be sufficient to conduct several experiments.

2. Dialyze RNase A stock solution against ∼1 liter 15 mM potassium acetate buffer, pH 5.5, overnight at 4°C using a dialysis membrane with a ∼6.0-kDa MWCO.

3. After dialysis, filter the RNase A solution through a 0.22-μm filter. Determine the exact concentration of the stock solution by measuring its absorbance at 278 nm using an extinction coefficient of 9800 $M^{-1}cm^{-1}$. Store the dialyzed stock of RNase A up to several weeks at 4°C.

4. Prepare 2′CMP stock solution in a 12 × 75–mm glass tube. Filter 15 mM potassium acetate buffer, pH 5.5, used for dialysis using a filter with a 0.22-μm pore size. Dissolve the lyophilized 2′CMP (or 5′CMP) in the filtered buffer to a final concentration of 5 mM. Determine the exact concentration of the stock solution by measuring its

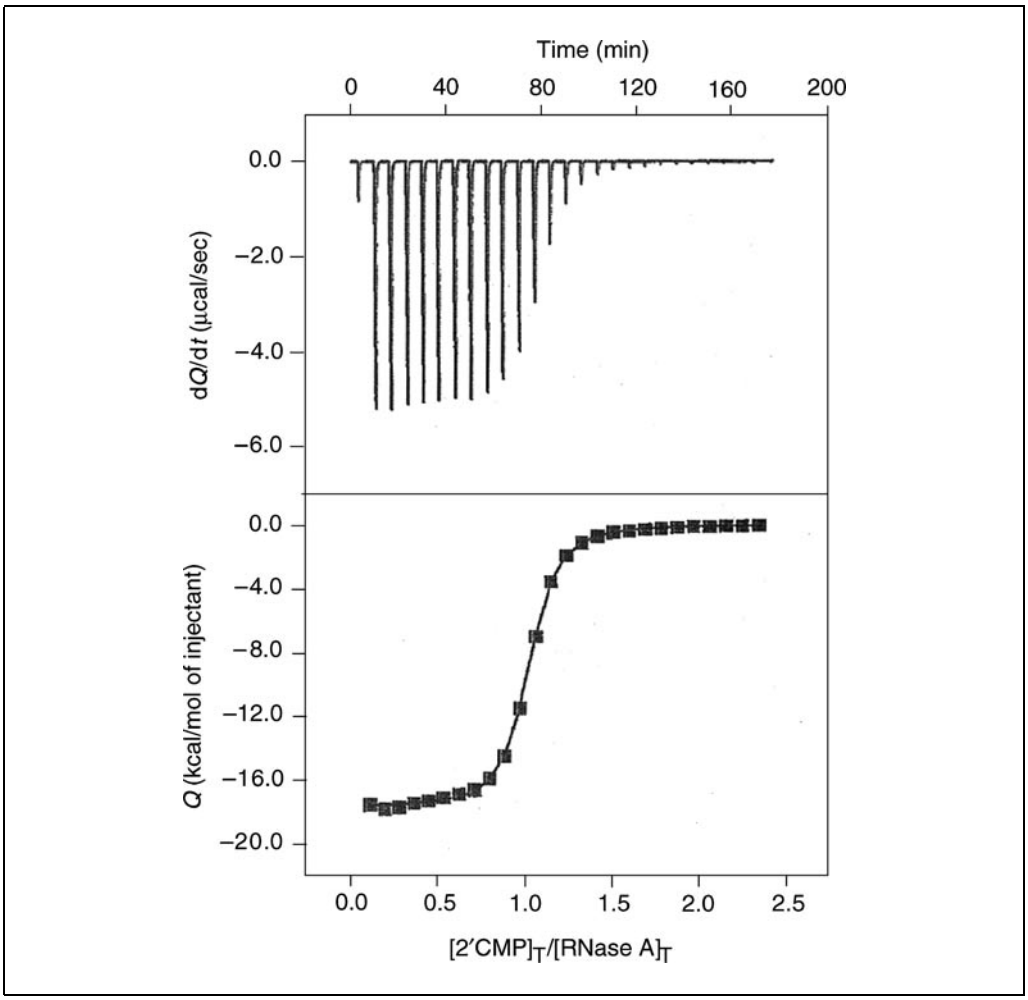

Figure 17.8.3 Titration of RNase A with 2′CMP. The experiment was performed in 15 mM potassium acetate, pH 5.5, at 25°C. The concentration of reactants are 76 μM RNase A and 1.13 mM 2′CMP. The solid line corresponds to the theoretical curve with $n = 1.02$, $K_a = 2.9 \times 10^6$ M^{-1} and $\Delta H = -19.3$ kcal/mol.

absorbance at 260 nm using an extinction coefficient of 7400 $M^{-1}cm^{-1}$ in 100 mM phosphate buffer, pH 7.0.

A final volume of 1 ml should be sufficient to conduct several experiments.

5. Dilute the dialyzed RNase A stock to a final concentration of 50 to 100 μM in 15 mM potassium acetate buffer, pH 5.5.
6. Prepare cell sample (2.2 ml of diluted RNase A) to ensure proper loading of the cell.
7. Dilute the 2′CMP stock to a final concentration of 0.5 to 1.5 mM in 15 mM potassium acetate buffer, pH 5.5, depending on the concentration of RNase A.
8. Prepare syringe sample (0.5 ml of diluted 2′CMP) to ensure proper loading of the syringe.
9. Degas 10 ml of the same buffer employed, cell sample solution, and syringe sample solution 20 to 30 min.

   This buffer solution will be used for rinsing the sample cell.

10. After preparation, transfer the syringe solution to a 6 × 50–mm glass tube to fill the syringe.
11. Set the instrument settings, run the experiment, and analyze the data (see Basic Protocol 1 and Support Protocol).

    Figure 17.8.3 shows the result from an experiment in which 2′CMP binds to the enzyme RNase A. The thermodynamic parameters obtained from this experiment are: $K_a = 2.0 \times 10^6\ M^{-1}$, $\Delta H_a = -17.8$ kcal/mol, $n = 0.99$.

BASIC PROTOCOL 3

MACROMOLECULE/MACROMOLECULE INTERACTION WITH MODERATE AFFINITY

The same equations above (see Support Protocol) apply to macromolecule/macromolecule binding. The formalism can be applied to this case by considering the macromolecule in the syringe as the ligand. As in every situation, the less soluble reactant should be placed in the calorimetric cell.

This protocol uses commercially available porcine pancreatic trypsin (PPT), a well-studied serine protease of 23.8 kDa, and its commercially available inhibitor, soybean trypsin inhibitor (STI), of 20.0 kDa. The binding of STI to PPT is an example of an endothermic binding reaction, and the binding constant for this reaction is within the range measurable by conventional ITC (El Harrous and Parody-Morreale, 1997).

Materials

Porcine pancreatic trypsin (PPT), lyophilized powder (Sigma)
25 mM potassium acetate/10 mM calcium chloride, pH 4.5
Soybean trypsin inhibitor (STI), lyophilized powder (Sigma)

10-kDa MWCO dialysis tubing
0.22-μm filter

Prepare samples

1. Dissolve PPT in 25 mM potassium acetate/10 mM calcium chloride buffer, pH 4.5, to a final concentration of ∼400 μM.

   A final volume of 1 ml of this PPT stock solution should be sufficient.

2. Dissolve STI in 25 mM potassium acetate/10 mM calcium chloride buffer, pH 4.5, to a final concentration of ~30 μM.

   A final volume of 5 ml of this STI stock solution should be sufficient.

3. Dialyze PPT and STI against ~1 liter of 25 mM potassium acetate/10 mM calcium chloride buffer, pH 4.5, overnight at 4°C using a dialysis membrane with a ~10-kDa MWCO.

4. After dialysis, filter the solutions through 0.22-μm pore filters.

5. Determine the exact concentration of the PPT and STI stock solutions by measuring their absorbances at 280 nm using extinction coefficients of 35,700 and 18,200 $M^{-1}cm^{-1}$, respectively. Store the dialyzed stocks for several weeks at 4°C.

6. Prepare cell sample. Prepare 2.2 ml of STI at a concentration of ~30 μM.

   Since STI has very low solubility compared to PPT, the former will be placed in the calorimetric cell.

7. Prepare syringe sample. Prepare 0.5 ml of PPT at a concentration of ~400 μM.

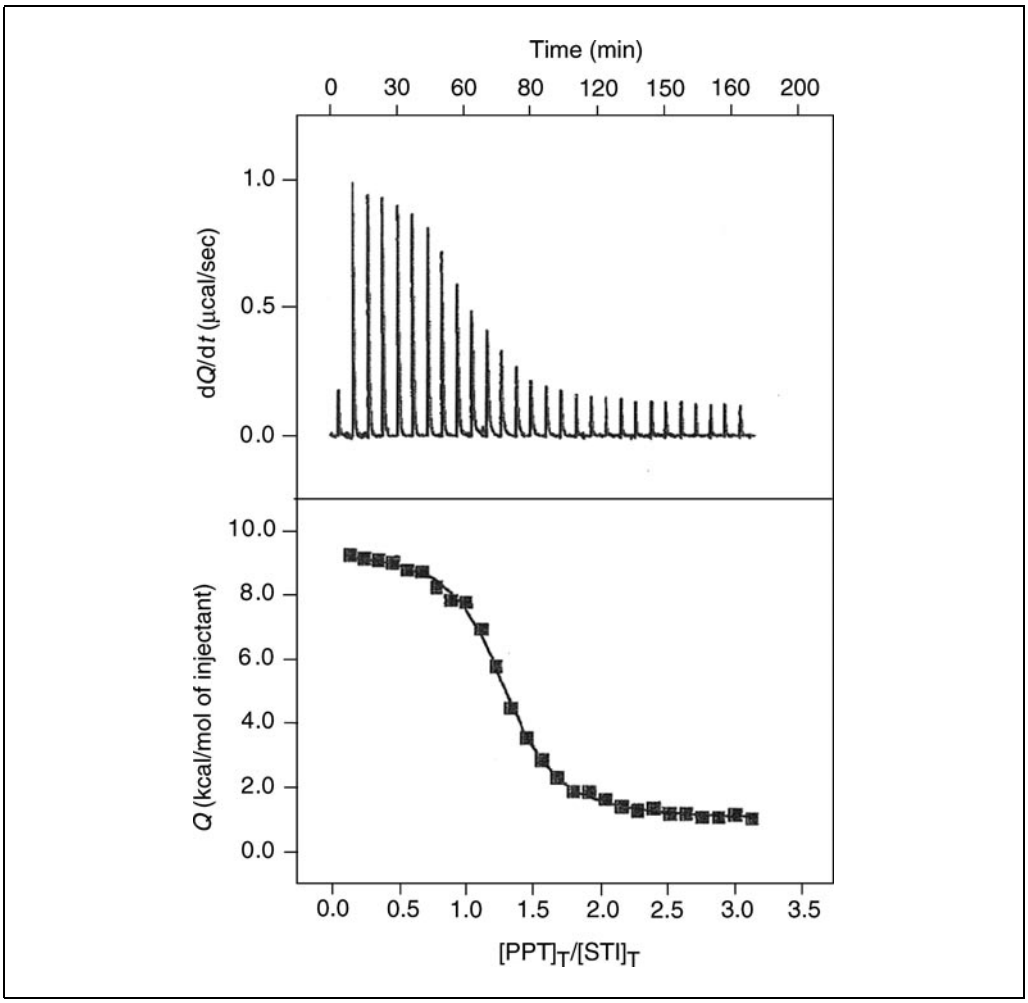

Figure 17.8.4 Titration of STI with PPT. The experiment was performed in 25 mM potassium acetate, pH 4.5/10 mM calcium chloride, at 25°C. The concentrations of reactants are 21 μM STI (in cell) and 312 μM PPT (in syringe). The inhibitor was placed in the calorimetric cell due to its low solubility. The solid line corresponds to theoretical curve with $n = 1.26$, $K_a = 1.5 \times 10^6$ M^{-1} and $\Delta H_a = 8.4$ kcal/mol.

8. Set instrument settings, run the experiment, and analyze the data (see Basic Protocol 1 and Support Protocol).

Figure 17.8.4 shows the result from an experiment in which STI binds to PPT. The thermodynamic parameters obtained from this experiment are: $K_a = 1.5 \times 10^6\ M^{-1}$, $\Delta H_a = 8.4$ kcal/mol, $n = 1.26$.

ALTERNATE PROTOCOL 1

MACROMOLECULE/LIGAND BINDING WITH HIGH AFFINITY

If the affinity between the reactants is too high ($K_a > 10^8\ M^{-1}$), the affinity of binding cannot be reliably measured. To determine the affinity directly, the concentrations of the reactants need to be lowered to levels below the sensitivity limit of the calorimeter. However, in the case of tight binding ligands, the binding enthalpy can be measured very accurately.

Traditionally, several methods have been employed to determine high affinity. All of them rely on changing the experimental conditions (temperature, pH) to reduce the apparent affinity to a measurable value (Doyle et al., 1995; Doyle and Hensley, 1998). The disadvantages are important: (1) appropriate equations (e.g., van't Hoff relationship) have to be used in order to extrapolate (with cumulative errors) to the initially intended experimental conditions; and (2) changing experimental conditions can compromise the stability or the solubility of the reactants.

A method that does not require a change in the experimental conditions is the displacement method (Sigurskjold, 2000). In this method, the ligand solution is placed in the syringe and a solution of the macromolecule pre-bound to a weaker, competitive ligand is placed in the cell. In this way, the apparent affinity of the potent ligand is reduced because it has to displace the weak ligand from the binding site to bind to the macromolecule, therefore, incurring in an energy penalty. Thus, the thermodynamic parameters for the binding of the weak ligand and also the linkage equations for the binding of the potent ligand in the presence of the weak one should be well known.

The same reasoning as in the basic case is made: from the mass conservation equations and the mass action law, it is possible to reach a cubic equation from which the concentration of all species, free and bound, can be obtained and the analysis can be done in an exact manner. The details are explained elsewhere (Sigurskjold, 2000).

However, even if the exact analysis is always the one to be performed, an approximation can be considered when the weak ligand concentration is much higher than the macromolecule concentration, so that the concentration of free weak ligand is assumed to be equal to the concentration of total weak ligand (Zhang and Zhang, 1998). In this approximation, the apparent binding parameters in the displacement binding are related to the individual binding parameters as in Equations 17.8.6 and 17.8.7:

$$K_{a,A}^{app} = \frac{K_{a,A}}{1 + K_{a,B}[B]}$$

Equation 17.8.6

$$\Delta H_{a,A}^{app} = \Delta H_{a,A} - \Delta H_{a,B} \frac{K_{a,B}[B]}{1 + K_{a,B}[B]}$$

Equation 17.8.7

where A and B are the potent and the weak ligands, $K_{a,A}$ and $\Delta H_{a,A}$ are the affinity and enthalpy of binding of the potent ligand, and $K_{a,B}$ and $\Delta H_{a,B}$ are the affinity and enthalpy

of binding of the weak ligand, and the free concentration of ligand B can be approximated by its total concentration.

One of the most important applications of ITC is in the field of structure-based drug design. The goal in any drug design process is to obtain inhibitors with very tight binding affinities to the desired target, while minimizing the binding of the inhibitor to unwanted targets. Another goal is to design inhibitors that are able to adapt to genetic polymorphisms in their target. Genetic polymorphisms can arise as a result of natural population polymorphisms or mutations that cause drug resistance in viral, microbial, and parasitic targets.

Understanding the detailed mechanism and thermodynamic differences in the binding of various inhibitors allows the development of guidelines essential to the design of highly specific drugs that are able to adapt to genetic polymorphisms in their target. The first structure-based drugs were targeted against HIV-1 protease, an aspartic protease essential for the processing of the HIV virus. Measuring the thermodynamic parameters of the binding of HIV-1 protease inhibitors to their target is compounded by the very tight binding of these inhibitors ($K_a > 10^8$ M^{-1}), which makes direct titration impossible. A displacement assay, in which a tight-binding inhibitor competes with a weaker binding inhibitor ($K_a = 10^6 - 10^7$ M^{-1}), allows the measurement of all thermodynamic parameters in a single ITC experiment. This protocol uses HIV-1 protease, a well-studied aspartic protease of 21.6 kDa, and its commercially available inhibitors nelfinavir and acetyl-pepstatin. Unlike acetyl-pepstatin, the affinity of the binding of nelfinavir to HIV-1 protease is beyond the higher limit of measurable range by conventional ITC.

Three titrations should be made: two direct titrations with nelfinavir and acetyl-pepstatin binding to HIV-1 protease, respectively, and one displacement titration of nelfinavir binding to protease prebound to acetyl-pepstatin.

Materials

Acetyl pepstatin (Bachem)
9 mM NaOH
Nelfinavir (Viracept; or any other clinical or experimental inhibitor)
100% DMSO
HIV-1 protease (Todd et al., 1998 and Velazquez-Campoy et al., 2002)
10 mM sodium acetate, pH 5.0/2% (v/v) DMSO

Prepare samples

1. Prepare acetyl-pepstatin stock solution: dissolve the lyophilized acetyl-pepstatin in 9 mM NaOH (this compound is very insoluble in pure water) to a concentration of 8 to 9 mM.

2. Determine the concentration by analytical quantitative nitrogen content determination (Jaenicke, 1974; Pace et al., 1995).

   Acetyl-pepstatin shows no absorbance at 280 nm.

3. Prepare nelfinavir stock solution at >15 mM in 100% DMSO.

   Nelfinavir is not water soluble. The solution in pure DMSO should be very concentrated (15 to 40 mM). When DMSO is diluted in aqueous buffer, the concentration of nelfinavir is closer to 200 to 300 μM.

4. Prepare cell sample for first titration by purifying HIV-1 protease according to Todd et al. (1998) and Velázquez-Campoy et al. (2002) and storing at ∼20°C at a

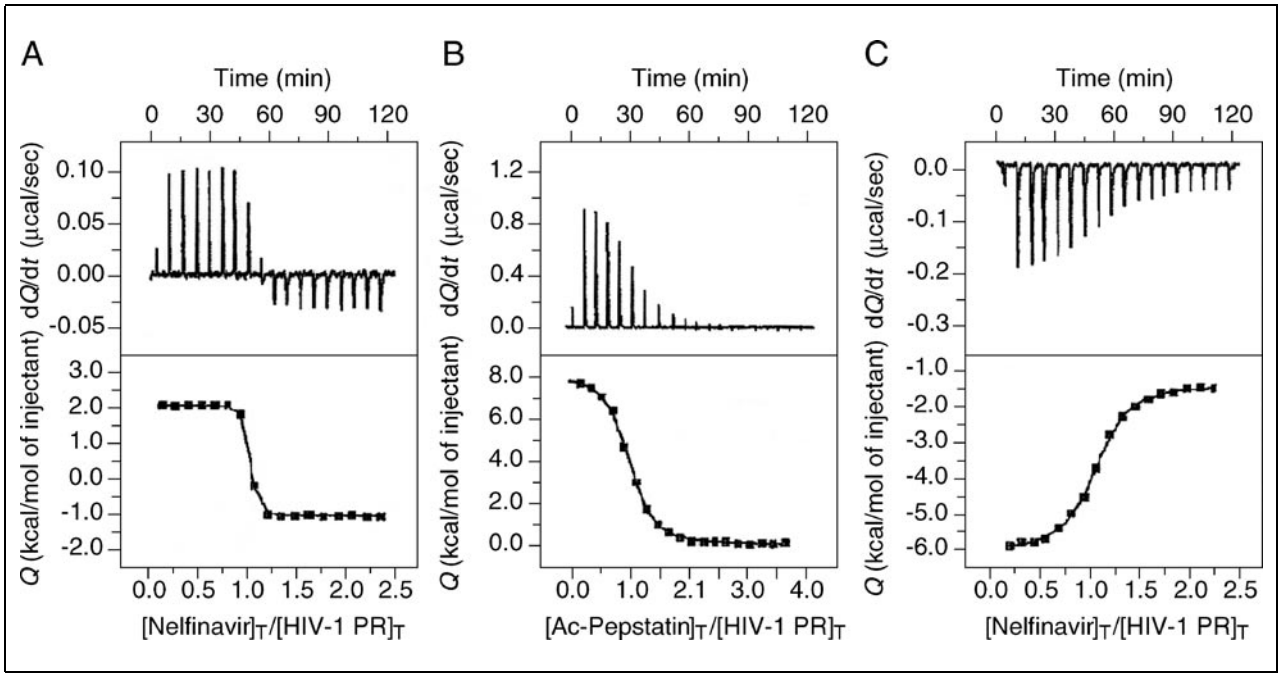

Figure 17.8.5 Set of calorimetric titrations corresponding to the implementation of the displacement protocol for the estimation of very high affinity. The concentrations of reactants are: (**A**) HIV-1 protease 11 μM in cell and nelfinavir 130 μM in syringe; (**B**) HIV-1 protease 19 μM in cell and acetyl-pepstatin 300 μM in syringe; and (**C**) HIV-1 protease 10 μM and acetyl-pepstatin 200 μM in cell, and nelfinavir 130 μM in syringe. The thermodynamic parameters obtained from these experiments are: nelfinavir binding to protease: $\Delta H_a = 3.1$ kcal/mol, $n = 1.02$, and K_a cannot be reliably obtained; acetyl-pepstatin binding to protease: $K_a = 2.3 \times 10^6$ M^{-1}, $\Delta H_a = 8.0$ kcal/mol, $n = 0.98$; nelfinavir binding to protease pre-bound to acetyl-pepstatin $K_a = 2.2 \times 10^9$ M^{-1}, $\Delta H_a = 3.3$ kcal/mol, $n = 0.99$.

concentration of >2.5 mg/ml. Dissolve the protein to a final concentration of 20 μM in 10 mM sodium acetate, pH 5.0/2% DMSO.

5. Determine the exact concentration of the cell sample by measuring its absorbance at 280 nm using an extinction coefficient of 25,500 M^{-1} cm^{-1}.
6. Prepare syringe sample for first titration: 2.2 ml of nelfinavir stock diluted to a concentration of ~300 μM in 10 mM sodium acetate, pH 5.0. If necessary, add DMSO to a final concentration of 2% to ensure that the inhibitor is dissolved in the aqueous buffer.
7. Perform the first titration with HIV-1 protease in the cell and nelfinavir in the syringe.
8. Prepare cell sample for second titration. Repeat step 4.
9. Prepare syringe sample for second titration: 0.5 ml of acetyl-pepstatin diluted to a concentration of ~300 μM in 10 mM sodium acetate, pH 5.0. Add DMSO to a final concentration of 2%.
10. Perform the second titration with HIV-1 protease in the cell and acetyl-pepstatin in the syringe.
11. Prepare cell sample for third titration. Repeat step 4 adding acetyl-pepstatin to the HIV-1 protease in the sample cell solution to a final concentration of 200 μM.
12. Prepare syringe sample for third titration. Repeat step 6.
13. Perform third titration.

Figure 17.8.5 shows the results from an experimental scheme aimed at determining the thermodynamic parameters for the binding of nelfinavir to HIV-1 protease. The thermodynamic

parameters obtained from these experiments are: nelfinavir binding to protease: ΔH_a = 3.1 kcal/mol, n = 1.02; acetyl-pepstatin binding to protease: $K_a = 2.3 \times 10^6\ M^{-1}$, ΔH_a = 8.0 kcal/mol, n = 0.98; nelfinavir binding to protease prebound to acetyl-pepstatin: $K_a = 2.2 \times 10^9\ M^{-1}$, ΔH_a = 3.3 kcal/mol, n = 0.99 (applying the exact equations for the displacement experiment in the data analysis).

MACROMOLECULE/LIGAND BINDING WITH LOW AFFINITY

ALTERNATE PROTOCOL 2

If the affinity between the reactants is too low ($K_a < 10^4\ M^{-1}$), neither the affinity nor the enthalpy of binding can be reliably determined.

One way to determine both is again by using the displacement strategy (Zhang and Zhang, 1998). In this case, the binding parameters for the weak ligand are obtained from the change in the binding parameters of the potent ligand binding to the free macromolecule and its binding to the macromolecule pre-bound to the weak ligand. The same considerations and analysis procedure explained in the case of very high affinity ligands applies here.

Many natural ligands show very low affinity ($K_a < 10^4\ M^{-1}$) for their biological targets. To measure such affinity, the displacement protocol can be implemented again.

In the case of the CMP inhibitors of RNase A, a change in the position of the hydroxyl group from 2′ to 5′ position causes a dramatic decrease in the strength of the interaction. This example illustrates the effect of minor modifications in the ligand on the thermodynamic parameters of binding.

To estimate the binding affinity for 5′-cytidine-monophosphate (5′CMP) binding to RNase A, a similar set of titrations as in the previous section should be done: two direct titrations with 2′CMP and 5′CMP binding to RNase A and one displacement titration of 2′CMP binding to RNase A prebound to 5′CMP.

For materials, see Basic Protocol 2.

Prepare samples

1. Prepare RNase A and inhibitors 2′CMP and 5′CMP stock solutions following instructions in the Basic Protocol 2.
2. Prepare cell sample for first titration: 2.2 ml of RNase A diluted to a concentration of 50 to 100 μM in 15 mM potassium acetate buffer, pH 5.5.
3. Prepare syringe sample for first titration: 0.5 ml of 2′CMP diluted to a concentration of ∼0.5 to 1.5 mM in 15 mM potassium acetate buffer, pH 5.5.
4. Prepare cell sample for second titration. Repeat step 2.
5. Prepare syringe sample for second titration: 0.5 ml of 5′CMP diluted to a concentration of ∼0.5 to 1.5 mM in 15 mM potassium acetate buffer, pH 5.5.
6. Prepare cell sample for third titration. Repeat step 2 adding 5′CMP to the solution to a concentration of 0.6 mM.
7. Prepare syringe sample for third titration. Repeat step 3.

Figure 17.8.6 shows the results from an experimental scheme aimed at determining the thermodynamic parameters for the binding of 5′CMP to RNase A. Three titrations are shown: 2′CMP binding to RNase A, 5′CMP binding to RNase A, and 2′CMP binding to RNase A pre-bound to 5′CMP. In the first titration, the binding parameters are obtained as described earlier. It is not possible to obtain a reliable value for either the affinity or the enthalpy of binding from the second titration. On the other hand, applying the exact analysis

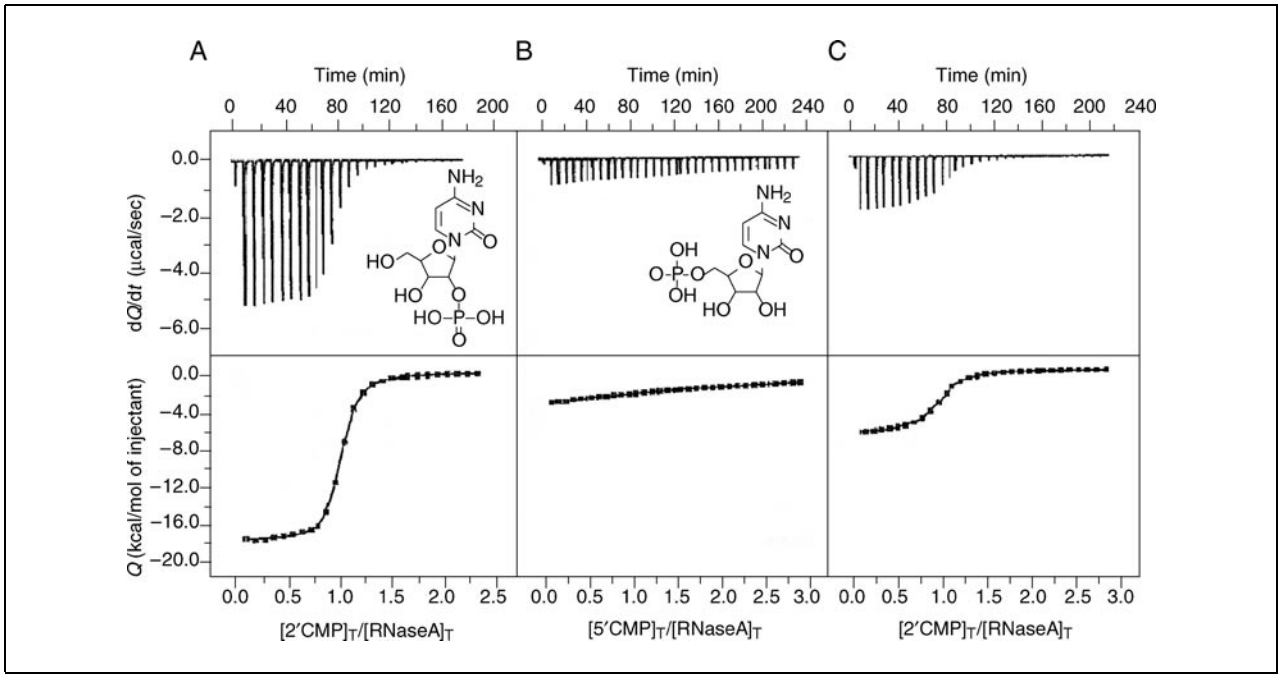

Figure 17.8.6 Set of calorimetric titrations corresponding to the implementation of the displacement protocol for the estimation of very low affinity. The concentrations of reactants are: (**A**) RNase A 76 μM in cell and 2′CMP 1.13 mM in syringe; (**B**) RNase A 76 μM in cell and 5′CMP 1.07 μM in syringe; and (**C**) RNase A 76 μM and 5′CMP 600 μM in cell, and 2′CMP 1.13 mM in syringe. The first titration corresponds to the one shown in Figure 17.8.1. In the second titration neither the binding affinity nor the binding enthalpy can be estimated. In the third titration, the thermodynamic parameters for the binding of 5′CMP obtained applying the exact analysis are: $K_a = 4250\ M^{-1}$, $\Delta H_a = -16.3$ kcal/mol, $n = 0.99$. If using the approximation method, the values obtained for the binding of 5′CMP are: $K_a = 4300\ M^{-1}$, $\Delta H_a = -15.7$ kcal/mol, $n = 0.98$, which are in agreement with the previous ones.

to the third titration yields the following thermodynamic parameters for the binding of 5′CMP: $K_a = 4250\ M^{-1}$, $\Delta H_a = -16.3$ kcal/mol, $n = 0.99$. Using the approximation method, the values obtained for the binding of 5′CMP are: $K_a = 4300\ M^{-1}$, $\Delta H_a = -15.7$ kcal/mol, $n = 0.98$, which are in reasonable agreement with the exact analysis.

ALTERNATE PROTOCOL 3

BINDING OF HOMODIMERIC PROTEINS

When the objective is to determine the thermodynamic parameters for the formation of homodimers, Basic Protocols 1 and 2 are not useful since they require the physical separation between reactants. However, it is still possible to modify the standard procedure towards that goal. In this case, the only reactant is placed in the syringe and the cell is filled with the appropriate buffer solution. The experiment consists of performing a series of injections of the reactant solution into the calorimetric cell. Since the concentration of reactant in the syringe is constant throughout the experiment, the fraction of monomers and dimers within the syringe remains constant. However, the dilution of the reactant in the cell upon injection promotes the dissociation of dimers into monomers. In these circumstances, the area under the peak associated with each injection is simply the heat released or absorbed during the dissociation reaction. Details and examples can be found in the literature (Burrows et al., 1994; Lovatt et al., 1996).

ALTERNATE PROTOCOL 4

BINDING OF UNSTABLE PROTEINS

Sometimes the unique nature of some macromolecules impedes the implementation of Basic Protocol 1 for ITC binding studies. Certain proteins tend to denature or aggregate under the vigorous stirring conditions of the calorimetric cell, which makes conducting standard ITC assays impossible.

However, it is possible to modify the protocol to determine the enthalpy of binding of ligands to such proteins. A solution of the ligand is placed in the calorimetric cell and a solution of the macromolecule is placed in the syringe. Concentrations of reactants should be chosen so that, when injecting, all of the macromolecule binds to the ligand. Therefore, all the heat associated with the injection can be assigned to the binding of all injected macromolecules to the ligand. To obtain the enthalpy of binding, it is necessary to estimate how much heat is coming from binding and how much from unspecific processes (e.g., injection, friction, dilution). Blank experiments, in which buffer solution alone (without ligand) is placed in the cell, are needed to evaluate the non-binding heat. The binding enthalpy is obtained by subtracting such contribution from the observed heat (see Equation 17.8.8):

$$\Delta H_a = \frac{Q_T - Q_{Blank}}{v[S]_0}$$

Equation 17.8.8

where Q_T is the heat associated with the injection of macromolecule into the ligand solution, Q_{Blank} is the heat associated with the injection of macromolecule into the buffer solution, v is the injection volume, and $[S]_0$ is the concentration of reactant in the syringe.

Similar experiments can also be used in Basic Protocol 1 to estimate the heat produced by ligand dilution and to determine if the ligand self-associates or aggregates at high concentration in the syringe. Details and examples can be found in the literature (Nezami et al., 2002, 2003).

MEASURING THE HEAT CAPACITY CHANGE ASSOCIATED WITH BINDING

ALTERNATE PROTOCOL 5

A single ITC assay can provide information regarding the binding constant, the Gibbs free energy of binding, the binding enthalpy, the binding entropy, and the stoichiometry of the binding reaction. In addition to this information, the change in heat capacity upon binding and the change in ionization state upon binding can be obtained by repeating the experiment with varying temperature or buffer conditions.

The heat capacity change, at constant pressure, is simply the temperature derivative of the enthalpy change (see Equation 17.8.9):

$$\Delta C_P = \left(\frac{\partial \Delta H}{\partial T} \right)_P$$

Equation 17.8.9

Therefore, one can determine its value by measuring the enthalpy change of a binding reaction at different temperatures. Plotting ΔH versus temperature would yield ΔC_P as its slope. The heat capacity of binding reflects the burial of polar and non-polar surfaces as a consequence of the binding reaction (Privalov and Makhatadze, 1992; Murphy and Freire, 1992; Gómez et al., 1995).

ΔC_P is usually determined by measuring the enthalpy of binding from 15° to 35°C at 5° intervals under identical buffer and pH conditions. Figure 17.8.7 shows the temperature dependence of the binding enthalpy of amprenavir and TMC-126, a clinical and an experimental inhibitor of HIV-1 protease, respectively (Ohtaka et al., 2002).

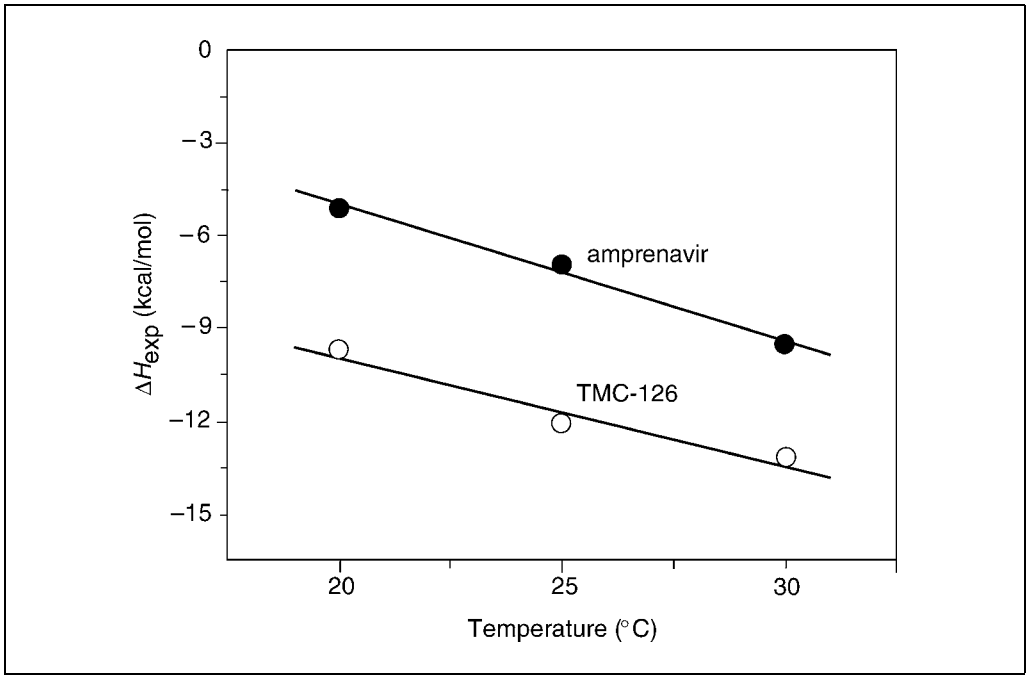

Figure 17.8.7 Temperature dependence of the binding enthalpy for amprenavir and TMC-126 binding to HIV-1 protease (Ohtaka et al., 2002). The experiments were done in 10 mM sodium acetate, pH 5.0/2%DMSO. The slope of the plot is equal to the heat capacity change upon binding and it is related to the burial of accessible surface areas from both the protein and the ligand. The values of the binding heat capacity for amprenavir and TMC-126 are −440 cal/K·mol and −350 cal/K·mol, respectively.

The heat capacity change of binding processes between a protein and a ligand is usually negative and <1 kcal/K·mol in absolute value. However, the binding of two macromolecules can be associated with a higher heat capacity change, which is indicative of a larger burial of solvent-accessible surface area upon binding or the structuring of some regions of the macromolecule.

ALTERNATE PROTOCOL 6

MEASURING PROTONATION/DEPROTONATION PROCESSES COUPLED TO BINDING

The change in the protonation state of certain residues involved in the binding process produces a proton transfer between the complex and the bulk solution. This phenomenon can be studied by detecting the heat effect produced by the protons exchanged between the protein and the buffer as a consequence of the inhibitor binding (Gómez and Freire, 1995; Baker and Murphy, 1996, 1997). In this case, the experimental enthalpy of binding, ΔH_{exp}, is the sum of the intrinsic enthalpy of the binding reaction, $\Delta H_{binding}$, independent of the buffer used and a term proportional to the enthalpy of ionization of the buffer (see Equation 17.8.10):

$$\Delta H_{exp} = \Delta H_{binding} + N_{H^+} \Delta H_{ion}$$

Equation 17.8.10

where the proportionality constant, N_{H^+}, is the number of protons that are exchanged between the complex and the bulk solution, and ΔH_{ion} is the ionization enthalpy of the buffer. Experiments are done under the same pH and temperature, using buffers with different ionization enthalpies. Figure 17.8.8 shows the protonation/deprotonation effect associated with the binding of amprenavir and TMC-126 to HIV-1 protease (Ohtaka et al., 2002). The coupling of protonation/deprotonation processes to the binding of a

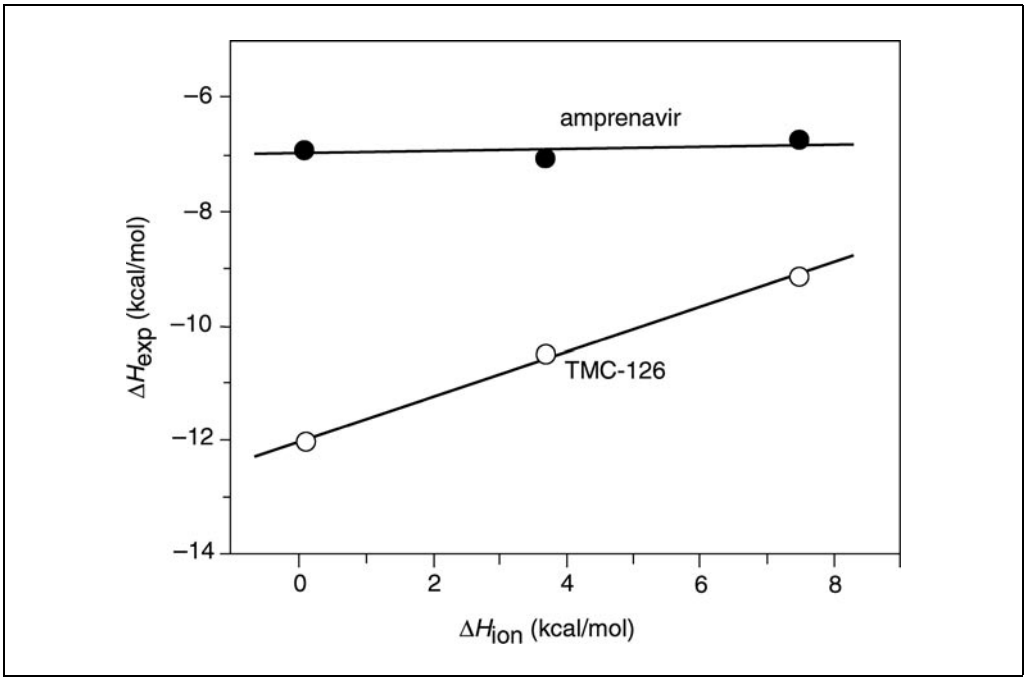

Figure 17.8.8 Dependence of the binding enthalpy for amprenavir and TMC-126 binding to HIV-1 protease on the ionization enthalpy of the buffer used in the experiment (Ohtaka et al., 2002). The experiments were done at pH 5.0 in 2% DMSO and 10 mM buffer concentration with buffers of different ionization enthalpy (acetate 0.12 kcal/mol, MES 3.72 kcal/mol, ACES 7.51 kcal/mol). The number of protons exchanged (slope) for amprenavir and TMC-126 is 0.02 and 0.39, respectively. The buffer-independent binding enthalpy (intercept with *y*-axis) for amprenavir and TMC-126 is −6.9 kcal/mol and −12.0 kcal/mol, respectively. Unlike in the case of amprenavir, where there is no net proton exchange between the ML complex and bulk solution upon binding, for TMC-126 there is a significant proton transfer.

ligand could make the experimental enthalpy measured directly, ΔH_{ion}, very different (even opposite) from the actual binding enthalpy, $\Delta H_{binding}$, if either N_{H^+} or ΔH_{ion} is large enough.

COMMENTARY

Background Information

Isothermal titration calorimetry (ITC) is a technique that directly measures the energetics associated with the binding of two components. ITC is the only biophysical method that directly determines the enthalpy (ΔH) associated with binding and provides a complete thermodynamic profile of the interaction, including binding affinity (K_a), number of binding sites (n), entropy change (ΔS), and Gibbs energy change (ΔG). ITC can be utilized for determining very low (10^3 M^{-1}) to very high binding affinities (10^{12} M^{-1}). Besides providing fundamental information about binding, ITC does not require immobilization of the binding components and takes very little time, unlike other techniques [e.g., surface plasmon resonance (*UNIT 17.6*) and ultra-centrifugation]. Moreover, since heat is universally generated or absorbed during any molecular interaction, ITC has become a more common and general detection method without the need of reporter labels. An ITC instrument has a simple setup consisting of two identical cells, a sample cell that contains a solution of one of the reactants and a reference cell that serves as a temperature reference. The instrument is equipped with a syringe that contains the second binding component and adds aliquots stepwise to the sample cell. In the last two decades, ITC has become an important technique in determining the binding energetics of various biochemical processes (Wiseman et al., 1989; Freire at al., 1990; Doyle, 1997; El Harrous and Parody-Morreale, 1997; Jelesarov and Bosshard, 1999; Leavitt and Freire, 2001; Ward and Holdgate, 2001; Ladbury, 2001), including protein-ligand binding, protein-protein binding, DNA-protein binding, protein-carbohydrate binding,

protein-lipid binding, and antigen-antibody binding. Moreover, with the ability to precisely determine the enthalpic and entropic components of binding, ITC has become an important component of the drug discovery process.

Thermodynamics of binding

Consider a binding reaction at equilibrium where a biological macromolecule M binds another molecule L (ligand; see Equation 17.8.11):

$$M + L \leftrightarrow ML$$

Equation 17.8.11

Assuming that there is a single binding site, the binding affinity or association constant, K_a, which is the inverse of the dissociation constant, K_d, determines the partition of the reactants into free and bound species, is given by (see Equation 17.8.12):

$$K_a = [ML]/[M][L]$$

Equation 17.8.12

The binding affinity is related to the free energy of binding, ΔG (see Equation 17.8.13):

$$\Delta G = -RT \ln K_a$$

Equation 17.8.13

where R is the gas constant and T the absolute temperature. The free energy of binding can be expressed in terms of the enthalpy (ΔH) and entropy (ΔS) of binding (see Equation 17.8.14):

$$\Delta G = \Delta H - T\Delta S$$

Equation 17.8.14

and therefore (Equation 17.8.15):

$$\Delta G = -RT \ln K_a = \Delta H - T\Delta S$$

Equation 17.8.15

As it can be seen from Equation 17.8.15, enthalpy (ΔH) and entropy (ΔS) are the two determinants of the binding affinity. The binding enthalpy primarily reflects the strength of interactions between the ligand and the target (non-covalent interactions, e.g., van der Waals, hydrogen bonds, electrostatics) relative to those existing with the solvent. On the other hand, the entropy change mainly reflects two contributions, changes in solvation entropy, ΔS_{solv}, and changes in conformational entropy, ΔS_{conf} (Lee at al., 1994; D'Aquino et al., 1996; D'Aquino et al., 2000). Other energetic contributions, such as those due to the loss of translational degrees of freedom are similar for all bimolecular associations and amount to 8 to 10 cal/K-mol (Murphy et al., 1994; Amzel, 1997, 2000). As the ligand binds to the macromolecule, desolvation occurs, and water molecules are released from the binding site and the ligand, producing a significant increase in degrees of freedom. This desolvation process is favorable to binding as it increases the entropy of the system. At the same time, however, the ligand and certain groups in the protein lose conformational freedom as they bind to each other (relative to their conformational degree of freedom in water). Therefore, this loss in conformational entropy, ΔS_{conf}, is usually unfavorable for the binding process, unless the binding reaction is coupled to the loss in structure of distal regions from the binding site. Since the enthalpy and entropy changes are the manifestation of different types of inter- and intra-molecular interactions, two ligands that exhibit different enthalpic and entropic contributions to the Gibbs energy of binding reflect different binding mechanisms, even if their binding affinities might be the same (Myzska et al., 1997; Parker et al., 1999; Velázquez-Campoy et al., 2000a,b; Velázquez-Campoy et al., 2001). Additional information and more advanced formalism and developments about binding thermodynamics can be found in the literature (Cantor and Schimmel, 1980; Wyman and Gill, 1990; Luque and Freire, 1998; Van Holde et al., 1998).

Applications

ITC has evolved to become a very useful technique in determining the energetics of a wide variety of chemical and biochemical interactions. Furthermore, ITC can be utilized as a standard technique in determining the precise binding affinities of components from nanomolar range to micromolar range and coupling of the binding reaction to protonation/deprotonation processes. The implementation of displacement titration experiments has extended range for affinity determination, as explained below.

Ligand binding energetics

The useful range for an accurate binding affinity measurement by standard ITC is between 10^4 and 10^8 M^{-1}. However, the practical range of binding affinities experimentally accessible can be expanded to 10^3 to 10^{12} M^{-1} by using an appropriate well-characterized secondary ligand (ITC displacement technique). This is particularly useful in the drug design

process, where the ability to accurately measure binding affinities in the sub-nanomolar range is crucial during the lead optimization stage. ITC displacement experiments will be discussed in detail in later sections.

Drug development

ITC has been utilized in the characterization and optimization of lead compounds as viable drug candidates as it provides complete information of the binding affinity of a ligand to a target in terms of its thermodynamic components ΔG, ΔH, ΔS, and ΔC_P. Current strategies for lead identification and optimization depend almost exclusively on binding affinities or Gibbs energy of binding. The Gibbs energy of binding is a result of a delicate balance between the enthalpic and the entropic contributions, and different combinations of ΔS and ΔH can give rise to the same ΔG values and, therefore, elicit the same binding affinity. A higher affinity can be achieved by two means: (1) obtaining a more favorable (negative) enthalpy change, i.e., improving ligand-protein interactions over those with the solvent, and (2) obtaining a more favorable (positive) entropy change, which in turn can be achieved by making a ligand more hydrophobic in order to maximize the solvation entropy, and/or pre-shaping the ligand in order to minimize the loss of conformational entropy. Traditional drug-design methods rely on hydrophobicity and pre-shaping compounds through the use of conformational constraints, therefore, giving rise to entropically optimized compounds (Todd et al., 2000; Velázquez-Campoy et al., 2002; Ohtaka et al., 2002). Such an approach exhibits several pitfalls, the most important ones being the lack of specificity, the susceptibility to mutations in the target, and the impossibility to achieve extremely high affinity. For example, in the case of HIV-1 protease inhibitors, there is not a single reported case of an entropically driven inhibitor with an affinity stronger than 0.3 nM (Todd et al., 2000; Ohtaka et al., 2002). Therefore, ITC can be utilized not only to characterize existing ligands but also to provide a step-wise guide in the design process by permitting a direct evaluation of the energetic effects of specific chemical modifications.

Evaluation of mutations effects

Genetic diversity and mutations associated with drug resistance are the two major causes of failure of drug therapy in various bacterial and viral diseases, e.g., HIV infection. These two phenomena involve changes in the drug binding sites of the target molecules. Since drug molecules developed under the traditional drug-design paradigm, based on the lock-and-key concept, are conformationally constrained and pre-shaped to the geometry of the target molecule, they cannot effectively adapt to changes in binding site geometry due to naturally occurring polymorphisms or drug resistance mutations (Velázquez-Campoy et al., 2002; Ohtaka et al., 2002). As a result, they lose significant binding affinity. Therefore, a major challenge in drug design is the integration of binding site heterogeneity in the design process. An ideal molecule would be one that is able to adapt to the variability in the target while simultaneously displaying high binding affinity and specificity. ITC being the only technique to provide the individual components of the Gibbs free energy of binding (ΔH, ΔS, and ΔC_P), is able to determine subtle changes in the binding process arising from polymorphisms or mutations in the target. Therefore, ITC can be utilized in the design process of an adaptive ligand that will overcome the current deficiency in the drug design process against variable targets (Velázquez-Campoy et al., 2001; Velázquez-Campoy and Freire, 2001; Freire, 2002; Nezami et al., 2003).

Critical Parameters and Toubleshooting

For a titration experiment to be successful and well designed, the following critical points should be considered.

1. ITC measures the global heat effect associated with the binding of two molecules. This includes the actual heat of binding (binding enthalpy) and all other heat effects originated from non-specific events (dilution of reactants, friction of injected liquid, etc.). Therefore, it is important to ensure that these contributions are minimized or considered in the analysis. For example, in the case of the dilution of reactants, the last peaks in the experiment after saturation can be an estimate of the heat effect due to such unspecific phenomena. Also, a titration of the reactant in the syringe into the buffer solution gives an estimation of the dilution effect of the titrant. In the case of friction of the injected liquid, small injection volumes (between 3 and 10 μl) and the recommended rate of injection (0.5 μl/sec) should be employed.

2. Regarding the possibility of aggregation or association of the reactants, the reactant with the lower solubility should be placed in the calorimetric cell.

3. As explained above, the appropriate range of concentrations and the proper ratio of ligand/macromolecule concentrations needs to be employed to guarantee completion of titration, reaching the saturation point in a reasonable number of injections (<30). If saturation is achieved in fewer injections (<5), then, the ligand/macromolecule concentration ratio should be lowered. On the contrary, if saturation is hardly reached, then the ratio should be increased.

4. A perfect match between the buffers has to be achieved to avoid spurious heat effects due to protonation of different species and mixing of different components that could be larger than the actual heat effect associated with the binding reaction. Accordingly, extreme care should be taken when using organic co-solvents (e.g., DMSO), because a mismatch in the concentration of these components between the solutions in the cell and the syringe will cause large heat effects.

5. From a practical point of view, it should always be emphasized that a clean cell and a perfectly straight syringe are decisive to avoid spurious results and to give excellent baselines with high signal-to-noise ratio.

Anticipated Results

Different titration experiments and representative examples are shown in each protocol.

Typical titration experiments in the range of moderate affinity ($K_a \sim 10^6$ M^{-1}) corresponding to exothermic and endothermic binding processes are shown in Figures 17.8.3 and 17.8.4, respectively. The following are several features that will indicate the quality of the experiment:

1. The curvature of the titration curve is appropriate to obtain a reliable estimation of the binding affinity.

2. The saturation point has been achieved and the final molar ratio is ~2.5 to 3.

3. There is a good signal-to-noise ratio. The data in Figure 17.8.3 is better than that of Figure 17.8.4 because the concentrations of reactants used in the titration are ten times higher. A good signal-to-noise ratio will guarantee small errors in the integration stage in data analysis.

4. In terms of thermal power between the peaks before and after the titration, there is a 50-fold decrease (5 μcal/sec compared to 0.1 μcal/sec, in absolute value) and a five-fold decrease (1 μcal/sec compared to 0.2 μcal/sec, in absolute value) in Figure 17.8.3 and 17.8.4, respectively. The standard deviation of the noise is 0.002 μcal/sec and 0.004 μcal/sec in Figure 17.8.3 and 17.8.4, respectively, much lower than the height of the peaks before and after saturation.

Time Considerations

The time required for a complete ITC experiment can be divided into different steps. Preparing sample solutions requires ~30 min. Running the ITC experiment takes ~2 to 3 hr. Cleaning the ITC instrument requires ~20 min. Analyzing the results takes ~30 min.

Rational Design and Evaluation of FRET Experiments to Measure Protein Proximities in Cells

Defining the repertoire of interactions that a particular protein can undergo is crucial for understanding its function and regulation. Characterizing where and when these interactions occur is a major goal of cell biology. Although biochemical approaches (e.g., immunoprecipitation, pull-down assays, and cross-linking) are indispensable for identifying protein-protein interactions, they do not provide spatial and temporal information in the context of an intact cell. Conversely, immunofluorescence localization or genetically encoded fluorescent tags such as green fluorescent proteins (GFP) can provide spatial information regarding an individual protein, but little insight into its interacting partners. While co-localization of two proteins (e.g., in the same organelle) is a prerequisite for their interaction, an interaction cannot be concluded just because two proteins are co-localized by fluorescence microscopy. Clearly, a combination of fluorescence-based visualization of proteins (in their cellular context) that simultaneously provides subnanometer resolution of their proximities (i.e., whether they can physically interact) is highly desirable in nearly all areas of cell biology. For this reason, numerous approaches have been developed to meet these demands.

Because a protein's localization is one of its most basic features, there are enormous numbers of reagents for visualizing individual proteins by fluorescence microscopy. These include an ever-growing collection of fluorescent protein–tagged constructs as well as high-affinity mono-specific antibodies suitable for immunofluorescence. Given the wide range of color variants of both fluorescent proteins and fluorescent dyes, visualizing two or more proteins simultaneously is now routine. To convert this basic methodology to additionally report on close (subnanometer) proximities of the fluorescently marked proteins, one needs to employ fluorescence resonance energy transfer (FRET). In essence, measurement of FRET between two appropriately labeled proteins containing fluorophores with suitable properties can be used to infer the spatial and temporal characteristics of protein interactions in their native cellular environment.

How does this work? FRET refers to the nonradiative transfer of energy from one fluorescent molecule (the donor) to another fluorescent molecule (the acceptor; *UNITS 4.14 & 17.1*). Hence, energy that is captured by the donor upon its excitation is transferred to the acceptor. This results in the donor *failing* to emit a photon, while the acceptor emits a photon at its characteristic wavelength (despite the fact it was not directly excited). Although a wide variety of parameters influences the probability of FRET (see Matyus, 1992; Clegg, 1995; Wouters et al., 2001 for detailed discussions), the most important are the distance separating the donor and acceptor, and their respective fluorescence spectra. Multiple experimental methods and instruments exist for measuring FRET (Jares-Erijman and Jovin, 2003). Selecting the appropriate method and instrumentation can be daunting, even for experienced fluorescence microscopists. Each of the techniques has particular advantages and disadvantages, and the appropriateness of a technique depends on the nature of the hypothesis being tested.

The method that can be most widely and simply implemented, quantified, and interpreted is the acceptor-photobleaching FRET technique (also see *UNIT 17.1*). In this method, the presence of FRET between a donor and acceptor is revealed upon destruction (by photobleaching) of the acceptor. If the donor fluorescence now gets brighter, one can infer that it had been in sufficiently close proximity to the acceptor to undergo FRET. The extent of increase is a quantitative and direct measure of FRET efficiency. As described below, acceptor photobleaching represents a robust technique that can be exploited to detect changes in the composition and organization of subunit proteins within a multiprotein complex and even to gain insight into relative stoichiometries of proteins within the complex.

To obtain high-quality FRET data, care must be taken to select appropriate controls, maximize the signal-to-noise ratio, and

Contributed by Erik L. Snapp and Ramanujan S. Hegde
Current Protocols in Cell Biology (2006) 17.9.1-17.9.20

perform sufficient numbers of measurements for the intended questions. In addition, subtleties of FRET theory have implications for accurate interpretation of experimental results. In this unit, strategies, tools, and background for designing and interpreting acceptor-photobleaching FRET experiments in cells are described. As mentioned above, the proteins of interest can be labeled in many ways: fluorescent antibodies, genetically encoded fluorescent protein tags, direct conjugation to dyes, or even fluorescent ligands. Different combinations of all of these methods have been exploited in various FRET methods. For this unit discussion will be limited to two proteins both labeled with fluorescent antibodies. However, the principles, particularly those related to the planning and interpretation stages of the experiment, can be applied easily to other methods of labeling. The basic protocols for cell fixation, labeling, dye-labeling of antibodies, and acceptor photobleaching are provided in *UNIT 17.1* and will be referred to as appropriate.

BACKGROUND INFORMATION

Fluorescence resonance energy transfer (FRET) refers to the nonradiative transfer of energy from an excited donor fluorescent molecule to an acceptor molecule. Multiple parameters influence the probability of FRET (see Matyus, 1992; Clegg, 1995; Kenworthy, 2001; Wouters et al., 2001; Wallrabe and Periasamy, 2005; and *UNITS 4.14 & 17.1* for detailed discussions). The most important parameters are the distance separating the donor and acceptor and their respective fluorescence spectra. Because FRET efficiency is inversely dependent on the sixth power of the distance separating the donor and acceptor, it is a highly sensitive measure of even small (subnanometer) changes in the relative proximities of the dyes. For a single donor and acceptor fluorophore, the probability of FRET upon excitation of the donor is $1/[1 + (r/R_0)^6]$, where r is the distance separating the fluorophores, and R_0 is the distance at which a 50% probability of FRET is observed (the so-called Förster distance; Förster, 1948).

The applications of FRET are numerous. For the cell biologist, FRET has been used to create biosensors of ions (e.g., the calcium-sensing cameleon fluorescent indicators; Miyawaki et al., 1997) or the active state of a protein, measure protein proximities, and measure changes in organization or composition of a protein complex. FRET biosensor assays have been well characterized and typically are measured using sensitized emission (see the Commentary in *UNIT 17.1*; Miyawaki and Tsien, 2000; Van Rheenen et al., 2004) or fluorescence lifetime imaging microscopy (FLIM; *UNIT 4.14*). These FRET assays benefit from the presence of both FRET dyes on the same molecule, which obviates the need to separately express donor and acceptor molecules at comparable levels. In contrast, studies of complexes containing multiple proteins are more theoretically and technically complex. The appropriate design and interpretation of such FRET experiments depend upon a careful consideration of the theoretical expectations.

A critical yet often overlooked concept in understanding FRET measurements is that FRET is a stochastic, all-or-nothing phenomenon. In other words, for any given donor molecule and acceptor molecule, FRET either happens or it does not happen; there is no such thing as partial transfer of energy. If FRET is an all-or-nothing phenomenon, why aren't reported FRET values either 0% or 100%, but something in between? The short answer is that FRET measurements in cells and solutions reflect the *averaged probability* of energy transfer between a very large number of donor and acceptor molecules in the sample. This means that a FRET value is the mean detected energy transfer efficiency for multiple FRET events. Furthermore, each measurement also reflects whether FRET occurs for all of the fluorophore molecules in each pixel of an image. A fluorescence image is a collection of fluorescence photon intensity values for each pixel (Michalet et al., 2003). A single pixel can contain multiple fluorophores. The intensity value of a pixel also reflects the time for collecting photons at that point, either the dwell time of a scanning laser in a confocal microscope or the detection time for a charge-coupled device (CCD) on a wide-field microscope. Therefore, a typical FRET measurement for each pixel in a cell is an ensemble measurement that averages numerous FRET events. For this reason, FRET measurements are often described as per cent energy transfer efficiency. Thus, a measurement reflects how frequently FRET events occur for a population of fluorophores under the given conditions.

Often, investigators focus on the Förster distance of a donor/acceptor pair in FRET studies, the rapid drop in energy transfer efficiency with distance, and the power of FRET measurements as a "spectroscopic ruler" (Stryer and Haugland, 1967). In the case of single-molecule studies or well defined and homogeneous biochemical samples, FRET

can indeed be used to measure absolute distances between fluorophores. However, interpretation of FRET measurements between pairs of proteins expressed in cells is complicated by the number of proteins being assayed and by how the donor and acceptor proteins are labeled.

For this unit, it is assumed that the investigator will label the proteins of interest with at least one antibody and either a variant fluorescent protein (i.e., GFP), a small dye (FlAsh and ReAsh), or another antibody. The dimensions of the antibody probes (~14 nm) are substantially larger than the distances over which FRET occurs, and the number and distribution of dyes on the antibody surface are random. Furthermore, the antibodies, as well as the dyes conjugated to them, are flexible enough to substantially influence their absolute positions. These and other variables complicate the relationship between the observed FRET and the distance separating the antigens to which donor and acceptor antibodies are bound (Dewey and Hammes, 1980; Haas and Steinberg, 1984). The consequences of these properties are that FRET cannot be used as a "spectroscopic ruler" for measuring absolute distances of native cellular proteins. This is not to imply that FRET can't be used to detect discrete changes in protein proximity, but rather to emphasize the difference between measuring absolute versus comparative distances. For most cell biologists, the *absolute* FRET values are far less important to the interpretation of the results than the *relative* differences obtained for direct comparisons. For example, the absolute FRET values are generally not used to calculate or draw conclusions regarding distances between components; rather, it is the *changes in FRET that are used to infer changes in complex organization or structure*.

OPTIMIZATION OF ACCEPTOR-PHOTOBLEACHING FRET

Acceptor-Photobleaching FRET in Cells

There are several ways to measure FRET (Jares-Erijman and Jovin, 2003) in cells including sensitized emission (Miyawaki and Tsien, 2000), FLIM (Deniz et al., 2001; Haj et al., 2002; *UNIT 4.14*), fluorescence anisotropy (Krishnan et al., 2001; Rizzo and Piston, 2005), and acceptor photobleaching (Kenworthy and Edidin, 1998; Haj et al., 2002; Snapp et al., 2004; *UNIT 17.1*). Acceptor-photobleaching FRET has several advantages that make it suitable for studying protein interactions in cells. First, FLIM and anisotropy measurements require access to instruments that often must be custom designed and built by the user. In contrast, suitable laser scanning confocal microscopes that can be used for acceptor-photobleaching experiments are both commercially available and accessible at most institutions. In addition, even a standard fluorescence microscope with a mercury lamp can be used to perform acceptor photobleaching (Kenworthy and Edidin, 1998). Second, sensitized emission depends on acceptor emission and often suffers from signal bleed-through from the donor, requires multiple correction factors, and provides no information about the relative populations of associated proteins (see Commentary in *UNIT 17.1*). In contrast, acceptor photobleaching can be quantitated with a simple arithmetic equation, is unaffected by bleed-through, and can be used to gain insights into associated and unassociated populations of proteins. A noteworthy disadvantage of acceptor-photobleaching FRET is that it requires destruction of the probe, which prevents more than one measurement in a region of a cell. In addition, photobleaching to background levels of fluorescence intensity is often slow and either requires cells to be fixed or the proteins of interest to be relatively immobile.

An important consideration for experimental design is whether the goal of the study is to distinguish between two distinct readout states or a continuum of states. It is often not feasible to synchronize multiple protein complexes in their dynamic changes. In contrast, measuring the change between a treated and untreated sample is more experimentally tractable for samples in cells. The measurement of discrete states permits cells to be fixed. While the aesthetic and intellectual appeal of live cell data is undeniable, the actual requirement for using live cells is worth considering. If the experimental readout is treated versus untreated cells, then cells in the two states can be fixed and assayed. Fixation of cells for 15 min in 3.7% formaldehyde retains substantial cell structure and does not significantly promote nonspecific protein interactions (Jackson, 1999; Metz et al., 2004; Snapp et al., 2004). Formaldehyde is a remarkably specific cross-linker and has been used for years in chromatin immunoprecipitation (ChIP; *UNIT 17.7*) assays to identify proteins that bind to unique DNA sequences in the nucleus (Jackson, 1999). It is still possible to perform live-cell acceptor-photobleaching FRET studies, though the investigator must now contend with the issue of diffusion.

Many proteins are not immobile (Lippincott-Schwartz et al., 2001). Because complete photobleaching of a fluorophore can take several seconds to minutes, acceptor photobleaching benefits substantially from immobilizing proteins with fixation.

Based on the background information above, acceptor-photobleaching FRET of native proteins in cells is most appropriate for the following types of questions. Does a pair of proteins interact to a significant degree in a particular region of a cell? Does a protein complex undergo changes in composition? Do protein subunits undergo changes in their proximity or organization in a protein complex? Are two different protein subunits present at equivalent amounts in a complex? In contrast, acceptor photobleaching is poor at detecting small subpopulations of interacting proteins (e.g., only 10% of a protein is in a complex, and the complexes are homogenously distributed throughout the cell), quantitating absolute distances between protein subunits, and detecting small continuous changes in a mixed population of protein complexes.

Before investing the time and resources into performing FRET experiments, the investigator will benefit from critical analyses of the questions to be addressed, the available reagents, and anticipated outcomes under idealized conditions. For example, a failure to consider expression levels when choosing which of two proteins to label as the donor, or attempting to measure absolute distances between proteins with antibody-based FRET will result in low probabilities of success. To enhance the probability of detecting the highest possible FRET signal for a pair of proteins, several conditions need to be empirically optimized.

Determine Which Protein Will Be the Donor and the Acceptor

In acceptor-photobleaching experiments, this choice can significantly impact the observed FRET value. There are two key points to consider. First, unpaired donors (i.e., those not in complex with the acceptor) dilute the detectable FRET signal. Second, unpaired acceptors have little effect on acceptor-photobleaching FRET values, and are thus effectively invisible in this assay format. The percent of unpaired molecules can be minimized by labeling the protein of lower stoichiometry (if known from independent studies) with the donor fluorophore. Note that if the stoichiometry of the two proteins is not known, a discrepancy in FRET values upon exchanging donor and acceptor status can provide insight into this issue (see Reciprocal FRET section).

Select an Appropriate Labeling Scheme

The method of labeling the proteins of interest will directly affect the ability of FRET to detect changes in protein proximities. For this unit it is assumed that proteins of interest will be proteins expressed in the cell. These proteins can be labeled either with fluorescent dye-labeled antibodies, variant fluorescent proteins (i.e., GFP) or newer fluorescent tags including FlAsh and ReAsh (Adams et al., 2002). After designating which protein will be the donor and which will be the acceptor, the investigator must choose a suitable labeling scheme. If a donor protein is present at low levels and overexpression changes a cellular phenotype, then antibody labeling is likely to be better than using a fluorescent fusion protein. Not only will the antibody boost the fluorescent signal due to multiple dyes on the antibody, but the multiple dyes can also enhance the probability of detecting FRET (see Fig. 17.9.1). If the donor and acceptor are abundant proteins and the donor remains functional when fused to a fluorescent protein, such as GFP, then addition of a fluorescent protein tag or epitope tag may provide flexibility in experimental design. It is not recommended to have an antibody donor and a fluorescent protein acceptor. In this case, there would be multiple dyes on the antibody that might fail to exhibit FRET with a single fluorophore acceptor. Again, the key principle is to avoid situations with excess donor molecules or limiting acceptor molecules.

If using antibodies to label the protein(s) of interest, either monoclonal or mono-specific polyclonal antibodies (raised against short peptide sequences of ~8 to 20 amino acids) are preferable to broad specificity antibodies. A single protein epitope is likely to ensure that only a single antibody molecule will bind any given copy of a protein. This is an especially useful quality when an investigator is trying to determine whether a complex contains more than one copy of a protein. A single epitope will provide more specific information concerning protein organization and can aid in experimental design. For example, an epitope against the cytoplasmic domain of a membrane protein has a higher probability of undergoing FRET with the cytoplasmic epitope of a partner protein.

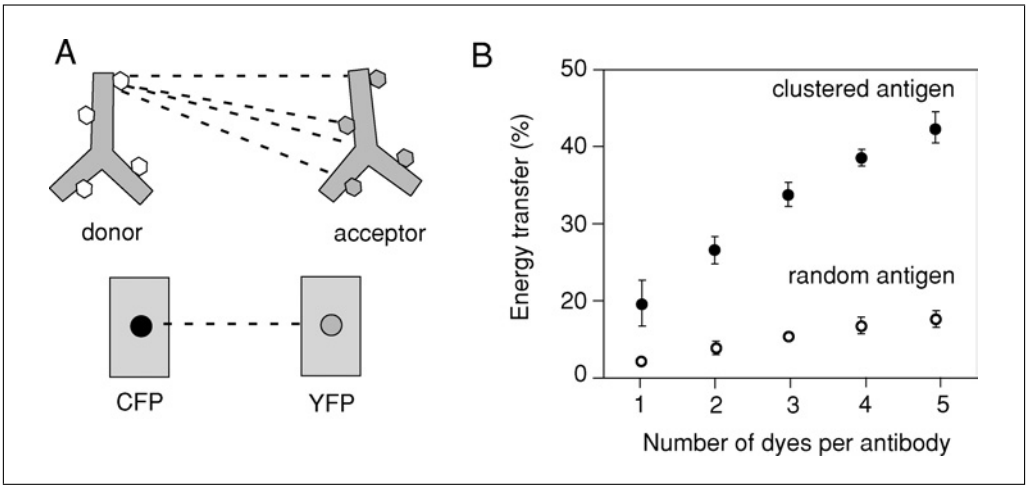

Figure 17.9.1 Illustration of the advantage of using antibody probes labeled with multiple dyes. (**A**) Cartoon illustrates how each donor dye on an antibody has the potential to transfer energy to four different acceptor dyes on an acceptor antibody. In contrast, a cyan fluorescent protein (CFP) molecule can only potentially transfer energy to one yellow fluorescent protein (YFP) acceptor. The consequence is that multiple dye–labeled acceptor antibodies enhance the probability of detecting FRET. (**B**) The relationship of dye number on each donor and acceptor antibody as plotted with simulated data for antibodies bound to antigens that are either assembled in a multiprotein complex (clustered) or distributed in a random manner. See Snapp et al. (2004) for details concerning the simulation parameters. Note that the value calculated for a single dye will not be equivalent to the CFP-YFP pair because the simulated dye placement on the antibodies was random and could include distances up to three times greater than for the fluorescent fusion proteins.

Select the Donor and Acceptor Fluorophores

The donor should be a fluorophore that is excited at a lower wavelength than the acceptor, and with an emission spectrum that overlaps significantly with the excitation spectrum of the acceptor. The degree of spectral overlap is a key determinant of the efficiency of FRET. A useful measure of the suitability of a donor-acceptor pair for FRET is known as the Förster value: the distance at which the probability of FRET between the donor and acceptor is 50%. Optimal FRET pairs are constantly being updated. A popular and well characterized donor-acceptor pair is the dyes Cy3 and Cy5, with a Förster distance of ~5 nm (Bastiaens and Jovin, 1996). Another useful FRET pair in cells is GFP and Cy3 with a Förster distance of 6 nm (Haj et al., 2002). A second parameter important in FRET efficiency is the brightness and stability of the fluorophores. Photostability is a desirable quality in the donor and less desirable for the acceptor. For example, Alexa fluorophores photobleach poorly and will thus be poor choices as acceptor, but they are reasonable choices for donors.

Optimize Antibody Dye Labeling Ratios

See *UNIT 17.1* for the Cy3/Cy5 dye labeling protocol. Addition of dyes to antibodies requires balancing of three properties: maximal FRET signal, antibody intensity quenching, and antibody binding inhibition. For Cy3 and Cy5 dyes, four dye molecules per antibody generally give excellent results (Snapp et al., 2004). This number of dye molecules tends to maximize the fluorescent signal and FRET efficiency while minimizing the disruption of binding activity. It goes without saying that it should be confirmed that the directly conjugated antibody recognizes antigen with specificity similar to the unconjugated starting antibody.

Identify Relevant Positive and Negative Controls

The importance of the choice of controls cannot be overstated. Quite simply, controls define the limits and scale for interpretation of experimental FRET values. Regardless of the predicted Förster distance for a FRET pair, actual FRET data is very much dependent on the properties of the system and must take into account the geometry of the protein complex, cellular autofluorescence, the method of FRET measurement, the size of the fluorescent label, and effects of the cellular environment on fluorophore properties. Therefore, the investigator should select controls that: (1) use the same FRET pair of fluorophores; (2) mimic the spatial environment of the proteins of

interest (i.e., if membrane proteins are being investigated, the controls should also be membrane proteins); (3) label cells with similar fluorescence intensities relative to the experimental labeling; and (4) display co-localization in immunofluorescence images (i.e., in the same organelle) for both positive and negative controls. This last point is obvious for a positive control because proteins that do not co-localize at the level of light microscopy will not exhibit FRET. However, using co-localized proteins for the negative control is also important because the goal of the experiment is to get spatial resolution that is higher than light microscopy can deliver. Thus, it is important to demonstrate that noninteracting proteins close enough to co-localize in the cell do not give significant FRET. For acceptor-photobleaching FRET using antibodies, a simple but nice positive control is an acceptor-labeled primary antibody bound by a donor-labeled secondary antibody. In this instance, all donor-labeled antibodies are necessarily adjacent to an acceptor-labeled antibody, and should necessarily yield highly efficient FRET.

Empirically Determine Antibody Labeling Conditions

It is assumed that the investigator is familiar with the basic operation of a confocal microscope. The investigator should understand both the concept and the operation of scan speed, zoom, detector gain, laser power, photobleaching, and collection of a time series on a laser scanning confocal microscope. A series of simple immunofluorescence experiments should be performed to determine the several imaging and labeling conditions (see below). Cells can be assayed with a fluorescence microscope fitted with a charge-coupled device (CCD) or a confocal microscope with a photomultiplier tube (PMT). It is important to collect the data and quantitate intensities using software provided by the microscope maker or a program such as NIH Image, ImageJ, or Metamorph. The human eye is remarkably poor at quantifying subtle differences in intensity. Also carefully consider the method used for monitoring intensities. If the proteins of interest localize to a discrete structure or only a few dispersed structures, it will be more informative to assay a region of interest that includes only the structure of interest. Large regions of interest that include large unlabeled regions will average out differences in the fluorescence intensities of structures.

Initially, fix, permeabilize, and label cells separately with donor and acceptor antibodies to separately optimize each to maximize signal intensity and reduce nonspecific labeling. Typically, the donor antibody is used at ~0.2 to 1.0 μg/ml and the acceptor is used at ~2 to 4 μg/ml (this refers to the concentration of the specific antibody; hence, crude IgG from a polyclonal serum would be used at ~10-fold higher concentrations since only ~10% is specific antibody). A donor/acceptor ratio at or below 1:4 (usually ~1:8) will help maximize FRET efficiency without making the donor fluorescence intensity too dim to easily visualize. Incubation times will vary depending on antibody affinity and will need to be determined for each antibody. In general, 60 to 120 min is sufficient for optimal antibody labeling, as assessed by maximal fluorescence intensity and minimal nonspecific staining. Each of these modifications increases the efficiency of FRET as would be expected if the occupancy of antigens were improved. The goal is to maximize occupancy of the antigens bound by the acceptor antibody and have a sufficiently bright but highly specific labeling of the donor. Recall that excess acceptor is effectively invisible to FRET, as measured by acceptor photobleaching, so some nonspecific binding by the acceptor is acceptable. In contrast, optimization of conditions that give highly specific donor labeling is critical.

Another important control is to label cells separately with donor followed by acceptor, acceptor followed by donor, and donor and acceptor simultaneously and then measure mean fluorescence intensities of the whole cell or relevant structures. This control will reveal whether the antibodies sterically affect accessibility of protein epitopes and potentially affect labeling. A similar control experiment that tests the same parameter is to systematically change the concentration of one antibody and determine whether the efficiency of labeling by the other antibody of the donor-acceptor pair in cells is affected.

Identify Optimal Photobleaching Conditions for the Acceptor

Photobleaching the acceptor by high-intensity laser illumination is influenced by laser power, magnification, dwell time of the laser, number of bleach iterations, and sample preparation. The goal should be to optimize conditions where more than 90% of acceptor fluorescence can be bleached. Dyes such as Cy5 may require hundreds of iterations

of laser photobleaching to deplete acceptor fluorescence to background levels. If a large area is to be photobleached or the viewing field is at a low magnification, then the time required to achieve sufficient photobleaching will become burdensome. So choose the highest magnification that allows the regions of interest to be visualized completely. Also, perform the optimization at different magnifications (optimum conditions will differ) so that in the future, a complete set of bleach conditions for whatever application might arise has been obtained. Once optimized, be sure that the selected imaging conditions do not result in photobleaching of the cell outside of the photobleach region of interest.

Make and Quantify FRET Measurements

Once the above parameters are optimized, the samples (along with the predetermined positive and negative controls) can be prepared in which both donor and acceptor are labeled. To make measurements, find some appropriate cells or regions of interest. This is best done by visualization of the cells using the absolute lowest illumination as possible to prevent premature partial bleaching of the sample. One can use phase-contrast microscopy to find suitable cells, or if fluorescence microscopy is used, illuminate only the donor while searching. Once the area is focused and imaging/bleaching conditions are set, the procedure is to take pre-bleach images of the donor and acceptor fluorescence, photobleach the acceptor in a region of interest, and take a second set of post-bleach images of the donor and acceptor. It is critical to avoid sample movement, change in focal plane, or any change in imaging conditions between the pre- and post-bleach images. Once completed, there should be four images for the measurement: pre- and post-bleach donor images, and pre- and post-bleach acceptor images. Although only the donor images are absolutely required for the calculation of FRET efficiency, capture and save the acceptor images because they contain additional information that aids in the interpretation.

The calculation of FRET efficiency from these images can be done manually, or automated using relatively straightforward custom macros for a program like NIH image (see section on automated image analysis). To manually calculate FRET, measure the donor intensity in both the pre- and post-bleach images within the region that was bleached (referred to here as D_{pre} and D_{post}). Subtract background intensity (i.e., the value obtained in an area where there are no cells) from both intensity values. Once these values are obtained, the % FRET (also referred to in various publications as % energy transfer, $\%E$, or just E) can be calculated as:

$$\%E = (D_{post} - D_{pre})/D_{post}$$

All that has been done is to calculate the percent of total donor fluorescence that had been quenched in the presence of the acceptor. It is important to confirm that in an area of the image that was NOT subject to photobleaching, the donor intensity does not change significantly between the pre- and post-bleach images. If it does, it means that the sample may have moved or changed focus between the two images, or that perhaps the acceptor was partially bleached unintentionally between capturing the two donor images. If conditions have been optimized as outlined above, this should not happen (except for occasional sample movement or change in focus).

An increase in donor intensity selectively in the region of acceptor photobleaching is indicative of FRET (with numerous caveats outlined in the next section). Instead of doing the manual calculation on the entire bleached region as a whole, one can calculate FRET for subregions of the sample to gain insight into the spatial distribution of FRET (which could for example reflect differences in protein-protein interaction in different regions of the cell). Although this can be done manually, it is cumbersome. The macro the authors developed for NIH image does this automatically on individual 8×8–pixel regions throughout the image and displays the results in a color-coded map of FRET. This can be extremely useful for visualizing spatial differences in FRET measurements in different areas of the cell. The macro may be obtained by sending an e-mail request to *esnapp@aecom.yu.edu*.

INTERPRETATION OF RESULTS

Of equal importance to the actual collection of FRET data is a rational interpretation of the results (also see *UNIT 17.1*). This is critical to ensure that any observed FRET is actually due to the proximities of the proteins of interest. Sometimes it is easy to forget that the FRET values are indirect measurements based on a series of assumptions (such as specificity of the antibodies) that may or may not have been thoroughly validated. Furthermore, other potential artifacts must be taken into account and excluded to maximize the likelihood of correct interpretation. Some of these issues are listed below.

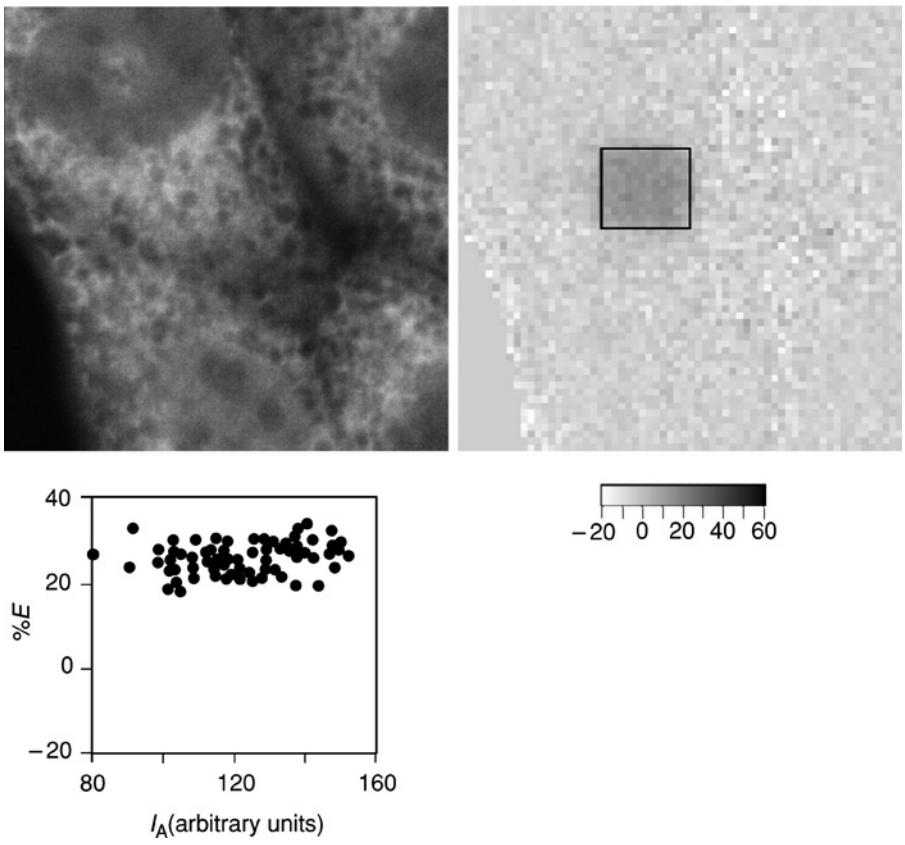

Figure 17.9.2 Control for acceptor density dependence. The top left panel is an image of the acceptor-labeled cell prior to photobleaching. The top right panel shows an energy transfer efficiency map with the extent of energy transfer revealed by acceptor photobleaching in the box. The scale indicated below the map is the energy transfer efficiency (%*E*). The plot in the lower left panel displays %*E* as a function of acceptor-fluorophore intensity (I_A). Note that similar FRET values (%*E*) are observed over a broad range of acceptor intensities, demonstrating that FRET is not acceptor density dependent for this experiment.

Restrict Quantitative Comparisons to Experiments Performed at the Same Time

Experimental FRET values can be affected by batch-to-batch differences including variations in cell density, cell cycle, alignment of the photobleaching laser (which will affect completeness of the photobleach), and antibody degradation. While the overall trends and relationships in the data should be robustly repeatable, the absolute values in the data will tend to vary by as much as 20% between experiments. This observation also emphasizes the importance of including a positive control with every experiment to assist in detecting batch-to-batch variability.

Be Aware of Artifactual Reasons for Changes in Donor Fluorescence

It was recently reported that upon photobleaching, the Cy5 fluorophore is photoconverted into a fluorescein-like fluorophore that has the potential to confound FRET analyses using the acceptor-photobleaching method (Nichols, 2003; Snapp et al. 2004). This is because the photoconverted Cy5 has a fluorescence spectrum that overlaps with the Cy3 spectrum and therefore interferes with its quantitative measurement. This is particularly relevant if the Cy3 fluorescence is extremely dim relative to Cy5 and/or if the Cy3 excitation light intensity or Cy3 detector gains are set at very high levels. Because of the potential to substantially influence the apparent FRET that is observed, it is important and worthwhile to carefully consider this phenomenon in interpreting the results.

The artifactual FRET signal due to photoconversion shows a direct dependence on Cy5 intensity (e.g., Nichols, 2003; Snapp et al. 2004). A useful control is to measure the effect of decreasing the donor concentration (with constant acceptor concentration) on FRET efficiency. All other things being equal, FRET

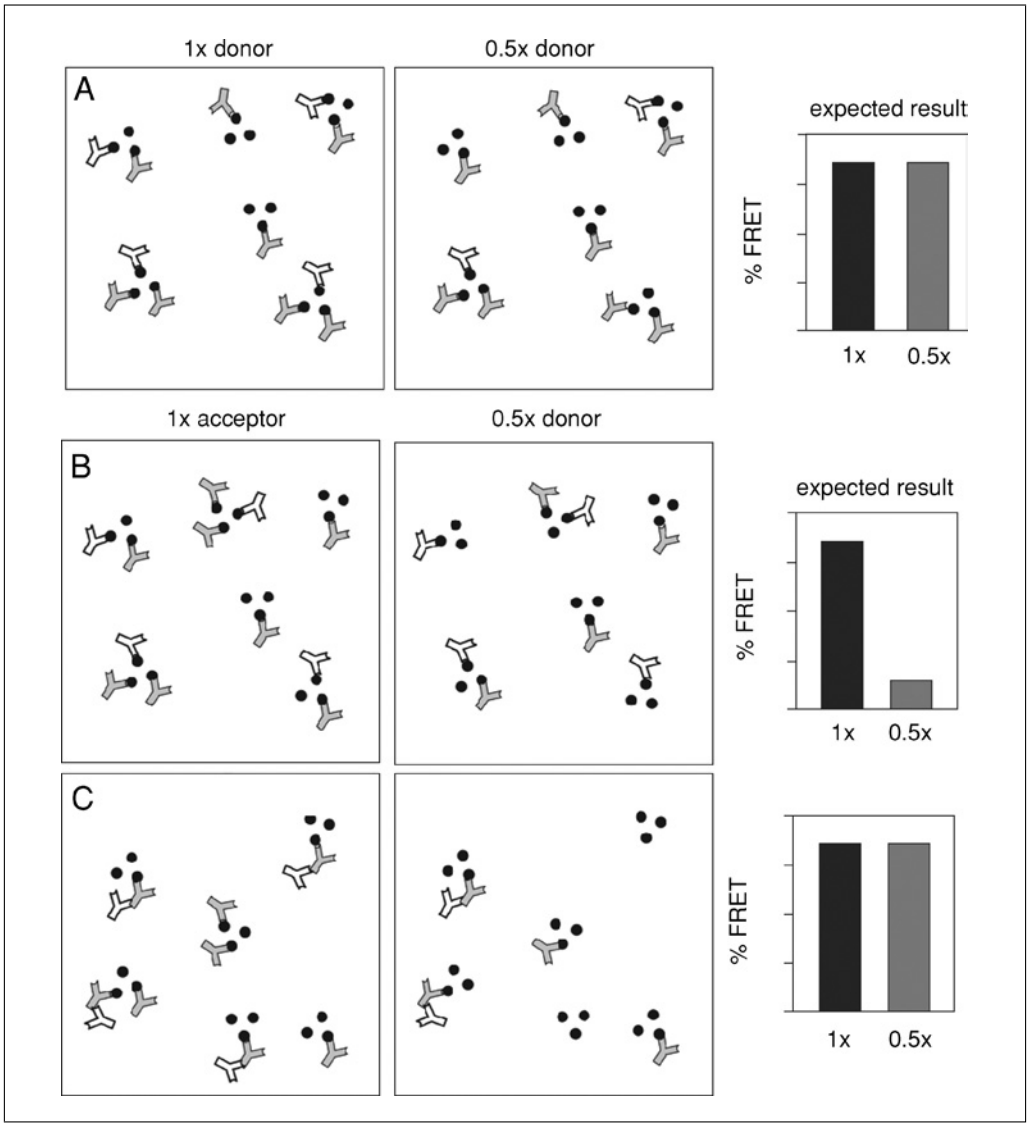

Figure 17.9.3 Relationship of donor and acceptor concentrations to FRET. (**A**) Schematic diagram illustrating the effect of donor concentration on FRET. Oligomers of antigens (black dots) are shown randomly labeled with donor (white) and acceptor (gray) antibodies. The right diagram indicates one half the amount of donor antibody than that in the left panel. Although the donor fluorescence is expected to be lower for the right panel, the proximity of each donor to acceptor antibodies predicts that FRET efficiency should stay the same. The situation is very different for acceptor antibody concentration. (**B** and **C**) Antibody distributions are illustrated for donor (white) and acceptor (gray) antibodies on a hypothetical clustered three-antigen oligomer (black dots). Panel (B) shows the situation where the donor and acceptor antibodies bind their antigens, but do not interact with each other. Panel (C) shows the situation where the acceptor binds its antigen, but the donor antibody interacts with the acceptor antibody. In both cases, the right panel shows the consequence of reducing the acceptor concentration by one half, and the predicted effect on FRET.

efficiency should be independent of donor intensity. If photoconversion is contributing significantly to the Cy3 fluorescence measurements, halving the donor concentration will substantially increase the apparent FRET signal. This is because the photoconverted product continues to contribute the same amount of fluorescence to the Cy3 measurements; however, the starting donor intensity is decreased. Thus, the photoconverted product will cause the Cy3 measurements to increase by a much higher percent upon Cy5 photobleaching, resulting in erroneously high FRET values. By contrast, genuine FRET without interference from photoconversion should be largely independent of donor intensity and occupancy. Indeed, a useful analysis of one's FRET data is to plot *%E* vs. absolute donor intensity. The

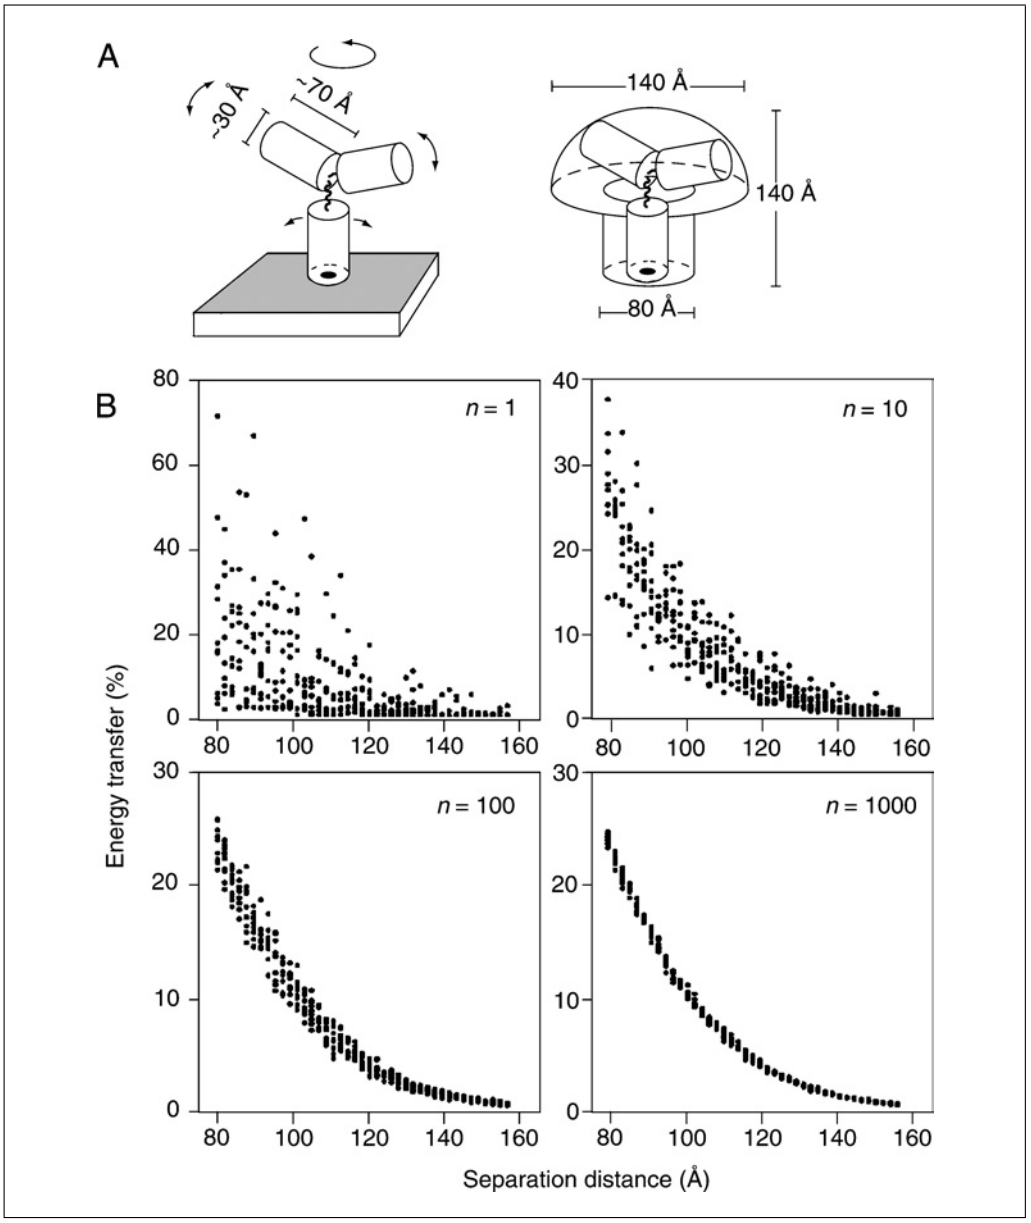

Figure 17.9.4 Sampling size and the resolving power of antibody-mediated FRET. (**A**) Diagram of a model IgG molecule bound to an antigen on the membrane surface (left). The Fc and each Fab domain are modeled as a cylinder of diameter 30 Å, height 70 Å, connected by flexible hinges. Arrows indicate directions of allowed rotational flexibility. The range of potential positions that can be occupied by dyes conjugated to the antibody surface is indicated on the right. Dyes are allowed to be on the surface of the stalk of the mushroom-shaped space, and anywhere in the volume of the head. (**B**) A simulated donor and acceptor labeled antibody (4 dyes/IgG, randomly distributed as described in panel (A) were bound to antigens separated by distances of between 80 and 160 Å, and the % energy transfer between the dyes calculated and plotted. Each datum represents the average of between 1 and 1000 such simulations as indicated (*n*) on each graph. Custom macros (available upon request from the authors) were written for NIH Image 1.62 to perform the antibody-mediated FRET simulations. In essence, an algorithm was designed to simulate the stochastic binding of a mixture of donor- and acceptor-labeled antibodies to a set of antigens on a membrane surface, followed by a calculation of the FRET between the randomly distributed dyes on all of the bound antibodies. The algorithm encompassed the following steps:

continued

relationship should be horizontal line. If FRET efficiency increases as the donor intensity decreases, then the investigator should suspect photoconversion of the acceptor fluorophore to a donor-like spectral emission.

One approach to this problem is to correct for photoconversion by using a standard curve in which defined intensities of the acceptor are correlated with the respective amounts of photoconverted product upon photobleaching (Nichols, 2003). However, data correction is often not necessary in cases where photoconversion contributes less than ~5% of the value of observed FRET signals. This phenomenon can be monitored by plotting $\%E$ as a function of acceptor intensity for different regions of an image (Fig. 17.9.2). Additionally, a substantial contribution from photoconversion can be ruled out if it is demonstrated that the FRET signal is lost solely by changing the choice of donor antibody to one that recognizes an unrelated antigen. An alternative solution to the photoconversion problem is to use different donor/acceptor pairs. This can be difficult if one has already invested substantial time and effort in one FRET pair, but may be feasible early in the experimental design or project.

Ensure That the Antibodies Do Not Interact Directly with Each Other

It is assumed that antibodies do not directly interact with each other to generate FRET, but instead simply mark the positions of the antigens against which they are directed. Thus, a FRET signal between antibodies is taken to reflect the proximities of the antigens to which the antibodies are bound, and not to nonspecific interactions among the antibodies themselves. It is therefore critical to the interpretation of the results that the antibodies not interact with each other. FRET between directly interacting antibodies is largely insensitive to changes in concentration of the acceptor antibody (Fig. 17.9.3A). This is because the only donor labeling that occurs is via binding to an acceptor. Thus, although reduced labeling occurs due to the reduced acceptor concentration, all donors are still adjacent to an acceptor and therefore generate a high FRET signal (see Fig. 17.9.3A).

In marked contrast, FRET between the antibodies as a consequence of the fact that their antigens are in close proximity is highly sensitive to acceptor concentration (Fig. 17.9.3B). Here, the donor antibodies still bind to their antigens, but some of the acceptor antigens will now be unoccupied by acceptor antibodies (Fig. 17.9.3C). The presence of donor antibodies unaccompanied by nearby acceptors reduces the FRET signal and helps rule out inappropriate interactions between antibodies.

For an additional control, measure FRET between the donor and acceptor antibodies with and without a peptide competitor corresponding to the antigen for the acceptor antibody. Inclusion of the peptide during the antibody incubation should result in both decreased labeling of cells by the acceptor antibody (but not the donor antibody), and a loss of the FRET signal. Taken together, these controls help confirm that FRET between dye-labeled antibodies is due to the proximities of the antigens to which the antibodies bind, and not due to interactions between the antibodies themselves.

Figure 17.9.4 *(at left)* (1) The *x-y* positions of the appropriate number of antigens were distributed on a hypothetical surface of defined area (usually 0.5×0.5 μm) at the indicated density and configuration (either randomly distributed, or in clusters of three). Clusters were not allowed to overlap, and the minimal distance separating adjacent antigens was limited to 8 nm, as determined by the steric hindrance of bound IgG molecules. (2) Each antigen was randomly assigned to either be unoccupied, bound by a donor antibody, or bound by an acceptor antibody. The relative probabilities of each assignment were determined by the desired occupancy and donor/acceptor ratio. (3) The *x-y-z* positions of dyes were randomly chosen relative to each antigen by the criteria outlined in the text. (4) Once the *x-y-z* positions for all of the donor and acceptor dyes were set, the summed FRET efficiency that would be expected for this distribution of dyes was calculated according to previously established equations (Förster, 1948; Dewey and Hammes, 1980).

Optimize Sample Size

Part of the power of FRET methods is the ability to quantitate small changes in protein proximities. However, achieving this quantitation requires sufficient statistical sampling. The amount of sampling dramatically increases as the investigator attempts to monitor single nanometer changes. At a minimum, perform multiple, at least $n \geq 10$, measurements to permit statistical analysis to identify significant changes in FRET efficiency values.

Expression levels of the proteins of interest will affect both the cell and the sensitivity of the planned measurements. Proteins, such as kinases or transcription factors, tend to be expressed at nanomolar concentrations (Huang and Ferrell., 1996). This translates to a few hundred copies of a protein or less per cell, in some cases. Consider that a homogeneously distributed fluorescent protein must be present at 200 nM to be visualized over background cellular fluorescence (Niswender et al., 1995). Thus, experimental questions involving cellular expression of a fluorescently tagged protein may require unnaturally high expression levels of a protein that may affect a cell phenotype. In contrast, dye-labeled antibodies rarely require overexpression of a protein of interest and also avoid problems related to whether a fluorescent fusion protein is functional (*UNIT 21.4*). Measurement sensitivity will be dependent on the available number of proteins to be assayed in a region of interest. Too few proteins will result in a low signal-to-noise ratio and low sampling sizes.

For purposes of experimental design, measuring absolute states of associated and nonassociated proteins should be readily discernable even for low protein sampling sizes. This is illustrated in Figure 17.9.4. The first graph of Figure 17.9.4B ($n = 1$) shows a scatter plot of the range of FRET values obtained for any single antibody pair separated by various distances. At a separation distance of 80 Å, the FRET efficiencies ranged broadly from less than 5% to nearly 80% (Fig. 17.9.4B; $n = 1$). This tremendous variability reflects the stochastic distributions of the donor and acceptor dyes over a large volume, combined with the extreme sensitivity of FRET to small changes in the distances separating them. Indeed, it has been shown previously that if the number of sampled molecules is small, such dramatic fluctuations can be anticipated (Haas and Steinberg, 1984).

Although a trend is observed in which increased separation distance between the antibodies results in lower FRET, a single interaction cannot be used to discriminate different antigen positions (except to say that antigens are either within ~15 nm of each other, or further away). However, the resolving power increases substantially as more antibody pair interactions are sampled and averaged (Fig. 17.9.4B; $n = 10$ through $n = 1000$). At a sampling size of 1000, differences in separation distance of between 0.2 and 0.4 nm can be resolved with confidence. Thus, subnanometer changes in antigen separation can be resolved using FRET between dye-conjugated antibodies despite the highly flexible and large nature of the probes, the stochastic distribution of the dyes bound to them, and the complex relationships for FRET between ensembles of donor and acceptor fluorophores.

Create a Model for the FRET Experiment

If sufficient information about the proteins of interest is available, it is worthwhile to model and simulate FRET experiments to assist with experimental design and expectations for results. Simulated results serve to illustrate the capabilities, sensitivity, and specificity of an approach and provide boundaries for the type of questions that can be addressed. In particular, two issues are of direct relevance to most studies of protein complex assembly: the discrimination of assembled from disassembled multiprotein (or oligomeric) complexes and the discrimination of small changes in the structure of a complex that remains assembled in the same general configuration.

Monte Carlo simulations, rather than theoretical calculations using simplifying assumptions, can provide insight into not only the expected FRET efficiency, but also the degree of variability that can be anticipated from measurement to measurement due to the stochastic nature of many of the variables involved (e.g., see Haas and Steinberg, 1984). For example, FRET between subunits of a membrane protein complex containing three subunits was modeled (Fig. 17.9.5A). Donor and acceptor antibodies labeled with four dyes at random positions were simulated in binding to the proteins with varying ratios. A visual representation of the relative proximities of subunit proteins and fluorescent dyes in the disassembled and assembled states for a small section of membrane is shown in Figure 17.9.5B as a two-dimensional illustration. Then the expected FRET efficiency for each ensemble of fluorophores was calculated according to previously established equations (Dewey and Hammes, 1980).

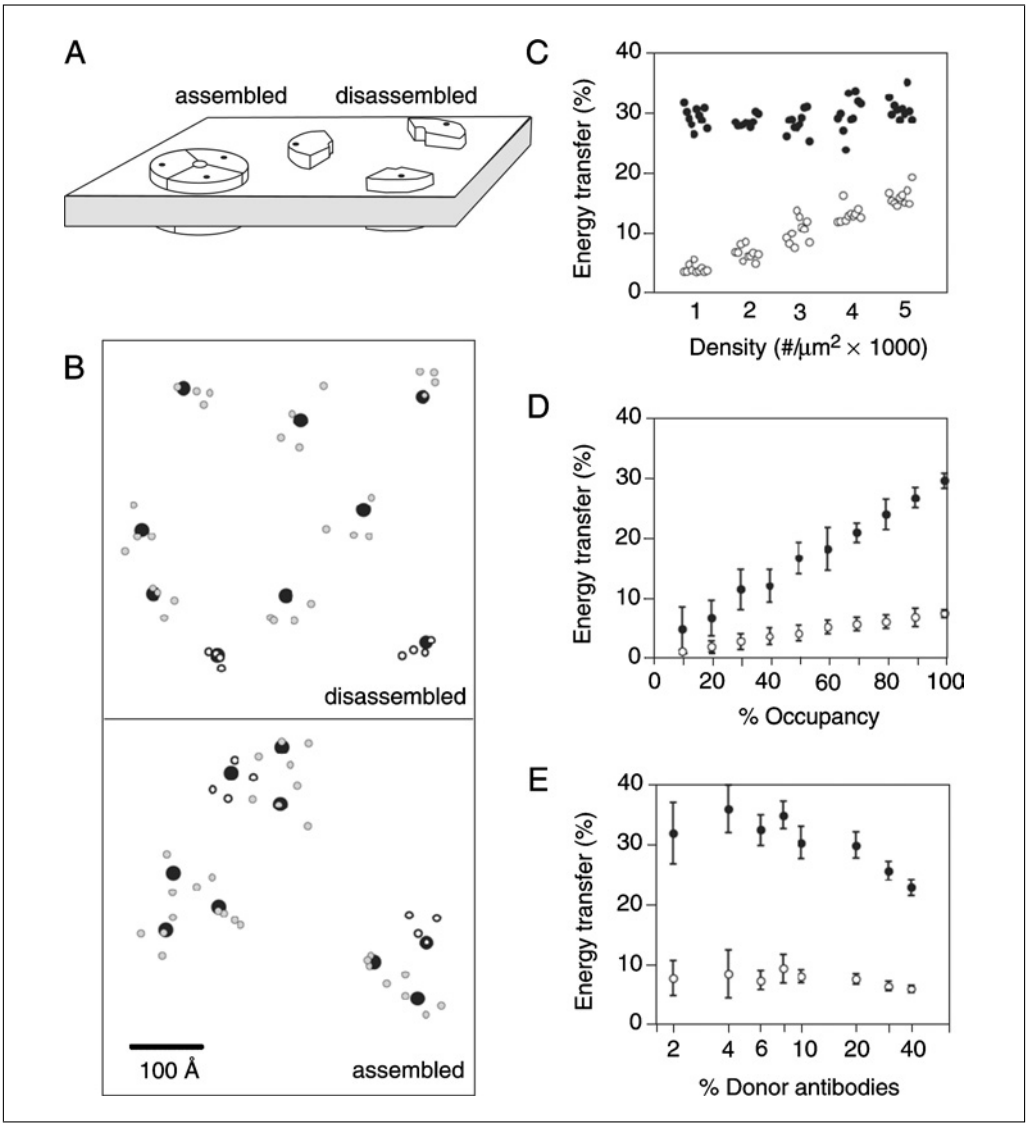

Figure 17.9.5 Simulations of FRET for assembled versus unassembled oligomers. (**A**) Idealized configurations of an oligomeric channel in the membrane in an assembled and disassembled configuration. The positions of a putative antigen present as three copies in the channel are indicated with a black dot. (**B**) Surface view of a 70 × 70–nm section of membrane containing antigens (black dots) at 2000 copies per mm^2 in assembled and disassembled configurations as in (A). The two dimensional projection of the positions of donor (clear outlined) and acceptor (gray) dyes on antibodies bound to these antigens is also indicated. An antibody was assigned a 20% probability of containing donor dyes. (**C**) Monte Carlo simulations were used to calculate the FRET efficiencies in a 0.25 μm^2 section of membrane containing donor and acceptor labeled antibodies (at a donor/acceptor ratio of 1:4, each containing 4 dye molecules per IgG) bound to antigens (with 100% occupancy) at densities of 1000 to 5000 copies per μm^2. The antigens were distributed in the membrane surface either randomly (open circles) or assembled into clusters of three (closed circles). The simulation was repeated ten times for each condition, with each point representing the FRET from a single simulation. Note that FRET in the nonclustered configuration displays a clear density-dependence that is not seen in the clustered configuration. (**D**) Monte Carlo simulations of FRET as a function of the degree of occupancy of the antigen by antibody. Randomly distributed antigens (open circles) were compared to clustered antigens (closed circles). Note that %*E* is always higher for the clustered situation regardless of % occupancy. (**E**) Simulation of FRET as a function of the proportion of antibodies that carry donor dyes. Note that the best discrimination between random (open circles) and clustered (closed circles) antigens is seen at donor antibody values below 20%. In (D) and (E), the mean ± SD of ten simulations is plotted for each condition. When not being specifically varied, antibodies contained four dyes each, 20% of antibodies were donors, antigen occupancy was 100%, and antigen density was 2000 copies per μm^2.

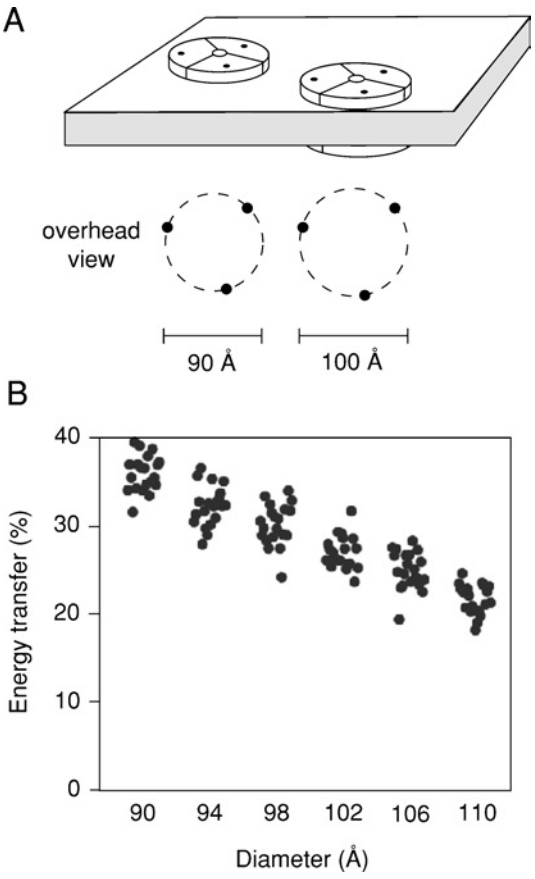

Figure 17.9.6 Simulations of FRET for multiprotein complexes undergoing a conformational change. (**A**) Scale diagram of a complex of 90- versus 100-Å diameter. The modeled complex is of three antigens around a circle of the indicated diameter. (**B**) Clusters of three antigens in circles of diameters ranging from 9 to 11-nm were randomly distributed in 0.25 μm^2 areas, and the FRET between the bound antibodies calculated by Monte Carlo simulations as in Figure 17.9.5. Each set of 20 measurements was statistically significant from an adjacent set. These findings illustrate that with sufficient sampling even modest changes (in the subnanometer range) to the configuration of a complex can be detected using FRET.

The putative assembled versus disassembled states of a protein complex represent the extremes of configurations, thereby making them easily distinguishable by antibody-mediated FRET. Because the active versus inactive configurations of the complex may instead represent a more subtle change in arrangement of its components, the authors used the simulations to ask whether such small changes could also be distinguished. As seen in Figure 17.9.4, even such small changes can be distinguished given sufficient sampling. Under these conditions, twenty areas of 0.25 μm^2, each containing assemblies at a density of ~667 per μm^2 (Fig. 17.9.6), was sufficient to distinguish a 0.4-nm difference. This modest sampling size (e.g., a total of ~5 μm^2) represents the lower limit for distinguishing such small changes using idealized conditions. Thus, *changes* to a multiprotein structure, whether it is simple or complex, are likely to be detectable with antibody-mediated FRET. While different geometries of a protein complex can produce different absolute FRET values compared to an idealized complex, changes within the confines of a different structure are still detectable with antibody-mediated FRET (Snapp et al., 2004). These simulations were in fact very useful in concluding that antibody-mediated FRET is a feasible method to monitor both gross and subtle changes in complex structure in cells.

The details of the simulation model system benefit from data on the size, structure, and abundance of the complex to be studied. Parameters to test include: simulated FRET between fluorophores with varying parameters such density of antigens (Fig. 17.9.5C), percent occupancy of antigens by antibodies

(Fig. 17.9.5D), relative ratios of donor to acceptor antibodies (Fig. 17.9.5E), proximities of protein subunits, and configuration of antigens (e.g., randomly distributed versus assembled into clusters of defined size). It is beyond the scope of this unit to provide a detailed guide for model design and simulation. For more background on designing molecular simulations, the investigator is referred to Frenkel and Smit (2001). Examples of simulation design are described in the supplemental data sections for Snapp et al. (2004) and Sharma et al. (2004) and the appendix in Kenworthy and Edidin (1998).

RECIPROCAL FRET

When a protein complex contains more than two different proteins, determining the relative stoichiometries of the protein subunits can be valuable. The choice of acceptor and donor will significantly affect the FRET values if one protein is present at lower levels of expression (Fig. 17.9.7). The inherently asymmetric relationship between donor and acceptor molecules during acceptor-photobleaching FRET measurements makes it possible to assess whether protein subunits are present at comparable stoichiometries. While acceptors adjacent to a donor are essential for FRET to occur, the presence or absence of *additional* acceptor molecules that are unaccompanied by an adjacent donor does not change the overall FRET efficiency. In contrast, the presence of donor molecules that are unaccompanied by an adjacent acceptor causes an overall reduction of FRET efficiency. This is because the excess donors increase the overall donor fluorescence intensity without changing the absolute amount of energy that is transferred to the acceptor, thereby resulting in a net decrease in the *percent* of total energy transferred. That is, excess acceptors are effectively invisible and do not affect FRET values, while excess donors decrease FRET values.

A schematic illustration of this principle is shown in Figure 17.9.7. In panel 17.9.4A, all copies of two interacting components (represented by squares and circles) are paired with each other, with neither containing excess copies. The FRET efficiency in this scenario should be equivalent regardless of which component serves as the donor or acceptor. In

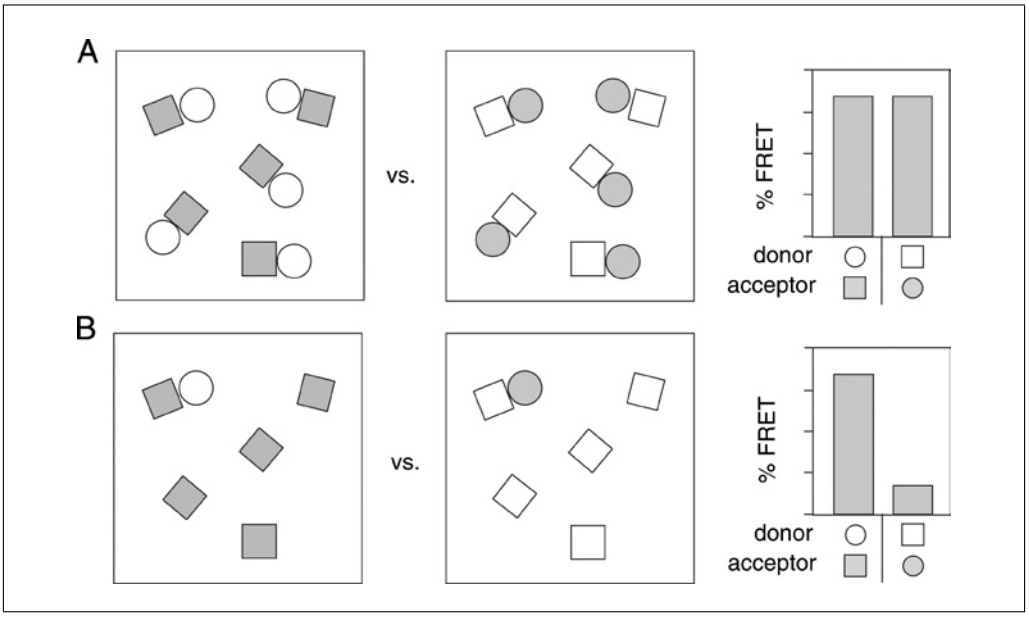

Figure 17.9.7 FRET-based analysis of multiprotein complex component interactions and stoichiometry. (**A** and **B**) Cartoon of reciprocal FRET measurements between a hypothetical interacting pair of molecules (squares and circles) at different stoichiometries. The two fields in each panel represent situations in which each shape is labeled as donor (open) or acceptor (gray). The histograms to the right represent relative FRET efficiencies for each situation. Equal numbers of paired squares and circles (A) yields equivalent FRET values regardless of which protein is the donor or acceptor. In contrast, a substoichiometric number of circles, with excess unpaired squares, results in a discordance in FRET between the reciprocal measurements (B). These findings illustrate that by changing the labeling scheme systematically it is theoretically possible to gain insight into the relative stoichiometry between two interacting proteins.

Figure 17.9.7B, however, one of two interacting components is present in excess (i.e., the squares). In this case, the FRET efficiency will be substantially lower if the squares serve as the donor than if the circles serve as the donor. Thus, a greater than 2-fold discordance in the FRET efficiencies upon switching the donor and acceptor molecules can be used to infer that at least some copies of one of the components exists in the absence of the other component. Reciprocal FRET will not necessarily reveal the precise stoichiometry, as the FRET relationships are not inherently linear. Nonetheless, the method should enable the investigator to distinguish between proteins present as single or multiple copies in a complex, and whether this changes in response to some treatment or manipulation. In general, it is not appropriate to perform reciprocal FRET when one of the proteins is labeled with a fluorescent fusion protein. Expressing a fluorescent fusion protein may significantly increase the levels of the protein of interest and result in protein that isn't incorporated into complexes or overexpression-related changes in cell behavior (*UNIT 21.4*).

To perform reciprocal FRET, use the optimized acceptor-photobleaching protocol established in the acceptor-photobleaching FRET strategy with the following modifications:

1. When using antibodies to label donor and acceptor proteins, the experimental protocol is reversed, though the labeling protocol for the antibodies needs to be optimized. Determine labeling conditions (see Empirically Determine Antibody Labeling Conditions). Specifically, identify appropriate antibody labeling ratios for each antibody, maintain a ratio of ~1:4 to 1:8 donor/acceptor antibodies, and optimize amounts of antibodies to achieve maximal labeling intensity without causing nonspecific labeling or a decrease in FRET due to excess donor. In addition, confirm that order of addition of antibodies does not affect labeling efficiency and that FRET values are independent of donor intensities.

2. Using a fluorescent microscope, perform acceptor-photobleaching FRET for each combination of donor and acceptor, and then switch the labeling of each protein to make the initial donor now the acceptor and the initial acceptor now the donor. If one protein is present at significantly lower concentration than the other or if one protein is always bound to a partner while the other protein is only sometimes bound, a significant difference in FRET under the two conditions will be observed. Because the absolute FRET efficiencies can vary somewhat depending on the number of dyes per antibody and labeling conditions, it is suggested that only discordance differences more than 2-fold be considered meaningful.

AUTOMATED IMAGE ANALYSIS

To process multiple data sets, automation of FRET analysis can be readily performed and one such scheme and macro are described. The authors have created an acceptor-photobleaching FRET analysis macro for NIH Image 1.62 (freely available from the authors by sending an e-mail request to *esnapp@aecom.yu.edu*). The macro quantitates FRET within the photobleached area and generates an energy transfer map. Briefly, the macro performs the following operations in sequence: (1) The pre-bleach and post-bleach images are registered to optimal alignment. (2) The area of photobleaching is identified. (3) The percent change in donor intensity (after background subtraction) is calculated in each 8 × 8–pixel region (0.56 × 0.56 μm) of the image and drawn as a pseudocolored map. (4) The average change within the entire photobleached and non-bleached regions is calculated. The user is free to either write her own or modify the authors' macro as necessary for specific applications. To use the macro, the user must perform the following steps:

1. Name image files as 101000.tif, 101001.tif, 102000.tif, 102001.tif. for consecutive files. Note that the nomenclature is as follows: the first digit is the sample number (or the chamber number to indicate which chamber of an 8-well chambered coverslip is being used); the next two digits are the trial number within this sample; and the last three digits are necessarily "000" to indicate a pre-bleach image and "001" to indicate a post-bleach image. Each image must be an 8-bit 512 × 512–pixel RGB file in which the red channel contains the acceptor image and the green channel contains the donor image. The photobleached region must be a 75 × 75–pixel region; the portion of the image that contains the bleach box does not matter (the macro automatically finds this).

2. Place all images in a single folder. Within that folder, the user must create a new folder entitled "processed images."

3. Load the macro into NIH image and run. Before the macro starts, the user is asked a series of questions as follows. The user will

be asked how many chambers. This is usually between 1 and 8. The user is then asked how many experiments are in a chamber (e.g., how many trials for each sample). Enter the number of experiments from 1 to 99. The user is next asked for a threshold (background value). The default is 10, but the user can decrease or increase this value as necessary based on the imaging conditions used. The user is asked the size of the sampling square. The default value is 8. This means that the FRET calculations are performed on each 8 × 8–pixel square within the image and the average FRET value within this area is plotted in the map. The averaging helps reduce image noise. It also affects the speed of the program. A smaller sampling square will slow the analysis because more pixels must be individually calculated.

4. When the user is asked to open the first image of the set, select OK. Then NIH image will open a browsing window to find the folder containing the images. Open this folder, select the first image, and select Open. This points the program to the place where the data set of interest is stored. The program will now run until all of the images in this folder have been processed.

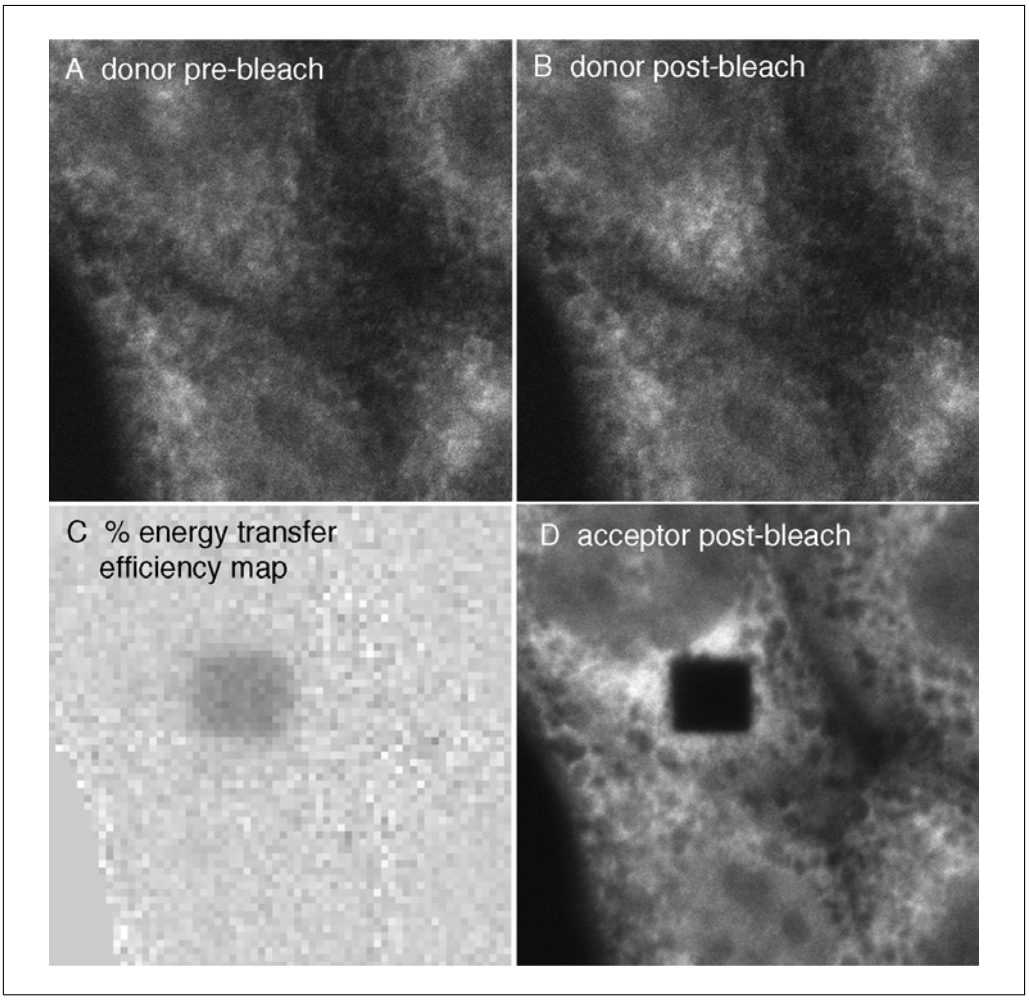

Figure 17.9.8 Output from the macro developed by the authors to assist in data interpretation (see Automated Image Analysis section). In this experiment, two proteins known to interact were labeled with Cy3-labeled donor and Cy5-labeled acceptor antibodies. Shown are the images from a typical FRET measurement. (**A**) Image of the donor fluorescence prior to photobleaching of the acceptor. (**B**) Image of the donor fluorescence immediately after photobleaching of the acceptor fluorescence in a small square near the center of the image (see panel D). Note that the donor fluorescence has selectively increased in intensity in this region. (**C**) Quantitation of the change in donor fluorescence between pre-bleach and post-bleach images (i.e., the %*E* map). The darker gray region near the center of the image indicates an area of significantly increased donor fluorescence relative to the remainder of the image, and reflects a positive FRET signal. (**D**) Image of the acceptor fluorescence after photobleaching a square region near the center of the image.

Table 17.9.1 Troubleshooting Guide for Acceptor-photobleaching FRET

Problem	Possible cause	Solution
FRET efficiency low, even for positive control	Acceptor fluorophore photobleached before performing FRET measurement	Do not image labeled cells with a fluorescent lamp, which will cause significant photobleaching; instead use low intensity laser power, using the donor fluorescence to find cells and focus them. Keep imaging time to a minimum before making the FRET measurement. Any loss of acceptor fluorescence will reduce the difference between the quenched and unquenched donor fluorophore.
	Acceptor fluorophore incompletely photobleached	Be sure to identify photobleaching conditions to reduce fluorescence of the acceptor to background levels; otherwise, the donor will not be completely dequenched.
High and low FRET observed along edges of fluorescent structures	Pre- and post-bleach images not registered, causing a slight shift of positions of areas with low fluorescence in a pre-bleach image to areas with significant fluorescence and resulting in an apparent increase in the donor channel	Align pre- and post-bleach images in an image manipulation program (e.g., Photoshop, ImageJ or NIH Image; then perform FRET analysis with the modified images. Note that the authors' macro includes a registration step.
FRET detected when using fluorescent fusion proteins as negative controls (if the proteins used authentically do not interact)	Fused fluorescent proteins dimerizing (may occur at high concentrations; see Zacharias et al., 2002 and Snapp et al., 2003)	Be sure to make fluorescent fusion proteins with fluorescent proteins that contain monomerizing mutations.
FRET observed between negative control proteins in a fluorescence intensity-dependent manner	FRET due to density-dependent clustering of proteins most likely caused by (1) nonspecificity of an antibody or (2) labeled proteins present at such high concentrations that their proximities are sufficiently close for FRET to occur	Confirm specificity by preincubating antibody with peptide that antibody was raised against; restrict analysis to regions of cells in which FRET occurs in an intensity independent manner (problem may be unavoidable in cases where the protein is concentrated within an organelle); use smaller fluorescent probes instead of antibodies; or consider other FRET methods including FLIM and fluorescence anisotropy (see supplementary data and appendix in Kenworthy and Edidin, 1998 and Sharma et al., 2004).

At the end of the program, the processed data file will include data images and a quantitation text file. The data images will contain the pre- and post-bleach donor images, an energy map, and the post-bleach acceptor image, in that order (Fig. 17.9.8).

The quantitation file can be opened in a spreadsheet such as Microsoft Excel. The first column is the chamber number, the second column is the experiment number, the third column is the background subtracted post-bleach intensity of the donor, and the fourth column is the background-subtracted pre-bleach donor intensity for the bleach region of interest. The final column is the calculated percent energy transfer.

CONCLUSION

The strategies described in this unit and *UNIT 17.1* should permit the investigator to design, carry out, and interpret an acceptor-photobleaching FRET experiment to study

protein interactions in cells. The investigator can use the same methodology to gain insight into comparative stoichiometry of proteins in a complex. Finally, the modeling methods described allow the investigator to simulate potential results to optimize the experimental setup and interpretation. Table 17.9.1 discusses methods to troubleshoot acceptor-photobleaching FRET.

Identification and Analysis of Multiprotein Complexes Through Chemical Crosslinking

Completion of many genome projects in conjunction with the development of proteomic tools has enabled the large-scale isolation of multiprotein complexes and the identification of their subunit composition (see *UNIT 17.5*). In contrast, relatively little information exists about the structural organization of these complexes, i.e., the stable interaction of subunits with each other as well as their transient interactions with cellular proteins. Techniques such as GST pull-downs, co-immunoprecipitations, or two-hybrid screens can give information about an interaction of two polypeptides outside of their physiological multiprotein context, i.e., in purified form in the absence of the other subunits of the multiprotein complex. They can also provide information about interactions involving intact multiprotein complexes without information on which of the polypeptides within the multiprotein complexes directly interact. The main advantage of crosslinking studies is that they can be performed in the context of intact protein complexes. This is important because subunits of multiprotein complexes often interact synergistically with several polypeptides simultaneously, and subunit interactions often lose specificity outside of their native contexts (Melcher, 2004).

Chemical crosslinking is the covalent linkage of molecules in very close proximity to each other. In the case of proteins, this linkage can be achieved by incubation with small molecules (crosslinkers) that (1) efficiently and constitutively react with free amino, carboxy, or sulfhydryl groups on amino acid side chains, (2) upon light induction form short-lived intermediates that insert relatively nonspecifically into proteins, or (3) upon oxidation generate highly reactive radicals within aromatic side chains. Most crosslinkers have two terminal reactive groups separated by spacers that allow attack and covalent linkage of two amino acid side chains in close proximity within the same polypeptide (intramolecular crosslinking) or between interacting proteins (intermolecular crosslinking). Versatility of crosslinking applications is often further extended by introducing labeled groups or affinity handles into crosslinkers or by localizing crosslinkers to a bait protein. The bait protein is protein from the multiprotein complex under investigation that has been modified with a covalently linked crosslinker. It is used to probe other proteins (targets) in the multiprotein complex for a possible interaction (see Bait-localized crosslinkers in the Strategic Planning section). Most of these studies are performed in vitro although some crosslinkers can be employed in vivo (see Crosslinking Chemistries in the Strategic Planning section).

Assessments of protein interaction data in which structures of the protein complexes are known have revealed that crosslinking studies are less prone to artifacts than two-hybrid screens (which typically use highly overexpressed bait and prey proteins; see *UNIT 17.3*), or pull-down experiments (*UNIT 17.5*) with recombinant or in vitro translated proteins (Edwards et al., 2002). However, crosslinking methods also have a propensity for false negatives (failure to identify specific interactions) and false positives (interactions that do not occur in native complexes in vivo). This unit compares different crosslinking approaches and discusses strategies for maximizing the number of trapped physiological interactions and minimizing the occurrence of false positive and false negative interactions. This general section is followed by two protocols with examples of crosslinking methods that the authors consider particularly useful for the analysis of large multiprotein complexes (see Basic Protocols 1 and 2).

STRATEGIC PLANNING

Chemical crosslinking does not represent a single distinct technique but rather a smorgasbord of techniques that greatly differ in both chemistry and scope. This section guides the reader through the complexities of crosslinking to find the most suitable approach for a given biological question. This general section will be complemented with sample protocols for two localized, inducible, crosslinking methods that the authors consider to be particularly useful for the analysis of large multiprotein complexes.

Crosslinking Chemistries

Amine-reactive crosslinkers

Lysine residues are the amino acids that are most frequently targeted by chemical crosslinking. They are present in large numbers on the surfaces of most proteins, and the ε-NH_2 side groups of lysine residues react efficiently under physiological conditions with various crosslinking reagents to yield amide or amine bonds. Typical lysine-reactive crosslinkers are N-hydroxysuccinimide (NHS)-esters and imidoesters (Fig. 17.10.1).

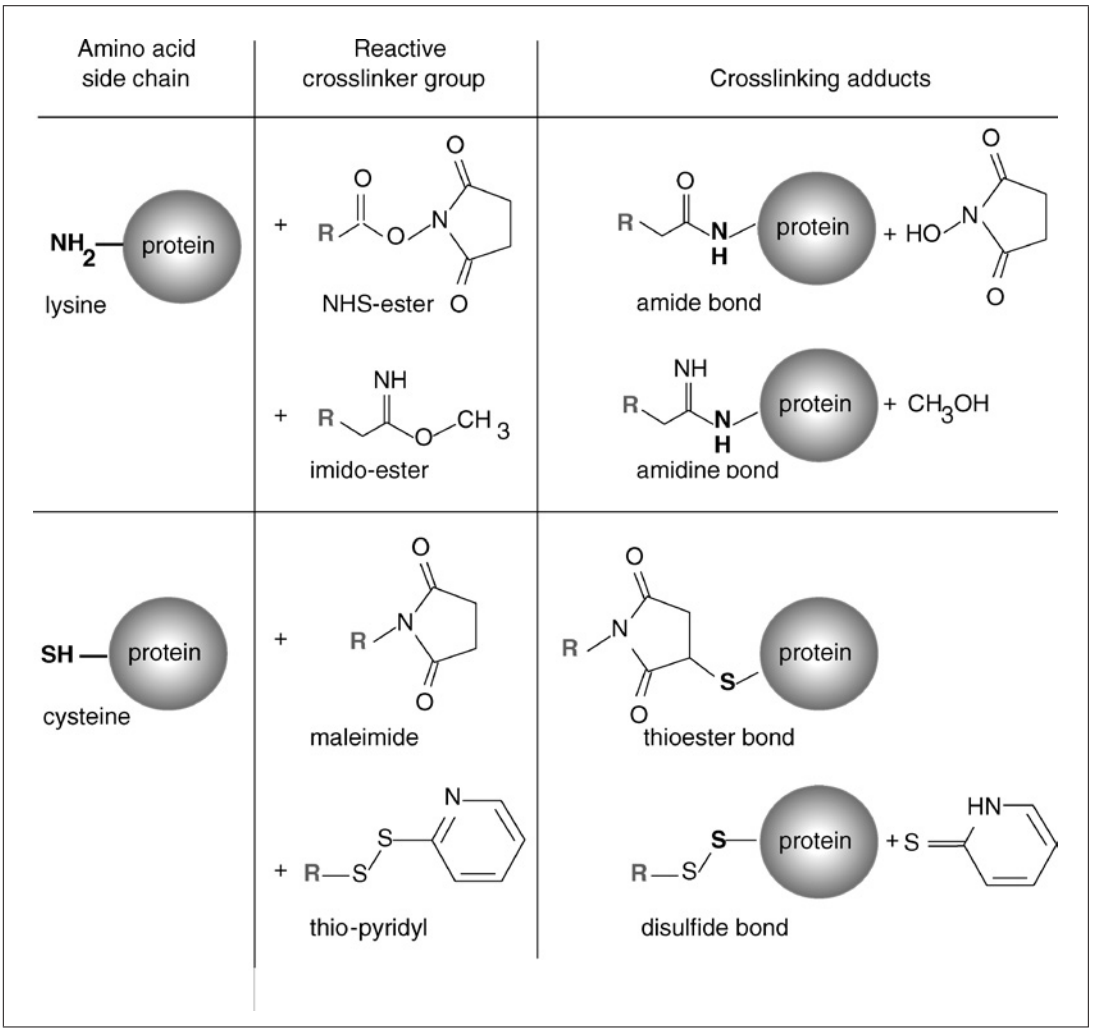

Figure 17.10.1 Crosslinker groups that react with lysine or cysteine residues on proteins of interest and the resulting crosslinking adducts. R is the nonreactive moiety of the crosslinker.

Sulfhydryl-, carboxyl- and carbohydrate-reactive crosslinkers

The second most frequently targeted groups are sulfhydryl groups on cysteine residues. Cysteine is present less frequently on the surfaces of proteins but is often introduced site-specifically into proteins by in vitro mutagenesis. Commonly used sulfhydryl-reactive crosslinkers are maleimides, which form thioester bonds with cysteines, and thiopyridyl compounds, which undergo disulfide exchange reactions (Fig. 17.10.1). Thiopyridyl-protein crosslinking can be reversed by using reductants like dithiothreitol (DTT). Other groups targeted in proteins include carboxyl groups and the carbohydrate moieties of glycoproteins (see the Pierce Web site at *http://www.perbio.com/upload/Literature_1601191%20XLinking%20handbook.pdf* for an excellent overview on different crosslinkers and crosslinking chemistries).

Photoactivatable crosslinkers

Amine- and sulfhydryl-reactive crosslinkers must be chemically relatively stable in an aqueous environment. This stability, however, comes at the price of a relatively low chemical reactivity towards their target groups. Therefore, these reagents need to be incubated with proteins for periods of 30 min to more than 1 hr. In contrast, photoactivatable crosslinkers remain largely nonreactive until induced by exposure to UV light to undergo photolysis, after which they require a much shorter crosslinking time. The most commonly employed photoactivatable groups are aryl azides, which upon photolysis form highly reactive, short-lived nitrenes (see Fig. 17.10.2A). These activated species

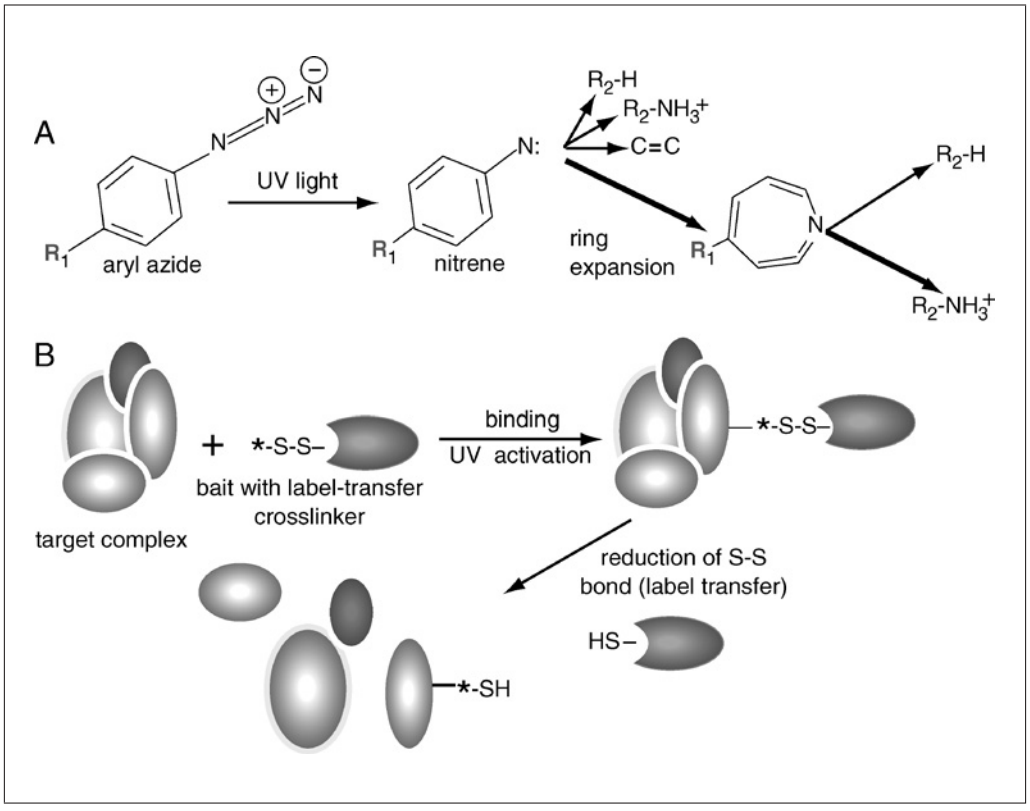

Figure 17.10.2 Photoactivatable crosslinking and label transfer. (**A**) Aryl azide photoactivation and formation of crosslinking adducts. UV illumination of aryl azides triggers photolysis to form short-lived nitrenes that either directly, or after ring expansion, attack chemical bonds in target proteins. The most frequently attacked groups are primary amines (thick arrows). R_1, nonreactive moiety of the crosslinker; R_2, target protein. (**B**) Label-transfer crosslinking. A labeled (∗) photoactivatable crosslinker with a cleavable disulfide (S-S) bond is first covalently attached to a bait protein that is subsequently incubated with a target complex. UV illumination triggers crosslinking with directly interacting target subunits. Reducing agents cleave the disulfide bond, thereby transferring the label to the target polypeptide.

can insert nonspecifically into chemical bonds, initiate addition reactions into double bonds, or react with nucleophiles like primary amines. Aryl azide–containing crosslinkers are therefore not limited to only one specific side group that may not be available at an appropriate distance on the surfaces of interacting proteins, and they require crosslinking times of only 1 to 15 min.

Disulfide crosslinking

Exposure of proteins to mildly oxidative conditions can trigger the reversible formation of nonphysiological disulfide bonds between appropriately spaced cysteine residues. Disulfide bond formation has been exploited in combination with the insertion of site-specific cysteine substitution mutants to map domain interactions within a protein (e.g., Cai et al., 2003) or between proteins (e.g., Bonner et al., 2000; van der Sluis et al., 2002).

Metal-catalyzed oxidative crosslinkers

In the presence of transition metals complexed with strong donor ligands, relatively mild oxidative conditions can lead to the formation of highly reactive, short-lived radicals in aromatic or sulfhydryl side chains of proteins. These in turn efficiently form covalent bonds with interacting proteins (Kodadek et al., 2005). Reactions are thought to proceed via oxidation of metals to highly electrophilic, high-valency species that subtract electrons from nearby aromatic side chains. Proton release then generates radicals that rapidly form adducts with nearby oxidizable amino acids or the peptide backbone (Fig. 17.10.3; Melcher, 2004; Kodadek et al., 2005).

This principle is exploited in localizing a crosslinking reaction to a bait protein that has been genetically tagged with a sequence of six histidine residues (His6; Fancy et al., 1996) or an N-terminal Gly-Gly-His sequence (GGH; Brown et al., 1998). Ni(II) complexed by a His6 or GGH tag can be oxidized by magnesium monoperphtalate (MMPP) to Ni(III) to induce formation of highly reactive radicals within the tagged protein. In contrast to heterobifunctional localized crosslinkers, bait proteins do not have to be isolated and chemically modified, but instead can be expressed under physiological conditions and allowed to assemble into native complexes in vivo.

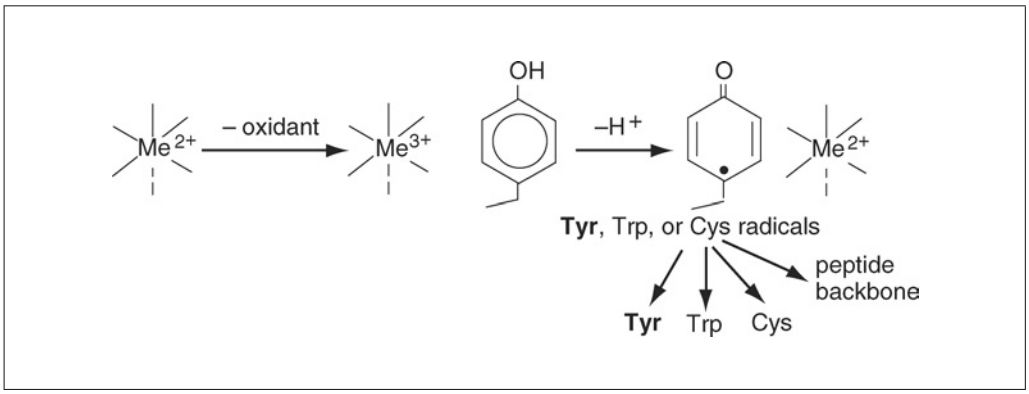

Figure 17.10.3 Oxidative crosslinking and formation of crosslinking adducts. Complexed transition metal ions (Me^{2+}), e.g., Ni^{2+} chelated by hexahistidine (His6) and Ru^{2+} chelated by tris(2,2′-bipyridyl), can be oxidized to highly electrophilic Me^{3+} species that subtract electrons from oxidizable amino acid side chains (e.g., Tyr, Trp, Cys) within the tagged protein. Tyrosine (**Tyr**) is the amino acid side chain shown in the figure and the most efficient electron donor for His6-mediated crosslinking. Subsequent proton release generates highly reactive radicals that can form adducts with susceptible amino acid residues in side chain or backbone components of the target protein.

Another application of oxidative crosslinking is nontargeted, photo-induced crosslinking. Visible light irradiation of proteins in the presence of tris(2,2′-bipyridyl)ruthenium(II) ions [Ru(II)$(bpy_2)_3^{2+}Cl_2$] and ammonium persulfate can efficiently crosslink proteins within less than a second (Fancy and Kodadek, 1999). The remarkable speed of this reaction minimizes the chances of false positive interactions (see False Positive and False Negative Results) and makes this method suitable for kinetic analyses of protein-protein interactions.

Organization of Reactive Groups

Homobifunctional and heterobifunctional crosslinkers

Most crosslinkers are bifunctional, i.e., they posses two reactive groups separated by a spacer. Homofunctional crosslinkers contain identical reactive groups while heterofunctional crosslinkers consist of reactive groups with specificities towards different amino acid side chains (most often lysine and cysteine; see Fig. 17.10.4 for examples). Spacer lengths in both homo- and heterobifunctional crosslinkers typically range from 4 Å to >20 Å. Without prior knowledge of the distance between reactive amino acid side chains in proteins of interest, it is important to employ a series of crosslinkers with different spacer lengths.

Bait-localized heterobifunctional crosslinkers

Instead of being distributed randomly over the surface of a bait protein, heterobifunctional crosslinkers can be localized to a specific amino acid side chain of the bait. Crosslinkers like N-succinimidyl 3-(2-pyridylthio)propionate (SPDP; Fig. 17.10.4), which has one cysteine-reactive and one lysine reactive group, can first be attached under defined conditions to cysteine residues (ideally a single cysteine engineered into an appropriate location on the protein) of an isolated bait protein. After removal of excess crosslinker, the activated adduct can be incubated with other proteins to determine interactions by crosslinking with accessible surface lysine residues on the other proteins. This approach minimizes the risk of inactivating the bait protein through excessive modification and

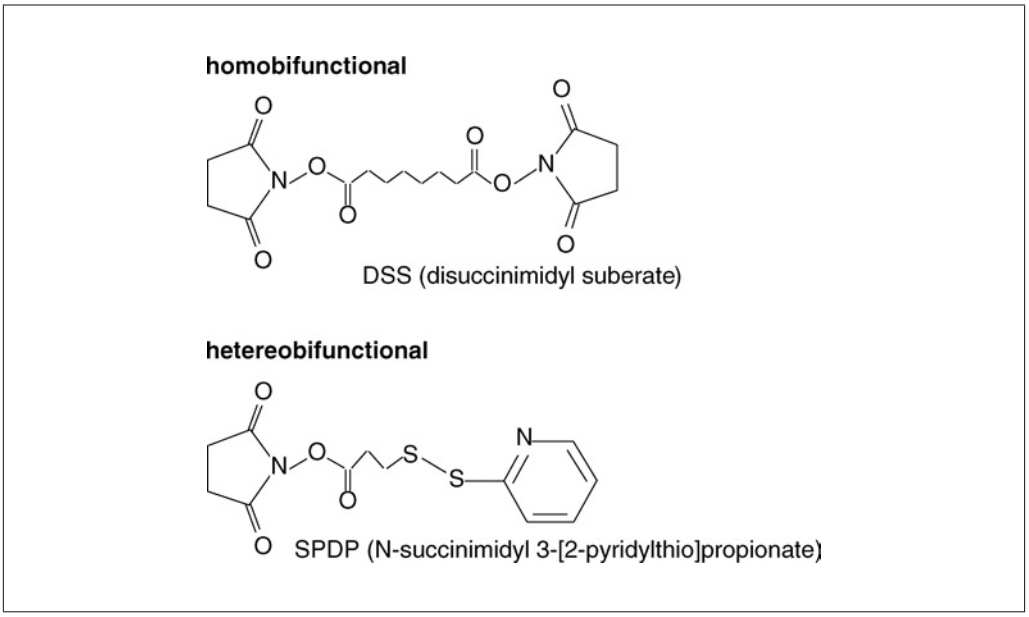

Figure 17.10.4 Structures of the lysine-targeting homobifunctional crosslinker disuccinimidyl suberate (DSS) and the heterobifunctional crosslinker *N*-succinimidyl 3-(2-pyridylthio)propionate (SPDP). SPDP consists of a lysine-targeting NHS group that is separated by a cleavable disulfide bond from a cysteine-targeting pyridyldisulfide group.

localizes the crosslinker the bait protein. Localization reduces the degree of formation of difficult-to-analyze high-molecular-weight multimeric adducts and minimizes the number of chemically distinct crosslinking adducts between the same two polypeptides, which could complicate subsequent analysis by mass spectrometry or immunodetection (Rappsilber et al., 2000). It also greatly facilitates analysis of individual crosslinking adducts (see Detection of Crosslinking Adducts and Fig. 17.10.5).

Label-transfer reagents

A photoactivatable label-transfer crosslinker consists of a labeled photoactivatable group that is separated from a sulfhydryl- or amide-coupling group by a cleavable disulfide bond. These crosslinkers are first attached to isolated bait proteins that are subsequently incubated with interacting proteins to form covalent protein-bait adducts upon exposure to UV light. The disulfide bond within the crosslinker can then be cleaved by addition of reducing agents to result in transfer of the label from the bait protein to the interacting protein (see Fig. 17.10.2B and Fig. 17.10.8). Photoactivation can lead to significant nonspecific protein labeling due to label release during photoactivation, a risk that is reduced by using heterotrifunctional crosslinkers. These reagents consist of a sulfhydryl- or amide-coupling group, a labeled group, and a photoactivatable group; the physical separation from a highly reactive photoactivated group stabilizes the labeled group.

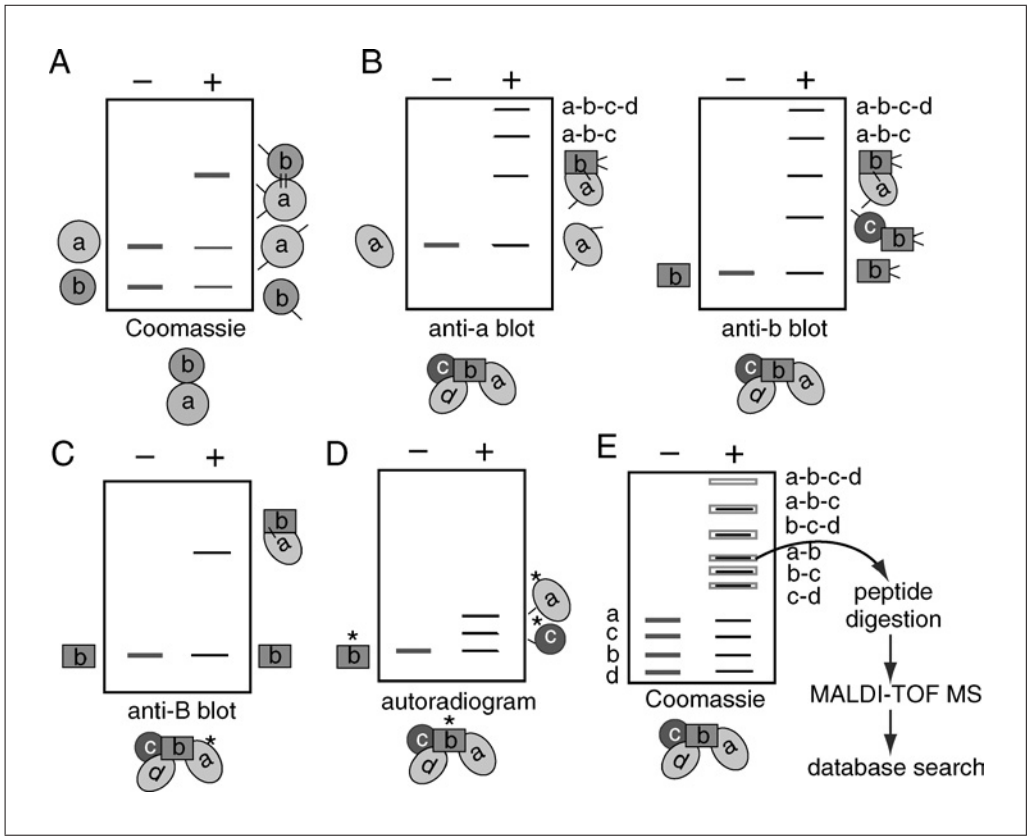

Figure 17.10.5 Cartoon comparing different methods for detection and analysis of crosslinking adducts. A protein complex consisting of subunits (a, b, c, and d; panel A contains only two subunits, a and b) is subjected to crosslinking. Reactions are separated by SDS-PAGE and analyzed by Coomassie staining (**A**), immunoblotting (**B**) and (**C**), autoradiography (**D**), and MALDI-TOF MS (**E**). Samples have either been treated with diffusible crosslinkers (panels A, B, and E), with localized crosslinkers (panel C), or with-label transfer crosslinkers (panel D). Please note that bifunctional crosslinkers (depicted by thin bars) can either covalently connect two amino acid side chains within or between subunits or modify a single amino acid chain. See text for further details. Abbreviation: $*$, radioactive label; $-$, without crosslinking; $+$, with crosslinking.

Labels can be radioactive ^{125}I (see Basic Protocol 2 and Fig. 17.10.8), fluorophores, or biotin. Recently, a variant of localized oxidative crosslinking has been developed for biotin labeling of proteins that interact with His6- or GGH-tagged baits (Amini et al., 2002); it allows localized labeling reactions within native, in vivo–assembled protein complexes.

Detection of Crosslinking Adducts

Coomassie or silver staining

Crosslinking reaction products are usually separated by denaturing polyacrylamide gel electrophoresis (SDS-PAGE; *UNIT 6.1*). If crosslinking is performed with purified homomultimeric or heterodimeric protein complexes, separated proteins and protein adducts can simply be stained with Coomassie brilliant blue or silver (*UNIT 6.6*) and distinguished by their electrophoretic mobilities. Crosslinking will result in reduced band intensities for the monomeric subunits and the corresponding appearance of covalently linked crosslinking adducts (see Fig. 17.10.5A). These adducts typically (but not always) migrate close to their calculated molecular weight positions.

Immunodetection

The composition of crosslinking adducts can be confirmed by immunoblotting (*UNIT 6.2*). While immunoblotting obviously requires the availability of antibodies against the subunits of the protein complex under analysis, it does have the advantage of allowing performance of crosslinking reactions with more complex mixtures of proteins. In the example of the heterotetrameric complex in Figure 17.10.5B, crosslinking would generate three new bands recognized by an antibody against subunit a. The sizes of two of these bands correspond to higher-order crosslinking adducts (i.e., adducts that consist of more than two subunits and that are therefore more difficult to analyze) while the mobility of one of the bands would be consistent with a dimeric a-b crosslinking product. This assumption can be further substantiated by reprobing the blot with an antibody against subunit b, which needs to bind and detect the same position on the blot. However, it is important to realize that the same position could potentially represent two fortuitously co-migrating crosslinking adducts (e.g., a-*x* and b-*y*) rather than a genuine a-b heterodimer. This lack of resolution will be strongly aggravated with increasing subunit complexity. Thus immunodetection in reactions with standard nonlocalized crosslinkers is in most instances not suitable for the mapping of large multiprotein complexes.

In contrast, immunodetection can unambiguously determine the composition of dimeric crosslinking adducts in instances where crosslinking is strictly localized to a single modified subunit: these adducts must contain both the modified subunit as well as the immunologically detected subunit (Fig. 17.10.5C).

Radioactive, fluorescent, and chemiluminescent labeling

Label-transfer crosslinking allows the identification of labeled interacting proteins (rather than adducts) by size (Fig. 17.10.5D), or, often in combination with affinity purification, by mass spectrometry (see below). Labeled species within SDS-PAGE-separated crosslinking reactions are visualized by autoradiography, fluorography, or by streptavidin horseradish peroxidase–catalyzed chemiluminescence. Detection by size requires crosslinking reactions with limited complexity for unambiguous identification. The bait modified with the labeled crosslinker is typically the most strongly labeled protein in the reaction. Target proteins should therefore clearly differ in size both from the bait protein as well as from other subunits (i.e., other potential targets) of the protein complex under investigation.

Mass spectrometry

The most attractive method for determining the composition of crosslinking adducts is the use of mass spectrometry (MS), particularly MALDI-TOF MS. MS can unambiguously identify proteins in adducts separated by SDS-PAGE (*UNIT 6.1*) or by liquid chromatography without the need of highly specific antibodies (which may not be available) or epitope tags introduced into target proteins (which may interfere with protein function). Also, MS usually allows the unbiased identification of polypeptides in adducts without prior knowledge of their involvement, and it even has the potential to map crosslink sites within adducts of low-complexity crosslinking reactions (e.g., intramolecular crosslinking or homo- or hetero-dimeric crosslinking reactions).

Purified complexes of low to medium complexity can be directly crosslinked, fractionated by SDS-PAGE (*UNIT 6.1*), and stained with Coomassie blue or silver (*UNIT 6.6*). Protein bands produced as a result of crosslinking can be excised from the gel and their compositions determined by peptidase digestion and MS analysis of the resulting peptide mixture (Fig. 17.10.5E). This approach has been successful for the analysis of several dimeric protein complexes and also for a few multimeric complexes, employing either several different bifunctional crosslinkers (Rappsilber et al., 2000) or metal-catalyzed oxidative crosslinking (Denison and Kodadek, 2004). The major limitation of this approach is its dependence on clearly separated dimeric crosslinking adducts. Large multimeric complexes form a multitude of crosslinking adducts, resulting in excised bands that contain more than two proteins (Denison and Kodadek, 2004). This problem is further aggravated by the formation of different crosslinking adducts between the same two polypeptides, which migrate differently due to variations in protein modifications (Denison and Kodadek, 2004).

False Positive and False Negative Results

False negative results

The occurrence of crosslinking depends on a suitable position and distance of reactive groups on the surfaces of two interacting polypeptides. Interactions between proteins that lack such correctly spaced groups will not be identified (or "trapped") by crosslinking, resulting in reactions that erroneously suggest a lack of interaction (false negative interaction). This risk is particularly high for sulfhydryl- and amide-reactive bifunctional crosslinkers with defined spacer lengths; therefore, it is imperative to evaluate a variety of different crosslinkers both in terms of crosslinking chemistry as well as spacer length (Rappsilber et al., 2000). Spacer lengths are much less of a concern for photoactivatable aryl azides, which depend on chemistries with very broad substrate specificities, or for oxidative crosslinking reagents, which function without spacers and which also have relaxed substrate specificity. Still, it is important to realize that photoactivatable and oxidative reagents are also biased towards particular amino acid side chains and will therefore trap protein-protein interactions with variable efficiencies.

False positive results

The occurrence of false positive results is more difficult to understand than that of false negative results. False positive results are defined as the formation of crosslinking adducts between polypeptides that, under physiological conditions, do not interact with each other. In the simplest case, they are due to random collisions between two polypeptides in solution, particularly during extended incubation at high concentrations of polypeptides and crosslinkers. This background can usually be eliminated by titration of crosslinkers and bait and target proteins as well as by incorporation of appropriate controls (e.g., reactions with noninteracting variants or proteins). In the case of stable multiprotein complexes crosslinked using bifunctional reagents with long spacers, false positive results

can also be due to crosslinking of subunits that are close to each other in space, but not in direct contact. In this case it may be necessary to test identified polypeptides in isolation for direct interaction by methods such as GST pull-downs or co-immunoprecipitation assays. However, these methods will not be able to confirm interactions that exclusively occur in the context of an intact physiological multiprotein complex.

However, the most serious concern is the alteration of protein-protein interactions due to protein modifications during crosslinking reactions. Incubation of protein complexes with nonlocalized crosslinkers typically results in extensive protein modifications, as well as intramolecular crosslinking, before crosslinkers covalently connect two interacting polypeptides. Modifications by amide-reactive crosslinkers can be particularly disruptive because they neutralize the positive charge of lysine residues, which often serve as important determinants of interaction specificities.

Modifications by sulfhydryl-reactive crosslinkers may be less critical for protein-protein interactions because cysteine residues are less frequently directly involved in protein-protein interactions. However, cysteines often have catalytic roles, or they can stabilize structural domains; therefore, modifications to cysteine residues can inactivate proteins and disrupt subunit-subunit interactions, causing subunit dissociations or rearrangements within complexes. This in turn can result in the crosslinking of subunits that, under physiological conditions, would not touch each other, and it is very likely the reason for the high rates of false positives when multiprotein complexes are analyzed using standard nonlocalized bifunctional crosslinkers (Edwards et al., 2002; Denison and Kodadek, 2004).

Use of localized bifunctional or trifunctional crosslinkers largely limits the risk for disruptive modifications to the coupling reaction of the crosslinker to the bait protein. That is because the subsequent step, binding of bait-localized crosslinkers to target proteins, directly results in covalent bait-target coupling. In other words, any modification of target proteins would occur as a consequence of bait-target crosslinking rather than preceding it. The risk of inactivating modifications occurring during the initial bait-crosslinker coupling can be minimized by generating a panel of bait protein variants by in vitro mutagenesis, with each variant having a single cysteine residue at a nonessential amino acid position. Sulfhydryl-targeted conjugation of the crosslinker to the bait protein will then result in an array of bait proteins with crosslinkers localized at different single positions (e.g., Brown et al., 2001; Chen and Hahn, 2003; Fishburn et al., 2005; see also Basic Protocol 2).

While oxidative crosslinking conditions can also modify proteins (e.g., by inducing the formation of nonphysiological disulfide bonds), ultra-fast photoinduced oxidative crosslinking appears to cause very few, if any, false positive crosslinking interactions (Denison and Kodadek, 2004).

Crosslinking Reactions Involving Large Multiprotein Complexes

Analyses of large multiprotein complexes are the most demanding crosslinking applications. Reactions should be fast, lack extensive modifications of target proteins, and allow the unambiguous identification of the composition of crosslinking adducts. Photoactivatable label-transfer crosslinking, particularly in combination with affinity purification and mass spectrometry, is probably the most appropriate and most established method for determining interactions between an isolated bait protein and intact protein complexes. Basic Protocol 2 provides an example of this method.

Label-transfer crosslinking is less suited for the analysis of subunit interactions within stable complexes because bait proteins are derivatized in vitro and hence cannot assemble in vivo into native complexes. Analysis of inter-subunit interactions is therefore best

performed using localized crosslinking that involves genetically introduced tags (His6- or GGH-mediated crosslinking) or nonlocalized crosslinking in combination with mass spectrometry. Currently the best method using nonlocalized crosslinking appears to be photo-induced metal-catalyzed oxidative crosslinking because of its fast reaction time, very high reactivity, and low rate of false positive interactions (Denison and Kodadek, 2004), although nonlocalized crosslinking/MS has also been successful in combination with standard bifunctional crosslinkers (Rappsilber et al., 2000). His6-mediated localized crosslinking overcomes the limitations on the analysis and separation of very complex mixtures of crosslinking adducts; however, experience with His6-mediated crosslinking is limited and it has so far not been used in combination with mass spectrometry. Detailed protocols for photo-induced metal-catalyzed oxidative crosslinking have been published recently (Fancy and Kodadek, 1999; Kluger and Alagic, 2004), and Basic Protocol 1 provides a sample laboratory protocol for His6-mediated nickel-catalyzed oxidative crosslinking.

BASIC PROTOCOL 1

HIS6-MEDIATED CROSSLINKING

The crosslinking method described in this protocol is based on the introduction of a Ni^{2+}-binding His6 tag into a bait protein. His6-Ni(II) complexes can be induced by addition of diffusible oxidizers, such as magnesium monoperphtalate (MMPP), to trigger electron subtraction and formation of highly reactive radicals in nearby oxidizable amino acid side chains, in particular tyrosine residues (see Fig. 17.10.3 and Strategic Planning, Crosslinking Chemistries). Baits can either be specific subunits of multiprotein complexes or polypeptides transiently interacting with multiprotein complexes. Since targets are identified immunologically, this protocol depends on either the availability of target-specific antibodies or the introduction of epitope tags into targets.

While a standard His6-tagged bait is sufficient for crosslinking studies, the use of composite tags allows for the purification or enrichment of multiprotein complexes prior to crosslinking and the analysis of crosslinking adducts by analytical proteolysis. This protocol employs a composite tag (His6-GST-TEVcs) consisting of His6 for crosslinking the bait with the complexing proteins; glutathione-*S*-transferase (GST) for immobilizing the bait to a glutathione-Sepharose bead and enriching the interacting protein complexes by GST pull-down and one- or two-step affinity enrichment (along with His6; see step 17); and a tobacco etch virus protease cleavage site (TEVcs) to enhance crosslinking efficiency (see step 26) and allow proteolytic tag removal to verify presence of the bait in crosslinking adducts (see step 33; Fig. 17.10.7).

This protocol has been developed to identify subunits of large, multiprotein coactivator complexes that directly interact with transcriptional activator proteins. Some of the protocol steps may have to be modified for use with other proteins and in other organisms. Because targets are identified immunologically, this protocol depends on either the availability of target-specific antibodies or the introduction of epitope tags into targets.

Materials

Saccharomyces cerevisiae cultures: source of multiprotein complexes, either wild-type cells or cells in which putative target polypeptides are genomically epitope-tagged (see Klein et al., 2003)
YEPD medium (see recipe)
Extract buffer (see recipe)
0.5-mm glass beads, (e.g., Scientific Instruments), prechilled to −20°C
Siliconized glass wool, sterile (see recipe)

Ammonium sulfate, finely ground with mortar and pestle or with coffee grinder
1 M KOH
Dialysis buffer (see recipe)
Glutathione-Sepharose immobilized proteins (see recipe) in A50 buffer (see recipe)
  ~80 μg His6-GST-TEVcs-bait protein
  ~20 μg His6-GST-TEVcs (control)
A50 buffer (see recipe)
Wash buffer: A50 buffer (see recipe) without DTT
4× and 2× SDS sample buffer (see recipe)
12 mM nickel acetate
12 mM magnesium monoperphtalate (MMPP; Aldrich): prepare fresh just before use
TEV protease cleavage buffer (see recipe)
TEV protease (Invitrogen or USB)

Visible light spectrophotometer
50-ml centrifuge tube
Refrigerated centrifuge
30-ml round-bottom Corex tube
10-ml syringe
Ultracentrifuge (e.g., Beckman 70.1Ti) and corresponding ~10-ml ultracentrifuge tubes, precooled to 4°C
25-ml beakers
Magnetic stir plate and stir bars
Dialysis tubing or dialysis cassettes (10,000 to 12,000 kDa MWCO; e.g. Slide-A-Lyzer cassettes from Pierce)
0.5-ml microcentrifuge tubes
Nutator

Additional reagents and equipment for determining protein concentration (*APPENDIX 3H*), performing SDS-PAGE (*UNIT 6.1*), and detecting proteins by immunoblotting (*UNIT 6.2*)

Grow and harvest yeast

1. Grow *Saccharomyces cerevisiae* in 800 ml of YEPD medium at 30°C, with shaking at 200 to 250 rpm to ~1 OD_{600}.

   Preparation of extracts is based on Wootner et al., 1991.

2. Centrifuge cells 6 min at 6000 × *g*, 4°C. Discard the supernatant and resuspend cells in ~20 ml cold water. Transfer cells to a preweighed 50-ml centrifuge tube on ice, and centrifuge 4 min at 3000 × *g*, 4°C.

3. Decant the supernatant and weigh the tube containing the cells. Subtract the weight of the empty tube to determine the weight of the cells. Resuspend the cells in ~1 ml/g cells of cold extract buffer and transfer to a 30-ml Corex tube on ice.

   Alternatively, cell pellets may be frozen and stored up to several months at –80°C.

   Round-bottom glass Corex tubes are preferred because they work well for cell breakage using the glass bead methods describe in steps 4 and 5, but other round-bottom tubes may be used as well.

Lyse cells

4. Add 0.5-mm prechilled glass beads to the cell suspension to a final fill height of about two-thirds of the suspension.

5. Vortex at least ten times for 30 sec each at full speed, with 30 sec cooling on ice between each vortex cycle.

   Hold tubes as close to the top as possible to achieve maximal vortex amplitude. Instead of a vortex, yeast cells can be efficiently broken by the glass bead method using a specialized bead beater (e.g., BioSpec) following the manufacturer's recommendations.

Collect whole-cell lysate

6. For each extract plug the end (where the needle is inserted) of one 10-ml syringe with a small amount of sterile, siliconized glass wool.

7. Separate extract from glass beads by pouring the suspension into the glass wool–plugged syringe and pressing out the extract with the plunger directly into a precooled ultracentrifuge tube.

8. Wash the remaining glass beads with 1 to 2 ml of additional extract buffer, pass through syringe, and combine with the first pass-through from step 7.

9. Adjust the extract buffer to 4.5 ml/g cell pellet and centrifuge 75 min at 300,000 × *g*, 4°C.

Precipitate proteins

10. Carefully pipet supernatants in to 25-ml beakers on ice. Record volume, add stir bars, and stir on ice.

    Stirring on ice can be done most conveniently by placing an ice bucket with beaker directly onto a magnetic stir plate. Alternatively, ammonium sulfate precipitation can be done in a cold room.

11. Add 0.337 g finely ground ammonium sulfate powder per milliliter of supernatant slowly spaced equally over the course of 1 hr. Also add a total of 10 µl of 1 M KOH per gram ammonium sulfate in six aliquots every 10 min. Stir for an additional 30 min on ice.

    To avoid high local concentrations of ammonium sulfate, it is important to add ammonium sulfate continuously in as small amounts as possible over the whole period of one hour.

12. Transfer the mix to 10-ml centrifuge tubes on ice and centrifuge 30 min at 20,000 × *g*, 4°C.

Dialyze precipitated proteins

13. Completely remove supernatant including the lipid phase with a pipet and resuspend the pellet in 1 ml dialysis buffer.

14. Thoroughly rinse and equilibrate dialysis tubing or casettes for at least 5 min in dialysis buffer.

15. Transfer the resuspended pellet to dialysis tubing or casettes and dialyze for at least two 2-hr changes against 1 liter dialysis buffer at 4°C.

16. Remove dialysate from dialysis tubing or casettes. Use a small amount to determine protein concentration (*APPENDIX 3H*) and store whole cell extract (WCE; ~1.5 ml) in 100-µl aliquots up to 1 year at –80°C.

    The dialysate is the whole cell extract that is used as a source of target protein complexes for crosslinking. Typical yield: ~ 400 mg total protein.

Enrich bait-interacting complexes

17. Place 500 µl glutathione-Sepharose immobilized proteins in A50 buffer into each of five 0.5-ml microcentrifuge tubes on ice: one control tube containing ~20 µg of

His6-GST-TEVcs and four reaction tubes each containing ~20 μg of the His6-GST-TEVcs-bait protein.

The required amount of glutathione-Sepharose-immobilized protein depends on the affinity of the bait-target interaction and may need to be optimized for a particular target protein. The amount of immobilized bait protein used in this protocol is suitable for interactions with a dissociation constant, K_D, in the range of 10^{-7} M. An interaction with a ten times lower K_D would require an approximately ten times lower amount of bait protein.

Total bead volume should be sufficiently large to minimize the chance of bead losses during washes, but low enough to minimize unspecific binding or precipitation. A total volume of 5 to 10 μl packed beads per reaction generally works well. If protein concentrations vary, add free glutathione-Sepharose beads to samples with high concentration of immobilized protein until all samples contain about the same volume of total beads.

Note that the efficiency of the enrichment of bait-target protein complexes can be increased by a two-step procedure, in which complexes are first selectively bound to Ni-agarose and eluted with imidazole prior to the GST pull-down (see Melcher, 2000). This additional step is not required if crosslinking adducts are analyzed by immunoblotting (as described in this protocol), but would be important for analysis by mass spectrometry.

18. Centrifuge the glutathione-Sepharose immobilized protein suspensions 30 sec at 16,000 × *g*, 4°C, and discard supernatants.

19. Add 200 μl cold A50 buffer plus whole cell extract (WCE; from step 16) corresponding to ~0.5 mg total protein to the glutathione-Sepharose immobilized protein pellet. Keep an aliquot of the WCE as input control.

20. Nutate at 4°C for 1 hr.

    Ideally it is best to keep the reaction cold at all times. However, the authors use a nonrefrigerated microcentrifuge for the remaining centrifugations, immediately removing the tubes from the centrifuge after the short centrifugation step and placing them on ice. This way the samples are kept sufficiently cold without the need for a refrigerated microcentrifuge.

21. Centrifuge 20 sec at 10,000 × *g*, 4°C, and carefully remove supernatants with a pipettor.

22. Resuspend each bead pellet in 550 μl cold wash buffer, centrifuge 20 sec at 10,000 × *g*, 4°C, and carefully remove supernatants with a pipettor. Repeat this step two more times for a total of three washes.

23. Resuspend the pellets in 550 μl wash buffer. Remove 120 μl of each suspension and centrifuge 30 sec at 16,000 × *g*, 4°C. Remove supernatant and resuspend beads in 12 μl 2× SDS sample buffer.

    These reserved samples will serve as pull-down controls.

Crosslink bait and target proteins

24. Centrifuge the remaining bead suspension from step 23 for 30 sec at 16,000 × *g*. Remove supernatants (~430 μl each) with a pipettor and allow the beads to remain in a residual volume of 20 to 25 μl.

    To estimate a volume of 20 to 25 μl, compare to the volume of two reference tubes filled with 20 and 25 μl buffer, respectively.

25. Add 1.5 μl of 12 mM nickel acetate (final concentration: 0.6 to 0.8 mM Ni-acetate) and nutate 10 min at room temperature.

    The indicated amount of Ni-acetate should be sufficient to saturate Ni(II) complexation by His6 tags. However, if crosslinking efficiency is low, the concentration of the Ni-acetate solution may be titrated over a range of 4 to 60 mM.

26. Create the crosslinking and control reaction mixes by adding:

    a. 1.5 µl 12 mM MMPP (600 µM final concentration) to His6-GST-TEVcs reaction tube (control)
    b. 1.5 µl water to a His6-GST-TEVcs -bait protein reaction tube (mock reaction)
    c. 1.5 µl 4 mM MMPP to a His6-GST-TEVcs -bait protein reaction tube
    d. 1.5 µl 12 mM MMPP to a His6-GST-TEVcs -bait protein reaction tube
    e. 1.5 µl 40 mM MMPP to a His6-GST-TEVcs -bait protein reaction tube.

    The three reactions treated with different MMPP concentrations identify optimal crosslinking conditions. Once established, a single crosslinking reaction will be sufficient.

    The optimal amount of MMPP is critical for the success of the protocol. Because high concentrations of oxidant may destabilize protein complexes during crosslinking (see False positive results in the Strategic Planning section), it is important to use the minimal concentration of oxidant that allows efficient crosslinking. Complex integrity will be tested by analyzing both beads and buffer supernatants of crosslinking reactions as well as a mock reaction prior to denaturation (see step 23). In some cases, MMPP concentration may need to be tested over a broader range (100 µM to 10 mM final MMPP concentration).

    Crosslinking efficiency depends on the position of the His6 tag relative to an appropriately spaced oxidizable amino acid, such as tyrosine, and the central tyrosine residue in the cleavage site for TEV protease (ENLYFQG) has been shown to increase crosslinking yield in the context of the His6-GST-TEVcs composite tag (Fancy and Kodadek, 1998; Klein et al., 2003).

27. Nutate 5 min at room temperature.

28. Centrifuge 20 sec at 16,000 × *g*, 4°C. Add supernatants to 6 µl of 4× SDS sample buffer to use as a complex integrity control.

    If target protein dissociated from the complex during crosslinking, small amounts of target protein will appear in the supernatant of the crosslinking reaction, but not the supernatant of the mock reaction, in which case crosslinking conditions must be modified.

29. Divide each bead sample (suspended in the residual supernatant) into two aliquots.

30. Add 6 µl of 2× SDS sample buffer to one half of the beads crosslinking reaction.

    This aliquot will constitute the crosslinking reaction without TEV protease treatment.

Cleave crosslinking adducts

31. Resuspend the other half of the beads in 550 µl cold TEV protease cleavage buffer. Centrifuge 20 sec at 10,000 × *g*, 4°C or room temperature and carefully remove supernatants with pipettor.

32. Repeat step 31 two more times for a total of three wash steps.

    These steps will remove remaining traces of MMPP.

33. Resuspend washed beads in 10 µl cleavage buffer and add 1 µl TEV protease. Incubate 30 min at room temperature.

    TEV protease cleaves its recognition sequence with exquisitely high specificity under a variety of different incubation conditions (Dougherty et al., 1988; Polayes et al., 1994; http://mcl1.ncifcrf.gov/waugh_tech/faq/tev.pdf).

    Treatment with TEV protease is recommended as a control to confirm presence of the tagged bait protein in crosslinking adducts. Treating part of the crosslinking reaction with and part without TEV protease will generate crosslinking adducts that do or do not contain the relatively large (~27 kDa) His6-GST-TEVcs tags. These indicative size differences between treated and untreated crosslinking adducts will only occur if adducts contain the cleavable tag and therefore serve as direct evidence for the presence of the tagged bait protein (see Fig. 17.10.6 and 17.10.7C).

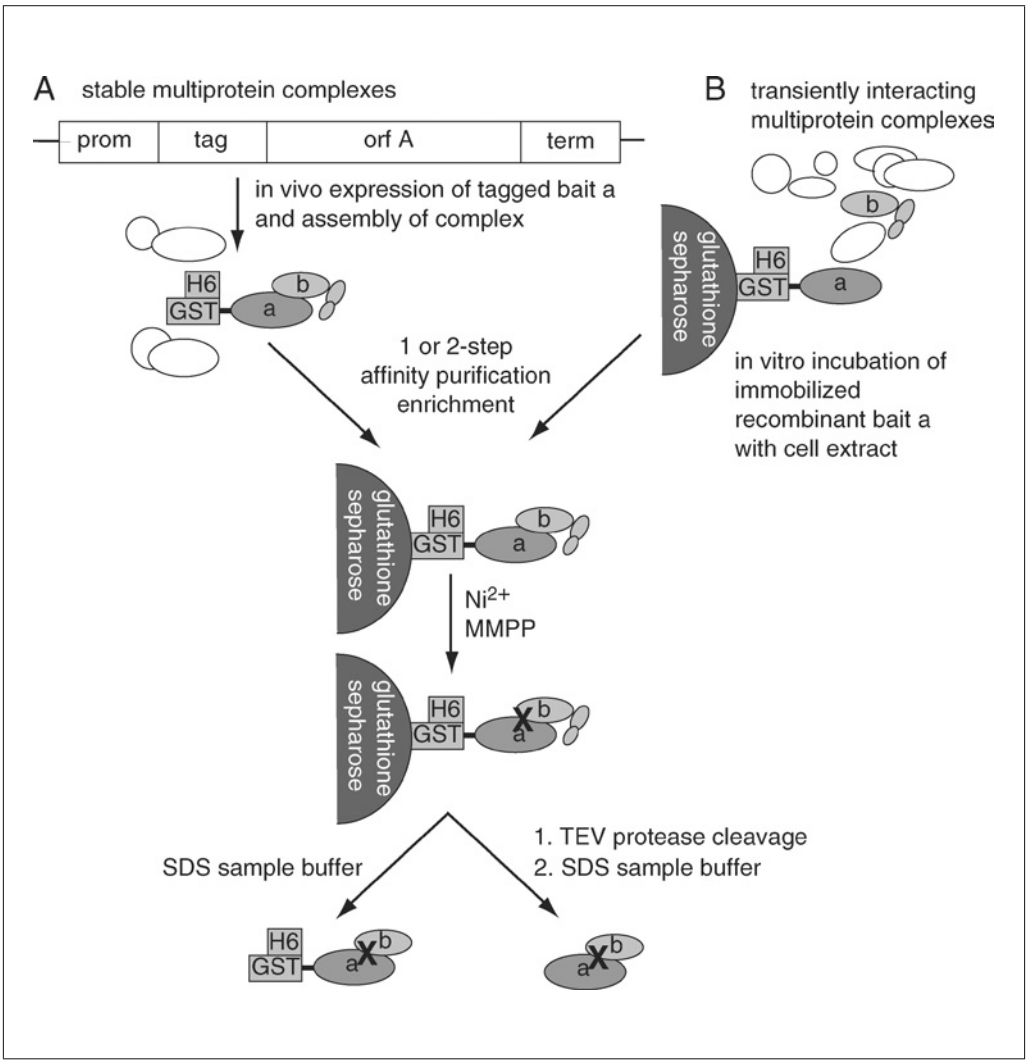

Figure 17.10.6 Cartoon depicting steps in isolating interacting proteins using a bait protein. (**A**) Baits that form subunits of stable protein complexes can be allowed to assemble in vivo prior to affinity purification of the bait-containing protein complex. (**B**) Baits that transiently interact with protein complexes can be first purified as glutathione Sepharose bead–immobilized recombinant bait proteins and allowed to interact in vitro with cell extracts. The bait (a) containing complexes are enriched or isolated by affinity purification, and the interacting protein (b) is crosslinked and analyzed (with or without removal of the His6-GST-TEVcs-tag) by SDS-PAGE. Abbreviations: H6, His6 tag; GST, glutathione-*S*-transferase tag; MMPP, magnesium monoperphtalate. Crosslinking is indicated by the large, bold X, and the cleavage site for TEV protease is indicated by a thick bar.

The authors produce their own recombinant TEV protease. Commercial suppliers of TEV protease include Invitrogen and USB.

34. Centrifuge 30 sec at 16,000 × *g*, 4°C. Add the supernatant to 6 µl of 4× SDS sample buffer.

Analyze samples

35. Heat all samples (from steps 30 and 34) 4 min at 95°C, separate by SDS-PAGE (*UNIT 6.1*), and detect proteins of interest (target proteins) by immunoblotting (*UNIT 6.2*) with appropriate antibodies.

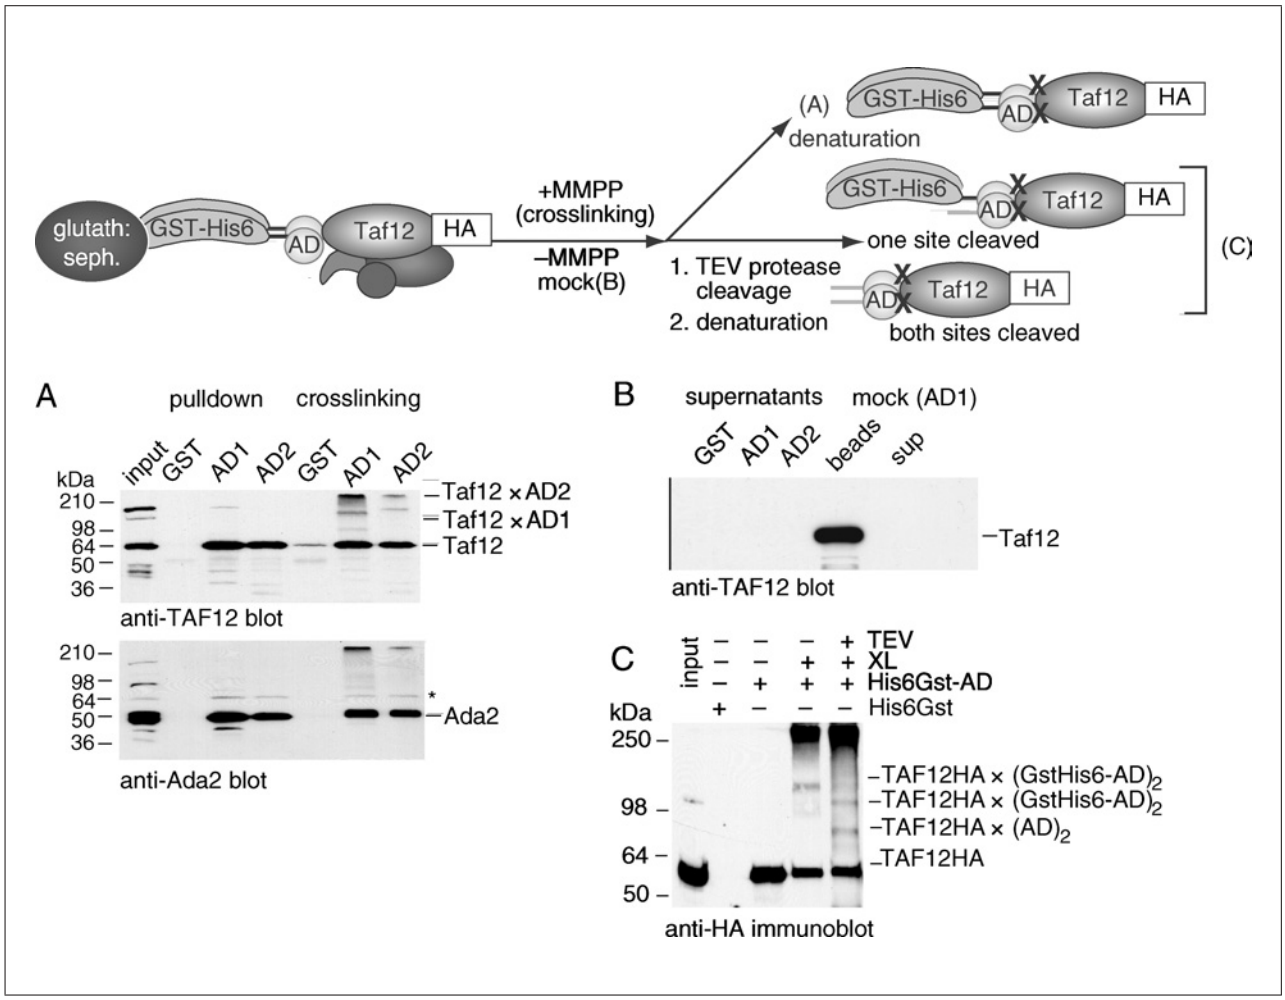

Figure 17.10.7 Crosslinking of two acidic activation domains (ADs) with Taf12, TAF12 is a subunit of both coactivators SAGA (the example used for the gels shown in this figure) and TFIID (the example illustrating Basic Protocol 2), and the complex depicted at the top of the figure can represent either. Immobilized His6-GST-TEVcs-AD fusion proteins of two different sizes (AD1 and AD2) were incubated with yeast whole cell extract. Native complexes bound to the bait proteins were crosslinked, and the crosslinking reaction mix was separated by SDS-PAGE. (**A**) Top: immunoblot with anti-Taf12 antibodies. A, bottom: the same blot stripped and reprobed with an antibody against a different SAGA subunit, Ada2. The asterisk (∗) indicates residual TAF12 signal after stripping. (**B**) Immunoblot of supernatants of the crosslinking reaction and a mock reaction. (**C**) Part of the crosslinking reaction was treated with TEV protease prior to denaturation and immunoblotting with anti-HA (heme agglutinin epitope tag) antibody. The cleavage site for TEV protease is indicated by a thick bar. Modified from Klein et al., 2003; see Klein et al., 2003 for details.

BASIC PROTOCOL 2

BAIT-LOCALIZED PHOTOACTIVATABLE CROSSLINKING

This protocol describes the bait-localized photoactivatable crosslinking (photocrosslinking) method suitable for elucidating the binding targets of a protein of interest within a transient multiprotein complex. The strategy for using a photocrosslinker is depicted in Figure 17.10.8. First, the heterobifunctional photocrosslinker, N-[(2-pyridyldithio)ethyl]-4-azidosalicylamide (PEAS; Chen et al., 1994, Ebright et al., 1996) is iodinated at its phenyl ring with radioactive iodine (^{125}I). Second, the radiolabeled photocrosslinker ^{125}I-PEAS is conjugated to a unique cysteine on the bait protein through a disulfide bridge. Third, the modified bait protein sample is added into an in vitro multiprotein complex formation assay to react with its binding target(s). Fourth, the resulting complex is irradiated with UV light of wavelength ~350 nm to activate covalent bond formation (crosslinking) between the azido group of the crosslinker and its nearest neighboring protein. Finally, the radiolabeled crosslinker is transferred to the crosslinked target(s) in

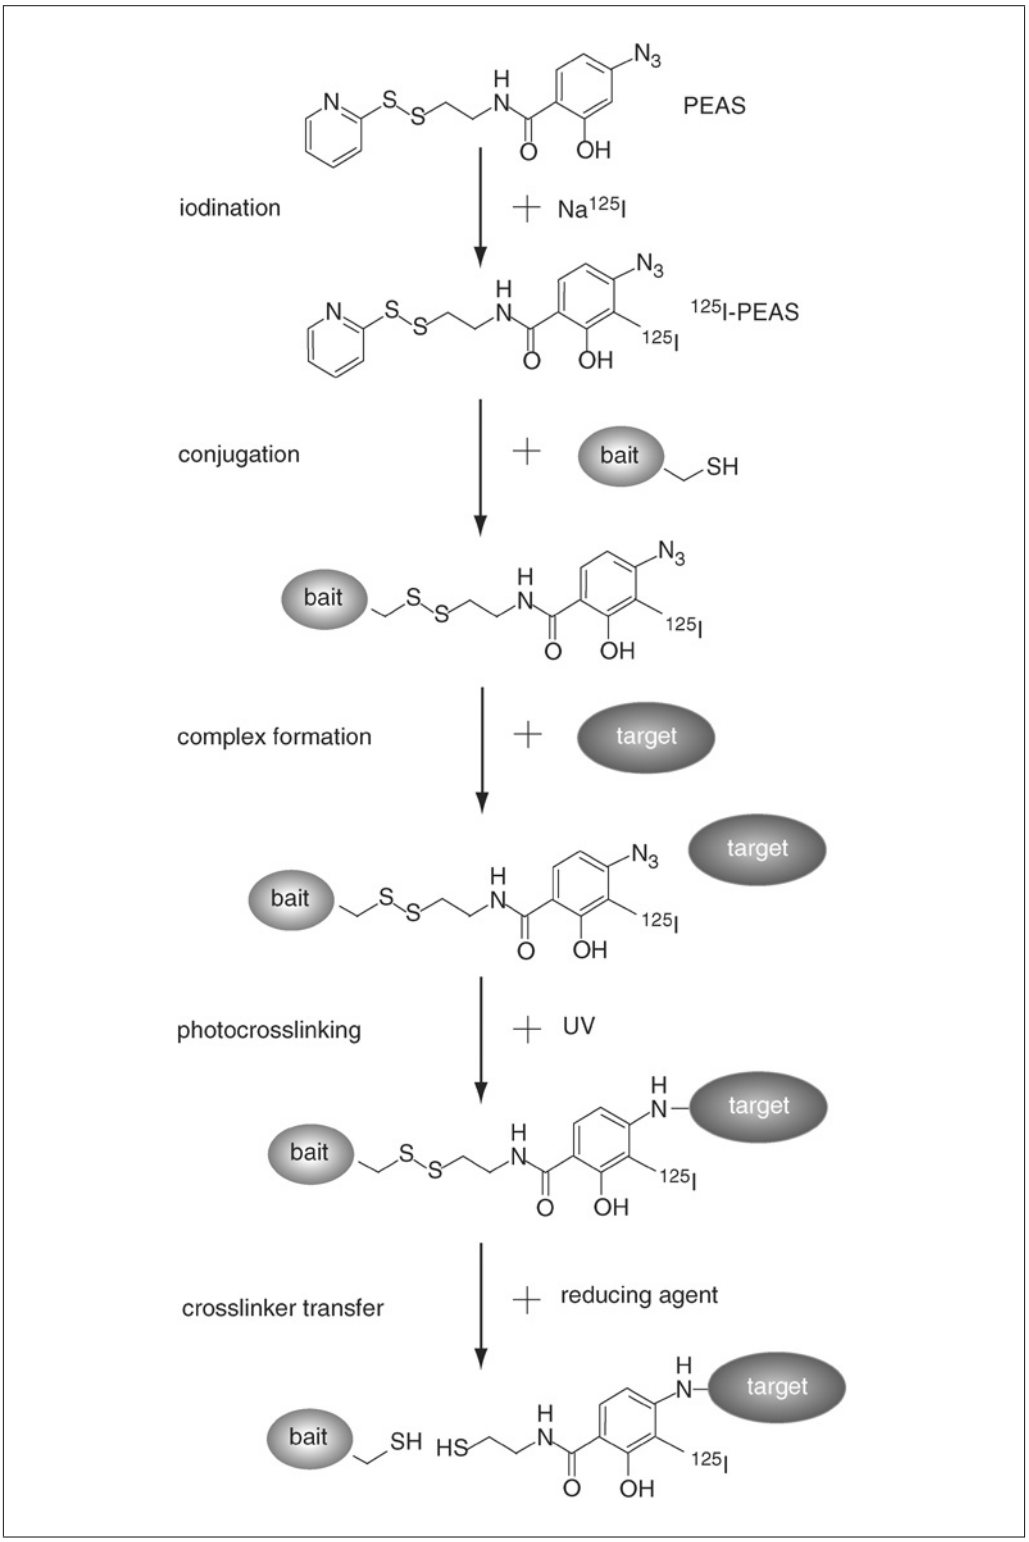

Figure 17.10.8 Flow chart demonstrating a strategy for the use of protein-protein photocrosslinking with radiolabeled bait protein to identify the protein binding target.

the presence of a reducing agent (i.e., DTT or 2-mercaptoethanol). The crosslinked proteins are analyzed by SDS-PAGE electrophoresis (*UNIT 6.1*) followed by autoradiography (*UNIT 6.3*).

Generally, all endogenous surface cysteines of the bait protein are genetically altered to non-cysteine residues and a unique cysteine residue is inserted on the protein surface of interest for incorporation of the photocrosslinker. The protein is bacterially expressed to allow chromatographic purification of a large quantity of the protein sample. In this protocol, general procedures are provided for iodination and conjugation reactions with reagents and parameters specific for conjugating an example protein, purified yeast transcription factor TFIIB. Because the conditions for assembling multiprotein complexes differ greatly in various cases and must be optimized for each protein, a detailed description of a specific protein complex formation assay is not practical for the purpose of this protocol; therefore, only a procedure for photocrosslinking on a preassembled multiprotein complex is described. This procedure uses the PEAS-conjugated TFIIB, yeast nuclear extract, and DNA template immobilized on magnetic beads to form the RNA polymerase II pre-initiation complex (PIC; see Chen and Hahn, 2003). Even this procedure and the parameters listed below will require certain modifications for adaptation in specific cases because the properties of proteins and the biological contexts differ in various multiprotein complexes.

CAUTION: When working with radioactivity, take appropriate precautions to avoid contamination of the experimenter and the surroundings. Carry out the experiment and dispose of wastes in appropriately designated areas, following guidelines provided by the local radiation safety officer (also see *APPENDIX 1D*).

CAUTION: Use of the radioisotope ^{125}I requires appropriate shielding and special handling, including the use of a fume hood.

Materials

600 mM N-[(2-pyridyldithio)ethyl]-4-azidosalicylamide (PEAS) stock solution: prepare by dissolving the solid compound (Invitrogen) in DMSO; store up to 2 years at −70°C in an amber bottle
0.1 M sodium phosphate buffer, pH 7.4 (*APPENDIX 2A*)
Na^{125}I in NaOH solution, pH 8.0-12.0 (e.g., Amersham Biosciences, specific activity >0.6 TBq/mg iodide, 15 Ci/mg iodide)
50 mM tyrosine in water
7.5 μM purified yeast transcription factor TFIIB: pass the purified protein sample through a desalting column (Chen and Hahn, 2003) to remove the reducing agent in the purification buffer and elute in TFIIB conjugation buffer (see recipe)
TFIIB conjugation buffer
Dry Ice
Multiprotein complex: e.g., RNA polymerase II pre-initiation complex (PIC) on beads formed using the immobilized template assay (Chen and Hahn, 2003)
Acetate transcription buffer (see recipe)
Reducing agent: dithiothreitol or 2-mercaptoethanol

IODO-GEN precoated iodination tube (Pierce)
Desalting column: NAP-5 Sephadex G-25 column (Amersham Biosciences)
Scintillation counter for gamma counting
−70°C freezer
Magnet
UV irradiation device: ∼350-nm wavelength
Additional reagents and equipment for performing SDS-PAGE (*UNIT 6.1*) and autoradiography (*UNIT 6.3*)

Radiolabel photocrosslinker with ^{125}I

1. Pipet 1 µl PEAS stock solution (in DMSO) into 0.6 ml 0.1 M sodium phosphate (pH 7.4) buffer to a final concentration of 1 mM in a 1.5-ml microcentrifuge tube.

   Ideally, the entire experimental process from this point to photocrosslinking is conducted in the dark or reduced lighting to prevent activation of crosslinker with residual UV irradiation from laboratory fluorescent light. However, it has also been reported that there is no difference between results obtained from experiments performed under normal laboratory lighting and in the dark (Zecherle et al. 1992).

2. Pipet ~24 µl of $Na^{125}I$ (10 mCi; 3.8 nmole), 36 µl PEAS (36 nmole), and 0.1 M sodium phosphate buffer, pH 7.4 to a total volume of 90 µl in an IODO-GEN pre-coated iodination tube. Incubate the solution 10 min at room temperature.

   CAUTION: *The labeling experiment should be conducted inside a chemical fume hood to prevent any vaporized radioactive iodine from getting into the laboratory space.*

   The protocol provided here is designed to prepare ^{125}I-PEAS for conjugating with multiple protein samples with a combined total quantity of 18 nmole if the molar ratio of crosslinker to protein in the subsequent conjugation reaction is 2; therefore, the amounts of $Na^{125}I$ and PEAS should be adjusted according to the total quantity of protein samples.

   At pH above 7, ^{125}I remains as iodide ion in aqueous solution. The amount of ^{125}I used in this reaction is substoichiometric (1/10 of PEAS). Lower amounts (≤5 mCi) of ^{125}I may also be used with satisfactory results.

   The use of the IODO-GEN pre-coated tube is to supply iodous ions ($^{125}I^+$), which is generated by oxidation of iodide ($^{125}I^-$) by IODO-GEN iodination reagent. The iodous ion can subsequently undergo electrophilic attack at the ortho position of the phenyl ring of the crosslinker.

3. Transfer the iodination solution to a 1.5-ml microcentrifuge tube containing 4 µl of 50 mM tyrosine to quench the iodination reaction.

   The radiolabeled photocrosslinker ^{125}I-PEAS is now ready for subsequent conjugation with the protein sample or can be temporarily stored on ice before conjugation with protein. Tyrosine is used to scavenge the unincorporated iodide that can later react with certain aromatic residues (tyrosine or histidine) of proteins. The extent of iodination can be assessed by TLC chromatography analysis (Zecherle et al., 1992). Because the amount of ^{125}I is substoichiometric and the iodination reaction is rapid, ^{125}I is likely to be completely incorporated into PEAS. Therefore, the use of tyrosine is optional. The concentration of the resulting ^{125}I-PEAS is 400 µM (400 pmole/µl).

Conjugate radiolabeled photocrosslinker to bait protein

4. *Recommended:* Pass the purified bait protein through a desalting column to remove the reducing agent in the purification buffer and elute it in TFIIB conjugation buffer.

   Alternatively, dialyze the purified bait protein.

5. Pipet 15 µl of ^{125}I-PEAS (from step 3) and 400 µl of the bait protein in TFIIB conjugation buffer into a 1.5-ml microcentrifuge tube for conjugation. Incubate the reaction mixture 30 min on ice or at room temperature.

   Ideally, the conjugation buffer is the same as the buffer used for protein purification except that the reducing agent is omitted. Alternatively, the conjugation could also be the same as the reaction buffer used in assembling the multiprotein complex.

   The conjugation procedure is designed for conjugating 15 µl of the ^{125}I-PEAS (400 pmole/µl) to a protein sample (i.e., TFIIB; see above) with the concentration of 7.5 µM (7.5 pmole/µl) and the sample volume of 400 µl; therefore, the molar ratio of the radiolabeled crosslinker to the protein is 2 in the reaction mixture.

A conjugation reaction at a higher temperature and/or with a longer incubation can provide higher conjugation efficiency; however, certain proteins could be destabilized with elevated temperature and prolonged incubation. These two reaction parameters should therefore be adjusted to achieve optimal conjugation efficiency. Due to the subsequent step for removal of the unincorporated ^{125}I-PEAS using the NAP-5 desalting column, the maximum reaction volume is limited to the maximal sample volume (i.e., 500 μl) of the desalting column.

6. Transfer the conjugation mixture to a desalting column, which is pre-equilibrated with 10 ml TFIIB conjugation buffer.

7. Elute the modified bait protein from the desalting column with 1000 μl TFIIB conjugation buffer. Measure radioactivity of γ radiation of a 100-μl aliquot in a scintillation counter.

   The modified protein sample is expected to have a concentration of 3 μM based on the assumption of 100% recovery of the protein sample. The sample should have a radioactivity of ~1 mCi (specific radioactivity 0.33 μCi/pmole).

8. Pipet 10 μl of the eluted modified bait protein to each of two 1.5-ml microcentrifuge tubes.

   These two samples will be analyzed by SDS-PAGE electrophoresis in step 14 in the presence and absence of the reducing agent to assess the formation of the disulfide linkage between the crosslinker and the cysteinyl SH group of the protein.

9. Dispense 0.2-ml aliquots of the modified bait protein sample into microcentrifuge tubes and freeze the tubes on dry ice. Store up to 6 months at −70°C.

Assemble and crosslink protein complex

10. Add 2.4 μl of modified bait protein (the conjugated TFIIB in this example) to 100 μl PIC multiprotein complex on beads in a 1.5-ml microcentrifuge tube and incubate for 40 min.

    Because the conditions for assembling protein complexes vary greatly, specific parameters and reagents vary for the protein assembly assay. For forming the PIC, see Chen and Hahn, 2003. Other examples for assembling multiprotein complexes and photocrosslinking can be found in Cai et al. (2001) and Chen et al. (1994).

    It is important to note that the reaction buffer and protein samples should not contain any reducing agent to avoid cleavage of the disulfide linkage between the crosslinker and the bait protein before photocrosslinking. Generally, the amount of each protein in the reaction mixture ranges from 0.1 pmole to 1 nmole, and the total reaction volume ranges from 10 to 1000 μl; consequently, the protein concentration is 0.1 nM to 100 μM. Small reaction volumes could allow direct addition of the gel sample buffer for SDS-PAGE; in contrast, large volumes will require concentration of the proteins by methods such as affinity pull-down (UNIT 17.5) or TCA precipitation.

11. Place the sample tube on a magnet to precipitate the beads with bound PICs and remove the supernatant. Wash beads three times with 400 μl acetate transcription buffer, remove the supernatant, and resuspend beads in 100 μl acetate transcription buffer. Split the sample into two by pipetting one half of the sample into a new microcentrifuge tube.

    One of the samples will be used as a negative photocrosslinking control to which the UV irradiation is not applied.

12. Apply UV irradiation (~365 nm) to one of the samples from step 11 for 1 to 20 min to allow effective photolysis. Generally, place the sample tube at a distance of 5 to 10 cm from the irradiation source.

As reaction conditions and types of proteins samples vary, a survey for an effective photocrosslinking condition is required. Most of the common UV equipment can achieve maximal crosslinking within minutes. For the authors' photocrosslinking experiment, the optimal time length is 2 min with a UV lamp that provides an intensity of 21,700 μW/cm^2. Various equipment for UV irradiation have been used in the literature, including a hand-held UV lamp, a UV transilluminator, a Spectrolinker UV Crosslinker (Spectronics), and a Rayonet photochemical reactor (Southern New England Ultraviolet).

13. Place the sample tube on a magnet to precipitate the beads with bound PICs. Remove the supernatant.

Transfer radiolabeled photocrosslinker

14. Pipet 15 μl 1× SDS-PAGE sample buffer into the UV-irradiated sample and the negative control (the non-irradiated sample). For the UV-irradiated sample, include reducing agent (i.e., DTT or 2-mercaptoethanol) in the sample buffer to permit transfer of the radiolabeled crosslinker to the crosslinked protein.

The resulting samples can be frozen on dry ice and stored overnight at −70°C before SDS-PAGE.

15. Analyze photocrosslinking by SDS-PAGE (*UNIT 6.1*) on a 4% to 12% gel. After electrophoresis, dry gel and expose to autoradiography film or storage phosphor screen (Phosphorimager) for autoradiography (*UNIT 6.3*).

REAGENTS AND SOLUTIONS

Use deionized, distilled water or equivalent in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

A50 buffer

25 mM Tris·HCl, pH 7.5
50 mM KCl
5 mM $MgCl_2$
5% (v/v) glycerol
0.1% (v/v) Triton X-100
Autoclave and store up to several years at 4°C
Immediately before use add:
DTT to 1 mM
Phenylmethyhlsulfonyl fluoride (PMSF; see *APPENDIX 2A*) to 0.1 mM
Leupeptin (Roche or Calbiochem) to 1 μg/μl
Pepstatin (Roche or Calbiochem) to 1 μg/μl

Acetate transcription buffer, 5×

100 mM HEPES, pH 7.6
500 mM potassium acetate
5 mM EDTA
25 mM magnesium acetate
Store up to 2 years at −20°C
Dilute to 1× with H_2O just before use

Dialysis buffer

20 mM HEPES
10 mM Mg-acetate
20% (v/v) glycerol
1 mM EDTA
Adjust to pH 7.5 with 1 M KOH
Prepare fresh and cool to 4°C

continued

Immediately before use add:
DTT to 5 mM
PMSF (phenylmethylsulfonyl fluoride; see *APPENDIX 2A*) to 0.1 mM

Extract buffer

200 mM Tris·base
390 mM $(NH_4)_2SO_4$
10 mM Mg-acetate
20% (v/v) glycerol
1 mM EDTA
Titrate with acetic acid to pH 7.9
Autoclave and store up to several years at 4°C
Immediately before use add:
DTT to 1 mM
PMSF (phenylmethylsulfonyl fluoride; see *APPENDIX 2A*) to 0.1 mM
Leupeptin (Roche or Calbiochem) to 1 μg/μl
Pepstatin to (Roche or Calbiochem) 1 μg/μl

Glutathione-Sepharose immobilized proteins

Introduce open reading frames into plasmid pKM263 (Melcher, 2000; obtainable from EUROSCARF at *http://web.uni-frankfurt.de/fb15/mikro/euroscarf/*). Express the His6-GST-TEVcs tagged proteins in *E. coli* and purify by binding to glutathione-Sepharose using standard published protocols (e.g., Melcher, 2000). Store up to 2 weeks at 4°C.

Plasmid pKM263 is a pET vector (Novagen) derivative that contains the His6-GST-TEVcs composite tag. Open reading frames cloned into pKM263 will be expressed as His6-GST-TEVcs fusion proteins.

For expression in other organisms to allow in vivo assembly into complexes, amplify the tag-encoding region by PCR and clone into appropriate expression vectors in A50 buffer.

SDS sample buffer, 4×

130 mM Tris·Cl, pH 6.8
10% (w/v) SDS
0.5% (w/v) bromphenol blue
50% (v/v) glycerol
Store up to several years at 4°C
Immediately before use mix 4 volumes of this buffer with 1 volume of 2-mercaptoethanol.
For 2× SDS sample buffer: Dilute 4× SDS sample buffer (containing 2-mercaptoethanol) 1:1 with water.

Siliconized glass wool

Place small loose heap of glass wool (e.g., Riedel-deHaen, #18421) together with a beaker containing ~1 ml of 5% dimethyldichlorosilane in heptane (silanization solution I, Fluka) in desiccator. Briefly apply vacuum, then close connection to vacuum pump and allow silanization solution to completely evaporate and coat glass wool. Bake for 2 hr at 180°C. Store up to several years at room temperature.

TEV protease cleavage buffer

20 mM sodium phosphate, pH 7.3
50 mM NaCl
1 mM DTT
0.5 mM EDTA
Prepare fresh and cool to 4°C

TFIIB conjugation buffer

20 mM Tris·Cl, pH 7.8
300 mM potassium acetate
10 % (v/v) glycerol
Store up to 1 year at 4°C

This buffer is specifically used for conjugating the TFIIB protein.

YEPD medium

1% (w/v) yeast extract
2% (w/v) peptone
2% (w/v) glucose
Autoclave
Store up to 1 month at room temperature

COMMENTARY

Background Information

Early crosslinking methods employed diffusible, nonlocalized crosslinkers in combination with size separation of unlabeled adducts. This approach was, and still is, very useful for the analysis of interactions within low-complexity, typically heterodimeric or homomultimeric, complexes. The two protocols described in this unit are capable of extending the application of crosslinking to the identification of interacting polypeptide subunits in the context of highly complex multimeric assemblies because the methods incorporate bait-localized crosslinkers as well as labels or immunological reagents.

Critical Parameters

Basic Protocol 1

Controls. The authors routinely use two types of controls: one is used to confirm correct pull-down and crosslinking conditions, the other to confirm identity and composition of crosslinking adducts.

Controls to confirm pull-down and crosslinking reactions. To detect any potential bead loss during GST pull-down, it is advisable to fractionate part of each pull-down reaction by SDS-PAGE and stain the gel with Coomassie blue stain. The presence of higher-order crosslinking adducts (adducts that contain multiple subunits) on blots serves as control for successful crosslinking. This analysis is important to exclude any failure to detect direct bait-target adducts due to inefficient crosslinking. Where an interactor is already known for a given bait, blots with crosslinking reactions can also be reprobed with antibodies to the known interactor to confirm correct execution of the crosslinking protocol.

Controls to confirm identity and composition of crosslinking adducts. This control is a mock reaction, in which samples are treated without MMPP. Crosslinking adducts can then be identified as bands on immunoblots that are visible in the crosslinking reaction, but not in the mock reaction (compare Fig. 17.10.7 panels A and B). All crosslinking adducts should contain the immunologically detected protein and the tagged bait protein. In addition to absolute size, the presence of the bait protein can be confirmed by using differently sized variants of the bait (e.g., 60-kDa bait AD1 versus 70-kDa bait AD2 in Fig. 17.10.7A) and by TEV protease cleavage of crosslinking adducts (Fig. 17.10.6 and 17.10.7C). Both TEV protease cleavage and crosslinking with differently sized bait variants result in diagnostic mobility shifts.

The final control is the immunological analysis of supernatants after crosslinking. The presence of immunoblot bands in supernatants of crosslinking reactions, but not of mock reactions, would indicate complex destabilization during crosslinking. While the authors have not seen complex dissociation or rearrangement at the low levels of oxidizer recommended in the protocol, if they do happen they could artificially put proteins that under physiological conditions would not touch each other in direct contact and may therefore result in false positive interactions.

Choice of buffers. Crosslinking is quenched by oxidizable buffers like HEPES and PIPES, and oxidizable buffer additives, such as DTT and β-mercaptoethanol (Brown et al., 1995). Where possible, these substances should be avoided in all parts of the protocol. Otherwise, buffers have to be exchanged immediately prior to crosslinking. It is not recommended

to overcome the reducing power of buffer additives by simply increasing the concentration of the oxidizer MMPP because high concentrations of MMPP may destabilize protein complexes. Similarly, Ni-chelators such as EDTA should be avoided or removed prior to the addition of nickel acetate.

Amino acid compositions of bait and target proteins. As with conventional crosslinkers, chemical crosslinking efficiencies vary for different proteins. For instance, when crosslinking transcriptional activation domains to co-activator complexes, the authors have experienced higher crosslinking efficiencies for baits containing the activation domains of yeast Gal4p and Herpes simplex VP16 than for baits that contain the activation domain of a different, slightly less potent activator, yeast Gcn4p. Similarly, the Swi/Snf co-activator complex crosslinks less efficiently to Gal4- and VP16-containing baits than the TFIID and SAGA complexes (J. Klein, S. Hauptmann, and K. Melcher, unpub. observ.). A weak, but specific, crosslinking signal may therefore be just as meaningful as a strong signal, and lack of a crosslinking signal cannot be taken as evidence for lack of interaction.

Crosslinking of large proteins. Detection of crosslinking adducts depends on the electrophoretic separation of the free (monomeric) target protein from bait-target adducts. Target proteins that migrate at the exclusion limit of SDS-PAGE, such as the 435-kDa Tra1p subunit of the SAGA co-activator complex, can therefore not be analyzed by His6-mediated crosslinking in combination with immunoblotting.

Basic Protocol 2

Cysteine mutations. To avoid potential background crosslinker conjugation at unwanted positions, extensive mutagenesis of the bait protein is required to alter the endogenous cysteines to non-cysteine amino acids. However, it is not necessary to completely mutate all endogenous cysteines. The cysteine residues that are buried or involved in thiol-metal coordination are generally inert for crosslinker conjugation; thus, these non-reactive endogenous cysteines can be kept unchanged.

Selection of a suitable position in the bait protein for inserting the cysteine residue requires knowledge of the structure and function of the protein. Residues that are directly involved in binding target proteins are likely not suitable for cysteine mutation; in contrast, residues located near the interface of interaction are ideal for mutation. Frequently, the functionally important protein residues and surfaces can also be inferred from genetic studies.

Photocrosslinkers. PEAS photocrosslinker contains a flexible ethyl spacer group between the end-moieties pyridyldithio and azidosalicylamido groups to allow crosslinking within a diameter of ~14 Å from the Cα of the cysteine residue of the bait protein to the photoreactive atom (Chen et al., 1994). Another similar photocrosslinker, N-[4-(p-azidosalicylamido)butyl]-3′(2-pyridyldithio)propionamide (APDP; Pierce), contains a longer spacer group that can provide a larger crosslinking diameter of ~21 Å (Zecherle et al., 1992).

Choice of desalting columns. The choice of a desalting column for removing the unincorporated crosslinker from the modified protein sample is dependent on the properties of the proteins. An ideal desalting column should have relatively low affinity for the protein and small size to permit high recovery and minimal dilution of the resulting protein sample.

Efficiency of crosslinker conjugation. Although the formation of disulfide bonds can take place under mild conditions (4°C to 25°C) in a biological buffer, the conjugation efficiency is highly dependent on the structural location of the cysteine residue on the protein. If the unique cysteine is not completely exposed to react with the photocrosslinker, conjugation may require a longer incubation time to provide satisfactory efficiency. Raising the conjugation temperature or the photocrosslinker concentration could also achieve higher efficiency. However, conjugation with prolonged incubation, elevated temperature, or higher crosslinker concentration can result in inactive proteins, possibly caused by non-specific crosslinker-protein interactions that destabilize the protein. It is important to conduct several parallel experiments to determine an optimal reaction condition.

The disulfide bond formation between the crosslinker and the cysteinyl SH group of the bait protein is analyzed by SDS-PAGE in the presence of the reducing agent DTT or 2-mercaptoethanol. As the disulfide linkage is cleavable by the reducing agent, a complete loss of radioactivity is indicative of successful conjugation (see Fig. 17.10.9A). More accurate measurement of conjugation efficiency could be obtained through spectroscopic analysis (Zecherle et al., 1992) of the conjugation adduct.

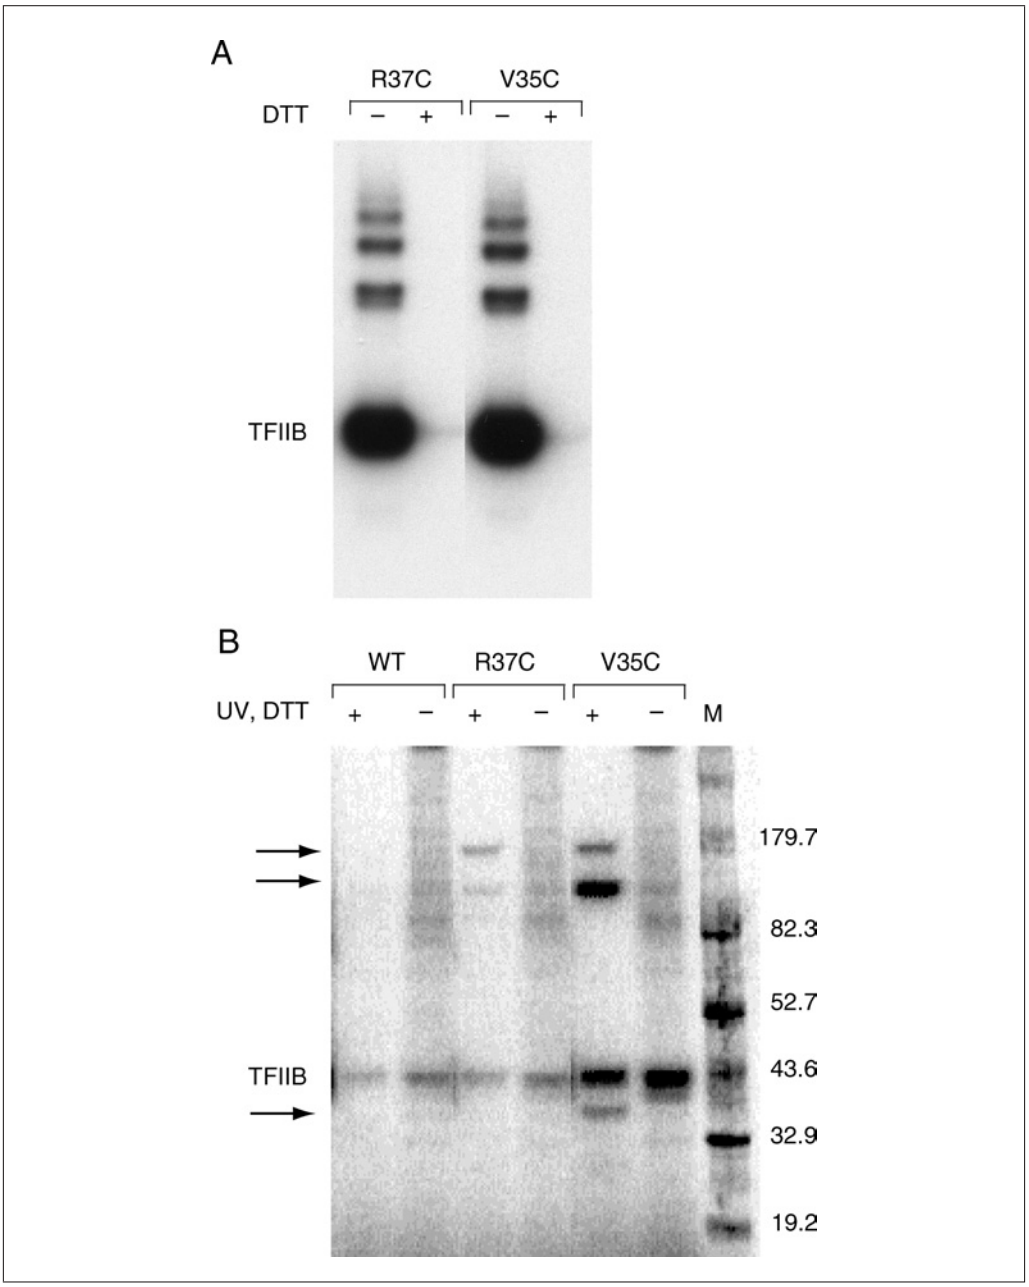

Figure 17.10.9 Autoradiograms of radiolabeled crosslinker conjugation and photocrosslinking products from TFIIB complexes. (**A**) Protein complexes formed using two TFIIB mutants (R37C and V35C) with surface cysteine residues conjugated to ^{125}I-PEAS and analyzed by SDS-PAGE electrophoresis in the presence (+) and absence (−) of DTT. A complete loss of radiolabeling of the modified protein sample in the presence of 50 mM DTT indicates cleavage of the disulfide linkage between the crosslinker and the inserted surface cysteine residue of the protein. Each lane contains 10 μl of protein sample from the conjugation reaction. (**B**) Protein complexes formed using two TFIIB mutants (R37C and V35C) with surface cysteine residues conjugated to ^{125}I-PEAS as well as a control protein (WT, wild type) without a surface cysteine in the formation of the polymerase II transcription pre-initiation complex (PIC). Photocrosslinking samples treated with UV irradiation and DTT are indicated by +. Arrows point to the crosslinked polypeptides. Lane M contains ^{14}C molecular weight markers.

Controls. Proper control experiments are critical for analyzing photocrosslinking, as the background radioactive signals, likely due to crosslinkings from non-specific interactions, are generally high. In addition to the negative control without UV-irradiation, it is necessary to conduct the same procedure for a non-cysteine mutant that contains no surface cysteine.

Because nonspecific interactions are unlikely to be avoided, additional measures can be employed to reduce the problem. One of the popular approaches is to engineer affinity tags to components involved in the complex assembly. The affinity tag permits application of the pull-down process with concomitant stringent washes to remove non-specific bindings, and thus allows purification of the complex assembly that retains mostly high-affinity specific bindings within the complex.

Identification of the crosslinker polypeptides

Identification of the crosslinking targets relies on determining the approximate molecular weight from the gel mobility of the radiolabeled crosslinked protein band on the autoradiogram. However, for a complex assembly that contains a large number of polypeptides with similar molecular weight, it becomes impossible to determine the identity of the targets with this method alone. Additional analyses such as immunostaining (Western analysis) of the SDS-PAGE resolved proteins or mass spectrometry (e.g., Cai et al., 2001) could be used to provide further information on the crosslinked proteins. Another effective method is to incorporate an epitope tag to individual polypeptide candidate and repeat the photocrosslinking experiment using the tagged polypeptide. The correct crosslinked candidate, therefore, can be determined based on the altered gel mobility of the crosslinked protein caused by the tag (Chen and Hahn, 2003).

Troubleshooting

See Table 17.10.1 for troubleshooting information for chemical crosslinking.

Anticipated Results

Figure 17.10.7 presents the results from the crosslinking of two immobilized transcriptional activation domain (AD) baits to complexes in extract. AD1 is the 34-amino acid core activation domain from yeast Gal4p; AD2 the 78-amino acid activation domain from Herpes simplex VP16. Reactions were separated by SDS-PAGE and probed by immunoblotting for the presence of Taf12, a shared subunit of the co-activator complexes SAGA and TFIID. The top blot of panel A shows that Taf12-containing complexes were specifically retained by both immobilized His6-GST-TEVcs-AD bait proteins (AD1 and AD2), but not by His6-GST-TEVcs alone. In the lanes containing the AD crosslinking reactions, three bands were detected by anti-Taf12 antibody: one corresponding in size to monomeric Taf12 (61 kDa), one corresponding to the expected sizes of the Taf12-(His6-GST-TEVcs-AD)$_2$ adducts (120 kDa for AD1 and 130 kDa for AD2), and one band that did not enter the gel corresponding to a high-molecular-weight complex.

Only the band corresponding in size to monomeric Taf12 was detected in the bead fraction of the mock reaction (Fig. 17.10.7B) indicating that the two other bands contained crosslinking adducts. Formation of the high-molecular-weight band is indicative of crosslinking to multiprotein complexes and thus can be taken as a crosslinking control. These bands are believed to result from higher-order crosslinks due to radicals that move through more than one protein in the complex. The size difference between AD1 and AD2 is reflected in the difference of mobilities of the AD1-Taf12 and AD2-Taf12 adducts and thus serves as an additional control for the correct assignment of crosslinking adducts.

The second, more generally applicable control for the presence of bait proteins in crosslinking adducts is the TEV protease digest shown in panel C. Incubation with TEV protease resulted in the disappearance of the presumed Taf12-(His6-GST-TEVcs-AD2)$_2$ adduct and the formation of two distinct new bands with mobilities corresponding to adducts with either one or both of the His6-GST tags cleaved (Fig. 17.10.7C).

The bottom blot in Figure 17.10.7A shows the same membrane after stripping and reincubation with an antibody against a different SAGA subunit, Ada2p. Ada2p was also retained by both ADs (pull-down lanes), consistent with Taf12 and Ada2p being subunits of the same intact complex. However, the same samples and same reactions that contained direct Taf12-AD adducts did not form bands of sizes corresponding to direct Ada2p-AD adducts, suggesting that the two ADs bound the SAGA complex without directly contacting Ada2p. Probing of multiple subunits in the same reaction ensures that

Table 17.10.1 Troubleshooting Guide for Chemical Crosslinking (Basic Protocol 1)

Problem	Possible Cause	Solution
Absent or weak crosslinking bands (including high-molecular-weight bands)	Inactive or insufficient MMPP (MMPP can be labile in certain environments)	Store MMPP under argon or nitrogen
		Increase concentration of MMPP
		Reduce amount of protein
	High concentrations of bait or target protein or MMPP may cause formation of multiple diffused crosslinking bands, rather than defined bands	Increase complexity of protein mixture to reduce unspecific interactions
		Increase concentration of salt or nonionic detergent
		Titrate MMPP concentration
	Amino acid composition of bait-target interaction surface may not support crosslinking	Analyze interaction by different crosslinking chemistry; test crosslinking efficiency by Coomassie-staining gel with His6-GST-TEVcs tag control. If a His6-GST-TEVcs tag dimer fails to become visible after crosslinking, check possible causes above.
Very high concentration of MMPP or Ni^{2+} required	Inactive MMPP	Store MMPP under argon or nitrogen
	Presence of oxidizable buffer components or additives; presence of Ni chelators	Omit reductants and chelators or exchange buffers prior to crosslinking by multiple washes
Nonspecific crosslinking	Artificial interactions due to high local concentrations of bait and target subunits upon complex destabilization	Titrate MMPP concentration
		Include stabilizers such as glycerol
		Reduce MMPP and/or Ni^{2+} incubation times

differences in the formation of crosslinking adducts are not due to differences in crosslinking conditions. Unspecific antibody cross-reactivity could be essentially excluded by detecting Taf12-HA in crosslinking adducts by both anti-Taf12 antibodies (Fig. 17.10.7A and 17.10.7B) as well as anti-HA antibodies (Fig. 17.10.7C).

Figure 17.10.7B contains an anti-Taf12 blot with supernatants of mock and crosslinking reactions. The absence of Taf12 in the supernatant of the mock reaction indicates that interaction between Taf12-containing complexes and the immobilized AD baits was stable during the course of the experiment. Finally, the absence of target complex subunits in crosslinking reactions suggests that complex integrity was not affected by MMPP treatment and that Taf12-AD adducts were not formed upon artificial contacts due to Taf12 dissociation, rather than by specific TAF12-AD interaction.

Another example is from a photocrosslinking study to identify binding targets for the general transcription factor TFIIB within the yeast (*Saccharomyces cerevisiae*) RNA polymerase II (Pol II) transcription pre-initiation complex (PIC; similar to the closed complex in the bacterial RNA polymerase transcription initiation) on a yeast promoter (Chen and Hahn, 2003). Individually, this tightly regulated transient complex is assembled at the promoter region of a Pol II-specific gene in the nucleus of a eukaryotic cell and is poised to start mRNA synthesis upon the supply of nucleotides.

In the crosslinker-protein conjugation experiment, individual recombinant TFIIB

cysteine mutants were conjugated with ^{125}I-PEAS to generate the modified bait proteins, which were analyzed by SDS-PAGE in the presence and absence of DTT to provide evidence of disulfide bond formation between the crosslinker and the protein. This analysis is illustrated in Figure 17.10.9A in which a complete loss of radiolabeling (^{125}I-crosslinker) occurred in the presence of the reducing agent, DTT.

In the multiprotein assembly assay, referred to as the immobilized template assay, 240 μg yeast nuclear extract (containing all essential transcription factors and Pol II), 120 ng (3 pmole) modified TFIIB from ^{125}I-PEAS conjugation, and 1.1 pmole promoter DNA (PCR-generated 595-bp DNA containing the yeast *HIS4* promoter) attached to magnetic beads were used to assemble the PIC in solution. After stringent washes to remove excess proteins, UV-irradiation was applied to the complex to permit crosslinking between the crosslinker and the nearest polypeptides, i.e., the TFIIB binding targets. From a parallel experiment, the amount of TFIIB assembled into the PIC was estimated to be 0.15 pmole based on the immunoblot analysis.

As demonstrated in Figure 17.10.9B from a photocrosslinking experiment of the Pol II immobilized template assay, the crosslinked proteins, which appear as radioactive gel bands, can easily be distinguished by comparing with bands from the negative controls. Generally, a dried SDS-PAGE gel with 10 samples produces approximately 1000 cpm with gamma counting. The autoradiogram was obtained from 2-day exposure to a Phosphorimager storage phosphor screen.

Time Considerations

After initial optimization, Basic Protocol 1 can be completed within 3 days. On the first day extracts are prepared and dialyzed and may be stored at −80°C for several months. Pull-downs (about 3 hr), crosslinking (1 hr), TEV protease cleavage (1 hr), and SDS-PAGE (2 to 3 hr) can all be completed on the same day. Blotting of proteins can be done either the same day (semi-dry blotting, about 1 hr) or over night (tank blotting). On the final day membranes are blocked (about 2 hr or overnight), incubated with primary and secondary antibodies (4 to 8 hr including wash steps), and incubated with detection solution and exposed (30 min to 2 hr).

The procedure for conjugation of the photocrosslinker can be finished within 1 day, and the modified protein sample can be stored for later use. The protein complex formation assay and photocrosslinking can be conducted in 1 day. After SDS-PAGE, it requires overnight or up to a week exposure to a storage phosphor screen to generate a high-intensity autoradiogram. The length of exposure is dependent on the efficiency of crosslinker conjugation and the yield of photocrosslinking.

Visualization of RNA Using Fluorescence Complementation Triggered by Aptamer-Protein Interactions (RFAP) in Live Bacterial Cells

Maria Valencia-Burton[1] and Natalia E. Broude[1]

[1]Center for Advanced Biotechnology, College of Engineering, Department of Biomedical Engineering, Boston University,Boston, Massachusetts

ABSTRACT

This unit describes a method allowing RNA visualization in live cells. The method is based on fluorescent protein complementation regulated by RNA-aptamer/RNA-binding protein interactions. Based on these two principles, a fluorescent ribonucleoprotein complex is assembled inside the cell only in response to the presence of the aptamer sequence on the target RNA. *Curr. Protoc. Cell Biol.* 37:17.11.1-17.11.20. © 2007 by John Wiley & Sons, Inc.

Keywords: protein complementation • aptamer-protein interactions • RNA localization • fluorescent proteins • eukaryotic initiation factor 4A • bacterial cells

INTRODUCTION

RNA is an indispensable, multifunctional molecule that acts as a key player in the complex and tightly regulated process of gene expression. In eukaryotic cells, gene expression includes synthesis and processing of RNA within the nucleus, export from the nucleus, transport through the cytoplasm, and translation within ribosomes. Additionally, an ever-growing class of noncoding RNA molecules participate in a variety of post-transcriptional and post-translational events that take place in different cellular compartments. Noncoding RNAs play a role in editing and modifications of other RNAs as well as in RNA quality control, DNA methylation, and protein modifications (Kiss, 2002, Mattick, 2003; Huttenhofer et al., 2005). To perform these multiple roles, RNA must be present in the right place at the right time. Thus, spatial and temporal localization of RNA molecules within the cell has emerged as an important mechanism in cell biology. It has been realized that localization of RNA not only regulates protein synthesis, but also creates a gradient of morphogens and determines formation of organelles and cell lineages (for review, see Kloc et al., 2002).

The unstable nature of RNA on the one hand and its complex functions linked to its dynamic behavior on the other has generated great interest, and has also posed a challenge for many scientists. Despite the difficulties in studying RNA in vivo, the last decade has yielded much information about mechanisms of RNA localization, functional ribonucleoprotein complex formation, and the movements of such complexes within the cell (see Anderson and Kedersha, 2006; Czaplinski and Singer, 2006, for reviews). The vast majority of these new data have been acquired using fluorescent methods of RNA labeling.

This unit describes a new method for in vivo RNA visualization, which is based on two principles: fluorescent protein complementation and interaction of an RNA-binding

Current Protocols in Cell Biology 17.11.1-17.11.20, December 2007

protein with its interacting sequence, an RNA aptamer. Based on these two principles, a fluorescent ribonucleoprotein complex is assembled inside the cell only in response to the presence of the aptamer sequence on the RNA of interest (target RNA). In the absence of target RNA, cell fluorescence is very low. In this approach, the RNA-binding protein is the eukaryotic initiation factor 4A (eIF4A), consisting of two globular domains. The eIF4A protein is dissected into two fragments, which are separately fused with two inactive fragments of a marker protein, the enhanced green fluorescent protein (EGFP). Simultaneous binding of the eIF4A fragments to an RNA aptamer inserted into a target RNA brings the two inactive fragments of EGFP in close proximity, and results in the reassembly of the functional protein, reconstitution of fluorescence, and detection of the RNA of interest (Fig. 17.11.1). Using this approach, we visualized an aptamer-tagged noncoding RNA, an mRNA, and 5S ribosomal RNA in bacteria. As a result, we observed distinct localization patterns reflecting the nature of each transcript (Valencia-Burton et al., 2007).

This unit contains three basic protocols which describe key steps for the labeling of any RNA in bacteria. First, the three components of the complementation complex are cloned into appropriate prokaryotic expression vectors (Basic Protocol 1). Second, the constructs are transformed and coexpressed in bacteria (Basic Protocol 2), and, finally, fluorescence is analyzed by flow cytometry (Basic Protocol 3) and/or microscopy (Basic Protocol 4).

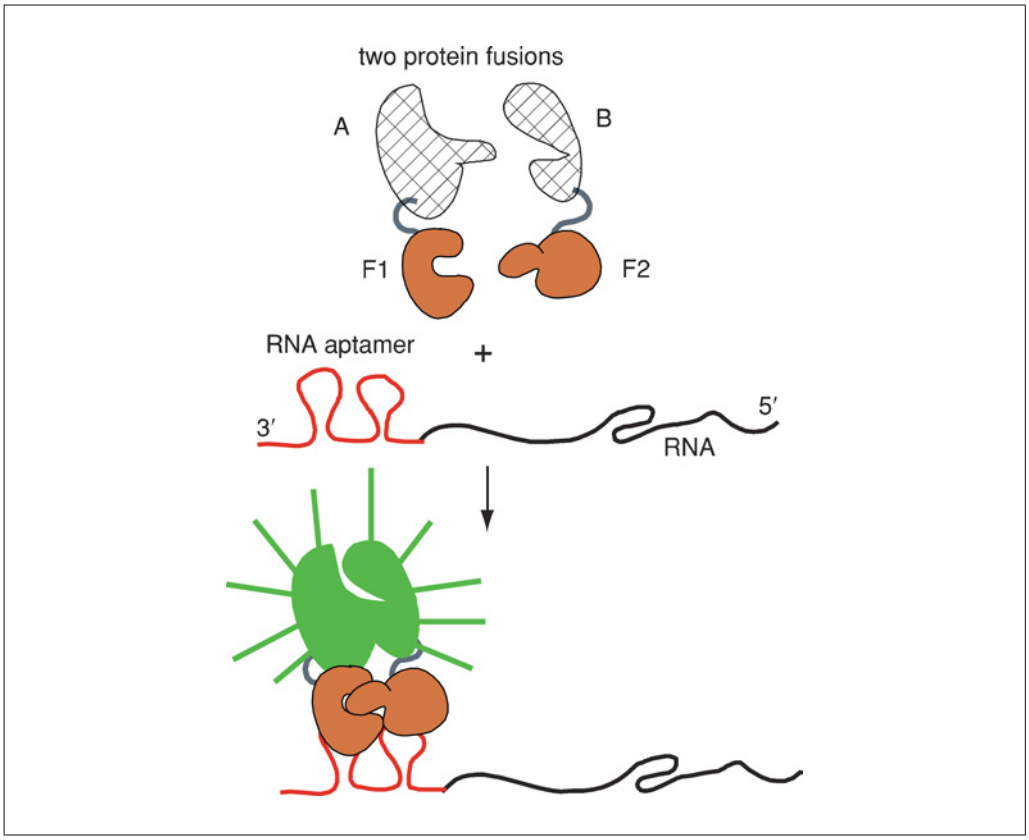

Figure 17.11.1 Diagram of RFAP assay for localization and detection of RNA in vivo. Two fragments (A and B) of the enhanced green fluorescent protein (EGFP) are fused to two fragments (F1 and F2) of eukaryotic initiation factor 4A (eIF4A), an RNA-binding protein. These protein fusions are coexpressed in the presence of an RNA target modified with eIF4A-interactive aptamer sequence inserted into the 3′ UTR of the gene. Binding of F1 and F2 fragments of eIF4A to the aptamer motif brings the EGFP fragments in close proximity to reconstitute a functional fluorescent protein. This RNP complex generates a signal that can be used to track RNA in real time.

DESIGN AND CLONING OF DNA CONTRUCTS FOR THE EXPRESSION OF PROTEIN AND RNA COMPONENTS OF THE COMPLEMENTATION COMPLEX

This protocol describes the design and cloning of two interacting protein fusions and target RNA tagged with the aptamer. The first protein component consists of a C-terminal fusion of amino acids 1 to 158 of EGFP (A), with the N-terminal fragment of eIF4A comprising the first 215 amino acids (F1). These fragments are separated by a 10-amino-acid flexible linker to aid in the refolding of the fragments and reconstitution of fluorescence upon RNA interaction. The second interacting protein fusion similarly consists of amino acids 159 to 238 of EGFP (B) fused at the C-terminus of eIF4A, with amino acids 216 to 406 (F2) connected via a 10-amino-acid-long flexible linker (Fig. 17.11.2). Both fusions are cloned into a vector designed for the coexpression of two genes, e.g., the Duet vector series from Novagen. The target RNA is modified to include a 58-nucleotide-long aptamer sequence with high affinity for eIF4A. The binding of F1 and F2 fragments of eIF4A in the presence of the aptamer sequence brings together the inactive EGFP fragments, generating a fluorescence signal that can be used to track RNA in live cells. To clone these components of the complementation complex, we have used both conventional and nonconventional techniques.

Materials

ThermoPol reaction buffer (New England Biolabs)
10 mM dNTP solution (containing all four dNTPs; see *APPENDIX 3F*, but prepare at 10 mM)
10 mM primers (see Table 17.11.1)
EGFP template: DNA encoding EGFP (Clontech)
Vent exo$^-$ DNA polymerase (New England Biolabs)
eIF4AI template: DNA encoding mouse eIF4AI (plasmid pGEX-4AI; available from Chris Proud, University of Dundee, U.K., *c.g.proud@dundee.ac.uk*)
1% agarose gel (Voytas, 2000)
PCR purification kit (QIAquick PCR Purification Kit, Qiagen)
Appropriate restriction enzymes (*Nco*I, *Bam*HI, *Sal*I, *Not*I, *Dpn*I, *Xbo*I, *Xho*I; New England Biolabs)
DNA purification kit (QIAprep Spin Miniprep Kit, Qiagen)
Cloning vectors: pACYCDuet 1 or pETDuet-1 (Novagen)
T4 DNA ligase and 10× buffer
Competent *E. coli* cells (also see Seidman et al., 1997): e.g., XL-10 (Stratagene), DH5αPRO (Clontech)
LB plates and liquid medium (*APPENDIX 2A*) containing appropriate antibiotic
Thermostable DNA polymerase appropriate for amplifying long templates (e.g., DNA polymerase from Expand Long Template PCR System; Roche Diagnostics) and corresponding 10× buffer
Pfu Turbo DNA Polymerase (Stratagene) and corresponding 10× buffer

Thermal cycler
16° and 65°C water baths

Additional reagents and equipment for agarose gel electrophoresis (Voytas, 2000), transformation of *E. coli* (Seidman et al., 1997), DNA miniprep from bacteria by alkaline lysis (Wilson, 2001), and gel purification of DNA (Moore et al., 2002)

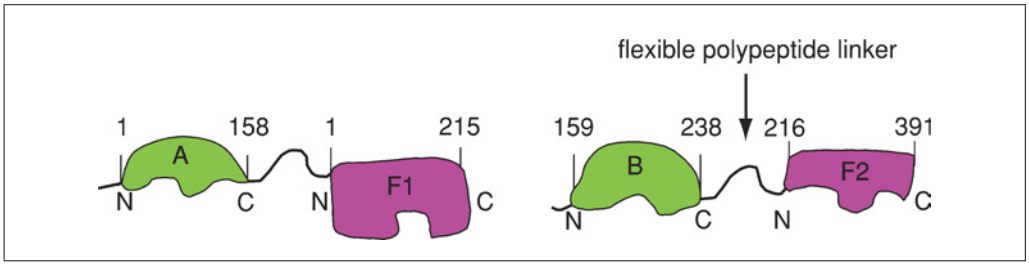

Figure 17.11.2 Schematics of the design of RNA-interacting protein fusions. Carboxy-terminal fusions of EGFP fragments to eIF4A fragments were made with an intervening linker sequence of 10 amino acid residues.

Table 17.11.1 Primers for Amplifying Gene Fragments for Cloning

Primers	Sequence (5′ to 3′)[a]
GFP-A1	CCCGACCATGGTGAGCAAGGGCGAGGAGCTGTTC
GFP-A2	CCCGAGGATCCCTGCTTGTCGGCCATGATATAGAC
GFP-B1	CCCGACCATGGGCAAGAACGGCATCAAGGTGAAC
GFP-B2	CCGAGGATCCCTTGTACAGCTCGTCCATGCCGA
eIF4A-F1-1	CCCGAGTCGACATGGAGCCGGAAGGCGTCATCGA
eIF4A-F1-2	CGAGCGGCCGCTCAAGGGTCTCTCATAAATTTCTT
eIF4A-F2-1	CCCGAGTCGACATTCGGATTCTTGTCAAGAAGGAAG
eIF4A-F2-2	CGAGCGGCCGCTCAAATGAGGTCAGCAACGTTGAG

[a]Underlined bases correspond to restriction enzyme sites used for cloning into appropriate vectors.

Clone EGFP fragments A and B and eIF4A fragments F1 and F2 into prokaryotic expression vectors

In the steps below, each protein fragment is amplified by PCR and cloned separately into either pACYCDuet-1 or pETDuet-1 vectors. Fragments A and F1 and fragments B and F2 are cloned in the same vector but at different sites (Fig. 17.11.3) so that a fusion of these fragments can be accomplished later on using the method of Vasl et al. (2004).

1. In a sterile microcentrifuge tube, mix the following, starting with distilled water and then proceeding in the order below:

   5 µl 10× ThermoPol reaction buffer
   1 µl 10 mM dNTPs
   1 µl 10 µM primer GFP-A1
   1 µl 10 µM primer GFP-A2
   1 µl (10 to 50 ng) EGFP DNA template
   1 µl (1 U) Vent exo$^-$ DNA polymerase
   H_2O to 50 µl final.

   This reaction will amplify the A fragment of EGFP.

2. Set up another reaction as above, but this time using primers GFP-B1 and GFP-B2.

   This will amplify the B fragment of EGFP.

3. Set up two more reactions identical to that in step 1, but replace the template for EGFP with a DNA template encoding the eIF4AI gene and use a combination of primers eIF4A-F1-1 and eIF4A-F1-2 in one reaction for amplifying the F1 domain of eIF4AI and a combination of primers eIF4A-F2-1 and eIF4A-F2-2 in the other reaction for amplifying the F2 domain of eIF4AI.

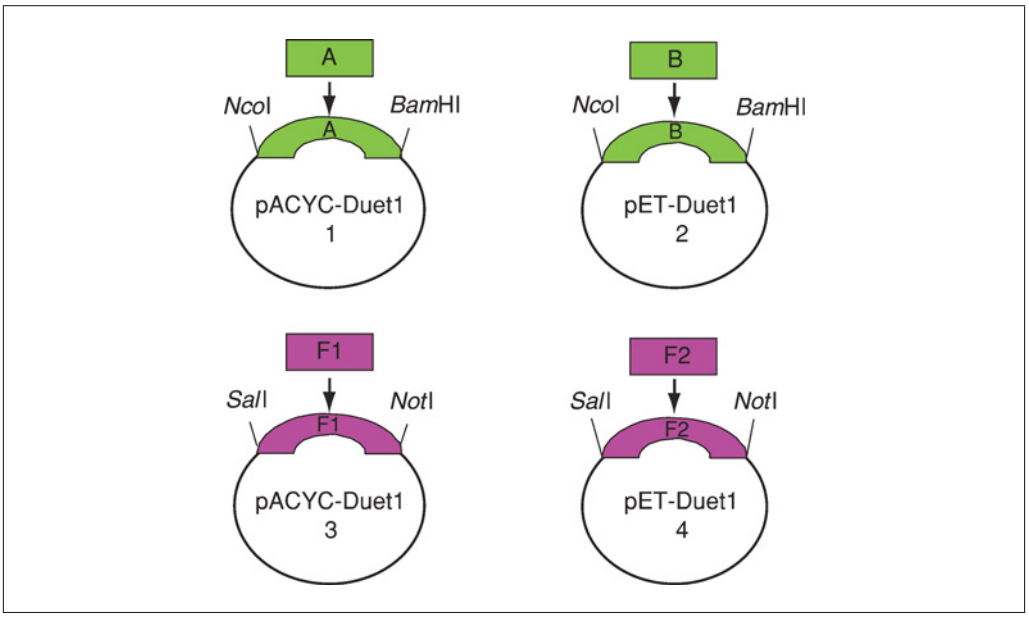

Figure 17.11.3 Step-wise cloning of EGFP and eIF4A fragments into prokaryotic expression vectors. Each fragment is PCR-amplified and cloned into two different vectors used for the co-expression of one or more genes in bacteria. The A and F1 fragments are cloned between *Nco*I-*BamH*I and *Sal*I-*Not*I sites of pACYCDuet-1, respectively. Fragments B and F2 are cloned in a similar manner, but in vector pETDuet-1. These constructs are later used in the fusion of these fragments as in Basic Protocol 1 (also see Figure 17.11.4).

4. Perform PCR on each of the reaction mixes to amplify the respective fragment, in a thermal cycler using the following reaction conditions:

1 cycle:	1 min	95°C	(initial denaturation)
	30 sec	95°C	(denaturation)
	30 sec	52°C	(annealing)
	1 min	72°C	(extension)
25 to 30 cycles:	30 sec	95°C	(denaturation)
	30 sec	52°C	(annealing)
	1 min	72°C	(extension)
1 cycle:	5 min	72°C	(final extension)
	indefinite	4°C	(hold).

5. Remove an aliquot (3 to 5 μl) from each reaction mixture and analyze it by electrophoresis on a 1% agarose gel (Voytas, 2000).

   A successful PCR should produce a clearly visible band of the expected size: e.g., ~470 bp for fragment A; ~290 bp for B; ~650 bp for F1; and ~530 bp for F2.

6. Clean up each of the amplified products using a PCR purification kit according to the manufacturer's instructions.

7. Set up restriction enzyme digest reactions of the PCR products and the cloning vector plasmids, as directed by the supplier. Digest fragment A and cloning vector pACYCDuet-1 with restriction enzymes *Nco*I and *Bam*HI as outlined in Fig. 17.11.3. Similarly, cut fragment B and plasmid pETDuet-1 with *Nco*I and *Bam H*I. Cut fragments F1 and F2 with *Sal*I and *Not*I to be cloned into pACYC and pET vectors, respectively, that have also been digested with *Sal*I and *Not*I enzymes.

8. Clean up the products of the digest reactions using a DNA purification protocol or kit, e.g., using the PCR purification kit from Qiagen.

   We recommend treating the cut vectors with a phosphatase to increase the efficiency of cloning, and then gel purifying the treated vectors to remove traces of the enzyme.

9. Ligate each fragment with its corresponding plasmid vector as outlined in Figure 17.11.3, setting up a ligation reaction in a microcentrifuge tube as follows:

   50 to 100 ng cut/dephosphorylated vector
   200 to 300 ng amplified DNA
   1× ligase buffer (added from 10× buffer)
   1 U T4 DNA ligase
   H_2O to 20 μl final.

   As a control, set up a reaction that contains all of the reagents except for the amplified DNA.

10. Incubate the ligation mixture for 4 hr at 16°C.

11. Use 1 to 4 μl of the ligation mixture to transform chemically competent *E. coli* cells (Seidman et al., 1997). Plate the transformed cultures on LB plates supplemented with 34 μg/ml chloramphenicol for ligations with the pACYC vector and 100 μg/ml ampicillin for ligations with the pET vector. As a control, transform *E. coli* cells with the self-ligated vector.

12. Pick several recombinant colonies and grow cultures in liquid LB medium supplemented with the appropriate antibiotic. Confirm the presence of the cloned fragment by restriction enzyme digest and/or PCR. Perform DNA minipreps (Wilson, 1997, or use QIAprep Spin Miniprep Kit) to obtain the plasmids containing each fragment, to be used later in step 14.

Prepare A-F1 and B-F2 fusions with a flexible polypeptide linker

This method describes the generation of chimeric genes without the need for subcloning (Vasl et al., 2004). For this approach to work, it is critical that the genes to be fused be cloned in the same or in a related vector. Next, two phosphorylated primers are designed, with one placed at the end of one gene and the second placed at the beginning of the other gene. These primers have opposite orientations and their 5′ ends are at the site of junction between both genes (Fig. 17.11.4). A linker sequence is added to the 5′ end of the primer, and each plasmid is cleaved at a site near the 5′ end of each primer. This creates linear templates with homologous sequences that can be annealed during PCR and then extended to a final length. The designed primers help in the amplification of this new DNA molecule. Template plasmids are removed by treatment with the enzyme *Dpn*I, and the new plasmid is circularized via blunt-end ligation.

13. Design two types of 5′-phosphorylated primers as follows:

    a. A reverse primer containing the sequence encoding the amino acids GSSGSS and the *last* 20 to 22 bp of the A or B fragment (primers Chimeric-P1 and Chimeric-P3, Table 17.11.2).

    b. A forward primer containing the sequence encoding amino acids GSGS and the *first* 20 to 22 bp of the F1 or F2 fragments (primers Chimeric-P2 and Chimeric-P4, Table 17.11.2).

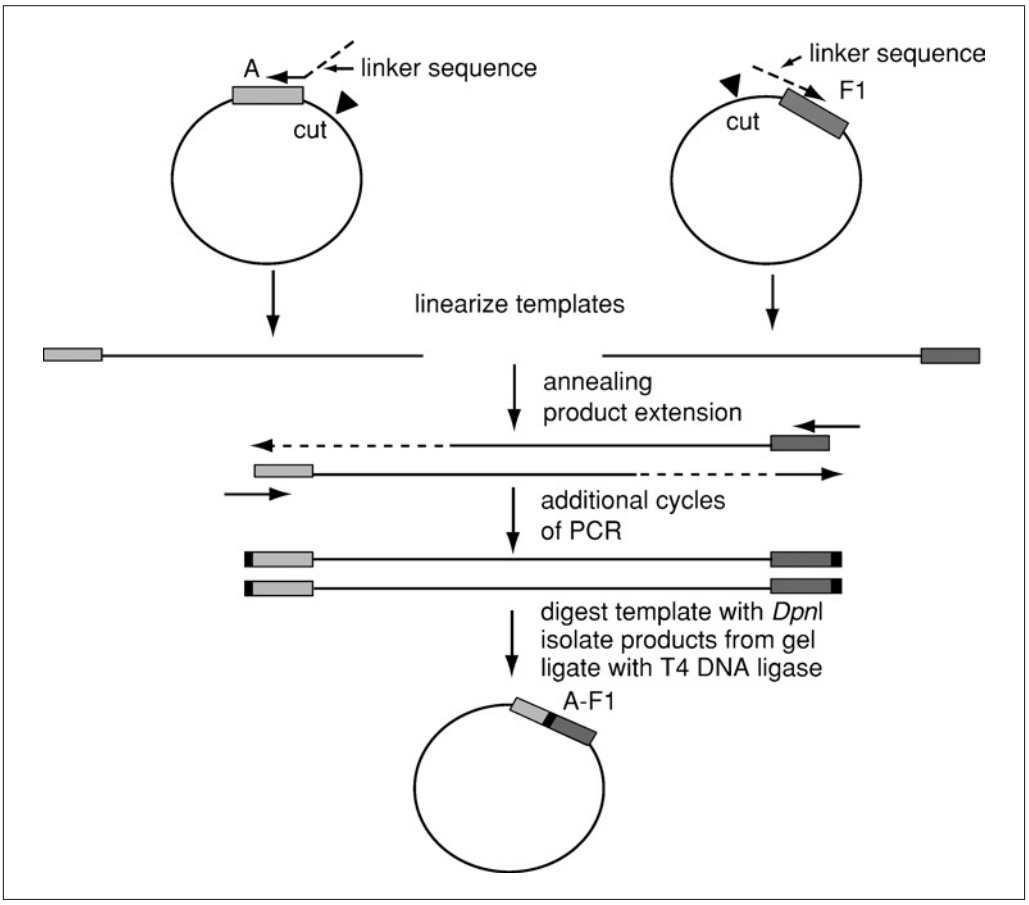

Figure 17.11.4 Outline of the procedure followed to create A-F1 and B-F2 fusions without the need for subcloning (Vasl et al., 2004). This procedure consists of four basic steps: (1) linearization of template plasmids using different restriction enzymes; (2) PCR using linearized templates and phosphorylated primers; (3) isolation of product and removal of template plasmids; (4) ligation and transformation of product into competent *E. coli* cells.

Table 17.11.2 Primer Sequences for Creating Gene Fusions Separated by a Polypeptide Linker

Primers	Sequence (5′ to 3′)[a,b]
Chimeric-P1	pCGAAGATCCAGAGGATCC*CTGCTTGTCGGCCATGATATAG*
Chimeric-P2	pGGTTCTGGTAGC*ATGGAGCCGGAAGGCGTCATCGA*
Chimeric-P3	pCGAAGATCCAGAGGATCC*CTTGTACAGCTCGTCCATGCC*
Chimeric-P4	pGGTTCTGGTAGC*ATTCGGATTCTTGTCAAGAAGGA*

[a]In primers Chimeric-P1 and Chimeric-P3, sequences in italics correspond to sequences complementary to the last 20 bp of the A and B gene, respectively. In primers Chimeric-P2 and Chimeric-P4, sequences in italics correspond to the first 20 bp of F1 and F2 genes, respectively. The rest of the sequence corresponds to the complementary sequence encoding GSSGSS in primers Chimeric-P1 and Chimeric-P3, and homologous sequences encoding the amino acid stretch GSGS in primers Chimeric-P2 and Chimeric-P4.
[b]The letter "p" represents the 5′ phosphate.

14. Linearize the plasmids carrying the fragments to be fused (step 12) with a restriction enzyme that cuts 5′ with respect to the site where the primers anneal (Fig. 17.11.4).

15. After digestion, heat-inactivate the restriction enzyme by incubating at 65°C for 20 min, and take 1 to 2 µl for use in the next PCR.

16. Set up the following PCR:

    10 µl 10× thermostable DNA polymerase buffer
    2 µl 10 mM dNTPs
    2 µl 10 µM primer Chimeric-P1
    10 µM primer Chimeric-P2
    100 ng linearized plasmid 1
    100 ng linearized plasmid 2
    1 µl (1 U) Expand Long Template DNA polymerase
    H_2O to 100 µl final.

    For this reaction, we recommend the use of a thermostable DNA polymerase that can efficiently and accurately amplify long templates, e.g., DNA polymerase from the Long Template PCR kit (Roche Diagnostics).

17. Amplify the fragments in a thermal cycler using the following reaction conditions:

1 cycle:	3 min	94°C	(initial denaturation)
	1 min	94°C	(denaturation)
	30 sec	60°C	(annealing)
	10 min	68°C	(extension)
30 cycles:	1 min	94°C	(denaturation)
	30 sec	60°C	(annealing)
	10 min	68°C	(extension)
	11 min	68°C	(final extension)
	indefinite	4°C	(hold).

18. Add 10 U of *Dpn*I to the PCR mixture and incubate the reaction at 37°C for 3 hr to remove any methylated template DNA.

19. Remove an aliquot (3 to 5 µl) from the reaction mixture and analyze it by electrophoresis on a 1% agarose gel (Voytas, 2000).

    The size of the expected product band corresponds to the size of the vector plus the size of the fused fragments.

20. Gel purify this product (Moore et al., 2002) and circularize it via the 5′ phosphorylated ends by setting up a DNA ligase reaction as in step 9.

21. Use 2 to 4 µl of the circularized product to transform chemically competent *E. coli* cells (Seidman et al., 1997). Perform a DNA miniprep (Wilson, 1997) on the recombinant colonies to obtain the plasmids containing A-F1 or B-F2 to be used in step 23. Screen the plasmids by restriction enzyme digest and PCR. Confirm by sequencing.

Clone B-F2 fragment in the same plasmid containing A-F1 by PCR-mediated integration (Geiser et al., 2001)

22. Design primers to amplify a B-F2 fragment with 20- to 25-bp vector flanking sequences (Table 17.11.3).

    Flanking sequences correspond to the second multiple cloning site (MCS) of the pACYC vector backbone. Sequences were chosen so that B-F2 will be integrated between the NdeI and XhoI sites of pACYC.

23. Set up a PCR as in step 1 to 4 using the primers designed in step 22 and a plasmid containing B-F2 sequences (generated in steps 13 to 21). Analyze and purify PCR product from this reaction as in steps 5 to 6.

Table 17.11.3 Primer Sequences to Amplify B-F2 Fragment

Primers	Sequence (5′ to 3′)[a]
20-Beta*Nde*I	*GTATAAGAAGGAGATATACATATG*GCAGATCTCAAGAACGGCATCAAG
F2*Xho*I	CCAGACTCGAGGGTACCGACTCAAATGAGGTCAGCAACGTTGAG

[a]Sequences in italics correspond to vector sequences. The rest of the sequence is gene-specific B-F2 sequence.

24. Take 200 to 300 ng of this amplified product and 50 to 100 ng of the recipient vector and set up the following amplification reaction:

    5 µl 10× thermostable DNA polymerase buffer
    1 µl 10 mM dNTPs
    300 ng amplified product (step 23)
    100 ng recipient vector containing A-F1 (from step 21)
    1 µl (1 U) *Pfu* Turbo DNA polymerase
    H_2O to 50 µl final.

    The amplified product serves as the primer for polymerization of the entire plasmid and fragment sequence.

25. Amplify the new plasmid in a thermal cycler using the following reaction conditions:

1 cycle:	30 sec	95°C	(initial denaturation)
	30 sec	95°C	(denaturation)
	30 sec	55°C	(annealing)
	2 min/kb recipient DNA	68°C	(extension)
18 cycles:	30 sec	95°C	(denaturation)
	30 sec	55°C	(annealing)
	2 min/kb recipient DNA	68°C	(extension)
	indefinitely	4°C	(hold).

26. Add 10 U of *Dpn*I and incubate the reaction at 37°C for 3 hr to remove any methylated/template plasmid.

27. Clean up the amplified product by using a DNA purification kit or protocol (e.g., Q1A quick PCR purification Kit).

28. Use 3 to 6 µl of the amplified and purified plasmid to transform chemically competent *E. coli* cells (Seidman et al., 1997).

29. Perform DNA minipreps (Wilson, 1997) of the recombinant colonies or transformants. Analyze the DNA by restriction digest or PCR.

    The correct plasmid should contain both A-F1 and B-F2 sequences. The new plasmid will be used for the coexpression of proteins and RNA in Basic Protocol 2, step 1.

Preparation of a target gene modified with an aptamer sequence

To label RNA in vivo, the target gene is modified at the 3′ end by inserting the eIF4A aptamer recognition sequence. Tagging of the gene at the 3′ end has proven to be more advantageous, since it does not seem to interfere with the level of gene expression (M. Valencia-Burton, unpub. observ.) and RNA localization and dynamics in the cell (Bertrand et al., 1998; Beach et al., 1999; Corral-Debrinski et al., 2000; Beach and Bloom, 2001). If the RNA target contains a 3′ UTR sequence that is essential for localization of the message, we recommend cloning this sequence right after the aptamer tag (see Critical Parameters). The eIF4A aptamer consists of a 58-nucleotide-long sequence (Oguro et al.,

Table 17.11.4 Primer Sequences for Amplifying Aptamer

Primers	Sequence (5′ to 3′)[a]
IF4Aapt 30-R	p*GCCTCACTCACATGTGGGGCGCGGTCCCCTG*TCTAGAGGGGAATTGTTATCCGCTCAC (reverse)
IF4Aapt 30-F	p*CGAAACGTAGATTCGACAGGAGGCTCACAAC*CCTAGGCTGCTGCCACCGCTGAG (forward)
pET-*Bcl*I	CCAGCGGATAGTTAATGATAGCCCAC (forward)
pET-*Bgl*II	GCGCTCGGCCCTTCCGGCTG (reverse)

[a]Sequences in italics correspond to half of the aptamer sequence (primers IF4Aapt 30-R and IF4Aapt 30-F) while the rest of the primer consists of vector sequences. In this case it is pETDuet (Novagen).

2003) with affinity for eIF4A in the nanomolar range. This strong affinity will provide the binding force necessary for the reassembly of the labeling complex on RNA.

30. Design two phosphorylated primers, one forward and one reverse (primers 1 and 2, Table 17.11.4) each containing half of the aptamer sequence (31 bp) plus vector sequences directly upstream and downstream from the cloning site or site of insertion. Also, design two 20-mer to 22-mer oligonucleotides (primers 3 and 4) in the opposite orientation from the phosphorylated primers to generate two fragments that will later be ligated via 5′ phosphorylated ends.

31. Run two standard PCRs as in steps 1 to 4 with primers IF4Aapt 30-R and pET-*Bcl*I and primers IF4Aapt 30-F and pET-*Bgl*II (Table 17.11.4), using a vector that can be used for coexpression along with pACYCDuet-1 as the DNA template.

    Because the plasmid carrying the protein components (pACYCDuet vector, Novagen) contains a p15A origin of replication and the cat gene (chloramphenicol resistance), the RNA component should be expressed from a vector with a different replicon and selection marker—e.g., ColE1 bla gene (ampicillin resistance) as is the case with pETDuet-1.

32. Ligate the two fragments obtained in step 31 using equimolar amounts of each product (see reaction mixture described in step 9) and incubate the reaction for 4 hr at 16°C.

33. Use 1 to 2 μl of the ligation mixture to reamplify the resulting ligated product with primers 3 and 4 (Table 17.11.4).

    For reaction mixture and cycling program, see steps 1 to 4.

34. Digest the product and the cloning vector pETDuet-1 with restriction enzymes *Xbo*I and *Xho*I and follow steps 8 to 12 for cloning and screening transformants containing plasmid coding for eIF4A-binding aptamer sequence.

BASIC PROTOCOL 2

EXPRESSION OF RNA LABELING COMPONENTS IN *E. COLI*

Once protein and RNA-expressing constructs are made, they need to be introduced into an appropriate bacterial strain designed for expression from the strong T7 promoter. Since both protein and RNA are under the control of the same promoter, only one inducer molecule, IPTG, needs to be added to the culture to assemble the RNA labeling complex in vivo (see Critical Parameters under "Time and temperature," for growth conditions).

Materials

Competent *E. coli* cells (also see Seidman et al., 1997): e.g., BL21(DE)3 (Stratagene)
Plasmid encoding protein fusions (Basic Protocol 1, step 29)
Plasmid encoding tagged RNA (Basic Protocol 1, step 34)

LB plates (*APPENDIX 2A*) containing appropriate antibiotic
LB medium (*APPENDIX 2A*) containing appropriate antibiotic
LB medium (*APPENDIX 2A*) containing 1 mM IPTG

Additional reagents and equipment for transformation of *E. coli* (Seidman et al., 1997)

1. Cotransform bacterial cells, e.g., BL21(DE)3, with the plasmid expressing the fusion proteins and the plasmid expressing the tagged RNA.

   The strain should be able to activate the promoters driving the expression of all parts of the complex.

   Protocols for transformation of E. coli are presented in Seidman et al. (1997).

2. Plate transformed cultures on LB plates supplemented with antibiotics needed for the selection of both plasmids (100 μg ampicillin and 34 μg/ml chloramphenicol).

3. Pick a single colony from this transformation and start a day culture in 3 ml LB supplemented with appropriate antibiotics (100 μg ampicillin and 34 μg/ml chloramphenicol) by incubating the cultures at 37°C for 3 hr with vigorous shaking.

4. Dilute cultures 1:250 to 1:500 into 3 ml LB medium containing 1 mM IPTG and the abovementioned antibiotics. Grow cells at room temperature (25°C) for 14 to 16 hr or until cultures reach an optical density of 0.5 to 0.6.

   It is critical that cells be allowed to grow in the presence of the inducer for more than 3 to 4 hr for fluorescence to be detected. Growth of cells at 25°C seems to favor proper maturation of the fluorophore and formation of a robust signal (see Critical Parameters under time and temperature).

ANALYSIS OF CELLS BY FLOW CYTOMETRY

BASIC PROTOCOL 3

This procedure constitutes the first assessment of the formation of the fluorescent RNP complex in vivo. This method also allows for the quantification of the efficiency of the RNA-labeling complex formation by comparison with an uninduced sample or a sample lacking the RNA component. A successful experiment should result in cell fluorescence, which may range 5- to 20-fold above background levels. Background fluorescence is determined by the signal that comes from cells expressing only the protein fragments or from uninduced cells containing the complex. Another control experiment is to measure fluorescence of cells expressing protein fusions and an RNA without the interacting aptamer sequence. If fluorescence of such cells is several-fold lower than fluorescence of the cells expressing the tagged RNA, then the experiment can be considered successful, and cell fluorescence is the result of protein complementation dependent on the presence of the target RNA. The signal-to-background ratio depends on the nature of the RNA. Structured RNAs (e.g., tRNA) consisting of complex hairpins and bulges may produce higher background and lower signal to background ratio than less structured mRNAs. We believe this is the case because of the nature of eIF4A protein, which interacts with RNA via secondary structures. Thus, we found that aptamer-tagged *lacZ* RNA usually produces a better signal-to-background ratio of 4- to 5-fold, compared to aptamer-tagged 5S rRNA, where signal-to-background ratio was about 2-fold.

For cells expressing only protein fusions, the authors use a modification of Basic Protocol 2, step 1, where BL21(DE)3 cells are transformed only with plasmid encoding protein fusions (from Basic Protocol 1, step 29). For cells expressing an untagged RNA, we cloned the coding sequence for the β-galactosidase gene (*lacZ*) from the pBAD/His/lacZ plasmid (Invitrogen) as a *Bam*HI-*Xho*I fragment into cloning vector pACYC following a procedure similar to that of Basic Protocol 1, steps 1 to 12.

Materials

Cells expressing protein and RNA components of the complementation complex (Basic Protocol 2, step 1)
Cells expressing only protein fusions (Control 1; Basic Protocol 2, step 29)
Cells where protein expression have not been turned on (lacking IPTG, Control 2; perform steps 1 to 4 of Basic Protocol 1, but omit IPTG in step 4)
Cells expressing protein fusions and an untagged RNA template (pET plasmid, Novagen)
Phosphate-buffered saline (PBS; *APPENDIX 2A*)
Flow cytometer with 488-nm excitation filter for collection of green fluorescence

1. Allow all cells to grow to 0.5 to 0.6 OD_{600} units. Pellet cells by microcentrifuging 0.5 ml of cell suspension 1 min at 10,000 rpm at 4°C, and removing the supernatant. Wash cells once by resuspending in 0.5 ml PBS, centrifuging again as before, and removing the supernatant. Resuspend each cell pellet in 0.5 ml PBS.
2. Analyze cell fluorescence on the flow cytometer. Excite fluorescence with a 488 nm argon laser and a 515 to 545 nm emission filter (FL1).
3. Measure the fluorescence of 100,000 cells in each sample at a low flow rate. Select a small forward scatter and side scatter gate to decrease fluorescence variation due to cell size.
4. Compare fluorescence of induced cells with those of uninduced cultures. Also, measure fluorescence of cells transformed only with the plasmid expressing fusion proteins in the absence of interacting RNA. To further determine the specificity of the signal, measure cell fluorescence of samples expressing the protein fusions and an untagged RNA.

BASIC PROTOCOL 4

ANALYSIS OF CELLS BY MICROSCOPY

The RFAP assay allows for direct visualization of RNA particles in the cell via complementation of fluorescent protein fragments induced by aptamer-eIF4A interactions. Moreover, the localization of these fluorescent complexes in a bacterial cell changes depending on the nature and function of the target RNA (Valencia-Burton et al., 2007). Specifically, localization of three different RNAs—untranslated RNA, mRNA, and 5S ribosomal RNA—was distinctly different and consistent with the functions of these RNA molecules (Valencia-Burton et al., 2007). In all cases, the target RNA was modified with an aptamer sequence, which was introduced into the 3′ UTR right after the stop codon (in the case of the *lacZ* gene and 5S RNA gene). The cells expressing the entire complementation complex and corresponding controls should be grown and induced as in steps 3 to 4 of Basic Protocol 2.

Materials

Agarose
Phosphate-buffered saline (PBS; *APPENDIX 2A*)
Cells expressing protein and RNA component of the complementation complex (Basic Protocol 2, steps 3 to 4)
Cells expressing only protein fusions (Control 1; Basic Protocol 1, step 29)
50°C water bath
Vacuum aspirator
15-well multi-test microscope slides (e.g., MP Biomedicals)
Long (e.g., 24 × 50–mm) coverslips
Inverted fluorescence microscope allowing excitation at 490 to 500 nm and emission detection at 525 to 535 nm, equipped with neutral density (ND) filters

Additional reagents and equipment for fluorescence microscopy (*UNIT 4.2*) and differential interference contrast microcopy (*UNIT 4.1*)

1. Prepare a 1% (w/v) agarose solution in PBS by heating up the solution in a microwave oven at high power for 15-sec increments until the agarose is melted (solution appears clear). Keep solution warm at 50°C in a water bath prior to use.
2. Place 20 μl of agarose solution into each of 15 wells of a multi-test slide.

   Do not make the agarose pads too tall, as they will then prop open the coverslip.

3. Immediately dispense a 10- to 20-μl aliquot of cell culture (0.5 to 0.6 OD units) over its corresponding well (enough to cover the agarose).

   It is important not to wait too long or the agarose pads will dry up.

4. Allow the cells to settle on the pads for 4 min at room temperature.
5. Carefully aspirate excess liquid covering the pads using a vacuum aspirator. Take care not to disrupt or remove pads from the slide.
6. Cover the slide with a long coverslip.
7. Image cells using an inverted fluorescence microscope with a 100× oil immersion objective and an epifluorescence system allowing excitation at 490 to 500 nm and emission detection at 525 to 535 nm (also see *UNIT 4.2*).
8. Compare fluorescence images with differential interference contrast images (*UNIT 4.1*) to examine cell morphology and growth state. Also, compare these images with those obtained with cells expressing only fusion proteins and with cells expressing full-length EGFP.

COMMENTARY

Background Information

The study of RNA in live cells is a challenging and exciting field that promises a better understanding of mechanisms of cell function. In bacteria, it is especially a challenge due to the small size and the apparent lack of compartmentalization in these cells.

Recently, two groups performed RNA kinetic studies in *E. coli* (Golding and Cox, 2004; Golding et al., 2005; Le et al., 2005) using a strategy that was originally developed to study RNA in live eukaryotic cells (Bertrand et al., 1998; Beach et al., 1999; Takizawa and Vale, 2000; Beach and Bloom, 2001). This strategy is based on the interaction of an RNA-binding protein with protein-binding motifs introduced in the target RNA. To make the resulting RNP complex fluorescent, the RNA-binding protein is fused with a fluorescent protein. This technique represents the first successful attempt to combine fluorescent proteins with RNA detection in vivo. However, a considerable limitation of this approach is high background signal in the absence of the target RNA produced by the full-length fluorescent protein fused to the RNA-binding protein (Golding and Cox, 2004; Le et al., 2005). Here, specific precautions should be taken to exclude possibilities of protein aggregation that would produce a signal similar to that of RNA. An alternative technique using RNA-specific prelabeled probes has also been used for RNA localization in live cells (Bratu et al., 2003, Santangelo et al., 2004, Silverman and Kool, 2005, Dirks and Tanke, 2006). This approach, however, requires invasive methods of probe delivery into the cell.

The new method allowing RNA visualization in live cells is rooted in two techniques: protein fragment complementation and binding of RNA aptamers with RNA-binding proteins. Both components are produced within the cell, giving this new technique specificity and strength. Application of protein fragment complementation substantially reduces nonspecific background fluorescence and thus increases signal-to-background ratio. The high affinity of an aptamer for its corresponding protein provides great specificity for detection of the target RNA.

Protein fragment complementation

The protein complementation assay (PCA) is a comparatively new method developed for

protein interaction studies both in vivo and in vitro (for review, see Remy and Michnick, 2007). In PCA, a marker protein is split into two inactive fragments in such a way that they cannot reassemble into functional protein by themselves. Proper folding and restoration of the activity of the marker protein takes place only when proteins fused to inactive marker fragments interact and bind (Johnsson and Varshavsky, 1994; Pelletier et al., 1998; Remy and Michnick, 1999; Paulmurugan et al., 2002). Refolding of the marker protein from two fragments is a cooperative process, which means that the signal generated by complementation has a larger dynamic range as compared, for example, with fluorescence resonance energy transfer (FRET; Michnick, 2003; de Virgilio et al., 2004).

PCA also has great advantages over other methods used to study protein-protein interactions (Michnick, 2003; Remy and Michnick, 2007) such as the yeast- and bacterial two-hybrid systems. Unlike these methods that rely on transcriptional induction, PCA is capable of detecting direct protein-protein interactions as well as interactions that take place in cellular compartments outside the nucleus. PCA is now being used to study changes in protein interactions caused by chemical or physical perturbations in the cell (Remy and Michnick, 2001), as well as for high-throughput drug screening (MacDonald and Westwick, 2007; MacDonald et al., 2006). This assay also makes it possible to study transient and weak protein interactions (de Virgilio et al., 2004, Remy et al., 2004; Remy and Michnick, 2006; Schmidt et al., 2006), including membrane proteins participating in the secretory pathway (Nyfeler et al., 2005). Other recent applications include detection of duplex DNA formation in vitro (Demidov et al., 2006) and determination and monitoring of DNA-protein interactions (Ooi et al., 2006), as well as analysis of the methylation state of DNA (Stains et al., 2006).

Different proteins have been used as markers in PCA. Among them are β-lactamase, dihydrofolate reductase, luciferases, and fluorescent proteins. The use of fluorescent proteins in PCA has substantially extended the range of applications for this technique. (Ghosh et al., 2000; Paulmurugan et al., 2002; Hu and Kerppola, 2003; Remy and Michnick, 2004; Magliery et al., 2005). For example, it has allowed the simultaneous study of different protein-protein interactions by using fluorescent proteins with unique spectral characteristics (Hu and Kerppola, 2003; Hu et al., 2002).

PCA has also been applied to the study of RNA-protein interactions in vivo (Rackham and Brown, 2004). In this assay, the RNA binding protein of interest is fused to a portion of a split fluorescent protein, while the second protein fusion consists of another fragment of a split fluorescent protein and the MS2 coat protein. The target RNA contains the MS2 binding motif, which tethers one fragment of the fluorescent protein to the RNA via the MS2 protein-motif interaction. Protein complementation occurs when an RNA binding protein fused with the complementary fluorescent protein fragment interacts with a specific sequence adjacent to the MS2 binding motif (Rackham and Brown, 2004). Fluorescent signal in this case is indicative of the interaction between the protein of interest and a specific sequence on the target RNA.

Despite its advantages, fluorescent protein complementation has limitations stemming from the slow rate of chromophore maturation and the stability of the reassembled fluorescent protein complex. Thus far, it is assumed based on in vitro studies that re-assembled fluorescent proteins can persist in vivo even after the supporting interactions are gone (Hu et al., 2005; Magliery et al., 2005). This presumed stability can make experiments designed to measure kinetics difficult to interpret (Zhang et al., 2002; Magliery et al., 2005; Nyfeler et al., 2005; Remy and Michnick, 2007). Complex stability, however, can prove to be beneficial for the detection of transient and relatively weak protein interactions (Nyfeler et al., 2005; Remy and Michnik, 2006).

Interaction of RNA aptamers with RNA-binding proteins

The second component in the design of a fluorescent RNA complex capable of labeling RNA within the cell is the interaction between an RNA aptamer and an RNA-binding protein. Aptamers are relatively short RNA or DNA oligonucleotides, which bind ligands and are isolated in vitro using selection procedure called SELEX (Systematic Evolution of Ligands by Exponential enrichment; Ellington and Szostak, 1990; Tuerk and Gold, 1990). Because the selection procedure is driven by binding of ligands, aptamers bind their cognate target with high affinity and adopt secondary structures, which are optimized for ligand binding (Herman and Patel, 2000). In this respect, aptamers resemble antibodies

by selectively binding a corresponding ligand from complex chemical or biological mixtures. High specificity of aptamer interaction with cognate ligand makes them an attractive tool in molecular engineering.

When expressed in the cell, RNA aptamers function as predicted from experiments in vitro, and their expression does not seem to interfere with other cellular functions (Choi et al., 2006; Hafner et al., 2006; Mi et al., 2006).

Characteristics of RNA visualization through fluorescence complementation triggered by aptamer-protein interactions (RFAP)

Combining both of the above principles, we were able to label and detect three different RNAs in live bacterial cells. This technique does not seem to interfere with localization of the message, as each transcript showed a unique distribution pattern in the cell. Furthermore, we observed interesting fluorescence changes over time that could be related to dynamics of gene expression. The application of this technique in RNA studies presents several advantages over existing fluorescent RNA labeling techniques. First, we can independently induce protein and RNA components of the complementation complex. In this way, the synthesis of fluorescent protein fragments can be done in advance to allow enough time for chromophore formation. Once proteins are synthesized and folded, RNA expression could be induced, and its fate followed by fluorescence measurements in real time. Second, one protein marker and one RNA-binding protein could be used in studies of different RNAs, thus providing a universal approach for RNA studies in vivo.

Other useful features of the new approach are the direct visualization of the target RNA in its natural cellular environment; there is no need to perform any additional procedures such as permeabilization or fixing of cells. The low background fluorescence allows simple analysis of RNA concentration and localization by either flow cytometry or fluorescence microscopy. Finally, interpretation of the data does not require post-acquisition image processing.

The application of this technique in quantitative kinetic studies, however, should be done with more caution. The issue in this case is the stability of the fluorescent complex in in vitro experiments in which the disassembly of the complex is practically irreversible (Magliery et al., 2005). There are still not enough data supporting such stability of the reassembled EGFP in vivo. More experiments are needed to reveal the stability of the reassembled complex in vivo.

Critical Parameters and Troubleshooting

Design of ribonucleoprotein complementation complex to visualize RNA in vivo

To express fluorescent RNA in vivo, the RNA of interest should contain an aptamer tag capable of interacting with the RNA-binding protein. At the same time, introduction of the aptamer sequence within RNA should not change RNA function and localization pattern. The RNA-binding protein must consist of two dissectible domains, so that each protein fragment can be fused with fragments of a split fluorescent protein. All three components of the complementation complex should be co-expressed in the cell.

Splitting of the marker protein

Splitting of fluorescent protein into two fragments could be performed in different ways (see *UNIT 21.3*). We split EGFP within the loop formed by amino acids 153 to 161, according to the scheme previously used in many protein complementation studies (Ozawa et al., 2000; Ghosh et al., 2000; Ozawa et al., 2001a,b; Hu et al., 2002; Hu and Kerppola, 2003; Remy and Michnick, 2004; Magliery et al., 2005). This splitting has been shown to result in fragments that are not capable of spontaneous self assembly, both in vitro and in vivo (Ghosh et al., 2000; Hu et al., 2002; Magliery et al., 2005; Demidov et al., 2006).

Splitting of eIF4A as an RNA-binding protein

Eukaryotic initiation factor 4A (eIF4A) is a small, 29-kDa protein that acts as an ATP-dependent RNA helicase working in a complex with other initiation factors (4B, 4H, 4G, 4F). This RNA-binding protein consists of two globular domains, and its crystal structure resembles a dumbbell—the compact N-terminal and C-terminal domains are connected via a flexible linker consisting of 11 amino acids (Caruthers et al., 2000). These structural features make eIF4A a useful candidate for domain dissection. Furthermore, recent studies reported the isolation of several high-affinity aptamers that bind eIF4A with a binding constant in the nanomolar range (Oguro et al., 2003). Oguro et al. also showed that the aptamer sequence could be as short as 58 nt while

still preserving high-affinity binding. Furthermore, these authors showed, using a nitrocellulose filter assay, that neither of the dissected eIF4A domains can bind aptamer alone, but rather both domains of eIF4A need to be present for tight RNA binding to occur (Oguro et al., 2003). The affinity of the eIF4A-aptamer interaction is in the same range as that of the MS2 coat protein-MS2 RNA interaction used to monitor RNA within the cell (Bertrand et al., 1998; Beach et al., 1999; Beach and Bloom, 2001; Golding and Cox, 2004; Chubb et al., 2006).

Fusion polarity and linkers

To create fusion proteins containing fragments of fluorescent protein with fragments of the RNA-binding protein, one can use different schemes (see for example *UNIT 21.3*). In our work, we used C-terminal fusions—EGFP fragment A (amino acids 1 to 158) was fused with the N-terminus of the F1 fragment of eIF4A through its C-terminus, and the C-terminus of the EGFP fragment B (amino acids 159 to 238) was fused with the N-terminus of the eIF4A F2 fragment. However, a different scheme where only N-terminal fusions are done or where one fusion is C- and the other N-terminal is also acceptable.

In each particular case, self-assembly of protein fusions should be tested. If there is some spontaneous reassembly resulting in notable fluorescence, several steps can be undertaken to reduce fluorescent background: (1) to change polarity of fusions; or (2) to decrease concentration of protein fusions by using a plasmid with a lower copy number, lower promoter strength, or lower concentration of the inducer.

The linkers connecting the two protein domains in each fusion should allow enough flexibility for interaction with the mutually complementary protein partner and RNA aptamer. We used a 10-amino-acid-long glycine-serine $(GSS)_2(GS)_2$ linker in all fusions (Valencia-Burton et al., 2007), since similar linker sequences have been successfully used in other PCAs (Remy and Michnick, 2001).

Position of the aptamer sequence within RNA

To visualize RNA in the cell, it should be modified to contain an aptamer tag, which will be recognized by the protein complementation complex. To reliably use this system for RNA studies, one needs to make sure that incorporation of the aptamer tag does not interfere with RNA synthesis and function.

Previous studies showed that aptamer sequences can be incorporated within 5′ or 3′ untranslated regions (UTR) without interfering with RNA synthesis (Hanson et al., 2003; Nickens et al., 2003), although it may affect the efficiency of translation, especially if the aptamer interacts with a translational regulator such as tetracycline (Hanson et al., 2003). Our results showed that in *Saccharomyces cerevisiae*, incorporation of the eIF4A-specific aptamer in the 3′ UTR (right after the stop codon) of a marker gene did not affect its expression as compared with the untagged gene control. However, incorporation of the aptamer sequence in the 5′ UTR substantially reduced the level of expression of the marker protein. These results showed that the 3′ UTR is a preferred location for insertion of the aptamer sequence in this tag. Other RNA localization studies employing the MS2 coat protein-motif interaction have also placed these binding motifs in the 3′ UTR of a gene without altering gene expression or RNA localization (Bertrand et al., 1998; Beach et al., 1999; Fusco et al., 2003; Golding et al., 2005).

Coexpression of protein fusions and RNA tagged with aptamer

To assemble a fluorescent ribonucleoprotein complex within the cell, several important conditions must be fulfilled. First, there should be equimolar amounts of the fusion proteins for efficient re-assembly to occur. The best way to accomplish this is to express both fusions from the same vector and under the control of the same promoter. In our experiments, we did this by cloning our protein fusions in the Duet vector, pACYCDuet-1 from Novagen, which can coexpress two messages from two independent T7 promoters. Second, concentration of proteins should exceed that of RNA, to allow efficient and robust binding of RNA molecules. Finally, the RNA should be expressed from a compatible vector, e.g., pETDuet-1 (Novagen), with a promoter strength equivalent to that of the protein-expressing construct. In our case, both protein and RNA were expressed from the strong T7 promoter that is activated by the addition of IPTG to the culture medium. Uncoupling of protein and RNA expression should be done with an inducible promoter of similar or equal strength.

Time and temperature

For fluorescence development, both protein and RNA constructs need to be coexpressed for at least 12 to 14 hr at room temperature

in the presence of the inducer IPTG. For this, we recommend that cultures be diluted 1:600 to 1:1000 in the presence of the inducer and that they be grown overnight at room temperature (20° to 25°C). Usually, cultures grown under these conditions will reach an optical density of 0.4 to 0.6 at the time of examination, which is ideal for microscopic and flow cytometric analysis. We failed to observe fluorescence above background levels when culture was incubated at 30° or 37°C, even after the cultures reached an optical density of 1.

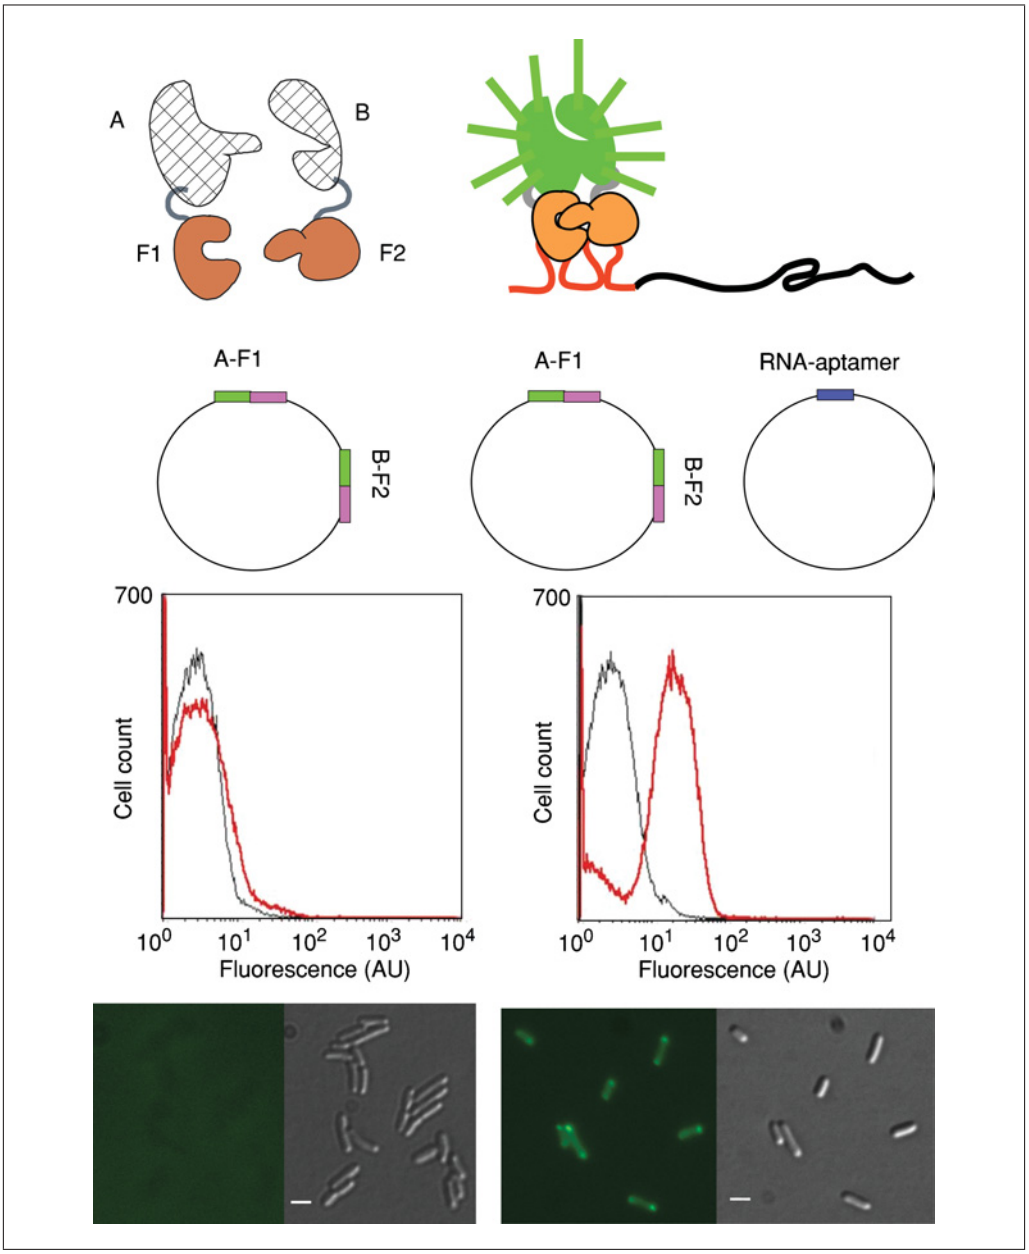

Figure 17.11.5 Localization of untranslated RNA in live bacterial cells using the RFAP method. The left-hand side of the figure illustrates expression of two protein fusions, each containing a fragment of a split eIF4A and a split EGFP, that does not result in a fluorescent signal. The right-hand side of the figure illustrates coexpression of two protein fusions and the RNA transcript with aptamer, which results in a fluorescent signal often localized to the cell. Top row, molecular constructs expressed in *E.coli*; second row, plasmids expressing components of the complementation complex; third row, fluorescence distributions of cells expressing EGFP-complementing complexes, obtained by flow cytometry—black, before IPTG induction, red, after IPTG induction; and bottom row, fluorescence micrographs of *E. coli* cells expressing corresponding components of the complementing complexes. Scale bar = 2 μm. For the color version of this figure go to *http://www.currentprotocols.com*.

In the protocols described above, we simultaneously induced both components of the detection system, proteins and RNA. Therefore, in this system it is impossible to determine the optimal time to observe a signal, because two critical parameters, the time necessary for chromophore formation and the RNA concentration, increase after the start of transcription and cannot be measured independently.

To determine optimal temperature and time conditions for maximal fluorescent signal, a system allowing separate induction of protein and RNA is necessary. Such a system would be also preferable in RNA kinetic studies.

Anticipated Results

The RFAP technique allows RNA detection and localization within live bacterial cells. The efficiency of the RNA-labeling complex formation can be assessed by comparing fluorescence of the cells expressing the entire complex with an uninduced sample or a sample lacking the RNA component. A successful experiment should result in cell fluorescence, which may range 5- to 20-fold above background levels. A useful control includes cells expressing target RNA without the aptamer tag. If fluorescence of cells with untagged RNA is several-fold lower than fluorescence of the cells expressing the tagged RNA, then the experiment can be considered successful, and cell fluorescence is the result of protein complementation dependent on the presence of the target RNA. Figure 17.11.5 exemplifies an experiment with localization of a short untranslated RNA that, in most cells, is visible as a bright particle at one or both poles.

As we mentioned above, the signal-to-background ratio depends on the nature of the RNA. Structured RNAs (e.g., tRNA) consisting of complex hairpins and bulges may produce higher background and lower signal-to-background ratio than less structured mRNAs. We believe this is the case because of the nature of eIF4A protein, which interacts with RNA via secondary structures. Thus, we found that aptamer-tagged *lacZ* RNA usually produces a better signal-to-background ratio of 4- to 5-fold, compared to aptamer-tagged 5S rRNA where signal-to-background ratio was about 2-fold (Valencia-Burton et al., 2007).

Time Considerations

The preparation of DNA constructs expressing protein fusions and RNA tagged with an aptamer sequence may take from 2 to 4 weeks. Transformation of these constructs into a protein-expression bacterial strain will only take a day. The coexpression of protein and RNA will take 2 days, since cells need to grow overnight at room temperature (20° to 25°C) to allow enough time for chromophore formation and maturation. Analysis of the fluorescence signal by flow cytometry or microscopic analysis takes 1 day. When cells are analyzed using fluorescence microscopy, enough time should be set aside for cell examination and image acquisition. Depending on the experiment, time-lapse photographs every 10 or 30 min can be taken to study the dynamic behavior of the signal and/or its distribution over time. Also, depending on the nature of the RNA being examined, we recommend a careful examination of cells in the field, since it can reveal unique distribution and localization patterns. In all, the time-limiting steps for this protocol are those for the construction of plasmids. Once the constructs are made, the cytological analysis mentioned above takes 1 week, including all the necessary controls that can and should be done simultaneously.

CHAPTER 18
Cellular Aging and Death

INTRODUCTION

This chapter covers two distinct processes, cellular aging and cellular death. It is essential for multicellular organisms that the attainment of a permanent non-dividing state (replicative senescence) and patterned cell death (apoptosis) occur in a highly regulated manner. While the aging and death of cells are not strictly linked mechanistically, they are juxtaposed within this chapter since both processes occur at the end of the cellular life span and since the failure of both processes is intimately linked to tumor formation and cancer.

Somatic cells do not divide indefinitely under normal circumstances, although they may acquire the ability to do so if they, for instance, express viral gene products that allow them to escape the controls of senescence. Senescence is marked by phenotypic changes such as irreversible growth arrest and altered differentiated functions, as well as an increased resistance to apoptotic stimuli.

One useful marker for this transition is the accumulation of senescence-associated β-galactosidase (SA-β-gal; *UNIT 18.9*). Some level of lysosomal β-galactosidase can be detected in most cells at an optimum pH of around 4.0. However, the grossly exaggerated expression of β-galactosidase after the onset of senescence allows the differential detection of β-galactosidase activity in the senescent cells under suboptimal conditions (pH 6.0). This assay is straightforward and comparatively robust, allowing the detection of senescent cells in culture and tissue samples.

Senescence is also closely associated with changes in telomeric structures. Telomeres are structures at the ends of linear chromosomes that are composed of short, repeated DNA sequences and specialized proteins associated with these repeats. These structures are essential for the stability of linear chromosomes, but each round of DNA replication results in shortening of the telomeric repeats because the replication machinery inevitably leaves an unreplicated 3′ overhang. It has been proposed that senescence is triggered when telomeres shorten below some critical length, and considerable evidence is consistent with this hypothesis. Experimentally, telomere length can be measured by a number of different methods, including Southern blotting of chromosome terminal restriction fragments (*UNIT 18.6*), Q-FISH (*UNIT 18.4*) or Flow FISH. The elegant work of Blackburn and colleagues has demonstrated that the enzyme telomerase is capable of de novo addition of telomeric repeats to the ends of chromosomes. However, most somatic cells do not express telomerase, although immortal cells do. Some tumor cell lines express telomerase, but it does not appear that telomerase expression is strictly necessary or sufficient to escape senescence. Experimentally, telomerase activity can be measured by a sensitive PCR-based protocol known as telomere repeat amplification or TRAP (*UNIT 18.6*).

As discussed in *UNIT 18.1*, cell death can occur in either a programmed (apoptotic) or more accidental (necrotic) manner. Apoptosis is generally a preferred mode of cell death in multicellular organisms, since it is a more orderly dismantling of cellular structures and degradation of the cell's macromolecular contents and is therefore less likely to cause damage to surrounding cells. Apoptosis occurs in response to a number of stimuli,

Current Protocols in Cell Biology 18.0.1-18.0.2, June 2010
Published online June 2010 in Wiley Interscience (www.interscience.wiley.com).
DOI: 10.1002/0471143030.cb1800s47

including developmental signals and the engagement of receptors for cell death stimuli, DNA damage, or large amounts of unfolded protein within the endoplasmic reticulum. Apoptosis and necrosis can be distinguished by a number of criteria including cellular morphology and the patterns of DNA fragmentation (*UNIT 18.3*).

Mitochondria play a central role in the regulation and execution of apoptosis. *UNIT 18.5* describes protocols for the assessment of mitochondrial status during apoptosis. This unit includes protocols for the preparation of mitochondria, for the detection of mitochondrial release of cytochrome *c* and other intermembrane-space proteins, and for assaying apoptosis-associated transitions in mitochondrial membrane permeability and calcium release.

Apoptotic pathways promote the activation of cysteinyl aspartases (caspases; *UNIT 18.2*), a family of related proteases that act in a proteolytic cascade to bring about the fragmentation of the cellular contents and cell death. Activation of poly(ADP-ribose)polymerase 1 (PARP1) is an early event after DNA damage (*UNIT 18.7*). Once active, poly(ADP-ribosyl)ation by this enzyme is likely to promote chromatin remodeling in order to allow DNA repair and changes in gene expression. Caspase-7 and Caspase-3 efficiently cleave PARP1 after the activation of apoptotic pathways, allowing the use of its breakdown intermediates and enzymatic products to be used as a sensitive indicator of cell physiology during apoptosis.

The activation of DNA fragmentation programs during apoptotic cell death is most readily detected using TdT-mediated dUTP-biotin nick end-labeling (TUNEL) assays (*UNIT 18.3*). TUNEL methods can be adapted for use in flow cytometric assays (*UNIT 18.8*). Phospholipids are asymmetrically distributed between the inner and outer leaflets of the plasma membrane, with phosphatidylserine located on the inner surface. This asymmetry is lost during apoptosis, exposing phosphatidylserine on the outside surface of the plasma membrane. This fact has been exploited for the staining of apoptotic cells using the fluorochrome-conjugated annexin V, which binds with high affinity to phosphatidylserine. Like DNA fragmentation, phosphatidylserine exposure can be effectively monitored in flow cytometric assays, as can caspase activation, PARP1 cleavage, collapse of the mitochondrial transmembrane potential, and other apoptotic changes in cell physiology (*UNIT 18.8*). Moreover, these methods may be likewise adapted for high throughput live cell imaging (*UNIT 18.10*), to facilitate the identification of pro-apoptotic compounds or the discovery of apoptosis regulators through RNAi-based screens.

Finally, it should also be noted that many of the processes of apoptosis have been reconstituted within cell-free mammalian and *Xenopus* systems (*UNIT 11.12*), and these systems should be increasingly helpful in understanding the molecular events surrounding programmed cell death.

Mary Dasso

Current Concepts in Cell Death

This unit attempts to define cell toxicity that leads to cellular demise, with a strong emphasis on cell death via both apoptosis and necrosis, by summarizing some of the more recent developments in cellular, molecular, and biochemical studies of the events that govern the induction and execution of cell death.

CELL DEATH

Cell death can occur via two processes, which are fundamentally different in their nature and biological significance (Kerr et al., 1972). These are termed necrosis and apoptosis and their features are summarized in Table 18.1.1.

Necrosis, or "accidental" cell death, was the classic model and was thought to be the universal mode of cell death until apoptosis was identified in 1972 as a separate mode of cell death. In general, necrosis is considered to be a passive process (Trump and Ginn, 1969) that is usually caused by extreme trauma or injury to the cell (Kerr et al., 1972). In tissues, necrosis is often seen as a lesion or patch consisting of many disintegrated cells. Typically, necrosis involves irreversible changes within the nuclei (such as karyolysis), loss of cytoplasmic structure, dysfunction in various organelles (especially mitochondria), and finally, cytolysis as a result of high-amplitude swelling. The release of the dying cell's contents into the extracellular space can cause further injury or even death of neighboring cells, and may result in inflammation or infiltration of proinflammatory cells into the lesion, leading to further tissue damage (Haslett, 1992).

The first references to a different type of cell death came from developmental studies. Glucksmann (1951) emphasized the existence of this phenomenon for the first time. This was followed by a surge of interest in the 1960s (for review see Lockshin, 1981). In the 1970s, histochemical studies of lysosomal changes in hepatic ischemia provided direct evidence for the existence of two distinct types of cell death (Kerr, 1971; Kerr et al., 1972). It was observed that rounded masses that developed in dead hepatic tissue contained cells that were morphologically different from those found in necrosis. These differences initially caused some confusion—i.e., the process was mistaken for a variation of necrosis and was called "shrinkage necrosis" (Kerr, 1971). The following year, Kerr, Wyllie, and Currie proposed the term "apoptosis" to describe the distinct morphological changes associated with this form of cell death (Kerr et al., 1972).

Apoptosis has been described as a form of cellular suicide, since death appears to result from induction of active processes within the cell itself. Typically, apoptosis involves margination and condensation of nuclear chromatin (pyknosis), cytoplasmic shrinkage, membrane blebbing, nuclear fragmentation, and finally, formation of apoptotic bodies.

A cell that is dying, whether by apoptosis or necrosis, undergoes rapid changes, which are reflected in its structure, morphology, and biochemistry. These are generally a result of various enzymes activated through elaborate signaling pathways. Since the first description of apoptosis in 1972, there has been a surge of interest in the study of apoptosis, and very little attention has been given to necrosis. This lack of parallel study of the two processes is also reflected in the degree of detail provided here describing apoptosis and necrosis.

STRUCTURAL CHANGES DURING CELL DEATH

Considerable biochemical changes occur within the apoptotic cell, which facilitate neat packaging and removal of apoptotic bodies by neighboring cells; however, as described above, necrosis is accompanied by high-amplitude cell swelling. Modifications in the cytoskeleton and cytoplasmic membranes are required for both shrinkage and swelling to occur. During apoptosis, this results in the loss of cell-cell contact, untethering of the plasma membrane, and rapid blebbing or zeiosis (Saunderson, 1982). Similarly, necrotic cells undergo membrane blebbing, but in contrast to apoptosis, the tracts of contiguous dying necrotic cells collapse without loss of contact with neighboring cells. This results in clumps of necrotic cells rather than single cells.

Tissue transglutaminase, a Ca^{2+}-dependent protein-glutamine γ-glutamyltransferase, is induced and activated in liver hyperplasia and in glucocorticoid-treated thymocytes (Fesus et al., 1987). This enzyme cross-links cytokeratin, a component of the cytoskeleton, through ε-(γ-glutamyl) lysine bonds. During apoptosis there is a significant increase in transglutaminase mRNA, as well as in the protein itself, its

Current Protocols in Cell Biology (2001) 18.1.1-18.1.18

Table 18.1.1 Features of Apoptosis and Necrosis

Characteristics	Apoptosis	Necrosis
Stimuli	Physiological or pathological	Pathological (injury)
Occurrence	Single cells	Groups of cells
Reversibility	Limited	Limited
Cellular level		
Cell shape	Shrinkage and formation of apoptotic bodies	Swelling and later disintegration
Adhesion between cells	Lost (early)	Lost (late)
Phagocytosis by other cells	Present	Absent
Exudative inflammation	Absent	Present
Cellular organelles		
Membranes	Blebbing	Blebbing proir to lysis
Cytoplasm	Late-stage swelling	Very early swelling
Mitochondrial permeability transition	Present	Present
Nucleus	Convolution of nuclear outline and breakdown (karyorrexis)	Disappearance (karyolysis)
Biochemical level		
Gene activation	Present[a]	Absent[a]
Requirement for protein synthesis	Present[a]	Absent[a]
Lysosomal enzyme release	Present	Present
Activation of nonlysosomal enzymes	Present	Present
Activation of caspases	Present	Absent
Cleavage of specific proteins	Present	—[a]
Changes in cytoskeleton	Present	Present
Level of ATP required	High	Low
Bcl-2 protection	Present	Present
Nuclear chromatin	Compaction in uniformly dense masses	Clumping not sharply defined
DNA breakdown	HMW and internucleosomal	Randomized
RNA degradation	Present	—[a]
Phosphatidylserine exposure	Present	Absent

[a]This feature is not a universal event or there are conflicting reports.

enzyme activity, and protein-bound (γ-glutamyl) lysine (Fesus et al., 1987). It is thought that transglutaminase activity may stabilize apoptotic cells and prevent membrane leakage during the early stages of the process by forming a shell around the cell. In contrast, transglutaminase activity does not appear to change during necrosis. For example, it was recently reported that ethanol-induced cytotoxicity in astroglial cells was due to necrotic cell death, and that it occurred in the absence of any change in transglutaminase activity (Holownia et al., 1997).

A critical part of apoptosis is the efficient recognition and removal of the apoptotic cells by phagocytes (Savill and Fadok, 2000). This involves the rearrangement and biochemical alteration of the plasma membrane in the dying cell. There are a number of changes that occur in the plasma membrane of apoptotic cells. One such change results in the alteration of carbohydrates on the plasma membrane, which helps preferential binding of macrophages to apoptotic cells (Duvall et al., 1985). Recognition of apoptotic cells by macrophages can also be

mediated via the vitronectin receptor (CD36; Savill and Fadok, 2000). The loss of phospholipid asymmetry in the plasma membrane of cells undergoing apoptosis is yet another significant change leading to the externalization of phosphatidylserine at the surface of the cell, thereby enabling cell recognition by macrophages (Fadok et al., 2000). Development of fluorescently labeled annexin V, which binds specifically to phosphatidylserine residues, enables detection of this externalization in apoptotic cells (Koopman et al., 1994); however, under in vitro culture conditions, where phagocytic cells are absent, apoptotic cells and their fragments lyse in a process very similar to that observed in necrosis. This phenomenon is termed secondary necrosis or post-apoptotic necrosis. Necrotic cells do not undergo phagocytosis to a similar extent, and the spillage of their cellular contents through plasma membrane disruption into the extracellular milieu induces cellular inflammatory responses.

Cell-volume changes are another feature of cell death. Interestingly, the cell volume changes during apoptosis and necrosis go in different directions. Apoptotic cell shrinkage, which leads to a loss of 30% to 50% of the cell volume (Saunderson, 1982), has been proposed to be due to budding of the endoplasmic reticulum. Vesicles thus generated migrate and fuse to the plasma membrane, releasing their contents into the extracellular region. This process requires energy (ATP), since water is moved against the osmotic gradient (Saunderson, 1982). Mitochondria, which are postulated to remain structurally and functionally intact during the early phase of apoptosis, provide the necessary energy. In contrast, during necrosis the cell loses control of ion flux, resulting in a reduction in concentration gradients of Na^+, K^+, Ca^{2+}, and Mg^{2+}, as well as changes in osmotic pressure. This, in turn, leads to uptake of water, giving rise to high-amplitude swelling of the cell and its organelles. This process is energy-independent and does not require a large amount of ATP.

MACROMOLECULAR DEGRADATION DURING CELL DEATH

Cell death is associated with activation of lipases, nucleases, and different classes of proteases. In apoptosis there is an efficient and neat packaging of the cell contents into apoptotic bodies. This requires the rearrangement and breakdown of lipids, proteins, and nucleic acids. Another possible reason for efficient degradation of macromolecules in apoptotic cells prior to their phagocytosis is that contents from dead cells are thus prevented from entering the phagocyte or neighboring cells to cause injury. In necrosis, the enzymes activated appear to be different, with very little overlap with the apoptotic enzymes. The necrotic enzymes are largely lysosomal acidic hydrolases with less substrate specificity than the apoptotic enzymes. These enzymes are thought to be activated also in late apoptosis and in the absence of phagocytosis, when the cells undergo secondary necrosis. Thus, there is a similarity between the features of necrotic cells and those of apoptotic cells undergoing secondary necrosis. The major macromolecules and the mode of their degradation during apoptosis and necrosis are discussed below.

DNA Degradation

Three patterns of DNA degradation are already known to occur during apoptosis. One or more of these may occur during the progression of apoptosis in a single cell (for review see Robertson et al., 2000). These are: single-strand nicks (Gorczyca et al., 1992), chromatin cleavage with the formation of large (i.e., 50- to 300-kbp) fragments (Brown et al., 1993; Zhivotovsky et al., 1994), and finally formation of nucleosome-size fragments of 180 to 200 bp, which produce the ladder pattern that has long been accepted as a biochemical hallmark of apoptosis (Wyllie, 1980).

One or more nuclear endonucleases have been suggested as being responsible for these patterns of DNA fragmentation, since isolated nuclei can be induced to produce the same pattern of fragmentation. A number of endonucleases have been identified in different cell systems, with different ion requirements for their activity (for review see Robertson et al., 2000). For example, the endonuclease in thymocytes is Ca^{2+}/Mg^{2+}-dependent, whereas the endonuclease operating in HL-60 cells appears to function independently of these ions.

Among the different Ca^{2+}/Mg^{2+}-dependent endonucleases, DNase I is of particular interest. Several years ago, it was suggested that DNase I is involved in radiation-induced lymphoid cell death (for review see Robertson et al., 2000). DNase I is a secreted digestive enzyme that produces DNA strand breaks containing 3′-OH end groups—the same end groups found in DNA fragmentation products during apoptosis. This enzyme is localized within the rough endoplasmic reticulum, the Golgi complex, and in small (secretory) vesicles. In apoptotic cells,

DNase I is also found within the perinuclear space, which led to the speculation that during apoptosis damage to endoplasmic reticular and nuclear membranes permits entry of this enzyme into the nucleus where it is involved in DNA fragmentation. It is important to note that DNase I activity is inhibited by G actin gelsolin segment 1, suggesting that cytoskeletal interaction might play a role in the control of this enzyme. A potential problem in linking DNase I activity with apoptosis is the fact that this enzyme is believed to produce mainly single-strand breaks in DNA with 10-bp periodicity and only in the presence of Mn^{2+} can it introduce double-strand breaks; therefore, additional experiments are required to further clarify the role of DNase I in effecting DNA fragmentation during apoptotic cell death.

Endonuclease activities that are completely or partially independent of Ca^{2+} and Mg^{2+} have also been described. Specifically, endonuclease activity that is independent of Ca^{2+} and dependent on Mg^{2+} was implicated in the formation of high-molecular-weight DNA fragments, whereas Ca^{2+}/Mg^{2+}-independent and Mn^{2+}-dependent endonuclease activity was linked to the formation of DNA ladders in several experimental models (for review see Robertson et al., 2000). Moreover, some cell types appear to lack any constitutive Ca^{2+}-dependent endonuclease activity.

Little is known about the ionic requirement for the DNA fragmentation factor-40/caspase-activated DNase (DFF-40/CAD) and, hence, it is difficult to associate this enzyme with any of the nuclease classifications described above. Under normal or unstressed conditions, DFF-40/CAD is bound in an inactive form to DNA fragmentation factor-45/inhibitor of CAD (DFF-45/ICAD), which is an inhibitory component of DFF-40/CAD (for review see Nagata, 2000). In the presence of proapoptotic stimuli, DFF-45/ICAD is cleaved by specific proteases (caspases, see below) and liberates DFF-40/CAD resulting in the activation of nuclease activity, nuclear condensation, and DNA fragmentation. ICAD knock-out mice are refractory to DNA fragmentation and nuclear condensation in response to different apoptotic stimuli, indicating that the inhibitory molecule to CAD is required for normal function of this enzyme (for review see Nagata, 2000). Lastly, a recent study by Liu et al. (1999) indicated that DFF activation is dependent upon the association of DFF-40 with histone H1 and high-mobility group 2 protein, which grants DNA-binding ability and nuclease activity to this molecule. DFF-40/CAD cleaves DNA at internucleosomal spaces.

Endonuclease activity in cells undergoing apoptosis can be regulated by protooncogenes and tumor-suppressor genes, such as *c-myc*, Ha-*ras*, *bcl-2*, and *p53*, as shown by analysis of genetic control of susceptibility to apoptosis (Arends et al., 1993). The apoptotic endonuclease or endonucleases cleave DNA at the exposed linker regions, and it has been suggested that these nucleases are topologically constrained rather than sequence constrained. Results obtained from cloning and sequencing DNA fragments from apoptotic cells show that the nuclease has no preference for specific DNA sequences or for the type of DNA to cleave. This randomness may be functionally important, and reflects the known properties of the endonucleases. The finding that apoptotic endonucleases are constitutive enzymes and that their activity can be modulated by different signals in cells undergoing apoptosis underlines the important role of nucleases in both physiological and pathophysiological processes. Although the role of intracellular endonucleases is not yet understood, one may speculate that a major function is to maintain genomic stability. Unfortunately, both purpose and mechanisms of DNA fragmentation in apoptotic cells are still unclear. Such fragmentation could serve to destroy the genetic information of unwanted cells and thus act as an irreversible step in the process. On the other hand, it may be simply a mid-to-late event that reflects ion redistribution and subsequent chromatin hypersensitivity to endonuclease(s) present in apoptotic cells. Alternatively, it may facilitate cleavage of DNA before uptake of apoptotic bodies during phagocytosis. Whatever the reason, it is still important to understand the mechanisms of this intriguing step of apoptosis.

As compared to apoptosis, at least two patterns of DNA degradation are recognized as occurring during necrosis. The first is the formation of both single- and double-strand DNA breaks. The second is randomized chromatin fragmentation. It is unclear if there is a link between these two steps of chromatin disintegration, although the probability for that is rather high. DNA fragments isolated from necrotic cells contain 5′-OH and 3′-PO_4 end groups. Among different endonucleases isolated and characterized up to now, only one is able to produce such DNA fragments—i.e., DNase II, which is localized in lysosomes. This makes sense, since the activation of lysosomal enzymes has been observed in necrotic cells.

The search for enzymes responsible for cleavage of chromatin during necrosis is still in progress in many laboratories.

Several publications have implicated the involvement of DNase II in apoptosis as well, although its precise role in the apoptotic process remains unclear given the following considerations: (1) DNase II is a lysosomal enzyme and in order to cleave nuclear DNA in intact cells, this enzyme would need to be released from lysosomes and transported into the nucleus. While this scenario is possible, it seems unlikely since it has been demonstrated that lysosomes maintain membrane integrity during apoptosis. (2) DNase II–mediated cleavage of DNA produces 3′-phosphates, which have not been linked to cells undergoing apoptosis. Nevertheless, it cannot be ruled out that DNase II may contribute to DNA fragmentation during apoptosis when the intracellular pH may be more acidic. Recently, it was reported that intracellular acidification during apoptosis can occur even in the absence of a nucleus, suggesting that intracellular acidification and DNA fragmentation are independent consequences of caspase action during apoptosis (Wolf and Eastman, 1999). In this respect, it is likely that DNase II does not induce DNA fragmentation in whole cells, but digests chromatin within phagocytes, where pH is low and apoptotic remnants must be processed. Indeed, two recent publications have suggested that the DNA fragmentation that occurs during apoptosis not only can result from DFF-40/CAD or any other endonuclease activities within the apoptotic cell but can also be attributed to a lysosomal acid DNase after the apoptotic cells are engulfed (McIlroy et al., 2000; Wu et al., 2000).

In conclusion, it is still unclear how all of the nuclease activities described in this section correlate with each other and are involved in apoptosis. It may be that there are cell type and/or insult-dependent specificities for the activation of different enzymes, or it could be that different enzymes involved in DNA fragmentation are active at different stages in the overall process.

RNA Degradation

Changes in ribosomal counts occurring in response to cell injury have been known for a number of years. This phenomenon may be a result of the release of ribosomes from the endoplasmic reticulum at particular stages leading to necrosis (for review see Bowen, 1981). A detailed analysis of the role of ribosomes in the pathogenesis of liver-cell necrosis was conducted by Bernelli-Zazzera (1975). He showed that ischemia resulted in a decrease in the number of ribosomes, and that stripped rough endoplasmic reticulum from ischemic cells bound fewer added ribosomes than did the reticulum from normal cells. It was concluded that there is a "loosened relationship" between endoplasmic reticulum membranes and ribosomes in ischemic livers; however, it is unknown how specific these changes are for necrosis and what relationship they bear to this type of cell death.

There are also a number of reports that RNA, as well as DNA, is susceptible to cleavage during apoptosis. The changes in ribosomal RNA (rRNA) during apoptosis are best studied. Ribosomal RNA consists of conserved and divergent (or variable) domains numbered from D1 to D12 (for review see Houge and Doskeland, 1996). The cleavage of rRNA during apoptosis selectively affects the two largest divergent domains, D2 and D8, in the large 28S rRNA molecule of the 60S ribosomal subunit, while the 18S rRNA molecule in the 40S ribosomal subunit remains unaffected (Houge et al., 1993); however, the pattern of rRNA cleavage occurring during apoptosis cannot be reproduced in necrotic cells or when exposing cell lysates to random RNase activity, suggesting that it is specific to apoptotic cells.

Recently it was demonstrated that rRNA and DNA cleavages can occur independently in apoptotic cells (Samali et al., 1997). In other words, the previously observed correlation is likely to be coincidental. The absence of apoptotic rRNA cleavage in some cell types suggests that this phenomenon is tightly regulated and unrelated to DNA fragmentation; therefore it appears that the pattern of rRNA fragmentation seen during apoptosis is not part of a scheme for general macromolecular disintegration and degradation, but rather a trait present in only some cell types.

Protein Degradation

The prerequisite for proteolysis in apoptosis is well documented. Several proteolytic activities were implicated in both the induction and execution steps of cell killing (for review see Zhivotovsky et al., 1997). Early evidence of a role for proteases in apoptosis came from studies on granule proteases (granzymes/fragmentins). These investigations identified granzymes involved in the exocytosis pathway of lymphocyte-mediated cytotoxicity, which are responsible for the lethal damage inflicted by these cells upon target cells (Shi et al., 1992). More recently, a family of aspartic acid–spe-

cific cysteine proteases have been discovered in mammalian cells, which share homology with the *Caenorhabditis elegans* death gene, *ced-3* (Yuan et al., 1993). The newly adopted nomenclature for these enzymes, caspases, refers to the aspartic acid–specific cysteine protease activity specific to this family (Alnemri et al., 1996). At least fourteen of these proteases have now been purified and their genes cloned (for review see Budihardjo et al., 1999; Fadeel et al., 2000). The activation of the caspase family of proteases has been detected in numerous tissues and cell types and may function as a common pathway through which apoptotic mechanisms operate. Caspases are synthesized as zymogens, and an apoptotic signal converts the precursors into mature enzymes (Stennicke and Salvesen, 2000). Caspases differ in the length and sequence of their N-terminal prodomain and can be divided into two subgroups: procaspases-1, -2, -4, -5, -8, -9, and -10 with long prodomains, and procaspases-3, -6, -7, -11, and -13 with short prodomains. In the long prodomain–containing group of caspases, two distinct modules essential for protein-protein interaction have been identified. The first is referred to as the death effector domain (DED) and is present in both procaspases-8 and -10. The second is termed caspase recruitment domain (CARD) and is found in procaspases-1, -2, -4, and -9. The CARD domain is also present in Apaf-1, the mammalian homologue of the CED-4 protein. It seems that most, if not all, of the long prodomain–containing caspases are activated via oligomerization-induced autoproteolysis. For example, the oligomerization of procaspases-2 and -8 at the plasma membrane is sufficient for their autoactivation. The activation of procaspase-9 requires binding to Apaf-1 and the presence of at least two other components—i.e., dATP and cytochrome *c*. Apaf-1 first forms oligomers and then facilitates procaspase-9 autoactivation by oligomerizing its precursor molecules. On the other hand, the activation of short prodomain–containing caspases requires an initial first step cleavage (e.g., by active caspases or granzyme B) followed by a second autoproteolytic step. For full activation short prodomain–containing caspases also require cleavage in the interdomain linker. Thus, activated caspase-9 can initiate a caspase cascade involving the downstream executioners, caspases-3, -6, and -7.

All members of the caspase family share a number of amino acid residues crucial for substrate binding and catalysis. Despite their uniform requirement for an aspartate residue in the P_1 position of the substrate, caspases can be divided into three different groups according to their substrate preferences (Nicholson and Thornberry, 1997). The predicted caspase specificities correspond to the cleavage sites in the different intracellular target proteins. The effects of caspases in apoptosis appear to be accomplished by the cleavage of a large number of proteins located in the cell membranes, cytoplasm, and nucleus, although the significance of the particular cleavages for the cell death process is still unclear.

There have been a large number of reports on caspase involvement in apoptosis; however, there is very little evidence for the involvement of this family of proteases in necrosis. Recent work from our own group has shown that menadione-induced necrosis of hepatoma cells is independent of caspase activation (Samali et al., 1999a). Furthermore, Tomaselli and coworkers (Armstrong et al., 1997) observed the activation of caspase-3 in cerebellar granule neurons undergoing apoptosis but not necrosis. These results appear to be in line with the work carried out in our laboratory which has shown that after the acute, necrotic death of cerebellar granule neurons exposed to glutamate, the remaining neurons undergo a delayed, apoptotic death (Ankarcrona et al., 1995); however, we did not detect any caspase activation during the "necrotic" step of our experimental model (M. Ankarcrona, B. Zhivotovsky, S. Orrenius, and P. Nicotera, unpub. observ.).

Apart from the caspase family of proteases, a number of other proteolytic enzymes are also implicated in cell death. Studies from our laboratory have suggested the involvement of Ca^{2+}-dependent proteolytic activity in oxidant injury in the liver (Nicotera et al., 1986). Although the substrates for this protease activity during cell injury remain largely unidentified, it appears that cytoskeletal and membrane-integral proteins may be a major target for this proteolytic event during chemical toxicity (Mirabelli et al., 1989). Calpain, another Ca^{2+}-dependent neutral protease and member of the papain family of cysteine proteases, degrades a number of key cellular proteins including protooncogenes, steroid-hormone receptors, protein kinases, and cytoskeletal proteins (Croal and DeMartino, 1991; Vanags et al., 1996). Calpain, one of the degradative nonlysosomal proteases, is implicated in both apoptosis and necrosis (Arai et al., 1990).

In apoptotic cells calpain cleaves a number of substrates, including fodrin, which can also be cleaved by caspase-3. The cleavage sites for

both proteases are different, and it is still unclear why several enzymes should cleave the same protein during cell death. In vitro, calpain can cleave procaspase-3, although it is unclear if this cleavage activates or inactivates this very important effector caspase (for review see Johnson, 2000). Calpain also cleaves several apoptosis regulatory proteins, such as p53, Bax and procaspase-9; however, the impact of calpain-mediated cleavage of these substrates in vivo remains to be elucidated. Enhanced calpain activity has been observed in anoxic hepatocytes and neurons. Moreover, inhibition of calpain by acidosis, calpain protease inhibitors, and glycine delays anoxic injury. Precise mechanisms responsible for the stimulation of calpain activity during either necrosis or apoptosis are still unclear. More recently, it has been shown that hepatocellular carcinoma cells resist necrosis during anoxia by preventing phospholipase-mediated calpain activation (Arora et al., 1996); however, it is unknown whether sustained calpain activity promotes necrosis as a "deathase" by degrading key cytoskeletal proteins such as spectrin or by acting as a "signaling protease." Thus a better understanding of the protein substrates cleaved in necrosis will be required before the role of calpains in necrosis can be elucidated.

Another example of noncaspase proteases that may be involved in apoptosis is seen in the plasminogen activator system, which is a major proteolytic complex responsible for the breakdown of the extracellular matrix. Expression of the plasminogen activator inhibitor type 2 (PAI-2) in HeLa cells, which do not synthesize PAI-2, protects them from tumor necrosis factor–(TNF-) induced apoptosis (Dickinson et al., 1995). Interestingly PAI-2 has a high degree of structural similarity to crmA, which inhibits caspase-1-induced apoptosis (Dickinson et al., 1995). PAI-2 itself is not spared during apoptosis, and it loses its activity after cleavage by other proteases (Jensen et al., 1994). There are no reports about the involvement of this protease in necrosis.

An alternative proteolytic system, which is thought to play a role in cell death, is that of proteasomes. The contribution of proteasomal activity during apoptosis has primarily been evaluated by using inhibitors. There are several observations that show that inhibition of proteasomal activity by "specific" peptide inhibitors either fails to prevent receptor-mediated apoptosis (B. Zhivotovsky, D.H. Burgess, I. Ares-Pörn, and S. Orrenius, unpub. observ.) or drives cells into apoptosis (Shinohara et al., 1996); however, there are a few experimental models in which proteasome inhibitors antagonized apoptosis (for review see Orlowski, 1999). Currently there is no evidence that these enzymes directly activate caspases. Thus, a conclusive role for this enzymatic system in apoptosis remains to be elucidated.

The lytic nature of lysosomal enzymes and their release by various experimental procedures suggested long ago that they might be responsible for cell necrosis in damaged cells and tissues (for review see Bowen, 1981). The concept of the lysosome as a "suicide bag" was developed in the 1960s by de Duve (1963). This hypothesis states that particle-bound acid hydrolase can be released into the surrounding cytoplasm under appropriate conditions and bring about the cell's ultimate destruction. Such a response might occur during cellular injury. Much attention was paid to acid hydrolases in earlier publications. Hydrolases, however, were later shown to occur in association with the Golgi and/or Golgi–endoplasmic reticulum lysosomes, endoplasmic reticulum extracisternal spaces, and plasma membranes (for review see Bowen, 1981). In reference to inflammatory cells, it has been shown that acid hydrolases are directly transferred from the endoplasmic reticulum into foci of cytoplasmic degeneration (Van Lancker, 1975). It was later concluded that when cells die, areas of the cytoplasm become segregated for autolysis, and that these areas are supplied with hydrolases, either from primary lysosomes or directly from the endoplasmic reticulum. Furthermore, an accumulation of free acid phosphatases around ribosomes in the extracisternal space of the endoplasmic reticulum has been linked to this type of cell death (for review see Bowen, 1981). This early extracisternal buildup appears as a prelude to cell autolysis. On the other hand, histochemical studies showed that the liberation of acid phosphatases and esterases was not an early change (Kerr et al., 1972), and the authors of that study suggested that the release of lysosomal enzymes is not responsible for the initiation of necrotic cell death, but rather accompanies this type of death. There is no evidence for preferable degradation of any proteins by lysosomal proteases during necrosis. Thus, although the involvement of both lysosomal and nonlysosomal protease activities in necrosis was documented, the precise role of these protease activities in either induction or execution of necrosis, as well as the specific cleavage of cellular proteins, remain to be elucidated.

Recently some lysosomal proteases have entered the "apoptotic death scene" (Salvesen, 2001). It has been shown that in vitro cathepsins can readily cleave several caspases; however, it is unclear whether cathepsin-mediated cleavage of procaspases results in the activation of these enzymes. Moreover, it is unknown whether this cleavage occurs in whole cells (for review see Johnson, 2000). Given the lack of evidence for a direct role in caspase activation by lysosomal proteases in vivo, the authors hypothesized that an indirect mode of caspase activation may involve the Bcl-2 family member Bid (Stoka et al., 2001). Indeed, Bid is cleaved by lysosomal protease(s) and this cleavage may represent a mechanism by which proteases that leak from the lysosomes can participate in perpetuation of the apoptotic pathway. It seems that lysosomal rupture can trigger apoptosis in certain pathological conditions as well as during normal aging. Nevertheless additional work is required to understand the precise role of lysosomal enzymes in induction and execution of apoptosis.

CELLULAR SIGNALING DURING CELL DEATH

Signal transduction is thought to play a key role in the onset of both apoptosis and necrosis, and this may be mediated by an increase in intracellular Ca^{2+} levels, protein kinase C (PKC), cyclic adenosine monophosphate/protein kinase A (cAMP/PKA), or phosphatases. It has been demonstrated that glucocorticoid-induced cell death involves Ca^{2+} influx in lymphocytes and that this type of cell death can be mimicked using calcium ionophores (Kaiser and Edelman, 1978). Based on these observations, it appears that intracellular Ca^{2+} levels may initiate a death signal, probably through the activation of Ca^{2+}-dependent enzymes (proteases, phospholipases, and endonucleases) in this system. The evidence for a role of Ca^{2+} in necrotic cell killing is particularly strong in the central nervous system. Ca^{2+} appears to mediate the neurotoxicity of cyanide, heavy metals like lead and mercury, and organotin compounds (for review see Nicotera and Orrenius, 1998). Furthermore, intracellular Ca^{2+} overload, resulting from excessive stimulation of excitatory amino acid receptors and enhanced Ca^{2+} influx through membrane channels, appears to play an important role in ischemic brain damage. Much recent research has focused on glutamate-induced excitotoxicity and its contribution to brain damage in various diseases (Ankarcrona et al., 1995; Sims and Robinson, 1999 and references therein). The calcium ion plays a critical role in this process, and intracellular Ca^{2+} overload appears to mediate the lethal effect of *N*-methyl-D-aspartate (NMDA) receptor overactivation. This mechanism is responsible not only for the brain damage induced by certain neurotoxins, but also for excitotoxicity, which is strongly implicated in neuronal death following insults such as ischemia and trauma. Thus, NMDA receptor antagonists not only block Ca^{2+} influx and neuronal death elicited by glutamate or NMDA in vitro, but can also reduce the volume of infarction produced by focal ischemia in vivo. As discussed above, glutamate can trigger the onset of both apoptosis and necrosis in cerebellar granule cells (Ankarcrona et al., 1995). Radical scavengers and agents that inhibit the generation of nitric oxide by nitric oxide synthase were ineffective in preventing cell death in this system, whereas NMDA receptor/channel blockers prevented both necrosis and apoptosis in glutamate-treated cerebellar granule cells. These data suggest that Ca^{2+} overload, mediated by NMDA-receptor-operated channels, is sufficient to induce either necrosis or apoptosis in cerebellar granule neurons in vivo. It is clear that intracellular Ca^{2+} overload is an important factor in various in vitro models, and results from clinical studies appear to support this hypothesis. The Ca^{2+} overload seems to result from increased Ca^{2+} influx through both receptor-operated and L-type Ca^{2+} channels, as indicated by the neuroprotective effects of glutamate-receptor antagonists and L-type channel blockers. Various Ca^{2+}-dependent degradative processes have been found to contribute to Ca^{2+}-mediated necrotic cell killing in in vitro studies, and although their relative contribution is unclear, it appears that perturbation of cytoskeletal organization, impairment of mitochondrial function, and/or activation of certain proteases may be of particular importance. For example, it has been proposed that activation of phospholipase A2 by a sustained increase in cytosolic calcium plays an important role in necrotic cell killing. Support for this hypothesis comes from several observations that necrosis in the liver and heart caused by ischemia, as well as in hepatocellular carcinoma cells in anoxic condition, is prevented by inhibitors of this enzyme or by the inhibition of calpain activation (for review see Nicotera and Orrenius, 1998). Thus, it is likely that the calcium ion may play a determinant role in the necrotic process.

One of the classic signaling pathways is that of PKC, which is a multifunctional ser-

ine/threonine kinase that utilizes diacylglycerol as a second messenger (Nishizuka, 1984). Twelve different isoforms of PKC have been identified to date and are classified according to their calcium dependence and phorbol ester binding activity (for review see Lavin et al., 1996). There are some reports as to the involvement of PKC in apoptosis. For example, it has been reported that treatment of mouse thymocytes with phorbol esters, which activate PKC, induces apoptosis (Kizaki et al., 1989). Similarly, apoptosis induced by the calcium ionophore A23187 can be inhibited by the PKC inhibitor H7; however, most of the evidence to date indicates that PKC activation inhibits apoptosis (McConkey et al., 1996). This paradox may be explained by the large number of isoforms, which may be differentially regulated during apoptosis (Forbes et al., 1992).

Similarly, the role of protein phosphatases during apoptosis is not clear. There are some reports that a number of cell lines react to okadaic acid by undergoing apoptosis (Boe et al., 1991), while there are other reports that the inhibition of protein phosphatase activity blocks apoptosis in some other cell lines (Baxter and Lavin, 1992). From these reports it appears that protein activation/modification, through reversible protein phosphorylation by kinases and protein phosphatases rather than by de novo protein synthesis, may play a more central role in the regulation of apoptosis in some cells.

The anatomy of receptor-mediated death signaling machinery is well characterized. This pathway involves initiation of a cascade of signaling events leading to the activation of caspases. Members of this family, such as CD95 (Apo1/Fas), contain a death domain (DD) in their cytoplasmic tail, which is essential for transducing the apoptotic signal. Upon binding with its natural ligand, CD95-L, receptors undergo trimerization followed by very fast formation of death-inducing signaling complex (DISC). The first step in DISC formation involves binding of DD in CD95 with DD present in the adaptor protein Fas-associated death domain (FADD), which also carries a so-called death effector domain (DED). Next, DED in FADD by homologous interaction recruits the DED in another protein, FLICE, which contains on C-termini procaspase-8. During CD95-initiated cell death, small-accelerator for death signaling (SADS) enhances interaction of FADD and FLICE, and formation of DISC, thereby accelerating processing/activation of procaspase-8 (for review see Krammer, 2000). Active caspase-8 is either directly involved in cleavage and activation of procaspase-3, which results in completion of the cell death process, or it cleaves Bid, a Bcl-2 family member, which in turn activates the so-called, mitochondria-mediated pathway.

ROLE OF MITOCHONDRIA DURING CELL DEATH

Work from several laboratories has indicated that mitochondrial damage may be a common event in the development of cell injury caused by various agents (Nicotera and Orrenius, 1998). It was postulated that mitochondrial damage is initially manifested by a decrease in the mitochondrial membrane potential followed by ATP depletion (Zamzami et al., 1995). During necrosis, these changes occur irreversibly and usually lead to disruption of the mitochondrial structure. These changes set necrosis aside from apoptosis, during which mitochondrial structure remains morphologically intact. Mitochondria have nevertheless been implicated in apoptosis ever since the discovery that the Bcl-2 protein localizes to the outer mitochondrial membrane (Hockenbery et al., 1990). Moreover, by using different cell-free systems, it has been shown that nuclear apoptosis depends on the presence of ATP (Lazebnik et al., 1993; Newmeyer et al., 1994; Kass et al., 1996). It has been demonstrated that cytochrome *c* can induce cleavage and activation of procaspase-3 in cytochrome *c*–minus cytoplasmic extracts (Liu et al., 1996). It has also been shown that cytochrome *c* is released from the mitochondrial intermembrane space into the cytosol by cells undergoing apoptosis. In this case cytochrome *c* release is not preceded by changes in mitochondrial membrane potential (for review see Hengartner, 2000).

During apoptosis a number of proteins that are normally confined to the intermembrane space of the mitochondria are translocated to the cytosol, where they trigger reactions that give rise to the apoptotic process. The role of cytochrome *c* in activation of procaspases has already been described. Recently mitochondrial localization of at least three procaspases (2, 3, and 9) was described. It is still unclear whether any of these procaspases become active within the mitochondria or after their release into the cytosol. Mitochondrial procaspase-3 is present in a complex with HSP10 and 60, and upon induction of apoptosis, procaspase-3 is dissociated from the HSP complex simultaneously with the release of HSP from mitochondria and activation of caspases (Samali et al., 1999b). Another important regu-

lator of apoptosis, second mitochondria-derived activator of caspases (Smac) or direct IAP binding protein with low pH (DIABLO), is released from mitochondria into the cytosol, where it eliminates the inhibitory effect of many inhibitors of apoptosis proteins (IAPs) on the activation of several caspases (for review see Hengartner, 2000). Apoptosis-inducing factor (AIF) is also located in the intermembrane space of mitochondria and upon apoptosis induction redistributes to the nucleus where it is involved in nuclear chromatin condensation and chromatin fragmentation with formation of high-molecular-weight DNA fragments (Daugas et al., 2000). The role of other proteins released from mitochondria (i.e., adenylate kinase-2 and sulfite oxidase) in the apoptotic process is unknown.

Two groups have presented evidence that a high ATP level is required during the apoptotic process and suggested that the level of intracellular ATP determines whether a cell will die by apoptosis or necrosis (Nicotera and Leist, 1997; Tsujimoto, 1997). During exposure to glutamate, both mitochondrial membrane potential and ATP levels decline in many neurons (Ankarcrona et al., 1995). In neurons with irreversibly dissipated mitochondrial potentials, necrosis rapidly ensued. The surviving population recovered both mitochondrial membrane potential and energy levels and subsequently underwent delayed apoptosis. It was postulated that the loss of energy and the onset of rapid necrosis simply prevents the activation of the default apoptotic program. This postulate was supported by the observation that treatment of cerebellar granule cells with a combination of glutamate and the irreversible mitochondrial uncoupler carbonyl cyanide *m*-chlorophenylhydrazone (CCCP) resulted in necrosis for most of the neuronal population, rather than in the delayed apoptosis observed with glutamate alone.

There is abundant evidence for an ATP requirement in several apoptosis models, although the critical ATP-dependent steps in the process have not been characterized in detail. They are likely to be linked to both the signaling and the execution phases of apoptosis. It was suggested (Tsujimoto, 1997) that the caspase protease cascade is regulated by ATP-dependent reactions, and it has been shown (Yasuhara et al., 1997) that the active nuclear transport mechanism, which requires ATP hydrolysis, is involved in the apoptotic changes of the nuclei. It is likely that another ATP-dependent step or steps downstream from caspase activation is important for perpetuation of the apoptotic process. This fact could explain the previously published data on the ATP requirement for induction of nuclear apoptosis induced by different cytoplasmic extracts (Lazebnik et al., 1993; Newmeyer et al., 1994; Kass et al., 1996). Thus, it is not surprising that the depletion of cellular ATP blocks various events in apoptosis. The question that remains to be answered is whether and how ATP depletion redirects the death process towards necrosis when cells have been triggered with apoptotic stimuli, such as anti-CD95 antibodies. In addition to the possible requirement of ATP for caspase activation, redirection could also be explained by an unknown mechanism, which shortens the survival time of cells that would eventually die by necrosis resulting from energy deprivation.

The next important question that remains to be resolved is an apparent contradiction between, on the one hand, the induction of the mitochondrial permeability transition associated with a cessation of mitochondrial ATP synthesis, and on the other, a need for maintenance of the intracellular ATP level during development of apoptosis, which may take many hours or days. In addition, hyperproduction of reactive oxygen species (ROS) results from the loss of cytochrome *c* from the respiratory chain; yet the cell needs to maintain a reducing environment for optimal caspase activity. These controversies could be resolved if the proposed apoptosis-induced changes were restricted to a subset of mitochondria, or that the maintenance of the energy level required by cells to undergo apoptosis could occur by glycolysis. This would be consistent with the observation by Jacobson et al. (1993) that cells lacking mitochondrial DNA and a functional respiratory chain can still undergo apoptosis. It is very likely that the mitochondrial permeability transition associated with a cessation of mitochondrial ATP generation plays an important role in necrotic cell death, whereas leakage of cytochrome *c* from morphologically intact mitochondria via a yet unknown and more selective pathway than outer-membrane rupture following permeability transition–induced mitochondrial swelling plays an important role in apoptotic cell death.

GENETIC MODULATION OF APOPTOTIC CELL DEATH

In recent years, enough evidence has been gathered to suggest a role for the protein products of a number of oncogenes and tumor-suppressor genes, as well as stress proteins and acute phase proteins, in the modulation of cell

death. These can be grouped into genes whose products are positive or negative regulators of cell death. The genes with a key role in the modulation of cell death and their effects on both apoptosis and necrosis are reviewed below.

c-myc

The *c-myc* proto-oncogene is a short-lived nuclear protein and a member of a family of closely related genes that also include *v-myc*, *n-myc*, and *b-myc*. The *Myc* family plays a key role in the regulation of cell proliferation (for review see Ryan and Birnie, 1996). It has been demonstrated that *c-myc* is capable of driving apoptosis (Evan et al., 1992). For instance, when T cell hybridomas were stimulated through their CD3/T cell receptor, they rapidly underwent apoptosis that could be blocked using an antisense oligonucleotide to *c-myc* mRNA. Furthermore, in fibroblasts, *c-myc* overexpression can induce apoptosis. The decision to proliferate or die in cells overexpressing *c-myc* seems to depend on the presence or absence of extracellular survival factors (Evan and Littlewood, 1998).

p53

The p53 protein is the product of a tumor-suppressor gene, which is mutated in over half of all human tumors, thus implicating p53 inactivation in tumorigenesis. Nevertheless, the main functions of p53 appear to be in mediating the cellular response to DNA damage and maintaining genomic stability (Kastan et al., 1991). Many forms of genotoxic stress induce a rapid increase in p53 protein levels, through both stabilization of the protein (Kastan et al., 1991) and an increase in p53 mRNA levels (Sun et al., 1995). This protein induces growth suppression by regulating cell-cycle arrest and/or inducing apoptosis. Reintroduction and overexpression of wild-type p53 in cells that have lost endogenous p53 function may induce apoptosis (Yonish-Rouach et al., 1991). In this regard, p53 is shown to be required for both irradiation-induced G1 arrest and apoptosis in several cell systems (Lowe et al., 1993). Induction of growth arrest by p53 has been shown to be transcription activation–dependent and appears to involve induction of *p21* (*Waf1/Cip/sdi1*) and growth arrest and DNA damage-inducible gene 45 (*Gadd45*; for review see Somasundaram and El-Deiry, 2000).

Although transcriptional activation appears to be involved in the induction of growth arrest, little is known about the possible downstream elements in this apoptotic pathway. p53 has been shown to induce apoptosis in the presence of transcriptional activation, in which case p53 may induce expression of CD95. Moreover, p53 transcription activates several genes whose products can translocate to the mitochondrial outer membrane (e.g., the two proapoptotic Bcl-2 family members Bax and Noxa) or to an unknown submitochondrial compartment, presumably to the mitochondrial matrix (p53AIP1). In addition, direct death signal–induced translocation of p53 to mitochondria has been documented (for review see Ferri and Kroemer, 2001).

Recent identification of two homologues, p63 and p73, revealed that p53 is a member of a family of related transcription factors. Given that they share amino acid sequence identity, all three proteins should have redundant functions in the regulation of gene expression. Indeed, p73 can activate p53-regulated genes and suppress growth or induce apoptosis. Moreover, p73 and p53 are both induced by DNA damage, albeit through distinct mechanisms. Other evidence, however, suggests that p63 and p73 are important for regulation of normal development and in many p53-independent pathways (for review see Levrero et al., 2000; Yang and McKeon, 2000).

Bcl-2 family

This is a family of genes in which many members hold key positions in the apoptotic machinery. The proteins in this family share highly conserved regions, which have been referred to as *Bcl-2* homology domains (i.e., BH1 to BH4; for review see Gross et al., 1999). Family members that act as inhibitors of cell death harbor at least BH1, BH2, and BH4 domains, which are required for protein-protein interaction and the suppression of apoptosis, whereas BH3 serves as the minimal "death domain" in the proapoptotic members studied so far (for review see Fadeel et al., 1999).

Bcl-2 was the first member of this family to be identified in follicular B cell lymphomas (Bakhshi et al., 1985). Several other family members, which were discovered later, may function to inhibit apoptosis, including *Bcl-2, Bcl-X_L, Bcl-W, Bfl1/A1, Mcl-1, Bag-1, BRAG-1, NR-13, Boo/Diva,* and *BHRF-1,* while others function to accelerate the rate of apoptosis once it has been induced, including *Bax, Bcl-X_s, Bad, Bak, Bar, Bid, Bik/Nbk, Bok/Mtd, Bim/Bod, Blk, Hrk/DP5, Noxa, Bnip3, Nix, Bcl-G,* and *MAP-1* (for review see Fadeel et al., 1999).

Localization is an important theme in signal transduction and increased evidence has been

provided that the regulation of apoptotic signals by Bcl-2-like proteins is dependent on their specific intracellular movement.

Bcl-2 protein is localized to the mitochondria, endoplasmic reticulum, and nuclear membrane (Hockenbery et al., 1990). Bcl-2 appears to have antioxidant properties, as it can inhibit apoptosis induced by reactive oxygen species (Hockenbery et al., 1993); however, it has also been demonstrated that Bcl-2 can inhibit cell death under conditions that preclude the formation of reactive oxygen species (Jacobson et al., 1993). Thus, the ability of Bcl-2 to protect against the damaging effects of free radicals does not appear to account for the suppression of cell death by Bcl-2.

Bax is more ubiquitously expressed than Bcl-2 (Krajewski et al., 1994). The *bax* gene promoter contains four p53-binding sites, and it has been shown that the levels of its protein can be up-regulated by p53. The countervailing roles of pro- and antiapoptotic Bcl-2 family members can be regulated through protein-protein interaction and formation of homo- and/or heterodimers. Thus, Bcl-2 can heteromerize with Bax, Bid might interact with Bax and Bak, and Bax can also interact with Bcl-X_L, Mcl-1, and A1. Function of Bcl-2 like proteins in addition to homo- or heteromerization can be regulated via phosphorylation (i.e., Bcl-2, Bcl-X_L, Bim, and Bad), *N*-myristoylation (Bid), translocation (Bid, Bax, Bcl-X_L, and Bad), insertion (Bcl-2, Bcl-X_L, Bax, and Bid), conformational changes (Bak and Bax), and cleavage (Bcl-2, Bcl-X_L, and Bax). Many protein-protein interactions take place either at the level of mitochondria or induce the movement of proteins to mitochondria. Thus, after cleavage by caspase-8, the cleaved Bid (tBid) interacts in the cytosol with Bax. This interaction leads to conformational changes of Bax, its insertion into mitochondrial membrane and oligomerization. All these events result in cytochrome *c* release. Cleaved Bid can also translocate and insert into the outer mitochondrial membrane, where it might induce conformational changes of Bak constitutively anchored to this membrane. This again leads to oligomerization of Bak, its insertion into the membrane, and release of cytochrome *c*. The antiapoptotic proteins Bcl-2 and Bcl-X_L inhibit the conformational changes and/or oligomerization and insertion of Bax and Bak. Antiapoptotic proteins from the Bcl-2 family may counteract the effect of both caspase-dependent and caspase-independent models of cell death through manifold independent functions. Although much progress has been made toward understanding the mechanisms of pro- and antiapoptotic functions of Bcl-2 family proteins, numerous issues remain unresolved.

It has been shown that overexpression of Bcl-2 can also inhibit necrosis, at least in neuronal cells, when induced by such diverse stimuli as viruses, hypoxia, oxidative stress, or exposure to toxicants (Lezoulac'h et al., 1996; Shimizu et al., 1996). Whether this effect is cell-specific remains unclear. The mechanism of action of Bcl-2 in cells undergoing necrosis may simply involve antioxidant activity. The second possibility is that Bcl-2 prevents the consequences of mitochondrial dysfunction (i.e., collapse of the mitochondrial transmembrane potential, uncoupling of the respiratory chain, hyperproduction of superoxide anions, disruption of mitochondrial biogenesis, outflow of matrix calcium and glutathione, and release of soluble intermembrane proteins), all of which can lead to a bioenergetic catastrophe culminating in the disruption of plasma membrane integrity, which is the ultimate result of necrosis (Kroemer, 1997); however, more work should be done to justify this hypothesis and to understand the mechanism of Bcl-2-induced protection from necrosis.

Ras

Members of the Ras family of proteins play an essential role in the control of normal cell growth and may induce transformation. Certain evidence has led a number of groups to advocate that Ras, in addition to inducing transformation, can also prevent cell death as overexpression of the *ras* gene was shown to inhibit apoptosis in a number of cases (Wyllie et al., 1987; Arends et al., 1993). Ras appears to be a focal point for the convergence of many signaling pathways, especially during receptor/ligand interaction, such as epidermal growth factor (EGF), fibroblast growth factor (FGF) and nerve growth factor (NGF), T cell receptor–CD3 (TCR-CD3), and CD95. The question as to which protein downstream of the pathway is the key effector of the antiapoptotic signal through Ras is unclear, but it may involve the activation of MAP kinase or phosphotidylinositol 3 kinase or both.

Stress Proteins

The stress proteins are a set of evolutionarily conserved proteins that are synthesized or activated in response to stress (for review see Lindquist and Craig, 1988). The main function of these proteins is to afford protection to cells

in times of stress. When the stress element is removed, these cells continue to function normally and the levels drop back to normal. Heat-shock proteins (HSPs), a subgroup of stress proteins, were first demonstrated to be induced as a response to elevated temperatures.

There is strong evidence suggesting that the induction of HSPs coincides with the acquisition of tolerance to higher doses of stress, which may otherwise be lethal to the cell. In this regard, it was demonstrated that a mild heat shock induces the rapid synthesis of a number of HSPs (Jaattela et al., 1992; Mosser and Martin, 1992) and that heat-shocked or thermotolerant cells demonstrated a greater degree of resistance to environmental stress (Jaattela et al., 1992), probably by resisting apoptosis (Samali and Cotter, 1996). Indeed, several recent publications reveal an important role for heat-shock proteins in apoptosis (for review see Xanthoudakis and Nicholson, 2000). These proteins can positively or negatively regulate the apoptotic process. Thus, a direct interaction of caspase-3 with HSP60 ultimately results in stimulation of proenzyme maturation. Direct binding of HSP70 or HSP90 to Apaf-1 precludes the eventual recruitment of procaspase-9 to the apoptosome complex. HSP70 can inhibit apoptotic processes downstream of the release of cytochrome *c* and upstream of the activation of caspase-3 as well as exert a protective effect against apoptosis by targeting one or more steps downstream of caspase-3. Elevated levels of HSP70 prevent the morphological changes that are characteristic of dying cells as well as the death of tumor cells despite the presence of cytochrome *c* and active caspase-3 in the cytosol. In addition, HSP27 was shown to bind to cytochrome *c* upon its release from mitochondria, thus preventing its interaction with Apaf-1. HSP27 might also directly bind and inhibit processing of procaspase-3. Thus, it remains to be determined whether these observations reflect a difference in signaling between different cell types or whether the results can be reconciled on the basis of some experimental variable. It was demonstrated that thermotolerant or HSP-overexpressing cells are more resistant to cell death induced by hyperthermia or growth-factor withdrawal (Mailhos et al., 1993). This may suggest a possible role for HSPs in the resistance mechanism. Furthermore, HSPs are also implicated in drug resistance (McClean and Hill, 1992) and heat-shocked or HSP-overexpressing cells become more resistant to the cytotoxic effects of some anticancer drugs (Oesterreich et al., 1993) that are otherwise capable of inducing both apoptosis and necrosis (Martin et al., 1990).

CONCLUSIONS

Cell damage leading to cell death may occur via apoptosis or necrosis. The mode of cell death depends on the nature of the stimuli but in extreme situations the final outcome is cell disruption and disintegration. In other words, necrosis is the acute type of cell death or the cellular response to extreme injury. During necrosis, chromatin adopts a highly flocculated form, and the DNA from these cells is digested randomly to give a smear when analyzed by agarose gel electrophoresis. The main feature of necrosis is an increase in cell volume. The rapid increase in cell volume results in membrane rupture and cell lysis (for review see Trump and Berezesky, 1995).

After two decades of research and development in the field of cell death, it is now universally accepted that apoptosis is an essential strategy for maintaining the dynamic balance and equilibrium of living systems, and is observed to occur as a normal mechanism in development and homeostasis, as well as an altruistic mode of inducible cell death. Classification of cell death is now based on morphological and biochemical criteria, their circumstantial occurrence, or a combination of both. Although morphological characterization of apoptosis and the features distinguishing it from necrosis have been well documented, progress in our understanding of the mechanisms underlying the process has been quite slow.

There is now much evidence that classic apoptosis and necrosis represent only definitive endpoints for these two processes; however, both types of cell death can occur either simultaneously or sequentially in the same cell population or tissue depending on type and/or dose of toxic insult. This suggests that some early biochemical and morphological events might be similar or even identical in both types of cell death. If this is the case, different downstream events might be important in determining whether the cell will undergo apoptosis or necrosis. It could also be that after intensive treatment, the cellular apoptotic machinery becomes suppressed, after which necrosis would predominate. The events summarized in Table 18.1.1 can be observed at different levels of cellular organization. Thus, both physiological or pathological stimuli can induce apoptosis, but only pathological injury leads to necrosis. Apoptosis, in contrast to necrosis, occurs in individual cells in an asynchronous fashion

without damaging neighboring cells. Both processes can be protected by certain inhibitors before a point of no return is reached. Once the cascade of caspase proteolytic activities becomes active, apoptosis cannot be completely reversed. The point of no return during necrosis remains to be elucidated. Nevertheless, cells can be rescued from necrosis as well as from apoptosis.

Cellular shrinkage is a hallmark of apoptosis and is seen in many if not all cell types that undergo this type of death. Cell-volume regulation is a complex phenomenon, involving the homeostasis of intracellular ions such as chloride, sodium, and potassium. As the most abundant intracellular ion, K^+ has been implicated in several of the regulatory mechanisms governing cell volume, including regulatory volume decrease. It has been shown that intracellular K^+ content decreases in cells undergoing apoptosis induced by diverse stimuli (for review see Yu and Choi, 2000). Work in the authors' laboratory has shown a potential link between glutathione (GSH) efflux and apoptotic cell shrinkage (Nobel, 1997). Inhibitors of apoptotic GSH efflux were able to inhibit cell shrinkage in thymocytes induced to undergo apoptosis by etoposide without affecting DNA fragmentation. Moreover, the GSH efflux was accompanied by K^+ efflux in Jurkat cells treated with anti-CD95 antibody. The K^+ efflux was not blocked either by the inhibitor of GSH efflux or by any known inhibitors of K^+ channels and cotransporters tested. Concomitant with apoptotic K^+ efflux, significant inhibition of Na^+/K^+-ATPase activity was observed. Inhibition of this enzyme by ouabain caused a K^+ efflux of similar magnitude to that induced by anti-CD95 antibody, and it potentiated CD95-mediated cell shrinkage. This suggested that with Na^+/K^+-ATPase activation, K^+ and GSH effluxes facilitated apoptotic cell shrinkage, which was followed by the formation of apoptotic bodies. In contrast, necrotic cells showed extensive swelling, which resulted in subsequent disintegration of cells.

Apoptotic cells lose adhesion at the very early stages, while necrotic cells stay adherent until very late stages. As mentioned before, individual apoptotic cells can be efficiently recognized either by neighboring cells or professional macrophages and can be removed by phagocytosis. This step of the apoptotic process involves rearrangement of the plasma membrane. Removal of the dead-cell fragments before their plasma membranes are lysed has important implications for other cells within the tissues. It is assumed that apoptosis occurs without inflammation. Lysis of plasma membranes in necrotic cells seems to precede the removal of these remnants, and exudative inflammation is a common event during necrosis.

The significance of apoptosis is based on the fact that apoptotic cells tend to be "environmentally friendly" and package their contents into membrane-bound vesicles ready for ingestion by phagocytic cells, without releasing their contents into the intercellular matrix. Hence there is no inflammatory response. Apoptosis is also an altruistic mode of cell death, in that damaged or injured cells commit suicide to allow the neighboring cells to continue to proliferate without being affected by the death of the neighbor. In addition, sacrifice of individual abnormal, or potentially malignant, cells benefits the whole organism.

Most if not all mechanisms leading to cell death involve molecular damage that is potentially reversible by cellular repair mechanisms; therefore, if the repair mechanisms operate effectively, they may prevent cell death. It could be that in cells undergoing apoptosis, the cell-repair machinery is repressed by specific signals, which program cells to die. On the other hand, in cells undergoing necrosis this machinery might be directly suppressed by extremely strong insult (high doses of drugs or irradiation). Since apoptosis is a gene-directed process and many genes are involved in the regulation of this multistage action, the repression of repair processes can also be regulated on this level. There is no evidence for expression of any specific genes during necrosis, which is why it is difficult to discuss the possible requirement of gene regulation for necrotic cell death. Thus, it seems that classic necrosis is a passive process. An inhibition of the activity of a number of gene products involved in apoptosis can switch the death pathway from apoptosis to necrosis. Also rapid changes in the cellular ATP level, discussed above, and an imbalance in the ratio of nitric oxide and superoxide can switch the form of cell death. Recently, an additional form of cell death was described and named paraptosis by the authors (Sperandio et al., 2000). This internally programmed cell death is related to pathogenesis in the central nervous system and to development of some primitive eukaryotes. Although experiments indicate that this type of death depends on RNA and protein synthesis, the machinery required for apoptosis is inactive in paraptotic cells. Thus, morphologically these cells are characterized by swelling of endoplasmic reticulum and cytoplasmic vacuolization,

and do not display nuclear fragmentation and formation of apoptotic bodies. Paraptotic cells are TUNEL-negative and their DNA does not fragment. Moreover, paraptotic death is independent of well known sequential caspase activation, although expression of caspase-9 in the presence of pan-caspase inhibitors induced nonapoptotic cell death; therefore it is clear that there is "more than one way to go" (Wyllie and Golstein, 2001). The search at both molecular and biochemical levels for mechanisms of apoptosis, necrosis, and paraptosis, along with attempts to understand the differences/similarities between these types of cellular response to treatment, are currently subject to intense biological research.

Analysis of Caspase Activation During Apoptosis

This unit describes methods for the detection of caspase activation as cells undergo apoptosis. Caspases are intracellular cysteine proteases that are synthesized as zymogens and then proteolytically activated early in the course of apoptosis. This activation process can be detected by assays for cleavage of suitable fluorogenic or chromogenic substrates, by immunoblotting with monospecific antibodies, or by affinity labeling with reactive substrate analogs. Because the caspases are organized into distinct proteolytic cascades, identifying the caspases that are activated and their order of activation can provide insight into the biochemical pathways involved in that activation.

Three different approaches for assessing caspase activation are described. Enzymatic assays using suitable substrates are simple and relatively quantitative (see Basic Protocol 1). Because the various low-molecular-weight substrates available for these assays are not selective, however, the assays do not accurately distinguish between various caspases. Immunoblotting can be utilized to follow the activation of specific caspases (see Basic Protocol 2 and Alternate Protocol 1). When coupled with subcellular fractionation (Graham and Rickwood, 1997), this method can provide large amounts of temporal and spatial information about caspase activation. Like all immunological methods, however, immunoblotting is limited by the quality and availability of immunological reagents. Finally, affinity labeling can be utilized to detect active caspases in whole-cell lysates (see Basic Protocol 3 and Alternate Protocol 2) or subcellular fractions. With suitably designed affinity labels, this method can detect active caspases even when their identity and substrate specificity are unknown (e.g., when caspases are being explored in a new species before immunological reagents are available). Affinity labeling, however, is the most labor intensive of these techniques. In addition, because some procaspases label poorly with commercially available affinity labels, the lack of affinity labeling does not absolutely rule out the presence of active caspases.

ENZYMATIC ASSAYS FOR CASPASE ACTIVITY

BASIC PROTOCOL 1

In principle, the easiest method for determining whether caspases have been activated in apoptotic cells is to assay for their activity. This approach became feasible after the identification of sequences that are cleaved in various caspase substrates during apoptosis (reviewed in Nicholson and Thornberry, 1997; Earnshaw et al., 1999) and the subsequent synthesis of low-molecular-weight substrates containing the appropriate peptides coupled to fluorogenic or chromogenic leaving groups (Thornberry et al., 1992; Nicholson et al., 1995; Martins et al., 1997). It must be kept in mind, however, that the apoptotic caspases show varying degrees of preference rather than absolute specificity for the currently available caspase substrates. Accordingly, these enzymatic assays can indicate that caspases have been activated but will not necessarily provide an accurate indication of the individual caspases that have been activated.

The following protocol describes the preparation of cytosol and an assay for cleavage of the substrate acetyl-Asp-Glu-Val-Asp-7-amino-4-trifluoromethylcoumarin (acetyl-DEVD-AFC). For this procedure, cells are initially subjected to conditions that are thought to induce apoptosis. These apoptosis-inducing treatments must be optimized for each cell line and inducing reagent before the protocol can be carried out. Because caspases are intracellular proteases, cells must then be lysed or fractionated. After the protein content in the lysates or subcellular fractions is measured, samples containing equal amounts of protein are incubated with the fluorogenic substrate. The change in

Current Protocols in Cell Biology (2001) 18.2.1-18.2.29

fluorescence is measured and compared to a standard curve constructed using known amounts of the fluorescent product.

Materials

Cells of interest and appropriate medium
Apoptosis-inducing stimulus
CMF-DPBS (*APPENDIX 2A*), ice cold
Lysis buffer (see recipe), 4°C
0.5 M EDTA, pH 7.4 (see recipe)
1 M dithiothreitol (DTT; *APPENDIX 2A*)
5 mM EDTA (pH 7.4)/1 mM DTT in lysis buffer, ice cold
20 mM (14.6 mg/ml) acetyl-Asp-Glu-Val-Asp-7-amino-4-trifluoromethylcoumarin (acetyl-DEVD-AFC; Biomol), or other fluorogenic or chromogenic caspase substrate, in dimethyl sulfoxide (DMSO)
HEPES/CHAPS buffer (see recipe), room temperature and ice cold
10 mM (4.6 mg/ml) 7-amino-4-trifluoromethylcoumarin (free AFC; Sigma), or appropriate standard for other substrate, in DMSO

Cell scraper (optional)
2-ml (total volume) tight-fitting Dounce homogenizers
Beckman TL100 ultracentrifuge and TL100.2 rotor, or equivalent, 4°C, and appropriate ultracentrifuge tubes
Fluorometer

Additional reagents and equipment for Ficoll-Hypaque density sedimentation (*UNIT 2.2*), cell trypsinization (for adherent cell lines only; *UNIT 1.1*), trypan blue staining to detect lysed cells (*UNIT 1.1*), and determination of protein concentration (*APPENDIX 3B*)

NOTE: Fluorogenic and chromogenic caspase substrates are available from a number of suppliers, including Bachem Bioscience, Biomol Research Laboratories, Calbiochem-Novabiochem, Molecular Probes, and Osaka Peptide Institute. Stock solutions for substrates and standards are prepared as 20 mM solutions in DMSO and stored in aliquots for up to 1 year at −20°C.

Induce apoptosis

1. Remove cells that have spontaneously become apoptotic before starting assay. For adherent cell lines, tap the flask containing cells of interest and change the medium to remove the dead cells. For nonadherent cell lines, remove dead cells by Ficoll-Hypaque density sedimentation (*UNIT 2.2*).

   This step reduces the background activity in this assay. For most adherent cell lines, apoptotic cells become nonadherent and can be simply washed away. Nonadherent cell lines such as leukemia and lymphoma cells require Ficoll-Hypaque density sedimentation to remove dead cells (Martins et al., 1997).

2. Treat cells with a suitable apoptosis-inducing stimulus or mock treatment. Use 1–3 $\times 10^8$ cells per time point for treatment and controls.

   The optimal treatment regimen (e.g., Kaufmann and Earnshaw, 2000) must be determined separately for each cell type and inducing agent. For reasons that are unclear, some cell lines (particularly leukemia cell lines) undergo apoptosis within 3 to 6 hr, whereas other cell lines (fibroblasts and solid tumor cell lines) take several days to die even though the same fraction of cells will ultimately die. These differences reflect varied lengths in the latent phase of apoptosis.

Harvest cells

3. Harvest cells for each time point. For adherent cells, use a cell scraper or trypsinization (*UNIT 1.1*) to release cells from their substratum.

   When working with an adherent cell line, cells that have become detached during the course of the experiment should also be collected. For many cell lines, one of the changes that occurs during apoptosis is detachment from the substratum. Discarding detached cells will cause an underestimation of the amount of apoptosis.

4. Transfer cells to a 50-ml conical centrifuge tube and centrifuge 10 min at 200 × *g*, room temperature.

5. Remove supernatant, resuspend cells in 10 ml ice-cold CMF-DPBS, and centrifuge 10 min at 200 × *g*, room temperature. Repeat once.

   All subsequent steps should be performed at 4°C unless otherwise indicated.

Isolate cell extracts

6. Remove supernatant and resuspend pellet in 1 ml ice-cold lysis buffer.

   This yields a cytosolic extract with a protein concentration ranging from 4 to 8 mg/ml.

7. Incubate sample 20 min on ice, then lyse cells in a 2-ml tight-fitting Dounce homogenizer.

   Glass-glass homogenizers work well for homogenizing cells under the conditions specified. Note that the power stroke with the homogenizer is the upstroke. Excessive force on the downstroke will cause a fountain effect. For leukemia cell lines, which have a sparse cytoskeleton, 20 to 30 strokes in a tight-fitting homogenizer are generally adequate. For epithelial cell lines, which have a dense cytoskeleton, many more strokes may be required. For some cell lines, alternative procedures such as freeze-thawing (see Basic Protocol 3) may also be employed. However, freeze-thawing disrupts membrane-enclosed compartments, making it difficult to assess subcellular distribution of activities.

8. Confirm cell lysis by mixing 3 to 5 µl homogenate with an equal volume of 0.4% (w/v) trypan blue in Hanks' balanced salt solution and examining with a hemacytometer (*UNIT 1.1*).

   If plasma membranes have been successfully disrupted, nuclei will stain blue. Continue homogenization until >95% of the nuclei stain blue.

9. Transfer homogenate to a suitable tube and centrifuge 10 min at 800 × *g* or 3 min at 16,000 × *g*, 4°C, to remove the nuclei.

10. Transfer the postnuclear supernatant to an ultracentrifuge tube. Add 0.01 vol of 0.5 M EDTA, pH 7.4.

    EDTA is added only after removal of nuclei to avoid the high viscosity that accompanies extraction of chromatin after chelation of divalent cations.

11. Centrifuge the postnuclear supernatant 60 min at 280,000 × g_{max}, 4°C, in a Beckman TL100 ultracentrifuge with a TL100.2 rotor.

12. Collect the supernatant (cytosol) and use an aliquot to determine its protein concentration (*APPENDIX 3B*).

    Caspase activity can also be examined in other fractions after suitable purification procedures (Martins et al., 1997).

    The authors generally use the bicinchoninic acid method (Smith et al., 1985) for protein concentration determination. Alternatives include the Lowry method (Cadman et al., 1979), the Coomassie blue method (Bradford, 1976), and the nitric acid method (Bible et al., 1999). No matter which method is utilized, protein measurements are required to adjust various samples to the same concentration.

13. To the remaining cytosol, add 1 M DTT to a final concentration of 1 mM.

    DTT is added to maintain sulfhydryl groups at caspase active sites in a reduced state. It could be added at earlier steps but would interfere with some protein assay methods.

14. Freeze the cytosol in 50-µl aliquots at −70°C.

    The authors generally avoid repeated freezing and thawing steps by freezing small aliquots. Control experiments from the authors' laboratory have indicated that activity capable of cleaving acetyl-DEVD-AFC is stable for ≥3 months at −70°C.

Measure enzymatic activity

15. Thaw a sample aliquot at 4°C and transfer a volume containing 50 µg cytosolic protein to a microcentrifuge tube. Dilute to 50 µl with ice-cold 5 mM EDTA (pH 7.4)/1 mM DTT in lysis buffer.

16. Add 50 µl ice-cold 5 mM EDTA (pH 7.4)/1 mM DTT in lysis buffer to a second microcentrifuge tube and treat in parallel as a negative control reaction.

    Alternatively, a reagent blank containing 50 µg boiled cytosolic protein or bovine serum albumin would also be acceptable.

17. Prepare 100 µM acetyl-DEVD-AFC in HEPES/CHAPS buffer and add 225 µl to each tube. Incubate 2 hr in a 37°C water bath.

    The 100 µM working substrate solution should be prepared immediately before use.

18. To stop the reaction, add 1.225 ml ice-cold HEPES/CHAPS buffer (final 1.5 ml) and place samples on ice.

    As indicated below, the authors have found the release of product to be a linear function of time for up to 4 hr when saturating substrate concentrations (five times the K_M) are utilized. If the reaction is run as an endpoint assay as described above, it is important to verify its linearity over time. Alternatively, continuous monitoring of fluorochrome release can be utilized to examine the kinetics of product release and/or the kinetics of enzyme inhibition if suitable equipment is available (Thornberry et al., 1992).

19. Use 10 mM free AFC in DMSO to set up a series of tubes containing a range of concentrations for a standard curve. Use 0 to 1500 pmol free AFC in 50 µl of 5 mM EDTA (pH 7.4)/1 mM DTT in lysis buffer. Add 1.45 ml HEPES/CHAPS buffer (final 1.5 ml at 0 to 1 µM AFC).

20. Measure the fluorescence of all samples in a fluorometer using an excitation wavelength of 400 nm and an emission wavelength of 505 nm.

    Under the conditions specified, the reaction is fairly robust and can be monitored in a relatively inexpensive filter fluorometer. Alternatively, for continuous monitoring, fluorometric plate readers and fluorometers with thermostatically controlled cuvette holders are available.

    Some filter fluorometers do not have excitation and emission filters of the correct wavelength for AFC fluorescence. The authors have successfully used an excitation wavelength of 360 nm and an emission wavelength of 475 nm to measure AFC.

21. Prepare a standard curve from the fluorescence intensity of the known amounts of free AFC (step 19). Compare the fluorescence values in the cell extracts to determine the absolute amount of AFC liberated in each sample.

22. Subtract the amount of AFC liberated in the reagent blank (step 16) from each value to determine the amount of enzyme-mediated release.

23. Convert this to an activity measurement by expressing the data as product released per unit protein per unit time.

DETECTION OF CASPASE ACTIVATION BY IMMUNOBLOTTING

BASIC PROTOCOL 2

Immunoblotting provides an alternative method for detecting active caspases within cells. Caspases are synthesized as zymogens that undergo proteolytic cleavage during their activation (see Background Information, discussion of immunoblotting). Accordingly, the precursors and active caspase species can be distinguished by size differences on immunoblots using anti-caspase antibodies. The usual practice is to look for disappearance of zymogen and corresponding appearance of processed caspase subunit(s). Alternatively, it is possible to use antibodies that recognize neoepitopes (i.e., epitopes generated during caspase maturation, such as epitopes that contain the carboxylate moiety of aspartate at the C terminus of the large subunit or the free α-amino group at the N terminus of the small subunit). These anti-neoepitope antibodies have the advantage that they recognize species present only in cells containing active caspases. In using either type of antibody, the overall approach for detecting caspase activation is the same (also see *UNIT 6.2*). A second method for cell lysis is described (see Alternate Protocol 1).

Table 18.2.1 Selected Properties of Human Caspases[a]

[a]Modified from Earnshaw et al. (1999).

[b]The appearance of multiple entries indicates partially processed and fully processed large (Lg) and small (Sm) subunits that result from sequential cleavage at the C-terminal end of the large subunit followed by removal of the linker peptide from the small subunit and the prodomain (Pr) from the large subunit. A blank in this column indicates that the molecular weight of the processed forms has not been reported.

[c]The left and right columns indicate the preferred low-molecular-weight substrate specificity reported by two groups: Talanian et al. (1997) and Thornberry et al. (1997), respectively. It is important to note, however, that additional factors also affect caspase cleavage of full-length polypeptides. Not all sites conforming to the indicated sequences are cleaved, perhaps due to limited accessibility. Conversely, polypeptides are sometimes cleaved at sites that would not be predicted based on analysis of the tetrapeptide preferences indicated in this table (Samejima et al., 1999).

[d]Abbreviations: BP, BD PharMingen; BTL, BD Transduction Laboratories; CI, Chemicon International; CN, Calbiochem-Novabiochem; NEB, New England Biolabs; ORP, Oncogene Research Products; UB, Upstate Biotechnology.

Materials

CMF-DPBS (*APPENDIX 2A*), ice cold
Serum-free tissue culture medium (appropriate for cells of interest), ice cold, optional
SDS sample buffer (see recipe)
Fast green dye solution: 0.1% (w/v) fast green FCF/20% (v/v) methanol/5% (v/v) acetic acid
Fast green destain: 20% (v/v) methanol/5% (v/v) acetic acid
Blocking buffer (see recipe)
Anti-caspase primary antibody (Table 18.2.1)
PBS-T (see recipe)
Appropriate secondary antibody conjugated to horseradish peroxidase (HRP), alkaline phosphatase (AP), or a radiolabel
3% (w/v) nonfat dry milk in CMF-DPBS
Enhanced chemiluminescence reagents (e.g., ECL from Amersham Pharmacia Biotech), for HRP-conjugated secondary antibodies
X-ray film

Cell scraper (optional)
Sonicator equipped with microprobe (e.g., Branson)
70° or 100°C water bath or heating block

Additional reagents and equipment for inducing apoptosis (see Basic Protocol 1), trypsinizing and counting cells (optional; *UNIT 1.1*), SDS-polyacrylamide gel electrophoresis (*UNIT 6.1*), and electrophoretic transfer of polypeptides to a solid support (*UNIT 6.2*)

Induce apoptosis

1. Subject the desired number of cells to an apoptotic stimulus or mock treatment (see Basic Protocol 1, steps 1 and 2).

   It is convenient to load 2–5 × 10^5 cells per well for immunoblotting. To permit the running of multiple duplicate gels, each processed sample should contain 1–10 × 10^6 cells.

Harvest cells

2. Harvest cells at an appropriate time point. For adherent cells, use a cell scraper or trypsinization (*UNIT 1.1*) to release cells from their substratum.

   When working with an adherent cell line, cells that have become detached during the course of the experiment should also be collected. For many cell lines, one of the changes that occurs during apoptosis is detachment from the substratum. Discarding detached cells will cause an underestimation of the amount of apoptosis.

3. Transfer cells to a 15-ml conical centrifuge tube. Centrifuge 10 min at 200 to 400 × *g*, room temperature.

4. Remove supernatant and resuspend cells in 10 to 15 ml ice-cold CMF-DPBS or serum-free tissue culture medium.

   The purpose of this step is to remove serum proteins so that they do not interfere with subsequent protein determination, electrophoresis, or immunoblotting.

5. Count the cells in the sample (*UNIT 1.1*).

   If samples will be loaded based on protein concentration, cells do not need to be counted.

6. Centrifuge 10 min at 200 to 400 × *g*, room temperature. Remove supernatant without disturbing cell pellet.

Lyse cells

7. Add 20 µl SDS sample buffer per 2–5 × 10^5 cells to lyse cells. Vortex sample vigorously.

   If a cell count was not performed, a suitable sample volume is determined empirically by the inability to sonicate volumes that are too small and the inability to load volumes that are too large onto SDS-polyacrylamide gels. An alternative procedure for lysing cells in larger volumes and then concentrating them is given (see Alternate Protocol 1).

8. Use a sonicator equipped with a microprobe to deliver 40 pulses (0.33 sec each at 40% of the maximal output of the power supply) to the sample to shear the DNA.

9. Freeze sample indefinitely at −80°C or proceed to step 10 immediately.

   If samples are going to be loaded based on protein content, it is convenient to remove an aliquot for protein assays prior to freezing. Protein should be estimated using an assay that is not subject to interference by SDS, urea, or reducing agents, such as the nitric acid method (Bible et al., 1999) or the Lowry method after protein precipitation (APPENDIX 3B).

Electrophorese sample

10. Heat sample 20 min to 70°C or 3 min to 100°C in a water bath or heating block.

    This heat treatment is required to denature the protein and ensure that polypeptides are uniformly bound to SDS. If frozen samples are not heated prior to electrophoresis, there is a risk that SDS will not be uniformly bound to polypeptides and migration will be aberrant.

11. Immediately load a volume of sample containing 2–5 × 10^5 cells in the lane of an SDS-polyacrylamide gel with suitable separating capabilities.

    Alternatively, samples containing equal amounts of protein can be loaded.

    The authors prefer 20 × 20–cm gels for better resolution. Adequate results, however, can be obtained with minigels (6 × 8–cm).

    Because the subunits of active caspases are 10 to 12 kDa and 16 to 35 kDa, a gel that separates in this molecular-weight range is required. If the standard 30:0.8 acrylamide/bisacrylamide ratio (Laemmli, 1970) is utilized, a gel containing somewhere between 12% and 16% acrylamide is required to resolve in this molecular-weight range. Alternatively, a 5% to 15% or 5% to 20% gradient gel gives adequate separation of caspases and also permits analysis of their substrates by immunoblotting.

12. Electrophorese gel (*UNIT 6.1*) and electrophoretically transfer (*UNIT 6.2*) sample to a nitrocellulose or PVDF membrane.

    Because of their small sizes, caspases should readily transfer even from gels containing a high acrylamide content. If desired, transfer of higher-molecular-weight caspase substrates from these gels can be facilitated by including 0.02% to 0.1% (w/v) SDS in the transfer buffer. If this approach is taken, it is important to cool the transfer apparatus, as the SDS increases the current flow during transfer.

13. Stain the membrane for 1 min using fast green dye solution to confirm equal transfer of sample proteins. Remove unbound stain by rinsing briefly in fast green destain.

    Alternatively, blots can be stained in 0.1% (w/v) Ponceau S in 5% (v/v) acetic acid (UNIT 6.2).

14. Rinse membrane several times in CMF-DPBS to remove residual acetic acid.

15. Incubate membrane on an orbital platform shaker ≥1 hr in blocking buffer at room temperature to block unoccupied protein-binding sites.

    This blocking step should be performed immediately after the transfer if PVDF membranes are used. Nitrocellulose membranes can be dried and blocked later.

Perform immunoblotting

16. Dilute an anti-caspase primary antibody in blocking buffer according to supplier's instructions.

    Most antisera or antibodies give good results when diluted in milk-containing buffer. Some, however, yield cleaner results when a different carrier protein, such as 1% to 3% (w/v) bovine serum albumin, is used.

17. Incubate membrane with diluted primary antibody on an orbital platform shaker overnight at room temperature.

    Some investigators prefer to incubate filters with antibody for a shorter period of time. The authors have obtained good signals after a 4 to 6 hr incubation with primary antibody. Others have reported good signals with incubation times as short as 1 hr, although the authors' experience has been that higher concentrations of antibody are required to detect a signal after a 1-hr incubation.

18. Remove the primary antibody and store it at 4°C for subsequent use.

    Aliquots of primary antibody can be used three to four times without detectable loss of signal. Additional penicillin, streptomycin, and sodium azide can cut down on microbial growth if the antibody is to be stored for several weeks.

19. Wash the membrane three times in 100 ml PBS-T (for a 20 × 20–cm membrane) for 15 min each.

    If there is extensive background on the film after an initial immunoblotting experiment, it may be helpful to use a wash buffer of increased stringency (e.g., PBS-T supplemented with 2 M urea or additional NaCl).

20. Wash the membrane twice with 100 ml CMF-DPBS for 5 min each.

21. Dilute an appropriate secondary antibody in 3% (w/v) nonfat dry milk in CMF-DPBS according to the supplier's instructions.

    If HRP-coupled secondary antibodies are used, it is important to avoid sodium azide from this point onward because azide inhibits peroxidase.

22. Add diluted secondary antibody to the membrane and incubate on an orbital platform shaker 1 hr at room temperature.

23. Discard the secondary antibody and wash filter with 100 ml PBS-T as follows:

    twice for 5 min each
    twice for 15 min each
    twice for 5 min each.

24. Follow manufacturer's instructions for enhanced chemiluminescence reagents for HRP- or AP-conjugated secondary antibodies.

    This step is omitted if radioconjugated secondary antibodies are used.

25. Expose the membrane to X-ray film for an appropriate length of time.

    When using ECL enhanced chemiluminescence reagents, the authors start with an initial 2-min exposure and then adjust the exposure time empirically.

    Primary and secondary antibodies can be removed from the membrane for reprobing (see Support Protocol 1).

CELL LYSIS WITH GUANIDINE HYDROCHLORIDE FOR IMMUNOBLOTTING

ALTERNATE PROTOCOL 1

It is sometimes inconvenient to lyse and sonicate cells in a small enough volume to permit loading on a gel. In addition, high concentrations of SDS and 2-mercaptoethanol (2-ME) interfere with many protein estimation methods. Finally, some of the authors' observations have raised the possibility that active caspase species bound to cleaved intermediate filaments (MacFarlane et al., 2000) might not be solubilized efficiently by SDS sample buffer (T.J.K. and S.H.K., unpubl. observ.). The following protocol provides an alternative that allows cells to be rapidly lysed in the strong denaturing agent guanidine hydrochloride, dialyzed into dilute SDS, and then concentrated to the desired volume prior to electrophoresis. This protocol is suitable for detecting a variety of polypeptides in addition to caspases (Kaufmann et al., 1997).

Additional Materials *(also see Basic Protocol 2)*

Guanidine hydrochloride lysis buffer (see recipe)
100 mM PMSF (*APPENDIX 2A*)
2-Mercaptoethanol (2-ME)
1.54 M (285 mg/ml) iodoacetamide in guanidine hydrochloride lysis buffer, prepared fresh
4 M urea (see recipe)/50 mM Tris·Cl, pH 7.4 at 4°C (*APPENDIX 2A*)
0.1% (w/v) SDS
1-cm dialysis tubing (MWCO 8000 to 10,000), double knotted at one end, and dialysis clips

Additional reagents and equipment for determining protein concentration (*APPENDIX 3B*)

CAUTION: 2-ME has a strong odor and its use is confined to the hood in some laboratories.

NOTE: All steps involving iodoacetamide should be performed under subdued light because of the light sensitivity of the carbon-iodine bond.

Prepare cell lysate

1. Subject cells of interest to apoptosis-inducing or mock treatment, harvest, and wash as described (see Basic Protocol 2, steps 1 to 6). Remove as much supernatant as possible after the second centrifugation.
2. To 1 ml guanidine hydrochloride lysis buffer add 10 µl of 100 mM PMSF and 10 µl of 2-ME. Immediately add this mixture to cell pellet and vortex vigorously.
3. Use a sonicator equipped with a microprobe to deliver 40 pulses (0.33 sec each at 40% of the maximal output of the power supply) to the sample to shear the DNA.

   At this point samples can be stored ≤10 weeks at room temperature without loss of reactivity as detected by a variety of antibodies.

4. Add 0.1 vol of 1.54 M iodoacetamide in guanidine hydrochloride lysis buffer to each sample. Incubate 1 hr at room temperature.

   This reaction blocks free sulfhydryl groups, which can otherwise reoxidize to form large disulfide-cross-linked polypeptide oligomers in the wells of an SDS-polyacrylamide gel.

5. Add 0.01 vol of 2-ME.

   This reducing agent reacts with any remaining iodoacetamide.

Dialyze lysate

6. Transfer sample to a length of knotted 1-cm dialysis tubing and close tubing with a dialysis clip.

7. Dialyze sample at 4°C against four or five changes (≥90 min each) of 10 to 100 vol ice-cold 4 M urea/50 mM Tris·Cl, pH 7.4.

   The purpose of dialyzing into urea initially is to avoid the simultaneous presence of guanidine and SDS, which form a poorly soluble salt. Because each change of dialysis buffer decreases the concentration of solutes by a multiplicative factor, the key to effective dialysis is multiple changes with moderate volumes rather than a few changes with large volumes. Sufficient time should be permitted for equilibration to occur before each buffer change.

8. Dialyze sample at 4°C against three changes (≥90 min each) of 10 to 100 vol of 0.1% SDS.

9. Transfer sample to a 2-ml microcentrifuge tube. Remove a small aliquot and determine its protein concentration (*APPENDIX 3B*).

   The authors prefer the bicinchoninic acid BCA method (Smith et al., 1985) or the folin (Lowry) method suitably modified for samples containing SDS (Cadman et al., 1979).

10. Measure and record the volume of the remaining sample and then lyophilize it until dry.

    Lyophilized sample can be stored up to 5 years at –20°C.

Electrophorese and immunoblot caspases

11. Reconstitute the lyophilized sample in SDS sample buffer at 5 mg protein/ml, transfer 10 to 15 µl to a microcentrifuge tube, and continue with analysis as described (see Basic Protocol 2, steps 10 to 25).

    The authors find it convenient to reconstitute samples at 5 mg protein/ml SDS sample buffer and then load 50 to 75 µg protein per well, which is about the loading limit of a 2-mm-wide × 0.75-mm-thick lane.

SUPPORT PROTOCOL 1

REMOVING (STRIPPING) PRIMARY AND SECONDARY ANTIBODIES FROM BLOTS

It is often useful to probe filters with more than one antibody solution. If the antigens of interest have sufficiently different molecular weights, it is possible to reprobe a blot without stripping it. Likewise, if the primary antisera were raised in different species and can therefore be distinguished by different secondary antibodies, it is not necessary to strip blots. However, sometimes it is useful to remove antibodies without removing the original proteins transferred to the blot. The following protocol serves this purpose.

Materials

Nitrocellulose or PVDF membrane with bound antibodies (see Basic Protocol 2 or Alternate Protocol 1)
Blot erasure buffer (see recipe)
CMF-DPBS (*APPENDIX 2A*)

Resealable plastic bags
65°C water bath

1. Place a nitrocellulose or PVDF membrane with bound antibodies in a resealable plastic bag.

2. Add 50 ml blot erasure buffer (for a 20 × 20–cm membrane). Seal the bag.
3. Incubate 20 to 30 min in a 65°C water bath with gentle agitation every 5 to 10 min.

   When blotting is performed after transfer of polypeptides to nitrocellulose, complete removal of some antibodies requires heating of blot erasure buffer to ≥50°C for 20 to 30 min (Kaufmann et al., 1987). On the other hand, after immobilization of polypeptides on PVDF, antibodies are efficiently dissociated by erasure buffer at room temperature.

4. Discard the erasure buffer. Wash the blot twice for 5 min each with 50 to 100 ml CMF-DPBS.
5. Reprobe the membrane as described (see Basic Protocol 2, steps 15 to 25).

   Although some antigens are destroyed by the stripping process, most can be readily detected even after blots have been stripped multiple times (Kaufmann et al., 1987).

   Be sure to incubate the membrane in blocking buffer after each stripping to ensure that all nonspecific binding sites are coated.

LABELING AND DETECTING ACTIVE CASPASES USING BIOTINYLATED SUBSTRATE ANALOGS

BASIC PROTOCOL 3

A protocol for detection of active caspases in cytosol preparations using *N*-(*N*$^{\alpha}$-benzyloxycarbonylglutamyl-*N*$^{\varepsilon}$-biotinyllysyl)aspartic acid ([2,6-dimethylbenzoyl]oxy)methylketone, or zEK(bio)D-aomk, is described below. Although not as sensitive as assays based on cleavage of substrate polypeptides in intact cells or fluorogenic substrates under cell-free conditions, this assay can nonetheless detect picogram levels of active caspases when combined with very sensitive chemiluminescent substrates currently available. This affinity-labeling approach is particularly useful in at least three situations. First, this assay can be utilized to unequivocally identify active caspase species in apoptotic cell extracts by comparing migration of species present in the extracts with migration of similarly labeled recombinant caspases (Martins et al., 1997). Second, by taking advantage of the affinity of streptavidin for the biotin moiety, it is possible to purify the affinity-labeled caspases for further study (Nicholson et al., 1995; Faleiro et al., 1997). Third, because only two inhibitor molecules bind to each caspase tetramer, the labeling procedure can be used to determine the molar concentration of labeled active caspases.

Materials

Incomplete KPM buffer (see recipe), 4°C
Complete KPM buffer (see recipe), 4°C
100 µM *N*-(*N*$^{\alpha}$-benzyloxycarbonylglutamyl-*N*$^{\varepsilon}$-biotinyllysyl)aspartic acid ([2,6-dimethylbenzoyl]oxy)methylketone [zEK(bio)D-aomk; Osaka Peptide Institute] in dimethyl sulfoxide (DMSO), stored in aliquots up to 2 years at −80°C
3× SDS sample buffer (see recipe)
5% (w/v) nonfat dry milk in PBS-T
PBS-T (see recipe)
Peroxidase-coupled streptavidin (e.g., Amersham Pharmacia Biotech)
Enhanced chemiluminescence reagents (e.g., ECL; Amersham Pharmacia Biotech)

Cell scraper (optional)
8 × 34–mm polycarbonate ultracentrifuge tubes (e.g., Beckman)
Beckman Optima TLX tabletop ultracentrifuge and TL100.1 rotor, or equivalent, 4°C

Additional reagents and equipment for inducing apoptosis (see Basic Protocol 1), cell trypsinization (optional; *UNIT 1.1*), protein determination (*APPENDIX 3B*), SDS-polyacrylamide gel electrophoresis (*UNIT 6.1*), and electrophoretic transfer of polypeptides to a solid support (*UNIT 6.2*)

Induce apoptosis

1. Subject ~8×10^6 cells of interest at the desired density to suitable apoptosis-inducing conditions or mock treatment (see Basic Protocol 1, steps 1 and 2).

   It is important to include a sample that contains control (nonapoptotic cells) so that endogenous biotinylated proteins can be distinguished from species that label with zEK(bio)D-aomk. A second control for labeling specificity (see Support Protocol 2) can also be included.

   The authors estimate that a 10-cm tissue culture plate will yield ~8×10^6 cells or 400 μg cellular protein when prepared as described.

Harvest cells

2. At an appropriate time point, collect cells in a 15-ml tube, releasing cells from their substratum by trypsinization (*UNIT 1.1*) or scraping if they are adherent.

   All subsequent steps prior to incubation with the affinity labeling agent should be performed at 4°C.

3. Centrifuge cells 5 min at 300 × *g*, 4°C. Gently resuspend them in 5 to 10 ml incomplete KPM buffer and centrifuge again.

   In this and all following steps, incomplete and complete KHM buffer (see Alternate Protocol 2) can be substituted for incomplete and complete KPM buffer, respectively.

4. Gently resuspend cells in 1 ml complete KPM buffer and transfer them to a 1.5-ml microcentrifuge tube.

5. Centrifuge cells 3 min at 800 × *g*, 4°C. Remove supernatant and resuspend cell pellet in a volume of complete KPM buffer approximately equal to that of the pellet.

Prepare cytosolic lysates

6. Lyse cells using three cycles of freezing in liquid nitrogen (or on dry ice) and incubating in a 37°C water bath until sample thaws.

   It is not necessary for the cells to reach 37°C. The freeze-thaw lysis procedure ruptures mitochondria and lysosomes, providing cell lysates that contain soluble polypeptides from multiple subcellular organelles. As an alternative, it is possible to prepare various subcellular fractions and then affinity label them with zEK(bio)D-aomk (Martins et al., 1997).

7. Transfer lysed cells to an 8 × 34–mm polycarbonate ultracentrifuge tube and centrifuge 1 hr at 157,000 × g_{max}, 4°C, in a Beckman Optima TLX tabletop ultracentrifuge with a TL100.1 rotor.

8. Transfer cleared lysate to a 1.5-ml microcentrifuge tube.

9. Measure protein concentration (*APPENDIX 3B*).

   The authors prefer the folin (Cadman et al., 1979), BCA (Smith et al., 1985), or Coomassie blue methods (Bradford, 1976).

10. Dilute lysates to a final protein concentration of 5 mg/ml in complete KPM buffer. Freeze 200-μg aliquots up to 2 months at −80°C.

Affinity label lysate

11. Thaw an aliquot of lysate on ice.

12. To 40 μl cell lysate (200 μg) add 0.4 μl of 100 μM zEK(bio)D-aomk. Mix the sample thoroughly without forming bubbles and incubate 5 min at 37°C.

    When mixing the sample, it is important to avoid forming bubbles (e.g., by vortexing), as enzymes can be denatured at the resulting air-liquid interface.

13. Add 25 μl of 3× SDS sample buffer. Boil the sample 5 min.

Electrophorese labeled lysate

14. Apply samples (10 to 40 μg protein) to a 16% SDS-polyacrylamide gel (*UNIT 6.1*).

    Because the large subunits of active caspases have molecular weights of 17 to 35 kDa, a 16% gel gives good separation of various caspase species. Optimal resolution of the caspases is obtained using 0.75-mm-thick, 6 × 8–cm gels with separation at 200 V constant voltage for 1 hr. Alternatively, separation of charge variants of caspase species can be accomplished by two-dimensional isoelectric focusing/SDS-polyacrylamide gel electrophoresis (Martins et al., 1997; also see UNIT 6.4). With this technique, 16% gels also give good separation in the second dimension.

    As an alternative to SDS-polyacrylamide gel electrophoresis and ligand blotting, the derivatized caspases can be affinity purified using immobilized avidin (Nicholson et al., 1995; Faleiro et al., 1997).

15. Transfer polypeptides electrophoretically to a nitrocellulose membrane (*UNIT 6.2*).

    For example, polypeptides can be transferred 30 min at 12 V, current limited to 5.5 mA/cm^2, in a Bio-Rad TransBlot SD SemiDry Transfer Cell.

Visualize labeled caspases

16. Incubate membranes in 5% (w/v) nonfat dry milk in PBS-T for 1 hr at room temperature to block unoccupied binding sites.

17. Wash membrane once for 15 min and two times for 5 min each with PBS-T.

18. Dilute peroxidase-coupled streptavidin in PBS-T and incubate blot 3.5 hr at room temperature in this solution.

    The authors use a 1:3000 dilution of peroxidase-coupled streptavidin supplied by Amersham Pharmacia Biotech. Suitable dilutions of similar reagents from other suppliers will need to be determined empirically.

19. Wash blot once for 15 min and four times for 5 min each with PBS-T to remove unbound peroxidase-coupled streptavidin.

20. Visualize the bound streptavidin using enhanced chemiluminescence reagents as described by the supplier.

    The membrane can be stripped and probed with a suitable antibody to confirm the activation of specific caspases (see Support Protocol 3).

IN VITRO ACTIVATION OF CASPASES IN NAIVE LYSATES FOLLOWED BY AFFINITY LABELING

ALTERNATE PROTOCOL 2

It is sometimes useful to assess the competence of lysates from nonapoptotic cells to activate caspase pathways. This can be accomplished by incubating lysates with reagents that are known to activate caspase cascades, such as active caspase-8 (Muzio et al., 1997) or cytochrome *c* plus dATP (Liu et al., 1996; Mesner et al., 1999). Detailed below is a protocol for the detection of active caspases following cytochrome *c* and dATP–dependent apoptosome formation or caspase-8 activation. For such experiments, lysates are prepared from nonapoptotic cells essentially as described (see Basic Protocol 3).

Additional Materials *(also see Basic Protocol 3)*

Incomplete KHM buffer (see recipe), 4°C
Complete KHM buffer (see recipe), 4°C
5 μg/ml active caspase-8 (BD PharMingen) in complete KHM buffer *or* 5 mg/ml cytochrome *c* (Sigma) in complete KHM buffer
10 mM dATP (Sigma) in complete KHM, pH 7.4, optional

100 µM *N*-(*N*$^{\alpha}$-benzyloxycarbonylglutamyl-*N*$^{\epsilon}$-biotinyllysyl)aspartic acid ([2,6-dimethylbenzoyl]oxy)methylketone [zEK(bio)D-aomk; Osaka Peptide Institute] in dimethyl sulfoxide (DMSO), stored in aliquots up to 2 years at −80°C

1. Prepare cell lysates from nonapoptotic cells (i.e., untreated cells; see Basic Protocol 3, steps 1 to 11), using incomplete and complete KHM buffer instead of incomplete and complete KPM buffer, respectively, throughout.
2. To 8 µl (40 µg) cell lysate add 10 µl of 5 µg/ml active caspase-8 in complete KHM buffer or 10 µl of 5 mg/ml cytochrome *c* in complete KHM buffer and 2 µl of 10 mM dATP (optional).

   Active caspase-8 can be utilized to trigger the caspase activation process without interfering with affinity labeling of endogenous caspases because caspase-8 does not label with zEK(bio)D-aomk. In contrast, caspase-9 does label with zEK(bio)D-aomk. To trigger caspase activation using endogenous caspase-9, cytochrome c can be added to cytosol (Li et al., 1997). It is important to keep in mind, however, that extracts from some cells contain sufficiently high levels of ATP to support this reaction, whereas other cell lysates might require addition of dATP or ATP (Liu et al., 1996; Mesner et al., 1999).

3. Mix the sample thoroughly without forming bubbles and incubate 1 hr at 37°C.

   It is important that mixing be performed without creating froth in the sample. Caspases, like other enzymes, can be denatured at air-water interfaces.

4. Add 0.2 µl of 100 µM zEK(bio)D-aomk in DMSO. Mix the sample and incubate 5 min at 37°C.
5. Add 10 µl of 3× SDS sample buffer. Boil the sample 5 min.
6. Electrophorese and detect the biotinylated species as described (see Basic Protocol 3, steps 14 to 20).

SUPPORT PROTOCOL 2

CONTROLS FOR SPECIFICITY OF AFFINITY-LABELED ACTIVE CASPASES

It is possible to competitively inhibit binding of the affinity label with caspase inhibitors. For example, preincubation of lysates with certain peptide chloromethyl ketones or fluoromethyl ketones completely abolishes subsequent labeling with zEK(bio)D-aomk (Martins et al., 1997). This type of competition experiment serves two purposes. First, cell lysates contain many polypeptides that are intrinsically biotinylated. These are unaffected by preincubation of the lysates with 100 µM acetyl-Tyr-Val-Ala-Asp-chloromethyl ketone (acetyl-YVAD-CMK), whereas labeling of caspases can be completely suppressed under the same conditions (Martins et al., 1997). Second, the same approach can sometimes be utilized to suggest the identity of the labeled caspase responsible for a particular biological function. For example, the SPI-2 serpin from rabbitpox virus and underivatized peptides corresponding to the lamin A cleavage site—two different types of reversible caspase inhibitors—were shown to inhibit lamin cleavage in vitro and simultaneously inhibit affinity labeling of one particular caspase (Takahashi et al., 1996a). In performing this latter type of experiment, it is important to optimize the labeling conditions so that the length of exposure to the affinity labeling reagent is minimized (e.g., 1 min). Because reversible inhibitors continually dissociate and rebind to the caspase active site (thereby providing an opportunity for binding to the affinity label), longer labeling times allow covalent modification of caspases even in the presence of a potent reversible inhibitor.

STRIPPING MEMBRANE IN THE PRESENCE OF d-BIOTIN FOR REPROBING WITH ANTIBODY

It is sometimes useful to confirm the activation of specific caspases detected by affinity labeling using suitable antibodies. In order to do so, it is necessary to dissociate the peroxidase-coupled streptavidin without removing the biotinylated caspases. To minimize removal of the membrane-bound caspases, the authors have devised a way to compete the peroxidase-coupled streptavidin from the membrane using biotin.

Additional Materials *(also see Basic Protocol 3)*

Membrane containing affinity-labeled caspases (see Basic Protocol 3)
2 mM d-biotin (Sigma) in PBS-T

1. Wash a membrane containing affinity-labeled caspases two times for 15 min each with PBS-T.

   It is convenient to use 50-ml of buffer for a 6 × 8–cm blot.

2. Incubate membrane 1 hr with 2 mM d-biotin in PBS-T at room temperature.

3. Wash membrane once for 15 min and two times for 5 min each with PBS-T.

   The membrane can be stored dry up to 6 months at room temperature.

4. Perform immunoblot procedure with an appropriate antibody as described (see Basic Protocol 2, steps 16 to 25).

REAGENTS AND SOLUTIONS

Use deionized or distilled water and ACS reagent–grade chemicals (or better) in all recipes and protocol steps. Filter sterilize buffers that are to be stored for long periods. For common stock solutions, see ***APPENDIX 2****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Blocking buffer

10 mM Tris·Cl, pH 7.4 (*APPENDIX 2A*)
150 mM NaCl
10% (w/v) nonfat dry milk
100 U/ml penicillin G
100 µg/ml streptomycin
1 mM sodium azide
Store up to 4 weeks at 4°C

CAUTION: *Sodium azide is poisonous. Follow appropriate precautions for handling, storage, and disposal.*

A 100× penicillin G/streptomycin solution is commercially available from Life Technologies.

Blot erasure buffer

62.5 mM Tris·Cl, pH 6.8 at 21°C
2% (w/v) SDS
Store up to 6 months at 4°C
Add 100 mM 2-mercaptoethanol (2-ME) immediately before use

CAUTION: *2-ME has a strong odor and its use is confined to the hood in some laboratories.*

CLAP, 1000×

Dissolve 5 mg chymostatin, 5 mg leupeptin, 5 mg antipain, and 5 mg pepstatin A (all from Sigma) in a total volume of 5 ml dimethyl sulfoxide (DMSO), for a final concentration of 1 mg/ml each. Store 50-µl aliquots up to 1 year at −20°C.

CMF-DPBS containing 0.05% Tween 20 (PBS-T)

To 900 ml H_2O add:
11.5 g Na_2HPO_4
2.96 g NaH_2PO_4
5.84 g NaCl
Add H_2O to 1 liter
Add 2.5 ml 20% (w/v) Tween 20 (e.g., Bio-Rad)

The pH of the CMF-DPBS should be 7.5 (before addition of Tween 20).

Complete KHM buffer

50 ml incomplete KHM buffer (see recipe)
50 µl 100 mM PMSF (*APPENDIX 2A*; 0.1 mM final)
50 µl 20 mM cytochalasin B (see recipe; 20 µM final)
500 µl 100 mM Na_3VO_4 (see recipe; 1 mM final)
50 µl 1000× CLAP (see recipe; 1× final)
Prepare on ice immediately before use

Complete KPM buffer

50 ml incomplete KPM buffer (see recipe)
50 µl 100 mM PMSF (*APPENDIX 2A*; 0.1 mM final)
50 µl 20 mM cytochalasin B (see recipe; 20 µM final)
500 µl 100 mM Na_3VO_4 (see recipe; 1 mM final)
50 µl 1000× CLAP (see recipe; 1× final)
Prepare on ice immediately before use

Cytochalasin B, 20 mM

Dissolve 10 mg cytochalasin B (Sigma) in 1 ml dimethyl sulfoxide (DMSO).
Store 50-µl aliquots up to 1 year at −20°C.

EDTA, 0.5 M, pH 7.4

Add 93.1 g $Na_2EDTA{\cdot}2H_2O$ to 400 ml H_2O. While stirring and continuously monitoring pH at room temperature, add two pellets solid NaOH every 5 to 10 min. Adjust pH to 7.4. Add H_2O to 500 ml. Store indefinitely at 4°C.

The white crystalline EDTA will go into solution as the pH rises toward 7.0.

EGTA, 0.5 M, pH 7.0 and pH 7.4

Add 19.02 g EGTA to 75 ml H_2O. Adjust pH to 7.0 with 10 M NaOH or to 7.4 with 5 M KOH, stirring vigorously. Add H_2O to 100 ml. Store indefinitely at 4°C.

The EGTA will not go into solution until the pH approaches 7.0. As the solution starts to clear, be careful not to overshoot the desired pH.

Guanidine hydrochloride lysis buffer

114.64 g guanidine hydrochloride (Sigma; 6 M final)
50 ml 1 M Tris·Cl, pH 8.5 at 21°C (*APPENDIX 2A*; 250 mM final)
4 ml 0.5 M EDTA, pH 7.4 (see recipe; 10 mM final)
Bring to 200 ml final volume
Store indefinitely at room temperature

HEPES, 1 M, pH 7.4

Dissolve 23.8 g HEPES in 50 ml H_2O. Adjust pH to 7.4 with 5 M KOH. Add H_2O to 100 ml. Store indefinitely at 4°C

HEPES/CHAPS buffer

To 450 ml H_2O add:
2.98 g HEPES (25 mM final)
Adjust pH to 7.5 with 10 M NaOH
Add 0.77 g dithiothreitol (DTT)
500 mg 3-[(3-cholamidopropyl)dimethylammonio]-1-propanesulfonate (CHAPS; 0.1% final)
H_2O to 500 ml
Store up to 2 months at 4°C
Immediately before use, for each 1 ml buffer add:
100 U aprotinin (Bayer)
10 µl 100 mM PMSF (*APPENDIX 2A*)

Incomplete KHM buffer

5 ml 1 M HEPES, pH 7.4 (see recipe; 50 mM final)
2.5 ml 2 M KCl (50 mM final)
2 ml 0.5 M EGTA, pH 7.4 (see recipe; 10 mM final)
100 µl 2 M $MgCl_2$ (2 mM final)
H_2O to 100 ml
Store indefinitely at 4°C

Incomplete KPM buffer

5 ml 1 M PIPES, pH 7.0 (see recipe; 50 mM final)
2.5 ml 2 M KCl (50 mM final)
2 ml 0.5 M EGTA, pH 7.0 (see recipe; 10 mM final)
100 µl 2 M $MgCl_2$ (2 mM final)
H_2O to 100 ml
Store indefinitely at 4°C

K-EDTA, 0.1 M, pH 7.4

3.72 g $Na_2EDTA{\cdot}2H_2O$
50 ml H_2O
Adjust pH to 7.4 with 1 M KOH
Add H_2O to 100 ml
Store indefinitely at room temperature

Lysis buffer

To 450 ml H_2O add:
2.98 g HEPES (25 mM final)
0.238 g $MgCl_2$ (5 mM final)
1 ml 0.5 M EGTA, pH 7.0 (see recipe; 1 mM final)
Adjust pH to 7.5 at 4°C with 10 M NaOH
Add H_2O to 500 ml
Store indefinitely at 4°C
Immediately before use, for each 1 ml buffer add:
10 µl 100 mM PMSF (*APPENDIX 2A*)
1 µl 10 µg/ml pepstatin A in ethanol
1 µl 10 µg/ml leupeptin in ethanol

Pepstatin A and leupeptin in ethanol can be stored indefinitely at −20°C.

Na_3VO_4, 100 mM

Add 1.84 g Na_3VO_4 (Sigma) to ~75 ml H_2O (pH ~14). Add concentrated HCl until the pH is 10. The solution will turn yellow at this point. Boil 3 min. The pH will then be ~9 and the solution will be almost white. Add 2.5 ml of 1 M NaOH and boil 3 min. Add H_2O to 100 ml. Store 1-ml aliquots indefinitely at −20°C.

PIPES, 1 M, pH 7.0

Dissolve 30.24 g PIPES in 50 ml H_2O. Adjust pH to 7.0 with 5 M KOH. Add H_2O to 100 ml. Store indefinitely at room temperature.

PIPES powder will not dissolve until the pH is adjusted to ≥6.7.

SDS sample buffer

To 200 ml H_2O add:
31.25 ml Tris base (62.5 mM final)
1 ml 0.5 M EDTA, pH 7.4 (1 mM final)
Adjust to pH 6.8 with concentrated HCl
Add 10 g SDS (2% final)
250 ml 8 M urea (see recipe; 4 M final)
Add H_2O to 500 ml
Store up to 3 months at 4°C
Immediately before use, add 50 µl of 2-mercaptoethanol (2-ME) per 950-µl aliquot

CAUTION: *SDS is a severe irritant. Use a dust mask to prevent inhaling SDS powder. 2-ME has a strong odor and its use is confined to the hood in some laboratories.*

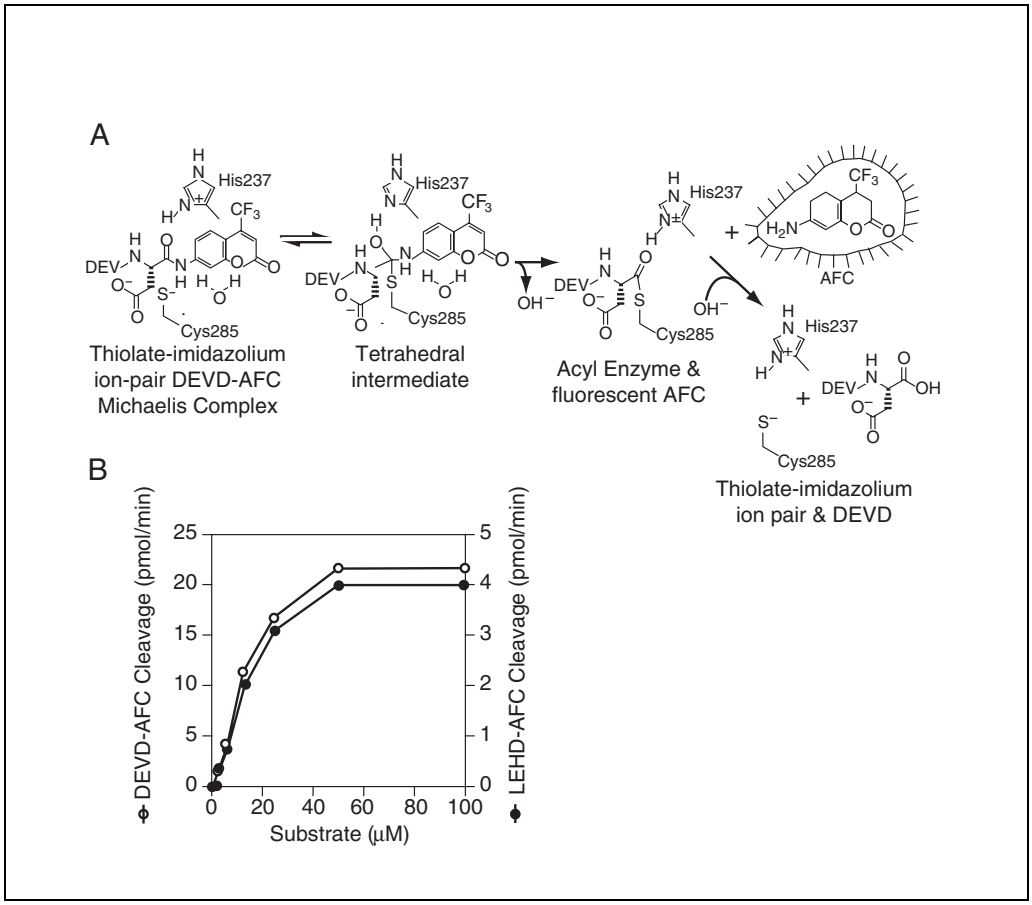

Figure 18.2.1 Measurement of caspase activity using a fluorogenic substrate. (**A**) Conversion of the substrate acetyl-Asp-Glu-Val-Asp-7-amino-4-trifluoromethylcoumarin (acetyl-DEVD-AFC) to tetrapeptide and free 7-amino-4-trifluoromethylcoumarin (AFC). (**B**) Velocity versus substrate concentration curves for caspase-3. Purified recombinant human caspase-3 was incubated for 2 hr with increasing concentrations of acetyl-DEVD-AFC or acetyl-Leu-Glu-His-Asp-7-amino-4-trifluoromethylcoumarin (acetyl-LEHD-AFC). From these data it is possible to determine that the maximal velocity is 5-fold lower for acetyl-LEHD-AFC than for acetyl-DEVD-AFC, whereas the concentration that results in half-maximal velocity (K_M) is the same (~12.5 µM) for each substrate.

SDS sample buffer, 3×

30 ml 0.5 M Tris·Cl, pH 6.8 at 20°C (150 mM final)
45 g sucrose (45% final)
6 ml 0.1 M K-EDTA, pH 7.4 (see recipe; 6 mM final)
30 ml 20% (w/v) SDS (9% final)
6 ml of 0.5% (w/v) bromphenol blue (0.03% final)
H_2O to 100 ml
Store 3-ml aliquots at −20°C
Just before use add 0.1 vol of 2-mercaptoethanol (2-ME; 10% final)

CAUTION: *SDS is a severe irritant. Use a dust mask to prevent inhaling SDS powder. 2-ME has a strong odor and its use is confined to the hood in some laboratories.*

Urea, 8 M

Gradually add 1920 g urea to 2 liters H_2O while stirring. Add H_2O to 4 liters. Filter through four layers of cheesecloth. Store 500-ml aliquots up to 2 months at room temperature. Prior to use, deionize aliquot with AG 501X-8 D mixed-bed resin (Bio-Rad).

Deionization removes cyanate breakdown products that can carbamylate polypeptides.

COMMENTARY

Background Information

Enzyme activity assays

Measurements of caspase enzymatic activity are performed to determine whether caspases have been activated after various treatments and to assess the timing of caspase activation relative to other events occurring as cells undergo programmed cell death. Similar assays can also be utilized to study the biochemistry of the caspase activation process under cell-free conditions and to purify active caspases.

The chemistry of the basic enzyme assay is illustrated in Figure 18.2.1A. Cell extracts (or recombinant proteases) are generally incubated with a substrate that generates a highly fluorescent or colored product when the amide bond on the C-terminal side of aspartate is cleaved. The substrates utilized in these reactions have been patterned after the cleavage sites in known caspase substrates (Sleath et al., 1990; Lazebnik et al., 1994; Takahashi et al., 1996b) or identified by studying relative rates of cleavage of libraries of derivatized peptides (Thornberry et al., 1992, 1997). The assays based on these substrates are not absolutely specific for caspases but are relatively specific because most mammalian proteases do not cleave very efficiently on the carboxyl terminal side of aspartate. Indeed, at the present time, the only other mammalian protease known to prefer aspartate in the P_1 position (i.e., immediately to the amino side of the cleavage site) is granzyme B, a serine protease that appears to be expressed exclusively in the granules of cytotoxic lymphocytes (Pham and Ley, 1997).

The principal advantages of assessing caspase activation using an enzymatic assay are its sensitivity and reliance on commonly available reagents and equipment. Because each caspase molecule can cleave multiple substrate molecules, there is an inherent amplification compared to techniques like affinity labeling (see Basic Protocol 3). Previous studies from the authors' laboratory have demonstrated low but detectable amounts of caspase activity in subcellular fractions whose content of active caspases is below the limit of detection by affinity labeling (Samejima et al., 1998). Moreover, the assay described above can also be performed with chromogenic substrates (e.g., commercially available peptidyl-*p*-nitroanilides), making it possible to assay for active caspases in any laboratory that has a spectrophotometer.

The principal disadvantage of this approach is its lack of specificity for any particular caspase. Currently available fluorogenic and chromogenic substrates were designed to mimic the sites that are cleaved in various substrate polypeptides (Earnshaw et al., 1999). Because most caspases have similar cleavage-site specificities (Table 18.2.1), these assays are not specific for individual caspases. Several examples illustrate this problem.

Analysis of tetrapeptide preferences has demonstrated that caspase-9 prefers acetyl-Leu-Glu-His-Asp-7-amino-4-trifluoromethyl

coumarin (acetyl-LEHD-AFC) to other peptides tested (Thornberry et al., 1997). Contrary to the common interpretation of these results, this does not mean that acetyl-LEHD-AFC is a specific substrate for caspase-9. When caspase-3 is incubated with increasing concentrations of acetyl-DEVD-AFC or acetyl-LEHD-AFC, the enzyme displays the same K_M for these two substrates (Figure 18.2.1B). Although caspase-3 does display a lower turnover rate or maximum initial velocity (V_{max}) for acetyl-LEHD-AFC than acetyl-DEVD-AFC, it nonetheless cleaves both substrates quite well. Accordingly, cleavage of acetyl-LEHD-AFC in a cell lysate cannot be taken as evidence that caspase-9 has been activated. Indeed, if acetyl-LEHD-AFC is cleaved in a cellular extract, it is not immediately obvious how to determine the amount that has been cleaved by caspase-9 as opposed to the more abundant caspase-3.

This problem is not limited to acetyl-LEHD-AFC. Acetyl-DEVD-AFC, a substrate modeled after the cleavage site in poly(ADP-ribose) polymerase (PARP; Lazebnik et al., 1994), can be cleaved by caspases-1, -2, -3, -4, -6, -7, -8, -10, and -14 (Fernandes-Alnemri et al., 1995, 1996; Boldin et al., 1996; Srinivasula et al., 1996; Talanian et al., 1997; Hu et al., 1998; Faubion et al., 1999). Thus, when acetyl-DEVD-AFC cleavage activity is detected in a cell lysate, it

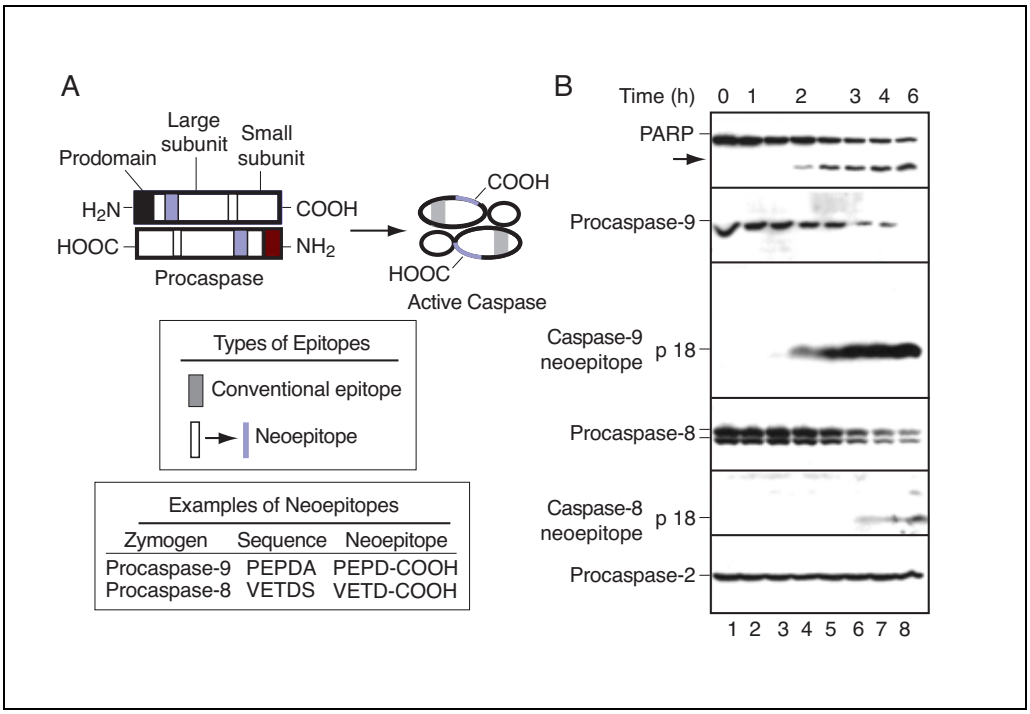

Figure 18.2.2 Assessment of caspase activation by immunoblotting. (**A**) Caspase activation. The prodomain, large subunit, and small subunit are indicated. Two types of epitopes, a conventional linear epitope in the large subunit and a neoepitope at the C terminus of the large subunit, are indicated. The lower box indicates the peptide sequences of procaspase-9 and procaspase-8 at the junction between the large and small subunits. When cleavage occurs on the C-terminal side of aspartate, new C-terminal epitopes (neoepitopes) are formed. (**B**) Results obtained when HL-60 human leukemia cells are treated with 68 μM etoposide, a topoisomerase II–directed agent that causes DNA damage, for 0, 1, 1.5, 2, 2.5, 3, and 4 or 6 hr. Adjacent lanes were loaded with 50 μg of total cellular protein harvested according to the guanidine hydrochloride cell lysis procedure (see Alternate Protocol 1). Blots were probed with monoclonal anti–poly(ADP-ribose) polymerase (PARP), a sensitive marker of caspase activation (Lazebnik et al., 1994); reagents that detect procaspases-2, -8, and -9; or anti-neoepitope sera that react with active caspase-9 (Mesner et al., 1999) or active caspase-8 species. Two major splice variants of procaspase-8 are detected in these cells. The arrow indicates the product resulting from PARP cleavage by caspases. The anti-neoepitope antisera were raised by immunizing rabbits with the neoepitope tetrapeptides indicated in (A). Note that the increased signal for active caspase-9 is at least as readily detected with the anti-caspase-9 neoepitope serum as it is with the anti-procaspase-9 serum. Also note that the signal for procaspase-2 does not change during the course of apoptosis in this cell line, illustrating the selective cleavage of some procaspases and not others during the course of apoptosis in situ (Martins et al., 1997).

is unclear whether the activity reflects caspase-3 activity or not. A more formal analysis of the K_M and k_{cat} (forward rate constant) of purified caspases acting on a variety of low-molecular-weight substrates (Talanian et al., 1997) revealed that caspases-3 and -7 preferred the *p*-nitroaniline (pNA)-coupled peptide acetyl-DEVD-pNA (K_M = 11 and 12 μM, respectively), caspase-1 preferred acetyl-YEVD-pNA (K_M = 7.3 μM), and caspase-6 preferred acetyl-VEID-pNA (K_M = 30 μM). Further analysis, however, revealed that these preferences were not absolute. Caspase-3 displayed a k_{cat}/K_M (a measure of catalytic efficiency) of 21.8×10^4 sec^{-1} for acetyl-DEVD-pNA, 6.1×10^4 sec^{-1} for acetyl-VEID-pNA, and 3.9×10^4 sec^{-1} for acetyl-YEVD-pNA, indicating that the cleavage efficiencies for the various substrates differed by only a factor of five. Aside from the inefficient cleavage of acetyl-DEVD-pNA by caspase-6, other caspases showed similar promiscuity. This lack of specificity of currently available substrates must be taken into account in interpreting results of these assays.

Given the ability of multiple caspases to cleave the same substrate, it is logical to ask whether other classes of proteases can also cleave these compounds. It has been reported that the proteasome can cleave acetyl-YVAD-AFC, albeit relatively inefficiently (Kobayashi et al., 1996). The possibility that other proteases might also cleave these substrates cannot absolutely be ruled out. Two approaches can be utilized to help ensure that cleavage of caspase substrates by other proteases is not misinterpreted as caspase activity. First, it is possible to perform the assay in the presence of a battery of protease inhibitors that inhibit many potentially confounding protease activities. The protease inhibitors used in Basic Protocol 1 will inhibit a wide range of serine, cysteine, and acid proteases and metalloproteinases. Second, it is usually important to bolster the conclusion derived from activity assays with some other measure of caspase activation (e.g., immunoblots showing cleavage of caspase zymogens or caspase substrates).

As an alternative to tetrapeptide or pentapeptide substrates, in vitro translated proteins have also been used as substrates to assay caspase activity in vitro (Nicholson et al., 1995; Liu et al., 1997; Margolin et al., 1997). Work of Andrade et al. (1998) has demonstrated the feasibility of measuring the K_M and k_{cat} using these more relevant macromolecular substrates. Recent data suggest that caspase cleavage preferences derived solely from the study of tetrapeptide-based substrates might not accurately predict cleavage sites in substrate polypeptides (Samejima et al., 1999). Additional experiments have shown that phosphatase treatment of extracts has no effect on cleavage of acetyl-DEVD-AFC but causes a significant increase in cleavage of PARP (Martins et al., 1998). Collectively, these studies suggest that macromolecular substrates might still have an important role in the study of caspases. On the other hand, disadvantages of this alternative approach include the need to perform both in vitro transcription and translation reactions to generate substrates and SDS-PAGE followed by fluorography to analyze results. In short, this labor-intensive approach is not suitable for casual inquiry.

A second disadvantage of using enzymatic assays to assess caspase activation is the potential to underestimate caspase activation in certain cell types. Previous studies have demonstrated that a number of caspase substrates are cleaved in MCF-7 human breast cancer cells. Nonetheless, activity that cleaves acetyl-DEVD-AFC is undetectable in cytosol prepared from this cell line (Janicke et al., 1998). Further analysis has revealed that caspase-3 and other active caspases can form tight complexes with caspase-generated fragments of intermediate filaments (MacFarlane et al., 2000) and are not solubilized under the conditions described. Whether this is a problem unique to the MCF-7 line, or whether substantial amounts of active caspases are also sequestered in an insoluble fraction in other cell types, remains to be established.

Immunoblotting

The ability to detect caspase activation by immunoblotting reflects the fact that these proteases are synthesized as zymogens that undergo proteolytic processing during the course of activation. The zymogens have the general organization shown in Figure 18.2.2A. An N-terminal prodomain is followed by sequences encoding a large subunit and a small subunit. In some procaspases, these two subunits are separated by a small spacer. Maturation of each zymogen appears to proceed by an ordered series of proteolytic cuts (Earnshaw et al., 1999). The first incision, which appears to increase the catalytic activity of the protease, occurs at the C terminus of the large subunit. If a spacer is present between the subunits, it is usually excised next. The final cut, which appears to be catalyzed by the caspase molecule

that is being matured, severs the prodomain from the rest of the molecule.

Three further aspects of caspase maturation require additional comment. First, mature caspases are $\alpha_2\beta_2$ tetramers consisting of two large subunits and two small subunits. Because the large subunit derived from one zymogen molecule associates with the small subunit derived from a second zymogen molecule in the dimeric precursor, caspase maturation actually involves cleavage of two zymogen molecules. Of course, the quaternary structure of the precursor and the mature caspase is lost under denaturing conditions. Second, the maturation of caspases appears to involve conformational changes as well as proteolytic cleavages. These conformational changes can be observed by immunofluorescence using certain conformation-sensitive anti-caspase antibodies (Srinivasan et al., 1998). Again, because SDS-PAGE and immunoblotting are performed after protein denaturation, these conformational changes are not detected by the present protocols. Finally, it is not clear that all caspases require cleavage for activation. In particular, recent results suggest that apoptotic protease activating factor-1 (Apaf-1) is capable of acting as an allosteric activator of procaspase-9 (Rodriguez and Lazebnik, 1999), even under conditions where procaspase-9 cannot be cleaved (Stennicke et al., 1999). Thus, when procaspase-9 is cleaved to its signature fragments (Table 18.2.1), this can be taken as presumptive evidence of procaspase-9 activation; but the lack of procaspase-9 cleavage cannot be taken as proof for a lack of caspase-9 activation.

Two types of reagents are available for detecting caspase cleavage by immunoblotting. First, antibodies raised against epitopes present in either the large or small subunits of the active enzymes are commercially available from a number of sources (Table 18.2.1). These antibodies should theoretically recognize the corresponding zymogen and active caspase with equal affinities. More recently, antibodies generated against neoepitopes (i.e., epitopes that are generated during the proteolytic activation of caspases) have been developed (Fig. 18.2.2). Such an antibody might recognize the C terminus of the large subunit, including the COOH group that is only present after zymogen cleavage at the proper site (i.e., activation). These reagents, which selectively detect active caspases on immunoblots, are becoming increasingly available.

The advantage of antibodies raised against epitopes present in the large or small subunit is the possibility that decreased zymogen levels can be directly correlated with increased amounts of processed caspases. Interestingly, a stoichiometric relationship between loss of caspase zymogen and appearance of processed caspase is rarely observed. Usually a decreased signal for caspase zymogen is accompanied by a much weaker increase in signal for the active caspase large or small subunit. One possible explanation for this phenomenon is a rapid degradation of caspase species once they are activated. Another possibility is that active caspases might leak from cells as they undergo secondary rupture late in the process of apoptosis. Whatever the explanation, the lack of a 1:1 relationship between loss of zymogen and appearance of active caspase species in cells undergoing apoptosis has practical implications: It makes it difficult to detect the decrease in zymogen levels and the appearance of active caspase species on the same blot with a single exposure of X-ray film. In many studies, a decrease of a procaspase signal is presented as the sole evidence of caspase activation. Whereas a decrease in zymogen level is consistent with caspase activation, it is also consistent with proteolytic degradation to fragments that lack caspase activity. Ideally, X-ray films exposed for different lengths of time are presented, one showing decreased zymogen levels and another showing the appearance of active subunits.

Anti-neoepitope antisera provide an alternative approach for detecting caspase activation (Fig. 18.2.2B). These sera are raised against epitopes that are present at the sites where caspases are cleaved during maturation. Accordingly, if these reagents are of high quality, they recognize only caspases that have been cleaved at the proper site to allow their activation to mature species. Cleavages at other sites will not liberate the epitopes and will not yield a signal. In other words, these sera provide information not only about the size of the caspase fragments that are generated during apoptosis, but also about the precise location of one of the cleavages giving rise to those fragments. The disadvantages of these anti-neoepitope antisera, however, are their current lack of widespread availability and the possibility that they might recognize the same two- to four-amino-acid epitope in other proteins that are cleaved during apoptosis. Nonetheless, these are potentially quite useful reagents.

Affinity labeling

The mapping of caspase cleavage sites in PARP, the lamins, and other substrates (Lazebnik et al., 1994; Takahashi et al., 1996a,b; Nicholson and Thornberry, 1997; Earnshaw et al., 1999) enabled the design of caspase-specific affinity labeling reagents. Each of these reagents consists of a four- or five-amino-acid peptide linked to a detector group (e.g., biotin) and a reactive group that irreversibly binds the caspase active site (e.g., chloromethyl, fluoromethyl, or acyloxymethyl ketone). In principle, the peptide binds to the substrate binding pocket of the caspase, the reactive group forms a covalent bond with the active site cysteine (Thornberry et al., 1994; Wilson et al., 1994), and the covalently modified subunit of the enzyme is then detected or purified using a reagent that reacts with the detector group (e.g., avidin, streptavidin).

This approach is feasible because caspases can tolerate the insertion of detector groups on substrate-like peptides. As was first shown for caspase-1 (Sleath et al., 1990), these enzymes

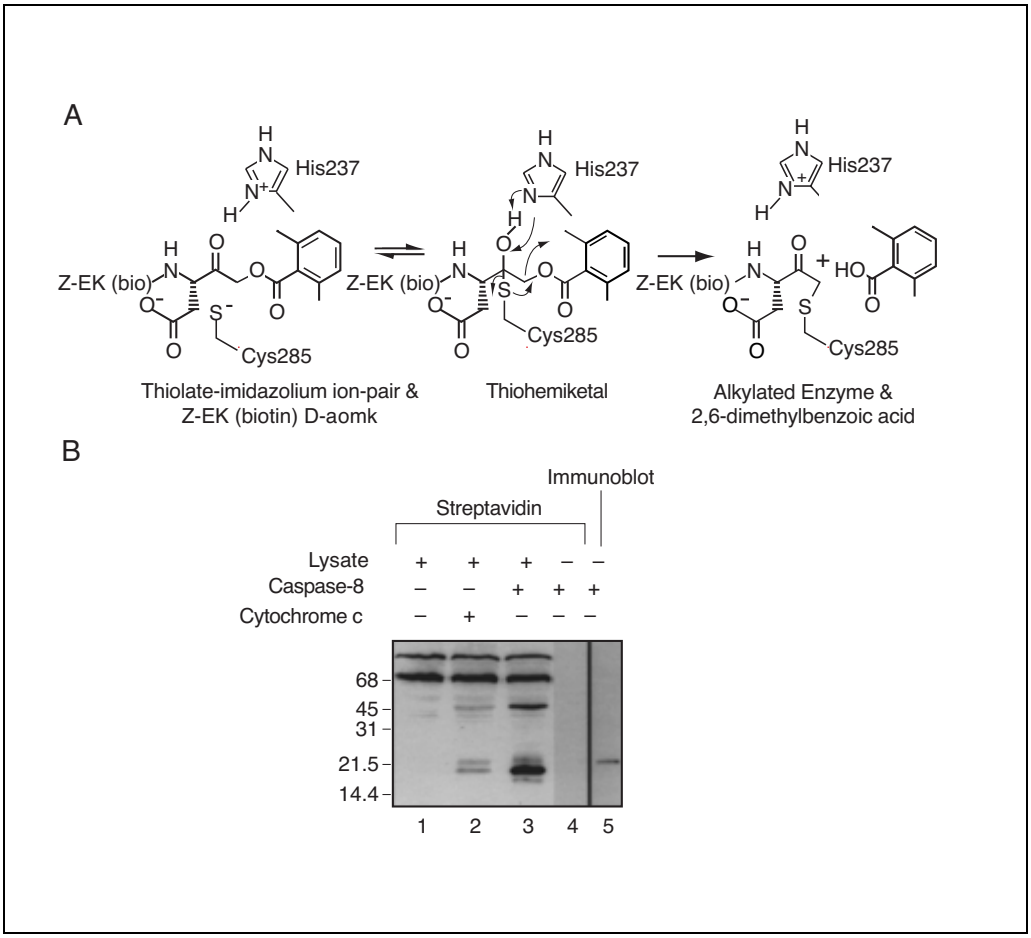

Figure 18.2.3 Labeling of active caspases by acyloxymethylketones. (**A**) The reaction mechanism of zEK(bio)D-aomk (Martins et al., 1997). The active site cysteine initially forms a reversible thiohemiketal. In a slower reaction, the methyl group of the substituted methylketone undergoes SN_2 attack by the same active site thiolate to form the thioether (alkylated enzyme) and liberate the leaving group 2,6-dimethylbenzoic acid. (**B**) Results obtained when *N*-(*N*$^{\alpha}$-benzyloxycarbonylglutamyl-*N*$^{\epsilon}$-biotinyllysyl)aspartic acid ([2,6-dimethylbenzoyl]oxy)methylketone (zEK[bio]D-aomk) is used to detect caspase activation. Cytosol from 1×10^6 cells (40 μg) was incubated for 1 hr at 37°C with diluent (lane 1), 100 ng cytochrome *c* (lane 2), or 50 ng active caspase-8 (lane 3). Samples were then covalently modified with zEK(bio)D-aomk as described in Basic Protocol 3. Lanes 4 and 5: 50 ng of active caspase-8 without cell lysate. Samples in lanes 1 to 4 were visualized using peroxidase-coupled streptavidin and enhanced chemiluminescence reagents. Lane 5 was probed with anti-caspase-8 antiserum followed by peroxidase-coupled secondary antibody. Collectively, these results demonstrate that endogenous biotinylated species are visualized by this technique (lane 1), that multiple zEK(bio)D-aomk-modified bands between 15 and 50 kDa are detected after caspase activation (lanes 2 and 3), and that active caspase-8 does not label with this reagent (lanes 4 and 5). Numbers at left, molecular weights of marker proteins in kilodaltons.

exhibit an absolute requirement for aspartate in the P_1 position. In contrast, because the sidechain of the P_2 residue is pointed away from the enzyme (Wilson et al., 1994), a wide range of unmodified or modified amino acids is permitted at this position (Thornberry et al., 1992). The observation that lysine is tolerated in the P_2 position (Thornberry et al., 1992) opened the door to a new family of labeling reagents that contain biotin on the ε-amino group of lysine. The first member of this family, acetyl-Tyr-Val-(ε-biotin)Lys-Asp-([2,6-dimethylbenzoyl]oxy)methylketone (YVK[bio]D-aomk), was shown to be a potent inhibitor of caspase-1 that could easily be detected with avidin-based reagents (Thornberry et al., 1994). The reagent utilized in Basic Protocol 3, *N*-(N^{α}-benzyloxycarbonylglutamyl-N^{ε}-biotinyllysyl)aspartic acid ([2,6-dimethylbenzoyl]oxy) methylketone (zEK[bio]D-aomk; Martins et al., 1997), was synthesized based on the sequence of the caspase cleavage site in PARP (EVD↓G; Lazebnik et al., 1994) and lamin A (EID↓N; Takahashi et al., 1996a). This reagent has recently become commercially available.

The reaction leading to caspase derivatization by zEK(bio)D-aomk is illustrated in Figure 18.2.3A. Evaluation of the reaction of caspase-1 with a large number of aspartic ketones (Brady et al., 1999) has revealed that the inhibitory effects of these compounds could be classified as reversible, inactivating, or bimodal (i.e., reversible inhibition followed by slow inactivation). The acyloxymethyl ketone inhibitor zEK(bio)D-aomk can be categorized as a bimodal inhibitor, with a first-order rate of conversion of the reversible thiohemiketal complex to the inactive thioether. The thiolate-imidazolium ion pair of the active site Cys^{285} and His^{237} reversibly binds to the zEK(bio)D-aomk inhibitor to form a thiohemiketal complex. Here the imidazolium functions to polarize the carbonyl, enabling subsequent attack by the thiolate anion. The S-C-C_{α}-LG dihedral angle thereby adopts a 180∞ conformation necessary for SN_2 displacement. This conformation places the His^{237}Nd in a position that allows it to stabilize the charge that develops on the leaving group during the displacement reaction. In an irreversible SN_2 displacement reaction the thiolate attacks the $C_{\alpha'}$ carbon, thereby displacing the 2,6-dimethylbenzoic acid leaving group and simultaneously forming a thioether bond (and an alkylated enzyme). It is this alkylated enzyme that is detected upon subsequent blotting with streptavidin.

Critical Parameters

Enzyme activity assays

When setting up assays to measure caspase activity, there are a number of critical parameters to consider. Some of these relate to the experimental design, whereas others relate to the reagents utilized.

In terms of experimental design, it is important to remove cells that spontaneously become apoptotic before starting an experiment. For adherent cell lines, spontaneously apoptotic cells can be removed simply by changing the tissue culture medium at the start of the experiment. For nonadherent cells, these spontaneously apoptotic cells can be removed by Ficoll-Hypaque density gradient sedimentation (Martins et al., 1997). If this is not done, the spontaneously apoptotic cells contribute to a high level of caspase activity in the control sample.

At the time of the enzyme assay, it is important to use an appropriate substrate concentration. If the assay is being performed to quantitate relative amounts of enzyme present, as is usually the case, it is important to use saturating substrate concentrations (e.g., four to five times the K_M of the enzyme). The K_M can be estimated from data such as those presented in Figure 18.2.1B. If the substrate concentration is not saturating, changes in the amount of product released might be due to changes in either the number of active enzyme molecules (altered V_{max}) or the affinity for the substrate (altered K_M). Importantly, the common interpretation that changes in the amount of product released correspond to changes in the number of active enzyme molecules is only valid when the reaction is run under conditions where the substrate is saturating.

When the assay is run as an endpoint assay (see Basic Protocol 1), it is important to confirm that product release is a linear function of the length of incubation. If extracts are prepared from a variety of human cell lines after induction of apoptosis, the assay described above is linear for up to 4 hr under the specified conditions. If the assay is not linear, the most common causes of nonlinearity are substrate exhaustion and enzyme instability. Substrate exhaustion occurs when the enzyme uses most of the substrate, causing the actual substrate concentration to drop below saturating levels. This potential explanation for nonlinearity is suggested by the presence of a high concentration of product (i.e., approaching the nominal concentration of the substrate added). This problem

can be solved by decreasing the amount of enzyme (extract) present or by adding more substrate and determining whether linearity is restored.

If nonlinearity occurs in the absence of substrate exhaustion, the possibility of caspase instability needs to be considered. Based on the authors' experience, it does not appear that the caspases themselves are intrinsically labile at 37°C. However, nonlinearity can also arise if caspases are degraded by other components in the cellular extracts (e.g., proteases that are resistant to the cocktail of protease inhibitors). For certain tissues or cell types, it might be necessary to add additional protease inhibitors in order to preserve caspase stability in the apoptotic extracts.

Another critical parameter for these assays is the quality of the substrate utilized. The authors have found that acetyl-DEVD-AFC from some suppliers (not listed above) yields high levels of fluorescence when diluted in buffer without caspases, apparently as a consequence of contamination by free AFC.

Immunoblotting

When attempting to assess caspase activation by immunoblotting, there are at least two critical parameters. The first involves the method for preparing cell lysates. It has been reported that lysis of lymphoid cells in neutral detergents such as Triton X-100 can lead to artifactual caspase activation by granzyme B present in cytotoxic granules (Zapata et al., 1998). Other serine proteases can also activate certain caspases under cell-free conditions (Zhou and Salvesen, 1997), again raising the potential for artifactual caspase activation during preparation of cell lysates. To avoid this potential pitfall, it is important to solubilize cells under conditions that prevent procaspase cleavage and activation after cell lysis. The protocols described above involve lysis of cells under strongly denaturing conditions, such as in 2% (w/v) SDS containing 4 M urea and reducing agent (Martins et al., 1997; see Basic Protocol 2) or in 6 M guanidine hydrochloride containing reducing agent (Kaufmann et al., 1997; see Alternate Protocol 1). These conditions should avoid spurious caspase activation.

A second critical parameter is the quality of the anti-caspase antibody. Some currently available antibodies exhibit such a weak signal that the instructions accompanying them indicate that they can be used to detect caspase zymogens only in cells that have been transfected with cDNA encoding the procaspase under the control of a strong promoter. Other commercially available anti-caspase antibodies recognize purified recombinant protein but exhibit extensive cross-reactivity when applied to whole-cell lysates. Clearly, these reagents are not useful for the studies envisioned by most cell biologists. Because of the cost of obtaining commercially available antibodies from multiple sources (to say nothing of the frustration of failed experiments), it is important to assess the sensitivity and cross-reactivity of reagents whenever possible before purchasing them.

Affinity labeling

Several parameters are critical for successful detection of active caspases using the affinity labeling approach. First, it is essential to optimize detection conditions in order to achieve maximum signal and minimum background. High backgrounds can be a serious problem with this assay, particularly when caspase concentrations in the cell lysates are low. The most common cause for high backgrounds in the authors' experience is the choice of blocking agent. Although milk is traditionally discouraged when using avidin-biotin detection systems, the authors have found nonfat dry milk to be far superior to biotin-free blocking agents. However, they have also found that nonfat dry milk from different sources results in different levels of background. Accordingly, nonfat dry milk from several different sources might have to be compared to arrive at an optimal signal-to-noise ratio.

A second critical parameter is the chemistry of the reactive group on the affinity labeling reagent. The authors have found that affinity labeling reagents from some commercial sources give unacceptably high background labeling of polypeptides in nonapoptotic cells. Part of this problem might relate to the choice of reactive group. Chloromethyl ketones are highly reactive but relatively nonspecific reagents that covalently modify a wide range of sulfhydryl-containing enzymes (Shaw, 1990). Fluoromethyl ketones are also widely reactive with sulfhydryl-containing enzymes, as illustrated by the demonstration that zVAD-fmk and acetyl-DEVD-fmk can irreversibly inhibit cathepsins B and H (Faubion et al., 1999; Schotte et al., 1999) and by the observation that biotinylated zVAD-fmk can affinity label cathepsin B (Schotte et al., 1999). Accordingly, the authors recommend using peptidyl acyloxymethyl ketones in preference to the more readily available chloromethyl or fluoromethyl ketones.

A third critical factor is the quality of the affinity labeling reagent. The authors have found that the quality of commercially available acyloxymethyl ketones varies widely. These compounds are extremely difficult to synthesize cleanly. When the authors analyzed some commercially available reagents by high performance liquid chromatography, mass spectroscopy, and nuclear magnetic resonance, they noticed several problems, most notably cyclization and racemization of the aspartate. These alterations might reflect the reaction conditions utilized to synthesize these molecules, the quality of the purification step after the multistep synthesis, or the subsequent conditions used to store or ship these somewhat labile molecules. In any case, these impurities can contribute to lack of ability of the reagents to react with caspases and/or spurious reactions with other proteins.

Unfortunately, cost and quality of available reagents remains a consideration in deciding whether to apply this approach. Hopefully the presence of a potentially lucrative market will stimulate suppliers to improve the quality and availability of these reagents.

Anticipated Results

Enzyme activity assays

Despite all the caveats and limitations listed above, activity assays can be extremely useful when applied appropriately. They have been utilized as one means of successfully confirming that caspases are activated under a wide range of conditions. In addition, they have proven particularly useful in assessing the timing of caspase activation relative to other apoptotic events, in comparing the ability of cells to undergo apoptosis after different treatments, and in assessing the mechanism by which various antiapoptotic agents exert their effects. Compared to the immunoblotting and affinity labeling procedures, activity assays are easier and more quantitative. They must, however, be interpreted cautiously because they do not yield a definitive identification of the caspases that are activated.

Immunoblotting

Shown in Figure 18.2.2B are results obtained when HL-60 human leukemia cells were treated with the topoisomerase II poison etoposide, lysed in guanidine hydrochloride lysis buffer, and subjected to immunoblotting using several immunological reagents. Caspase activation, as reflected by the cleavage of the caspase substrate PARP (Lazebnik et al., 1994), is first detectable at 2 hr. Loss of caspase-9 zymogen, reflecting presumed proteolytic activation, and appearance of a species corresponding to the large subunit of active caspase-9 is also evident at 2 hr. Thus, immunoblotting with antibodies against either caspases or their substrates can be utilized to assess the timing of caspase activation. In addition, examination of other immunoblots in Figure 18.2.2B shows that some caspase zymogens are degraded to active species after caspase-9 activation (e.g., caspase-8) or are not activated at all (e.g., procaspase-2). Thus, by employing a series of reagents that recognize zymogens and active caspases, it is possible to confirm that specific caspases have been activated and to assess the relative timing of their activation in a population of cells undergoing somewhat synchronous apoptosis.

Affinity labeling

Results obtained in a typical experiment are shown in Figure 18.2.3B. In this example, cell lysate prepared from nonapoptotic cells has been treated with cytochrome *c* or active caspase-8 to activate endogenous caspases. After treatment with zEK(bio)D-aomk, the samples have been subjected to SDS-PAGE followed by detection with peroxidase-coupled streptavidin. As illustrated in lane 1, this technique detects several endogenous biotinylated polypeptides. Most of these have molecular weights above M_r ~50,000 and do not interfere with the detection of active caspase species. As shown in lanes 2 and 3, the most prominent polypeptides that label after caspase activation are species of M_r ~15,000 to 22,000. Two-dimensional gel electrophoresis has demonstrated that multiple discrete charged species are hidden in each band (Martins et al., 1997). Two different approaches have revealed that the most abundant species detected in apoptotic cell lysates are active forms of caspase-3 and caspase-6 (Faleiro et al., 1997; Martins et al., 1997). Further analysis has suggested that caspase-3 and caspase-6 each give rise to at least two size variants, a mature variant lacking the prodomain and a partially processed intermediate containing the prodomain. The charge variants appear to reflect, at least in part, differences in caspase phosphorylation (Martins et al., 1998).

As also illustrated in Figure 18.2.3B, zEK(bio)D-aomk does not react with active caspase-8. In contrast, biotinyl-DEVD-fmk has been reported to derivatize this enzyme (Muzio

et al., 1997). These observations illustrate the potential importance of testing several different affinity labeling reagents before concluding that active caspases cannot be detected in a particular biological system by affinity labeling.

Time Considerations

Enzyme activity assays

The entire enzyme activity assay procedure can be completed in 1 day. After the induction of apoptosis, the time required for preparing cell extracts is ~3 hr. These extracts can be stored for several months at −70°C without appreciable loss of caspase activity. Protein assays take 1 to 2 hr to complete. If the solutions are premixed, the assay itself can be set up in 30 min to 1 hr and then read 2 to 4 hr later.

Immunoblotting

It takes several days from start to finish to treat cells, prepare cell lysates, perform SDS-polyacrylamide gel electrophoresis, transfer polypeptides to nitrocellulose, and probe immunoblots. It should be obvious, however, that there are many stopping points in the procedure. The process can be speeded up by using minigels and a minitransfer apparatus, but the resolution of the smaller blots might be somewhat limited.

Affinity labeling

The entire affinity labeling procedure outlined above can be completed in 2 days. After the induction of apoptosis, the time required for preparing cell extracts is ~3 hr. These extracts can be stored for several months at −80°C without appreciable loss of reactivity. Protein assays take 1 to 2 hr to complete. The samples can then be subjected to electrophoresis (1 hr), transferred to nitrocellulose (30 min), blocked (overnight at 4°C), and incubated with streptavidin and visualized (4 to 5 hr).

Assessment of Apoptosis and Necrosis by DNA Fragmentation and Morphological Criteria

Cell death may occur by two mechanisms: apoptosis, or programmed cell death, and necrosis, or cell death due to injury or trauma (see *UNIT 18.1*). Both types of cell death have their own specific and distinct morphological and biochemical hallmarks. Apoptotic cells share a number of common features, such as phosphatidylserine (PS) exposure, cell shrinkage, chromatin cleavage, nuclear condensation, and formation of pyknotic bodies of condensed chromatin. Necrotic cells exhibit nuclear swelling, chromatin flocculation, loss of nuclear basophilia, breakdown of cytoplasmic structure and organelle function, and cytolysis by swelling. Cell death can be induced by a wide variety of stimuli, such as growth factor withdrawal, heat shock, cold shock, radiation, heavy metals, genotoxic drugs, and a number of biological ligands such as Fas-L and tumor necrosis factor (TNF). Most if not all of these can induce both apoptosis and necrosis in a time- and dose-dependent manner.

A variety of techniques have been developed to assess cytotoxicity in untreated and/or treated cells, most of which are based on the loss of plasma membrane integrity. Membrane disruption can be detected based on the uptake of vital dyes (see Basic Protocol 1) However, during apoptosis, the cell membrane remains intact for a relatively long time, and therefore some of these assays cannot detect the early stages of apoptosis. Alternatively, assays that detect all types of cell death do not discriminate between apoptosis and necrosis. Therefore, more specific techniques have been developed to determine cell death, and the combination of several methods is required to distinguish between the two separate types. These techniques rely on specific morphological and molecular or biochemical changes associated with these two processes.

This unit describes some of the techniques most commonly used to detect cell death. Morphological assays include trypan blue exclusion (see Basic Protocol 1), differential staining (see Basic Protocol 2), and Hoechst staining (see Basic Protocol 3). Methods to detect chromatin cleavage include TUNEL assays for whole cells (see Basic Protocol 4) and paraffin sections (see Alternate Protocol 1), DNA fragmentation assays using whole cells (see Basic Protocol 5), assays of total genomic DNA (see Alternate Protocol 2), analysis of DNA fragmentation by agarose gel electrophoresis (see Alternate Protocol 3), phenol extraction of DNA for analysis of fragmentation (see Alternate Protocol 4), a quantitative assay for DNA fragmentation (see Basic Protocol 6), and detection of DNA fragmentation by pulsed-field gel electrophoresis (see Basic Protocol 7). A protocol is also provided for Cytospin preparations from cell suspensions (see Support Protocol 1). Table 18.3.1 describes how these assays are used to distinguish apoptotic cells from necrotic cells.

MORPHOLOGY ASSAYS

Loss of membrane integrity, which occurs late in apoptosis and relatively early in necrosis, can be detected by cellular uptake of the vital dye trypan blue (see Basic Protocol 1). Apoptosis and necrosis also can be identified morphologically based on the criteria described elsewhere (Bowen, 1980). These include cell shrinkage, nuclear condensation, and cleavage for apoptotic cells; and nuclear swelling, chromatin flocculation, and loss of nuclear basophilia for necrotic cells. The levels of both apoptosis and necrosis in a particular cell population can be estimated from Cytospin preparations (see Support Protocol 1) stained with RAPI-DIFF (see Basic Protocol 2; see Figure 18.3.1), Hoechst stain (see Basic Protocol 3), or propidium iodide.

Contributed by Boris Zhivotovsky and Sten Orrenius

Current Protocols in Cell Biology (2001) 18.3.1-18.3.23

Table 18.3.1 Methods for Determination of Apoptosis and Necrosis

Method	Protocol	Result for	
		Apoptosis	Necrosis
Morphological/cytological analysis			
Trypan blue staining	Basic Protocol 1	No staining (early apoptosis) Blue staining (late apoptosis)	Blue cells
Differential staining	Basic Protocol 2	Membrane blebbing, chromosome condensation and nuclear shrinkage, cytoplasmic constriction and loss of cell volume	Nuclear swelling, chromatin flocculation, membrane blebbing and disruption, appearance of cell "ghosts"
Hoechst staining	Basic Protocol 3	Increased blue fluorescence, fragmented or condensed nuclei	Blue nucleus with diffuse staining
Flow cytometry	—	Reduced forward and side scatter	Increased forward and side scatter
Annexin V binding and PI staining	—	Positive fluorescence response for annexin V binding; exclusion of PI	Positive fluorescence; uptake of PI
Assays for chromatin cleavage			
TUNEL assay	Basic Protocol 4 and Alternate Protocol 1	Detection of strand breaks	Detection of strand breaks
Whole-cell DNA fragmentation	Basic Protocol 5	DNA ladder	DNA smear
Total genomic DNA fragmentation	Alternate Protocol 2	DNA ladder	DNA smear
Simple protocol for DNA fragmentation	Alternate Protocol 3	DNA ladder	DNA smear
Phenol extraction for DNA fragmentation	Alternate Protocol 4	DNA ladder	DNA smear
Quantitative assay of DNA fragmentation	Basic Protocol 6	Increase in the percentage of fragmented DNA	Increase in the percentage of fragmented DNA
Pulsed-field detection of high-molecular-weight DNA	Basic Protocol 7	High-molecular-weight bands	DNA smear
Assays for caspase activation			
Specific substrate cleavage assay	*UNIT 18.2*	Positive detection of cleaved fluorescent substrate	No changes in fluorescence detected
Immunodetection of caspase activation	*UNIT 18.2*	Positive detection of cleavage products of procaspase	No cleavage products detected

BASIC PROTOCOL 1

Measurement of Cell Death by Trypan Blue Exclusion

This common cell viability assay is based on the ability of a cell with an intact membrane to exclude the dye trypan blue. Therefore, this assay allows one to distinguish between cells with intact and disrupted membranes. Since this method does not give an indication of the mode of cell death, it should be used only in conjuction with a more informative morphological method.

Materials

Cell suspension to be assessed
2× PBS tablets, pH 7.2 to 7.4 (Sigma) or 2× PBS (*APPENDIX 2A*)
0.2% (w/v) trypan blue (Sigma) in 2× PBS (store up to 1 to 2 months at 4°C)

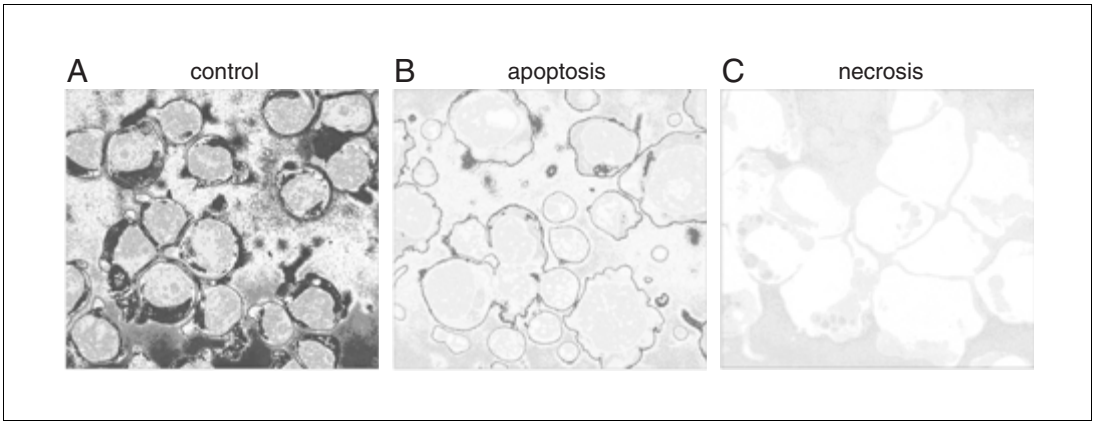

Figure 18.3.1 RAPI-DIFF staining of Cytospin preparation of HL-60 cells. Cells were treated with different concentrations of a cytotoxic drug to induce apoptosis or necrosis. (**A**) Untreated cells, (**B**) apoptotic cells, and (**C**) necrotic cells.

Hemacytometer: improved Neubauer type (Karl Hecht; Baxter) or equivalent
Coverslips (e.g., Chance Propper)
Light microscope

1. Remove from the cell suspension a sample containing ~5×10^4 cells.
2. Add an equal volume of 0.2% trypan blue, mix, and incubate 1 to 2 min at room temperature to permit dye uptake.
3. Load samples onto the hemacytometer.
4. Count the total number of cells and the number of unstained cells in five of the major sections of the hemacytometer (see Fig. 1.1.1). Calculate the average number of cells per section.
5. Calculate the number of cells/ml culture medium by multiplying the average number of cells per section by the dilution factor (2 in this case) and hemacytometer index (10^4). Determine the percentage viability according to the following formula:

$$\% \text{ viability} = \frac{\text{number of unstained cells}}{\text{total number of cells}} \times 100$$

Control cells and cells in early stages of apoptosis exclude trypan blue; cells in the late stages of apoptosis and necrotic cells take up the dye and appear as blue cells.

Differential Staining of Cells

BASIC PROTOCOL 2

This staining procedure involves three steps: first cells are fixed in 100% methanol, then the nuclei are stained with an acid dye, and finally the cytoplasm is stained using a basic dye. Such three-step procedure allows differential staining and contrast between the cytoplasm and the nucleus. Apoptotic cells exhibit membrane blebbing, chromatin condensation and nuclear shrinkage, cytoplasmic constriction and loss of cell volume, and formation of apoptotic bodies. Necrotic cells undergo nuclear swelling, chromatin flocculation, cell membrane blebbing and disruption, and finally cell lysis resulting in the appearance of "ghost cells" (see Figure 18.3.1). This method can also be applied to cells growing attached to coverslips or chambered culture slides.

Materials

Cytospin preparations of cells (see Support Protocol 1)
100% methanol
Acid dye: 0.1% (w/v) eosin Y/0.1% (w/v) formaldehyde/0.4% (w/v) sodium phosphate dibasic/0.5% potassium phosphate monobasic
Basic dye: 0.4% (w/v) methylene blue–polychromed/0.4% (w/v) azure/0.4% (w/v) sodium phosphate dibasic/0.5% (w/v) monobasic potassium phosphate
DPX mountant (in solution; BDH)

Coverslips (e.g., Chance Propper)
Microscope slides (e.g., Menzel-Glaser)
Light microscope

1. Fix cells after Cytospin preparation (see Support Protocol 1) by immersing the slide ten times in 100% methanol.

   The three solutions required for this procedure are available as a kit, called RAPI-DIFF Stain kit, from Diagnostic Developments. The solutions can be stored 1 to 2 months at room temperature.

2. Stain the cell nuclei by dipping the slide in the acid dye ten times.
3. Stain the cell cytoplasm by dipping the slide in basic dye ten times.
4. Rinse the slide by dipping in distilled water, let it air dry, and mount it using DPX mountant.
5. Score the cells as normal, apoptotic, condensed and/or fragmented nuclei, or necrotic swollen cells, based on their morphological appearance under a light microscope (see *UNIT 18.1* and Fig. 18.3.1).

BASIC PROTOCOL 3

Hoechst Staining of Cells

Hoechst 33342, a bisbenzimide dye, is a cell-permeant, minor group–binding DNA stain that fluoresces bright blue upon binding to DNA. It is water soluble and relatively nontoxic. Hoechst 33342 can be excited with the UV lines of the argon-ion laser and most conventional fluorescence excitation sources, and it exhibits relatively large Stokes shifts (excitation and emission maxima ~350 and 460 nm), making it suitable for multicolor labeling experiments (Pollak and Ciancio, 1990). Cells are scored as apoptotic if they have fragmented nuclei. This method can also be applied to cells growing attached to coverslips or chambered culture slides.

Materials

Cell suspension
1× and 2× PBS, pH 7.2 to 7.4 (from Sigma 2× PBS tablets, or see *APPENDIX 2A*)
4% (w/v) paraformaldehyde (see recipe)
10 μg/ml Hoechst 33342 dye (Molecular Probes) in PBS (*APPENDIX 2A*)
50/50 (v/v) PBS/glycerol

Microscope slides (e.g., Menzel-Glaser)
Coverslips (e.g., Chance Propper)
Fluorescent microscope

Additional reagents and equipment for Cytospin preparations (see Support Protocol 1)

1. Place an aliquot of cell suspension containing $0.3–0.5 \times 10^6$ cells in a microcentrifuge tube, and centrifuge 5 min at $1000 \times g$, 4°C.

2. Remove and discard supernatant. Resuspend the dry pellet in 30 to 50 µl of 4% paraformaldehyde.
3. Spin the fixed cells onto a glass slide using a Shandon/Lipshaw Cytospin centrifuge (see Support Protocol 1). Alternatively, spread the cells onto a slide with a pipet tip, and air dry slide.
4. Stain slide with 10 µg/ml Hoechst dye.

   Hoechst 33342 dye can be diluted from 100× stock kept in the dark at 4°C.
5. Leave slide in the dark for 10 min at room temperature.
6. Rinse by dipping slide five times in distilled water, and let it air dry in the dark.
7. Mount slide with coverslip using PBS/glycerol. Monitor fluorescence with a blue filter in the fluorescence microscope, and score cells with fragmented nuclei as apoptotic.

   This method is useful for discrimination of apoptotic from nonapoptotic (untreated or necrotic) cells.

Cytospin Preparation of Cells for Analysis

SUPPORT PROTOCOL 1

Cytospin preparations can be used in many protocols for cell biology. Once slides are prepared they can be stained with variety of dyes and analyzed using light, fluorescent, and confocal microscopy, depending on the dye type. Before staining, slides can be stored up to 1 year at −20°C covered with aluminum foil. Fixed and stained slides can be stored indefinitely once mounted permanently.

Materials

Cell suspension
PBS (*APPENDIX 2A*)
Cytospin centrifuge and cups (Shandon/Lipshaw)

1. Place a sample of cell suspension containing ~0.5–1 × 10^5 cells in a microcentrifuge tube, and centrifuge 5 min at 1000 × *g*, 4°C.
2. Remove and discard supernatant. Resuspend pelleted cells in 100 µl PBS.
3. Add suspension to the Cytospin cup and slide setup, and centrifuge 2 min at 500 × *g*, 4°C.
4. Air dry the slide.

ASSAYS FOR CHROMATIN CLEAVAGE

Chromatin cleavage is a hallmark of apoptosis and involves the formation of high-molecular-weight (>50-kbp) and nucleosome-sized (200-bp) DNA fragments. The high-molecular-weight fragments can be separated by pulsed-field gel electrophoresis, and the nucleosome-sized fragments, when separated on a conventional agarose gel, demonstrate a ladder pattern. The DNA from necrotic cells, on the other hand, has a random and general cleavage pattern and produces a smear when electrophoresed on either a pulsed-field or conventional gel (see Fig. 18.3.2). Prior to the formation of the cleavage products, endogenous nucleases must generate a large number of DNA strand breaks. These strand breaks in DNA can be detected by attaching biotin-conjugated nucleotides to the 3′ hydroxyl termini in a reaction catalyzed by exogenous terminal deoxynucleotidyl transferase (TdT). A number of methods can be used to identify apoptotic or necrotic DNA. All of these methods are equally successful and require the same number of cells.

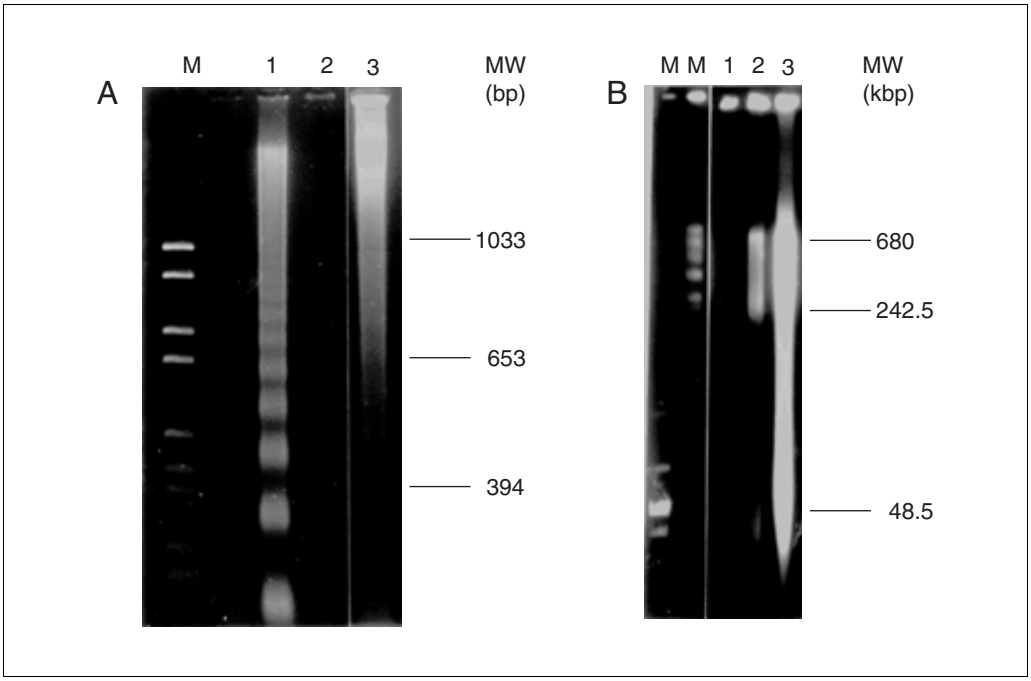

Figure 18.3.2 Gel electrophoresis of DNA from Jurkat cells treated with different concentrations of a cytotoxic drug. (**A**) Conventional gel: M, marker; lanes 1 to 3, DNA from apoptotic, untreated, and necrotic cells, respectively. The DNA ladder, when present, is a strong indicator of apoptosis. (**B**) Pulsed-field gel: MM, markers; lanes 1 to 3, DNA from untreated, apoptotic, and necrotic cells, respectively.

BASIC PROTOCOL 4

TUNEL Assay for DNA Fragmentation in Cells

Induction of apoptosis results in the generation of single-strand DNA breaks. These can be detected using the TdT-mediated dUTP-biotin nick end-labeling (TUNEL) method (Gavrieli et al., 1992). This method requires cell fixation with cross-linking agents such as formaldehyde, which, unlike some of the alcohols (such as ethanol), prevents the extraction of degraded DNA. In other words, this fixation step prevents the loss or reduction of the cellular DNA content after the extensive washings and staining involved in this protocol. Once cells are fixed with formaldehyde, treatment with alcohols does not affect the DNA content of cells.

Materials

Cell suspension
100% methanol, –20°C
PBS, pH 7.2 to 7.4 (*APPENDIX 2A*)
1% (v/v) formaldehyde
70% ethanol, ice cold
Terminal deoxyribonucleotidyltransferase (TdT; 25 U/ml) and 10× buffer (0.3 M Tris base/1.4 M sodium cacodylate, pH 7.2/1 mM DTT; e.g., Boehringer Mannheim)
25 mM $CoCl_2$
1 mM Bio-16-dUTP (e.g., Boehringer Mannheim)
Termination buffer: 300 mM NaCl/30 mM sodium citrate (e.g., Sigma or equivalent)
Staining buffer (e.g., Sigma; see recipe)
FACS fluid (e.g., Becton Dickinson; optional; for flow cytometry)
DPX mountant (BDH)
5 µg/ml propidium iodide in PBS (*APPENDIX 2A*)

Flow cytometer (e.g., Becton Dickinson) and tubes; *or* fluorescent microscope
Coverslips (e.g., Chance Propper)
Microscope slide (e.g., Objektträger, Menzel-Glaser)

1. Wash a sample of cell suspension containing ~10^6 cells by centrifuging 5 min at 1000 × *g*, 4°C, discarding supernatant, and resuspending in PBS. Transfer to microcentrifuge tube and centrifuge 5 min at 1000 × *g*, 4°C.
2. Remove and discard supernatant. Resuspend cells in 1% formaldehyde and fix for 15 min on ice.
3. Centrifuge 5 min at 1000 × *g*, 4°C. Remove and discard supernatant. Resuspend cell pellet in PBS, and repeat centrifugation. Remove and discard supernatant.
4. Resuspend cell pellet in 0.5 ml PBS and add to 5 ml ice-cold 70% ethanol.

   Cells can be stored in ethanol for several weeks at −20°C.
5. Centrifuge 5 min at 1000 × *g*, 4°C. Remove and discard ethanol. Resuspend cells in PBS, and repeat centrifugation.
6. Prepare elongation buffer (50 µl per sample):

   41.5 µl ultrapure water
   5 µl 10× TdT buffer
   2 µl 25 mM $CoCl_2$
   1 µl 1 mM Bio-16-dUTP
   0.5 µl 25 U/µl TdT enzyme.

   Add 50 µl elongation buffer to each cell pellet and resuspend. Incubate 30 min at 37°C.

   It is recommended that more than the required amount of elongation buffer be prepared; that is, multiply the total number of samples + 1 by 50 µl (the volume of the elongation buffer per sample) when calculating how much buffer to prepare. This buffer needs to be made fresh.
7. Add 5 ml PBS and centrifuge 5 min at 1000 × *g*, 4°C. Remove and discard supernatant.

   The reaction may first be stopped by incubating cells with termination buffer for 15 min at room temperature, though omission of this step does not appear to affect the results.
8. Resuspend cell pellet in 100 µl staining buffer, and incubate 30 min at room temperature.

   Again, it is recommended that extra buffer be prepared.
9. Add 2 ml PBS, resuspend cells, and centrifuge 5 min at 1000 × *g*, 4°C. Remove and discard supernatant. Repeat.
10. Add 1 ml of 5 µg/ml propidium iodide and incubate 30 min at room temperature in the dark.
11. Centrifuge 5 min at 1000 × *g*, 4°C, and remove supernatant.

12a. *For flow cytometry:* Resuspend cells in sufficient amount of PBS or FACS fluid and measure fluorescence (for FITC, 488 nm excitation, 520 ± 20 nm emission, FL-1 channel; for PI, 560 nm excitation, 640 nm emission, FL-2 or FL-3 channels).

12b. *For fluorescence microscopy:* Resuspend cells in 50 to 100 µl of PBS and spin them onto a slide as described under Cytospin preparations (see Support Protocol 1). Mount slides with DPX mountant and observe fluorescence with green and red filters under microscope.

Cells for fluorescence microscopy can be counterstained with hematoxylin for ≤30 sec, and then rinsed with water, before microscopy.

The number of single-strand breaks is increased during the early stages of apoptosis (increase in green fluorescence) without any change in the DNA content (measured by PI staining). With time the DNA content is decreased (red fluorescence) due to formation of apoptotic bodies, which also results in the reduction of TUNEL signal.

ALTERNATE PROTOCOL 1

TUNEL Assay in Paraffin-Embedded Sections

The TUNEL assay can also be performed on paraffin-embedded tissue sections.

Additional Materials *(also see Basic Protocol 4)*

Paraffin-embedded tissue sections on slides
4% (w/v) paraformaldehyde (see recipe) *or* 4% formaldehyde, in PBS (*APPENDIX 2A*)
96%, 90%, and 80% ethanol
Xylene
BSA (e.g., Sigma)
10 mM Tris·Cl, pH 8 (*APPENDIX 2A*)
20 µg/ml proteinase K in 10 mM Tris·Cl (*APPENDIX 2A* for Tris·Cl)
3% (v/v) methanol
2% (w/v) BSA in PBS (*APPENDIX 2A* for PBS)
ExtrAvidin-peroxidase (Sigma) diluted 1:50 in PBS/1% BSA/0.5% Tween 20
3-Amino-9-ethylcarbazole (AEC)

Fluorescent microscope
Coverslips (e.g., Chance Propper)
Microscope slide (e.g., Objektträger, Menzel-Glaser)

1. Fix section in 4% paraformaldehyde or formaldehyde, then immerse in PBS.
2. Remove paraffin from sections by incubating slide 10 min at 70°C or 30 min at 58° to 60°C.
3. Rehydrate sections by sequential incubation in xylene (twice, 5 min each), 96% ethanol (twice, 3 min each), 90% ethanol (3 min), and 80% ethanol (3 min), followed by 3 min in water.

   Because paraffin traces might interfere with the enzymatic reaction in tissue sections, use of fresh solvents is recommended.
4. Treat sections with 10 mM Tris·Cl, pH 8, for 5 min, then incubate 15 min in 20 µg/ml proteinase K at room temperature. Wash slide four times in ultrapure water, 2 min each time.
5. Incubate sections in 3% methanol for 30 min at room temperature, and rinse by dipping five times in ultrapure water.
6. Prepare 100 µl per slide of elongation buffer (see Basic Protocol 4, step 6; the buffer needs to be fresh). Incubate the sections 60 min at 37°C in humid atmosphere.
7. Rinse the sections by dipping three times in ultrapure water, and incubate in termination buffer for 15 min at room temperature.
8. Place sections sequentially in PBS (5 min), 2% BSA (10 min), and PBS (5 min), all at room temperature.

   Addition of BSA prevents nonspecific binding of ExtrAvidin-peroxide.
9. Incubate the sections in ExtrAvidin-peroxidase for 15 min at room temperature.
10. Incubate the sections in 2% BSA, and wash four times in PBS.
11. Stain the sections with AEC for 30 min at 37°C, then rinse by dipping three times in ultrapure water.
12. Mount slides and observe for fluorescence.

    After mounting the covered slides can stored for many months at 4°C.

    Tissue sections, like cells, can be counterstained with hematoxylin for ≤30 sec, followed by rinsing in water.

Detection of DNA Fragmentation in Whole Cells

In 1976, Skalka et al. reported that the DNA in chromatin of irradiated lymphoid tissues degrades in vivo into oligonucleosome-length fragments. This observation was first linked to endonuclease activation in 1980 (Wyllie, 1980). Since then several methods have been developed to measure internucleosomal DNA fragmentation. This method was adapted from the protocol first described by Sorenson et al. (1990) and does not require DNA purification. Appearance of a DNA ladder will correspond to apoptosis, whereas a DNA smear will indicate necrosis. This also applies to all the alternate protocols in this section.

Materials

1× and 5× TBE buffer (see recipe), pH ~8.0 at room temperature (do not adjust pH)
SeaKem GTG agarose (FMC Bioproducts)
Cell suspension
50 mg/ml RNase A (see recipe)
4× DNA loading buffer: 4× TBE buffer (see recipe) containing 40% (w/v) sucrose and 0.25% (w/v) bromphenol blue (e.g., Sigma; store up to 2 to 3 weeks at 4°C)
Ultrapure agarose (Life Technologies)
10% (w/v) SDS (see recipe)
20 mg/ml proteinase K in water (store in aliquots up to 1 year at −20°C)
1× DNA loading buffer: 1× TBE buffer (see recipe) containing 10% (w/v) sucrose and 0.25% (w/v) bromphenol blue (e.g., Sigma)
DNA marker VI (pBR328 DNA cleaved with *Bgl*I and *Hin*fI; Boehringer Mannheim), 1 µl in 20 µl of 1× DNA loading buffer
TE buffer, pH 8.0: 10 mM Tris·Cl/1 mM EDTA
10 mg/ml ethidium bromide (see recipe)

Boiling water bath or microwave oven
Gel electrophoresis apparatus: GNA-100 (Amersham Pharmacia Biotech), Buffer Puffer (Owl Scientific), or equivalent
Power supply (Power-Pac 300, Bio-Rad, or equivalent)
Shaker at 4°C
MacroVue UV Transilluminator (Hoefer Scientific Instruments) or equivalent
Photoman Polaroid gel documentation system (Hoefer Scientific Instruments) or equivalent

Prepare agarose gel for electrophoresis

1. Prepare sufficient volume of 1× TBE to cast the gel and to fill the electrophoresis tank.

   It is important to use the same batch of electrophoresis buffer in both the electrophoresis tank and in the gel. Differences in pH or ionic strength can greatly affect the DNA mobility.

2. Weigh 0.9 g SeaKem agarose in a flask, and add 50 ml of 1× TBE (for GNA-100 gel electrophoresis apparatus). Heat in a boiling water bath or microwave oven until dissolved, then allow the agarose to cool to 60°C for 10 to 15 min.

   This is a standard 1.8% agarose gel. The volume should not occupy >40% of the volume of the flask.

   For the Buffer Puffer gel electrophoresis apparatus, use 2.7 g agarose and 150 ml TBE.

3. Pour gel into mold. Remove unwanted air bubbles. Place comb in the gel and allow gel to set 1 hr.

Prepare sample

4. Place a sample of cell suspension containing 4–5 × 10^5 cells in a microcentrifuge tube, and centrifuge 3 min at 1000 × *g*, 4°C.

   If necessary, the pellet may be stored up to 2 to 3 weeks in microcentrifuge tubes at −20°C before proceeding.

5. Carefully remove supernatant and resuspend pellet in 16 µl ultrapure water.
6. Add 4 µl of 50 mg/ml RNase A (final concentration 10 mg/ml), mix, and leave 20 min at room temperature.
7. Add 5 µl of 4× DNA loading buffer.
8. Using a scalpel, cut out a piece of gel between the comb and the upper edge of the gel (do not remove the comb), leaving the gel above the first one or two wells intact.

Prepare digestion gel

9. Prepare 5 ml of digestion gel by weighing 40 mg Ultrapure agarose, adding 2.75 ml ultrapure water, and stirring on a hot plate to dissolve.

   Do not use the SeaKem agarose in this step because it causes SDS to come out of solution.

   For the Buffer Puffer gel electrophoresis apparatus, prepare 10 ml of digestion gel.

10. When steam starts to rise from the flask, add 1 ml of 5× TBE and 1 ml of 10% SDS. When agarose has boiled and dissolved, take flask off the heat and allow gel to cool to 50°C.
11. Add 250 µl of 20 mg/ml proteinase K, mix gently, and pour into the gap above the main gel. Allow to cool, and remove the comb.

Set up for electrophoresis

12. Mount the gel in the electrophoresis tank, and add just enough 1× TBE buffer to cover it to a depth of 1 mm.
13. Add 1 µl DNA marker VI to 30 µl of 1× DNA loading buffer and load the marker into the well that is separated from the digestion gel. Load all other samples into the wells connected with the digestion gel.

    For the Buffer Puffer apparatus, use 2 µl DNA marker VI dissolved in 30 µl of 1× DNA loading buffer.

14. Run the gel overnight (~14 hr) at 20 V to facilitate digestion of the sample.
15. Turn the voltage up to 90 V and run for an additional 1.5 hr.

    For the Buffer Puffer apparatus, run gel 2 hr at 100 V after the initial 20-V overnight run.

Develop gel

16. Remove the gel from the tank and rinse with water.
17. Add 100 ml TE buffer and 40 µl of 50 mg/ml RNase A. Place gel on shaker for 3 to 4 hr.
18. Rinse the gel with distilled water. Add 100 ml TE buffer and 5 µl of 10 mg/ml ethidium bromide. Place gel on the shaker for 40 min.
19. Wash several times with fresh TE to remove ethidium bromide, and photograph under UV light.

Detection of DNA Fragmentation in Total Genomic DNA

ALTERNATE PROTOCOL 2

This method is a modified version of the protocol described by McGahon et al. (1995). The presence of ethidium bromide in the gel avoids later staining and destaining of the gel. Although Basic Protocol 5 and this alternate protocol are equally sensitive, the latter is less time consuming. In addition, dry loading prevents the loss of material.

Additional Materials *(also see Basic Protocol 5)*

Lysis buffer: 2 mM EDTA/100 mM Tris·Cl, pH 8.0/0.8% (w/v) SDS (store at room temperature)

1. Place sample of cell suspension containing 4–6 × 10^5 cells in a 1.5-ml microcentrifuge tube. Centrifuge 5 min at 2000 × *g*, 4°C.
2. Remove and discard supernatant. Add 20 µl lysis buffer.
3. Add 2 µl of 50 mg/ml RNase A. Mix well by flicking the tip of the tube. Do not apply vigorous vortexing. Incubate at least 30 min at 37°C.
4. Add 10 µl of 20 mg/ml proteinase K, and incubate at least 1.5 hr at 50°C.
5. Add 8 µl of 4× DNA loading buffer.

   If necessary, after this step the samples can be stored for at least 1 week at 4°C.
6. Place 0.9 g SeaKem agarose (1.8%) in 50 ml of 1× TBE buffer in a flask (for GNA-100 gel electrophoresis apparatus). Heat in a boiling water bath or microwave oven until dissolved. Allow the agarose to cool to 60°C for 10 to 15 min. Add 3 µl of 10 mg/ml ethidium bromide.
7. Dry load the samples. Dissolve 1 µl DNA marker VI in 30 µl of 1 × DNA loading buffer and load into the gel. Apply low current (~35 mA) for ≥7 hr or higher current (~60 mA) for 4 hr.

   Samples are dry loaded and enough TBE buffer is added to the apparatus so it touches both sides of the gel but does not cover it. This is to ensure that the sample is not lost. After 10 min, when the samples have entered the gel, the current is stopped and more TBE is added so it covers the whole gel, and the current is then reapplied.
8. Photograph the gel under UV light.

Simple Protocol for Detection of DNA Fragments

ALTERNATE PROTOCOL 3

This simple protocol was developed in the authors' laboratory. It is particularly useful for detection of chromatin cleavage in lymphoid cells (Zhivotovsky et al., 1995) but less so for hepatocytes and epithelial cells. For these types of cells, see Alternate Protocol 4.

Additional Materials *(also see Basic Protocol 5)*

Lysis buffer, 4°C: 5 mM Tris·Cl, pH 8.0/20 mM EDTA/0.5% (v/v) Triton X-100
100% ethanol, −20°C
5 M NaCl (*APPENDIX 2A*)
RNase T1/A stock (see recipe)
Vacuum lyophilizer (e.g., Hetovac, Heto-Holten)

Prepare DNA sample

1. Place sample containing 1–2 × 10^6 cells in a microcentrifuge tube, and centrifuge 5 min at 2000 × *g*, 4°C. Resuspend pellet in 1 ml PBS and repeat centrifugation.
2. Resuspend pellet in 250 µl TE buffer, add 250 µl of 4°C lysis buffer, and vortex. Refrigerate 30 min.
3. Centrifuge sample 15 min at 15,000 × *g*, 4°C.

4. Transfer supernatant to a fresh microcentrifuge tube. Add 1 ml −20°C ethanol and 30 µl of 5 M NaCl. Mix and place in −20°C freezer overnight.
5. Centrifuge sample for 15 min at 15,000 × *g*, 4°C. Remove and discard supernatant.
6. Place precipitate in vacuum lyophilizer for 20 to 25 min.
7. Add 20 to 30 µl TE buffer and 1 µl RNase T1/A stock. Incubate 1 hr at 37°C.
8. Add 1 µl of 20 mg/ml proteinase K, and incubate an additional 1 hr at 37°C.
9. Add 8 µl of 4× DNA loading buffer.

Cast and run the gel

10. Dissolve 0.9 g SeaKem agarose in 50 ml TBE buffer (for GNA-100 gel electrophoresis apparatus) or 2.7 g SeaKem agarose in 150 ml TBE buffer (for Buffer Puffer gel electrophoresis apparatus). Heat in a boiling water bath or microwave oven until dissolved, then cool gel and pour into mold.
11. Mount the gel in the electrophoresis tank, and add just enough 1× TBE buffer to cover the gel to a depth of 1 mm.
12. Load DNA marker VI in the first well and samples in the rest of wells (see Basic Protocol 5, step 13).
13. Run the gel at 60 mA (for GNA-100) or 70 mA (for Buffer Puffer) until the bromphenol blue front is ~1 to 2 cm from the end of the gel.
14. Stain gel with ethidium bromide and photograph under UV light (see Basic Protocol 5, steps 18 to 19).

ALTERNATE PROTOCOL 4

Phenol Extraction of DNA Fragments for Agarose Gel Electrophoresis

This protocol is a modification of the classical method described by Wyllie (1980). This method requires DNA purification. Although it takes much more time than other techniques and needs many more cells for preparation, it yields very clean, protein-free DNA fragments.

Additional Materials *(also see Basic Protocol 5)*

Lysis buffer (see Alternate Protocol 3), 4°C
100% ethanol, −20°C
5 M NaCl (*APPENDIX 2A*)
RNase T1/A stock (see recipe)
Phenol, TE-saturated (see recipe)
24:1 (v/v) chloroform/isoamyl alcohol (store mixture at room temperature in a fume hood)
0.5% (w/v) SDS

Prepare DNA sample

1. Place sample containing 2–5 × 10^6 cells in microcentrifuge tube, and centrifuge 5 min at 2000 × *g*, 4°C.
2. Resuspend pellet in 250 µl TE buffer, add 250 µl of 4°C lysis buffer, vortex, and refrigerate 30 min at 4°C.
3. Centrifuge sample 15 min at 15,000 × *g*, 4°C.
4. Transfer supernatant to fresh microcentrifuge tube. Add 1 ml −20°C 100% ethanol and 30 µl of 5 M NaCl. Mix and place in −20°C freezer overnight.
5. Centrifuge sample 15 min at 15,000 × *g*, 4°C. Remove and discard supernatant.

6. Add 500 µl TE buffer and 5 µl RNase T1/A stock to pellet. Incubate 30 min at 37°C.
7. Add 250 µl TE-saturated phenol and 250 µl of 24:1 chloroform/isoamyl alcohol. Vortex, and centrifuge for 2 to 3 min at 5000 × *g*, 4°C. Transfer upper layer to fresh 2-ml microcentrifuge tube.
8. Add 500 µl of TE buffer to lower layer; repeat step 7. Transfer upper layer to 2-ml microcentrifuge tube and mix with upper layer from step 7.
9. Extract the mixed samples from steps 7 and 8 with 1000 µl of 24:1 chloroform/isoamyl alcohol and centrifuge again.
10. Transfer the upper layer to 1.5-ml microcentrifuge tubes, 500 µl per tube. Precipitate overnight with ethanol and NaCl as in step 4.
11. Repeat step 5.
12. Place precipitate in vacuum lyophilizer for 20 to 25 min.
13. Dissolve and mix precipitates from both microcentrifuge tubes in a total of 20 to 30 µl TE buffer/0.5% SDS. Add 5 µl of 4× DNA loading buffer.

Cast and run the gel

14. Mix a 1.8% agarose gel by dissolving 0.9 g agarose in 50 ml TBE buffer (for GNA-100 gel electrophoresis apparatus) or 2.7 agarose in 150 ml TBE buffer (for Buffer Puffer). Cool gel and pour into mold.
15. Mount the gel in the electrophoresis tank, and add just enough 1× TBE buffer to cover the gel to a depth of 1 mm.
16. Load DNA marker VI in the first well (see Basic Protocol 5, step 13) and samples in the rest of the wells.
17. Run the gel at 60 mA (for GNA-100) or 70 mA (for Buffer Puffer) until the bromphenol blue front is ~1 to 2 cm from the end of the gel.
18. Stain gel with ethidium bromide (see Basic Protocol 5, steps 18 to 19) and photograph under UV light.

Quantitative Assay of DNA Fragmentation

BASIC PROTOCOL 6

In addition to qualitative analysis by gel electrophoresis, DNA fragmentation can be quantitatively determined by using the diphenylamine reagent. This method, introduced by Burton (1956), cannot, however, discriminate between apoptotic and necrotic chromatin cleavage.

Materials

Cell suspension to be assessed
Lysis buffer (see Alternate Protocol 3), ice cold
10% (w/v) and 5% (w/v) trichloroacetic acid (TCA; keep at room temperature in dark flasks)
Diphenylamine reagent (see recipe)

10-ml conical glass tubes
Round-bottom glass tubes
Water bath, 100°C

1. Prepare cell suspension containing $1–10 \times 10^6$ cells in a 1-ml volume.
2. Transfer 0.8 ml of cell suspension to microcentrifuge tube. Add 0.7 ml ice-cold lysis buffer. Vortex, and allow lysis to proceed 15 to 30 min at 4°C.

3. Centrifuge 15 min at 15,000 × *g*, 4°C. Transfer supernatant to labeled conical glass tube.
4. Add 0.65 ml of 5% TCA to the pellet in microcentrifuge tube, and add 1.5 ml of 10% TCA to the sample in labeled glass tube.
5. Precipitate both samples overnight (≥4 hr) at 4°C.
6. Centrifuge conical tube 10 min at 2500 × *g*, room temperature.
7. Remove supernatant after centrifugation and add 0.65 ml of 5% TCA to the pellet. Prepare two blank tubes with 0.65 ml of 5% TCA to be treated the same for the remaining steps.
8. Make hole on the top of each microcentrifuge tube from step 5, and cover each conical tube with a marble.
9. Boil both sets of tubes for 15 min in 100°C water bath.
10. Cool to room temperature. Centrifuge samples 5 min at 2500 × *g*, room temperature.
11. Transfer 0.5 ml of each supernatant (from both glass and microcentrifuge tubes) to labeled, round-bottom glass tubes.
12. Add 1 ml diphenylamine reagent to each tube. Incubate ≥4 hr at 37°C with a marble covering each tube.
13. Read absorbance at 600 nm in spectrophotometer. Set zero with blanks from step 7. Express results as the percentage of DNA fragmented:

$$\% \text{ fragmented DNA} = \frac{\text{absorbance of the supernatant}}{\text{absorbance of supernatant + pellet}} \times 100$$

BASIC PROTOCOL 7

Detection of High-Molecular-Weight Chromatin Fragments by Pulsed-Field Agarose Gel Electrophoresis

Not all forms of apoptosis are accompanied by internucleosomal DNA fragmentation (Oberhammer et al., 1993a). However, the formation of high-molecular-weight apoptotic DNA fragments of 50 to 700 kbp (see Figure 18.3.2B), which was first observed by Walker et al. (1991), has been reported to occur in all the cell types studied to date (see Background Information in Commentary).

One of the forms of pulsed-field gel electrophoresis, field-inversion gel electrophoresis (FIGE), has been successfully used in several laboratories to identify high-molecular-weight DNA fragments in apoptotic cells and a smear in the same range of DNA size in necrotic cells. The authors have used both vertical and horizontal gel chambers; resolution of DNA fragments is the same. This protocol is an adaptation of an earlier method described by Anand and Southern (1990).

Materials

Cell suspension
Agarose buffer (for molds; see recipe)
SeaPlaque GTG low-melting-point agarose (FMC Bioproducts)
20 mg/ml proteinase K in water (store in aliquots up to 1 year at −20°C)
Proteinase buffer (for plugs; see recipe)
TE buffer, pH 8.0:10 mM Tris·Cl/1 mM EDTA
50 mM EDTA, pH 8.0 (*APPENDIX 2A*)
SeaKem GTG agarose (FMC Bioproducts)
5× TBE buffer (see recipe)

DNA size pulse markers: chromosomes from *Saccharomyces cerevisiae* (225 to 2200 kbp) and a mixture of λDNA *Hin*dIII fragments, λDNA, and λDNA concatemers (0.1 to 200 kbp; Sigma; supplied premade in syringe)

Gel leveling table

100-µl insert molds (Amersham Pharmacia Biotech), stored in 0.1 M HCl

12- or 24-well tissue culture plates

50°C incubator

100°C water bath or microwave oven

Pulsed-field gel electrophoresis system: vertical gel chamber with cooling elements (Protean II, Bio-Rad); horizontal gel chamber (HE 100B); power supply (PS 500 XT); and Switchback pulse controller (PC 500, Hoefer Scientific Instruments)

Thermostatic circulator Multi Temp III (Amersham Pharmacia Biotech)

Prepare sample plugs of agarose

1. Rinse insert molds extensively in distilled water and dry. Wrap Parafilm around the bottom of the molds and place them on ice to chill at least 10 min before pouring in the gel.

   Make sure to mark the sample wells with pencil or pen.

2. Place sample of cell suspension containing 1×10^6 cells in a microcentrifuge tube, and centrifuge 3 min at $2000 \times g$, 4°C. Remove and discard supernatant. Resuspend pellet in 100 µl of agarose buffer.

3. Prepare 1% low-melting-point agarose in agarose buffer, and place in a 60°C water bath until melted.

4. Add 100 µl of molten 1% agarose to the cell suspension, and mix with pipet. Immediately pipet mixture into two prechilled insert molds, 100 µl per mold.

5. Place the filled insert molds on ice for 10 to 15 min.

6. Remove Parafilm from the bottom of the insert molds, and dislodge each plug into separate well of a tissue culture plate.

   It is convenient to use 12- or 24-well tissue culture plates for this purpose.

7. Add 1 ml of proteinase buffer and 10 µl proteinase K (final concentration 0.2 mg/ml plug) to each well. Wrap Parafilm or clear tape around the plate, and incubate ≥24 hr on a shaker at 50°C.

8. Remove wrapping from plate, and remove buffer with pipet.

   If it is necessary to simultaneously analyze the low-molecular-weight DNA, it is possible to remove the DNA fragments that have leached out from the plugs during incubation with proteinase K by precipitating them from this buffer over 48 hr at −20°C. Add 0.2 volume of 10.5 M ammonium acetate and 2 volumes of cold absolute ethanol. This DNA can then be lyophilized, dissolved in 1× DNA loading buffer, and analyzed by conventional gel electrophoresis.

9. Wash each plug three times with 1 ml TE buffer, 2 hr per wash, on a shaker at 4°C.

10. Remove TE buffer, and add 1 ml of 50 mM EDTA.

    Plugs are now ready to put on a gel. To save samples for a long time, store the plugs in EDTA, in which DNA is stable for several months, at 4°C.

Prepare separating gel

11. Prepare 1% agarose (SeaKem GTG) gel in 0.5× TBE.

For horizontal gels

12a. Dissolve 2.5 g agarose in 250 ml 0.5× TBE in a boiling water bath or microwave oven. Allow the agarose to cool to 60°C for 10 to 15 min.

13a. Seal the edges of the gel platform with tape, and place platform on leveling table.

14a. Pour the gel into the mold, and remove unwanted air bubbles. Place the comb into the gel, and allow to set for 1 hr.

15a. Remove the comb very carefully so as not to break the gel. Remove tape.

For vertical gels

12b. Clamp two frosted glass plates together with 3-mm spacers in between. Seal the bottom with Parafilm to prevent leakage of warm agarose.

13b. Warm glass plates for 30 min in 50°C incubator.

14b. Melt agarose as in step 12a (1 g agarose in 100 ml 0.5× TBE), and pour into the prewarmed gel assembly to ~5 mm below top of plates. Insert comb into the gel, and allow to set for 1 hr.

15b. Remove the comb very carefully so as not to break the gel, and wash the wells with 0.5× TBE to remove partially polymerized agarose.

Load and run gel

16. Using a scalpel, cut out a 2-mm slab from one marker, and insert into first well of the gel with a spatula.

17. Repeat this procedure with the second marker.

    Make sure that the slab is flat on the bottom of the well. This applies to loading of samples as well.

18. To load sample, cut off 3 mm from sample plug, and insert it into individual well with a spatula. Repeat same procedure for all samples. Avoid introducing any air bubbles into the wells.

    Note and record the order of the samples!

19. Cement the slabs into wells with the remaining molten 1% agarose.

20. Transfer the loaded gel (either horizontal or vertical) into a precooled tank filled with 0.5× TBE.

    The buffer temperature should be 11° to 12°C at the beginning of the experiment.

21. Run the gel at a constant voltage with a suitable switcher program to achieve the desired resolution. The programs listed in Table 18.3.2 give good resolution of 50-, 300-, and 700-kbp fragments.

22. Remove gel carefully, and stain it in ethidium bromide for 1 hr (see Basic Protocol 5, step 18). Destain it in 0.5× TBE for 2 to 3 hr.

23. Visualize and photograph bands under UV light.

METHODS FOR ANALYSIS OF CASPASE PROTEOLYTIC ACTIVITY

Several proteolytic activities are implicated in apoptosis and necrosis (see *UNIT 18.1*). The activation of caspases, a family of apoptotic proteases, plays a key role in apoptosis induced by diverse stimuli. Caspases, which have been detected in numerous tissues and cell types, are synthesized as a precursor form, or proenzyme, and an apoptotic signal converts the precursor into mature enzyme. Moreover, until now there has been no

Table 18.3.2 Parameters for Running Pulsed-Field Agarose Gels

	Horizontal gel	Vertical gel
Running voltage[a]	170 V	200 V
Procedure	10 min: run the DNA into gel with continuous forward pulse	10 min: run the DNA into gel with continuous forward pulse
	6 hr: apply 20 sec forward time, 3:1 forward/back ratio, ramp factor 1.5[b]	2 hr: apply 12 sec forward time, 3:1 forward/back ratio, ramp factor 2[c]
	6 hr: apply 10 sec forward time, 3:1 forward/back ratio, ramp factor 2	3 hr: apply 2.4 sec forward time, 3:1 forward/back ratio, ramp factor 5.0
	12 hr: apply 0.8 sec forward time, 3:1 forward/back ratio, ramp factor 12.5	2.5 hr: apply 8.0 sec forward time, 3:1 forward/back ratio, ramp factor 3.0
Total running time	24 hr, 10 min	7 hr, 40 min

[b] This means that at the end of these 6 hr, the forward time should be 30 sec.

[c] This means that at the end of these 2 hr, the forward time should be 24 sec.

evidence for the involvement of caspase activities in necrosis. Therefore the detection of caspase activity in cells can be used as a discriminating criterion to distinguish apoptosis from necrosis.

All members of the caspase family of proteases share a number of amino acid residues crucial for substrate binding and catalysis. Despite their uniform requirement for an aspartate residue at the P_1 position of the substrate site, caspases can be divided into three different groups according to their substrate preferences. The first group (caspases 1, 4, and 5) has the optimal substrate cleavage sequence WEXD; the second (caspases 2, 3, and 7) preferentially cleaves targets at the DEXD motif; and the third (caspases 6, 8, and 9) has the optimal substrate cleavage sequence (L/V)EXD (Thornberry et al., 1997). The predicted caspase specificities correspond to the cleavage sites in the different intracellular caspase targets. Analysis of caspase activation is also based on the substrate specificity of the enzymes (see *UNIT 18.2*).

REAGENTS AND SOLUTIONS

*Use Milli-Q-purified or other ultrapure water for all recipes and protocol steps. For common stock solutions, see **APPENDIX 2**; for suppliers, see **SUPPLIERS APPENDIX**.*

Agarose buffer *(for molds; used in Basic Protocol 7)*

Prepare 500 ml in H_2O:
0.15 M NaCl
2 mM KH_2PO_4/KOH, pH 6.8
1 mM EGTA
5 mM $MgCl_2$
Filter sterilize through 0.2-µm filter
Store at 4°C

Diphenylamine reagent

100 ml glacial acetic acid
1.5 g diphenylamine
1.5 ml concentrated sulfuric acid
0.5 ml 16 mg/ml acetaldehyde stock
Prepare just before use

Prepare acetaldehyde stock in ultrapure water; store in a dark flask up to 1 month at 4°C.

Ethidium bromide, 10 mg/ml

Stir 10 mg/ml ethidium bromide in water on magnetic stirrer for several hours. Store up to 2 months in a dark bottle at 4°C.

Paraformaldehyde, 4% (w/v)

Add 8 g paraformaldehyde powder (e.g., Sigma) to 100 ml water and heat to 60°C in a fume hood. If necessary, add NaOH dropwise (one or two drops each time) to help dissolve the powder. When the solids have completely dissolved, let the solution cool to room temperature. Then add 100 ml of 2× PBS (*APPENDIX 2A*). Store at 4°C.

Because this solution cannot be kept indefinitely, it is better to prepare small volumes every week.

Phenol, TE saturated

Allow phenol to warm to room temperature, and then melt it at 68°C. Add hydroxyquinoline to a final concentration of 0.1%. Add a volume of TE buffer, pH 8.0 (10 mMTris·Cl/1 mM EDTA), equal to the volume of phenol, and vortex extensively. Allow the two phases to separate, and aspirate the upper aqueous phase. Repeat this saturation with TE buffer two to three times until volume of TE remains unchanged and the pH of the phenol phase has reached 8.0 (as measured with pH paper). Remove the aqueous phase, and add 0.1 vol fresh TE. Store up to 1 month in the dark at 4°C.

Hydroxyquinoline, a yellow antioxidant, provides a convenient way to identify the organic phase during extraction.

Proteinase buffer *(for treatment of plugs)*

Prepare 500 ml of buffer consisting of:
10 mM NaCl
10 mM Tris·Cl, pH 9.5
25 mM EDTA

Add *N*-lauroylsarcosine (Sarkosyl) to 1% final concentration and dissolve using magnetic stirrer. Check pH, and if necessary adjust to 9.5 with NaOH. Filter through 0.2-µm filter and store at 4°C.

RNase A, 50 mg/ml

Dissolve RNase A (e.g., Sigma) at a concentration of 50 mg/ml in 10 mM Tris·Cl, pH 7.5/15 mM NaCl. Heat 15 min at 50°C. Allow to cool at room temperature. Divide into aliquots and store up to several months at −20°C.

RNase T1/A stock

Mix 50 µl of 500,000 U/ml RNase T1 and 50 mg of RNase A in 5 ml of 10 mM Tris·Cl, pH 7.5/15 mM NaCl. Heat for 15 min at 50°C. Allow to cool at room temperature. Divide into aliquots and store up to several months at −20°C.

SDS, 10% (w/v)

Dissolve 10 g of sodium dodecyl sulfate (SDS) in 90 ml of water by mixing on magnetic stirrer for several hours or by heating to 65°C to assist dissolution. Adjust the volume to 100 ml with water. Store at room temperature for up to 1 month.

Staining buffer

54.2 µl water
25 µl 20× sodium cacodylate (SSC) stock solution
20 µl blotto (25% low-fat dried milk in PBS)
0.7 µl avidin-FITC (160×)
0.1 µl Triton X-100
Store up to several weeks at 4°C

TBE (Tris/borate/EDTA) buffer, 5×

445 mM Tris base
445 mM boric acid
10 mM trisodium EDTA
Store at room temperature

All components may be obtained from Sigma. Do not adjust pH, which should be about 8.0 at room temperature. When this solution is stored for a long time, a precipitate forms. To avoid problems, discard batches that develop a precipitate.

COMMENTARY

Background Information

A number of techniques have been developed to detect cytotoxicity and cell death in various cell types. The methods developed in the last two decades have been aimed at distinguishing between cell toxicity leading to apoptosis and that leading to necrosis. The choice of a particular method for analysis of cellular toxicity depends on the cell system; the toxin or toxicant; the expected mode of cell death; the type of information being sought; and, finally, technical limitations. There is no one single method that is satisfactory for obtaining all the information required. This is largely a result of technical and practical limitations. Therefore, to make the right interpretation of data and to draw the correct conclusions regarding the mode of cell death, a combination of some of the methods mentioned above should be used. It is recommended that a combination of at least three criteria of cell death be evaluated: cell morphology, DNA fragmentation (see Assays for Chromatin Cleavage), and/or caspase activation (see *UNIT 18.2*).

Although morphological changes are obviously secondary to biochemical alterations, many of the published reports on cellular toxicity are based mainly on histological, cytological, and electron microscopy studies (Kerr et al., 1972; Bowen, 1980). The interpretation of histological data is based on the changes in membrane permeability. However, as mentioned in the introduction to this unit, analysis of plasma membrane integrity fails to identify cells in the early stages of apoptosis, although it can be used to identify necrotic cells in a population of interest. Alternative morphological methods draw on a mixture of optical and electron microscopy techniques. Combination of these methods allows one to distinguish between apoptotic changes—cell shrinkage, high cytoplasm density, membrane blebbing, compaction of chromatin, and formation of apoptotic bodies—and those indicative of necrosis—chromatin clumping, gross swelling of organelles, early membrane breakdown, and cell disintegration. In addition, confocal microscopy allows the combination of morphological analysis with subcellular localization of biochemical changes within damaged cells.

Other changes that accompany cell death can be used as indicators of the mode of cell death. It has been shown that phagocytosis is a response to cell death and is particularly efficient in apoptosis. Apoptotic cells can be recognized by macrophages through a number of cell surface markers. The presence of PS on the outer plasma membrane is one such marker, and it can be detected efficiently by phagocytic cells, as blockage of PS renders phagocytosis less efficient. Therefore, PS exposure can be considered a biochemical feature of apoptosis with physiological importance (Koopman et al., 1994). Annexin V has recently been utilized as a probe to monitor changes in phospholipid distribution in the plasma membrane of cells undergoing apoptosis. In combination with propidium iodine, annexin V staining can reliably discriminate apoptosis from necrosis. Flow cytometry is a useful technique to examine not only changes in the plasma membrane, but also changes in cell size and granularity (Darzynkiewicz et al., 1994; Robinson et al., 1999). Apoptosis is accompanied by a dramatic

loss of water and consequent cell shrinkage, which can be distinguished from necrosis by a difference in light-scatter pattern. This is a rapid technique to identify apoptotic versus necrotic cells and is very widely used nowadays.

Several biochemical methods based on the detection of changes in chromatin structure have been developed. These vary from methods for detecting single-strand DNA nicks or breaks, to those for demonstrating high-molecular-weight DNA fragments, to those for showing the subsequent internucleosomal cleavage. DNA nicks can be detected using TUNEL (see Basic Protocol 4; Gavrieli et al., 1992). However, this method apparently recognizes not only nicks formed during apoptosis, but also those formed during necrosis. Thus this method should always be used in combination with other more discriminating methods.

Some other methods used for the analysis of DNA or chromatin damage appear to be better suited to discriminate between the two types of cell death. The different DNA gel electrophoresis techniques that are described here (see Basic Protocol 5; see Alternate Protocols 2, 3, and 4) can be utilized for a qualitative analysis (Wyllie, 1980; Sorenson, 1990). Although the quantitative analysis (see Basic Protocol 6) can provide limited information concerning the general cleavage of chromatin (Burton, 1956), the combination of different methods of gel electrophoresis provides more specific information concerning the type of chromatin cleavage (high-molecular-weight DNA fragments, DNA ladder, or smear). It has been shown that DNA laddering is not apparent in all apoptotic systems (Oberhammer et al., 1993a). In many types of cells, chromatin cleavage is restricted to the formation of high-molecular-weight DNA fragments (Walker et al., 1991; Oberhammer et al., 1993b). In such cases, again, the combination of two independent methods assists in drawing the correct conclusions in the study of cell death or toxicity. However, when DNA laddering occurs, it is highly indicative of apoptosis.

Activation of the caspase family of proteases has been detected in numerous cell systems and appears to function as a pathway through which apoptotic mechanisms operate (for review see Zhivotovsky et al., 1997). Upon apoptotic triggering, a hierarchy of caspases is believed to become activated in a process where more proximal caspases cleave and activate downstream caspases, giving rise to a proteolytic cascade that serves to amplify the death signal. However, not all of these caspases normally function in cell death. A recent classification divided caspases into two groups, one involved in cytokine processing (caspase 1–like proteases) and the other playing a role in cell death (Alnemri et al., 1996; Cryns and Yuan, 1998). This latter group can be further subdivided according to function as activators or executioners of cell death. Up to now there has been no evidence concerning the involvement of caspase activities in necrosis. Therefore the detection of caspase activity in cells can be used as a discriminating criterion to distinguish apoptosis from necrosis. Caspase activity is assessed by proteolytic cleavage of flurogenic substrates (see *UNIT 18.2*) or by immunodetection of protein bands corresponding to active caspases (see *UNIT 18.2*).

In summary, a combination of morphological and biochemical methods is recommended to discriminate between the mode of cell death, especially if the manifestations of cell death or the stimuli used have not been previously characterized in the cell type of interest.

Critical Parameters and Troubleshooting

Morphological assays

A characteristic feature of apoptosis is that membrane integrity of the dying cell is maintained long after the process has begun. However, a reduction in membrane integrity usually occurs during the late stages of apoptosis when the cells undergo a process commonly called "secondary necrosis" or "postapoptotic necrosis." Therefore, a disadvantage of the trypan blue exclusion assay (see Basic Protocol 1) is underestimation of the level of apoptosis in a cell population.

If the cytopsin preparations are understained after a full cycle of fixation and differential staining (see Basic Protocol 2), then the procedure can be repeated a second time until the desired staining is achieved. If overstaining is the problem, preparations can be destained by immersing them in 100% methanol for up to 5 sec, followed by rinsing with water. Because membrane blebbing is a feature common to both apoptosis and necrosis, one should take care not to use this as the sole criterion for determination of the mode of cell death.

If assessing the nuclear changes in apoptotic cells is problematic, then use other conventional methods of inducing apoptosis in cells as a positive control, stain cells treated both ways with Hoechst dye (see Basic Protocol 3), and observe nuclear changes under the UV micro-

scope. If no apoptotic changes are evident in cells, try to increase the time of incubation with apoptosis-inducing agents.

Chromatin cleavage assays

The TUNEL technique (see Basic Protocol 4) is used to detect DNA strand breaks. There are rare situations when apoptosis proceeds without DNA degradation. Conversely, extensive DNA degradation may accompany necrosis. Thus, one should always use another independent assay, along with the TUNEL method, to confirm whether cells have undergone apoptosis. Costaining cells with propidium iodide or Hoechst is a very useful method to discriminate between apoptosis and necrosis in samples that have stained positively with the TUNEL technique. TUNEL-positive cells that express condensed, fragmented nuclei after staining with PI or Hoechst are apoptotic, whereas those with diffuse staining of the nuclei with PI or Hoechst are necrotic.

If a high background is present in TUNEL-treated samples, make sure that there is no DNase contamination in the test tubes or buffers. It is also possible that the number of DNA strand breaks is so large that one cannot quantify the degree of cell labeling. To eliminate this problem, use fewer cells or decrease the incubation time.

For exogenous enzymes, such as the TdT enzyme used in TUNEL, to enter the cell, the plasma membrane has to be permeable. In many cases, the fixation procedure is sufficient to permeabilize cells; however, sometimes an additional short incubation on ice or short (1- to 2-min) treatment with proteinase is required. To avoid loss of low-molecular-weight DNA, the permeabilized cells have to be fixed with formaldehyde before permeabilization. This fixation cross-links DNA fragments to other cellular constituents and prevents their leakage during the permeabilization step.

The procedures for assessment of DNA fragmentation in whole cells (see Basic Protocol 5) may cause the samples to become viscous and difficult to load into gel sample wells. If this is the case, dilute samples with 1× DNA loading buffer. If no detectable DNA laddering is observed in a population of cells that are known to be apoptotic, increase the number of cells used for the assay. If it is difficult to observe distinctive bands because of high background, wash gel extensively with water. If an unusual band appears in the middle of the gel in all lanes, incubate gel longer with RNase (step 17).

For analysis of fragmentation in total genomic DNA (see Alternate Protocol 2), the reagents are optimized for the stated number of cells. If larger numbers of cells are used, RNA and protein digestion will not be complete, which may interfere with electrophoresis. In addition, the procedures cause the samples to be viscous. Therefore, for minimum sheering of DNA, it is better to use pipet tips that have the ends (3 to 4 mm) cut off with a razor blade to make wide-bore tips.

If no laddering is observed in DNA phenol extracted from a population of apoptotic cells (see Alternate Protocol 4), the DNA may have been lost in the organic phase during extraction. The aqueous phase should be removed carefully during extraction to prevent DNA loss. Another possible reason for failure to detect laddering may be degradation of DNA by exogenous nucleases. All solutions must be free of nuclease contamination. If, instead of a DNA ladder, a smear appears on the gel, this indicates random and general cleavage of chromatin, indicative of necrosis (see Figure 18.3.2A, lane 3).

For quantitative assays of DNA fragmentation (see Basic Protocol 6), if absorbance of DNA in supernatant samples is below the sensitivity of detection, increase the number of cells. If all absorbance is present in the supernatant and absent from the pellet, then the pellet was mistakenly transferred together with supernatant to the labeled conical glass tubes (step 4).

There could be several reasons for large fragments not to appear on the pulsed-field electrophoresis gel (see Basic Protocol 7). If the material is still in the wells, the pulse generator power supply may not have been working properly. If some of the material is in the wells, but no sharp bands are visible and the material moved in the wrong direction, the current may not have been applied in the correct direction. If there is no material in the wells, the chromatin may have been digested by exogenous exonucleases during the preparation. If very little material is in the well, a bigger slab may have to be cut from the sample plugs. If too much material is in the lane, a smaller slab may have to be cut from the sample plugs. If thin stripes appear in any lanes in the gel, it means that either a bubble was in the well or the slab was not placed flat. Sometimes there is a leakage of buffer from the top reservoir, which may also influence the results.

Anticipated Results

Morphological assays

In the trypan blue exclusion assay (see Basic Protocol 1), several thousand cells are sufficient

to quantify the number of trypan blue–positive cells and to count the percentage of cells with an intact plasma membrane. Necrotic cells with rapidly disrupted membrane take up trypan blue as well.

Differential staining (see Basic Protocol 2) is one of the fastest and easiest methods for identifying dead cells. Cells are viewed under a light microscope (40× magnification), and ~300 cells are counted from separate fields of view and scored as normal, apoptotic, or necrotic based on the following morphological characteristics: membrane blebbing, chromatin condensation and nuclear shrinkage, cytoplasmic constriction and loss of cell volume, and formation of apoptotic bodies for apoptotic cells; nuclear swelling, chromatin flocculation, cell membrane blebbing and disruption, and finally cell lysis resulting in the appearance of "ghost cells" for necrotic cells (see Figure 18.3.1).

Because chromatin condensation is one of the early events of apoptosis, apoptotic cells stained with Hoechst 33342 have increased blue fluorescence compared with live cells similarly stained (see Basic Protocol 3). The intensity of the blue fluorescence changes with the incubation time, so that an optimal incubation time should be found for each cell system for discrimination of apoptotic cells (usually 5 to 10 min). For quantification of apoptosis, a minimum of 150 cells, from 10 to 15 fields, should be evaluated for the changes described above.

Chromatin cleavage assays

In both TUNEL protocols (see Basic Protocol 4 and Alternate Protocol 1), very little material is required for quantitative measurement of TUNEL-positive cells. Proportions of apoptotic cells as low as 10% to 15% can be detected by this method. Although the enzymatic labeling methods are time consuming (due to multiple incubation and washing steps), they are very sensitive. The method can also be applied to cryostat sections. In this case, the proteolytic pretreatment (see Alternate Protocol 1, step 4) can be shorter or even be omitted.

The whole-cell DNA fragmentation method (see Basic Protocol 5) requires only $4–5 \times 10^5$ cells. It can be used for cells growing in suspension as well as attached cells. Usually, the resolution of DNA fragmentation using this protocol is distinct and high. This method does not require DNA purification and is relatively simple and fast. Although Basic Protocol 5 and Alternate Protocol 2 are equally sensitive, the latter is less time consuming. In addition, the dry loading prevents the loss of material. Alternate Protocol 3 is particularly useful for detecting chromatin cleavage in different lymphoid cells.

Phenol extraction (see Alternate Protocol 4) is the most commonly used technique for investigating internucleosomal chromatin cleavage. Although it takes much more time than other techniques (almost 2.5 working days) and needs many more cells for preparation ($2–5 \times 10^6$ cells), it yields very clean, protein-free DNA fragments.

The quantitative assay of DNA fragmentation described (see Basic Protocol 6) is only one quantitative method for measurement of DNA fragmentation. This method is very simple, and very reproducible results can usually be obtained.

Pulsed-field gel electrophoresis can be used to detect the presence of high-molecular-weight DNA fragments in apoptotic cells (see Basic Protocol 7). The method is very sensitive and requires 5×10^5 cells. Depending on which system is available, one can use either horizontal or vertical gel systems. If necessary, plugs can be kept for several months and run on another gel.

Time Considerations

Morphology assays

The time required for preparing solutions for trypan blue exclusion is 20 to 30 min; the solutions can then be kept up to 1 to 2 months at 4°C. Trypan blue staining takes 5 min, and calculation takes 10 min.

It takes 30 min to prepare the solutions for differential staining (which can be stored 1 to 2 months at room temperature); this time is not required if the commercial kit is used. 1 hr is required to prepare and analyze samples, and 30 min to evaluate results.

It takes about 30 to 40 min to prepare solutions for Hoechst staining and 1 hr to run the test. No more than 30 min are required to evaluate results.

Chromatin cleavage assays

Approximately 3 to 4 hr are required to run TUNEL assays. The evaluation of results requires an additional 1 to 2 hr, depending on the investigator's experience.

About 1 to 2 hr are required to prepare the buffers for assessment of fragmentation in whole cells, which then can be stored for at least 1 month. Usually, gel and sample preparation, which can be done simultaneously, take 2 hr, and gel electrophoresis takes 15 to 16 hr (over-

night is better). Incubation with RNase, staining, and destaining take another 6 to 7 hr. Thus, the whole experiment takes almost 1.5 days.

Analysis of fragmentation in total genomic DNA takes 1 working day.

Preparing solutions for quantitative analysis of DNA fragmentation takes 1.5 to 2 hr; however, the solutions can be stored for up to several weeks. The procedure takes 1.5 working days and 1 hr to evaluate results.

It takes about 1 week to perform the whole pulsed-field gel electrophoresis procedure. Vertical gels require a relatively shorter time (1 day less) compared with horizontal gels, with no difference in resolution.

Quantitative Fluorescence In Situ Hybridization (Q-FISH)

This unit describes a quantitative technique for measuring the lengths of telomere repeat sequences in individual chromosomes from single metaphase cells (see Basic Protocol). The technique is based on fluorescence in situ hybridization (FISH) adapted for use with peptide nucleic acid (PNA) probes. PNA is an example of novel synthetic oligonucleotide "mimetic" which has a higher affinity than regular oligonucleotide (RNA or DNA) probes for complementary single-strand (ss) DNA sequences. PNA oligonucleotides have excellent penetration properties due to their small size (typically 15 to 18–mers) and can be directly labeled with fluorochromes. These properties have been exploited to develop quantitative fluorescence in situ hybridization (Q-FISH) onto denatured single-stranded chromosomal DNA target sequences. The latter can be present in preparations of fixed metaphase cells on slides (Q-FISH) or in heat-treated (interphase) cells in suspension (flow-FISH).

Q-FISH requires fluorescence microscopy in combination with digital image acquisition to measure the length of telomere repeats in preparations of metaphase chromosomes. The basic Q-FISH techniques are also very suitable to obtain qualitative information about the presence of specific repeat sequences in the nuclei of cells. The bright fluorescence signals combined with the low background of directly labeled PNA probes offer unique possibilities for a variety of studies including studies of nuclear organization. Such studies are not discussed here but can be explored using the Basic Protocol provided.

The Q-FISH technique described here consists of four distinct steps: (1) sample preparation; (2) image capture; (3) image analysis; and (4) telomere length normalization and calibration. First, slides suitable for Q-FISH analysis are prepared. For this purpose, fixed metaphase cells are dropped onto slides and hybridized with directly labeled PNA probes using an optimized FISH technique (see Basic Protocol). Second, images of telomeres and chromosomes are captured using digital fluorescence microscopy (see Support Protocol 1). Third, the captured images are analyzed to extract telomere fluorescence and chromosome identification (karyotype) information (see Support Protocol 2). Finally, similar procedures incorporating all the three components are used to calibrate and validate Q-FISH for quantitative purposes and determine calibration values for telomere length measurements (see Support Protocol 3).

USING PNA PROBES TO VISUALIZE TELOMERES IN METAPHASE SPREADS

BASIC PROTOCOL

The following is a basic "generic" method to visualize telomeres and chromosomes in metaphase cells using fluorescence hybridization with directly labeled PNA probes. The slides that result from application will typically be of high quality and can be used for any type of qualitative analysis. However, in order to extract the quantitative information that is contained within these preparations, close attention to all steps described in subsequent protocols (see Support Protocols 1, 2, and 3) is essential.

The aim is to first prepare and deposit metaphase cells onto microscope slides. Standard cytogenetic techniques are used to prepare metaphase chromosomes from dividing cells. After fixation, metaphase cells are dropped onto slides and air-dried. A small volume of hybridization mixture containing Cy3- or FITC-labeled telomere (PNA) probe is placed onto coverslips and added to the chromosome preparations on the slides. The slides are subsequently heated at 80°C for 3 min using a thick metal (aluminum) plate preequili-

Contributed by Steven S.S. Poon and Peter M. Lansdorp
Current Protocols in Cell Biology (2001) 18.4.1-18.4.21

brated to 80°C in an oven. The heat and high (70%) formamide content of the hybridization mixture will result in complete denaturation of chromosomal DNA. Removal of the slides from the oven and subsequent incubation of the slides at room temperature result in conditions that allow hybridization of the PNA probes to chromosomal target sequences but not the renaturation of complementary DNA. Conventional FISH procedures (using RNA or DNA probes) must use hybridization conditions that allow renaturation of complementary DNA strands as well. In Q-FISH only the PNA probes can hybridize to the denatured telomere repeat target sequences in chromosomal DNA. As a result, the number of probes attached to target sites will correlate to the number of repeat sequences at that site. In this way, telomere probes provide information on the length of telomere repeats at individual telomeres. After hybridization, the slides are washed to remove unbound PNA, dried, and sealed using a coverslip and a small volume of an antifade solution containing DAPI (4′,6-diamidino-2-phenylindole,fs15 dihydrochloride) as a DNA counterstain. DAPI allows the visualization of cells and individual chromosomes and facilitates subsequent image acquisition, karyotyping, and telomere length analysis steps described in Support Protocols 1, 2, and 3.

Materials

Cells of interest
Cell-specific tissue culture medium supplemented with growth factors
10 μg/ml Colcemid (Life Technologies)
75 mM hypotonic KCl buffer (12.3 mM HEPES/0.53 mM EGTA/64.4 mM KCl; or commercially available from Stem Cell Technologies or Life Technologies), 37°C
3:1 (v/v) methanol/glacial acetic acid fixative (Fisher; BDH)
70%, 90%, 95%, and 100% ethanol
Phosphate buffered saline, pH 7.4 (PBS; without Ca^{2+} and Mg^{2+}, Stem Cell Technologies; also see recipe)
37% formaldehyde, reagent-grade (BDH)
Pepsin (Sigma-Aldrich)
1 N HCl, pH 2.0
Hybridization mixture (see recipe)
Wash solution I (see recipe)
Wash solution II (see recipe)
Mounting medium containing antifade and DAPI (see recipe)

25-cm^2 tissue culture flasks with vented blue plug seal caps (Becton Dickinson)
15- and 50-ml polypropylene conical tube (Becton Dickinson)
Precleaned microscope slides for hematology and histology (e.g., Micro World; *http://www.mwrn.com/)*
Lint-free paper towels
Phase-contrast microscope
100- and 150-ml glass slide staining jars and corresponding slide rack
Coverslips (22 × 60–mm; VWR)
Thick metal plate (~1-cm aluminum), e.g., 6 ×10–in.
80°C oven
Molded plastic slide box for 25 slides (Fisher)
Parafilm
Platform shaker (Barnstaed/Thermolyne)
Light-protected slide storage box

NOTE: All solutions and equipment coming into contact with live cells must be sterile, and aseptic techniques should be used accordingly. Furthermore, it is prudent to consider cultured and primary human cells as biohazardous and adhere to appropriate biohazard

containment and disposal guidelines. Consult your institutional safety officer for specific instructions.

NOTE: All incubations are performed in a humidified 37°C, 5% CO_2 incubator unless otherwise specified. Some media (e.g., DMEM) may require altered levels of CO_2 to maintain pH 7.4.

CAUTION: To avoid inhalation of fumes from glacial acetic acid, methanol, formaldehyde, and formamide solutions, it is recommended that cell fixation and formamide washes be performed in a fume hood. Formamide is a harmful and irritant organic solution. Wear suitable protective clothing and gloves when handling; avoid inhalation of fumes and skin contact. Use an excess of water in case of skin contact. Refer to Material Safety Data Sheet and consult your institutional guidelines for appropriate disposal of chemical waste.

Prepare metaphase-arrested cells

1. Culture cells for several days in tissue culture medium supplemented with growth factors in 25-cm^2 tissue culture flasks.

   It is important to maximize the fraction of dividing cells in order to obtain sufficient mitotic cells and metaphase cells (chromosomes) in subsequent steps.

2. Add 10 µg/ml Colcemid to the culture medium (final 0.05 µg/ml) prior to harvesting mitotic cells.

   The duration of the Colcemid treatment varies with cell type (e.g., for lymphocytes, from 30 min to 2 hr; for fibroblasts, from 6 to 24 hr), the proportion of dividing cells, and the required quality of the metaphase chromosomes (the longer the Colcemid treatment, the more condense the chromosomes).

3. Harvest the cells by trypsinization and/or pipetting as required and transfer to 15-ml tubes.

4. Centrifuge cell suspension 8 to 10 min at 200 to 300 ×*g*, room temperature.

5. Remove supernatant, resuspend pellet in remaining supernatant (<0.5 ml) by vortexing the tube and adding 2 to 10 ml of prewarmed (37°C) 75 mM hypotonic KCl buffer depending on the size of the pellet.

6. Incubate 20 to 30 min in a 37°C water bath.

Fix cells

7. Centrifuge cells 8 to 10 min at 200 to 300 ×*g, room temperature, remove all but 0.5 ml of the hypotonic KCl solution, resuspend the cell pellet by hand tapping the tube, and add 1 to 5 ml of fresh 3:1 methanol/glacial acetic acid fixative with a Pasteur pipet. Let stand 15 min at room temperature.*

8. Centrifuge the tubes again as in step 7, discard supernatant, and suspend the cells in 1 to 5 ml fresh 3:1 methanol/glacial acetic acid fixative. Repeat this step one or two times until a suitable cell pellet is obtained.

   A suitable preparation will show nuclei devoid of cytoplasm as judged by microscopy after dropping the cells onto slides.

   After the last fixation, cells can be stored in fixative in a closed tube for at least 3 months at −20°C prior to the preparation of slides. However, typically, slides are prepared within 7 days.

Prepare slides

9. Clean glass microscope slides with 95% ethanol. Wipe slides with dry lint-free paper towels.

   Alternatively, precleaned slides can be used directly.

10. Resuspend the cells in a small amount of fresh 3:1 methanol/glacial acetic acid fixative until the suspension looks slightly turbid (~5×10^6 cells/ml). Drop 3 to 4 drops evenly on a slide covered with a thin film of distilled water. After the slide is completely dry, examine with a phase-contrast microscope to check the cell density and spread of metaphase chromosomes.

    If the cell density is too high, add a few more drops of fixative to the cell suspension. If the cell density is low, centrifuge the suspension and resuspend the pellet in a smaller amount of fixative.

11. With a Pasteur pipet, let two drops of cell suspension fall onto each cleaned, wet slide. Mark the slide with a diamond pen or a pencil. Air dry slide(s) overnight in the fume hood.

12. Pour 150 ml PBS without Ca^{2+} and Mg^{2+} in a 150-ml staining jar with a removable slide rack. Place slides in glass slide rack and immerse in PBS to rehydrate for 15 min at room temperature.

Fix slides in formaldehyde

13. In a fume hood, prepare 4% formaldehyde in PBS by adding 21.6 ml of 37% formaldehyde stock solution to 200 ml PBS.

14. In the fume hood, transfer the 4% formaldehyde solution into a staining jar. Transfer the slides in a slide rack into the fixative solution and fix for 2 min. Save fixative so it can be reused in step 18.

15. Wash slide(s) in three changes of fresh PBS for 5 min each change.

Treat slides with pepsin

16. Prepare pepsin solution by dissolving 200 mg pepsin in 200 ml of 0.01N HCl, pH 2.0. Pour the pepsin solution into a staining jar and equilibrate in a 37°C water bath. Prepare this solution during PBS washes (step 15).

17. Transfer slide(s) to pepsin solution and incubate 10 min at 37°C. Wash slides two times, 2 min each, in PBS.

18. Repeat the fix and wash steps (steps 14 and 15 above).

19. Dehydrate slide(s) in an ethanol series: 5 min each in 70%, 90%, and 100% ethanol.

Hybridize PNA probe

20. Leave slides in a vertical position to air dry or use air stream to dry.

21. Deposit two 10-µl drops hybridization mixture, with a micropipet, onto a clean 22 × 60–mm coverslip.

22. Gently place the slide(s) with fixed cells (upside down) on top of the coverslip (placed on a bench or glass plate). Turn slide so that coverslip faces up prior to complete spreading of the hybridization mixture between the slide and the coverslip.

    Avoid introducing air bubbles by holding the slide under a slight angle prior to contacting the drops of hybridization mixture on the coverslip.

Heat denature DNA

23. Denature chromosomal DNA by placing the slide(s), coverslip up, on a thick metal plate equilibrated at 80°C in a preheated oven for 3 min.
24. Place the slide(s) in a plastic slide box and place this box into a plastic beaker containing a damp paper towel.
25. Cover the beaker with Parafilm and let the sample hybridize for 1 to 2 hr at room temperature.

Wash slides

26. Prepare 500 ml of wash solution I and 500 ml of wash solution II.
27. In the fume hood, remove coverslips by soaking the slides in 100 ml of wash solution I. Use gloves and forceps to place slides back into a glass slide rack that fits into glass staining jars. Wash the slide(s) two times, 15 min each, in the remaining solution I.

    Do not force the coverslips off the slides, as this will damage the cells.

28. Wash the slide(s) three times, 5 min each, in wash solution II on a platform shaker.
29. Dehydrate the cells 5 min each in 70%, 90%, and 100% ethanol and allow the sample to air dry.
30. Place two 10-µl drops of mounting medium containing antifade and DAPI on a fresh coverslip.
31. Place the sample slide(s) on top of the coverslip (as in step 22).
32. Lift the slide (coverslip attached) and incubate in the dark, in a light-protected slide storage box, for at least 15 min to allow DAPI staining of DNA.

    The slides are now ready for analysis (see Support Protocols 1, 2, and 3) and can be stored in a light-protected storage box for several weeks at 4°C prior to fluorescence microscopy and Q-FISH analysis.

IMAGE CAPTURE

SUPPORT PROTOCOL 1

The following is a method for capturing images of telomeres and chromosomes prepared using the Basic Protocol. In order to capture images in a constant manner such that they can be used for quantitative analysis, special attention must be given to the steps described herein and in the selection of the appropriate microscope/image capture system. As there are a variety of microscope and image acquisition systems that are used in various laboratories, the method described here has been generalized to encompass the diversity of these systems. Thus, specific instructions of how to use a particular program or how to operate the microscope are not given. For specific details, the reader is referred to the manufacturers' manuals. For example, when instructions to adjust the focus are provided, the user could perform this task manually, using computer control, or via a separate focus controller, all of which would accomplish the same task.

In this protocol, reference images of fluorescent beads are first captured. The bead images indicate proper system set-up and operation. In addition, the fluorescence values extracted from the beads are used to calibrate and normalize subsequently captured telomere fluorescence data. A metaphase cell on the sample slide is then manually selected and placed into the field of view of the camera. Next, the best focus image of the telomeres is captured. The corresponding chromosome image is then captured and these images are stored as a pair for analysis (see Support Protocol 2). In a typical experiment, ~15 metaphase cells from a sample are required.

Materials

Immersion oil for fluorescence and general microscopy (NA = 1.5150 ±0.0002, Cargille Laboratories)

Sample slide of labeled telomeres and chromosomes (see the Basic Protocol)

Reference slide of fluorescent beads (see Support Protocol 3)

Fluorescence microscope (Zeiss Axioplan or equivalent) with the following components:

- Excitation and emission filters to match the probes used (DAPI/CY3 dichroic mirror/emission filter set, Chroma Technology)
- One high-quality objective lens (e.g., Plan Apochromat 63×/1.4, Zeiss or equivalent)
- Stable fluorescent light source (e.g., 200 W hybrid mercury/xenon lamp, OptiQuip)
- Fine focusing adjustment in ≤0.2-μm increments (e.g., piezo electric focus drive attached to the objective lens or fine focus control provided by the microscope)

Camera (e.g., MicroImager MI1400-12, Q-Imaging or equivalent) with the following characteristics:

- Variable exposure times with a maximum time of at least 10 sec to capture weak fluorescence signals
- At least 8 bits of photometric resolution (higher bit depth cameras generally are better as the upper 8 bits are less noisy and allow the user to select a sub-range of interest from the full range)
- Small pixel size (~7 × 7–μm such that better localization of the small telomere spots can be made)
- Large number of pixels (~1000 × 1000 such that the entire metaphase spread is captured within the camera's field of view)
- No automatic gain control or the ability to disable this function (e.g., manual gain control)

Image acquisition software with the following features:

- Visualization of the captured image on a monitor
- Capture and storage of images in the proprietary ".IMG" format or the Windows Bitmap 8 bit/pixel ".BMP" format
- Histogram option to display the intensity variation in the image (this feature will give an indication of the values of the minimum and maximum pixel intensity values that are present in the image)
- Feature to store the raw image data from the camera (such that unmodified images captured under controlled conditions can be consistently and objectively analyzed later)
- Feature to capture and display images in continuous mode (optional)
- Feature to switch into "intensity enhancement" mode where low light levels are scaled to appear much brighter and is useful for focusing (optional)
- Feature to switch into "binning" mode, an acquisition mode where images are captured at a faster rate (e.g., lower exposure times) but at a lower spatial resolution and is useful for focusing (optional)

CAUTION: Ensure that all automatic gain features are turned off when capturing data for image analysis. This includes the gain control setting on the camera. It also includes the "intensity enhancement", "binning" modes, and other similar modes that are available on various imaging systems.

NOTE: Ensure that the immersion oil on the slide connects evenly with the objective as this will reduce the optical distortion of the captured and viewed images.

Set focus for reference beads

1. Turn on the fluorescence light source and camera.

   These components need to warm up and become stabilized for ≥30 min prior to data acquisition. Other components in the system do not need a warm-up period and hence, these other components need only be powered on (if not already powered) just prior to performing the next step.

2. Place a reference slide of fluorescent beads (see Support Protocol 3) onto the fluorescence microscope and view this sample under the microscope with the 63× objective using the Cy3 excitation/emission filter set, and an ND3.0 neutral density filter (0.1% transmission) in the light path of the microscope.
3. Focus and capture an image of the beads.
4. Generate a histogram plot of the captured image and ensure that very few pixels, and preferably no pixels, are saturated (above the maximum intensity level of the camera).

   In cameras that have defective pixels, make allowances for saturated defective pixels that arise with long camera exposure times. The optimum image should have maximum signal intensities at ~230 out of 256 gray levels. For some images, the optimum values could not be achieved without going to higher exposure times that are beyond the capability of the camera. As a result, the lack of sensitivity in the system compromises the precision of the system. If saturation occurs, reduce the camera exposure time, re-capture the image, generate the histogram and verify that the image is not saturated.

5. If there is no continuous acquisition or live capture mode available, repeat the process manually, capturing an image after each time the focus has been changed. Select the focus position that produces the best focus.

   If the system supports continuous capture mode, adjust the focus of the object in small increments and observe the image on the monitor until the sharpest image is obtained. Repeat step 4 to ensure that the focused image has not crept into saturation as a result of better focus. If the system supports 'intensity enhancement' and 'binning' modes, use these options as this will speed up the acquisition process and thus will help to reduce the time to get the best focus image. However, remember to switch such modes off when the actual image is captured for analysis (to avoid creating erroneous images for analysis).

6. Capture and store the best focus image for later analysis. Record the exposure time used to capture the image and the mean fluorescence intensity of the captured image.

   These numbers should be very similar from experiment to experiment. Hence, they may be used as rough indicators of changes and problems with the overall set-up of the system.

7. Remove the bead slide and place the sample slide on the microscope.

Capture telomere images

8. Switch to the DAPI filter set and find a metaphase cell of interest in the sample.
9. Switch to the Cy3 filter set and perform steps 4 and 5 above to obtain the best focus image of the telomeres for telomere analysis.
10. Capture and store the best focus image of the telomeres for later analysis.

    If the software does not store the exposure time in the "IMG" file format, record the exposure time used and the file name of the stored image, as these values will be used later in the analysis program for normalization purposes. Alternatively, the exposure time can be fixed throughout the experiment and, thus, the exposure time only needs to be recorded once. The exposure time will differ between human and mouse telomeres and faint telomeres may require long exposure. As a result, the images acquired with a fixed exposure time may not be optimal. More importantly, there is a risk that some images may have saturated telomere values that will greatly compromise subsequent analysis (see Troubleshooting and Fig. 18.4.1).

11. Switch to the DAPI filter set and perform steps 4 and 5 above to obtain the best focus image of the metaphase chromosome image for karyotype analysis.

    The best focus is not as crucial for the chromosome images since these objects are larger and occupy a larger focal depth. As the microscope is adjusted for parfocality, the best focus level for the telomeres should be the same or at a fixed offset from the best focus level of the chromosomes.

12. Capture and store the image of the chromosomes for later analysis. Choose a file name that is similar to that for the telomere image as these files will be entered as pairs into the image analysis software (e.g., image 001c.bm for Cy3 stained telomeres and image 001d.bmp for DAPI stained chromosomes).

    Only grayscale/8 bit images are accepted. TIFF files can be opened in Adobe Photoshop and changed to gray scale. The best way is to copy the image to clipboard and paste into TFL-Telo and save as .IMG file (TIFF file formats are currently not supported by TFL-Telo but will be supported in later versions of this analysis software program)

    Some image acquisition software stores images in the TIFF or other proprietary file formats. In this instance, another utility program such as Adobe Photoshop will be needed to convert the combined TIFF file into individual telomere and chromosome BMP file formats.

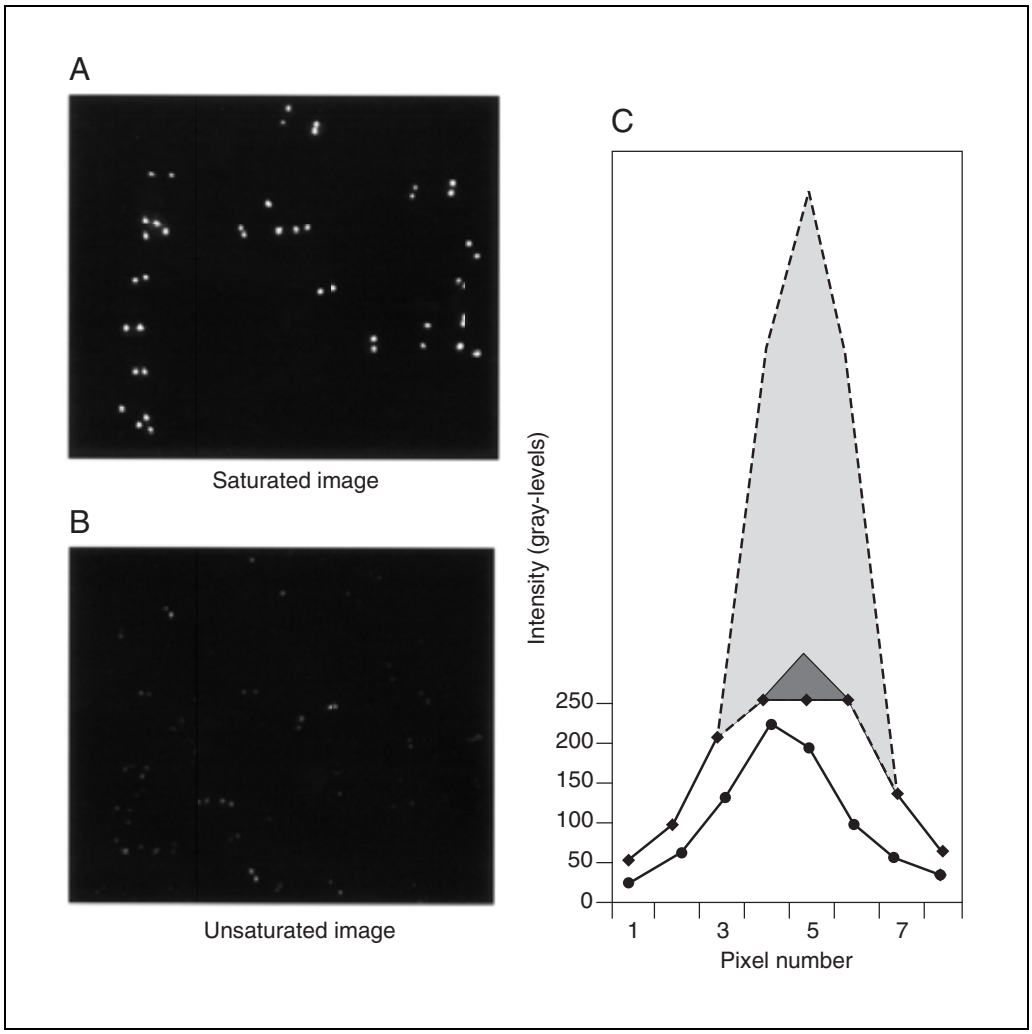

Figure 18.4.1 Intensity profile of saturated (**A**) and unsaturated (**B**) telomere signals. (**C**) There is no ambiguity in determining the total fluorescence of the unsaturated telomere signal (circles). However, there is uncertainty in the true fluorescence of the saturated signal (diamonds). Two possible estimates of the fluorescence signal (shaded regions) are shown.

13. Repeat steps 4 to 12 for ≥15 metaphase cells to obtain statistically relevant results for the sample.

    The number of metaphases for statistical relevance will vary from sample to sample. Variations in cell preparation (see Basic Protocol) and the quality of the microscope and imaging system components will also reduce the sensitivity of the system. Such variations can only be partially compensated by an increase in the number of metaphases that are analyzed.

14. To verify that the system has not drifted over the course of the experiment, repeat steps 2 to 5 using the reference bead slide.

    The fluorescence intensity of the beads should be similar to the values obtained earlier in the experiment and to the values from previous experiments.

IMAGE ANALYSIS

SUPPORT PROTOCOL 2

The following method uses the TFL-Telo image analysis software to measure the telomere values of individual chromosomes. A typical telomere/chromosome analysis session is shown in Figure 18.4.1. From the chromosome and telomere images, the program generates a combined image of the detected telomeres and chromosome boundaries superimposed onto the chromosome image. The user then interactively edits the image to correct for mistakes made in the segmentation (definition of the boundaries) of chromosomes, to karyotype the image, to assign and correct for the nomenclature of the telomeres on the p and q arms of the chromosome, and to split nearby telomeres on a specific arm of the chromosome into two. The results are saved into a formatted text file that can be imported into spreadsheets (e.g., Microsoft Excel) or statistical packages (e.g., Microsoft Origin) for analysis. Calibration/normalization of the results can then be performed using the reference bead image and the calibration parameters obtained from Support Protocol 3. To study the variation of the results and compare them to those of other metaphase cells, use a spreadsheet program to cut and paste the results into a combined results file.

Materials

Images of telomeres (see Support Protocol 1)
Corresponding images of chromosomes (see Support Protocol 1)
TFL-Telo (telomere image analysis software, this software is available upon request from the authors: plandor@bccancer.bc.ca)
Pentium-based personal computer with the following:
  Minimum of 8 Mb of RAM
  Graphics card with at least 256 colors and a display resolution of 640 × 480 pixels
  High resolution video monitor to match the video card
  Microsoft Windows 95, 98, or NT operating system

1. From the "Application Menu" in the TFL-Telo program, select the "Chromosome/Telomere" option.

2. First, enter the names of the files associated with the pair of chromosome (DAPI) and telomere images (Cy3) of the metaphase spread that is to be analyzed (i.e., the names assigned to the files stored from Support Protocol 1).

   If the files are not stored in the ".IMG" file format, enter the corresponding exposure time used for the telomere image. There is a threshold column value in this window with a default setting of 5. The threshold can be increased or deceased as required (e.g., when telomere signals are too faint or too bright on particular chromosomes).

3. Finally, enter the name of the file to store the results.

   The output file has to be in the ".IMG" format.

4. Double click on the "OK" button when all the fields for the file name have been entered. The program will then automatically determine the borders of the chromosomes and telomeres and calculate the total fluorescence value for each detected telomere in each chromosome.

   Once the program finishes its processing, a combined image of the telomere and chromosome results are displayed on the screen (see Fig. 18.4.1). A different color is assigned to the border of each of the telomeres in the chromosome for ease of user recognition (purple, red, blue, cyan, orange, and green are assigned to telomere number 1, 2, 3, 4, 5, and 6, respectively, or more). Similarly, a different color border is used to indicate the number of "telomere" objects in the chromosome (cyan, green, and yellow are assigned to ≤3, 4, and 5, respectively, or more objects). Each chromosome is also labeled with a unique number.

   Once the processing has been performed on the telomere/chromosome pair, the processed results can be reloaded into the program. To reload, select the "Open" option from the "File" menu and then enter the file name of the processed results. The combined telomere and chromosome image of the processed results will then be displayed.

5. From the "Options" menu, select the "Chromosome Statistics" option.

   A window will then appear showing a table with the following information: the label assigned to the chromosome number, karyotype number of the chromosome, up to five telomere values for the chromosome, and a number of other telomere and chromosome statistics.

6. Select the "Edit" option to open a submenu to edit the parameters for the selected chromosome such as the telomere belonging to the p or q arm of the chromosome and the karyotype number of the selected chromosome.

7. Select the "Save" option to save the changes made (changes are automatically saved in the latest version of the TFL-Telo software).

8. Find the mean fluorescence value of the beads. Perform system calibration by following Support Protocol 3, steps 6 to 8, for the fluorescent bead image and assign the mean value to $Bead_{exp}$.

9. To normalize the results, import the telomere fluorescence result from the output file with one of the following file extensions "*.LB2" or "*.LB3" (the last four columns are the telomere fluorescence values) into a spreadsheet program such as Microsoft Excel. Multiply the measured telomere fluorescence values using the following formula ($slope_{cal}$ and $bead_{cal}$ are obtained from Support Protocol 3):

$$\text{length (base pairs)} = \text{measured fluorescence} \times slope_{cal} \times bead_{exp}/bead_{cal}$$

SUPPORT PROTOCOL 3

SYSTEM CALIBRATION

The following method illustrates how data from different experiments can be normalized and how the telomere fluorescence measurements can be converted to telomere length estimates. While slides with fluorescent beads are used on a daily basis to calibrate the microscope, slides with hybridized plasmids are used occasionally to calibrate telomere fluorescence relative to telomere length. For the latter, plasmids (DNA with fixed numbers of telomeric repeat sequences) are used to verify and determine the linearity of the system using these protocols. In order to compensate for differences in illumination and other intensity variations from experiment to experiment, the total fluorescence measurements of fluorescent beads from each experiment is used for normalization purposes.

Materials

0.2-µm fluorospheres carboxylate-modified microspheres, orange fluorescent (540/560, Molecular Probes)
1:1 (v/v) PBS/FCS
Antifade reagent in glycerol/PBS (Slow Fade Antifade kit, component A, Molecular Probes)
PSXneo plasmids containing fixed numbers of telomere repeats (Hanish et al., 1994; Martens et al., 1998)

22 × 30–mm coverslips
Slide box
1.5-ml "sure lock" tubes (Rose Scientific)
Thermomixer (e.g., Eppendorf Model 5436) or 80°C water bath

Additional reagents and equipment for PNA probe hybridization (see Basic Protocol), image capture (see Support Protocol 1), and image analysis (see Support Protocol 2)

1. Prepare calibration slides with fluorescence microspheres. Dilute 0.2-µm fluorospheres carboxylate-modified microspheres 25× in a 1:1 mixture of PBS/FCS. Deposit 2 to 3 µl of microsphere suspension on to periphery of a 22 × 30–mm coverslip. With a regular slide, produce a thin homogenous smear over the coverslip (like a blood smear). Let the coverslip dry. Keep coverslips in slide box until use.

2. Prepare a calibration slide on the day of acquisition by depositing 5 µl of slow fade reagent on a slide and adding microsphere-coated coverslips.

   Note the different antifade reagent. Vectashield is not optimal for the preparation of calibration slides with fluorescence beads.

3. Prepare calibration slides with fluorescence plasmids. Add PSXneo plasmid DNA to hybridization mixture. For example, add 1 µl of plasmid DNA with 144 bp of telomere DNA at 0.1 µg/ml in 10 mM Tris·Cl to 99 µl of hybridization mixture in a 1.5-ml "sure lock" tube (see Basic Protocol).

4. Denature 10 min at 80°C in a thermomixer or water bath. Incubate 60 min at room temperature and put two 50-µl drops on a precleaned slide.

5. Incubate 30 min in the dark; some of the plasmids hybridized with fluorescent PNA will noncovalently attach to the glass surface. Proceed with wash steps, alcohol dehydration as described in Basic Protocol, steps 28 to 32.

Calibrate Q-FISH image acquisition and analysis system

6. Set up and prepare the microscope and image acquisition system for image capture (see Support Protocol 1, step 1).

7. Capture and store an image of fluorescence beads (see Support Protocol 1, steps 2 to 6).

8. Capture and store images of plasmids that contain 144 bp of telomere repeats (see Support Protocol 1, steps 9 and 10).

   Choose areas on the slide where the plasmids are spread out and not clumped. Adaptation to darkness is essential to see very faint spots of plasmids corresponding to a maximum of eight Cy3 molecules per plasmid. Ensure that a total of ≥50 to 100 plasmids are collected in one field. Too low a density of plasmids on the slides complicates acquistion and discrimination between plasmid and background fluorescence. Capture and store more images as required such that the desired minimum number of plasmids are acquired.

9. Repeat step 3 for the slides that contain plasmids with 400, 800, and 1600 bp of telomere repeats and capture the images.

Analyze the data

10. Execute the TFL-Telo program.
11. Select the "Open" option from the "File" menu to open a stored plasmid file.
12. Select the "Spot IOD" option from the "Application" menu.

    The program will then automatically find the telomere spots and then calculate the total fluorescence values of each detected spot.

    The calculated value needs to be normalized with the exposure time that was used to capture the image. If this value is entered with the image file, the program will make the calculation. Otherwise, divide the value obtained with the manually recorded exposure time for that image.

13. Select "Object Histogram" option from the "Option" menu to obtain the histogram of the fluorescence distribution of all detected objects. Obtain the mean fluorescence number of the telomeres by first rejecting the artifacts from the image as follows. First, point the mouse to the minimum fluorescence value of the objects in the histogram. Hold down the left mouse button and drag the mouse up the intensity scale of the histogram (i.e., towards the right). Release the button to select the maximum value of the intensity range. The selected range in the histogram will change color and the corresponding borders of the objects in the image will also change color. Repeat the range selection until the desired objects are highlighted (i.e., do not include debris or cluster objects). Record the mean fluorescence value for the selected range.
14. Repeat steps 11 to 13 for the other files containing images of plasmids that have different telomere insertion lengths.
15. Repeat steps 11 to 13 for the image of the fluorescent beads. Record the mean bead fluorescence value as $bead_{cal}$.

    This value will be used later for calibrating the results (see Support Protocol 2).

16. Plot the telomere fluorescence values as a function of the number of base pairs of telomere repeats in the plasmid.
17. Find the slope of the plot. Record this value as $slope_{cal}$ for use in image analysis (see Support Protocol 2).

REAGENTS AND SOLUTIONS

*Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see **APPENDIX 2A**; for suppliers, see **SUPPLIERS APPENDIX**.*

BSA stock solution, 10%

Dissolve 10 g BSA in 100 ml water by gently placing BSA powder on top of the water. Use a magnetic stirrer to dissolve. Do not stir at high speed, slow hydration works best. Filter through 0.4- and 0.2-μm filters to remove bacteria and debris. Store up to several years at −20°C in 1-ml aliquots.

Formamide, deionized

Add 5 g of resin beads to 100 ml of ultrapure formamide, pH 7.0 to 7.5 (Life Technologies). Stir for 2 hr in a fume hood. Filter through Whatmann no. 1 filter paper. Aliquot in 1-ml portions and store at −20°C.

Hybridization mixture

For 100-µl mix (5 slides):
70 µl deionized formamide (see recipe)
10 µl NEN blocking solution (see recipe)
5 µl 0.1 M Tris·Cl, pH 7.4 (*APPENDIX 2A*)
5 µl 10 µg/ml PNA Cy3-telomere probe (see recipe)
5 µl $MgCl_2$ buffer (82 mM NaH_2PO_4/9 mM citric acid/20 mM $MgCl_2$, pH 7.4)
5 µl distilled H_2O
Store up to a week at 4°C

Mounting medium

To 1 ml of Vectashield, add 1 µl of DAPI stock solution (0.2 mg/ml in water) to give final concentration of 200 ng DAPI/ml of antifade. Dilute with Vectashield if DAPI staining is too bright and is visible in Cy3 fluorescence filter combination. Store up to a week at 4°C.

NEN blocking solution

Dissolve (layer) 2.5 g of NEN blocking reagent (PE Biosystems or Life Sciences) in 100 ml distilled water in a glass beaker. Stir gently overnight. Filter through 0.4-µm filter and dispense into 3- to 4-ml aliquots. Store at −20°C.

PBS, 10×stock solution (pH 7.4)

Solution A:
16.02 g $Na_2HPO_4·2H_2O$
73.84 g NaCl
900 ml H_2O

Solution B:
2.76 g $NaH_2PO_4·H_2O$
16.56 g NaCl
200 ml H_2O

Adjust solution A to pH 7.4 with solution B. Store up to a year at room temperature.

Peptide nucleic acid probes

PNA probes can be synthesized manually or with dedicated equipment by chemists familiar with peptide and/or nucleic acid synthesis. Alternatively Cy3-labeled PNA can be ordered from DAKO as a kit (Telomere PNA FISH/Cy3) or from Boston Probes (*www.bostonprobes.com*) or Applied Biosystems as a custom order. The latter is the more economical because many hundreds of experiments can be done with just a few OD_{260} units of labeled PNA.

Good results will be obtained with FITC or Cy3-OO-CCCTAACCCTAACCCTAA-carboxy-terminus. More information on how to order and use PNA probes can be found at the website of Applied Biosystems (http://www.appliedbiosystems.com/ds/pna).

Wash solution I

For 500 ml:
5 ml 1 M Tris·Cl, pH 7.4 (*APPENDIX 2A*, 10 mM final)
350 ml deionized formamide (see recipe, 70% v/v final)
5 ml 10% BSA stock solution (see recipe, 0.1% w/v final)
140 ml H_2O
Check pH and adjust to pH 7.4, if necessary, with 1 M NaOH or 1 M HCl
Store up to a week at 4°C

Wash solution II

For 500 ml:

50 ml 1 M Tris·Cl, pH 7.4 (*APPENDIX 2A*, 0.1 M final)

50 ml 1.5 M NaCl (0.15 M final)

0.5 ml Tween 20 (0.1 % v/v final)

400 ml H_2O

Store up to a week at 4°C.

COMMENTARY

Background Information

PNA probe hybridization

Telomeres are specialized structures at the ends of chromosomes consisting of repetitive DNA and associated proteins (Blackburn, 1994; Zakian, 1995) that are maintained by the reverse transcriptase enzyme telomerase (Greider, 1995). In most somatic cells, telomere repeats are lost with each cell division and with age. Because telomere loss has been shown to limit the replicative life span of cells, the loss of telomere repeats is believed to be important in the aging of tissues with continuous cell turnover. Progressive telomere shortening has, furthermore, been shown to result in chromosome fusions and genetic instability (Blasco et al., 1997). This is increasingly recognized as an important mechanism contributing to malignant progression and the "mutator" phenotype of cancer cells (Wan et al., 1997; Artandi et al., 2000). Questions about the role of telomere shortening in aging and cancer have encouraged the development of novel techniques that can provide information about the length of telomere repeats present in individual chromosomes (Q-FISH; Lansdorp et al., 1996; Zijlmans et al., 1997; Martens et al., 1998) and in individual cells (flow FISH; Rufer et al., 1998, 1999). Such information cannot be obtained by the standard Southern blotting method to measure telomere length because it requires genomic DNA typically isolated from $>10^5$ cells (reviewed in de Lange, 1995).

Fluorescence in situ hybridization (FISH) with PNA probes has some distinct differences with the more established FISH procedures that employ DNA or RNA probes. The major differences are the inclusion of protein in the hybridization mixture to prevent nonspecific binding of the PNA probes and the use of very stringent hybridization conditions that are unsuitable for annealing of DNA or RNA probes to DNA target sequences. The denaturation of chromosomal DNA in the presence of the PNA probe simplifies the FISH procedure. Because hybridization of PNA probes to specific target sequences is fast and specific, the procedure is furthermore fast relative to conventional FISH procedures. The major advantage of Q-FISH with PNA probes over conventional FISH procedures with conventional telomeric DNA probes is that Q-FISH allows extraction of quantitative information. Such information is much more difficult to obtain using conventional FISH procedures because in conventional FISH procedures the hybridization of probes competes with the renaturation of complementary strands of the denatured genomic DNA. This competition inevitably introduces a stochastic component in conventional FISH experiments with the eventual probe signal depending on the concentration and size of the DNA or RNA probe, the efficiency of the denaturation of the genomic DNA, and the repetitive nature of DNA target sequences. The conditions that favor binding of small oligonucleotide probes to highly repetitive telomeric DNA, unfortunately, also result in efficient renaturation of genomic DNA. Even with multiple rounds of immunological amplification the net result of conventional hybridization for telomere targets is a highly variable signal on some but not all telomeres (Moyzis et al., 1988). Even to the inexperienced, the difference in telomere fluorescence obtained with indirect conventional labeling procedures using small RNA or DNA telomere probes and directly labeled PNA probes will be striking. The use of Q-FISH for quantitative purposes is supported by the overall good correlation between fluorescence from sister chromatids, the good correlation between telomere length data obtained by Southern blotting analysis, and Q-FISH analysis, and the analysis of plasmids with defined T_2AG_3 content (Lansdorp et al., 1996; Martens et al., 1998). While telomere repeats are ideal for use with PNA probes (little or no sequence divergence), other repeat sequences such as chromosome-specific alphoid

repeat sequences, can also be detected efficiently using selected 15- to 18-mer PNA probes (Taneja et al., 2000).

Image capture

Image acquisition and analysis systems have been around for a number of decades (Young and Roberts, 1951; Walton, 1952). However, it was not until the last decade that high-resolution, variable-exposure-time cameras were commercially available; these cameras can detect and measure weak fluorescent telomere signals (Poon and Hunter, 1994). The increased use of FISH analysis has also lead to a number of improvements to the fluorescence microscope, such as more efficient and wavelength-specific excitation and emission filters, better quality objective lenses for fluorescence detection, and better and more precise fine focus controls. While, in particular, the light source of standard fluorescence microscopes remains problematic, all these improvements have brought quantitative analysis from capture images of telomeres hybridized to directly labeled PNA probes within reach of dedicated experimentalists. It is expected that further improvements will make quantitative analysis a standard feature of future fluorescence microscope and imaging systems.

Image analysis

Interest in telomere length measurements has led to incorporation of a telomere analysis feature in the current version of a commercial chromosome analysis package (Metasystems V2.0). The automation of karyotyping by this software would greatly reduce the time required to identify chromosomes and assign telomere fluorescence values to specific chromosomes. Although, the accuracy of telomere analysis in this software needs to be validated, there is an option to export the karyotype results and link it with the telomere measurements obtained from the TFL-Telo program. A description of the algorithms used in the TFL-Telo program is presented elsewhere (Poon et al., 1999a,b).

Another new development for estimating the average telomere length in single cells in a sample is flow-FISH. This method uses the speed and power of the flow cytometer to quickly measure the total intensity of the fluorescent telomere probes in the cell. All these methods have specific advantages and disadvantages in studies of telomerase/telomere biology.

System calibration

Data normalization and calibration are the best means of ensuring that data from one experiment can be correlated to that of another. As the objective of the study is to measure telomere lengths, a good choice of test objects to use on the system would be those where the telomere lengths are known. Plasmids containing telomere inserts are good candidates as the telomere length inside the circular DNA sequence structure does not change as a function of cell division. Hence, these test objects can be duplicated for calibration purposes. As there can only be a limited number of telomeres that can be inserted to a plasmid, calibration points for long telomere lengths are extrapolated from the linear results of fluorescence intensities from different smaller-length telomeres. The smallest size insert also gives an indication of the telomere detection limit of the system. While the use of hybridized plasmids will allow conversion of arbitrary fluorescence units to telomere fluorescence units (TFU, with each unit corresponding to 1 kb of telomere repeats), comparisons of telomere length measurements by Southern blot analysis and Q-FISH are required to further validate the use of Q-FISH for telomere length measurements.

Critical Parameters

PNA probe hybridization

A number of issues in the Q-FISH protocol deserve careful consideration and attention. In general, it is recommended to include controls such as a slide with nicely fixed metaphase cells and a slide, done in a previous experiment, with good hybridization signals. These controls will help to identify common errors with metaphase preparation and/or microscope set-up. Sometimes it is difficult to obtain sufficient good quality metaphase spreads from cells. If this is the case, continuing with the hybridization procedure will not produce satisfactory results. Instead, it is probably a better idea to increase the yield of dividing cells and improve the metaphase preparation procedure. There are many tricks of the trade of a cytogeneticist, and there is undoubtedly an aspect of art to the preparation of good metaphase spreads. For example, for a discussion of the synchronization of cell cultures to increase the mitotic index or the climate-dependency of optimal results, the reader is referred to cytogenetic protocols for chromosome preparations. A visit to the local cytogenetic department may greatly help to resolve problems with metaphase prepara-

tions (one may even obtain some slides to do the first Q-FISH experiment).

The following issues are important if slides with satisfactory metaphase spreads have been obtained.

Prior to hybridization, slides with fixed cells should be dried extensively. Drying overnight in a fume hood produces satisfactory results. Shorter periods of drying (i.e., on a 65°C plate) may work, but insufficient dehydration (i.e., for 1 hr at room temperature) increases the nonspecific binding of the PNA probe.

The pepsin treatment can be omitted, but the signals at telomeres will be more variable.

The wash steps with formamide after hybridization can be replaced by washing for 5 min with wash solution II at 65°C. However, for optimal telomere signal and chromosome morphology, the authors recommend washes with wash solution I as described in the protocol.

Before adding antifade with DAPI, ensure that slides are completely dry again.

Image capture

The microscope set-up and sample preparation play a key role in the success of the experiment. It is important that the illumination over the field of interest (i.e., the metaphase spread) is constant. Otherwise, the fluorescence measurements taken from one area of the image will not be the same as those taken from another area. A slide of fluorescent beads or a plastic fluorescent slide could be used to check on the homogeneity of illumination over the field of view. Use objective features in the acquisition software (such as histograms) to measure the fluorescence intensity distribution over the

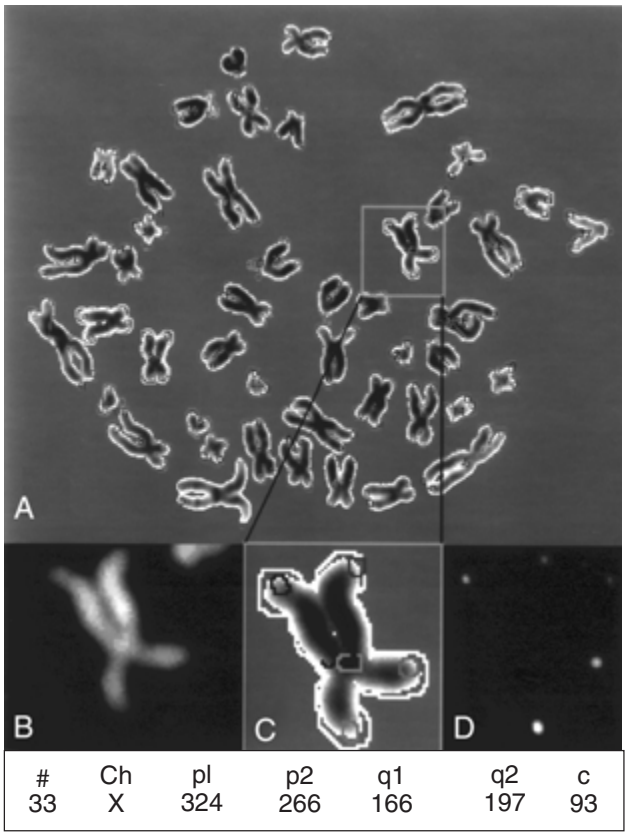

Figure 18.4.2 Output of TFL-Telo telomere length analysis software program. From imported image files the program generates an output image file shown in (**A**) in which chromosomes are given an arbitrary number. Telomere fluorescence values corresponding to that chromosome are calculated by the program and provided in a table. After editing and karyotyping by the user, the table provides information on the telomere fluorescence values for the two telomeres at the short (p) and long (q) arm of each selected chromosome (Ch X in the figure). The fluorescence intensity at the centromere is also calculated (c in the table). (**B**) A magnified view of a selected chromosome of the raw DAPI image file, (**C**) the output of the TFL-Telo program, and (**D**) the raw telomere fluorescence image are shown.

field of view rather than relying on subjective visual judgment. In instances where the light intensity varies significantly (e.g., >5%) between pixels, an appropriate correction of fluorescence values will increase the accuracy of results. Use flat-field correction in which all fluorescence pixel values are multiplied by a factor depending on the pixel location in the field of view that corrects for uneven illumination of the field.

The sensitivity of the acquisition system to detect the probes that are used has a major impact on the outcome of the experiment. Hence, it is worth the initial effort to experiment and choose the best components to use before starting experiments. For example, some objective lenses allow much more Cy3 fluorescence to pass through than other similar magnification lenses. The spectrum of the excitation and emission filters also plays a key role in the intensity of the observed fluorescence and the amount of interference or overlap of fluorescence from other wavelengths. The sensitivity of the camera and size of the camera pixels also affect the precision of the results obtained. Image fluorescence intensities, which span the 256-level intensity map of the camera, would give higher precision results than if the intensities were hovered around the lower levels. Similarly, smaller size pixels would give higher precision results than larger pixels as the area of the telomere can be defined better.

The focus of the telomeres also has an effect on the precision of the fluorescence measurements. Generally, calculations of total probe fluorescence can be made over a larger area that encompasses the probe, and hence focus variations do not play a major factor. However, telomeres can lie very close to each other, and as a result the signals will interfere with its neighbors' if they are out-of-focus. The TFL-Telo software has been written to identify the area occupied by an individual telomere and distinguish this from other nearby telomeres. A typical output of the TFL-Telo program is shown in Figure 18.4.2. As the algorithm used is focus-sensitive, the objects captured should be within 0.1-μm from best focus. Otherwise, the values obtained would be significantly lower than expected (see Fig. 18.4.3).

Photobleaching is another important aspect to consider in quantitative fluorescence microscopy. Antibleaching agents are often used to minimize the fading effects of probes used. If a sample shows significant photobleaching, a method will need to be incorporated to determine the amount of photobleaching so that the results generated can be correlated or compared with that of other cells. This will add to the complexity of the experiment since an estimate of how long the cells have been exposed to light will need to be determined, and extra care is needed to keep track of the locations on the slide that have been previously exposed to light. To avoid this complexity, it is better to experiment

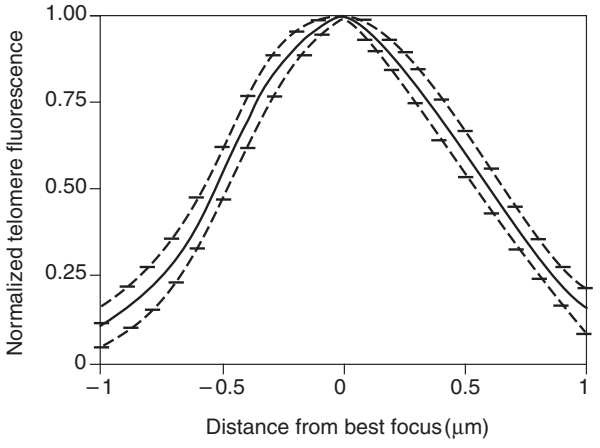

Figure 18.4.3 Variation of measured telomere fluorescence as a function of focus. In this experiment, the focus was varied at precise intervals using a piezzo electric drive connected to the objective lens. The telomere images were acquired and telomere fluorescence values calculated using the TFL-Telo program. Shown is the average (± s.d.) telomere fluorescence of all telomeres in the image (n = 184). Note that changing the focus by 0.5-μm results in a drop of calculated telomere fluorescence of up to 50%.

with the intensity of the light source and with different antifade agents. For example, the introduction of PNA probes tagged with different fluorescence dyes such as Cy5 that are specific for chromosome-specific alphoid repeats at centromeres may require a different antifade agent. Hence, experimentation with different antifade agents is needed when new sample preparation procedures are introduced. Reducing the intensity of the illumination (i.e., controlling the power applied to the lamp or placing a neutral density filter in the light path) is another method to reduce the effects of photobleaching. Although longer exposure times will be required, the results will typically be less dependent on the timing of the image capture. Closing the shutter between image captures is another good approach to reduce the effects of photobleaching.

The effects of photobleaching, light source stability, and system variability can be checked by repeatedly capturing images of the same metaphase (e.g., every 15 to 30 sec) over a 10-min interval. During this experiment, check and ensure that the focus of the metaphase does not drift over time. The images are then analyzed and the total fluorescence values from a number of selected telomeres are plotted as a function of time (Fig. 18.4.4). The slope of the graph gives an indication of the amount of photobleaching in the sample. The variability between adjacent measurements gives an indication of the amount of variability in the system. As a general rule, photobleaching (slope of plot) should be <5% of the total or average intensity over a 5-min working interval. In addition, the amount of variation in fluorescence intensity between consecutive captured images should be <10%. With experience, the acquisition time will typically decrease resulting in reduced photobleaching and improved data.

Troubleshooting

PNA probe hybridization

Poor morphology of chromosomes. The denaturation time and temperature are critical and may vary to some extent between cells from different tissues or between cell lines. Denaturation at too high a temperature or for >3 min will result in blurred chromosomes and poor morphology. Too low a temperature or too short a denaturation step will result in nice DAPI staining of chromosomes but poor telomere fluorescence signals. Consider reducing the amount of pepsin or the duration of the pepsin treatment for improved morphology. Do not skip fixation steps before or after pepsin treatment.

Poor signals. Include pepsin treatment of cells. Increase temperature and/or duration of denaturation step until morphology is compromised. Decrease salt concentration in hybridization mixture. Decrease time or temperature

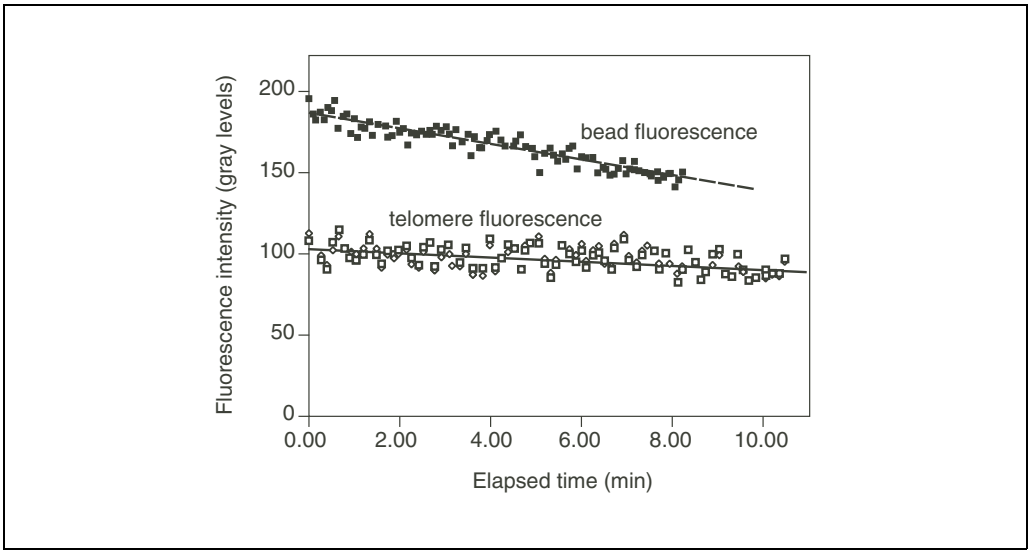

Figure 18.4.4 Photobleaching of fluorescent calibration beads and actual telomere fluorescence spots following PNA FISH and slide preparation as described in the text. Note that photobleaching of calibration beads (acquired at 0.1% of standard illumination) exceeds that of telomeres acquired at full light intensity and that photobleaching of telomere fluorescence over a 5-min period is <10%. The more pronounced variation in fluorescence values of beads and telomeres between sequentially acquired image files almost certainly reflects variation in the output of the light source.

of high-stringency wash with 70% formamide post hybridization.

High background PNA binding. If binding is localized to cytoplasm, increase number of fixation steps with methanol/acetic acid fixative when preparing fixed metaphase cells. If it is over the whole slide area, use different blocking protein or change concentrations of blocking protein in hybridization mixture. Insufficient drying of slides prior to denaturation will also increase background PNA fluorescence.

Image capture

As mentioned earlier, capturing an image of fluorescent beads at the beginning of every acquisition session helps to give an indication of the system setup. If the observed fluorescence intensity of the calibration beads differs significantly from the previous experiment (different intensity or similar intensity but at different exposure times), the change in the way the system is set up should be identified and corrected. If possible, confirm that the measured values with calibration beads correspond to the values obtained at the previous acquisition session.

If the telomere distribution plot of a sample appears to be skewed to the right of a normal distribution, check the raw image data for saturated pixels. Saturated images are excellent image candidates for the traditional spot counting as all telomeres can readily be seen (Fig. 18.4.5). However, telomere lengths are underestimated in saturated images giving rise to a large number of telomeres with fluorescence values clustered near the upper portion of the telomere length distribution. As illustrated in Figure 18.4.5, the underestimate in telomere length can be a few percent to a few hundred percent of the estimated fluorescence value.

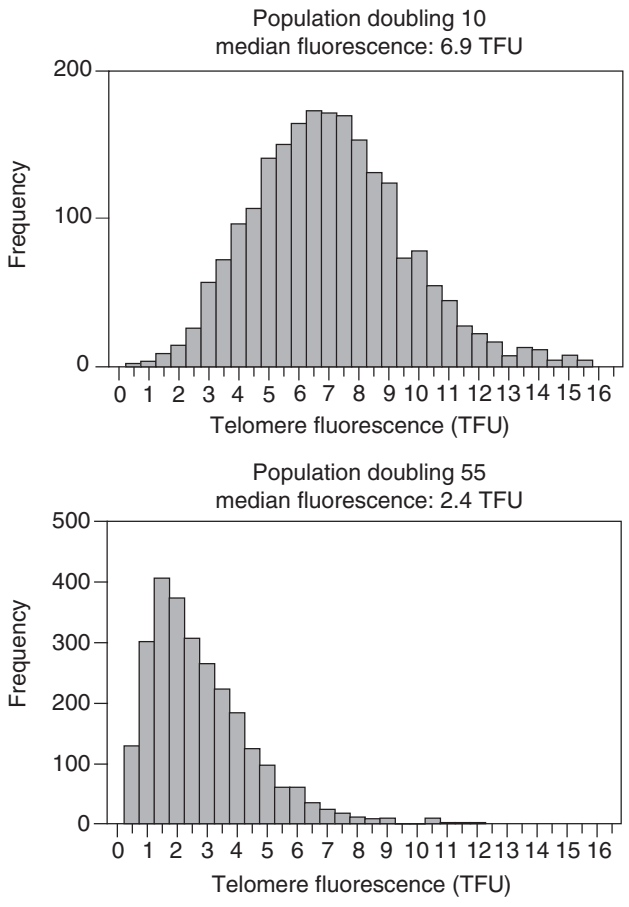

Figure 18.4.5 Accumulation of short telomeres in fibroblasts prior to replicative senescence. Note that the telomere fluorescence in early passage normal human fibroblasts shows a relatively normal distribution whereas at population doubling 55 (close to the Hayflick limit for these cells) the distribution is highly skewed towards the left. These observations indicate that a minimal number of telomere repeats need to be present on all chromosome ends in order for a cell to enter mitosis.

System calibration

The measured fluorescence values should be linearly related to the telomere length of the object. If the plot (see Support Protocol 3, step 12) does not generate a linear relationship, repeat the experiment to ensure that errors were not introduced in the sample preparation and image acquisition steps. For lower-sensitivity systems (microscope, camera), measurements of the smaller-size plasmids (e.g., 144 bp) may not be reliable, and hence this data point should be ignored from the determination of the slope used for calibration. Check also that the exposure time has been incorporated into the fluorescence measurement calculations.

Anticipated Results

PNA probe hybridization

All telomeres in normal human cells should easily be detectable. The signals from sister chromatids should be similar in intensity, and fluorescence of the telomere probe should be restricted to chromosome ends (sometimes a faint spot on human chromosome 2 identifies the area where two short primate chromosomes are fused to give rise to human chromosome 2 during evolution (Ijdo et al., 1991). Chromosomes should be easily identified using DAPI staining. No DAPI staining should be visible when analyzing telomere fluorescence.

Image capture

A typical experiment would give results that show the telomere fluorescence values of individual chromosomes. Figure 18.4.2 shows a raw DAPI image of chromosomes (B), a raw image of corresponding telomere spots (D), the image produced by the TFL-Telo program using the two raw image files (A,C), and the calculated telomere fluorescence of the p and q arms of the selected chromosomes in the metaphase as an example of the tabulated output of the TFL-Telo program.

Image analysis

Typical telomere length distributions of young and old cells are shown in Figure 18.5.5. These distributions resemble those obtained with the Southern blot technique (Oexle, 1998). Studies have been performed to show that telomeres on certain chromosomes are consistently shorter than others (Martens et al., 1998), and that there is a large variation in telomere lengths in mouse cells (Zijlmans et al., 1997). Other examples of telomere length studies using this protocol can be found in the literature (Blasco et al., 1997; Zhu et al., 1998; d'Adda di Fagagna et al., 1999; Hande et al., 1999a,b; Surralles et al., 1999; Wan et al., 1999; Martens et al., 2000; Niida et al., 2000).

Time Considerations

PNA probe hybridization

The time for the Colcemid treatment for different cell types can vary from 30 min to 24 hr. After the treatment, the preparation of metaphase chromosomes typically takes 2 to 3 hr. The Q-FISH protocol, on the next day, typically takes 5 to 6 hr to perform.

Image capture

The time to capture images also varies from user to user depending on the density of metaphase cells on the slide and one's experience in finding suitable metaphase spreads, focusing objects, as well as other aspects. Typically, after 30 min of initial setup, it takes ~1 hr to capture 15 metaphases on a slide with good quality metaphase spreads.

Image analysis

The time to analyze the data also varies from user to user as well as with the quality of the metaphases. The TFL-Telo program takes <1 min to extract the telomere length measurements (depending on the CPU speed and RAM of the computer). Editing the results can take up to 30 min per metaphase. If karyotyping is to be performed, then up to 1 hr can be added to the time for each metaphase.

System calibration

As mentioned earlier, telomere length measurements of plasmids need not be performed on a daily basis with each experiment. It takes several hours to prepare the plasmid slides, 1 to 2 hr to capture the images, and ~1 hr to extract the results.

Analysis of Mitochondrial Dysfunction During Cell Death

For many years mitochondria were considered only as a main energy supplier in the cell. In the middle of the 1990s it became clear that mitochondria actively participate in apoptosis, a form of cell death characterized by specific biochemical and morphological changes.

The following protocols represent basic tools widely used in estimating functional activity of mitochondria. The protocols are organized into three groups. The first group describes direct assessment of mitochondria in apoptotic cells—collection of proteins released from isolated mitochondria (see Basic Protocol 1), and from mitochondria within the cell (see Basic Protocol 2), immunoblot analysis of released proteins (see Basic Protocol 3), assessment of the mitochondrial membrane potential in apoptotic cells stained with TMRE (see Basic Protocol 4), and microscopy of apoptotic cells stained with MitoTracker Red (see Basic Protocol 5). The second group of protocols describes measurement of the mitochondrial permeability transition (MPT)—measurement of Ca^{2+} fluxes with an electrode (see Basic Protocol 6) or spectrophotometrically (see Alternate Protocol 1), measurement of the mitochondrial membrane potential with a TPP^{+} electrode (see Basic Protocol 7) or spectrophotometrically (see Alternate Protocol 2), estimation of mitochondrial swelling (see Basic Protocol 8), and measuring Ca^{2+} accumulation in permeabilized cells (see Basic Protocol 9). Support Protocols are included for the preparation of mitochondria from a number of sources—liver (see Support Protocol 1), brain (see Support Protocol 2), and cultured cells (see Support Protocol 3)—and for assessing the quality of the prepared mitochondria (see Support Protocol 4).

EVALUATION OF THE RELEASE OF PROTEINS FROM INTERMEMBRANE SPACE OF MITOCHONDRIA

The release of certain proteins from mitochondria in apoptotic cells is believed to be one of the key events in apoptosis. Therefore, estimation of the release of these proteins is important for understanding the role of mitochondria in apoptosis.

Collecting Samples of Proteins From Isolated Mitochondria

BASIC PROTOCOL 1

This method is based on the estimation of the amount of cytochrome *c* or any other protein released from the intermembrane space of mitochondria that remains in the incubation buffer after the mitochondria are removed by centrifugation. This protocol describes collecting samples of proteins released from isolated mitochondria incubated under different experimental conditions. Such experiments are very helpful in order to estimate a possible effect of certain pro-apoptotic compounds on mitochondria.

Materials

Isolated mitochondria (Support Protocols 1 to 3)
Buffer

1. Incubate mitochondria at a concentration of 1 mg protein/ml (time, conditions of incubation, and buffer to be used depend on the aim of the experiment).

   This buffer can be used for mitochondria isolated from different cources. The composition of the buffer is determined mainly by the aims of the experiment (see also Background Information section, MPT-dependent release of cytochrome c). For example, estimationof the release of cytochrome c is more suitable to perform in KCl-based ionic buffer, since the

Contributed by Vladimir Gogvadze, Sten Orrenius, and Boris Zhivotovsky
Current Protocols in Cell Biology (2003) 18.5.1-18.5.27

binding of cytochrome c to the inner mitochondrial membrane is significantly weaker as compared to mannitol-sucrose buffer. If the aim of the experiment is to assess MPT-independent release of cytochrome c, a calcium chelator EGTA, or cyclosporin A should be included.

2. Take a 200-µl aliquot and transfer to a microcentrifuge tube.
3. Microcentrifuge 5 min at 10,000 × *g*, 4°C.
4. Gently remove the supernatant without disturbing the pellet.
5. Resuspend the pellet in the original volume of the same buffer used for the incubation in step 1.
6. Freeze samples of supernatant (step 4) and pellet (step 5) and keep them at −20°C.

The samples are now ready for detection, e.g., of cytochrome c via immunoblotting (see Basic Protocol 3).

BASIC PROTOCOL 2

Evaluation of Cytochrome *c* Release from the Mitochondria of Apoptotic Cells

In order to analyze the release of certain proteins from mitochondria of apoptotic cells, the cellular plasma membrane should be disrupted and cytosolic fraction should be separated from membrane material. This can be achieved by preincubation of cells in a hypotonic solution that induces cell lysis.

Materials

Cells of interest (e.g., Jurkat cells, U 937, HeLa)
Apoptotic stimuli (e.g., etoposide, staurosporine)
Phosphate-buffered saline (PBS; *APPENDIX 2A*), ice-cold
S100 buffer (see recipe), ice-cold
Refrigerated low-speed centrifuge and ultracentrifuge
Additional reagents and equipment for immunoblot analysis (*UNIT 6.2* and Basic Protocol 3 in this unit)

1. Incubate cells with apoptotic stimuli (type, concentration, and incubation time determined by cell type).
2. Wash cells twice, each time with 5 ml of ice-cold PBS.
3. Resuspend cells at 75×10^6 cells/ml in ice-cold S100 buffer.
4. Incubate on ice for 10 to 20 min.
5. Centrifuge cells 15 min at 10,000 × *g*, 4°C.
6. Transfer supernatant to ultracentrifuge tube and ultracentrifuge 1 hr at 100,000 × *g*, 4°C.
7. Use supernatant for immunoblot analysis (see Basic Protocol 3 and *UNIT 6.2*) with an antibody specific for cytochrome *c*.

BASIC PROTOCOL 3

Immunoblot Analysis of Proteins Released from the Mitochondria During Apoptosis

After separation as in Basic Protocol 1 or 2, the supernatant contains proteins released from mitochondria, while the pellet represents proteins associated with the organelles. The detection of these proteins is performed using electrophoresis with subsequent blotting and probing with specific antibodies.

Materials

Sample collected from apoptotic mitochondria (see Basic Protocol 1 or 2)
4× Laemmli's loading buffer (see recipe)
15% (w/v) SDS-PAGE gel (*UNIT 6.1*)
5% (w/v) nonfat milk in PBS (see *APPENDIX 2A* for PBS)
Antibody specific for apoptotic protein of interest (e.g., Becton Dickinson Biosciences)
PBS (*APPENDIX 2A*) containing 2.5% (w/v)
Nonfat dry milk
Phosphate-buffered saline (PBS; *APPENDIX 2A*) containing 1% (w/v) bovine serum albumin and 0.01% (w/v) azide (NaN_3)
PBS (*APPENDIX 2A*) containing 15% (v/v) Tween 20
Horseradish peroxidase–conjugated secondary antibody (e.g., Pierce)
ECL Western Blotting Detection Reagents kit (Amersham Biosciences)

Additional reagents and equipment for SDS-PAGE (*UNIT 6.1*) and electroblotting (*UNIT 6.2*)

Perform electrophoresis

1. Mix 40 µl of sample with 12.5 µl of 4× Laemmli's loading buffer. Boil 5 min.
2. Separate the proteins on a 15% SDS-PAGE gel at 130 V (*UNIT 6.1*).

Perform immunoblotting and detect apoptotic proteins

3. Transfer proteins to nitrocellulose membranes by electroblotting (Basic Protocol 1 in *UNIT 6.2*) for 2 hr at 100 V.
4. Block membranes for 1 hr with 5% nonfat milk in PBS at room temperature.
5. Probe overnight in a cold room with an antibody (diluted 1:2500 in PBS containing bovine serum albumin and 0.01% NaN_3) specific for the apoptotic protein of interest.
6. Rinse membranes for 10 min in 30 to 40 ml of PBS.
7. Rinse membranes for 15 min in 30 to 40 ml of PBS with 0.15% Tween 20.
8. Rinse membranes for 10 min in 30 to 40 ml of PBS.
9. Incubate with a horseradish peroxidase–conjugated secondary antibody (diluted 1:10,000 in PBS containing 2.5% nonfat dry milk).

Visualize bound antibodies

10. Following incubation with the secondary antibody, rinse the membranes for 10 min in 30 to 40 ml of PBS.
11. Rinse membranes for 15 min in 30 to 40 ml of PBS with 0.15% Tween 20.
12. Rinse membranes for 10 min in 30 to 40 ml of PBS.
13. Detect bound antibodies using enhanced chemiluminescence (ECL kit) according to the manufacturer's instructions.

Assessment of the Mitochondrial Membrane Potential in Apoptotic Cells

BASIC PROTOCOL 4

The mitochondrial membrane potential ($\Delta\psi$), which drives oxidative phosphorylation (Mitchell and Moyle, 1967) and which also drives mitochondrial calcium uptake, is generated by an electron-transporting chain. When electron transport ceases, for example during ischemia, the inner-membrane potential is developed at the expense of ATP

hydrolysis by the mitochondrial ATP synthase. An early manifestation of apoptosis is often a decrease in the $\Delta\psi$, which is usually demonstrated using flow cytometry. The relationship between mitochondrial depolarization and apoptosis remains controversial. Some investigators consider a decrease in $\Delta\psi$ an early irreversible signal for apoptosis (Zamzami et al., 1996), while others describe it as a late event (Bossy-Wetzel et al., 1998).

Materials

Cells of interest (e.g., Jurkat cells, U 937, HeLa)
RPMI-1640 medium (Life Technologies) supplemented with 5% (v/v) heat-inactivated fetal bovine serum, 2 mM L-glutamine, penicillin (100 U/ml), and streptomycin (100 µg/ml)
25 mM TMRE stock solution: dissolve 12.8 mg tetramethylrhodamine methyl ester (TMRE; Molecular Probes) in 1 ml ethanol; store per manufacturer's instructions
HEPES buffer (see recipe)
Flow cytometer (e.g., FACS; Becton Dickinson)

1. Prepare an aliquot of 10^6 cells in RPMI-1640 medium.
2. Dilute TMRE stock solution 1:1000 with HEPES buffer (for a concentration of 25 µM).
3. Add an aliquot of the diluted (25 µM) TMRE to cells for a final concentration of 25 nM.
4. Incubate cells with TMRE 20 min at 37°C.
5. Further dilute the 25 µM TMRE 1:1000 with HEPES buffer for a final concentration of 25 nM. Centrifuge cells 5 min at 200 × *g*, room temperature, and resuspend in fresh HEPES buffer containing 25 nM TMRE.
6. Analyze membrane potential by flow cytometry according to the manufacturer's instructions for the instrument used.

BASIC PROTOCOL 5

Microscopy of Apoptotic Cells Stained with MitoTracker

Fluorescent probes for mitochondria such as rhodamine 123 or tetramethylrosamine are readily sequestered by mitochondria. However, in experiments that require fixation of the organelles, these stains are easily washed out. In contrast, mitochondria-selective probes—e.g., MitoTracker Red (Molecular Probes)—are concentrated by active, energized mitochondria and retained during fixation. Once mitochondria are labeled, the cells can be fixed for further processing, for example, if cells are going to be subsequently labeled with antibody.

Materials

Cells of interest (e.g., Jurkat cells, U 937, HeLa) and appropriate culture medium
MitoTracker Red (Molecular Probes); store according the manufacturer's instructions
Dimethylsulfoxide (DMSO)
4% (w/v) paraformaldehyde in serum-free culture medium
Phosphate-buffered saline (PBS; *APPENDIX 2A*)
PBS (*APPENDIX 2A*) containing 0.2% (v/v) Triton X-100
PBS (*APPENDIX 2A*) containing 1% (v/v) fetal bovine serum (FBS)
Mounting medium: 50% (w/v) glycerol/PBS
Fluorescent or scanning confocal microscope (e.g., Bio-Rad), with 581 nm excitation filter and 644 nm emission filter
Additional reagents and equipment for cell culture (*UNIT 1.1*)

1. Grow cells on coverslips inside a petri dish filled with the appropriate culture medium to the optimal density.

   The optimal cell density depends on the cell type.

2. Open fresh vial of MitoTracker Red and add DMSO to create a 1 mM stock. Protect from light.

3. Dilute 1 mM MitoTracker Red to final working concentration in the culture medium used to grow the cells.

   Recommended Mito Tracker Red concentration is 100 to 500 nM. Diluted MitoTracker Red can be stored up to several months at –20°C

4. When cells have reached the desired confluence, remove the medium from the dish and add the prewarmed (37°) growth medium containing MitoTracker probe. Incubate for 30 min.

5. Replace the loading solution with fresh prewarmed medium.

Fix and permeabilize cells

6. Remove the growth medium covering the cells and replace it with fresh prewarmed medium containing 4% paraformaldehyde. Incubate 15 min at 37°C.

7. Rinse cells three times, each time for 5 min with room temperature PBS.

8. Incubate fixed cells in PBS containing 0.2% Triton X-100 at room temperature for 5 min.

9. Rinse cells three times, each time for 5 min with PBS containing 1% FBS.

10. Mount coverslips on glass slides in 50% glycerol/PBS and examine under fluorescent or scanning confocal microscope with excitation at 581 nm and emission at 644 nm.

ASSESSMENT OF THE MITOCHONDRIAL PERMEABILITY TRANSITION IN ISOLATED MITOCHONDRIA

The mitochondrial permeability transition (MPT) is one of the mechanisms that can lead to the release of cytochrome *c* from mitochondria during apoptosis. MPT is a consequence of Ca^{2+} overload. Accumulation of Ca^{2+} in mitochondria is driven by the mitochondrial membrane potential supported either by mitochondrial respiration or by ATP hydrolysis. Mitochondria release Ca^{2+} when the membrane potential is dropped either by inhibitors of mitochondrial respiratory chain (if the potential is supported by oxidation of a substrate) or by inhibitors of ATPase (if the source of potential is hydrolysis of ATP).

Retention of Ca^{2+} by mitochondria stimulates processes that result in mitochondrial deterioration. Mitochondria swell and become leaky, whereupon the membrane potential drops and Ca^{2+} is released. Although Ca^{2+} is obligatory for MPT induction, the sensitivity of mitochondria to permeability transition can be enhanced by different factors. Among these factors are elevated levels of phosphate, oxidative stress, and the depletion of adenine nucleotides. When phosphate or organic peroxide is added to Ca^{2+}-loaded mitochondria these organelles swell, membrane potential decays, and accumulated Ca^{2+} is released. All of these manifestations can be prevented by cyclosporin A (CsA), an inhibitor of pore opening. Therefore, MPT in isolated mitochondria can be assessed by monitoring either swelling, membrane potential, or the level of Ca^{2+} in the incubation buffer.

Accumulation of Ca^{2+} by mitochondria, as well as Ca^{2+} retention and release induced by different stimuli, can be monitored using a Ca^{2+}-sensitive electrode or spectrophotometrically with the Ca^{2+}-sensitive dye arsenazo III.

BASIC PROTOCOL 6

Monitoring of Ca^{2+} Fluxes Across the Inner Mitochondrial Membrane with a Ca^{2+}-Sensitive Electrode

One relatively easy method applicable to mitochondria and permeabilized cells employs a Ca^{2+}-sensitive electrode to follow the Ca^{2+}. Accumulation of Ca^{2+} by mitochondria can be followed by a decrease in the concentration of Ca^{2+} in the incubation buffer.

Materials

Incubation buffer for calcium-sensitive electrode (see recipe)
Isolated mitochondria (Support Protocol 1, 2, or 3)
2.5 mM rotenone: dissolve 1 mg rotenone (Sigma) in 1 ml ethanol; store frozen at –20°C up to 1 month
10 mM $CaCl_2$: dissolve 1.47 mg $CaCl_2 \cdot 2H_2O$ in 1 ml H_2O; store frozen at –20°C up to 1 month
0.5 M KH_2PO_4: dissolve 136.1 mg KH_2PO_4 in 2 ml H_2O and adjust pH to 7.4 with KOH; store frozen at –20°C up to 1 month

Apparatus for membrane potential measurement consisting of:
Glass (or plastic) sample chamber large enough for incubation volume, which can be warmed by being connected to a water bath and can be constantly stirred
Ca^{2+}-sensitive electrode (e.g., Orion)
pH meter as source of current
Chart recorder with variable input and chart speed
Any commercially available reference electrode for pH measurements

1. Add 2 ml of incubation buffer for calcium-sensitive electrode to the sample chamber of the measurement apparatus and set to conditions of constant stirring. Add a volume of mitochondrial suspension (which will depend on the concentration of the mitochondrial preparation) containing 2 mg of protein to the sample chamber.
2. After 30 sec, add 2 µl of 2.5 mM rotenone, for a final concentration of 2.5 µM.

   When mitochondria are energized with the complex II substrate succinate, rotenone prevents formation of oxaloacetate, an inhibitor of succinate dehydrogenase that supresses mitochondrial respiration.

3. Turn on the chart recorder.
4. After 1 min (or when stabilization has been achieved as observed by recorder trace) add 50 to 60 nmol Ca^{2+} (from 10 mM $CaCl_2$ stock) per milligram of mitochondrial protein.

   The addition of Ca^{2+} to mitochondria leads to a rapid increase in the level of this cation in the reaction buffer, followed by a return to the initial level as mitochondria accumulate the excess Ca^{2+}.

5. After 1 min, add 20 µl of 0.5 M KH_2PO_4, for a final concentration of 5 mM.

   Inorganic phosphate is a trigger for permeability transition in mitochondria loaded with calcium.

6. Follow the retention of Ca^{2+} by its release as seen from the recorder trace.

Monitoring of Ca^{2+} Fluxes Across the Inner Mitochondrial Membrane with a Spectrophotometer

ALTERNATE PROTOCOL 1

Spectrophotometric estimation of Ca^{2+} fluxes across the mitochondrial membrane should be performed using a dual-wavelength spectrophotometer, in order to avoid interference from the turbidity of mitochondrial suspension.

Additional Materials *(also see Basic Protocol 6)*

25 mM arsenazo III: dissolve 19.4 mg arsenazo III (Sigma) in 1 ml H_2O; store frozen at –20°C up to 1 month

Dual-wavelength recording spectrophotometer set at 675 versus 685 nm, with appropriate cuvettes

1. Place 2 ml of incubation buffer for calcium-sensitive electrode in a spectrophotometric cuvette and set to conditions of constant stirring. Add 2 µl of 25 mM arsenazo III, for a final concentration of 25 µM.
2. Add an aliquot of mitochondrial suspension containing 2 mg of protein, for a final concentration of 1 mg/ml.

   The volume of the mitochondrial aliquot will depend on the concentration of the mitochondrial preparation.

3. After 30 sec add 2 µl of 2.5 mM rotenone, for a final concentration of 2.5 µM.
4. After 1 min add 50 to 60 nmol Ca^{2+} (from 10 mM $CaCl_2$ stock) per mg of mitochondrial protein.

   The addition of Ca^{2+} to mitochondria leads to a rapid increase in the level of this cation in the reaction buffer, followed by a return to the initial level as mitochondria accumulate the excess Ca^{2+}.

5. After 1 min, add 20 µl of 0.5 M KH_2PO_4, for a final concentration of 5 mM.

   The retention of Ca^{2+} is followed by its release upon induction of MPT as can be seen from the recorder trace.

DETERMINATION OF MITOCHONDRIAL MEMBRANE POTENTIAL

Estimation of the mitochondrial membrane potential ($\Delta\psi$) can be performed using an electrode sensitive to the lipophilic cation tetraphenylphosphonium (TPP^+) or spectrophotometrically with a $\Delta\psi$-specific dye, safranin.

Measurements of Mitochondrial Membrane Potential with a TPP^+-Sensitive Electrode

BASIC PROTOCOL 7

Energized mitochondria rapidly accumulate TPP^+ from the incubation buffer and release this cation as $\Delta\psi$ decays. Accumulation of TPP^+ by mitochondria can be followed by a decrease in the concentration of TPP^+ in the incubation buffer.

Materials

Incubation buffer for TPP^+-sensitive electrode (see recipe)

TPP^+ stock solution: dissolve 3.75 mg tetraphenylphosphonium chloride (Aldrich) in 10 ml H_2O; store up to 1 month at room temperature

Isolated mitochondria (Support Protocol 1, 2, or 3)

2.5 mM rotenone: dissolve 1 mg rotenone (Sigma) in 1 ml ethanol; store frozen at –20°C up to 1 month

10 mM $CaCl_2$: dissolve 1.47 mg $CaCl_2 \cdot 2H_2O$ in 1 ml H_2O; store frozen at –20°C up to 1 month

0.5 M KH_2PO_4: dissolve 136.1 mg KH_2PO_4 in 2 ml H_2O and adjust pH to 7.4 with KOH; store frozen at –20°C up to 1 month

Apparatus for membrane potential measurement consisting of:

Glass (or plastic) sample chamber that can accommodate 2 ml of incubation buffer, which can be warmed by being connected to a water bath and can be constantly stirred

TPP^+ electrode (purchase from Microelectrodes, Inc. or prepare in the laboratory, Kamo et al., 1979)

pH meter as source of current

Chart recorder with variable input and chart speed

Any commercially available reference electrode

1. Place 2 ml of incubation buffer for TPP^+-sensitive electrode in the sample chamber of the measurement apparatus and set conditions to constant stirring. Add 4 µl of TPP^+ stock, for a final concentration of 2 µM TPP^+, and turn on the chart recorder.

   The recorder trace shows the basal level of TPP^+ in incubation buffer.

2. Add mitochondrial suspension to a final concentration of 1 mg/ml to the incubation buffer under conditions of constant stirring.

   The volume of the mitochondrial aliquot will depend on the concentration of mitochondrial preparation.

   Mitochondria accumulate TPP^+ according to the membrane potential so that the level of TPP^+ in the incubation buffer decreases.

3. After 30 sec add 2 µl of 2.5 mM rotenone, for a final concentration of 2.5 µM.

4. After 1 min, add 50 to 60 nmol Ca^{2+} (from 10 mM $CaCl_2$ stock) per milligram of mitochondrial protein.

   Upon addition of Ca^{2+}, the mitochondrial membrane potential decreases, with subsequent restoration when Ca^{2+} is accumulated.

5. After restorationof the membrane potential, add 20 µl of 0.5 M KH_2PO_4 for a final concentration of 5 mM and monitor the release of TPP^+ from mitochondria, which is indicative of the drop of the membrane potential upon induction of MPT.

   If Ca^{2+} loading is not sufficient to induce permeability transition, mitochondria will maintain membrane potential. In this case Ca^{2+} loading should be increased.

ALTERNATE PROTOCOL 2

Measurement of Mitochondrial Membrane Potential Using a Spectrophotometer

Spectrophotometric measurement of the membrane potential can be performed using safranin, a cationic dye, because of its accumulation in mitochondria and a shift in absorption spectrum that occurs when membrane potential is high. In these experiments, a dual-wavelength spectrophotometer should be used in order to avoid a contribution by the turbidity of the mitochondrial suspension to light absorption.

Additional Materials *(also see Basic Protocol 7)*

Incubation buffer for calcium-sensitive electrode (see recipe)

10 mM safranin: dissolve 3.5 mg safranin in 1 ml H_2O; store frozen at –20°C up to 1 month

Dual-wavelength recording spectrophotometer set at 511 versus 533 nm, with appropriate cuvettes

1. Place 2 ml of incubation buffer for calcium-sensitive electrode in a spectrophotometric cuvette and set to conditions of constant stirring. Add 2 µl of 10 mM safranin, for a final concentration of 10 µM.
2. Add an aliquot of mitochondrial suspension containing 2 mg of protein, for a final concentration of 1 mg/ml.

   The volume of the mitochondrial aliquot will depend on the concentration of the mitochondrial preparation.
3. After 30 sec add 2 µl of 2.5 mM rotenone, for a final concentration of 2.5 µM.
4. After 1 min add 50 to 60 nmol Ca^{2+} (from 10 mM $CaCl_2$ stock) per milligram of mitochondrial protein.

   Upon addition of Ca^{2+}, the mitochondrial membrane potential decreases, with subsequent restoration when Ca^{2+} is accumulated.
5. After restoration of the membrane potential, add 20 µl of 0.5 M KH_2PO_4, for a final concentration of 5 mM, and monitor the decrease in the membrane potential upon induction of MPT.

Estimation of Mitochondrial Swelling

BASIC PROTOCOL 8

One of the most reliable manifestations of mitochondrial permeability transition is swelling of the organelles. Nephelometric or turbidometric techniques have generally been used to monitor mitochondrial swelling. Mitochondrial swelling can be monitored continuously as changes in OD_{540}.

Materials

Incubation buffer for swelling (see recipe)
Isolated mitochondria (Support Protocol 1, 2, or 3)
10 mM $CaCl_2$: dissolve 1.47 mg $CaCl_2 \cdot 2H_2O$ in 1 ml H_2O; store frozen at –20°C up to 1 month
2.5 mM rotenone: dissolve 1 mg rotenone (Sigma) in 1 ml ethanol; store frozen at –20°C up to 1 month
0.5 M KH_2PO_4: dissolve 136.1 mg KH_2PO_4 in 2 ml H_2O and adjust pH to 7.4 with KOH; store frozen at –20°C up to 1 month

Spectrophotometer with 540-nm filter, or multiwavelength spectrophotometer
Chart recorder with variable input and chart speed

1. Place 2 ml of incubation buffer for swelling in a spectrophotometric cuvette and set to conditions of constant stirring. Add a volume of mitochondrial suspension (which will depend depends on the concentration of mitochondrial preparation) for a final concentration of 0.5 mg/ml.
2. After 30 sec, add 2 µl of 2.5 mM rotenone, for a final concentration of 2.5 µM.
3. After 1 min add 50 to 60 nmol Ca^{2+} (from 10 mM $CaCl_2$ stock) per milligram of mitochondrial protein.
4. After 1 min, add 20 µl of 0.5 M KH_2PO_4.
5. Monitor gradual decrease in OD_{540} nm due to mitochondrial swelling.

Estimation of Mitochondrial Ca^{2+} Accumulation in Digitonin-Permeabilized Cells

Permeabilization of the plasma membrane allows measurement of mitochondrial activity in situ, without isolation of these organelles and the accompanying potential risk of mitochondrial damage. For the permeabilization, a steroid glycoside, digitonin, is widely used. The affinity of digitonin for cholesterol allows a selective disruption of the plasma membrane, making mitochondria accessible to specific substrates and Ca^{2+}. The concentration of digitonin must be chosen carefully and usually should not exceed 0.005% (w/v), since higher concentrations might affect the outer mitochondrial membrane barrier functions.

Permeabilization of the plasma membrane allows estimation of the main functional parameters of mitochondria, such as respiration, membrane potential, and accumulation and release of Ca^{2+}. A description of the monitoring of Ca^{2+} fluxes is given below.

Induction of MPT in apoptotic cells is thought to be one of the reasons for the decrease in $\Delta\psi$. Pore opening during apoptosis (even in a subpopulation of mitochondria) will impair the ability of the total mitochondrial population to accumulate Ca^{2+}; therefore estimation of a threshold level of Ca^{2+} loading (the Ca^{2+} capacity of mitochondria) in cells might be a criterion for changes on the mitochondrial level.

Materials

Cells of interest (Jurkat cells, U 937, HeLa)
Phosphate-buffered saline (PBS; *APPENDIX 2A*)
Incubation buffer for digitonin-permeabilized cells (see recipe)
1% (w/v) digitonin: dissolve 10 mg digitonin in 1 ml H_2O; shake vigorously before adding to cells; store up to 2 to 3 months at room temperature
2.5 mM rotenone: dissolve 1 mg rotenone (Sigma) in 1 ml ethanol; store frozen at –20°C up to 1 month
10 mM $CaCl_2$: dissolve 1.47 mg $CaCl_2 \cdot 2H_2O$ in 1 ml H_2O; store frozen at –20°C up to 1 month

Apparatus for membrane potential measurement consisting of:
Glass (or plastic) sample chamber large enough for incubation volume, which can be warmed up by being connected to a water bath and can be constantly stirred
Ca^{2+}-sensitive electrode (e.g., Orion)
pH meter as source of current
Chart recorder with variable input and chart speed
Any commercially available reference electrode for pH measurements

1. Centrifuge $3–5 \times 10^6$ cells 5 min at $200 \times g$, room temperature. Remove supernatant, resuspend cells in PBS, and centrifuge again under the same conditions.
2. Resuspend cells in 50 µl of incubation buffer for digitonin-permeabilized cells, then add the resuspended cells to 450 µl of the same buffer in sample chamber with Ca^{2+} electrode at constant stirring. Turn on the chart recorder.
3. Following a 2-min stabilization period, add 1% digitonin to a final concentration of 0.005% and 2.5 mM rotenone to a final concentration of 5 µM.
4. Load mitochondria with pulses of Ca^{2+} (20 to 25 nmol each, added from 10 mM stock) to induce MPT, which can be observed by the release of accumulated Ca^{2+} as measured by the Ca^{2+}-sensitive electrode.

The calcium capacity is calculated as a sum of the amount of Ca^{2+} in each addition.

ISOLATION OF MITOCHONDRIA

Experiments with isolated mitochondria are a helpful supplement to experiments on a cellular level. The former type of experiments provide better understanding of the mechanisms responsible for the mitochondrial changes in apoptotic cells. All the methods of isolation of mitochondria are based on the disruption of tissue and subsequent differential centrifugation of homogenate.

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) or must conform to governmental regulations regarding the care and use of laboratory animals.

NOTE: Mitochondria should be kept on ice at all times.

Isolation of Rat Liver Mitochondria

SUPPORT PROTOCOL 1

Isolation of liver mitochondria represents a relatively "easy" procedure giving a high yield. The liver from a 150 to 200-g rat weighs 5 to 6 g. Liver can be easily disrupted and homogenized. The most important thing is keeping the temperature not higher than 4 to 6°C.

Materials

150- to 200-g rat
Buffer A for liver (see recipe)
Buffer B: Buffer A (for liver) without EDTA

Dissecting equipment
Motor-driven glass Dounce homogenizer and tight Teflon pestle
Refrigerated centrifuge and 50-ml centrifuge tubes

Additional reagents and equipment for protein assay (*APPENDIX 3H*) and determination of the respiratory control ratio for mitochondria (Support Protocol 4)

NOTE: All operations should be done on ice, using ice-cold buffers and instruments.

Harvest the liver

1. Let the rat starve overnight.

   This step is necessary to decrease the content of fat and glycogen in the liver.

2. Sacrifice rat in accordance with institutional guidelines and the aims of the experiment.

   Donovan and Brown (1995) provide a variety of protocols for rodent euthanasia.

3. Remove liver and immerse immediately in ice-cold buffer A for liver.

4. Cut liver into pieces with scissors and wash several times by replacing the ice-cold buffer A with fresh ice-cold buffer, in order to remove as much blood as possible.

Homogenize the liver

5. Homogenize the liver in 60 ml of buffer A with 5 to 6 up-and-down strokes of the tight Teflon pestle.

   Homogenization occurs as the piston of the homogenizer rotates (driven by an electrical motor) and the pestle is slowly moved up and down 5 to 6 times, so that there are no pieces of liver big enough to be seen by eye.

6. Transfer homogenate into two cold centrifuge tubes and balance them.

7. Centrifuge the homogenate 8 min at 600 × *g*, 4°C, to remove nuclei and unbroken cells.

Isolate mitochondria

8. Discard the pellet and centrifuge supernatant 15 min at 5500 × *g*, 4°C, to form a mitochondrial pellet.
9. Remove floating fat droplets with a paper towel or piece of tissue paper.
10. Detach the pellet from the bottom of the tube with the piston of the homegenizer, add 0.2 to 0.3 ml of buffer A for liver, resuspend the pellet using the pestle, and pass mitochondria gently 3 to 4 times through the tip of a 1-ml pipet tip using automatic pipettor.
11. Dilute the mitochondrial suspension with 30 ml of buffer B, then centrifuge again as in step 9.
12. Resuspend the final mitochondrial pellet to a volume of ~1 ml in buffer B by gentle passing through a 1-ml pipet tip, then transfer into a 10-ml tube and keep on ice.

Assess the preparation

13. Determine the protein concentration using Lowry's method (or any other method available; see *APPENDIX 3H*) with bovine serum albumin as a standard.

    The protein concentration of a final suspension usually is about 90 to 100 mg/ml.

14. As a control of the mitochondrial preparation, estimate the respiratory control ratio (see Support Protocol 4). Use within 4 hr.

    Measurements can be started directly after mitochondrial isolation.

SUPPORT PROTOCOL 2

Isolation of Brain Mitochondria

Another source of mitochondria frequently used in the investigation of mitochondrial functioning (e.g., during apoptosis) is the brain. The method for isolation of brain mitochondria is similar to that for liver mitochondria (see Support Protocol 1); however, in order to get a purer preparation, a purification of homogenate with a Ficoll gradient is involved.

Materials

150- to 200-g rat
SET buffer (see recipe), ice-cold
3% and 6% (w/v) Ficoll solutions (see recipe)
MSH buffer (see recipe)

Motor-driven glass Dounce homogenizer and tight Teflon pestle
Refrigerated centrifuge and 50-ml centrifuge tubes

Additional reagents and equipment for protein assay (*APPENDIX 3H*) and determination of the respiratory control ratio for mitochondria (Support Protocol 4)

Dissect brain

1. Sacrifice rat in accordance with institutional guidelines and the aims of the experiment.
2. Open the skull with scissors, gently remove the brain, place it in ice-cold SET buffer, and chop it into pieces with scissors.

3. Wash pieces of brain several times in ice-cold SET buffer in order to remove as much blood as possible.

Homogenize brain

4. Homogenize manually chopped brain in 30 ml of SET buffer at 4°C using a Dounce homogenizer with six up-and-down strokes of the tight pestle.
5. Dilute homogenate to a final volume of 80 ml with SET buffer.
6. Place the homogenate in two cold centrifuge tubes, balance them, and centrifuge 3 min at 2000 × *g*, 4°C.
7. Decant supernatant and centrifuge again for 3 min at 2000 × *g*, 4°C.

Isolate mitochondria

8. Collect the supernatant and centrifuge 15 min at 12,000 × *g*, 4°C, to obtain a crude mitochondrial fraction.
9. Resuspend the pellet in 6 ml of ice-cold 3% Ficoll solution and layer onto 25 ml of ice-cold 6% Ficoll solution.
10. Centrifuge 10 min at 11,500 × *g*, 4°C.
11. Resuspend the final pellet in MSH buffer to a final volume of ~1 ml and keep on ice.

Assess preparation

12. Determine the protein concentration (*APPENDIX 3H*).
13. As a control of the mitochondrial preparation estimate the respiratory control ratio (see Support Protocol 4). Use within 4 hr.

Measurements can be started directly after mitochondrial isolation.

Isolation of Mitochondria from Cultured Cells

SUPPORT PROTOCOL 3

Isolation of mitochondria from cultured cells is more problematic than isolation from tissue, since it is difficult to disrupt the cell membrane without affecting the mitochondrial membrane. In order to make the plasma membrane more vulnerable, different tactics are used. The plasma membrane can be sensitized to disruption by using a buffer that contains digitonin, a steroid glycoside with a high affinity for cholesterol that selectively disrupts the cholesterol-rich plasma membrane. Another approach is based on passing cells through a needle. Both methods are followed by a differential centrifugation commonly used for preparation of mitochondria.

Materials

Tissue culture cells (e.g., Jurkat cells, U 937, HeLa; *UNIT 1.1*)
Complete RPMI medium (*UNIT 1.2*) or appropriate medium for cells
Buffer A for cultured cells (see recipe), ice-cold
Buffer B: Buffer A (for cultured cells) without EGTA
1% (w/v) digitonin: dissolve 10 mg digitonin in 1 ml H_2O; shake vigorously before adding to cells; store up to 2 to 3 months at room temperature
Refrigerated centrifuge and tubes

1. Take an aliquot containing 5×10^7 cells growing in culture in complete RPMI medium and centrifuge 5 min at 200 × *g*, 4°C. Remove supernatant.
2. Resuspend cells in buffer A for cultured cells. Centrifuge 4 min at 200 × *g*, 4°C.

3. Add 1% digitonin to buffer A for a final concentration of 0.01%. Resuspend cells in 5 ml of the buffer A containing 0.01% digitonin and incubate 10 min on ice.
4. Add 5 ml of ice-cold buffer A and mix well. Sediment lysed cells by centrifuging 7 min at 500 × *g*, 4°C.
5. Discard the pellet and centrifuge supernatant 15 min at 5500 × *g*, 4°C, to form a mitochondrial pellet.
6. Detach the pellet from the bottom of the centrifuge tube with a pipet tip and resuspend the pellet in 0.1 ml of buffer B using an automatic pipettor.
7. Dilute the mitochondrial suspension with 2 ml of buffer B and centrifuge again for 15 min at 5500 × *g*, 4°C.
8. Resuspend the final mitochondrial pellet in buffer B by gently passing through a pipet tip, then transfer into an microcentrifuge tube and keep on ice.

Measurements can be started directly after mitochondrial isolation.

Unfortunately, the yield from this protocol is sufficient material for an experiment but not enough to assess protein concentration and respiratory control ratio as well.

SUPPORT PROTOCOL 4

Estimation of the Quality of Isolated Mitochondria: Measuring the Respiratory Control Ratio (RCR)

One of the keystones of the chemiosmotic theory of energy transduction is impermeability of the inner mitochondrial membrane to protons. Oxidation of substrates results in extrusion of protons from the mitochondrial matrix to generate the mitochondrial membrane potential. High membrane potential suppresses further extrusion of protons and therefore inhibits respiration. Under resting conditions, the rate of respiration of mitochondria is quite low and determined by a passive leakage of protons into the matrix space.

Phosphorylation of ADP requires translocation of protons into the matrix through mitochondrial ATP synthase. This results in a decrease in membrane potential that stimulates respiration. Comparison of the rates of respiration in the resting state and during phosphorylation of ADP is a useful measure of the efficiency of mitochondrial functioning. The most reliable and widely used criterion of the quality of a mitochondrial preparation is the respiratory control ratio (RCR). RCR is defined as the rate of respiration in the presence of ADP (phosphorylating respiration, state 3) divided by the rate obtained following the expenditure of ADP, state 4.

Materials

Mitochondria (Support Protocol 1, 2, or 3)
Incubation buffer for testing mitochondrial quality (see recipe)
2.5 mM rotenone: dissolve 1 mg rotenone (Sigma) in 1 ml ethanol; store frozen at –20°C up to 1 month
0.5 M sodium succinate: dissolve 135 mg of sodium succinate in 1 ml of H_2O, store frozen at –20°C up to 1 month
50 mM ADP: dissolve 23 mg of ADP in 1 ml H_2O and adjust pH to 7.5 with KOH; store frozen at –20°C up to 1 month
1 mM CCCP: dissolve 0.2 mg CCCP in 1 ml ethanol and mix thoroughly; store frozen at –20°C up to 1 month
Biological oxygen monitor equipped with a Clark-type oxygen electrode (Yellow Spring Instrument Co.) or similar equipment (operate per manufacturer's instructions)
Chart recorder with variable input and chart speed
10- and 50-µl Hamilton syringes (e.g., Sigma)

1. Place 2 ml of incubation buffer for testing mitochondrial quality into the sample chamber of the oxygen monitor and set conditions to constant stirring. Add an aliquot of mitochondrial suspension (the volume of which will depend on the concentration of the mitochondrial preparation) for a final concentration of 2 mg/ml mitochondrial protein.
2. After 30 sec add 2 µl of 2.5 mM rotenone, for a final concentration of 2.5 µM.
3. Stop stirring and insert the electrode into the sample chamber. Expel all air through the slot in the plunger (slight twisting of the electrode helps to gather the bubbles at the slot) and set the chart speed.

   The desirable chart speed should be 10 to 15 mm/min.
4. After 1 min stabilization observed by recorder trace add 20 µl of 0.5 M sodium succinate, for a final concentration of 5 mM, through the slot on electrode's body with a Hamilton syringe.

   Mitochondria will now start to consume oxygen. The slope of the curve shows the rate of respiration.
5. After stabilization of respiration (~2 min) add 10 µl of 50 mM ADP.

   The rate of respiration will increase (state 3) with subsequent restoration of the initial rate of respiration (state 4) when all added ADP is phosphorylated.
6. Add 2 µl of 1 mM CCCP, for a final concentration of 1 µM.

   CCCP lowers the mitochondrial potential that stimulates oxygen consumption.
7. Calculate the rate of respiration from the recorder trace as the amount of oxygen consumed in 1 min.

   Assume that at room temperature and normal atmospheric pressure the concentration of oxygen in the incubation buffer is 250 µM.
8. Calculate the RCR by dividing the state 3 respiration rate by the state 4 respiration rate.

   Mitochondria with a respiratory control ratio above 4 are acceptable for use in the experiments.

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Buffer A for cultured cells

38.26 g/liter mannitol (210 mM final)
23.96 g/liter sucrose (70 mM final)
0.2g/liter $MgCl_2 \cdot 6\ H_2O$ (1 mM final)
1.2 g/liter HEPES (5 mM final)
0.38 g/liter EGTA (1 mM final)
Adjust pH to 7.5 with KOH
Store up to 3 to 4 days at 4°C

Buffer A for liver

38.26 g/liter mannitol (210 mM final)
23.96 g/liter sucrose (70 mM final)
1.2 g/liter HEPES (5 mM final)
2 ml/liter 0.5 M EDTA (1 mM final)
Adjust pH to 7.5 with KOH
Store up to 3 to 4 days at 4°C

Ficoll dilution buffer

0.25 M mannitol
60 mM sucrose
100 μM potassium EGTA
10 mM Tris·Cl, pH 7.5 (*APPENDIX 2A*)
Store up to 3 to 4 days at 4°C

Ficoll solutions, 3% and 6% (w/w)

Prepare 20% (w/v) Ficoll (Sigma) stock solution in Ficoll dilution buffer (see recipe). Store 3 to 4 days at 4°C. Before the experiement perpare 6% (v/v) and 3% (v/v) solutions by diluting 20% solution wiht Ficoll dilution buffer.

HEPES buffer

2.38 g/liter HEPES (10 mM final)
8.76 g/liter NaCl (150 mM final)
0.37 g/liter KCl (5 mM final)
0.2 g/liter $MgCl_2 \cdot 6H_2O$ (1 mM final)
Adjust pH to 7.4 with NaOH
Store up to 2 to 3 days at 4°C

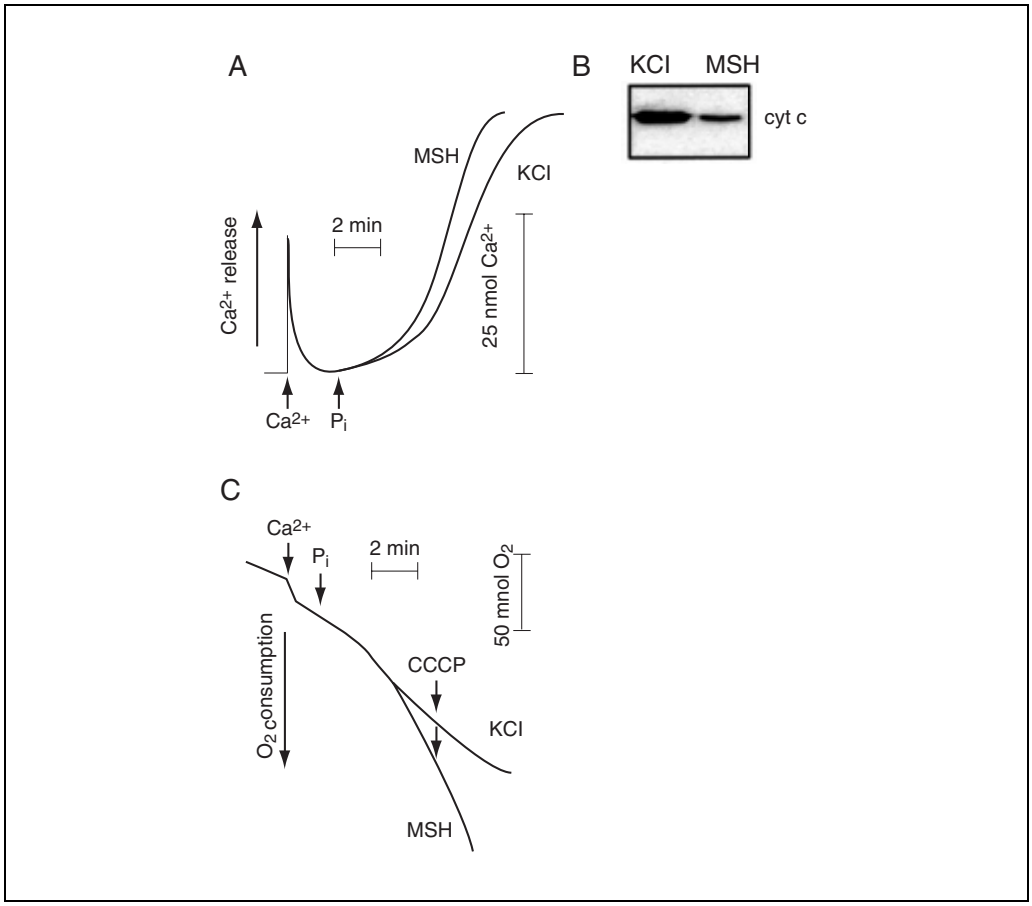

Figure 18.5.1 MPT-induced release of cytochrome *c* from mitochondria incubated in either MSH or KCl buffer. (**A**) Mitochondria were added to buffer at a concentration of 1 mg/ml. After a 2-min stabilization period, mitochondria were loaded with Ca^{2+} (50 nmol/mg protein), and MPT was induced by adding 5 mM inorganic phosphate (P_i). (**B**) Mitochondrial suspensions from (A) were centrifuged and the resulting supernatants were separated by SDS-PAGE and immunoblotted as described in Basic Protocol 3. (**C**) Mitochondrial respiration following MPT induction in either MSH or KCl buffer was analyzed as described in Support Protocol 4. The concentration of CCCP was 1 μM.

Incubation buffer for calcium-sensitive electrode

1.11 g/100 ml KCl (150 mM final)
13.1 mg/100 ml KH_2PO_4 (1 mM final)
60 mg/100 ml Tris (5 mM final)
135 mg/100 ml sodium succinate (5 mM final)
Adjust pH to 7.4 with HCl
Store up to 2 to 3 days at 4°C

Incubation buffer for digitonin-permeabilized cells

150 mM KCl
5 mM KH_2PO_4
1 mM $MgCl_2$
5 mM sodium succinate
5 mM Tris·Cl, pH 7.4 (*APPENDIX 2A*)
Store up to 2 to 3 days at 4°C

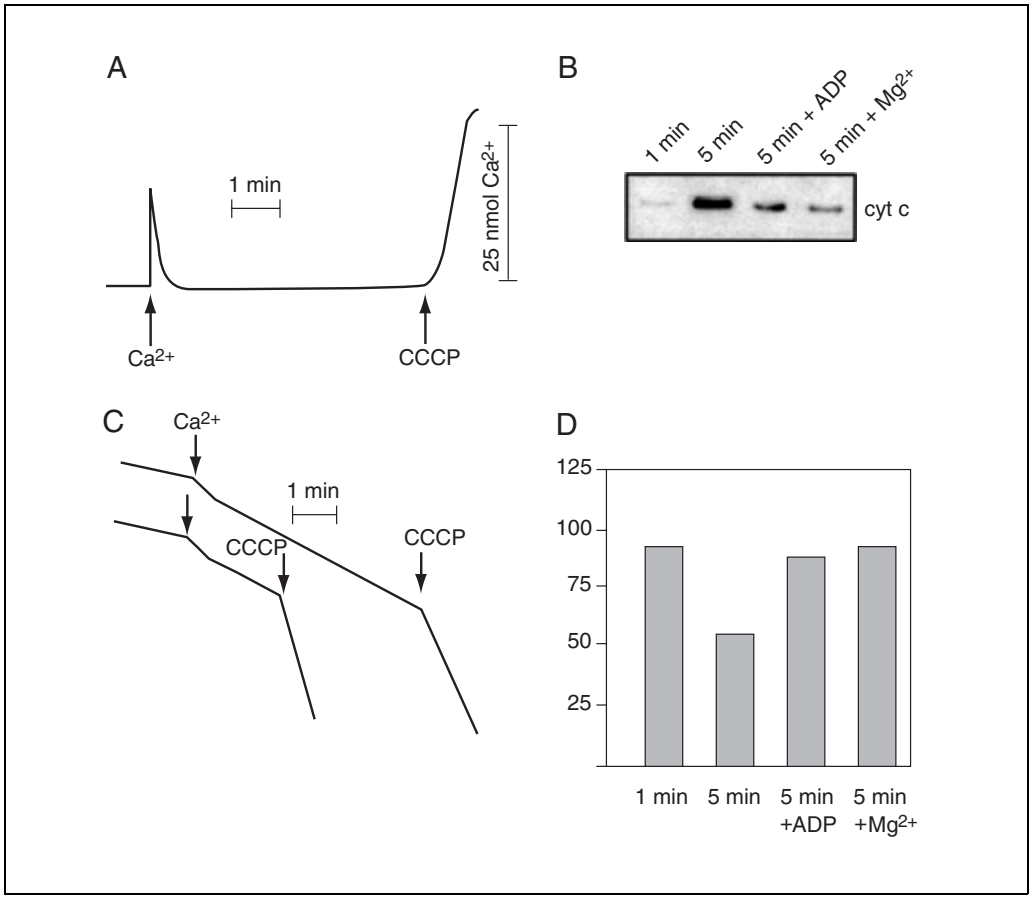

Figure 18.5.2 Ca^{2+}-induced release of cytochrome *c* from mitochondria in the absence of observable MPT. (**A**) Mitochondria (1 mg/ml) were incubated in KCl-based buffer. After a 2-min stabilization period, mitochondria were loaded with Ca^{2+} (25 nmol/mg protein) prior to the addition of 1 μM carbonyl cyanide *m*-chlorophenyl hydrazone (CCCP) at 5 min. (**B**) The amount of cytochrome *c* released from mitochondria after 1 and 5 min of Ca^{2+} retention in the presence and absence of 0.5 mM ADP or 1 mM Mg^{2+}. (**C**) Samples incubated under the same conditions as (A) were used to evaluate the rate of uncoupled respiration after 1 and 5 min. (**D**) Samples incubated under the same conditions as conditions as (B) were used to determine the effect of inhibitors of MPT on the rate of uncoupled respiration of Ca^{2+}-loaded mitochondria.

Incubation buffer for swelling

1.11 g/100 ml KCl (150 mM final)
6.8 mg/100 ml KH_2PO_4 (0.5 mM final)
60 mg/100 ml Tris (free base; 5 mM final)
135 mg/100 ml sodium succinate (5 mM final)
Adjust pH to 7.4 with HCl
Store up to 2 to 3 days at 4°C

Incubation buffer for testing mitochondrial quality

1.11 g/100 ml KCl (150 mM final)
13.1 mg/100 ml KH_2PO_4 (1 mM final)
60 mg/100 ml Tris (free base; 5 mM final)
Adjust pH to 7.4 with HCl
Store up to 3 to 4 days at 4°C

Incubation buffer for TPP^+-sensitive electrode

1.11 g/100 ml KCl (150 mM final)
27 mg/100 ml KH_2PO_4 (2 mM final)
60 mg/100 ml Tris (free base; 5 mM final)
135 mg/100 ml sodium succinate (5 mM final)
Adjust pH to 7.4 with HCl
Store up to 2 to 3 days at 4°C

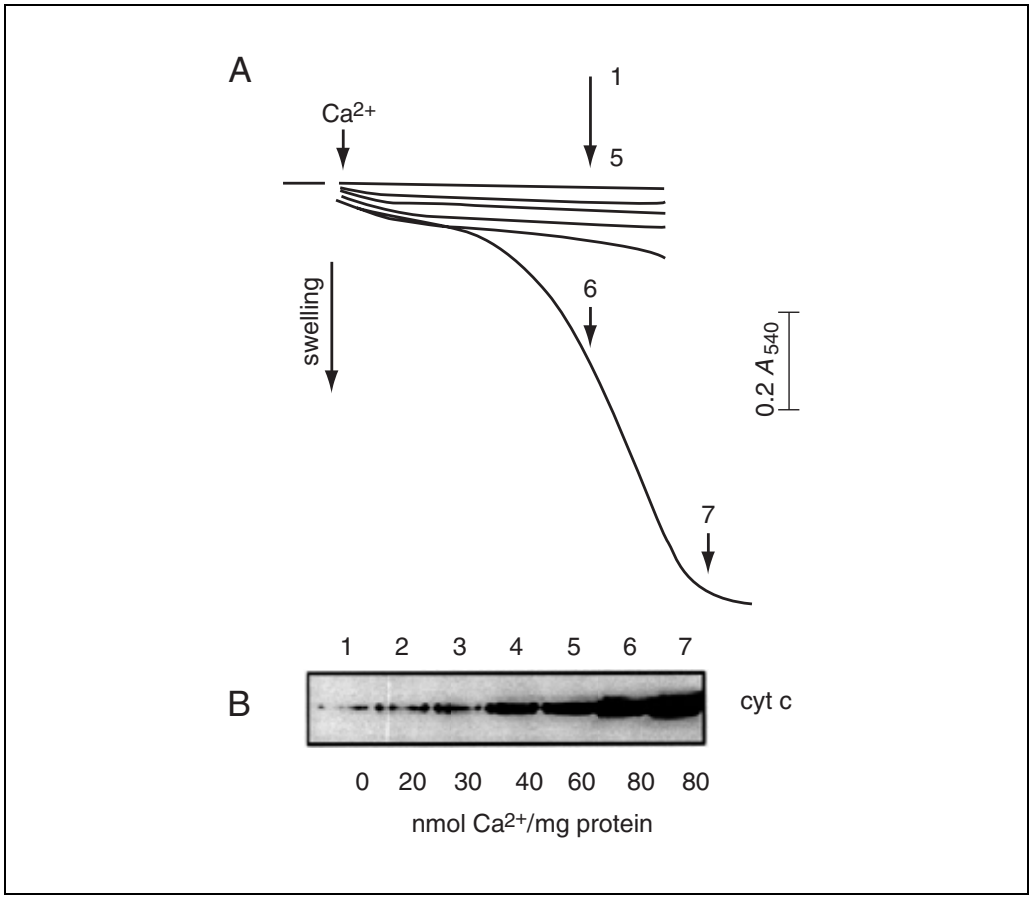

Figure 18.5.3 The effect of Ca^{2+} loading on mitochondrial swelling and the release of cytochrome *c*. Mitochondria (0.5 mg/ml) were incubated in 2 ml of KCl-based buffer. (**A**) Mitochondria were loaded sequentially with varied amounts of Ca^{2+} until MPT was induced. (**B**) Samples were taken after 5 min (lanes 1 to 6) or 8 min (lane 7) of incubation and the supernatants evaluated for cytochrome *c* content.

Laemmli's loading buffer, 4×

3.125 ml 1 M Tris·Cl, pH 6.8 (*APPENDIX 2A*)
4 ml glycerol
0.8 g sodium dodecyl sulfate
8 mg Bromphenol blue
0.8 ml 2-mercaptoethanol
H_2O to 10 ml
Store up to several weeks at 4°C

MSH buffer

210 mM mannitol
70 mM sucrose
5 mM HEPES
Adjust pH to 7.4 with KOH
Store up to 2 to 3 days at 4°C

S100 buffer

20 mM HEPES, pH 7.5
10 mM KCl
1.5 mM $MgCl_2$
1 mM EGTA
1 mM EDTA
0.1 mM PMSF
10 mg/ml leupeptin
5 mg/ml pepstatin A
2 mg/ml aprotinin
25 mg/ml calpain I inhibitor
1 mM DTT
Store at 4°C; prepare weekly

SET buffer

8.58 g/100 ml sucrose (0.25 M final)
0.5 ml of 100 mM potassium EGTA stock solution/100 ml (0.5 mM final)
120 mg/100 ml Tris (free base; 10 mM final)
Adjust pH to 7.4 with HCl

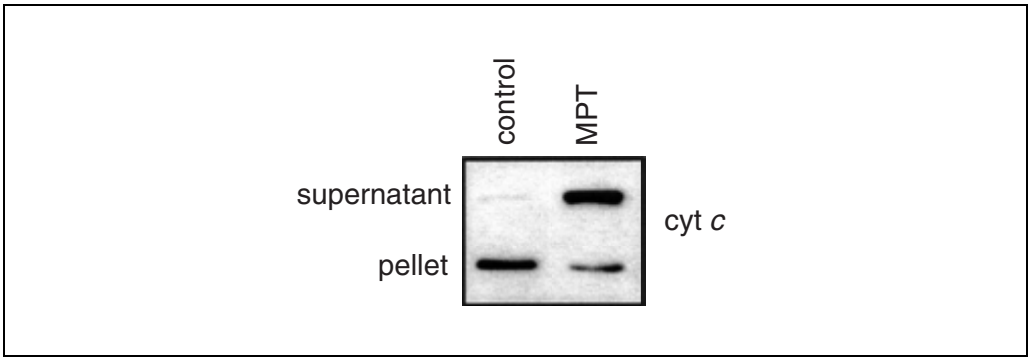

Figure 18.5.4 The release of cytochrome c from isolated rat liver mitochondria as a result of mitochondrial permeability transition (MPT). Mitochondria (1 mg/ml) were incubated in KCl-based buffer. After a 2-min stabilization period, mitochondria were loaded with Ca^{2+}, and, when accumulation was complete, MPT was induced by 5 mM KH_2PO_4. A 200-µl aliquot of mitochondrial suspension was centrifuged and the resulting supernatant and pellet were separated by SDS-PAGE and immunoblotted as described under in Basic Protocol 3. Control mitochondria were incubated for the same time but without Ca^{2+} loading.

COMMENTARY

Background Information

Mitochondrial function in apoptotic cells

Attempts to identify a common, unifying step in the apoptotic program, in response to various cytotoxic stimuli, have focused on the role of mitochondrial participation in this form of cell death (Petit et al., 1997). Specifically, the release of several proteins, normally located in the intermembrane space of mitochondria, has been observed during the early stages of apoptotic cell death (Green and Reed, 1998). Among these proteins are cytochrome *c* and other intermembrane-space proteins, including AIF (apoptosis-inducing factor), HSPs (heat shock proteins), DIABLO/Smac (direct IAP-binding protein with low pI/Second mitochondria-derived activator of caspase), AK-2 (adenylate kinase-2), several pro-caspases (Mancini et al., 1998; Köhler et al., 1999; Samali et al., 1999a; Susin et al., 1999; Zhivotovsky et al., 1999; Du et al., 2000; Verhagen et al., 2000), endonuclease G, and sulfite oxidase. Although the role of many of these proteins in the apoptotic process is well characterized, the involvement of others (AK-2, sulfite oxidase) is still unclear. It is important to note that the function of the released proteins in the cytoplasm is different from their functions within mitochondria. The best-studied of these proteins is cytochrome *c*.

Cytochrome *c*, is a component of the electron transport chain that shuttles electrons between complexes III (bc1) and IV (cytochrome oxidase). Apo-cytochrome *c* is encoded by a nuclear gene, synthesized in the cytosol, and imported into the mitochondrial intermembrane space in an unfolded configuration where it receives its heme group. Covalent attachment of this heme group stimulates a conformational change, and holo-cytochrome *c* subsequently assumes its functional role as a component of the electron transport chain.

During the early phase of apoptosis, cytochrome *c* is released into the cytosol and interacts with Apaf-1 to form the apoptosome complex together with dATP and pro-caspase-9 (Li et al., 1997).

The mechanisms regulating cytochrome *c* release remain obscure. However, two distinct models for cytochrome *c* release have emerged, and these can be distinguished on the basis of whether Ca^{2+} is required for the event. In one instance, mitochondrial Ca^{2+} overload results in opening of a pore in the inner mitochondrial membrane, with subsequent swelling and rupture of the outer membrane followed by the release of cytochrome *c* and other intermembrane space proteins (Crompton, 1999). The Ca^{2+}-independent model asserts that a more selective protein release occurs without changes in mitochondrial volume. This mecha-

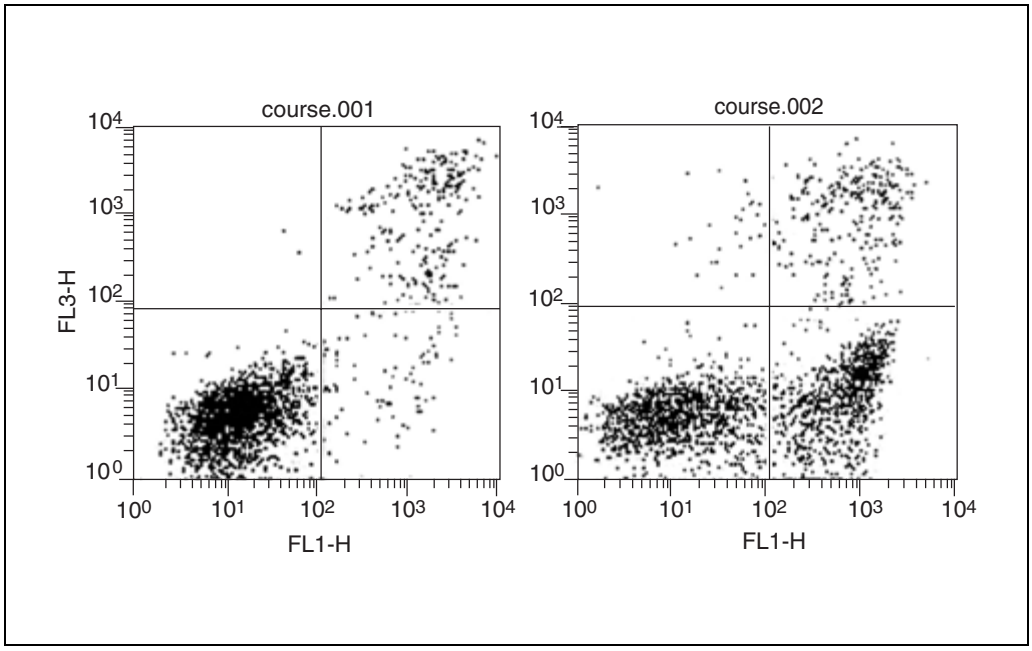

Figure 18.5.5 A typical image of FACS analysis of mitochondrial membrane potential in the cells undergoing apoptosis. Apoptosis was induced in Jurkat cells by 1 μM staurosporine and samples were analyzed 3 hr after initiation of apoptosis.

nism involves specific channels/pores in the outer mitochondrial membrane that may be opened and regulated by certain pro-apoptotic members of the Bcl-2 family of proteins, including Bax (Robertson and Orrenius, 2000). The precise manner in which Bax modulates cytochrome *c* release is controversial. In particular, the authors have reported recently that depending on the experimental conditions this protein can either act directly on mitochondria to stimulate the release of cytochrome *c* by forming a selective pore in the outer membrane, or it may facilitate opening of the permeability transition pore (Gogvadze et al., 2001). Recent evidence indicates that truncated Bid induces a conformational change in Bax that allows this protein to insert in the outer membrane, oligomerize, and stimulate cytochrome *c* release (Eskes et al., 2000).

Mitochondrial permeability transition

Energized mitochondria can take up and retain added Ca^{2+}. However this ability is not limitless. Mitochondria swell and become leaky; the membrane potential, which is the driving force for Ca^{2+} accumulation, drops, and accumulated Ca^{2+} is released. This process is called mitochondrial permeability transition (MPT). These changes are identified as a result of the opening of Ca^{2+}-dependent pore in the mitochondrial inner membrane.

MPT-dependent release of cytochrome c

Although the kinetics of MPT are unaffected by the composition of the incubation buffer (KCl versus MSH; Fig. 18.5.1A), the amount of cytochrome *c* released is much higher when mitochondria are incubated in the physiologically more relevant KCl buffer as compared to MSH buffer. Immunoblot analysis revealed that most cytochrome *c* was present in the supernatant fraction following MPT induction in KCl buffer, whereas only partial release of cytochrome *c* was observed in MSH buffer (Fig. 18.5.1B). Further evidence of this comes from the different effects that cytochrome *c* release has on mitochondrial respiration in the two buffers (Fig. 18.5.1C). Specifically, the induction of MPT in MSH buffer resulted in a time-dependent acceleration of oxygen consumption that persisted until all oxygen was consumed. In contrast, incubation of mitochondria in KCl buffer resulted in an initial acceleration of respiration that was followed by its suppression, and no additional stimulation of oxygen consumption was observed upon the addition of the uncoupler carbonyl cyanide *m*-chlorophenylhydrazone (CCCP). Taken together, these data indicate that while MPT-induced uncoupling of mitochondria occurs in both buffers, respiration is suppressed only in KCl buffer, an effect most likely due to a loss of cytochrome *c*.

It should be taken into account that mitochondrial preparations are heterogeneous. At a given concentration of Ca^{2+}, a certain subpopu-

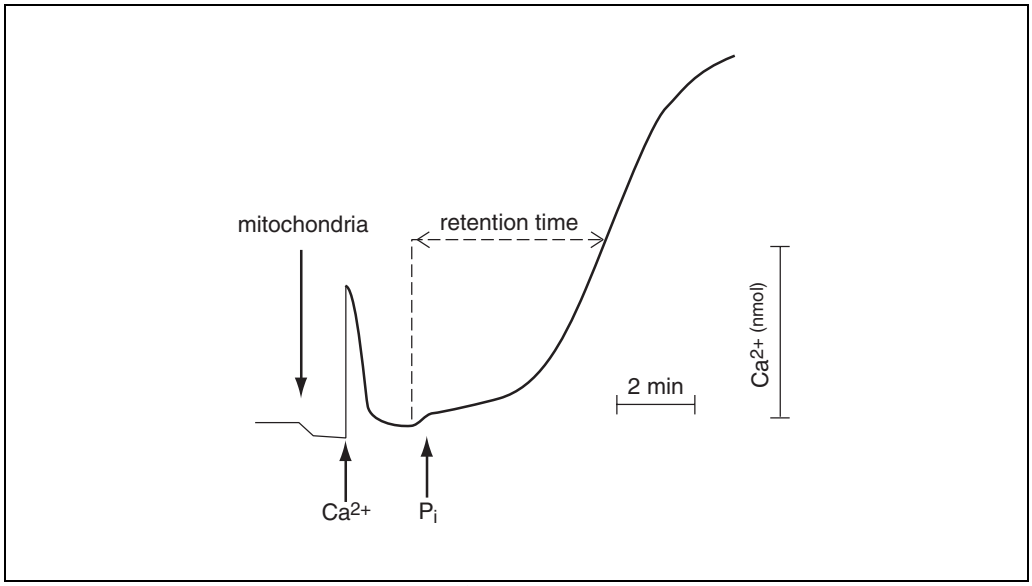

Figure 18.5.6 MPT monitored with a Ca^{2+}-sensitive electrode. Mitochondria (1 mg/ml) were incubated in KCl-based buffer. After a 1-min stabilization period, mitochondria were loaded with Ca^{2+}, and, when accumulation was complete, MPT was induced by 5 mM KH_2PO_4.

lation (more susceptible) of mitochondria have undergone permeability transition at a given time, while the released Ca^{2+} is accumulated by more resistant mitochondria, which thereby increase their load until they also undergo permeabilization (Zoratti and Szabo, 1995).

In the aforementioned protocols, cytochrome *c* release was a consequence of MPT induction, accompanied by swelling of mitochondria and rupture of the outer membrane. When Ca^{2+} loading is insufficient to induce observable manifestations of MPT, the release of cytochrome *c* can still occur despite the absence of changes characteristic of MPT.

As seen in Figure 18.5.2A, moderate Ca^{2+} loading of mitochondria did not induce MPT, and this cation was retained by mitochondria unless the uncoupler CCCP was added. The accumulation of Ca^{2+} by mitochondria in the absence of observable MPT was nevertheless sufficient to stimulate a release of cytochrome *c*, an effect that was considerably more pronounced the longer mitochondria retained the accumulated Ca^{2+}. Inhibitors of MPT, such as Mg^{2+} and ADP, suppressed this release (Fig. 18.5.2B). In addition, Ca^{2+}-loaded mitochondria exhibited controlled respiration (Fig. 18.5.2C), although increasing the Ca^{2+} retention time from 1 to 5 min prominently diminished the rate of CCCP-directed uncoupled respiration (upper trace versus versus lower trace). Inhibitors of MPT, such as Mg^{2+} and ADP, suppressed this release (Fig. 18.5.2D) and restored the rate of uncoupled respiration.

Additional evidence of cytochrome *c* release in the absence of observable MPT is presented in Figure 18.5.3A, where the sequential addition of Ca^{2+} pulses to isolated mitochondria led to a step-wise decrease in the overall optical density without the large-amplitude swelling characteristic of MPT. Meanwhile, the amount of cytochrome *c* released from mitochondria was enhanced as Ca^{2+} loading increased (Fig. 18.5.3B). This release reflected MPT induction in a subpopulation of mitochondria, which was further supported by the fact that cotreatment of isolated mitochondria with 1 μM CsA (cyclosporin A) eliminated cytochrome *c* release induced by Ca^{2+} additions ranging between 20 to 80 nmol/mg protein (data not shown). Cytochrome *c* release ultimately reached a pinnacle at 80 nmol Ca^{2+}/mg protein (Fig. 18.5.3B, lanes 6 and 7) as all mitochondria underwent MPT (Fig. 18.5.3A).

MPT-independent release of cytochrome c

Although it was originally believed that MPT induction was the root mechanism responsible for cytochrome *c* release in response to different cytotoxic stimuli, more recently this notion has been challenged and the precise mechanisms regulating the release of this pro-

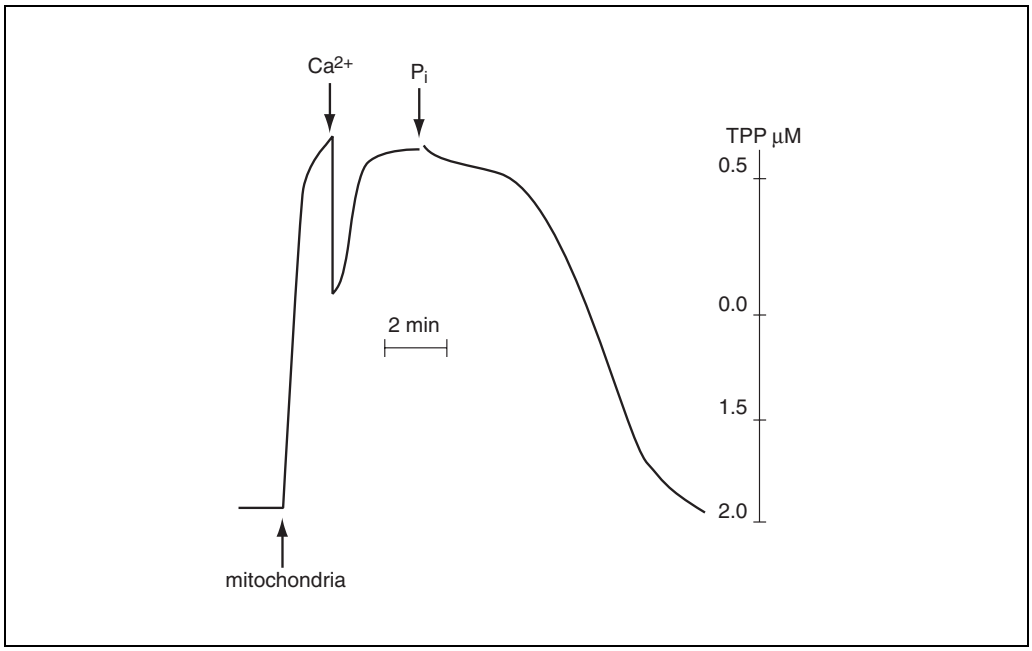

Figure 18.5.7 MPT monitored with a Δψ-sensitive electrode. Mitochondria (1 mg/ml) were incubated in KCl-based buffer. After a 1-min stabilization period mitochondria were loaded with Ca^{2+}, and, when accumulation was complete and potential was restored, MPT was induced by 5 mM KH_2PO_4. The concentration of TPP^+ was 2 μM.

tein are unclear. In fact, many of the early results on mechanisms of cytochrome *c* release were generated using cell-free systems wherein isolated mitochondria and nuclei were treated with different MPT pore activators, which, in turn, led to mitochondrial swelling, the release of cytochrome *c* (and other proteins), and subsequent changes in nuclear morphology that were characteristic of apoptosis. However, ample evidence from more recent studies suggests that, while MPT is likely to be a mechanism responsible for cytochrome *c* release, it is no longer regarded as *the* mechanism.

In case of MPT induction, mitochondrial swelling leads to a rupture of the outer membrane; without MPT, permeabilization can be achieved by Bcl-2 family proteins Bax or Bid that form pores in the outer membrane, leaving the inner mitochondrial membrane intact.

Discrimination between MPT-dependent and MPT-independent release of cytochrome c

While analyzing the release of cytochrome *c* from mitochondria, one should keep in mind that even without added Ca^{2+}, MPT may occur in a subpopulation of mitochondria if the trace amount of Ca^{2+} in buffers is enough to induce MPT in "susceptible" mitochondria. Therefore the release of cytochrome *c* observed in the absence of added Ca^{2+} can be mistaken for MPT-independent release of cytochrome *c*. In order to distinguish between the MPT-dependent and -independent release of cytochrome *c*, experiments should be performed in the presence of the Ca^{2+} chelator EGTA, which sequesters Ca^{2+} and therefore prevents MPT induction. Similar results can be achieved with CsA.

Critical Parameters and Troubleshooting

Collecting released proteins (Basic Protocols 1 and 2)

Separation of the mitochondria from the supernatant should be done thoroughly. Aliquots of supernatant should be taken without disturbing the pellet.

Immunoblot analysis of released proteins (Basic Protocol 3)

For immunoblot analysis, too many bands on the membrane may indicate too high a concentration of primary and/or secondary antibodies. If the background of nonspecific binding of immunological probes is unacceptably high, increase the length of the time of washing with PBS. If there is no band on the film, increase the duration of incubation with primary antibodies. If a white spot on the film makes it difficult to detect the protein band of interest, a bubble may have been introduced during blotting and the whole procedure must be repeated. If a band on the film is too strong, decrease exposure time of X-ray film to the ECL-stained membrane. If the gel runs too fast

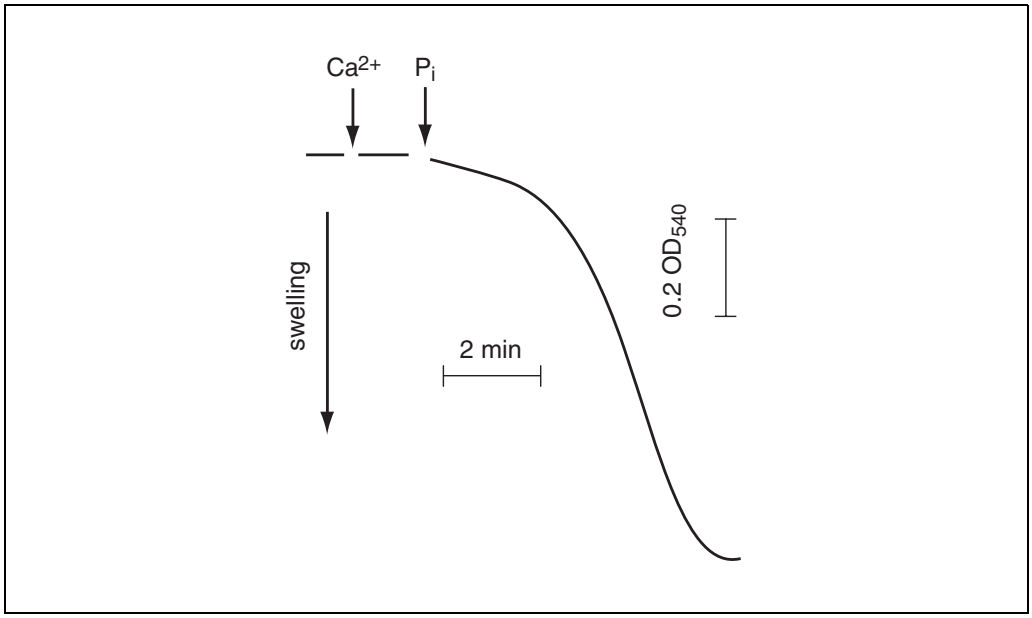

Figure 18.5.8 MPT assessed by mitochondrial swelling. Mitochondria (0.5 mg/ml) were incubated in 2 ml of KCl-based buffer. Mitochondria were loaded with Ca^{2+} and 5 mM phosphate was added. Swelling was monitored by a decrease of optical density at 540 nm.

or too slow and poor resolution of protein occurs, decrease or increase voltage, respectively, or check the buffer recipe. If no prestained markers appear on the nitrocellulose filter, check the transfer buffer recipe, or reposition the location of gel towards the cathode and anode.

FACS analysis of TMRE-stained cells (Basic Protocol 4)

FACS analysis needs an appropriate gating of the cells—a selection of the population of interest, especially if the initial population is a mixture of different types of cells (for example when blood samples are analyzed).

Another critical parameter is time. The analysis of the membrane potential should be done shortly after staining of the cells. TMRE is only accumulated by mitochondria with high membrane potential and any delay in analysis may negatively affect the functional state of the mitochondria and therefore cause leakage of the dye.

Microscopy of apoptotic cells stained with MitoTracker Red (Basic Protocol 5)

To reduce potential artifacts from overloading, the concentration of dye should be kept as low as possible. However if cells are not sufficiently stained, the concentration of dye or time of incubation should be increased.

Measurement of calcium release and membrane potential (Basic Protocols 6 and 7)

The release of Ca^{2+} from mitochondria may result not from opening of the pore, but simply because of a drop of the membrane potential. This may happen, for instance, if the mitochondria consume all available oxygen. However at a mitochondrial protein concentration of 1 mg/ml (or less), and with rapid stirring of the suspension, MPT usually occurs before the exhaustion of oxygen. If higher concentrations of mitochondrial suspension are used, possible anaerobiosis can be prevented by fine flow of oxygen blown onto the surface of the suspension.

Mitochondrial swelling (Basic Protocol 8)

Mitochondrial swelling assessed by a decrease in optical density of mitochondrial suspension represents one of the most reliable parameters of MPT induction in isolated mitochondria. However it should be kept in mind that anaerobiosis and subsequent release of accumulated Ca^{2+} due to the drop in membrane potential may prevent pore opening and terminate swelling. Anaerobiosis can be prevented by a fine flow of oxygen blown onto the surface of the suspension. On the other hand, a relatively low concentration of mitochondria (up to 1 mg/ml) should not lead to anaerobiosis.

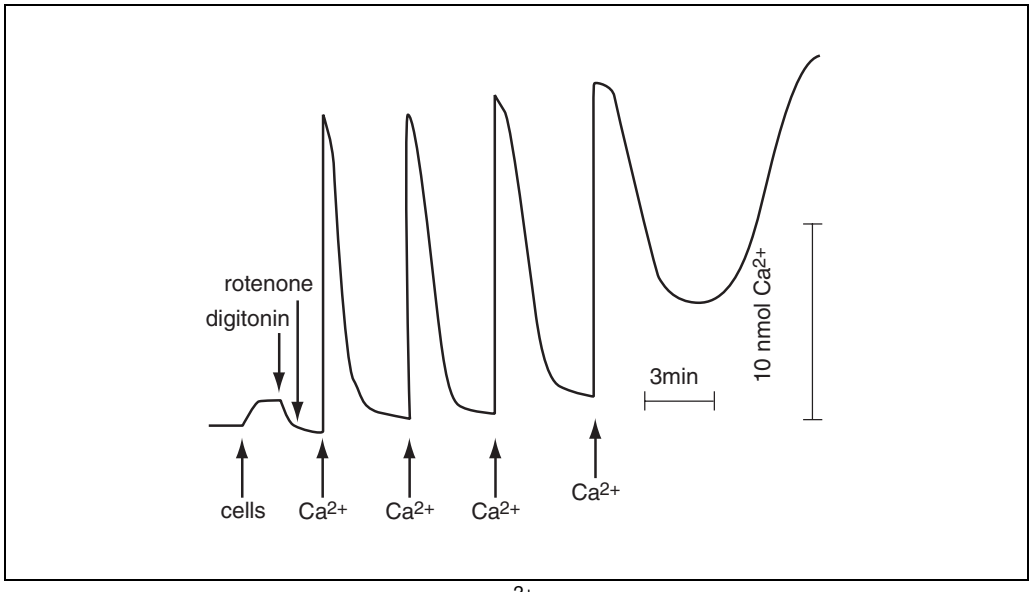

Figure 18.5.9 Estimation of mitochondrial Ca^{2+}accumulation in digitonin-permeabilized cells. Jurkat cells (2.5×10^6) were washed in PBS, resuspended in 500 µl of KCl-based buffer, and added to the incubation chamber. Following a 2-min stabilization period, cells were permeabilized with 0.005% digitonin, and 5 µM rotenone was added in order to maintain pyridine nucleotides in a reduced form. MPT was induced by sequential additions of $Ca^{2+}$and changes in the level of this cation were monitored using a Ca^{2+}-selective electrode.

Estimation of mitochondrial Ca^{2+} accumulation in digitonin-permeabilized cells (Basic Protocol 9)

Digitonin generally permeabilizes plasma membrane, which contains cholesterol; therefore, this detergent should be used with caution because relatively high concentrations of digitonin can affect also the outer mitochondrial membrane. The minimal concentration of digitonin that is necessary for the outer-membrane permeabilization can be detected with a Ca^{2+}-sensitive electrode. Cells do not accumulate added Ca^{2+}, since plasma membrane is permeable neither to Ca^{2+} nor to succinate, oxidation of which provide a driving force for Ca^{2+} accumulation. Upon addition of digitonin, the plasma membrane becomes permeable and the mitochondria start to accumulate Ca^{2+} from the incubation buffer.

Preparation of mitochondria (Support Protocols 1, 2, and 3)

The temperature during isolation should be kept around 4°C. Elevation of the temperature may result in activation of catabolic enzymes, in particular, mitochondrial phospholipase A_2, which leads to accumulation of free fatty acids in mitochondria. Free fatty acids are known as natural protonophores (agents that facilitate transport of protons through membrane); therefore, accumulation of fatty acids will decrease the mitochondrial membrane potential and destabilize mitochondria.

Anticipated Results

Analyzing functioning of isolated mitochondria and mitochondria in apoptotic cells: collection of released proteins and immunoblot analysis (Basic Protocols 1, 2, and 3)

Depending on the mechanisms involved in the release of cytochrome *c* or other proteins from mitochondria, the final result will be different. If the release was associated with mitochondrial swelling and the rupture of the outer membrane, most of the cytochrome *c* will be found in the supernatant after sedimentation of mitochondria. In such a situation, it would be informative also to present the data concerning changes in the content of cytochrome *c* in the pellet. Figure 18.5.4 represents a typical blot showing the release of cytochrome *c* from isolated liver mitochondria upon induction of MPT in KCl-based buffer.

FACS analysis of TMRE-stained cells (Basic Protocol 4)

A typical image of FACS analysis of mitochondria in the cells undergoing apoptosis is present in Figure 18.5.5. The lower left quadrant contains living cells, the lower right, apoptotic cells, and upper right, necrotic cells.

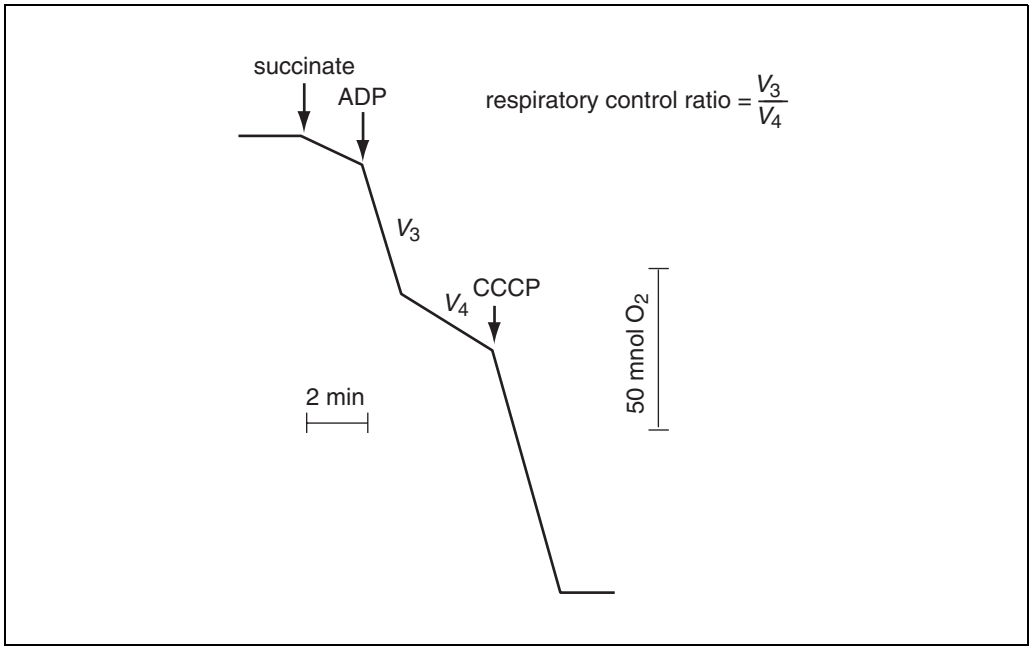

Figure 18.5.10 Estimation of mitochondrial respiration as described in Support Protocol 4.

Measurement of calcium release (Basic Protocol 6)

A typical response of mitochondria to Ca^{2+} is shown in Figure 18.5.6. Addition of Ca^{2+} to isolated mitochondria results in a quick rise in the basal level of Ca^{2+} in the incubation buffer, followed by restoration of the initial level due to accumulation of Ca^{2+} in mitochondria, whereupon a new steady state is reached. After addition of phosphate, mitochondria start releasing accumulated Ca^{2+}. The lag time before the onset of MPT induction, as well as the rate of release, depend on the Ca^{2+} load. If Ca^{2+} and other conditions are held constant, the effect of phosphate on MPT induction is dose-dependent. Therefore, the opening of the pore can be modulated either by varying the Ca^{2+} concentration while keeping the concentration of phosphate constant, or by varying the concentration of phosphate.

Both methods (spectrophotometric and ion-selective electrodes) are equally sensitive, and the choice is dictated by the availability of the equipment.

Measurement of membrane potential (Basic Protocol 7)

Energized mitochondria rapidly accumulate TPP^+ from the incubation buffer and release this cation as $\Delta\psi$ decays. A typical change in mitochondrial membrane potential upon MPT induction is shown on Figure 18.5.7. As can be seen in that figure, upon induction of MPT, two distinct phases of decrease in membrane potential occur. First, a relatively slow decrease starts when an MPT-inducing agent (P_i) is added, which is followed by a second, rapid phase, which reflects the induction of MPT in the whole population of mitochondria.

Measurement of mitochondrial swelling (Basic Protocol 8)

Figure 18.5.8 shows a typical example of results from measurement of mitochondrial swelling. When mitochondria are added to incubation buffer at a concentration of 0.5 mg/ml, the initial light absorption at 540 nm is about 1.3 to 1.4. Addition of Ca^{2+} to the mitochondria, followed by inorganic phosphate, results in a time-dependent decrease in the optical density (OD) of the mitochondrial suspension.

Estimation of mitochondrial Ca^{2+} accumulation in digitonin-permeabilized cells (Basic Protocol 9)

The addition of Ca^{2+} to a permeabilized cell suspension leads to a rapid increase in the level of this cation in the reaction buffer, followed by a return to the initial level as mitochondria accumulate the excess Ca^{2+} (Fig. 18.5.9); this is an effect that can be completely abrogated by 2 μg/ml antimycin, an inhibitor of mitochondrial respiratory chain (data not shown). Mitochondria accumulate sequential additions of Ca^{2+} until MPT is induced and the accumulated Ca^{2+} is released.

Preparation of mitochondria and assessing their quality (Support Protocols 1 to 4)

Isolation of mitochondria usually takes about 60 to 75 min. For liver the yield is about 20 to 25 mg protein of mitochondria per 1 g of tissue. High concentration of the final mitochondrial preparation is a prerequisite of mitochondrial stability.

A typical respiratory response of mitochondria and the method of calculating RCR are shown in Figure 18.5.10. Addition of CCCP when added ADP is phosphorylated and state 4 respiration is stabilized allows one to determine the rate of uncoupled respiration that represents the activity of the mitochondrial respiratory chain.

Time Considerations

The time of collecting samples and preparing for immunoblotting depends on the incubation conditions as well as the experience of a researcher. Basic Protocol 1 requires 45 to 60 min, Basic Protocol 2, 2 to 2.5 hr, and Basic Protocol 3, 2 days. TMRE (Basic Protocol 4) and MitoTracker Red (Basic Protocol 5) staining takes 1 hr and 1.5 hr, respectively. Measurement of the mitochondrial permeability transition (Basic Protocols 6, 7, 8, and 9 and Alternate Protocols 1 and 2) can be completed in 5 to 20 min.

Mitochondrial preparation (Support Protocols 1, 2, and 3) takes 60 to 80 min. Assessment of respiratory control ratio takes 20 to 35 min.

Analysis of Telomeres and Telomerase

This unit describes techniques to analyze telomeric length (Basic Protocol 1) and telomerase activity (Basic Protocol 2) in human cells. These assays can be used to study the in vitro cellular effects of aging and cancer treatments on telomere biology and telomerase activity.

Telomere length can be determined by a modification of Southern blotting in which the analysis of chromosome terminal restriction fragments (TRFs), as visualized with a radiolabeled telomeric repeat probe (Support Protocols 2 and 3), provides the average lengths of all telomeres in a cell population. A labeled molecular weight marker (Support Protocol 1) is used to determine telomere length.

Telomerase activity can be measured in vitro by a sensitive and efficient polymerase chain reaction (PCR)–based detection method, also known as telomeric repeat amplification protocol (TRAP). This method can use either radiolabeled or fluorescently labeled (Alternate Protocol) primers. Support Protocol 4 describes the preparation of tissue samples for TRAP; the preparation of other reagents that are needed for TRAP are described in Support Protocols 5 and 6.

CAUTION: When working with radioactivity, take appropriate precautions to avoid contamination of the experimenter and surroundings. Carry out the experiments and dispose of wastes in appropriately designated area, following guidelines provided by the local radiation safety officer (also see *APPENDIX 1D*).

TERMINAL RESTRICTION FRAGMENT SIZE DETERMINATION TO MEASURE AVERAGE TELOMERE LENGTHS

BASIC PROTOCOL 1

The simplified method for isolating DNA described below was developed in the authors' laboratory to efficiently process a large number of samples by eliminating phenol/chloroform extractions and avoiding alcohol precipitation. Because there are no steps where significant losses can occur, DNA concentrations can be calculated based on initial cell numbers, a more reproducible method than optical density measurements, which are frequently distorted by contaminating RNA. The measurement of telomere length relies on the absence of restriction enzyme recognition sites within the TTAGGG tandem repeat sequences. The length of telomeric repeats can be indirectly measured by analyzing the length of the terminal restriction fragment (TRF), the large DNA fragments remaining after the rest of the genomic DNA has been reduced to small sizes by digestion with frequent cutters (restriction enzymes with recognition sequences of four bases, such as *Hin*fI). There is also a region of mostly repetitive subtelomeric DNA, probably ranging from 2 to 5 kb in length in humans, that lacks functional restriction sites and contributes to the measured size of telomeres on gels. The DNA is probed with a labeled oligonucleotide containing TTAGGG repeats. The measured size of the TRF corresponds to the sum of the sizes of the subtelomeric DNA that lacks functional restriction sites and the length of the telomere repeats. Because small oligonucleotides easily penetrate dried agarose gels, it is more rapid and convenient to perform in-gel hybridization rather than Southern blot transfers.

Materials

Cell pellet from ≥300,000 cells and appropriate medium
Quick-prep lysis buffer (see recipe)
Triton X-100
20 mg/ml proteinase K

Contributed by Brittney-Shea Herbert, Jerry W. Shay, and Woodring E. Wright
Current Protocols in Cell Biology (2003) 18.6.1-18.6.20

TE buffer, pH 7.5 to 8.0 (*APPENDIX 2A*)

Restriction enzyme mix: equal volumes of *Hin*fI, *Rsa*I, *Msp*I, *Cfo*I, *Hae*III, and *Alu*I restriction enzymes (Boehringer Mannheim; 10 U/µl each before mixing, final 1.67 U/µl each)

10× TAE buffer (*APPENDIX 2A*)

10× TBE buffer (*APPENDIX 2A*)

10,000 cpm radiolabeled molecular weight markers mixed with ≥500 ng unlabeled, *Sty*I-digested λ DNA (or other appropriate unlabeled, digested DNA; see Support Protocol 1)

Denaturing solution: 0.5 M NaOH/1.5 M NaCl

Neutralizing solution: 1.5 M NaCl/0.5 M Tris·Cl, pH 8.0 (see *APPENDIX 2A* for Tris·Cl)

Hybridization solution (see recipe)

Radiolabeled telomeric repeat probe (see Support Protocols 2 and 3)

20× SSC (see recipe)

0.1× SSC/0.1% (w/v) SDS

2-ml polypropylene screw-cap tubes (Sarstedt) with an optional extra set of screw caps to be cut vertically with jigsaw to form open screw-cap ring (Fig. 18.6.1A)

37°, 55°, and 70°C water baths heating blocks, or PCR machine

Dialysis membrane sheets or tubing (e.g., Spectra/Por; Spectrum), molecular weight cutoff (MWCO) ≥6000 to 8000

Wide-bore pipet tips

Whatman 3MM filter paper

Hybridization oven, 42°C, and appropriate hybridization containers, or equivalent

PhosphorImager, including phosphor screens and ImageQuant software (Molecular Dynamics)

Additional reagents and equipment for agarose gel electrophoresis (*APPENDIX 3A*)

Lyse cells

1. Resuspend cell pellet from ≥300,000 trypsinized cells in medium and pellet cells in a 2-ml polypropylene screw-cap tube. Remove supernatant and freeze pellet at −80°C or proceed to next step.

   It is not necessary to wash cells with phosphate-buffered saline (PBS), as the small amount of medium in the cell pellet does not interfere with subsequent steps. At least 300,000 cells should be used; however, the collection of more cells is desirable (~3 million).

   Cell pellets can simply be placed at −80°C; it is not necessary to snap-freeze them.

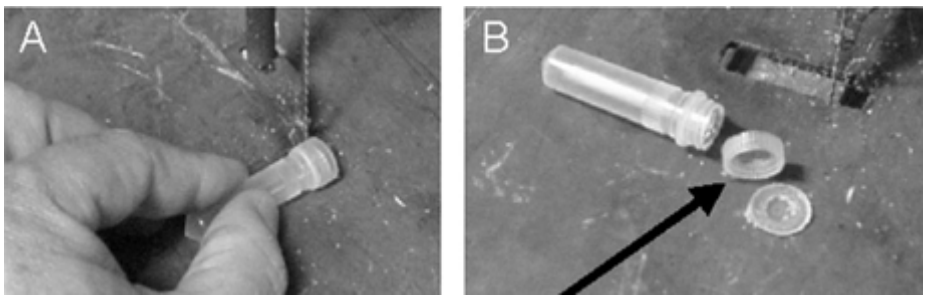

Figure 18.6.1 Construction of the dialysis tube for the terminal restriction fragment (TRF) protocol (see Basic Protocol 1). Large numbers of these open-ended caps can easily be prepared as follows. (**A**) Screw the caps onto a tube so that the tube functions as a handle and cut off the end of the cap using a jigsaw. (**B**) The threads of the cap are attached as a ring on the tube (arrow). These rings are reusable as tube closures.

2. Thoroughly resuspend cell pellet (fresh or just after thawing from −80°C) in quick-prep lysis buffer, using 30 µl per million cells.

   100 mM EDTA is used in the lysis buffer to very rapidly inhibit nucleases in these concentrated cell suspensions. The lysis buffer should be added immediately to cells as they are thawing on ice to prevent nucleases from degrading the DNA.

3. Add Triton X-100 to 1% (v/v) final concentration and 20 mg/ml proteinase K to 2 mg/ml final concentration.

   Triton X-100 rather than SDS is used so that residual detergent present after dialysis does not inhibit digestion with restriction enzymes.

4. Incubate samples ≥2 hr at 55°C and inactivate proteinase K by heating 30 min at 70°C.

   Heat inactivation of proteinase K avoids the need to phenol/chloroform extract the DNA, and the residual protein present after dialysis does not inhibit enzyme digestion.

   After digestion with proteinase K, DNA should only be handled using wide-bore tips to prevent shearing of the DNA.

Dialyze sample

5a. *To dialyze sample in screw-cap tube:* Place a 1- to 2-cm^2 piece of dialysis membrane over top of tube and secure with an open screw-cap ring. Invert tube, making sure that sample (and not a bubble) is at the membrane, and place on floating rack in ≥200 vol TE buffer (Fig. 18.6.2). Dialyze 1 to 2 hr at 4°C with constant stirring.

   For larger volumes (>0.3 ml for >10 million cells), conventional dialysis (step 5b) can be used.

   Dialysis reduces salt and EDTA so that digests will not be inhibited later on.

5b. *To dialyze sample in dialysis tubing:* Wet dialysis tubing with distilled water and clip one end shut. With a wide-bore pipet tip, carefully collect sample and place in tubing without creating bubbles. Smooth any bubbles out and clip the other end shut, leaving room for buffer exchange and volume expansion. Place tubing in ≥200 vol TE buffer and dialyze 1 to 2 hr at 4°C with constant stirring.

   Dialysis reduces salt and EDTA so that digests will not be inhibited later on.

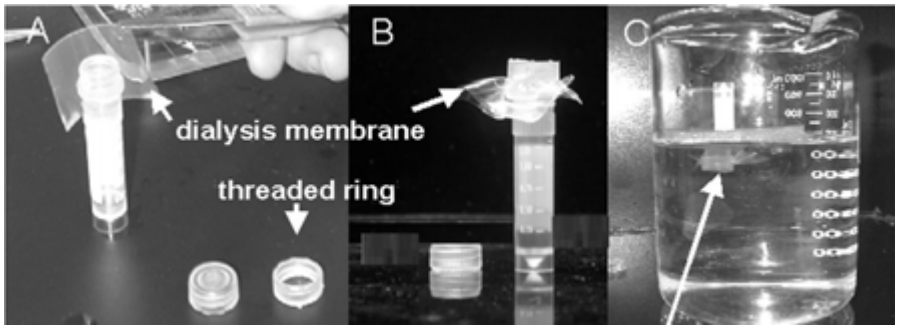

Figure 18.6.2 Assembly of the dialysis tube for the terminal restriction fragment (TRF) protocol (see Basic Protocol 1). (**A**) A wet 1- to 2-cm^2 piece of dialysis membrane is placed on the tube containing the sample (save the original screw cap). (**B**) An open-end screw cap (threaded rings) is carefully threaded on the tube over the membrane without tearing. (**C**) The tube (arrow) is inverted and placed in a floating rack in 1× TE buffer. There should be no droplets remaining on the walls of the tube and no bubbles on the membrane when inverted, as this will prevent dialysis.

6. Change buffer to ≥200 vol fresh TE buffer and dialyze samples overnight at 4°C with constant stirring.

7. Discard dialysis membrane, replace threaded ring with a closed cap, and save threaded rings for re-use. Alternatively, remove sample from dialysis tubing and place in a fresh tube. Calculate the DNA concentration.

   DNA concentration is calculated at 6 μg/10^6 diploid cells or 10 μg/10^6 aneuploid cells divided by the final volume after dialysis. The samples should be viscous and they can now be stored for 1 year at 4°C (or for ≥1 year at −20°C) until they are digested.

Digest and electrophorese DNA

8. Digest 1 μg DNA to completion for 4 hr to overnight at 37°C with ≥1 U/μg restriction enzyme mix.

   The six enzymes ensure that genomic DNA, but not telomeric DNA, is digested. The authors generally use 1 μl enzyme mix/1 μg DNA (1.67 U each enzyme/μl) with 1× buffer A (supplied with the enzyme; Boehringer Mannheim).

9. Separate digested DNA on a 0.7% (w/v) agarose gel stained with ethidium bromide (0.5 μg/ml) for 16 hr at 70 V for a 25-cm-long gel in 1× TAE or 0.5× TBE buffer. Load 20,000 cpm radiolabeled molecular weight markers mixed with ≥250 ng unlabeled, *Sty*I-digested λ DNA on either side of the samples.

   0.5× TBE can be used to analyze telomeres less than ~8 kb, whereas 1× TAE buffer allows for better separation in the 8- to 20-kb range. The gel should be handled carefully as it may be fragile. Electrophoresis should be stopped temporarily before the <1-kb molecular weight markers migrate off the gel to document complete digestion of the DNA by photographing the gel. Actual time and voltage varies with each power supply and gel apparatus. Digested DNA will run as a smear below the 1-kb molecular weight marker. Anything above this size is incompletely digested. If the sample is not digested completely, it is usually sufficient to use an additional 1 μl enzyme mix for a longer amount of time. If the sample is completely undigested, the viscous sample may have floated up out of the well when the gel was loaded. Electrophoresis (at higher voltage) should be continued until the 1- to 1.5-kb marker is near the bottom of the gel.

   Radiolabeled molecular weight markers will allow the markers to be seen after hybridization with the telomere sequence–specific probe. The unlabeled, digested λ DNA is included so the markers can be visualized with ethidium bromide after electrophoresis.

Hybridize DNA

10. Denature gel 20 min in enough denaturing solution to cover the gel, rinse 10 min in distilled water, and dry gel upside down (so that the openings of the wells are against the paper) on two sheets of Whatman 3MM filter paper under vacuum for 1 hr at 50°C.

    Denaturing the DNA before rather than after drying the gel increases the signal intensity ~3- to 5-fold, presumably by permitting a much greater diffusion of the denatured DNA strands in the 0.7% agarose gel than in the very high percentage dried and rehydrated gel, and thus inhibiting the reannealing of the parental strands, which would compete with the probe.

    Rinsing with distilled water gets rid of the NaOH and substantially reduces sticking of the gel to the Whatman paper. Some loss of lower-molecular-weight DNA (particularly <400 bp) occurs during drying.

    Because most of the DNA samples do not fill the wells and are thus in the bottom half of the gel, the gels are flipped and dried with the upper surface against the filter paper support. This increases the distance between the DNA samples and the filter paper, and significantly reduces the loss of lower-molecular-weight DNA.

11. Neutralize gel 10 to 15 min in enough neutralizing solution to cover the gel, rinse 10 min in distilled water.

12. Prehybridize gel ≥10 min with 10 ml hybridization solution.

13. Hybridize gel overnight at 42°C in hybridization solution containing all of the radiolabeled telomeric repeat probe made in Support Protocol 2.

    The volume of the hybridization solution used depends on the gel size and hybridization setup. For a 20 × 25–cm gel rotating inside a glass cylinder in a hybridization oven, 10 ml is sufficient.

    Using DNA polymerase fill-in of uracil-containing templates (see Support Protocol 3) results in a probe with higher specific activity.

14. Wash gel 15 min at room temperature in 2× SSC and then one to three times for 10 min each in 0.1× SSC/0.1% SDS at room temperature. Expose gel ≥4 hr to a phosphor screen and then scan with a PhosphorImager and visualize using ImageQuant software.

    The number of washes can be adjusted as needed. Two 15-min washes with 0.1× SSC are generally sufficient.

15. Calculate mean TRF lengths from PhosphorImager scans of gels hybridized to the telomeric repeat probe. Position a grid of 30 boxes over each lane and determine the signal intensity and size (kb) corresponding to each box. Calculate the mean TRF length as the weighted mean using the following formula: $\Sigma(OD_i)/\Sigma(OD_i/L_i)$, where OD_i is the PhosphorImager output (signal intensity) and L_i is the length of the DNA at position *i*. Calculate sums over the range of the molecular weight marker used in the hybridized gel.

    TELORUN, a program that performs these calculations, is available (see Internet Resource).

MAKING A LABELED MOLECULAR WEIGHT MARKER FOR RUNNING ON AN AGAROSE GEL

SUPPORT PROTOCOL 1

Running a radiolabeled molecular weight marker on either side of the gel allows for quantitation of the telomere lengths.

Materials

~250 ng/µl DNA molecular weight marker (e.g., λ DNA digested with *Sty*I)
10× React 2 buffer (Roche)
100 µM dAGT mix: 100 µM each dATP, dGTP, dTTP in H_2O, stored up to 1 year at −20°C
[α-^{32}P]dCTP (3000 Ci/mmol)
2 U/µl Klenow fragment of *E. coli* DNA polymerase I
QIAquick nucleotide removal kit (Qiagen)

1. In a tube, mix the following:

   10 µl of ~250 ng/µl DNA molecular weight marker
   2 µl of 10× React 2 buffer
   5 µl of 100 µM dAGT mix
   5 µl [α-^{32}P]dCTP
   1 µl of 2 U/µl Klenow fragment

   Incubate 30 min at 37°C.

   The authors use Roche React 2 buffer because it is the same buffer used to digest the λ DNA with StyI. Any other buffer compatible with the Klenow fragment of DNA polymerase can be used.

2. Remove unincorporated label with QIAquick nucleotide removal kit.
3. Determine the cpm of the radiolabeled marker using a scintillation counter.

SUPPORT PROTOCOL 2

MAKING KINASED RADIOLABELED TELOMERIC REPEAT PROBE

Empirically, the G-rich probe tends to have higher signals, for unknown reasons, but both probes work reasonably well. G-rich probes generally give about 2-fold better signals than C-rich probes (probably due to possible G-quartet formation by the target G-strands which inhibits hybridization), so making a G-rich probe with 3000 Ci/mmol radioisotope is recommended if maximum sensitivity is needed.

Materials

$(T_2AG_3)_4$ or $(C_3TA_2)_4$ oligonucleotide (20 pmol/µl or 0.16 µg/µl)
[γ-^{32}P]ATP (3000 Ci/mmol)
5× forward or exchange reaction buffer (GIBCO/BRL)
10 U/µl T4 polynucleotide kinase (GIBCO/BRL)
QIAquick nucleotide removal kit (Qiagen)

1. In a tube, mix the following:

   2 µl $(T_2AG_3)_4$ or $(C_3TA_2)_4$ oligonucleotide
   24 µl [γ-^{32}P]ATP
   10 µl of 5× forward reaction buffer
   12 µl H_2O
   2 µl T4 polynucleotide kinase.

   Incubate 30 min at 37°C.

2. Remove unincorporated label with QIAquick nucleotide removal kit (Qiagen).
3. Determine the cpm of the radiolabeled marker using a scintillation counter (≥5000 cpm/µl). Store <2 weeks at −20°C.

SUPPORT PROTOCOL 3

SYNTHESIS OF A HIGH–SPECIFIC ACTIVITY TELOMERIC REPEAT PROBE

In this protocol, the template oligonucleotide contains uracils so that it can be degraded later with uracil deglycosylase, thus leaving a single-stranded probe. The template also contains a small mismatch at one end (GGGAAA rather than GGGTTA), so that the priming oligonucleotide will preferentially anneal in the correct spot rather than anywhere along the template. The template, GTU4, is an oligonucleotide of four G-rich telomeric repeats with uracil. The oligonucleotide T3C3+9 begins with TTTCCC followed by nine nucleotides of correct telomeric sequence. The annealed product of these two oligonucleotides is shown in Figure 18.6.3. Thus, six cytosines will be incorporated per synthesized product. If 50 µCi of [α-^{32}P]dCTP (3000 Ci/mmol) is used, then one has 16.7 pmol of [α-^{32}P]dCTP available. Assuming the target is to incorporate 10 pmol so that one gets mostly full-length products, then 1.7 pmol of annealed target is needed. In general, the efficiency of incorporation is so high that it should not be necessary to remove unincorporated dCTP. If desired, one can use plug dialysis on 20% (w/v) acrylamide. The authors currently use [α-^{32}P]dCTP as the radioisotope because they routinely have it on hand. G-rich probes generally give about 2-fold better signals than C-rich probes (probably because of possible G-quartet formation by the target G-strands, which inhibits hybridization), so making a G-rich probe with 3000 Ci/mmol radioisotope is recommended if maximum sensitivity is needed.

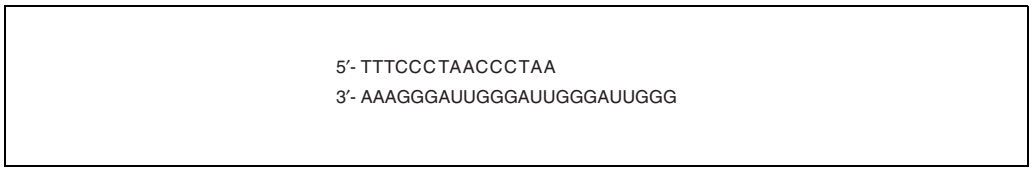

Figure 18.6.3 Annealed priming and template oligonucleotides for synthesis of a high–specific activity telomeric repeat probe. The template contains a small mismatch at its 3′ end (GGGAAA rather than GGGTTA) so the priming oligonucleotide will anneal in the correct spot.

Materials

10 pmol/µl GTU4 oligonucleotide dissolved in TE buffer:
5′-GGGUUAGGGUUAGGGUUAGGGAAA-3′
100 pmol/µl T3C3+9 oligonucleotide dissolved in TE buffer:
5′-TTTCCCTAACCCTAA-3′
1 M NaCl
10× buffer M: 10 mM Tris·Cl (pH 7.5)/10 mM $MgCl_2$/50 mM NaCl/1 mM dithioerythritol (DTE; Roche)
2 M Tris·Cl, pH 7.4 to 7.6 (*APPENDIX 2A*)
10 mg/ml BSA (e.g., Ambion)
1.25 mM dAdT: 1.25 mM each of dATP and dTTP
[α-^{32}P]dCTP (3000 Ci/mmol)
5 U/µl Klenow large fragment of *E. coli* DNA polymerase I
1 U/µl uracil deglycosylase (UDG)

37°, 95°, and 99°C water baths heating blocks, or PCR machines
PhosphorImager, including phosphor screens (Molecular Dynamics)

Additional reagents and equipment for DNA acrylamide gel electrophoresis (*APPENDIX 3A*)

1. To make 1.7 pmol/µl annealed template oligonucleotide stock, mix the following:

   3.4 µl 10 pmol/µl GTU4 oligonucleotide
   15.6 µl 100 pmol/µl T3C3+9 oligonucleotide
   1 µl 1M NaCl (50 mM final salt concentration).

   Incubate 1 min at 99°C, 15 min at 37°C, and 15 min at room temperature.

   The template oligonucleotide can be stored indefinitely at –20°C.

2. To make 8× buffer M, mix the following (total volume 625 µl):

   500 µl 10× buffer M
   100 µl 2 M Tris·Cl, pH 7.4 to 7.6
   25 µl 10 mg/ml BSA.

   Buffer M is the equivalent of Klenow buffer (50 mM Tris·Cl, pH 7.5; 10 mM $MgCl_2$; 1 mM DTT; 50 µg/ml BSA; 50 µM dNTP) without dNTP and with extra salt so that the oligonucleotides do not melt. It is very stable at –20°C.

3. To prepare the reaction mixture, mix together:

   3.125 µl of 8× buffer M (step 2)
   1 µl annealed template oligo (step 1)
   1 µl of 1.25 mM dAdT (final 50 µM)
   13.875 µl dH_2O
   5 µl [α-^{32}P]dCTP
   1 µl Klenow large fragment.

Incubate reaction mixture (25 µl total) 30 min at room temperature and then 5 min at 95°C.

The incubation at 95°C is important because if the Klenow is not inactivated, then the probe is degraded during UDG treatment.

4. Add 0.5 µl of 1 U/µl UDG and incubate 10 min at 37°C and then 10 min at 95°C.

   This step is to cleave deglycosylated uracils and release probe as a single-stranded molecule after denaturing the UDG.

5. To check probe, run 30 fmol labeled probe on a 20% (w/v) acrylamide minigel (170 V, 20 min), wrap gel in cellophane (while still attached to one glass plate), and expose 10 min to a phosphor screen. Visualize with a PhosphorImager to confirm that adequate signal is present. Store the probe <2 weeks at −20°C.

   The screen is saturated after a 1-hr exposure. A 10-bp ladder can be used for size markers, or a kinased probe or free dCTP can be used for reference, if desired.

   Approximately 40% of the [α-^{32}P]dCTP should be incorporated into the full-length probe.

   Either all or half the probe is used for the assay (>20,000 cpm/µl).

BASIC PROTOCOL 2

MEASUREMENT OF TELOMERASE ACTIVITY BY THE TELOMERIC REPEAT AMPLIFICATION PROTOCOL

The telomeric repeat amplification protocol (TRAP) is a highly sensitive in vitro assay used for the detection of telomerase activity by the polymerase chain reaction (PCR) amplification of the products produced by the processive elongation of an oligonucleotide primer (Fig. 18.6.4). The current TRAP is a modification of the assay first described by Kim et al. (1994). This improved version allows for the elimination of the need for a wax barrier hot start, reduction of amplification artifacts, and better estimation of telomerase processivity by using a modified reverse primer sequence. Incorporation of an internal standard control allows for quantitation of telomerase activity. The TS primer is a nontelomeric sequence that telomerase can nonetheless recognize as a substrate. The reverse primer ACX contains several modifications (an anchor sequence at its 5′ end and two mismatches within the telomerase repeats) that both reduce PCR artifacts and more faithfully amplify the distribution of telomerase-elongated products than occurs with unmodified telomeric sequence primers.

Materials

100,000 cells grown in culture or tissue lysate containing 6 µg protein (see Support Protocol 4)
Liquid nitrogen
NP-40 lysis buffer (see recipe), ice cold
RNase
50× dNTP mix: 2.5 mM each dATP, dTTP, dGTP, and dCTP in RNase-free water
10× TRAP buffer (see recipe)
Radiolabeled TS primer (see Support Protocol 5)
Primer mix (see Support Protocol 6)
RNase-free H_2O (DEPC-treated)
50 mg/ml BSA, ultrapure (Ambion)
5 U/µl *Taq* DNA polymerase
Loading dye (see recipe)
0.5 M NaCl/50% (v/v) ethanol/40 mM sodium acetate (pH 4.2), optional

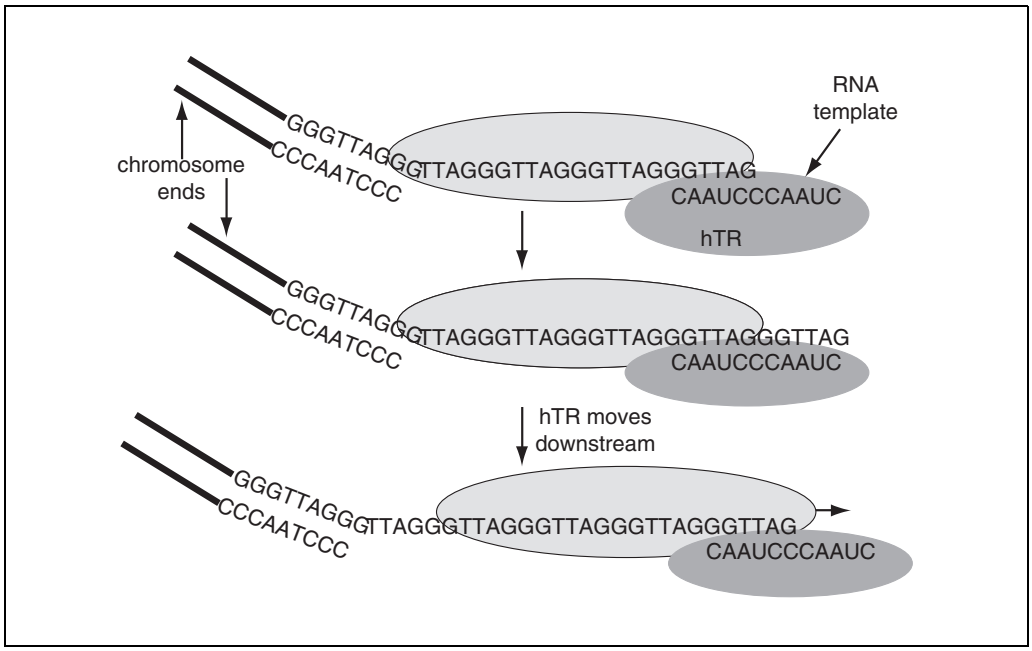

Figure 18.6.4 Telomere elongation by telomerase. Telomerase acts on the ends of chromosomes to add telomeric repeat sequences. Telomerase (hTERT) adds hexameric TTAGGG repeats by using its own RNA template (hTR) as a primer to add nucleotides. Telomerase then repositions its template RNA downstream for the addition of more telomeric repeats.

DNase-, RNase-free 0.5-ml microcentrifuge and PCR tubes
Tabletop centrifuge (e.g., 5415D; Eppendorf), room temperature and, optionally, 4°C
37°C water bath or 85°C heating block
Thermal cycler
PhosphorImager with phosphor screens and ImageQuant software (Molecular Dynamics)
Additional reagents and equipment for nondenaturing acrylamide gel electrophoresis (*UNIT 6.5*)

NOTE: Most of the reagents are included in the TRAPeze kit (Intergen).

Prepare sample

1. Place 100,000 cells in a DNase-, RNase-free 0.5 ml microcentrifuge tube. Pellet cells 6 min in a tabletop centrifuge at 6000 rpm (2940 × *g*), room temperature. Discard supernatant.

   Care must be taken not to contaminate any step in the TRAP assay with RNAses. RNA-Zap (Ambion) can be used to help eliminate RNAses.

   Much lower cell numbers can be used because one generally analyzes only 100 to 1000 cell equivalents.

   Washing the pellet is not necessary.

2. Snap freeze cell pellet in liquid nitrogen and store at −80°C until ready to lyse.

   Lead shot beads can be used as an alternative to snap freezing in liquid nitrogen. The beads are poured into a container and placed at −80°C. Samples added to the beads are snap-frozen in a couple of minutes.

   Alternatively, the cell pellet can be assayed immediately.

3. Resuspend sample (before it is fully thawed) in 100 µl ice-cold NP-40 lysis buffer and incubate 30 min on ice.

4. *Optional:* Centrifuge sample 20 min at 14,000 × *g*, 4°C, after lysis. Collect 80% of the supernatant in a fresh tube, making sure that no traces of cell debris from pellet are withdrawn.

   The whole cell lysate can be used instead of pelleting the insoluble material. The authors have found that recovery of telomerase activity is higher and more reproducible when the samples are not centrifuged and the entire lysate is analyzed. Centrifugation is usually needed only when tissues are used (see Support Protocol 4).

5. Snap-freeze lysate in liquid nitrogen and store at −80°C until analyzed by TRAP assay.

   Lead shot beads can be used as an alternative to snap freezing in liquid nitrogen. The beads are poured into a container and placed at −80°C. Samples added to the beads are snap-frozen in a couple of minutes.

   The TRAP assay can be performed using a radioactive or nonradioactive (see Alternate Protocol) primer.

   To prevent contamination with PCR-amplified products, the TRAP assay should be performed in a separate room from which the lysis took place.

Perform primer extension

6. As a negative control, incubate 5 µl lysate with 1 µg RNase for 20 min at 37°C or heat inactivate 10 min at 85°C prior to telomerase assay.

   A lysis-buffer-only control should also be included to check for presence of PCR contamination in the lysis buffer.

7. Place 1 to 2 µl lysate (equal to 100 to 1000 cells) in the bottom of an RNase-free PCR tube on ice and add the following:

   1 µl of 50× dNTP mix (50 µM final)
   5 µl of 10× TRAP Buffer
   2 µl radiolabeled TS primer
   1 µl primer mix
   38.6 µl RNase-free H_2O.

   Mix and add 0.4 µl of 50 mg/ml ultrapure BSA (20 µg final) and 0.4 µl of 5 U/µl *Taq* DNA polymerase (2 U final). Incubate 30 min at room temperature.

   This recipe is designed for one sample. A stock reaction mixture can be made just before assembling the reaction by combining the appropriate amount of dNTP mix, 10× TRAP buffer, BSA, primer mix, and water. The radiolabled TS primer and Taq DNA polymerase should be added immediately before the reaction mixture is added to each sample.

   To prevent contamination by PCR products, the preparation of samples and the assembly of the TRAP assay should take place in a separate room from that in which the PCR and electrophoresis are performed.

   During the initial 30-min incubation in the presence of the TS primer, varying numbers of hexameric repeats are added by telomerase. Subsequent amplification will yield a 6-bp incremental ladder.

8. Amplify extension products by polymerase chain reaction (PCR) in a thermal cycler as follows:

Initial step:	90 sec	94°C (to inactivate telomerase)
24 to 27 cycles:	30 sec	94°C
	30 sec	60°C.

Analyze extension products

9. Add 5 µl loading dye to 20 µl TRAP reaction mixture and run on a 10% (w/v) nondenaturing acrylamide gel in 0.5× TBE.

10. *Optional:* Fix gel 30 min in 0.5 M NaCl/50% ethanol/40 mM sodium acetate, pH 4.2.

    Fixing the gel to prevent diffusion of the bands may be performed when overnight exposure times are expected.

11. Wrap gel in plastic wrap and expose gel, without drying, to phosphor screens 30 min to overnight and visualize on a PhosphorImager using ImageQuant software.

12. Sum the intensities of the bands in the TRAP ladder and divide by the intensity of the internal standard control band to determine relative TRAP activity. Compare the activity of each sample with the negative and positive controls.

MEASUREMENT OF TELOMERASE ACTIVITY BY THE TELOMERIC REPEAT AMPLIFICATION PROTOCOL USING FLUORESCENT PRIMERS

ALTERNATE PROTOCOL

Measurement of telomerase activity using fluorescent primers rather than radiolabeled primers can be used as an alternative to Basic Protocol 2 to reduce the exposure to radioactivity. This alternative procedure may be slightly less sensitive than the radioactive method.

Additional Materials *(also see Basic Protocol 2)*

100 ng/µl fluorescently labeled TS primer: 5′-Cy5-AATCCGTCGAGCAGAGTT (Integrated DNA Technologies), HPLC or PAGE purified

1. Prepare cells or tissue lysate as described (see Basic Protocol 2, steps 1 to 5).

2. Set up a negative control and TRAP reaction mixture as described (see Basic Protocol 2, steps 6 and 7), but use 100 ng/µl fluorescently labeled TS primer instead of radiolabeled TS primer in step 7.

3. Amplify extension products by polymerase chain reaction (PCR) in a thermal cycler as follows:

Initial step:	90 sec	94°C (to inactivate telomerase)
30 cycles:	30 sec	94°C
	30 sec	52°C
	45 sec	72°C.

4. Electrophorese the TRAP reaction mixture and fix the gel, if desired, as described (see Basic Protocol 2, steps 9 and 10).

   Fixing of the gel for nonradioactive TRAP allows for easier handling when the gel is placed on a PhosphorImager.

5. Wrap gel in plastic wrap and scan under Cy5 (Blue) fluorescence with a PhosphorImager using ImageQuant software (Molecular Dynamics). Analyze the TRAP ladder as described (see Basic Protocol 2, step 12).

SUPPORT PROTOCOL 4

LYSIS OF TISSUE SAMPLES FOR THE TELOMERIC REPEAT AMPLIFICATION PROTOCOL

This procedure can be used to obtain lysates to analyze telomerase activity from tissue samples. Because the sample will be used in an RNase-sensitive procedure, standard precautions to avoid RNase contamination should be observed.

Additional Materials *(also see Basic Protocol 2)*

50 to 100 mg tissue sample, frozen at −80°C
Washing buffer (see recipe), ice cold
BCA protein assay kit (Pierce)

Kontes tubes and disposable pestles (VWR)
Hand-powered drill

1. *Optional:* Wash 50 to 100 mg frozen tissue sample in enough ice-cold washing buffer to cover the tissue. Centrifuge and remove buffer from tissue. Mince tissue with scalpel.
2. Homogenize tissue with 200 µl ice-cold NP-40 lysis buffer in a Kontes tube on ice using a disposable pestle rotating at 450 rpm with a hand-powered drill. Use short (<10- to 15-sec) pulses.

   Care must be taken not to overheat the samples and destroy the telomerase activity in the tissue.
3. Incubate sample 25 min on ice, centrifuge lysate 20 min at 16,000 × *g*, 4°C. Collect 80% of the supernatant in a fresh tube. Save an aliquot for protein assay. Rapidly freeze the supernatant in liquid nitrogen. Store up to ~1 year at −80°C.
4. Measure the concentration of protein in the lysate using a BCA protein assay kit (*APPENDIX 3H*).

   An aliquot of the extract containing 6 µg of protein will be used for each telomerase assay (see Basic Protocol 2, step 7).

SUPPORT PROTOCOL 5

MAKING RADIOLABELED TS PRIMER FOR TELOMERIC REPEAT AMPLIFICATION PROTOCOL

For the radioactive TRAP assay (see Basic Protocol 2), the TS primer (5′-AATC-CGTCGAGCAGAGTT-3′) is end-labeled with T4 polynucleotide kinase and [γ-^{32}P]ATP. The following protocol makes enough primer for ten samples, and the amounts can be adjusted appropriately for varying number of samples.

Materials

100 ng/µl TS primer (5′-AATCCGTCGAGCAGAGTT-3′)
[γ-^{32}P]ATP (3000 Ci/mmol), sterile
10 U/µl T4 polynucleotide kinase and 5× forward kinase buffer (GIBCO/BRL)
Sterile, RNase-free H_2O

RNase-free 1.5-ml microcentrifuge tubes
37° and 85°C water baths or heating block, or PCR machine

1. Mix together the following in a RNase-free 1.5-ml microcentrifuge or PCR tube:

   10 µl of 100 ng/µl TS primer
   2.5 µl [γ-^{32}P]ATP
   4 µl of 5× forward kinase buffer
   3 µl sterile, RNase-free H_2O
   0.5 µl of 10 U/µl T4 polynucleotide kinase.

   Incubate 20 min at 37°C.

2. Heat inactivate enough kinase for one assay 5 min at 85°C and use immediately or freeze up to 2 weeks at −20°C. Do not freeze and thaw more than once.

MAKING THE PRIMER MIX FOR TELOMERIC REPEAT AMPLIFICATION PROTOCOL

SUPPORT PROTOCOL 6

The primer mix includes the reverse primer (ACX), the substrate for the 36-bp internal standard control (TSNT), and the reverse primer for the internal standard (NT). Preparation of the stock TSNT primer should be done in a separate room from the other TRAP steps and prepared with separate micropipettors. The TSNT primer should be purchased from a different company from the other two primers because it is possible to contaminate them at the production facilities with the TSNT oligonucleotide. This protocol makes enough primer mix for 100 sample reactions.

Materials

TSNT oligonucleotide:
5′-AATCCGTCGAGCAGAGTTAAAAGGCCGAGAAGCGAT-3′
RNase-free H_2O
1 µg/µl ACX primer: 5′-GCGCGGCTTACCCTTACCCTTACCCTAACC-3′
1 µg/µl NT primer: 5′-ATCGCTTCTCGGCCTTTT-3′
10% (v/v) bleach
RNase-free 0.5-ml PCR tubes, including some that are siliconized

1. Dilute dry TSNT oligonucleotide in RNase-free water to 100 µM (1.0×10^{-10} mol/µl) in a siliconized, RNase-free PCR tube. Perform three dilutions (1:100, 1:1000, and 1:1000) in siliconized tubes so that the final concentration of the TSNT stock is 1.0×10^{-18} mol/µl.

   This step should be done in a separate room with separate micropipettors and tips from the other steps. Because extremely dilute solutions of the TSNT substrate are required, siliconized tubes should be used for all dilutions. The actual amount added to the primer mix below is empirically adjusted to compensate for experimenter error.

2. Mix 10 µl each of the 1 µg/µl ACX and NT primers (100 ng/µl final) and 79.0 µl RNase-free water together in an RNase-free tube.

3. Move to the area where the TSNT was prepared and add 1 ml dilute TSNT oligonucleotide (0.01 × 10-18 mol/ml final) to the mix. Clean the outside of the tube with 10% bleach.

4. Return to the nonTSNT work area and divide the primer mix into 25-µl aliquots. Use aliquots immediately or store up to 1 year at −20°C. Do not freeze and thaw more than once.

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Denhardt solution, 100×

10 g Ficoll 400
10 g polyvinylpyrrolidone
10 g BSA (Pentax Fraction V; Miles Laboratories)
H_2O to 500 ml
Filter sterilize and store at −20°C in 25-ml aliquots

Hybridization solution

5× SSC buffer (see recipe)
5× Denhardt solution (see recipe)
10 mM Na_2HPO_4
1 mM $Na_2H_2P_2O_7$
Store up to 6 months at −20°C

Loading dye

0.25% (w/v) each of bromophenol blue and xylene cyanol in 50% (v/v) glycerol/50 mM EDTA. Store up to 1 year at 4°C.

For nonradioactive TRAPs, the xylene cyanol should be removed, as this shows up while imaging the gel.

NP-40 lysis buffer

10 mM Tris·Cl, pH 8.0 (*APPENDIX 2A*)
1 mM $MgCl_2$
1 mM EDTA
1% (v/v) NP-40
0.25 mM sodium deoxycholate
10% (v/v) glycerol
150 mM NaCl (*APPENDIX 2A*)
5 mM 2-mercaptoethanol
0.1 mM AEBSF (4-(2-aminoethyl)-benzenesulfonyl fluoride hydrochloride)
Store up to 6 months at −20°C

Quick-prep lysis buffer

100 mM NaCl
100 mM EDTA, pH 8.0 (*APPENDIX 2A*)
10 mM Tris·Cl, pH 8.0 (*APPENDIX 2A*)
Store up to 1 month at room temperature

SSC (sodium chloride/sodium citrate), 20×

3 M NaCl (175 g/liter)
0.3 M Na_3citrate·$2H_2O$ (88 g/liter)
Adjust pH to 7.0 with 1 M HCl (*APPENDIX 2A*)
Store up to 6 months at room temperature

TRAP buffer, 10×

200 mM Tris·Cl, pH 8.3 (*APPENDIX 2A*)
15 mM $MgCl_2$
630 mM KCl
0.5% (v/v) Tween 20
10 mM EGTA
Store up to 6 months at −20°C

Washing buffer

10 mM HEPES (adjusted to pH 7.5 with KOH)
1.5 mM $MgCl_2$
10 mM KCl
1 mM DTT (*APPENDIX 2A*)
Store up to 6 months at 4°C

COMMENTARY

Background Information

Cells contain repeated TTAGGG DNA sequences, called telomeres, at the ends of chromosomes to provide genomic stability. Telomeres provide a source of expendable DNA, which alleviates the end-replication problem in which one DNA strand cannot complete copying all the way to its end during cell division (reviewed in Collins, 2000). An in-gel Southern hybridization analysis of the chromosome terminal (i.e., telomeres) restriction fragments (TRFs) allows for the determination of all telomere lengths in a cell population (Harley et al., 1990; Ouellette et al., 2000). Telomere length has been shown to decrease with time and with increasing age (Allsopp et al., 1992). Most normal human cells lack telomerase activity, and their telomeres shorten with each cell division until they enter replicative senescence, where cells cease to proliferate (Harley et al., 1990; Wright et al., 1996). Cells are mortal unless a rare survivor activates a mechanism to maintain its telomeres.

The mechanism predominately used to maintain human telomeres is the addition of telomeric sequences by telomerase. Human telomerase is an RNA-dependent DNA polymerase complex consisting of a reverse transcriptase catalytic subunit (hTERT), which uses the integral RNA component (hTR) of the complex as a template for adding TTAGGG repeats to the end of the chromosome (Fig. 18.6.4; reviewed in Greider and Blackburn, 1985; Cong et al., 2002). Telomerase is expressed in only a small number of normal proliferating cell types such as germline and somatic stem cells, but it is found in ~90% of human cancer cells. Once telomerase is activated, it stabilizes telomere length and permits continued cell division (Counter et al., 1992).

The development of a highly sensitive assay to detect telomerase activity in cells and tissues enhanced the evaluation of a wide variety of human tissue and tumor cells (Kim et al., 1994). The telomeric repeat amplification protocol (TRAP) measures in vitro telomerase activity by a primer extension assay in which telomerase synthesizes telomeric repeats onto oligonucleotide primers (Fig. 18.6.5; Kim et al., 1994). The products can then be amplified by the polymerase chain reaction (PCR) and run on an acrylamide gel. There are several publications describing modifications and alternative methods of extracting and detecting telomerase activity in human samples using the TRAP assay (Piatyszek et al., 1995; Wright et al., 1995; Holt et al., 1996; Norton et al., 1998; Gollahon and Holt, 2000). The protocol described in this unit incorporates the modifications suggested in these reports. Together with the TRF analysis, telomerase has been shown to be directly involved in telomere maintenance and has been linked with immortality (Kim et al., 1994).

Critical Parameters

Terminal restriction fragments

It is desirable to obtain ≥300,000 cells for the determination of telomere length so that 1 to 2 μg DNA can be assayed for each TRF analysis. The amount of DNA is estimated at 6 $\mu g/10^6$ diploid cells or 10 $\mu g/10^6$ aneuploid cells; therefore, 300,000 cells yields 1.8 μg DNA. Triton X-100 rather than SDS is used in the lysis so that the residual detergent present after dialysis does not inhibit subsequent digestion by restriction endonucleases. High concentrations of EDTA (100 mM) are present to inhibit nucleases very rapidly in these concentrated cell suspensions. Frozen cell pellets are first suspended in lysis buffer to quench nuclease activity and obtain a uniform distribution of cells before adding Triton X-100. Including Triton X-100 in the initial suspension buffer leads to a rapid clumping of cells. Lysis buffer should be added before cell pellets are fully thawed to prevent nuclease digestion. Heat inactivation of the proteinase K avoids the need to phenol/chloroform extract the DNA, and the residual salt, EDTA, and peptides present after dialysis do not inhibit enzyme digestion. After digestion with proteinase K, DNA should be handled using only wide-bore pipet tips to

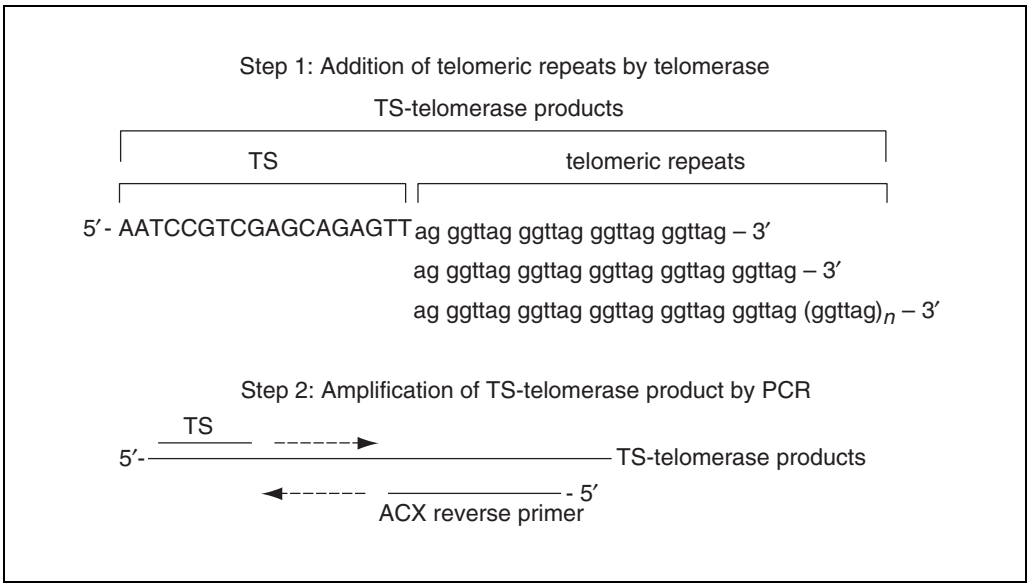

Figure 18.6.5 The telomeric repeat amplification protocol (TRAP; see Basic Protocol 2). In the first step, telomerase-mediated extension occurs on a nontelomeric oligonucleotide that serves as a substrate for telomerase (TS). In the second step, the TS-telomerase products are specifically amplified by the polymerase chain reaction (PCR) using the TS as an upstream primer and ACX as the reverse, downstream primer. The addition of telomeric repeats in the first step results in a TRAP ladder of 6-bp increments as seen on a 10% (w/v) acrylamide gel. Adapted from the manual for the TRAPeze Telomerase Detection Kit (Intergen).

prevent shearing of the DNA. The final DNA solution should be viscous. Lack of viscosity suggests nonspecific nuclease degradation of the DNA, which is easily tested by running 100 ng undigested DNA on a 0.7% (w/v) agarose gel. Degraded DNA is frequently seen the first time an investigator attempts this DNA purification procedure, but generally it is rarely present thereafter. If the DNA concentration is too low after dialysis to load a sufficient quantity on a gel, then concentration on a 30,000-molecular-weight spin-filter or ethanol precipitation of the DNA may be necessary. This is rarely necessary when starting with $\geq 1 \times 106$ cells.

Digested DNA should run as a smear below the 1-kb molecular weight marker. Anything above this size is incompletely digested. If the sample is not digested completely, an additional microliter of enzyme mix can be added to the sample and allowed to digest for a longer amount of time. It is essential to have the genomic DNA completely digested to have interpretable results after hybridization with the telomeric probe. If digestion problems persist, completion of the restriction digest can be checked ahead of time by electrophoresing 250 ng DNA on a small agarose gel stained with ethidium bromide.

TRF gels should be handled carefully as they are fragile until they are dried. The dried gel can be hybridized directly without the need to transfer the DNA to a membrane. Denaturing the DNA in the gel before rather than after drying the gel increases the signal intensity ~3- to 5-fold, presumably by permitting a much greater diffusion of the denatured DNA strands in the agarose gel than in the very-high-percentage dried and rehydrated gel, and thus inhibiting the reannealing of the parental strands, which would compete with the probe. Rinsing the denatured gel with distilled water gets rid of the NaOH used in the denaturing solution and substantially reduces sticking of the gel to the Whatman 3MM paper. Because most of the DNA samples do not fill the wells and are thus in the bottom half of the gel, the gels are flipped and dried with the upper surface against the filter paper support. This increases the distance between the DNA samples and the filter paper and significantly reduces the loss of lower-molecular-weight DNA. Some loss of lower-molecular-weight DNA (particularly <400 bp) occurs during drying, and this results in the lower limit of detection in the TRF analysis.

Telomeric repeat amplification protocol

Because the TRAP assay is a highly sensitive PCR-based assay, precautions must be taken to eliminate RNases and PCR product contamination. The following guidelines en-

Table 18.6.1 TRAP Troubleshooting Guide[a]

Problem	Possible cause	Solution
No visible products in any lane, including the internal standard control band	PCR not initiated	Check that all assay components were added, especially *Taq* DNA polymerase. Check thermal cycler for proper settings and operation.
Few visible TRAP ladder bands and weak internal control band	Cell or tissue extract contains *Taq* inhibitors	Dilute sample with lysis buffer.
No visible TRAP products in any lane but internal standard control band is present	Telomerase activity not initiated Possible presence of RNase contamination	Always use RNase-free tips, tubes, and solutions. Use fresh aliquots of solutions. Do not let pipet tips touch anything except the solutions. Keep samples on ice and reactions below 25°C. Add RNase inhibitor to lysis buffer.
Visible TRAP product in all lanes including lysis-buffer-only control	PCR carryover contamination	Use fresh aliquots of each component of the assay. Perform each step in a separate room with separate micropipettors and tips.
Several bands in the lysis-buffer-only control lane	Primer-dimer artifacts	Incorporate hot start into the PCR reaction: Assemble reaction mixture as described, except eliminate *Taq* polymerase, heat reaction 2 min at 94°C, add *Taq*, and continue PCR procedure as described.
Products in the heat-treated extracts	Insufficient heat inactivation, primer-dimer artifacts, or contamination of extract with TRAP products	Check temperature of heating block. Make and test new extract and check for PCR carryover contamination. Extreme care must be taken to prevent pipetting into multiple samples or solutions.
Extra bands between internal standard control band and TRAP ladder bands		
Weak intensity of internal standard control band	Telomerase activity too high	Dilute samples.

[a]Adapted from the manual for the TRAPeze Telomerase Detection Kit (Intergen).

sure that contamination is kept to a minimum. Gloves must be worn at all times and each step of the protocol should be done in separate rooms or at least in areas separated by barriers. DEPC-treated water must be used for all solutions, solutions should be kept from other solutions in the laboratory, and small aliquots of the solutions should be made and used only once. Separate micropipettors should be designated to be used only for the TRAP assay, and only aerosol-resistant pipet tips should be used with these micropipettors. Samples and solutions should also be kept on ice or snap-frozen, unless otherwise specified, to prevent degradation of telomerase.

Troubleshooting

The most common problem associated with the TRF assay is that the genomic DNA is not completely digested. This results in a smear or tight band >1 kb as visualized by ethidium bromide staining, and this interferes with the interpretation of telomere lengths after hybridizing the gel with a telomeric probe. A test gel using 200 ng of DNA digested with the enzyme mix can show whether the samples have been completely digested. If the DNA is not completely digested, the usual cause is that the sample contains too much EDTA, which interferes with the restriction enzymes. This usually results from dialyzing too many samples against an insufficient volume, or from a failure to ensure that all the liquid rests against the membrane, resulting in a few microliters of 100

mM EDTA failing to get dialyzed. Other occasional failures result from using too much DNA because of an inaccurate measurement of the viscous DNA. Another problem is that the sample may not contain any detectable DNA because of a tear in the dialysis membrane. Weak signals after scanning the hybridized gel may be due to too stringent washing or insufficiently labeled probe. Use a Geiger counter to ensure that the background signal of the gel is low but that the areas expected to have telomeres contain a higher signal before exposing the gel. Check to make sure that the probe is specific for telomeric sequences and that the radioisotope and other components are fresh.

Table 18.6.1 lists some common problems and solutions associated with the TRAP assay. The most common problems associated with the TRAP assay are RNase and PCR contamination or forgetting to add one of the components in the reaction, such as the *Taq* polymerase. Careful handling of the samples and reagents in the TRAP assay ensures successful detection of telomerase activity.

Anticipated Results

The results of an in-gel Southern hybridization of digested genomic DNA with a telomeric probe yields a smear that corresponds to the distribution of all telomere lengths within the population of cells collected (Fig. 18.6.6). Including a labeled molecular weight marker on the hybridized gel allows for calculation of the average telomere length as well as the longest and shortest telomere lengths.

Once the conditions for the TRAP assay have been optimized and RNase contamina-

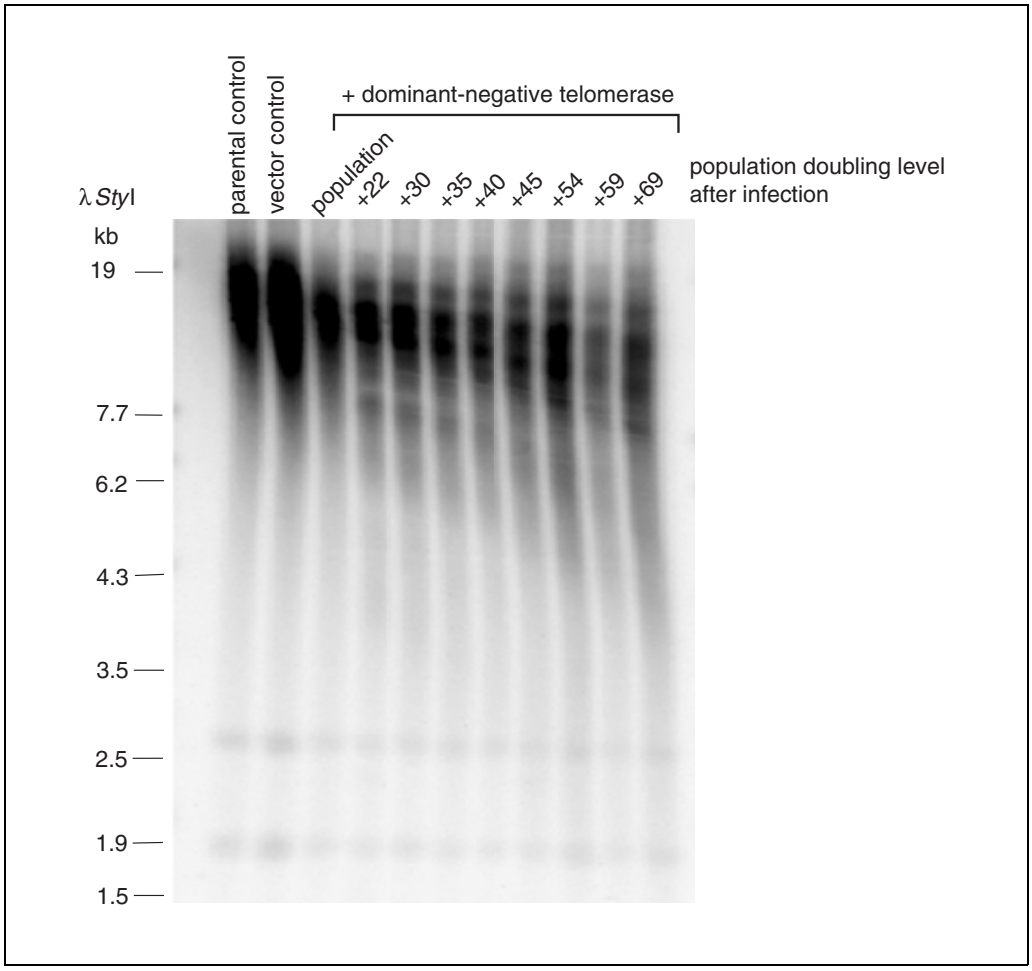

Figure 18.6.6 Determination of telomere length using the terminal restriction fragment (TRF) protocol in sequentially passaged (indicated by the population doubling level, or the number of doublings the population has accrued, after infection) H1299 lung carcinoma cells infected with a dominant-negative mutant of human telomerase to inhibit telomerase and induce telomere shortening. Telomere length was determined by digesting genomic DNA with a mixture of six restriction enzymes having four-base recognition sites (see Basic Protocol 1), and then analyzing the DNA on a 0.7% (w/v) agarose gel. λ DNA cut with *Sty*I was used as a molecular weight marker.

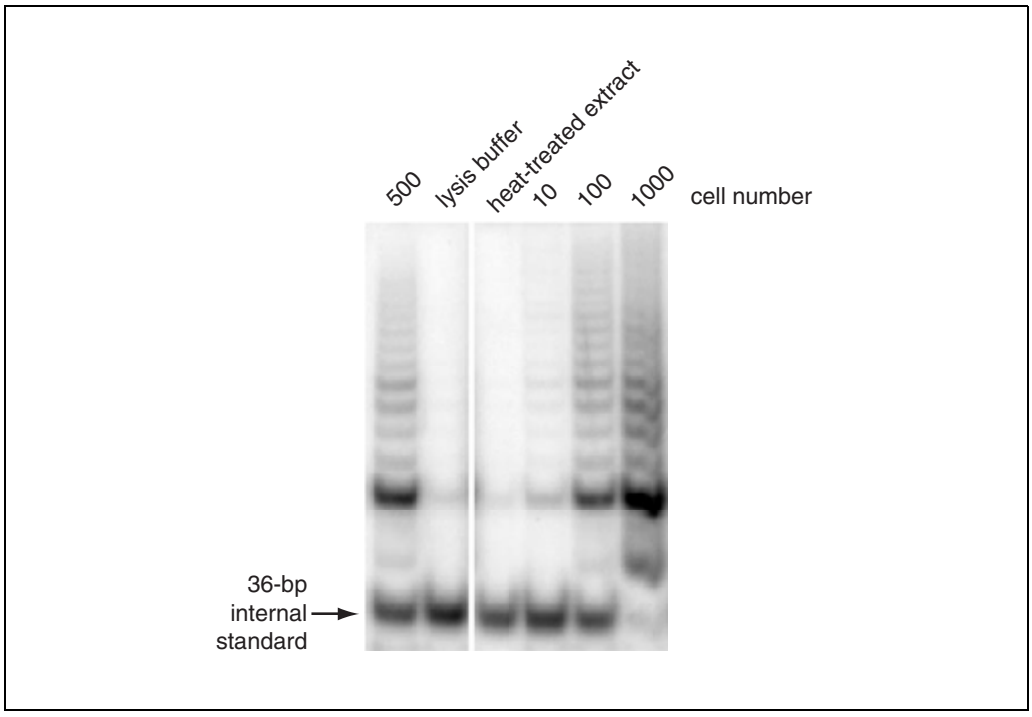

Figure 18.6.7 Analysis of telomerase activity using the telomeric repeat amplification protocol (TRAP; see Basic Protocol 2). Human cancer cell extracts (500 cell equivalents of H1299 lung carcinoma cells) are positive for telomerase activity as evidenced by the 6-bp incremental TRAP ladder. Treating the extract with heat inactivates the telomerase activity as evidenced by no TRAP ladder. Lysis buffer only serves as a negative control. Each TRAP reaction includes a 36-bp internal standard control. Ten-fold increases of H1299 cell equivalents (100 to 1000 cell equivalents) results in increased intensity of the TRAP ladder. The 1000 cell sample in this gel cannot be readily quantitated because of the faint signal in the internal standard (due to competition by excess telomerase products).

tioniseliminated,theamplifiedtelomerase-extended products can be seen as an incremental ladder (Fig. 18.6.7). Because human telomerase is processive, the 30-min incubation yields a TS primer extended by a variable number of hexameric repeats. When the resulting 10% (w/v) acrylamide gel is visualized by a PhosphorImager, a 6-bp DNA incremental ladder is seen as well as the internal standard control band. The lysis buffer only and the heat-treated sample lanes should contain only the internal standard control band. The intensities of each of the bands in the TRAP ladder can be summed together and divided by the internal standard control band to determine relative TRAP activity. Too much telomerase activity will result in intense ladders and a failure to amplify the internal standard. The actual amount of the TSNT primer used is empirically adjusted so that one gets an internal standard signal roughly equivalent to the most intense first band of the telomerase ladder using 100 to 1000 positive tumor cells as a control. The activity of each sample can then be compared with the negative and positive controls.

Time Considerations

The entire TRF procedure can be performed in 4 days (day 1: harvest and digest cells with proteinase K and dialyze overnight; day 2: restriction digest DNA and run gel overnight; day 3: dry gel and hybridize overnight; day 4: wash and expose gel). Alternatively, isolated genomic DNA can be stored at 4°C (or at −20°C for longer storage) until it is digested. The TRAP assay can be performed in 1 day or separated into a 3-day procedure: one day for lysing the samples, a second day for the PCR assay, and a third day for running and exposing the gel.

Nonisotopic Methods for Determination of Poly(ADP-Ribose) Levels and Detection of Poly(ADP-Ribose) Polymerase

The techniques presented in this unit are designed to allow quantification and characterization of pADPr synthesized in vitro, in cultured cells, or in tissues from whole animals. Treatment of cells with DNA-damaging agents such as hydrogen peroxide or DNA-alkylating compounds stimulates PARP activity. After treatment, activated PARPs cleave nicotinamide adenine dinucleotide (NAD) into nicotinamide and ADP-ribose and synthesize pADPr polymers covalently attached to nuclear proteins. Following TCA precipitation of poly(ADP-ribosyl)ated proteins, the acid-insoluble fraction is used to purify pADPr in order to determine pADPr levels and its size distribution in intact cells (see Basic Protocol 1). This section presents novel applications for the immunodetection of pADPr in intact cells, such as immunodot blot analysis (see Basic Protocol 2), ELISA detection (see Alternate Protocol 1), size-distribution analysis by immunodetection (see Basic Protocol 3), detection of modified protein by immunoblot (see Basic Protocol 4), and cellular localization by immunocytochemistry (see Basic Protocol 5). In addition to determining the presence of pADPr, methods are also provided for detection of the PARPs themselves by immunoblot (see Basic Protocol 6), proteolytic cleavage during cell death (see Alternate Protocol 2), and nonisotopic–activity immunoblot (see Basic Protocol 7).

NONISOTOPIC METHODS FOR DETERMINATION OF POLY(ADP-RIBOSE) LEVELS IN INTACT CELLS

Poly(ADP-ribose) polymerase-1 (PARP-1) is the main enzyme responsible for poly(ADP-ribose) (pADPr) synthesis in response to DNA strand breaks caused by genotoxic agents. Analysis of pADPr is the easiest method that provides direct proof of PARP activation following genotoxic treatment in cells. Furthermore, monitoring changes in pADPr metabolism could serve as an important diagnostic tool to determine the impact of low-dose exposure to DNA-damaging agents.

The main challenge in pADPr research is its very low concentration in cells: ~2 to 10 pmol/mg DNA in untreated cells. To bypass this problem, some investigators have used isolated nuclei or permeabilized cells in order to study poly(ADP-ribosyl)ation of proteins following a DNA-damaging treatment; however, while this procedure provides higher levels of pADPr due to the loss of cellular integrity, the results are, by definition, nonphysiological. More recently, the availability of highly specific anti-poly(ADP-ribose) antibodies has become a powerful tool to investigate pADPr metabolism in cultured cells. The establishment of nonisotopic methods to study pADPr synthesis has provided safer and simpler laboratory procedures.

Poly(ADP-Ribose) Preparation from Cell Cultures

BASIC PROTOCOL 1

PADPr synthesis is a useful biological parameter for the investigation of cellular processes such as DNA repair and cell death. Cell treatments with DNA-damaging agents such as hydrogen peroxide or DNA alkylating compounds cause PARP-1 and -2 activation. It must be kept in mind that these pADPr-inducing treatments must be optimized for each cell line. The following protocol was first described by Aboul-Ela et al. (1988) and was subsequently modified in the authors' laboratory (Shah et al., 1995). These procedures are based on the principle that pADPr is covalently bound to proteins present in the TCA precipitate and released under alkaline conditions. Once released from proteins, the

Current Protocols in Cell Biology (2003) 18.7.1-18.7.26

pADPr can be further purified by dihydroxyboryl Bio-Rex 70 (DHBB) chromatography (Alvarez-Gonzalez et al., 1983). This purification step is required to eliminate major contaminants such as DNA, RNA, and residual proteins present in the cell extract. In practice, it is useful to eliminate these contaminants to decrease background when using immunodetection techniques for pADPr analysis.

Materials

Cells of interest in appropriate medium
DNA-damaging agent
PBS, pH 7.4 (*APPENDIX 2A*), ice cold
20% (w/v) trichloroacetic acid (TCA), ice cold
100% ethanol, ice cold
1 M KOH/50 mM EDTA
AAGE9 buffer (see recipe)
HCl, concentrated
50% (w/v) dihydroxyboryl Bio-Rex 70 (DHBB) affinity resin (Alvarez-Gonzalez et al., 1983)
1 M ammonium acetate, pH 9.0
H_2O, 37°C

Rubber policeman
37° and 60°C water baths or heat blocks
10-ml Econocolumn (Bio-Rad)

Prepare acid-insoluble fraction from cultured cells

1. Treat cells of interest in medium with an appropriate DNA-damaging agent and incubate for sufficient time to allow for PARP activation.

   For example, treat confluent C3H10T½ mouse fibroblasts (ATTC# CCL-226) with 200 μM hydrogen peroxide or 100 μM N-methyl-N-nitro-N-nitrosoguanidine (MNNG) for 20 to 30 min at 37°C. This is a typical procedure for PARP-1 activation. An optimal incubation time must be determined by the investigator if using other DNA-damaging stimuli or other cell types. This time should be determined carefully, as pADPr can decrease rapidly at longer time points due to NAD depletion or repair processes.

2. Remove and discard the medium from the cell culture and quickly wash the monolayer with 5 ml ice-cold PBS, pH 7.4.

3. Remove the PBS, add 5 ml ice-cold 20% (w/v) TCA, and incubate cells 15 min on ice.

   This step is critical to prevent catabolism of polymer by poly(ADP-ribose) glycohydrolase and must be done as quickly as possible.

4. Scrape the TCA-insoluble material with a rubber policeman and transfer cells to a centrifuge tube. Pellet by centrifuging 10 min at 1800 × *g*, 4°C.

5. Wash the cell pellet once with ice-cold 20% TCA and twice with 5 vol ice-cold 100% ethanol.

6. Air dry the cell pellet.

   The pellet may be stored up to 6 months at −30°C or −80°C or directly processed as follows.

Isolate pADPr from cell pellet

7. Dissolve the TCA precipitate in 1 ml of 1 M potassium hydroxide/50 mM EDTA and mix by vortexing.

   In the case where TCA has not been thoroughly removed from the pellet, it may be necessary to utilize a glass homogenizer to disperse the pellet as much as possible.

8. Incubate the alkali-digest reaction mixture 1 hr at 60°C with occasional vortexing to promote separation of the pADPr from the proteins.

   Following this incubation, a small aliquot can be removed from each sample for determination of DNA content, if required.

Purify pADPr by DHBB chromatography

9. Add 9 ml AAGE9 buffer to the alkali-digested pADPr and adjust the pH to 9.0 ± 0.2 with concentrated hydrochloric acid.

   AAGE9 buffer contains 250 mM ammonium acetate, pH 9.0, 6 M guanidine·hydrochloride, and 10 mM EDTA.

10. Transfer 1 ml of 50% (w/v) DHBB suspension (0.5 ml packed affinity resin) into a 10-ml Econocolumn (Bio-Rad). Equilibrate with 5 ml AAGE9 buffer, 10 ml water, and 10 ml AAGE9 buffer, successively. Verify that the column pH is 9.0.

    The description and detailed preparation of DHBB resin is presented in Alvarez-Gonzalez et al. (1983).

11. Pass the alkali digest sample twice through the DHBB column. Wash with 25 ml AAGE9 buffer followed by 10 ml of 1 M ammonium acetate, pH 9.0.

12. Elute the pADPr with 0.5 ml water prewarmed to 37°C. Repeat four more times.

    The pADPr will be in fractions 2 and 3.

13. Lyophilize the eluted pADPr and keep frozen until further analysis (up to 1 year).

Quantification of pADPr by Immunodot Blot

BASIC PROTOCOL 2

The following protocol describes the utilization of an immunodot blot technique for the determination of DHBB-purified pADPr from cell extracts. This nonisotopic immunodetection method, developed in the authors' laboratory (Affar et al., 1999a), is based on the covalent binding of pADPr to a positively charged nylon membrane under alkaline conditions. The detection is carried out using an anti-poly(ADP-ribose) primary antibody, followed by an appropriate peroxidase-conjugated secondary antibody. Quantification is done with chemiluminescence reagents for HRP-conjugated secondary antibodies. This technique can be used routinely for rapid quantification of pADPr at femtomolar concentrations, so it provides great advantages over other procedures. In addition to a great sensitivity, the immunodot blot procedure is applicable to in vitro synthesized polymer as well as to cell culture isolated pADPr. More samples can be processed simultaneously by this method than is possible using HPLC methods.

Materials

DHBB-purified pADPr (see Basic Protocol 1)
0.4 M NaOH/10 mM EDTA
0.4 M NaOH
PBS-MT (see recipe)
Anti-pADPr primary antibody
Peroxidase-conjugated secondary antibody
PBS-T: PBS containing 0.1% (v/v) Tween 20
PBS (*APPENDIX 2A*)
Chemiluminescence reagents for HRP-conjugated secondary antibodies

7.8 × 11.5–cm Hybond N^+ nylon membrane (Amersham Bioscience)
Dot blot manifold system (Life Technologies)
Orbital platform shaker

Cooled CCD camera with ChemiImager 4000 and Digital Imaging and Analysis System (Alpha Innotech) *or* X-ray film

Additional reagents and equipment for autoradiography and densitometry (*UNIT 6.3*; optional)

1. Dilute DHBB-purified pADPr in a vol of 0.4 M sodium hydroxide/10 mM EDTA.
2. Load samples onto a 7.8 × 11.5–cm Hybond N^+ nylon membrane using a dot blot manifold system.
3. Wash the membrane with 50 ml 0.4 M sodium hydroxide, remove from the manifold, and keep in water for further processing.
4. Incubate the membrane in 50 ml PBS-MT on a orbital platform shaker for at least 1 hr at room temperature.
5. Dilute anti-pADPr primary antibody in PBS-MT and incubate 50 ml with the membrane on a orbital platform shaker overnight at room temperature.

   Two antibodies, 10H and LP96-10, are commercially available for the detection of polymer ranged between 1 and 1000 fmol. Generally, experiments are performed with 10H antibody diluted 1:250 or LP96-10 at 1:5000. Under these specific conditions, both antibodies recognize pADPr in a dose-dependent manner, but LP96-10 polyclonal antibody shows a higher sensitivity (also see Critical Parameters).

6. Wash the membrane three times with 50 ml PBS-MT for 15 min each.
7. Dilute an appropriate peroxidase-conjugated secondary antibody in PBS-MT according to supplier's instructions.
8. Incubate the membrane 30 min with 50 ml secondary antibody on a orbital platform shaker at room temperature.
9. Discard the secondary antibody and wash the membrane as follows:

   Twice with 50 ml PBS-MT for 5 min each
   Three times with 50 ml PBS-T for 15 min each
   Twice with 50 ml PBS for 5 min each.

10. Illuminate the blot using chemiluminescence reagents for HRP-conjugated secondary antibodies according to instructions.

11a. *Quantify using digital imaging:* Quantify the amount of pADPr using a cooled CCD camera equipped with ChemiImager 4000. Analyze the data with the Digital Imaging and Analysis Systems.

   This is the technique used in the authors' laboratory. It removes the nonlinear steps involved in film exposure and developing, but traditional use of X-ray film and densitometry techniques (see below) are also effective, if the film is exposed correctly. With either technique, pADPr standards should be used to ensure that quantification is linear and accurate.

11b. *Quantify by densitometry:* Use standard X-ray densitometry techniques (*UNIT 6.3*) to quantify the signal from the secondary antibody.

Quantification of pADPr by Enzyme-Linked Immunosorbant Assay

The enzyme-linked immunosorbent assay (ELISA) is an interesting alternative method to the immunodot blot procedure (see Basic Protocol 2) for quantification of the pADPr synthesized following DNA-damaging or apoptosis-inducing treatments. This technique was developed to provide a simple procedure to investigate pADPr metabolism without radiolabeled compounds. The conditions of fixation and washing to detect low cellular levels of pADPr were optimized in the authors laboratory (Affar et al., 1999a). Briefly, pADPr isolated from cell cultures are alkali digested and fixed in a 96-well microplate. This cellular pADPr is incubated with a specific anti-poly(ADP-ribose) primary antibody. Following incubation with appropriate secondary antibodies, the 2,2′-azino-bis(3-ethyl-benzothiazoline-6-sulfonic acid) (ABTS) coloration is measured and compared to a standard curve made with known amounts of DHBB-purified pADPr synthesized in vitro.

Additional Materials *(also see Basic Protocol 2)*

1 μg/ml poly-L-lysine in PBS-T_2
PBS (*APPENDIX 2A*)
DHBB-purified pADPr samples (see Basic Protocol 1) in PBS-T_2
PBS-T_2: PBS (*APPENDIX 2A*)/0.05% (w/v) Tween 20
PBS-MT_2 (see recipe)
Anti-pADPr primary antibody diluted in PBS-MT_2
Peroxidase-conjugated secondary antibody
ABTS/H_2O_2 solution (see recipe)

96-well microtiter plate (Falcon 3912)
Microtiter plate reader

Prepare a microtiter plate

1. Coat a 96-well microplate with 200 μl per well of 1 μg/ml poly-L-lysine in PBS-T_2.
2. Incubate the plate overnight at 4°C.
3. Wash the plate twice with 200 μl/well PBS for 5 min each.

Add sample

4. Add each DHBB-purified pADPr sample prepared in PBS-T_2 (final volume 50 μl) to a well.
5. Incubate samples overnight at 37°C.
6. Wash the plate three times with 200 μl/well PBS-T_2 for 2 min each.

Block plate

7. Saturate the plate for 1 hr with PBS-MT_2 at 37°C.

   This blocking step should be done with 250 μl per well of PBS-MT_2 to efficiently saturate unoccupied binding sites.

8. Remove PBS-MT_2 from the plate and add 50 μl/well of anti-pADPr primary antibody diluted in PBS-MT_2.

   Generally, the authors use LP96-10 polyclonal antibody at a dilution of 1:5000. Other investigators have used monoclonal 10H antibody at a dilution of 1:250. The LP96-10 antibody is preferred because some studies have revealed that the 10H monoclonal antibody fails to recognize poly(ADP-ribose) smaller than 25 residues (also see Critical Parameters).

Incubate plate with antibody

9. Incubate pADPr samples 1 hr with the primary antibody at 37°C.
10. Wash the plate three times with 200 µl/well PBS-T_2 for 2 min each.
11. Dilute an appropriate peroxidase-conjugated secondary antibody 1:1000 in PBS-MT_2.
12. Incubate the plate 30 min with 50 µl/well secondary antibody at 37°C.
13. Discard the secondary antibody and wash the plate as follows:

    Three times with 200 µl/well PBS-T for 2 min each
    Twice with 200 µl/well PBS for 5 min each.

    At this stage, it is important to remove all traces of Tween 20 because it can interfere with the peroxidase assay.

Visualize bound antibody

14. Add 100 µl ABTS/H_2O_2 solution to each well and let the color develop 15 min at room temperature.
15. Read the absorbance at 405 nm using a microtiter plate reader.

BASIC PROTOCOL 3

High-Resolution Gel Electrophoresis and Immunodetection of pADPr

It has been observed that the size distribution of pADPr varies between unstimulated cells and cells subjected to DNA-damaging agents (Malanga and Althaus, 1994). With this information in mind, it can be useful to measure the levels of pADPr synthesized following DNA-damaging treatments. In order to characterize the size distribution of pADPr synthesized in treated cells, the authors have developed a novel immunodetection method involving the transfer of electrophoresed pADPr onto a positively charged membrane, followed by blotting with specific anti-pADPr antibodies to evaluate the size distribution of pADPr synthesized in vivo (Affar et al., 1999a). All pADPr larger than octamers were detected with this technique. Careful analysis of the blot has shown that short polymers (3 to 8 residues) have a weak binding capacity for the positively charged membrane. This class of pADPr is lost during washing in the immunodetection procedure.

Materials

20% (w/v) polyacrylamide gel (see recipe)
Electrode buffer: 54 mM Tris-borate buffer (pH 8.3)/1.2 mM EDTA
Alkali-digested pADPr sample isolated from cell culture (see Basic Protocol 1, step 8) or lyophilized DHBB-purified sample (see Basic Protocol 1)
Modified Laemmli sample buffer (see recipe)
Transfer buffer: 35 mM Tris-borate buffer (pH 8.3)/1 mM EDTA
PBS-MT (see recipe)
Anti-pADPr primary antibody
Peroxidase-conjugated secondary antibody
PBS-T: PBS containing 0.1% (v/v) Tween 20
PBS (*APPENDIX 2A*)
Chemiluminescence reagents for HRP-conjugated secondary antibodies
Purified pADPr standard (see Basic Protocol 1)

Nitrocellulose Hybond N^+ membrane (Amersham Bioscience)
Hair dryer
312-nm UV source
X-Omat blue film (Kodak)

Additional reagents and equipment for preparing and running acrylamide gels (*UNIT 6.1*), immunoblot detection (see Basic Protocols 2, steps 5 to 10, and (*UNIT 6.2*), and autoradiography and densitometry (*UNIT 6.3*)

Prepare polyacrylamide gel

1. Prepare a $20 \times 20 \times 0.15$–cm 20% polyacrylamide gel.
2. Prerun the gel 1 to 2 hr in electrode buffer at 400 V.

Prepare pADPr

3. *Optional:* Air dry the alkali-digested pADPr isolated from cell culture.
4. Dilute the dried polymer (i.e., from alkali digested pADPr or lyophilized DHBB-purified sample) in modified Laemmli sample buffer.

   Do not heat the sample as pADPr can be degraded at higher temperatures. The use of bromophenol blue and xylene cyanol as standards is useful since they co-migrate with poly(ADP-ribose) molecules of ~8 and 20 residues, respectively.

5. Load a volume of sample containing 25 to 50 pmol pADPr per lane on the prerun polyacrylamide gel (step 2).

   pADPr is quantitated by immunodot blot (Basic Protocol 2) or ELISA (Alternate Protocol 1).

Electrophorese sample

6. Replace the electrophoresis buffer and electrophorese the sample at a constant voltage of 400 V for a period varying with the pADPr size of interest.

   The ratio of acrylamide/bisacrylamide (19:1) is not the same as that usually prepared for the SDS-PAGE. Consequently, use the recipes given in Reagents and Solutions.

   If the size is unknown, run the gel until the bromophenol blue reaches 5 cm from the end of the gel.

7. Electrotransfer the sample onto a nitrocellulose Hybond N^+ membrane 1.5 hr in transfer buffer at a constant current of 0.4 A at room temperature (*UNIT 6.2*).
8. Dry the membrane with a hair dryer. Cross-link the pADPr by exposing the membrane to a 312-nm UV source for 5 min.

Immunoblot and detect pADPr

9. Incubate the membrane in 50 ml PBS-MT on a orbital platform shaker for at least 1 hr at room temperature.
10. Perform immunoblot detection with an appropriate anti-pADPr antibody as described (see Basic Protocol 2, steps 5 to 10).

    This procedure was optimized to immunodetect quantities of 1 pmol pADPr isolated from cells when using the LP96-10 (1:5000) as anti-pADPr antibody (see Critical Parameters). The authors noticed that, with this technique, the 10H (1:250) anti-pADPr antibody failed to detect pADPr below 25 mers.

11. Expose the membrane to X-Omat blue film (Kodak; *UNIT 6.3*) for an appropriate length of time.

BASIC PROTOCOL 4

Detection of Poly(ADP-Ribosyl)ated Proteins by Immunoblotting

Poly(ADP-ribosyl)ation is a post-translational modification occurring on glutamate residues of nuclear acceptor proteins, including PARP-1 itself. A large number of acceptor proteins have been identified in a variety of cellular processes. The existence of pADPr in intact cells is a transient event, because poly(ADP-ribose) glycohydrolase (PARG) rapidly catabolizes pADPr by virtue of its exo- and endo-glycohydrolase activities. Under normal growth conditions, cultured cells display low basal levels of polymer, which can dramatically increase when cells are exposed to DNA-damaging agents. On immunoblots, basal protein-bound pADPr generally appears in concentrated smears that originates at ~116 and 89 kDa, likely representing automodification of PARP-1 and its apoptotic fragment (Boyonoski et al., 2002a,b); however, other molecular weights are observed, and the patterns vary between tissues. As a complementary approach to determine the presence of active PARPs, the following protocol provides a simple assay to monitor the accumulation of pADPr in a cellular or tissue extract. This assay uses a specific anti-pADPr primary antibody to quantify the accumulation of pADPr covalently bound to proteins. This technique provides an estimation of the total quantity of pADPr, chain lengths, and molecular weights of major acceptor proteins.

Materials

Cells in appropriate medium *or* pretreated anesthetized animal
DNA-damaging agents, oxidative stress, or apoptosis-inducing stimulus
HeBS (*APPENDIX 2A*), ice cold
HeBS containing 1 mM PMSF and Complete protease inhibitor cocktail (Roche), ice cold
Extraction buffer (see recipe)
2× SDS sample buffer (*APPENDIX 2A*)
Reducing sample buffer (see recipe)
Ponceau S dye (see recipe)
PBS-MT (see recipe)
Anti-pADPr primary antibody
Peroxidase-conjugated secondary antibody
PBS-T: PBS containing 0.1% (v/v) Tween 20
PBS (*APPENDIX 2A*)
Chemiluminescence reagents for HRP-conjugated secondary antibodies
Prestained molecular weight standards (optional)

Cell scraper (optional)
15-ml conical centrifuge tube
Sonicator
65°C water bath
0.45-µm nitrocellulose membrane (Amersham Bioscieince)
Orbital platform shaker
X-Omat blue film (Kodak)

Additional regents and equipment for cell trypsinization (*UNIT 1.1*; optional), gel electrophoresis (*UNIT 6.1*), electrotransfer (*UNIT 6.2*), and immunoblotting (see Basic Protocol 2, steps 5 to 10)

Prepare samples

For cultured cell samples

1a. Subject cells of interest in appropriate medium to DNA-damaging agents, oxidative stress, or apoptosis-inducing treatments to stimulate pADPr synthesis.

2a. Remove and discard the medium from the cell culture and quickly wash the monolayer with 5 ml ice-cold HeBS.

3a. Harvest adherent cells in ice-cold 5 ml HeBS containing 1 mM PMSF and Complete protease inhibitor cocktail. Use a cell scraper or trypsinization (*UNIT 1.1*) to completely release cells from the dish.

The protease inhibitors may be excluded if direct immunoblotting is to be carried out.

Prepare tissue sample

1b. Remove tissues of interest as rapidly as possible from anesthetized pretreated animals. Flash freeze in liquid nitrogen and store up to 1 year at −80°C.

2b. Add chunks of frozen tissue to ice-cold extraction buffer. Homogenize on ice using a power unit.

The authors use ~0.25 g of tissue/ml buffer.

3b. Prepare ~100 to 200 µl tissue homogenate per milliliter of 2× SDS sample buffer and proceed immediately to step 9.

Lyse cells

4. Transfer harvested cultured cells to a 15-ml conical centrifuge tube and centrifuge 10 min at 600 × *g*, 4°C.

5. Wash the cell pellet twice with 5 ml of ice-cold HeBS, centrifuging as described (step 4).

6. Remove supernatant and lyse cells in reducing sample buffer at a concentration of 2×10^6 cells per milliliter.

The presence of urea in the sample buffer favors the dissociation of PARP-1 from DNA.

7. Sonicate resuspended cells on ice for three 20-sec bursts at 40% maximal output to shear the DNA.

8. Immediately freeze sample in liquid nitrogen and store up to 3 months at −80°C. Alternatively, proceed immediately to step 9.

This procedure was designed to obtain a cell extract inactivated as quickly as possible, because the pADPr is rapidly degraded by poly(ADP-ribose) glycohydrolase in whole cells.

Electrophorese sample

9. Incubate samples 15 min in a 65°C water bath.

10. Load a volume of sample equivalent to $1–2 \times 10^5$ cells or 20 µg protein/well onto a 6 × 8–cm 8% resolving SDS-polyacrylamide minigel (*UNIT 6.1*).

Do not forget to add appropriate molecular weight standards at this stage.

11. Electrophorese the gel (*UNIT 6.1*) and electrotransfer (*UNIT 6.2*) samples onto a 0.45-µm nitrocellulose membrane.

12. Stain the membrane with Ponceau S dye for 1 min and then wash extensively in deionized water to remove all residual dye.

This step is useful to identify molecular weight standards, confirm equal transfer of proteins, and visualize the protein profile of the samples. This step can be excluded if prestained molecular weight standards are used, although prestained standards are also less accurate if a close identification of molecular weight is required.

13. Incubate the membrane at least 1 hr in 50 ml PBS-MT on an orbital platform shaker at room temperature to block unoccupied protein-binding sites.

Immunoblot

14. Perform immunoblot detection with an appropriate anti-pADPr antibody as described (see Basic Protocol 2, steps 5 to 10) except incubate the membrane in anti-pADPr primary antibody at 4°C rather than room temperature (see Basic Protocol 2, step 5).

15. Expose the membrane to X-Omat blue film (Kodak; *UNIT 6.3*) for an appropriate length of time.

BASIC PROTOCOL 5

Immunocytochemical Detection of pADPr

Some investigators have proposed that the synthesis of pADPr could be a useful parameter to identify apoptotic cells (Donzelli et al., 1997; Scovassi and Poirier, 1999; Chang et al., 2002). The combination of pADPr synthesis with other apoptotic markers and the presence of PARP-1 cleavage (see Alternate Protocol 2) facilitates the determination of apoptosis in cell culture. PADPr synthesis is also a sensitive indicator of DNA damage from a variety of sources, such as alkylating agents and oxidative stress. The following procedure provides a sensitive and rapid method for identification of endogenous cellular pADPr synthesis, following DNA damage, by immunocytochemistry (see Fig. 18.7.1B). Alternatively, this procedure can be used to localize PARP family members in cultured cells.

Materials

Cells of interest in appropriate medium
DNA-damaging stimulus (e.g., 100 μM MNNG, 200 μM H_2O_2)
PBS (*APPENDIX 2A*), ice cold
70:30 (v/v) methanol/acetone, ice cold
PBS containing 1% (w/v) Triton X-100 and 10% (v/v) FBS
Anti-pADPr primary antibody
Fluorophore-conjugated secondary antibody
Fluoromount-*G* (Southern Biotech)

Coverslips and slides
Humid chamber (i.e., a petri dish lined with a wet paper towel)

Additional reagents and equipment for fluorescence microscopy (*UNIT 4.2*)

1. Grow cells of interest in appropriate medium on coverslips and expose them to DNA-damaging stimulus.

   Most DNA-damaging agents, oxidative stress, and apoptosis-inducing treatments can induce pADPr synthesis in different cell types. The authors prefer to treat mouse fibroblast C3H10T½ cells either with 100 μM MNNG for 15 min or with 200 μM hydrogen peroxide for 15 min. These two methods both give good results.

2. Wash the cells with 2 ml ice-cold PBS.

3. Fix cells by incubating them 15 min on ice in 2 ml ice-cold 70:30 methanol/acetone.

   A large number of fixation methods can be used at this stage. The authors have also obtained good results when cells were fixed for 10 min on ice with 10% ice-cold TCA (Lankenau et al., 1999); however, methanol/acetone fixation is preferred because traces of residual TCA may alter the integrity of the antibody used to detect pADPr.

4. Remove the methanol/acetone solution and wash four to five times with 2 ml ice-cold PBS.

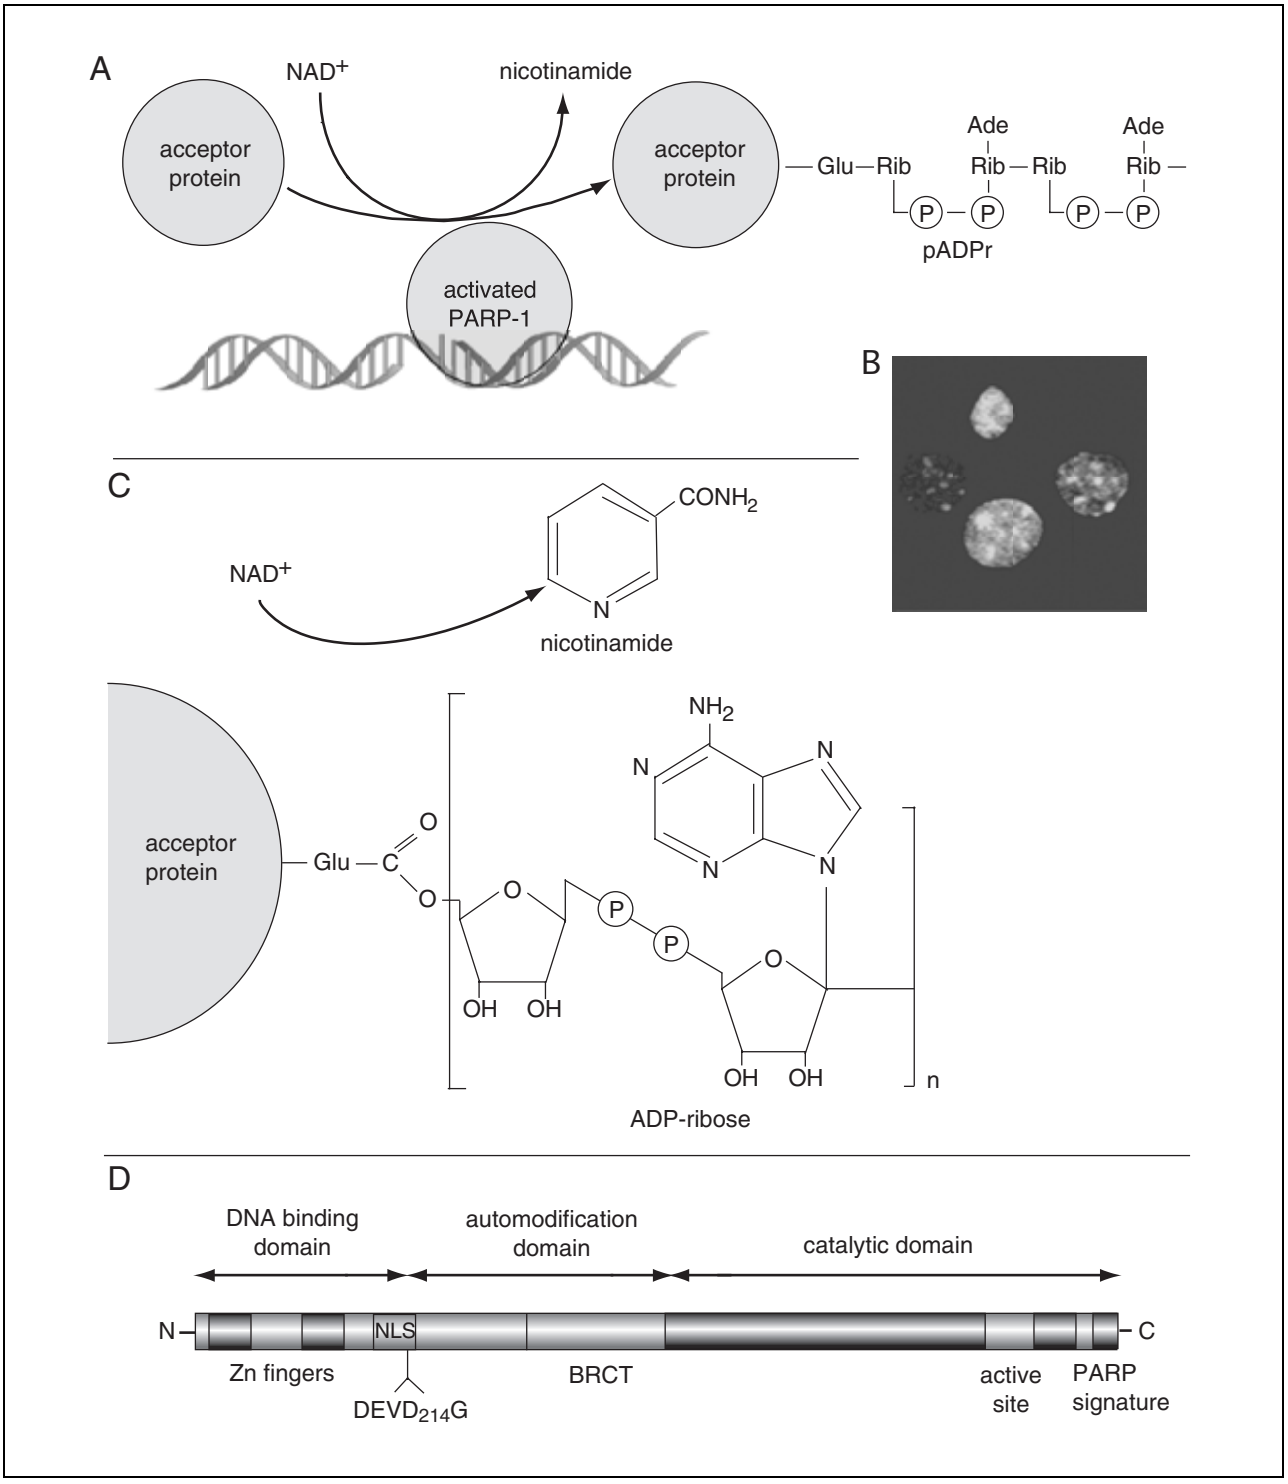

Figure 18.7.1 Poly(ADP-ribosyl)ation reaction and poly(ADP-ribose) polymerase-1 (PARP-1) structure. (**A**) PARP-1 is selectively activated by DNA strand breaks and transfers ADP-ribose from NAD^+ to a set of acceptor proteins. (**B**) Immunocytochemical detection of pADPr synthesized in mouse fibroblast C3H10T$_{1/2}$ cells exposed 15 min to 200 μM H_2O_2. Immunodetection was carried out with LP96-10 anti-pADPr polyclonal antibody (1:100) and revealed with 1:100 Texas Red–conjugated anti-rabbit second antibody (1:100). (**C**) The sequential addition of ADP-ribose units to a glutamic acid residue of an acceptor protein results in the formation of a long linear and branched chain of pADPr that is structurally similar to nucleic acids. (**D**) Schematic representation of PARP-1 domains. PARP-1 enzyme can be divided into three major domains (also see Fig. 18.7.2): a 46-kDa DNA binding domain, a central 22-kDa automodification region that contains the BRCT domain, and a 54-kDa C-terminal region that comprises the active site and the PARP signature. During caspase-dependent apoptosis, caspase-3 and -7 recognize a DEVD motif in the nuclear localization signal (NLS) and cleave PARP-1 into a p89 and a p24 fragment. (Adapted from the PARP link Web site: *http://parplink.u-strasbg.fr/index2.html*).

5. Permeabilize cells in 2 ml ml PBS containing 1% (w/v) Triton X-100 and 10% (v/v) FBS for 15 min at room temperature.

   FBS is used to block unspecific epitopes.

6. Remove permeabilizing solution and wash once with 2 ml ice-cold PBS.
7. Dilute the appropriate anti-pADPr primary antibody in PBS containing Triton X-100 and FBS according to supplier's instructions.
8. Incubate coverslips with 80 µl diluted primary antibody overnight at 4°C in a humid chamber.

   A petri dish lined with wet paper toweling is a suitable humid chamber.

9. Wash coverslips three to five times with 2 ml PBS.
10. Dilute an appropriate fluorophore-conjugated secondary antibody in PBS containing 1% Triton X-100 and 10% FBS according to supplier's instructions.
11. Incubate the coverslips 30 min with diluted secondary antibody at room temperature.

    This step should by done in darkness to avoid fluorochrome quenching.

12. Wash the coverslips several times with 2 ml PBS.
13. Mount coverslips on microscope slides with mounting medium (i.e., Fluoromount-*G*) according to manufacturer's instructions.

    Mounting slides with Fluoromount-G reduces fluorochrome quenching during analysis of slides by fluorescence microscopy. This mounting medium also provides a semipermanent seal for long-term storage of slides.

14. Allow mounted slides to air dry 5 min before analyzing the localization of cellular pADPr by fluorescence microscopy using an appropriate filter (*UNIT 4.2*).

DETECTION OF POLY(ADP-RIBOSE) POLYMERASE FAMILY MEMBERS IN CELLS

Poly(ADP-ribosyl)ation is a post-translational modification catalyzed mostly by the 116-kDa enzyme poly(ADP-ribose) polymerase-1 (PARP-1), a nuclear enzyme that transfers an ADP-ribose moiety onto a limited number of nuclear proteins, including itself (D'Amours et al., 1999). When cells are exposed to environmental stresses such as alkylating agents or free radicals, there is up to a 500-fold increase in net pADPr synthesis in response to DNA strand breaks. The enzyme responsible for 80% to 90% of this stimulated pADPr synthesis is PARP-1, while other PARPs are responsible for the remaining 10% to 20%. The physiological meaning of these phenomena is not clear; however, it can be interpreted as a way of translating an event occurring on DNA to the nucleus by protein modification and finally to cytoplasm via NAD^+ depletion (Chiarugi, 2002). It has also been proposed that the presence of negatively charged pADPr at the site of DNA damage may play several roles in regulation of base excision repair, p53 functions, and apoptosis.

In the past few years, several additional proteins catalyzing poly(ADP-ribosyl)ation have been identified (Fig. 18.7.2). These new members of the PARP family (Shall, 2002) include PARP-2, PARP-3, vPARP (PARP-4), tankyrase-1 (PARP-5) and -2 (PARP-6), and finally Ti-PARP (PARP-7). However, recent characterization of PARP-2 demonstrated that it possesses a nuclear distribution similar to PARP-1. PARP-2 also possesses an N-terminal DNA-binding domain and is activated in response to DNA damage (Ame et al., 1999). The similarities between the activity and functions of PARP-1 and -2, and the fact that PARP-1 knockout cells still have the ability to undergo apoptosis, suggest that PARP-2

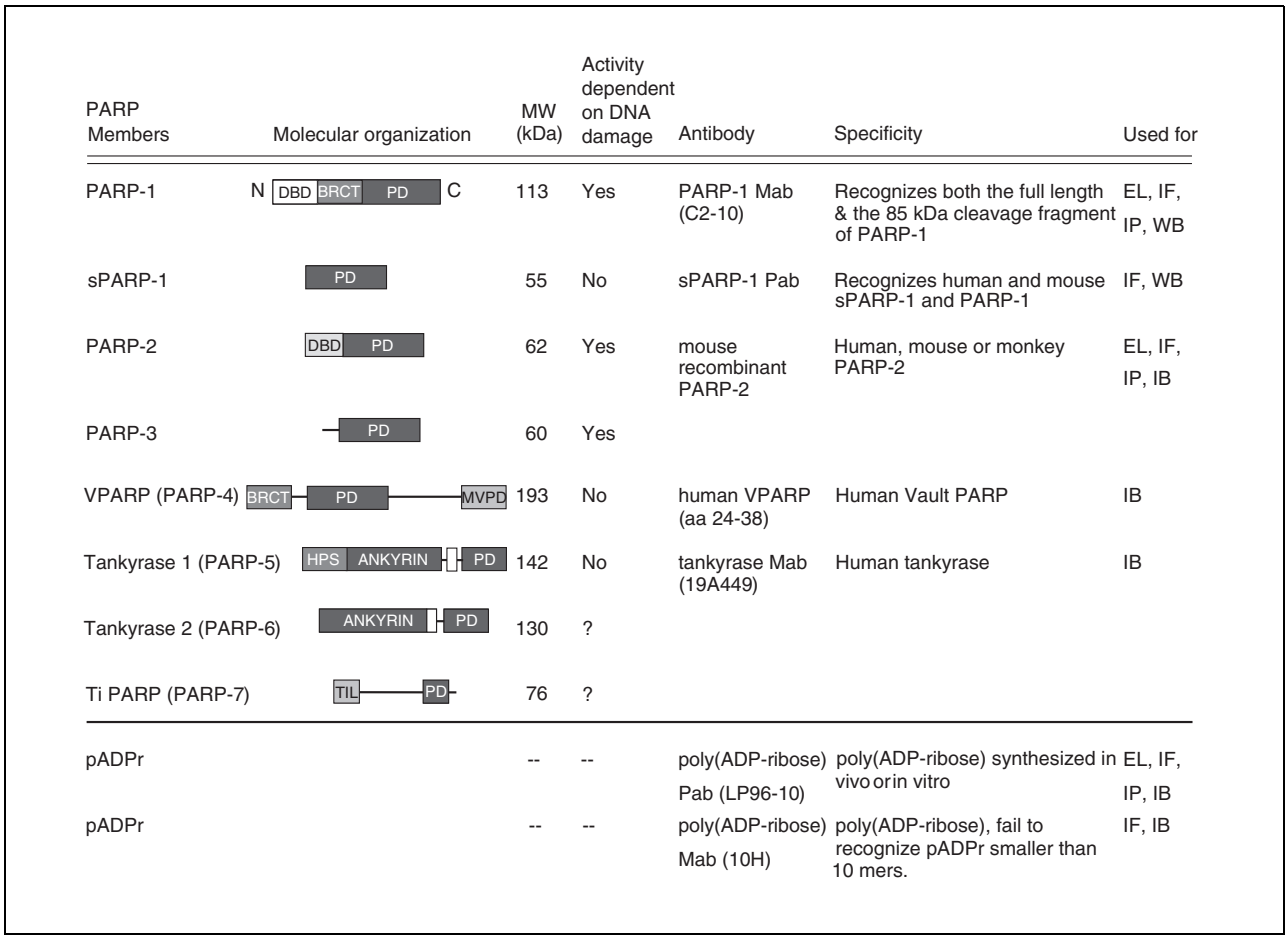

Figure 18.7.2 Poly(ADP-ribose) plolymerase family members and their antibodies. Abbreviations: EL, ELISA; IB, immunoblotting; IF, immunofluorescence; IP, immunoprecipitation.

may also play a role in apoptosis. Recent data suggest that PARP-3 is involved in centrosome duplication and cell cycle progression. The nucleoplasmic PARPs tankyrase-1 and -2 possess an N-terminal ankyrin domain and a C-terminal PARP domain and their PARP domains contain all of the amino acids necessary for catalysis (Cook et al., 2002). These PARPs have been described as being strand-break independent and are probably not responsive to DNA damage. A predominantly cytoplasmic PARP, vPARP, is a component of vault particles (Kickhoefer et al, 1999), but it is also observed in nuclear locations at some points of the cell cycle.

Detection of Poly(ADP-Ribose) Polymerase Enzymes by Immunoblot

BASIC PROTOCOL 6

Recently, identification of novel poly(ADP-risosyl)ating enzymes with distinct structures has led to a reconsideration of the role of pADPr in a large number of cellular process, such as DNA damage response, genomic stability, apoptosis, and chromatin modulation. PARP-1 has been shown to be stimulated directly or indirectly by free radicals or agents causing free radical release (Herceg and Wang, 2001). It is likely that PARP-1 is involved in the response to several different types of cell toxicity, because it can bind with very high affinity to double- or single-stranded breaks, and it consumes the NAD^+ pool in cells following genotoxic insults. Immunoblotting provides a useful method for the detection of various PARPs in cultured cells. Detailed below is a protocol for detection of PARP-1, but this procedure can also be applied to the detection of any PARP family member when an appropriate primary antibody is used (Fig. 18.7.2).

Materials

Tissue, fresh
Extraction buffer (see recipe), ice cold
2× SDS sample buffer (*APPENDIX 2A*)
HeBS (*APPENDIX 2A*), ice cold
Reducing sample buffer (see recipe)
Anti-PARP primary antibody
PBS-MT (see recipe) with and without 1 mM NaN_3
Horseradish peroxidase–conjugated secondary antibody
PBS-T: PBS/0.1% (v/v) Tween 20
PBS (*APPENDIX 2A*)
Chemiluminescence reagents for HRP-conjugated secondary antibodies

Glass homogenizer with Teflon pestle
15-ml conical centrifuge tube
Sonicator
65°C water bath
0.45-µm nitrocellulose membrane
Orbital platform shaker
X-Omat blue film (Kodak)

Additional reagents and equipment for preparation of cell extracts (see Basic Protocol 4, steps 2 to 11), electrophoresis (*UNIT 6.1*), electrotransfer (*UNIT 6.2*), and autoradiography (*UNIT 6.3*)

Prepare tissue extracts

1. Homogenize fresh tissue in ice-cold extraction buffer using 10 to 20 strokes of a Teflon pestle in a glass homogenizer. Dilute the homogenized tissue to a final concentration of 2.5 to 5 mg/ml by adding enough 2× SDS sample buffer.

   A small aliquot should be kept after homogenization for subsequent protein determination.

   Alternatively, frozen tissue can be pulverized in liquid nitrogen using a mortar and pestle and then suspended in extraction buffer and diluted in 2× SDS sample buffer. Note that frozen tissues may display partial proteolysis of enzymes and give poor results.

Prepare cell extracts, electrophorese and transfer

2. Perform cell extraction, electrophoresis, and transfer as described above (see Basic Protocol 4, steps 2 to 11).

Immunoblot

3. Dilute an appropriate anti-PARP primary antibody according to the supplier's recommendation in PBS-MT supplemented with 1 mM sodium azide. Incubate along with the membrane on an orbital platform shaker overnight at room temperature.

   A large number of antibodies against PARP-1 are commercially available. The monoclonal antibodies F1-23 (BioMol Research) and the C2-10 (BioMol Research) recognize the N-terminal region of PARP-1, which is not present in other PARP. Thus, they are currently used for specific detection of PARP-1. In mouse tissues, where blood contamination is frequent, the authors recommend the use of LP96-72 (BioMol Research), polyclonal antibody raised against affinity-purified PARP-1; however, in all cases, it is often useful to test the conditions of immunoblotting to obtain optimal results.

   C-2-10 is a mouse monoclonal antibody generated by immunization of mice with purified calf thymus PARP-1 that recognizes full-length (116 kDa) PARP as well as the 85 to 90 kDa apoptosis-related cleavage fragment of PARP.

4. Wash the membrane three times with 50 ml PBS-MT for 15 min each.

5. Dilute an appropriate horseradish peroxidase-conjugated secondary antibody in PBS-MT according to supplier's recommendations.
6. Incubate the membrane with 50 ml secondary antibody on a orbital platform shaker for 30 min at room temperature.
7. Discard the secondary antibody and wash the membrane as follows:

   Three times with 50 ml PBS-MT for 10 min each
   Three times with 50 ml PBS-T for 15 min each
   Twice with 50 ml PBS for 5 min each.

8. Analyze the blot using chemiluminescence reagents for HRP-conjugated secondary antibodies according to the manufacturer's instructions.

   When extracts from limited quantities of cells are used for the immunoblotting procedure, the authors recommend using of the SuperSignal West Dura Extended Duration Substrate system (Pierce) for low signal detection.

9. Expose the membrane to X-Omat blue film (*UNIT 6.3*) for an appropriate length of time.

Detection of PARP-1 Cleavage During Cell Death

ALTERNATE PROTOCOL 2

It may be useful to monitor several apoptotic parameters in a unique sample. Recently, several authors have reported that poly(ADP-ribosyl)ation plays a critical role in the apoptotic process (Soldani and Scovassi, 2002). They suggested that proteolysis of PARP-1 is a sensitive marker for identifying apoptotic cells (Scovassi and Poirier, 1999). During apoptosis induced by a variety of chemotherapeutic agents, two caspases, caspase-3 and -7, cleave PARP-1 into its apoptotic 24- and 89-kDa fragments (Germain et al., 1999). PARP-1 was among the first caspase substrates to be identified. In particular, its cleavage by caspase-3 is well documented. The appearance of the 89-kDa proteolytic product is an early event in the apoptotic process (Kaufmann et al., 1993). It displays DNA-independent enzyme activity, and it may be poly(ADP-ribosyl)ated and thus recognized by an anti-polymer antibody in a variety of processes that lead to cell death. This protocol describes a method for the detection of PARP-1 cleavage that can also be used for the detection of cleavage of other caspase substrates.

Prepare apoptotic cell extracts

1. Treat cells of interest with an appropriate apoptosis-inducing agent and incubate for a sufficient length of time.

   For example, 1×10^6 HL-60 human promyelocytic leukemia cells may be treated with 68 μM etoposide for 0 to 12 hr. This procedure constitutes a positive control for immunoblotting of caspase cleavage targets including PARP-1 in etoposide-induced apoptosis. A variety of apoptosis-inducing agents can induce the cleavage of PARP-1, although with different kinetics; therefore, the incubation time producing maximal PARP-1 cleavage must be determined for each of these agents.

2. After drug treatment, remove and discard medium from cell culture. Quickly wash the monolayer with 5 ml ice-cold HeBS.
3. Harvest adherent cells and prepare apoptotic cell extracts as described (see Basic Protocol 4, steps 4 to 8).

   The apoptotic cell extract may be stored at –30°C or –80°C at this stage or directly processed on an SDS-PAGE gel (UNIT 6.1).

Electrophorese and immunoblot

4. Perform electrophoresis and immunoblotting of samples as described (see Basic Protocol 4, steps 9 to 16).

BASIC PROTOCOL 7

Nonisotopic-Activity Immunoblot Detection of Poly(ADP-Ribose) Polymerases

This technique involves automodification of nitrocellulose-immobilized poly(ADP-ribose) polymerases using nonisotopic NAD^+ as the substrate. Detection of pADPr synthesis is done using anti-pADPr antibodies to immunoblot. This technique may be useful to study the activity of apoptosis-associated fragments of PARPs that remain active upon cleavage by caspases. The use of anti-pADPr antibodies to detect polymer synthesis on nitrocellulose-immobilized PARPs enables the detection of these enzymes isolated from many species for which anti-polymerase antibodies are not available. In brief, this procedure is divided into four major steps: (1) reduction of oxidized cysteines in the gel, (2) renaturation of proteins resolved on nitrocellulose membrane, (3) synthesis of polymer, and (4) detection of pADPr by 10H or LP96-10 antibodies.

Materials

Tissue, fresh
Extraction buffer (see recipe), ice cold
2× SDS sample buffer (*APPENDIX 2A*)
HeBS (*APPENDIX 2A*), ice cold
Reducing sample buffer (see recipe)
6 × 8–cm 8% or 10% resolving SDS-polyacrylamide minigel (*UNIT 6.1*)
Prestained or biotinylated molecular weight standards
Running buffer (*UNIT 6.1*) containing freshly added 0.7 M 2-mercaptoethanol
Renaturation buffer (see recipe) with and without 100 μM NAD
Nonisotopic-activity immunoblot reducing buffer (see recipe)
PBS-MT (see recipe)
Anti-pADPr primary antibody
Horseradish peroxidase–conjugated secondary antibody
PBS-T: PBS/0.1% (v/v) Tween 20
PBS (*APPENDIX 2A*)
Chemiluminescence reagents for HRP-conjugated secondary antibodies

Glass homogenizer with Teflon pestle
15-ml conical centrifuge tube
Sonicator
65°C water bath or heat block
Orbital platform shaker
X-Omat blue film (Kodak)

Additional reagents and equipment for SDS-PAGE (*UNIT 6.1*), immunoblotting (*UNIT 6.2*), and autoradiography (*UNIT 6.3*)

Prepare cellular and tissue extracts

1. Homogenize fresh tissue in ice-cold extraction buffer using 10 to 20 strokes of a Teflon pestle in a glass homogenizer. Dilute the sample to a final concentration of 2.5 to 5 mg protein/ml in 2× SDS sample buffer.

   A small aliquot should be kept after homogenization for subsequent protein determination.

   Alternatively, frozen tissue can be pulverized in liquid nitrogen using a mortar and pestle then suspended in extraction buffer and diluted in 2× SDS sample buffer. Note that frozen tissues may display partial proteolysis of enzymes and give poor results.

Lyse cells

2. Transfer cells to a 15-ml conical centrifuge tube and centrifuge 10 min at 600 × *g*, 4°C.
3. Wash the cell pellet twice with 5 ml of ice-cold HeBS, centrifuging as described (step 2).
4. Remove supernatant and lyse cells in reducing sample buffer at a concentration of 2 × 10^6 cells per milliliter.

   The presence of urea in the sample buffer favors the dissociation of PARP-1 from DNA.

5. Sonicate resuspended cells on ice for three 20-sec bursts at 40% maximal output to shear the DNA.
6. Immediately freeze sample in liquid nitrogen and store up to 6 months at −80°C. Alternatively, proceed immediately to step 7.

Electrophorese and transfer

7. Incubate sample 15 min in a 65°C water bath or heat block.
8. Load a volume of sample equivalent to 75,000 cells or 20 µg protein in a well of a 6 × 8–cm 8% or 10% resolving SDS-polyacrylamide minigel. Also load prestained or biotinylated standards.

   Prestained or biotinylated molecular weight standards are used to avoid staining under acidic conditions, which may be detrimental to the polymerase activity (step 11).

9. Electrophorese gel as for a classical SDS-PAGE (*UNIT 6.1*).
10. After electrophoresis, soak gel 1 hr in running buffer containing freshly added 0.7 M 2-mercaptoethanol at 37°C.

    This treatment is necessary to avoid cross-linking between proteins and reduction of the cysteines present in poly(ADP-ribose) polymerases.

11. Transfer proteins to a nitrocellulose membrane as for a classical immunoblotting (*UNIT 6.2*).

    Do not stain the membrane with Ponceau S dye.

Renature proteins

12. Incubate the membrane on an orbital platform shaker 1 hr at room temperature in renaturation buffer without NAD.

    This step is important because it allows the restoration of the active PARP conformation.

13. Soak the nitrocellulose membrane on an orbital platform shaker for 1 hr at room temperature in 50 ml of renaturation buffer with 100 µM NAD.
14. Wash the membrane in 50 ml renaturation buffer without NAD four times for 15 min each at room temperature.
15. Wash the membrane in 50 ml nonisotopic-activity immunoblot reducing buffer to remove noncovalently bound pADPr.

Immunoblot

16. Wash the membrane three times with 50 ml PBS-MT for 15 min each.
17. Dilute an appropriate horseradish peroxidase–conjugated secondary antibody in PBS-MT.

18. Incubate the membrane with 50 ml of an appropriate horseradish peroxidase–conjugated secondary antibody on a orbital platform shaker for 30 min at room temperature.

19. Discard the secondary antibody and wash the membrane as follows:

    Three times with 50 ml PBS-MT for 10 min each
    Three times with 50 ml PBS-T for 15 min each
    Twice with 50 ml PBS for 5 min each.

20. Analyze the blot using chemiluminescence reagents for HRP-conjugated secondary antibodies according to the manufacturer's instructions.

    When extracts from limited quantities of cells are used for the immunoblotting procedure, the authors recommend using the SuperSignal West Dura Extended Duration Substrate system (Pierce) for low signal detection.

21. Expose the membrane to X-Omat blue film (*UNIT 6.3*) for an appropriate length of time.

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

AAGE9 buffer

250 mM ammonium acetate, pH 9.0
6 M guanidine hydrochloride
10 mM EDTA
Store 6 months at room temperature

ABTS/H_2O_2 solution

Just before use, prepare 100 ml citrate-phosphate buffer by dissolving 0.103 g anhydrous citric acid (MW 192.1) and 0.108 g anhydrous dibasic sodium phosphate in 100 ml water. Adjust to pH 4.6 with 1 N HCl. To this buffer, add 50 mg of 2,2′-azino-bis(3-ethylbenzothiazoline-6-sulfonic acid) and 50 µl of 30% (v/v) hydrogen peroxide.

Acrylamide/bisacrylamide (19:1), 30% (w/v)

28.5 g acrylamide
1.5 g bis(acrylamide)
100 ml H_2O
Store for a maximum of 4 weeks at 4°C in a brown bottle.

Extraction buffer

50 mM glucose
25 mM Tris·Cl, pH 8.0 (*APPENDIX 2A*)
10 mM EDTA
1 mM PMSF
1× Complete protease inhibitor cocktail (Roche)
Prepare fresh

Modified Laemmli sample buffer

6 M urea
25 mM NaCl
4 mM EDTA
0.02% (w/v) xylene cyanol
0.02% (w/v) bromophenol blue
Store up to 6 months at room temperature

Nonisotopic-activity immunoblot reducing buffer

50 mM Tris·Cl, pH 8.0 (*APPENDIX 2A*)
100 mM NaCl
1 mM dithiothreitol (DTT)
2% (w/v) SDS
Prepare fresh

PBS-MT

PBS (*APPENDIX 2A*)
5 % (w/v) nonfat dried milk
0.1% (v/v) Tween 20
Prepare fresh

PBS-MT$_2$

PBS, pH 7.4 (*APPENDIX 2A*)
5% (w/v) nonfat dried milk
0.05% (v/v) Tween 20
Prepare fresh

Polyacrylamide gel, 20% (w/v)

100 ml 30% 19:1 (w/v) acrylamide/bisacrylamide (see recipe)
30 ml TBE electrophoresis buffer 5× (see recipe)
19 ml H_2O
Store up to 4 weeks at 4°C
Just before use add 0.75 ml 10% (w/v) ammonium persulfate (APS)
0.06 ml *N*,*N*,*N*′,*N*′-tetramethylethylenediamine (TEMED)

Ponceau S dye

2 g Ponceau S
30 g trichloroacetic acid (TCA)
30 g sulfosalicylic acid
100 ml H_2O
Store up to 1 year at room temperature

Reducing sample buffer

62.5 mM Tris·Cl, pH 6.8 (*APPENDIX 2A*)
4 M urea
10% (v/v) glycerol
2% (w/v) SDS
0.00125% (w/v) bromophenol blue
Store up to 6 months at room temperature
Just before use, add 2-mercaptoethanol to 5% (w/v)

Renaturation buffer

50 mM Tris·Cl, pH 8.0 (*APPENDIX 2A*)
100 mM NaCl
1 mM dithiothreitol (DTT)
0.3% (v/v) Tween 20
2 mM $MgCl_2$
Prepare fresh

TBE electrophoresis buffer, 5×

54 g Tris base (890 mM)
27.5 g boric acid (890 mM)
980 ml H_2O
20 ml 0.5 M EDTA, pH 8.0 (20 mM final; see *APPENDIX 2A*)
Store up to 6 months at room temperature

TBE stands for Tris/borate/EDTA.

COMMENTARY

Background Information

PARP-1 structure and function

The enzyme poly(ADP-ribose) polymerase-1 (PARP-1; EC 2.4.2.30) is a multifunctional enzyme that can be divided into three major domains (see Fig. 18.7.1D). A 41.5-kDa N-terminal region comprises the DNA binding domain (DBD), which contains two zinc-finger motifs and a nuclear localization signal (NLS). This region recognizes both double- and single-stranded DNA breaks in a nonsequence-dependent manner through the first and second zinc finger, respectively. A 16-kDa central automodification domain contains fifteen highly conserved glutamate residues thought be the targets of self-poly(ADP-ribosyl)ation, and a 55.4-kDa C-terminal region contains both the NAD binding site and the catalytic domain which synthesizes poly(ADP-ribose) (pADPr). The primary structure of the enzyme is highly conserved in eukaryotes (D'Amours et al., 1999; Pieper et al., 1999; Burkle, 2001; Herceg and Wang, 2001; Virag and Szabo, 2002).

Poly(ADP-ribosyl)ation is a post-translational modification of nuclear proteins, in which PARP-1 itself is the main poly(ADP-ribosyl)ated protein in vivo. PARP-1 is selectively activated by DNA strand breaks to catalyze the addition of pADPr from its substrate, nicotinamide adenine dinucleotide (NAD), to a set of acceptor proteins (see Fig. 18.7.1A). After initiation, PARP catalyzes elongation and branching reactions to synthesize a highly branched and complex structure of over 200 ADP-ribose residues into a large homopolymer that is structurally similar to nucleic acids (see Fig. 18.7.1C). The massive automodification of PARP-1 dramatically changes its physical properties. Thus, PARP-1 molecules carrying long, highly negatively charged, branched ADP-ribose polymers lose their affinity for DNA and are then inactivated. The automodification process represents a major regulatory mechanism leading to the down-regulation of the enzyme activity (reviewed in Lindahl et al., 1995).

Signaling function of pADPr

PADPr that is synthesized in response to massive DNA damage has a short half-life. It is rapidly hydrolyzed at ribose-ribose bonds and converted to free ADP-ribose units by the enzyme poly(ADP-ribose) glycohydrolase (PARG; Davidovic et al., 2001). The rapid response of PARG to pADPr synthesis indicates that pADPr degradation is also an important nuclear response to DNA damage. PARG constitutes an important component in the control of nuclear pADPr levels, which will in turn have direct effects on the activity of poly(ADP-ribosyl)ated proteins and on the levels of free pADPr. If there is a pADPr concentration threshold required to trigger apoptosis, the level at which PARG controls pADPr levels becomes critical for the decision point of apoptosis versus DNA repair and cell survival. The possible function of PARG in apoptosis and DNA repair is also supported by the fact that free pADPr generated by PARG may target many DNA damage checkpoints and DNA repair proteins. These cytoplasmic and nuclear proteins could interact strongly with free pADPr, by noncovalent interactions possibly mediated by a pADPr binding motif and alter their functions (Pleschke et al., 2000).

Poly(ADP-ribosyl)ation is involved in a variety of physiological events such as chromatin decondensation, DNA replication, DNA repair, apoptosis, and cellular differentiation (reviewed in Virag and Szabo, 2002). For example, poly(ADP-ribosyl)ation of histones decondenses chromatin structure, whereas subsequent degradation of the polymer restores chromatin to its condensed form. Relaxation of chromatin by poly(ADP-ribosyl)ation might facilitate the access of DNA regulatory and repair enzymes at sites of damage as well as at origins of replication and transcription initiation sites. In addition to modifying chromatin structure, PARP-1 has been shown to affect the function of several transcription factors, DNA replication factors and signaling molecules (i.e., NF-κB, AP-2, Oct-1, DNA-PK, p53, Topoi-

somerase-1, Lamin B) by noncovalent protein-protein interactions and by active poly(ADP-ribosyl)ation.

PARP-1 activation appears to be a sensitive marker of DNA damage at an early stage of the DNA damage response (see Fig. 18.7.3). Poly(ADP-ribosyl)ation is considered to be a major player in the cellular response to DNA damage because a large number of nuclear proteins are covalently modified with pADPr immediately following DNA breakage (Donzelli et al., 1997; Scovassi and Poirier, 1999; Duriez and Shah, 1997; Soldani and Scovassi, 2002). Moreover, the binding of PARP-1 to DNA strand breaks and the resulting synthesis of pADPr might constitute an emergency signal of damaged DNA to other compartments of cells, such as the mitochondrion (Chiarugi and Moskowitz, 2002).

PARP cleavage during cell death

When programmed cell death is activated, caspase-7 and -3 efficiently cleave and inactivate PARP-1 into a 24-kDa fragment containing the N-terminal DNA binding domain and a 89-kDa peptide comprising the central automodification domain, the C-terminal domain, and the catalytic domain (see Fig. 18.7.2). Proteolytic cleavage of PARP-1 into these two characteristic fragments was first recognized by Kaufmann and colleagues at an early stage of etoposide-induced apoptosis in treated human HL-60 cells (Kaufmann et al., 1993). The site of PARP-1 cleavage ($DEVD_{213}$ in human PARP-1) is located within the nuclear localization signal and is highly conserved. Separating the two zinc fingers from the catalytic domain renders the 89-kDa fragment insensitive to activation by additional DNA strand breaks, resulting in the inactivation of PARP-1 activity. However, several studies have shown that this 89-kDa apoptotic fragment can also serve as an early marker of apoptosis induced by a variety of chemotherapeutic agents.

The concept of PARP-mediated cell death following excessive DNA damage is supported by a number of studies that show prevention of cell death by specific PARP inhibitors and in mice deficient in PARP-1 (Shall and de Murcia, 2000; Burkle, 2001; Chiarugi, 2002; Virag and Szabo, 2002). For example, the PARP inhibitor, 3-aminobenzamide, has been shown to slow down the rejoining of DNA strand breaks and to increase the frequency of sister chromatid exchanges in MNNG-induced DNA damage (Oikawa et al., 1980). PARP inhibition also rendered cells more sensitive to cytotoxicity induced by DNA-damaging agents.

PARP-2

Studies from many laboratories have demonstrated the presence of additional proteins which are able to synthesize pADPr. This observation explains why PARP-1-deficient cells have some residual PARP activity. However, research on the biological role of these novel PARP enzymes is at an early stage. Moreover, some interesting differences in their structural domain, subcellular localization, and ability to be activated by DNA strand breaks have already been established (Fig. 18.7.2). PARP-1 is the best characterized of a growing family of enzymes; however, recent data have provided a model for the biological role of PARP-2 (Ame et al., 1999; Schreiber et al., 2002). This 62-kDa protein is capable of auto-poly(ADP-ribosyl)ation but could not poly(ADP-ribosyl)ate histones. Despite the fact that the BRCT domain is missing in PARP-2 and that the DNA binding domain (DBD) is very short, this enzyme also localizes to nuclei and is activated by DNA strand breaks. This led to the hypothesis that PARP-2 might be implicated in PARP-mediated cell death. Recently, PARP-2 has been demonstrated to be cleaved by caspase-8 in ischemia-induced neuronal apoptosis (Benchoua et al., 2002). Interestingly, cleavage of PARP-2 by caspase-8 dissociates the DNA binding domain (DBD) of PARP-2 from its catalytic domain, resulting in the inactivation of its DNA-dependent pADPr synthesis activity.

PARP-1 activation time course

Several investigators have examined the time course of PARP-1 activation and cleavage during apoptosis. They used immunofluorescence microscopy (see Basic Protocol 5 and Alternate Protocol 2) as well as immunoblot analysis with antibodies to PARP-1 and pADPr in intact cells or tissues (see Basic Protocols 4 and 6). The authors' laboratory has been actively involved in the establishment and improvement of several methods to study pADPr synthesis and catabolism (Shah et al., 1995; Affar et al., 1999a,b; Boucher et al., 2001). The development of standardized procedures to analyze pADPr synthesis and PARP-1 cleavage during cell death using in vitro models and in cultured cells yield specific tools to study many cell functions influenced by pADPr metabolism. One or more of the techniques presented

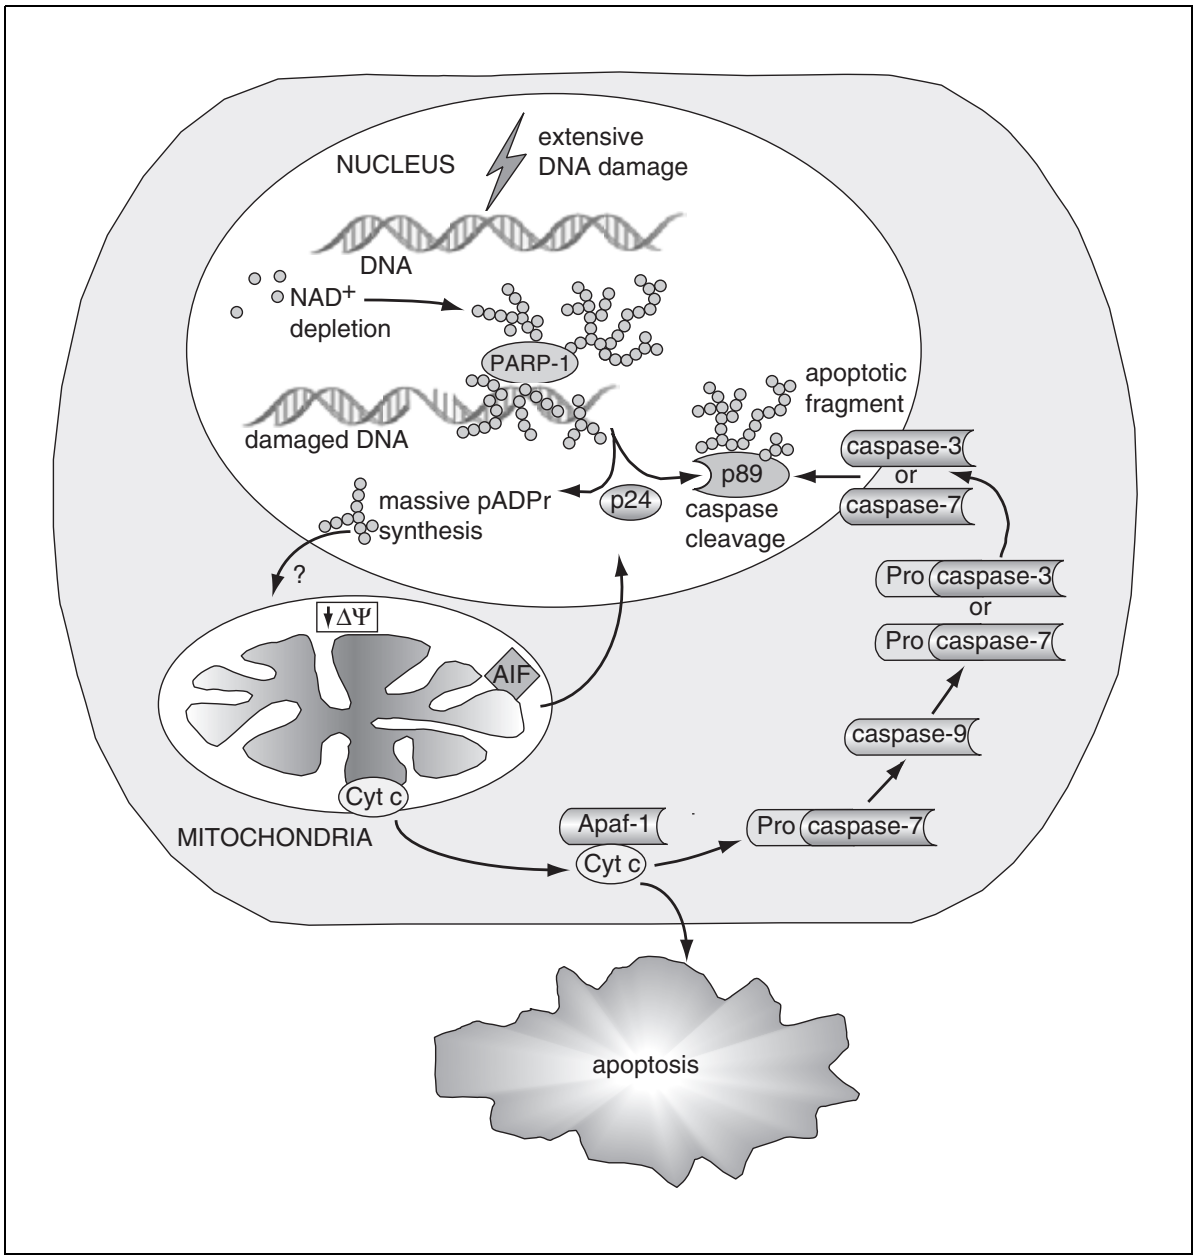

Figure 18.7.3 The concept of PARP-1-mediated cell death. Excessive DNA damage activates PARP-1 in the nucleus, leading to massive pADPr formation and resulting in a NAD^+ depletion. This high concentration of pADPr may trigger mitochondrial depolarization ($\downarrow\Delta\Psi$) and drive apoptosis through an unknown mechanism. Activated PARP-1 can mediate cell death by caspase-dependent and -delayed pathways. In the caspase-delayed pathway, the insults to DNA, produced by oxidative stress or DNA alkylating agents, induces the release of mitochondrial factors, such as AIF, that translocates to the nucleus and induces caspase-independent chromatin fragmentation into large 50-kDa fragments. However, in caspase-dependent apoptosis, caspase-3 and -7 cleave PARP-1 into two fragments: p89 and p24. Generation of 24-kDa apoptotic fragment contribute to PARP-1 inactivation. The early cleavage PARP-1 serves as preserving cellular ATP for the proper function of further energy-dependent stage of apoptosis.

in this unit has been used routinely for the detection of apoptotic events in numerous models of cell death. There are many reasons for using PARP-1 cleavage and pADPr synthesis as a sensitive assay for apoptosis. Although PARP-1 is not the only protein cleaved during apoptosis, it is a convenient tool to study caspase activity, and a wide range of detection reagents are currently available from various commercial suppliers. Nevertheless, most of the protocols presented in this unit can be used for studies of other PARPs in order to determine their possible role in cell death.

Critical Parameters

Immunodetection of pADPr

Several points should be considered when using the immunodot method to quantify the levels of pADPr in intact cells. To successfully quantify polymer levels in intact cells, a known concentration of pADPr sample should be used to make a standard curve. This will ensure a more accurate quantification. Quantities loaded should stay within the linear, or mildly curvilinear portion of the response curve. Measurement of polymer concentrations following DNA damage has been described in cultured cells (Affar et al., 1998), but quantitation in animal tissues may be more difficult (Boyonoski et al., 2002a,b). To efficiently quantify the concentration of pADPr in animal tissues, a known amount of protein-bound pADPr from rat liver samples, analyzed by HPLC methods, and/or automodified PARP-1 can be used as standards. These standards reflect chain length and branching similar to that found in other tissues from the whole animal. pADPr made in vitro and in many cultured cells appears to be larger and more complex than observed in vivo.

Although only a limited number of anti-pADPr antibodies are commercially available, monoclonal (10H) and polyclonal (LP96-10) anti-pADPr antibodies can serve for immunodetection of pADPr. The authors prefer LP96-10 antibody because some studies have revealed that the 10H monoclonal antibody fails to recognize pADPr smaller than 25 residues. The specificity of the anti-pADPr antibody LP96-10 or LP98-10 was confirmed in an in vitro competition study (Affar et al., 1999a), and it was shown that NAD, AMP, and ADP-ribose (10 nM) did not significantly interfere with antibody-pADPr binding. Cross-reactivity with nucleic acids is minimal with genomic and nicked DNA, transfer RNA, and total RNA, in contrast to the strong signal obtained with pADPr.

Detection of PARP-1 cleavage

The relationship between PARP-1 cleavage and apoptosis has been observed by a number of investigators. When immunoblotting detection methods are used for PARP-1 cleavage (see Alternate Protocol 2), one should always keep in mind the possibility of cross-reactivity between the anti-mouse IgG secondary antibodies and polypeptides present in cell lysates. Thus, the detection of PARP-1 cleavage should always be assessed along with morphological changes and DNA fragmentation observation, two other well defined markers of apoptosis. In cases where immunoblotting remains equivocal, it might even be necessary to use a PARP activity immunoblot (see Basic Protocol 7). When poly(ADP-ribose) polymerases are subjected to SDS-PAGE, transferred to nitrocellulose, renatured, and incubated with radioinert NAD, the synthesis of pADPr polymer can be detected using anti-pADPr antibodies. One advantage of this simple nonradioactive activity immunoblot technique is that it can detect any PARP activity in any sample.

Preparation of cell samples

Other critical parameters should be considered when preparing the cell extract. The pADPr synthesized following DNA damage has a very rapid turnover, due to its hydrolysis by PARG (see Basic Protocol 4). Consequently, work as quickly as possible during preparation of cell extracts to avoid the action of activated PARG. This can be achieved by retaining cell extracts on ice or using a specific inhibitor of the PARG enzyme. Note that the procedures described in this unit were optimized to have minimal pADPr degradation during processing of cell samples.

Anticipated Results

Quantitation of pADPr

Most cell lines have a basal level of pADPr in the range of 2 to 30 pmols/mg DNA or 10^8 cells (Affar et al., 1999b); however, in some cell lines, such as human keratinocytes, basal pADPr levels are ~50 to 65 pmols/mg DNA or 10^8 cells (Malanga and Althaus, 1994). Treatments with alkylating agents, such as MNNG, generally induce a 10- to 100-fold stimulation in pADPr synthesis following the formation of DNA strand breaks. The two quantitation methods described in this unit (see Basic Protocol 2

and Alternate Protocol 1), allow the detection of femtomolar concentrations of pADPr.

Immunodetection of pADPr

High-resolution gel electrophoresis, combined with immunodetection of pADPr (see Basic Protocol 3), provides a valuable method to quantify different sizes of pADPr in cultured cells. With this protocol, as little as 1 pmol pADPr may be detected. This high sensitivity can be used for monitoring changes in pADPr size distribution following DNA damage. Although Basic Protocol 2 and Alternate Protocol 1 could also serve to quantify the concentration of pADPr, these techniques do not provide much information about size distribution.

Immunocytochemical detection

The typical results obtained with immunocytochemical detection of pADPr are presented in Figure 18.7.1B. Generally, when mouse fibroblast C3H10T½ cells are grown on coverslips and stained for pADPr with pAb LP96-10, basal levels of polymer are not detected. However, the burst of pADPr synthesis, which occurs rapidly following DNA damage, peaks and can be visualized within 15 min (see Basic Protocol 5). The use of TCA as the method of fixation gives reliable and reproducible results, since pADPr is insensitive to TCA treatment. However, this method may be incompatible with colocalization experiments due to the possible loss of epitopic sites in some proteins. For pADPr colocalization experiments, methanol/acetone may be a better method of fixation.

Detection of PARP-1 Cleavage

It is generally accepted that PARP-1 proteolysis is a hallmark of caspase-dependent apoptosis. PARP-1 is cleaved by caspases 3 and 7 in the DEVD↑G_{214} during DNA damage–induced cell death. Both fragments can be easily recognized by immunoblot (see Alternate Protocol 2) with several antibodies. The visualization of PARP-1 and its apoptotic fragment is facilitated by the presence of urea in the sample buffer. However, due to the strong association of PARP-1 and DNA stands, it has been found that DNA-bound PARP-1 may be resistant to caspase-3 cleavage (D'Amours et al., 1998). The cleavage of PARP-1 remains a useful parameter to identify apoptotic cells when it is used in combination with other parameters like DNA fragmentation and morphological change.

Time Considerations

Preparation and quantification of pADPr

Several days (3 to 5) are necessary to perform accurate quantification of pADPr by ELISA or by immunodot blot. The entire quantification involves pADPr induction in cells, preparation of cell lysates, isolation and purification of pADPr from cell pellets, and quantification by immunological methods. Therefore, the process can be stopped at many specific steps and some steps can be done simultaneously. For example, during the induction of pADPr synthesis (~15 to 30 min) the DHBB resin could easily be equilibrated. The TCA precipitate cell pellets and lyophilized DHBB-purified samples can be stored for several months at −80°C. Also note that when the incubation time for the primary antibody is reduced to 2 hr in the immunodot blot procedure (see Basic Protocol 2, step 5) the signal is not sharp.

High-resolution gel electrophoresis

The entire electrophoresis and immunodetection procedure can be completed in 2 days.

After pre-electrophoresis of the 20% polyacrylamide gel, the time required to obtain a fine separation for each size class of pADPr is ~3 to 4 hr. The electrotransfer onto a nitrocellulose membrane takes 1.5 hr, blocking takes 1 hr, incubation with primary antibody is done overnight and finally, washes and incubation with secondary antibody takes ~2 hr. However, pADPr separated by high-resolution electrophoresis can be stained directly on the gel using GELCODE color silver stain kit (Pierce), a procedure less sensitive than the immunodetection method presented in Basic Protocol 3 but allowing the detection of polymer sizes up to 3 mers within the same day. This method has been improved by the group of Althaus for pADPr size quantification (Malanga et al., 1995).

Immunoblotting

This procedure usually takes more then a single working day to treat cells, prepare cell lysates, perform SDS-PAGE, transfer to nitrocellulose, and probe immunoblots. Therefore, samples could be prepared on the first day and the gels run on the second day. Here again, the incubation time for the primary antibody could be reduce to 2 hr. The process could also take advantage of minigels and a minitransfer apparatus, but note that the resolution of the smaller blots will be limited especially if the sample is highly complex.

Immunocytochemical detection of pADPr

The entire immunocytochemical detection of pADPr extends over 2 days. After cells are growing on coverslips, a 15-min DNA-damaging treatment will induce pADPr synthesis. The limiting step after treatment is the overnight incubation in primary antibody. Subsequently, second antibody incubation, washes, and microscopy analysis take no more than 1 hr.

Internet Resources

http://parplink.u-strasbg.fr/index2.html

The PARP Link Web Resource contains useful biological resources and pertinent information to the poly(ADP-ribose) polymerases (PARP) family of proteins and to their role in maintaining the integrity of the eukaryotic genome. This site offers instant access to the latest information and data on the PARP proteins and poly(ADP-ribosyl)ation and provides a valuable resource to the scientific community.

Figure 18.7.1 Poly(ADP-ribosyl)ation reaction and poly(ADP-ribose) polymerase-1 (PARP-1) structure. (**A**) PARP-1 is selectively activated by DNA strand breaks and transfers ADP-ribose from NAD^+ to a set of acceptor proteins. (**B**) Immunocytochemical detection of pADPr synthesized in mouse fibroblast C3H10T½ cells exposed 15 min to 200 μM H_2O_2. Immunodetection was carried out with LP96-10 anti-pADPr polyclonal antibody (1:100) and revealed with 1:100 Texas Red–conjugated anti-rabbit second antibody (1:100). (**C**) The sequential addition of ADP-ribose units to a glutamic acid residue of an acceptor protein results in the formation of a long linear and branched chain of pADPr that is structurally similar to nucleic acids. (**D**) Schematic representation of PARP-1 domains. PARP-1 enzyme can be divided into three major domains (also see Fig. 18.7.2): a 46-kDa DNA binding domain, a central 22-kDa automodification region that contains the BRCT domain, and a 54-kDa C-terminal region that comprises the active site and the PARP signature. During caspase-dependent apoptosis, caspase-3 and -7 recognize a DEVD motif in the nuclear localization signal (NLS) and cleave PARP-1 into a p89 and a p24 fragment. (Adapted from the PARP link web site: *http://parplink.u-strasbg.fr/index2.html*.

Figure 18.7.2 Poly(ADP-ribose) plolymerase family members and their antibodies. Abbreviations: EL, ELISA; IB, immunoblotting; IF, immunofluorescence; IP, immunoprecipitation.

Figure 18.7.3 The concept of PARP-1-mediated cell death. Excessive DNA damage activates PARP-1 in the nucleus, leading to massive pADPr formation and resulting in a NAD^+ depletion. This high concentration of pADPr may trigger mitochondrial depolarization ($\downarrow\Delta\Psi$) and drive apoptosis through an unknown mechanism. Activated PARP-1 can mediate cell death by caspase-dependent and -delayed pathways. In the caspase-delayed pathway, the insults to DNA, produced by oxidative stress or DNA alkylating agents, induces the release of mitochondrial factors, such as AIF, that translocates to the nucleus and induces caspase-independent chromatin fragmentation into large 50-kDa fragments. However, in caspase-dependent apoptosis, caspase-3 and -7 cleave PARP-1 into two fragments: p89 and p24. Generation of 24-kDa apoptotic fragment contribute to PARP-1 inactivation. The early cleavage PARP-1 serves as preserving cellular ATP for the proper function of further energy-dependent stage of apoptosis.

Flow Cytometry of Apoptosis

This unit describes the most common methods applicable to flow cytometry that make it possible to: (1) identify and quantify dead or dying cells, (2) reveal a mode of cell death (apoptosis or necrosis), and (3) study mechanisms involved in cell death. Gross changes in cell morphology and chromatin condensation, which occur during apoptosis, can be detected by analysis with laser light beam scattering. An early event of apoptosis, dissipation of the mitochondrial transmembrane potential, can be measured using a number of fluorochromes that are sensitive to the electrochemical potential within this organelle (see Basic Protocol 1). Another early event of apoptosis, caspase activation, can be measured either directly, by immunocytochemical detection of the epitope that characterizes activated caspase (see Basic Protocol 2), or indirectly by immunocytochemical detection of the caspase-3 cleavage product, the p85 fragment of poly(ADP-ribose) polymerase (see Basic Protocol 4). Exposure of phosphatidylserine on the exterior surface of the plasma membrane can be detected by the binding of fluoresceinated annexin V (annexin V–FITC); this assay is combined with analysis of the exclusion of the plasma membrane integrity probe propidium iodide (PI; see Basic Protocol 5). Also described are methods of analysis of DNA fragmentation based either on DNA content of cells with fractional (sub-G_1) DNA content (see Basic Protocol 6 and Alternate Protocol 1) or by DNA strand-break labeling (Terminal deoxynucleotidyltransferase–mediated dUTP Nick End Labeling, TUNEL; or In Situ End Labeling, ISEL; see Basic Protocol 7). Still another hallmark of apoptosis is the activation of tissue transglutaminase (TGase), the enzyme that cross-links protein and thereby makes them less immunogenic. Methods for analyzing TGase activation are presented in Basic Protocol 8 and Alternate Protocol 2.

STRATEGIC PLANNING

The choice of a particular method often depends on the cell type, the nature of the inducer of apoptosis, the desired information (e.g., specificity of apoptosis with respect to the cell cycle phase or DNA ploidy), and technical restrictions. For example, sample transportation or prolonged storage before the measurement requires prior cell fixation, thereby eliminating the use of "supravital" methods that rely on analysis of freshly collected live cells.

Positive identification of apoptotic cells is not always simple. Apoptosis was recently defined as a caspase-mediated cell death (Blagosklonny, 2000). Activation of caspases, therefore, appears to be the most specific marker of apoptosis (Shi, 2002). The detection of caspase activation, either directly (e.g., by antibody that is reactive with the activated enzyme; see Basic Protocol 2) or indirectly by the presence of poly(ADP-ribose) polymerase (PARP) cleavage product (PARP p85; see Basic Protocol 4), provides the most definitive evidence of apoptosis. Extensive DNA fragmentation is also considered as a specific marker of apoptosis. The number of DNA strand breaks in apoptotic cells is so large that intensity of their labeling in the TUNEL reaction (see Basic Protocol 7) ensures their positive identification and discriminates them from cells that have undergone primary necrosis (Gorczyca et al., 1992). However, in the instances of apoptosis when internucleosomal DNA degradation does not occur (Collins et al., 1992; Catchpoole and Stewart, 1993; Ormerod et al., 1994; Knapp et al., 1999), the number of DNA strand breaks may be inadequate to distinguish apoptotic cells by the TUNEL method. Likewise, in some instances of apoptosis, DNA fragmentation stops after the initial DNA cleavage to fragments of 50 to 300 kb (Collins et al., 1992, Oberhammer et al., 1993). The frequency of DNA strand breaks in nuclei of these cells is low, and therefore, they may not be easily detected by the TUNEL method.

Contributed by Piotr Pozarowski, Jerzy Grabarek, and Zbigniew Darzynkiewicz
Current Protocols in Cell Biology (2003) 18.8.1-18.8.33

The ability of cells to bind annexin V is still another marker considered to be specific to apoptosis. One should keep in mind, however, that use of the annexin V binding assay is hindered in some instances, e.g., when the plasma membrane is damaged during cell preparation or storage, leading to the loss of asymmetry in distribution of phosphatidylserine across the membrane. Furthermore, macrophages and other cells engulfing apoptotic bodies may also be positive in the annexin V assay (Marguet et al., 1999).

Apoptosis can be recognized with greater certainty when the cells are subjected to several assays probing different apoptotic attributes (Hotz et al., 1994). For example, the assay of plasma membrane integrity (exclusion of PI) and annexin V binding combined with analysis of PARP cleavage or DNA fragmentation may provide a more definitive assessment of the mode of cell death than can be determined by each of these methods used alone.

A plethora of kits designed to label DNA strand breaks and applicable to flow cytometry are available from different vendors. Most of these kits were designed by the authors (Gorczyca et al., 1992; Li and Darzynkiewicz, 1995). For example, Phoenix Flow Systems, BD PharMingen, and Alexis Biochemicals provide kits to identify apoptotic cells based on a single-step procedure utilizing either TdT and FITC-conjugated dUTP (APO-DIRECT; Li et al., 1995) or TdT and BrdUTP, as described in Basic Protocol 7 (APO-BRDU; Li and Darzynkiewicz, 1995). A description of the method, which is nearly identical to the one presented in this unit, is included with the kit. Another kit (ApopTag), based on a two-step DNA strand-break labeling with digoxygenin-16-dUTP by TdT, also designed by the authors (Gorczyca et al., 1992), was initially offered by ONCOR, later by Intergen, and most recently by Serologicals.

BASIC PROTOCOL 1

MITOCHONDRIAL TRANSMEMBRANE POTENTIAL ($\Delta\psi_m$) MEASURED BY RHODAMINE 123 OR DiOC$_6$(3) FLUORESCENCE

The critical role of mitochondria during apoptosis is associated with the release of two intermembrane proteins, cytochrome *c* and apoptosis-inducing factor (AIF), that are essential for sequential activation of pro-caspase 9 and pro-caspase 3 (Liu et al., 1996; Yang et al., 1997). AIF is also involved in proteolytic activation of apoptosis-associated endonuclease (Susin et al., 1997). Still another protein, Smac/Diablo, that interacts with the inhibitors of caspases, thereby promoting apoptosis, is released from mitochondria (Deng et al., 2002). Dissipation (collapse) of mitochondrial transmembrane potential ($\Delta\psi_m$), also called the permeability transition (PT), likewise occurs early during apoptosis (Cossarizza et al., 1994; Kroemer, 1998; Zamzani et al., 1998). However, a growing body of evidence suggests that this event may be transient when associated with the release of cytochrome *c* or AIF, and mitochondrial potential may be restored for some time in the cells with activated caspases (Finucane et al., 1999; Scorrano et al., 1999; Li et al., 2000).

The membrane-permeable lipophilic cationic fluorochromes such as rhodamine 123 (R123) or 3,3′-dihexyloxacarbocyanine iodide [DiOC$_6$(3)] can serve as probes of $\Delta\psi_m$ (Johnson et al., 1980; Darzynkiewicz et al., 1981, 1982). When live cells are incubated in their presence, the probes accumulate in mitochondria, and the extent of their uptake, as measured by intensity of cellular fluorescence, reflects $\Delta\psi_m$. A combination of R123 and PI discriminates among live cells that stain only with R123, early apoptotic cells that have lost the ability to accumulate R123, and late apoptotic/necrotic cells whose plasma membrane integrity is compromised and that stain only with PI (Darzynkiewicz et al., 1982; Darzynkiewicz and Gong, 1994). The specificity of R123 and DiOC$_6$(3) as $\Delta\psi_m$ probes is increased when they are used at low concentrations (<0.5 μg/ml). Still another probe of $\Delta\psi_m$ is the J-aggregate-forming lipophilic cationic fluorochrome 5,5′,6,6′-tetrachloro-1,1′,3,3′-tetraethylbenzimidazolylcarbocyanine iodide (JC-1). Its uptake by

charged mitochondria driven by the transmembrane potential is detected by the shift in color of fluorescence from green, which is characteristic of its monomeric form, to orange, which reflects its aggregation in mitochondria (Cossarizza and Salvioli, 2001). In light of the recent evidence that the collapse of $\Delta\psi_m$ may not be a prerequisite for release of cytochrome c, AIF, and other apoptotic events (Finucane et al., 1999; Scorrano et al., 1999; Li et al., 2000), one should be cautious in interpreting the lack of collapse of $\Delta\psi_m$ as a marker of non-apoptotic cells.

Materials

Cells of interest in appropriate complete culture medium
10 µM rhodamine 123 (R123; see recipe) *or* 10 µM $DiOC_6(3)$ (see recipe for 0.1 mM stock solution) *or* 0.2 mM JC-1 stock solution (see recipe)
Phosphate-buffered saline (PBS; *APPENDIX 2A*)
1 mg/ml propidium iodide (PI; Molecular Probes) in distilled water; store at 4°C in the dark

12 × 75–mm tubes suitable for flow cytometer
Flow cytometer with 488-nm excitation and filters for collection of green, orange, and red fluorescence

Stain with R123 or $DiOC_6(3)$ and PI

1a. Add either 20 µl of 10 µM R123 (200 nM final) or 5 µl of 10 µM $DiOC_6(3)$ (50 nM final) to ~10^6 cells suspended in 1 ml complete tissue culture medium (with 10% serum), and incubate 20 min at 37°C in the dark.

2a. Centrifuge cells 5 min at 300 × *g*, room temperature. Resuspend cell pellet in 1 ml PBS.

3a. Add 10 µl PI solution and incubate 5 min at room temperature in the dark.

4a. Analyze cell fluorescence on the flow cytometer. Excite fluorescence with blue (488-nm) laser. Set the signal-triggering threshold on forward- and side-scatter signals. Collect green fluorescence [R123 or $DiOC_6(3)$] at 530 ± 20 nm and red fluorescence (PI) above 600 nm.

Stain with JC-1

1b. Suspend cell pellet (~10^6 cells) in 1 ml complete tissue culture medium with 10% serum.

2b. Add 10 µl of 0.2 mM JC-1 stock solution. Vortex cells intensely during addition and for the next 20 sec. Wash cells two times with PBS; centrifuge each time 5 min at 200 × *g*, room temperature.

Addition of JC-1 to the cell suspension without vortexing may lead to formation of precipitate. Vortexing too vigorously, on the other hand, may cause cell damage.

3b. Incubate cells 15 min at room temperature in the dark.

4b. Analyze cell fluorescence on the flow cytometer, using 488-nm excitation. Collect green fluorescence at 530 ± 20 nm and orange fluorescence at 570 ± 20 nm with a band-pass filter or above 570 nm with a long-pass filter.

BASIC PROTOCOL 2

IMMUNOCYTOCHEMICAL DETECTION OF ACTIVATED CASPASES BY ZENON TECHNOLOGY

Caspases are activated by transcatalytic cleavage of their zymogen procaspase molecules into large and small subunits. The subunits then assemble to form the heterotetramer consisting of two small and two large subunits, which is the active caspase (Budihardjo et al., 1999; Earnshaw et al., 1999). Antibodies that are specific to activated caspase-3, caspase-8, and caspase-9 are now commercially available and one expects that antibodies reactive with other active caspases will soon be developed as well. It is possible, therefore, to detect caspase activation by immunocytochemical means. This protocol combines the use of activated caspase-specific antibody with staining of cellular DNA by propidium iodide (PI) to concurrently detect cells with activated caspases and relate caspase activation to the cell-cycle position.

The immunocytochemical detection of caspase-3 in this protocol makes use of Zenon technology (Haugland, 2002). Zenon technology consists of a labeling complex that is formed by a fluorochrome-labeled Fab fragment (Zenon Alexa Fluor 488) of an anti-IgG antibody that is directed against the Fc portion of a mouse (or rabbit) IgG_1 antibody. Mixing of the labeled Fab fragment with the primary antibody forms the labeling complex. Excess unbound labeled Fab fragments is removed by admixture of nonspecific mouse (or rabbit) IgG. The labeling complex is then used to stain cells in the same manner as a covalently labeled primary antibody (Haugland, 2002).

Materials

Cells of interest, both untreated (control) and induced to apoptosis (e.g., exponentially growing HL-60 cells incubated 2 to 4 hr with 0.15 μM camptothecin)
Phosphate-buffered saline (PBS; *APPENDIX 2A*)
Fixatives:
1% (v/v) methanol-free formaldehyde (Polysciences) in PBS, 0° to 5°C
4% (v/v) methanol-free formaldehyde (Polysciences) in PBS, room temperature
70% (v/v) ethanol, –20°C
Rinse solution (see recipe)
Primary antibody: cleaved (activated) caspase-3 antibody (Cell Signaling Technology, cat. no. 9661)
Zenon Alexa Fluor 488 rabbit IgG labeling kit (Molecular Probes, cat. no. Z-25302)
10% (v/v) Triton X-100 in PBS
DNA staining solution with PI (see recipe)

12 × 75–ml tubes suitable for use on flow cytometer
Flow cytometer with 488-nm excitation and filters for collection of green and red fluorescence

1. Suspend ~10^6 cells in 0.5 ml PBS.
2. Fix cells by transferring the above cell suspension into tubes containing 4.5 ml of 1% methanol-free formaldehyde in PBS at 0° to 5°C. Let stand 15 min at 0° to 5°C.
3. Centrifuge 5 min at 300 × *g*, room temperature. Decant supernatant.
4. Resuspend cell pellet in 3 ml of 70% ethanol at –20°C. Allow to sit at least 2 hr (cells can be stored several days in 70% ethanol at –20°C).
5. Bring the cell suspension in 70% ethanol to room temperature, add 2 ml PBS to this suspension, and let sit 5 min at room temperature.
6. Centrifuge 5 min at 300 × *g*, room temperature. Decant supernatant.

7. Resuspend cell pellet in 5 ml PBS and let sit 5 min at room temperature.
8. Centrifuge 5 min at 300 × *g*, room temperature. Decant supernatant.
9. Resuspend cell pellet in rinse solution. Let stand 30 min at room temperature.
10. Prepare the staining solution as follows.
    a. Mix 4 µl primary antibody (anti-caspase-3) with 16 µl rinse solution and with 5 µl solution A Zenon (from kit) in a 1.5-ml microcentrifuge tube.
    b. Keep 5 min in the dark at room temperature.
    c. Add 5 µl solution B Zenon (from kit).
    d. Keep 5 min in the dark at room temperature.
    e. Add 0.3 µl of 10% Triton X-100 in PBS.
11. Centrifuge the cell suspension (from step 9) 5 min at 300 × *g*, room temperature. Thoroughly drain the rinse solution by blotting on filter paper. Add 15 µl of the staining solution prepared in step 10, and 85 µl rinse solution, for a final volume of 100 µl. Resuspend the cell pellet.
12. Incubate cells with the staining solution 1 hr in the dark at room temperature.
13. Add 5 ml PBS, centrifuge 5 min at 300 × *g*, room temperature, and decant supernatant.
14. Resuspend cell pellet in 1 ml of 4% methanol-free formaldehyde in PBS and let stand 5 min at room temperature.
15. Centrifuge cells 5 min at 300 × *g*, room temperature. Decant supernatant.
16. Resuspend cell pellet in 1 ml DNA staining solution with PI.
17. Analyze cell fluorescence on the flow cytometer, using 488-nm excitation (or a mercury arc lamp with a BG12 filter). Collect green Alexa 488 fluorescence at 530 ±20 nm and red PI fluorescence above 600 nm.

DETECTION OF APOPTOTIC CELLS USING FLUOROCHROME-LABELED INHIBITORS OF CASPASES (FLICAs)

BASIC PROTOCOL 3

Exposure of live cells to fluorochrome-labeled inhibitors of caspases (FLICAs) results in uptake of these reagents by apoptotic cells (Smolewski et al., 2001). Unbound FLICAs are removed from the nonapoptotic cells by rinsing the cells with wash buffer. The cells may also be fixed with formaldehyde; after fixation only apoptotic cells retain the label. Cells labeled with FLICAs can be examined by fluorescence microscopy, or their fluorescence can be measured by flow cytometry. FLICAs are convenient markers of apoptotic cells, and when used in combination with PI as described in the protocol below, they reveal three sequential stages of apoptosis. FAM-VAD-FMK, the inhibitor designed to react with all caspases, except perhaps caspase-2, is used in this protocol. It should be stressed, however, that FLICAs appear to react in apoptotic cells also with targets other than activated caspases. Cell labeling with FLICAs, therefore, although perhaps reflecting caspase activity and although reflecting caspase activation, cannot be interpreted as indicating reactivity with active enzyme centers of caspases only.

Materials

Cells of interest
Medium supplemented with 10% (v/v) serum or 1% (w/v) serum albumin
FLICA kit (Immunochemistry Technologies) containing:
  FAM-VAD-FMK reagent (see recipe)
  Fixative
  Hoechst stain
Rinse solution: 1% (w/v) BSA in PBS (*APPENDIX 2A*)
1 mg/ml propidium iodide (PI; Molecular Probes) in distilled water; store at 4°C in the dark

12 × 75–ml tubes suitable for use on flow cytometer
Flow cytometer with 488-nm excitation and filters for collection of green and red fluorescence

1. Suspend ~10^6 cells in 0.3 ml medium containing 10% serum or 1% serum albumin.
2. Add 10 µl FAM-VAD-FMK working solution to this cell suspension (final concentration 10 µM). Mix gently and incubate 1 hr at 37°C.

   Sulforhodamine-labeled FLICA (SR-VAD-FMK) may be used instead of FAM-VAD-FMK to make apoptotic cells fluorescence in the red.

3. Add 2 ml rinse solution, mix gently, and centrifuge 5 min at 200 × *g*, room temperature.
4. Resuspend cell pellet in 2 ml rinse solution and centrifuge as in step 3.

   Cells may be fixed 15 min in 1% formaldehyde in PBS, then suspended in 70% ethanol and stored for several days. A fluorochrome of a different color than FLICA may be used to counterstain other cellular components (e.g., DNA) or other markers of apoptosis (e.g., DNA strand breaks).

5. Resuspend cell pellet in 1 ml rinse solution. Add 1.0 µl of 1 mg/ml PI stock solution. Keep 5 min at room temperature.

   Protect samples from light at all times.

   Staining with PI is optional. It allows one to distinguish the cells that have compromised plasma-membrane integrity (e.g., necrotic and late apoptotic cells, cells with mechanically damaged membranes, or isolated cell nuclei) to the extent that they cannot exclude PI.

6. Analyze cell fluorescence on the flow cytometer, using 488-nm excitation (or a mercury arc lamp with a BG12 filter). Collect green FAM-VAD-FMK fluorescence at 530 ± 20 nm and red PI fluorescence above 600 nm.

BASIC PROTOCOL 4

DETERMINATION OF POLY(ADP-RIBOSE) POLYMERASE (PARP) CLEAVAGE

PARP is a nuclear enzyme that is involved in DNA repair and activated in response to DNA damage (de Murcia and Menissier-de Murcia, 1994). Early in apoptosis, PARP is cleaved by caspases, primarily by caspase-3 (Kaufmann et al., 1993; Lazebnik et al., 1994; Alnemri et al., 1996). The specific cleavage of this protein results in distinct 85-kDa and 24-kDa fragments, usually detected electrophoretically, and this is considered to be a hallmark of the apoptotic mode of cell death.

The development of antibodies that recognize the cleaved PARP products prompted their use as immunocytochemical markers of apoptotic cells. The antibody that recognizes the 85-kDa fragment (PARP p85) was initially used to score the frequency of apoptosis in tissue sections (Sallman et al., 1997; Kockx et al., 1998). Recently, this antibody has been adapted to label apoptotic cells for detection by flow cytometry and laser scanning

cytometry (LSC; Li and Darzynkiewicz, 2000; Li et al., 2000). A good correlation was observed between the frequency of apoptosis detected cytometrically with PARP p85 Ab and that detected by the DNA strand-break (TUNEL) assay. However, at least in some cell systems, the cleavage of PARP occurs prior to the onset of DNA fragmentation (Li and Darzynkiewicz, 2000). In these instances, the correlation may not be apparent at early stages of apoptosis because the apoptotic index estimate based on PARP cleavage may exceed the estimate based on the TUNEL reaction. Cytometric analysis of cells differentially stained for PARP p85 and DNA, similar to the TUNEL assay, makes it possible not only to identify and score apoptotic cell populations but also to correlate apoptosis with the cell cycle position or DNA ploidy.

The classic immunocytochemical indirect (two-step) method to detect the 85-kDa PARP fragment is presented below. Alternatively, however, one can use the Zenon technology as described above (see Basic Protocol 2) for detection of activated caspases.

Materials

Cells of interest
Phosphate-buffered saline (PBS; *APPENDIX 2A*)
1% methanol-free formaldehyde (Polysciences) in PBS (*APPENDIX 2A*)
70% ethanol
0.25% (v/v) Triton X-100 (Sigma) in PBS (*APPENDIX 2A*); store at 4°C
PBS/BSA solution: 1% (w/v) bovine serum albumin (Sigma) in PBS; store at 4°C
Anti-PARP p85 antibody (Promega anti-PARP-85 fragment, rabbit polyclonal)
Fluorescein-conjugated anti-rabbit immunoglobulin antibody (Dako)
1 mg/ml propidium iodide (PI; Molecular Probes) in distilled water; store at 4°C in the dark
RNase stock solution (see recipe)

12 × 75–mm centrifuge tubes suitable for use on the flow cytometer
Pasteur pipets
Flow cytometer with 488-nm excitation and filters for collection of green and red fluorescence

1. Suspend ~10^6 cells in 0.5 ml PBS. Transfer this suspension to a 12 × 75–mm (5-ml) tube containing 4.5 ml of 1% methanol-free formaldehyde and fix cells 15 min on ice. Centrifuge the cells 5 min at 300 × *g*, 4°C, wash once with 5 ml PBS, centrifuge 5 min at 300 × *g*, and resuspend the cell pellet in 0.5 ml PBS. With a Pasteur pipet, transfer this cell suspension into a new 12 × 75–mm centrifuge tube containing 4.5 ml of ice-cold 70% ethanol.

   The cells may be stored several days in ethanol at –20°C.

2. Centrifuge cells 5 min at 200 × *g*, room temperature, and resuspend the cell pellet in 5 ml PBS; repeat centrifugation.

3. Resuspend cells in 5 ml 0.25% Triton X-100/PBS for 10 min.

4. Centrifuge cells 5 min at 300 × *g*, room temperature, and resuspend in 2 ml BSA/PBS solution for 10 min.

5. Centrifuge cells 5 min at 300 × *g*, room temperature, and resuspend in 100 µl BSA/PBS containing anti-PARP p85 Ab diluted 1:200. Incubate 2 hr at room temperature, or overnight at 4°C.

6. Add 5 ml BSA/PBS solution, let sit 5 min, and centrifuge 5 min at 300 × *g*, room temperature.

7. Resuspend cell pellet in 100 µl PBS/BSA containing fluorescein-conjugated secondary Ab [$F(ab')_2$ fragment, swine anti-rabbit immunoglobulin] diluted 1:30. Incubate 1 hr in the dark at room temperature.
8. Add 5 ml BSA/PBS, centrifuge 5 min at 200 × *g,* room temperature, and resuspend cell pellet in 1 ml PBS. Add 20 µl of 1 mg/ml PI and 50 µl RNase solution. Incubate 20 min in the dark at room temperature.
9. Analyze cell fluorescence on the flow cytometer, using 488-nm excitation (or a mercury arc lamp with a BG12 filter). Collect green FITC-anti-PARP p85 fluorescence at 530 ± 20 nm and red PI fluorescence above 600 nm.

BASIC PROTOCOL 5

ANNEXIN V BINDING

Phospholipids of the plasma membrane are asymmetrically distributed between the inner and outer leaflets of the membrane. Phosphatidylcholine and sphingomyelin are exposed on the external leaflet of the lipid bilayer, while phosphatidylserine is located on the inner surface. During apoptosis, this asymmetry is disrupted and phosphatidylserine becomes exposed on the outside surface of the plasma membrane (Fadok et al., 1992; Koopman et al., 1994; van Engeland et al., 1998). Because the anticoagulant protein annexin V binds with high affinity to phosphatidylserine, fluorochrome-conjugated annexin V has found an application as a marker of apoptotic cells, in particular for their detection by flow cytometry (van Engeland et al., 1998). The cells become reactive with annexin V prior to their loss of plasma membrane ability to exclude cationic dyes such as PI. Therefore, by staining cells with a combination of annexin V–FITC and PI, it is possible to detect unaffected, non-apoptotic cells (annexin V–FITC negative/PI negative), early apoptotic cells (annexin V–FITC positive/PI negative), and late apoptotic ("necrotic stage" of apoptosis) as well as necrotic cells (PI positive).

Materials

Cells of interest
Fluorescein-conjugated annexin V (see recipe) in binding buffer (see recipe)
1 mg/ml propidium iodide (PI; Molecular Probes) in distilled water; store at 4°C in the dark
Flow cytometer with 488-nm excitation and filters for collection of green and red fluorescence

1. Suspend 10^5 to 10^6 cells in 1 ml fluorescein-conjugated annexin V in binding buffer for 5 min at room temperature in the dark.
2. Prior to analysis, add an appropriate volume of 1 mg/ml PI solution to the cell suspension to have a final PI concentration of 1.0 µg/ml. Incubate 5 min at room temperature in the dark.
3. Analyze cells on the flow cytometer, using 488-nm excitation. Set gates based on light scatter. Collect green annexin V fluorescence at 530 ± 20 nm and red PI fluorescence above 600 nm.

DNA FRAGMENTATION: DETECTION OF CELLS WITH FRACTIONAL (SUB-G_1) DNA CONTENT USING PI

Endonucleases activated during apoptosis target internucleosomal DNA sections and cause extensive DNA fragmentation (Kerr et al., 1972; Arends et al., 1990; Nagata, 2000). The fragmented, low-molecular-weight DNA can be extracted from the cells following their fixation in precipitating fixatives such as ethanol. Conversely, fixation with cross-linking fixatives such as formaldehyde results in the retention of low-molecular-weight DNA in the cell and therefore should be avoided. Generally, the extraction occurs during the process of cell staining in aqueous solutions after transfer from the fixative. As a result, apoptotic cells often end up with deficient DNA content, and when stained with a DNA-specific fluorochrome, they can be recognized by cytometry as cells having less DNA than G_1 cells. On the DNA content frequency histograms, they form a characteristic sub-G_1 peak (Umansky et al., 1981; Nicoletti et al., 1991; Gong et al., 1994). It should be noted that loss of DNA may also occur as a result of the shedding of apoptotic bodies containing fragments of nuclear chromatin.

The degree of DNA degradation varies depending on the stage of apoptosis, cell type, and often the nature of the apoptosis-inducing agent. Hence, the extractability of DNA during the staining procedure also varies. A high-molarity phosphate-citrate buffer enhances extraction of the fragmented DNA (Gong et al., 1994). With some limitations, this approach can be used to extract DNA from apoptotic cells to the desired level in order to achieve their optimal separation by flow cytometry.

Materials

Cells of interest
PBS (*APPENDIX 2A*)
70% ethanol
DNA extraction buffer (see recipe)
DNA staining solution with PI (see recipe)

12 × 75–mm tubes suitable for use on the flow cytometer
Flow cytometer with 488-nm excitation and filter for collection of red fluorescence

1. Suspend 1–2 × 10^6 cells in 0.5 ml PBS and fix cells by adding suspension to 4.5 ml of 70% ethanol in a 12 × 75–mm tube on ice.

   Cells may be stored several weeks in fixative at −20°C.

2. Centrifuge cells 5 min at 200 × *g*, decant ethanol, suspend the cell pellet in 5 ml PBS, and centrifuge 5 min at 300 × *g*, room temperature.

3. Suspend cell pellet in 0.25 ml PBS. To facilitate extraction of low-molecular-weight DNA, add 0.2 to 1.0 ml DNA extraction buffer.

4. Incubate 5 min at room temperature, then centrifuge 5 min at 300 × *g*, room temperature.

5. Suspend cell pellet in 1 ml DNA staining solution with PI. Incubate cells 30 min at room temperature in the dark.

6. Analyze cells on the flow cytometer, using 488-nm excitation (or a mercury arc lamp with a BG12 filter). Collect forward light scatter and red fluorescence above 600 nm.

ALTERNATE PROTOCOL 1

DNA FRAGMENTATION: DETECTION OF CELLS WITH FRACTIONAL (SUB-G_1) DNA CONTENT USING DAPI

Cellular DNA may be stained with other fluorochromes instead of PI, and other cell constituents may be counterstained in addition to DNA. The following is the procedure used to stain DNA with DAPI. This protocol requires a UV laser.

Additional Materials *(also see Basic Protocol 6)*

DNA staining solution with DAPI (see recipe)
Flow cytometer equipped with UV excitation and filter for collection of blue fluorescence

1. Follow Basic Protocol 6, steps 1 to 4. Then, suspend the cell pellet in 1 ml DNA staining solution containing DAPI. Keep on ice 20 min.

2. Analyze cells on the flow cytometer, using UV excitation (e.g., 351-nm line from an argon-ion laser, or mercury lamp with a UG1 filter). Collect blue DAPI fluorescence in a band from 460 to 500 nm.

BASIC PROTOCOL 7

DNA FRAGMENTATION: DETECTION OF DNA STRAND BREAKS (TUNEL ASSAY)

DNA fragmentation during apoptosis, particularly when it progresses to internucleosomal regions (Arends et al., 1990; Oberhammer et al., 1993), generates a multitude of DNA strand breaks in the nucleus. The 3′-OH ends of the breaks can be detected by attaching a fluorochrome. This is generally done directly or indirectly (e.g., via biotin or digoxygenin) using fluorochrome-labeled deoxynucleotides in a reaction catalyzed preferably by exogenous terminal deoxynucleotidyltransferase (TdT; Gorczyca et al., 1992, 1993; Li and Darzynkiewicz, 1995; Li et al., 1995). The reaction is commonly known as TUNEL, from TdT-mediated dUTP-biotin nick-end labeling (Gavrieli et al., 1992). This acronym is actually a misnomer, since double-stranded DNA breaks are labeled, rather than single-stranded nicks. Of all the markers used to label DNA breaks, BrdUTP appears to be the most advantageous with respect to sensitivity, low cost, and simplicity of reaction (Li and Darzynkiewicz, 1995). When attached to DNA strand breaks in the form of poly-BrdU, this deoxynucleotide can be detected with a FITC-conjugated anti-BrdU Ab, the same Ab commonly used to detect BrdU incorporated during DNA replication. Poly-BrdU attached to DNA strand breaks by TdT, however, is accessible to the Ab without the need for DNA denaturation, which otherwise is required to detect the precursor incorporated during DNA replication.

It should be stressed that the detection of DNA strand breaks by this method requires pre-fixation of cells with a cross-linking agent such as formaldehyde. Unlike ethanol, formaldehyde prevents the extraction of small pieces of fragmented DNA. Thus, despite cell permeabilization and the subsequent cell washings required, the DNA content of early apoptotic cells (and the number of DNA strand breaks) is not markedly diminished through extraction. Labeling of DNA strand breaks in this procedure, which utilizes fluorescein-conjugated anti-BrdU Ab, can be combined with staining of DNA by a fluorochrome of another color (PI, red fluorescence). Cytometry of cells that are differentially stained for DNA strand breaks and for DNA allows one to distinguish apoptotic from non-apoptotic cell subpopulations and reveals the cell cycle distribution in these subpopulations (Gorczyca et al., 1992, 1993).

Materials

Cells of interest
1% (v/v) methanol-free formaldehyde (Polysciences) in PBS (*APPENDIX 2A*), pH 7.4 (primary fixative)
PBS (*APPENDIX 2A*)
70% ethanol (secondary fixative)
5× TdT reaction buffer (see recipe)
2 mM BrdUTP (Sigma) in 50 mM Tris·Cl, pH 7.5
TdT in storage buffer (both from Roche Diagnostics), 25 U in 1 µl
10 mM cobalt chloride ($CoCl_2$; Roche Diagnostics)
Rinsing buffer: PBS with 0.1% (v/v) Triton X-100 and 0.5% (w/v) BSA
FITC-conjugated anti-BrdU MAb (see recipe)
PI staining buffer: PBS with 5 µg/ml PI and 200 µg/ml DNase-free RNase
Flow cytometer with 488-nm excitation and filters for collection of green and red fluorescence

Fix cells

1. Fix 1–5 × 10^6 cells in suspension 15 min in 1% methanol-free formaldehyde in PBS, pH 7.4, on ice.
2. Centrifuge 5 min at 200 × *g*, 4°C, resuspend cell pellet (~2 × 10^6 cells) in 5 ml PBS, centrifuge 5 min at 200 × *g*, 4°C, and resuspend cells in 0.5 ml PBS.
3. Add the 0.5-ml cell suspension from step 2 to 5 ml ice-cold 70% ethanol.

   The cells can be stored several weeks in ethanol at −20°C.
4. Centrifuge 5 min at 200 × *g*, 4°C, remove ethanol, and resuspend cells in 5 ml PBS. Repeat centrifugation.

Stain cells

5. Resuspend the pellet (not more than 10^6 cells) in 50 µl of a solution that contains:

   10 µl 5× TdT reaction buffer
   2.0 µl 2 mM BrdUTP stock solution
   0.5 µl TdT in storage buffer (12.5 U final)
   5 µl 10 mM $CoCl_2$ solution
   32.5 µl dH_2O.
6. Incubate cells in this solution 40 min at 37°C.

   Alternatively, incubation can be carried out overnight at 22° to 24°C.
7. Add 1.5 ml rinsing buffer and centrifuge 5 min at 200 × *g*, room temperature.
8. Resuspend cells in 100 µl FITC-conjugated anti-BrdU MAb solution.
9. Incubate 1 hr at room temperature or overnight at 4°C. Add 2 ml rinsing buffer and centrifuge 5 min at 200 × *g*, room temperature.
10. Resuspend cell pellet in 1 ml PI staining solution containing RNase. Incubate 30 min at room temperature in the dark.
11. Measure cell fluorescence on the flow cytometer, using 488-nm excitation (or a mercury arc lamp with a BG12 filter). Collect green FITC-anti BrdU MAb fluorescence at 530 ± 20 nm and red PI fluorescence above 600 nm.

BASIC PROTOCOL 8

DETECTION OF TISSUE TRANSGLUTAMINASE ACTIVATION BY CELL RESISTANCE TO DETERGENTS

Extensive protein cross-linking takes place during apoptosis. The ubiquitous transglutaminase TGase 2 (also called "tissue transglutaminase"; tTGase) was identified as the enzyme responsible for this reaction (Fesus et al., 1987; Melino and Piacentini, 1998). It is presumed that activation of TGase 2 during apoptosis prevents release of soluble and immunogenic proteins from dying cells because protein cross-linking makes these proteins less soluble and thereby decreases a possibility of induction of autoimmune reaction. Furthermore, protein packaging into apoptotic bodies may be facilitated when proteins remain in solid state rather than in solution. The additional role of TGase 2 as one of the "executor enzymes" during apoptosis is still being debated.

This protocol is a simple and rapid approach to identify apoptotic cells with activated TGase 2. The method is based on the propensity of cross-linked protein to withstand treatment with detergents. The authors have noticed that when live, nonapoptotic cells are subjected to treatment with solutions of nonionic detergents, lysis of their plasma membrane and release of the content of cytoplasm is complete, resulting in preparation of isolated nuclei. In contrast, apoptotic cells resist the detergent treatment; their cytoplasmic protein remains insoluble and attached to the nucleus in the form of a shell-like cover (Grabarek et al., 2002). It is possible, therefore, by flow or laser scanning cytometry to distinguish apoptotic cells from the nuclei isolated from nonapoptotic cells, by means of the abundance of protein in the former. In addition, bivariate gating analysis of cellular DNA and protein content makes it possible to reveal the cell cycle distribution separately for the population of cells with cross-linked protein (activated TGase 2) and for the population of cells that did not show protein cross-linking (Grabarek et al., 2002).

Alternate Protocol 2 combines the detection of TGase 2 activity by binding of fluoresceinated cadaverine (F-CDV) with analysis of the cell cycle.

Materials

Cells of interest
DAPI/sulforhodamine 101/detergent solution (see recipe)
Flow cytometer equipped with UV excitation and filters for collection of blue and red fluorescence

1. Collect ~10^6 cells from the culture and centrifuge 5 min at $300 \times g$, room temperature.
2. Suspend the cell pellet in 1 ml DAPI/sulforhodamine 101/detergent solution and vortex 20 sec.
3. Analyze cells on the flow cytometer, using UV excitation (e.g., 351-nm line from an argon-ion laser, or mercury lamp with a UG1 filter). Collect blue DAPI fluorescence in a band from 460 to 500 nm and red fluorescence of sulforhodamine 101 above 600 nm.

ALTERNATE PROTOCOL 2

DETECTION OF TGase 2 ACTIVATION BY FLUORESCEINATED CADAVERINE (F-CDV) BINDING

This alternate protocol is based on the covalent attachment, by the activated TGase 2, of the fluorescein-tagged cadaverine to the respective protein substrates within the cell (Lajemi et al., 1998). This assay was adapted to flow cytometry and combined with concurrent analysis of cellular DNA content (Grabarek et al., 2002). Like the detergent-based assay, this method is simple and also offers good distinction between apoptotic cells with activated versus nonactivated TGase 2.

It should be noted that when the cost of the reagents for the procedure is taken into account, the detergent-based assay (see Basic Protocol 8) is less expensive by several orders of magnitude than this F-CDV assay.

Materials

Fluoresceinated cadaverine solution (F-CDV; see recipe)
Cells of interest
100% methanol
DNA staining solution with PI (see recipe)
Flow cytometer with 488-nm excitation and filters for collection of green and red fluorescence

1. Add aliquots of F-CDV stock solution (1 part per 50) directly to cell cultures (10^6 to 10^7 cells) to obtain 50 µM final F-CDV concentration in the culture.
2. Incubate cells in the presence of F-CDV for the desired time interval during which activity of TGase 2 has to be detected (e.g., one to several hours).

   Because cross-linking is a cumulative process, intensity of cell labeling increases with time of incubation.

3. Harvest the culture by centrifuging 5 min at 200 × *g*, room temperature.
4. Suspend the cells in 0.5 ml PBS and fix in 5 ml of 100% methanol on ice. Keep in methanol ≥2 hr at 0° to 4°C; cells may be stored in the fixative for several days.
5. Centrifuge cells 5 min at 200 × *g*, room temperature, decant the fixative thoroughly, and suspend cell pellet in 2 ml DNA staining solution with PI.
6. Keep ≥30 min at room temperature.
7. Measure cell fluorescence on the flow cytometer, using 488-nm excitation (or a mercury arc lamp with a BG12 filter). Collect green FITC-CDV fluorescence at 530 ± 20 nm and red PI fluorescence above 600 nm.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Binding buffer

10 mM HEPES-NaOH, pH 7.4
140 mM NaCl
5 mM $CaCl_2$
Store several weeks at 4°C

DAPI/sulforhodamine 101/detergent solution

Dissolve 100 µg DAPI, 2 mg sulforhodamine 101 (Molecular Probes), and 0.1 ml Triton X-100 in 100 ml PBS (or 0.1 ml Nonidet NP-40). Store several weeks at 0° to 4°C.

$DiOC_6$ (3) stock solution

Prepare a 0.1 mM solution of $DiOC_6$ (3) (Molecular Probes) by dissolving 5.7 mg dye in 10 ml dimethyl sulfoxide (DMSO). Store for weeks in small (e.g., 0.5- or 1-ml) aliquots protected from light at −20°C. Prior to use, dilute ten-fold with PBS to obtain 10 µM concentration.

DNA extraction buffer, pH 7.8

192 ml 0.2 M Na_2HPO_4
8 ml 0.1 M citric acid
Store for months at 4°C

DNA staining solution with DAPI

Dissolve 100 µg DAPI in 100 ml PBS. Store at 0° to 4°C for several weeks.

DNA staining solution with PI

200 µg propidium iodide (PI)
2 mg DNase-free RNase
10 ml PBS
Prepare fresh before use

FAM-VAD-FMK

Stock solution: following kit directions, dissolve FAM-VAD-FMK in dimethyl sulfoxide (DMSO) to obtain 150× solution. Store aliquots protected from light ≤3 months at −20°C.

Working solution: Just prior to use, prepare a 30× solution by diluting FAM-VAD-FMK stock solution 1:5 in PBS. Mix the vial until the solution becomes transparent and homogenous. Protect all FAM-VAD-FMK solutions from light. Discard unused portions. Do not store.

FITC-conjugated anti-BrdU MAb solution

100 µl PBS (*APPENDIX 2A*)
0.3 µg FITC-conjugated anti-BrdU MAb (Becton Dickinson)
0.3% (v/v) Triton X-100
1% (w/v) BSA
Prepare fresh before use

Fluoresceinated cadaverine solution

Dissolve 5-[(5-aminopentyl)thioureidyl]fluorescein dihydrobromide (F-CDV; Molecular Probes) in distilled water to obtain a 2.5 mM stock solution. Store aliquots (0.2 to 0.5 ml) of this solution several weeks at −20°C.

Fluorescein-conjugated annexin V

Dissolve FITC-conjugated annexin V (1:1 stoichiometric complex; e.g., from BRAND Applications) in binding buffer (see recipe) at a concentration of 1.0 µg/ml. This solution must be prepared fresh just prior to use.

JC-1 stock solution

Prepare a 0.2 mM solution of JC-1 (Molecular Probes) by dissolving 1.3 mg dye in 10 ml *N*,*N*-dimethylformamide (Sigma). Store for weeks in small (e.g., 0.5- or 1.0-ml) aliquots protected from light at −20°C. Use glass containers; *N*,*N*-dimethylformamide will dissolve plastics.

Rhodamine 123 (R123) stock solution

Prepare a 0.1 mM solution of R123 (Molecular Probes) by dissolving 0.38 mg dye in 10 ml methanol. Store for months in small aliquots protected from light at −20°C. Prior to use, dilute ten-fold with PBS to obtain 10 µM concentration.

Rinse solution

1 g BSA
0.1 ml Triton X-100
100 ml PBS (*APPENDIX 2A*)
Store up to 1 week at 4°C

RNase stock solution

Dissolve 2 mg RNase A (e.g., Sigma) in 1 ml distilled water. If the RNase is not DNase free, heat the solution 5 min at 100°C to inactivate any traces of DNase. Store ≤1 year at 4°C.

TdT reaction buffer, 5×

1 M potassium (or sodium) cacodylate
125 mM Tris·Cl, pH 6.6 (*APPENDIX 2A*)
0.125% bovine serum albumin (BSA)
Store for weeks at 4°C

COMMENTARY

Background Information

Applications of flow cytometry in cell necrobiology have two distinct goals (for reviews, see Darzynkiewicz et al., 1992, 1997; Ormerod, 1998; van Engeland et al., 1998; Vermes et al., 2000). One goal is to elucidate molecular and functional mechanisms associated with cell death. For this purpose, flow cytometry is used to measure cellular levels of components involved in the regulation and/or execution of apoptosis or cell necrosis. The most frequently studied are pro- and anti-apoptotic members of the Bcl-2 protein family, caspases, proto-oncogenes (e.g., *c-myc* or *ras)*, or tumor suppressor genes (e.g., p53 or pRB). Flow cytometry is also widely used to study functional attributes of the cell such as mitochondrial metabolism, oxidative stress, intracellular pH, or ionized calcium, all closely associated with mechanisms of apoptosis. The major advantage of flow cytometry in these applications is that it provides the possibility of multiparametric measurements of cell attributes. Multivariate analysis of such data reveals the correlation between the measured cell constituents. For example, when one of the measured attributes is cellular DNA content (the parameter that reports the cell cycle position or DNA ploidy), an expression of the other measured attribute can then be directly related to the cell cycle position (or cell ploidy) without a need for cell synchronization. Since individual cells are measured, intercellular variability can be assessed, cell subpopulations identified, and rare cells detected.

The second goal of cytometry applications is to identify and quantify dead cells and discriminate between apoptotic and necrotic modes of death. Dead-cell recognition is generally based on the presence of a particular biochemical or molecular marker that is characteristic for apoptosis, necrosis, or both. Numerous methods have been developed, especially for the identification of apoptotic cells. Apoptosis-associated changes in the gross physical attributes of cells, such as cell size and granularity, can be detected by analysis of laser light scattered by the cell in forward and side directions (Swat et al., 1981; Ormerod et al., 1995). Some methods rely on apoptosis-associated changes in the distribution of plasma membrane phospholipids (Fadok et al., 1992; Koopman et al., 1994). Others detect the loss of active transport function of the plasma membrane. Still other methods probe the mitochondrial transmembrane potential (Cossarizza et al., 1994; Kroemer, 1998; Zamzani et al., 1998). The detection of DNA fragmentation provides another convenient marker of apoptosis; apoptotic cells are then recognized either by their fractional (subdiploid, sub-G_1) DNA content due to extraction of low-molecular-weight DNA from the cell (Umansky et al., 1981; Nicoletti et al., 1991), or by the presence of DNA strand breaks, which can be detected by labeling their 3′-OH termini with fluorochrome-conjugated nucleotides in a reaction utilizing exogenous terminal deoxynucleotidyl transferase (TdT; Gorczyca et al., 1992, 1993; Li and Darzynkiewicz, 1995; Li et al., 1996). More recently, flow cytometric methods have been developed to detect activation of caspases and tissue transglutaminase (TGase 2; Grabarek et al., 2002). It should be noted, however, that the fluorochrome-labeled inhibitors of caspases (FLICAs), initially described as markers of caspase activation (Smolewski et al., 2001), or serine proteases, although convenient markers of apoptotic cells and most likely detecting activation of these proteases, do not have sufficient specificity to be used as specific probes of their active enzymatic centers (Pozarowski et al., 2003).

A variety of kits are commercially available to identify apoptotic cells using the methods presented in this unit. Since the reagents are

already prepackaged and the procedures are described in cookbook format, the kits offer the advantage of simplicity. Their cost, however, is many-fold higher than that of the individual reagents. Furthermore, the kits do not allow one the flexibility that is often required to optimize procedures for a particular cell system. In many situations, therefore, the preparation of samples for analysis by flow cytometry as described herein may be preferred.

Light-scattering changes during apoptosis

Intersection of cells with the laser light beam in a flow cytometer results in light scattering. Analysis of light scattered in different directions reveals information about cell size and structure. The intensity of the forward light-scatter signal correlates with cell size. Side scatter, on the other hand, yields information on light-refractive and light-reflective properties of the cell and reveals optical inhomogeneity of the cell structure resulting from condensation of cytoplasm or nucleus, granularity, and so on.

As a consequence of cell shrinkage, a decrease in forward light scatter is observed at a relatively early stage of apoptosis (Swat et al., 1981; Ormerod et al., 1995). Initially, there is little change in side scatter during apoptosis. In fact, in some cell systems, an increase in intensity of side-scatter signal may be seen, reflecting perhaps chromatin and cytoplasm condensation and nuclear fragmentation, the events that may lead to an increase in the light-refractive and light-reflective properties of the cell. When apoptosis is more advanced and the cells shrink in size, the intensity of side scatter also decreases (Fig. 18.8.1). Late apoptotic cells, therefore, are characterized by markedly diminished intensity of both forward- and side-scatter signals. In contrast to apoptosis, the early stages of cell necrosis are marked by cell swelling, which is detected by a transient increase in forward light scatter. Rupture of the plasma membrane and leakage of the cytosol during subsequent steps of necrosis correlate with a marked decrease in intensity of both forward- and side-scatter signals.

Analysis of light scatter is often combined with other assays, most frequently surface immunofluorescence (to identify the phenotype of the dying cell), or another marker of apoptosis. It should be stressed, however, that the change in light scatter alone is not a specific marker of apoptosis or necrosis. Mechanically broken cells, isolated nuclei, cell debris, and individual apoptotic bodies may also display diminished light-scatter properties. Therefore, the analysis of light scatter must be combined with measurements that can provide a more definite identification of apoptotic or necrotic cells.

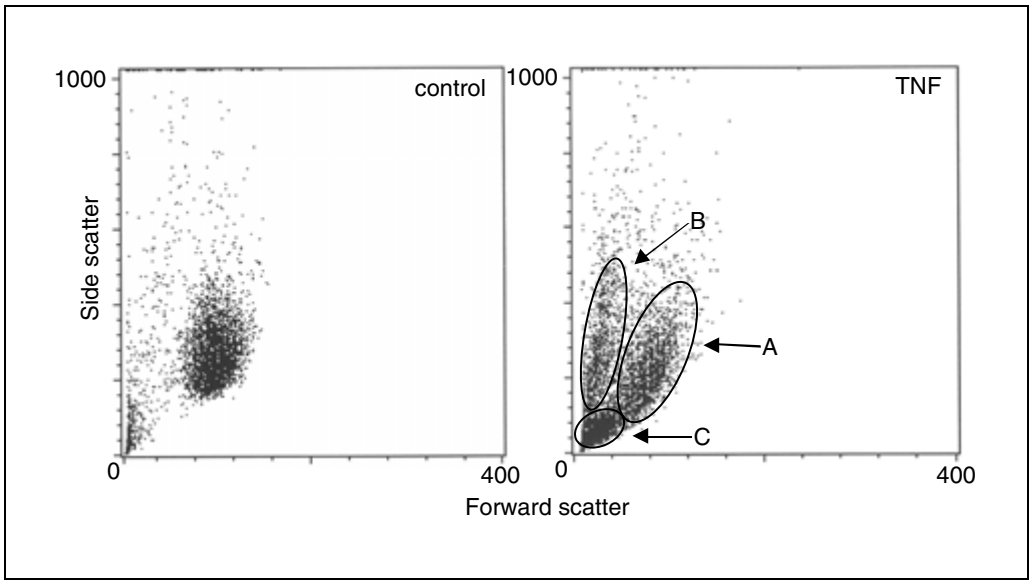

Figure 18.8.1 Changes in light scattering properties of cells undergoing apoptosis. HL-60 cells were untreated (left panel) or treated 3 hr with TNF-α and cycloheximide (CHX) to induce apoptosis (right panel). Cell population **A** in the treated culture (right panel) represents cells that have light scattering properties similar to those of untreated cells. Early apoptotic cells (**B**) have diminished forward scatter and are very heterogenous with respect to side scatter. Late apoptotic cells (**C**) have both forward and side scatter diminished.

Mitochondrial potential

A point to consider in measuring $\Delta\psi_m$ is that the mitochondrial potential probes lack absolute specificity and also accumulate in the cytosol. Probe distribution in mitochondria versus cytosol follows the Nernst equation, according to which the ratio of mitochondrial to cytosolic free cation concentration should be 100:1 at 120 mV mitochondrial transmembrane potential (Waggoner, 1979). However, the specificity of particular mitochondrial probes towards mitochondria is higher at low probe concentrations. It is advisable, therefore, to use these probes at the lowest possible concentration. The limit for the minimal dye concentration that still provides an adequate signal-to-noise ratio during the measurement is dictated by sensitivity of the instrument (laser power, optics, photomultiplier sensitivity) and by the mitochondrial mass per cell; the latter varies depending on the cell type or upon mitogenic stimulation (Darzynkiewicz et al., 1981).

A series of MitoTracker dyes (chloromethyltetramethylrosamine analogs) of different colors was introduced by Molecular Probes as new mitochondrial $\Delta\psi_m$-sensitive probes. Some of these dyes remain attached to mitochondria following cell fixation using cross-linking agents (Poot et al., 1997; Haugland, 2002). It should be noted, however, that because these dyes bind to thiol moieties within mitochondria, their retention after fixation may not be a reliable marker of the transmembrane potential (Ferlini et al., 1998; Gilmore and Wilson, 1999). Furthermore, they are potent inhibitors of respiratory chain I and may themselves induce dissipation of $\Delta\psi_m$ (Scorrano et al., 1999). Because it is likely that other $\Delta\psi_m$ probes may predispose the cells to the permeability transition, one has to be cautious in interpreting the data on their use in analysis of apoptosis.

It has been reported that other mitochondrial probes, 10-nonyl acridine orange, MitoFluor Green, and MitoTracker Green, are markers of mitochondrial mass and are not sensitive to $\Delta\psi_m$ (Ratinaud et al., 1988; Poot et al., 1997). It was proposed, therefore, to measure both $\Delta\psi_m$ and mitochondrial mass by using a combination of $\Delta\psi_m$-sensitive and $\Delta\psi_m$-insensitive probes (Petit et al., 1995). Recent observations, however, indicate that 10-nonyl acridine orange, MitoFluor Green, and MitoTracker Green are quite sensitive to changes in $\Delta\psi_m$ and therefore, either alone or in combination with $\Delta\psi_m$-sensitive probes, cannot be used as markers of mitochondrial mass (Keiji et al., 2000).

Caspases

Caspases (cysteine-aspartic acid specific proteases) are activated in response to different inducers of apoptosis (Kaufmann et al., 1993; Lazebnik et al., 1994; Alnemri et al., 1996). The process of their activation is considered to be the key event of apoptosis, a marker of cell commitment to disassemble the machinery that supports cell life (for reviews, see Budihardjo et al., 1999; Earnshaw et al., 1999; Shi, 2002). Caspases recognize a four-amino-acid sequence on their substrate proteins; within this sequence, the carboxyl end of aspartic acid is the target for cleavage. Detection of caspase activation is of primary interest in oncology as well as in other disciplines of medicine and biology, and several methods have been developed to accomplish this.

One approach that is potentially useful for cytometry utilizes fluorogenic caspase substrates. The peptide substrates are colorless or nonfluorescent, but upon caspase-induced cleavage, they generate colored or fluorescing products (Gorman et al., 1999; Hug et al., 1999; Liu et al., 1999; Komoriya et al., 2000; Telford et al., 2002). Many kits designed to measure activity of caspases using fluorometric or colorimetric assays are commercially available (e.g., from Biomol Research Laboratories or Calbiochem). Some kits can be used to detect activation of multiple caspases, while other are based on the substrates that are specific for caspase-1, caspase-3, or caspase-8.

The second approach in studies of caspase activation applicable to cytometry is based on immunocytochemical detection of the epitope of these enzymes that is characteristic of their active form. This epitope appears as a result of conformational changes that occur during activation of caspases, such as those associated with the transcatalytic cleavage of the zymogen pro-caspases (for reviews, see Budihardjo et al., 1999; Earnshaw et al., 1999). Antibodies developed to react only with the activated caspases have recently become commercially available (e.g., from Promega). These antibodies can be used in standard immunocytochemical assays. Basic Protocol 3 describes the methodology of detection of caspase-3 activation based on this principle, combined with the convenient immunocytochemical Zenon technology (Haugland, 2002). Another approach that was proposed to probe caspase activation utilizes fluorochrome-labeled inhibitors of caspases (FLICAs; e.g., FAM-VAD-FMK), which are reagents designed as affinity labels to the active enzyme center of these enzymes (Smolewski et al.,

2001). It was recently found, however, that these reagents lack the desired specificity with respect to the active enzyme center of caspases (Pozarowski et al., 2003). However, they are convenient and specific markers of apoptotic cells and can be used as such, particularly when there is a need to distinguish between apoptotic and necrotic modes of cell death. Basic Protocol 3 describes application of FAM-VAD-FMK to identify three sequential stages of apoptosis. Finally, caspase activation can be detected indirectly, by identifying specific protein fragments which are the products of cleavage by particular caspases. For example, immunocytochemical detection of the poly(ADP-ribose) polymerase 85-kDa fragment (PARP p85 fragment), which results from cleavage of the PARP substrate by caspase-3, is described in Basic Protocol 4. Concurrent analysis of cellular DNA content allows one to correlate activation of caspases with the cell cycle position or DNA ploidy. Using immunocytochemical methods, however, one has to remember that, often, antibodies that are applicable to immunoblotting or immunoprecipitation may not always be useful in immunocytochemical assays, and vice versa.

Critical Parameters and Troubleshooting

Positive and negative controls

There are instances when cells die by a process of atypical apoptosis that lacks one or more characteristic apoptotic features. Obviously, apoptosis cannot be detected if the feature serves as a marker. It is also possible that the assay (kit) used to identify apoptotic cells malfunctions for technical reasons. For example, the enzyme TdT used in the TUNEL assay may be inactive due to improper storage. A mistake might be made during the staining procedure. It is essential, therefore, to distinguish between the genuine lack of apoptosis and the inability to detect it due to technical causes. The distinction can be made using a positive control consisting of cells known to be apoptotic (confirmed by a standard method and inspection of cell morphology). Such control cells have to be processed in parallel with the investigated sample through all the prescribed protocol steps. Some vendors provide positive and negative control cells with their kits (e.g., APO-BRDU from Phoenix Flow Systems).

The positive control cells can be prepared in large quantity and stored in aliquots to be used during each experiment. Such a convenient control may be, to give an example, exponentially growing HL-60 or U-937 leukemic cells treated 3 to 6 hr in culture with 0.2 μM camptothecin (CPT) to induce apoptosis. The cells so treated consist of subpopulations of apoptotic (S-phase) and non-apoptotic (G_1-phase) cells, present in the same sample. However, to induce apoptosis of S-phase cells with CPT, it is critical to have the cultures in the exponential phase of growth, at relatively low cell density (<800,000 cells/ml); subconfluent cultures are quite resistant to CPT. A large batch of cells treated in such a manner can be appropriately fixed in 70% ethanol and then stored in aliquots at −20°C to be used as a positive and negative control for each assay that utilizes fixed cells. For the assays that require live cells, controls should be freshly made and must not be fixed. Cells from healthy, untreated cultures may also serve as negative controls.

False-positive apoptosis

The exposure of phosphatidylserine on cell surfaces that occurs during apoptosis (Fadok et al., 1992; Koopman et al., 1994) makes apoptotic cells and apoptotic bodies attractive to neighboring cells, which phagocytize them. The ability to engulf apoptotic bodies is not solely the property of professional phagocytes, but is shared by cells from fibroblast or epithelial lineages. It is frequently observed, especially in solid tumors, that the cytoplasm of both nontumor and tumor cells located in the neighborhood of apoptotic cells contains inclusions typical of apoptotic bodies. The remains of apoptotic cells engulfed by neighboring cells contain altered plasma membrane, fragmented DNA, and other constituents with attributes characteristic of apoptosis. Thus, if the distinction is based on any of these attributes, the live, nonapoptotic cells that phagocytized apoptotic bodies cannot be distinguished from genuine apoptotic cells by flow cytometry. For example, nonapoptotic cells that engulf apoptotic bodies become reactive with annexin V (Marguet et al., 1999). Most likely this is due to the fact that during engulfment, the plasma membrane of apoptotic bodies fuses with the plasma membrane of the phagocytizing cell. It has also been shown that nonapoptotic cells (primarily monocytes and macrophages) in bone marrow of patients undergoing chemotherapy have large quantities of apoptotic bodies in their cytoplasm and are strongly positive in the TUNEL reaction (Bedner et al., 1999).

Even after relative mild treatment such as trypsinization, mechanical agitation, detach-

ment with rubber policeman, or electroporation, the plasma membrane of live nonapoptotic cells may have phosphatidylserine, reactive with annexin V, exposed on the surface. Such cells may also be erroneously identified as apoptotic cells.

Distinction between apoptosis, necrosis, and the "necrotic stage" of apoptosis

There are several differences between typical apoptotic and necrotic cells (Kerr et al. 1972; Arends et al., 1990; Majno and Joris, 1995) that provided a basis for development of numerous markers and methods that can discriminate between these two modes of cell death (Darzynkiewicz et al., 1992, 1997). The major difference stems from the early loss of integrity of the plasma membrane during necrosis. This event results in a loss of the cell's ability to exclude charged fluorochromes such as trypan blue or PI. In contrast, the plasma membrane and membrane transport functions remain, to a large extent, preserved during the *early stages* of apoptosis. A cell's permeability to PI or its ability to retain some fluorescent probes, such as products of enzyme activity (e.g., fluorescein diacetate hydrolyzed by esterases), is the most common marker distinguishing apoptosis from necrosis (Darzynkiewicz et al., 1994). A combination of fluorochrome-conjugated annexin V with PI distinguishes live cells (unstainable with both dyes) from apoptotic cells (stainable with annexin V but unstainable with PI) from necrotic cells (stainable with both dyes; Koopman et al., 1994). The same holds true for a combination of PI with FLICA (Smolewski et al., 2001). However, while this approach works well in many instances, it has limitations and possible pitfalls.

(1) Late-stage apoptotic cells resemble necrotic cells to such an extent that the term "apoptotic necrosis" was proposed to define them (Majno and Joris, 1995). This is a consequence of the fact that the integrity of the plasma membrane of late apoptotic cells is compromised, which makes the membrane leaky and permeable to charged cationic dyes such as PI. Since the ability of such cells to exclude these dyes is lost, the discrimination between late apoptosis and necrosis cannot be accomplished by methods based on the use of dye exclusion (PI, trypan blue) or annexin V binding.

(2) The permeability and asymmetry of plasma membrane phospholipids (accessibility of phosphatidylserine) may change, as a result of prolonged treatment with proteolytic enzymes (trypsinization), mechanical damage (e.g., cell removal from flasks by rubber policeman, cell isolation from solid tumors, or even repeated centrifugations), electroporation, or treatment with some drugs.

(3) Many flow cytometric methods designed to quantify the frequency of apoptotic or necrotic cells are based on the differences between live, apoptotic, and necrotic cells in the permeability of plasma membrane to different fluorochromes such as PI, 7-AAD, or Hoechst dyes. It should be stressed, however, that plasma membrane permeability probed by dye accumulation in the cell may vary depending on the cell type and other factors unrelated to apoptosis or necrosis (e.g., very active efflux mechanism that rapidly pumps dye out of the cell). The assumptions, therefore, that live cells maximally exclude a particular dye, while early apoptotic cells are somewhat leaky and late apoptotic or necrotic cells are fully permeable to the dye, and that these differences are large enough to identify these cells, are not universally applicable.

It is particularly difficult to discriminate between apoptotic and necrotic cells in suspensions from solid tumors. Necrotic areas form in tumors as a result of massive local cell death due to poor accessibility to oxygen and growth factors when tumors grow in size and their local vascularization becomes inadequate. Needle-aspirated samples or cell suspensions from the resected tumors may contain many cells from the necrotic areas. Such cells are indistinguishable from late apoptotic cells by many markers. Because the AI in solid tumors, representing spontaneous or treatment-induced apoptosis, should not include cells from the necrotic areas, one has to eliminate such cells from analysis. Because incubation of cells with trypsin and DNase selectively digests all cells whose plasma membrane integrity is compromised, i.e., primarily necrotic cells (Darzynkiewicz et al., 1994), such a procedure may be used to remove necrotic cells from suspensions. It should be noted, however, that late apoptotic cells have partially leaky plasma membrane and are also expected to be sensitive to this treatment.

In conclusion, examination of cells by microscopy may be the only way to distinguish between apoptosis and necrosis, based on their characteristic differences in morphology.

Preferential loss of apoptotic cells during sample preparation

Cell detachment in culture. Early during apoptosis, cells detach from the surface of culture flasks and float in the medium. The standard procedure of discarding the medium, trypsinizing the attached cells or treating them with EDTA, and collecting the detached cells results in selective loss of those apoptotic cells that are discarded with the medium. Such loss may vary from flask to flask depending on how the culture is handled, e.g., the degree of mixing or shaking, efficiency in discarding the old medium, and so on. Surprisingly, some authors still occasionally report discarding the medium and trypsinizing the cells. Needless to say, such an approach cannot be used for quantitative analysis of apoptosis. To estimate the frequency of apoptotic cells in adherent cultures, it is essential to collect floating cells, pool them with the trypsinized ones, and measure them as a single sample. It should be stressed that trypsinization, especially if prolonged, results in digestion of cells with a compromised plasma membrane. Thus, collection of cells from cultures by trypsinization is expected to cause selective loss of late apoptotic and necrotic cells.

Density-gradient centrifugation. Similarly, density-gradient separation of cells (e.g., using Ficoll-hypaque or percoll solutions) may result in selective loss of dying and dead cells, because early during apoptosis the cells become dehydrated and have condensed nuclei and cytoplasm, and therefore have a higher density than nonapoptotic cells. Knowledge of any selective loss of dead cells in cell populations purified by such an approach is essential when one is studying apoptosis.

Centrifugations, mechanical agitations. Repeated centrifugations lead to cell loss by at least two mechanisms. One involves electrostatic cell attachment to the tubes and may be selective for a particular cell type. For example, preferential loss of monocytes and granulocytes is observed during repeated centrifugation of white blood cells, while lymphocytes remain in suspension (Bedner et al., 1997). Cell loss is of particular concern when hypocellular samples ($<5 \times 10^4$) are processed. In such a situation, carrier cells in excess (e.g., chick erythrocytes) may be added to preclude disappearance of the cells of interest through centrifugation. The second mechanism of cell loss involves preferential disintegration of fragile cells. Because apoptotic cells are very fragile, especially at late stages of apoptosis, they may selectively be lost from samples that require centrifugation or are repeatedly vortexed or pipetted. Addition of serum or bovine serum albumin to cell suspensions, shortened centrifugation time, and decreased gravity force all may have a protective effect against cell breakage by mechanical factors. Apoptotic cells may also preferentially disintegrate in biomass cultures that require constant cell mixing.

It should be noted that sensitivity of apoptotic cells to mechanical factors depends on activation of TGase 2. Cells with activated TGase 2 have their cytoplasmic protein crosslinked and are resistant to mechanical stress. They also resist treatment with detergents. In contrast, apoptotic cells that do not activate TGase 2 are overly sensitive and easily undergo disintegration. It was observed that cells may often undergo apoptosis without evidence of TGase 2 activation (Grabarek et al., 2002).

Abundance of extractable (fragmented) DNA is not a quantitative measure of apoptosis

A common misconception in analysis of apoptosis is that the amount of fragmented (low-molecular-weight, "extractable") DNA detected in cultures, tissue or cell extracts, or other samples reflects incidence of apoptosis. Many methods have been developed to estimate the abundance of fragmented DNA and numerous reagent kits are being sold for that purpose. They include direct quantitative colorimetric analysis of soluble DNA, densitometry of DNA ladders on gels, and immunochemical assessment of nucleosomes. These approaches and the related kits are advertised as quantitative, in that they provide information regarding the incidence of apoptosis in cell populations. Such claims are grossly incorrect for the reason that the amount of fragmented (low-molecular-weight) DNA that can be extracted from a *single* apoptotic cell varies over a wide range depending on the *stage* of apoptosis. Although at an early stage of apoptosis only a small fraction of DNA is fragmented and extractable, nearly all DNA can be extracted from the cell that is more advanced in apoptosis. Thus, the total content of low-molecular-weight DNA extracted from the cell population, or the ratio of low- to high-molecular-weight fraction, does not provide information about the *frequency* of apoptotic cells (AI), even in relative terms, e.g., for comparison of cell populations. For this simple reason, biochemical methods based on analysis of fragmented DNA can be used to *quantitatively* estimate the frequency of apop-

tosis only when comparing cell populations that have identical distribution of cells across the stages of apoptosis.

DNA laddering observed during electrophoresis provides evidence of internucleosomal DNA cleavage, which is considered one of the hallmarks of apoptosis (Arends et al., 1990). Analysis of DNA fragmentation by gel electrophoresis to detect such laddering is thus a valuable method to demonstrate the *apoptotic mode* of cell death; however, it should not be used as a means to quantify the *frequency* of apoptosis.

It should be noted that in some cell types, particularly of fibroblast and epithelial lineages, apoptosis may occur without internucleosomal DNA cleavage. The products of DNA fragmentation in these cells are large (50- to 300-kb) DNA sections that cannot be extracted from the cell (Oberhammer et al., 1993). Obviously, in these cases, apoptosis cannot be revealed by the presence of DNA laddering on gels or by analysis of low-molecular-weight products. These large DNA fragments, however, can be identified by pulse-field gel electrophoresis.

Changes in cell morphology, the "gold standard" for identification of apoptosis

Apoptosis was originally defined as a specific mode of cell death based on very characteristic changes in cell morphology (Kerr et al., 1972; Fig. 18.8.2). These changes are still considered the "gold standard" for identification of apoptotic cells. Although particular markers may be used in conjunction with flow cytometry for detection and quantitative assessment of apoptosis in cell populations, the mode of cell death should always be confirmed by inspection of cells by light or electron microscopy. If there is any ambiguity regarding the mechanism of cell death, the morphological changes should be the deciding factor in resolving the uncertainty.

The characteristic morphological features of apoptosis and necrosis are listed in Table 18.8.1. The most specific (and generic to apoptosis) of these changes is chromatin condensation; the chromatin of apoptotic cells is very "smooth" (structureless) in appearance, and the structural framework that otherwise characterizes the cell nucleus is entirely lost. Because of the condensation, chromatin shows strong hyperchromicity with any of the DNA-specific

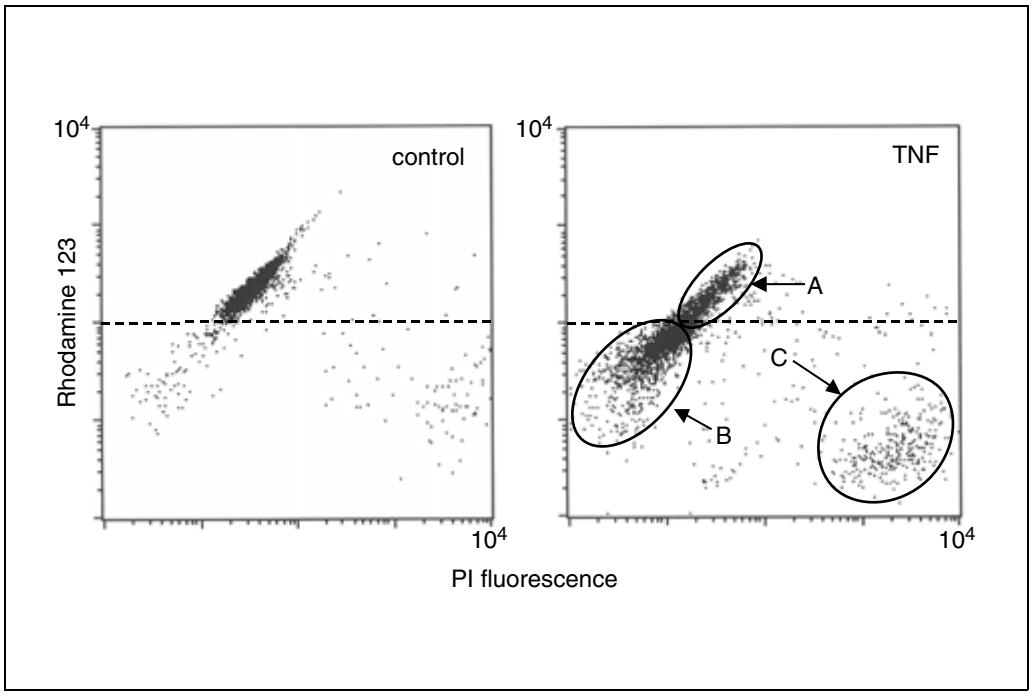

Figure 18.8.2 Detection of the collapse of mitochondrial electrochemical potential (ψ_m) by rhodamine 123 (R123). HL-60 cells were untreated (control; left panel) or treated 3 hr with TNF-α and CHX (right panel) to induce apoptosis. The cells were then incubated with R123 and PI according to Basic Protocol 1. The early apoptotic cells have diminished green fluorescence of R123 but exclude PI (cell population B). The late apoptotic (also necrotic) cells are stained strongly by PI (population C).

Table 18.8.1 Morphological Criteria for Identification of Apoptosis or Necrosis

Apoptosis	Necrosis
Reduced cell size, convoluted shape	Cell and nuclear swelling
Plasma membrane undulations ("blebbing," "budding")	Patchy chromatin condensation
Chromatin condensation (DNA hyperchromicity)	Swelling of mitochondria
Loss of the structural features of the nucleus (smooth, planate appearance)	Vacuolization in cytoplasm
Nuclear fragmentation (karyorrhexis)	Plasma membrane rupture ("ghost-like" appearance of lysed cells)
Presence of apoptotic bodies	Dissolution of nuclear chromatin (karyolysis)
Dilatation of the endoplasmic reticulum	Attraction of inflammatory cells
Relatively unchanged cell organelles	
Shedding of apoptotic bodies	
Phagocytosis of the cell remnants	
Cell detachment from tissue culture flasks	

dyes (Hotz et al., 1992). Apart from chromatin condensation, however, other changes are less generic to apoptosis and may not always be apparent. For example, nuclear fragmentation, although commonly observed during apoptosis of hematopoietic-lineage cells, may not occur during apoptosis of some epithelial- or fibroblast-lineage cells. Likewise, cell shrinkage, at least early during apoptosis, is not a universal marker of the apoptotic mode of cell death.

It should be stressed that optimal preparations for light microscopy require cytospinning of live cells followed by fixation and staining on slides. The cells become flat, facilitating assessment of their morphology. On the other hand, when cells are initially fixed and stained in suspension, transferred to slides, and analyzed under the microscope, their morphology is obscured by unfavorable geometry; the cells are spherical and thick, and require confocal microscopy to reveal details such as early signs of apoptotic chromatin condensation.

Differential staining of cellular DNA and protein of cells on slides with DAPI and sulforhodamine 101, respectively, is rapid and simple and provides very good morphological resolution of apoptosis and necrosis (Darzynkiewicz et al., 1997). A combined cell illumination with UV light (to excite the DAPI or other DNA fluorochrome) and light-transmission microscopy utilizing interference contrast (Nomarski illumination) is the authors' favorite method of cell visualization to identify apoptotic cells. Other DNA fluorochromes, such as PI, 7-aminoactinomycin D, or acridine orange, can be used as well.

In conclusion, regardless of which cytometric assay has been used to identify apoptosis, the mode of cell death should be confirmed by inspection of cells by light or electron microscopy. Morphological changes during apoptosis have a very characteristic pattern (Kerr et al., 1972; Majno and Joris, 1995) and should be the deciding factor in situations where any ambiguity arises regarding the mode of cell death. It should be noted, however, that the laser scanning cytometer (LSC), offering many attributes of flow cytometry and simultaneously providing the means to examine morphology of the measured cells (Darzynkiewicz et al., 1999; Kamentsky, 2001), appears to be the instrument of choice in analysis of apoptosis (Bedner et al., 1999).

Membrane potential

It should be stressed that $\Delta\psi_m$, like other functional markers, is sensitive to minor changes in cell environment. The samples to be compared, therefore, should be incubated and measured under identical conditions, taking into an account temperature, pH, time elapsed between the onset of incubation and actual fluorescence measurement, and other potential variables.

Annexin V

Interpretation of the results may be complicated by the presence of non-apoptotic cells with damaged membranes. Such cells may have phosphatidylserine exposed on the plasma membrane and therefore, like apoptotic cells, bind annexin V. Mechanical disaggregation of tissues to isolate individual cells, extensive use of proteolytic enzymes to disrupt cell aggregates, to remove adherent cells from cultures, or to isolate cells from tissue, mechanical removal of the cells from tissue-culture flasks (e.g., with a rubber policeman), or cell electroporation all affect the binding of annexin V. Such treatments, therefore, may introduce experimental bias in the subsequent analysis of apoptosis by this method.

Even intact and live cells take up PI upon prolonged incubation. Therefore, fluorescence measurement should be performed rather shortly after addition of the dye.

DNA fragmentation

It should be stressed that the degree of extraction of low-molecular-weight DNA and consequently the content of DNA remaining in apoptotic cells for flow cytometric analysis varies markedly depending on the extent of DNA degradation (duration of apoptosis), the number of cell washings, and the pH and molarity of the washing and staining buffers. DNA fragmentation is often so extensive that most DNA is removed during the post-fixation rinse with PBS and in the staining solution, and a DNA extraction step is therefore unnecessary. Conversely, when DNA degradation does not proceed to internucleosomal regions but stops after generating 50- to 300-kb fragments (Oberhammer et al., 1993), little DNA can be extracted, and this method may fail to detect such apoptotic cells. It also should be noted that if G_2, M, or even late S-phase cells undergo apoptosis, the loss of DNA from these cells may not be adequate to place them at the sub-G_1 peak, as they may end up with DNA content equivalent of that of G_1 or early S-phase cells and therefore be indistinguishable from the latter.

It is a common practice to use detergents or hypotonic solutions instead of fixation in the process of DNA staining for flow cytometry (Nicoletti et al., 1991). Such treatments cause lysis of plasma membrane and release of the nucleus. Although this approach is simple and yields excellent resolution for DNA-content analysis, when used to quantify apoptotic cells it introduces bias owing to the fact that nuclei of apoptotic cells are often fragmented. Lysis of cells with fragmented nuclei releases nuclear fragments rather than individual nuclei, and consequently several fragments can be released from a single cell. Likewise, lysis of mitotic cells that happen to be in the specimen releases individual chromosomes or chromosome aggregates. In the case of micronucleation (e.g., after cell irradiation), the micronuclei are released upon cell lysis. Each nuclear fragment, chromosome, or micronucleus is then recorded by the flow cytometer as an individual object with a sub-G_1 DNA content. Such objects are then erroneously classified as individual apoptotic cells. This bias is increased if DNA content is displayed on a logarithmic scale. Such a scale allows one to record objects with DNA content as little as 1% or even 0.1% of that of G_1 cells, which certainly cannot be individual apoptotic cells.

Activation of TGase 2

Although apoptotic cells with activated TGase 2 can be detected using either Basic Protocol 8 or Alternate Protocol 2, the differences between these assays should be underscored. The most distinct is the difference in the length of the time window that may be measured by the respective assay. Namely, the detergent-based assay (see Basic Protocol 8) detects cumulative protein cross-linking, reflecting the integrated cross-linking, from its onset to the time of cell harvesting. In contrast, the assay based on incorporation of F-CDV (see Alternate Protocol 2) detects cross-linking that occurs only during the time interval when this reagent is present in the culture. Thus, if F-CDV is included at time zero, i.e., when the inducer of apoptosis is added, its incorporation is a reflection of the cumulative protein cross-linking and thus is comparable with the detergent-based assay. However, if it is added during the final hour or two, it will reflect the cross-linking that took place only during this 1- or 2-hr time window. This difference between the assays should be kept in mind when comparing frequency of TGase 2–positive cells, which may vary between the assays, depending on the length of the respective time window.

Situations (e.g., following treatment with particular drugs) may occur in which cell proteins may become less soluble and more detergent resistant, not necessarily because of TGase 2 activation, but because of alteration by the drug. Some treatments unrelated to TGase 2 activity may also result in attachment of F-CDV to cellular proteins. Some cell types may be

more resistant to detergents. In all these cases, the assay may detect the "false-positive" TGase 2–positive cells. As with other markers of apoptosis, one has to be careful and additionally identify these cells by microscopy based on the characteristic changes in their morphology.

Apoptosis can be induced and may progress in some cells with no apparent TGase 2 activation (Grabarek et al., 2002). In general, the activation of TGase 2 is seen to occur in cells that show a high degree of chromatin and cytoplasm condensation leading to pronounced nuclear and cell shrinkage, and that either lack or have very limited nuclear fragmentation. In contrast, the apoptotic cells that appear larger and whose nuclei are excessively fragmented do not show activation of TGase 2. Apoptosis without activation of TGase 2 appears to occur more frequently when induced with higher drug doses, i.e., when cells enter the apoptotic process more rapidly following treatment. Thus, a note of caution should be added, that since TGase 2 activation may not be detected in some instances of apoptosis, the absence of its activation should not be considered a marker of nonapoptotic cells.

Anticipated Results

Light scatter. A decrease in forward light scatter characterizes early apoptotic cells (Fig. 18.8.1, cluster B). Late apoptotic cells and perhaps also larger apoptotic bodies show marked decrease in both forward and side light scatter (cluster C).

Mitochondrial potential. A combination of PI and R123 identifies nonapoptotic cells that stain only green, early apoptotic cells whose green fluorescence is diminished, and late apoptotic or necrotic cells that stain with PI and have red fluorescence only (Fig. 18.8.2). Likewise, a combination of $DiOC_6(3)$ and PI labels live nonapoptotic cells green, early apoptotic cells dim-green, and late apoptotic and necrotic cells red (not shown).

The change in binding of JC-1 is manifested by a loss of the orange fluorescence that represents the aggregate binding of this dye and that characterizes charged mitochondria (Fig. 18.8.3). JC-1 green fluorescence is expected to increase as a result of disaggregation of the complexed JC-1. However, either no change or a decrease in green fluorescence may be seen if JC-1 concentration within the cell is too high, which causes quenching of its fluorescence.

Caspases. Caspase-3 activation during apoptosis induced by topotecan (TPT), a camptothecin (CPT) analog, is reflected by the cells' ability to bind antibody that is reactive with the activated (cleaved) form of this enzyme (Fig. 18.8.4). Concurrent staining of cellular DNA with PI makes it possible to correlate caspase-3 activation with the cell cycle position. Note that activation of caspase-3 occurs preferentially in S-phase cells.

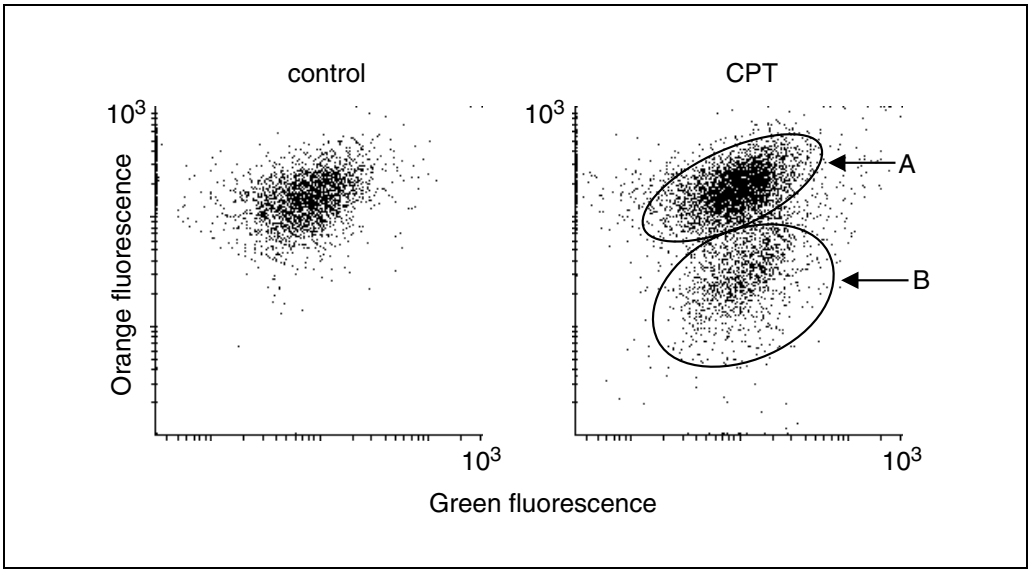

Figure 18.8.3 Detection of the collapse of mitochondrial electrochemical potential using the aggregate dye JC-1. HL-60 cells were untreated (control, left panel) or treated 3 hr with camptothecin (CPT, right panel) to induce apoptosis. Cells were then stained with JC-1 and their orange and green fluorescence was measured by cytometry, as described in Basic Protocol 2. Decreased intensity of orange fluorescence (subpopulation B) characterizes the cell with collapsed potential.

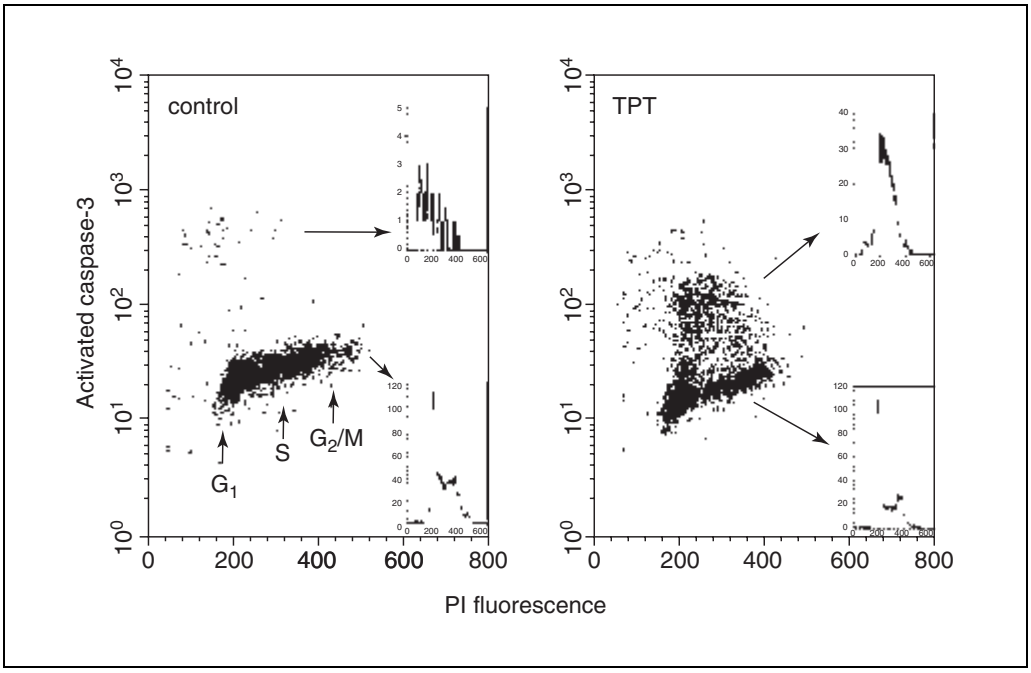

Figure 18.8.4 Immunocytochemical detection of caspase-3 activation using antibody reactive with the activated (cleaved) caspase-3. Apoptosis of HL-60 cells was induced by topotecan (TPT), an analog of CPT. Zenon technology (Haugland, 2002) was used to detect caspase-3 as described in Basic Protocol 2. Top and bottom insets in each panel show cellular DNA content frequency histograms of cells with activated and nonactivated caspase-3, respectively. Note that S-phase cells preferentially contain activated caspase-3 after induction of apoptosis by TPT.

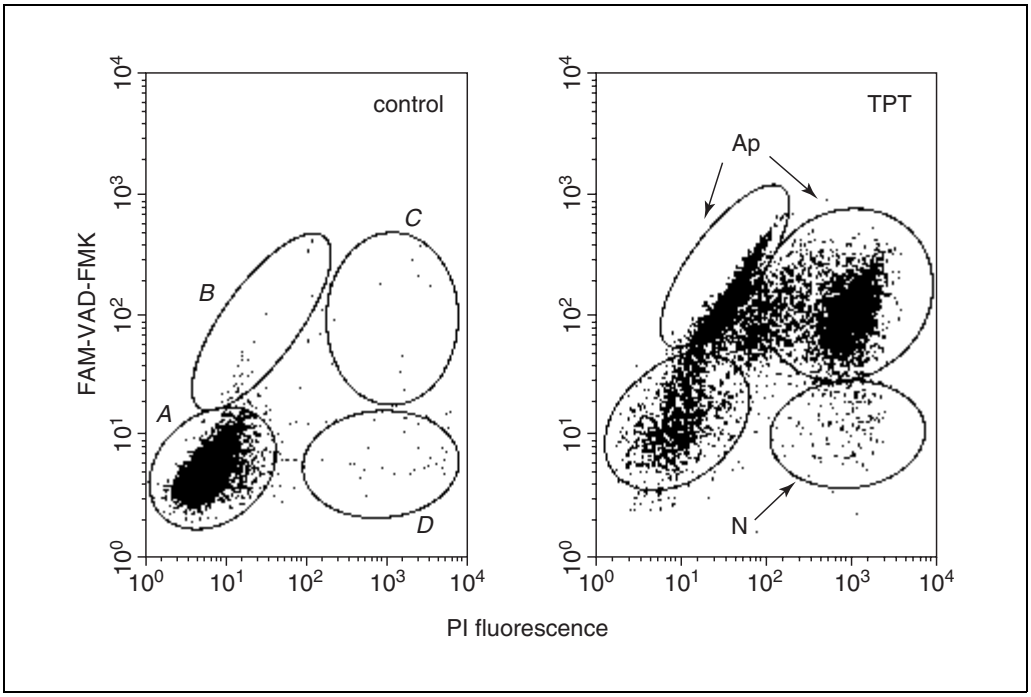

Figure 18.8.5 Binding of fluorochrome-labeled inhibitor of caspases (FLICA; FAM-VAD-FMK) and PI during apoptosis. Apoptosis of HL-60 cells was induced by TPT. The cells were stained according to Basic Protocol 3. Green (FAM-VAD-FMK) and red (PI) cellular fluorescence was measured by flow cytometry. Four cell subpopulations (A to D) can be identified, differing in their capability to bind FAM-VAD-FMK and PI. They represent sequential stages of apoptosis, starting with binding of FAM-VAD-FMK (B), loss of plasma membrane integrity to exclude PI (C), and loss of reactivity with FAM-VAD-FMK (D).

The bivariate distributions (scatterplots) of green and red fluorescence intensity representing cells supravitally stained with FAM-VAD-FMK (FLICA) and PI reveal the presence of four distinct subpopulations (Fig. 18.8.5). Nonapoptotic cells show neither FLICA nor PI fluorescence ($FLICA^-/PI^-$; subpopulation A). Early apoptotic cells bind FAM-VAD-FMK and still exclude PI ($FLICA^+/PI^-$; subpopulation B). More advanced in apoptosis are the cells that bind FAM-VAD-FMK but lose the ability to exclude PI ($FLICA^+/PI^+$; subpopulation C). The cells most advanced in apoptosis are FAM-VAD-FMK negative and are stained with PI ($FLICA^-/PI^+$; subpopulation D). Because the late phase of apoptosis during which the plasma membrane becomes permeable to cationic dyes such as PI or trypan blue has been defined as the "necrotic stage" of apoptosis (Majno and Joris, 1995; Darzynkiewicz et al., 1997), the $FLICA^+/PI^+$ and $FLICA^-/PI^+$ cells thus represent two consecutive phases of the "necrotic stage." It should be noted that genuine necrotic cells, i.e., cells that die by the mode of necrosis ("accidental" cell death), not having activated caspases and unable to exclude PI (Darzynkiewicz et al., 1997), have the same properties ($FLICA^-/PI^+$) as very late apoptotic cells.

As mentioned earlier, because of lack of specificity, the labeling of apoptotic cells with FAM-VAD-FMK, while likely the marker of caspase activation, is not in and of itself evidence of its binding to the active enzymatic center of caspases (Pozarowski et al., 2003).

PARP cleavage. Differences in intensity of PARP p85 immunofluorescence versus PI fluorescence (cellular DNA content) allow one to identify apoptotic cells and reveal the cell cycle distribution of both apoptotic (PARP p85–positive) and nonapoptotic (PARP p85–negative) cells (Fig. 18.8.6). It is quite evident that predominantly S-phase cells were undergoing apoptosis upon CPT treatment (Li and Darzynkiewicz, 2000).

Annexin V. Live nonapoptotic cells stained according to Basic Protocol 5 have minimal green (annexin V-FITC) fluorescence and also minimal red (PI) fluorescence (Fig. 18.8.7; subpopulation A). At early stages of apoptosis, cells stain green but still exclude PI and therefore continue to have no significant red fluorescence (subpopulation B). At late stages of apoptosis, cells show intense green and red fluorescence (subpopulation C). It should be noted that isolated nuclei, cells with severely damaged membranes, and very late apoptotic cells stain rapidly and strongly with PI and may not bind annexin V (subpopulation D).

DNA fragmentation. Apoptotic cells have decreased PI (or DAPI) fluorescence and diminished forward light scatter relative to cells in the main peak (G_1; Fig. 18.8.8). Optimally, the sub-G_1 peak representing apoptotic cells should be separated from the G_1 peak of the

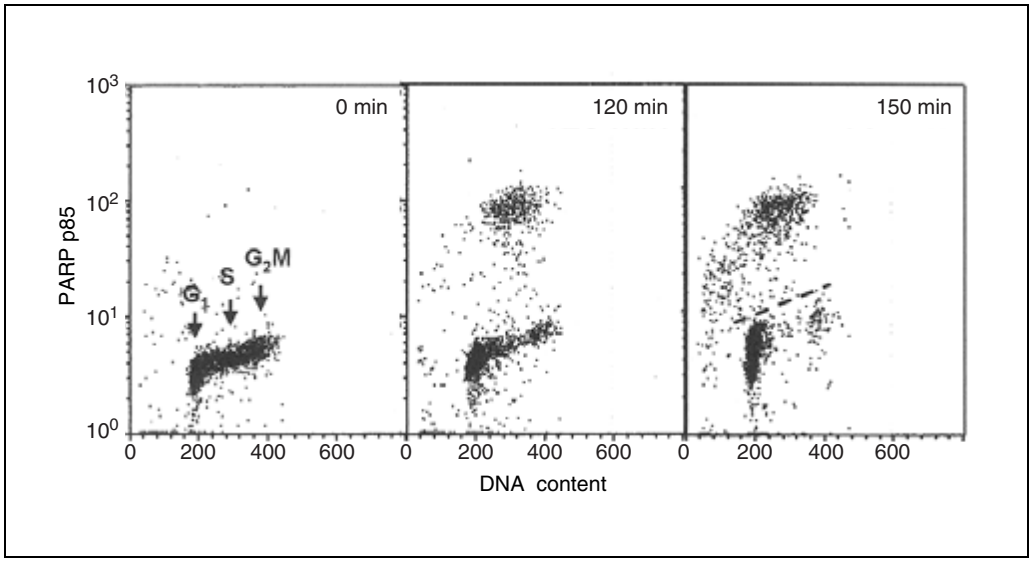

Figure 18.8.6 Identification of apoptotic cells by flow cytometry based on the immunocytochemical detection of the 85-kDa PARP cleavage fragment. To induce apoptosis, HL-60 cells were treated 60 min with TNF-α in the presence of CHX (Li and Darzynkiewicz, 2000). PARPp85 was detected immunocytochemically and DNA was counterstained with PI, as described in Basic Protocol 3.

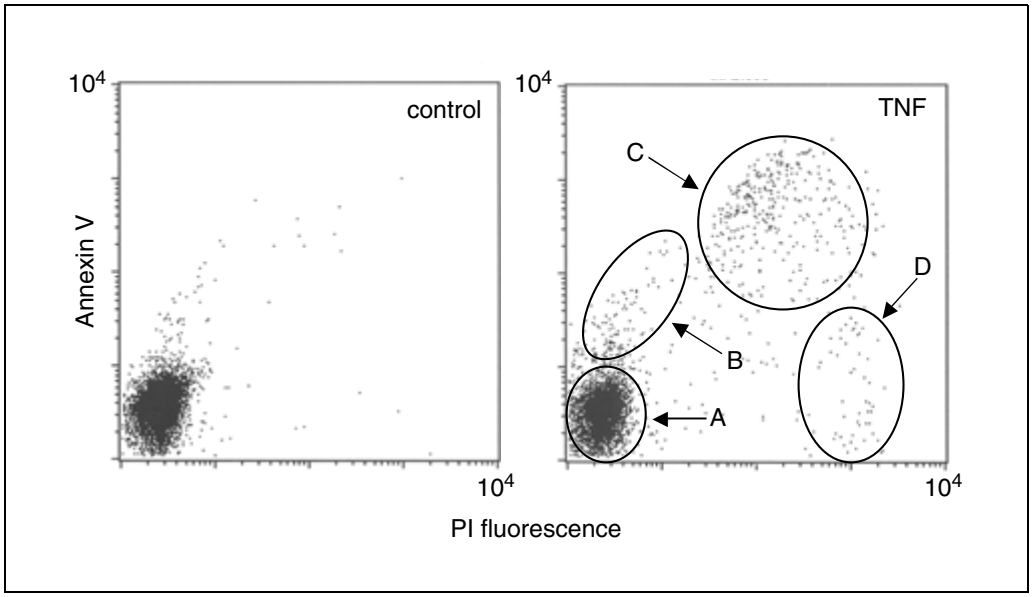

Figure 18.8.7 Detection of early and late apoptotic cells after staining with annexin V–FITC and PI. To induce apoptosis, HL-60 cells were treated 2 hr with TNF-α and CHX. Untreated (control; left panel) and TNF-α-treated (right panel) cells were then stained with annexin V-FITC and PI.

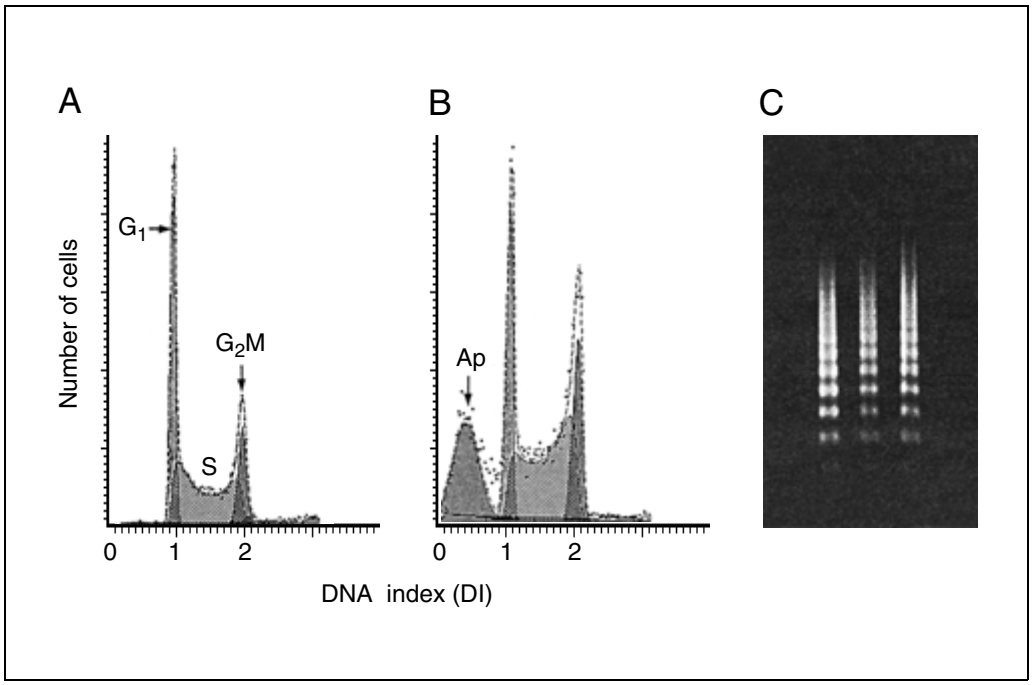

Figure 18.8.8 Detection of apoptotic cells by flow cytometry based on cellular DNA content analysis. (**A**) Normal cell plot. (**B**) To induce apoptosis, HL-60 cells were treated with the DNA topoisomerase II inhibitor fostriecin (Hotz et al., 1994). Cells were fixed in 70% ethanol, suspended in high-molarity phosphate buffer to extract fragmented DNA, and then stained with PI. A subpopulation of apoptotic cells (Ap) with fractional (sub-diploid) DNA content, i.e., with DNA index (DI) <1.0 (sub-G_1 cells), is apparent. Note also the increase in the proportion of S-phase cells in the nonapoptotic population. (**C**) The fragmented DNA extracted from the apoptotic cells by the buffer was subjected to gel elecrophoresis (Gong et al., 1994). Note “laddering" that reflects preferential DNA cleavage at internucleosomal sections, the characteristic feature of apoptosis (Arends et al., 1990).

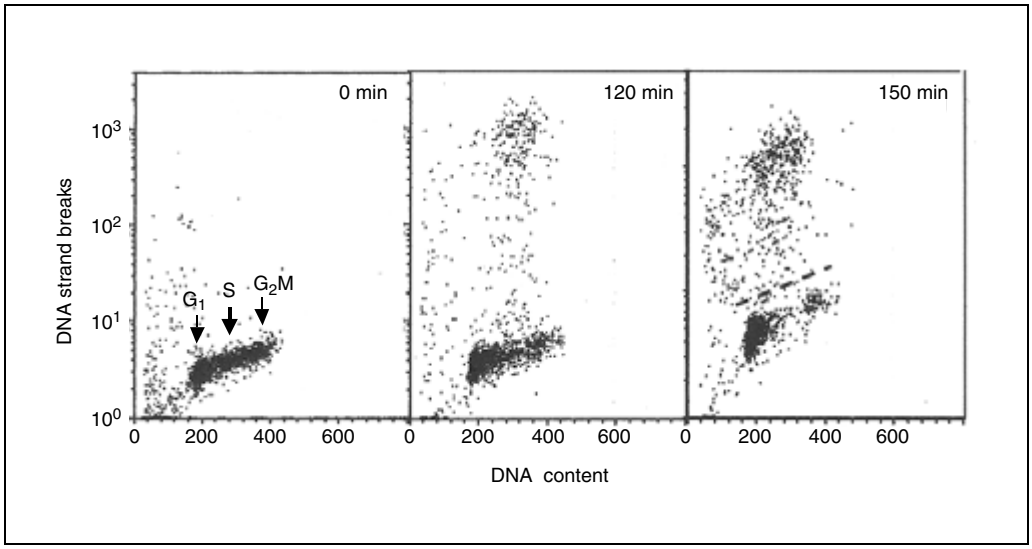

Figure 18.8.9 Detection of apoptotic cells by flow cytometry based on the presence of DNA strand breaks. To induce apoptosis, HL-60 cells were treated 120 or 150 min with CPT (Li and Darzynkiewicz, 2000). DNA strand breaks were labeled with BrdUTP using exogenous terminal deoxynucleotidyl transferase. The cell cycle distribution of both apoptotic and nonapoptotic cell subpopulations can be estimated based on the DNA content of individual cells. Note that in analogy to PARP cleavage (Fig. 18.8.6), preferentially S-phase cells undergo apoptosis following CPT treatment.

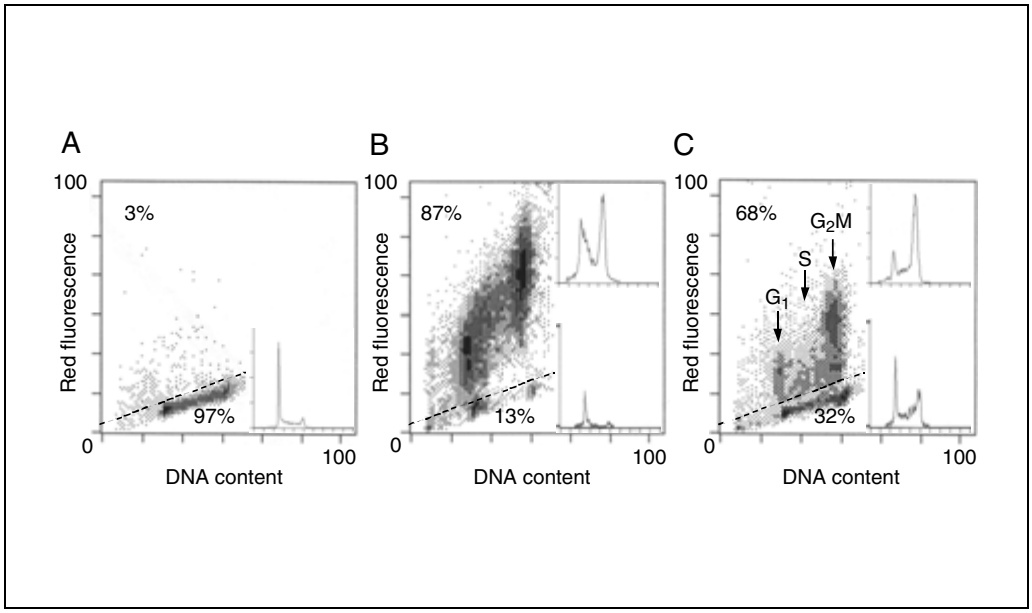

Figure 18.8.10 Detection of tissue transglutaminase (TGase 2) activation during apoptosis by the acquired resistance of the cytoplasmic proteins to detergent. Bivariate distributions illustrating red fluorescence of sulforhodamine 101 (protein content) versus blue fluorescence of DAPI (DNA content) of HL-60 cells, untreated (**A**) or exposed to hyperthermia (72 hr at 41.5°C) in the absence (**B**) and presence (**C**) of the cytotoxic RNase onconase (1.67 μM; Grabarek et al., 2002). Following cell lysis by Triton X-100 and staining with DAPI and sulforhodamine 101, the isolated nuclei of nonapoptotic cells from control culture (**A**) show low and uniform intensity of red fluorescence, reflecting low protein content. Subpopulations of apoptotic cells in **B** and **C** have their cytoplasmic protein crosslinked and therefore are resistant to detergent. They stain intensely with sulforhodamine 101. Note differences in DNA content (cell cycle) distribution of the cells with activated (top insets; cells gated above the dashed line) versus nonactivated TGase 2 (bottom insets; cells gated below the dashed line) in **B** and **C**. Percentage of cells with activated and non-activated TGase 2 in the respective cultures is indicated in each panel.

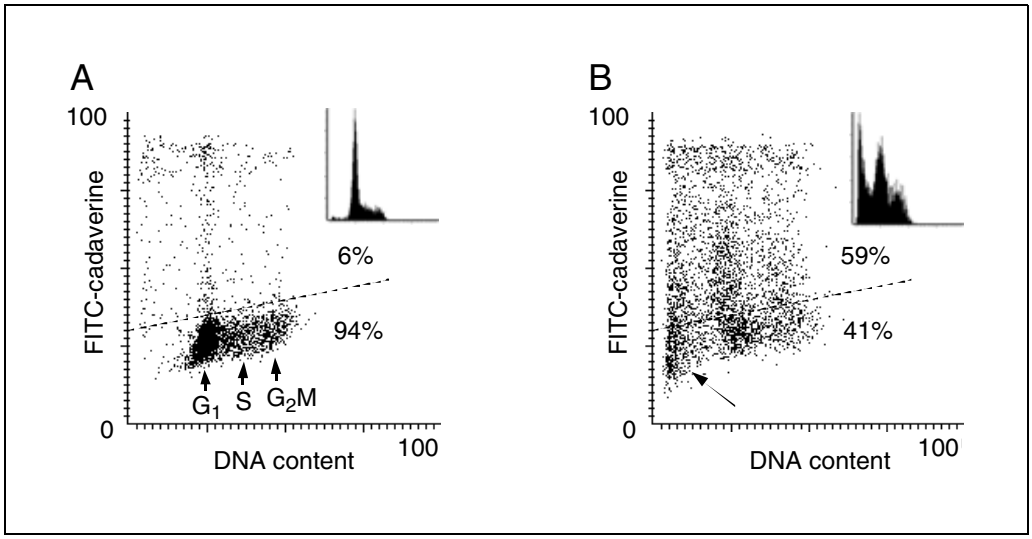

Figure 18.8.11 Detection of TGase 2 activity in HL-60 cells using FITC-conjugated cadaverine (F-CDV) as the enzyme substrate. Cultures of untreated (**A**) and hyperthermia (5 hr at 41.5°C)-treated (**B**) HL-60 cells were incubated 5 hr with 100 μM F-CDV. Cells were then fixed and their DNA was counterstained with PI in the presence of RNase. Note the presence in the untreated culture (**A**) of few cells that incorporated F-CDV (spontaneous apoptosis), and large numbers of F-CDV-labeled cells in the treated culture (**B**). Note also that some apoptotic cells with fractional DNA content (sub-G_1 subpopulation) in the treated culture do not show incorporation of F-CDV (arrow). Percentage of cells with activated and nonactivated TGase 2 in the respective cultures is indicated. The inset shows the cellular DNA content distribution histogram of all cells (Grabarek et al., 2002).

nonapoptotic cell population with little or no overlap between these two.

TUNEL. DNA strand breaks in apoptotic cells are strongly labeled with fluoresceinated anti-BrdU Ab that distinguishes them from the nonapoptotic cells (Fig. 18.8.9). Because of the high intensity of their green fluorescence, an exponential scale (logarithmic PMTs) often must be used for data acquisition and display. Simultaneous measurement of DNA content makes it possible to identify the cell cycle position of cells in apoptotic and nonapoptotic populations. It should be noted, however, that late apoptotic cells may have diminished DNA content because of prior shedding of apoptotic bodies (which may contain nuclear fragments), or due to such massive DNA fragmentation that small DNA fragments cannot be retained in the cell even after fixation with formaldehyde. Such late apoptotic cells may have sub-G_1 DNA content as shown in Figure 18.8.8.

Tissue transglutaminase (TGase 2). Detergent (Triton X-100) treatment of nonapoptotic cells as well as apoptotic cells without activated TGase 2 results in cell lysis and release of isolated nuclei or nuclear fragments that have minimal protein content. Such isolated nuclei or nuclear fragments have very low red fluorescence after staining with sulforhodamine 101 (Fig. 18.8.10, panel A). Apoptotic cells with activated TGase 2, on the other hand, have cross-linked proteins and resist lysis under these conditions. Intensity of their red fluorescence is several times higher than that of the isolated nuclei (subpopulations represented by the scatter plots above the dashed lines in panels B and C). Note the high heterogeneity among individual TGase 2–positive cells in intensity of their red fluorescence.

Because cellular DNA content (PI fluorescence) is measured concurrently with protein content, induction of protein cross-linking can be correlated with the cell cycle position. It is evident that the effects are cell cycle phase specific. Both hyperthermia and onconase lead to preferential protein cross-linking in G_2/M-phase cells.

Activation of TGase 2 in HL-60 cells, detected by cell labeling with F-CDV combined with cellular DNA content analysis, is shown in Fig. 18.8.11. As in the case of protein content (Fig. 18.8.10), populations of cells with activated TGase 2 either undergoing spontaneous apoptosis in control culture (Fig. 18.8.11A) or subjected to hyperthermia (Fig. 18.8.11B) are heterogeneous in terms of their TGase 2–related fluorescence. In the hyperthermia-treated culture, a large number of cells have fractional

DNA content, forming a characteristic sub-G_1 population typical of apoptotic cells. This population is heterogeneous in terms of intensity of F-CDV fluorescence, with many F-CDV-negative sub-G_1 cells (arrow). Thus, the degree of activation of TGase 2 is uneven, and many cells with apoptotic features (sub-G_1 DNA content) have undetectable level of TGase activity.

Time Considerations

Basic Protocol 1 takes ~15 min to prepare cells for incubation with mitochondrial probes followed by an additional 15- to 30-min incubation.

Basic Protocol 2 (activated caspase detection by Zenon techology) requires ~2 hr to complete (cell fixation not included).

In Basic Protocol 3, FLICA (FAM-VAD-FMK) is added directly to cultures at least 30 min before cell centrifugation. Optimal labeling is achieved after a 1- to 2-hr incubation with FLICA. Cell rinses and staining with PI require an additional ~15 min before cells are measured by flow cytometry.

Basic Protocol 4 requires ~4 hr to process cells from fixation through primary and secondary Ab incubations followed by staining with PI before they are analyzed by flow cytometry.

Basic Protocol 5 is a rapid procedure that can be completed in 15 min.

Basic Protocol 6 requires ~40 min to carry out cell rinsing and staining with PI following removal from fixative.

In Alternate Protocol 1, cell rinsing and staining can be completed in 25 to 30 min.

Basic Protocol 7 takes ~3 hr to carry out all steps of cell rinsing and incubations with the respective reagents after removal of cells from fixative.

Basic Protocol 8 is a rapid procedure. Cells can be analyzed by flow cytometry ~5 min after their removal from cultures.

In Alternate Protocol 2, the reagent F-CDV is added directly to cultures at different time intervals. It takes ~40 min following cell fixation to carry out cell rinsing and labeling with PI.

Figure 18.8.1 Changes in light scattering properties of cells undergoing apoptosis. HL-60 cells were untreated (left panel) or treated 3 hr with TNF-α and cycloheximide (CHX) to induce apoptosis (right panel). Cell population **A** in the treated culture (right panel) represents cells that have light scattering properties similar to those of untreated cells. Early apoptotic cells (**B**) have diminished forward scatter and are very heterogenous with respect to side scatter. Late apoptotic cells (**C**) have both forward and side scatter diminished.

Figure 18.8.2 Detection of the collapse of mitochondrial electrochemical potential (ψ_m) by rhodamine 123 (R123). HL-60 cells were untreated (control; left panel) or treated 3 hr with TNF-α and CHX (right panel) to induce apoptosis. The cells were then incubated with R123 and PI according to Basic Protocol 1. The early apoptotic cells have diminished green fluorescence of R123 but exclude PI (cell population B). The late apoptotic (also necrotic) cells are stained strongly by PI (population C).

Figure 18.8.3 Detection of the collapse of mitochondrial electrochemical potential using the aggregate dye JC-1. HL-60 cells were untreated (control, left panel) or treated 3 hr with camptothecin (CPT, right panel) to indice apoptosis. Cells were then stained with JC-1 and their orange and green fluorescence was measured by cytometry, as described in Basic Protocol 2. Decreased intensity of orange fluorescence (subpopulation B) characterizes the cell with collapsed potential.

Figure 18.8.4 Immunocytochemical detection of caspase-3 activation using antibody reactive with the activated (cleaved) caspase-3. Apoptosis of HL-60 cells was induced by topotecan (TPT), an analog of CPT. Zenon technology (Haugland, 2002) was used to detect caspase-3 as described in Basic Protocol 2. Top and bottom insets in each panel show cellular DNA content frequency histograms of cells with activated and nonactivated caspase-3, respectively. Note that S-phase cells preferentially contain activated caspase-3 after induction of apoptosis by TPT.

Figure 18.8.5 Binding of fluorochrome-labeled inhibitor of caspases (FLICA; FAM-VAD-FMK) and PI during apoptosis. Apoptosis of HL-60 cells was induced by TPT. The cells were stained according to Basic Protocol 3. Green (FAM-VAD-FMK) and red (PI) cellular fluorescence was measured by flow cytometry. Four cell subpopulations (A to D) can be identified, differing in their capability to bind FAM-VAD-FMK and PI. They represent sequential stages of apoptosis, starting with binding of FAM-VAD-FMK (B), loss of plasma membrane integrity to exclude PI (C), and loss of reactivity with FAM-VAD-FMK (D).

Figure 18.8.6 Identification of apoptotic cells by flow cytometry based on the immunocytochemical detection of the 85-kDa PARP cleavage fragment. To induce apoptosis, HL-60 cells were treated 60 min with TNF-α in the presence of CHX (Li and Darzynkiewicz, 2000). PARPp85 was detected immunocytochemically and DNA was counterstained with PI.

Figure 18.8.7 Detection of early and late apoptotic cells after staining with annexin V–FITC and PI. To induce apoptosis, HL-60 cells were treated 2 hr with TNF-α and CHX. Untreated (control; left panel) and TNF-α-treated (right panel) cells were then stained with annexin V-FITC and PI.

Figure 18.8.8 Detection of apoptotic cells by flow cytometry based on cellular DNA content analysis. (**A**) Normal cell plot. (**B**) To induce apoptosis, HL-60 cells were treated with the DNA topoisomerase II inhibitor fostriecin (Hotz et al., 1994). Cells were fixed in 70% ethanol, suspended in high-molarity phosphate buffer to extract fragmented DNA, and then stained with PI. A subpopulation of apoptotic cells (Ap) with fractional (sub-diploid) DNA content, i.e., with DNA index (DI) <1.0 (sub-G_1 cells), is apparent. Note also the increase in the proportion of S-phase cells in the nonapoptotic population. (**C**) The fragmented DNA extracted from the apoptotic cells by the buffer was subjected to gel electrophoresis (Gong et al., 1994). Note laddering that reflects preferential DNA cleavage at internucleosomal sections, the characteristic feature of apoptosis (Arends et al., 1990).

Figure 18.8.9 Detection of apoptotic cells by flow cytometry based on the presence of DNA strand breaks. To induce apoptosis, HL-60 cells were treated 120 or 150 min with CPT (Li and Darzynkiewicz, 2000). DNA strand breaks were labeled with BrdUTP using exogenous terminal deoxynucleotidyl transferase. The cell cycle distribution of both apoptotic and nonapoptotic cell subpopulations can be estimated based on the DNA content of individual cells. Note that in analogy to PARP cleavage (Fig. 18.8.6), preferentially S-phase cells undergo apoptosis following CPT treatment.

Figure 18.8.10 Detection of tissue transglutaminase (TGase 2) activation during apoptosis by the acquired resistance of the cytoplasmic proteins to detergent. Bivariate distributions illustrating red fluorescence of sulforhodamine 101 (protein content) versus blue fluorescence of DAPI (DNA content) of HL-60 cells, untreated (**A**) or exposed to hyperthermia (72 hr at 41.5°C) in the absence (**B**) and presence (**C**) of the cytotoxic RNase onconase (1.67 μM; Grabarek et al., 2002). Following cell lysis by Triton X-100 and staining with DAPI and sulforhodamine 101, the isolated nuclei of nonapoptotic cells from control culture (**A**) show low and uniform intensity of red fluorescence, reflecting low protein content. Subpopulations of apoptotic cells in **B** and **C** have their cytoplasmic protein cross-linked and therefore are resistant to detergent. They stain intensely with sulforhodamine 101. Note differences in DNA content (cell cycle) distribution of the cells with activated (top insets; cells gated above the dashed line) versus nonactivated TGase 2 (bottom insets; cells gated below the dashed line) in **B** and **C**. Percentage of cells with activated and non-activated TGase 2 in the respective cultures is indicated in each panel.

Figure 18.8.11 Detection of TGase 2 activity in HL-60 cells using FITC-conjugated cadaverine (F-CDV) as the enzyme substrate. Cultures of untreated (**A**) and hyperthermia (5 hr at 41.5°C)-treated (**B**) HL-60 cells were incubated 5 hr with 100 μM F-CDV. Cells were then fixed and their DNA was counterstained with PI in the presence of RNase. Note the presence in the untreated culture (**A**) of few cells that incorporated F-CDV (spontaneous apoptosis), and large numbers of F-CDV-labeled cells in the treated culture (**B**). Note also that some apoptotic cells with fractional DNA content (sub-G_1 subpopulation) in the treated culture do not show incorporation of F-CDV (arrow). Percentage of cells with activated and nonactivated TGase 2 in the respective cultures is indicated. The inset shows the cellular DNA content distribution histogram of all cells (Grabarek et al., 2002).

Analysis of Cellular Senescence in Culture In Vivo: The Senescence-Associated β-Galactosidase Assay

The senescence-associated β-galactosidase (SA-β-gal) assay is based on a senescence-induced increase in levels of lysosomal β-galactosidase (Dimri et al., 1995). In nonsenescent cells, the lysosomal hydrolase β-galactosidase cleaves galactose from glycoproteins at an optimum pH of 4.0 to 4.5. Lysosomal β-galactosidase activity can be detected in most mammalian cells by performing a cytochemical assay at pH 4.0 in which cleavage of Xgal by β-galactosidase leads to the formation of a blue precipitate (Kurz et al., 2000). However, during senescence, there is an increase in lysosomal β-galactosidase protein levels and an overall increase in lysosomal size. The increase in β-galactosidase levels allows the detection of β-galactosidase activity at the suboptimal pH of 6.0 during senescence (Kurz et al., 2000).

ASSESSMENT OF CELLULAR SENESCENCE IN CULTURE USING THE SENESCENCE-ASSOCIATED β-GALACTOSIDASE ASSAY

BASIC PROTOCOL

In this protocol, cells are first fixed with a formaldehyde/glutaraldehyde mixture and then incubated together with the β-gal substrate in an acidic buffer. The development of a perinuclear blue color, which is indicative of senescent cells, can be followed using a standard light microscope (without phase; Fig. 18.9.1).

It is important to include quiescent cells, which are also growth arrested but do not express SA-β-gal, as negative controls in the assay.

Materials

Cells to be analyzed
1× PBS (*APPENDIX 2A*)
Fixing solution (see recipe)
Staining solution (see recipe)
Mounting medium
Colorless nail polish

Coverslips, sterile
10-cm-diameter petri dishes
Platform or orbital shaker
Light microscope
Glass microscope slides

1. Seed cells on coverslips (resting in petri dishes) at ∼50% confluence 24 hr before staining. Incubate 24 hr at 37°C.

   Seeding more cells may result in a confluent population and may produce nonspecific staining.

2. Wash cells three times, 2 min each, with 1× PBS at room temperature with gentle agitation on a platform or orbital shaker.

3. Aspirate the last wash solution and add enough room temperature fixing solution so that the cells are submerged.

   For 6-well plates, use 1.5 ml per well; for a 10-cm dish, use at least 6 ml fixing solution.

Contributed by Debdutta Bandyopadhyay, Catherine Gatza, Lawrence A. Donehower, and Estela E. Medrano
Current Protocols in Cell Biology (2005) 18.9.1-18.9.9

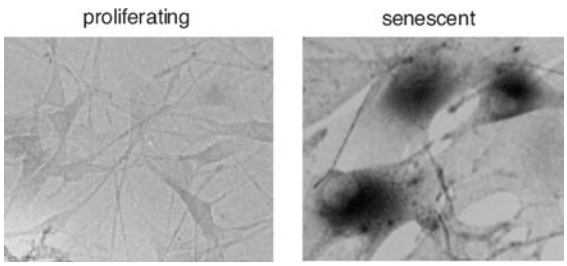

Figure 18.9.1 Senescence-associated β-galactosidase staining in normal human melanocytes (as performed in Basic Protocol). Senescent cells exhibit strong perinuclear activity. Note the enlarged, flat morphology of the senescent melanocytes compared with the much smaller, spindle-shaped morphology of the proliferating melanocytes. Similar morphological changes are also observed in other senescent cell types. This black and white facsimile of the figure is intended only as a placeholder; for full-color version of figure go to *http://www.interscience.wiley.com/c_p/colorfigures.htm*

4. Incubate cells 5 min at room temperature with gentle agitation on a platform of orbital shaker.

   Incubation time should be determined uniquely for each cell type. Time course of fixation and integrity of cellular structure may be monitored using a microscope.

5. Aspirate fixing solution and immediately add room temperature 1× PBS.

   The volume of 1× PBS added should be at least two times that of the fixing solution.

6. Aspirate PBS, and then add just enough staining solution to cover cells completely.

   The same volume of staining solution may be used as for the fixing solution in step 3.

7. Incubate petri dishes containing coverslips in a 37°C incubator.

   The petri dishes should be placed in a 37°C incubator without carbon dioxide circulation. The presence of CO_2 will alter the pH of the staining solution, and nonspecific staining will result. Petri dishes should be incubated with lids closed to prevent evaporation. In addition, care should be taken to ensure that the plates are not tilted and the staining solution covers the whole area of the dish.

8. Using a light microscope, check for the development of a blue color in senescent cells. As soon as such coloration is detected, aspirate the staining solution and wash cells three times with distilled water.

   Time required for blue coloration to develop depends on cell type. Wait 2 to 4 hr after adding the staining solution before monitoring. Color development usually is complete after 16 hr. Some nonspecific staining, which is caused by loss of the buffering capacity of the staining solution, may be observed after a long staining incubation.

   Compare experimental sample with a negative control to detect color development. A proliferating cell population and/or a quiescent cell population may serve as good controls.

   After >8 hr of incubation, some salt crystals may be observed. These crystals can be removed by repeated washing with water.

9. Rinse coverslips briefly by dipping into distilled water and then mount upside down on glass microscope slides using any mounting solution. Aspirate excess mounting solution from the edge of the coverslip, and then seal coverslip to the slide with colorless nail polish.

   Coverslips protected in this way are stable for months at 4°C.

10. Visualize slides using light microscopy using direct light transmission.

ASSESSMENT OF CELLULAR SENESCENCE IN MURINE TISSUE USING THE SENESCENCE-ASSOCIATED β-GALACTOSIDASE ASSAY

ALTERNATE PROTOCOL

Historically, the identification of senescent cells in situ has been difficult, since many of the assays used to identify senescent cells in culture are not amenable to use in vivo. However, the discovery that senescent cells exhibit β-galactosidase activity at pH 6, whereas nonsenescent cells do not, has allowed the identification of senescent cells in human cell lines and tissues. Since this discovery, the same principle has been applied successfully in mouse and rat cell lines. Slight modifications in the protocol used to assay such cell lines also allow the successful identification of senescent cells in murine tissues.

The following protocol describes the identification of senescent cells in murine liver, spleen, and kidney tissue using the SA-β-gal assay. With some optimization of staining times, it is likely that this assay could be adapted for use in other tissue types. For use in this assay, tissue must be frozen in optimum cutting temperature (OCT) compound and sectioned using a cryotome (ThermoShandon). Immediately after cutting, sections are fixed and stained with a SA-β-gal staining solution and then counterstained with hematoxylin to identify the nucleus. The SA-β-gal-stained slide is then viewed under light microscopy, and the average number of senescent cells (i.e., those that exhibit perinuclear blue staining) is counted over a number of microscope fields. To determine the average number of total cells per field, a parallel slide is stained with hematoxylin and eosin and then viewed under light microscopy. The percentage of senescent cells is determined by dividing the average number of SA-β-gal-positive cells by the average number of total cells and multiplying the result by 100.

Additional Materials *(also see Basic Protocol)*

Tissue of interest (e.g., liver, spleen, kidney)
Optimum cutting temperature (OCT) compound
Liquid nitrogen
0.5% (v/v) glutaraldehyde (see recipe)
Senescence-associated β-galactosidase stain (see recipe)
Hematoxylin (Sigma) Mounting medium
Eosin (Sigma)

Cryomold
Standard cryotome (Thermo Electron Anatomical Pathology or equivalent)
Positively charged glass slides (e.g., VWR)
Humidity chamber: plastic box with lid
Pap pen
Coplin jars

Prepare tissue sections

1. Harvest tissue of interest from animal.
2. Cover the bottom of the cryomold with OCT compound. Place the tissue sample in the cryomold and cover completely with OCT compound. Allow OCT and tissue to freeze gradually in liquid nitrogen vapor. Store frozen tissue at −80°C until use.

   Gradual freezing of the tissue sample in OCT compound prevents tissue damage and the formation of air bubbles.

3. Using a cryotome, cut 4-μm (spleen and kidney) or 6-μm sections (liver), depending on tissue of interest. Mount sections on positively charged glass slides to increase tissue adhesion. Keep sections on dry ice until fixed.

   Cut multiple sections from each sample to ensure that good-quality sections, which are important for optimum staining, are obtained. Sections that are of poor quality (i.e., ripped, torn, or folded) can under- or overstain.

4. Immediately after cutting the sections, fix them by covering with 300 μl of 0.5% glutaraldehyde and incubating 15 min at room temperature. Rinse the sections with 1× PBS. To prevent sections from drying out, keep in 1× PBS until the staining solution is added.

   It is important to fix and stain the sections immediately after cutting. A loss of senescence-associated β-galactosidase staining activity can occur if sections are stored after cutting.

Stain for SA-β-gal-positive cells

5. Prepare a humidity chamber by placing wet paper towels in the bottom of a plastic box and closing the lid. Warm to 37°C.

6. Remove excess PBS from around the tissue section using a Kimwipe. Do not allow the tissue to dry out. Use a Pap pen to outline the tissue section, and cover with 300 μl fresh SA-β-gal stain. Place the slides in the humidity chamber and incubate at 37°C for up to 18 hr.

   For optimum staining, it is important to prepare the SA-β-gal stain immediately before use. The optimum staining time is 10 hr for liver tissue and 6 hr for spleen and kidney tissue. Optimum staining times can be determined for other tissue types.

7. After staining, rinse away the SA-β-gal stain with 1× PBS.

8. Counterstain the sections by immersing for 30 sec in a Coplin jar containing hematoxylin and then rinse with 1× PBS. Incubate the sections 2 min at room temperature in fresh 1× PBS in a Coplin jar. Use a Kimwipe to wipe away excess PBS and any remaining Pap pen markings.

9. Coverslip sections with mounting medium and dry slides overnight at room temperature in the dark.

10. Using a standard light microscope, count the SA-β-gal-positive cells in a number of different microscope fields, and use the results to calculate the average number of positive cells per field.

    This calculation will determine the average number of SA-β-gal-positive cells in a given tissue sample. Senescent cells will show strong perinuclear blue staining (see Fig. 18.9.2A), whereas nonsenescent cells will not.

Stain for total number of cells

11. Cut and fix sections for hematoxylin and eosin staining as previously described in steps 1 to 4.

12. Immerse the fixed sections in a Coplin jar containing hematoxylin for 30 sec at room temperature. Rinse with 1× PBS. Incubate in fresh 1× PBS for 2 min at room temperature.

13. Immerse sections in a Coplin jar containing eosin for 35 sec at room temperature. Rinse with distilled water. Remove excess distilled water and any remaining Pap pen markings with a Kimwipe. Do not allow sections to dry out.

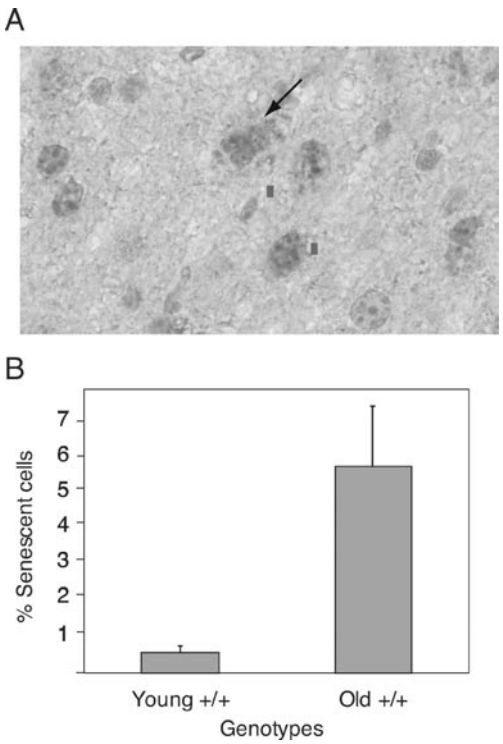

Figure 18.9.2 (**A**) Senescence-associated β-galactosidase staining in murine liver (performed as in Alternate Protocol). Senescent cells exhibit blue perinuclear staining (arrow) upon exposure to Xgal at pH 6.0, whereas nonsenescent cells do not. Nuclei are stained with hematoxylin. (**B**) Analysis of senescence in young (3-month-old) and old (21-month-old) wild-type murine liver tissue. 6-μm sections of young and old liver were treated with the senescence-associated β-galactosidase stain as described in the Alternate Protocol. Sections were observed under light microscopy to determine the percentage of senescent cells present. Levels of senescence were elevated in old wild-type liver compared with young wild-type liver ($n = 4$ for both sample sets). This black and white facsimile of the figure is intended only as a placeholder; for full-color version of figure go to *http://www.interscience.wiley.com/c_p/colorfigures.htm*

14. Coverslip sections with mounting medium and dry slides overnight at room temperature.

    Optimal hematoxylin and eosin staining times vary according to tissue type and strength of reagents and can be determined empirically.

15. Using a standard light microscope, count all cells in a number of different microscope fields, and use the results to calculate the average number of cells per field.

    This calculation will determine the average total number of cells in a given tissue sample.

Calculate percentage of senescent cells

16. Divide the average number of SA-β-gal-positive cells per field by the average total number of cells per field and multiply the result by 100.

    This calculation yields the percentage of senescent cells in a given tissue sample. This value can be graphed and compared with values for other samples (see Fig. 18.9.2B).

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Citric acid, 40 mM/sodium phosphate solution

Prepare 0.1 M citric acid by dissolving 2.1 g citric acid monohydrate in 100 ml water. Prepare 0.2 M dibasic sodium phosphate solution by dissolving 2.84 g Na_2HPO_4 in 100 ml water. Mix 36.85 ml of 0.1 M citric acid with 63.15 ml of 0.2 M dibasic sodium phosphate. Verify that pH is 6.0. Adjust pH to 6.0 with 0.1 M citric acid if necessary. Store at room temperature in the dark.

Fixing solution

1× PBS (APPENDIX 2A) containing:
2% (v/v) formaldehyde (commercially available formaldehyde is usually 37% v/v)
0.2% (v/v) glutaraldehyde (commercially available glutaraldehyde is usually 25% v/v)
Prepare fresh before each use

Glutaraldehyde, 0.5% (v/v)

200 µl 25% (v/v) glutaraldehyde
9.8 ml 1× PBS (*APPENDIX 2A*)
Prepare fresh before each use

Senescence-associated β-galactosidase (SA-β-gal) stain

40 mM citric acid/sodium phosphate, pH 6.0 (see recipe) containing:
1 mg/ml Xgal (add from 20 mg/ml stock in dimethylformamide [DMF]; store up to several months at −20°C in the dark)
5 mM potassium ferricyanide
5 mM potassium ferrocyanide
150 mM NaCl
2 mM $MgCl_2$
Prepare fresh before each use
Prepare long-term stocks of all of the above solutions (except for Xgal; see above) and store at room temperature in the dark
The pH of the citric acid/sodium phosphate solution in this stain is critical to the assay.

Staining solution

1 ml of 1 mg/ml Xgal (5-bromo-4-chloro-3-indolyl-β-galactopyranoside) in DMF
4 ml of citric acid/sodium phosphate solution (see recipe)
1 ml of 100 mM potassium ferrocyanide
1 ml of 100 mM potassium ferricyanide
0.6 ml of 5 M NaCl (*APPENDIX 2A*)
40 µl of 1 M $MgCl_2$ (*APPENDIX 2A*)
Make up to 20 ml with distilled H_2O
Prepare fresh before each use

COMMENTARY

Background Information

Replicative senescence, originally described by Leonard Hayflick almost four decades ago (Hayflick, 1965), is defined as the irreversible loss of the proliferative capacity of cells with maintenance of the metabolic functions necessary for cell survival. Cellular senescence can be induced by a variety of cellular stimuli, including shortened telomeres, DNA damage, oncogene expression, mitogenic signals, and chromatin disruption (Campisi, 2003). In response to these cellular stresses, the induction of cellular senescence may prevent neoplastic transformation by permanently arresting cell growth. Several tumor suppressors, including p53, $p16^{INK4A}$, p21, and Rb, have been shown to regulate the induction of cellular senescence (Bringold and Serrano, 2000).

Senescent cells permanently arrest in G_1 and do not enter S phase in response to mitogenic signals. Despite this permanent arrest, senescent cells remain metabolically active, and some cell types have been shown to be resistant to apoptosis during senescence. Due to their inability to proliferate and their resistance to apoptosis, it is thought that senescent cells can accumulate in vivo with age. An accumulation of senescent cells over time may contribute to aging phenotypes and pathologies such as loss of proliferative and tissue regenerative activity. The majority of evidence suggesting that senescent cells may accumulate in vivo comes from in vitro studies; however, the use of the senescence-associated β-galactosidase assay provides the investigator with a powerful tool for the examination of senescence levels in vivo.

Almost all cells express a lysosomal β-galactosidase that is optimally active at pH 4. Dimri et al. (1995) first reported that senescent cells express β-galactosidase, detectable by cytochemical staining with Xgal, at a pH of 6.0. Importantly, this senescence-associated β-galactosidase activity was not simply present in cultured human fibroblasts but was specific to senescent cells, as no staining was observed in quiescent or terminally differentiated cells. By examining human skin samples from donors of different ages, Dimri et al. (1995) were able to demonstrate an age-dependent increase in levels of SA-β-gal staining. (There are increases in lysosomal β-gal protein levels and lysosomal size that are thought to lead to the detection of β-gal at a suboptimum pH in senescent cells; to date, no other genes have been implicated in this phenomenon.) The results of this study suggested that SA-β-gal staining could serve as an in vivo marker of senescence.

More recently, it has been demonstrated that SA-β-gal activity can also be used to identify senescent cells in a variety of human, nonhuman primate, mouse, and chicken cell lines (Price et al., 2002; Paradis et al., 2001; Kim et al., 2002; Choi et al., 2000; Mishima et al., 1999). The SA-β-gal assay has also been used successfully to identify senescent cells in murine embryonic fibroblasts (MEFs) as well as whole murine embryos (Kim et al., 2002; Cao et al., 2003). In addition, a slight modification in the protocol has allowed the assay to be adapted for use in murine tissue. As a result, senescent cells can be identified in situ, and increased levels of senescence can be confirmed in mouse tissue sections without the creation of MEFs. This capability may prove to be important, as the standard method of culturing MEFs has recently been found to increase the accumulation of mutations (Busuttil et al., 2003).

Confirming increased levels of senescence in tissue can be difficult; most work on the identification of senescent markers has been performed in vitro. One potential approach to assaying senescence in tissue samples involves immunoblotting for various inducers of senescence. It is known that in vitro, levels of p53, $p21^{Waf-1}$, and $p16^{INK4a}$ are increased during senescence (Bringold and Serrano, 2000). By assessing tissue levels of these markers, one can also confirm an increase in the number of senescent cells within the tissue as a whole.

Critical Parameters and Troubleshooting

There are several critical parameters to consider when performing the SA-β-gal assay in tissue. Preparation of the tissue prior to the experiment is very important. Slowly freezing the tissue in OCT compound helps stabilize the tissue during cutting and also prevents cracking and bubble formation in samples. Good sections are critical for optimum staining in this assay. Sections that are ripped, torn, or folded will not stain properly. Preparation of good-quality sections can take practice, but the acquisition of several sections per sample will assure that some high-quality slides are available.

Once high-quality sections have been obtained, it is very important that sections be fixed and stained immediately after cutting.

Sections that are cut and then stored at −80°C for any length of time, even overnight, have been observed to exhibit decreased levels of SA-β-gal staining.

The SA-β-gal assay is based on the observation that senescent cells stain with Xgal at pH 6.0 and nonsenescent cells do not. Therefore, it is critical that the pH of the citric acid/sodium phosphate solution be 6.0. Nonsenescent cells stain with Xgal within a pH range of 4.0 to 4.5. Thus, alterations in the pH of the staining solution could lead to nonspecific staining. For optimum staining, it is also crucial to prepare fresh SA-β-gal staining solution before each use. In addition, for maximum activity, the Xgal used in the solution should be fairly new. All long-term stock solutions used to prepare the SA-β-gal staining solution should be stored away from light, as this appears to result in optimal activity.

By assessing staining at various time points, optimum staining times for each tissue type can be determined. Kidney, liver, and spleen tissues do not exhibit higher levels of staining with longer staining times. SA-β-gal staining is typically dark blue and localized to the perinuclear area. High levels of background staining are often observed in clusters around rips, tears, or folds in poor-quality sections. Background staining can appear as a diffuse, light-to-dark blue coloring throughout the section, and resectioning and restaining should be performed when high levels of such staining are encountered. Some tissues (particularly those obtained from young animals) show very low levels of senescence. Increasing the number of fields counted in these tissues allows quantification of the data and ensures accuracy.

Anticipated Results

The SA-β-gal staining assay is a good technique for analyzing levels of senescence in situ. Figures 18.9.1 and 18.9.2A show typical SA-β-gal staining in cultured melanocytes and liver sections, respectively. SA-β-gal staining is seen as a dark blue perinuclear coloring. Counterstaining cells with hematoxylin allows for easier detection of SA-β-gal staining by giving nuclei a contrasting purple color. Background levels of blue staining are expected to be relatively low, and senescence-associated staining should be fairly distinct. SA-β-gal staining is seen primarily in adult hepatocytes in liver and in both red and white pulp in spleen. Kidneys show staining primarily in cortical areas, with significantly lower levels observed in the medulla.

Typical results are presented in Figure 18.9.2B, in which percent senescence is compared between young and old wild-type liver tissues. Levels of senescence will vary with tissue type, but wild-type mice generally show low levels at a young age and higher levels with increasing age.

Time Considerations

The entire SA-β-gal staining assay can be completed in 2 days. Once tissue has been harvested and frozen in OCT compound, it can be stored at −80°C until use. Sections must be cut and stained on the same day, but tissue can be stained overnight (up to 18 hr) as an alternative stopping point. Typically, 45 min is required to take samples from the PBS wash to the point at which the stain is added. Staining times vary with tissue type. Spleen and kidney tissue require 6 hr to stain optimally, while liver requires 10 hr. Optimum staining times can be determined empirically for other tissue types. The time it takes to count positive cells will vary according to the level of senescence, according to the individual performing the counting, and according to the number of samples to be evaluated. However, it should be possible to easily complete counting on the second day of the experiment.

ABSTRACT

Apoptosis is important for embryonic development, tissue homeostasis, and removal of cells with (potentially transforming) DNA lesions or other types of injuries. Functional genomics screens performed to unravel apoptotic signaling cascades in the context of toxicant-induced cell injury commonly use apoptosis as an end-point. Here, a method to detect the accumulation of apoptotic cells in real time that is well suited for high-throughput screens is described. The method uses automated microscopy in a 96-well format setting to visualize binding of fluorescent annexin V to the outer membrane leaflet of apoptotic cells. The automated image acquisition is followed by quantitative analysis using bioinformatics software. A protocol for each of the steps in this kinetic method is described, which includes the caspase-dependent apoptotic response to toxic compounds in multiple cell types and demonstrates that RNAi-based gene silencing of candidate apoptotic regulators affects the apoptosis kinetics as expected. This protocol will be useful for functional genomics as well as chemical (drug) screens. *Curr. Protoc. Cell Biol.* 47:18.10.1-18.10.13.

Keywords: apoptosis • image analysis • annexin V • cell death • microscopy

INTRODUCTION

Apoptosis is a complex and tightly regulated process also known as programmed cell death (Elmore, 2007). It is important for tissue formation during development and for tissue homeostasis in adults. It plays a key role in the removal of inflammatory cells, wound healing, and elimination of cells that contain DNA lesions that cannot be repaired and that could potentially lead to malignancies. Deregulation of signal transduction cascades in control of apoptosis can lead to pathologies, including developmental defects, autoimmune diseases, neurodegeneration, early aging, or cancer.

The method described here makes use of recombinant annexin V (Hanshaw and Smith, 2005) to detect phosphatidylserines that have translocated to the outer leaflet of the membrane in apoptotic cells. By coupling annexin V to a fluorescence dye, apoptosis can be detected in living cells using real-time fluorescence microscopy and quantified using image analysis software.

This unit describes a high-throughput method for detecting apoptosis in drug-treated cells (see Basic Protocol). Support protocols describe production of fluorescently labeled recombinant annexin V to use as a probe (see Support Protocol 1) and quantification of image analysis (see Support Protocol 2)

HIGH-THROUGHPUT ANALYSIS OF APOPTOSIS

BASIC PROTOCOL

This protocol is used to detect apoptosis in vitro in real time using high-throughput fluorescence microscopy. It makes use of recombinant fluorescently labeled annexin V, which binds to phosphatidylserines that accumulate in the outer leaflet of the plasma

Current Protocols in Cell Biology 18.10.1-18.10.13, June 2010
Published online June 2010 in Wiley Interscience (www.interscience.wiley.com).
DOI: 10.1002/0471143030.cb1810s47

membrane of apoptotic cells. The protocol describes how to prepare cultures of adherent cells in multi-well imaging plates, how to optimize annexin V concentration and exposure times, how to perform drug exposure studies, and how to perform real time imaging for kinetic analysis of the accumulation of apoptosis.

NOTE: All reagents and equipment coming into contact with living cells must be sterile and aseptic techniques should be used accordingly.

NOTE: All incubations should be performed in a humidified 37°C, 5% CO_2 incubator unless otherwise specified.

NOTE: For high-throughput purposes automated liquid handling robotics can be applied to these steps.

Materials

Cells
0.1% (w/v) gelatin in water
1 mg/ml bovine plasma fibronectin solution (Sigma)
Phosphate buffered saline (PBS; *APPENDIX 2A*)
0.05% (w/v) trypsin/EDTA
Pre-warmed culture medium
0.4% trypan blue in PBS
Labeled annexin V (0.5 mg/ml stock concentration; see Support Protocol 1)
Toxicant
Drugs to be tested
100 mM z-VAD-fmk stock solution (Bachem)

96- or 24-well plates, e.g., CELLSTAR SensoPlate or CELLSTAR μClear plates (Greiner)
Hemacytometer
Inverted fluorescence microscope system with automated stage, automated focus control, and temperature- and CO_2-controlled incubation system

Prepare cell cultures

1. Split cells 48 hr before the drug exposure (step 19) to reach a subconfluent culture.

   This protocol is applicable to a variety of cell lines as well as embryonic stem (ES) cells. Standard culture conditions for these cell types are used.

Coat multi-well plate(s)

2. Prepare a solution of 0.1% (w/v) gelatin in water or prepare a solution of 5 μg/ml bovine plasma fibronectin in PBS.

3. Add 100 μl protein solution per well in a 96-well plate or 350 μl/well in a 24-well plate.

   The multi-well plates used in this protocol must be suitable for cell culture as well as for high-quality image acquisition. For this purpose, CELLSTAR SensoPlate glass bottom or CELLSTAR μClear bottom plates (both from Greiner) can be used. Both types have optically clear bases bonded onto a black polystyrene frame that minimizes light cross-talk between wells.

   For glass-bottom plates and, to a lesser extent, for plastic-bottom plates, coating with adhesive substrates will optimize the formation of a healthy monolayer of cells.

4. Incubate for at least 1 hr at room temperature.

5. Remove the solution by aspiration 10 min before adding the cell suspensions (step 10).

6. Add PBS (100 µl per well in a 96-well plate or 500 µl/well in a 24-well plate) and remove by aspiration (plates are now ready to add the cell suspension). Take care not to let the plates dry out.

Prepare cells for drug exposure

7. Before (24 hr) the drug exposure, aspirate medium from the cell culture, wash once with PBS, and add 1 ml of (25-cm^2 flask) 0.05% trypsin/EDTA to detach cells.

8. Resuspend the cells gently in 4 ml (for 25-cm^2 flask) medium.

9. Remove a small sample, mix with trypan blue, and count cells on a hemacytometer (*UNIT 1.1*).

10. Plate cells in desired cell density in the coated multi-well plate(s).

    A good starting density is 1×10^4 cells per well in a 96-well plate and 1×10^5 cells per well in a 24-well plate.

    For ES cells, it is essential that this procedure is performed fast and gently and that cells are seeded at 75% confluency to maintain background cell death at a minimum.

    For high-throughput purposes, automated liquid handling robotics can be applied to these steps.

Titrate labeled annexin V and optimize exposure time for image acquisition

11. Seed cells for titration 24 hr prior to the experiment in the desired format as indicated above.

    At least 16 wells are needed for this titration experiment.

12. From the 0.5 mg/ml stock of annexin V, prepare a series of dilutions of labeled annexin V in culture medium, e.g., 1:10000, 1:5000, 1:1000, 1:500, 1:200, 1:100, and 1:50, and prepare a control tube without annexin V.

    A volume of 200 µl is needed for a 96-well plate and 700 µl is needed for a 24-well plate.

13. Divide each dilution into two tubes, and add a toxicant of choice to one of the tubes at a concentration that is expected to induce massive apoptosis in the cell type used.

    Some examples of toxicants are cisplatin (cis-diamminedichloroplatinum(II), CDDP), doxorubicin (hydroxydaunorubicin), vincristine (leurocristine), thapsigargin, hydrogen peroxide (H_2O_2), and tamoxifen.

14. Add the control (annexin V only) and toxicant-containing medium (100 µl for 96-well plates and 500 µl for 24-well plates) to the cells and follow the accumulation of fluorescence until the majority of cells exposed to toxicant have become positive.

15. Acquire images using a range of exposure times and choose the time that allows detection of fluorescent cells while maintaining a black background.

    Overexposure of the detectors would cause saturation and underestimation of the accumulation of apoptosis. The optimal exposure time must be determined in advance for a given microscope system and fluorophore. This is especially important given that fluorescence is typically expected to be absent at the start of any experiment. Optimization is done by exposing cells to a high concentration of toxicant that is expected to induce massive apoptosis in the presence of a high concentration of labeled annexin V (typically 0.05 mg/ml) to ensure a maximal signal.

16. Acquire fluorescence images every hour using the exposure time determined in step 15.

17. Determine the optimal annexin V concentration for the experimental conditions.

    The optimal annexin V concentration is that where fluorescence in the absence of toxicant is minimal while fluorescence in the presence of toxicant is maximal. For most cell types, efficient non-toxic labeling is reached using 5 μg/ml labeled annexin V.

Perform drug exposure studies

18. Generate a concentration range of the desired test drug in culture medium.

    Prepare sufficient amounts of the dilutions to test their effect in triplicate wells.

    For cisplatin, a typical range is 0.5 to 50 μM.

19. Based on the results obtained in the titrations, add the volume of labeled annexin V to achieve the optimal concentration to each tube.

20. Wash the multi-well plate with cells seeded 24 hr earlier, and that are ready to be exposed, once with warm PBS (100 μl/well for a 96-well plate; 500 μl/well for a 24-well plate).

    This will remove any floating, dead cells that would otherwise cause background signal.

21. Add 100 μl (96-well plate) or 500 μl (24-well plate) per well of fresh, warm medium containing the desired drug concentration and labeled annexin V.

    Cell death measured by this method may include cells dying through non-apoptotic pathways including necrosis. To exclude this, proper controls are needed. A recommended control consists of a duplicate for each test condition in which the general caspase-inhibitor z-VAD-fmk is added at a final concentration of 100 μM (see Fig. 18.10.1).

    For a combined detection of apoptosis and necrosis, incubation with propidium iodide can be incorporated into the procedure to detect necrotic (leaky) cells. However, this requires an additional exposure step, whereby enhancing the risk of phototoxicity.

22. Place the multi-well plate into the temperature- and CO_2-controlled imaging environment.

Acquire real-time image

23. Define at least four fields of interest for each well.

    When using a 10× objective, four fields allow a near complete coverage of a well in a 96-well plate.

24. Collect a fluorescence image (8-bit, gray-scale) for each field of interest, for each well, and for each time-point. Name the files "well01xy01time01C01.tif; well01xy02time01C01.tif; etc.", where C01 is the annexin V fluorescence channel. Use the exposure time determined by the concentration of annexin V, the fluorophore used, and the microscope system, as determined in the titration experiment (steps 15 and 16).

25. (Optional) Obtain a DIC (differential interference contrast; see Fig. 18.10.1) or phase contrast image (depending on the microscope system used) at the same time to correlate accumulation of apoptotic cells to total cell numbers. Name these files "well01xy01time01C02.tif; well01xy02time01C02.tif; etc.", where C02 is the DIC or the second fluorescence channel.

    As an alternative, cells may be engineered to express any variant of GFP that can be detected separately from the annexin V fluorophore. In this case, obtain a second, distinct fluorescence image at the same time to correlate accumulation of apoptotic cells to total cell numbers.

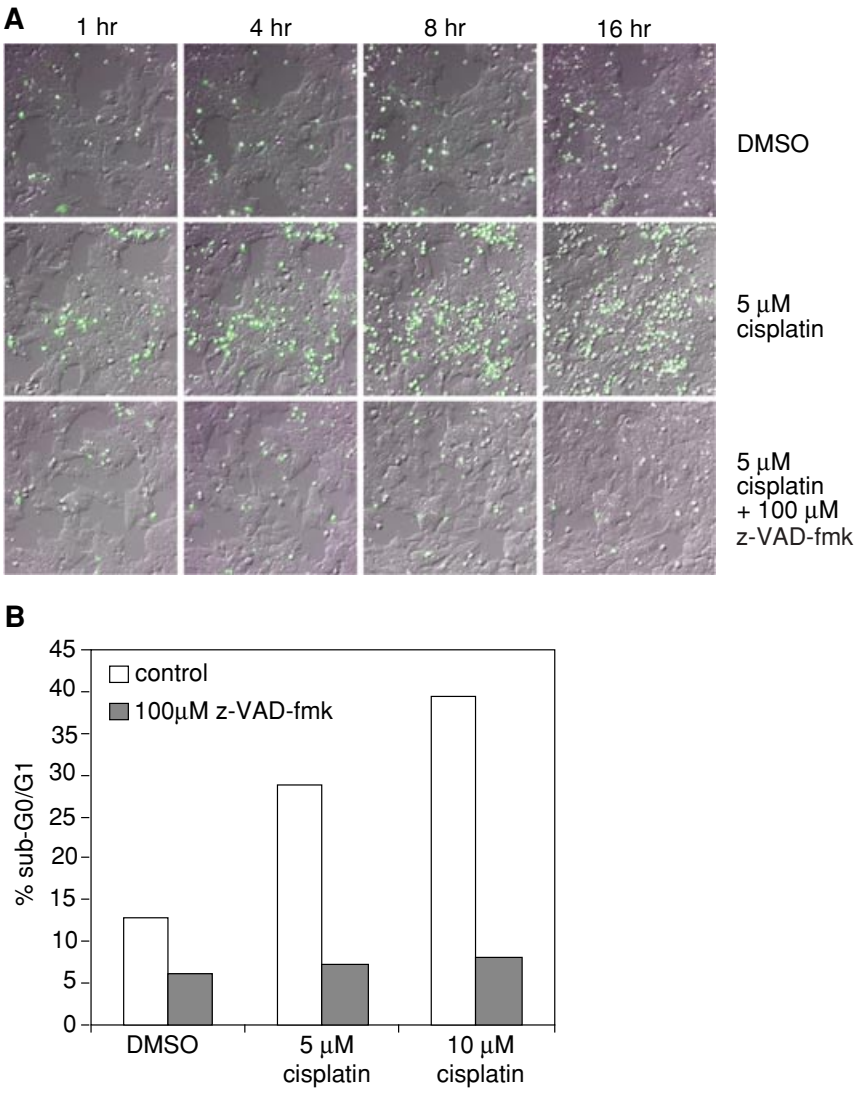

Figure 18.10.1 Accumulation of annexin V-FITC positive cells induced by cisplatin exposure. (**A**) Mouse ES cells were exposed to 5 μM cisplatin, annexin V-FITC. DIC and fluorescent images were taken during 16 hr. Over time, apoptotic cells accumulated in cisplatin, but not DMSO (control)-treated cells. In the presence of the pan-caspase inhibitor z-VAD-fmk signal accumulation was prevented, indicating that cells die by caspase-mediated apoptosis. (**B**) Comparison of this method with an alternative FACS-based assay gives similar results. Mouse ES cells were exposed to 5 μM and 10 μM of cisplatin in the presence or absence of the pan-caspase inhibitor z-VAD-fmk. Propidium iodide was added to determine the percent of sub-G0/G1 fraction by flow cytometry.

26. Acquire images of the fields of interest (step 23) every 30 min, for 16 to 48 hr depending on the cell type/toxicant combination.

    For instance, apoptosis develops in ES cells treated with 5 μM Cisplatin within 12 hr, whereas, U2OS cells treated with higher concentrations of Cisplatin require 24 to 48 hr (see Fig. 18.10.2).

    To perform automated analysis of apoptosis using this methodology, several robotic and microscopy units can be applied: (1) automated liquid handling for cell seeding and exposure to toxicants; (2) automated microscopy for real-time image acquisition; (3) combination of automated liquid handling and image acquisition (such as BD Pathway 855 from Becton Dickinson).

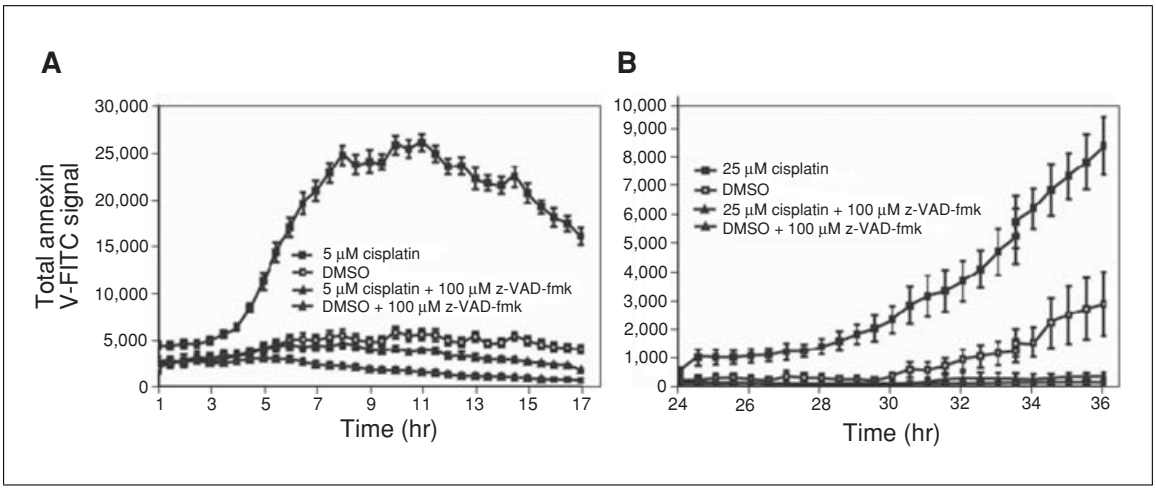

Figure 18.10.2 Increase of cisplatin-induced apoptosis in mouse ES cells and human U2OS cells detected by accumulation of annexin V-FITC positive cells. Mouse ES cells (**A**) and human osteosarcoma cells (U2OS; **B**) were exposed to the indicated concentrations of cisplatin in the presence or absence of z-VAD-fmk. Note that despite the much higher cisplatin concentration used for U2OS, the onset of apoptosis takes longer (time frame starts at 24 hr post-exposure for U2OS).

SUPPORT PROTOCOL 1

PREPARATION OF FLUORESCENTLY LABELED ANNEXIN V

Recombinant annexin V is isolated from a bacterial lysate and fluorescently labeled to use as a probe for apoptosis.

Materials

Bacteria: *E. coli* BL21-pLysS transformed with a pET/annexin V expression vector (available from Erik H.J. Danen; e.danen@lacdr.leidenuniv.nl)
LB medium containing 25 μg/ml chloramphenicol and 50 μg/ml kanamycin
IPTG
Spheroblast buffer (SBB; see recipe)
10 mg/ml lysozyme in SBB
Ultracentrifugation working solution (UCB; see recipe)
Bovine brain extract (Sigma)
1:2 (v/v) chloroform/methanol
Argon source
Diethyl ether
Liposome buffer (see recipe)
300 mM $CaCl_2$
Buffer 1: liposome buffer (see recipe) plus 5 mM $CaCl_2$
Buffer 2: liposome buffer (see recipe) plus 10 mM EDTA
Buffer 3: 20 mM bis-Tris, pH 6/0.02% (w/v) sodium azide
DEAE-Sepharose fast-flow column (~14 × 150–mm)
500 mM NaCl
Alexa fluor 488 protein labeling kit (Molecular Probes)

37°C incubator
250-ml Erlenmeyer flasks
Spectrophotometer
500-ml centrifuge tubes
Refrigerated centrifuge
50-ml plastic tubes
30-ml ultracentrifugation tubes
Refrigerated ultracentrifuge

250-ml glass beakers
10-kDa dialysis membranes

Additional reagents and equipment for SDS PAGE gel electrophoresis (*UNIT 6.1*) and Coomassie staining (*UNIT 6.6*)

Produce recombinant annexin V

1. Prepare an overnight culture of *E. coli* BL21-pLysS transformed with a pET/annexin V expression vector in 100 ml of LB medium containing 25 μg/ml chloramphenicol and 50 μg/ml kanamycin in a 250-ml Erlenmeyer flask at 37°C with shaking.
2. Dilute the culture 1:20 by adding 50 ml of overnight culture to 950 ml of fresh LB containing 25 μg/ml chloramphenicol and 50 μg/ml kanamycin.
3. Grow (~2 hr) at 37°C to $OD_{600} = 0.5$.
4. Add IPTG to 0.4 mM final concentration.
5. Incubate 4 hr at 37°C.

Produce crude extract containing recombinant annexin V

6. Split the culture in 500-ml centrifuge tubes and centrifuge 15 min at 5000 × g, 4°C.
7. Resuspend each bacterial pellet 25 ml SBB.
8. To each tube, add 2.5 ml of 10 mg/ml lysozyme stock in SBB (final concentration 1 mg/ml) and mix gently.
9. To each tube, add 192.5 ml of diluted SBB (1:1 in water) and mix gently.
10. Incubate 30 min on ice to allow spheroblast formation.
11. Centrifuge 30 min at 14,000 ×g, 4°C, to remove soluble components.
12. Resuspend and combine the four pellets in a total volume of 100 ml UCB working solution to open spheroblasts by osmotic shock.
13. Split into 25-ml aliquots in six 30-ml ultracentrifuge tubes.
14. Centrifuge overnight at 100,000 × g, 4°C, to remove large membrane parts.
15. Collect and combine the supernatants containing annexin V in a crude extract and store up to 2 years at −80°C.

Purify recombinant annexin V using bovine brain extract

16. Dissolve 500 mg of bovine brain extract in 6 ml of 2:1 chloroform/methanol in a 50-ml flask and dry under argon for 30 min.
17. Add 2.5 ml diethyl ether to the brain extract, mix, and dry under argon.
18. Dissolve in 20 ml liposome buffer.
19. Thaw the bacterial supernatant (which contains the annexin V in a crude extract) from step 16 slowly on ice.
20. In a 250-ml glass beaker on ice, mix the supernatant (100 ml) with the brain extract (20 ml) from step 20.
21. Add 300 mM $CaCl_2$ to a final concentration of 5 mM to bind the annexin V.
22. Stir for 30 min on ice.
23. Transfer to six 30-ml ultracentrifuge tubes and centrifuge 45 min at 40,000 × g, 4°C.
24. Resuspend the pellet in 40 ml of buffer 1.

25. Centrifuge 30 min at 50,000 × g, 4°C.
26. Resuspend the pellet in 20 ml of buffer 2.
27. Remove the liposomes by centrifuging 60 min at 50,000 × g, 4°C.
28. Collect the supernatant and dialyze overnight using a 10-kDa dialysis membrane at 4°C against 2 liters of buffer 3.

    Annexin V is ~30 kDa.

29. If a precipitate forms during dialysis, centrifuge 30 min at 20,000 × g, 4°C and collect the supernatant.

Column purify annexin V

30. Pre-rinse a DEAE-Sepharose fast-flow column (~14 × 150–mm) with 200 ml of buffer 3.
31. Add the annexin V-containing solution to the column.
32. Elute the annexin V protein with a linear NaCl gradient (0 to 500 mM; 1 ml/min).
33. Collect 4-ml samples.

    Annexin V elutes at 80 to 90 mM NaCl.

34. Run 4 µl of the 60 to 110 mM NaCl fractions on a 10% SDS PAGE gel (*UNIT 6.1*) to detect the 32-kDa annexin V protein by Coomassie staining (*UNIT 6.6*).
35. Combine fractions containing annexin V and store 1-ml aliquots up to 2 years at −80°C.

    The aliquots obtained will contain ~2 mg/ml of annexin V.

Fluorescently label purified annexin V

36. Fluorescently label annexin V (one aliquot at a time) with the Alexa fluor 488 protein labeling kit following the manufacturer's instructions.

    Protein labeling reagents are commercially available from multiple sources. The authors have successfully used the Alexa Fluor 488 kit from Molecular Probes but the choice of fluorophore is amendable. For use in combination with GFP for instance, Cy3 or Alexa 633 can be used. For labeling methodologies, refer to the methods included in such labeling kits.

    As an alternative, fluorescently labeled annexin V can be obtained from a number of suppliers (e.g., Immuno Tools, BD Biosciences). However, this protocol yields high amounts of pure fluorescently labeled annexin V at a cost that the authors have calculated to be ~20 times lower than that available from most commercial sources.

37. After labeling, adjust the concentration as desired (e.g., 0.5 mg/ml) and prepare small aliquots (e.g., 50-µl) store aliquots up to 2 years at −80°C.

    Subsequent protocols are based on a stock concentration of 0.5 mg/ml labeled annexin V.

SUPPORT PROTOCOL 2

QUANTITATIVE IMAGE ANALYSIS

The following steps describe the macro that is used to extract quantitative information on the accumulation of annexin V–positive cells over time. The macro has been designed by using Image Pro Plus from Media Cybernetics. This macro is available for download from *http://www.toxicologyleiden.nl*. This protocol describes an overview of the macro indicating the different steps that can be easily programmed into a comparable macro based on other image analysis software packages (see Fig. 18.10.3). In this particular macro, the DIC channel is used to determine cell numbers. If a second fluorescence marker is used for this purpose, then the macro can be adapted.

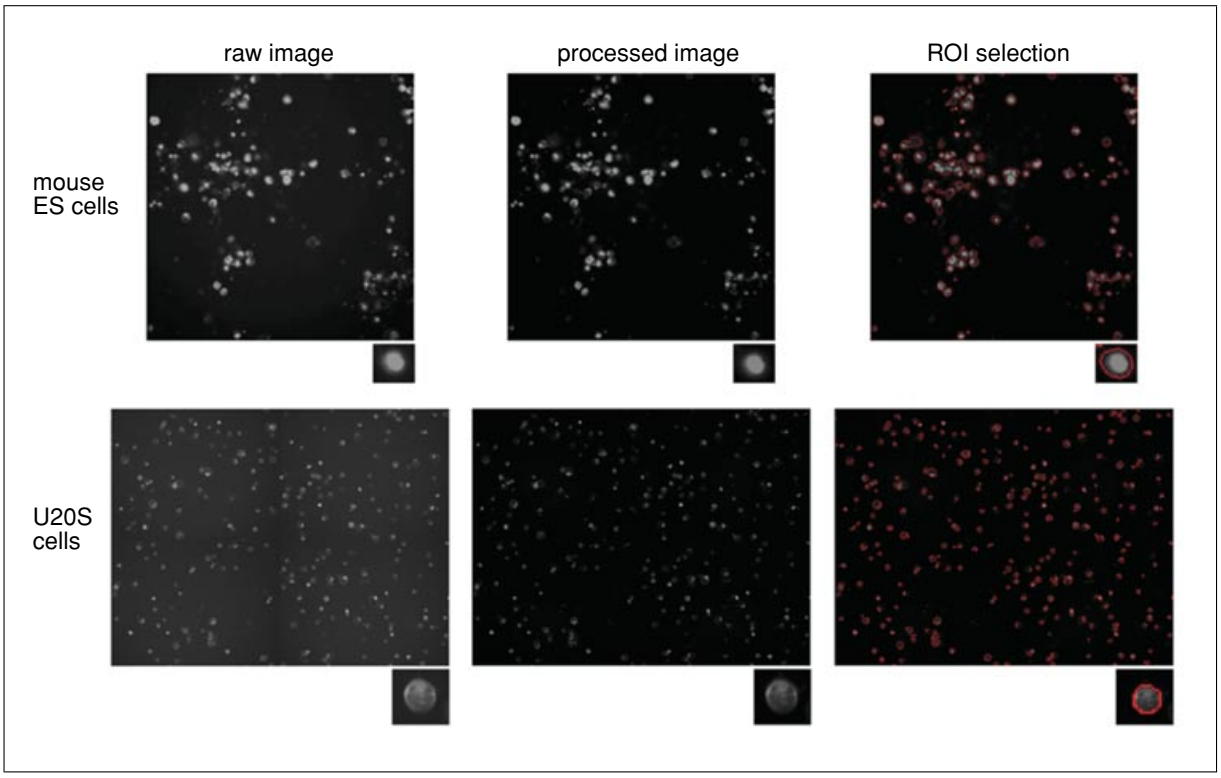

Figure 18.10.3 The accumulation of annexin V-FITC at the outer leaflet of the cell membrane is imaged and quantified. Three consecutive images are presented: a raw image corresponding to image directly acquired; a processed image that corresponds to the image after being adjusted to enhance the fluorescence label and reduce background noise; and finally the ROI selection image after the threshold is determined and the regions of interest are delineating the cells. The upper panel corresponds to mouse ES cells images acquired with a Nikon inverted fluorescent microscope, whereas the lower panel corresponds to U2OS cells images acquired with a BD Pathway 855 imager. Comparison of these data means that diverse types of image acquisition systems can be used to generate images that can be finally analyzed and quantified making use of the method presented in this unit. For the color version of this figure go to *http://www.currentprotocols.com/protocol/cb1810*.

Materials

Computer with tif images
Image Pro Plus software (Media Cybernetics; *http://www.toxicologyleiden.nl*)
Spreadsheet software (Excel)

Convert image from tif to avi

1. Convert the 8-bit, grayscale .tif image files created by the image acquisition software to uncompressed .avi files to generate time-lapse movies for each field of interest (using, for instance, Image J). Name these files "well01xy01C01.avi; well01xy01C02.avi; well01xy02C01.avi; well01xy02C02.avi; \ldots etc.", where C1 represents the annexin V fluorescence channel and C2 represents the DIC channel.

Start macro

2. Run macro in Image Pro Plus and open folder with .avi files.

   If, in addition to the annexin V fluorescence, DIC has been recorded to analyze total cell number, two .avi files are present for each field of interest for each time point. The macro sorts these file names alphabetically.

3. Select file "well01xy01C01.avi" and start Excel.

Define annexin V fluorescence intensity threshold

4. In the well01xy01C01.avi file, move to the image representing a time-point containing fluorescent cells.

5. Click Threshold button to open histogram model.
6. Move threshold ruler until fluorescent cells are red and background is black.

   Defining a threshold that is too low would result in overestimation of apoptosis while a threshold that is too high would cause underestimation of the number of apoptotic cells.

Define cell size in fluorescence and DIC channel

7. To exclude particles smaller than cells from the analysis, manually define the area of a cell in both channels. In well01xy01C01.avi and well01xy01C02.avi files, manually draw a region of interest (ROI) defining the area of a single cell (note that for the C01 file, a time-point is chosen where fluorescence has accumulated). To do this, click the button on the right side of "min" in the "area" window.

   If the area representing a single cell is already known from earlier experiments, this value can be introduced directly into the "area" window.

   It is advised to check the cell area also at the latter time-points as it may change during the experiment due to swelling or shrinking in response to toxicants. In such cases, draw a ROI representing the area of a single cell at later time-points and enter by clicking the button at the right side of "max" in the "area" window. The macro interpolates the values for the time-points in between the first and last.

   It is possible to obtain data without correcting for cell size. In this case, enter the value "1" in the "min" and "max" position.

Adjust DIC Edge filter settings for definition of cell-covered area

8. If using DIC to determine cell numbers, set background correction for DIC images.
9. In well01xy01C02.avi file, identify the total area covered with cells.

   The "Edge filter" extracts and enhances positive edges that are bright features on a dark background and is used here to optimize differentiation between plate surface and cells.

10. Select "high, medium, or low" settings for the [Width, Height, Strength, Passes] options of the "Edge filter" and run the macro followed by visual inspection.

    This must be done by trial and error and is determined by the DIC image acquisition settings. However, for a high-quality microscope system, once determined, the Edge filter settings can be applied to the entire experiment.

Run macro for fluorescence images

11. Click "calculate folder" to run the macro for all "well.xy.C01.avi" files (the annexin V fluorescence files). The macro will proceed with the following steps:

    a. Load file.
    b. Apply Edge Filter. Set values at: width: 4001; height: 4001; strength: 1; passes: 1.
    c. Select first frame.
    d. Set options to fill holes in segmentation.
    e. Segment picture with intensity threshold.
    f. Apply area range filter to avoid artifacts such as noise from particles smaller than the cells.
    g. Determine the sum of all segmented pixels (= total annexin V fluorescence).
    h. Divide total segmented pixels by the cell area (= number of positive cells).

       If the value "1" was entered in for the cell area, the total accumulation of annexin V signal is determined instead of the number of positive cells.

    i. Write result to Excel.
    j. Checks if 'Shift+S' key (signal to abort) is pressed. If 'Shift+S' is not pressed, the Macro will continue to the next .avi file.

Run macro for DIC images

12. If DIC files are present, run the macro for all "well.xy.C02.avi" files. The macro will go proceed with the following steps:

    a. Load file.
    b. Apply flatten background filter to reduce uneven illumination. Values will be set at: BrightOnDark: 1; ObjectSize: 20.
    c. Apply Edge Filter.
    d. Select first frame.
    e. Set options to NOT fill holes in segmentation.
    f. Segment picture with intensity threshold; this value will be automatically adjusted using the mean value of the Histogram Model.
    g. Apply area range filter, to avoid artifacts such as noise from particles smaller than the cells.
    h. Determine the sum of all segmented pixels (= total cell covered area).
    i. Divide total segmented pixels by the cell area (= number of cells; if the value 1 was entered in step h, number of cells is not determined).
    j. Write result to Excel.
    k. At this step the macro will check if 'Shift+S' key is pressed to stop the process. If 'Shift+S' is not pressed, the Macro will continue.

Calculate number of apoptotic cells

13. In Excel, divide the number of annexin V–positive cells obtained from the fluorescence files (step 11) by the total number of cells obtained from the DIC files (step 12) and multiply by 100 to obtain the percent of apoptotic cells.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Liposome buffer

20 mM Tris·Cl, pH 8 (*APPENDIX 2A*)
3 mM $MgCl_2$
100 mM NaCl
Store up to 3 days at 2° to 8°C

Spheroblast buffer (SBB)

0.5 mM EDTA
750 mM sucrose
200 mM Tris·Cl, pH 8.0 (*APPENDIX 2A*)
Store up to 3 days at 2° to 8°C

Ultracentrifugation buffer (UCB) stock solution

2 mM EDTA
5 mM $MgCl_2$
100 mM NaCl
20 mM Tris·Cl, pH 8.0 (*APPENDIX 2A*)
0.1% (w/v) Triton X-100
Store up to 3 days at 2° to 8°C

continued

UCB working solution
To 100 ml UCB stock solution, add:
2 mM PMSF (2 ml of 100 mM stock in ethanol)
0.5 μg/ml pepstatin A (50 μl of 1 mg/ml stock in DMSO)
0.1 mg/ml RNaseA (1 ml of 10 mg/ml stock in TE)
10 U/ml benzonase (40 μl of 25 U/μl stock in TE)
Store up to 1 day at 2° to 8°C

COMMENTARY

Background Information

There are two main pathways that can drive apoptosis: the extrinsic or death receptor pathway, and the intrinsic or mitochondrial pathway. An additional third pathway is named the perforin/granzyme route, and it involves T cell–mediated, perforin-granzyme-dependent, cytotoxicity. The three pathways converge in the same final execution pathway, which is initiated by the activation of executioner caspases such as caspase-3. Caspases are expressed in an inactive proenzyme form and, once activated, proteolytically cleave their substrates. These substrates also include other procaspases, thus initiating an irreversible amplification cascade.

Typical characteristics of apoptotic cells include extensive protein cross-linking through the expression and activation of tissue transglutaminase, DNA fragmentation by Ca^{2+}- and Mg^{2+}-dependent endonucleases and caspase-activated DNase, cell shrinkage, nuclear fragmentation, plasma membrane blebbing, and ultimately, cell fragmentation into apoptotic bodies, which are destined to be eliminated by phagocytosis.

A number of methods are currently available for the detection of apoptotic cells. These include detection of the typical profile of DNA laddering in cell lysates, TUNEL labeling, immunodetection of cleaved caspase-3, and flow cytometric analysis of DNA content to detect the sub-G0/G1 fraction using DAPI or propidium iodide in fixed cells. Since these methods require fixation or lysis of cells, they are by definition fixed endpoint methods. Although the response to apoptotic stimuli can be analyzed at several time-points, it would be preferable to detect the accumulation of apoptotic cells in real time to obtain kinetic information on the process of apoptosis. For this purpose, fluorescent probes are now commercially available for real-time imaging of caspase-3 activation.

In healthy cells, phosphatidylserines preferentially localize in the inner membrane leaflet due to the action of the aminophospholipid translocase that moves aminophospholipids from the outer to the inner leaflet. Endogenous annexin V proteins associate with the inner leaflet of the plasma membrane by binding to these phosphatidylserines (Gerke and Moss, 2002). In apoptotic cells, aminophospholipid translocase is inactivated while a scramblase, which catalyzes the randomization of phospholipids across the membrane bilayer, is activated. As a result, phosphatidylserines become exposed on the outer surface of apoptotic cells (Martin et al., 1995). Together with the expression of ligands for phagocytic cell receptors, this forms a signal for elimination by phagocytic cells. The method described in this unit makes use of recombinant, fluorescently labeled annexin V to detect apoptotic cells on the basis of accumulated phosphatidylserines on the outer surface of the plasma membrane.

Critical Parameters

The optimal concentration of labeled annexin V depends on the cell type used. For sensitive cell types, such as ES cells, excessive amounts of annexin V may be toxic. In addition, too low annexin V concentrations may require excessive exposure-times during image acquisition, which may cause phototoxicity and, hence, disturb the experiment. Therefore, a titration is required.

Overexposure of the detectors would cause saturation and underestimation of the accumulation of apoptosis. The optimal exposure time must be determined in advance for a given microscope system and fluorophore. This is especially important given that fluorescence is typically expected to be absent at the start of any experiment. Optimization is done by exposing cells to a high concentration of toxicant that is expected to induce massive apoptosis in the presence of a high concentration of labeled annexin V (typically 0.05 mg/ml) to ensure a maximal signal.

Anticipated Results

The authors' findings indicate that this method can be used for analysis of multiple

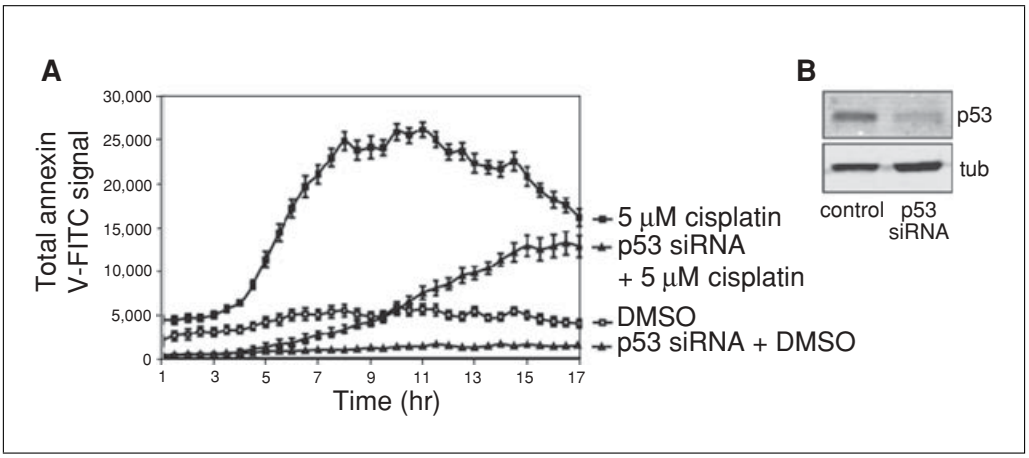

Figure 18.10.4 Cisplatin-induced apoptosis is inhibited by silencing p53. (**A**) Mouse ES cells were exposed to cisplatin in the presence or absence of a siRNA smartpool (Dharmacon; 50 nM) silencing the tumor suppressor gene p53. Silencing p53 in this cell type resulted in a strong delay of apoptosis. (**B**) p53 knock down efficiency is shown by western blot using p53 antibody or tubulin (tub) loading control antibody.

cell types, including ES cells and cancer cells, which undergo dose- and time-dependent apoptosis when exposed to a DNA-damaging drug such as cisplatin. Signal accumulation can be prevented using a pan-caspase inhibitor, z-VAD-fmk, indicating that it specifically depicts apoptosis. In addition, silencing the tumor suppressor gene p53 results in a delay of the apoptotic process as expected. Thus, the high-throughput live cell imaging method described in this unit provides kinetic information about the apoptotic process. Apoptosis is of special interest to toxicity studies. This particular analysis method can be performed for screening purposes to determine time- and dose-dependent responses to compounds and to investigate interactions between drugs, with special emphasis on the kinetics of the process. Moreover, RNA interference focused on understanding the apoptotic process can be very well approached with this methodology (see Fig. 18.10.4).

In vitro studies are often performed on different types of cell lines and using various compounds to induce apoptosis. It must be noted that due to the different characteristics of the chosen cell/drug combinations, responses are expected to display highly diverse kinetics. Obviously, exposure or pre-exposure periods to certain drugs in different cell types must be adjusted experimentally before moving toward larger scale screens (see Fig. 18.10.2).

Time Considerations

After the optimization phase (see Basic Protocol, steps 11 to 17), a complete single experiment will take ~24 hr. It should be mentioned here that automation is required for the multi-point imaging in multi-well plates (see Basic Protocol, steps 23 to 26). In addition to this, automation will greatly speed up the process of treating cells with concentration ranges of multiple drugs. Finally, for siRNA experiments, robotics will be required to efficiently move from analysis of small gene sets to larger screening efforts.

CHAPTER 19
Whole Organism and Tissue Analysis

INTRODUCTION

The ultimate test of cell biological principles is in the intact organism. Ideally, concepts and conclusions based on in vitro biochemistry, molecular biology, or tissue culture studies should be validated in vivo in intact tissues and organisms. In addition, some studies can be performed only in living animals or plants. There are innumerable examples of conclusions from in vitro studies that have needed major qualification after analysis in vivo. One common class involves substantially altered conclusions about the necessity of a specific protein after testing whether it is essential by gene knockout analysis. Others include changing concepts about gene regulatory pathways in development and about the mechanisms and inhibitors of malignancy. An obvious reason is that organisms have complex microenvironmental, regulatory, and system-redundancy properties that are not mimicked adequately in vitro.

This chapter will provide detailed protocols for studies in whole organisms and tissues. Although experimental analyses in intact systems could theoretically span all of biology, the focus will be on current techniques particularly relevant to cell biology. The study of cancer metastasis shows the particular value, but also the many pitfalls, of analyzing the cell biology of this complex type of process in animals. In *UNIT 19.1*, members of a leading laboratory in the field (Paweletz, Charboneau, and Liotta) provide an insightful and thought-provoking overview of metastasis assays. The unit starts with a review of key cell biological principles and concludes with discussions of what constitutes a "good" animal model and some state-of-the-art approaches. As discussed in detail in the overview presented in *UNIT 19.1*, metastasis involves a plethora of cell biological steps. Relevant processes include angiogenesis, cell adhesion, cell motility and invasion, and local proteolysis, each of which will need understanding both in vitro and in the context of the living organism.

UNIT 19.2 by Elkin and Vlodavsky then provides practical details, focusing on the most frequently used approach, the analysis of metastasis by tail vein assay. This approach, often termed "experimental metastasis," involves injecting single-cell suspensions of cells into the tail vein of mice or rats. The cells lodge particularly effectively in lungs, where they form tumor colonies that can be quantitated. This procedure permits analyses of the steps of metastasis that occur during and after the extravasation of tumor cells from blood vessels into target organs. It has been used widely, and should continue to provide valuable insight into the mechanisms of metastasis and a system for testing candidate anti-metastatic drugs. An alternative to using adult rodents is the use of chick embryos for analyzing metastasis. Procedures for handling chick embryos are described in *UNIT 19.5*.

UNITS 19.3 & 19.4 provide complementary approaches to solving the difficult problem of how to obtain reliable quantitative determinations of gene expression with very small quantities of material. For example, tiny pieces of embryonic tissue or even laser-microdissected sites from histological sections are often the optimal sources of material for analyzing gene expression patterns in a specific part of a tissue from an intact organism. However, standard RT-PCR approaches for amplifying low quantities of nucleic acids from these sources can introduce distortions in gene expression data resulting from preferential

amplification of some transcripts and sequence errors introduced by *Taq* DNA polymerase. *UNIT 19.3* by Sakai, Larsen, and Yamada provides a procedure for analyzing ultra-micro amounts of sample, such as from laser-microdissected bits of tissue cut out of frozen sections, using high-fidelity T7-based RNA amplification. It also provides a detailed protocol for the Serial Analysis of Gene Expression (SAGE) procedure based on published protocols, which can provide digital quantification of gene expression. If larger (though still relatively tiny) amounts of sample are available, e.g., 1 to 2 μg of RNA, risks of amplification can be avoided by using the procedures described in *UNIT 19.4* by Cai, Ash, and Jabs, followed by SAGE analysis. In both cases, SAGE provides an approach that can identify novel genes that are not yet present in DNA microarrays and quantify expression levels for the full spectrum of genes expressed in each tissue.

Assays for angiogenesis in vivo are important for verifying predictions from in vitro angiogenesis models and for studying this complex process in the intact organism. The simplest in vivo angiogenesis model is the chick chorioallantoic membrane (CAM) assay. In *UNIT 19.5*, Ponce and Kleinman describe the advantages, caveats, and detailed protocols for this assay, which can be performed in virtually any laboratory without the need for an animal facility.

Although tumor metastasis is most frequently studied in mouse model systems, an attractive alternative is described in *UNIT 19.6* by Wilson and Chambers. The chick embryo provides an inexpensive and convenient system that has the added advantage of being immune-deficient and thus useful for analyzing tumor cells from any species including human without concerns about immunological compatibility. Besides methods for experimental metastasis assays using chick embryos, a protocol is provided for live-cell in vivo video microscopy. This procedure for real-time microscopy analysis of the thin, readily visualized chick embryo chorioallantoic membrane permits direct visualization of specific steps of metastasis as the injected tumor cells interact with host vasculature and invade tissues. New approaches now permit detailed characterizations of tumor cell invasion in vitro. In *UNIT 19.7*, Kedrin, Segall and colleagues provide detailed protocols for studying the real-time dynamics of migrating and invading cancer cells in rodent models. The authors describe their methods for dual-color imaging of invading tumor cells in living animals using GFP and CFP simultaneously, microscopy and image analysis, and additional supporting protocols.

The biogenesis of complex three-dimensional tissues, e.g., organogenesis and branching morphogenesis, can now be characterized and experimentally analyzed using serum-free organ culture. *UNIT 19.8* provides protocols for culturing several embryonic mouse organs. In that unit, Sakai and Onodera describe stepwise procedures and provide video demonstrations for dissecting mouse embryos to isolate specific organs. They then describe conditions for three-dimensional organ culture.

Experimental studies of the biology and pathology of human skin are now possible in vitro using three-dimensional models termed human skin equivalents. *UNIT 19.9* from Garlick and coauthors provides detailed protocols for establishing three-dimensional human skin models by combining epidermal cells with dermal fibroblasts grown in a collagen matrix. These models closely mimic normal human skin, and they can be used to study growth, differentiation, wound repair, and cancer of human skin.

Transgenic and knockout mouse technologies have revolutionized the study of normal in vivo physiology and biochemistry–as well as disease processes–by allowing genetic manipulation to over-express or ablate specific genes. A series of five units in this chapter from members of a facility specializing in gene targeting spans the spectrum of techniques for genetic modification of the mouse. *UNIT 19.10* by Haruyama, Cho, and Kulkarni provides a general overview of the process of producing appropriate DNA constructs

and engineering transgenic mice. It reviews principles and techniques for producing transgenic mice over-expressing a particular gene, as well as emerging techniques and typical problems that might be encountered. *UNIT 19.11* by Cho, Haruyama, and Kulkarni then provides highly detailed protocols for generating transgenic mice using pronuclear injection. A variety of methods and tips are provided that should provide the practical knowledge important for efficient production of transgenic mice.

The opposite approach to transgenic over-expression of a gene for determining function is to generate gene knockout mice using targeted homologous recombination. In *UNIT 19.12*, Hall, Limaye, and Kulkarni provide an overview of the principles of this process that uses electroporation of a custom DNA targeting construct into totipotent mouse embryonic stem cells to allow homologous recombination. *UNIT 19.13* by Limaye, Hall, and Kulkarni provides in-depth protocols for maintaining, transfecting, and selecting mutated pluripotent embryonic stem cells. Cells with successful gene knockout must then be injected into blastocyst embryos and implanted into pseudopregnant mice as described by Longenecker and Kulkarni in *UNIT 19.14*. The detailed techniques, practical advice, and troubleshooting information provided by these experts should facilitate the successful production of knockout mice.

Kenneth M. Yamada

Overview of Metastasis Assays

Cancer treatment and diagnosis usually begins at a late stage when most patients already have acquired occult or overt metastasis adding significantly to the diminishing success rates for localized surgery and cytotoxic approaches (Astrow, 1994). Consequently, metastatic dissemination is responsible for the majority of treatment failures and deaths.

During tumor progression, cells acquire genetic and proteomic changes as they transform from normal to hyperplastic, through dysplasia, to carcinoma in situ, and finally to invasive and metastatic. The time course of progression may extend as far back as 10 years prior to diagnosis (Fig. 19.1.1). Discerning the mechanism whereby tumor cells execute metastatic dissemination may provide the foundation necessary for successful treatment of the disease. For example, direct genetic evidence has linked in situ breast cancer to invasive carcinoma of the breast (Zhuang et al., 1995) supporting the generally accepted assumption that carcinoma in situ of the breast is a clonal expansion of hyperproliferating cells (Gallager and Martin, 1969; Spratt et al., 1986). This in turn may provide a more comprehensive and/or functionally directed target strategy for intervention and prevention of breast cancer.

Cancer metastasis is a highly complex process that involves the deregulation of interacting proteins and genes that are responsible for invasion, angiogenesis, circulation of tumor cells in blood vessels, colonization at secondary organ sites, and finally evasion of host defense systems (Fig. 19.1.2). Invasion can, furthermore, be subdivided into cellular adhesion, local proteolysis, and motility. While all cohorts mentioned above are necessary for successful metastasis, none alone is sufficient to cause metastasis.

Angiogenesis

The critical turning point in tumor progression is the initiation of local invasion and neovascularization leading to metastasis. Neovascularization, the formation of new blood vessels, is not only necessary for continuous tumor maintenance by providing adequate nutritional support but is also required for metastasis by providing a mechanism to allow tumor cells to

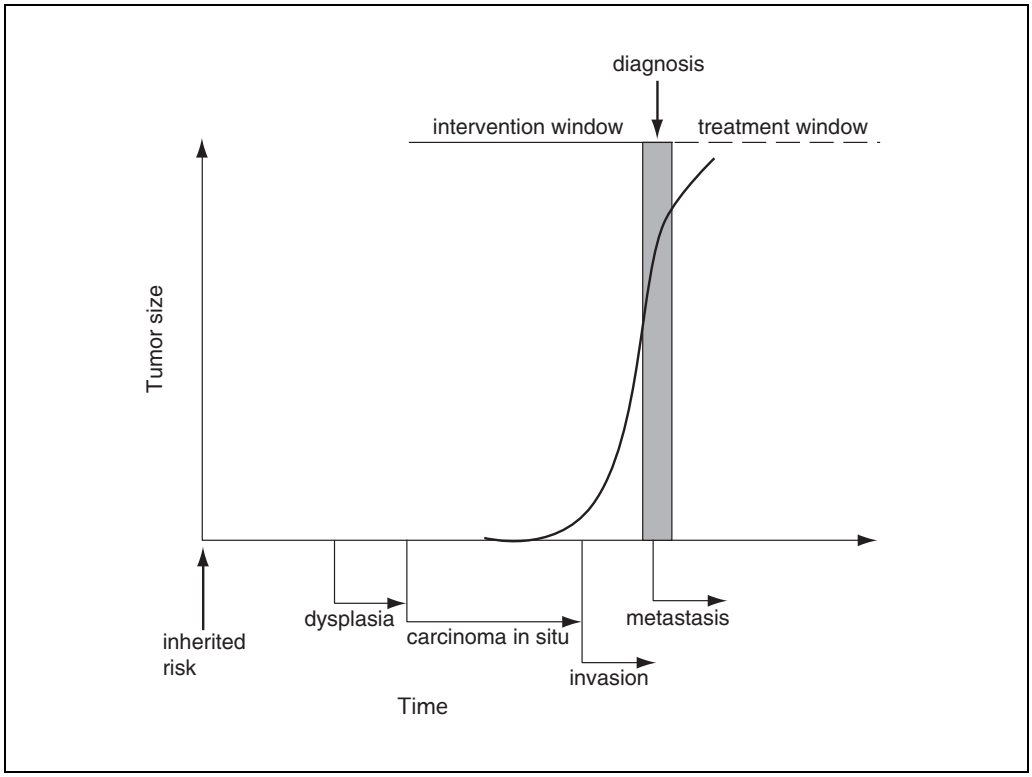

Figure 19.1.1 Theoretical improvement for intervention strategies as a function of time. Diagnosis of cancer usually is performed late into the disease, when most patients already present occult metastasis. However, progression of cancer from dysplasia to metastatic dissemination may extend as far back as 10 years providing a much larger window for intervention strategies before metastasis occurs.

Current Protocols in Cell Biology (2001) 19.1.1-19.1.9

enter the blood circulation. A vascular entry port to dissemination is achieved by induced proliferation of highly permeable capillaries by tumor cells (Dvorak et al., 1995). These local capillaries mainly arise by angiogenic stimuli released by tumor or host cells. However, angiogenesis will cease when the local stimulus is removed. A variety of molecules have been found to mediate angiogenesis in vitro and in vivo. Among these are fibroblast growth factors (bFGF), angiogenin, vascular permeability factor (VPF), and transforming growth factor α and β (TGF-α, TGF-β; Folkman and Klagsbrun, 1987).

Neovascularization is not regulated by a single event but rather consists of tightly regulated molecular events that cause endothelial cells to degrade the basement membranes, proliferate, migrate, and initiate growth of capillaries (Fidler and Ellis, 1994; Folkman, 1995). Angiogenesis occurs in parallel with initiation of invasion. Rapidly growing tumors are capable of shedding up to millions of tumor cells into vascular circulation by angiogenesis and invasion alone (Liotta et al., 1974). Furthermore, experimental studies show that <0.05% of circulating tumor cells are successful in initiation of metastatic colonies making metastatic dissemination a highly inefficient process (Liotta et al., 1974; Nicolson, 1991). These studies are also further validated by the observation that circulating tumor cells are detected in patients who never form a metastasis.

Invasion

Invasion is the active translocation of neoplastic cells across tissue boundaries and through host cellular and extracellular matrix barriers. Cellular adhesion, local proteolysis, and motility characterize successful invasion. While all three cohorts are necessary for successful metastasis, none alone is sufficient enough to cause metastasis. Invasion is not due to growth pressure but involves additional genetic and proteomic deregulation over and above those molecular events that cause uncontrolled proliferation. Instead, cellular invasion is dependent on the coordinated activity of a series of interacting proteins extending from the inside of the cell to the cell surface and the imminent microenvironment.

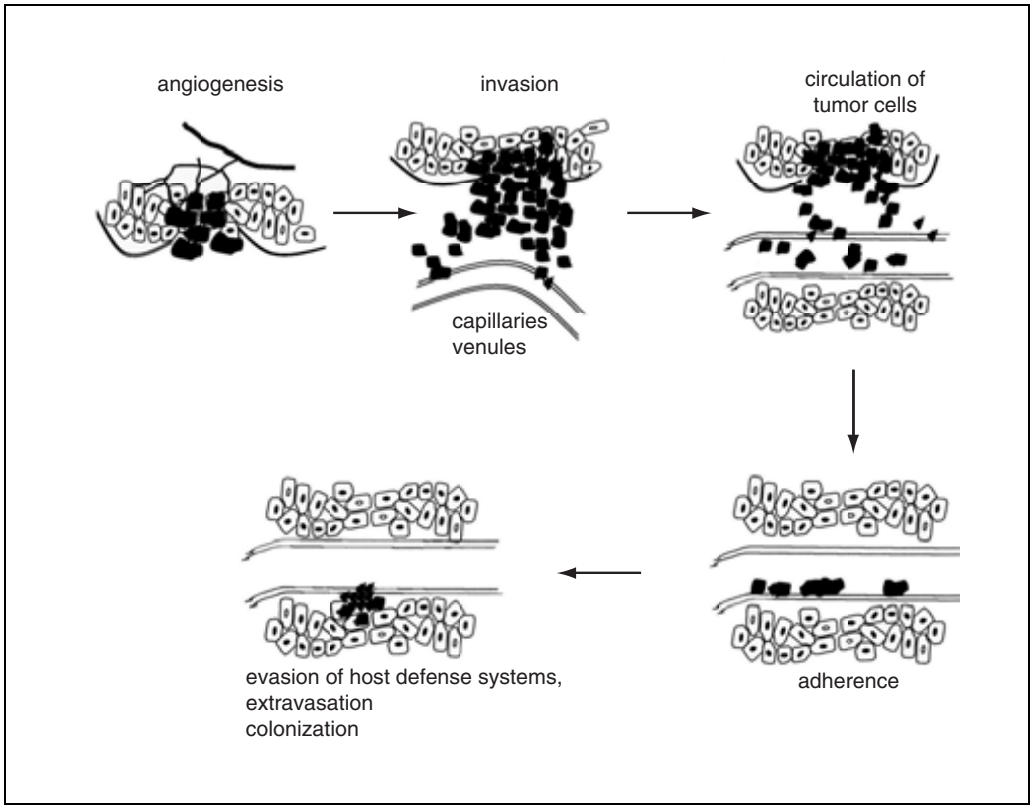

Figure 19.1.2 Pathogenesis of cancer. Cancer metastasis is a highly complex process that involves the deregulation of interacting proteins and genes that are responsible for angiogenesis, invasion, circulation of tumor cells in blood vessels, colonization at secondary organ sites, and finally evasion of host defense systems.

Cellular Adhesion

Maintaining cellular integrity with the extracellular matrix and/or basement membrane involves the rapid ability to respond to extracellular signals at receptors, which in turn affects corresponding intracellular signal transduction pathways that regulate proliferation, differentiation, and migration. These receptors can be membrane surface receptors that become activated by ligands (such as growth factors), or cytosolic/nuclear receptors that transmit hormone signals to regulate gene expression. Among the many types of cell surface receptors several classes have been shown to be predominant during tumorigenesis. These include integrins, cell adhesion molecules (CAMs), and cadherins.

The integrin family of cell surface extracellular matrix proteins consists of heterodimeric units, designated α (140 kDa) and β (95 kDa). An important aspect of this family is that integrins can either exist in an "on" or "off" state, thereby selectively changing its affinity for corresponding ligands, and changing molecular events in doing so (Hynes, 1992; Juliano and Haskill, 1993). Activation of integrins has been shown to be involved in cell migration, cell proliferation, and dissemination. However, loss of stimulus of integrins has been associated with apoptosis. This suggests a diverse switch-on/switch-off function for integrins. Increased expression of integrin receptors on cell surfaces has been associated with an invasive phenotype of melanoma and squamous carcinoma of the head and neck, whereas loss of expression status has been shown in cancers of breast, prostate, and colon (Chammas and Brentani, 1991; Natali et al., 1991).

The cadherins, on the other hand, comprise a family of transmembrane glycoproteins that mediate Ca^{2+}-dependent cell adhesion (Takeichi, 1991). Special intracellular proteins, the catenins, form zipper-like structures to form extracellular cell-cell bonds with the cell cytoplasm. These interactions are regulated by tyrosine phosphorylation as well as additional cell-to-cell communications. Down regulation of epithelial cadherin transcription, E-cadherin, has been shown to cause a more aggressive cancer cell phenotype (Frixen et al., 1991; Vleminckx et al., 1991). For example, transforming Madin-Darbey canine kidney cells (MDCK) by H-*ras* not only diminshed E-cadherin expression but also increased the invasive behavior of these cells. This effect could be reversed by transfecting E-cadherins back into the transformed cells (Behrens et al., 1989; Mareel et al., 1991; Vleminckx et al., 1991). Furthermore, overexpression of E-cadherin in highly invasive tumor types (i.e., bladder, breast, lung, and pancreas) showed loss of invasiveness in their respective transformed cell line.

Cellular adhesion receptors (CAMs) have also been studied in the context of cancer invasion. These include but are not limited to: intercellular adhesion molecules (ICAMs), L-, E-, and P-selectins, vascular cell adhesion molecules (VCAM), neural cell adhesion molecules (NCAM), and neuroglial cell adhesion molecules (NG-CAM). These adhesion receptors provide the necessary framework for the interaction of tumor cells with the microenvironment forming a vital part of cancer invasion and metastasis. Unlike other receptors that bind proteins, selectins bind carbohydrate ligands on endothelial cells. While adhesion alone may not be sufficient for metastasis, disregulation of any of the surface receptors above may alter signaling pathways responsible for positive and negative feedback controls and may therefore result in a more aggressive invasive phenotype.

Local Proteolysis

A positive correlation between tumor aggressiveness and protease levels has been documented (Liotta et al., 1980). Not only are proteases upregulated in tumor cells, and protease inhibitors down regulated, but zymogens are also activated into active protease enzymes. Local proteolysis by itself is not a sole metastatic phenomenon, and it is routinely observed in trophoblast implantation, embryo morphogenesis, wound healing, tissue remodeling, and angiogenesis. Local proteolysis is a tightly regulated process in normal tissue by appropriate protease inhibitors. Furthermore it has been indicated that deregulation between the equilibrium of protease to protease inhibitor regulates vascular morphogenesis and invasion (Ura et al., 1989). Metastasis cannot simply be a product of unbridled production of degradation enzymes as cell dissemination and invasion concomitantly are dependent on adhesion and motility. Deregulation of this tightly regulated process causes secretion of proteases by tumor cells that creates local access points across the basement membrane and/or extracellular matrix. This process takes place by coordinations of proteases including serine, aspartyl, cysteinyl, and metalloproteases (Nakajima et al., 1987; Ostrowski et al., 1988; Reich et al., 1988). Sufficient evidence exists that proteases

inside the cell may also be involved during invasion (Koblinski et al., 2000). Invasion is mostly hindered by collagens, which form with laminin, fibronectin, triple helical proteins, and vitronectin, important structural components of the basement membranes and extracellular matrices. Collagen I and III are located in stromal collagens, and collagen IV and V are predominant in the basement membrane. Among the many types of proteases involved in metastasis such as tissue-type plasminogen activator (tPA), plasmin, cathepsin -D, -B, -L, -G, the urokinase plasminogen activator (uPA), metalloproteinases, and the heparanases deserve special mentioning.

Urokinase plasminogen activator, a serine protease, has been shown to correlate with a metastatic phenotype of cells. Antibodies against uPA block human HEP-3 cell invasion and murine B16-F10 melanoma cell metastasis after tail vein injection (Ossowski and Reich, 1983; Esheicher et al., 1989). Alternatively, overexpression of uPA in H-*ras* transformed cell lines enhances lung metastases (Axelrod et al., 1989).

Enzymatic cleavage of collagens, necessary for invasion of tumor cells into the vascular vessel, is mostly carried out by metalloproteinases (MMP). Inhibition of metalloproteinases has been demonstrated to inhibit cell invasion (DeClerck et al., 1991). These inhibitors have also been shown to block metastasis. MMPs can be divided into three general classes: (1) interstitial collagenases; (2) stromelysins; and (3) gelatinases. Interstitial collagenase, degrade types I, II, III, and VII collagens. Stromelysins degrade types I, III, IV, V, IX collagens, laminin, fibronectin, and gelatin. The third group of the MMP family, the gelatinases (MMP-2 and MMP-9), are capable of degrading collagen types I, II, III, IV, V, VII, IX, and X, as well as fibronectin (Emonard and Grimaud, 1990). An important difference between the gelatinases and the other MMPs is that they are capable of interacting with endogeneous tissue inhibitor of metalloproteinases (TIMPs) of which there are two major subgroups, TIMP-1 and TIMP-2. Inhibition of MMP-2 by TIMP-1 has shown to reduce cellular invasion. Involvement of MMP-2 and MMP-9 in invasive phenotypes is abundant. Induction of H-*ras* oncogene enhances expression of MMP-2 and MMP-9. Invasive colonic, gastric, ovarian, and thyroid adenocarcinomas showed positive immunoreactivity for MMP-2, whereas normal colorectal, gastric mucosa, and benign ovarian cysts showed reduced or negative staining (Monteagudo et al., 1990; Levy et al., 1991). A fragile balance between TIMPs and MMPs may act as a postive and negative feedback control regulating vascular morphogenesis and invasion (Mignatti et al., 1989). Additional functions of MMPs besides degradation of tissue boundaries are also ascribed to its involvement in angiogenesis (Chambers and Matrisian, 1997).

Additional major components of tissue barriers to be degraded by proteases besides collagen, fibronectin, and laminin are heparan sulfate proteoglycans (HSPG). Involvement of heparanases, whose function involves the degradation of ubiquitous expressed heparan sulfate glycosaminoglycan side chains, with respect to metastasis has previously been demonstrated (Nakajima et al., 1988; Vlodavsky et al., 1995). Not only did heparin and similar polysaccharides inhibit metastasis (Parish et al., 1987), increased expression of heparanase genes and proteins were also found in tumor cells compared to normal cells (Vlodavsky et al., 1999). Discerning the fundamental mechanism whereby heparanases cause metastatic cell dissemination has become more achievable with the completion of the cloning of the heparanase gene (Hullet et al., 1999; Vlodavsky et al., 1999). In these studies, transfection of nonmetastatic murine T-lymphoma Eb cell lines with full-length human heparanase cDNA enhanced its metastatic phenotype, as shown by increased invasiveness of cells and a higher mortality rate of tumor-injected mice (Vlodavsky et al., 1999).

In the end, the coordination of families of proteases with adhesion molecules and locomotion is required for successful invasion. None alone can cause invasion, and it is likely that many other proteases will be found in the near future.

Motility

Translocation of individual cells across tissue membranes inevitably is a major part of invasion. However, as with local proteolysis and angiogenesis, cell migration is also part of normal cell development such as gastrulation and organogenesis. Diminishing cell adhesion single cell locomotion, and cohort cell translocations, have been reported to be involved in malignancy and metastasis (Liotta and Stetler-Stevenson, 1993; Nabeshima et al., 1999).

Early events in cell motility consist of extensions by pseudopods prior to translocation of the whole cell body (Stossel, 1993). These nuclear-free vessels would have all the neces-

sary requirements to sense and protrude within the three-dimensional structure of the tumor mass leading cell migration away from the primary organ (Condeelis, 1993; You et al., 1996). However, unregulated protease interactions alone cannot ad infinitum translocate the pseudopod, as the vessel would dig itself into a hole and thereby immobilize itself. Adhesion, interaction, and detachment with the ECM are essential parts of locomotion (Liotta et al., 1991; Damsky and Werb, 1992). Proteinases at the tip are vital for the disruption of the ECM, but as the matrix becomes more and more disrupted, the pseudopod must adhere to the matrix and pull the cell forward. At the rear of the pod, detachment from adjacent cells is necessary.

Movement across tissue boundaries is initiated by a chemotactic (directional) mechanism. A variety of chemoattractive compounds, among them certain cytokines (e.g., hepatocyte growth factor), collagen peptides, formyl peptides, or autocrine growth factors (e.g., autotaxin), have been identified to be important in metastasis locomotion (Anzano et al., 1983; Guirguis et al., 1987; Di Renzo et al., 1995; Nam et al., 2000). It needs to be realized, even if there exists a direct tumor host interaction, chemoattractant release to the migrating cell may only be sporadic at best and could not sustain metastatic dissemination. These factors are secreted by surrounding stroma, the tumor cells themselves, or by peptides affiliated with the extracellular matrix. For example, it has been demonstrated that the human melanoma cell line A2058 as well as human breast cell lines stimulate their own motility factors when treated with serum-free medium. Motility, like adhesion and local proteolysis, is necessary for metastasis but cannot alone cause metastasis.

In Vivo Models and Metastasis

Successful metastasis only occurs if positive and negative regulatory mechanisms that govern angiogenesis, proteolysis, motility, evading host defense systems, and cellular adhesion events are concomitantly deregulated. Metastasis is a multifactorial event that includes deregulations above and beyond those found during disturbances of cell proliferation and homeostasis. Ultimately, there exists a need to investigate proteins and genes involved in metastasis and invasion in vivo. While there exists a variety of assays to study any one of those specific characteristics in vitro, such as the modified Boyden chamber assay for the study of motility, transgenic, knock-out, and xenograft animal models are the only accurate tools available to investigate molecular mechanisms responsible for metastasis in an organism (Fidler and Hart, 1982; Guan et al., 2000; Zuber et al., 2000).

Organ trophism varies widely depending on the morphology and anatomic location of primary tumors. Clinical studies indicate that most metastases form micro-colonies in the first capillary bed found by circulating, invasive tumor cells. For example, lung cancer metastasizes predominately to the brain, or colorectal cancers to the liver. However, not all metastatic sites can be predicted by anatomical considerations alone. For example, clear-cell carcinoma of the kidney metastasizes to the bone and thyroid. Animal models that either show preferential organ metastases by purposeful selection or have not undergone purposeful selection have been designed to accompany and simulate these observations (see Table 19.1.1; Nicolson, 1988).

A "good" animal model is based on the following three basic axioms: (1) metastasis is not a random phenomenon; (2) neoplasms are heterogeneous in their cell make up and therefore observe different metastatic outcomes; and (3) the outcome of the metastasis is dependent on both the tumor cell and the host cell interactions (Fidler, 1991).

The human genome project in conjunction with other projects, such as the CGAP initiative of the NCI, is expected to provide a wealth of information of possible tumor (or metastasis) suppressor genes and oncogenes that are recessives and mutated dominants, respectively (Strausberg et al., 1997). However, it is necessary to establish whether these genes are actually involved in metastasis or tumorigenesis in vivo. A logical way is to transfect mutant forms of these candidate genes into a noninvasive cell line of the tumor to be studied, inject these modified cell lines intravenously, and determine the number of lung colonizations. Alternatively, the effects of possible oncogenes toward metastasis can be investigated by knock-out mice lacking certain candidate genes (Granovsky et al., 2000). The oncogene-deficient mice can then be compared to nondeficient mice by counting lung colonies of micro metastases and comparing tumor weight. Substantial decrease in colonies and tumor weight is expected if the gene that is "knocked out" is involved in metastasis.

An excellent example of how transfection of a gene provided valuable insights into metastasis was recently demonstrated by Vlo-

davsky et al. (1999). Initially, there existed sufficient evidence that heparanases may be involved in metastasis, as an increased level of heparanase was found in patient's urine and serum samples (Vlodavsky et al., 1999). However, the gene itself was (1) not cloned; and (2) not expressed in an animal model making accurate presumptions about its function difficult. After successful cloning of the gene, full-length human heparanase cDNA was transfected into nonmetastatic murine T-lymphoma Eb cell lines. Injection of transferred cell lines into DBA/2 mice not only increased the metastatic phenotype as shown by liver colonization but also decreased survival rates of injected mice. However, a word of caution is advised because transfection of genes and subsequent ectopic injections may cause "false-negatives," as it is possible to inject cells in such a way that they do not form metastases even if the cell possesses a real metastatic phenotype (Kerbel et al., 1991).

At present, there does not exist a completely accurate animal model that simulates a specific human histologic tumor type and its complete metastatic behavior. While the positive and negative attributes of animal models can be debated, their positive productive role in dissecting molecular mechanisms for metastasis and treatment cannot be disregarded.

Conclusion

Even though studies on metastasis have traditionally lagged behind other fields in cancer research, substantial progress has been made over the last 10 years. This is partly due to the separation of cancer metastasis into distinct fields such as angiogenesis, invasion, metastatic suppressor genes, and others. For each distinct field, novel technologies and methodologies have provided important insights. However, exciting and emerging technologies such as in vivo microscopy of cell motility (Farina et al., 1998) or proteomics combined with laser capture microdissection (Lawson et

[d]Common animal models used in the study of metastasis.

al., 1991; Emmert-Buck et al., 2000; see *UNIT 2.5*) will provide valuable insights into the field. For example, it is feasible to microdissect patient-matched normal, tumor, and metastatic tissue cells and analyze their corresponding DNA, mRNA, and protein levels, giving a true cellular snapshot. Information acquired through these studies will almost certainly target signal transduction pathways that may provide alternative intervention and prevention strategies much earlier than is possible today.

Tail Vein Assay of Cancer Metastasis

The most damaging change during cancer progression is the switch from a locally growing tumor to a metastatic killer. This switch involves numerous alterations that allow tumor cells to complete the complex series of events needed for metastasis (*UNIT 19.1*). In considering steps required for successful metastasis, extravasation from blood vessels in target organs is regarded as a critical process. Circulating tumor cells arrested in the capillary beds of different organs must invade the endothelial cell lining of blood vessels and degrade its underlying basement membrane in order to escape into the extravascular tissue where they establish metastasis. This unit describes the most common assay applied to evaluate the metastatic potential of blood-borne tumor cells. The protocol is often called "experimental metastasis", distinct from "spontaneous metastasis", where the tumor cells are first allowed to form a primary tumor in the site of injection and then escape into lymphatic or blood circulation. The Basic Protocol is to apply intravenous injection as a method for introducing tumor cells into circulation. For this purpose, cells maintained in tissue culture are dissociated into a single cell suspension, counted, and injected into the tail vein of mice or rats. After 12 to 20 days, the animals are euthanized and their lungs are removed, rinsed, and fixed. The number of pulmonary tumor colonies is then counted with the aid of a dissecting microscope. When an organ containing extensive secondary foci is seen, it is also removed and fixed for subsequent enumeration of tumor foci.

NOTE: All solutions and equipment coming into contact with living cells must be sterile, and aseptic techniques should be used accordingly.

NOTE: All culture incubations should be performed in a humidified 37°C, 7% CO_2 incubator unless otherwise specified. Some media (e.g., DMEM) may require altered levels of CO_2 to maintain a pH 7.4.

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) or must conform to governmental regulations regarding the care and use of laboratory animals.

Materials

Cells of interest growing in tissue culture (e.g., B16 mouse melanoma, ATCC#CRL-1619; 3LL Lewis lung carcinoma; A375 human melanoma, ATCC#CRL-6322; 13762 MAT rat mammary adenocarcinoma)
Supplemented high-glucose DMEM-10 (*UNIT 10.4*)
Trypsin/EDTA solution (*UNIT 10.4*)
CMF-DPBS: divalent cation-free Dulbecco's PBS (CMF-DPBS; Life Technologies; *APPENDIX 2A*)
Mice for injection (or rats)
70% ethanol
3.8% (v/v) formaldehyde
Bouin's solution (see recipe; optional)

6-cm tissue culture dishes
15-ml polypropylene tubes
Sorvall RT6000D centrifuge and H-1000B rotor or equivalent
Beaker containing warm water (~50° to 60°C)
Lamp with 150-W light bulb (optional)
Restraining device (restrainer)
1-ml syringe, tuberculin type
27-G, ¾-in. needles
Dissecting microscope

Contributed by Michael Elkin and Israel Vlodavsky
Current Protocols in Cell Biology (2001) 19.2.1-19.2.7

Additional reagents and equipment for counting cells with hemacytometer (*UNIT 1.1*)

Prepare cells

1. Culture a sufficient number of cells in supplemented high-glucose DMEM-10 in 6-cm tissue culture dishes in a humidified 37°C, 7% CO_2 incubator.

   Other size dishes (i.e., 35-mm, 10-cm) can be used.

2. Aspirate medium from subconfluent cultures (0.5–1 $\times 10^5$ cells/cm^2), add 2 ml trypsin/EDTA solution per 6-cm tissue culture dish, and incubate 2 to 3 min at 37°C, or until the cells have rounded up, but are not detached.

3. Aspirate trypsin/EDTA solution, resuspend cells in 5 ml warm supplemented high-glucose DMEM-10, transfer into a 15-ml polypropylene tube, centrifuge 7 min at ~350 ×*g* (1000 rpm Sorvall RT6000D centrifuge, H-1000B rotor, or equivalent), room temperature, and resuspend in 5 ml warm CMF-DPBS.

   Trypsin/EDTA solution is commonly used to detach adherent cells. Its action is terminated by resuspending the cells in supplemented high-glucose DMEM-10. Prolonged (and unnecessary) trypsinization of tumor cells can alter their survival and metastatic behavior in vivo. Trypsinization >3 min may affect lung colony formation and should be avoided.

   Serum-free DMEM can be used instead of CMF-DPBS.

4. Count cells on a hemacytometer (*UNIT 1.1*), and prepare working cell suspension at 2.5 $\times 10^5$ to 1 $\times 10^6$ cells/ml, depending on the metastatic potential of the cells (e.g., 2.5 $\times 10^5$ B16F10 or A375SM cells/ml; 1 $\times 10^6$ A375 cells/ml).

   It is important to guard against clumping or aggregation of cells. The number of lung colonies is affected not only by the number of tumor cells injected, but also by the aggregation of cells and the tumor embolus size. To avoid clumping of cells, the cell preparations must be free of serum, and cells should be injected in a divalent cation- free balanced salt solution, which also serves to decrease clumping.

   Obviously, the trypsinization step is not applied when nonadherent cells (e.g., mouse Eb T-lymphoma) are tested. Cells growing in suspension are washed in CMF-DPBS, or serum-free medium, counted, and suspended at the desired cell density.

Intravenously inject tumor cells

5. Dilate the lateral tail veins by immersing the tail for 1 to 2 min in warm (50° to 60°C) water.

   The tail vein is dilated to facilitate the insertion of a 26- or 27-G needle. Alternatively, animals housed in a well-ventilated cage are placed for ~5 min under a lamp with a 150-W light bulb. The distance of the lamp from the cage can vary, but 4 to 8 in. is sufficient.

6. Place the mouse in a restrainer by grasping the mouse by the tail out of the cage and placing with tail protruding through the opening in the wall of a restraining device.

7. Fill 1-ml syringe (tuberculin type) with the cell suspension and remove air bubbles.

8. Hold the distal third part of the tail between thumb and middle finger, wipe clean with 70% ethanol, and rotate to position the lateral vein. Stabilize the vein with the index finger. Apply slight pressure to straighten the tail and further dilate the lateral vein.

9. Hold the 1-ml syringe with a 27-G, ¾-in. needle in the other hand. Direct the bevel of the needle upward. Force the needle gently through the skin (at a slight angle) and then immediately thread it almost parallel into the vein. When the vein is canulated, advance the needle into the lumen an additional 5 mm and slowly inject 0.2 to 0.3 ml of the cell suspension.

No significant pressure should be applied at this stage. If the needle is not in the vein, bleb formation and tissue resistance to the inoculum can easily be felt, indicating failure to canulate the vein. Perform the first injection at the distal third of the tail. In case of failure, additional attempts may be made proximally in the same or opposite lateral vein. Intravenous injection of anaesthetized mice, or of mice that struggle violently should be avoided.

Tail vein injection is delicate and requires pretraining, usually, 20 to 30 mice may suffice. Locating the lateral vein is relatively difficult with C57BL mice compared to Balb/c mice.

Enumerate pulmonary tumor colonies

10a. After 2 to 3 weeks post-injection, euthanize mice (or rats) by CO_2 asphyxiation or cervical dislocation (or other approved method), remove the lungs, rinse in tap water, fix in 3.8% formaldehyde, and count colonies with the aid of a dissecting microscope.

An illuminated colony–counting magnifying lens can be used instead of a dissecting microscope.

When an organ containing extensive secondary foci is observed, it is also removed, rinsed, and fixed for subsequent enumeration of tumor foci. Most pulmonary tumor colonies in mice are found near or on the surface of the lungs. Therefore, pigmented colonies that differ in color from the lung parenchyma (such as melanoma) can be counted when adequately magnified.

Tumor colonies that are not pigmented and do not differ in color from the pulmonary parenchyma are more difficult to enumerate. To induce contrast between tumor colonies and the lung parenchyma perform step 10b.

10b. *Optional:* Remove lungs (or other organs) and rinse in tap water. A few minutes later, place the lungs in a beaker containing Bouin's solution. After 24 hr, rinse the lungs in water to remove excess Bouin's solution and count the tumor colonies with the aid of a dissecting microscope.

The lung parenchyma will immediately turn yellow. After 24 hr, the white tumor colonies can readily be distinguished from the yellow lung parenchyma.

11. Specify the actual number of pulmonary colonies counted for each mouse, or show the range of counts by indicating the lowest and highest numbers of colonies observed within a given experimental group. Present the average number of nodules per mouse ± standard error or standard deviation, using the two-tailed student's *t*-test. Murine lungs with >300 colonies are reported as such.

Instead of actual counting of pulmonary colonies, one can remove and weigh the lungs of each mouse and express the results as average lung weight ± standard deviation. Normal lung weight is ~200 mg.

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Bouin's solution

0.9% (v/v) picric acid
9% (v/v) formaldehyde
5% (v/v) acetic acid
Store up to 1 year at room temperature

COMMENTARY

Background Information

Metastasis is the foremost cause of death from cancer. Fortunately, metastasis is an extremely inefficient process, with few of the many cells shed from a primary tumor successfully forming secondary tumors (Hart and Fidler, 1980; Liotta, 1986; Fidler and Ellis, 1994; Ruoslahti, 1996). Sequential steps in the metastatic process are as follows: escape of cells from the primary tumor, entry of cells into lymphatic or blood circulation (intravasation), survival and transport in circulation, escape of cells from circulation (extravasation), and growth of cells to form secondary tumors in a new organ environment (Hart and Fidler, 1980; Liotta, 1986; Fidler and Ellis, 1994; Ruoslahti, 1996). The majority of cells that successfully escape from a primary tumor will not complete all of the steps necessary to give rise to metastatic tumors. Steps that have been considered to be major contributors to this inefficiency, and thus, rate limiting for metastasis, include cell survival in, and escape from, circulation (Hart and Fidler, 1980; Liotta, 1986; Fidler and Ellis, 1994; Ruoslahti, 1996). Once in circulation, the tumor cells often attach at or near junctions between adjacent endothelial cells, followed by retraction of the endothelial cells borders, and migration toward the exposed underlying basement membrane (BM). The invading tumor cells then degrade the subendothelial BM in order to migrate out of the vascular compartment. These steps are collectively addressed by the tail vein assay, commonly applied in vivo as a route for introducing cells into blood circulation (Fidler, 1973a, b).

Experimental metastasis, measured by the tail vein assay, is inhibited by molecules (i.e., RGD-containing peptides, laminin-derived peptides, sulfated polysaccharides) and antibodies which inhibit cell-cell and cell-matrix interactions (Humphries et al., 1986; Iwamoto et al., 1987). Because basement membranes underlying epithelial and endothelial cells appear to be clear barriers to metastasis, enzymes degrading BM proteins and glycosaminoglycans are regarded as promising targets for cancer therapy (Stetler-Stevenson et al., 1993; Finkel, 1999; Vlodavsky et al., 1999). Invasion through a reconstituted basement membrane (Matrigel; *UNIT 10.2*) is most often used to model extravasation (*UNIT 12.2*). Cell invasiveness in vitro correlates with the metastatic potential (i.e., lung colonization) of intravenously injected cells. Moreover, inhibitors of ECM degrading enzymes inhibit both BM invasion in vitro and experimental metastasis in vivo, further emphasizing the significance of the BM as a prominent physical barrier to metastasis (Parish et al., 1987; Stetler-Stevenson et al., 1993; Vlodavsky et al., 1994). Some of these molecules are being examined in cancer patients (Kohn and Liotta, 1995). Taking into account the complexity of the metastatic process, it is now understood that the mechanistic conclusions on the significance of a certain step and/or action of a given molecule cannot be drawn based on the endpoint outcome of the tail vein assay (i.e., number of metastases counted at the end of the experiment; Chambers and Matrisian, 1997). A procedure, intravital videomicroscopy (IVVM), for direct in vivo observation of early steps in metastasis, has recently provided evidence that some of the assumptions about mechanisms of metastasis need to be revised (Chambers and Matrisian, 1997; Al-Mehdi et al., 2000; Cameron et al., 2000). Unlike early studies, direct IVVM observation of intravenously injected cancer cells revealed that a large proportion of the injected cells not only survive injection and arrest in a target organ, but also succeed in extravasation (Chambers and Matrisian, 1997; Al-Mehdi et al., 2000; Cameron et al., 2000). It was suggested that, unlike previous assumptions, extravasation may be a relatively easy process and that metastatic inefficiency depends, to a large extent, on the inhibition of growth in a subset of extravasated cells (Cameron et al., 2000). Availability of a favorable microenvironment in the target organ is critical for seeding and proliferation of the disseminated cells ("seed and soil" theory; Killion et al., 1998).

Previous research has concentrated on the contribution of individual genes to metastasis. Initially, there was hope that a single metastasis-specific gene could be identified to be responsible for conversion to a metastatic phenotype. Although some cells could be converted to a metastatic phenotype by DNA transfection of certain genes, including those encoding ECM-degrading enzymes (Stetler-Stevenson et al., 1993; Vlodavsky et al., 1999), there is no single master "metastasis" gene that regulates cellular abilities necessary for cancer metastasis (Chambers and Matrisian, 1997). Gene-expression profiling, using high-density DNA microassays combined with the tail vein assay, led to the identification of several genes involved in ECM assembly and in regulation of the

actin-based cytoskeleton that are selectively upregulated in metastatic mouse and human melanoma cells (Clark et al., 2000). A particular significance was ascribed to RhoC, which may regulate metastasis by controlling cytoskeletal events essential for cell motility in response to extracellular factors (Clark et al., 2000).

Critical Parameters and Troubleshooting

General considerations for metastasis. The pathogenesis of metastasis begins with the invasion of tissues, blood vessels, and/or lymphatics by cells originating from a primary cancer. Following their release into circulation, most tumor emboli are initially arrested in the lung tissue, simply because the lung capillary bed is the first to be encountered (Fidler, 1973a; Hart and Fidler, 1980), although some cells recirculate and are trapped in other organs. It is because of this that the majority of intravenously injected cells extravasate and form metastatic colonies in the lungs, as in fact evaluated by the tail vein assay described in this unit. It should be noted that this assay, also known as "experimental metastasis", is restricted to evaluate the metastatic potential of circulating blood-borne cells. In contrast, the more complete cascade can be studied using the "spontaneous metastasis" assay in which the tumor cells are injected subcutaneously to first form a primary tumor. The tumor is either allowed to grow (Vlodavsky et al., 1999), or is resected when it reaches a certain size (Fitzer-Attas et al., 1997). The latter protocol better mimics the situation in patients who undergo resection of their primary tumor, a procedure which is often associated with stimulated vascularization and growth of already spread metastatic nodules (O'Reilly et al., 1994). Briefly, for measurements of spontaneous metastasis, mice are most often inoculated in the footpad with 2×10^5 cells per mouse. Local tumors are measured with calipers. When individual tumors reach a diameter of 8 mm, tumor-bearing legs are amputated (Fitzer-Attas et al., 1997). Two to 3 weeks post-amputation, the mice are euthanized and the number of pulmonary colonies or lung weights are determined as described for intravenously injected tumor cells (Fitzer-Attas et al., 1997).

Single cell suspension. A major problem likely to be encountered with the tail vein assay is the broad variation in the number of pulmonary colonies obtained among mice of the same group. In some experiments, these may vary between 10 and 100 nodules per mouse. This variation may primarily be due to inappropriate standardization of the cell suspension. Every effort should be made to obtain a single-cell suspension since cell clumping and aggregation often result in an increased number of lung colonies (Fidler, 1973b). Clearly, cell aggregation and clump (embolus) size influence the outcome of experimental metastasis assays. For example, mice injected with 10,000 clumps of 4 to 5 cells will develop more pulmonary foci than mice injected with 50,000 single tumor cells (Fidler, 1973b). The significance of cell aggregation is also demonstrated by the greatly increased number of tumor foci obtained when the tumor cells are injected simultaneously with lethally irradiated tumor cells, or with live syngeneic embryonic cells (Fidler, 1973b; Hart and Fidler, 1980). To avoid clumping, trypsinization and centrifugation of the cultured cells should be gentle and the dissociated cells should be suspended in serum-free, Ca^{2+}/Mg^{2+}-free balanced salt solution. Routine viability tests (e.g., trypan blue exclusion) and even-plating efficiency in vitro do not necessarily predict or correlate with the in vivo metastatic potential of over-trypsinized cells (Fidler, 1973b). Also, the 15-ml tube, as well as the syringe containing the cell suspension should be gently rotated from time to time and not be left standing for long periods of time (i.e., >30 min) to prevent the cells from settling and aggregating at the bottom of the tube or in the syringe. The cells should be pipetted gently prior to being taken up into the syringe for injection. Failure to obtain a single-cell suspension will result in a diverse and broad range of colony number among mice of the same experimental group, and in differences in colony size in the same mouse.

Cultures. An important parameter is the health of the cells. Cultures should be actively growing, but should be passaged at least 48 hr prior to the day of the tail vein assay. Also, the use of early passaged cultures (<20) is recommended. Relatively poor metastatic potential is often observed with late-passage cells. If the cells tend to loose their metastatic ability, it is advisable to go back and select for highly metastatic cells by means of a repeated isolation of pulmonary metastases and subsequent growth in culture, according to the scheme first described by Fidler (1973a) and applied by many other groups (Clark et al., 2000). Briefly, to select for highly metastatic tumor cells, pulmonary metastatic nodules are removed aseptically, minced, grown in vitro, and re-injected

intravenously into the tail vein of host mice. This procedure is repeated 2 to 5 times.

Anticipated Results

Using highly metastatic cell lines (e.g., B16-F10 or B16-BL6 mouse melanoma, A375SM human melanoma, 13762 MAT rat mammary carcinoma, D122 3LL Lewis lung carcinoma; Fidler, 1973a; Parish et al., 1987; Zhang et al., 1991; Vlodavsky et al., 1994; Fitzer-Attas et al., 1997; Clark et al., 2000), it is anticipated to obtain 200 to 300 pulmonary metastases per mouse (or rat) injected with 5×10^4 cells. The actual number of pulmonary colonies may range from ~80 to 350 in different mice of the same group. The lung weight of a C57BL mouse injected with 5×10^4 D122 3LL cells is expected to be ~800 ±140 mg versus a normal lung weight of ~200 mg (Fitzer-Attas et al., 1997). The effect of compounds that inhibit cell adhesion (mediated by selectins and integrin receptors, for example), or certain degradative enzymes (i.e., matrix metalloproteinases, plasminogen activator, heparanase) can be easily evaluated using the tail vein assay. The inhibitory molecule can be added to the cell suspension prior to the intravenous injection, or administered separately, subcutaneously or intraperitoneally. Generally, the test compound can be injected up to 12 hr prior to the cells, depending on its half-life time, but no later than 30 min following the tail vein injection of the cells. Effective compounds may decrease the number of visible pulmonary metastases by ~95% (Parish et al., 1987; Vlodavsky et al., 1994).

An example is presented in figure 19.2.1, showing a profound inhibition of experimental metastasis in mice treated with a chemically modified, non-anti-coagulant fragment of heparin (Vlodavsky et al., 1994). This effect is attributed primarily to efficient inhibition of heparanase activity (Vlodavsky et al., 1994). The heparanase enzyme has been shown to promote tumor angiogenesis and metastasis (Vlodavsky and Friedmann, 2001).

Time Considerations

Cell harvesting and tail vein injection require 2 to 4 hr, depending on the number of mice and treatment groups. The mice are generally euthanized 14 to 18 days after injection, unless injected with very low metastatic cells (i.e., A375 melanoma) where up to 8 weeks after injection may be required (Clark et al., 2000). The actual removal of lungs and enumeration of pulmonary colonies can be carried out in 1 day for a typical experiment of 4 to 5 groups, 6 to 8 mice each. In the case of tumor colonies that are not pigmented, it is recommended that lungs be first incubated in Bouin's solution for 24 hr.

Microanalysis of Gene Expression in Tissues Using T7-SAGE: Serial Analysis of Gene Expression After High-Fidelity T7-Based RNA Amplification

Comprehensive gene-expression data obtained from individual cell types in tissues and organs will provide novel insights into the fundamental molecular biology of embryonic development, disease, and other cell biological processes. There are presently two major types of gene expression profiling techniques, microarray analyses and serial analysis of gene expression (SAGE). SAGE has an advantage over microarray analysis in that it provides absolute transcript numbers in a digital format, and can readily identify previously unknown genes (Velculescu et al., 1995, 1997; Ishii et al., 2000). Microarrays have the advantages of being relatively easy to use and more suitable for high-throughput applications; however, mRNA quantitation is more accurate with SAGE than with microarrays (Polyak and Riggins, 2001).

A major disadvantage of SAGE is that it requires microgram quantities of starting poly(A)$^+$ mRNA, which prevents its use when mRNA is limited. Several techniques have been developed to overcome this limitation, but they mostly depend on amplification using the polymerase chain reaction (PCR). SAGE-Lite (Peters et al., 1999) and PCR-SAGE (Neilson et al., 2000) convert poly(A)$^+$ mRNA to cDNA, which is then amplified by PCR. Alternatively, MicroSAGE (Datson et al., 1999) and SAGE adaptation for downsized extracts (SADE; Virlon et al., 1999) depend on PCR amplification of SAGE ditags. Although the recently reported MicroSAGE protocol does not require a reamplification step (see *http://www.sagenet.org*), it is optimized for between 5×10^4 and 2×10^6 cells (St. Croix et al., 2000), and extra PCR amplifications would be necessary for fewer cells, such as when using laser-capture-microdissected tissue sections (Emmert-Buck et al., 1996).

Although PCR is a powerful method for amplifying rare DNA species from tissue samples, the widely used *Taq* DNA polymerase has relatively low fidelity, and it propagates errors through subsequent cycles of amplification (Van Gelder et al., 1990). The error rate of 1×10^{-3} for *Taq* polymerase (1 mismatch per 1000 bases synthesized) will result, on average, in several erroneous bases in most PCR-amplified cDNAs (Eberwine et al., 1992). Even though SAGE ditags are of approximately equal length for ditag amplification by PCR during SAGE, preferential amplification of some ditags cannot be completely prevented (Datson et al., 1999).

This unit begins with a procedure for T7-based RNA amplification (see Basic Protocol 1). In order to avoid extra PCR or other forms of amplification, the authors incorporate only two cycles of T7-based RNA amplification as the initial step in Basic Protocol 1. This T7-based amplification step has high accuracy, since a combined error rate of 2×10^{-4} has been calculated for avian myeloblastosis virus (AMV) reverse transcriptase and T7 RNA polymerase (Sooknanan et al., 1994). In addition, T7 RNA polymerase has high processivity (Muller et al., 1988) and functions effectively even when broad stretches of nucleotides are being amplified—unlike *Taq* polymerase, which works most efficiently for amplification of small regions of a few hundred nucleotides. Although no protocol that includes an amplification step can claim to permit determination of absolute transcript number, since slight changes in estimated transcript frequency are always possible, T7 procedures appear to be the safest to date (Wang et al., 2000; Bashiardes and Lovett,

Contributed by Takayoshi Sakai, Melinda Larsen, and Kenneth M. Yamada
Current Protocols in Cell Biology (2002) 19.3.1-19.3.30

2001). A procedure for T7-like amplification of tiny amounts of mRNA using the RiboAmp kit from Arcturus Engineering is also included (see Alternate Protocol).

In this unit, the authors describe a new technique, T7-SAGE (see Basic Protocol 2), in which a high-fidelity T7 amplification step is combined with SAGE analysis. This new T7-SAGE procedure should facilitate application of SAGE for gene-expression profiling using minimal quantities of starting material, such as from embryonic tissues and microdissected cells from histological sections of tissues.

Support Protocols are also provided for: preparation of total RNA (see Support Protocol 1); a phenol/chloroform procedure using Phase Lock Gel Light which is suitable for the numerous DNA extractions in T7-SAGE (see Support Protocol 2); kinasing to generate the linkers used in T7-SAGE (see Support Protocol 3); a gel-shift test (see Support Protocol 4) for completeness of biotinylation, used to evaluate the biotinylated oligo(dT) primer with which the biotinylated cDNA is synthesized in Basic Protocol 1; preparation of gels for the numerous PAGE procedures involved in T7-SAGE (see Support Protocol 5); and direct sequencing of PCR products from a SAGE library (see Support Protocol 6).

NOTE: Investigators should first become familiar with the underlying strategies of SAGE *(UNIT 19.4)* and then practice ahead of time (ideally several times) using larger amounts of starting material before performing the final T7-SAGE procedure with precious samples. Researchers are advised to access the SAGE home page on the internet at *http://www.sagenet.org/* organized by Kenneth Kinzler and co-workers at the Molecular Genetics Laboratory of the Johns Hopkins Oncology Center at Johns Hopkins University, which describes SAGE concepts, new SAGE applications, and recent publications.

NOTE: The quality of the data obtained from T7-SAGE libraries depends on the quality of the RNA and DNA used in its many steps. Consequently, DEPC-treated water should be used for all steps involving RNA. DNase-free water (e.g., obtained from a commercial source) is also recommended.

BASIC PROTOCOL 1

T7-BASED RNA AMPLIFICATION

This protocol describes how to perform high-fidelity T7-based RNA amplification, starting with only small amounts of total RNA, for use in SAGE procedure (Velculescu et al., 1995, 1997). This method can be used with tissue culture cell lines or with homogenates from animal tissues or organs. The protocol is a general method applicable to total RNA isolated in various ways in quantities as small as 4 ng. The Alternate Protocol is specifically designed for laser-microdissected histological samples, where quantities are even lower.

CAUTION: Investigators should wear gloves for all procedures involving RNA and take precautions in order to avoid cross-contamination of samples. See *APPENDIX 2A* for general guidelines when working with RNA. DEPC-treated water (*APPENDIX 2A*) must be used for steps 1 to 41.

Materials

4 to 5 ng purified total RNA from tissues or cells in a volume of 10.5 µl (see Support Protocol 1)

0.5 mg/ml T7-oligo(dT) primer:
5′-TCTAGTCGACGGCCAGTGAATTGTAATACGACTCACTATAGGGCGT$_{21}$-3′
(custom-synthesized, e.g., by Integrated DNA Technologies or core facility)

Superscript Choice System for cDNA Synthesis kit (Invitrogen), including:
  5× first-strand reaction buffer
  0.1 M dithiothreitol (DTT)
  10 mM dNTP mix (10 mM each dATP, dCTP, dGTP, dTTP)
  SuperScript II reverse transcriptase
  40 U/µl RNaseOUT recombinant ribonuclease inhibitor (Invitrogen)
  5× second-strand reaction buffer
  10 U/µl DNA polymerase I
60 U/µl RNase H (PanVera)
60 U/µl DNA ligase (PanVera)
DEPC-treated H_2O (Quality Biological or other supplier; also see *APPENDIX 2A*)
8 U/µl T4 DNA polymerase (Promega)
QIAquick PCR Purification Kit (Qiagen)
Ampliscribe T7 High Yield Transcription Kit (Epicentre Technologies), including:
  Ampliscribe T7 reaction buffer
  100 mM ATP
  100 mM CTP
  100 mM GTP
  100 mM UTP
  0.1 M dithiothreitol (DTT)
  T7 RNA polymerase solution
10 U/µl DNase I (Boehringer Mannheim)
RNeasy Mini Kit (Qiagen)
1 mg/ml random primers (Invitrogen)
0.5 mg/ml biotinylated oligo(dT) primer: 5′- [biotin]T_{18} -3′ (custom-synthesized, e.g., by Integrated DNA Technologies or core facility), gel-purified; test for complete biotinylation before use by gel-shift test (see Support Protocol 4)

16°, 42°, 70°, and 95°C water baths
GeneQuant pro RNA/DNA Calculator (Amersham Pharmacia Biotech) or any other spectrophotometer for determining UV absorbance of small samples (e.g., 20 to 50 µl)

Perform reverse transcription (RT) of RNA

1. Mix 4 to 5 ng purified RNA (in 10.5 µl; see Support Protocol 1) in a 1.5- to 1.7-ml microcentrifuge tube with 1 µl of 0.5 mg/ml T7-oligo(dT) primer to initiate first-strand synthesis.

   In general, small samples should be mixed by vortexing for 5 sec, then momentarily microcentrifuged at maximum speed (accelerate to maximal speed of 13,000 to 15,000 rpm, then immediately brake) to collect the sample at the bottom of the tube.

2. Incubate the primer and RNA at 70°C for 10 min, then incubate at 42°C for 5 min.

3. Add the following reagents to the microcentrifuge tube and mix:

   4 µl 5× first-strand reaction buffer
   2 µl 0.1 M DTT
   1 µl 10 mM dNTP mix
   0.5 µl 40 U/µl RNaseOUT RNase inhibitor
   1 µl SuperScript II reverse transcriptase.

4. Incubate at 42°C for 1 hr.

5. Add the following reagents to the tube and mix:

   30 µl 5× second-strand reaction buffer
   3 µl 10 mM dNTP mix
   1.5 µl 10 U/µl DNA polymerase I
   0.25 µl 60 U/µl RNase H
   0.25 µl 60 U/µl DNA ligase
   95 µl DEPC-treated H_2O.

6. Incubate at 16°C for 2 hr.

7. Add 2.5 µl of 8 U/µl T4 DNA polymerase and incubate for an additional 10 min at 16°C.

8. Purify the double-stranded (ds)-cDNA with a QIAquick PCR purification kit according to the manufacturer's instructions.

9. After collection from the column, vacuum dry the ds-cDNA to ~5 µl, then adjust the volume to 8 µl with DEPC-treated H_2O using a micropipettor, in preparation for in vitro transcription.

   Samples should not be evaporated to complete dryness, which reduces the efficiency of recovery. Instead, try to reduce the volume to ~5 µl, periodically checking the progress of volume reduction. Volumes can be determined using an adjustable 10-µl micropipettor: draw the sample up into a micropipet tip, then adjust the dial that sets the volume of the micropipettor until there is a precise match to the volume of the sample (i.e., after drawing up, no extra volume is left in the tube and no air is left at the bottom of the tip). Once the volume is reduced to <8 µl, the difference in volume to achieve the final 8 µl can be calculated and added using DEPC-treated water.

Amplify antisense RNA (aRNA) using T7 RNA polymerase

10. Mix the 8 µl ds-cDNA (from step 9) with the following reagents in the tube:

    2 µl 10× Ampliscribe T7 reaction buffer
    1.5 µl each of 100 mM ATP, CTP, GTP, and UTP
    2 µl 0.1 M DTT
    2 µl T7 RNA polymerase solution.

    All of the above reagents are included with the Ampliscribe T7 High-Yield Transcription kit from Epicentre Technologies.

11. Incubate at 42°C for 3 hr.

12. Add 1 µl of 10 U/µl DNase I, mix, and incubate at 37°C for 15 min.

13. Purify the resulting aRNA using an RNeasy Mini Kit according to the manufacturer's instructions.

14. Dry the aRNA down to ~5 to 10 µl using a vacuum concentrator, then adjust the volume to 10.5 µl using a micropipettor and DEPC-treated water.

Perform a second round of aRNA amplification

15. To the aRNA from the first-round amplification (step 14), add a 1-µl aliquot of 1 mg/ml random primers in a 1.5- to 1.7-ml microcentrifuge tube, and mix.

16. Incubate the mixture at 70°C for 10 min.

17. Chill the mixture on ice, and then allow it to equilibrate at room temperature for 10 min.

18. Add the following reagents (from the SuperScript kit) to the tube and mix:

    4 µl 5× first-strand reaction buffer
    2 µl 0.1 M DTT
    1 µl 10 mM dNTP mix
    0.5 µl 40 U/µl RNaseOUT RNase inhibitor
    1 µl SuperScript II reverse transcriptase.

19. Incubate at room temperature for 5 min and then at 37°C for 1 hr.

20. Add 0.5 µl of 60 U/µl RNase H, mix, and incubate at 37°C for 20 min.

21. Heat the reaction mixture to 95°C for 2 min and then chill it on ice.

22. For second-strand cDNA synthesis, add 1 µl of 0.5 mg/ml T7-oligo(dT) primer, mix, and incubate the mixture at 70°C for 5 min and then at 42°C for 10 min.

23. Add the following reagents to the tube and mix:

    30 µl 5× second-strand reaction buffer
    3 µl 10 mM dNTP mix
    1.5 µl 10 U/µl DNA polymerase I
    0.25 µl 60 U/µl RNase H
    0.25 µl 60 U/µl DNA ligase
    95 µl DEPC-treated H_2O.

24. Incubate the mixture at 16°C for 2 hr.

25. Add 2.5 µl of 8 U/µl T4 DNA polymerase, mix, and incubate at 16°C for 10 min.

26. Purify the ds cDNA with a QIAquick PCR purification kit according to the manufacturer's instructions.

27. Vacuum dry the cDNA to ~5 µl and adjust volume to 8 µl with DEPC-treated water.

    See annotation to step 9, above, for details of this procedure.

28. Using the same tube, add the following reagents to the 8 µl of ds cDNA (from step 27) and mix:

    2 µl 10× Ampliscribe T7 reaction buffer
    1.5 µl each of 100 mM ATP, CTP, GTP, and UTP
    2 µl 0.1 M DTT
    2 µl T7 RNA polymerase solution.

29. Incubate at 42°C for 3 hr.

30. Add 1 µl DNase I, mix, and incubate at 37°C for 15 min.

31. Purify the aRNA using an RNeasy Mini Kit according to the manufacturer's instructions.

32. Dry the aRNA down to 5 to 10 µl using vacuum concentrator, then adjust volume to 10.5 µl using a micropipettor and DEPC-treated water.

Synthesize biotinylated double-stranded cDNA (bds cDNA)

33. Mix the 10.5 µl aRNA from the second-round RNA amplification (step 32) with 1 µl of 1 mg/ml random primers.

34. Incubate the mixture at 70°C for 10 min, chill it on ice, and then allow it to equilibrate at room temperature for 10 min.

35. Add the following reagents to the tube and mix:

    4 µl 5× first-strand reaction buffer
    2 µl 0.1 M DTT
    1 µl 10 mM dNTP mix
    0.5 µl 40 U/µl RNaseOUT RNase inhibitor
    1 µl SuperScript II reverse transcriptase

36. Incubate at room temperature for 5 min and then at 37°C for 1 hr.

37. Add 0.5 µl of 60 U/µl RNase H, mix, and incubate the mixture at 37°C for 20 min.

38. Heat this reaction mixture to 95°C for 2 min, and then chill it on ice.

39. Add 1 µl of 0.5 mg/ml biotinylated oligo(dT) primer (5′- [biotin]T_{18} -3′) and mix.

    Before use, the biotinylated oligo(dT) primer should be tested for complete biotinylation by the gel-shift test (see Support Protocol 4).

40. Incubate the mixture at 70°C for 5 min and then at 42°C for 10 min.

41. Add the following reagents to the tube and mix:

    30 µl 5× second-strand reaction buffer
    3 µl 10 mM dNTP mix
    1.5 µl 10 U/µl polymerase I
    0.25 µl 60 U/µl DNA ligase
    0.25 µl 60 U/µl RNase H
    93.5 µl DEPC-treated H_2O.

42. Incubate the mixture at 16°C for 2 hr.

43. Purify the bds cDNA using a QIAquick PCR purification kit according to the manufacturer's instructions.

44. Elute with 60 µl of water.

45. Check the concentration of bds cDNA synthesized using a spectrophotometer appropriate for determining UV absorbance of small samples.

    A total of ~1 µg is needed to proceed to the SAGE protocol.

SUPPORT PROTOCOL 1

PREPARATION OF TOTAL RNA

Total RNA from tissues or cells can be prepared by any of the methods listed in Table 19.3.1, following the company's protocol if a commercial kit is used. A final yield of at least 4 ng total RNA in 10.5 µl water is needed. The column methods are generally recommended for isolating RNA from small samples, such as those obtained using laser microdissection of histological sections. DNase treatment, as described in the steps below, is needed to avoid any genomic DNA contamination. The integrity of RNA should be checked by gel electrophoresis, RT-PCR, or Northern blot hybridization.

Materials

Tissues or cells of interest
Kit or reagents for total RNA isolation (Table 19.3.1)
DEPC-treated H_2O (*APPENDIX 2A*; or supplied with isolation kit)
10× DNase I buffer (Ambion)
2 U/µl DNase I (RNase-free; Ambion)
40 U/µl RNaseOUT recombinant ribonuclease inhibitor (Invitrogen)
RNeasy Mini Kit (Qiagen)

Table 19.3.1 Methods for Preparing Total RNA from Tissues or Cells

Method	Supplier or Reference
Standard solution-based methods	
Guanidium isothiocyanate method	Chomczynski and Sacchi (1987)
TRIzol reagenty	Invitrogen
RNAgents Total RNA Isolation System	Promega
Micro RNA Isolation Kit	Stratagene
Column methods	
RNeasy Mini Kit	Qiagen
Pinpoint Slide RNA Isolation System	Zymo Research
PicoPure RNA Isolation Kit	Arcturus
Micro-FastTrack 2.0 mRNA Isolation Kit	Invitrogen

CAUTION: Investigators should wear gloves for all procedures involving RNA and take precautions in order to avoid cross-contamination of samples. See *APPENDIX 2A* for general guidelines when working with RNA.

1. Isolate RNA from tissues or cells of interest using an appropriate method (Table 19.3.1).
2. Adjust the volume of the isolated RNA to 16 µl using DEPC-treated water.
3. Add the following reagents to the tube and mix:

   2 µl 10× DNase I buffer
   1 µl 2 U/µl DNase I
   1 µl 40 U/µl RNaseOUT RNase inhibitor.
4. Incubate at 37°C for 30 min.
5. Purify the treated RNA using an RNeasy Mini Kit according to manufacturer's instructions.

   Follow the RNeasy Mini Protocol for RNA Cleanup.
6. Vacuum dry the eluted RNA solution down to 10.5 µl.

   The product will be ready at this point for T7-based RNA amplification (see Basic Protocol 1).

SUBSTITUTION OF A COMMERCIAL KIT FOR AMPLIFYING TINY QUANTITIES OF RNA

ALTERNATE PROTOCOL

When samples are obtained by laser microdissection for isolation of cells from histological sections, or if investigators prefer to use a commercial kit for the RNA amplification, the RiboAmp kit from Arcturus is recommended for reliable T7-like amplification of tiny amounts of mRNA. This kit, designed to isolate and amplify extremely small amounts of material, can be substituted directly for Basic Protocol 1 through step 32. This kit generates antisense RNA that can be used for the synthesis of biotinylated double-stranded cDNA (bds cDNA).

Additional Materials *(also see Basic Protocol 1)*

RiboAmp RNA Amplification Kit (Arcturus Engineering)

1. Isolate RNA from samples and synthesize aRNA following the manufacturer's instructions for the RiboAmp RNA Amplification Kit.
2. Dry the aRNA down to 5 to 10 µl using a vacuum concentrator and then adjust the volume to 10.5 µl with DEPC-treated water.
3. Use the product in Basic Protocol 1 starting at step 33.
4. Check the concentration of bds cDNA using a spectrophotometer appropriate for determining UV absorbance of small samples.

BASIC PROTOCOL 2

T7-SAGE PROCEDURE

The following protocol is a modification of the SAGE technique developed by Kinzler and co-workers at Johns Hopkins University (Velculescu et al., 1995, 1997; see also SAGE Detailed Protocol version 1.0e at *http://www.sagenet.org*). Key alterations include the following changes:

a. The procedure is started with biotin-labeled double-stranded cDNA generated from antisense mRNA produced by T7 amplification.

b. Use of the commercial mRNA Capture Kit (Roche Molecular Biochemicals) is substituted for the first three steps involving binding of biotinylated double-stranded cDNA (bds cDNA) to streptavidin-magnetic beads, *Nla*III enzyme cleavage of cDNA and ligating of linkers, and release of cDNA tags using *Bsm*FI enzyme. This substitution permits completion of all three steps within two streptavidin-coated microcentrifuge tubes, which significantly reduces losses of material between successive steps.

c. Phase Lock Gel (PLG, Light; Eppendorf) for optimizing phase separation at several steps in the SAGE procedure for recovering DNA after phenol extraction; this technique significantly increases the recovery and purity of the DNA.

Materials

1 µg of bds cDNA generated by T7-based amplification (see Basic Protocol 1) in ~50 µl
mRNA Capture Kit (Roche Molecular Biochemicals) including:
  Streptavidin-coated PCR tubes
  Washing solution
10× NEBuffer 4 (New England Biolabs; supplied with corresponding restriction enzymes)
10 U/µl restriction endonuclease *Nla*III (New England Biolabs)
100× (10 µg/µl) BSA (New England Biolabs; supplied with corresponding restriction enzymes)
DNase-free H_2O
1 U/µl and 5 U/µl T4 DNA ligase and 10× ligase buffer (Invitrogen)
LoTE buffer (see recipe)
15 ng/µl annealed linker 1 (formed by annealing linkers 1A and 1B; see Support Protocol 3)
15 ng/µl annealed linker 2 (formed by annealing linkers 2A and 2B; see Support Protocol 3)
2 U/µl restriction endonuclease *Bsm*FI (New England Biolabs)
20 mg/ml glycogen (Boehringer Mannheim)
7.5 M ammonium acetate

70% and 100% ethanol
5× second-strand reaction buffer (Invitrogen; supplied with SuperScript kit, also see Basic Protocol 1)
10 mM dNTP mix (10 mM each dATP, dCTP, dGTP, dTTP; Invitrogen; supplied with SuperScript kit; also see Basic Protocol 1)
5 U/ml Klenow fragment of DNA polymerase (Amersham Pharmacia Biotech or USB)
10× PCR buffer (see recipe)
Dimethyl sulfoxide (DMSO)
350 ng/µl primer 1: 5′-GGATTTGCTGGTGCAGTACA-3′ (custom-synthesized, e.g., by Integrated DNA Technologies or core facility)
350 ng/µl primer 2: 5′-CTGCTCGAATTCAAGCTTCT-3′ (custom-synthesized, e.g., by Integrated DNA Technologies or core facility)
5 U/µl Platinum *Taq* polymerase (Invitrogen)
12% and 8% polyacrylamide gels (see Support Protocol 5)
6× Loading Dye Solution (LDS; Fermentas)
10- and 25-bp DNA ladders (Invitrogen)
SYBR Green I (Molecular Probes)
1× TAE buffer (e.g., Advanced Technologies, or prepare as in *APPENDIX 2A*)
TE buffer, pH 7.4 (*APPENDIX 2A*), cold
Ready-to-Go 100-bp DNA ladder (Fermentas)
pZERO-1 plasmid (Invitrogen)
5 U/µl restriction endonuclease *Sph*I (New England Biolabs)
10× NEBuffer 2 (New England Biolabs; supplied with corresponding restriction enzymes)
1% and 3% agarose gels (see *APPENDIX 3A*)
One Shot TOP10 Electrocompetent *E. coli* cells (Invitrogen)
SOC medium (see recipe)
10-cm Zeocin-containing low-salt LB plates (see recipe)
350 ng/µl M13 forward primer: 5′-GTAAAACGACGGCCAGT-3′ (custom-synthesized, e.g., by Integrated DNA Technologies or core facility)
350 ng/µl M13 reverse primer: 5′-GGAAACAGCTATGACCATG-3′ (custom-synthesized, e.g., by Integrated DNA Technologies or core facility)
QIAquick 96 Multiwell PCR Purification Kit (Qiagen)
10 mg/ml ethidium bromide

16°, 50°, and 65°C water baths
2-ml PCR tubes
System for PCR using 96-well plates (e.g., GeneAmp PCR system 9600 or 9700, Applied Biosystems)
96-well PCR plates (Applied Biosystems)
Power Pac 200 power source (Bio-Rad)
18-G needle (1- to 1.5-in. length)
SpinX columns with collection tubes (Costar)
Gene Pulser II and Pulse Controller Plus (Bio-Rad) and 0.1-cm electroporation cuvettes
15-ml polypropylene snap-top tubes
Bacterial shaker
Micropipettors with sterile aerosol-barrier tips
SAGE 2000 software (freely available for noncommercial use; see *http://www.sagenet.org*) and Microsoft Access

Additional reagents and equipment for phenol/chloroform extraction using Phase Lock Gel Light (see Support Protocol 2), polymerase chain reaction (*APPENDIX 3F*), polyacrylamide gel electrophoresis (see *APPENDIX 3A* and Support Protocol 5), and agarose gel electrophoresis (see *APPENDIX 3A*)

Generation of Linked SAGE Tags

Capture the biotinylated cDNA

1. Add 25 µl of bds cDNA to each of two streptavidin-coated PCR tubes provided in the mRNA Capture Kit (~0.5 µg per tube).

   This step can be scaled up by using more bds cDNA and more pairs of tubes, keeping a ratio of approximately 0.5 µg bds cDNA per tube.

2. Incubate at 37°C for 5 min to allow the bds cDNA to attach to the walls of the tubes.

3. Aspirate the solution to remove non-bound bds cDNA and wash the tubes three times, each time with 50 µl of the washing solution provided in the mRNA Capture Kit.

Cleave the biotinylated cDNA with the anchoring enzyme NlaIII

4. After aspirating the washing solution, wash the streptavidin-coated PCR tubes (which contain the bds cDNA bound to the walls) three times, each time with 50 µl 1× NEBuffer 4.

5. Add the following reagents to each tube:

   2 µl 10 U/µl *Nla*III
   0.25 µl 100× (10 µg/µl) BSA
   2.5 µl 10× NEBuffer 4
   20 µl DNase-free H_2O.

6. Vortex the mixtures very gently (to avoid bubbles) for 10 sec, then momentarily centrifuge at maximum speed in a microcentrifuge.

7. Incubate for 3 hr at 37°C. Mix occasionally by flicking the tube with a finger or by slow vortexing.

8. Heat the tubes at 65°C for 20 min to inactivate the enzyme.

   NlaIII is easily inactivated at ambient or high temperature.When ordering NlaIII, request that it be shipped in dry ice. If dry ice shipping is not requested, this enzyme may be sent with an ice pack and arrive at room temperature, with a resulting loss of activity. Aliquots of NlaIII should be stored at –80°C, which helps to prolong its activity. Ensure that the enzyme is fresh, since it appears to have a half-life of only a few months even when stored at −80°C.

Ligate linkers to the bound cDNA

9. Aspirate the solutions, which will contain digested, unbound cDNA, from each of the streptavidin-coated PCR tubes. Keep the tubes and discard the solutions.

10. Wash the PCR tubes three times, each time with 50 µl washing solution (from the kit), then once with with 50 µl of 1× ligase buffer.

11. Add 5 µl 5× ligase buffer and 18 µl LoTE buffer to each tube.

12. Add 1 µl of 15 ng/µl annealed linker 1 to tube 1.

13. Add 1 µl of 15 ng/µl annealed linker 2 to tube 2.

14. Mix and heat the tubes for 2 min at 50°C and then let stand for 15 min at room temperature.

15. Add 1 µl of 5 U/µl T4 DNA ligase to each of the tubes and mix.

16. Allow the mixtures to ligate by incubating at 16°C for 2 hr.

    After ligation, the mixture can be stored at 4°C overnight.

Release cDNA tags using the tagging enzyme BsmFI

17. Remove the ligation solutions, and wash each of the PCR tubes three times, each time with 50 µl washing solution (from the mRNA Capture Kit).

18. Wash the PCR tubes once with 50 µl 1× NEBuffer 4.

19. Add the following reagents to each tube:

    2.5 µl 10× NEBuffer 4
    0.25 µl 100× (1 µg/µl) BSA
    21.25 µl LoTE buffer.

20. Add 1 µl of 2 U/µl *Bsm*FI to each tube and mix. Digest 1 hr at 65°C. Mix occasionally by flicking the tube with a finger or slow vortexing.

    BsmFI is the "tagging enzyme" that cuts cDNA 14 bp away from the enzyme site GGGAC to generate SAGE tags.

    Do not discard the supernatant, which contains the SAGE tags after BsmFI digestion.

Generation of 26-mer SAGE Ditags

Prepare the released, linked SAGE tags for blunt-ending

21. After the *Bsm*FI digestion, increase the volume of each reaction solution containing the released linked SAGE tags to 200 µl by adding LoTE buffer, then mix.

22. Transfer the reactions to 2-ml tubes numbered 1 and 2, each containing precentrifuged Phase Lock Gel Light (see Support Protocol 2). Perform phenol/chloroform (PC8) extraction as in Support Protocol 2, and finally pipet 200 µl of the SAGE tags contained in the respective aqueous upper phases into fresh 1.5- to 1.7-ml microcentrifuge tubes numbered 1 and 2.

23. Add the following reagents to each of the tubes containing the 200 µl SAGE tag preparation.

    3 µl 20 mg/ml glycogen
    133 µl 7.5 M ammonium acetate
    700 µl 100% ethanol.

24. Mix well by vortexing and place the tube on dry ice for 10 to 20 min.

25. Microcentrifuge 30 min at maximum speed, 4°C.

26. Carefully remove the supernatants and discard them. Be careful not to disturb the pellets.

27. Wash the pellets twice, each time by gently adding 500 to 1000 µl of 70% ethanol solution down the wall of the tube using a micropipet, taking care to avoid disrupting the pellet, and decanting the solution gently.

28. After the final wash, microcentrifuge again briefly at maximum speed to collect any residual ethanol. Carefully remove all of the ethanol with a micropipet and air dry the pellet for 5 to 10 min.

29. Resuspend each pellet in 20 µl LoTE buffer.

Blunt-end the linked SAGE tags

30. Add the following reagents to the tubes 1 and 2 containing 20 µl of linked SAGE tags.

    6 µl 5× second-strand reaction buffer
    0.3 µl 100× (1 µg/µl) BSA
    1.25 µl 10 mM dNTP mix
    1.0 µl 5 U/µl Klenow fragment of DNA polymerase.

31. Mix well, microcentrifuge briefly to collect the solution at the bottom of the tube, and incubate at 37°C for 30 min.

32. Adjust the volume of each blunt-ending reaction to 200 µl by adding LoTE buffer. Mix, then transfer each mixture (no. 1 and no. 2) to a labeled 2.0-ml tube containing precentrifuged Phase Lock Gel Light. Perform phenol/chloroform (PC8) extraction as in Support Protocol 2, and finally pipet the SAGE tags contained in each aqueous upper phase into 1.5- to 1.7-ml microcentrifuge tubes numbered 1 and 2.

33. Precipitate the SAGE tags and wash and dry the pellets as in steps 23 to 28.

34. Resuspend each pellet in 4 µl LoTE buffer.

Ligate the linked SAGE tags to form linked ditags

35. Prepare the following reaction mix on ice in a sterile microcentrifuge tube.

    0.8 µl 5 U/µl T4 DNA ligase
    1.2 µl 5× ligase buffer
    2 µl blunt-ended sample 1 from tube 1 (see step 34)
    2 µl blunt-ended sample 2 from tube 2 (see step 34).

36. Prepare a parallel negative control reaction mix without ligase on ice in a sterile microcentrifuge tube.

    0.8 µl LOTE buffer
    1.2 µl 5× ligase buffer
    2 µl blunt-ended sample 1 from tube 1 (see step 34)
    2 µl blunt-ended sample 2 from tube 2 (see step 34).

37. Mix each of the reactions and incubate overnight at 16°C.

38. After the incubation, make up the volume in each (reaction and control) tube to 20 µl by addition of 14 µl LoTE buffer and mix.

Choose the optimal dilution for PCR amplification of the linked ditags

39. Dilute the following samples with sterile water as described below.

    Negative control (prepared in step 36; no ligase) to 1/5 (i.e., 1 vol of sample plus 4 vol of DNase-free H_2O).
    Template (prepared in step 35; ligated product) to 1/5, 1/10, 1/20, 1/40, and 1/80.

    Set up seven PCR reactions on ice using sterile PCR tubes labeled as:

    Tubes 1 to 5: Different dilutions of the template (1/5, 1/10, 1/20, 1/40, and 1/80)
    Tube 6: Negative control (no template, just H_2O)
    Tube 7: Negative control (no ligase, just H_2O).

To each tube, add the following:

5 µl 10× PCR buffer
3 µl DMSO
7.5 µl 10 mM dNTP mix
1 µl 350 ng/µl primer 1
µl 350 ng/µl primer 2
30.5 µl DEPC-treated H_2O
1 µl 5 U/µl Platinum *Taq* polymerase
1 µl ligation product or negative control at appropriate dilution.

Mix each of the reactions.

Ex Taq (PanVera) appears to produce the same results for SAGE ditag amplification as Platinum Taq, and the former source of Taq polymerase is at present slightly less expensive than the latter.

40. Transfer 50 µl of each reaction mixture into wells of a 96-well PCR plate. Amplify using the following cycling parameters:

1 cycle:	1 min	94°C	(denaturation)
26-30 cycles:	30 sec	94°C	(denaturation)
	1 min	55°C	(annealing)
	1 min	70°C	(extension)
1 cycle:	5 min	70°C	(final extension).

41. Select the optimal dilution of linked ditag as follows:

    a. Mix 5 µl of each PCR product (the various amplified dilutions as well as the no-ligase control and no-template control) with 1 µl of 6× Loading Dye Solution (LDS, from Fermentas).

    b. Load the 6 µl of each sample mixture in a lane of a 12% PAGE gel. Load DNA ladder in additional lanes. Perform electrophoresis (see Support Protocol 5) at 150 V for 1.5 to 2 hr. Stop electrophoresis when the bromphenol blue marker is 1 cm from the bottom of the gel.

    c. Stain gels with a 1:10,000 dilution of SYBR Green I in 1× TAE buffer for 20 min.

    d. Wash gels with 1× TAE buffer for 5 min.

    e. Examine the gel with a UV transilluminator. Compare the lanes with the various dilutions and pick the lowest dilution (highest concentration of linked ditags) that gives a clear 102-bp band (an 80-bp band represents self-ligated linkers, and cannot be used).

    The dilution series and PAGE analysis are necessary to check the successful formation of SAGE ditags (102-bp band) and to identify the optimal concentration for the subsequent large-scale PCR amplification.

42. Perform multiwell large-scale amplification of linked ditag at optimal dilution (selected in step 41) as follows:

    a. Dilute the template (i.e., the remaining template solution from step 38) with water to the optimal dilution (determined in step 41).

    For example, 1/10 dilution of 19 µl will make 190 µl of diluted PCR product.

    b. Set up 198 to 288 individual PCR reactions in two to three 96-well PCR plates as in step 40, using 50 µl of the optimally diluted template per well.

    c. Amplify PCR reactions as in step 40.

    Experience has shown that, at least with presently available equipment, it is best to divide the reaction mixtures up into tiny (50-µl) aliquots and to perform PCR in a 96-well

thermocycler configuration to ensure high-efficiency amplification. Usually, 192 PCR reactions (using two 96-well PCR plates) are performed in parallel, although three to four 96-well plates may be needed if the SAGE ditags are diluted to a lower concentration.

Isolate linked ditags

43. Pool the PCR products from all of the wells of the 96-well plates from the large-scale amplification into one 50-ml tube containing precentrifuged Phase Lock Gel Light.

    There should be ~4.5 ml from each 96-well-plate.

44. Perform phenol/chloroform (PC8) extraction as in Support Protocol 2, and finally transfer half of the aqueous phase (containing linked ditags) to each of two fresh 30-ml Oak Ridge centrifuge tubes.

45. To ~5 ml of the sample in each tube, add the following reagents:

    80 µl 20 mg/ml glycogen
    2 ml 7.5 M ammonium acetate
    15 ml 100% ethanol.

46. Mix well by vortexing and place the tubes on dry ice for 20 min. Microcentrifuge 30 min at maximum speed, 4°C.

47. Carefully remove and discard the supernatant. Be careful not to disturb the pellets.

48. Wash the pellets twice, each time with 25 ml of 70% ethanol.

49. Carefully remove the ethanol and air dry the pellets for 5 to 10 min.

50. Resuspend each pellet in 300 µl LoTE buffer.

51. Add 60 µl of 6× Loading Dye Solution (LDS) to the sample (total volume, 360 µl) and mix.

52. Load 10 µl of the sample mixture in each lane of a 10-well, 12% polyacrylamide gel, for a total of 36 lanes on four gels. Use a 10-bp DNA ladder as a marker on each gel. Perform gel electrophoresis at 150 V for 1.5 to 2 hr using a Power Pac 200 power source (or equivalent). Stop electrophoresis when bromophenol blue marker is 1 cm from the bottom of the gels.

53. Stain the gels with SYBR Green I at 1:10,000 dilution in 1× TAE for 20 min.

54. Wash gels with 1× TAE for 5 min.

55. Make a hole through the bottom of a 0.5-ml sterile microcentrifuge tube using an 18-G needle, and insert the tube into a 1.7-ml microcentrifuge tube.

    For safety, the hole should be punched from the inside toward the outside of the tube: insert the sharp end of a 1- to 1.5-in. 18-G needle into the microcentrifuge tube and slide it down to the center of the V-shaped bottom of the tube; push (away from one's hand) through the bottom of the tube to make the hole, then discard the needle in appropriate manner.

56. Visualize the bands in the gel using a UV transilluminator, taking care to keep all exposed areas of skin covered, e.g., with UV eye and face shielding, gloves, and laboratory coat. Using a single-edge razor blade, excise the 102-bp product from all 36 lanes of the gel by cutting out each band as a small rectangle.

57. Scoop up three excised gel pieces with a corner of the razor blade and place into a 0.5-ml sterile tube. Snap the lid of the 0.5-ml tube closed. Repeat this process for the remaining gel pieces. If there is a lid attached to the 1.7-ml microcentrifuge tube, cut through the plastic hinge with scissors or razor blade and discard the lid. Microcentrifuge 3 min at maximum speed, at room temperature. Discard the 0.5 ml tube, which should be empty, leaving behind fragmented gel in the 1.7-ml tube.

The purpose of this step is to fragment the gel by forcing it to pass through the needle hole by centrifugal force. The outer tube needs to be large enough to permit passage of all of the gel through the hole, so a 1.7-ml tube or even a 2.0-ml tube may be preferable to a 1.5-ml tube to permit collection of all gel fragments, depending on the shape of each of the microcentrifuge tubes.

58. Mix 5 vol of LoTE buffer with 1 vol of 7.5 M ammonium acetate. Add 300 µl of this mixture to the 1.7-ml microcentrifuge tube containing the fragmented gel. Make sure that all gel pieces are covered with buffer. Mix well by vortexing.
59. Incubate at 4°C overnight and then at 65°C for 30 min to elute the DNA from gel.
60. Transfer the contents of the tube to SpinX columns fitted to collection tubes.
61. Microcentrifuge 5 min at maximum speed, at room temperature.
62. Transfer the eluates (each ~300 µl) to new 1.5 to 1.7 ml microcentrifuge tubes.
63. Precipitate, wash, and air dry the DNA pellet as in steps 23 to 28, above.
64. Resuspend each pellet in 7 µl LoTE and then combine all samples (~126 µl).
65. Store the 102-bp ditags at −20°C for up to 1 month.

Purify the SAGE ditags

66. Aliquot the 102-bp product (126 µl) equally into two separate sterile microcentrifuge tubes (63 µl per tube). Add the following reagents to each of the two tubes:

    15 µl 10× NEBuffer 4
    2 µl 100× (1 µg/µl) BSA
    12 µl 10 U/µl *Nla*III (10 U/µl)
    58 µl DNase-free H_2O.

67. Mix the contents well and incubate for 2 hr at 37°C.
68. Adjust the volume in each tube to 200 µl by adding 50 µl LoTE buffer and mix.
69. Analyze 5 µl of the reaction by electrophoresis on a 12% gel to check the efficiency of *Nla*III digestion (see Support Protocol 5).

    Problems with incomplete NlaIII digestion may be due to contaminants, which may be resolved by further purifying the gel-purified 102-bp ditag preparation with a gel-filtration purification step (Angelastro et al., 2000).

70. Transfer the reaction to 200 µl with LoTE buffer and transfer to a 2-ml tube containing precentrifuged Phase Lock Gel Light. Perform phenol/chloroform (PC8) extraction as in Support Protocol 2, and finally pipet the SAGE tags contained in the aqueous upper phase into a fresh tube.
71. Precipitate the SAGE tags and wash and dry the pellets as in steps 23 to 28.
72. Combine the pellets and resuspend, on ice, in a total volume of 30 µl using cold TE buffer, pH 7.4.

    Note that standard TE buffer, pH 7.4, prepared as in APPENDIX 2A is used through step 76 instead of LoTE buffer. LoTE buffer is again used in step 81. The SAGE ditags are more stable in the presence of the higher-salt TE buffer (see Anticipated Results).

73. Mix with 6 µl of 6× LDS. Load 9 µl into each of 4 lanes of 10-well 1.5-mm-thick 12% polyacrylamide gel. Use a 10-bp DNA ladder to provide markers. Perform gel electrophoresis at 150 V for 1.5 to 2 hr. Stop electrophoresis when the bromophenol blue marker is 1 cm from the bottom of the gels.

74. Stain gels with SYBR Green I at 1:10,000 dilution in 1× TAE for 20 min. Wash the gels with water for 5 min.

75. Locate and excise each band containing the 26-bp product using the technique described in step 56, above. Referring to steps 55 to 63, above, combine two excised gel bands and fragment through each of two punctured microcentrifuge tubes, elute DNA (except use standard TE buffer in place of LoTE at step 58 and incubate at 37° instead of 65°C at step 59), then purify on SpinX columns and precipitate and wash DNA pellet according to steps 60 to 63.

    When eluting, be careful to incubate at 37°C instead of 65°C (see step 59); otherwise, the 26-bp cDNA SAGE tags may be degraded.

76. Resuspend the pellet in a total volume of 6.75 µl cold TE buffer on ice. Proceed immediately to the next step.

Ligate the SAGE ditags to form concatemers

77. Set up the following ligation reaction on ice and mix:

    6.75 µl SAGE ditag sample (step 76)
    2 µl 5× ligase buffer
    1.25 µl 5 U/µl T4 DNA ligase.

    Incubate 3 hr at 16°C.

78. After the ligation is complete, add 2 µl of 6× LDS, mix, and heat for 20 min at 65°C.

79. Load the 10-µl sample from step 78 in a single lane of a 10-well 1.5 mm-thick 8% polyacrylamide gel. Also load a 100-bp DNA ladder as a size marker. Perform electrophoresis at 100 V for 3 to 3.5 hr. Stop electrophoresis when bromophenol blue marker reaches a point 1 cm from the bottom of the gel.

80. Stain the gel with SYBR Green I at 1:10,000 dilution in 1× TAE for 20 min. Wash the gel with water for 5 min.

81. Locate and excise the product between 600 and 1200 bp from the sample lane of the gel using the technique described in step 56, above. Referring to steps 55 to 63, above, fragment the excised gel band through a punctured microcentrifuge tube, elute DNA, then purify on SpinX column and precipitate and wash DNA pellet according to steps 60 to 63.

    These procedures are performed exactly as in steps 55 to 63; use LoTE buffer and elute with incubation at 65°C.

    To be safe, save the gel region between 400 and 600 bp in case it is needed later; discard it if step 105 is successful.

82. Resuspend the pellet in a total volume of 6 µl LoTE buffer on ice. Proceed immediately to the next step.

Cloning and Sequencing of Concatemers (SAGE Tags)

Linearize pZero vector

83. Digest pZero-1 plasmid with *Sph*I by combining:

    1 µl 1 µg/µl pZero-1
    1 µl 5 U/µl *Sph*I
    0.2 µl 100× (10 µg/µl) BSA
    22 µl 10× NEBuffer 2
    15.8 µl sterile H_2O.

    Incubate at 37°C for 15 min.

84. Add 180 µl LoTE buffer to digestion mix, then transfer to a 2.0 ml tube containing precentrifuged Phase Lock Gel Light. Perform phenol/chloroform (PC8) extraction as in Support Protocol 2, and finally pipet the digest contained in the aqueous upper phase to a fresh tube.

85. Precipitate, wash, and air dry the plasmid DNA as in steps 23 to 28.

86. Resuspend the DNA in a total volume of 50 µl using LoTE buffer.

    The final concentration of the digested vector should be about 20 ng/µl.

87. Check the efficiency of *Sph*I digestion by agarose gel electrophoresis (*APPENDIX 3A*) using a 2-µl aliquot of the digestion mix and a 2-µl aliquot of 100 ng/µl undigested pZero-1 diluted with water on a 1% agarose gel. Use linearized pZero-1 vector immediately (step 88).

    The DNA can be stored for 1 to 2 weeks at −20°C but the cloning efficiency may decrease.

Ligate concatemers into SphI-digested vector

88. Set up the following 10-µl ligation reaction on ice and mix:

    6 µl concatemer sample (step 82)
    1 µl of ~20 ng/ml digested pZero-1 vector (step 87)
    2 µl 5× ligase buffer
    1 µl 5 U/µl T4 DNA ligase.

    Incubate for 3 hr at 16°C.

    Do not ligate at room temperature.

89. Adjust the volume of the above reaction mixture to 200 µl with LoTE buffer, and transfer to a 2-ml tube containing precentrifuged Phase Lock Gel Light. Perform phenol/chloroform (PC8) extraction as in Support Protocol 2, and finally pipet the concatemer ligated to digested contained in the aqueous upper phase, into a fresh 1.5- to 1.7-ml tube.

90. Precipitate, wash, and air dry the DNA pellet as in steps 23 to 28, above.

91. Resuspend the pellet in 12 µl water.

Transform DNA into E. coli

92. Add 1 µl of the resuspended DNA to 50 µl of One Shot TOP10 Electrocompetent *E. coli* suspension and mix gently.

93. Carefully transfer the cells and DNA to a chilled 0.1-cm electroporation cuvette on ice.

94. Electroporate the samples using Gene Pulser II and Pulse Controller with the following settings: voltage, 1.8 kV; capacitance, 25 µF; resistance, 200 Ω.

95. Add 950 µl of room temperature SOC medium to the cuvette, mix, and transfer the contents to a 15-ml polypropylene snap-top tube. Shake the tube in a bacterial shaker at 37°C for 1 hr at 200 to 225 rpm with the lid vented.

96. Plate 50 µl from each transformation on a test 10-cm low-salt Zeocin-containing LB plate.

97. Incubate each of the test plates at 37°C to grow the transformed bacteria for 12 to 16 hr and store the remaining transformation reactions at 4°C.

98. The next day, depending on the number of colonies observed from the previous test plating, plate out all of the transformation reaction or dilute the transformation reaction appropriately to ensure sufficient space between colonies, and plate all bacteria on 10-cm low-salt Zeocin-containing plates.

The ideal number of colonies is roughly 200 to 300 per 10-cm plate.

Identify insert sizes

99. Set up 96 PCR reactions on ice using sterile 0.2 ml PCR tubes containing the following components:

2.5 µl 10× PCR buffer
1.25 µl DMSO
1.25 µl 10 mM dNTP mix
0.5 µl 350 ng/µl M13 forward primer
0.5 µl 350 ng/µl M13 reverse primer (350 ng/µl)
19 µl H_2O
0.2 µl 5 U/µl Platinum *Taq* polymerase.

100. Add PCR components to wells of a 96-well PCR plate.

101. Use a micropipettor with a sterile 10-µl tip containing an aerosol barrier to collect each colony (about 2 µl of cell suspension). Transfer each colony to a separate well of PCR mix by pipetting the solution in and out several times.

102. Perform PCR using a 96-well thermal cycler using the following cycling parameters:

1 cycle:	2 min	95°C	(denaturation)
25-30 cycles:	30 min	95°C	(denaturation)
	1 min	56°C	(annealing)
	1 min	72°C	(extension)
1 cycle:	5 min	70°C	(final extension).

103. Purify the resulting PCR products using the QIAquick 96 PCR purification kit system according to the manufacturer's instructions.

104. Perform gel electrophoresis using 2 µl of each sample plus 0.4 µl of 6× LDS on a 3% agarose gel (see *APPENDIX 3A*). Stain with ethidium bromide (use 1 µg/ml by mixing 5 µl 10 mg/ml ethidium bromide with 50 ml water; also see *APPENDIX 3A*).

105. Examine gel with a UV transilluminator. Select only wells showing PCR products over 600 bp, which should contain at least 25 tags, for sequence analysis.

To avoid low sequencing efficiency, an additional centrifugation step is recommended if the vacuum available for use with the QIAquick 96 PCR purification kit system is not sufficiently strong to remove all residual solution. Before eluting the PCR products with water, centrifuge the 96-column system at 3000 × g for 5 min using a 96-well plate holder in a low-speed centrifuge.

Sequence the SAGE library and analyze the SAGE tags

106. Sequence the PCR products in 96-well plates by sending them to a DNA sequencing facility or company that can directly sequence PCR products, or sequence in-house (see Support Protocol 6).

107. Extract SAGE tags from sequence files using the newest version of SAGE 2000 Software.

SAGE software is required in order to extract SAGE tag data and to generate quantitative information from the raw sequence data. A widely used software system for this purpose is

SAGE 2000, which is freely available for noncommercial use through a Material Transfer Agreement with Johns Hopkins University. Following the instructions for obtaining the software on the Web site http://www.sagenet.org. This software uses the Windows 2000 or Windows 98 operating system and requires the prior installation of Microsoft Access. An alternative SAGE software system is eSAGE, developed by Margulies and Innis (2000), which is also freely available for noncommercial use (the e-mail contact is ehm@umich.edu). This latter software uses the Windows 95/98 or NT version 4.0 operating system, and also requires the installation of Microsoft Access.

108. Identify transcripts using the NCBI SAGE tag database: *http://www.ncbi.nlm.nih.gov/SAGE.*

PHENOL-CHLOROFORM (PC8) EXTRACTION

SUPPORT PROTOCOL 2

The application of Phase Lock Gels as part of the SAGE procedure, for purification of the DNA after phenol extraction, significantly increases the purity and recovery of the DNA. If using a 50-ml tube, a centrifuge with a swinging-bucket rotor is recommended.

Materials

Phase Lock Gel Light (PLG; Eppendorf; purchased in 2- or 50-ml tubes)
DNA solution to be extracted
PC8 solution (see recipe)

1. Precentrifuge Phase Lock Gel Light tube without added sample immediately prior to use. If using a 2-ml tube, microcentrifuge 20 sec at maximum speed, room temperature; if using a 50-ml tube, centrifuge 1 min at 1500 × *g*, room temperature.
2. Add the sample and an equal volume of PC8 solution to the tube.
3. Shake to mix; e.g., by inverting the tube seven times.
4. If using 2-ml tubes, microcentrifuge 5 min at maximum speed, room temperature; if using 50-ml tubes, centrifuge 5 min at 1500 × *g*, room temperature, in a swinging-bucket rotor.
5. Transfer aqueous (top) layer to a new microcentrifuge tube using a pipet.

KINASING OF LINKERS

SUPPORT PROTOCOL 3

To ligate DNA with oligonucleotide linker, 5′ phosphorylation of the oligonucleotide linkers prior to ligation is necessary.

Materials

Linkers 1A, 1B, 2A, and 2B (see recipe)
LoTE buffer (see recipe)
10× kinase buffer (NEB)
10 mM ATP (NEB)
10 U/µl T4 polynucleotide kinase and 5× ligase buffer
6× Loading Dye Solution (Fermentas)
10-bp DNA ladder
12% polyacrylamide gel (see Support Protocol 5)
10 mg/ml ethidium bromide
1.5- to 1.7-ml RNAse/DNAse-free microcentrifuge tube (PGC Scientific or other supplier)
16°, 50°, and 65°C water baths or heating blocks

Additional reagents and equipment for polyacrylamide gel electrophoresis (see Support Protocol 5)

1. Dilute linkers 1A, 1B, 2A, and 2B to 350 ng/µl with water.
2. Prepare the following reaction mixes in two separate ~1.5-ml RNase/DNase-free microcentrifuge tubes:

   Tube 1:

   9 µl 350 ng/µl linker 1B
   6 µl LoTE buffer
   2 µl 10× kinase buffer
   2 µl 10 mM ATP
   1 µl 10 U/µl T4 polynucleotide kinase.

   Tube 2:

   9 µl 350 ng/µl linker 2B
   6 µl LoTE buffer
   2 µl 10× kinase buffer
   2 µl 10 mM ATP
   1 µl 10 U/µl T4 polynucleotide kinase.
3. Incubate at 37°C for 30 min.
4. Heat-inactivate at 65°C for 10 min.
5. Mix 9 µl of 350 ng/µl linker 1A with 20 µl of the kinased linker 1B (i.e., from the reaction mix in tube 1).

   The final concentration of both linker 1A and linker 1B should be 217.2 ng/µl.
6. Mix 9 µl of 350 ng/µl linker 2A with 20 µl of the kinased linker 2B (i.e., from the reaction mix in tube 2).

   The final concentration of both linker 2A and linker 2B should be 217.2 ng/µl.
7. Anneal linkers by heating as follows:

   95°C for 2 min
   65°C for 10 min
   37°C for 10 min
   Room temperature for 20 min.

   Store at –20°C.

   The result of the kinasing reaction will be "annealed linker 1" and "annealed linker 2," used in Basic Protocol 2.
8. Test effectiveness of the kinase reaction as follows.

   a. Prepare the following mixture in a sterile microcentrifuge tube on ice to self-ligate each annealed linker pair:

      1 µl 200 ng/µl linker 1 (annealed linker 1A and 1B, see step 5)
      1 µl 200 ng/µl linker 2 (annealed linker 2A and 2B, see step 6)
      5 µl LoTE buffer
      2 µl 5× ligase buffer.

   b. Complete the ligation reaction exactly as described in steps 14 to 16 of Basic Protocol 2.

c. Mix 5 µl of reaction with 1 µl of 6× Loading Dye Solution (LDS from Fermentas) and load on a 12% PAGE gel. Use a 10-bp DNA ladder to provide markers. Perform gel electrophoresis at 150 V for 1.5 to 2 hr (see Support Protocol 5). Stop electrophoresis when the bromphenol blue marker is 1 cm from the bottom of the gel.

d. Stain with ethidium bromide (use 1 µg/ml prepared by mixing 5 µl of 10 mg/ml ethidium bromide with 50 ml water).

e. Examine on a UV transilluminator for linker-linker dimers.

Kinased linkers should allow linker-linker dimers (80 to 100 bp) to form after ligation, while unkinased linkers will prevent self-ligation. Only linker pairs that self-ligate >70% should be used.

When linkers 1 and 2 are to be used at 15 ng/µl in steps 12 and 13 of Basic Protocol 2, 15 µl of each linker (200 ng/µl) are diluted with 185 µl of water.

GEL-SHIFT TEST FOR COMPLETE BIOTINYLATION OF BIOTIN-OLIGO dT

SUPPORT PROTOCOL 4

Biotinylated oligo(dT) primers synthesized by Integrated DNA Technology or by Invitrogen were used by the authors. Efficiency of binding to the streptavidin tube is an important factor for successfully constructing the T7-SAGE library and should be checked by investigators if they substitute another company's oligo(dT) primer.

Materials

Biotinylated oligo(dT) primer (custom-synthesized, e.g., by Integrated DNA Technologies or core facility; gel-purified)
1 µg/µl streptavidin
6× Loading Dye Solution (Fermentas)
100-bp DNA ladder
12% polyacrylamide gel (see Support Protocol 5)
10 mg/ml ethidium bromide

1. Prepare the following reaction mixes.

Tube 1:

2 µl 0.5 mg/ml biotinylated oligo(dT) primer
2 µl 1 µg/µl streptavidin
6 µl H_2O.

Tube 2 (negative control, no streptavidin):

2 µl 0.5 mg/ml biotinylated oligo(dT) primer
8 µl H_2O.

Tube 3 (negative control, no primer):

2 µl 1 µg/µl streptavidin
8 µl H_2O.

2. Incubate mixtures 15 min at room temperture.

3. Add 2 µl of 6× loading dye solution (LDS from Fermentas) to 5 µl of each reaction.

4. Load 6 µl of each reaction solution on a 12% PAGE gel. Use a 100-bp DNA ladder to provide markers. Perform gel electrophoresis at 150 V for 1.5 to 2 hr (see Support Protocol 5).

5. Stain with ethidium bromide (use 1 µg/ml prepared by mixing 5 µl of 10 mg/ml ethidium bromide with 50 ml of water). Examine on a UV transilluminator.

If the oligo dT is well-biotinylated, the entire band should be shifted to a single band of higher molecular weight, and this gel shift should occur only in the lane containing the streptavidin.

SUPPORT PROTOCOL 5

PREPARATION OF POLYACRYLAMIDE GELS USED IN SAGE ANALYSIS

Gels should be poured according to the following procedures before they are used in the respective protocols.

Materials

40% polyacrylamide (19:1 acrylamide:bis; Bio-Rad)
40% polyacrylamide (37.5:1 acrylamide:bis; Bio-Rad)
10× TAE buffer (*APPENDIX 2A*)
10% (w/v) ammonium persulfate (prepare fresh)
TEMED

XCELL II mini cell (Invitrogen)
Gel electrophoresis cassettes with 1.5 mm spacers (Invitrogen)
10-well combs (Invitrogen)
Power Pac 200 power source (Bio-Rad)

CAUTION: Refer to the manufacturer's instructions for electrophoresis conditions specific for the investigator's apparatus.

To prepare 12% PAGE gel (for purification of PCR products and ditags)

1a. Combine and gently mix (avoiding bubbles) the following reagents:

10.5 ml 40% polyacrylamide (19:1 acrylamide:bis)
20.7 ml H_2O
3.5 ml 10× TAE buffer
350 µl 10% ammonium persulfate
30 µl TEMED.

2a. Immediately pour into vertical gel apparatus (XCELL II mini cell) cassette with 1.5 mm spacers, or equivalent equipment. Add 10-well comb and allow gel to polymerize for at least 30 min.

To prepare 8% PAGE gel (for purification of concatemers)

1b. Combine and gently mix (avoiding bubbles) the following reagents:

7 ml 40% polyacrylamide (37.5:1 acrylamide:bis)
24.2 ml H_2O
3.5 ml 10× TAE buffer
350 µl 10% ammonium persulfate (make fresh)
30 µl TEMED.

2b. Immediately pour as described for 12% PAGE gel (step 2a).

DIRECT SEQUENCING USING A COMMERCIAL SEQUENCING KIT

If local arrangements can be made for direct sequencing of PCR products from the SAGE library after investigator preparation of samples for loading on an automated DNA sequencer, the following protocol using the ABI BigDye terminator sequencing system is recommended. This kit is suitable for performing fluorescence-based cycle sequencing reactions on PCR fragments using high-sensitivity dyes, e.g. 6-carboxyfluorescein (6-FAM).

Materials

ABI PRISM BigDye Terminator v3.0 Ready Reaction Cycle Sequencing Kit (Applied Biosystems)
30 ng/µl PCR product to be sequenced (>600 bp; see Basic Protocol 2)
1 pmol/µl M13 forward primer

Low-speed centrifuge with 96-well plate holder
System for PCR using 96-well plates (e.g., GeneAmp PCR system 9700, Applied Biosystems)
Centri-Sep 96 plate (Princeton Separations)
Automated DNA sequencer (e.g., ABI Prism 3100 genetic analyzer system, Applied Biosystems)

1. For each reaction to be sequenced, combine the following reagents in individual wells of a 96-well PCR plate:

   8 µl Terminator ready reaction mix from kit
   4 µl 30 ng/µl PCR product
   4 µl 1 pmol/µl M13 forward primer (1 pmol/µl)
   4 µl H_2O.

2. Mix well and centrifuge 1 min at 3000 × *g*, 4°C. using a 96-well plate holder in a low-speed centrifuge.

3. Perform PCR using the following cycling parameters.

25 cycles:	10 sec	96°C	(denaturation)
	5 sec	50°C	(annealing)
	4 min	60°C	(extension).

4. Perform a rapid thermal ramp down to 4°C and hold at that temperature until ready to purify.

5. Microcentrifuge briefly at maximum speed to bring down the contents of the tubes.

6. Transfer extension products to a Centri-Sep 96 plate using a multichannel pipet. Purify according to the manufacturer's instructions for the Centri-Sep plate.

7. For the library, cycle-sequence the concatemer inserts (PCR products) using an ABI Prism 3100 genetic analyzer system according to the manufacturer's instructions.

REAGENTS AND SOLUTIONS

*Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see **APPENDIX 2A**; for suppliers, see **SUPPLIERS APPENDIX**.*

Linkers

Linker 1A:
5′ TTT GGA TTT GCT GGT GCA GTA CAA CTA GGC TTA ATA GGG ACA TG 3′
Linker 1B:
5′ TCC CTA TTA AGC CTA GTT GTA CTG CAC CAG CAA ATC C [amino-modified C7] 3′
Linker 2A:
5′ TTT CTG CTC GAA TTC AAG CTT CTA ACG ATG TAC GGG GAC ATG 3′
Linker 2B:
5′ TCC CCG TAC ATC GTT AGA AGC TTG AAT TCG AGC AG [amino-modified C7] 3′

When purchasing the above oligonucleotides from a company that custom synthesizes oligonucleotides (the authors recommend Integrated DNA Technologies), or when submitting requests to a DNA synthesis core facility, the modifications described above must be communicated along with the sequence: i.e., for linkers 1B and 2B, a 3′ modification consisting of an amine moiety with a 7-carbon spacer. These oligonucleotides must be gel-purified; the investigator should request that this be done by the custom-synthesis company or core facility.

Amino-modified C7 is helpful to eliminate the native 3′-OH group from the oligo, which functionally blocks the oligo from participating as a primer in DNA synthesis, sequencing, or PCR (http://www.idtdna.com/program/techbulletins/amino.asp).

LoTE buffer

3 mM Tris·Cl, pH 7.5 (*APPENDIX 2A*)
0.2 mM EDTA, pH 7.5 (*APPENDIX 2A*)
Store at 4°C

PC8 solution

Combine the following in the order indicated:
480 ml phenol, prewarmed to 65°C
320 ml 0.5 M Tris·Cl, pH 8.0 (*APPENDIX 2A*)
640 ml chloroform

Shake and place at 4°C. After 2 to 3 hr, shake again. After another 2 to 3 hr, aspirate aqueous (top) layer. Divide into aliquots and store at −20°C.

PCR buffer, 10×

166 mM $(NH_4)_2SO_4$
670 mM Tris·Cl, pH 8.8 (*APPENDIX 2A*)
67 mM $MgCl_2$
100 mM 2-mercaptoethanol
Store at −20°C

SOC medium

0.5% yeast extract
2% tryptone
10 mM NaCl
2.5 mM KCl
10 mM $MgCl_2$
10 mM $MgSO_4$
20 mM glucose
Store at room temperature (stable for years)

Zeocin-containing low-salt LB plates

For 1 liter:
10 g tryptone
5 g yeast extract
5 g NaCl

Adjust the pH to 7.5 and add 15 g Bacto agar. Autoclave solution. Allow to cool to 50°C, then add Zeocin to 50 μg/ml and pour into 10-cm plates.

COMMENTARY

Background Information

In order to acquire reliable gene expression data from nanogram quantities of total RNA, this set of protocols optimizes amplification of low-abundance RNA samples by combining T7-based antisense RNA (aRNA) amplification (Van Gelder et al., 1990) with serial analysis of gene expression (SAGE). The T7 procedure yields up to 10^6-fold linear amplification of high-fidelity aRNA from very small amounts of total RNA and is applicable regardless of whether total RNA or poly(A)$^+$ RNA is used. The effectiveness and accuracy of T7 amplification has been confirmed in microarrays (Wang et al., 2000). Recently, this method has been applied to microarray analyses with laser-capture microdissected samples (Luo et al., 1999), generation of full-length cDNA libraries from a single prostate cancer–cell (Ying et al., 1999) and analysis of gene expression of single live neurons (Eberwine et al., 1992).

For T7 amplification, an RNA polymerase promoter is incorporated into each cDNA molecule by priming cDNA synthesis with a synthetic oligonucleotide containing the T7 RNA polymerase promoter. After synthesis of double-stranded cDNA (ds-cDNA), T7 RNA polymerase is added, and aRNA is transcribed from the cDNA template. The repetitive synthesis of multiple RNA molecules from a single cDNA template results in amplified aRNA, which serves as the starting material for synthesizing first-strand cDNA with reverse transcriptase using random primers.

This T7-SAGE protocol includes some modifications to increase the efficiency of the procedure. Biotinylated ds-cDNA (bds-cDNA) containing the T7 promoter, rather than plain ds-cDNA, is synthesized using a biotinylated primer in place of the usual T7 primer after two cycles of T7 amplification. As a result, bds-cDNA is synthesized from amplified aRNA, instead of poly(A)$^+$ RNA, using a biotinylated primer. Consequently, the product can be added directly after silica-gel membrane column purification to a streptavidin-coated tube in order to immobilize it for SAGE. This tube-based modification reduces losses of valuable material.

This technique synthesizes a broad range of sizes (~100 to 3000 bp) of double-stranded cDNA (bds-cDNA) of high purity. However, the *Nla*III enzyme used for subsequently making ditags is sensitive to different conditions. It has been observed that *Nla*III often digests DNA templates with low efficiency because of its short half-life, improper storage, or the sensitivity of this enzyme to the digestion conditions (Angelastro et al., 2000). In order to maximize the effectiveness of *Nla*III, the bds-cDNA for this protocol is purified by a silica-gel membrane column. The resulting 102-bp bands were clearer and easier to excise from the gel than in published microSAGE (Datson et al., 1999) and SAGE-Lite (Peters et al., 1999) procedures. In order to isolate and amplify very small quantities of samples in this SAGE procedure, the authors used the mRNA Capture Kit (Boehringer Mannheim) to carry out in single tubes the multiple steps of enzyme cleavage of cDNA, ligation of linkers to bound cDNA, and release of cDNA tags (Datson et al., 1999).

The use of tiny quantities of starting material demands an amplification step. The authors found that only two cycles of T7 amplification were necessary for 4 ng of starting material. In the original SAGE procedure, 25 to 28 cycles of PCR are performed to amplify the pool of ditags. Although this PCR step should be relatively free of bias because all ditags are of approximately equal length, preferential amplification of some ditags will occur and will increase the possibility of duplicate ditags (Datson et al., 1999). Because the possibility of duplicate ditags occurring by chance is generally very low, their presence is thought to be the result of nonrepresentative overamplification (van Kampen et al., 2000). The SAGE software counts each exclusive ditag combination only once, thereby removing duplicate ditags. However, the frequency of duplicate ditags, and of ditags that are too long or short, are good parameters for judging the accuracy of a SAGE

library (van Kampen et al., 2000). Two-step ditag PCR amplifications were found to yield large numbers of duplicate ditags (Peters et al., 1999) and the artifactual ditag 5′-TCCCCGTA-CANNNTTAATAGGGA-3′ (Datson et al., 1999). In recent testing of the present protocol, the resultant T7-SAGE library contained only 0.8% repeated ditags (25 duplicated ditags out of 2986 tags), in contrast with a miniSAGE library containing 4% (160 duplicated ditags out of 3838 tags; Ye et al., 2000). The authors' T7-SAGE results also compared favorably with previously reported results using SAGE-Lite and conventional SAGE: 8.6% (994 duplicated ditags out of 11,495 tags; Peters et al., 1999) and 8.3% (5726 duplicated ditags out of 68,691 tags; Velculescu et al., 1997), respectively. The reason that the frequency of duplicated ditags is lower with T7-SAGE and miniSAGE is most likely due to the elimination of additional PCR amplification. Moreover, besides having a lower rate of duplicate ditags, the T7-SAGE

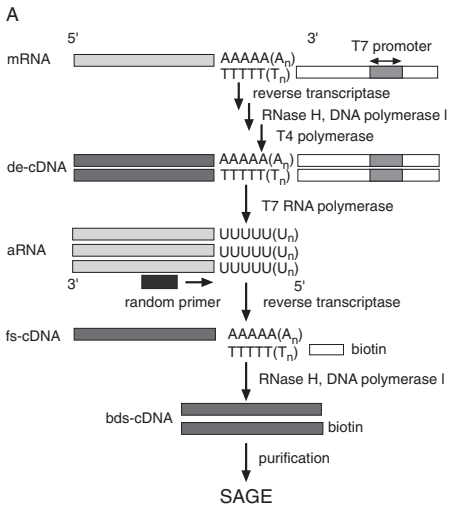

Figure 19.3.1 T7-based mRNA amplification and cDNA synthesis. (**A**) Schematic diagram of T7-based mRNA amplification. Modified from Van Gelder et al. (1990). Whole RNA is reverse-transcribed using a synthetic primer containing the T7 RNA polymerase binding site (sequences listed in Materials section of Basic Protocol 1). Second-strand cDNA synthesis to produce double-stranded (ds) cDNA is performed with *E. coli* DNA polymerase I and RNase H. After the cDNA is blunt-ended with T4 DNA polymerase, the cDNA is purified and transcribed with T7 RNA polymerase, yielding amplified antisense RNA (aRNA). These steps are repeated once to amplify the aRNA further. The amplified aRNA is reverse-transcribed using random primers to produce first-strand (fs) cDNA. Finally, biotinylated double-stranded (bds) cDNA is synthesized using a biotinylated oligo(dT) primer, *E. coli* DNA polymerase I, and RNase H, and then purified for SAGE. (**B**) Synthesis of biotinylated double-stranded (bds) cDNA from T7-amplified antisense RNA (aRNA). Input of total aRNA for the synthesis of bds cDNA is 4 nanograms, as indicated in Basic Protocol 1. This synthesis resulted in libraries of bds cDNA molecules that vary in length from ~100 to 3000 bp. Fragment sizes of the 100-bp DNA ladder are shown in bp.

library had no ditags that were too short, no ditags that were too long, and no other ditags indicative of artifacts.

Analysis of SAGE results is routinely performed using the NCBI SAGEtag database. Ongoing database additions continue to increase its value for the analysis of SAGE tags, and cDNA sequence data from RIKEN, NCI, and other sources should continue to promote SAGE research and to facilitate the identification of novel genes. Commercial databases using SAGE may also prove useful (e.g., Celera).

In conclusion, this T7-SAGE procedure, a new modification of SAGE, can be utilized in studies where mRNA is extremely limited. However, it is also effective for larger amounts of RNA, from which a 4- to 5-ng aliquot can be used. However, if large amounts of RNA are available, standard SAGE without amplification is recommended. Because studies of gene expression generally require confirmation of initial findings by independent methods such as RT-PCR and Northern blot analysis, any remaining RNA not used for this protocol can be saved for such additional analyses. Although

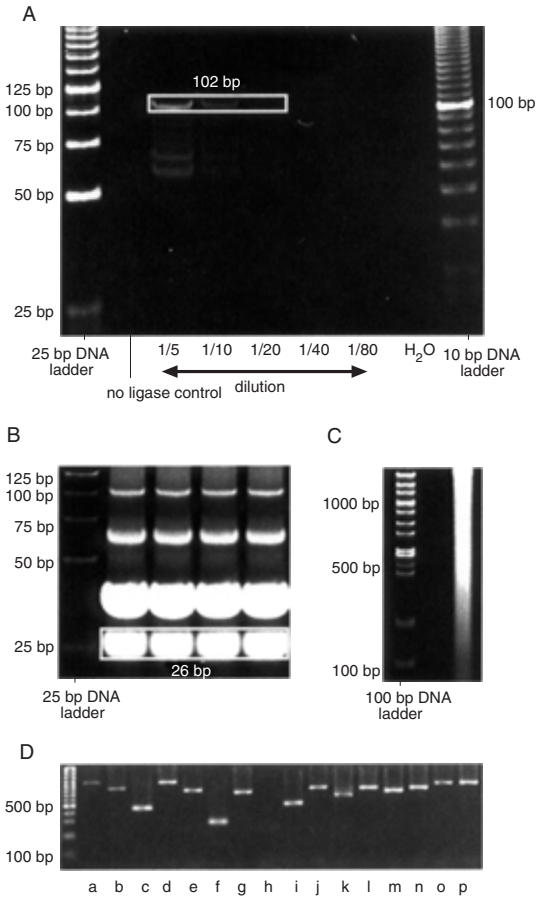

Figure 19.3.2 Selected steps of the SAGE procedure. (**A**) Linked SAGE ditags generated by T7-SAGE and separated on a 12% polyacrylamide gel. The 102-bp bands corresponding to amplified linked SAGE ditags are indicated by the rectangle. Shown after 28 PCR cycles are the no-ligase control, 1/5, 1/10, 1/20, 1/40 and 1/80 dilutions of the linked SAGE ditags, and the negative H_2O control (lanes 2-8), respectively. Lane 1, 25-bp DNA ladder. Lane 9, 10-bp DNA ladder. (**B**) SAGE ditags digested by *Nla*III and separated on a 12% polyacrylamide gel. Clear 26-bp bands (SAGE ditags), 40-bp bands (linkers) and 60- to 102-bp bands (products with incomplete *Nla*III digestion) should be observed. Fragment sizes of the 25-bp DNA ladder are shown in bp. (**C**) SAGE concatemer separated on an 8% polyacrylamide gel. A smear from ~100 bp to >1 kb should be observed. Fragment sizes of the 100-bp DNA ladder are shown in bp. (**D**) Example of sizes of inserts present in the T7-SAGE library. An insert of >300 bp (>500 bp band) will be contained in most of the clones (lanes a, b, d, e, g, and i to p). Lanes c and f contain small inserts. A 226-bp band indicates no insert (not shown). Fragment sizes of the 100-bp DNA ladder are shown in bp.

the authors have used T7-SAGE for global analysis of gene expression using only 4 ng of total RNA, they expect that the amount of starting material can be decreased further, perhaps down to a single cell. Microscale applications of SAGE such as this T7-SAGE method should help to broaden its future applications in studies of gene expression.

Critical Parameters and Troubleshooting

RNA preparation

It is essential to start with a clean preparation of RNA that is free of any salts or other substances that might inhibit reverse transcription. Successful RNA isolation from minute tissue samples depends on the complete elimination of ribonucleases. RNA and antisense RNA (aRNA) should be checked for intactness on a denaturing gel before cDNA synthesis if the investigator has sufficient RNA, or especially aRNA.

Purity of oligonucleotides

The quality of the primers is crucial to the success of the procedure. Where indicated (see materials lists of respective protocols), primers should be gel-purified, e.g., by the custom synthesis company from which they are purchased.

Production of 102-bp ditag-containing PCR products

Possible pitfalls in the synthesis of the 102-bp ditags include the following possible problems.

1. The cDNA was of poor quality or there were insufficient amounts. Check cDNA quality by gel electrophoresis and PCR. Check the extent of linker kinasing by self-ligation (see Support Protocol 3) and the extent of biotinylation of the oligo dT by a biotin gel shift test (see Support Protocol 4).

2. The protocols were not followed in exact detail. Because specific conditions in the protocol have been optimized, they should be followed as precisely as possible. For example, use the exact PCR sample sizes, buffers, and cycle temperatures described in the protocol.

3. Some reagent(s) were not of adequate quality. Obtain fresh reagents from the recommended companies.

4. The concentration of dNTPs was too high in the 102-bp PCR amplification. Although adding more dNTPs can increase amounts of PCR product, slightly exceeding a threshold can cause a paradoxical loss of the PCR product. Because of lot-to-lot variations in dNTP concentration, dNTPs should be titrated in a preliminary test before doing the large-scale preparation, e.g., starting with the lowest dNTP concentration of 0.5 mM.

NlaIII digestion of 102-bp ditag-containing PCR products

There are several reasons why the *Nla*III digestion may yield poor results.

1. The *Nla*III was not sufficiently active. *Nla*III should be stored in aliquots at −80°C, which helps to prolong its activity. Make sure the enzyme is fresh, since its half-life is only a few months even under optimal conditions. If the *Nla*III is less active and/or there are high yields of PCR product, more enzyme may be needed.

2. There was exonuclease contamination. The CATG cutting site of the PCR product may be missing because of exonuclease contamination or activity, e.g., from the DNA polymerase I. Phenol extractions and the use of Phase Lock Gel (PLG) is recommended to remove enzymes completely.

3. There were other interfering contaminants. The gel-purified 102-bp ditag preparation can be further purified by gel filtration before *Nla*III digestion as described by Angelastro et al. (2000).

Generation of large concatemers

Formation of sufficiently large concatemers depends on having sufficient amounts and purity of the ditags, as well as good ligation.

1. Problems can be caused by insufficient quantities of ditags present in the ligation reaction. The PCR protocol specified in the basic T7-SAGE protocol routinely uses 192 to 288 50-µl PCR reactions to ensure efficient production of 10 to 20 µg of 102-bp ditags. If a lower quantity of ditags is found, the safest course is to repeat the process to obtain at least 10 µg of ditags in order to ensure sufficient quantities for the *Nla*III digestion, so that enough 26-bp ditags are available for the ligation step to form concatemers.

2. The 26-bp ditags appear to degrade easily and should be kept at 4°C and in high-salt buffer at all times to prevent loss.

3. The 26-bp bands in gels are purified away from contaminating linkers by cutting them out with a razor blade. The cuts should be as close as possible to the bands to reduce contamination by materials of slightly different size, especially linkers, which interfere with the ligation reaction.

4. If linker contamination still appears to be causing poor concatemer formation, biotin-la-

beled primers can be substituted for primers 1 and 2 and then removed by binding to streptavidin beads (Powell, 1998).

Anticipated Results

Amplification of mRNA

The T7-based RNA amplification method (Fig. 19.3.1A) should be able to amplify the starting mRNA by ~1000-fold with one cycle (Luo et al., 1999). Theoretically, from 1 ng of total RNA containing roughly 1% mRNA (~10 pg), one mg of antisense RNA (aRNA) can be obtained after 2 cycles of T7 amplification. A clearly visible but smeared band (representing a range of RNA sizes) of amplified aRNA should be seen after running the sample on a gel.

Synthesis of biotinylated double-stranded (bds)-cDNA from aRNA

This synthesis should also result in a clearly visible but smeared zone of bds-cDNA molecules after running the sample on a gel; the bds-cDNA varies in length from ~100 to 3000 bp (Fig. 19.3.1B).

Synthesis of SAGE ditags (102 bp)

The102-bp bands corresponding to amplified linked SAGE ditags should be clearly visible for excision and purification away from several other background bands (Fig. 19.3.2A). In the large-scale PCR amplification step using 96-well plates, 192 to 288 50-µl PCR reactions are routinely performed. After pooling, this generates a total of 10 to 20 µg ditags (see Basic Protocol 2, step 65).

NlaIII digestion of SAGE ditags

The 26-bp band corresponding to SAGE ditags without linker should be visible for purification away from other background bands (Fig. 19.3.2B). If the 26-bp band cannot be seen clearly, the investigator should confirm the efficiency of the *Nla*III enzymatic reaction (see Troubleshooting above) and consider the possibility of degradation of ditags. The ditags occasionally melt in the presence of low salt, especially if the temperature rises above room temperature or if the DNA pellets are allowed to dry, although the ditags are stable in the presence of high salt. Therefore, subsequent procedures in Basic Protocol 2, such as, step 72, the overnight incubation in step 75, and then step 76, are performed under cold conditions, before the samples are placed in the high-salt TAE gel buffer. In addition, pellets are resuspended in TE instead of LoTE buffer.

Formation of SAGE concatemer

A clear high-molecular-weight smear above 400 bp should be visible in the gel (Fig. 19.3.2C). If the investigator cannot see evidence of these large concatemers, linker contamination or insufficient initial quantities of ditags are likely causes (see Critical Parameters and Troubleshooting).

The size of inserts present in the T7-SAGE library

An insert of >300 bp (>500-bp band) should be visible in most of the clones (Fig. 19.3.2D). A 226-bp band indicates the absence of any insert (negative control).

Time Considerations

In Basic Protocol 1, the entire procedure of T7-based RNA amplification, from steps 1 to 44, will require several days. In the Alternate Protocol, the procedure of T7-based RNA amplification using the RiboAmp kit from Arcturus will also require several days.

In Basic Protocol 2, the SAGE procedure from steps 1 to 105, can take several weeks, depending on the number of tags. Sequencing clones and analysis of sequence data, from steps 106 to 108, can require several weeks to months, depending on the number of tags and the efficiency of the sequencing facilities used.

In Support Protocol 1, RNA extraction takes about 1 hr, depending on the type of kit used. In Support Protocol 2, PC8 extraction requires about 30 min. In Support Protocol 3, the kinasing reaction for linkers takes about 4 hr. In Support Protocol 4, testing biotinylation of biotin-oligo dT requires about 3 hr. Support Protocol 5 takes 1 hr, and Support Protocol 6 takes 12 hr.

SAGE Analysis from 1 µg of Total RNA

Serial analysis of gene expression (SAGE; Velculescu et al., 1995; also see *UNIT 19.3*) is a powerful transcription-profiling method that allows simultaneous expression analysis of thousands of transcripts, provides absolute digital readout of the expression level, and identifies new genes. A disadvantage of SAGE is the relatively high amount of input RNA required. Consequently, several techniques have been developed to overcome this limitation, so that SAGE can be applied to very limited amounts of starting material, e.g., small biological samples such as tissue biopsies or microdissected materials. Here we describe a modified version of the original microSAGE protocol (Datson et al., 1999; also see *http://www.sagenet.org*), which requires only 1 to 2 µg total RNA. This method avoids PCR amplification of cDNA (Peters et al., 1999; Neilson et al., 2000) and reamplification of ditags (Datson et al., 1999; Virlon et al., 1999), procedures which potentially compromise the quantitative nature of this technique. Compared with conventional SAGE, this modified microSAGE protocol has several advantages: (1) reduction of material loss between steps with the use of a "single-tube" procedure for all steps from RNA isolation to tag release; (2) increase in the reaction efficiency with the use of Dynal magnetic beads instead of streptavidin-coated PCR tubes to ensure uniform surface contact; and (3) increase in the recovery and purity of the cDNA with the use of Phase Lock Gel for optimizing phase separation in the several steps that involve phenol extraction.

CONSTRUCTION OF SAGE LIBRARY FROM 1 µg OF TOTAL RNA

BASIC PROTOCOL

The protocol described here is suitable for creating a SAGE library from 1 to 2 µg of total RNA; for less starting material, refer to *UNIT 19.3*. After isolation of polyadenylated RNA using Dynabeads, the procedure includes the following operations: reverse transcription of mRNA into cDNA, digestion with *Nla*III to form one end of the tags, ligation with linkers 1 and 2, cleavage with *Bsm*FI, filling in 5′ overhangs, and PCR amplification with ditag primers 1 and 2. To complete construction of the library, release of 26-bp ditags, ligation of ditags to form concatemers, cloning into pZERO vector, and sequencing are then performed as in *UNIT 19.3*, Basic Protocol 2.

Materials

1 to 2 µg of total RNA from tissues or cells
DEPC-treated H_2O (*APPENDIX 2A*)
Dynabeads mRNA Purification Kit (Dynal) including:
  Oligo$(dT)_{25}$ beads
  Binding buffer
  Washing buffer B
1× first-strand/glycogen buffer (see recipe)
Superscript Choice System for cDNA Synthesis kit (Invitrogen), including:
  5× first-strand reaction buffer
  0.1 M dithiothreitol (DTT)
  10 mM dNTP mix (10 mM each dATP, dCTP, dGTP, dTTP)
  SuperScript II reverse transcriptase
  40 U/µl RNaseOUT recombinant ribonuclease inhibitor
  5× second-strand reaction buffer
  10 U/µl *E. coli* DNA polymerase I
  10 U/µl *E. coli* DNA ligase
  2 U/µl *E. coli* RNase H
  1 U/µl T4 DNA polymerase
0.5 M EDTA, pH 7.5 (*APPENDIX 2A*)

Contributed by Jerry Cai, David Ash, and Ethylin Wang Jabs
Current Protocols in Cell Biology (2002) 19.4.1-19.4.10

1× B&W/SDS/glycogen buffer (see recipe)
1× B&W/BSA buffer (see recipe)
1× NEBuffer 4/BSA solution (see recipe)
LoTE buffer (*UNIT 19.3*)
100× (10 µg/µl) BSA (New England Biolabs; supplied with corresponding restriction enzymes)
10× NEBuffer 4 (New England Biolabs; supplied with corresponding restriction enzymes)
10 U/µl restriction endonuclease *Nla*III (New England Biolabs)
5 U/µl T4 DNA ligase and 10× ligase buffer (Invitrogen)
Annealed linker 1 and annealed linker 2 (see *UNIT 19.3*, Support Protocol 3)
7.5 M ammonium acetate
20 µg/µl glycogen
70% and 100% ethanol
10 U/µl Klenow fragment of DNA polymerase (Amersham Pharmacia Biotech or USB)
Platinum *Taq* DNA polymerase (Invitrogen) and 10× PCR buffer

16°, 50°, 65°, and 75°C water baths or heating blocks
Safe-Lock tubes (Eppendorf) or microcentrifuge tubes
Magnetic Particle Collector (MPC; Dynal, cat. no. 120.20)
Sample mixer (Dynal, cat. no. 947.01)
8-well PCR strips, sterile (USA Scientific)
Thermal cycler

Additional reagents and equipment for PCR (*APPENDIX 3F*) and constructing a SAGE library (see *UNIT 19.3*, Basic Protocol 2)

Isolate polyadenylated RNA

1. Suspend 1 to 2 µg total RNA in a final volume of 100 µl DEPC-treated water in a Safe-Lock or microcentrifuge tube.
2. Heat 2 min at 65°C to disrupt secondary structure. Place on ice.
3. Resuspend Dynabeads oligo$(dT)_{25}$ beads provided in the mRNA Purification Kit by vortexing.
4. Add 100 µl of the resuspended oligo$(dT)_{25}$ beads to a new Safe-Lock or microcentrifuge tube. Put on magnetic particle collector (MPC) for 30 sec, then remove the supernatant solution.
5. Resuspend the beads in 100 µl binding buffer from the Dynabeads kit. Put on MPC for 30 sec, then remove the solution.
6. Add 100 µl binding buffer and the RNA solution from step 2 to the beads, for a total volume of 200 µl in the tube.
7. Rotate on the sample mixer for 3 to 5 min at room temperature to allow hybridization of poly$(A)^+$ RNA to the oligo$(dT)_{25}$ which is immobilized on the beads. Put on MPC for 30 sec, then remove supernatant.
8. Gently wash beads twice, each time by adding 200 µl washing buffer B (provided with the kit) to the beads, then placing the tube on the MPC for 2 min and removing the solution.

Synthesize cDNA with SuperScript Choice kit

9. Wash beads four times with 100 µl 1× first-strand/glycogen buffer using the technique described in step 8.

10. Add the following reagents (provided in the SuperScript kit) to the tube:

    8 µl 5× first strand reaction buffer (directly from kit; no glycogen)
    4 µl 0.1 mM DTT
    2 µl 10 mM dNTP mix
    24 µl DEPC-treated H_2O.

11. Mix the contents by gently vortexing and collect the reaction at the bottom of the tube by microcentrifuging for 3 sec at maximum speed. Incubate 2 min at 37°C.

12. Add 2 µl SuperScript II reverse transcriptase. Incubate 1 hr at 37°C with gentle vortexing every 10 to 15 min, then place on ice to terminate the reaction.

13. Add the following reagents to the tubes:

    40 µl first-strand reaction buffer
    60 µl 5× second-strand reaction buffer
    182 µl DEPC-treated H_2O
    6 µl 10 mM dNTP mix
    2 µl 10 U/µl *E.coli* DNA ligase
    8 µl 10 U/µl *E.coli* DNA polymerase I
    2 µl 2 U/µl *E.coli* RNase H.

14. Mix the contents of the tube by gently vortexing, then collect the reaction at the bottom of the tube by microcentrifuging briefly at maximum speed. Incubate at 16°C for 2 hr, vortexing gently every 10 to 15 min.

15. Add 4 µl 1 U/µl T4 DNA polymerase. Incubate 5 min at 16°C.

16. Add 20 µl 0.5 M EDTA, pH 7.5, to terminate the reaction.

Wash the beads

17. Add 300 µl of 1× B&W/SDS/glycogen buffer, then heat at 75°C for 10 min.

18. Put on MPC for 30 sec, then remove the supernatant. Add 300 µl of 1× B&W/SDS/glycogen buffer, resuspend by vortexing, then put on MPC for 30 sec. Remove the supernatant.

19. Wash beads four times with 300 µl of 1× B&W/BSA buffer using the technique described in step 8.

Cleave the cDNA with anchoring enzyme NlaIII

20. Wash the beads with the bound ds cDNA in the Safe-Lock tube or microcentrifuge tube once with 200 µl of NEBuffer 4/BSA solution using the technique described in step 8.

21. Add the following reagents to the tube:

    173 µl LoTE buffer
    2 µl 100× (10 µg/µl) BSA
    20 µl 10× NEBuffer 4
    5 µl 10 U/µl *Nla*III.

22. Mix by vortexing gently, making sure to avoid bubbles. Collect the reaction in the bottom of the tube by microcentrifuging briefly at maximum speed, then incubate at 37°C for 1 hr, vortexing gently every 10 to 15 min.

23. Inactivate *Nla*III by washing the beads twice with 750 µl 1× B&W/SDS/glycogen buffer using the technique described in step 8. Wash an additional four times with 750 µl 1× B&W/BSA buffer in the same manner.

24. Add 150 µl of 1× T4 DNA ligase buffer and mix by vortexing. Put on MPC for 30 sec, then remove the supernatant.

25. Add 150 µl of 1× T4 DNA ligase buffer. Resuspend by vortexing. Split into two new Safe-Lock or microcentrifuge tubes, each of which should contain 75 µl solution with beads. Label these tube 1 and tube 2.

Ligate linkers to the bound cDNA

26. Put the two tubes prepared in step 25 on the MPC for 30 sec, then remove the supernatants.

27. Add the following to tube 1 and tube 2, respectively:

    Tube 1:
    13 µl LoTE buffer
    2 µl annealed linker 1
    4 µl 5× T4 DNA ligase buffer.

    Tube 2:
    13 µl LoTE buffer
    2 µl annealed linker 2
    4 µl 5× T4 DNA ligase buffer.

    Mix each tube, then heat 2 min at 50°C, and let stand 15 min at room temperature.

28. Add 1 µl of 5 U/µl T4 DNA ligase to each of the tubes, and mix. Incubate 2 hr at 16°C, vortexing gently every 10 to 15 min.

29. Wash beads five times, each time with 50 µl of 1× B&W/BSA buffer, using the technique described in step 8.

Release cDNA with the tagging enzyme BsmFI

30. Wash each tube twice, each time with 200 µl of 1× NEBuffer 4/BSA solution, using the technique described in step 8.

31. Add the following to each of the tubes:

    86 µl LoTE buffer
    10 µl 10× NEBuffer 4
    2 µl 100× (10 µg/µl) BSA
    2 µl 2 U/µl *Bsm*FI.

    Mix each of the reactions by vortexing gently and collect at the bottoms of the tubes by microcentrifuging briefly at maximum speed. Incubate at 65°C for 2 hr.

32. Put the tubes on the MPC for 2 min. Collect and retain the supernatants in separate tubes.

33. Wash beads in each tube twice with 50 µl LoTE buffer, using the technique described in step 8. Pool washings with the corresponding supernatants from step 32.

    Each tube should now contain 100 + (2 × 50) = 200 µl of solution.

34. Perform phenol/chloroform/isoamyl alcohol extraction on supernatants from each tube using Phase Lock Gel Heavy (see Support Protocol).

35. Ethanol precipitate by adding the following:

    133 µl 7.5 M ammonium acetate
    3 µl 20 µg/µl glycogen
    1000 µl 100% ethanol.

    Mix well and place on dry ice for 10 to 20 min. Microcentrifuge 30 min at maximum speed, 4°C, then carefully remove and discard the supernatants without disturbing the pellets.

36. Wash each pellet twice, each time by adding 200 µl of 70% ethanol down the wall of the tube with a micropipet, taking care to avoid disrupting the pellet, then decanting slowly. After the final wash, microcentrifuge briefly at maximum speed to collect residual ethanol. Remove all of the ethanol with a micropipet and air dry the pellets for 5 to 10 min. Resuspend each of the two pellets in 10 µl LoTE buffer.

Blunt-end the linked SAGE tags

37. Add the following reagents to tubes 1 and 2 containing 10 µl linked SAGE tags:

    10 µl 5× second-strand buffer (from SuperScript kit)
    1 µl 100× (10 µg/µl) BSA
    2.5 µl 10 mM dNTP mix
    23.5 µl H_2O
    3 µl 10 U/µl Klenow fragment of DNA polymerase.

    Incubate at 37°C for 30 min.

38. Adjust the volume in each tube to 200 µl by adding LoTE buffer, then combine the solutions in both tubes (for a total of 400 µl solution). Mix well and split into two new tubes labeled "+Ligase" and "–Ligase," each containing 200 µl solution.

39. Perform phenol/chloroform/isoamyl alcohol extraction on each of the solutions using 200 µl Phase Lock Gel Heavy (see Support Protocol). Ethanol precipitate the DNA from each of the tubes as in steps 35 to 36, then resuspend each pellet in 4 µl LoTE.

Ligate the linked SAGE tags to form linked ditags

40. Prepare the following two reaction mixes as follows:

    +Ligase:

    4 µl resuspended DNA from "+Ligase" sample (step 39)
    1.2 µl 5× T4 DNA ligase buffer
    0.8 µl 5 U/µl T4 DNA ligase.

    –Ligase:

    4 µl resuspended DNA from "–Ligase" sample (step 39)
    1.2 µl 5× T4 DNA ligase buffer
    0.8 µl H_2O.

    Mix each of the reactions and incubate at 16°C overnight.

41. After ligation, add 14 µl LoTE buffer to each of the reaction mixtures to raise the final volume to 20 µl.

PCR amplify ditags

42. Dilute the following samples (from step 41) with sterile water as follows:

    "–Ligase" (control) to 1/5 (1 µl sample + 4 µl H_2O).
    "+Ligase" (ligation product) to 1/5, 1/20, 1/50, 1/100, 1/200, 1/400.

43. Set up 8 PCR reactions using a sterile 8-well PCR strip as follows:

    Positions 1 to 6: Different dilutions of the template ("+ligase"; step 42)
    Position 7: No-ligase ("–ligase") control
    Position 8: H_2O control.

44. To each well add the following:

    5 µl 10× PCR Buffer (supplied with Platinum *Taq* polymerase)
    1 µl 10 mM dNTP mix
    1.5 µl 50 mM $MgCl_2$
    1 µl 350 ng/µl primer 1 (*UNIT 19.3*)
    1 µl 350 ng/µl primer 2 (*UNIT 19.3*)
    38.5 µl H_2O
    1 µl Platinum *Taq* DNA polymerase
    1 µl ligation product (at various dilutions) or control (see step 43).

45. Mix and amplify using the following cycle conditions:

1 cycle:	4 min	95°C	(denaturation)
26-30 cycles:	30 sec	95°C	(denaturation)
	1 min	55°C	(annealing)
	1 min	72°C	(extension)
1 cycle:	4 min	72°C	(final extension).

46. Pick the lowest dilution of template that gives a clear 102-bp PCR product.

    The optimum PCR conditions are critical for isolating adequate DNA for SAGE. Using too few cycles or a substrate that is too diluted will result in a low yield, which may cause problems in the subsequent steps. Too many cycles or a substrate that is too concentrated will give erratic results. Therefore, it is very important to pick the right parameters to do large-scale PCR.

47. Using the PCR conditions in step 45 and the dilution identified in step 46, perform several hundred PCR reactions.

    Usually 384 reactions are performed in four 96-well plates to generate 10 to 20 µg DNA.

48. Complete the construction of the SAGE library continuing with step 43 of Basic Protocol 2 in *UNIT 19.3* ("Isolating Linked Ditags").

SUPPORT PROTOCOL

PCI EXTRACTION

Phase-Lock Gel will form a semisolid barrier, so one can extract the aqueous layer without contacting the organic phase. The advantage to using Phase-Lock Gel over the standard phenol/chloroform/isoamyl alcohol extraction is that it saves time while optimizing the recovery of DNA.

Materials

DNA solution to be extracted
25:24:1 (v/v/v) phenol/chloroform/isoamyl alcohol solution (PCI; Invitrogen)
Phase-Lock Gel Heavy in 2-ml tubes (Eppendorf)

1. Microcentrifuge the 2-ml Phase-Lock Gel Heavy tube for 1 min at maximum speed without added sample.
2. Add the sample and an equal volume of PCI solution to the tube.
3. Shake to mix.
4. Microcentrifuge 5 min at maximum speed.
5. Transfer the top aqueous phase to a new microcentrifuge tube using a pipet.

SUBSTITUTING *Hsp*92II FOR *Nla*III AS THE ANCHORING ENZYME

ALTERNATE PROTOCOL

The anchoring enzyme *Nla*III is used, but it is very unstable, even at −80°C. *Hsp*92II has the same recognition and cut site, 5′-CATG-3′, as *Nla*III, so it can also be used as an anchoring enzyme.

Additional Materials *(also see Basic Protocol)*

10 U/µl restriction endonuclease *Hsp*92II (Promega)
100× BSA and 10× buffer K (provided with *Hsp*92II)

1. Isolate polyadenylated RNA and synthesize cDNA with SuperScript system (see Basic Protocol, steps 1 to 19).
2. Wash the beads with the bound ds cDNA in the Safe-Lock or microcentrifuge tube from step 19 of the Basic Protocol once with 200 µl of 1× NEBuffer 4/BSA solution, using the washing technique described in step 8 of the Basic Protocol.
3. Add the following reagents to the tube:

   173 µl LoTE buffer
   2 µl 100× BSA
   20 µl 10× Buffer K
   5 µl 10 U/µl *Hsp*92II.

4. Mix by vortexing gently, making sure to avoid bubbles. Collect the reaction in the bottom of the tube by microcentrifuging briefly at maximum speed, then incubate at 37°C for 1 hr, vortexing gently every 10 to 15 min.
5. Inactivate *Hsp*92II by washing twice with 750 µl 1× B&W/SDS/glycogen buffer using the washing technique described in step 8 of the Basic Protocol, then wash an additional four times with 750 µl 1× B&W/BSA buffer in the same manner.
6. Continue with the SAGE procedure (see Basic Protocol, steps 24 to 48).

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

B&W/BSA buffer, 1×

To prepare 4 ml, mix the following:
2 ml 2× B&W buffer (see recipe)
40 µl 100× (10 µg/µl) BSA (New England Biolabs; provided with the restriction enzymes)
1.96 ml H_2O
Store up to 1 week at 4°C

B&W buffer, 2×

To prepare 10 ml, mix the following:
100 µl 1 M Tris·Cl, pH 7.5 (*APPENDIX 2A*)
20 µl 0.5 M EDTA, pH 7.5 (*APPENDIX 2A*)
4 ml 5 M NaCl (*APPENDIX 2A*)
5.88 ml H_2O
Store up to 1 week at room temperature

B&W/SDS/glycogen buffer, 1×

To prepare 3 ml, mix the following:
1.5 ml 2× B&W buffer (see recipe)
30 µl 1 µg/µl glycogen
300 µl 10% (w/v) SDS
1.17 ml H_2O
Prepare fresh just prior to use

First strand/glycogen buffer, 1×

To prepare 500 µl, mix the following:
100 µl 5× first-strand buffer (Invitrogen; provided with the SuperScript II kit)
5 µl 1 µg/µl glycogen (prepare with DEPC-treated H_2O; store at 4°C)
395 µl DEPC-treated H_2O (*APPENDIX 2A,* or provided with SuperScript II kit)
Store up to 1 week at 4°C

NEBuffer 4/BSA solution, 1×

To prepare 2 ml, mix the following:
200 µl 10× NEBuffer 4 (New England Biolabs)
20 µl 100× (10 µg/µl) BSA (New England Biolabs; provided with restriction enzymes)
1.78 ml H_2O
Store up to 1 week at 4°C

COMMENTARY

Background Information

The Basic Protocol in this unit optimizes the construction of a SAGE library from 1 µg of total RNA by combining Dynabeads mRNA isolation with SAGE. Preparation of high-quality and full-length mRNA is essential for gene-expression studies. Dynabeads Oligo$(dT)_{25}$ was chosen in the protocol to isolate poly$(A)^+$ RNA from total RNA. The isolation protocol relies on the base pairing between the poly(A) residues at the 3′ end of mRNA and the oligo (dT) residues covalently coupled to the surface of the Dynabeads. The unique paramagnetic properties of Dynabeads facilitate easy and efficient handling, while also reducing the requirement for centrifugation and precipitation steps, thereby significantly increasing yield. Using a solid phase enables all procedures to be conducted in a single tube and ensures that losses caused by multiple sample manipulations are minimized. This is particularly important in this protocol, since the starting total RNA is only 1 to 2 µg, and the detection of low-abundance transcripts is desired. The true spherical shape and the hydrophilic surface of the Dynabeads Oligo$(dT)_{25}$ also eliminates clumping and nonspecific binding associated with irregularly shaped particles, achieving uniformity of the reaction. The isolated mRNA can then be reverse transcribed to double-stranded cDNA and subjected to the standard SAGE procedure (also see *http://www.sage-net.org*).

It is well known that *Nla*III is very unstable even at −80°C. *Nla*III often digests DNA with low efficiency because it is very sensitive to digestion conditions. Recently the authors switched to *Hsp*92II, which is an isoschizomer of *Nla*III, but has a long half-life and is not very sensitive to digestion conditions. The resulting digestion (see Alternate Protocol) is improved and more consistent, giving a better yield of SAGE tags.

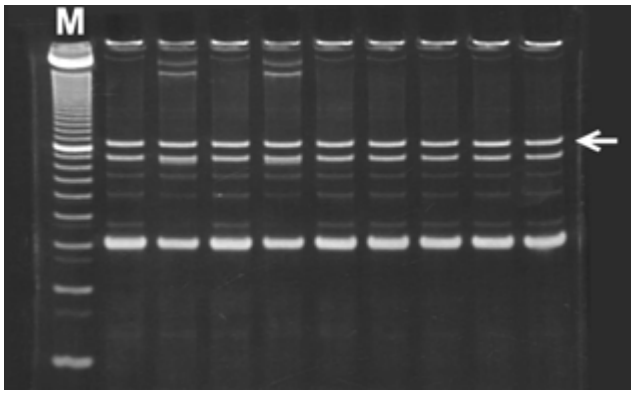

Figure 19.4.1 Linked SAGE ditags from large-scale PCR amplification are separated on a 12% polyacrylamide gel. The 102-bp bands corresponding to the linked SAGE ditags are indicated by an arrow. Lane M, 10-bp DNA ladder.

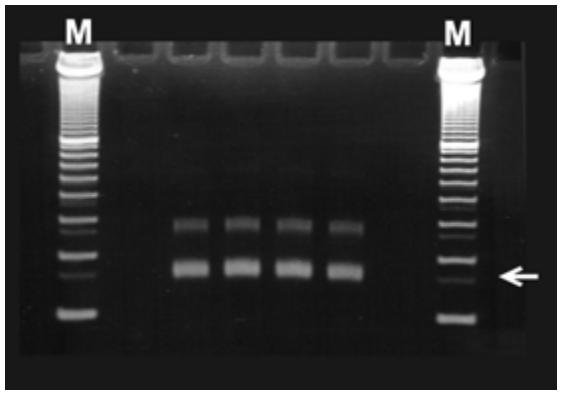

Figure 19.4.2 SAGE ditags digested by *Nla*III are separated on a 12% polyacrylamide gel. The 26-bp bands corresponding to the SAGE ditags without linkers are indicated by an arrow. The other bands (around 40-bp) are linkers. Lane M, 10-bp DNA ladder.

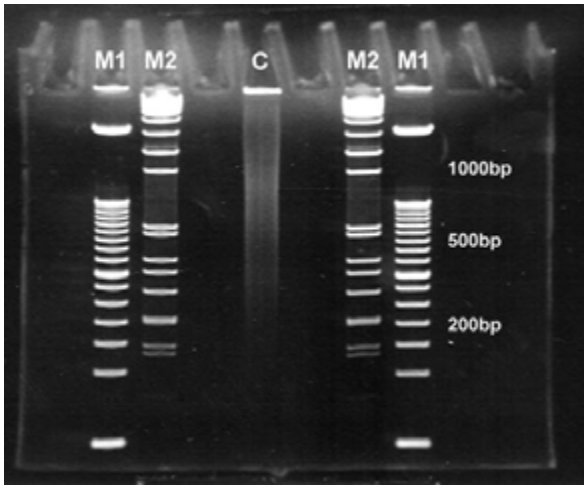

Figure 19.4.3 SAGE concatemers are separated on an 8% polyacrylamide gel. The concatemers appear as a smear in the lane indicated by C. Lane M1, 50-bp DNA ladder; lane M2, 1-kb DNA ladder.

Readers should also see the Commentary in *UNIT 19.3* to get more background information about SAGE.

Critical Parameters and Troubleshooting

RNA preparation

RNA quality is very critical to the success of the SAGE protocol. A high-quality RNA preparation without DNA contamination, salt, or other substances that might inhibit enzymatic activities is desired. If there is sufficient RNA, the integrity of the RNA should be checked on a denaturing RNA gel before the experiment.

mRNA isolation and cDNA synthesis

Isolation of mRNA is performed with the Dynabeads mRNA isolation kit. Since the beads tend to precipitate to the bottom, it is necessary to mix the solution from time to time during the incubation period by hand vortexing (flicking the bottom of the tube with one's finger) to ensure the uniformity of bead suspension.

Also see the Critical Parameters and Troubleshooting section in *UNIT 19.3* for more information.

Anticipated Results

Synthesis of 102-bp SAGE ditags

Figure 19.4.1 shows the typical result after large-scale PCR reaction. The 102-bp bands of linker SAGE ditags should be clearly visible for purification. This step usually generates 10- to 20-µg ditags.

NlaIII digestion of SAGE tags

Figure 19.4.2 shows a typical result after releasing 26-bp ditags by *Nla*III digestion. The 26-bp bands of SAGE ditags without linkers should be clearly visible from background bands. Since *Nla*III is unstable even at −80°C, *Hsp*92II may be used instead (see Alternate Protocol).

Formation of SAGE concatemers

Figure 19.4.3 shows a typical result of formation of SAGE concatemers. A smear should be clearly visible.

Sequencing clones and analysis of sequence data

From 1 to 2 µg total RNA, it is possible to generate 50,000 SAGE tags.

Time Considerations

In the Basic Protocol, steps 1 to 47 (including the large-scale PCR performed in step 47) take 1 week to complete. After large-scale PCR, step 48 in the Basic Protocol of this unit (which would comprise steps 43 to 106 in Basic Protocol 2 of *UNIT 19.3*) takes 2 weeks to complete.

The time requirement for sequencing clones and analysis of sequencing data depends on the number of tags and efficiency of the sequencing facilities used.

The Chick Chorioallantoic Membrane as an In Vivo Angiogenesis Model

BASIC PROTOCOL

This unit presents the basic steps involved in the chick chorioallantoic membrane (CAM) assay, a model originally developed to study the angiogenic activity of tumor samples (Ausprunk et al., 1974; Auerbach et al., 1974). One of the major advantages of this method is that it is the simplest of the in vivo angiogenic models. In contrast to other in vivo models, the CAM assay does not require any major training or highly technical surgical skills. In addition, there is no need for sophisticated equipment, and it does not require an animal protocol. The uninitiated can quickly learn this simple method. Although the CAM assay is a simple procedure, it requires considerable "hands-on" effort for the following two reasons. First, the initial number of eggs needed per data point (~20) is large due to embryo mortality during the assay, and second, the background of positive responses is ~20%. Other disadvantages to this assay include the fact that it takes 10 days to complete and that the number of samples that can be tested is limited by the number of embryos required. Therefore, the CAM assay is not recommended as a screening technique, but rather as a procedure that can be used to confirm results from other experiments suggesting that a substance has a potential to be active in vivo. Overall, the advantages well outweigh the disadvantages, since it is an in vivo assay that can be readily performed in any laboratory setting.

Materials

3-day-old embryonated chicken eggs (~20 eggs/condition), maintained in 37°C incubator (an egg incubator is not necessary)
70% ethanol
Test substance(s)
Positive control: bFGF (PeproTech) or another angiogenic stimulus
Phosphate-buffered saline (PBS; *APPENDIX 2A*)
Heavy cream

Sterile dissecting implements:
- Scalpel
- Curved tweezers
- Smooth-tipped (nonserrated) tweezers
- Scissors

6-ml syringes, sterile
20-G, 1.5-in. (3.5-cm) needles, sterile
1-in. (2.5-cm) wide clear adhesive tape
Single-edged razor blades
13-mm-diameter Thermanox coverslips (Nunc), sterile
Stereoscopic microscope of variable magnification, equipped with camera and light source

NOTE: As an additional, optional sterility precaution, this protocol may be performed in a sterile laminar-flow hood (also see *UNIT 1.3*).

Contributed by M. Lourdes Ponce and Hynda K. Kleinman
Current Protocols in Cell Biology (2003) 19.5.1-19.5.6

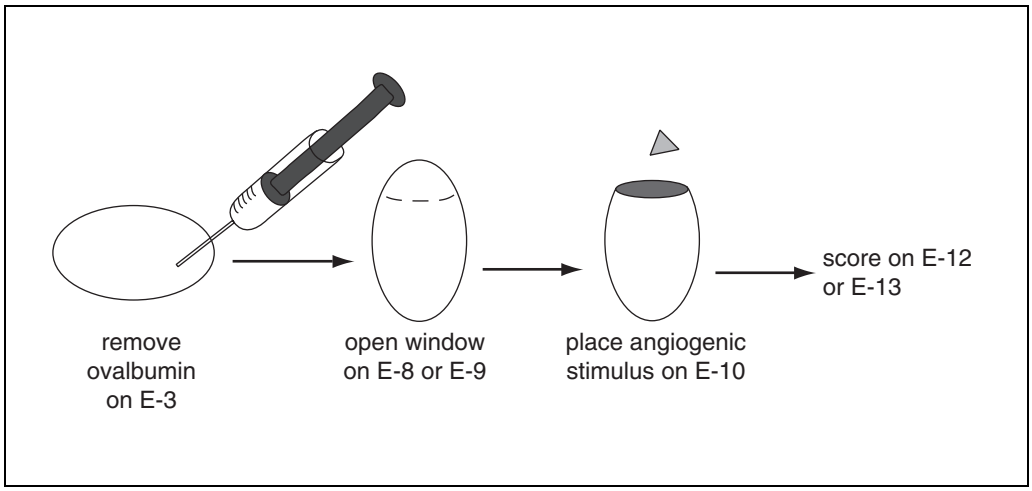

Figure 19.5.1 Schematic representation of the CAM procedure. Using a syringe and needle, the first step is to remove 3 to 4 ml of ovalbumin from 3 day-old embryonated eggs. The next step is to open a window on E-8 or E-9 after scoring the shell with a razor blade and pulling the egg shell out with a pair of tweezers. After the sample is dried out on the coverslip, the stimulus is placed on the CAM for 2 to 3 days. The eggs are then evaluated for angiogenesis under a stereoscopic microscope.

Prepare eggs

1. On embryonal day 3 (E-3), when the embryo is still small, prepare eggs to be used for the procedure by spraying them with 70% ethanol to minimize contamination. Make a small hole with a scalpel on the wide end of the egg, where the air sac is located (Fig. 19.5.1).

   IMPORTANT NOTE: Also spray eggs with 70% alcohol before each subsequent step in which they are to be opened.

2. Lay the egg sideways (Fig. 19.5.1). Insert the sterile needle with syringe into the hole at an angle of ~45°, without touching the far end of the egg shell, to a depth of ~1 to 1.25 in. (equivalent to 2.5 to 3.1 cm), and gently remove 3 to 4 ml of ovalbumin. Return the egg to its original position.

   If yolk is being removed, withdraw the needle and reposition it to withdraw ovalbumin.

   The ovalbumin ("egg white") is pale yellow in color. If any bright yellow-orange material is seen in the syringe, yolk is being aspirated and the viability of the embryo could be compromised. Ovalbumin is removed to lessen the volume of material in the egg so contents do not spill out when the window is opened.

   If only a small amount of yolk is removed, continue to incubate the egg as the embryo may survive.

3. Cover the hole with a small piece of tape, 0.5 to 0.75 in. (1.25 to 1.9 cm) long. Proceed in a similar manner with the rest of the eggs, making sure to return them to the incubator within 45 min to avoid decreased viability. Continue incubation.

4. On E-9, using a single-edged razor blade, score a circle (~1 in., or 2.5 cm, in diameter) or a square (of ~1 $in.^2$, or 6.25 cm^2) through the tape covering the egg (Fig. 19.5.1). Insert sterile curved tweezers through the needle hole created on E-3, puncturing the tape, and gently push up from inside the egg against the eggshell and all around the scored area until the shell comes out to produce an opening of the above dimensions in the eggshell. Remove any remaining membrane from the area immediately inside the window and close the opening with tape. Discard unviable embryos or unfertilized eggs.

If it is not possible to open the window on E-9, it can alternatively be done earlier on either E-7 or E-8, as necessary. Earlier times are not recommended since it increases the chances of contamination and decreases the number of viable chicks.

Unviable or dying embryos can be detected by observation. In these cases, vessels do not appear intact, the egg yolk looks discolored, and/or the embryo no longer moves.

Prepare the angiogenic stimuli

5. On E-10, examine embryos and determine the number of viable eggs; discard unviable or dying embryos (see annotation to step 4). Calculate the number of samples to be prepared for each condition.

   It is important that there be at least 12 eggs for each sample since some of the embryos will continue to die.

6. Using sterile conditions and instruments, cut the coverslips into quarters with scissors while holding with sterile smooth-tipped tweezers in such a way as to avoid scratches.

7. Dissolve the test substance in distilled water and place a 5-µl aliquot containing the desired amount to be tested in the center of one quarter of a coverslip. Prepare a minimum of 12 coverslips per sample (it is advisable to test at least two different concentrations of each test substance). Include controls that contain water only (negative control) or 50 ng of bFGF (positive control).

   Samples should be dissolved in water. The presence of buffers or salts might create crystal deposits that can yield false positive results. Variations of the assay that allow the presence of salts, buffers, media or cells have been developed using small collagen gels (see Gho et al., 2001).

8. Allow the coverslips to air dry for 10 to 20 min. Open the window by cutting off the tape from each egg, then place the air-dried coverslip containing the corresponding sample on top of the CAM with the sample in direct contact with the CAM. Cover the eggs with tape, and return them to the incubator.

   The area selected for placing the coverslip should be free of large vessels and away from any eggshell that might had fallen in on the CAM, since the shell can induce angiogenesis.

Score CAM for angiogenesis and photograph

Scoring of the CAM can take place on either day E-12 or E-13 depending on the degree of angiogenesis elicited by the test compound. Therefore, it is recommended that the CAM be examined on both days and that the best day for scoring be determined depending on the number of positive samples observed.

9. Remove the tape from the egg and using a stereoscopic microscope, look at the area where the coverslip was placed.

10. Score the CAMs by assessing the number of positive or negative responses or by assigning a score number varying from 0 to 3, in which 0 is no response and 3 is a strong response.

    A strong positive angiogenic stimulus will result in vessels that radiate from the center of the coverslip simulating spokes from a wheel (Fig. 19.5.2). When the effect is not as strong, smaller and fewer vessels will be observed. In some instances, a very weak response can be detected in the form of small capillaries. Another way in which a very weak response can be seen is by observing the orientation of the major vessels near the area of the stimulus; the vessels may appear to make a turn towards this area, which is evidence of a very weak stimulus. These very weak responses are scored as 1 (see Fig. 19.5.2).

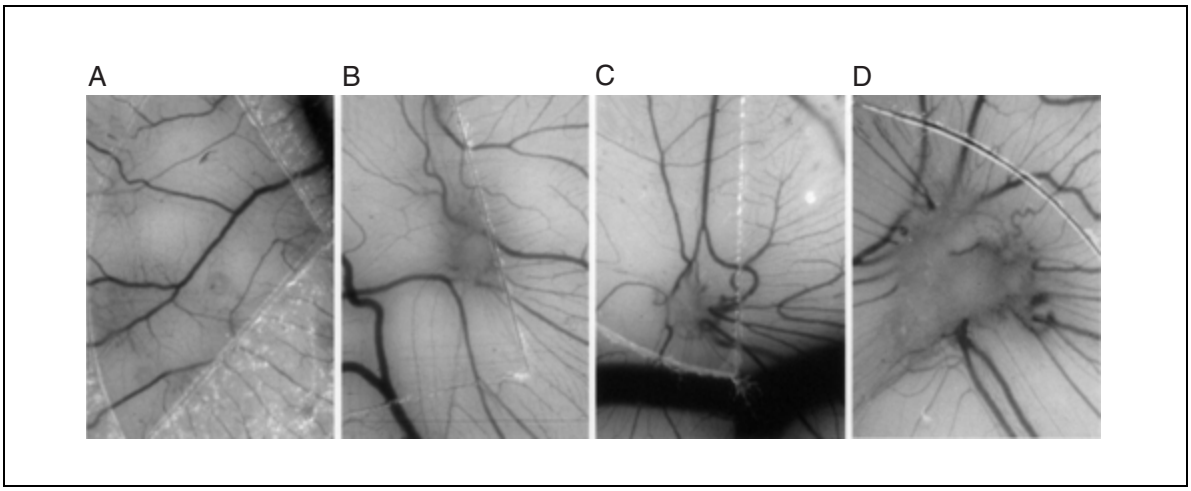

Figure 19.5.2 Positive responses and scoring. Examples of CAMs show different degrees of positive response. (**A**) A typical negative control showing normal CAM vessel levels but no induction of angiogenesis. Score = 0. (**B**) A slight response is observed in which some of the major vessels turn towards the stimuli. Smaller newly formed vessels are also observed. Score = 1. (**C**) A stronger angiogenic response is present. More, larger vessels are recruited to the area and a small "spoke wheel" begins to appear. Score = 2. (**D**) An intense angiogenic response is shown with large vessels and many smaller ones. The spoke wheel is present. Score = 3.

11a. *Photograph the CAM in situ:* Without dissecting, inject 3 to 4 ml of contrasting medium under the CAM consisting of a 1:1 mixture of PBS and heavy cream (or a similar substance with high buoyancy that would provide a contrasting background).

11b. *Photograph the CAM in dissected membrane:* Dissect out the area where the stimulus was placed using scissors and forceps, transfer it to a tissue culture dish, place the dish on a contrasting material, and photograph using the camera attached to the stereoscopic microscope.

COMMENTARY

Background Information

The formation of new blood vessels from pre-existing ones, i.e., angiogenesis, is important for physiological processes that occur during pregnancy, the menstrual cycle, and wound repair (Smith, 2001; Reynolds and Redmer, 2001; Sherer and Abulafia, 2001; Tonnesen et al., 2000). In addition, several pathological conditions have been associated with changes in the normal number of vessels present in various tissues. For instance, an increase in the level of the vascular supply has been linked to rheumatoid arthritis, psoriasis, corneal angiogenesis, and diabetic retinopathy, one of the leading causes of blindness in the U.S.A. (Arbiser, 1996; Yoshida et al., 1999; Campochiaro, 2000; Brenchley, 2001; Chang et al., 2001; Spanger and Pfeiffer, 2001). Vascular insufficiency, on the other hand, can also lead to serious conditions, such as myocardial ischemia, a form of heart disease, or ischemia of the limbs which can result, in extreme cases, in amputation (Majesky, 1996; Freedman and Isner, 2001; Vale et al., 2001). In recent years, angiogenesis has been the focus of numerous studies that utilize antiangiogenic agents to inhibit cancer. The vascularization of tumors is essential for their growth and, in advanced stages, for mestastasis. In essence, tumor growth and metastasis could be prevented by utilizing drugs that stop new vascularization. A number of laboratories have focused their efforts on the development of new antiangiogenic therapies that can affect tumor vessel formation. Several of these compounds are currently in clinical studies, including, but not limited to, endostatin, which is a collagen XVIII fragment, as well as thalidomide, interferon α, and antibodies to vascular endothelial growth factor and to integrin $\alpha v\beta 3$.

Angiogenesis is a complex multistep process that is usually initiated by a signal, an angiogenic stimulator, produced and/or released in the surrounding microenvironment. When the signal reaches the endothelium and binds to its receptor, the cell becomes activated

and the angiogenic cascade is initiated. This cascade includes degradation of the matrix, migration of endothelial cells, proliferation, establishment of a new matrix, and tubule formation and maturation. Due to the large number of conditions that are affected by angiogenesis and to the complexity of the process, it has been necessary to develop numerous methodologies for its study. Various in vitro assays have been used for this purpose and include migration, proliferation, formation of tubes on Matrigel or collagen gels, and aortic ring sprouting. In vivo studies include the rabbit corneal pocket assay, implanted sponges, subcutaneous Matrigel plugs, and the chick chorioallantoic membrane (CAM) assay, among others.

Angiogenesis in the chick CAM is a process that can be readily studied. During the development of the chick, the CAM undergoes rapid neovascularization—i.e., the formation of new vessels—which is complete by embryonal day 10 (E-10). When this neovascularization stops, the angiogenic process can be investigated. For this reason, the CAM assay is usually initiated on E-10, although some investigators have reported the application of the sample at earlier time points. It should also be noted that neovascularization can also be examined using the model described here, except that the sample is applied at an earlier stage (E-5 or E-6) when neovascularization is still taking place. In this case, the results are also observed 2 or 3 days later. In a similar manner, angiogenesis inhibitors can also be examined by mixing them together with an angiogenesis stimulator such as bFGF (Ponce et al., 2001).

Troubleshooting

As mentioned above, one of the caveats of the CAM assay is the high number of spontaneous positive responses obtained. In addition, false-positive responses can also be caused by the presence of salt crystals in the sample or pieces of eggshell that become lodged inside the egg. These responses are usually characterized by an inflammatory response that can cause indirect induction of angiogenesis.

Embryo viability, which can range between 30% and 70%, can also be seriously affected, in some cases, by the length of transportation between the farm and the laboratory, as well as the conditions of the trip, including bumpy rides and the time the eggs spend outside of the incubator. Although some of these issues can be addressed, often they are beyond the control of the investigator. Another serious problem that can reduce embryo viability and/or the number of samples is contamination. This problem can be reduced by following more stringent sterile techniques including the use of sterile equipment, careful swiping of the eggs with betadine or 70% alcohol before opening, working in a sterile hood in extreme cases, or maintaining a low incubator humidity.

At a minimum an experiment requires 12 embryos per treatment group, 12 embryos for a negative control, and 12 embryos for a positive control. If at the end of an experiment the number of embryos is too low and no statistical differences are observed between the negative and positive controls, the experiment should be discarded.

Anticipated Results

Many angiogenic and anti-angiogenic compounds have been tested using this assay including growth factors, such as bFGF, VEGF, and ICAM, antibodies (anti-bFGF, VEGF, and integrins), peptides and protein fragments (laminin and fibronectin, thrombospondin and collagen-derived), and small molecules (Auerbach and Auerbach, 1994; Ribatti et al., 2001). The angiogenic response will vary according to the strength of the compound being tested. For example, bFGF will usually give a strong response in which a well-formed spoke-wheel can be observed in as many as 80% of the eggs tested. Less angiogenic substances may not form a spoke-wheel, but the number of positive CAMs and strength of the response will vary depending on their angiogenicity and/or concentration. This will aslo be the case for anti-angiogenic molecules, in which the most potent ones will greatly reduce the angiogenicity of the inducing agent at lower amounts, whereas, weaker ones could require much larger amounts to observe a decreased response. All these factors will ultimately have to be experimentally determined by the investigator.

Time Considerations

The CAM assay takes 9 to 10 days to complete. The amount required for each one of the steps is as follows. Removal of ovalbumin on the first experimental day, E-3, requires ~1 to 1.5 hr per every 100 eggs. Opening of the windows on E-9 will take a minimum of 3.5 hr per 100 eggs depending on experience. On E-10, allow 2 to 3 hr for sample preparation and placing the coverslips on the CAM. On E-12, allow 0.5 to 1 hr for checking the angiogenic response. On the final day, E-12 or E-13, allow 2 to 3 hr to score and photograph the CAMs.

Experimental Metastasis Assays in the Chick Embryo

Tumor metastasis is the spread of cancer from a primary tumor to form secondary tumors in distant organs. This process consists of a series of steps, starting with the release of cancer cells from a primary tumor into the blood or lymphatic circulation (intravasation), the transport of cells to distant organs via the circulation, arrest in capillaries in these sites, exit of the cancer cells from the circulation into the tissues of the new organ (extravasation), and the growth of some of these cells to form metastatic tumors in the new organ. Experimental metastasis assays model the latter half of this process by injection of cancer cells into the circulation of an experimental animal and the detection of the formation of metastatic tumors. This is in contrast to spontaneous metastasis assays, in which a primary tumor is created by injection of cancer cells into an appropriate tissue of an experimental animal and the presence of metastatic tumors in distant organs is assessed, which will not be discussed here.

Mice are most commonly used for experimental metastasis assays; however, for a variety of reasons (see Background Information), there are some distinct advantages to using alternate assays. For example, the chick embryo can provide a convenient and cost-effective animal model in which to study the process of tumor metastasis. It is a naturally immune-deficient host and can thus be used to assess the metastatic potential of cancer cells from a variety of species, including human and mouse. Also, housing requirements are minimal and accessible to most laboratories. Chicken embryos are readily available and experimental metastasis assays in this system are straightforward. Experimental metastasis assays can be combined with in vivo videomicroscopy on readily accessible thin tissues, such as the chick embryo chorioallantoic membrane (CAM), in order to learn about individual steps in the metastatic process. Methods for using chick embryos for experimental metastasis assays (see Basic Protocol 1) and in vivo videomicroscopy (see Basic Protocol 2) are provided in this unit, as are the details of routine maintenance of the embryos (see Support Protocol 1). Additional protocols for labeling cells with fluorescent nanospheres (see Support Protocol 2) and for assessing cells in tissues using fluorospheres (see Support Protocol 3) are also included.

NOTE: All protocols using live animals must be first reviewed and approved by the appropriate Institutional Animal Care and Use Committee (IACUC) and must follow officially approved procedures for the care and use of these animals.

NOTE: All solutions and equipment coming into contact with cells and tissues must be sterile, and proper aseptic technique should be used accordingly.

NOTE: All culture incubations should be performed in a humidified 37°C, 5% CO_2 incubator unless otherwise specified. Do not use a culture incubator for eggs.

EXPERIMENTAL METASTASIS ASSAY IN THE CHICK EMBRYO

BASIC PROTOCOL 1

Experimental metastasis assays measure the ability of cells injected intravenously into the circulation to form metastatic tumors in distant organs (see Welch 1997 for general review of techniques commonly used). In this assay using the chick embryo, which was described in 1982 by Chambers et al. (see Chambers and Tuck, 1988 for review), cells are injected intravenously (i.v.) into chorioallantoic membrane (CAM) veins. An illustration of this experimental approach is presented in Figure 19.6.1, which diagrams the injection of cells into a CAM vein of an 11-day-old chick embryo. Cells injected by this

Contributed by Sylvia M. Wilson and Ann F. Chambers
Current Protocols in Cell Biology (2003) 19.6.1-19.6.24

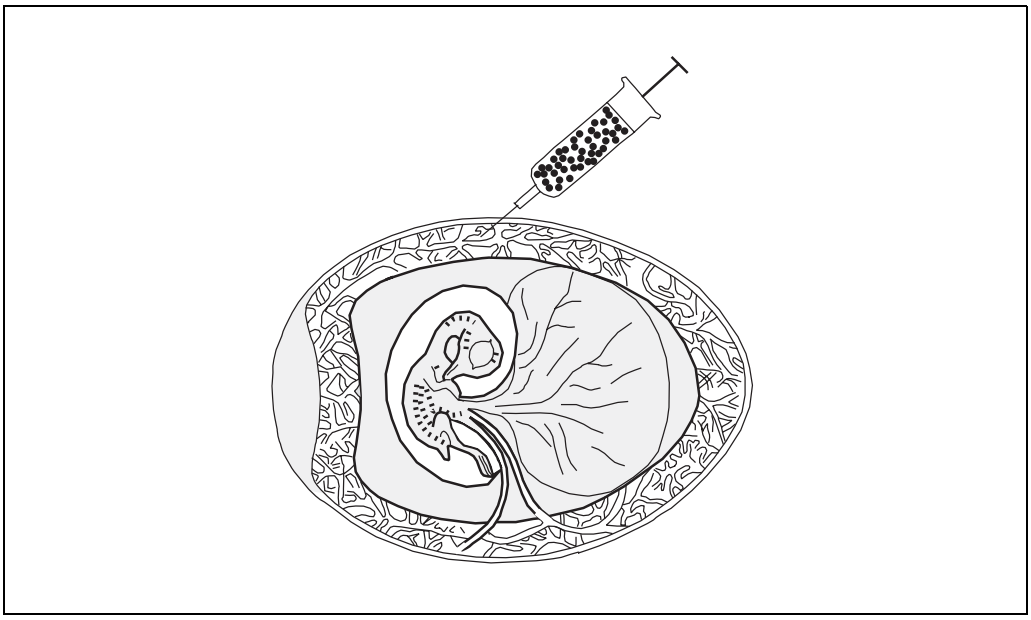

Figure 19.6.1 Diagram of experimental metastasis assay in chick embryos. Cancer cells are injected via a chorioallantoic membrane (CAM) vein, through a window opened in the shell of 11-day-old chick embryos. Cells injected via this route travel via the circulation first to the embryonic liver. After incubation for up to 7 days, metastatic cells in an embryonic organ such as liver are quantified using the ouabain plating assay, or (for rapidly growing cell lines) macroscopic metastases can be quantified. Republished with permission of Anticancer Research from Chambers and Tuck (1988).

route are taken by the circulation first to the embryonic liver. Some cell lines may grow rapidly in vivo in the chick, such that macroscopic metastatic tumors are visible in the liver and other internal organs at 7 days postinjection (Chambers and Ling, 1984; Chambers and Wilson, 1988); however, many cell lines, even highly metastatic ones, may not grow visible tumors in the time period available before embryo hatching. For these cell lines, the ouabain plating assay was developed (Chambers et al., l982). This assay permits the quantification of numbers of viable rodent cells in chick organs at various times after injection.

The ouabain plating procedure is based on natural interspecies differences in sensitivity to the cytotoxic effects of the drug ouabain: rodent cells are inherently considerably more resistant to ouabain than chick cells, while human cells are more sensitive than chick cells (Chambers et al., 1982; Chambers and Ling, 1984). Due to this latter sensitivity, this assay cannot be used for human cells in chick tissues. However, this approach can be adapted for use with human cells that carry a selectable drug resistance marker, such as neo/G418 (Chambers and Wilson, 1988). Because the assay requires adherent colonies to form, it is best suited for rodent cells that grow as adherent, monolayer cultures, rather than for cells that grow as suspension cultures.

A suspension of chick organ cells, in which there are unknown numbers of rodent cells, is plated in a concentration of ouabain sufficient to kill the chick cells while allowing the rodent cells to grow and form clonal colonies in vitro. At the end of the assay (the timing of which will depend on the growth rate of the cancer cells in vitro, in order to form clonal colonies of countable sizes), the rodent cell colonies that grow out from the chick liver suspension can be stained with methylene blue and counted to determine the number of viable (rodent) cells per chick embryo liver. Alternatively, viable cells can be recovered from some plates by standard trypsinization procedures to study the properties of cells that have been selected in vivo in the chick embryo (Chambers and Ling, 1984; Bondy et al., 1985; Chambers and Wilson, 1985; Hill et al., 1988).

Materials

Eggs containing 11-day-old chick embryos (see Support Protocol 1)
Adherent rodent tumor cells, optionally labeled with nanospheres (see Support Protocol 2)
Medium and serum used to grow tumor cells
Paraplast wax
Paraffin oil
70% ethanol
Sterile calcium- and magnesium-free PBS, 4°C (see recipe)
Hank's balanced salt solution (HBSS), 4°C (see recipe)
0.3% (w/v) collagenase/0.02% (w/v) trypsin (see recipe)
DNase I (see recipe)
2×10^{-3} M ouabain (see recipe)
Detergent or other decontaminating solution
Methylene blue stain (see recipe)

Egg candler (local farm supply store)
Pencil
Enclosed still hood with glass front, interior light, and electrical outlet
Dremel Moto tool with polishing wheel, $\frac{6}{8} \times \frac{1}{8}$–in. thick (available at local hobby shop)
38.5°C (99° to 100°F) automatic rotating egg incubator with 80% to 82% humidity (e.g., March Farms Roll-X incubators, Lyon Electric; available at farm supply stores)
Hemacytometer (*UNIT 1.1*) or Coulter counter
Adjustable gooseneck light source and fiber optic unit (e.g., Schott Glas Fiber Optics unit, Carl Zeiss unit) or focused intense light source
Egg support stand (i.e., three rubber corks glued on a plastic petri dish; Figs. 19.6.3 and 19.6.4)
1-cc syringes
30-G ½-in. needles
Cotton swab
Disposable underpad
1-liter plastic beaker lined with a 12-lb. plastic bag
Small plastic beaker
Dissecting instruments, autoclaved:
  Straight medium-point dissecting forceps, 115 mm in length
  Straight narrow-blades dissecting scissors with fine points, 110 mm in length
  Two straight fine-point dissecting forceps, 110 mm in length
  Two scalpel handles with no. 10 disposable blades
150 × 20–mm plastic dishes
100 × 15–mm nontissue and tissue culture dishes
24-well tissue culture plates
100-mm glass dishes (autoclave in a canister)
5-ml pipet
17 × 100–mm polystyrene test tubes
500-ml wash bottle
Funnel
Plastic wash basin with drainage holes drilled half-way up each end

Additional reagents and equipment for trypsinization (*UNIT 1.1*), adding accounting spheres (see Support Protocol 3), and inspecting for gross surface tumors (Chambers et al., 1982; Chambers and Wilson, 1988)

NOTE: During dissection, all instruments should be rinsed in 70% alcohol, wiped clean with a tissue, and flame sterilized between each step

Prepare egg windows

1. In a dark room, hold an egg candler directly against the shell on the air sac (blunt end) of an egg, which has been incubated for 11 days.

   The 11-day-old embryo and the CAM veins should be clearly visible under the shell. Dead or deformed embryos can be readily identified when candled, as they will have either no veins present or black, darkened areas. These eggs should be disposed of carefully without cracking, as they may have a strong sulfur odor.

2. Gently rotate the egg in hand to identify a large dark vein branched in a Y shape near the air sac. With a pencil (not pen or marker), mark a 10 × 10–mm square on the shell over this vein indicating the area to be drilled.

   Do not select veins that move freely when the egg is rotated with quick turns, as these cannot be injected. Drilling a square that is too small will make injection difficult, while if the square is too large, the window will cave in after drilling.

3. In an enclosed still hood with glass front, interior light, and electrical outlet, drill all four sides of the marked square using a Dremel Moto tool with a ⅝ × ⅛–in. polishing wheel using the following method (Fig. 19.6.2):

   a. Hold the egg with two fingers and the thumb of the left hand (assuming that the researcher is right-handed) so that the egg is at a slight angle, with the air sac end up, and the square marked for drilling facing up and toward the experimenter.

   b. Hold the Dremel drill in the right hand as if it were a large pencil.

   c. Bring the drill bit at right angles to the marked square on the shell. Use only gentle pressure to start cutting since the drill operates at high speed.

Figure 19.6.2 The drilling of the marked square or window on the egg over the selected vein area with a Dremel Moto tool is done in an enclosed still hood. To minimize breathing of eggshell dust, hang a cloth from the bottom of the glass front (or alternatively wear a mask and protective eyewear). Drill all four sides of the window, with the egg at a slight angle and the air sac end (blunt end) up and the marked window facing toward the person drilling. The bit of the Dremel tool is brought at right angles to the surface of the shell. Gentle pressure is sufficient for cutting due to the high speed of the drill. Only the shell is cut while avoiding the underlying smoother papery-white membrane or the underlying CAM.

d. Cut *only* the shell (which looks pebbly), and not the underlying papery-white shell membrane or the viable CAM tissue under this membrane. Do not remove the resulting window.

CAUTION: *For safety, minimize inhalation of egg shell dust by hanging a cloth from the bottom of the glass front on the enclosed still hood. Alternatively, or additionally, a mask and protective goggles can be worn.*

This step requires practice and a steady hand. If the CAM is nicked or bleeds, the egg should be discarded.

4. *Optional:* After drilling, return the eggs to a nonrotating egg incubator (i.e., with rotation turned off) for up to 1 hr before injection.

This step is useful when large numbers of eggs are to be injected in a single experiment; it helps to keep the embryos healthy.

Prepare tumor cells

5. Prepare a single-cell suspension of adherent rodent tumor cells from an 80% confluent culture, optionally with nanospheres, using standard laboratory procedures for trypsinization (*UNIT 1.1*). Count the cells using either a hemacytometer (*UNIT 1.1*) or Coulter counter.

6. Using the same medium and serum used to grow the tumor cells, adjust the volume to give the desired number of cells per embryo in a total injection volume of 0.1 ml per embryo. If desired, add accounting spheres (see Support Protocol 3).

The number of cells to inject into each chick depends on the metastatic properties of the cells. The number can range from 1–5 × 10^6 cells per embryo for poorly and nonmetastatic cells (Hill et al. 1988), down to 5 × 10^3 cells per embryo for highly metastatic cell lines (Chambers and Wilson, 1988).

The prepared cell suspension can be briefly (i.e., up to 2 hr) stored at 4°C until the eggs are ready for injection.

Set up injection equipment and area

7. In a small glass beaker melt Paraplast wax on a hot plate set at 60°C.

CAUTION: *Paraplast is flammable and should be carefully watched during this procedure; do not allow it to get hot enough to smoke.*

8. Set up the equipment needed for injection in the following manner:

a. Open the front of a tissue culture hood and place a fiber optic unit or focused intense light source near the back of the hood with the gooseneck light source extended to the front.

b. In front of this light source, position the egg support stand so that the egg will sit parallel to it.

c. Place empty 1-cc syringes, 30-G ½-in. needles, Kimwipes tissues, and a 1-cc syringe without needle half filled with paraffin oil into the hood.

d. When all the equipment is ready, place the eggs (windows cut but not removed, step 3 or 4) on their sides in an egg tray with the windows up and bring them into the tissue culture hood.

e. Once the Paraplast has melted, allow it to cool, but still remain liquid, and place it in the hood.

The arrangement of these components in preparation for egg injection is illustrated in Figure 19.6.3.

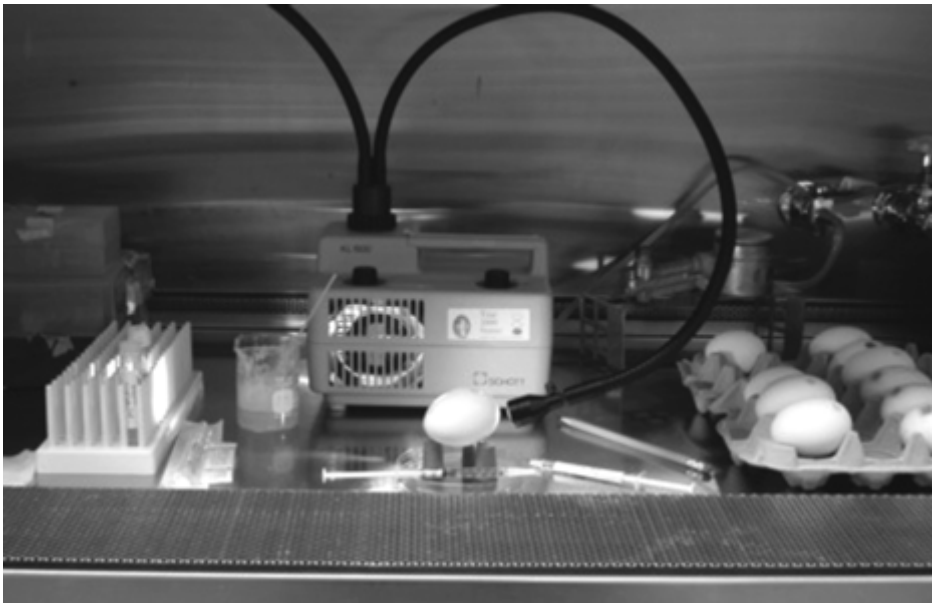

Figure 19.6.3 The arrangement of equipment inside the tissue culture hood just before injections proceed. The front of the hood is opened for easier access during the procedure with adequate sterility still being maintained. The gooseneck arm of the fiber optics light is illuminating the air sac end of an egg positioned on the egg stand (made by gluing three rubber corks onto a plastic petri dish) ready for injection. The remaining eggs have had the shell of the drilled window carefully removed over the vein area and are placed in a tray with the windows facing upwards awaiting injection. The cell suspension has been prepared at a predetermined concentration ready to be drawn up into the 1-cc syringe following gentle vortexing. The other 1-cc syringe contains the paraffin oil of which a drop will be placed on the exposed window area prior to injection. The melted Paraplast in the glass beaker (left) is cooling in preparation for sealing of the entire window area following injection.

Inject eggs

9. Gently remove the cut square of the shell from each egg with a pair of fine forceps. If the shell membrane or the underlying CAM become nicked or damaged, the egg cannot be used.

   This step also requires practice and a steady hand.

10. Set one of the eggs on the support stand with the air sac end facing the fiber optics so the veins inside the egg are illuminated. Add a drop of the paraffin oil from the 1-cc syringe to the surface of the shell membrane to further enhance visualization of the vein.

11. Gently vortex the suspension of cells to be injected (step 6). Draw the cell suspension up into a 1-cc syringe, attach the 30-G needle, and remove air plus any excess liquid with a Kimwipe.

    As a control, to determine the effect of passage of the cell suspension through a 30-G needle, it is recommended to perform an in vitro plating efficiency assay. For the cell lines used by the authors, passage of cells through a 30-G needle has not led to reduced plating efficiency of the cells.

12. Inject the CAM vein with tumor cells as follows (Fig. 19.6.4):

    a. With the beveled tip of the needle facing upwards and in line with the numbers on the barrel of the syringe (i.e., so both numbers and bevel face the experimenter), gently insert the needle into the CAM vein in the direction of blood flow.

    The paraffin oil enhances the visibility of the vein and thereby allows the quality of the injection to be monitored. When the CAM window is illuminated, vessels appear bright red and the egg contents appear yellow.

    b. Inject 0.1 ml quickly and evenly into the vein.

    c. Withdraw the needle carefully and smoothly from the vein to prevent bleeding.

    d. If any bleeding occurs or a clot forms at the injection site, discard the embryo.

    e. Return the injected egg to the egg tray in the hood, placing it on its side with the window facing upwards.

    To determine blood flow direction, follow the vein to where it branches; blood will generally travel along the two arms toward the single arm (Y). Areas of the vein near the branch seem to withstand injection the best. If a proper injection is done, the clear inoculum entering the vein will be visible as blood flow is temporarily blocked as will the pulsing of the blood flow beyond the end of the needle. See inset of Figure 19.6.4.

Figure 19.6.4 Injection of cells into a chick embryo CAM vein. Position the egg on the egg stand, with the fiber optics light illuminating the air sac end for visualization of the large Y shaped vein. The addition of a small drop of paraffin oil onto the injection site enhances the clarity of the vein. The beveled tip of the needle is facing upwards for gentle insertion into the branch area of the Y (see inset) just until the beveled end is completely into the vein. The needle should be at the angle seen in the picture above to prevent damage to the vein. If a proper injection is performed, the vein will temporarily become clear as the 0.1-ml inoculum is smoothly injected, and there will be no blood seeping from the injection point either during or after the injection.

13. Repeat steps 10 to 12 for each egg to be injected.

    When injecting several eggs from the same syringe of cells, be sure to agitate the syringe gently between injection, to avoid settling of the cells. This will ensure that all eggs receive the same number of cells.

14. Seal the exposed windows with cooled, but still melted Paraplast using a cotton swab. Cover the entire window area including at least 5 mm of shell on each side. After the Paraplast has hardened, apply a second coat to ensure a complete seal.

15. With a pencil, label the side of each egg with the date, cell line, and other important details.

Allow tumor cells to metastasize

16. Return the eggs, on their sides, to a nonrotating egg incubator (i.e., turn off rotator) for further incubation, up to a maximum of 7 days (hatching occurs on day 19 to 21). Use the same conditions of humidity and temperature as during the initial incubation (see Support Protocol 1)

    The incubation time depends on the type of assay, either having a single 7-day end point or, if determination of the growth kinetics of the cell is desired, a time course of intervals from 0 to 7 days from the time of injection.

    The temperature may be altered at this point if experiments are being performed to test the effects of temperature-sensitive mutants (Chambers and Wilson, 1985).

    Much information can be obtained from kinetics studies on the growth of injected cells in embryonic organs (Chambers et al., 1982; Chambers and Ling, 1984; Chambers and Wilson, 1985). Figure 19.6.5 shows an example of kinetic data, quantifying the in vivo increases in numbers of tumor cells (ouabain-resistant; i.e., rodent) in chick liver over time after injection. Figure 19.6.5B also illustrates how the chick embryo assay can be used to assess the in vivo effects of temperature-sensitive (ts) genes, by maintaining the embryos at different temperatures. In the example shown, the LA23-NRK cells carry a ts-src oncogene, which is active at 36° but inactive at 38°C, resulting in dramatic in vivo growth abilities of the cells shown in Figure 19.6.5B (Chambers and Wilson, 1985).

17. Check the viability of the embryos to be dissected by candling (step 1) in a darkened room.

    The embryo should be clearly visible and veins still present. If there are no veins or the eggs contain discolored interiors, the embryos have died and should be carefully discarded.

Set up dissection equipment and area

18. On a bench top near the tissue culture hood spread a disposable underpad. On the underpad, place a 1-liter plastic beaker lined with a 12-lb. plastic bag for disposal of the egg shells and other waste.

19. Place 115-mm, straight, medium-point dissecting forceps on the underpad outside of the hood. Place the remaining autoclave-sterilized dissecting instruments into a small plastic beaker containing 70% ethanol. Transfer the beaker with ethanol into the tissue culture hood.

Isolate chick embryo

20. Remove the embryo from the shell on the bench over the disposable underpad, as follows:

    a. Hold the egg with the air-sac end up. Break the shell at the air-sac end of the egg with a sharp tap from the handle of the 115-mm forceps.

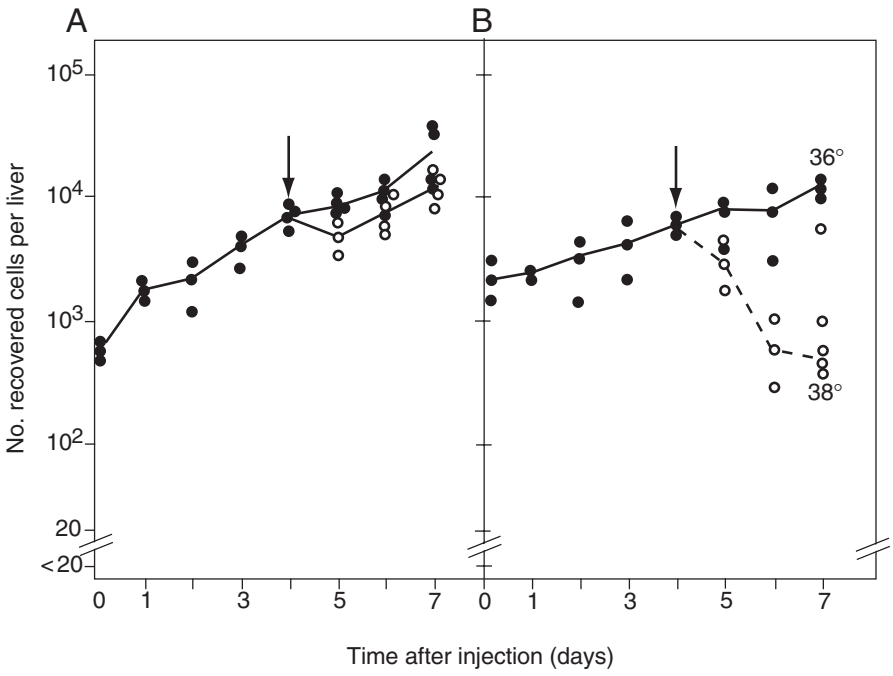

Figure 19.6.5 Example of in vivo growth kinetics results that can be obtained with the chick embryo experimental metastasis assay and the ouabain plating assay to recover rodent (and thus, ouabain-resistant) cells at various times after injecting cells via a CAM vein. (**A**) B77-NRK (normal rat kidney) cells transformed with the src oncogene, or (**B**) LA23-NRK cells (NRK cells carrying a temperature-sensitive src oncogene, which is active at 36° and inactive at 38°C were injected into CAM veins at 5×10^4 cells per embryo. Closed circles: embryos maintained at 36°C; Open circles: embryos transferred to 38°C at day 4. Each point represents the number of viable ouabain-resistant cells present in the liver of one embryo; lines connect median points. Republished with permission of American Society of Microbiologists from Chambers and Wilson (1985).

b. Over the 1-liter plastic-lined beaker, break through the air sac membrane towards the embryo.

c. Position the 115-mm forceps around the neck of the embryo and extract it from the shell.

Gloves should be worn for these steps.

21. Use the remaining shell to pull away any residual yolk or other tissue to completely free the embryo; discard the shell into the plastic-lined beaker.

The CAM lies directly under the shell membrane, and usually remains attached to the inside of the shell. It can be peeled from the inside of the shell and examined for tumor growth—e.g., if melanoma cells have been injected that produce easily visible tumors (Chambers et al., 1982)—or it can be used for histological assessment.

22. Use a 150 × 20–mm plastic dish to transfer the embryo to the tissue culture hood. Place each embryo into a 100 × 15–mm nontissue culture dish and decapitate the embryo with 110-mm, straight, narrow-blades, dissecting scissors with fine points. Cover with the lid.

The embryos can be left in the dishes inside the tissue culture hood until all the embryos have been extracted from the eggs.

Expose liver

23. Start dissecting by turning the embryo onto its back with the breast facing upwards. Just below the pectoral (breast) muscle, gently lift the skin with a pair of 110-mm, straight, fine-point dissecting forceps.

24. With sterile scissors, cut the skin above the breast all the way to the neck. Pull away the skin to the sides to expose the pectoral muscle, as well part of the liver (gold in color) and the gut.

25. Expose the entire liver and the heart as follows:

    a. Lift the area below the pectoral muscle at the point where a thin white membrane forms a V.

    b. Cut upwards through the middle of the pectoral muscle towards the neck, slightly lifting the muscle during cutting to avoid damaging the liver underneath.

    c. At the neck, make a transverse cut, then pull back the pectoral muscle to each side to expose the heart and entire liver.

Isolate liver

26. With sterile forceps, carefully detach the three areas of attachment of the liver to the other organs: two on the left side under one lobe and one under the right lobe.

27. Slip sterile opened forceps around the liver and move towards the heart which is the last point of attachment. Pinch the forceps together and lift out the liver.

28. In the tissue culture hood, transfer the liver to a well of a 24-well tissue culture plate containing 4°C sterile calcium- and magnesium-free PBS.

    The liver can remain up to 2 hr at 4°C.

    During this procedure (steps 25 to 27), do not puncture the gut while removing the areas of attachment under the liver. The gall bladder, situated directly under the liver, is usually dissected out at the same time as the liver. Avoid puncturing it if possible, but if this does occur, it will only discolor the PBS and not affect viability of cells present in the liver.

Dispose of waste and visually inspect livers for tumors

29. Incubate any undissected but viable eggs at 4°C for at least 1 hr prior to disposal to avoid hatching. Wrap the dissected embryos and shells in plastic bags and dispose by incineration.

30. Inspect the livers (and other organs) for gross surface tumors (Chambers et al., 1982; Chambers and Wilson, 1988) or abnormalities before dissociation, using proper sterile technique.

    Alternatively, organs may be fixed for histological examination and identification of internal micrometastases (Chambers and Ling, 1984).

Wash liver

31. Rinse each liver in a series of three sterile PBS washes in a 24-well plate by transferring the liver with sterile forceps from one well to the next.

    This allows six livers to be washed per 24-well dish.

32. Place the rinsed liver into a sterile 100-mm glass dish. Mince the liver into tiny pieces with crossed sterile scalpel blades.

    One scalpel can hold the tissue in place while the other cuts, then use both blades to finely mince the tissue. Avoid spreading the tissue over a large area to minimize drying.

Homogenize liver

33. Add 5 ml HBSS. Resuspend the minced liver tissue by pipetting up and down using a 5-ml pipet.

34. Dispense this suspension into a 17 × 100–mm polystyrene test tube (one tube per liver). Rinse the glass dish with another 5 ml HBSS to ensure all the tissue is removed from the petri dish. Pool with the 5 ml tissue suspension already in the test tube.

35. Centrifuge the liver suspension 10 min at 3000 × *g*, room temperature. Gently remove and discard the supernatant, leaving the liver pellet.

Prepare single-cell suspension

36. Add 3 ml freshly prepared 0.3% collagenase/0.02% trypsin and 0.5 ml DNase I into the tube and vortex.

37. Incubate ~1 hr in a 37°C heat block or water bath. Vortex occasionally during the incubation until a single-cell suspension is produced and there are no visible tissue fragments.

    The length of time necessary for complete dissociation of the liver tissue is dependent upon the age of the embryo—i.e., 18-day-old embryos require 1 hr, while 11-day-old embryos may require only 20 to 30 min. Other organs can also be dissociated; times will vary according to type of tissue and age of the embryo.

38. Centrifuge the single-cell suspension 10 min at 3000 × *g*, room temperature. Gently remove and discard the supernatant, leaving the liver cell pellet.

Select tumor cells with ouabain

39. Add 10 ml appropriate medium with serum for the cells injected with a final concentration of 2×10^{-5} M ouabain. Vortex the suspension to thoroughly mix.

40. Plate two dilutions of each liver suspension in 100 × 15–mm labeled tissue culture dishes containing 15 ml medium plus serum with 2×10^{-5} M ouabain. Use two to three plates per dilution.

    The total amount of liver cells plated should not exceed 1/20 of an 18-day old embryo liver per 100-mm dish, to avoid background problems due to large numbers of dying liver cells. All of the cells from younger (e.g., 11-day) livers can be plated in one to three dishes, without background problems. The fraction of the liver plated should reflect the expected number of rodent cells present in the liver and should be adjusted to give numbers of ouabain-resistant rodent colonies per dish that can be counted (optimal being 10 to 250 colonies per dish). Some suggestions of appropriate dilutions are 1/20 and 1/100 per 100-mm dish of a liver suspension for potentially low metastatic cell lines, and up to 1/100 and 1/2000 of liver suspension for a highly metastatic one.

41. Gently swirl each dish three times in both directions to ensure proper distribution of the cells over the bottom of the dish. Incubate the dishes undisturbed for 10 to 21 days, depending upon the doubling time of the injected cells.

    During the incubation of the diluted cell suspensions, the dishes should not be moved or small satellite colonies will be seeded that will make counting colonies difficult. Periodically, checking one plate during the incubation will assist in determining when to recover the cells from the colonies (following counting) for culturing or to stain for counting. Note which plate is used for these observations.

    Prior knowledge of the plating efficiency of the cell line injected will assist in determining the length of the incubation time.

Stain colonies and dry

42. Gently pour off the medium from the dishes into a beaker containing detergent or other decontaminating solution.

43. Add 5 ml methylene blue stain, from a 500-ml wash bottle, by allowing it to run down the side of the dish onto the bottom without disturbing the colonies. Make sure the bottom of the dish is completely covered with the stain. Allow to sit at least 15 min or until the colonies are a dark blue.

    The glutaraldehyde and alcohol in the stain will fix the cells to the dish.

44. Pour the stain off the colonies, collecting it into a 500-ml wash bottle using a funnel.

    This stain can be collected back into the 500-ml wash and reused.

45. Place a plastic wash basin with drainage holes drilled half-way up into a sink. Gently run tap water continously into the basin. Wash each dish individually by gently moving it slowly through the water. Do not allow direct water flow to dislodge colonies from the dish.

    The holes in the basin will allow the stained water to go down the sink while fresh water is poured in from the tap.

Determine number of rodent cells in each chick liver

46. Allow washed dishes to dry inverted, using the lids as a support to assist drying. Count colonies on the dried dishes any time, with the stained colonies being a permanent record.

47. Calculate the number of rodent cells present in each chick liver based on the fraction of liver plated in each plate.

    For example, calculate the mean of the total stained colonies counted per dish at a particular liver dilution multiplied by the dilution factor of the liver—e.g., (45 + 54 + 48)/3 × 20 (1/20 of liver plated per dish) = 980 cells per liver. For most dissociations, two separate liver dilutions are performed. In this case, do the above calculation for the second set of plates from the same liver—e.g., (9 + 11 + 10)/3 × 100 (1/100 of liver plated per dish) = 1000 cells per liver. To calculate the total number of cells per liver, take the two values obtained from each dilution and average: (980 + 1000)/2 = 990 cells per liver. The previously known plating efficiency in vitro of the cell line injected must be factored into this averaged value. If the cell line has a plating efficiency of 90% then calculate as follows: 990/0.9 =1100. Therefore, the mean final number of viable cells present in the chick livers would be 1100 cells. Standard deviations can be calculated from the variations in original cell counts per plate.

SUPPORT PROTOCOL 1

ROUTINE MAINTENANCE OF EGGS

Fertilized chick eggs (outbred White Leghorn) can be delivered fresh from a local hatchery on a regular schedule depending on experimental need (e.g., once a week). Larger eggs tend to be stronger and thus lead to more successful injections. During transport from the local hatchery, the eggs should not be subjected to extreme temperature changes and should be transported to the laboratory promptly. An insulated carrier may be necessary to keep them cool. When the eggs arrive in the laboratory, they should immediately be placed at 4°C, where they can be kept for up to one week before starting incubation. A schedule should be determined to provide embryos that have been incubated for exactly 11 days on the day on which the experiment is to be performed.

Materials

Fresh fertilized eggs (standard outbred White Leghorn), 4°C
Pencil
38.5°C (99° to 100°F) automatic rotating egg incubator with 80% to 82% humidity (e.g., March Farms Roll-X incubators, Lyon Electric; available at farm supply stores)
Hygrometer to routinely monitor egg incubator humidity

1. To start the incubation, remove fresh fertilized eggs from 4°C storage. On the blunt, rounded end of the egg, where the air sac is located, write the date when the incubation is begun in pencil.

   Do not use pen or marker, as these may be toxic to the embryos.

2. Place the eggs in a 38.5°C automatic rotating egg incubator with 80% to 82% humidity, with the air sac end up and the date clearly visible.

   The rotating incubator will prevent deformities from occurring in the embryos during incubation, by rotating the eggs at proper time intervals (New, 1966; Sturkie, 1976).

   Do not use a CO_2 incubator designed for tissue culture, as this will kill the embryos. The temperature is critical since a slightly lower incubator temperature will result in developmentally younger embryos that will not survive injection at day 11.

3. Continue incubating until eggs are the appropriate age. Record daily temperature readings to note fluctuations in temperature. Maintain the humidity by daily checking with a hygrometer and addition of either tap or distilled water into the interior egg incubator reservoir according to manufacturer's instructions.

   The incubators should be connected to an emergency back-up supply to prevent embryo death in case of a power failure.

INTRAVITAL VIDEOMICROSCOPY OF THE CHICK EMBRYO CAM

BASIC PROTOCOL 2

The technique of intravital videomicroscopy (IVVM) uses a videocamera attached to an inverted microscope to visualize, record, and quantify the movement of blood through microcirculatory pathways of intact organs in living animals. General information about this procedure can be found in MacDonald et al. (1992, 1998, 2002), and Chambers et al. (2002). Here the applications of this approach to studying the interactions of injected cancer cells with the chick embryo chorioallantoic membrane (CAM) will be discussed.

IVVM uses a fiber optic light source to supply oblique illumination of an organ of an experimental animal (e.g., chick embryo, mouse) placed on the stage of an inverted microscope. This approach yields high-resolution, three-dimensional images of the microcirculation. IVVM thus allows for the real-time observation of the hematogenous metastasis process involving the initial arrest of cancer cells, as well as their extravasation, post-extravasation migration, and replication to form tumors. This technique is able to visualize these events in thick tissues, such as mouse liver, to a depth of 50 to 100 μm. It is also very easy to visualize these events in thin tissues, such as mouse or rat mesentery, or chick CAM. Interactions between tumor cells and the host microvasculature and/or the surrounding tissues of the CAM of the chick embryo have been reported (e.g., Chambers et al., 1992; MacDonald et al., 1992; Koop et al., 1994, 1996; Morris et al., 1997).

The capillary network of the CAM closely resembles that of the lung (Sethi and Brookes, 1971), and at the embryonic stage it has a capillary plexus with a complete basement membrane, which is fully lined with endothelial cells (Rizzo and Defouw, 1993). This is an appropriate model for studying various aspects of metastasis, in that tumor cells in the

circulation are required to cross the endothelium and basement membrane barrier in order to form metastases. The CAM also provides an immune-deficient model easily accessible for observation without the need for surgery.

Labeled cells are injected intravascularly into the CAM vein of 11-day-old chick embryos (see Basic Protocol 1). Examination by IVVM of individual eggs can be done immediately (up to 4 hr) or at various times post-injection, up to 7 days. This provides a visual record of the interactions of the cancer cells with the CAM vasculature, which provides valuable data that can complement results from other procedures.

Materials

Eggs containing 11-day-old chick embryos (see Support Protocol 1)
Adherent tumor cells with or without nanospheres (see Support Protocol 2)
Medium and serum used to grow tumor cells
Citrate saline (see recipe)
Paraffin oil
Plasticine

Egg candler (local farm supply store)
Pencil
Enclosed still hood with glass front, interior light, and electrical outlet
Dremel Moto tool with polishing wheel, $\frac{6}{8} \times \frac{1}{8}$–in. thick (available at local hobby shop)
38.5°C (99° to 100°F) automatic rotating egg incubator with 80% to 82% humidity (e.g., March Farms Roll-X incubators, Lyon Electric; available at farm supply stores)
30-G ½-in. needle attached to a PE-10 cannula and 1-cc syringe
Hemacytometer (*UNIT 1.1*) or Coulter counter
Vinyl tape
No. 1 coverslip, 45 × 50–mm
180 × 130 × 3–mm acrylic viewing center with 40 × 40–mm hole cut in the center
Masking tape
Inverted microscope (e.g., Nikon Diaphot TMD) with 10× to 60× or 100× objectives and mercury arc lamp with B2-A filter block (570-nm dichroic mirror and 520-nm barrier filter; 450- to 490-nm excitation wavelength; Nikon)
Infrared heat lamp
Fiber optic light source with 150 W halogen bulb
Newvicon tube video camera with extended red sensitivity (Panasonic WV1550 or Hamamatsu C2400)

Additional reagents and equipment for preparing windows in eggs (see Basic Protocol 1, steps 1 to 6 and step 9) and injecting tumor cells into eggs (see Basic Protocol 1, steps 10 to 13 and steps 15 to 16)

Prepare eggs for injection

1. Prepare 11-day-old embryos for injection with tumor cells (see Basic Protocol 1, steps 1 to 6, and 9).

   Tumor cells can be labeled with fluorescent nanospheres (Support Protocol 2) to aid in their detection. Accounting spheres (Support Protocol 3) can be used to monitor blood flow and delivery of cells to the tissue.

2. Prepare to observe the initial interactions between injected cells and CAM microcirculation:

   a. Carefully place a 30-G ½-in. needle attached to a PE-10 cannula and 1-cc syringe containing warmed citrate saline rinse into the large CAM vein. Keep in place with vinyl tape.

   b. Inject 0.25 ml citrate saline, keeping the cannula filled with solution, to avoid vessel blockage by air bubbles.

Prepare window for IVVM

3. Remove the shell and outer shell membrane from the air sac region of the egg by gently using forceps to open an observation area ~3 cm in diameter and leaving the CAM at the same level as the border of the shell.

4. Apply paraffin oil to the inner shell membrane, covering the entire air sac area of the CAM to be observed so it becomes transparent.

5. Secure a no. 1 coverslip on the opening of the acrylic viewing platform, using masking tape, so that the CAM comes into direct contact, forming a window. Place the windowed egg on the platform, so that the CAM covered in paraffin oil comes in direct contact with the coverslip, thus creating a window to directly view the capillary plexus of the CAM.

Set up microscopic viewing system

6. Carefully place the acrylic platform and egg setup on the stage of an inverted microscope equipped with 10× to 60× or 100× objective, mercury arc lamp, and Nikon B2-A filter block.

   Refer to UNIT 4.2 for a discussion of fluorescence microscopy.

7. Keep the egg in place using vinyl tape on the shell and microscope stage and building a protective wall around the shell on the platform with Plasticine where the egg meets the acrylic platform, to provide stability and prevent cracking of the egg shell during the experiment. Maintain the temperature of the egg using an infrared heat lamp.

   The arrangement of the egg and CAM tissue on the stage of the inverted microscope is illustrated in Figure 19.6.6.

   With an inverted microscope, the thin CAM tissue rests on a stationary coverslip, minimizing the effects of embryonic and respiratory movement. By focusing up and down, the CAM tissue can be optically sliced throughout its depth.

8. Use the lateral window prepared for cell injection for oblique illumination using a fiber optic light source with 150 W halogen lamp. Direct the light at an angle of ~45° to the optical axis.

   This oblique angle will assist in obtaining high-contrast views of the microcirculation. This type of illumination refracts more light from one side of the cells than the other, producing a shadowy effect that gives a three-dimensional quality to the image. Fluorescent labeling of the cells aids in identifying them in vivo. To avoid quenching, however, the fluorescence illumination should only be used periodically (i.e., for positive identification of cells). Transillumination using the fiber optic light source should be used otherwise. The video camera with the extended red sensitivity avoids the problem of having a monochromatic red image due to the high blood volume in the light path.

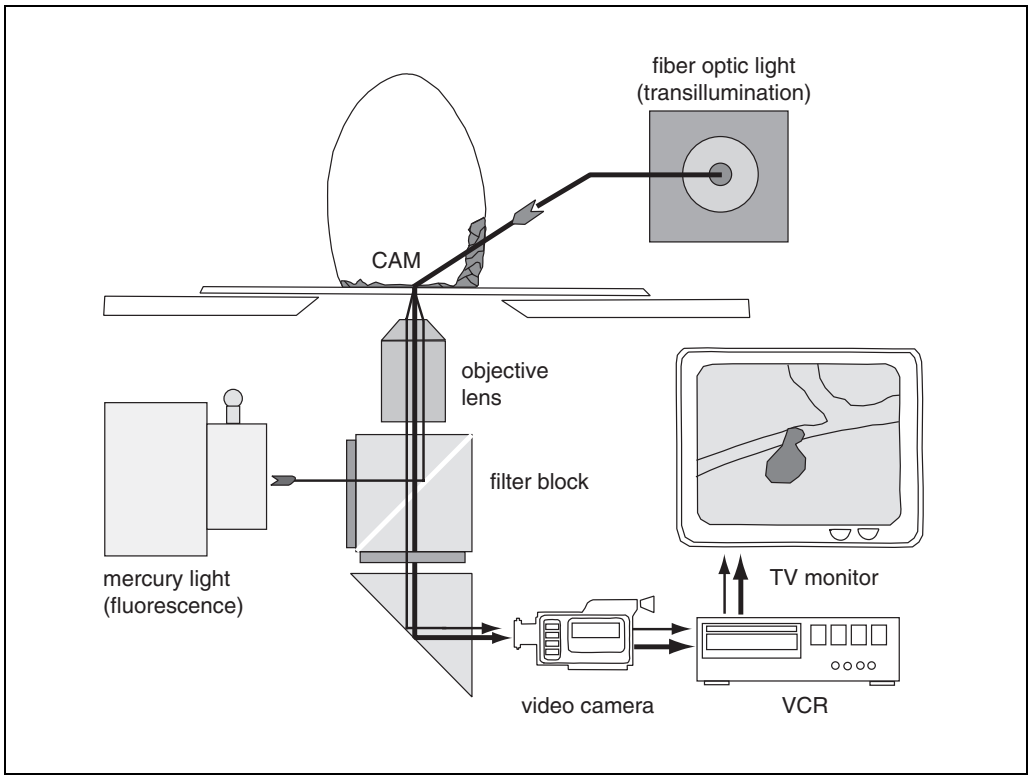

Figure 19.6.6 Schematic of the intravital videomicroscopy technique, as used for real-time observations of the interactions of injected cancer cells with the CAM microcirculation. The CAM is exposed and positioned on a plastic platform with a coverslip window above the objective lens of inverted microscope. For visualization of fluorescently labeled cancer cells, oblique transillumination is provided by the fiber optic light and epifluorescence through the objective aids in positive identification of the cancer cells. Images are collected through the video camera and saved to SVHS tape or digitally on a computer. Diagram by S. Koop and I.C. MacDonald, republished with permission of Plenum Publishers from Chambers et al. (1995).

Perform IVVM

9. Capture the microcirculation images using a Newvicon tube video camera with extended red sensitivity and appropriate capture device.

   These black-and-white images can be viewed directly on a video monitor, recorded on a SVHS videocassette recorder, or captured by computer programs such as Optimas Image Analysis (Media Cybernetics) or Northern Eclipse (Empix Imaging). A 35-mm camera can also be attached to the microscope for color photographs of the CAM. A character generator adds time, date, and stopwatch information to the video signal. A stage micrometer can be used to calibrate the magnification of the video image for each objective lens. Images can be obtained using either transillumination or epifluorescence alone, or a combination of both.

10. When the entire system is set up for viewing the CAM, inject 0.1 ml tumor cell suspension through the 30-G needle attached to the cannula (step 2).

11. View the cells at various magnifications starting with 10× to identify the cells. Carry out detailed examination of these cells and their immediate environment at higher magnification. Use video replay to measure cell and vessel dimensions, locations, and other parameters.

    Refer to Chambers et al. (1992), MacDonald et al. (1992, 1998), and Koop et al. (1994, 1995, 1996) for further discussion.

IVVM observations can be carried out for up to 4 hr post-injection without visible changes in blood flow or embryo movement. After the observations, the CAM tissue can be fixed in neutral-buffered formalin for later histopathological analysis.

The calibration scale on the fine-focus knob of the microscope permits the measurement of the cancer cell depth below the capillary plexus of the CAM. As a reference point for these measurements, the red blood cells within the plexus are clearly imaged, then the distance below this point, where the fluorescence image of the cancer cells are in sharpest focus, is determined using the fine-focus knob of the microscope.

Perform real-time in vivo kinetic analyses

12. Observe later stages of the interactions between tumor cells and CAM microcirculation by injecting as described (see Basic Protocol 1, steps 10 to 13 and 15 to 16). At specific time intervals (1 to 7 days postinjection) remove individual eggs from the incubator and observe as described above.

    Since the injection window is sealed, a new small window for observation with oblique illumination must be prepared (see Basic Protocol 1, step 3). The observation procedures are then carried out as described above.

LABELING CELLS WITH FLUORESCENT NANOSPHERES

SUPPORT PROTOCOL 2

In order to allow positive identification of cancer cells, human or rodent, within the CAM (or in mouse tissues), it is necessary that the cells be labeled in some way. Some lines, such as melanoma cells (e.g., B16F1), express melanin, which can be detected by eye (Chambers et al., 1982, 1992; Koop et al., 1994). Exogenous labels such as Calcein-AM (Chambers et al., 1992; Morris et al., 1994) or fluorescent nanospheres (~0.05-µm labeled polystyrene microspheres; Morris et al., 1994; Naumov et al., 2002) have been used to label the cytoplasm of cells to be injected without any effect on membrane integrity or growth potential of these cells. Alternatively, the gene for green fluorescence protein (GFP) can be transfected into cell lines, providing a heritable label that does not dilute with cell division (Naumov et al., 1999, 2002). Clones of GFP-transfected cells must be tested for brightness for use with IVVM as well as maintaining genotypic and phenotypic properties of the parental cell line (Chambers and Wilson, 1988; Naumov et al., 1999). Most cell lines readily take up the fluorescent nanospheres when incubated with them in vitro, prior to injection.

Materials

0.05-µm-diameter, fluorescent, carboxylated P(S/V-COOH), dragon-green (480/520 nm) nanospheres (Bangs Laboratories) for cell labeling; store at 4°C in the dark
OptiMEM serum-reduced medium (InVitrogen)
Cells to be labeled

Sonicator
50-ml conical polystyrene centrifuge tubes
0.2-µm syringe filter and 10-ml syringe
Aluminum foil
75-cm^2 tissue culture flask
150 × 15–mm tissue culture dishes
Tissue culture incubator, standard, 37°C, 5% CO_2

Additional reagents and solutions for culturing, trypsinizing, and counting cells (*UNIT 1.1*)

Prepare fluorescent nanospheres

1. Sonicate a 10-ml vial of 0.05-µm-diameter, fluorescent, carboxylated P(S/V-COOH), dragon-green nanospheres 15 min.
2. In a tissue culture hood, add 75 µl nanospheres to 10 ml OptiMEM serum-reduced medium or 375 µl nanospheres to 50 ml OptiMEM medium in a 50-ml conical polystyrene centrifuge tube.
3. Sterilize the nanosphere suspension by passing through a 0.2-µm syringe filter, attached to a 10-ml syringe, into a clean, sterile 50-ml conical centrifuge tube. Wrap the tube in aluminum foil and store undisturbed at 4°C overnight.

Prepare cells to be labeled

4. The next day, centrifuge the nanospheres 10 min at 3000 × *g*, room temperature. Carefully remove the upper 2.5 ml for a 10-ml suspension or 30 ml for a 50-ml suspension. Avoid disrupting the sediment at the bottom of the tube. Vortex the suspension.
5. Cells to be labeled to 80% confluency by standard laboratory methods (*UNIT 1.1*) in either a 75-cm^2 tissue culture flask or 150 × 15–mm tissue culture dish.
6. Wash the cells twice with 10 ml OptiMEM medium.

Allow cells to take up nanospheres

7. Completely remove the last wash and add either 7.5 ml filtered nanospheres for a 75-cm^2 tissue culture flask, or 20 ml for a 150 × 15–mm tissue culture dish.
8. Incubate 2 hr at 37°C in CO_2 incubator, swirling occasionally to distribute the nanospheres evenly.
9. Following the incubation, wash cells twice with 10 ml OptiMEM to remove excess nanospheres.

Prepare cells for injection

10. Trypsinize the cells by standard laboratory procedures (*UNIT 1.1*).
11. Perform a cell count with a hemacytometer to determine cell number (*UNIT 1.1*).
12. Using the medium and serum in which the cells are normally grown, resuspend and adjust the volume of the cell suspension to give the desired number of cells per 0.1 ml injection volume. Store the cells at 4°C for up to 2 hr prior to injection (see Basic Protocol 1, step 5).

    In general, fluorescent labeling of cells should be carried out using cytoplasmic rather than nuclear markers. Cells labeled with the nuclear stain acridine orange were shown to be prone to lysis, which markedly affects their metastatic properties in vivo (Morris et al., 1994). Alternatively, cells can be detected using stably transfected fluorescent markers such as green fluorescent protein (GFP; Naumov et al., 1999).

13. Determine if the uptake of the nanospheres affects the viability or growth of the cells by plating labeled and unlabelled cells in six 60-mm dishes at 100 cells per dish. Incubate undisturbed for 11 to 14 days. Stain colonies, count, and determine plating efficiencies:

    Plating efficiency = (no. colonies/no. cells plated) × 100%.

CELL ACCOUNTING IN TISSUES

This experimental procedure enables one to quantify the survival of cells injected into the CAM. To do this, the number of cells actually observed in a sampled volume of tissue at any time must be expressed relative to the number of cells that originally entered that volume. Based on the standard method of measuring blood flow, inert plastic microspheres (10 μm) are added to the cell suspension, prior to injection, at a known ratio (e.g., 1 microsphere:10 cells). These microspheres become trapped by size restriction in the blood capillaries where they remain indefinitely. Thus, the total number of microspheres in a particular volume of tissue provides a reference marker for the total number of cells that originally entered this area, and they can be assessed by either IVVM (see Basic Protocol 2) or histology on thick sections (30 to 50 μm). General information about this procedure can be found in Koop et al. (1995), Morris et al. (1997), and MacDonald et al. (1998).

Materials

Tumor cell suspension, with or without fluorescent nanospheres (see Support Protocol 2)
10-μm-diameter, yellow/green (505/515 nm) fluorescent, plastic microspheres (fluorospheres; Molecular Probes)
60-mm tissue culture dishes

Additional reagents and equipment for fluorescent microscopy (*UNIT 4.2*)

1. Prepare a tumor cell suspension labeled with fluorescent nanospheres if desired (see Support Protocol 2).

2. Calculate the final injection volume and adjust the tumor cell concentration in a smaller volume so the same number of cells are being injected, compensating for the additional volume of the predetermined amount of accounting spheres that will be needed to give the final volume of 0.1 ml per embryo.

   For example, the injection suspension is calculated as follows to compensate for the additional volume of the accounting sphere suspension: 1 ml (the final volume that will contain the predetermined number of cells and accounting spheres) minus the volume containing this number of accounting spheres (e.g., $^1/_{10}$ the number of tumor cells) = the volume of growth medium in which to resuspend the tumor cells.

3. Add the appropriate amount of 10-μm-diameter, yellow/green, fluorescent, plastic microspheres to the cell suspension.

   The fluorospheres, also known as accounting spheres, are at a known concentration and are already sterile. A recommended ratio is 1 accounting sphere:10 cells.

4. Confirm the intended calculated ratio by putting a drop of the suspension to be injected onto a microscope slide, and counting cells and beads in a given area using a standard light microscope (*UNIT 4.1*).

   The prepared suspension of cells with accounting spheres are now ready for injection and can be maintained at 4°C until injection into the CAM.

5. Inject the cell/microsphere suspension into the CAM.

6. Examine the embryonic tissue for the presence of accounting microspheres and fluorescently labeled cells (nanospheres). Use the numbers to calculate injected cell survival.

The ratio in the tissues at various times after injection, divided by the ratio in the syringe before injection, is referred to as the cell survival (CS) index (Koop et al., 1995; Morris et al.; 1997; MacDonald et al., 1998). Thus, a CS index of 1.0 (i.e., 10 cells observed in vivo for every microsphere in a given tissue volume) would imply 100% survival, whereas a decrease in CS index would imply <100% survival (i.e., if only five cells were observed for every microsphere in a given tissue volume at some time after injection, 50% of the cells could be accounted for, and 50% of the cells would have been lost, either by cell death or by passage through the organ). This assay allows for cell accounting relative to the total number of injected cells rather than the percentage of observed cells remaining in vivo at times after injection.

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Citrate saline

4.4 g/liter sodium citrate
10.0 g/liter KCl
Sterilize by autoclaving 20 min
Store up to 3 months at 4°C

No pH adjustment is necessary.

Collagenase, 0.3%/trypsin, 0.02%

Prepare a trypsin stock by adding a 10-ml bottle of trypsin to 100 ml sterile HBSS (see recipe) using proper sterile technique. Store up to 2 weeks at 4°C.

Prepare a fresh collagenase stock by combining 300 mg collagenase IV with 80 ml HBSS. Stir 1 hr and filter through a 0.8-µm filter, then through 0.2-µm filter.

Prepare the collagenase/trypsin mix by adding 20 ml trypsin stock to 80 ml collagenase stock. Mix well and store up to 2 weeks at 4°C.

DNase I

Add 1 mg DNase I per milliliter HBSS (see recipe). Sterilize by passing through a 0.2-µm filter. Store up to 2 weeks at 4°C.

HBSS

Autoclave 450 ml water in a 500-ml bottle, then allow to cool. Under sterile conditions, add 50 ml of 10× HBSS solution (InVitrogen) and 1.5 ml of 7.5% sodium bicarbonate (InVitrogen), and adjust to pH 7.0. Store up to 3 months at 4°C.

Methylene blue stain

Prepare a 1% (w/v) solution of methylene blue in 70% ethanol. Stir for a few hours until the crystals are completely dissolved. Add glutaraldehyde to a final concentration of 1%. Store in a 500–ml plastic wash bottle up to 2 months at room temperature. Supplement with glutaraldehyde every third staining. If a precipitate forms, filter through chromatography paper.

Ouabain, 1×10^{-3} and 2×10^{-5} M

Prepare a 10^{-3} M stock by dissolving 72.86 mg ouabain in 100 ml tissue culture medium with serum for the cell line used. Filter sterilize by passing through a 0.2-µm filter. Store up to 2 weeks at 4°C.

Prepare the 2×10^{-5} M working solution by adding 10 ml of 10^{-3} M stock to a 500-ml bottle of tissue culture medium with serum. Store up to 2 weeks at 4°C.

PBS, calcium and magnesium free

8.0 g NaCl
0.2 g KCl
0.2 g KH_2PO_4
1.15 g Na_2HPO_4
Adjust to 1 liter with water
Autoclave for 20 min
Store up to 3 months at 4°C.

This buffer is calcium and magnesium free.

Trypsin, 2.5% (w/v), in citrate saline

Add one 10-ml vial of Difco Bacto-Trypsin to a 500-ml bottle of sterile citrate saline (see recipe). Store up to 3 months at 4°C. Warm in a 37°C water bath before trypsinization of cells.

COMMENTARY

Background Information

The experimental metastasis assay in the chick embryo chorioallantoic membrane (CAM) allows for two standard types of experiments. First, single time-point experiments are generally terminated 7 days after injection. These assays give a measure of metastatic growth ability of injected cancer cells in the chick liver, which is the first capillary bed reached by cells injected via CAM veins. These assays are useful for quickly comparing the metastatic properties of different cell lines or treatments. This end point would be analogous to single-time-point experiments in mice, in which the numbers and sizes of metastatic foci are determined at some time after i.v. injection. For quickly growing tumor cell lines, this end point (macroscopic tumors detected at the liver surface) can also be used in the chick embryo. In contrast, in the ouabain plating assay, the numbers of tumor (rodent) cells are counted. This number will be related to the number of metastases that grow, their growth rate, and the numbers of cells that remain without division.

Kinetic experiments can also easily be performed with the chick assay, by measuring the numbers of viable rodent cells in chick organs at various times after injection, as illustrated in Figure 19.6.5. See Chambers et al. (1982), Chambers and Ling (1984), and Chambers and Wilson (1985), for examples of the results that can be obtained with this assay. The fate of injected cells over time after arrival in the target organ determines the growth or death rates of cells in vivo. This information is generally not obtained from experimental metastasis assays in mice, because information on the cells is not obtained until metastases are large enough to be detected by the eye, and then only from a single end point. It should be noted that due to the short experimental time of this assay, genetically-manipulated cells which may have unstable genotypes should be considered for this assay rather than long-term tumor formation assays. The ability to easily perform growth kinetics, from immediately after injection to 7 days post-injection, is a strength of the chick embryo experimental metastasis assay.

The ability of the chick to develop over a range of temperatures can be a powerful genetic tool when applied to the study of metastatic properties of cancer cells having temperature-sensitive mutations. The experimental metastasis assay is also very sensitive to small changes in growth ability, to the point of being able to detect a response within a day of a change in growth conditions, as described for temperature-sensitive *src*-transformed cells shown in Figure 19.6.5B (see Chambers and Wilson, 1985).

The laboratory mouse is the most commonly used animal for in vivo metastasis assays. Many of these assays require the use of an immune-deficient host, such as athymic nude or SCID mice, which are expensive and require special care and housing. The authors have previously shown that the cost of assessing the metastatic properties of cell lines in the experimental metastatic assay using the chick embryo is approximately one-quarter the cost of testing the same cells in nude mice, and approximately one-fifth the cost of testing in nude mice and plating mouse livers to recover viable cells (Chambers et al., 1990). It should be noted that these calculations did not include the start-up cost for expensive facilities to house the immune-deficient mice. In contrast, the equipment for maintaining the chick embryo is inex-

pensive and readily available (Chambers et al., 1990). The experimental metastasis assay in the chick embryo is thus a cost-effective method that can be useful for prescreening cells, which can subsequently be tested in nude or SCID mice, using considerably smaller numbers of mice. The authors have shown that results from the two assays can give comparable results for individual cell lines (Chambers et al., 1990). In addition, in some institutions, use of chicken embryos may be subjected to less complex animal care and use regulations than those applied to the use of mice in tumor studies. Overall, the use of chick embryos to study metastasis provides a useful alternative to metastasis assays in mice and may offer advantages for many researchers.

Critical Parameters and Troubleshooting

Many of the critical parameters have been outlined above in the appropriate protocol sections. In general, several steps require a steady hand, such as the drilling of windows in the egg shells, lifting the shell to form the injection window, and injection of cells into CAM veins. These steps are not hard but do require practice. A good approach to developing injection skills is to carry out experiments in which a melanotic cell line, such as murine B16F1 or B16F10, are injected into CAM veins. Success of the injections can be determined 7 days later, as these cell lines form macroscopic tumors in the CAM tissue and liver; these can be readily detected upon dissection of the embryo and inspection by eye.

The fertility rate of chick embryos may vary seasonally and with geography and weather conditions; however, with experience, this rate can be predicted for the local situation. Extra eggs should be ordered until this fertility rate is known.

Anticipated Results

In Basic Protocol 1, some rapidly growing cancer cell lines (such as B16F1 and B16F10 melanoma) form metastases detectable by eye during a 7-day incubation period following injection into chick CAM veins (e.g. Chambers and Wilson, 1988, Koop et al., 1994). Detection of these may be aided by production of melanin by some cell types. Growth of many other cancer cell types can be detected using the ouabain recovery procedure, and these have been compared with results from experiments in mouse (Chambers et al., 1990). The in vivo growth kinetic analysis (Fig. 19.6.5). offers an especially powerful approach to characterizing in vivo behavior of cancer cell growth in metastatic sites and permits subtle changes in growth to be detected (e.g., due to a temperature shift, affecting a temperature-sensitive oncogene in the example shown; Chambers and Wilson, 1985).

Further information on the behavior of cancer cells in vivo can be obtained by direct observations, as permitted by the use of in vivo videomicroscopy (Basic Protocol 2). For example, use of this procedure permitted the in vivo effects of over-expression of tissue inhibitor of metalloproteinase-1 (TIMP-1) in B16F10 cells to be determined (Koop et al., 1994). While it had been expected that TIMP-1 would inhibit escape of cancer cells from the microcirculation, that study found instead that the TIMP-1 overexpressing cells extravasated well, but had a defect in micrometastatic growth. Because the CAM is a thin structure, it is relatively easy to determine if cells are intravascular or extravascular, permitting kinetics and efficiency of extravasation to be easily quantified (e.g., Koop et al., 1995, 1996). These studies showed that the large majority of cells injected into the CAM circulation successfully extravasate, a finding also seen in mice (Chambers et al., 1995, 2002). The chick embryo thus can provide a low-cost, simple complement to more expensive and complex experiments in mice.

Time Considerations

The experimental metastasis assay (see Basic Protocol 1) involves injecting 11-day-old chick embryos and then collecting data at time intervals from time 0 to 7 days post-injection. Experiments must be planned ahead, in order to have embryos of the desired age on the appropriate day. The set-up time required for injection of the embryos is ~2 hr including the preparation of the cells for injection. The injection time is dependent on the number of embryos being injected. The dissection of the chick embryos, dissociation of the livers, and setting up of the ouabain plating assay usually require 3 hr, again depending on the number of embryos in the experiment. The in vitro part of this assay requires 10 to 14 days for formation of colonies, depending on the growth rate of the cells in vitro to form colonies.

IVVM of chick embryo CAMs (see Basic Protocol 2) can generate data in as short a time as 2 min post-injection and up to 4 hr. The embryos can be used from time 0 to 7 days post-injection. The set-up time for the embryo before visualization is ~2 hr including the cell

suspension preparation. IVVM, although a powerful observational tool, is generally a labor-intensive procedure, as information can be obtained in real-time for only one embryo at a time.

For Support Protocol 1, daily monitoring of the eggs in the incubator and addition of water takes ~15 min per day. For Support Protocol 2, labeling of cells with nanospheres, preparation of the nanospheres the day before the experiments requires 0.5 to 1 hr. Labeling of the cells and preparation of the cells on the day of the experiment takes ~4 hr. Addition of accounting spheres in Support Protocol 3 will require ~1 hr of preparation time.

Figure 19.6.1 Diagram of experimental metastasis assay in chick embryos. Cancer cells are injected via a chorioallantoic membrane (CAM) vein, through a window opened in the shell of 11-day-old chick embryos. Cells injected via this route travel via the circulation first to the embryonic liver. After incubation for up to 7 days, metastatic cells in an embryonic organ such as liver are quantified using the ouabain plating assay, or (for rapidly growing cell lines) macroscopic metastases can be quantified. Republished with permission of Anticancer Research from Chambers and Tuck (1988).

Figure 19.6.2 The drilling of the marked square or window on the egg over the selected vein area with a Dremel Moto tool is done in an enclosed still hood. To minimize breathing of eggshell dust, hang a cloth from the bottom of the glass front (or alternatively wear a mask and protective eyewear). Drill all four sides of the window, with the egg at a slight angle and the air sac end (blunt end) up and the marked window facing toward the person drilling. The bit of the Dremel tool is brought at right angles to the surface of the shell. Gentle pressure is sufficient for cutting due to the high speed of the drill. Only the shell is cut while avoiding the underlying smoother papery-white membrane or the underlying CAM.

Figure 19.6.3 The arrangement of equipment inside the tissue culture hood just before injections proceed. The front of the hood is opened for easier access during the procedure with adequate sterility still being maintained. The gooseneck arm of the fiber optics light is illuminating the air sac end of an egg positioned on the egg stand (made by gluing three rubber corks onto a plastic petri dish) ready for injection. The remaining eggs have had the shell of the drilled window carefully removed over the vein area and are placed in a tray with the windows facing upwards awaiting injection. The cell suspension has been prepared at a predetermined concentration ready to be drawn up into the 1-cc syringe following gentle vortexing. The other 1-cc syringe contains the paraffin oil of which a drop will be placed on the exposed window area prior to injection. The melted Paraplast in the glass beaker (left) is cooling in preparation for sealing of the entire window area following injection.

Figure 19.6.4 Injection of cells into a chick embryo CAM vein. Position the egg on the egg stand, with the fiber optics light illuminating the air sac end for visualization of the large Y shaped vein. The addition of a small drop of paraffin oil onto the injection site enhances the clarity of the vein. The beveled tip of the needle is facing upwards for gentle insertion into the branch area of the Y (see inset) just until the beveled end is completely into the vein. The needle should be at the angle seen in the picture above to prevent damage to the vein. If a proper injection is performed, the vein will temporarily become clear as the 0.1-ml inoculum is smoothly injected, and there will be no blood seeping from the injection point either during or after the injection.

Figure 19.6.5 Example of in vivo growth kinetics results that can be obtained with the chick embryo experimental metastasis assay and the ouabain plating assay to recover rodent (and thus, ouabain-resistant) cells at various times after injecting cells via a CAM vein. (**A**) B77-NRK (normal rat kidney) cells transformed with the src oncogene, or (**B**) LA23-NRK cells (NRK cells carrying a temperature-sensitive src oncogene, which is active at 36° and inactive at 38°C were injected into CAM veins at 5×10^4 cells per embryo. Closed circles: embryos maintained at 36°C; Open circles: embryos transferred to 38°C at day 4. Each point represents the number of viable ouabain-resistant cells present in the liver of one embryo; lines connect median points. Republished with permission of American Society of Microbiologists from Chambers and Wilson (1985).

Figure 19.6.6 Schematic of the intravital videomicroscopy technique, as used for real-time observations of the interactions of injected cancer cells with the CAM microcirculation. The CAM is exposed and positioned on a plastic platform with a coverslip window above the objective lens of inverted microscope. For visualization of fluorescently labeled cancer cells, oblique transillumination is provided by the fiber optic light and epifluorescence through the objective aids in positive identification of the cancer cells. Images are collected through the video camera and saved to SVHS tape or digitally on a computer. Diagram by S. Koop and I.C. MacDonald, republished with permission of Plenum Publishers from Chambers et al. (1995).

Imaging Tumor Cell Movement In Vivo

Understanding of the contribution of genetics to cancer has expanded greatly over the past several decades. However, studies of the functional significance of changes in oncogenic gene expression in vivo, as well as the effects of drugs on the oncogenic targets in vivo at the cellular level, have been limited by lack of technologies and associated techniques that would allow for dynamic high-resolution analysis. Moreover, the invasiveness of primary tumor cells makes a significant contribution to malignancy. Local invasion can enable tumor cells to spread from the primary tumor through neighboring connective tissues, and is responsible for poor patient prognosis in tumors that cannot easily be surgically removed, such and glioblastoma and head and neck cancer. Local invasion can also be important for the spread of tumor cells from the primary tumor into blood vessels or lymphatics in many other tumor types, including breast cancer. Although in vitro studies of cell motility and invasion are useful surrogates for beginning to understand the mechanisms that regulate invasiveness, the complexity of the in vivo microenvironment, with a wide variety of cell types, vessels, and extracellular matrix, is not yet possible to reproduce in vitro. Thus, it is important to evaluate tumor cell invasiveness using in vivo assays. In particular, the ability to image tumor cells as they are invading allows the direct evaluation of tumor cell motility and opens up experimental evaluation of specific mechanisms for tumor cell invasion.

This unit describes the methods that the authors of this unit have been developing for analyzing tumor cell motility in mouse and rat models of breast cancer metastasis. Rodents are commonly used in order to provide a mammalian system both for studying human tumor cells as xenografts in immunocompromised mice and for following the development of tumors from a specific tissue type in transgenic lines. Basic Protocol 1 describes the standard methods used for generation of mammary tumors and imaging them. Additional protocols for simultaneous CFP and GFP imaging (Alternate Protocol 1), microscope setup (Support Protocol 1), second harmonic imaging (Support Protocol 4), labeling macrophages (Support Protocol 2), blood vessel imaging (Support Protocol 3), and image analysis (Basic Protocol 2 and Alternate Protocol 2) are also included.

NOTE: All protocols using live animals must be reviewed and approved by the local Institutional Animal Care and Use Committee (IACUC) and conform to governmental regulations regarding the care and use of laboratory animals.

GENERATION AND IN VIVO IMAGING OF MAMMARY TUMORS

BASIC PROTOCOL 1

MTLn3, a highly metastatic rat mammary adenocarcinoma cell line, is often used by the authors' laboratory (Neri et al., 1982). The cells have been transfected with GFP (eGFP from pEGFP-N1 subcloned into PLXSN) so that they can be imaged. In general, cell lines used must stably express GFP, or any other fluorescent protein that can be imaged by the multiphoton microscope, because of the growth that occurs to form a tumor prior to the imaging step. The following protocol is specifically used for MTLn3 and its derivatives. A discussion of alternatives for other lines is provided in Wyckoff et al. (2005). Female 5- to 6-week-old BALB/c SCID mice or 7- to 8-week-old Fischer 344 rats are used. The animals are injected with 0.1 ml of cell suspension in the mammary fat pad, under the second nipple anterior from the tail, and tumors are allowed to grow for 3 to 4 weeks.

Materials

MTLn3 cells (available from authors; *segall@aecom.yu.edu*)
MTLn3 growth medium (see recipe)

Contributed by Dmitriy Kedrin, Jeffrey Wyckoff, Erik Sahai, John Condeelis, and Jeffrey E. Segall
Current Protocols in Cell Biology (2007) 19.7.1-19.7.17

2 mM EDTA (Invitrogen cat. no. 15575-038) in calcium- and magnesium-free Dulbecco's phosphate-buffered saline (CMF-DPBS; Invitrogen; also see *APPENDIX 2A*)

Dulbecco's phosphate-buffered saline (with calcium and magnesium; DPBS; Invitrogen; also see *APPENDIX 2A*)

Female 5- to 6-week-old BALB/c SCID/Ncr mice (National Cancer Institute), Fisher 344 rats (The Jackson Laboratory), or transgenic mouse tumor models (e.g., MMTV-pyMT; The Jackson Laboratory)

70% (v/v) ethanol

Isoflurane,USP (AERRANE, Baxter)

15-cm tissue culture dishes (Falcon)

15-ml conical polypropylene centrifuge tubes, sterile

Cell scrapers

Centrifuge (e.g., Sorvall GLC-1)

1-ml syringes with 25-G needles for cell injections

Oxygen/anesthesia apparatus (Forane Vaporizer, model 100, from SurgiVet)

100% compressed oxygen tanks to be used in combination with vaporizer

Surgical instruments

In vivo imaging microscope setup (Support Protocol 1)

Multiphoton apparatus setup (Support Protocol 4)

Surgical tape (optional)

Additional reagents and equipment for tissue culture techniques including counting cells (*UNIT 1.1*), housing of immunocompromised mice (Donovan and Brown, 1995), imaging blood vessels (Support Protocol 2 or 3; optional), inhalant anesthesia of rodents (Donovan and Brown, 1998), and image analysis and quantitation (Basic Protocol 2)

NOTE: All solutions and equipment coming into contact with living cells must be sterile, and aseptic technique should be used accordingly.

NOTE: All tissue culture incubations should be carried out in a humidified 37°C, 5% CO_2 incubator unless otherwise specified. Some media (e.g., DMEM) may require altered levels of CO_2 to maintain pH 7.4.

Grow and prepare cells for injection

1. Grow MTLn3 cells in MTLn3 growth medium to 50% to 70% confluence in a 15-cm tissue culture dish.

   UNIT 1.1 describes basic cell culture techniques.

2. Under sterile conditions, rinse the dishes three times, each time with 10 ml of 37°C sterile CMF-DPBS containing 2 mM EDTA.

   Since the cells are tightly attached to the dish, it is possible to aspirate all of the medium and gently add fresh medium to the side of the dish without losing many cells.

3. Add 12 ml of CMF-DPBS/2 mM EDTA and place at room temperature to detach cells.

   Depending on the thoroughness of the previous rinse steps, this can take from 10 to 30 min. Once 75% of the cells are detached after tapping the dish on a surface, the cells are ready to be collected.

   It may also be possible to use trypsin/EDTA without adverse affects on the cells. In this case, take care not to over-trypsinize, neutralize the trypsin with some serum, and then wash cells. Also see UNIT 1.1.

4. Add 6 ml DPBS containing Ca and Mg and detach the remaining cells by gently rinsing.

5. Collect the cells into two 15-ml sterile tubes, scraping the dish to collect the matrix and adding it to the tube as well. Take an aliquot and count cells using a hemacytometer (*UNIT 1.1*).

   Cell counting may be performed during the subsequent centrifugation step.

6. Centrifuge cells 5 min at 180 to 200 × *g*, room temperature.

7. On the basis of the cell count performed on the aliquot taken in step 5, determine the appropriate volume for resuspending the pellet to obtain a cell density of $\sim 1 \times 10^7$ cells/ml. Resuspend cells in sterile DPBS at 1×10^7 cells/ml, and recount (*UNIT 1.1*) to confirm actual density.

   Dilutions as low as 5×10^6 cells/ml can also be used, which produce tumors slightly more slowly.

8. Transfer cell suspension to a sterile 1.5-ml microcentrifuge tube and keep on ice until injection.

Inject cells for xenograft

9. With two people working together, one to hold the animal and another to inject the cells using a 1-ml syringe fitted with a 25-G, prepare for injection of cells.

   As one person prepares the mouse by picking it up by the back of the neck and holding the back leg with another hand, the second person takes the cell suspension off the ice and fills the syringe.

10. Spray the area at the second lowest nipple with 70% ethanol and insert the needle subcutaneously at a shallow angle in the mammary fat pad. Inject 100 µl of cell suspension and notice a slight bulge in the skin above the injected area.

    At this step it is important that the needle only penetrate the skin and stay within the mammary fat pad, so no cells spread into the peritoneum. To ensure this, keep the angle of injection very shallow.

    Injection of Fischer 344 rats is done in the same manner, but injection volume can be increased to 150 to 200 µl.

11. Keep the animals in the barrier-room facility (see Donovan and Brown, 1995) until the tumors are large enough to image (0.5 to 1 cm diameter for mice or up to 1.5 cm for rats, typically 3 to 4 weeks). Check tumor size on a regular basis to make sure it is growing.

    The tumor should be palpable after 1.5 weeks. After 3 to 4 weeks, the tumor should be about 5 to 7 mm in diameter (mice) or 1 cm in diameter (rats), at which time the animals are ready to be imaged.

    Smaller tumors are harder to image due to lack of good surfaces, because the tumor has not grown through the fat layers of the fat pad, which interferes with image collection. Larger tumors tend to become necrotic, thus destroying adequate imaging surfaces on the tumor, or the large tumor can invade the peritoneum, thus preventing skin-flap surgery from being adequate for imaging purposes.

    Alternatively, transgenic animals, such as those described by Wyckoff et al. (2004), can be used to image tumors. For this purpose, animals are grown until tumors reach a size adequate for imaging. Palpable tumors are large enough to image in transgenic animals, but due to staging of tumor progression, intravasion and metastasis do not occur generally until late-stage carcinoma. Therefore, each tumor model will be different in determining the best time for imaging.

Prepare animal for imaging

12. Place the animal under anesthesia with 5% isoflurane in O_2 using an oxygen/anesthesia apparatus.

    Isoflurane is to be administered via an oxygen mask to the animal prior to surgery, for the time of surgery, and while animal is used to collect imaging data.

13. *Optional:* Inject Texas red–dextran to image blood vessels (see Support Protocol 2 or 3).

14. Place the animal on the surgery stage and swab the tumor area with 70% ethanol. Perform a medial skin incision, exposing the tumor.

15. Clear the area around the tumor from fascia and fat while maintaining blood vessel supply as much as possible and keeping bleeding to a minimum.

    This must be done carefully and meticulously to avoid destroying the vasculature or cutting into the tumor itself.

16. Transfer the animal to a prewarmed imaging stage (30°C) with the exposed tumor placed on the coverslip (objective) for imaging. If necessary, use surgical tape to hold the tumor in place.

    The tumor should be isolated away from the animal as much as possible and secured to the microscope platform. Stages can be designed so as to make it possible to pin the skin around the tumor to cork; alternatively, the skin flap can be taped to the stage. This must be done carefully and without compressing the tumor too much. The tumor should be separated as far as possible from the mouse so as to minimize vibrations due to breathing.

    Fat cells work as lenses in the tumor and disrupt the multiphoton events. Fat should be removed as much as possible without disrupting the blood flow to the tumor, to allow for better image quality.

17. During imaging, sequentially lower isoflurane level in steps of 0.25% every 20 to 30 min to maintain a constant low breathing rate, defined as one or fewer distortions per image at 166 lines per second scan speed.

    Maintenance of breathing and minimization of drift and movement of the animal is key for successful time-lapse data collection. The best way to minimize breathing is by controlling the isoflurane level. The isoflurane should be monitored to control the amount of breathing during the imaging session, as described above. The ability to manipulate the breathing is why using isoflurane is a better choice than injectable anesthesias.

    If breathing is too rapid, distortions might make acquired data difficult to interpret, at which point the anesthesia levels should be adjusted or the position of the animal on the imaging platform should be adjusted to minimize drift and breathing artifact. With time, less anesthesia is required to maintain a low breathing rate; too much anesthesia will kill the animal. Typical final isoflurane levels are 2% to 3.5%.

Perform intravital microscopy

Each image is essentially in the *x-y* imaging plane. A *z*-series of individual *x-y* images is collected by stepping through the images. No specific detail on how to collect the *x-y* images is provided here; that will depend on the instrument used.

18. Focus in on fluorescence of the GFP tumor, looking for areas with flowing blood vessels by viewing through the eyepiece in epifluorescence mode. Upon finding an area that has bright fluorescence and flowing vessels, switch to imaging via the multiphoton mode.

    For one-color GFP imaging, the animal is placed under anesthesia as described above and imaged. On, average, each imaging sequence lasts 20 to 30 min, and the same animal can be maintained on the microscope for up to 4 hr.

19. While imaging in the multiphoton mode, move around the tumor until a good imaging area is obtained.

    If vessel imaging is desired, find a vessel to be imaged, or find the edge of the tumor, judging by fluorescence.

    Good imaging fields for cell invasion and intravasation are areas around flowing vessels with well defined cell boundaries and extracellular matrix. Flowing vessels can be visualized by labeling with a fluorescent dextran or by viewing vessels through the oculars of the microscope.

    The authors find that focusing at the outer tumor surface, where cells are just invading the matrix, and generating a z-series stepping into the tumor until the image degrades to a point where cell morphology is not well defined, gives the best images for analysis. Many systems now can vary the laser power as a function of z-position, allowing the use of more power to image greater depths without damaging or overexposing the tissue closer to the objective.

20. For the outermost plane of the *z*-series, focus in on the outside of the tumor by visualizing the collagen fiber network in the second harmonic channel (Fig. 19.7.1A).

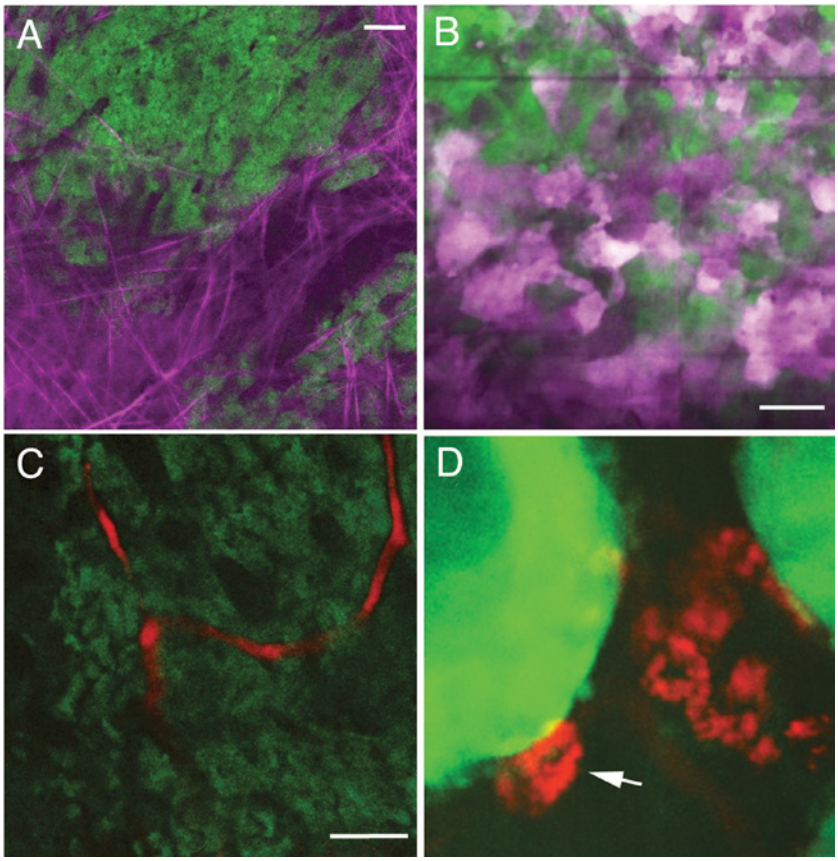

Figure 19.7.1 Multiphoton imaging of MTLn3 xenotransplant tumor in mouse. (**A**) GFP-expressing tumor cells are shown in the green channel and matrix second harmonic image is shown in both red and blue channels (for contrast). (**B**) Mix of GFP-expressing cells (green channel) with CFP-expressing cells (red and blue channels) in a single tumor. (**C**) Simultaneous imaging of GFP-expressing tumor cells (green) and blood vessels (red) following intravenous injection of Texas Red–dextran. (**D**) Imaging of macrophages labeled with Texas Red–dextran (red) in GFP-expressing MTLn3 tumor. Scale bars for A and C represent 50 μm, those for B and D represent 25 μm. For the color version of this figure go to *http://www.currentprotocols.com.*

Depending on the goal of the imaging session, the size of the z-series that is selected is constrained by: (1) the desired quality of each image, (2) the time-lapse interval desired between images at a particular plane, and (3) the z-axis resolution desired. The quality of each image is determined by the brightness of the fluorescence. For brightly labeled tumors, shorter imaging times per frame are needed, but for dimly labeled tumors, imaging time may become limiting. The authors typically use a scan rate of 166 lines per second for moderate-quality and 50 lines per second for high-quality images. The time-lapse interval required is determined by the type of structures that are being imaged. Subcellular shape changes using a high-magnification (40× or 60×) objective may require 10- to 30-sec time intervals. General tumor cell tracking using lower magnification objectives (20×) may be adequate at 1- to 3-min intervals.

21. Set up the time-lapse *z*-series (generally 10-μm steps for 100 μm and 1-min intervals for 30 min) and start collecting images.

    For time-lapse multiphoton imaging, as many z planes should be taken as is possible given the above constraints on image quality and time-lapse interval. Especially during the first 30 min of imaging, there is significant (typically >10 μm) drift. This z-series collection can compensate to some degree for this drift, but in the authors' experience, tracking a cell from one plane in a z-series to the neighboring plane always generates an artifact for the time interval during which the shift occurs. For detailed tracking of individual cells, 2.5- to 5-μm step sizes are best. For experiments in which one wishes to sample through as great a depth as possible to compare behavior at the periphery versus the interior of the tumor, 10-μm or larger steps may be required.

    This step provides information regarding the depth of tumor cells moving within the tumor.

22. Euthanized the animal at the end of data collection.

23. Perform image analysis (Basic Protocol 2).

SUPPORT PROTOCOL 1

IN VIVO IMAGING MICROSCOPE SETUP

A 10-W Tsunami Ti-Sapphire femtosecond pulsed laser from Spectra Physics is used in the authors' setup. This laser is used to run a Radiance 2000 multiphoton system (Bio-Rad). This system gives an output of 850 mW at 960 nm. Although the instrument from Bio-Rad is no longer sold, similar systems are available from Zeiss, Leica, and Prairie. This wavelength is optimal for imaging GFP fluorescence, but the authors have found that working between 860 and 880 nm is optimal for imaging GFP, CFP, matrix fibers, and Texas Red at the same time. The inverted Olympus IX70 microscope is ideal for placing an animal on the imaging platform.

It is important to have the animal in a 30°C environment; there is some tumor cell movement at lower temperatures but it is less, while at higher temperatures the animal begins to hyperventilate, presumably due to overheating. Also, other cell types are much more sensitive to temperature effects; T cells may be particularly affected. Thus, in the authors' laboratory there is a thermal chamber erected surrounding the imaging platform to maintain the animal's physiology while under anesthesia. The chamber takes air from a heating element and maintains a temperature of 30°C. An alternative is to cover the animal during imaging with a heating pad or small cloth, depending on the temperature of the room. Rooms that are highly air conditioned in order to keep the electronics from overheating may be too cool.

The objectives used are as follows: 20× Plan Apo 0.7NA (air); 40× LUMPlan/IR 0.8NA (water); and 60× LUMPlan/IR 0.9NA (water). The filters used are as follows (all from Chroma): 450/80 (blue), 480/30 (CFP), 515/30 (green) and 620/60 (red). The multiphoton instrumentation can be calibrated so that the images taken on separate days are of the same intensity by using fluorescent beads and doing a *z*-series at laser powers that give a range of intensity equal to a standard *z*-series performed when the laser has been

perfectly aligned. Laser power and gain settings are determined by the brightness of the chromophore in the tumor. An image should have a good dynamic range to be considered usable for data interpretation. Depending on the precise measurements and depth of image stack desired, it may be useful in some cases to be at saturation in cells in the uppermost slice to allow adequate signal from cells in deeper slices.

LABELING MACROPHAGES TO VISUALIZE BLOOD FLOW

SUPPORT PROTOCOL 2

To provide information about blood flow in and around the tumor, macrophages are labeled with Texas red–dextran by injecting the dye in the tail vein of a tumor-bearing animal.

Materials

Mouse with xenograft-induced tumor (Basic Protocol 1)
20 mg/ml Texas Red–dextran (70 kDa, Invitrogen) in DPBS (Invitrogen; also see *APPENDIX 2A*)
70% (v/v) ethanol

Mouse restrainer (Donovan and Brown, 2006)
1-ml syringe with 26-G needle
Superglue

Additional reagents and equipment for mouse restraint (Donovan and Brown, 2006)

1. Warm up the tail vein of the tumor-bearing animal by immersing the tail for 1 to 2 min in warm (50° to 60°C) water.

   This causes the tail vein to dilate so that a 26-G needle can be inserted. The animals can also be placed 4 to 8 in. (~10 to 20 cm) away from a lamp with 150-W light bulb for 5 min.

2. Place mouse into restrainer by holding it by the tail, and close the restrainer so the tail is easily accessible.

3. Wipe the tail with 70% ethanol and rotate it to position the lateral vein for injection. Stabilize the vein by holding the tail between thumb and middle finger and securing the vein with the index finger.

4. Prepare a 1-ml syringe with a 26-G needle containing 200 µl of 20 mg/ml Texas Red–dextran. Inject the mouse by orienting the bevel of the needle facing upward and forcing it gently through the skin, parallel to the vein, 1 to 1.5 in. (~2.5 to 4.25 cm) from the base of the tail.

   Successful insertions into the vein are indicated by easy sliding of the needle into the vein and easy injection of the solution without accumulation at the needle tip.

5. Inject slowly so that the 200 µl of the dextran solution enters the vein.

   If too much force is required for injecting the solution, that indicates the needle is not inserted into the vein. In this case, attempt additional injections, moving slightly closer to the base of the tail with each attempt.

6. Place the mouse back into the cage for later imaging.

   The animals are left for 1 to 2 hr. Because the ability to image macrophages depends on their ability to take up dextran molecules by phagocytosis, the authors have found that this time interval is adequate for labeling.

7. Image macrophages with red filter (Fig. 19.7.1D) while imaging the tumor with the green filter (515/30 filter).

   See Basic Protocol 1 for imaging steps.

SUPPORT PROTOCOL 3

BLOOD VESSEL IMAGING USING AN INDWELLING CATHETER

Either of two procedures can be used for blood vessel imaging: 200 μl of 20 mg/ml Texas Red–dextran (70-kDa Molecular Probes) is injected at a concentration of 20 mg/ml in Dulbecco's PBS via the tail vein (see Support Protocol 2) or via an indwelling intravenous catheter in the jugular vein of the rat or mouse as described in the protocol below. Tail-vein injection can be performed after anesthesia, but before surgery, whereas the indwelling catheter can be perfused while the animal is being imaged, if need be, when it is necessary to visualize vessels (Fig 19.7.1C). After introduction of dextran into the circulation, it can be visualized using the Texas Red channel of the Bio-Rad confocal microscope or by a comparable filter in the Bio-Rad Radiance 2000 multiphoton microscope.

This procedure requires some practice because catheter insertion is not trivial. It is also important to note that since multiphoton imaging requires another nonsurvival surgery, the incision for the catheter insertion should be minimized. Alternatively, direct catheterization of the tail vein can be performed.

Additional Materials *(also see Basic Protocol 1)*

Mouse with xenograft-induced tumor (Basic Protocol 1)
Heparinized PBS solution (Baxter, cat. no. FKB0953G)

Indwelling tail vein catheter (no. MTV-01, SAI Inc.; *http://www.sai-infusion.com*)
1-ml syringes
Waterproof marker (e.g., Sharpie)

Prepare catheter

1. Prepare indwelling catheter by pulling out the guide wire and attaching a 1-ml syringe filled with heparinized PBS.

   A catheter designed for the tail vein is used, but it will be inserted into the jugular vein for this protocol.

Insert the catheter

2. Insert the catheter into the guide needle so that 4 mm of catheter extends out the tip of the needle. Mark the catheter using a Sharpie where it inserts into the rear of the needle, as a guidepoint for the depth of insertion in to the vein.
3. With the animal anesthetized using 5% isoflurane (see Basic Protocol 1), spray the right thorax area with 70% ethanol.
4. Make a small incision to expose the left external jugular vein and the overlaying muscle layer.
5. Insert the guide needle through the muscle into the overlying jugular vein.
6. Push the catheter 4 mm into the vein and, while holding the catheter in the vein with a small forceps, pull out the guide needle over the catheter.
7. Place a drop of glue (e.g., Superglue) over the site of insertion of the catheter into the vein to hold it in place.

Test the catheter

8. Allow the glue to dry for several seconds and push a few microliters of PBS through the syringe to see if there is any leakage (an indicator of a bad insertion).
9. Try drawing blood to make sure that the catheter is patent.

   If correctly inserted, blood should be drawn into the catheter. However, in some cases, if the catheter tip is against the wall of the vessel, it may be difficult to draw blood.

Inject the dextran

10. Prepare another 1-ml syringe filled with 20 mg/ml Texas Red–dextran. Switch the catheter from the PBS syringe to the 20 mg/ml Texas Red–dextran syringe and prepare the animal for imaging (Basic Protocol 1).

11. After an area containing a flowing blood vessel has been discovered, inject the Texas Red–dextran into the vessel and observe the fluorescence by collecting a time-lapse image of the area (Basic Protocol 1).

SECOND HARMONIC FIBER IMAGING

SUPPORT PROTOCOL 4

A valuable benefit of multiphoton microscopy is the ability to use the second harmonic scattering effect (Zipfel et al., 2003; see *UNIT 4.15*) to generate images of extracellular matrix fibers (ECM) around the carcinoma cells of the tumors. The size, amount, and condition of the ECM fibers that are imaged can be determined by measuring the signal intensity and morphology of the images generated by the second harmonic (Ahmed et al., 2002). However, it is important to appreciate that such images label only a very restricted subset of matrix molecules that may be present. Typically only large, type I collagen fibers are likely to be imaged. With alternative wavelength comparisons, elastic fibers may also be identified (Zipfel et al., 2003), but other structures including small fibers, basement membrane, fibronectin fibers, and other cell types are not imaged. The authors are able to excite the second harmonic signal with wavelengths of 760 to 960 nm, and because the work is typically more concerned with imaging cells, the excitation wavelength is selected based on the cell to be imaged (860 to 880 nm for GFP), and the second harmonic image that is generated is then collected using a 450- to 480-nm-cutoff filter.

SIMULTANEOUS CFP AND GFP IMAGING

ALTERNATE PROTOCOL 1

The authors' group has previously shown that it is possible to image two separate populations of cancer cells in vivo using the multiphoton microscope (Sahai et al., 2005). To image two populations, it is important to choose the correct fluorescence pair, based on the excitation wavelength, so that both fluorophores can be excited at a single excitation wavelength (a common limitation of current multiphoton imaging is the difficulty in changing excitation wavelengths). In the authors' studies, CFP and GFP (Fig. 19.7.1B) are used due to the ease of excitation with the Ti-sapphire laser as well as the expression tolerance in most cell types. In the authors' experience, other fluorescent proteins such as YFP and RFP are not useful, due to the weak excitation at wavelengths attainable by the laser used. The optimal wavelength for imaging CFP and GFP was determined to be around 880 nm (Sahai et al., 2005). Because detection of the CFP signal in the system used by the authors overlaps with GFP, it was found that the gain for collection between the two signals needs to be set so that the CFP signal is equal in both fields. Also for ease of collection with a two-detector system, because the second harmonic image is captured with the same PMT as the CFP image, by making the gain equal between the CFP image and the GFP image the collagen fibers can also be identified as structures that are only present in the CFP channel and not in the GFP channel.

MULTIPHOTON TIME-LAPSE IMAGE ANALYSIS USING ImageJ AND CUSTOM MACROS

BASIC PROTOCOL 2

The authors of this unit have found ImageJ, a free image-processing program developed by Wayne Rasband at the NIH, to be a tremendously valuable image-manipulation program. ImageJ is written in Java, has the source code available, and is developing an ever larger user group. The authors have developed plugins for multiphoton time-lapse analysis

using ImageJ version 1.36b and running Java 1.5.0_06 under Windows XP; these are available at *http://asb.aecom.yu.edu/segall/ImageJ%20plugins/ImageJIntro.html*. People running an earlier version of either should try downloading the latest versions from *http://rsb.info.nih.gov/ij/download.html*. Download and install the latest version bundled with the JRE from that page.

It is useful to have a machine with lots of RAM for generating slice movies from *z*-series stacks (probably twice the total amount in the *z*-series files to be converted to movies, on the order of a gigabyte for current uses) because all the data are loaded into RAM in order to reshuffle them. Thus, an amount of RAM at least equal to the total file size must be allocated to ImageJ in the `.cfg` file before running it (i.e., the `-Xmx340m` command could be changed to `--xmx500m` to correspond to 500 Mb of RAM). If RAM is limited, it is possible to combine just a fraction of the total *z*-series, either by reducing the time resolution (i.e., taking every second or third *z*-series to make the movies), or else by making movie fragments that can be merged using the Concatenator plugin (downloaded from the ImageJ plugins download site).

The discussion below involves three typical procedures that are performed:

1. Generating time-lapse movies from time-lapse *z*-series.
2. Eliminating *x-y* drift in time-lapse movies.
3. Marking areas of interest in time-lapse movies.

Generating Time-Lapse Movies from Time-Lapse *z*-Series

The authors of this unit typically generate a sequence of *z*-series in which one *z*-series is accumulated every minute or so. In order to then image the motility that is occurring in a particular image plane in the stack, it is necessary to track particular planes. Currently, the authors have a set of plugins that are modifications of plugins available on the ImageJ Web site (in the Stacks to Movies folder). Place the entire folder in the plugins folder of ImageJ and start ImageJ. Next, in the plugins drop-down box, select the Stack to Movies option and click on StackstoMovies. The plugin begins by asking for a name that will be attached to each movie slice, and then asks whether it is a blue-green *z*-series (files ending in `01.pic` will be put in red and blue channels; files ending in `02.pic` will be in green channels), or red/green *z*-series (files ending in `01.pic` will be put in green channel; files ending in `02.pic` will be in red channel). These options can be modified by changing the `js1stepRGB_Stack_Merge.java` file. The program then loads the files, assembles color stacks, concatenates the stacks, rearranges them into movies of slices, and then checks where to save each one. The results can then be viewed using ImageJ and *x-y* drift can be compensated using the plugins described in the next section.

Items to put in Plugins folder

Stacks to Movies folder (*http://asb.aecom.yu.edu/segall/ImageJ%20plugins/ImageJIntro.html*).

Procedure

1. Start ImageJ.
2. Select StackstoMovies from the plugin drop-down menu.
3. Provide a name to be appended to each slice number.
4. Determine whether `...01.pic` files are to be red (option 1) or `...02.pic` files are to be red (option 2).

5. Select a place to store the completed slice movies and approve saving of each slice movie.

Possible memory issues for this step

It is necessary to have a machine with lots of RAM (probably twice the total amount in the *z*-series files that are to be converted to movies) because all the data are loaded into RAM in order to reshuffle them. In addition, an amount of RAM at least equal to the total file size must be allocated to ImageJ in the `.cfg` file before running it (i.e., the `-Xmx340m` command could be changed to `--xmx500m` to correspond to 500 Mb of RAM). If RAM is limited, it is possible to combine just a fraction of the total *z*-series, either reducing the time resolution or else making movie fragments which can be merged using various stack commands that can be downloaded from the ImageJ plugins download site.

Eliminating *x-y* Drift in Time-Lapse Movies

Philippe Thévenaz has written a valuable series of registration plugins that can reduce/eliminate *x-y* drift from color time-lapse sequences. This involves first downloading a plugin called TurboReg, and then downloading StackReg. In each case, the downloads are `.zip` files, which should be extracted to the plugins folder of Image J. The extractions will generate two folders in the plugins folder named `stackReg` and `TurboReg`. It is necessary to restart ImageJ, open the movie (only have one movie open at a time) from which drift is to be eliminated, and then go to the plugins drop-down menu in Image J, move to the StackReg line, and click on the StackReg box that appears. Various transformations can be chosen, but probably the default choice (rigid body) is best. More information is available at the download site *(http://bigwww.epfl.ch/thevenaz/stackreg/)*. Note that this plugin runs quite slowly: it can easily take a minute to step through a 30-frame movie. It registers each frame relative to the previous frame, and thus with time, black areas appear on the sides opposite the direction of drift of the movie. The program may not be able to accommodate rapid, large changes in position. In these cases, one can use TransformJ (again available from the plugins section of the ImageJ Web site) to shift sets of slices of the movie in the *x-y* plane in order to reduce the jumps enough for StackReg to track them. Changes in *z*-axis are extremely difficult to compensate for, requiring more extensive *z*-series collection (perhaps every 1 to 3 μm, depending on the scale of magnification) and then manually assembling images from the appropriate planes of each *z*-series.

Items to put in Plugins folder

StackReg folder: *http://bigwww.epfl.ch/thevanaz/pointpicker/*.

TurboReg folder: *http://bigwww.epfl.ch/thevanaz/pointpicker/*.

Procedure

1. Start ImageJ.
2. Open movie to be registered.
3. Select StackReg from the plugins drop-down menu.
4. Select Rigid body transformation.
5. Wait patiently until the progress bars in the ImageJ command bar stop appearing and the movie has stepped through all of its frames.

Marking Sites of Interest in Time-Lapse Movies

It can be useful to mark sites of interest in time-lapse movies; for example, the authors mark where tumor cells are moving as part of quantitating tumor cell motility, and they have written a simple series of macros/plugins that make use of another valuable plugin written by Philippe Thévenaz, called Pointpicker (*http://bigwww.epfl.ch/thevenaz/pointpicker/*). Pointpicker keeps a record of the *x*-*y* coordinates of the mouse when clicked and allows them to be saved or copied. The authors typically are just counting instances of tumor cell movement and thus wish to mark their locations and keep track of the total number. Usually, this is most accurately done viewing just the tumor cell channel in black and white; however, Pointpicker will work on either color or black-and-white movies.

For GFP-labeled cells, there is a simple plugin, Greentopointpicker, that selects the green channel and begins the Pointpicker plugin.

Items to put in Plugins folder

Greentopointpicker plugin: *http://asb.aecom.yu.edu/segall/ImageJ%20plugins/ImageJIntro.html*.

jsgetGreen plugin: *http://asb.aecom.yu.edu/segall/ImageJ%20plugins/ImageJIntro.html*.

Pointpicker: *http://bigwww.epfl.ch/thevanaz/pointpicker/* (folder with Pointpicker plugin and files in it).

Procedure

1. Start ImageJ.
2. Open time-lapse movie of slice to analyze (preferably already registered to remove drift, jitter, etc).
3. *Optional:* Select the color desired for the crosses by going to Edit-options-colors and change the selection color to the desired color, e.g., red.
4. *Optional:* Run the plugin Greentopointpicker: this extracts the green image (typically the cell image to be tracked) and then starts Pointpicker.
5. *Optional:* Convert crosses to just one color (double click on the pen+ [leftmost] button and choose monochrome).
6. Click on the "Apply to all slices" button (sixth from the left, has a sliced cube image on it) so that the crosses will be on all slices.
7. *Optional:* It can be useful to magnify the image 1× (click on magnifying glass, click on image, then click on the pen+ [leftmost] button to go back to marking mode).
8. *Optional:* It can be helpful to play the movie at high speeds, looping back and forth continuously to see motions (Stacks–animation options).
9. *Optional:* Expand the image to be tracked to the full screen (this is good for seeing small movements).
10. Start the movie running in a continuous loop.
11. Mark all the sites of interest (i.e., tumor cell motility) by clicking on the pen+ (leftmost) button and clicking with the mouse of the specific sites. A cross should appear at each marked site.

12. *Optional:* Errors can be removed by clicking on the pen– button (third from left) and clicking the mouse anywhere on the screen. However, this simply removes the marks in reverse order from that in which they were made; specific marks cannot be removed from this sequence.
13. Stop the movie and shrink the image back down to view the ImageJ tool bar.
14. Reveal the points list by clicking on the "document" button (eighth from left) and clicking on the "show" button from the drop-down menu.
15. The results box will appear with point, *x*, *y*, slice, and color columns. The information in each slice should be identical. Highlight the rows with the appropriate slice number corresponding to the slice currently being analyzed and paste them into an Excel file. For different analyses, the file can have different worksheets (i.e., tumor cell motility, host cell motility, movement on matrix, orientation towards blood vessel, etc). This then stores the number and coordinates of the locations of cell movement together with the slice number. Next, close the results box. If `jsDrawDot1` is to be used to mark the sites on a *z*-stack, copy and save the results with the number in the slice column being the slice number plus 1 (this provides the correct registration of the dots with the *z*-series using `jsdrawDot2`).
16. It is usually good to save the Excel file at this point. A file name indicating the date of the experiment and other distinguishing information is helpful for keeping the data organized.
17. *Optional:* To further analyze the same movie for a new category, remove the current markings by selecting the pen− button (third from the left) and click on the image until all the crosses are gone (and the pen+ button will automatically depress).
18. Repeat steps 10 through 16 for as many categories as desired.
19. Close the movie image.
20. Click the "return" button to return to the standard ImageJ menu, open the next file to be analyzed, and repeat the process.
21. *Optional:* save the Excel data file with the file name of the experiment in the same directory as the registered files.

Marking Specific Locations with Red Circles in a *z* Stack Using the Data Acquired from Pointpicker

Plugins used (put both just in the Plugins folder of ImageJ)

JsdrawDot1: *http://asb.aecom.yu.edu/segall/ImageJ%20plugins/ImageJIntro.html*.

IntLoader2: *http://asb.aecom.yu.edu/segall/ImageJ%20plugins/ImageJIntro.html*.

Procedure

1. To superimpose the dots on a *z*-series of the data, copy the columns (not the header column) and paste as unformatted text into a Word file, then save the Word file as plain text. This makes the data readable for `IntLoader2` (called by `jsdrawDot2`).
2. Open the *z*-series upon which you wish to superimpose the sites.
3. Run `jsdrawDot2`. It will remind the user what is required, and after clicking OK, it will ask for the location of the plain text file that has the data acquired from Pointpicker.

4. The program will note "All done" when finished.

The Manual Tracking plugin by Fabrice Cordelieres can be useful for following individual cells in two and three dimensions. Link to this plugin from ImageJ site: http://rsb.info.nih.gov/ij/plugins/track/track.html.

ALTERNATE PROTOCOL 2

IMAGE ANALYSIS AND QUANTIFICATION

Motility, invasion, and polarization

Because the data are collected as a time-lapse in *x,y* plane as well as a *z*-series, measurements of cell behavior, such as polarity, motility, and intravasation can be visualized.

1. Collect images for ~30 min at 1-min intervals.

   Each image is collected as an x-y image; the z-series (or z-stack) refers to a number of x-y images in a z plane.

2. Convert images into time-lapse movies using NIH ImageJ.

   This will depend on individual microscope image acquisition software. Macros can be written to shuffle the z-series slices into time-lapse movies in each image plane. Please see Basic Protocol 2 for image analysis using ImageJ.

3. Visually inspect the slices for moving cells and record their behavior patterns (e.g., movement on or off matrix fibers, interaction with host cells, movement towards blood vessels).

   Most MTLn3 cells will not be moving, but motile cells will move with speeds of up to 10 μm/min.

4. Examine each time-lapse *z*-series for the number of moving cells.

   This can be done by counting individual cells in each of the planes and adding them up. DIAS analysis can be used to determine such variables as speed, persistence, distance, and direction (Farina et al., 1998; Ahmed et al., 2002; Wang et al., 2003). For more detailed description of DIAS image analysis, see Cammer et al. (1997).

5. For quantification of cell orientation towards blood vessels, collect images as described above, with animals injected with Texas Red intravenously during imaging.

   Cells within two diameters of the vessels are defined as polarized if a cell's length is at least twice its width and directed towards the vessel.

6. Quantify motility along fibers and other cell-matrix interactions if the second harmonic images are collected as well.

7. Quantify attachment indirectly (by comparison only) by quantifying differences in cell-matrix colocalization, or by quantifying differences in cell-matrix locomotion (Ahmed et al., 2002).

Color (CFP-GFP) image analysis

8. Use the Image Calculator feature of ImageJ (available from *http://rsb.info.nih.gov/ij/*) to subtract the CFP fluorescence captured using either 450/80 or 480/30 filters from the mixture of GFP/CFP fluorescence passing through 515/30 filter.

   This procedure will yield the GFP fluorescence alone.

9. To normalize for differences in cell number in any given field, calculate the number of pixels for each cell type.

10. Monitor two separate populations of cells in the same tumor (Fig. 19.7.1B). By analyzing the time-lapse *z*-series of the tumors, compare the cells in terms of motility, morphology, protrusion, and polarization.

    Please refer to the Basic Protocol 2 for image analysis discussion.

REAGENTS AND SOLUTIONS

Use deionized, distilled water or equivalent in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

MTLn3 growth medium

Minimal Essential Medium, α modification (α-MEM; Invitrogen) containing:
5% (v/v) fetal bovine serum (Fisher cat. no. SH3008803IR)
1× penicillin/streptomycin (Invitrogen)

COMMENTARY

Background Information

In recent years, the use of multiphoton laser scanning microscopy, with its benefits of tissue penetration depth and high resolution, has shed light on many aspects of tumor microenvironment. Multiphoton fluorescence excitation uses a laser beam to focus photons of a wavelength two times longer than the excitation wavelength of the fluorophore at a single point (Wang et al., 2003; *UNIT 4.15*). This allows for greater penetration with less phototoxicity and bleaching during *z*-series collection.

Troubleshooting

Imaging tumors that are closer to the chest cavity is more difficult due to breathing possibly interfering with image collection. Animals with such tumors must be kept more sedated, and this may affect the length of the imaging session.

Data collection requires a large amount of hard drive space (500 Mb to 1 Gb/4D series), so make sure that the computer is up to date and able to handle large amounts of data for storage and transfer.

Anticipated Results

Using the metastatic MTLn3 rat mammary adenocarcinoma cell line transfected with GFP (Wyckoff et al., 2000), and comparing to the nonmetastatic MTC cell line, it is anticipated that ∼57% of blood vessels in tumors generated from the metastatic cell line have at least four cells oriented towards them, compared to ∼24% for the nonmetastatic cell line. Other parameters, determined as the number of fields with associated events that were found to be distinct, were protrusion (62% versus 47%), translocation (17% versus 10%), and cell fragmentation (6% versus 32%; Wyckoff et al., 2000).

Carcinoma cells in the metastatic MTLn3 cell line–derived tumors (Fig 19.7.1A) were found to be associated with and to locomote on collagen-containing fibers when compared to the nonmetastatic MTC cell line (Ahmed et al., 2002). Correlation of tumor cell behaviors with gene-expression analysis allows for a novel way of exploring cancer-related genes (Wang et al., 2005). From their experiments, the authors have found that the minimum motility machine genes are coordinately up-regulated in both metastatic tumors as compared to nonmetastatic tumors (Wang et al., 2004) and in the invasive population when compared to the metastatic tumor (Wang et al., 2004).

Using multicolor imaging (CFP and GFP cell populations with different metastatic potential in the same tumor), the authors were able to observe (Fig 19.7.1B) morphological differences, such as the movement speed between the two cell lines in the same microenvironment, and showed that motile cells often follow the same path (Sahai et al., 2005). Coinjection of parental MTLn3 cells with ErbB1-overexpressing MTLn3 cells showed that the ErbB1 overexpressor cells moved at a greater frequency than the parental cells and that more metastatic differences could be observed (Xue et al., 2006).

Host cells could be seen as shadows crawling over the background of the GFP fluorescence (Wyckoff et al., 2000). Some of these cells were determined to be macrophages by injecting Texas Red–dextran intravenously and allowing the macrophages to phagocytose the dextran (Fig. 19.7.1D). Imaging of tumor cell and macrophage cell interactions confirmed a paracrine loop involving EGF and CSF-1 and their corresponding receptors, which was discovered by using an in vivo invasion assay developed in the authors' laboratory (Wang et al., 2004). Tumor cells and macrophages could be imaged moving toward the bevel of a needle containing Matrigel and EGF and CSF-1, respectively (Wang et al., 2004).

Transgenic mice containing the PyMT antigen have been crossed with a *Cre-lox*-β–actin promoter-GFP to create mice with fluorescent mammary tumors (Ahmed et al., 2002). The

PyMT-generated tumors have been shown to mimic human disease (Lin et al., 2003). Many of the morphological characteristics seen in the orthotopically injected models have been seen, including cell motility, invasion, and intravasation. The authors have also crossed the PyMT mice with other GFP-containing transgenics to observe the role of host cells in tumors. These include Tie2-GFP mice with fluorescent endothelial cells (Motoike et al., 2000), lys-GFP mice (Faust et al., 2000), and C-fms-GFP mice (Sasmono et al., 2003) that label macrophages and granulocytes.

Time Considerations

Depending on the cell line used, it can take several months for animals to develop tumors (this is mainly true for human cell lines). In the authors' experience, MTLn3—a fast-growing cell line—is ideal in this respect, with tumors developing in ~3 weeks.

Each animal can stay on the microscope for up to 4 hr, under ideal conditions; thus, it is important to manage the breathing rate (by gradually reducing the isoflurane levels) to make sure that each animal is able to breathe steadily and evenly. Generally, time-lapse *z*-series images are collected for 30 min; macrophages are labeled 2 hr prior to imaging, and vessels are perfused with dextran immediately prior to imaging.

ABSTRACT

This unit provides detailed protocols for dissecting embryonic organs and performing organ culture to study questions in developmental biology. Procedures are described here for dissecting organs such as kidney, lung, and salivary gland. The unit also contains commentary including troubleshooting for embryonic organ culture. *Curr. Protoc. Cell Biol.* 41:19.8.1-19.8.8. © 2008 by John Wiley & Sons, Inc.

Keywords: embryonic organ culture • salivary gland • lung • kidney • branching morphogenesis

INTRODUCTION

Although cell culture model systems provide sensitive tools for the analysis of the molecular and cellular events of cytodifferentiation, they have only limited value when evaluating aspects of three-dimensional cell assembly during organogenesis and when exploring processes such as cell polarization and intercellular communication. Organogenesis involves many cellular processes, such as cell proliferation, cell adhesion, apoptosis, cell differentiation, changes in cell shape, and cell migration. Embryonic organ culture technology was developed for studying these processes in a three-dimensional environment.

Organ culture techniques, originally developed in the 1920s, make it possible to examine embryonic tissue fragments and whole organ rudiments under reproducible in vitro conditions. These techniques have also proven valuable in some toxicological studies. Studies undertaken using organ cultures provide advantages over cell cultures, since differentiation and certain physiological functions persist rather well (Saxen et al., 1983).

The transfilter technique created by Grobstein for analyzing kidney development has proven to be very effective, and it has been used for a great variety of other tissues as well (Grobstein., 1953, 1956, 1957). Grobstein's original setup consisted of a membrane filter as the substrate, supported by a Plexiglas ring fixed to a pair of glass rods. The original studies either used an embryonic organ on top of the filter or separated epithelial and mesenchymal tissues glued onto both sides of the filter membrane by a clot and cultivated in vitro. Various types of Millipore filters were used. These filters are made of cellulose ester and are available in different thicknesses and pore sizes. Millipore filters have a spongy structure and irregular pores, and they were later replaced by commercially available Nucleopore filters (Wartiovaara et al., 1974a,b). These latter filters are made of polycarbonate tape treated by exposure to charged particles in a nuclear reactor followed by chemical etching of the tracks. As a result of this process, the filters have a relatively uniform pore size and straight channels. The transfilter technique has simplified organ culture experiments, and culturing on filters is currently the standard approach.

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) and must conform to governmental regulations for the care and use of laboratory animals.

Current Protocols in Cell Biology 19.8.1-19.8.8, December 2008
Published online December 2008 in Wiley Interscience (www.interscience.wiley.com).
DOI: 10.1002/0471143030.cb1908s41

NOTE: All reagents and equipment coming into contact with living cells must be sterile, and aseptic technique should be used accordingly.

NOTE: All culture incubations should be performed in a humidified 37°C, 5% CO_2 incubator unless otherwise specified. Some media (e.g., DMEM) require altered levels of CO_2 to maintain pH 7.4.

NOTE: When handling mice, investigators should wear gloves, laboratory coat, and surgical (dust or mist) mask to reduce exposure to mouse antigens. For dissections and culturing, investigators should wear gloves for all procedures and take precautions to avoid contamination. Gloves can be either presterilized surgical gloves or examination gloves that have been externally sprayed and rubbed with 70% ethanol after they have been put on.

BASIC PROTOCOL 1

MOUSE DISSECTION

Practicing dissections permits beginners to learn about the internal and external anatomical structures of animals (Rugh, 1968; Tuan, 2000). By taking a hands-on learning approach, beginners can obtain a practical sense of the relationships between embryonic organs and surrounding tissues. To dissect embryonic organs, the anatomical structure of pregnant mice and embryos must first be understood (see Background Information). Investigators should first become familiar with these dissections by practicing ahead of time (ideally several times) on, for example, E14 or E15 embryos using small amounts of starting material, before performing the dissection of embryonic organs in earlier stages such as E11 or E12.

Materials

70% ethanol
DMEM/F12 medium (Invitrogen), sterile
Pregnant ICR strain mice: embryonic day 12 (E12) to day 14 (E14)

Dissecting instruments including:
- Curved forceps, length 120 mm
- Two straight dissecting forceps, length 110 mm
- Straight scissors, length 140 mm
- Scalpel blade, size no. 11
- Glass dissection plate

100-mm and 30-mm culture dishes, sterile
Glass dissection plate, 10 to 15 cm, square or circular
Dissection microscope

Additional reagents and equipment for euthanasia of the mouse (Donovan and Brown, 2006)

Dissect uterus

1. Sterilize curved forceps and straight scissors by soaking in 70% ethanol for a minimum of 5 min. Keep instrument handles dry.
2. Prepare a 100-mm culture dish with ~10 ml cold DMEM/F12 on ice, then euthanize the pregnant mouse by CO_2 asphyxiation or cervical dislocation (Donovan and Brown, 2006).
3. Place the euthanized mouse in the supine position. Disinfect the abdomen of the mouse by thoroughly soaking with 70% ethanol using a squirt bottle.

   Washing the carcass with ethanol protects the tissues from artifacts caused by hair dragging through them.

   A video of this technique is available for CP Online subscribers.

4. Use straight scissors to make a ventral midline incision in the skin from the groin to the stomach.
5. Pull the skin back on the sides.
6. Dissect out the uterus of the mouse. Lift up the uterus with curved forceps and use straight scissors to cut the mesometrium away from the uterus. Do not squeeze embryos while grasping the mesometrium.
7. Place the uterus containing the embryos in the 100-mm culture dish containing DMEM/F12.

Isolate mouse embryos

8. Using two sterilized straight dissecting forceps, gently separate the embryo away from associated tissues (muscular wall of the uterus, Reichert's membrane, and the visceral yolk sac).
9. Remove the embryos from the uterus using two sets of sterilized straight dissecting forceps to open the uterine wall (embryos will usually "pop out" intact).

   A video of this technique is available for CP Online subscribers.

   When holding on to the animal during dissection, do not grab the near portion that includes the organ you want to culture (e.g., grasp the abdomen if you want to culture salivary glands or grasp the head if you want to culture lungs or kidneys).

10. Store embryos in the culture dish containing DMEM/F12 at 4°C or on ice before dissection.

Dissect organ of interest

All three of the sets of organs mentioned below can be harvested from the same animal if careful dissection technique is used.

For salivary submandibular glands

11a. Prepare a 35-mm culture dish with 3 ml DMEM/F12 and a sterile glass dissection plate.

12a. Place the embryo on its side in the lateral position onto the glass dissection plate.

   A video of this technique is available for CP Online subscribers.

13a. Stabilize the head using forceps and slice the head off with a scalpel blade, cutting between the neck and chin.

14a. Cut off the mandibles with a scalpel blade by cutting through the mouth above the tongue moving toward the back of the head.

   If it is hard to detect the mouth position, pushing gently below the nose with the non-cutting side of the scalpel blade should be helpful in finding the mouth opening.

15a. Place the mandibles into the 35-mm culture dish containing 3 ml DMEM/F12.

16a. Working under a dissection microscope, put the mandible onto a glass dissection plate caudal side up and cranial (tongue) side down. Turn the tip of the tongue to the 12 o'clock position (Fig. 19.8.1A, B).

   A video of this technique is available for CP Online subscribers.

17a. Using two sterile straight dissecting forceps, make a short longitudinal tear from the mandible tip (Fig. 19.8.1C). Scrape Meckel's cartilage from tongue base using sterile forceps, then pull off the tongue together with the two attached submandibular glands (Fig. 19.8.1D,E).

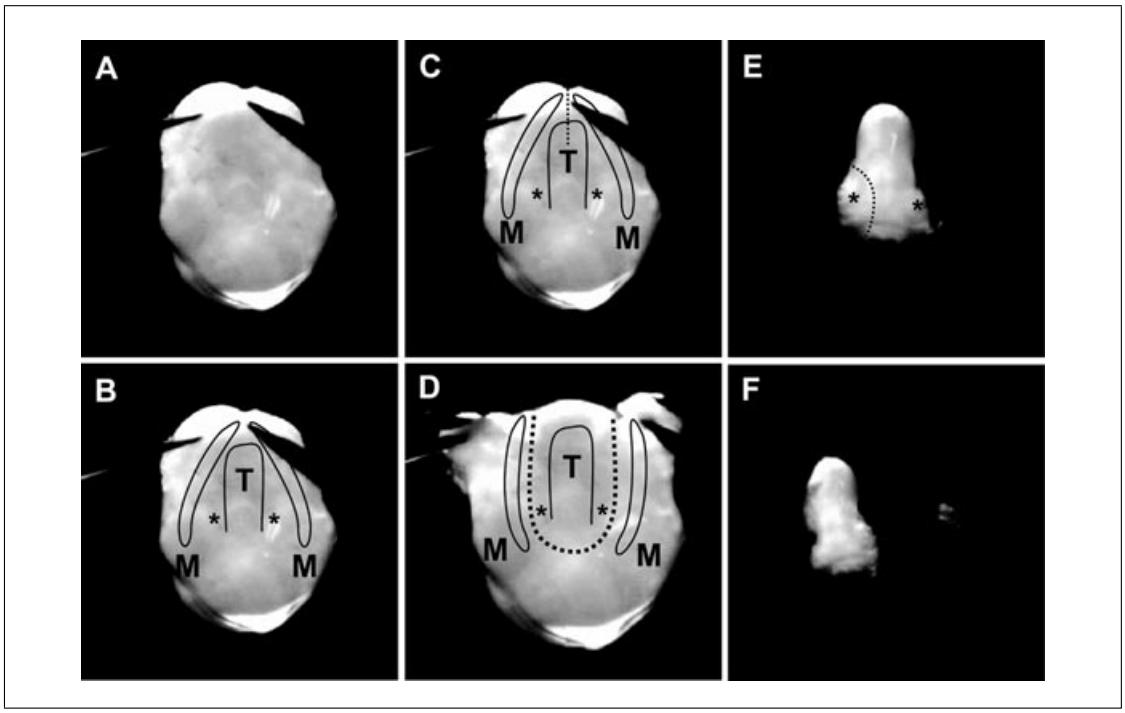

Figure 19.8.1 Salivary gland dissection. (**A, B**) Axial section of mandible tissue, oriented with the caudal side toward the objective and the front (anterior) of the embryo at the top. M, Meckel's cartilage; T, tongue; *, salivary gland. (**C**) The front of the mandible above the tongue is cut along the dashed line. (**D**) Meckel's cartilage is then discarded after cutting along the dashed line. (**E**) Isolated tongue with salivary glands. Cut along the dashed line to isolate the left salivary gland. (**F**) Separated tongue (left) and one of the salivary glands (right).

18a. Prick the center of the tongue with a pair of forceps to stabilize it, then cut off each submandibular gland from the tongue. Place the glands in a 35-mm culture dish containing 3 ml DMEM/F12 at 4°C, until ready for organ culture (Basic Protocol 2).

The organs may be stored up to several hours under these conditions.

For kidney

11b. Slice the head off by cutting at the neck, and place the embryo in the lateral position with the head end downward. Hold the posterior of the embryo with a set of forceps and cut out the liver, heart, and stomach using another pair of forceps.

A video of this technique is available for CP Online subscribers.

12b. Insert the forceps between the posterior body wall and the aorta/kidneys. Detach the aorta and kidneys carefully from the posterior wall (Fig. 19.8.2A-D) using closed forceps like a knife cutting parallel to the aorta. Next, with partially open forceps acting like a fork, lift the aorta and kidneys away from the body wall. Cut the aorta above the kidneys. Peel the aorta and kidneys away from the embryonic body wall using a single motion in the caudal direction toward the embryonic tail.

13b. Pick up the aorta above the kidneys and pull it away en bloc with both kidneys attached (Fig. 19.8.2E,F).

14b. Remove the remaining digestive organs, and cut off both kidneys using forceps. Place kidneys in a 35-mm culture dish containing 3 ml DMEM/F12 at 4°C, until ready for organ culture (Basic Protocol 2).

The organs may be stored up to several hours under these conditions.

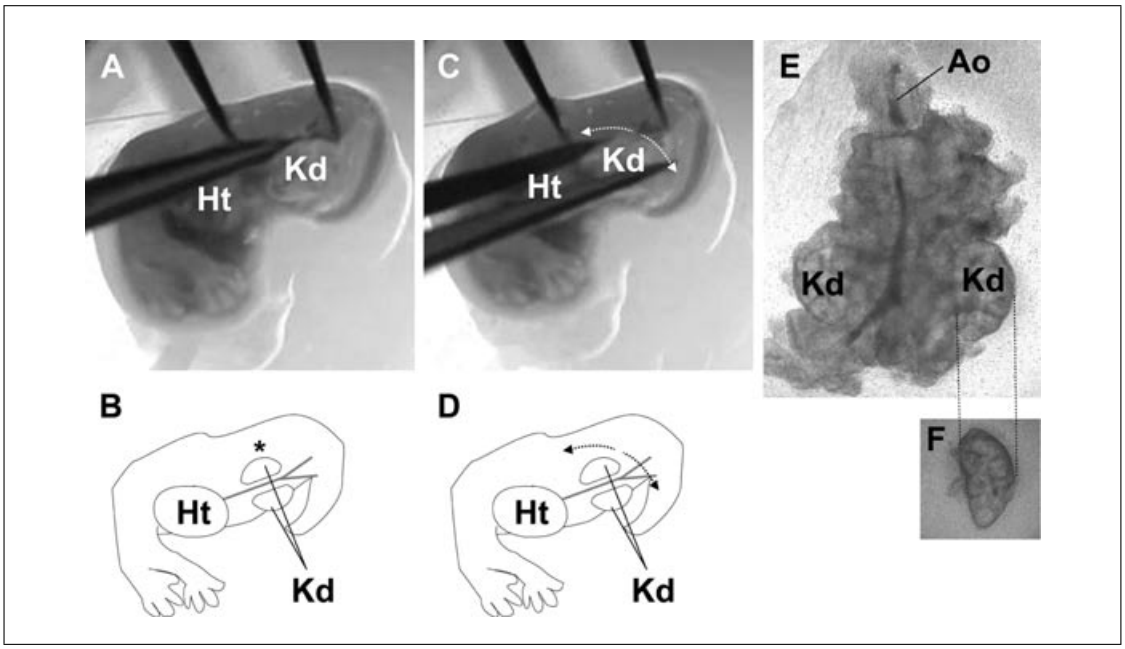

Figure 19.8.2 Kidney dissection. (**A**) Embryonic mouse in a lateral position with the front (anterior) facing down toward the bottom of the page. Ht, heart; Kd, kidney. (**B**) Proper insertion site for forceps. *, insertion site. (**C, D**) After insertion, open the forceps to move the aorta and kidneys in the direction of the dashed arrows. (**E**) Isolated aorta/kidneys. Ao, aorta; Kd, kidney. (**F**) Kidney isolated from aorta.

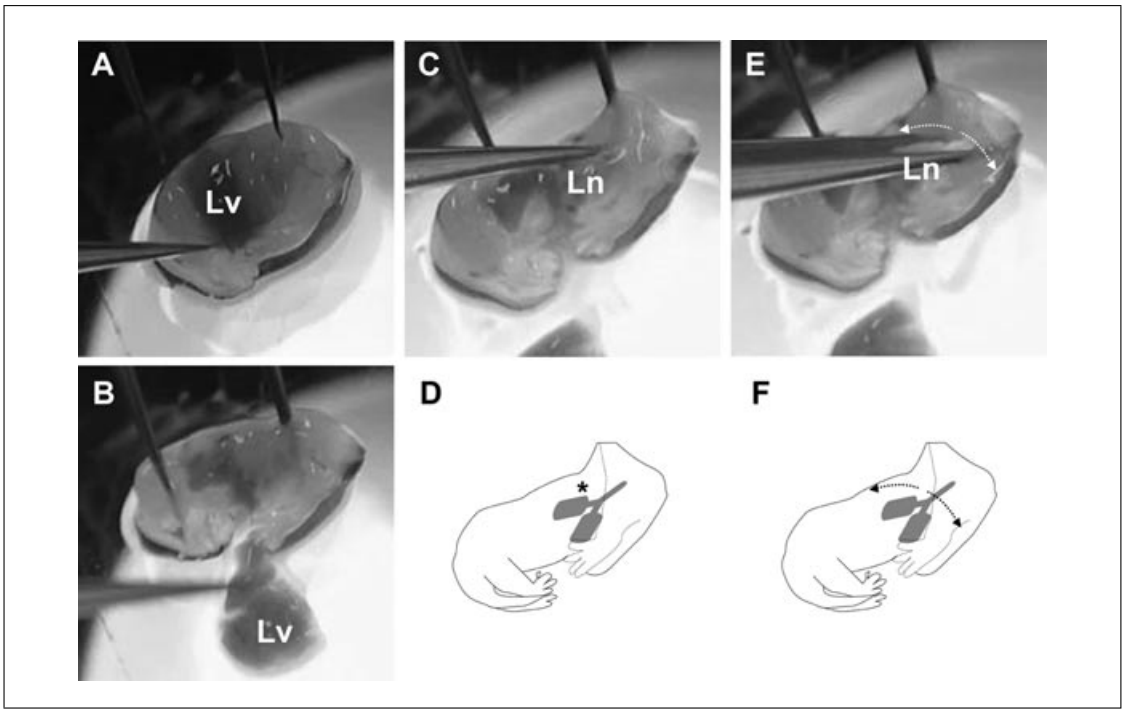

Figure 19.8.3 Lung dissection. (**A**) Embryonic mouse in lateral position with front (anterior) facing the bottom of the page. Lv, liver. (**B**) Scrape the liver toward the front using forceps. (**C**) Insert closed forceps tips between the posterior body wall and the trachea. (**D**) Diagram showing the proper insertion site of forceps. *, insertion site. (**E, F**) Open the forceps to separate the lungs away from the body as indicated by the dashed arrows.

For lungs

11c. Slice the head off by cutting at the neck, and place the embryo in the lateral position with the head end downward.

A video of this technique is available for CP Online subscribers.

12c. Holding the posterior of the embryo with a pair of forceps, remove the liver and heart with another pair of forceps (Fig. 19.8.3A,B).

13c. Detach the trachea carefully from the posterior body wall by piercing the tissue between the body wall and the trachea with a closed pair of forceps and opening the forceps to cut the tissue, freeing the trachea from the body wall (Fig. 19.8.3C-F).

14c. Carefully pull out the trachea and lungs. Lift the lungs gently away from the body wall with a pair of partially open forceps, to avoid injuring the lungs.

15c. Remove the remaining esophagus carefully if it is attached to the lungs. Place lungs in a 35-mm culture dish containing 3 ml DMEM/F12 at 4°C, until ready for organ culture (Basic Protocol 2).

The organs may be stored up to several hours under these conditions.

BASIC PROTOCOL 2

ORGAN CULTURE

This protocol describes how to perform the organ culture of embryonic salivary glands, kidneys, and lungs. Investigators should wear gloves for all procedures and take precautions in order to avoid cross-contamination of samples. Culture plate preparation should be done before organ dissection.

Materials

Culture medium (see recipe)
Mouse embryonic organs (Basic Protocol 1)

50-mm glass-bottom dish (MatTek Corporation)
Filter membrane (diameter 13 mm, polycarbonate, pore size 0.1 μm; Whatman)
Straight dissecting forceps, length 110 mm
Dissection microscope

1. Open the cover of a 50-mm glass-bottom dish.

   A video of this technique is available for CP Online subscribers.

2. Add 200 μl culture medium to the dish.

3. Using forceps, place the membrane on the surface of the culture medium so that the shiny side is on the top and the cloudy side is on the bottom.

4. Using forceps, gently place the organs of interest on the membrane.

   Be careful not to squeeze the organ; instead, scoop the organ up with the forceps. If the embryonic organ is in a drop of liquid, approach it with the open forceps' tips at a nearly horizontal angle and gradually close the tips to draw up the liquid and organ between the tips, then lift the organ in the drop of liquid.

5. Incubate in a 37°C, 5% CO_2 incubator for 3 days.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Culture medium

Purchase DMEM/F12 (in 500-ml bottle) from Invitrogen. Add penicillin to a final concentration of 100 U/ml and streptomycin to a final concentration of 100 μg/ml. Store at 4°C. Just before use, add vitamin C to 150 μg/ml and transferrin to 50 μg/ml.

COMMENTARY

Background Information

The great advantage of organ culture is that the overall three-dimensional structure of the tissue is retained. To avoid damaging vital organs, and to understand the procedures, an understanding of the anatomy is essential. *The Atlas of Mouse Development* (Kaufman, 1992) is recommended for beginners to study basic anatomy of the embryonic mouse.

Critical Parameters and Troubleshooting

Embryonic mouse organ dissection (salivary submandibular gland, kidney, lung)

It is essential to start with a fresh embryo so that it is easy for beginners to dissect organs; otherwise, embryos that are not fresh can make precise dissection difficult. Sharp forceps and

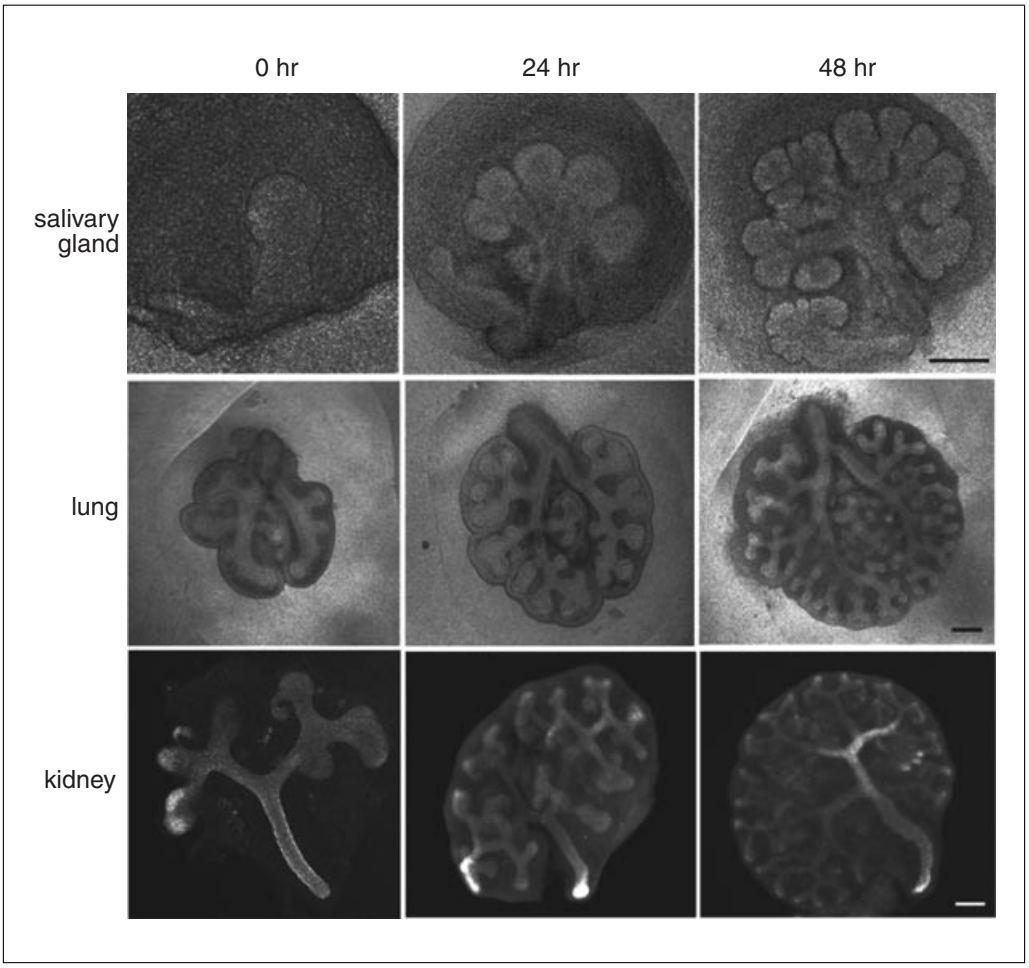

Figure 19.8.4 (**A** to **C**) The mouse submandibular salivary glands from E12 to E14 embryos were cultured for 72 hr based on these protocols. (**D** to **F**) Mouse lungs from E11.5 to E13.5 embryos. (**G** to **I**) Mouse kidneys from E11.5 to E13.5 embryos. The branching ureteric buds of all kidneys were visualized with anti-E-cadherin antibody as previously described (Sakai, 2003). Scale bar = 200 μm.

scalpel blades are recommended because embryonic tissues stick to scissors. Organ dissection from small tissue samples must be done quickly to ensure freshness and quality of tissues.

Anticipated Results

Each of the organs for which cultures are described in this unit have characteristic branching patterns. The organ culture method should produce growth of embryonic organs such as salivary glands, kidneys, and lungs (Fig. 19.8.4). Well-formed branching patterns should be visible in each organ.

Time Considerations

In Basic Protocol 1, the entire procedure for mouse dissection, mouse embryo isolation, and organ dissection will require a few hours for several pregnant mice. It is best to dissect as quickly as possible to ensure successful organ culture. In Basic Protocol 2, the procedure for setting up the organ culture technique can take several minutes, depending on the number of embryos. Cultures can be carried out for 48 to 72 hr with this method.

ABSTRACT

Over the last decade, the development of in vitro, human, three-dimensional (3D) tissue models, known as human skin equivalents (HSEs), has furthered understanding of epidermal cell biology and provided novel experimental systems. Signaling pathways that mediate the linkage between growth and differentiation function optimally when cells are spatially organized to display the architectural features seen in vivo, but are uncoupled and lost in two-dimensional culture systems. HSEs consist of a stratified squamous epithelium grown at an air-liquid interface on a collagen matrix populated with dermal fibroblasts. These 3D tissues demonstrate in vivo–like epithelial differentiation and morphology, and rates of cell division, similar to those found in human skin. This unit describes fabrication of HSEs, allowing the generation of human tissues that mimic the morphology, differentiation, and growth of human skin, as well as disease processes of cancer and wound re-epithelialization, providing powerful new tools for the study of diseases in humans. *Curr. Protoc. Cell Biol.* 41:19.9.1-19.9.17. © 2008 by John Wiley & Sons, Inc.

Keywords: organotypic culture • three-dimensional model • human skin • wound repair • intraepithelial neoplasia

INTRODUCTION

The development of human, three-dimensional (3D) models for advancing insights into the biology of skin keratinocytes requires the ability to construct tissues that mimic their in vivo counterparts. The linkage that exists in tissues between growth and differentiation is optimal only when cells are spatially organized to display the architectural features seen in vivo; it is lost in two-dimensional culture systems (Bissell and Radisky, 2001). Over the last decade, the development of tissue-engineered models that mimic human skin, known as human skin equivalents (HSEs) or organotypic cultures, have provided novel experimental systems for studying epidermal biology (Kolodka et al., 1998; Andriani et al., 2003). This unit describes methods for constructing 3D models of human epidermis that mimic the architectural features and behavior of normal human skin and the changes that occur during early skin cancer progression and wound re-epithelialization. This unit describes the construction of a multilayered epithelium that is composed of skin keratinocytes and grown upon a collagen substrate populated with dermal fibroblasts. When these protocols are used, keratinocytes differentiate upon exposure to an air-liquid interface to enable the tissue to recapitulate the morphologic and biochemical processes of human epidermis.

This unit describes the fabrication of normal skin and includes modifications to these protocols that will create novel environments that mimic disease states in cutaneous tissues. Basic Protocol 1 describes the fabrication of normal HSEs using primary keratinocytes, which allows the generation of tissues that mimic the morphology, differentiation, and

growth of human epidermis. An Alternate Protocol provides a tissue model that mimics the early stages of skin cancer progression; it incorporates keratinocytes from both a normal and a squamous cell carcinoma cell line. Basic Protocol 2 describes a skin-like tissue model for cutaneous re-epithelialization, in which 3D tissues are wounded and keratinocytes close the wound defect to re-establish epithelial integrity. A Support Protocol addresses alternative substrates for fabrication of HSEs.

While the methods described below are for the fabrication of HSEs using skin keratinocytes, they can be adapted to grow tissues from other stratified epithelia, e.g., the oral and cervical mucosa, esophageal lining, laryngeal epithelium, and conjunctiva. It is suggested that efforts be made to optimize the growth of these cells in monolayer culture before incorporating them into HSEs.

NOTE: All solutions and equipment coming into contact with cells must be sterile, and proper aseptic technique should be used accordingly.

NOTE: All culture incubations should be performed in a humidified 37°C, 5% CO_2 incubator unless otherwise specified.

BASIC PROTOCOL 1

CONSTRUCTION OF A THREE-DIMENSIONAL MODEL OF NORMAL HUMAN SKIN

The 3D tissue model of normal skin consists of a stratified epithelium harboring differentiated keratinocytes that are grown on a contracted collagen matrix populated with dermal fibroblasts. As seen in the schematic figure describing HSE assembly (Fig. 19.9.1), normal tissues are constructed through the following sequential steps: (1) A thin, acellular layer of collagen (acellular collagen layer) is constructed first and acts as an attachment substrate for the cellular collagen that is fabricated above it. This thin layer prevents the cellular collagen from contracting from the insert membrane and detaching from it. (2) A collagen matrix with human dermal fibroblasts (cellular collagen layer) is constructed and allowed to contract for 7 days while submerged in medium. Fibroblasts mixed within the collagen gel remodel the matrix upon production of extracellular matrix (ECM) proteins and cause contraction of the gel. (3) After contraction is complete and the matrix is stabilized, keratinocytes are added to the surface of the matrix and allowed to attach to this substrate to generate a confluent cellular monolayer that will initiate tissue stratification (epithelialization). (4) Tissues are raised to an air-liquid interface to enable complete stratification, as well as full morphological and biochemical differentiation (tissue stratification, organization, and differentiation).

Materials

Human foreskin fibroblasts
Fibroblast culture medium (see recipe)
Acellular and cellular collagen matrices (see recipe)
Feeder layer of mitotically inactivated mouse 3T3 fibroblasts (e.g., see Rheinwald and Green, 1975)
Human neonatal foreskin keratinocytes
Keratinocyte culture medium (see recipe)
Trypsin/EDTA (see recipe)
EDTA/PBS (see recipe)
PBS (phosphate-buffered saline; Invitrogen, cat. no. 14190; also see *APPENDIX 2A*)
Human skin equivalent (HSE) culture media (see Table 19.9.1) including:
  Epidermalization medium I
  Epidermalization medium II
  Cornification medium
10% (v/v) formalin
2 M sucrose

Embedding medium: Tissue-Tek optimal cutting temperature (OCT) medium (Ted Pella)
Liquid nitrogen

Pipets, chilled 15 min at −20°C before use
10-cm^2 cell culture plates
6-well tissue culture plate with 3-μm porous polycarbonate membrane inserts (Organogenesis, cat. no. MS-10-3-5)
15-ml centrifuge tubes
Centrifuge capable of 500-1000 × *g*
Scalpel
Tissue processing cassette
Aluminum foil
~2-cm bottle or cap (to use as a mold form)
Narrow-tip forceps
Metal rack (for embedded tissue)
Styrofoam box

Additional reagents and equipment for trypsinizing (*UNIT 1.1*) and counting (*UNIT 1.1*) cells

Fabricate cellularized collagen

1. Seed ~1×10^6 human foreskin fibroblasts (HFFs) in 10 ml fibroblast culture medium to a standard 10-cm^2 cell culture dish so that they are almost confluent 1 day before incorporation into the collagen. Change the medium every 2 days.

   After the fibroblasts have been passaged once from the frozen state, they will reach confluency in ~3 days.

2. The day before incorporation, passage fibroblasts at a 9:10 split ratio, i.e., resuspend the trypsinized cells (see *UNIT 1.1*) in 10 ml fibroblast culture medium, and add 9 ml of the cell suspension to a new plate.

   Passaging cells from a confluent plate ensures a higher fraction of actively dividing cells upon incorporation into collagen gels.

3. On the day of incorporation, prepare the acellular collagen mixture on ice. Use chilled pipets (15 min at −20°C) to prevent warming of collagen when it is mixed. Avoid creating air bubbles when mixing.

   Preparing the mixture on ice prevents premature gelation.

   Collagen should be a straw-yellow to light pink color to ensure optimal gelation. If the color is bright yellow, add a single drop of sodium bicarbonate and triturate until a straw-yellow color is seen.

4. Add 1 ml acellular collagen matrix to each 6-well tissue culture plate insert. Ensure that the gel coats the entire bottom surface of the insert and allow it to gel 20 min at room temperature. Do not move the plate while the mixture is undergoing gelation.

   The color will turn pink when the collagen has fully gelled.

5. Trypsinize (*UNIT 1.1*) with trypsin/EDTA, count viable cells in an aliquot (*UNIT 1.1*), and resuspend the fibroblasts to a final concentration of 3×10^5 cells/ml.

   A total of 5×10^5 fibroblasts will be used per 6-well plate.

6. Prepare the cellular collagen mixture on ice, adding the reagents in the order listed so that the cells (added last) will not be damaged by the acidic pH of the unneutralized collagen.

   It is important to neutralize the collagen so that the cells will not be damaged by the acid pH that exists before neutralization.

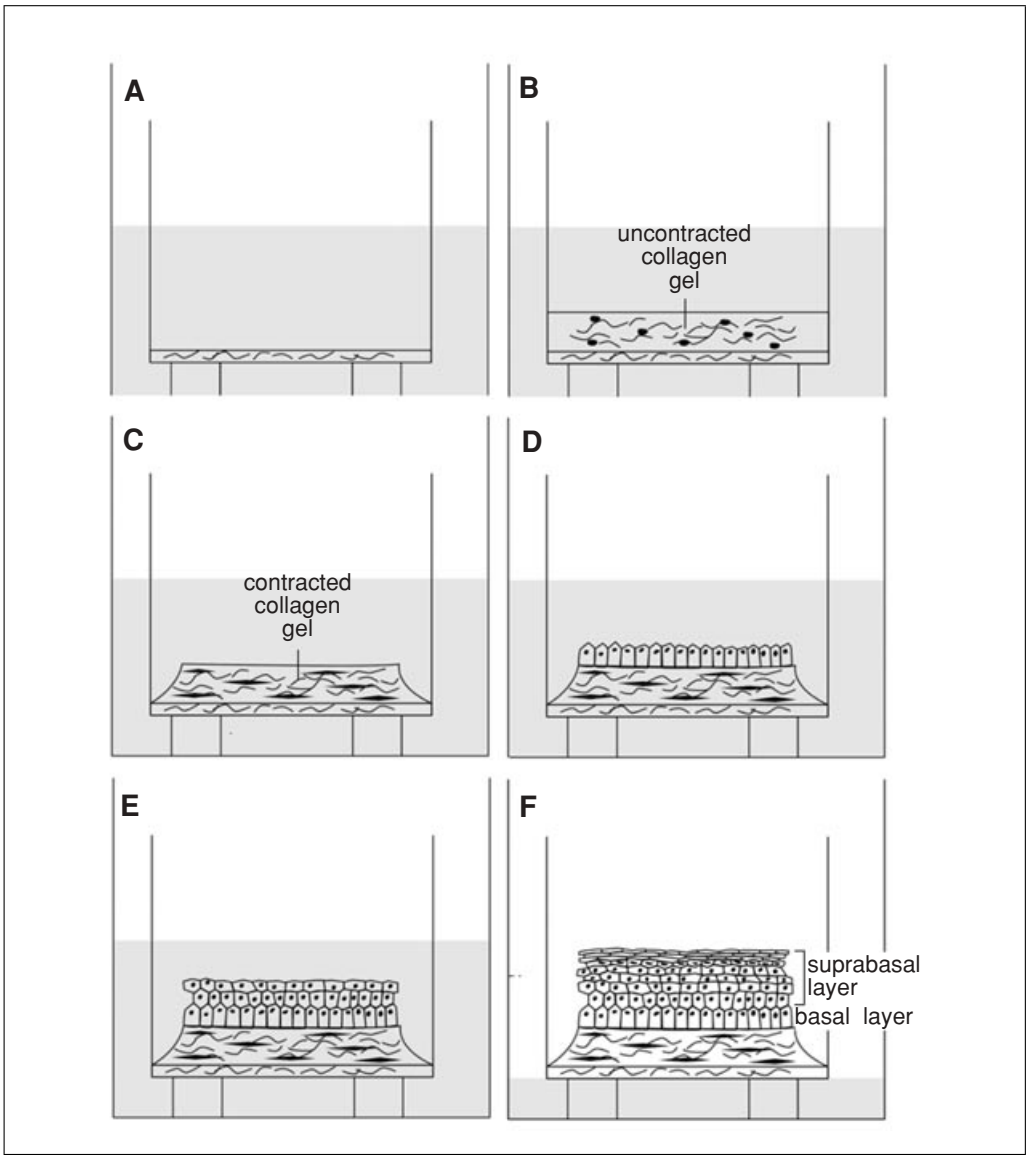

Figure 19.9.1 Schematic of three-dimensional tissue construction. (**A**) A thin, acellular layer of collagen is first constructed; it provides an attachment substrate for the cellular collagen. (**B**) A collagen gel embedded with human dermal fibroblasts is layered onto the acellular layer. (**C**) While submerged in medium for 7 days, dermal fibroblasts remodel the collagen matrix, causing it to contract away from the walls of the insert. The contracted collagen forms a plateau. (**D**) Keratinocytes are then added to the center of the plateau of contracted collagen and allowed to attach to the collagen (or intervening substrate such as AlloDerm) to create a monolayer that will form the basal layer of the tissue. (**E**) Tissues are raised to an air-liquid interface to initiate stratification. Keratinocytes stratify and differentiate and form a suprabasal layer that mimics in vivo skin both morphologically and biochemically. (**F**) Further exposure to the air-liquid interface and additional feedings with cornification medium results in an increase in the thickness of the spinous and cornified layers of the tissue.

7. Add the fibroblasts to the mixture last, gently triturate the cellular matrix to evenly incorporate fibroblasts into the collagen matrix, and add 3 ml into each insert on top of the gelled acellular collagen matrix. Gently transfer the mixture to the incubator for 30 min.

8. When the cellular matrix has turned pink and is completely gelled (usually less than 30 min), feed the gels with 12 ml of fibroblast culture medium by adding 10 ml of medium to the well around the insert and 2 ml of medium directly onto the insert.

Table 19.9.1 Supplements for HSE Organotypic Media[a]

Ingredient	Stock concentration	Final concentration	Epidermalization I (ml)	Epidermalization II (ml)	Cornification (ml)
O1O medium[b]			363	363	237
Ham's F12 supplements			120	120	237
L-glutamine	200 mM	4 mM	10	10	10
Adenine[b]	18 mM	40 μM	1	1	1
Hydrocortisone[b]	500×	1 μM	1	1	1
Triiodothyronine (T3)[b]	500×	20 nM	1	1	1
Transferrin[c]	5 mg/ml	10 μg/ml	1	1	1
Insulin[b]	5 mg/ml	10 μg/ml	1	1	1
Progesterone[b]	2 μM	2 nM	0.5	0.5	0
PES[c]	500×	1×	1	1	1
Calcium chloride	0.5 M	1.8 mM	0	1.8	1.8
FBS[d]			0.5	0.5	10

[a]Media construction for epidermalization I, epidermalization II, and cornification media, including stock concentrations, final concentration, and volume of each supplement for a 500 ml total volume.
[b]See recipe.
[c]Biosource.
[d]Fetal bovine serum (Hyclone, cat. no. 30071). The user is highly encouraged to test different FBS lots to find the optimal one. Lots used successfully by the authors include: ALG14153, AQC23532, AMA15402, and APB20546.

9. Incubate the matrix 5 to 7 days to allow complete gel contraction.

   During the first few days, the sides of the gel contract and will form a plateau in the center. Gels are stable from 5 to 10 days after initial construction.

Add keratinocytes

10. Aspirate off the medium from a feeder layer of mitotically inactivated mouse 3T3 fibroblasts and seed the feeder layer with 1×10^6 keratinocytes in 10 ml keratinocyte culture medium. Grow keratinocytes to no more than 50% confluence to minimize the number of differentiated cells seeded onto the collagen matrix.

    We typically expand 3T3 feeder cells (J2 line preferred in our lab) in ∼20 T-125 flasks, which yield ∼1×10^8 cells. It is important when expanding 3T3 cells to not let them lose their "stellate" morphology before irradiating; passage at ∼70% confluency during expansion is optimal.

    Trypsinized suspensions of the cells should be lethally irradiated. The irradiation level is determined by the user to provide cells that will still attach and survive for ∼1 week, but will not continue to divide.

    Frozen, irradiated cells last ∼3 months at −80°C, or indefinitely in liquid nitrogen. Each batch should be tested to verify support of normal human keratinocyte growth before large 3D experiments are started.

    After the keratinocytes have been passaged once from the frozen state, they will reach confluency in ∼3 days. One change of medium may be necessary.

    Alternatively, keratinocytes can be grown in monolayer culture in a low-calcium, serum-free medium (see Critical Parameters).

11. Remove the 3T3 feeder cells from the culture by incubating the dish in 5 ml EDTA/PBS for 5 min at 37°C. Displace the 3T3 cells by gentle pipetting so that keratinocytes will remain attached.

    It is important not to allow the cultures to incubate for an excessive time in EDTA/PBS, as the keratinocytes may detach from the dish as well.

12. As soon as the 3T3 cells have begun to detach, replace the EDTA/PBS with 5 ml PBS, gently rinse the plate three times with 5 ml PBS until all 3T3 cells have been completely removed, then remove the PBS, leaving only keratinocyte colonies attached to the dish.

13. Trypsinize (see *UNIT 1.1*) the keratinocytes with 2 ml trypsin/EDTA for 5 min at 37°C to obtain a single-cell suspension. Transfer the detached cells into a 15-ml tube containing 9 ml keratinocyte culture medium (to neutralize the trypsin) and count viable cells in an aliquot (*UNIT 1.1*).

14. Dispense the desired number of cells into a 15-ml tube. Centrifuge the cells 5 min at 1000 × *g*, room temperature, and resuspend in a volume of epidermalization I medium so that a total of 5×10^5 keratinocytes can be used per insert in 50 µl.

15. Remove all fibroblast culture medium from the plates with the contracted collagen 20 min before seeding keratinocytes so that keratinocytes can be seeded onto a moist collagen gel.

    Keratinocytes should be seeded directly onto the contracted collagen gels in an aliquot of 50 µl containing 5×10^5 cells. To modify the nature of the substrate on which keratinocytes are seeded, de-epidermalized dermis or coated polycarbonate inserts can be applied directly on top of the contracted collagen gels at this point (see the Support Protocol for specialized substrates).

16. Carefully add 50 µl of the cell suspension to the center of the contracted collagen gel (or onto the center of the intervening substrate placed on the collagen gel). Do not move the plate for 15 min, to allow the keratinocytes to attach. Then incubate 30 to 60 min at 37°C (without any additional medium) to allow the keratinocytes to fully adhere.

17. Add 12 ml of epidermalization I medium to each insert, adding 10 ml to the bottom of the well and 2 ml gently into the insert on top of the keratinocytes. Incubate at 37°C.

18. Feed each culture with medium every 2 days with appropriate HSE culture media as follows:

    a. Day 4: Add 12 ml epidermalization II medium.
    b. Day 6 until termination of the experiment: Add 7 ml cornification medium to the bottom of the well so that the insert just contacts the medium every two days. Aspirate medium from the inside of the insert so that tissues can be grown at the air-liquid interface.

    The morphological appearance of tissues at various stages of their development is shown in Figure 19.9.2.

Harvest tissues for analysis

19. Remove the medium from the inserts and gently rinse tissues twice in 5 ml PBS.

20. Cut away the insert membrane from the plastic insert at its base using a scalpel, and bisect the culture.

To fix the tissue

21a. Place one half of the culture in a tissue processing cassette and immediately immerse in 10% formalin for 1 hr.

    Tissues are very thin and thus only require a short fixation (1 hr).

22a. Proceed with tissue processing and paraffin embedding by sequential dehydration in graded ethanols and xylene, using standard techniques.

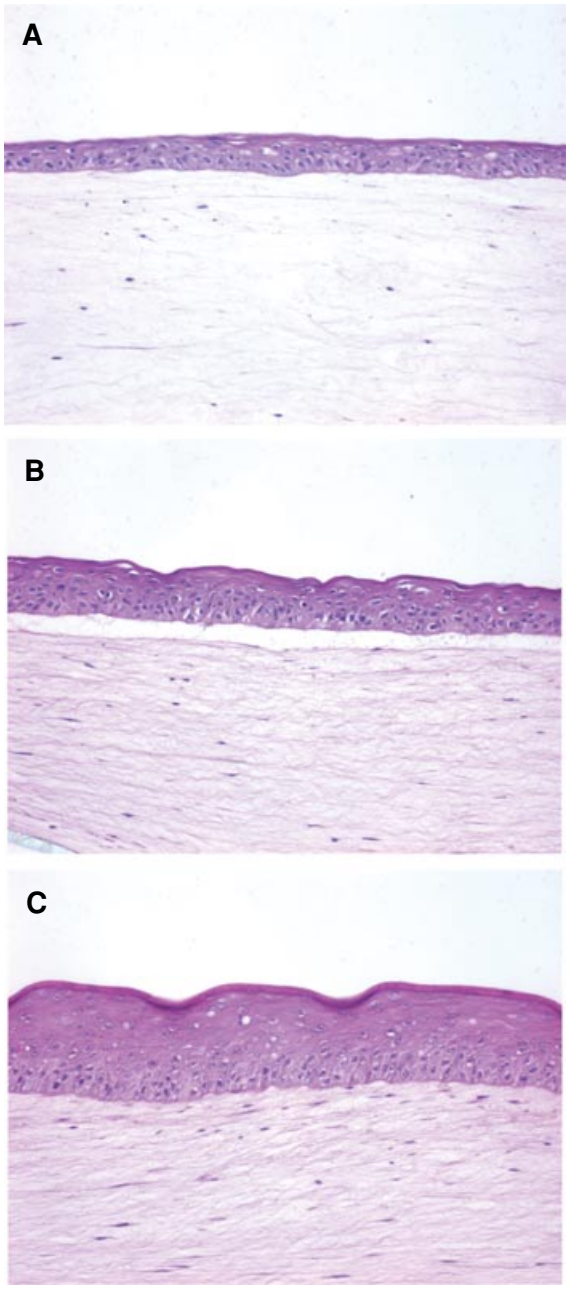

Figure 19.9.2 Morphologic development of human skin equivalents. Keratinocytes were grown directly on collagen gels for 4 days (**A**), 6 days (**B**), and 10 days (**C**). (A) Early epithelial development, evidenced by a thin epithelium, is seen while tissues are still submerged in epidermalization II medium. (B) The epithelium demonstrates a greater degree of tissue architecture and organization, demonstrated by the presence of cuboidal basal cells, after the tissue is exposed to the air-liquid interface for 2 days. (C) Full morphologic differentiation and stratification are seen after cells are exposed to the air-liquid interface for 6 days. Note that the clear space between the epidermis and dermis in panels A and B likely represents separation along the epithelium-stromal interface due to incomplete organization of the basement membrane at early time points of tissue development. A more mature tissue (C) has a more well developed basement membrane and is more resistant to separation during tissue processing.

To preserve the tissue by freezing

21b. Place the other half of the tissue in a 2 M sucrose solution. Soak the tissue in the sucrose solution at least 1 hr, but not more than 24 hr, at 4°C.

Sucrose replaces water in the hydrated collagen gel and protects against freezing damage during embedding and processing.

22b. Make a small mold with aluminum foil, using the cap or bottom of a small bottle (roughly 2 cm in diameter) as a form. Fill three-quarters of the mold with embedding medium.

23b. Gently remove the tissue from the sucrose using narrow-tip forceps, making sure to keep the tissue on the nylon insert membrane. Gently touch the membrane side of the tissue to a Kimwipe to remove excess sucrose solution.

24b. Place the tissue in the embedding medium and allow the tissue to soak 20 to 30 min at room temperature.

25b. Place a metal rack inside a Styrofoam box and fill it with liquid nitrogen to a height just under the top of the metal rack. Place the aluminum foil mold on top of the rack and stand the tissue inside to an upright position.

The liquid nitrogen vapors will freeze the embedding medium and tissue in about 5 min. The tissue can then be stored for decades at −80°C.

SUPPORT PROTOCOL

INCULDING SPECIALIZED SUBSTRATES FOR GROWTH OF HUMAN SKIN EQUIVALENTS ON BASEMENT MEMBRANE OR EXTRACELLULAR MATRIX PROTEINS

Specific applications may necessitate growing 3D tissues on basement membrane or defined extracellular matrix proteins using either de-epidermalized dermis or a coated polycarbonate membrane, respectively.

Materials

AlloDerm (de-epidermalized basement membrane; LifeCell, cat. no. 102-009)
PBS (phosphate-buffered saline; Invitrogen, cat. no. 14190; also see *APPENDIX 2A*)
6-well cell culture PET membrane inserts coated with the appropriate material:
  Collagen I (Becton-Dickinson, cat. no. 354442)
  Laminin I (Becton-Dickinson, cat. no. 354446)
  Fibrillar Collagen I (Becton-Dickinson, cat. no 354472)
  Fibronectin/collagen I (Becton-Dickinson, cat. no 354633)
  Fibronectin (Becton-Dickinson, cat. no 354440)
  Collagen IV (Becton-Dickinson, cat. no 354544)
Serum-free, low-glucose Dulbecco's modified Eagle medium (DMEM; Invitrogen)
1.4-cm stainless steel dermatological punch (Delasco, cat. no. KP-14)
Scalpel

To make de-epidermalized dermis substrate:

1a. Cut the de-epidermalized dermis (AlloDerm) with a dermatological punch to fit the diameter of the contracted collagen gel.

2a. Rehydrate the substrate in PBS 1 hr at 37°C before use.

To make coated insert substrates

1b. Cut the coated membrane from the inserts with a dematological punch.

2b. Rehydrate the coated membranes in serum-free DMEM for 1 hr at 37°C.

Add membrane or coated insert to collagen

3. Layer the de-epidermalized membrane or the coated membrane from the insert onto the contracted collagen gel 20 min before adding keratinocytes in step 15 of Basic Protocol 1.

FABRICATION OF THREE-DIMENSIONAL MODEL OF HUMAN SKIN CANCER

ALTERNATE PROTOCOL

The tissue microenvironment is defined by the complex network of intercellular interactions that are mediated by physical attachment (as in direct cell-cell or cell-extracellular matrix interactions) and by biochemical signals mediated by soluble molecules (Hagios et al., 1998). Cell adhesion is essential for the assembly of cells into 3D tissues and is required to maintain normalization of tissue architecture and homeostasis. In this way, cells receive adhesive cues that control their polarity, proliferation, differentiation, and survival. In recent years, evidence has accumulated that cancer is a disease of altered tissue architecture and that neoplastic progression is a consequence of abnormal interactions between tumor cells and their tissue microenvironment. As a result, it is essential to study the impact of the tissue microenvironment on cancer progression in human tissues that incorporate 3D tissue context so that they faithfully mimic their in vivo counterparts. Monolayer, 2D culture systems do not generate the spatially organized, 3D structures that are seen in vivo and have been of limited use in studying complex cellular responses. These inherent limitations have driven the construction of 3D tissue models that now provide novel experimental paradigms for studying cancer progression in biologically relevant tissues.

In one example of such tissue fabrication, it is now possible to construct 3D models of cutaneous, human squamous cell carcinoma that replicate multiple stages of its progression. To recapitulate the precancerous stages of progression of skin cancer, 3D tissue models must be constructed to reflect alterations in cell-cell interactions that could propel the tissue towards a neoplastic fate (Margulis et al., 2005). This has been accomplished by developing tissue models in which the fate of potentially malignant cells can be mapped by mixing normal keratinocytes with genetically-marked (with β-galactosidase) tumor cells at varying ratios to mimic precancerous conditions. We have previously found that interactions between genetically marked tumor cells and adjacent normal cells lead to tissue normalization and elimination of tumor cells when the two cell types are mixed in a ratio greater than 1:1 (normal cells/tumor cells) (Javaherian et al., 1998). Thus potentially malignant cells enter a quiescent state known as intraepithelial dormancy, in which the neoplastic potential of the tissue is conditionally suppressed and not realized. These studies have used 3D tissue models to directly implicate tissue architecture mediated by cell-cell interactions as a dominant regulator of the neoplastic phenotype.

Carcinoma cell lines can be grown as pure cultures at an air-liquid interface to simulate a carcinoma in situ, or they can be grown as mixtures with normal keratinocytes to mimic an earlier stage of epithelial dysplasia. Previous studies with different SCC cell lines indicate that tumor cells may either be maintained as individual cells within the tissue (Javaherian et al., 1998), or they may undergo intraepithelial expansion (Vaccariello et al., 1999). These tissues can be constructed by following the steps in Basic Protocol 1 for construction of normal skin equivalents and including the modifications presented below.

Additional Materials *(also see Basic Protocol 1)*

Cancer cell line of interest

1. Prepare cellularized collagen as described in Basic Protocol 1, steps 1 to 9.
2. Prepare a single cell suspension of normal keratinocytes as described in Basic Protocol 1, steps 10 to 13.

3. Culture the desired cancer cell line in a 10-cm^2 tissue culture dish in medium appropriate to the cell line.
4. Prepare a single cell suspension by incubating the cells with trypsin/EDTA for 5 min. at 37°C. Transfer the detached cells to a 15-ml tube and count viable cells in an aliquot (*UNIT 1.1*).
5. Dispense the desired number of normal keratinocytes and cancer cells into separate 15-ml tubes. Centrifuge the cells 5 min at 2000 × *g*, room temperature.
6. Resuspend each cell pellet in an appropriate volume of epidermalization I medium at 5×10^5 cells/50 μl.
7. Mix cancer cells with normal keratinocytes in the desired ratio, and seed a total of 5×10^5 combined cells/50 μl for each insert.
8. Proceed with Basic Protocol 1, starting at step 15, to culture tissues at the air-liquid interface and harvest for analysis.

BASIC PROTOCOL 2

FABRICATION OF THREE-DIMENSIONAL WOUND HEALING MODEL OF HUMAN SKIN

In vitro studies of wound re-epithelialization have often been limited by their inability to simulate wound repair as it occurs in humans. For example, wound models using skin explants or monolayer, submerged keratinocyte cultures demonstrate limited stratification, partial differentiation, and hyperproliferative growth culture systems have been helpful in studying keratinocyte migration in response to wounding. However, they have been of limited use in studying the complex nature of keratinocyte response during wound repair, as these cultures do not provide the proper tissue architecture to study the in vivo wound response.

We have previously found that HSEs adapted to study wound repair in human epithelium simulate the chronology of events that occur during re-epithelialization in human skin, and we have advanced the understanding of the healing of wounds in human skin and other stratified epithelia (Garlick and Taichman, 1994b; Garlick et al., 1996). This tissue model has allowed direct determination of the key response parameters of wounded epithelium including cell proliferation, migration, differentiation, growth-factor response, and protease expression. The application of tissue engineering technology demonstrates the utility of HSEs in studying phenotypic responses that are characteristic of the switch from a normal to a regenerative epithelial tissue during wound re-epithelialization.

This protocol describes a method for determining the response of HSEs that mimics re-epithelialization of wounded human skin, from the initiation of keratinocyte activation until restoration of epithelial integrity. Using these protocols, HSEs are fabricated as described in Basic Protocol 1. They are wounded 7 days after keratinocytes are seeded onto the contracted collagen gel. One week before wounding these tissues, an additional collagen gel, using both acellular and cellular collagen, is fabricated; this gel serves as a substrate to which the wounded tissue will be transferred. This method requires sequencing the experiment so that preparation of the additional collagen gel will be initiated one week in advance of wounding (see Fig. 19.9.3), i.e., at approximately the same time that the keratinocytes are seeded onto the first collagen matrix.

Materials

Human skin equivalent (HSE; see Basic Protocol 1, steps 1-18) with keratinocyte cultures at day 7
Contracted collagen gel (prepared 1 week in advance of the wounding; Basic Protocol 1 steps 1-9)
Cornification medium (see Table 19.9.1)

10-cm^2 sterile tissue culture dish
1.4-cm stainless steel dermatological punch (Delasco, cat. no. KP-14), optional
Forceps
Dental mirror
Scalpel with #22 blade, sterile

Wound the tissue

1. Aspirate all medium from the HSE culture after 7 to 10 days of culture.
2. Remove the insert from the well and place it upside down in a sterile dish.
3. Using a scalpel, cut away the insert membrane and place the culture in a 10-cm^2 sterile dish right-side up.
4. Trim the culture with the scalpel by cutting around the raised, mesa-like region to remove the part of the collagen gel not covered by keratinocytes.

   This will facilitate the removal and transfer of the wounded tissue from the membrane.

5. Wound the cultures with either an incisional or excisional wound.

   An incisional wound can be generated by incising tissues with a scalpel in a way that will allow the wound edges to be separated to generate an elliptical wound.

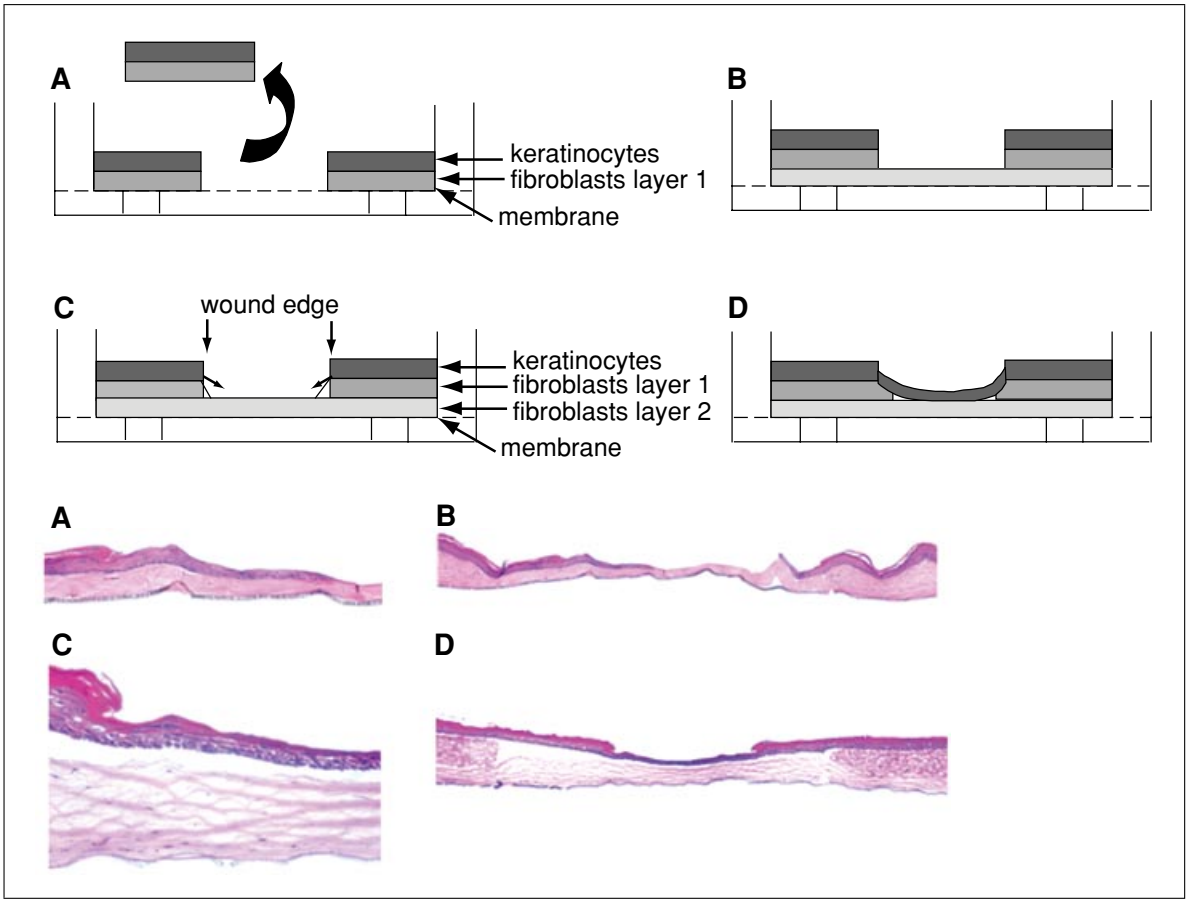

Figure 19.9.3 Three-dimensional tissue model of wound re-epithelialization: schematic (upper panels) and photomicrographs (lower panels; magnification: 5×). (**A**) A wound is generated through the full thickness of a human skin equivalent (HSE) and the excised tissue is removed. (**B**) The wounded tissue is placed on a second, contracted collagen gel. (**C**) Keratinocytes undergo migration to close the wound gap. (**D**) Keratinocytes have restored epithelial integrity, have closed the wound gap, and undergo stratification.

An excisional wound can be generated using an elliptical dermatological punch that completely penetrates the center of the tissue through the epidermis, collagen, and membrane. The excised tissue can be fixed and preserved for H&E staining in 10% formalin.

Transfer tissue to new gel

6. Use forceps to gently lift the edge of the wounded tissue by separating the collagen gel from the membrane. Drag the tissue onto a dental mirror while leaving the membrane behind.

   The transfer may be easier if the mirror is moistened with medium.

7. Unfold any wrinkles in the culture by gently moving the tissue back and forth on the mirror using the forceps. Once the culture is smooth, pull one side of the culture slightly over the edge of the mirror.

8. Move the mirror directly over the second contracted collagen matrix so that the edge of the mirror and wounded tissue are in contact with the matrix. Slide the tissue onto the second collagen gel by teasing it gently with a closed forceps as the mirror is slowly pulled away, leaving the culture on the contracted collagen gel.

9. Using the forceps, tease apart the tissue wounded by incision to create an elliptical space that should be 2 to 3 mm at its greatest width. Smooth the tissue with the forceps to ensure that it is completely free of any folds or wrinkles.

10. Maintain the tissue at an air/liquid interface by adding 8 ml of cornification medium beneath the insert, and change the medium every 2 days until the end of the experiment.

Histologically analyze wound repair

11. For histological analysis, process the tissue as described in Basic Protocol 1, steps 19 to 25, making sure to bisect the tissue perpendicular to the long axis of the wound (i.e., along the greatest width of the wound). Mount the tissue for sectioning en face so that the greatest width of the wound is sectioned first.

    It is essential to capture the first two sections as these will be the most informative sections of the wound.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Acellular and cellular collagen matrices

10× MEM (minimum essential medium with Earle's salts; Cambrex, cat. no. 12-684F)
200 mM L-glutamine (Invitrogen, cat. 25030-081)
Fetal bovine serum (FBS; Hyclone, cat. SH30071)
187 µl 71.2 mg/ml $NaHCO_3$ (Cambrex, cat. no. 17-605E)
Bovine type I collagen (Organogenesis, cat. no. 200-055)
3×10^5 fibroblasts/ml (see Basic Protocol 1)

NOTE: Keep all components on ice and mix in the order listed to avoid alteration in pH that will result in inability of collagen to gel.

See Table 19.9.2 for volumes to use for acellular and cellular matrix construction. Prepare fresh and use immediately. Do not store the final matrix.

Table 19.9.2 Construction of Collagen Matrix

Component[a]	Acellular collagen matrix[b]	Cellular collagen matrix[b]
10× MEM	0.6 ml	1.8 ml
L-glutamine	54 µl	162.5 µl
FBS	0.68 ml	2.02 ml
Sodium bicarbonate	187 µl	0.56 ml
Collagen	5 ml	15 ml
Fibroblasts	–	1.65 ml

[a]See recipe for acellular and cellular collagen matrix components for more information about component solutions and the fibroblast suspension.
[b]Component volumes are listed for the construction of acellular collagen and cellular collagen matrices. Volumes are for six inserts. Use 1 ml per insert for acellular collagen matrix and 3 ml per insert for cellular collagen matrix.

Adenine, 18 mM

Dissolve 0.972 g adenine (MP Biomedicals, cat. no. 100190) in 2.4 ml 4 N NaOH. Bring to 400 ml with water. Store up to 1 year at −20°C.

Cholera toxin, 10^{-7} M

Dissolve cholera toxin (Sigma, cat. no. C-8052) at 9 ng/ml in water and store up to 1 year at −20°C.

EDTA/PBS

50 ml of 5 mM EDTA: dilute 5 ml of 0.5 M EDTA, pH 8.0 (Invitrogen, cat. no. 15575) to 500 ml with PBS (Invitrogen, cat. no. 14190; also see *APPENDIX 2A*); store up to 1 year at room temperature

EGF, 10 µg/ml

Dissolve human recombinant epidermal growth factor (EGF; Austral Biological) at 10 µg/ml in 0.1% (v/v) bovine serum albumin (BSA; tissue culture tested); store up to 1 year at −20°C.

Fibroblast culture medium

500 ml serum-free, low-glucose Dulbecco's modified Eagle medium (DMEM; Invitrogen)
55.6 ml fetal bovine serum (FBS; Hyclone, cat. no. SH30071; 10% final)
5.6 ml 800 mM HEPES (see recipe; 8 mM final)
3.4 ml 100× penicillin/streptomycin (Invitrogen)
Store up to 2 weeks at 4°C

HEPES, 800 mM

Dissolve 47.24 g HEPES (Sigma) in 250 ml H_2O. Store up to 1 year at −20°C.

Hydrocortisone, 0.25 mg/ml (500×)

Dissolve 0.0538 g hydrocortisone (Sigma) in 200 ml H_2O. Store up to 1 year at −20°C.

The concentration in this solution is 0.55 mM.

Insulin, 5 mg/ml

Dissolve 50 mg insulin (Sigma) in 10 ml of 0.005N HCl. Store up to 1 year at −20°C.

Keratinocyte culture medium

338 ml serum-free, low-glucose Dulbecco's modified Eagle medium (DMEM; Invitrogen)
112 ml F12 nutrient mixture (Ham), containing L-glutamine (Invitrogen)
25 ml fetal bovine serum (FBS; Hyclone, cat. no. SH30071; 5% final)
5 ml 18 mM adenine (see recipe; 0.18 mM final)
3.4 ml 100× penicillin/streptomycin (Invitrogen)
5 ml 800 mM HEPES (see recipe; 8 mM final)
1 ml 0.25 mg/ml hydrocortisone (see recipe; 0.5 μg/ml final)
0.5 ml 10^{-7} M cholera toxin (see recipe; 10^{-10} M final)
0.5 ml 10 μg/ml EGF (see recipe; 10 ng/ml final)
0.5 ml 5 mg/ml insulin (see recipe; 5 μg/ml final)
Store up to 2 weeks at 4°C

CAUTION: *Cholera toxin is very toxic. Use appropriate precautions when handling stock solutions.*

O1O Medium

43 g DME powder, containing no glucose and no $CaCl_2$ (JRH Biosciences, special order)
5 liters H_2O
0.5 g $MgSO_4$
18.5 g $NaHCO_3$
Store up to 6 months at 4°C

Progesterone, 2 μM

Dissolve 1 mg progesterone (Sigma, cat. no. P-8783) in 1 ml absolute ethanol and then add 14.7 ml H_2O. Dilute 1 ml of this solution in 100 ml serum-free, low glucose Dulbecco's modified Eagle medium (DMEM; Invitrogen). Store up to 1 year at −20°C

Triiodothyronine (T3), 500×

1 ml 3,3′,5-triiodo-L-thyronine sodium salt (Sigma, T-5516)
99 ml H_2O
Store up to 6 months at 4°C

Trypsin/EDTA

50 ml of 0.1% (v/v) trypsin: prepared by diluting 50 ml 0.25% trypsin (Invitrogen, cat. no. 15050) with 75 ml PBS (Invitrogen, cat. no. 14190; also see *APPENDIX 2A*); store up to 1 year at −20°C
50 ml of 5 mM EDTA: prepared by diluting ultrapure 0.5 M EDTA, pH 8.0 (Invitrogen, cat. no. 15575) with PBS; store up to 6 months at room temperature
Store up to 1 year at −20°C

COMMENTARY

Background Information

A biologically relevant 3D human tissue model of epidermis must faithfully recreate the morphological and biochemical features of the in vivo tissue. Upon fabrication, HSEs become spatially organized as they undergo growth and differentiation, due to stromal-epidermal communication (see Fig. 19.9.2). This provides numerous advantages in the study of epidermal biology when compared to 2D monolayer culture systems (Carlson et al., 2007), as components of the model can be altered and tissue outcomes monitored in order to investigate morphological and molecular responses. The ability to manipulate either the cells or the tissue microenvironment provides opportunities to investigate cancer progression and injury response in human skin. For example, soluble

factors (e.g., growth factors) can be added to the medium to directly observe HSE response. A pulse of bromodeoyuridine (BrdU) can be added to the medium to enable analysis of the proliferation rates of the cells in 3D tissues.

The protocols described above enable tissue growth on a variety of ECM substrates. Substrates can be selected to answer specific questions about the impact of different environments and how they affect tissue development. De-epidermalized dermis (AlloDerm, LifeCell) provides an interface on which the assembly of basement membrane is optimized, while HSEs grown on a contracted collagen gel do not assemble structured basement membrane (Andriani et al., 2004). Tissues grown on polycarbonate membranes coated with specific ECM proteins can be used to study how specific ECM or basement membrane (BM) proteins affect tissue growth and architecture (Segal et al., 2008).

Observations from early studies performed in monolayer 2D culture systems revealed that cell-cell contact between normal cells and adjacent tumorigenic cells could suppress the transformed phenotype. However, the mechanistic basis for these observations remained unclear due to a lack of human tissue models that could more fully mimic the biologically meaningful pathways that couple the cell-cell adhesion and in vivo phenotype, and more accurately represent these early events in tumorigenesis as they occur. Three-dimensional tissue models have now been designed to reflect the incipient stages of spontaneous tumors in human epithelial tissues, where potentially neoplastic cells are found in the context of normal, cellular neighbors during the premalignant stage of epithelial cancer development.

Three-dimensional tissue models can be adapted to understand the intraepithelial dynamic that occurs in precancerous legions. The fate of potentially malignant cells can be monitored in 3D tissues by mixing normal keratinocytes with genetically marked (with β-glactosidase) tumor cells at varying ratios. These models can reflect the alterations in cell-cell interactions that could propel the tissue towards a neoplastic fate. Using this approach, we had previously found that interactions between genetically marked tumor cells and adjacent normal cells led to normalization and elimination of tumor cells. Thus, potentially malignant cells entered a quiescent state known as intraepithelial dormancy, in which the neoplastic potential of the tissue was conditionally suppressed and not realized. This dormant state can be overcome by altering tissue dynamics in response to the tumor promoter TPA (Karen et al., 1999), irradiating with UV light (Mudgil et al., 2003), decreasing adhesive interactions between tumor cells and adjacent epithelia, or enabling tumor cells to interact with basement membrane proteins (Andriani et al., 2004). Both TPA and UV have different effects on normal versus premalignant cells. For example, premalignant cells are resistant to UV-induced apoptosis and undergo selective expansion in the presence of TPA, leading to intraepithelial expansion of premalignant cells. Thus, the opportunities created through the use of 3D tissue models have directly implicated tissue architecture, mediated by cell-cell interactions, as a dominant regulator of the neoplastic phenotype since maintenance of normal tissue architecture can constrain cancer progression at a premalignant stage.

Critical Parameters

The proliferative potential of keratinocytes is a critical factor in the successful fabrication of HSEs with normalized tissue architecture. Most keratinocytes seeded onto HSE cultures will adhere to the connective tissue substrate, but only replicating cells will grow after seeding. Keratinocytes that have undergone terminal differentiation while in submerged culture will also attach to the substrate, but will not undergo further proliferation to become well stratified HSEs. In order to generate tissues with normalized tissue architecture, it is critical that keratinocytes seeded to generate HSEs have an elevated growth potential. Nearly all keratinocytes seeded in HSEs will adhere to their connective tissue substrate, but only replicating cells will grow.

It is, therefore, important to grow keratinocytes so that a high growth fraction is present in the monolayer cultures at the time of passage to HSEs. This can be accomplished by growing keratinocytes as small colonies at high clonal density in submerged cultures on 3T3 feeder layers so that terminal differentiation will be minimized and the fraction of replicating cells will be maximized. Alternatively, keratinocytes can be grown in low calcium medium before passage to HSEs, using defined medium conditions without 3T3 fibroblasts.

Keratinocyte strains can be tested in HSEs to determine those that will provide the best growth and morphologic differentiation. This may also be accomplished by testing the clonogenic growth of keratinocyte strains in monolayer cultures on feeder layers in order

to determine the growth potential of these cells. We have observed variations in growth and morphology of HSEs when different keratinocyte and fibroblast strains are incorporated. Therefore, keratinocyte strains should be screened by constructing HSEs to identify strains that can achieve optimal morphologic differentiation and tissue architecture.

An advantage of studying keratinocyte phenotype in HSEs lies in the ability to control and modify the cellular milieu in which these tissues are grown. For example, it is possible to add soluble factors directly to these cultures to determine the phenotypic response to such environmental conditions. In addition, growth conditions can be modified by culturing tissues in the absence of fibroblasts by eliminating them after contraction of the collagen gel (Andriani et al., 2003). Furthermore, control of the milieu facilitates analysis of these tissues, as it is possible to directly determine proliferation indices by adding a pulse of BrdU directly to the medium.

The protocols described in this unit provide techniques that allow growth of epithelial tissues on a variety of connective tissue substrates, each of which can be tailored to answer experimental questions. The interface of tissues grown on the de-epidermalized dermis promotes the rapid assembly of structured basement membrane and optimization of tissue morphology (Andriani et al., 2003). One source of such a dermal substrate is AlloDerm, a commercially available cadaveric dermis that is used in a variety of clinical applications to treat burns, periodontal disease, and surgical defects (LifeCell). Tissues grown directly on contracted collagen gels do not assemble intact basement membrane, but provide excellent support for keratinocyte growth and differentiation. Cultures grown on polycarbonate membranes coated with specific extracellular matrix proteins can be used to directly study the effect of these proteins on tissue architecture and phenotype of these tissues (Segal et al., 2008).

Troubleshooting

We have found some variability in the degree to which fibroblast strains support keratinocyte growth after their incorporation into collagen gels. It appears that fibroblast support of HSE organization and growth is directly related to the degree to which fibroblasts are able to contract the collagen gel. Fibroblast strains demonstrating more shrinkage of the collagen gel before adding keratinocytes are better able to support keratinocyte growth. This parameter can be used to screen fibroblast strains for optimal growth-support when planning initial experiments.

It is critical to preserve tissue architecture during processing of tissues after culture is complete. Since collagen gels are greatly hydrated, they can undergo significant artifactual damage during tissue processing. For this reason, tissues are soaked in 2 M sucrose for 2 hr at room temperature or overnight at 4°C in order to replace water in the tissue and prevent freezing damage. Furthermore, tissues need to be gradually frozen in liquid nitrogen vapor to prevent destruction of tissue architecture. Tissues should never be snap-frozen by immersing them in liquid nitrogen.

Fabrication of the collagen matrix requires that all components be kept on ice until the gel mixture is placed onto the insert. This will ensure that collagen will not prematurely precipitate from these solutions. Plastic pipets used for collagen should be chilled before use.

Anticipated Results

Several points regarding some subtleties of keratinocyte behavior in HSEs should be mentioned. The first concerns the length of time which cultures can be maintained at the air-liquid interface. In our experience, cultures can be kept at this interface for 7 to 14 days. After this time, the surface layers of the epithelium become very thick due to a failure to desquamate. As a result, lower layers of the epithelium become compressed and the longevity of cultures is limited. A second and related issue concerns the growth potential of keratinocytes in HSEs. While HSEs demonstrate a basal level of proliferation that is greater than human skin, it has been shown that these cultures have a tremendous potential for cell growth and are very responsive to external growth stimuli. For example, we have shown that disruption of HSEs upon wounding results in a 10-fold increase in basal cell proliferation (Garlick and Taichman, 1994a).

It should be kept in mind that although keratinocytes grown in HSEs share many morphologic and biochemical features with their in vivo skin and mucosal keratinocytes, there are differences in tissue phenotype. For example, integrin receptors (the αv integrins) not normally expressed in skin are constitutively expressed in keratinocytes grown in HSEs. In addition, HSEs are somewhat deficient in barrier function. Keratinocytes grown

in HSEs can be thought of as tissues undergoing de novo development (e.g., newly re-epithelialized, healed wounds in vivo) wherein morphologic differentiation is complete, but cells are still in a somewhat activated state.

Time Considerations

Construction of HSEs requires ~3 to 4 weeks from the time HFF are seeded in monolayer culture until 3D tissues are fully mature. HFF cells should be confluent two days before construction of the collagen gels. At that time, cells should be passaged at a 9:10 ratio, to provide cells with a growth stimulus before incorporation into collagen gels. Complete contraction of the collagen gels requires 7 to 10 days, during which time the normal human keratinocytes cell cultures are initiated and expanded. Growth and differentiation of keratinocytes on the contracted collagen gels requires, sequentially, 2 days in epidermalization I medium, 2 days in epidermalization II medium, and 7 to 10 days in cornification medium to allow full tissue organization and stratification. Histological analysis takes 2 to 3 days.

Overview: Engineering Transgenic Constructs and Mice

Naoto Haruyama,[1] Andrew Cho,[1] and Ashok B. Kulkarni[1]

[1]National Institute of Dental and Craniofacial Research, National Institutes of Health, Department of Health and Human Services, Bethesda, Maryland

ABSTRACT

Cell biology research encompasses everything from single cells to whole animals. Recent discoveries concerning particular gene functions can be applied to the whole animal for understanding genotype-phenotype relationships underlying disease mechanisms. For this reason, genetically manipulated mouse models are now considered essential to correctly understand disease processes in whole animals. This unit reviews the basic mouse technologies used to generate conventional transgenic mice, which represent a gain-of-function approach. First, an overview of transgenic construct design is presented. This unit then explains basic strategies for the identification and establishment of independent transgenic mouse lines, followed by comments on historical and emerging techniques. It then describes typical problems that are encountered when researchers start to generate transgenic mice. *Curr. Protoc. Cell Biol.* 42:19.10.1-19.10.9. © 2009 by John Wiley & Sons, Inc.

Keywords: transgenic mice • plasmid vector • constructs • gene expression • reporter gene

INTRODUCTION

Genetically manipulated mouse models are now considered essential for studying gene functions in whole animals. Gene knockout mice represent a loss-of-function strategy, whereas the transgenic mice discussed in this unit represent a gain-of-function approach to define molecular and cellular functions of a gene of interest. This approach can also be used to analyze tissue-specific or developmental stage–specific gene expression by introducing reporter genes, such as β-galactosidase (*lacZ)* or green fluorescent protein (GFP), under the control of a specific gene promoter. If the functional domain of a gene of interest is well characterized, it is possible to create transgenic mice with gene ablation by introducing the dominant negative forms of the gene into the mouse genome. Typically, transgenic mice are generated by microinjecting the transgenic construct into a fertilized egg (oocyte or zygote). An alternative way to effectively introduce a transgene into an egg is the use of a retroviral vector. However, the retroviral method has limitations: high titers must be used to obtain the vector integration, and mosaic mice may be generated that do not carry the transgene in each and every cell. Another method to generate transgenic mice is to transfect a transgenic construct into mouse embryonic stem (ES) cells and then inject these cells into mouse blastocysts. This method is particularly useful to obtain a low copy number of the transgene in the mice, especially when embryonic lethality is expected in the resultant transgenic mice. Chimeric mice generated by the ES cell transfer method may be able to transmit the transgene to embryos, allowing analysis of transgenic embryos in the dams that have mated with the chimera.

This unit presents the most widely used strategies for generating plasmid-based transgenic constructs to be injected into fertilized mouse eggs, identifying potential founders by genotyping, and establishing separate founder lines. Frequent problems that can be encountered when researchers start to generate transgenic mice will be discussed in the Commentary sections.

DESIGN OF THE TRANSGENIC CONSTRUCT

Like other plasmid constructs used to express proteins in a cell culture system, transgenic constructs must have all the critical elements for gene expression to occur, such as promoters, introns, the protein coding sequence of interest (cDNA or genomic DNA) and a poly(A) site (Fig. 19.10.1A). A cloning strategy should be clearly planned with a good understanding of each functional element so as to obtain the expected expression

DOI: 10.1002/0471143030.cb1910s42

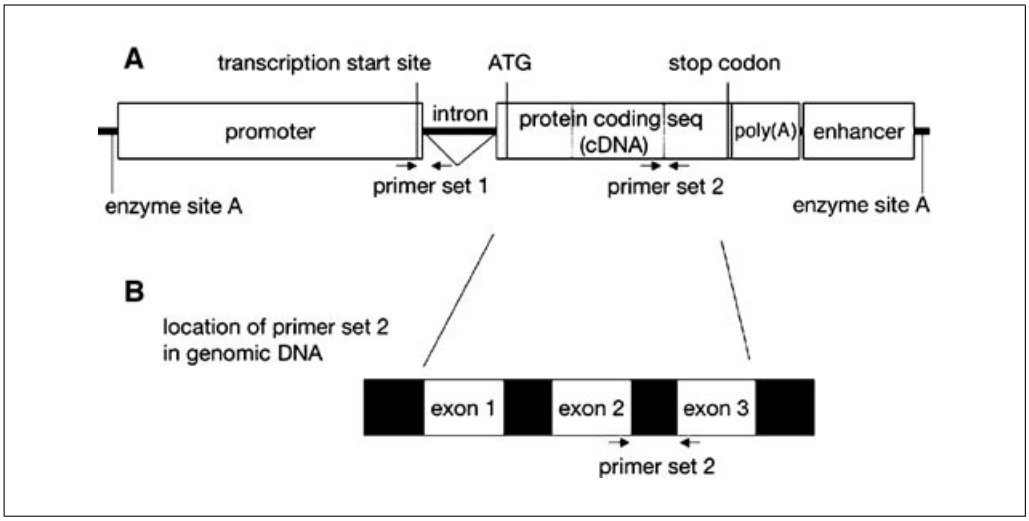

Figure 19.10.1 Representative transgenic construct and primer designs for genotyping. (**A**) Typical transgene construct is depicted, consisting of promoter, intron, protein-coding sequence (cDNA) from a gene of interest, stop codon, poly(A) sequence, and enhancer sequences. The promoter sequence normally contains the transcriptional start site, although there are variations. The inclusion of an intron leads to a greater percentage of active transgene expression in mouse lines. The protein coding sequence (cDNA) needs to have a translation start site, typically consisting of a Kozak consensus sequence in addition to an ATG start codon. The entire fragment can be cut out from the vector backbone by a single restriction enzyme (site A) prior to zygote injection. A restriction enzyme site that can be cut only once inside of the fragment should be considered at the construct-design stage for future genotyping by Southern blotting. Primer set 1, designed at the junction of 2 different elements, can amplify a unique sequence. (**B**) Alternative strategy of primer design. The primers for genotyping can also be designed in cDNA to bridge between two or more different exons so that the endogenous gene would be amplified with a larger size at low efficiency. ATG, translation start codon; stop, translation stop codon; seq, sequence.

of a transgene. Well defined expression in a cell line is certainly a good indicator that a transgenic construct was properly designed, although this will not guarantee transgene expression in vivo. A transgene must be excised out of the vector backbone prior to injection into mouse eggs (see *UNIT 19.11*). Unnecessary sequences from a plasmid vector (derived from prokaryotic sequences) should be removed as much as possible to increase the probability of transgene expression in mice, although the expression seems unaffected by up to 100 extra bases. Inclusion of extra sequences between each element of a transgene does not usually affect the transgene's function as long as some regulatory elements are not inadvertently created. To release a transgenic cassette from a vector, the construct must be designed with unique restriction enzyme sites flanking the transgenic cassette (Fig. 19.10.1A). The size of a transgene does not affect efficiency of generating transgenic mice.

Promoter

A promoter is a critical sequence required for regulating the spatial and temporal expression pattern of a transgene. Promoter sequences are isolated from upstream regions of endogenous mammalian genes. A promoter sequence normally includes a transcriptional start site as well as transcription regulatory sequences. Many promoters have been reported that can successfully achieve tissue-specific and developmental stage–specific expression of transgenes. A database search such as PubMed or the International Mouse Strain Resource (see Internet resources with annotations) is the preferable way to find promoters for a tissue or cell type of interest. Promoters should be tested to determine if they contain the appropriate transcriptional regulatory elements. For example, transgenic mice harboring 0.9 kb of the type I collagen (*Col1a1*) promoter expressed the transgene at relatively low levels, almost exclusively in the skin. On the other hand, mice with a sequence containing 2.3 kb of this proximal promoter expressed the transgene at high levels in mineralized tissues, but not in other type I collagen–producing cells. Transgenic mice harboring 3.2 kb of the proximal promoter showed an additional high-level expression of the transgene in tendon and fascia fibroblasts (Rossert et al., 1995).

The best way to choose a promoter to generate transgenic mice is to review original papers that examined its endogenous expression patterns. To prevent any significant difference from the original work, investigators should ask the group that published the work to provide the vector with detailed information about the promoter sequence.

Inducible expression of a transgene in mice is possible by utilizing inducible promoters. For example, the metallothionein-1 promoter is induced by heavy metals like zinc (Mayo et al., 1982; Sumarsono et al., 1996), and interferon-inducible gene expression has been reported for Cre (P1 bacteriophage cyclization recombinase) in transgenic mice (Kühn et al., 1995). Tetracycline, used for tightly regulated expression of a transgene, is the most frequently used promoter and activator of binary systems (Gossen and Bujard, 1992; see *UNIT 20.8*). In this system, the expression of a fusion protein, consisting of the viral transactivation domain and the prokaryotic tetracycline repressor (*tetR*) domain, is controlled by a tissue- specific promoter. Because the fusion protein binds to both tetracycline and the operator sequences (*tetO*) of the tet operon in the target transgene, the target transgene can be controlled by a minimal promoter that contains only a TATA box, depending on the tetracycline concentrations in tissues. There are two options in this system: in the first one, the tetracycline-controlled transactivator (tTA) cannot bind to DNA when the tetracycline is present (tet-off), whereas in the second one, the reverse tTA (rtTA) binds to DNA only when tetracycline is present (tet-on).

Protein-Coding Sequence and Transcription Start Site

A protein-coding sequence is usually a full-length cDNA derived from the RNA of a gene of interest. This sequence normally contains a translational start codon (ATG), a translational stop codon, and a Kozak sequence upstream of the start codon so that the ribosome can scan and recognize the proper translation start and stop sites on mRNA. An authentic 10- to 15-nucleotide sequence found at the 5′ end of the start codon in a gene of interest can be assumed to have appropriate translational start signals. Alternatively, a Kozak consensus sequence such as GCCGCC (G/A) NN ATG G can be incorporated as a translational start site (Kozak, 1987). The sequence between the transcriptional start site and the translational start site should be checked for inadvertent ATG start codons, stop codons, or other potential regulatory elements created during construction of a transgene.

Adding protein tag sequences such as VSV, 6×His, HA, V5, or Myc to the transgene may be useful to detect transgene expression because reliable antibodies to these epitopes are available. Additionally, a tag sequence provides a way to differentiate between endogenous gene expression and transgene expression. It is important to avoid disruption of transgene function when adding a tag sequence. Introducing an internal ribosomal entry site (IRES) followed by a reporter gene such as *lacZ* or GFP is also useful for checking the expression pattern and for genotyping, although the efficiency of IRES-mediated bicistronic expression may require additional studies.

If cDNA cloning is difficult because of highly repetitive sequences, and if a genomic clone containing all of the required exons and introns is available, then the promoter can be ligated with the genomic sequence (Tanaka et al., 2001).

Roles of Intron, Stop, Poly(A) Addition, and Enhancer Sequences

Variation in transgene expression levels is influenced by a number of factors. However, inclusion of an intron in a transgene construct leads to significantly greater transgene expression (Brinster et al., 1988); Fig. 19.10.1). The intron seems to have important effects on mRNA stabilization and the efficient translocation from nucleus to cytoplasm (Huang and Gorman, 1990). Examples of introns commonly used are the rabbit β-globin intron or the simian virus 40 (SV40) intron. The first authentic intron located upstream of exon 2, which often contains a translational start site, can also be used in experiments where tissue-specific expression is important. Each transgene must also contain a transcriptional stop signal to match the transcriptional start signal. Eukaryotic transcriptional stop signals include a poly(A)-addition sequence (AAUAAA), as well as hundreds of downstream nucleotides whose function is important but not clearly understood. The transcriptional stop signal including poly(A) addition sequence (designated poly(A) as shown in Figure 19.10.1) is added at the 3′ end of the protein coding sequence. Examples of transcriptional stop sequences are those from SV40, bovine growth hormone (BGH), and human growth hormone (hGH; Sheets et al. 1987; Goodwin and

Rottman 1992). If an enhancer sequence for the gene of interest is identified, it can be included at either end of all the fragments mentioned above.

IDENTIFICATION OF POTENTIAL FOUNDERS AND GENOTYPING STRATEGY

About 3 weeks after the zygote injection, potential founders (F0) should be born. Genomic DNA for genotyping should be isolated from either ear-punch or snipped tail according to the approved animal study protocol. All the founders should be screened for the presence of the transgene to establish separate transgenic lines. The founders will have variable copy numbers and unique transgene insertion sites because of the random integration of the transgene.

Polymerase chain reaction (PCR) and Southern blotting are the most commonly used methods to detect the presence of the transgene. Southern blotting is highly recommended to identify founder animals because of the low false-positive rate and because more information can be obtained from the blot. If investigators obtain too many potential founders to be genotyped by Southern blotting, a PCR assay can be used to screen for positive mice first, and Southern blotting can be used with the reduced sample size. PCR is probably the best method for genotyping the offspring of the founders, but the result of the PCR assay should be validated with Southern blotting at least once. In either case, the validation protocol must ensure that the methods have enough sensitivity to detect one copy of the transgene and that established lines can be maintained without loss in the future.

PCR Method to Identify the Transgene

Because of the high sensitivity of PCR, cross-contamination between samples and low primer sensitivity should be eliminated prior to genotyping. It is, therefore, always preferable to use wild-type mouse genomic DNA as a negative control and a positive control of wild-type mouse genomic DNA spiked with a transgene fragment or a plasmid at 1 and 10 copies per diploid genome. Neither the pure transgene fragment nor the plasmid should be used for the positive control.

The input DNA for PCR should be 20 to 200 ng of genomic DNA for a 25-µl reaction. If the PCR products smear in the electrophoresed gel, the amount of input DNA should be decreased. PCR primers should consist of around 30 nucleotides and produce a short amplicon of between 100 and 500 nucleotides for robust and specific amplification. The best primer pair can be designed in flanking sequences of the junction between two elements uniquely combined in the transgene (primer set 1 in Fig. 19.10.1A). This primer pair distinguishes the transgene from the endogenous gene. Alternatively, if a transgene construct has a foreign sequence from other species, such as a GFP, the primers designed in the sequence can amplify the unique product. If a cDNA is used as a coding sequence, the primers can be designed to bridge between two or more different exons so that the endogenous gene will be amplified as a larger product (primer set 2 in Fig. 19.10.1A and B).

Southern Blotting Method to Identify the Founders

A restriction enzyme that can cut only once in the transgene fragment is frequently used to digest genomic DNA for the genotyping of transgenic mice by Southern blotting. Since the majority of cytosines in the context of the CpG dinucleotide are methylated in normal adult somatic tissues, a restriction enzyme that is CpG methylation sensitive should not be used. Because the transgenic construct integrates as multiple head-to-tail tandem copies in the mouse genome in most cases, digestion with a restriction enzyme that cuts at one site in the transgene will result in a fragment that is the same size as the original transgene (enzyme site A in Fig. 19.10.2A). These fragments will appear as the most intense band by using either a transgene-specific probe or a probe made from the entire injected fragment. The transgene flanking fragments, which consist of the genomic sequence and a part of the transgene, can also be detected as two obvious bands with different sizes depending on the integration sites. These bands can be used as single-copy standards to calculate the absolute copy numbers of the transgene. If more than three different flanking sequences appear, the founder mouse may have multichromosomal integration (Fig. 19.10.2B, Lane E).

We recommend using the entire injected fragment as a probe (Fig. 19.10.2A). Because the promoter sequence in the probe fragment binds to the endogenous promoter region, the band derived from the endogenous promoter region can be used as a control to check whether equal amounts of DNA were used for each of the samples. In addition, the band from the endogenous promoter could be used as a

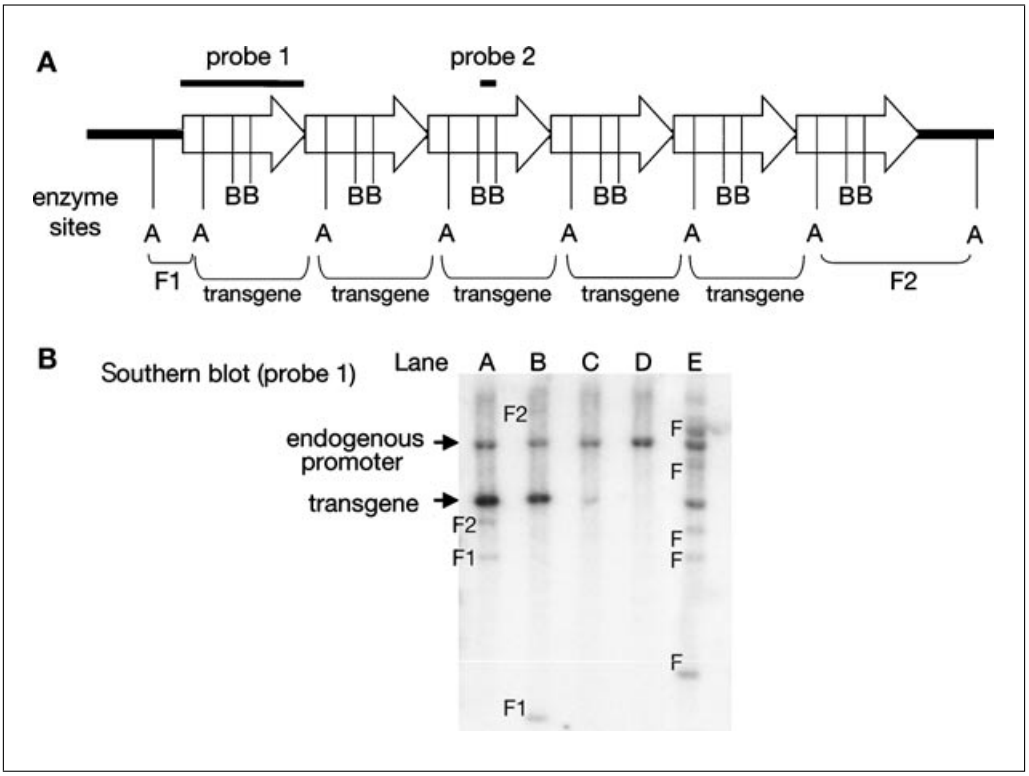

Figure 19.10.2 Diagrams of transgenes integrated in the mouse genome and the strategy for genotyping by Southern blotting. (**A**) The scheme assumes there are six copies of a transgene integrated head-to-tail. (**B**) Example for genotyping of transgenic mouse by Southern blotting. Enzyme sites A and B in panel (A) represent hypothetical locations of the restriction enzyme sites in integrated locus. If the genomic DNA containing the transgenes is digested with enzyme A, five copies of transgenes with the size of the injection fragment (transgene) and two flanking sequences (F1 and F2) will be released from the genomic DNA. The five copies of transgene fragments will be detected as the most intense band by using a probe made from the entire injected fragment, probe 1 (transgene in panel B, lane A). The flanking fragments of the transgene, which consist of the genomic sequence and a part of the transgene, can also be detected as two obvious bands with unique sizes depending on the integration sites (bands F1 and F2 in panel B, lane A). These bands can be used as single copy standards to calculate the absolute copy numbers of the transgene. Because the transgene is randomly integrated in the mouse genome, different lines show different sizes of flanking sequences (bands F1 and F2 in panel B, lane B). The band from an endogenous promoter may also be detected in all the samples (endogenous promoter in panel B). Lane C in panel B shows a transgene band with less intensity (~1 copy), suggesting that this line may be a mosaic mouse. If more than three different flanking sequences appear, the founder mouse may have multichromosomal integration (bands F in panel B, lane E). Lane D represents the wild-type mouse control. If the transgene fragment is too long to resolve using standard Southern blotting (>15 to 20 kb), a restriction enzyme that cuts two or more times in the injected fragment can be used (enzyme site B in panel A). In this case, probe 2 detects six copies of transgene fragments generated by enzyme B with no flanking sequences.

single-copy standard in case only one endogenous promoter with a unique sequence exists in the mouse genome. For example, if the transgene band has an apparent low intensity compared to the promoter band, the founder may be mosaic (Fig. 19.10.2B, Lane C).

In some cases, it may not be possible to use a restriction enzyme that can cut only once in the transgene. Especially if the transgene is longer than 15 to 20 kb, the fragment will be too long to resolve using standard Southern blotting (pulsed-field gel electrophoresis might be used). If that is the case, a restriction enzyme that cuts two or more times in the injected fragment can be used (enzyme site B in Fig. 19.10.2A). A probe designed in one of the internal fragments can hybridize and detect the intense band provided by the transgene. A series of wild-type genomic DNA samples spiked with 1 to 100 copies of the transgene can be used to generate a standard curve for calculating the copy numbers.

Calculation of Transgene Mass to Spike One Copy per Diploid Genome

Assume the mouse genome has around 6.0×10^9 bp/cell and the injected transgenic fragment has 6.0 kb (6.0×10^3 bp).

The ratio (the size difference) between the foreign DNA fragment and the mouse genome is:

$$(6.0 \times 10^3 \text{ bp})/(6.0 \times 10^9 \text{ bp}) = 1.0 \times 10^{-6}$$

To obtain a single copy of the fragment, the size difference or the ratio between the fragment and the total genome should be translated into the concentration of the DNA.

For example, if 10 μg of genomic DNA is to be analyzed by Southern blotting, multiply the difference to obtain a single-copy amount of transgene, i.e., 10 μg of genomic DNA $\times$ $1.0 \times 10^{-6} = 1.0 \times 10^{-5} = 10$ pg.

Therefore, 10 pg of the 6.0-kb transgene fragment is equal to 1 copy.

If 200 ng of genomic DNA is used for the PCR reaction, the single-copy amount for spiking is 0.20 pg. Note that the copy number of transgene usually has a strong correlation with the transgene expression level, although it will not guarantee the expression level of protein (see Transgene silencing and leaky expression, below).

ESTABLISHMENT OF INDEPENDENT MOUSE LINES FOR EXPERIMENTAL USE

Once the founders reach sexual maturity, they can be crossed with wild-type mice to establish separate transgenic lines. However, the wild-type mouse strain should be considered before the founders are mated. Because the phenotype may vary depending upon the strain background, generating littermates with a variety of genetic background ratios should be avoided. If the founders are generated from inbred strains such as C57BL6/J or FVB, the same background should be maintained by crossing with the same strain so that no mixed backgrounds will result. After verifying transmission from founder mice (F0) to offspring (F1), transgene expression within each line of the F1 or F2 generation has to be examined in most of the organs to prove that the line has proper temporal and spatial gene expression patterns and no leaky expression. Undesirable leaky (ectopic) expression in organs or tissues may result in unexpected phenotypes. In case the transgene is integrated into multiple chromosomes, further crossing with wild-type mice is necessary for the transgene to be segregated into different chromosomes to establish separate mouse lines.

Reverse transcriptase–polymerase chain reaction (RT-PCR) and/or northern blotting can be used for the screening of expression patterns. It is advisable to perform northern blots to minimize the effect of trace amounts of genomic DNA contaminations in RNA, especially when cDNA is used as a transgene. Immunoblots should also be performed to verify that the desired proteins were translated from transgenes.

At least two or three different lines generated from the same construct should be established and analyzed. Because each line should have different transgene insertion sites, copy numbers, and protein expression levels, an analysis of multiple transgenic lines may provide dose-dependent phenotypes. Multiple-line analysis also rules out the possibility of analyzing phenotypes from an unknown gene mutation or ectopic expression of the transgene.

GENERAL CONSIDERATIONS

Background Information

Generation of the first transgenic mouse was reported by Gordon et al. (1980). They produced transgenic mice by pronuclear injection of a pBR322-based plasmid containing HSV (herpes simplex virus) and the SV40 DNA sequence. After this report, the technique spread immediately and was well pursued. It is now an indispensable tool when gene functions need to be analyzed at the whole-body level, such as in developmental biology, immunology, and neuroscience. A large number of promoters have been characterized that direct a wide variety of transgene expression patterns. Varieties of transgenic mice that express Cre (P1 bacteriophage cyclization recombinase) in a tissue-specific manner are now available for creating conditional knockout mice utilizing the Cre-*loxP* system (Sauer and Henderson 1988; Gu et al. 1994).

Historically, the majority of transgenic mice were generated by injecting plasmid-based recombinant DNA, which limited the insert size to less than 20 kb because of the cloning capability of bacteria, but investigators could still expect faithful amplification, easy manipulation, and a good yield of recombinants. Relatively shorter inserts excised from plasmids can integrate as tandem-repeat concatemers, resulting in high copy number in most cases. To a certain extent, transgene silencing is inevitable from position effects

caused by the use of shorter transgenes (see Transgene silencing and leaky expression).

To overcome the problems related to size-restricted plasmid vectors, larger constructs can be made in YAC (yeast artificial chromosome), BAC (bacterial artificial chromosome), or PAC (P1-derived artificial chromosome). A premade BAC library can especially facilitate the cloning and identification of the gene of interest. The advantages of using a large clone such as YAC are reported in a number of papers (e.g., Giraldo and Montoliu, 2001). Transgenic mice created from large genomic clones showed position-independent, copy number–dependent expression of the transgene, suggesting that most of the regulatory sequences are needed to stably maintain the expression. Recently, Lois et al. (2002) reported that an alternative method of introducing a transgene by lentiviral vectors was successfully used to generate transgenic mice. This virus can be introduced either by microinjection in the perivitelline space or by coincubation with a denuded zygote. Furthermore, this method could be adapted with tightly regulated tet-on/off RNA interference (RNAi) technology to achieve conditional gene expression and knock-down in mice (Szulc et al. 2006). These emerging technologies will provide further insights for analyzing gene functions and developing therapeutics.

Troubleshooting

No founders born

If no founder mice are obtained, it may be the result of technical problems with microinjection. Alternatively, if a transgene carries fatal mutations or integrates at very high copy number, it may become toxic to embryos. Another possibility is that the transgene functions may be critical for the development of mouse embryos or for survival before the weaning stage. Investigators may need to reconsider these issues prior to repeating microinjections. There is also a possibility that the potential founder may be a false positive because of poor specificity for PCR primer sets or probes (see Identification Of Potential Founders and Genotyping Strategy). Lethal phenotypes can be analyzed in the founder mice during the embryonic development.

Germline transmission

The offspring (F1) from founder mice (F0) should inherit the transgene at almost 50% according to the Mendelian ratio, if the transgene is integrated into a single chromosome.

If investigators encounter no germline transmission, the genotype of the founder should be verified again. If F1 offspring inherit the transgene at a rate substantially less than 50%, the founder is most likely a mosaic mouse, which means that not all of the cells carry the transgene because of late integration. The mosaic founder may never transmit the transgene to offspring, or it may transmit it at very low efficiency, depending upon how many germ cells carry the transgene. If the transgene is integrated into multiple chromosomes, more than 50% of the offspring will inherit the transgene. Separate lines may be obtained if the transgenes can be successfully segregated to different chromosomes in the F1 generation. If the transgene integrates into the X chromosome of male founders, the female offspring will inherit the transgene at 100%, but the male offspring will inherit none.

Transgene silencing and leaky expression

Transgene silencing occurs when a transgene is inserted into a transcriptionally inactive region in the mouse genome. Even though the transgene is present in the genome, the transcript (mRNA) cannot be made because of positional effects. Thus, the copy numbers of an integrated transgene will not necessarily correlate with the transgene expression level. Transcriptionally inactive regions may result from repressor sites near the inserted promoter, insertion of the transgene into a gene with a repressed promoter, DNA methylation, X-inactivation, or genome imprinting. The use of an insulator sequence, which can insulate or buffer the activity of transgene from the effects of the activity of *cis*-acting regulatory elements, such as enhancer or silencer regions of the DNA, may decrease the probability of transgene silencing caused by the positional effects (Rivella et al., 2000). On the other hand, leaky (ectopic) expression of a transgene in unexpected tissues, or unrestricted temporal expression, can result from insertion into the vicinity of an endogenous enhancer or promoter. The transgene expression level may decrease after several generations and may eventually stop in some cases. This epigenetic silencing happens when the animals with high copy number become older. To reduce this risk, creating two or more lines of transgenic mice is preferable.

Table 19.10.1 Time Line for Identifying Founders and Establishing Lines

Week	Action
0	Microinjection
3	Birth of potential founders (F0)
4∼6	Tag (tattooing), tail biopsy, genotyping for founder identification
6	Wean
9	Set up founder mating
12	Birth of first founder offspring (F1)
13∼15	Tag (tattooing), tail biopsy, genotyping for transgenic mouse identification

Unknown gene mutations as a result of random integration

Because the transgene integrates randomly into mouse genomes, there is a possibility of disrupting a normal gene sequence. Such insertion may lead to an unexpected phenotype even in heterozygous mice because of haploinsufficiency. Since the phenotype caused by most of the mutations should be recessive, the phenotype may not appear until homozygotes are generated by crossing heterozygotes. Homozygotes may also have higher transgene expression compared to hemizygotes. To rule out the possibility of unknown gene knock-down phenotypes, more than two independent lines should be examined, because the independent lines should not have the same insertion site.

Mixing different lines

Transgenic mice created from the same construct may have similar but different phenotypes. It is always important to maintain independent lines without mixing them. The results of PCR genotyping will produce the same amplicon from different lines with same transgene, so regular PCR genotyping cannot distinguish lines accidentally mixed. In this case, Southern blotting can distinguish such lines by comparing the different sizes of flanking fragments.

Time Considerations

Table 19.10.1 outlines the major events in creating a transgenic line. Potential founders are born 3 weeks after zygote injection. Pups are typically genotyped before weaning. After founders are identified, mating can be set up once the founders reach sexual maturity around 9 weeks of age. The founders' offspring (F1) can be used for the initial phenotypic analysis. Germline transmission and transgene copy numbers should also be verified in this generation. If all F1 pups from a founder have the same copy numbers and flanking sequences, any positive mouse among the F1 littermates could be used as a single established line.

INTRODUCTION

The technology for gene transfer into the early developing embryos has enabled researchers to make animal models to study human development, diseases, and disorders. We can now generate transgenic, knockout, conditional-knockout, or knock-in mice to elucidate the precise functions of candidate genes implicated in development, disease, and disorders. Transgenic mouse models are now considered ideal tools to delineate the molecular mechanisms of the gene products and their interactions with one another that influence all cellular processes that form the basis of physiological systems. The technique for generating the genetically altered animal models has been perfected over the years, and it is now used widely in many laboratories.

This unit describes the pronuclear-microinjection technique in detail to successfully generate transgenic mice, which represents a gain-of-function approach. In short, generating transgenic mice involves five basic steps: purification of transgenic construct (Basic Protocol 1), harvesting donor zygotes (Basic Protocol 2), microinjection of transgenic construct (Basic Protocol 3), implantation of microinjected zygotes into the pseudopregnant recipient mice (Basic Protocol 4), and genotyping and analysis of transgene expression in founder mice (Basic Protocol 5). The timeline for generating transgenic mice is shown in Table 19.10.1.

NOTE: Mice to be used for generating transgenic mice should be purchased from approved animal vendors that provide healthy and pathogen-free mice suitable for research. The number of mice and methods for housing, breeding, and manipulating the mice for the purpose of generating transgenic mice must be approved by the appropriate Institutional Animal Care and Use Committee (IACUC) and conform to governmental regulations.

PURIFICATION OF TRANSGENIC CONSTRUCT USING A SUCROSE GRADIENT

BASIC PROTOCOL 1

To generate transgenic mice successfully, every step is critical, from designing the transgenic construct to embryo transfer. Preparing a clean DNA sample is a vital step because it affects the health of the embryo and the DNA integration efficiency. Only a DNA fragment without any trace of vector sequence should be microinjected. The vector sequence, as well as any chemical residues remaining in the final DNA solution are generally toxic to mouse zygotes and will result in death of the embryo or poor efficiency in generating

Current Protocols in Cell Biology 19.11.1-19.11.22, March 2009

DOI: 10.1002/0471143030.cb1911s42

transgenic mice. The final purified DNA should be dissolved in a microinjection buffer and should be centrifuged to remove any impure particles in the solution just before performing microinjection. In the case of a larger DNA construct such as bacterial artificial chromosomes (BAC) DNA, it should be dissolved in a specialized buffer. We routinely use a sucrose gradient or a gel-purification method (Alternate Protocol) to purify the DNA.

Materials

Plasmid DNA of interest, digested to remove plasmid backbone
TE buffer, pH 7.4 (KD medical)
10% (w/v) and 40% (w/v) sucrose solutions (see recipes)
1.2% agarose gel
Microinjection buffer *or* BAC DNA buffer (see recipes)

Sucrose gradient DNA purification apparatus (Fig. 19.11.1) containing:
  Custom-made sucrose mixer
  Stirrer/hot plate
  Glass microcapillary (Kimble Glass)
  Rubber tubing
  Magnetic bar
  14 × 95–mm centrifuge tubes (Beckman)
Ultracentrifuge (e.g., Beckman Coulter, model L-70)
Swinging-bucket rotors (e.g., Beckman Coulter, model SW 40 Ti)
1.7-ml microcentrifuge tubes
Microcapillary pipet (Kimble Glass, 20-μl)
Dialysis cassette (Pierce, 10,000 MWCO)

Additional reagents and equipment for checking the DNA concentration using a spectrophotometer (*APPENDIX 3D*)

Prepare the gradients

1. Start out with the plasmid digest containing the transgene fragment and the vector backbone at a concentration of ~50 μg in 500 μl TE buffer.
2. Prepare 10% (w/v) and 40% (w/v) sucrose solutions. Dispense 6.5 ml of 10% sucrose into chamber 1 (containing a small magnetic stirring bar) and 6.5 ml of 40% sucrose into chamber 2 of the custom-made sucrose gradient mixer shown in Figure 19.11.1.
3. Prepare a 10% to 40% sucrose gradient from top to bottom of the 14 × 95–mm ultracentrifuge tube by gently mixing the two sucrose concentrations by opening two pigots, and gently spinning a small magnetic bar in chamber 1 using a stirring plate.

Separate transgene and vector

4. After the ultracentrifuge tube is filled up to the top with the gradient, slowly discard 500 μl of the sucrose gradient from the top, and load 250 μl of the digested plasmid DNA to the top of the gradient.
5. Separate the transgene fragment from the vector backbone by ultracentrifuging at 16 hr at ~160,000 × *g* (30,000 rpm in a Beckman Coulter, SW 40 Ti rotor), 4°C in the swinging-bucket rotor.

Figure 19.11.1 *(at right)* Purification of a transgenic construct using the sucrose gradient method. (**A**) Sucrose mixer with dimensions of 3-in. (W) × 2-in. (H) × 1 7/8-in. (D) is made by making two chambers of 5/8-in. (D) × 2-in. (H), which are connected together on the bottom with an outlet and two spigots that open and close controlling the sucrose flow into the ultracentrifuge tube. (**B, C**). A picture and schematic drawing showing how gradients are made from 10% to 40% sucrose.

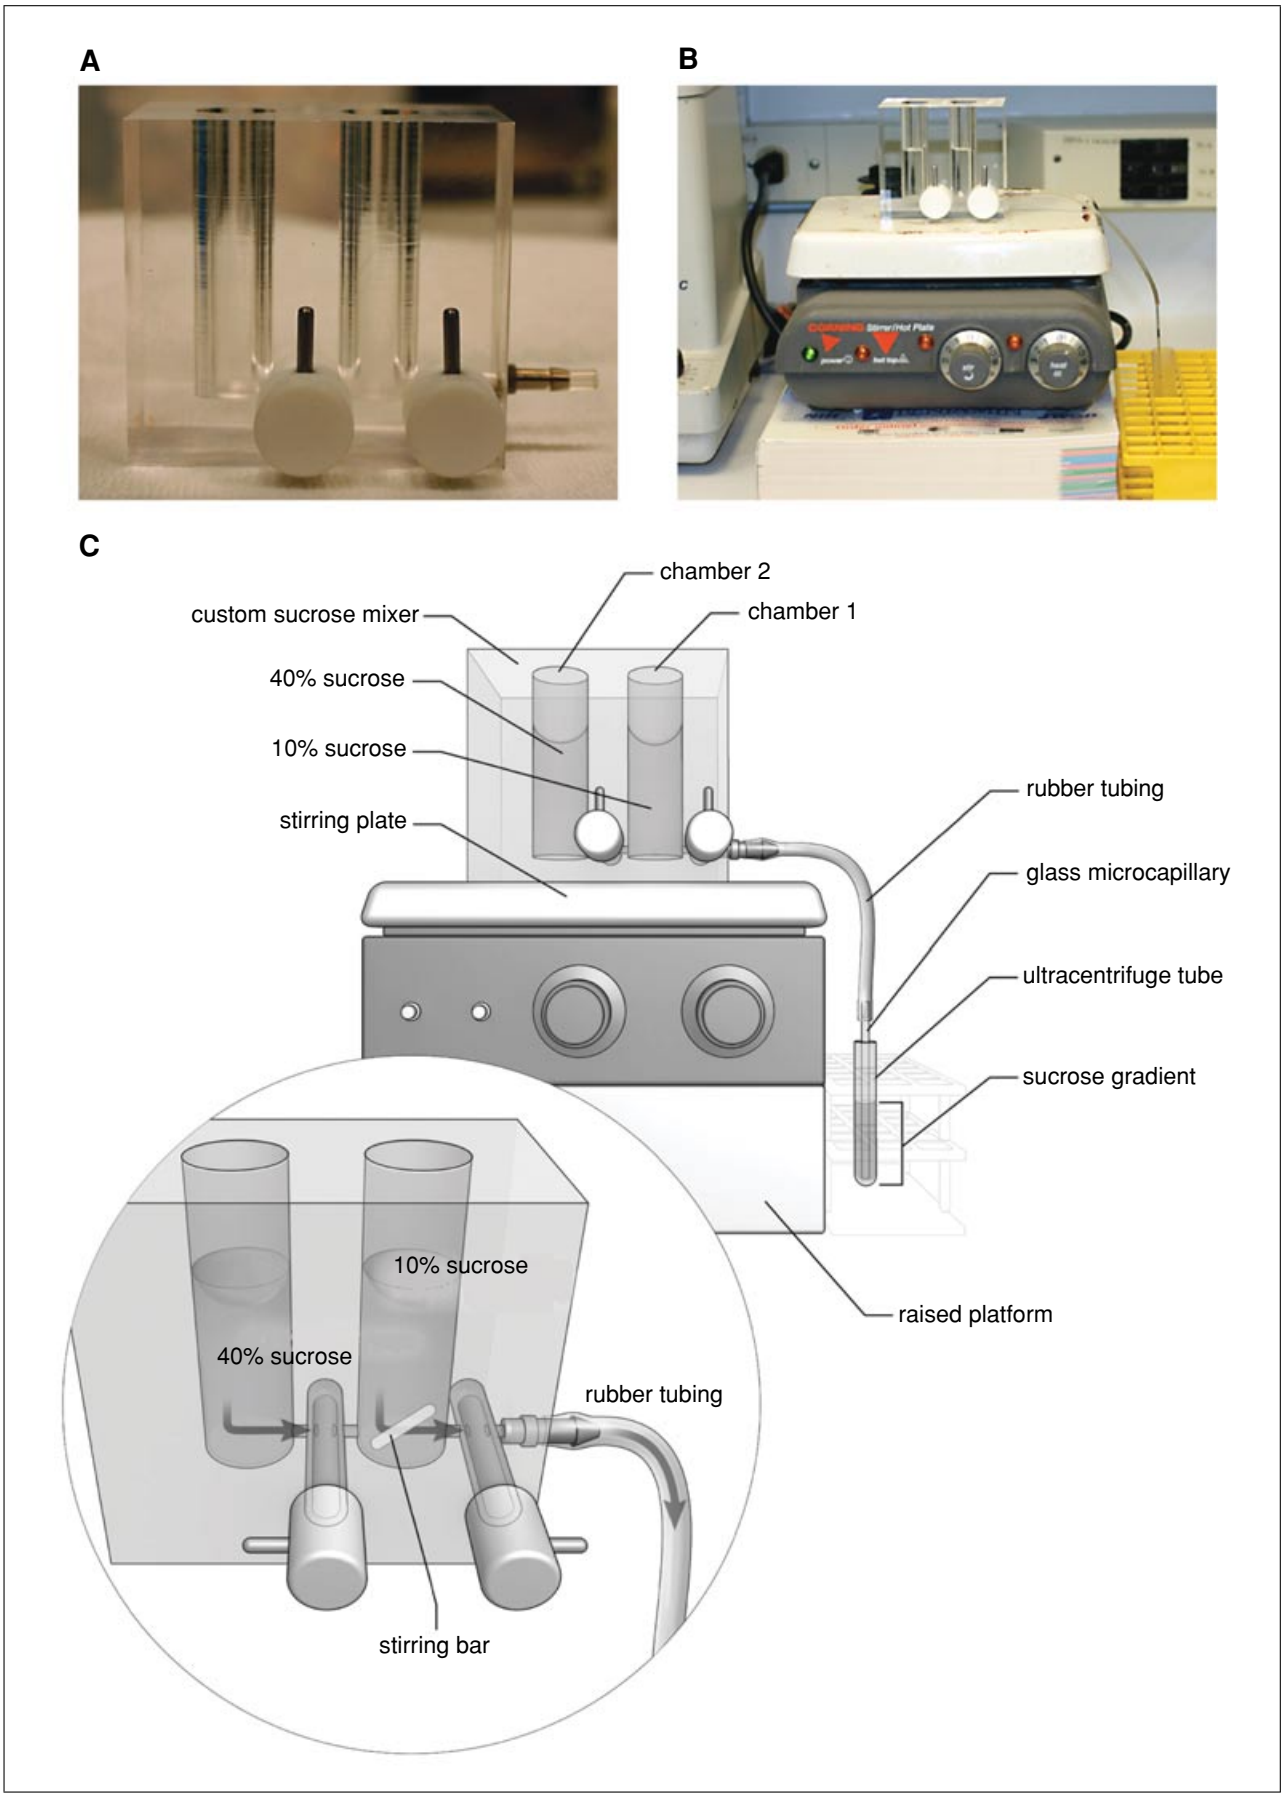

Figure 19.11.1 *(legend at left)*

6. Serially elute the gradient by collecting ~200 µl fractions in 1.7-ml microcentrifuge tubes through a hole in the bottom of the centrifuge tube.

7. Load 20 µl of the eluted fractions onto a 1.2% agarose gel in 1× TE buffer to determine which fractions contain only the transgene fragment (and not the vector DNA).

   The size of the transgene should be sufficiently different from the vector for better separation by ultracentrifugation and subsequent check by gel electrophoresis. Pooled fractions to be used for the next step should contain only the transgene DNA fragment.

Dialyze the transgene DNA

8. Pool the transgene-containing fractions from the microcentrifuge tubes containing the transgene fragments and dialyze against the microinjection buffer according to the manufacturer's instruction. Dialyze three more times against the fresh microinjection buffer to purify the DNA.

9. Centrifuge the dialyzed solution 2 min at 16,000 × *g*, room temperature, to remove any particulate impurities. Check the DNA concentration using a spectrophotometer (*APPENDIX 3D*).

10. Based on the accurate DNA concentration, carefully dilute the DNA to 2 ng/µl with the microinjection buffer.

    The dialyzed DNA can be stored up to 1 week at 4°C or in −20°C freezer for a longer period.

ALTERNATE PROTOCOL

PURIFICATION OF TRANSGENIC CONSTRUCT USING A GEL-BASED DNA PURIFICATION METHOD

We routinely use either of two methods to purify DNA (sucrose gradient or a gel-purification method). Both methods have merits of their own in that the sucrose gradient method yields the purest DNA for microinjection, whereas the gel purification method is a quick and easy method to yield adequately clean DNA for microinjection.

Transgene DNA of interest, digested to remove plasmid backbone (see Basic Protocol 1)
QIAEX II Gel Extraction Kit (QIAGEN, cat. no. 20051) including the following components:
Buffer QX1
QIAEX II DNA binding particles
Buffer PE

Razor blade
50°C water bath
Vortex

Gel-purify the construct

1. Run the digested plasmid DNA transgenic construct (see Basic Protocol 1) on a 1.2% agarose gel in 1× TE buffer.

2. Excise the transgene DNA band from the agarose gel with a clean razor blade.

   You can visualize the DNA bands under low-intensity UV light to minimize the damage to the DNA.

Extract the DNA

3. Weigh the gel slice and add 3 vol of buffer QX1 to 1 vol of gel for a DNA fragment between 100-bp and 4-kb in size. If the DNA fragment is >4 kb add 3 vol of buffer QX1 plus 2 vol of dH_2O to 1 vol of gel.

Purify the DNA

4. Resuspend the QIAEX II DNA binding particles, add the binding particles to the sample in step 3, and mix gently. If the amount of DNA is <2 μg add 10 μl of QIAEX II or add 30 μl if the DNA amount is between 2 and 10 μg. Add an additional 30 μl for each additional 10 μg of DNA.

5. Incubate 10 min at 50°C in a water bath to solubilize the agarose gel and allow QIAEX II particles to bind to the DNA. Mix the tubes by vortexing every 2 min to maintain QIAEX II in suspension.

6. Centrifuge the sample 30 sec at 16,000 × *g*, room temperature and carefully discard the supernatant.

Wash the construct-containing pellet

7. Wash the pellet by adding 500 μl of Buffer QX1, vortexing, centrifuging 30 sec at 16,000 × *g*, room temperature and discarding the supernatant.

8. Wash the pellet twice, each time by adding 500 μl of Buffer PE, vortexing, centrifuging 30 sec at 16,000 × *g*, room temperature, and discarding the supernatant.

9. Air dry the pellet for 10 to 15 min.

Elute the DNA

10. Elute the DNA from the pellet by adding 20 μl of microinjection buffer followed by vortexing. Incubate the mixture 5 min at room temperature for a DNA amount of <4 kb size, or incubate 5 min at 50°C for DNA size between 4 and 10 kb, or 10 min at 50°C if >10 kb.

11. Centrifuge the mixture 30 sec at 16,000 × *g*, room temperature and carefully pipet out the supernatant containing the purified DNA into a 1.7-ml clean tube.

12. With the remaining material, repeat steps 10 and 11 to increase the DNA yield and combine the eluted fractions.

13. Dissolve the DNA pellet in 100 μl of microinjection buffer.

14. Centrifuge the purified DNA solution 2 min at 16,000 × *g*, room temperature to remove all the traces of impurities that might still be present in the final DNA solution. Carefully pipet out the supernatant into another clean tube.

Prepare construct DNA for microinjection

15. Measure the DNA concentration (*APPENDIX 3D*) and dilute the DNA to 2 ng/μl in microinjection buffer or to 1 ng/μl in a BAC buffer if transgene is BAC DNA.

    The methods for preparing BAC DNA suitable for microinjection are detailed in Conner (2004).

HARVESTING DONOR ZYGOTES (FERTILIZED EGGS) FOR MICROINJECTION

BASIC PROTOCOL 2

To obtain the maximum number of donor zygotes to use for microinjection to generate a large number of transgenic founders with minimal effort and cost, all egg-donor female mice need to be superovulated by injecting PMSG (pregnant mare's serum gonadotropin) and HCG (human chorionic gonadotropin) prior to mating them with the stud mice. We routinely harvest ~250 zygotes from 15 superovulated and plugged female mice. The donor mouse strain we typically use is FVB/N, which is one of the most widely used inbred mouse strains because its embryos have a relatively large pronucleus and are robust enough to withstand the microinjection procedure.

Materials

PMSG (pregnant mare's serum gonadotropin; Sigma Chemical Inc., cat. no. G4877-2000IU)
20 donor female mice (4- to 5-week-old FVB/N mice)
HCG (human chorionic gonadotropin; Sigma Chemical Inc., cat. no. CG10-1VL)
20 stud male mice (sexually mature male, 2- to 12-month-old, FVB/N mice)
M16 medium (Sigma Chemical, cat. no. M7292)
M2 medium (Sigma Chemical, cat. no. M7167)
Hyaluronidase (Sigma Chemical, cat. no. H3884-1G)

35 × 10–mm tissue culture dish (Falcon, cat. no. 353001)
60 × 10–mm tissue culture dish (Falcon, cat. no. 353002)
Dissecting microscope for handling zygotes (Zeiss, Stemi SV II Apo)
Light source for dissecting microscope (Zeiss, KL 1500 LCD)
Surgical scissors (Roboz, RS-5840)
Microdissection forceps (Roboz, RS-5055)
Mouth-controlled pipet assembly (Fig. 19.11.2) including the following items:
Plastic mouth piece
Portion of a 1-ml pipet that includes cotton piece
Rubber tubing, 1/8-in. i.d., 1/32-in. wall thickness (Thomas Scientific, cat. no. 9521R67)
Glass tubing to make embryo-handling pipets (Drummond Scientific, cat. no. 9-000-1181)
Glass tubing with a rubber cap (Drummond Scientific, cat. no. 1-000-0300)
Bunsen burner
CO_2 incubator (Thermo Electron Corporation, Model 370)

Additional reagents and equipment for peritoneal injections (Donovan and Brown, 2006a) and euthanasia of mice (Donovan and Brown, 2006b)

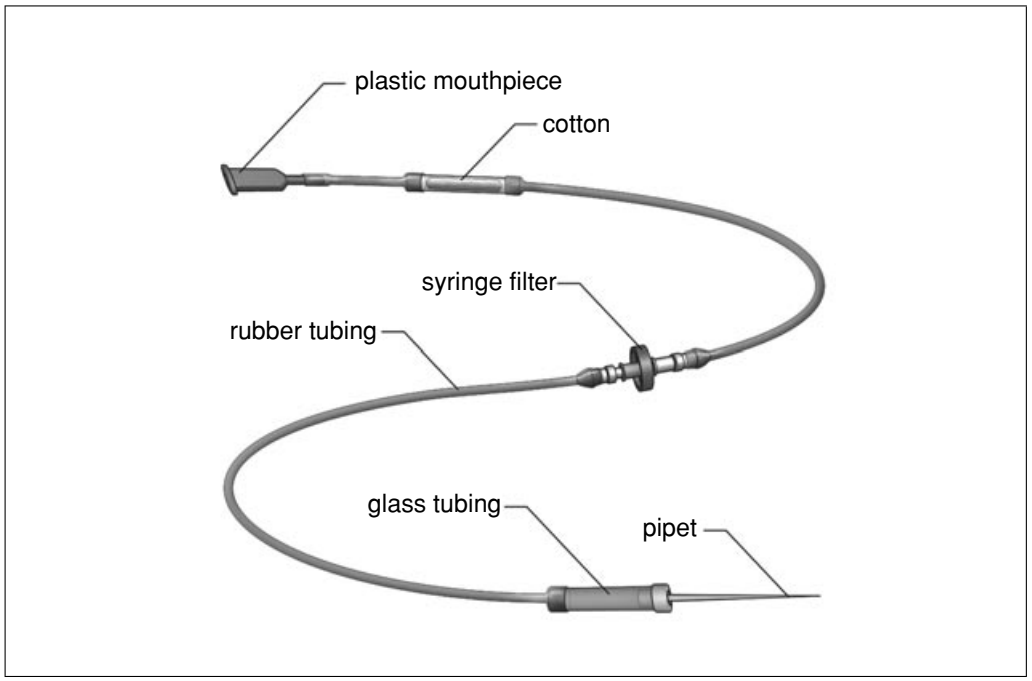

Figure 19.11.2 Schematic diagram of the components necessary for preparing a mouth-controlled pipet device for handling zygotes. Rubber tubing with 1/8-in. i.d. and 1/32-in. wall is cut in three pieces, and the mouth piece, 0.2-μm syringe filter unit, 1-ml pipet cotton piece, and glass tubing are attached to each end of rubber tubing.

Prepare donor females

1. To obtain the maximum number of zygotes for microinjection, superovulate the donor mice by administering an intraperitoneal (i.p.) injection (Donovan and Brown, 2006a) of 5 U of PMSG per mouse at 2:00 PM 2 days prior to HCG injections and mice matings.
2. Inject each mouse intraperitoneally (Donovan and Brown, 2006a) with 5 U of HCG at 1:00 PM 2 days after PMSG injections.
3. Following the HCG injection, set up mating pairs consisting of one superovulated female and one stud male per cage.

   Mating one female to one male mouse will enhance the plugging performance.

   Set up mating at late afternoon so that the mice will mate during the dark cycle.
4. Check the donor female mice to see if mice have mated overnight by checking for the presence of vaginal plugs the next morning, preferably before 9 AM.

   To get fresh fertilized eggs, harvest them from the plugged female mice before noon as described below.

Isolate the ovary and oviduct

5. Prepare two 35 × 10–mm dishes of M16 medium, by transferring 200 µl to the center of the dish and cover the medium with 5 ml of mineral oil. Then, prepare three 35 × 10–mm dishes with 5 ml of M2 medium and one 35 × 10–mm dish of M2 medium containing 1.5 mg of hyaluronidase in 5 ml of M2 medium, as shown in Figure 19.11.3A.

   Carry two M16 dishes in a 60 × 10–mm dish for easy transportation and incubate both dishes containing M16 medium at 37°C in the 5% CO_2 incubator.
6. Kill the plugged female mouse by cervical dislocation (Donovan and Brown, 2006b), put it on its back, and using a pair of surgical scissors and microdissection forceps open the body cavity (as shown in Fig. 19.11.3B).
7. Locate and harvest the entire ovary and the oviduct by cutting between the upper part of the uterus and the fat body. Transfer the oviduct and ovary to one of the 35 × 10–mm dishes containing M2 medium, as shown in Figure 19.11.3 panels C and D.

Free and wash the zygotes

8. To release the zygotes from each oviduct, transfer one dissected tissue at a time to the dish containing M2 medium with hyaluronidase. Locate the ampulla (swollen area of the oviduct) and carefully tear open the corner of the ampulla using microdissection forceps to release the eggs into the medium, as shown in Figure 19.11.3 panels E and F.
9. Let the eggs separate from the surrounding cumulus cells in the M2/hyaluronidase solution, as shown in Figure 19.11.3G.

   By the time all ampullas are torn open, the zygotes will be separated from the cumulous cells and should be ready for transfer to the next petri dish.
10. Pick up each zygote that is separated from cumulus cells using the mouth-controlled pipet assembly and transfer it to fresh M2 medium for washing.

    To make good embryo handling pipets, flame the middle part of the glass tubing over the Bunsen burner to melt it, and when it gets red hot, pull from each end to make a pipet with a long, thin shaft. Then, cut the stretched middle part with a diamond pencil to make two embryo handling pipets with blunt ends.
11. Wash embryos at least four times by picking them up and transferring them to different drops of M2 medium. At this stage, remove any unfertilized or abnormal eggs.

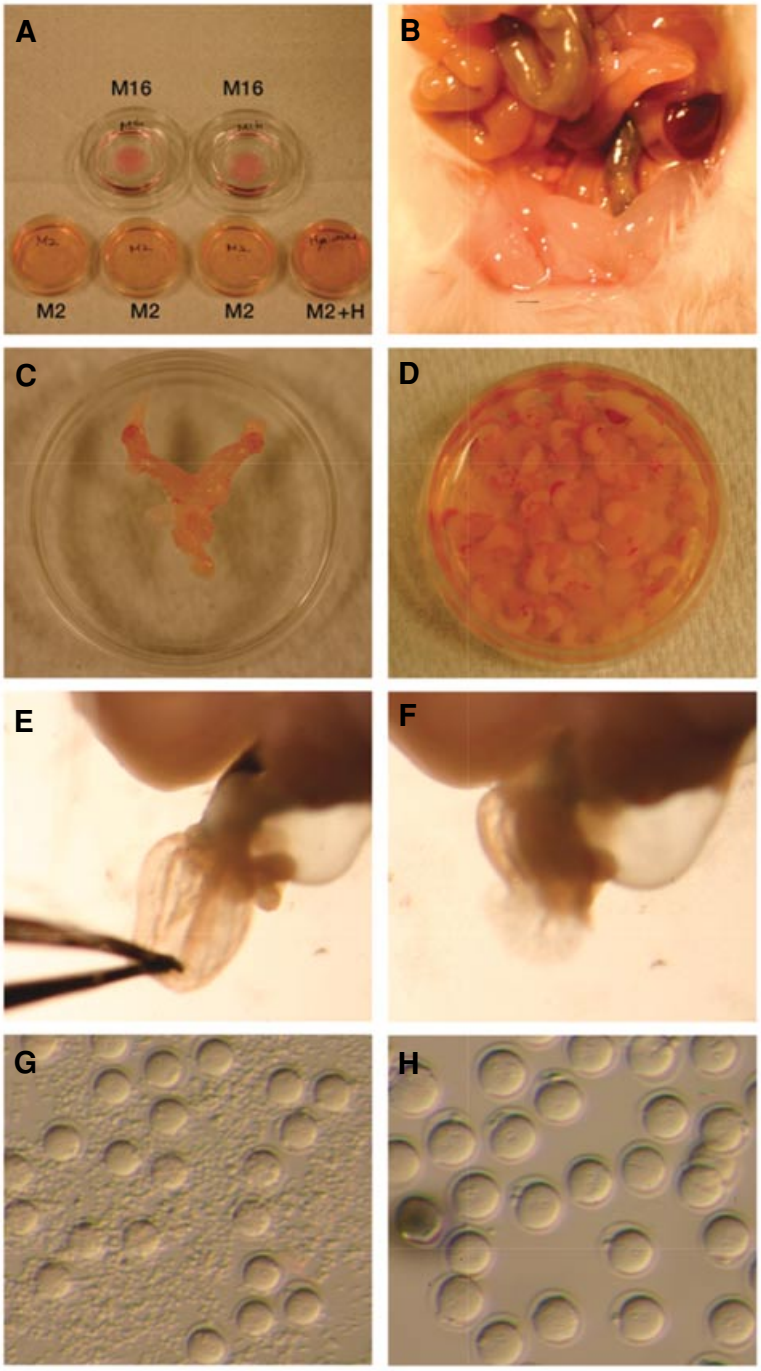

Figure 19.11.3 Sequence of embryo harvesting: (**A**) Two M16, three M2, and one M2 medium with hyaluronidase plates are prepared for handling or culturing embryos throughout the whole process of transgenic mice generation. (**B, C**) The reproductive organs: uterus, ovary, and oviduct are removed from the donor mice. (**D**) All the oviducts are collected in a single M2 dish. (**E**) The ampulla is located and torn apart with forceps under the microscope. (**F**) The zygotes and the cumulus cells are spilled into the M2 medium with hyaluronidase. (**G**) The zygotes are slowly separated from the surrounding cumulus cells. (**H**) Thoroughly washed zygotes are ready for microinjection.

12. Transfer washed eggs into one of the two M16 culture medium dishes that have been pre-incubated at 37°C in the 5% CO_2 incubator. Put the dish back into the incubator until ready for the microinjection procedure.

The second M16 culture medium dish will be used later for eggs after they are microinjected with DNA.

MICROINJECTION OF THE TRANSGENE DNA CONSTRUCT INTO MOUSE ZYGOTE

BASIC PROTOCOL 3

To ensure a successful transfer of foreign DNA into mouse zygotes, and to increase the chance of integration into the host genome, a number of parameters have to be carefully evaluated and applied when performing microinjection. First, the purified DNA should be diluted to obtain an optimal DNA concentration. We use a DNA concentration of 2 ng/μl for the microinjection. A DNA concentration that is too high may cause zygotes to lyse, and a DNA concentration that is too low may yield poor or no integration of DNA. In our experience, a DNA concentration of 2 ng/μl gives the best transgenic efficiency. Second, the injection pressure with which the DNA solution is injected into the pronucleus should be low enough not to damage the DNA. We use a constant flow rate of 50 hPa (hectopascal) to deliver the DNA using an automated microinjector. There are many advantages in using the constant-flow function. It ensures that every zygote gets the same amount of DNA solution as long as the injection time is equal for each zygote. It also helps the operator because there is no need to push the injecting button every single time for each zygote. Third, the manner in which the injection is performed is very important. Gentle yet swift injections of DNA minimize the trauma to the zygotes. This is done first by carefully breaking the tip of the needle against the holding pipet in order to create ideal DNA flow out of the injection needle. Puncture the zygote and pronucleus membranes as quickly as possible to avoid injecting DNA into the cytoplasm. Lastly, the timing of the microinjection should be strictly followed since the optimal window for DNA integration into the mouse genome is narrow and easy to miss if you start the procedure late. Our injection time window is between 11:00 AM and 2:00 PM (about 11 to 13 hr post-conception) to give the pronuclei of microinjected zygotes plenty of time to prepare to fuse together to initiate the first round of cell division. Injections done later than 2:00 PM may yield no integration, or may result in the generation of mosaic mice, in which only certain cell populations will carry the transgene.

Materials

M2 medium (Sigma Chemical, cat. no. M7167)
Mineral oil (Sigma Chemical, cat. no. M3516-1L)
Washed, ready-to-inject zygotes (Basic Protocol 2)
M16 medium (Sigma Chemical, cat. no. M7292)

Microforge (Technical Products International Corporation, MF-1)
Microinjection system including the following components (Fig. 19.11.6 A):
  Inverted microscope (Zeiss, Axiovert 135M)
  Anti-vibration table (Kinetic systems)
  Automated DNA injector (Eppendorf, Femptojet)
  Capillary holder for holding pipet (Mitutoyo)
  Micromanipulator (Narishige, model MO-202U)
  Compressed Nitrogen gas cylinder
Needle/pipet puller (Kopf Instruments, model 720)
Glass tubing for microinjection needles (Sutter Instrument, cat. no. BF100-78-10)
Microloaders (Eppendorf, cat. no. 930001007)
One-chambered plastic slide to be used for the microinjection platform (Nalge Nunc International, cat. no. 177372)
Mouth-controlled pipet assembly for handling zygotes (Fig.19.11.2)
CO_2 incubator (Thermo Electron Corporation, model 370)

Prepare for microinjection

1. Make a holding pipet using the microforge as shown and described in Figure 19.11.4. Insert a holding pipet into the capillary holder on the left side of the microscope. Connect this holder to the oil-based hydraulic system.

   To make good holding pipets, bring the hand-pulled pipet close to the heated glass ball until you get a diameter on the open end that is ~1/3 of the diameter of an embryo. The opening should have a smooth edge.

2. Make injection needles using a vertical pipet puller (as shown in Figure 19.11.5) at a setting of 16 (heating filament intensity) × 2.5 (force of pulling down), and insert it into the capillary holder on the right side of the microscope. Connect this holder to the automatic microinjector.

   Making successful injection needles can be achieved using the pipet puller. The setting mentioned above gives us good sharp needles with long shafts to minimize the damage to the embryo during the microinjection process.

3. Load the DNA solution in the back of the injection needle using a microloader pipet.

   To ensure a clean DNA solution free of debris for microinjection, first microcentrifuge the tube containing the DNA solution 2 min at maximum speed, room temperature to settle any suspended debris that might clog the injection needle. After that, check the DNA concentration (APPENDIX 3D) and dilute it to 2 ng/μl for the plasmid DNA constructs or 1 ng/μl for BAC DNA constructs.

   When handling BAC DNA, do not vortex at any time for it may shear the DNA.

Prepare the microinjection platform

4. Prepare the microinjection platform by putting a few drops of M2 medium in the middle of the one-chambered slide followed by overlaying the medium with mineral oil, as shown in Figure 19.11.6B.

5. Transfer forty zygotes to the upper portion of the M2 medium to be prepared for microinjection.

6. Transfer the slide carefully onto the microscope stage.

Microinject zygotes

7. Test the holding needle by holding and releasing one zygote.

   Make sure that not too much oil is flowing out of the holding pipet onto M2 medium. When lowering the holding pipet onto the glass slide, first go to the mineral oil field and control the oil flow, then go into M2 medium. Once the holding pipet is inside the M2 medium, draw up a little bit of the medium into the pipet before attempting to hold the zygote.

8. Set the automatic microinjector to continuous flow mode at a pressure of 50 hPa, and lower the injection needle into the M2 medium on the slide. Inject the DNA into the male pronuclei inside the zygote, as shown in Figures 19.11.7 and 19.11.8.

   Prior to microinjection, carefully break the tip of the injection needle against the holding pipet to obtain a good DNA flow. Inject the first egg and watch how fast the pronucleus expands to determine the condition of the injection needle. The pronucleus should expand noticeably if the needle is good. If the pronucleus swells too fast and bursts open, the injection needle is too big and it should be changed to a new one immediately. Also, when microinjecting, be sure to puncture the pronucleus as quickly as possible to avoid injecting DNA into the cytoplasm.

   Inject one batch of eggs (~40 eggs) at a time to avoid keeping zygotes outside the incubator for too long.

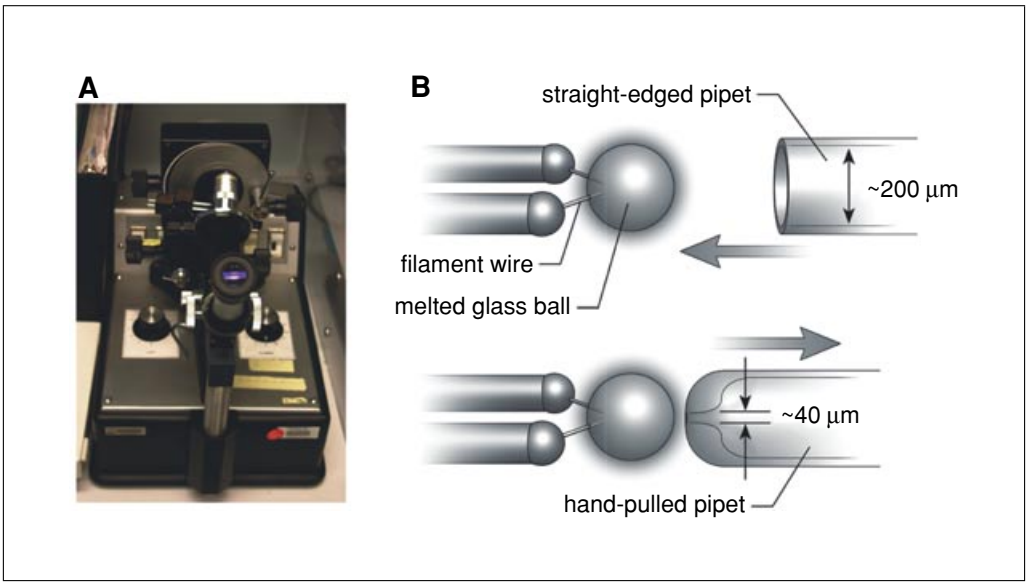

Figure 19.11.4 Making of a holding pipet. (**A**) Microforge. (**B**) The schematic diagram of preparing holding pipets. The hand-pulled and diamond pencil-cut straight-edged pipet is selected and is brought closer to the heated glass ball to melt evenly to give a polished holding pipet with a small opening of ~20 μm.

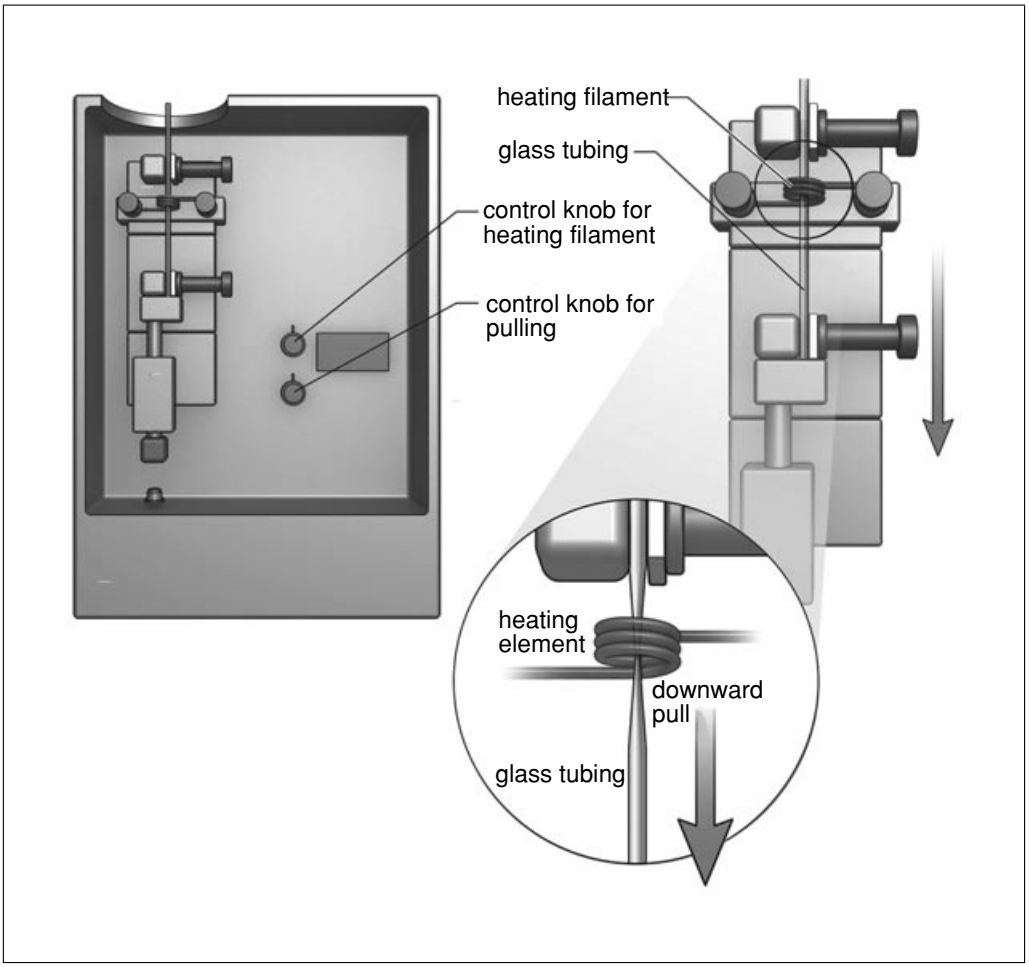

Figure 19.11.5 A schematic diagram for preparing injection needles. A glass tubing of 1.0-mm o.d. × 0.78-mm i.d. is inserted between two rubber pads and is pulled downward with the setting of 2.5 (downward force) × 16 (heat intensity) to prepare excellent and reproducible injection needles.

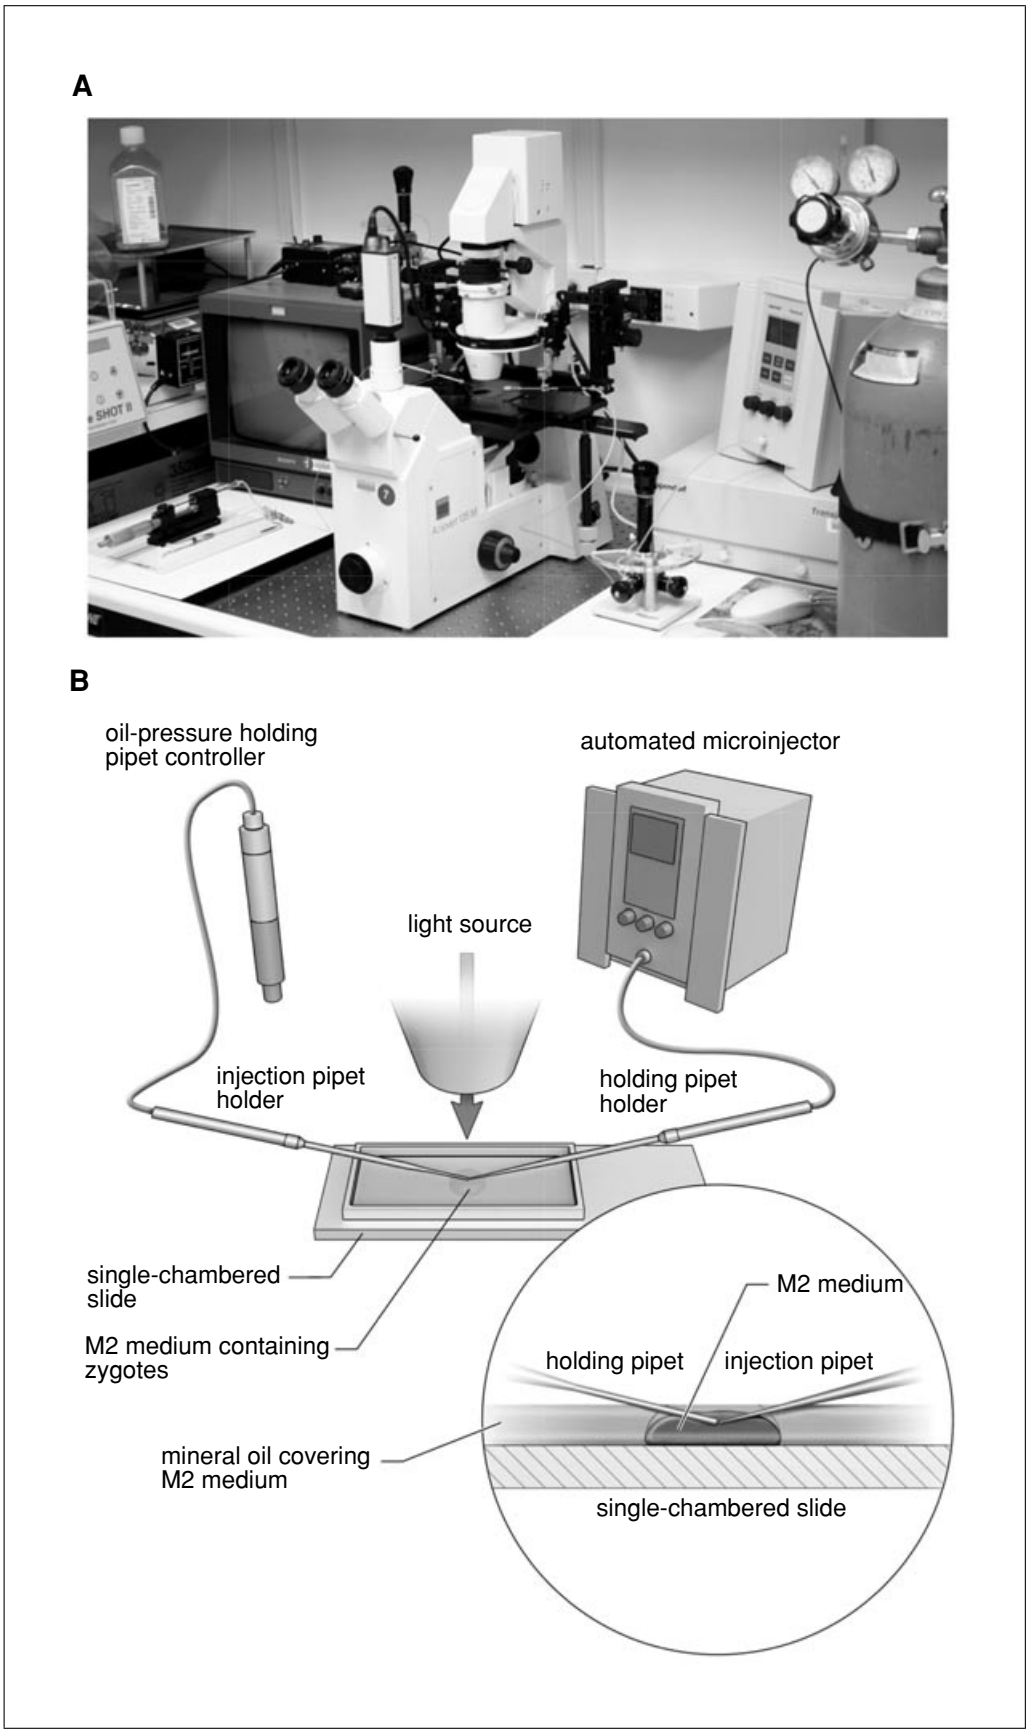

Figure 19.11.6 Microinjection setup. (**A**) A microinjection system. (**B**) Schematic diagram of the microinjection setup. A holding pipet is attached to the oil-pressured controller on the left side of the microscope whereas the injection pipet (needle) is attached to the automatic microinjector on the right side.

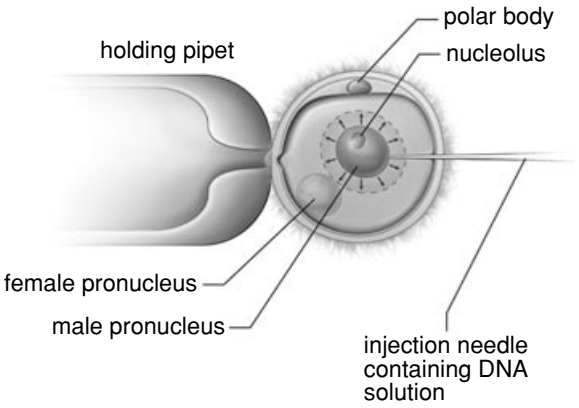

Figure 19.11.7 A schematic diagram depicting microinjection of transgenic DNA into the pronucleus. The size of the microinjected male pronucleus expands as the DNA is injected. A quick horizontal injection maneuver while minimizing damage to the zygote is critical for successful gene delivery.

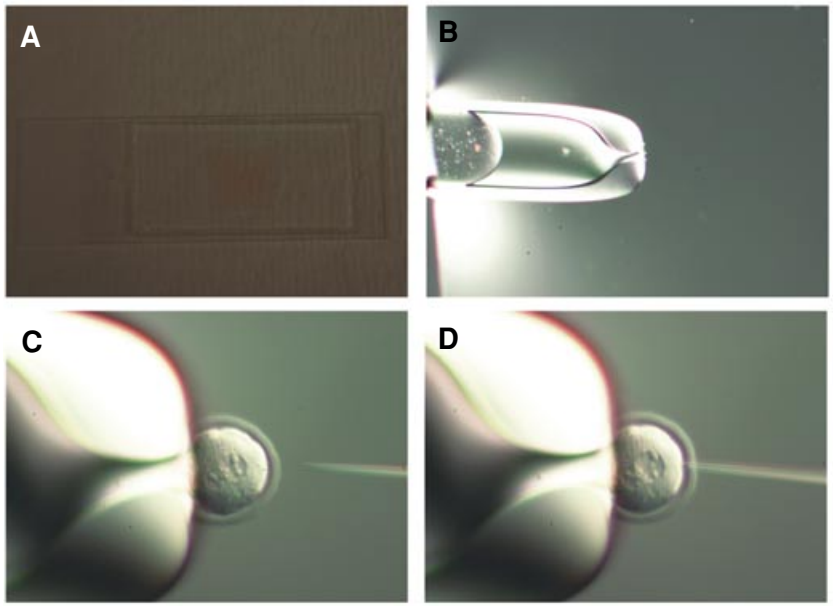

Figure 19.11.8 A sequence of events for the microinjection technique. (**A**) Injection platform for microinjection. Note the rectangular M2 medium in the center that is overlaid with mineral oil. (**B**) A polished holding pipet is lowered onto the injection platform and a small volume of M2 medium is sucked into the pipet. (**C**) A zygote is held in place by the holding pipet and the injection needle is lowered and the tip is focused. (**D**) DNA solution is injected into the male pronucleus. Note the swelling of the pronucleus, which confirms the successful transfer of the transgene.

9. To differentiate microinjected zygotes from uninjected ones during microinjection, after injecting each egg, move the microscope stage down and release the zygote on the bottom of the M2 medium.

10. Transfer all the microinjected zygotes into the one remaining, pre-incubated, fresh M16 culture medium dish. (See Basic Protocol 2, step 12.) Maintain the zygotes at 37°C in a 5% CO_2 incubator until ready for implantation into recipient mice.

IMPLANTATION OF MICROINJECTED ZYGOTES INTO PSEUDO-PREGNANT RECIPIENT MICE

The surgical steps required for embryo transfer need to be mastered first if one wants to be proficient in generating transgenic mice. The technique requires much patience and practice to become a skillful and efficient generator of the transgenic mice. Locating the infundibulum, the opening of an oviduct into which the microinjected zygotes need to be transferred, is hard for beginners, and inexperienced hands can cause massive bleeding problems around the surgical site. Steady hands are critical to avoid rupturing blood vessels and for successful embryo transfers. The embryo transfer can be performed on the same day that the embryos are harvested and injected or the next day after culturing zygotes to the two-cell stage overnight. In our experience, we found no difference between either the timing of the embryo transfer on the development of embryos or on the litter size.

Materials

Forty wild-type female mice (CB6F1, 6- to 8-weeks-old) to be mated with vasectomized mice to generate pseudo-pregnant recipient mice
Twenty vasectomized BALB/c mice (housed in separate cages)
M16 dish containing microinjected zygotes (see Basic Protocol 3)
70% ethanol
0.25% (v/v) Avertin for anesthesia
Alcohol swabs
Betadine antibiotic swabs
0.5% (v/v) Marcaine for analgesia

Animal cages
CO_2 incubator (Thermo Electron Corporation, model 370)
Glass bead sterilizer for the surgical instruments (Fine Science Tools, type 250)
Dissecting microscope for transferring zygotes (Zeiss, Zeiss Stemi SV II Apo)
Electric clippers
Surgical instruments (Sigma Surgical Instrument) including:
- Forceps
- Scissors
- Clamp skin closer with wound clips
- Sutures
- Curved forceps

Mouth-controlled pipet assembly (Fig. 19.11.2)
Inverted microscope to perform surgery (Zeiss, Stemi 2000)
Light source to illuminate the surgical area (Zeiss, KL 1500 LCD)
Slide warmer preheated to 37°C (Lab-line Instruments, model 26005)

Additional reagents and equipment for anesthetizing the mouse (Donovan and Brown, 2006c) and intraperitoneal injections (Donovan and Brown, 2006a)

Prepare pseudo-pregnant recipient mice

1. Set up twenty mating cages by putting two wild-type female mice to one vasectomized male mouse per cage 1 day before embryo surgery is to be performed.
2. On the day of the embryo transfer, check each female mouse for the presence of a vaginal plug.
3. Pool all the vaginal-plugged female mice to be used as pseudo-pregnant mice for embryo transfer surgery.

Collect materials for surgery

4. Transport the dish containing the microinjected zygotes (see Basic Protocol 3) to the embryo transfer room, if applicable.
5. Place the dish containing microinjected zygotes at 37°C, in a 5% CO_2 incubator of the embryo transfer room.
6. Sterilize the surgical area with 70% ethanol and sterilize all surgical tools using a glass bead sterilizer.
7. Anesthetize a recipient mouse (Donovan and Brown, 2006c) with a dose of 0.25% (v/v) Avertin (0.015 to 0.017 ml/g) into the peritoneal cavity (Donovan and Brown, 2006a; e.g., 0.3 ml for a 20-g mouse).

Load embryos

8. Take out the dish containing the microinjected eggs from the CO_2 incubator, and load the transfer needle with the following items using the sequence as shown in Figure 19.11.9: small amount of M16 medium, small air bubble, medium, air bubble, medium, air bubble, medium, air bubble, fifteen to twenty tightly packed zygotes (transferred using the mouth-controlled pipet). Place the mouth-controlled pipet around the neck of the microscope until ready to transfer.

   Transferring fifteen to twenty microinjected zygotes on each side of the mouse will allow for the optimum number of pups to be born.

Prepare the recipient mouse

9. Put the anesthetized recipient female mouse on its belly, and shave the mouse back from the hump to just above the legs on both sides with an electric clipper as shown in Figure 19.11.10A.
10. Clean the surgical sites of the mouse with alcohol and Betadine antiseptic swabs three times alternately.
11. Make a small incision of ~0.5 cm on the right side of the mouse skin above where the ovary is located, as shown in Figure 19.11.10B.
12. Locate the ovary beneath the transparent muscle membrane, make a small incision of ~0.2 cm on the muscle membrane, and pull out the ovary by grabbing the fat pad using a small surgical metal clip, as shown in Figure 19.11.10C.

    Make sure not to cut the big blood vessel that runs across the muscle membrane when making an incision.

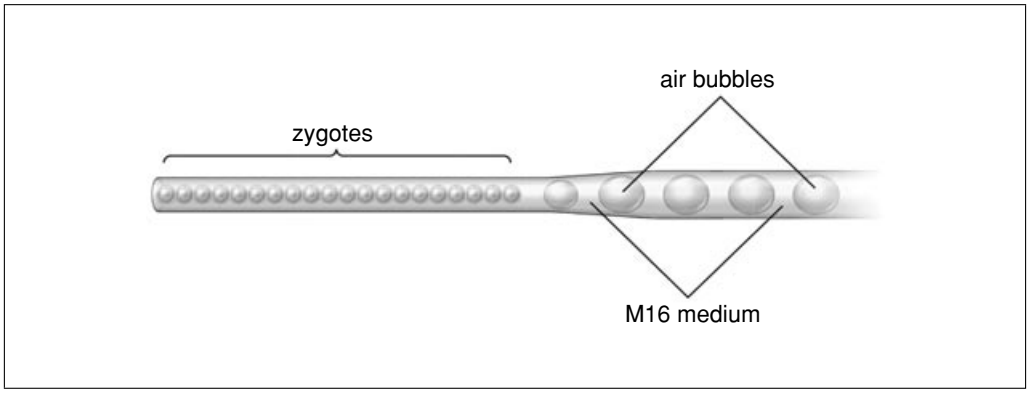

Figure 19.11.9 A schematic diagram of preparing transfer pipets for zygote transfers. A hand-pulled and diamond pencil-cut straight-edged pipet with ~100-μm opening size is first loaded with the five alternate sequence of M16 medium and small bubbles and followed by fifteen to twenty tightly packed zygotes.

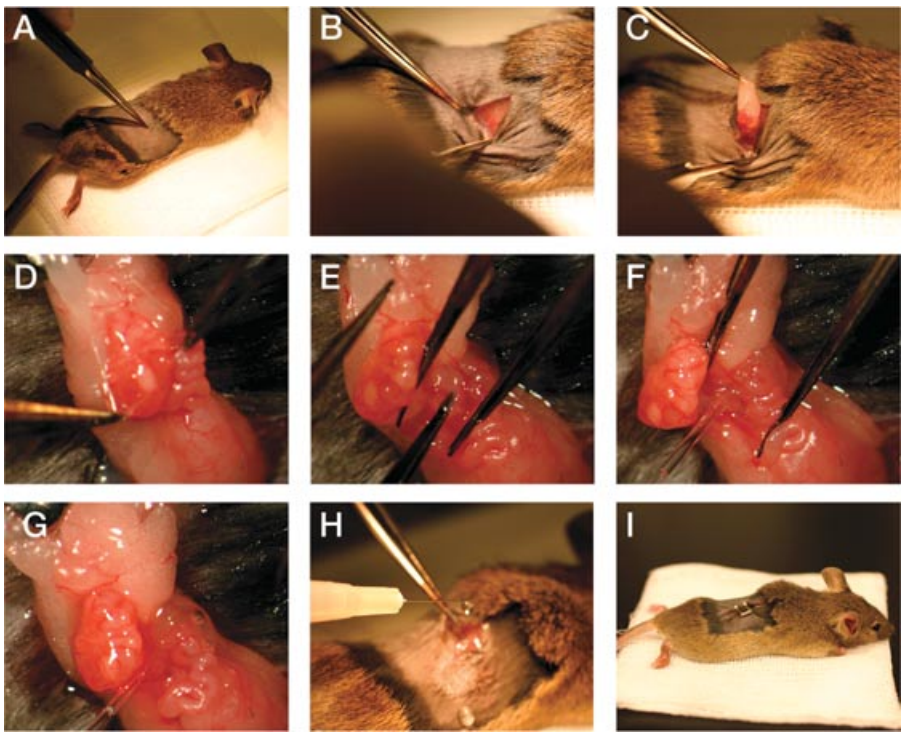

Figure 19.11.10 A sequence of events for zygote transfer into oviduct. (**A**) A surgical site is located and shaved. (**B**) A small skin incision is made and the ovary and fat pad are located before the muscle membrane incision is made. (**C**) The ovary and an oviduct are pulled out by the fat pad with the small metal clip. (**D**) The bursa is carefully peeled off and tucked under the ovary with a pair of forceps. (**E**) The space between the ovary and oviduct is opened with a pair of forceps while the tip of another forceps is inserted into the opening of the oviduct called the infundibulum for locating and testing prior to transferring zygotes with transfer pipet. (**F, G**) The transfer pipet is inserted into the infundibulum and the whole embryo content is blown slowly into the oviduct. (**H**) The muscle membrane is sutured and one drop of analgesia is administered to relieve pain during recovery. (**I**) the recipient mouse is placed on the slide warmer at 37°C.

13. Carefully tear open the thin, transparent membrane called bursa covering the ovary with fine forceps, and tuck it behind the ovary as, shown in Figure 19.11.10D.

    Again, when tearing open the membrane, avoid tearing the blood vessels.

14. Carefully open the space between the oviduct and the ovary using forceps, and locate the opening of the oviduct (infundibulum), as shown in Figure 19.11.10E.

    After locating the infundibulum, check it with the tip of the forceps to make sure it is the opening before inserting the transfer needles to transfer the zygotes.

Deposit the embryos

15. Using a mouth-controlled pipet, slowly blow in the fifteen to twenty microinjected zygotes into the infundibulum along with a few air bubbles to make sure the eggs are blown into the swollen area of the oviduct (ampulla), as shown in Figures 19.11.11 and 19.11.10F.

    After blowing in the zygotes, push two air bubbles trapped in the oviduct to the ampulla using the forceps to ensure all the eggs are pushed into the ampulla (as shown in Fig. 19.11.10G).

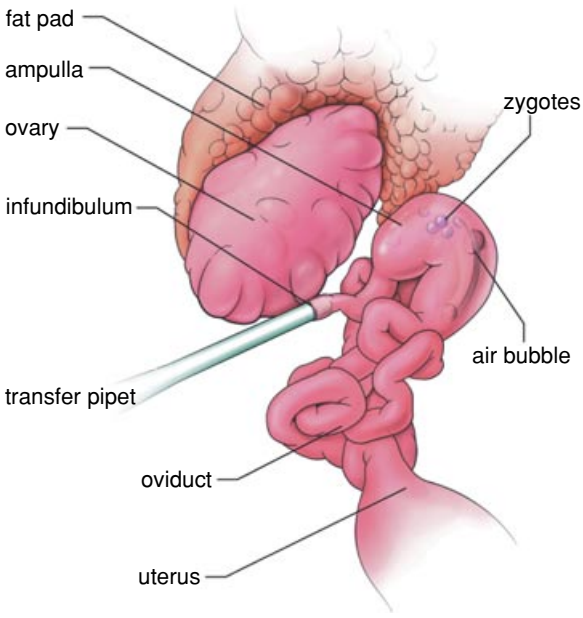

Figure 19.11.11 A schematic diagram depicting zygote transfer into the infundibulum, which is often hidden within coils of oviduct. The infundibulum can be made visible by peeling off the bursa membrane that covers the ovary and by separating the space between the ovary and the oviduct using fine forceps.

Complete the surgery

16. After the transfer is complete, carefully tuck the oviduct and ovary back into the body cavity.
17. Suture the muscle membrane and administer one drop of 0.5% (v/v) Marcaine on the sutured surgical site to relieve pain during recovery (as shown in Fig. 19.11.10H).
18. Staple the skin together using a wound clip.
19. Repeat the procedure for the other side (steps 11 to 18).
20. Place the animal on a slide warmer that has been preheated to 37°C for recovery, and wait for the mouse to move, which takes ~1 hr, before putting the mice into the new cage, as shown in Figure 19.11.10I.
21. Repeat this procedure for other recipient mice until you finish transferring all zygotes.
22. Put the cages into the mice rack in the animal room.

PREPARATION OF TISSUE SAMPLES FOR GENOTYPING FOUNDER MICE

BASIC PROTOCOL 5

After microinjection and embryo transfers, most recipient mice should be pregnant and deliver the pups after 20 days. Before pups are born, sometime around embryonic day 17, each pregnant mouse should be housed separately to avoid having multiple litters in the same cage. After delivery of pups, the pups should be monitored every day to see if they develop normally. Any pups that have retarded or abnormal growth should be noted. After 10 days from birth, a tissue biopsy, either a small piece of tail or a piece of ear, should be obtained for the purpose of genotyping to determine the transgenic founders. We snip ~0.50 cm from the tail to isolate DNA as described below, and we tattoo the mouse finger for identification by piercing it with a 30-G needle stained with tattoo paste.

Materials

Potential founder mice
Tail lysis buffer (see recipe)
Proteinase K
Phenol
Chloroform
100% and 70% ethanol
1× TE buffer

Microtattoo system (Fine Science Tools, cat. no. 24201-00)
Green tattoo paste (Fine Science Tools, cat. no. 24201-01)
30-G needle (Becton Dickinson, cat. no. 305106)
Labeled microcentrifuge tubes
Hybridization oven (Boekel, Little Shot II, Model 230501)

Additional reagents and equipment for tail DNA isolation for Southern blotting (Brown, 1993) and PCR (*APPENDIX 3F*)

Prepare the DNA

1. Snip from the potential founder mouse tail 0.5-cm length, tattoo the mouse finger for identification by piercing it with a 30-G needle stained with tattoo paste, and transfer it to labeled microcentrifuge tubes corresponding to the tattooed mouse finger number.
2. Add 0.5 ml of tail lysis buffer (excluding proteinase K) to each tube.
3. Add 10 μl of 10 mg/ml proteinase K to each tube.

Extract the DNA

4. Rotate the tubes in a hybridization oven overnight at 55°C.
5. Add 500 μl of phenol and 500 μl of chloroform to each tube.
6. Rotate the tubes in the rotating rack for 1 hr at room temperature.
7. Centrifuge the tubes 5 min at 16,000 × *g*, in the microcentrifuge at room temperature.
8. Carefully take out the supernatant and transfer it to the newly labeled tubes.

   Take out ~250 μl of the supernatant to avoid taking cell debris.

9. Add 700 μl of chloroform to each tube.
10. Rotate the tubes in the rotating rack for 1 hr at room temperature.
11. Centrifuge the tubes 5 min at 16,000 × *g*, in the microcentrifuge at room temperature.
12. Carefully take out the supernatant and transfer it to the newly labeled tubes.
13. Add 100% ethanol at 2.2× the amount of the supernatant in step 12 and mix tubes gently by hand to precipitate the DNA.
14. Centrifuge the tubes 30 sec at 16,000 × *g*, in the microcentrifuge at room temperature to pellet the DNA.

Wash the DNA

15. Add 600 ml 70% ethanol to wash the DNA.
16. Centrifuge the tubes 30 sec at 16,000 × *g*, in the microcentrifuge at room temperature to pellet the DNA.
17. Decant the 70% ethanol and air dry the DNA pellet for 1 hr.

18. Add 200 μl of 1× TE buffer to the DNA pellet to dissolve the DNA.

19. Check the DNA concentration for genotyping the mice by PCR (*APPENDIX 3F*) or Southern blot analysis (Brown, 1993).

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

BAC DNA buffer

10 mM Tris·Cl, pH 7.4
0.1 mM EDTA, pH 8.0 (*APPENDIX 2A*)
100 mM NaCl
30 μM spermine
70 μM spermidine

For preparing the buffer, use ultrapure water.

Microinjection buffer

5 mM Tris·Cl, pH 7.4
0.1 mM EDTA, pH 8.0 (*APPENDIX 2A*)

For preparing the buffer, use ultrapure water.

Sucrose solutions, 10% (w/v) and 40% (w/v)

10% (w/v) sucrose solution
For 100 ml:
10 g sucrose
5 ml 1M Tris·Cl, pH 7.4
20 ml 5M NaCl
2 ml 0.5M EDTA, pH 8.0 (*APPENDIX 2A*)
Adjust volume to 100 ml using 1× phosphate-buffered saline (PBS)

40% (w/v) sucrose solution
For 100 ml:
40 g sucrose
5 ml 1M Tris·Cl, pH 7.4
20 ml 5M NaCl
2 ml 0.5M EDTA, pH 8.0 (*APPENDIX 2A*)
Adjust volume to 100 ml using 1× phosphate-buffered saline (PBS)

Tail lysis buffer

100 mM Tris·Cl, pH 7.4 (*APPENDIX 2A*)
5 mM disodium EDTA pH 8.0
0.2% (v/v) SDS
200 mM NaCl
100 μg/ml proteinase K (due to differing storage conditions, add separately after the other buffer components have been added)
Store up to 6 months at room temperature (6 months at 4°C for proteinase K)

COMMENTARY

Background Information

In 1981, Gordon and colleagues reported the generation of the first transgenic mouse using the pronuclear injection technique with a foreign gene sequence of a pBR322-based plasmid containing the herpes simplex virus and simian virus 40 DNA sequence that could be integrated into the mouse genome. Shortly thereafter, several other groups reported similar success (Brinster et al., 1981; Wagner

et al., 1981). Since then, thousands of transgenic mice have been generated to unravel the functions of many genes implicated in human development, diseases, and disorders. There are other methods to deliver transgenes into the genome of the mouse. The use of the retrovirus carrying the transgene to infect the pre-implanted embryos and its successful germline transmission has been reported (Jahner et al., 1985; Van der Putten et al., 1985; Lois et al., 2002). However, this method did not gain much popularity because of cloning limitations of the retroviral vectors.

Recently, the discovery of new vectors such as YACs, PACs, and BACs have enabled the cloning of larger transgenes, which are more advantageous in transgene expression than plasmid vector–based cloning technology. (Sternberg et al., 1992; Schedl et al., 1993; Giraldo et al., 2001). Sometimes, minitransgenes (10 kb or less) that are introduced into the genome can cause mouse lethality by complicating normal mouse development. This might be due to the positional effect of the genes surrounding the transgene integration site or the true effect of the transgene. BACs, however, do not suffer from such positional effect because of its representation of the full gene with all the regulatory elements of the endogenous genes. Therefore, BACs play an important tool in functional genomics due to their large cloning capacity (around 150 kb), and due to their greater convenience in handling over other large cloning vectors like YACs and PACs (Testa et al., 2004). Moreover, the availability of high-quality, arrayed BAC libraries encompassing the mouse or human genome makes identification and isolation of specific clones relatively trivial (Conner, 2004). The newly developed Red/ET recombination method that allows BAC-based cloning is relatively easy (Zhang et al., 1998, 2000; Muyrers et al., 1999). There are variations of the method that can be used to make a large transgene for microinjection into oocytes from the BACs (Testa et al., 2004) that make pronuclear injections more attractive than ever in functional genomics.

Critical Parameters

Every step involved in creating transgenic mice requires tremendous focus and attention. To generate transgenic mice at the expected efficiency on a regular basis, all the parameters have to be examined and evaluated. For example, the stud males and the vasectomized male mice have to be replaced every 10 months, the hormone stock should be fresh at all times, and techniques to handle the embryos and the mice throughout the transgenic mice production have to be consistent. Other factors that cannot be controlled such as variations in the mouse responses to the hormone treatment, anesthetic agent, and environment have to be identified immediately and should be addressed as soon as possible. All the procedures should be evaluated from time to time to ensure that they are being performed at an optimal level and that there is no deviation from the best practices. The learn this technology, one should master the implantation surgery skill before learning injections and zygote harvesting. An experienced transgenic generator should focus her/his efforts on making transgenic mice before any other duties to maintain the highest efficiency. Good animal husbandry practices are a must to maintain mice at their best, including mating performance, response to hormone or anesthetics, and recovery after the surgery.

Troubleshooting

No transgenic founders and/or very low transgenic efficiency

Possible solutions: (1) Check the transgene to make sure it is the right transgenic fragment. (2) Make sure the DNA is ultraclean with no trace of vector DNA. (3) Check to make sure the DNA concentration is 2 ng/μl. (4) Be sure to set the injection pressure to 50 hPa and the injection mode to continuous flow. (5) Inject the mice as early as possible and finish the injections before 2:30 PM at the latest on the injection day. (6) If all of the above are followed and there are still no positives, check to see if the transgene is causing embryonic lethality.

Having a hard time injecting the DNA

Suggestions: (1) DNA contains impure particles. Centrifuge the DNA solution for 2 min at maximum speed in the microcentrifuge, take the DNA from the upper portion of the solution and check the DNA concentration, and inject. (2) Injection needle is too thin. Break the tip of the injection needle to increase the diameter slightly and inject. (3) Injection needle is clogged with cell debris from the zygotes. Change the injection needle immediately.

The founder mice are mosaic

Recommendation: Start injecting early and finish long before the 2 pronuclei get close to fusing together, with our strain, inject between 11 AM and 2 PM.

Getting very small litter size

Possible explanations: (1) The mother does not take care of the pups or kills the pups. (2) The transgene causes embryonic lethality, especially if the pups are delivered but die soon after birth.

Anticipated Results

Mating of 15 to 20 mice should be set up to provide at least 200 zygotes to be microinjected. With good DNA and injection technique, at least 95% of the zygotes should survive the injection procedure and be ready for implantation. The injected zygotes should be implanted into at least 4 recipient mice per each transfer day. From 30 to 40 implanted zygotes per mouse (15 to 20 zygotes in each side of the mouse), at least 10 pups (25%) should be born. Out of the total pups born, 10% to 20% should be the founder mice. Most founder mice are expected to transmit the transgene to their offspring.

Time Considerations

To generate several transgenic founders for each DNA construct, a total of 4 days are needed from the injection of hormone to the implantation surgery. Although much attention has been placed on aspects of the technique, animal care and preparation are also important. The donor mice are received and housed every week, hormone has to be prepared and administered, and mice must be mated and checked for plugs, all of which takes substantial amounts of time. After the implantation, the mice need to be separated and housed individually to avoid having multiple litters; a mouse tissue sample, either a piece of tail or a piece of ear, must be obtained, and the mouse has to be tagged for identification (Table 19.10.1). The harvesting of zygotes from mice takes ~2 hr, microinjection takes ~2 hr, and surgery takes ~3 hr.

ABSTRACT

The technique of gene targeting allows for the introduction of engineered genetic mutations into a mouse at a determined genomic locus. The process of generating mouse models with targeted mutations was developed through both the discovery of homologous recombination and the isolation of murine embryonic stem cells (ES cells). Homologous recombination is a DNA repair mechanism that is employed in gene targeting to insert a designed mutation into the homologous genetic locus. Targeted homologous recombination can be performed in murine ES cells through electroporation of a targeting construct. These ES cells are totipotent and, when injected into a mouse blastocyst, they can differentiate into all cell types of a chimeric mouse. A chimeric mouse harboring cells derived from the targeted ES cell clone can then generate a whole mouse containing the desired targeted mutation. The initial step for the generation of a mouse with a targeted mutation is the construction of an efficient targeting vector that will be introduced into the ES cells. *Curr. Protoc. Keywords: gene targeting • homologous recombination • gene knockout

INTRODUCTION

Two discoveries have been instrumental in creating the ability to generate knockout mice—the isolation of stem cells and the discovery of homologous recombination. The significance of these findings was demonstrated when Mario Capecchi, Oliver Smithies, and Martin Evans were awarded the 2007 Nobel Prize in Physiology or Medicine for their work in establishing the knockout mouse model (Vogel, 2007). The key step needed for making knockout mice was the isolation of embryonic stem cells (ES cells). The ES cells were isolated from the inner cell mass of a 3.5-day post-coitum mouse blastocyst (Evans and Kaufman, 1981; Martin, 1981). These stem cells could progressively grow in tissue culture and were pluripotent (also see *UNIT 19.1*). By injecting the stem cells into a mouse blastocyst, Bradley et al. (1984) were able to generate chimeric mice. The production of chimeric mice proved that the stem cells were able to differentiate into multiple cell lineages and were able to contribute to the development of the mouse embryo. Germline transmission was also achieved by using the pluripotent ES cells. After breeding the chimeric mice, the resulting offspring were clearly derived from the ES cells, as seen by the transmission of coat color. Therefore, the introduced stem cells could become established into the germline of the chimeric mice. The isolation of stem cells basically meant that an ES cell clone that was genetically modified in culture could eventually be used to derive a mouse.

The second important step in the establishment of knockout mice was the discovery of homologous recombination within mammalian cells (also see Mortensen et al., 2006, for basic principles of this technique). Lin et al. (1984) were first able to demonstrate that homologous recombination was feasible by reconstructing a functional thymidine kinase gene in mouse L cells. Later, Smithies et al. (1985) were able to modify the β-globin locus with the insertion of the neomycin-resistance gene. This work provided a means for specifically targeting the DNA insert to a planned genetic locus, in contrast to the random integration of a construct that is used with transgenic technology.

The convergence of these two technologies provided the means to generate knockout mice. The first ideal genetic locus to test gene targeting was for the enzyme hypoxanthine-guanosine phosphoribosyl transferase (*HPRT*). Loss of the *HPRT* gene could be tested with treatment using

Current Protocols in Cell Biology 19.12.1-19.12.17, September 2009

DOI: 10.1002/0471143030.cb1912s44

6-thioguanine, while restoration of the gene could be selected in *HPRT*-null cells with addition of hypoxanthine/aminopterin/thymidine (HAT) medium. In addition, the *HPRT* gene is X-linked so that, with male stem cells, only one allele needed to be targeted for drug selection. Doetschman et al. (1987) proved that a mutant *HPRT* gene could be corrected through homologous recombination in ES cells, while Thomas and Capecchi (1987) demonstrated targeted gene disruption. These experiments led the way to targeting of nonselectable genes, starting with *int-2* and *c-abl* knockout mice (Mansour et al., 1988; Schwartzberg et al., 1989).

Since the first knockouts, there has been an explosive growth in the number of animal models derived through the technique of gene targeting. While mouse stocks with spontaneous or radiation-induced mutations existed in the past, the mutated alleles did not correspond to the majority of biologically important cloned genes (Mak, 1998). Through homologous recombination, a cloned gene could be directly utilized to disrupt the target allele. Currently, a targeting strategy is often planned shortly after the mouse gene is originally cloned. Therefore, targeted recombination has become well established as an important tool to inactivate a gene in order to study its function in vivo.

The process of gene targeting provides a means to alter a specified gene in order to better discern its biological role. Through homologous recombination, an engineered mutation can be directed to a designated genetic locus. In this manner, a potentially important genomic clone can directly be utilized to create a mutation in a selected gene. Even within the 2.5 Gb of the mouse genome, the cellular DNA repair mechanisms are able to align a targeting vector with its corresponding region of homology and cause recombination into the chromosome.

While the goal of transgenic technology is to overexpress a gene to study its biological role in vivo, homologous recombination is typically employed to create a loss-of-function mutation. The most common application of gene targeting is to produce knockout mice, where a drug-resistance marker replaces an essential coding region in a genetic locus. In the majority of cases, the importance of a gene cannot be determined by simply recognizing amino acid motifs in the protein (Iredale, 1999). Additionally, the role of a gene often cannot be completely revealed by examining closely related family members. Therefore, gene inactivation is the best way to delineate the biological role of a protein, and gene targeting is a direct means to disrupt a gene's open reading frame and block its expression in a mouse. Not surprisingly, during the twenty years that gene-targeting techniques have been available, thousands of genes have been knocked out. To date, about 11,000 genes have been knocked out in mice, which accounts for roughly half of the mouse genome (Sikorski and Peters, 1997; Vogel, 2007). Through a combination of gene targeting and gene trapping, a global effort is underway to make a knockout mouse for each of the 25,000 mouse genes (Grimm, 2006).

The knockout mouse has been a valuable tool for geneticists to discern the role of a gene in embryonic development and in normal physiological homeostasis. Mice act as a good analog for most human biological processes, since humans and mice share ~99% of the same genes (Capecchi, 1994). Additionally, mice are useful experimental animals because they are small, have relatively short life spans, and are prolific. So, for geneticists, the targeted deletion of a gene in a mouse provides an important means to determine the biological role of a genetic allele.

While useful for studying in vivo gene function, some knockout mice have also served as valuable animal models for human genetic diseases. When a human mutation is found to disable a protein, the corresponding knockout mouse can be an important resource to study the underlying pathophysiology and to develop therapies to treat a genetic disease (Majzoub and Muglia, 1996). Additionally, pharmaceutical companies obtain clues about inhibiting a protein by first looking at the phenotype of a knockout mouse (Zambrowicz and Sands, 2003). Thus, knockout mice can provide insight into a gene's physiological role in humans.

Rather than just inactivating a gene, however, some genetic diseases result in the expression of a mutated protein. Point mutations, microdeletions, or insertions are responsible for many human genetic diseases. These subtle mutations can also be mimicked in a mouse model using gene targeting. Instead of disrupting a gene, as in most knockout mice, homologous recombination is employed to swap the normal copy of an exon with a mutated version. As long as a similar mutation can be reproduced in the mouse protein, then the corresponding amino acid substitution, deletion, or insertion can be targeted into a gene of interest to replicate the human disease. The effects

of the altered protein can then be studied in the animal model.

With some knockout mouse models, the severity of the phenotype can preclude analysis of a gene's role in the organogenesis of a particular tissue. For example, about 15% of all knockout mice have mutations that result in developmental lethality (*http://www.genome.gov/12514551*). To circumvent this problem, Cre/loxP technology has been employed to create conditional knockout mice. Derived from the P1 bacteriophage, the Cre recombinase will excise any region of DNA placed between two *loxP* sites (locus of crossing over; Sternberg and Hamilton, 1981; Sauer and Henderson, 1998). The *loxP* site is a 34-bp nucleotide sequence that can be genetically targeted around an essential exon in a gene (Gu et al., 1994). The resulting mice contain the floxed (flanked by *loxP* sites) allele in all tissues, but are phenotypically wild-type. These floxed mice are then bred to Cre-expressing transgenic animals, wherein the promoter used to drive Cre expression will determine the site of the gene deletion. For spatial inactivation of a gene in a mouse, a cell-type-specific promoter is used to limit Cre expression to a particular tissue.

Although less commonly used than Cre/loxP technology, the Flp recombinase also provides a similar means to rearrange a genetic locus. Flp (flippase) was isolated from *Saccharomyces cerevisiae* and, like Cre, the recombinase will also excise DNA flanked between 34-bp sequences known, in this case, as FRT sites (Dymecki, 1996). So, through the use of either the Cre/loxP or the Flp/FRT systems, gene expression can be disrupted in a spatial and temporal manner, and the lethality of a knockout mouse phenotype can be overcome. With this versatility, mice utilizing Cre/loxP or the Flp/FRT systems are often shared among research laboratories studying differing physiological systems.

In addition to spatial excision of a floxed allele, temporal control of Cre-mediated recombination is also possible in a conditional knockout mouse. The timing of recombination can be regulated by use of a tamoxifen-inducible Cre (Feil et al., 1997; Hayashi and McMahon, 2002). In this strategy, Cre is ligated to a mutated ligand-binding domain of the estrogen receptor that restricts transcription until tamoxifen is present. Cre is, therefore, not expressed until tamoxifen is applied either topically or through injection. Another inducible Cre system takes advantage of the reverse tetracycline-controlled transactivator (rtTA; Utomo et al., 1999). Doxycycline is administered to activate the rtTA which, in turn, will induce transcription of Cre. Lastly, Cre can also be delivered through injection of a viral vector (Anton and Graham, 1995). When and where the Cre is expressed is controlled by the timing and site of injection for the virus. The amount of DNA rearrangement can be adjusted by varying the titer of the virus. The numbers of conditional knockout mice have dramatically increased since Cre/loxP and Flp/FRT technologies were introduced into gene targeting. This proliferation of conditional animal models attests to the value of the recombinases as a molecular switch.

Another interesting application of gene targeting is knock-in technology, in which any gene of interest can be placed under the cis-acting regulatory elements of another gene (Cohen-Tannoudji and Babinet, 1998). Originally, knock-in mice were derived as a means to visualize a gene's expression due to targeted recombination of the *lacZ* reporter gene into a genetic locus (LeMouellic et al., 1990). The initial coding sequence of a gene would be replaced with the *lacZ* marker, which is inserted under the direction of the gene's promoter. The strategy of using homologous recombination to knock in a reporter gene, like *lacZ*, allows not only for the creation of homozygous null mice for a gene, but also provides a technique to study the targeted gene's expression in the heterozygous mice, which are often phenotypically normal. The knock-in idea was later elaborated to include the replacement of a gene by the sequence coding for a similar isoform of the protein (Hanks et al., 1995). Similar protein isoforms could thus be tested for redundancy. Through knock-in mice, genetically similar proteins can be examined to determine if two isoforms are truly biologically distinct or if the proteins are basically functionally equivalent. with differing patterns of expression being the only key divergence.

VECTOR DESIGN

Homologous recombination takes advantage of a cell's own DNA-repair machinery to replace a targeted genetic locus with homologous genomic sequence. The targeted event probably occurs through strand transfer by the recombination RAD52 epistasis group (Rijkers et al., 1998; Vasquez et al., 2001). For recombination to occur at all in a cell, around 2 kb of sequence homology is required (Melton, 2002). However, 6 to 14 kb of homology is typical for targeting constructs. In

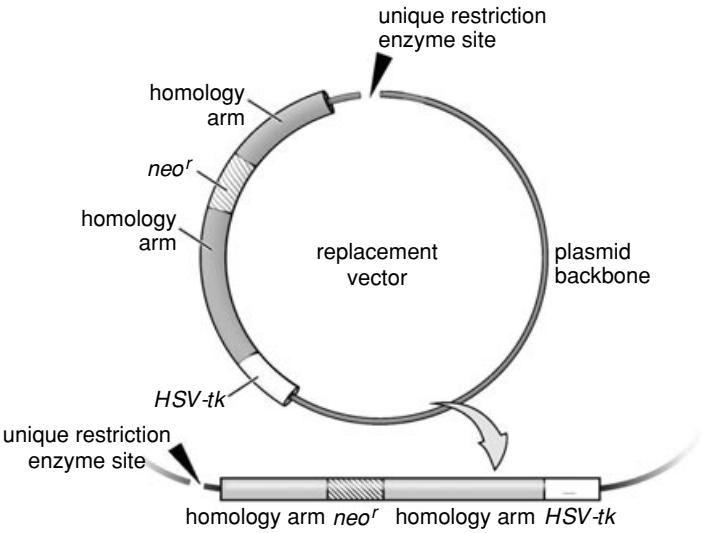

Figure 19.12.1 A schematic of a replacement vector. Two homology arms flank a positive drug-selection marker (*neo*^{r}). A negative-selection marker (*HSV-tk*) is placed adjacent to one of the targeting arms. A unique restriction-enzyme site is located between the vector backbone and the homology arm. When linearized for gene targeting, the vector backbone will then protect the *HSV-tk* from nucleases.

addition, linear DNA was found to be the preferred substrate for the recombination proteins (Hasty et al., 1992). The actual targeted event takes place in only a small percentage of cells, as homologous recombination occurs at a rate ~1000-fold lower than random insertions (Sargent and Wilson, 1998). During a stem cell experiment, only about 10^{-2} to 10^{-3} of the DNA integrations are homologous recombination events (Melton, 2002). Therefore, a thorough screening process employing Southern blotting or PCR is necessary to identify cells with the targeted event. Electroporation became the preferred way to deliver the replacement vectors into a large number of stem cells. While microinjection has a better targeting ratio (1:15 targeted recombinants to random integrants), a mass delivery system was needed to introduce the targeting constructs into cells, and electroporation provided the most efficient technique (1:2400 targeting ratio; Vasquez et al., 2001). However, since the transformation efficiency is low (10^{-3}), a positive selection marker is needed to enrich clones that have inserted the targeting vector into their genome (Ledermann, 2000). The likelihood of recombination peaks when cells are in early to mid-S phase, and the process occurs rapidly, in ~30 min after the construct is taken into the nucleus (Wong and Capecchi, 1987; Cappecchi, 1989). The rate of homologous recombination is not dependent on the input concentration of vector used in the targeting experiment (Thomas et al., 1986; Capecchi, 2005). So, the capacity to locate homologous sequence within the recipient cell genome is not a rate-limiting step, since this would be influenced by the input concentration of DNA. Rather, the cellular machinery performing the homologous recombination sets the reaction rate for gene targeting.

Primarily, two classes of vectors have been used to generate targeted mutations. Most gene-targeting experiments employ replacement vectors (Fig. 19.12.1), which have been particularly instrumental for efficiently generating knockout mice. In the design of a replacement vector, the open reading frame of a genomic clone is disrupted by the placement of an intervening drug-selection marker. Two homologous recombination events function to insert the targeting construct containing the drug-resistance gene into a homologous genetic locus (Fig. 19.12.2). The drug-resistance gene works for the positive selection of cells that have integrated the targeting vector into their chromosome. Neomycin is the most common drug used for positive selection. Integration of the neomycin phosphotransferase (*neo*^{r}) gene allows for resistance to neomycin, an aminoglycoside that interferes with protein synthesis in eukaryotic cells. Other drug-selection markers include resistance genes for puromycin and hygromycin.

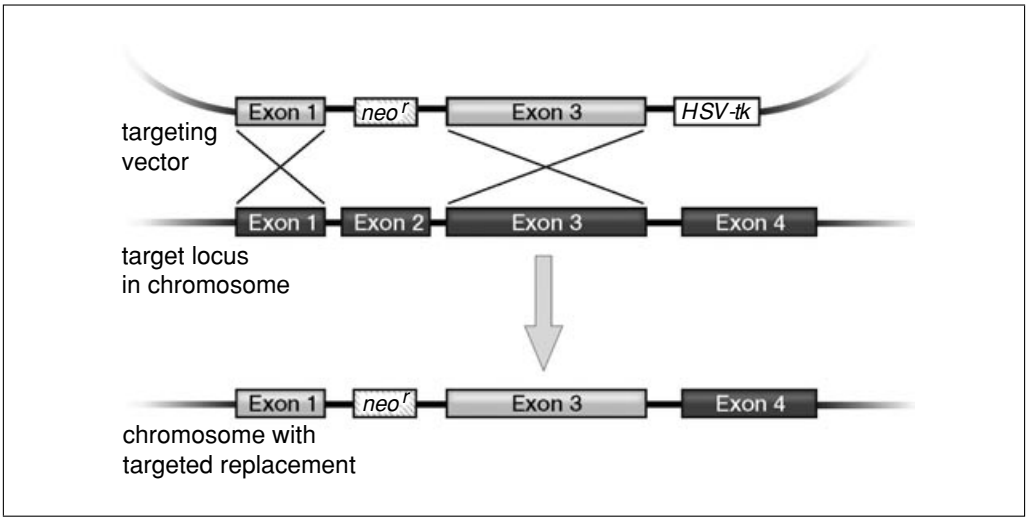

Figure 19.12.2 Gene inactivation through a replacement vector. Homologous recombination with a replacement vector requires a positive-selection marker (*neo*^{r}), a negative-selection marker (*HSV-tk*), and two targeting arms (homologous sequence is depicted with exons in light gray). A representative target gene (with exons in dark gray) is aligned with the targeting vector. For this example, the targeting vector is designed so that Exon 2 is substituted by the *neo*^{r} gene. The replacement of Exon 2 by the *neo*^{r} gene is then recapitulated in the target locus as homologous recombination exchanges genomic sequence for the homologous sequence of the targeting vector. Two homologous recombination events (depicted through the crosses) occur via the long and short targeting arms to introduce nonhomologous sequence (i.e., *neo*^{r}) into the designated gene. Insertion of the *neo*^{r} gene is selected for by treatment of cells with neomycin sulfate (G418) in tissue culture. The negative-selection marker (*HSV-tk*) is not recombined into the chromosome and is lost during gene targeting. If the targeting construct is randomly integrated anywhere in the genome, the *HSV-tk* gene would be intact. Random integrants can be selected against by either gancyclovir or FIAU treatment.

Mansour et al. (1988) established positive and negative selection for gene targeting by the additional placement of the HSV thymidine kinase (*HSV-tk*) gene adjacent to one of the vector arms containing targeted homology to a genetic locus. Random integrants will usually contain an intact form of the *HSV-tk* gene when inserted into the genome. Cells with random integrants are killed during negative selection via treatment with gancylovir or FIAU [1-(2′-deoxy-2′-fluoro-β-D-arabinofuranosyl)-5-iodouracil], compounds that require phosphorylation by HSV-tk to inhibit DNA synthesis. An ~2000-fold enrichment of targeted clones can occur with this type of vector. Even with positive and negative selection, a substantial number of ES cell clones that arise in culture are false positive, since *HSV-tk* can be inactivated before recombination by events like partial deletions. The random integrants are, therefore, insensitive to negative drug selection. To avoid subjecting the ES cells to drugs like gancyclovir and FIAU, some targeting vectors omit using *HSV-tk* in favor of a negative-selection marker like the diphtheria toxin gene (Yagi et al., 1990). In a gene-targeting experiment, a replacement vector directs the disruption of an essential coding exon (or exons) of a gene through the insertion of a positive drug-resistance marker. This replacement occurs via recombination at the two flanking homology arms. Any important coding region that is essential for a gene's function can be thereby targeted for deletion.

When designing a targeting construct, a few factors should be considered that could result in an incomplete knockout. A gene may be residually expressed if there exist alternative or cryptic promoters that are not disrupted in the targeted allele (Müller, 1999). Differential splicing could also generate RNA species where the selection marker is skipped. Read-through transcription of the drug-resistance gene is another way mutant mRNA that has some coding sequence from the targeted allele can appear. In gene targeting via a replacement vector, a strong promoter is typically used to drive the *neo*^{r} marker in the stem cells, but the poly(A)-addition site can sometimes be skipped during transcription of the drug-resistance gene. Therefore, as the *neo*^{r} gene is transcribed, downstream exons could possibly be spliced into the mRNA. The *neo*^{r} gene is often oriented in the opposite direction with

respect to gene transcription for the targeted allele, to avoid any potential transcription of downstream exons. In addition, this orientation also ensures that the strong promoter on the *neo*^{r} gene does not influence any downstream genes. Therefore, the size and location of the targeted deletion should be carefully considered when designing a replacement vector, to help avoid an incomplete knockout of the gene function.

Double replacement vectors are a variation of the knockout vector design that is primarily used to target subtle mutations into a selected genetic allele (Askew et al., 1993; Stacey et al., 1994). Also known as tag and exchange, this strategy requires two rounds of homologous recombination to create the desired mutation. In contrast to a replacement vector, the *HSV-tk* gene is placed adjacent to *neo*^{r}, rather than at the end of the construct. Both the positive and negative selection markers are inserted into the targeted genomic site, with the homology arms flanking both genes. In the first tag step, a targeted stem cell clone is isolated with only neomycin treatment. Once isolated, the ES cells then undergo a second round of electroporation with a targeting vector that will exchange both drug-selection markers for a mutated exon. This second targeting vector is basically a genomic clone containing the desired point mutation, deletion, or insertion. During this second round of gene targeting, gancyclovir is added to isolate cells that have lost the *HSV-tk* gene from homologous recombination with the second vector. The *HPRT* gene can be used to replace both the *neo*^{r} and *HSV-tk* genes in the construct design. The *HPRT* gene is part of a purine salvage pathway that can be adapted as a drug marker for both positive and negative selection (Melton, 2002). HAT (hypoxanthine/aminopterin/thymidine) medium is used for positive selection, since it forces a cell to depend on the salvage pathway that needs an intact copy of the *HPRT* gene. Negative selection involves the purine analog 6-thioguanine, which is phosphorylated by the *HPRT* gene to generate a toxic compound for the cell. ES cells with a mutated copy of their endogenous *HPRT* gene, however, are needed for this type of strategy. So, with a double replacement vector, two rounds of targeted recombinations are required to obtain the final ES cell clones with the expected subtle mutation. Several mutations can readily be placed into the modified gene once targeted ES cell clones from the first electroporation are isolated.

Subtle mutations can also be introduced with vectors that take advantage of Cre/loxP technology (Fig. 19.12.3; Ferradini et al., 1996; Cohen-Tannoudji and Babinet, 1998). Similar to a replacement vector, the targeting construct is designed with a drug-selection marker flanked by two homology arms. Both positive and negative selection are required to isolate cells with the properly recombined mutation. Instead of replacing an entire exon with a drug-selection marker, the goal, here, is to exchange normal coding sequence in a targeted allele for a mutated version. One homology arm will carry the planned point mutation, micro-deletion, or insertion to be introduced into the targeted gene. However, in this strategy, the positive drug-selection marker needs to be removed because it will interfere with transcription of the mutated allele. Using a *neo*^{r} gene that is floxed allows a way to eventually remove the drug-selection marker by using Cre recombinase. In the construct design, the *neo*^{r} gene is inserted into a noncoding region. Upon recombination, only a 34-bp *loxP* site remains in the intron, creating a clean mutation (without a drug-selection marker) in the targeted genetic locus. Without disruption by a drug-selection marker, the modified allele should be transcribed to produce the expected mutant protein, and the remaining *loxP* site within an intron should not interfere with gene expression. Like double replacement vectors, this strategy is also a two-step process, except that Cre is used to remove the drug-selection marker rather than a second round of homologous recombination.

Making a targeting construct for a conditional knockout is essentially like making a clean mutation, but, with this strategy, the inserted mutation results in the addition of *loxP* sites into a targeted genetic locus (Fig. 19.12.4). In the final targeted allele, two *loxP* sites will flank an essential exon (or exons) to be excised by Cre in a conditional manner (Gu et al., 1994; Cohen-Tannoudji and Babinet, 1998). As with the clean mutation, a floxed *neo*^{r} gene is needed for positive selection and will eventually be removed using Cre. This process of Cre excision will leave one of the necessary *loxP* sites required to flox a targeted exon(s). One of the homology arms from the replacement vector is then used to insert the other flanking *loxP* on the opposite side of this exon(s). Both *loxP* sites must be positioned in the introns of the targeted gene, and should not interfere with the either the coding sequences or the promoter of the gene,

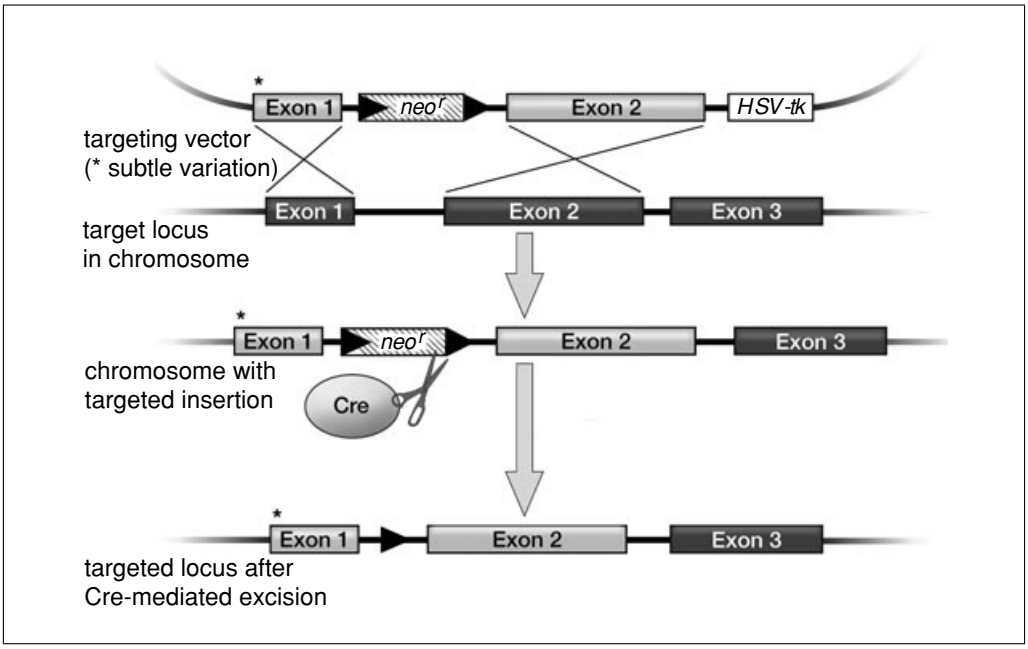

Figure 19.12.3 Gene targeting to insert a subtle mutation. In the targeting vector, a subtle mutation (depicted by the asterisk) is designed into one of the homology arms. Subtle mutations can consist of point mutations, microdeletions, or insertions. When sequence in the target gene is exchanged with homologous sequence from the targeting vector, the subtle mutation is introduced into the chromosome. Homologous recombination occurs through both the long and short homology arms. A positive drug-selection marker (*neo*^{r}) is needed in this strategy to select for clones that have undergone recombination. With a clean mutation, the *neo*^{r} gene is inserted into the targeted locus, but no exons are lost as a result of recombination. The *neo*^{r} gene needs to be removed so that it does not interfere with transcription of the recombined allele. The *loxP* sites (depicted as black triangles) are used to flank the *neo*^{r} gene in order to facilitate its removal. These 34-bp *loxP* sites are recognized by the Cre recombinase, which can be introduced into targeted stem cells by transient transfection. If the *loxP* sites are in the same direction, the Cre recombinase will circularize out any intervening sequence. With Cre-mediated recombination, only a single *loxP* site will remain. The *loxP* site in the recombined allele is situated within intron sequence so that it does not interfere with transcription of the mutant protein.

nor with any neighboring genes. After homologous recombination, the mutated genetic locus will initially have three *loxP* sites consisting of the floxed exon(s) followed by a floxed *neo*^{r} gene. Once the targeted clones are identified, the targeted ES cells are then transiently transfected with a Cre expression vector to remove the *neo*^{r} gene. Three scenarios arise when Cre is used to recombine the targeted allele. In one situation, the targeted allele is properly recombined and Cre only excises the *neo*^{r} gene. However, recombination can also result in the exclusion of the floxed exon(s) or both the exon(s) and the *neo*^{r} gene. A second round of genomic screening by Southern blot or PCR is needed to find the ES cell clone that is missing the *neo*^{r} gene, but which has the floxed exon intact. Transcription of the targeted gene should not be impacted when the final floxed allele is generated. The mutated mice are then bred to a Cre-expressing transgenic line to allow for conditional disruption of the gene in the tissue of interest.

Knock-in strategies basically adapt replacement vectors to usurp the endogenous promoter of a gene to transcribe an exogenous cDNA of interest (Fig. 19.12.5; LeMouellic et al., 1990; Hanks et al., 1995; Cohen-Tannoudji and Babinet, 1998). During recombination, the protein start site of the targeted gene is disrupted when a selected cDNA is knocked into the promoter, essentially resulting in a targeted transgenic mouse. For this vector design, both the cDNA to be knocked in and the *neo*^{r} gene are brought into the genome by two flanking homology arms. The 5′ arm, in this case, will typically contain homologous genomic sequence that is upstream from the protein start site. Similar to a transgenic construct, this regulatory sequence is followed by a cDNA and a poly(A)-addition signal. For positive selection, a drug-resistance gene like

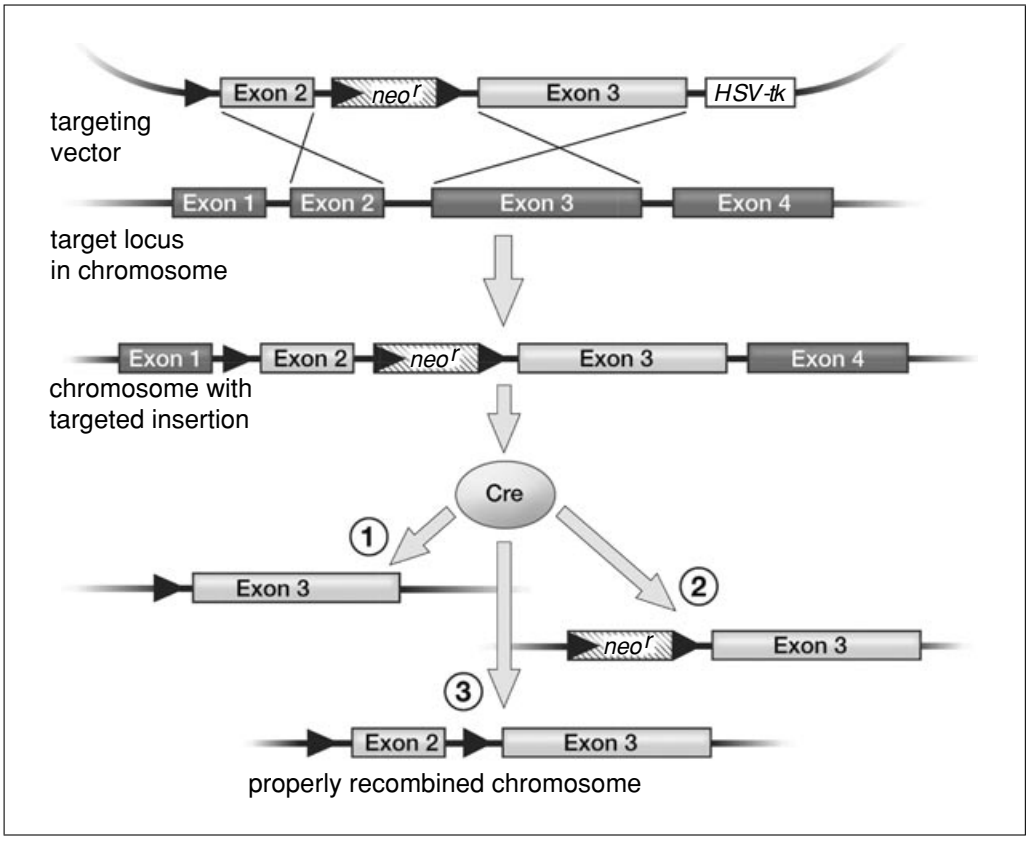

Figure 19.12.4 Gene targeting to create a conditional knockout. In this strategy, the targeting construct is designed so that a *loxP* site (indicated with a black triangle) is located next to an essential exon within the homology arm. A floxed *neo*^{r} gene is then positioned on the opposite side of this exon. Both the *loxP* site and the floxed *neo*^{r} gene are introduced into the target locus through homologous recombination. Unlike a conventional knockout experiment, the targeting vector is assembled so that no exons are lost as a result of homologous recombination. After the stem-cell clone with the properly targeted insertion is identified, the Cre recombinase is then introduced into the cells through a transient transfection. The Cre recombinase can produce three types of recombinations. In the first example (shown as a circled "1"), both Exon 2 and the *neo*^{r} gene are excised from the chromosome, leaving only one *loxP* site. In the second scenario, (shown as "2"), only Exon 2 is removed while the floxed *neo*^{r} gene remains in the targeted chromosome. In the third case ("3"), just the *neo*^{r} gene is excised while two *loxP* sites remain to flank Exon 2, creating a floxed allele. Only the stem-cell clones with this specific recombination are injected into blastocysts to generate floxed mice. Conditional deletion of Exon 2 in vivo is then accomplished typically by breeding the floxed mice with a Cre-expressing transgenic line. After the removal of *neo*^{r} in tissue culture and subsequent conditional deletion of Exon 2 in vivo, the final allele has only one *loxP* site remaining within the intron sequence of the targeted gene (as depicted in "1").

neo^r is placed downstream of the cDNA. A second 3′ homology arm then follows after the *neo*^{r} gene. Like a replacement vector, two homologous recombination events function to replace the coding sequence of the gene with the cDNA and *neo*^{r} drug marker in the construct. If positioned correctly, the knocked-in cDNA should then be in frame and expressed by the recombined gene. Through this design, a gene can be knocked out as the cDNA of closely related isoform is simultaneously knocked in. Protein domains can be switched by homologous recombination as well. In addition, marker genes, like *lacZ*, can be knocked in not only to produce a null mouse, but also to help track the targeted gene's expression pattern through the mutated gene. Even though knock-in mice are more time consuming to generate than transgenic mice, the knocking in of a cDNA into a targeted genetic locus can be useful to overcome problems of unreliable transgene expression that sometimes occur from the randomness of the site of integration and the variability in transgene copy number (Jasin et al., 1996; Ledermann, 2000). If the knocked-in cDNA is correctly in frame, expression of the knocked-in transgene should more faithfully mirror the transcription pattern

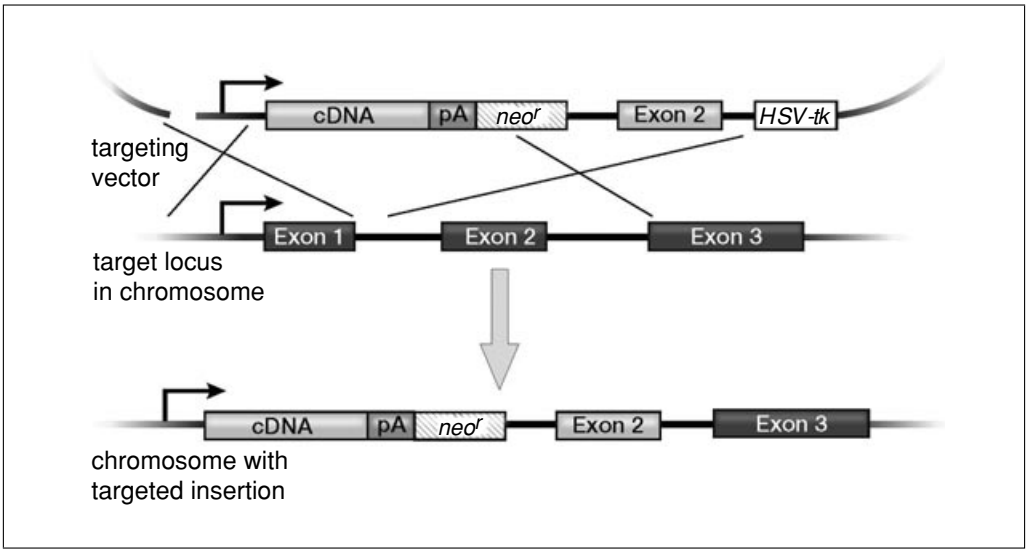

Figure 19.12.5 Knock-in of a cDNA through the use of gene targeting. Knock-in constructs are similar in design to conventional knockout gene-targeting vectors, except that additional sequence (i.e., a cDNA or protein domain of interest) is inserted into the target gene. Through homologous recombination, this foreign sequence is introduced in frame into the target locus to be expressed by its promoter. Essential coding sequence in the target locus is simultaneously lost during recombination with the targeting construct. In this example, homologous recombination places a cDNA under the control of the promoter of the target gene. Concurrently, the translational start sequence in Exon 1 of the target gene is also replaced by the cDNA. The cDNA, in this example, has a poly(A)-addition signal (pA) which will stop any further transcription downstream of the targeted insertion. For a knock-in targeting vector, one of the homology arms must consist of genomic sequence upstream of the planned insertion site for the cDNA. To knock in a cDNA, as shown, a targeting vector must use promoter sequence for one of its homology arms (as depicted with the directional arrow). A positive drug-selection marker (*neo*^{r}) is still needed to select for clones that have inserted the designated cDNA into the target gene. Two homologous recombination events serve to insert the cDNA and *neo*^{r} gene into the target location while knocking out Exon 1.

for the targeted promoter. In one such example, Cre was targeted to the Cd19 genetic locus in order to maintain all of the regulatory elements for transcription in B cells (Rickert et al., 1997).

Lastly, gene targeting with a replacement vector can be applied to generate a single-copy transgenic mouse. The use of *HPRT*-null ES cells allows for only a single copy of a transgene to be integrated at a known insertion site (Bronson et al., 1996). With this replacement-vector design, homologous recombination is needed to correct the *HPRT* gene. The homology arms of the targeting construct restore two missing exons needed for a functional copy of the *HPRT* gene during recombination in the stem cells. During homologous recombination, a single copy of a transgene is carried into the restored *HPRT* genetic locus. The transgene flanked by the targeting arms has its own promoter, selected cDNA, and poly(A)-addition site. With a reconstituted *HPRT* gene available as a drug-selection marker, clones with the proper homologous recombination can then be isolated with HAT medium.

Another less commonly used gene-targeting strategy employs insertion vectors to disrupt a genetic locus (Fig. 19.12.6). These insertion vectors are designed using just one arm of homologous sequence, and a single recombination event is all that is required to insert a drug-selection gene like *neo*^{r} into the targeted gene (Hasty et al., 1991). A restriction-enzyme site located within the homology arm is used to linearize the construct, so that homologous recombination can occur. Instead of replacing sequence, the whole insertion vector is integrated into the genome. In this case, the homology arm serves merely to direct the site of integration to the targeted gene. Insertion vectors result in gene duplication during homologous recombination because the entire targeting construct is inserted where the homology arm was linearized. In most cases, the *neo*^{r} gene will interfere with transcription in the targeted gene to create a loss-of-function mutation. However, since homologous recombination with an insertion vector produces gene duplication, mutant RNA species may still be expressed through altered splicing.

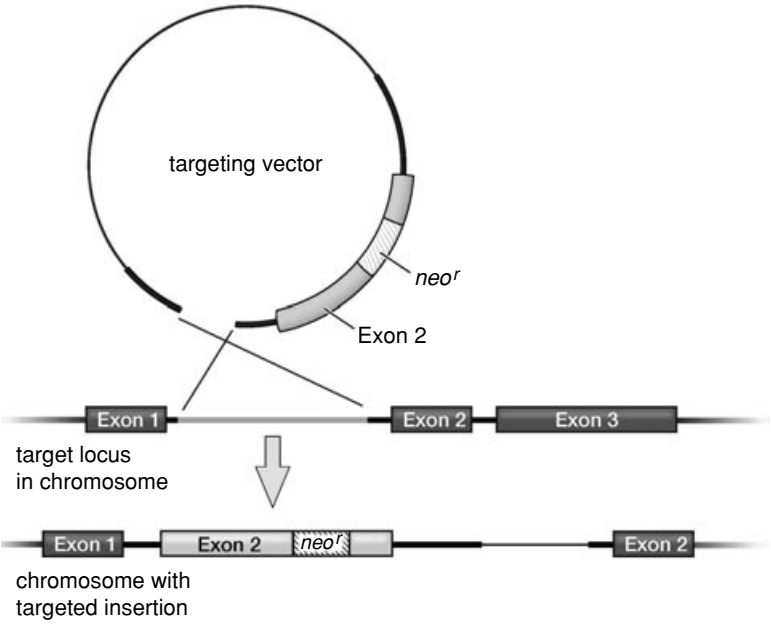

Figure 19.12.6 Gene inactivation with an insertion vector. For an insertion vector, only one homologous recombination event is needed for targeted insertion of DNA into a designated gene. In this case, recombination occurs around a double-strand break that is located in the homology arm of the targeting construct. The entire insertion vector is then incorporated into the gene, including the plasmid backbone (represented by the thin line). A drug-selection marker like the *neo*^{r} gene is still needed for positive selection, but this marker can be positioned either in the targeting arm or in the plasmid backbone of the insertion vector. In this example, the positive drug-selection marker is designed into the homology arm in order to replace essential coding sequence of the target gene (as shown with the disruption of Exon 2 by the *neo*^{r} gene). For insertion vectors, a knockout allele is essentially generated because the target gene is disrupted with insertion of the *neo*^{r} gene and by duplication of exonic sequence.

In addition, intrachromosomal recombination can also lead to regeneration of the wild-type allele. Compared with replacement vectors, though, constructs of this type have a higher frequency of recombination (Hasty et al., 1991). A variation of the insertion-vector strategy is to create a subtle mutation through a hit-and-run or in-out strategy (Vanlancius and Smithies, 1991). With this technique, the homology arm contains a desired mutation to be inserted into the targeted gene. Through homologous recombination, both the *neo*^{r} and *HSV-tk* genes are inserted into the targeted gene. After initial positive selection with *neo*^{r}, the isolated cells then undergo a second round of drug selection with gancyclovir. During this next step, the duplicated gene should align in such a way as to undergo intrachromosomal recombination. Both drug-selection markers will then be lost in the process. The remaining recombined allele will retain the subtle mutation, and the mutated protein will be expressed.

STRATEGIC PLANNING FOR DESIGNING A KNOCKOUT TARGETING CONSTRUCT

While creating a knockout mouse is costly and labor intensive (>$12,000 and ~1 year from electroporation of the targeting vector in ES cells to the generation of homozygous null mice; *http://www.med.umich.edu/tamc*), the understanding of gene functions in mammalian physiology and development have made the efforts worthwhile. To design a vector for gene targeting, the following steps are suggested:

1. After selecting a gene to be disrupted, the genomic structure of the target allele should be researched. Exon/intron sequence information should be gathered. The size of the gene and the chromosomal location of the allele to be targeted should also be known. Lastly, the location of most major restriction enzyme sites should be identified to aid with subcloning. A good restriction-enzyme map of the genomic locus will be useful in

the construction of the replacement vector. Once an allele is selected for targeted deletion, the flanking genomic sequence should be examined to ensure that any possible neighboring genes are not disrupted during recombination (Olson et al., 1996). Check for potential open reading frames that could be disturbed when a targeted mutation is generated. Most genomic sequence information can be gathered through the Mouse Genome Sequencing Consortium (MGSC). The mouse genome sequence is freely available in public databases (GenBank accession number CAAA01000000) and is accessible through various genome browsers (*http://www.ensembl.org/Mus_musculus/*; *http://genome.ucsc.edu/*, and *http://www.ncbi.nlm.nih.gov/genome/guide/mouse/*; Mouse Genome Sequencing Consortium, 2002). Lastly, perform a thorough search to ensure that your gene of interest has not been knocked out already. About 700 knockouts have been made three or more times (Grimm, 2006).

2. A mouse genomic fragment containing a large portion of the gene to be targeted needs to be isolated to create the homology arms in the targeting construct. A 129/Sv genomic clone is most commonly used for constructing targeting vectors, since most stem cells were derived from this mouse strain. Using a genomic clone of a mouse strain different from the ES cell strain can reduce the frequency of homologous recombination. In general, homologous recombination is four to five times more efficient with targeting vectors using isogenic DNA (Deng and Capecchi, 1992). For any given genetic locus, however, the rate of recombination will depend on the amount of nonhomologous sequence between the mouse strains, as a 20-fold decreased efficiency has been reported with the use of nonisogenic DNA in the targeting vector (te Riele et al., 1992). Searching a BAC (Bacterial Artificial Chromosome) library is one means to get the genomic sequence needed to make a targeting vector. Due to sequencing of the mouse genome, BLAST can be used to readily find a BAC clone that contains the selected gene for targeted disruption. Genomic DNA from a female 129S6/SvEvTac (Taconic) mouse, for example, was used to create the RPCI-23 BAC library. A BAC clone will generally contain from 100 to 300 kb of genomic sequence. Another means to obtain the homology arms for the targeting vector is through PCR. PCR can be used to amplify the homology arms, if a source of purified 129/Sv genomic DNA is available. A high-fidelity *Taq* polymerase is needed that can amplify long stretches of genomic DNA. Even with a high-fidelity *Taq* polymerase, however, the PCR products must be carefully sequenced to ensure that no coding errors were generated during the reaction. Lastly, a mouse 129/Sv Lambda phage genomic library is another option to isolate the sequence for the gene to be targeted. A probe containing some homology to the chosen allele is used to screen the phage library. Once a genomic clone is isolated, most of the common restriction enzyme sites should be verified.

The total amount of homology needed in most successful gene-targeting experiments is about 5 to 10 kb in length. The efficiency of homologous recombination increases when increasing the length of homology in the targeting construct, but this peaks after 14 kb of sequence (Deng and Capecchi, 1992). For a typical replacement vector, the total length of homologous sequence will consist of roughly a 1- to 2-kb span of DNA for a short homology arm and a separate, larger 4- to 6-kb genomic fragment as a long homology arm. The short arm can be as small as 0.5 kb, however, without affecting targeting efficiency (Hasty et al., 1991). In the case of the long arm, though, increasing the length of homology from 8 up to 110 kb does not enhance the frequency of homologous recombination (Lu et al., 2003). In the construct, the short and long arms will share homology with genomic sequences that flank the designated coding region to be deleted from the gene to be targeted.

3. Both positive and negative selection genes need be chosen to construct the targeting vector. The most common positive-selection marker is the neomycin phosphotransferase (*neo*^{r}) gene. The drug-resistance genes for puromycin and hygromycin have also been used as positive-selection markers. When designing a targeting vector, the sequence of the *neo*^{r} gene is often inserted in the opposite orientation to transcription in the target allele. With negative selection, the HSV thymidine kinase (*HSV-tk*) gene is often used to select against random integrants. If the targeting construct is randomly integrated, the cells will mostly contain an intact copy of the *HSV-tk* gene that will phosphorylate gancyclovir into a cytotoxic drug (Mansour et al., 1988). The diphtheria toxin gene has also been used for negative selection against random integrants (Yagi et al., 1990). A frequently used plasmid for making replacement vectors is pPNT (Tybulewicz et al., 1991). This plasmid contains both the *neo*^{r} and *HSV-tk* genes. All that

is required is to ligate the two homology arms into the unique restriction enzyme sites that flank the *neo*^{r} gene.

With the acquisition of the drug markers and a genomic clone, one can proceed with piecing a targeting construct together.

DESIGNING A KNOCKOUT TARGETING CONSTRUCT (REPLACEMENT VECTOR)

1. Once a gene is chosen for targeted inactivation, determine the best region of genomic sequence to disrupt through homologous recombination. With a replacement vector, two homologous recombination events will occur at the targeted locus via the long and short homology arms. The positive drug-resistance gene is inserted into a gene while coding sequence is simultaneously deleted. The length of genomic sequence replaced by the drug-selection marker is governed by the location of these homology arms. So, any intervening sequence situated between the two directed sites of recombination is omitted during the process of homologous recombination. The length of sequence that can be replaced by the positive-selection marker does not seem to influence the efficiency of homologous recombination. Up to 15 kb of sequence, for example, was deleted with a replacement vector to generate the T cell–receptor knockout mouse (Mombaerts et al., 1991). With most targeting constructs, however, one to a few critical exons are generally disrupted in gene-targeting experiments. Small deletions of 0.5 to 1 kb in length are typical for most gene-targeting experiments, and are usually sufficient to inactivate a gene (DeChiara, 2001). Genetic coding sequence essential for protein function should be selected for targeted deletion because there is the possibility that the inserted drug marker can be bypassed during transcription of the targeted allele. Any resulting truncated protein generated should, therefore, not be functional and would hopefully be rapidly degraded so as not to interfere with the cell's normal physiology. Generally, deleting 5′ exons provides a better chance to totally disrupt the formation of protein than a strategy that targets downstream exons at the C-terminus (Hasty et al., 1993). With genes smaller than 20 kb in length, some investigators prefer to design replacement vectors that disrupt all the coding exons in order to absolutely ensure gene inactivation (Cheah and Behringer, 2001). For any gene-targeting strategy, though, be sure that no neighboring genes are affected during homologous recombination.

2. After designating a location for targeted deletion, identify neighboring restriction-enzyme sites that are convenient for generating a short homology arm (~1 to 2 kb in length) as well as the long homology arm (~4 to 6 kb). A total amount of 5 to 8 kb of homology is typical in most targeting vectors (Hasty et al., 1993). Both the short and long homology arms may need to be subcloned into a vector such a pBluescript (Stratagene) in order to facilitate the assembly of the final targeting construct. Often, DNA-modifying enzymes are needed with subcloning, since convenient restriction enzyme sites may not be readily available in the genomic clone. The following DNA modifications may need to be applied for subcloning the homology arms:

a. Incompatible overhangs produced from a restriction enzyme digest can be blunted to help facilitate the subcloning of a homology arm. Blunt ligatable ends can be generated with enzymes like mung bean nuclease (to remove a 3′ overhang) or Klenow polymerase (to fill in a 3′ recessed end). However, sticky end modification can result in reduced ligation efficiency.

b. Adaptors can be purchased (from New England Biolabs, Stratagene, etc.) to insert a desired restriction enzyme site onto blunt-ended DNA. Alternatively, oligonucleotide adaptors can be generated to insert a restriction-enzyme site into cleaved DNA with sticky ends. Oligos must be designed so that, upon annealing, sticky ends are generated that are compatible to the cleaved DNA. The synthesized oligos are diluted to a concentration of 100 ng/μl in a buffer of 10 mM Tris·Cl/50 mM NaCl, pH 8.0. This solution is then heated at 95°C for 15 min and cooled to room temperature. The annealed oligos are ligated with the cleaved DNA at a 500 to 1000 molar excess. This high concentration helps to facilitate ligation of the oligo and inhibits mere re-ligation of the vector.

c. For ligation, the vector may need to be modified to prevent re-ligation, particularly if only one restriction enzyme is being used to cleave the DNA. In this case, the vector needs to be dephosphorylated to prevent re-ligation. Dephosphorylation of the DNA can be achieved by incubating the cleaved vector with an alkaline phosphatase (typically either calf intestinal phosphatase or shrimp alkaline phosphatase).

As mentioned above, PCR provides another means to clone out the homology arms, but careful attention should be made to ensure that no coding errors were generated during the reaction.

3. The targeting construct can be assembled after both homology arms and the drug-selection markers have been gathered. The targeting construct should be ligated so that the long and short homology arms flank the positive-selection marker. A negative-selection marker is subcloned outside of this grouping. Try to ligate the vector so that, upon recombination, the positive-selection marker is transcribed in the opposite orientation with respect to the targeted gene. A unique restriction enzyme site must be maintained to linearize the targeting construct to improve the efficiency of homologous recombination (Hasty et al., 1992). This restriction enzyme site should be located outside the regions of homology, typically between the plasmid backbone and a targeting arm. With linearization of the targeting construct, the plasmid DNA will protect the negative-selection marker (e.g., *HSV-tk* gene) from nucleases (Cheah and Behringer, 2001). The placement of either the long or the short arm between the two drug markers has varied among targeting vectors. While some investigators prefer to locate the *HSV-tk* adjacent to the long targeting arm (Torres and Kühn, 1997), other vectors place the *HSV-tk* gene at the end of the short targeting arm because this design may help improve the efficiency of negative selection (Melton, 2002).

Plasmids such as pPNT (Tybulewicz et al., 1991) or the pKO Scrambler Series (Lexicon Genetics; *http://www.lexgen.com*) can be useful in designing targeting constructs, since these vectors contain both *neo*^{r} and thymidine kinase genes. In addition, common restriction enzyme sites are positioned in locations that facilitate the subcloning of the homology arms. With pPNT, for example, one homology arm can be subcloned into the restriction enzyme sites (*Xba*I, *Bam*HI, *Kpn*I, and *Eco*RI) located between the *neo*^{r} and *HSV-tk* genes. Both of these drug-selection marker genes in this vector are driven by the 3-phosphoglycerate kinase promoter (PGK; McBurney et al., 1991), with the PGK pA-addition site. PGK is a housekeeping enzyme and the promoter is useful to drive high expression of these drug markers. The second homology arm can then be placed adjacent to the *neo*^{r} gene with *Not*I and *Xho*I restriction enzyme sites. Since *Not*I is a rare 8-base-pair cutter, this site is useful for linearizing targeting constructs. An example of a targeting construct is illustrated in Figure 19.12.1.

4. While the replacement vector is being constructed, a strategy to identify the targeted clones can be planned using all the collected sequence information about the genomic clone. Typically, to be certain of proper recombination, a Southern blot test should be designed to identify the targeted stem cell clone. With a Southern blot, an appreciable fragment-size difference must appear between the wild-type and the mutated allele. An ideal restriction enzyme should be identified that will best show a band difference from the digested genomic DNA. Southern blot analysis usually tests either the insertion or deletion of a restriction enzyme site due to homologous recombination. A fragment of the genomic clone is generally retained to make a Southern probe that contains sequence flanking the homology arms. This ensures that the Southern probe will not bind with random integrants. Therefore, the only bands to be detected with the Southern probe will be from either the recombined allele or the wild-type gene. PCR can also be used to find properly targeted clones. PCR can provide a fast, high-throughput means to test for targeted clones. With PCR, one primer will typically be designed within the *neo*^{r} gene and the other primer will be located outside the short arm of the replacement vector. Screening by PCR, however, can be tricky since long PCR products need to be amplified. In addition, there is always the risk of either false positives or negatives when using PCR to find a clone. Once a positive clone is identified, though, PCR becomes the preferred strategy to genotype the resulting mutant mice.

DESIGNING A KNOCK-IN TARGETING CONSTRUCT

Designing a knock-in construct follows the same basic rules as a knockout replacement vector. One homology arm, however, must consist of genomic sequence upstream of the protein initiation site. In this case, the 5′ and 3′ homology arms will flank both the knocked in cDNA and a positive drug-selection marker. Be sure to include a pA-addition signal for the knocked in cDNA. Upon recombination, the promoter in the targeted gene will drive expression of the inserted cDNA (Fig. 19.12.5). For efficient homologous recombination, the length of nonhomologous DNA (i.e., the cDNA and *neo*^{r} gene) inserted into a target locus should not exceed

the length of total homology (the long and short arms of the targeting construct).

DESIGNING A CONDITIONAL KNOCKOUT TARGETING CONSTRUCT

With a conventional knockout vector, an essential coding region in the targeted gene is replaced with a drug-selection marker during homologous recombination. For a conditional knockout mouse, however, the final targeted allele needs to be functionally intact. In this case, the end result of gene targeting is the placement of *loxP* sites around an essential coding region to create a floxed allele. Therefore, no sequence should be omitted by gene targeting. Basically, a continuous length of homologous genomic sequence is ideal in making a vector for a conditional knockout. A fragment of the genomic clone is merely cut in two with a restriction enzyme to derive a long and short homology arm. This design contrasts with a conventional knockout, where two separate lengths of homologous genomic sequence are needed to make the targeting vector. One of the homology arms is then modified to position a *loxP* site next to an essential exon for conditional deletion.

While a positive drug-selection marker (i.e., *neo*^{r} gene) is needed for initial enrichment of targeted clones, it must be floxed so that it will not interfere with the final mutated gene. Once the targeted clones are identified, this drug marker is removed by transient transfection to express Cre recombinase. If the correct recombination event occurs, then only a *loxP* site will remain after Cre excises the *neo*^{r} gene. In combination with the *loxP* site in the targeting arm, the exon(s) designated for conditional deletion should basically be floxed upon Cre-mediated rearrangement. However, Cre recombination can also result in the exclusion of the floxed exon(s) or both the exon(s) and the *neo*^{r} gene, so stem-cell clones must be screened to determine the correct rearrangement (Fig. 19.12.4).

1. A homologous 129/Sv genomic fragment continuous with the gene of interest needs to be isolated and characterized. The length of genomic DNA needed for a targeting vector follows the same rules listed for a conventional knockout vector, with roughly 5 to 10 kb of homologous sequence required for efficient recombination. Exon/intron boundaries and restriction-enzyme sites need to be mapped. Afterwards, the coding region to be floxed should be determined. The final *loxP* sites should be located within intronic sequence so that gene expression is not affected. In addition, a *loxP* site should not be designed into any promoter regulatory sequence, as this may interfere with transcription. In the floxed allele, all the coding sequence should be in frame. Again, check for any neighboring open reading frames that could be disrupted after Cre recombination.

2. A plasmid with a floxed *neo*^{r} gene should be acquired to create the targeting construct. A negative-selection marker should also be obtained, such as the *HSV-tk* gene.

3. Restriction enzyme sites in the genomic clone should be identified to aid in the placement of the *loxP* sites. It is best if two unique restriction enzyme sites can be found that flank a vital coding region for placement for the floxed *neo*^{r} gene, as well as a *loxP* site. As mentioned, the *loxP* sites should only be placed in intronic sequences. If available, the floxed *neo*^{r} gene can be subcloned into one of the unique restriction enzyme sites. In the second unique restriction enzyme site, a synthetic *loxP* site can then be ligated into the vector. Oligonucleotides with the *loxP* site and restriction-enzyme site overhangs can be synthesized, annealed, and ligated into the vector. The annealed synthetic oligo should be as shown in Figure 19.12.7.

A *loxP* site consists of two 13-bp inverted repeats that flank an asymmetric 8-bp core (underlined in Fig. 19.12.7). The asymmetric core determines the directionality of the *loxP* site. All *loxP* sites in the targeting construct must be in the same orientation. Otherwise, if the *loxP* sites are in opposite orientation, the floxed sequence will be inverted rather than deleted from the gene. To anneal the oligos, dissolve the DNA to form a 100 ng/μl solution in 10 mM Tris·Cl/50 mM NaCl, pH 8.0. Combine

sense and antisense strands in a microcentrifuge tube, heat at 95°C for 15 min, then let slowly cool to room temperature for proper annealing. If needed, the vector pBS246 can be obtained to procure the *loxP* sites. This plasmid has two *loxP* sites that flank a multiple cloning site (Sauer, 1993). Sequence can then be ligated around the *loxP* sites to get the desired floxed allele.

4. After proper placement of the floxed *neo*^{r} gene and a *loxP* site within the homologous genomic fragment, this cluster should then be ligated together with a negative-selection marker like *HSV-tk*. Again, a unique restriction enzyme site must be located adjacent to the homology arm so that the targeting vector can be linearized.

5. Eventually, after electroporation and isolation of targeted clones, the floxed *neo*^{r} gene should be removed by transient expression of Cre. Therefore, a Cre expression vector must be acquired for generation of the final mutated allele. One such plasmid is pBS185 (Sauer and Henderson, 1990). This vector will express Cre under the CMV promoter.

6. A PCR protocol should be designed to identify the floxed allele. With the sequence information from the genomic clone, primers can be designed to detect wild-type, floxed, and Cre-recombined alleles. If possible, cell culture work should be performed to test Cre excision and PCR analysis before the actual electroporation of the targeting construct into the stem cells.

ABSTRACT

The establishment of mouse embryonic stem (ES) cell lines has allowed for the generation of the knockout mouse. ES cells that are genetically altered in culture can then be manipulated to derive a whole mouse containing the desired mutation. To successfully generate a knockout mouse, however, the ES cells must be carefully cultivated in a pluripotent state throughout the gene-targeting experiment. This unit describes detailed step-by-step protocols, reagents, equipment, and strategies needed for the successful generation of gene knockout embryonic stem cells using homologous recombination technologies. *Curr. Protoc. Cell Biol.* 44:19.13.1-19.13.24. © 2009 by John Wiley & Sons, Inc.

Keywords: mouse embryonic stem cells • homologous recombination

INTRODUCTION

The isolation of murine embryonic stem cells (ES) has been an important discovery necessary for the development of mice with designer mutations (*UNIT 19.12*). Stem cells are capable of self-renewal in culture and can be maintained in an undifferentiated state under certain growth conditions (Support Protocol 2). Stem cells are also totipotent, and, when injected into a host blastocyst (*UNIT 19.14*), can contribute to the somatic and germ-cell lineages of the resulting chimeric mouse. If germline transmission occurs, an offspring of the chimeric mouse can be produced that was derived from the injected ES cell clone. The ability to pass on germline transmission means that a mouse can be generated from ES cells that are genetically manipulated in culture.

With the discovery of homologous recombination, stem cells were seen as an ideal tool that could be used to make genetically altered mice. Homologous recombination in stem cells was first applied for the development of knockout mice through targeted gene inactivation. Eventually, these techniques were adapted for creating conditional knockout mice, knock-in mice, and mice with subtle mutations, such as genetic point mutations, deletions, and insertions. With gene targeting in mice, scientists have been able to create animal models that mimic human genetic diseases. Additionally, these animal models have also provided an important tool for delineating the function of a gene in vivo.

For knockout mouse production, the mouse ES cells must be transformed with a plasmid bearing the target gene construct (*UNIT 19.12*). Electroporation is the method of choice for transforming the cells. Once electroporated, the ES cells are subjected to drug selection, cloned, frozen, and characterized (Basic Protocol 2).

NOTE: All solutions and equipment coming into contact with living cells must be sterile, and aseptic technique should be used accordingly.

NOTE: All cell culture incubations should be carried out in a 37°C, 5% CO_2 humidified incubator unless otherwise indicated.

BASIC PROTOCOL 1

INTRODUCTION OF PLASMID DNA INTO PLURIPOTENT MOUSE EMBRYONIC STEM CELLS

With the discovery of homologous recombination, scientists quickly realized that ES cells would be useful for gene-targeting experiments. A targeting construct is delivered into a stem cell where homology arms in the vector align with a targeted genetic locus to introduce a gene modification. While not exactly the most efficient technique for producing homologous recombination events, electroporation (Basic Protocol 1) became the preferred and easiest way for mass delivery of targeting constructs into a large number of stem cells (Vasquez et al., 2001). Targeting constructs usually contain a positive drug-selection marker to enrich for clones that have successfully taken up the vector. The neomycin phosphotransferase (*neo*^{r}) gene is a well known positive-selection marker that confers resistance to the drug neomycin sulfate (G418) in tissue culture. In addition, gene-targeting vectors also generally include a negative drug-selection marker outside of the homology arms to select against random integrants (Mansour et al., 1988). For example, the HSV thymidine kinase (*HSV-tk*) gene is a widely used negative selection marker that phosphorylates drugs like gancyclovir or FIAU (1-[2′-deoxy-2′-fluoro-β-D-arabinofuranosyl]-5-iodouracil) into cytotoxic compounds. Clones with random integration of the complete vector are thereby excluded upon drug treatment. Thus, after electroporation of the targeting construct, the stem cells are plated onto culture dishes and treated for about 10 days under drug selection to select for clones that have undergone a true homologous recombination event. Once a stem cell with the designated genetic alteration is identified, the ES cell clone is then usually expanded and injected into a blastocyst to derive a chimeric mouse containing cells with the targeted mutation (*UNIT 19.14*). The mice produced from mating chimeric mice with the wild-type mice will be either wild-type or heterozygous for the targeted mutation, and these heterozygous mice must be bred to homozygosity.

Materials

Naïve (non-electroporated) ES cells growing in culture (Support Protocol 2) on mitotically arrested feeder layers (Support Protocol 1) in 6-cm^2 dishes
Embryonic stem cell medium (ESM; see recipe)
Targeting vector (*UNIT 19.12*)
Electroporation buffer (EB; see recipe)
Calcium- and magnesium-free Dulbecco's phosphate-buffered saline (CMF-DPBS; Cellgro)
0.25% (w/v) trypsin/EDTA (Invitrogen)

15- and 50-ml sterile disposable centrifuge tubes
Refrigerated centrifuge
Electroporation cuvette 0.4-mm gap (BioRad)
Gene Pulser Xcell electroporation system with capacitance extender (BioRad)
250-ml disposable plastic Erlenmeyer flask, sterile (Corning)
6-cm^2 tissue culture plates of PMEF cells (MMC-treated; Support Protocol 1)

Additional reagents and equipment for restriction enzyme digestion (Bloch and Grossman, 1995), confirmation of linearized targeting vector (e.g., agarose gel electrophoresis; Voytas, 2000), ethanol precipitation of DNA (Moore and Dowhan, 2002), and counting cells (*UNIT 1.1*)

Prepare ES cells and vector

1. Refeed the ES cell culture dishes with ESM to encourage cell growth before electroporation. Grow cells to 70% to 80% confluency.

   Cells should be ready for electroporation (step 10) in 2 to 3 days, depending upon the plating density.

2. Linearize the targeting vector with the appropriate restriction enzyme (Bloch and Grossman, 1995). Confirm that the targeting vector is linearized by running a small aliquot of the digested vector on an agarose gel (Voytas, 2000). Dry the vector, generally through ethanol precipitation (Moore and Dowhan, 2002).

   The plasmid should be free of any contaminants such as ethanol and phenol.

3. Dissolve 25 μg of targeting vector in 25 μl of EB to make a final concentration of 1 μg/μl DNA.

   In other protocols, the targeting vector is dissolved in sterile CMF-DPBS.

Collect ES cells

4. Aspirate the medium from the ES cell dishes, and wash with 2 ml of CMF-DPBS per dish.

5. Aspirate the CMF-DPBS and then cover the cells with 1 ml of 0.25% trypsin/EDTA per dish. Incubate for 3 min at 37°C.

6. Inactivate the trypsin by adding 4 ml ESM per dish. Pipet the cells vigorously up and down to dissociate the stem cell colonies into a single-cell suspension.

7. Pool the cell/medium mixture from all the dishes and collect in a 50-ml centrifuge tube. Wash any residual cells remaining on the culture dishes with an additional 5 ml of ESM and add to the pooled cell suspension.

8. Centrifuge the ES cells 5 min at 693 × *g*, 4°C.

9. Aspirate the supernatant and resuspend the pellet in 5 to 10 ml ESM.

   10 ml is a convenient volume for calculation of total number of cells.

Prepare cells for electroporation

10. Count a small aliquot of the ES cells using either a hemacytometer (*UNIT 1.1*) or an automated cell counting device.

    If using the hemacytometer, the ES cells will appear rounder and smaller than the arrested feeder cells. Some investigators use trypan blue to differentiate between dead and live cells. The dead (blue) cells will not be able to remove the trypan blue and should be excluded from the count if using a hemacytometer.

11. Select a volume of cell suspension that will ensure that at least 1×10^7 cells are available for the electroporation and transfer to a 1.5-ml microcentrifuge tube.

12. Centrifuge the ES cells 5 min at 693 × *g*, 4°C. Aspirate the supernatant and resuspend the cell pellet in 0.8 ml of EB.

    Some investigators have used sterile phosphate-buffered saline on ice as the buffer for electroporation.

13. Transfer the cell suspension to a sterile 1.5-ml microcentrifuge tube.

Electroporate the cells

14. Add the targeting construct (from step 2) to the tube containing the ES cells, and gently mix the DNA with the ES cells.

    At this stage, it is important to have a single-cell suspension.

15. Transfer the mixture to a 0.4-mm electroporation cuvette (try to avoid forming air bubbles).

16. Place the cuvette into the shock pod of the electroporator so that the metal plates on the cuvette are in contact with the metal plates of the shock pod.

17. Electroporate the cell suspension at the appropriate setting.

For most cells, e.g., R1, use settings of 230 V, 500 μF, and an electrode gap of 0.4 cm with an exponential decay. With these settings, the time constant should be between 5.6 to 8.0 msec, depending upon the solutes in the medium and the cell concentration. Alternatively, settings of 400 V and 25 μF have been used. In this case, the time constant should be between 0.4 and 0.5 msec.

After the shock, bubbles or foam at the top of the cuvette may be apparent, signaling that current has passed through the solution.

Optimal settings will vary depending upon ES cell type and must be determined experimentally.

Plate the electroporated cells

18. After electroporation of the cells, leave the cuvette containing the electroporated cells at room temperature for 10 min.

For mammalian cells, it is not critical to chill the cells before or after electroporation.

19. Transfer the entire contents of the electroporation cuvette to 200 ml of ESM in a sterile disposable 250-ml Erlenmeyer flask, resulting in a concentration of 5×10^4 cells per ml to be plated onto feeder dishes. Wash the cuvette with about 0.8 ml of the ESM and transfer to the flask to retain as many of the electroporated cells as possible.

As a result of electrophoretic shock, many of the cells will die off and will be seen floating in the medium. With the initial cell density of 1×10^7 cells, enough cells should survive to undergo drug selection.

20. Plate 4 ml electroporated cells per 6-cm^2 plate with mitomycin C–treated PMEF feeder cells. Incubate at 37°C.

BASIC PROTOCOL 2

SELECTING, FREEZING, AND CHARACTERIZING DRUG-RESISTANT ES CELLS

Successfully electroporated ES cells are exposed to a selecting drug based on the plasmid structure. These cells will survive the selection process and can be used for creating chimeric mice.

Materials

Electroporated ES cells (Basic Protocol 1) growing in 6-cm^2 dishes
Embryonic stem cell medium (ESM; see recipe)
Positive selection agent (G418; see recipe)
Negative selection agent (FIAU; see recipe)
Naïve (non-electroporated) ES cells
Calcium- and magnesium-free Dulbecco's PBS (CMF-DPBS; Cellgro)
0.25% (w/v) trypsin/EDTA (Invitrogen)
2× ES cell freezing medium (see recipe)
0.2% gelatin (from porcine skin, type A; Sigma) in tissue culture-grade water, sterilized by autoclaving
Liquid nitrogen

Pipettor from 20 μl to 200 μl to mix cell suspensions, plus sterile tips (Rainin)
Pipettor from 200 μl to 1000 μl to mix cell suspensions, plus sterile tips (Rainin)
Repeat pipetting device from 100 μl to 1000 μl (useful but optional; Eppendorf)
Light-Touch Pipetting System (Rainin; optional) requires less hand pressure and reduces fatigue
24-well tissue culture plates (Fisher Scientific)
Forceps

Flame sterilizer (Fireboy Plus, Integra Biosciences)
Glass cloning cylinders in petri dish (see recipe)
2-ml liquid nitrogen cryovials (Nalgene/Nunc)
12-well tissue culture plates (Fisher Scientific)
Mr. Frosty slow-cool chamber (Nalgene) containing isopropanol (Fisher Scientific)
Liquid nitrogen freezer (Thermo-Forma)

Additional reagents and equipment for preparation of PMEF feeder plates (Support Protocol 1), purification of DNA by isopropanol precipitation (Laird et al., 1991), Southern blotting (Brown, 1993), and PCR (*APPENDIX 3F*)

Treat electroporated ES cells with selective drugs

1. Begin drug selection for resistant clones (as described in the steps below) within 20 hr of electroporation of targeting vector DNA into ES cells (see Basic Protocol 1).

   Drug selection helps reduce the population of nontargeted ES cells.

2. Treat the majority of dishes with ESM supplemented with positive drug-selection agent (G418) and negative selection agent (FIAU). Treat one or two dishes with ESM and G418 only (i.e., only positive drug selection) to check for the degree of random targeting vector insertion (targeting vector inserted randomly in the genome should include the *HSV-tk* cassette, and this would be toxic to the ES cell colony).

   If diphtheria toxin A (DTA) is the negative selection cassette, no negative selection agent is necessary.

   The ideal G418 concentration must be determined experimentally for each ES cell strain by performing a kill curve. Briefly, plate 1 × 10^6 naïve (non-electroporated) ES cells. Start with a G418 concentration of 150 μg/ml and increase in 50- to 100-μg increments to a maximal concentration of 350 μg/ml. Grow the cells 3 to 4 days, feeding daily. On the third or fourth day, assess the number of viable cells (UNIT 1.1) per concentration. Select the lowest concentration that kills all of the naïve ES cells within 3 to 4 days of selection pressure to use for drug selection.

   The FIAU is used at an 0.2 μM concentration. To obtain this concentration in the ESM plus G418 plus FIAU medium, add 0.444 ml of the 270 μM negative selection agent (FIAU) stock solution (see recipe in Reagents and Solutions) to 600 ml of the ESM plus G418 solution (G418 concentration determined as described above), which will result in 0.2 μM FIAU.

3. Replace the medium daily with ESM plus G418 plus FIAU for 4 to 5 days, followed by ESM plus G418 only for 3 to 4 days.

   The total period for drug selection should be about 8 to 10 days.

4. After this period, assess the dishes for pinpoints of circular, white, drug-resistant colonies that are visible without a microscope. Lift each dish and circle the underside of the dish to mark candidate colonies for expansion.

   Colonies that are starting to differentiate will sometimes appear more flat, with a diffuse haze around them. Avoid picking these colonies.

Prepare PMEF plates for receiving colonies

5. The day before picking colonies, prepare 24-well MMC-treated PMEF feeder plates to receive the targeted clones for expansion as described in Support Protocol 1, at a concentration of 0.8 to 1.0 × 10^5 cells/ml. Dispense 0.5 ml of the feeder suspension per well on gelatinized 24-well plates. Prepare enough plates and wells to receive at least 200 colonies.

   The gelatinization of the plates is also described in Support Protocol 1.

6. The next day, replace the 0.5-ml volume per well in the 24-well plates with 1 ml of ESM, before starting to pick the stem cell colonies from the 6-cm^2 dishes.

Pick colonies

7. Aspirate the medium from one 6-cm^2 dish of drug-treated ES cells and replace with 1 to 2 ml of CMF-DPBS.

   The CMF-DPBS washes away the serum from the ESM, which would inhibit the action of trypsin in subsequent steps.

8. Aspirate the CMF-DPBS from the dish of cells. Sterilize a pair of forceps with a flame sterilizer and use the forceps to vertically lift the cloning cylinders swiftly off the glass dish.

   The grease should be evenly distributed along the bottom of the cylinder.

9. Place a greased cloning cylinder around a marked suitable colony and gently press onto the culture dish. Ensure that the cylinder is positioned around only a single colony so that no adjacent colonies are harvested in the process.

   Whenever possible, try to avoid picking two colonies in close proximity to each other. In such cases, one colony may pass on neomycin resistance to the nearby colony, and as both colonies would fit under the same cloning cylinder, they would be picked together. This is called the "bystander effect."

10. Repeat these steps (flaming the forceps each time) until all good colonies on the dish have a cloning cylinder above them.

11. Using the repeat pipettor, dispense 200 µl of 0.25% trypsin/EDTA into each cloning cylinder.

    The vacuum grease will hold the liquid inside the cylinder, acting as a miniwell.

    Usually it is best to limit the number of dishes to one or two at a time, to prevent over-trypsinizing the colonies.

12. Incubate the dish in the tissue culture incubator for 3 min at 37°C.

13. After 3 min, use a 200-µl pipet and a sterile tip to pipet the trypsin up and down in the cloning cylinder.

    Pipetting is needed to disperse the colony clumps. If dissociated correctly, a single-cell suspension should be achieved through trypsinization.

14. Take the entire contents of each miniwell on the dish and dispense into one well of the 24-well plate (prepared in steps 5 to 6) containing MMC-treated PMEFs in 1 ml of ESM supplemented with G418 (see step 2 annotation for determining appropriate concentration).

15. Repeat steps 13 and 14, using new pipet tips each time, until all the colonies have been transferred to the 24-well plates of feeders.

16. Replace the medium in the 24-well feeder plates every day with 1.0 ml/well of ESM supplemented with G418 until the ES cells have grown sufficiently. Watch the stem cells daily. Be prepared to freeze the cells whenever the growing colonies in the well appear to be getting confluent or close to touching.

    The stem cells should be ready for harvesting within a few days after the colonies are isolated with the cloning cylinders.

    While an ample number of cells need to be grown for storage and freezing, ensure that the stem cell culture does not become overgrown and start to differentiate. The ES cell colonies should have very smooth, sharp borders (see Figure 19.13.3) and should not appear flat.

If the medium indicator appears orange to yellow, then the colonies are probably over-confluent and may be ready to differentiate. These wells should be avoided whenever possible.

17. Prepare the 2× ES cell freezing medium at this stage (see Reagents and Solutions). Dispense 0.5 ml of 2× ES cell freezing medium into each 2-ml cryovial and store at 4°C.

18. Prepare gelatinized 12-well plates by adding 1 ml/well of 0.2% gelatin and then incubating ~30 min at room temperature in a sterile laminar flow hood. Discard gelatin solution and allow dishes to dry to provide a surface for cells to attach.

    These plates will be needed for DNA testing of the potentially targeted clones.

19. Examine each well daily to determine which colonies need to be frozen down. Mark the appropriately confluent wells on the 24-well plates to prepare for harvesting, leaving the subconfluent wells unmarked until they become confluent.

    The growth rate of the stem cell colonies will vary among the wells on the tissue culture plate. Often, these differences can be due to the number of cells recovered when picking the colonies.

Freeze clones

20. Aspirate the medium from the marked wells and replace with 1 ml/well of CMF-DPBS.

21. Replace the CMF-DPBS with 200 µl of 0.25% trypsin/EDTA and transfer to the incubator for 3 min at 37°C.

22. Neutralize the trypsin with 800 µl of ESM.

    The total volume in each well of the marked 24-well plates should be 1 ml.

23. Using a 1-ml pipettor with a sterile tip, pipet up and down to make a single-cell suspension.

    It is often convenient to use a pipettor that requires less force to pipet up and down, particularly when many clones are to be frozen down. We have used the Light-Touch Pipetting System pipettors and pipet tips (Rainin) for this purpose.

24. Remove 500 µl of the cell suspension and transfer it to a prefilled freezer vial (see step 17) to make the total volume 1 ml. Place the freezer vials in a slow-cool chamber and place the chamber in a –80°C freezer.

25. Add 500 µl ESM to each gelatin-coated well of a gelatinized 12-well plate (see step 18). Transfer the remainder of the cell suspension (~500 µl) to an ESM-containing well of the plate. Transfer the 12-well plates to the incubator.

    Over several days, the ES cells in the 12-well plates should differentiate and overgrow, resulting in the color of the indicator in the medium turning yellow. It is not necessary to maintain pluripotency in the 12-well plates, since the cells will only be used to purify genomic DNA.

26. After collecting the stem cell freezer vials, transfer the vials in the slow-cool chamber into a −80°C freezer (the temperature in the chamber should drop about 1°C/min).

27. Once the freezer vials are frozen to −80°C, transfer the vials to a liquid nitrogen freezer for longer-term storage.

    Generally, these tubes should be stored in the vapor phase of the freezer, which minimizes the chance of the plastic cracking, which would result in liquid nitrogen seeping into the freezer vials and cross-contaminating the samples.

Verify that the clones contain the desired sequence

28. Purify genomic DNA from the clones on the gelatinized plates with medium that has turned yellow, indicating overgrown cells (Laird et al., 1991).

    Briefly the cells are lysed with proteinase K solution and DNA is precipitated using an equal volume of isopropanol. The DNA clump is picked out of solution, briefly dried, then transferred to water or 1× TE buffer.

29. Use the purified DNA to determine whether a targeted event has taken place, either by Southern blot hybridization (Brown, 1993) or by PCR (*APPENDIX 3F*).

SUPPORT PROTOCOL 1

CULTURE OF PRIMARY MOUSE EMBRYONIC FIBROBLASTS AND PREPARATION OF MOUSE EMBRYONIC STEM CELL FEEDERS

For a gene-targeting experiment, mouse embryonic stem cells in culture need to be maintained in a pluripotent stage until they are injected into mouse blastocysts. Usually, to maintain these conditions, a feeder cell layer is used to provide an environment that helps to prevent differentiation. The feeder cells secrete unknown growth factors that help preserve pluripotency. Feeder cells are produced from either STO embryonic fibroblasts or primary mouse embryonic fibroblasts (PMEFs). PMEFs are typically employed in gene-targeting experiments and are derived from embryonic day 14.5 embryos. The embryos are minced, and the dissociated cells are placed into culture. The adherent fibroblasts are then usually passaged a few times to obtain an adequate number of cells to be frozen in aliquots. PMEFs can also be purchased from commercial sources, which can save time and cage space. One important point is that the PMEFs should be resistant to whichever positive selection cassette is used within the gene-targeting construct (e.g., neomycin). Otherwise, this feeder layer will not support ES cell growth once the drug selection is introduced. PMEFs can be generated from the embryos of an established knockout mouse that bears the same drug-resistance cassette (see Support Protocol 1 materials list). Fibroblasts derived from the knockout mice should have the necessary resistance cassette integrated into their genome. Feeder cells need to be growth inhibited before coculture with ES cells. Typically, the cells are mitotically inactivated either by treatment with the drug mitomycin C or through γ irradiation. If using mitomycin C treatment, be sure to wash the cells thoroughly since this drug can cause differentiation of the stem cells. To enhance the growth conditions needed to maintain pluripotency, the culturing of ES cells on PMEFs is usually supported by the use of gelatin-coated plates and the addition of LIF (leukemia inhibitory factor) to the stem cell medium. LIF is a cytokine that helps to prevent differentiation of the cells. While ES cells can be maintained with LIF in the absence of PMEFs, an increased tendency towards differentiation will develop with long-term culture of these cells (Nichols et al., 1990). This seems to be the case especially with ES cells that have undergone many passages. A brief illustration depicting the critical steps in the generation of targeted embryonic stem cells is shown in Figure 19.13.1.

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) and conform to governmental regulations regarding the care and use of laboratory animals.

Materials

Male mice harboring a positive-resistance cassette on both alleles (e.g. homozygous knockout mice such as α-galactosidase A knockout mice obtained from The Jackson Laboratory, Accession no. 003535); and homozygous knockout female mouse

Calcium- and magnesium-free Dulbecco's phosphate-buffered saline (CMF-DPBS; Cellgro)

70% ethanol
0.05% (w/v) trypsin/EDTA (Invitrogen)
Embryonic feeder medium (EFM; see recipe)
2× PMEF cell freezing medium (see recipe)
0.2% gelatin (from porcine skin, type A; Sigma) in tissue culture-grade water, sterilized by autoclaving
Embryonic feeder medium (EFM) containing 10 μg/ml mitomycin C (see recipe)
10-cm^2 and 6-cm^2 tissue culture-grade dishes (non-gelatin-coated; Fisher Scientific)
Curved iris scissors (Roboz Surgical Instruments)
Straight fine scissors (Roboz Surgical Instruments)
Forceps
Sterilizer pouches to autoclave instruments (Fine Science Tools)
Single-edged razor blades
50- and 15-ml conical centrifuge tubes
Dedicated centrifuge able to achieve 4°C (e.g., Beckman-Coulter Allegra X-22R)
2-ml cryovials (Nalge/Nunc)
Mr. Frosty slow-cool chamber (Nalgene) containing isopropanol (Fisher Scientific)
250-ml disposable plastic Erlenmeyer flasks, sterile (Corning)
Additional reagents and equipment for euthanasia of the mouse (Donovan and Brown, 2006) and counting cells (*UNIT 1.1*)

Collect embryos

1. Mate homozygous knockout male mice harboring a positive resistance cassette to a similar homozygous knockout female mouse.
2. The next morning, observe the copulation plug (embryonic day 0.5) and wait until the embryos are embryonic day 13.5 to 14.5.
3. Prepare three 10-cm^2 tissue culture dishes each containing 15-ml sterile CMF-DPBS; also prepare sterile, autoclaved scissors and forceps.
4. Euthanize the mouse by CO_2 asphyxiation, cervical dislocation, or whichever method has been approved by your Institutional Animal Care and Use Committee.

   Donovan and Brown (2006) provides protocols for all common methods of mouse euthanasia.

5. Wipe the fur surrounding the abdominal cavity with 70% ethanol to clean it and to prevent fur and dander from entering into the abdominal cavity.
6. Make a vertical incision into the abdominal cavity and locate the uterus.

   The uterus should be swollen with embryos, resembling a sac with many bulges.

7. Detach the uterus at both ends with the straight scissors and remove from the abdominal cavity with fine-tipped scissors. Place the uterus into one of the 10-cm^2 dishes filled with 15 ml sterile CMF-DPBS that were prepared in step 3.
8. Move the uterus around in the dish to wash off some of the blood.
9. Carefully cut open the uterus, releasing the embryos into the CMF-DPBS.

Dissect embryos

10. Remove the placenta and membranes. Transfer the embryos to a new 10-cm^2 dish of CMF-DPBS (prepared in step 3).
11. Hold each embryo with forceps, scoop out the liver, and decapitate the embryos with a single-edged razor blade.

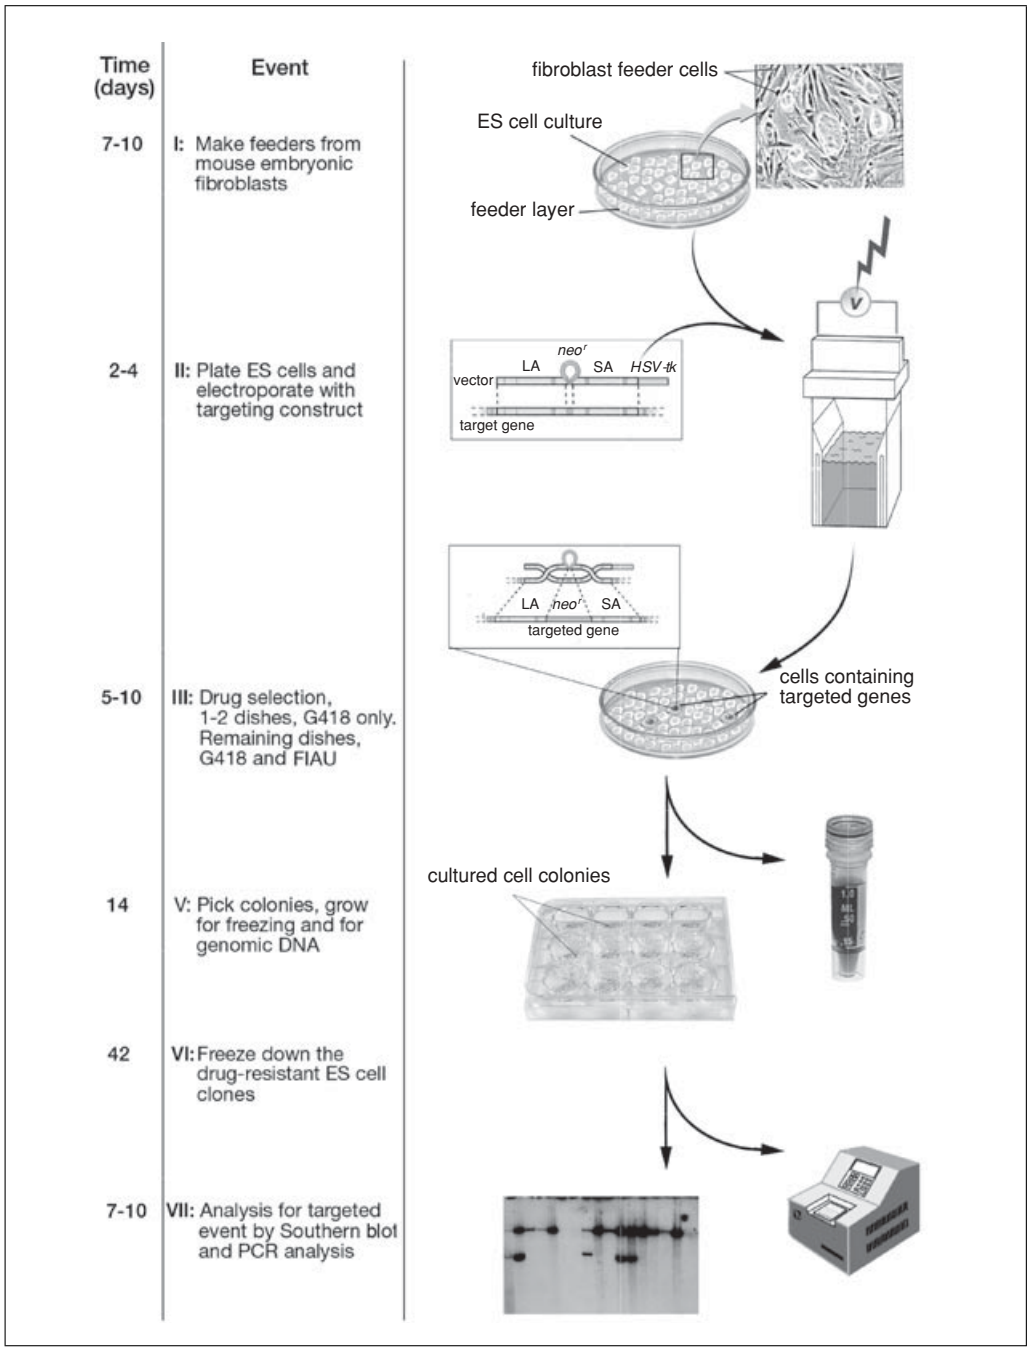

Figure 19.13.1 Overview of electroporation and selection. The left column shows the approximate number of days at each critical stage in the preparation of targeted embryonic stem cells. The middle column describes key procedural events. The right column is an illustration of each critical event. Note that in stages II through V, embryonic stem cells should remain as close to pluripotent as possible. Once the cultured ES cells have been plated to the tissue culture plate depicted in stage V, they may become differentiated. These cells will used for DNA screening as depicted in stage VII. In stage VII, the left panel represents an autoradiographic film image of a Southern blot. Southern blotting is the definitive test for detection of a targeted event. Many investigators first screen all clone DNA samples by PCR followed by confirmation with Southern blot. A strategy for differentiating between the knockout allele and the wild-type allele should be worked out in advance of initiating a targeting experiment.

12. Rinse the embryo carcasses and transfer to the third new 10-cm^2 dish of CMF-DPBS that was prepared in step 3. Try to get rid of as many red blood cells as possible.

Digest embryos

13. Prepare one 10-cm^2 tissue culture dish with 15 ml of 0.05% trypsin/EDTA. Place this dish inside a clean laminar flow hood. Place the decapitated embryos into the trypsin dish and quickly mince the tissue with the forceps and curved scissors until the tissue can be sucked up into a 10-ml serological pipet. Pipet minced tissue up and down into the same dish six to seven times.

14. Add another 5 ml of 0.05% trypsin/EDTA, and continue to disperse the tissue with a narrower-bore 5-ml pipet, using the technique described in step 13.

15. Place this dish in the incubator for 10 min.

Collect cells

16. Transfer the contents of the dish to a sterile 50-ml conical tube and allow the undigested tissue to settle at the bottom of the tube.

    This should take about 2 min.

17. Decant the supernatant to a new, empty sterile 50-ml tube and bring the volume up to 50 ml with EFM.

18. Centrifuge this tube 5 min at 193 × *g*, 10°C. Discard the supernatant.

Culture the cells

19. Resuspend the cell pellet in 50 ml fresh EFM. Transfer 10 ml of suspension to a sterile 10-cm^2 tissue culture dish.

20. Allow the fibroblasts to attach overnight in the incubator. The next day replace the medium from each dish with 10 ml EFM. Allow these fibroblasts to grow until the plates appear confluent.

    At this point the primary mouse embryonic fibroblasts (PMEF) will be passage 0.

    Often, passage 0 fibroblasts are "split" into several more dishes to permit preparation of a bigger batch of frozen PMEF.

Expand PMEFs for frozen stock

21. To split the PMEF, aspirate the EFM from each plate. Add ~5 ml CMF-DPBS to each dish, and then aspirate the CMF-DPBS off of the dish.

    This wash reduces the number of dead cells and removes any serum remaining from the medium, which can inhibit the action of trypsin.

22. Add 2 ml 0.05% trypsin/EDTA to the dish and place in the tissue culture incubator at 37°C for 3 min.

23. Gently tap the side of the tissue culture dish and check that the PMEF have detached from the bottom of the dish.

24. Add 3 ml EFM to the dish to stop the action of trypsin. Pool all the dishes that were trypsinized in a 50-ml sterile tube and bring the volume up to the amount necessary for 10 ml of cells per 10-cm^2 dish. Replate cells at 10 ml/10-cm^2 dish and return to incubator.

    For example a splitting ratio of 1:3, would require 10 ml cell suspension to 20 ml EFM.

    The passage number of the newly split cells would now be passage 1 (P1). Depending upon the density of the PMEF, the dishes will be confluent in about 4 or 5 days.

Freeze aliquots of PMEFs

25. Prepare cell suspensions as described in steps 21 to 24.

    We generally freeze down aliquots of PMEF at passage 3.

26. Count a small aliquot of the cell suspension with a hemacytometer (*UNIT 1.1*) or automated counting device.

    Using a hemacytometer, 10 μl of cell suspension is added to the chamber and will flow by capillary action to the counting grid. Count the number of PMEF in each outer corner square. Divide this total number by 4 for the average number per square. Multiply this value by 1×10^4 (the cubic volume) to get the number of cells per ml.

    The number of dishes prepared for freezing should be sufficient for 2×10^7 cells per 0.5 ml volume.

27. Combine 0.5 ml of the cell suspension with 0.5 ml of 2× PMEF cell freezing medium per 2-ml cryovial. Freeze a large batch of vials by placing the vials into a slow cool chamber. Transfer the chamber to a –80°C freezer overnight. Then, transfer the vials to a liquid nitrogen freezer for longer term storage.

    The final concentration will be 1×10^7 cells per vial.

28. Test two or three representative vials for mycoplasma and other potential mouse pathogens before a stem cell experiment is initiated.

    Many commercial services perform this mouse pathogen testing (e.g., GlobalStem, Rockville, Maryland; http://www.globalstem.com).

Expand PMEFs for production of feeders

29. Prewarm 9 ml of EFM in a sterile 15-ml tube to 37°C.

30. Thaw a vial of PMEF in the 37°C water bath until the cells are half thawed.

31. Clean the exterior surface of the vial with 70% ethanol.

32. Take one-half of the vial's total volume (generally a total of 1 ml) and transfer to the centrifuge tube with the prewarmed EFM (prepared in step 29), then transfer a portion of the prewarmed medium back into the cryovial to thaw the remaining PMEF stock.

    This ensures the rapid thawing of the PMEF and the quick dilution of the freezing medium containing DMSO.

33. Aspirate the entire contents of the cryovial back into the centrifuge tube.

34. Centrifuge the cells 5 min at $693 \times g$, 4°C, and aspirate the supernatant.

35. Resuspend the cell pellet in 20 ml EFM, and then dispense the medium and cells at 10 ml per dish to give two 10-cm^2 dishes.

36. Transfer the dishes to a tissue culture incubator at 37°C with 5% CO_2.

    After 3 to 4 days, depending upon the density of cells, the PMEFs should be confluent. It is not necessary to re-feed the confluent PMEFs prior to splitting.

37. Once confluent, aspirate the medium from each dish and wash the cells by adding 2 ml/dish CMF-DPBS (to cover the cells).

38. Aspirate the CMF-DPBS, and then cover the cells with cold 0.05% trypsin/EDTA (2 ml per dish).

39. Incubate for 3 min at 37°C until the PMEFs to detach from the dish.

40. Neutralize the trypsin by adding EFM (3 ml per dish). Pipet up and down several times to detach the cells and make a single-cell suspension.

41. Pool the medium from both dishes into a 50-ml centrifuge tube. Wash off any remaining cells on the culture dishes with an additional 5 ml EFM and add to the pooled medium.

42. Centrifuge 5 min at 693 × *g*, 4°C.

43. Aspirate the supernatant, resuspend the cells, and dilute in a sterile 250-ml Erlenmeyer flask with EFM to a volume of 150 to 200 ml total.

44. Add 10 ml of the cell suspension per 10-cm^2 dish to make 15 to 20 dishes of PMEFs.

Treat PMEFs with mitomycin C (MMC)

45. Gelatinize about forty 6-cm^2 dishes by adding 4 ml/dish of 0.2% gelatin and incubating for ~30 min at room temperature in a sterile laminar flow hood. Discard the gelatin, and allow the dishes to dry to provide a surface for the PMEF to attach.

46. Replace the EFM medium in 15 dishes (~5 dishes at a time) of PMEF with EFM containing 10 μg/ml mitomycin C. Reserve the remaining 5 dishes of PMEF for MMC treatment later in this protocol.

    CAUTION: *MMC is a potent toxin, so care must be taken to handle it carefully and to dispose of it as chemical waste.*

47. Place the MMC-treated PMEF in the incubator for 3 hr to permit mitotic arrest of the PMEF.

48. Aspirate the EFM with the MMC into the appropriate chemical waste container. Wash each dish three times, each time with 5 ml CMF-DPBS, to ensure total removal of the MMC. Treat the washes as hazardous chemical waste.

49. Add 2 ml/dish of 0.05% trypsin/EDTA to cover the fibroblasts in each dish and incubate 3 min at 37°C.

50. Neutralize the action of trypsin by adding 3 ml/dish of EFM, and pool the volume (5 ml) from each dish into a 50-ml centrifuge tube. Wash each stack of 5 dishes with an additional 5 ml of EFM and add to the pooled cell suspension.

51. Centrifuge 5 min at 693 × *g*, 4°C.

52. Aspirate the medium, then resuspend the pooled cell pellets in a convenient concentrated volume (e.g., one-tenth of the original volume, ~15 ml).

53. Count a small aliquot of the cell suspension using either a hemacytometer (*UNIT 1.1*) or an automated cell counting device. Dilute the cells in EFM to a concentration of 0.8–1.0 × 10^5 cells per ml.

    This concentration is ideal to form a monolayer for the ES cells to grow.

54. Transfer this cell suspension to at least 25 gelatin-treated 6-cm^2 dishes that were prepared in step 45.

    Within the next day or two, the feeders will assume a cobblestone-like appearance (see Figure 19.13.2). These feeders will secrete factors into the medium, which will provide an environment along with LIF (leukemia inhibitory factor) for the mouse ES cells to grow.

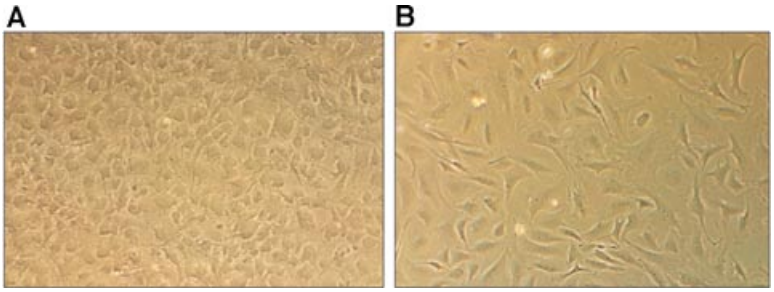

Figure 19.13.2 Mitotically inactivated ES cell feeders and PMEF. (**A**) Primary mouse embryonic fibroblasts that have been treated with mitomycin C. Note that occasionally the mitomycin–C treated PMEFs will not appear as dramatically different as shown in panel A when compared with panel B. The treatment arrests the cell division and the cells produce cytokines, which inhibit differentiation of ES cells. Note that the cell bodies appear swollen and suggest a cobblestone-like appearance. (**B**) PMEFs that have not been treated with mitomycin C. These fibroblasts have a elongated and sickle-shaped appearance. For color version of figure go to *http://www.currentprotocols.com/protocols/cb1913*.

SUPPORT PROTOCOL 2

CULTURING MOUSE EMBRYONIC STEM CELLS

Embryonic stem cells must be cultured under carefully controlled conditions to maintain the pluripotent state and prevent differentiation.

Materials

Embryonic stem cell medium (ESM; see recipe)
Pluripotent mouse embryonic stem cells (as frozen stocks; lower passage preferred, usually no more than 20 passages) e.g.:
R1 (129 strain–based; ATCC, cat. no. SCRC-1011)
W4129/S6 (129 strain–based; Taconic, cat. no. ES_W412956)
Bruce4 (C57BL/6 strain–based; Millipore, cat. no. SF-CTMI-2)
Pluristem B6 albino (C57BL/6 strain–based; Millipore, cat. no. SCR011; note these cells require IMDM media and 7% CO_2 humidified incubation)
Mouse embryonic feeder in 6-cm^2 tissue culture dishes (Support Protocol 1)
0.25% (w/v) trypsin/EDTA (Invitrogen)
15-ml centrifuge tubes, sterile

1. Prewarm 9 ml of filter-sterilized ESM in a sterile 15-ml centrifuge tube to 37°C.
2. Thaw one vial of ES cells (1 ml) by warming until half-thawed at 37°C. Transfer half the contents to the medium-containing tube (from step 1) and mix. Transfer 0.5 ml of the medium back to the cryovial, thaw the remaining cells, then transfer to the medium-containing 15-ml tube and mix.

   This dilution is done in order to dilute out the DMSO cryoprotectant.

   Generally, the ES cryovial should contain about 1×10^6 cells. If the vial contains too few cells, then growth may be inhibited. If the vial contains too many cells, then differentiation may occur, as the cells will be too close to each other.

3. Centrifuge the ES cells 5 min at $693 \times g$, 4°C.
4. Gently resuspend the cells in 5 ml ESM then transfer to a 50 ml tube and add another 10 to 15 ml ESM at 37°C.
5. Aspirate the EFM from three to four feeder dishes created in Support Protocol 1, and replace with 4 ml of the ES cell suspension (from step 4) per dish.

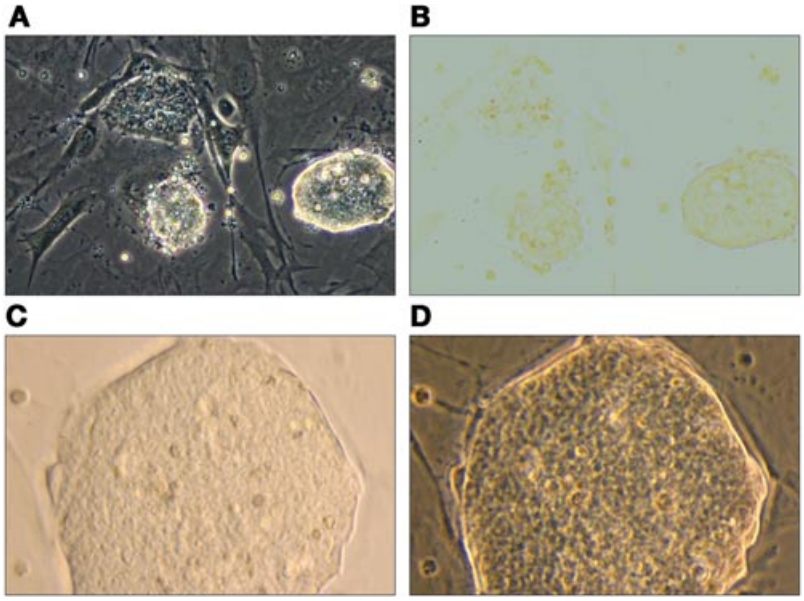

Figure 19.13.3 (**A, D**) Images of embryonic stem cells taken with phase-contrast filter. (**B, C**) Bright field images of the same cells in (A, D). The advantage of the phase-contrast filter is in highlighting the sharp borders of the ES cell colonies as well as the underlying feeder cells. (**A**) Embryonic stem cells under drug-selection pressure. The far-right colony appears to be surviving drug selection (note the sharp, bright border). The other two colonies (rough border) probably would not survive drug selection. (**D**) A high magnification of a good embryonic stem cell colony. The border appears very sharp and the embryonic stem cells within the mass appear indistinguishable from each other. For color version of figure go to *http://www.currentprotocols.com/protocols/cb1913.*

6. Once ES cells have been plated onto feeders, feed daily with ESM (which contains LIF to help maintain pluripotency).

   Depending upon the freezing density of the ES cells, the plate should be ready for harvesting in 2 to 3 days.

   Under suitable conditions, the ES-cell colonies should have very smooth, sharp borders with respect to the underlying feeders and have a dome-like, almost shiny appearance (see Figure 19.13.3 panel A and D).

7. Split stem cells maintained in culture 1:3 or 1:4 every 2 to 4 days to prevent differentiation. Use 0.25% trypsin to dissociate the ES cells and form a single-cell suspension; stop the action of trypsin by adding ESM (see Basic Protocol 1).

   Differentiation can occur if the stem cells are plated at either too low or too high a density. The stem cell colonies should not be allowed to become large and overgrown, and the ES cells within these cultured colonies should appear indistinguishable. Differentiation is generally seen when stem cell colonies become large and flattened with jagged borders.

REAGENTS AND SOLUTIONS

For culture recipes and steps, use sterile tissue culture–grade water. For other purposes, use deionized, distilled water or equivalent in recipes and protocol steps. For suppliers, see ***SUPPLIERS APPENDIX****.*

Electroporation buffer (EB)

10% (v/v) Hanks' balanced salt solution (HBSS; Invitrogen)
20 mM HEPES buffer solution (add from 1 M stock; Invitrogen)
1 mM sodium hydroxide (NaOH) in water
110 μM 2-mercaptoethanol, tissue culture grade (Invitrogen)
Store for the duration of the electroporation experiment at 4°C, then discard

Embryonic feeder medium (EFM)

Dulbecco's modified Eagle medium (DMEM) with high glucose and phenol red (purchase in 500-ml bottle from Invitrogen) supplemented with:
50 U/ml (1×) penicillin/streptomycin (add from 1000× stock; Invitrogen)
6 mM (1×) L-glutamine solution (add from 100× stock; Invitrogen)
10% (v/v) fetal bovine serum (FBS, Gemini BioProducts)
Store for the duration of the experiment at 4°C, then discard

Embryonic feeder medium (EFM) containing 10 μg/ml mitomycin C

Dissolve one 2-mg vial of mitomycin C (MMC; Sigma, cat. no. M-0503) in 1 ml of calcium and magnesium-free Dulbecco's PBS (CMF-DPBS; Cellgro). Transfer all of this solution into 199 ml of EFM (see recipe) for a 10 μg/ml final concentration. Store at 4°C for the duration of the experiment, then discard into a chemical waste container.

Embryonic stem cell medium (ESM)

Dulbecco's modified Eagle medium (DMEM) with high glucose and phenol red (purchase in 500-ml bottle from Invitrogen; for certain cells as directed in Support Protocol 2 substitute Iscove's Modified Dulbecco Medium, IMDM, also from Invitrogen) supplemented with:
15% fetal bovine serum (FBS, embryonic stem cell qualified; Gemini BioProducts)
50 U/ml (1×) penicillin/streptomycin (add from 1000× stock; Invitrogen)
6 mM (1×) L-glutamine (add from 100× stock; Invitrogen)
90 μM 2-mercaptoethanol, tissue culture grade (Invitrogen)
100 μM nonessential amino acids (add from 100× stock; Invitrogen)
1000 U/ml leukemia inhibitory factor (LIF; Chemicon-Millipore)
Store up to 4 weeks at 4°C

ESM should be used in less than 4 weeks before glutamine begins to degrade.

Lots of FBS should be screened to ensure that the serum is able to maintain stem cell cultures in an undifferentiated state. An alkaline phosphatase antibody staining kit is available from Millipore to test the quality of the FBS. Stem cell cultures which are undifferentiated will stain pink to red, in contrast to the differentiated ES cell cultures.

Since FBS can contain growth factors that may encourage differentiation, a serum-free formulation, KnockoutSR, can be substituted. It is available from Invitrogen.

ES cell freezing medium, 2×

90 ml ESM (see recipe)
30 ml fetal bovine serum (FBS, ES cell–qualified; Gemini BioProducts)
Filter sterilize using a 0.22-μm filter (Millipore)
Add 30 ml dimethyl sulfoxide (DMSO; Sigma-Aldrich)
Dispense 0.5-ml aliquots into 2-ml cryovials (Nalgene/Nunc)
Store up to 4 weeks at 4°C

Addition of the DMSO to the filter unit sometimes clogs the membrane; therefore DMSO is added after filtering.

Glass cloning cylinders

Purchase 8 × 8–mm cloning cylinders (Bellco Glass). Lightly and evenly apply high-vacuum grease (Fisher Scientific) to the bottom of a 150 × 20–mm KMX glass petri dish (PGC Scientific). Fill the dish by placing the flat bottoms of the cloning cylinders into the grease. Cover and autoclave. Store indefinitely at room temperature after autoclaving.

Negative selection agent (FIAU)

Dissolve the entire contents of a 1-mg vial of FIAU [1-(2′-deoxy-2′-fluoro-β-D-arabinofuranosyl)-5-iodouracil; Moravek Biochemicals] in 1 ml 50% ethanol/50% water (the FIAU will dissolve slowly over 1 to 2 hours; vortex periodically). Ensure that no precipitate is present at the bottom of the vial. The resulting solution is 2.7 mM. Transfer the entire vial contents to 9 ml of ethanol/water mix (for a stock concentration of 270 μM). Aliquot into several tubes and store at –20°C for ~6 months (the manufacturer states that the decay rate is 0.2% per month).

To use, add 444 μl of this stock to 600 ml of ESM plus G418 (see annotation to step 2 of Basic Protocol 2) for a final concentration of 0.2 μM. Filter-sterilize through a 0.2-μm filter. Store at 4°C for the duration of the experiment, then discard.

PMEF cell freezing medium, 2×

2 ml fetal bovine serum (FBS, Gemini BioProducts)
6 ml embryonic feeder medium (EFM; see recipe)
Filter sterilize using a 0.22-μm filter
Add 2 ml dimethyl sulfoxide (DMSO; Sigma)

For freezing large batches of PMEFs, the volume of each ingredient must be increased. The ratio ingredients is kept the same. Store at 4°C until the ready for freezing, then discard.

Positive selection agent (G418 sulfate)

Add 1 g G418 sulfate powder (743 μg/mg activity; Invitrogen) to 10 ml tissue culture-grade water to make a stock solution. Refrigerate at 4°C up to 1 to 2 weeks.

To use, supplement a 600-ml bottle of ESM (see recipe) with 2.1 ml of the G418 solution described above for a final G418 concentration of 350 μg/ml (adjust volume of G418 stock solution to add depending upon the optimal concentration for the particular ES cell line, depending upon the "kill curve"; see Basic Protocol 2, step 2). Filter-sterilize ESM plus G418 medium before use. Store at 4°C for the duration of the experiment, then discard.

G418 is an analog of neomycin.

COMMENTARY

Background Information

The earliest attempts to culture mouse embryos were basically unsuccessful. In general, when a mouse blastocyst was placed in culture, the trophectoderm layer would grow into giant cells while the inner cell mass (ICM) would fail to proliferate (Cole and Paul, 1965). Long-term cultures were eventually developed from mouse blastocysts, but over time, these would primarily consist of either epithelioid or fibroblastic cells (Sherman, 1975).

Because of the initial problems in culturing blastocysts, many researchers turned to embryonal carcinoma (EC) cells to study embryonic development. Researchers discovered that when embryonic day 1- to embryonic day 7.5 mouse embryos were transplanted into extrauterine sites in a host mouse, a teratocarcinoma would eventually develop (Solter et al., 1970; Stevens, 1970). EC cell cultures were then derived from these teratocarcinomas. Most of the EC cell lines were obtained through experiments with 129 mice, a mouse strain that was known to develop spontaneous testicular teratomas (Stevens and Little, 1954). These cultured EC cells behaved like cells seen in an early embryo. In addition, the pluripotent EC cells could differentiate into all three primary germ layers and could be directed to form embryoid bodies in culture (Martin and Evans, 1975). Unlike normal embryonic cells, however, the EC cells had an abnormal karyotype.

Investigations into embryonic development were further augmented by the ability to generate chimeric mice. The cell-cell interactions that occur in a developing embryo could be studied by the injection of foreign cells into a host mouse blastocyst. R.L. Gardner (Gardner, 1968) was the first investigator able

to show how the injection of cells into a blastocyst could produce mouse chimeras. This technique was then applied to show that EC cells could differentiate into various cell lineages to populate the developing chimeric mouse embryo (Brinster, 1974; Papaioannou et al., 1975). The EC cells, however, were not transmitted through the germ line to produce progeny of the chimeric mouse.

The lessons learned from culturing EC cells led to the isolation of embryonic stem (ES) cells. The optimal stage of embryonic development was determined by comparing cell-surface antigens and patterns of protein synthesis between EC cells and mouse embryonic cells at various stages (Evans and Kaufman, 1981). In addition, the growth conditions used in maintaining EC cells were instrumental for the eventual isolation of ES cells. The transformed feeder cells used in some EC cell cultures, for example, were helpful in preventing differentiation of the embryonic cells. Evans and Kaufman (1981) were the first to isolate ES cells by explanting whole blastocysts. Independently, G.R. Martin (Martin, 1981) was able to obtain ES cells by isolating the inner cell mass using immunosurgery. The isolated stem cells could propagate in culture and were able to differentiate into various cell types under specified growth conditions. Unlike EC cells, the stem cell cultures were karyotypically normal. Bradley et al. (1984) showed that, when injected into a blastocyst, these stem cells could populate a chimeric mouse, further proving the pluripotency of the ES cells. Of major significance, though, was the ability to achieve germ-line transmission with the newly isolated cell cultures, a finding that could be confirmed through transmission of coat color. The cytokine leukemia inhibitory factor (LIF) was later added to cultures to suppress differentiation. Before being cloned and characterized, LIF was initially added to EC cultures under the name DIA (differentiation inhibitory activity). With improvements in culturing conditions, ES cells from mouse strains other than 129 could be isolated.

The properties of ES cells include pluripotency and self-renewal in tissue culture. Embryonic stem cells were originally derived from the inner cell mass of an embryonic day 3.5 mouse embryo and were grown successfully in vitro (Evans and Kaufman, 1981; Martin, 1981). These isolated stem cells remain karyotypically normal in culture and do not transform into teratocarcinomas. Under specified growth conditions, ES cells can also be induced to form multiple cell types and even embryoid bodies. This pluripotent property allows scientists to test which growth factors are involved in turning an undifferentiated cell into specified cell types. With the capability to differentiate into various cell lineages, stem cells are also being tested for efficacy in regenerative medicine. An additional characteristic of the pluripotent stem cells is the ability to incorporate into a developing mouse embryo when injected into a blastocyst (Bradley et al., 1984; *UNIT 19.14*). The stem cells participate in the development of the host embryo to produce chimerism in the resulting mouse. The production of mouse chimeras, an important step required to generate genetically modified mice, can alternatively be achieved by aggregating ES cells together with an embryonic day 2.5 morula-stage embryo (Nagy and Rossant, 2000; Eakin and Hadjantonakis, 2006). If truly undifferentiated, the cells derived from an ES cell clone will be established in the germ line of a chimeric mouse. Characteristics of the ES cell, such as coat color, can then be transmitted from the germ line into the progeny of the chimeric mice. Thus, an ES cell clone that has been mutated in tissue culture can then be used to eventually derive a mouse containing this genetic modification.

Culture conditions

Important clues about ES cell culture were originally derived by observations of teratocarcinomas. Grafting of early embryos ectopically into a histocompatible host leads to experimentally derived teratocarcinomas from which embryonic carcinoma (EC) cell lines could be cultured (Solter et al., 1970; Stevens, 1970). EC cells can differentiate into all three types of precursor tissues necessary for the development of a mouse, namely the ectoderm, mesoderm, and endoderm. Maintaining the EC lines on feeder cells of transformed mouse fibroblasts, however, helped to prevent differentiation (Martin and Evans, 1974, 1975). EC cells were found to share similar morphology and appearance with preimplantation-stage embryos (Evans and Kaufman, 1981). The knowledge gained by studying EC cells, including the use of feeders to prevent differentiation, allowed for the eventual isolation of stem cells from the mouse embryo. Initial isolation of ES cells was performed by either explanting whole blastocysts (Evans and Kaufman, 1981) or by isolating the inner cell mass by immunosurgery (Martin, 1981). In the two decades since the initial isolation of these stem cells, more the 1200 scientific papers have been published with mouse ES cells

as a research emphasis (Downing and Battey, 2004).

One very important factor that aided in the culture of undifferentiated ES cells was myeloid leukemia inhibitory factor (LIF). This cytokine was initially given the name DIA for differentiation inhibitory activity and was isolated from various sources as a soluble factor capable of inhibiting differentiation in both ES and EC cells. Eventually DIA was cloned and characterized as the molecule LIF (Williams et al., 1988). LIF is a multifunctional cytokine that acts as a hemopoietic regulator. In addition, LIF is expressed by the trophectoderm of a developing embryo. Embryonic stem cell and embryonic carcinoma cell lines were shown to display high-affinity receptors for LIF. When highly purified recombinant LIF was added to cultures, more than 95% of the resultant colonies displayed the stem cell phenotype of compact colonies. In contrast, cells cultured in normal culture medium (without LIF) eventually differentiated to form colonies of large, flat differentiated cells. LIF mediates cell signaling, particularly through the activation of STAT3, and plays a key role in promoting ES cell propagation while blocking cellular differentiation (Burdon, et al., 1999). Other refinements to the ES cell culture medium have included the addition of β-mercaptoethanol and nonessential amino acids, which are useful to maintain the viability of the cultured stem cells (Robertson, 1987).

Characteristics of ES cells

Recently, key transcription factors have been identified that may be responsible for maintaining pluripotency in stem cells. The combination of four transcription factors—Oct-3/4, Sox2, c-Myc, and Klf4—was shown to be able to reprogram mouse embryonic fibroblasts (MEFs) into a stem cell–like state (Maherali et al., 2007; Okita et al., 2007; Wernig et al., 2007). Oct-4, in particular, has been seen as a key regulator of pluripotency, and high expression of this transcription factor is characteristic of undifferentiated stem cells (Niwa et al., 2000). Upon retroviral infection of these transcription factors, MEFs are transformed into induced pluripotent stem (iPS) cells that behave similarly to ES cells. After proper selection, these iPS cells could populate a chimeric mouse and be transmitted through the germ line. The expression of the transcription factor Nanog, a downstream target of Oct3/4 and Sox2, is also critical for the maintenance of pluripotency in stem cells. Nanog deficiency in mice results in the inability of the inner cell mass to form an epiblast (Mitsui et al., 2003). Therefore, expression of Nanog is also related to maintenance of pluripotency.

Changes in the expression of cell-surface molecules can additionally be studied to determine if the stem cell cultures are undergoing differentiation. For example, changes in the expression level of stage-specific embryonic antigens (SSEA) are useful in determining if stem cells are undifferentiated. Differentiation of murine ES cells results in the loss of SSEA-1 expression and an increase in both SSEA-3 and SSEA-4 (Solter et al., 1979). This shift, however, is exactly opposite to what is seen with human ES cells. Lastly, a high level of alkaline phosphatase is also a good indicator that the stem cells are in an undifferentiated state (Pease et al., 1990).

Mouse strains

Historically, the most common ES cell lines were derived from the 129sv inbred mouse strain. The 129 mouse was often used to develop stem cells because this strain was commonly used to study embryonic development and was the favored strain in the derivation of EC cells. ES cells obtained from the 129 strain were unusually adept in colonizing and competing with cells from the inner cell mass of blastocysts. Commonly used 129-derived ES cell lines include ES-D3 (Doetschman et al., 1985), J1 (Li et al., 1992), and R1 (Nagy et al., 1993). Initially, only 129 strain mice were conducive or permissive for establishing ES cells in vitro. As cell culture conditions were improved to favor proliferation and reduce differentiation, stem cell lines could be maintained in culture for more passages and ES cells could be isolated from previously nonpermissive strains, such as from C57 mice (Ledermann and Bürki, 1991; Köntgen and Stewart, 1993) and BALB/c mice (Noben-Trauth et al., 1996; Baharvand and Matthaei, 2004).

Gene targeting

In addition to their use in gene targeting, ES cells have been used as a vehicle for transgenesis. ES cells can be genetically modified in culture through transfection of a transgenic construct. This ES cell route to making a transgenic mouse provides researchers with a means to screen for the desired genetic alteration before producing an animal model (Gossler et al., 1986). Along with electroporation (*UNIT 20.5*) or calcium phosphate transfection (*UNIT 20.3*) of transgenic

constructs, viruses have also been a commonly employed for gene transfer into ES cells. One of the first experiments in genetic manipulation of ES cells involved the delivery of exogenous DNA through a retroviral vector (Robertson et al., 1986). The modified ES cells were then used to create genetically altered mice. Transduction of ES cells has been performed with adenoviral and lentiviral vectors as well (Smith-Arica et al., 2003; Kosaka et al., 2004). Gene transfer through viral vectors has sometimes provided better transduction efficiency and less cytotoxicity than electroporation.

Transgenesis using gene-trap vectors is an alternative means of making knockout mice, although via indiscriminant gene inactivation (Gossler et al., 1989; Stanford et al., 2001). Unlike gene targeting, gene-trap vectors are not site directed through homology arms, and are therefore only a random means to disrupt a gene. Gene-trap vectors generally consist of a promoterless reporter gene like *lacZ* (β-galactosidase), whose expression is dependent on random integration into a functioning gene. A splice acceptor is also commonly placed preceding the *lacZ* gene to ensure expression when integrated within a gene intron. Additionally, a gene trap vector usually will contain a neo^r gene for positive drug selection.

Homozygous null ES cells can also be derived in tissue culture by treating a properly targeted clone to increased positive drug-selection pressure. For example, clones with a targeted insertion of the neo^r gene can be treated with a high concentration of G418 to force the replacement of the wild-type gene for the mutated copy (Mortensen et al., 1992). The high concentration of G418 seems to force another homologous recombination event to accommodate for the increased drug-selection pressure. Null stem cells can then be characterized in culture to determine if gene inactivation affects the differentiation into various cell lineages. The homozygous null ES cells can also be injected into a mouse blastocyst to make a chimeric mouse. In the chimeric mouse, the development of the null cells can then be followed to determine if the effects of gene inactivation are cell-autonomous.

As techniques were perfected in applying homologous recombination for gene targeting, researchers quickly realized that murine stem cells could be used as a means by which to make genetically altered mice. With the convergence of these technologies, a targeting construct is first delivered into cultured ES cells to introduce a desired mutation into a selected gene. The designated mutation is inserted into the targeted gene via recombination at sequences of genetic homology. The stem cell clone with the desired recombination event is then used to derive a mouse with the targeted mutation through injection into a blastocyst. The combination of homologous recombination and ES cells was first applied in gene targeting of hypoxanthine-guanosine phosphoribosyl transferase gene (*HPRT*). The *HPRT* gene was an ideal candidate to test gene targeting, since both correction (Doetschman et al., 1987) and inactivation (Thomas and Capecchi, 1987) of this gene could be easily tested in tissue culture. Later refinements allowed for the production of knockout mice via targeted inactivation of nonselectable genes, such as *int-2* and *c-abl* (Mansour et al., 1988; Schwartzberg et al., 1989). These refinements included positive and negative drug selection (Mansour et al., 1988). Soon, the methods used to make knockout mice were modified to create other gene-targeted mutations. In this manner, conditional knockout mice, knock-in mice, and mice with subtle genetic mutations were generated. The significance of gene targeting was seen when Mario Capecchi, Oliver Smithies, and Martin Evans won the 2007 Nobel Prize in Physiology or Medicine. Additionally, the explosive growth in the number of animal models derived through gene targeting attests to the usefulness of these discoveries. With targeted gene inactivation in mice, the precise role of a gene can be discerned by analyzing its absence in vivo. Through gene targeting to disrupt genes or create subtle mutations in mice, human genetic disease can be mimicked in an animal model. Therefore, using stem cells in combination with gene targeting has been a valuable means to gain insights into mammalian biology.

Alternate method

In general, one can expect a targeting efficiency (number of clones possessing the recombined allele divided by the total number of clones) of about 1 to 3 percent (te Riele et al., 1992). In many cases, it is advantageous to have more than one targeted clone to increase the chances of obtaining good chimeric mice. The protocol described here can be very labor intensive, particularly at the steps where clones are picked and individually frozen. It is not uncommon to freeze 200 to 300 clones per project. Other investigators have developed a less laborious method that uses 96-well tissue culture plates and a multichannel pipettor to reduce fatigue

(Ramirez-Solis et al., 1993). In this method, feeders are plated onto 96-well tissue culture plates instead of 24-well plates. After drug selection, ES cell clones are scraped around the colony and plucked from the dish using a pipet tip, and are then trypsinized and transferred to corresponding 96-well feeder plates. When the cells are confluent and ready to freeze, a multichannel pipettor is used to wash, add trypsin and medium, and resuspend the cells. This method can generate many more clones and reduce the time involved and the resulting fatigue. Many investigators have used this method, particularly if they use only positive selection or when there is concern regarding TK-induced sterility of transgenic males (e.g., conditional knockout mice where the exon has flanking *loxP* sites and an incorporated *HSV-tk* cassette; Salomon et al., 1995) or when it is not feasible to include a negative-selection cassette due to a lack of appropriate restriction enzyme sites. There are, of course, disadvantages using this high-throughput method. The chief disadvantage is that there is less cell lysate from the 96-well as compared to the 24-well method. Usually, there is only enough lysate to permit one Southern blot. Secondly, an entire plate must be harvested when the cells are ready to freeze if a multichannel pipettor is used, and the number of cells per well will vary.

Feeder-free system

The methods detailed above use mouse embryonic fibroblast cells that have been arrested; these feeders provide not only the cytokines necessary to maintain undifferentiated embryonic stem cells, but also a support for the stem cell colony to grow on. In some cases where the population of dispersed embryonic stem cells is sparse relative to the number of feeder cells, it is difficult to differentiate between the wild-type genomic DNA from the feeder cells and the genomic DNA from the potentially null stem cells. In addition, it may be necessary to culture the PMEF for 1 or 2 weeks, adding time to any project. These problems led to identifying the particular growth factors in feeder cells that sustained self-renewal in embryonic stem cells. This possibility was especially useful in the propagation of primate stem cells where generation of feeders would be impractical. For a feeder-free system, LIF and the bone morphogenetic proteins (BMP-4) seem to be the only growth factors necessary for mouse ES cells to remain undifferentiated (Ying et al., 2003) without the presence of feeder cells. Millipore has developed a feeder-free kit for murine embryonic stem cell culture, and information for this kit can be obtained from their Web site (*http://www.millipore.com*).

Critical Parameters and Troubleshooting

Embryonic stem cell passage number

Occasionally, after targeted clones have been injected, chimeric mice are not produced, or chimeric mice are bred but the targeted ES cells do not contribute to the germline. One reason for this appears to be the amount of time and passages spent in vitro. The steps necessary to generate and test new stem cell lines can be very time consuming and require considerable skill. As a result, many facilities purchase stocks of these stem cell lines then freeze down large batches. If the passage number becomes very high, then the ability of these clones to contribute to the germ line diminishes. One such study found that previously euploid (40 chromosome count in mice) ES cell clones, when passaged in vitro for more than 20 passages, rapidly became aneuploid (higher chromosome counts), and the capacity to contribute to the germ line dropped to zero (Longo et al., 1997). Some facilities routinely screen new stem cell line batches by karyotyping chromosomal spreads, and some facilities offer this screening as a service. Karyotyping or G-banding naïve ES cell batches may help when troubleshooting problems with germline transmission.

Mouse strain

When planning to make genetically altered mice, careful consideration should be made in choosing the mouse strain from which to derive ES cells to use for experimentation. Most stem cells are derived from the 129 strain of mice because, historically, these mice were commonly used for the derivation of EC cell lines. However, extensive genetic variation has been reported between the 129 mouse substrains and the ES cells derived from these mice (Simpson et al., 1997). Additionally, the 129 strain of mice tend to have reduced fertility as compared with other mouse strains. Lastly, some reports indicated that this background displays some abnormalities in anatomy, immunology, and behavior (Seong et al., 2004). Still, 129 stem cells are easier to propagate in vitro when compared with stem cells from other mouse strains. In addition, stem cells from other mouse strains do not populate a blastocyst as efficiently and are less capable of leading to germ-line transmission. This is

particularly seen with higher-passage-number stem cells (Schoonjans et al., 2003). Therefore, of the thousands of targeted mice described in the literature, most were created using the 129 mouse strain background. For example, only 38 targeted mice have been developed with a C57BL/6 background even though two C57BL/6-derived ES cell lines have been available for more than a decade (Seong et al., 2004). To get a pure breeding background, though, requires at least another year of backcrosses. Therefore, trying a stem cell from strains other than 129 can sometimes be a worthwhile option. For example, stem cells from the BALB/c mouse were derived because this strain is commonly used for experiments in immunology (Dinkel et al., 1999). The C57 strain of mice is also favored for studying various phenotypes, since this strain has been well characterized. Therefore, C57BL/6 stem cell lines have been developed, and more genomic DNA libraries have recently been constructed from C57 strain mice to help enable investigators to develop knockout mice with this background. With this strategy, C57-derived ES cells (e.g., LK1 or Bruce4) are microinjected into C57 donor blastocysts and foster mothers. Coat color cannot be used as a marker for chimerism since the pups would have a black coat color regardless of recombined ES cells or native (from the donor blastocyst) ES cells. Recently, C57 ES cells have been developed with a tyrosinase mutation that imparts a white color (albino), allowing coat-color assessment of chimerism. Although the C57-derived ES cells require more fastidious care than the 129-derived cell lines, the targeting frequency between these two strains is roughly similar (Seong et al., 2004). In addition, while the 129-derived ES cells are better able to proliferate in a host blastocyst, the capacity to transmit the targeted event through the germ line is not very different between the two strains. Regardless of which strain of ES cell lines is used, care must be taken to ensure that these ES cells remain pluripotent until they are transferred to a host blastocyst and foster mouse.

Anticipated Results

The transformation efficiency of electroporation of ES cells is between 1% and 3%, so that an electroporation of 1×10^7 ES cells should produce $1–3 \times 10^5$ transformed cells. Of these, 200 to 300 survive and form colonies. Of the colonies formed, ~2 to 3 contain the desired mutant gene structure.

Time Considerations

It takes ~2 weeks to prepare PMEFs for use as feeder layers. PMEFs should not be used beyond passage 6.

Electroporation requires ~3 hr. Positive/negative drug selection takes at least 5 to 10 days. Picking colonies takes 3 to 4 hr, depending on the number of colonies. Expansion of the colonies before freezing requires ~2 days. Screening the colonies by Southern blotting requires 2 to 3 weeks, and by PCR takes 1 to 2 days.

Generation of Gene Knockout Mice by ES Cell Microinjection

Glenn Longenecker[1] and Ashok B. Kulkarni[1]

[1]National Institute of Dental and Craniofacial Research, National Institutes of Health, Department of Health and Human Services, Bethesda, Maryland

ABSTRACT

This unit describes protocols used in the production of chimeric mice that are then used for the generation of gene knockout mice. These protocols include the collection of blastocyst embryos, ES cell injection, and uterine transfer of injected blastocysts. Support protocols for the superovulation of blastocyst donor mice, generation of pseudopregnant recipients, fabrication of glass pipets for embryo and cell manipulations, and generation of germline mice are also included. Practical tips and solutions are mentioned to help troubleshoot problems that may occur. *Curr. Protoc. Cell Biol.* 44:19.14.1-19.14.36.

Keywords: embryonic stem cells • blastocyst • blastocyst injection • uterine transfer • chimeric mice • knockout mice

INTRODUCTION

The generation of knockout mice through the process of creating chimeric mice via embryonic stem (ES) cell injection is a powerful tool for understanding in vivo functions of a particular gene of interest. Knockout mouse models may be used to elucidate the molecular mechanisms underlying human diseases, and could aid in the creation of new therapies to treat these diseases.

ES cell injection is the most common method used to generate these chimeras, but morula aggregation is also used. There is a very narrow time window in embryonic development for the ES cell injection procedure to be successful in the generation of chimeric mice. For this reason, all components of the procedure for generating chimeric mice—harvesting (Basic Protocol 1), injection (Basic Protocol 2), and surgical transfer of the mouse blastocysts (Basic Protocol 3)—are usually done the same day and require good planning and coordination.

A timeline for the generation of knockout mice by the methods described in this unit is shown in Table 19.14.1.

Learning all of the procedures involved requires time and practice. It also requires skills not everyone might possess. How quickly and easily these techniques are learned will depend on previous experience, natural abilities, and the desire to learn them.

NOTE: All solutions and equipment coming into contact with living cells must be sterile, and aseptic technique should be used accordingly.

NOTE: All cell culture incubations should be carried out in a 37°C, 5% CO_2 humidified incubator unless otherwise indicated.

NOTE: All animal work performed must be approved by the Institutional Animal Care and Use Committee of the institution where the work will be taking place and must conform to governmental regulations for animal care and use. The animal facility where the mice are held should ideally be pathogen free.

Table 19.14.1 Timeline for the Generation of Knockout mice[a]

Event	Timing
Injection of targeted ES cells into C57BL6 host blastocyst	Day 1
Transfer of injected blastocyst into foster mother	Day 1
Chimeric pups born	~3 weeks
Chimerism seen in chimeric mice	~1 month
Mating of chimeric mice to C57BL6 mice	~1.5 months
Birth of potential F1 heterozygote founders	~2 months, 1 week
Determination of germline transmission by coat color	~2.5 months
Mating of F1 heterozygous pair	~3 months, 3 weeks
F2 knockouts born	~4.5 months

[a]This is a suggested timeline and may vary due to animal reproduction.

BASIC PROTOCOL 1

COLLECTION OF BLASTOCYSTS

Embryonic day (E) 3.5 blastocysts can be found free-floating in the uterine horn. Note that all embryonic day designations in this unit refer to days post-coitum (p.c.) from the time of the appearance of the copulation plug. To collect these embryos, the uterine horns are generally flushed out with medium. Although this is considered a straightforward technique, it does require a certain amount of manual dexterity. Another important component is the ability to use a mouth pipet in the collection and washing of embryos. Without this ability it would be hard, if not impossible, to collect the mouse embryos. Even though, in theory, only blastocysts should be obtained from this procedure, it is not uncommon to obtain earlier-stage embryos as well. Of these earlier-stage embryos, morulas should be kept in culture along with blastocysts. Depending on the stage of development, the morulae may become blastocysts in culture and can be used for ES cell injections if needed. When flushing out the blastocysts, a zoom setting of 1.2 is suggested for the dissecting microscope, since it will allow a viewing of the uterine horn all the way to the opening of the cervix. For washing blastocysts, a zoom setting of 3.2 is recommended, because this setting offers enough magnification to discern the blastocyst well, but still allows for a relatively large viewing area to see the embryos in the dish.

Materials

C57BL/6NCr 3.5-day post-coitum (p.c.) superovulated female mice (see Support Protocol 1; 10 are needed)
Injection medium (see recipe)
70% ethanol
Microdrop cultures (see recipe)

Bench paper (absorbent material with plastic backing)
35 × 10–mm tissue culture dishes (Falcon 3001 or equivalent)
3-cc tuberculin syringes
30-G, 0.5-in. needles (Becton Dickson, cat. no. 305106 or equivalent)
70% ethanol pads
Surgical instruments (cleaned and sterilized with alcohol pads):
  Dissection scissors (Roboz RS-5880 or equivalent)
  No. 55 forceps (Roboz RS-5063 or equivalent)
Dissecting microscope
Transfer pipet (see Support Protocol 2)
Mouth pipet assembly (see Fig. 19.11.2) including:
  Mouthpiece (Fisher Scientific no. 13-647-10 or equivalent)

Saliva trap (cotton plug from a 1-mm pipet; BD Falcon, cat. no. 7521, or equivalent)
Syringe filter, 0.22-μm (Gelman no. 4602 or equivalent)
Pipet insert and reservoir (Drummond microcaps no. 1-000-0300 or equivalent); a modified 1000-μl pipet tip can be used as a reservoir.
Approximately 23 in. of natural latex tubing (1/8-in. i.d.; 1/32-in. wall)
Male luer, 5/32-in. (Ark-Plas Products no. 10-12ML016N or equivalent) to connect female end of syringe filter to rubber tubing
Female luer, 5/32-in. (Ark-Plas Products no. 10-15FL016N or equivalent) to connect male end of syringe filter to rubber tubing

Additional reagents and equipment for euthanasia of the mouse (Donovan and Brown, 2006a)

Harvest uterine horns

1. Take out injection medium from the refrigerator and allow it to warm to room temperature.
2. Place bench paper on the area where the mice will be euthanized.
3. Pour injection medium into a 35 × 10–mm tissue culture dish, and also load injection medium into a 3-cc syringe and attach a 30-G needle onto it. Tap the syringe to allow bubbles to travel to the plunger end.
4. Swab a pair of no. 55 forceps and dissection scissors with 70% ethanol pads and allow to dry.
5. Euthanize a mouse by cervical dislocation (Donovan and Brown, 2006a).

   It is suggested that all ten blastocyst donor females be used even if a plug is not seen in some of them. These females could potentially be plugged even though a copulation plug was not seen. Failure to use all of the mice could potentially decrease the embryo yield.

6. Place each mouse on its back (Fig. 19.14.1), and orient it such that the head and tail are in the 3 o'clock and 9 o'clock positions, respectively. With a squeeze bottle filled with 70% ethanol, spray the abdomen of each mouse.

   Figure 19.14.1 illustrates many of the manipulations described in the following steps.

7. Gently, with the fur placed between the index finger and thumb of each hand, pull the skin apart toward the head and tail of the mouse.
8. With a pair of no. 55 forceps and dissection scissors, grasp the peritoneal abdominal muscle wall and make a vertical incision. Move the intestines to the anterior side, away from the ovaries.
9. Next, using the no. 55 forceps, grasp the white fat pad of the ovary and snip the ligamentum latum attached to the uterus and the kidney. Carefully cut away the fat and blood vessel structure (mesometrium) running along the uterine horn, and cut at the cervix. Avoid cutting the side of the uterine horn.
10. Repeat step 9 on the other horn, cut at the oviduct, and place the uterus into the dish containing the injection medium.
11. Repeat steps 5 through 9 for the remaining mice until all uteri have been harvested and placed in the same 35 × 10–mm tissue culture dish.

Flush uterine horns

12. Take the uteri out of the dish one at a time and place in another 35 × 10–mm dish that has no injection medium in it.
13. Under a dissecting microscope, straddle the uterine horn, without the ovary attached, with forceps, holding the outer edges.

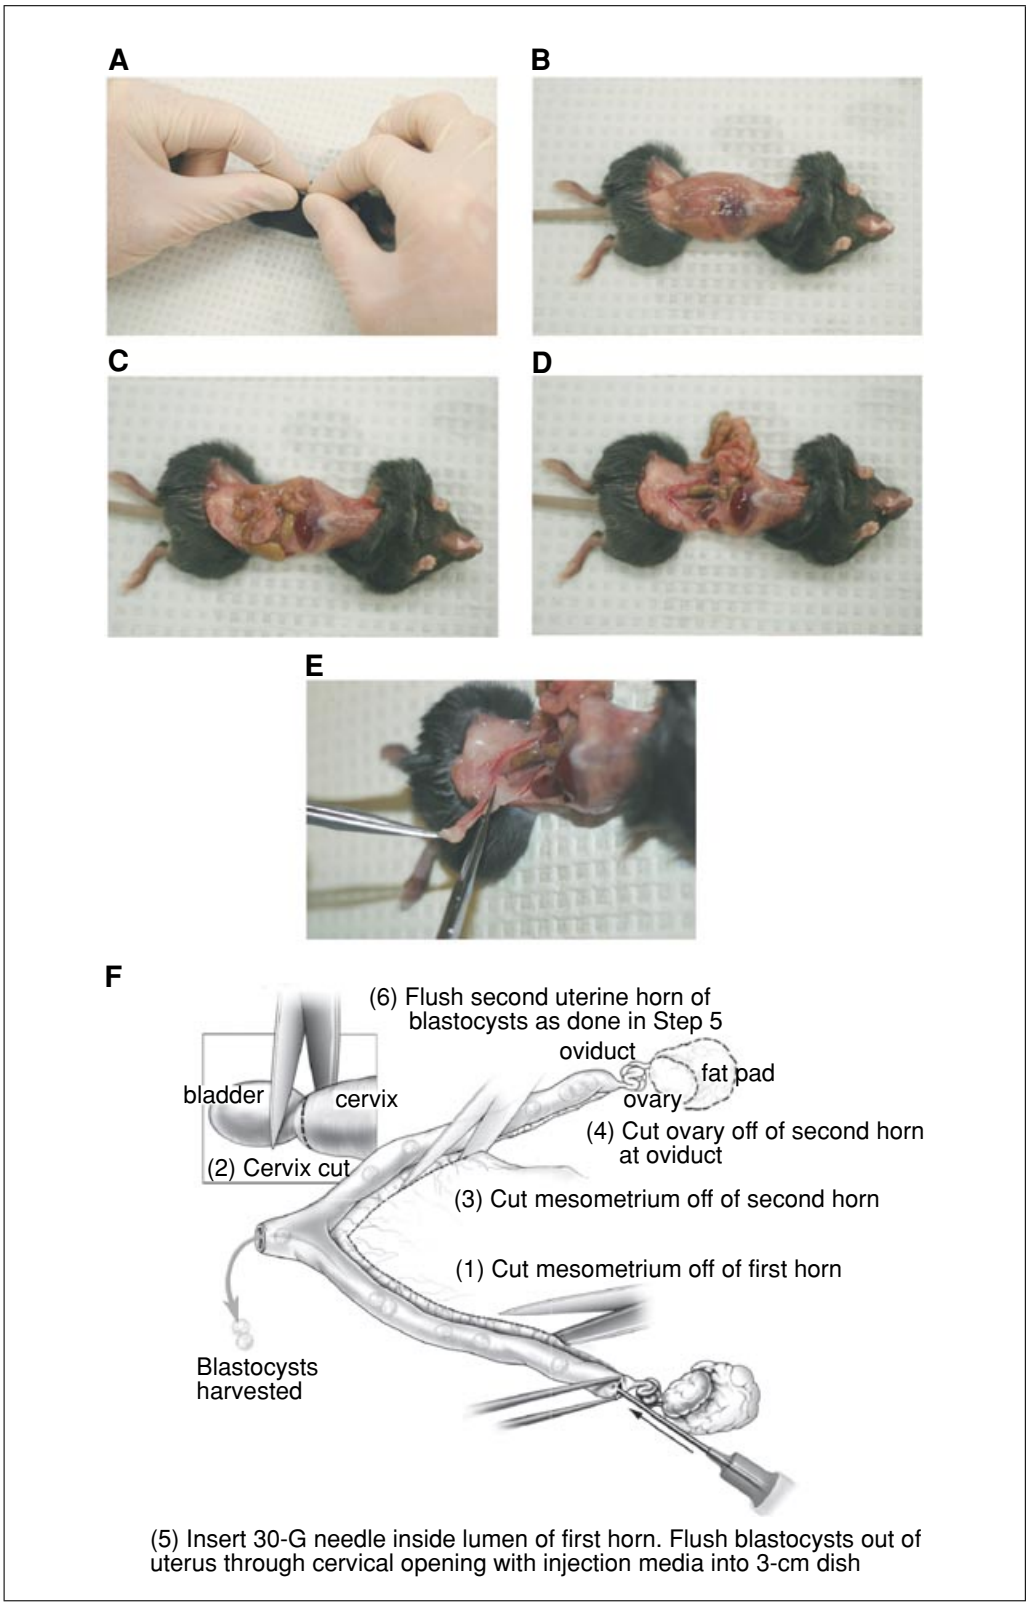

Figure 19.14.1 Collection of blastocyst embryos. (**A**) Holding of skin and fur prior to removal. (**B**) Removal of skin and fur. (**C**) Removal of peritoneal membrane. (**D**) Uterine horns exposed. (**E**) Removal of mesometrium tissue from the uterine horns. (**F**) Drawing showing the harvesting and flushing of uterine horns.

14. Insert the 30-G needle (attached to the 3-cc syringe with injection medium; see step 3) into the tip of the uterine horn inside the lumen. Inject medium through the cervix while holding the uterine horn down onto the dish until it is flushed well with medium.

    If the needle does not move freely, and the uterine wall expands, the needle is not inside the lumen. A good sign that the uterine horn is being flushed out properly is that the medium can be seen coming out of the cervix and the uterine horn expands, showing the rib-like structures of the uterine wall.

    When flushing out through the cervix, orient the cervix opening so that it is to the side and slightly up. This allows one to see the medium being flushed out and helps prevent medium from squirting out of the dish. It should take one or two quick and forceful presses on the syringe to fully flush out each uterine horn. The amount of medium required would be about 0.25 to 0.5 ml per uterine horn.

15. Repeat step 14 on the other uterine horn with the ovary still attached.

16. Repeat steps 13 to 15 for all mice in one or two tissue culture dishes if more medium is required to flush out the uterine horns.

Wash and collect blastocysts

17. When all flushing is complete, working under a dissection microscope with a polished transfer pipet (prepared as in Support Protocol 2) attached to a mouth pipet (with a cotton plug from a 1-mm pipet as a saliva trap), collect the embryos on the dish while avoiding the collection of any debris in the process.

    Transfer pipets used for washing the embryos should be a little larger than the embryo diameter to allow for microcapillary action, but not so large that there is no control in the mouth pipetting of embryos.

    It would be expected that on average 60 unhatched blastocysts will be recovered. The authors only use injection medium and no oil, due to the fact that the debris may stick to the oil, possibly making the transfer pipet unusable.

18. Transfer embryos into a second 35 × 10–mm dish containing injection medium until all the embryos are mostly free of any debris or other tissue.

19. Repeat step 18 again on a third 35 × 10–mm dish containing injection medium, to continue the wash.

20. Transfer the washed embryos with the transfer pipet into a microdrop culture (30-µl drop of injection medium under light mineral oil on a 35 × 10–mm plate; see Reagents and Solutions), and place this in a 37°C incubator until ready to inject.

    Prepare additional plates of medium/ with oil overlays for blastocysts to be injected.

SUPEROVULATION OF EMBRYO DONOR FEMALES

SUPPORT PROTOCOL 1

C57BL/6 females at 3 weeks of age are considered to be the best choice for superovulation in the production of blastocysts. If not available, then 4-week-old females would be the next best choice. Mice that are 5 to 6 weeks of age or older are not considered the best choice for superovulation because of the fact that the females would be producing the comparable hormones themselves. If using C57BL/6 females at 5 to 6 weeks of age, you should not use hormones for superovulation; rather, let the mice naturally ovulate instead. An advantage of superovulation is that fewer mice are needed to produce the number of blastocysts required for ES cell injections. Four times more females would be needed for each injection day for naturally ovulating females versus superovulated females (Hogan et al. 1994). The drawback with superovulation is the tendency to produce abnormal embryos. However, once at the blastocyst stage, most abnormal or defective embryos should have died or stopped at an earlier developmental time point. C57BL/6 blastocysts are generally considered the standard in blastocyst injection to generate chimeric mice.

However, other groups have used different strains for this purpose. The strain of mice chosen will depend on the ES cell line being used.

One hormone that we use in our lab is pregnant mare serum gonadotropin (PMSG), which is a follicle-stimulating hormone (FSH) involved in the formation of the egg follicles. Another hormone we use is human chorionic gonadotropin (HCG), which is a luteinizing hormone (LH) that releases the formed eggs and also acts as an attractant to the stud male (Hogan et al., 1994). Ten C57BL/6 females are used for each injection day, and one female is mated to each stud male housed in a separate cage. C57BL/6 males are only used once per week to ensure plugging and fertility. A light/dark cycle of 14 hr of light/10 hr of dark is a good choice for the rooms where the animals will be held, as this is thought to be more conducive to mating.

Materials

C57Bl/6NCr females or equivalent strain (3 to 4 weeks of age; ten are needed per injection day
50 IU/ml pregnant mare's serum gonadotrophin (PMSG; see recipe)
50 IU/ml human chorionic gonadotrophin (HCG; see recipe)
10 C57Bl/6NCr males (7 weeks to 10 months of age)

1-cc tuberculin syringes
30-G, 0.5-in. needles (Becton Dickson no. 305106 or equivalent)

Additional reagents and equipment for injection of mice (Donovan and Brown, 2006b)

1. At a time point 6 days before the planned day of blastocyst injections, intraperitoneally inject 0.1 ml of 50 IU/ml PMSG at 1300 hr into each C57BL/6NCRr female mouse.

   Intraperitoneal injection is described in Donovan and Brown (2006b). For this injection and that in the following step, use a 1-cc tuberculin syringe and a 30-G, 1/2-in. needle.

2. At a time point 2 days (47 hr) later, intraperitoneally inject 0.1 ml of 50 IU/ml HCG at 1200 hr into each C57BL/6NCRr female mouse.

3. Mate C57BL/6NCRr females 1:1 (one female mated with each male) with C57BL/6NCr males right after all females are injected with HCG.

4. The next morning, before 0900 hr, check females for copulation plugs.

   Actual times may vary depending on your animal facility and other variables. The plugging by C57BL/6 males becomes variable after 10 months of age, with a reduced number of blastocysts and a greater number of earlier-stage embryos. At about 11 months to 12 months of age, mice that are superovulated may produce only zygote-stage embryos at E3.5 p.c. At one year of age the C57BL/6 males will be become sterile. The C57BL/6 stud males are replaced at 9 to 10 months of age.

SUPPORT PROTOCOL 2

FABRICATION OF GLASS PIPETS

Some of the pipets used in the making of chimeric mice require much more skill and practice than others to prepare. The pipet that is the most difficult to make is the injection pipet, followed by the transfer pipet, and then the holding pipet.

The injection pipet has a similar inner diameter to that of the holding pipet, but has a much more gradual taper. This aids in the control of loading and expelling ES cells during blastocyst injections. The holding pipet has a more dramatic taper, which aids in holding of the blastocyst onto the holding pipet during ES cell injections. Control in this instance is not as important as it is for the injection pipet. The transfer pipet, in general, has a much larger opening to allow blastocysts to enter inside for washing after harvesting,

transferring between the oil overlay and injection dishes, and transferring of blastocysts during surgical uterine transfer.

Three variables that will affect the quality of pipets produced are the melting of the glass tubing, the length of time the glass tubing is pulled, and how much force is applied to the glass tubing during the pull. When first learning to pull the transfer pipet under a microflame, these variables are harder to control. Experience is required to control these variables and pull a good transfer pipet. For the pipet puller that the authors use in the laboratory, time and force of the pull on the glass tubing are controlled by the solenoid, and temperature is set by the heater control knob. How fast the ends of the pipets are melted by the glass bead on the microforge will depend upon how close the pipet is to the glass bead, the heat level setting of the filament, and the size of the glass bead.

Both injection and holding pipets can be purchased from vendors, but these premade pipets can be costly if many of them will be used. After the initial expenditure of buying the equipment, such as a microforge and pipet puller, the real expense is that of the glass tubing. See Figure 19.14.2 for a summary of these procedures.

Materials

Plasticene (Fisher Scientific, cat. no. P148-1LB or equivalent)
1.25% Tween 80 solution (see recipe)
Glass tubing (Drummond Scientific no. N-51A: I.D. 0.8 mm × O.D. 1.0 mm × length 150 mm or equivalent)
Microflame assembly (for pulling transfer pipets and polishing ends of pipets, consisting of:
  Rectangular support stand plus rod (PGC Scientific, or equivalent)
  Alumaloy tri-grip utility buret clamps with micro clamp holder (PGC Scientific, or equivalent)
  9-in. Pasteur pipet shortened to 7 in. (clamped vertically to the support stand, using the buret clamps, to emit a small flame)
  Tygon tubing, formulation R-3603 (I.D. 1/4 in. × O.D. 3/8 in. × wall 1/16 in.) for conveying gas to the Pasteur pipet
Diamond pencil
Microforge (Defonbrune style, with 10× eye pieces and reticle, 4× and 10× objectives or equivalent; Technical Products International, *http://www.nuhsbaum.com*); glass bead added to platinum wire filament in the laboratory with pulled injection or holding pipet
Instrument holder to hold pipets (Leica, cat. no. 520145 or equivalent)
C-flex tubing: I.D. 1/32 in. × O.D. 3/32 in. × wall 1/32 in. × length ~4 mm long (Cole Parmer, cat. no.6424-60 or equivalent) to hold pipets inside instrument holder
150 × 25–mm tissue culture dish (Falcon 3025 tissue culture plate or equivalent)
Pipet puller (Kopf 1720 vertical pipet puller with nichrome heater coil or equivalent)
Top of 100 × 20–mm tissue culture dish (Falcon 3010 tissue culture plate or equivalent)
Dissecting microscope (10×/23 eye pieces, 0.6-6.6× zoom, with base illumination)
1-cc tuberculin syringe
30-G, 0.5 in. needle (Becton Dickson, cat. no. 305106 or equivalent)
35 × 10–mm tissue culture dishes (BD Falcon, cat. no. 3001, or equivalent)
Syringe pipet assembly (to coat injection pipets with 1.25% Tween 80 solution) including:
  12-cc tuberculin syringe
  Female luer 1/8 in. (Ark-Plas Products no. 10-15FL012N or equivalent) to connect syringe with tubing

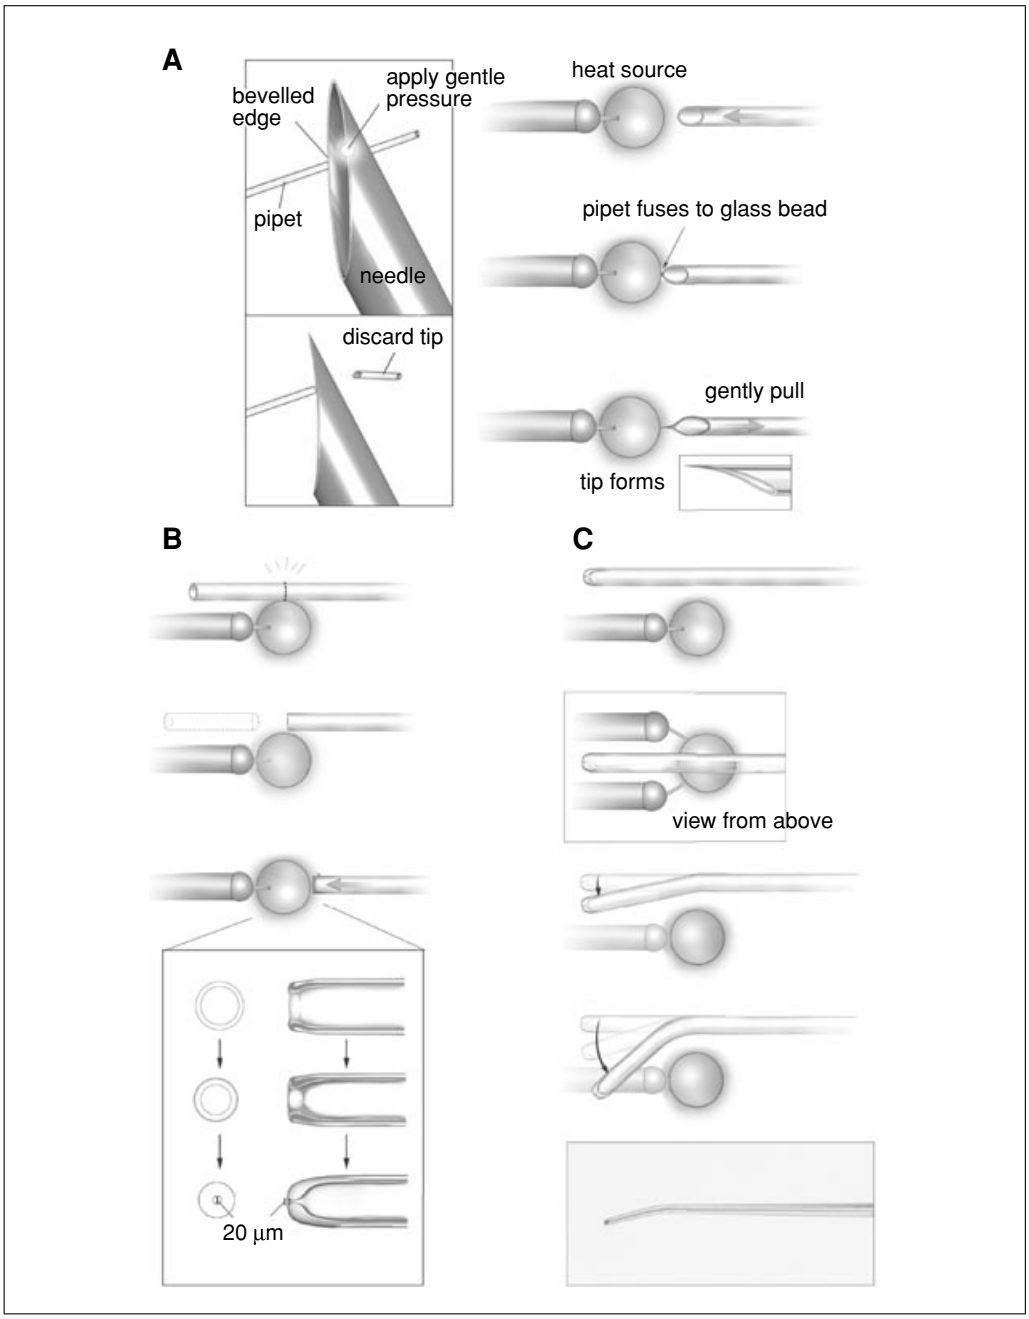

Figure 19.14.2 Fabrication of pipets with a microforge. (**A**) Breaking pulled injection pipet with a 30-G needle and sharpening tip with the microforge. A broken injection pipet is moved to the glass bead so that the tip is touching the glass bead. The injection pipet is allowed to fuse and is pulled slightly. The power is turned off and the glass allowed to contract, providing a sharp-tipped pipet with an inner diameter of 20 μm. (**B**) Breaking and polishing a holding pipet using the glass bead of the microforge. A pulled holding pipet is moved to the glass bead so that the edge of the tubing is touching the top and allowed to fuse. The power is turned off and the tubing broken by contraction. The inner diameter is melted to ∼20 μm. (**C**) Bending then holding pipet at 30° using glass bead. The holding pipet is brought near the glass bead of the microforge and allowed to bend at ∼30°. A transfer pipet would be made the same way in panel B, except the edges of the pipet are only polished and are not bent at a 30° angle.

Pipet insert and reservoir (Drummond microcaps no. 1-000-0300 or equivalent); a modified 1000-μl pipet tip may also be used as a reservoir.
Natural latex tubing (I.D. 1/8 in. × wall 1/32 in. × ~8 in. long)

Prepare transfer pipets

1. While holding both ends of a piece of glass tubing, one in each hand, place the tubing into a microflame.
2. Leave the glass tubing in the upper part of the flame until it becomes soft and can be easily moved up and down.
3. Quickly, take the glass tubing out of the flame and pull it apart in one continuous motion.
4. After the pipets have been pulled and allowed to cool for a few seconds, position the narrow end of each of the two tapering pieces of glass tubing between the thumbnail and forefinger and break apart.

   The pipets can be broken right after the pipets have been pulled and allowed to cool for a few seconds. A diamond pencil can be used to score the glass first before breaking it.

5. Look at the pulled pipet to see if it is the right size.

   Viewing the pulled transfer pipet takes practice. The only way to gauge the size of the transfer needle is to use a microforge that has a reticle in the eyepiece.

6. Insert a previously pulled transfer pipet into a pipet holder on a microforge.
7. Orient the transfer pipet so that the one can see it in the microforge optics.
8. Under 40× magnification, adjust the focusing knob so that the outer diameter of the transfer pipet is in focus.
9. Move the filament so that the outer diameter of the glass bead is also in focus, especially the area that will touch the transfer pipet.
10. Turn on the power for the filament that will heat the glass bead, and touch an area near the tip of the pipet.

    The authors use a power filament setting of 3. A different setting may work better, depending on the microforge unit you are using and the amount of glass that is in the glass bead.

    Avoid any areas that are chipped, broken, or cracked.

11. When the transfer pipet has fused with the glass bead on the platinum wire filament, turn off the power to the filament and allow the glass bead to contract, breaking the transfer pipet.

    When the transfer pipet fuses with the glass bead, a small indentation will form on the pipet.

12. Repeat steps 10 and 11 if the pipet becomes distorted and there is not a clean break.
13. Turn on the power to the filament to reheat the glass bead, and bring the glass bead next to the opening of the transfer pipet. Polish the opening, but not so much that the polishing actually narrows the opening of the transfer pipet.

    The authors use a power setting of 6 on the microforge to polish the edges of the transfer pipet. A different setting may work better depending on the microforge unit you are using and the amount of glass that is in the glass bead.

14. If needed, shorten the nontip side of the transfer needle with a diamond pencil by scoring the glass tubing and breaking at the score.

15. Store in a 150 × 25–mm tissue culture dish containing two strips of Plasticene to hold the pipets. Store all pipets facing in one direction.

    IMPORTANT NOTE: *The inner diameter of the transfer pipet should be large enough so that the fully expanded blastocysts are not constricted, which could possibly damage them. A pipet that is too small is more susceptible to blockage by blood clotting. The pipet should also not be too large that the blastocysts are bunched up together side-by-side instead of being lined up in a row. A general range for the inner diameter would be approximately 8 to 10 units at 40× magnification. A washing pipet would require a larger diameter due to the fact that some of the blastocysts may be fused together, and because of the debris that can be encountered. If using a reticle to make different types of pipets for ES cell injection, the measurement scale for the reticle at 40× magnification is 1 unit = 2.5 μm, and at 100×, 1 unit = 10 μm.*

Prepare holding pipets

16. Insert glass tubing into a pipet puller, adjust settings, and pull pipet.

    The authors use a heat setting of 12.0 units and a solenoid setting of 1.0 A for pulling holding pipets in the pipet puller.

17. Insert a previously pulled holding pipet into a pipet holder on a microforge.

18. Looking through the optics, move the pipet until it is the correct outer diameter on the reticle scale.

    At 40× magnification, this is ∼5 units and at 100× magnification this would be ∼12 to 13 units.

19. Make sure that the holding pipet is in focus, and then orient the glass bead on the filament so that it is also in focus, especially the edge of the glass bead that will touch the holding pipet.

20. With the edge of the holding pipet and the edge of the glass in the same plane, turn on the power of the filament that will heat the glass bead and gently touch the holding pipet. Allow the edge of the holding pipet to fuse with the glass bead.

    When the holding pipet fuses with the glass bead, a small indentation will form on the pipet.

21. Turn off the power to the filament and glass bead and allow the holding pipet to break.

    The authors use a power filament setting of 3. A different setting may work better depending on the microforge unit you are using and the amount of glass that is in the glass bead.

22. Repeat steps 20 and 21 if the pipet becomes distorted and there is no clean break.

23. Turn on the power to the filament and glass bead, and bring the glass bead up next to the opening of the holding pipet.

24. Melt the inner diameter of the holding pipet to 20 μm in size.

    At 100× magnification, this would be 2 units on the reticle scale.

    For the 20-μm inner diameter of the holding pipet, it is necessary to use a higher magnification than 40×. Magnification of at least 100× will work well for this purpose. If 40× magnification is used, the inner diameter will be inconsistent, and most likely larger than 20 μm. Inconsistency in size will lead to control problems with the holding pipet. This is especially important if the blastocyst is held by the trophoblasts and not the inner cell mass during injections. This can make injections very difficult, and the blastocyst could be suctioned into the holding pipet.

The authors use a power setting of 6 to melt the inner diameter of the holding pipet. A different setting may work better depending on the microforge unit that you are using and the amount of glass that is in the glass bead.

25. Turn on the power to the filament and glass bead, and, at some distance from the end of the holding pipet, bring the glass bead next to the holding pipet and make a 30° bend in the holding needle.

    The authors use a power setting of 6 to make this bend of the holding pipet. A different setting may work better depending on the microforge unit that you are using and the amount of glass that is in the glass bead.

26. Polish the back end of the holding pipet with a microflame by briefly putting the end into the flame.

    If the pipet is allowed to stay too long in the flame, it will be sealed closed.

27. Store in a 150 × 25–mm tissue culture dish containing two strips of Plasticene to hold the pipets. Store all pipets facing in one direction.

Prepare injection pipets

28. Insert glass tubing into a pipet puller, adjust settings, and pull pipet.

29. Place a previously pulled injection pipet on top of a lid from a 100 × 20–mm plastic tissue culture dish under a dissection microscope.

30. With a 30-G needle attached to a 1-cc syringe, gently tap the glass pipet at a perpendicular angle with the edge of the needle to break the glass (see Fig. 19.14.2A).

    IMPORTANT NOTE: *When viewing the bevel from the side, it is easier to see the edge of the 30-G needle (see Fig. 19.14.2A).*

31. Under a dissecting microscope, check the tip of the broken injection pipet. If the tip of the injection pipet needle appears to be in good shape overall, with no barbs, breaks, or jagged edges, save the pipet.

    With the settings that authors use for pulling injection pipet, the pipet can be broken a few times to get a proper broken pipet. After several attempts, it is best to use another pulled pipet.

32. Place previously broken injection pipet into a pipet holder on a microforge.

33. Orient the injection pipet so that it can be seen in the microforge optics.

34. Under 100× magnification, check again if the broken injection pipet appears to be free of defects and is of good size and shape. If defects are seen, discard the pipet.

    For the inner diameter of the injection pipet, we prefer a size of ∼20 μm.

35. If the pipet appears to still be of good quality, orient the pipet such that the bevel opening is either facing directly toward or away from you under the optics.

36. Focus the tip of the injection pipet and then orient the glass bead on the filament so that it is also in focus. Orient the tip of the injection pipet so that it is either facing toward or away from you.

37. Turn on the power to the filament that will heat the glass bead, and gently touch the tip of the pipet to the glass bead and allow it to melt just a little.

    The temperature setting should not be too high, or the inner diameter will become smaller. The authors use a power setting of 4.75 to melt the tip of injection pipet. A different setting may work better depending on the microforge unit that you are using and the amount of glass that is in the glass bead. The temperature of the glass bead should be high enough

to actually melt the pipet tip. Melting and pulling the pipet tip too much will create a bevel that is too long, which would make ES cell injections more difficult. If the tip is too long or there is a filament-like structure on the tip, the tip can be gently broken again and the melting of the tip can be repeated. If the tip is still is too short after the first melting, it can be repeated. If the inner diameter becomes too narrow or has a bevel too long, it is best to start over with another broken injection pipet. The authors prefer an injection pipet with an inner diameter of ~20 μm, which can be successfully obtained by using a heat setting of 14.2 units and a solenoid setting of 4.2 A when pulling injection pipets.

38. Pull away the glass bead only very slightly, and turn off the power to the filament, allowing the tip of the needle to contract from the glass bead.
39. Take the sharpened injection pipet out of the holder and set it aside.
40. Pour 1.25% Tween 80 solution into a sterile 35 × 10–mm dish.
41. Insert the injection pipet inside the rubber insert of the glass reservoir of the syringe pipet assembly.
42. Withdraw the Tween 80 solution inside the injection pipet to the hub and expel it back into the dish.
43. Lift out the injection pipet and continue expelling the Tween 80 solution out of the injection pipet to remove any excess.
44. Repeat steps 14 and 15 if necessary to ensure that the inside of the injection pipet is coated.

    Coating the inside of the injection pipet will help minimize debris and oil sticking to the inside of the pipet (Wells, 1993; Hogan et al., 1994).

45. Polish the back end of the injection pipet with a microflame by briefly putting the blunt end into the flame.

    If the pipet is allowed to stay too long in the flame, it will be sealed closed.

46. Store in a 150 × 25–mm tissue culture dish containing two strips of Plasticene to hold the pipets. Store all pipets facing in one direction.

BASIC PROTOCOL 2

INJECTION OF BLASTOCYSTS WITH ES CELLS

When injecting ES cells into blastocysts, the optimal type of blastocyst to inject would be between the middle and late stages, with a good-sized blastocoel cavity. Larger, more developed blastocysts tend to re-expand more quickly after injection, but are more susceptible to collapse prior to injection. Trying to inject any hatched blastocysts (see Fig. 19.14.3) can be difficult because they lack rigidity from the loss of the zona and have a very sticky outer surface, so they should be avoided. The morphology of ES cells to inject should be round and smooth and cells should appear opaque in nature. It is not uncommon to have small, medium, and large cell sizes. Medium-sized cells would be the preferred choice in that they will likely provide a higher chance for germline transmission, and they are less likely to be differentiated. Avoid the largest cells because they are mouse embryonic fibroblasts (MEFs; Stewart, 1993; see Fig. 19.14.3). Morula injections could be used instead of blastocyst injections to increase the success of generating chimeras, and have higher germline efficiency. A circulating pump may be used during the cooling stage in place of the dish to cool the ES cells and blastocysts. A suggested microinjection setup is listed in the materials list below (also see Fig. 19.14.4).

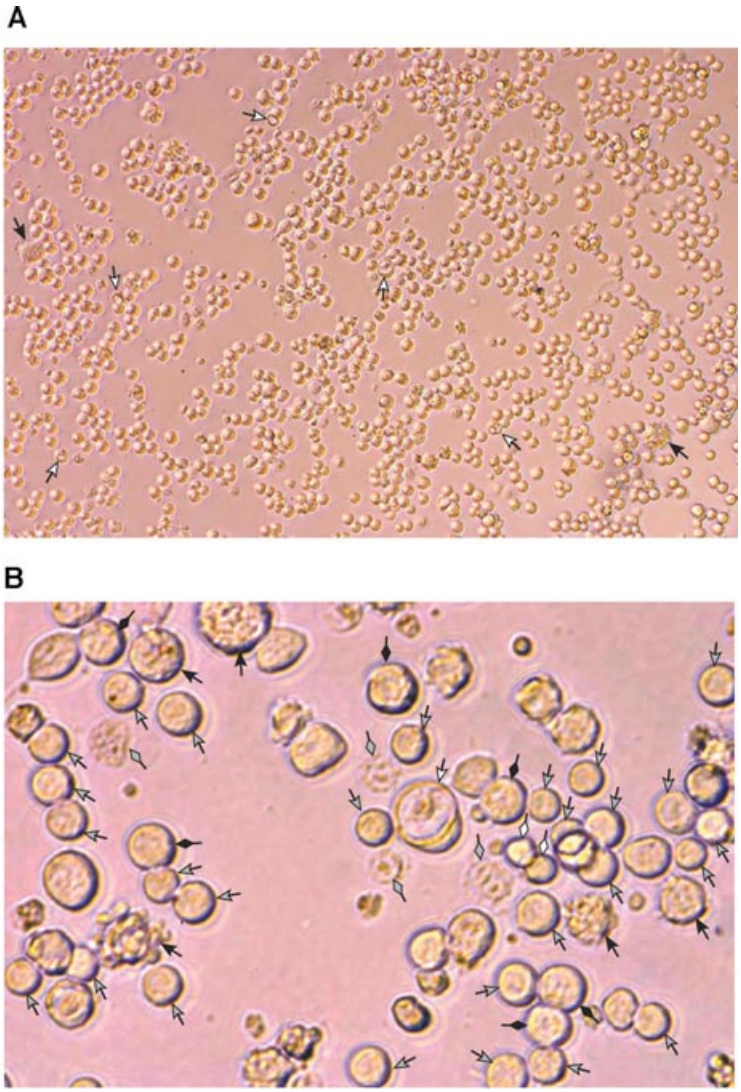

Figure 19.14.3 ES cell morphology. ES and MEF cell suspension and the different types of cells and morphology seen. (**A**) 100× magnification. Larger MEF cells are denoted by black arrows and differentiated ES cells by white arrows. (**B**) 400× magnification. Various types of cells seen in suspension. MEF cells are marked by black arrows. Differentiated ES cell is marked by a white arrow. Good morphology, medium-sized ES cells are marked by a gray arrows. Good-morphology, large, undifferentiated ES cells are marked by a black diamond. Small ES cells are marked by a white diamond. Translucent ES cells are marked by a gray diamond. It is suggested that medium-sized, good-morphology ES are the cells to inject into the blastocysts for optimal results.

Materials

Dulbecco's phosphate-buffered saline (DPBS) without calcium and magnesium (Mediatech, cat. no. 21-031-CV, or equivalent)
Liquid soap (e.g., VioNex; any liquid soap will probably work)
Injection medium (see recipe)
ES cell suspension (1×10^6/ml) transformed with desired transgene (*UNIT 19.13*)
Filtered light white mineral oil (Sigma M-3516 embryo-tested or equivalent)
Blastocysts (see Basic Protocol 1)

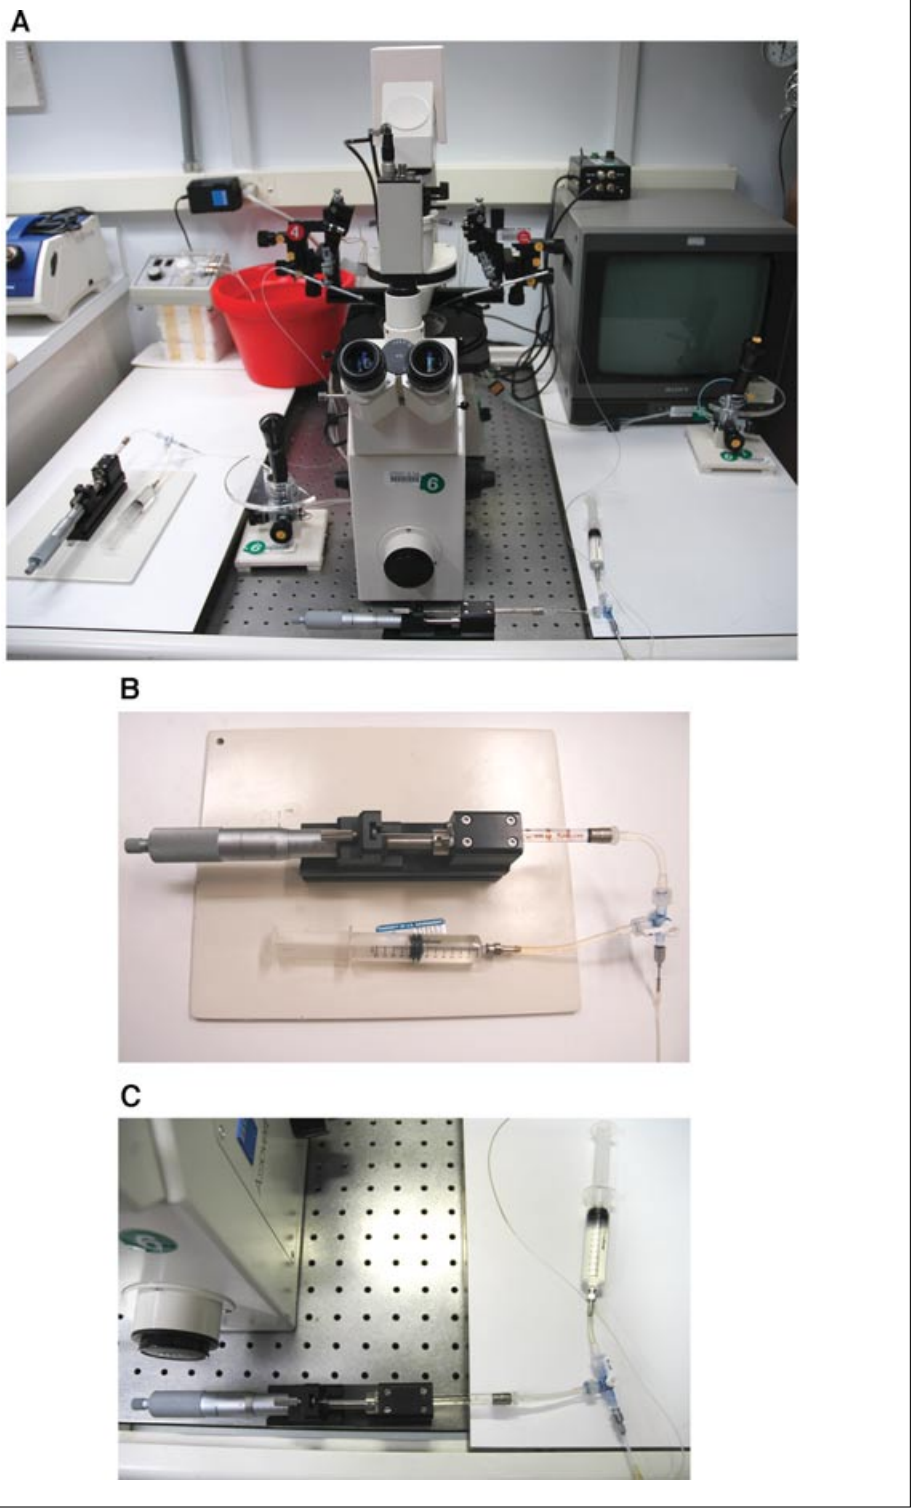

Figure 19.14.4 ES microinjection setup. (**A**) Picture of microinjection setup. (**B**) Picture of holding system detailing micrometer syringe assembly, syringe reservoir, stopcock, tubing, and fittings. (**C**) Picture of injection system detailing micrometer syringe assembly, syringe reservoir, stopcock, tubing, and fittings.

60 × 15–mm tissue culture plate (Falcon 3002 or equivalent)
70% ethanol pads
Injection chamber with cooling system (Fig. 19.14.5)
  Water circulating pumps (Baxter, cat. no. 8329 or equivalent)
  Siliconized tubing, I.D. 3/16-in., with plastic connections
  Male luers with 1/16 in. barb (Cole Parmer, cat. no. 31507-62 or equivalent) to connect plastic connections of silicone tubing to inflow and outflow Tygon tubing
  Injection dish (see Fig. 19.14.5)
  Tygon tubing for inflow and outflow cooling lines, I.D. 3/32 in. × O.D. 5/32 in. × wall 1/32 in.
  60 cc tuberculin syringe with Tygon tubing to load water jacket of injection dish
  Female luer with 3/16 in. to 1/4 in. barb (Cole Parmer, cat. no. 31507-62 or equivalent) connected to inflow tubing as a weight in ice water
Transfer pipet, cleaned and polished (Support Protocol 2)
Mouth pipet assembly (see Fig. 19.11.2 and Basic Protocol 1)
Dissecting microscope (10×/23 eye pieces, 1.0× objective, 0.6 to 6.6× zoom, with base illumination)
Injection pipet (see Support Protocol 1)
Holding pipet (see Support Protocol 1)
Microinjection setup (see recipe and see Fig. 19.14.4) consisting of:
  Injection apparatus:
  Inverted microscope (Zeiss 135M or equivalent)
  Coarse micromanipulators (microscope-mounted; Narishige MMN-1 or equivalent)
  Fine micromanipulators (Joy-stick micromanipulator; Narishige MO-202U or equivalent)
  Mounting bracket for mounting Narishige course manipulators
  Video camera (Dage-MTI CCD-72 or equivalent)
  Video monitor (Sony PVM-137 or equivalent)
  Injection line:
  Instrument holder to hold injection pipet (Leica, cat no.520145 or equivalent)
  Tygon tubing AAC00001: I.D. 1/16 in. × O.D. 1/8 in. × wall 1/32 in. × ∼4-mm long tubing insert for instrument holder to connect injection pipet to PE 60 tubing
  Polyethylene tubing for injection line (Becton Dickinson PE 60, no. 427415, I.D. 0.030 in. × O.D. 0.048 in. × length ∼2 ft. or equivalent)
  Tygon tubing AAC00001: I.D. 1/16 in. × O.D. 1/8 in. × wall 1/32 in. × ∼8 mm long or equivalent to connect between Tygon tubing AAC00002 and PE 60 tubing
  Tygon tubing AAC00002: I.D. 1/16 in. × O.D. 1/8 in. × wall 1/32 in. × ∼1 cm long or equivalent to connect Tygon AAC00001 tubing to PE 200 tubing
  Polyethylene tubing for injection line (Becton Dickson PE 200; Clay Adams no. 427440, I.D. 0.055 in. × O.D. 0.075 in. or equivalent), ∼3.5 cm. in length
  Female luer flare type adapter (Popper no. 6193 or equivalent) to connect PE 200 tubing to 3-way stopcock
  3-way stopcock (Baxter no. K177A or equivalent)
  Tygon tubing (Cole Parmer no. 6408-63, I.D. 3/32 in. × O.D. 5/32 in. × wall 1/32 in. or equivalent) for injection line between the stopcock and to either the syringe reservoir or the Hamilton syringe
  Female luer with barb (BioRad, cat. no. 7318223 or equivalent) to connect Hamilton syringes to Tygon tubing
  Male luer with barb (BioRad, cat. no. 7318226 or equivalent) to connect to luer lock connection of stopcock to Tygon tubing

Micrometer syringe (Minnetonka Instruments or equivalent) with Mitutoyo syringe, 0 to 50 mm, with 50-μl gas-tight syringe (Hamilton no. 80920 or equivalent for injection line)

Female luer connection with barb (Cole Parmer no. 31507-65 or equivalent) to connect Cole Parmer 6408-63 to tuberculin syringe reservoir

Tuberculin syringe (12 cc) containing Dow Corning silicone oil 200 for reservoir

Holding line:

Instrument holder to hold holding pipet (Leica, cat. no. 520145 or equivalent)

Tygon tubing AAC00001: I.D. 1/16 in. × O.D. 1/8 in. × wall 1/32 in. × length ~4 mm or equivalent tubing insert for instrument holder to connect holding pipet to PE 60 tubing

Polyethylene tubing for holding line (Becton Dickinson PE 100; Clay Adams no. 427425, I.D. 0.034 in. × O.D. 0.06 in. × approximate length 2 ft., or equivalent)

Tygon tubing AAC00001: I.D. 1/16 in. × O.D. 1/8 in. × wall 1/32 in. × length ~1.8 cm, or equivalent, to connect between PE 100 tubing and blunted 19-G needle

Blunted 19-G needle to connect male luer end of stopcock to Tygon AAC00001 tubing

3-way stopcock (Baxter, cat. no. K177A or equivalent)

Tygon tubing (Cole Parmer no. 6408-63: I.D. 3/32 in. × O.D. 5/32 in. × wall 1/32 in., or equivalent) for injection line from the stopcock to either the syringe reservoir or the Hamilton syringe

Female luer with barb (BioRad, cat. no. 7318223 or equivalent) to connect Hamilton syringe to Tygon tubing

Male luer with barb (BioRad, cat. no. 7318226 or equivalent) to connect luer lock connection of stopcock to Tygon tubing

Micrometer syringe (Minnetonka instruments or equivalent) with Mitutoyo syringe, 0 to 50 mm with 250 μl gas-tight syringe (Hamilton, cat. no. 81120 for holding line)

Female luer connection with barb (Cole Parmer, cat. no.31507-65 or equivalent) to connect Cole Parmer 6408-63 to tuberculin syringe reservoir

Tuberculin syringe (12 cc) containing silicone oil 200 for reservoir

Ice bucket containing ice and water

Air suspension platform setup:

Air suspension table (Kinetic Systems 9101-02-46 or equivalent)

Gas regulator (Curtis Mathis 1H-580 or equivalent)

Nitrogen gas cylinder (Roberts Oxygen no. R-31 or equivalent)

Check microinjection apparatus

The microinjection system should be functioning properly before proceeding with injection of ES cells into blastocysts. Address all problems before starting the actual microinjection procedure. Both injection and holding systems should be in good working order before attempting ES cell injections. See Critical Parameters and Troubleshooting for details on problems encountered when injecting blastocysts.

1. Fill a 60 × 15–mm tissue culture dish with DPBS, and check the condition of both the injection and holding pipets by using them to take up the DPBS.

   The pipets should be in good condition and not clogged or broken, with no debris sticking to the inside. The uptake of DPBS into both pipets should be a smooth and fluid motion.

2. If using a silicone- or mineral oil-based system, check to see that there are no bubbles or leaks present in either the injection or holding line systems.

   If bubbles or leaks are present, severe control problems can occur.

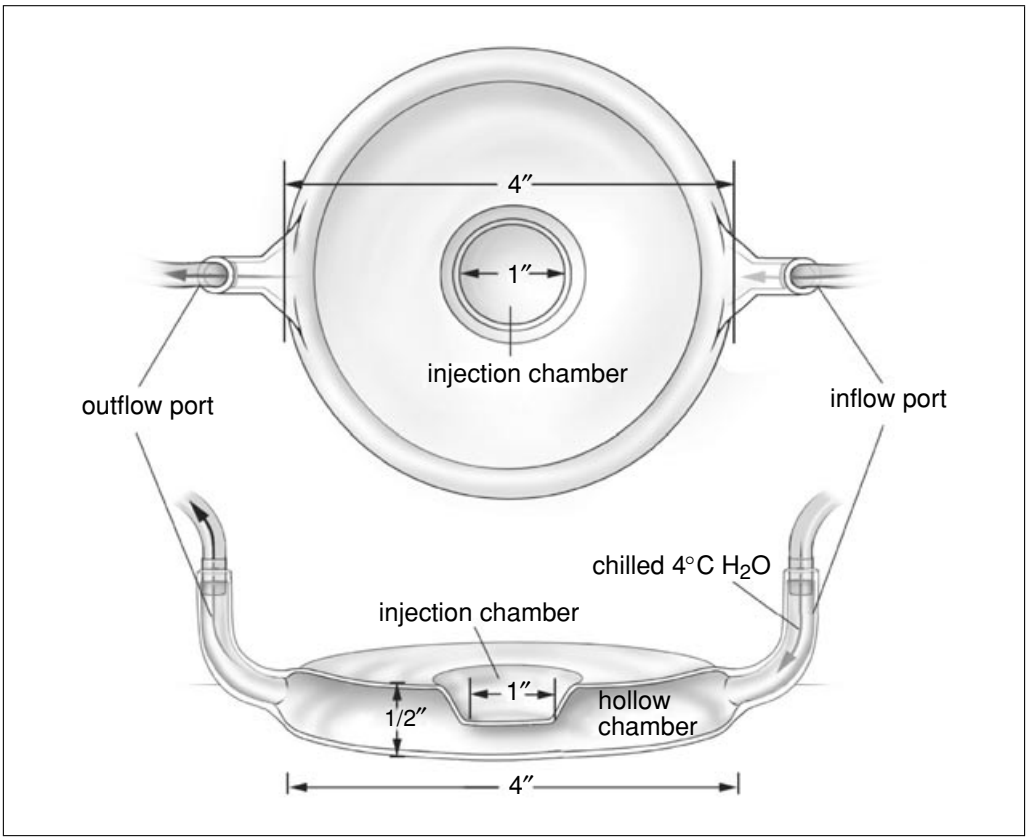

Figure 19.14.5 Diagram of injection dish. The dish has an outer diameter of 4 in., an inner diameter of ~1 in., and a height of 0.5 in. The dimensions of the inflow and outflow ports are ~1.5 in. long with an inner diameter of 3/8 in.

Prepare injection dish

For a cooling system, we use a glass injection chamber with an internal hollow opening around the injection chamber to allow for chilled (4°C) water to circulate (see Fig. 19.14.5). There are two reasons to use some sort of cooling apparatus. The first is to delay the re-formation of surface proteins after trypsinizing the cells so they do not become sticky. Secondly, cooling is conducive to the rigidity of the blastocysts. The injection dish should be free of alcohol, as this can cause differentiation of the ES cells. For the following steps, refer to Figure 19.14.5.

3. Swab the injection chamber area thoroughly with a 70% ethanol pad, then wash liberally with sterile DPBS.
4. Add a very light film of liquid soap under the bottom of the injection dish to prevent water droplets from forming during the cooling process.
5. Attach inflow tubing from the water circulating pump to the input opening of the injection dish.
6. Next, insert outflow tubing into the output opening of the injection dish, which has been placed in a chilled water reservoir, and then start the circulating pump.
7. Pipet 1.5 ml injection medium into the well of the injection dish and add 30 μl of the 1×10^6 cells/ml ES cell suspension.

   The authors recommend a cell suspension of 1×10^6 per ml. This is more than enough cells for injection purposes. If too many cells are added to the injection dish, the cells tend to become sticky. A high ratio of ES cells to feeder cells is best for injections. Having

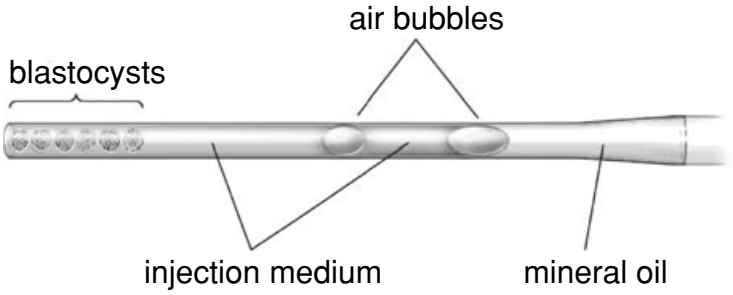

Figure 19.14.6 Diagram of transfer pipet loaded with blastocysts. The air bubbles are omitted for blastocyst injection (Basic Protocol 2), but are used when loading a transfer pipet for uterine implantation (Basic Protocol 3). Mineral oil is first loaded inside the pipet. This is followed by the first bubble, injection medium, another bubble, and then the blastocysts.

some feeder cells can be a benefit in that they can be used to clear debris from inside the injection pipet. This is done by loading a feeder cell inside the injection pipet and moving it back and forth to dislodge any debris inside the pipet.

8. Overlay with light mineral oil.

Transfer embryos to microinjection dish

Blastocysts are more tolerant to pH and temperature changes than earlier-stage embryos such as zygotes. Lowering the temperature will delay the onset of blastocyst hatching. Keeping blastocysts in the cold injection chamber too long might be detrimental to their vitality.

9. Take the dish containing the blastocysts with mineral oil and injection medium out of the incubator (see Basic Protocol 1, step 20).

10. Take a clean and polished transfer pipet, and mouth pipet light mineral oil to the hub of the pipet (Fig. 19.14.6).

11. Load unhatched blastocysts inside the transfer pipet from the dish containing the blastocysts (see Figure 19.14.6).

    The air bubbles shown in Figure 19.14.6 are omitted for this procedure. The authors use only oil and media, and no bubbles, to transfer the blastocysts from the medium and oil overlay dish to the injection dish and back.

12. Take the transfer pipet and gently expel the embryos into the chamber of the injection dish, while clearing an area for injections in the cell suspension. Only transfer as many blastocysts to the injection dish as can be injected within 30 min.

    Any investigator with a reasonable skill level should be able to inject 10 to 20 blastocysts, depending on injection conditions.

Inject ES cells

When first learning ES cell injections, 200× magnification should be used. Focus on the outer ring of trophoblast cells and then the tip of the injection pipet before attempting to inject inside the blastocoel cavity. This ensures that the injection pipet is in the correct plane of the z axis, being approximately in the center of the blastocoel cavity. After becoming proficient in ES cell injections, a tapping technique, which looks at indentations on the blastocyst, can be employed to make sure the injection pipet is in the right plane. 100× magnification will work well with this procedure and has the advantage of a broad field of view to collect the ES cells, and changing the objective is not required. The general range for the number of ES cells that can be injected inside a blastocyst

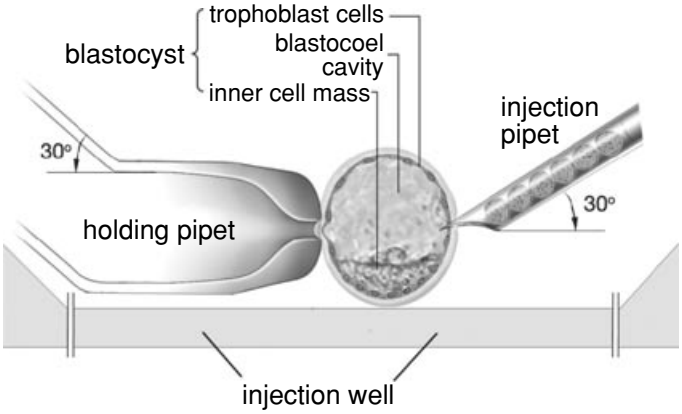

Figure 19.14.7 Diagram of blastocyst injection chamber. The blastocyst is held by the holding pipet and is touching the bottom of the injection well for stability. The injection pipet is unbent and is inside the blastocoel cavity at a 30° angle.

is considered to be between 10 and 20 (Papaioannou and Johnson, 2002). The authors' preference is to inject 15 ES cells, which balances the chance of germline transmission versus normal homeostasis in embryonic development. It is advisable not to inject more than 20 ES cells (Wells, 1993), as this is thought to be detrimental to the developing mouse embryo.

13. After blastocysts have been transferred to the bottom of the inner chamber on the injection dish, lower the holding and injection pipets (Fig. 19.14.7).

    All blastocysts should be injected within 30 min of putting them on the injection dish.

14. With the injection micrometer syringe, take up a small amount of injection medium inside the injection pipet.

    This will allow a buffer area between the cells and the oil and help prevent injection of oil inside the blastocoel cavity.

15. Load 15 ES cells inside the injection pipet with as little injection medium as possible.

    The ES cells do not have to be touching each other when inside the injection pipet. If the cells are touching, there is a possibility that they may stick to each other and, consequently, many of the cells may come out of the blastocyst when withdrawing the injection pipet.

16. Orient the blastocyst so that the inner cell mass (ICM) is in the 6 o'clock position with the injection pipet. Make sure the bevel of the injection needle is pointed down (Fig. 19.14.8).

    The blastocyst can be oriented with respect to the injection pipet by moving the joystick in either a clockwise or counterclockwise motion. Using the holding pipet to orient the blastocyst will disperse the cells away from the injection area and also other blastocysts.

17. With the holding micrometer syringe, take up injection medium inside until the blastocyst is held securely to the holding pipet. Lower the holding pipet until the blastocyst is just touching the bottom of the injection dish.

18. Focus on the zona and outer trophoblast layers of the blastocyst, and then move the injection pipet so it is also in focus.

    This puts the injection pipet in the correct plane of the z axis.

    It is better to inject at the junction between the trophoblast cells, reducing damage to the embryo. Sometimes this junction may be hard to see.

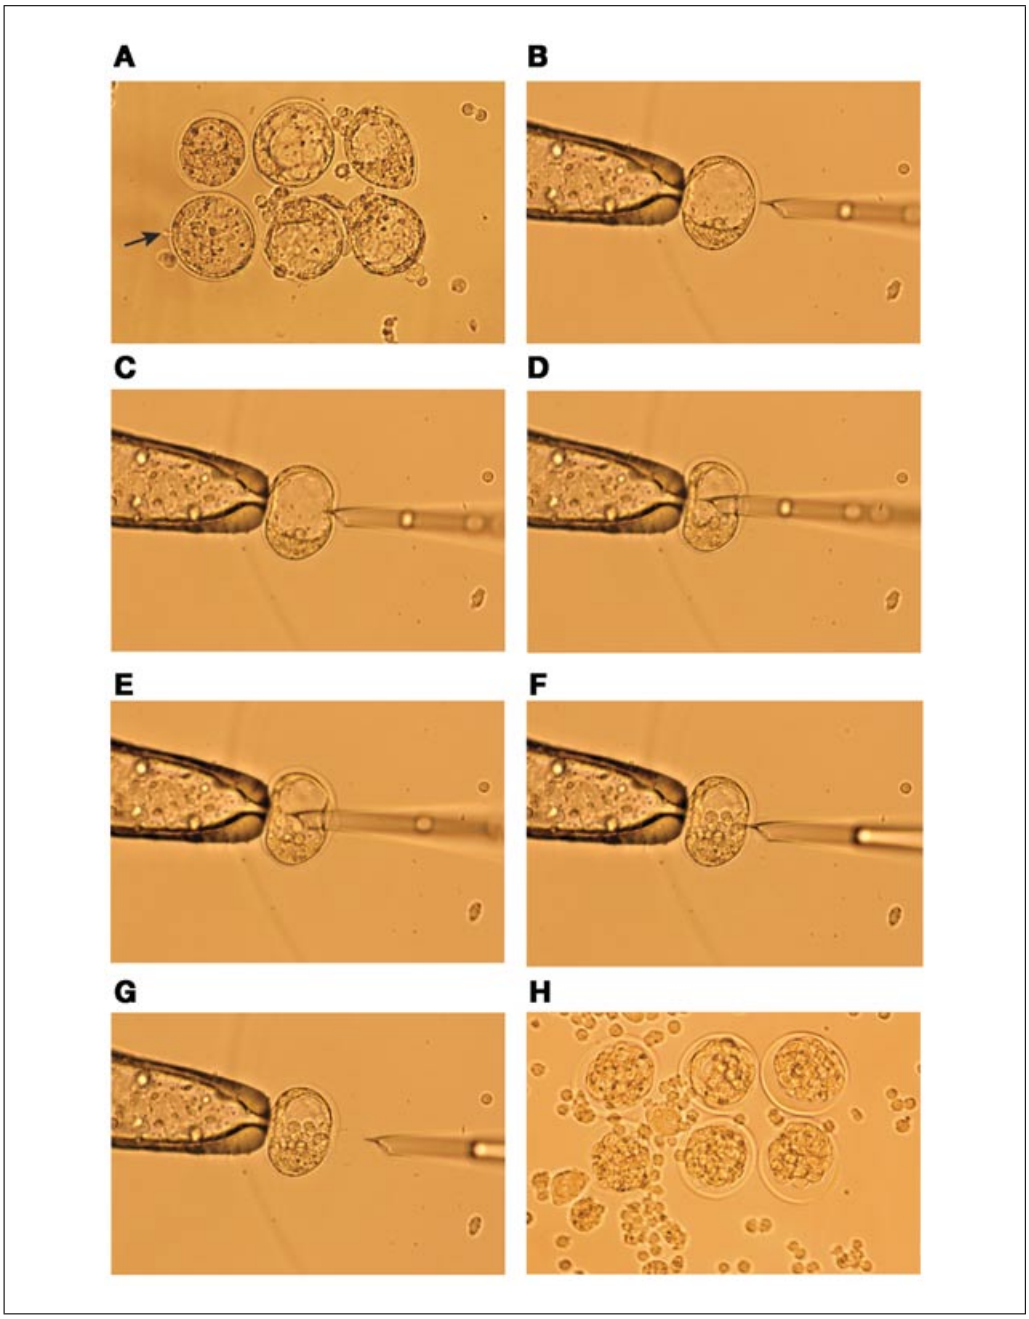

Figure 19.14.8 Blastocysts and sequential ES injection. (**A**) Blastocysts at various stages of development: top left, early stage blastocyst; top middle, middle-to-late stage blastocyst; top right, oval-shaped blastocyst; bottom left, blastocyst in the process of hatching (arrow) showing early bud structure; bottom middle, blastocyst on the verge of hatching with pronounced trophoblast morphology; and bottom right, hatched blastocyst. (**B-G**) Panels showing sequential steps in blastocyst injection. (**H**) Injected blastocysts in various stages of collapse.

19. With a quick, short popping and jabbing motion, insert the injection pipet inside the blastocoel cavity, being careful not to touch the ICM. Pull back the injection pipet slightly after inserting into the blastocoel cavity.

    Touching the ICM is considered harmful to the blastocyst. If the injection pipet is inserted too slowly, the blastocyst will likely collapse, making injection difficult. If the pipet is only partially inside the blastocoel cavity and the blastocyst collapses, medium can be injected to re-expand the blastocyst, and another attempt to inject the blastocyst can be made. Otherwise, move the blastocyst to the side and perform injection on another.

20. Gently expel the ES cells inside the blastocoel cavity onto the ICM, being careful not to inject oil into the blastocoel cavity.

21. Withdraw the injection pipet slowly out of the blastocoel cavity, avoiding the expulsion of the ES cells outside of the blastocyst. Allow the injection site to close before fully withdrawing the injection pipet.

    Letting some medium escape will enhance the settling of the injected ES cells onto the ICM.

    When injecting, consider the pressure inside the blastocoel cavity. If too much medium is injected inside the blastocyst or too much holding force is applied by the holding pipet, the injected ES cells may be forced out of the blastocoel cavity.

22. After injection of the blastocyst, move it to an area away from the uninjected ones on the injection dish with the injection pipet using a technique similar to that described in step 16.

23. When all blastocysts on the injection dish have been injected, use a transfer pipet to place the injected blastocysts into a new microdrop culture (see recipe and see Basic Protocol 1, step 20) and put back into the incubator.

24. Allow the blastocysts to re-expand in culture.

    Re-expansion of the blastocoel cavity of the blastocyst is a possible sign of its vitality.

    The ES cell clones should be injected (see Basic Protocol 3) within 2 hr after putting them on the injection dish.

    If both the holding and injection pipets are flushed out with oil, they have the potential to be reused for another injection day.

UTERINE TRANSFER OF INJECTED BLASTOCYSTS

BASIC PROTOCOL 3

Surgical transfers have to be performed on the same day as the ES cell injections, and E2.5-day pseudopregnant recipient females are generally used to allow the blastocyst to catch up developmentally prior to implantation at E4.5 to E5.0 days. If E2.5 recipients are unavailable, the authors have had success with E1.5 and E2.0 recipients with this procedure. Pups are generally born 18 to 21 days p.c. of the pseudopregnant recipient.

The authors recommend a zoom setting of 3.2 for the surgical microscope, which will allow a large enough field of view for the uterine horn and still make it possible to see the hole in the uterine horn wall.

Materials

Injection medium (see recipe)
Filtered light white mineral oil (Sigma M-3516 embryo tested or equivalent)
Injected blastocysts in microdrop cultures (see Basic Protocol 2)
2.5-day p.c. pseudopregnant B6D2F1 female mice or equivalent (see Support Protocol 3)
2.5% Avertin working solution (see recipe)
0.5% Marcaine (Hospira, cat. no. NDC 0409-1610-50; *http://www.hospira.com/*) or 0.5% Naropin analgesic (AstraZeneca, cat. no. NDC0186-0863-61)

Transfer pipets (see Support Protocol 2)
Mouth pipet assembly (see Fig. 19.11.2 and Basic Protocol 1)
35 × 10–mm tissue culture dishes (BD Falcon, cat. no. 3001)

100 × 20-mm tissue culture dish (BD Falcon, cat. no. 3010) containing two Plasticene rolled strips (Fisher Scientific, cat. no. P148-1LB or equivalent); do not sterilize prior to surgery

Dissecting microscope (10×/23 eye pieces, 1.0× objective, 0.6 to 6.6× zoom, with base illumination)

Mouse fur clippers (Oster finisher trimmer no. 76059-030 or equivalent)

70% ethanol pads

Betadine swabs

Surgical stand (6-1/8 in. × 7-1/2 in. Nalgene container top with vinyl bumpers attached to bottom, or equivalent)

Surgical microscope (16×/16 eye pieces, 0.63× objective, 0.8 to 6.6× zoom) with Diagnostics SMS6B sliding zoom stand or equivalent)

Fiber-optic light source (Zeiss KL-1500 or equivalent)

Surgical instruments, cleaned and sterilized by placing in glass bead sterilizer (Fine Science Tools FTS 250 or equivalent) for 10 sec prior to use in surgery:

Dissection scissors (Roboz RS-5880 or equivalent)

No. 7 curved forceps (Roboz RS-5064 or equivalent)

Foerster forceps, straight tips (Roboz RS-5065 or equivalent)

Dieffenbach clamp (Roboz RS 7422 or equivalent)

Wound clip–removing forceps (Roboz RS-9268 or equivalent)

Wound clip applier, Reflex 9 (Roboz RS-9260 or equivalent)

9-mm wound clips (Roboz 9262 or equivalent)

Autoclaved sterilization pouch 5-1/4 in. × 10 in. (Fisher Scientific, cat. no. 01-812-54 or equivalent) to serve as sterile field for instruments

Sterile gauze, 2 × 2-in. and 4 × 4-in.

25-G, 5/8-in. needles

1-cc tuberculin syringes

Sterile cotton swabs

37°C slide warmer

Additional reagents and equipment for injection of the mouse (Donovan and Brown, 2006b)

Load transfer pipets with injected blastocysts

1. Take an already-made transfer pipet and load mineral oil to the hub of the transfer pipet by mouth pipetting (see Fig. 19.14.6).
2. On the inside of the top section of a 35 × 10–mm tissue culture dish, place a small amount (one drop) of injection medium.
3. Under low-power magnification, (a zoom control knob setting of 1.2 with 10× eye pieces and 1× objective), place the transfer pipet into the drop of medium and then onto the area that does not contain medium, and then gently take up the medium, forming an air gap.
4. Immediately place the transfer pipet into the drop of medium, while keeping the air gap, to form a bubble.
5. Repeat steps 3 and 4 to form a second air bubble.
6. Under high power (a zoom control knob setting of 6.6 with 10× eye pieces and 1× objective), take the plate containing medium with injected blastocysts under oil and place the transfer pipet into the medium drop. Take up the medium until the last bubble is just out of the field of view.

If an oil droplet forms on the outside of the transfer pipet upon placing it into the drop of medium, gently shake the transfer pipet back and forth until the drop of oil comes off.

7. Next, take up the injected blastocysts slowly one at a time, allowing as little medium as possible to be drawn up along with them, until all embryos for a given recipient mouse are loaded into the transfer pipet.

8. Make sure the blastocysts are stabilized inside the transfer pipet so that the embryos do not move. If they do move up the transfer pipet, repeat steps 1 through 7.

9. Store transfer pipets with loaded embryos in a tissue culture dish containing two strips of Plasticene prior to surgery.

   The tissue culture dish with Plasticene is not sterilized prior to surgery. Loaded and unloaded transfer pipets are oriented in the same direction on this dish. Only load the transfer pipets that will be used on the next surgical transfer. Since the blastocysts are loaded in the transfer piper just prior to surgery, they are not kept in the incubator while in the transfer pipet. Make up two transfer pipets if surgery is to be performed on both uterine horns.

Surgically transfer embryos

10. Swab the abdomen of an E2.5-day pseudopregnant mouse with an ethanol pad and anesthetize the mouse by intraperitoneal injection (Donovan and Brown, 2006b) of 0.015 to 0.017 ml/g body weight of 2.5% Avertin.

11. When the mouse is fully anesthetized, prepare the animal by shaving the surgical area using clippers.

12. With a 70% ethanol swab, wipe away all loose fur, and then swab the skin with a Betadine swab. Repeat again with another ethanol and Betadine swab in the same order. Place the surgically prepared mouse on a surgical stand and illuminate the surgical area with a fiber-optic light source.

13. Next make a 5-mm incision in the skin ~1 cm away from the thigh area of the hind limb on the back of the mouse, holding the skin with a no. 7 curved forceps (Fig. 19.14.9).

14. Once an incision has been made through the skin, grasp the underlying muscle with a pair of Foerster forceps, and cut through until reaching the peritoneal cavity.

15. Under the surgical microscope, look for the fat pad and the ovary and, using Foerster forceps, gently pull out the ovary by the fat pad.

    The ovary and fat pad may be seen through the dorsal muscle if there is a low amount of fat on the mouse. The ovary will have a bright red color due to the formation of the corpus luteum. Do not use mice that lack a corpus luteum on the ovary. This would indicate that the mouse is not pseudopregnant. The ovarian fat pad will appear bright white in color with a smooth texture. Avoid the rough-looking, beige tissue that is attached to the spleen, which is most likely the pancreas.

16. Grab the fat pad with a Dieffenbach clamp and gently lay it over the other side of the back onto 2 × 2–in. sterile gauze.

    The mesometrium structure should be on the bottom of the field of view.

17. Orient the mouse in such a way that the ovary and fat pad are in the 9 o'clock position. Gently grasp the uterus with Foerster forceps, and, with a 25-G needle attached to a 1-cc syringe, make a hole in the uterus under the forceps into the lumen.

    The hole for the transfer pipet should be made near the tip of the uterine horn just as the taper from utero-tubal junction ends and becomes full size. This will allow for a higher rate of implantation than transferring near the cervix. This offers the added advantage of being easier than transferring at the very tip of the uterine horn, especially since there is a much bigger lumen to put the 25-G needle and transfer pipet into.

    If the needle is inside the lumen, it should move freely with no resistance.

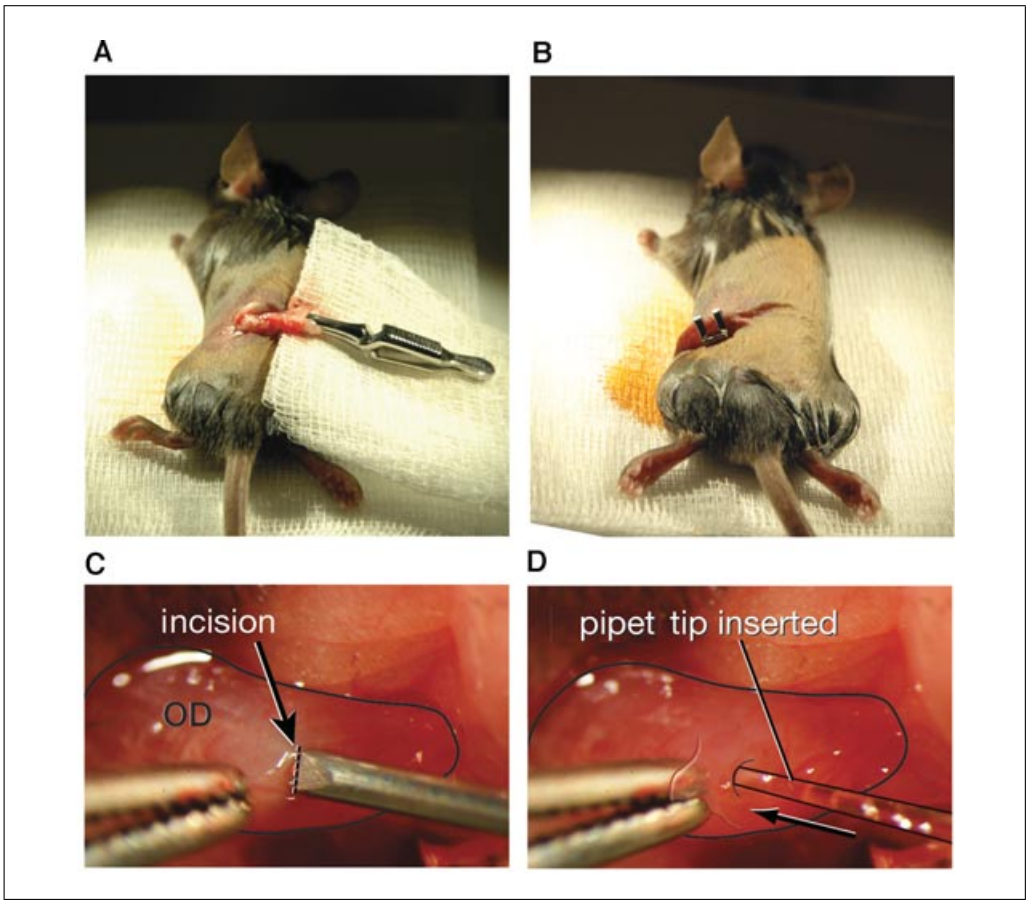

Figure 19.14.9 Diagram of uterine transfer of blastocysts. (**A**) The uterine horn has been extracted from the peritoneal cavity. (**B**) The surgical incision closed by wound suture. (**C**) Hole made in the uterus by 25-G needle into the lumen. (**D**) Transfer pipet placed inside the hole of the uterus into the lumen, showing air bubbles present inside the pipet.

18. Insert the transfer pipet, loaded with injected blastocysts, just barely inside the hole in the uterus. Gently blow the embryos inside the uterus by mouth pipetting, using the bubbles as a marker to see if the blastocysts are inside the lumen.

    If the bubbles inside the transfer pipet do not move when blowing them into the lumen of the uterus, the transfer pipet may be touching the inside uterine wall. Slightly pull back the transfer pipet and try again. If this does not work, take out the transfer pipet and place in a dish containing a small amount of injection medium under the dissecting microscope. If a blood clot is seen, dislodge it and reload the transfer pipet again with the injected blastocysts. Repeat step 18.

19. Under a dissecting microscope, check to see if there are any embryos left in the transfer pipet. Repeat step 18 if blastocysts are left inside the transfer pipet.

20. Release the Dieffenbach clamp and hold the fat pad with the Foerster forceps. Place the uterus and ovary back inside the peritoneal cavity. Do this while holding the incision open by the skin with the curved no. 7 forceps.

21. Gently swab the lateral dorsal muscle incision with a sterile cotton swab saturated with 0.5% Marcaine or 0.5% Naropin analgesic.

22. Hold together the skin incision with a no. 7 curved forceps, and close the wound with a 9-mm wound clip.

23. Repeat steps 13 to 22 if transferring blastocysts to the other uterine horn.

24. Place the mouse on a 37°C slide warmer that has gauze placed on top of it. Allow the mouse to stay on the slide warmer until it wakes up.

25. Place the mouse in a cage for further recovery. When the mouse appears fully recovered from the Avertin, transfer it back into the animal room.

Enough embryos should be transferred to allow the pups to be born healthy. If too few embryos are born, the pups will tend to be large in size, causing trauma to the pups and mother, as well as decreased lactation. If too many embryos are transferred, the pups could be severely runted and die. Based on the authors' experience using B6D2F1 and B6CBAF1 recipient mice, only six mice will be implanted per uterine horn; none of the blastocysts will migrate to the other uterine horn. Five to ten embryos should be transferred into each uterine horn, with a maximum of twelve embryos transferred if transferring into both horns (Hogan et al., 1994). If new to this surgical procedure, allow for a greater number of embryos when transferring, to allow for enough embryos to implant.

GENERATION OF PSEUDOPREGNANT RECIPIENT FEMALES

SUPPORT PROTOCOL 3

Various strains of mice can be used for the purpose of serving as pseudopregnant foster mothers. Outbred mice tend to be the best mothers, and two notable examples are the Swiss Webster and CD1 strains. C57BL/6 hybrid strains are another alternative, as well as B6D2 and B6CBA. The use of inbred strains is generally not recommended, but if it is unavoidable, the FVB/N strain is the best choice. The strain of mouse chosen should be proven to have good mothers that take care of their offspring.

Vasectomized males of just about any strain could be used as long as they are known for their ability to plug females. Balb/c males seem to be the most commonly used for this purpose, though other strains of males could be used.

Even if the vasectomized mice are from a reliable supplier, the males should be tested for sterility. Before the vasectomized males become too old and lose their plugging ability, new ones should be ordered, and these should be tested prior to use. The new vasectomized males could be housed with one or two females up to a maximum of 2 months to test for sterility. If time is a factor, there is the option of superovulating the females with PMSG and HCG (Support Protocol 1) and then housing them with the vasectomized males to see if the latter are truly sterile.

Table 19.14.2 shows a schedule for embryo collection and transfer into recipient females.

Materials

B6D2F1 (C57Bl/6NCr x DBA/2NCr) female mice, or equivalent strain (10 to 12 weeks of age)

Balb/cAnNCr vasectomized male mice, or equivalent strain (at least 6 to 7 weeks to 18 months of age)

1. Mate one female to one vasectomized male 4 days prior to the harvest date for collection and injection of blastocysts.

2. The next morning, before 0900 hr, check the mated females for copulation plugs. Remove the plugged females into another cage and mark with the date they were plugged.

The authors initially mate 25 females 4 days before the start of ES cell injections. An additional 25 females are used to replace any plugged females. Unplugged females are kept with the males until 2 days prior to the last injection day for the week. Any unused females will then be separated out from the males and then can be reused for future matings. A period of at least 5 days should elapse before the mice are mated again. This will allow the mice to reestablish the estrus cycle.

Table 19.14.2 Embryo Collection and Recipient Schedule[a,b,c]

Day	Collect embryos	PMSG (1:00 p.m.)	HCG (12:00 p.m.)	Separate embryo donor females	Pseudopregnant recipient females
Monday	C		B		Separate, and mate again
Tuesday		C		B	Separate, and mate again
Wednesday	A				Separate
Thursday		A	C		No matings, rest day
Friday	B			C	Mate (25 B6D2 F1)
Saturday		B	A		Separate, and mate again
Sunday				A	Separate, and mate again

[a]Each letter denotes a group of (ten) C57B16 females used for a certain injection day.
[b]Recipient females that are plugged are separated and each is replaced with another B6D2 female, for a total of 50 B6D2 females for the week of injections.
[c]Group A females could be separated on Monday instead of Sunday if it is not necessary to know the number of plugged donor females.

The time window from when the female is plugged by the male to when the plug can no longer be seen is thought to be 12 hr. If necessary, females can be mated with the males in the morning to generate plugged pseudopregnant recipients in the afternoon. The plugs should look white or beige in color. If the females are checked for plugs soon after being impregnated by the male, the plugs will look very large, and after a longer period they will look smaller.

BASIC PROTOCOL 4

GENERATION OF GERMLINE KNOCKOUT MICE

Cells from various strains can, in theory, be used as the host blastocyst and as the ES cell line. Generally the most common strain of mouse used for the host blastocyst is C57BL/6 mice and, for the ES cells, the 129 strain. It is best to use strains of mice that are different in coat color for the blastocyst and the ES cell line. The mating scheme to generate germline knockout mice will be determined by what strains of mice are used in the generation of chimeric mice.

If one is using a C57BL/6 donor strain for the blastocyst, the chimeras could be mated with either a C57BL/6 or a Black Swiss to generate germline mice. Each of these mice has disadvantages and advantages. The Black Swiss mice are better breeders, and the mothers take better care of their offspring and, unlike C57BL/6 females, are not disturbed easily by noise and vibration (Doetschman, 1999). However, if C57BL/6 mice are used, the genetic background is conserved, and if Black Swiss mice are used, this might be lost since they are outbred mice. This could have possible implications for the phenotype of the knockout mouse created. Also, if using either the C57BL/6 or Black Swiss strains of mice to mate with the chimeric mice, the germline mice will be on a mixed strain background, and in order to achieve an isocongenic C57BL/6, FVB/N, or other strain background, the mice will have to be back-crossed at least ten times (Silver, 1995). It is possible to use speed congenics and PCR methodology to limit the number of back-crosses needed for a deleted gene of interest on a particular isogenic strain background (Wong, 2002). This would be done by obtaining tail snips from the offspring of parental founder transgenic or gene knockout mice that have been mated to a certain isocongenic strain of interest. DNA is then extracted from these samples and microsatellite markers amplified by PCR to determine the amount of isocongenic purity of these offspring. The offspring with the highest isocongenic purity is then mated back to the same isocongenic strain.

Another option is the mating of the C57BL/6 × 129 chimera with an isogenic strain of 129 mice that has been used to generate an ES cell line. The 129 isogenic strain can be mated to the chimera to obtain F1 founder mice on the isogenic strain of the ES cell line in only one back-cross generation. One drawback to this scheme is that some strains of 129 mice have low fecundity, and this may result in breeding problems in the analysis of the mouse knockout phenotype. If ES cells have contamination from other strains in the genetic background (Simpson et al., 1997), then the mice will still have to be back-crossed in order to obtain isocongenic purity.

If using a coat-color marker to determine the chimeric composition of the ES cells, it is best to choose the chimeras with the highest contribution possible. They should be robust and preferably male, and they should not be dwarfs. Female chimeras could be used if needed, but are not preferred in that ES cells are generally male. Any female chimera would likely have lost the Y chromosome, becoming XO, and this is thought to be more unstable (Papaioannou and Johnson, 2002).

Female chimeras have been known to generate germline mice even with the loss of the Y chromosome. Another advantage of using male chimeras over females is that a large number of offspring can be generated in a short period of time, ensuring the transfer of the knockout allele to the F1-generation offspring.

When mating the chimeras, the most efficient mating scheme would be the mating of two females to one male chimera, Another approach is the so-called "shotgun" approach, the mating of four females to one male chimera. One drawback to this approach is that there could be a delay in the generation of offspring because of the fact that the males may become distracted by so many females and delay plugging. Furthermore, there could be a lot of mice generated at one time, which would take up a lot of cage space.

The mating scheme chosen to generate germline mice must conform to the IACUC regulations of the institution where the animal work is taking place.

REAGENTS AND SOLUTIONS

Use tissue culture-grade water and reagents when working with cells and embryos. For common stock solutions see ***APPENDIX 2B****; for suppliers see* ***SUPPLIERS APPENDIX****.*

Avertin, 2.5% (w/v)

To make 100% Avertin stock solution: Add 50 ml of tertiary amyl alcohol (Fisher Scientific, cat. no. A730-1) to 50 g of 2,2,2-tribromoethanol (Fluka, cat. no. 90710). Add the smallest stirring bar possible to the mixture and place on a stirring plate. Not all 50 ml of the tertiary amyl alcohol may fit inside the 2,2,2-tribromoethanol bottle due to the stirring bar inside. Allow the mixture to stir at room temperature until the stirring bar is heard. Keep stirring the mixture overnight at 4°C to make sure the 2,2,2-tribromoethanol is dissolved. The next day, using a 1-ml pipet, check to see if the 2,2,2-tribromoethanol is completely dissolved. If there are no solid crystals in solution, the stock solution is ready. The color of the Avertin stock solution should have a clear to very pale yellow color. If the solution has a dark brown color, discard.

continued

For the 2.5% working solution: Allow sterile Dulbecco's phosphate-buffered saline (DPBS without calcium or magnesium; Mediatech cat. no. 21-031-CV or equivalent) to warm up to room temperature. To 10 ml of DPBS, add 250 μl of the 100% Avertin stock solution, then shake and vortex until fully dissolved. Filter this solution through a 0.22-μm, nonpolystyrene filter unit. Store in a polypropylene tube covered with foil.

There will be some variation in each batch of stock Avertin, so it is essential that it be tested on mice. prior to using in surgery, for efficacy and toxicity. Both solutions should be stored for a minimal period of time at room temperature and shielded from light, which will cause the breakdown of Avertin into toxic products. If a glass container is unavailable, use plastic containers such as polypropylene. Avoid using polystyrene, as it will chemically react with the Avertin stock solution and become toxic to the mouse, possibly leading to peritonitis.

The recommended dosage of Avertin is between 0.015 and 0.017 ml/g body weight. If the working solution is being reused, it is suggested that the solution be refiltered soon after use to reduce the risk of possible bacterial contamination. If it is thought that the working solution is contaminated, discard it.

Human chorionic gonadotropin (HCG), 50 IU/ml

Under sterile conditions, add 10 ml DPBS (without calcium or magnesium, Mediatech, cat. no. 21-031-CV or equivalent) to a vial containing 10,000 IU of chorionic gonadotropin (Sigma, cat. no. CG10). Take 2 ml of this solution and dilute into 40 ml of PBS. Aliquot this solution into tubes and store up to 6 months in a –30°C freezer.

Injection medium

81 ml Dulbecco's Modified Eagle's Medium (DMEM) containing 4500 mg/liter D-glucose, L-glutamine, and HEPES (Invitrogen, cat. no. 12430054)
8 ml of fetal bovine serum (FBS; preferably already ES-cell tested)
0.5 ml penicillin/streptomycin solution containing 10,000 units per ml penicillin and 10,000 μg/ml streptomycin (Invitrogen, cat. no. 15140-122)

Filter the prepared medium with a 0.22-μm filter unit. Divide the injection medium into three 50-ml tubes. Store up to 1 month at 4°C. Use one tube for each injection day.

Microdrop cultures

Place 30 μl of injection medium (see recipe) on a 35 × 10–mm tissue culture plate. Overlay the drop of medium with prefiltered, embryo-tested mineral oil (Sigma, cat. no. M-3516 or equivalent).

Microinjection setup

An inverted microscope is generally used, and it should have 10× and 20× objectives, with the 40× objective being optional. The 20× objective is more useful for those who are first learning ES cell injections, but the 10× objective is used more often by more experienced researchers. There are three optical systems most commonly used for microinjections. Hoffman generally works best for viewing items through plastic, Nomarski or differential interference contrast (DIC) is better suited for looking through glass, and phase contrast can be used for either plastic or glass (see *UNIT 4.1* for the principles of these optical systems). In the authors' laboratory, DIC optics are used in the microinjection microscope. General injection

continued

and holding line systems would consist of a syringe-type unit, line tubing, and pipet holder, and may or may not have a stopcock attached to an oil-filled syringe. Luer-locking or other types of connection systems should be used whenever possible to minimize or eliminate possible leaks that might occur. For the injection and holding line systems, a syringe that is filled with oil, rather than air, will tend to give better control. Silicone oil would be a better choice than mineral oil in that mineral oil will tend to shrink, causing air bubbles that affect control. An injection line system with a stopcock and a tuberculin-type syringe with an oil-filled reservoir will allow the flushing out of debris and air bubbles from the injection and holding lines and both pipets. A 12-cc oil-filled syringe reservoir will allow the microsyringe units to be aligned back to the midpoint, as opposed to a system that does not use an oil-filled syringe.

For a microsyringe controlling unit, the authors prefer a device made by Minnetonka Instruments, which has an internal Hamilton syringe and an external Mitutoyo syringe. The injection line tubing and Hamilton syringe should be a smaller volume than the holding system because the injection pipet is much smaller than the holding one. As for micromanipulators, the authors have had successful experience with Narishige and Leica manual manipulators. There are multiple options available, and users should decide which model will work best for their use. It should include fine as well as coarse movement. A manual model is preferred for the actual injection of the blastocyst, because it allows for more precise movement and control, unlike some powered systems. To avoid any vibration problems that could affect microinjections, an air suspension table using N_2 or CO_2 gas cylinders should be considered.

Also see Basic Protocol 2 and Figure 19.14.4 for the makeup of the microinjection system.

Pregnant mare serum gonadotropin (PMSG) 50 IU/ml

Under sterile conditions, add 3 ml of sterile PBS to a vial of 2000 units of PMSG (Sigma, cat. no. G 4527). Add this solution to a tube containing 40 ml of DPBS (without calcium or magnesium, Mediatech, cat. no. 21-031-CV or equivalent) aliquot it into tubes, and store the tubes up to 6 months in a –30°C freezer.

Tween 80 solution, 1.25% (v/v)

Add 1.25 ml of Tween 80 solution (Fluka, cat. no. 93780) to 98.75 ml of sterile water. Filter through a 0.22-μm filter unit. Store up to 1 year at 4°C.

COMMENTARY

Background Information

Early cancer studies in mice initially done by Stevens (1970, 1973) led to the generation of the strain of mice known as 129. Subsequent developmental studies in these mice made possible the creation of two major mouse cell lines, the embryonal carcinoma (EC) cells and the embryonal stem (ES) cells. EC cells were originally derived from teratomas that came from Stevens' mice (Kahan and Ephrussi, 1970; Rosenthal et al., 1970). ES cells were initially derived from the inner cell mass (ICM) of mouse blastocyst-stage embryos from 129 mice (Evans and Kaufman, 1981; Martin, 1981).

With the development of the cell injection technique into blastocyst mouse embryos (Gardner, 1968), the true potential of these cell lines to be able to contribute to the developing mouse embryo could then be assessed. The EC cells initially showed promise with pluripotency in the formation of chimeric mice and the contribution to various tissues (Brinster, 1974). However, EC cells had problems with developmental abnormalities, tumors, and a lower germline transmission efficiency compared to ES cells (Papaioannou and Rossant, 1983). ES cells, on the other hand, showed this pluripotency in chimeric formation, as well as totipotency in germline

transmission to the offspring, without the problems associated with EC cells (Bradley et al., 1984).

Upon understanding the mechanisms of homologous recombination, generating knockout mice became possible. Folger et al. (1982) were the first to demonstrate that, through homologous recombination, nonreplicating DNA could be transferred into a mammalian cell. This would later lead to gene targeting of a plasmid into the β-globin gene of mammalian cells (Smithies et al., 1985). The first gene to be targeted in ES cells was the hypoxanthine phosphoribosyltransferase (*HPRT*) gene (Thomas and Capecchi, 1987; Doetschman, et al. 1988). This had the benefit of being X-linked, so recombination of only one copy was needed to show deletion in male ES cells. Later, ES cells with the *HPRT* mutation would be shown to possess the ability for germline transmission (Hooper et al., 1987; Kuehn et al., 1987; Koller et al., 1989; Thompson et al., 1989). While the generation of a mutant mouse with this gene showed initial promise as a model for Lesch-Nyhan syndrome, the phenotype did not correlate with the human disease (Samuel et al., 1993). The *HPRT* knockout mouse phenotype highlights what may happen when one attempts to delete a human gene in the mouse.

An alternative approach for generating chimeric mice is the ES embryo aggregation technique. This technique can be further divided into two basic methods. One of them is the diploid aggregation technique, which involves ES cells cultured with morula-stage embryos. This can further be divided into two techniques. One technique developed by Wood et al. (1993) involves culturing the morula on a layer of ES cells. The other technique, devised by Khillan and Bao (1997), also uses morulas and ES cells, but with a defined microwell and a given number of cells. A second morula aggregation method, in contrast, uses a tetraploid developed by Nagy et al. (1993)—2-cell embryos are electrically fused together and cultured until the 4-cell stage. These 4-cell tetraploid embryos, which are developmentally compromised, are then used to sandwich the ES cells, allowing integration (fusion) to occur. This is done in a well on a tissue culture plate. All three methods have the advantage of not requiring injection skills or the expensive equipment needed to perform the ES microinjection procedure. Ultimately the success rate of all these methods mentioned, as well as blastocyst injection, is determined by parental line used and targeted clones obtained from this line.

The last key component for generating chimeric mice and subsequent knockout mice is the uterine surgical transfer technique. This technique was initially developed by McLaren and Michie (1956). They determined that a critical parameter for success in the uterine transfer technique is the surgical transfer of E3.5 blastocyst embryos into E2.5-aged recipient females. Based on this work, McLaren and Biggers (1958) cultured morula-stage embryos in vitro to the blastocyst stage and surgically transferred them by the uterine technique to successfully generate live offspring.

A recent development suggests the possibility of using other types of stem cells instead of ES cells to generate chimeric and knockout mice. Guan et al. (2006) isolated spermatogonia stem cells (SSC) and maintained them under ES cell growth conditions. As a result, these cells retain characteristics of both SSC and ES cells, and they were subsequently named multipotent adult germline stem cells (maGSCs). This technique may be another method to derive cells that are ES cell capable, without having to obtain them from the inner cell mass of a blastocyst. This may make it easier to acquire ES-like cells from a strain of mouse where currently none is available.

Critical Parameters and Troubleshooting

There are three main areas where problems may be encountered while creating chimeric mice: harvesting blastocyst embryos, injecting ES cells into the blastocyst embryo, and surgically reimplanting embryos into pseudopregnant female mice. The ES injection technique can largely be controlled by conditions in the laboratory, which can make problems in this area easier to solve. The other two areas—harvesting the blastocyst embryos and surgically reimplanting them—depend on conditions in the lab, the in vivo variability of the mice themselves, and conditions in the animal facility. Thus, solving problems in these last two areas can be quite complex. It is probably best to look at laboratory conditions first, which are more easily controlled, then proceed to looking at the mice themselves and the animal-facility conditions. It is important that detailed notes be taken, which can greatly help to pinpoint problems. Aspects of all related procedures should be assessed periodically so that potential problems can be addressed early.

Low number of blastocysts collected

The number of blastocysts obtained through the process of superovulation and harvesting of blastocyst embryos can depend on several factors. The age of the mice and the conditions in the animal facility are two areas affecting blastocyst yield. Females that are 3 weeks old are preferable because they appear to be more affected by the PMSG and HCG hormones. If 3-week-old females are not available, 4-week-old females are the next best choice. Female mice at 6 weeks or older should be producing their own reproductive hormones, which could interfere with any hormone injected intraperitoneally. For the breeding stud males, a range of 7 weeks to ~10 months of age has worked well in our experience. Around 10 months of age, plugging by the stud males becomes variable. Another sign that the stud males are too old is that only very early-stage embryos are recovered. Replacing the stud males will solve both of these problems. In the animal room where the mice are being held, the most important factor is the timing of the light and dark cycle. A light and dark cycle of 14 hr light and 10 hr dark is considered to be conducive to mating by the mice. The light cycle should be checked if there is any doubt that it is working correctly.

Hormone-related issues can also influence blastocyst yield. These would include the source where the hormones came from, a possible bad lot, or how the hormones were prepared. A reputable source that others have had success with should be the first choice. Another lot number of the same hormones should be tried to see if similar results are obtained. If the hormones have not been diluted to the proper concentration, they should be discarded. Freezing and thawing of hormones is to be avoided, as this will decrease the activity and effectiveness. The proper dosage of hormone being injected intraperitoneally and the timing of the hormone injections are also important.

What day and time the blastocysts are to be harvested will determine the timing of the hormone injections. If, at the desired time of day, only morula- or earlier-stage embryos are obtained, both of the hormone injections should be done at earlier times. If only hatched blastocysts are collected, hormone injections should be done at later times.

When new to the technique of harvesting and collecting blastocysts, it is not uncommon to obtain a lower embryo yield than that of someone who is experienced. Blastocysts can be lost while harvesting the uterine horns. Since the blastocysts are free-floating inside the uterine horns, care should be taken to not cut holes in the uterine wall when cutting off the mesometrium structure. Letting the uterine horns snap like a rubber band should also be avoided when extracting out the uterine horn, as this can also contribute to losing blastocysts. After all of the uterine horns have been taken out of the original holding dish, check to see if there are any blastocysts left on the dish. If there are a lot of them on the dish, then there is likely a problem with the harvesting technique. Practice is needed until the technique is mastered. The way the uterine horns are flushed out can also affect blastocyst yield. The opening of the cervix should be oriented slightly up and to the side. This will allow one to see the injection medium being flushed out of the cervix while keeping the flushed medium inside the 35 × 10–mm dish. In our experience, a 30-G needle works best for flushing the blastocysts out of the uterine horns. A good amount of pressure can be applied to the syringe with less chance of medium coming out of the dish, unlike that which occurs with larger-gauge needles. It should be noted that, even under optimal conditions, the process of superovulation and harvesting the blastocysts does not always work well all of the time. There will be days when very few embryos are recovered.

Blastocyst injection procedure

Blastocyst-stage embryos are very hardy and can withstand injections quite well, unlike embryos at earlier developmental stages, such as zygotes. There are three main areas where problems might arise during ES cell injections of blastocysts: the injection and holding line systems, the injection pipet, and the holding pipet (Bradley, 1993).

In the injection and holding line systems, problems that may commonly occur are that the oil does not move inside the pipet, there is a lack of control or the movement is very slow, or the cells are continuously taken up by the holding and injection pipet when the line is open. These problems could be due to air in the system, a leaky or worn-out stopcock, or a leaky joint or connection. If air is found in the system, a 19-G needle and syringe filled with oil (or the oil-filled syringe reservoir) is a good way to purge this out. A leaky stopcock due to wear must be replaced with a new one. Reconnect the loose joint or connection and replace any fittings or pieces of tubing if necessary.

Another area where problems might arise is the injection pipet. Debris or oil can become

stuck to the inside and outside of the injection pipet; there may be blockage or air bubbles that form inside the injection pipet; or cells may lyse inside the injection pipet. The injection pipet may not penetrate inside the blastocyst, and may cause it to collapse before penetrating the blastocoel cavity. Debris, silicone oil, air bubbles, or other types of blockage may be flushed out with the syringe reservoir filled with silicone oil. If this method does not remove the debris or oil attached to the inside of the pipet, a smaller MEF cell may be used much like a pipe-cleaning device. Debris on the outside of the injection pipet may be removed by moving up the injection pipet through the medium/oil and oil/air interfaces. The holding pipet could be used to pull debris off the injection needle, but care should be taken not to block the inside of the holding pipet. The reason for lysis of ES cells inside the injection pipet could be the fact that some of the ES cells inside the pipet are too large, are of poor quality, or have come in contact with oil. ES cells should be well trypsinized to remove cell-surface proteins, and kept cold to inhibit them from reforming. If not, this can cause stickiness inside and outside the injection pipet, impeding injections. If the inner diameter of the injection pipet is too small, then the cells could lyse. Failure to inject into the blastocoel cavity can be the result of a dull or badly damaged injection pipet. It is best to inject in the junction between the ICM and the trophoblast cells, which will make injections easier. The injection pipet should be at approximately the midpoint of the blastocyst height, so that it will be in the center of the blastocoel cavity. If it is on the bottom of the blastocoel cavity, it will be harder to inject. The injection pipet should be raised up to avoid this. It is very important to have extremely good injection pipets when new to the injection procedure, as this will make injections much easier and can help avoid much of the frustration that is often encountered when learning the injection technique. If all other attempts fail to correct problems encountered in injections of the blastocyst, the injection pipet needs to be replaced.

The third and last area where problems can occur is the holding pipet. It could become blocked with debris or have air bubbles forming inside. Erratic holding control may be experienced, or there may be no holding suction at all. If bubbles form or the inside of the holding pipet becomes blocked, the holding pipet may be flushed out with the syringe reservoir filled with silicone oil. Usually, this method will not work with a large blockage. If this happens, the holding pipet will need to be replaced. In our experience, a holding pipet with an inner diameter of ~20 μm works best for holding control. A smaller diameter may not have enough holding power, while a larger diameter tends to give more erratic control and the possibility of the blastocyst ending up inside the holding pipet. If the blastocyst moves when attempting to inject, this could be due to the fact that the holding pipet is too low with respect to the surface of the well of the injection dish and there is not enough room between the holding pipet and the surface of the well. It also may mean that the holding pipet is not properly aligned or is too close to the shoulder of the injection dish. Touching the blastocyst to the bottom of the well adds much-needed stability for holding.

Low birth and survival rate

There could be a number of reasons for a small litter size or for pseudopregnant females not taking care of the pups. The best place to start is to do in utero analysis of uninjected blastocysts by extracting out the uterine horns of pseudopregnant recipient females and looking at E9.5 embryos. If there is a low percentage of embryos being implanted, this could most likely be due to factors related to the surgical technique.

Surgical technique can be influenced by several factors. Only perform the uterine surgical transfer procedure on mice that have the corpus luteum (red spots) present on the ovary. Absence of the corpus luteum suggests the female was not plugged or was not in estrus when plugged by the vasectomized male. Avoid touching the uterine horns and ovary when possible, except to hold the uterus to make the hole into the lumen and insert the transfer pipet. When making the surgical incision in the dorsal muscle wall, avoid cutting the blood vessels, which can cause excessive bleeding, making it hard to find the ovary and fat pad. Like the surgical incision, avoid the blood vessels in the uterine wall when inserting the 25-G needle in the uterine wall to make the hole in the lumen. If a blood vessel is damaged during this procedure, bleeding might clog the inside of the transfer pipet, and mouth pipetting the embryos will be difficult if not impossible. Reload the transfer pipet, and make another attempt to transfer the blastocysts. Both the 25-G needle and transfer pipet should pass freely inside the hole in the uterine wall. This indicates that both have entered inside the lumen. The attempt to transfer the

blastocysts will not be successful if there is any obstruction. The procedure of mouth pipetting, the quality of the transfer pipet, and how the transfer pipet is loaded can influence the outcome of the surgical transfer procedure. As the investigator becomes skilled in using the mouth pipet, this factor can largely be ruled out. If the inner diameter of the transfer pipet is too small, there is a tendency for the transfer pipet to become easily clogged by bleeding which can happen during the procedure, and if the inner diameter is too big, this may affect the control in that it will be too sensitive and the blastocysts will migrate up the transfer pipet. Also, a transfer pipet that is too small in diameter may make it difficult to blow the blastocysts inside the lumen of the uterus. The way a transfer pipet is loaded with blastocysts can make a difference in the transfer results. There is a lot of variation in the way a transfer pipet can be loaded with blastocysts. Air bubbles and oil are factors that can help to stabilize the embryos inside the transfer pipet, but they will move as the embryos are blown out with the mouth pipet. After the transfer of the blastocysts has taken place, examine the transfer pipet under a dissecting microscope to see if there are any embryos left inside. If any blastocysts are left, they should be transferred until they are no longer in the transfer pipet.

If the rate of implantation of E9.5 embryos is high, then there may be factors other than the surgical technique that affect survival and litter size; one of these is related to the culture conditions of the ES cells and blastocyst embryos. Reagents that are used to grow the ES cells or that may come into contact with the blastocysts could be the culprit. Serum, DMEM medium, and oil should be tested on the parental cell line first before they are used on targeted ES cell clones. Reagents used more specifically with the in vitro blastocyst should be tested before the blastocysts are to be injected with ES cells. If these reagents have been tested before, they are most likely not the cause. However, if a new lot is now being used, it is worthwhile to investigate. Another lot should be tried to see if similar results are obtained. If a new lot of a particular reagent has been determined as the cause of survival failure, it should be discarded and replaced as soon as possible.

Haploid insufficiency of the targeted gene, or the way the construct is designed, may influence embryo lethality and pup death; if other targeted ES cell clones are generally doing well, then this could be the cause.

The other area that may affect the gestation of the pseudopregnant recipient litters concerns the conditions in the animal room where the mice are being housed. Care should be exercised not to stress the recipient mother, because that could cause physiological conditions leading to reabsorption of the mouse embryos in utero or the death of the newborn pups. Probably the key embryonic developmental time points where this stress would likely be the most detrimental are at E4.5 to E5, when the embryos implant, and then shortly before birth. The first week of life is the most critical time for the newborn pups. If they survive this week, there generally should be no complications. Another stress factor is the Bruce effect, whereby the odor of strange males can induce abortion of the surgical pregnancy. Other factors to consider are ammonia levels, noise, vibration, animal handling, animal food nutrition, ventilation, and the light/dark cycle. These conditions in the room should be monitored to determine which of them might be the cause. Infectious agents such as viruses (Brayton et al., 2004), which may be present as a latent infection in the animal colonies, can affect knockout mouse production. Ideally the mice should be housed in specific-pathogen-free facility to avoid pathogen exposure.

Finding the exact cause of embryo lethality can be difficult and time-consuming, as numerous factors affecting pregnancy need to be ruled out. Even the simplest of factors might be the cause of the problem and should not be overlooked. For example, we determined that a defective wheel on one of the animal racks was the possible cause for the pups being reabsorbed in utero and the pseudopregnant mothers not taking care of the pups after birth. When the rack was replaced, these problems went away. Lastly, one factor that is often overlooked is the effect of lighting on embryos (Takenaka et al., 2007), whether it is in the lab or surgical room. This could cause apoptosis to occur in the ICM of the blastocyst embryo, which would have detrimental effects on injected embryos and the potential for live pups being born.

Anticipated Results

With practice, this surgical transfer technique should result in at least 70% to 80% of the surgical recipients giving birth. Even uninjected blastocysts, when surgically transferred and implanted, may end up being reabsorbed during gestation. This can happen as early as E9.5. The number of pups born will be

influenced by the strain of female mouse used for the pseudopregnant recipient. In our experience, the B6D2 and B6CBA strains of mice have given birth to no more than six pups per uterine horn, regardless of how many were surgically transferred. If more than six embryos are surgically transferred, these extra embryos most likely will not implant.

Blastocyst-stage embryos are very hardy, especially when compared to earlier stages. They tolerate changes in temperature, pH, and the technique of ES injection. Unless there is a severe trauma to the embryos, like damage to the ICM, the embryos should not be negatively impacted. In the hands of a skilled injectionist, the ES cell injection procedure should not adversely affect the birth rate of pups being born.

There are numerous ES cell lines available for the purpose of making chimeras to generate knockout mice. The parental ES cell lines the investigator plans to use should first be evaluated for any possible ill effects from these cells. Their efficiency in generating chimeric mice needs to be evaluated before carrying out any gene targeting–related experiments on them. Some markers to look at in evaluating the effectiveness of the parental cell include the percentage of chimerism, the ratio of the number of male chimeras born to females, and the ability to generate germline offspring. In a good parental ES cell line, the chimerism should be high, the male-to-female ratio high, and the number of pups needed to see germline transmission low. It is possible to see chimerism or germline transmission at as early as 5 days, when a small patch of fur becomes visible. This is much easier to see if an albino ES cell line is used, in that these white areas would appear nude before the fur starts to grow in. Germline transmission is detected on other types of 129 ES cell lines used with a C57BL/6 host blastocyst as either a medium brown or agouti (golden brown) appearance.

Even if good parental lines are used, there can be great variability in a targeted clone's ability to create a high percentage of chimeras, and in the germline potential of these chimeric mice. This is most likely due to trauma that the ES cells have to undergo in the electroporation of the gene-targeting construct and selection process to determine a correctly targeted clone. In theory, it should take only two clones to generate two different germline chimeric lines, leading to the establishment of two independent knockout mouse lines. This would confirm that the phenotype is due to the gene-targeting construct and not to the cells themselves. Several targeted clones should be available to ensure that there is germline transmission from two independent clones, should some of the clones give low chimerism and not be germline.

A situation may arise where lethality is most likely related to the clones being injected or the construct that is electroporated inside the ES cells. This can result in no chimeric pups being born at all, or only a few surviving to birth and then dying shortly thereafter. If everything is generally going well with other constructs and ES cell clones, then other factors affecting gestation can be ruled out. If the ES clones in question have been injected additional times and large numbers of blastocysts have been injected with similar results, then this further suggests a construct-related problem. Further injections of ES cells with the suspect construct will most likely be of little use.

There is also the possibility of embryonic and perinatal lethality occurring in the germline F1 mice. As previously mentioned with chimeras, this could be due to targeting construct–related issues. The construct should be re-evaluated and any problems corrected. Additional clones can be generated and injections performed. Lastly, lethality could be due to the function of the gene deleted and its essential role in embryonic development. This haploid insufficiency may be the reason for embryonic and pup lethality. If this occurs, the only kinds of phenotypic analyses that might be carried out would be in utero analysis of the developing embryos or in vitro tissue culture analysis.

Time Considerations

Plan to start the initial intraperitoneal PMSG hormone injections 1 week before the day when the blastocysts will be needed. The entire process of harvesting the blastocysts, injecting them, and surgically transferring them back to a pseudopregnant recipient female is generally performed on the same day. Even for the experienced injectionist, this can make for a long day, especially when problems with the injection system and bad cell morphology of the ES cell clones occur on the same day. The surgical procedure should be practiced before attempting the injection procedure, since it generally takes longer to master. Having a video display for all the procedures aids greatly in the visualization of these techniques and can shorten the time required to

learn them, which is expected to take up to 6 months. How long it takes will ultimately depend on previous experience, the person teaching the procedures, and the desire of the investigator to learn the procedures.

CHAPTER 20
Expression and Introduction of Macromolecules into Cells

INTRODUCTION

Cells are fundamentally insular, isolated and protected from their surroundings by their plasma membranes. However, it is frequently necessary for cell biologist to overcome the isolation of the cell's interior in order to probe its workings at a molecular level. As a result, many experimental strategies employed by cell biologists rely upon the introduction or expression of particular macromolecules within cells of interest. The goals of such techniques include the expression or introduction of fluorescently-tagged proteins, allowing the examination of the subcellular localization and behavior of the protein within living cells. Similarly, these techniques can be used to perturb the function of particular proteins through the addition of antibodies, inhibitors or mutant forms of the protein or through inappropriate expression with altered abundance or timing of protein accumulation. Additionally, techniques for introduction of macromolecules into cells are frequently utilized to load cells with impermeant dyes that can be used to monitor various aspects of cellular physiology, including changes in ion concentrations. This chapter will cover methods that have been developed for such experimental strategies. The first two units of this chapter discuss simple and inexpensive methods for the introduction of a variety of macromolecules (*UNIT 20.1*) or specific fusion proteins (*UNIT 20.2*) into cells. *UNITS 20.3*, *20.4*, *20.5*, *20.6 & 20.7* discuss the introduction of nucleic acids into cells for the purpose of altering gene expression.

UNIT 20.1 provides a variety of flexible protocols that can be inexpensively used to load a broad range of macromolecules into cells. Methods covered in *UNIT 20.1* include scrape loading, scratch loading, bead loading and syringe loading. These techniques all rely upon the physical disruption of the plasma membrane to promote the uptake of target molecules, and upon the capacity of cell to re-seal the plasma membrane after damage. The techniques discussed in *UNIT 20.1* have a number of advantages, including the fact that their implementation does not require specialized equipment and that they can be utilized to simultaneously load a large number of cells. They are also useful because a large range of macromolecules can be introduced in this manner. These techniques would not be preferred under conditions where the macromolecule being loaded is particularly precious, since each of the techniques require a relatively large amount of such material.

UNIT 20.2 describes the introduction of proteins into cells using an eleven amino acid sequence from the HIV-TAT transduction domain. This amino acid sequence has the remarkable property of allowing the HIV-TAT protein to pass through the intact plasma membrane and enter the cytoplasm of cells. It has also been shown to confer this property to a number of other proteins when expressed as a fusion moiety. Thus, investigators can express this sequence as a tag to their proteins of interest in bacteria, purify the resultant fusion peptide using standard biochemical means, and introduce the fusion protein into cells by simply introducing the fusion protein to the cell culture medium. Like the methods discussed in *UNIT 20.1*, these techniques have considerable advantages because of their simplicity and because of the fact that they are economical and have minimal requirements for specialized equipment.

Contributed by Mary Dasso
Current Protocols in Cell Biology (2005) 20.0.1-20.0.2

While *UNITS 20.1 & 20.2* offer the possibility of direct introduction of proteins into cells, expression of cloned genes from transfected plasmids is more commonly used to probe protein function. *UNITS 20.3*, *20.4*, *20.5*, *20.6 & 20.7* discuss transfection protocols to introduce DNA into cells for this purpose. These protocols include calcium phosphate transfection (*UNIT 20.3*), DEAE dextran transfection (*UNIT 20.4*), electroporation (*UNIT 20.5*) and lipid-mediated transfection (*UNIT 20.6*). Calcium phosphate (*UNIT 20.3*) and DEAE dextran (*UNIT 20.4*) chemically induce the association of plasmid DNA to the cell surface, resulting in its uptake through endocytosis. Cationic lipids spontaneously associate with nucleic acids through charge interactions. In the case of plasmids, the resulting DNA-lipid structures are also capable of transducing genes into cells through endocytosis (*UNIT 20.6*). In all cases, the pathway through which DNA eventually enters the nucleus after endocytosis is poorly defined. By contrast, electroporation uses an electric field to open pores in the cell to allow the entry of DNA through diffusion. Electroporation is less dependent upon special characteristics of the cell than other transfection techniques and can therefore be used for introduction of plasmid DNA into a very broad spectrum of cell types. Calcium phosphate, DEAE dextran, and lipid-mediated transfection are typically employed in the transfection of adherent cell lines. Lipid-mediated transfection and electroporation are typically used for non-adherent cells. Since the successful use of all transfection methods depends heavily on the cell line under study and conditions of the particular experiment, *UNIT 20.7* discusses strategies for optimization of transfection efficiency using reporter systems.

It is frequently desirable to control the expression of mRNA from plasmids after their introduction into cells, particularly those that encode toxic protein products. *UNIT 20.8* describes the use of tetracycline-regulated gene expression systems for this purpose. This system is based upon an artificial transcriptional transactivator (tTA), derived from the fusion of the tetracycline repressor of *E. coli* to the transcriptional activation of the herpes simplex VP16 protein. In the absence of tetracycline, this fusion protein binds to and activates transcription of plasmids bearing tetracycline-resistance operator elements from the Tn10 operator. *UNIT 20.8* further discusses selection of stable cell lines bearing such plasmids, which provides a mechanism for quick and synchronous expression of target proteins in a population of cultured cells.

Together, these techniques comprise some of the most basic tools available to cell biologists. In each case, they are designed to overcome the challenges posed by the insular nature of cells and to help us to manipulate and understand the machinery of the intact cell.

Mary Dasso

Direct Introduction of Molecules into Cells

Techniques for introducing normally impermeant macromolecules into the living cell—referred to as "cell-loading techniques"—open up many possibilities for the cell biologist. Examples of the investigations that can be carried out using such methods include measuring cytosolic ion concentrations accurately by means of a large, highly membrane-impermeant fluorescent probe; defining the native location of a protein (fluorescently tagged) dynamically in time and space; perturbing the normal functioning of a cellular protein (for example, by introducing antibodies or other specific inhibitors); or altering the genome (by introducing antisense or expression-vector nucleotide sequences). Microinjection is probably the most commonly used technique for introducing fluorescent probes, fluorescently tagged proteins, and antibodies into living cells for short-term studies of cell physiology and protein location and function. It is, however, not the only technique available, nor the easiest or least expensive to implement. Among the alternatives are several closely related techniques that, like microinjection, rely on the cell's ability to reseal a mechanically induced plasma membrane disruption (see McNeil, 2002, for a review) created in order to gain temporary access to cell cytosol. Four such techniques are described here: scrape loading (see Basic Protocol), scratch loading (see Alternate Protocol 1), bead loading (see Alternate Protocol 2), and syringe loading (see Alternate Protocol 3). Although these techniques may not be competitive with microinjection in terms of economy of use of the macromolecule to be loaded, or as efficient at loading very large macromolecules (>100,000 mol. wt.), their implementation does not require the acquisition of a specialized skill or expensive equipment. Additionally, unlike microinjection, they allow one to rapidly load (in a matter of minutes) thousands or even many millions of many types of mammalian cells with normally impermeant molecules, and so to facilitate quantitative analyses of the effect of loading (Doberstein et al., 1993).

STRATEGIC PLANNING

An excellent probe for testing the effectiveness of each of the loading techniques below, and for working out the critical parameter of imposed mechanical load (see Critical Parameters), is fluorescein-labeled dextran (available from Sigma or Molecular Probes). It is inexpensive and can be purchased in a range of molecular weights (from ~3×10^3 to 5×10^6), allowing one to approximately match it in terms of size to the protein or other probe ultimately to be loaded. Fluorescein-labeled dextran is available in a fixable form (conjugated with lysine residues), allowing it to be used initially with fixed rather than living cell specimens.

Because the loading techniques described in this unit, like microinjection, damage cells, it is important to compare control populations of loaded cells, such as those loaded with fluorescein dextran only, with experimental cells loaded with both fluorescein dextran and the molecule of interest, before concluding that an effect of loading is specific to the molecule loaded. Mixing the molecule of interest with fluorescein dextran creates a "loading solution" that will provide this experimental population. It is important also to compare the relevant behavior of the fluorescein dextran–loaded "control" population with that of undisturbed (nonfluorescent) cells, which are always present in the populations generated by these techniques. In this way, those effects on cell behavior that are caused by the loading procedure alone can be detected. In this regard, the authors of this unit have noticed that cells suffering plasma membrane disruptions often contain more intracellular vesicles than undisturbed neighbors (this is probably related to the membrane-membrane fusion process that mediates resealing; Terasaki et al., 1997), but, in the cell types that have been studied in the authors' laboratory, there has been no evidence

Contributed by Paul L. McNeil

Current Protocols in Cell Biology (2003) 20.1.1-20.1.7

that apoptosis is induced among loaded cells. Indeed, one can observe fibroblasts that have been scratch-loaded with fluorescein dextran locomoting into adjacent denuded zones of the coverslip within 60 min post-wounding, and then undergoing cell division there 12 to 24 hr later (Swanson and McNeil, 1987). Cytosolic levels of Ca^{2+} are rapidly (within seconds to minutes) restored to normal levels after wounding (by microinjection or other, more radical means of making cell-surface disruptions)—another indication of the remarkable, and biologically essential, capacity of cells to rapidly reseal and hence survive plasma membrane disruptions (McNeil, 2002).

One or more of these techniques should be applicable to any type of mammalian cell, and also to other eukaryotic cells that lack an external cell wall. For cells that must be loaded or are most conveniently loaded as a suspension, syringe loading is the technique of choice. For adherent cells, any of the additional techniques described below could be used.

A final question is what quantity of one's, often precious molecule is needed? The answer to this question will depend, of course, on the experimenter's goal. If it is simply to produce a fluorescent signal readily visualized or measured microscopically or via a flow cytofluorometer, then initial tests with a fluorescent dextran of appropriate size and concentration (e.g., the size and concentration of the molecule of interest) should provide a useful preliminary answer. The authors find that 0.5 to 1.0 mg/ml solutions of fluorescein dextran (mol. wt., 10 to 70 kDa) result in a readily assayed or measured fluorescent signal from cells loaded by any of these techniques. Sample volume is another important issue. Some of these techniques require that only a very small volume of loading solution be employed. For example, using syringe loading, an ultramicropipettor (1- to 10-µl range), and ultramicro pipet tips, no more than 1 µl is needed. In general, the minimum usable volume is that which prevents the cells from being damaged by drying during the ~1 to 2 min required to execute the crucial plasma membrane–disrupting step of each of these techniques.

BASIC PROTOCOL

SCRAPE LOADING

Transient, survivable plasma membrane disruptions are produced in the presence of the molecule to be loaded by tearing the cells off of their culture substratum (McNeil et al., 1984).

Materials

Adherent cells of interest, growing in tissue culture (also see *UNIT 1.1*)
Dulbecco's phosphate-buffered saline (DPBS; *APPENDIX 2A*) or equivalent physiological saline containing 1 to 1.5 mM $CaCl_2$ at physiological temperature (37°C for mammalian cells)
Loading solution: DPBS (with 1 to 1.5 mM calcium) containing molecule to be loaded, at physiological temperature (37°C for mammalian cells)

Rubber policeman
Circular tissue culture dishes

Additional reagents and equipment for cell culture (*UNIT 1.1*)

1. Culture cells on a substratum to which they adhere strongly and which allows an unobstructed approach with a rubber policeman (see step 4).

   Circular-profile tissue-culture-grade dishes are usually a good choice for mammalian cells, as unimpeded access is available after the lid has been removed.

   Basic techniques for culturing mammalian cells are presented in UNIT 1.1.

2. Wash the cells twice with 37°C DPBS (or other physiological saline compatible with the macromolecule to be loaded and with cell viability).

   This and all saline solutions used in subsequent steps should be maintained as closely as possible to 37°C, the optimum resealing temperature.

3. Remove the second DPBS wash. Add the loading solution and swirl to mix it thoroughly with any plain saline that might still be present on top of the cell layer.

   The minimal volume required is that which will prevent cell-drying damage during the minute or two of the scraping procedure.

4. Scrape the cells off of their substratum using a rubber policeman. Leave the cells 5 to 10 min in the loading solution before proceeding with the next step. Check for completeness of cell removal by examining with a phase-contrast microscope.

5. Mix the now suspended and loaded cell population with a 10-fold or larger volume of plain DPBS, and wash the cells several times by centrifuging for 10 to 20 min at 5000 × *g*, at a temperature appropriate for the cell type, removing the supernatant, resuspending the cells in ≥10 volumes of DPBS, and repeating the centrifugation.

6. Replate the cells and return them to normal culturing conditions if the goal is to study adherent, loaded cells, e.g., for microscopic analysis, or use them immediately after washing if the goal is to study suspended, loaded cells, e.g., for flow cytofluorometric analysis.

SCRATCH LOADING

ALTERNATE PROTOCOL 1

Partial, rather than total, cell removal (as in Basic Protocol), as well as severing of cell processes, is used to create plasma disruptions (Swanson and McNeil, 1987).

Additional Materials *(also see Basic Protocol)*

30-G syringe needle or similar sharp implement (e.g., Fisher)
Glass coverslips

1. Culture cells on any substratum to which they adhere strongly and which allows approach with a syringe needle tip (see step 4).

   A glass coverslip is a good choice, especially if the goal is to observe loaded cells under the microscope. Basic techniques for culturing mammalian cells are presented in UNIT 1.1.

2. Wash the cells twice with DPBS (or other physiological saline compatible with the macromolecule to be loaded and with cell viablility).

   If using a coverslip, the washings are easily accomplished by grasping the coverslip with forceps and then transferring it from one beaker containing saline wash to another.

   This and all saline solutions used in subsequent steps should be maintained as closely as possible to 37°C, the optimum resealing temperature.

3. Cover the monolayer with loading solution and mix well to ensure that the loading solution combines thoroughly with any plain saline still present on top of the layer.

   If a coverslip is being used, pipetting the loading solution onto and off of the cells several timers will accomplish this.

4. Scratch the monolayer surface one or more times with a 30-G syringe needle.

   This will denude small (two- to four-cell-wide) strips of the monolayer. Loaded cells will be present along these denuded zones but not elsewhere in the culture. Increasing the number of scratches will increase the proportion of loaded cells.

5. Wash the monolayer three to four times thoroughly with plain DPBS or other appropriate physiological saline.

6. Examine or experiment with the cells.

   The cells are ready for immediate microscopic analysis. Many of the successfully loaded cells along the denudation sites will have morphologies quite normal in appearance; others will be slightly rounded. Within ~30 min, loaded cells will display obvious signs of viability—locomotion into the denuded zone and division there ~12 to 24 hr later.

ALTERNATE PROTOCOL 2

BEAD LOADING

Survivable plasma membrane disruptions are produced in the presence of the molecule to be loaded by the impact of glass beads falling onto and rolling across cells, which remain adherent to the culturing substratum (McNeil and Warder, 1987).

Additional Materials *(also see Basic Protocol and Alternate Protocol 1)*

Glass beads, 50- to 500-μM diameter (Sigma)
Glass coverslips

1. Culture cells on any substratum to which they adhere strongly and which will allow glass beads to be added and removed (see steps 3 and 4).

   A glass coverslip is convenient for this purpose. Basic techniques for culturing mammalian cells are presented in UNIT 1.1.

2. Wash cells twice with DPBS and immerse them in loading solution (see Alternate Protocol 1, steps 2 and 3). Mix the loading solution well with any residual DPBS.

3. Sprinkle glass beads (50- to 500-μm diameter) onto the cell monolayer evenly, until ~75% of the monolayer surface appears, by eye, to be covered by them.

   To increase the frequency of loading, cause the beads to roll around on the monolayer by rocking it to and fro several times. The glass beads can be used "off the shelf," or sterilized by autoclaving if desired in experiments where sterility must be maintained.

4. Wash monolayer thoroughly with plain DPBS to remove beads and loading solution (see Alternate Protocol 1 for technique).

5. Examine or experiment with cells.

   As with Alternate Protocol 1, many cells will have apparently normal morphologies immediately after this loading procedure.

ALTERNATE PROTOCOL 3

SYRINGE LOADING

Survivable plasma membrane disruptions are created in the presence of the molecule to be loaded by shear forces generated by aspirating and expelling cells repeatedly through a narrow orifice, such as that of a syringe needle or micropipettor tip (Clarke and McNeil, 1992).

Additional Materials *(also see Basic Protocol)*

Adherent *or* suspension cells of interest, growing in tissue culture (*UNIT 1.1*)
30-G syringe needle and 1-ml syringe *or* micro- or ultramicropipettor (1- to 10-μl range) and appropriate pipet tips (e.g., Fisher)

1. Trypsinize or otherwise harvest cells (*UNIT 1.1*), and wash twice, each time by centrifuging for 10 to 20 min at 5000 × *g*, at a temperature appropriate for the cells, removing the supernatant, resuspending the cells in ≥10 volumes of PBS, and repeating the centrifugation.

   Basic techniques for mammalian cell culture, including trypsinization, are presented in UNIT 1.1.

2. Resuspend the pellet from the final wash in the loading solution.

3. Draw the cell suspension up into a 1-ml syringe fitted with a 30-G needle, or into a micro- or ultramicropipet tip and then expel it (five to ten times is a good starting point). Repeat this maneuver as many times as necessary in order to achieve the desired compromise of loading level in comparison to cell viability (see Critical Parameters).

4. Wash the cells (see Basic Protocol, step 5).
5. Replate the cells and return them to normal culturing conditions if the goal is to study adherent, loaded cells, e.g., for microscopic analysis, or use them immediately after washing if the goal is to study suspended, loaded cells, e.g., for flow cytofluorometric analysis.

COMMENTARY

Background Information

The capacity to seal a plasma membrane disruption is critical to the survival of many cells (McNeil, 2002). This is because many normal, mechanically active cell environments, including many tissues of the body, promote membrane disruption injury. Resealing, in other words, is not merely Nature's gift to the experimental biologist. Knowledge of this capacity did, however, lead to the development of each of the techniques described in this unit. Conditions that promote resealingphysiological temperature and calcium levelsmust be maintained during each procedure.

How does one choose among the various methods presented—scrape loading, scratch loading, bead loading, and syringe loading? If analysis post-loading is best done on a suspension of cells, e.g., flow cytofluometry, then scrape or syringe loading should be used; if it is best done on adherent cells, e.g., microscopy, then scratch or bead loading should be used. However, scrape, scratch, and bead loading require adherent cells as starting material.

Microinjection is the most obvious alternative method. In cases where there is a minimal, limited amount of reagent for loading, microinjection is unrivaled in its economy of reagent: one needs only enough of the reagent to load a microneedle, e.g., less than a microliter. However, mictoinjection requires special equipment and is labor intensive. The loading techniques described in this unit are by comparison, far less costly to implement and easier to learn. Moreover, they can produce virtually unlimited numbers of loaded cells in minutes.

Critical Parameters

The common feature of all of these techniques is that they bring mechanical force to bear on cells in order to create transient plasma membrane disruptions. Normally impermeant molecules can then enter into the cytosol, until resealing prevents further access. Therefore, to increase loading efficiency by these mechanically based techniques, one simply increases the force applied and hence the number and size of the disruptions. On the other hand, as the extent of plasma membrane disruption increases, viability decreases. Hence, when first attempting to load a particular cell by these techniques, it will usually be advisable to vary the mechanical force imposed over a wide range, and then to select the loading conditions that provide an acceptable level of both loading and viability.

The following provides some guidelines for manipulating the level of mechanical force imposed by each technique.

In scrape loading (see Basic Protocol), the extent of plasma membrane disruption is mainly a function of the strength of cell-substratum attachment. Agents such as poly-L-lysine can, for many cells, be used to increase adhesion and therefore loading efficiency. Conversely, a wash or two with Ca^{2+}-free saline decreases adhesion for many cultured cells, and therefore decreases the level of loading. These same considerations apply also to the closely related technique of scratch loading (Alternative Protocol 1).

In bead loading (see Alternate Protocol 2), the extent of plasma membrane disruption depends on the size of the beads employed (the authors have used beads ranging from 50 to 500 μm in diameter), the number of beads sprinkled onto the cells, and the degree to which the beads are caused to roll around on the monolayer.

In syringe loading (see Alternate Protocol 3), the size of the orifice and probably other hydrodynamic factors related to barrel length and shape are important. Certainly, smaller orifices, which produce greater shear forces, result in increased loading. Additionally, higher ejection pressures increase loading efficiency. The authors of this unit have described an automated device that allows one to precisely control pressure, but this is not necessary unless one desires a high level of reproducibility between one loading procedure and the next (Clarke and McNeil, 1994). Any narrow-bore orifice can be used, and the authors often find it convenient in minimizing loading solution volume to employ a micropipettor and pipet tips instead of a syringe and needle.

Resealing does not occur in the cold or in the absence of Ca^{2+}, so these conditions must be avoided during the step when plasma mem-

brane disruptions are being created, and for ~1 min thereafter (McNeil and Steinhardt, 1997).

Troubleshooting

Successful loading by the techniques described in this unit requires: (1) that sufficient mechanical force be brought to bear on the cell plasma membrane for tearing or disrupting it; and (2) that the cell then be able to reseal the disruption thus created. Poor efficiency in loading can be explained by a problem in either or both of these two areas.

One or more, though not necessarily all, of the techniques described above will result in the imposition of sufficient force for the loading of most mammalian cells. For example, cells smaller than a typical cultured mammalian cell kept in suspension (~10 μm diameter or greater) may not be amenable to syringe loading with a 30-G needle; a needle of this bore may not impose sufficient shear stress, and another technique must be utilized. As a case in point, the authors have found that mammalian red blood cells (~5 μm diameter) are not susceptible to wounding by syringe loading (P. McNeil, unpub. observ.). Red blood cells can, however, be wounded by scraping after they have been stuck to a plastic substratum coated with poly-L-lysine.

On the other hand, too much force can create disruptions too large or too numerous to be resealed. Low (<50%) recovery of viable cells is a key indicator of this problem, which can be solved by reducing the amount of mechanical force applied. For example, this can be accomplished by using smaller beads in the bead-loading technique, by using a larger-gauge needle or fewer intake and expulsion strokes in the syringe-loading technique, or by treatments that loosen cell substratum adherence (such as prescraping rinses with low-calcium medium for mammalian cells) in the scrape-loading technique. Moreover, it is essential for cell viability when applying these membrane-disrupting techniques that resealing occur. For this to happen, cells need physiological levels of extracellular Ca^{2+} and a near-physiological temperature. Thus, if loading fails, with a heavy loss of cell viability, one should check to ensure that these two requirements have been met—both during the loading procedure, when disruptions are being created, and for the 1- to 5-min period after membrane disruption is initiated, when resealing is taking place.

A few cell types, notably echinoderm eggs, reseal extremely rapidly (even with disruptions >1000 μm^2 in extent), and so provide the experimenter much less temporal access to cytosol. Indeed, it is the authors' experience that these cells are difficult to load by the techniques described, but easy to microinject since they are rarely killed by this membrane-disrupting technique. In theory, this rapid resealing capacity could be countered by reducing extracellular Ca^{2+} below physiological levels or by chilling the cells that rapidly reseal.

Anticipated Results

The authors and others have successfully loaded fibroblasts, endothelial cells, smooth muscle cells, epithelial cell lines, neurons, and free-living amebas with these techniques. It is expected that they will work on almost any cell type lacking a cell wall.

The extent of loading is a direct function of the concentration of the macromolecule and an inverse exponential function of its molecular weight. Both of these observations are similar to what would be predicted for a process dependent on diffusion down a concentration gradient through a hole in an otherwise impermeable barrier. Therefore smaller molecules are more effectively loaded than larger ones, and the highest possible concentration of the molecule to be loaded should be employed in the loading solution. One can expect from all of these techniques that the extent of loading will vary over a large range (three-log scale as assessed by flow cytofluorometry). This can be of advantage if one wishes to conduct, for example, a dose-response type of experiment. If, on the other hand, a homogeneous population of, say, heavily loaded cells is desired, then some selection process must be employed, such as flow sorting or microscopic discrimination, based on whole-cell fluorescence derived from the macromolecule loaded.

Time Considerations

These techniques are very rapid, generally taking <30 min.

Protein Transduction: Generation of Full-Length Transducible Proteins Using the TAT System

Described here is the technology that allows an investigator to transduce full-length proteins by utilizing a minimal, eleven–amino acid, HIV-TAT transduction domain that can be fused to a protein of choice using the pTAT or pTAT-HA protein expression plasmids. Bacterial expression (see Basic Protocol 1), followed by solubilization of protein aggregates with a denaturing agent, affords high yields of transducible fusion protein. The fusion protein, once added to the culture medium, can cross the cell membrane and then be degraded or refolded by the cellular machinery. Correct targeting and function of the fusion protein can be easily examined by fluorescent microscopy or immunohistochemistry.

This strategy was established and improved to its current state by the purification and transduction of a multitude of fusion proteins. Because the pool of fusion proteins span many different functions including sequestering proteins (i.e., p16, p27, and CDK2DN), proenzymes (caspase-3), viral proteins (HPV E6, E7, and E1A), enzymes (HIV protease, β-galactosidase), GTPases (rac, rho and cdc-42), and transcriptional regulators (E2F-1-5, pRb), the protocols cover a wide variety of commonly used protein isolation and characterization methods. Table 20.2.1 lists a few examples of some of TAT fusions and details the size, optimal isolation method, dose required to yield a phenotypic result, biological result obtained, and time in which the result was observed.

No special equipment is necessary to generate or transduce fusion proteins, although Basic Protocol 2 does recommend the use of fast protein liquid chromatography (FPLC) to reproducibly bind and elute denatured fusion proteins. FPLC, although recommended, is not required. Bulk ion-exchange resins are available and have been successfully used in place of the Mono Q/Mono S resins that Basic Protocol 2 describes. Another frequently used column is the PD-10 column (Amersham Pharmacia Biotech). This is a disposable column, packed with a gel-filtration resin, which is ideal for the removal of small molecules such as salt, urea, or unconjugated fluorescent molecules.

The unit illustrates the steps of the basic procedure with various fusions, to give the investigator a broader base of information upon which to begin specific isolations.

CAUTION: TAT-protein fusions have been shown to cross most lipid bilayers, including all tissues in a mouse. Therefore, when designing and using TAT-fusion proteins, precautions regarding safe handling and disposal are necessary. It is very important to analyze the health effects of each fusion protein individually and to observe appropriate biosafety procedures for disposal and decontamination. The authors suggest using a 0.1% (w/v) trypsin solution to decontaminate any large spills of fusion proteins. NIH Biosafety Level 2/3 containment should be used at all times. Also, refer to Backus et al. (2001), which provides further guidelines for the safe handling of TAT-transducing proteins.

STRATEGIC PLANNING

This unit is broken down into two sections: (1) isolation, optimization, and large-scale production of the fusion protein (see Basic Protocols 1 and 2 and Alternate Protocols 1 to 4) and (2) analysis of the transduction of the fusion proteins into target cells (see Basic Protocol 3 and Alternate Protocol 5). This unit contains a compilation of different

Current Protocols in Cell Biology (2003) 20.2.1-20.2.25

Table 20.2.1 Detailed Description of Selected TAT-Fusions

Fusion protein	Apparent size (kDa)	Isolation method	In vitro dose (nM)	Biological effect	Time biological effect was examined	References
TAT-p16 WT	24	Denaturing/ PD-10	200-1000	Inhibitor of CDK4/6, and induces G1 arrest	30 hr after addition, to G1-arrested, synchronized cells	Ezhevsky et al., 1997
TAT-HA-p27 WT	35	Denaturing/ Mono S ion-exchange	100-200	Inhibitor of CDK2/4/6 complexes, and induces cell scattering	30 min	Nagahara et al., 1998
TAT-E1A WT	60	Denaturing/ rapid dialysis	100	Sequesters pRb	15 min	Unpub. observ.
TAT-HA-E7 Wt	20	Denaturing/ PD-10	100	Sequesters pRb	3 hr	Lissy et al., 1998
TAT-HA-CDK2 DN	40	Soluble/ PD-10	200	Inactivates cyclin E:CDK2 complexes, resulting in G1 arrest	30 hr after addition to synchronized cells	Nagahara et al., 1998
TAT-HA-Caspase 3 WT	39	Denaturing/ Mono Q ion-exchange	100	Processed form induces apoptosis	1-6 hr	Vocero-Akbani et al., 1999
TAT-HA-HIV protease	20	Denaturing/ Mono S ion-exchange	100	Cleaves HIV protease Recognition sequence	1-6 hr	Vocero-Akbani et al., 1999
TAT-HA-β-galactosidase	120	Soluble/ PD-10	100	Cleaves ONPG and Xgal	30 min	Schwarze et al., 1999
TAT-HA-cdc42	21	Denaturing/ PD-10	25	Filopodia formation	5 min	Becker-Hapak et al., 2001

techniques that have been used to successfully isolate many different fusion proteins. One rule of thumb that must be remembered is that every TAT fusion protein is unique, and, while the method described in this unit can cover many fusions, every fusion is different. Therefore the following describes a starting point to begin one's isolations. Figure 20.2.1, outlines the overall strategy.

Isolation and Purification of Fusion Protein

In general, first identify bacterial clones expressing the cDNA of interest using the pTAT or pTAT-HA expression vector (Fig. 20.2.2). The plasmid containing the appropriate insert is then transformed into an *E. coli* strain that is specifically designed for the expression of recombinant proteins. Then, clones expressing the desired fusion may need to be boosted with inducer molecules such as IPTG to yield sufficient quantities of fusion protein for the desired study. The pTAT/TAT-HA vector utilizes a 6-His domain for the convenient isolation of recombinant protein by Ni-NTA chromatography resin. The 6-His domain can lead to fusions that are generally insoluble and compartmentalized into inclusion bodies within *E. coli*. Therefore, buffered urea is routinely used as a denaturing agent to obtain large quantities of unfolded recombinant protein that can bind to the nickel affinity resin. Once the protein is bound and the resin washed, imidazole is used as a competitor to elute the fusion protein from the nickel resin.

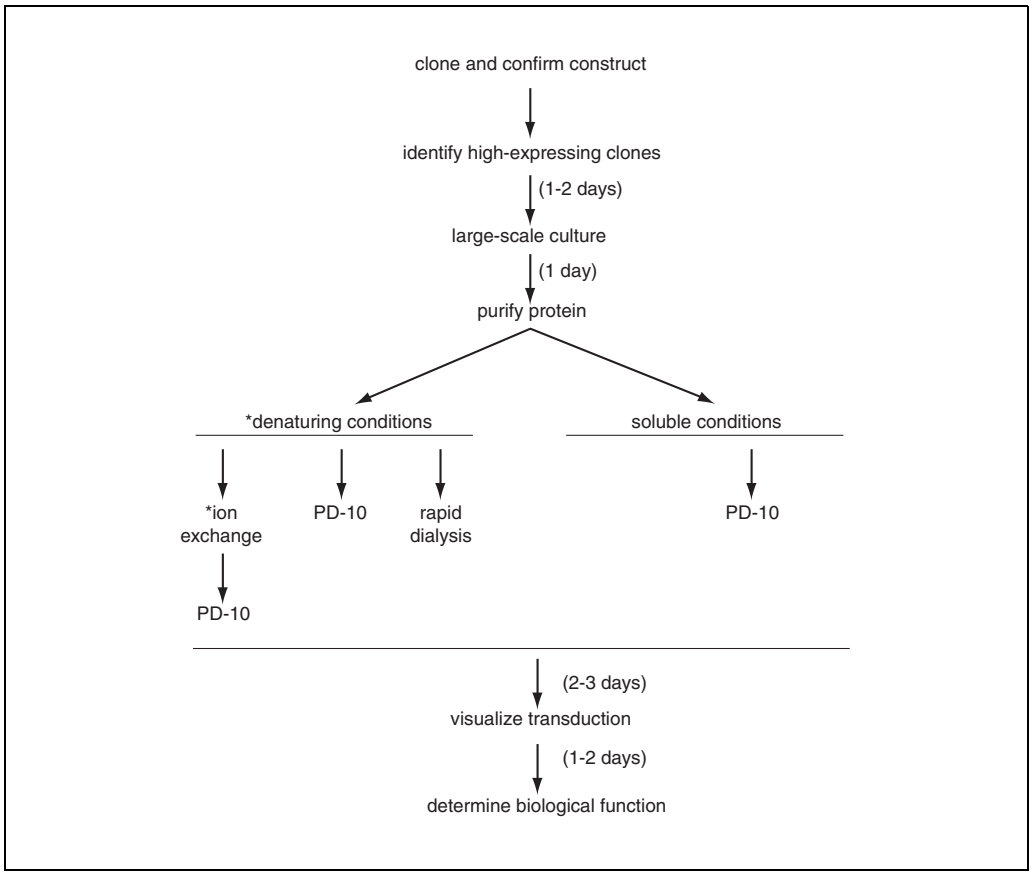

Figure 20.2.1 Flow diagram outlining the overall strategy and time frame required to perform protein transduction using the TAT system. Asterisks (*) denote the preferred methods that consistently lead to fusions that are biologically active.

To remove the urea from the peak nickel affinity protein fraction, one of three different approaches can be used: ion-exchange, gel filtration, or rapid dialysis. The most reliable method for producing transducible recombinant proteins from inclusion bodies is through the use of strong ion-exchange resins to capture the unfolded protein by its ionic charge on an anion (Mono Q) or cation (Mono S) exchange resin using an FPLC platform. Once the unfolded protein is captured, the environment in the column is immediately changed to an aqueous one. The protein is quickly released from the resin using a salt bump, which theoretically leads to a pool of correctly folded and misfolded proteins. The pool of proteins is then desalted and ready for use or storage. The routine method of urea removal from bacterially expressed proteins involves the removal of the denaturant by slow dialysis. While this method works when preparing small quantities of soluble, properly folded proteins, dialysis of high concentrations of the TAT-fusion proteins usually leads to dramatic protein precipitation. Another method of urea removal utilizes a disposable gel-filtration column (PD-10) to exchange the buffer environment around the protein. This procedure has afforded somewhat better success than dialysis, but it is not routinely advisable. Note that the PD-10 column is used in this unit for more than one purpose. While it is not recommended to routinely remove urea from the nickel chromatography purification portion of the procedure, it is ideal for buffer exchange and removal of small molecules such as unconjugated FITC.

In some cases, the 6-His TAT-fusion proteins are maintained in the bacterium in a soluble conformation. In these rarer cases, the fusion protein can be isolated after simply suspending the bacteria in an aqueous buffer, sonicating then clarifying the suspension, and finally performing nickel affinity chromatography.

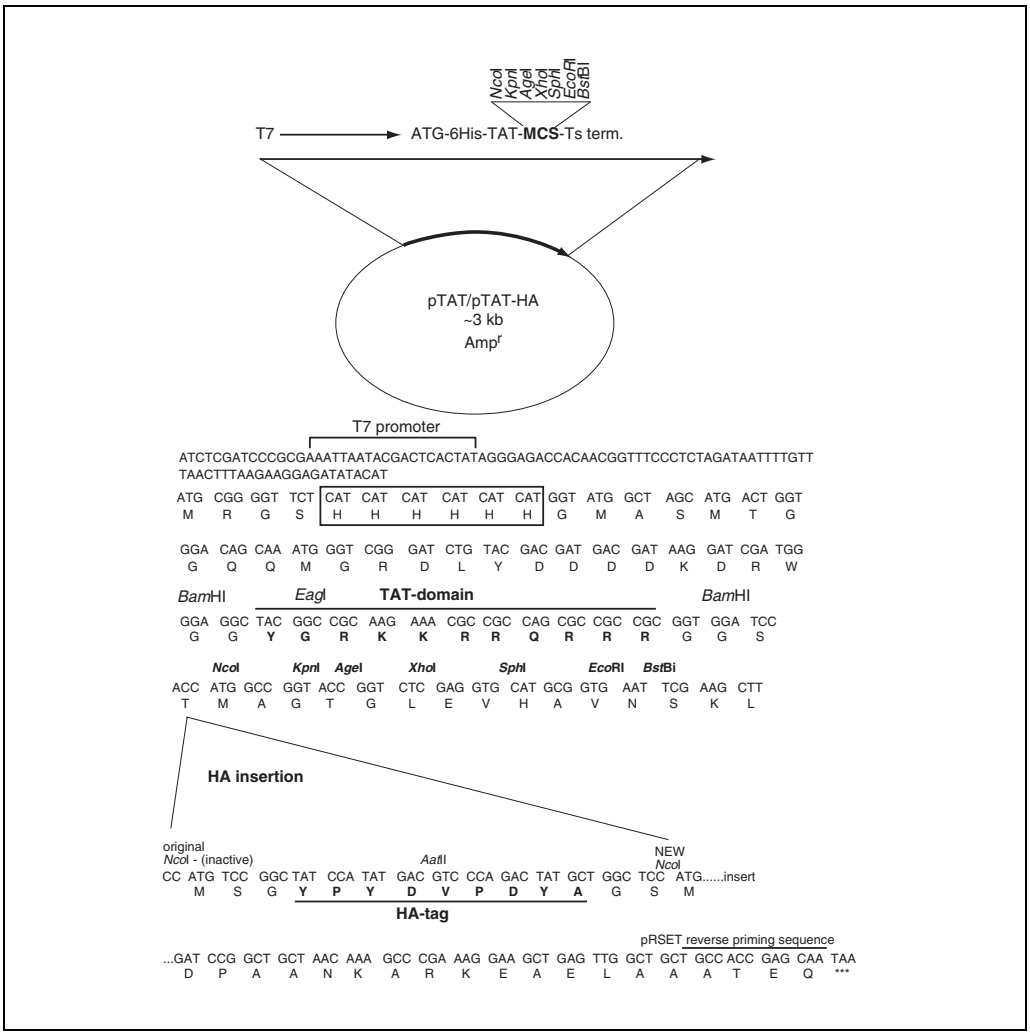

Figure 20.2.2 Vector map of pTAT/pTAT-HA. The functional domains are in boldface. Convenient forward and reverse priming sequences are noted, as well as the peptide sequence of the TAT-HA leader. The pTAT vector does not contain the HA insert. Insertion of desired cDNA using any of the restriction enzymes noted in the multiple cloning site (MCS) will yield an in-frame fusion.

Tranduction and Detection

Two general methods are given for monitoring of full-length TAT-fusion transduction into target cells. The first method detects the intracellular location of the fusion protein, by fluorescently labeling the protein using fluorescein isothiocyanate (FITC), adding the labeled protein to the target cells, washing, fixing, and then observing the resultant transduction by fluorescence microscopy. This standard method for protein labeling covalently attaches the fluorescein molecule to basic residues such as lysine and arginine. Eight out of the eleven amino acids in the TAT-transduction domain are comprised of these basic residues and over-labeling in this functional domain can lead to artificial inhibition of transduction.

The second method given to detect protein transduction is indirect immunofluorescence. This method uses commercially available, fluorescent antibodies to detect transduced protein within cells that have been subjected to the fusion protein over various amounts of time, washed, and then fixed. It is the method of choice when detecting transduction on adherent cells.

Both of these methods focus solely on detection of the fusion protein inside the cell and provide no evidence of fusion protein function. Phenotypic results of fusion-targeted

events are clearly the ultimate detection of protein transduction however, these methods are fusion specific and will not be covered in this unit.

Controls

Depending on the goal of the study, one may choose to use one of two negative controls. The first control to consider is the preparation of a 6-His-fusion of the protein of interest without the transduction domain. This control would be advantageous in cases where proof of the transduction is required. If this is necessary, simply digest the pTAT/pTAT-HA vector containing the cDNA of interest with *Bam*HI, purify, and re-ligate. This will "pop out" the TAT domain of the protein while maintaining the expression of the 6-His-HA tagged protein of interest. Removal of the TAT transducing domain can be verified by digestion of the re-ligated plasmid with the restriction enzyme *Eag*I (Fig. 20.2.2). If the transducing domain has been removed, it will no longer be possible to linearize the plasmid with this restriction enzyme. The purification of this species is generally the same as for the TAT-fused protein.

The second control to consider is the creation of a site-specific mutant within the protein of interest. These fusions are highly recommended when doing in vitro studies in order to prove the specificity of the TAT-fusion protein. Generally, no major deviations from the already optimized protocol for the wild-type fusion will be necessary.

EXPRESSION, VERIFICATION, AND YIELD OPTIMIZATION OF TAT-FUSION PROTEINS

BASIC PROTOCOL 1

This protocol assumes that the investigator has already confirmed the insertion of the cDNA of interest into the TAT expression vector, as well as the identity of the cDNA. It is important that the DNA sequence be confirmed and that the possibility of frame shifts or point mutations be eliminated. The verified plasmid should be stored as a glycerol stock in *E. coli*, DHSα. Storage of the plasmid in bacteria used for protein expression is not generally recommended because of possible plasmid instability. If the investigator needs further background into creating fusion cDNA, see *APPENDIX 3A*, which provides references for procedures that are not described in detail in this unit.

Materials

Pure pTAT/pTAT-HA expression vectors (Nagahara et al., 1998) with and without the gene of interest inserted (available from Dr. S. Dowdy, sdowdy@ucsd.edu)

E. coli strains BL-2 (DE3) pLysS (Novagen) and DH5α (Invitrogen, Life Technologies)

LB medium and plates both containing 50 μg/ml ampicillin (see recipe)

2× SDS-PAGE sample buffer (*APPENDIX 2A*)

Antibody specific for target protein *or* anti-HA mAb (Berkeley Antibody Company) if using pTAT-HA vector

Glycerol, ultrapure, 50% (v/v), sterile filtered

Additional reagents and equipment for SDS-PAGE (*UNIT 6.1*), immunoblotting (*UNIT 6.2*), Coomassie blue staining (*UNIT 6.6*), and basic molecular biology procedures (including transformation of bacteria and IPTG induction; see *APPENDIX 3A*)

1. Transform the verified, pure plasmid, into competent *E. coli* strain BL-21(DE3)pLysS (*APPENDIX 3A*). Select transformants on LB plates containing 50 μg/ml ampicillin. Also transform the original vector (without the gene of interest) in the same *E. coli* strain for later use as a whole bacterial protein control (empty-vector control).

   This bacteria will not produce any detectable 6-His fusion protein if using the pTAT vector, or will express the hemagglutinin antigen (HA-tag) if using the pTAT-HA vector (6 to 9 kDa).

2. Incubate the agar plate overnight. Pick 6 to 10 colonies from the fusion-positive plate and grow in 3 ml of liquid LB medium containing 50 μg/ml ampicillin, overnight at 37°C with shaking at 220 rpm. Pick one colony from the empty-vector control plate and grow in the same fashion.

3. Vortex the overnight cultures. Remove 50 μl of each culture and place into an individual microcentrifuge tube containing 50 μl of 2× SDS-PAGE sample buffer.

4. Vortex briefly and heat samples 5 min in a boiling water bath.

5. Microcentrifuge the lysate 3 min at maximum speed, room temperature, to bring down any particulates.

6. Load 20 μl of each supernatant from step 5 (including that from the negative control) on two separate SDS-PAGE gels of the appropriate percentage (*UNIT 6.1*).

   One gel will be stained with Coomassie Brilliant Blue (UNIT 6.6) and the other will be transferred to nitrocellulose for immunoblotting (UNIT 6.2).

7. Place one of the two gels in Coomassie Brilliant Blue staining solution for 1 hr with gentle agitation, then remove staining solution and replace with destain solution. Change the destaining solution every 15 min until desired background is achieved.

   The procedures and solutions used here are described in UNIT 6.6.

8. In the lanes containing the clones of interest, determine if there is an overexpressed band at the appropriate size when compared to the lane loaded with lysed bacteria transformed with pTAT or pTAT-HA alone (the empty-vector control). If no clear differences are evident, rely on the immunoblot for confirmation of the expression of the fusion protein.

9. Perform immunoblotting and detection procedures (*UNIT 6.2*). Use the anti-HA mAb at a 1:5000 dilution for the primary antibody if using the HA tag as a marker to follow fusion protein expression. For an antibody against a specific protein, use the dilution recommended by the manufacturer. Use the secondary antibody (*UNIT 6.2*) at a concentration of 1:1000.

   The authors typically use extended-life chemiluminescent development reagents such as SuperSignal (Pierce).

10. Using the results from the immunoblot, determine the size of the fusion protein.

    The TAT/TAT-HA fusion proteins run 6 to 9 kDa larger than the untagged gene of interest.

11. *Optional:* If a sufficient level of overexpression of the desired fusion is not observed by immunoblotting, induce the system using IPTG (*APPENDIX 3A*).

    See Troubleshooting for other possible solutions to poor fusion expression.

12. Determine the clone or clones that express the protein of interest at the highest levels. Prepare glycerol stocks by adding 700 μl of overnight culture into 300 μl of sterile 50% glycerol, and freeze at −80°C.

    As mentioned earlier, not all fusions are stable in BL-21(DE3)pLysS bacteria. If this is discovered, transform into the expression bacteria, let the cells recover for 1 hr without antibiotic selection, and then prepare a 100-ml overnight inoculum in LB medium containing 5 μg/ml ampicillin. Use this culture to inoculate a large-scale culture as described in the next section.

    Also, for permanent storage of the unstable plasmid, transform the plasmid into DH5α and store as glycerol stock at −80°C as mentioned earlier.

LARGE-SCALE ISOLATION OF THE TAT-FUSION PROTEIN

This protocol describes the large-scale isolation of the TAT-fusion protein from the high-expressing clones identified in the previous steps. See Key References for more information on these approaches. To perform ion exchange, it is necessary first to determine the isoelectric point (pI) of the purified protein. This can be done easily on various molecular biology Web sites (see Internet Resources for one of these). It is then necessary to determine which ion-exchange resin will best suit the protein. The pI of the fusion protein will, in large measure, determine whether to use a Mono Q column (for basic proteins) or a Mono S column (for acidic proteins). Although the TAT leader is a basic entity (8 of 11 residues are basic), it has been the experience of the authors that ~50% of all TAT fusion proteins will bind to the Mono S resin regardless of pI predictions. Following the successful elution of the protein, pool the appropriate fractions and exchange the buffer using a PD-10 column. The columns are provided as prepacked disposable columns of 30 per box and should be stored at 4°C.

In general, when isolating proteins from crude extracts, the preparation should be kept in the cold or on ice. However, in this procedure, it is not necessary to keep the preparation on ice until the urea has been removed from the sample, except when sonicating the bacteria. In fact, if the Ni-NTA purified fractions are kept on ice after elution from the column, crystallization of the eluate will be observed. Therefore, during this phase, avoid cold conditions unless it is necessary to freeze the partially purified protein for storage and later purification.

Materials

LB medium containing 50 µg/ml ampicillin (see recipe)
Glycerol stock of clone with high expression of TAT fusion protein (see Basic Protocol 1)
Phosphate-buffered saline (PBS; *APPENDIX 2A*)
Buffer Z (see recipe) containing 1× protease inhibitors (see recipe)
5 M (340 g/liter) imidazole (store in foil-wrapped bottle at 4°C)
50% (w/v) stock suspension of Ni-NTA agarose (Qiagen)
100 mM, 250 mM, 500 mM, and 1 M imidazole in buffer Z (see recipe for buffer Z), prepared fresh daily
PBS (*APPENDIX 2A*) containing 0.1% (w/v) sodium azide
20 mM HEPES, pH 8 (for Mono Q resin) or pH 6.5 (for Mono S resin)
Buffer A (binding): 20 mM HEPES, pH 8.0, for Mono Q; pH 6.5 for Mono S
Buffer B (elution): 20 mM HEPES/1 M NaCl, pH 8.0, for Mono Q; pH 6.5 for Mono S
PBS (*APPENDIX 2A*) containing 1× protease inhibitors (see recipe)
Bovine serum albumin (BSA)
Glycerol (ultrapure), 50% (v/v) sterile filtered

Sorvall refrigerated centrifuge with GSA rotor, or equivalent
Sonicator with microprobe (Branson)
Disposable 50-ml Econo columns (Bio-Rad)
Mono Q or Mono S 5/5 or 10/10 ion-exchange FPLC columns *or* bulk resin (Resource Q or S), all products of Amersham Pharmacia Biotech
FPLC apparatus
PD-10 gel filtration columns (Amersham Pharmacia Biotech)

Additional reagents and equipment for SDS-PAGE (*UNIT 6.1*) and Coomassie blue staining (*UNIT 6.6*)

Prepare fusion-protein-containing lysate

1. Inoculate 200 ml of LB medium containing 50 µg/ml ampicillin with a sterile loop or scraping of the high-expressing clone glycerol stock (see Basic Protocol 1). Incubate overnight at 37°C with shaking at 220 rpm.

2. Pour the entire contents of the overnight culture into 1 liter of LB medium containing 50 µg/ml ampicillin. Incubate 5 to 6 hr at 37°C with shaking at 220 rpm.

   Protein production usually decreases after stationary phase has begun in E. coli.

   If it has been determined that IPTG is required to obtain large quantities of the protein, be sure to add it at this step.

3. Centrifuge the cell suspension 5 min at 5000 × *g*, 4°C, in a Sorvall GSA or equivalent rotor. Discard supernatant.

4. Resuspend pellet in PBS. Centrifuge the suspension again as in step 3.

   The washed pellet can be stored at −20°C for one month if necessary.

5. Decant supernatant and add 10 ml buffer Z with protease inhibitors to the pellet. Make a homogenous suspension by pipetting up and down using a wide-bore pipet, or by vortexing.

   A homogenous suspension is critical for efficient lysis of the bacteria by sonication in the next step.

6. Sonicate the suspension using four 15-sec on/off cycles at 60% (microtip limit), at 4°C or on ice.

   The cold temperatures are required to keep the proteins from being irreversibly denatured by the heat generated during the sonication process.

7. Centrifuge the suspension 10 min at 12,000 × *g*, 4°C. Carefully decant the supernatant into a clean tube and measure its volume, then add sufficient 5 M imidazole to a final concentration of 20 mM imidazole.

   The concentration of imidazole to add at this point must be determined experimentally. In most cases the fusion protein binds specifically at 20 mM imidazole; however, some proteins will require lower concentrations (from 5 to 15 mM). At lower imidazole concentrations, the background (non-6-His labeled proteins) can also bind to the nickel resin. Usually, this is not a problem because the desired protein is in vast excess with respect to the contaminating proteins. Additionally, the contaminating bacterial proteins do not contain the transduction domain and therefore will not transduce.

Purify fusion protein on Ni-NTA agarose

8. Prepare a 5-ml bed volume Ni-NTA affinity column by adding 10 ml of the 50% stock suspension of Ni-NTA agarose to a 50-ml Bio-Rad Econo-Column with the Luer lock in place to control the flow of buffers or extract to be added.

9. Wash the resin twice, each time with 10 bed volumes (50 ml) of Milli-Q water, to remove the resin storage buffer.

10. Equilibrate the resin with 10 bed volumes of buffer Z containing 20 mM imidazole (or whatever concentration of imidazole was added as in step 7).

    Remember to save a small portion of each purification step so that it will be possible to follow the protein purification by SDS-PAGE.

11. Apply the clarified sonicated bacterial lysate (from step 7) to the resin.

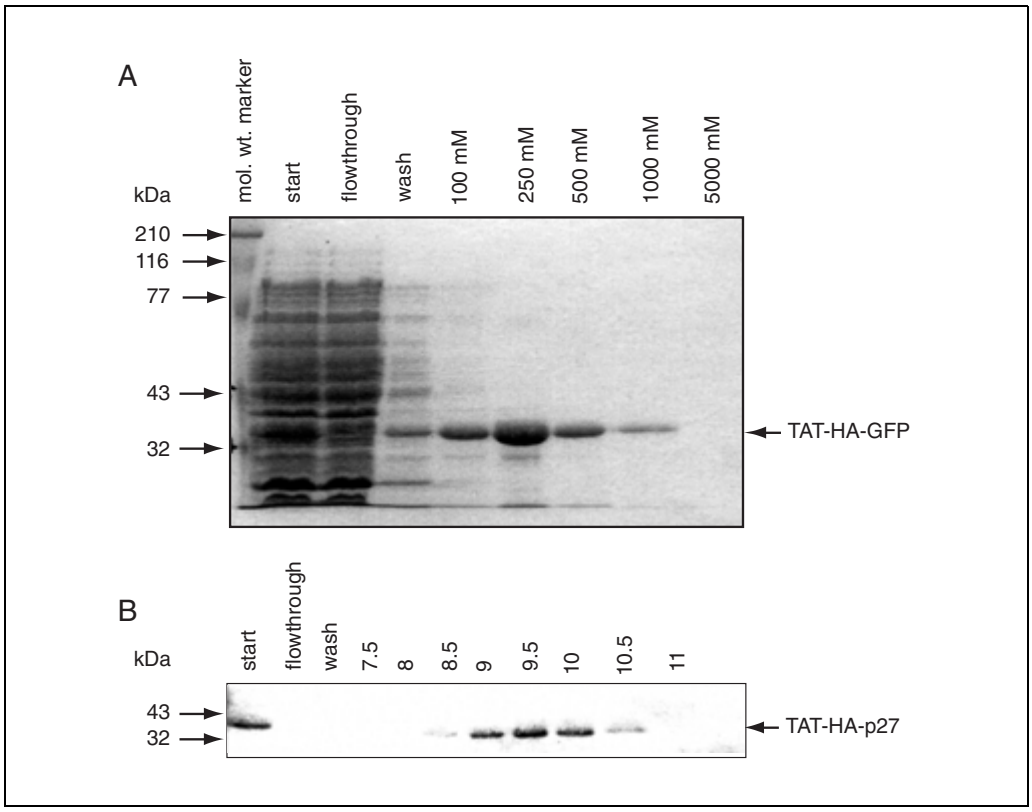

Figure 20.2.3 (**A**) Typical elution profile of TAT-fusion protein (TAT-HA-GFP) from a Ni-NTA agarose resin. BL-21(DE3)pLysS bacteria were transformed with pTAT-HA-GFP plasmid and cultured in 200 ml of LB medium containing 50 μg/ml ampicillin, overnight. This inoculum was then added to 1 liter of LB-ampicillin and cultured for another 5 hr with shaking at 220 rpm, 37°C. The bacteria were lysed in buffer Z with protease inhibitor cocktail (see Reagents and Solutions), clarified, and the imidazole concentration was brought up to 20 mM. The crude lysate was applied to a 5-ml-bed-volume Ni-NTA column and washed with 50 ml of buffer Z containing 20 mM imidazole. The fusion protein was then eluted with 5 ml aliquots of buffer Z containing 100, 250, 500, 1000, and 5000 mM imidazole. The 12.5% SDS-PAGE gel was loaded with 5 μl of each fraction noted. The gel was stained for 60 min with Coomassie Blue and destained as necessary. (**B**) Ion-exchange profile of TAT-p27 WT on a Mono S (5/5) column, equilibrated in buffer A and loaded with a 1:1 dilution of a Ni-NTA elution fraction. The column was washed with 40 ml of buffer A. TAT-HA-p27 WT fusion protein consistently eluted after 8 through 11 ml of buffer B. 10 μl of each elution fraction was separated on a 15% SDS-PAGE gel and stained with Coomassie Blue for 1 hr, then destained as necessary. The numbers above each band denote the volume of elution buffer (buffer B) that had passed through the Mono S (5/5) column.

Some lysates can be very viscous. If this is observed, dilute the lysate with more buffer Z or apply the lysate directly and use slight pressure on the column to gently force the lysate through the resin. If the lysate is not very viscous and clears the resin too quickly, reduce the flow rate and apply the lysate over the resin again.

Remember to maintain the imidazole concentration (20 mM or other concentration added at step 7) throughout the column application and wash steps.

12. Wash the resin with 10 ml of buffer Z containing 20 mM imidazole, then with an additional 40 ml of buffer Z containing 20 mM imidazole (ten bed volumes total).

    The first 10 ml of wash will contain flow through proteins. The subsequent 40 ml is the wash that removes weakly bound proteins.

13. Elute the protein stepwise by sequential addition of 5 ml each of 100 mM, 250 mM, 500 mM, and 1 M imidazole in buffer Z, and collect fractions. Finally, strip the resin with 5 ml of 5 M imidazole.

14. Wash the resin with 20 bed volumes of PBS. Store the column at 4°C in PBS containing 0.1% sodium azide.

15. Load 10 µl of each purification fraction (from step 13) on an appropriate-percentage SDS-PAGE gel (*UNIT 6.1*). Perform electrophoresis, then stain the gel with Coomassie Brilliant Blue for 1 hr and destain appropriately (*UNIT 6.6*).

    Note that purified protein can be readily observed as early as 2 min after placing the gel in the staining solution.

16. Determine the fraction(s) that contain the desired protein.

    See Fig. 20.2.3A for an example of a typical urea elution profile.

    The procedure can be suspended at this step if necessary. The imidazole-eluted fractions may be stored at −20°C until the SDS-PAGE is completed and one is ready to do the urea-removal steps (no more than one month).

Purify by ion-exchange chromatography

17. Pool the Ni-NTA fractions containing the peak protein concentration determined by SDS-PAGE.

18. Dilute the pooled fractions 1:1 with 20 mM HEPES, pH 8.0 (for Mono Q), or pH 6.5 (for Mono S).

    This dilutes the protein pool to a low-enough salt and denaturant concentration to allow binding to the ion-exchange resin.

19. Inject the sample into a 10/10 (preferably) Mono Q or S column attached to an FPLC apparatus and equilibrated in buffer A.

    A gravity column may be used in place of FPLC (see Alternate Protocol 1).

20. Wash with ~50 ml buffer A and elute with 10 ml buffer B, collecting 0.5-ml fractions.

    Switching from the non-urea-containing buffer A to buffer B results in elution via a single 1 M NaCl step.

21. Analyze the fractions by SDS-PAGE (*UNIT 6.1*) and stain with Coomassie Brilliant Blue (*UNIT 6.6*).

    Figure 20.2.3B shows an example of an elution profile from ion-exchange chromatography. The sample is ready at this point for desalting on a PD-10 column equilibrated in PBS, followed by collection and final analysis by SDS-PAGE (steps 22 to 26). The only decision that must be made by the investigator at this point is the equilibration buffer to be used. The authors recommend desalting into PBS and adding sterile glycerol to a minimum concentration of 10% (v/v). For further discussion on the use of this column see Becker-Hapak (2001).

    IMPORTANT NOTE: *If the protein fails to bind to the predicted resin, or weak binding of protein is observed, try the other column type (Mono Q or Mono S) regardless of predicted pI. If strong binding is observed with weak elution, decrease (for Q resin) or increase (for S resin) the pH of buffer A by steps of 0.5 pH units, until a small amount of protein is detected in the flowthrough fraction. Also see Troubleshooting for problems associated with the ion-exchange step.*

Perform buffer exchange using PD-10 column

22. Drain the storage buffer from the PD-10 column and equilibrate the column with 25 ml of PBS with 1× protease inhibitors.

    Culture medium such as RPMI-1640 (e.g., Life Technologies), without serum and antibiotics, but containing 1× protease inhibitors, can be used in place of the PBS.

23. Apply the pooled protein fraction to the column (do not exceed 2.4 ml), and allow the solution to absorb into the resin. Apply 4 ml PBS with 1× protease inhibitors to the column and collect fourteen 0.5-ml fractions.

    The protein will begin eluting in the sixth or seventh fraction. If 2.4 ml of protein was applied to the resin, then the protein will stop eluting in the thirteenth or fourteenth fraction.

    The column can be reused once by applying another 25 ml of buffer with protease inhibitors onto the column; however, it is not wise to reuse the column if working with different fusion proteins, because it is always possible to carry over contaminants from a previous preparation.

24. Analyze the fractions by SDS-PAGE (*UNIT 6.1*) using BSA as a standard. Load 0.1 to 2 µg protein standard per lane and a known volume of the purified fusion protein on the same gel.

25. Stain the gel with Coomassie Blue and destain as desired (*UNIT 6.6*).

26. Pool the appropriate fractions and add glycerol to a final concentration of 10% (v/v). Divide into 0.25-ml aliquots and flash freeze on dry ice. Store fractions at −80°C.

    Fusions have been stored for over 2 years in this manner and still maintained activity.

USE OF ION-EXCHANGE GRAVITY COLUMNS INSTEAD OF FPLC

ALTERNATE PROTOCOL 1

If an FPLC system is not available, bulk ion-exchange resin can be used to pack a gravity-flow column.

Additional Materials *(also see Basic Protocol 2)*

30-µm Resource Q or S ion-exchange resin (Amersham Pharmacia Biotech; see Basic Protocol 2 for choice of resin)
50-ml Econo columns (Bio-Rad)

NOTE: Perform all steps at 4°C and add 1× protease inhibitors (see recipe) to all solutions.

Replace steps 19 to 21 of Basic Protocol 2 with the following:

1. Pack a 10-ml bed-volume ion exchange column using 30-µm Resource Q or S resin.
2. Wash the resin with 20 bed volumes of Milli-Q water to remove the storage buffer and rehydrate the resin.
3. Wash the column with 10 bed volumes of buffer A.
4. Apply the diluted sample (see Basic Protocol 2, step 18) onto the resin and allow the protein to enter the gel bed slowly.
5. When the protein has completely entered the gel, wash with 10 bed volumes of buffer A.
6. Elute with two bed volumes of ml buffer B, collecting 0.5-ml fractions. Analyze the fractions by SDS-PAGE (*UNIT 6.1*) and pool the fractions containing the protein of interest.

    IMPORTANT NOTE: *At this point the fusion protein is very pure. It is absolutely necessary to maintain the protein on ice from this point on. Failure to do so will yield degraded protein.*

7. Perform buffer exchange and analyze the final fractions (see Basic Protocol 2, steps 22 to 26).

ALTERNATE PROTOCOL 2

DIRECT BUFFER EXCHANGE OF UREA-DENATURED PROTEIN

In theory, rapid desalting of a denatured protein from 8 M urea through an aqueous interface of PBS or culture medium without serum forces the protein to rapidly hide its hydrophobic residues and become soluble in an aqueous environment. The PD-10 desalting column has a 1:1.4 dilution factor; therefore denatured proteins are rapidly separated from each other, helping to avoid aggregation of the proteins and subsequent precipitation on the column. In this procedure, 1 to 1.5 ml of the Ni-NTA affinity-purified TAT fusion protein in 8 M urea (i.e., in buffer Z) is applied to the PD-10 column equilibrated in PBS/HEPES buffer or serum-free culture medium. Column fractions of 0.5 ml are isolated and analyzed by SDS-PAGE as in Basic Protocol 2. Reasonable success has been achieved by this rapid and inexpensive procedure, however, use of this method routinely leads to dramatic protein precipitation. While some soluble protein can be obtained using this protocol, more soluble (and therefore, transducible) protein can be obtained by working out the ion-exchange conditions.

Additional Materials *(also see Basic Protocol 2)*

Serum-free culture medium (e.g., RPMI-1640) without antibiotics, containing 1× protease inhibitor cocktail (see recipe) *or* PBS plus 1× protease inhibitor cocktail

Replace steps 17 to 26 of Basic Protocol 2 with the following:

1. Equilibrate PD-10 column with 25 ml of culture medium without serum or antibiotics but with 1× protease inhibitors.

   Alternatively, the fusion can be buffer exchanged into PBS plus 1× protease inhibitor cocktail.

2. Load a maximum of 1.5 ml of the peak protein fraction from the Ni-NTA affinity column (see Basic Protocol 2, steps 16 and 17) on to the gel bed.

3. After the sample has completely entered the gel bed, apply more of the culture medium with protease inhibitors to the column and collect 0.5-ml fractions.

   Protein can precipitate as it is eluted from this column. Microcentrifuging the fractions immediately for 5 min at maximum speed, 4°C, can minimize this precipitation. Transfer the supernatant fractions in separate microcentrifuge tubes.

4. Keeping the fractions on ice at all times, determine which fractions contain the desired protein by SDS-PAGE (*UNIT 6.1*).

5. Pool the fractions containing the protein of interest and and add glycerol to a final concentration of 10% (v/v). Store the protein in 0.2-ml aliquots at −80°C.

   Some proteins may require the additional 0.1% (w/v) BSA to stabilize the pure protein. This must be determined experimentally. In general, storing the protein in the 10% glycerol will be sufficient. Also, keep in mind that if the fusion protein is an enzyme, it may not be active if frozen at any point.

ALTERNATE PROTOCOL 3

DIALYSIS OF THE UREA-DENATURED PROTEIN

One may choose to rapidly dialyze the Ni-NTA affinity-purified protein into the desired buffer, replacing the ion-exchange and gel-filtration steps (Basic Protocol 2, steps 17 to 23). However, 6-His fusion proteins are highly susceptible to precipitation when using this method to remove urea. Also, some proteins are not biologically active after dialysis, whereas ion-exchange chromatography will routinely yield proteins with higher biological specific activity. For example, TAT-p27 WT, if prepared by rapid dialysis, will not

cause G1 arrest, whereas if it is subjected to ion-exchange chromatography, it does (Nagahara et al., 1998). Conversely, other proteins such as TAT-E1A and TAT-E7 are biologically active when desalted by rapid dialysis (Beker-Hapak, unpub. observ.).

Additional Materials *(also see Basic Protocol 2)*

Slide-A-Lyzer dialysis cassettes (Pierce) with membrane of MWCO appropriate for protein of interest

Replace steps 17 to 23 of Basic Protocol 2 with the following:

1. If the protein in the purified fraction is > 5 μg/μl, dilute at least 1:1 in buffer Z.
2. Apply the sample to the dialysis cassette. Be sure to remove all air bubbles.

   In the authors' laboratory, use of the Slide-A-Lyzer cassettes with large surface-to-volume ratio provided by Pierce has proven to yield more soluble protein than regular dialysis tubing.

3. Dialyze the protein at 4°C against 4 liters of pre-chilled buffer appropriate for the downstream application. Change the buffer after 1 hr, then again 2 hr later, and let stir overnight. After the overnight incubation period, remove the protein from the dialysis cassette and remove any solids by centrifuging 10 min at 5000 × *g* , 4°C, prior to use or storage.

   For example, if using the protein for orthophosophate labeling, use 20 mM HEPES/137 mM NaCl, pH 7.2, but if simply adding the protein to tissue culture cells, use 1× PBS at 4°C.

4. Analyze the protein concentration with BSA standards on a SDS-PAGE gel and store the protein in aliquots (see Basic Protocol 2, steps 24 to 26).

ISOLATION OF SOLUBLE TAT-FUSION PROTEINS

ALTERNATE PROTOCOL 4

Some proteins can or must be isolated under soluble (nondenaturing) conditions. For example TAT-β-galactosidase is not active if purified in the presence of any urea. Use of nondenaturing conditions can reduce yield as well as transduction efficiency; therefore, use of this protocol is not generally recommended. However, several reports successfully utilized the isolation of TAT fusions under nondenaturing conditions. According to the authors' experience, the yield can be much lower than proteins prepared under denaturing conditions and the transduction efficiency may be lower. Exact effects must be determined experimentally.

For materials, see Basic Protocol 2.

1. Prepare pellet of cells from 5- to 6-hr culture (see Basic Protocol 2, steps 1 to 4).
2. Resuspend the pellet fraction in 10 ml of PBS containing 1× protease inhibitors. Perform Ni-NTA purification (see Basic Protocol 2, steps 5 to 14), replacing the buffer Z with PBS with protease inhibitors. Identify the fractions containing the protein of interest by SDS-PAGE (see Basic Protocol 2, steps 15 and 16).

   Sonication of cells in PBS is more difficult than when done in buffer Z. One may need to modify the sonication procedure to optimally lyse the bacteria without damaging the fusion protein.

   The ion-exchange steps (Basic Protocol 2, steps 17 to 21) are not performed.

3. After Ni-NTA chromatography, remove the imidazole and exchange the buffer using PD-10 column, and store the protein in 10% (v/v) glycerol at −80°C (see Basic Protocol 2, steps 22 to 26).

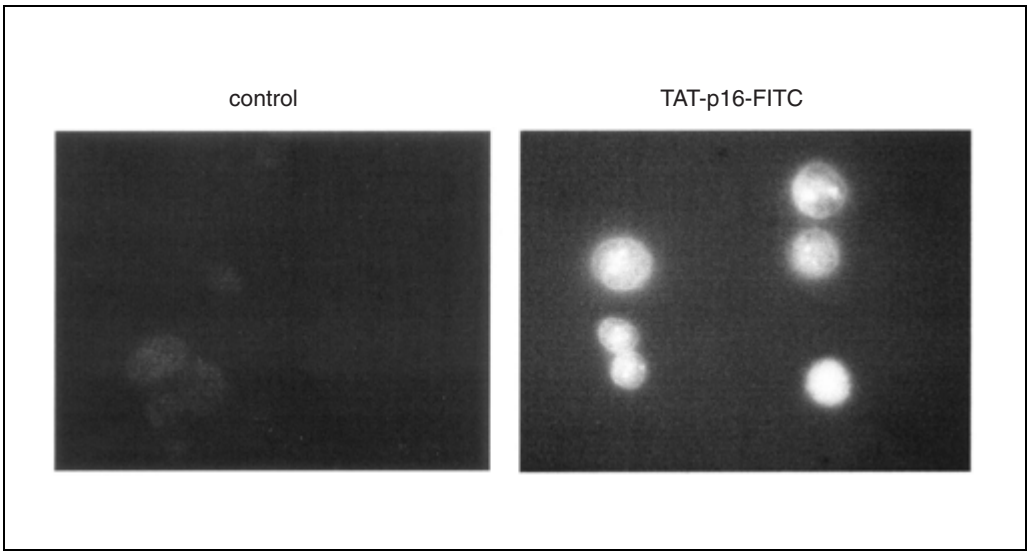

Figure 20.2.4 Confocal microscopy analysis of Jurkat T cells transduced with p16 WT-FITC, control (left panel) or TAT-p16WT-FITC protein (right panel). Jurkat T cells were transduced for 1 hr with the FITC-labeled pure protein. Cells were washed in PBS and fixed with 4% paraformaldehyde, washed again, and then mounted on slides with antifade mounting medium. Note the generalized fluorescence of TAT-p16WT-FITC protein in the cell. Higher-intensity staining can be observed in the nucleoli, typical of nuclear targeted TAT-fusions. The cells treated with non-TAT-fused FITC-labeled p16 show little to no fluorescence.

BASIC PROTOCOL 3

TRANSDUCTION AND DETECTION WITH FLUOROPHORE-LABELED FUSION PROTEIN

TAT-mediated protein transduction occurs without the use of specialty reagents or instrumentation. A TAT-fusion protein can be simply added to cultured cells along with the culture medium. The process is concentration dependent but seemingly temperature independent (see Commentary for a detailed discussion of all of the parameters affecting transduction). This unit will not detail a regimen for transduction because the procedure will be different for every fusion, cell type, and cell culture system. To optimize, the researcher should consider trying several different doses of the transducing protein (10 to 200 nM) in culture medium, varying incubation times with the target cell population to achieve the lowest concentration of protein in shortest time frame required to achieve the phenotypic effect. Suspension (e.g., Jurkat T-cell) and adherent (e.g., NIH 3T3) cell lines, are used in this section to illustrate two different and routinely used methods for visualizing transduced proteins in tissue culture cells. This protocol describes transduction of a fusion protein labeled with fluorescein. Alternatively, other fluorescent molecules such as Alexa (Molecular Probes) can be used to label the fusion. These molecules are reported to have a higher half-life when compared to FITC. The authors recommend using the manufacturer's labeling protocol whenever using an alternative fluorophore.

Materials

Fluorescein isothiocyanate (FITC; Molecular Probes)
DMSO
Purified fusion protein (see Basic Protocol 2 and Alternate Protocols 1 to 4)
10× FITC conjugation buffer (see recipe)
PBS (*APPENDIX 2A*) containing 1× protease inhibitors (see recipe)
Glycerol, ultrapure
Cell line of interest for transduction or Jurkat T cell culture
Paraformaldehyde fix solution (see recipe)
Antifade mounting medium (Molecular Probes)

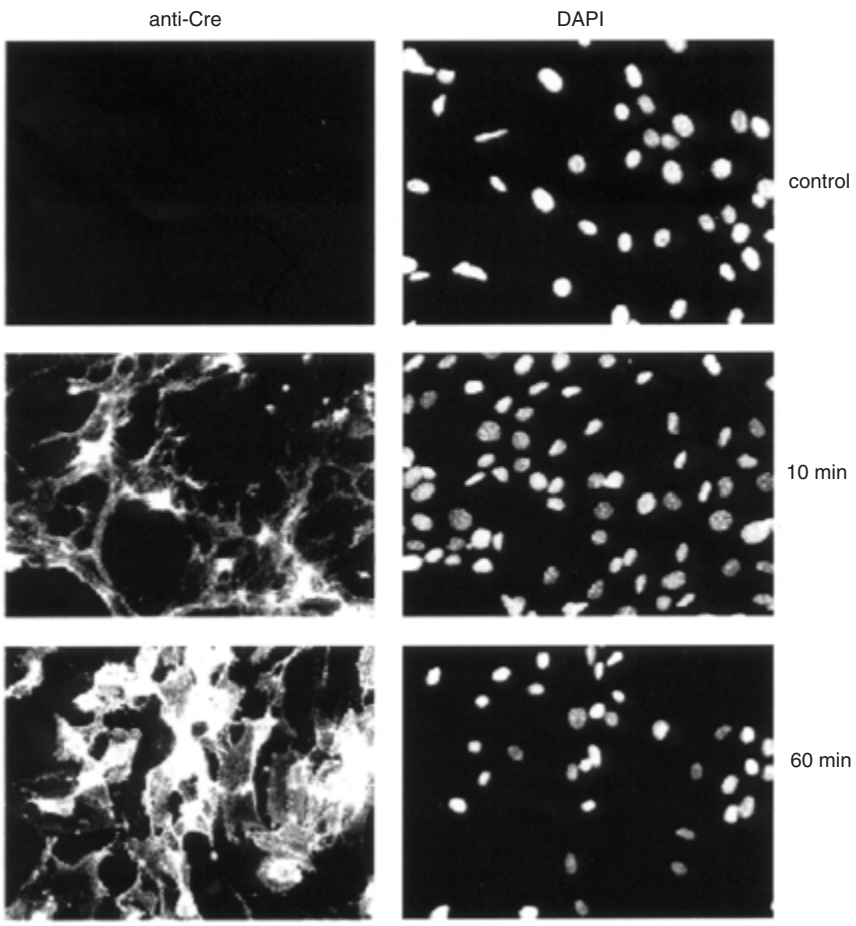

Figure 20.2.5 Detection of TAT-HA-Cre transduced into NIH-3T3 cells containing a phloxed β-galactosidase gene. Cells were transduced for 0 (no TAT-HA-Cre), 10, and 60 min in 8-chamber Lab-Tek slides. The cells were washed and fixed as described in Alternate Protocol 5. Rabbit anti-Cre polyclonal antibody was used at a 1:3000 dilution and a TRITC-labeled goat anti-rabbit secondary antibody was used at a 1:1000 dilution. TAT-HA-Cre is detected as early as 10 min after introduction of the protein into the cells. The panel showing the cells treated for 10 min clearly shows that many of the cells have detectable protein in the cytoplasm. Accumulation of the fusion protein in most cell nuclei is evident at 60 min.

Clear nail polish

PD-10 gel-filtration columns (Amersham Pharmacia Biotech)
Microscope slides and coverslips

Label TAT fusion protein

1. Prepare a FITC stock solution by dissolving 1 mg FITC per 0.5 ml DMSO. Keep in the dark.

   The FITC stock solution should be prepared fresh daily.

2. Prepare the labeling reaction by combining:

   540 µl (0.1 to 0.5 µg) purified fusion protein
   60 µl 10× conjugation buffer
   1 µl FITC stock solution (see step 1).

It is wise to set up at least three separate labeling reactions of high, medium, and low protein concentration to be conjugated to FITC. Overlabeling can cause inhibition of the transduction, presumably due to blockage of the basic groups in the transduction domain. Therefore, it is a good idea to label and purify the reactions prepared at all three protein concentrations; one of them will provide the best visualization of the transduction.

3. Incubate at room temperature in the dark for 2 hr.

Purify the fluorophore-labeled fusion protein

4. Equilibrate a PD-10 column with 25 ml of PBS with 1× protease inhibitors.
5. Apply the entire labeling reaction from step 3 to the column.
6. After the volume enters the gel bed, apply more PBS with protease inhibitors and collect twelve 0.5-ml fractions.

   The unconjugated FITC will remain in the gel bead because of its small size. Do not reuse the column.

7. Pool fractions 6 to 8 containing the labeled protein (which will be slightly yellow), add glycerol to 10% (v/v), and store at −80°C.

Transduce labeled fusion protein

8. Incubate various volumes of FITC-labeled TAT fusion protein with 5×10^5 suspension cells (e.g., Jurkat T cells) in 200 µl culture medium (i.e., RPMI/10% FBS) for 30 min at 37°C.

   Equilibration is reached in as little as 5 to 15 min.

9. Microcentrifuge 5 min at 5000 rpm, 4°C. Remove the supernatant, add 0.5 ml of ice-cold PBS and immediately microcentrifuge again. Remove the supernatant to complete the wash.

Fix and visualize cells

10. Resuspend the pellet in 500 µl paraformaldehyde fix solution and incubate cells for 15 min at room temperature on an end-over-end rotator.
11. Gently pellet the cells by microcentrifuging 5 min at 5000 × *g*. Resuspend the cell pellet in 200 µl of PBS and mount onto slides (using antifade mounting medium if slides are to be stored overnight prior to examination). Seal the coverslips with clear nail polish.
12. Examine slides by fluorescence microscopy using excitation and emission wavelengths appropriate to the fluorophore (*APPENDIX 1E*).

    See Figure 20.2.4 for an example of FITC-labeled TAT-p16 WT transduced into Jurkat T cells.

ALTERNATE PROTOCOL 5

TRANSDUCTION AND DETECTION BY INDIRECT IMMUNOFLUORESCENCE

When the necessity of colocalization of transduced protein to cellular organelles or substructure is required, use of indirect immunofluorescence is highly desirable. The method described below will allow the researcher to make direct observations of where the TAT fusion protein is located within an individual cell. Use of the Lab-Tek 8-chamber slides makes it easy to examine and manipulate many conditions (i.e., antibody concentration) at the same time. Be sure to include a secondary antibody control to ensure low nonspecific binding of the fluorescent secondary antibody. An example of immunofluorescence completed on NIH 3T3 cells transduced with TAT-Cre is shown in Figure 20.2.5.

Materials

Adherent cells of interest for transduction, e.g. NIH 3T3 cells
Culture medium for NIH 3T3 cells (i.e., DMEM/10% FBS)
Purified fusion protein (see Basic Protocol 2 and Alternate Protocols 1 to 4)
Phosphate-buffered saline (PBS; *APPENDIX 2A*), ice-cold and room temperature
Paraformaldehyde fix solution (see recipe)
100% ethanol, ice-cold
1% and 0.1% (w/v) bovine serum albumin (BSA) in PBS (prepare from 10% w/v BSA stock)
Primary antibody: antibody of choice to fusion protein or mAb to the HA epitope (Berkeley Antibody Company)
TRITC- or PE-labeled secondary antibody
0.2 µg/ml DAPI (prepare fresh from 1 mg/ml DAPI stock; store stock in dark at 4°C)
Slowfade mounting medium (Molecular Probes)
Clear nail polish

Lab-Tek 8-chamber glass slides with lids (Nalge Nunc International)
40°C heat block
50 × 24–mm coverslips (Fisher)

Prepare cells in chamber slides

1. Culture 1000 NIH 3T3 cells/chamber on a Lab-Tek 8-chamber slide overnight in a minimum volume of 0.5 ml of culture medium.
2. Wash the cells by flooding the chambers with fresh medium followed by removal of the medium by gentle aspiration.

   It is a good idea to aspirate from the same position in the well for each wash to minimize loss of cells during the wash steps.

Transduce fusion protein

3. Transduce fusion protein into cells as desired for specific time points.

   The useful concentration of the protein will vary from 10 to 200 nM and the times for transduction will also vary depending on the investigator. The minimum volume to cover the cells is 200 µl per chamber. Transduction can be detected in as early as 5 min and usually maximizes between 2 and 6 hr after protein addition (this is fusion dependent).

4. Remove medium and wash once with ice-cold PBS using the technique described in step 2.
5. Fix cells by adding 400 µl of ice-cold paraformaldehyde fix solution per chamber and incubating on ice for 15 min.

   It is critical that the fixation buffer be prepared fresh daily; its pH must be verified prior to use.

Expose transduced cells to antibody reagents

6. Wash three times with ice-cold PBS using the technique described in step 2.
7. Permeabilize the cells by adding 400 µl of ice-cold 100% ethanol and incubating on ice for 10 min.
8. Wash three times with ice-cold with PBS using the technique described in step 2.
9. Block with 1% BSA and incubate 10 min on top of a 40°C heat block.
10. Wash five times with PBS at room temperature using the technique described in step 2.

11. Dilute the primary antibody in PBS containing 0.1% BSA according to the manufacturer's recommendation. Add 400 µl of the diluted antibody to each chamber and incubate 15 min at 40°C.

    For anti-HA, a 1000- to 3000-fold dilution is optimal.

12. Wash five times with with PBS at room temperature.

13. Dilute TRITC- or PE-labeled secondary antibody 1000- to 5000-fold in PBS containing 0.1% BSA. Add 400 µl of the diluted antibody to each chamber and incubate 15 min at 40°C.

    If the background (i.e., cells stained with secondary antibody alone) is high, increase the dilution of this antibody.

14. Wash five times with PBS at room temperature.

Counterstain cells with DAPI

15. Counterstain with DAPI by adding 200 µl of 0.2 µg/ml DAPI to each chamber and incubating 15 min at room temperature.

16. Rinse chambers with water, remove the attached chambers and seal, then dry in the dark.

Visualize the results

17. After drying is complete, add 5 drops of Slowfade to mount, add 50 × 24–mm coverslip then seal coverslip with nail polish. Keep in dark until ready to view.

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Buffer Z

480.0 g urea
8.0 g NaCl
4.8 g HEPES
Adjust the pH to 8.0 with NaOH
Add H_2O to 1 liter
Store up to 1 month at room temperature

FITC conjugation buffer, 10×

Dissolve 0.84 g $NaHCO_3$ in 9 ml of H_2O. Adjust to pH 9.0 with NaOH, then add H_2O to a final volume of 10 ml. Store at room temperature; prepare fresh solution every week.

LB medium and plates

LB liquid medium: Add 25.0 g LB broth mix (Sigma) per liter of water. Autoclave for 30 min on liquid cycle. Let cool to 50°C and add ampicillin to final concentration of 50 µg/ml.
LB plates: Prepare as above, but include 5 g/liter agar and pour plates.

Paraformaldehyde fix solution 4% (w/v)

4 g paraformaldehyde
100 ml of PBS (without calcium or magnesium; *APPENDIX 2A*)
Heat gently with constant stirring (do not boil).
Adjust pH to exactly 7.2 after solution has cooled to room temperature
Chill on ice prior to use
Store up to one week at 4°C

Protease inhibitor stock solutions

Prepare stocks:

1 mg/ml aprotinin in H_2O (1000× stock; store up to 1 year at 4°C)

1 mg/ml leupeptin in H_2O (1000× stock; store up to 1 year at 4°C)

10 mg/ml phenylmethylsufonyl fluoride (PMSF) in 100% ethanol (200× stock; store up to 1 year at −20°C)

Add each inhibitor to desired solution for a final concentration of 1×

COMMENTARY

Background Information

There are many methods that can be used to introduce biologically interesting molecules into live cells. Most of these methods such as electroporation, microinjection, and lipofection can be inefficient or laborious. Other methods, such as the use of small peptides, which can essentially diffuse into a live cell, are not desirable because of the high concentrations of the peptides required to achieve the biological effect. Therefore, a method which can deliver full-length, target-specific, concentration-dependent, and biologically active molecules into a live cell in the absence of harsh conditions or mechanical disruption would be highly advantageous.

Domains that have the ability to transport (transduce) heterologous molecules have been identified in many different biological systems (Wadia and Dowdy, 2002). Briefly, four different biological systems have been exploited as tools for the exogenous delivery of heterologous proteins: the Antennapedia protein from *Drosophila* (Derossi et al., 1998),VP22 protein from HSV (Elliot and O'Hare, 1997), MPG domain (synthetic fusion peptide of HIV-1 gp41and the NLS of SV40 large T-antigen; Morris et al., 1997), and TAT from HIV (Fawell et al., 1994). The focus of the method described here, is the transduction domain that originated from the 87 amino acid HIV-Tat protein. The transduction phenomenon was first identified in 1988 when full-length, exogenously added HIV-Tat protein was shown to trans-activate a reporter gene when added to cultured cells at concentrations as low as 1 nM. Fawell et al. (1994) expanded on this observation by demonstrating that proteins chemically cross-linked to a 36 amino acid peptide (residues 37-72) of HIV-Tat were able to transduce into cells. Vives et al. (1997) using a FITC-labeled Tat-peptide showed that residues 37-60 were important for transduction ability. This region was shown to adopt an α-helical structure with amphipathic characteristics from residues 38-49 but a cluster of basic amino acids from residues 49-58 appeared to be unstructured due to charge repulsions (Loret et al., 1991). The eleven amino acids used in the pTAT/pTAT-HA vectors encompass residues 47-57 of the HIV-Tat molecule. Residues 53-57 (QRRR) seem to be essential for the transduction since FITC-labeled peptides devoid of this region failed to transduce into HeLa cells (Vives et al., 1997). Various mutations in this minimal domain have been completed and certain substitutions have been shown to enhance transduction of peptides (Ho et al., 2001). Translation of these transduction domains (PTDs) into expression vectors is the subject of ongoing investigation, and use of these domains could provide even greater transduction potential (S.F. Dowdy, unpub. observ.).

To date, the exact mechanism of HIV Tat-mediated transduction across cellular membranes remains unclear. An attempt at defining this mechanism was reported in 1997 (Vives et al., 1997) using various versions of residues 37-72. They determined that internalization of TAT peptides did not involve endocytosis (temperature sensitive), potocytosis (caveolae or non-coated plasmalemmal vesical–mediated), or membrane destabilization. Another proposed mechanism is analogous to the Penitratin-1 transduction system. In this case, internalization could be caused by local reorganization of the lipid bilayer, resulting in inverted micelles and eventual delivery of the protein in the cytoplasm (Vives et al., 1997). Alternatively, the Tat transduction domain could utilize heparan sulfate proteoglycans as a means of gaining entry into the cell (Tyangi et al., 2001). Clearly differences in mechnisms of transduction between peptides using protein transduction domains (PTDs) and full-length fusions could vary, and this may explain the differences observed in these studies. Although the mechanism by which full-length TAT-fusion proteins gain entry into cells is not concrete, phenotypic effects of these proteins are being observed in many biological systems (Table 20.2.2), and

Table 20.2.2 Selected TAT-Fusions and the Various Cell Types Transduced

TAT fusion	Function	Cell type/line transduced	Reference

[a]A C-terminal TAT-fusion molecule.

new reports of novel applications of this technique are rapidly growing.

A TAT fusion protein can be easily constructed using the pTAT/pTAT-HA vectors. The pTAT-HA vector has several features that make it ideal for use as an expression vector. The HA tag can be used to follow the fusion protein throughout purification and transduction in a specific system. A 6-His domain in the N-terminus of the fusion protein affords a simple method of affinity purifying the protein on a nickel affinity resin pre- or post-transduction. The vector contains a multiple cloning region that yields an in-frame fusion protein. A 3′ transcriptional terminator is also present if truncations of the fusion proteins are desired. Other fusion vectors have recently been described in which the HIV-Tat transduction domain has been used for C-terminal fusions (Darbiniah et al., 2001) instead of N-terminal fusions that pTAT/pTAT-HA would yield (see Table 20.2.2).

Many bacterially expressed recombinant proteins are stored as insoluble inclusion bodies because the bacteria lack the machinery to correctly fold the eukaryotic protein they are forced to produce. The bodies are insoluble aggregates that cannot be resolublized without the use of detergents or denaturing agents such as guanidine·HCl or urea. The system described in this unit makes use of 8 M urea to denature the aggregates, allowing binding to an ion-exchange resin, and immediate exchange of the protein into an aqueous environment. This yields protein that is stable enough to be added to tissue culture media where it can be correctly refolded or degraded once inside the cell. Fluorescently labeled fusion proteins have been shown to distribute uniformly in the nucleus and cytoplasm of all cells tested, including: peripheral blood lymphocytes (PBLs), diploid human fibroblasts, keratinocytes, bone marrow stem cells, osteoclasts, fibrosarcoma cells, leukemic T cells, osteosarcoma, glioma, hepatocellular carcinoma, renal carcinoma, NIH 3T3 cells, and all cells present in whole blood, in a concentration-dependent manner (Nagahara et al., 1998). A TAT-β-galactosidase fusion has been shown to penetrate every cell type in an intact live mouse and remain enzymati-

cally active after traversing all of the cellular layers in various organs, including the brain (Schwarze et al., 1999). Fusion proteins of up to 120 kDa have been successfully transduced and shown to be biologically active; therefore the size of the fusion protein does not appear to retard transduction or function, unlike other transduction domains (Wadia et al., 2002). The concentration of the transduced protein required to achieve a biological function is very low when compared to peptide mimetics. This feature of TAT transduction technology makes it ideal when targeting therapeutic strategies.

The method has already been applied to many biological questions. For example, fusions of TAT-p16 were used to define the phosphorylation events of the retinoblastoma protein (pRb) in cell cycle progression (Ezhevsky et al., 1997); TAT-E7 has been shown to sequestor pRb and rescue T-cells from T-cell Receptor-Activated Induced Cell Death (TCR-AID; Lissy et al., 1998); and the role of p27 in inducing hepatocellular carcinoma cell scattering was elucidated using TAT-p27 (Nagahara et al., 1998). This technology has been exploited to "trick" an HIV-infected cell into committing suicide by inducing caspase-3 cleavage (Vocero-Akbani et al., 1999). The implications of this idea are broadly applicable to any disease that depends upon protease-specific cleavage of pro-molecules. Many more applications have been and continue to be reported (Table 20.2.2).

The limitations for the use of this strategy seem to be three-fold. First, mammalian systems have evolved to defend against foreign proteins. Clearly, proteolytic degradation of exogenously added fusion proteins found in serum reduces the effective half-life of the protein in vitro and can be amplified in vivo. Similarly, inhibitors within serum can interfere with function of transduced molecules. For example, TAT–thymidine kinase prepared by the soluble method described in this unit (see Alternate Protocol 4) is fully functional and rapidly transduces into cells; however, the fusion protein showed no enzymatic activity after lysis of the transduced cells (S.R. Schwarze, unpub. observ.) because of a serum-derived enzymatic inhibitor. Culture systems can minimize the serum effects by using protease inhibitors or by increasing the dosage of the fusion proteins. Additionally, one can use agents such as TNF/cyclohexamide in vitro (Embary et al., 2001) to slow the cellular machinery and allow the cell to refold the transduced proteins more rapidly. The second limitation to this technology may be easily addressed. Since some eukaryotic proteins are modified post-translationally (i.e., phosphorylation and glycosylation), and bacteria do not have the ability to make such modifications, a eukaryotic fusion protein expression system must be designed in order to achieve fully functional protein. Lastly, localization of membrane fusion proteins is probably impossible. Studies with fluorescinated TAT-PTEN (which contains a C2 domain that is known to bind to phospholipid membranes; Lee et al., 1999) showed aggregation of the fusion protein at LnCaP cell membranes (S.R. Schwarze, unpub. observ.).

Critical Parameters

Maintaining protein solublility

Since many TAT-fusion proteins will be isolated in 8 M buffered urea and then quickly exchanged into an aqueous buffer, it is important to determine if the protein maintains stability after freeze/thaws and addition into the culture medium. Centrifuging the proteins at $5000 \times g$ for 10 min at 4°C will ensure that only soluble protein will be added to the cells. If a pellet is evident after centrifugation, another SDS-PAGE gel comparing protein concentrations should be completed.

If precipitation of the fusion protein is noticed on the cells during the transduction procedure, the buffer in which the fusion is stored should be changed. Use of the PD-10 column to exchange the buffer for cell-specific culture media without serum or any other additives usually solves the problem. If the protein is stored in the culture medium, the authors suggest using 0.1% (w/v) BSA to stabilize the protein. Also, when freezing the protein, always add at least 10% (v/v) glycerol, prior to flash freezing and storage at –80°C.
